This paper deals with a ventilation system with a recovery wheel and several related operation parameters. The first aim was to develop a commissioning tool using computer-based tools. The second aim was to find a better energy management control strategy for the ventilation system. The problem in the ventilation system could imply both too warm air and poor air quality. The simulation and optimization tools used in the study are *EnergyPlus*[1] and *GenOpt*[1]. To evaluate the performance of the ventilation system components, it is important to establish the relations between the components. The result of the study suggests measures for retrofit in overcoming a part of the problem of too warm air. In addition, the results indicate energy savings from *15* to *30 %*.

INTRODUCTION

A survey among Norwegian building facilities shows that there is a problem of too warm air and poor air quality in the buildings [1]. This study gives an example how to start an analysis for developing a commissioning tool. In addition, few retrofit measures are tested using *EnergyPlus*.

The heat recovery efficiency is usually studied separately from buildings themselves. Considering significant influence of the heat recovery wheel on the indoor air temperature, it is necessary to study together with the building and HVAC equipment as mentioned in [2]. This study shows how to deal with such a challenge by using computer-based tools. The existing energy management control strategies are mostly heuristic, so there is a necessity for systematically examining the existing energy management control functions and improving them [3]. The study develops the control strategy for the supply-water and tests it.

The building model is developed in *EnergyPlus*. The building has a ventilation system with a heat recovery wheel and a water heating coil. The simple configuration of the equipment is chosen for establishing a basic overview of such a ventilation system. The weather data for Trondheim (Norway) are used in this study.

BUILDING AND VENTILATION SYSTEM DESCRIPTION

The model in this study is developed in *EnergyPlus*. The base of the building is shown in Figure 1. Figure 1 shows the building zoning such that the exterior zones extend six meters inside from the exterior surface as recommended in [4]. Such a way of zoning implies two

[1] Copyright by Lawrence Berkeley National Laboratories, Berkeley, CA, USA

exterior zones, which are ventilated. Hatched zones are ventilated (Figure 1). The ventilated zones have a common ventilation system. In Figure 1, "N" implies the north direction.

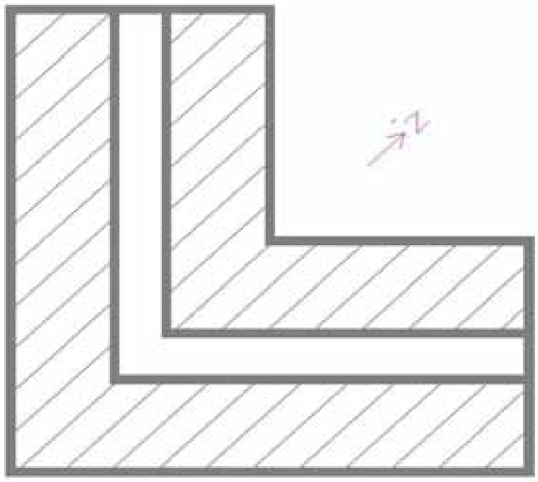

Figure1. Ventilated zones are hatched in building base

The building facades are shown in Figure 2 and Figure 3. The total area of the building is *1350* m^2. The attic and the core zone (non-hatched zone) are assumed to be unconditioned zones. This study treats only the external zones at the first floor, the hatched zones in Figure 1. The total area of these zones is *546* m^2.

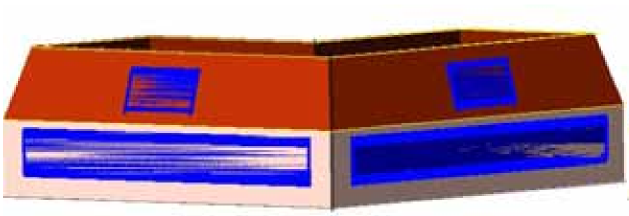

Figure 2. South side of the building

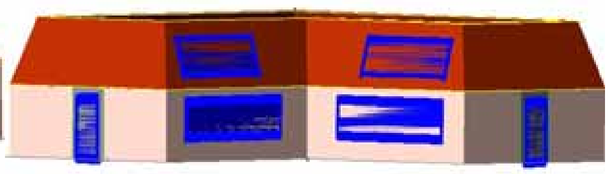

Figure 3. North side of the building

A sketch of the ventilation system is shown in Figure 4. One of the objectives of this study is to find the mutual influence between the heat recovery wheel and the water heating coil. The air flow through the system is *3.3* m^3/s, the larger zone consumes *2* m^3/s, while the smaller consumes *1.3* m^3/s. The amount of air is chosen according to ASHRAE recommendations for air changing per hours in office buildings [5].

Figure 4. Ventilation system

The only internal loads are assumed to be the loads from occupants. The density of people is *0.1 persons/m²* [6]. This implies *32* persons in the larger zone and *22* persons in the smaller zone.

The supply-water temperature of the heating coil is shown in Figure 5. Figure 5 is obtained from BEMS (Building Energy Management System) for the actual building.

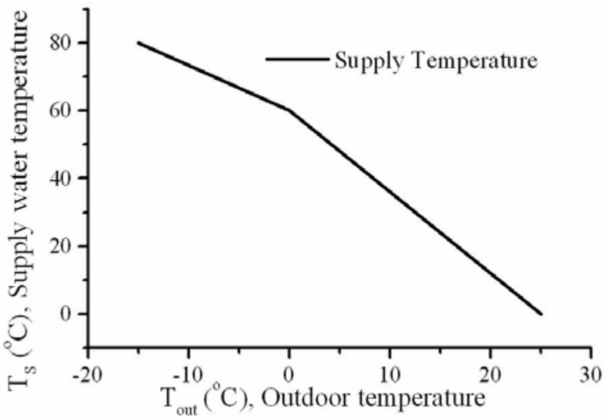

Figure 5. Supply-water temperature curve

The curve in Figure 5 is the same for all the equipment that are using heating energy, except that the heating coil does not operate when the outdoor temperature is above *5°C*. Therefore, the outdoor temperature range from *-15°C* to *5°C* is actual for this study, and the baseline energy use is calculated in the same outdoor temperature range. This outdoor temperature range implies 190 days for the weather data for Trondheim.

METODOLOGY

To find a better energy management control strategy for the ventilation system, it is important to find the mutual relationships between the important parameters. This study finds these relationships by establishing an optimization problem and post-processing the optimization results. Before the optimization problem is defined, the heat recovery model is involved.

EnergyPlus **model for the heat recovery wheel**

The sensible energy efficiency of the heat recovery unit, ε , in *EnergyPlus* is:

$$\varepsilon = \frac{T_{2,i} - T_{1,i}}{T_{1,o} - T_{1,i}}. \tag{1}$$

The notation in Equation 1 is according to Figure 4, where $T_{1,i}\left({}^{o}C\right)$ is the air temperature of inlet air before the heat recovery wheel, $T_{2,i}\left({}^{o}C\right)$ is the air temperature of the inlet air after the heat recovery wheel, and $T_{1,o}\left({}^{o}C\right)$ is the air temperature of the outlet air before it enters the recovery wheel.

The capacity of the heat recovery wheel is:

$$\dot{Q} = \dot{V} \cdot c_p \cdot \rho \cdot \left(T_{2,i} - T_{1,i}\right), \tag{2}$$

where $\dot{Q}\left(W\right)$ is the heat recovery rate of the wheel, $\dot{V}\left(m^3/s\right)$ is the volumetric air flow rate, which is defined by the user in *EnergyPlus*, $c_p\left(J/kgK\right)$ is the specific heat capacity of air, and $\rho\left(kg/m^3\right)$ is the air density. The surface area of the heat recovery wheel is not taken into consideration in this *EnergyPlus* model.

Optimization Problem

The optimization problem is defined in *GenOpt*. Since the aim is to increase the heat recovery rate of the wheel, the objective function is defined to be the maximum of the heat recovery rate of the wheel, Q_{rec}. Therefore the optimization problem is defined as:

$$\max Q_{rec}, \tag{3}$$

$$\text{and the variables are } \begin{bmatrix} UA \\ T_S \end{bmatrix}. \tag{4}$$

The variables in this problem are: the *UA* (*W/m*^{2}) value of the heating coil and $T_S\left({}^{o}C\right)$, the supply temperature of the heating coil. The *UA* value is multiply of the overall heat transfer coefficient, *U* (*W/m*^{2}*K*), and the area of a heat exchanger. The water flow rate of the heating coil is not considered in this optimization problem, because the defined value of the maximum flow rate in *EnergyPlus* is only a limit for the simulation. The water flow is calculated at each time step, so that the load requested of the coil is met at a flow rate which is less than the defined flow rate. This implies that changing the maximum flow rate will not change any results. The entire optimization process is performed for the volumetric air flow of *3.3* m^3/s. In addition, the same optimization process is repeated for the different values of the outdoor temperature. The range of the outdoor temperatures in this optimization problem is from -15^oC to 0^oC.

The optimization problem is shown in Figure 6. The optimization variable is the *UA* value, but *NTU*, the number of transfer units, is more used in practice to express a characteristic of heat exchangers. The *NTU* value is defined as:

$$NTU = \frac{UA}{\dot{m}c_p}, \tag{5}$$

where $\dot{m}(kg/s)$ is water mass flow rate and $c_p\ (J/kgK)$ is the specific heat capacity of water.

Figure 6 gives the optimization results for the volumetric air flow of *3.3* m^3/s (*11880* m^3/h). The results are obtained for the range of the outdoor temperature from *-15*^oC to *0*^oC. For the particular couple of *NTU* and the supply-water temperature, the heat recovery rate of the wheel can be obtained from Figure 6. This heat recovery rate gives a particular value of the inlet air temperature after the heat recovery wheel, $T_{2,i}$, for a particular value of the outdoor temperature.

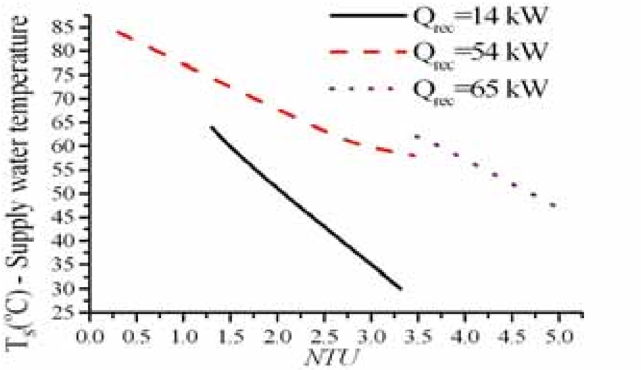

Figure 6. Curves of constant wheel capacity

Figure 6 shows that if the supply-water temperature of the heating coil increases and the value of *NTU* increases, then the heat recovery rate of the wheel increases. Similar figures could be established for the heat rate of the heating coil, Q_{coil}, and zone indoor temperature, T_i.

Post-processing of the optimization results
By using the optimization results from the above problem, the appropriate relations for minimizing energy use can be established.

The optimization results are used to establish two relations:
1. Heat recovery rate of the wheel vs. heat rate of the heating coil, and
2. Indoor temperature vs. heat rate of the heating coil.

The above relations are established for the different values of the outdoor temperature, T_{out}, and in this case they are: *-15*^oC, *-10*^oC, *-5*^oC, and *0*^oC. The results are shown in Figure 7. All the results are valid for the optimal combinations of the optimized parameters.

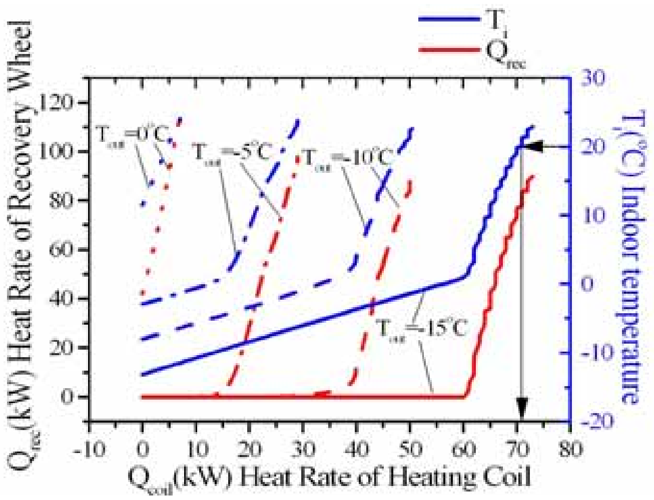

Figure 7. Heat recovery rate of the wheel and
Indoor temperature vs. Heat rate of the heating coil

Figure 7 shows that the relationships between the heat recovery rate and the heating coil rate are different depending on whether the heat recovery wheel recovers energy or not. For example, for $T_{out} = -15^oC$, the heat recovery rate of the wheel is negligible until the heat rate of the heating coil reaches *60 kW*. In addition, the slope of the indoor temperature line is different depending on whether the recovery wheel recovers energy or not. If the heat recovery wheel recovers energy the slope is steeper. This appears because when the recovery wheel recovers the energy, then the reached indoor temperature is higher. Figure 7 shows that when the outdoor temperature increases, the heat rate of the heating coil is negligible comparing to the heat recovery rate of the wheel.

RESULTS

The results in Figure 7 show that it is possible to use a lower supply temperature and to shut down the coil when the outdoor temperature is higher than 0^oC. Based on the optimization results, it is possible to obtain the new values for the new supply temperature curve. Both the new and the current supply temperature curves are given in Figure 8. The consequences of such a measure on energy consumption are shown in Figure 9.

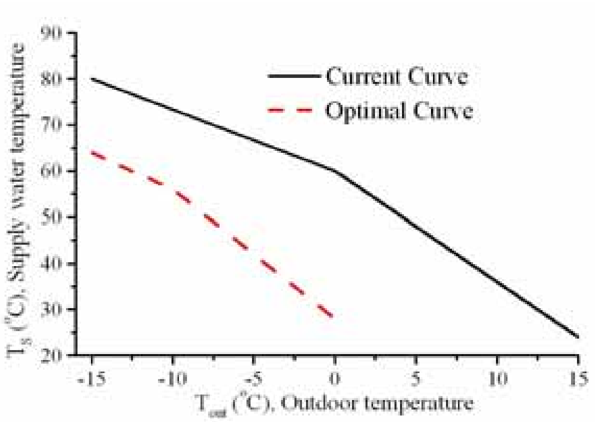

Figure 8. Optimal and Current supply temperature

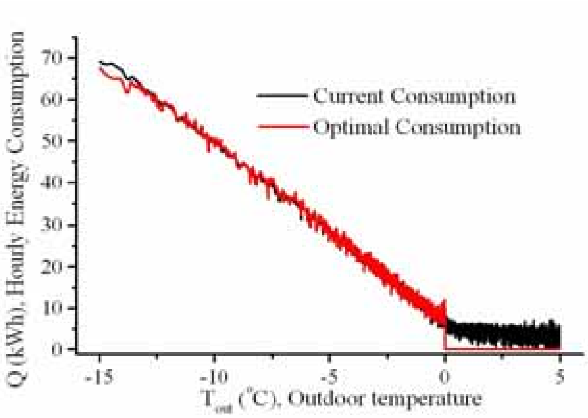

Figure 9. Hourly energy consumption

Figure 8 shows that it is possible that the supply temperature is lower, while the achieved indoor temperature is the same. Figure 9 gives the hourly energy consumption for the outdoor temperatures from -15^oC to 5^oC. In addition, when the coil uses the supply-water temperature as in Figure 5, it works until the outdoor temperature is 5^oC. While, when the coil uses the new curve, it works until the outdoor temperature is 0^oC. The results in Figure 9 are normalized by the outdoor temperature. The highest energy saving by using this measure is archived after the coil is shut down. The energy consumption of the coil is slightly lower when using this optimal supply temperature curve. The reason is that the same amount of the energy is necessary to achieve the desired indoor temperature regardless to the level of the supply temperature.

The energy saving can be determined based on [7] by using an equation, which compares the difference between the continuous end-use baseline and continuous post-retrofit energy use measurement. In this study the energy saving is calculated as:

$$ES = 100 \cdot (Q_b - Q_{pr})/Q_b \tag{6}$$

where $ES\ (\%)$ is the energy saving, $Q_b\ (kWh)$ is the total baseline energy consumption, and $Q_{pr}\ (kWh)$ is the total post-retrofit energy consumption. The energy savings are calculated in the same way for both heating and electric energy. In this study the post-retrofit consumption is possible energy consumption, if the measure would be implemented.

Figure 9 shows that the system shut down implies the highest energy saving, so different cases are tested to estimate when it is possible to achieve the highest energy saving. The cases are the following:

- case 1: the current supply temperature (the supply temperature as in Figure 5);
- case 2: the new supply temperature (the supply temperature as the red-dashed curve in Figure 8) is applied and the coil is shut down when $T_{out}=0^oC$;
- case 3: the current supply temperature and the coil is shut down when $T_{out}=0^oC$;
- case 4: the new supply temperature, the coil is shut down when $T_{out}=0^oC$, and the entire system is shut down in four hours after *20:00*;
- case 5: the current supply temperature, the coil is shut down when $T_{out}=0^oC$, and the entire system is shut down in five hours after *20:00*.

The resulting energy savings from the above measures are given in Table 1. Table 1 gives the energy savings in both the heating and the electrical energy. The energy consumption in Table 1 is the total energy consumption when the outdoor temperature ranges from -15^oC to 5^oC. The heating energy, Q_{coil}, is the energy consumed by the heating coil, while the electric energy, Q_{el}, is the energy for the fans, pump, and the motor for the heat recovery wheel.

Table 1. The energy savings implied by each measure

Case	Q_{coil}(MWh)	Q_{el}(MWh)	Heating Energy Saving (%)	Electric Energy Saving (%)
1	55.6	26.2	0	0
2	44.7	26.2	19.6	0
3	47.0	26.0	15.5	0
4	38.2	21.7	31.0	17.1
5	38.2	20.5	31.0	21.8

The largest part of the total power consumption is made by the fans. Therefore there is no big difference in the electric consumption between the first three cases. When the entire system shut down is applied, there is also a significant energy saving in the electric energy. The energy saving is *19.6 %* when the new curve is applied for the supply temperature. In addition, it is possible to save *15.5 %* of energy by using the current curve for the supply temperature, but shut down the coil when the outdoor temperature is higher than 0^oC. The highest possibility of the heating energy saving of *31 %* is possible when the entire system is shut down during non-working hours.

The results of the study show that the supply-water temperature, as in Figure 5, is high when the outdoor temperature is above 0^oC. The supply-water temperature of the heating coil could be controlled in different way than in Figure 5. In addition, the heating coil works until the outdoor temperature is 5^oC, while the heating coil should be shut down then according to the results. This can be proved from Figure 7, which shows that for the outdoor temperature of 0^oC the heat rate of the heating coil is negligible compared to the heat recovery rate of the wheel.

CONCLUSION

The paper gives the better energy management control strategy for the ventilation system developed by using the computer-based tools. In addition, it defines the optimization problem, and gives the procedure how to post-process the optimization results to get the useful relationships. The results show that the current controlling strategy is one of the causes for too warm air. The results show the possibilities for energy savings from *15* to *30%*. The study did not treat the size of the heating coil, because it was not available. The future work should treat the size of the equipment, and should apply similar measures on a real building.

ACKNOWLEGEMENT

The authors are thankful to the NTNU Operating Department for contribution to our research. In addition, the authors are thankful to Rune Aarlien for help in English.

SUMMARY

In the current study, minimisation of Life Cycle Cost (LCC) for a single family detached house is achieved by combined simulation and optimisation. The house has a typical Finnish construction with initial U-values in accordance with the Finnish National Building Code C3 of 2003. The house is heated by a direct electric heating system. The implemented approach is coupling the IDA ICE 3.0 building performance simulation program with the GenOpt 2.0 generic optimisation program to find optimised values of five selected design variables in the building construction and HVAC system. These variables are three continuous variables (insulation thickness of the external wall, roof and floor) and two discrete variables (U-value of the windows and type of heat recovery of ventilation air) which are defined within set limits.

The assumptions for the LCC data are: number of years under study (20 and 50 years), escalation of electric energy price (1 and 5%) and real interest rate (2.94 and 4.90%). The general solution for the LCC minimisation goes towards reducing the energy cost for space heating by investing in the insulation of the house and using better windows. It suggests lowering the U- values for the external wall, roof, floor and the window from their initial values to be equal to, and sometimes lower than, those for the so-called “Low Energy House”. The optimisation results indicate that 28 to 49% reduction in space heating is achieved compared with the reference case (Standard House 2003).

Keywords: life cycle cost, heating energy, simulation, optimisation

SIMULATION AND OPTIMISATION

Simulation tools are increasingly used in analysing building performance. If the designer decides to improve the building envelope and/or HVAC system parameters, he usually makes a guess for the values of the design parameters to be modified and runs the simulation many times trying to find the effect of the changes on the simulation output and to conclude a relation between the studied parameters. This is an inefficient procedure in time and labour. Besides, the relation between the parameters may not be simply understood, especially when there are many parameters to be studied, due to nonlinear interaction between the parameters.

To overcome such difficulties, it is possible to do automatic simulation-optimisation using search techniques that require little effort and time. GenOpt, a generic optimisation program can be used for such a purpose. GenOpt 2.0 [1] is an optimisation program for the minimisation of a cost function that is evaluated by an external simulation program. It is developed for optimisation problems where the cost function is computationally expensive and its derivatives are not available or may not even exist. GenOpt can be coupled to any simulation program that reads its input from text files and writes its output to text files. The independent variables can be continuous variables (with lower and upper bounds), discrete variables, or both. It is to note that minimisation of the cost function could represent minimisation (or maximisation) of any specified objective function (e. g. annual energy consumption, indoor air quality, equipment efficiency etc). However, optimisation is not easy: The efficiency and success of any optimisation is strongly affected by the properties and the formulation of the objective function and by the selection of an appropriate optimisation algorithm. Refs. [2 and 3] indicate that GenOpt has been implemented in the optimisation of building design and HVAC system parameters.

GenOpt has an open interface on both the simulation program side and the optimisation algorithm side. In this study GenOpt is combined with the IDA Indoor Climate and Energy 3.0 program (IDA ICE 3.0). IDA ICE 3.0 is a whole-building dynamic simulation program which makes simultaneous performance assessments of all issues fundamental to a building design: shape, envelop, glazing, HVAC systems, controls, light, indoor air quality, comfort, energy consumption etc. The accuracy of the IDA ICE 3.0 was assessed through the IEA solar heating and cooling programme, Task 22, sub Task C [4]. IDA ICE 3.0 has been chosen by a group of specialist as one of the major twenty building energy simulation programs which are subjected to analysis and comparison [5].

The task in the current study is to minimise the Life Cycle Cost (LCC) of a single family detached house having Finnish construction by combined simulation and optimisation (IDA ICE 3.0 and GenOpt 2.0).

DESCRIPTION OF THE HOUSE AND HVAC SYSTEM

The dimensions and construction of the detached house are generally based on those for the RET project [6]. The dimensions are indicated in Fig. 1.

The U-values for the external wall, roof and floor are 0.25, 0.16, 0.15 W/m^{2}K, respectively. Among other layers in the construction, following are the thickness and thermal conductivity λ (W/mK) of the insulation: 122 mm mineral wool (λ = 0.035) in External wall, 299 mm Blow-in wool (λ = 0.050) in Roof, and 165 mm Polyurethane (λ = 0.026) in Floor. The windows are 3 layers glass having U = 1.4 W/m^{2}K. The U-value for external doors is 0.35 W/m^{2}K. The loss factor of the building's thermal bridges is 8.3 W/K. Those U-values are in accordance with the Finnish National Building Code C3 for 2003 [7]. Therefore, this construction will be called here "Standard House 2003".

The heating system is a direct electric heating system where heating energy is supplied by two means: electric radiators inside the rooms and an electric heater in the air handling unit (AHU). The AHU heater keeps the supply air temperature at 18 ^{o}C when the incoming outdoor air temperature is lower than this limit. There is a thermostat on the electric radiators to keep the temperature of air inside the zone at a lower set-temperature of 21^{o}C. The ventilation system (always ON) supplies fresh air to the house by a supply fan (62 dm^3/s) and an exhaust fan (67 dm^3/s). The exhaust air flow = 0.65 air change per hour. There is a heat exchanger for heat recovery from exhaust air (efficiency = 70%). Good air tightness of the house is considered: the air leakage value n_{50} = 1.0 l/h. The internal heat gain is 5.1 W/m^2 of the floor area. The location of the house is in Jyväskylä in middle of Finland. The hourly weather file for 1979 is considered.

The building with the above mentioned specifications for the construction and HVAC system is considered as a **reference case** in this study.

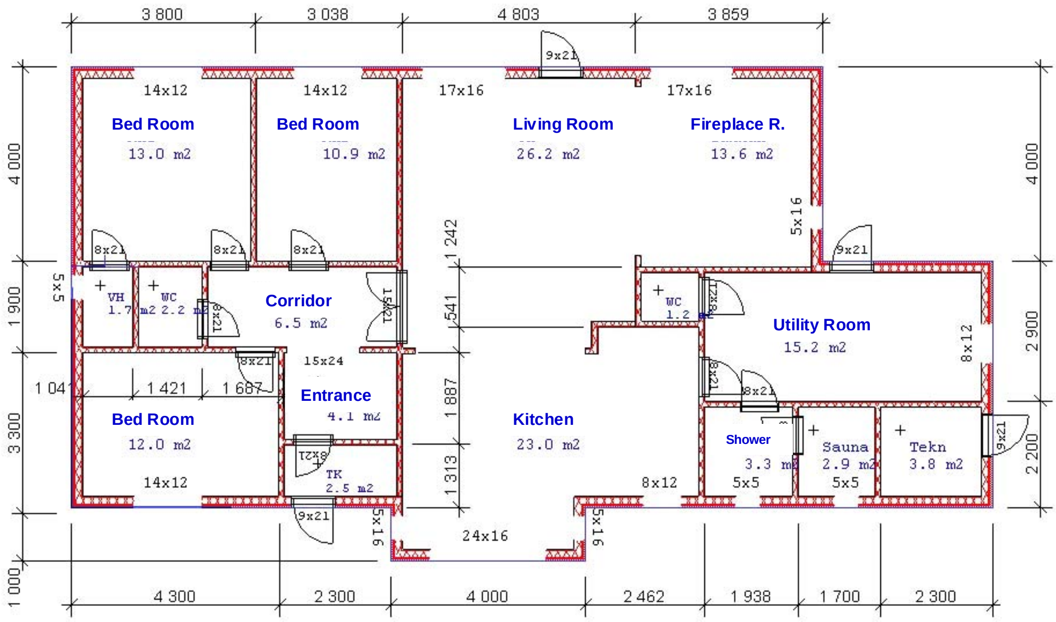

Fig. 1. Dimensions of the single family detached house (internal height is 2.5 and net floor area is 142 m^2) [6].

CALCULATION OF LIFE CYCLE COST

The life cycle cost (LCC) is the sum of the investment and running costs for the building and the system over a specified life span. In the current investigation, the absolute value of the LCC is not calculated but the difference in the LCC for any case (dLCC) from that for the reference case. This way, it is not necessary to include data for all components of the building and system but only the differences produced by variation of specified parameters between the reference case and any other case. Besides, variations in the maintenance cost are not considered. Thus the LCC difference dLCC (€) calculated at present date is

$$\text{dLCC} = \text{dIC} + \text{dOC} + \text{dRC}$$

where dIC is the difference in the investment cost for specified items, dOC is the difference in the operating cost and dRC is the difference in the replacement cost.

The difference in the operating cost is due to the difference in electric energy consumption of the heating system $\text{dOC} = a\, e_p\, \text{d}E$ where e_p is the electric energy price at present date (€/kWh), dE is the difference in annual electric energy consumption E of the heating system (kWh), a is the discount factor which takes into account the effects of inflation and escalation of electric energy price $a = (1-(1+r_e)^{-n})/r_e$, n is the number of years under study, r_e is the real interest rate including effect of escalation of electric energy price $r_e = (r-e)/(1+e)$, e is the escalation in electric energy price (%/a), r is the real interest rate $r = (i - f)/(1 + f)$, f is the inflation rate (%/a) and i is the nominal interest rate (%/a).

The difference in the replacement cost is due to replaced items in specified years $dRC=dR_o/(1+r)^k$, where dR_o is the difference in the replacement cost at present date, k is the year number at which the replacement takes place.

The following data are assumed for the LCC calculations:
Nominal interest rate i = 7% and *inflation rate f* = 2%. Accordingly, the *real interest rate r* = 4.90%. Two values are assumed for the *escalation in electric energy price e* = 1% and a high value of 5%. Two values are assumed for the *life span n* = 50 and 20 years. Two discrete variables are considered (window type and heat recovery type), which have lower life than 50 years. Therefore, two replacements are assumed to take place in year number k =17 and 34 when n = 50 years. When n = 20 years, no replacement costs are considered. The electrical energy price e_p for direct electric heating is 0.0767 €/kWh at 1.4.2005 [8]. *Insulation price* are according to data from Isover Company : Prices for mineral wool in the external wall, blow-in wool in the roof and Polyurethane in the floor are, respectively, 5.63, 3.25 and 26.8 €/m^2 per 10 cm thickness. The change from windows having U-value of 1.4 to 1.0 W/m^{2}K is considered to cost 397 € for all of the windows of the house. The change of the heat-recovery exchanger from a plate type (efficiency = 70%) to a rotary type (efficiency = 80%) is considered to cost 730 €.

DESIGN VARIABLES AND OBJECTIVE FUNCTION

Five design variables are considered in this study: Three continuous variables and two discrete variables. The continuous variables are additional insulation thickness dX of the existing insulation material in the external wall, roof and floor. The discrete variables are: U-value of the window (with two options, 1.4 and 1.0 W/m^{2}K) and type of heat recovery (with two options, plate type with 70% efficiency and rotary type with 80% efficiency). Table 1 shows these variables. Constraints on the continuous variables are indicated as minimum and maximum bounds. The initial and the minimum values correspond to the reference case which means that the optimisation starts from the Standard House 2003.

Table 1. Variable parameters and bounds.

	dXextwall (m)	dXroof (m)	dXfloor (m)	Uwindow (W/m^{2}K)	Heat Recovery
Min (m)	0	0	0	1.0	Plate type (Eff= 0.7)
Max (m)	1.0	1.0	1.0	or	or
Step (m)	0.05	0.05	0.05	1.4	Rotary (Eff=0.8)
Initial value (m)	0	0	0	1.4	Plate type (Eff= 0.7)

The task is to find optimised values of the specified five variables which result in a minimum value for the objective function (dLCC). The combined simulation tool (IDA ICE 3.0) and optimisation tool (GenOpt 2.0) are used to find the optimum values in each case. IDA ICE is iteratively called by GenOpt. The objective function result is checked and values of the design variables are changed in each iteration till a solution is reached. The required annual energy for space heating is calculated by IDA ICE 3.0 based on the hourly input weather file for one year. The used optimisation algorithm is the GPSPSOCCHJ [1]. This is a hybrid global optimisation algorithm that initially does a Particle Swarm Optimisation for all variables and then switches to the Hooke-Jeeves Generalized Pattern Search algorithm to refine the continuous variables.

OPTIMISATION RESULTS

Five cases are studied, and as indicated by table 2, with the following assumptions: Two life spans n = 20 and 50 years, two values for the escalation of electric energy price e = 1% and 5%. These four cases are with a real interest rate r = 4.90%. Case 5 is same as case 3 but with r = 2.94% (nominal interest rate i = 5% and inflation rate f = 2 %). It is to note that 50 years is closer to the building life, while 20 years is closer to the system life. The optimisation results are indicated in table 2. It shows that minimum value of dLCC is reached (negative value) as a result of the reduction made in the electric energy cost for heating (negative value) due to the investment made (positive value) in the insulations, windows and heat recovery and associated replacement costs and as shown in Fig. 2. Highest reduction in LCC is obtained in case 4 when e = 5% and n = 50 years.

* including those for replacement.

Relevant values for the reference case (Standard House 2003) and values from the INDUCON building concept report [9] for the Low Energy House and Minimum Energy House are indicated on the y-axis of Figs 3 and 4 for comparison with results obtained by this study.

The IDA ICE 3.0 calculations show that the required space heating is 99 kWh/m^2a for the reference case compared with 100 kWh/m^2a for the Standard House 2003 as defined by [9]. The optimisation results indicate that 28 to 49% reduction in space heating is achieved compared with the reference case. The highest is for case 4. Fig. 3 shows the required space heating for the studied cases. It shows that for the studied cases, the space heating for the optimum house is lower than that for the Low Energy House.

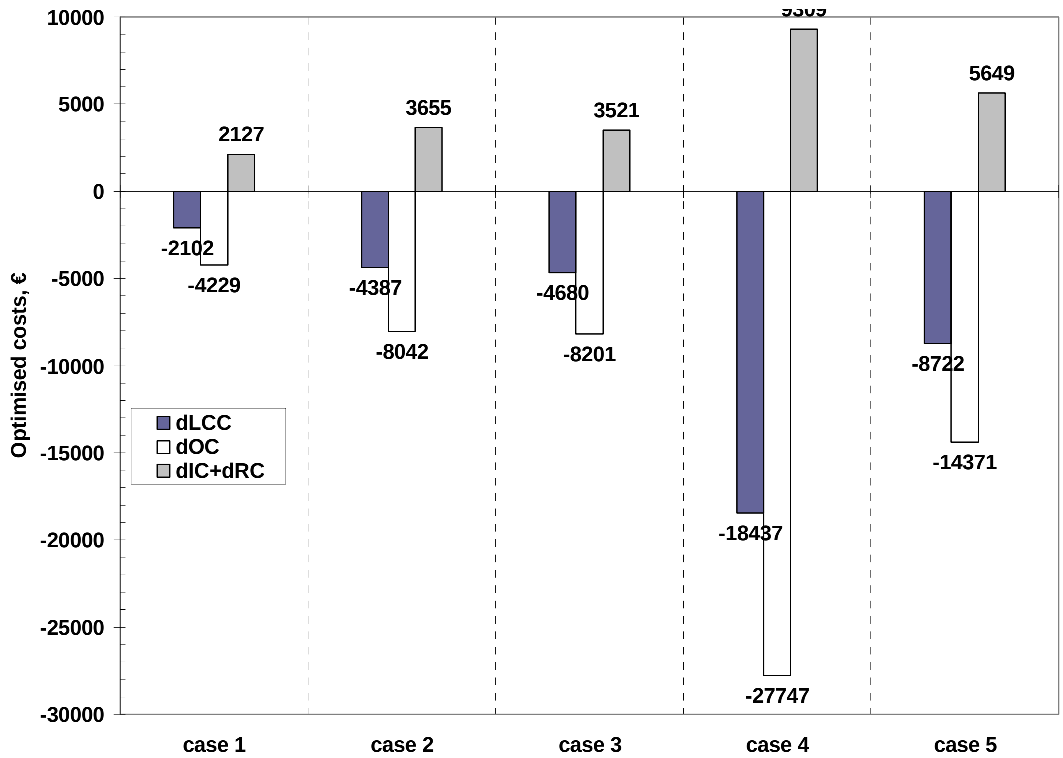

Fig. 2. Difference in LCC (dLCC), energy cost (dOC) and investment and replacement costs (dIC+dRC) for the studied cases.

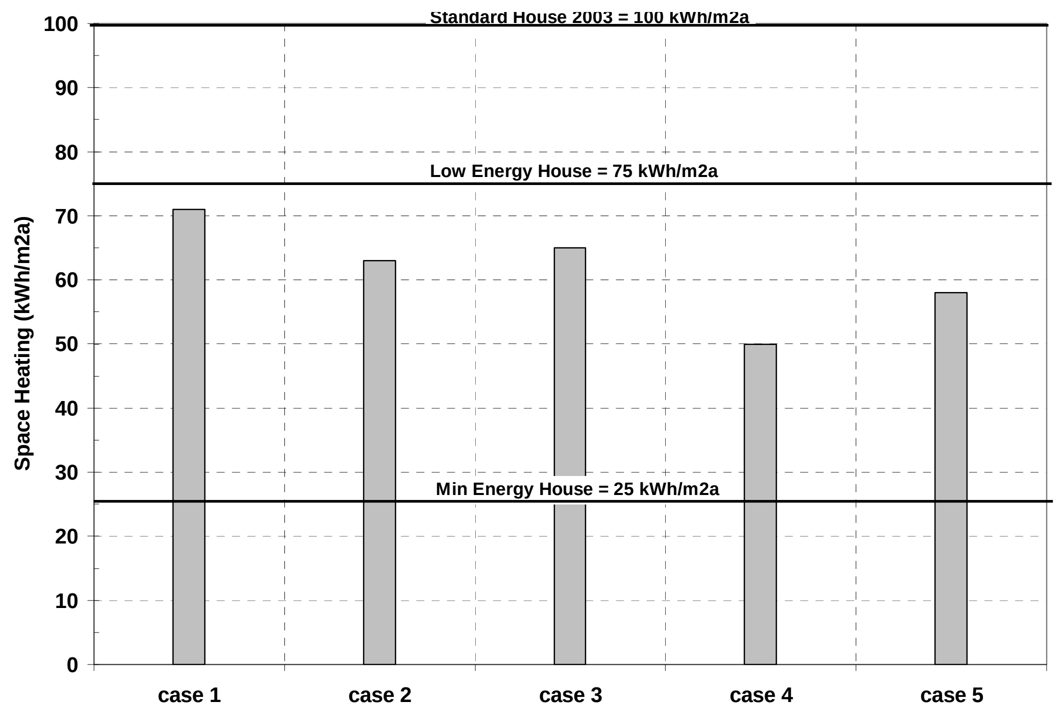

Fig. 3. Space heating of the optimised house for the studied cases.

The results for the U-values are shown in Fig. 4. The optimised U-values for the external wall $U_{extwall}$ are much lower than that for the Standard House 2003. The optimisation suggests increasing the thickness of the mineral wool insulation in the external wall so that $U_{extwall}$ is lower than that for the Low Energy House and even lower than that for the Minimum Energy House for most cases. The U-value of the roof U_{roof} comes close to that for the Low Energy House (which is also the Minimum Energy House) and is even lower for two cases. Due to the high price of Polyurethane as insulation in the floor, the optimisation keeps U_{floor} at its initial value according to the Standard House 2003 (which is equal to that for the Low Energy House) for four cases, while it drops to a lower value for case 4, when e = 5% and n = 50. Polyurethane high price is due to its good characteristics (low thermal conductivity, good compressive strength and resistance to moisture ingress).

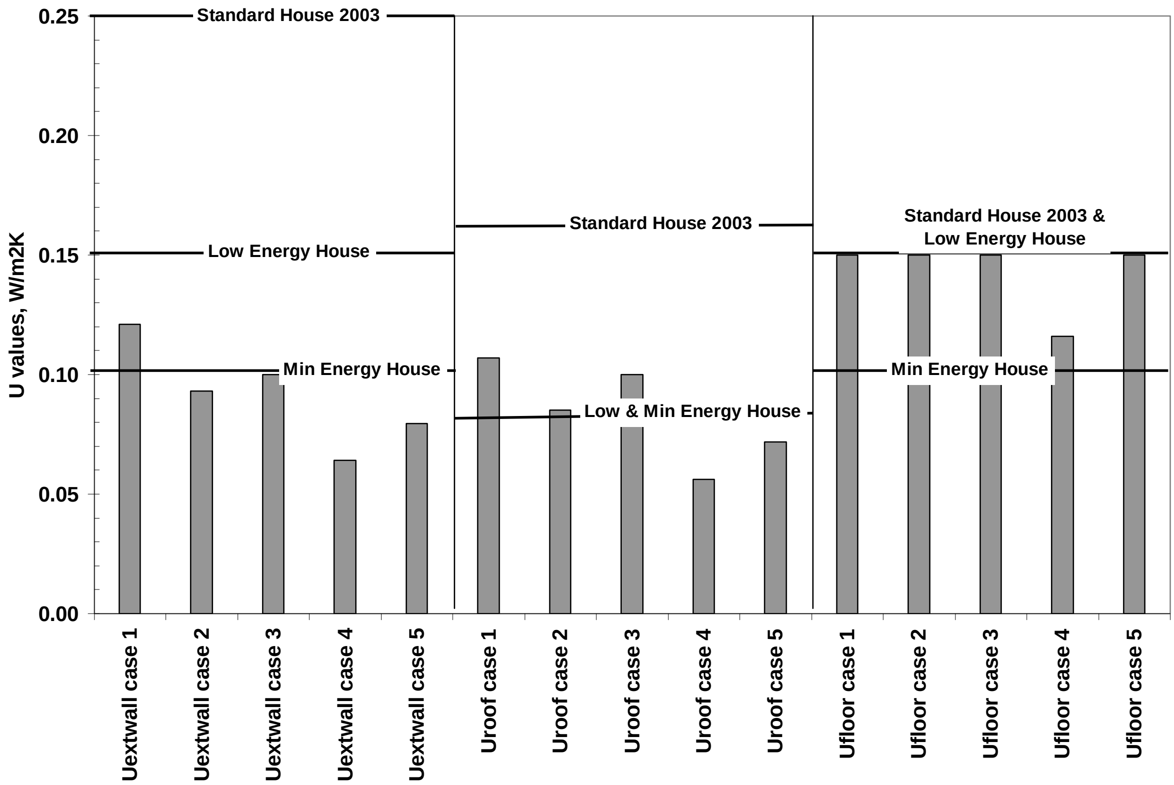

Fig. 4. Optimised U-values for the external wall, roof and floor for the studied cases.

For the two studied discrete variables, table 2 indicates that the optimised U-value for the windows U_{window} is 1.0 W/m^{2}K for the five cases, which is equal to that for the Low Energy House. While for the heat recovery, the rotary type with efficiency of 80% is selected for three cases when e = 5% or r = 2.94%. For case 5, it is concluded from table 2 that assuming the real interest rate r = 2.94% allows making higher investment which produces higher saving in electric energy and higher reduction in dLCC compared with case 3 (r = 4.90%).

CONCLUSIONS

This investigation shows the advantages gained from the implemented approach of combining the IDA ICE 3.0 simulation program with the GenOpt 2.0 generic optimisation program in the minimisation of the life cycle cost of a typical Finnish detached house. The house is electrically heated. This approach enabled finding optimised values of selected design variables in the building construction (insulation thickness of the external wall, roof, floor and U-value of the windows) and HVAC system (type of heat recovery unit) which achieved minimum LCC value for the studied cases.

With different assumptions for the following LCC data; number of years under study (20 and 50 years), escalation of electric energy price (1 and 5%) and real interest rate (2.94 and 4.90%), the general trend of the solution goes towards investing in the insulation of the house and using better windows. It suggests lowering the U-value for the external wall, roof, floor and window to be close to, and sometimes lower than, those for the Low Energy House. The change of the heat recovery system to a more efficient type seems to be feasible for the studied cases when the escalation in the electric energy price is 5% or the real interest rate is 2.94%. The space heating energy for the optimised house is between 50 and 71 kWh/m^{2}a which makes a reduction between 28 and 49% compared with the reference case (Standard House 2003).

SUMMARY

Field tests of a proposed efficient air flow model calibration method were performed on two classroom/office buildings. Models developed using CONTAM multizone software were tuned via an iterative procedure that sought to maximize the fraction of correctly predicted interzonal flow directions. Site measurements during a concentrated period of testing, including HVAC air flows, envelope leakage, and site weather data were used to update the multizone models. Following an initial group of mandatory measurement, CO_2 tracer gas experiments were conducted to permit independent assessment of model quality using ASTM Standard D5157-97. In one case, the procedure was quite effective, improving the number of correct interzonal flow directions from an initial value of 52% to a final value of 81% and significant improvement was also indicated by the ASTM method. Tuning produced only minor improvement in the second building. Greater difficulties in acquiring site measurements and the greater complexity of the second building are possible reasons that performance was less satisfactory in that case.

INTRODUCTION

In recent years, the public, governmental agencies, and the HVAC industry have shown increased interest in understanding and predicting air and contaminant movement through buildings for purposes of indoor air quality evaluation and the analysis of extraordinary incidents. A number of documents available to the public [1, 2] give generic guidance on making buildings resistant to airborne chemical and biological releases. However, prediction of air and contaminant flow for a particular building of interest is necessary for risk assessment, development of emergency procedures, and system design for building protection against both intentional and accidental events.

Modeling with various types of software can be a quick and cost-effective way to analyze the consequences of an event of interest. Multizone models, although limited by the use of the well-mixed zone assumption, are considered the most practical and useful choice for modeling air and contaminant flows in whole buildings [3]. However, due to the many simplifications and assumptions inherent in multizone methods, an uncalibrated model may be a poor representation of a particular real building. Although highly desirable, calibration can be a time consuming and expensive process.

Field tests were performed as part of a project to develop a method for rapidly developing and tuning multizone air flow models of real buildings constructed with the widely used CONTAM software [4] via relatively simple, inexpensive measurements taken at the site.

This paper summarizes the findings of those tests with respect to the degree of model quality improvement achieved as a result of the tuning process.

METHODS

Equipment and Measurement Techniques

The procedure requires a variety of measurements and the appropriate instruments to perform them, including indoor temperature (hand held thermometer), diffuser air flow rate (flow measuring hood), differential pressure for leakage tests (wireless pressure sensor), interior air flow direction (smoke bottle), AHU flow rates (fan inlet airflow sensor or pitot traverse), and weather conditions (portable weather station). Additionally, transient CO_2 tracer gas tests were performed in an effort to validate the procedure (portable infrared CO_2 gas analyzers).

Test Sites

Calibration exercises were performed for two buildings. The first (RB-1) is a three story (plus basement), 3,810 m^2 building mainly comprised of office spaces, but also including conferences areas and a snack bar. The building is air-conditioned by three air handling units (AHUs). AHU 1 serves three large conference spaces on the first floor with ducted supply and return. AHU 2 serves the remainder of the first floor and the entire second floor. The first floor has ducted supply and return, while the second floor has ducted supply and plenum return. AHU 3 serves the third floor with ducted supply and return. Bathrooms are connected to an exhaust system and receive makeup air through transfer grilles.

The second building (RB-2) is a larger, more complex five story (plus basement), 8,500 m^2 structure comprised of classrooms, office spaces, and conferences areas. The area excluding the basement, which was not modeled, is 6,920 m^2. The first two floors house classrooms and medium-sized lecture halls, while the third through fifth floors house faculty, staff, and graduate student offices. Each floor is served by its own AHU via ducted supply and return. The first floor also has two large lecture halls with dedicated single-zone AHUs, but these are isolated from the rest of the building and were not considered in the modeling.

Model Tuning Procedure

The tuning procedure was initially developed from “virtual building” testing in which a simplified multizone model was tuned to match a reference model through the use of simulated measurements (i.e., the use of data values from the reference model to update the simplified model) [5 - 7]. The approach is similar to the heuristic method described by Musser et al [8], differing mainly through the use of a more structured technique based on iterative improvement of a suitable performance metric.

One possible quality measure is ASTM Standard D5157-97 [9]. However, this standard requires the use of tracer gas testing and was deemed too difficult and costly for widespread application by building modelers or owners. After considering various options, the fraction of correctly predicted interzonal flow directions (or equivalently, the relative pressurization of zones) was selected as the principle quality metric. A flow direction map of a building can be developed rapidly and inexpensively using simple hand-held flow visualization devices such as smoke bottles.

The first step in the procedure is initial model development. This model is based on construction documents and data values from literature (e.g., component leakage, terrain coefficients, etc) and requires no site data, although sources such as commissioning reports may be of use, if available.

At the beginning of the site measurement phase, a weather station should be set up to log ambient conditions throughout the test. The first iteration of building measurements includes mapping of interzonal flow directions and measurement of main air flows such as supply, return, and outside air at air handlers and, if possible, envelope and shaft leakage. The model is updated with these data.

Prior to the first model update and after each update, predicted flow directions are compared with measure directions to determine the value of the performance metric and to identify areas of discrepancy within the building. Air flows to zones connected by flow path with incorrectly modeled flow direction are measured (Figure 1), the model is updated, and new predictions of interzonal flows are generated. This process is repeated until a stopping criteria is reached, which may be the point of diminishing returns in improvement of the predicted flow direction distribution, the completion of all possible measurements, or some other condition determined by the analyst.

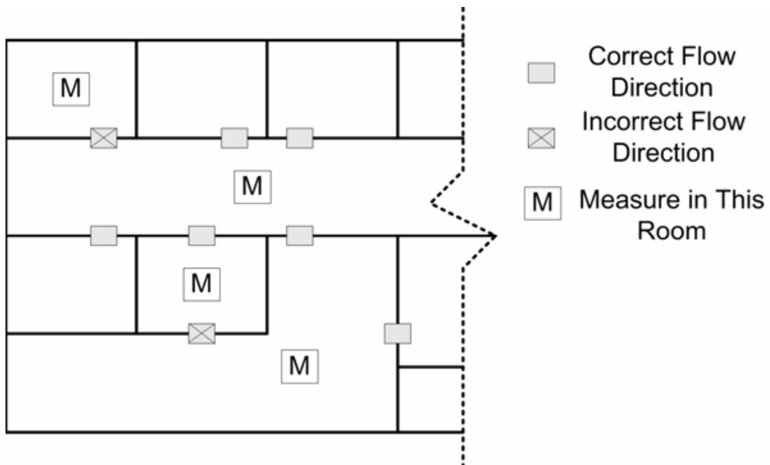

Figure 1. Example of measurement guidance based on location of incorrect airflow directions

The final step in tuning is an analytical process in which optimal (in the sense of reducing error) values of difficult or impossible to measure model parameters are determined. To date, this processs has been applied to four parameters: average exterior leakage, average interior leakage, average shaft leakage, and terrain coefficient (used to calculate wind pressure on the envelope in CONTAM). Any of these parameters that have been measured previously are excluded from this step.

Validation Methodology

Two key questions arise in the validation of the tuning procedure. The first is whether the measurement and model correction process leads to improvement in the correct flow direction performance measure. The second is whether improvement in this metric parallels improvement as measured by an independent standard such as ASTM D5157.

ASTM D5157 employs six statistical measures (correlation coefficient, regression slope, regression intercept, normalized mean square error, fractional bias, and fractional variance) to compare modeled and observed tracer concentrations at a given sampling location. Satisfactory ranges are defined for each parameter. How to apply the standard to multiple sampling points is not discussed in the standard. In the present case, the approaches used were 1) to tabulate the percentage of all metrics (six per sampling location) that fell within the satisfactory range at each stage of correction and 2) to examine the distribution of values of a particular metric at different points in the tuning process.

In RB-1, releases were performed in all three AHUs in turn and measured at all AHU returns (three locations) with a repeat of each release. In RB-2, releases were performed at the AHUs serving floors one, three, and five and measured at all five AHU returns. The quantity of CO_2 injected was intended to raise concentration in the area served by the release AHU by1600 ppmv in order to obtain an easily measured signal.

RESULTS

RB-1 Model Tuning

Tuning of the model of RB-1 was completed in seven iterations, as outlined in Table 1. It should be evident from the decreasing number of measurements at later iterations that the measurement time per iteration decreased significantly as the process progresses.

Table 1. Summary of RB-1 Tuning Process

Iteration	Description
0	Model developed using design document data
1	Interzonal air flow directions and supply, return, and outdoor air flows of all AHUs are measured. Recording of weather conditions (temperature, wind speed) begins.
2	122 diffuser measurements based on location of incorrect airflow directions
3	24 diffuser measurements based on location of incorrect airflow directions
4	10 diffuser measurements based on location of incorrect airflow directions
5	6 diffuser measurements based on location of incorrect airflow directions
6	2 diffuser measurements based on location of incorrect airflow directions
7	Interior leakage, exterior leakage, shaft leakage, and terrain coefficient & exponent are adjusted based on minimization of regression equation.

Figure 2 shows the progression of the percentage of correct interior airflow directions and the percentage of satisfactory ASTM metrics for the seven iterations described in Table 1. A single point in the ASTM data set represents, in this case, one hundred and eight data points: 2 sets of releases x 3 releases per set (at AHU 1, 2, and 3) x 3 measurement points per release x 6 statistical metrics per measurement points. The percentage of correct interior airflow directions is initially 52% and increases to a final value of 81% over the course of the tuning exercise. The greatest improvement occurs during iterations one (to 63%) and two (to 72%). The automated tuning process (iteration 7) produced no change in this metric, probably because the only parameter changed was shaft leakage value.

In the base model, 31% of ASTM D5157 metrics were within satisfactory ranges. The first iteration of tuning increased the total to 41%, but subsequent iterations, evaluated in this way, produced little change. The lack of improvement in later iterations is very likely the result of there having been a small number of measurement locations in the field test, and the placement of those sampling points in the AHU returns. The concentration of tracer returning to these locations represents the average of all connected zones, therefore, changes in flows between zones are likely to have little effect on what is observed there. Sampling points within spaces would be needed to provide a more refined indication of the effect of local flow adjustments. Previous application of ASTM D5157 during “virtual building” tests permitted evaluation of the ASTM statistical metrics in every zone. In these tests, improvement in quality as measured by the ASTM standard paralleled quality as indicated by improvement in correct flow directions and continued throughout the tuning process [5-7]

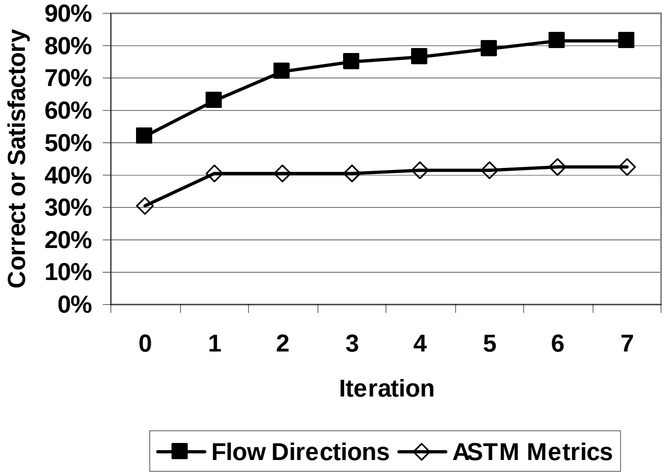

Figure 2. Correct interzonal flow direction and satisfactory ASTM metrics for RB-1 model tuning.

The use of a binary satisfactory/not satisfactory criterion for evaluating model quality using ASTM D5157 does not account for the possibility that unsatisfactory metrics move closer to the satisfactory range as a result of tuning. They may remain unsatisfactory as defined by the standard, but nevertheless are improved. One way to investigate this issue is to compare the distribution of values of a metric with the ASTM D5157 criterion over the course of several tuning iterations. For example, Figure 3 shows a cumulative distribution plot of correlation coefficient values from iterations 0 and 1 (during which essentially all of the change in ASTM metrics occurred). Lines indicating perfect and minimally acceptable values are shown for reference. . This result was the same for all statistical measures (except normalized mean square error, which showed no change), so this way of analyzing the data lends credence to the previous analysis.

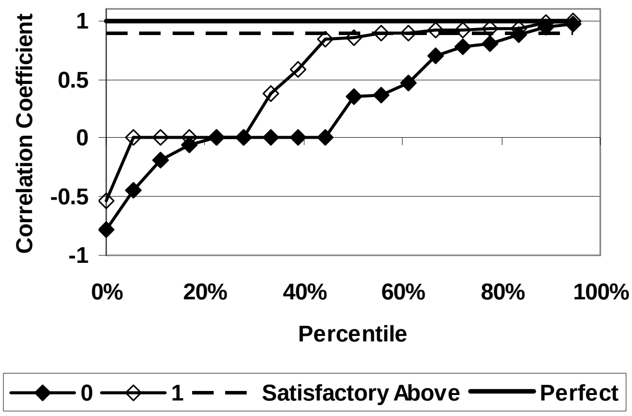

Figure 3. Percentile distribution of correlation coefficient for RB-1 tuning for iteration 0 and iteration 1.

RB-2 Model Tuning

The model of RB-2 was tuned in four iterations, described in Table 2. Iterations 4a and 4b are Alternative applications of regression to determine unmeasured parameters. Iteration 4a included estimation of exterior leakage while 4b did not.

Table 2. RB-2 tuning steps

Iteration	Description
0	Model developed using design document data
1	Interzonal air flow directions and supply, return, and outdoor air flows of all AHUs are measured. Recording of weather conditions (temperature, wind speed) begins.
2	229 diffuser measurements based on location of incorrect airflow directions
3	52 diffuser measurements based on location of incorrect airflow directions
4a	Interior leakage, exterior leakage, shaft leakage, and terrain coefficient & exponent are adjusted based on minimization of regression equation.
4b	Interior leakage, exterior leakage, shaft leakage, and terrain coefficient & exponent are adjusted based on minimization of regression equation. Measured exterior leakage is used

Figure 4 shows the progression of the percentage of correct interior airflow directions and the percentage of satisfactory ASTM metrics.

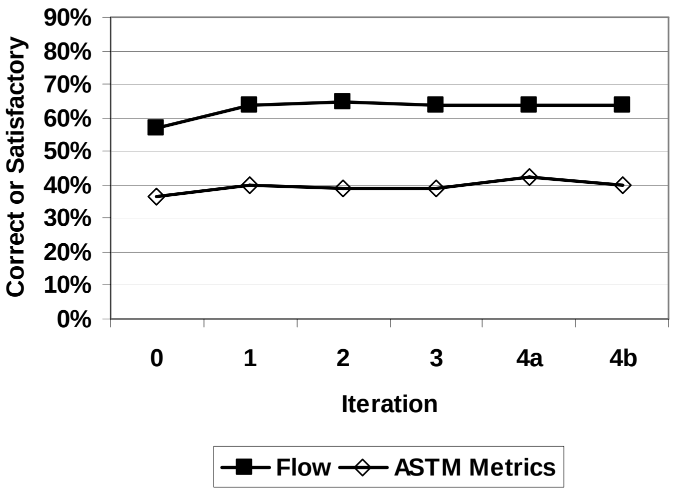

Figure 4. Correct flow direction and satisfactory ASTM metrics for RB-2 model tuning.

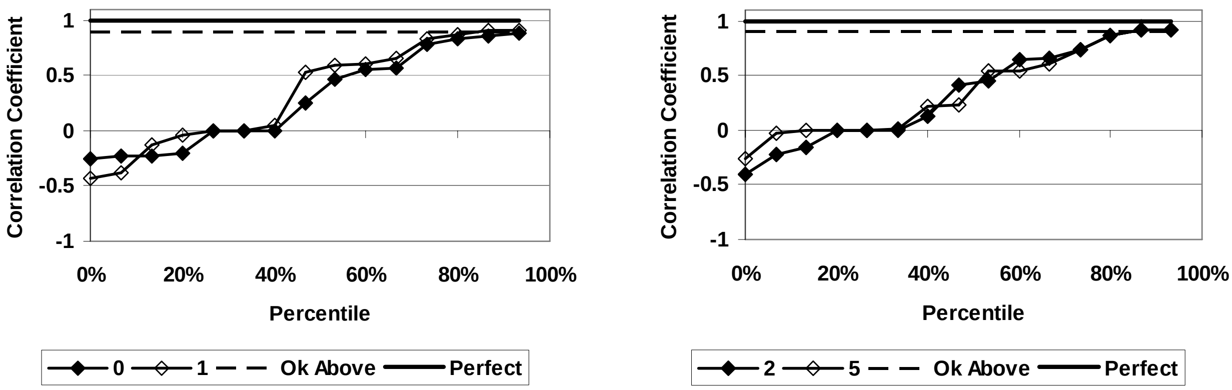
The intial percentage of correct interior airflow directions was 57%. The first iteration increased correctly modeled directions to 64%. Subsequent efforts to tune the model achieved only an additional 1% improvement. Automated tuning did not change the interior, exterior, or shaft leakage, only the terrain coefficient and wind pressure exponent. Since there was not much wind at the time of the test, it is not surprising that this change had little effect.

The overall change in the percentage of satisfactory ASTM metrics also was small, starting at 37%, and increasing to 40% after iteration 1. Regression based tuning of leakage and terrain data increased the satisfactory metrics to 42%. Use of measured envelope leakage characteristics resulted in slightly worse performance (40% satisfactory) than use of a predicted value.

Distributions of correlation coefficient calculated as part of the ASTM D5157 analysis (Figure 4) also show modest improvement from iteration 0 to iteration 1 and little change thereafter, for the same reasons noted with respect to building RB-1. It should be noted in Figure 5 that in this application of the proposed method correlation coefficient at some locations improved as a result of tuning while at others it degraded.



(a) (b)

Figure 5. Percentile distribution of correlation coefficient for RB-2 model tuning. (a) Iterations 0 and 1. (b) Iterations 2 and 5.

DISCUSSION AND CONCLUSIONS

The tuning of smaller, simpler building RB-1 was successful in terms of improvement in both predicted interzonal flow directions and as indicated by ASTM D5157. The application of the tuning process to the larger more complex building RB-2 produced little evidence of improvement. One possible explanations for the lack of success in tuning the RB-2 model are that the model failed to capture certain important features of the building that were not affected by any of the model modifications made on the basis of measured data. A second possibility is that factors like distribution system leakage that were not measured played a role. A third possibility is that control errors occurred during testing that put the system in some other status than was assumed.

Main air flow measurements assigned to the first iteration produced the largest improvements in both cases. Diffuser measurements based on the location of incorrect interior airflow directions produced smaller, local improvements in air flow direction for RB-1, but had little impact on RB-2. As noted, improvement in ASTM D5157 metrics after iteration 1 was predictably small because of the limited number of tracer measurement points and their location in AHU return air streams. Using regression equation optimization to tune difficult to measure leakage and wind parameters was the least effective tuning measure.

It was observed that the characterization of model quality can vary significantly with the measure used. In the tuning of the model of RB-1, the airflow direction metric improved significantly throughout the tuning process, while the interpretations of ASTM D5157 improved mainly during the first iteration. Results of RB-2 tuning demonstrated that an aggregate measure of quality such as the total number of satisfactory ASTM D5157 metrics can disguise finer scale changes.

Although ASTM D5157 is quite detailed, it leaves unresolved several significant issues regarding what it measures and how it should be applied. First, it defines quality at a particular sampling point relative to a particular tracer release. If the release or sampling location changes, the assessment of model quality will also change. Second, it defines quality in terms of six different metrics and does not indicate whether a model can be satisfactory if one or more of these measures falls outside the satisfactory range. Finally, it does not address the issue of how to judge model quality in a complex building in which multiple sampling locations are used. All of these issues should be addressed in future development of this standard.

ACKNOWLEDGEMENTS

The authors thank Andrew Persily and Heather Davis of the U.S. National Institute of Standards and Technology for providing instrumentation and technical support for the tracer gas studies conducted during this research. The assistance of Penn State graduate student Ponkamon Aumpansub with field testing is also gratefully acknowledged. This work has been supported by The Technical Support Working Group under contract W91CRB-04-C-0039 with funding from the U.S. Department of Homeland Security.

SUMMARY

This presents a research effort toward an integrated model-based approach to energy-efficient operation of building systems. The ingredients of the corresponding concept are as follows: i) A comprehensive building state model underlines all operative entities and activities in the life-cycle of the building. This model includes information on building context (e.g. weather conditions), building topology, components, and systems, as well as building occupancy (user presence and actions); ii) The model is updated real-time via a sensory infrastructure including sensors for outdoor and indoor environmental conditions, occupancy presence and actions, state changes in control devices; iii) The building state model is provided to multiple applications pertaining to facility management and control systems. Such applications use various tools (including building performance simulation, trend analysis and learning algorithms) in order to anticipate the state of building and indoor climate as a result of alternative control options.

INTRODUCTION

Complex buildings are frequently affected by shortcomings in the configuration and operation of building service systems, resulting in sub-par indoor climate conditions and poor energy performance. To address these concerns, this contribution presents a research effort toward an integrated model-based approach to energy-efficient operation of building systems. The ingredients of the corresponding concept are as follows: i) A comprehensive building state model underlines all operative activities in the life-cycle of the building. This model includes information on building context (e.g. weather conditions), building topology, components, and systems, as well as building occupancy (user presence and actions); ii) The model is updated real-time via a sensory infrastructure including sensors for outdoor and indoor environmental conditions, occupancy presence and actions, state changes in control devices; iii) The building state model is provided to multiple applications pertaining to facility management and control systems. Such applications use various tools (including building performance simulation, trend analysis and learning algorithms) in order to anticipate the state of building and indoor climate as a result of alternative control options. To demonstrate the viability of the proposed approach, a 1:1 two-cell office space has been set up in our laboratory. The facility is equipped with systems for heating, ventilation, lighting, and shading. The state of weather conditions is monitored via a weather station. Indoor environment data are collected via sensory units measuring temperature, relative humidity, air flow speed, illuminance, etc. Changes in the configuration of the cells and workstations (e.g. location of furniture and partition elements) as well as occupancy information are captured via an optical location-sensing system. These data are updated regularly and provided to the building systems control unit along with users' feed-back regarding their indoor climate preferences. The building systems control unit uses building performance simulation to predict the implications of alternative control device states and identifies (through comparison and ranking of the simulation results) and brings about a configuration of the control device states that is preferable both in terms of energy efficiency and indoor climate.

We first describe two instances of automated model actualization, namely the actualization of a context mode (sky luminance distribution pattern) that can be used for real-time simulation-based lighting systems control, and the actualization of the room configuration model via location sensing. We then describe the principles and application of a model-based systems control strategy using the example of lighting controls. Subsequently, we illustrate the development of a test-bed for the integrated realization of a model-based multi-system energy-efficient building systems control strategy.

APPROACH AND RESULTS

To realize a model-based building control strategy, the building must possess a model of itself, including both context and components. To illustrate this point in this section, we first use the case of dynamic generation of sky luminance model that can be used for real-time simulations toward lighting systems control. We then illustrate the process of room geometry and configuration model generation and updating via location sensing.

Sky-Scanning

The sky model is generated on a real-time basis using calibrated digital photography. Toward this end, the building's weather station is augmented with a digital camera with a fish-eye converter. From images, the sky luminance model is extracted in terms of distinct luminance values for 256 sky patches (Figure 1). Digital images of the sky are continuously taken, analyzed and calibrated real-time to construct the sky model for the simulation application. The calibration is necessary, as the camera is not a photometric device. It is possible, however, to derive reliable photometric data from properly calibrated digital images [1]. The approach to calibration involves measuring global horizontal illuminance data simultaneously with digital sky photography.

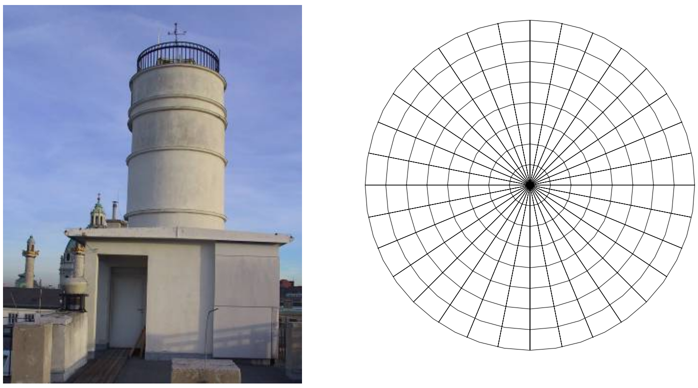

Figure 1. Weather station and the pattern for sky luminance mapping.

The external illuminance data is obtained from the building's weather station. For each image, the initial estimate of the illuminance resulting from all sky patches on a horizontal surface can be compared to the measured illuminance. The digitally-derived sky patch luminances can be corrected to account for the difference between measured and digitally estimated horizontal illuminance levels [2].

Location Sensing

In previous studies, we showed how a simulation-based lighting systems control [3] [4] may be supported by provision of dynamically updated room models that are generated based on the vision-based location-sensing system VIOLAS [5]. Thereby, it was shown how a set of networked pan-tilt cameras in a facility can regularly provide updated models of room geometry and objects within the buildings that can be used for facility management and building control applications. VIOLAS involves five major blocks, whereby each block has a distinct role in context data extraction (Figure 2).

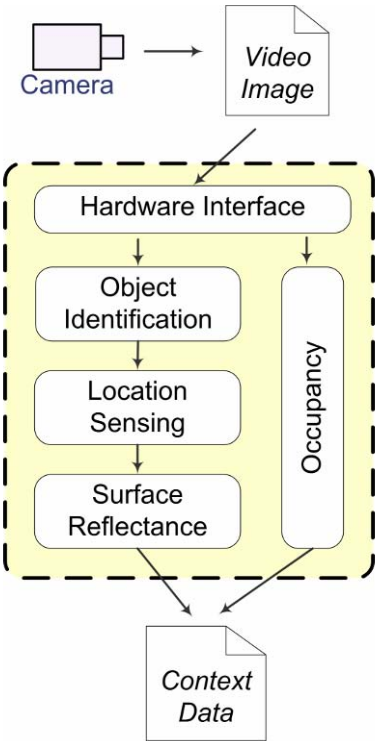

Figure 2. "Sensing core" in VIOLAS.

The Hardware Interface block permits multi sensor data acquisition. In our first attempt, due to the possibilities introduced by the usage of integrated computing, netcams equipped with pan/tilt units were used. However, netcams also generate relatively low-quality data due to data compression resulting in low resolution and blurred images without sharp details. Moreover, pan-tilt netcam solutions are rather bulky, expensive, and involve moving elements. Due to these circumstances, we proposed to study the possibility of improving the VIOLAS system by means of digital cameras with fisheye lenses. Already employed within VIOLAS, the location sensing module is adapted from TRIP system (cp. [6] and Figure 3). A circle on the target plane generates an ellipse on the image plane of the camera. From the known parameters of the ellipse, it can be back-projected to the original circle enabling the extraction of the orientation and the position of the target plane with respect to the camera origin [7]. In order to implement this algorithm, barcode-like tags with circular marks are used. Any regular black-and-white printers can be used to reproduce these tags enabling low-cost and low-maintenance tags without the necessity of power input. Identification is achieved by the codes printed around the circular mark (reference circle). Contrasting with the TRIP system that uses ternary coding, VIOLAS uses binary coding, where the tags are divided into

16 equal sectors (Figure 4) resembling pie slices. The presence or absence of the black mark on the sector denotes the 1 or 0 coding respectively. The pattern of "0111" code sequence defines the start bit sequence, and is not repeated in the code string to avoid ambiguity.

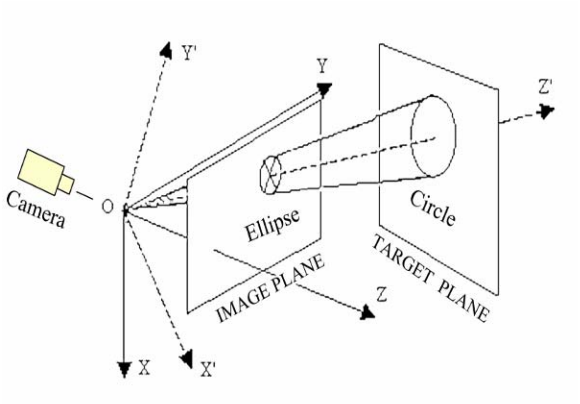

Figure 3. "Pose from circle" algorithm. (*X*,*Y*,*Z*) denotes the coordinate system of the image plane whereas (*X'*,*Y'*,*Z'*) denotes the coordinate system of the target plane. The outcomes of the algorithm are the parameters of the transformation between two coordinate systems.

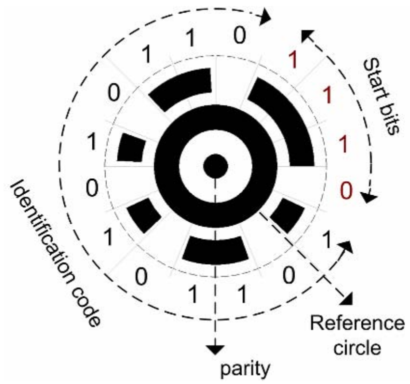

Figure 4. Tag structure is illustrated with a sample tag coded with 0111-011010101101 data string (even-parity = 1). Identification number corresponds to 1709 in decimals.

With the remaining 12 sectors we are able to encode 2031 distinct tagged objects. The TRIP system divides the location sensing procedure into two phases. In the first phase, "target recognition", where the tags are detected, parameters of the reference ellipse (projection of the reference circle on the camera image) are extracted and the identification numbers are decoded. In the second phase, "pose extraction", the locations of the tags are computed from the outputs of the first phase [6]. VIOLAS improves the original TRIP method by incorporating two additional algorithms (Figure 5). An "adaptive sharpening algorithm" [8] on the input image prior to "target recognition" (Figure 5) is applied, resulting in an enhanced output image. As the pixel resolution of the tag images decreases with increasing distance between the tags and the camera, code identification becomes difficult, despite the fact that the tags are being detected and reference ellipses are being correctly extracted. In order to resolve this problem, "edge-adaptive zooming" [9] is applied locally to spurious tags from which the code could not be deciphered or validated. Edge-adaptive zooming, rather than its equivalents such as bilinear and cubic interpolation, enhances the discontinuities and sharp luminance variations in the tag images. This procedure is recurring until the "target recognition" is successful or the zoomed image region loses its details (Figure 6). In the latter case, a false alarm or an unidentified tag will be retrieved.

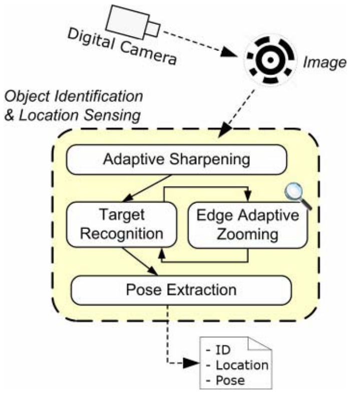

Figure 5. Algorithm flow of object identification and location sensing in the "sensing core".

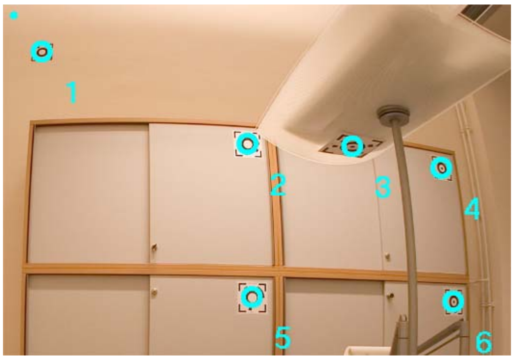

Figure 6. Example of a successful tag localization.

Model-Based Control

To demonstrate a model-based building systems control strategy, we consider the case of lighting and shading systems control in an office space (see Figure 7) [10]. This office's two windows are equipped with automatically controllable blinds. Artificial illumination is provided by two free-standing luminaires. The room model entails information about room geometry, furniture, the location and size of windows as well as the physical properties of room components (such as reflectance and transmittance) as well as the position of virtual sensors that monitor pertinent performance parameters (such as illuminance levels or glare indices). The room is equipped with the aforementioned location-sensing system, which automatically tracks changes in the position of moveable furniture elements (including the aforementioned luminaires). Presence of the people in the room (at the workstations) is monitored with occupancy sensors. User preferences (e.g. desirable illuminance levels, relative weights for objective function) can be communicated to the lighting control application via occupants' and facility manager's computers. The room model provides the basis for the system's internal representation and is updated dynamically using an optically-based location-sensing system.

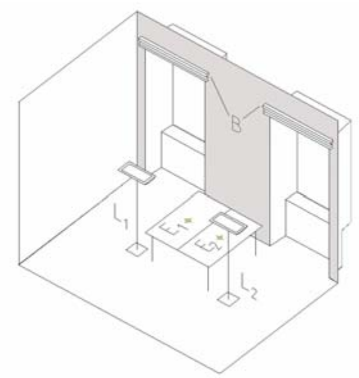

Figure 7. Illustration of the test space (L_1, L_2: Luminaires; B: Blind; E_1 and E_2: virtual illuminance sensors).

Control Devices and Control State Space

Three control devices are considered, namely the two luminaires (L_1, L_2) and the window blinds (B). In the control scenarios considered in this paper, the two blinds are controlled simultaneously. As a primary indicator of lighting performance, we considered the two mean illuminance levels E_{m1} and E_{m2}. Since all these devices affect both E_{m1} and E_{m2}, a central control instance (C) is required to coordinate the three devices toward the most preferable control state. The overall behaviour of the control system is determined through a utility function (UF). The overall objective of the control process is to maximize UF, which, in our test runs, pertains to preferences for illuminance levels, cooling load, and electrical energy consumption. The following scenario involving a control cycle is repeated regularly (in this case, every 15 minutes). At every time step $t_{i,}$ each device (i.e., L_1, L_2, B) submits to the controller application C a list of candidate device states for time step t_{i+1}. In the present case, each device submits four alternative options. These options are: the device's current position, the 2 adjacent positions, and a fourth – randomly chosen – option from the rest of the device's control state space. Thus, the control application considers the resulting overall option space involving a maximum of 64 distinctive control states. To illustrate the working of the above-described control method, we documented the operation of the system in the course of fifteen days (fourteen days in May and one day in June 2005). In this case the control systems reassessment of the desirable control state occurs regularly every 15 minutes. The following figures illustrate this operation in terms of system recommendations and its performance. Given this paper's space limitation, figures 10 to 12 exemplify data only for one day, namely 14th May 2005, in terms of: measured external global horizontal illuminance and control system's predictions of the illuminance levels E_{m1} and E_{m2} as a result of the control system's recommended shading and luminaire states (Figure 8); recommendations of the control system for dimming positions of the two luminaires and the blind position (Figure 9).

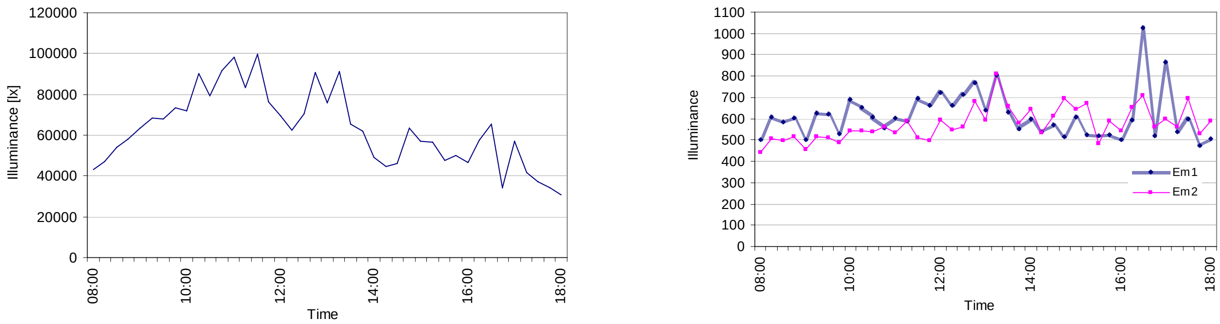

Figure 8. Prevailing external global horizontal illuminance levels in the course of one day and task illuminance levels (E_{m1} and E_{m2}) as the result of system's operation.

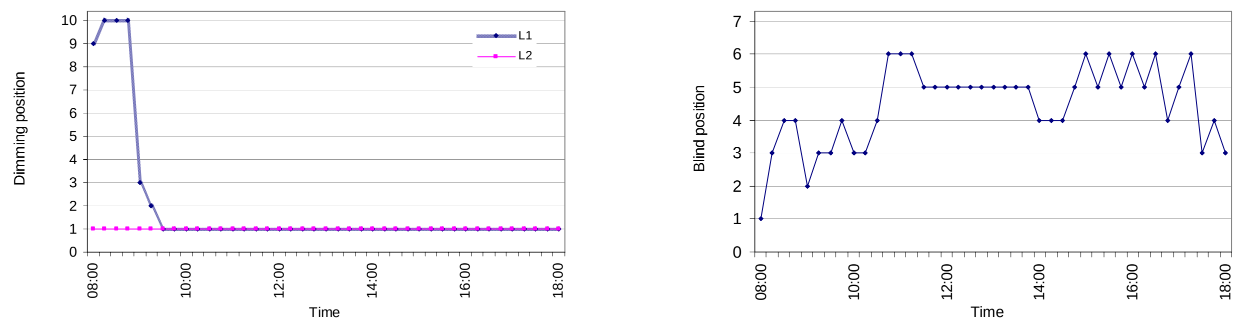

Figure 9. System's recommendations for the luminaires' dimming states and the blind positions.

Development of the Test Bed

The test bed is being started "from scratch" as a full-scale mock-up of two office rooms in a test booth located in the building physics laboratory at TU Wien. The current objectives of the test bed are to enable replication of the results of the above mentioned lighting control study and extension of the lighting control model to include a system for heating, ventilation and air-conditioning (HVAC). Current plans for test bed equipment installation in the existing light-weight structure include: *i)* HVAC system; ii) Electrical lighting system; *iii)* Active daylighting system; iv) Enclosure systems; v) Furniture systems; vi) Control systems; and vii) Information systems. An overview of the test bed layout is shown in Figure 10, below.

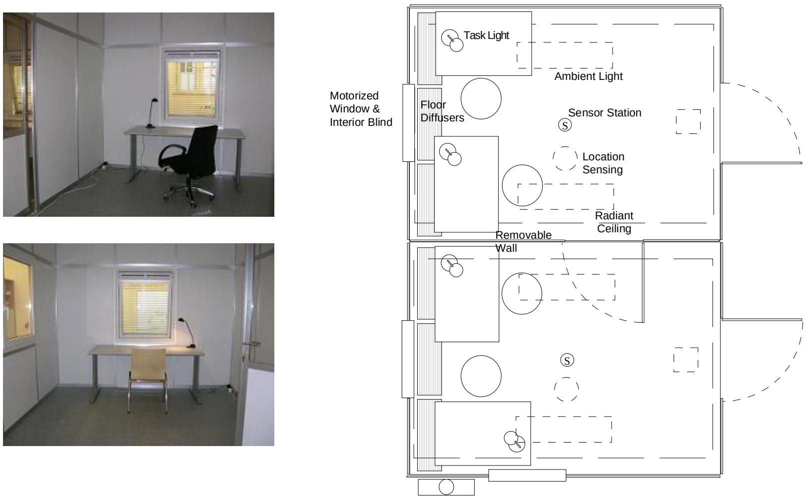

Figure 10. Interior and plan views of the test bed under development.

Simulation-assisted control involves two types of information, those typically transmitted over local area networks, such as data from local servers and weather stations, and data exchanged between the controller and the actual test bed, e.g. for sensor – actuator interaction. Most commercially available building systems for automation communicate on a LON-bus [11]. The test bed uses both bus systems for an authentic demonstration of the model-based control strategy. The test bed can be seen as a continuation of previous experiments in simulation-assisted control. Table 1 shows an overview of control parameters and illustrative control states.

Table 1: Illustrative represententation of the control state space of the test bed.

Control Parameter	Control Variable	Actuator	States (Values)
Natural Ventilation	Window Tilt Position	Window Actuator (% open)	1. 0% 2. 100%
Daylighting	Blind / Louver Position (vertical & horizontal)	Blind Actuator (shading rate, descending)	1. vertical & fully down 2. horizontal & fully down 3. vertical & 2/3 down 4. horizontal & 2/3 down 5. vertical & 1/3 down 6. horizontal & 1/3 down 7. fully pulled up
Electrical Lighting	Dimming Level of Ceiling Fixtures (power output in Watts)	Lighting Actuator (% dimmed, descending)	1. 0% ; 2. 20%; … 10. 100%
Room Air Temperature (mechanical heating)	Supply Air Temperature (dry-bulb temperature, °C)	Throttle at supply air terminal (% closed)	1. 10%; 2. 40%; 3. 70%; 4. 100%
Room Supply Air Volume (mechanical ventilation)	Fan speed (power output)	Fan actuator (% running)	1. 0%; 2. 50%; 3. 100%

CONCLUSIONS

We described a test bed for the prototypical realization of an integrated (multi-system) model-based building control strategy. A comprehensive self-actualizing building model is at the core of the implementation. It encompasses information regarding building context, components and processes. Regularly updated, it provides a real-time source of information for facility management and building systems control operations. Ongoing research is expected to expand the already developed simulation-based lighting and shading control systems to cover further environmental systems for heating, cooling and ventilation. Moreover, innovative user-interface systems are being tested to facilitate an intuitive interaction modus between occupants and the building's environmental control systems.

Summer season temperature control in Finnish apartment buildings

Jarek Kurnitski, Pasi Tauru and Jari Palonen

Helsinki University of Technology, Finland

Corresponding email: jarek.kurnitski@tkk.fi

SUMMARY

In modern apartment buildings with good insulation and heat recovery, often having large windows and high internal heat gains, overheating may be a serious problem not only in summer season, but also during heating season. This study determined the design curves for the assessment of room temperatures and cooling demand in apartments. The design curves are based on many simulations and they show the effects of window airing, solar protection glasses, window size and orientation, cooled supply air and room conditioning. Determined graphs allow to check quickly the thermal comfort in apartments and this will be a step forward from today's practice not to do such check. They suit well for preliminary design and are useful for architects and HVAC-consultants not using indoor climate and energy simulation software.

INTRODUCTION

Modern apartment buildings are well insulated, heat recovery is used in ventilation and they often have large windows and high internal heat gains especially in well-equipped apartments. These factors may cause overheating not only in summer season, but also during heating season. In the building process, it is common that the architect decides quite independently important choices as regards temperature control. Such issues are the shape and solar protection of building, window size, orientation and glass properties and the selection of structures. After that, the task of HVAC-consultant is to design heating and ventilation. This means in practice the sizing of heating and ventilation system according to architect's choices, not the indoor climate design.

Occupant questionnaires have shown that the building process described gives good results for heating season, but in the summer, apartments are often overheated. This problem is seldom noticed when apartments are for sale, but usually afterwards, when it is not easy to fix the problem. Temperature control has also a concern of public health, which will be stressed with increasing frequency of heat waves. In the summer excess mortalities caused by high temperatures are between 100–200 cases per year [1] in Finland.

Questionnaire survey conducted as a part of a wide European HOPE project [2] studied thermal comfort in apartments in summer and winter. Thermal responses in 7-point scale are shown in Figure 1. The responses of 3, 4 and 5 show acceptable conditions. Good thermal comfort was reported by 73% of occupants in the winter and by 60% in the summer. In the summer about 40% of occupants report that temperature is too high and even in the winter 11% reported too high temperature. There was high variation in the responses depending on the orientation of the apartment and presence of balcony glazing.

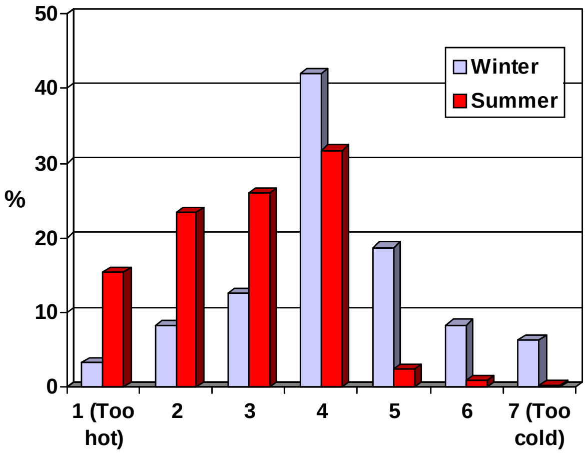

Figure 1. Thermal comfort reported by occupants in 7-point scale (n=600) in winter and summer.

The main problem in the design of apartment buildings is that the temperature simulations are usually not conducted for typical flats. However, the results of the simulations should be taken into account in the choices of architect and in the design and sizing of ventilation and cooling. In this study we tried to overcome this problem by conducting a large number of simulations for typical cases and presenting the results in the form of design curves which can be used for the design of thermal comfort in all typical apartment buildings. These design curves give a simple design tool for architects and HVAC-consultants.

METHODS

We simulated two apartments from relatively new apartment building, construction year 2001, representing typical construction solutions and size of apartments. The building consisted of 10 apartments with two bedrooms (70,5 m^2) and 33 apartments with one bedroom (60,1 m^2). On apartment of both types was modeled with IDA-ICE indoor climate and energy simulation software, Figure 2 and 3. All apartments were equipped with mechanical supply and exhaust ventilation with heat recovery. Total design supply airflow rate was 50 L/s and exhaust 60 L/s in all of apartments.

Figure 2. A photo of the simulated apartment building.

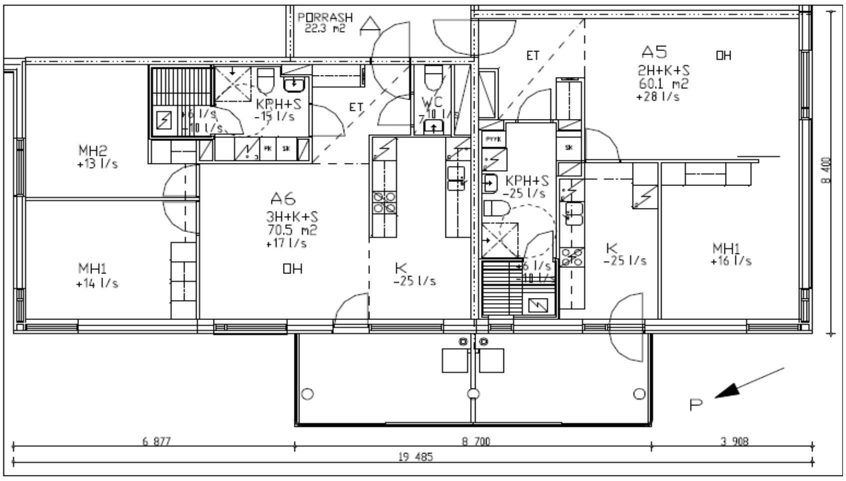

Figure 3. Simulated apartments with 2 and 3 bedrooms.

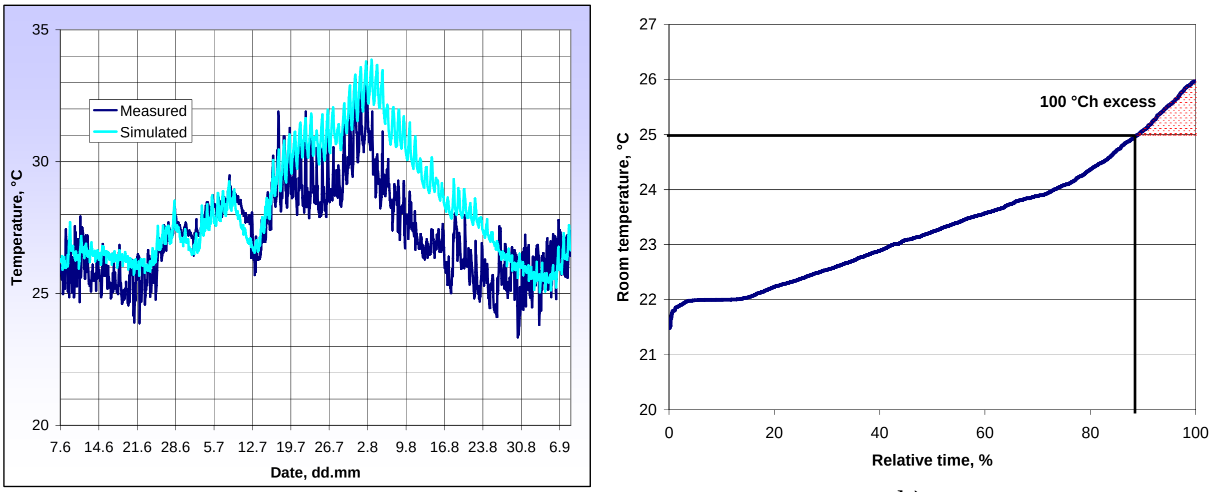
Summer time temperature measurement data from one flat was used for the verification of the IDA-ICE model, Figure 4, a). This was not the attempt of detailed validation as the occupancy data and the use of window airing was not known. However, such comparison indicates how realistic temperatures are predicted by the model.



a) b)

Figure 4. a) Typical measured temperature from the summer of 2003. The simulated temperature shows some discrepancy as window airing is not taken into account. b) Accepted temperature exceeding for good indoor climate category S2 during three months in the summer.

In the parametric simulations the effect of 22 building and HVAC-factor was studied. Based on these simulations, the most important factors were chosen for sensitivity analyses. Three basic cases were studied:

1. the reference case corresponding to measured apartment building without cooling
2. cooling of the supply air
3. room conditioning unit in the apartment

For these basic cases sensitivity analyses were conducted for the following parameters:

- orientation of the building (four main directions)
- window area equal to the reference case, and increased by 1,5 and 2 times

- with and without window airing
- with solar protection glasses and with common clear panes
- 5 W/m^2 and 10 W/m^2 internal heat gains

The results are presented as simple graphs, from which the effect of each factor can be seen for two defined indoor climate classes. Indoor climate classes were defined because exact key figures are needed for the comparison of design alternatives. For that purpose the target values of Finnish indoor climate classification [3] and the weather data of 2003 was used. This approach follows the principles given in new indoor climate standard prEN 15251 [4] and leads to categories:

- Basic category S3, where room temperature is usually below 27°C
- Good indoor climate category S2, where room temperature is usually below 25°C

For both indoor climate categories the exceeding of the limit temperature by 100 °Ch degree hours is accepted during the summer period from June 1st to Aug 31st, Figure 4, b).

RESULTS

Design curves for room temperature and cooling demand

Design curves are intended for the assessment of room temperatures and cooling demand in apartments and can be used by architects and HVAC-consultants. They show the effects of window airing, solar protection glasses, window size and orientation, cooled supply air and room conditioning. All design curves are given for the four main directions and as a function of the ratio of window area to floor area.

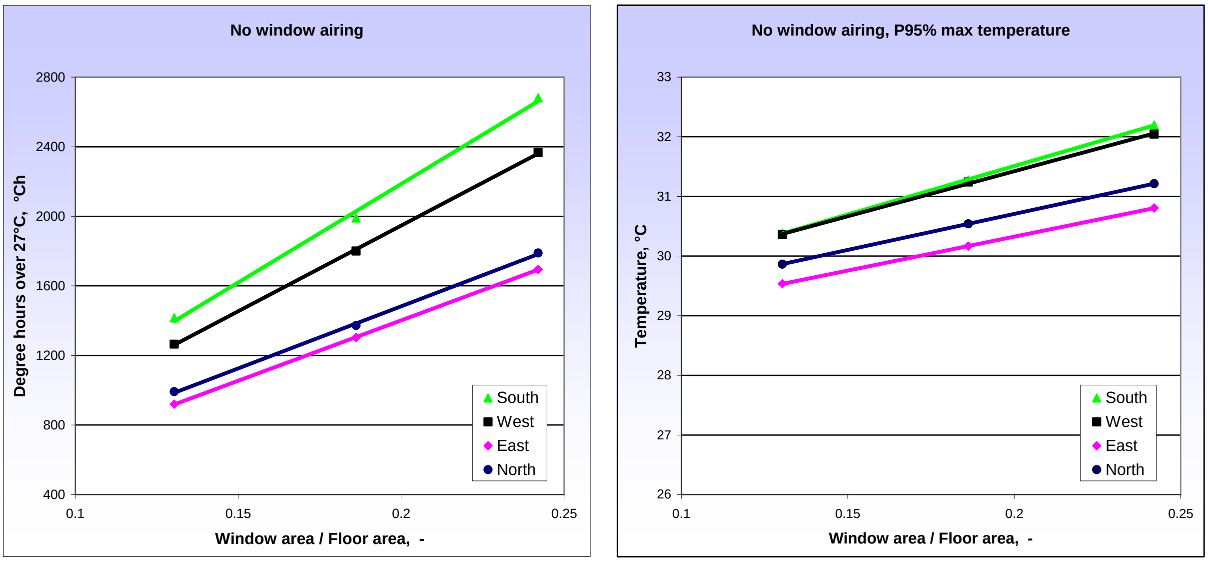
Design curves show, would the indoor climate category achieved in the studied case or what should be changed to achieve the category. Room conditioning curves are for the good indoor climate category S2 and all other curves for the basic category S3. Design curves are not sensitive to the apartment size and may be used for sizing of full range of apartments. However, they are sensitive to internal gains. 5 W/m^2 applies for common apartments (including occupants, lighting and equipment). In well equipped apartments with relatively small floor area the gains may be higher. In that case 5 W/m^2 curves may still be used if the part of gains exceeding 5 W/m^2 will be removed by increasing the airflows in the case of cooled supply air or cooling power in the room conditioning case respectively.

All cases are calculated with solar protection by blinds between the outer panes in three pane window. Possible shading by neighboring buildings, etc. is not taken into account, i.e. all curves apply for fully exposed building. Solar shading may have significant effect especially in apartments on lower floors. This can be roughly estimated, if in the case of clear panes the curves of solar protection glass are used.

In the graphs, the degree-hours exceeding the room temperature of 25 or 27 ºC are shown. For the estimation of maximum room temperature, P95% values of the room temperature frequency distribution curves are given (this is considered as reasonable estimate of maximum room temperature during hot days). Room temperature assessment should be done according to the room showing the highest temperature (= highest window are to south or west). If the room has windows facing to two directions, the window areas may be summed and the higher result can be used, or the result may be interpolated by weighting with window area.

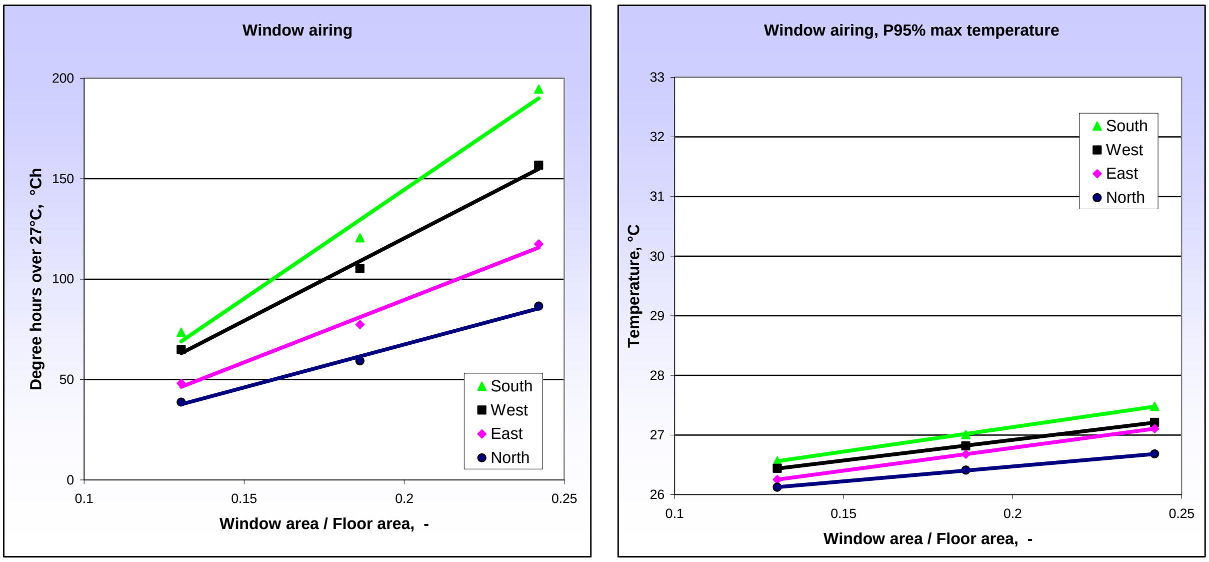
The effect of window airing and solar protection glass (no cooling)

The overheating corresponding to current building practice is shown in Figure 5. The results apply for the building with clear window panes and if window airing is not used. In that case the apartments are hot independently of window area; room temperatures in the hottest days are over 30°C. Solar protection will decrease the temperatures, but this is not sufficient measure as alone, because the rooms are still hot, about 29…30°C. Effective cross ventilation by window airing will reduce room temperatures to acceptable level, Figure 6. With reasonable window areas the basic indoor climate category S3 is achievable. In the case of solar protection glasses, about 1.5 times higher window areas in south and west facades may be used compared to ones in Figure 6.



a) b)

Figure 5. a) The degree hours exceeding the limit temperature of 27°C, and b) the estimate of max room temperature during the hottest days, for the building with clear window panes and without window airing.

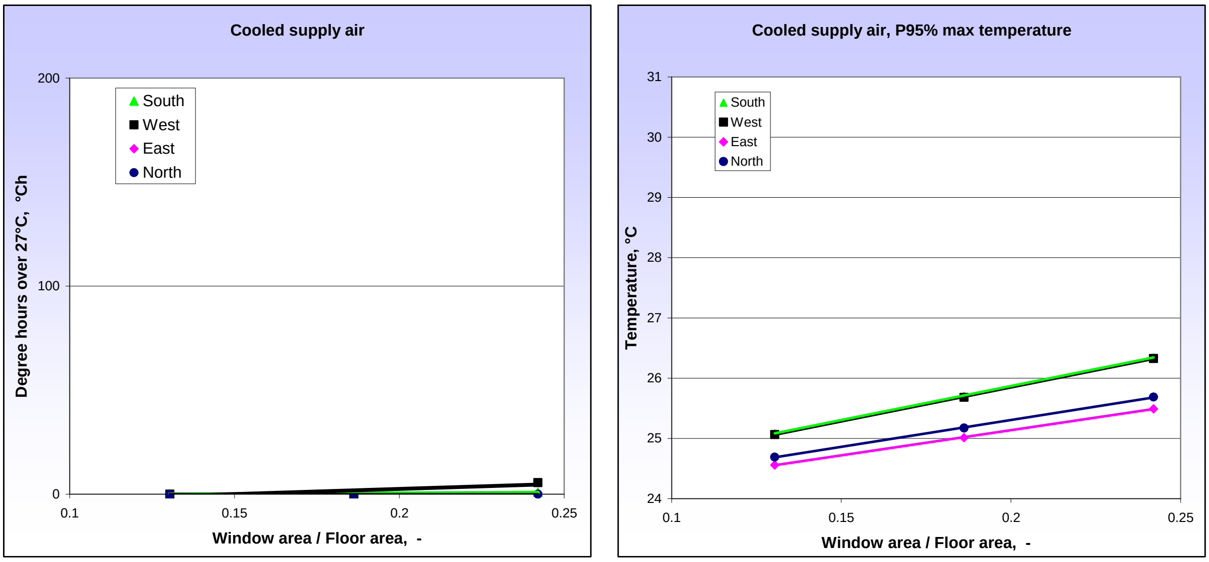


a) b)

Figure 6. The effect of cross ventilation. Clear window panes and open windows (with size of 0.6 m^2) on two facades.

Cooling of supply air

Cooled supply can satisfy a relatively low cooling need of 10…15 W/m^2. It is important to insulate supply air ducts. The following results apply for the supply airflow rate of 0.7 L/s per m^2 and temperature control so that the minimum supply air temperature to the room is 16°C (should be lower from the air handling unit). Supply air temperature is controlled according to exhaust air temperature. Results show that cooled supply air is not sufficient in the case of windows with clear panes. The basic category S3 is achievable, if solar protection glasses are used in south and west facades together with cooled supply air, Figure 7 (window airing is not used).

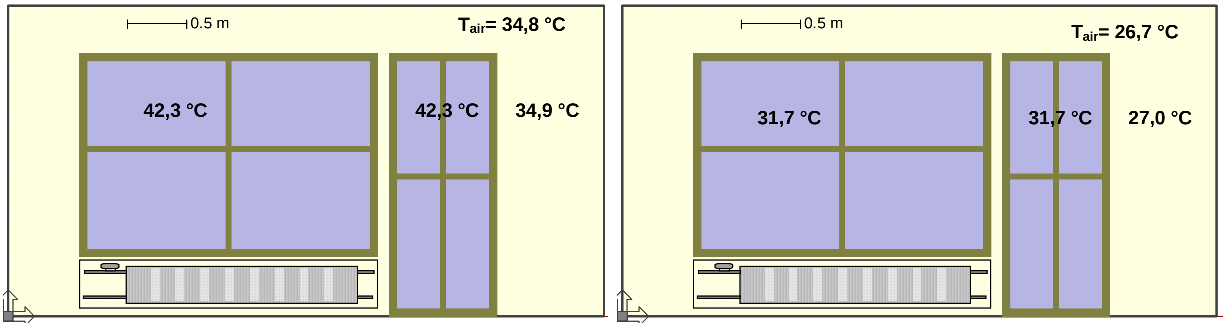


a) b)

Figure 7. Cooled supply air (supply air temperature to the room of 16°C and airflow rate 0.7 0.7 L/s per m^2) and solar protection glasses with solar heat gain coefficient of 0.33.

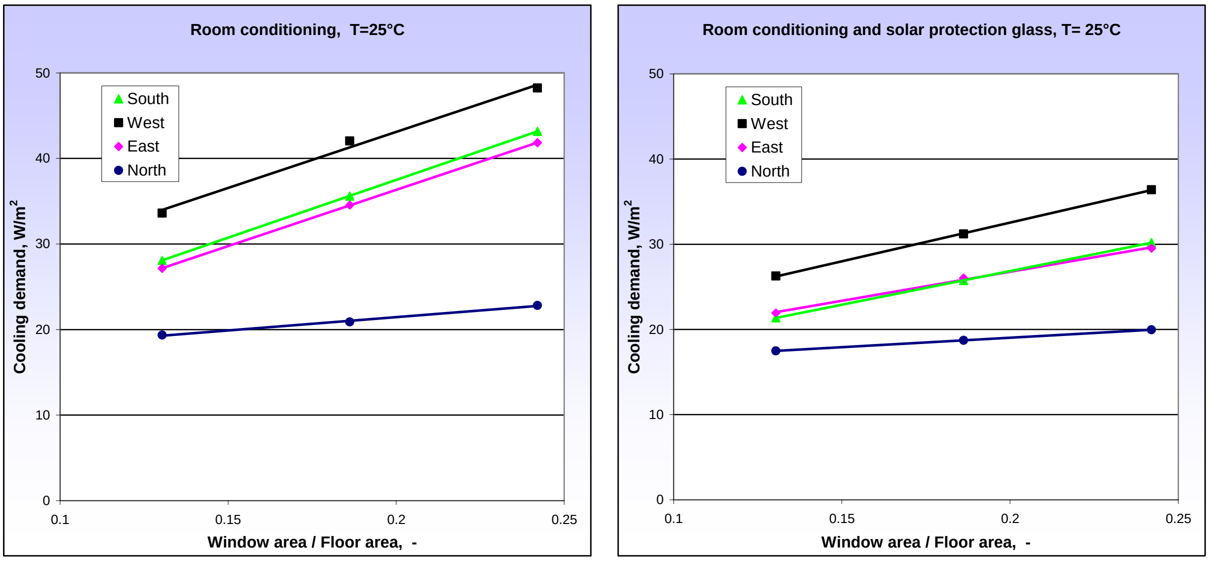
Room conditioning

Room conditioning devices give all possibilities for temperature control. In common apartments, good results are often achieved with one centrally located device (in the living room or in the entrance-hall in open plan apartments) if bedrooms' doors are kept open during the daytime. Due to higher investment cost, better indoor climate category S2 is recommendable to guarantee sufficient temperature control in all cases. For the reduction of cooling demand and the surface temperature of windows, the use of solar protection glasses is recommended on south and west facades. An example of the effect of solar protection glass on the surface temperature of the window is shown in Figure 8. Cooling demands are calculated room by room with the curves given in Figure 9.



a) b)

Figure 8. An example of the effect of solar protection glass on the surface temperature of window. a) 20 W/m^2 cooling and clear window panes, b) 20 W/m^2 cooling and solar protection glasses.



a) b)

Figure 9. Cooling demand for rooms with clear panes a), and with solar protection glasses b).

DISCUSSION

The results show that the current buildings tradition leads to strong overheating in apartments. The basic indoor climate category S3 (room temperature of the 27 ºC with 100 ºCh excess) is achievable with effective cross ventilation and relatively small window size. Cooling of the supply air used together with solar protection glasses is enough for S3 category at internal gains level not exceeding 5 W/m^2. This solution is sensitive to internal gains, and for higher gains level the temperatures were out of the comfort range. For the room conditioning case, the graphs show the cooling load corresponding to the good indoor climate category S2. Determined graphs allow to check quickly the thermal comfort in apartments and this will be a step forward from today's practice not to do such check. They suit well for preliminary design and are useful for architects and HVAC-consultants not using indoor climate and energy simulation software.

SUMMARY

Fault diagnosis method for HVAC equipment was developed with Support Vector Machine (SVM) and BMS data. By this, the early detection and correspondence of unusual operating became possible. It aims for the reduction in cost and time to spend on fault diagnosis. Normal data and fault data were generated by the physical model of AHU as a training data for SVM. Trained SVM is validated with data obtained from a real building after introducing artificial faults. Results of the diagnosis of actual measurement data of unusual operating, it was apparent that it had some diagnosis ability.

INTRODUCTION

In late years environmental problems such as global warming have become international issues, and measures are needed for reduction of greenhouse gas. In the field of building engineering, particularly effective measures to reduce environmental load are expected. From this, to secure good building as social overhead capital, aiming at the sustainable building that attached great importance to the life cycle management is important issues. On realizing such a social demand, the role that HVAC equipment serves as is big, and maintenance and management of HVAC equipment are important.

Studies such as measures or maintenance to fault and deterioration of HVAC equipment were made to some extent. However, as for these studies, the history is still superficial, and it is the present conditions that leave some problems[1)]. For example, about fault diagnosis method, it was developed the diagnosis method how provided data by a simulation model made based on knowledge and actual measurement data were analyzed statistically. However, it is necessary for a database in various states of HVAC equipment to be prepared in this method beforehand, and, with that in mind, making of the most suitable parameter to perform fault diagnosis is demanded[2)]. In this case it is difficult to perform fault diagnosis from directly after the completion of a building because the operating situation of HVAC equipment must be measured till data reliable are provided.

A purpose of this study is to establish algorithm of Fault diagnosis for HVAC equipment which can be used from directly after the completion. Since the method enables early diagnosis and early correspondence of deterioration or fault of HVAC equipment, it will prevent waste of costs such as time and expense to spend on fault diagnosis.

METHODS

The Equipment of Study

In this study, an air handling unit (AHU) was the equipment of study. The AHU was installed in Waseda Research Park Communication center (WRPC), which is educational facility located in Honjo City Saitama in Japan.
Sensors were installed to record physical conditions around the AHU. Figure 1 shows placement of the sensors. AHU includes a fan and a coil which are characteristic facilities of the air-conditioning system. In addition, it is used for various buildings. For these reasons, it is very likely that the developed method has high versatility.

Support Vector Machine[3)4)]

Support vector machines (SVM) are a set of related supervised learning methods used for classification and regression. They belong to a family of generalized linear classifiers. Equation (1) is an identification function of linear threshold node. Linear threshold node calculates two output values for an input vector.

$$y = sign(\omega^T X - h) \tag{1}$$

where y is the mean value of output vector and ω is the parameter for synapse load, X mean value of input vector, h is the threshold value.
Function sign (u) is a symbolic function that takes 1 when u >0 and takes -1 when u < 0. When think about this geometrically, this operation is equivalent to an identification plane dividing input space into 2. A training sample that is the nearest the classification plane which is called a support vector, and the distance up to this support vector is called a margin. A special property of SVM is that they simultaneously minimize the empirical classification error and maximize the geometric margin. Hence it is also known as the maximum margin classifier.
As a result, SVM can show high classification performance for unlearned data.

Study Process

A flow of the study is as follows.
1) Modeling of AHU.
   The modeling of AHU was performed in dynamic simulation program HVACSIM + (J). Each parameter of AHU was set from a maker book or actual measurement data.

2) Generation of normal and fault data by a model of the AHU.
   Four groups of dataset are generated.
   a) Dataset of normal operating state for training SVM.
   b) Dataset in unusual condition for training SVM.
   c) Dataset of normal operating state for SVM.
   d) Dataset in unusual condition for SVM.
   Parameters were modified to represent unusual conditions.
3) Training of the SVM.
   Train SVM by dataset a) and b).
4) A classification of simulation results and inspection of the effectiveness.
   Dataset c) and d) were classified by trained SVM to confirm diagnosis performance.
5) A classification of actual measurement data and inspection of the effectiveness.
   BMS data got by actual measurement were classified by trained SVM to confirm diagnosis performance.

Data Acquisition

Table 1 shows an inspection system and generating methods of the unusual state. An artificial unusual state occurred in AHU and data at the time of unusual operating were measured. After that inspection of the effectiveness of this developed method was performed. The inspection data were BMS data collected with a sensor installed in WRPC.

Data are obtained from a real building after introducing artificial faults.
It shows that are procedures and results of actual measurement as follows. A purpose of actual measurement was collected as data to inspect developed methods.

Table 1. Inspection system and generating methods of unusual state.

Condition	Method
Filter blockage	Filter part blockage
Coil blockage	Coil part blockage
Unusual air supply temperature	Squeeze a valve of cool and warm water
Unusual Fan belt tension	Tension adjustment of fan belt

Table 2. An inspection condition and an actual measurement schedule.

Condition	Actual Measurement Schedules
Supply air temperature is too high or low	06/08/21 09:00~15:00
Fan belt is too tight or slacken	06/08/21 15:00~17:00
Filter blockage (half-open)	06/08/22 09:00~15:00
Coil blockage (half-open)	06/08/22 09:00~15:00
Filter blockage (full-open)	06/08/23 09:00~15:00
Coil blockage (full-open)	06/08/23 09:00~15:00

This is an actual measurement procedure and occurrence methods of unusual states as follows.
1) AHU filter blockage
   A board of the area obstructive to 1/3, 1/2, 2/3 was established on a filter part to cause blocking of a filter.
2) AHU coil blockage
   A board obstructive same as A on a filter part was established to disturb heat exchange.
3) Unusual air supply temperature

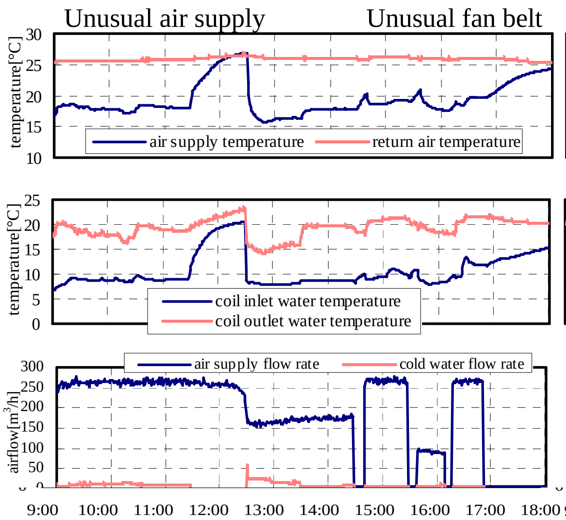
A valve of cool and warm water sent to AHU was squeezed to half-open, all shut, and predetermined air supply temperature was not provided. 1), 2), 3) interlaced, and actual measurement of filter confinement and coil confinement in a half-open state of a valve was performed.

4) Unusual AHU fan belt

Fan belt tension of the AHU inside was regulated.

Actual Measurement Result

Results about data item to use for modeling in HVACSIM+(J) and input to SVM was rounded up along the actual measurement schedule. There are the times when a value is 0 and the times when a value goes up and down momentarily in figure 3-5, that is because operating of AHU which stopped at one time.



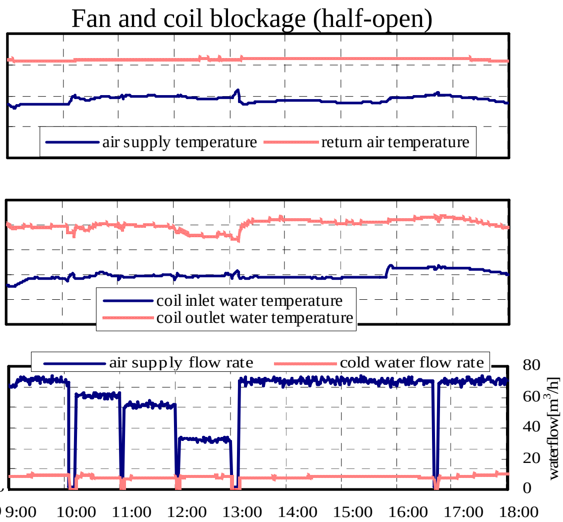


Figure 2. Actual measurement results in 8/21. Figure 3. Actual measurement results in 8/22.

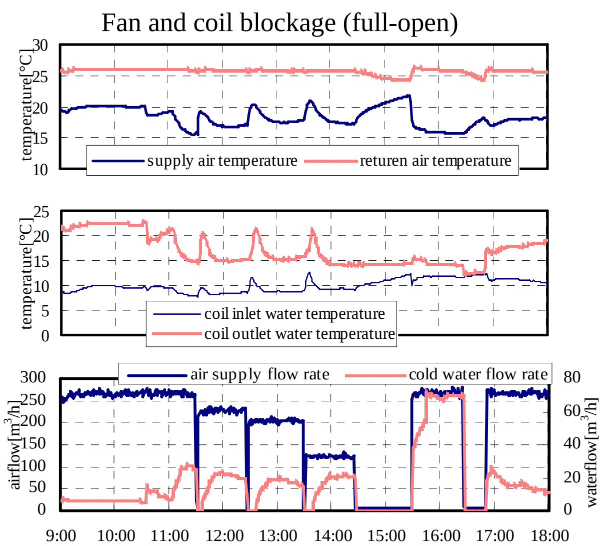

Figure 4. Actual measurement results in 8/23.

Modeling of AHU
HVACSIM+(J)

HVACSIM is a dynamic air-conditioning system simulation program developed in former NBS (National Bureau Standards) of the American Department of Commerce[5)]. The thing which various models were added to in this HVACSIM was HVACSIM+(J) and AHU was modeled with Type602"Cooling or Dehumidifying Coil".

Input and Output Values of a AHU Model

HVACSIM+(J) is a simulation program designed to calculate the output from the input data given based on set parameters. Figure 6 displays the concerning input and output values of a model of AHU. The input values are given as interface variable which every second changes into. In this study, outlet air temperature, outlet air absolute humidity and outlet water temperature were used among the output shown in a figure 6.

Input		Output
Air mass flow Inlet air temperature Inlet air absolute Absolute humidity Water weight flow Inlet water temperature	→	Outlet air temperature Outlet air absolute humidity Outlet water temperature Sensible heat load of coil All heat load of coil

Figure 5. The input and the output of an AHU model

Simulation Result
The result of simulation demonstrated that the coil outlet water temperature and the dynamic outlet dry-bulb air temperature became the values that were near to results data which was displayed in figure 6. It did not agree to the results data about the outlet air absolute humidity.

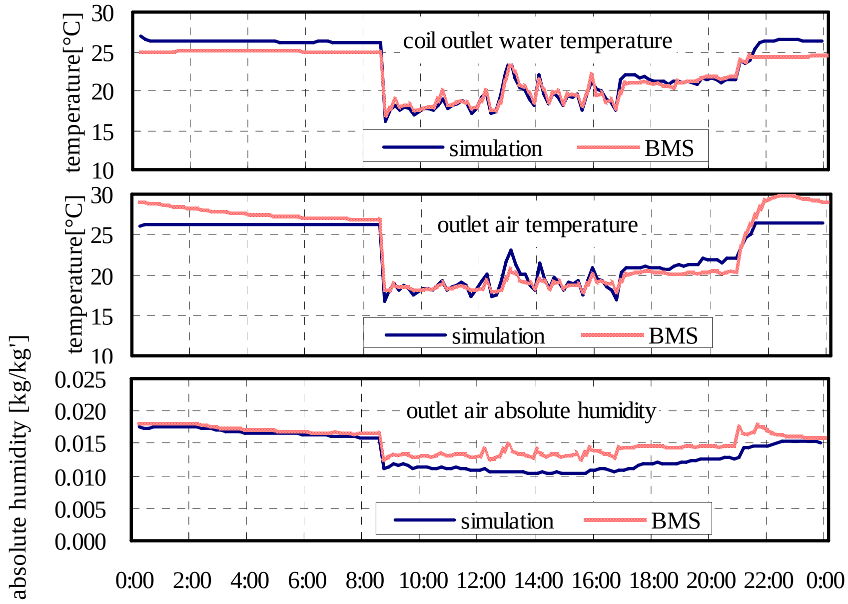

Figure 6. Simulation results

Normal and Fault Data Generation

Normal data and fault data for learning and diagnosis performance confirmation of SVM with a simulation model of AHU were generated.
Data in normal operating state are values of the simulation result that mentioned above. The various kinds of fault were occurred from a change of fouling factor. And the unusual data were generated. Fouling factor is the value to express a heat transmission inhibitory degree of fouling which stuck to heat transmission, and 0 is in condition not to be stained at all. Fouling factor is generally obtained from dividing thickness of a fouling by the thermal conductivity. However, fouling factor used in HVACSIM+(J) is no dimension, and a unit is not determined. Fouling factor is calculated from thickness and thermal conductivity of fouling in HVACSIM+(J), and this is not given as a parameter, and the reason is because HVACSIM+(J) treats fouling factor for numerical value to merely express degree of fouling. Put simply, a user of HVACSIM+(J) can decide a value of fouling factor so that precision of a model improves freely. A user can decreases temperature of coil outlet water and temperature of raise air supply by changing fouling factor.

RESULTS

Learning and Diagnosis of Simulation Data by SVM

Diagnosis of normal operating and unusual operating were performed by SVM based on provided data from the AHU model. Improved computing speed without finding complete diagnosis performance and aimed at diagnosis that had precision in tolerance level. Much time suffers from a calculation when they classify it in search of complete classification performance. In addition, noises to be included in data are not permitted. This is not practical and does not really match a purpose introducing from immediately after the completion.
At first, before a classification of actual measurement data, a classification of normal or fault data generated by simulation was performed. The fault simulation data which fouling factor was changed into and normal simulation data in operating time (9:00~18:00) were given as learning data, and similar data on other days were given as test data.

SVM could classify with probability of 100% in this condition, and classification performance was confirmed.

Adjustment of learning data and selection of input variable

Because the effectiveness of SVM was able to confirm, classification of actual measurement data was performed next. Fouling factor was set to 2.6 or 2.7, and the fault data of learning data were classified. That is because when fouling factor is equal to or less than 3 more than 2, SVM was not able to diagnosis it at all. Therefore fouling factor was a state among two or three, and a classification was performed. When data generated with 2.6 or 2.7 were used as learning data, diagnosis performance was the highest. As for this, a value of fouling factor is not for 2.6 and 2.7 to be most suitable in constant. It was shown that this value was most suitable for actual measurement in this study. When this developed method is introduced, facilities designer, HVAC equipment maker and facilities manager can decide a level of unusual operating and can regulate diagnosis precision by setting the fouling factor.

As the input (feature vector) to give SVM, the input of a model (air flow rate, water flow rate, coil inlet temperature and air inlet temperature) and the output of a model (coil outlet temperature, air outlet temperature) were given. However, SVM which gave all these six input may not get high diagnosis precision for unlearned data. That because it may includes the non effective features for the models. Therefore variable selection was performed by R-square method. As a result, It was shown that model which all variables were given or model removed outlet air temperature comparatively has high performance. It is thought that the reason is because the accuracy of outlet air temperature of a simulation model is worse than coil outlet temperature of a simulation model.

Diagnoses Results of Actual Measurement Data

Figure 7-12 are diagnosis results. For reference, actual measurement data of outlet air temperature appear in the same figure.

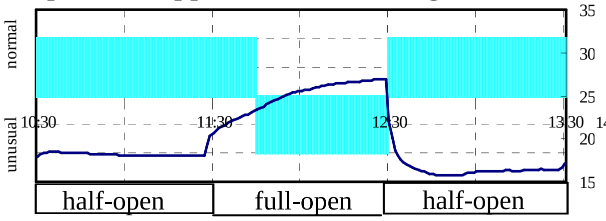

Figure 7. Unusual air supply temperature.

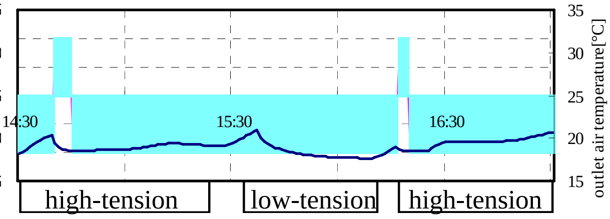

Figure 8.Unusual fan belt tension.

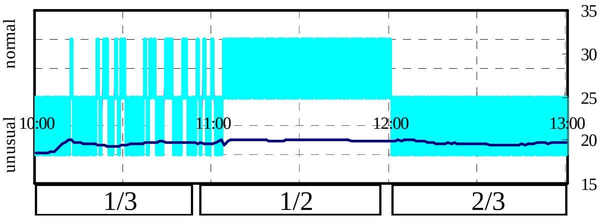

Figure 9. Filter and coil blockage (half-open).

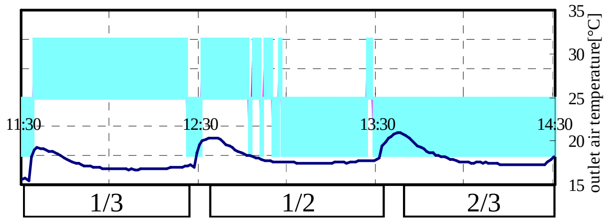

Figure 10. Filter and coil blockage (full-open).

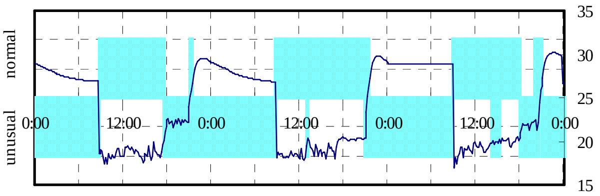

Figure 11. Normal operating state.

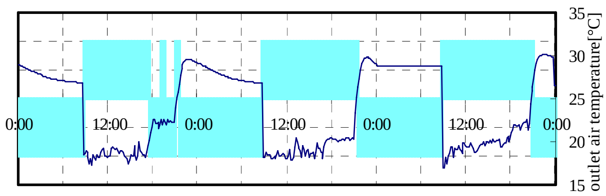

Figure 12. Normal operating state.

DISCUSSION

Normal and fault classification results were replaced each other between actual measurements. A correlation was seen between fault degree and classification.
However, an enough classification has not been possible. Because the each actual measurement time was short. "Filter blockage (full-open)" and "Coil blockage (full-open)" in particular was not able to be diagnosed under steady state. In addition, a diagnosis was difficult because precision of a model was not complete and supply air absolute humidity and return air absolute humidity were not given as the input of SVM.
The situations were observed that a diagnosis result to be fault even when actual measurement of fault operating was not performed. It is because that HVAC operating state is not always normal at the beginning and end of the control and when it was stopped. This tendency was

observed on BMS data of normal operating day with the same learning data as presented in figures 11 and 12.
The diagnosis result every actual measurement item are mentioned as follows.
1) Unusual air supply temperature
As for the diagnosis result at the time of unusual air supply state, it was able to be classified only in the case when of all shut state a valve, but it was not able to be classified in a half-open state a valve.
2) Unusual fan belt
In the case of unusual fan belt SVM was able to classify fault data.
3) Filter blockage (half-open) and Coil blockage (half-open)
Because a change in 2/3 blockage was the biggest, SVM was able to classify fault data. However in the case of 1/3, 1/2 blockage state, SVM did not succeed.
4) Filter blockage (full-open) and Coil blockage (full-open)
Even filter and coil blockage (full-open) became diagnosis performance that was 2/3 confined situations. In the case of 1/3 blockage state, SVM failed classification. In the case of 1/2 blockage state, classification of SVM shows good result, when the state of system becomes almost steady.

As a result of BMS data diagnosis of unusual operating, there was a difference every actual measurement item, but it was confirmed that developed method had some diagnosis ability. However, for improving classification precision, long-term measurements have to be implemented and AHU model representations have to be raised.

ACKNOWLEDGEMENT

The research investigation of this report was complemented as a part of a study of Project Research Institutes, Comprehensive Research Organization, WASEDA UNIVARSITY "Institute of Architectural Environment and Information management system". Authors are very grateful to the people who had a research investigation cooperate.

SUMMARY

Air handling unit (AHU) is defined as a self-contained unit that the conditions of air vary while passing through it and reach to the desired temperature and humidity. To perform variations in weather conditions various processes such as heating, cooling, humidification, dehumidification and mixing are applied. In this research thermodynamic modeling and mathematical optimization of air handling units approaching minimum energy consumption is achieved. The objective function for optimization is pressure drop of air crossing coil per cooling and heating load of the system. This function comprises all thermal and geometrical parameters of the coils such as coil surface area, number of rows, fin spacing and air side pressure drop of the coil. The objective function is minimized using Lagrange multipliers method. The optimization results are composed of minimum pressure drop, optimum area, optimum number of rows and fin spacing. The effects of varying the cooling and heating load, fin efficiency and the surface area of the coil on fan power consumption are investigated as well.

INTRODUCTION

The major utilities in residential, commercial and industrial buildings are electrical distribution networks, air conditioning systems, steam systems and compressed air systems. The utilities must operate at the highest possible overall efficiency for minimization of the building's energy requirement. Generally, the energy consumption is minimum when the sources such as electrical energy perfectly track the loads. These loads might be cooling or heating loads, which are directly affecting the human comfort conditions. When there is mismatch between the source and load, energy losses will be higher [1]. One of these utilities is air handling unit in which there are a few studies about the energy efficiency about it. An AHU is the primary equipment in an air system of a central hydronic system. It handles and conditions the air and distributes it to various conditioned spaces. AHUs utilize various types of equipments, arranged in specific order, so that space conditions can be maintained. AHUs may consist of a supply fan and coil section with a chilled water or direct expansion coil, preheat or reheat coil, heating coil section, filter section, mixing box, or combination of mixing box and filter [2,3]. In AHUs one of the major components in energy consumption of system are coils. The pressure drop of air passing the system depends on thermal and geometrical parameters of coil. In this research heating coils are modeled by log mean temperature difference and cooling and dehumidifying coils are modeled by log mean enthalpy difference. Since then their optimization proceeds. Attempts show that the investigation of AHUs has been performed considering only one component of the AHU. Robinson [4] investigated experimentally damper control characteristics and mixing box effectiveness of air handling units. The results from tests indicated that the mixing effectiveness of the mixing box was a function of the damper position. Liu et al. [5] developed an air filter pressure loss model for fan energy calculation in air handling units and showed to be highly consistent with available experimental data. Roulet et al. [6] investigated real heat recovery with air handling units. Their research addressed real energy recovery with air handling units from a theoretical point of view and presented results of measurements on 13 units. Sanaye and malekmohammadi [7] developed a new method of thermal and economical optimum design of air conditioning units with vapor compression refrigeration system. The objective function for optimization was total cost per unit cooling load of the system including capital investment for components as well as the required electricity cost.

THERMODYNAMIC MODELING

1. Heating coil modeling

The total heat transfer rate from a heating coil is:

$$q = U_o A_o \Delta T_m , \qquad (1)$$

where U_o is overall heat transfer coefficient, A_o is total outside surface area of the coil and ΔT_m is log mean temperature difference. Considering the tube material to be copper having high thermal conductivity, so the thermal resistance of copper tubes is ignored and the overall heat transfer coefficient based on the outside surface area of the coil U_o can be calculated as

$$U_o = \frac{1}{\frac{A_o}{A_i h_i} + \frac{1-\eta}{h_o\left(A_o/A_F + \eta\right)} + \frac{1}{h_o}} , \qquad (2)$$

where h_i is inner surface heat transfer coefficient, h_o is outer surface heat transfer coefficient, A_i is inner surface area of the coil, A_F is total surface area of fins and η is fin efficiency.
McQuiston [8,9] developed the correlation between Chilton-Colburn j factors and parameter JP for dry coils which is as follows:

$$\begin{aligned} j_s &= \left(\frac{h_o}{G.c_{p,a}}\right)\mathrm{Pr}^{2/3} = 0.00125 + 0.27JP \\ JP &= \mathrm{Re}_D^{-0.4}\left(\frac{A_o}{A_p}\right)^{-0.15} \\ \mathrm{Re}_D &= \frac{G.D_o}{\mu} \end{aligned} , \qquad (3)$$

In equation (3), A_p is total outside surface area of tubes, G is mass velocity, D_o is outside diameter of tube and μ is fluid viscosity.

$$G = \rho . V_{\min} , \qquad (4)$$

where ρ is fluid density and $V_{\min}$ is air velocity at minimum flow area. For hot and chilled water at turbulent flow inside the tubes, the inner surface heat transfer coefficient h_i, can be calculated by Dittus-Boelter [10,11] equation:

$$\frac{h_i D_i}{k_w} = 0.023\,\mathrm{Re}^{0.8}\,\mathrm{Pr}^{n} , \qquad (5)$$

In equation (5), D_i is inside diameter of tube and k_w is thermal conductivity of water. When the tube wall temperature $T_t > T_{bulk}$, $n = 0.4$ and when $T_t < T_{bulk}$, n=0.3. Here T_{bulk} indicates the bulky water temperature beyond the boundary layer.

2. Cooling and dehumidifying (wet) coil modeling

In cooling and dehumidifying coil, both heat and mass transfer occurred. With dehumidification, the air side surface is wetted with liquid water. Since water vapor transfer does not depend on temperature difference alone, it follows that the method generally used in the analysis of dry air side surface does not suffice. In this paper, a modeling procedure for wet cooling coils will be presented by adopting the method of Threlkeld [12] which bases the analysis on enthalpy potential. The total heat heat transfer rate for cooling and dehumidifying coil is:

$$q = U_{o,w} A_o \Delta h_m , \qquad (6)$$

where $U_{o,w}$ is overall heat transfer coefficient for wet coil and Δh_m is log mean enthalpy difference. If the thermal resistance of copper tubes is ignored, the overall heat transfer coefficient based on the outside surface area of the wet coil $U_{o,w}$ can be calculated as

$$U_{o,w} = \frac{1}{\dfrac{b_R A_o}{A_i h_i} + \dfrac{b_{w,m}(1-\eta_w)}{h_{o,w}\left(A_o / A_F + \eta_w\right)} + \dfrac{b_{w,m}}{h_{o,w}}} , \qquad (7)$$

In Eq. (7) the combined wet surface coefficient $h_{o,w}$ must be calculated by Eq. (8). In equation (7), η_w is wet fin efficiency. The quantity b is the slope of Eq. (9) which represents saturation enthalpy of air as a function of temperature over a small temperature range.

$$h_{o,w} = \frac{1}{c_{p,a} / (b_{w,m} h_o) + y_w / k_w} , \qquad (8)$$

The quantity b_R should be evaluated at the mean water temperature inside tubes t_R while the quantity $b_{w,m}$ should be evaluated at the mean water film surface temperature.

$$h_{as} = a + b.t_{as} , \qquad (9)$$

where h_{as} is enthalpy of saturated moist air and t_{as} is temperature of saturated moist air.
In Eq. (8) the term y_w / k_w is usually small, so that an estimate of water film thickness is not critical [13]. The convection heat transfer coefficient h_o in Eq. (8) can be calculated by Eq. (3). The inner surface heat transfer coefficient h_i is determined by Eq. (5).

OPTIMIZATION

The objective function for optimization is pressure drop of air passing coil per cooling (heating) load of the system. Air side pressure drop over a finned-tube coil is expressed by [14]

$$\Delta P = \frac{G^2 v_i}{2}\left[\left(1+\sigma^2\right)\left(\frac{v_o}{v_i}-1\right)+f\,\frac{A_o}{A_{\min}}\frac{v_m}{v_i}\right], \qquad (10)$$

where v_i is air specific volume at the inlet of coil, v_o is air specific volume at the outlet of the coil, v_m is mean specific volume and f is friction coefficient. In Eq. (10) the parameters are:

$$\sigma = \frac{A_{\min}}{A_a}, \qquad (11)$$

$$G = \frac{\dot{m}_a}{A_{\min}} = \frac{\rho \dot{V}_a}{\sigma A_a}, \qquad (12)$$

where $\dot{m}_a$ is mass flow rate of air and $\dot{V}_a$ is air volume flow rate.

$$f = 0.124\,\mathrm{Re}^{-0.21}, \qquad (13)$$

The ratio of free flow (or minimum flow) area to face area σ is usually 0.54 to 0.6 [9]. The face area A_a is determined by selecting a proper face velocity of 2.5 to 3 m/s .

$$A_a = \frac{\dot{V}_a}{V_a}, \qquad (14)$$

Substituting Eqs. (11)- (14), in Eq. (10), ΔP can be expressed as:

$$\Delta P = \rho\left(\frac{\dot{V}}{A_{\min}}\right)^2\left[\left(1+\left(\frac{A_{\min}}{A_a}\right)^2\right)\left(\frac{v_o}{v_i}-1\right)+0.124\left(\frac{\rho \dot{V} D_o}{\mu A_a}\right)^{-0.21}.\frac{A_o}{A_{\min}}.\frac{v_m}{v_i}\right], \qquad (15)$$

Except A_o and $A_{\min}$, all other parameters of Eq. (15) are known for a coil. Therefore air side pressure drop of a coil, ΔP can be expressed as

$$\Delta P = f_1\left(A_o, A_{\min}\right), \qquad (16)$$

Total outside surface heat transfer area of heating and cooling and dehumidifying coils can be determined from Eqs. (1) and (6) respectively. Substituting inside and outside surface heat transfer coefficients in Eqs. (2) and (7) and by using Eqs. (1) and (6), the total outside surface heat transfer area can be expressed as

$$A_o = f_2\left(\frac{A_o}{A_i}, \frac{A_o}{A_p}, \frac{A_o}{A_F}\right), \qquad (17)$$

Total outside surface area of a coil as a function of number of rows and face area expressed as

$$A_o = F_s A_a N \,, \qquad (18)$$

In equation (18), F_s is coil core surface area parameter and N is number of rows. Using Table 1, coil surface ratios are defined as the following functions in terms of number of rows and fin spacing.

Table 1 Finned- tube coil construction parameters [9]

Fin Spacing S_F (fins/m)	A_o/A_p	A_o/A_i	A_F/A_o	F_s
315	7.85	7.95	0.873	9.91
394	9.68	9.68	0.896	12.07
472	11.54	11.40	0.913	14.21
551	13.46	13.17	0.925	16.37
591	14.47	14.03	0.928	17.48

$$\begin{aligned}
&\frac{A_o}{A_i} = 0.8694 S_F + 0.9872 \\
&\frac{A_o}{A_p} = 0.9442 S_F + 0.2584 \\
&\frac{A_o}{A_F} = 0.001 S_F^2 - 0.0322 S_F + 1.3399 \\
&F_s = 1.0795 S_F + 1.2698
\end{aligned} \qquad , \qquad (19)$$

Substituting Eqs. (17)- (19) in Eq. (16), the objective function, ΔP is obtained as

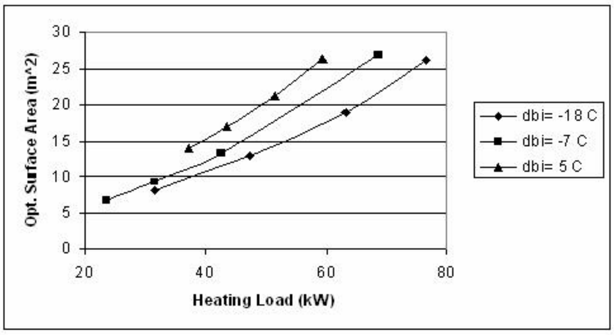
$$\Delta P = f_3(N, S_F)\,, \qquad (20)$$

To find the system optimum design parameters, the objective function (20) is minimized by Lagrange multipliers method [15,16]. The boundary conditions of problem are number of rows and fin spacing. Fin spacing is usually expressed in fins per meter, and it often varies from 315 to 591 fins/m (1.6 to 3.1-mm fin spacing) for coils used in air conditioning systems. The number of tube rows in heating coils varies from 1 to 4 rows and in cooling and dehumidifying coils varies from 4 to 8 rows [9].

RESULTS

1. Heating coil

Figure 1 shows the influence of heating load on optimum surface area and pressure drop of heating coil in 4200 m^3/hr air flow rate. Since the conditions of air entering the AHU can be different, optimum design parameters is determined in three different entering temperatures namely, $-18°C$, $-7°C$ and $5°C$. In the optimization process of heating coil, the entering water temperature to coil is always $82°C$ and leaving water temperature from it is $71°C$. In Fig 1, by increasing the heating load, the optimum surface area of coil increases. If two different inlet temperatures are considered, at a constant heating load, optimum surface area of greater temperature of entering air is higher than optimum surface area of smaller inlet temperature. To justify this result one can say that by increasing the inlet temperature of air, log mean temperature difference decreases and by using Eq. (1) and considering constant heating load, optimum surface area of coil increases. In this Figure, by increasing the heating load, optimum pressure drop of coil increases, since by increasing the heating load, optimum surface area of coil increases and relevant with Eq. (10), pressure drop is proportional to surface area of coil. Also at a constant heating load, optimum pressure drop of greater inlet temperature is higher than the optimum pressure drop of smaller inlet temperature. This result can be justified by considering proportion of pressure drop with surface area.



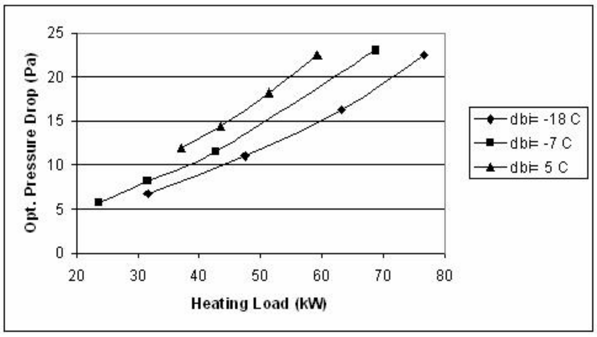


Figure 1 The influence of heating load on optimum surface area and pressure drop

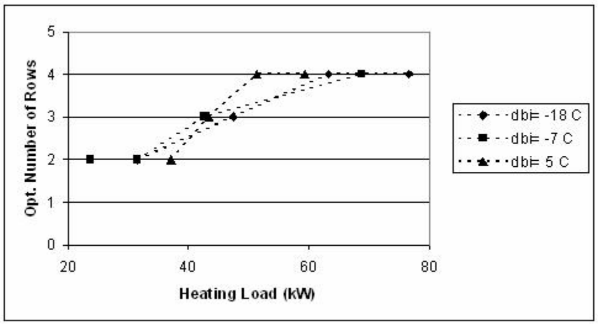

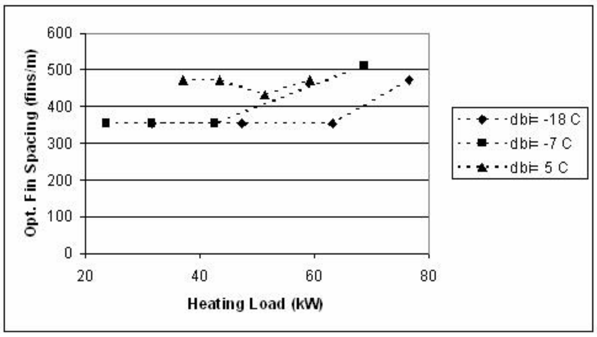

Figure 2 The influence of heating load on optimum number of rows and fin spacing

Figure 2 shows the influence of heating load on optimum number of rows and fin spacing of heating coil in 4200 m^3/hr air flow rate. In this Figure, at the inlet temperature of $-18°C$, it is observed that by increasing the heating load, primarily the number of rows increase and fin spacing remains constant, then the number of rows remain constant and fin spacing increases. At the inlet temperature of $-7°C$, by increasing the heating load, at first number of rows and fin spacing remain constant and then both of them increase. At the inlet temperature of $5°C$, by increasing the heating load, fin spacing decreases since with decreasing fin spacing, the number of rows increases, as a result of this, consequently optimum surface area of coil increases. In Figure 2 in some cases with increasing heating load, the number of rows or fins remains constant, because in that heating range, coil can have further heat transfer without increasing number of rows or fins.

2. Cooling and dehumidifying coil

In Figure 3 the influence of cooling load on optimum surface area and pressure drop of cooling and dehumidifying coil in three different conditions of air is shown. In the optimization process of cooling and dehumidifying coil, the entering water temperature to coil is always $7°C$ and leaving water temperature from it is $13°C$.

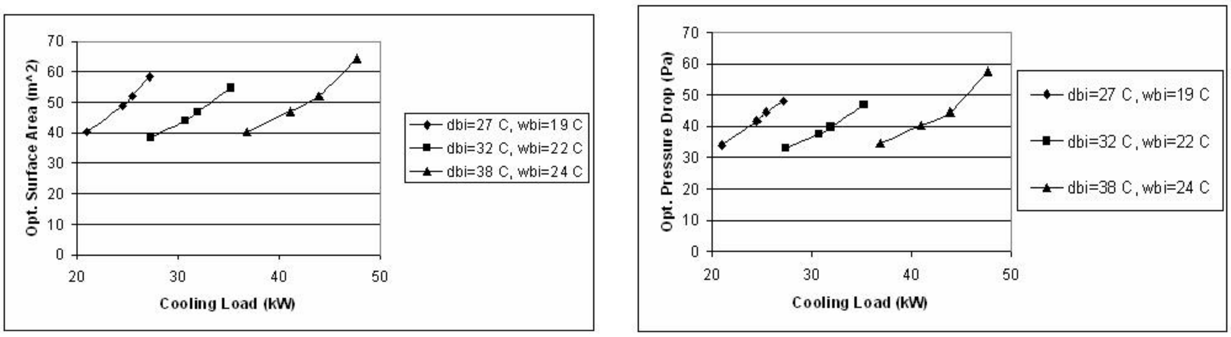

Figure 3 The influence of cooling load on optimum surface area and pressure drop

In Figure 3 by increasing the cooling load, optimum surface area of coil increases. Optimum pressure drop of passing air is proportional to outside surface area of coil and with increasing the cooling load, it increases. If two different conditions of entering air are considered, at a constant cooling load, optimum surface area of greater dry bulb temperature of entering air is smaller than optimum surface temperature of smaller dry bulb temperature of entering air. To justify this result, one can say that by increasing dry bulb temperature of entering air, log mean enthalpy difference increases and by using Eq. (6) and considering constant cooling load, optimum surface area of the coil decreases.

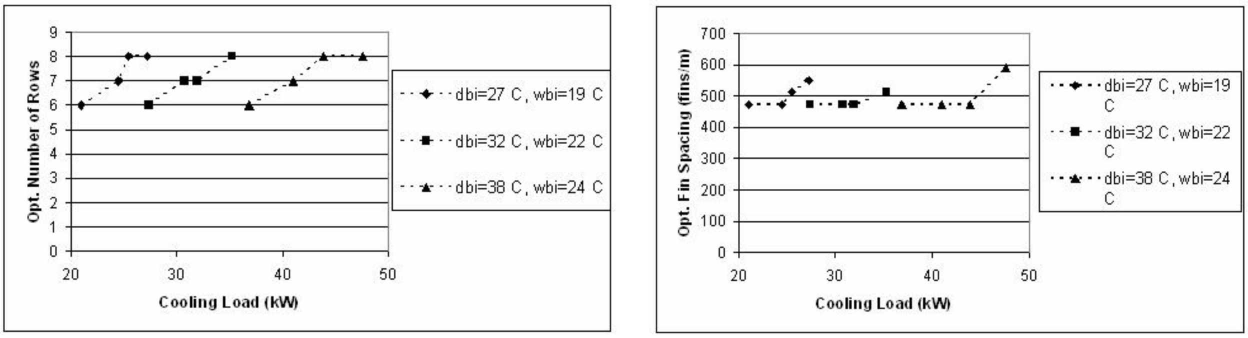

Figure 4 The influence of cooling load on optimum number of rows and fin spacing

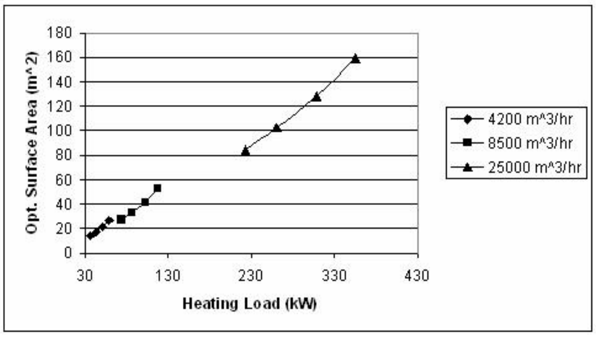
In Figure 4 by increasing the cooling load may one of the following cases may occur and at all cases with increasing the cooling load, optimum surface area increases.

a. Number of rows remains constant and fin spacing increases.
b. Both number of rows and fin spacing increase.
c. Number of rows decrease and fin spacing increases.
d. Number of rows increase and fin spacing decreases.
e. Number of rows increase and fin spacing remains constant.

3. Influence of air flow rate on optimum surface area of the coil

Figure 5 show the influence of air flow rate on optimum surface areas of heating coil and wet coil. In both coils by increasing air flow rate, cooling or heating load increases with the subsequent of increase of optimum surface areas of coils.



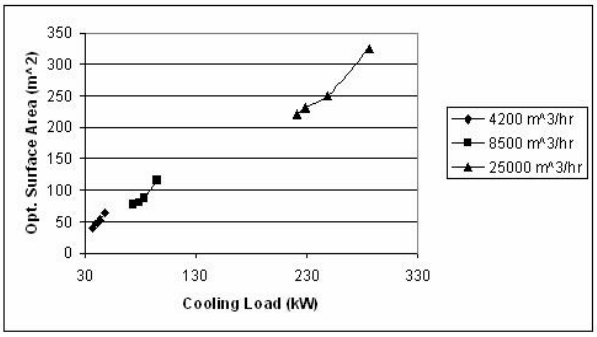


Figure 5 The influence of air flow rate on optimum area of heating and wet coils

4. Influence of fin efficiency on optimum surface area of the coil

In Figure 6 the influence of fin efficiency on optimum surface areas of heating coil and wet coil is shown.

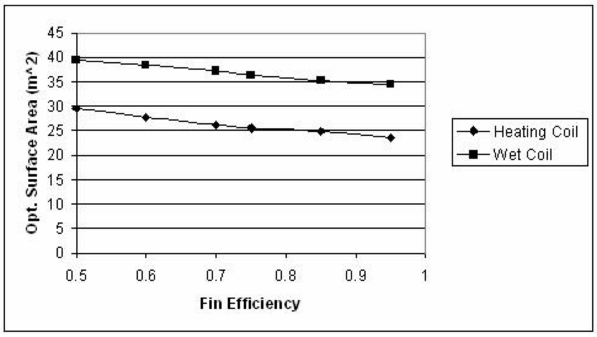

Figure 6 The influence of fin efficiency on optimum areas of heating and wet coils

At a constant heating or cooling load, by increasing fin efficiency, optimum surface areas of heating coil and wet coil decrease. To justify this result, one can say that by increasing fin efficiency, overall heat transfer coefficient increases and at the constant load, by using Eqs. (1) and (6) the optimum surface areas of coils decrease. In another word, by increasing fin efficiency, heating resistance of the coil decreases and it may have the same heat transfer in a smaller heating load.

DISCUSSION

In this paper, a method for thermodynamic modeling and mathematical optimization of air handling units having cooling and heating coils is proposed. The design parameters include thermal and geometrical parameters of cooling and heating coils. On the basis of the previously discussed results the following conclusions have been extracted.

1. The optimum conditions of coils composed of the surface area, pressure drop of passing air, number of rows and fin spacing in different conditions of air and different heating or cooling loads are determined.

2. In heating coils, by increasing the heating load, the optimum surface area of coil increases. In two different inlet temperatures and at a constant heating load, optimum surface area of greater inlet temperature is higher than optimum surface area of smaller inlet temperature.

3. In wet coils, by increasing the cooling load, optimum surface area of coil increases. In two different inlet conditions of air and at a constant cooling load, optimum surface area of greater dry bulb temperature is smaller than optimum surface area of smaller dry bulb temperature.

4. In both heating and wet coils by increasing air flow rate, optimum surface areas of coils increase.

5. At a constant heating or cooling load, by increasing fin efficiency, optimum surface areas of both heating and wet coils decrease.

Integrated HVAC systems in Central Europe climate

Karel Kabele and Pavla Dvořáková

SUMMARY

Sustainable building heating/cooling design concept in climate conditions of Central Europe aims to minimise building energy performance as well as embodied energy and environmental pollution and at the same time to achieve healthy indoor environment. As a result of building science and practice development in last years we have to solve new issues related to changes in a modern building design like need for summer cooling also in Central Europe conditions, different ratio of internal and external loads or problems with room ventilation resulted from infiltration rate minimising.

As the output of radiant system is limited by acceptable surface temperature, often asked questions are – "Is this system suitable for Central Europe climate? The purpose of this paper is to evaluate indoor environment and system energy performance in case study, focusing on office rooms, to evaluate properly different heating/cooling energy transmission systems like chilled/heated ceilings, floors and walls and their operation control strategy.

INTRODUCTION

Recent low-energy building heating and cooling design concept in climate conditions of Central Europe is based on minimizing energy consumption as one of the critical criterions in building design aiming to decrease total energy consumption and environmental pollution at the same time with preserving or improving indoor air quality.

Sustainable approach to a building and its energy system design, as next step after the low-energy approach, leads to evaluate besides the operational energy also energy embodied in the building and the system material (Kabele et al. 2006).

The typical need for climate conditions of Central Europe (Czech Republic) is space heating during heating period (approx 230 days a year). There were no active cooling systems considered in traditional buildings. Due to low internal gains, high thermal inertia and optimised glazing ratio this building could be operated without any active cooling.

Figure 1. Integrated heating/cooling ceiling system with capillary mats

Current modern buildings, with high internal gains, high galzing ratio, low mass and well-insulated walls (U value less than 0,3 W/m2K) and windows (U value less than 1,8 W/m2K) must be nowadays equiped with an active

cooling system to follow the comfort requirements also in summer period. In many cases, in these buildings the cooling load finally exceeds the heating load.
Traditonal approach to the technical solution of a heating /cooling system in such a buildings was to design two independent systems (radiator heating and split units cooling). One of the modern technical solutions, which could be considered as a sustainable one, is an integrated heating/cooling ceiling system. Capillary mats, embedded in the gypsum plaster layer of the ceiling structure are supplied by the heating/cooling water (four-pipe system) (figure 1). Ceiling surface transmits energy into the heated/cooled room via radiation and convection heat transfer modes. Comparing to a traditional system, this technical solution integrates two systems into one and reduces air change rate need to hygienic minimum. The strong point of this solution is a significant reduction of the used material or rather embodied energy in a heating, cooling and ventilating system (Roulet et al. 1999).
The main problem is in the technical limits of this system (Petráš 2001). During the heating operation, output is limited by a hygiene limit reducing highest intensity of radiation on the skull-cap up to 200 W/m2. During the cooling operation it is limited by surface temperature, which should not drop below the dewpoint temperature (surface condensation).

PROBLEM DESCRIPTION

The main purpose of this paper is to investigate integrated heating/cooling system performance during typical Central Europe climate conditions with office operation load profile. This task arose from common practice, when several problems with system application occured despite following all the common recommendations (Kabele et al. 2002).
The questions to be answered were: Is the integrated ceiling heating/cooling system able to secure compliance with comfort requirements during the whole year operation in modelled case? Are the existing design recommendations in terms of maximum heating/cooling output of the ceiling applicable particularly in climate conditions of Central Europe?

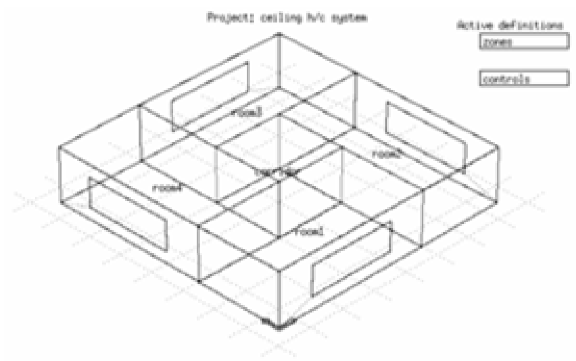

Figure 2 .ESP-r model of the building

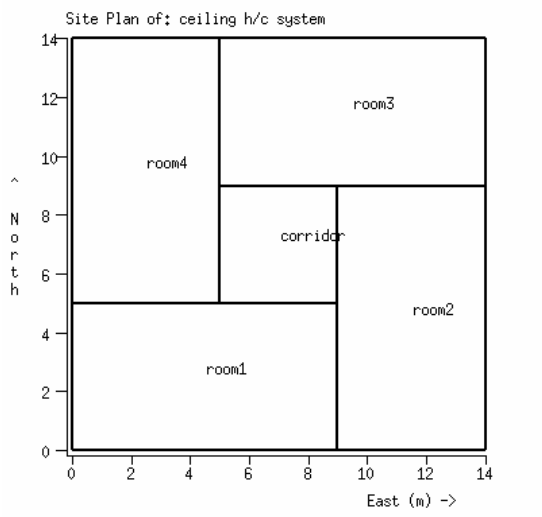

Figure 3. Site plan of the model

RESEARCH METHOD

We used problem analysis followed by computer simulation of an annual building energy performance on a case study to analyze selected parameters, that may have an influence on the possibility of system application. ESP-r, an energy system performance simulation program, was used for this purpose (ESRU 2004).

MODELING AND SIMULATION

Model Description

A five - zone model was created for this purpose (Figure 2, Figure 3). The model contains four equal zones with following dimensions 5 m x 9 m x 3, each facing different cardinal point, and a corridor in the centre with following dimensions 4 m x 4 m x 3m. Each of the zones has a window 5 m x 1.6 m in a longer exterior wall. Medium-heavy constructions were considered with the value of overall coefficient of heat transmission according to Czech building regulations (ČSN 730540 2005). For an external wall U = 0.239 W/m^{2}K, for an internal wall U = 1.561 W/m^{2}K and for a window it is 1.198 W/m^{2}K.

Room dimensions in model follows reccomended values for the proportion of hight to depth of the room from the point of day lighting (h/d = 1.66), typical in the Central Europe geographical conditions. The size of glazing surface represents 30 % of the façade surface.

No heat flux through ceilings and floors was assumed.

Heating and cooling system is radiant low temperature heating/high temperature cooling system with capillary mats placed inside the layer of gypsum plaster in a ceiling construction and defined by heating capacity controlled according to established practice in a range of 0-130 W/m^2, cooling capacity 0-80 W/m^2 in each of the rooms (Jeong et al. 2004). This technical solution is carried out in the model by placing a cooling and heating capacity to the axis of gypsum plaster layer. (R.K. Strand and K.T. Baumgartner 2005) The active ceiling construction contains layers according to Figure 4

The control of the system is running as basic heat and cool controller according to sensors, located in each of the rooms, sensing dry bulb temperature. Set point for heating is 22°C; for cooling 26°C. There is no humidity control considered.

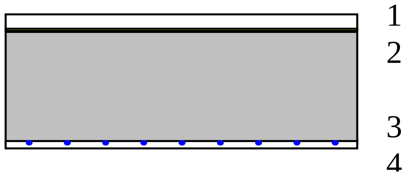

Figure 4. Active Ceiling/Floor construction:
1 Flooring, 2 Polyurethane foam board, 3 Heavy mix concrete, 4 Gypsum plaster with capillary mats

Ventilation. Mechanical ventilation 0,7 h^{-1} besides the infiltration 0,3 h^{-1} is considered. Supply air temperature is 20°C

Occupation and casual gains. Sensitive and latent heat load by persons is 7,8 W/m^2 during working hours (weekdays 7:00-18:00), sensitive heat load by equipment is 15 W/m^2 and lights 25 W/m^2 during whole day.

Simulation

The whole year period was studied using Prague (Czech Republic) ASHRAE IWEC climate files (Figure 5). An integrated building simulation was used, with time step 1 hour and initial period 11 days. Shorter time step has been tested during model tuning, but didn't have any important impact on the results and so the picked one hour step ensured sufficient accuracy. During simulation, no major problems were detected by the program. The discussion about the results was focused on heating/cooling energy consumption. PMV and PPD parameters were used to evaluate thermal comfort (Yang 1997, ČSN EN ISO 7730 2005). The third thing to follow was the possibility of condensation on the ceiling surface during the cooling period.

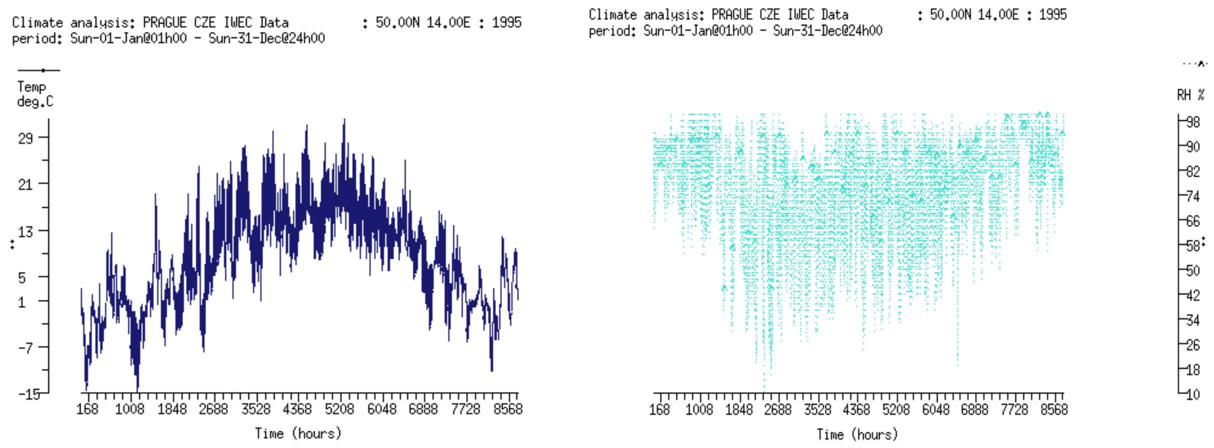

Figure 5 Annual ambient air temperatures(a) and ambient air relative humidity(b) in Czech Republic

SIMULATION RESULTS AND DISCUSSION

In following tables and diagrams there are selected simulation results from ESP-r, related to the problem.

Energy

From the point of annual energy consumption the results show a significant impact of the internal heat loads which decrease energy demand for heating and increase energy demand for cooling comparing to unoccupied space. The effect of an aspect in both heating and cooling energy demand in all of the solved cases is also considerable.

Table 1 Annual energy h/c consumption

Zone	En. for Heating	Operating time	En. for Cooling	Operating time
	[kWh]	[h]	[kWh]	[h]
room1	283	264	-12211	4455
room2	436	392	-11049	4146
room3	253	282	-11415	4247
room4	328	301	-13007	4633
Total	**1301**		**-47682**	

Thermal comfort – resulting temperature

To get to know if the system capacity is well designed we focused on the interior temperatures first

The temperature curve confirmed the ability of the heating/cooling system capacity to guarantee set temperatures within all of the zones during nearly the whole year. Set point for cooling was exceeded only in several hot days during summer with maximum value 31.5°C.

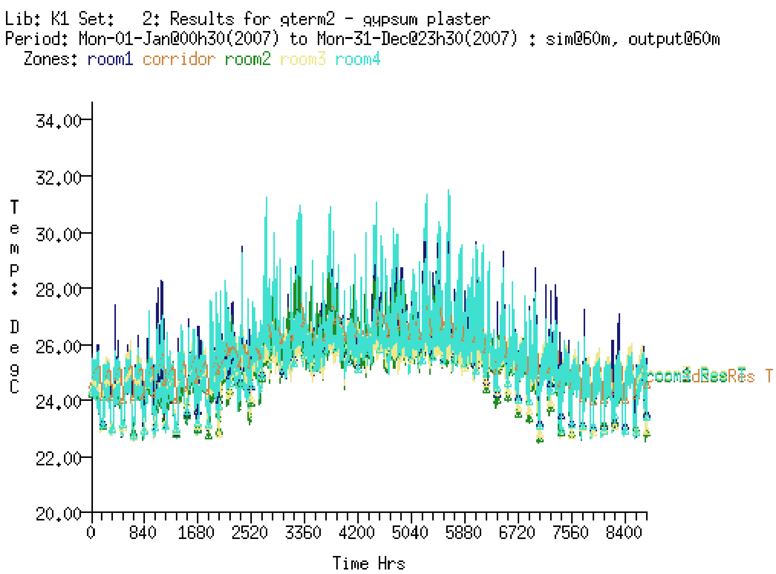

Figure 6 Annual resulting temperatures in all zones

Table 2 Resultant temperature extremes

zone	Maximum [°C]	Minimum [°C]	Mean value [°C]	Standard deviation
room1	29.7	22.5	25.3	1.2079
room2	28.5	22.5	25.1	1.1186
room3	27.8	22.5	25.1	1.0106
room4	31.5	22.5	25.4	1.3316
corridor	27.5	23.9	25.7	0.85953

Thermal comfort – PMV, PPD

Thermal comfort evaluation is based on PMV and PPD classification of heated/cooled spaces. PMV is defined by six thermal variables from indoor-air and human condition that is air temperature, air humidity, air velocity, mean radiant temperature, clothing insulation and human activity. The value of PMV index has range from −3 to +3, which corresponds to human sensation from cold to hot, respectively where the null value of PMV index means neutral to maintain the PMV at level 0 with a tolerance of ±0.5 to ensure a comfortable indoor climate. The PPD index is a description of estimated thermal comfort and a function of four physical parameters: dry bulb temperature, mean radiant temperature, relative humidity and air velocity, and parameters connected to the occupant such as clothing level, metabolic rate and external work. Comfort evaluation is based on activity level 1.2 met with clothing level equal to 0,7 clo (ASHRAE 2005, CSN EN ISO 7730).

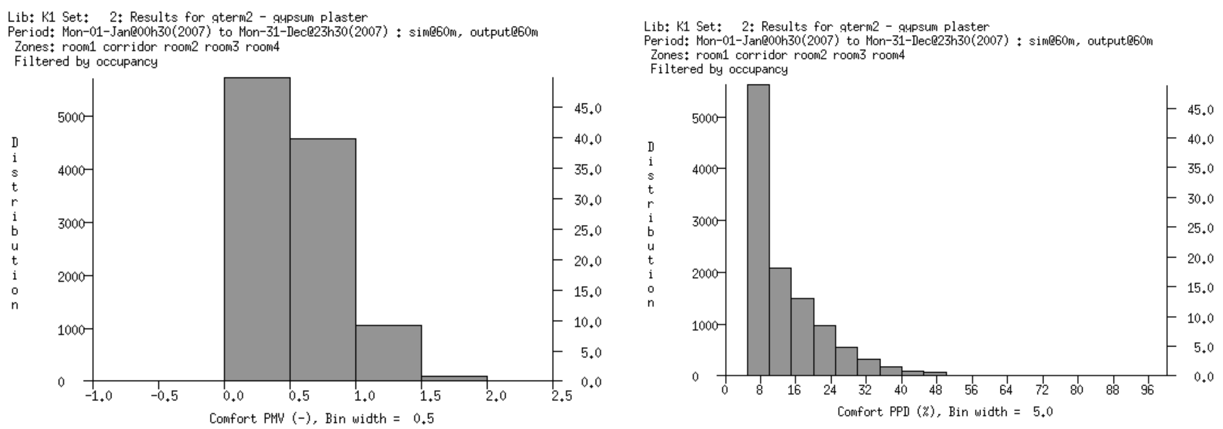

Figure 7 Annual distribution of PMV and PPD index

In this case PMV index appeared from -0.5 to 2.0. Index PPD in 48% of the time is up to 10% which means that during this time the number of dissatisfied occupants will not exceed 10%. Index PPD during 99% of the time is up to 50%.

From the point of heating there is no problem with thermal comfort in all of the examined cases; minimum value for PMV during heating period is -0.5, which means better than slightly cool.

On the other hand several problems with thermal comfort during cooling period were detected. In this case the maximum PMV index reached 2.0, which means warm.

Active ceiling surface temperatures and condensation

The active ceiling surface temperatures coming out from the simulation are in figures. Figure 8 shows temperature difference between active ceiling surface temp and dew point temperature during the year, to identify critical days, marked with circle. Detailed analysis of critical time is on the figure 9.

The possibility of surface condensation occurred in a range of one or two hours during one critical day of the year in summer, when the exterior relative humidity was very high.

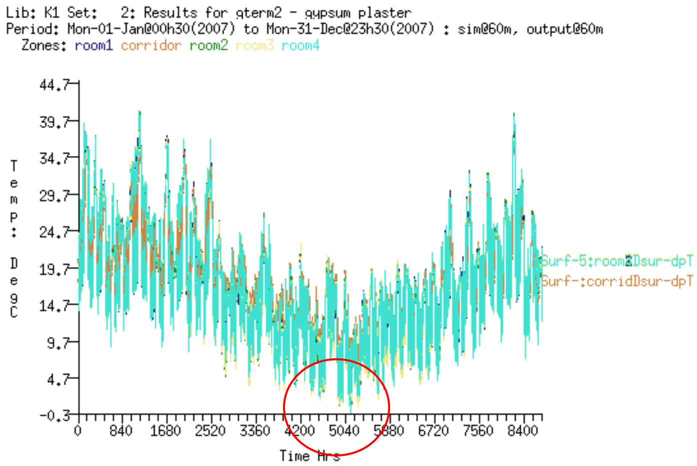

Figure 8 Difference between active ceiling surface temp and dew point temp during the year

CONCLUSION

The simulation results are concentrated on looking for the answer, if in a modern building, built according to valid Czech standards with respect to energy efficiency, in Czech climate conditions, is possible to use an integrated heating/cooling ceiling system. The question has been analyzed and parameterized. Based on this analysis, a case study, describing typical example of this technology application was created to predict thermal behaviour of the room heated/cooled with this system and to describe thermal comfort behaviour in time during a whole year operation. ESP-r, a modelling tool was applied. The case study was focused on the evaluation of the impact of the room orientation and internal loads describing typical office room use. System is running in switching operation mode which means, that during the whole year both heating and cooling energy sources are available and the technical solution of the system enables to switch heating mode to cooling mode (and vice versa) automatically according to the control system.

In all of the cases there are no problems with the heating. The system can reliably guarantee the required temperature during the whole year. At the same time the simulation shows that common designed heating/cooling capacities (130 and 80 W/m^2) of the ceiling surface are appropriate. Several problems are detected with the cooling, when the designed capacity cannot cover the temperature requirements and occasionally a short-term condensation can occur. This means that the application of this integrated system is limited by its capacity. Especially in the buildings with higher internal gains and connected cooling demand this application is disputable. Following the effect of building orientation individual control of the zones is recommended.

The results from above and the conclusions made from them are valid for the conditions of this simulation.

The future work in this field will be focused on sensitivity analysis on other parameters affecting energy and environmental behaviour of an integrated system aiming to create general design conditions of integrated heating/cooling systems in Czech Republic.

SUMMARY

In this study, a new optimal design method for buildings and urban energy systems is proposed. Also its applicability is analyzed using a simple case study. Genetic Algorithms (GA) are adopted for this optimization. This method has two optimization steps, equipment capacity and system operation. These optimization steps are calculated simultaneously. The results showed that the proposed method has the potential to be applied to very complex energy systems and achieve significant improvements.

INTRODUCTION

Energy conservation in the building sector is now in great demand given the increased attention throughout the world to environmental preservation of the Earth. Thanks to advances in technology for building facilities, many choices are available when designing an energy system in a building or in an urban area, such as cogeneration systems, triple-effect absorption refrigerators, air source heat pumps, etc. Although so many choices exist, it is difficult to make a quantitative evaluation about which energy system is best, i.e. lowest cost or minimum environmental impact. Reasons for such problems are thought to include:

- Numerous combinations of equipment can be considered when designing systems.
- Operational efficiency of the system is highly dependent on how it is used.
- Prediction of building energy demand at the design stage is very difficult.

In order to resolve these problems, some research on optimization methods for energy system operation using linear programs are proposed [1]. Under such methods, the energy input/output relationship is assumed to be linear. However, with technological progress such as “inverter control” for machine operation, functions concerning energy input/output cannot be considered linear. Also, energy efficiency is highly dependent on equipment size and the operational load factor. Therefore, a new optimal method which can be applied to nonlinear problems is required for improved optimization.
Since the last decade, optimization methods for solving nonlinear optimization problems have advanced steadily. Write and Hanby [2] applied the direct search method, but there may be some inaccuracy if boundary conditions are encountered. On the other hand, the Genetic Algorithms (GA) introduced by Holland [3] have been applied to a diverse range of scientific, engineering, and economic problems. GAs are very suitable for handling complicated optimization problems with nonlinear, discrete and constrained search spaces. Huang et al. [4]

adopted GA for heating, ventilating and air-conditioning (HVAC) control problems. Also Obara et al. [5] applied this method to the control problems of energy systems consisting of fuel cells, thermal storage, and heat pumps, etc. Write et al. [6] applied GA to investigate multi-objective (building energy cost and occupant thermal discomfort) problems to identify the optimal pay-off characteristics. Hongwei et al. [7] applied GA to mixed integer and nonlinear programming problems in an energy plant in Beijing, and made a detailed economic investigation by changing the economic and environmental legislative contexts.

In this paper, a new optimal design method for energy systems is proposed. This method optimizes both equipment capacity and operational control planning simultaneously by using GA. It will be helpful for engineers who design energy systems in buildings or urban areas. Moreover, the application validity of the method was examined by means of a simple case study.

INTRODUCTION

Structure of Optimal Method

Figure 1 shows the process flow of the optimal design method proposed here. There are four steps to achieve optimal solution.

1) Selection of the basic systems (each system is characterized by the difference in combination of equipment composing systems).
2) Optimization of equipment capacity composing each energy system. (Using GA)
3) Optimization of the operational process of each energy system. (Using GA)
4) Selection of the best design by comparing each local optimal solution.

In the 1st step, enumerate selection among the basic energy systems prepared beforehand is conducted, rather than optimal selection. These form the energy system database. The 2nd and 3rd steps are the optimization stages. These optimization problems, both equipment capacity and system operation, cannot be resolved separately due to the strong relationship between capacity and operation. Thus, these two steps are solved simultaneously. In the final 4th step, the best energy system which scores the highest rating among all local optimal solutions of each base system is selected as the optimal solution.

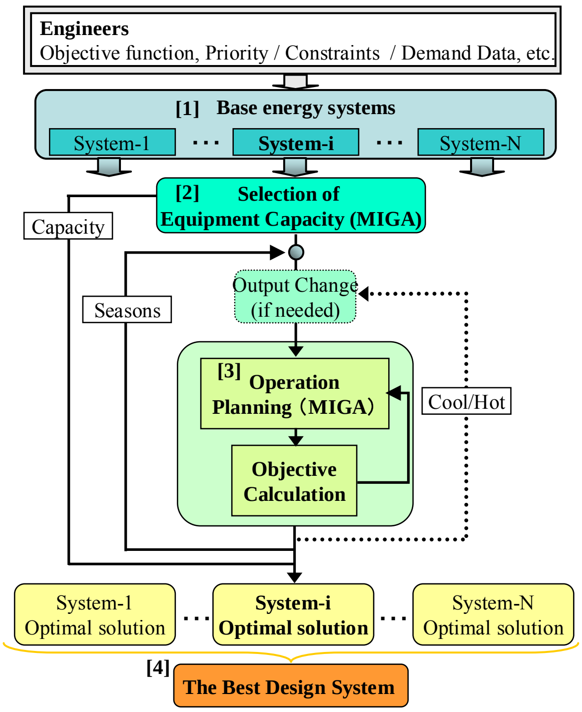

Figure 1.Optimal Design Process using MIGA.

Input Data

The main data used in these optimal calculations are as follows:

Energy Demand Data

Default data from the "Computer Aided Simulation for Cogeneration Assessment & Design III" (CASCADE III) released by The Society of Heating, Air-Conditioning and Sanitary Engineers of JAPAN is used. Figure 2 shows the data applied in this paper.

Equipment Data

Figure 3 shows an example of the equipment performance. With recent technological progress, such as "inverter controls" for equipment operation, functions concerning energy input/output have become nonlinear. A database of equipment performance is prepared and used in the calculation programs.

Application of Genetic Algorithms

GA is a method of solving optimization problems by imitating the evolutionary process based on the mechanics of Darwin's natural selection. Since its introduction by Holland in 1975 [3], GA has been applied to a diverse range of scientific, engineering and economic problems. In GA programs, the optimum solution candidate, which is termed an "individual", is considered to be a living entity. As per the evolution of organisms, each individual's information is ぅ described by sign rows called "chromosomes", which match the individual and the chromosome one to one. GA performs genetic operations such as selection, crossover, and mutations to the chromosomes of each individual, and the subsequent fitness (objective function) of each individual is calculated for evaluation. The individual with the highest fitness value of all the enquired individuals becomes the optimum individual.

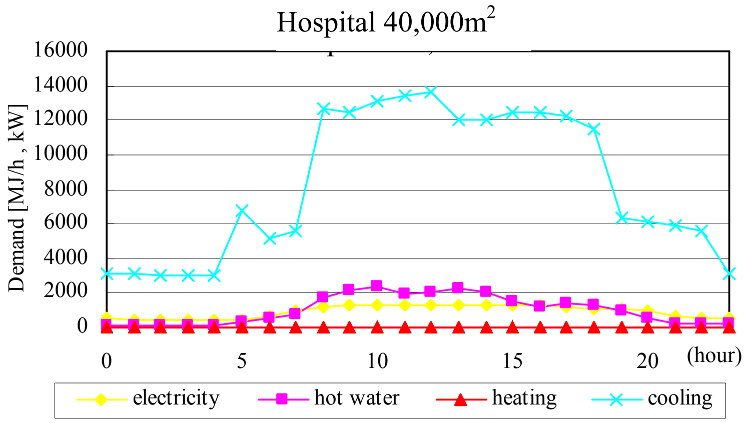

Figure2. Demand data (Aug.)

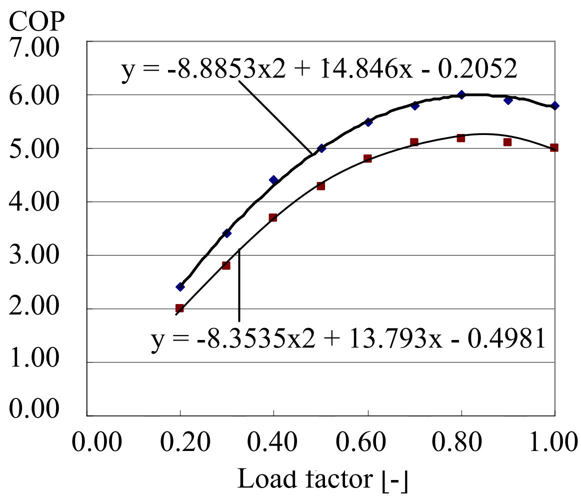

Figure3. Equipment Data (for example)

Moreover, a more efficient GA called a "Multi-island Genetic Algorithm (MIGA)" is used in this research [8]. MIGA involves a distributed genetic algorithm. The outstanding feature of this method is that the population in one generation is divided into several sub-populations called "Islands", and the genetic operations are performed independently on each sub-population. This independency enables the calculation to avoid converging partial optimal solutions. The exchange of individual information, termed "migration", is carried out periodically between sub-populations. Figure 4 shows ideal diagrams of the MIGA description for the operational control problem. Each cell in the "chromosomes" corresponds to a time division, and a number of operation load rates would be arranged in each cell.

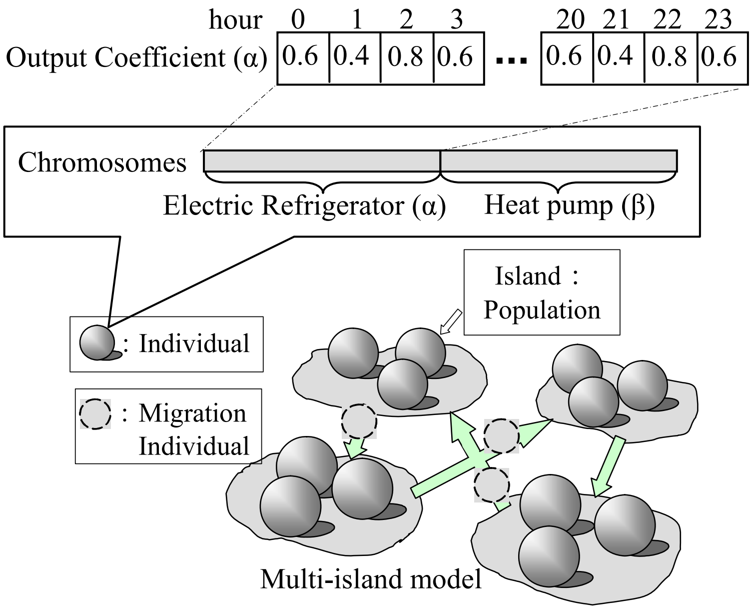

Figure 4.Diagrams of MIGA operations

OPTIMIZATION ANALYSIS

To examine the validity of this optimal design method, analysis for a unit building was investigated experimentally. Before this analysis, a simple-case analysis was conducted [9]. In this case, only the operation planning was optimized by using MIGA. Figure 5 shows a comparison between the optimal solution based on MIGA and the "correct" solution, which was derived by calculation of all operation plans. Here, the optimal solution from the MIGA shows good agreement with the "correct" solution, even though it has a few discrepancies.

In this paper, MIGA is used in two stages, capacity optimization and operational optimization. An analytical outline is described below.

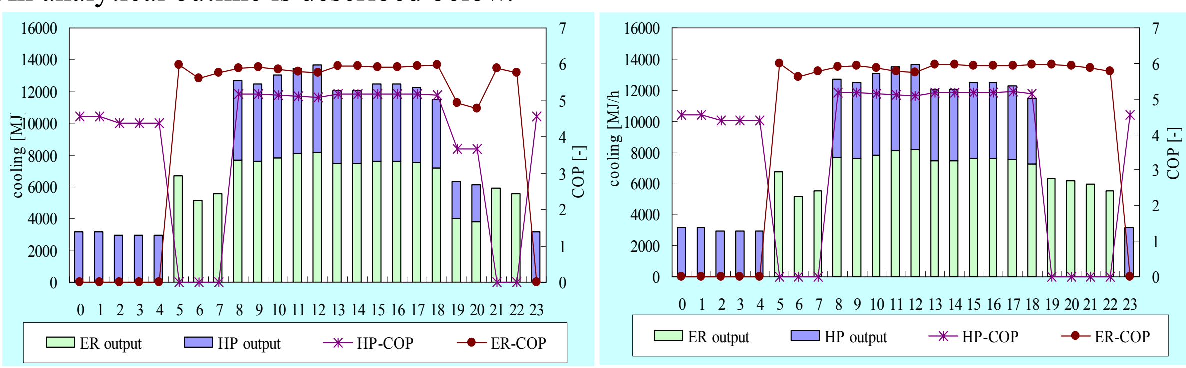

Figure5. Comparison between optimal solution by MIGA (left) and "correct" solution (right)

Analysis Conditions

1) Objective Building: Hospital in Tokyo, Total floor area; 40,000 m^2

2) Analysis term: Representative 1day in Aug. (24h)

3) Energy System: The objective energy system is shown in Fig. 6. In this study, only one system is analyzed. There are two heat pumps for hot water supply (HPw). Operation optimization problems are in Cooling Demand (CD) and Hot Water Demand (WD).

4) Variables: Shown in Table 1. Further details are as follows:

- Equipment Capacity: Set 5-6 types of capacity to each type of equipment composing the energy system
- Operation Plans: Combination of the 24 coefficient numbers for hourly output of the electric refrigerator [CDer (α)] and HPw1 [WDhp1 (β)] are optimized by using GA.

5) Objective Functions: The amount of CO_2 exhaust and energy consumption converted to primary energy.

6) Constraints: The main constraints applied to this analysis are as follows:

- If Heating Demand (HD) is 0 [MJ] for 24h, heat pump for cooling/heating ("HP" in figure 6) is automatically changed to "cooling" operation mode.
- To avoid extreme hourly changes in equipment load, there is a penalty when the hourly load difference is over 60%.
- To avoid frequent ON/OFF operation, the minimum running time is set to 2 hours. Here is also a penalty when this rule is broken.

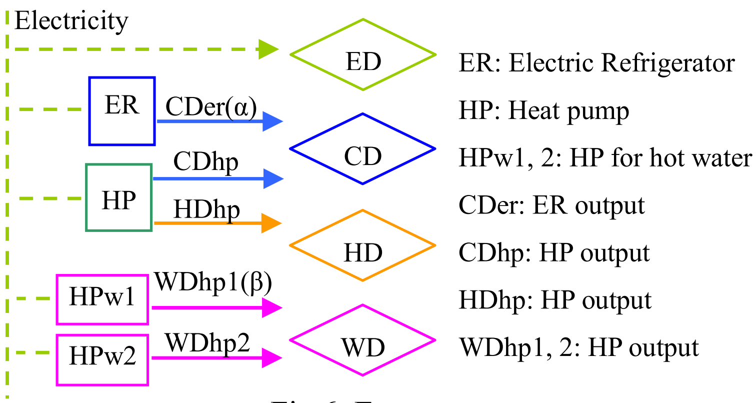

Fig.6: Energy system

Table 1: Variables in optimization

Capacity	
ER	1600, 1900, 2200, 2500, 2800 [kW]
HP1	700, 1000, 1300, 1600, 1900 [kW]
HPw1	450, 500, 550, 600, 650, 700 [kW]
HPw2	50, 100, 125, 150, 175, 200 [kW]
Load Factor	
Cooling (ER)	α_i(i=0_23): (0 , 0.2, 0.4 , 0.6 , 0.8 , 1.0)
Hot water (HPw1)	β_i(i=0_23): (0 , 0.2, 0.4 , 0.6 , 0.8 , 1.0)

Parameters

Table 2 shows the MIGA parameters in this study. To determine the accuracy of the optimization, parameters are decided by checking the effect of the parameters on the optimal solution. Figure 7 shows the effect of the generation number on the optimal solution. 250 is selected as the number of generations because a stable solution can be obtained after almost 200 generations in Fig. 7.

Table 2: MIGA parameters

MIGA parameters	Capacity selection	Operation planning
Size of Sub-Population	5	8
Number of Island	2	3
Population size	10 (5×2)	24 (8×3)
Number of Generation	30	250
Rate of Migration	0.5	0.5
Interval of Migration	5	5
Rate of crossover	1	1
Rate of mutation	0.01	0.01

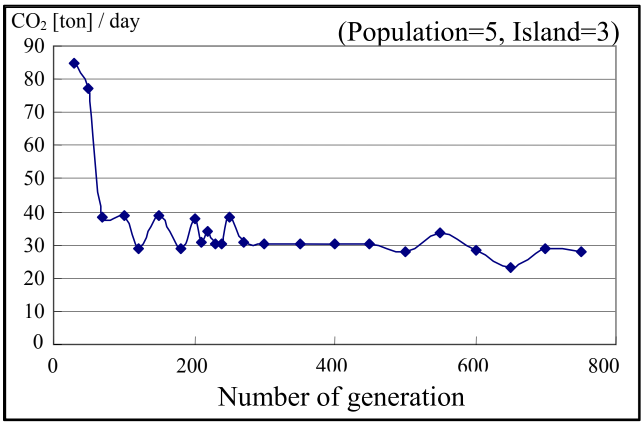

Fig. 7: Effect of the number of generations on the optimal

RESULTS & ANALYSIS

Results of this research are given in Table 3 and Fig. 8. The optimal solution for operation is illustrated in the chromosomes shape.

Cooling Operation

In the capacity optimization step, ER: 2,500 kW and HP1: 1,600 kW are selected as heat sources for cooling which can realize efficient operation. The total capacity is 4,100 kW (=14,760 [MJ/h]), which represents about 10% over the peak for the Cooling Demand (≈13,660 [MJ/h]). Here, smaller equipment such as ER: 2,300 kW or HP: 1,300 kW can be selected under the same constraints. However, if those smaller heat sources are selected, the operational load will be around 100% of its capacity. This results in lower efficiency compared with the optimal result, at which equipment can be operated at 70~90% of capacity. This is because the functions of the equipment efficiency are nonlinear, and this method can take into consideration nonlinear characteristics.

Also in the operation planning step, each equipment is loaded to about 80~90% of each unit's capacity for the peak hours, not that one equipment is loaded 100% of its capacity and another

Table 3: Optimization results.

Selected Capacity

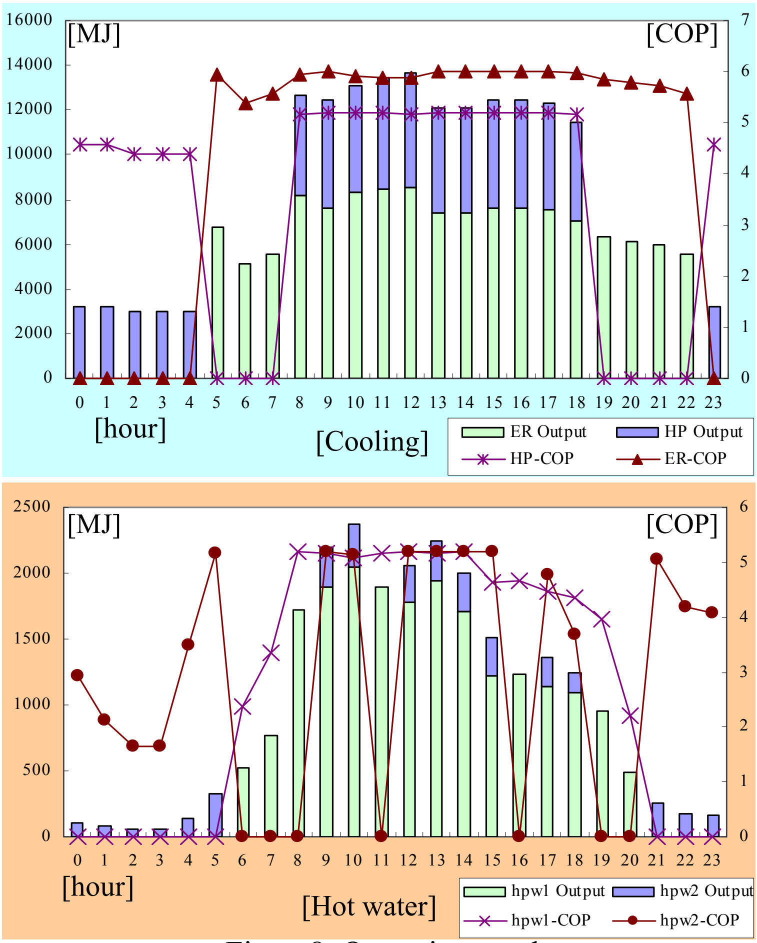

Figure8. Operation results.

is loaded to meet the rest of the demand. Here, the characteristics of nonlinear functions are also taken into account. As a result, a higher COP can be realized.

These results show the advantage of the proposed optimal design method, which can optimize both equipment capacity and operation planning simultaneously. Additionally, for hours with a low Cooling Demand (23~4), only smaller equipment is selected. In this way, the COP can be kept at a high level. And also there is detailed discussion about hot water source operation in previous paper [10]. The total amount of CO_2 exhaust is 23.11 [t/day]. This figure represents about 135 [kg/year·m^2] bearing in mind energy demand distribution for each season. Compared with public data for the amount of CO_2 discharged from existing hospitals in Tokyo, which is about 140-190 [kg/year·m^2], this optimal solution shows good efficiency.

CONCLUSIONS

A new optimal design method for energy systems which can optimize both equipment capacity and its operation planning is proposed. By conducting an experimental analysis, through the application for this method to a building, the validity of the method has been confirmed.

SUMMARY

A thermal simulation program called IDA-ICE was used in the evaluation of the energy efficiency and indoor climate of a pilot-building in Jyväskylä, Finland. The simulation model was calibrated concerning the heating and cooling energy, because the performance of the building was evaluated using results of the calibrated simulation model as reference to the measured performance. The calibrated simulation model was built for continues commissioning. This paper explains the calibration process and its results. The measured and calculated energy use of the building corresponded to each other as the result of the calibration.

INTRODUCTION

The purpose of the study was to evaluate, how calibrated simulation model can be used in assessment of the building energy performance. The heat use and electricity use of the HVAC-system were evaluated as well as the indoor temperatures.

In the year 2003 the first version of the simulation model was established and the pilot-building was constructed. The measured and simulated results differed from each other about 30 % concerning the heat use and 15 % concerning the electricity use in the first year. The results are presented more exactly in sources [1] and [2].

The simulation model was calibrated utilizing building automation system (BAS) and building energy management system (BEMS). The building automation system was used in determining the ventilation air flow rates, the set point temperatures of the room devices and of the supply air. The air flow rates, which were underestimated in the original model, were corrected to the calibrated model. The measured air flow rates and temperature of the supply air and the electricity use of the lighting and the office devices were used as time dependent input parameters in the simulation model. The building energy management system was utilized in determination of the electricity use and the heat use of the building. The input files needed in the simulations were generated from BAS and BEMS.

The indoor temperatures were evaluated using duration curves concerning utilization time of the building. The duration curves were also compared to the simulated temperatures.

Basic Information of the Building

The case building is situated in Jyväskylä, 350 km from the Finnish capital, Helsinki. The building gives accommodation for the Department of Information Technology of Jyväskylä

Polytechnic. The construction works was finished by May 2003 and the building was taken into actual use in August 2003.

The five-storey building consists mainly of classrooms. The building has also an assembly hall, a library, an auditorium, a lunchroom, a kitchen and a bomb shelter, which are situated in the ground floor. The working rooms of teachers are situated in the fifth floor.

The floor area of the Pilot building is approximately 9 500 m^2 and its exterior volume is 38 700 m^3. Over 1 000 students are studying and more than 40 teachers and other personnel are working in the building.

The Principle of the HVAC System

The classrooms and the working rooms of the case building have heating and cooling panels detached from the ceiling. Floor heating is used all over the ground floor. The conventional radiators are not used for heating.

The building is heated by district heating and it is cooled by electricity using two refrigeration compressors and one storage tank and in addition free cooling by outdoor air is used. The ventilation system has combined heating-cooling-free cooling coils and a rotating heat recovery unit. HVAC-system has also a mechanism, which recovers the indoor overheat from the cooling panel's liquids to the supply air. The innovative patented system is advance low temperature heating system. The principle of the HVAC-system is explained in reference [3].

The building is conditioned using an integrated heating, ventilation and cooling system. The heating and cooling liquids are transferred through a 3-pipe system with common return liquid. The HVAC-system is presented in **figure 1**.

The building has variable air volume (VAV) ventilation system [4], which is controlled with the both indoor air temperature and carbon dioxide level [5].

EMS and BEMS

The case building has separate energy building management system (EMS) and building automation system (BAS).

BES measures hourly heat, electricity and cold water uses. Measured values are reported monthly, daily and hourly using tables and figures. Heat use, which is weather corrected by degree day method, is also available. Besides the control of the HVAC-system, building automation system measures temperatures in 20 of the total 50 rooms, temperatures of liquids, position of valves, rotation speeds of the motors of fans and pumps as well as chamber pressures in air-handling-units. Also timetables of the AHUs and set points and set point curves can be viewed on the BAS.

BAS can be used over internet, using a password protected user interface. A part of the measured data is saved to the BAS server of the case building, and it can be transferred trough the Internet using three file formats, HTML, CSV and XML. CSV-protocol was used in the evaluation of the performance of the building.

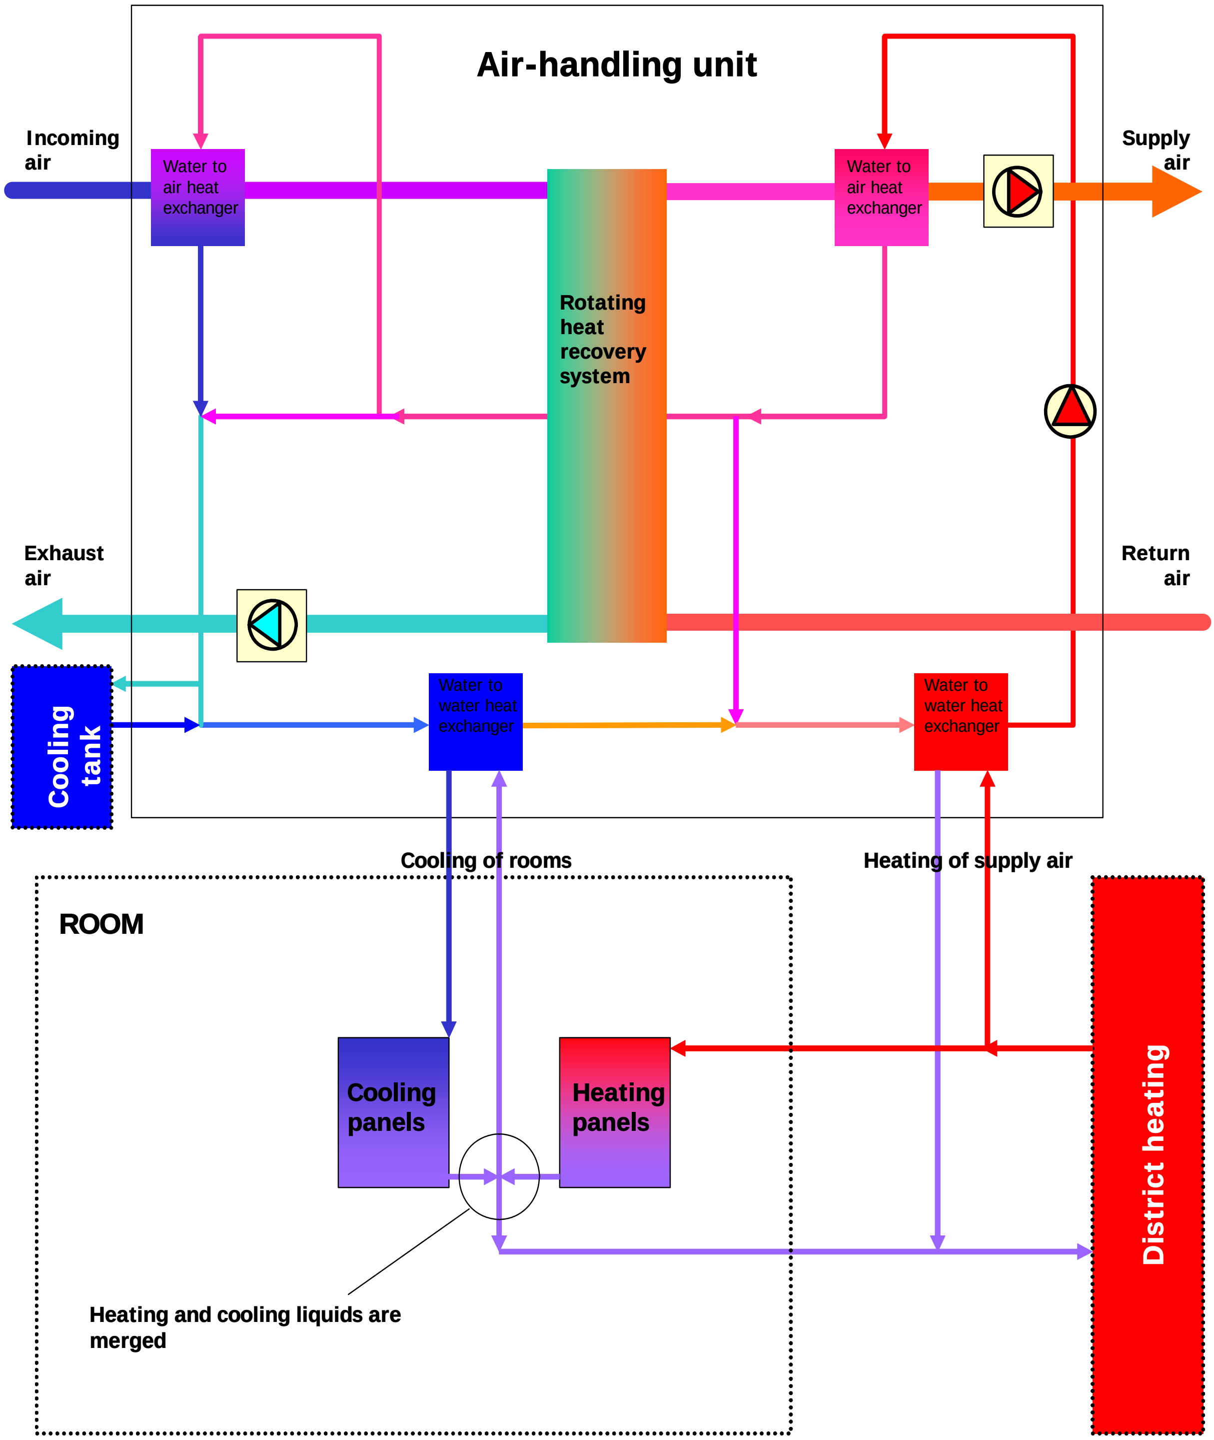

Figure 1 The HVAC-system of case building

METHODS

Simulation Program

IDA-Indoor Climate and Energy is a program designed for studying the indoor climate of zones of a building and for simulating energy consumption of a building [6]. IDA-ICE is an extension to an IDA simulation environment and an advanced user can simulate any system with the aid of the general functionality of the IDA simulation environment.

In normal circumstances, the building to be simulated consists of one or more zones and a primary (heat producing) system and one or more air handling units. The weather data is supplied by weather data files or it can be synthetically generated. The shading of the surrounding buildings is also evaluated.

Predefined building components and other parameter objects can be loaded from a database. This can also be used to store personally defined building components. The mathematical models of IDA-ICE are described in terms of equations using a formal language named NMF, which can be used to make new modules or to replace existing program modules. The actual function of the components and relationship between the components models are modeled using NMF-files.

Calibration of the Simulation Model

The calibration of the simulation model of the case building included the following steps:
1. Developing a model which determines the volume flows of VAV-system using the rotation speed and pressure rice over the fans in calculation
2. The internal heat gains from the electric devices were determined using hourly electricity measurements from the BEMS
3. The leaking of the building was evaluated using information from the literature
4. The set temperatures of the supply air as well as the room temperatures were determined using the BAS
5. The set temperatures of the entering heating and the cooling liquids were also determined using the measurements of the BAS
6. The simulated output values, for instance for the indoor air temperature, the temperature of return liquids, and the energy consumptions, were compared to measured ones to evaluate the validity of the input parameters

The first version of the simulation model of case building was made by a Finnish HVAC engineer company Olof A. Granlund. They modeled the building with a simulation program RIUSKA [7], which is based on DOE 2.1 E.

Case building was modeled again by the researchers IDA-ICE and the model was calibrated using the measurements of building automation system. The principle of the calibration process is presented more precisely in the reference [8] concerning the commissioning and in the reference [9] concerning simulation model itself.

The volume flows to each of the rooms were calculated based on the calculated indoor temperature and the calculated carbon dioxide emission from the people. However, the calculated total volume flows differed much from the measured ones, because the exact patent protected control strategy and the real occupancy level were not known. Due to that the measured and calculated heat uses differed quite much from each other.

At the next phase the volume flows of each of the VAV-flow AHUs were taken directly from BAS-measurements based calculation model to the simulation program. The volume flows were divided in the rooms in the proportion of the floor areas, because the exact volume flows of the rooms were not saved to database of the BAS. At the same time the electricity use of the rooms were determined from the hourly electricity measurements and divided in the rooms with the same principles as the division of the volume flows. The electricity use of the HVAC was reduced from the total electricity use.

RESULTS

Use of Energy for Heating

Figure 2 presents the measured and calculated heat use of the case building in the first and second year of the building in use. The measured heat use was 30 % more than the simulated one during the first year. The difference was mainly due to the difficulty to determine the actual volume flows of VAV-system.

The heat use of the second year was calculated after several corrections to the model. The calibration process included procedure explained in the previous chapter. The most important measure was to determine the variable air volume flows using a model. It was found out comparing the first estimation of the volume flows afterwards, that volume flows were underestimated with 30 % in the first year.

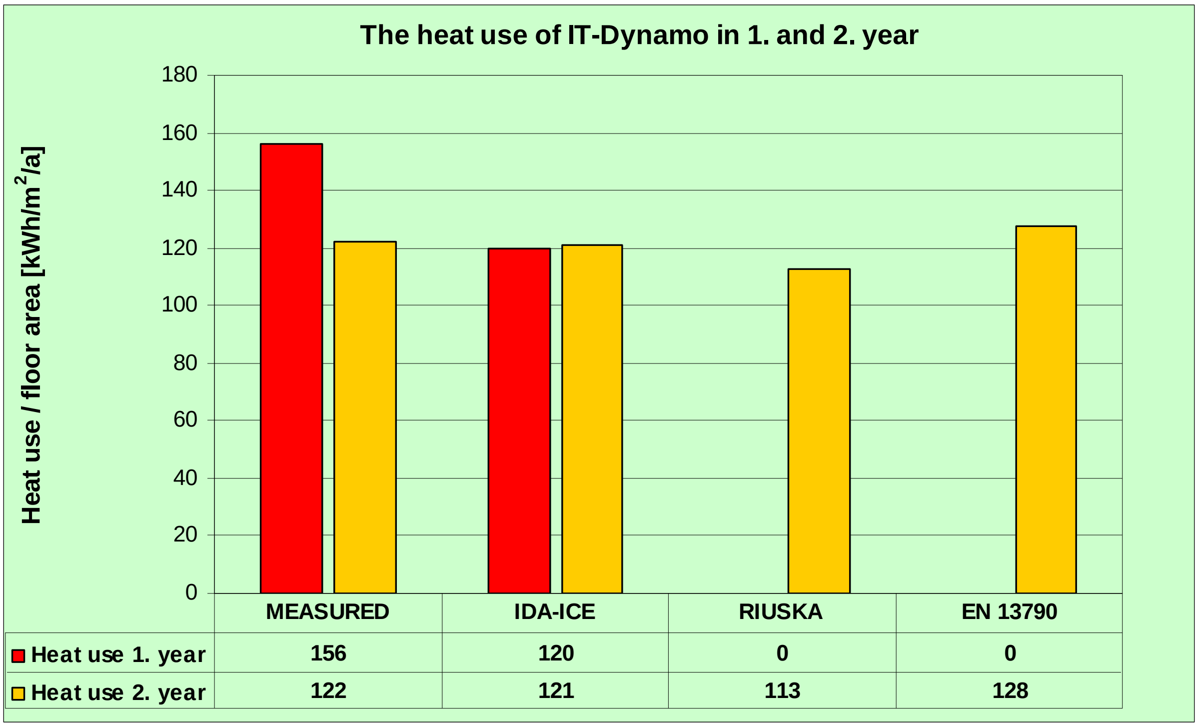

Figure 2 The heat use of the case building during the first and second year in use

The heat use of the second year was calculated using three different calculation programs, two simulation program IDA-ICE and RIUSKA and a standard calculation method (EN 13790) [10]. The results of RIUSKA were not calibrated, and that is why the results of calibrated model of IDA-ICE correspond best to the measured heat use in the second year. The result of standard calculation overestimated the heat use with several percents.

The Electricity use of HVAC-system

Evaluation of the electricity use HCAC-system including fans, pumps, cooling devices etc. was difficult due to the same problems as in the determination of the heat use. The electricity use of the fans was dominant concerning the electricity use of HVAC. That is why the determination of the volume flows [4] was important also to find out the exact electricity use of fans and therefore the whole HVAC-system.

In the first year the measured electricity use of HVAC was 47 kWh/floor-m^2/a as while the calculated one was 35 kWh/floor-m^2/a. The measured and calculated electricity use of HVAC -system was according to both the measurement and the simulation 40 kWh/floor-m^2/a in the second year. The difference between the measured and calculated values disappeared because of the calibration.

Besides the determination of the volume flows, the electricity of the cooling devices was able to be determined more exactly in the second year than in the first year. That was done developing a mathematical model based on measurements. The electricity use of the cooling system was according to electricity measurements 12 kWh/floor-m^2/a. The energy production of the free cooling system was according to the measurement based model 36 kWh/floor-m^2 and according to simulations 33 kWh/floor-m^2/a. The whole panel cooling energy use of was according to the measurements and the simulations 48 kWh/floor-m^2/a at the same time, and therefore 75 % of the cooling power was produced using the free cooling. The measured and the calculated total cooling energy need are presented in **figure 3**. The total and free energy needs were underestimated a little in the simulations compared to the measurements in spring 2005.

	9/04	10/04	11/04	12/04	1/05	2/05	3/05	4/05
Total measured	6	7	7	7	8	8	13	9
Free measured	6	5	7	6	7	9	12	8
Total calculated	8	8	8	6	5	6	6	7
Free calculated	5	6	7	6	5	6	6	6

Figure 3 The measured and calculated energy use for cooling in the case building between

Approximately 23 kWh/m^2/a of the total electricity use of the HVAC-system 40 kWh/m^2/a was consumed by the fans in the ventilation system. The electricity use for the cooling was 12 kWh/m^2/a. The rest of the electricity 5 kWh/m^2/a was consumed by the pumps and the control devices. The electricity use of the lighting, PC:s and other office devices was 83 kWh/m^2/a in the second year, which was two times higher compared to the consumption of a similar buildings in Finland.

Free Energy Savings

An estimation of the energy production of the free cooling system was measured to be 286 MWh and simulated to be 259 MWh between 09/2004-08/2005. The total COP of the cooling system is estimated to be 1.2, which is typical COP-value of the whole cooling system. The total COP includes all the power losses in the production of the cooling energy. It is not the same as COP of a refrigerator, which is normally between 2 and 3.

The savings of heat use were 162 or 107 MWh according to measurements and calculations respectively. In the calculations the lowering in efficiency of the heat recovery unit was taken into account. The total energy savings was about 14 % in heat use, 25 % in electricity use and 20 % in the average according to the measurements. The same values were a little lower according to the simulation results, but the differences are because the deficiencies in the model. Savings are calculated also in euros in a year and current value of the savings in ten years calculated with an interest rate of 5 %. The investment costs of the system are not remarkable more than in a regular system according to manufacturer of the system. The results are presented in **Table 1**.

Table 1 Comparison of calculated and measured savings in the case building

	Measured			Simulated		
	Electricity	**Heat**	**Total**	**Electricity**	**Heat**	**Total**
Total energy use in MWh	1140	1159	2299	1150	1150	2299
Energy saving in MWh	286	162	448	259	107	366
Saving in %	25	14	20	23	9	16
Saving in euro	22895	8107	31002	20704	5358	26062
Current value in euros / 10 years	176793	62596	239389	159869	41375	201244

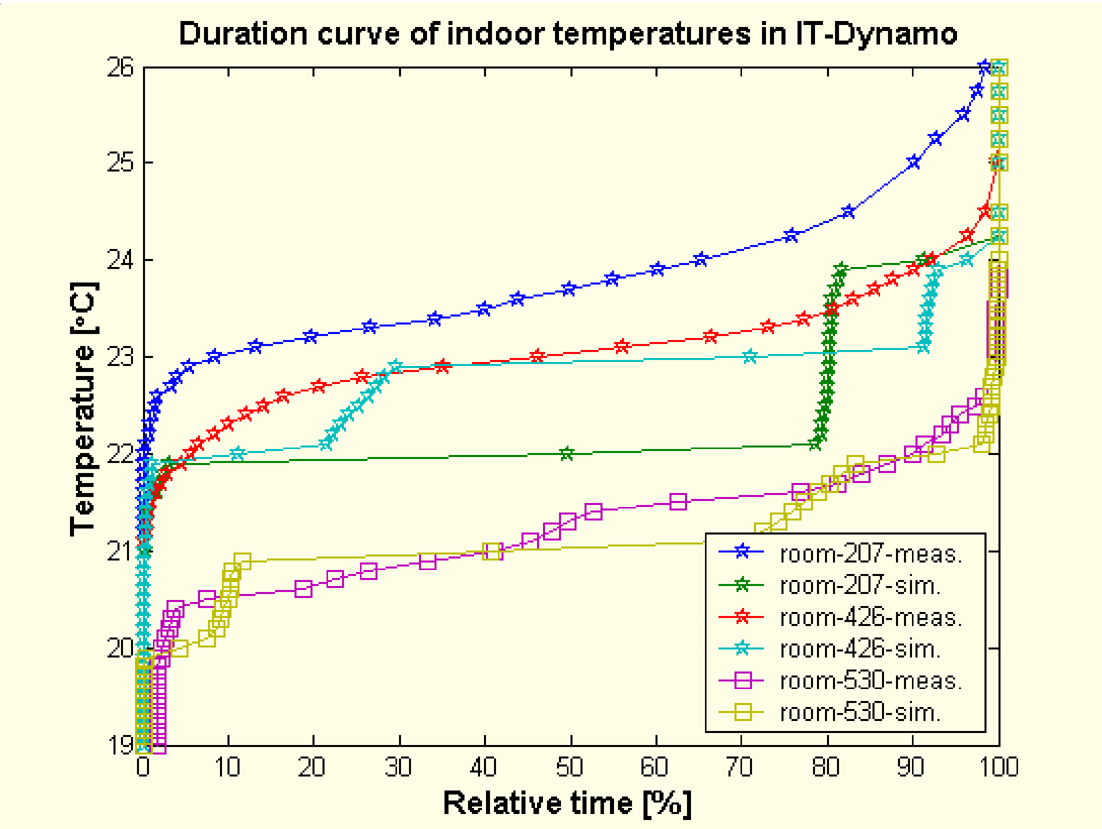

Figure 4 Duration curves of the indoor temperatures in the case building

Evaluation of the Indoor Climate

The indoor temperatures of the class rooms and the working rooms were estimated using duration curves. The duration curves presented in **figure 4** were calculated concerning the time, when the building has been in actual use. The temperature has remained between 21 °C and 26 °C in the class rooms and between 20 °C and 23 °C in the working room. The calculated and measured temperatures correspond quite well to each other in a little working room 530, but differed about 1 °C from each other in large classrooms 207 and 426 between 1.9.2004 and 30.5.2005.

DISCUSSION

The energy performance and the indoor climate of an educational building were evaluated using measurements results and simulation model. The calibration of the simulation model was done based on measurements of the building automation system and energy management system. The calibration process took two years, but after that the measurement and simulation results to correspond to each other.

The main reason for differences between measurement and calculation results were the difficulties in determining the exact volume flows, the control strategy and the actual the utilization factor of the building. The lack of the information of the exact control strategy was found out to be the main reason for difficulties to calculate the exact volume flows, the indoor temperatures and the energy use for cooling. When the volume flows and indoor set temperature was taken from measurement results of BAS, the calculated heat use and electricity use of HVAC-system correspond to each other quite well.

The simulation model should be kept as simple as possible when assessing a real system. The complicated models are difficult to calibrate, when the calculation parameters are more difficult to find out. The duration of the calibration process should also be much shorter, one month or two at the most, to make the calibration cost-effective.

ABSTRACT

The term heating, ventilating and air conditioning (HVAC) covers a wide range of equipments. An air conditioning system maintains desired environmental conditions within the zone. In most cases term heating, ventilating and air conditioning (HVAC) systems, a central air supply provides air at the controlled temperature and flow rate for heating or cooling the space. The main objective of this project was to develop an accurate, dynamic and non-linear digital model of an HVAC system using SIMBAD that could be implemented in the MATLAB/Simulink environment [13]. HVAC system models have been implanted in many proprietary and public domain programs. However, our goal was to implement a model in MATLAB/Simulink, a software system and tool box widely used to study dynamic response and control systems. This paper documents the model for the benefit of those interested in studying HVAC control. The model was also verified by comparing its output to the dynamic response of an experimental HVAC system (see [16]for a discussion of the experimental facility). Our point of departure was the SIMBAD toolbox from CSTB Paris, used in the MATLAB/Simulink environment [12].

INTRODUCTION

The SIMBAD toolbox provided many of the components of HVAC systems used in the modeling. The components of the system are modeled using standard Simulink block diagrams and models compiled in C code. The main characteristics of the SIMBAD tool box is the definition of connection vectors. The main two vectors used are :

The air vector : Air dry bulb temperature [C], Air humidity ratio [kg/kg], Static pressure [Pa], Mass flow rate [kg/s]

The water vector : Water temperature [C], Static pressure [Pa], Mass flow rate [kg/s]

SIMBAD is obviously in a state of evolution (and like most software will probably always be in that state). Therefore we developed or modified models to reflect our needs, to consider North American versus European design practice, and to introduce options for multi input multi output control.

MODELING

The literature is quite rich about dynamic modeling of HVAC systems using linear approximation. This research is mainly concerned with the non-linear modeling and simulation of various HVAC components and the overall HVAC system.

Components that are modeled here are : Dynamic heating and cooling coil, Electrically heated boiler, Variable speed pump, Two-way convergent air duct, Outside and return dampers, Three-way mixing valve, Variable speed fan, PI controllers.
The first four component models came from the SIMBAD toolbox. The next three were developed in- house and the PI controller model was taken from the Simulink controls tool kit.

Modeling of heat exchanger
Almost every thermal environmental system involves heating or cooling of the atmospheric air. It forms the part of both water and air cycle. The parameters for our heat exchanger modeled are: 4 pass, 23 run, plate fin and counter flow type heat exchanger. The tube material is copper and the tube core is 0.01 m in diameter. The fins have a pitch of 472/m,are 0.25 mm thick and are made of aluminum. These parameters are by way of example. Any rational set of parameters can be used in the model.

Simulink elements and five programs in "C" language calculate specific variables such as: Geometry,

Exchange coefficients, Pressure calculations, Heat transfer, Temperature (C programs), Pressure (C programs), Humidity ratio (C programs), and Mass flow rates (C programs).

Temperature calculations
This section deals with the calculations of output air temperature. The equations used are :

$$T_{ao} = T_{ai} - Q_s / (C_{pi} * m_a) \qquad (1)$$

T_{ao} = Outlet air temperature (C), T_{ai} = Inlet air temperature (C), Q_s = Sensible heat transfer rate (kW), m_a = Mass flow rate (kg/s).

The sensible heat transfer rate is the heat transfer rate which is solely manifested in raising the temperature of the incoming air.

$$C_{pi} = C_{pa} + C_{pg} * G_i \qquad (2)$$

C_{pi} = Inlet air specific heat capacity (kJ/kg K), C_{pa} = Specific heat capacity of air (kJ/kg K), C_{pg} = Specific heat capacity of steam (kJ/kg K), G_i = Humidity ratio of inlet air (kg/kg).

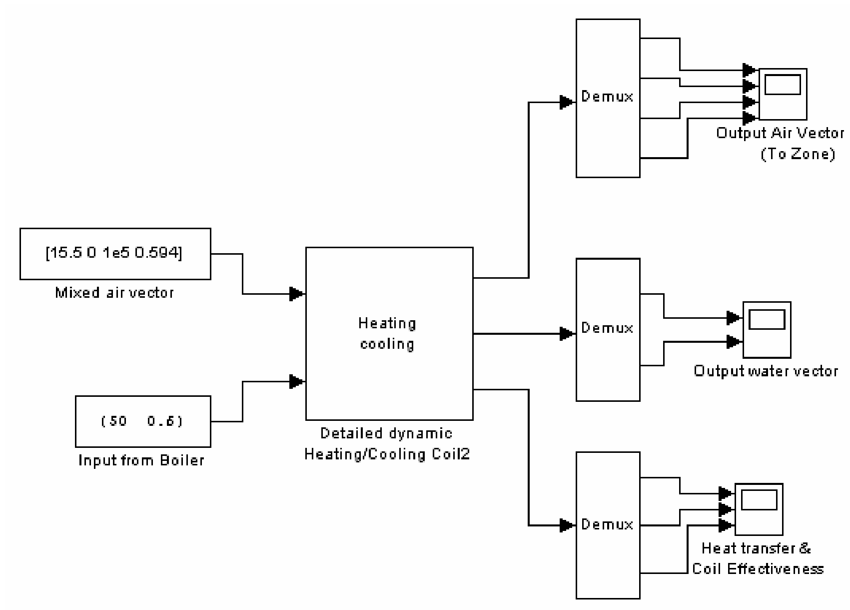

Figure 1 Dynamic model of the heat exchanger

$$Q_s = Q_a * SHR \qquad (3)$$

Q_s = Sensible heat transfer rate (kW), Q_a = Heat transfer rate on air side (kW), SHR = Sensible heat ratio (kg/kg).

$$Q_a = (T_{ai} – T[0]) / R_{st1} \qquad (4)$$

T_{ai} = Inlet air temperature (C), R_{st1} = Air-side thermal resistance (K/kW), T[0] = Initial coil temperature (C), R_{st1} depends on the type of regime, either dry or wet . Here it is assumed to be a dry regime.

$$R_{st1} = B_f * R_{st} \qquad (5)$$

R_{st} = Coil total thermal resistance (K/kW), B_f = By-pass factor for dry coil.

$$R_{st} = 1.0 / [Effect * m_{cp}] \qquad (6)$$

Effect = coil effectiveness, m_{cp} = minimum capacity rate (kW/K)

$$C_{air} = C_{pi} * m_a \qquad (7)$$

C_{air} = Air capacity rate (kW/K), C_{pi} = Inlet air specific heat capacity (kJ/kg.K), m_a = Mass flow rate of air (kg/s).

$$C_{water} = C_{pw} * m_w \qquad (8)$$

C_{water} = Water capacity rate (kW/K), C_{pw} = Water specific heat capacity (kJ/kg.K), m_w = Flow rate of water (kg/s).

Pressure Calculations

Here, we are introducing one independent variable **u,** and another dependent variable, **x** . Both u and x are not used in the model. It is used here to explain the model clearly.

$$AD = (273.16 / (273.16 + T_{ai})) / 1.293 \qquad (9)$$

AD = Air density (kg/m^3), T_{ai} = Inlet air temperature (C).

$$u = (1 / AD) * m_a \qquad (10)$$

$$x = u^2 * \text{Resistance coefficient} \qquad (11)$$

u = Volumetric flow rate (m^3/s), x = Pressure drop (Pa), m_a = mass flow rate of air (kg/s) and the resistance coefficient is an input parameter into the heat exchanger .

$$P_o = P_i - x \qquad (12)$$

P_o = Output pressure (Pa), P_i = Inlet pressure (Pa).

Humidity ratio calculations :
The equation used to calculate humidity ratio is :

$$G_o = G_i - (Q_a - Q_{sensi}) / (HFG * m_a) \qquad (13)$$

G_o = Outlet air humidity ratio (kg/kg), G_i = Inlet air humidity ratio (kg/kg), Q_a= Heat transfer rate on air side (kW), Q_{sensi} = Sensible heat transfer rate (kW), HFG = Latent heat of vaporization of water (kJ/kg), m_a = Mass flow rate of air (kg/s).

Mass flow rate calculations
There is no change in the mass flow rate of air through the heat exchanger. On the water side there are only two variables-temperature and flow rate. As the flow rate remains constant, the only calculation is that of temperature.

$$T_{wo} = T_{wi} + Q_r / C_{water.} \qquad (14)$$

T_{wo} = Water output temperature (C), T_{wi} = Water input temperature (C), Q_r = Heat transfer rate on water side (kW), C_{water} = Water capacity rate (kW/K).

$$Q_r = (T_{ci} - T_{wi}) / R_{st2\,.} \qquad (15)$$

T_{ci} = Initial coil temperature (C), R_{st2} = Water + metal thermal resistance (K/kW), T_{wi} = Water inlet temperature (C).

$$R_{st2} = 0.001 * R_{st} \qquad (16)$$

R_{st} = Total coil thermal resistance (K/kW). The value for R_{st} comes from program header files.

$$C_{water} = C_{pw} * m_w \qquad (17)$$

C_{pw} = Specific heat capacity of water (kJ/kg.K), m_w = Mass flow rate of water (kg/s).

Electrical Boiler
The boiler modeled here is an electric heat boiler. The design of electric boilers is largely determined by the shape and heat release rate of electric heating elements used. The example boiler has a capacity of 14 kilowatts. The heater is controlled through a PI control loop that tracks the set point temperature under transient conditions as illustrated in figure 2. The boiler output water temperature can also be calculated using steady state calculations.

The boiler model has two main sections, the thermal cycle and hydraulic cycle. The thermal cycle model calculates the output temperature of the water and the hydraulic cycle model calculates output pressure depending on the flow rate.

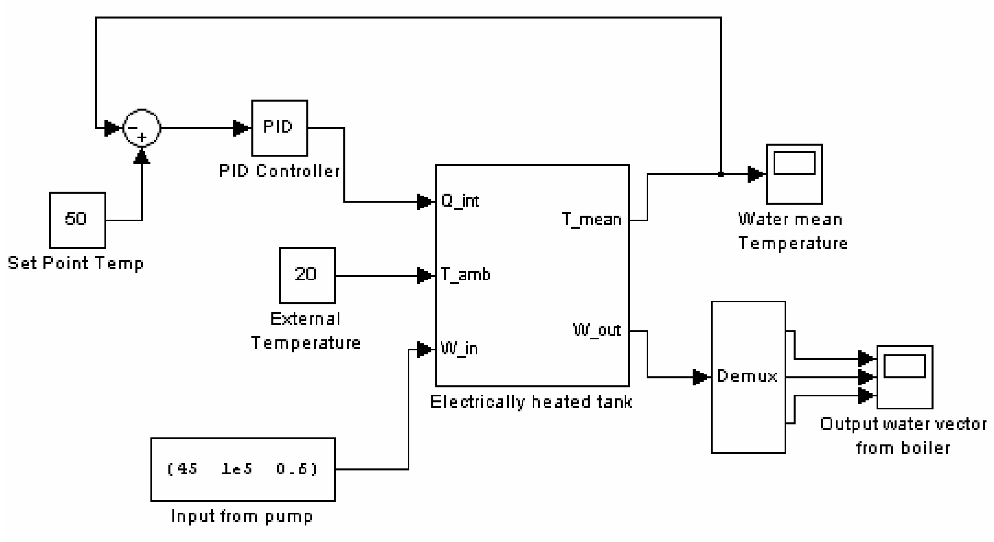

Figure 2 Electrically heated boiler

Thermal Cycle

The inputs to the thermal model are:

Q_{int} = Command from the controller. This entity depends on the required hot water temperature.
W_{in} = Input water vector
T_{amb} = Ambient temperature (C)
The inputs are used to define a column matrix. The matrix will have 3 entities, A, B and U. These three entities will be used to calculate outlet water temperature both in steady state and in transient conditions.

Defining the matrix :

$$A = ((m_{wi} * C_w / MC) + (Ah_{tank} / MC))* \text{Gain} \qquad (18)$$

m_{wi} = Inlet flow rate of water (kg/s), C_w = Specific heat capacity of water (kJ/kg.K) Ah_{tank} = Surface heat exchange product (kW/K), MC = Total thermal mass (kJ/K).

$$MC = mC_p\_water + mC_p\_metal \qquad (19)$$

mCp_water = Total thermal mass of water (kJ/K), mCp_metal = Total thermal mass of metal (kJ/K)

$$mC_p\_water = V\_water * \rho_{water} * C_w \qquad (20)$$

ρ_{water} = Density of water (1000 kg/m^3)
V_water = Volume of water in the boiler (m^3), C_w = Specific heat capacity of water (kJ/kg.K),

$$mC_p\_metal = V\_metal * \rho_{copper} * C_{pm} \qquad (21)$$

V_metal = Volume of metal on the boiler (m^3), C_{pm}= Specific heat capacity of metal (kJ/kg.K), ρ_{copper} = Density of copper (8000 kg/m^3).

As per Simbad, the value of the gain is constant at –1. As shown in the equation, the values of C_w and Ah_{tank} are normalized with MC.
The second element in the matrix is B. It has three entities, B1, B2, B3.

$$B1 = m_{wi} * C_w / MC \qquad (22)$$

$$B2 = Ah_{tank} / MC \qquad (23)$$

$$B3 = 1 / MC \qquad (24)$$

The vector B can be defined as

$$B = [\ B1 \ \ B2 \ \ B3\ ] \qquad (25)$$

The last and final element in the matrix U is also a vector consisting of

$$U = [\ T_{wi}\ T_a\ Q_{int} * P_{nom}] \qquad (26)$$

T_{wi} = Inlet water temperature (C), T_a = Ambient temperature (C), Q_{int} = Controller input, P_{nom} = Total capacity of the coil (14 kW)
Subsequently the matrix will have three outputs: **[A B U].** Here we have considered transient calculations. The matrix defined above forms the input for the transient calculations. For this purpose, we are defining two variables x and y.

Where

$$x = \sum (B * U) \qquad (27)$$

and

$$y = A + x \qquad (28)$$

Now the output water temperature is calculated by the formula

$$T_{wo} = A * \int y \qquad (29)$$

The output water temperature, in the transient calculation is determined by integrating the inlet water temperature, with matrix A, over time, until the set point temperature is attained.

Hydraulic Cycle :
The hydraulic phenomena calculates output pressure depending on the pressure drop during the nominal flow rate of the fluid. In this model we have assumed the pressure drop to be zero.

Pump

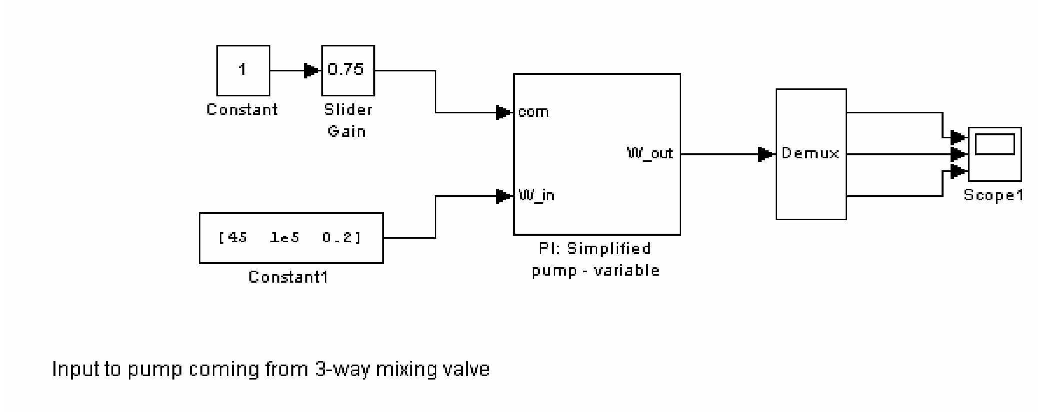

Figure 3 Variable speed pump

One of the main methods for transporting thermal energy into, out of, and within a building is with *water*. The pump inputs the required flow rate into the water circuit. The flow rate from the pump depends on the command input given at the 'com' input port as illustrated in figure 3. The pump speed can be varied to vary the flow rate of the fluid as required up to the maximum flow capacity of the pump.

The equation is given as

$$F_w = Com * \text{Maximum flow rate. (kg/s)} \qquad (30)$$

Maximum flow rate is an input function of the pump.
It is predominantly a linear function. The output water vector will have the same temperature and pressure as the input; only the flow rate will be changed depending on the command.

Two-way convergent air duct
The two-way convergent air duct gives the resultant air vector due to mixing of two air vectors - the fresh air vector from the atmosphere that comes through the outside air damper and the return air vector from the zone coming through the return damper. The flow rates of the two vectors are added and no head loss is considered.

Mixing temperature

$$T_{mix} = (T_{a1} * m_{a1} + T_{a2} * m_{a2}) / (m_{a1} + m_{a2}) \qquad (31)$$

T_{a1} = Temperature of outside air (C), T_{a2} = Temperature of return air (C), m_{a1} = Flow rate of outside air (kg/s), m_{a2} = Flow rate of return (kg/s.

Mixing humidity

$$U_{mix} = (U_1 * m_{a1} + U_3 * m_{a2}) / (m_{a1} + m_{a2}) \qquad (32)$$

U_1 = Humidity ratio of outside air (kg/kg), U_3 = Humidity ratio of return air (kg/kg) m_{a1} = Flow rate of outside air (kg/s), m_{a2} = Flow rate of return air (kg/s)..

Mixing pressure

$$P_{mix} = (P_1 * m_{a1} + P_2 * m_{a2}) / (m_{a1} + m_{a2}) \qquad (33)$$

P_1 = Pressure of outside air (Pa),P_2 = Pressure of return air (Pa), m_{a1} = Flow rate of outside air (kg/s), m_{a2} = Flow rate of outside air (kg/s)

The values of both P1 and P2 are equal at the entrance of the mixing box. The resultant flow rate will be the sum total of both the individual flow rates.

The following components were designed and built in-house. The same components in SIMBAD were not working in accordance with the components in the experimental facility.

Three-way mixing valve

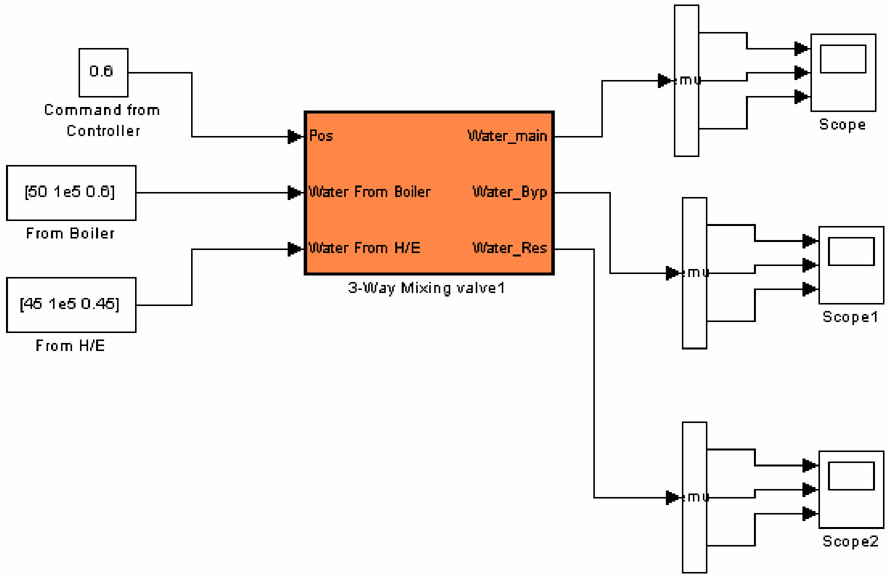

Figure 4 Three way mixing valve

The valve has three inputs and three outputs. The three inputs are: Command signal from the controller depending on the set point temperature, Input port for water coming from boiler, Input port for water retuning from the heat exchanger, The three outputs are: Main water vector going into the heat exchanger, and Water vector going into the bypass circuit.
The resultant water port mixes water vectors from the heat exchanger and bypass circuit. The bypass water vector and the water vector are mixed internally. Thus the bypass port is used for monitoring purposes and it is not connected anywhere in the system.

The valve has three parts:
Flow fraction determination: Depending on the command from the controller, which in turn is determined by the set point temperature, a look up table between the command and flow fraction determines the percentage of total flow going into the heat exchanger. The command from the controller is in effect the percentage opening of the valve.

Flow calculations: The input to this function is the flow fraction in the form of percentage of the total flow going into the heat exchanger. The flow fraction in the by pass circuit is determined by formula::

$$m_{w\ (bypass)} = m_w - m_{w\ (main)} \qquad (34)$$

m_w = Total flow rate of water from the boiler (kg/s), $m_{w\ (main)}$ = Flow rate of water into the main circuit (kg/s), $m_{w\ (bypass)}$ = Flow rate of water into the bypass circuit (kg/s).

Temperature calculations: The main purpose of this block is to calculate the resultant water temperature after mixing between return water and bypass water vectors. Inputs to this block are flow fraction, temperature of water returning from the heat exchanger and temperature of water in the bypass vector. The flow rate of the resultant water vector is the summation of the two water vectors of bypass and return vector from the heat exchanger; no head loss is considered.
The resultant temperature of the water is determined by the relation:

$$T_{res} = (T_{he} * m_{w\_he} + T_{bypass} * m_{w\_bypass}) / (m_{w\_he} + m_{w\_bypass}) \qquad (35)$$

T_{he} = Temperature of water returning from heat exchanger (C), T_{bypass} = Temperature of water in bypass circuit (C), m_{w_he} = Flow rate of water returning from heat exchanger (kg/s), m_{w_bypass} = Flow rate of water in bypass circuit (kg/s)

Actuator

The actuating action required here is linear motion of a piston. Depending on the set-point temperature, the valve regulates the flow of water into the heat exchanger. The actuator modeled here has a transfer function :

$$F(s) = 0.005 / (3s+0.005) \qquad (36)$$

Now the inverse laplace transform of the above transfer function is :

$$f(t) = 1/600 * e^{-1/ 600*t} \qquad (37)$$

From the equation the time constant of the actuator is τ = 600 s. The time constant indicates that the response decays exponentially every 600 seconds.

Dampers :

Dampers are used for the control of airflow to maintain temperature and/or pressure. An important entity in the design of dampers is the dimensionless entity loss coefficient, C_d. Over most of the operating range, the loss coefficient is an exponential function of blade angle for both parallel and opposed blade dampers. That is,

$$C_d=k_1.e^{k2.\theta} \qquad (38)$$

Where k1 and k2 are constants, and θ is the blade angle in degrees.
Now the fraction of full flow is calculated by using the formula

$$\text{Fraction of full flow} = \sqrt{\frac{C_{do}}{f\ .\ C_d + (1-f).\ C_{do}}} \qquad (39)$$

C_{do} = loss coefficient for the wide-open damper, C_d = loss coefficient, a function of blade angle, f = open damper resistance as a fraction of the total system resistance

The values of C_{do} and f are obtained from ASHRAE fundamentals (1997). Since return and outside dampers are used in tandem, one control loop is used to control both dampers depending on the set point temperature.

Actuator :

The main task of the actuator in a damper is to precisely open or close the damper blades depending on the command from the controller. Since the action required is circular motion of the damper blades, the actuator modeled here is a motor having the transfer function,

$$F(s) = 5 / (3s+5) \qquad (40)$$

Now the inverse laplace transform of the above transfer function is :

$$f(t) = 5/3 * e^{-5/3t} \qquad (41)$$

From the equation the time constant of the actuator is $\tau = 0.6$ s. This time constant indicates that the response decays exponentially every 0.6 seconds.

Variable speed fan

The fan modeled here has one input and two outputs. The input to the fan is the air vector coming from the heat exchanger . The outputs are: Air vector going into the zone and the total power imparted by the fan on the air.

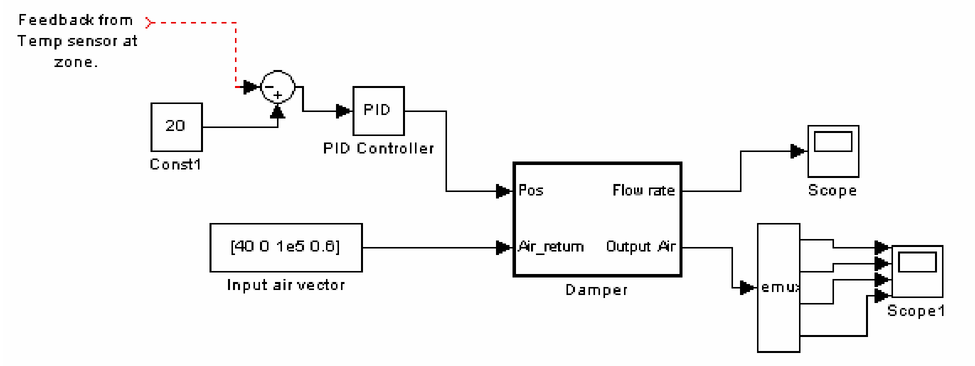

Figure 5 Damper

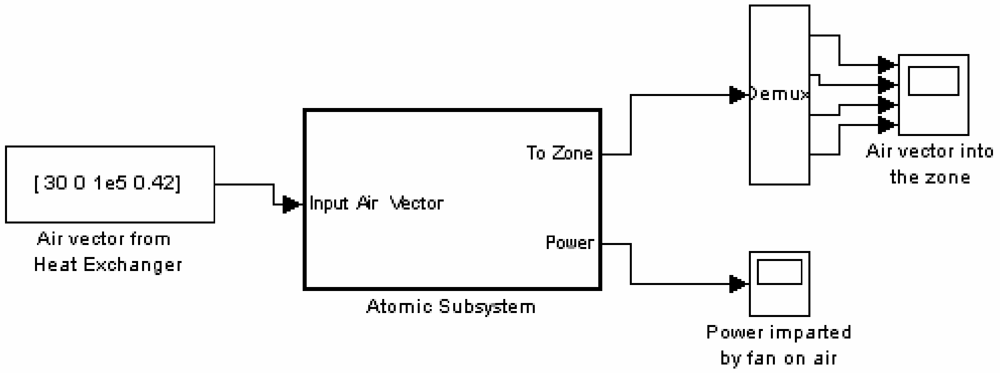

Fig 6 Variable speed fan

The fan model has two lookup tables : The relationship between volume flow and pressure loss and the relationship between volume flow and RPM. Depending on the mass flow rate of the input air vector the volume flow rate is calculated by:

$$Q = m_a / \rho \qquad (42)$$

Q = Volume flow rate (m^3/s), m_a = mass flow rate (kg/s), ρ = Density of the air (kg/m^3)

The volume flow rate thus obtained will be used to get the RPM from the second lookup table and the pressure loss from the first lookup table.
The inertial effects of the fan impeller are calculated to make the model dynamically more accurate. The value of the RPM from the lookup is used to calculate the angular velocity (radians/s).

$$\theta' = RPM * 2 * \pi / 60 \qquad (43)$$

The angular acceleration is:

$$\theta'' = \theta' / t. \qquad (radian/s^2), \text{ with t=time constant taken as 10 s} \qquad (44)$$

Now the total energy imparted by the fan to the air is given by:

$$W = Q*(P1-P2) + m * \theta'' + c * \theta' \qquad (45)$$

W = Total energy imparted by the fan on air (kW), Q = Volume flow rate (m^3/s), P1 = Set point pressure in the zone (Pa), P2 = Pressure coming into the zone after all losses (Pa), m = Mass of the fan impeller (kg), c = Coefficient of bearing friction, θ” = Angular acceleration (m/s^2), θ’ = Angular velocity (m/s)

Speed change time constant
The action required here is to change the circular motion of the fan impeller. Depending on the set-point temperature the fan regulates the volume of air flow into the zone. The motor has a transfer function:

$$F(s) = 1 / (10s+1) \qquad (46)$$

Now the inverse laplace transform of the above transfer function is :

$$f(t) = 1/10 * e^{-1/10t} \qquad (47)$$

From the equation the time constant of the actuator is τ = 10 s.
The time constant indicates that the response decays exponentially every 10 seconds

RESULTS

Steady State

The following table gives simulation test results for steady state testing.

Twi	Two	Ts	Tai	Tao	m_w	m_a	Q_a	Q_w	EB
(C)	(C)	(C)	(C)	(C)	(kg/s)	(kg/s)	(kW)	(kW)	
55	13.86	18	10.96	17.99	0.0298	0.7191	5.086	5.058	0.027
55	27.39	25	13.46	25.12	0.0829	0.8197	9.624	9.571	0.053
55	35.76	30	20.96	30.04	0.1569	0.1.38	12.66	12.62	0.03
55	38.41	35	25.37	35.00	0.2185	1.5662	15.18	15.15	0.030
55	42.27	40	30.09	39.99	0.2851	1.5249	15.2	15.17	0.031
55	46.491	45	35.97	45.00	0.3543	1.3898	12.63	12.61	0.027

Steady state energy balances were calculated using EES Software.

Dynamic testing :

Dynamic tests were performed with step changes given to a set point temperature. The temperature set point was changed from 40 ^{0}C to 50 ^{0}C .

The following graphs show the comparison between experimental data and the simulation data. In all the cases the temperature set points were 40^{0}C (initial value) and 50^{0}C (final value).

CONCLUSIONS

The primary objective of this project was to develop a Simulink model of an HVAC system to allow simulation in a software environment that will allow the study of intelligent control systems –MATLAB/Simulink are the preferred tools for studying dynamic response and control. This paper documents the models.

A second objective, achieved and reported here was the experimental verification of the models. Agreement is good. This builds confidence that users can apply the model to study control problems. The “code” is available upon request – first visit our web site at http://www.engr.colostate.edu/nnhvac/.

SUMMARY

The importance of Life Cycle Energy Management (LCEM) has been recognized from the view of life cycle energy saving of sustainable buildings. The purposes of this research are proposal of an LCEM framework and development of a prototype of HVAC system simulation tools for LCEM. In this paper, necessity of energy simulation tools for LCEM is discussed, and the outline and solution method of the simulation tool are shown. In addition, method of system integration using the developed tool and details of component models that comprise HVAC systems are shown.

INTRODUCTION

Everyone can easily recognize the importance of the maintenance and operation phase that consume much energy when sustainable construction is considered from the viewpoint of countermeasures against global warming. Proper management is indispensable, however, in the life cycle from the planning and design phase to the operation phase of the facility itself to realize truly appropriate maintenance.

This study is conducted to establish the concept of the basic framework of life cycle energy management (LCEM) and develop an energy simulation tool for required air-conditioning systems (hereinafter referred to as "air-conditioning system simulation tool"). This paper describes the framework of the LCEM tool, necessity of the air-conditioning system simulation tool, and the outline of the tool. In addition, it describes changing equipment characteristics into mathematical formulae, verification of mathematical formula precision, and concrete simulation tool.

LCEM EXAMINATION COMMITTEE

The LCEM Examination Committee (Chairman: Shuzo Murakami (Keio University)) was organized under the Public Buildings Association, Japan to establish the concept of the basic framework of LCEM and develop an energy simulation tool for air-conditioning systems in

2003. In this section, we summarize some achievements[1)2)] of the LCEM Examination Committee.
The LCEM Examination Committee consists of one study group and four working groups. The study group manages and adjusts the whole committee, and the working groups are in charge of the following work:

(1) Equipment Performance Survey Working Group: This group surveys the characteristics of the air-conditioning equipment and creates experimental formulae.
(2) Air-Conditioning Simulation Tool Development Working Group: This group develops the entire tool including equipment.
(3) Case Study Working Group: This group indicates concrete manner of utilization in each phase from the planning phase to the operation phase.
(4) Input Condition Setting Working Group: This group organizes and offers the thermal load conditions required for the tool.

This organization is managed through cooperation by the Land, Infrastructure and Transportation Ministry, academic experts, energy companies, consultants, construction companies, etc. The completed tool is distributed for free through the Land, Infrastructure and Transportation Ministry in principle. Distribution of the prototype tool was started for the first time in July 2006.

CURRENT SITUATION OF ENERGY MANAGEMENT

Energy management is performed mainly for the operation phase currently, but the following unsolved problems remain:

(1) Inefficient operation is performed daily using excessive equipment unsuitable for the actual status of operation in many cases.
(2) In equipment manufacturing and trial operation, it is checked mainly whether the rated specifications are satisfied. The performance in the off-peak period and the energy-saving performance throughout all periods are not checked.
(3) Operation is continued while the design intent and construction intent are not reflected in many cases.

It is estimated that the above problems are caused because the setting of energy-saving targets throughout the life cycle, corresponding control indicators, check methods, etc. are not made clear.

NECESSITY OF LCEM AND SIMULATION TOOL IN LCEM

Consistent energy management from the planning phase to the operation phase is indispensable to solve various problems related to energy management described above. And it is important to develop an energy simulation tool to achieve appropriate LCEM. It should macroscopically predict and evaluate the energy performance of the air-conditioning system, be able to grasp defects of the air-conditioning system with a rough sieve, and be easily handled by workers including operators in each phase in the life cycle. The following three points are regarded as important especially from the viewpoint of LCEM:

(1) The user can easily handle the tool, understand the contents, and modify and expand the contents.

(2) The table calculation method is simple, and calculation processes are not black box in most cases.
(3) The tool can calculate status values in the partially loaded status, and the user can understand the annual and periodical performance of each equipment/sub system.

SOLUTION USING OBJECT CELLS METHOD

The developed tool emphasizes practical utility. Accordingly, most equipment characteristics consist of experimental formulae to facilitate comparison and collating with actual equipment. The user can manipulate the GUI (graphical user interface) using only the basic functions of general-purpose spreadsheet software, and obtain the equilibrium state among equipment using the "repeated calculation" function.
The general-purpose spreadsheet software "Excel" is used for creation and solution of these programs. Macro programs are to be used only in annual calculation in principle.

The developed tool obtains the operation status values of the air-conditioning system using a solution called object cells method.

Table calculation is generally performed while mathematical formulae and numbers are input to cells on the sheet as shown on the left in Figure.1. In this technique, mathematical formulae constructing an equipment model are input to two or more cells as shown on the right in Figure1, and such cell group is handled as one piece of equipment (that is, object).

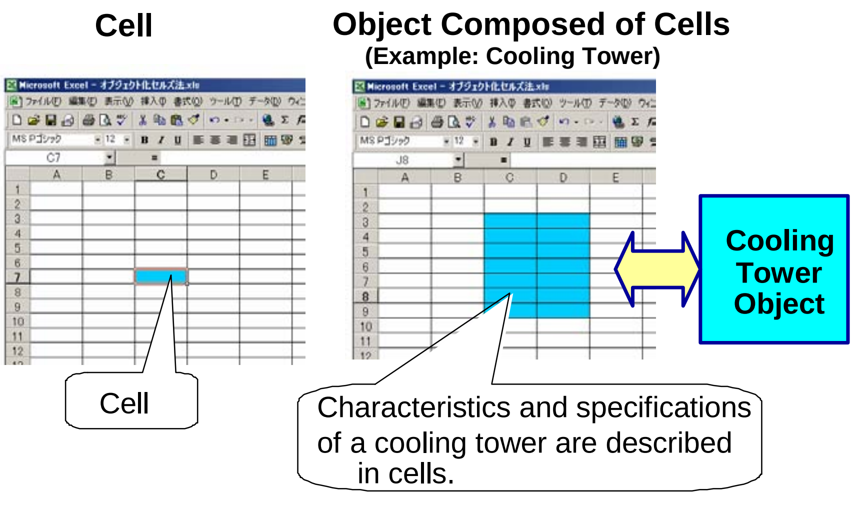

Figure 1 Cell and object consisting of cell group

CONSTRUCTION OF LCEM AIR-CONDITIONING SYSTEM

At first, prepare required objects in the object menu shown on the upper left in Figure 2. Next, "select", "copy" and "paste" required objects using the Excel functions to construct the air-conditioning system. As soon as required objects are pasted, the tool starts calculation among the objects. They are graphical operations. This form of individual, distributed, and mutual calculation without using the main program is regarded as object-oriented programming using the GUI.

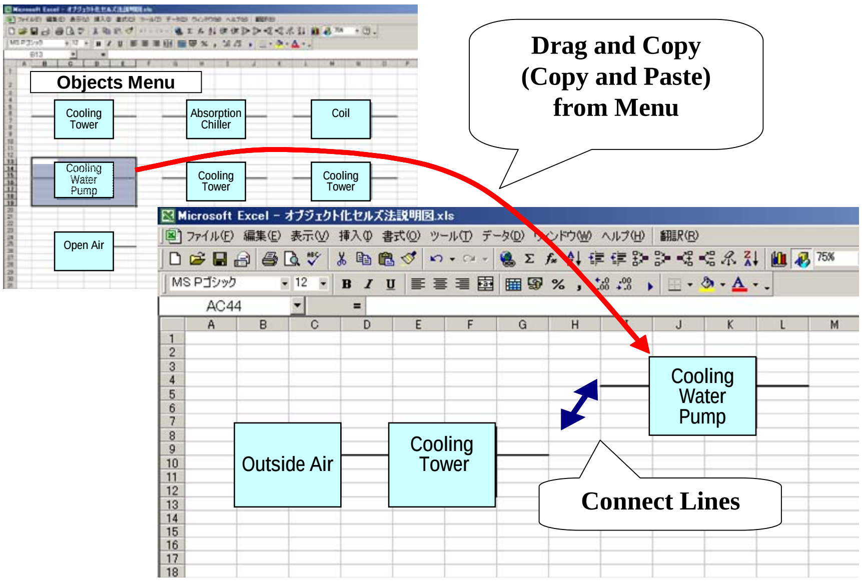

Figure 2 Object menu and system construction method

Figure 3 shows an example of objects. An object is composed of “Communication section”, “Control section”, “Method section” and “Property section”.

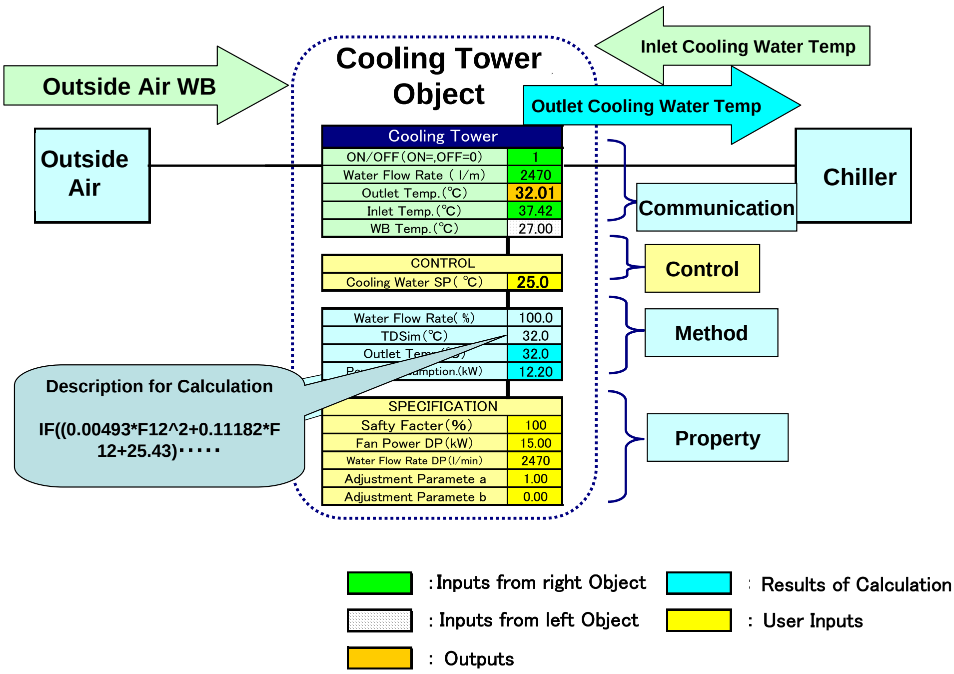

Figure 3 Example of object (Cooling Tower Object)

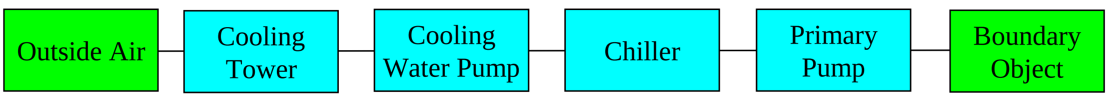

Figure 4 System construction example

Figure 4 shows a heat source subsystem where the outside air object, cooling tower object, cooling water pump object, chiller object and chilled water pump object are connected in the same way. When the outside air wet-bulb temperature and the temperature and flow rate of chilled water are given as the boundary conditions, the tool simulates the sub system.

In the case of Figure 3, the cooling water supply temperature and the cooling water return temperature are cross-referenced to each other by each cell in the table calculation. These items perform circular reference to each other, and can cause an error. However, the tool allows circular reference and offers convergent solution by repeated calculation when the user selects “Tools” -> “Options” -> “Calculation Method” in table calculation, and turns ON the “Repeated calculation” check box shown in Figure 5.

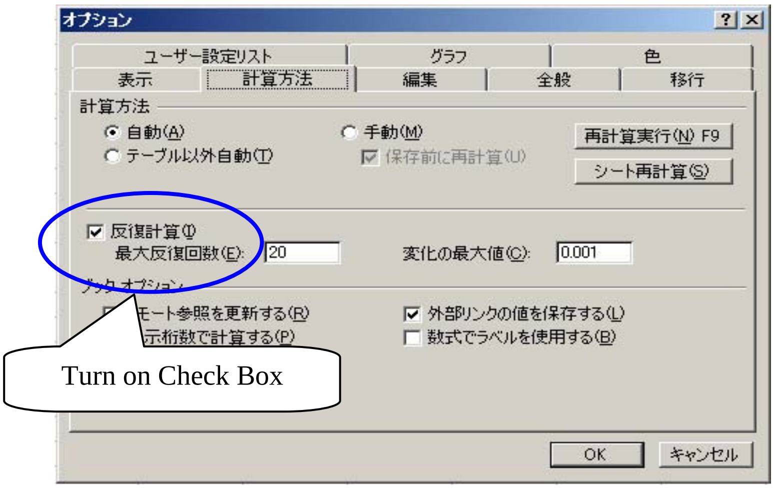

Figure 5 Circular reference and repeated calculation

All the user has to do is to connect objects when constructing a system using the object cells method. As a result, the user can easily create a large system.

DEVELOPMENT OF OBJECTS

In this section, details of some objects are described. The characteristics of the object can be changed by replacing the mathematical formulae in the objects.

Cooling tower object

Convergent calculation is required generally for the cooling tower. The developed tool, however, obtains the cooling water supply temperature T_d using an assembly of coefficients shown in quadratic expressions. The cooling tower consists of the parameters (1) to (3) below indicating the cooling performance and the parameters (4) and (5) related to operation.

(1) Cooling water return temperature (temperature of the cooling water flowing into the cooling tower)
(2) Cooling water volume
(3) Outside air wet-bulb temperature
(4) Cooling water temperature set value
(5) Cooling tower margin coefficient

In the model, the cooling water supply temperature is obtained from the experimental formula below:

$$T_d = T_{ds} \times C_2 \times C_3 \times C_4 \qquad (1)$$

$$T_{ds} = a_1 WB^2 + b_1 WB + c_1$$
$$C_2 = a_2 T_{dr}{}^2 + b_2 T_{dr} + c_2$$
$$C_3 = 1 - (1 - C_4)\frac{T_{dr} - WB}{27 - a_3}$$
$$C_4 = a_4 V_d{}^2 + b_4 V_d + c_4$$

where T_{ds} is the function of outside air wet-bulb temperature, T_{dr} is the cooling water return temperature, C_2 is the cooling water return temperature influence coefficient, C_3 is the cooling water volume influence coefficient and C_4 is the cooling water volume influence coefficient.

The cooling tower fan power ratio C_{tPW} is obtained from the formula below:

$$C_{tPW} = \frac{T_{dr} - T_{dset}}{T_{dr} - T_d} \qquad (2)$$

where T_{dset} is the set temperature when the fan is forcibly stopped, and T_d is the cooling water supply temperature in the free cooling status. Simple linear approximation is adopted here.

Figure 3 shows the cooling tower object.
The cooling tower object is located inside the dotted line frame in the center, and outside air object and cooling water pump object are connected on the both sides.
The cooling tower object is divided into the communication part, control part, method (calculation) part and property part from the top.

(1) In the communication part, the tool receives data from and sends data to adjacent objects. The user can easily create a large system only by considering connection to adjacent objects because communication is allowed only with adjacent objects.
(2) In the control part, the user determines the control condition.
In the cooling tower, the user sets the cooling water supply temperature.
(3) In the method (calculation) part, the equipment characteristics formula is written. The tool calculates the cooling water supply temperature and fan electric power using the communication, control and property data, and then displays the calculation result in the communication part.
(4) In the property part at the bottom, the user inputs the rated specification of the equipment and correction coefficients for easily correcting the characteristics formula.

Gas adsorption chiller/heater object

The object includes examination of cooling water fluctuating volume control and chilled water fluctuating volume control that are adopted recently, and offers models handling five influence coefficients - cooling water temperature, chilled water temperature, chiller load factor, cooling water volume and chilled water volume.
Products having the same characteristics are generalized. The gas consumption G_{ref} is calculated by multiplying the gas consumption ratio g_{ref} by the rated gas consumption G_{ref_r} as shown in the formula below:

$$G_{ref} = g_{ref} \times G_{ref\_r} \qquad (3)$$

The gas consumption ratio g_{ref} consists of five parameters, "C_1: Load factor q", "C_2: Cooling water return temperature T_d", "C_3: Cooling water volume ratio v_d", "C_4: Chilled water supply temperature T_c" and "C_5: Chilled water volume ratio v_c". Each parameter is 1.0 and g_{ref} is 1.0 at rating.

$$g_{ref} = C_1 \times C_2 \times C_3 \times C_4 \times C_5 \qquad (4)$$

$$C_1 = a_1 q^2 + b_1 q + c_1$$
$$C_2 = a_2 T_d^2 + b_2 T_d + c_2$$
$$C_3 = a_3 v_d^3 + b_3 v_d^2 + c_3 v_d + d_3$$
$$C_4 = a_4 T_c^2 + b_4 T_c + c_4$$
$$C_5 = a_5 v_c^2 + b_5 v_c + c_5$$

The cooling water return temperature T_{dr} is obtained analytically as shown in the formula (5) based on the fact that the exhaust heat increases or decreases in accordance with the ratio of the coefficient of performance at partial load and at rating $C_7 = COP/COP\text{-}r$. Here, T_d is the cooling water supply temperature, and V_d is the cooling water volume.

$$G_{ref} = C_6 \times C_7 \times V_d \times (T_{dr} - T_d)$$
$$T_{dr} = G_{ref} / (C_6 \times C_7 \times V_d) + T_d \qquad (5)$$

C_6: Correlation coefficient of cooling water heat quantity and gas heat quantity
C_7: Ratio of coefficient of performance at partial load and at rating

OBJECT VERIFICATION

We have verified the validity of the precision of calculation models using the air-conditioning operation data in an office building. We have confirmed that the calculation model has sufficient precision in any object in energy performance evaluation.

Cooling tower object

Figure 6 shows the calculated cooling water supply temperature in the X axis, and the measured cooling water supply temperature in the Y axis for comparison. Calculated values basically agree with measured values even if the input conditions change.

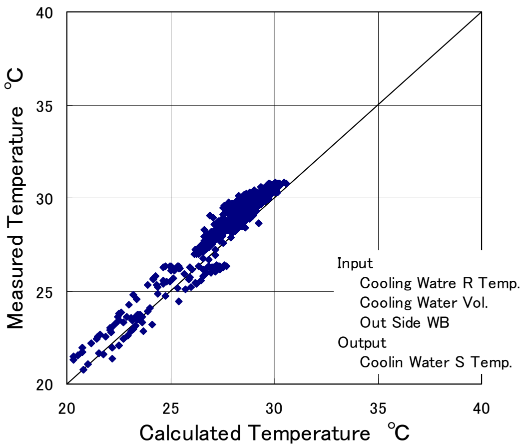

Figure 6 Cooling water supply temperature verification result

Gas adsorption chiller/heater object

Figure 7 shows the gas consumption in the chiller in the same way as the cooling tower, and Figure 8 shows the cooling water exit temperature (cooling water return temperature) from the chiller. Calculated values agree well with measured values, and the precision is sufficient in practical use.

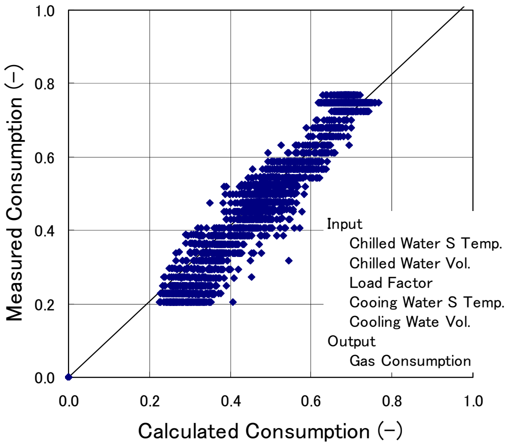

Figure 7 Gas specific-consumption verification result

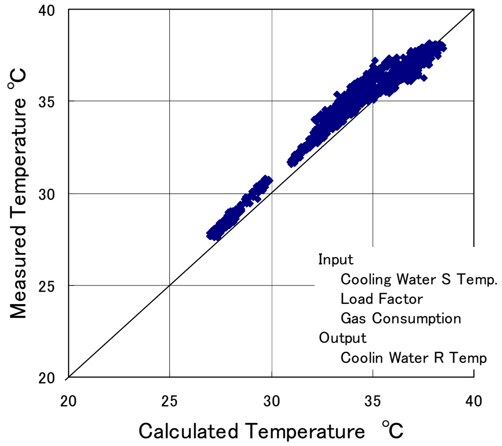

Figure 8 Cooling water return temperature verification result

CONCLUSION

We have developed an air-conditioning simulation tool that adopts the object cells method, is easily handled, and is available in every phase from planning to operation for application to life cycle energy management.

This paper indicates incorporated mathematical formulae for equipment characteristics, and verifies that the tool offers sufficient precision in energy management.

ACKNOWLEDGEMENT

We would like to thank the members of the committee for this work.

SUMMARY

To properly evaluate the performance of ventilation system, the interaction among ventilation rate, indoor air-quality, and cooling/heating load should be analyzed. In this study, an integrated simulation tool based on TRNSYS will be suggested to analyze the performance of ventilation system. Some modules to calculate the changes in indoor concentration of pollutants with ventilation system and to decide the operation mode of ventilation system were newly developed. In addition, the developed modules were coupled with building load and heating/cooling simulation modules. To verify the developed integrated simulation tool, the comparison study between simulation and field study were accomplished. The simulation tool developed in this study can be used to predict the performance of ventilation system with high accuracy.

INTRODUCTION

Utilization of both healthy construction materials that produce less contaminants and ventilation system are essential to maintain the indoor air quality. Furthermore, when a ventilation system operates to improve the indoor air quality of a residential building, heating and cooling load should also be solved at the same time.

In order to comprehensively evaluate the performance of a ventilation system, experiment and field measurement over a long period of time are required. However, due to time and cost restrictions, simulation is generally used to analyze a ventilation system with heating and cooling loads.

Simulation tools are often used for assessing indoor air quality according to ventilation as well as calculating the heating/cooling load, which can be categorized both CFD and network simulations.

(1) The CFD simulation(1) is widely used due to its capability of describing in detail the generation and diffusion of contaminants from construction materials for a unit space. However, it has severe restriction for portraying reduction and discharge characteristics of contaminants over a long period of time or movement of contaminants between rooms.

(2) Conventional network simulation tools(2,3) generally focus on the movement of contaminants between rooms and changes in contaminant concentrations according to ventilation (e.g. CONTAMW, COMIS), or characteristic analysis of the building and heating/cooling loads separately (e.g. TRNSYS)(4). Therefore, conventional network simulation tools alone have a limitation in comprehensively portraying the correlated performances of ventilation system.

This study aims at developing an integrated simulation tool capable of comprehensively simulating the indoor air pollutant level, operation of the ventilation system for controlling the contaminant concentration, changes in the indoor contaminant concentration according to ventilation rate, as well as changes in the indoor thermal environment and heating/cooling load.
In this paper, the concept of the integrated simulation tool proposed in the study will be described, and the simulation tool will be validated with comparison between simulation and field measurements results. Moreover, the indoor air-quality control characteristics and heating/cooling load characteristics of ventilation system with various control logics will be discussed using the proposed integrated simulation tool.

CONCEPT OF THE INTEGRATED SIMULATION TOOL

Building, heating and cooling load simulation-TRNSYS

The integrated performance evaluation tool for ventilation system developed by this study is based on the TRNSYS(TRansient System Simulation) capable of dynamic simulations. TRNSYS was developed in 1975 by the Solar Energy Laboratory at the University of Wisconsin in the U.S. to analyze the solar energy collector, and it is currently being used in Europe as well as other parts of the world. Based on its modular structure and outstanding expandability, TRNSYS allows the user to create the mathematical modules based on the derivation from experiments or theories. Furthermore, the source codes of the basic modules are made available and can be modified so that the interaction among the system elements can be simulated in detail according to the purposes.

Development of simulation modules for describing indoor contaminant generation and contaminant removal characteristics of ventilation system

Since the basic TRNSYS does not offer the modules to simulate the changes in indoor air quality and changes in heating/cooling load according to the ventilation rate and indoor air sterilization methods(ventilation, air-cleaning), some new modules were developed to simulate the generation of a contaminant from construction materials as well as the changes in CO_2 concentration.
Indoor air quality methods can be classified as source control, removal control and dilution control. The source control means the controlling the amount of contaminant emission from the construction material. Removal control corresponds to the elimination of the contaminant in the air with air cleaning unit, and dilution control alleviates the contaminant concentration through ventilation. The developed modules can describe all the three indoor air control methods. Table 2 shows the indoor air control method adopted in this study.

Table 2 IAQ control method

mode	control method
VM1	mechanical ventilation only
VM2	mechanical ventilation with air cleaning unit
VM3	air cleaning only

CO_2 and HCHO(formaldehyde) were selected as control subjects under the considerations of the current indoor air quality regulations in Korea.

Prediction of the indoor contaminant concentration under the initial condition

In order to determine the initial concentration of the indoor pollutant prior to operation IAQ control system, contaminant generation from the construction materials or the persons in the room with the passage of time and the dilution effect due to infiltration should be considered[5,6].

Equation 1 is used for predicting the amount of CO_2 generated indoors.

$$C_{cp} = \{(C_{cf} + SC \times C_{c1}) \div VOL_z \times 10^6) \times (VOL_z - VOL_{\inf}) + C_{cout} \times VOL_{\inf}\} \div VOL_z , \qquad (1)$$

where C_{cp} : CO_2 concentration at time-step prior to ventilation, C_{cf} : CO_2 concentration at former time step prior to ventilation, C_{c1} : CO_2 emission per person, C_{cout} : CO_2 concentration in outdoor condition, S_C : presence schedule of dweller, VOL_z : air volume of the analyzed room, VOL_{inf} : air-volume induced by infiltration

Equation 2 is used for predicting HCHO concentration at each time step.

$$C_{hp} = \{(C_{hf} + S_h) \times (VOL_z - VOL_{\inf}) + C_{hout} \times VOL_{\inf}\} \div VOL_z , \qquad (2)$$

where C_{hp} : HCHO concentration at time-step prior to ventilation, C_{hf} : HCHO concentration at former time step prior to ventilation, S_h : HCHO emission at time step, C_{hout} : HCHO concentration in outdoor condition, VOL_z : air volume of the analyzed room, VOL_{inf} : air-volume induced by infiltration

Prediction of indoor contaminant elimination with ventilation mode

(1) IAQ control mode : ventilation(VM 1)

Indoor concentration levels of CO_2 and HCHO after turning on the ventilation unit can be calculated based on the assessment of the contaminant concentration before ventilation (Equation (1) and (2)) and after ventilation (Equations (3) and (4)).

$$C_{cv} = C_{cp} \times (1 - ACH_{vm}) + C_{cout} \times ACH_{vm} , \qquad (3)$$

$$C_{hv} = C_{hp} \times (1 - ACH_{vm}) + C_{hout} \times ACH_{vm} , \qquad (4)$$

where C_{cv}: CO_2 concentration after ventilation, C_{cp} : CO_2 concentration prior to ventilation, HCHO concentration at per time-step prior to ventilation, C_{cout} : CO_2 concentration in outdoor condition, C_{hv} : HCHO concentration after ventilation, C_{hp} : HCHO concentration prior to ventilation, C_{hout} : HCHO concentration in outdoor condition, ACH_{vm} : air-volume induced by ventilation system

Figure 1 shows the logic of the indoor air control module for ventilation mode proposed by this study. The operations algorithm is designed to turn on the ventilation system when either of the two contaminants (CO_2, HCHO) concentration exceeds the existing permissible level in Korea.

Since the air volume of outside air induced by ventilation system varies according to the operation mode and signal, it is reflected in ACH_{vm} of equations (3) and (4). Therefore, if the signal of the ventilation unit is off, the value of ACH_{vm} becomes 0. Moreover, the air volume of outside air introduced by infiltration or ventilation for each time-step can be reflected in ACH_{vm}. The signal of the ventilation system consists of high and low, night and off modes.

(2) IAQ control mode : ventilation + air cleaning (VM 2)

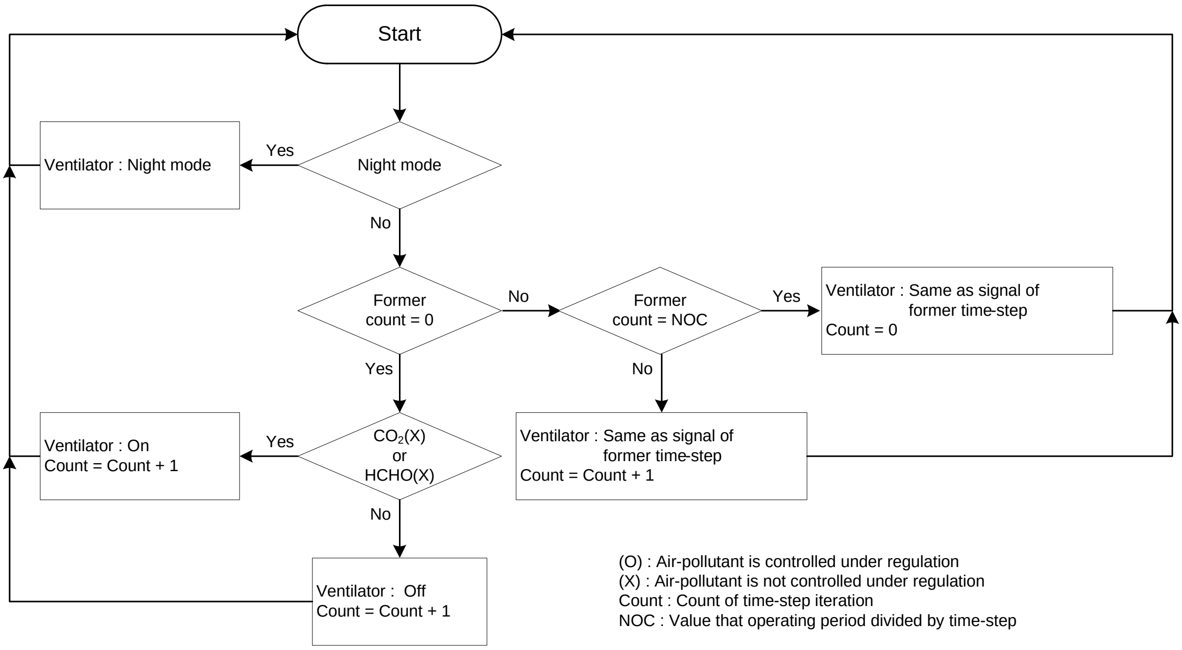

Fig. 1 Operation algorism of indoor air control (VM1, mechanical ventilation only)

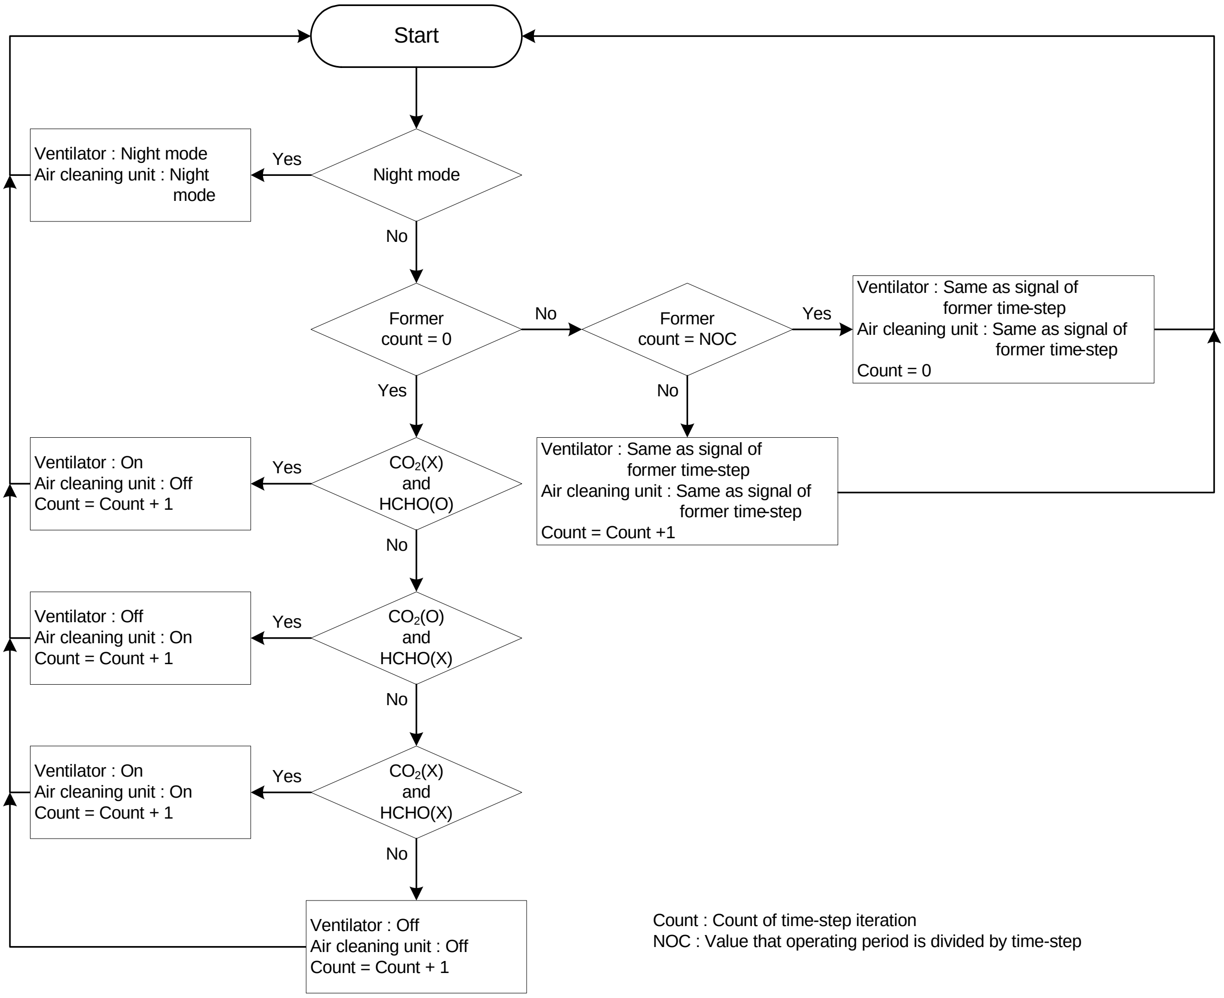

Fig. 2 Operation algorism of indoor air control (VM2, mechanical ventilation + air cleaning)

Figure 2 shows the algorithm for determining the operation signals of the ventilation and air-cleaning units. In this mode, two operation modes are operated independently or simultaneously. When HCHO concentration of the indoor air is below the permissible level and CO_2 concentration level is above the permissible level, the ventilation system will be operated. Conversely, if CO_2 level is below the permissible level and HCHO is above the permissible level, only the air-cleaning unit will be operated. If both CO_2 and HCHO concentration levels exceed the permissible level, both the ventilation and air-cleaning units will be activated.
The CO_2 concentration after the ventilation or air-cleaning unit activates can be expressed as Equation (3) and the change of HCHO concentration level can be defined as Equation (5).

$$C_{hv} = \{C_{hp} \times (1 - ACH_{vm}) + C_{hout} \times ACH_{vm}\} \times \left((1 - \eta_c) \times \frac{CHM_{fm}}{VOL_z} \right), \qquad (5)$$

where C_{hv} : HCHO concentration after ventilation, C_{hp} : HCHO concentration prior to ventilation, C_{hout} : HCHO concentration in outdoor condition, ACH_{vm} : air-volume induced by ventilation system, η_c : filtering efficiency of air-cleaning unit within one time circulation

HCHO is diluted when the ventilation unit is operating, and removed in case of an air-cleaning unit is operated. Consequently when the ventilation unit is off, the HCHO concentration will be controlled by the air-cleaning unit. In other words, when only the air-cleaning unit is operating, it does not affect the indoor CO_2 concentration.
The removal efficiency of the filter to evaluate the contaminant removal performance of the air- cleaning unit is generally defined as the ratio of contaminant concentrations in the initial generation state to contaminant concentration level in certain period after the generation stops and the air-cleaning unit operates[7]. However, contaminants are constantly generated indoors in an actual condition, and the contaminants are removed continuously when the air-cleaner is operating. Hence the concept of one-pass removal efficiency is often used in numerical simulation. One-pass removal efficiency is the ratio of the difference between the inflow gas concentration (S1) and outflow gas concentration (S2) divided by the inflow gas concentration (S1) as shown in Fig. 3.

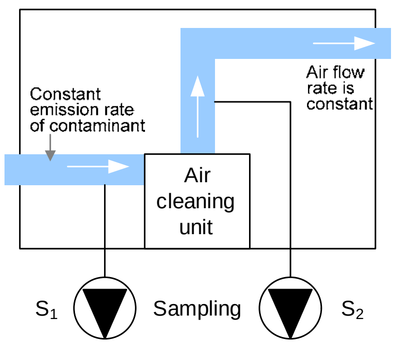

Fig. 3 Schematic of one-pass removal efficiency of air cleaning unit

(3) IAQ control method：Air-Cleaning(VM 3)
When only the air-cleaning unit is operated, the ventilation unit signal is turned off and the control algorism of VM3 is identical to the VM2 except for fixing the airflow of the ventilation unit (ACH_{vm}) at 0.

Validation

In order to examine the validity of the developed simulation modules for predicting the contaminant removal characteristics of IAQ control system, the comparison analysis between the field measurement of the ventilation system and the prediction with the developed module were accomplished. Based on the results of comparison study, the logics of the developed module were modified.

(1) Field measurement

The ventilation system was installed in an actual multi-residential house to practice performance evaluation field tests. The analyzed house was newly built and elapsed 3 month after the completion. No one was occupied in the analyzed house at that time. As shown in Fig. 4, the analyzed space is limited as living room, kitchen and dinning room. And all the exits to adjoining rooms were sealed off to eliminate air flow. A ventilation system with a rated capacity shown in Table 3 was installed under the ceiling of the living room. After activating each operation mode of the ventilation system such as VM1(ventilation), VM2(ventilation+air-cleaning), VM3(air-cleaning only), the changes in indoor contaminant concentration was measured according to the standard test method for indoor air-quality suggested by MOE (Ministry of Environment Republic of Korea). HCHO emission rate was measured two times every day. First measurement was conducted 30 minutes prior to operation of ventilation system and 30 minutes after quitting the ventilation system. The measurement condition and results are shown in Table 4, Table 5, respectively.

Fig. 4 Analyzed house

Table 3 Air-flow rate of ventilation system

Ventilator	Air cleaning unit
70[CMH]	180[CMH]

*One-pass removal efficiency of air cleaning unit is set at 0.35(35%).

Table 4 Measurement conditions

Outdoor condition	Dry B. Tem. : 10～15℃, Relative Humi. : 22～36%
Indoor condition	Dry B. Tem. : 25℃, Relative Humi. : 30%
Infiltration rate	0.2[ACH]
Outdoor concentration	HCHO : 0.036[mg/m^3], CO_2 : 350[PPM]

Operation mode	Concentration(HCHO) Before operating(Base concentration) [mg/m^3]	Concentration(HCHO) After operating [mg/m^3]
Ventilator only	0.236	0.083
Ventilator and air cleaning unit	0.224	0.062
Air cleaning unit	0.367	0.113
Indoor emission rate of HCHO	0.00812[mg/hr・m^3]	

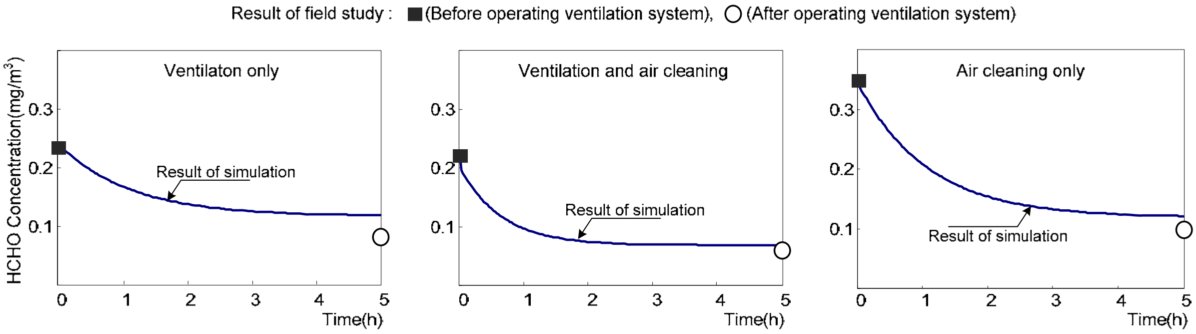

Fig. 5 Comparison between field measurement results and simulation results

(2) Validation of simulation modules

The comparison simulation for evaluating the validity of developed simulation modules were accomplished based on the field measurement conditions and results.

Figure 5 displays the results of the field measurement and numerical simulation. As shown in Fig. 5, the simulation results have a good agreement with the measurement results for the the ventilation+air-cleaning and air-cleaning mode. Meanwhile, in case of ventilation only mode, both results are somewhat different, however, the difference can be regarded as insignificant when the field measurement errors are considered.

In order to perform more accurate comparison and verification, the contaminant concentration should be measured with a shorter interval than this time field measurement.

Integrated simulation tool to predict the performance of ventilation system

In order to predict the performance of ventilation system such as indoor air control characteristics and building heating and cooling load effect, the integrated simulation method was suggested in this study. The integrated simulation method is based on the TRNSYS and the developed IAQ control module is added to make up for the limitation of TRNSYS.

Fig. 6 displays the layout of integrated simulation tool embedded in TRNSYS. Fig. 7 shows the information flow in the integrated simulation. Basic TRNSYS simulation module deals with outdoor air characteristics, indoor thermal environment, building load, heating/cooling system and energy. The new modules such as contaminant concentration prediction module, ventilation system signal and ventilation rate determinant module, heat recovery efficiency calculation module, and the module to link the ventilation system and the heating/cooling system were added in the integrated simulation.

A total of seven cases are analyzed in this study (see Table 7). Case 1 shows the results for the air current between rooms occurred by infiltration only, and Case 2 and 3 corresponds to the results for the ventilation system installed in living room and whole room respectively. Here, with the state of door opened and closed, the cases are divided into two sub-cases. The cases with -1 show the condition that the door between the rooms is opened. -2 represent the cases which the door is closed. Table 4 shows the air flow rate of ventilation system that is installed in each room. In whole rooms, the air change rate is set at 0.9times/h constantly. It is based on the results of measurement.

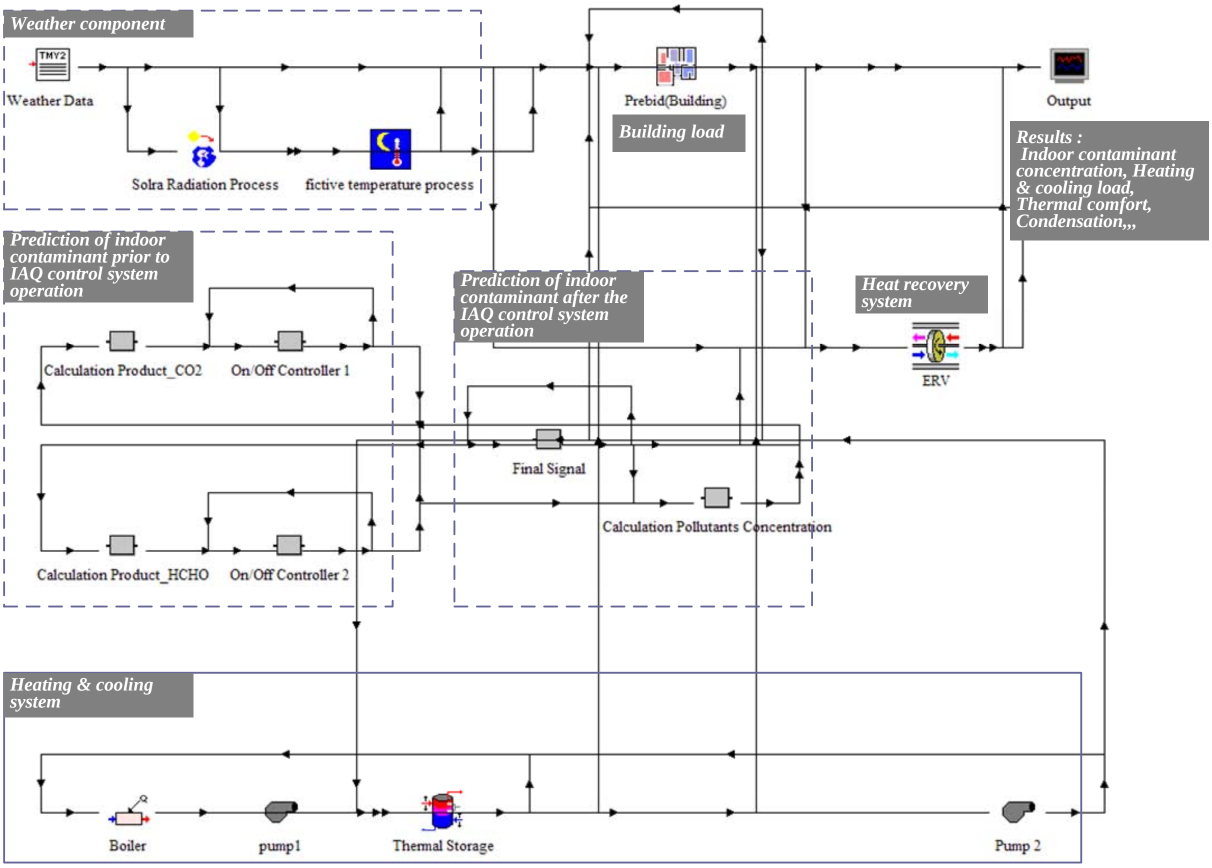

Fig. 6 Layout of the integrated simulation tool embedded in TRNSYS

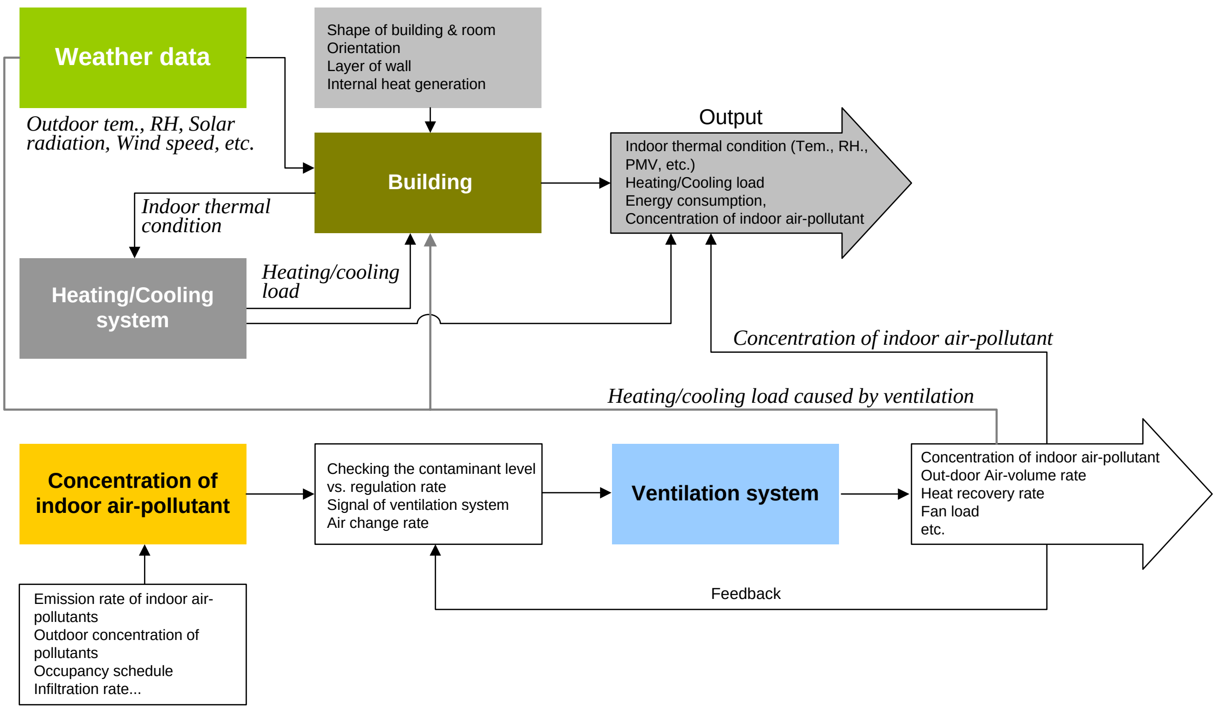

Fig. 7 Schematic of integrated simulation tool

CASE STUDY

In order to demonstrate the usefulness of integrated simulation tool, fairly detailed case study will be presented in this section.

Detailed simulation conditions

The simulation conditions such as analyzed space, infiltration rate, indoor contaminant emission rate, outdoor air conditions and the ventilation system operation conditions were identical to the field measurement conditions and results. The efficiency of heat exchange unit installed in ventilation system is about 70% in the cooling mode and 75% in the heating mode. The latent heat exchange efficiency is about 40% for both heating, and cooling under the airflow is set at 120 CMH. Moreover, the movements of contaminant between rooms were not considered for simulation as like the field measurement. The time-step for maintaining the on/off state of ventilation system was set at 30 minutes, which is identical to the field measurement condition, and the time-step for simulation was set at 1 minute 30 seconds. The detailed conditions and cases for integrated simulation are illustrated in Table 6, 7, respectively.
A total of seven cases are analyzed in this study (see Table 7). Case 1 corresponds to the present regulation of ventilation rate for residential building in Korea. And the Case 2 represents the installed ventilation system in field measurement in this study. Case 3 corresponds to the cases that satisfy the regulation level of both indoor CO_2 and HCHO in Korea. In Table 7, the cases with C show the constant air flow ventilation mode and F represent the feed-back control which the ventilation system is operated when the CO_2 or HCHO level is exceed the regulation level with operating time step (30 minutes).

RESULTS

Indoor Air Quality Control

Among the analyzed cases, only the case 3 satisfy the minimum requirements for CO_2 and HCHO level in Korea when the ventilation unit operates alone for 24 hours. In other words, the CO_2 and HCHO level will be controlled under the minimum requirements only if the air change rate should be 1.0 times/hour or more (Fig.8(a)). Moreover, even if the operation mode is set at feedback control as in Case 2-2 and Case 3-2, the ventilation system was actually operated in 24 hour constant air-flow mode. However, when the ventilation and air-cleaning units were simultaneously operated with 0.9 times/hour of 24 hour constant air-flow mode(Case 2-3) the two contaminants below the permissible level. In Case2-4 where feedback control was applied, there were some times when concentration rose above the permissible level with the ventilation system off, but the overall control characteristics were determined to be positive(Fig.8(b)).

Heating and Cooling Load

Among the analyzed cases, heating and cooling load are investigated only if the cases 3-1 and 2-4 since they satisfied the indoor air quality control guideline. Three cases were examined: Case 3-1(ventilation unit alone (1.4 ACH)), 24 hour constant air-flow), Case 3-1 with heat exchange unit, and Case 2-4(ventilation unit + air-cleaning unit (0.9 ACH, feedback control).
Indoor and outdoor conditions were identical for all three cases, and the difference among the loads for the three cases as shown in Fig. 9 can be considered as the ventilation load.
As shown in Fig. 9, the difference in the cooling load according to the ventilation can be regarded as minimal. However, in case of the heating load, when the heat recovery unit was

added there was about 75% reduction compared to the results of Case 3-1. Moreover, in case of the heat recovery unit was added to the Case 2-4, there were heating load reductions of 85% and 35% from Case 3-1 where there was no heat recovery unit and Case 3-1 + heat recovery unit, respectively. These results suggest that operating the ventilation system with air-cleaning unit can reduce the heating and cooling load as well as the amount of ventilation required for controlling the indoor air quality.

Table 6 Simulation conditions

Weather data	Standard weather data(Seoul)	
Set-point	Cooling	Heating
	Dry B. Tem. : 26℃ Relative Humi. : 60%	Dry B. Tem. : 20℃ Relative Humi. : 40%

CONCLUSION

In this study, integrated simulation was proposed to evaluate the performance of ventilation system. The developed tool is based on TRNSYS and integrates the indoor air quality control characteristics for each operation mode and the changes in the heating &cooling load according to ventilation system operation.
The validity of the developed simulation module was verified by comparing the results of the field measurement of the air quality control performance of the ventilation system and the results predicted by IAQ control module of ventilation system developed from this study. In addition, an integral simulation tool was developed for simultaneously examining the indoor air quality control characteristics and heating and cooling load characteristics according to different ventilation methods.
Integrated simulation tool for evaluating the performance of ventilation system that considers the indoor air flow and contaminant concentration changes between rooms will also be presented in the near future.

Whole Building CFD Simulation of a Swedish Low-Energy Building

Fredrik Karlsson and Bahram Moshfegh

Division of Energy Systems, Department of Management and Engineering, Linköping University, Sweden

Corresponding email: Fredrik.Karlsson@liu.se

SUMMARY

When taking measures to increase energy effectiveness it is important not to deteriorate the indoor climate. In the present study a Computational Fluid Dynamic (CFD) model was built to investigate temperature and airflow patterns in a Swedish low-energy building. A full-scale model of the house has been generated in the commercial code Icepak 4.1. The commercial CFD code Fluent 6.2.16 is used for the numerical solution. The RNG k-ε model is used as turbulence model. Four cases were simulated representing Winter, Summer and Autumn climatic conditions, the last with both low and high airflow rates. The results are compared with measured air temperatures and velocities. The results show small temperature gradients in the rooms and small temperature differences between floor levels. The air velocities are generally less than 0.15 m/s in the whole building.

INTRODUCTION

The energy demand of the built environment could be decreased either by increasing the effectiveness of the external power or by taking efficient measures on the demand side, e.g. minimizing the heat losses through walls and windows, or by ventilation. In Gothenburg, Sweden, twenty terraced low-energy houses were built with the aim of minimizing the losses. When taking measures to increase energy effectiveness, the indoor climate must not be deteriorated. Earlier measurements made on the object of this study emphasized the thermal environment [1], [2]. Building energy simulation has earlier been used to predict the thermal comfort in the building [3] but this tool does not give a proper description of the airflow and temperature pattern within specified zones. This paper aims to describe a model of a low-energy building and use the outcome for whole-building Computational Fluid Dynamic (CFD) simulations.

Studied object

The object of this study consists of a ground floor, an upper floor and an attic with a total floor area of 120 m^2 and total volume of 340 m^3. A detailed description about the object can be found in Karlsson, 2006 [4]. The ground floor consists of a kitchen, a living room and a toilet. On the upper floor there are three bedrooms with high ceilings, and a washing room with a toilet (Figure 1). Both floor levels have contact with the attic through the stairwell. The houses are well insulated with low *U*-values and low-emissivity windows and utilize an air-to-air heat exchanger to minimize the heat losses due to ventilation. The supply air terminal devices are placed in the three bedrooms and in the living room. The exhaust air terminal devices are placed in the toilets on both floor levels. The ventilation duct is mounted in the framing of joists, causing the supply air terminal devices on the upper floor (e.g. the bedrooms) to be placed on the floor but near the ceiling on the ground floor. One of the twenty houses was used as a test house during the first two years of occupation. Measurements from this house have been used in this paper.

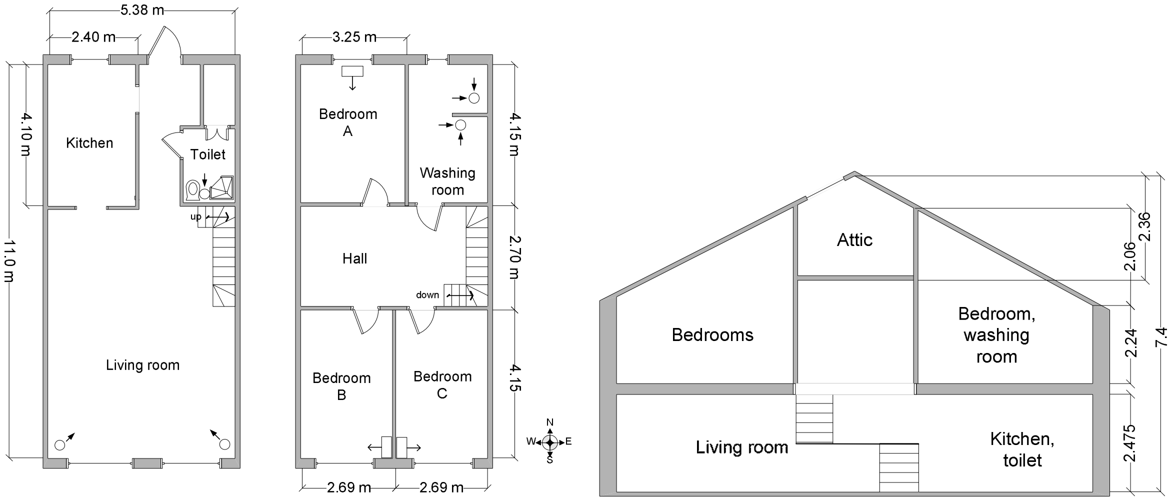

Figure 1. Ground and upper floors of the terrace house.

MATHEMATICAL MODELLING

A steady state three-dimensional model is considered for analyzing the flow and heat transfer in the whole building. The flow is assumed to be turbulent. The following assumptions are also considered: thermo-physical properties of the air are assumed to remain constant except for the buoyancy term of the *y*-momentum equation, i.e. the Boussinesq approximation, see Gray and Giorgini [5]. The radiation heat transfer is included. The radiative surfaces are assumed to be grey-diffuse with constant emissivity and the participating fluid, i.e. air, does not interact with the radiative process directly. Based on the above assumptions and using The Renormalization Group k-ε model (RNG) for the turbulence modeling the governing equations are obtained as follows:

$$\frac{\partial U_i}{\partial x_i} = 0\,, \tag{1}$$

$$\frac{\partial (U_j U_i)}{\partial x_j} = -\frac{1}{\rho}\frac{\partial p}{\partial x_i} + \nu\nabla^2 U_i + \frac{\partial}{\partial x_j}\left(2\nu_t S_{ij} - \frac{2}{3}k\delta_{ij}\right) + g_i\beta(T_0 - T)\,, \tag{2}$$

$$\frac{\partial (U_j T)}{\partial x_j} = \nabla\cdot[(\alpha+\alpha_t)\nabla T]$$

$$\frac{\partial (U_j k)}{\partial x_j} = \nabla\cdot\left[\left(\nu + \frac{\nu_t}{\sigma_k}\right)\nabla k\right] + \nu_t S^2 + \beta g_i \alpha_t \frac{\partial T}{\partial x_i} - \varepsilon\,, \tag{4}$$

$$\frac{\partial (U_j \varepsilon)}{\partial x_j} = \nabla\cdot\left[\left(\nu + \frac{\nu_t}{\sigma_\varepsilon}\right)\nabla \varepsilon\right] + C_{\varepsilon1}\frac{\varepsilon}{k}\nu_t S^2 - C^*_{\varepsilon2}\frac{\varepsilon^2}{k} + C_{\varepsilon3}\left(\beta g_i\alpha_t\frac{\partial T}{\partial x_i}\right)\frac{\varepsilon}{k}\,, \tag{5}$$

where $\eta = Sk/\varepsilon$, $\eta_0 = 4.38$, $\beta = 0.012$, $C_\mu = 0.0845$, $C_{\varepsilon1} = 1.42$, $C_{\varepsilon2} = 1.68$, $\sigma_\kappa = \sigma_\varepsilon = 0.7178$, $\mathrm{Pr}_t = 0.9$, $\alpha_t = \nu_t/\mathrm{Pr}_t$, $Sk/\varepsilon C^*_{\varepsilon2} = C_{\varepsilon2} + \frac{C_\mu\eta^3(1-\eta/\eta_0)}{1+\beta\eta^3}$, $S_{ij} = 0.5\left(\frac{\partial U_i}{\partial x_j} + \frac{\partial U_j}{\partial x_i}\right)$, and $S = \sqrt{2S_{ij}S_{ij}}$.

The radiation model used in the present study is the Discrete Ordinates (DO) radiation model, which takes into account the heat transfer exchanges between different objects by solving a so-called a radiative transfer equation (RTE) for a finite number of discrete solid angles, each associated with a vector direction fixed in the global Cartesian system (x, y, z). The solution method used for RTEs is the same as the flow and energy equations; for more information see Fluent 6.2.16 [6]. Due to the size of the model, the RTEs are solved once every ten iterations in order to reduce the impact on the available computational resources and the CPU time.

Geometry and boundary conditions

The CFD model of the house is built to resemble the real object as closely as possible. However, the stairwell is not included in the CFD model to simplify the mesh generation. The test house was only sparsely furnished during the measuring period, as is the CFD model. All doors, except the doors to the toilet and the toilet/washing room, are assumed to be open and are removed in the model. A small gap of 5 cm is left below the toilet doors to allow airflow into the toilets.

The heat fluxes through the building structure are calculated based on measured climatic data and designed U-values adjusted for no convection heat transfer at the inside surface. The solar irradiation is included in the model as a heat flux applied to the floor surface in the living room and the two small bedrooms (B and C) upstairs. The average absorbed insolation over two days is used to consider the thermal inertia of the building. Table 1 summarizes the heat fluxes used for the simulations. The no-slip condition is used at the surfaces, which implies that the velocity vanishes at the surfaces. For near wall-treatment the standard wall function proposed by Launder and Spalding [7] is used. The radiation surfaces are assumed to be grey-diffuse with a constant emissivity equal to 0.9 except for the supply and discharge boundaries where the emissivity is set to 1.0.

Table 1. Heat fluxes applied to surfaces in the model for the simulated cases.

	Heat flux [W/m^2]		
Construction	*Winter case*	*Summer case*	*Autumn case**
External walls	-0.78	-0.52	-0.78
Main door	-7.21	-4.8	-7.21
Windows	-7.17	-4.78	-7.17
Floor in the kitchen and entrance hall	-1.3	-1.86	-1.3
Floor in living room	0.7	-0.84	0.7
Floor bedrooms B & C	3.3	4.9	3.3
Ceiling	-0.6	-0.4	-0.6

**The boundary conditions were used for both low and high airflow rate cases.*

In the living room and bedroom B, respectively, a human representative is standing that emits 55.6 W. In the living room there is a TV represented by a block that emits 50 W. On the upper floor, a 40 W heat source is applied in bedrooms A and C. Further, in the kitchen a heat gain of 120 W representing a fridge and a freezer is present.

The airflow through the devices used in the simulation is based on measured results [2], found in Table 2. The supply temperature is changed between 19°C in the Summer case to 21ºC in the Winter case. The Autumn case is simulated for both low and high airflow rate levels, while for the Winter and Summer cases the low airflow rate level is considered. The inlet turbulence intensity is assumed to be 10% and is applied to all supply terminals. Those values are implemented in the model using a constant airflow with a specified temperature and a uniform velocity profile normal to the supply device. A zero-gradient boundary condition is applied at the exhaust, assuming similar conditions in the flow direction (i.e. a fully developed flow). The outlets in the washing room on the upper floor are defined as an outflow.

Table 2. Airflow rate through supply and exhaust devices used as boundary conditions in the simulation model.

Device	Velocity [m/s], low airflow rate	Velocity [m/s], high airflow rate
Supply device in bedroom *A*	0.19	0.28
Supply device in bedroom *B*	0.10	0.15
Supply device in bedroom *C*	0.16	0.24
Supply devices in living room	0.88	1.32
Exhaust device in toilet on the ground floor	2.81	4.22
Outer exhaust device in toilet on the upper floor	-	
Inner exhaust device in washing room	-	-

Computational grids

ICE Pack 4.16 is used to generate the 3-D unstructured grid. Different grid densities are checked and finally the model composed of 694,544 hexahedral cells is found to be sufficient for the present study, as a trade-off between accuracy and efficiency. The grid distribution is effectively controlled by clustering the mesh towards the walls and edges in such a way that the wall function can be applied properly, see Figure 2. With this grid, it takes about 30 hours of CPU-time on a desktop computer with a 2.66 GHz processor to get a fully convergent result.

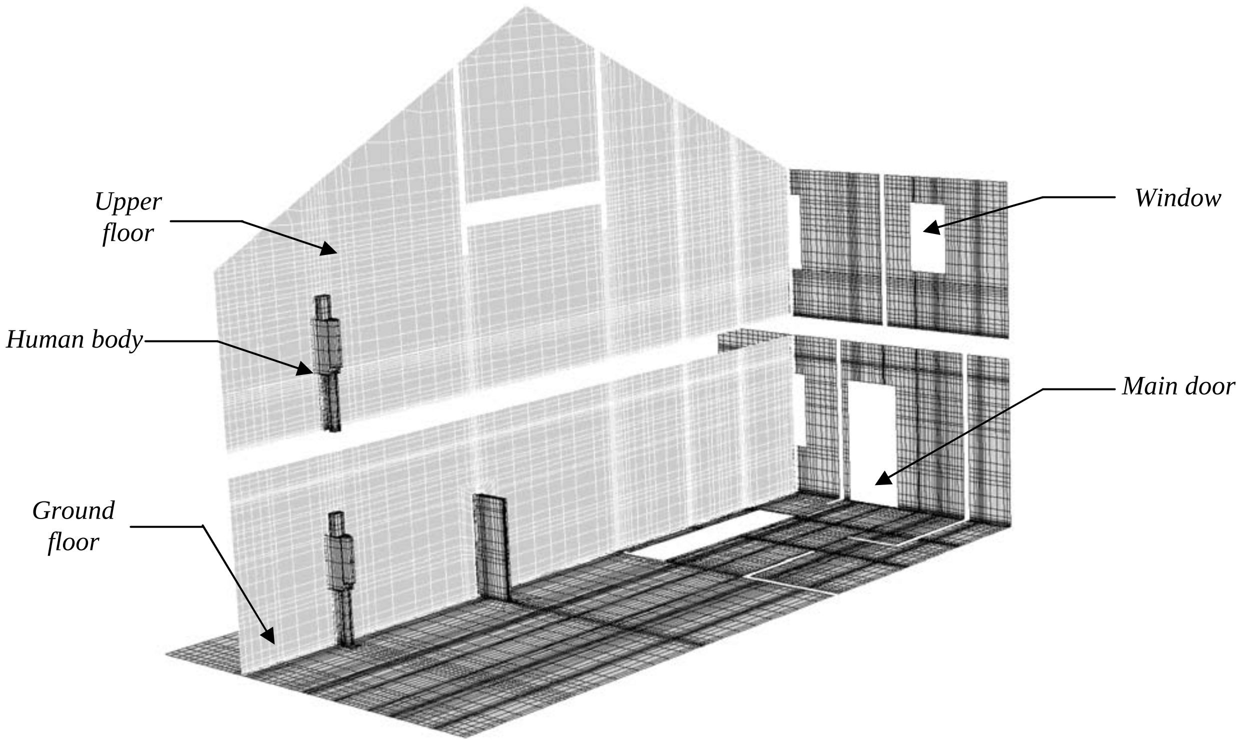

Figure 2. A perspective of the computational grid used in the model

Numerical accuracy

FLUENT 6.2.16 is used to numerically simulate the flow and thermal behaviour of the air in the whole building. The governing equations are solved with a segregated scheme. The momentum, energy, turbulent kinetic energy and turbulent energy dissipation equations, and the radiative transport equations (RTE) are discretized spatially with a second-order upwind scheme and for the pressure the body force weighted scheme was used. The pressure-velocity coupling algorithm SIMPLE is used to solve the pressure term. The following under-relaxation values were used for the pressure, momentum, turbulent kinetic energy, dissipation rate of turbulence, temperature and radiation, respectively: 0.5, 0.05, 0.5, 0.5, 1.0 and 1.0. The simulation is declared converged when the parameters and the residuals no longer change with successive iterations or the residuals from all the variables (except for the temperature) in all the cases were less than 10^{-3} and for the temperature less than 10^{-7}.

RESULTS

The simulated values for the Autumn case show temperatures within the building ranging from 19.1ºC to 32.4ºC, where the latter is found near the humans and the TV. The average measured temperature in the living room during the same period is 25.4°C and for the kitchen 24.6°C. This can be compared to the values in the third column in Table 3 where the average simulated temperature for the Autumn case is found. The simulated values are slightly lower than the measured values, which can be explained by the fact that the simulated value includes temperatures at the window surfaces. Table 3 shows the average simulated indoor air temperatures.

Table 3. Average indoor simulated temperatures on the ground floor and the upper floor including the attic, respectively.

Simulated temperatures (°C)	Winter case	Summer case	Autumn case, low airflow rate	Autumn case, high airflow rate
Average air temperature ground floor	19.36	23.69	24.49	23.62
Average air temperature upper floor and attic	19.48	22.62	22.73	21.92
Difference	-0.12	1.07	1.76	1.7

The simulated air velocities for Winter conditions in the *z*-direction in the door opening between room *B* and the upper hall has been compared to measured values and show a similar pattern. However, the measured velocity magnitudes are rather low, and hence the measured values are uncertain.

Figures 3 to 6 show the temperature and velocity contours for the Summer and the Winter cases in the *xy*-plane at z = 5.5 m (mid-plane). The Summer case was simulated with a supply air temperature of 19°C, which is not always possible to achieve during real summer conditions. The temperatures in the real object will therefore be higher during a hot summer.

An air circulation pattern is found in the attic and there is air exchange between the attic and the rest of the house. High air velocities are found on the ground floor near the kitchen and in the upper hall. The airflow in the upper hall near the floor and ceiling comes from rooms *A* and *B*, respectively. Almost the same flow pattern and velocity magnitude have been observed for the Winter case, while the temperature level is approximately 3°C lower in the Winter case than in Summer case. In the Summer case the average temperature on the upper floor is higher than on the ground floor, while for the Winter case the situation is the opposite.

Figures 4 and 6 show that there is an airflow through the stairwell to the attic, which is in agreement with results from constant concentration tracer gas measurements that showed that the flow of fresh air to the attic was considerable [2].

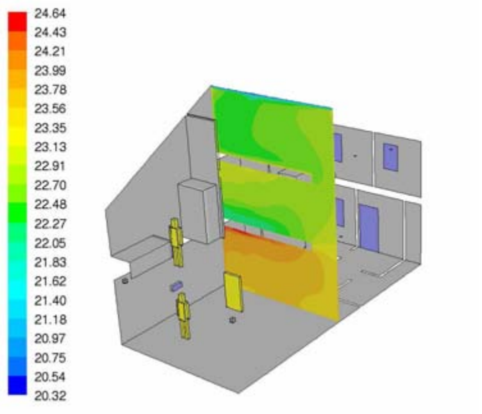

Figure 3. Contours of temperature in the *xy*-plane at *z* = 5.5 m (mid-plane) for the Summer case.

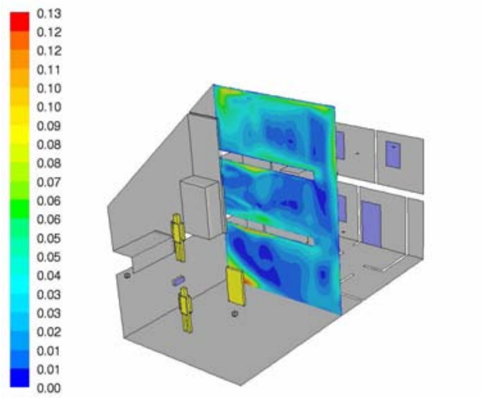

Figure 4. Contours of velocity magnitude in the *xy*-plane at *z* = 5.5 m (mid-plane) for the Summer case.

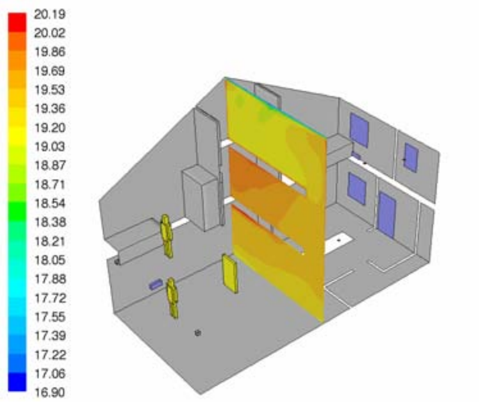

Figure 5 Contours of temperature in the *xy*-plane at *z* = 5.5 m (mid-plane) for the Winter case.

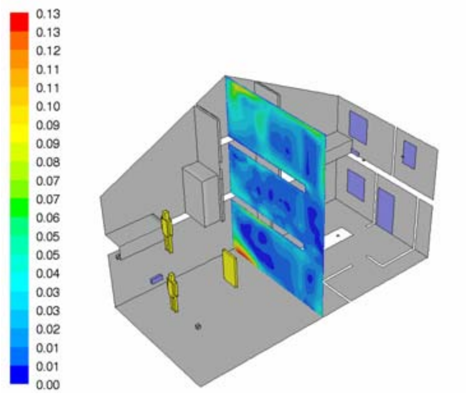

Figure 6 Contours of velocity magnitude in the *xy*-plane at *z* = 5.5 m (mid-plane) for the Winter case.

Figures 7 and 8 show the contours of the velocity magnitude for both the Summer and the Winter cases in the *yz*-plane at *x* = 1.5 m. The predicted airflow around and above the human representative can be compared to calculations of plume velocities according to empirical findings for a heat source. The airflow to and from rooms *A* and *B* into the hall is also shown and it is more pronounced in the Summer case.

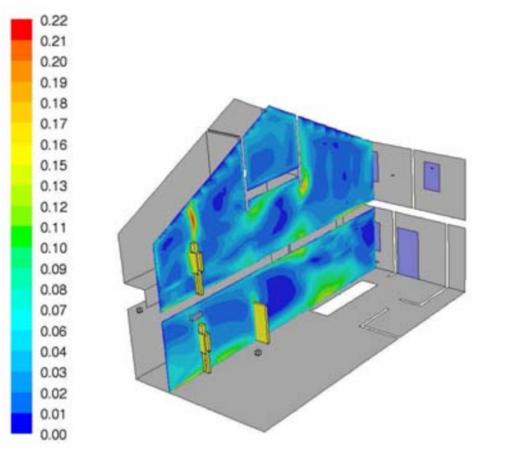

Figure 7 Contours of the velocity magnitude in the *yz*-plane at x = 1.5 m for the Summer case.

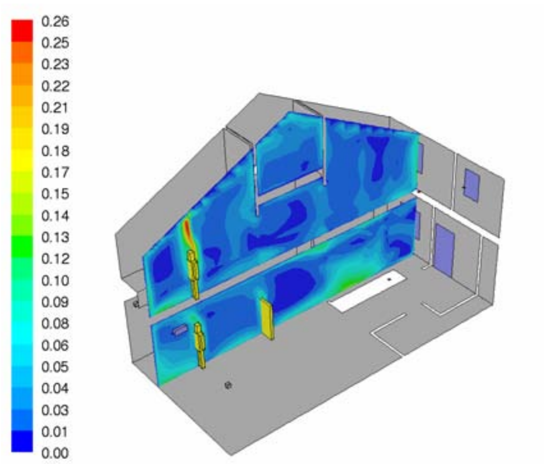

Figure 8 Contours of the velocity magnitude in the *yz*-plane at x = 1.5 m for the Winter case.

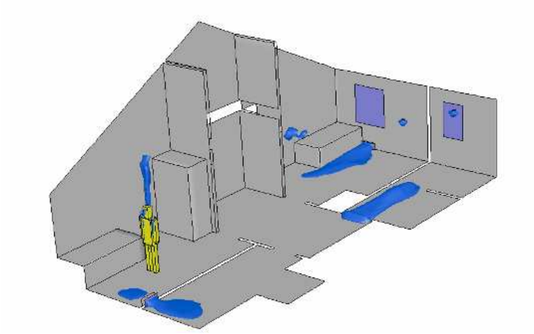

Figure 9 The iso-velocity 0.15 m/s on the upper floor for the Summer case.

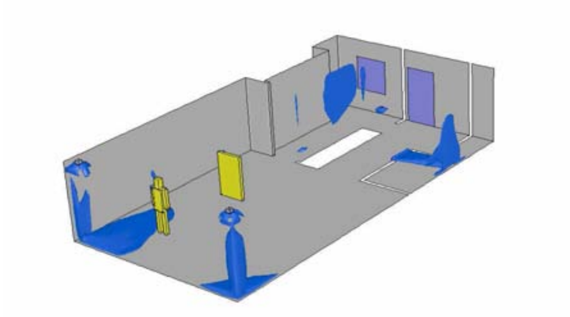

Figure 10 The iso-velocity 0.15 m/s on the ground floor for the Summer case.

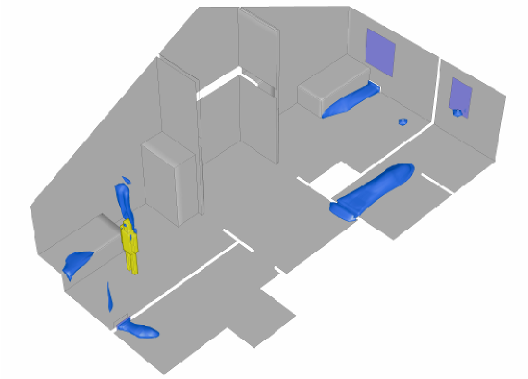

Figure 11 The iso-velocity 0.15 m/s on the upper floor for the Winter case.

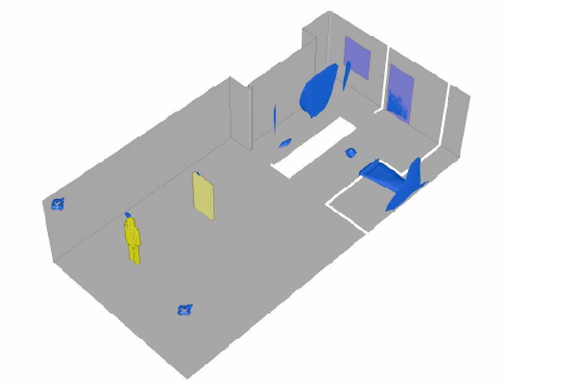

Figure 12 The iso-velocity 0.15 m/s on the ground floor for the Winter case.

Figures 9 to 12 show the iso-velocity 0.15 m/s contour for the Summer and Winter cases for both the ground and the upper floors. The air velocity 0.15 m/s is the limit to avoid discomfort due to draught during the cold season. This value can be increased to 0.25 m/s in the Summer time without causing draughts. As it is shown in the figures the air velocity close to the supply device in rooms *A* and *C*, above the human body's head on the upper floor, in the kitchen and at the air gap below the toilet doors on both floors is 0.15 m/s. The toilets are the location that the occupants of the low-energy buildings mention connected to draught in interviews about the indoor climate [8]. The downdraught from the supply devices in the living room is more pronounced in the Summer case compared to the Winter case. The air velocity is in general lower or equal to 0.15 m/s in occupied zones in all simulated cases and consequently, the risk of local discomfort due to the draught is very low

DISCUSSION

The object of this study is a low-energy house that was built with the aim of showing that it is possible to live in low-energy houses despite the cold Swedish climate. In low-energy buildings, the social load affects the thermal environment substantially. Fairly small heat loads will increase the temperature locally. It is important that heat is distributed all over the building to prevent over-heating and that surplus heat can be removed properly. The layout of a low-energy building is therefore important for providing a suitable airflow pattern. CFD simulation is a valuable tool for predicting airflow patterns within the whole building as is been shown in this paper. The results from the simulations show that the temperature differences are small and the air velocities are rather low, generally less than 0.15 m/s in the whole building. The results presented here concern temperature and airflow patterns in only a few cases. The model will be further developed to provide results about the indoor climate with other boundary conditions to represent various households and technical conditions.

SUMMARY

The role of computational modelling as a development and engineering tool has recently become more significant. The major advantage is that modelling enables the testing of different geometries without having to build expensive test constructions. When a whole new building is in question, modelling is the only way to see inside it before it's finished.

The aim of this work was by using numerical simulation to investigate ventilation and heating system in an educational institute, which is under thorough renovation work. The main emphasis was put on studying whether the designed system is sufficient in extreme conditions especially in a three-story lobby and two industrial kitchens.

Only details important for ventilation were included in the models describing the room geometry. As the result of the simulation several modifications were made to the design in order to ensure, that the temperature remains in convenient level and velocities don't rise too high.

INTRODUCTION

The role of computational modelling as a development and engineering tool has recently become more significant. The major advantage is that with the help of modern modelling tools testing of different geometries is possible and no expensive test constructions are needed. Modelling is often also the only way to see inside the device; it is either too complicated for measuring equipment or it may even not exist yet. If the device in concern is a whole new building, there really are no other options than modelling.

The aim of this work was to investigate heating and ventilation in an educational institute by using numerical modelling. The building itself is under thorough renovation work, during which only its bearing outer walls were kept. Not only were its inside parts reconstructed but also totally new parts were added. Naturally its ventilation and heating system is reconstructed during this year too.

Since the major part of the vocational institute is used by the students of the catering college, the ventilation faces extreme conditions. The real challenge especially for the heating, however, is an eight meters high and 13 meters wide window in the lobby. This window in the summer time is exposed to direct sunlight, but during a cold winter day the outside temperature might be as low as -35 degrees centigrade. While the temperature and air velocities in the large three-story lobby must be remained in convenient level, hot fumes and smoky smells from the fully operating educational and commercial kitchens must be kept out of the hallways and removed.

Main emphasis was though put on finding out whether the designed system is sufficient to fulfil the requirements given. Besides the lobby two different kitchens were modelled. In order to provide as accurate information to the modelling software as possible the models representing the real geometry were made in close cooperation with the architects and designers. On the other hand, one of the most important tasks was to familiarize these experts with simulation so that its capabilities are known and can be used in further projects.

METHODS

Computational fluid dynamics

Computational fluid dynamics (CFD) is nowadays widely used in different kind of engineering applications. When modelling project is started the aim of the simulations must be specified, since it further defines what the geometrical model should be like and what kinds of boundary conditions are needed.

Geometrical representation based on real measures of the device in concern is created in a specific pre-processor. Depending on the goal of the simulation the actual geometry is either modelled accurately or simplified, when unnecessary details can be left out. The resulting model is then filled with computational mesh, which is needed in finite element based solution method of the equations describing the flow. Before calculating the actual solution for the problem, material types, mass flows and temperatures describing the situation in question must be given to the solver. After the final solution is achieved, the results can be post processed for example using numerical reports or contour plots so that the main findings can be easily seen. In this work commercial state-of-the-art computer software for modelling fluid flow and heat transfer was used.

Turbulent flows are characterized by fluctuating velocity fields. These fluctuations are too computationally expensive to simulate directly in practical engineering calculations. Instead, the instantaneous governing equations can be averaged or otherwise manipulated to remove the small scales, resulting in a modified set of equations that are computationally less expensive to solve. However, the modified equations contain additional unknown variables, and turbulence models are needed to determine these variables in terms of known quantities. [1]

In turbulence models the central issue is how the eddy viscosity is computed. The mixing-length zero-equation turbulence model uses a simple relation to calculate turbulent viscosity. The viscosity of the fluid is changed from a constant value to one defined by

$$\mu_t = \rho \ell_m^2 S \,, \tag{1}$$

where μ_t is turbulent viscosity, ρ density, ℓ_m the distance the turbulent mixing takes place and S the modulus of the mean strain rate tensor. This model, known also as the algebraic model, is very economical and suitable for most design purposes in cooling solutions [2]. Since the degree of turbulence and its details were not the major interest, this very simple model was used in the simulations presented in this paper.

As a heat transfer equations a simple balance equation for sensible enthalpy is written as

$$\frac{\partial}{\partial t} = (\rho h) + \nabla \cdot (\partial h \vec{v}) = \nabla \cdot [(k + k_t)\nabla T] + S_h, \tag{2}$$

where t is time, ρ is density, h is enthalpy, v is velocity, k is the molecular conductivity and k_t is the conductivity due to the turbulent transport. Source term S_h includes any volumetric heat sources, which might be defined in the model. [3]

The radiation heat transfer plays significant role especially if velocities are fairly slow. This is often the case in heating and cooling solutions, since the velocities are intended to keep in a fairly low level to avoid the feeling of draught. The radiative heat transfer equation for an absorbing, emitting and scattering medium at position $\vec{r}$ in the directions $\vec{s}$ is

$$\frac{dI(\vec{r},\vec{s})}{ds} + (a + \sigma_s)I(\vec{r},\vec{s}) = an^2 \frac{\sigma T^4}{\pi} + \frac{\sigma_s}{4\pi}\int_0^{4\pi} I(\vec{r},\vec{s}\,')\Phi(\vec{r},\vec{s}\,')d\Omega', \tag{3}$$

where I is the radiation intensity, a is the absorption and σ_S the scattering coefficient, n is the refractive index, s Stefan-Boltzmann constant and Ω solid angle. T is the local temperature in the domain. In the code used this equation is treated by writing the intensity of the radiation as a series, from which a source term can directly be added to the balance equation of enthalpy [4,5].

Modelled cases and boundary conditions

In this work two kitchens and large lobby were modelled. One of the kitchens is used by the students of the catering college during the academic terms; the other is the main lunch kitchen of the whole institute. It serves also the à la carte restaurant, which can be booked throughout the year for large special occasions like weddings. This restaurant is in direct connection to the lobby, which sets strict requirements for the ventilation.

For both kitchens all fixed cabinets and shelves as well as kitchen appliances, such as stoves, ovens and dishwashers, were included in the models as simple block and plate type objects. These together with the walls of the rooms formed the outlines of the geometrical model.

Heat was generated from several different sources. Kitchens were modelled in conditions corresponding to the sunny summer afternoon, which means that the solar heating coming through the windows was taken into account by providing the outer temperature and the heat transfer coefficient for the window. Single lighting devices were not modelled; instead the thermal power of the lamps was estimated to be half of the illumination power, which was set as a planar source in the ceiling. Stoves and small appliances were modelled in the similar manner, but the heating powers of larger devices were given as volumetric sources. When all the devices are operating, there also are several people inside the room. Persons were modelled as separate blocks obstructing the air flow and with small thermal power. Total heating power in the simulations of the educational kitchen was 25 kW and in the à la carte kitchen 28 kW. Example of the geometrical model and heat sources are presented in figure 1.

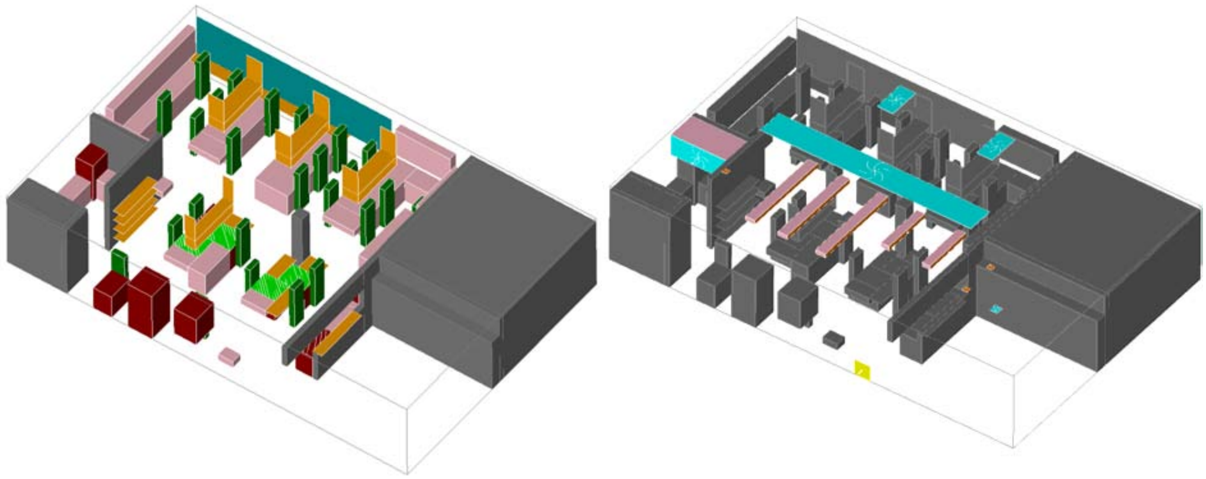

Figure 1 Model example of the educational kitchen (left) and details of the ventilation (right). Planar heat sources are coloured green and volumetric sources red. Blocks describing the students are dark green. Window is blue. Fixed cabinets are pink, shelves yellow and internal wall structures grey. Low velocity units are coloured turquoise, grease filters in the ventilation ceiling and valves orange. Grille in the door is bright yellow.

Air was provided to the kitchens mainly in two ways: through low velocity unit in the ceiling and supply air hoods. The hoods were placed above critical kitchen units and were also used to effectively exhaust the hot fumes. In addition to this in the educational kitchen air was removed via ventilation ceiling equipped with grease filters. The amount of incoming air was given to the program by fixing volume flows and temperatures. Outflow was designed to be slightly larger, and it was defined by fixing velocities. Grilles in the doors are used to balance the mass flow. This is meant to secure, that flow direction is towards the kitchen, not out of it. In the à la carte kitchen were two openings: the one through which the food is served and the one through which the dirty dished are returned. These were left fully open so, that the air could freely flow either in or out.

Lobby was modelled in circumstances, which correspond to warm midsummer afternoon and cold winter day. All three stories of open space and staircases in between were included, but no furniture was modelled.

During the wintertime there are several radiators, which heat the lobby. Furthermore, computers provided by the institute are available for the students throughout the year on the third floor. These all were taken into account as planar heat sources. Illumination was modelled as in the kitchens. Outer temperature was affecting the inside climate through the heat transfer coefficients of the outer walls and roof as well as windows and foundations. In the winter the glass of the large window on the second level up to three meters was heated with a constant power.

Ventilation is very complex and there are multiple air terminal devices in every floor. In the ceiling of the first floor, next to the demo kitchens, air is provided through four supplies, which gently blow the air in two directions along the roof. In the main floor swirl diffusers also slightly circulate the flow, but they were modelled only as supplies with appropriate swirl. On the upper floor there are two large rectangular diffusers, which also function as exhausts. They are turned off in the winter. To control the effect of the large window to the room temperature two fan coil units are installed in the floor between the second and the third level. In addition to these there are two large grille diffusers next to the large window on the second floor and in the hallway of the third floor. Air is removed from the lobby via several single valves in the ceiling and in the walls. The amount of air in the lobby was controlled and fed to the program by setting volume flows and velocities and temperatures for all together 23 supplies and 16 exhausts.

RESULTS

Simulations results were illustrated by multiple contour plots and numerical reports of the velocities and temperatures in the modelled domains.

In that part of the educational kitchen which is closer to the window temperature remains quite cool despite the heavy thermal load on the other side of the room. The flow pattern from the low velocity air units disappears almost totally before it reaches the working level and velocities do not rise too high down near the floor either. Air is heated up by the kitchen appliances before is exits the room via grease filters. Under the ventilation ceiling the temperature is clearly warmer than near the windows, but all warm air is immediately removed from the room. This is illustrated in figure 2 by the path lines released from the low velocity unit and coloured by temperature. Based on the simulations results the ventilation system for this kitchen was totally adequate and no changes to the original plan were made.

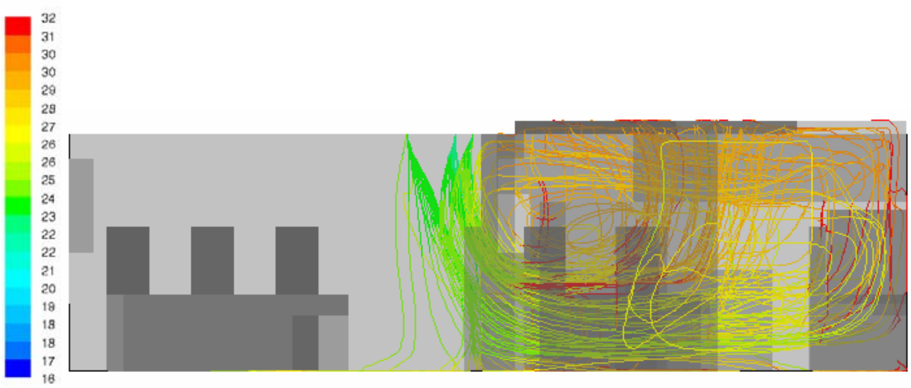

Figure 2 Pathlines released from the low velocity air supply and colored by temperature (^{o}C).

In the à la carte kitchen those appliances which have the greatest thermal power are quite close to each other. In this area major part of the food is prepared and cooked, and therefore the proper ventilation is essential. The simulations showed, however, that part of the hot fumes escaped under the supply air hood instead of being removed. The reason for this was that the screen between the two most important compartments was not as high as the ventilation designer had thought. A simple change was made to the dimensions of the supply air hood, which extended it over the screen. At the same time one large low velocity unit was split into two, since the original unit created too cool conditions in the baking area of the kitchen. The other part of the unit was transferred near the screen to provide more fresh air to the problem area. New results proved that the change made was efficient; almost all hot air escapes and the temperature level throughout the kitchen is more equal. Contours of temperature in the à la carte kitchen in the baking and cooking area are presented in figure 3 before and after the modification.

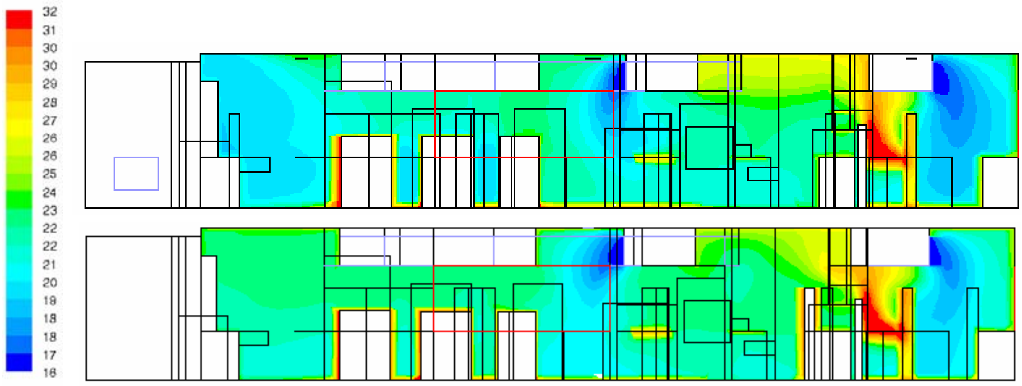

Figure 3 Temperature (^{o}C) in a cross cut of the à la carte kitchen before (top) and after (bottom) the modifications made to the low velocity unit and air supply hood. Baking area is on the left and cooking area is on the right.

In the lobby the overall temperature level and temperature difference between the floors were of special interest. Based on the simulations in the summer the difference between the bottom and the top floor was too high. In addition to this the temperature on the first floor was too high compared to the outside temperature, which might feel uncomfortable when entering the hall. Therefore the aim of the second simulation was to raise the temperature level in the two bottom floors without changing the already quite warm temperature on the third floor. This was done by raising the inlet temperature of all other air supply devices except the fan coil units in the ceiling of the top floor. To be sure that the ventilation is still adequate, 25 groups of four people with small thermal power were placed in the main floor to present the guests of a large celebration. Resulting temperature field is much smoother and the temperature difference in the lobby is only a couple of centigrade at its largest, as can be seen in figure 4.

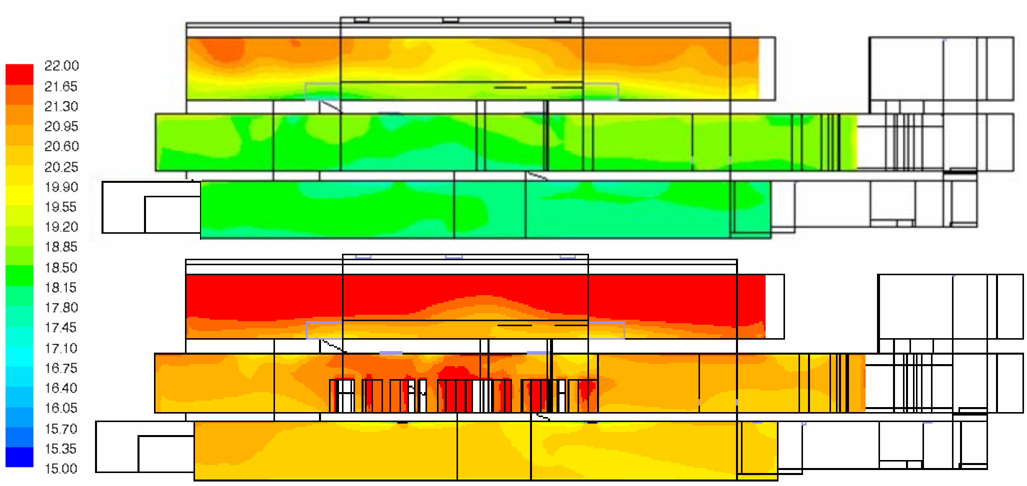

Figure 4 Temperature (^{o}C) in a cross cut of the lobby before (top) and after (bottom) the modifications made to the ventilations system in order to even out the temperature differences between the floors.

During a cold winter day, when the radiators were turn on, the temperature in the hall was too high. Even the cold windows did have hardly any effect at all. The reason was found to be in the exaggerated heating powers compared to the outer temperature, which was corrected to the simulation model too. Heating capability was designed noting, that some cold air will eventually be carried into the hall. The effect of cold air was now also included in the model as heat sinks near the cold windows. These changes decreased the overall temperature levels in the whole lobby, and the differences between the floors are still very moderate.

Finally the bottom part of the large window in the lobby was replaced by a normal plain glass window. The purpose was to study whether the quite expensive heating system is necessary or not. As the result the largest differences in the temperature were now in the main hall of the second floor. The effect is one degree of order and it stretches all the way from the window to the staircase in the back. Especially near the floor the air is colder, which might together with the air flows feel as draught. Heating keeps the surface temperature of the glass in adequate level, whereas without the heating it is close to zero centigrade. Even though the temperature difference in the hall was not that remarkable, conditions near the heated glass feel more pleasant to a person who stands near the window. Surface temperatures of all windows in the lobby are presented in figure 5.

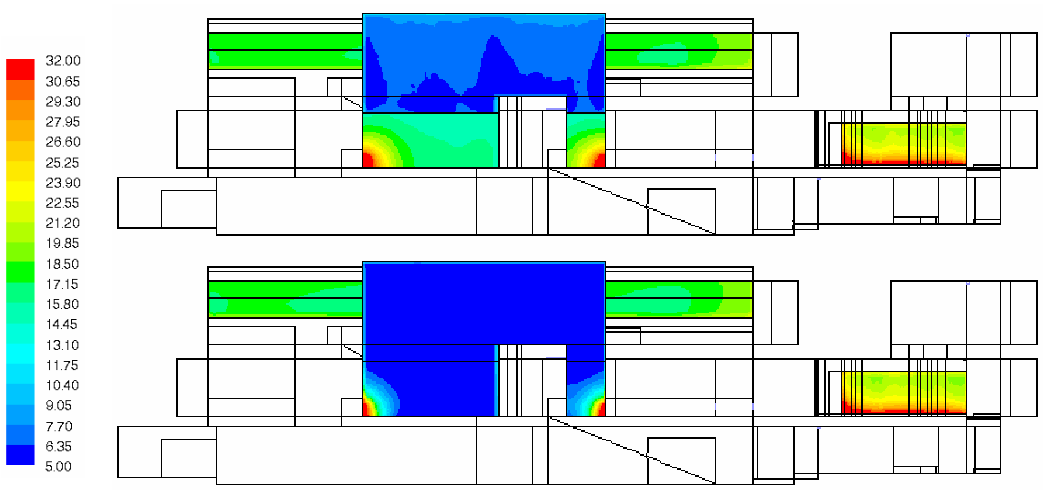

Figure 5 Surface temperature (^{o}C) on the windows of the lobby when the bottom part of the large window is heated (top) and when the whole window is made of ordinary glass (bottom). Warm areas in the corners are due to radiators located next to the window.

DISCUSSION

Since the modelling tools were not familiar to all participants of the simulation project in advance, the possibilities and restrictions of simulation were discussed over in several meetings, during which also the results were gone through in detail. Even though CFD is a powerful tool in obtaining information on large variety of even highly detailed devices, one must also keep in mind its limitations. No result can be more accurate as the geometry description and boundary conditions provided to the software. The desired goal determines what the model should be like; if the purpose is to simulate a whole building and find out the trends of the temperature and velocity profiles, there is no use to include small items such as a single casserole or door knob. CFD is at its best when cases can be compared after slight modifications, like it was made in this project.

The main purpose in this work was to secure, that working conditions are acceptable throughout the building. Temperature levels and the differences between the floors and compared to the outside temperature must not be too high. Velocities should stay on the moderate level to avoid the feeling of draught. Based on the simulation results several modifications were made to the heating and ventilation system. Most of the findings would not have been noted until the renovation work would have been totally completed. With the help of CFD some weaknesses from the design could be pointed out and corrected before the final choices were made and system constructed on site.

ACKNOWLEDGEMENT

The authors would like to thank Jyväskylä Vocational Institute and Haahtela Rakennuttaminen Oy as well as Jeven Oy for providing the funding of this work. The help of the staff of Arkkitehtitoimisto Pertti Nousiainen Ky, Insinööritoimisto Chydenius Oy and Jeven Oy in obtaining the boundary conditions for structures and devices is highly appreciated. Without the help and knowledge of fellow colleagues in Process Flow Ltd Oy this work would never have been finished.

SUMMARY

The objective of this paper is to present the results of a study that determinates the building's heat loss, a system thought up itself that permits to obtain the energy consumption by square meter of the dwellings (W/m^{2}K) in unsteady. The system was composed by vertical fan heaters that maintained the dwelling in uniform conditions of temperature. So much interior temperatures were measured like outsides in each one of the walls of the dwelling. Measurements in 8 types of dwellings were carried out, 7 dwellings correspond at building object of the study, and the last dwelling was carried out in another building. Experiences in the unsteady were carried out, obtaining the value in the steady-state. And it was obtained that the consumption was affected by the type of glazing.

INTRODUCTION

Casas Bioclimáticas, S.L. is dedicated to the promotion and construction of dwellings since its foundation in the year 2001. It forms part of the business group that heads Promociones y Construcciones M.D., S.L., with an experience in the sector of more than 25 years.
The business is dedicated mainly to the residential building, in its great of new dwellings promotions majority (one-family, semidetached and flats), mainly in Spain (in the province of Valencia). The differential element of these dwellings situates in the criteria of sustainability, bioclimatic, environmentalism and energy efficiency, besides the use of the automated one, utilized in the construction of the dwellings.

This company concerned about improving the energy efficiency of its buildings signed in the 2006 a contract of investigation with the research team Group of Design and Development of Sensors with the objective of analyzing the energy consumption of the dwellings.

The energy consumption of a specific building depends mainly on the building type, climatological conditions, building construction, annual hours of use, installations for heating, cooling, production of domestic hot water and lighting [1]. According to the Danish Environmental Protection Agency, the residential energy use per capita varies widely among European countries, from 150–350 kWh/capita in south Europe [2]. Energy is mainly used for space conditioning (heating and cooling primarily in southern Europe), sanitary hot water production, cooking, lighting and electrical appliances (i.e. refrigerators, washing machines and entertainment equipment).

Recently, in Spain, under the umbrella of the Directive 2002/91/CE, a new building technical code (CTE) has been developed [3]. The CTE has as an objective to obtain a rational use of the necessary energy for the use of buildings, reducing its energy consumption and utilizing for it sources of renewable energy. Thus the CTE establishes the requirement to incorporate energy efficiency criteria and the solar, thermal or photovoltaic use of energy in the new buildings or in those that be going to restore. The Basic Document contains four basic energy demands: limitation of the energy demand, where the values limit for the building's envelope are established (facades, glasses, covers, etc.); energy efficiency of the installations of lighting, where they are set for the first time in the Spanish regulation, some requirements to comply for these installations above all for buildings of the tertiary sector; the demand relating to the solar contribution of domestic hot water obliges that the production of domestic hot water be carried out with a contribute obligatory of thermal solar energy that will vary between a 30% and a 70% in function of the daily volume predicted of hot water demanded; and the minim contribution photovoltaic of electric energy, that establishes that in the new buildings of the tertiary sector of a determined surface.

The CTE implements two different indicators for the energy assessment of buildings, both of which are indirect indicators and far away from the absolute quantification of the building energy performance in terms of the kW h m^{-2} $year^{-1}$ of primary energy consumed. In its simplified option, the main indicators are the stationary heat transfer coefficients from the different components of the building's envelope, without properly taking into account solar irradiation. In its general option, the implemented indicator is the energy demand of the object building envelope in relative value to the building envelope energy demand of a variable reference building, being both energy demands evaluated with a dynamic code, called LIDER, that has been specifically developed for the CTE, and that presents important limitations in relation to its capabilities to properly assess the energy performance of different building design approaches.

Casals [4] coincides that building performance indicators implemented in the CTE are completely inappropriate. The indicator of the simplified option, the stationary heat transfer coefficient, is obviously absolutely inappropriate both for assessing the effect of many building energy issues, as well as for providing quantitative information about the building's energy consumption.

The need for a more realistic evaluation of thermal building performance in the local climatic conditions is undoubtedly necessary for a more accurate assessment of the thermal performance and for better energy efficient design.

METHODS

The building

Figure 1. Building's elevations.

The residential building is situated on the outskirts of Valencia's city, in the village of Paterna, will be destined for residential use, by means of system of rental submitted at subsidized housing and focussed on people younger than 36 years; have been built 44 dwellings, being 4 adapted for people with mobility reduced, and all they with lower surfaces to the 70 m^2 useful; and 44 parking spaces, being 2 adapted for people with mobility reduced. A very exact measure of the energy consumption of the dwelling could be obtained owing to the clearing of the building. In addition there would be that to indicate that this consumption would be able to be seen reduced in a 60% on account of the losses in case that the adjacent dwellings were conditioned they would be for the facade toward the outside.

They were analyzed some of the building's dwellings, a four-story building, whose situation they are stood out in the figures 2 and 3. In the figures 4 and 5 is shown the type of external walls, as for the dwellings analyzed as for the dwelling situated on the outskirts of Valencia's city, in the village of Tavernes Blanques.

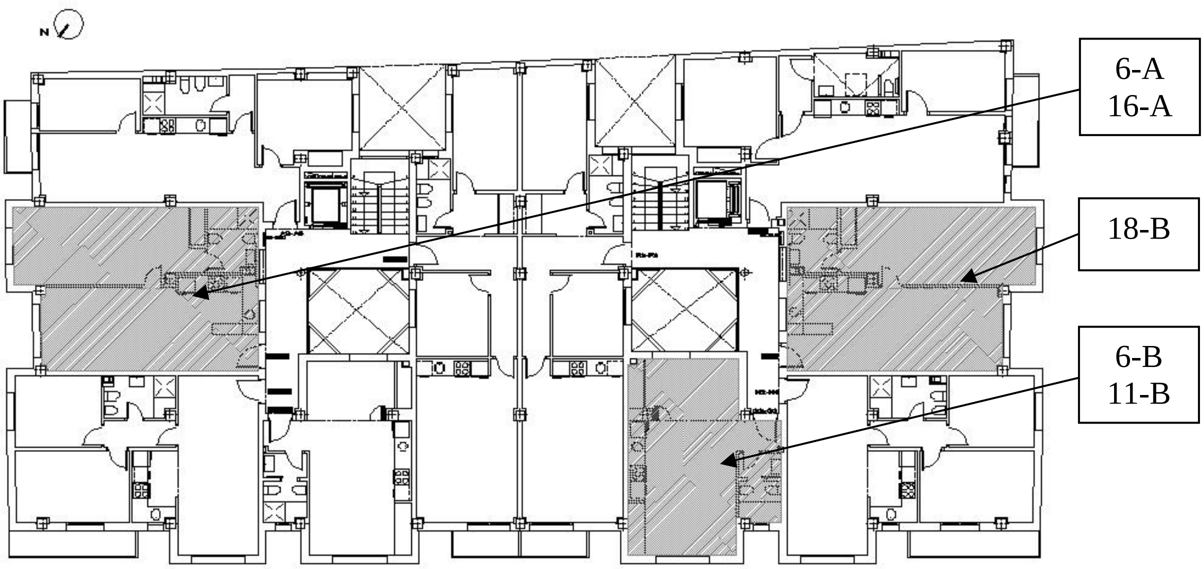

Figure 2. Type floor, which includes first, second and third floors.

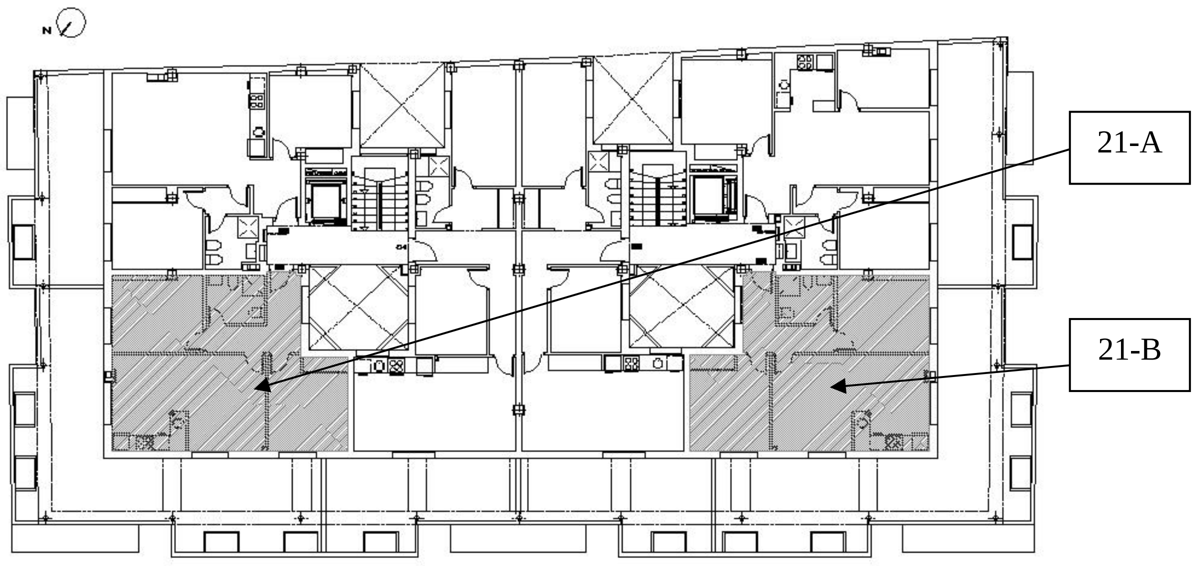

Figure 3. Top floor, housing 21-A y 21-B.

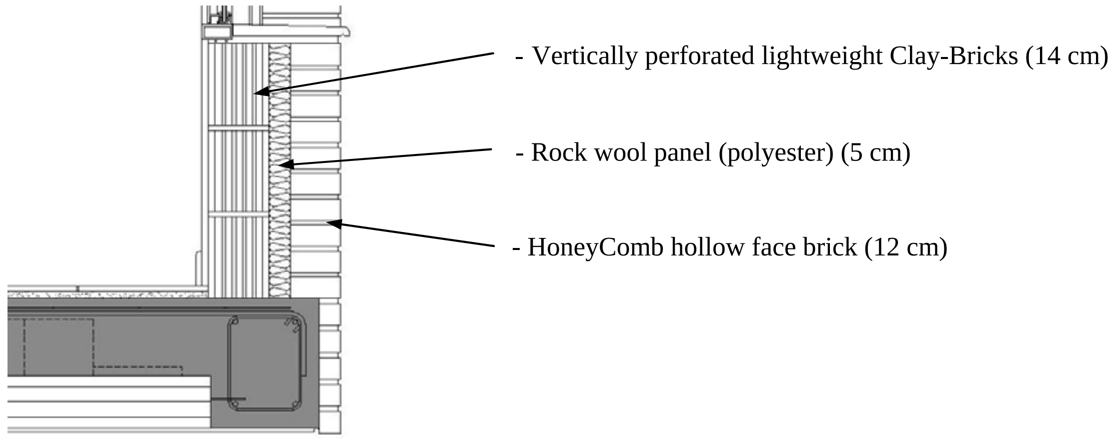

Figure 4. Section of residential building’s external walls.

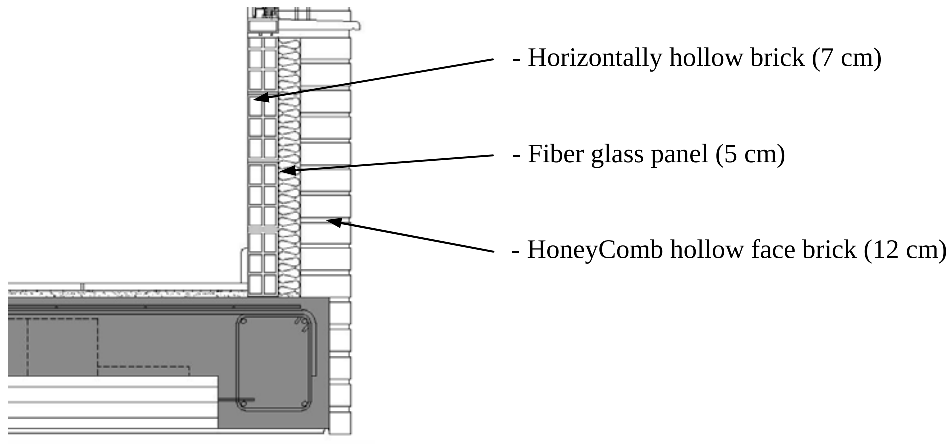

Figure 5. Section of residential building’s external walls situated on Tavernes Blanques.

With the objective to maintain a gradient temperature vertical fan heaters distributed by the entire house were utilized whose characteristics are shown in the table 1.

Table 1. Vertical fan heaters’s characteristics.

Maximum power (W)	2500
Voltage (V)	230
Power selector	2
Protection	IP 20
Thermostat	High precision

Instrumentation

The basic concept was to use existing meters and sensors and an existing data collection system already installed by the housing company in order to monitor the performance.
Data for the gradient thermal obtained from thermo couples placed on the external walls and a thermo couples portable in the closeness apartments.

RESULTS

Measurements in 8 types of dwellings were carried out, 7 dwellings correspond to the building described in the previous section, and the last dwelling was carried out in another building, which was found partly occupied, although all of the adjacent flats were found empty.

The measurements were carried out from 1 December 2006 until 1 January 2007. The results obtained were energy consumption, and exterior and interior temperatures, in relationship with the time. The instrumentation has been described in the previous section. Having differences among the different rooms' temperatures of the dwellings, it was obtained a value average that was weighted in function of their volume. Finding differences of adjacent dwellings' temperatures, it was obtained a value average was praised in function of the surface of the dividing wall.

For the calculation of the energy consumption by square meter of dwelling is utilized the following expression:

$$\varphi = \frac{Q}{t \cdot S \cdot \Delta T}, \qquad (1)$$

where ΔT is the average difference of temperatures and S is the dwelling's surface, t is the time passed between measurements, and Q is the heat consumed by the heating system. In the figure 6 they are shown for 4 dwellings the energy consumption by square meter of dwelling (W/m^2K) versus the time.

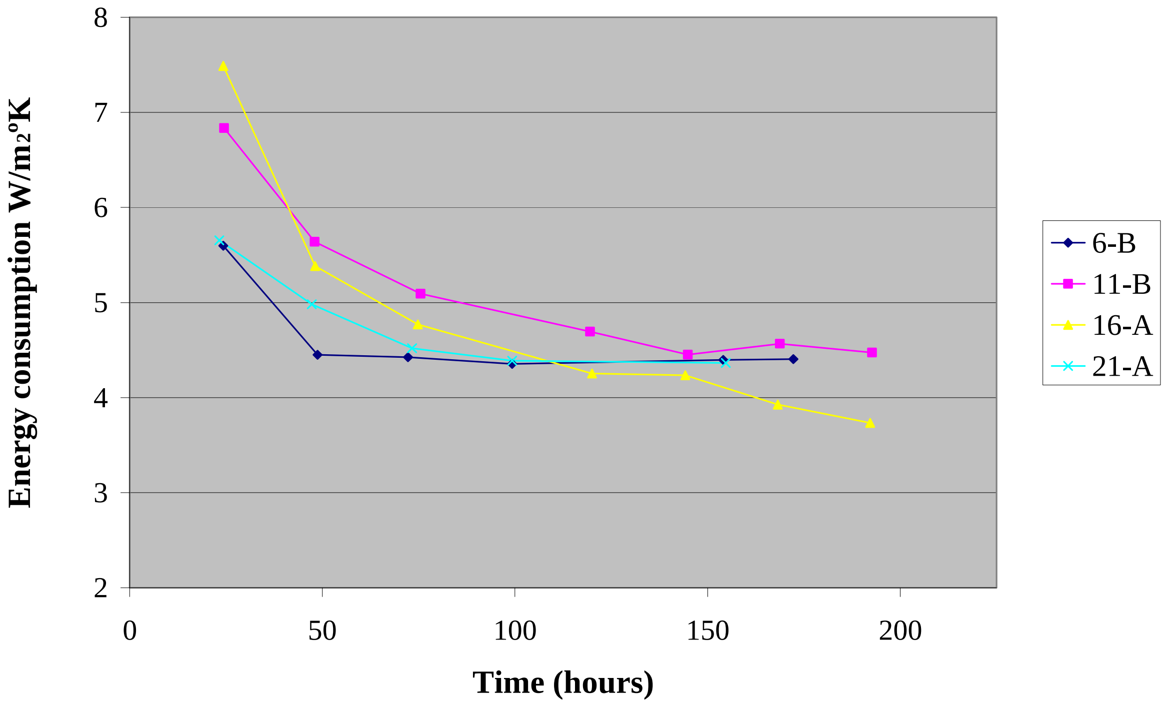

Figure 6. Energy consumption by square meter of dwelling (W/m^2K) versus the time.

Experiences in the unsteady were carried out, and obtaining the value in the steady-state by the representation of Ln φ against the time's inverse. In the figure 7 they are shown for 4 dwellings the Ln φ versus time's inverse.

In the figure 8 the results obtained are shown for all the dwellings analyzed after obtaining the intersection in the axis of the straight obtained adjusted by linear minimum mean square error.

It was discussed that the losses by windows could be important. In the table 2 they are shown the surface of windows of each one of the dwellings. It was detected that the type of window in the dwelling situated in Tavernes Blanques corresponded with the type Aluminium frame / double glazing 22 mm fold-up window with vertical axis. While in the dwellings situated in Paterna the window corresponded with a window track of Aluminium frame / double glazing 18mm, whose losses were difficult to estimate.

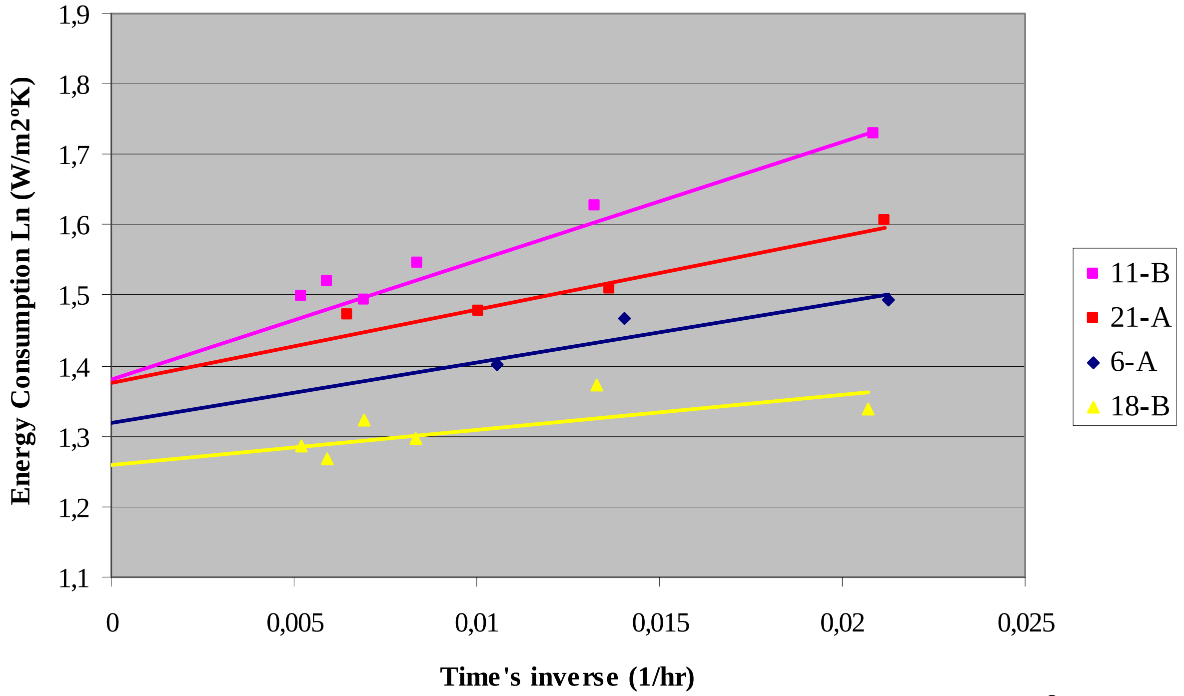

Figure 7. Logarithm of the energy consumption by square meter of dwelling (W/m^{2}K) versus time’s inverse.

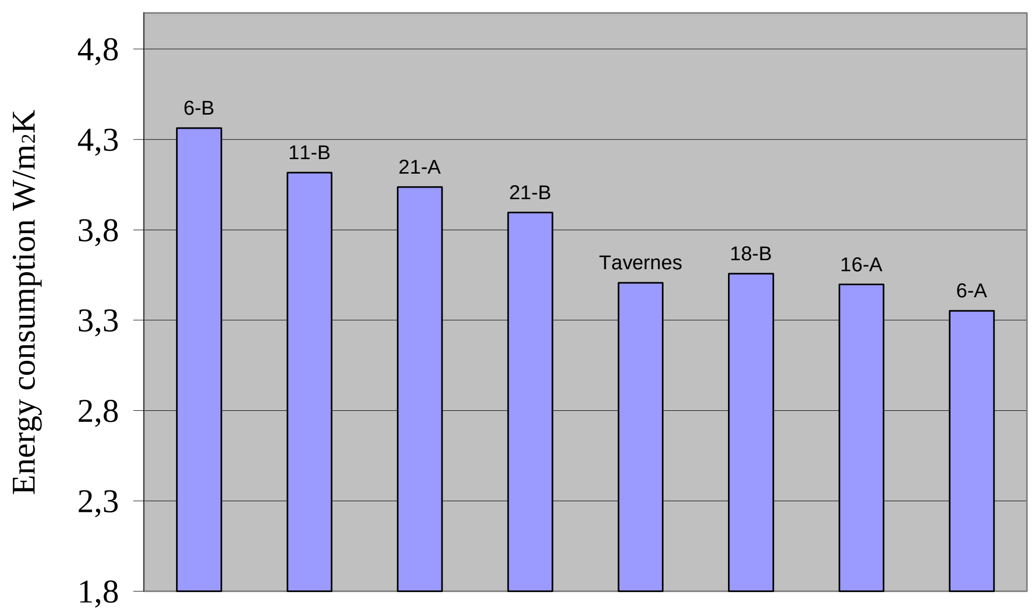

Figure 8. Energy consumption by square meter of dwelling.

Table 2. Window's surface.

dwelling	Window surface (m^2)
6-A	5,58
6-B	5,14
11-B	5,14
21-B	13,72
21-A	13,72
18-B	5,58
16-A	5,58
TAVERNES	11,64

Supposing that walls' losses should be similar in all the dwellings the value of the heat transfer coefficient was calculated (U_{window}) linear minimum mean square error by means of the following expression:

$$\varphi_{cerramiento} = \frac{\varphi_{vivienda} \cdot S_{vivienda} - U_{ventana} \cdot S_{ventana}}{S_{vivienda}}, \qquad (2)$$

To obtain the adjustment was supposed that the $U_{tavernes}$ was 3,1 W/m^2K, being reached an U_{window} equal to 3,6759 W/m^2K. The results of walls' energy consumption of the dwelling are shown in the figure 9.

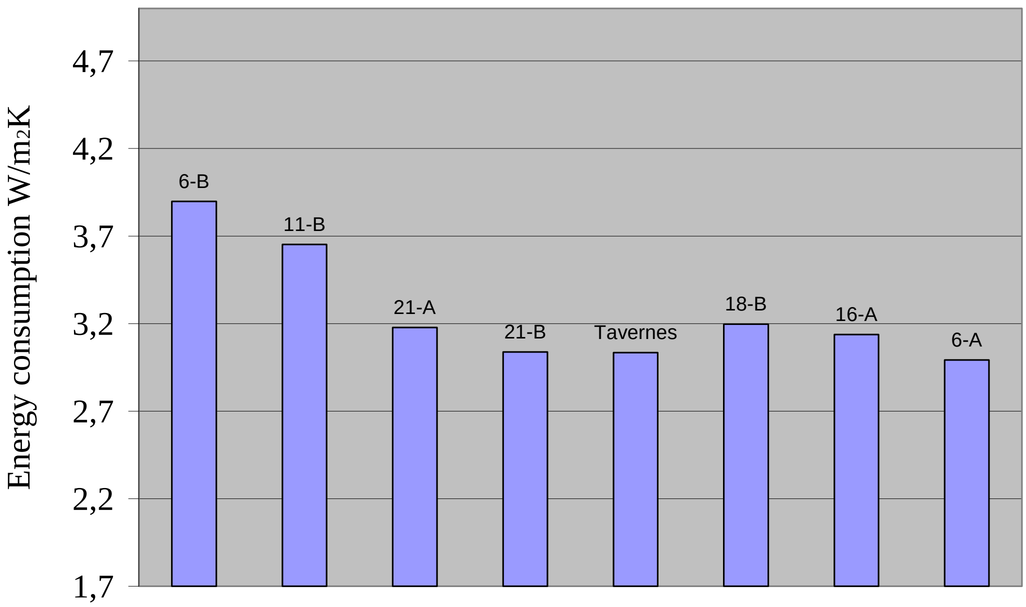

Figure 9. Walls' energy consumption by square meter of dwelling.

Observing the figures 8 and 9 can be appreciated that dwellings, that in principle, had better thermal behaviour when is analyzed the exterior wall is observed that its characteristics are very similar that other dwellings.

Supposing that the heating only is utilized 8 hours by day, and knowing that the city of Valencia have 515,9 heating degree days with base temperature 15-15. It is obtained that the consumption of the dwellings varies between 18 and 14 kW h m^{-2} $year^{-1}$, some values that compared to results of other works [1,2], for 800 heating degree days they are observed that they vary between 80 and 25 kW h m^{-2} $year^{-1}$. Those results indicate that the values obtained are inside the building of high energy efficiency. In case that the adjacent dwellings were conditioned as the losses would be practically by the facade toward the outside, then the consumption would vary between 13 and 3 kW h m^{-2} $year^{-1}$.

DISCUSSION

The thermal behaviour of different dwellings of a building has been analyzed. Experiences in the unsteady were carried out. And it was found that if the logarithm of the energy consumption by square meter of dwelling was represented (W/m^2K) with respect to the time's inverse (1/hr) could be obtained the value in the steady-state in the intersection with the axis.

It was discussed that the losses by windows could be important. It was compared with a dwelling with fold-up window with vertical axis. While in the other dwellings the glazing corresponded with a window track, being obtained the value of the heat transfer coefficient (U) of the window.

Representing the energy consumption of the exterior walls of the dwellings, after rejecting the losses by the glazing, was obtained that the differences were lows among dwellings. Even thus a pair of dwellings exists that themselves they are not found inside the rank. This would be able due to solar profits of the other dwellings through the glazing, or would also be able due to the predominant wind direction in the experience's execution that would be able to increase them lost in these dwellings.

SUMMARY

In this work a numerical model, that simulates the building's thermal response and evaluates the internal thermal comfort and air quality, in transient conditions, is used. This software, after being validated in a school building with complex topology in Winter and Summer conditions, is used in the thermal project of school buildings, located in the South of Portugal, with low energy consumption level.
In this study a new school building is projected and is evaluated an existing one, in Winter conditions. The new school building, with 118 compartments, will be used for teenager students, while the existent building, with 25 compartments, is used for infant students. In both school buildings the internal air temperature and the global thermal comfort levels, using the PMV index, that students are subjected, are calculated.

INTRODUCTION

In the Algarve region, located in the South of Portugal, with a climate with Mediterranean characteristics, is very important to develop school buildings, adapted to this region, that can promote the increase of the comfort conditions for students, teachers and other occupants, as well as to promote the decreasing of energy consumption level for the buildings. In general, in Winter conditions the external air temperature values are relatively lower and the solar radiation are relatively higher, in Summer conditions the external air temperature values are very higher and the solar radiation is also very higher and, in Spring and Autumn conditions, the external air temperature values and the solar radiation are higher. The teenager students are, in general, in holidays during the Summer conditions, nevertheless most of the infant students are in holidays only in August.
In general, in all school buildings, in Winter conditions, renewable resources are used, like direct solar radiation, in order to increase the internal air temperature level, nevertheless in Summer conditions is important to use adequate shading devices to reduce this direct solar radiation. The compromise of these two situations implicates a detailed study to the building thermal behavior, considered the several buildings structure details, the orientation in new buildings and inclusively the surrounding buildings.
In this study, the thermal results of a new and of an existing building, for two distinct students ages are analyzed in Winter conditions. In the first one, that will be built in the future for teenager students, the best building orientation that can promote acceptable thermal conditions is analyzed, while in the second one, used by infant students, the present thermal conditions are evaluated, including the influence of surrounding buildings, and some improvements in order to increase the internal thermal comfort and air quality conditions are

promoted. In all situations, in this study, only is considered the natural air renovation, the occupation cycle is not considered, the windows and doors are closed and the internal curtains are open.

NUMERICAL MODEL

The multi-nodal buildings thermal behavior model (see details in [1]), that works in transient conditions, is based in energy and mass balance integral equations. The energy balance integral equations are developed for the air (inside the several compartments and ducts system), the different windows glasses, the interior bodies (located inside the several spaces) and the different layers of building's main bodies and ducts system, while the mass balance integral equations are developed for the water vapour (inside the several spaces, ducts system and in the interior surfaces) and air contaminants (inside the several spaces and ducts system). In the resolution of this equations system the Runge-Kutta-Fehlberg method with error control is used. The model considers the conductive, convective, radiative and mass transfer phenomena. The conduction is verified in the building's main bodies (doors, ceiling, ground, walls, etc.) and ducts system (fluid transport) layers. In the convection the natural, forced and mixed phenomena are considered, while in the radiation, verified inside and outside the building, the short-wave (the real distribution of direct solar radiation in external and internal surfaces) and long-wave (heat exchanges between the building's external surfaces and the surrounding surfaces and among the internal surfaces of each space) phenomena are considered. In the radiative calculus the shading effect caused by the surrounding surfaces and by the internal surfaces is considered.
The input data in the software are the geometry (introduced in a three-dimensional design software), the boundary condition, the materials thermal proprieties and other conditions (like the external environmental and geographical conditions, the initial conditions, the several heat and mass load, the occupation cycle, the occupants' clothing and activity levels and the air ventilation topologies).

SIMPLIFIED BUILDING GEOMETRY

The analyzed modern school building (see Figure 1), occupied by teenager students, is divided in three floor levels (the first floor, the second floor and the roof) and three blocks (West and East Block used for lessons and North Block used for the nourishment and the administration). Each floor is formed by different compartments, building's main bodies and windows glasses. In relation to the main bodies all existing external bodies that promote shading effects were also considered. In this analyzed modern school building, that will be built in Albufeira, with three floor levels, divided in 118 compartments, 1986 building's main bodies and 231 windows glasses, are considered.
The second building (see Figure 2), occupied by infant students, divided in 24 compartments, 498 building's main bodies and 42 windows glasses are considered. This building, built in Olhão, has three classrooms, for 3, 4 and 5 years old children, and other spaces for offices, administrative, WC, teachers and non teachers staff and meeting room.
In Figures 1 and 2, the grid generation used in the numerical simulation of the school building for teenager and infant students, respectively, are presented. This numerical grid, used in the internal and external direct solar radiation determination, was spaced 30 cm in both directions.

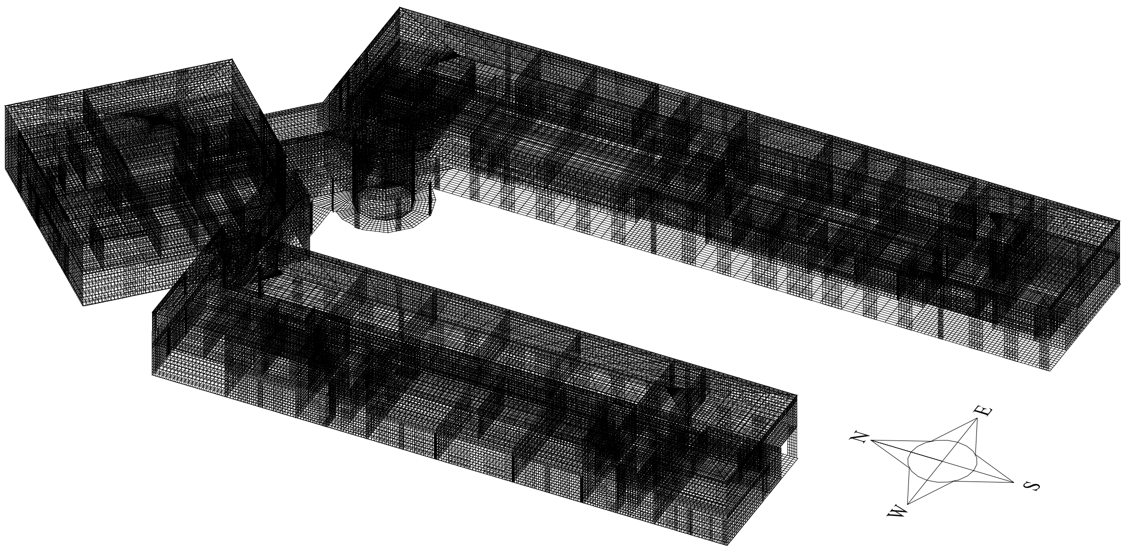

Figure 1. Grid generation in the new school building for teenagers, used by children between 15-18 years old. This geometry is based in the “Escola Secundária de Albufeira”.

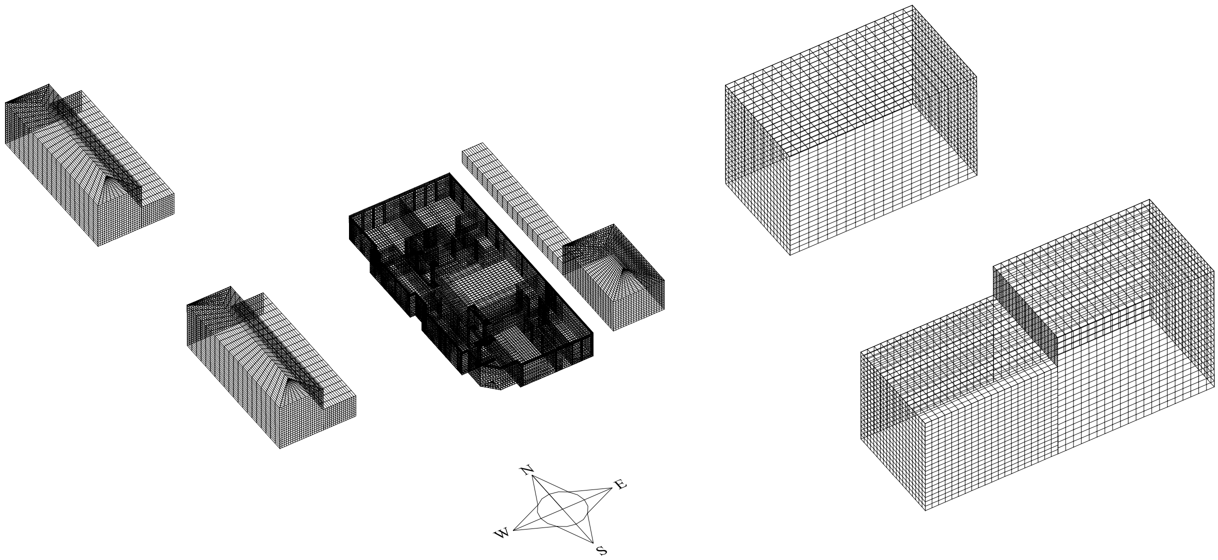

Figure 2. Grid generation in the school building for infants, used by children between 3 to 5 years old. This geometry is based in the “Jardim-de-Infância Nº1 de Olhão”.

RESULTS AND DISCUSSION

In this study, the software that simulates the school building’s thermal response, with complex topology, in transient conditions, and evaluates the indoor thermal comfort and air quality levels was used. After being validated this numerical model in Winter (see [2]) and in Summer (see [3]) conditions, two different buildings situations, for teenagers and infants, are analyzed.

In these simulations the doors and windows were closed and the internal shadings devices were open. The air exchange rate by natural renovation of 0.71 h^{-1}, determined experimentally in [4], and the non-occupation are also considered in the simulation.

The new and the existing buildings, used for teenagers and infants, respectively, were studied in Winter conditions. In both school buildings, in order to evaluate the real building thermal inertia, the previous 5 days were also simulated.
In this simulation, in order to promote acceptable thermal comfort level, was decided to use the Category B of [5].

School Building for Teenagers

The school building for teenagers was subjected to a preliminary study in order to analyze the influence of the building orientation in the thermal behavior. In accord to the energy consumption decrease and thermal comfort increase philosophy, was decided to orientate the building in the South-North direction, with the classroom windows turned East and West. The idea of this philosophy, mainly in Winter conditions, is to use the solar radiation as heating system.
The evolution of internal air temperature and thermal comfort level, for the classrooms, the laboratories, the offices and the corridors are presented, respectively, in figures 3, 4, 5 and 6. In figure 3 the classroom number 18, with windows turned North, is located in the first floor, while the other classrooms are located in the second floor: number 60 in the West block with windows turned West, number 61 in the West block with windows turned East, number 103 in the East block with windows turned West and number 115 in the East block with windows turned West.

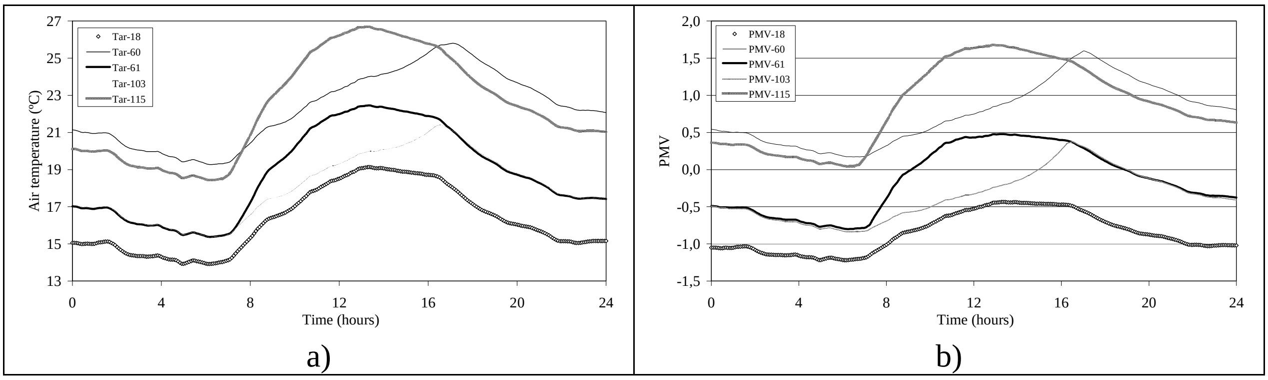

Figure 3. Internal air temperature a) and thermal comfort level b) evolution for the classrooms.

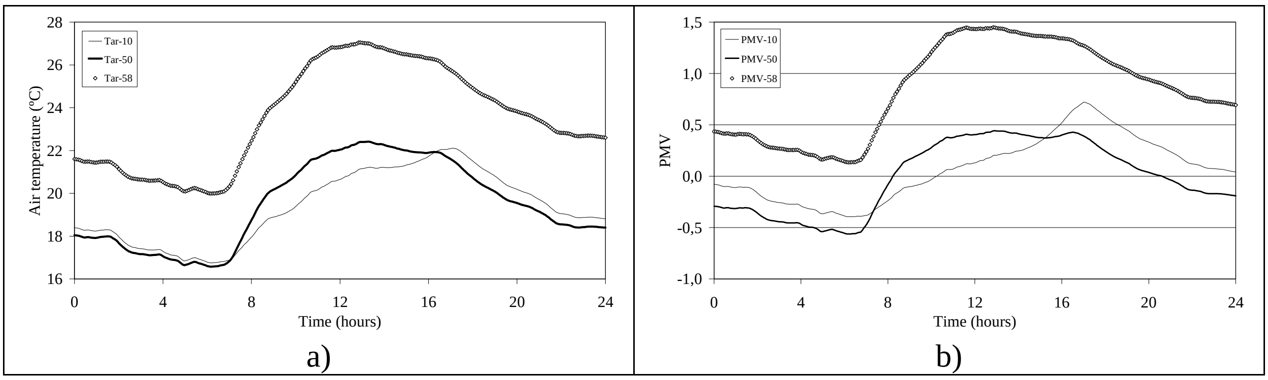

Figure 4. Internal air temperature a) and thermal comfort level b) evolution for the laboratories.

In figure 4 the laboratories 10, 50 and 58 are located, respectively, in the first floor in the West block with windows turned East and West, in the first floor in the East block with windows turned East and West and in the first floor in the East block with windows turned East, West and South.

In figure 5 the offices are located in the second floor in the North block, with windows turned West. The window of the office number 81 is shaded by the West block, while the windows of the office number 82 are not shaded.

In figure 6 the corridor number 30 is located in the first floor, while the corridor number 90 in the second floor. Both main corridors, located in the East and North blocks, are equipped with windows turned South-West.

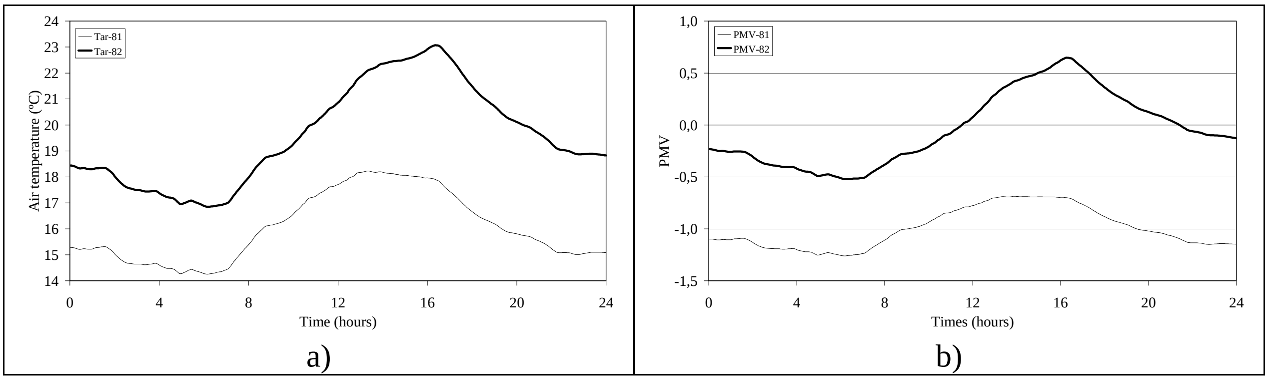

Figure 5. Internal air temperature a) and thermal comfort level b) evolution for the offices.

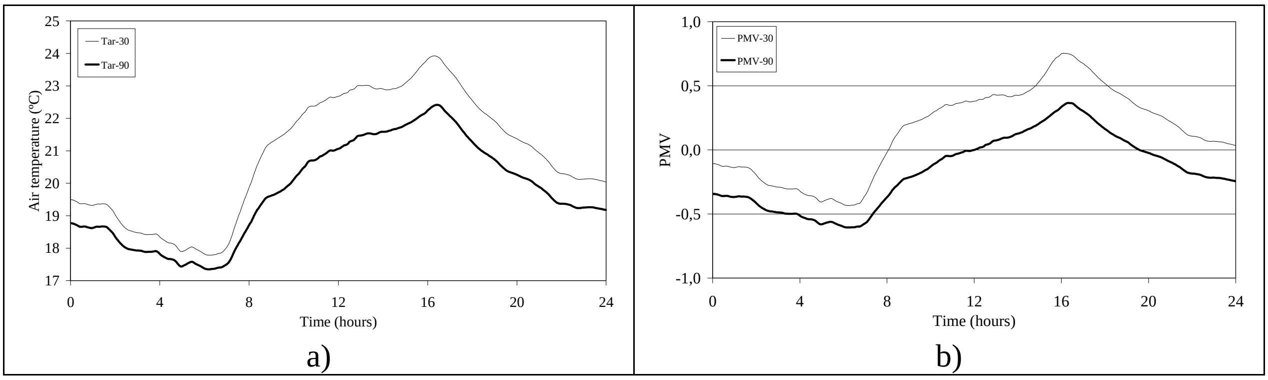

Figure 6. Internal air temperature a) and thermal comfort level b) evolution for the corridors.

In accord to the obtained results is possible to conclude that:

- In classrooms with windows turned East the air temperature increases mainly in the morning, while in the classrooms with windows turned West the air temperature increase mainly in the afternoon. Nevertheless, the shading effect caused by the East block in the morning and the West block in the afternoon is very important;
- The classrooms with windows turned East, shaded by the East block in the morning, the thermal comfort levels are in accord to the Category B of [5]. In the classrooms with windows turned West, shaded by the East block in the afternoon, the thermal comfort level is also in accord to the Category B of [5].
- When the windows are not shaded by the East block, uncomfortable thermal comfort conditions, by positive PMV values, are verified. When the West windows are not shaded by the West block, uncomfortable thermal comfort conditions, by positive PMV values, are also verified. Thus, it is recommended to use internal shading devices in compartments with windows not localized between the blocks.
- In the classroom with windows turned North (see room number 18 in figure 3) the minimum thermal comfort level is not obtained. Thus, is recommended in this compartment to introduce a window turned to West direction;

- In the laboratories, in the first floor, with windows turned to East and West, with some external shading devices caused by columns and blocks, acceptable thermal conditions, are verified. Nevertheless, when the laboratories are built with windows turned East, West and South (see room number 58), uncomfortable thermal comfort levels are obtained by positive PMV values;
- The conclusions verified in the small rooms, like work and help laboratories rooms, are similar to the previous verified conclusions;
- The offices, located in the North block, subjected to shading devices due to the West block are thermally uncomfortable, while the others not subject to shading devices are thermally comfortable;
- In the main corridors, with windows subjected to solar radiation, thermal comfort conditions are verified, while in the others this is not verified;
- Similar conclusions are verified in the other spaces. Nevertheless, the other spaces (like auditorium, canteen, students' room, teachers' room and library) with high occupation level are suggested to be analyzed in a numerical simulation with occupation.
- In other spaces, located in the second floor in the North block, like secretary and offices with windows subjected to shading devices, the introduction of a heating system is recommended.

School Building for Infants

In this study two kinds of simulations were made: with and without surrounding buildings. In figure 7 the evolution of the air temperature value, in compartments with windows turned to West (room 18) and East (room 11), with and without surrounding buildings are presented.
In the results presented in figures 8 and 9 the surrounding buildings effects are considered. The evolution of the air temperature and thermal comfort level for the classroom is presented in figure 8. Finally, in figure 9 the air temperature evolution in the atria, corridors and playground are presented.
The classroom number 3 is equipped with windows turned South, the classroom number 13 is equipped with windows turned East and North, while the classroom number 14 is equipped with windows turned West and North.
The atrium number 2 is equipped with windows turned to South and West, the corridor number 25 is interior and playground number 10 is equipped with windows turned to East.

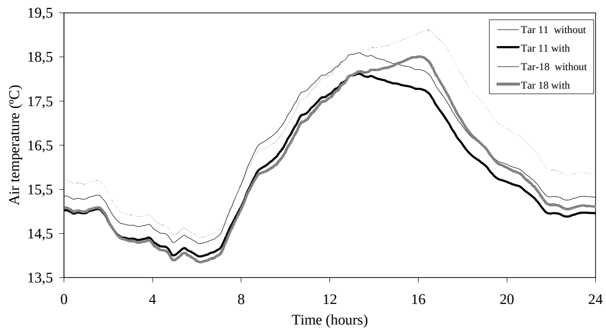

Figure 7. Internal air temperature with and without surrounding buildings.

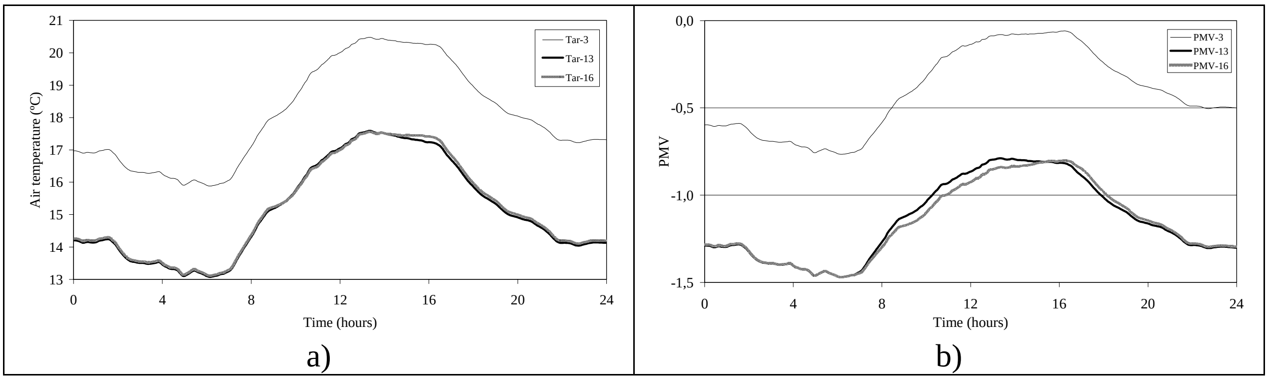

Figure 8. Internal air temperature a) and comfort level b) evolution for the classrooms.

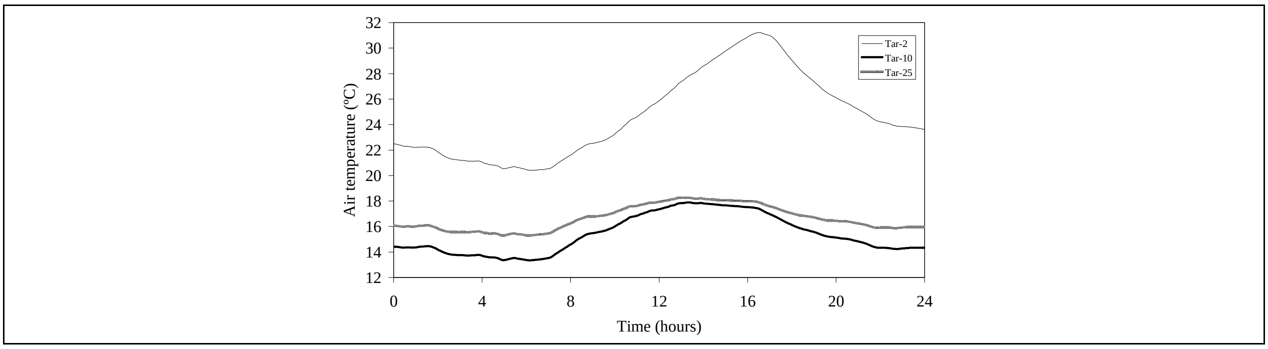

Figure 9. Internal air temperature for the atria, corridors and playground.

In accord to the presented results is possible to conclude:

- It is important, in a numerical simulation, to consider the surrounding buildings. In general, the introduction of the surroundings buildings decreases the internal air temperature level. The main difference in compartments with windows turned East is verified around 9 a.m., while in compartments with windows turned West is verified around 17 p.m.;
- In the classrooms with windows turned South, thermal comfort levels by negative PMV values are verified, nevertheless, in classrooms with windows turned North the thermal comfort levels are not verified;
- Finally, the air temperature in the atria area, verified during the day, is very high. Thus, in future works is suggested to consider the atria spaces as air collectors and to use this air to heat the classrooms with windows turned North.

CONCLUSIONS

In this work a numerical model, that simulates the building's thermal response and evaluates the internal thermal comfort and air quality, in transient conditions, is used in the thermal project of two school buildings, located in the South of Portugal, used by teenager and infant students.
It was verified in school buildings for teenagers, in classrooms, help laboratories and work rooms with windows located between the blocks, in general, are subjected to shading devices in the morning (caused by the East block) and in the afternoon (caused by the West block). The rooms with windows not located between the blocks are thermally uncomfortable by positive PMV values. It is suggested to introduce, in these windows, internal shading devices. Other particular situations as uncomfortable conditions are verified in spaces with windows

turned South, by positive PMV values, in spaces with windows turned North, by negative PMV values, and in spaces with windows shaded by other blocks, by negative PMV values.
In the school building for infants was verified that the surrounding buildings must be considered in the numerical simulation. It was also verified that the classrooms with windows turned South are thermally comfortable, nevertheless the classrooms with windows turned North are thermally uncomfortable. It is suggested in future simulations to consider the warm air in the atria to increase the thermal comfort level in classrooms with windows turned North.
In future works, more simulations are recommended, with inclusion of the occupants and ventilation, and other validation tests, mainly considering the surrounding buildings shape. The presence of occupants in the simulation will increase the thermal level and the introduction of the air ventilation decrease this level. Nevertheless, in spaces with high occupation level is important to introduce these changes.

Numerical Models for Simulation of Space Thermal Energy Demand

Daniela Popescu, Ema Carmen Panaite and Florina Ungureanu

Technical University Iasi Romania

Corresponding email: daniela_popescu@tuiasi.ro

SUMMARY

The paper presents soft computing methods developed for simulation and prognosis of space heating energy consumption using statistic and neural networks models.

The statistical model is a nonlinear one, based on weighing of the input variables: the outdoor temperature, the indoor temperature, the wind velocity, the supply temperature at the exit of the substation, the average fluid flow rate one hour ago and the outdoor temperature T_τ at a previous time. A detailed analysis that is referring to the heat transfer through the inertial structural elements is developed.

Artificial neural networks (ANNs) are computational systems that recognize patterns based on the data used to train them and may be used to make predictions of the output value for new different input data. The training and prediction results of proposed ANN in comparison with statistical model are presented. For both models, predicted and experimental values of heat load demand are well matched and highlight the success of applying statistic and neural networks models in predicting.

The methods were verified by comparing the modeling results with acquired data via a monitoring system from the District Heating Company of the city of Iasi (Romania).

INTRODUCTION

Sustainable development and increase of energy efficiency are important objectives for European energy research area. About 250 district heating systems work in Romania. Even if a lot of consumers had preferred individual heating, 54% of urban population still uses district heating networks. Documents regarding national saving energy policy stipulate that if 1 Euro is invested for increasing the energy efficiency, then a decrease of 1.26 Euro for acquisition of primary resources is realized. Implementation of national strategies regarding district heating production and distribution [1] is in progress, and financial support for numerous projects concerning rehabilitation and modernization of thermo energetic domain already generated hundreds of millions of Euros investments.

The most important objectives for the Romanian district heating system rehabilitation policy are the improvement of the energy efficiency and technical performance and the diminution of costs and pollutions. The recommended measures require institutional, technological, social, market, and financial decisions. Some of the most important are [2], [3]: process control should be updated according to the actual level of technology, the district heating enterprises should implement an integrated monitoring system involving a database together with regular and systematic control of the network and the substations, the customers should be given technical means and appropriate incentives to control their heating.

It may be noticed that monitoring the thermal energy consumption is essential for an efficient management. In Romania, some control systems exist at the heat source and in the substations, but only a few at the customers. This results in an imbalance of the production and the real need of heating, because little information is available from the customers' side.

In the last years, monitoring system started to be developed in Romania, so detailed information concerning the consumers' heat demand are available. It is time for a new step, the transformation of the district heating systems into demand driven systems. Therefore, soft computing programs are needed and this is the aim of this study. The paper presents soft computing methods created for simulation and prognosis of space heating energy consumption using statistic and artificial neural networks models. Such models allow evaluating the heat load dynamic of buildings. The validation was done by comparing the modeling results with acquired data via a monitoring system from the District Heating Company of the city of Iasi (Romania).

METHODOLOGIES FOR THERMAL ENERGY DEMAND SIMULATION

In order to match heat load demand to the thermal energy generated by a power plant it is essential to know heat load profile. Mathematical models are appropriate to predict heat request of buildings determined by climate and specific construction features. It is all it can be done in design stage, but when a district heating system works, subjective factors as family income, cultural background, ability to pay the bills may bring important changes to the daily heat load profile.

A method of formulating energy load profile for UK domestic buildings has been identified by Yao R. and Steemers K. [4] . They proposed to classify the energy demand into two types of determinants: a behavioral and a physical one. Their work focused on the behavioral determinants influenced by people's occupancy pattern, age, number of persons per household. Interesting results were obtained for energy consumption of domestic hot water, domestic appliances and lighting. For space heating load, a control algorithm related to occupancy pattern has been embedded within the thermal model based on physical factors such as building thermal characteristics, orientation, internal air temperature, control and local climate. Cluster analysis method has been applied based on different scenarios of occupancy patterns and the results are encouraging. Unfortunately, it is difficult to extend these results to Romania, not only because building characteristics are different, but mainly because pressing social problems generate different decisions of the inhabitants.

The prognosis of hourly heat load profile is very important for decentralised power production in "micro-CHP" installed in buildings, a modern solution that has been developed in the last years. For instance, A. Nystedt, J.Shemeikka, and K.Klobut [5] elaborated a computer program for calculating the heat demand of a building supplied by a micro-CHP and connected to the district heating network in order to sell the excess heat. The mathematical model is based on classical engineering equations without disturbing human factors. The study recommends the use of these self-sufficient buildings in East and Central Europe, where a lot of blocks of flats are connected to a district heating network and at the same time to a natural gas network.

A realistic evaluation of the fuel consumption necessary for a District Heating System releases on knowing the total heat request of the users. Barelli L., Bidini G., Pinchi E. M. [6] developed a model of the thermal daily and hourly load of a neighbourhood, based on experimental data. The statistical simulation model uses the power installed in the thermal power plant, the seasonal operation hours, the timetable of the heating service distribution and the outdoor temperature as input parameters. The calculated values differs from the corresponding real data of about 5.5%, a value that was considerate acceptable by the authors.

NOMENCLATURE

a	thermal diffusivity [m^2/s]	T	actual temperature [K]
A	area [m^2]	T_τ	previous outdoor temperature [K]
h	convection heat transfer coefficient [W/m^{2}K]	T_{SP}	temperature at the exit of the substation [K]
k	thermal conductivity [W/mK]	V	wind velocity [m/s]
Nu	Nusselt number	x	spatial coordinate [m]
q	heat flux [W/m^2]	δ	thickness [m]
q_a	average mass flow rate [kg/s]	τ	inertial time [hours]
Q	heat load [W]		
R	thermal resistance [m^{2}K/W]	*Subscripts*	
Re	Reynolds number	i	indoor
t	time [s]	o	outdoor

This paper studies two mathematical models for simulation and prediction of the heat load demand of buildings: a statistical one and an artificial neural network one. The models release on six input parameters: the outdoor temperature T_o, the indoor temperature T_i, the wind velocity V, the supply temperature at the exit of the substation T_{SP}, the average fluid flow rate one hour ago q_a, the previous outdoor temperature T_τ.

The statistical model for calculation of the heat load demand (1) is a nonlinear one, based on weighing of the input variables by means of six constants $k_1 ... k_6$ which may be calculate for each building by regression analysis

$$Q = k_1 + k_2 T_o + k_3 \left(T_i - T_o\right) V^{\frac{4}{3}} + k_4 T_{SP} + k_5 q_a^{\frac{4}{5}} + k_6 T_\tau \qquad (1).$$

The first two terms and the last one illustrate the heat transfer through the building envelope, walls, ceiling, glass, roof and floor. The previous outdoor temperature T_τ introduces the thermal inertia that depends on the structural characteristics of the building. A detailed analysis that is referring to the inertial time spent for heat transfer through the inertial structural elements is presented in the following paragraph. The third term $k_3(T_i - T_o)V^{4/3}$ represents the heat required for air infiltration losses. Generally, the buildings from Romania are characterized by reduced window tightness so that the losses corresponding to the heating of the cold infiltrate air can represent an important component. The fourth term $k_4 T_{SP}$ is used as a corrective term, because the supply temperature at the exit of the substation varies when the values settled for the control loop change. The term depending on the average fluid flow rate q_a indicates that the previous average fluid flow rate has a direct effect on the heat load demand. The heat convection through the distribution pipes and radiators depends on the correlation $Nu = f\left(\mathrm{Re}^{4/5}\right)$, that is equivalent to $Q = f\left(q_a^{4/5}\right)$.

The temperature changes affect the indoor conditions of the buildings after a specific time τ, called inertial time, in this paper. This time parameter depends on the structure of the exterior walls namely on the thickness and thermal conductivity. Because of the heat transfer through inertial building elements, the actual heat load demand at a specific time t will be influenced by the outdoor temperature at a previous time t- τ. The delay may be calculated using the differential heat equation for a plane wall without thermal energy generation:

$$\frac{\partial T}{\partial t} = a \frac{\partial^2 T}{\partial x^2} \ . \tag{2}$$

In order to find the temperature distribution through the wall $T(x,t)$, it is necessary to specify an initial condition and two boundary conditions for asymmetrical thermal load. By the Bernoulli integration method, an exact solution of the equation (2) has been obtained and finally the following relation for the heat flux on the inner surface of the wall [7]:

$$q = -k \frac{\partial T}{\partial x}\bigg|_{x=\delta} = \frac{T_i - T_o}{R} - \sum_n D_n h_i \exp\left(-a m_n^2 t\right). \tag{3}$$

The infinite series solution can be approximated by the first term of the series and thus the heat flux relation becomes

$$q = \frac{T_i - T_o}{R} - D_1 h_i \exp\left(-a m_1^2 t\right). \tag{4}$$

For a given wall structure, the D_1 parameter depends on: the initial temperature distribution through the wall, the constant indoor temperature, the instantaneous outdoor temperature.

The initial temperature distribution into the wall is calculated within the equation (5) and illustrates a steady-state heat transfer characterized by temperatures T_i and T_τ

$$f(x) = T_i - \frac{T_i - T_\tau}{R}\left(\frac{1}{h_i} - \frac{x}{k}\right), \tag{5}$$

where T_τ is the outdoor temperature corresponding to the initial conditions, respectively outdoor temperature at the previous time t- τ and R is the thermal resistance calculated with the equation

$$R = \frac{1}{h_i} + \frac{\delta}{k} + \frac{1}{h_o}. \tag{6}$$

The m_1 constant depends on: the thermal conductivity k, the thickness δ and the convection heat transfer coefficients h_i and h_o.

The final form of the heat flux equation due to thermal inertia is:

$$q = \frac{T_i - T_o}{R} - const\left(T_\tau - T_o\right)\exp\left(-a m_1^2 t\right). \tag{7}$$

In table 1, the values of the parameter time τ for different building structures are calculated. Thermal insulation consists of extruded polystyrene with thickness δ = 0.084 m and thermal conductivity k = 0.044 W/mK.

Table 1

Wall structure	Thickness [m]	Thermal resistance [mK/W]	Inertial time [hours]
Reinforced concrete	0.29	0.3095	8
Vertical cavity bricks	0.24	0.487	8
Clay bricks	0.4	0.887	12
Reinforced concrete + thermal insulation	0.20+0.084	2.076	9
Vertical cavity bricks + thermal insulation	0.24+0.084	2.396	9

In this study, numerical simulation procedures based on the statistical model (1) are developed for a reinforced concrete structure of 0.29 m thickness, a type of building common in Romania. For this type of wall the inertial time is 8 hours.

Data acquired in the period 1-31 December 2006, with a monitoring system from the District Heating Company of Iasi (Romania), has been used for simulation and prediction. The constants k_1, k_2, ...k_6 were estimated by regression analysis using the *nlinfit* function from Statistics Toolbox of MATLAB.

The second approach is focused on the artificial neural networks (ANNs) modeling. ANNs are built from a large number of very simple processing elements, neurons that individually deal with pieces of a big problem. A neuron multiplies an input by a set of weights, and nonlinearly transforms the result into an output value. The power of neural computation comes from the massive interconnection among the neurons and from the adaptive nature of the parameters (weights) that interconnect them. The neurons are connected in different topologies. Typically, an ANN has an input layer, at least a hidden one and an output layer.

A backpropagation ANN is the most common type of neural network and it undergoes its learning phase by calculating the error between the predicted and measurement values. The ANN topology chosen for modeling incorporates a hidden layer that is used to establish the relationships between the input variables and the output to minimize the error between the measurement and predicted output. The hidden layer has 27 neurons, the activation function is tanhsigmoid and the learning rule used is delta rule.

In the training phase the correlative patterns between various inputs and the corresponding outputs for different patterns of input data were identified and learnt by the ANNs. The epoch size is the number of training cases the model goes through before it readjusts the weightings of the processing elements that determine the value of the output. Once the NNs has been trained, the weights are frozen, the testing set is fed into the network and the network output is compared with the desired output in order to validate the ANNs performance.

RESULTS

Several buildings were chosen for this study. Some results obtained with the statistical model (1) based on data from six representative days are presented in Table 2. The error parameter was determined with the equation

$$r = \left| \frac{Qm - Qe}{Qm} \right| \cdot 100\% \tag{8}$$

where Qm and Qe represent the measured and the estimated thermal energy demand for an entire day. The mean square error (R) and the relative error parameter (r) for the simulation model were calculated for every building.

Table 2

	k_1	k_2	k_3	k_4	k_5	k_6	R	r
B1	-35.495	0.0655	-0.0226	-0.0013	0.1535	1.1194	0.9491	0.0036%
B2	-39.504	-0.0229	0.0331	0.0008	0.0204	1.4067	0.9232	0.0046%
B3	-28.760	-0.5250	-0.0474	-0.0024	0.1373	1.0220	0.9095	0.004%
B4	-24.661	-0.1146	-0.0663	-0.0019	0.2562	1.1038	0.9518	0.0026%

The purpose of this work is to develop accurate prediction models. The values of the relative error parameters, both for the statistical model and the artificial neural networks models are presented in table 3.

Table 3

r%	Statistical Model		Articifial Neural Networks Model	
	2nd December 2006	14th December 2006	2nd December 2006	14th December 2006
B1	2.34	3.04	3.76	2.14
B2	4.35	3.16	3.96	3.29
B3	0.60	1.18	0.44	0.05
B4	0.58	2.94	4.38	0.33

It can be noticed that the differences between the measured and the predicted energy during an entire day is less than 4.5%, an error considered acceptable [6]. In order to find if these models may be used to predict the heat load dynamic of buildings some graphs were drawn.

In figure 1 an artificial neural networks model is presented. The mathematical model pursues with accuracy the experimental data. Figs 2-5 show the experimental and the predicted values in the test process of the statistical and the artificial neural networks models. The predicted values were obtained by using experimental data for other days not considered initially as representative. Details regarding the difference between measured thermal energy marked with a thin line and predicted data marked with points indicate a remarkable match between the aspect of the graph for the measured data and the profile of the graph for the predicted data. This observation indicates that statistical and artificial neural networks methodologies presented in this paper are recommended not only to appreciate the necessary heat load for a future day, but also to predict the heat load dynamic of a building.

CONCLUSIONS

The paper studies soft computing methods created for simulation and prognosis of space heating consumption. Because of overcome problems connected with constructing a reliable analytical model for buildings heat load demand, a statistical model and an ANN one were studied. This approach is strongly based on the accuracy of a large collection of acquired data via a district heating monitoring system. The models were verified by testing different experimental data collected in a substation from the District Heating Company of the city of Iasi (Romania).

The statistical model is a nonlinear one, based on weighing of the input variables by means of six constants which may be calculate for each building by regression analysis. A detailed analysis that is referring to the inertial time spent for heat transfer through the inertial structural elements is presented.

An ANN with backpropagation topology, one hidden layer, the sigmoidian activation functions and generalized delta learning rule was chosen. For each building, the ANNs were trained for 3000 epochs and the obtained results were very good, this meaning correlation coefficients higher than 0.95.

The error parameter calculated for both models is less than 4.5%, denoting that errors introduced by data processing in models construction do not exceed the inherent errors resulted from data acquisition. The graphs drawn with measured and predicted data indicate that the models are appropriate also for the prediction of the heat load's dynamic.

ACKNOWLEDGEMENT

This paper is based on the research project "Intelligent Systems and Methods for Optimization, Monitoring and Control of District Heating Networks" financed by the Ministry of Education and Research from Romania (Research of Excellence Program 2006).

The authors would like to thank to the staff of Iasi District Heating Company and to ELSACO Company for providing some of the acquired data.

SUMMARY

This paper discusses several issues concerning the CFD analysis or car parks during fire situations. A common modeling approach and given parameters are needed to obtain reliable results for the indication of the performance of the smoke evacuation systems. There are many modeling parameters which influence the results. CFD is a powerful tool that can be used for smoke evacuation simulation when properly used. There is a clear need for a simulation guideline that describes the following points:

- Demanded mesh sizes
- Detailed fire curve
- The fire material composition and particulate soot yield.
- Description of visibility calculation method.
- Turbulence model
- Fluid properties
- The time steps to be analyzed.
- Parameters to be analyzed (including scale).
- Clear description of demanded performance.

For the different steps in the modeling process parameters of importance are discussed. An advisable use of parameters is given either based on practical experience or on literature.

INTRODUCTION

Due to the increasing population density in the urban environment, the need for car parking spaces is growing. More and more large scale underground parking lots are being developed world wide. With this growth the concerns regarding safety within enclosed parking lots arose. Especially fire and smoke control became more difficult during the development of ventilation systems and legislation. Legislation mainly is based and developed upon dimensioning rules and simple calculation. Followed by implementing demands and wishes of the local authorities [1]. Nowadays mostly CFD (Computational Fluid Dynamisc) is used to verify the smoke and fire control by the proposed ventilation system.
The application of commercial CFD packages in verifying the efficiency of the safety ventilation systems has grown significantly in recent years. However, the available calculation procedures allow the user a very wide margin of freedom in the selection of the algorithms and related coefficients to be used in each case, which can lead to appreciable deviations in the end results [2, 3]. The inexistence of standards at European level, which could set clear criteria and guide the analyst through the simulation process, adds to this effect. The flexibility of the CFD tool is one of its biggest advantages but also its biggest threat, as the number of variables and parameters that it manipulates is significant and must be adapted to each type of calculation. It is therefore important that standard procedures are defined in order to ensure the reliability of the results.

The study presented in this article investigates and correlates several calculation techniques in order to define the complete calculation procedure. It includes several practical recommendations for preparing and running complete simulations, which were identified through extensive experience in this field.

RESULTS AND BEST PRACTICE

The simulation to predict the performance of a parking ventilation system is conducted in several steps. Per step several choices can be made which have different levels of consequences for the end results. The modeling steps are discussed briefly including the possibilities for the simulation tool user. Furthermore the choices for best practice are proposed.

Building and meshing the simulation domain

When translating the architectural and ventilation design drawings in a 3-dimensional model an adequate level of detail should be chosen in order to obtain reliable results. The level of detail affects the number of cells and will eventually affect the computation time. Small structures result in small cells. When defining the importance of details a simulation expert should consider and or research the effect of an object on the fluid flow. In case of a parking it is of importance to at least include beams and pillars. Furthermore the architectural design characteristics need to be evaluated. If the width of an object is smaller then 100 mm it is possible to neglect the object, if it is reasonably assumable that the flow will not be significantly influenced by the object. Beams are of particular importance because of the ceiling jet principle: due to the high temperature of the fire, a small layer of smoke is distributed at high velocity along the ceiling [4].

The fluid volume within the parking will be divided in a mesh grid in order to solve the Navier-Stokes partial differential equations. In many CFD packages the finite volume method is used for representing and evaluating these partial differential equations as algebraic equations. Values are calculated at discrete places on a meshed geometry. "Finite volume" refers to the small volume surrounding each node point on the mesh. In this method, volume integrals in a partial differential equation that contain a divergence term are converted to surface integrals, using the divergence theorem. These terms are then evaluated as fluxes at the surfaces of each finite volume.

The properties of the mesh are critical for the quality and reliability of the results but the available guidelines on this subject do not set clear statements regarding the mesh properties to be used for car fire simulation. There are different types of finite volume elements that can be used, to be known hexahedron, tetrahedron, prism and pyramids (figure 1).

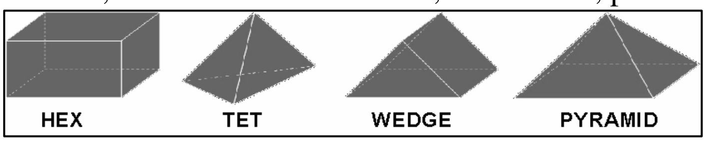

Figure 1- mesh types.

During the performed literature study there are no studies found regarding a comparison between the different mesh types. Based on practical experience it is advisable to mesh the fluid volume with tetrahedron and at least 3 prism layers along the ceiling. A tetrahedron mesh is unstructured, allowing the user to build complex geometries and locally dense mesh. The prism layers are used to simulate near wall flow accurate. In case the number of cells exceed the possible calculation number it is advisable to use a combined structured and unstructured mesh (hexahedron, prism and tetrahedron) mesh to reduce the number of volumes and nodes [5].

Special attention should be given to the mesh definition near the fire and the ventilation system components. For these locations it is advisable to use mesh sizes between 30 and 300 mm, depending on the complexity of the garage. The surface mesh should at least consist of 3 cells in each direction. But the mesh size has a critical influence on the processing calculation resources and calculation time. Care must be exercised not to exceed the number of cells that can be solved with nowadays computers.

Defining boundary conditions

The flow and dispersion of smoke within the fluid volume depends on the assumptions made for the boundary conditions. The boundary of the model can have an energy and or mass influence on the volume. Over the construction itself only a heat transfer can occur. Through openings, supply grills and exhaust grills mass transfer will be established. Furthermore in case of fire and smoke modeling an extra source within the model will be introduced. In the guidelines for car fire simulations in closed parkings there are no practical recommendations on how to model these components.

Supply grills can be modeled by representing the flow characteristics on either the grill surface or on a surrounding box. In case of fire modeling density differences will occur, which can influence the impulse of the supply air in case of the box method.

In the different guidelines there are no statements or recommendations made regarding the modeling approach. It is assumable that the slab is a heavy construction. Accumulation of heat in the concrete structure will influence the temperatures within the fluid volume. The temperature differences within the solid domain are large. It can be assumed that 3-dimensional conduction will occur. Most CFD packages include a simple wall heat transfer model. The software in that case calculates the 1 dimensional temperature difference dependent heat transfer according to the average heat transfer coefficient. In case of fire modeling this will over exaggerate the energy loss from the parking. Resulting in under estimating the temperatures in the fluid domain. In case a solid is taken into account in the model energy losses will be influenced by the accumulation and three dimensional heat transfer.

Fire modeling

For modeling the fire itself, two procedures are available: the combustion model and the inert fire model, each with its own advantages and disadvantages. When using a combustion model the different materials and their properties need to be added to the simulation. Once a predefined part of the car catches fire, the fire spread is calculated as a function of the spatial distribution of temperature, fuel, oxygen and their variation in time. Although this method is the most realistic, the calculation time and complexity of this type of simulation are very high and the results difficult to interpret. An added obstacle is that it requires a very large amount of input parameters that are normally not available.

In the inert model, a flame domain is created in which the energy is released. Smoke is added to the model in the ‘ground’ surface of the flame domain. Fire growth and decay can be controlled by the user as well as the smoke production, whose mass flow is in this case related to the rate of heat release from the car fire. This enables designers to compare results for different systems and or different parking layouts.

In both cases radiation is excluded from the model. It is not possible to correctly model the radiation from a smoke cloud, due to the lack of reliable data.

The inert model gives a good representation of the situation occurring during a fire resulting from a fixed burning process. Beside the fact that the results are comparable to experimental data [5, 6], it is also the best choice regarding time efficiency. The flame model can be presented on top of the car in which the energy is released. It is important to use fire curves per car, since the energy is released in that particular flame domain. The curve shown in figure 2 represents experimental data of the heat release rate for one car based. Depending on the local legislation the curve can be changed regarding the total energy and mass assumed to be burned during the fire. Nevertheless the growth and decay are equal. The criteria for defining flash-over between the first and second car depends on local legislation. It is advisable that the second car catches fire after 8 minutes and the third 4 minutes later. In a discussion with local authorities a maximum time for the fire department to extinguish the fire should be set, normally between 20 and 25 minutes. The period after extinguishing the fire should also be simulated in order to indicate the time needed to clear the garage.

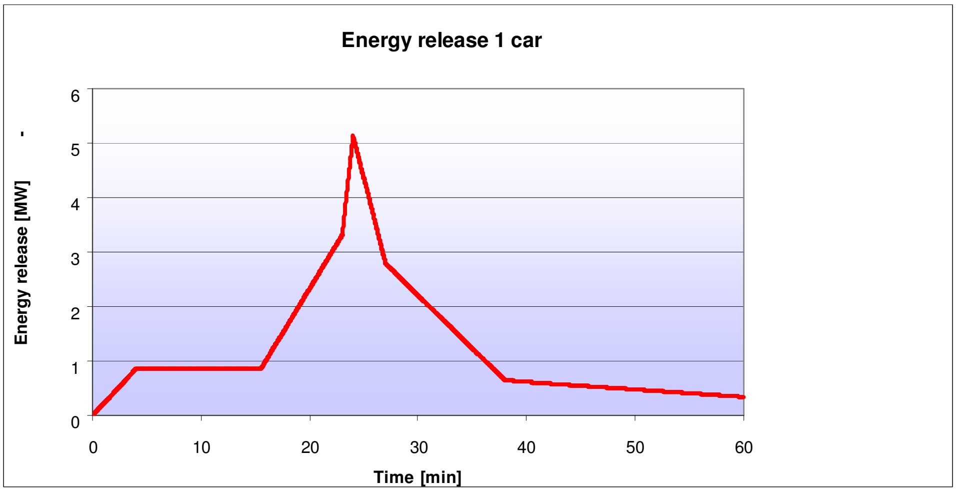

Figure 2- one car energy release curve

Smoke modeling

The most commonly used criterion to quantify the smoke spread and to judge the performance of the parking ventilation systems during a fire situation is the resulting visibility in the occupied spaces. The visibility in the smoke cloud is calculated as a function of the root mass per volume and the burned material. The calculation methods are based on empirical data resulting from several test performed to relate soot production to mass loss of specific material samples. The results of these tests are published in terms of particulate soot yield or the optical density of smoke [8, 9, 10]. The optical smoke density depends also on the type of combustion, this being fuel dependent or oxygen dependent, in other words, a well or poorly ventilated fire. It is known that the effect of smoke on the visibility is also depending on temperature; unfortunately, no empirical laws have been derived describing this effect. It is also not possible at this moment to calculate the coalescence of smoke particles when they collide.

The smoke mass flow is calculated as function of the total released energy (convective + radiation). The chemical reaction of the burning process is excluded and the smoke mass flow is equal to the mass loss of the fuel (car). A car fire in a parking is classified as a well ventilated fire, the fire is fuel controlled meaning that the oxygen level is not a relevant parameter.

The mass flow is calculated using equation 1:

$$\phi_{m\_smoke} = Q_{fire} / \Delta H_{eff}, \qquad (1)$$

ϕ_{m_smoke} = mass flow smoke production [g/s]

Q_{fire} = energy release car fire [kW]

ΔH_{eff} = Effective heat of combustion [kJ/g]

The smoke optical density corresponding to the assumed composition can be calculated as followed.

$$OD = \frac{y_{smoke} \cdot K_m}{\ln(10)}, \qquad (2)$$

OD = Optical density [m^2/g]

y_{smoke} = Particulate yield [g/g]

K_m = Extinction coefficient [m^2/g]

The particulate yield corresponds to the composition of materials. The Extinction coefficient for flaming combustion is 7600[m^2/g] [10].
Large scale car fire tests have been carried out by several institutes. The result of these tests is that the optical density of a car fire is estimated to be 400 [m^2/kg]. Results show that the value is in between 200 [m^2/kg] and 600 [m^2/kg] [11 - 17].
The smoke and energy are released in the flame domain. The local smoke temperature is calculated within the CFD program.
Because radiation is not simulated and adiabatic walls are used, a reduction factor is used to calculate the convective heat release. A value of 0.7 has proven to produce reliable results.
The formula for the energy in the sub domain now becomes:

$$Q_{conv} = 0.7 \cdot Q_{fire}, \qquad (3)$$

Q_{conv} = convective energy release [kW]

Sub models

Several additional choices must be made when conducting a simulation process, namely when selecting sub-models used. The most important of these is the turbulence model, of which the most commonly used is the Kappa Epsilon model. This model predicts the behavior of vortices smaller then the local mesh cells and while research has been carried out in order to investigate the bias created by this assumption, its results are commonly accepted.
More precise turbulence models are available, but these result in significantly more complex meshes and computing requirements, which with the computer technology currently available to engineering designers make their use impractical.

Fluid model

The fluid properties in the model should be based on the properties of an ideal gas. In this way the density difference due to temperature is included in the simulation. This is of importance for the exhaust fans, since they exhaust a volume flow. Of course the natural convection depends on density differences as well.

Turbulence model

Underground parking lots are mostly low structures with a large floor area. As discussed before the flow along the ceiling is of high importance. The near wall function is related to the used turbulence model. It should be considered if the used turbulence model gives a well prediction of the flow near the wall. Furthermore the flow around construction parts should be checked. More detailed turbulence model needs a more dense mesh, resulting in larger calculation times. With the current computer technology it is advisable to choice either for the Kappa-epsilon or the Shear Stress Transport turbulence model.

Simulation result analysis
The advanced sophisticated simulation software currently available allows for both steady state and time-dependent (transient) solutions. For the type of problems and phenomena modeled in the case of a car fire, transient simulations must be performed.

The performance indicators used to evaluate the parking ventilation system are visibility [9, 10, 12] and temperature. The effect of soot on visibility depends on the dilution and the burned material. In general the visibility is calculated as follows:

$$S = \frac{C}{K_m \cdot y_{smoke} \cdot \rho_{smoke}}, \qquad (4)$$

C	=	Empirical factor	[-]
S	=	Length of sight	[m]

The empirical factor depends on a large amount of factors, e.g. light-emitting or light-reflecting characteristics of signage elements, individual visual acuity, colour and others. In practice, the following values can be used:

C	=	3	light-reflecting signs
C	=	8	light-emitting signs

The particular yield and extinction factor are both very much influenced by the type of fire (ventilated, smoldering, material etc). Therefore it is more accurate to combine formulas 2 and 3 and use data gained by experience.

$$S = \frac{C}{\ln(10) \cdot Dm \cdot \rho_{smoke}}, \qquad (5)$$

The temperature is used to indicate the situation created by the fire and to evaluate the possible damage to the parking structure. Nevertheless, as the parking is modeled adiabatic the modeled temperature on the construction surface will be higher then what will actually occur.

Parameter analyses
As for each simulation and calculation applies rubbish in is rubbish out, this as well counts for CFD simulations. In order to give an impression of the sensitivity of the smoke/soot production two parameters are analyzed for their maximum and minimum values [18]. As shown in equation 1 the smoke/soot production depends on soot yield, effective rate of heat release and energy release. The total energy release is kept stable for all cases. The most common soot yield is approximate 0.15 [kg/kg]. Material study shows that it can vary between 0.1 [kg/kg] and 0.2 [kg/kg]. The specific rate of heat release is common set at 30 [MJ/kg]. Depending on the type of car considered this can vary between 20 [MJ/kg] and 40 [MJ/kg] . The used fire for the analyses is a 4 minute delay of three cars according to figure 1.

Graphs 1 and 2 show the resulting smoke production in time by varying the parameters as described above. The total range by varying the parameters at the same time is shown in graph 3. The average assumed time for the fire brigade to arrive at the location is between the 20 and 30 minutes. This, as shown in graph 3, results in an absolute minimum smoke production of 5.8 [kg] and an absolute maximum of 68 [kg]. It can be concluded that the system is highly sensitive to these values. As appointed earlier there is a need for clear guidance to create parkings that are equally safe in terms of fire hazards.

SUMMARY

Cooling modern office buildings significantly contributes to their CO_2 emissions during summer. One possible approach to improve their summer energy performance in moderate climates would be to cool the building's floor slab by passing cold air through it at night. During the day, warm ambient air is passed through the cold slab and thus it enters the air-conditioning system of the building at a lower temperature. In order to evaluate the energy performance benefits of such a concept, a combination of full-scale experimental studies, Computational Fluid Dynamics modelling (using ANSYS CFX) and network modelling (using IES Apache and TRNSYS) has been performed. Both IES Apache and TRNSYS models agree well in their predictions and the energy benefit of the concept is clearly demonstrated.

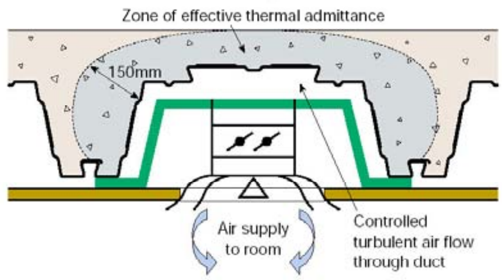
INTRODUCTION

Many modern office buildings need constant air-conditioning in the summer in order to remove heat gains and achieve acceptable levels of indoor thermal comfort. In moderate climates, one promising approach used to reduce the air conditioning energy demand of office buildings without reducing comfort is passive cooling by night ventilation in conjunction with utilising the thermal mass of the building. Passive cooling by night ventilation means passing cool night air through the office space to ensure absorption of the "coolth" by the building elements, such as the floor, walls, furniture etc. However, this system suffers from a lack of control of the amount of "coolth" absorbed and discharged by the office space. As a result the office space is often overcooled in the morning and may require additional cooling to bring temperature to a comfortable level. One way to minimize this effect is to introduce the cooling to the inner parts of the building elements e.g. by embedding air ducts within the floor slab.

The Air Cooled Slab (ACS) concept used in this work is based on a composite flooring system with air ducts, which would offer both an integrated service capability and a thermal storage system. Extensive experimental, Computational Fluid Dynamics and Whole Building Energy studies of the ACS were carried out under the European RFCS funded EEBIS project and details can be found in [1].

Throughout the nighttime during hot periods, cold outside air is passed through the ducts embedded in the slab thereby cooling it. Throughout the daytime, when cooling loads increase due to solar and internal gains and ambient temperature rise, external air is pre-cooled by passing it through the slab. The storage capacity of the slab depends on its thickness and its effective penetration depth. In a typical building with natural ventilation only a relatively thin depth of concrete (typically 50mm to 75mm) is effective for efficient heat transfer and storage

[2]. If the flow inside the slab is enhanced, the thermal capacity of the slab increases for a 24-hour temperature cycle to around 150mm [3], which is illustrated in Figure 1.
The climate in the UK has a large diurnal temperature swing, approximately 12K, with the night minimum temperature during summer being much lower than 22ºC. It means that there is a considerable potential for "coolth" storage during the night time and possibly enough to significantly reduce the need for an air-conditioning system in the building.
Figure 2 illustrates the three modes of operation that characterise the use of the ACS. In the night cooling mode, cold ambient air is forced through the channels using mechanical ventilation. During this mode the temperature of the slab is reduced to approximately 18-20ºC. In the morning, when the ambient air has a low temperature, it is used directly for ventilation (mechanical or natural, mode 2). The passive cooling mode 3 is activated during day when ambient temperature rises and solar and internal heat gains cause the office temperature to cause thermal discomfort. Warm ambient air is passed through the slab and could either be directly introduced (via floor or ceiling diffusers) in the office space or additionally cooled by the air-conditioning system of the building.



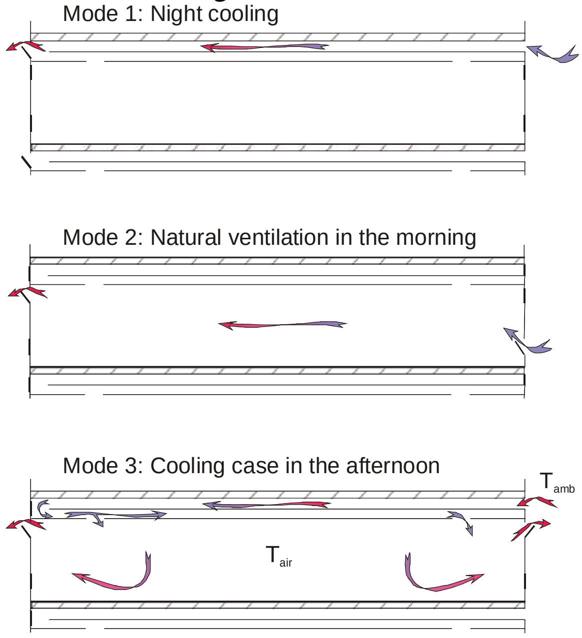


Figure 1 Zone of effective thermal admittance of the ACS (Variation with ceiling diffuser and distribution in the active trough)

Figure 2 Running modes of ACS

Figure 3 shows a cross section of the floor slab. In the inactive channels air does not have a direct contact with the slab and serve as distribution ducts only (Figure 3)

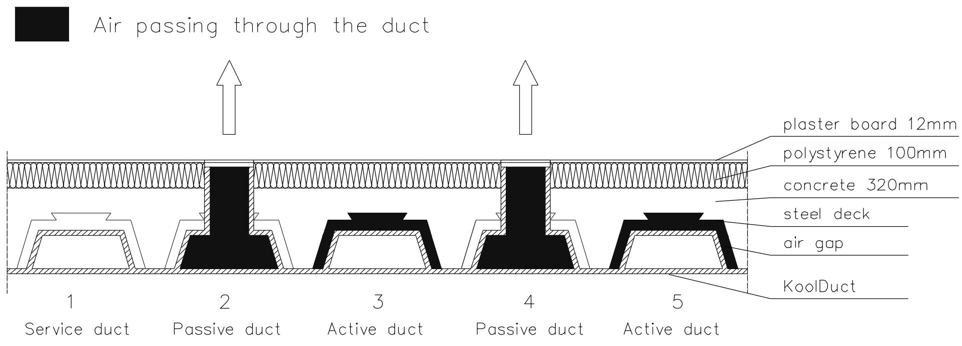

Figure 3 Cross section of the ACS. In the active ducts air has direct contact with the slab. The passive ducts are only used for distribution of the air into the office space and in these air does not have a direct contact with the slab. An additional duct is used for services.

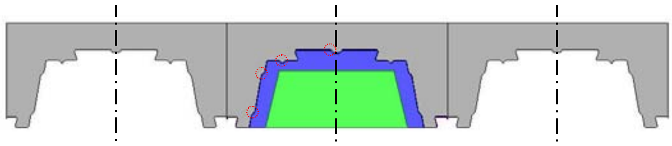
This article presents a numerical study of the performance of the ACS in a realistic energy efficient building. The main objective of this article is to compare the performance of the ACS using two different modelling approaches embedded into two different software packages for building energy analysis (TRNSYS and IES Apache). The rest of the article is organised as follows: the modelling section presents details of the models and their validation followed by a results section. The article concludes with a discussion section.

METHODS

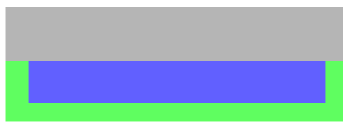
Development of a reduced model of the ACS for use with a whole building simulation models

As mentioned in the introduction of the article a series of experiments were performed on a full scale ACS prototype (12m long, 5 channels) and these results are presented elsewhere [1]. In parallel with the experiments a Computational Fluid Dynamics (CFD) model of the ACS was developed and validated against the experimental data [1]. The results from the CFD model have been used to create a submodel of the ACS for use with IES Apache and this is described in the rest of this section.

The Apache environment provides models for standard HVAC elements, such as rooms, boilers, chillers, heating and cooling coils, fans, chilled ceilings, but a user defined model is needed to account for the effects of the thermal storage of the slab. The ACS is modelled as a separate room, which behaves in a similar way as the ACS. Apache is a zone model in which flow variables are assumed to remain constant within a given zone, which normally represents a room. Each wall of this room is assumed to be at a uniform temperature and a heat transfer coefficient with respect to the average room temperature accounts for the convective heat transfer to the wall.



a)



b)

Figure 4 Reduction of the ACS model for use with Apache. a) sketch of a cross section of the ACS; b) simplified model of ACS for use with Apache. The grey, blue and green areas correspond to concrete, air and insulation, respectively.

A sketch of a cross section of the ACS model is presented in Figure 4a) and the reduced model for use with Apache in Figure 4b). The depth of the concrete corresponds to the depth of the zone of effective thermal admittance of the ACS, which is 150mm, as estimated in [3]. The thermal properties of the concrete in the reduced model are matched with the ones of the experimental prototype. An important parameter controlling the heat transfer to the concrete slab is the surface heat transfer coefficient between the air and the concrete slab and needs to be specified as a parameter in Apache. The heat transfer coefficient depends on the flow rate and a series of 6 CFD simulations for flow rates ranging from 10 l/s to 240 l/s were run with real weather data.

In Apache, the heat transferred to a wall (Q [W]) is given by

$$Q = h_c(T_b - T_s),$$

where h_c ([W/m^{2}K), T_b [C] and T_s [C] are the heat transfer coefficient, bulk room and surface temperature. An energy balance of the ACS gives the following relation:

$$Ah_c(T_s - T_b) = \dot{m}c_p(T_{in} - T_{out}),$$

where A [m^2], T_{in} [C], T_{out} [C], $\dot{m}$ [kg/s] and c_p [J/kgK] are the surface area, inlet temperature, outlet temperature, mass flow rate and heat capacity of the air. We can therefore compute h_c as:

$$h_c = \xi \frac{\dot{m} c_p}{A}, \text{ where } \xi = \frac{T_{in} - T_{out}}{T_s - T_b}.$$

T_{in} , T_{out} , T_b and T_s are found by appropriate averaging from CFD simulations of the ACS at selected $\dot{m}$. By minimizing the residual R:

$$R = \left(\sum_{i=1}^{n} \left(\left(T_{in,i} - T_{out,i}\right) - \xi \left(T_{s,i} - T_{b,i}\right) \right)^2 \right)^{\frac{1}{2}},$$

where the index i runs over the time series for T_{in} , T_{out} , T_b and T_s obtained from the CFD model a value for ξ is found that best satisfies $\xi = \frac{T_{in} - T_{out}}{T_s - T_b}$. The value of ξ minimizing R satisfies $\left(R^2(\xi)\right)' = 0$ and is:

$$\xi = \frac{\sum_{i=1}^{n} \left(T_{in,i} - T_{out,i}\right)\left(T_{s,i} - T_{b,i}\right)}{\sum_{i=1}^{n} \left(T_{s,i} - T_{b,i}\right)^2}$$

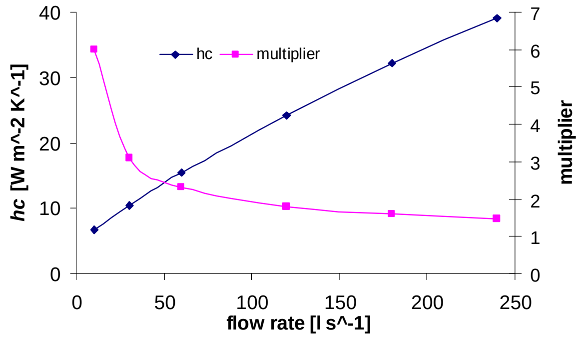


Figure 5 The multiplier ξ and heat transfer coefficient h_c for different flow rates.

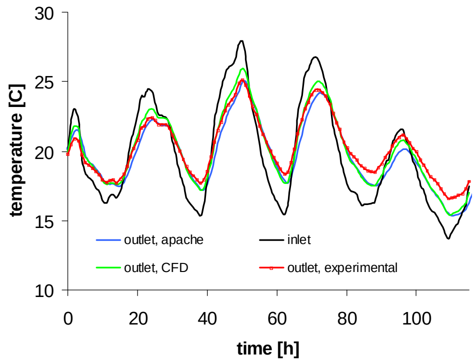

Figure 6 *Comparison between predictions for a single room model of ACS from Apache, experimental and CFD data. The flow rate is 120l/s.*

This procedure applied to flow rates ranging from 10 l/s to 240 l/s gives values for the multiplier ξ as shown in Figure 5. The heat transfer coefficient h_c is finally obtained by substituting $\dot{m}$, c_p and A into $h_c = \xi \frac{\dot{m} c_p}{A}$ and is presented in Figure 5.

IES Apache Model development and validation

The validity of the reduced model has been checked by comparison with results from the full scale physical and the CFD models. In the physical test, ambient air has been passed through the ACS at a fixed flow rate and the air temperature at the outlet has been monitored. Figure 6 shows the inlet (ambient) temperature and compares the temperature at the outlet of the ACS from the physical experiment, from the CFD and IES Apache models. It could be seen that the results from the reduced model compare very well with the ones from the experiment and CFD. Therefore the reduced model could reliably be used to further assess the performance of ACS under realistic conditions.

TRNSYS Model development and validation

TRNSYS is a zone model for building simulation, in which the building is represented by interconnected modules. TRNSYS offers a special type for the simulation of water or air flow through building components. Generally, TRNSYS is working with a transfer function for describing the thermal behaviour of walls and other planar components. For thermally activated building components a special type was developed using a limited two-dimensional, rectangular Finite Differences Model (maximum number of elements: 100). A representative section of the deck system has to be transformed into simplified mesh as shown in Figure 7 for the ACS.

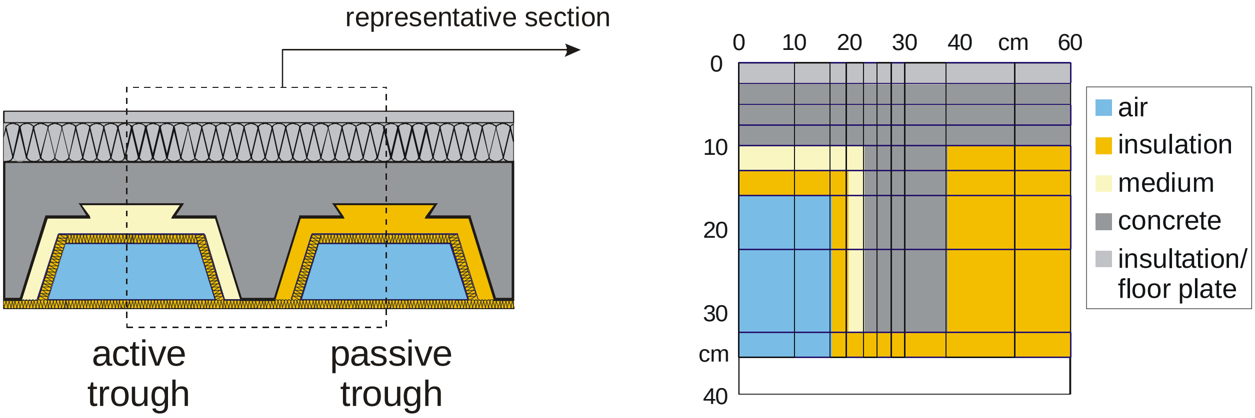

Figure 7 Development for reference section for TRNSYS Type 160 / 360

Based on this reference section the whole active deck element can be described (see Figure 8): In flow direction a partitioning into a number of equivalent sections is assumed (here: 6 partitions, each 2 m). Within a partition a logarithmic development of the medium temperature is considered. To get the full width of the deck element, a sufficient number of reference sections has to be assembled in parallel (here: 6 reference sections).

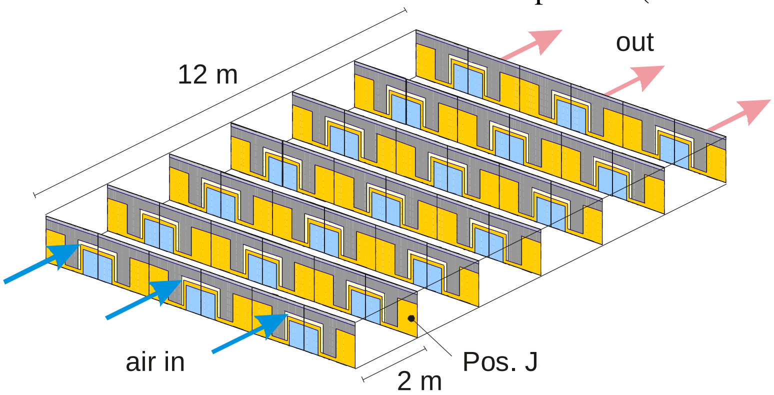

Figure 8 Expansion to a deck element

For the Validation of this numerical model measured data from [1] were taken. This measured data contain the temperature depending on the time (after switching the fans on) and over the length of the deck element. Figure 9 shows, that in the first minutes after forcing the ventilation there is a deviation between measured and calculated air temperatures, but after approximately 1 h the calculations fit very well with the measured values. Figure 10 shows the temperature over the length of the panel, the good correlation (after run time of two hours) is obvious.

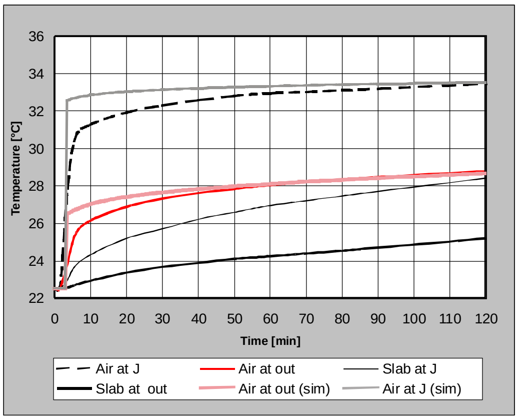

Figure 9 Switching on the panel, comparison of measured and calculated results

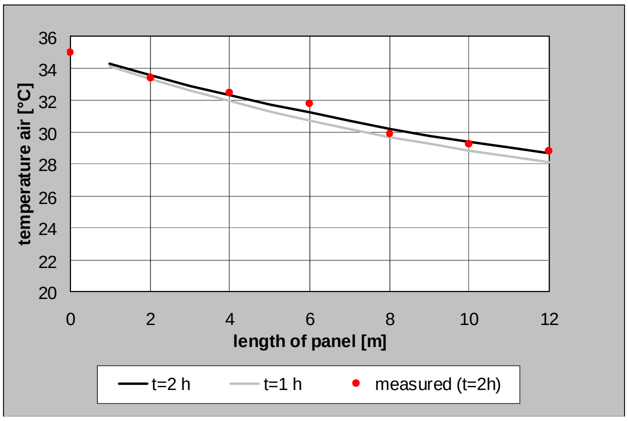

Figure 10 Development of temperature along the panel, comparison of measured and calculated results

RESULTS

The validated numerical models were used to simulate a whole office building, which is illustrated in Figure 11 and has been designed as a part of the EEBIS project [1]. The building has 4 storeys, the façades are oriented north and south, where the south façade is a transparent double façade. This building concept was investigated with the climatic data of Kew, UK, 1994.

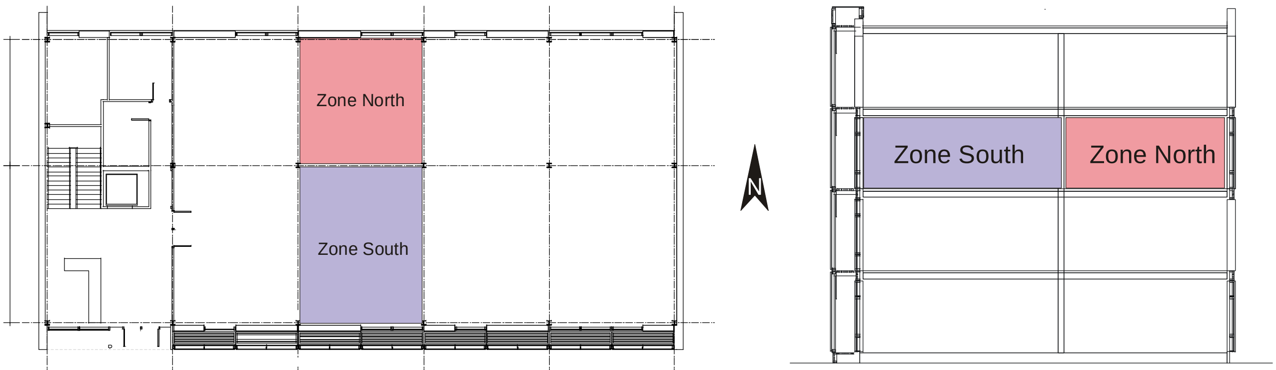

Figure 11 Office building with air cooled slab, ground plan and section plan

Figure 12 shows a comparison of the room temperatures (computed with the Apache and TRNSYS models) for the south oriented part of the third storey of the building. A hot period of the weather data was chosen in order to show the effect of the ACS. In the morning, the room temperature increases as in a conventional building. At noon the room temperature decreases due to the ACS being activated - pre-cooled air is entrained into the room. In the afternoon the air temperature rises again, but not as much as in a conventional building. Parallel calculations without ACS show, that the maximum temperature can be reduced about 4 K. At night, the cool ambient air is used to refresh the "coolth" storage of the ACS system. This work shows mainly two results:

a) relatively lightweight composite deck systems can be used as an efficient passive cooling system,
b) two different simulation tools, which were calibrated against measured values agree very closely.

The efficiency of the Air-cooled slab is shown in comparison to a conventional, non-air-conditioned building. Using a climate of south England, the maximum room temperature can be reduced by about 4 K. Also in combination with an air-conditioning, the results are interesting: the cooling demand (net energy) can be reduced from 10.1 to 2.8 kWh/m²a (set temperature cooling: 26 °C). The good correlation of Apache and TRNSYS results is evident, the differences are below 0.5 K for this investigated period. This shows that under similar assumptions both tools give similar results and could be reliably used to study similar problems.

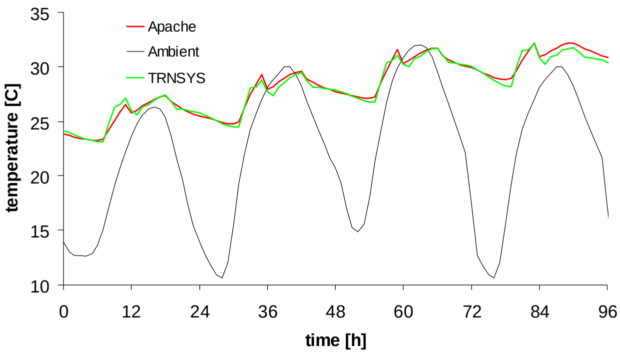

Figure 12 Comparison between predictions from TRNSYS and Apache.

DISCUSSION

Composite deep deck systems, which are the basis for the air cooled slab discussed in this paper, are generally not suitable for passive night cooling. Due to their shape they often come with a false ceiling and the thermal inertia has no contact to the room. The concept of forced air cooling of this deck system changes the situation: The mass of the slab can be efficiently used, the maximum room temperatures are similar to an exposed conventional concrete slab. Additionally the room temperature can be controlled, the surface temperature does not reach unwanted low values and an energy efficient combination with an air conditioning system is possible.

A disadvantage is the need for ducts, flaps and fans to run and control this system. In a further step the energy demand for conveying the air and the control system has to be taken into account. Regarding the investment costs it will be most interesting, if an airconditing system can be removed.

ACKNOWLEDGEMENT

The work on the EEBIS project has been carried out with a financial grant of the Research Programme of the Research Fund for Coal and Steel. These funds are gratefully acknowledged.

SUMMARY

Compared to conventional heating and cooling systems, panel heating and cooling systems offer a number of advantages. Besides the lower air circulation, these advantages especially consist in the factor that the heat exchange between the heating system and the heated room takes place primarily by radiation and less by convection. It has been proved that this circumstance is physiologically advantageous for the occupant. Furthermore, such panel heating systems are very well suited to be used together with reversible heat pump systems, running on regenerative sources of energy.
In order to be able to dimension that kind of systems more effectively and to evaluate their economic efficiency, a software is implemented in MATLAB®. The software is to simulate the heat transfer occurring when panel heating (and cooling) systems are used, as close to reality as possible.
In a first step, the view factors between the surfaces that take part in the radiation exchange are specified. As the surfaces are assumed to be real grey emitters and the dependence of the intensity of emission as well as absorption on the angle is also taken into account, this can be carried out only numerically.
In a second step, an equation system which describes the radiation heat transfer between the surfaces, both heated and not heated, is to be solved. Therefore, either the surface temperatures or the provided thermal outputs need to be assumed. The equation system includes a balance (at steady state) between the heat received by a certain surface through radiation, and the heat lost to the environment through transmission.
In a further step, in addition to the radiation heat transfer, the convective heat transmission is to be taken into account. The corresponding heat transfer coefficients are being determined using Nusselt's laws. An overall heat transfer coefficient, consisting of a convective as well as a radiation part is to be accumulated.
The heat transfer inside the heated panel is also taken into account, and the solution of the corresponding heat conduction equation and the temperature distribution on the heated surface – at steady state regime - are provided by a MATLAB®-PDE-Toolbox. Thereby all the material characteristics of the surface as well as the overall heat transfer coefficient mentioned above are integrated into the solution of Fourier's differential equation as boundary conditions. Graphical presentation of the temperature distribution on the surface is used in order to illustrate the results.

INTRODUCTION

The purpose of this paper is to model the steady state heat transfer processes occurring when using panel heating/cooling systems.

The motivation for this paper consists of:

- product information given by manufacturers of panel heating/cooling systems is often not reliable;
- powerful tools to simulate such systems hardly exist.

On the other hand, the low temperature heating systems and the high temperature cooling systems are more and more used in connection with the re-generable sources of energy and the heat pumps. Thus, they become very interesting from the energy efficiency point of view.

METHODS

In order to be able to make a statement on the characteristics of a heating/cooling panel system, its behavior has to be modeled numerically.
A heating/cooling panel system is responsible to cover the heat loses/gains of the room where it is mounted, in order to provide the comfortable indoor climate.
The general equation for the heat balance of a room (for heating case only) states:

$$\dot{Q}_{nec} = \dot{Q}_{transmission} + \dot{Q}_{\inf iltration} \qquad (1)$$

where:

$\dot{Q}_{nec}$	is the necessary heat to be provided to the room;
$\dot{Q}_{transmission}$	is the transmission heat loss through inertial elements (walls) and non-inertial elements (windows);
$\dot{Q}_{\inf iltration}$	is the heat needed to heat the infiltrated outdoor air up to the indoor temperature.

When panel heating/cooling systems are used, the following types of indoor heat transfer occur:

- Radiation heat transfer between the active panel(s) and the indoor environment, but also between the non-active elements.
- Convective heat transfer between the active as well as the non-active elements and the surrounding indoor air.
- Heat conduction inside the active panels, especially from the heating pipes to the surface.

The whole heat transfer process is modeled with the aid of MATLAB®.
Several sets of data must be initialized – these are dealing with: the room geometry, the surface radiation properties and the ventilation data. This information will be processed further on by the program.
Briefly, the program consists of the following three crucial steps:

- Calculation of the view factors matrix (between all surfaces, assuming real-grey emitters);
- Calculation of the resulting temperatures of the non-active surfaces (temperatures of active panels are given, assumed to be the variable of the controlled process);
- Calculation of the resulting air temperature in the room under survey.

The logical diagram of the MATLAB® program is presented in Figure 1.

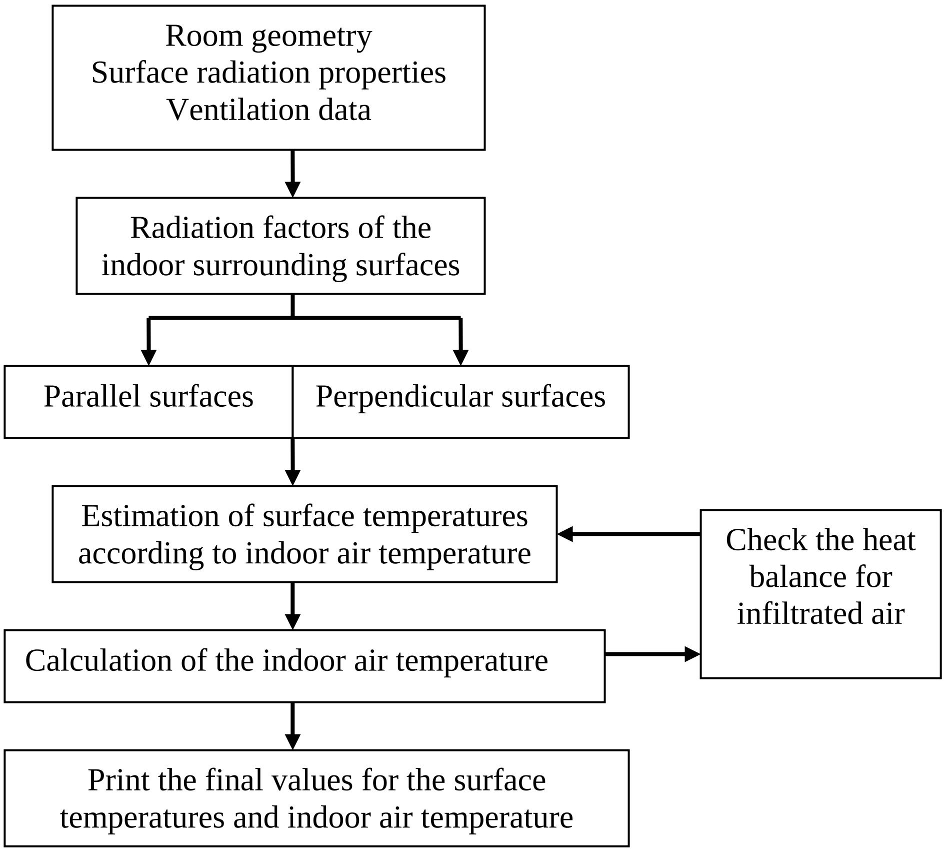

Figure 1. Logical diagram of the MATLAB® program

The geometry of the room modeled as an example in this paper is presented in figure 2.

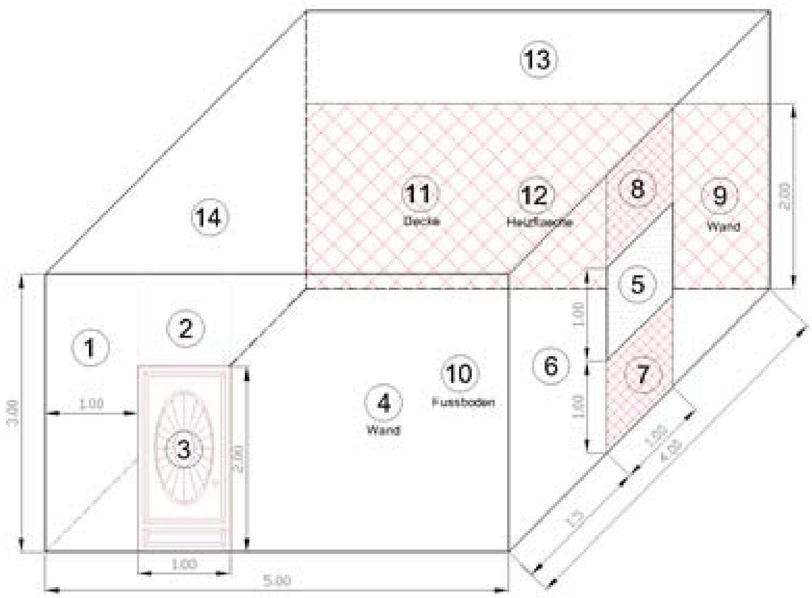

Figure 2. The geometry of the room under consideration

Possible properties for the 14 single surfaces of the example room geometry are given in Table 1.

Table 1. Possible properties for the 14 inner surfaces of the example geometry

Surface number	Emission factor for heat radiation normally on the surface ε_n	Heating surface yes/no	Temperature of the heating surface	Modified U value	Temperature of outdoor air	Observations
	-	-	°C	W/m²K	°C	-
1	0.93	no	-	1.20	20	Interior wall
2	0.93	no	-	1.20	20	Interior wall
3	0.93	no	-	2.40	20	Interior door
4	0.93	no	-	1.20	20	Interior wall
5	0.90	no	-	2.80	-15	Window
6	0.93	no	-	0.37	-15	Outer wall
7	0.93	yes	32	-	-	Heating surface
8	0.93	yes	32	-	-	Heating surface
9	0.93	no	-	0.37	-15	Outer wall
10	0.93	no	-	0.55	20	Floor
11	0.93	no	-	0.55	10	Ceiling
12	0.93	ja	30	-	-	Heating surface
13	0.93	nein	-	0.37	-15	Outer wall
14	0.93	nein	-	1.00	12	Interior wall

The indoor surfaces are considered to be real-grey emitters, meaning that their emission coefficients ε obey the conditions:

$$\varepsilon<1 \tag{2}$$

and

$$\varepsilon = f(\beta) \tag{3}$$

For most non-metal materials, the emission coefficient can be approached by the relation [1]:

$$\varepsilon(\beta) = \varepsilon(90°) \cdot \frac{1-(1-\cos\beta)^8}{0,978} \tag{4}$$

RESULTS

The modeling of radiation heat transfer carried out in MATLAB® takes place as follows:

- Numerical calculation of the view factors (for real-grey emitters) between <u>all</u> surfaces by a program implemented in MATLAB® (leading to a matrix) – presented as an example in Table 2, according to [2];
- Solution of an equation system leading to the intrinsic brightness for every single surface, depending on the surface temperatures;
- Calculation of temperatures of the non-active surfaces and of the indoor air, and the specific heat flux emitted by every surface;

Table 2. The resulted view factors for the example geometry

The convective heat transfer between the indoor surrounding surfaces and the indoor air takes place as follows:

- The information regarding the geometrical orientation of the surfaces (floor, ceiling, wall) must be provided;
- The convective heat transfer coefficients are calculated using Nusselt's law [3].

In order to calculate the surrounding surfaces temperatures, as well as the indoor air temperature, the radiation heat transfer must be combined with the convective heat transfer. The computation steps are as follows:

- The surrounding surfaces temperatures of the active panels (controlled process variable) need to be initialized;
- The temperatures of the non-active surfaces are iteratively calculated using the following balance of steady-state-condition for every single surface:

$$\dot{Q}_{res,i} = \dot{Q}_{rad,i} + \dot{Q}_{conv,i} + \dot{Q}_{cond,i} = 0 \tag{5}$$

- $\dot{Q}_{rad,i}$ is the heat flux a certain surface receives by radiation from the surrounding surfaces, expressed in [W];
- $\dot{Q}_{conv,i}$ is the heat flux a certain surface exchanges with the surrounding air by convection (depending on the air temperature and the convective heat transfer coefficient), expressed in [W];
- $\dot{Q}_{cond,i}$ is the heat flux a certain surface looses to the environment by heat conduction (depending on the material properties and the virtual outside temperature), expressed in [W] [4];

- The resulting mean air temperature in the room is iteratively calculated. Therefore, the number of air changes (caused by infiltration), as well as the outside air temperature need to be given.
- The following balance between the heat losses (due to the infiltrated air), $\dot{Q}_{air,loss}$, and the convective heat wins, $\dot{Q}_{conv,win}$, is used:

$$\dot{Q}_{air,loss} + \dot{Q}_{conv,win} = 0 \tag{6}$$

The heat losses $\dot{Q}_{air,loss}$ can be computed as follows:

$$\dot{Q}_{air,loss} = \frac{1}{3600} \cdot n_{air\ changes} \cdot V_{Room} \cdot \rho_{air} \cdot c_{p,air} \cdot \left(\vartheta_{air,indoor} - \vartheta_{air,outdoor}\right) \tag{7}$$

where:

$n_{air\ changes}$	is the number of air changes, expressed in [h^{-1}];
V_{Room}	is the volume of the room, expressed in [m^3];
ρ_{air}	is the density of the air, expressed in [kg/m^3];
$c_{p,air}$	is the air heat capacity, expressed in [J/kg K];
$\vartheta_{air,indoor}$	is the indoor air temperature, expressed in [°C];
$\vartheta_{air,outdoor}$	is the outdoor air temperature, expressed in [°C].

The heat wins $\dot{Q}_{conv,win}$ can be computed as follows:

$$\dot{Q}_{conv.win} = \sum_{i=1}^{n} A_i \cdot \alpha_{conv,i} \cdot \left(\vartheta_{air,indoor} - \vartheta_{surf,i}\right) \tag{8}$$

where

A_i	is the surface of element "i", expressed in [m^2];
$\alpha_{conv,i}$	is the convection coefficient calculated on the basis of the Nusselt law, expressed in [W/m^2K];
$\vartheta_{surf,i}$	is the temperature of the surface element "i", expressed in [ºC].

Finally, the indoor air temperature (which is the parameter that must be achieved) is compared to the medium radiation temperatures of the surface elements in the room, in order to be able to achieve the indoor thermal comfort [5].

After setting the temperature of the heating panel, the MATLAB®-PDE-Toolbox can be used to establish the temperature distribution and the local temperature gradient inside the panel as well as the heat flux provided. The model is based on Fourier's Partial Differential Equation. Therefore, the material properties of the panel as well as the boundary conditions (heat transfer coefficient, heat flux or boundary temperatures, calculated in the step before) need to be given.

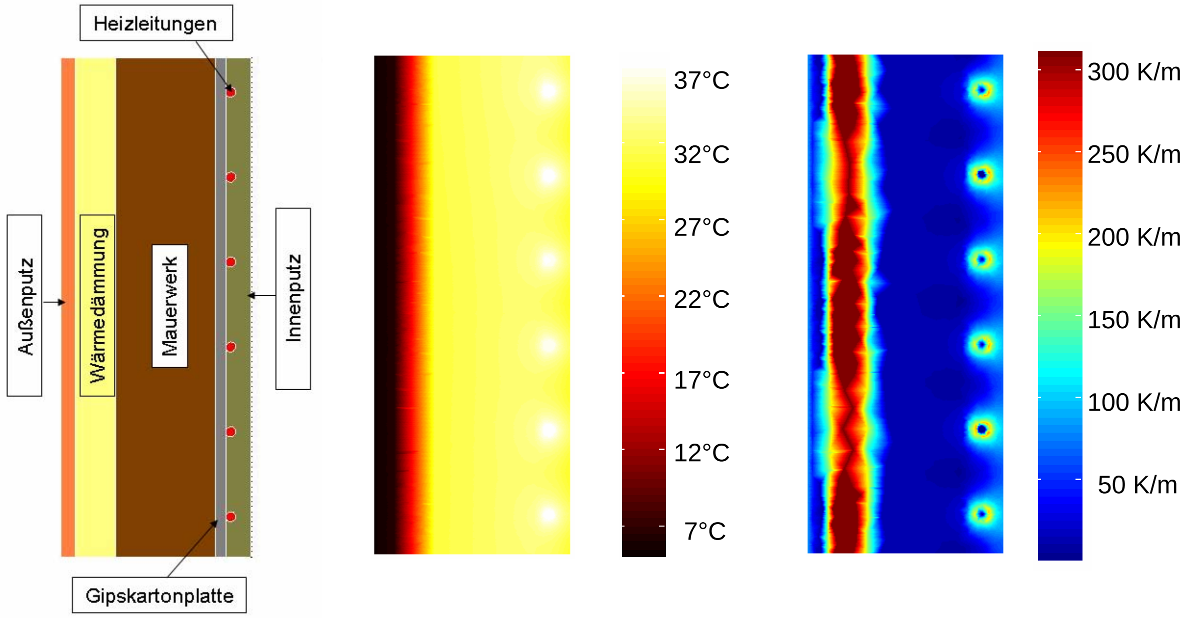

Figure 3. Example for a possible panel geometry, the possible temperature distribution inside and the local temperature gradient inside, 4000 s after switching on the heating panel

DISCUSSION

The work presented in this paper represents a starting model for the calculation of low-temperature-heating/high-temperature-cooling systems, and therefore has several limitations. First of all, the calculation of the surfaces temperatures inside the room, and of the indoor air temperature is made under steady state conditions and in the absence of any occupants (people, furniture pieces, etc.), whilst the calculation of the temperature distribution and heat flux inside the active wall can be performed dynamically. On the other hand, the theoretical model has not yet been verified in practice, such experiments are to be performed in the near future in the frame of a doctoral thesis.
A further development phase is previewed to connect the "room - active wall" system to the heating/cooling source (reversible heat pump), and to dynamically simulate them as a whole.
Nevertheless, the pragmatic approach and the thorough understanding of phenomena represent a strong advantage for future developments.

ACKNOWLEDGEMENT

This paper is the result of the work performed at the Department of Technical Thermodynamics of the Faculty for Building Services Engineering Bucharest (Romania) by the German student Johannes Georg Leib [6]. This was made possible due to the Socrates agreement between the Technical University for Civil Engineering Bucharest (Romania), and the Rheinisch Westfälische Technische Hochschule Aachen (Germany).
The authors would like to express their gratitude to Prof. Dan Constantinescu (INCERC Bucharest - Romania), whose expertise in buildings' Thermodynamics and kind advise were extremely useful.

SUMMARY

This paper describes an ongoing demonstration project on the use of personalized ventilation in practice. Several designs of air supply devices for PV were developed, tested and optimised based on the efficiency of clean air supply to occupants' breathing zone, control functionality, aesthetic, etc. Pilot installation of the PV system in a number of offices was used to gather better experience on the interaction between occupants and the PV system. The second stage of the project includes installation of the system and its performance in an office building. Computer based questionnaire survey on occupants' comfort and performance as well as measurement of the indoor environment in the offices will be performed before and after installation of the PV system. Surveys will be performed during the following winter and summer seasons. It is expected that the obtained results will provide knowledge important for future application of PV in practice.

INTRODUCTION

Numerous studies have associated the quality of indoor air with people's complaints and with their performance. It has been shown that poor air quality causes Sick Building Syndrome (SBS) symptoms such as increased prevalence of headache, decreased ability to think, increased dizziness, etc. [1]. Providing good air quality, on the other hand, increases occupant's productivity [2, 3, 4, 5]. Furthermore, it has been documented that the quality of inhaled air of low enthalpy (low temperature and humidity) is perceived to be better than when the enthalpy is high [6]. Thus an increased productivity due to improved indoor air quality and thermal environment will have an enormous economic impact which may cover all the capital and running costs of operating the building. The gain will often be greater than all other costs relating to the construction and operation of the building [7].

The first important step in improving indoor air quality is to remove or decrese the pollution sources. However it is not possible to remove all pollution sources. Occupants also generate pollution. Supply of more clean air to the room will dilute the polluted air and will improve air quality. This approach however leads to increase of initial costs due to larger ducts, air supply devices, etc., as well as increased energy consumption. Instead, it is better to keep the ventilation rate low but to distribute the air more efficiently in the room. With this respect the ventilation effectiveness, *VE*, defined as the ratio of the pollution concentration in exhaust air divided by the pollution concentration in air inhaled by occupants can be used to assess the performance of ventilation systems.

The total-volume ventilation systems (mixing and displacement) are capable of achieving only relatively low levels of ventilation effectiveness. The mixing ventilation aims for as good as possible mixing of the supplied clean air with the polluted room air and therefore typically has *VE* ≈ 1. Higher values of *VE* (*VE*≈6) can be achieved with displacement ventilation under laboratory conditions depending on the type and location of the pollution source. In practice *VE*≈1.4 is typically achieved in rooms with displacement ventilation [8]. However displacement ventilation may cause draught discomfort. Field study in 120 rooms with displacement ventilation identified that up to 50% of occupants were dissatisfied with indoor air quality [9].

Personalized ventilation (PV) aims to supply clean air directly to the breathing zone of room occupants and therefore it has potential to achieve *VE* substantially higher (*VE≈50* or more*)* than the *VE* of mixing and displacement ventilation [10]. The significant improvement in people' thermal comfort and perceived air quality, decrease in the reported Sick Building Syndrome (SBS) symptoms and tendency for improved work performance when PV is used, has been documented in human subject experiments performed in field laboratories [11, 12, 13]. Furthermore it has been shown that PV can efficiently protect occupants from airborne transmission of infectious agents, which are present in air exhaled by sick occupants [14].

Personalized ventilation has been applied for many years in theatres and vehicle cabins, in most cases in order to improve occupants' thermal comfort. Only few studies report on the performance of PV in office buildings [15, 16]. The effectiveness of the personalized ventilation depends greatly on the design of the PV Air-Terminal Device [17, 18, 19]. Design of PV with high *VE* easily applicable in practice is not an easy task. Apart of the *VE* other factors, such as background room air distribution, control strategies, occupant activities, appearance of air supply devices, etc., are also important [20, 21].

This paper describes an ongoing demonstration project on development, optimization and installation of PV in an office building. Computer based questionnaire survey on occupants' comfort and work performance as well as continuous measurement of the indoor environment in the offices is used for monitoring and evaluating the performance of the PV.

THE PERSONALIZED VENTILATION

Design

The first step of the project was focused on development and optimization of an air terminal device (ATD) for the personalized system. Some of the important criteria for the design of the ATD were: 1) to be able to supply maximum clean (personalized) air to inhalation; 2) to cause minimum draught discomfort for the occupants; 3) to improve occupants' thermal comfort and 4) to cause minimum transport of infectious agents between occupants. With this respect the knowledge obtained from previous research was carefully evaluated [10, 17, 19]. Other factors important for the practical use of the PV were considered as well. The most important of those were related to levels of control provided to users, installation at different workplaces, aesthetic and appearance. As a result several prototypes were developed. Figure 1 shows one of the designs. The ATD is attached to an arm which can be rotated around its vertical axis. This allows for changing the direction of the personalized flow in horizontal plan. The design of the ATD allows also for changing the direction of the supplied personalized flow in a vertical plan. In this way the occupant can direct the personalized flow to the face or chest or any other angle. The flow rate of the personalized air supplied through the arm to the ATD can be controlled, i.e. the occupant can adjust the preferred target velocity at his/her face or body. The size of the ATD was defined based on its appearance and on the aerodynamic of the generated personalized flow.

Figure 1. The personalized ventilation in use.

Performance of the ATD

The performance of the ATDs was tested in a full-scale air movement room. The room was ventilated by mixing ventilation (swirl diffuser placed in the middle of the ceiling). Breathing thermal manikin resembling human was used during the experiments. Experiments at different flow rate supplied from the PV, different distance between the ATD and the manikin and different angle of discharge of the personalized flow were performed. The velocity field in the personalized flow generated by the developed ATD was carefully identified. The most important part of the test was to identify the performance of the PV with regard to providing clean air in inhalation. For this purpose tracer gas was mixed with the supplied ventilation air (mixing ventilation). The supplied personalized air was free of tracer gas. The concentration of tracer gas in air inhaled by the manikin, the air exhaust from the room, at several points in the room and in the supplied personalized flow was measured. The data were use to calculate the personal exposure effectiveness (PEE) defined as:

$$PEE = \frac{C_{I,O} - C_I}{C_{I,O} - C_{PV}} \qquad (1)$$

where:
$C_{I,O}$ – is the pollution (tracer gas) concentration in the inhaled air without PV;
C_I – is the pollution (tracer gas) concentration in the inhaled air with PV;
C_{PV} – is the pollution (tracer gas) concentration in the personalized air;

The personal exposure efficiency, PEE, is an index representing the percentage of clean air contained in the inhaled air. It is developed for evaluation of the performance of personalized ventilation systems [17].

The results of the tests showed an improvement in inhaled air quality by 40% (*VE*≈1.7) in comparison with mixing ventilation alone (*VE*≈1). The ATDs were further improved in order to increase their performance.

Testing of the PV under real conditions

Pilot installations of the PV system were tested in order to gather better experience on the interaction between occupants and the PV system. The administration building of the manufacture of the PV systems was use. The PV was installed at three workplaces used by several of the employees for shorter (several hours) or longer (several days) periods of time. The response of the users was very positive. Apart of the achieved preferred thermal comfort and improved quality of the inhaled air (the inhaled air was felt fresh and clean) the users reported an improved self-estimated performance with the PV, especially during the afternoon hours. The response of the users with regard to the provided control of the local velocity and direction of the personalized flow as well as the appearance of the PV was positive as well. Further modifications and improvements of the developed PV systems are in progress.

APPLICATION OF THE PV IN PRACTICE

Installation of the PV system in an office building

A consulting company (partner in this project) was requested by a building owner to improve the indoor environment of a 200 years old building where severe indoor climate problems were reported. The building, located downtown Copenhagen, is occupied by a company dealing with preparation of regulatory documents (low, taxation, etc.). Thus the employees perform office work in front of computer screens. The building (the old building) does not have mechanical ventilation. The ventilation through the windows is insufficient to ventilate and cool down the building. The opening of the windows for getting fresh air creates a lot of thermal discomfort during the winter. Therefore among other improvements of the building (better roof isolation, better solar shading, floor renovation with low polluting materials, etc.) installation of mechanical ventilation was requested. Since the office work performed in the building is rather responsible and requires deep concentration a high quality environment for each occupant was requested.

The ceiling height in many of the rooms in the old building is below 2.4 m (2.2 m in several rooms). Furthermore there is not enough space (typically needed in practice) for installation of air terminal devices and ducting system. This made the task more difficult. The design of the total volume ventilation ended with mixing room air distribution with air supply devices located on the walls. In order to account for the occupants' preferences with regard to thermal comfort and to provide them with high quality of inhaled air personalized ventilation in conjunction with the mixing ventilation was designed. The mixing ventilation can be used alone or in conjunction with the personalized ventilation. The design allows for maximum 20 L/s per occupant outdoor air in total, supplied by the two systems. The minimum amount of outdoor air supplied to each room is 5 L/s per occupant. The outdoor air is distributed between the total volume system and the personalized ventilation systems depending on the occupants' preferences. The PV systems at each workplace supply maximum of 15 L/s and the personalized flow rate can be reduced to 0 L/s. The installation of the system will start by the end of April 2007.

Field survey

A survey on the impact of the PV system in regard to occupants' health, comfort and performance is designed. Occupants' cognitive stress level is in the focus of the survey as well.

The survey will be performed before and after renovation of the building. Two groups of occupants are included in the survey: group A includes occupants working in the building which will be renovated (the old building) and group B includes occupants working in the attached relatively new building (the new building) which will not be renovated (this group will be used as a reference). Much less complains due to poor indoor environment have been recorded in the new building. The two buildings are interconnected. They are rented by the same company. Three Phases are considered. Phase 1 includes a survey before renovation of the old building. This phase is in progress. After renovation of the old building two more phases are planned: Phase 2 when mixing ventilation is used alone and Phase 3 when personalized ventilation in conjunction with mixing ventilation is used. In this way the effect of the ventilation in general and of the personalized ventilation in particular will be identified. Future surveys during following winter and summer seasons are planned in order to identify the level of occupants' satisfaction after use of the personalized system for relatively long period of time.

The method of survey includes long term survey and short term survey. Both, the long term and the short term surveys will be performed before and after the renovation of the old building. The long term survey is planned to continue for 3-4 weeks during each of the phases of the project, i.e. before the renovation and after the renovation twice (only mixing ventilation and mixing ventilation in conjunction with personalized ventilation). The long term survey includes occupants' response to the indoor environment collected by questionnaires, work performance test and continues physical measurements. The questionnaire survey and the work performance tests are computer based and performed via internet [22]. At least three times during a week (in the afternoon of different days) an invitation for participation appears on the screen of each participant in the survey. The occupant votes on short questionnaire including questions on occupants' thermal comfort (7 point ASHRAE scale) and its acceptability (continues scale from clearly unacceptable to unacceptable and then from acceptable to clearly acceptable), acceptability of air quality, acceptability and preferences of air movement as well as where it is felt, SBS symptoms (eye irritation, headache, ability for concentration, tiredness, stress level, etc.) and self-assessed performance. After completion of the short questionnaire follows work performance test which includes proof reading of text with errors which have to be found. The time for this test is limited to 5 min. The work performance of each participant will be analyzed based on the number of identified errors and the length of the processed text. The long term survey includes also continuous measurement of air temperature, relative humidity and CO_2 concentration in the surveyed rooms.

The short term survey will be performed during each of the three phases. It will be performed only once during the 3-4 weeks long survey. It will include detail paper questionnaire on occupants' comfort, health conditions, work environment. Simultaneously spot measurements of velocity and temperature at each workplace at different heights will be performed as required in the present thermal comfort standards [23, 24]. This short term survey will last not more 15 min at each workplace.

CONCLUDING REMARKS

The field survey before installation of the ventilation system and renovation of the building (Phase 1) is in progress. Phases 2 and 3 are expected to take place in August- September 2007. It is expected that the obtained results will provide knowledge important for future application of PV in practice.

ACKNOWLEDGEMENT

The field survey is supported by the Danish Research Council (STVF) and Magnus Informatik A/S, Denmark.

Opportunities in the design of control-on-demand HVAC systems

Per Fahlén[1], Caroline Markusson[1], Mari-Liis Maripuu[1]
Chalmers University of Technology, Building Services Engineering, Gothenburg, Sweden

SUMMARY

Control-on-demand operation of HVAC-systems can reduce energy for heating, cooling, and the drive energy of fans and pumps resulting in better control at a lower operational cost. Analysis of typical Nordic CAV and VAV systems indicates a potential for substantial savings using new components and alternative system design. Component developments include more efficient motors, variable speed drives, pumps and fans as well as laminar flow heat exchangers and smart air-supply devices. Alternative system designs can reduce pressure drops by replacing valves and dampers with direct speed control of the pumps and fans and reduce mean flow rates by means of control-on-demand. Furthermore, separating the conditioning and distribution pressure drops, e.g. going from in-line to parallel conditioning, adds another dimension of design to further reduce the energy to fans and pumps.

INTRODUCTION

Demand patterns of buildings have changed considerably over the past 20 years, in particular for offices and other types of commercial building. As a result, space conditioning is largely accomplished by means of variable outdoor air flows instead of using heaters and coolers.

Design capacity and utilization

Increasing internal loads combined with improved building envelopes and heat recovery has drastically reduced heating and full capacity heat recovery operation. On the other hand, demand for cooling has increased. In Nordic countries, however, the use of free cooling by means of outside air still makes the duration of active cooling of supply-air quite short. Hence, the *design capacity and utilization* of new HVAC systems have to be studied carefully. The design capacities of the systems for heating, heat recovery ventilation and cooling are rarely used and must therefore be turned down most of the year to match demand with supply. The short operating periods for supply-air heating, cooling and heat recovery, together with large variations in occupancy, is an open invitation for *control-on-demand* (COD) systems with new possibilities of system design.

Control-on-demand (COD)

Control-on-demand implies a variation of supply in response to a variation of demand of some utility. In HVAC systems, the utilities involved are usually heating, cooling and volumes of clean air. Traditionally, heating and cooling systems operate with COD of room temperature based on feed-back control by means of a room sensor. Often a complementary feed-forward control, based on the outdoor temperature, is used for heating but rarely for cooling. The occupant determines the demand level by means of the room thermostat.

In ventilation, constant flow CAV systems have commonly been used. Even modern VAV systems often operate with fixed minimum outdoor-air supply rates and there is no feed-back regarding air-quality. On the other hand, the flow will normally vary in response to room temperature, i.e. thermal COD. In special applications, such as rooms with large variations in occupancy (lecture rooms, theatres, etc.), feed-back control by means of an indicator for the load or the actual air-quality is becoming increasingly popular. VAV systems with feed-back control are often known as DCV systems. This category should include all kinds of ventilation with feed-back control and not only those with respect to air-quality. With COD, not only the control strategy per se, but also the hydraulic *system design* is important for good results.

System design

Utilization of the design capacity and the wish for COD imposes conditions which must bear on the system design. With a focus on electric drive energy, new system designs can provide saving opportunities primarily by means of reduced pressure drops and reduced mean flow rates. In this respect, there are two basic system design factors: flow design and control.

In this study we have looked at two alternatives to common design practice. The first concerns reduction of pressure drop by replacing dampers and valves for flow control by direct speed control of fans and pumps [4]. The second underlines the importance in variable flow systems to distinguish between transport and conditioning pressure drops.

Drive energy to pumps and fans

A major objective of this study has been to find ways of reducing the drive energy to the fans and pumps of HVAC-systems. Second only to lighting, drive energy to fans and pumps dominate the use of electricity for building operation. SFP values help in reducing the specific use but do not address the rise in absolute terms from increasing demand. The principle ways to accomplish low energy use in this sector is by means of reduced design pressure drops (alternative system layout, new components and sizing), reduced mean flow rates and mean pressure drops (COD), and improved efficiency of pumps, fans, motors and motor drives.

METHODS

This study primarily looks at the opportunities of saving drive energy to fans and pumps in control-on-demand HVAC systems in general and some alternative system designs in particular. Since conditioning of the supply-air totally dominates the space demand for heating, cooling and ventilation, the case-studies will look at possible savings in this area (c.f. the section on system design). Important aspects are: *Design capacity and its utilization*, *control-on-demand* principles of ventilation, heat recovery, heating and cooling, *capacity control of air-coils*, *system design*, and savings on *drive energy to fans and pumps*.

Design capacity and utilization

Modern offices and other commercial buildings have very short demand periods for heat recovery and heating. The use of novel air-supply devices [6] also permits low supply-air temperatures with no comfort problems and thus provides a possibility to maximize the use of free cooling by means of outdoor air. Equations (1) to (3) are used to illustrate the difference in relative design capacities and operating times for heat recovery, supply-air heating and supply-air cooling (see Figure 3 for designations of heat exchanger outlet temperatures).

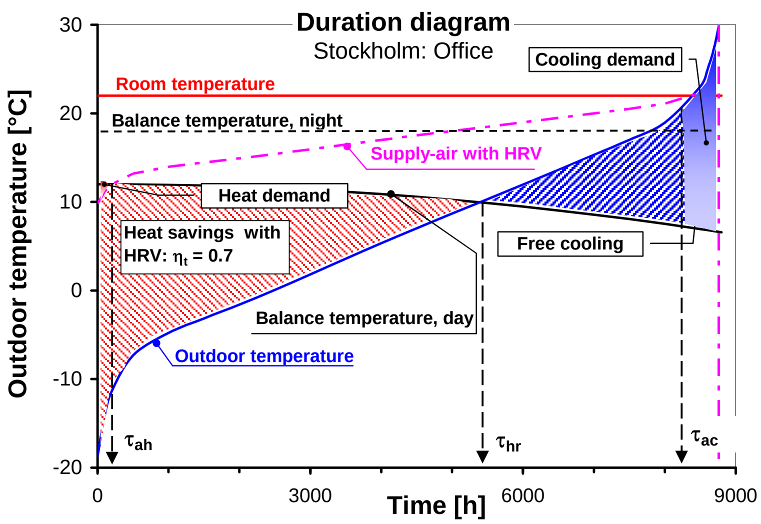
$$\dot{q}_{hr,d} = \frac{\dot{Q}_{hr}}{\dot{Q}_{sah,\max}} = \frac{t_{sa2} - t_{oa,\min}}{t_{ea} - t_{oa,\min}} \text{ at } \tau = 0\,[\text{h}] \text{ and } R_{\tau,hr} = \frac{\tau_{hr}\,[h]}{8760\,[h]} \tag{1}$$

$$\dot{q}_{ah,d} = \frac{\dot{Q}_{ah}}{\dot{Q}_{sah,\max}} = \frac{t_{sa3} - t_{sa2}}{t_{ea} - t_{oa,\min}} \text{ at } \tau = 0\,[\text{h}] \text{ and } R_{\tau,ah} = \frac{\tau_{ah}\,[h]}{8760\,[h]} \tag{2}$$

In Nordic climatic conditions, dehumidification of supply air is not a major problem and the specific enthalpies *h* below can be approximated by the temperature *t*.

$$\dot{q}_{ac,d} = \frac{\dot{Q}_{ac}}{\dot{Q}_{sac,\max}} = \frac{h_{sa4} - h_{sa3}}{h_{oa\max} - h_{sa6}} \text{ at } \tau = 8760\,[\text{h}] \text{ and } R_{\tau,ac} = 1 - \frac{\tau_{ac}\,[h]}{8760\,[h]} \tag{3}$$

Fahlén [2] describes how the design capacity of air-heaters and air-coolers can be modulated from design values by means of temperature control and/or flow control on the liquid side. Another possibility, which is pointed out, is the direct effect of controlling capacity with a variable air flow rate in coils with the minimum heat capacity flow rate on the air-side (the normal situation). This is not a viable option in traditional, in-line air-handling units, but an interesting possibility in alternative, parallel designs (c.f. Figure 4 a).



Input data:

$\bar{t}_{year}$ = 6.6 °C

$t_{oa,\min}$ = -19 °C

$t_{oa,\max}$ = 30 °C

t_{room} = 22 °C

Δt_{sun} = 5.4 °C

Δt_{int} = 10 °C

$t_{sa,\min}$ = 18 °C

$\eta_{t,\max}$ = 0.7

Figure 1. Duration diagram of the temperatures of outside air t_{oa}, supply-air t_{sa2} (after heat recovery) and the balance temperature t_{bt} for an office building.

Figure 1 provides an example of the temperature duration diagram for an office building. This illustrates the low daytime utilization factors of heat recovery, heating and cooling in such buildings, which opens up for *control-on-demand systems* and alternative *system designs*.

Control-on-demand (COD)

Although not the focus of this study, COD per se is obviously a major design factor [1, 3]. There are two main objectives for COD in air-conditioning HVAC systems: satisfaction of room thermal comfort and air quality. Feedback of the room status controls the three subsystems of heat recovery, heating and cooling to provide a thermal environment in relation to demand. The subsystem of air volume supply handles the air-quality aspect. Control can also be enhanced with feed-forward of load related disturbance factors.

The wide range of operation of COD systems affects the control difficulty. Fahlén [1, 2] advocates feed-forward control of the supply temperature to modify the capacity of air-coils in relation to demand. This effectuates a COD of the open loop gain, which greatly reduces the control difficulty. Otherwise the dynamic difficulty, D_{dyn} [1] according to (4), will increase as demand goes down. For instance, a reduction of the air flow will increase the delay time τ_d (transport time between heat exchanger and control sensor) and Δy_{max} (maximum change of the output variable) will increase if the thermal capacity of the coil remains constant while the air flow goes down. The control difficulty also goes up with a high required static accuracy, i.e. a low value of the permissible control deviation Δy_s.

$$D_{dyn} = \frac{\Delta y_{\max}}{\Delta y_s} \cdot \frac{\tau_d}{\tau_r} \tag{4}$$

Equation (5) below illustrates the need for COD of heat recovery. Below the balance temperature t_{bt}, the heat recovery system operates with constant, maximum efficiency $\eta_{t,max}$. Above the balance temperature, η_t is controlled in relation to demand. With a CAV system, the heat capacity flow rate $\dot{C}_{sa}$ and the maximum efficiency $\eta_{t,max}$ are constant and can be moved outside the integral. In the case of a VAV system, however, neither $\dot{C}_{sa}$, $\eta_{t,max}$ or η_t are constants since both $\dot{C}_{sa}$ and η_t are controlled on demand and $\eta_{t,max}$ is a function of $\dot{C}_{sa}$.

$$\dot{Q}_{hr} = \int_{\tau_0}^{\tau_{ah}} \dot{C}_{sa} \cdot \eta_{t,\max} \cdot (t_{ea} - t_{oa}) \cdot d\tau + \int_{\tau_{ah}}^{\tau_{hr}} \dot{C}_{sa} \cdot \eta_t \cdot (t_{ea} - t_{oa}) \cdot d\tau \tag{5}$$

The air heating coil only operates below the balance temperature. Eq. (6) is subject to the same considerations regarding CAV and VAV systems as indicated above. The capacity of the air heating coil has to vary in relation to variations of outside loads (outdoor temperature $\rightarrow t_{oa}$, insolation $\rightarrow t_{bt}$) and inside loads (occupancy $\rightarrow \dot{C}_{sa}$, t_{bt}, equipment $\rightarrow \dot{C}_{sa}$, t_{bt}).

$$\dot{Q}_{ah} = \int_{\tau_0}^{\tau_{ah}} \dot{C}_{sa} \cdot \left[t_{bt} - (1 - \eta_{t,\max}) \cdot (t_{ea} - t_{oa})\right] \cdot d\tau \tag{6}$$

Finally, equation (7) provides the necessary air-coil cooling capacity presuming that free cooling covers demand between τ_{hr} and τ_{ac} (see figure 1). At the time τ_{ac}, the COD system reduces air flow to the level decided by air-quality feed back or the estimated minimum.

$$\dot{Q}_{ac} = \int_{\tau_{ac}}^{\tau_{year}} \dot{C}_{sa} \cdot \left[t_{bt} - (1 - \eta_{t,\max}) \cdot (t_{ea} - t_{oa})\right] \cdot d\tau \ \text{ with } \ \tau_{year} = 8760\,[\text{h}] \tag{7}$$

Control-on-demand (COD) of air-coils

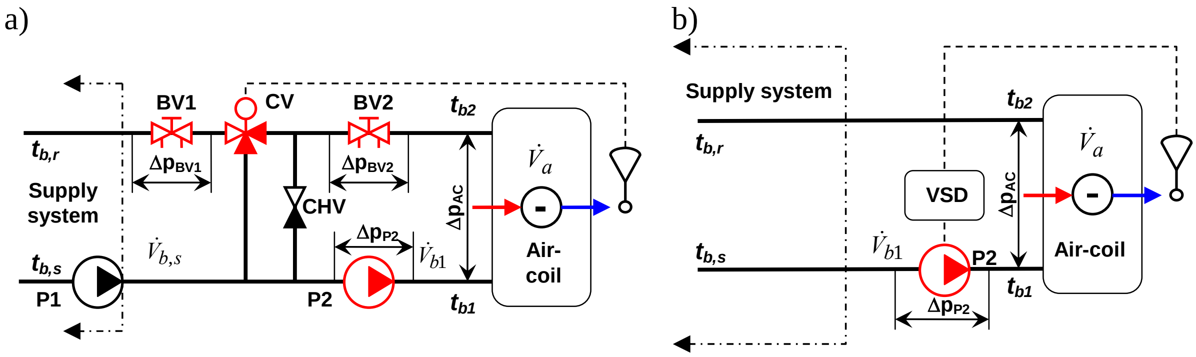


Figure 2. Control by means of a) variable inlet temperature and b) variable coil flow.

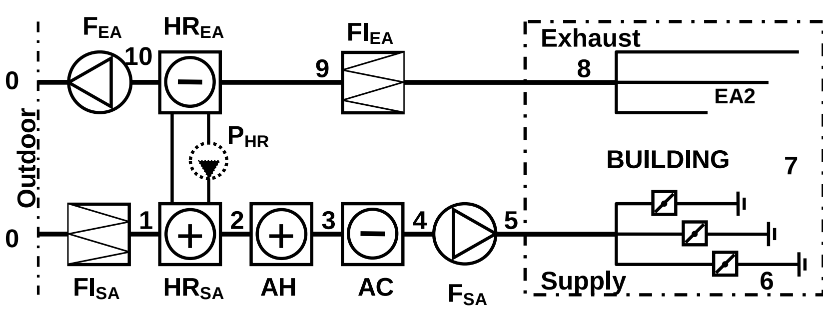
Trüschel [7] has categorized and studied current practice of capacity control of coils. Fahlén [2] also discusses the pros and cons of alternative control arrangements with the objective of maximizing the heat transfer capacity in relation to the drive energy of fans and pumps. There are three basic control methods: 1) Variable system supply temperature, 2) variable coil inlet temperature (with constant or variable coil liquid flow) and 3) variable coil liquid flow (c.f. Figure 2). Changing the coil control subsystem from traditional valve control (figure 2a) to direct, variable speed pump control (figure 2b) rids the system of all the control pressure drops of balance and control valves. This will not only drastically reduce the drive energy to pumps but also greatly simplify the system.

System design

Due to the wide range of operation of COD systems, small inputs and losses, which are considered insignificant in traditional systems, must be considered in COD [4, 6]. New designs should also maintain controllability and operability over a wide range of demand to achieve better control at a lower cost of energy. Figure 3 provides a schematic of a traditional dedicated outdoor air system with in-line air-conditioning units.



AH air-heater
AC air-cooler
EA exhaust-air
F fan
FI filter
HR heat recovery
P pump
SA supply-air

Figure 3. Typical supply and exhaust ventilation system with heat recovery.

In this arrangement, the pressure drops of heat exchangers (HR, AH, AC) require fan power all the time even though the utilization may be quite low. It would be desirable to have the same integration period for drive power, eq. (8), as for heat transfer capacity, eq. (5)-(7). Figure 4 presents two alternative designs based on a parallel arrangement of the conditioning units. In this type of design, the conditioning units can operate independently of the general ventilation system. Hence the coils and fans can be individually optimized for efficient heat transfer and controlled by demand. It is also feasible to add or subtract units without affecting the rest of the system.

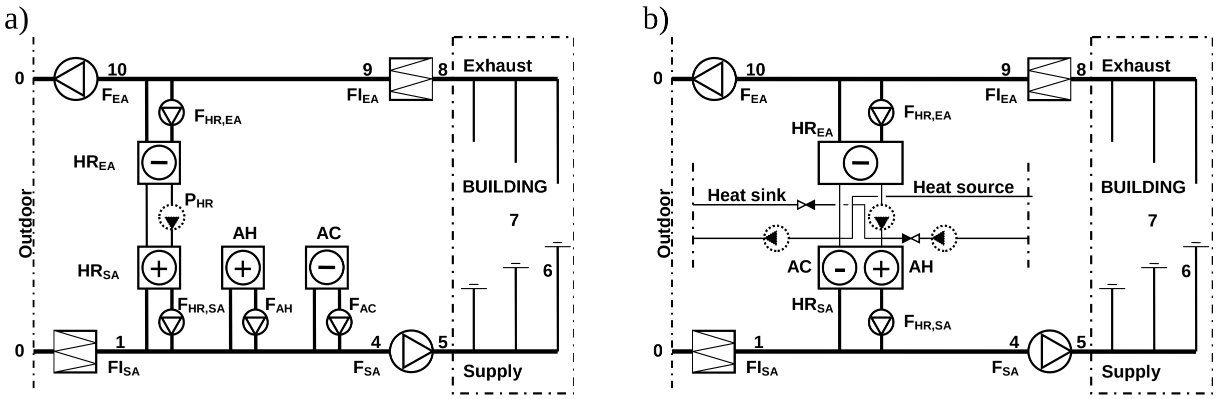


Figure 4. Alternative mechanical exhaust and supply air systems with heat recovery:
a) Parallel arrangement; b) integrated heat recovery, heating and cooling with ground storage.

Finally, there will of course always be opportunities for more efficient components such as new electric motors, drives, fans, pumps and smart air-supply devices. Furthermore, laminar flow heat exchangers can further reduce the pressure drop while simultaneously improving the efficiency of motors and motor drives (different torque characteristics in laminar flow).

Drive energy to fans and pumps

The drive energy to fans and pumps can be reduced through the following actions (individually or in combinations): 1) reduce the number of pumps, 2) the operating hours, 3) the flow rates and pressure drops and 4) increase the efficiencies. Alternative system layouts, control strategies, and the selection of coils will influence the first three items. New pump motor controls enhance the possibilities of more efficient control. Improved hydraulic design and more efficient motors will address the final savings opportunity. COD related variations of flow and operating time will determine the aggregated drive energy according to eq. (8):

$$W_e = \int_{\tau 1}^{\tau 2} \frac{\dot{V} \cdot \Delta p(\dot{V})}{\eta_p(\dot{V})} \cdot d\tau \quad [\mathrm{W}] \qquad (8)$$

In the case of an in-line system, $\tau_1 = 0$ and $\tau_2 = \tau_{year}$ whereas a parallel system will have the same integration time as the heat transfer duty, i.e. $\tau_2 = R \cdot \tau_{year}$. For a CAV system, the integrand will be a constant and $W_{ep} = \dot{W}_{ep} \cdot \tau_{year}$.

RESULTS

The results of simple calculations show the importance of considering the wide range of operation of modern COD air-conditioning systems.

Design capacity and utilization

In apartment buildings, low internal loads result in a balance temperature in the range 14 - 19 °C, depending on the time of year, and with average utilization factors for heating and heat recovery. There is little need for active cooling which is usually avoided. Regarding office buildings, however, internal loads result in much lower balance temperatures, 7-12 °C as a diurnal average and much lower on a daily basis. This results in low utilization factors for heating and heat recovery. Active cooling is limited to outdoor temperatures exceeding 20 °C.

Table 1 compares the design capacities of the air-coils for heat recovery, heating and cooling of an office and an apartment building, see eq. (1) to (3). The table also compares the relative operating times of the respective units. It is obvious from the table that the design conditions will be very different and that the low utilization of heat exchanger duty should reflect on the design of office systems.

Table 1. Relative design capacities $\dot{q}$ and relative operating times R_τ of heat recovery (hr), air-heaters (ah) and air-coolers (ac).

Building type	**Relative design capacities**			**Relative operating times**		
	$\dot{q}_{hr} \approx$	$\dot{q}_{ah} \approx$	$\dot{q}_{ac} \approx$	$R_{\tau,hr} \approx$	$R_{\tau,ah} \approx$	$R_{\tau,ac} \approx$
Apartment building	0.70	0.23	0.75	0.80	0.52	0.04
Office building	0.70	0.05	0.54	0.60	0.02	0.09

Pressure drop, drive energy to fans and pumps and thermal losses

The minimum pump power, $\dot{W}_{ep,\min}$, of a liquid-air coil is that required to overcome the heat transfer pressure drop of the coil. Fahlén [2] has shown that direct flow control with a VSD pump can reduce the required pumping power at the design capacity of a coil from 2.5 to $1.0\,\dot{W}_{ep,\min}$ and at half the design capacity the pumping powers are 1.5 and 0.13 respectively!

Using design pressure drops of an in-line system design based on data from Saetre [5] and comparing the total pressure drop with a parallel system based on the same components, the maximum difference is 25 %. A realistic savings potential would be around 10 % with the relative operating times of the presented case-study. In systems with careful design and sizing of ductwork, filters etc., the relative benefit of using a parallel design will increase.

Regarding thermal losses, Maripuu [6] has shown by practical and theoretical investigations that the temperature change can be substantial at low flow rates even if the ducts are apparently well insulated. For instance, going from an air velocity of 5 m/s to 0.5 m/s, the relative temperature loss can change from 0.2 to 0.9 over a distance of 100 m. Even from this respect, a distributed conditioning system may have advantages over a central layout.

DISCUSSION

Only a fraction of the design capacities for heating, cooling and ventilation are used on average. Hence, COD of HVAC systems can drastically reduce the energy use for space conditioning. Much of the conditioning of modern Nordic offices is in fact primarily handled by COD of the ventilation flow rate (DCV) with little use of heat recovery or heating and cooling coils. With little need for supplementary heating or cooling, the pressure drops of heat exchangers become important factors for energy efficiency. Also, when duct systems have been sized and shaped to minimize pressure drops, the dominating pressure drops will be those of filters, terminal devices, balance dampers and heat exchangers. The first two can be addressed on a component level by development of efficient, low pressure difference, air filters and terminal devices. The last two items, however, can also be mitigated on a system level.

Commonly, HVAC systems have a centralized structure, with a common supply unit and distribution via branches with balance dampers or valves. However, there are alternative solutions based on a combination of central and local distribution of fans or pumps with variable speed drives. Such designs can get rid of the balance and control pressure drops. Furthermore, it is possible to avoid the pressure drops of heat exchangers during all those hours of operation when they are out of the action by choosing a parallel arrangement instead of the common in-line system. Supply-air heaters, for instance, will often be active during less than 2 % of the year but provide a flow resistance 100 % of the time.

Separating the heat transfer pressure drop from the distribution pressure drop with a parallel arrangement also adds another dimension for optimizing the control. With in-line systems, the air flow rate is always determined by ventilation requirements and not by heat transfer conditions. Depending on the type of supply of heating and cooling, it may be more or less beneficial to use a different air flow rate than that required by ventilation. This permits better use of available temperature. For instance, large differences are desirable with district heating and district cooling whereas low differences may be of interest for heat pumps with ground storage. This will extend the period of free cooling and avoid supplementary heating during heat pump operation (low water supply temperature to air-heaters, high brine supply temperature to air-coolers). Parallel air-conditioning units and fans will also contribute to a system with high flexibility. Since adding or subtracting parallel units will not affect the operation of others, it is possible to adapt the capacity without costly changes in other parts of the system.

Capacity of air-coils can be controlled by means of the liquid supply temperature and/or flow rate and the air flow rate. The optimum combination will depend on the heating or cooling supply but moving from traditional valve control to direct flow control by means of local variable speed pumps saves on drive energy and, as a bonus, provides a simpler subsystem. The pumps may be small but they often operate constantly and the energy use is much larger than reflected by their drive power. Such parasitic powers become noticeable when the large inefficiencies of HVAC systems have been mitigated. Another example of such parasitic losses is the relative increase of heat leakage in supply ducts at reduced flow rates. At low flow, the temperature rise may render the supply temperature insufficient for the required cooling duty.

NOMENCLATURE

c	specific heat capacity [J/(kg·K)]			$\dot{V}$	volume flow rate [m^3/s]

SUMMARY

In this study the influence of occupant behaviour on energy consumption were investigated in simulations of a single room occupied by one person. The simulated occupant could manipulate six controls, such as turning on or off the heat and adjusting clothing. All control actions were carried out with the aim of keeping the PMV value within predefined limits in accordance with CR1752 [1]. An energy consuming and an energy efficient behavioural mode were simulated. A reference simulation was made during which the occupant had no control over the environment.

The occupant was able to keep the thermal indoor environment close to neutral when he/she had the possibility to manipulate the controls. The energy consumption was similar within each behavioural mode regardless of the PMV limits. However, the energy consumption in the energy consuming behavioural mode was up to 330 % higher than in the energy efficient behavioural mode.

INTRODUCTION

Buildings account for more than 40 % of the energy consumption in the EU member states and households are responsible for consuming more than 26 % [2]. Consequently, reductions of the energy consumption in buildings are instrumental to the efforts of alleviating the EU energy import dependency and comply with the Kyoto Protocol.

Indeed, occupant behaviour influences the amount of energy consumed to sustain a comfortable indoor environment. However, the extent to which occupant behaviour affects building energy consumption is largely unknown. The purpose of this study was to investigate the extent of this influence. This paper describes simulations of a naïve and a rational behaving occupant. The naïve occupant controlled the indoor climate using an energy expensive behaviour, while the rational occupant controlled the indoor climate in an energy efficient way.

METHODS

The simulations were carried out using a dynamic building simulation software [3]. The model consisted of a single room (4 m x 7 m) with a single occupant seated in the middle of the room. The room had one exterior wall (facing south) with a window and a heater underneath it. The building was placed in a suburban environment in Copenhagen, Denmark. All simulations were annual simulations using the Danish Design Reference Year for Copenhagen.

The simulated occupant could manipulate four different controls to adjust the environment (table fan, window opening, blinds, and heating) and two controls by which the occupant could adjust to the environment (clothing insulation and metabolic rate). All control actions were carried out with the aim of keeping the PMV value within predefined limits. Two behavioural modes were simulated. In the behavioural mode 1, the indoor environment was controlled in an energy expensive manner (naïve occupant), while the controls were operated in an energy efficient way in behavioural mode 2 (rational occupant). In both behavioural modes, three limits for the PMV index were set in accordance with the guidelines in CR1752 (+/-0.2, +/-0.5 and +/-0.7 for quality categories A, B, and C, respectively) [1], resulting in a total of six simulations. A seventh reference simulation was made during which the occupant had no control over the environment. In this simulation the occupant only controlled the clothing insulation and the metabolic rate.

Table 1: Setup of the simulations.

Criteria	Behavioural mode 1	Behavioural mode 2
A (-0.2<PMV<0.2)	Simulation 1A	Simulation 2A
B (-0.5<PMV<0.5)	Simulation 1B	Simulation 2B
C (-0.7<PMV<0.7)	Simulation 1C	Simulation 2C

In each simulation, all control actions were used to maintain PMV within the predefined limits. An example of the two behavioural modes for criterion A is given in Figure 1. Here it is seen that in behavioural mode 1, at increasing PMV, the table fan was turned on at PMV=0.03. If that did not stop the increase in PMV, the window was opened at PMV=0.06, blinds drawn at PMV=0.09, a clothing garment was removed at PMV= 0.11 and the metabolic rate was decreased to 1 met when PMV was higher that 0.14. Finally the heating was turned off when the PMV value increased beyond 0.17. When the PMV decreased below 0, the heating was turned on, the metabolic rate and clo value was increased, blinds opened, window closed and the fan was turned off, in that specific order.
In behavioural mode 2, the order of controls was inverted so the occupant turned off the heat as the first thing, when feeling warm – instead of turning on the fan.
In simulations B and C, the sequence of control actions at increasing or decreasing PMV were unchanged but the PMV value at which a control action was taken was increased according to the +/- 0.5 and +/- 0.7 criterion.

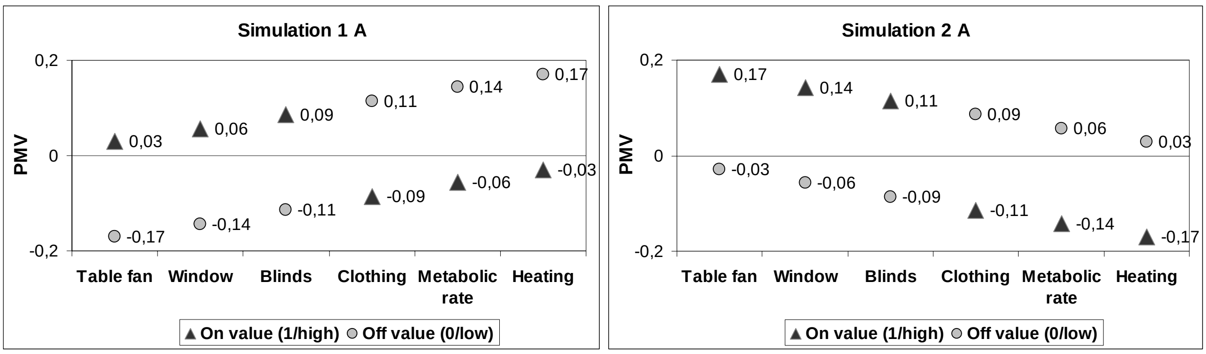

Figure 1: The control scheme for the energy consuming and the energy saving Behavioural modes for criterion A.

The occupant was constantly present in the room and was sleeping from 22:30 till 6:00 in the morning. During weekends the occupant slept from 24:00 till 8:00. During the sleeping periods the on and off values for the controls that adjusted the environment were multiplied by two to simulate that it takes a higher level of discomfort to act while sleeping than while being awake. The control of clothing and metabolic rate during the night is described below.

Table fan: When the fan was turned on the air speed at the occupant was increased by 1 m/s and the electric power consumption was increased by 50 W. These values were based on measurements using a normal table fan and a hot sphere manometer. During the measurements an average increase in air speed of approximately 1 m/s was detected when the fan was pointed directly at the occupant at a distance of 3 m. When the fan was pointed slightly to one of the sides of the occupant an airflow increase of 0.25 m/s was measured. Due to numerical problems in A simulations, the air speed was only increased by 0.25 m/s in simulation 1A and 2A. The power was kept at 50 W.

Window: The aerodynamic size of the window opening (corresponding to the size of a sliding window) was set each time the window was opened and remained unchanged until the window was closed. The opening size of the window depended linearly on the air change rate in the time step previous to the opening event. An air change rate of 0 h^{-1} in the time step prior to the opening event lead to an opening size of 0.6 m² while an air change rate of 2 h^{-1} in the time step prior to an opening event lead to an opening size of 0.12 m². When the air change rate with closed window exceeded 2.5 h^{-1}, the window was not opened even though PMV exceeded the window opening control value.
This was chosen because the air change rate depended on the wind speed outside the building. When there was a strong wind the air change rate was high and the window opening was small when the window was opened. When there was no wind the air change rate was small and when the window was opened it was opened completely
When the window was open the air speed at the location of the occupant was increased by:

$$V_{air} = 0.2 \cdot \frac{Q \cdot Vol}{A_{opening} \cdot 3600} \qquad (1)$$

Where
V_{air} is the air velocity at the occupant [m/s], Q is the air change rate [h^{-1}], Vol is the volume of the room, $A_{opening}$ is the aerodynamic area of the window opening.
The fraction in equation 1 is the air speed in m/s in the opening. The factor of 0.2 is multiplied because the airspeed decreased as a function of the distance to the window opening.
When the window was closed and the fan was off the air speed at the location of the occupant was 0.1 m/s.

Blinds: The binds were on/off controlled. They were external blinds that reduced the solar heat gain coefficient by a factor of 0.14 and reduced the direct energy transmission (short wave) by a factor of 0.09. The blinds were closed every night.

Clothing: The clothing insulation of the occupant could assume two values (Hi and Low), which were set each day at 6 o’clock in the morning on the basis of the outdoor temperature. This was done to model the action of taking on or off a piece of clothing. Both the time of day when the clothing insulation values were determined and the clothing insulation values were modelled according to [3] in the area of natural ventilation. The clothing insulation values were calculated using the following relation:

$$Clo_{Hi} = -0.024 \cdot T + 1.1 \quad (2)$$

$$Clo_{Low} = -0.015 \cdot T + 0.83 \quad (3)$$

Where *Clo* is the insulation of the occupants clothing [Clo], *T* is the outdoor temperature at 6:00 in the morning [°C].
During the night the clothing value was regulated continuously between 1.0 Clo and 2.5 Clo depending linearly on the PMV value. This was done to model a blanket or duvet that can be taken on or off in small increments while sleeping.

Metabolic Rate: The metabolic rate depended linearly on the PMV value assuming 1.0 Met at the PMV=off control value and 1.3 Met at the PMV=on control value. The metabolic rate of the occupant was 0.8 Met while sleeping.

Heating: The heating system comprised a water based radiator and a boiler with an efficiency of 66 %. The supply temperature to the radiator was 65 °C at outdoor temperatures below -12 °C and 20 °C at outdoor temperatures above 17 °C. Between -12 °C and 17 °C the supply temperature varied linearly with the outdoor temperature. The water flow through the heater was either on or off.

Infiltration rate: The simulated building had two cracks at different heights in each exterior wall. All cracks connected the interior of the building to the exterior environment. The local wind pressure coefficient of the faces of the building was determined according to [5]. The opening area of the cracks was determined by running a simulation with closed window and aiming for an average infiltration rate of 0.25 h^{-1}. In a study from 1985 [6] the average infiltration rate in 14 Danish dwellings ventilated by natural ventilation was measured. In this study, an average value of 0.19 h^{-1} was obtained, but it is stated that the 14 dwellings were among the most tightly sealed in the Danish housing mass.

Lighting: When the occupant was awake, the electrical lighting was turned on when if the daylight level dropped below 150 lux on a horizontal surface 0.6 m above the floor level at the location of the occupant (in the middle of the room). The light was only turned off when the occupant went to sleep, resulting in the light being on for the entire day if it was turned on in the morning.

RESULTS AND DISCUSSION

As seen in figure 2, the PMV index was close to neutral for a very large part of the year in all the simulations with active occupant behaviour. For the reference case with passive behaviour the PMV was far from neutral in a large part of the year (below -1 or above 1 during 72% of the year).
The PMV index was similar in the simulations with active occupant behaviour and attained values outside the control criteria for only small parts of the year. This means that the occupant was successful in controlling the environment within the comfort criteria.

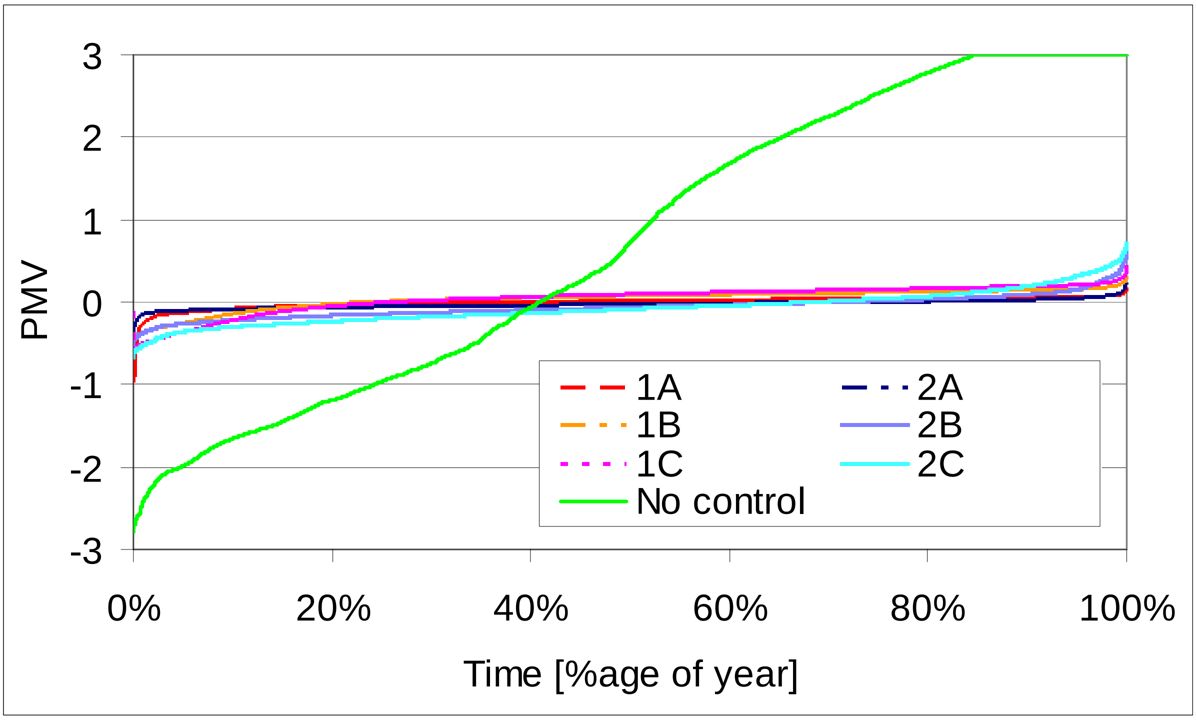

Figure 2: Duration curves for the PMV index in the 6 simulations and for the reference simulation. The figure shows how long time (in percentage of a year) the PMV index was below a certain value.

The total energy consumption refers to primary energy consumption. According to the Danish building code [7] this was calculated as the sum of all energy consumptions, where the electric consumptions were multiplied by 2.5. The highest primary energy consumption of 3948 kWh/year (simulation 1A) was 3.30 times higher than the lowest primary energy consumption of 1198 kWh/year (simulation 2C). Within each comfort control criteria the largest difference in primary energy consumption between the two behavioural modes was 324 % (3882 kWh/year simulation 1C was 3.24 times higher than 1198 kWh/year in simulation 2C). Within the two behavioural modes the largest difference in primary energy consumption was 117 % (1400 kWh/year in simulation 2A was 1.17 times higher than 1198 kWh/year in simulation 2C). This means that the comfort control criteria had much less impact on the primary energy consumption than the behavioural mode.

Table 1: Energy consumption in the simulations. The primary energy was calculated by multiplying electricity consumption by 2.5 according to the Danish building code. [7]

energy consumption pr. Year [kWh/year]	1A	1B	1C	2A	2B	2C	No control
Heating	2532	2372	2346	923	768	720	1812
Fan	380.1	423.6	431.0	1.4	0.3	0.1	0.0
Circulation Pump	13	13	13	3	2	2	13
Lighting	174	172	171	187	189	189	131
Primary energy for heating, ventilation and lighting	3948	3891	3882	1400	1246	1198	2171

Heating: The heating was turned on more often in Behavioural mode 1 than in Behavioural mode 2. Similarly, narrowing the control criteria resulted in higher energy consumption for heating.

Fan: A narrowing of the control criteria resulted in a decrease in the energy consumed by the fan in Behavioural mode 1. In Behavioural mode 2 this was opposite. In Behavioural mode 1 the fan was turned on as the first action when the occupant felt warm and turned off as the last control action when the occupant felt cold. In Behavioural mode 2 this was opposite meaning that the fan was turned on as the last control action when the occupant felt warm and was turned off as the first control action when the occupant felt cold. This meant that the fan was turned off more frequently as the control criteria narrowed in Behavioural mode 1. In Behavioural mode 2 the fan was turned on more frequently when the control criteria narrowed.

Circulation pump: In the behavioural mode 1 simulations, the heating was on for a longer period than in behavioural mode 2. This meant that the circulation pump was on for a longer period, which resulted in larger energy consumption in behavioural mode 1 than in behavioural mode 2.

Lighting: The differences in energy consumption for lighting are due to differences in daylight level. These differences were caused by differences in the use of blinds in the simulations.

CONCLUSIONS

Occupant behaviour affected the energy consumption in the building by up to 330 %. The behavioural mode affected the energy consumption in the room by up to 324 %, while the control criteria affected the energy consumption by up to 117 %.
All simulations with active occupant behaviour resulted in near neutral thermal sensation, compared to passive occupant behaviour.

The results of the study underline the importance of appropriate occupant behaviour for the consumption of energy to climatize buildings by quantifying the difference between a naïve and a rationally behaving occupant.

ACKNOWLEDGEMENT

This study was carried out as part of a Ph.D. study which is generously funded by the Danish companies: Danfoss, Velux and WindowMaster.
The authors would like to thank Professor Gerhard Zweifel, Sven Moosberger and Iwan Plüss from Hochschule Für Technik+Architektur Luzern, Fachhochschule Zentralschweiz who have contributed a substantial amount of help with the simulation programme.

User control actions in buildings: Patterns and impact

A. Mahdavi, A. Mohammadi, E. Kabir, L. Lambeva

Vienna University of Technology, Austria

Corresponding email: amahdavi@tuwien.ac.at

SUMMARY

In most buildings, occupants operate control devices such as windows, shades, luminaries, radiators, and fans to bring about desirable indoor environmental conditions. Knowledge of such user actions is crucial toward accurate prediction of building performance (energy use, indoor climate) and effective operation of building service systems. This paper describes an effort to observe control-oriented occupant behavior in two office buildings in Austria over a period of one year. Thereby, user control actions as related to one or more of the building systems for ambient lighting, shading, window ventilation, and heating were monitored together with indoor and outdoor environmental parameters. The collected data is being analyzed to explore relationships between the kinds and frequency of the control actions and the magnitude and dynamism of indoor and outdoor environmental changes. Moreover, implications of user actions for building performance (e.g. energy consumption) are studied.

INTRODUCTION

Multiple studies have been (and are being) conducted internationally to collect data on building users' interactions with building control systems and devices (see, for example, [1], [2], [3] and [4]). Such data can bring about a better understanding of the nature, type and frequency of control-oriented user behavior in buildings and thus support the development of corresponding behavioral models for integration in building performance simulation applications. Moreover, such data could support the effective (and proactive) operation of building service systems for indoor environmental control. The present contribution describes an effort to observe control-oriented occupant behavior in 42 offices in two office buildings over a period of one year. Specifically, states and events pertaining to occupancy, systems, indoor environment, and external environment were monitored. Weather stations, a number of indoor data loggers, and digital cameras were used to continuously monitor – and record every five minutes – such events and states (occupancy, indoor and outdoor temperature and relative humidity, internal illuminance, external air velocity and global irradiance, status of electrical light fixtures, position of shades). The results reveal distinct patterns in the collected data. Specifically, control behavior tendencies show dependencies both on indoor and outdoor environmental parameter. A summary of these tendencies are presented and their principal potential as the basis of empirically grounded user action models are explored.

METHODS

Object

Data collection was conducted in two office buildings in Vienna, Austria. One of these belongs to the Vienna University of Technology. We refer to this building henceforth as FH.

The second building is a large high-rise office complex (referred to, in this paper, as "VC"). An important feature of VC is its use as one of the major seats of international organizations, resulting in a very diverse occupancy profile in cultural terms. We selected 13 scientific staff offices in FH and 29 single-occupancy offices in VC. All selected offices in FH face east, situated on the 4th, 5th and 6th floors. Ten offices are single-occupancy, two are double-occupancy, and one is triple-occupancy. In case of VC, 15 offices face north (code: "VC_NO") and 14 face south-west (code: "VC_SW"). The offices are located on the 12th and 13th floor of the building. To exemplify the layout of these rooms, Figure 1 provides the schematic layout of two single-occupancy and one double-occupancy offices in the 5th floor of FH and three single occupancy offices in the 12th floor of VC_SW. The working stations are equipped with desktop computers and in some cases with task lights. Both VDT-based and paper-based tasks are performed.

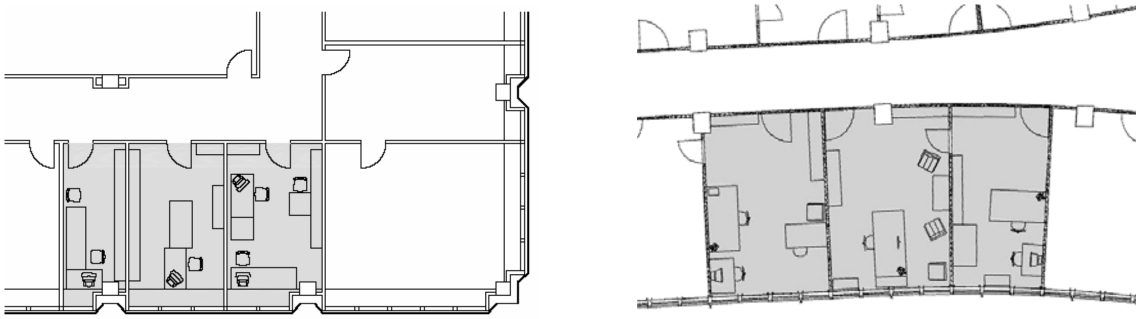

Figure 1. Schematic plan of sample offices: Left: FH; Right: VC_SW

The offices in FH are typically equipped with the followings environmental control systems: Three/four luminaries (58W each), divided into two circuits manually controlled via switches near the office door; External motorized screen shades operated by a switch mounted on a panel under the window; Fan coil under the window for fine adjustment of temperature.
The systems installed in the offices of VC_SW+NO are as follows: Three rows of luminaries with 9 or 12 fluorescent lamps (38 W) divided into two circuits and manually controlled by two switches near the entrance door; internal manually operated shading; Three to four fan coil units under each window for fine adjustment of temperature.

Monitored parameters

The intention was to observe user control actions pertaining to lighting and shading systems while considering the indoor and outdoor environmental conditions under which those actions occurred. Occupancy and the change in the status of ambient light fixtures were captured using a dedicated sensor. Shading was monitored via time-lapse digital photography: The degree of shade deployment for each office was derived based on regularly taken digital photographs of the façade. Shade deployment degree was expressed in percentage terms (0% denotes no shades deployed, whereas 100% denotes full shading). The external weather conditions were monitored using a weather station, mounted on the top of the building in case of VC_SW+NO and, in case of FH, on the rooftop of a close by university building. Internal climate conditions (temperature, relative humidity, illuminance) were measured with autarkic loggers distributed across the workstations. To obtain information regarding user presence and absence intervals, occupancy sensors were applied, which simultaneously monitored the state of the luminaries in the offices. All of the above parameters were logged regularly every 5 minutes. Monitored indoor parameters included room air temperature (in ^{o}C), room air relative humidity (in %), ambient illuminance level at the workstation (in lx), luminaries' status (on/off), and occupancy (present/absent). Monitored outdoor environmental parameters included air temperature, relative humidity, wind speed (in m.s^{-1}) and wind direction, as well as horizontal global illuminance and horizontal global irradiance (in W.m^{-2}). Vertical global irradiance incident on the façade was computationally derived based on measured horizontal global irradiance [5]. Collected data were stored and processed in a data base for further analysis. Thereby, the primary data structure follows a distinction between various types of "events" and "states" that occur at a certain point in time or persist over a certain time period [2]. For the purposes of the present analysis the range of data considered was limited to working days between the hours 8:00 to 20:00. The collected data was primarily analyzed to explore hypothesized relationships between the nature and frequency of the control actions on one side and the magnitude and dynamism of indoor and outdoor environmental changes on the other side.

RESULTS

Occupancy

Figure 2 shows the mean occupancy level in FH and VC_SW+NO over the course of a reference day (averaged over the entire observation period). Note that these values represent the presence in/at the users' offices/workstations, not merely the presence in the building. Moreover, as Figure 3 demonstrates, the occupancy patterns can vary considerably from office to office.

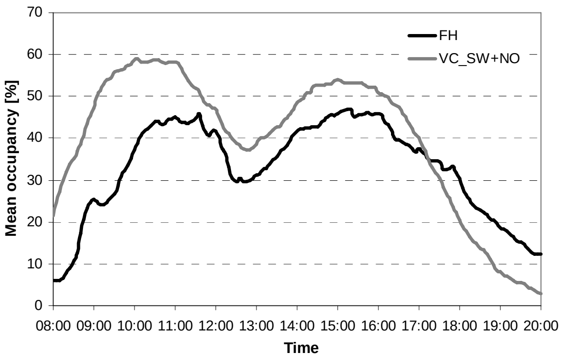

Figure 2. Mean occupancy level for a reference day in FH and VC_SW+NO.

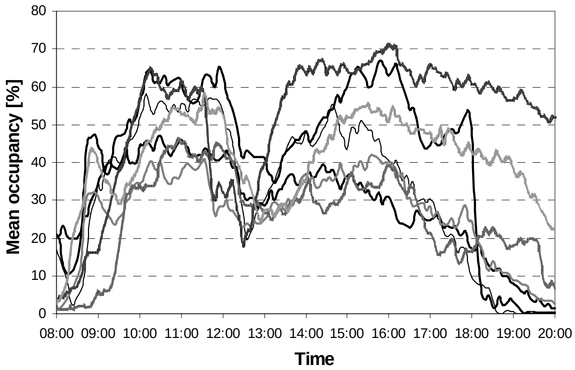

Figure 3. Observed occupancy levels in 7 different offices in FH for a reference day.

Lighting

Figure 4 shows the observed effective lighting operation in the course of a reference day expressed in terms of effective electrical power. The information in this Figure concerns the general light usage in all observed offices. Figure 5 shows the probability that an occupant would switch the lights on upon arrival in his/her office as a function of the prevailing task illuminance level immediately before arrival. Figure 6 shows the normalized relative frequency of (intermediate) actions "switching the lights on" (by occupants who have been in their office for about 15 minutes before and after the occurrence of the action) as a function of the prevailing task illuminance level immediately prior to the action's occurrence. Normalization denotes in this context that the actions are related to both occupancy and the duration of the time in which the relevant illuminance ranges (bins) applied. Figure 7 shows the normalized relative frequency of all "switching the lights on" actions (upon arrival and intermediate) as a function of the time of the day. In this case too, actions are normalized with regard to occupancy. Note that Figure 7 includes also the corresponding mean global horizontal irradiance levels.

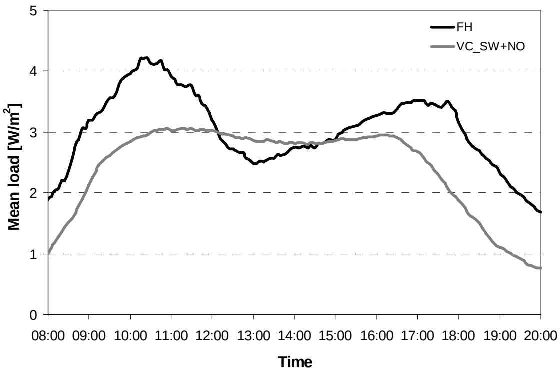

Figure 4. Lighting operation in FH and VC_SW+NO offices.

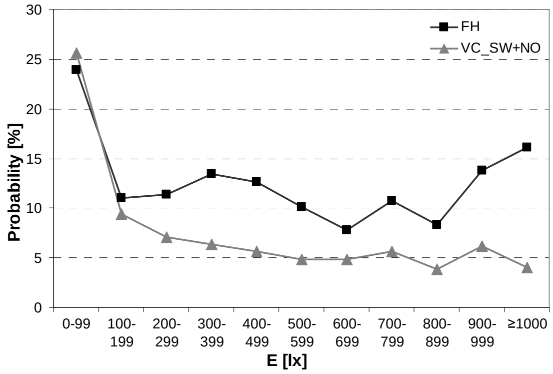

Figure 5. Probability of switching the lights on upon arrival in the office in FH and VC_SW+NO.

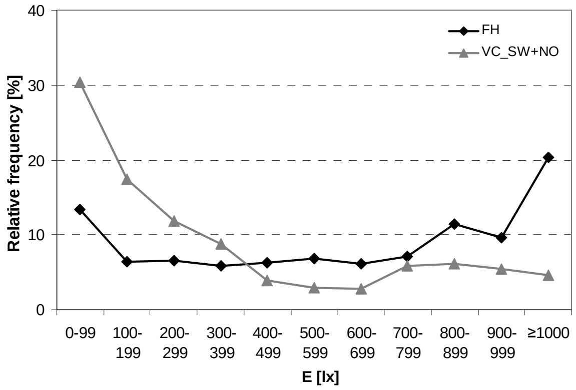

Figure 6. Normalized relative frequency of intermediate light switching on actions in FH and VC_SW+NO.

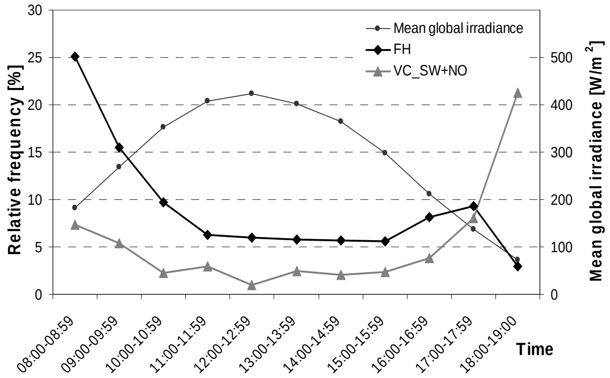

Figure 7. Normalized relative frequency of switching the lights on actions in FH and VC_SW+NO over the course of a reference day.

Figure 8 shows the probability that an occupant would switch off the lights upon leaving his/her office as a function of the time that passes before he/she returns to the office. Figure 9 shows the normalized frequency of the (intermediate) "switching the lights off" actions as a function of the prevailing illuminance level immediately prior to the action's occurrence. Normalization denotes in this case the consideration of occupancy and the applicable durations of the respective illuminance bins while deriving the actions' frequency.

Shades

Figure 10 shows the mean monthly shade deployment degree for FH, VC_NO and VC_SW. Figure 11 shows the mean shade deployment degree as a function of the incident irradiance on the façade. Figures 12 and 13 show the normalized relative frequency of the actions "opening shades" and "closing shades" as a function of global vertical irradiance incident on the facade. Normalization means that the frequency of actions (opening and closing shades) is related here to both occupancy and the duration of times in which the prevailing irradiance was within a certain range (bin).

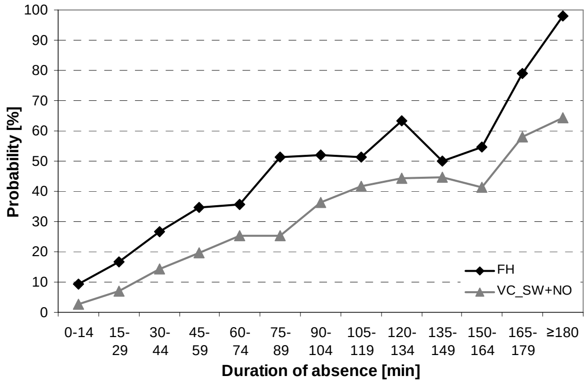

Figure 8. Probability of switching the lights off as a function of the duration of absence from the offices in FH and VC_SW+NO.

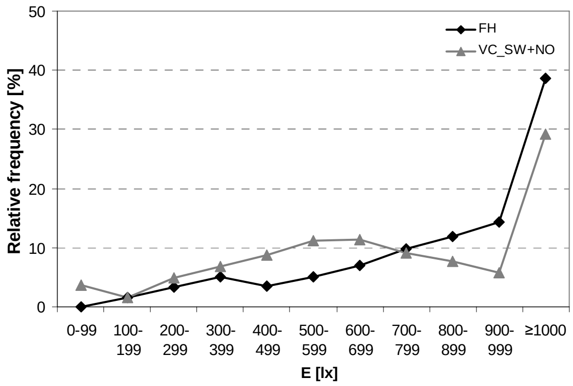

Figure 9. Normalized frequency of intermediate switching the lights off actions in FH and VC_SW+NO offices.

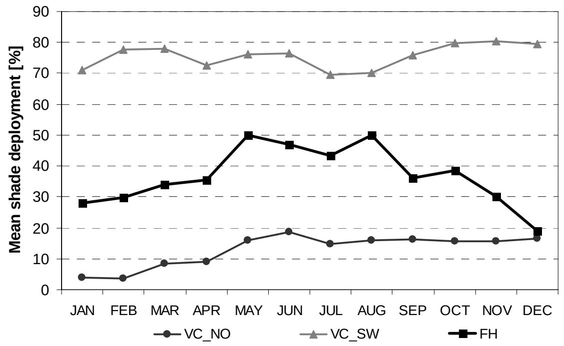

Figure 10. Mean monthly shade deployment degree in FH, VC_NO and VC_SW.

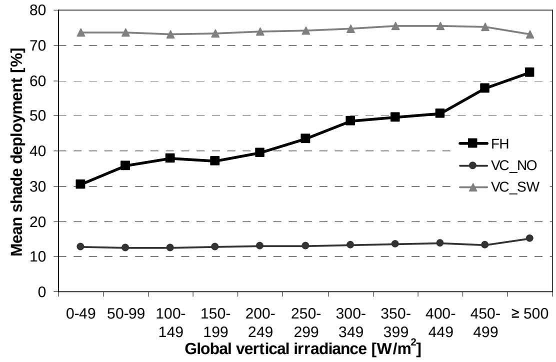

Figure 11. Mean shade deployment degree as function of global vertical irradiance in FH, VC_SW and VC_NO.

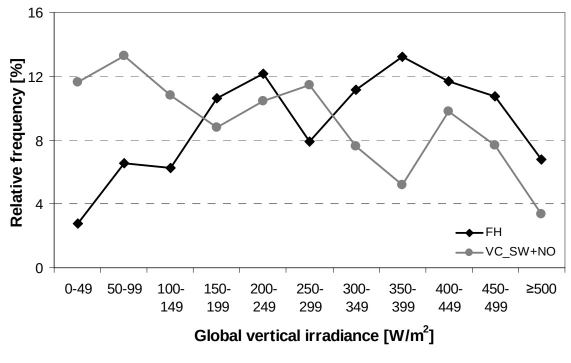

Figure 12. Normalized relative frequency of opening shades as a function of the global vertical irradiance in FH and VC_SW+NO.

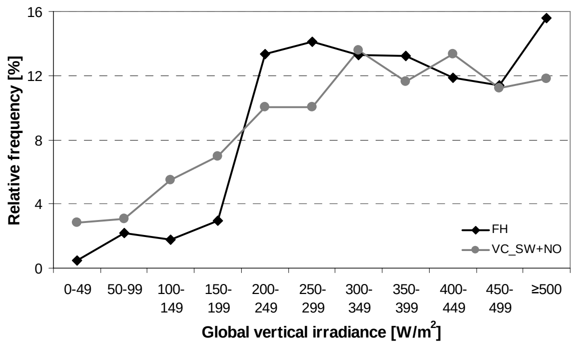

Figure 13. Normalized relative frequency of closing shades as a function of the global vertical irradiance in FH and VC_SW+NO.

Note that in the above figures opening/closing actions are not limited to actions resulting in fully opening/closing the shades. Rather, they denote a relative occupant-driven change in the position of the shades. This means that even an incremental change (e.g. changing from 80% to 40% or changing from 20% to 40%) is considered to be an opening/closing action.

DISCUSSION

The monitored occupancy in FH and VC (Figure 2) and the obviously related lighting loads (see Figure 4) reveal a similar pattern (also known from other office buildings). However, the maximum occupancy levels are different. This may be due to the circumstance that FH houses offices for teaching and research staff, who spend a considerable amount of time in classrooms and laboratories. This underscores the need for typologically differentiated occupancy models for different buildings. Patterns of this kind can be used for simulation runs in terms of corresponding hourly schedules (see Figures 14 to 16). Such simulations can be applied, for example, to explore the impact of thermal improvement measures on the building's energy use. On a more general level, our observations regarding these buildings suggest that the environmental systems in a considerable number of office buildings may in fact be "over-designed", in a sense that they are dimensioned for occupancy levels that seldom occur. The dependency of the action "switching on the lights" on prevailing illuminance levels for the two monitored buildings (see Figures 5 and 6) shows no clear pattern. The data merely suggests that only illuminance levels below 100 lx are likely to trigger actions at a non-random rate.

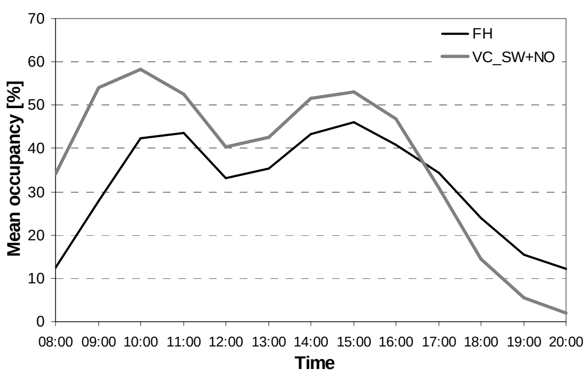

Figure 14. Illustrative simulation input data regarding mean hourly occupancy levels for FH and VC_SW+NO.

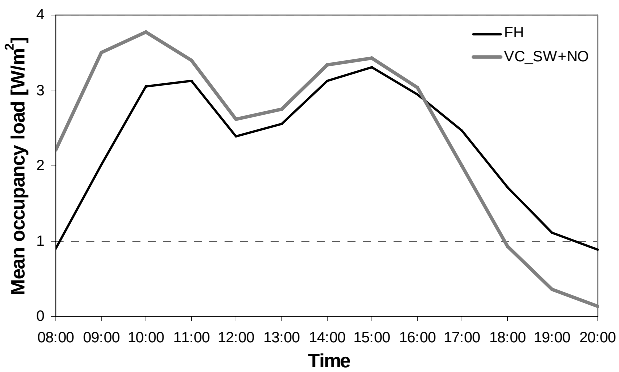

Figure 15. Illustrative simulation input data regarding mean hourly people (sensible) load for FH and VC_SW+NO.

As to the action "switching the lights off", a clear relationship to the subsequent duration of absence is evident for both FH and VC_SW+NO (see Figure 8). Occupants do switch off the lights more frequently if they are going to be away from the offices for longer periods. On the other hand, lights are not necessarily switched off by the occupants if the illuminance level in the office is already sufficient (or more than necessary) for performing typical tasks. In fact, such intermediate switching off actions appear to occur at a noticeably higher rate only once the illuminance level in the office rises above 1000 lx (see Figure 9).

The mean shade deployment levels differ from building to building and façade to façade (see Figures 10 and 11). In case of FH, where we studied the east-facing façade, a difference in the level of shade deployment can be seen between the high-radiation summer months and the low-radiation winter months (Figure 10). Moreover, an evident relationship between shade deployment and the magnitude of solar radiation is observable (Figure 11). The latter provides a very effective basis for modeling the state of shades for this building (see Figure 17). In case of VC_SW and VC_NO the shade deployment level does not vary much in the course of the year or in terms of vertical irradiance classes, but there is a significant difference in the overall shade deployment level between these two facades (approximately 75% in the case of south-west-facing façade, 10% in the case of the north-facing façade). The relative small variation range in the monthly shade deployment levels in VC_SW and VC_NO may be partly due to the fact that the manual shade operation mechanism is, in this case, much more difficult to handle than the mechanically supported shade operation system in FH.

Our observations did not reveal a clear relationship between "opening shades" actions and the incident radiation on the façade (see Figure 12). However, the corresponding analysis of the "closing shades" actions shows for both FH and VC_SW+NO a higher action frequency once the incident radiation rises above 200 W.m^{-2} (see Figure 13).

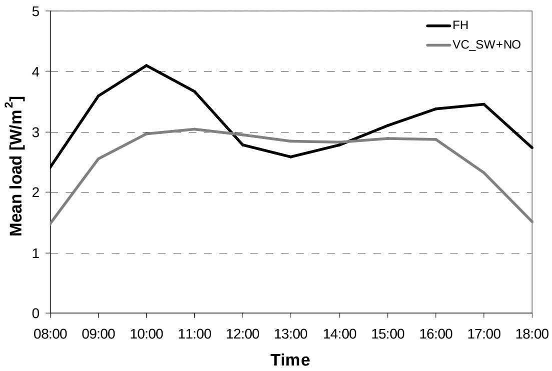

Figure 16. Illustrative simulation input data regarding mean hourly lighting load for FH and VC_SW+NO.

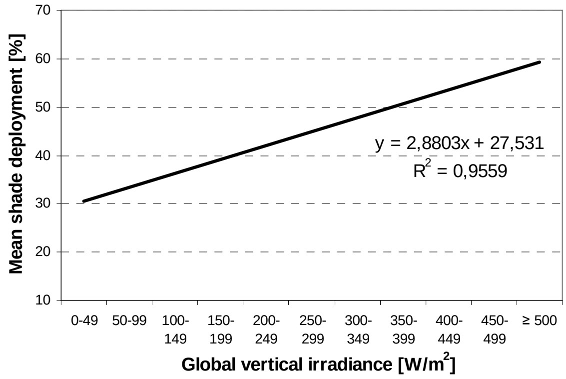

Figure 17. Illustrative model of shade deployment as a function of incident irradiance on FH's façade.

Figure 18 illustrates the potential for reduction of electrical energy use for lighting in the sampled offices. Thereby, three (cumulative) energy saving scenarios are calculated. The first scenario requires that the lights are automatically switched off after 10 minutes if the office is not occupied. The second scenario implies, in addition, that lights are switched off, if the daylight-based task illuminance level equals or exceeds 500 lx. The third scenario assumes furthermore an automated dimming regime, whereby luminaries are dimmed down so as to maintain an illuminance level of 500 lx while minimizing electrical energy use for lighting.

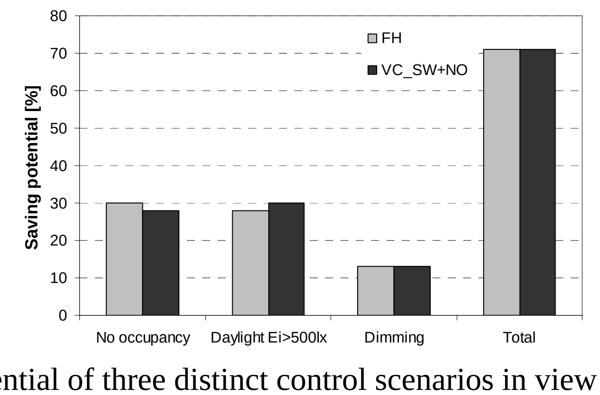

Figure 18. Saving potential of three distinct control scenarios in view of electrical energy use for lighting in FH and VC_SW+NO

The estimated saving potential in electrical energy use for lighting of the sampled offices is significant. The cumulative energy saving potential for all sampled offices in FH and VC_SW+NO is 71% (Table 1). This translates (for VC_SW+NO) into a cumulative annual energy saving potential of 17 kWh.m^{-2} or (given current energy prices) 1.3 €.m^{-2}. This would imply, that in the VC complex, annually roughly 130,000 € could be saved by a comprehensive retrofit of the office lighting system toward dynamic consideration of occupancy patterns and daylight availability. (Note that a lighting system retrofit and the resulting electrical energy use reduction would increase the heating loads and decrease the cooling loads. Given the magnitude of required cooling loads in office buildings, the overall thermal implications of a lighting retrofit are positive both in energetic and monetary terms.)

Table 1. Saving potential (electrical energy for lighting) for various scenarios and buildings

		Energy saving scenarios			
Building	Saving potential in	1	2	3	1+2+3
FH	%	30	28	13	71
VC_SW+NO	[%]	28	30	13	71
	$kWh.m^{-2}. a^{-1}$	6.8	7.2	3.0	17.0
	$€.m^{-2}. a^{-1}$	0.53	0.56	0.24	1.32

CONCLUSION

We presented a case study concerning user control actions in two office buildings in Vienna, Austria. The results imply the possibility of identifying general patterns of user control behavior as a function of indoor and outdoor environmental parameters such as illuminance and irradiance. The compound results of the ongoing case studies are expected to lead to the development of robust occupant behavior models that can improve the reliability of building performance simulation applications and enrich the control logic in building automation systems. Moreover, the obtained information will support the assessment of energy saving potential due to consideration of occupancy and behavioral patterns in office buildings.

SUMMARY

This paper reports on the occupants' behavior in various workplaces. The investigation was conducted by measurements and questionnaire to identify seat occupancy rate, occupancy rate and number of steps during working hours in real offices where occupants' behavioral pattern seemed different depending on work contents. Seat occupancy rate and occupancy rate of three different offices were ranging from about 20 to 50% during working hours. The seat occupancy rate and the occupancy rate of T Engineering Laboratory, in which the number of the occupants going in and out of the office seemed larger than that in other offices, were lower than those in the other offices where our previous studies were conducted. Although rather large difference among individuals in the number of steps was observed, the average number of steps an hour was about 550 steps. And the average walking distance an hour was estimated about 300 m.

INTRODUCTION

Comfort and energy conservation should be compatible in office buildings. Task and ambient air-conditioning system can be one of the solutions of that matter. In that system, chamber studies have identified that adjusting to the individual thermal preference contributed to the occupants' comfort [1] [2]. However, it has been pointed out that regular operation of task air-conditioning system may not accomplish energy conservation. General office workers are not always in their seats or around their seats. Usually in Japan, air-conditioning system is designed under the assumption that the occupied area per person is 5~10 m^2. In our previous studies, it was found that the number of occupants in office was smaller than that assumption. The capacity of existing air-conditioning systems in office may be excessive. The actual number of the occupants seated should be identified to operate task and ambient air-conditioning systems or other HVAC systems appropriately.
In this study, field investigation on the following items was conducted to identify the occupants' behavioral pattern during working hours.

1) Seat occupancy rate
- to understand the occupants' behavioral pattern in workplace for appropriate control of task air-conditioning systems in office.

2) Occupancy rate
- to understand the proper capacity of ambient air-conditioning systems in office based on energy conservation.

3) Number of steps
- to understand individual variation in metabolic rate.

4) Place to rest
- to understand the actual conditions how and where occupants use office except when they work.

METHODS

The investigation was conducted for all 15 days in 3 seasons (summer : August 22~26, 2005, autumn : October 17~21, 2005, winter : January 16~20, 2006) on the third floor in T Engineering Laboratory.
Figure 1 a) shows the plan of T Engineering Laboratory and the measurement points. Figure 1 b) shows the picture of measuring instrument. Table 1 shows the measurement items. Questionnaire survey was conducted to the all occupants to identify their work contents and their place to rest. The temperature sensor was settled on the surface of the chair at 30 points shown in Figure 1 a). Whether he/she seated or not was judged by the change of the surface temperature of the seats in one minute [3]. The number of the occupants who passed through the entrance was counted by the measurement device that was equipped with a infrared sensor in the shoulder height (+1400mm) [4]. Occupancy rate was calculated from the number of the occupants going in and out of the office. Nineteen occupants were chosen as the subjects to measure the number of steps during working hours. They carried the memory type pedometer. The walking distance was calculated from the number of steps and his/her length of a step. It is quite usual in laboratories that the occupants often go back and forth between the office, the different room on the other floor and the other building to do experiment etc. So that it was supposed that the number of steps in laboratories was larger than that in other buildings. Similar investigations were conducted in other buildings shown in Table 2 in our previous studies.

Table 1. Measurement items and method

Measurement items	Measurement method
Work contents Place to rest	Questionnaire
Occupancy rate	Count the number of the passing occupants by measuring of the voltage generated by infrared sensor
Seat occupancy rate	Temperature change on the surface of the seat
Number of steps	Memory type pedometer

Table 2. Outline of the buildings in our investigations

	S Building	J Building	T Building	T Engineering Laboratory
Investigation period	September 2003	December 2004	September－November 2001	3 seasons (Aug, Oct, 2005, Jan, 2006)
Total Number of the target workers during the investigation	43	257	240	31
Work contents	Clerical work, engineering	Clerical work	Clerical work, engineering, sales and marketing	Research
Measurement items	Seat occupancy rate Occupancy rate	Occupancy rate	Seat occupancy rate	Seat occupancy rate, Occupancy rate, Walking distance

RESULTS

1) Seat occupancy rate (compared with our previous studies)

In this study, seat occupancy rate was defined as follows.

seat occupancy rate = (the number of the subjects seated) / (the total number of the subjects) (1)

The working hours in each building was defined as 9:00~18:00. Figure 2 shows the variation of seat occupancy rate and Table 3 shows the average seat occupancy rate during working hours of each building. Seat occupancy rate of T Engineering Laboratory is the average of 3 different investigation periods. The results of T building and S building are also shown.
The seat occupancy rate during working hours was ranging from about 20 to 50%. The seat occupancy rate became lower in each building at lunchtime. The average seat occupancy rate in T Bldg. was 28%, that in S Bldg. was 42% and that in T Lab. was 26%. Seat occupancy rate in laboratory was lower than those in other office buildings.

Figure 3 shows the frequency of the seating for each length of time. It could be seen that about half of the seating was within 5 minutes in each building.

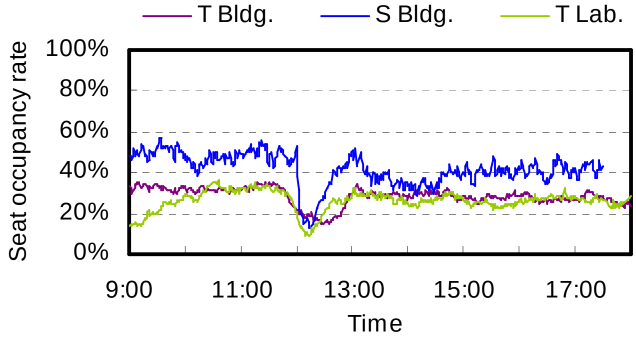

Figure 2. Seat occupancy rate during working hours of three different buildings.

Table 3. Average seat occupancy rate (9:00~18:00)

	T Bldg.	S Bldg.	T Lab.
Average seat occupancy rate	28%	42%	26%

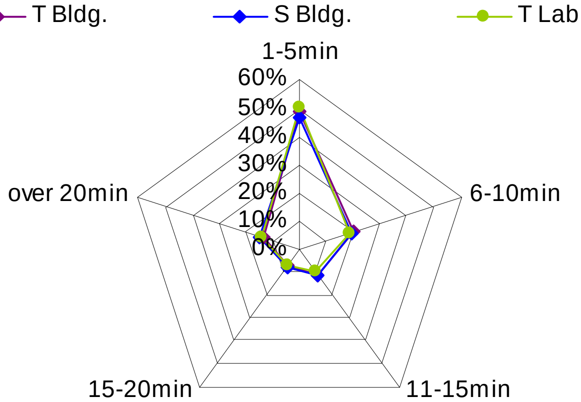

Figure 3. Frequency of the seating for each length of time.

2) Occupancy rate (compared with our previous studies)

In this study, occupancy rate was defined as a ratio of the number of the occupants in the office including the occupants who were standing or walking in the office to the number of the occupants on register.

occupancy rate = (the number of the occupants in the office) / (the number of the occupants on register) (2)

Figure 4 shows the variation of the occupancy rate in three offices. Table 4 shows the average occupancy rate of each office during working hours. Occupancy rate of T Engineering Laboratory is the average of 3 different investigation periods. The occupancy rate during working hours was ranging from about 20 to 50%.

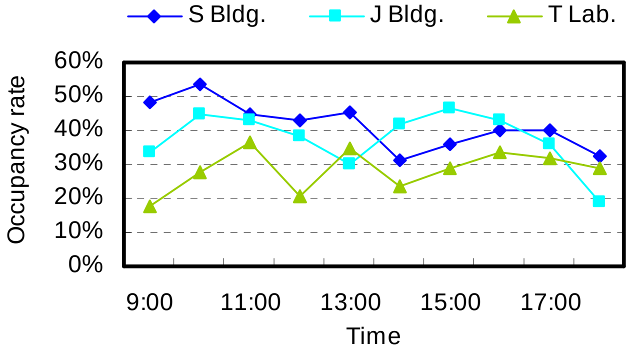

Figure 4. Occupancy rate during working hours.

Table 4. Average occupancy rate (9:00~18:00)

	S Bldg.	J Bldg.	T Lab.
Average occupancy rate	41%	38%	30%

3) Number of steps (T Engineering Laboratory)

Figure 5 shows the variation of the number of steps an hour during working hours of representative subjects in each investigation period. The characteristics of the number of steps of each subject are as follows.

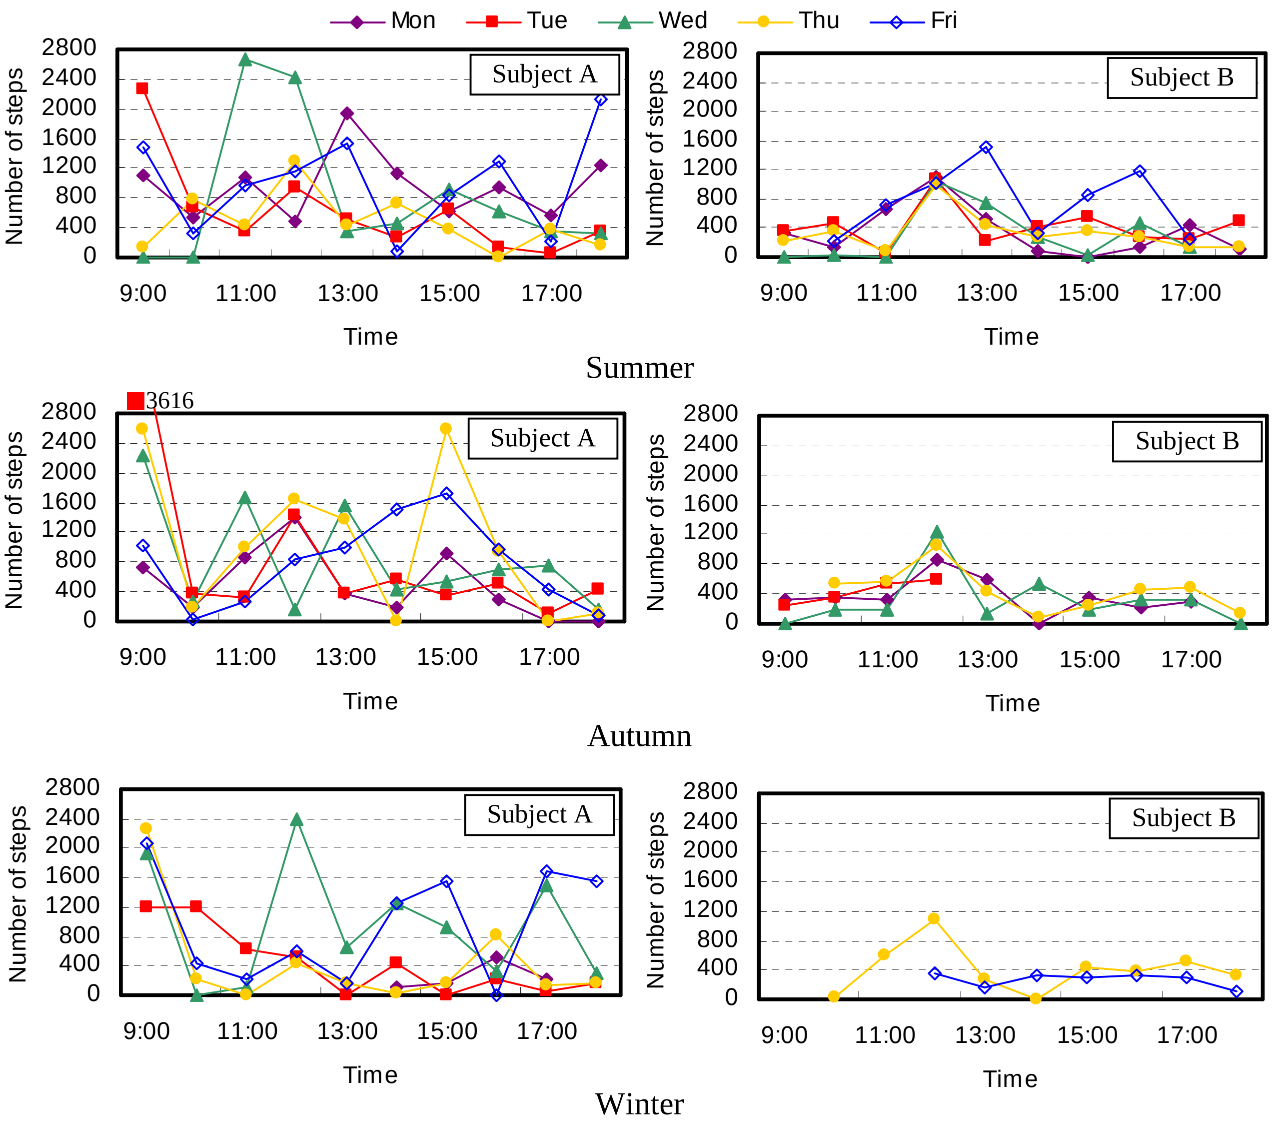

Figure 5. Number of steps of representative subjects.

Subject A

There was a large difference in the number of steps between each time. The maximum difference in the number of steps an hour was 2657 steps (see 10:00 and 11:00 on Wednesday in summer). It was supposed that there was a large difference in metabolic rate during these hours. The variation of the number of steps between each time of subject A was larger than subject B in each investigation period.

Subject B

Subject B was absent from work for 3 days in January, so the results of subject B in winter consisted of only 2 days' data.

In summer, the number of steps on Tuesday, Wednesday and Thursday showed a similar change from 11:00 to 12:00. Also the number of steps on each day except for Friday showed a similar change from 12:00 to 13:00. The number of steps of subject B was usually smaller than 800 steps excluding at 12:00 in each period. The variation of the number of steps between each time was similar in every period.

There was a large difference among individuals in the number of steps as can be seen between subject A and subject B.
It was supposed that there was a large difference among individuals in metabolic rate due to walking. Walking distance of each occupant was calculated from the following equation under the assumption that the length of each step was fixed individually. The length of a step was measured for each subject.

$$\textit{walking distance} = (\textit{the number of steps per hour}) \times (\textit{length of a step}) \qquad (3)$$

The average walking distance an hour of nineteen subjects was about 300 m. In fact, the length of a step was not always fixed. However walking distance in this study was roughly estimated, it could be one of the indices to grasp the difference in metabolic rate.

4) Place to rest (T Engineering Laboratory)
Figure 6 shows the frequency of each place to rest that was daily used by the occupants in T Engineering Laboratory. The percentage of the smokers in that laboratory was 30% and 24% of the occupants chose “smoking area” as a place to rest. That is to say, almost all the smokers in that laboratory took rest in the smoking area. The total percentage of “his/her desk” and “around his/her desk” was 40%. That is, nearly half of the occupants took rest around their desks. It can be said that the occupants did not go far from their desks to take rest.

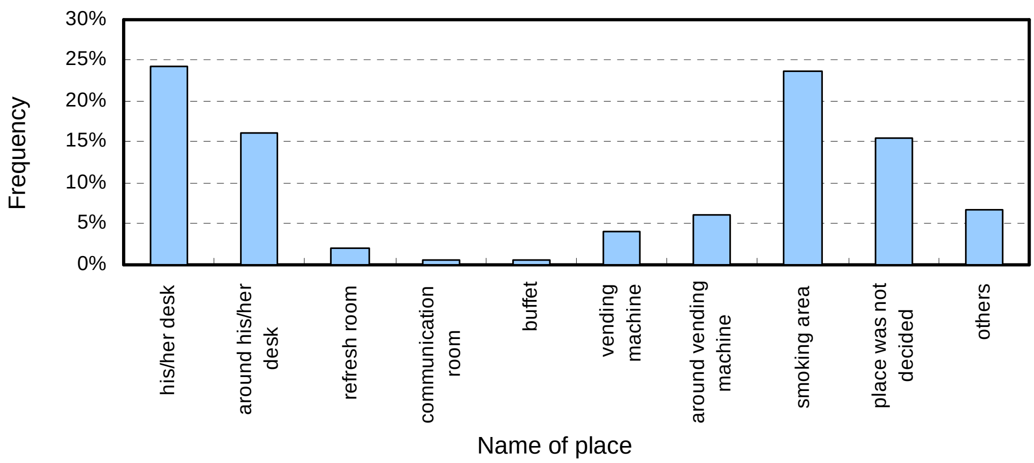

Figure 6. Place to rest.

DISCUSSION

The number and the length of the occupants stay in their task region and in ambient region are expected to differ due to work contents. Although it was supposed that the seating time in laboratories was shorter than that in general offices where clerical works, engineering and sales have done together, there could be seen a similar tendency that most of the occupants stayed in their seats for a short time (within 5 minutes) in any kinds of workplaces.
HVAC systems were so far designed under the assumption that occupants usually stay seated. However the results of the investigations in this study have identified that the time of the

occupants seated was much shorter. Also about half of the occupants on register worked out of the office. Who is the target of air-conditioning systems? Occupants' behavioral pattern should be applied to air-conditioning system design in workplaces to manage both comfort and energy conservation. The results of this study can contribute to design appropriate air-conditioning systems or HVAC systems based on the occupants' behavioral pattern. Also the results of the number of steps have indicated that there was a large difference among individuals in metabolic rate. The individual difference in metabolic rate should be considered for much meticulous control of task air-conditioning system. It is supposed that personal air-conditioning system is effective to resolve discomfort due to the individual difference in metabolic rate. Moreover about half of the occupants took rest around their desk. The environmental design based on appropriate evaluations of the occupants' behavioral pattern may achieve occupants' comfort and energy conservation in office building simultaneously.

CONCLUSIONS

In this study, occupants' behavior in workplaces was evaluated by seat occupancy rate, occupancy rate, number of steps and place to rest. The following results were obtained.

1) Seat occupancy rate during working hours was ranging from about 20 to 50%. Seat occupancy rate at lunchtime became lower in each building. About half of the seating was within 5 minutes in each building.

2) Occupancy rate during working hours was ranging from about 20 to 50%.

3) There was a great difference among individuals in the number of steps.

4) Almost all the smokers in the office took rest in the smoking area. About half of the occupants did not go far from their desks to take rest and took rest around their desks.

ACKNOWLEDGEMENT

The authors thank Mr. Hideyuki Amai (then a graduate student of Waseda University) for his cooperation in the investigation and thank Ms. Etsuko Mochizuki (then JSPS Research Fellow, Waseda University) for her cooperation in this report.

Using Semiotics to Understand the Interplay Between People and Buildings

Penny Noy, Kecheng Liu and Derek Clements-Croome

SUMMARY

The purpose of this study is to examine the usefulness of semiotics in deepening our understanding of the interplay between people and buildings, and for providing the basis for personalizing intelligent buildings using intelligent software agents. The context is the increasing demand for improved working conditions at the same time as conserving energy. Semiotics, the study of signs, has a wide and varied scope. The study first decides relevant approaches; the two approaches used here are i) considering design as communication and ii) particular techniques from a branch dealing with organizations, Organizational Semiotics - *semantic* and *norm* analysis, including *ontology charting*. These methods are applied to the overall building scenario as well as the personalization system. Recommendations for designers are to use this approach to focus on designing to influence behaviour, and to use semantic and norm analysis to capture and embed norms explicitly.

INTRODUCTION

The overall aims of our work are increased well-being and energy conservation in indoor environments. In this context there are the following specific motivations:

- To encourage the saving of energy. The recent Stern Review [1] proposes three policies to address the threat of climate change: carbon pricing, innovation, increasing awareness and encouragement of energy saving. Each of these policies provides motivation for understanding better how people interact with building systems.
- To apply and investigate new technology impact, e.g. ambient intelligence, sensors.
- To understand more about individual responses to the environment, to be able to personalize the environment to improve health, general well-being and productivity.
- To protect and enhance people's well-being indoors. As a global average, we now spend 80% of our time indoors [2] and people are living longer, increasing their interest in what habits and conditions are important short and long term.
- To create better models and predictions. Predictions from physical models often only account for a portion of actual performance, sometimes due to human factors.

Intelligent Buildings

A variety of definitions have been proposed for the term intelligent building, but for our purposes we consider two main approaches: one view based on the use of technology [3], and the other view as a broader concept based on a mirroring of human intelligence, where the building behaves intelligently in a holistic sense, within its environment [4]. Both these definitions are useful for this discussion: technology gives us new kinds of environments to investigate (how will people react to and use these new environments?); energy conservation and well-being are both part of sustainability (how can we encourage people to interact with intelligent buildings to improve sustainability?).

The specific context of our work is a project to personalize intelligent buildings, extending work of a number of research teams [3] [5] [6] [7] [8]. These systems use artificial intelligence and sensor networks to control environmental variables such as temperature, light, sound and air quality. The design of such systems provides requirements for the study of building/people interplay, though our perspective is not limited to these, because of the more general motivations described above. Figure 1 gives an overview of our proposed system which involves sensor networks sensing the environment and the people's actions, a multi-agent system representing the people, and controlling actuators. The horizontal part shows the sensors giving environmental and occupancy data to the agent system, which controls the actuators. The diagonal part shows the involvement of people: the occupants are represented by their individual preferences learnt from data collected by the personal agents and by direct input; the other stakeholders, such as the facilities manager and the owner, supply policy in the form of rules, or norms, relating to the allowed and desired behaviour of the personal agents. A key aspect of the design is the provision for occupants to be actively involved in the system operation [9].

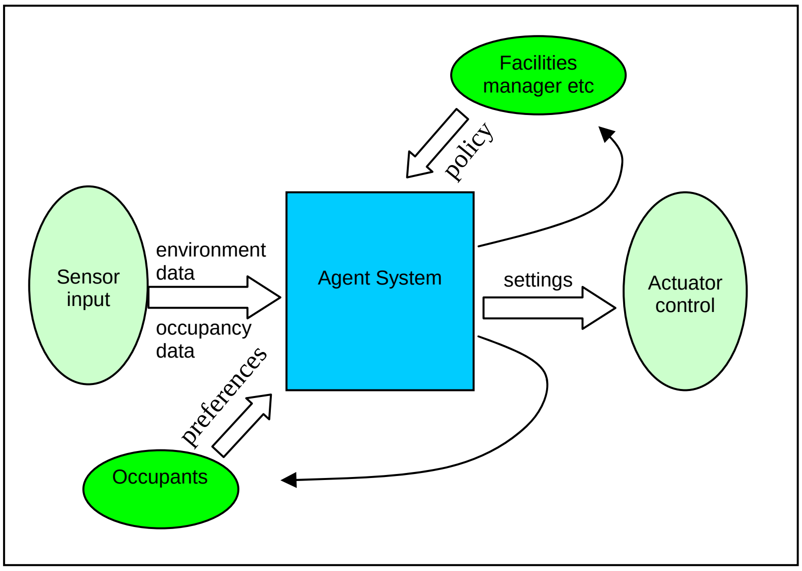

Figure 1. Overview of multi-agent system for control of the building environment

Semiotics

We propose using semiotics to deepen our understanding of the interplay between people and buildings, because semiotics, the study of signs, concerns how things are signified to us. What messages is the building giving us, visually, and through our other senses, directly (experientially) and indirectly (via information)? How do we know what we can do in a building? How do we understand how to do those things? How can buildings elicit responses from us? Semiotics, the study of signs, is a wide and varied field used across disciplines (art, advertising, linguistics and others) (for an introduction see e.g. [10]). A broad definition of semiotics is given by Eco: 'semiotics is concerned with everything that can be taken as a sign' ([11], p7, quoted in [10], p2). Thus, a sign is anything that can stand for something else – encompassing words, images, sounds, gestures and objects. Semiotics became a major approach to cultural studies in the late 1960s, but has not played such a role in computer science, though it is considered by some as providing a much needed part of knowledge representation [12], and of particular relevance for human computer interaction [13]. A development specific to the examination of communication and information in organizations, Organizational Semiotics (OS) [14] gives specific concepts and methods for examining organizations. As semiotics has been applied so widely, there are a variety of methods available. Within the context given above, and to obtain specific as well as general results, our objectives are to identify semiotic techniques that are appropriate for analyzing people/building interplay, and then apply the identified techniques.

METHODS

This section describes the semiotic approaches chosen for our context: *design as communication,* and specific techniques from OS.

Design as communication

A particular application of semiotics considers how the design communicates to the user. We can consider a large object, such as a building, or a small object such as a soap dish [15]. The message that an object gives us has intrinsic and extrinsic aspects. Intrinsic aspects concern the object itself, for instance whether it has a handle of some sort, inviting us to pick it up – 'by their look they invite certain actions' ([16] quoted in [17], p234). Extrinsic aspects concern such things as the context (e.g. where the soap dish is placed), and our own knowledge, deductive powers and experience. A consideration of the communication aspects of an object constitute good design, which may or may not include a conscious evaluation of the product as message. [17] discusses this issue in terms of 'stimulus-response capability', giving examples of door latches and numeric keypads, but also stressing the difficulty of making explicit the user's implicit knowledge and the need to watch what people do, not just listen to what they say. From a different perspective, [18] examines shopping malls, exposing their meaning of 'consume' on different levels. [19] examines how an organization's values, ethos, beliefs and behavioural codes are 'made visible' in the workplace.

Signs can be classified in different ways, which assists breaking down the message into its components. Pierce (1839-1914), one of the founders of semiotics, suggests three main forms of signs: i) symbol/symbolic: fundamentally arbitrary; ii) icon/iconic: resembles the signified; iii) index/indexical: indicates the sign in some way, so that the sign can be inferred (natural examples are smoke, thunder and footprints).

Organizational Semiotics

OS [14] provides specific methods for examining communication and information in organizations. A key concept in OS is that of *affordance*. An affordance refers to functionality (action that is *afforded*) that is provided by an environment to a responsible agent. By analyzing descriptions, problem statements, and other material, the agents, environments and affordances can be established; then a diagram can be drawn showing these relationships. Such a diagram is referred to as an ontology chart. Ontology charts can be used to gain insight into a problem and as a way of eliciting and representing user requirements. *Norms* can then be associated with affordances; these norms are the rules governing the normal use of the affordance.

RESULTS

In this section we examine the interplay from the point of view of design as communication on the macro (the overall building, building system) and micro (individual products such as radiators) levels, then apply semantic and norm analysis to the personalization system design.

Design as Communication

In recent years much effort has been expended upon creating more efficient products, including applying whole-life energy analysis, but less emphasis has been given to designing products that *encourage* energy-efficient *use*. In other words, the product as a *communication of how to reduce energy* is not considered. Designers are beginning to address this, for instance the Toyota 'EcoDrive Indicator' gives feedback to the driver – showing when they are driving in a fuel-efficient manner [21]. Since human use of products has so much impact on energy consumption, attention is beginning to focus on buildings (e.g. the 'Wattson', http://www.diykyoto.com/). Three ways that the product can encourage energy conservation have been identified by Lilley et al. [22]:

1. Intelligence. By observing the user's interaction and automatically adjusting to be more energy efficient. This can include decreasing irresponsible or anti-social behaviour.
2. Behaviour steering (scripts, affordances and constraints). By encouraging the user to use the product in a more energy efficient way through design.
3. Eco-feedback. Providing information to users to encourage pro-environmental behaviour.

For a wider view, specific to building control systems, consider these three together with the four manual and automatic control features given in [23], which also stresses the importance of designers making their 'intended operating strategies obvious, convenient and effective'.

If we consider buildings and building systems from the point of view of the messages they are giving us, we are asking not, do the spaces have the facility for X?, but, how is the facility for X indicated to the user? and how (assuming we want to encourage X) is the use of X (or a particular use of X) encouraged? When we enter a room, we see windows that can (maybe) be opened, a radiator that can be turned on etc. However, nothing tells us that we need to save energy, or how to save energy. We simply perceive (and expect) the freedom to use the objects as we want. So the system conveys to us the message that energy is free and available - the same message that has been driving society to use more and more energy.

Now consider the signs involved for an individual actuator, such as the thermostatic radiator valve in Figure 2, relating to existence, functionality, and how to operate.

Figure 2. Thermostatic Radiator Valve

- Firstly we can see that there is a control, the shiny silver top attracts us.
- It *invites* us to twist it by its shape. By handling it we can see that it twists clockwise and anti-clockwise. Anti-clockwise is iconic with opening.
- We can see numbers on the side and these go up when we turn the valve anti-clockwise, though they are on the side and so we can't see them very well. These suggest that the temperature will go up.
- There is a red band that gets wider as the valve is opened. This is iconic, red ≡ hot, so we think that opening ≡ hotter.

However, there is an ambiguity here. Does this mean that the radiator is hotter, or that the temperature of the air around the radiator is hotter? It seems that it should refer to the radiator as the valve is attached to the radiator. We are misled by the 'opening' of the valve - perhaps if it is partly opened, the radiator will be partly on? Of course, this is not the case, as this is a thermostatically controlled valve, so is sensing the temperature around the valve. This example shows that we need prior experience to read the conventions (e.g. twisting clockwise), but further understanding to fully control the device. Here the designers have included signs of functionality, but ambiguity remains without further knowledge.

Organizational Semiotics

Now we apply semantic and norm analysis techniques from OS, so that we can provide concrete specifications and, particularly, so that we: i) avoid loss of signification in moving toward automated systems (by analyzing the manual operation); ii) elicit and embed functionality and norms in automatic systems, so that they can be updated. Semantic analysis has four phases: problem definition, candidate affordance generation, candidate grouping and ontology charting [14]. A partial listing of semantic units extracted from the problem statement for the personalization system is shown in Table 1.

actuator action (of occupant) agents air quality (ventilation and CO2 levels) allowed alters amount (of clothing) ….	feedback goals group (of occupants) health and safety (agent) heart rate how good how well identification ….	personal agent personal profile personalizes policy preferences presence record repositories ….

Table 1. Partial listing of semantic units for the personalization system

From the semantic units, agents and affordances are identified, and then arranged as possible, or *candidate*, groupings. By combining these candidate groupings, a complete ontology chart can be drawn. Note that by following the procedure, the chart is derived exclusively from the requirements documents, so that it adopts the language and logic of the problem owners. The ontology chart for the proposed personalization system is too large to show here, so the manual situation is shown in Figure 3. A database structure can be generated from the ontology chart, for example in the form of a semantic temporal database (STDB) [14].

Norms govern the way individuals behave, think, judge and approach the world within a community [14]. Norms can be categorized in different ways; here we consider the category of behavioural norms, as most rules and regulations in organizations belong to this category. These concern what people must, may, and must not do, equivalent to the deontic operators ‘is obliged’, ‘is permitted’ and ‘is prohibited’. The general form of such a norm is

whenever <context>
if <condition>
then <agent>
is <deontic operator>
to <action>

Applying this to the building system example:

whenever a person occupies a room
if the person is staying in the room for a while AND (is an employee of the organization responsible for the room OR has been invited by the organization)
then the person
is permitted
to alter the room controls (window, actuators)

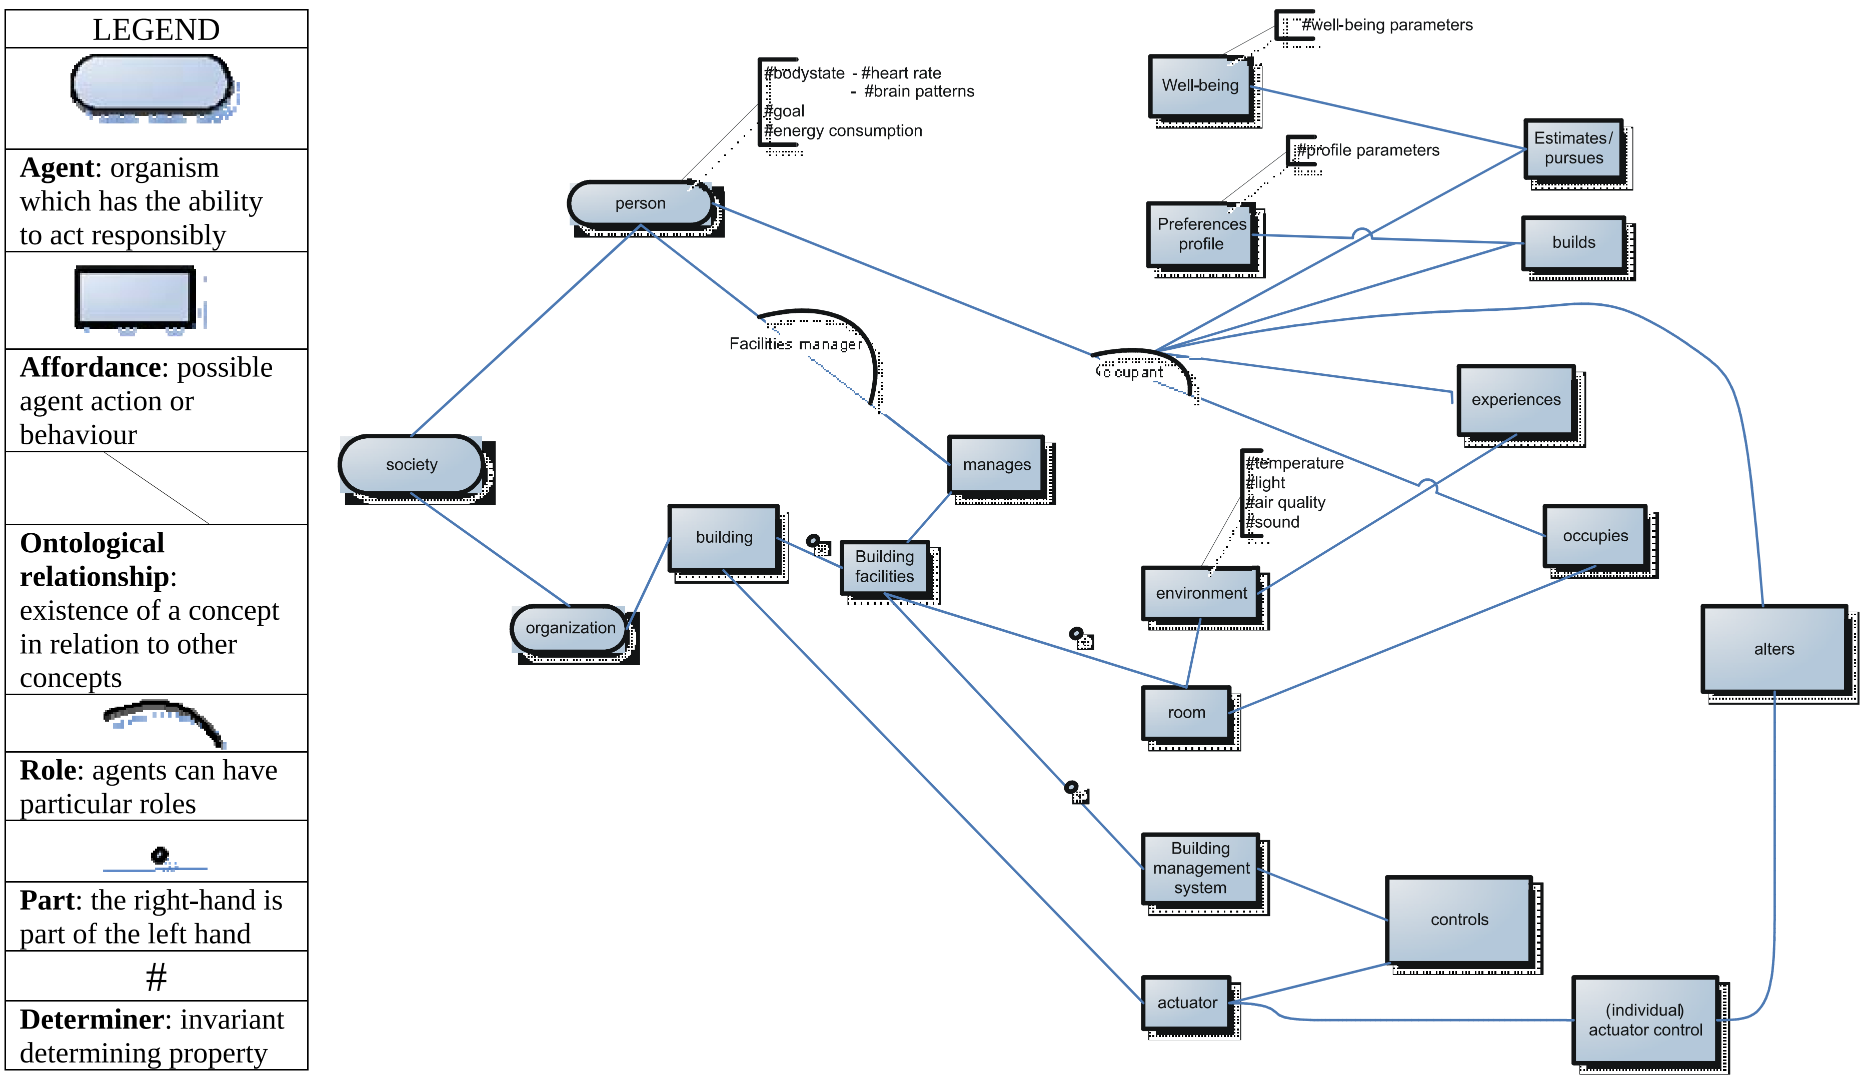

Figure 3. Ontology chart for manual control of environment

These norms can be kept computationally in a norm store, providing conditions and constraints for the system operations and being associated with the relevant affordances in the STDB. In this way, appropriate norms can be invoked whenever an action is requested. For the building example given above, the context is a person entering a room. If that person meets certain criteria, they are given permission to alter the room controls. The example can be translated into a norm specification language as follows:

```
whenever staying(person,room) AND (employs(organization,person) OR
invites(organization,person))
permitted to start alters(person,controls)
```

This shows that this norm is connected with the affordances ‘staying’, ‘employs’, ‘invites’ and coupled with the affordance ‘alters’ in the STDB, and the inner brackets show each context and agent associated with each affordance. Every time there is an operation *`to start alters(person,controls)`*, this norm will be invoked. Thus, each norm is associated with patterns of activity described in the ontological chart, so that the requirements of the system can be defined in detail. The condition specification given here is only one of many possible, for instance this one could be changed and only specify the owner of the room to alter the room controls. Capturing this level of detail, having a way of storing it in the system, and the ability to access and change it later (as well as the possibility of discovering norms by observing behaviour) is of importance for autonomous systems which replace manual operations and need to be able to change and evolve at the same time as involving a variety of stakeholders.

DISCUSSION

The ‘design as message’ approach enables us to focus on the overall message of the design, as well as affordances and constraints. Currently little is being done to convey energy conservation messages within the product itself. We are relying on general education, but this is inadequate, especially since there is actually a constant rise in electricity consumption due to electrical goods. The energy demand in the home from acquisition of more electrical equipment has increased by 70% between 1970 and 2001 [24]. The radiator thermostat example suggests a means of decomposing the signage of products, and can be applied to other levels, such as the overall system and the software application. Semantic analysis provides a different approach for the elicitation, verification and recording of requirements, which can be used for the design phase, as well as the embedding of behaviour norms. This will help to see whether the product conveys the message the designer wanted, as well as measuring usability and functionality [13]. Norm analysis gives a form for capturing behaviour as rules and thus provides an explicit representation for computational use.

This initial study shows that semiotic techniques are promising and indicates the value of furthering the work. Specific recommendations are to:

- Apply ‘design as communication’ perspective on different system levels.
- Use ontology charts to capture the signification from the start.
- Use norm embedding to enter rules explicitly and enable storage and updating.

Variable ventilation airflow rate in dwellings – costs and benefits

SUMMARY

Ventilation systems with variable airflow rates (VAV) can be used to decrease the amount of energy used to heat and cool the supply air and move the supply and exhaust air. Additionally, the occupancy detection system can work together with the heating and cooling system and decrease other energy uses by changing the indoor climate demands when building is not occupied. However, a VAV system has higher installation and maintenance costs than a system with constant airflow rate (CAV). This paper gives examples of energy use and life cycle costs (LCC) for different ventilation systems in dwellings. The LCC was calculated with a computer program for LCC calculations of indoor climate systems, ProLive. The occupancy level of a building is one of the most important parameters regarding the energy use calculations of VAV systems. The results show that it can be beneficial with variable airflow rate in dwellings from an LCC perspective.

INTRODUCTION

People spend up to 90% of their time indoors [1]. To ensure people’s health and comfort when they are indoors, the indoor air quality and thermal comfort must be appropriate. An indoor climate system, consisting of heating, cooling and ventilation, serves this purpose [2,3]. The aim of the indoor climate system is to provide the building with a good thermal comfort and indoor air quality. The indoor climate system must also use as little energy as possible.

This paper focuses on the ventilation systems and the airflow rates of the ventilation systems in detached houses and multifamily dwellings. Each ventilation system can either have a constant airflow rate (CAV) or a variable airflow rate (VAV). The idea behind having a variable airflow rate is to cool with air, to heat with air, or to decrease the airflow rate at lower occupancy levels to ventilate when there is a need for it only. Variable airflow rate ventilation based on the demand for air only is sometimes called Demand Controlled Ventilation (DCV). Ventilation systems with variable airflow rate based on the demand for air can be used to decrease the used amount of energy to heat and cool the supply air and move the supply and exhaust air. However, a variable airflow rate ventilation system has higher installation and maintenance costs than a system with constant airflow rate.

This paper presents the life cycle costs (LCC) for different ventilation systems in dwellings both with and without variable airflow rate based on the occupancy. In dwellings in Sweden, variable airflow rate is very rare except for the fact that the stove hood often can be set to different airflow rates. This is a smaller part of the total airflow rate and the idea is not to reduce the airflow rate at low occupancy levels.

Objectives and limitations

The life cycle costs of the heating and ventilation systems were simulated using a computer program for life cycle costs of indoor climate systems, ProLive. The life cycle costs were done both with and without variable airflow rate for multifamily apartments and detached houses.

The occupancy level of a building is one of the most important parameters regarding the application of variable airflow rate ventilation systems. The occupancy level has not been measured. However it has been a parameter in the calculations. Only theoretical buildings have been simulated, one typical multi family dwelling and one typical detached house. Field measurements were not an alternative, since it would be difficult to measure the life cycle cost, particularly for variable airflow rate ventilation, that rarely exists in dwellings.

METHODS

One problem with the design of an indoor climate system is that there has been a predominant focus on initial costs. A life cycle approach could improve both the energy and economic performance of the indoor climate system. The life cycle cost of a product is the sum of all costs related to that product over its entire life span. Future costs are discounted to the value of today, the net present value, by the use of a discount rate of interest.

The computer program ProLive was developed to calculate life cycle costs for indoor climate systems in offices, schools and dwellings [4]. It handles thousands of combinations of heating, cooling and ventilation systems typical for Sweden and takes into account the initial costs for buying and mounting components through a power demand calculation, energy costs, maintenance costs, repair costs and costs for space loss due to system components. Costs are based on Swedish prices from Sektionsfakta [5], which is a known cost database for the building sector. Outdoor climate is obtained from the computer program Meteonorm [6], which simulates outdoor climate data for the entire world. ProLive has features to model productivity and health costs based on indoor temperature and airflow rate even if the user has to provide the correlation data between the parameters and the costs. ProLive uses Swedish costs in SEK excluding VAT (25% value added tax). 1 SEK ≈ 0.14 US$ ≈ 0.11 € as of 2007-02-15.

In this study, the price of heat was set to 0.6 SEK/kWh and the price of electricity was set to 0.8 SEK/kWh excluding VAT. The discount interest rate was assumed to be 1% for electricity, 2% for heat and 3% for other costs representing a real price increase for heat and even more for electricity. An annual value of 800 SEK/m² was assumed for space loss. It was assumed that there is a 20% deduction from the initial costs for both air and hydronic components compared to Wikells [5]. A 40 year calculation period was used. The scrap value was assumed to be zero. The occupancy detection cost was assumed to be 766 SEK, which is supposed to be equal to an IR occupancy sensor and the mounting of it. This could consist of a manually operated switch inside each apartment and the detached house respectively.

Buildings

None of the buildings were set up with cooling. Hydronic radiators were used for heating. Assumed data for the buildings are given by Table 1. The outdoor climate data are from

Stockholm, Sweden. Table 2 gives the apartment areas, the window areas, the heat transmission areas and the number of people per apartment. The rooms with supply devices are the rooms that are not kitchens or bathrooms. Exhaust devices are located in the kitchen and in the bathrooms.

The multifamily dwelling was assumed to have four storeys with two one-room, two two-room, two three-room and two four-room apartments on each storey. It was assumed that there were two exhaust devices for each apartment, except for the four-room apartments where it was assumed that there were three exhaust devices. The building was assumed to be a medium weight construction.

The detached house was set up with two storeys. There were three exhaust devices on the bottom floor and two on the second floor while there were two supply diffusers or air inlets on the bottom floor and three on the second floor. It was assumed that four persons were living in the house.

Table 1. Data for the simulated buildings. Internal load refers to the internal heat gain excluding people. Heat transmittance is the average value for the building.

	Detached	Multi family		Detached	Multi family
Storey height	3 m	3 m	Chiller COP	2	2
Building length	12 m	43.3 m	Room temperature	22°C	22°C
Building width	8 m	12 m	Internal load presence	3 W/m²	3 W/m²
Total floor area	192 m²	2080 m²	Internal load abscence	1 W/m²	2 W/m²
Heat transmission area	288 m²	Table 2	Heat recovery eff.	0.8	0.8
Window area	15 m²	Table 2	Heat plant eff.	90%	0.9
Heat transmittance	0.25 W/(m²·K)	0.365 W/(m²·K)	Solar rad. trans.	0.5	0.4
Supply air temperature	18°C	18°C	Leakage at 50 Pa	0.8 l/(s·m²)	0.8 l/(s·m²)

Table 2. Data for the multi family dwelling. The building was set up to consist of two of each of the listed apartments per storey and four storeys.

Nbr of rooms/apartment	1 room	2 rooms	3 rooms	4 rooms
Nbr of persons/apartment	1	2	3	4
Window area	3 m²	6 m²	8 m²	9 m²
Apartment area	30 m²	50 m²	80 m²	100 m²
Heat transmission area	34.2 m²	57.0 m²	91.2 m²	114 m²

Ventilation systems

Specifications of the indoor climate regarding thermal comfort and air quality are determined by requirements, recommendations, national regulations, or by the building's user. This helps to simplify the design process of an indoor climate system. Usually, the minimum and maximum temperatures and the supply airflow rate are set according to the amount of activity in the building. In Sweden, the requirement is currently 0.35 l/(s·m²), where the area refers to the floor area [3]. If nobody is in the building, there is no need for airflow at all if no situation may arise with health risks indoors. This can be solved by a certain minimum airflow rate or by starting the ventilation a certain time before the house or apartment is occupied. Since it requires planning from the user, the most realistic way is to set a minimum airflow rate.

The systems included in this study were, exhaust ventilation system (E) with air inlets at the windows in the rooms that were not kitchens or bathrooms, and supply and exhaust ventilations system with heat recovery (SEH) with ceiling diffusers for supply air. Constant airflow rate and variable airflow rate were simulated. In the case of the variable airflow rate system, an airflow control damper (two for the supply and exhaust system) and an occupancy detector for 766 SEK were assumed to be included for each apartment in the multifamily dwelling. That means that the airflow rate was varied for the entire apartment and not for each room in each apartment. For the detached house, it was assumed that the airflow rate for the entire house was varied in the same manner. There is need for an occupancy detector but not for dampers since it is enough to control the air handling unit, and that option is included in air handling units on the market.

Occupancy

The occupancy rate is noted O_P. It is the ratio between the actual number of people in the building at a certain time and the number of people the building is designed for. In this study, it was assumed that O_P was constant over the year, which reduces the number of parameters. Johansson [5] analyzed this simplification. The fan electricity was influenced slightly by the use of a time distributed occupancy rate since the fan power is not linear to the airflow rate. The energy for heating and cooling is influenced even less.

$O_p = 0$ means that the building is unoccupied. $O_P = 1$ means that the building has full occupancy. It is assumed that the designed airflow rate of 0.35 l/(s·m²) is needed when $O_p = 1$ and that it is reduced linearly according to Equation 1 when O_P decreases. The coefficient α sets the airflow rate ratio compared to 0.35 l/(s·m²) at $O_P = 0$ and q is the airflow rate in l/(s·m²) where the area refers to the floor. In the study, $\alpha = 0$ and $\alpha = 0.33$ were tested. At $O_P = 0$, that means an airflow rate of 0 for $\alpha = 0$ and 0.1155 l/(s·m²) for $\alpha = 0.33$. The occupancy rate also influences both the internal load from people and the internal load, excluding load from people according to Table 1.

$$q = 0.35 \cdot \left(O_P + \alpha\left(1 - O_P\right)\right) = 0.35 \cdot \left(O_P\left(1 - \alpha\right) + \alpha\right), \qquad (1)$$

RESULTS

Table 3 gives the resulting life cycle costs for the different simulated buildings and ventilation systems at $O_P = 60\%$ and $\alpha = 0.33$. From here, it is shown that it is best to live in a detached house with a supply and exhaust ventilation system with heat recovery and variable airflow rate. In the costs hydronic heating, connection to district heating is included.

Figure 1 shows the life cycle cost and the energy cost for the different systems in the multi family dwelling as a function of O_P. Lower O_P means reduced average internal heat load which increases the need for heating but if the airflow rate is reduced at the same time, this increase is dampened or turned to a decrease. Figure 2 gives the life cycle and energy costs for the detached house. Figure 3 shows the accumulated life cycle cost over time, which is the life cycle cost at a certain calculation period for both simulated buildings. It takes a little less than ten years to benefit from heat recovery and around 15 years to benefit from variable airflow rate.

Table 3. Output data from ProLive for the two simulated buildings. The costs and the LCC refers to the entire calculation period, 40 years. The areas in the denominators of the units are the floor area. O_P = 60% and α = 0.33.

Building	Multi family dwelling				Detached house			
Ventilation system	E		SEH		E		SEH

Cost, space loss / SEK	108	108	278	278	25	25	84	84
Life cycle cost / SEK	1804	1643	1726	1682	1828	1650	1685	1630

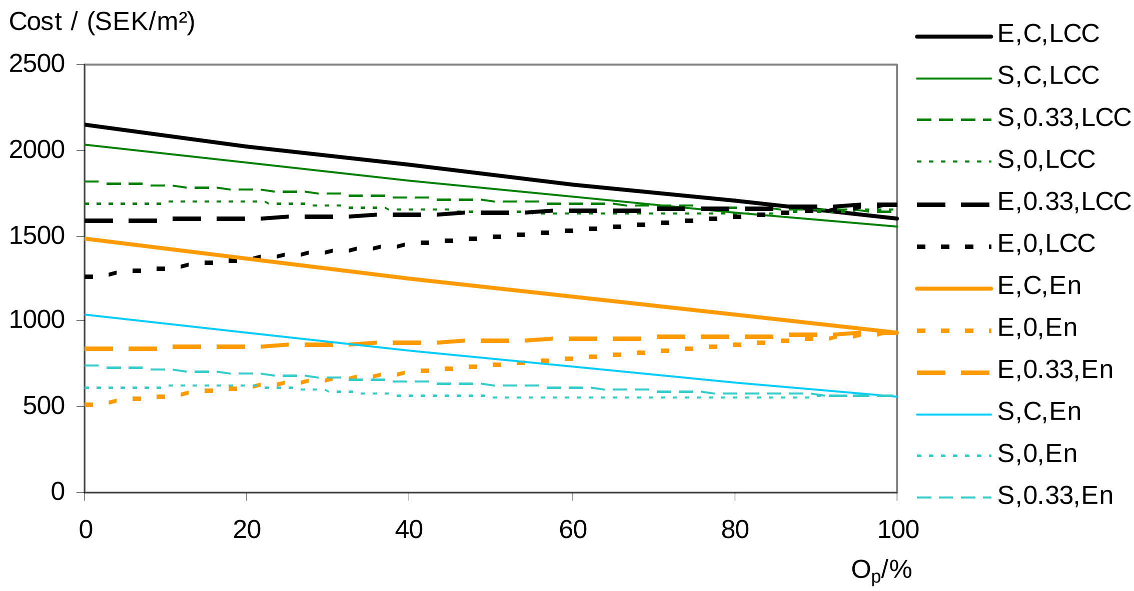

Figure 1. Life cycle cost (LCC) and energy cost (En) per floor area for the multi family dwelling. E means exhaust ventilation, S means supply and exhaust ventilation, C means constant airflow rate, 0 means α = 0 and variable airflow rate and 0.33 means α = 0.33.

The average U-value, which describes the heat transmittance through the building per area and temperature difference, and the building length, which affects the floor area, was varied for the detached house with the results shown in Figure 4. Bought energy would also be needed for household electricity and tap water which is not included in this simulation.

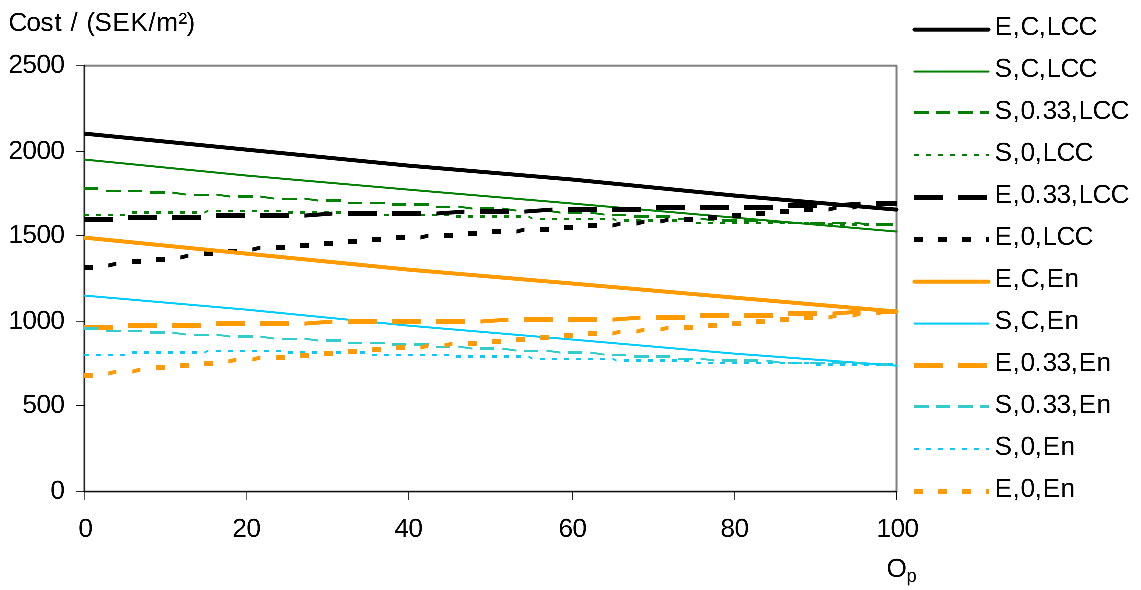

Figure 2. Life cycle cost (LCC) and energy cost (En) per floor area for the detached house. E means exhaust ventilation, S means supply and exhaust ventilation, C means constant airflow rate, 0 means $\alpha = 0$ and variable airflow rate and 0.33 means $\alpha = 0.33$.

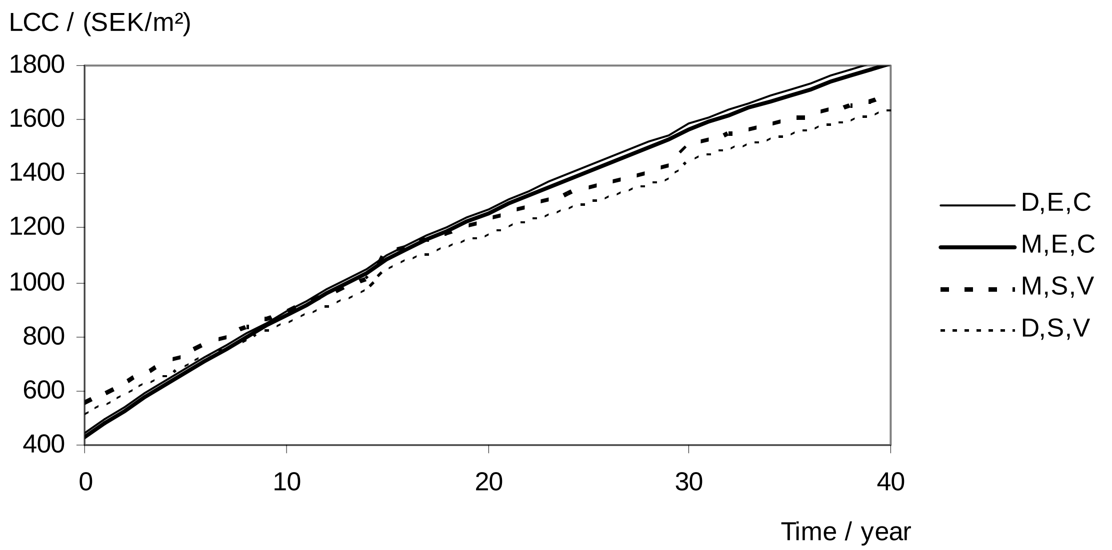

Figure 3. Accumulated life cycle cost (LCC) per floor area. E means exhaust ventilation, S means supply and exhaust ventilation, C means constant airflow rate, V means variable airflow rate with $\alpha = 0.33$, D means detached house and M means multi family dwelling. $O_P = 60\%$.

If it is assumed that the occupancy is either 100% or 0 in a certain apartment or house, a certain occupancy rate must correspond to a specific part of the day when the apartment or house is occupied. In Figure 5, it was assumed that the building was occupied during nights and empty during the days to test the assumption of using an average constant occupancy rate. This set up also gives the option to reduce the requirements on the indoor temperature when unoccupied. This possible temperature span decreases the energy use for this light weight detached house.

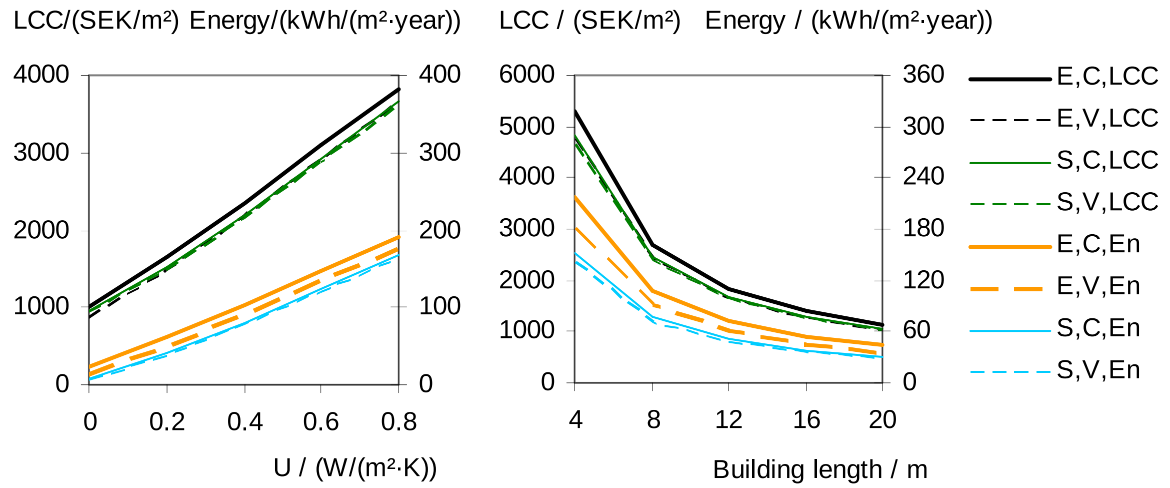

Figure 4. Life cycle cost (LCC) and annual energy use (En) for heating and fans for the simulated detached house when the U-value and building length were varied respectively. E means exhaust ventilation, S means supply and exhaust ventilation, C means constant airflow rate, V means variable airflow rate at α = 0.33.

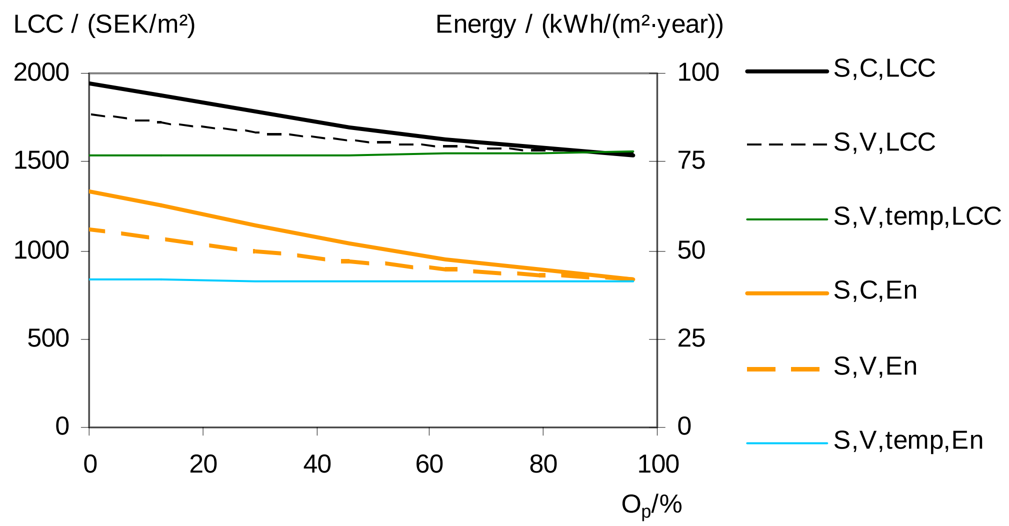

Figure 5. Life cycle cost (LCC) and annual energy use (En) for heating and fans for the simulated detached house as a function of O_P when the house was assumed to be occupied during nights. S means supply and exhaust ventilation, C means constant airflow rate and V means variable airflow rate at α = 0.33. temp means that the demands on temperature in that set up was changed during absence from 22°C to a span from 18°C to 26°C.

DISCUSSION

It has been shown that occupancy controlled variable airflow rate ventilation systems can be beneficial from a life cycle cost perspective in both multifamily dwellings and detached houses. The simulated occupancy detection cost was 766 SEK per apartment or house. This cost is reasonable for a manual system where the user chooses the number of people, for example at the main door. Right now, a lot of development is going on regarding cheaper sensors for detecting occupancy. There are indications that industry will come up with carbon dioxide sensors in this price range, which would be an alternative that is not dependant on the user to work properly. It would be possible to control each single room in each apartment or in the detached house instead of controlling the entire apartment or detached house but that would be more complicated and expensive. By doing that, air could be supplied where people are in the building which initiate a discussion of the form of the requirements on airflow rate. ProLive does not simulate that at this point of time but it could be a feature in the future.

It has also been shown that supply and exhaust ventilation with heat recovery can have a lower life cycle cost than exhaust ventilation systems, which has a lot of other disadvantages including draughts and poor control of the air movements as example [7].

Simplifications have been made. An example is the constant temperature efficiency of the heat recovery unit, which in reality would increase the benefit from lower airflow rate because of higher efficiencies at lower airflow rates. Another example is the constant occupancy rate over time. In fact, it varies both over the day, which does not seem to have much influence, and over the year which probably has more of an influence but such measured data is lacking.

With an occupancy detection system, it would be possible to control, for example, lighting or other use of house hold electricity. It is perhaps rather common that people switch off the lighting when they are not indoors but if it is assumed that 200 W per house could be controlled by the occupancy and O_P = 60%, 3.7 kWh/(m²·year) can be saved from the household electricity for the simulated detached house. On the other hand, the need for heating energy will increase since the internal heat load provides a certain amount of heat.

In this study, it has been assumed that the nominal airflow rate was set according to the Swedish building code. This airflow rate is based on the floor area and not on the occupancy rate, which should be the parameter controlling the airflow rate. It can be discussed whether or not the requirements in the building code are appropriate since the airflow rate per person will depend on the nominal floor area per person. From a moisture perspective, it can be argued that the indoor vapour content will increase if the airflow rate is reduced parts of the day. On the other hand, during winter time, the risk of having dry air will decrease with variable airflow rate. The occupancy detection could also be based on vapour production or a combination of occupancy parameters. More research is needed regarding the most apparent parameter in this study, the occupancy rate. Measurements will hopefully be performed in the future.

Demand Controlled Ventilation (DCV) and Energy Savings : application on sites

Jean-Luc Savin[1], Anne Marie Bernard[2] ,Laurent Jardinier[1]

SUMMARY

DCV is one of the main issues in the near future due to the large potential of energy savings, the importance of maintaining a good IAQ with an adequate ventilation rate and the optimisation of system sizing.
Nevertheless the technology or sensor used must adequately follow the actual demand. The study shows on site results on two different technologies.
The first site is a collective dwelling installed with natural ventilation system situated in Nangis, near Paris (France) which has been renovated with hybrid ventilation and humidity controlled outlets and inlets. HR-VENT is an in-situ monitoring which exceptional character lies in the dimension as well as in the used measurement means. With more than 700 million data saved during two years out of 55 occupied dwellings, the experimentation made it possible to measure the effectiveness of a new ventilation system and contributed to enrich the knowledge on the operation of natural and hybrid ventilation in collective dwellings. From January 2004 to December 2005, the data of relative humidity, temperature, pressure and extracted airflow were saved every minute in each technical room, using specifically developed sensors. Directly related to the meteorological data, these measurements allowed to evaluate the performances of the humidity sensitive ventilation and the contribution of the mechanical assistance; they also determined the capacity of the hybrid system to improve indoor air quality and to control the thermal losses.
The second site is a meeting room of an office building which has been installed with a mechanical DCV system using optical (infra-red) sensors to determine the number of occupants. The results on site show the performance of the system and adequate determination of the real number of occupants, assessed by webcam, and the induced results in IAQ and energy.
Although DCV is common in residential ventilation, it is not yet frequently used in non residential area. We expect an increase of DCV systems in the future to fulfil the targets of energy regulations. The potential of savings is tremendous on the market and products and solution are more and more common

INTRODUCTION

DCV (Demand Controlled Ventilation) is one of the main issues in the near future due to the large potential of energy savings, the importance of maintaining a good IAQ with an adequate ventilation rate and the optimisation of system sizing.
In France, residential ventilation systems controlled with humidity are commonly used in new buildings and this DCV is the reference solution proposed by the French energy regulation in buildings updated in 2006. As humidity is an adequate indication of occupancy (and activities) in dwellings, humidity controlled systems have also been developed for natural ventilation and can be used in retrofitting. This will be the subject of the first site instrumented we present in this paper (figure 1). The object of HR-VENT project was to carry out a validation and an actualization of the knowledge on the operation of ventilation in general, and more particularly on the role of the humidity sensitive ventilation and its mechanical assistance (hybrid ventilation). The selected site is a gather of residential

buildings located at Nangis (France). The experimentation applied on 5 buildings (Figure 1) representing a total of 55 occupied dwellings, which were instrumented during two years, from January 2004 to December 2005.

Figure 1 : View of buildings of HR-VENT project.

In non residential building like offices, meeting rooms…, humidity is less adequate to represent the occupation of rooms. CO2 sensors are commonly used but an alternative is to use infra-red optical sensors, to determine not only the presence but the number of occupants. Optical DCV systems are commonly used in small and medium size rooms with average height as an alternative cheaper and equally efficient to CO2 sensors. Energy savings are given by Technical Agreements and are based on several on site studies of the systems. We present in this paper one of them.

Figure 2 : view of various occupations studied in the meeting room

FIRST SITE: HUMIDITY CONTROLLED VENTILATION IN RESIDENTIAL BUILDING

METHODS

In this ventilation system, the fresh air is provided by the humidity sensitive air intakes located above the windows in the main rooms (bedrooms and living room). The stale air is then evacuated in the sanitary rooms (toilets and bathroom) by humidity sensitive extract grilles, and in kitchen through the exhaust duct of the connected gas appliance. The ducts are served by a low pressure assistance fan whose operation is managed by the external temperature.In each building, each stack of dwellings was instrumented in order to save every minute the parameters for pressure, opening section of extract grilles, temperature and relative humidity in the technical rooms. In the kitchen, the operation of the connected gas appliances was measured by the temperature of the extracted burned components. Information was then sent and stored in a specific acquisition device.

RESULTS

Measurements carried out made it possible to assess the behavior of the humidity sensitive extract grilles (opening proportional to the relative humidity) located in the sanitary rooms.

Adaptation to the needs and statistical airflow

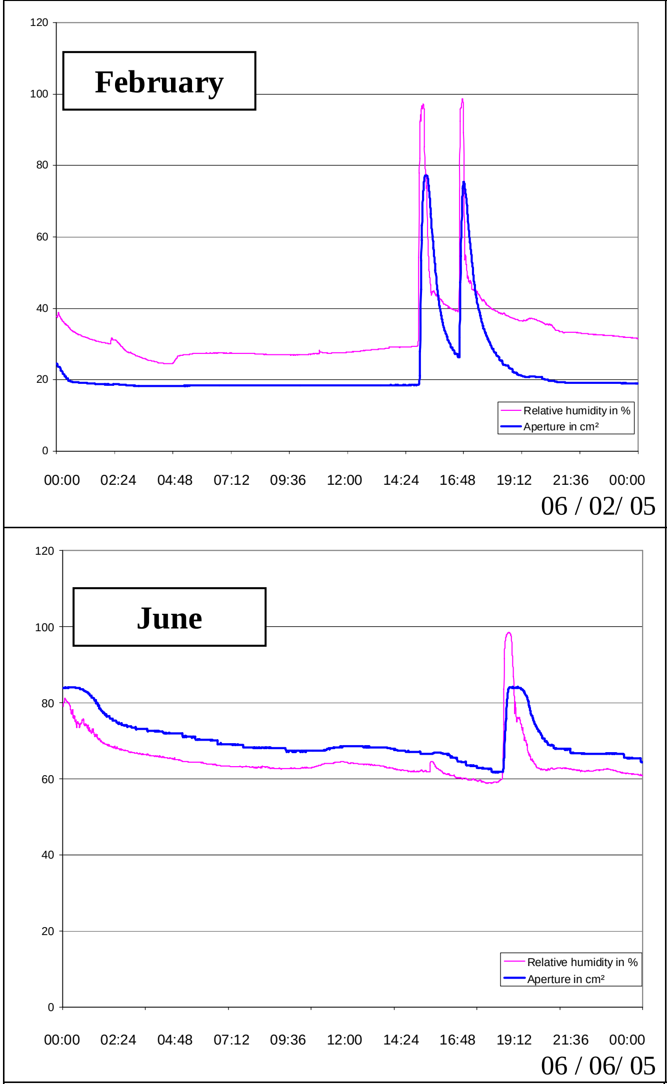

Figure 3 : Instantaneous view of the variation of opening (in cm², pink curve) and of the indoor relative humidity (in %, blue curve) of a humidity sensitive extract grille in bathroom, over 2 different climatic periods, on one day.

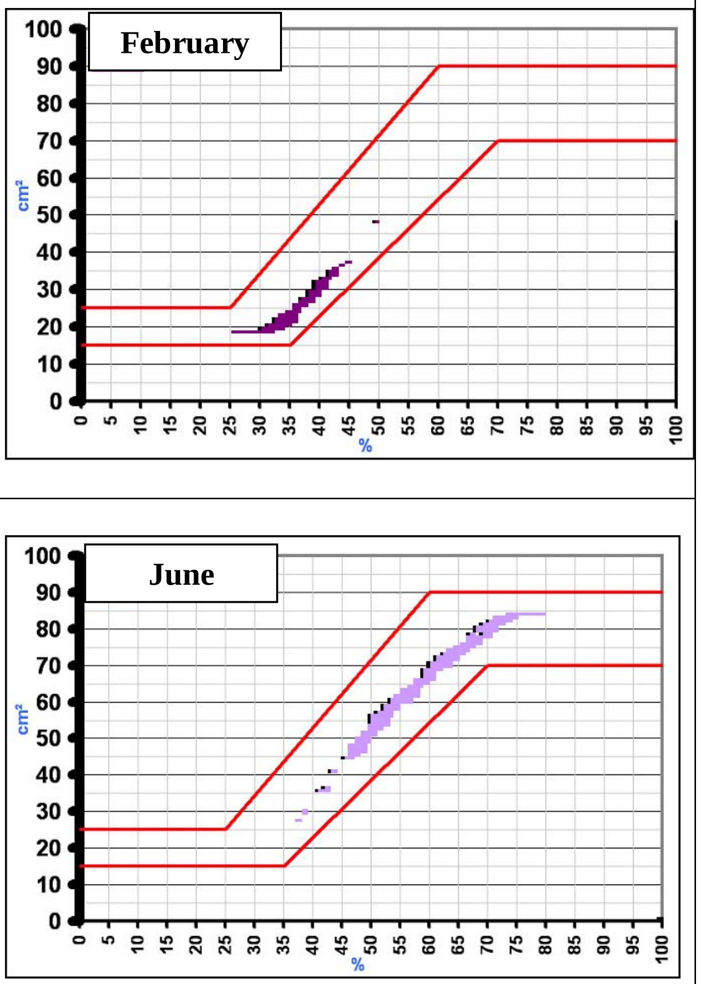

Figure 4 : Statistical view of opening (in cm²) according to the indoor relative humidity (in %) of a humidity sensitive extract grille in bathroom, over 2 different climatic periods, on one month*.

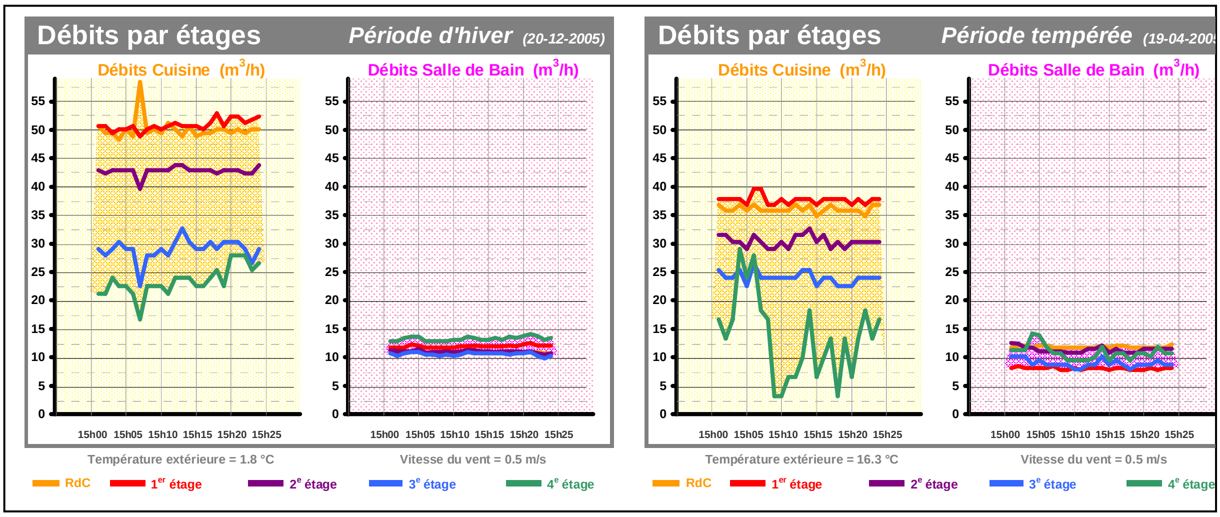
** This statistical representation corresponds to the cases without productions of humidity inside the room. Note: the red curves represent the tolerances of the product.*

As one can observe it on the graphs Figure 4, we can note that **<u>the average</u> opening of the humidity sensitive grilles depends on the season:** it is low in cold season and shifts towards a wider opening as the season becomes warmer, reflecting the seasonal evolution of the external absolute humidity along the year (low in winter, high in summer in Europe).

If the average airflow depends on the season, the **<u>instantaneous airflow</u>, for itself, follows the specific variations of relative humidity** in the room, as the graphs Figure 3 show it, and this occurs whatever the season. A shower, in summer as well as in winter, causes a fast rise in the interior relative humidity which will increase the opening of the grille during a few minutes, the time needed to evacuate the excess of humidity.

Balancing the airflow between the floors

Graphics Figure 5 present, for two different periods of the year, instantaneous airflow (each minute) in <u>natural ventilation</u> (without assistance nor humidity production) on nearly half an hour, in kitchens (fixed grilles) and bathrooms (humidity sensitive grilles), for five floors located on the same stack. The graphs from right-hand side show the **winter** measurements, those of left represent "**mid-season**".



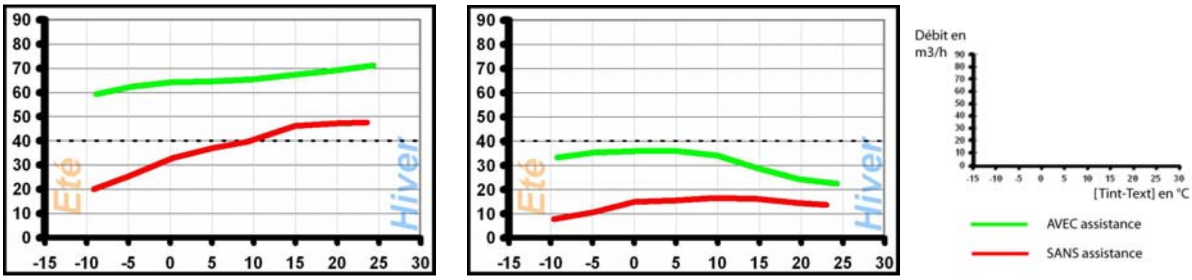
Fixed grille Humidity sensitive grille Fixed grille Humidity sensitive grille

Figure 5 : Airflow per floor - comparison between fixed grilles / humidity sensitive grilles

By balancing the airflows of the various floors at a stable and low average level without humidity production, humidity sensitive ventilation not only limits thermal losses; it also offers at each floor a great potential to answer to an important specific need for ventilation, as the common duct is not overloaded unnecessarily by the airflow of the other floors.

Contribution of the mechanical assistance

The results show **that the low pressure mechanical assistance succeeds in erasing any risk of reverse airflow, which is particularly visible in summer when the risk is the most important**. The mechanical assistance also showed a real capacity **to control the effect of thermal draught**, as one can note it on Figure 6. On the green curve (operation of the assistance fan), we can note an increase in the average flow of 30 m3/h for the fixed grille, 20 m3/h for the humidity sensitive grille which confirms the potential of the mechanical assistance for reducing the variation all the year long. The contribution of the mechanical assistance is actually stronger in summer than in winter, when its action is more needed.



Fixe grille **Humidity sensitive grille**

Figure 6 : Statistical evolution of the average airflow measured according to the temperature difference [Tint-Text] in all the dwellings.

Maximum and peak airflow

Figure 7 represents the airflow ranges (minimum-maximum) as well as the average airflow (red) measured for each day of the year on a humidity sensitive extract grille.

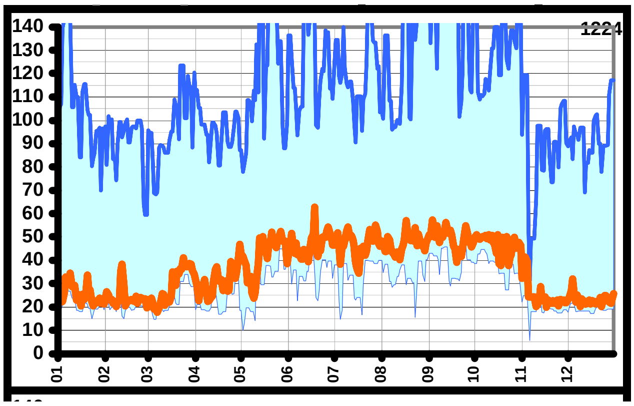


Figure 7: Daily airflow (range and average) measured in a bathroom over the year 2005. X-axis: time in days, Y - axis: airflow in m3/h.

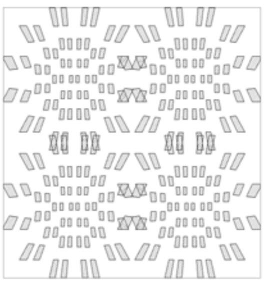
We can note the great capacity of the humidity sensitive extract grille to modulate the airflow since a typical range of 90 m3/h is observed every day. But because of the punctuality of maximum airflow periods (corresponding mainly to the periods of shower or bath), we can observe that the average airflow is very close to the daily minimum airflow. That way, the punctual great airflow periods ensure the IAQ without having negative impact on the energy consumption.

SECOND SITE: OPTICAL DCV IN MEETING ROOMS



METHODS

Several meeting rooms have been installed with webcams to control occupancy and a monitoring of CO_2 measurements, airflows and sensor detection have been made during more than 200 days. Synthesis of measurements on one of these rooms is presented there. This room was 8,7m x 4,7m. The sensors due to the number of faces on the lenses have a projection zone and detects any movement crossing these zones

Figure 8 : projection zones on a 8mx8m zone

RESULTS

Maximum CO2 levels measured in the rooms where between 500 ppm and 1200 ppm while outdoor level was 500 ppm. These measurements are consistent with the regulation airflows used in France which has been proposed to maintain 1000 ppm ± 300 ppm for 300 ppm outdoors. Figure 9 shows an example of measurements in the room for a large occupancy.

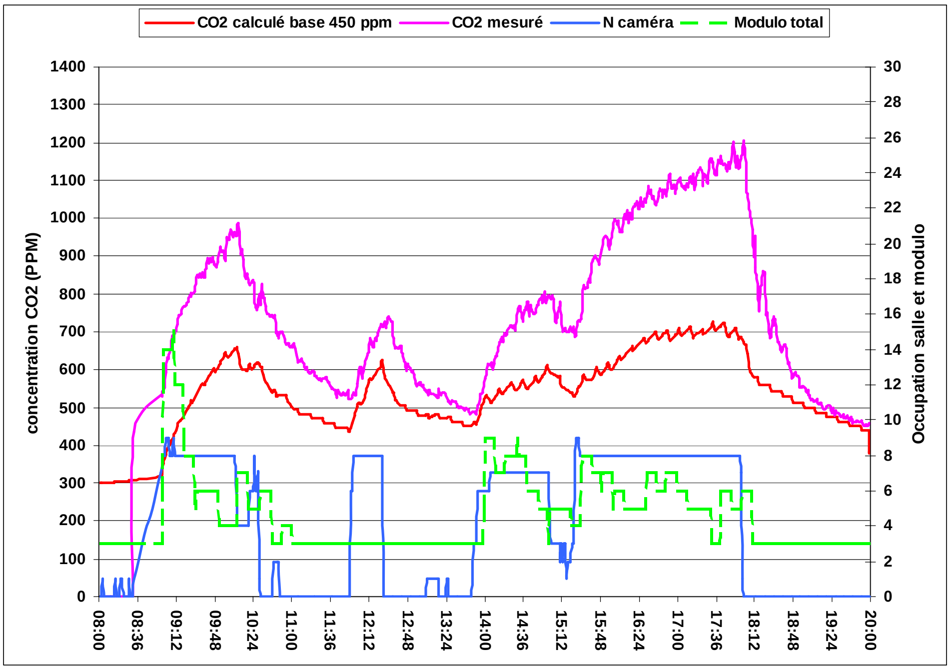


Figure 9 : Example of CO2 concentrations vs occupation
(red – calculated CO2, pink – measured CO2, blue – number of occupants (webcam))

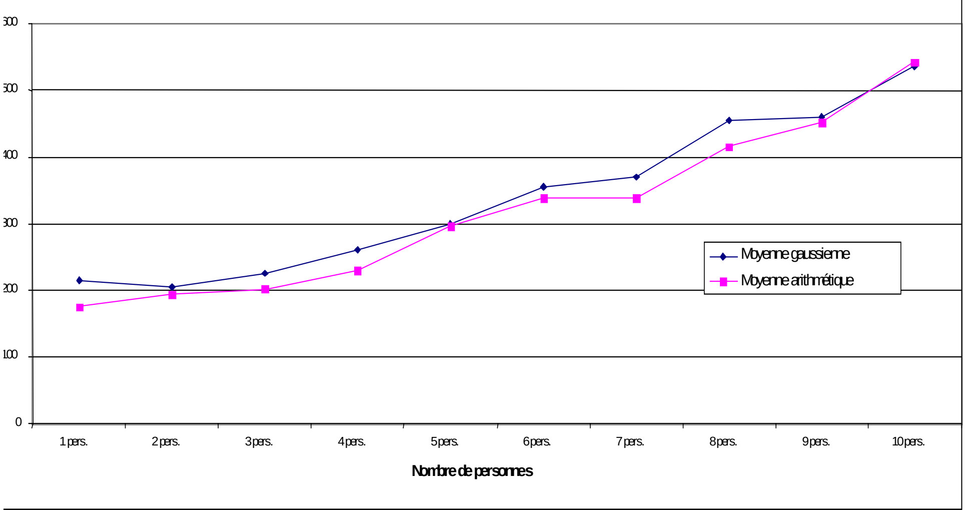

Figure 10 : number of detection vs number of occupants

In conclusion of various types of occupation, the number of occupants is correctly detected as shown in figure 10. Although it was requested to use the 3 rooms as much as possible, it was only used during 30 to 50% of time by in average 50% of the maximum occupation. This leads to an overall occupation rate (time x number) from 10 to 25%. This rate represents the potential of energy savings on the room, only based on heat losses during winter. The average payback time is less than 2 years and could be decreased to 1 year if the building were also air conditioned during summer. These values are coherent with a large study on 13 meeting rooms and 27 offices, realized by CETIAT, which led to 8% occupation rate in meeting rooms and 40% in offices. This study highlighted the huge amount of potential savings by implementing DCV.

CONCLUSION AND DISCUSSION

The measurements carried out within the framework of the HR-VENT project confirmed the performances of the humidity sensitive ventilation system in its capacity to improve indoor air quality, to erase the condensation risks and to limit the thermal losses. Its stabilizing role has been highlighted: it attenuates airflow imbalances between the floors, and limits the airflow variations over the year by offering a real control of the "natural motors" (wind and stack effect). Associated with humidity sensitive ventilation, the low pressure assistance fan optimizes the exploitation of the natural motors: the average airflow is limited in winter, contributing to the energy control, and positive airflow are assured all the year long, even in hot season. A complementary study made it possible to check that the system succeeds in removing the risks of condensation in all the main rooms, confirming the essential role of hybrid humidity sensitive ventilation system to ensure a good quality of air renewal. Even in refurbishment, the hybrid humidity sensitive ventilation system provides comparable airflow to those required by the regulation in force in the new building in France. A back quality control after 2 years of operation allowed also to check the performances of all tested humidity sensitive grilles, which confirms the reliability of this technology in time. The observations show the non-simultaneity and the time-distribution of the needs for ventilation, which confirms the relevance and the need for integrating this fact in calculations for ventilation networks dimensioning.

Measurements made on the meeting rooms showed that optical sensors can be used for detecting the number of occupants and offer a good detection for average height room. They have to been equally distributed in the room, each sensor covering a 4mx4m zone. These systems present a very good energy performance and payback time (<2 years) for small and average size rooms. For very large rooms, using only one CO2 sensor may become more profitable though. DCV systems had shown in previous study very good energy performance with a potential of savings of 92% for meeting rooms and 60% for offices.

Although DCV is common in residential ventilation, it is not yet frequently used in non residential area. We expect an increase of DCV systems in the future to fulfil the targets of energy regulations. The potential of savings is tremendous on the market and products and solution are more and more common

ACKNOWLEDGEMENTS
We thank CSTB and GAZ DE FRANCE for their collaboration in HR-VENT project; CETIAT and ALDES for their collaboration in optical DCV projects. We acknowledge and thank ADEME for the financial support of these studies

Humidistat-controlled Heating and Ventilation Systems to Create Preservation Conditions in Historic Buildings in the Dutch Climate

Edgar Neuhaus and Henk L. Schellen

Eindhoven University of Technology

Corresponding email: e.neuhaus@bwk.tue.nl

SUMMARY

In a marine temperate climate historic buildings that are equipped with thermostat-controlled heating systems show very low relative humidities (RH) during the heating season. This may lead to mechanical damage due to drying of hygroscopic materials like e.g. wood. Humidistat-controlled systems are investigated using two different cases. Two top monuments of the Netherlands serve for the case study: Hunting Lodge St. Hubertus and Muiden Castle.
The effectiveness of a humidistat-controlled heating system is investigated, both by simulation and by experiment. When using humidistat-controlled heating, the heating system is mainly used to maintain basic temperature levels during the heating season. During the humid seasons the heating system may be used to lower RH. Simulations are performed using Matlab Simulink. In the experimental setup a humidistat-controlled room is compared with a thermostat-controlled room. Simulation results show that humidistat-controlled heating is a good method to provide preservation conditions in historic buildings. Simulation results are validated by measurements. Though energy expenditure is significant lower, thermal comfort may decline.
A humidistat-controlled ventilation system is investigated by making use of simulation. In historic buildings with high visitor numbers, high moisture and CO_2-levels may occur. By selective ventilating with outdoor air, excessive moisture can be removed and low CO_2-levels maintained. Preservation effects mainly occur by eliminating high RH by ventilating with air that has a lower specific humidity or by slightly heating the ventilation air. To maintain healthy environment conditions, control of the system on CO_2-concentration is a priority.

INTRODUCTION

Originally, historic buildings did not have any other heating system than an open fire or some kind of local heating system. Sometimes a central heating system was installed afterwards. Measurements in one of the most valuable historic buildings in the Netherlands prove again that heating during the cold period leads to low indoor RH, causing damage to interior and objects [1]. Outside the heating season high RH often occurs, also causing risk for damage to interior and objects by e.g. mould growth [2]. In most cases the possibilities to fully control RH in a historic building, by e.g. installing a full air-conditioning system, is limited. Installing mechanical systems and ducts always will cause damage to the building and its historic authenticity. The high installation, maintenance and running costs are not even mentioned. Furthermore humidifying devices may lead to dramatic indoor air conditions with high surface humidities and condensation effects on cold indoor surfaces of the exterior walls, single glazing and roofs, or even condensation in the inner parts of the construction [3].

Theory

The principle of humidistat-controlled heating is controlling the heating system using a humidistat device [4]. High RH is prevented by starting heating. Reaching low RH during the cold season is prevented by limiting heating to maintain a certain lower temperature setpoint. The flowchart of the system is given in Figure 1a. The use of this control however is restricted. In summer it may be necessary to start heating and during wintertime it may be necessary to limit heating, causing thermal discomfort of occupants.

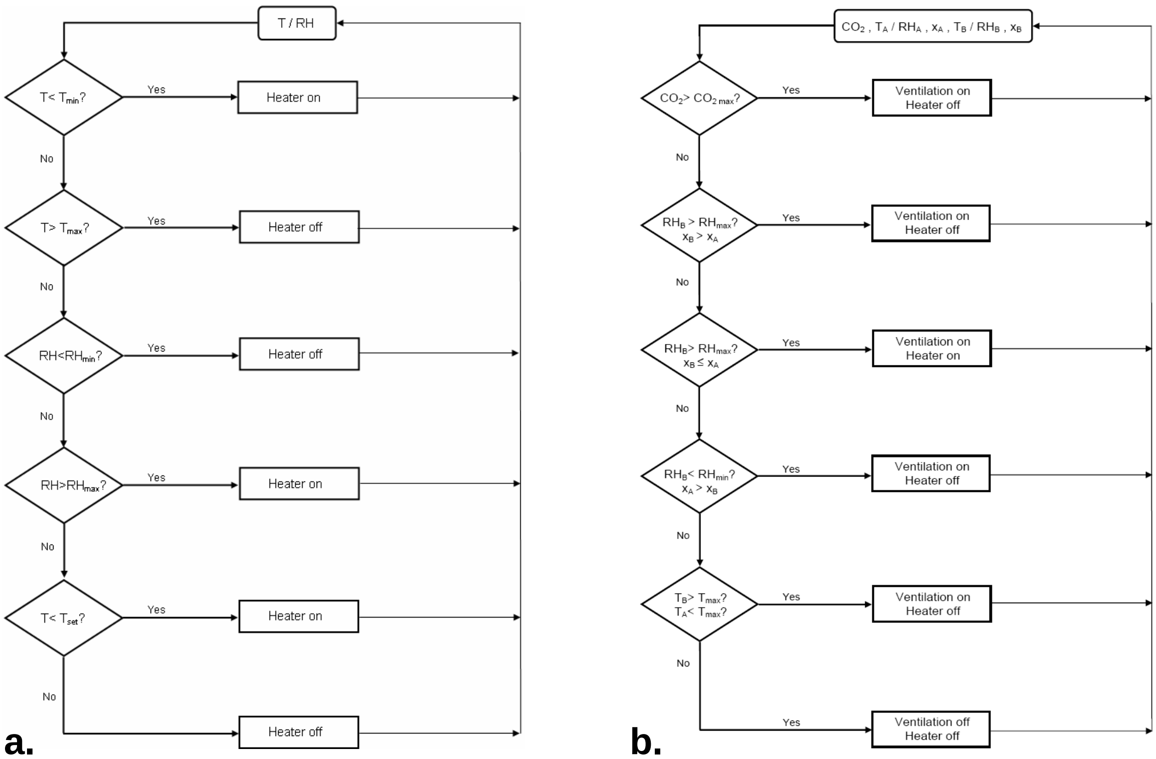

Figure 1. Flowcharts of the humidistat-controlled heating system for the case St. Hubertus (a) and the humidistat-controlled ventilation system for the case Muiden Castle (b).

The humidistat-controlled ventilation system is also being controlled by humidistat devices. Controlling RH is possible by ventilating with air that has a lower specific humidity or by slightly heating the inlet air. Humidistats and temperature sensors are installed in the location where ventilation air is extracted from, e.g. outside or an attic and in the location the where air is being supplied to (visitor zone). The specific humidity of both zones is calculated. Values are constantly monitored. To maintain a healthy and comfortable visitor zone, the CO_2 level is measured in the room the air is being supplied to. The objective of the ventilation system is to avoid high CO_2-levels and to control RH and temperature in the rooms. Ventilation only takes place if correction on CO_2 level, RH or temperature is needed. The flowchart of the system is given in Figure 1b.

Objectives

In the Netherlands there is little experience with humidistat-controlled heating and ventilation systems. The main objective of this research was to determine the suitability of humidistat-controlled systems in a maritime temperate climate like the Netherlands and to optimize the control strategy. Countries with a marine temperate climate have a cool winter, warm summer

and an uniform precipitation distribution, *Cfb* according to the Köppen climate classification system [5].
Second objective in the research was to construct heat and moisture simulation models in order to predict the suitability of humidistat-controlled systems in historic buildings.
Third objective is to gain insight on the (dis)advantages of these systems compared to basic heating systems or the use of full air-conditioning systems.

Cases

The effectiveness of humidistat-controlled systems is investigated using two cases. The first case describes the research of a humidistat-controlled heating system in Hunting Lodge St. Hubertus. The second case describes the research of the implementation of a humidistat-controlled ventilation system in Muiden Castle.

Case 1: humidistat-controlled heating
Hunting Lodge St. Hubertus was built from 1916 to 1922. Building and its interior were designed by the famous architect Berlage according to the legend of Saint Hubert. The building has the shape of the antlers of a deer's head. A large part at the ground floor level is now part of a guided tour. A part of the west wing is housed by the property manager. The building also serves as a location for weddings, receptions and occasionally, as housing for high placed guests. The annual visitor number in 2005 was 27.000.

Figure 2. An aerial view of Hunting Lodge St. Hubertus (left) and the dining room with its historic interior (right).

The exterior walls, floors and roof of the building are not thermally insulated. Exterior walls at ground floor level consist of masonry cavity walls. Floors are made of concrete, carried on metal beams. The windows consist of single glazing in steel frames. The roof is constructed out of wooden beams with slate covered sheathing.

Case 2: humidistat-controlled ventilation
Muiden Castle is a century old building that has played an important role in Dutch history. The castle dates back to the year 1283 and is one of the best conserved medieval castles in the Netherlands. In 1900 and 1960 the castle was renovated and since 1960 it is in use as a museum. Except from the museum function, the castle is also being used for activities like diners, parties and weddings. The annual visitor number in 2005 was 115.000.
Exterior walls are constructed out of masonry with a thickness ranging from 200 to 1600 mm. Indoor walls also consist of masonry and vary in thickness from 300 to 1300 mm. In most rooms indoor walls are decorated with plaster. The windows are all single glazed, mostly stained glass windows. The glazing is set in wooden or stone frames. Different windows of the castle can be blinded with wooden shutters. The floors consist of wooden planking on

wooden beams. Floors are mainly covered with tiles or marble. The roof is constructed out of a wooden sheathing covered with slates.

Figure 3. Muiden Castle as seen from the south side (left). The collection consists partly of medieval weaponry (right).

Apart from the historic interior, the castle houses an important collection consisting of paintings, furniture and artifacts like medieval weaponry. To optimize the visitor experience, an extensive renovation started in 2005. During times with high visitor numbers, the indoor air quality was poor [8]. In different locations throughout the castle mould growth was found on objects [9]. The planned renovation was a good opportunity to optimize indoor climate conditions by installing a humidistat-controlled ventilation system. Optimizing indoor conditions by making use of a humidistat-controlled ventilation system is not commonly used in the Netherlands. In this case, the effectiveness of the system will be investigated by making use of computer modeling.

METHODS

Case 1: humidistat-controlled heating

First, air temperature and RH measurements took place in different locations throughout the building for a period of one year. Next a simulation model for humidistat-controlled heating was developed to gain insight on the effect of the system on indoor climate, control strategies, needed heating capacities and optimal setpoints for the test set-up. The model was validated with measurements from the earlier monitoring. After the modeling an experimental set-up was installed in the monument. The experiment consisted of a humidistat-controlled room and a thermostat-controlled room. Testing started during the cold winter months and the tests were continued for a full annual cycle.

Modeling humidistat-controlled heating

Simulations on the indoor climate were performed using the heat and moisture model HAMBASE [5] coupled to Matlab Simulink [6]. The HAMBASE model contains the building model. The control strategy in the humidistat-controlled room is based on the flowchart as given by Figure 1a and modeled using Matlab Simulink [7]. First is checked if the room temperature is higher than the set minimum temperature T_{min}. If not so, the heater is switched on. Next is checked if the temperature is below the set maximum temperature. If not so the heater stays off regardless of RH conditions. If temperature is between the setpoints of minimum and maximum temperature, the controller continues to check if correction of RH is acquired by checking if the current RH is higher than the set maximum RH. If so, the controller switches the heater on until the RH is below RH_{max} or the temperature T_{max} is reached. In historic buildings where thermal comfort is needed, the possible provision of

limited thermal comfort by slightly expanding the controller is investigated. If RH is between RH_{min} and RH_{max}, heating is possible to raise indoor air temperature and increase thermal comfort. The heater will stay on until RH_{min} or the desired temperature T_{set} is reached.
The inputs of the HAMBASE-Simulink model are heat flow and moisture flow and the outputs are air temperature and relative humidity. Dependent on the input values is checked if heating is required according to the conditions as given in Figure 1. The output of the controller is zero or, if heating is required, the set heating capacity for this zone.
Setpoints of both types of controllers are given in Table 1. Settings of the thermostat-controlled room in the model and the experimental set-up are set to a constant temperature of 17°C to avoid fluctuations. Air exchange rate in the rooms was not measured and is set to an estimated value of 0.8 times per hour.

Table 1. Setpoints for the controller devices in the model.

Thermostat-controlled room		Humidistat-controlled room	
Start daytime	8 a.m.	T_{min}	10°C
Start nighttime	10 p.m.	T_{max}	25°C
T_{day}	17°C	T_{set}	17°C
T_{night}	17°C	RH_{min}	45%
		RH_{max}	55%

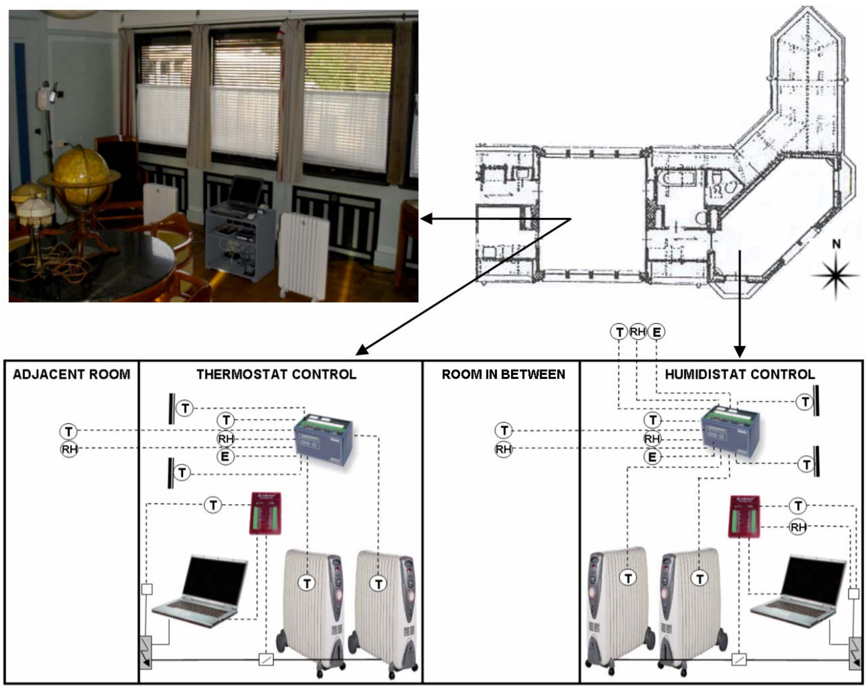

Figure 4. The upper left image shows the experimental set-up in the thermostat-controlled room. A floor plan of the two rooms where the set-up was installed in is given by the upper right image. A schematic representation of the configuration of the test set-up is given below.

Experimental set-up humidistat-controlled heating

For an experimental set-up two similar rooms in the historic building were selected on the first floor. During testing this part of the building was unused and doors and windows remained closed. There were no known moisture sources in this part of the building. Sun blinds were closed for about 60% of the window area during testing (Figure 4). The configuration used for the experimental set-up consisted in each room of a laptop computer for control, three oil filled electrical heaters of 3 kW each and a combined T/RH-sensor. The existing central heating system was switched off for these rooms. In one room the set-up was

installed to heat the room humidistat-controlled. The software was programmed according to the flowchart as shown in Figure 1. Every 10 seconds the software ran a loop with current air temperature and RH as input.
In another similar room the set-up was installed to heat the room thermostatically. Setpoints of both controllers were likewise as shown in Table 1. In the thermostat-controlled room day temperature is set to the same value as the night temperature. This is done to avoid deliberate fluctuations of RH in the historic interior and thereby limiting the risk of any damage done to the interior during the experiment. The electrical radiators were controlled by a simple on/off switch. Additional heat production was limited by using only a laptop computer per room to control the heaters. In the rooms under investigation indoor air temperature, surface temperature of north facing window and wall, RH and incoming solar radiation were monitored. In adjacent rooms air temperature and RH was measured. Outdoor climate properties like air temperature, RH and solar radiation were also monitored.

Case 2: humidistat-controlled ventilation

First, the indoor climate of the castle is modeled prior to the installation of the ventilation system. Indoor climate data unfortunately only are available for a short period of time, in the autumn of 2005. To obtain an indication of the indoor climate through the whole year, a model of the castle is created using HAMBASE. In this model only the basic heating system is integrated, like the situation prior to the installation of the ventilation system. Results are compared with the desired indoor climate conditions. The desired conditions are based on a healthy indoor air quality and conservation conditions for interior and objects (Table 2). RH boundaries are chosen to avoid e.g. mould growth and drying of organic objects. The maximum CO_2-level is based on the lowest class in the Dutch practice guidelines as given in NPR-CR 1752 [10].
Next, a model is set up to investigate the effectiveness of the ventilation system. This is done by making use of HAMBASE coupled to Matlab Simulink. In this case HAMBASE contains the building model and Matlab Simulink the model of the ventilation system and control. Obtained data are again compared with the desired indoor climate conditions. CO_2 levels are not modeled.

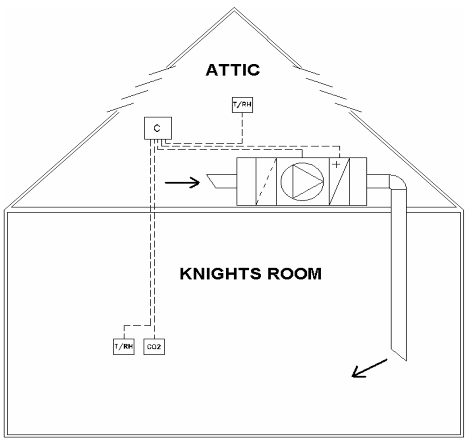

Figure 5. Principle of the humidistat-controlled ventilation system. The ventilation unit is controlled by the controller (C) which is fed with data from the sensors.

Table 2. Desired conditions for a healthy indoor climate and conservation conditions.

Relative Humidity	Maximal variation	Temperature [˚C]	Maximum CO_2-level [ppm]
40 – 65%	10	5 - 25	1520

The building is equipped with a central heating system with radiators and floor heating. During the renovation a ventilation system is installed in five important rooms, next to the existing heating system. Most of these rooms have a chimney. To minimize the impact on the construction, the existing chimneys are used to install the ducting. Each room has its own ventilation unit, which are installed on the attic. The ventilation units are composed of a ventilator, heater and filter section with EU7 quality. The ventilation system does not contain a humidifier or dehumidifier. Air is taken directly from the relatively air leak attic. Air is supplied in the underlying rooms through ducting in the existing chimneys and an inlet grille in the chimney. Inlet air leaves the room through exfiltration and opened doors. In this case the ventilation system of one of the five rooms, the Knights room, is lighted out. The ventilation unit for this room has a maximum ventilation capacity of 2200 m^3/h. This capacity is based on the amount of 35 m^3/h per person and is based on 62 persons. The ventilation capacity is controllable in different steps.

Modeling the indoor climate before the installation of the ventilation system

First a model of the situation prior to installing a ventilation system is created. In the simulation only the north part of the castle with five rooms (zones) are modeled. The Knights room is on the ground floor, with one underlying zone (cellar), one adjacent zone and three up lying zones. Non exterior or interzonal walls are modeled as adiabatic walls. The Knights room contains floor heating with a maximum capacity of 60 W/m^2 and a setpoint of 19˚C. The model is tuned using the available data as obtained in the autumn of 2005. Discrepancies between the results of model and measurements occur because the floor heating does not always have a constant temperature, which is assumed in the model. The air exchange rate of the rooms in the model is assumed to be constant 0.5 h^{-1} (Table 3).

Table 3. Settings for zone 2 (Knights room) of the models.

Before installation of ventilation system		After the installation of ventilation system	
Air exchange rate	0.5	Air exchange rate	At least 0.5
Start daytime	10 a.m.	T_{max}	25°C
Start nighttime	17 p.m.	RH_{min}	45%
T_{day}	19°C	RH_{max}	60%
T_{night}	19°C	T_{day}	14.5°C
		T_{night}	14.5°C

Modeling humidistat-controlled ventilation

Next, a model with the added ventilation system is developed. This is done by coupling the HAMBASE building model to Simulink. This model is constructed according to the flowchart as given in Figure 1b. First is checked if CO_2 levels are below the maximum desired level. Next is checked if correction on RH is needed to ventilate with possible drier air from the location air is being extracted from. Therefore both specific humidities are calculated and compared. If RH of the visitor zone is too high and the specific humidity of the extraction location is higher or equal to that of the visitor space, the ventilation air will be heated. If the measured RH is less than 5% out of the desired RH boundaries, the ventilation system will not work on full load. In this case the ventilator will work on 25% of its capacity to avoid high fluctuations in temperature and RH. If the CO_2 level and RH are within the desired boundaries, the temperature is checked. If the temperature in the visitor space is too high and the air in the extraction location has a lower temperature, ventilation starts.

Settings of the HAMBASE model are likewise as given in Table 3. In addition to the added ventilation system the setpoint of the floor heating system is lowered from 19.5˚C to 14.5˚C.

The air heater in the ventilation unit for the Knights room has a maximum heating capacity of 24 kW.

RESULTS

Case 1: humidistat-controlled heating

Figure 6 shows simulation results of temperature and RH zoomed in on January 14th to February 14th 2006 of the humidistat-controlled room in Hunting Lodge St. Hubertus. Simulation results are validated with measurements. Minor discrepancies occur possibly due to the estimated air exchange rate of 0.8. Visible is that with a T_{min} set to 10˚C it is not possible to maintain a minimum of 45% RH due to the low specific humidity of the outdoor air, which mostly occurs during wintertime (Figure 6: 22/01–04/02). Over the simulated period T_{min} has to be lowered to about 4˚C to maintain 45% RH in the Dutch climate.

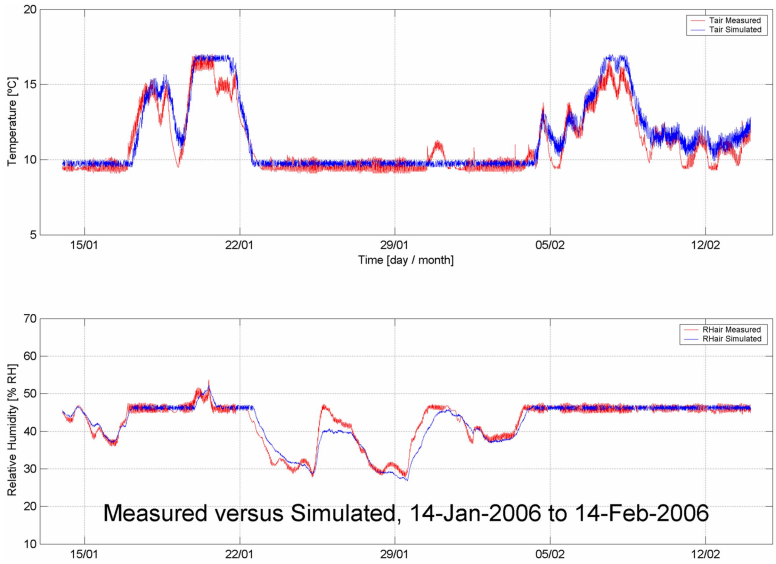

Figure 6. Simulation results of temperature and RH in the humidistatically heated room over the period from January 14th to February 14th 2006.

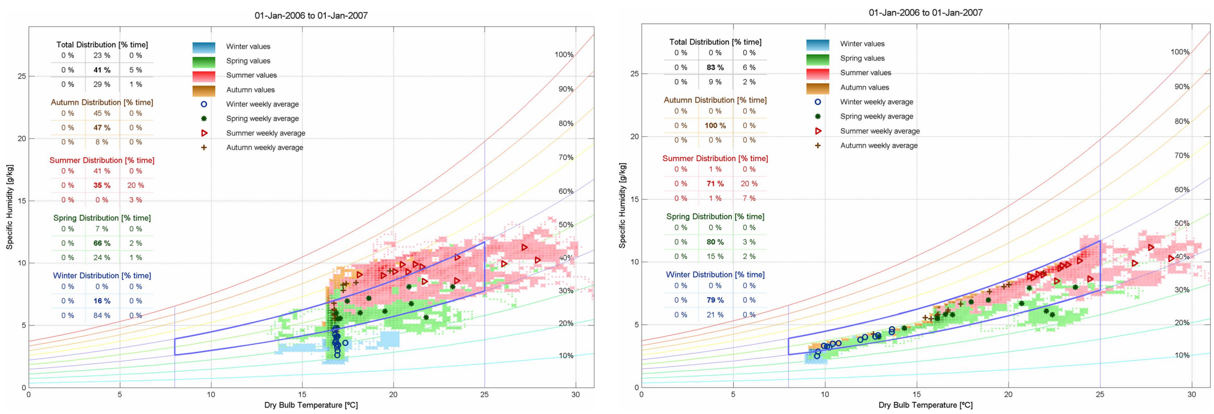

Figure 7. Psychrometric charts showing measurement results of the thermostat-controlled (left) and the humidistat-controlled (right) room from January 1st 2006 to January 1st 2007. In the thermostat-controlled room RH is for 30% of the data under 40% RH and for 23% of the data over 60% RH. RH in the humidistat-controlled room is for 11% of the data under 40% RH and for less than 1% over 60% RH.

In Figure 7 temperature and RH of the test set-up are plotted in a psychrometric chart both for a thermostat-controlled room as for the humidistat-controlled room.
In the thermostat-controlled room low RH occurred during periods of low specific humidity (winter time). In the same periods RH in the humidistat-controlled room is higher due to a lower indoor temperature.

In Table 4 annual energy expenditure of three different heating strategies is compared for one identical room. Values are obtained by HAMBASE simulation using the outdoor climate data of the year 2005. Results show that humidistat-controlled heating without limited comfort function uses about 30% less energy in comparison to a thermostat control.

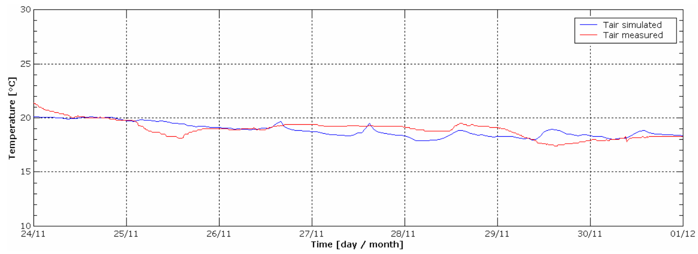
Table 4. Annual energy use of the identical zone using different heating strategies.

Heating strategy	Settings T/RH	Annual energy expenditure [kWh]
Thermostat-controlled[1]	15-20˚C / -	6133
Humidistat-controlled with limited comfort function[2]	10-25˚C / 45-55%	5431
Humidistat-controlled without limited comfort function	10-25˚C / 45-55%	4329

[1] day temperature 20˚C with a 5 K drop between 10 p.m. and 8 a.m.
[2] T_{set}= 17˚C

Case 2: humidistat-controlled ventilation

Indoor climate conditions are monitored from November 24th to December 1st 2005. In Figure 8 the measured results of the Knights room are compared to the simulation results over this period.



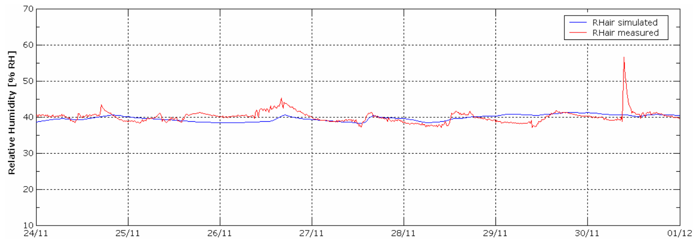


Figure 8. Results of the HAMBASE model compared with results obtained by measurement. The measured RH peak on the 30th of November is possibly caused by cleaning activities.

For the whole year, simulation results of the model prior to installation of the ventilation system show low RH during the heating season and high RH outside the heating season. In Figure 9 simulation results of the Knights room of the situation prior to installation and after the installation of the ventilation system are both plotted in the psychrometric chart. Results of the situation after installing the ventilation system show less low RH during the heating season. The main reason for this is a decrease in setpoint of the heating system from 19.5 to 14.5˚C. In the situation prior to installation 31% of the RH is below the desired minimum level of 40% RH. After the installation of the ventilation system this is 17%. Outside the heating season less high RH occurs thanks to the humidistat-controlled ventilation. In the situation prior to installation 28% of the RH is above the desired maximum level of 65% RH. After the installation of the ventilation system this is only 2%.

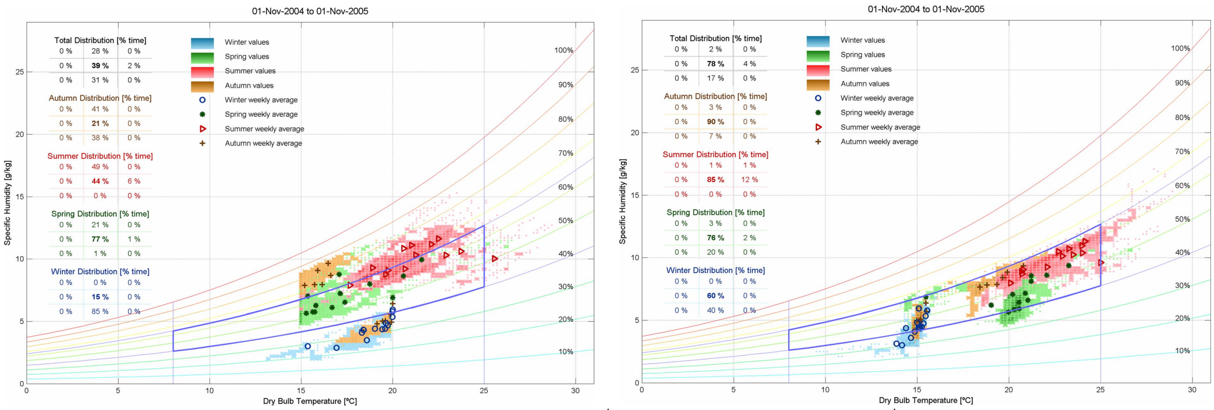

Figure 9. Simulation results from November 1st 2004 to November 1st 2005 before and after the installation of the ventilation system. Results show less low RH due to a decrease of the temperature setpoint and less high RH outside the heating season due to humidistat-controlled ventilation.

DISCUSSION

Humidistat-controlled heating is an efficient technique to create preservation conditions in historic buildings in the Dutch climate. The largest benefit is elimination of extremes in indoor RH. Temperature and RH fluctuations also are lower compared to thermostat-control with a night setback. Apart from providing improved conservation conditions energy expenditure is far lower compared to conventional heating to provide thermal comfort. Improved comfort can be provided by limited heating when RH is between desired boundaries, but this strongly depends on the specific humidity (g/kg) of the outdoor air. Historic buildings that are closed for winter season are ideal to implement a humidistat-controlled heating system. For humidistat-controlled heating T_{min} can be set to a lower value of about 4˚C to obtain a lower RH limit of around 45% in the Dutch climate. When comfort is required during specific times, the control strategy can be switched to a thermostat control in order to provide thermal comfort. In this case it is important to use a limiter to prevent too quick heating of the room. The use of a limiter in the control is also useful for situations that the installation restarts after e.g. a malfunction. The experimental set-up showed a side effect when having a room with humidistat control next to a room with thermostat control. This resulted in a wooden door that bend due to the difference in temperature and related RH. It is recommended to reduce these differences. Also literature shows heating may run out of control in rooms with a small air exchange rate and a high amount of hygroscopic materials, due to the release of moisture [11].

Historic buildings with high visitor numbers can be equipped with a ventilation system controlled by a humidistat device and a CO_2-sensor to improve indoor air quality and preservation conditions. Simulation results show that the implementation of a humidistat-controlled ventilation system can create more suitable conservation conditions in historic buildings. Indoor climate improvements consist of less low RH during the heating season due to a lower temperature setpoint. Outside the heating season high RH is corrected by slightly heating the ventilation air. Additional advantages of this system are the possibilities to filter the air and maintain healthy indoor air conditions by controlling CO_2-levels. Disadvantages

are the necessary ducting and a lower thermal comfort during the heating season due to a decrease of the temperature setpoint.
It is possible to maintain preservation conditions in historic buildings in the Netherlands without the use of (de)humidification. Values of the controller have to be selected for minimum use of the system, to be energy efficient and promote longevity of the components. Setting can differ per project and are dependent on both building physics and collection. If no comfort is needed the lower temperature setting has to be determined by assessing temperature sensitivity of collection or the presence of water filled pipework. Modeling is a useful tool to predict the impact of humidistat-controlled systems on the indoor climate, to determine optimal controller settings and to gain insight on energy expenditure.

ACKNOWLEDGEMENT

The authors wish to thank the staff of the Dutch Government Buildings Agency, the Netherlands Institute for Cultural Heritage, Park De Hoge Veluwe and Mrs. Mirjam Peters for their contribution in this research.

Home automation rather for safe or ease living than for control

Mervi Himanen

VTT and the Helsinki University of Technology (HUT), Finland

mervi.himanen@vtt.fi

SUMMARY

The feedback of the smart home control from both young families and senior citizens studied in the two EU 5th FP projects: the Demulog and the Elderathome gave proof of the possibilities to improve the environmental quality by smart house technology. Respondents from the English, the Finnish and the French families applying for social housing as well as the Finnish and the Spanish elderly, a hundred from each group in each country have been personally interviewed.

Home automation guarantees amenities for easy living and comfortable indoor environment. At the same time, it should be energy efficient and facilitate the prevention of energy supply peaks. In order to be accepted, the new control systems should improve control over the indoor environment − not reduce control opportunities − and bring significant benefits for example in improved comfort, safety or saved energy. The comparison of the result to two previous Finnish end-user studies and some literature studies confirmed the results.

THE END-USER EXPECTATIONS ON SMART TECHNOLOGIES

Smart housing is expected to easy every day routines at all homes. It is aimed to assist people with any limitations, in independent living. The social policies of the European governments coincide as the societies face growing numbers of old people whom smart housing could help to stay in their own homes as long as they wish. Many solutions for smart housing, independent living or gerontechnology[1] have been tailored to fulfill all these expectations.

Information and communication technology, ICT, born in the world of academic freedom has been adopted by business for an even more effective handling and transfer of information. Not only time, but also travelling, energy and natural resources can be saved by the use of ICT. In addition, construction industry takes its share of the information society by applying ICT for housing in the first place by integrated technologies aiming to:

- *Comfort and functionality* by amenities satisfying the residents with high indoor air quality by efficient energy use thanks to building automation, and with entertainment or edutainment[2] via multimedia, with smart appliances for easy every day domestic tasks by home control[3] and inter-house communications systems as well as automated facilities
- *Safety and security* by enabling smart home functions preventing unfavourable events and unauthorised use of property and other resources

---

[1] Gerontechnology is used for the technology targeted to senior citizens. Gerontology is the science of ageing.

[2] Edutainment is a term formed from words education and entertainment meaning information and communication services produced by end-user friendly interactive technologies

[3] Home control includes control and regulation of building service equipment. Such other control technology at home are automated doors, windows or curtains (called also as active structures), control of sophisticated home electronics and home appliance technology, gerontechnology, e-welfare, etc.

- *Controllability enabling sustainability and reliability* of housing technology in such a way that residents are aware of the controlling and regulation functions of the house − automatic and manual − and to interfere if needed
- *Equality* by mitigating difficulties to promote transparent information services and open up possibilities to learn ICT, and by removing obstacles from the physical environment to promote independent living by means of Design-for-All[4].

Latest housing production already incorporates many products with electrical engineering or digital information technology. Active operating systems are becoming as essential as other building services. New ideas and pioneering experiments concern intelligent construction materials and products. In old building stock, special expertise on the building methods and costs make the planning of new routes, refurbishment of networks and new installations possible. The information society in terms of the use of ICT is here to stay and so are media homes[5] relaying on implementation of ICT technology. Sophisticated applications of smart housing, such as active structures, flexible spaces and adaptable technology, develop slowly within conservative housing industry.

Modern smart house research finds solutions for everyday activities such as automated food preparing [1]. Problems of the integrated home, the sensor technology and integration of network protocols and automated systems together have been in focus. One idea is to find technology capable of identifying the presence of the occupant in order to help her or him in activities when she or he is in need of help. The integrated house features cover home automation, intelligent building services and active structures and integrate them as a functional combination, which makes everyday living easy for all, including the elderly.

Futures studies has identified that modern families in the industrialised world are in need of spare time and services. They lack easy everyday living conditions. The working life is demanding and people keep on working when shopping in self-service markets, cooking and laundering at home despite such conveniences as modern home appliances and prefabricated food products. They take care of their homes and garden, or have their car washed, escort their children to hobbies, keep up with information society and stay awake late for getting entertained or for having time of their own. Home has approached from two apart angles, focusing either on domestication of daily activities described above or on construction business of quality requirements of housing projects − based on provision of management, engineering, planning, estimating, tendering, ordering, etc. carried out during the whole building life-cycle. The same object, home is approached from the basis of both the technology push and the market pull concepts [2], [3], [4], [5].

Technology and our way of life are closely tied together in contemporary society and they mutually influence each other. How well-founded are the expectations on the technology and its ability to facilitate the everyday life of people in general? To understand the unsaturated smart housing markets the construction industry needs evidence-based end-user feedback of how to satisfy housing needs and wishes of their customers groups. Feedback on the use of smart home applications enables the satisfaction of the housing needs of the knowledge society where work and spare time are ever more fragmented and a holistic living

---

[4] Design-for-All principle means design strategies and methods, which promote usability, accessibility and attainability of environments, products and services.

[5] Home control, building automation and the use of ICT are leading applications for this type of smart house. They are applications related to automated buildings, where building logic, one of the forms of building intelligence, is the key attribute of the design. Such terms as responsive or media home describe these houses better than smart house (about the definition of the building intelligence ple. see [2]).

accumulates short intervals of work and other activities, enjoyment or rest. The latest trends in mastering ones own life and having individual life styles add the variations to the customer needs. Constant changes in working and society add the need to know of activities at home now and in the future. Service level of the community and attractiveness of the housing promote the business life while skilful people are willing to move and to stay in such a municipality and work for local companies [6]. More sophisticated smart homes applications − applying several forms of building intelligence other than building logic[6] have developed quite slowly. They make the house smart in a wider sense with ubiquitous and wearable products or adaptive and learning[7] ambient technology, with intelligent construction materials[8] or flexible spaces and active structures such as automated doors and windows. Ambient intelligence challenges integration of more sectors to smart housing such as smart textiles and clothing, intelligent transport, intelligent work place, smart fire fighting facilities, etc.

METHODS

Firstly, a summary of the HVAC technology related results of the end-user requirements of the smart home control was made by an international comparison between the various customer groups based on feedback from two previous studies (Table 3, Table 4) and a thorough literature review. The results have been completed by the responses from both young families and senior citizens studied in the two EU 5th FP projects. Within the Demulog project (Living Conditions and Preferences of Families in Housing Need, Table 1) the numerical analyses were carried out (using the SPPS program). The qualitative responses to the open ended questions from the Elderathome project (The Prerequisites of the Elderly for living at home: Criteria for Dwellings, Surroundings and Facilities, QLK6-CT-200-00405, Table 2) have been grouped, listed and summed up. Results from two corresponding Finnish studies were used as reference values (Table 3). All samples in each country were dominated by residents who dwell in blocks of flats and in most cases in cities as well as their demography represented quite well the national averages cf. [10].

6 The five forms of Building Intelligence (BI) have been derived from the seven forms of human intelligence by Howard Gardner (1983). They are connectivity (speech synthesising and speech recognition, pattern recognition and applications, artificial intelligence, user-interface, use of background music and other stimulators of senses, etc.); self-recognition (building knows the state of it and the occupants), spatiality or ambient (a more conscious understanding of the spatial expression of the architecture, structures, interior design), building kinaesthetic or dynamics (a sense of change, active and moveable structures, furniture and equipment, adjustable and learning technology), and building logic (systems integration, embedded sensors to monitor the occupants' daily activities, combinativity).

7 The product learns from the user behaviour. The control algorithm of the product is based on neural networking combined which is touch by the user behaviour during the use of the product. Often the algorithm benefits also fussy logic.

8 Such materials for covering or windows, which are easy to clean, soil repellent or self-cleaning (without any end-user involment) or energy efficient preventing heat go out or over heat come in or making the natural lighting favourable without any disturbing reflectections, etc.; materials which transform according to the circumstances making possible (regulation) mechanisms operated without any external power sources, etc.

Secondly, to put the in detail reported HVAC technology related knowledge into the wider context of the end-user responses of the smart housing technology and use of the ICT at home a summary of the involving studies is given firstly.

THE GAB BETWEEN INFORMATION SOCIETIES CLOSING UP

Feedback evidencing the occupants' own experiences and attitudes should be considered as an important measure of the feasibility of the technology as the technological progressiveness. As to a large extent information is lacking of post-occupancy experiences from residential living in smart homes, the following conclusions were principally drawn from the different pre-occupancy studies by summarising the references from [7] to [31]:

- Yet it cannot be taken as a given that all households in Europe have a telephone either as a fixed line or a mobile phone. The shift from the majority of fixed phone line owners to the majority of mobile phone owners has taken place in many countries and it is predicted to take place in the whole of Europe. Almost every studied young family wished to have a computer at home in Finland. It has been predicted too that domestic use dominates business users in computer markets in Europe, now using the value of the markets as a measure. Signals towards increased use of information services all over close up the gap between leading information societies and followers.
- In an advanced information society, it is possible to use ICT tools not only to a greater extent but also for more multiple purposes.
- There is a need to raise housing awareness in general and smart homes awareness, in particular. Firstly, the potential customers do not know what a smart home is and experts have different opinions of the definition. Secondly, expert lack knowledge how to satisfy the wide

variety of customer needs. Most importantly, occupants do not know how the qualitative built environment could help them to manage easier in their daily lives, or how they could manage to live independently or longer at their present homes when they face some kind of uneasiness or after they have grown old.

- Technology is supposed to help in everyday family routines of busy life styles. Despite the strong focus in RTD on smart homes applications for independent living, it is not necessarily the age or the disabilities that create the need for help and applicable technology. Smart homes technology is needed as well in carrier families due to busy lives of the two with children, as well as because of the activities and hobbies requiring special living conditions in any age. Furthermore, independent living relies on abilities that smart home facilitates.
- Safety facilities such as safety stoves, movement monitoring, water leakage detectors or fire alarms, automatic on/off system of home appliances, and smart home security system are important for all end-user groups. For example, a well-equipped kitchen with easily moveable kitchen fitments facilitate safety while difficulties in reaching objects such as dishes and china do not cause any more accidents at home and also people with limitations in mobility can work easier in the kitchen than earlier.
- The automatic doors are most probably the most common active structure. For example, the elderly thought they might need moveable walls less frequently than the respondents representing all age groups, of whom a half thought that there is a need to move walls from every 5^{th} to 10^{th} year. Other active structures will be readily accepted when needed such as kitchen fitments which can easily be moved either manually thanks to a disengage mechanism or automatically by pushing a button. The same goes also with flexible thresholds, which will fall down automatically when one steps on them.
- Contradictorily to the willingness to use home automation, there is always a portion who does not want to have it and when asked, how much they would be willing to pay for a home control system, they may say they are not ready to take if they would get it even for free.
- National circumstances and cultural differences in lifestyles influence how ICT will be used in homes or how smart homes technology is welcomed as well as how willing the dwellers are to learn how to use this new technology.
- For example, the cultural norms of the personal social contacts can affect on the use of emails and phoning. The Spanish respondents kept in touch with children, relatives and friends by phoning and meeting them, while the Finnish did this also, but in addition, they used mail and email for the purpose. No one from Spain sent letters, however (a cultural difference between the more literate Finns and the more outspoken Spanish).
- For example the Finnish elderly unlike the Spanish elderly either already know how to use ICT or they want to learn it especially if there will be the need.
- For example studies show that the social services are connected quite rarely. The possibility of using the Internet for looking for medical advice or making an appointment with a doctor is promising if asked how many have ever tried it. When asked to consider a more dependent use of health information most elderly respondents did not accept the eservice.
- For example, videophones are not popular although experiments on using videophones in a service home in the city of Tampere gave proof of its usefulness in preventing loneliness, because contact by a videophone is more personal than by a voice phone. The few who would like to have videophones found the most important purpose for it to get help in emergence situations − women more often than men felt so. The possibility to know, how relatives are doing was the second best reason for having a videophone − men were some more interested than women in it.
- Customer profiles have turned out to be problematic because surprisingly customers have started to buy products which are not designed for their profiles. Older ladies buy products designed for young men. Such demographic parameters as age, incomes and education alone

do not influence on the attitudes towards ICT or smart housing features. Contrary, gender or living style matter. A more careful look at the total life situation of customers counts more.

- The utilisation of new technology differs between genders. Women are interested in making everyday living easy. They wish to support social contacts, like educative or otherwise advantageous eservices. Men favour entertainment, sports and games, young men in particular. Men like to advance their knowledge and skills in ICT via the ICT.
- Because pensions cannot compete with salaries, the elderly cannot be expected to be the best buyers of the ICT to home, but they are by no means against having it and are not onlookers when the use of ICT is in concern. Those in a very high age may not at all make acquaintance with ICT or smart housing technology.
- The research on the intelligent office buildings has proved that neither one intelligent feature makes the building intelligent nor can any good quality feature substitute and even mitigate bad quality of building installations and properties. The reality of co-effecting factors tells to take care of the good quality of all of the features for gaining the satisfactory results.

CONTROLLING POWER OVER ENERGY EFFICIENCY AND INDOOR AIR

The Demulog interview proposed energy-saving measures based on the time limitations of the electricity supply to prevent electricity consumption peaks. The acceptance of energy saving technology was low if the basic needs are not satisfied comfortable enough or the control set disturbs the routines of daily life, which in the case concerned the restriction of room temperatures and the energy efficiency of home appliances [13]. Nevertheless, the respondents in general did not reject all energy saving measures, such as lower temperatures when nobody was at home or during the night and in bedrooms.

During the Elderathome interviews seniors in Finland and in Spain accepted a temperature delimiter for the faucet, aiming at saving hot water and contributing to energy conservation (Table 5). It also prevents people from scalding their hands. Many of them had this device already installed because of safety and energy saving. Likewise, they appreciated home control facilitating easy living and energy efficiency, e.g. remote control possibilities and lamps that turned on automatically when someone entered a room and switched off when the room was empty. Ease of living was a welcomed benefit of independent living technology. It concerns also the previously mentioned adjustable kitchen cabinets, which are safe and easy to use by all fulfilling the principles of Design-for-All at the same time.

Just as the younger families who answered the Smart house survey [9], also the Finnish elderly interviewed for the Elderly housing survey liked such safety facilities as a safety stove, movement monitoring, water leakage or fire alarm, etc. [10]. Also, another end-user study carried out in the Pirkanmaa region in 2004 proved the importance of the safety technology when out of 39 smart home facility options, the top five were about safety [31].

On the basis of the two case studies: the Demulog interview and the Elderathome interview, facilitation of living or safety rather than energy saving alone was an acceptable argument for control technology. Parallel to this finding, Karjalainen [20] found with a nationally representative sample that user interest in the user adaptive and other new control systems was quite low in Finland. Users are afraid of loosing control over the systems. To be accepted, the new control systems should improve control over the indoor environment − not reduce control opportunities − and bring significant benefits e.g. in improved comfort or saved energy.

Table 5. Testing popularity of effective regulations, standards and recommendations (the percentages of responses[3]) [8].

I have already		I'd like to have now			I'd like to have if I need		I don't want to have

1	10	5	46	Lamps that turn on automatically when entering a room and which turn off when no one is present	68	8	26	36

[1] FIN ≡ Finland, E ≡ Spain, [2] the question concerns both safety and comfort, [3] pick of several choices of multiple-choice questions possible, [4] relevant only in Finland, [5] asked only in Finland

CONTROL SWITCHES

The Elderly housing survey revealed that most of the Finnish respondents in the age of 55 to 70 (60 percent) stick to the traditional control devices [10]. The office workers also tend to trust the traditional or familiar control devices [15]. The popularity of other forms of home controls was as follows: remote control units (21 percent), a separate control panel (13 percent), door side panels (8 percent), speech control (7 percent) and a computer (3 percent). The result from the Smart homes survey was quite similar. Out of new lighting controlling possibilities, a natural light control and the timing of the switching were more often acceptable among the elderly than the other age groups (Table 6).

Despite the results to the Elderathome interview also showed that remote lighting controllers were not in use among the Finnish elderly, however the elderly did favour them, when they were needed (Table 5). Nevertheless, in Spain the remote control possibility was either in use more than in Finland or it was accepted more unconditionally, while 60 per cent wanted to have it right away. When during the Elderathome interview the Finnish sample with a majority of women and the Spanish sample with a majority of men were compared, it was found that the sample with the male dominance favoured the remote controller more unconditionally than the one with the female dominance. This result was parallel to the findings of Karjalainen [19], who found that men rather than women use the control devices although good indoor air was more important for women.

Again the comparison between the female and male dominant samples proved that the women did not use alarm buttons, safety bracelet, motion censor and other such equipment to facilitate connections to other people in emergency as often as the men did. However, more often the women than the men were interested in having it if needed (Table 5). Different reasons separately or together might cause this gender difference. First, the mode of control counts; men like remote controllers [19]. Further on, men are more interested in home controls in general. Second, the wish to have a contact to other people which Fox (2004) claimed to be important to women might make women interested in controlling. In addition, women feel more vulnarable than men do [8], and that is why they might have considered that they will become interested in control possibilities when an emergency was involved.

Of the importance of the vulnerability to the need of a safety facilitation gave proof the fact that a good share of the interviewed Spanish respondents had the emergency call facility most probably because of need while one third of the Spanish respondents dwelled in the special housing designed for elderly. Many of them wanted to have it if needed as did the majority of the Finnish respondents. The Elderly housing survey concluded that the control made was not acceptable until the need for existed. Then even the video monitoring could be accepted in some cases. Many elderly did not bother about new technology when they felt fit and function and wanted to enjoy life and the services technology could offer.

Table 6. The grounds for control of lighting after the Elder housing survey and the Smart homes survey, the percentages of the respondents

Control operation	Elderly	All ages
Control according to daylight	48	12
Dimming	45	32
Timing of the switching on and off	37	11
Presetting for various situations, e.g. reading, watching tv, dining, having guests	19	14
Remote control	-	12
Control panel for multiple purposes	-	11

The pick of several choices of multiple-choice question possible

DISCUSSION

It seems as if a certain point has been reached in the evolving markets of smart homes. The attitudes of the end-users were rather accepting than rejecting the smart home technology. A new direction for the R&D work concerning smart homes technology needs to be taken. In order to win the markets the producers will most probably be dependent on new ideas to apply smart homes in a broad sense. A lively debate between them is wanted in order to embed this radical product in to the market and empower the lives of various future end-user groups.

Estimating the relationship among occupant behaviours and indoor environmental parameters using Bayesian networks

Shaomin Wu and Derek Clements-Croome

The University of Reading, United Kingdom

Corresponding email: shaomin.wu@reading.ac.uk

This paper investigates the relationship among occupant behaviors and indoor environmental parameters. We collect data from three aspects: indoor environmental variables measured by a wireless sensor network, body sensors carried by occupants, and questionnaires completed by occupiers. The wireless sensor network measures four parameters: temperature, humidity, light and barometric pressure. The body sensors measure collect data including burned calories, physical activity, body position, and galvanic skin response from their wearers. The questionnaire collects data such as occupier's behaviour and mood. The experiment is conducted in an air-conditioned office where temperature can be controlled by the occupants. Based on such information, we build up a Bayesian network model revealing how indoor environmental parameters and occupant's behaviour impact physical parameters of human bodies. We also compare our models with Fanger's thermal comfort model.

1. INTRODUCTION

The increasing miniaturisation of RF devices and microelectro-mechanical systems (MEMS), as well as the advances in wireless technologies, has generated a great deal of research interest in the area of wireless sensor networks (WSNs), which provide a promising infrastructure for gathering information about parameters of the physical world.

A WSN system is a group of sensors linked by wireless medium to perform distributed sensing tasks. WSN systems have attracted a wide interest from academia and industry alike due to their diversity of applications. Recent advances in wireless sensor network technology have enabled the development of low-cost, low-power, multi-functional sensor nodes that are small in size and allow untethered communication over short distances. Such systems allow close monitoring and adaptive control of building equipment, materials performance (such as those in the façade) and environmental conditions including temperature, air flow, indoor air quality, lighting , sound and the stated well-being of the occupant in relation to their surroundings.

Systems will also enable a proper cohesive data management system to be organised for buildings which will help to understand the strategies required for operating the building so that energy and water savings are achieved; environments are healthier; and there is closer relationship between the occupant and the building. It will also help to achieve a leaner and more effective design, construction, operation and facilities management regime. For example we should be able to understand very much more deeply the patterns of use and also enable prediction of failure conditions thus informing maintenance regimes.

A Bayesian network is a graphical model that encodes probabilistic relationships among variables of interest. When used in conjunction with statistical techniques, the graphical model has several advantages for data analysis. Firstly, a Bayesian network can be used to learn causal relationships, and hence can be used to gain understanding about a problem domain and to predict the consequences of intervention. Secondly, because the model has both a causal and probabilistic semantics, it is an ideal representation for combining prior knowledge (which often comes in causal form) and data. Therefore, it is worthwhile to use Bayesian networks to explore the relationship among various variables that might influence indoor air quality, occupant's productivity, and other variables of interest. Readers are referred to Jensen (2001), and Neapolitan(2003) for better understanding in the Bayesian networks.

There is now much evidence to show that the environment of buildings can affect the work performance of the occupants and can alter their state of well-being (Clements-Croome, 2005). This means that environmental design can enhance the value of the built asset for an organisation. This paper investigates the relationship among occupant behaviors and indoor environmental parameters. We collect data from three aspects: indoor environmental variables measured by a wireless sensor network, body sensors carried by occupants, and questionnaires completed by occupiers. The wireless sensor network measures four parameters: temperature, humidity, light and barometric pressure. The body sensors measure collect data including burned calories, physical activity, body position, and galvanic skin response from their wearers. The questionnaire collects data such as occupier's behaviour and mood. The experiment is conducted in an air-conditioned office where temperature can be controlled by the occupants. Based on such information, we build up a Bayesian network model revealing how indoor environmental parameters and occupant's behaviour impact physical parameters of human bodies.

2. EXPERIMENT SETTINGS

We are interested to build a sense diary that can serve two-fold purposes: to minimise energy consumption, and to maximise occupant productivity. In order to achieve these two objectives, a research plan is set as shown in Figure 1. We planed to use wireless sensors to measure

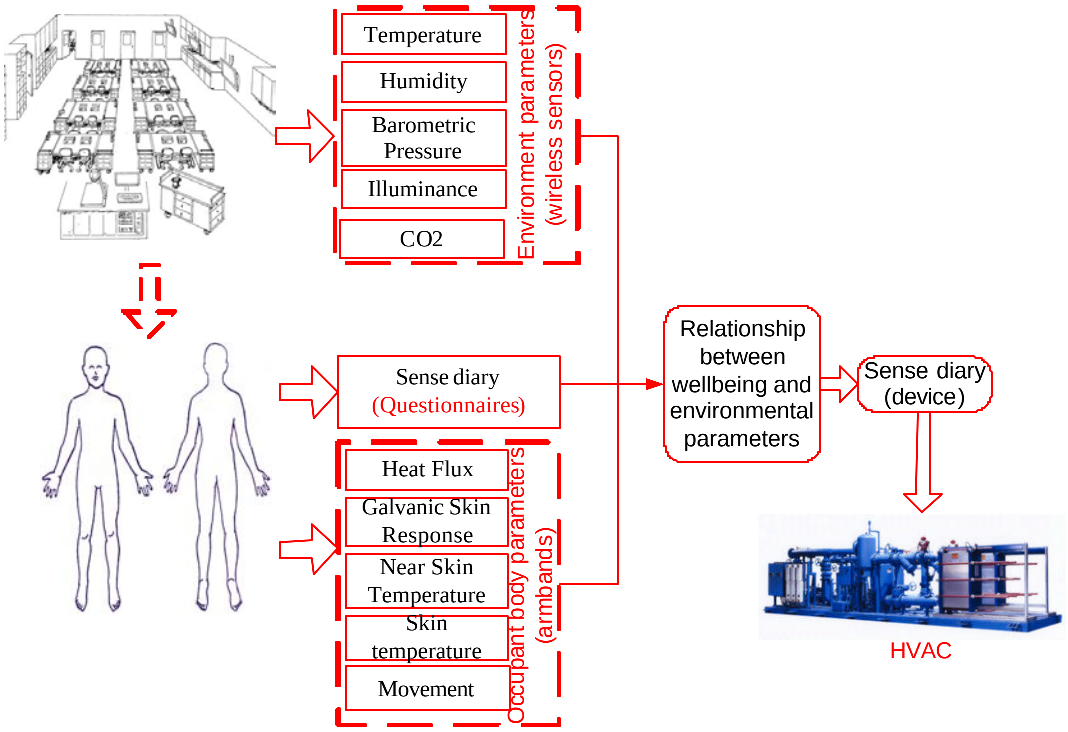

Figure 1. Research Plan

environmental parameters, and apply armbands to measure occupant's body parameters. The armbands can also be used to measure occupant behaviours through their embedded sensors. With such parameters, people are able to explore how the change of environmental physical parameters can impact on occupant body parameters such as skin temperature. As some characteristics can not be measured with sensors, we designed a questionnaire, also called ***soft sense diary*** (see Appendix). The collected data are then analysed, and relationship among variables are explored. The wireless sensor kit was bought from Crossbow (www.xbow.com), and three identical armbands from BodyMedia (www.bodymedia.com/).

The wireless sensor kit has four smaller sized sensors, each of which measures temperature and relative humidity (see Figure 2a); and two larger sized, each of which measures temperature, relative humidity, and light (see Figure 2b).

The armband measures several parameters, below lists some

- **Accelerometer** measures vertical and horizontal motion of its wearer;
- **Heat flux** measures how much heat the wearer's body is giving off.
- **Galvanic skin response** measures skin conductivity affected by physical exertion and emotional stimuli such as psychological stress
- **Skin temperature** reveals the body's core temperature trends affected by the level of a person's physical exertion or lack thereof

Figure 2a

Figure 2b

Figure 2c

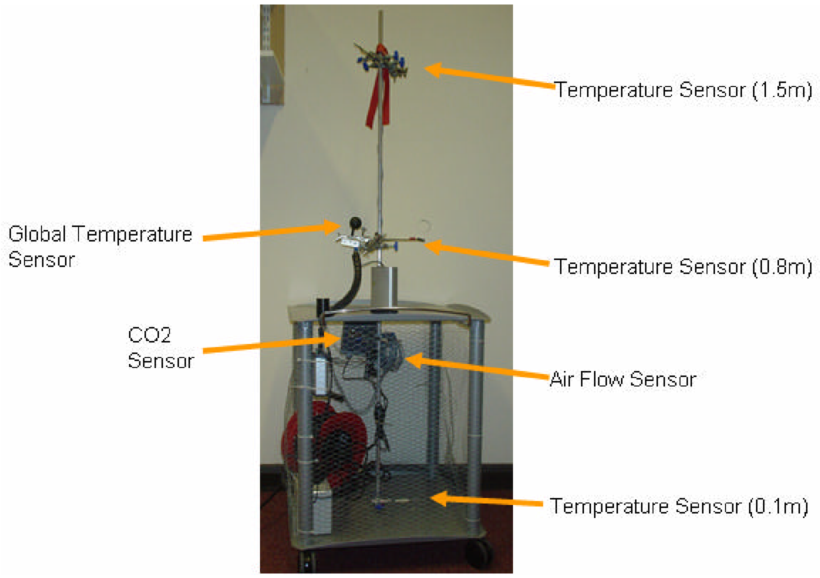

Figure 3 A sensor set

In order to collect Carbon dioxide and mean radiant temperature, a sensor set was used to measure these parameters (see Figure 3). As shown in Figure 3, apart from three temperature sensors and an air flow sensor, a carbon dioxide sensor and a global temperature sensor are installed in the sensor set.
Figure 4 shows an example of parameter distributions collected from an armband wearer. For the figure, for example, around 10:00 o'clock, there is a dramatic change in heat flux and skin temperature, this is because the armband wearer went outside in a lower temperature environment.

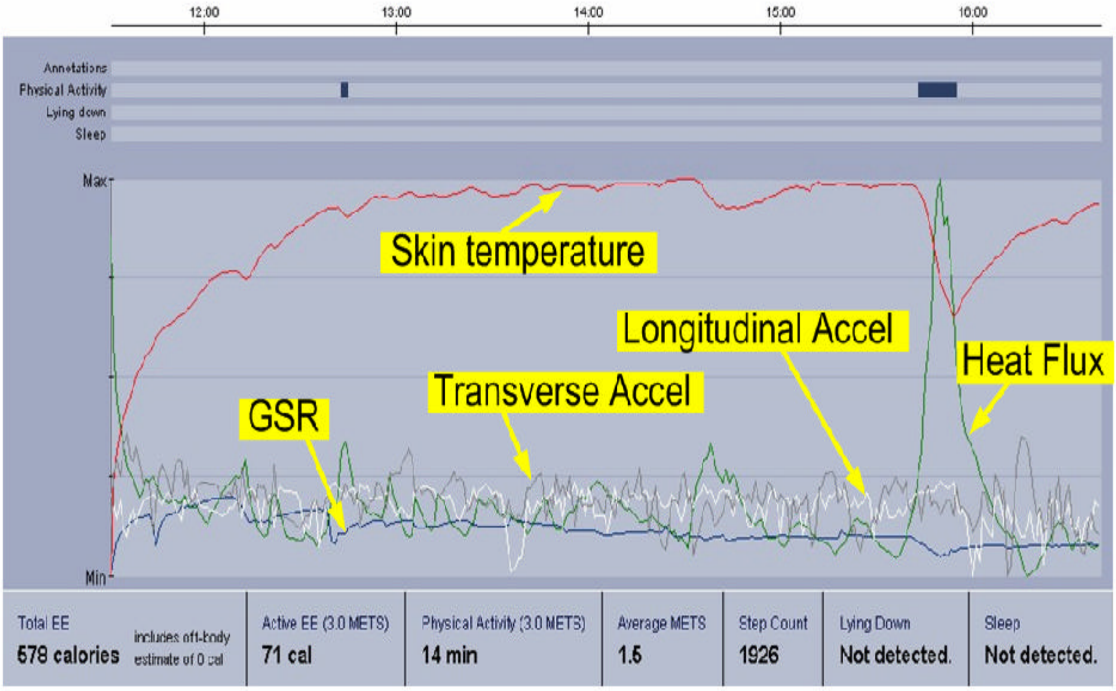

Figure 3: an example of the parameter distributions of an object

We set three day experiment in a 3m×5m office. In the experiments, objects wearing armbands were working in the office, and the sensor set and the wireless sensor kit were placed in the office. By adjusting the air-conditioner temperature one degree Celsius every 40 minutes, the temperature was changed from 16 to 28 degree Celsius.

The object profiles are listed in Tables 1, 2 , and 3.

The first experiment (8th November, 2006)

Subjects	Gender	Age range	Height (cm)	Weight	Clothing
A	Female	20-25	160-165	55	0.8
B	Male	35-40	180-185	75	0.8
C	Male	45-50	180-185	80	0.8

Table 1. Object profiles in the first day experiment

The second experiment (9th November, 2006)

Subjects	Gender	Age range	Height (cm)	Weight	Clothing
B	Male	35-40	180-185	75	0.8
C	Male	45-50	180-185	80	0.8
D	Male	45-50	170-175	70	1.0

Table 2. Object profiles in the second day experiment

The third experiment (8th December, 2006)

Subjects	Gender	Age range	Height (cm)	Weight	Clothing
E	Female	45-50	170-175	75	0.8
F	Male	40-45	170-175	80	0.8

Table 3. Object profiles in the third day experiment

In a certain degree, Galvanic skin response (GSR) can reflect wearer's mood. Hence, we compare the GSR of the objects in Figure 4, from which one can see the different patterns.

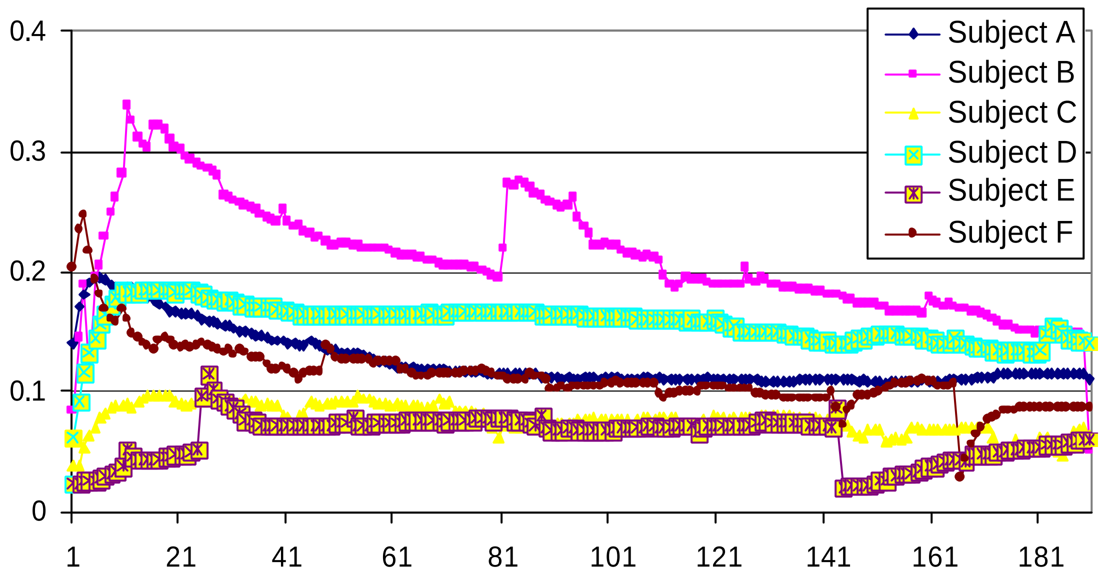

Figure 4. A comparison of GSR of the armband wearers

3. BAYESIAN NETWORK DEVELOPMENT

Through the above experiment, data were collected, and then analysed. A Bayesian network model is then built based on the data. The algorithm of building a Bayesian network model can be found from to Jensen (2001), and Neapolitan (2003).

For convenience, we borrowed a Bayesian software package developed by Cheng (2001). The Bayesian network model built on our collected data is shown in Figure 5. It shows, for example, that the Near Body Temperature (shown in *Near_body_tem* box) is a factor resulting in the

change of GSR (shown in *GSR_averag* box), while GSR is one of dependent factors to Energy Expenditure (shown in *Energy_expend* box).
The strength of the causal relationships can also be estimated from the Bayesian network models. For example, from the model, it shows that the causal relationship between Near Body Temperature and GSR is stronger than the causal relationship between GSR and Energy Expenditure.

CONCLUSIONS

Improving indoor environment to achieve a high quality living and work area can improve people's well-being and productivity.
This paper applies Bayesian networks to model the causal relationships between indoor environmental parameters and occupant's body parameters, on the basis of the data collected by a wireless sensor network, and body sensor sets.
Essentially, occupant behaviour, building services systems, indoor and outdoor environments are factors relevant to energy consumption, and occupant productivity. By revealing their relationships, it would be helpful for practitioners to design and maintain a better indoor environment for occupants.

Achieving Effective Power Demand Control on A University Campus by Applying Quality Projection Methods

Chih-Ting Lin, Chun-Yu Chen and Kwo-Guang Chong

Energy and Environment Laboratory/Industrial Technology Research Institute, Taiwan

Corresponding email: chunyuchen@itri.org.tw

SUMMARY

Current power demand control techniques are achieved by power measurement, demand projection, and utility unloading capabilities. According to the metering readings, the actions of unloading utilities will be taken if the projection demands exceed the contract capacity level (desired demand power). As the chosen projection method can affect the performance of the demand control strategy, the aim of bill cutting highly relies on the precision of the projection methods. In this project, the power usage of Tsing Hua University in Taiwan was metered and base on the metered data, different power demands were projected due to projection methods. These projection demands were used to compare with the real power demand, and the comparison results will be used to examine the accuracy of each projection methods. Moreover, utility unloading strategies will be applied with the projection demands to prevent the power demand to exceed the desired level.

INTRODUCTION

The power demand is increasing continuously due to the fast economic growth and the change of life style. The demand required for air conditioning systems during the summer in Taiwan can cause serious problems to the power supply system as the peak load is approaching the maximum capacity. As a result, the power supply company has to invest more money to build up the reserve margin capacity for demand needs. In addition, the cost of energy is increasing obviously as the rising of Brazil, Russia, India and China. Therefore, it is crucial to reduce the problems of short of reserve margin capacity by controlling the growth of power demand. On the other hand, the strategy to achieve good energy usage efficiency is often adopted by power demand side around the world. In addition, the methods to reduce the peak load such as load management, demand control and off-peak power usage are often applied in developed countries. Later on in this paper, the roles of demand control techniques, demand projection methods and the simulation of projection methods in energy management will be shown.

The power demand increasing due to air conditioning systems in summer brings big problems to the power supply system in Taiwan. Even though the Tai-power company is applying reason rate to reduce the peak load, the result is very limited. Hence, the only solution for Tai-power is to build up more reserve margin capacity. However, building up the power plants to match the future needs is a difficult task in Taiwan as the compact to the environment and the short of land. Hence, it is necessary to find out the methods to reduce the growth of power demand by applying efficient energy saving under the pressure of energy shortage.

The definition of contract capacity is the average power consumption in a fixed period of time which is called the demand interval. The demand interval is regulated by each power supply company, and it is 15 minutes with Tai-power in Taiwan. The contract capacity is the agreement between the power supply company and its end users. The volume of power demand indicates the requirements of the end users and it means that the least capacity that the power supply company has to offer to meet users' needs. For power supply companies to offer quality power for the users, it is necessary to invest more money to build up the reserve margin capacity while is needed, and the required investment is then be used to set up the rules for over demand surcharge (penalty charge).

The power demand control technologies were merely found in heavy industrial cases as the costs were high. By the advance of microcontroller technologies with power measurement and software, the prices of power demand control equipments are getting cheap and the performances are also getting better. As a result, the implementation of power demand control is getting popular these years in medium and small enterprises and residential and commercial users were targeted as the next focusing market. This is because that power demand control can bring benefits to both the power suppliers and the end users.

DEMAND MANAGEMENT

Analyzing the power consumption model in Taiwan, the heaviest demand during the peak load in summer comes from the use of air conditioners. Hence, minimizing the peak load by implementating the real-time load management over the air conditioners and related devices is considered as the best solution for effective results. According to the records, the peak load of the summer time occurs between 10 AM to 12 AM and 2 PM to 4 PM, and the second period consumes more than first period does. To a power supply company, enough reserve margin capacity is required to meet user's demand, and on the other hand, the users have to pay the bill because of the power consumption. For contract users, the power consumption required by many of the users is not always higher than the contract capacity levels, and money can be saved if good load control is implemented. Later on, the relationship between contract capacity and demand control will be explained.

The agreement between the end users and the power supply companies is often called the contract capacity and this means the highest power requirement from the users. The volume of contract capacity means the plan of generating capacity and reserved margin capacity to the power supply company. In the other hand, the contract capacity shows the relations between the power bill, fixed bill, and the over demand surcharge to the end users. Although a higher value of contract capacity can reduce the over demand surcharge (penalty charge), the fixed bill can take more money from the users and vise versa.

In Taiwan, the Tai-power meters several different types of data such as accumulated kW/h, maximum demand power and so on. The maximum demand level will be cleaned as zero after being recorded, and this piece of data will be compared with the contract capacity level every 15 minutes. If the newly recorded data is bigger than the old recorded data, the old data will be replaced, and the old data will be saved if the new data is smaller than the old one. As a result, the maximum demand power will be remained, and this data will be used to count the power bill and the penalty charge. To understand the power need of a system, the power demand is often a better solution than real-time power consumption as it is the average power consumptions during time intervals. Later on, four graphs will be used to show the meaning of metered data between the real-time power consumption and the demand power. First one is a real-time power consumption recorded in a convenience store, and power demand is used to show the trend of the power consumption in the second one. Figure 3 is the power consumption record of a university, and the demand power can show more details such as the time, the value and times when exceeding the desired demand level happens.

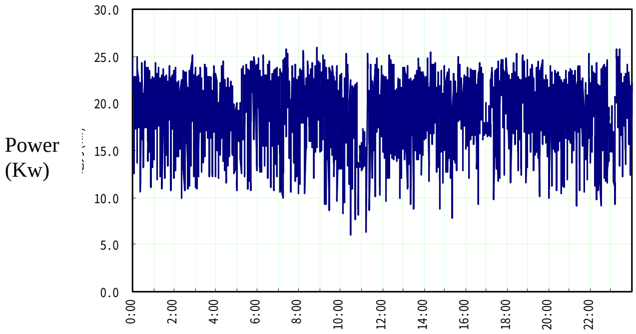

Figure 1: Real-time power consumption from a convenience store

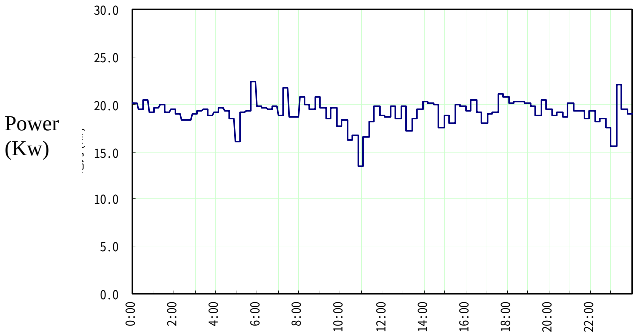

Figure 2: Power demand acquired by the convenience store

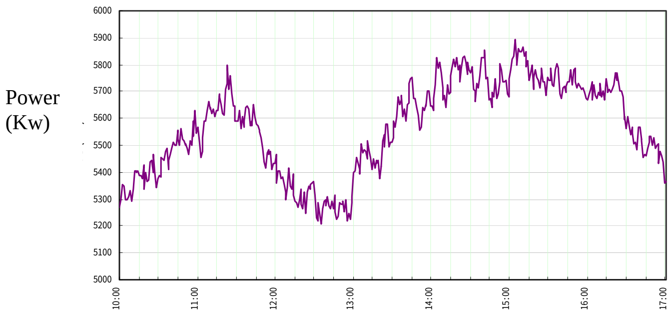

Figure 3: Power consumption recorded in a university

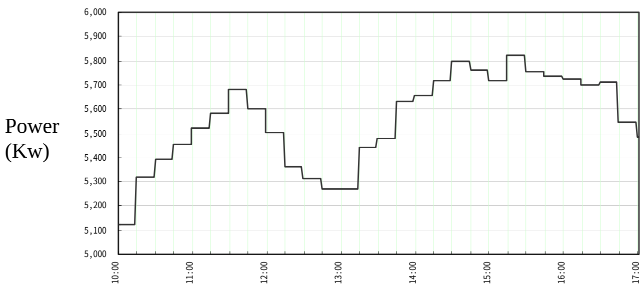

Figure 4: power demand recorded in a university

RESULTS

Demand control method

To achieve summer demand control in Taiwan highly depends on the load control plan and unloading strategy which can be used to indicate the unloading sequence of some secondary devices temporarily to achieve the power demand control to prevent the power usage not to exceed the contract capacity level. As the air conditioning devices including the fan systems, condensers and the pumps are the major targets, to apply real time control over these devices is considered as the best approach to reduce the power demand, and three key issues are: setting the best deal of desired power demand, the unloading strategy and the power demand control.

The desired power demand setting

The desired power demand which indicates the maximum volume of power demand is also the agreement between the Tai-power and the end users. Hence, power bill can be cut by setting an appropriate desired power demand level, and the power demand can be used as the target for load control. Very often, the desired power demand is calculated and analyzed by reviewing the power bill in the pervious year and the used devices.

Unloading strategy

The time interval defined by Tai-power is a 15-minute period, and the recorded maximum demand in a month will be used to charge the power bill including penalty charges. Therefore, users have to think the relation between their own systems composed by devices and the contract capacities. Every single device has it own priority while changing the operation mode to reduce the power demand to meet the desired demand level is needed. According to the priorities, the unloading plan of a system can be built and here use a fan system as an example, step1, to turn off the fan and step 2 to low the fan speed and so on. In addition, the plan of unloading devices will affect the performance of the demand control, e.g. to prepare 4 devices which need 100 KW individually to reduce 100 KW from exceeding the desired power demand is an idea plan.

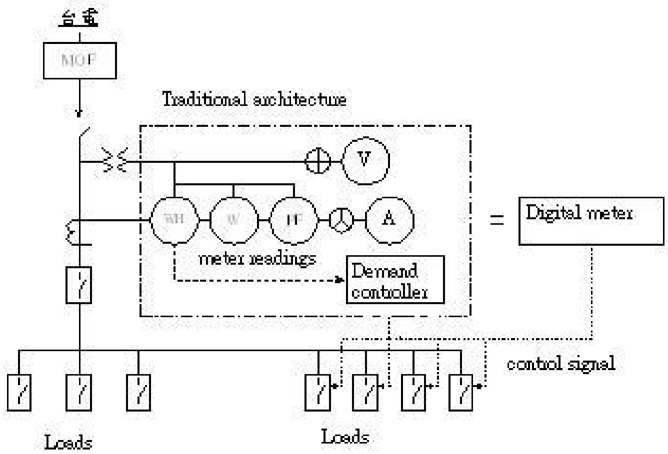

Figure 5: the architecture of a power system and a demand control system

Demand control strategy

Figure 5 shows the architecture of a power system and a demand control system which includes power meter, protecting relay and so on. In a traditional demand control system, the demand is projected by counting the pulses from the meter. If the projected value is higher than the desired demand level, the system will activate the relay to turn off the defined devices. Nowadays, as the progressing of mciroprocessing technologies, the demand control can be implemented within the power meter. As a result, the cost to implement power demand is much cheaper than it was and it will be a huge advantage while promoting this system.

rules of demand control

There are two parts included in the early stage of demand control system, the power metering and control. The front end, power meter, takes voltage transformer (VT) & current transformer (CT) to measure the power consumption. The measured data will be sent to the demand control part to unload devices while needed. The demand control includes parts such as signal input, function setting, display, record, calculate, unloading function and warming. The performance of device unloading comes from the accuracy of demand predicting. Figure 6 shows the rule of demand projection and unloading sequence. In the figure, Q indicates the projection demand, Ps is the desired demand and Pr is the targeted demand (Pr≦Ps). The cycle of demand projection, warning, device unloading, and device loading will take place every 15-minutes.

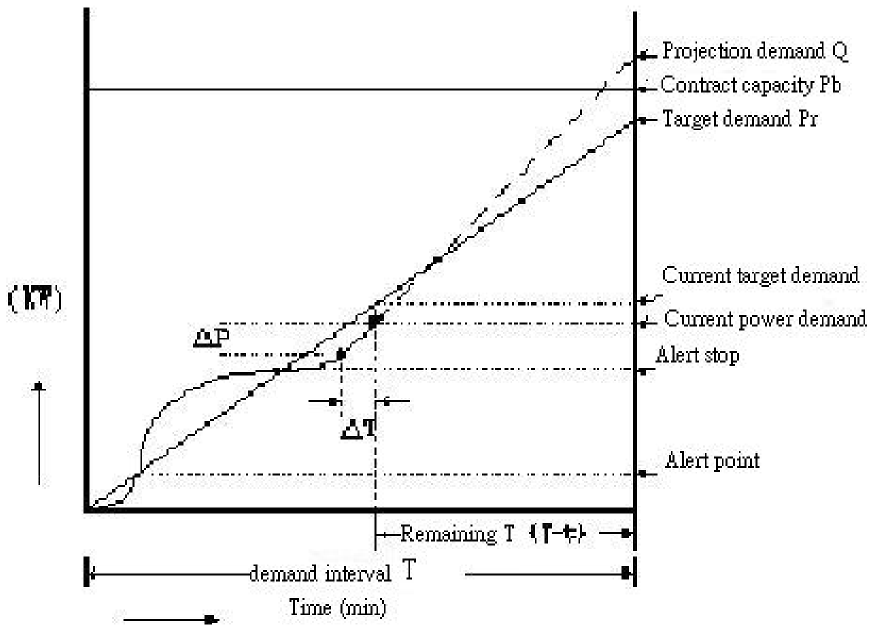

Figure 6: the rule of demand projection

Demand projection

Demand projection is an important function of demand control, as it directly affects the performance of demand control. After microcontroller and DSP were used in power metering, the function of demand projection is often implemented within a digital power meter. Despite of the rules mentioned in the previous section, there are few different rules for different power systems with different characteristics. Here uses a power meter as an example and the rule is:

$$\text{Demand} = \frac{1}{T} \bullet \int_{t}^{t+T} P(t)dt \quad \text{---------} \quad (1)$$

T：demand interval

P(t)：instantaneous power

Actually three different rules are offered to users, and they are instantaneous projection, first-order projection and second-order projection. Instantaneous projection shows the average demand in the past time interval. The first order presents the real-time power demand with the remaining time interval. The second order is used to indicate the changing rate of the first order result and the remaining time interval. Here are these rules:

$$\text{Demand} = \frac{1}{t2 - t1} \bullet \int_{t1}^{t2} P(t)dt \text{ ------- } (2)$$

In order to avoid a huge difference between the projection demand and the measure result, a synchronous mechanism to receive external signal is included within the demand control. While no external signal is available for synchronous, a sliding window method can be used. The main difference between the sliding window method with the previous method is that the time interval will be cut into several sub time interval, and this solution can delivery quality results while comparing with the measured meter reading.

Here use a university dormitory as an example, and several demand projection methods were applied to find out the hiding characteristics of these methods. These methods include instantaneous, first order, second order and sliding window method. From the simulation results, the results of demand projection are not quite the same due to the method, see Figure 7.

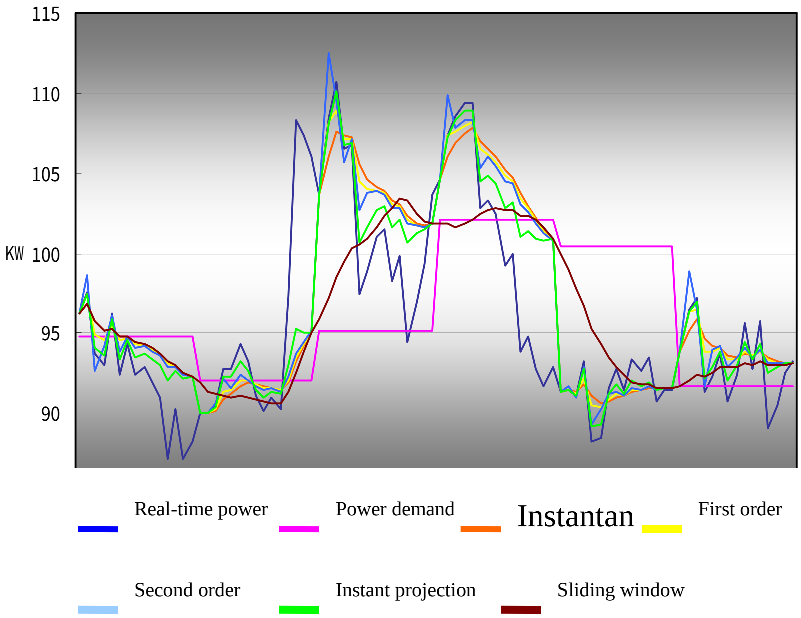

Figure 7: Demand projection results from different methods

DISCUSSION

Quality demand control can reduce the peak power requirement and also reduce the penalty charge because of exceeding the contact capacity. However, it is essential to set a desire demand level and unloading plan for achieving quality demand control. Through this research, it can be found that users has to apply different demand projection methods while the loading is constructed by different devices, e.g. to choose a fast reacting demand projection method while the ratio between unloading quantity and loading quantity is low. The finding of this research will be applied to the supermarket energy management project.

ACKNOWLEDGEMENT

Many thanks to the Bureau of Energy, Ministry of Economic Affairs in Taiwan, without their support, this project can not be carried out. Also thanks to the member of System Control Laboratory for helping to deliver this paper in time.

Long-term performance of VAV laboratory ventilation

Raimo Niemelä, Esko Tanner, Kalevi Nieminen, Ari Tuusa, and Sinikka Vainiotalo

Finnish Institute of Occupational Health, Finland

Corresponding email: raimo.niemela@ttl.fi

SUMMARY

The objective of the paper is to evaluate the long term performance of the HVAC system in a laboratory building equipped with an advanced fume cupboard technology and a building automation system. The exhaust airflow of the fume cupboard was controlled in terms of sash position and a control unit. In addition, selected fume cupboards were equipped with presence sensors. The air supply and exhaust flow rates of the laboratory rooms were monitored during two years in normal operation conditions. The data series were presented as cumulative distributions, which enabled comparisons of the air flows between various fume cupboards or laboratory rooms. The performance of the VAV fume cupboard system was compared with a hypothetic fume cupboard with constant exhaust airflow providing the same face velocity as the VAV system. It turned out that saving potential when using the VAV system was about 60%.

INTRODUCTION

Control of indoor climate in chemical, biochemical and toxicological laboratories is a challenging task from the point of view of occupational health, energy economy and maintenance. Airborne contaminants occurring in the laboratory environment may have irritating, allergic and carcinogenic effects or may affect specific organs, such as the central nervous system. Therefore, effective control of hazardous substances handled in these laboratories is absolutely essential.

The strict requirements for protection against airborne hazardous contaminants have led to the use of large air flow rates in laboratory buildings. Typically air flow rates in laboratory buildings are about 5 times higher than in office buildings [1]. Although high air flow rates in laboratory rooms are necessary for safety reasons, another reason for high energy consumption is the fact that standard design and control technology have been applied for decades. The technology for laboratory fume hoods, the first barrier in the prevention of exposure to air contaminants, and demand control ventilation have made notable advances during recent years. These advancements together with building automation systems (BAS) offer notable benefits for improving working environment and energy economy in laboratory buildings. The modern BAS produces vast amounts of data for remote monitoring, control, fault identification and diagnostics purposes.

In practice, it seems that service personnel use the BAS data quite narrowly to detect alarms and to react immediately in order to correct the faulty function and cancel the alarm signal. More systematic and automated fault detection and diagnostic procedures based on the on-line BAS data have been developed and validated in real buildings during recent years [2]. Both the alarm-oriented practice and automated on-line diagnostics are based on short term changes in the HVAC system. Although these procedures have proved very useful, long-term monitoring of the BAS data can offer further benefits. Long-term monitoring data reveals how the systems are used in real buildings. Such information is valuable for planning refurbishments in existing buildings and designing new laboratory buildings.

The general objective of the paper was to evaluate the long term performance of the HVAC system in a laboratory building equipped with advanced laboratory fume hood technology and building automation system. The specific objectives were as follows:

- to monitor the of use of the laboratory fume hoods in terms of sash position
- to compare the VAV hood system with the hood system involving constant air flow
- to describe dynamic behaviour of the hood system due to change of sash position
- to produce simple reporting methods to interpret the BAS data relevant to the laboratory hood technology from the standpoints of building owner, end-user and equipment manufacturer.

METHODS

Building

The long-term performance evaluations were carried out the recently built section of the Finnish Institute of Occupational Health located in the centre of Helsinki. The seven-floor building, built in 2000, consists of two parts: a laboratory wing and an office wing. The building was equipped with a modern building automation and monitoring system based on the Lon bus network. The general HVAC system consisted of mechanical supply air and exhaust systems and a cooling mode. Some one hundred laboratory fume cupboards were mounted in the laboratory wing of the building. During the design phase, the chemists and other users of laboratory facilities were asked to estimate the degree of use of the laboratory hoods. This information served as a rough estimate for designing the airflows in the laboratory wing.

The exhaust airflow of the fume cupboard hood (1.2 m wide, nominal exhaust flow 160 l/s) was controlled through sensor detecting sash position and a control unit with an alarm function. The control system (Fanison) maintained the face velocity at least at 0.4 m/s in the sash opening in the normal use of the fume cupboard. In normal working conditions the sash position higher than 33 cm was seldom used. At the lowest sash position, a slot of 2 cm remained between sash edge and cupboard table. The supply air flow was adjusted accordingly based on the exhaust air flow rate. In addition, selected fume cupboards were equipped with presence sensors. When the operator had left the sash open leading to too low face velocity, flashing light and sound alarms were launched.

The performance of the laboratory ventilation was monitored during two years in normal operation conditions including nights and holidays. The monitoring included supply and exhaust flow rates, sash position and presence of an operator in front of a laboratory hood. The sampling frequency of these data was once per minute. In addition, the set points of other operation parameters of the HVAC system were collected.

In order to analyse the huge amount of data collected, a database and a Java application for calculation purposes were created. This enabled versatile selections and filtering of data based on time periods of interest and other relevant parameters.

In order to prevent contaminant dispersion from the fume cupboard, it is necessary that the flow control system responses rapidly to changes in the sash position [3]. The response time of the sash sensing control system was tested in a laboratory room with three laboratory fume hoods by abruptly changing the sash position of one laboratory fume hood and recording the change of the joint exhaust air flow of fume hoods and supply air. The sampling frequency in recording in this test was 0.5 Hz.

RESULTS

The data series gathered by the building automation system was presented as cumulative distributions. The distributions enabled the consideration of parameters of interests including comparisons of the exhaust air flows of a fume hood at different time windows (Figure 1). The distributions in Figure 1 show differences in the exhaust flows of the fume hood analysed with different time windows over one year. Curve A represents the whole year including nights, weekends and holidays, Curve B working hours and C the time when a person was standing in front of the laboratory hood. From curves A and B we can see that about 80% of time the exhaust air was less than 50 l/s. In case of a person working with the fume hood, the corresponding value is 60 l/s. Lower part of curves A and B show that about 20% of time the exhaust flow was less than 40 l/s. This means that the operator had worked with a narrow sash opening or left the cupboard unintended with the sash slightly open. Generally, the curves show that the sash of the laboratory fume hood was left down or slightly open for most of the time. Curves A and B are close together but curve C representing presence by the hood showed higher air flows.

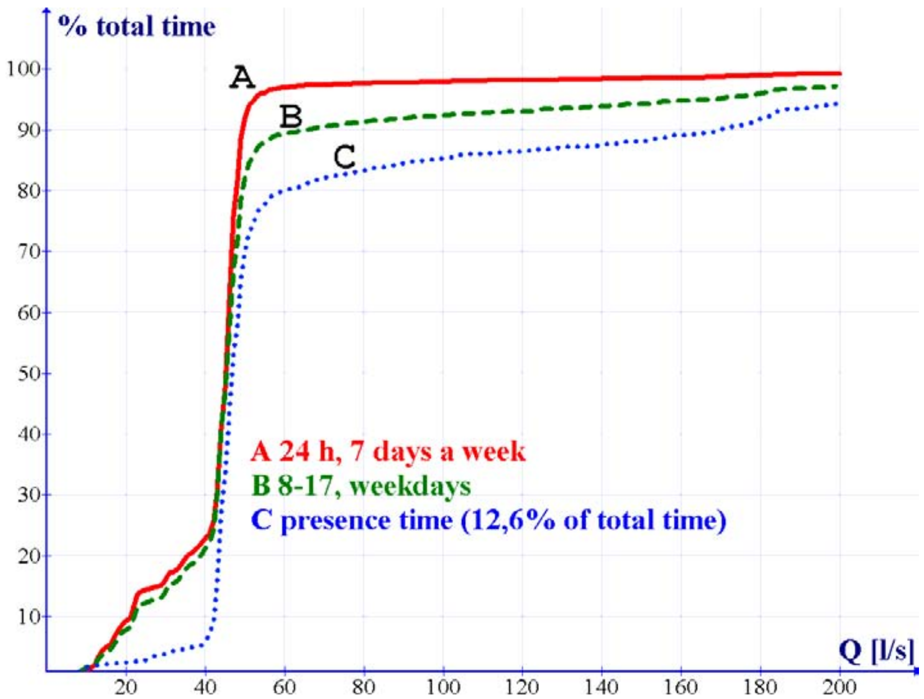

Figure 1. An example of the exhaust air flows of a laboratory fume hood in terms of cumulative distributions based on a monitoring period of one year.

The performance of the VAV fume cupboard system was compared to a hypothetic fume cupboard with constant air volume (CAV) providing the same face velocity as the VAV system (Figure 2). The saving potential of the VAV system was simply determined from the relation 1 - *A1/A2,* where A1 is the area restricted the cumulative air flow curve, y-axis and line of 100% (the VAV system) and A2 is a rectangular area (160 l/s x 100% i.e. the CAV system). Generally, it turned out that the saving potential with the VAV system ranged from 50% to 70%.

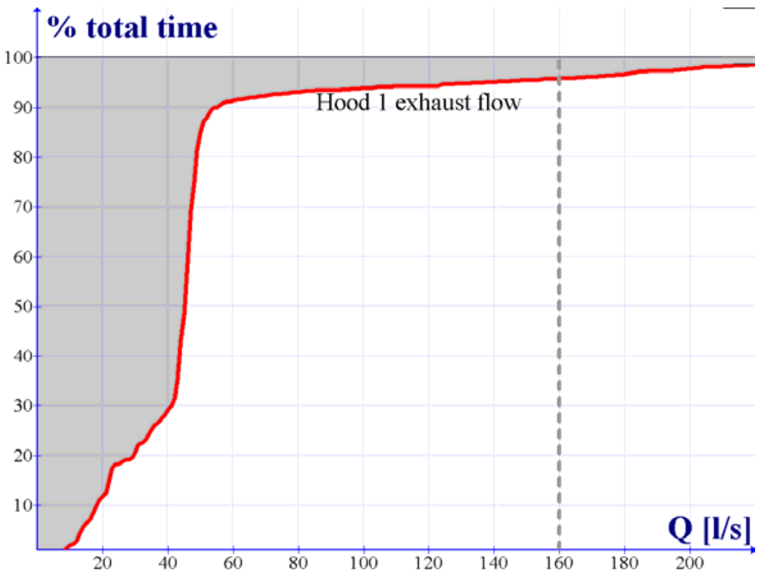

Figure 2. The idea for determination of the saving potential of the VAV system compared with the CAV system at the air flow of 160 l/s. In the case presented in Figure 2, the potential is 70%.

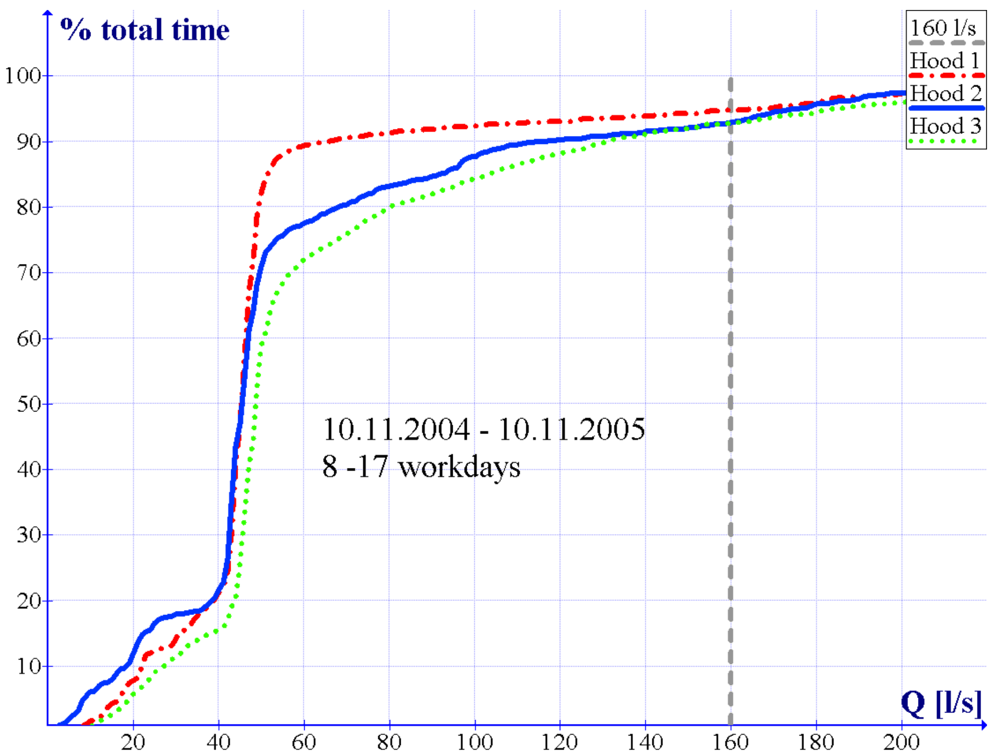

Figure 3. An example of cumulative exhaust air flows of three laboratory fume cupboards in a laboratory room monitored during working hours over one year. The saving potentials were as follows: Hood 1 67%; Hood 2 63%; and Hood 3 58%.

The curves in Figure 3 show that laboratory fume Hoods 2 and 3 were used more often than Hood 1. The saving potentials ranged from 58% to 67%.

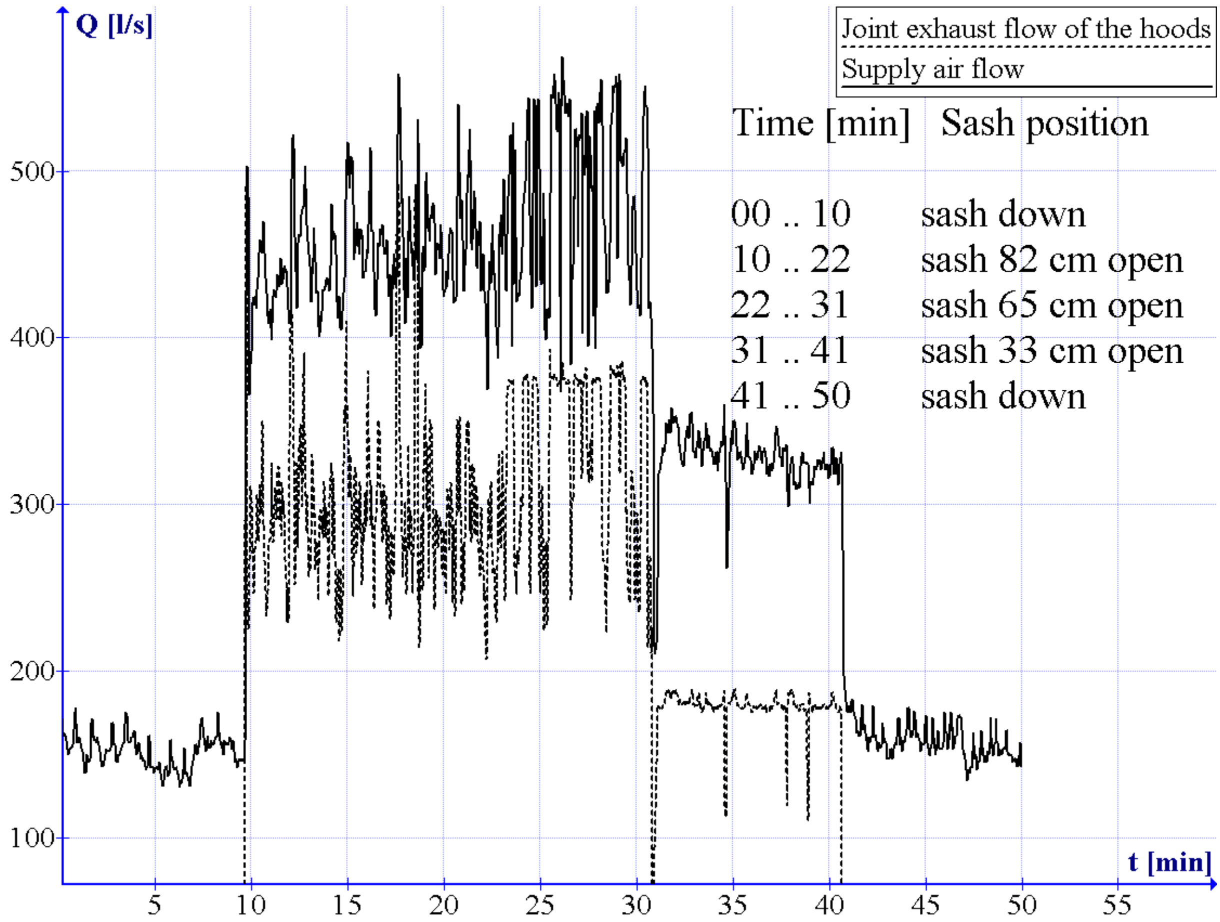

Figure 4. The dynamic behaviour of the VAV control system in a laboratory room.

The dynamic behaviour of the control system is described in Figure 4. It indicates that the exhaust flow of the hoods and the supply air flow into the room responded rapidly when the position of the sash was changed. In normal use the most common sash position is around 33 cm. The fume cupboard is fully open at sash position of 65 cm. The extreme position of 82 cm is not used. The test shows that the response time was less than three seconds, which can be regarded as short enough to prevent dispersion of air contaminants from the laboratory fume cupboard.

DISCUSSION

The paper demonstrates the benefits of long term monitoring of the BAS data of the laboratory building equipped with advanced laboratory fume hood technology and VAV ventilation. The two year monitoring produced information on how the laboratory HVAC systems were used in actual work. In order to analyze and present the gathered large data series a data base was created. The data base enabled consideration of air flows and other parameters of interest in terms of selected time windows. Cumulative distributions proved to be a simple and informative way to compress and present the data series.

Two 'knees' appeared in the typical cumulative distribution curves, one in the lower part and another in the upper part of the curve (see for instance Figure 3). The upper 'knee' revealed that higher airflows than 50 l/s were not used very often, only 20% to 30% of the working time. The lower 'knee' indicates that the exhaust air flow of the fume hoods was less than 40 l/s for some 20% of the working hours. This means that the sash position was low for most of the time. Consequently, one can conclude that the degree of use of the laboratory fume hoods was low in the demonstration building during the monitoring period. Yet, the conclusion is not so straightforward, as a laboratory fume cupboard may fulfill an important safety task without an operator if there is a contaminant releasing operation within the cupboard. It is also good to remember that it is typical of research laboratories that the number of chemical and biological analyses may vary heavily from one year to another depending on the research projects active at any given time.

The advanced hood technology with VAV ventilation proved to be very energy efficient compared to the CAV system. The saving potential introduced in this paper ranged from 50% to 70% measured against the energy consumption of the CAV system. These figures are in line with the results obtained in a study concerning the retrofitting of demand-controlled ventilation in a biochemical laboratory building [4].These figures strongly emphasize the benefits of advanced fume cupboard technology combined with the modern BAS system. Implementation of these technologies promotes energy economy without compromising the achievement of safety requirements.

ACKNOWLEDGEMENTS

SUMMARY

Personalized ventilation aims for supplying clean air to the breathing zone of each occupant. The impact of the direction of the personalized flow on the inhaled air quality was studied. Experiments were performed in a full scale room. Personalized ventilation in conjunction with mixing ventilation was used. Breathing thermal manikin resembled person seated at a desk. Tracer gas, mixed with room air was used to simulate pollution. No significant difference in inhaled air quality was identified when the flow was supplied from front, left, right and above at distance between the personalized air supply device and the face of the manikin, 0.3, 0.4 and 0.5 m. This result was obtained at different levels of dilution of the personalized air with the polluted room air.

INTRODUCTION

Personalized ventilation aims for supplying clean air close to the breathing zone of each occupant [1]. Therefore when it is well designed it has potential for improving significantly the inhaled air quality [2, 3]. In this respect the interaction of the personalized airflow with the free convection flow which exists around human body is of major importance. The interaction of the flows and thus the quality of the inhaled air is affected by several parameters, such as the characteristics of the personalized flow, e.g. mean velocity, turbulence intensity and direction, body posture, room air temperature, etc. [1].

The impact of personalized flow rate, e.g. the target velocity of the personalized flow, has been studied [2, 3]. The impact of the direction of the personalized airflow has been studied only partly [4]. The purpose of this study was to identify the impact of direction of personalized airflow on inhaled air quality.

METHODS

Experimental facilities and conditions

Experiments were performed in a full-scale test room (5.4 m x 4.7 m x 2.6 m (H)) located in a large hall where temperature was kept the same as in the test room. Test room was ventilated by mixing ventilation and was equipped with desk with PV system. The ventilation air was supplied trough a swirl diffuser located in the middle of the ceiling. The room air was exhausted through air terminal device located at one of ceiling corners.

The PV system had a circular air terminal device named round movable panel. This air terminal device is designed to supply airflow at low turbulence intensity. The initial diameter of the supplied jet is 0.185 m. 100% personalized air in inhalation can be achieved in points on the jet axis at distance up to 0.5 m from the air terminal device when the supplied flow rate is above 10 L/s. The air terminal device is attached to a flexible arm which allows for changes of direction of the supplied personalized flow against occupant sitting at the desk. Detail description of the device is given in [3].

A breathing thermal manikin simulated a person sitting on a chair behind the desk. The manikin is shaped as an average-size female. The body surface temperature is kept the same as the skin temperature of average person in state of thermal neutrality. The manikin was dressed in a long-sleeve blouse, panties, sports trousers, short socks and light sports shoes. The thermal manikin was simulating human breathing by the use of artificial lungs. The breathing pattern simulated was the normal for a seated person: 2.5 seconds of inhalation, 2.5 seconds of exhalation and one second of pause, giving a breathing cycle length of 6 sec. The respiration rate was 6 l/min. Exhalation was through the nose of the manikin, and inhalation – through the mouth. Figure 1 shows the manikin position at the desk with PV terminal device.

Figure 1.Experimental set-up.

The total volume ventilation system supplied 60 L/s air well mixed with tracer gas (Freon 134A). The supply air temperature was controlled in order to keep constant room temperature of 23 °C.

The PV ATD was always positioned in a way that the mouth of the manikin was in the centre of the supply air jet. The personalized air was supplied at flow rate of 12.5 L/s and at room temperature. Experiments at different dilution rate of the personalized air with the polluted room air were performed. This is shown in Table 1.

Table 1. Dilution rate of clean personalized air and polluted room air.

Experiment Number	1	2	3	4	5	6
clean air / re-circulated air (L/s / L/s)	12.5/0	10/2.5	7.5/5	5/7.5	2.5/10	0/12.5

The impact of the direction of the personalized flow against the face of the manikin and the distance between the PV air terminal device and manikin's face on the inhaled air quality was tested. The tested combinations of distance and direction are listed in Table 2. Figure 2 helps to understand better the experimental conditions. In total 36 experiments at different conditions were performed.

Table 2. Set of tracer gas measurements performed on each of the 6 workstations

Measurement Number	Position of the RMP in relation to the face of the manikin	Distance between the RMP and the manikin's face
1	Perpendicular	0.3 m
2	Perpendicular	0.4 m
3	Perpendicular	0.5 m
4	45° to the left	0.4 m
5	45° to the right	0.4 m
6	45° above	0.4 m

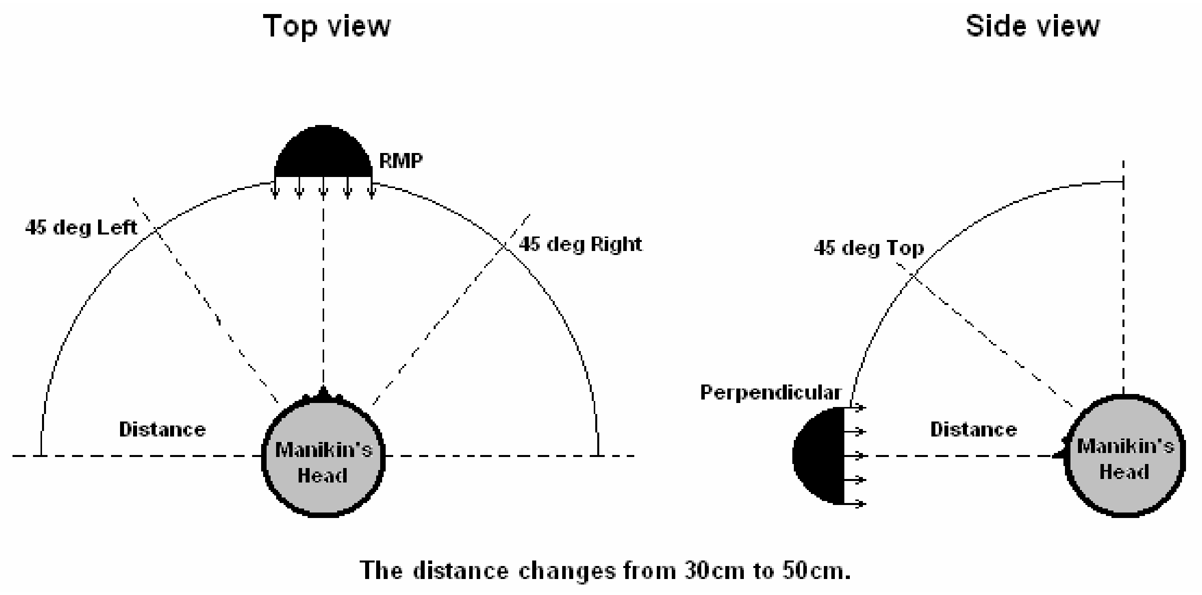

Figure 2. Positions of the RMP according to Manikin's face

Measurements and data analyses

During the experiments air temperature and humidity in the Tall Hall, air temperature and humidity in the test room, temperature of the air provided with PV was measured and controlled.

The tracer gas concentration in the outdoor air (referred as clean air), the exhaust air, in the middle of the room, at the PV supply, air inhaled by the manikin and outside the test room was measured. At each location concentration values from at least 8 consecutive measurements were obtained, and the averaged value was calculated. Photoacoustic Gas Analyser Innova 1302 was used to dose the tracer gas and to perform the concentration measurements. The measurements were performed after steady state conditions were reached.

The measured results were used to define the personal exposure effectiveness, PEE, by the following equations:

$$PEE = \frac{C_{I,O} - C_I}{C_{I,O} - C_{PV}} \qquad (2)$$

where:
$C_{I,O}$ – is the pollution (tracer gas) concentration in the inhaled air without PV;
C_I – is the pollution (tracer gas) concentration in the inhaled air with PV;
C_{PV} – is the pollution (tracer gas) concentration in the personalized air;

The personal exposure efficiency, PEE, is an index representing the percentage of clean air contained in the inhaled air. It is developed for evaluation of the performance of personalized ventilation systems [2].

In calculating the personal exposure effectiveness the tracer gas concentration in the exhaust air was used instead of the concentration in the inhaled air without personalized ventilation. The concentration in the inhaled air without PV is assumed to be the same as the concentration in the exhaust because mixing ventilation is used in the climate chamber.

RESULTS AND DISCUSSION

Figure 3 shows the PEE as a function of the distance between the supply air terminal device and the face of the manikin. The PEE obtained at different direction of the personalized flow against the face is shown in Figure 4. In the two figures the comparison is made at different dilution level. The results in Figure 3 show that the PEE decreased only slightly when the distance between the RMP and manikin's face was increased. This result was expected since the used air terminal device provides jet with relatively long potential core. The analyses of the results did not reveal significant impact of the personalised flow direction on the PEE. The results shown in Figure 4 are somehow scattered but without any tendency for an impact of the flow direction. The results in Figures 3 and 4 reveal that the PEE decreases with the increase of the dilution ratio. This result was expected.

The obtained results are important for analyses of perceived air quality reported by people provided with control of direction of personalized flow.

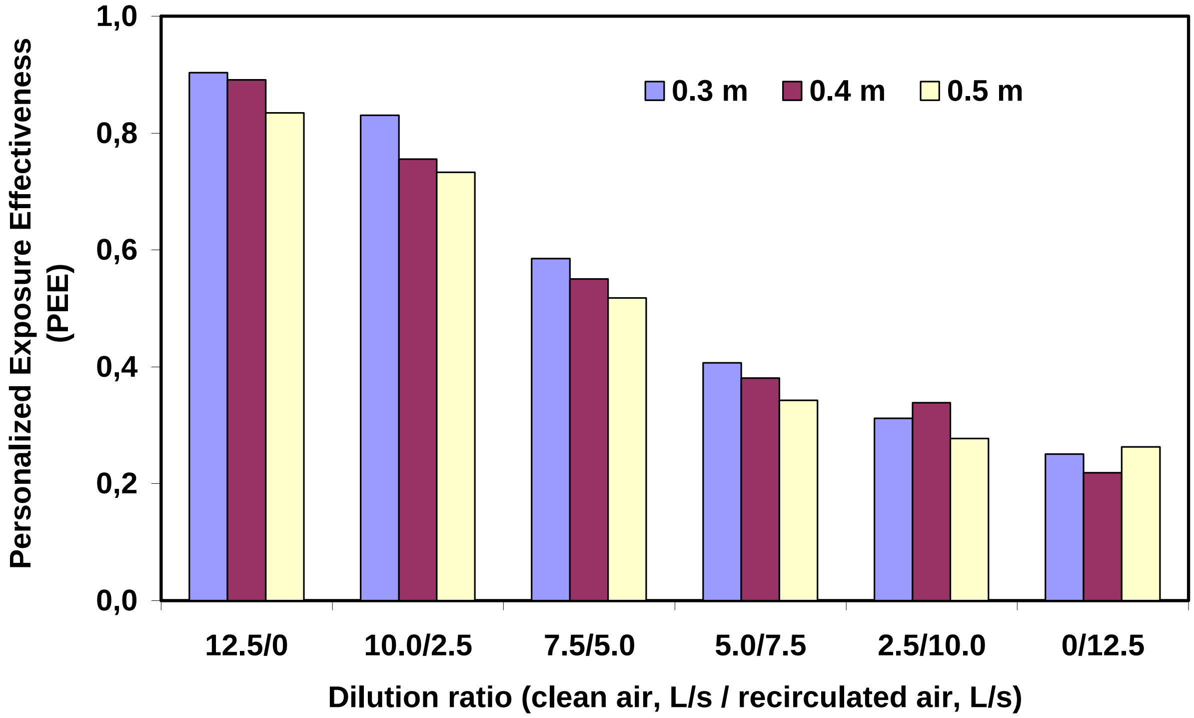

Figure 3. *PEE* as a function of the distance between the thermal manikin's face and the RMP positioned in front of the manikin's face.

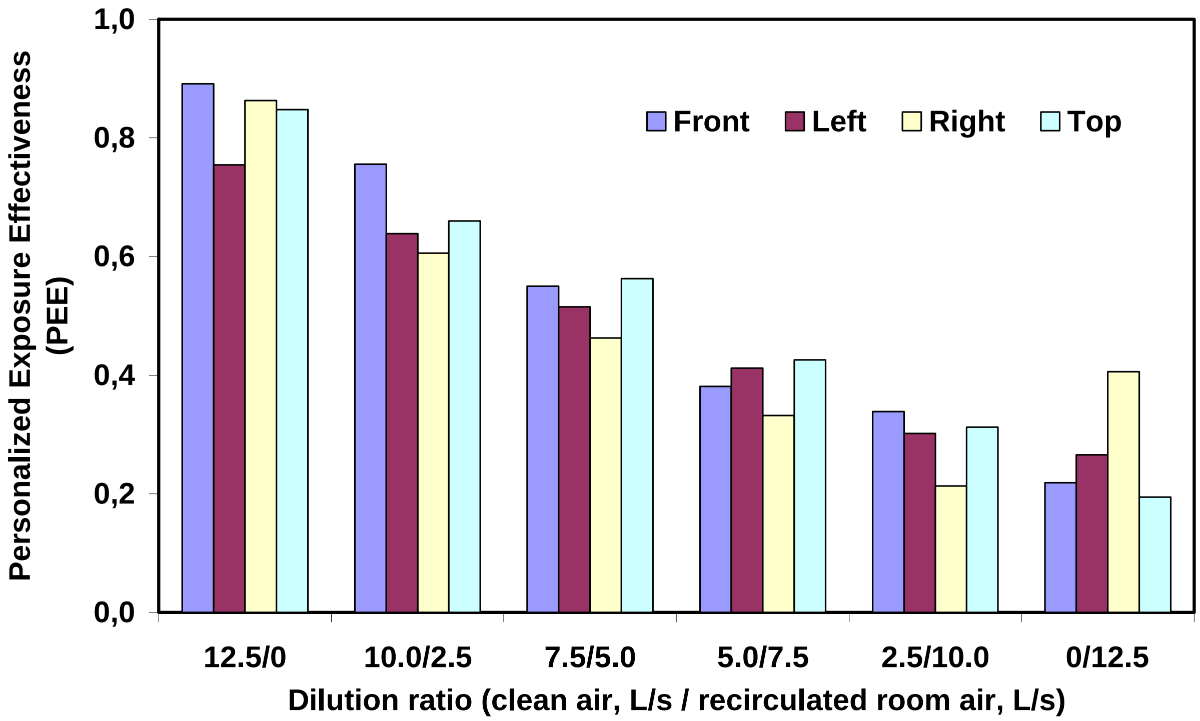

Figure 4. *PEE* as a function of the direction of the RMP according to the manikin's face. Distance between the RMP and the manikin's face is 0.4 m.

CONCLUSION

The results of this study reveal that the inhaled air quality measured by thermal manikin did not change when the personalized flow from a circular air terminal device (RMP) was supplied from front, left, right and above.

Cool the Office With Moving Air

Hans F. Levy, P.E.

Life Member ASHRAE

Corresponding email: argon1@aol.com

SUMMARY

Personal control over moving air will eliminate the number one complaint in the office environment – thermal discomfort. The use of moving air to cool provides the ability to accommodate different needs among people for comfort due to varying metabolism, efficiency of heat rejection, and clothing. Cooling with moving air saves substantial energy through increased ventilation effectiveness and higher operating temperatures. Increased comfort means increased productivity. Workstation design can be adapted to provide both personal air control and displacement ventilation at reduced first cost with faster construction, lower operating costs, cleaner air and 100% personal satisfaction.

DISCUSSION

The number one complaint of office occupants is an uncomfortable environment. People can, however, adjust conditions to meet their personal need for thermal comfort by simply adjusting air flow from a local air supply at their workstations. A study by Khedari and others [1] showed the dramatic effect of moving air on people. Also a survey by the University of California at Berkeley showed that most people in an office setting preferred more moving air.

The best use of the cooling effect of moving air is to get away from the mind set of air conditioning buildings with a “one environment fits all” approach that fits no one. The aircraft and automotive industries have taken advantage of moving air controlled by occupants for many, many years. Unfortunately, because of lack of space, the velocity of the air in both cases is high and tends to feel drafty.

Tests by Fred Bauman and his group at UC Berkeley have demonstrated that changing the air flow can change the cooling temperature perceived by occupants from 0° to 15°F (0° to 9°C). In the Khedari study of 288 college students, air at 80°F (27°C) moving at 400 FPM (2 m/s) feels like 65°F (18°C), a difference of 15°F (9°C).

ASHRAE Standard 55 through 2004 (p. 6) suggests the use of moving air, provided it’s under personal control. Khedari found that the effect shown in Standard 55 and reflected here (Fig. 1) as ASHRAE Thermal Comfort Tool, or TCT, is understated and probably is based on sensible cooling only. So, by varying the air flow you can control the perceived temperature from 80°F to 65°F (27° to 18°C). That range should satisfy 100% of occupants at all times. Providing personal control will eliminate the number one complaint – thermal discomfort – and improve productivity in every office. The system does this by accommodating the vastly different needs among people for comfort. Why is there so much difference in people's needs? Because basic metabolism varies from person to person (Fig. 2).

On top of that, metabolism can vary at any time due to varying conditions, such as controversial phone calls; or being rushed; or not feeling well due to health problems, etc.
People are comfortable when the heat removed is equal to the heat they generate and absorb from external sources, such as the sun, lights, office machines, etc.

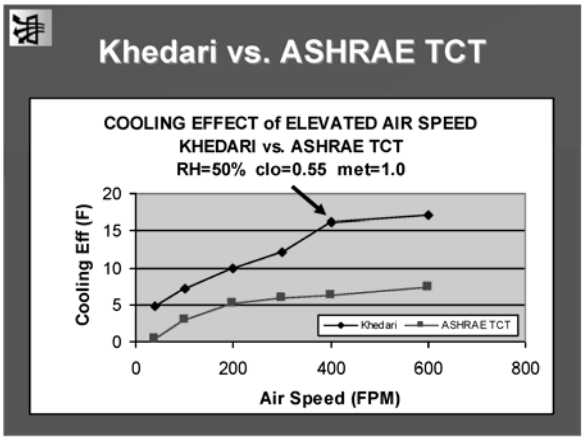

Figure 1.

According to information from the Mayo Clinic, the basal metabolic rate for people is 10-12 kilocalories per pound (22-26 kilocalories per kilogram) of body weight per day. Fig. 3 compares the caloric output of 1360 kilocalories for a typical woman weighing 125 pounds (54 kg) to that of 1960 kilocalories for a typical man weighing 180 pounds (86 kg): a difference of 600 kilocalories, or <u>44%</u>!

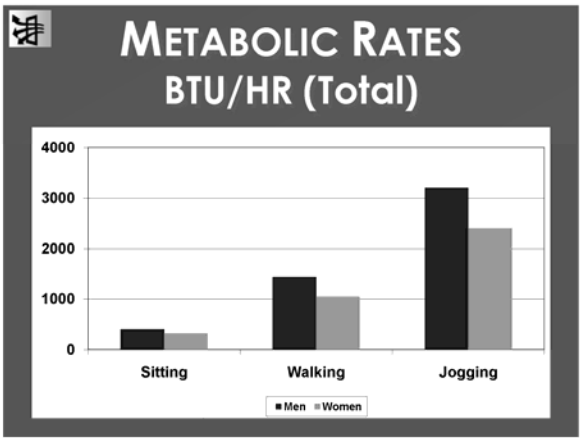

Figure 2.

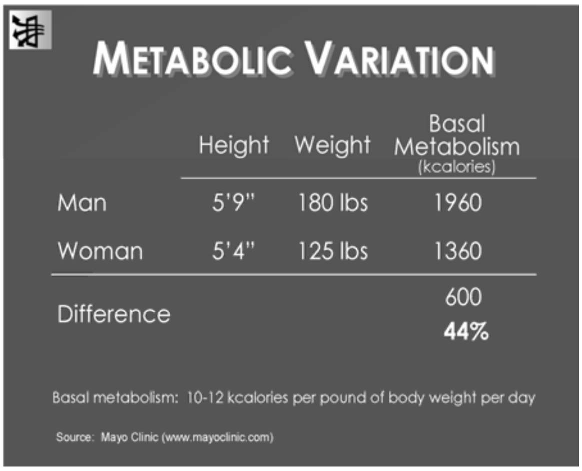

Figure 3.

If more heat than is generated through basic metabolism is removed, the person feels cold. Any less and he feels hot.

<u>Is it any wonder that both people cannot be comfortable under the same temperature conditions?</u>

In addition, differences in efficiency of heat rejection and clothing affect the cooling needs of men vs. women. A smaller body is a more efficient radiator, further increasing the need for individual environmental control. The simple solution is the system shown in Fig. 4.

By introducing air at the desk level, the occupant can change the cooling effect with a damper - just like in his car. Because of better space availability compared to a car, velocities are lower, and, therefore, air flow is quieter and more comfortable. This arrangement is familiar to everyone from his or her car without special training!

The system also saves substantial amounts of energy.

Tests at UC Berkeley have shown that discharging supply air flow near the occupant increases ventilation effectiveness - a savings both in energy and the cost of filtration (Fig. 5).

Figure 4.

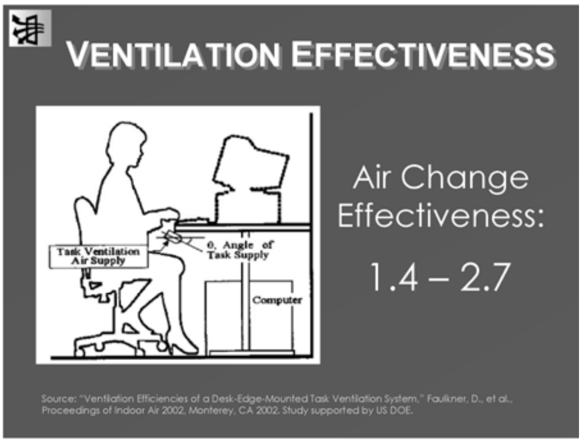

Figure 5.

Furthermore, a very great savings in energy is achieved by using moving air instead of cold air. Room temperatures can be set substantially higher because of the cooling effect of the moving air. As we have seen, moving air lets people set "perceived temperatures" from 80° down to 65°F (27° to 18°C) – a range of 15°F (9°C). The thermograph in Fig. 6 shows 60% of heat is given off by the upper body, and, thus, a personal air terminal positioned at the worksurface is most effective in making people comfortable with the least expenditure of energy. Many studies show that increased comfort means increased productivity [2]. Now let's put productivity in perspective.

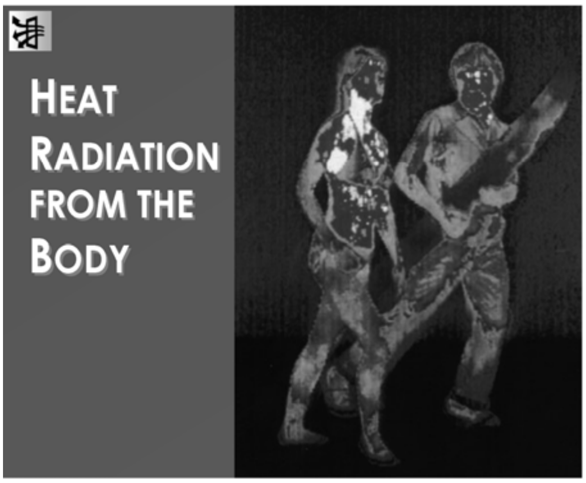

Figure 6.

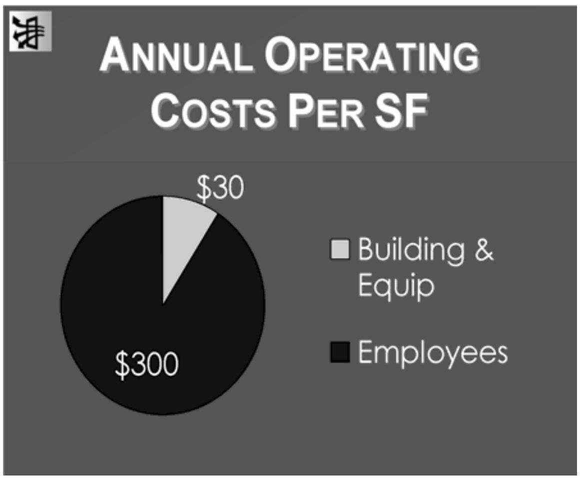

Figure 7.

Annual payroll costs in office buildings are approximately $200 to $300 per square foot ($2,150 to $3,225 per square meter), or 90% of the total costs of owning and operating an office facility. Even a small increase in productivity can offset total annual building costs of $20 to $30 per square foot ($215 to $323 per square meter).

Fig. 8 illustrates a desk or workstation with a personal air terminal. Note that displacement ventilation can easily be added for better IEQ, cleaner air and reduced cross contamination.

Displacement ventilation has been proven to increase comfort, save energy and reduce absenteeism.[3]

Fig. 9 shows a typical office with integrated task/ambient personal control and displacement ventilation. Note the near absence of floor grilles.

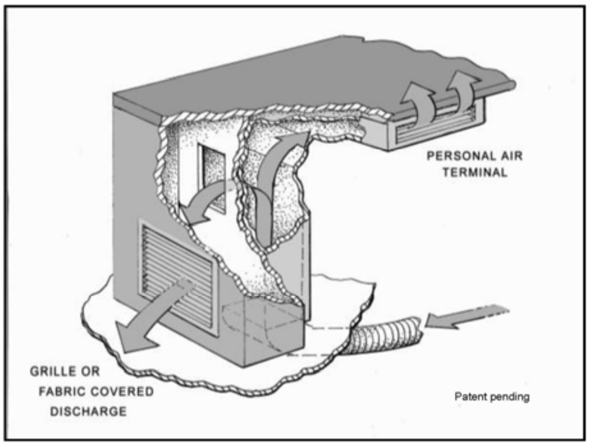

Figure 8.

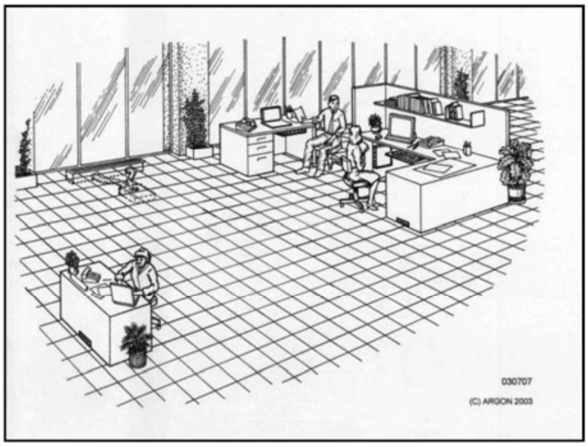

Figure 9.

Moving air with task/ambient personal control and displacement ventilation can eliminate the #1 complaint of office workers, save energy, have cleaner air and increase productivity. LEED credits can be earned with a sustainable green indoor environment, control by occupants, better IEQ, and lower energy cost.

All this can be done at reduced first cost.

Faster construction, lower operating costs, cleaner air and 100% personal satisfaction are the rewards.

Comfort Zone Or Acceptable Comfort Zone? : Comparison of Resident' Behavior of Operating Air Conditioner According to Charge for Energy

Suh-hyun Kwon, Nu-ri Bae, Chi-hye Bae and Chungyoon Chun

Yonsei University, Korea

Corresponding email: amy611@hanmail.net

SUMMARY

This research compared two groups' operation behavior of cooler, one is the resident of studio apartment who pays their energy charge per month, and the other is the resident of university dormitory who doesn't pay energy charge beside their rental fee. The amount of time to use a cooler and room temperatures were measured when they turn on/off air conditioner. Residents were interviewed about their cooling needs and decision factor on their operation behavior. Main results are as follows.

1. Dormitory group used the air-conditioner twice as much as studio apartment group.
2. Dormitory group turned on/off air-conditioner at lower temperature compare to the studio apartment group.
3. Studio apartment group's acceptable comfort zone was in or higher than ASHRAE summer comfort zone, but dormitory group's that is in or lower than ASHARAE comfort zone.

INTRODUCTION

Building systems have been developed and complicated, and it follows the energy which is consumed for the building is extending too. In a life cycle of the building, most using much energy is a dwelling phase. Big effects to these energy consumptions in a dwelling phase are the behavior and attitude of residents, and energy charge affects to these residents' behavior and attitude. Consequently, we can assume that there would be a big difference between the residents who pay for the energy or not; house and office. Meanwhile, the electric consumption in Korea was increased 4 times much as 20 years before. Big parts of these residential energy consumptions are consent, lighting and cooling. Especially, cooling demand is expected to increase fast. On this background, this research compared two groups' operation behavior of cooler according to charge for energy.

METHODS

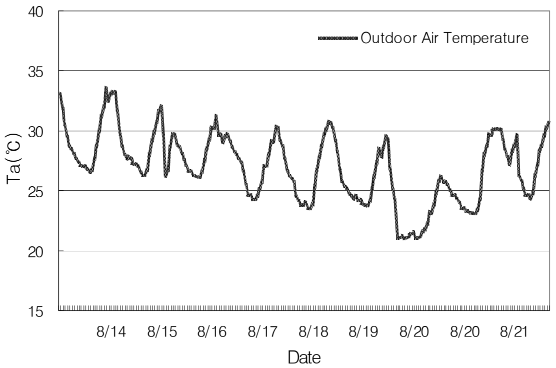
Thermal environment and using time of air conditioner are measured in seven studio-apartments and eight rooms in university dormitory where air conditioners were located. Measurement was conducted during 9 days from August 13th to 22nd in 2006. Subjects were selected to twenties who can operate air conditioner well and were limited to independent resident for restricting effects from other generations. We do an experiment in two groups' operation behavior of cooler; one is the residents who pay their energy charge per month, and the other is the residents of university dormitory who doesn't pay energy charge beside their rental fee. This is for finding out whether charging for energy has effect on using time of air conditioner. Air temperature and relative humidity were measured at 110cm high from the floor and air temperature blowing from air conditioner was also measured to detect the condition of on/off of air conditioner. Air temperature, relative humidity, and air temperature blowing from the air conditioner are measured with RH-temperature data logger.

Interviews were also conducted to investigate characteristics of residents' behaviors of operating air conditioner in addition to physical environment; time of staying at home, a way they operate air conditioner, a purpose that they use air conditioner, their Clo value, sex, age, kinds of AC, and spending electric power.

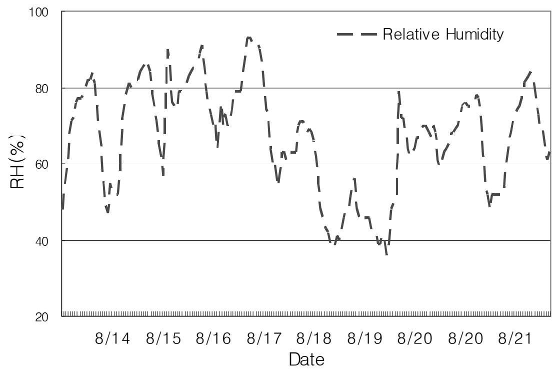
RESULTS

Outdoor temperature and relative humidity

Outdoor weather data was obtained form Korea Meteorological Administration. The mean outdoor temperature was 26.93℃ and relative humidity was 67% during experiment period.



a) Outdoor air temperature



b) Relative humidity

Figure 1. Climate during experiment periods

Comparison on the amount of time to use an air conditioner between two groups

Table1 shows that the results of the time used with air conditioner for two groups. The dormitory group used air conditioner twice as much as the studio-apartment group: Dormitory group spend 43hours 55minutes and studio-apartment group spend 23hours 21minutes in the experiment period. All of the residents in two groups were university students or graduate students. Although considering their life style was similar, we calculated index of amount of time to use an air conditioner to more accurate analysis. The method of calculating of index was that amount of time to use an air conditioner divided by mean time for which residents stayed at home. As the result, index of dormitory (0.4) was higher than that of studio apartment (0.17). Even though, we excluded A-6 and A-7 that never used air conditioner during experiment period from a calculating, index of studio apartment became 0.24 to be still lower than dormitory. It was one of the reasons that residents even maintained running air conditioner when they went out for thermal comfort to come back. While, when going out, residents of studio apartment always turned off their air conditioner.

A-3 of studio apartment group was the highest both time of use and index of time, because this one stayed at home by far than others. Most of studio apartment except A-3 was lower than dormitory in index of time. Also, despite of high temperature of outdoor, A-6 and A-7 never turned on air conditioner because of charge for energy.

Table 1. Operating time of air conditioner.

Studio-apartment			Dormitory		
Resident	Operating time (hour, minute)	Index of operating time	Resident	Operating time (hour, minute)	Index of operating time
A-1	29h 8m	0.29	B-1	49h 24m	0.50
A-2	10h 36m	0.10	B-2	45h 58m	0.46
A-3	64h 4m	0.44	B-3	73h	0.50
A-4	40h 40m	0.28	B-4	54h 52m	0.38
A-5	18h 8m	0.08	B-5	37h	0.37
A-6	0m	0	B-6	31h 32m	0.31
A-7	0m	0	B-7	33h 20m	0.37
			B-8	26h 16m	0.27
Avg.	23h 21m	0.17	Avg.	43h 55m	0.40

* Index of operating time = Operating time of air conditioner / inhabitant time

Indoor Thermal Environment when residents operate air conditioner

There was a gap between two groups about mean temperature at the point time that air conditioner turned on or off. Table 2 shows that indoor air temperature fight at the point time that residents turn on air conditioner and turn them off. It appeared that residents of the studio apartment start air conditioner at 29.9℃ of air temperature, and switch off at 27.0℃. While, residents of the dormitory turn on air conditioner at 27.0℃, and turn off at 23.7℃. It means that residents of studio apartment turn on and off at higher temperature than residents of dormitory.

Like above these results, we know that the dormitory group not to charge for energy used air conditioner in lower temperature than the studio apartment group to charge for energy.

Table 2. Mean indoor air temperature when AC was turned on or off.

Studio-apartment			Dormitory		
Resident	On(℃)	Off(℃)	Resident	On(℃)	Off(℃)
A-1	31.0	28.8	B-1	29.2	24.3
A-2	31.3	28.9	B-2	26.2	23.2
A-3	29.1	26.3	B-3	28.4	24.5
A-4	29.1	26.5	B-4	26.1	23.4
A-5	29.9	27.5	B-5	26.7	24.3
A-6	Never used		B-6	26.7	23.5
A-7	Never used		B-7	26.3	23.5
			B-8	26.5	21.1
Avg.	29.9	27.0	Avg.	26.9	23.7

Interview of resident' cooling behavior

Interview was conducted to help understanding about residents' behavior of operating air conditioner. When asked whether residents still remain air conditioner turn on for going out, more than 50 percent of the dormitory residents blamed 'yes', but all of the studio apartment residents answered 'no'. Setting temperature of air conditioner in both groups was similar, 20℃. They controlled indoor temperature by switch on and off, not the setting temperature. The main reason why they turn on air conditioner is high temperature, the other is to exsiccate. Also, it seems that their habituation of operating air conditioner is only to turn on or off cooler than to regulate. When they ho to sleeping, all in both groups stopped cooler and opened windows, but only one in the dormitory remained cooler running beside opening windows. Indoor mean Clo value of the studio apartment group was higher rather than the dormitory group: the studio apartment group was 0.15 clo and the dormitory group was 0.24 clo. When asked "How much could you pay for using air conditioner?", they answered each 34 dollars on the dormitory and 70 dollars on the studio apartment. It means that residents of the studio apartment who pay for energy have more recognition than them of the dormitory.

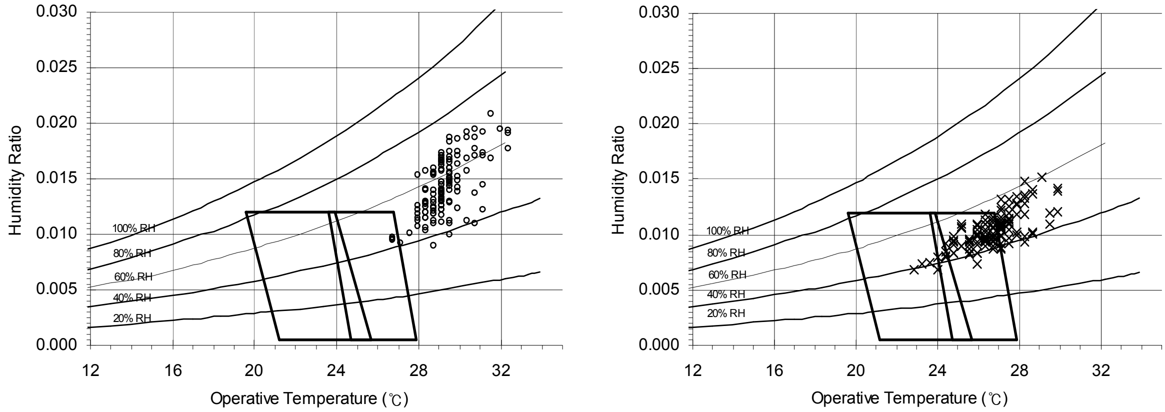
Comparison with a previous research

We compared this result with previous research, which was studied from Nu-Ri Bae for finding out resident' operating behavior of air conditioner according family members as well as charge for energy.[1] The previous research was conducted during 60days from July 3rd to August 31st in 2004 in six family apartments' living rooms there air conditioner were located. Indoor thermal environment was measured and air temperature blowing from air conditioner was also measured to find out the condition of on/off of air conditioner. Mean outdoor temperature was 25.2℃ and relative humidity was 76.5% in experiment period.

1. Thermal environment of three groups

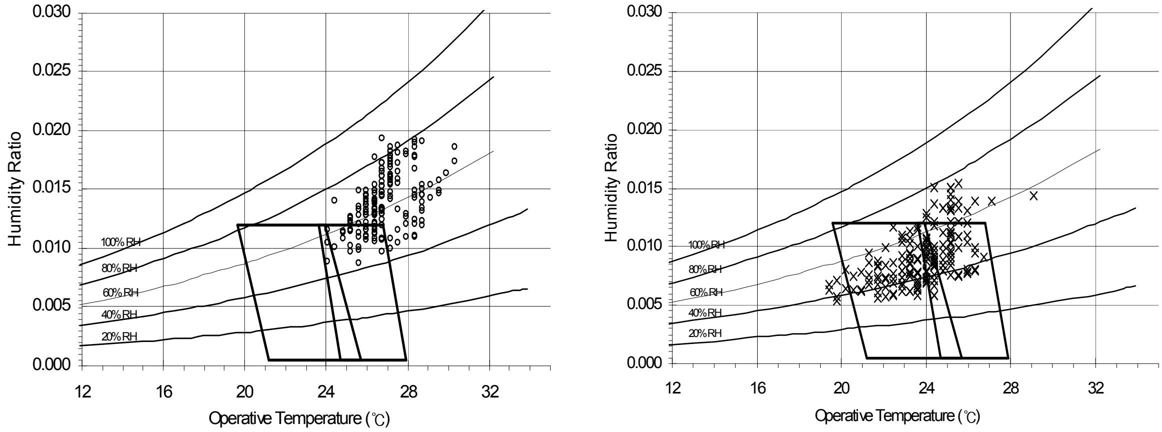
In Figure 2~ 4 thermal environments at the point time air conditioner was started and was stopped in three groups compared with thermal comfort range of ASHRAE Standard 55. [2]
First of all, compared with thermal environment according charge for energy, three groups have a clear distinction. Figure 2 shows that the result of studio apartment group. When residents started air conditioner, most cases of thermal environment were on very high temperature that is not contained ASHRAE comfort zone and when air conditioner was stopped, some cases was covered or accessed ASHRAE comfort zone of summer. Also, Figure 4 indicated that family apartment was as same as studio apartment but was rather high range. An air conditioner was started and switched off at thermal range that was not included ASHRAE comfort zone.

On the other hand, Figure 3 displayed that residents' behavior of the dormitory was different from other two groups. They turned on air conditioner at air temperature whose one third already was included on summer comfort zone of ASHRAE and turned off it at air temperature whose most was contained on lower air temperature, winter comfort zone, as well as summer comfort zone of ASHRAE. It means that range of thermal environment which residents controlled was significantly different according charge for energy. Judging from air temperature, residents can use air conditioner on very low air temperature in case of no charging for energy. From interview, there are some responses that residents still keep cooler in running until feeling cold and wear more clothes instead of stopping cooler.



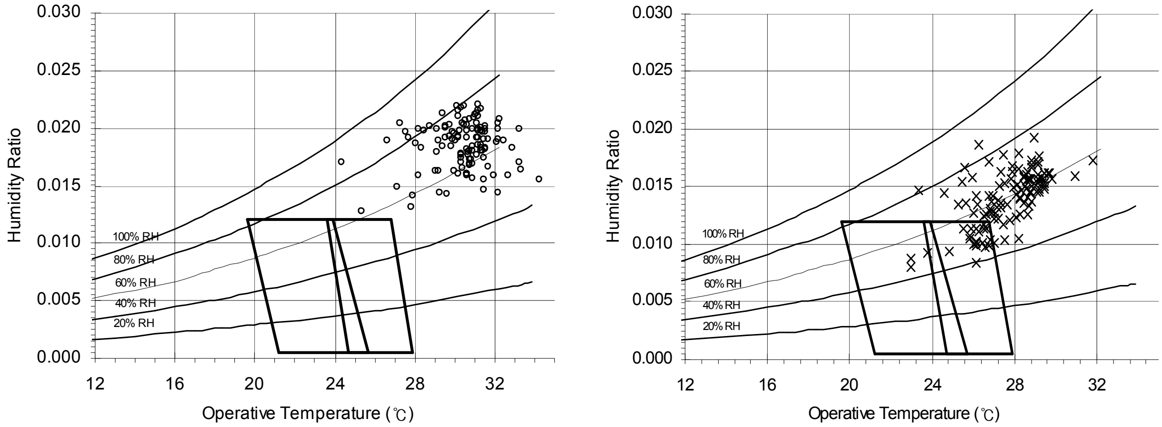
a) Thermal range when AC was turned on b) Thermal range when AC was turned off

Figure 2. Indoor thermal range on ASHRAE comfort zone when AC operated in studio apartment



a) Thermal range when AC was turned on b) Thermal range when AC was turned off

Figure 3. Indoor thermal range on ASHRAE comfort zone when AC operated in dormitory



a) Thermal range when AC was turned on b) Thermal range when AC was turned off

Figure 4. Indoor thermal range on ASHRAE comfort zone when AC operated in family apartment

2. Prediction of time to use air conditioner

What effect will outdoor weather factors including mean temperature, highest temperature, lowest temperature, mean relative humidity and highest wind velocity have on time to use air conditioner? The relationship between outdoor weather factor and using time was calculated by linear regression model. As a result, the relationship with both mean temperature and highest temperature is the strongest in the family apartment, the relationship with lowest temperature is the strongest in the dormitory and the relationship with both highest temperature and lowest temperature is the strongest in the studio apartment. It is appeared that residents of the family apartment start air conditioner when outdoor temperatures getting hotter but residents of the dormitory turn off it when weather become colder. In other words, residents in family apartment don't use air conditioner usually and then start it when air temperature reach the maximum, but the residents in dormitory use air conditioner always and then they switch off it when air temperature go down.

Table 3. Correlation coefficient between outdoor weather and time of using AC

Weather factor	Studio apartment	Dormitory	Family apartment
	R	R	R
Mean outdoor air temperature	0.33	0.34	0.36
Highest outdoor air temperature	0.32	0.34	0.35
Lowest outdoor air temperature	0.33	0.40	0.26
Mean relative humidity	0.19	0.27	0.34
Highest wind velocity	1E-06	0.02	0.11

Using time of air conditioner of each group was predicted through regression model with mean outdoor temperature that is related in all groups comparatively high. 26℃ and 30℃ of outdoor air temperature were applied to regression model, and mean using time of each group was calculated. Showing fig. 6, the dormitory has each value of 319 minutes and 540minutes, the studio apartment has each value of 222minutes and 364minutes and the family apartment has value of 119mimutes and 202minutes. From this graph, we can see the order of using time of air conditioner in same outdoor temperature is Dormitory, Studio apartment, and Family apartment. And an angle of inclination by temperature increasing shows same order.
The reason why residents of the family apartment use less time compared with studio apartment could be from generation gap about energy saving and charging for energy, different thermal sensation between ages, and housewife' economical conception, etc.

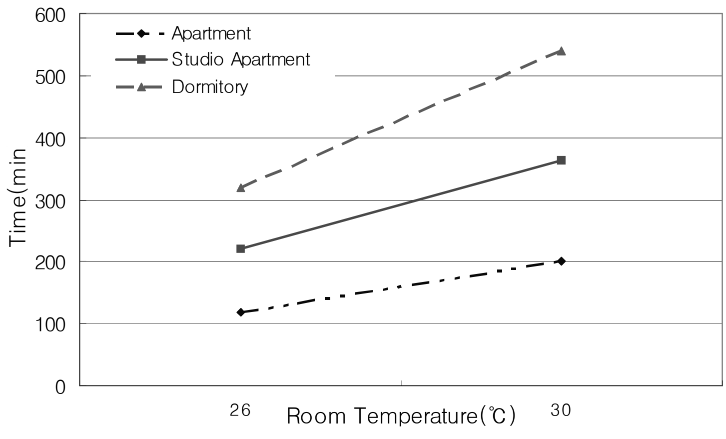


Figure 5. Predicted AC using time by outdoor air temperature

DISCUSSION

When people turn off air conditioner, which means room air temperature became cool enough to them. This enough cool temperature was different between three groups. Of course, it is because of economical factor. Thermal comfort zone like ASHRAE Std.55 is based on sensory comfort in climate chamber. It was calculated from experiment results in climate chamber. Subjects didn't get the influence from economical factor, and tried to find out "just comfortable" temperature.
If we call this "just comfortable" temperature as "sensory comfort zone", we can call acceptable comfort zone in this study as "cognitive comfort zone". Sensory comfort zone is related on human sensory system – physiological & physical characteristics. Cognitive comfort gets the influence from many factors – economical situation, thermal history, adaptation state, etc. These differences made the difference between many chamber study results and field study results. In ordinary, field study results show wider acceptable range than chamber study results. This tendency respected to the revise of ASHRAE Std. 55 (2004).
Both of them – Sensory & Cognitive Comfort – are necessary and worth. However, broad acceptable range may be desirable in point of human thermal adaptation and environment of the earth.

Calculation of energy performance and implementation of EPBD

HVAC System Efficiencies for EPBD Calculations

Roger Hitchin

BRE Environment, Watford, UK

Corresponding email: hitchinr@bre.co.uk

SUMMARY

Whole-building energy performance calculations are required by the EPBD as part of compliance with minimum standards for new buildings and of the energy performance certification process for existing buildings. These are integrated calculations that include the effects of the building design and of the installed or proposed HVAC and lighting systems. The performance of HVAC – and especially air-conditioning - systems can vary very widely and it is therefore important to estimate system efficiencies realistically. On the other hand, the calculation process itself should not be unduly onerous. This paper explains how these contradictory pressures have been dealt with in the development process of the HVAC component UK compliance tool for non-domestic buildings, SBEM (Simplified Building Energy Model) and summarises its main features..

INTRODUCTION

Energy-related building codes for new construction have traditionally focussed on building envelope issues and, in many countries, only on heating energy use. In recent years, however, there have been substantial increases in demand for electricity for lighting and air-conditioning, especially in commercial buildings. At the same time climate change and carbon emissions from all fuels have become a focus of energy and environmental policy. As a result this traditional emphasis on heating and insulation has come to look incomplete.

This is reflected in the requirements of the Energy Performance of Buildings Directive (EPBD), which calls for the use of integrated energy calculations that take account of all energy sources and all building-related end-uses of energy. These integrated calculation methods are to be used as the basis of building codes for new construction throughout Europe, though Member States have some flexibility to define the calculation process. In many countries the same calculation method will be used for the Energy Performance Certification of buildings when they are constructed, sold or let.

Crucially, these integrated calculations have to reflect system efficiencies as well as envelope performance. There are many alternative types of HVAC system of very different efficiency and so the impact of system selection and specification on carbon emissions can be as large as that from building envelope decisions, especially for new buildings. This is especially so for systems that provide cooling or ventilation in addition to heating. Increasing insulation requirements and moves to impose minimum efficiencies for boilers and other heat generators have already reduced heating demands, more of which are met by internal heat gains. Since the cost-effectiveness of increasing insulation thicknesses is subject to the law of diminishing returns, the economic benefits of further improvements are now relatively small.

Thus the realistic representation of HVAC systems in these calculation tools is of substantial importance. It is far from clear how best to do this as there are somewhat conflicting requirements for simplicity and consistency of use on the one hand, and technical robustness on the other. This paper describes the approach that has been adopted in the UK Simplified Building Energy Model (SBEM) and places this in the context of developing practices in other Member States.

OBJECTIVES

Calculation procedures for EPBD applications should ideally satisfy a number of somewhat contradictory requirements:

- Technical Credibility
    - Technically sound calculation process
    - Produce realistic results
- Discrimination
    - More efficient systems should give better figures
- Repeatability
    - Different users should get the same results
- Transparency
    - Both the data and the process should be auditable
- Ease of use and manageable data requirements
    - To reduce errors and cost

In practice it is difficult to satisfy these simultaneously and it is necessary to balance the competing requirements against each other. This balance is likely to be different for different applications - for example, the relative importance for design purposes may be different from that for Energy Performance Certification.

PRINCIPLES, OPTIONS AND EUROPEAN STANDARDS

The calculation of HVAC system efficiency can be addressed at several levels of complexity. At one extreme, the simplest methods may miss out or over-simplify important factors. On the other hand, complex methods such as detailed system modelling can be very data-intensive and time-consuming to apply. Poor data quality may introduce greater uncertainty than is associated with the modelling itself. [1] In existing buildings obtaining precise information is time consuming, costly and sometimes impossible. Absolute precision is not the most important consideration, especially if it compromises the other attributes such as repeatability. Given the uncertainties of data, of calculation and of the way that buildings are operated, any decision that is driven solely by small apparent differences in performance is fragile.

The important outcomes are the actions that result. For new buildings these are the design decisions that designers are encouraged to consider. For existing buildings they are: the selection (or at least consideration) of possible improvements and decisions on the selection from a range of options of buildings available to purchase or rent.

The calculation of heating and cooling *demands* of spaces and the associated energy *consumption* of HVAC systems that satisfy these demands are obviously closely linked processes. However, the two calculation processes have somewhat different constraints.

Heating and cooling demands can be adequately calculated at monthly intervals, for example by using the monthly heat balance and utilisation factor approach of EN13790[2]. Hourly demand calculations are used as design tools but regulatory applications are unusual in Europe. The EN13790 monthly procedure (now adapted to include sensible cooling as well as heating) is becoming the most widespread approach. [•]

For most HVAC systems, calculations using hourly (or shorter) time-steps are more natural, since this interval is better aligned to the inherent time constants of the systems. Hourly calculations can

[•] EN13790 also permits the use of hourly calculations and includes a simplified hourly procedure.

either be full system simulations or simpler “bin methods”. For some types of system – especially those providing only heating – an annual seasonal efficiency can be adequate. However, even here, the determination of annual seasonal efficiencies can become cumbersome for complex systems, such as those with bivalent heating. While the results from hourly demand calculations could be easily aggregated into monthly figures for a monthly system calculation the reverse procedure is much more difficult.

Definitions

The definition of “system efficiency” for HVAC systems is less straightforward than appears at first sight, because of the difficulty of attributing energy for fans, pumps and controls to the different end-uses (heating, cooling, ventilation). The EPBD standards resolve this by separating the energy associated with these, mainly transport, components from the losses associated with the generation of heating or cooling from fuels or electricity. The energy associated with fans and pumps (and controls) is treated as a separate item denoted as “*auxiliary energy*”. The consequent definitions for system heating and cooling efficiency then become more straightforward - but are now different from the more familiar meanings that include the auxiliary energy.

“Auxiliary Energy”: is the energy used by the fans pumps and controls of a system, irrespective of whether this supports heating, cooling or ventilation.

For heating, the “System Coefficient of Performance”, SCoP, is the ratio of the total heating demand in spaces served by an HVAC system divided by the energy input into the heat generator(s) - typically boilers. It takes account, for example, the efficiency of the heat generator, thermal losses from pipework and ductwork, and duct leakage. It does not include energy used by fans and pumps

For cooling the “System Energy Efficiency Ratio” SEER: is the ratio of the total cooling demand in spaces served by a system divided by the energy input into the cold generator(s) - typically chillers. It takes account of, for example, the efficiency of the cold generator, thermal gains to pipework and ductwork, and duct leakage. It does not include energy used by fans and pumps. Since many cooling demand calculations only estimate sensible cooling, the definition may be extended to include allowances for deliberate or inadvertent latent loads.

prEN15243

prEN15243[3] is the draft standard that deals with the calculation of HVAC system efficiencies. It contains a number of informative annexes that illustrate different approaches, but it does not prescribe specific calculation procedures. It permits HVAC system performance to be calculated either monthly or hourly. The draft standard provides a framework that can be used to assess whether particular methods are appropriate to particular circumstances.

The standard identifies nearly 40 mechanisms that can affect the relationship between the cooling demand of a building and the energy used by an HVAC system in meeting that demand. These are mapped against 20 or so types of HVAC system to show which mechanisms may apply to which system types. It then requires any calculation procedure to declare which system types it claims to cover, and how it addresses each of the applicable mechanisms. It does not prescribe how each mechanism should be handled (although there are “informative” suggestions). So, for example, the effect of heat gains to cold ducts could be calculated in detail or included as a fixed allowance (or ignored). Different degrees of sophistication may be appropriate to different situations. The draft standard simply demands that the user should know and thus be in a better position to judge whether a particular procedure is appropriate to his needs.

THE UK APPROACH

At the time of writing, few EPBD calculation methods for non-domestic buildings have been produced. This section deals with the methodology that has been in use in the UK since April 2006. Similar procedures are used in the Netherlands and Germany – some of the British procedures mimic those already in use in the Netherlands. The current Dutch procedures for HVAC systems appear to be less detailed (in some respects) - for example, in not explicitly including duct leakage. The German standard [4] includes more detailed calculation procedures in some areas, such as the calculation of pump energy use (including for heat rejection devices).

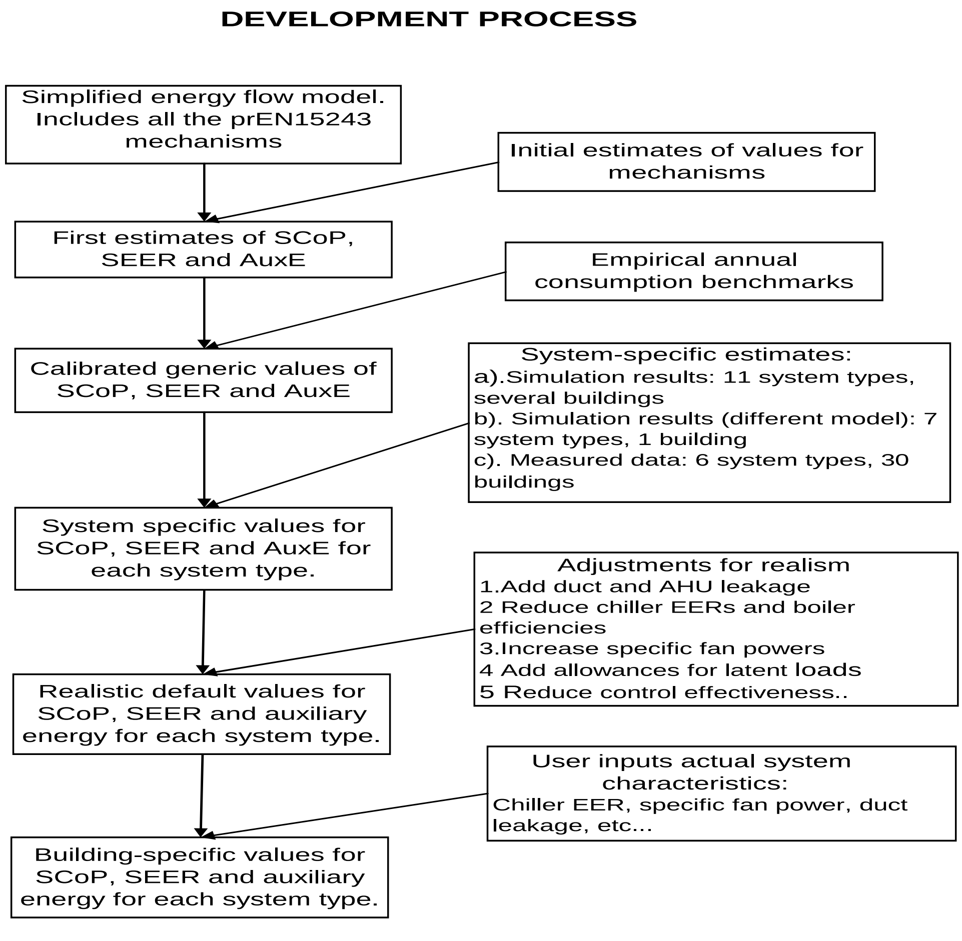
The standard calculation procedure for non-domestic buildings in the UK is the Simplified Building Energy Model (SBEM) [5] [6], although accredited hourly simulation procedures are also acceptable. The following section describes the development and basis of the HVAC system modelling in SBEM. The basic heating and cooling demand model is the monthly procedure from EN13790. [7] This imposes constraints on the way that the system performance is characterised. For consistency with the demand calculation, monthly values of the performance parameters (auxiliary energy, SCoP, SEER) are needed. •

The basis of the calculations in the UK is a comparison between the calculated carbon emissions of the proposed or actual building with those of a “notional” or reference building. The notional building has the same dimensions, geometry and use pattern as the actual building and is exposed to the same weather. However, the levels of insulation and the system efficiencies have fixed reference values. The notional building does not therefore have a specific HVAC system, but defined auxiliary energy, SCOP and SEER values.

Each serviced space in a building is assigned to an HVAC system. Each month the heating and (sensible) cooling demands and auxiliary energy are calculated and converted to energy demands by applying the appropriate SCoP and SEER. Each system type is associated with a vertical temperature gradient which is used to adjust the demands according to the height of the space and whether or not it is provided with de-stratification fans. There is also an adjustment to reflect the degree of direct radiant heat (or cooling) that falls on the occupied area. For most spaces and system these adjustments are small, but they can be significant in high, well-ventilated spaces.

The development procedure we adopted is summarised in Figure 1 and is described in more detail below. Because of the short timescale for implementation of the EPBD, there was limited time (or resources) for supporting research.

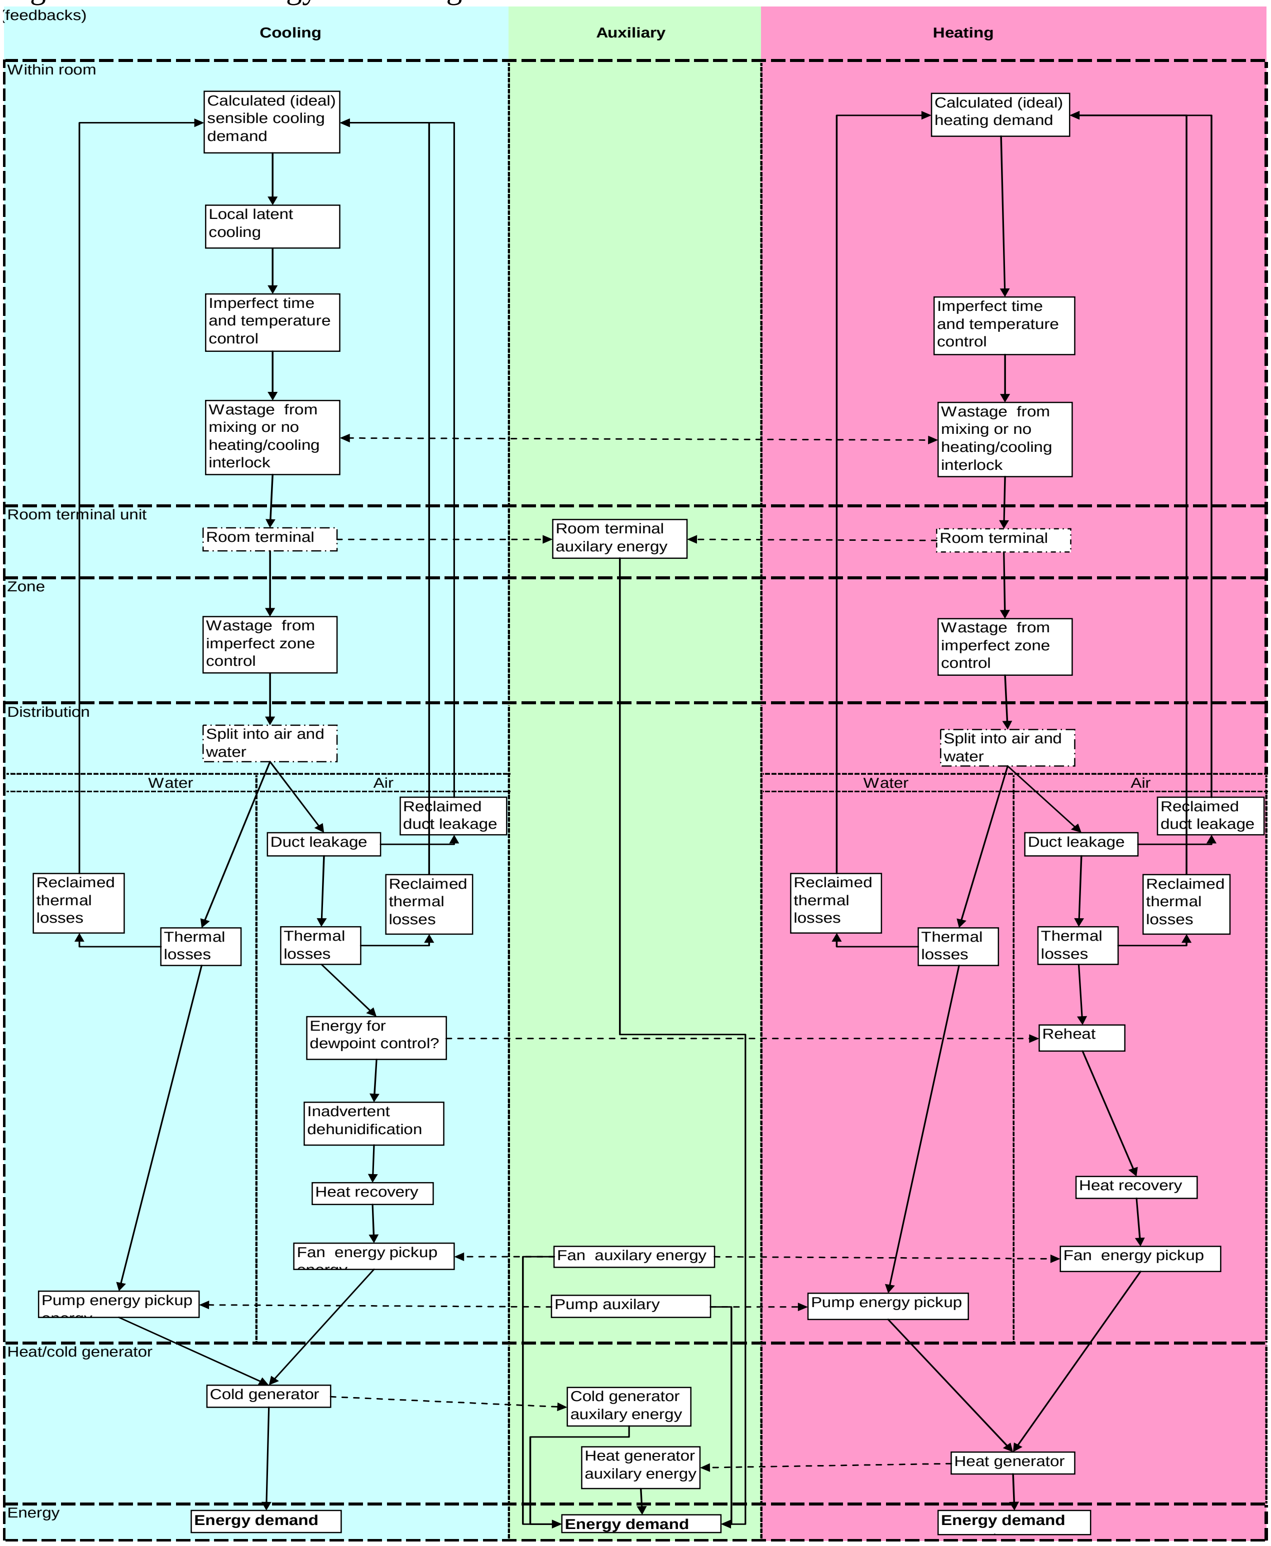
Figure 1 HVAC Model Development Process



• At present the parameters in SBEM are the same for each month. Values that varied monthly would be more realistic, and will be developed – especially for auxiliary energy – but the practical difference in terms of annual consumption estimates is actually rather small.

An energy flow diagram was constructed that included all the prEN15243 mechanisms. This flow diagram was implemented as a spreadsheet. The logic diagram is shown in Figure 2

Figure 2. HVAC Energy Flow Diagram



The basic philosophy is to provide a consistent set of parameters that address all the mechanisms in prEN15243. The energy flow diagram is simplified in that some of the parameters are relatively aggregated – for example, heat pickup in chilled water distribution pipework is expressed as a percentage of the cooling energy flow handled. There are many parameters whose values are difficult to determine reliably, many of which have only a small impact on the final result. System-specific default values are used for these. The user is be able to influence the system performance in two ways: firstly by his choice of system types (which sets the values of system-specific parameters) and secondly by adjusting the value of selected parameters. [•]

We next made first estimates of typical values of the flow sheet parameters and calculated initial figures of the three performance parameters (auxiliary energy, SCoP, SEER) . With some relatively small adjustments to the initial assumptions, the consumption figures that these implied were brought into in general alignment with empirical benchmarks [8] . This provided us with calibrated generic estimates of the parameter values.

In parallel with this, we brought together several sets of existing comparisons between the energy consumptions of different types of systems in offices. These included two sets of simulation results using different models to compare different systems in identical buildings. One of the studies examined 11 different system types in a number of buildings, while the other examined 7 system types in a single building – but modelled the system components in more detail. We combined these results with measured data from 30 buildings covering 6 system types [9], to develop a set of system-specific values for SCoP, SEER and auxiliary energy. For each system type, we then adjusted the spreadsheet parameters until the spreadsheet generated the same figures.

Since the simulations assumed idealised control and other conditions, we then degraded some parameters to provide less optimistic default assumptions. In particular we added duct and AHU leakage, reduced chiller EERs and boiler efficiencies, increased specific fan powers, added allowances for latent loads, and reduced control effectiveness.

The resulting "default" consumption levels straddle the "typical" consumption benchmarks (some systems being better than the benchmark, others worse). The idealised figures straddle the equivalent "good practice" benchmark.

As mentioned above, the user has the possibility of introducing specific values for some important parameters – currently specific fan power, duct leakage, chiller and boiler seasonal efficiency - in order to claim reasonable benefit from energy-efficient system design. In addition, of course, the choice of an inherently more efficient system is rewarded by the use of default values for that system type.

The calculation of the seasonal efficiency of boilers and (especially) chillers is not entirely straightforward, especially when there are multiple chillers and a degree of oversizing. Methods of handling this have been reported elsewhere. [10] [11]

DISCUSSION

This paper summarises the development of a practical approach to representing HVAC system in energy calculation software. Clearly there are other possibilities, notably the use of explicit hourly system modelling. In principle explicit modelling is more versatile, but it requires more data (for which default assumptions could be provided) and detailed assumptions about system configurations and sizing. The latter could probably be provided via standard system templates subject to later detailed specification. Such complexity is arguably more technically complete but this has to be balanced against the greater difficulties for those charged with checking calculations and verifying installations. The model described here allows the user to influence calculated system performance by choice of system and by defining the performance of the major system components,

---

[•] The provision of access to over-write more of the defaults is a likely future development.

but contains many fixed default values. These may be opened up to user modification if experience justifies this.

An alternative approach would be to define explicit engineering calculation rules for the energy use by different elements of the system. This is effectively the approach taken in Germany [12]. In principle this is more transparent and more flexible than the UK approach (at least in the latter's current implementation), but this transparency is somewhat offset by the need for large numbers of look-up tables and very extensive documentation. Nevertheless, when implemented as software, the result has a rather similar appearance to that of SBEM. It is intended that SBEM will continue to develop in the light of user experience – and taking note of parallel developments in other Member States. Although a single Europe-wide methodology seems unlikely, it does seem likely that, over time, there will be increasing convergence of approach.

The current version of SBEM has been developed to a tight timescale and time and resources have meant that a number of desirable features are not yet incorporated. The software has been in use since April 2006 It can be downloaded, together with a Userguide and associated (UK-focussed) databases from www.ncm.bre.co.uk .

Comparison of two calculation methods used to estimate cooling energy demand and indoor summer temperatures

Kai Sirén and Ala Hasan

Helsinki University of Technology, Finland

Corresponding email: kai.siren@tkk.fi

SUMMARY

As a part of the Finnish implementation of the Energy Performance of Buildings Directive, a computational exercise was carried out to choose a simple method for cooling energy estimation. Three different variants of the hourly calculation method and the monthly method were implemented. A model office building was used as the object for the cooling energy predictions. The IDA-ICE building energy software was used to produce reference results. The predicted space cooling energy numbers for a three-month summer-period were compared with the reference results. The comparison shows that the simplest one-capacity variant of the hourly method is underestimating the reference results up to 25% and overestimating up to 30%. A more detailed four-capacity variant is underestimating up to 21% and overestimating up to 19%. The monthly calculation method is not underestimating but overestimating the reference up to 75%. The hourly method is able to estimate the indoor summer maximum temperatures with a deviation less than two degrees from the reference.

INTRODUCTION

The 2003 published Energy Performance of Buildings Directive (EPBD) [1] is calling for a methodology for calculation of the integrated energy performance of buildings. The methodology shall be set at national or regional level. The Finnish approach was to develop a simple and transparent calculation method, which could be easily implemented. The heating energy calculation was principally based on an existing, simple and standardised method [2] working with a monthly calculation period. For cooling energy demand calculation a choice between two methods had to be done. The first method, running with a time-step of one hour, is based on a simplified thermal resistance-capacitance model of the building zone. It is in principle capable to predict the cooling energy demand and to follow the daily temperature changes inside the building. The second alternative is a variant of the monthly heating energy calculation method [2] now applied to estimate cooling energy demand. Proposals of both methods for EPBD use have been published [3, 4] but with a very restricted evidence of performance. Especially the local weather conditions and the culture for implementing buildings and their heating, cooling and ventilation systems influence the calculated results. For this reason it was important to have some further evidence and comparison results.

The objective of the study was to compare the two cooling energy demand calculation methods to have some facts and arguments for the Finnish EPBD methodology implementation work.

METHODOLOGY

The principle of the comparison study was to calculate the cooling energy demand of a well-defined building zone using the different methods and to compare these results with the results obtained with a reference. As a reference *IDA Indoor Climate and Energy 3.0* (IDA-ICE) building simulation software was used [5]. It is a detailed whole-building simulator allowing all issues fundamental to building energy calculation: shape, envelop, glazing, HVAC systems, controls, light, etc. The mathematical models are described in terms of equations in neutral-model-format (NMF), which makes it easy to replace and upgrade program modules. IDA ICE has been shown to perform well in several computational comparisons [6, 7].

The object of the computation exercise was one floor of a model office building, Fig 1. The dimensions, component properties, and load profiles of this building are described in detail in a model building report [8]. For the purpose of the implementation of the cooling energy calculation methods, four zones in the floor were selected: two office rooms (R1 and R2) with a floor area of 10.5 m^2 each and two open plan offices (O1 and O2) with a floor area of 295 m2 each, as shown by Fig. 1.

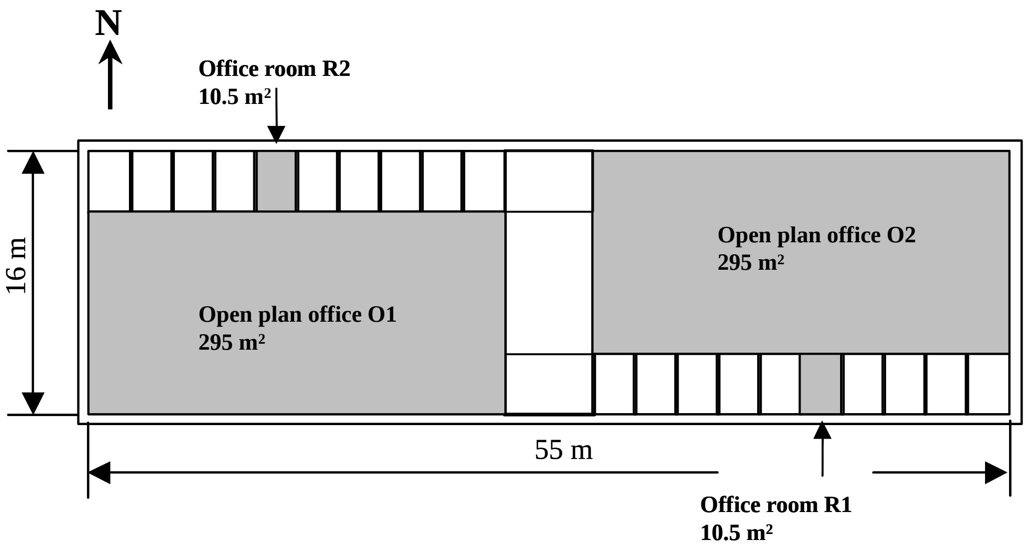

Figure 1. Model building floor plan and studied zones.

Two different constructions were specified for the model building. Construction 1 was a standard construction according to the model building [8] with light walls and a heavy concrete floor/ceiling. A second construction, Construction 2 was defined to find out the influence of the building mass on the calculation results. In Construction 2 walls are identical with Construction 1, but the floor and ceiling are considerably lighter. Table 1 shows the ceiling/floor for Construction 2.

Table 1. Ceiling/floor thermo physical properties for Construction 2.

		Thickness (mm)	Thermal conductivity (W/m K)	Density (kg/m^3)	Heat capacity (J/kg K)
1	floor covering	3	0.18	1390	1000
2	chipboard	22	0.14	400	1500
3	steelwork + air gap	200			
4	mineral wool sound insulation	50	0.045	110	840
5	plasterboard	13	0.21	800	840

The effective thermal thickness of the construction components was defined according to the simplified calculation of heat capacity Annex A of ISO 13786 [9].

The masses and thermal capacities for the office room and the open plan office for the two constructions are shown in Table 2. C_m is the effective heat capacity for the room and A_{floor} is the floor area.

Table 2. Masses and thermal capacities of construction components.

	Construction 1		**Construction 2**	
	Office room	Open office	Office room	Open office
Mass of external wall (kg)	96	1620	96	1620
Mass of internal walls (kg)	530	1825	530	1825
Mass of floor and ceiling (kg)	9116	256160	610	17166
C_m / A_{floor} (kJ / Km^2)	322	294	60.0	32.5

Components for heating and cooling exist in each room of the building. Ventilation air through a mechanical ventilation system is supplied to each room. The controlled ventilation air supply temperature is a function of the exhaust air temperature, where a linear relation exists for supply between 21˚C and 17˚C and exhaust between 22˚C and 24˚C, respectively. The ventilation supply has a daily and a weekly schedule. The heating and cooling systems and the ventilation maintain the indoor air temperature between specified set limits of 21˚C and 24˚C around the year.

A part of the input data, like internal gains, is defined in the model building description [8]. As weather data Helsinki 1979 weather was used. Other input data like solar heat gain through the window structure and infiltration are taken according to the reference software to focus on the calculation of the building zone thermal behaviour. The input data is arranged as hourly or monthly data, according to the method.

HOURLY CALCULATION METHOD

The hourly calculation method for cooling is based on the conservation of energy at the temperature node points of a simple resistance-capacitance model of the building zone. The base for this model was adopted from [3]. Because the base model did not include the description of mechanical ventilation, which is the usual way of system implementation in Finland, this feature was added to the model Variant_1, Fig 2.

The model runs on an hourly basis where the calculation time step is one hour and the input/output data are arranged as hourly data. The thermal mass of the calculation zone is lumped into one thermal capacitance. The heat transfer connections between the thermal nodes are described with four resistances. The mathematical solution is based on the Crank-Nicolson difference scheme. Both heating and cooling modes can be calculated, as well as variable room air temperature and variable cooling system operation. A node point and a heat capacity flow for mechanical ventilation supply are also included.

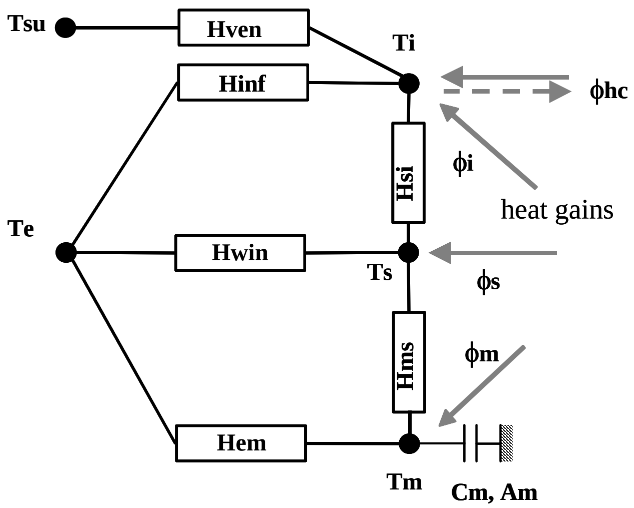

Figure 2. Hourly method, model Variant_1.

In Fig. 2, T_e is outdoor air temperature, T_i indoor air temperature, T_m mass temperature, T_s is a star (operative) temperature, H_{ven} ventilation heat flow, H_{inf} the infiltration heat flow, H_{win} the window thermal conductance, Hem the external structure thermal conductance, and H_{ms} and H_{is} thermal conductances between respective node points. The heating power added or cooling power removed from the room is ϕ_{hc}, heat gains to the internal nodes are $\phi_{i,}$ ϕ_s and $\phi_{m,}$ the effective heat capacity for the zone C_m and the equivalent area for the zone capacity A_m.

The computation procedure [3] begins with calculation of the internal gains, including the solar heat gain. The gains are allocated to the internal node points according to certain weights. The heating/cooling power is kept equal to zero at the first stage. The mass-node temperature is determined from the Crank-Nicolson energy conservation equation for the mass-node. The star temperature and the air temperature are determined from the node energy conservation equations. If the resulting air temperature T_i is in the temperature control set limits, the need for heating or cooling is zero and the calculation can proceed to the next hour. If the resulting air temperature is above the higher set limit, the air temperature is set equal to the upper limit (24 ^{o}C) and the cooling energy needed to keep this temperature level is calculated. In case of heating the procedure is analogous.

To find out whether increasing the number of the node points gives any advantage in the cooling energy demand calculation, the model Variant_1 was further modified into a four-capacity model Variant_2, Fig 3. The star node was rejected because the model was used for energy calculations and there was no need for an operative temperature. Two capacity nodes representing the building mass (walls, ceiling, floor) in more detail were added and the air node was also given a heat capacity.

The calculation procedure is in principle similar than for the previous variant. There are four differential conservation equations instead of one and no equation for star node. The solution is based on a difference scheme. To keep the mathematical manipulation as simple as possible, the usual matrix inversion is avoided by a sequential solution of the equations. The gains are identical but allocated in a slightly different way to the node points.

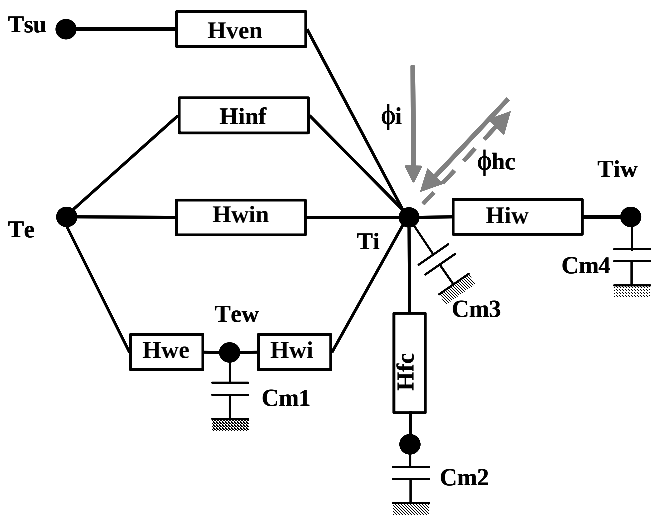

Fig. 3. Hourly method, model Variant_2.

Finally a third model Variant_3 was made out of Variant_2 by disengaging the external structure from the outdoor air point Te and engaging it to a new sol-air temperature node T_{sa} to account for the absorbed solar radiation on the external wall structures. The determination of the sol-air temperature was based on the energy balance of the building external surface.

MONTHLY CALCULATION METHOD

The monthly method to calculate cooling energy demand [4] is based on earlier methods used for heating energy calculation [2]. The time period for the calculation is one month. All input data is one-month average or cumulative values. The main principle of the method is the long-term energy balance for the building zone. Without cooling the cumulative energy from the heat gains (solar + internal) equal the heat losses. The indoor temperature is free floating and exceeds the set temperature from time to time. Introducing cooling to the zone keeps the internal temperature below or equal to the set temperature. The cooling energy is less than the gains because a part of the losses is compensating the gains:

$$Q_c = Q_g - \eta_l Q_l \tag{1}$$

where Q_c is cooling energy demand, Q_g is thermal energy from gains, Q_l is loss term and η_l is the utilization factor for heat losses. It has been shown [4] that equation (1) can be converted into

$$Q_c = (1 - \eta_g) Q_g \tag{2}$$

where η_g is now the utilization factor for heat gains initially used for the heating demand calculations. The utilization factor η_g depends on the gain-loss ratio, the time constant of the zone and two parameters a_0 and τ_0. Different values for these parameters have been used [4,10,11] depending on the application. Here the values a_0 = 1.83 and τ_0 =83.3 for cooling of non-residential buildings according to NEN 2916 standard were adopted [4].

RESULTS

With the hourly method and the reference software a period of four months May – August was calculated using the hourly weather data of Helsinki 1979. The first month was a pre-period to let the structure temperatures find their natural temperature levels. The three following months were for energy calculation. The monthly method was utilising the monthly average temperatures and cumulative energy values derived from the same hourly weather data.

Results for the space cooling energy demand during the period June, July and August for the different calculation methods, zones and building constructions are shown in Table 3.

In case of the single office rooms Table 3 shows that all three implementations of the hourly method mainly underestimate the reference values. Variant_3 seems to perform best except in case of the North facing lighter Construction 2, where it overestimates the reference value by 17 %. This is a consequence of the sol-air temperature, which is the only difference between Variant_2 and Variant_3. The monthly method predicts the cooling energy demand very close to the reference values for the south facing office rooms but overestimates up to 76% for the north facing rooms where the gains are much smaller.

Both methods overestimate the reference cooling energy demand numbers for the open space office case. The percentage difference is larger for the North facing office than for the South facing office. The construction type seems not to have any significant effect on the hourly method results. The monthly method overestimates less for the light structure Construction 2.

Table 3 Predicted space cooling energy demand for the period June – August.

Calculation method		Office room R1 facing South		Office room R2 facing North		Open office O1 facing South		Open office O2 facing North	
		cooling energy kWh	cooling/ reference	cooling energy kWh	cooling/ reference	cooling energy kWh	cooling/ reference	cooling energy kWh	cooling/ reference
constr. 1	Hourly V_1	131	0.79	38	0.75	2478	1.12	1531	1.24
	Hourly V_2	132	0.79	40	0.80	2385	1.08	1471	1.19
	Hourly V_3	149	0.90	49	0.98	2613	1.18	1649	1.33
	Monthly	179	1.08	88	1.76	3006	1.36	2158	1.75
	IDA	166	1	50	1	2211	1	1237	1
constr. 2	Hourly V_1	175	0.90	67	1.03	3279	1.12	2244	1.30
	Hourly V_2	155	0.80	57	0.87	3104	1.07	2050	1.18
	Hourly V_3	188	0.97	76	1.17	3511	1.20	2455	1.42
	Monthly	194	1.00	104	1.59	3464	1.19	2614	1.51
	IDA	194	1	65	1	2916	1	1732	1

In general, the rate of overestimation of the reference values is increasing with decreasing structure capacity and decreasing gains for the hourly calculation method, and vice versa. The monthly calculation method behaves in a different way. The rate of overestimation is increasing with increasing structure capacity and decreasing gains.

One important factor in assessing the need for active cooling is the behaviour of the indoor air temperature during the summer period. If this temperature is exceeding the specified limits without cooling, there obviously is a need for cooling. The hourly calculation method is able to provide this information. The temperature limits, which are used for energy calculation, are inactivated and the indoor air temperature is let to “float” during the computation. The results for the period June – August show that the hourly Variant_1 is overestimating the maximum indoor temperature by 2.2 ^{o}C compared with the reference result. The hourly Variant_2 is overestimating the maximum temperature only by 1.8 ^{o}C. The monthly method is not able to provide useful information related to temperature maximum or minimum values.

CONCLUSIONS

A computational exercise for the assessment of two simplified calculation methods, the hourly method and the monthly method has been carried out. The space cooling energy demand for four different zones of an office building was predicted with three variants of the hourly method and the monthly method. The IDA-ICE building energy software was used as a reference.

The predicted cooling energies for a three-month period vary from 75% to 175% compared to the reference results. The hourly method implementations underestimate the reference values for a heavy structure and high gain and overestimate for a light structure and small gain values. The monthly method mainly overestimates, the more the smaller the internal gains.

As a part of the Finnish implementation for the cooling energy calculation method of the Energy Performance of Buildings Directive, a one-capacity variant of the hourly calculation method was further developed, tested and proposed for the Finnish authorities. For the Finnish implementation of the EPBD the monthly calculation method was chosen.

Simplified Model of Seasonal Energy Consumption by Air Conditioning System in Non Residential Buildings

Kazimierz Wojtas

Cracow University of Technology, Poland

Corresponding email: kawoj@pk.edu.pl

SUMMARY

When analyzing the current standards issued to be complementary to the EPBD Directive, one can have an impression that the energy consumption by AC system depends on the specific heat gain and the air flow only. The author's main idea was to prove that there are some other but also very important parameters of the AC system design and operation which have to be also taken into account seriously. The most important of them are: type of air treatment and control, chillers' efficiency and their operating parameters, type of climatic conditions data. To prove this, a specific calculating procedure for cooling season energy consumption by HVAC system in office building placed in Kraków, Poland was defined. As a result of simulations and analysis provided for CAV type AC system, it can be clearly seen that in central European climatic conditions particular concern in each HVAC project must be paid on "cooling source" type, efficiency and control as well as air flow treated optimization.

INTRODUCTION

Officially starting from 1st of January 2006 all of the EC countries are obliged to follow the rules included in the EPBD Directive. Different countries are on different stages of preparation to this target. Different countries have also different structures of energy consumption in buildings. Northern countries pay more attention to heating systems and southern ones the opposite, to the A/C systems. Poland is somewhere in the middle of both. During last months a lot of documents and standards related to this subject were published in Brussels. For instance, when studying the prEN 13790 standard [1] one can come to the following conclusions:

- The calculation methods for energy consumption in building due to the space heating season only are already well developed and most of them are sufficiently precise
- For cooling and air conditioning the situation is not so much clear however the energy consumption of these systems makes substantial percentage of total energy consumption, particularly in mid and southern Europe
- Most of the models presented for cooling period are based on the "sensible heat" balance of the building envelope. This may lead to some "inaccuracies" because in most solutions cooling is coupled with dehumidification which produce an "additional energy consumption" in building.

So, the main target of the author's research was to prove how strongly the energy consumption during summer season is affected by the following aspects:

- Precisely defined class of the indoor thermal comfort
- Type of climatic data
- System components' characteristics, particularly chillers and fans

- Operating parameters and control

To achieve this target a simplified model for energy consumption in summer season was built and the basic assumptions and calculation results are discussed in this paper based on an example of typical “open space” type office located in Kraków (Poland).

METHODS

Air properties – Mollier diagram

All the calculations of the air thermodynamic properties have been provided using an “air properties model” based on formulas described in [2] and also on “graphic coordinates” of Mollier diagram built. In some cases it was necessary to find the thermodynamic parameters of a “crossing point” of two particular air treatment processes. It is important to mention that all the air treatment processes were built as linear in the diagram. The accuracies of determining the particular air parameters in this model were assessed higher then:

- temperature: ± 0,1 ^{o}C
- specific enthalpy: ± 0,1 kJ/kg
- relative humidity: ± 0,5 %
- humidity: ± 0,1 g/kg

Climatic data

The most difficult problem for summer season energy use calculations for buildings in Poland is to get representative and averaged climatic data including hourly defined outdoor conditions like: air temperature, air humidity, solar radiation heat flux. Those three are the minimum necessary to be used by the model presented in this paper. Because, so far these data are not officially available, the calculations had to be provided in two, following ways:

1) For quasi dynamic hourly calculations the following data and assumptions were used:

- temperature and humidity in “hourly mode” were applied as the recoded data in the year 2001, by one of the meteorological station in Kraków,
- for the solar heat gain calculations the data published in the polish standard [8] were used. It gives solar heat flux on particularly oriented outside walls hour by hour but only for one “representative” (“calculating”) day for each month of summer season. So it has to be assumed when determining the room or building “thermal characteristics” that all the days are the same in each month and they are similar to the “calculating day”.
- Because of lack of clear reationship between the outdoor air temperature and humidity and the solar radiation intensity, the model had used them separately (it means, the influence of outdoor temperature onto heat gain of the building was assumed to be almost negligible in comparison with solar- based ones)

2) For the “comparative” calculations to those described above it was assumed that:

- temperature and humidity of the outdoor air were taken from the same polish standard [8] as the solar flux data and all the days of the same month were concerned “the same” as the “representative” one.

Hopefully, in near future, polish government will publish full data according to the European standard [7] and in that case, the model will be amended to be fully hourly one.

Building heat gain calculations

There is no doubt that energy consumption of the building during the “summer season” strongly depends on both, the internal and external sources heat gains. The basic problem to cope with in calculations of energy use by HVAC system in summer is to have a simple but reliable model for calculations of heat gains to the building. Creating such a model let us in particular consider the following requirements and conditions:

- calculations of heat and humidity gains in "hourly mode"
- heat gain from solar radiation through windows and "transparent walls" should be done with highest attention. The accumulation in construction should be taken into account
- the heat gain through "non-transparent" walls may be treated as "less important" and it can be calculated assuming that heat flux transferred through the defined wall is quasi constant and it is a function of the difference between the "daily averaged solar outdoor temperature" and indoor air temperature.
- the gain from the inhabitants and users is achieved based on "average square area per person" [1]

Cooling & heating demand determination

CAV systems one can call as "supply air quality control" system because the transient heat and humidity balance for the building envelope is matched by changing the air supply parameters (represented by the point "N" at the Mollier's diagram). It means that supplied air have to balance both, the sensible and humidity gains of the building (represented respectively by equations 1 and 2.

$$V_S \cdot \rho \cdot c_p \cdot (T_p - T_N) = \sum \Phi_s \qquad (1)$$

$$V_S \cdot \rho \cdot (X_p - X_N) = \sum W \qquad (2)$$

This point can be called like a "target of the air treatment processes in the AHU". The base of the "a priori" optimization of the A/C system is *"to achieve this target when using as less energy as possible in current climatic conditions of the outside air"* .

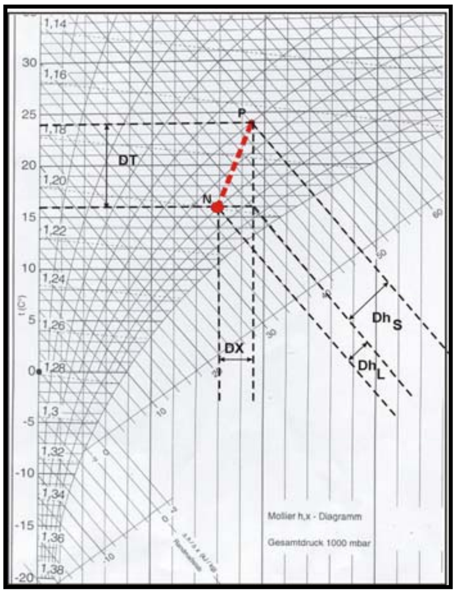

Figure 1. The supply air parameters determination in "h-X" diagram

No doubts that there are several strong links and limits which play major parts in this game:

- when extending DT we are loosing the thermal comfort lever in the users' zone
- when decreasing the DT we grow up with the air flow causing both the energy consumption (by fans) and investment costs (AHU and duct dimensions) increases.

Thus we can assume that "position" of the point "N" in the Molllier's diagram responds the current (transient) state of the building. The energy demand calculations were provided in hourly mode basing on that during each separate hour a determined supply air as well as the outdoor air parameters remain constant (points "N" and "Z" in the diagram). Then, according to the particular assumptions, the air treatment processes are automatically designed (see figure 2).

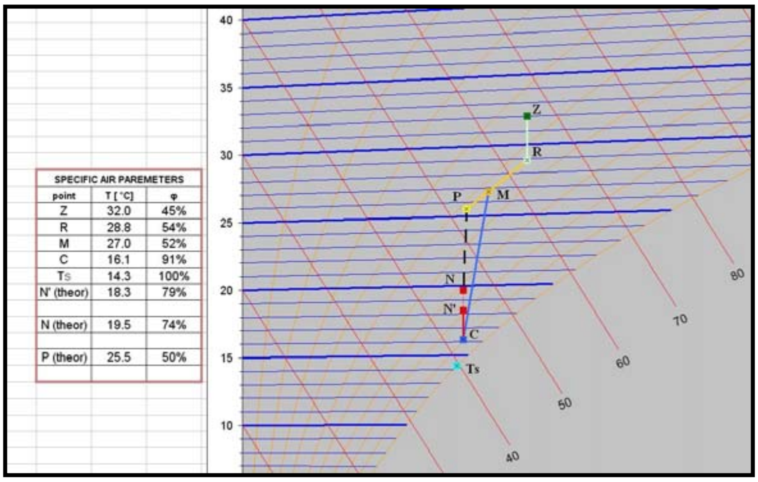

Figure 2. The air treatment processes designed with the help of the model converted into a software package

A crucial element of these calculations is the cooling coil and its capacity control which determines the chiller water outlet temperature which strongly influence the chiller efficiency and subsequently the electric power consumption. So the cooling coil model was identified taking into account that:

- the cooling coil supply water temperatures are in correlation with “average, weighted external surface temperature - Ts” of the cooling coil. (It was assumed, based on “good refrigeration practice” that Ts is approx. 1,0 ^{o}C lower then the water outlet temperature)
- for calculated system, contact factor “Cf” of a cooling coil remains constant.
- in all calculations the air treatment process in the cooling coil is represented by a “straight line” determined by two points, one representing the cooling coil air inlet parameters and the second representing the parameters “Ts” and relative humidity φ = 100 %
- the nominal operating parameters for the chiller were optimized to get the maximum available EER efficiency (maximum possible chilled water outlet temperature). Afterwards, the chiller is assumed to operate with the same set point through all over the season.
- to match the required cooling coil capacity (in transient conditions) 3-way mixing valve and continuous controller was used.

One of the author’s main concern was to determine as precisely as possible the EER efficiency of a chiller as a function of current operating conditions. After analysis it was developed a regression of EER as a function of both, outside air temperature and chilled water outlet temperature (see equation 3).

$$EER(T_{w2}, T_{az}) = (a \cdot T_{az} + b) \cdot T_{w2} + c \cdot T_{az} + d \qquad (3)$$

where:

T_{az} - outside air temperature

T_{w2} - water outlet temperature

a, b, c, d - linear regression factors

This function was currently done based on data of one selected manufacturer for the scroll chillers with R407C. It was validated for the ranges: T_{az} between +20 and 35 ^{o}C and T_{w2} between +5 and + 12 ^{o}C. In the future it is intended to develop this function as more general one (dependant also on the type of refrigerant and EUROVENT data).

Algorithm of the energy consumption for cooling season

First step of the calculations was to determine the **averaged, mean seasonal heat and humidity gains** into the building which was based on averaging of the solar heat gain for the daily operation period through allover the season. To get this the following formulas were used:

- The averaged seasonal sensible heat gain [W]:

$$\Phi_{s,mean}^{season} = \Phi_{g,mean}^{season} + \Phi_{w,mean}^{season} + \Phi_{s,u} \cdot \varphi_u + \Phi_{comp} \cdot \varphi_{comp} + \Phi_{add} \qquad [W] \qquad (4)$$

where:

$\Phi_{g,mean}^{season}$ - heat gain through the glass (windows or transparent walls”) [W]

$\Phi_{w,mean}^{season}$ - heat gain through the “non transparent” walls calculated on the base of “mean seasonal solar temperature” [W]

$\Phi_{s,u}$ - sensible heat gain from the users [W]

Φ_{comp} - sensible heat gain from computers [W]

Φ_{add} - extra, additional sensible heat gain in the building [W]

φ - “averaging factors”

- The average solar gain for the entire building was calculated using weighted factors for all of the windows' (glass walls) major orientations as shown in the equation 5.

$$\Phi_{g,mean}^{season} = \Phi_{g,mean,E}^{season} \cdot n_{g,E} + \Phi_{g,mean,SE}^{season} + ...+ \Phi_{g,mean,NE}^{season} + \Phi_{g,mean,H}^{season} \qquad [W] \qquad (5)$$

where:

$\Phi_{g,mean,E}^{season}$ - heat gain through the glass in the wall orientation "E" [W]

$\Phi_{g,mean,H}^{season}$ - heat gain through the glass in the horizontal "roof" [W]

$n_{g,E}^{s}$ - windows, glass walls surface in the wall orientation "E" divided by the total glass walls' area of the building

b) The seasonally averaged value of the humidity gain were calculated according to the following formula (6):

$$G_{w,mean}^{season} = w_{1,u} \cdot n_u \cdot \varphi_u^{season} \cdot 0{,}277 \cdot 10^{-6} + G_w^{ex} \qquad [kg/s] \qquad (6)$$

where:

$w_{1,u}$ - humidity gain from 1 person (user), related to the activity [g/hour]

n_u - total amount of the persons in the building

φ_u^{season} - seasonal averaging factor for the amount person in the building

G_w^{ex} - additional, "extra" humidity gain in the building [kg/s]

Finally it was possible to define the **mean seasonal air inlet parameters** (point $\mathbf{N}_{\boldsymbol{mean}}$ in the Mollier's diagram, Figure 3). These were calculated assuming that air supply flow volume $\mathbf{V_S}$ was already determined (for nominal conditions) and it rests constant as for the CAV system. Using the above parameters as a "target" for air treatment processes through allover the season, hour by hour it was calculated the cooling and heating (if required) demands, chiller efficiency and subsequently electrical power consumption for the predefined relevant outside air temperature and humidity.

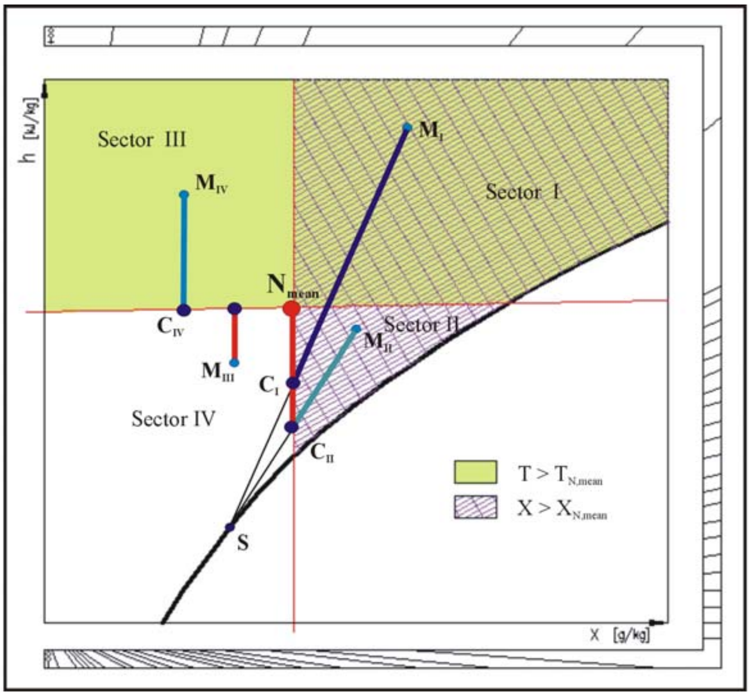

Figure 3. The air treatment processes dependent on cooling coil inlet parameters for cooling/heating demand calculations

Dependant upon different air treatment strategies applied including: mixing, heat recovery, free cooling as well as current outdoor air parameters, the cooling coil air inlet parameters were defined. (point "M", see figures 2 & 3). Relating to the particular position of point **M** the following air treatment control was realized:

i) If $X_M > X_{N,mean}$ (sectors I and II) then the cooling coil treats the air until $X_C = X_{N,mean}$ (with the constant "mean HE surface temperature" - point **S**). After this the secondary heater is activated to achieve the $\mathbf{N_{mean}}$ parameters.
ii) if $X_M \le X_{N,mean}$ and $T_M > T_{N,mean}$ (sector III) then the cooling coil treats the air until $T_C = T_{N,mean}$. No heating is required in that case. The indoor air humidity is subsequently lower then required. No more air treatment is done.
iii) if $X_M \le X_{N,mean}$ and $T_M \le T_{N,mean}$ (sector IV) then no cooling is required. Secondary heating coil heats the air until $T_C = T_{N,mean}$. The indoor air humidity is subsequently lower then required. No more air treatment is done.

In all cases above the **cooling capacity** was calculated for each separate operating hour as:

$$\Phi_i^C = V_S \cdot \rho \cdot (h_M - h_C) \quad \text{[kW]} \tag{7}$$

where:

ρ - air density [kg/m^3]

$h_M ; h_C$ - specific enthalpy of the cooling coil inlet and outlet air [kJ/kg]

At the same time the **heating capacity** required by secondary heater was derived from:

$$\Phi_i^H = V_S \cdot \rho \cdot c_p \cdot (T_{N,mean} - T_C) \quad \text{[kW]} \tag{8}$$

where:

C_p - air specific heat [kJ/{kg ^{o}C)]

$T_{N,mean} ; T_C$ - temperature of the heating coil inlet and outlet air [kJ/kg]

The electricity consumption of fans as well as pumps driving the water through the heat exchange coils were calculated according to the formula (9). There was assumed that both fans and pumps power consumption remains constant through allover the season.

$$P_{EF}^C = \sum \frac{V_F \cdot DP_F}{\eta_T} \quad \text{[W]} \tag{9}$$

where:

V_F - fluid volume flow [m^3/s]

DP_F - fan/pump available pressure required [Pa]

η_T - total efficiency of the fan/pump motor set [-]

So finally, the **total electricity consumption** by an HVAC during defined cooling season was provided according to the following formula (10):

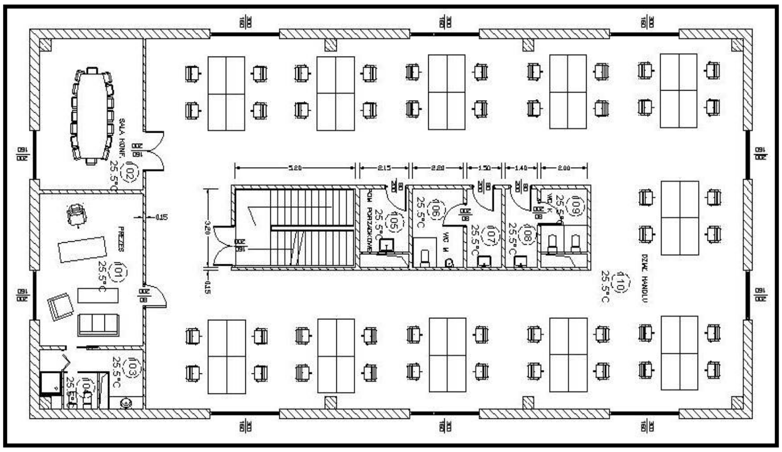
$$EC_E^{season} = \left(\sum_1^{\tau_{tot}} \frac{\Phi_i^C}{EER(T_{w2}, T_{az})_i} \right) + \frac{P_{EF}^C \cdot \tau_{tot}}{1000} \quad \text{[kWh]} \tag{10}$$

and **total heat consumed** by secondary heater (when necessary):

$$EC_H^{season} = \left(\sum_1^{\tau_{tot}} \Phi_i^H \right) \cdot 0{,}0036 \quad \text{[MJ]} \tag{11}$$

RESULTS

For testing this model one example of the new, designed building was calculated and entirely checked out using standard, traditional methods. This was “single floor, open space type office, air conditioned with CAV system” placed in Kraków. The basic assumptions and input data are shown in the figure 4



Input data							
Daily operating period time (5:00 - 19:00):		h	od		do		
			8		18		
working days (from 1 to 7):		days	5				
Beginning and end of the cooling season		d, m	start		end		
			d	m	d	m	
			1	4	30	9	
Building characteristics:							
Useful surface of the floor to be air conditioned	A_B	[m^2]	390,74				
Total surface of the external walls	A_{wo}	[m^2]	319,55				
Volume of the building to be conditioned	V_B	[m^3]	1367,59				
Mass of the building construction per 1 m2 of the floor air conditioned	m_{1A}	[kg/m^2]	300				
Heat transfer factors of the external walls	k	[W/m^2 K]	0,35				
Radiation absorption factor of the external walls	A		0,7				
Percentage of the "transparent walls" surface to the air conditioned floor	n_g		10,65%				
Percentage of the particular orientation "transparent wall" surface to the total "transparent walls" surface	n_g^x		N	E	S	W	H
			15%	35%	15%	35%	0%
Ratio of the transparent to entire window area	φ_{r1}		0,8				
Solar radiation protection device factor *(for nominal conditions)*	φ_{r2}		0,75				
Solar radiation protection device factor *(for mean seasonal conditions)*	φ_{r2}		0,9				
Transparency factor of the glass	φ_{rg}		0,8				
Floor area per person factor	A_{1u}	[m^2]	8,0				
Averaging factor for people (users) quantity	φ_u		0,9				
Floor area per computer factor	A_{1comp}	[m^2]	12,0				
Unitatry heat gain from a computer	q_{1comp}	[W]	200				
Extra, additional sensilbe heat gain in the building	Φ_{add}	[W]					
Extra, additional humidity gain in the building	$G_{w,add}$	[g/s]					
Indoor parameters:							
Thermal comfort category according to prEN 15251 ***(I, II or III)***			I				
Indoor air temperature according to prEN 15251	T_{in}^C	[°C]	25,5				
Indoor air realive humidity according to prEN 15251	RH_{in}^C	[%]	50%				
The nominal temperature difference between the supply and extract air	DT_{in}^C	[°C]	8				
The minimum outside outdoor air flow per person	V_{1f}	[m^3/h·os]	30				
Total heat gain per person (activity and clothing dependant, EN7730)	$q_{T,u}$	[W]	145				
Humidity gain per person (activity and clothing dependant, EN7730)	w_u	[g/h]	75				
Outdoor air nominal parameters:							
Nominal (calculating) outdoor air temperature for cooling (climatic zone)	T_{out}^C	[°C]	32				
Nominal outdoor air humidity for cooling (climatic zone)	RH_{out}^C	[%]	45%				

Figure 4 The most important input data for the calculations example

Using the presented model several different tests and comparisons were done. Because of limited volume of this article only one of them is presented in which two type of climatic data and following consequent calculations procedures were compared: the hourly defined outside air temperature and humidity (2001y) and averaged climatic data based on polish standard [6]. The results are presented in the table (Figure 5)

Simulations results comparison		PN 03420 [1]	Year 2001 [2]	Increase [2] above [1] in %
Mean seasonal gain of total heat	[kW]	**17,52**	**16,94**	-3%
Maximum cooling capacity required	[kW]	**35,80**	**44,12**	23%
Maximum heating capacity required	[kW]	**3,75**	**9,54**	154%
Seasonally averaged chiller efficiency		**4,03**	**4,29**	7%
Seasonal electricity consumption by chiller	[kWh]	**7 258,33**	**6 099,10**	-16%
Seasonal electricity consumption by cooling water pumps	[kWh]	**277,80**	**249,80**	-10%
Seasonal electricity consumption by heating water pumps	[kWh]	**1,84**	**4,72**	157%
Total electricity consumption by ACS during cooling season	[kWh]	**14 428**	**13 243**	-8%
Heat consumption by secondary heater during cooling season	[GJ]	**2,55**	**3,56**	40%

Figure 5. Most important figures comparisons for the example presented in the paper

DISCUSSION & CONCLUSIONS

When analyzing the tests results provided according to the presented model the following conclusions can be written:

- The source and type climatic data have rather poor influence on heat gains of a building and subsequently the size of AHU (air handling unit)
- Selection of the chiller and its efficiency is greatly significant in the total electricity consumption during cooling season
- Hourly model of energy used by chiller (based on the EER function of outdoor air and chilled water outlet temperatures) makes the result much more reliable and realistic. For this test example the averaged EER for the season were approx 40% higher then EUROVENT data !
- These presented results are only an example to show how important is such a model for air conditioning systems design process where on-line system energy consumption may be provided according to the EPBD Directive
- The government of each country where the EPBD Directive is obligatory should pay a great attention and make efforts to validate and publish as soon as possible climatic reference data in hourly mode coherent with the standard [5] which would allow to built and validate such tools as those presented in the text above

New correlations for the standard EN 1264

SUMMARY

The standard EN 1264 is born as technical standard for designing and installing radiant floors for heating purposes. In the last years a revision of the standard took place in order to extend the existing calculation method for determining heat flow output also to other radiant systems (walls and ceilings) and operating conditions (heating and cooling).

Nevertheless there are some aspects which have not so far been taken into account, like backward heat flows or how to determine, in cooling conditions, minimum surface temperature and related cooling capacity of the radiant system. In this paper the concepts for correctly consider those aspects are shown and the introduction of correlations and equations which can be integrated in the standard are presented.

INTRODUCTION

The Standard EN 1264 [1, 2, 3, 4] includes a simplified method for sizing radiant floors, by defining pipe spacing, pipe diameter and material type of insulation etc. Although it is a simplified method, its application has some limits, therefore it cannot always be applicable. The existing method has one limit, i.e. the determination of the downward heat flow, which is not directly specified and it is roughly estimated when defining the mass flow rate of the system.

The new draft of standard makes possible to size not only radiant floors, but also radiant ceiling and walls, by defining different heat exchange coefficients on the surfaces (Table 1). It is also defined how to calculate the cooling heating capacity in steady state conditions, but it is not clear how to fix by calculations the limits of the cooling capacity, since a minimum surface temperature in cooling conditions has to be set.

Table 1. Total heat exchange coefficients [W m^{-2} K^{-1}] proposed in the draft of the standard

Ceiling	6	10.8

BACKWARDS HEAT FLOW EVALUATION

When sizing a radiant system, reference to the operative temperature has to be made. (i.e. both the radiant and convective heat exchanges with the surroundings are considered). Once calculated the heat loss due to external surfaces, thermal bridges, and the ventilation load, the heating specific capacity of the radiant system is the ratio between the calculated load and the area of the radiant system. The radiant system can be thought as a heat exchanger, having on one side the water and on the other side a medium with infinite heat capacity (the room). The heating capacity is proportional to $(\Delta\vartheta_H)^n$, where n can be approximated to 1, since $1{,}00 < n < 1{,}05$ and where $\Delta\vartheta_H$ is the mean logarithmic temperature:

$$\Delta\vartheta_{\mathrm{H}} = \left(\vartheta_{\mathrm{VH}} - \vartheta_{\mathrm{1H}}\right) / \left(\ln \frac{\vartheta_{\mathrm{VH}} - \vartheta_{\mathrm{RH}}}{\vartheta_{\mathrm{RH}} - \vartheta_{\mathrm{1H}}} \right), \qquad (1)$$

For calculating the heat exchange coefficient in EN 1264 a simplified method, based on parameters reported in tables, is proposed, leading to the equation:

$$K_H = \mathrm{B} \prod_{\mathrm{i}} (\mathrm{a}_{\mathrm{i}}^{\mathrm{m_i}}), \qquad (2)$$

The resulting specific heating capacity of radiant systems is defined by the equation:

$$q_{1H} = \mathrm{B} \prod_{\mathrm{i}} (\mathrm{a}_{\mathrm{i}}^{\mathrm{m_i}}) \cdot \Delta\vartheta_{\mathrm{H}}, \qquad (3)$$

The backwards heat flow can be roughly approximated considering the heat flowing in the adjacent space calculated through the following equation:

$$q_{2H} = U_2 \cdot \left(\vartheta_w - \vartheta_{2H}\right), \qquad (4)$$

The backwards thermal transmittance U_2 may be calculated as inverse of the one dimension resistance of the whole structure from the conditioned room to the adjacent space R_{tot} (or the inverse U_{tot}-value), once known the upward resistance R_1 (or the inverse U_1), which can be calculated via the following equation (q_{1H} is calculated by equation 3):

$$q_{1H} = U_1 \cdot \left(\vartheta_w - \vartheta_{1H}\right), \qquad (5)$$

The thermal transmittance from pipes level to the adjacent room can be calculated as follows:

$$U_2 = \frac{1}{R_2} = \frac{1}{R_{tot} - R_1} = \left(\frac{1}{U_{tot}} - \frac{1}{U_1} \right)^{-1}, \qquad (6)$$

CASE STUDIES

The models used in the analysis are EN1264 method, Finite Element Method (FEM) and Finite Difference Method (FDM) for types A and B systems [2]. FEM can be considered as a reference method, since it allows to model the geometry of a circular pipe; FDM is also a correct method. Usually such models are based on a rectangular mesh and therefore there is the need to correctly model systems containing circular pipes. In heating case the pipe can be approximated by a square having length [6]:

$$\ell = \sqrt{\pi} r, \qquad (7)$$

and internal resistance

$$R_C = 2 \cdot D \cdot \ln[r/(r-d)]/(\pi \cdot k_p), \qquad (8)$$

As detailed methods two commercial software have been used: STRAUSS for FEM and HEAT2 for FDM.

The water inside pipes has been considered in turbulent flow (inner convection resistance negligible) and the same water temperature has been used in the different cases. Pipe material is PE-X (k = 0.35 W m^{-1} K^{-1}). Thermal conductivity of the concrete layer where pipes are embedded has been set to 1.2 W m^{-1} K^{-1}. The structural slab below the systems is 200 mm thick and two values for the thermal conductivity have been fixed: 0.67 W m^{-1} K^{-1} and 1.2 W m^{-1} K^{-1}.

Type A

Simulations have been carried out by considering the data reported in Table 1. For both the conditioned and the adjacent rooms the same temperature (20°C) has been used. Pipes have 20 mm external diameter and 2 mm thick. Pipe distances have been varied from 50 mm to 375 mm. As for the concrete layer and the position of the pipe within it, data can be seen in Table 2. Two values of floor covering materials have been simulated (0.015 m^2 K W^{-1} and 0.20 m^2 K W^{-1} thermal resistance respectively). The insulation layer is 30 mm thick and thermal conductivity is 0.04 W m^{-1} K^{-1}.

Table 2. Thickness of the concrete layer and position of the pipe within it

Thickness of the concrete layer [mm]	Position of the pipe above the insulation [mm]		
60	0	10	30
80	0	20	40

Type B

Simulations have been carried out by using the same boundary conditions of Type A. Two circular pipes have been considered: 20 mm external diameter (2 mm thick) and 10 mm external diameter (1.7 mm thick). Pipes are directly in contact with thermal insulation and distances between pipes have been varied from 50 mm to 450 mm. Three floor covering materials have been simulated (0.015 m^2 K W^{-1}, 0.15 m^2 K W^{-1} and 0.20 m^2 K W^{-1} thermal resistances). The concrete layer above pipes is 60 mm. The insulation layer is 30 mm or 40 mm thick and thermal conductivity is 0.04 W m^{-1} K^{-1}. The additional conductive element above pipes is 0.5 mm thick with 52 W m^{-1} K^{-1} thermal conductivity. Two dimensions have been considered: continuous covering (L = T) or 10 mm distance between each device (L = T – 0.01 m).

RESULTS AND DISCUSSION

Since simulations have been performed under the same conditions and with fixed temperature, in order to generalize the results reference has to be made in each simulation to the results of the FEM method q_{ref}, thus defining the heat flow ratio Ξ:

$$\Xi = q \,/\, q_{ref}, \qquad (9)$$

Type A

Results for the conditioned room heat flow ratio Ξ_1 and the adjacent room heat flow ratio Ξ_2 are reported in Table 3. As it can be seen, FDM gives the same results as FEM. Existing method is also accurate regarding heat flux from pipes to the conditioned room. The adjacent room heat flow calculated via equation (4) is not accurate and precision decreases as the pipes spacing enlarges (Figure 1). The heat flowing in the adjacent room Ξ_2 is dependent most of all on the covering material $R_{\lambda,B}$. Tile covering (0.015 m^2 K W^{-1}) and 20 mm wood covering (0.15 m^2 K W^{-1}) are the two extreme cases, i.e. for each pipes distance and resistance of covering layer, the value is always between the curves represented in Figure 1. It is therefore possible to consider the pipes spacing and the floor covering resistance as parameters for correcting the values of Ξ_2 through the equation (coefficients are reported in Table 4):

$$q_{2H} = U_2 \cdot (\vartheta_w - \vartheta_{2H}) \left[\left(a \cdot R_{\lambda,B}{}^{b} \cdot T\right)^2 + \left(c \cdot R_{\lambda,B}{}^{d} \cdot T\right) + \left(e \cdot R_{\lambda,B}{}^{f}\right) \right], \qquad (10)$$

At the end the proposed equation gives the results reported in the last column of Table 3. The error is slightly higher when pipe distance is great, but the result is on the safety side.

Table 3. Conditioned room heat flux ratio Ξ_1 and adjacent room heat flux ratio Ξ_2 for Type A

	Ξ_1		Ξ_2

a	b	c	d	e	f
$4.2686 \cdot 10^{-2}$	$-7.6348 \cdot 10^{-1}$	-1.1165	$-1.9091 \cdot 10^{-1}$	1.0490	$-1.3619 \cdot 10^{-2}$

Type B

Results for the conditioned room heat flow ratio Ξ_1 and for the adjacent room heat flow ratio Ξ_2 are reported in Table 5. Also in this case FDM gives the same results as FEM. Existing method is accurate regarding heat flux from pipes to the upper room. The heat flow in the adjacent room calculated via equation (4) is not accurate and precision decreases as the pipes spacing enlarges (Figure 2). The heat flow ratio Ξ_2 is depending most of all by the pipes spacing *T* and external diameter *D* of the pipe, but it does not depend on insulation layer thickness. It is possible to write the following equation for determining the heat flux towards the adjacent room (coefficients are reported in Table 6):

$$q_{2H} = U_2 \cdot (\vartheta_w - \vartheta_{2H}) \left[\left(a \cdot D^{b} \cdot T\right)^3 + \left(c \cdot D^{d} \cdot T\right)^2 + \left(e \cdot D^{f} \cdot T\right) + \left(g \cdot D^{h}\right) \right], \qquad (11)$$

In this way for each pipes spacing the curve is always between the curves reported in the diagram of Figure 2. The proposed equation gives the results reported in the last column of Table 5. The error is slightly higher when pipe distance is great, but also heat flow in the conditioned room is not very accurate in these cases.

MINIMUM TEMPERATURE IN COOLING CONDITION ANALYSIS

The existing EN 1264 takes into account the heat output from the radiant floor and it fixes a surface temperature which cannot be exceeded. For radiant floor 29°C for the occupancy space, 35°C for outside area. For radiant ceiling the surface temperature is related to the radiant asymmetry, but it is usually better not to exceed 35°C. For radiant walls the maximum allowed temperature is related to the risk of burning, i.e. about 40°C. Maximum surface temperature is the average surface temperature, i.e. the maximum surface temperature above or below the pipe in the section where water temperature is equal to:

$$\vartheta_{\mathrm{w}} = \vartheta_{1\mathrm{H}} + \Delta\vartheta_{\mathrm{H}}, \qquad (12)$$

When calculating the thermal output of a radiant floor in cooling conditions, the minimum allowable surface temperature must be taken into account. Such temperature for a radiant floor is 19°C, while for the other radiant systems the dew point temperature is the reference temperature. It must be underlined that such surface temperature is above the section where the supply water temperature occurs. The question is how to consider in a proper way the minimum temperature, once it is known the maximum output of the radiant system, since the cooling capacity has to be determined in the section where water temperature is equal to:

$$\vartheta_{\mathrm{w}} = \vartheta_{1\mathrm{C}} - \Delta\vartheta_{\mathrm{C}}, \qquad (13)$$

The idea is to evaluate, for the maximum heating capacity, the average temperature of the surface and determine the difference between such temperature and the maximum surface temperature. Therefore the following equation can be written:

$$\overline{\Delta\vartheta_{\mathrm{H}}} = \vartheta_{\mathrm{surf,max}} - (\vartheta_{1\mathrm{H}} + \mathrm{q}_{\mathrm{H}}/\alpha_{H}), \qquad (14)$$

At the same time for the cooling capacity a similar equation can be calculated:

$$\overline{\Delta\vartheta_{\mathrm{C}}} = (\vartheta_{\mathrm{iC}} - \mathrm{q}_{\mathrm{C}}/\alpha_{C}) - \vartheta_{\mathrm{surf,min}}, \qquad (15)$$

Case studies

Detailed simulations have been carried out for different systems with FDM, since the accuracy of the method has been previously demonstrated. The analysis has been carried out with the reference limit temperatures reported in Table 7. Simulations have been carried out by considering for the heat transfer coefficients the data reported in Table 1. The water inside pipes has been considered in turbulent flow (i.e. convective inner resistance negligible). Pipes have 20 mm external diameter and 2 mm thick. Material is PE-X (k = 0.35 W m^{-1} K^{-1}).

Table 7. Surface temperature limits [°C] considered in this work

	heating	**Cooling**
Wall	40	19
Floor	35	19
Ceiling	29	19

Type A

Internal resistance due to water convection in the pipe has been considered negligible Pipe distances have been varied from 50 mm to 300 mm. The concrete layer is 60 mm thick and the position of the pipe within it has been set above insulation layer or in the centre of the concrete layer. Three values of floor covering materials have been simulated: 0 m^2 K W^{-1}, 0.015 m^2 K W^{-1} and 0.20 m^2 K W^{-1} thermal resistance respectively. Thermal conductivity of the concrete layer where pipes are embedded has been set to 1.2 W m^{-1} K^{-1}. The insulation layer is 30 mm thick and thermal conductivity is 0.04 W m^{-1} K^{-1}. The structural slab is 200 mm thick with 0.9 W m^{-1} K^{-1} thermal conductivity.

Type B

In this case pipes are directly in contact with thermal insulation and distances between pipes have been varied from 50 mm to 300 mm. Four floor covering materials have been simulated, having thermal resistances 0 m^2 K W^{-1}, 0.015 m^2 K W^{-1}, 0.15 m^2 K W^{-1} and 0.20 m^2 K W^{-1}. The concrete layer above pipes is 70 mm thick and thermal conductivity has been set to 1.2 W m^{-1} K^{-1}. The insulation layer is 30 mm thick and thermal conductivity is 0.04 W m^{-1} K^{-1}. The structural slab is 200 mm thick with 0.67 W m^{-1} K^{-1} thermal conductivity. The additional conductive element above pipes is 0.5 mm thick and its thermal conductivity is 52 W m^{-1} K^{-1}. The dimension of the conductive covering equal to the pipes spacing ($L = T$).

Results and discussion

The two temperature differences given by equations (12) and (13) have the same value only when the overall heat transfer coefficient is the same for heating and cooling and if the following condition is valid:

$$\vartheta_{1C} - \vartheta_{\mathrm{surf,min}} = \vartheta_{\mathrm{surf,max}} - \vartheta_{1H}\,, \qquad (16)$$

Since equation (16) cannot be achieved and the heat transfer coefficients are not always the same for heating and cooling conditions, the error Λ can be calculated as follows:

$$\Lambda = \overline{\Delta\vartheta_{C}} - \overline{\Delta\vartheta_{H}}\,, \qquad (17)$$

Results of Λ for a set of simulations are reported in Figure 3 for type A and in Figure 4 for Type B. The overall thermal resistance from pipes level to conditioned room R_{tot} as well as the pipes spacing are the factors that mostly influence the results. The hypothesis of a linear relationship between Λ and pipes space T leads to the following equation:

$$\Lambda = -a \cdot R_{tot}^{-b} \cdot T + c \cdot R_{tot}^{-b}\,, \qquad (18)$$

where the coefficients are reported in Table 8 for the different cases.
In this case the minimum temperature can be directly calculated, once known the maximum allowable heating output for all configurations of radiant systems:

$$q_{CV} = \alpha_C \cdot \left(q_H / \alpha_H - \Lambda - \vartheta_{surf,\max} + \vartheta_{1H} - \vartheta_{surf,\min} + \vartheta_{1C}\right), \qquad (19)$$

where q_{VC} means the cooling output in the section of the supply temperature (i.e. in the section where the water enters in the room). Equation (19) can be solved for the different systems, leading to:

$$q_{CV} = \alpha_C \cdot \left(q_H / \alpha_H - \Lambda - p\right), \qquad (20)$$

where p = 2°C for a radiant floor, p = 13°C for a radiant wall and p = 8°C for a radiant ceiling.

Once known the heat flow q_{CV}, the calculation of the supply water temperature is possible, since K_c is known:

$$\vartheta_{VC} = \vartheta_{1C} - q_{CV} / K_C, \qquad (21)$$

From the supply water temperature, once fixed the maximum temperature difference between supply and return, it is possible to evaluate the maximum cooling output of the system q_C.

CONCLUSIONS

When pipes are approximated thorough equations (2) and (3) the use of FDM leads to no error and the accuracy can be assumed to be the same as FEM. As for hating flow behind the pipes, both for type A and B, correlation for determining the correct values are proposed and seem to be accurate (error less than 2% in the worst case for type B). Also modification for taking into account minimum temperature of supply water temperature in cooling conditions, starting by the value (calculated or measured) of the maximum allowable heating output, has been proposed and it seems to be accurate enough (on cooling heat flux less than 2%).

SUMMARY

The purpose of this paper is to develop the calculation method of energy consumption for hot water radiant heating system. The method was developed based on 40 experiments which were carried out in a wooden house built in an environmental chamber in the Building Research Institute (BRI). The method was steady state calculation for simplicity, of which necessary input information was limited to the one we can get easily in design stage such as catalogue value and design plan, besides the heating load calculated by simulation. Therefore, by using this method, we can design the heating system or use for rating of the system for energy saving. The calculation results of the energy consumption were compared with the measured results and then it was shown that these results agreed well with various condition.

INTRODUCTION

Up to now, in Japan, energy performance of residential buildings for heating and cooling has been evaluated by the heat loss coefficient and air tightness of the envelope. On the other hand, as residential heating/cooling equipments such as room air conditioner and radiant heating system have become more efficient, design of these equipments as well as the envelope has become more important for energy savings. Therefore, energy calculation methods for these various equipments have been required in order to compare and rating the energy performance of various heating systems based on primary energy consumption. In this paper, a calculation method of hot water radiant heating system is presented.

OUTLINE OF THE CALCULATION METHOD

Annual energy consumption of hot water radiant heating system can be calculated by using the method presented here. Before this energy calculation, heating load needs to be calculated by simulations. Necessary input information besides the heating load was limited to the one we can get easily in design stage such as catalogue value and design plan (Figure 1).

DEVELOPMENT OF THE CALCULATION METHOD

Outline

The method was developed on the basis of experiments. Various hot water radiant heating systems, of which components such as radiator, boiler, and hot water circulating piping were different, were constructed in a wooden house built in an environmental chamber in the Building Research Institute (BRI), and then heat loss and heat supply from the components were measured under various heat loads by changing the thermal insulation performance of the envelope, ventilation rate and external temperature. The method was based on the steady-state data for simplicity although heat flows and temperatures are usually changing. Therefore, experimental room was controlled to be steady state and then the data was used when all temperatures were constant.

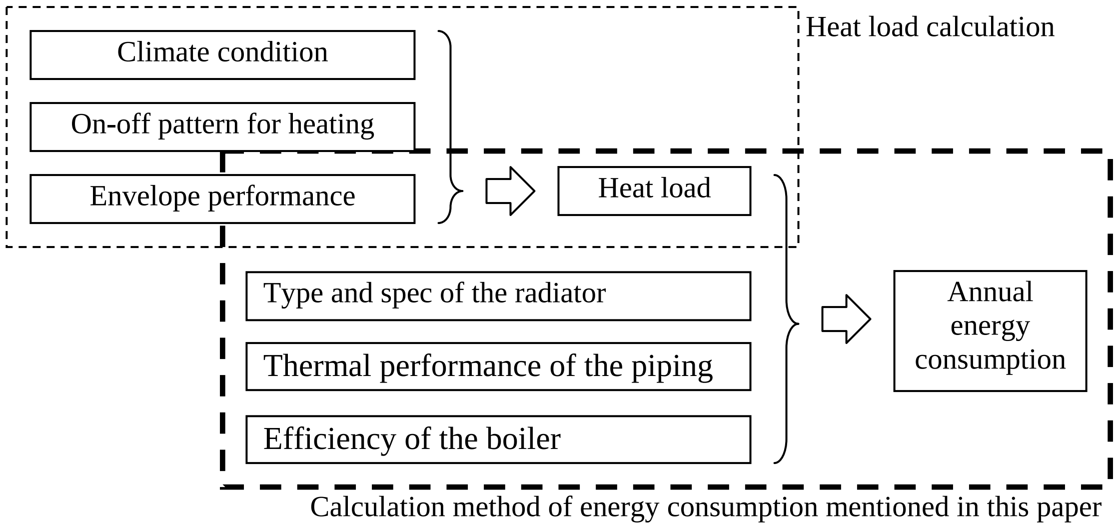

Figure 1. Necessary Input Information for Calculation Method

Experiment

1) Experimental House

A radiant floor panel was constructed at the 1st floor of a two-story wooden house (Fig. 2 and 3) in a chamber which temperature and humidity could be controlled. This wooden house is equipped with central ventilation system by which air supply and exhaust rate can be controlled. Thickness of the insulation at the floor and the wall can be changed.

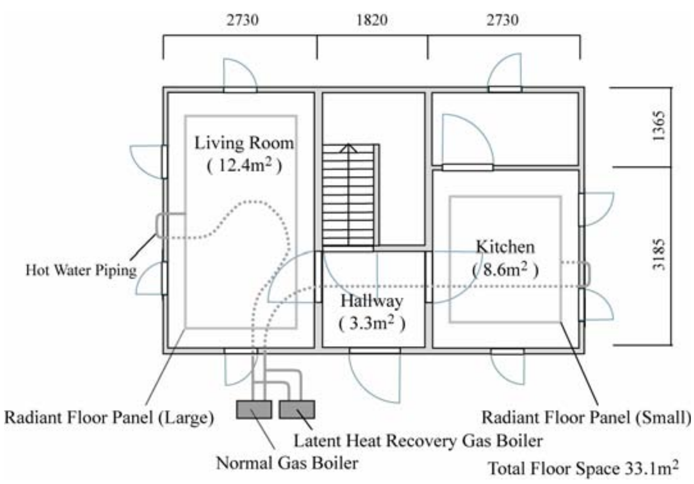

Figure 2. Floor Plan

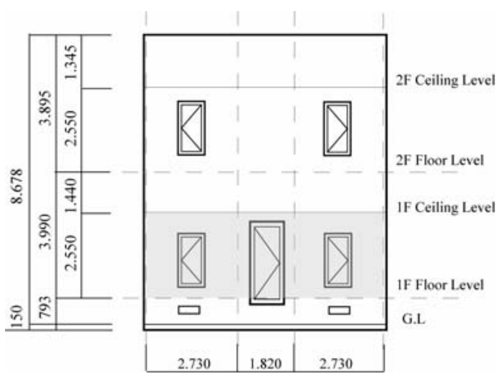

Figure 3. Elevation View

2) Floor Heating System

A normal gas boiler and a latent heat recovery gas boiler were tested, which were used for both floor heating and hot water supply. Supply water temperature of the normal gas boiler

for heating are 60 ^oC and that of the latent heat recovery gas boiler are 40 or 60 ^oC which can be selected with the controller. Even if 40 ^oC were selected, supply water temperature is controlled to be 60 ^oC when room temperature does not reach set temperature. Output of both boilers for heating is 2.56 ~ 14.0 (kW).
Two radiant floor panels were installed in the living room and the kitchen (Fig.2). Figure 4 shows the cross section of the panel.
Hot water piping consisted of two tubes for supply and return water which were bound up. Two types of the piping were used, which were insulated type and non-insulated type. The heat loss coefficient of non-insulated type was 0.21 (W/mK) and one of insulated type was 0.16 (W/mK). The length of the piping between the boiler and the panels was 10m.

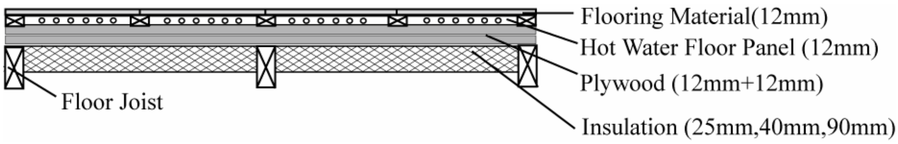

Figure 4. Cross Section of Radiant Floor Panel

3) Parameters of the experiments
The experimental parameters shown in Figure 5 were 1) type of the boiler and hot water supply temperature, 2) type of the piping, 3) ambient (chamber) temperature and 4) thermal performance of wooden house which was established with changing thickness of the floor insulation and ventilation rate of the rooms. With combining these parameters, 40 experiments were carried out.

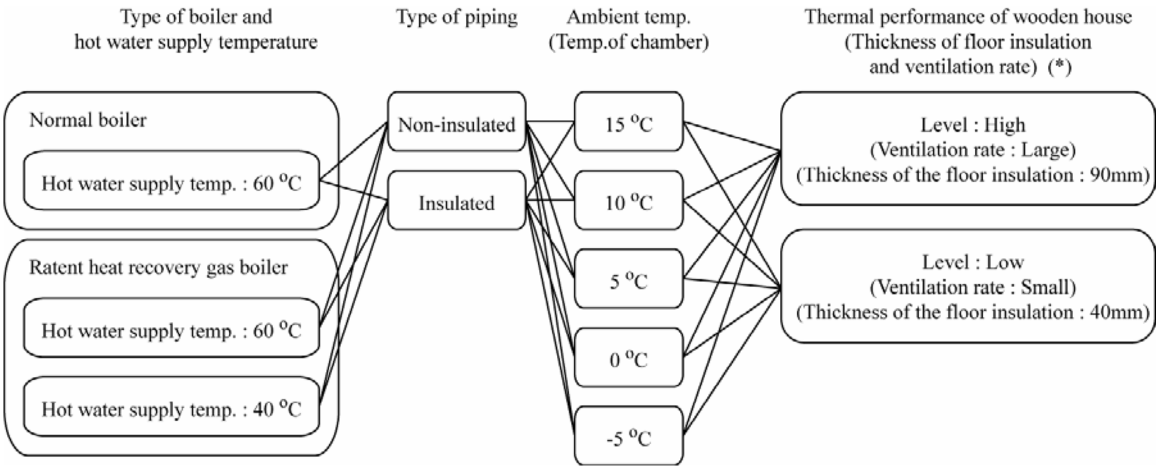

Figure 5. Combination of Experimental Patterns

* Heat loss coefficient per floor area of “level high” was 4.2 (W/m^2K) with ventilation rate 17.5 (m^3/h) and that of “level low” was 2.7 (W/m^2K) with ventilation rate 63(m^3/h).

4) Time of the operation and the measurement
The floor heating was operated for 6~11 hours until the temperatures of the floor and the panel became constant. The measurement was started an hour before the start of the operation and stopped 3 hours after the operation was stopped in order to observe the decrease of the temperatures.

5) Experimental results
Among 40 experiments, one result is shown in Figure 6, which was carried out under the situation that the boiler was normal gas boiler, the piping was non-insulated and the external temperature was 5 ^oC. Supply water temperature was kept about 75 ^oC for 60 minutes after

starting the operation to raise the floor surface temperature rapidly. The water from the boiler was intermittently supplied at about 60 ^oC and the cycle of on-off operation was 20 minutes. For 120-180 minutes, water was supplied for 15 minutes and stopped for five minutes as well as combustion of the gas boiler. After 170 minutes when the room temperature reached the set temperature 20 ^oC, the operation time shortened gradually. The floor surface temperature was constant at about 31 ^oC and moved somewhat up and down by on-off of the water supply. The supply water temperature at the input of the panel was approximately 3 ^oC lower than that at the output of the boiler and the decrease of the supply water temperature was shown. On the other hand, the decrease of the return water temperature was not found because the return water seemed to receive the heat from the supply water, which temperature was higher than that of the return water, in the pair tubes.

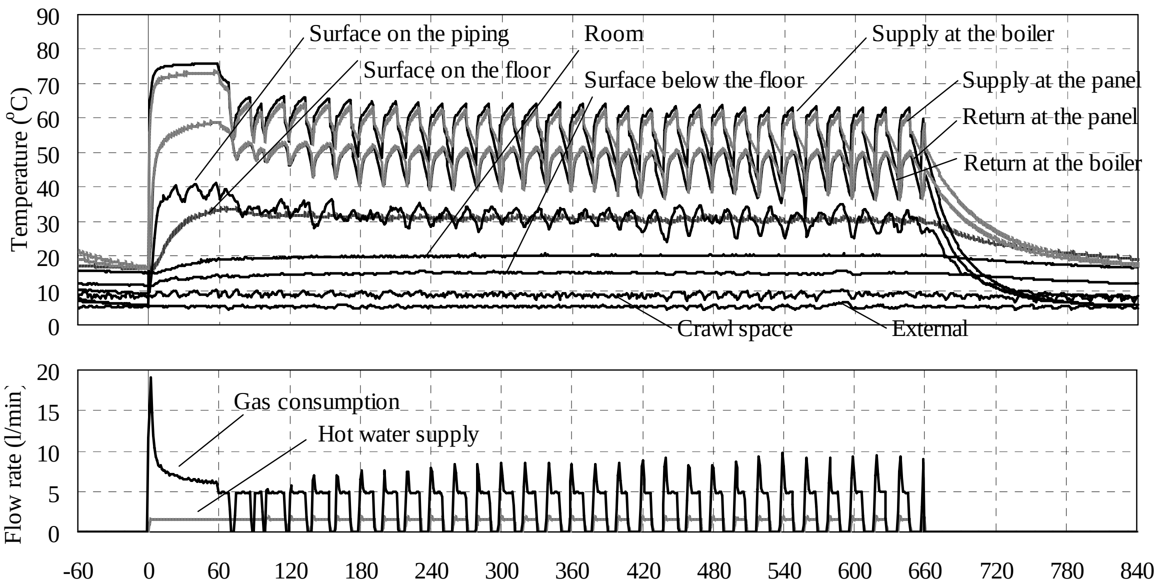

Figure 6. Experimental Result

Heat supply to the room, heat loss from the panel, heat loss from the piping and heat loss from the boiler which were defined in Figure 7, were calculated. The results were shown in Figure 8. The heat supply to the room as well as the heat loss from the piping increased as the external temperature lowered. The heat supply was influenced by the external temperature, e.g. 300~700 (W) with the external temperature 15 ^oC and 1500~2000 (W) with the external temperature -5 ^oC. On the other hand, heat loss from the boiler was not influenced well by the external temperature and heat supply to the room, and it was constant at 500~700 (W) at the normal gas boiler and at 250~400 (W) at the latent heat recovery gas boiler.

Figure 8. Heat Supply and Heat Loss

Development of the estimation method of the energy consumption

Energy consumption (E) of the boiler is given by,

$$E = \frac{1}{e_{hs}}\left(q_{pnl} + q_{pipe}\right), \tag{1}$$

where:

e_{hs} efficiency of the boiler;
q_{pnl} heat supply to the panel in W;
q_{pipe} heat loss from the piping in W.

Heat supply to the panel is given by,

$$q_{pnl} = q_{pnl,spy} + q_{pnl,loss} = \left(\frac{T_{pnl} - T_{room}}{R_u} + \frac{T_{pnl} - T_{crawl}}{R_d}\right) A_{fp} \tag{2}$$

where:

$q_{pnl,spy}$ heat supply from the panel to the room in W;
$q_{pnl,loss}$ heat loss from the panel in W;
T_{room} room temperature in ^{o}C;
Tcrawl crawl space temperature in ^{o}C;
R_u thermal resistance between the panel and room in m^{2}K/W;
R_d thermal resistance between the panel and crawl space in m^{2}K/W;
A_{fp} area of radiant floor panel in m^2.

Equation (2) can be modified without using T_{pnl} as follows;

$$\begin{aligned} q_{pnl} &= q_{pnl,spy} + \frac{1}{R_d}\left(q_{pnl,spy} \times R_u + T_{room} - T_{crawl}\right) \\ &= \frac{R_u + R_d}{R_d}\left(q_{pnl,spy} + \frac{T_{room} - T_{crawl}}{R_u + R_d}\right) \end{aligned} \tag{3}$$

In the parentheses in Equation 3, the first term represents heat supply from the panel to the room and this equals the loss from the room to the outside through the envelope except the floor (L_{env}). The second term represents heat loss from the room to the crawl space through the floor (L_{pnl}) when floor heating is not operated. Therefore, sum of the first term and the second term equals to the heat load (L) calculated heat load calculation and Equation 3 can be modified as follows;

$$q_{pnl} = \frac{R_u + R_d}{R_d}\left(L_{env} + L_{pnl}\right) = \frac{R_u + R_d}{R_d} L \qquad (4)$$

The calculated results of the heat supply to the panel as mentioned above were compared with the measured results in Figure 9. The calculated results agree well with the measured results.

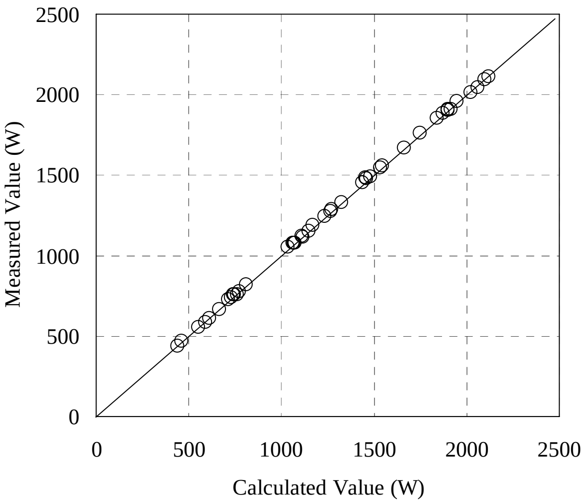

Figure 9. Comparison of q_{pnl}

Heat loss from the piping is given by,

$$q_{pipe} = K_{pipe} \times \left(T_{water,ctrl} - T_{crawl}\right) \times d \times l_{pipe} \qquad (5)$$

where:

K_{pipe}	thermal coefficient of the piping in W/mK,
$T_{water,ctrl}$	set temperature of supply water in ^{o}C,
T_{crawl}	crawl space temperature in ^{o}C,
d	decreasing rate of average water temperature,
l_{pipe}	length of the piping in m.

Decreasing rate of the average water temperature (d) is the coefficient which represents that average heat loss decreases when on-off operation because water temperature decreases when water supply stops and which is given by,

$$d = r + \frac{1 - e^{-\left(K_{pipe} h (1-r)/c\right)}}{K_{pipe} h / c} \qquad (6)$$

where:

r	operating rate which is the ratio of the water supply period,
c	thermal capacity of the water and pipes in J/mK
h	on-off operation cycle in s.

It is difficult to define operating rate (r) qualitatively because it depends on how to control the boiler. In this paper, r was calculated from the heat supply to the panel q_{pnl} conveniently assuming that r is relative to q_{pnl} which shows in Figure 10. Figure 11 shows comparison between the calculated heat loss from the piping and measured one. Calculated results do not agree well with the measured one. The difference between the average water temperature and the crawl space temperature could be explained well, so the assumption that Kpipe was constant did not seem to be relevant.

Figure 12 shows the measured efficiency of the boiler. When the output was higher than the lower limit of the boiler 2.56kW, the boiler ran continuously and the efficiency was constant. On the other hand, when the output was lower than 2.56kW, the boiler ran intermittently and the efficiency decreases. In this report, in case the output is lower than the lower limit, approximately curve of the efficiency was made on the assumption that heat loss was constant as below.

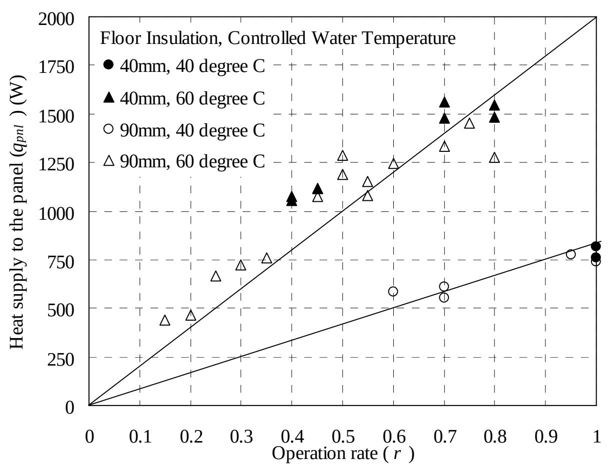

Figure 10. Relation between q_{pnl} and r

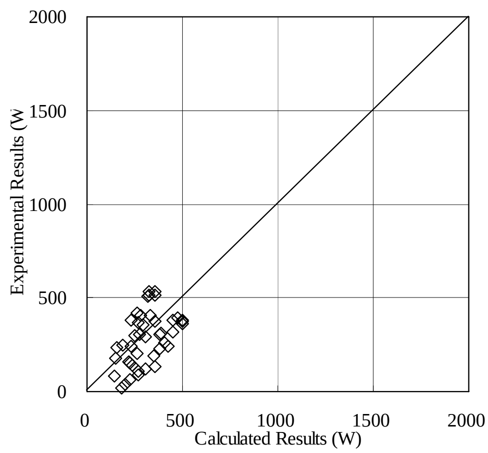

Figure 11. Comparison of Heat Loss from Piping

Table 1. Heat Loss from Boiler (which assumed in the calculation)

Normal gas boiler with output water temperature 40 ^{o}C	853 (W)
Latent heat recovery gas boiler with output water temperature 60 ^{o}C	640 (W)
Latent heat recovery gas boiler with output water temperature 40 ^{o}C	320 (W)

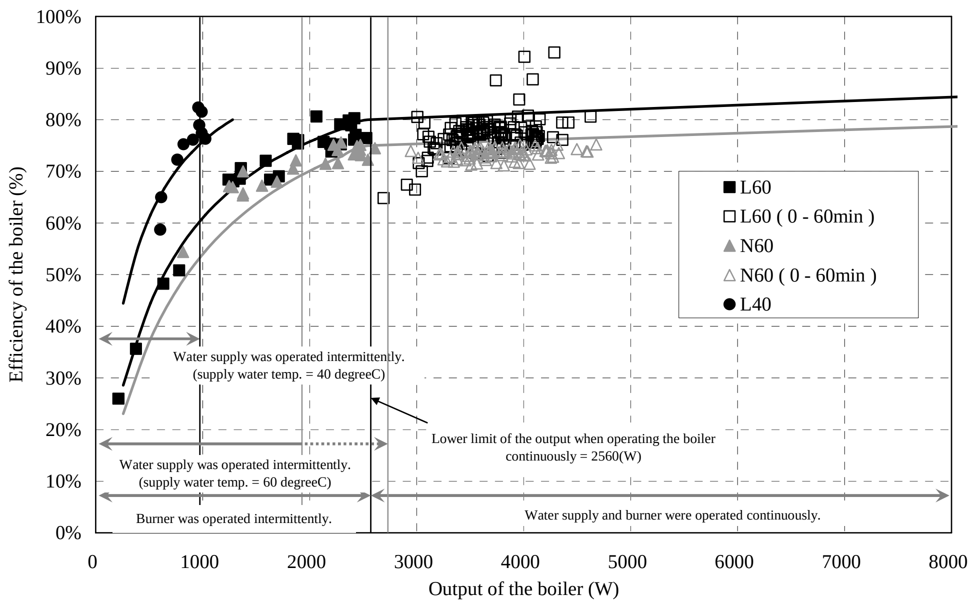

Figure 12. Efficiency of Boiler

Procedure of the calculation

Figure 13 shows the procedure to calculate the primary energy consumption from the heat load calculated by simulation and design value of the floor heating.

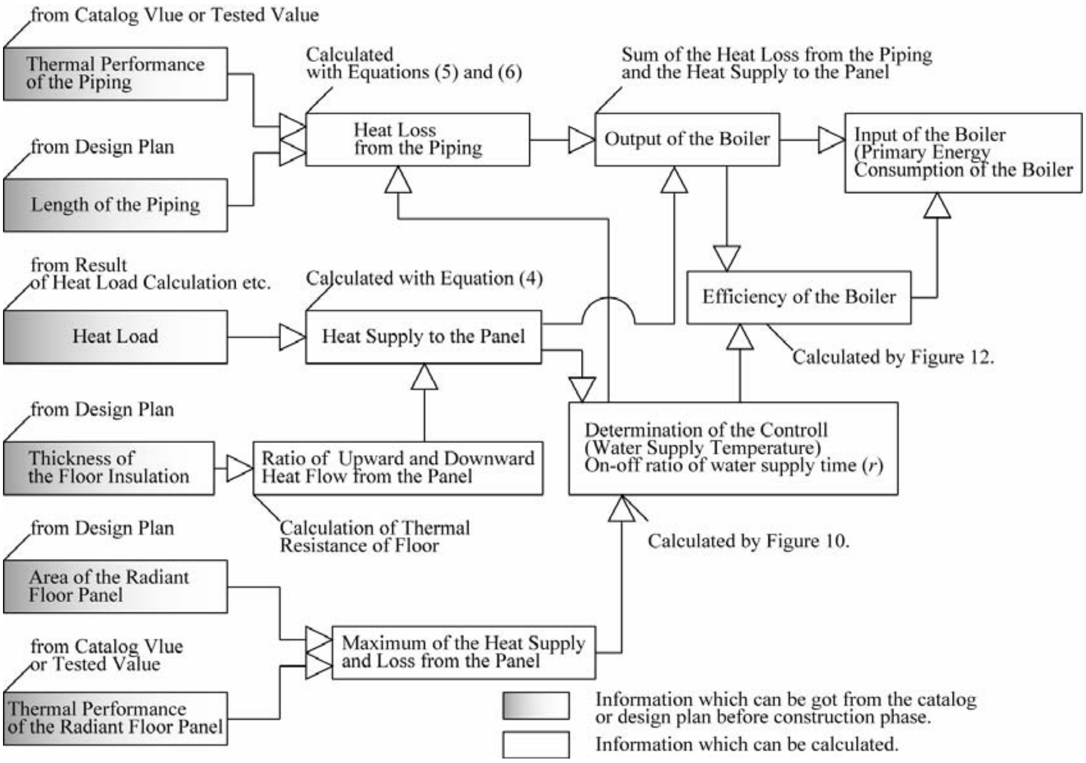

Figure 13. Procedure to Calculate Primary Energy Consumption

Comparison of the calculated energy consumption with measured one

Energy consumption which was calculated as mentioned above was compared measure one (Fig. 14). The calculated results agree well with the measured results.

CONCLUSION

The estimation method was developed based on the 40 experiments. The calculation results of the energy consumption agreed well with the measured one. This calculation needs input we can get by the heat load calculation and catalog value. Therefore, by using this method, we can decide which heating system should be used such as radiant heating, room air conditioner and so on, and in case of floor heating, we can decide the capacity of the boiler, type of the piping, thickness of the insulation of the floor and so on. This calculation can also be used for the rating of the heating system for energy saving.

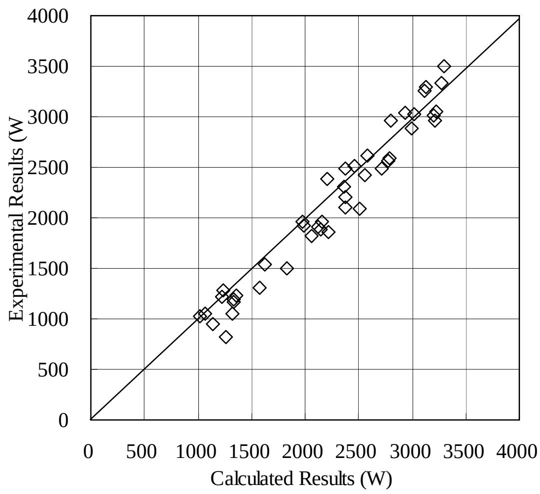

Figure 14. Comparison of Primary Energy Consumption

Energy consumption can not be calculated by this method a few minutes after the system on because the developed method was steady state calculation. In Japan, intermittent air-conditioning is more popular than continuous air-conditioning. Therefore, it is necessary to develop the non steady state calculation of the energy consumption.

Annual Variability of Energy Usage in a Small Office Building Due to Weather

Donald Colliver, PhD, PE, FASHRAE, PMASHRAE

University of Kentucky, Lexington, KY USA

Corresponding email: colliver@bae.uky.edu

SUMMARY

This paper gives an indication of the range of natural variability in energy usage of a particular building due solely to the variability in the outside weather conditions. The annual total, heating, and cooling energy usage of a small light frame office building was determined from 30 years of hourly weather data for 15 locations representing a cross section of the eight climate zones in the USA and the Typical Meteorological Year (TMY2) for the same 15 locations and for seven locations with Weather Year for Energy Calculations (WYEC). It was found that for the 15 cities, the 30-year range of the total annual energy usage averaged 18% of the 30-year average annual energy usage. The 15-city average coefficient of variation (standard deviation/average) for heating was 31.7% and 8.1% for cooling. The range over average was 132% for heating and 33% for cooling.

Substantial differences were found when the energy usages calculated from WYEC and TMY data were compared to the 30-year statistics for each location for the annual total, cooling and heating energy usages. Comparing the TMY or WYEC to the 30-year average by locations, there were 10 of 22, 21 of 22, and 12 of 21 cases which were outside the average plus or minus one standard deviation for total, cooling and heating annual energy usage respectively.

INTRODUCTION

Computer modeling of buildings is now a common technique to size heating and cooling equipment and to evaluate the potential energy savings of design alternatives. In order to simplify the process and speed the computations, a “typical” weather year is usually used in this modeling. Even though there has been considerable research in developing these “typical weather years”, unfortunately using a single synthesized weather year does not give an indication of the range or variability in the year-to-year differences in weather. This naturally occurring between-year variation is extremely important when trying to make comparisons between pre- and post- retrofit energy data. These variations can lead to disappointments when actual alternatives have been put into buildings and expected “savings” are not realized due to variation in the actual data from the weather data used in the estimation. The purpose of this paper is determine the range of natural variability in energy usage of a small light-frame office building due to the variability in the outside weather conditions and to evaluate how well the synthesized weather years compare to actual weather data for this particular type and size of building.

METHODOLOGY

The annual energy usage and extreme monthly electricity and gas demand of a small light-framed office building was determined for 15 locations representing the eight climate zones in the US using 30 years of hourly weather data. This information was also determined using the TMY2 weather data for each of the cities and for seven of the locations which had WYEC weather data sets available.

Description of Test Building

The building simulated was a single story, frame construction 455m^2 (4,900 ft^2) office building. It was arranged in a square plan form to avoid any orientation issues. The floor was a concrete slab with R-0.9, 0.6m (R-5, 2-ft) wide edge insulation. The walls were 2x4 0.4m (16”) on-center light frame construction. The window area was a 20% window-to-wall area ratio and the windows were equally distributed around the four walls. There were no overhangs or external shading devices. Insulation, window and door specifications, and equipment efficiencies were all as specified by ANSI/ASHRAE/IESNA Standard 90.1-1999. Wall and roof R-values were R-2.29 and R-5.28 (R-13 and R-30) respectively for all locations except for Fairbanks where the walls were R-2.29+R-1.32 (R-13+R-7.5) continuous insulation and a roof of R-6.7 (R-38) was used in Fairbanks and Helena. Occupancy sensors and outdoor air damper controls were not implemented. The occupancy, equipment, and lighting schedules are given in Colliver and Jarnagin [1]. Heating and cooling were supplied with a single zone packaged DX rooftop unit with gas heating. The efficiency of the equipment was the minimum specified in Std 90.1-1999 (AFUE-0.74 and EER-8.7). The heating setpoints were 21.1C (70F) during occupied periods, 18.3C (65F) unoccupied and the cooling setpoints were 23.9C (75F) occupied, 26.7C (80F) unoccupied.

Description of Locations Simulated

The US Department of Energy has identified eight climate zones for the United States. Weather data from the 15 cities presented in Figure 1 were used to simulate the energy usage. These fifteen cities were chosen to represent a wide variety of climate zones including a variation in temperature and humidity. Both dry and humid conditions were chosen for several of the climate zones.

Weather Data Sources

Thirty years of hourly weather data for each of the locations were obtained from the Solar and Meteorological Observation Network (SAMSON) [2]. An exception was Baltimore which had only had 28 years of data which could be converted into an acceptable format. The time period covered by these data was 1961-1990. More recent data are currently being used to generate a newer version of SAMSON, however these updated datasets are not yet available. The data were converted from the SAMSON format to the .bin format used by the simulation with a utility provided with the energy simulation program. An investigation of any long-term trend of the annual data to investigate any impacts of climate change is not included in this paper.

Rather than simulating multiple years of weather data, annual energy usage is typically estimated with some generated “typical” year of weather data which is supposed to represent the long-term weather conditions of the location. There are several types of these “typical” weather years such as: a) Test Reference Year (TRY), b) Typical Meteorological Year (TMY or TMY2 [3]), and c) Weather Year for Energy Calculations (WYEC2 [4] or IWEC [5]). All of these data sets have been generated by combining various months of actual weather data into a set of 8760 hours of weather data. The intended use of these data sets is for computer simulations of buildings and space conditioning systems to facilitate performance comparisons of different system types and building and equipment configurations. Because these data sets represent typical rather than extreme conditions, they are not suited for designing systems to meet the worst case conditions occurring at a location. It is valuable however to see the differences in peak usage between these "typical years" and actual weather years.

Figure 1. Locations Analyzed

The energy usage for all 15 of the locations was also simulated using the TMY2 data set and was determined for seven of the locations for which WYEC datasets were available. The seven WYEC2 locations were: Miami, Phoenix, El Paso, Albuquerque, Seattle, Boise and Chicago.

Energy Model Used

The simulations were run using a freeware 8760 hourly building energy use analysis tool based upon DOE 2.2 [6]. The model has been approved by the California Energy Commission as a 2001 Title 24 non-residential alternative calculation method.

RESULTS

Total Annual Energy Usage

The 30-year average, standard deviation, maximum value and minimum value of the total annual simulated energy usage for the building located in each of the 15 cities is presented in Table 1. It was found that standard deviation of the total yearly energy usage varies from 2.5 GJ/yr for San Francisco (a very mild climate) to 34.9 GJ/yr for Fairbanks (an extremely cold climate).

Table 1. Annual Energy Usage, GJ/yr

Climate Zone	City	Average	Std Dev	Max	Min	Coeff of Variation %	range/avg %	max/avg %	min/avg %
		30 years of weather data

6	Helena	323.3	22.5	382.2	285.3	6.9	30.0	118.2	88.2
7	Duluth	384.7	19.9	430.4	327.4	5.2	26.8	111.9	85.1
8	Fairbanks	553.8	34.9	621.5	453.5	6.3	30.3	112.2	81.9
		Average of 15 locations				4.1	18.5	109.5	91.0

The standard deviation of the total energy used over a number of years is not as informative as an indication of the relative annual fluctuations to the total average annual energy usage. The maximum annual and minimum annual usage values, and the coefficient of variation (defined as the standard deviation as a percentage of the mean) and the range as a percentage of the mean are also presented in Table 1.

It was found that the minimum fluctuation occurred in San Francisco where the standard deviation of the annual energy usage was only 1.2% of the annual usage and the maximum variation (range/average) was only 5.1% over all the years. This very mild location is representative of a maritime climate which has little fluctuations.

Greater between-year variations occur in most of the other locations and tend to increase in the colder climates. The coefficient of variation of annual energy usage varied from 1.2% in San Francisco to 7.2% in Boise with an average of 4.1% for all 15 locations. The ranges (maximum annual energy use minus minimum annual energy use) as a percentage of the average annual energy use varied from 4.9% in El Paso to 36.5% in Boise with an average of 18.5% for all 15 locations.

The distribution of the annual maximum and minimum uses were approximately evenly distributed around the average and did not appear to be skewed either high or low. The average of the 15 locations maximum annual usage for a location divided by the location average was 109.5% and 91.0% for the minimum/average. Stated alternatively, the 15-city average minimal and maximal annual energy usage was 91.0% and 109.5% respectively of the city's long-term average annual energy usage.

Annual Heating and Cooling Energy Use

The statistics for the variation of the annual heating and cooling energy uses are presented in Tables 2 and 3. Since there is negligible heating in any of the years for Miami, that location is not included in the heating statistics. Also since this was an office building with internal heat gains, there was cooling required even in the colder climates.

Table 2. Annual Heating Energy Usage, GJ/yr

	30 years of weather data

Helena	127.9	21.7	181.8	91.8	16.9	70.4	142.2	86.4
Duluth	181.5	19.2	227.1	124.0	10.6	56.8	125.1	76.4
Fairbanks	326.2	33.4	393.2	234.2	10.2	48.7	120.5	80.0
	Average of 14 locations				31.7	132.3	178.7	62.0

The standard deviation of the heating values range from a minimum of 0.4 GJ/yr in Phoenix to a maximum of 33.4 GJ/yr in Fairbanks. The standard deviation of the cooling values range from a minimum of 1.5 GJ/yr in Burlington to a maximum of 7.3 GJ/yr Phoenix.

Relative annual fluctuations for the heating and cooling are also presented in Tables 2 and 3. The fluctuations for heating were much greater in proportion than for total energy use with the larger fluctuations occurring in the warmer climates. The range/average percentage varied from 48.7% in Fairbanks to 319% in Houston with a fourteen-city average of 132.3%. The coefficient of variation varied from 10% in Fairbanks to 84% in Phoenix. The fourteen-city average of the annual-maximum-heating-energy/30-year-average-heating-energy percentage was 179% and the average of the annual-minimum-energy/30-year-average percentage was 62%.

Table 3. Annual Cooling Energy Usage, GJ/yr

City	30 years of weather data Average	Std Dev	Max	Min	Coeff of Variation %	range/avg %	max/avg %	min/avg %
Miami	89.9	4.7	98.5	80.5	5.2	20.0	109.5	89.5
Houston	67.1	4.2	75.7	56.4	6.3	28.8	112.9	84.1
Phoenix	87.8	7.3	102.1	72.9	8.3	33.3	116.3	83.0
El Paso	49.8	2.5	54.5	44.3	5.0	20.5	109.4	88.9
San Francisco	30.4	2.3	35.0	25.8	7.5	30.4	115.2	84.7
Memphis	54.6	4.2	63.9	46.2	7.8	32.5	117.1	84.6
Albuquerque	33.9	1.9	38.4	31.5	5.5	20.4	113.1	92.7
Baltimore	37.1	2.3	41.7	32.5	6.3	24.8	112.5	87.8
Seattle	17.8	1.7	21.6	14.2	9.4	41.8	121.1	79.3
Boise	27.2	2.4	31.8	23.3	8.8	31.2	116.6	85.4
Chicago	28.7	2.4	33.9	24.2	8.4	33.6	117.9	84.3
Burlington	20.6	1.5	25.0	17.7	7.5	35.1	121.1	86.0
Helena	16.2	2.0	21.5	12.6	12.1	54.6	132.5	77.9
Duluth	17.4	2.2	22.1	13.3	12.4	50.5	127.0	76.4
Fairbanks	17.3	1.8	20.6	13.3	10.3	42.0	118.9	76.8
	Average of 15 locations				8.1	33.3	117.4	84.1

The fluctuations for cooling were also much greater in proportion than for total energy use with the larger fluctuations occurring in the cooler climates with less cooling required. The range/average percentage varied from 20% in Miami to 54.6% in Helena with a fifteen-city average of 33.3%. The coefficient of variation ranged from 5.0% in El Paso to 12.4% in Duluth. The fifteen-city average of the annual-maximum-cooling-energy/30-year-average-cooling-energy was 117% and the average of the annual-minimum-energy/30-year-average was 84%.

Alternatively this can be interpreted as - on the average for all the locations considered the maximum annual energy used was 179% and 117% of the 30-year average annual energy usage for heating and cooling respectively; and the minimum annual energy used was 62% and 84% of the 30-year average annual energy usage for heating and cooling respectively.

Comparison to Annual “Typical” Weather Data

The total average annual energy use for the 15 locations using the 30 years of actual weather data and the annual energy use estimated from the seven WYEC and 15 TMY weather data sets are presented in Table 4.

For the fifteen locations, the annual energy usage with WYEC and TMY data were on the average 0.5 and 1.4 percent higher respectively than the 30-year average annual usage. However, it was found that the annual energy calculated from the WYEC weather data was less than the average minus one standard deviation in three of the seven WYEC locations available and was greater than the average plus standard deviation in one other WYEC location. The annual energy calculated from the TMY weather data was less than the average minus one standard deviation in two cases and higher than the average plus one standard deviation in four of the fifteen cases. In summary, the annual energy estimated using TMY and WYEC data was outside the +/- one standard deviation from the average in 10 of the 22 cases.

Table 4. Annual Total Energy Usage - 30-yr, WYEC and TMY Data, GJ/yr

City	Total Annual Energy Usage, GJ/yr				
	30-year Data Average	WYEC	TMY	WYEC/ 30-yr avg %	TMY/ 30-yr avg %
Miami	266.0	251.4*	253.9	94.5	95.5
Houston	243.4		237.1		97.4
Phoenix	274.9	261.9*	266.0	95.3	96.8
El Paso	230.4	223.9*	222.1*	97.2	96.4
San Francisco	203.5		191.4*		94.0
Memphis	242.7		236.6		97.5
Albuquerque	234.0	238.7	234.5	102.0	100.2
Baltimore	250.1		268.0**		107.1
Seattle	220.1	229.1**	219.9	104.1	99.9
Boise	270.1	279.6	278.2	103.5	103.0
Chicago	305.0	324.8	322.8**	106.5	106.1
Burlington	332.9		358.9**		107.8
Helena	323.3		336.5		104.1
Duluth	384.7		430.8**		112.0
Fairbanks	524.9		572.5		103.4
	Average of 15 locations			100.5	101.4

Notes: * Less than the 30-year average minus 1 standard deviation
** Greater than the 30-yr average plus 1 standard deviation

A greater disparity is pointed out when the annual heating and cooling are investigated independently. The annual heating and annual cooling energy predicted for the locations using the WYEC and TMY weather data sets are presented in Table 6. The average annual heating energy using WYEC and TMY was 154% and 136% respectively of the 30-year average annual heating energy. In four of the six WYEC locations and in eight of the 14 TMY locations the estimated heating energy was greater than the average plus one standard deviation of the 30-year average.

Table 5. Annual Heating and Cooling - 30-yr, WYEC and TMY Data, GJ/yr

City	Annual Heating Energy, GJ/yr					Annual Cooling Energy, GJ/yr				
	30-year Data Average	WYEC	TMY	WYEC/ 30-yr avg %	TMY/ 30-yr avg %	30-year Data Average	WYEC	TMY	WYEC/ 30-yr avg %	TMY/ 30-yr avg %
Miami	0.0					89.9	79.3*	81.3*	88.2	90.4
Houston	3.7		6.6**		176.8	67.1		59.9*		89.4
Phoenix	0.5	0.8	1.0**	173.3	228.8	87.8	77.5*	80.7	88.3	91.9
El Paso	3.8	8.3**	4.3	216.3	110.9	49.8	41.0*	43.7*	82.5	87.8
San Francisco	3.0		4.3**		145.5	30.4		20.6*		67.5
Memphis	15.5		18.8		120.9	54.6		46.9*		85.9
Albuquerque	21.3	31.4**	30.3**	148.1	142.2	33.9	29.6*	28.0*	87.3	82.4
Baltimore	39.1		61.0**		155.8	37.1		31.7*		85.3
Seattle	34.6	49.0**	39.5	141.7	114.2	17.8	12.4*	13.7*	69.6	76.9
Boise	65.0	79.8	79.6	122.7	122.3	27.2	22.4*	21.2*	82.0	77.7
Chicago	99.2	121.3**	120.3**	122.3	122.3	28.7	25.2*	23.6*	87.6	82.3
Burlington	134.4		162.6**		121.0	20.6		16.9*		82.1
Helena	127.9		144.1		112.7	16.2		13.3*		81.7
Duluth	181.5		230.8**		127.2	17.4		12.1*		69.8
Fairbanks	326.2		346.5		106.2	17.3		14.6*		83.9
	Average of 14 locations			154.1	136.2	Average of 15 locations			83.6	82.3

Notes: * Less than the 30-year average minus 1 standard deviation
** Greater than the 30-yr average plus 1 standard deviation

The average annual cooling energy using WYEC and TMY was 83.6% and 82.3% respectively of the 30-year average annual cooling energy. In all seven of the WYEC locations and in 14 of the 15 TMY locations, the estimated cooling energy was less than the average minus one standard deviation of the 30-year average.

Monthly Peak Demand

The statistics for the monthly peak electric and gas demand for each of the locations using the 30 years of weather data and the WYEC and TMY data were also determined. For the monthly peak electrical demand, the 15-city average of the range as a percentage of the 30-year average was 4.7% and the average coefficient of variation was 1.1%. Therefore it can be concluded that there was very little between-year variation in the peak monthly electrical demand. The 15-city average of the maximum/average and minimum/average was 102.5% and 97.8% respectively for monthly electrical demand. The monthly peak electric demand for one city was above the average plus one standard deviation and one city was below the average minus one standard deviation for both the WYEC and the TMY weather data sets.

For the natural gas demand, the 15-city average of the range as a percentage of the 30-year average was 48.4% and the average coefficient of variation was 11.8%. The 15-city average monthly maximum/average and minimum/average was 127.3% and 78.9% respectively. The monthly peak gas demand was above the average plus one standard deviation for three cities for the WYEC data sets and for one city using the TMY data sets. There were no WYEC nor TMY data sets which under predicted the peak gas demand by more than minus one standard deviation.

SUMMARY AND CONCLUSIONS

The annual energy usage of a small light frame office building was determined from 30 years of hourly weather data for 15 locations representing a cross section of the eight climate zones in the USA. The energy usage was also determined using the Typical Meteorological Year (TMY2) for the same 15 locations and for seven of the locations which had Weather Year for Energy Calculations (WYEC) data available. It was found that for the 15 cities, the 30 year range of the total annual energy usage averaged 18% of the 30-year average annual energy usage varying from 4.9% in El Paso TX to 36.5% in Boise, ID. There was greater variation when the annual heating and cooling usages were compared. The 14-city average coefficient of variation (standard deviation/ average) for heating was 31.7% and 8.1% for cooling. The range over average was 132% for heating and 33% for cooling.

Substantial differences were found when the WYEC and TMY energy usages were compared to the 30-year average of the annual energy usage for each location. Four of seven WYEC and six of 15 TMY annual energy usage values were outside +/- one standard deviation from the 30-year average of the corresponding location. However when cooling and heating were separated it was found that in all seven of the WYEC data and in 14 of the 15 TMY cities the electricity usage for cooling using the WYEC or TMY data was less than the average minus one standard deviation. For heating, in four of the seven WYEC and in 8 of 15 TMY cases the gas usage for heating was greater than the average plus one standard deviation of the 30-yr average heating energy. There was very little between-year variation in the peak monthly electrical demand and the average coefficient of variation for peak monthly gas demand was 11.8%. There were two locations in which the monthly peak electrical demand for either TMY or WYEC was outside +/- one standard deviation from the average and four locations where the peak gas demand was above the average plus one standard deviation.

This information gives an indication of the range of natural variability in energy usage of a particular building due solely to the variability in the outside weather conditions. This naturally occurring between-year variation is extremely important when trying to make comparisons between pre- and post- retrofit energy data. It also indicates that there needs to be additional work to investigate why there are such large differences between the long term data and the data customarily used to represent "typical" weather. It is suspected that variations in size and type of building, schedules and ventilation loads impact the applicability of these typical weather data to the specific case. It also points out that as the computational speeds have increased it may be time to start using actual long-term weather data rather than a synthesized weather data set. An investigation of any long-term trend of the annual data to investigate any impacts of climate change is not included in this paper.

ABSTRACT

The paper reflects the development of building energy performance legislation in Latvia and shows the current general requirements of Latvian building codes relating to building energy performance. Paper explores the possibility of implementation of Directive 2002/91/EC in Latvia, taking as an example trial buildings energy certification and labeling projects held in Ogre town in 2002-2006. These projects provided the opportunity to develop and examine in Latvia two schemes of building energy certification and labeling. The results of these projects are shown in the paper as well.

INTRODUCTION

Housing resources in Latvia are significantly growing up now. Since 1990 till 2005 the increase of housing area had reached 3.5 millions m^2. Until the end of 2002 it was possible to construct buildings in accordance with USSR building codes, which allowed poor insulation quality. Due to low buildings' energy performance the heat consumption of residential sector in 2003 took 74% of all produced heat. In order to improve that situation Latvian Building Code LBN 002-01 *"Thermal performance of building envelope"* [1] was prepared and came into force on January 1, 2003.

Since Latvia in May 2004 became a member state of the European Union it undertook the obligations to implement all EU legislation, including the requirements in the area of the energy efficiency of the buildings.

Currently Latvia is under the obligation to implement the requirements of the Directive 2002/91/EC on the energy performance of buildings [2]. According to that directive all member states of the European Union have to introduce buildings' energy performance certification. The directive does not forbid member states to implement their own buildings' energy certification schemes as no common methodology can be developed in so short time.

The implementation of this directive had to be done until 4th January 2006. Practically full transposition of the requirements of the directive in Latvia could be achieved not earlier than by the end of 2007. Until 2008 Latvia has to improve the existing legislation and to develop the new building codes in order to improve energy efficiency of buildings and to meet the requirements of the directive.

CURRENT LEGISLATION ON ENERGY PERFORMANCE OF BUILDINGS

Until the end of 2002 it was still possible to construct buildings in Latvia following the requirements of the outdated soviet building code – SniP II-3-79** "Building heat engineering" [3]. According to this code the average heat transfer coefficient of external walls was 1.25 (m^2·K)/W. At the beginning of 2006 the part of buildings which were constructed pursuant to SniP II-3-79** took 75% of all constructed buildings in Latvia or 3.5 millions m^2. Due to the poor quality of buildings' insulation properties the average total heat consumption of Latvian dwelling buildings at the end of 1999 was 250 kWh/m^2 [4] and hot water part took 56% of total heat consumption.

The municipality of Riga city adopted and on January 1, 2000 implemented the rules that provide for the installation of individual heat substations with heat meters in all the buildings. That measure was aimed at the reduction of heat consumption of buildings. The replacement of heat substations has resulted in reduction of buildings' annual specific heat consumption by 10, 52 % [4]. Nevertheless, it should be noted that such measure was successfully implemented only in one town of Latvia and the installation of individual heat substations by itself does not improve the thermal quality of the existing buildings.

The first step in order to improve situation in the field of energy efficiency of buildings at the scale of whole Latvia was developing of Latvian building code LBN 002-01 "Thermal performance of building envelope". This building code came into force on January 1, 2003 and it is mainly based on EN and ISO standards adapted to Latvian conditions. Since then the requirements to heat transfer coefficients for separate parts of buildings' envelope became at least three times better comparing to the previous building code SniP II-3-79**. The Latvian building code LBN 002-01 has radically changed the approach to the limiting of building heat losses. Instead of limitation of only thermal transmittance for the particular building elements it uses also the concept of reference building. The building heat losses should not exceed building heat losses of normative reference building:

$$H_T \leq H_{TR}\,, \qquad (1)$$

where: H_T - building heat loss coefficient, W/K and H_{TR} - building heat loss coefficient of reference building, W/K.

According to LBN 002-01 the reference building is built using the normative values of heat transfer coefficients of building's elements and external glazing of building takes ≤ 20% of the floor area. The heat transfer coefficients of real building's elements can be smaller or higher than the normative values but not higher than maximal level of heat transfer coefficients. The normative and maximal values of heat transfer coefficients according to requirements of LBN 002 - 01 "Thermal performance of building envelope" are given in Table 1. The external glazing of building can also be more or less than 20% of the floor area. The main requirement is that the heat loss coefficient of designed building must be in conformity with Equation 1.

Table 1. Normative and maximal values of heat transfer coefficients in LBN 002-01, $W/(m^2 \cdot K)$

Building element	Dwelling houses		Public buildings		Industrial buildings	
	U_{RN}	U_{RM}	U_{RN}	U_{RM}	U_{RN}	U_{RM}
Roofs and slabs that are in contact with outside air	0,2κ	0,25κ	0,25κ	0,35κ	0,35κ	0,5κ
Slab on ground	0,25κ	0,35κ	0,35κ	0,5κ	0,45κ	0,7κ
Walls with ρ<100kg/m^3	0,25κ	0,30κ	0,35κ	0,4κ	0,45κ	0,5κ
Walls with $\rho \geq$100kg/m^3	0,3κ	0,40κ	0,4κ	0,5κ	0,5κ	0,6κ
Windows, doors and glassed walls	1,8κ	2,7κ	2,2κ	2,9κ	2,4κ	2,9κ

Although new Latvian building code will have great effect on building energy performance it cannot be called an energy performance regulation as it deals only with one of the factors – building transmission heat loss. It is only the first step in the process of determining the mandatory value of Building Energy Performance. Taking into account that fact, it was decided to improve this Building Code. The last changes in LBN 002–01 were done in September 2006. According to the new requirements of LBN 002–01 the energy performance of each new designed building should be estimated.

For the evaluation of energy performance of new designed and reconstructed buildings the modified LBN 002–01 uses the specific heat losses coefficient which is calculated for standard climatic conditions according to LBN 003–01 "Building climatology". The specific heat losses coefficient is calculated according to the following equation:

$$e_G = E_{\Sigma G} / L, \quad kWh/m^2, \qquad (2)$$

where: A- heated built-in area, m^2 and $E_{\Sigma G}$ – building total estimated annual heat consumption in standard climatic conditions, kWh.

Building total estimated annual heat consumption is calculated as following:

$$E_{\Sigma G} = H_T \times T_{gd} \times 24 \times 10^{-3}, \text{ kWh}, \qquad (3)$$

where: T_{gd} - number of the degree-days of standard year.

The implementation of specific heat losses coefficient in Latvian normative base was the first step in creation of energy effective legislation in Latvia. Although that was not enough in order to implement the requirements of Directive 2002/91/EC. For that purpose the energy certification scheme for new and existing buildings should still be developed. Currently Latvian government works out the drafts for two new building codes, which will provide the requirements for the evaluation of energy performance of buildings.

FUTURE DEVELOPMENT OF LATVIAN BUILDING CODES

In order to create the normative basis for the evaluation of energy performance of new and existing buildings Latvian government prepared the draft of Law on energy efficiency. The main aim of this law is to create energy awareness of buildings' inhabitants and to reduce CO^2 emission. The draft legislation determines only general requirements for buildings' energy efficiency. According to these requirements buildings' energy efficiency is calculated on the basis of the following criteria: heat transfer coefficient of buildings' elements, parameters of heating, hot water and air conditioning systems, data on lighting, location of building, climatic conditions and indoor air parameters.

For existing buildings proof of energy efficiency (energy certificate) is calculated by district energy inspectors and for new and reconstructed buildings this document is prepared by buildings' designer. The energy certification for all buildings in Latvia should be done in three years period after the adoption of Law on energy efficiency. In order to implement this law it is necessary to choose the scheme of energy certification for existing and new buildings. At the moment there exist two buildings' energy certification schemes for existing buildings in Latvia.

The first scheme for energy certification of existing buildings on the basis of really measured energy consumption was created in 2000 by Institute of Heat, Gas and Water Technology of Riga Technical University [5]. This scheme is based on unique criteria – *standardized specific heat consumption* which takes into account only energy consumption for space heating and hot water supply. In order to improve this scheme in accordance with requirements of Directive 2002/91/EC the existing criteria was extended by electricity and gas consumptions [6]. The new energy certification criteria - standardized specific energy consumption is calculated using the following equation:

$$q_{st} = \frac{q_{heat} G_{st}}{G} + \frac{\left(q_{hw} + q_{el.} + q_g\right) A}{30n} + q_{el.c} \text{ , kWh/m}^2, \quad (4)$$

where: q_{st} – standardized total heat consumption, kWh/m^2 per year; q_{heat} – measured actual annual specific heat consumption for space heating, kWh/m^2 per year; q_{hw} – measured actual annual specific heat consumption for hot water needs, kWh/m^2 per year; G_{st} - number of degree-days in a standard year ; G - number of degree-days in a rating year; A – total heated space, m^2; *30* – standardized occupancy level, m^2/person; n – actual number of occupants, persons; $q_{el.}$ – electricity consumption of for household needs, kWh/m^2 per year; $q_{el.c}$ - electricity consumption for common utilities, kWh/m^2 per year; q_g – gas consumption, kWh/m^2 per year.

The developed energy certification scheme is based on results of the research on Latvian building energy consumption and it fits to Latvian climatic conditions. For development of structure of the energy certification scale the energy consumption of 488 buildings was analysed during the six year time period. The structure of the energy certification scale was harmonized with GBC2000 concept. The numerical values of the scale are based on two main consumptions: common energy consumption and best present consumption for which the level of LBN 002-01 was used. Energy consumption of all other levels can be found in Table 2 [6].

The second scheme for energy certification of existing buildings is proposed by State Dwelling Agency. This scheme is based on the principles of energy certification introduced in Denmark [7]. The rating scale for energy certification proposed by Dwelling Agency is shown in Table 3.

Table 2. The rating scale of buildings' energy certification by total energy consumption

Nr.	Description	Energy rating		Values, kWh/m^2·year
5	25% better than 3 level		Gold certificate	=125
4	10% better than 3 level		Silver certificate	=149
3	Best present consumption	A	Excellent	149.01-166
2	3 level +1/3(0 level - 3 level)	B	Very good	166.01-201
1	3 level +2/3(0 level - 3 level)	C	Good	201.01-235
0	Common consumption	D	Fair	235.01-270
-1	0 level +1/2(-2 level - 0 level)	E	Bad	270.01-313
-2	Worst consumption	F	Very bad	>313.01

Table 3. The rating scale of buildings' energy certification proposed by Dwelling Agency

Energy rating	Heat consumption, kWh/m^2	Water consumption, m^3/m^2	Electricity, kWh/m^2	CO^2, kg/m^2
A	0 – 95	0 – 0.6	0.0 – 12.6	0.0 – 17.0
B	95 – 111	0.6 – 0.7	12.6 – 15.8	17.0 – 25.6
C	111 – 126	0.7 – 0.8	15.8 – 19.0	25.6 – 34.1
D	126 – 143	0.8 – 1.0	19.0 – 22.1	34.1 – 42.6
E	143 - 159	1.0 – 1.1	22.1 – 25.3	42.6 – 51.1
F	159 – 175	1.1 – 1.3	25.3 – 28.4	51.1 – 59.7
G	175 – 190	1.3 – 1.4	28.4 – 31.6	59.7 – 68.2
H	190 – 206	1.4 – 1.5	31.6 – 34.8	68.2 – 76.7
I	206 – 222	1.5 – 1.7	34.8 – 37.9	76.7 – 85.2
J	222 – 238	1.7 – 1.8	37.9 – 41.1	85.2 – 93.8
K	238 – 254	1.8 – 2.0	41.1 – 44.2	93.8 – 102.3
L	254 – 270	2.0 – 2.1	44.2 – 47.4	102.3 – 110.8
M	≥270	≥2.1	≥47.4	≥110.8

According to this scheme of energy certification all Latvian existing buildings belong to rating less that "F". The reconstruction works of Latvian buildings in order to improve energy rating till "A" or "B" will be economically inexpedient. According to Latvian building code LBN002-01 the heat consumption of new buildings should be not higher that 145 kWh/m^2 – that is equal only to rating "E" pursuant to the scheme of Dwelling Agency. It should also be taken into account that prEN 15217 "*Energy performance of buildings - Methods for expressing energy performance and for energy certification of buildings*" provides for only seven energy classes from "A" to "G".

The general standards for energy certification are still not fully developed at the European level. The adoption of EN standards will be useful for all European member states, creating united approach to buildings' energy certification.

RESEARCH ON ENERGY PERFORMANCE OF EXISTING BUILDINGS IN LATVIA

In order to study the energy consumption of existing buildings and to test energy certification scheme proposed by Riga Technical University the trial energy certification project "ENCERB" was held in Latvia in 2004-2006. In the framework of this project the total energy consumption of 139 multi-storey apartment buildings with total area of 354 265 m^2 was analysed. This project was implemented with the support of EU LIFE programme in Ogre town.

The main energy certification indicators of the buildings examined during the project are given in Table 4.

Table 4 Main energy certification indicators of buildings

Indicator	2004/2005	2005/2006	Absolute differences	Difference, %
Degree days	3816.3	3978.7	162.4	4.3
Total energy performance of buildings, kWh/m^2	211.74	213.08	1.34	0.63
Standardized annual specific energy consumption, kWh/m^2	225.02	224.03	-0.99	0.44

In order to promote building energy certification and create energy awareness among inhabitants, it was decided to use buildings' energy labels. These labels were placed on buildings visible for all inhabitants. Anyone interested could easily study building's energy rating in comparison with other buildings.

The numeric values of changes in the categories of the energy consumption of the buildings during energy certification are given in Table 5.

Table 5.Comparison of the categories of the energy performance of the buildings

Category	A	B	C	D	E	F	Total:
Number of buildings in 2004/2005	0	18	80	37	4	0	139
Proportion, % in 2004/2005	0	12.9	57.6	26.6	2.9	0	100.00
Number of buildings in 2005/2006	0	20	81	36	1	1	139
Proportion, % in 2005/2006	0	14.36	58.3	25.9	0.72	0.72	100.00

The comparison of the categories of the energy performance of the buildings has revealed that in 2005/2006 the energy consumption of the buildings has been slightly reduced, since the number of the buildings rated "A" and "B" has been increased. When compare the energy consumption of the buildings in 2004/2005 and 2005/2006 one can see that the energy consumption has been increased only in one building.

The implementation of energy certification scheme proposed by Riga Technical University in Ogre town has let to create correct image of buildings' energy consumption and it gave the possibility to draw attention of inhabitants to buildings energy consumption, stimulating them to improve energy efficiency of buildings.

CONCLUSIONS

1. Until the end of 2002 it was still possible to construct buildings in Latvia following the requirements of the outdated USSR building code – SniP II-3-79** "Building heat engineering".
2. By the beginning of 2006 the part of buildings which were constructed pursuant to SniP II-3-79** took 75% of all constructed buildings in Latvia or 3.5 millions m^2. Due to the poor quality of buildings' insulation properties the average total heat consumption of Latvian dwelling buildings at the end of 1999 was 250 kWh/m^2.
3. The introduction of specific heat losses coefficient in Latvian building code LBN 002-01 "Thermal performance of building envelope" was the first step in creation of energy effective legislation in Latvia. Although that was not enough in order to implement the requirements of Directive 2002/91/EC.
4. In order to create the normative basis for the evaluation of energy performance of new and existing buildings Latvian government prepared the draft Law on energy efficiency. At the moment this law could not be implemented due to the lack of adopted energy certification scheme in Latvia. But it should be admitted that standards for energy certification are still not fully developed also in Europe. The adoption of EN standards will be useful for all European member states, creating united approach to buildings' energy certification.
5. The trial implementation of energy certification scheme introduced by Riga Technical University had shown that great majority of Latvian buildings belong to rating "C". The positive effect of implementation of energy certification scheme can be achieved using also energy labels.

SUMMARY

The EC Directive on Energy Performance of Buildings created a challenge for all Member States, especially in sense of adoption of new requirements and calculation methodology. This paper describes the Polish experts' solution. It has been suggested that the distinction between energy performance requirements and determination of building energy class should be introduced to Polish regulation. Two levels of requirements are considered: first regulation of gains and losses and second regulation on efficiency of hot water preparation and lighting efficiency. Assignment of energy class for particular building is proposed in relation to reference building and expressed by dimensionless integrated energy performance indicator WZE. The WZE is normalized in a sense that its value equal to 1 represents the building energy performance identical to the reference building. The methodology takes into account different impact of energy sources on environment by utilization of weightings representing specific energyware.

INTRODUCTION

All the Member States have faced a challenge related to implementation of the Directive EC/91/2002 on energy performance of buildings (EPBD) [1]. The implementation deadline has been met by some of the countries, whereas the others were delayed due to the different reasons. Poland is among the countries which asked for an extension time.

Implementation of requirements settled by European Directives is obligatory for all the member states but the way chosen is entirely left for the national decisions. To support harmonization of implementation towards Europe the Commission mandated CEN to prepare set of new standards supporting objectives of Directive.

In Poland, works on implementation of EPBD have been voluntarily undertaken by Association of Energy Auditors (non-profit organization of public benefit) in 2004. Five working groups have a structure reflecting typology of energy performance problems identical as in the CEN Umbrella document [2]. The idea was to follow the new CEN standards (also on a stage of project) as close as it was possible in order to facilitate harmonization with EU standardization in a future. The final proposal of the scope and form of energy certificate was a compromise between requirements of the drafts of standards and ability of its adaptation (lack of energy inventory of buildings and related metrological data). Once, after few years of assessment system operation, such a data will become available this fact should be easily taken into account in a process of updating the regulations. The method proposed [3] - has an additional advantage – it can be used along with changing energy performance requirements. It uses concept of reference buildings and introduces dimensionless indicator for the assessment which is not entirely in line with recommendation of the indicators proposed by prEN 15217 Energy performance of buildings - Methods for expressing energy performance and for energy certification of buildings [4]. Further, there was a clear agreement of the stakeholders that the assessment should follow asset rating instead the operational rating.

METHODS

Requirements and Energy Performance

Among the others the basic Directive aims are:

1. Establishment of new (more demanding) energy performance requirements, taking into account their updating according to changes in technological and economical circumstances;
2. Adoption of calculation methodology comprising elements of energy balance described in the Annex to the Directive.

These aims are obligatory for all member states both old and new ones. In spite of acceptance of the Directive before the extension of EU there was no any additional transition period foreseen for new members. However there are many projects financed by EIE program focused on different issues of EPBD. Concerted Action, the project dedicated to information exchange among the national experts working on Directive implementation is the example of the EC help to MS. All these projects showed a variety of approaches taken by the countries, but they also are indicating European efforts towards harmonization of setting requirements procedure and methodology of calculation. For illustration of the span of approaches, the energy performance as the term is differently understood across the Europe. Some of the countries are assigning to this term energy delivered or equivalent emission whereas the others are taking heat losses or gains. Detailed description of the approaches is provided in report of ENPER [5], the Proceedings of International Conference on the Energy Performance of Buildings, Brussels, September, 2005 [6].

Determination of Energy Performance Indicator

The distinction between energy performance requirements and determination of building energy class was introduced in Polish regulation. In regards to requirements, two levels are considered: first regulation of gains and losses and second regulation on efficiency of hot water preparation and lighting efficiency. Assignment of energy class for particular building is proposed in relation to so called reference building and expressed by dimensionless indicator called integrated energy performance indicator *WZE*. The *WZE* is not a subject of regulation - requirements; it is a result of application of partial lower level requirements. Integrated energy performance indicator (*WZE*) is described by Eqn.1.

$$WZE = N_g \cdot f_g + N_w \cdot f_w + N_o \cdot f_o + N_{ch} \cdot f_{ch}, \quad (1)$$

where coefficients N represents a level of requirements fulfilment (ratio of energy use in analyzed building to reference building) according to heating and ventilation, hot water, lighting and cooling that is denoted respectively by subscripts “*g*”, “*w*”, “*o*” and “*ch*”. The coefficients *f* describe share of energy use for specific purposes versus an overall energy use *Q*, taking into account whole building or analyzed operational zone (e.g. apartment) (eqn 3).

$$f_g = \frac{\sum_i \left(w_i \cdot \sum_j E_{gi,j} \right)}{Q} \qquad (2a)$$

$$f_w = \frac{\sum_i \left(w_i \cdot \sum_j E_{wi,j} \right)}{Q}, \qquad (2b)$$

$$f_o = \frac{\sum_i \left(w_i \cdot \sum_j E_{oi,j} \right)}{Q}, \qquad (2c)$$

$$f_{ch} = \frac{\sum_i \left(w_i \cdot \sum_j E_{chi,j} \right)}{Q}, \qquad (2d)$$

$$Q = \sum_i \left(w_i \cdot \sum_j E_{gi,j} \right) + \sum_i \left(w_i \cdot \sum_j E_{wi,j} \right) + \sum_i \left(w_i \cdot \sum_j E_{oi,j} \right) + \sum_i \left(w_i \cdot \sum_j E_{chi,j} \right), \qquad (3)$$

Summation by "*i*" is related to different sources of energy supplied to analyzed building. This summation takes into account different impact of energy sources on environment, weightings representing specific energyware w_i , are presented in table 1. Summation by "*j*" is related to a number of zones of specific operation (e.g. in case of heating "*j*" can indicate different temperature zones, in general number of zones within specific energy use can be different e.g. number of temperature zones can be different then the lighting zones). Symbols $E_{gi,j}$, $E_{wi,j}$ $E_{oi,j}$ $E_{chi,j}$ are denoting energy use for specific purposes in specific zone that is related to specific energy source.

Table 1. Weights assigned to energyware

Energyware	Weights (*w*)
Electricity (in Poland basically from coal burning)	2,5
Biomass	0,5
Solar, wind and geothermal energy	0
Other energywares	1

Table 2. Values of WZE indicator and related energy classes

	Values of *WZE* indicator	Energy class of building
	from 0 to 0,25	A
	from 0,26 to 0,50	B
	from 0,51 to 0,75	C
	from 0,76 to 1,00	D
	from 1,01 to 1,25	E
	from 1,26 to 1,50	F
	over 1,51	G

The *WZE* is normalized in a sense that its value equal to 1 represents the building energy performance identical to the reference building. The reference building is the building similar to assessed one in terms of shape, operational areas and, profiles of use but with components fulfilling minimum requirements for newly constructed building (e.g. *U* values), referenced system efficiencies, and energy weights equal to 1, except those used for media transport (eg. energy used for circulation pumps in heating system). To some extent *WZE* value indicates cost of energy in relation to the reference building. The *WZE* is divided by intervals representing the energy performance class of the building, table 2. Number of classes depends on marketing assumptions of energy assessment scheme. The values presented in table 2 are the proposals for case of Poland.

Determination of heating and ventilation component

Construction of heating and ventilation component in Eqn.1 can be done in the following steps:

1. Calculation of delivered energy demand E_g for each operational area of assessed buildings with respect to energyware, installation efficiencies, under standard use and weather. Calculation of net energy is performed according to Polish standard, but the intention is to use CEN EN 13790 [7] after its adaptation to Polish building stock features
2. Same as in p.1 but done for reference building E_{gr} with defined installation efficiencies in regards to production, distribution and regulation, as well as reference weights (basically equal 1).
3. Finally, the component N_g of Eqn.1. can be calculated according the formula:

$$N_g = \frac{\sum_i \left(w_i \cdot \sum_j E_{gi,j} \right)}{\sum_i \left(w_{r,i} \cdot \sum_j E_{gri,j} \right)} \qquad (4)$$

Energy demand for hot water preparation

Use of hot water depends on particular needs and therefore is not regulated in requirements. The only regulated requirements are efficiencies of 1 m^3 of hot water preparation and distribution, [8]. Calculation of hot water component of Eqn. 1:

$$N_w = \frac{\sum_i \left(w_i \cdot \sum_j E_{w1\,i,j} \right)}{\sum_i \left(w_{r,i} \cdot \sum_j E_{w1r\,i,j} \right)} \qquad (5)$$

where: *w* is energy weights, E_{w1} and E_{w1r} energy for m^3 of hot water preparation in assessing and in reference buildings. Equation 5 shows the level of fulfilment of energy performance requirements expressed in energy needed for 1 m^3 of hot water.

Moreover, for the purpose of energy class assignment some averages of hot water demands are listed in regulations as but just for use in calculation procedure of f_w coefficient. At the same time, for information purposes it is possible to estimate energy used for hot water in reference building.

Lighting component

Basic mean of energy reduction for lighting is application of energy efficient hardware. Thus, as the measure of lighting system efficiency for regulation purposes the specific corrected capacity of lighting unit W/(m^2·100 lx) is proposed, [9]. Again, the same approach as for hot water is applied, the regulation refers to technical solutions not to the use of lighting.

The coefficient of fulfilment of lighting energy requirements N_o for Eqn.1 is the ratio of weighted averages of the specific capacity of assessed and referenced lighting systems in the whole building. The averages are weighted by areas of different lighting demands. The referenced specific capacities vs. light fluxes for different lighting purposes are listed in the regulation.

Determination of coefficient f_o requires estimation of energy use for lighting. This can be done if a capacity of the unit and the operating time are known. The basic formula applied for this purpose is taken from the PrEN 15193: Energy performance of buildings — Energy requirements for lighting, [10] in GJ/year:

$$E_O = 3{,}6 \cdot 10^{-6} \left(\sum_j \left(P_{p,j} \cdot t_{p,j} \right) + \sum_j \left(P_j \cdot t_{u,j} \right) \right), \quad (6)$$

where $P_{p,j}$ is total installed capacity of emergency lighting units, W; $t_{p,j}$ is time of operation of emergency lighting units in a year, h/r; P_j is total installed capacity of built in lighting units W; $t_{u,j}$ is time of operation of built in lighting units in a year, h/r ; Summation on „j” goes over lighting zones.

RESULTS

Some analysis of buildings using energy performance indicator *WZE* has already been done. Very interesting study analysed school buildings in one of the towns in southern Poland [11]. The figure 1 presents the comparison of estimations of *WZE* with integrated energy characteristics EA according to Display campaign [12]. The figure presents pretty good correlation between these two methods (R^2= 0.6935). *WZE* indicator turned to be more generous for buildings that used renewable energy. Figure 2 presents changes of energy performance indicator *WZE* due to thermomodernization of schools. The modernization of schools reduced initial values of *WZE* by 10 to 70 % and in vast majority of cases reduced values of *WZE* below 1.

The proposal of Polish certificate counts four pages and covers information on energy use for all purposes for the assessed and reference buildings along with recommendation about potential improvements as well as graphical presentation of energy performance indicator WZE. The example for thermomodernized apartment building (no air conditioning) is presented below on Figure 3.

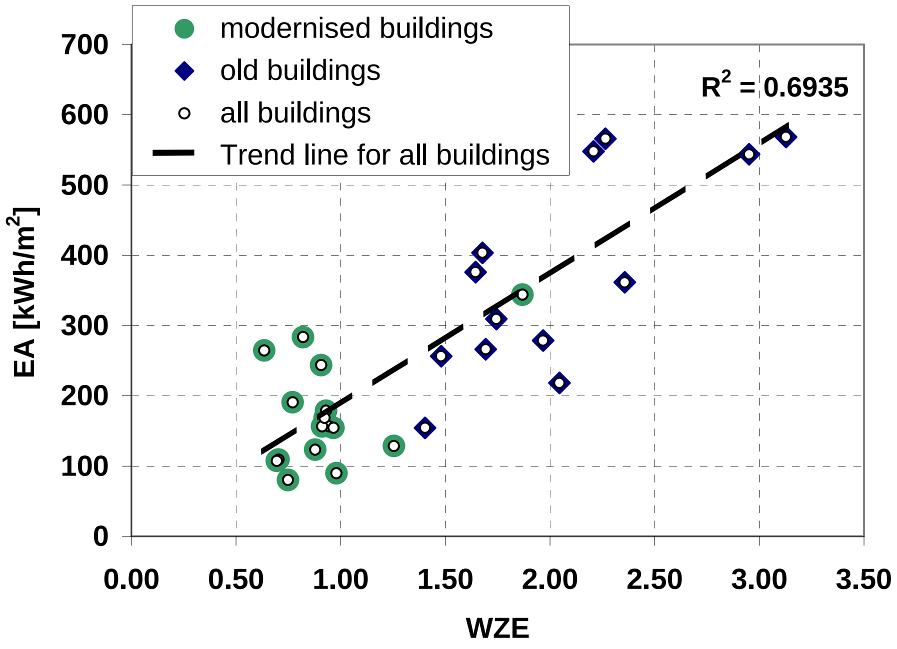

Figure 1. The comparison of energy performance of building evaluated using energy performance indicator *WZE* and integrated energy characteristics EA according to Display campaign [11].

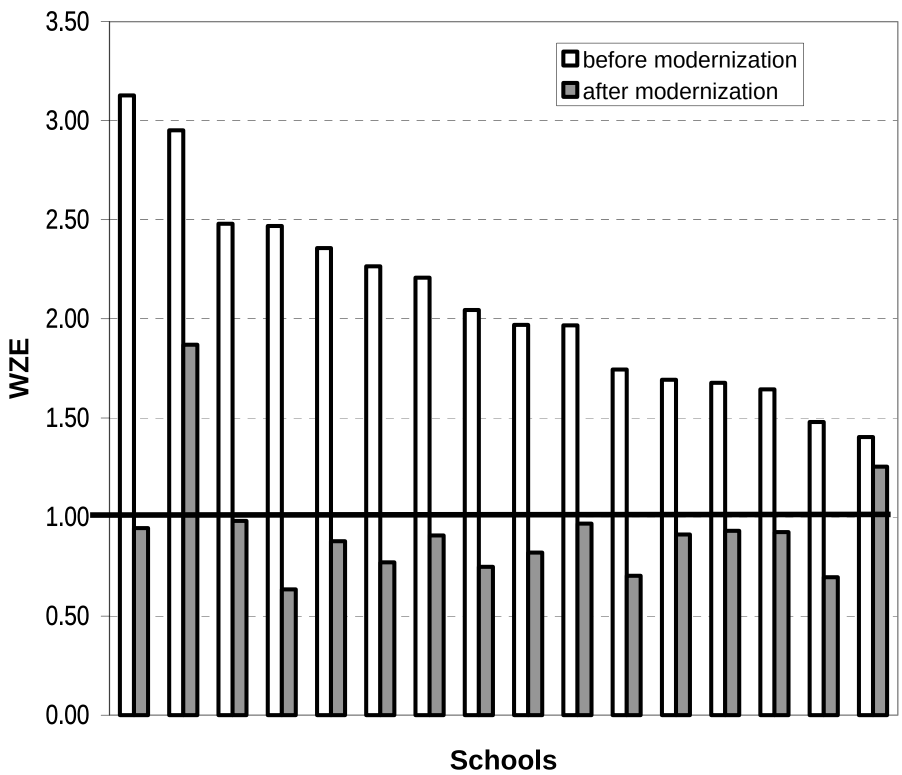

Figure 2. The change of energy performance indicator *WZE* for thermodedernized schools [11].

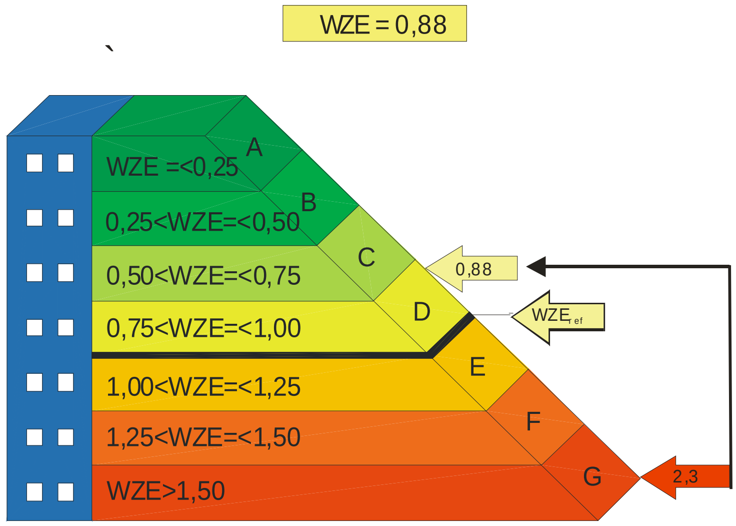

Figure 3. Label from energy certificate showing improvement of energy standard

The label on Figure 3 indicates strong improvement of building standard due to thermomodernization. *WZE* value has been changed from 2,3 to 0,88 that means the energy cost in building after investment is reduced approximately 2,6 times and finally is 12% lower then maximum normalized cost in similar newly constructed building (the reference building). Concept of reference buildings requires that reference values of all components influencing energy performance of buildings are specified.

DISSCUSSION

Presented method of determining integrated energy performance indicator and related to it energy class assignments are the basis for preparation of energy certificate according to the directive on energy performance of buildings. It is important that energy certificate can be elaborated for every type of building for which delivered energy and hot water requirements are estimated. For others types of building than apartment one the components of Eqn.1 related to lighting and cooling can be easily taken into account. Reference building concept made this approach general and easy to interpret (*WZE*=1 denotes the building fulfilling maximum/minimum permissible values with energy supplied from reference source).
Low values of *WZE* (< 1) indicates that buildings components have better parameters than reference ones or/and efficiencies of the systems are better than reference ones or/and energy source is more ecological than reference one. The *WZE* concept has moved the regulation requirements towards partial regulations (building components oriented). Energy class of a building is a resultant of partial requirements and technological solutions of installations.
Of course some Polish energy engineers are afraid that WZE calculations are more time consuming (analysed building is evaluated twice), however special software with data reference values base could solve this problem. Other doubts are associated with the fact that energy performance indicator *WZE* is not sensitive to building shape and allow architects to design buildings with low area to volume ratio.

The contradictory approach where the energy performance requirements are expressed in terms of energy or emissions normalised over the building area is undertaken is some countries. This gives even more freedom in architectural, constructional and material choices in extreme it would be acceptable to erect poor buildings entirely supplied by renewable.

Therefore, energy performance requirements are usually accompanied by additional regulations related to building components. Moreover, the requirements using energy terms needs detailed database of energy use along with coincident weather and profile of building use to decide about the energy class. In the absolute scale school without pool will be better ranked that one with it. Thus, very often, the typology of buildings is introduced, which means necessity of preparing number of scales related to number of identified building types and their equipments. In case of multi purpose buildings (eg. multifamily residential building, with shops on the first floor and restaurant on the roof level) the situation is extremely difficult to solve. Moreover as new CEN standards introduce the concept of different indoor environment categories the number of scales should by multiplied by number of indoor environment categories e.g. 3. If not buildings that use additional energy for creation of higher level of indoor environment would be punished by low energy performance category.

ACKOWLEGEMENT

The concept of energy performance indicator *WZE* has been developed by group of volunteers form Association of Energy Auditors. The work was cosponsored by the Ministry of Construction (formerly Ministry of Transportation and Construction).

SUMMARY

It is a fact that today in Cyprus there are no building-regulations concerning thermal insulation of the building envelope and consequently no restriction exist regarding energy performance. After joining the EU in May 2004, Cyprus has to comply with various directives of the Union. One of them is the Directive on the Energy Performance of Buildings 2002/91/EC. In order to comply with this requirement, a special committee was formed for the development of the required methodology and software to be used for this purpose. The objective of this paper is to present the methodology and program developed and its characteristics together with the type of output the user is expected to get. Considering that Cyprus is fully dependant on imported energy, it is believed that this new directive will lead to energy efficient buildings, and in the long run it will benefit the economy of the island.

INTRODUCTION

Today there are no building-regulations concerning thermal insulation of the building envelope in Cyprus and consequently no restriction exist regarding energy performance. After joining the EU on 1st May 2004, Cyprus has to comply with various directives of the Union. One of them is the Directive on the energy performance of buildings 2002/91/EC [1]. In order to comply with this requirement, a special committee was formed under the Ministry of Commerce, Industry and Tourism for the development of the required methodology and software to be used for this purpose. These are mostly based on the CEN/TC 89 'Energy performance of buildings – Calculation of energy use for space heating and cooling' [2] and the Cyprus standard CYS 98: part 1 published in 1999 on thermal insulation and rational use of energy in domestic buildings [3]. After a short description of the methodology the program developed for this purpose is described.

METHODOLOGY

The field of application of the present methodology covers both new residential buildings and new buildings that are not used as residences with floor area less than 1000 m^2, without central system for air treatment. The objective of the methodology is to establish the way and the standards that should be followed for the calculation of the energy performance of buildings as it is determined in the field of application, aiming to:

- Achieve indoor comfort conditions and ventilation requirements that will ensure the quality of the air inside the building and the hot water production requirements with the minimum possible consumption of energy.

- Avoid or minimize any pathological situations in respect of structural elements, arising from internal condensation, having negative effect on the durability of the structural elements and the quality of the air inside the building.

Despite its small size Cyprus has variable and distinctive weather patterns. For the purpose of this methodology, four climatic zones are set in the island; seaside, inland, semi-mountainous and mountainous as shown in Fig. 1. These zones were set according to the climatic data available from the Cyprus Meteorological Service.

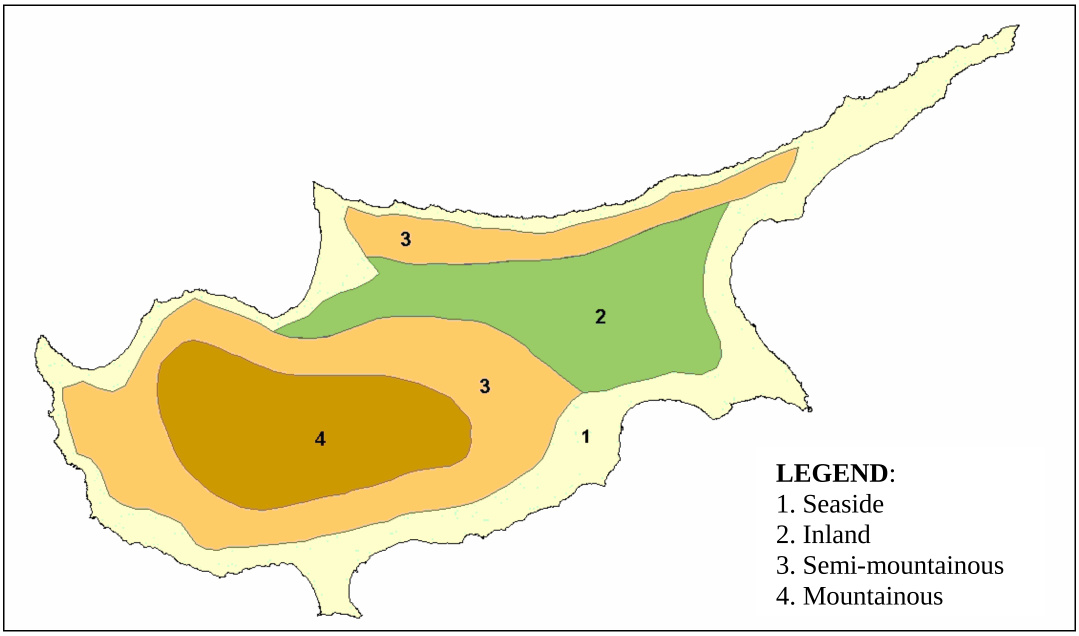

Fig. 1 Map of Cyprus showing the four climatic zones

Restrictions in the annual nominal useful energy needs and total annual consumption.

The annual nominal useful energy needs for heating a building, N_{ic}, examined with the present methodology, considering its form, thermal characteristics of the structural elements of its shell and the useful thermal gains from solar radiation entering the building, **should not exceed** the annual nominal useful energy needs for heating of the reference building, $N_{i.}$

Similarly, the annual nominal useful energy needs for cooling a building, N_{vc}, examined with the present methodology, considering its form, thermal characteristics of the structural elements of its shell and the thermal load from solar radiation entering the building, **should not exceed** the annual nominal useful energy needs for cooling of the reference building, N_v.

No restrictions are applied for the annual nominal useful energy needs for hot water production, N_{ac}.

The total annual consumption in primary energy of the building, N_{tc} in toe/m^2 per year, should not exceed the maximum allowed value of the total annual consumption in primary energy, N_t, as this is determined in the decree for the requirements of minimum energy efficiency, published by the Minister of Commerce, Industry and Tourism according to the law. This is calculated by adding the annual load for heating, cooling and hot water by multiplying each by its annual utilization factor (F_{pu}) and dividing by the equipment efficiency (η):

$$N_t = \frac{N_i F_{pui}}{\eta_i} + \frac{N_v F_{puv}}{\eta_v} + \frac{N_a F_{pua}}{\eta_a}, \qquad (1)$$

The annual nominal useful energy needs for heating and cooling the reference building should be achieved by using the following parameters:

1. Reference values of the thermal transmittance (U_{ref}) of the structural elements of the building that separate the building from the external environment or from areas not being air-conditioned or from other buildings attached to them.
2. Reference value for the solar factor ($g\perp_{ref}$).
3. 20% of the ratio of the area of the openings to the useful floor area.

The values presently applied are shown in Table 1.

Table 1 Reference values

Parameters	**Value**
Thermal Conductance of the roof, $U_{ref\text{-}roof}$	0.9 W/m^2 °C
Thermal Conductance of the walls, columns and beams, $U_{ref\text{-}walls}$	0.9 W/m^2 °C
Thermal Conductance of the exposed floor, $U_{ref\text{-}floor}$	0.9 W/m^2 °C
Thermal conductance of the openings, $U_{ref\text{-}openings}$	4.5 W/m^2 °C
Solar factor of the glazing, $g\perp_{ref}$	0.655
Note: The above values are subjected to periodical revision according to the decree for the requirements of minimum energy efficiency, published by the Minister of Commerce, Industry and Tourism according to the law.	

Each building should satisfy and not exceed the minimum requirements of the thermal characteristics of the building's shell as these are determined in the decree for the requirements of minimum energy efficiency, published by the Minister of Commerce, Industry and Tourism according to the law. The present values are shown in Table 2.

Table 2 Minimum requirements

Parameters	**Value**
Thermal Conductance of the roof, $U_{min\text{-}roof}$	1 W/m^2 °C
Thermal Conductance of the walls, columns and beams, $U_{min\text{-}walls}$	1 W/m^2 °C
Thermal Conductance of the roof, $U_{min\text{-}floor}$	1 W/m^2 °C
Thermal conductance of the openings, $U_{min\text{-}openings}$	5 W/m^2 °C
Note: The above values are subjected to periodical revision according to the decree for the requirements of minimum energy efficiency, published by the Minister of Commerce, Industry and Tourism according to the law.	

As this is the first implementation of this procedure, these factors are high enough compared with other Member States in order not to disturb the building industry. They will however be updated (possibly lowered) at least every 5 years.

Indoor comfort conditions are determined as follows:

1. The buildings should retain constant indoor temperature at 20°C for the heating period and 24°C for the cooling period.
2. The number of indoor air renewal, that will ensure its quality and comfort conditions, should not be less than 0.6 renewals per hour, which should be achieved naturally under usual conditions of operation (without mechanical ventilation).
3. For the consumption of hot water, 40 liters per person per day at the temperature of 37°C is considered (make-up water supply temperature of 15°C).

Calculation of annual nominal useful energy needs for heating, N_{ic}

The energy needs for heating of a building is the quantity of energy that is required in order to maintain the internal temperature constant during the period of heating. These needs do not represent the real consumption of energy because the tenants of the buildings do not maintain the same conditions and do not use the building the same way. In practice, the real consumption would be different depending on the habits of the owners.

Nevertheless, the energy needs for heating of a building is an objective criterion for the comparison of its thermal characteristics; the bigger they are the colder will be the building during the winter period or the more will be the consumption of energy required for maintaining internal comfort conditions.

The energy needs for heating are calculated by the method of calculation that is determined by European Standard EN ISO 13790. An important simplification is that the building is considered as one zone with the same temperature in all the spaces.

The annual nominal useful energy needs for heating, N_{ic} in kWh/m^2, is the algebraic sum of the heat losses by the shell of the building, Q_t; the heat losses due to infiltration and ventilation, Q_v; and the useful heat gains, Q_{gu}, as a result of the lighting, the tenants, the equipment and the rate of solar radiation that enters the building through the openings:

$$N_{ic} = \frac{\left(Q_t + Q_v - Q_{gu}\right)}{A_p}, \qquad (2)$$

The heat losses by the shell of the building, Q_t concern the heat losses through the walls, columns, beams, openings, the roof and the floor, because of the temperature difference between internal and external temperature. These are given by the following equation in kWh:

$$Q_t = Q_{ext} + Q_{ina} + Q_{pe} + Q_{pt}, \qquad (3)$$

where Q_{ext} is the heat losses through the walls, columns, beams, openings, the roof and the floor in direct contact with the external environment; Q_{ina} is the heat losses through the walls, columns, beams, openings, the roof and the floor in contact with spaces that are not being heated; Q_{pe} is the heat losses through the structural elements in contact with the ground; and Q_{pt} is the heat losses through thermal bridges.

Heat losses through the walls, columns, beams, openings, the roof and the floor in direct contact with the external environment are given by the following equation in kWh:

$$Q_{ext} = \frac{U * A * DD * 24}{1000}, \qquad (4)$$

where U is the thermal transmittance (W/m^2 °C); A is the area of element, measured internally (m^2); and DD is the Degree Days.

Heat losses through the walls, columns, beams, openings, the roof and the floor in contact with spaces that are not being heated, are given by the following equation in kWh:

$$Q_{ina} = \frac{U * A * DD * 24 * \tau}{1000}, \qquad (5)$$

where $\tau = \frac{1-(\Theta_\alpha - \Theta_{atm})}{(\Theta_i - \Theta_{atm})}$; Θ_α is the temperature of the unheated space (°C); Θ_{atm} is the temperature of the external environment (°C); and Θ_i is the indoor temperature (°C).

The value of τ may be calculated with precision, using the method that is determined in the standard EN ISO 13789 or simply be considered as a conventional value taken by a table given.

Heat losses through the structural elements in direct contact with the ground, are given by the following equation in kWh:

$$Q_{pe} = \frac{(\psi_j B_j) * DD * 24}{1000}, \qquad (6)$$

where ψ_j is the linear factor of thermal conductivity of the structural element, j (W/m°C); and B_j is the internal perimeter of the floor and/or of the horizontal length of wall in contact with the ground j, internally (m).

Heat losses through thermal bridges, are given by the following equation in kWh:

$$Q_{pt} = \sum(\psi_j B_j) * \frac{DD * 24}{1000}, \qquad (7)$$

where ψ_j is the linear factor of thermal conductivity of the thermal bridge j (W/m°C); and B_j is the length of the thermal bridge j (m).

Heat losses due to infiltration and ventilation, are given by the following equation in kWh:

$$Q_v = \frac{\rho * Cp * R_{ph} * A_p * P_d * DD * 24 * (1 - \eta_v)}{1000}, \qquad (8)$$

where ρ is the density of air (kg/m^3); Cp is the specific heat of air (J/kg°C); R_{ph} is the number of air changes per hour (h^{-1}) depending on the position and the height of the building; A_p is the useful floor area (m^2); P_d is the mean internal height of the building (m); and η_v is the efficiency of heat recovery system.

Useful heat gains, Q_{gu} in kWh, as a result of lighting, occupants, equipment and the rate of solar radiation that enters the building through the openings are given by:

$$Q_{gu} = \eta * (Q_i + Q_s), \qquad (9)$$

where η is the utilisation factor of the heat gains (not all the heat gains are useful since a percentage can lead to internal overheat); Q_i is the internal heat gains; and Q_s is the heat gains due to solar radiation.

The utilization factor depends on the thermal inertia of the building and on the ratio between total heat gains and the total thermal losses of the building.

Internal heat gains, Q_i in kWh are given by:

$$Q_i = \frac{q_i * A_p * M * days * hours}{1000}, \qquad (10)$$

where q_i is the internal loads (W/m^2); A_p is the floor area (m^2); and M is the duration of the heating period in months.

Heat gains due to solar radiation, Q_s in kWh are given by:

$$Q_s = G_{sul} * \sum_j \left[X_j * \sum_n A_{snj} \right] * M, \qquad (11)$$

where G_{sul} is the mean monthly solar radiation on a 1 m^2 vertical surface of south orientation for the heating period (=108 kWh/m^2); X_j is the orientation factor of openings j; A_{snj} is the area of surface n, in orientation j, (m^2); j is the orientation; n is the number of surfaces in orientation j; and M is the duration of heating period in months.

It should be noted that angles of inclination of 60^o are considered vertical, otherwise they are considered horizontal.

The area A_s is calculated for each opening or group of similar openings, as far as glazing factor, solar protection and shading, are of the same orientation:

$$A_s = A * F_s * F_g * F_w * g_{\perp}, \qquad (12)$$

where A is the total area of openings (m^2); F_s is the solar obstruction factor due to shading caused by obstacles as other buildings, hills, trees, etc., other parts of the building, overhangs, verandas, and vertical obstacles and fins; F_g is the ratio of glazing area to the area of the opening; F_w is the correction factor for the glazing inclination; and $g_{\perp}$ is the solar factor of the glass at the vertical direction and indicates the percentage of solar radiation that passes through it.

The factor F_s has a range of values between 0 and 1, but in practice it cannot ever be less than 0.27 (characteristic percentage of diffuse radiation).

Calculation of the annual nominal useful energy needs for cooling, N_{vc}

As in the heating case, for cooling the real consumption would be different than the one estimated from this methodology, depending on the habits of the owners. Nevertheless, the cooling needs of a building is an objective criterion for the comparison of its thermal characteristics; the higher the cooling needs the hotter will be the building during the cooling period or the more will be the consumption of energy needed in order to maintain comfortable conditions. The cooling needs are calculated by the method of calculation determined by European standard EN ISO 13790. An important simplification is that the building is considered as one zone with the same temperature, like it happened for heating.

This methodology is the same with the methodology for the calculation of the heating needs. While for the heating period the non useful heat gains are responsible for overheating, for the cooling period are the ones causing cooling load and need to be removed.

The cooling needs of a building, N_{vc} in kWh/m^2, are calculated by the equation:

$$N_{vc} = \frac{Q_g(1-\eta)}{A_p}, \qquad (13)$$

where Q_g is the total cooling loads of the building, (kWh), given by Eq. (14); η is the utilisation factor of cooling loads; and A_p is the useful floor area (m^2).

$$Q_g = Q_1 + Q_2 + Q_3 + Q_4, \qquad (14)$$

where Q_1 is the cooling loads because of the exposure of each individual building element to the external environment (effects of temperature difference and incident solar radiation); Q_2 is the cooling loads due to the solar radiation entering the building through the openings; Q_3 is the loads due to infiltration and ventilation; and Q_4 is the internal loads due to the equipment, occupants and artificial lighting.

Cooling loads because of the exposure of each individual building element to the external environment (effects of temperature difference and incident solar radiation) in kWh are:

$$Q_1 = M * U * A * (\Theta_m - \Theta_i) + U * A\left(\frac{\alpha * I_r}{h_e}\right), \qquad (15)$$

where U is the thermal transmittance of each building element of the shell, (W/m^2 °C); A is the area of element, (m^2); Θ_m is the mean external temperature of the cooling period, (°C); Θ_i is the indoor temperature, (°C); α is the solar absorption factor of the external surface; I_r is the mean monthly solar radiation on each orientation, (kWh/m^2); h_e is the exterior factor of transport of heat (e.g. 25 W/m^2 K); and M is the duration of the cooling period in hours.

Cooling loads due to solar radiation entering the building through the openings in kWh are:

$$Q_2 = \sum_j \left[I_{rj} \sum A_{snj} \right], \qquad (16)$$

For the calculation of solar factor $g_\perp$ of the openings, the solar protection factor, $g_\perp$’, is taken into consideration as well. During the heating period this factor was ignored, which means that during winter, no solar protection is considered, e.g. shutters are assumed to be open allowing the building to benefit from the solar radiation entering through the openings (solar gain). On the contrary, because during the cooling period this is considered as load, solar protection is applied.

Loads due to infiltration and ventilation in kWh are:

$$Q_3 = Q_v, \qquad (17)$$

Internal loads due to the equipment, the occupants and artificial lighting in kWh are:

$$Q_4 = q_i * M * A_p, \qquad (18)$$

where q_i is the internal load in W/m^2.

Annual nominal useful energy needs for hot water production, N_{ac}

The annual nominal useful energy needs for hot water production in kWh are calculated by:

$$N_{ac} = \frac{M_{aqs} * Cp_{water} * \Delta T * \eta_d}{A_p * 3600 * 1000}, \qquad (19)$$

where M_{aqs} is the mean daily hot water consumption (lt); Cp_{water} is the specific heat of water (J/kg°C); ΔT is the temperature difference between cold and hot water, (°C); n_d is the number of days the building is occupied; and A_p is the useful floor area, (m^2).

Contribution of Renewable Energy Sources (RES).

The contribution of RES should be calculated and justified. For this purpose the contribution of RES systems can only be used if the systems or the equipment are certified according to the rules and existing legislation.

SOFTWARE

The software developed, which is currently in version 1.0, can be used for the estimation of the energy requirements of residential buildings and buildings up to 1000m^2 without centralized air conditioning system, for heating, cooling and domestic hot water. From the results obtained by using the software it can be decided whether a building fulfils the minimum energy requirements specified. According to the directive no building should be built without fulfilling the minimum energy requirements. Additionally, the results can be used for the issue of the energy performance certificate of the building.

The software estimates the energy requirements based on the envelope and orientation of the building. The software cannot be used for design purposes or system sizing. The building is considered as one zone. The software is user friendly and it is provided free to all engineers. The software has libraries of readymade structures and materials (walls, openings, slabs, roofs, floors, etc.) that can be found in buildings erected in Cyprus for the last 20 years, whereas the user has the capability to add a new structure not included in the libraries, under some circumstances. By choosing a city, a municipality or a village from a database the climatic conditions are automatically obtained based on the altitude of the area. Additionally the user can use U-value for walls, slabs, roof and openings up to the values specified in Table 2 (the program does not allow higher values).

The output of the program for a case investigated is shown in Fig. 2. As can be seen the building satisfies the criterion for the heating but not the cooling one. In this case the engineer should take various measures in order to reduce the cooling load such as, use better type of fenestration or improved wall insulation and if these are not enough, in cooperation with the architect, should try to reduce the glazing area, add overhangs, etc.

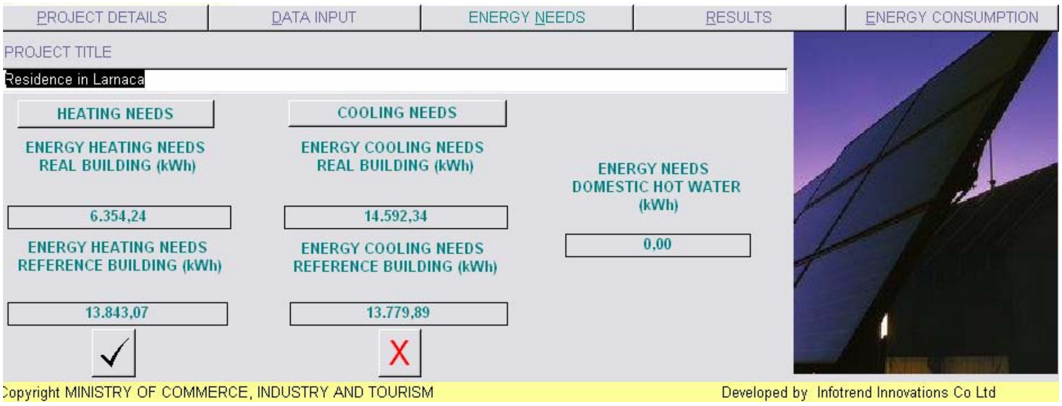

Fig. 2 Output of the software developed for the energy performance analysis of buildings

CONCLUSIONS

The methodology and program developed in Cyprus to satisfy the Directive on the energy performance of buildings is presented in this paper. It is believed by the authors that this methodology will improve the thermal performance of buildings in Cyprus as at the moment there are no building-regulations concerning thermal insulation of the building envelope. Considering that Cyprus is fully dependant on imported energy, it is believed that this new directive will lead to energy efficient buildings, and in the long run it will benefit the economy of the island. This will be more significant in a few years time as more strict minimum requirement will be imposed, not considered now in order not to upset the industry and the methodology will expand in new areas not covered at present (e.g. ventilation).

The simple hourly method of prEN 13790: a dynamic method for the future

Jean-Robert Millet

Centre Scientifique et Technique du Bâtiment, France

Corresponding email: millet@cstb.fr

SUMMARY

The heat and cooling needs of a building considering climate, building envelop, energetic and ventilation system and indoor climate is at the heart of the set of CEN standards devoted to the application of the European directive

This new standard described two methods: a monthly one, improved from the previous version of 13790 standard, and a new one, based on an hourly calculation considering the thermal balance of the room at each step

Why is it a simple method? Basically, one must consider the final user position. Then, and whatever the calculation method is, a simple method must rely on simple input (easy to obtain, easy to understand), and outputs easy to check. The simple hourly methods aims to fulfil these points as its inputs are the same as for the monthly method.
One application is the new French RT2005 regulation applicable to building built after 1st September 2005.

INTRODUCTION

The European Energy Performance in Building Directive (EPBD, 2002) demands that before the year 2006 all Member States of the European Union implement energy performance (EP) regulations, including minimum EP requirements for all new buildings and EP certificates for all existing buildings when built, sold or rent. In a short period, a whole set of European (CEN) standards have been developed to facilitate the Member States with suitable calculation methods and/or performance criteria for calculation methods. These methods cover building transmission and ventilation heat loss, internal and solar gains, daylighting, heating and cooling demand, heating and cooling system losses, energy consumption for hot water production, ventilation systems and lighting. Evidently they also include renewable energy systems.

The directive explicitly states that the European Commission intends further to develop standards such as EN ISO 13790, also including consideration of air-conditioning systems and lighting. EN ISO 13790 ‘Calculation of Energy Use for Space Heating', EN ISO 13790, 2003) is the international standard for the calculation of the energy use for space heating for residential and non-residential buildings. It is the successor of the possibly still better known residential-only EN 832 'Calculation of energy use for heating – Residential buildings’.

THE PREN 3790 STANDARD

STRUCTURE OF THE STANDARD

The structure of the draft of the revised EN ISO 13790 (2) has been adapted to maximize the common use of procedures, conditions and input data, disregarding the type of method:

- Full description of a monthly (and seasonal) method for cooling, very similar to the method in the current EN ISO 13790:2003 for heating.
- Full description of a simple hourly method for heating and cooling, to facilitate easier introduction of hourly and weekly patterns (e.g. controls, user behaviour)
- For dynamic simulation methods: procedures concerning boundary conditions and on input data, that are consistent with the boundary conditions and input data for more simplified types of methods.

The latter is to ensure compatibility and consistency between the different types of methods.

The standard provides for instance common rules for the boundary conditions and physical input data irrespective of the chosen calculation approach.

BASIS OF THE HOURLY METHOD

The model is a simplification of a dynamic simulation, with the following intention:

- same level of transparency, reproducibility and robustness as the monthly method:
- clearly specified, limited set of equations, enabling traceability of the calculation process,
- reduction of the input data as much as possible,
- unambiguous calculation procedures;
- with main advantage over the monthly method that the hourly time-intervals enable direct input of hourly patterns.

In addition, the model provides the following:

making new development easy by using directly the physical behaviour to be implemented;

keeping an adequate level of accuracy, especially for room-conditioned buildings where the thermal dynamic of the room behaviour is of high impact.

The model used is based on an equivalent resistance — capacitance (R-C) model. It uses an hourly time step and all building and system input data can be modified each hour using schedule tables (in general, on a weekly basis).

The model makes a distinction between the internal air temperature and mean temperature of the internal (building zone facing) surfaces (mean radiant temperature). This enables its use in principle for thermal comfort checks and increases the accuracy for taking into account the radiative and convective parts of solar, lighting, and internal heat gains, although one should be aware that the results of the simple method at hourly level are not validated.

The calculation method is based on simplifications of the heat transfer between the internal and external environment, as shown in Figure 1.

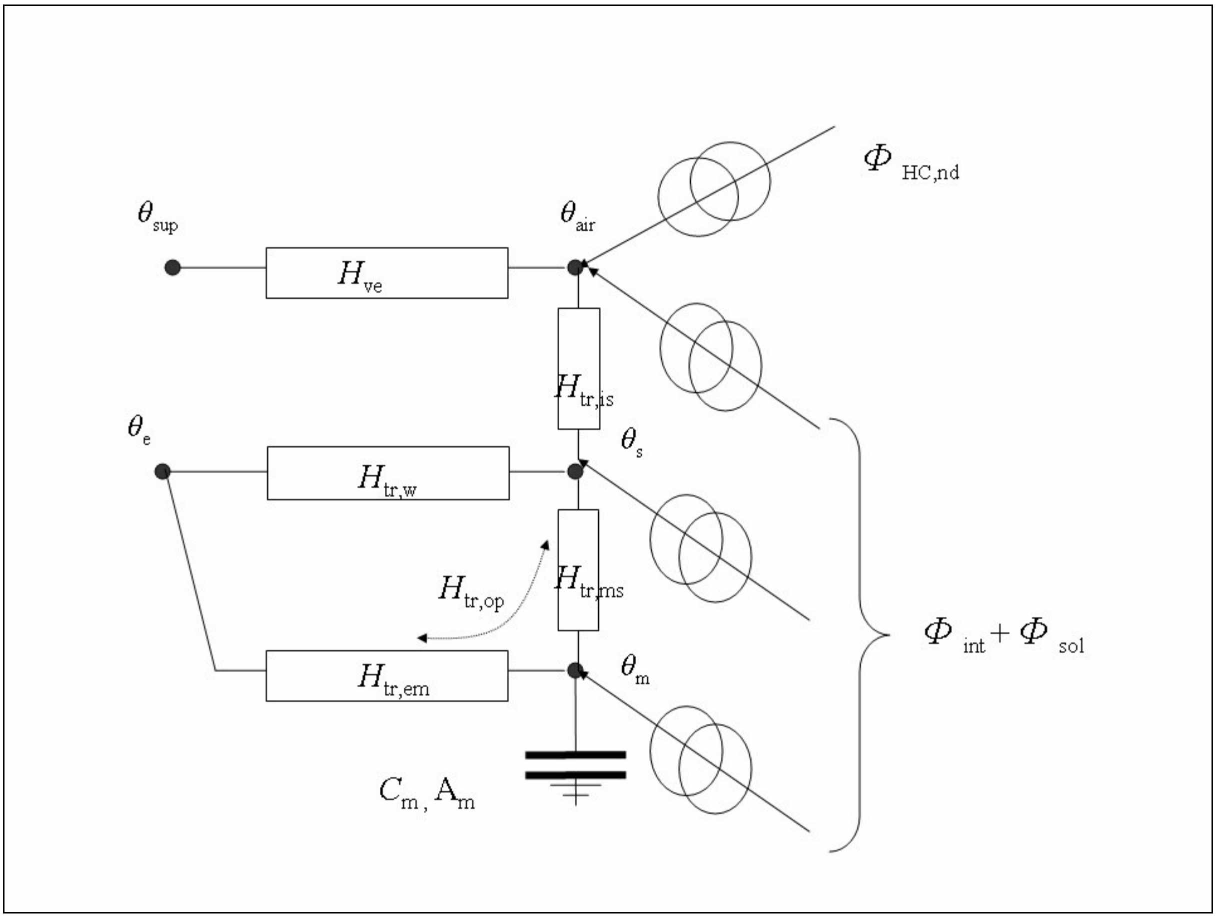

Figure 1 – 5R1C model

The heating and/or cooling need is found by calculating for each hour the need for heating or cooling power ΦHC,nd (expressed in watts and counted positive for heating and negative for cooling), that needs to be supplied to or extracted from the internal air node (□air) to maintain a certain minimum or maximum set-point temperature. The set-point temperature is a weigthed mean of air and mean radiant temperature. The default weighting factor is 0,5 for each.

Heat transfer by ventilation, Hve, is connected directly to the air temperature node θint, expressed in degrees Celsius, and to the node representing the supply air temperature θsup.

Heat transfer by transmission is split into the window part, Htr,w, expressed in watts per kelvin, taken as having zero thermal mass, and the remainder, Htr,op, expressed in watts per kelvin, containing the thermal mass which in turn is split into two parts: Htr,em and Htr,ms. Solar and internal heat gains are distributed over the air node, θair, the central node, θs (a mix of θair and mean radiant temperature θr,mn) and the node representing the mass of the building zone θm. The thermal mass is represented by a single thermal capacity, Cm, expressed in megajoules, located between Htr,ms and Htr,em. A coupling conductance is defined between the internal air node and the central node. The heat-flow rate due to internal heat sources, θint, expressed in watts, and the heat-flow rate due to solar heat sources, □sol, expressed in watts, are split between the three nodes.

The hourly energy needs for heating and/or cooling, QHC,nd, expressed in megajoules, are obtained by multiplying ΦHC,nd, expressed in watts, by 0,036. Similarly, the internal and solar heat gains, Qint and Qsol, expressed in megajoules, are obtained by multiplying Φint and Φsol respectively, expressed in watts, by 0,036.

VALIDATION TESTS

PRESENTATION OF THE PREN 15265 STANDARD (1)

This standard was prepared by the TC89 WG6 group. It specifies a set of assumptions, requirements and validation tests for procedures used for the calculation of the annual energy needs for space heating and cooling of a room in a building where the calculations are done on an hourly basis or less.

The standard does not impose any specific numerical technique for the calculation of the room heating or cooling need and the internal temperatures of a room.

The purpose of this standard is to validate calculation methods used to:

- describe the energy performance of each room of a building;
- provide energy data to be used as interface with system performance analysis) HVAC, lighting, domestic hot water, etc).

The validation procedure is used to check the energy need for space heating and cooling based on a transient sensible heat balance model, taking into account:

the external surface heat balance
the conduction through the building envelope
the thermal capacities of external and internal structures
the internal surface heat balance
the air heat balance
the heat balance solution method

All other aspects are given either by prescribed boundary conditions or by input data and are not part of the model validation. It is assumed that prescriptive calculation models have to be used according to existing European standards.
The system performance analysis and moisture balance are not within the scope of this standard.

VALIDATION TESTS

This standard does not impose any specific numerical technique for the calculation of the room heating or cooling load and the internal temperatures of a room.
For the validation of any existing or new numerical solution to the assumptions and the procedures defined in this standard, the procedures included in this clause shall be satisfied.
For the validation tests specified in this clause, the results provided by any numerical solution model shall be within the range indicated for each test.

The internal dimensions of the room are: length = 3,6 m; depth = 5,5 m; height = 2,8 m. The external wall including window glazing is facing West. The areas of the components of the reference room are given in Table 2.

Table 1 — Areas of reference room components

	External wall	Window Glazing	Internal wall left	Internal wall right	Internal wall back	Floor	Ceiling
Area (m²)	3,08	7,0	15,4	15,4	10,08	19,8	19,8

The solar parameters (considered here as independent of the solar angle) of the glazing component are given in Table 2:

Table 2 — Solar parameters of the window glazing components

Component	Transmittance	Reflectance	Absorptance
Shading	0,20	0,50	0,30
Pane	0,84	0,08	0,08

For opaque components the following values are taken:

solar absorptance of all wall surfaces □sr = 0,6

solar absorptance of the roof

αsr = 0,9

The thermophysical characteristics of the window components are:

a) Shaded DP - Double pane glass with external shading device (Figure 2):

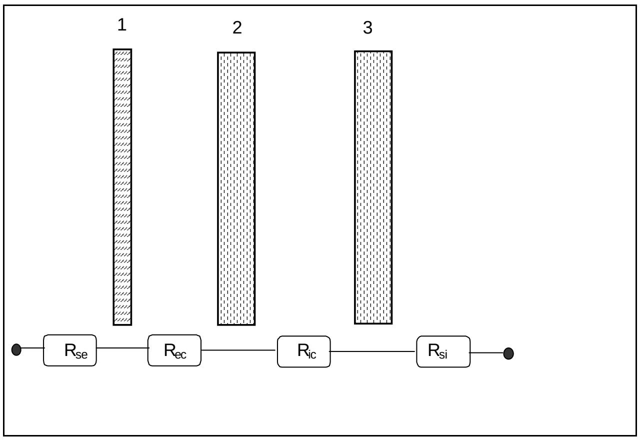

Figure 2 — Double pane window glazing with external shading

Thermal resistances including convection and long wave radiation:

external surface Rse = 0,0435 m2.K/W

cavity between external blind and external pane Rcav = 0,080 m2.K/W

cavity between external pane and internal pane Rie = 0,173 m2.K/W

internal surface Rsi = 0,125 m2.K/W

Thermal transmittance of the glazing system Ug = 2,37 W/(m2.K)

Total solar energy transmittance of the glazing systemg = 0,20

b) DP - Double pane glass without external shading device (Figure 3):

Thermal resistances:

external surface Rse = 0,0435 m2 K/W

cavity between external pane and internal pane Rie = 0,173 m2 K/W

internal surface Rsi = 0,125 m2 K/W

Thermal transmittance of the glazing system Ug = 2,93 W/(m2K)
Total solar energy transmittance of the glazing systemg = 0,77

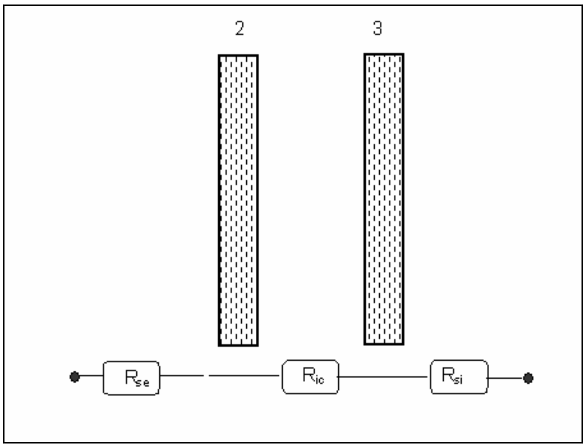

Figure 3 — Double pane window glazing without shading device

The thermophysical characteristics of the walls, ceiling and floor are given in Table 3.

Table 3 — Thermophysical properties of the opaque components
(order of layers from external to internal)

	d m	λ W/(m·K)	ρ kg/m³	cp kJ/(kg·K)
Type 1 (external wall)

concrete	0,20	2,1	2400	0,85

The hourly mean values of climatic data are given in an annex of the satndard, starting on 1st January and ending on 31st December.
The latitude is 49° and the values are given in solar time.

RESULTS AND DISCUSSION

The results for heating, QH, and cooling, QC, (expressed in kWh) are provided for the complete year (the hourly pattern of the calculated internal temperatures is not part of the validation) and compared to reference values by calculating: Different software were used to produce the reference results which are given in Tables 5 and 6.

rQH = abs(QH - QH,ref) / Qtot,ref
rQC = abs(QC – QC,ref) / Qtot,ref

Three levels of accuracy can be checked with levels: A,B,C. The validation tests are complied if for each of the cases 5 to 12 (8 test cases) :

Level A : rQH ≤ 0,05 and rQC ≤0,05
Level B : rQH ≤ 0,10 and rQC ≤0,10
Level C : rQH ≤ 0,15 and rQC ≤0,15

Table 4 — Reference results for tests 1 to 4 (informative)

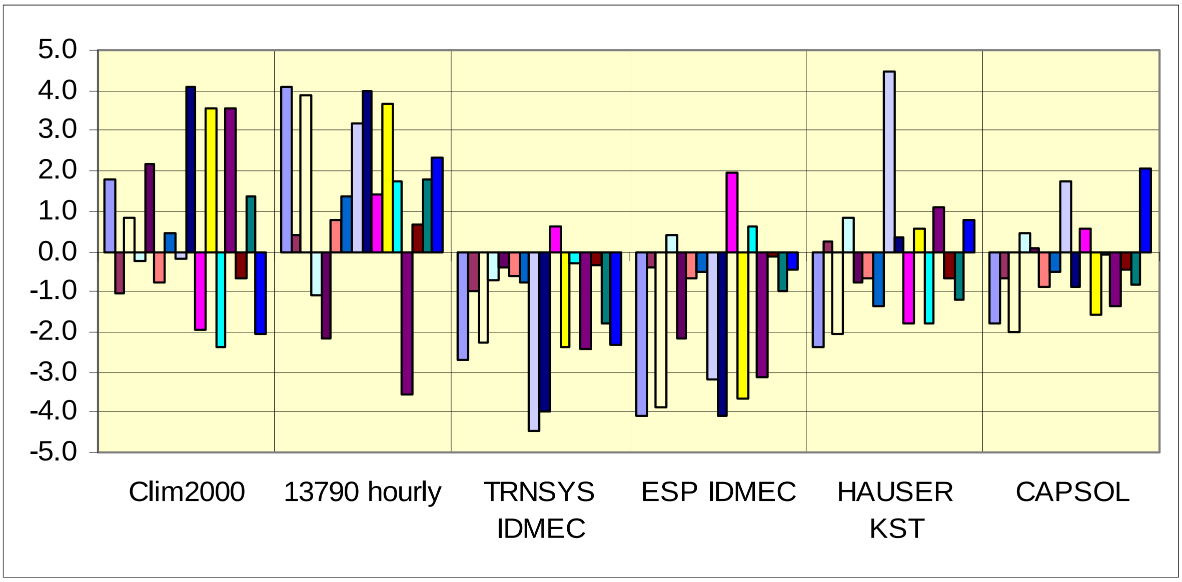
Test	QH,ref kWh	QC,ref kWh	Qtot,ref kWh
1	748,0	233,8	981,8
2	722,7	200,5	923,2
3	1368.5	43,0	1411,6
4	567,4	1530,9	2098,3

Table 5 — Reference results for tests 5 to 12 (normative)

test n°	QH,ref kWh	QC,ref kWh	Qtot,ref kWh
5	463,1	201,7	664,8
6	509,8	185,1	694,9
7	1067,4	19,5	1086,9
8	313,2	1133,2	1446,4
9	747,1	158,3	905,4
10	574,2	192,4	766,6
11	1395,1	14,1	1409,3
12	533,5	928,3	1461,8

The results obtained by different computer codes are shown in figure 3

Figure3 : results of test cases for different methods



The 13790 hourly method, though more simplified than the majority of the other ones, provides results with, as the other ones, the best level of accuracy (A).

CONCLUSION

The European Energy Performance in Building Directive (EPBD) requires methods for the calculation of the energy performance for use in the context of building regulations. A pair of simplified methods have been developed for the calculation of the energy needs for heating and cooling of buildings. A revised version of EN ISO 13790 has been prepared in which a level playing field is created for both simple and detailed methods, by introducing a coherent set of procedures with respect of boundary conditions and assumptions that applies to different types of methods. Validation tests show that the hourly simplified method is well suited for calculation both heating and cooling needs and therefore to be used in both warm, moderate and cold European climates while keeping input data as the same level of simplicity (and the robustness) than monthly ones..

SUMMARY

The paper presents a part of the methodology for energy efficiency calculation in buildings, elaborated in Romania, regarding especially the ventilated and air-conditioned buildings. After the adoption in our country of the EU regulation no. 91/2002 as internal law no. 325/2005, the Faculty of Building Services from the Technical University of Civil Engineering Bucharest was designed by the Public Ministry of Constructions to elaborate the calculation methodology for the energy efficiency of buildings. Knowing the extent of the EU regulations in this field, we decided that Romanian methodology could correspond to the greatest part of the European similar methodology. For the air-conditioned buildings, we selected the monthly simplified method as appropriate. For more particular cases, we recommend the simplified method with a one-hour time step and, for very special situations we recommend the use of specialized software, which should agree to the conformity tests proposed by the EU legislation. We made out observations regarding the difficulties faced out during our work, as well as comments regarding the capability of the simplified method to consider the energy consumed at the air-conditioning system level for water vapor condensation, a special situation appearing in our climate, even if the room internal humidity is not controlled.

INTRODUCTION

Consistent actions at national level, regarding building energy consumption performance and reduction, have been started by applying the law 10/1995 concerning the “Quality of Constructions”. Consequently, this law has established rules and objectives related to comfort, indoor air quality and energy consumption reduction for new buildings [1].

Two years later, several normatives (C107/1-5) has imposed design demands for thermal and humidity transfer through building envelope for new projects or rehabilitation actions. These normatives have been introduced limits concerning the minimal thermal resistance for external construction elements and global heat losses coefficient.

In addition, since 2000, there have been 3 national normatives (NP 047, 048 and 049) implemented for expertise, certification and audit energetic actions concerning existing buildings. The field of application for these normatives is dealing only with building envelope, heating and hot water production systems.

Moreover, the law 325/2002 has established a Rehabilitation National Programme for block of flats (collective dwellings) that represents the main type of dwellings within Romania’s cities. The specialist qualification in the field of energetic expertise, certification and audit projects for civil buildings has been conducted since 2003 by following the OG 550 (government legislative act emitted by Ministry of Transports, Constructions and Tourism). In the same time, the equivalent procedure for industrial buildings has been coordinated by Ministry of Energy.

METHODS

Implementation of European Building Performance Directive (EPBD) in Romania
More recently, in December 2005, the law 372/2005 dealing with energetic performance of buildings has been approved [2]. It is worthwhile to mention that this law transposes UE Directive 91/2002 in Romania. As a consequence, the Calculation Methodology of Buildings Energy Efficiency has been fulfilled in 2006 and adopted on January 1st 2007 [3]. This method comprises three distinct parts: the first one is dealing with envelope building issues, the second one concerns computations for heating, production of hot water, ventilation, air conditioning, and lighting energy consumption while the last one refers to energetic certification and audit. The field of application for this methodology refers *to all buildings* within Romania.

On another hand, there are specific actions for using specialized software in the field of energetic certification and audit:

- TRNSYS tests: this code has been extensively tested and validated following prEN 15265 procedures by the research team of Building Services Laboratory of Technical University of Civil Engineering Bucharest; taken into account that this code is very popular among the specialized research community, it is planned to develop special executable versions adopted for different kinds of buildings using more friendly interfaces (the computation method will be based on detailed hourly methods)
- cooperation between AIIR (Romanian Association of Building Services Engineers) and VABI (Society for Automation in Buildings and Building Services, Netherlands): the aim is to adapt and use VABI's software to specific Romanian conditions for energetic certification and audit projects completed by Romanian recognized experts
- use of software: any Romanian or foreign software that fulfills the testing demands recommended by prEN 15625 will be homologated for use by energetic auditors

We add here that another normative is to be prepared (by Ministry of Transports, Constructions and Tourism and Ministry of Industry and Commerce), concerning the method and the analysis of its results concerning the assessment of HVAC systems, as well as the procedure for specialist's training according to the proposed methodology. The objective of this action is to answer to the UE Directive 91/2002 specific demand related to inspection of air conditioning systems.

As actions carried out, we quote here the programs accomplished according to OG 211/2003 and OG 187/2005 (government legislative act). The way the population can be assisted to finance the expenses required for thermal rehabilitation works of the buildings within these programs is the following: 1/3 allowances from the state budget; 1/3 yearly approved funds to this aim from the local budgets and 1/3 repair funds of the owner associations. The main projects carried out or to be carry out are the following:

- pilot actions (2 blocks of flats – collective dwellings), 2003-2004
- Romania/Swiss Program (12 blocks of flats – collective dwellings, 2003-2004
- 31 locations within a new program assisted by Swiss Embassy, 2005-2007

- government action for 391 buildings in 17 localities (approximately 14,4 MEuro), 2006-2007

We present in the next section details regarding the application of Romanian computation method for buildings energy efficiency, with focus on issues dealing with ventilation and air conditioning systems energy consumption.

Particularities of Romanian Buildings Energy Efficiency Methodology

Romanian calculation methodology of buildings energy efficiency was basically developed using European standards and European proposed standards but also taken into account issues from Romanian normatives (referenced below).

As already stated, the method consists of 3 main parts:

a) thermal characteristics of building's envelope (building overall characteristics – HT, HV – SR EN ISO 13789 [4]; design thermal values – EN ISO 10456; thermal resistance and thermal transmittance – EN ISO 6946; thermal bridges and surface temperatures – EN ISO 10211, EN ISO 14683, EN ISO 13788; thermal performance of windows, doors and shutters – EN ISO 10077-1, EN ISO 10077-2, EN 410, EN 673, EN 13363; heat transfer via the ground – EN ISO 13370/national method as alternative)

b) building's services energetic consumptions (heating – SR EN ISO 13790 [5], prEN 15316), prEN15315 (primary energy, CO2), NP 048 (revised) as alternative calculation method; hot water - prEN 15316, NP 048 (revised) as alternative calculation method; ventilation/ air conditioning – SR EN ISO 13790, pr EN 15241, pr EN 15242, pr EN 15243, pr EN 15265, pr EN 13779 [6], pr EN 13792, alternative calculation method for energy consumption for cooling and free internal temperature in summer; lighting – pr EN 15193/1)

c) certification and energy audit

Concerning the method for assessing ventilation and air conditioning systems energy consumption, there are the following computation procedures:

- energy consumption for cooling (monthly method according to European standards)
- energy consumption for cooling (detailed hourly method according to European standards)
- evaluation of internal air temperature during summer (according to French normative– RT 2005)
- evaluation of real ventilation flow rates and ventilation systems energy consumption (according to European standards)
- evaluation of air conditioning systems energy consumption (according to European standards)

The procedures listed before follow generally the methods presented in European standards or proposal of European standards, adding local data and references. Concerning the estimation of energy consumption for cooling, another energy balance scheme was defined as explained further below.

The energy balance diagram (see figure 1) is extremely important for building – system coupling. It allows rapid assessment of energetic consequences in the case of system revision or adaptation of a part of the system. As a result, the auditor can correctly and quickly operate changes to improve the system energy consumption.

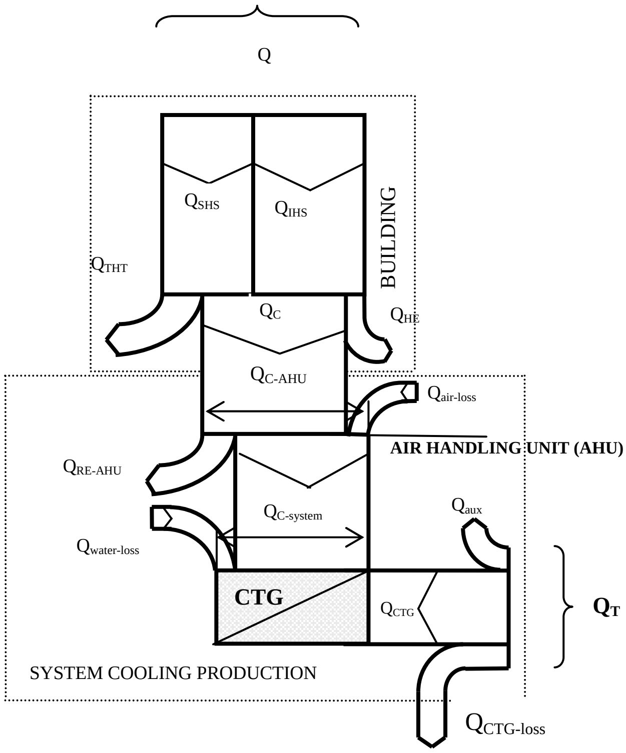

Figure 1: Flows and energy balances for building and systems
Q – overall building thermal balance ; Q_{SHS} – solar heat sources; Q_{IHS} – internal heat sources; Q_{THT} – transmission heat transfer; Q_{HE} – heat extracted by free cooling; Q_C – energy need for space cooling; $Q_{C\text{-}AHU}$ – energy need for cooling at AHU; $Q_{C\text{-}system}$ – energy need for cooling at system cooling production; $Q_{RE\text{-}AHU}$ – renewable energy for cooling used at AHU (energy gain); $Q_{air\text{-}loss}$ – energy loss due to air leakage and heating of the air in ducts; $Q_{water\text{-}loss}$ – energy loss in system distribution; Q_{CTG} – system cooling production energy consumption; $Q_{CTG\text{-}loss}$ – energy loss within system cooling production; Q_{aux} – energy consumption for auxiliary equipments within system cooling production (pumps, fans, etc.); Q_T - total delivered energy for cooling (total energy consumption for building cooling)

The diagram takes into account the system components and their task within the system, introducing 3 levels of energy balance: building, air handling unit and cooling production. An interface, labeled CTG – cooling thermodynamic generator (Figure 1), was placed between thermal energy extracted from the system and primary energy delivered in order to indirectly estimate the performance coefficient of thermodynamic cooling system. It is worthwhile to mention that in the Figure 1 other heat flows can be added depending on system characteristics. These can straightforwardly attached by the auditor (for example renewable energy sources or energy recovery that takes place frequently in the air handling unit). According to Figure 1, the building energy balance can be written in the following manner in order to evaluate the energy need for space cooling:

$$Q_C = Q_{SHS} + Q_{IHS} - Q_{HE} - Q_{THT} \qquad (1)$$

In addition, we can straightforwardly calculate the energy need for cooling at air handling unit, taken into account all the fluxes that take place at this level on Figure 1 (energy need for space cooling, adding energy loss due to air leakage and heating of the air in ducts and deducting renewable energy for cooling used at AHU that reduces energy demand for cooling at AHU):

$$Q_{C\text{-}AHU} = Q_C + Q_{air\text{-}loss} - Q_{RE\text{-}AHU} \qquad (2)$$

Taken into account energy loss within system distribution from cooling production to AHU (for example due to heat gain of chilled water and on occasion water leakage in system distribution), we can write the energy balance for system cooling production:

$$Q_{C\text{-}system} = Q_{C\text{-}AHU} + Q_{water\text{-}loss} \qquad (3)$$

Further, we can assess the total delivered energy (electricity, gas, coal, oil, etc.) for space cooling, given mainly by system cooling production energy consumption along with energy loss within this system and energy consumption for its auxiliary equipments (pumps, fans):

$$Q_T = Q_{CTG} + Q_{CTG\text{-}loss} + Q_{aux} \qquad (4)$$

We consider that such diagrams as that indicated in Figure 1 (completed with specific values for flux energy) could be extremely useful. This can be performed for different types of buildings (diverse structures and occupations) and climates. We believe that a European Project on this topic could lead to valuable data. For example, we can compare the diagram of a building and its cooling system with the better diagram achieved for a “reference” building equipped with a “reference” cooling system. This allows directly identifying the solutions for reducing energy consumptions. This kind of results could help enormously the auditors as well as the architects and engineers involved in building conception and its HVAC systems.

It is obvious that the latest form of the Methodology for Building Performance takes into account some simplifications. We decided to point out one of them, by showing some simulation results of latent and sensible cooling loads resulting from a cooling coil operation during a summer period, for a given location. The aim of these simulations was to judge the importance of the latent cooling power within the cooling process, knowing that the latest Methodology underestimates it, taking into account only the sensible cooling. The study is presented in the next paragraph.

Assessment of cooling demand for vapor condensation

The climate in Southern part of Romania is rather hot and humid during summer. For instance, external temperature and air moisture content taken into account for the design of HVAC systems in Bucharest are 34,5°C and 11,95 g/kg, respectively. Therefore the energy loss due to vapor condensation on cooling coils surface may be high and thus not be ignored without the risk to underestimate energy consumption for cooling. In order to verify this supposition, we carried out a TRNSYS simulation [7], in which we modeled a cooling coil operation under similar weather conditions taken from a typical weather file for Bucharest.

The TRNSYS model had focused on the cooling coil thermal behavior when this coil is part of an air handling unit traversed by an outdoor airflow equal to 15 000 m^3/h. The set point temperature of the air exiting the cooling coil is 22 ºC, temperature at which it will be supplied in the ventilated zone as primary air, for dilution purposes. The zone thermal load was supposed to be removed by an air-water system placed within the zone (fan coil units or similar).

The general overview of the TRNSYS model for the cooling coil is depicted in figure 2, where we can notice the following TRNSYS subroutines as component parts of the model:

- ”Weather” – corresponding to the weather data file processing, supplying information for the outdoor air entering the cooling coil; the weather file was taken from the Meteonorm database and corresponded to the town of Bucharest, Romania;

- ”Cooling coil” - models the cooling coil, describing the heat and mass transfer between the airflow passing through the coil and the chilled water circulating inside the coil pipes; the OUTPUTS of interest for this model which will be represented are: the outlet air temperature ($t_{out,CC}$), the total cooling power ($P_{tot, cool}$), the sensible cooling power ($P_{sens,cool}$) and the latent cooling power ($P_{lat,cool}$) resulted from the transfers within this heat exchanger;
- ”Water flow calculation” – which calculates the water flow entering the cooling coil, depending on the signal received from the ”Temperature controller” routine (a PID controller)-see figure 1; this signal results from the comparison between the air temperature setpoint imposed at the coil exit (22 ºC) and the effective temperature calculated by the model in the same place; the PID controller compares this temperature difference and conveys a signal to the vane actuator which will change the vane position to adjust the chilled water flow through the pipes, in order to reach the air temperature setpoint at the coil exit. If the air temperature entering the coil falls below the setpoint value (during the night), the model is able to assume that is no heat and mass transfer in the coil, so the exit air temperature will equal the entering one.
- ”By pass flow” – calculates the chilled water flow by-passing the cooling coil as a result of the PID regulation;
- ”Conversion routine”- transforms the TRNSYS default units for cooling power (kJ/h), in SI units (kW), for the three calculated cooling powers: total, sensible and latent.
- ”Psychrometrics” - calculates the remaining air parameters when two of them are supplied (e.g. dry air temperature and relative humidity);
- and finally, the subroutine ”Output to file” enables TRNSYS post processor to write the output variables of the model in a text file.

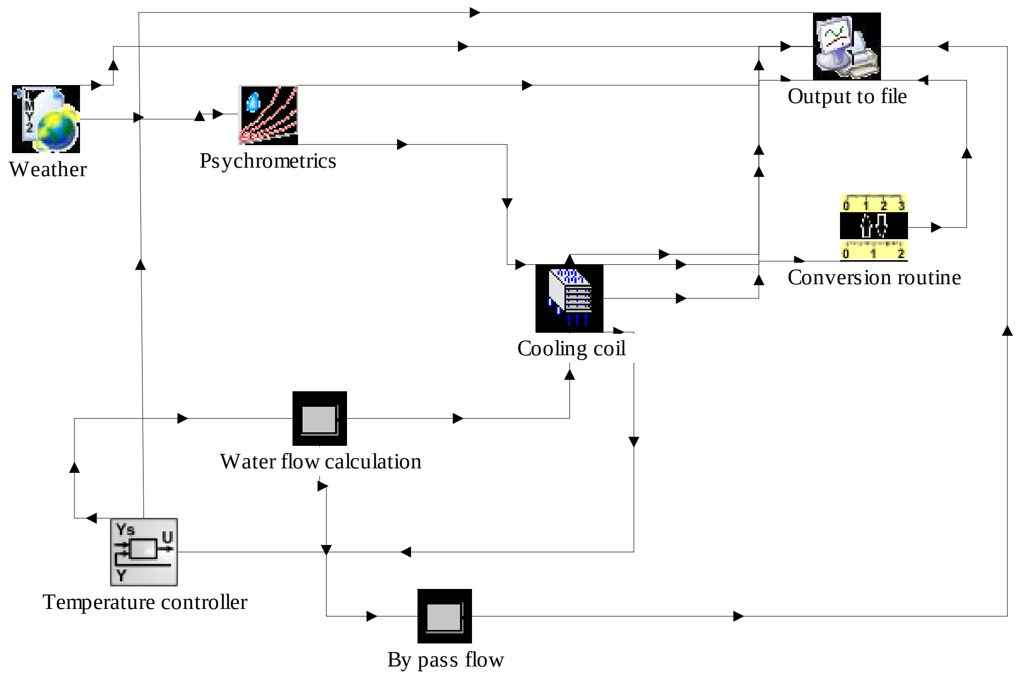

Figure 2: The general overview of the TRNSYS model of the cooling coil

The simulations were performed for one month summer period, more precisely: from 1st July to 31st July, considering the Bucharest weather file loaded in the TRNSYS model.
The results issued from these simulations are represented in the figures 3 and 4, for the first and the third week of the simulation period.

RESULTS

In the figure 3 are represented on the same graph the three component of the cooling power: total (Ptot_cool), sensible (Psens_cool) and latent (Plat_cool), as well as the outside air temperature entering the cooling coil (t_outside) and the exit air temperature from the cooling coil (t_out_CC). The results correspond to the second week of the simulation period (from 8 to 15th July). We can notice on this figure two important behaviors:

- the good regulation of the temperature t_out_CC at its setpoint value (22 ºC) during the periods when t_outside overtakes this value, and
- the small values of the latent power, appearing only when the dew point of the temperature entering the cooling coil (t_outside) is above the mean temperature of the coil surface (equivalent to the average chilled water temperature across the coil); this is equivalent to the difference between the moisture content of the air entering the cooling coil and the moisture content of the air exiting the cooling coil, producing condensation on the external coil surface.

If we integrate these cooling powers over the whole week, it results a total cooling load $Q_{tot,cool}$ = 4987 Kj and a latent cooling load $Q_{lat,cool}$= 260 kJ, or a 5,2% from $Q_{tot,cool}$.

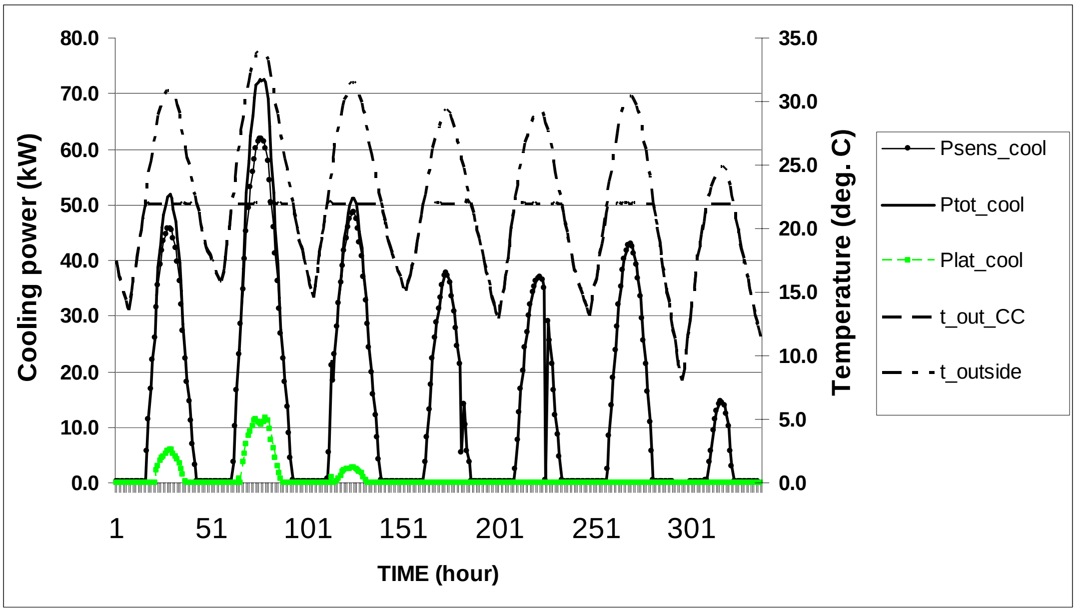

Figure 3: Temperatures and cooling powers calculated for the second week of simulation

A similar representation is depicted in figure 5, but for the third week of the simulation period (16th – 23rd July). We could notice than the latent power profile and magnitude is quite different than in the first case. This is due to the moisture content difference between the air entering and the air exiting the cooling coil, which is bigger for this period of time, according to the meteorological data picked from the Bucharest weather file.

If we integrate again these cooling powers over the third week, it results a total cooling load $Q_{tot,cool}$ = 4717 Kj and a latent cooling load $Q_{lat,cool}$= 1084 kJ, equivalent to 23% from $Q_{tot,cool}$. This result shows clearly that the moisture content of the air entering the cooling coil (in this case, outside air) is of great importance, and for warmer and more humid climates the percentage of the latent cooling load from the total cooling load could be even bigger than 23% and the neglecting of this part could mean to big underestimations.

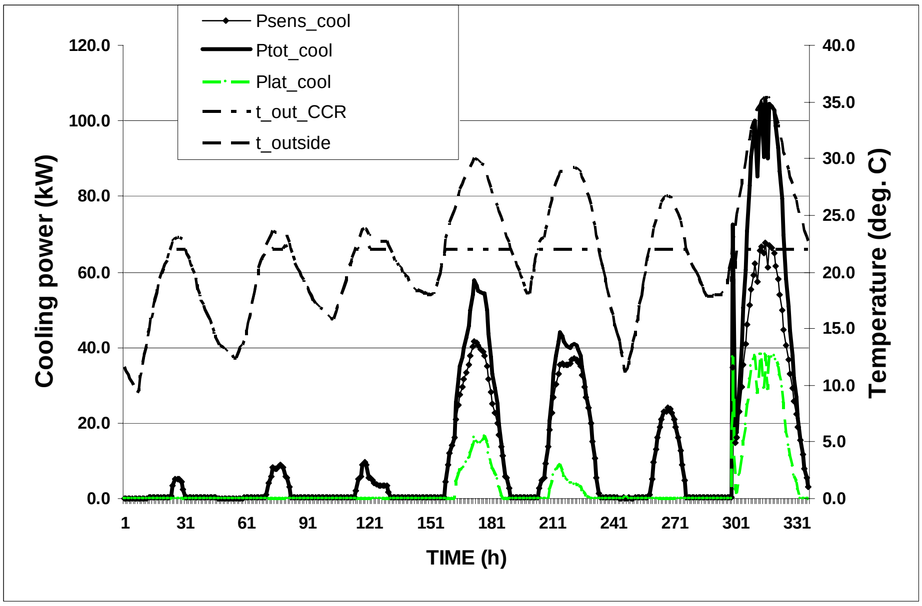

Figure 4: Temperatures and cooling powers calculated for the third week of simulation

DISCUSSION

Concerning the implementation of UE Directive 91/2002 in Romania, we notice that important steps forward have been made, especially by establishing Calculation Methodology of Buildings Energy Efficiency (based mainly on European documents within EPBD). On the other hand, there still is a lack of national data (as climatic data that need to be urgently updated). Moreover, it is necessary to elaborate a kind of “Application handbook” of national Buildings Energy Efficiency Method in order to add specific data for different parameters that can be used as “default” values.

There is a need also to improve the computation precision without making the methods more complicated. It was shown for instance that if we do not take into consideration energy demand for latent heat, the differences can reach 23% of energy underestimated from the total energy consumed for cooling.

ACKNOWLEDGEMENT

The scientific background for this study was based on the research meant by a work team from the Faculty of Building Services Bucharest, during its effort to change the Romanian Methodology for Building Performance, to join the actual E.U. standards. This work was financed with Romanian government funds, allocated by the Romanian Ministry of Transports, Constructions and Tourism.

Proposal of a statistical model for the estimation of energy demand for space heating in residential buildings

Matteo Caldera, Stefano P. Corgnati and Marco Filippi

Energy Department (DENER), Politecnico di Torino, Torino (Italy)

Corresponding email: matteo.caldera@polito.it

SUMMARY

This study deals with the statistical analysis of a set of data related to 50 multi-family residential buildings, located in the district of Torino (Italy), in order to find simplified correlations for the assessment of the energy demand for space heating.
Starting from the standard deterministic equations, this study revises them maintaining their physical basis, and simplifies the most involved terms. This simplification is carried out making a statistical analysis of the energy quantities that affect the performance of a building. Results are compared with those calculated in a detailed way using the Standard procedures, for the available sample of buildings.
The resulting formulas define the relations between the energy performance of a building, and its geometrical and thermal properties.
Therefore, this model is particularly useful to estimate energy demand for space heating for existing residential buildings in a simple and prompt way, and it may represent a useful tool for their energy certification.

INTRODUCTION

The study of the building energy demand has become a topic of great importance not only among technicians, because of the significant increasing of interest around energy sustainability which has grown up after the emanation of the EPB European Directive [1].
The topic of the evaluation of the energy requirements through a theoretical calculation, following the asset rating approach [2], can be aimed at characterizing the theoretical energy performance [3] and at foreseeing the actual consumption of a building [4], [5].
Moreover, the energy performance benchmarking of a large number of buildings needs tools reliable and trustworthy, but also simple and fast, to reduce costs and data processing time.
The number of actors, technicians and not, interested in holding energy consumption provisional tools has stimulated the search of new, and possibly simplified, models based on statistical analysis [6].
In Italy, an interesting example is CONSIP model [7]. CONSIP society, controlled by the Italian Finance and Economy Ministry, was born with the goal of rationalize expenses for the Public Administration assets and services. It has defined a methodology for the determination of the heating primary energy demand and the quality indicators of the offered service, regarding the tenders for the integrated management service supply (Global Service) of all the Public Administration buildings. In Consip model, the equation of the transmission loss coefficient has a statistical origin, because its proportionality coefficients for geometrical and thermo-physical quantities are obtained with a linear regression on a sample of buildings.
The present study considers only space heating of residential buildings, which are responsible of an important part of the total primary energy demand: in EU, space heating accounts for

more than 50% of primary energy demand of residential and service buildings, which account for 40% of total primary energy demand [8]; similar percentages are for the other developed countries.
Starting from Standard deterministic equations, we revises them maintaining their physical meaning, and simplify the most involved terms. This simplification is carried out making a statistical analysis of the same terms calculated in a rigorous way (using Standard EN 832) on a sample of 50 multi-family residential buildings placed in the district of Torino (Italy). They were built in different periods between the end of the Nineteenth Century and the end of the last Century. Relationships are searched between the age of the building and its main geometric and thermo-physical properties: the shape ratio, the volume, the opaque and glazed surfaces, their transmittances, the external and internal temperatures. All the available data are filtered with a statistical approach and are suitably combined to find out general relations. The analysis pays particular attention to model the free heat gains (e.g. internal and solar gains). As a result, the number of requested input data needed to evaluate the energy performance of a building is very limited: the thermal transmittances of the most important envelope components and geometric data.
To validate the model, results are compared with those from the application of the European Standard EN 832 (included in the available data set).
The correlations that we have found determine in a direct, simplified and fast way the energy demand parameter, which otherwise would require an involved procedure, if calculated according to Standards approach. Therefore, this model is particularly useful to estimate energy demand for space heating for existing residential buildings, and it may represent a useful tool for their energy certification.

METHODS

The proposed model estimates the energy demand for space heating in standard conditions of the entire building, whose control volume is defined by the external envelope. It is a single zone model.
The two most important performance indexes are the transmission loss coefficient (C_d, in W/(m^3°C)) and the normalised energy demand for space heating (*FEN*, in kJ/(m^{3}DD)). The available data set of 50 residential buildings contains these indexes and all the related quantities, calculated according to Standards [9], [10], [11], [12], [13], [14].
C_d evaluates the heat lost by transmission, and depends on the geometrical and thermo-physical characteristics of the building. It is defined as follows:

$$C_d = \frac{\dot{Q}_t}{V \cdot (T_a - T_e)}, \qquad (1)$$

$$\dot{Q}_t = m_1 \cdot \left(\sum_{i=1}^{n_{op}} \left(U_{op,i} \cdot f_{op} \cdot S_{op,i} \cdot (T_a - T_e)\right) + \sum_{i=1}^{n_f} \left(U_{f,i} \cdot S_{f,i} \cdot (T_a - T_f)\right) + \sum_{i=1}^{n_c} \left(U_{c,i} \cdot S_{c,i} \cdot (T_a - T_c)\right) \right) + $$
$$+ m_2 \cdot \sum_{i=1}^{n_w} \left(U_{w,i} \cdot f_w \cdot S_{w,i} \cdot (T_a - T_e)\right), \qquad (2)$$

where *V* is the gross volume, *U* are transmittances (W/(m^2°C)), *S* are the surfaces, T_a is the internal design temperature (20°C), T_e is the external temperature, *f* are the orientation coefficients, *m* are the thermal bridge coefficients; subscripts are: *op* for vertical opaque

elements, f for basement floor or concrete slab on pilotis, c for attic floor or plane roof, w for glazed surfaces .
The terms in equations (1) and (2) have been elaborated with a statistical approach, focalizing the following aspects:

1. determination of the most important heat transfer surfaces (S_{op}, S_f, S_c, S_w)
2. orientation coefficient for vertical elements (f_{op}, f_w)
3. thermal bridge coefficients (m_1, m_2)
4. basement and attic temperatures (T_f, T_c)

The envelope components that contribute to dispersions are: external walls, windows and floors toward ground and roof. Generally, external walls are characterised by a single value of transmittance K_{op}, and S_{op} is their total surface. Vice versa, the building may have different types of windows, e.g. double glazing in the apartments and single glazing in common parts (typically stairs). For this reason and for a purpose of detail without giving up simplicity, the model suggests to specify the properties of two types of windows per building (S_{f1}, S_{f2}). The terms related to the basement and the concrete slab on pilotis are distinct, like those related to the roof and to the attic floor, because the corresponding temperatures are different.
From the sample of buildings, a mean statistical orientation coefficient has been calculated both for the vertical walls, f_{op}, and for the windows (without distinction of glass type), f_w: it is the mean value of the ratio between the increased element surface and the actual surface, for the whole sample of buildings, and weighted on the respective areas.
The thermal bridge coefficient for vertical opaque surfaces m_1 follows the prescriptions of the CTI SC1 recommendation [9]. Coefficient m_2, related to windows, is set m_2 = 1.2.
In the available data set, the design temperatures of the basement and of the attic are obtained according to the Italian Standard [10]; the present model uses their corresponding mean values calculated on the analysed sample of buildings.
U transmittances are determined according to CTI Italian recommendation [9] for opaque components, and to the European Standard [14] for windows.
The ventilation loss coefficient C_v accounts for a hourly air change n = 0.5 h^{-1}; this is a standard value, typical of residential buildings; the conversion coefficients to calculate the net heated volume from the building gross volume are taken from [9], and they depend on the age of the building.
FEN estimates the primary energy demand for space heating. It is defined as follows [12]:

$$FEN = \frac{Q}{\left(T_a - \overline{T}_e\right) \cdot V \cdot N} \qquad (3)$$

Q is the conventional primary energy demand (kJ), N are the days of the heating season and $\overline{T}_e$ is the mean temperature of external air for the heating season according to [14]; $\overline{T}_e$ = 5.56°C for Torino. In particular, Q is the heat lost by transmission and ventilation, reduced by the free gains (solar, internal), the result increased to count for the global efficiency (production, distribution, control and emission mean seasonal efficiencies).
The proposed *FEN* is based on the assumption that the thermal equipment works continuously, without intermittence or attenuation. Equation (3) has been elaborated in order to maintain its physical meaning and to simplify its calculation, with a statistical approach. The following formula is an elaboration of (3), and it underlies the most significant contributions:

$$FEN = \left(1 - \eta_u \cdot \frac{E_g}{E_l}\right) \cdot \left(C_d + C_v\right) \cdot \frac{86.4}{\eta_g} \;, \quad (4)$$

where η_u is the energy gains utilization factor, η_g is the mean global seasonal efficiency of the system, E_g are the energy gains (solar and internal), E_l is the energy lost by transmission and ventilation. 86.4 is a time conversion factor from days to seconds.
The energy lost by transmission through the envelope (kJ) can be expressed as:

$$E_{d,stat} = C_{d,stat} \cdot V \cdot (T_a - \overline{T}_e) \cdot 86.4 \cdot N \quad , \qquad (5)$$

$C_{d,stat}$ is calculated with the statistical correlation reported in the Result section, formula (13); this is an approximation, because $C_{d,stat}$ requires the design temperatures and not the mean seasonal temperatures. Nevertheless the only terms involved in the approximation are those related to the attic and basement, that contribute (where present) very slightly to the energy calculation.
Similarly, the energy lost by ventilation through the envelope (kJ) is:

$$E_{v,stat} = C_{v,stat} \cdot V \cdot (T_a - \overline{T}_e) \cdot 86.4 \cdot N \quad , \qquad (6)$$

$C_{v,stat}$ is the ventilation loss coefficient; as explained, it is a constant value for residential buildings.
The energy gains are mainly solar and internal.
Internal energy gains are calculated using the following (in kJ):

$$E_i = Q_{i,spec} \cdot n_{apt} \cdot N \cdot 86.4 \quad , \qquad (7)$$

where n_{apt} is the number of apartments in the building and $Q_{i,spec}$ is the endogenous heat produced per apartment; in the available data set, $Q_{i,spec}$ is calculated with the formula reported in [9] for residential buildings:

$$\begin{aligned} Q_{i,spec} &= \left(6.25 - 0.02 \cdot S_{apt}\right) \cdot S_{apt} \qquad && S_{apt} \le 200\ m^2 \\ Q_{i,spec} &= 450 && S_{apt} > 200\ m^2 \end{aligned} \qquad (8)$$

The analysis of the results obtained with (8) led to express $E_{i,stat}$ with the following equation:

$$E_{i,stat} = \left(Q_{i,stat} \cdot C_{st} \cdot \frac{S_{rf}}{n_{apt,rf}} \right) \cdot n_{apt} \cdot N \cdot 86.4 \, , \qquad (9)$$

$Q_{i,stat}$ represents the endogenous heat per unit of area obtained applying (8) to the reference apartment of the examined sample of buildings, whose floor surface is the mean value of the standard apartment of these buildings ($S_{stat,ref}$ = 83 m^2, std.dev = 16 m^2). C_{st} is the reduction factor of the reference floor and it considers the common parts of the building included into the control volume (e.g. the stairs area); it is calculated as the mean value for the available data set. S_{rf} is the surface of the reference floor while $n_{apt,rf}$ is the number of apartments in the reference floor of the building. S_{rf}, $n_{apt,rf}$ and n_{apt} are input data of the model.
The starting point to calculate solar gains are formulas reported in [13]. The proposed approach substitutes suitable mean statistical values to the parameters included in these formulas. First of all, a unique value of the daily solar irradiation for the heating season $\overline{I}_s$ has been calculated: we computed the mean irradiation weighted on the days of the heating season for the eight main orientations for Torino, from data reported in [14]. Then we found their

linear correlation versus the orientation coefficients proposed by the Italian standard [10]. $\bar{I}_s$ corresponds to the calculated f_w coefficient: $\bar{I}_s$ = 6370 kJ/m^2.

Standard [13] prescribes a complex procedure to determine the properties of windows that affect solar gains. These properties are typical of the specific window of the specific building. On the contrary, the present model do not require all these information, though very difficult to determine, because it provides a constant coefficient C_w, that accounts for them. It is the mean value calculated on the available sample of buildings, of the product of the solar transmittance with the coefficients of curtains and frame, weighted on the corresponding glazed surfaces. The shading coefficient F_s is not included in C_w because the analysis demonstrated that it strongly depends on the single analysed case; however, the contribution of shading is accounted for in a simplified way, with the coefficient C_{sh}. It depends on the building and is another input data; it is defined as follows:

$$\begin{cases} F_s < 0.7 \rightarrow C_{sh} = 0.5 \\ 0.7 \le F_s < 0.85 \rightarrow C_{sh} = 0.75 \\ F_s \ge 0.85 \rightarrow C_{sh} = 0.95 \end{cases} \qquad (10)$$

The three categories are: buildings very shaded (C_{sh} = 0.5), with an average shading (C_{sh} = 0.75) and with poor or no shading (C_{sh} = 0.95). Finally:

$$E_{s,stat} = C_{opt} \cdot C_w \cdot C_{sh} \cdot \bar{I}_s \cdot S_{w,tot} \cdot N \qquad (11)$$

C_{opt} optimise the correlation between (11) and the corresponding Standard formulas in [13]. Now, we have the elements to express the ratio between the energy gains and losses:

$$\left.\frac{E_g}{E_l}\right|_{stat} = \left.\frac{E_s + E_i}{E_d + E_v}\right|_{stat} \qquad (12)$$

The energy gains utilization factor (η_u) and the mean global seasonal efficiency of the system (η_g) are calculated as the mean value over the available set of buildings.

RESULTS AND DISCUSSION

The goal of our study is to provide a useful tool for the assessment of the energy performance of new and, above all, existing buildings, easy and fast to use, which produces results in agreement with the Standards. The manipulation of classical analytical models by means of a statistical analysis has two advantages: it maintains the physical meaning of the classical models (increasing accuracy) and, being the new formulas simpler, it leads to rapid results. Table 1 reports the mean statistical orientation coefficients and the thermal bridge coefficients for vertical opaque and glazed surfaces, obtained from the analyzed sample of buildings. These coefficients are included in the proposed formula for C_d:

$$\begin{aligned} C_{d,stat} = {} & m_1 \cdot \left(1.117 \cdot U_{op} \cdot \frac{S_{op}}{V} + 0.65 \cdot U_{bs} \cdot \frac{S_{bs}}{V} + U_{pl} \cdot \frac{S_{pl}}{V} + 0.84 \cdot U_{at} \cdot \frac{S_{at}}{V} + U_{pr} \cdot \frac{S_{pr}}{V} \right) + \\ & + 1.2 \cdot \sum_{i=1}^{2} \left(1.115 \cdot U_{w,i} \cdot \frac{S_{w,i}}{V} \right) \end{aligned} \quad , \qquad (13)$$

where the subscripts are: *bs* for the basement floor, *pl* for the concrete slab on pilotis, *at* for the attic and *pr* for the plane roof.

Table 1. Coefficients used in the formula of C_d (13)

Coefficient	Units	Statistical mean value	Standard deviation
f_{op}	-	1.117	8.15e-3
f_w	-	1.115	18.5e-3
m_1	-	See table 1	-
m_2	-	1.2	-

Formula (13) is based on the following hypotheses. T_a = 20°C by default, while T_e = -8°C is specific for the district of Torino. The statistical values of the temperatures obtained from the available sample of buildings are: T_{bs} = 1.8°C (std.dev. 3°C) for the basement and T_{at} = -3.5°C (std.dev. 1.5°C) for the attic.
In (13), coefficients 0.65 and 0.84, that multiply the terms related to heat losses through basement and through the attic respectively, are affected by these assumptions about temperatures. However, in our sample of buildings the mean value of heat losses through the basement and the attic are, respectively, 8% (standard deviation 3.9%) and 10% (standard deviation 4.5%). Therefore, it is possible to use (13) for regions with climate different to Torino, with a modest error.
Compared with (1) and (2), equation (13) calculates the heat loss coefficient with less input data: only the transmittances of the most important envelope components and the geometric dimensions (surfaces and gross volume) of the building. The last data can be easily measured. Formula (13) is compared on the available sample of buildings with the methodology set by the Italian Standard, and the correlation is very good: $R^2 > 0.99$ and the proportionality coefficient is close to 1. The good correlation is because (13) is very similar to the Standard procedure; our purpose was to calculate C_d in a simpler way without giving up accuracy, because it is a very important quantity for *FEN*, as showed in (4).
Another important parameter is the ratio between energy gains and losses (12). The comparison with the same quantity obtained from the procedure prescribed in Standards [9], [13] shows a correlation index $R^2 > 0.85$ and a proportionality nearly unitary.
The proposed model strongly simplifies the solar gains; nevertheless, the comparison between their calculation according to the Standard procedure [13] and the proposed formula (11) shows a good correlation $R^2 = 0.92$, with a coefficient of proportionality of 0.976 (C_{opt}).
Efficiency η_g has been calculated as the mean value on the available data set. Unfortunately, equipment data were available only for a little number of buildings; for them, calculation according to Standard has given the mean value η_g = 0.804. Lacking specific data for every dwelling, this value has been extended to the whole sample, in coherence with their destination (all residential buildings).
All the parameters determined with the statistical approach and related to *FEN*, are collected in table 2. It also includes their standard deviation from the mean value.
The *FEN* proposed by our statistical study (FEN_{stat}), expressed in kJ/(m^{3}DD), results by introducing the foregoing terms in equation (4):

$$FEN_{stat} = \left(C_{d,stat} + C_{v,stat} - 0.968 \cdot \left(2.329 \cdot C_{sh} \frac{S_{w,tot}}{V} + 0.291 \cdot \frac{S_{rf}}{V} \frac{n_{apt}}{n_{apt,rf}} \right) \right) \cdot \frac{86.4}{0.804} \quad , \qquad (14)$$

$C_{d,stat}$ and C_{sh} are calculated according to (13) and (10) respectively. All the other quantities in (14) are only geometric, easy to determine.

Table 2. Coefficients determined from data of the available sample of buildings; they are used to calculate the proposed statistical *FEN*

Coefficient	Units	Statistical mean value	Standard deviation
$Q_{i,stat}$	W/m^2	4.6	-
C_{st}	-	0.914	45e-3
$\bar{I}_s$	kJ/m^2	6370	-
C_w	-	0.467	37e-3
C_{opt}	-	0.976	-
η_u	-	0.968	11e-3
η_g	-	0.804	43e-3

One limitation of the present model is that some of its coefficients have been calculated, with the statistical approach, on climatic data of the district of Torino. These data are: the temperatures related to the basement and to the attic in (13), the mean seasonal external temperature $\bar{T}_e$ and the mean global solar irradiance $\bar{I}_s$. However, the more the climate is similar to Torino, the smaller is the error that affects the correlations.
The results of equation (14) are reproduced in figure 1, having statistical *FEN* in abscissa and *FEN* according to Standard [13] in ordinate.

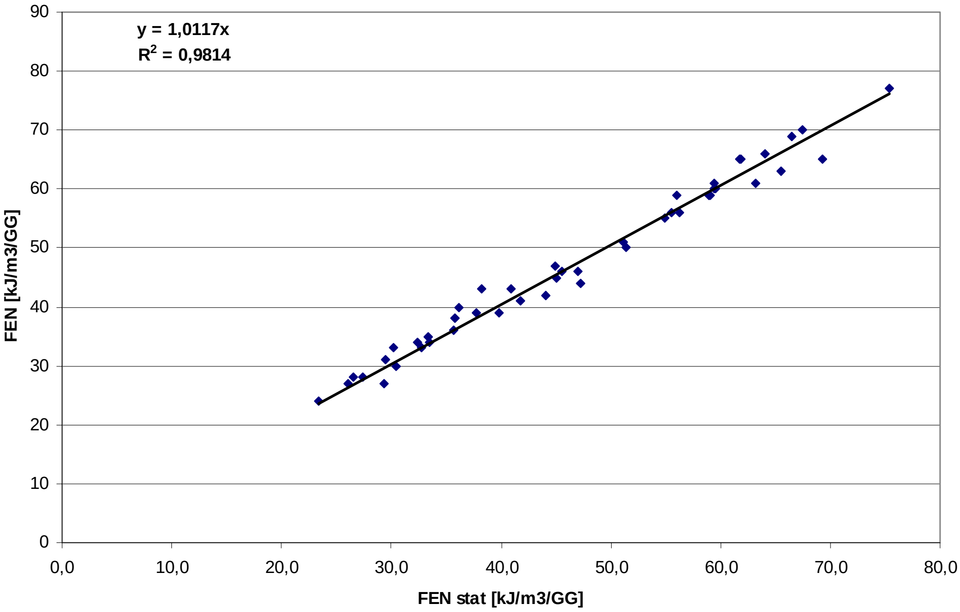

Figure 1. *FEN* calculated with Standard EN 832 versus *FEN* calculated with the proposed statistical formula (14); points refer to the available sample of buildings

The purpose of this graph is primarily to validate the proposed model. The results are in very good agreement, showing a proportionality coefficient close to 1 (1.012) and a correlation index $R^2 > 0.98$.
The most important result of our model is that it estimates in a direct, easy and quickly way the conventional energy demand parameter, which otherwise would require an involved procedure, if calculated according to the Standards approach.

The only required input data are the thermal transmittances of the most important components of the envelope, and some geometric dimension of the building. The last ones are easy to determine.
The model has been calibrated for the typical climate of the district of Torino; for buildings built in locations with analogous climatic conditions (external temperature, solar irradiance and DD), correlations (13) and (14) are in very good agreement with Standard procedure [9], [10], [12], [13].
Therefore, this model is particularly useful to estimate energy demand for space heating for existing residential buildings and it may represent a useful tool for their energy certification.

SUMMARY

Guiyang is the capital city of Guizhou province in southwest China, located in the Mild Climatic zone in China. With the economy booming in recent years, the energy consumption in heating and cooling buildings in Guiyang continues to increase. This paper presents a computer simulation studies using DeST software package, which is broadly used to simulate building energy consumption in China. The all-year round simulation for cooling and heating load for a small hotel building has been carried out with various parameters, and the results will be useful for the guidance of energy efficient building design in Guiyang.

INTRODUCTION

Guiyang is the capital city of Guizhou province in southwest China, located in the Mild Climatic zone in China. It's weather is featured comfort in summer and cool and humidity in winter. With the economy booming in recent years, the energy consumption in heating and cooling buildings in Guiyang continues to increase. As a result, the pollution from the energy consumption has been becoming more and more serious. In fact, Guizhou province is part of the districts where sour rain and SO_2 is limited by Chinese central government. The demands of coal in Guizhou province in 1990 is 27.14 million tonnes, and it is 45.91 million tonnes in 2000, According to the traditional forecast method, it will be 82.33 million tonnes in 2010. Furthermore, the SO_2 emission in 2000 is 2.18 million tonnes, it will be 39.1 million tonnes in 2010.Therefore, the analysis of the all year cooling and heating load in building will be useful for the guidance of energy efficient building design in Guiyang.

RESEARCH METHODS

In order to research the impact of thermodynamic parameters of envelop structure on all-year cooling and heating load of building, We present a computer simulation studies using DeST software package, which is broadly used to simulate building energy consumption in China. The all-year round simulation for cooling and heating load for a small hotel building has been carried out with various parameters. The model building consists of three floors, the ground floor consists of hall room and meeting room as well as porter room, it is 3.6 meters height. The first floor is for guests , it is 3.0 meters height. The second floor is for games such as playing card and chess, it is 3.0 meters height. The indoor temperature designed is 27℃, relative humidity designed is 50%, the actual thermodynamic parameters of the envelop structure in the building is as followings: the U-value of exterior wall is 1.49 w/(m^2.k), the U-value of roof is 0.812 w/(m^2.k), the U-value of exterior windows is 4.45 w/(m^2.k). And the heating sources in the building consists of lights and people. the planform of model building can be see in Figure 1.

Figure 1.Planform of model building

RESULTS

The impact of U-value of exterior wall on the all-year cooling and heating load

In DeST, we set up different U-value for the exterior wall but keep others stable. The result for the all-year cooling and heating load of the building is in Table 1

Table 1. All-year cooling and heating load on declining U-value of exterior wall

U-value of wall ($w/(m^2.k)$)	All-year heating load (kw.h)	All-year cooling load (kw.h)
2.095	95857	43566
1.519	85897	42567
1.275	81589	41999
1.079	79245	42545
0.976	77265	41819
0.902	76315	42363
0.824	74970	42212
0.706	72421	41543

0.591	70994	41863
0.532	70344	42202

The result from the simulation study shows: with the coefficient of heat transfer of exterior wall (U-value) decreasing each 0.1 w/(m^2.k), the all-year heating load in the building drops 1.98% in average, but the all-year cooling load almost holds the line.

The impact of U-value of window on the all-year cooling and heating load

In DeST， we set up the U-value of exterior wall as 1.0 w/(m^2.k) and keep other parameters stable, but change U-value for exterior windows, the result for the all-year cooling and heating load of the building is as Table 2.

Table 2. All-year cooling and heating load on declining U-value of glaze

U-value of wall (w/(m^2.k))	All-year heating load (kw.h)	All-year cooling load (kw.h)
5.8	79245	42545
4.5	77405	39967
3.2	72048	40068
2.5	69496	40137

The result from the Table2 shows: with U-value of exterior window decreasing from 5.8 w/(m^2.k) to 2.5 w/(m^2.k), the all-year heating load in the building drops 12%, but all-year cooling load doesn't change.

The impact of glazing ratio on the all-year cooling and heating load

In DeST， the U-value of exterior wall is set up as 1.0 w/(m^2.k),and the U-value of windows keep 3.2 w/(m^2.k),as well as the 0.812 w/(m^2.k) for roof， but we change the glazing ratio (window area to wall area), the result of the all-year cooling and heating load of the building is as following Table 3 and Table 4 .

Table 3. All-year heating load on rising glazing ratio（kw.h）

Glazing ratio	South	North	East	West
0.05	71037	71721	71667	73884
0.10	71454	74824	71496	73059
0.15	74957	80166	71352	72387
0.20	78920	85703	71234	71846
0.25	83134	91361	71139	71415
0.30	87514	97111	71065	71074
0.35	92013	102933	71008	70829
0.40	96597	108810	70969	70694
0.45	101253	114733	70946	70610
0.50	105970	120692	70937	70570
0.55	110740	126683	70952	70671
0.60	115556	132698	71014	70813
0.65	120408	138738	71087	71123

0.70	125294	144801	71170	71596

Table 4. All-year cooling load on rising glazing ratio（kw.h）

Glazing ratio	South	North	East	West
0.05	45220	48399	45627	36843
0.10	58175	59225	46385	39361
0.15	71359	69698	47185	42071
0.20	84478	79981	47984	45004
0.25	97547	90171	48799	48138
0.30	110575	100334	49641	51368
0.35	123499	110446	50512	54668
0.40	136363	120504	51432	58046
0.45	149140	130516	52389	61456
0.50	161808	140503	53358	64901
0.55	174412	150470	54346	68312
0.60	186988	160407	55372	71769
0.65	199497	170336	56336	75196
0.70	211976	180274	57330	78574

The result from the simulation shows: with the glazing ratio (window area to wall area) in south wall increasing each 5%, the all-year heating load in the building grows 4.47% and the all-year cooling load consumption grows 12.8% in average for a building implemented standard U-value in Guiyang; With the glazing ratio in north window increasing each 5%, the all-year heating load in the building grows 5.56% and the all-year cooling load grows 10.74% in average; it is interesting that with the changes of the glazing ratios in the east and west walls, the all-year heating load have no significant changes; with the glazing ratio in the east wall area increasing each 5%, the all-year cooling load grows 1.17% in average; the glazing ratio in the west wall increasing each 5%, the all-year cooling load 6.00 % in average.

CONCLUSION

From above case study, we draw the conclusions as the followings:

The coefficients of heat transfer (U-value) of exterior wall and window are the important factors to the all-year building heating load in Guiyang city, but it almost has no significant impact on the all-year cooling load;

The glazing ratios in south and north walls have a significant impact on all-year heating load, but those in east and west walls have less impact;

The glazing ratios in all orientations have significant impact on cooling load with importance degree order of north、south、east and west.

ACKNOWLEDGEMENT

The research in this paper is supported by the Centre of Sino-European Sustainable Building Design and Construction funded by European Commission(Contract No.CN/ASIA-

Link/011(91400)), which aims to raise awareness of the environment and simulate renewable energy in building design in China.

Empirical Correlations of Solar and Other Weather Parameters for the Capital Zone "Damascus" In Syria

Kamal Skeiker

Department of Scientific Services, Atomic Energy Commission, Damascus, Syria

Corresponding email:kskeiker@aec.org.sy

ABSTRACT

This work presents a mathematical representation of a few chosen weather parameters of the capital zone "Damascus" in Syria.

Seasonal models, as an alternative to the use of hourly historical weather data, were suggested and used to generate synthetic weather data for the following parameters:

- relative humidity;
- atmospheric pressure;
- global solar radiation intensity.

Such mathematical models were derived for the heating season (November to April) and for the air-conditioning season (June to September) in the zone involved. Moreover, daily sunshine-hours rate was also represented by single model throughout a year. These models were developed based on long time records of data.

The choice of the best model was based on three statistical parameters: the coefficient of determination R^2, the mean relative error e_m and the t-test.

The predicted values along with the recorded data were plotted on the same scale in order to consider a visual comparison between them. It is visually noticeable that good agreement between the predicted and observed data values was obtained.

Keywords: Building design; Thermal analysis; Mathematical models; Weather parameters

INTRODUCTION

Since the greatest share of the energy consumption is used in building [1], it was worth to carry out research in this field. Therefore, the research was mainly directed towards the development of mathematical models for thermal system calculations and simulations.

The proliferation of high power personal computers, have helped in the advancement of the science of system calculation and simulation. Currently, there exist many computer programs for the energy analysis of buildings, [2]. A list of these programs is beyond the scope of this article. Most of these programs require hourly meteorological data of the site as part of the input. Therefore, they are provided with an hourly Typical Meteorological Year "TMY" database for the considered locality. Such TMY database contains a sequence of 8760 hourly values of some chosen weather parameters. Since this TMY database occupy a large area on the PC's hard disc, effort to represent it by using a mathematical representation of the weather parameters were made ([4] to [9]). Therefore, a decision was made to identify seasonal models, as an alternative to the use of hourly historical meteorological data and to generate synthetic meteorological data. Consequently, within the framework of this paper, seasonal models were suggested for the following weather parameters:

- relative humidity;
- atmospheric pressure;
- global solar radiation intensity.

Such mathematical models were derived for the heating season (November to April) and for the air-conditioning season (June to September) in Damascus zone. Moreover, a single model throughout a year was derived also to generate daily sunshine-hours rate.

DATA USED

In order to identify mathematical seasonal models for the weather parameters mentioned in the introduction, the hourly data for each of those parameters, are required. Such hourly weather data used in this analysis are extracted from the hourly TMY database for the Damascus zone. The procedure used to organize and develop this TMY database is given in [3]. Development of such a TMY database was based on the available hourly weather data for the Damascus zone, which were measured by the Department of Meteorology.

SUGGESTED SEASONAL MODELS

New mathematical models representing the data of the sunshine-hours rate, relative humidity, atmospheric pressure and global solar radiation intensity are suggested. The procedure used to identify such mathematical model is described in detail in a previous article [10]. Initially, several models were attempted. Finally, one important type of curvilinear response model, namely a particular case of the multi-polynomial regression model, was considered [11 to 16]. Modern software was used to minimize the sum of the squares of the residuals and to perform the above mentioned calculations [17].

Daily sunshine-hours rate N was represented by single model throughout a year. The adequate model for predicting sunshine-hours rate, for an optional date during the year was obtained. This model is expressed in the following relation:

$$N(d) = a_0 + a_1 \text{Sin} [a_2 (d - a_3)] \qquad (1)$$

The explanatory variable for this parameter is d. d denotes the day under consideration and takes the values 1 (1st January) through 365 (31st December) representing the year's days. This model is mainly applicable within the range from 2-14h.

Weather parameters such as relative humidity, atmospheric pressure and global solar radiation intensity, show considerable changes both daily and annually. In the estimation studies, these parameters can be considered to consist of two components.

The relative humidity and atmospheric pressure at any instant during a day of the heating and air-conditioning seasons can be estimated from a single expression:

$$\mathbf{y}(\mathbf{t}_1,\mathbf{t}_2)=\mathbf{a}_0+\mathbf{a}_1\mathbf{t}_1+\mathbf{a}_2\mathbf{t}_1^2+\mathbf{a}_3\mathbf{Sin}\left[\frac{\pi}{12}(\mathbf{t}_2-10)\right] \qquad (2)$$

The suggested models for relative humidity are mainly applicable within the range from 50-100% and from 5-80% for the heating season and air-conditioning season, respectively. Moreover, the suggested models for atmospheric pressure are mainly applicable within the range from 900-1000mbar and from 930-1100mbar for the heating season and air-conditioning season, respectively.

The adequate models for predicting global solar radiation intensity for an optional time during the heating and air-conditioning seasons are obtained. These models are expressed in the following general relation:

$$I_t(t_1,t_2)=I_1(t_1)\,I_2(t_2) \qquad (3)$$

$I_1(t_1)$ and $I_2(t_2)$ are given in the following relations:

$$\mathbf{I}_1(\mathbf{t}_1)=\mathbf{a}_0+\mathbf{a}_1\mathbf{t}_1+\mathbf{a}_2\mathbf{t}_1^2 \qquad (4)$$

$$\mathbf{I}_2(\mathbf{t}_2)=\frac{1}{\pi}+\frac{1}{2}\mathbf{Sin}\left[\frac{\pi}{12}(\mathbf{t}_2-6)\right]-\frac{2}{\pi}\left\{\frac{\mathbf{Cos}\left[\frac{\pi}{6}(\mathbf{t}_2-6)\right]}{3}+\frac{\mathbf{Cos}\left[\frac{\pi}{3}(\mathbf{t}_2-6)\right]}{15}+\frac{\mathbf{Cos}\left[\frac{\pi}{2}(\mathbf{t}_2-6)\right]}{35}\right\} \qquad (5)$$

These models are mainly applicable within the range up to 600 W/m^2 and 1150 W/m^2 for the heating season and air-conditioning season, respectively.

The various estimators above, a_k, were determined by using the least square curve fitting technique. The estimators a_k and the statistical parameters R^2, $\sigma(\phi)$ and e_m of these models are listed in Tables 1 to 4.

Table 1: Estimators and statistical parameters for sunshine-hours rate model

Weather parameter	a_0	a_1	a_2	a_3	R^2	$\sigma(N)$ [h]	e_m
Sunshine-hour rate	8.6411	3.3957	172.142 10^{-4}	98.6487	0.92	0.71	0.073

Table 2: Estimators and statistical parameters for the seasonal models of air relative humidity

Season	a_0	a_1	a_2	a_3	R^2	$\sigma(\phi)$ [%]	e_m
Heating	59.9700	17.1947 10^{-3}	-4.9325 10^{-6}	-18.2980	0.90	5.33	0.071
Air-conditioning	38.9788	07.4552 10^{-3}	-1.5553 10^{-6}	-29.1878	0.95	4.56	0.086

Table 3: Estimators and statistical parameters for the seasonal models of atmospheric pressure

Season	a_0	a_1	a_2	a_3	R^2	$\sigma(p)$ [mbar]	e_m
Heating	0984.641	-27.9543 10^{-3}	7.5039 10^{-6}	19.4222	0.92	5.60	0.005
Air-conditioning	1014.300	21.2620 10^{-3}	-7.7477 10^{-6}	30.0247	0.96	4.48	0.003

Table 4: Estimators and statistical parameters for the seasonal models of global solar radiation intensity

Season	a_0	a_1	a_2	R^2	$\sigma(I_t)$ [W/m^2]	e_m
Heating	495.3268	-9.8596 10^{-2}	4.9532 10^{-5}	0.90	6.93	0.070
Air-conditioning	920.6284	0.0	0.0	0.96	6.16	0.024

The t-test (two sides) criterion was used to check whether the assumed models are adequate to represent the long-term set of weather data and correspond to the TMY. The test was achieved using a confidence level of 95% with the confidence limit $1.96(\sigma/\sqrt{\mathbf{n}})$. It was found that the P-values for sunshine hours rate, relative humidity, atmospheric pressure and global solar radiation intensity are 0.94, 0.96, 0.93 and 0.98 respectively. One can see that, for each of the four meteorological parameters used P-value>0.05.

CONCLUSION

Mathematical seasonal models were suggested for the following weather parameters:

- - Relative humidity,
- - Atmospheric pressure,
- - Global solar radiation intensity.

Such mathematical models were derived for the heating season and for the air-conditioning season in the Damascus zone.

It is proposed to estimate the above mentioned weather parameters at any instant during a day of the heating and air-conditioning seasons in terms of a single model consisting of seasonal and daily harmonics. Moreover, daily sunshine-hours rate was presented by single model throughout a year in the form of a sinusoidal periodic function. They were developed based on long time records of data. The technique used in determining the best-fitting curve is the method of 'least squares'

The choice of the best model was based on three statistical parameters: The coefficient of determination R^2, the mean relative error e_m and the t-test.

Since we deal with large sets of data (4344 or 2928 data points for the heating or air-conditioning season) the suggested models can estimate the above-mentioned parameters with acceptable R^2 and e_m.

The suggested mathematical models can be used in the CLIMA computer program for the dynamic analysis of heat transfer in building [2], as an alternative to the using hourly historical weather data.

Such approach needs to be followed for the remaining zones of the country under consideration.

ACKNOWLEDGMENTS

The author would like to express gratitude to Prof. Dr. Ibrahim Othman the Director General, for his continued interest and encouragement to this work. He is also grateful to Prof. Dr. Tawfik Kassam and Dr. Mohamed Tlass, for valuable discussions and suggestions. Finally, thanks are due to the Department of Meteorology, for giving the determined hourly weather data of Damascus zone for the available previous years.

1 Introduction

The paper implies that the methods most frequently used for cooling load calculation (simplified dynamic modelling like e.g. admittance procedure) can be also applied when estimating the annual cooling energy use of buildings. Such approach makes good use of well-established and recently improved tools in another area – in energy performance rating of buildings with regard to their sustainability.
The idea is to replace the design day for cooling load calculation by design day for cooling energy need (DEDCEN) while keeping the same calculation procedure. This would enable to introduce the dynamic impact of weather to the calculation of cooling energy use.

2 Methodology

Three different methods were developed and employed in searching for appropriate 12 DEDCENs representing individual months of a year. Two methods were based on statistical analysis of design reference year data. The statistical analyses were developed from TMY2 (M1) and EN ISO 15927-4 (M2) procedure [1] [2].
In the third method (M3) we used known values of the cooling energy need for well-defined building types to select the DEDCENs from all-year data.
Cooling energy need calculated with DEDCENs and admittance procedure should be as similar to known values of the cooling energy need for all of the building types as possible.
The results of the three tested methods were compared to each other and evaluated by the IEA building energy simulation test (BESTEST). Four realistic building configurations (600, 620, 900 and 920) were selected.

3 Results

The results show that the predictions of cooling energy use based on 12 DEDCENs varied from 96 to 108 % of the values obtained from the complete reference year data (Fig.1). The best results were obtained by the method M3, results were within 96 to 103 % of the all-year values. In other words, it was proved that instead of the all-year database representing 365 days (8760 hourly steps) we can use 12 DEDCENs (one for each month of the year) requiring only 288 hourly steps while keeping acceptable accuracy.

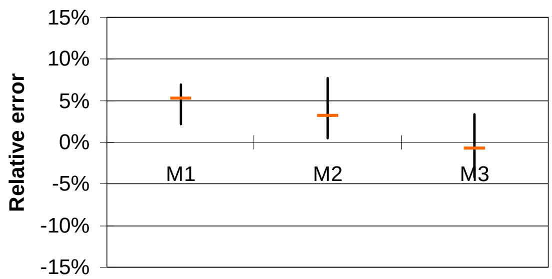

Figure1: Relative errors of cooling energy need calculation using DEDCENs compared to all-year data (set to 100%)

4 Conclusions

The developed methodology has a potential to improve standard procedures for the prediction of cooling energy use of buildings in terms of accuracy and efficiency.

Indicators for Study of Micro-Climate Impacts on Urban Sustainability

Kok Wee Ng and Hirota Keiko

University of New South Wales, Australia

Corresponding email: KokN@fbe.unsw.edu.au

SUMMARY

Key factors of urban sustainability development are energy efficiency measures that reduce carbon emissions, exhaust heat as well as strategies to mitigate climate change and Micro-Climate (MC). The paper details part of study in identifying a suite of environmental indicators that fulfill this role.

Reviews and comparison of current assessment tools conclude that economic, social and comfort parameters are not emphasized within assessment criteria of most tools for urban sustainable development (USD)(Ian Cooper 1999). Focus of tools seems to be on issues regarding energy, landscape, resources and built environment. The selection criteria for additional environmental assessment indicators are to decrease building energy consumption and alleviate heat island (HI) effects. Influence of climatic variables upon neighborhoods, urban activity and energy load of building envelope performance have an impact on mitigating MC and should be reflected in Urban Environmental Indicators (UEI) for building assessment criteria. Effectiveness of mitigation strategies for MC would lead to further understanding of contribution to energy demands on building envelope performance.

Coupling USD model to building envelope performance would relate consequences resulting from building thermal load to mitigate MC in terms of urban comfort. An investigation into developing methodology towards linking building energy demands and MC modifications is described. UEI for buildings are identified for further research to mitigate MC on USD and the energy demand of building envelope performance.

INTRODUCTION

Improving energy efficiency in buildings and infrastructure is often considered to be one of the most cost-effective measures for cutting down carbon emissions and considerable energy saving potential has been demonstrated in different countries. The purpose of energy conservation, in a narrow sense, is to efficiently maintain a comfortable indoor climate as an environmental unit. However, beyond the limits of this unit are larger external environmental units such as regional communities and urban cities which is an integral part of the global environment. Urban environment provides a good intervention point for building efficiency improvements as they can be coupled with urban renewal measures and provides synergy when linked together. Key factors of USD are energy efficiency measures that reduce environmental impacts such as greenhouse gas emissions (GHG), exhaust heat as well as strategies to mitigate climate change and MC impacts. Much of current research focus is on energy usage in urbanscape because energy consumption is related to production of GHG such as methane, carbon dioxide, ozone, nitrous oxide. Reports by (Intergovernmental Panel on Climate Change 1996) and OECD note that approximately 25 - 30% of total energy-related carbon dioxide (CO2) emissions come from buildings and infrastructure. (Kenneth Button 2002) provides comprehensive discussion of concepts regarding measurement of urban sustainability in terms of energy consumption and environmental impact.

Enhanced urbanization has an impact on MC conditions as a result of energy demands of buildings. Furthermore, atmospheric pollution, combined with pollutants emitted from building materials and anthropogenic activities, influence energy behavior of ventilation and air conditioning in a way that tend to enhance HI. Further to higher sophisticated factors of comfort levels such as thermal load, spatial design, social interaction concerns, there are additional expectations for the energy efficiency of a building for not only reducing environmental impacts but also providing more advanced quality of urban built environment.

Energy efficiency of building is dependant on performance of total building system and requirements for building performance evaluation gave rise to various types of assessment systems for designing energy efficient buildings. Current building assessment systems are predominantly focused on improvement in areas of urban ecological restructuring (UER) by improving urban spatial heterogeneity and energy efficiency of building envelope but lack depth of research in other dimensions such as socio-economic concerns and values of most investors, designers and urban planners. This study reviews current perspectives on market barriers to efficiency investments. Without pragmatic and realist economic assessment together with multiple disciplinary approaches tailored to particular circumstances, efficiency investments would not succeed in market transformation/acceptance. Value case for energy efficient buildings is compelling due to increasing number of case studies (Greg Kats 2003), employing conventional and advanced property valuation methods show that efficiency investment returns, cost and benefit analysis of good quality office buildings varies from 15% less to 11.5% with energy efficient features costing average of additional 2-6%. To further strengthen economic case for energy efficient property by investigations into key selection criteria for financial, environmental and social indicators. The next logical step is to research into design and development of integrated valuation methodology to investigate effectiveness of UER due to MC impacts and further understanding of energy demands on building envelope performance.

AIM

This paper is investigating whether the purpose and focus of attention of indicators and performance criteria for assessing the environmental performance of buildings and urban environment need to be reviewed. It is considering whether building assessment systems should move from addressing the already complex task of assessing environmental protection and resource efficiency to addressing a much more problematic one – the sustainability of the urban built environment. As argued by (Raymond J Cole 1999), the current building assessment framework is deficient since it only assess performance against relative rather than absolute, criteria. As a result, there is insufficient guarantee that buildings that scored highly in the assessment are making a substantive contribution to increased ‘environmental’ sustainability at urban or global scale. This is because current building assessment systems relate to sustainability of buildings and urban built environment as a simple matter of energy and resource flows without due regard to socioeconomic and political dimensions of sustainability(Ian Cooper 1999). It is unlikely the current building assessment systems, while capable of assessing individual aspects of building performance, could cope with the varying interests of wide range of stakeholders present in the built environment. In order to address sustainability in a wholesome, integrated and iterative approach, a range of co-coordinated methods and techniques for undertaking assessments of different components of sustainability should be adopted as the productive way forward(Raymond J Cole 2000).

Currently, this study is attempting to investigate whether it is feasible to reform existing, unified building assessment methods, such as GBC 2000, BREEAM, LEED and CASBEE, in an attempt to make them accommodate assessment of broader, non-environmental components of sustainability(Singh Intachooto and Vimolsiddhi Horayangkura 2007). It is important to note that there are many current different interpretations/methodologies to balance three macroeconomic concerns from industry and academic(Terry Boyd and Phillip Kimmet 2005). Nonetheless, this study represents one such approach deemed feasible for integrating environmental-socio-economic aspects into building assessment method so that the result of proposed integrated methodology would maximize the benefits of energy efficiency in building envelope, property value and the impacts on urban environment by analysis of total building system.

BUILDING PERFORMANCE INDICATORS

Improvement of building performance depends on various elements of technology from the level of material selection to building components and finally to the entire building (Singh Intachooto and Vimolsiddhi Horayangkura 2007). The development of energy-efficient building service systems and the methodology of technology integration into buildings by means of whole building approach need to be studied. This study focuses on commercial office building stock and research into methodology of linking building energy demands with UER from property valuation's point of view to balance conventional economic interests with environmental and social objectives as a framework for encouraging institutional concerns about sustainability by:

1 Assessment and formulation of an integrated valuation methodology for evaluating social, economic and environmental performance in commercial office buildings in urban context.
2 Verification of the valuation methodology in ensuring that social, economic and environmental performance standards are met.
3 Discussion of investigation into developing assessment indicators for property valuation and building envelope efficiency as well as microclimate mitigation strategies in urban context.

Based on the above, the research would include an assessment into the prediction of future short-and long-term scenarios, and a description of Business As Usual (BAU) scenario to be analyzed in relation to cutting GHG emissions from perspective of property investment(Marilyn A. Brown 1998). In addition to addressed concerns, implications of selection criteria for social, economic and environmental indicators to integrated valuation methodology are to be investigated. This is to be conducted by means of data mining and multiple regression analysis with microclimate and energy efficiency simulations. Case studies of conventional and green office buildings from property investment point of view are to be included as part of study. Results would undergo process of verification and review with respect to aim of investigation.

ENERGY EFFICIENCY INDICATORS

Energy efficiency of a building is dependant on the performance of the total building system, and the energy performance of the building system. Buildings consume more than 40% of final energy consumption within the EU and contribute to carbon dioxide emissions that cause global warming. In order to reduce GHG emissions, energy efficiency issues are addressed by reduction in energy consumption of buildings and enhancement of energy performance. Therefore, initiatives that reduce total energy consumption of buildings can be identified as one of the many important leverage points in the effort to reduce additional emissions of carbon dioxide emissions into the atmosphere.

The three main features listed by (Alan Meier ;Thomas Olofsson and Roberto Lamberts 2002) covers an adequate definition of an energy efficient building:

1 Containing energy efficient technologies, operating as designed, in reducing energy use
2 Supplying required amenities and features expected for standard use of commercial office building for at least 60 hours per week
3 Operated in a manner to be efficient, which gives evidence of low energy use when compared to other similar commercial office buildings

In addressing the objective and sub-objectives of research scope and focus, this study endeavors to address the following:

1 How to assess building energy efficiency of commercial office buildings in a transparent manner and which aspects can be identified for extraction of property valuation study?
2 How to verify proposed assessment procedure and to apply in study of existing green and ordinary commercial office building stock?
3 What implications of this proposed assessment procedure have for study of property valuation of green office buildings?

Studies from the U.S.A and Australia have shown that energy improvements have the potential to enhance these countries' economic prosperity and at the same time, lower GHG emissions(Australian Government Productivity Commission 2005). In this context, energy efficiency refers to maintaining or increasing the level of useful output or outcome while reducing energy consumption, encompassing both supply and demand side efficiency. Achieving greater energy efficiency is attractive to governments and environmental organizations concerned with climate change as it offers prospect of significant reductions in emissions – at low or negligible costs to energy users(Sam C.M.Hui 2003).

URBAN ENVIRONMENTAL INDICATORS

The enhanced urbanization has an impact on MC conditions as a result of energy demands of buildings. Furthermore, atmospheric pollution, combined with pollutants emitted from building materials and anthropogenic activities, influence energy behavior of ventilation and air conditioning in a way that tend to enhance HI.

Modification of earth's surface through urbanization has an impact on local climate. Urban areas, especially those of horizontal growth, are subject to bizarre weather patterns, collectively known as MC. These MC differ from prevailing weather patterns in neighboring rural areas. The particular MC phenomenon associated with urban areas is known as HI. HI phenomenon can occur at a range of scales; it can manifest around a single building, small canopy or a large portion of the urban environment. The magnitude of climate difference can be quite large depending on weather conditions, urban thermo physical and geometrical characteristics, and anthropogenic moisture and heat sources in the city(Haider Taha 1997). Depending on geographic location and prevailing weather conditions, HI may be beneficial or detrimental to urban dwellers and energy consumers. Generally speaking, HI are unwanted because they contribute to cooling loads, thermal discomfort, and air pollution or reduce heating energy requirements(Yoshika Yamamoto 2006).

In an urbanized environment, there are significant modifiers of natural cycle of heating and cooling(Linda A. George and William G Becker 2003). These include:

1 Human-made structures such as streets and buildings.
2 Urban surfaces tend to heat up faster than natural surfaces, such as vegetation, that retain water.
3 Introduction of anthropogenic heat sources from heating and ventilation systems, industrial processes and internal combustion engines.

To define and to make effective use of urban economic and environmental indicators requires an appreciation of the context in which they are developed. Urban areas, because of their concentration of population and productive capacity, are inevitably major generators of GHG emissions (Kenneth Button 2002). The need for UEI is to provide guidelines as to the damage being done to the urban environment and the links to economic activities. There are a number of key criteria for consideration in the selection of UEI:

1 Indicators should be relatively small in numbers and reflect important urban environmental effects and trends
2 Additional indicators to relate one another in key sectors with multi-dimensional effects
3 Important for indicators to be sensitive to prevailing underlying conditions and offer forecasts of possible occurrence
4 Indicators to be quantifiable
5 Indicators be consistent across urban areas

Urban planning is increasing confronted with climatic questions connected to projected land-use transformations. The growing awareness that HI and global warming are both the result of mass consumption of energy and resources led to adaptation of similar mitigation measures: energy and resource savings in buildings, energy-saving traffic systems and improvements to urban air circulation(Yoshika Yamamoto 2006). Current assessment system is designed only to assess buildings on an individual basis. There is therefore, a need for comprehensive techniques to assess the overall effects of mitigation strategies for entire cities in order to mitigate UHI effects. Although social and economic demands are currently dominating environmental issues, study have shown that planners are aware of the need for optimizing urban planning processes with respect to MC in order to achieve better public acceptance of their projects(D. Scherer 1999).

FINANCIAL INDICATORS

Studies(Green Building Council (Australia) 2006) have shown that households, businesses, investors, governmental agencies have numerous opportunities to invest in cost-effective, energy efficient buildings despite awareness of the environmental concerns and energy independence. The pursuit of energy efficiency would seem to be in the interests of any rational producer or consumer, firm or household yet the market is not adopting such measures even when it seems to be cost effective for them to do so(Jonathan Garo Koomey 1990).

Introducing environmentally responsible and innovative solutions in buildings is difficult. Major groups of barriers in construction projects include financial, technical, and psychological barriers in addition to complacent clients and incompetent professionals and conservative building codes. Other products and services face obstacles that hinder their adaptation, even when consumer economics appear favorable. Conditions hindering cost-effective investments in energy efficiency and clean energy resources received considerable attention because of widespread environmental, national security and macroeconomic repercussions. Understanding the barriers to this technological adaptation is essential in defining potentially effective investment strategies and governmental incentives(Marilyn A. Brown 2001).

Based on insights gained from investigating building professionals who pursue energy-efficient buildings in Austria, Canada, England, Germany, Scotland, Sweden, and Thailand (Singh Intachooto and Vimolsiddhi Horayangkura 2007), five circumstance which financial barriers would emerged have been identified:

1 Innovative solution affects multiple components requiring higher overall investment
2 Innovative solution may not be worthwhile within a reasonable period of time
3 Innovative technology commands higher investment than commonly used standard solutions
4 Budget lacks financial compensation for devising and developing innovative solutions
5 Mismatched design and construction budget – overspending in certain areas while hoarding expenditure on basics that are necessary for implementing innovative solution

The perception of property as a commodity is changing into emphasis of building characteristics and performance as major determinants of a property's worth and market value, thereby requiring new ways of assessing worth and value (Green Building Council (Australia) 2006). Commercial property valuation represents a major mechanism that could allow environmental and social considerations to be more aligned with economic return. Initial considerations are currently being explored for incorporation of environmental and social issues into valuation theory and practice(Thomas Lutzkendorf and David Lorenz 2005). Possible sustainability key performance indicators are identified and principles for assessing performance along the life cycle of buildings are being investigated(Terry Boyd and Phillip Kimmet 2005). The simultaneous consideration of economic, environmental and social issues can provide a more robust assessment approach and lead to greater reliability of assessment results(Rachel Castillo & Ngai Chi Chung 2004). This would create a more robust assessment approach and lead to greater reliability of valuation results. In addition, opportunities and implications afforded by synergies between sustainable design and risk management are identified for property risk assessment in investing and insurance functions are included as part of this study(Philip Kimmet and Per-Arne Wikstrom 2005).

DISCUSSION

The study aims for improvements in air quality, reduction in health risks and benefits for occupant productivity whilst reducing MC impacts through urban ecological restructuring and environmental efficiency(A.M. Papadopoulos and N. Moussiopoulos 2004).

Building automation and information systems

Web Service based integration of building information systems

Veijo Lappalainen and Kalevi Piira

VTT, Finland

Corresponding email: Veijo.Lappalainen@vtt.f i

SUMMARY

The development of new information technologies and standards like Internet and WWW, building control networks, data communication protocols, wireless sensors, mesh networks, product data technologies etc. enables the development of the intelligent, real-time buildings and related new business models in the marketplace of real estate information systems. On of the most promising integration technology in this context is Web Services technologies. The paper first introduces the starting points as well as needs and future challenges for the development. Basic generic ideas of Web Services technologies are then introduced. Main consideration is thereafter focused to the introduction of standard based building automation Web Services approaches: BACnet Web Services and Open Building Information Exchange (oBIX). The basic ideas and concepts of these two methods will be introduced and discussed.

INTRODUCTION

The operation and maintenance of buildings have become dependent on various building automation and information systems (HVAC control, electricity and lighting control, burglar alarm, access control, CCTV), technical building management systems (energy management, FM, BIM) and financial - administrative systems (accounting, personnel administration, renting, space management). In addition, integration of building systems with enterprise systems is becoming more and more important.

These existing building information systems are typically fragmented and isolated from each other forming “automation islands”, which do not communicate together. A consequence of this can be the different systems contain overlapping information, which creates a risk for data integrity. Also because the lacking communication between different systems, it is common nowadays that the information needed by the integrative applications must be collected up manually from different systems and reports.

One of the most important future challenges is the interfacing and integration of the existing applications and to enable the sharing of the information already existing in different systems. New information technologies and standards like Internet and Web, building control networks, data communication protocols, wireless sensors and mesh networks, product data technologies etc. enable the development of the integrated, intelligent real-time buildings and new ICT based building services. Regarding the systems integration, Web Services technologies have become the most promising integration technology.

Standard based open system architectures including object models, interface and service definitions are needed to enable the subsystem and component development. The most important standards official and industry standards will be discussed.

WEB SERVICES AS A GENERIC INTEGRATION TECHNOLOGY

In recent years Internet has become a basic element of data communication network infrastructure. A big challenge still is the integration the systems to enable automatic data transfer between various applications without the need of manual intervention. One solution is the programmable Internet, which fundamental building block is Web Services.

The idea of Web Services (http://www.w3.org/2002/ws/) is to connect applications (and machines) by the same way as e-mail connects people and Web connects people to information. Web Services are platform independent, specifications are based on existing standards and the easy programming of Web Services may affect for application-to-application (machine-to-machine, B2B) communication in the same way as the easy programming of html affects into the breakthrough of the www.

If the objective is performance or reliability, then there are better technologies than Web Services. If the objective is to integrate different loosely coupled components and services, which are decentralized over Internet, then Web Services is the right technology.

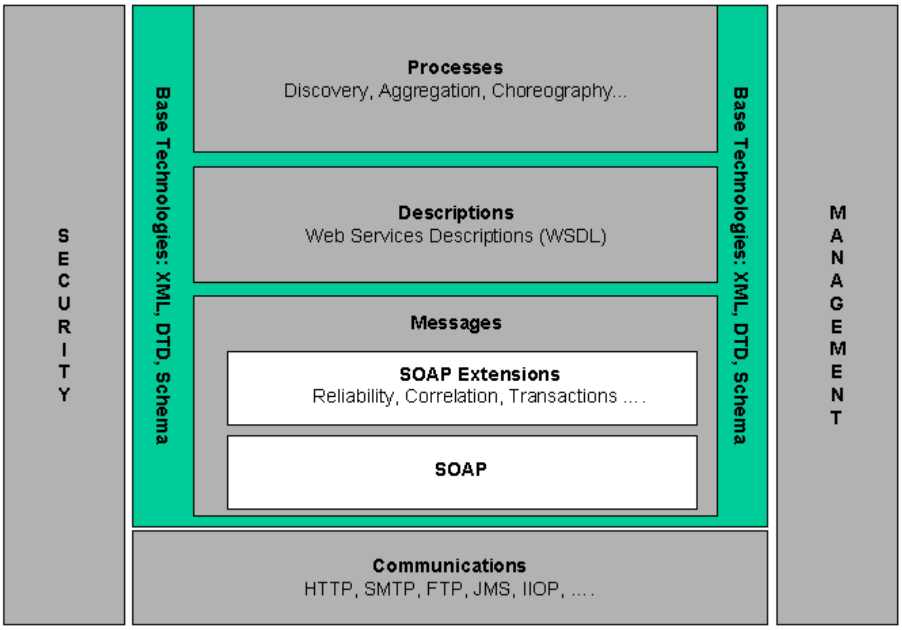

Figure 1 Web services architecture stack

The Web Services architecture is built on the Internet and the XML family of technologies. Main technologies are SOAP (communications protocol), WSDL (service describtion), UDDI (service discovery) and XML technologies (representation of documents) [5]. These Web Services technologies are language, platform, operating system and hardware independent technologies and they provide a standard means of interoperating between different software applications and decentralizing loosely coupled components and services into the Internet. The main Web Services architecture stacks are illustrated in Figure 1.

Unlike many other approaches to integration, Web Services connect devices simply by agreeing on message format, rather than forcing disparate devices to run identical software. Additional functionality for building secure, reliable, transacted Web Services—are possible through a set of recently published specifications (SOAP messaging formats) known as the Advanced Web Services architecture. The ubiquity of HTTP and the simplicity of SOAP make them an ideal basis for implementing Web Services that can be called from almost any environment. Web Services runtime communication is shown in Figure 2.

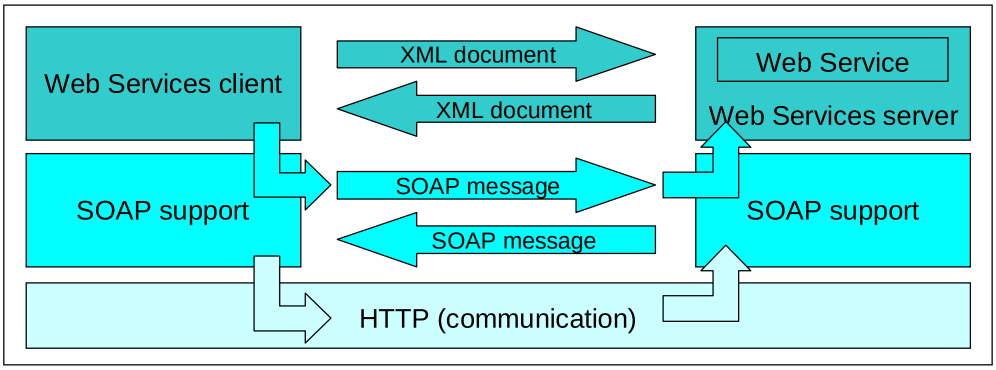

Figure 2. Web Services runtime communication

WEB SERVICES AS A INTEGRATION TECHNOLOGY OF BUILDING AUTOMATION AND INFORMATION SYSTEMS

Creation of the new Web Services Interfaces into building automation systems has been motivated by recognition that Web Services will be emerging as the predominant technology for the integration of a wide variety of enterprise information systems. The objective has been therefore to define standard means of using Web Services for integration and exchange of facility data from disparate data sources, including building control networks, with a variety of business enterprise applications.

The standardization efforts for the application of XML/Web Services to Building Automation started under the umbrella of CABA (http://www.caba.org) in April 2003, when the first meeting of the CABA XML Guideline Committee was held. In that time the different interest groups like BACnet, LON, Modbus, etc. societies worked together. At the end of 2003 it became clear that rather than a lightweight guideline an official or industrial standard was needed. Also it became clear CABA was not the right umbrella organization to bring the standard into the practice.

At that time the name oBIX (Open Building Information Xchange) was given to CABA’s XML/Web Services Guideline committee and discussion started about which standardization organization oBIX should be joined. There were finally two main alternatives: OASIS and ASHRAE. LonWorks and more business oriented members were targeting to IT like standard and were supporting OASIS. BACnet and HVAC oriented members wanted that the new standard should be HVAC and building domain originated and they were promoting ASHRAE, hosting also BACnet standardization.

The discussions took about six months without reaching consensus. The opinions were uncompromising and the consequence was that the CABA’s oBIX committee joined to OASIS but without BACnet society. The BACnet opposition started their own XML/WS standardization process with a new work item in ASHRAE SSPC 135 (Standing Standard Project Committee), in its XML working group (XML-WG).

BACnet/WS standardization progressed in the beginning quite quickly and the draft BACnet/WS standard was published for the first public review in October 2004. The second draft of the standard was published for the public review in March 2006. The final version of BACnet/WS standard [1] was approved by the ASHRAE Standards Committee and by the

ASHRAE Board of Directors in September 2006; and by the American National Standards Institute (ANSI) in October 2006.

The standardization work within OASIS oBIX committee did not start as fast as within BACnet/WS committee. However, several draft versions of the standard were published in Web. The first public review version was published in July 2006. After resolving the review comments OBIX TC approved the first version of the standard in December 2006 [4]. The objective is to get the standard approved by OASIS in early 2007.

BUILDING AUTOMATION WEB SERVICE TECHNOLOGIES

BACnet Web Services

The BACnet/WS standard *135-2004c-1 Adding BACnet/WS Web Services Interface* [1], addendum c to the BACnet standard is logically in two parts

- *Annex N - BACnet/WS Web Services interface (normative)* to the BACnet standard
- New *Clause H.6 - Using BACnet with the BACnet/WS Web Services Interface* to *Annex H* of the BACnet standard (*Combining BACnet with non-BACnet networks)*

This interface proposed in Annex N is intended to be "protocol neutral" so that the defined Web Services can be used with any underlying protocol including BACnet, LonWorks, Konnex, MODBUS or legacy proprietary protocols.

This has been accomplished by defining an application program interface (API) to read and write the common elements of all building automation and control systems such as values, schedules, trend logs, and alarm information using services such as 'getValue' and 'setValue' that use a simple "path" to define the intended data source. An example of such a path would be: "/ABC HQ/Conference Room A/Space Temperature".

The standard provides powerful mechanisms for "localization" where certain types of data such as time, date and numbers can be formatted according to local custom and language. Text names and descriptions may also be accessed using the local language.

The second part of the addendum, Clause H.6, prescribes the gateway mapping specifically to and from BACnet messages.

The combined effect of the BACnet/WS annexes is to provide a set of generic Web Services that can interfaced to any building automation protocol as well as to describe exactly how this interface would work with underlying BACnet systems.

Implementations of the services shall conform to the Web Services Interoperability Organization (WS-I) Basic Profile, which specifies the use of Simple Object Access Protocol (SOAP), over Hypertext Transfer Protocol (HTTP), and encodes the data for transport using Extensible Markup Language (XML), using the datatypes and canonical encodings defined by the World Wide Web Consortium XML Schema.

<u>Data Model</u>

BACnet/WS interface specification establishes a minimal set of requirements for the structuring and association of data exchanged with a BACnet/WS server.

Any node may have a value. The possible types for a node's value are limited to the primitive datatypes "String", "Integer", "Multistate", "Boolean", "Real", "Date", "Time", "DateTime", and "Duration". Nodes that have a value may also have other attributes related to that value, such as minimum, writable, etc.

An attribute is a single aspect or quality of a node, such as its value or its writability. Every node exposes a collection of attributes. Some attributes are required for all nodes, and some are conditionally required based on the value of other attributes. Some are localizable and may return different values based on an option in a service request.

A path is a character string that is used to identify a node or an attribute of a node. The hierarchy of nodes is reflected in a path as a hierarchy of identifiers arranged as a delimited series, similar to the arrangement of identifiers in URL for the WWW. A path like "/East Wing/AHU #5/Discharge Temp" identifies a node, and a path like "/East Wing/ AHU #5/Discharge Temp:InAlarm" identifies the InAlarm attribute of that node.

To allow for an arbitrary number of logical arrangements of nodes, a single node may logically appear to be in more than one place in the hierarchy through the use of a reference node. Reference nodes may be used to build alternate logical arrangements of nodes since the children of a reference node may differ from that of its referent node.

One of the basic concepts of the data model is Node representing the object of the model. The types of the Node are (the allowable values for the corresponding attribute): Unknown, System, Network, Device, Functional, Organizational, Area, Equipment, Point, Collection, Property and Other.

BACnet/WS includes the following Services: getValue, getValues, getArray, getArraySize, setValue, setValues Service, getHistoryPeriodic, getDefaultLocale, and getSupportedLocales.

Mapping BACnet to BACnet/WS

BACnet/WS interface is intended to be "protocol neutral" and the defined Web Services can be used with any underlying protocol. When applying BACnet/WS standard the underlying protocol has to be mapped to BACnet/WS concept.

Table 1 shows an example of the mapping when the underlying protocol is BACnet. In the table BACnet/WS values and value related attributes have been mapped to BACnet Object prosperities.

Table 1. Value and Value Related Attribute Mappings to BACnet Object Properties

BACnet Object Type	Value	ValueType	Units	Maximum	Minimum	Resolution
Accumulator	Present_Value	"Integer"	Units	Max_Pres_Value		
Analog Input	Present_Value	"Real"	Units	Max_Pres_Value	Min_Pres_Value	Resolution
Analog Output	Present_Value	"Real"	Units	Max_Pres_Value	Min_Pres_Value	Resolution
Analog Value	Present_Value	"Real"	Units			
Averaging	(varies)	"Real"				
Binary {Input	Present_Value	"Boolean"				
Binary Output	Present_Value	"Boolean"				
Binary Value	Present_Value	"Boolean"				
Calendar	Present_Value	"Boolean"				
Command	Present_Value	"Integer"				
Device	System_Status	"Multistate"				
Event Enrollment	Event_State	"Multistate"				
Life Safety Point	Present_Value	"Multistate"				

BACnet Object Type	Value	ValueType	Units	Maximum	Minimum	Resolution
Life Safety Zone	Present_Value	"Multistate"				
Loop	Present_Value	"Real"	Output_Units	Maximum_Output	Minimum_Output	
Multistate Input	Present_Value	"Multistate"				
Multistate Output	Present_Value	"Multistate"				
Multistate Value	Present_Value	"Multistate"				
Pulse Converter	Present_Value	"Real"	Units			
Schedule	Present_Value	(varies)				

Open Building Information Exchange – oBIX
The basic references for oBIX are the oBIX specification[4] and the official oBIX committee Website [5].

The core of the oBIX standard includes discovery, data access, historical trends and alarming services for HVAC, security, energy management and lighting. The services are autonomous and have a loosely coupled relationship to a central discovery service.

The data service allows clients to read and write oBIX set of primitive data types. This data could be real-time control points such as actuators and sensors, or it could be vendor properties. In addition to explicit client request for data values, the data service supports data subscription in two ways client initiated polling and server initiated callbacks.

Historical data is needed for reporting and analysis within a system for optimizing performance, efficiency and user experience. The oBIX historical data service will be used to query trend data that has been collected by the server as time-stamped value samples.

The alarm service will provide a normalized representation of an alarm event record. It will have the ability to query alarms that have occurred on the server, the ability to subscribe for new alarms that are generated and the ability to acknowledge existing alarms.

<u>oBIX architecture</u>

The oBIX architecture is presented in Figure 3. It is based on the following principles

- Object Model: a concise object model used to define all oBIX information.
- XML Syntax: a simple XML syntax for expressing the object model.
- URIs: URIs are used to identify information within the object model.
- REST: a small set of verbs is used to access objects via their URIs and transfer their state via XML.
- Contracts: a template model for expressing new oBIX “types”.
- Extendibility: providing for consistent extendibility using only these concepts.

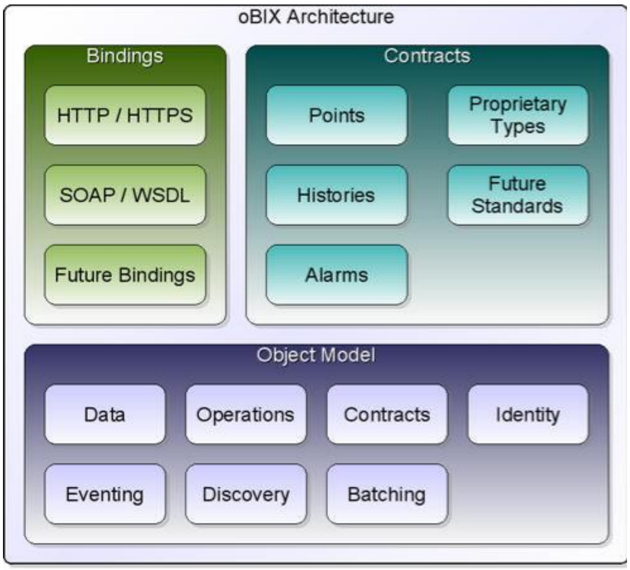

Figure 3. oBIX architecture

oBIX object model

The oBIX specification is based on a small, fixed set of object types. These object types map one to one to an XML element type. The oBIX object model is summarized in the illustration of Figure 4.

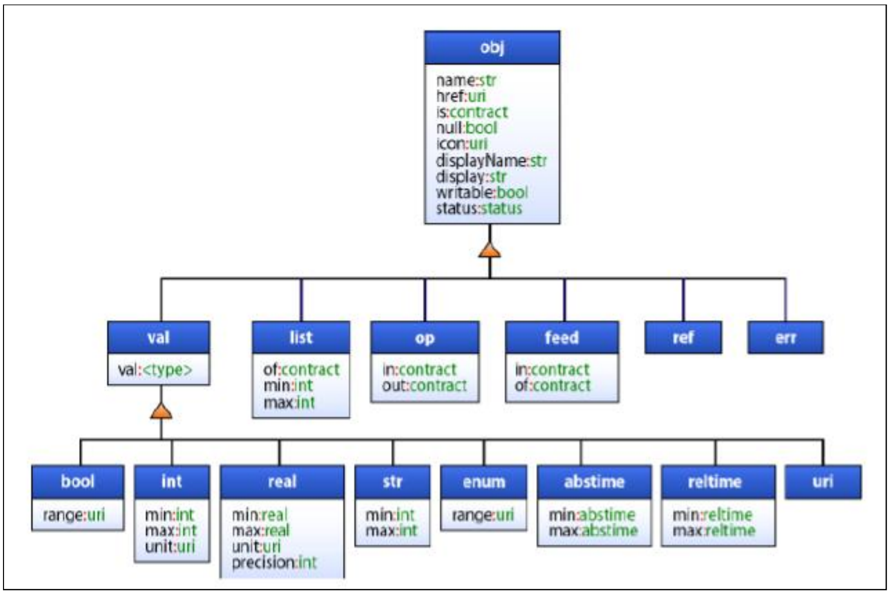

Figure 4. oBIX object mode

The root abstraction in oBIX data model is the *obj* element object. Every XML element in oBIX is a derivative of the *obj* element. Any *obj* element or its derivatives can contain other *obj* elements.

oBIX roadmap

A common view within oBIX community is that oBIX 1.0 is just the starting point towards more comprehensive applications and integration with enterprise systems. There are already preliminary ideas how oBIX 1.0 should be developed further. As an illustration a roadmap towards oBIX 2.0 is presented in Figure 5 [6].

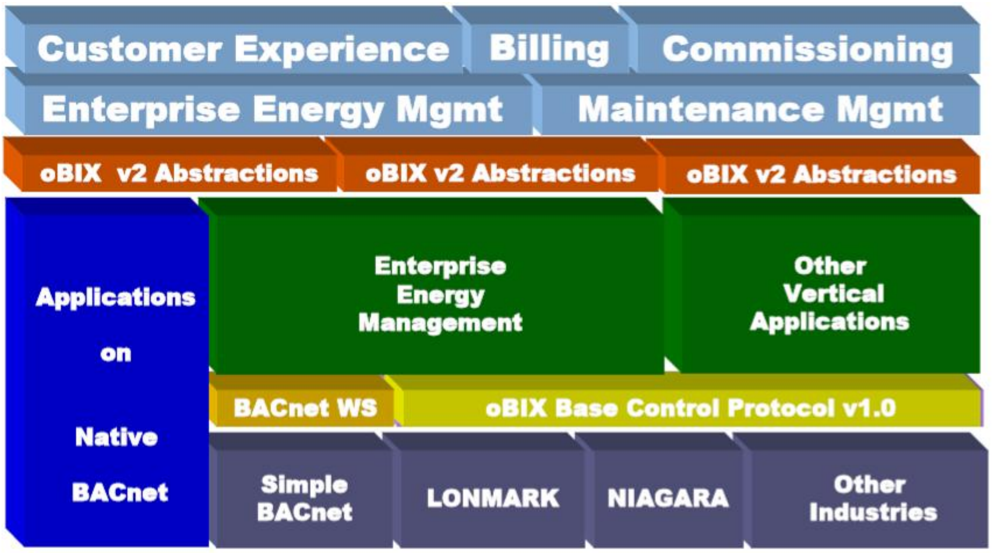

Figure 5. Roadmap to oBIX 2.0

Other Web Services approaches – OPC-UA

In addition to BACnet/WS and oBIX maybe the most important other Web Service approach in building industry is OPC Web Services. Its main application domain is industrial automation, but it is applicable to the building automation as well. However, because it is not building domain specific it won't be handled in more detail here. OPC Web Services are based on the new OPC Universal Architecture, OPC-UA [7], [8].

A big change compared to the earlier versions of OPC that users will notice right away is that OPC-UA is not based on Microsoft COM/DCOM. The whole world, including Microsoft, is embracing open, internet-based communication standards. OPC has done the same by basing UA on TCP/IP, HTTP, SOAP, and XML. Not being tied solely to Microsoft platforms makes OPC-UA highly scalable and applicable to different HW platforms.

DISCUSSION

A major problem in today's building information systems is that the building information systems are fragmented and isolated forming "automation islands", which don't communicate together. The systems can contain overlapping information for their applications because of lack of communication. Integration of the data of different sources to produce reliable real-time management information is very difficult. Systems are typically proprietary without compatibility in core information. These create also dependence from the system vendors.

Web Service technologies described in the paper enable the standard based solution to all these problems. From the viewpoint of technological development having competing approaches has positive influence. Negative is that there will still remains automation islands. In addition, Web Services technology without application area service specification (standards) is not very valuable. It means that it is important to develop new Web Services interfaces into building automation systems.

ACKNOWLEDGEMENT

The results of this paper are based mainly on the work done in co-operation with Fatman Oy within Eureka E!3083 AutoSpace project.

SUMMARY

The paper describes an open, extensible software and hardware framework supporting all aspects of control and monitoring of a Smart Building. We designed an 'intelligent', real-time control system capable of both autonomous process control and interaction with human operators. The system can easily accommodate both functional extensions and a broad array of sensors and control devices.

The system described below represents a clear bias towards pervasive, open-source, Internet and Web technologies and away from the proprietary or vertically specialized networks, protocols, and application frameworks typical for the current industrial automation systems. The basic goal of this research was to find out if and at what level of effort one can build a functional prototype of a Building Automation System (BAS) assembled exclusively from open-source elements. The answer we found is affirmative and the results of the experiment have the potential to affect the building-automation industry in a way similar to the impact of Linux in the domain of operating systems and of the Asterix server on the VoIP industry.

INTRODUCTION

When first analyzed by a technologist raised in the Internet cocoon, the current BAS's seem to have originated in a different technological civilization. The only commonality of the two technology stacks is the notion of a packet network; from this point on, there does not seem to be one concept or idea that is shared. This technological abyss only gets wider as we move up the protocol stack. This seems to translate into very different business models for software companies involved in both fields. We present a more detailed discussion of this "digital divergence" phenomenon in another paper submitted to this conference [1].

This paper focuses on a practical aspect of subverting the current technological status quo in building automation by creating a nucleus of a disruptive-technology framework, a time-honored mechanism of change and progress in the Internet-centric universe. The goal of this paper is to stimulate the change or, at least, to contribute to the metamorphosis that seems to be germinating in more than one research location. We have no doubt that the current BAS architectures will disappear within a decade, and that building control will completely converge with IP networks. The really interesting question is, "How do we get there?" To gain such an insight we have designed, implemented, integrated, and deployed a complete control system using only open-source or free standard software technologies and protocols, and off-the-shelf electronic components, assembly of which requires only basic technical skills. We hope that the findings described here will enable faster, cheaper, and more efficient implementation of automation systems. The application we particularly cherish is to provide research facilities with a complete, open software testbed for building automation, so that the researchers can focus on solving real problems in fields such as indoor-climate control, rather than having to struggle with cobbling together instrumentation necessary to perform experiments and measurements. We also hope to contribute to the discussion related to emerging standards, security issues, and "open vs. proprietary" software and business models.

METHODS

The overall system design is Internet-centric, following the critical requirement of providing an efficient mechanism to ensure an easier and faster process of bringing building automation systems into the fold of the global digitally converged communications infrastructure. The system uses only pervasive Internet network and open-source subsystems, applications, and application-development tools. These tools rely in turn on a number of standard protocols and/or software development methodologies.

All system functions are implemented as Web Services and all real-time signaling uses pervasive messaging technologies proven effective in mainstream communication systems, such as JMS. Sensors and control devices used with the system are required to be Internet Protocol-based, but the XML-coded device data structures are based on the BACnet networking standard [2].

Although our goal was to build a system with a broad functionality, potentially covering all important aspects of building automation, we have deliberately approached the project as a focused exercise in system design for rather specific functionality. The issue we address is climate control in a space where users can express their preferences for several factors and realize them using personal environmental modules, while the system is responsible for global optimization and resolution of potential conflicts.

Further, the research reported here differs from the work of several industrial consortia on unification of BAS protocols using XML [3-5] and standardize BAS related web services. Our focus is on the system architecture. We believe that the system described in this paper could be readily adapted to provide a reference implementation of protocols being designed in the arduous industrial standard setting process practiced by the ASHRAE BACnet/XML Working Group [3], oBIX [4], and CABA [5].

RESULTS

The requirements for the system can logically be grouped into three categories:

1. *Broad system goals:* a) The system should support interaction of the building automation elements with the human occupants of the space, and b) it should have the ability to make 'smart'[1] decisions in response to ever changing conditions in the building.
2. *Specific system functionality, including*: a) Adjusting environment variables to increase occupants' productivity; b) Tracking space occupants; c) Maintaining knowledge of the physical space including information about zones; d) Monitoring environmental factors in zones; e) Allowing individuals to communicate personal environmental preferences

[1] The notion of 'smart' or 'intelligent' system should be interpreted conservatively. The vocabulary merely implies that the system integrates an inference engine.

(temperature, noise, humidity, etc); f) Providing a visual interface (similar to a weather map) to monitor the space/zones and their parameters; and g) Possessing the ability to self-adjust based on user preferences and output from the inference engine.

3. *Additional considerations*: We aimed at building a solution that is vendor-independent, and uses only open-source tools and components, unless none were available, in which case we resorted to public standards.

BASIC CONCEPTS

We have used the following basic concepts in designing the system:

- *Controlled space* – a physical space where the system controls environmental factors such as temperature and humidity.
- *User presence* – Identity of the user (or users) present in the environmental zone.
- *Environmental zone* – a unit of space controlled by the system, which assumes that all environmental factors have uniform values within the environmental zone.
- *Environmental profile* – a set of key/value pairs that describe environmental parameters of the environmental zone. The system strives to maintain environmental parameters of the zone within a given range from the values specified by the environmental profile.*Environmental preference* – a set of key/value pairs that describe environmental parameters selected by the space occupant as the most desirable. Environmental preference of the user present in the environmental zone affects the environmental profile associated with this zone.*Device* – any hardware or software entity that can generate or accept data. The system receives information about environmental parameters of the environmental zone, and influences these parameters through devices installed in the zone.

TECHNOLOGIES AND STANDARDS

The following technologies have been used to assemble and integrate the system:

- Web Services [6] – communication among system components
- BACNet [2] – base for internal device description
- CLIPS [7] – open-source inference-engine platform
- Java 2 Enterprise Edition [8] – set of APIs for building enterprise applications
- Open Source technology stack:
  - JBoss [9] – J2EE Application Server
  - Struts [10] – Web Application framework
  - Axis [11] – Web Services framework
  - Hibernate [12] – Persistence framework
  - Hypersonic [13] – Database Management System
  - JMS [14] – Java Messaging System
  - AJAX [15] – Web GUI implementation methodology

SYSTEM ARCHITECTURE AND COMPONENTS

Figure 1 below shows all major components of the system. For each component, the communication interfaces and dependencies are depicted. The description of each interface contains information about the technology used for its implementation.

The communication pattern between system modules is based entirely on the Web Services model. This applies to both "read" and "write" operations, as described below. In addition, since devices and other modules can generate events that require handling, we implement two mechanisms to propagate event information: for time-critical events, we use JMS[2] [14]; for event supporting services, such as archiving, we use a pooling mechanism under Web Services.

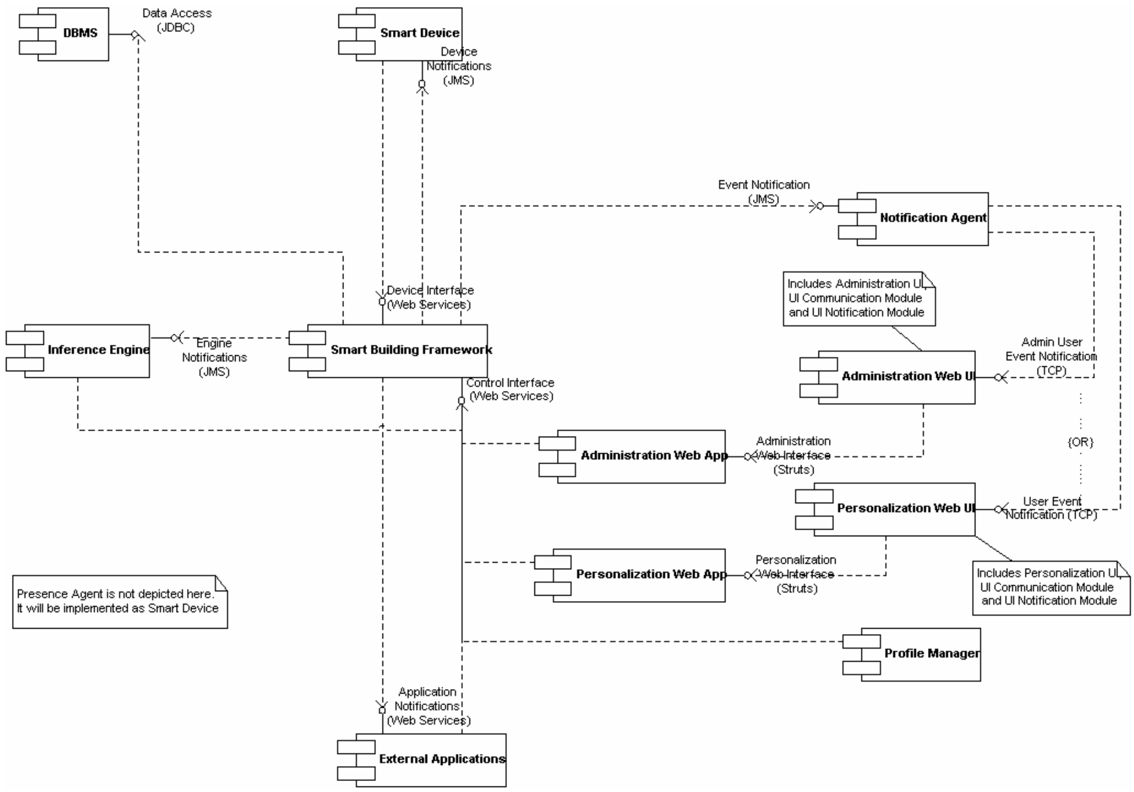

Figure 1. UML Diagram of System Components

Most of the modules on the diagram are self-explanatory. Software modules provide services roughly corresponding to the system requirements listed earlier in this section. Three modules of special interest are a) the Smart Building framework, b) the Inference Engine and its integration with the system, and c) the Smart Device. These three elements will be described below in more detail. The system is extensible, as it can accommodate External Applications of any kind. A good example might be an energy optimization engine, a computational fluid dynamics application, or a set of web services reaching out to external data sources, such as a weather forecast.

Smart Building Framework

The Smart Building Framework is the core of the Smart Building system to which all other system components connect. It implements the following services:

- *Device status monitoring and data collection*
- *Device data archiving and retrieval*
- *Access to and manipulation of an object-oriented representation of the system state*
- *Event-based communication among system entities*
- *System configuration*

[2] JMS engine is an integral part of the JBoss Application Server [9]

Web Service APIs

Most of the services described above are exposed through a set of ***web service APIs***:

1. *Device Web Service:* allows external devices to connect to the system. External devices use this service to register their presence and to report changes in their state.
2. *Object Access Web Service:* provides access to object-oriented representation of the system state maintained by the framework. The Object Access interface can be used to both read and write properties of the objects maintained by the system. Write operations on the system state may translate into commands issued to the components of the system controlled by the Smart Building Framework. The service is also used by system components that need to access the information about the system entities (for example, Inference Engine or Administration Interface).
3. *Event Access Web Service:* implements a messaging system for sending prioritized, point-to-point or system-wide alerts related to the state of the system. For example, the Inference Engine might send an alert to the Administration Interface component, if the readings from the external devices exceed a certain threshold. Both sending and retrieving operations are supported. The service is used by all system components that need to send and/or retrieve alerts.
4. *Archive Web Service:* allows starting and stopping archiving of the data submitted by the external devices connected to the system. It also allows retrieval of the archived information. The Archive Web Service is used by the system entities that rely on the archived information about devices.

The web services implemented by the Smart Building Framework can be accessed not only by the components of the Smart Building system but also by other external (remote) entities that need to access the information about the status of the building infrastructure.

Communication between modules

All components of the Smart Building system can learn about the system-state changes through polling functionality embedded in all implemented web services. This approach is simple and works well with standard web infrastructure. However, it also has significant drawbacks such as embedded latency in the system responses due to a set polling interval. To handle propagation of time-critical events we designed a server-side component implementing JMS-based notifications. Each component interested in receiving notifications from the Smart Building framework can embed JMS client functionality. This also applies to our wrapper for devices and to the Inference Engine, as well as to the Administration and Personalization Interfaces. The JMS messages may carry either actual module commands, or a request for a module to poll the message sender for information.

Smart Building Inference Engine

The inference engine provides the ‘intelligence’ driving the Smart Building Framework. While the devices connected to the framework might be autonomous enough to make their own limited decisions, there exists a range of decisions that are beyond the capabilities of any single device. The inference engine fills that gap by gathering information from the entire framework, making decisions based on the gathered data and then controlling the framework to execute the decisions.
Communication: The inference engine communicates with the rest of the Smart Building Framework via a set of web-service interfaces. These allow it to extract information necessary

for making a decision, and then to control the framework to execute a decision taken. In particular, the framework interfaces allow:

- reading device input
- controlling (writing to) devices)
- reading and modifying current environmental data
- sending system alerts

Since the communication mechanism is documented, it is possible to replace the engine with another agent that would drive the framework.

Engine: The inference engine is implemented as a stand-alone Java application. Its main functionality, the decision making, is split into *decision beans*. The application schedules a bean to execute at a specified time after the application start. From then on, a bean is in charge of its own scheduling. In addition to making decisions, the beans can also be used for simpler tasks, for example to translate the information retrieved from the devices into current condition data.

It remains unspecified whether the entire decision logic should be implemented as one complex bean, or as a several (possibly many) simpler beans. The inference engine supports any approach. Typically, when a bean is executed, it will gather required data, analyze them and send the results (a decision) back to the framework. The bean can then ask the inference engine to be scheduled again at some later time.

Simple decision beans can be implemented as Java objects. In the case of large systems and complex decision beans, the capabilities of the Java language might prove to be insufficient. For these scenarios, we have integrated a rule engine to allow us to use a more sophisticated decision making mechanism. The rule engine we used, CLIPS [7], can improve over Java in the areas of a) processing more advanced condition statements, b) resolving the conflicts among multiple conditions and c) general performance of complex-condition processing. Both Java and CLIPS decision beans can be used simultaneously.

Example: Below we provide a very simple example of a CLIPS script. The reader should not infer that this nearly trivial example represents the norm. There is no limit to the complexity of the rules that can be incorporated into the entire framework, and some of the rules we have implemented are rather complex.

The data retrieved from the framework are supplied to the script as CLIPS facts. The output of the script is also facts that are asserted or retracted based on the input.

```
;;;=========================================================================================
;;; This script establishes user presence in a zone based on a reading from a presence sensor
;;;  Input facts - presence-sensor; Output facts - zone-user
;;;=========================================================================================
;;;  DEFTEMPLATES
(deftemplate presence-sensor
  (slot status)
  (slot user-id)
  (slot activity))
(deftemplate zone-user
  (slot user-id))
;;;  RULES
(defrule current-user ""
  (presence-sensor (status active) (user-id ?u) (activity ?a))
  =>
  (assert (zone-user (user-id ?u)))
  (printout t "user present is: " ?u crlf))
```

Smart Device

The Smart Device component of the system is a Java wrapper implementing a generalized API used to communicate with real devices. This module provides a two-way translation between device proprietary protocols (if any) and Web Services used by the Smart Building Framework and it may implement a JMS client (see *Communication between Modules* section above). A driver for each real device in the system is a specialization of the Smart Device. As mentioned in Methods, we decided to use an XML-coded BACnet [2,3] data model to describe device data structures. This decision is a compromise we accepted for several reasons, some of them discussed in [1]. We recognized the facts that a) BACnet is a public standard under a committee control, b) its device data structures represent decades of domain-specific engineering experience and, as such, it is unlikely we will be able to come up with a better data model, and c) the particular choice of the device data model is not really relevant to the goals of this research[3].

We have implemented several devices to interact with the system, including a Universal Device (as a template for future development of device drivers), a Presence Agent identifying personnel entering a controlled space, and a simulated A/C heater-thermometer device simulating temperature changes according to a simple physical model driven by input from the Inference Engine. The most interesting device though is the so-called PEM controller. PEM (Personal Environment System) is a commercial product designed to provide an individually controlled work environment. The module, installed on the user's desk (Fig. 2) regulates air temperature and air supply to the desktop; controls the radiant heat panel output; and provides background noise masking and task lighting level. In its basic configuration, the module is locally controlled and not networked. It can be connected to a data bus, but the cost of the controller and proprietary software is substantial. For the purpose of the project we implemented an IP-based system controller for the PEM device. The controller is inserted between the manual slider board and the PEM proper. When active, the IP controller overrides manual user preferences, and instead adjusts the environmental parameters to the user preferences stored by the system, subject to optimizations necessary to take into account preferences of users in other cubicles and energy usage constraints in the controlled space. The system's Inference Engine implements the optimization procedures. Manual controls are replaced by a small application running on the user's workstation, which however can be deactivated by a system operator.

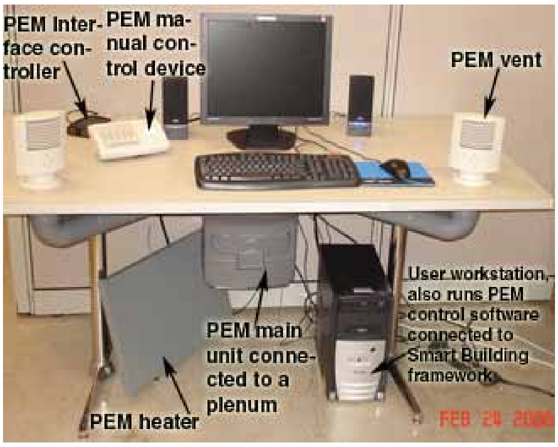

Figure 2: System controlled Personal Environment Module

The PEM controller is activated by user login to the workstation, although it can also be started by a signal when the building security system reports that the user is entering the building security gate. This *per se* is not particularly innovative, but the system offers certain niceties, such as biometrics identifying the person and transferring its environmental

[3] Use of such data structures does not imply that the system is compatible with BACnet network protocol layers, although, since the device data structures are rigorously derived from the BACnet paradigm [2], the system could be relatively easily adapted to access and control most of the existing BACnet BAS infrastructures.

preferences to the proper cubicle, together with the person's VoIP phone number. Further, the global optimization functionality mentioned provides a relatively new and interesting element. The PEM controller implements a complete HTTP server on top of the IP stack, and is simply connected to the office LAN. The application running on the server communicates with controller's A/D and D/A converters, providing full control of PEM control elements, as well as providing additional temperature and humidity sensors plus several auxiliary industrial standard 0–10V inputs and outputs.

DISCUSSION

While the existing implementation and deployment focus on environmental controls and human efficiency issues, we believe that the system described here offers a nontrivial technological advantage over current proprietary industrial solutions, and provides a sustainable foundation for future collaborative development of Smart Building software by academic and industrial consortia and alliances. To facilitate such a process, the system has also been carefully designed to avoid intellectual property infringement of existing patented or otherwise protected frameworks while replacing many aspects of their functionality [1].

The modular design of the system permits replacement of any of is components by a proprietary or simply different implementation. Our focus on open-source software provides an affordable starting configuration. Device drivers, which are a very significant obstacle to interoperability, can be implemented in a matter of days or even hours by extending or replacing software modules provided in templates. The selection of Web Services implemented in the framework covers all typical uses we have identified in BAS systems, and implementation of an operational system of medium complexity provides a strong proof of the concept.

The research presented here is complementary to the work of ASHRAE and OASIS/oBIX; those groups focus on protocols and we have focused on systems research. We believe that our system can provide an almost instant reference implementation of the results of the work of these industrial consortia. This represents an important step in validation of ideas leading to future Building Automation Systems.

Supporting disaster management by means of ICT

Kalevi Piira and Veijo Lappalainen

VTT, Finland

Corresponding email: Kalevi.Piira@vtt.fi

SUMMARY

In modern big buildings there are many different technical systems typically without any automated interoperation with building Facilities Management systems (FM). In the case of a disaster (fire) the problem is that the rescue personnel (fireman) can't get relevant up-to-date information of these buildings. A new advanced ICT support system has been developed, which reports focused real time information into the moving rescue vehicle in the case of fire using wireless data transfer. The support system combines the location based real time information about fire and building technical systems with static information of FM and reports it to different kind of end users. The system is in test use in several buildings in Finland. Generally the integration of building information systems enables the development of totally new kind of applications. The disaster management support system developed is a good example of the potential of this kind of systems integration.

INTRODUCTION

In shopping centers, hospitals, hotels, big office buildings, industrial areas and public underground spaces there are many different technical systems like building automation system, HVAC, fire alarm, fire protection, smoke control, access control, CCTV, lifts, etc. typically without any automated interoperation with building Facilities Management systems (FM). It's very common that the facility data is updated regularly (during the life cycle) in these kinds of buildings. In the case of a disaster (fire) however, the rescue personnel (fireman) can't get relevant up-to-date information even about these buildings (spreading of the fire, status of building technical systems, locations of dangerous materials, critical spaces for company's businesses etc.).

The aims of the work were to study which information about building and it's technical systems is needed in the case of disaster (fire), how to combine the absolutely correct and up-to-date location based real time information about fire and building technical systems with static information of FM and to report it to different kind of end users, and especially to develop a new prototype to report that information for different purposes like fire master in moving rescue vehicle going to lead the fire fighting and personnel inside the burning building.

METHODS

The first problem was to find out what information from building and it's technical system is needed most in the case of fire incident. The information needed about burning building was studied interviewing eight fire masters in different parts of Finland. Interviews consisted fixed and open questions and one interview took as an average two hours. The interviews were performed in 2003. The fixed questions were related to the information needed from spaces, structures, technical systems, dangerous materials, application usability, manner of representation (graphics etc.) and information needed in different situations (approach, first 10 minutes, after first 10 minutes, for archive). Open question was for example "what information the leader of fire fighters does really need in the case of fire".

The main problem was to find out the modern ICT solution (integration, data transfer and implementation technologies) to combine data from building's real time systems (automatic fire alarm, building automation, HVAC, automatic fire extinction, smoke abatement, motorized fire damper and other fire protection systems, safety and secure, access control, lifts, CCTV etc.), always up-to-date building facility management database information and maintained CAD pictures (layout, floor plans) and send it using wireless data transfer to the moving rescue car. The main approach was to use as much as possible existing building automation standards and standard based open technologies and integrate those existing "lego blocks" using modern Internet software integration technologies called web services (http://www.w3.org/2002/ws/).

The results of the interviews described above were utilised later on when directing the development work of the new prototype for disaster (fire) management support.

RESULTS

The results of the interview survey are presented in Table 1 [1]. The Table contains also information which building systems have to be integrated to get that information.

Table 1. Information need in the case of fire and systems containing a part of that information.

Information	FM	Fire alarming system	BAS	Other technical system
Fire initiation place	x	x		
Spaces under fire	x	x		
Layout picture (always up-to-date) • rescue ways • attach routes • locations of main valves, switches and building technical system centres	x			
Floor plans (always up-to-date) • dangerous spaces and materials • valuable spaces	x			
Localization diagrams	x			
Fire sections, fire doors, fire dampers (open or closed)	x		x	x
Supporting structures, intermediate floor structures	x			
Lifts, shafts, tewels	x			x
Smoke abatement zone	x			
Status information of sprinkler, ventilation and other technical systems (and effect areas)	x		x	(x)
Temperature levels	x		x	
Contact information (security company, service company, energy company, water supply plan, property owner etc.)	x			
Underground spaces	x			

At this stage of the study the architecture of ICT based disaster management system was developed. One of the most important decisions was the selection of web service technology as the system integration technology of the ICT system platform.

The main components and connections of the building disaster managements system are presented in Fig. 1. The main idea is to combine all necessary information of building and it's technical systems for different interest groups like authorities, service providers (security company) and people inside the building (personnel, security manager, control room persons etc.) in the case of disaster.

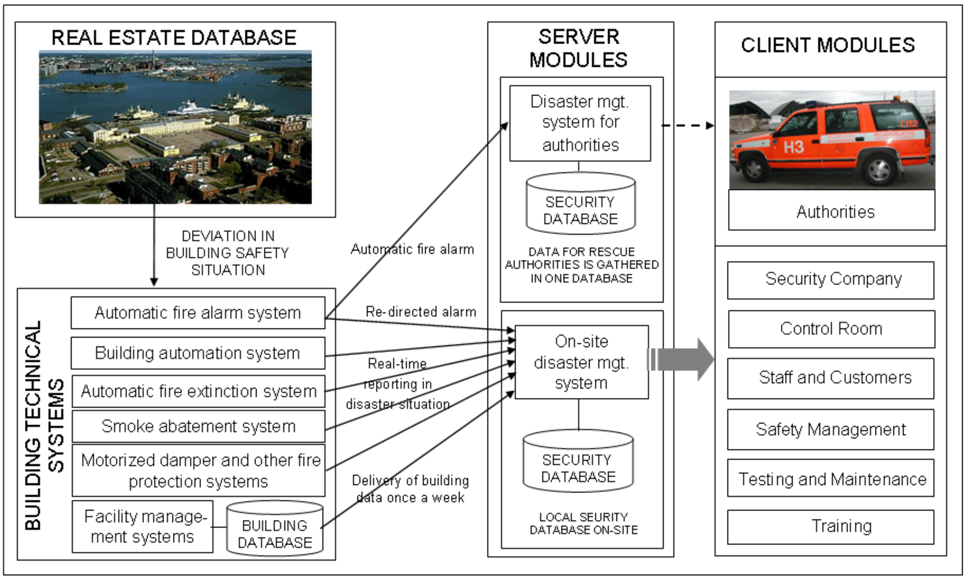

Figure 1. Main components and connection of ICT based building disaster managements system.

The work covered the study of two different versions of the system: authorities (emergency center and rescue center) version and version for people inside the building. The main components and connections of disaster management system for authorities (case fire incident) are presented in Fig. 2 and the data communication for that in Fig. 3.

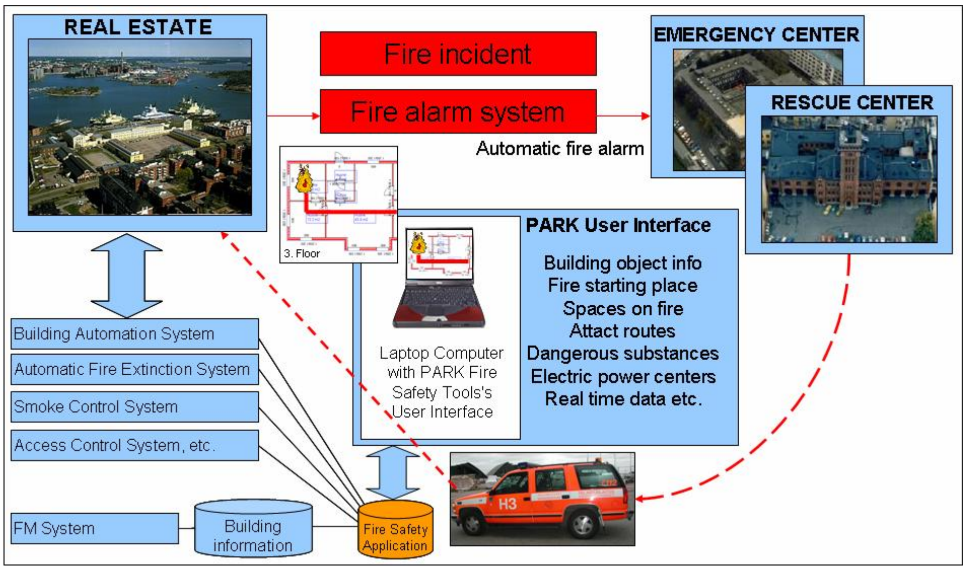

Figure 2. Main components and connection of disaster management system for authorities – case fire incident.

The main communication model for local users is based on the broadband data communication supported by short message service (SMS) based text messages. For the authority version wireless data communication like 3G, EDGE, GPRS and WLAN data transfer was selected.

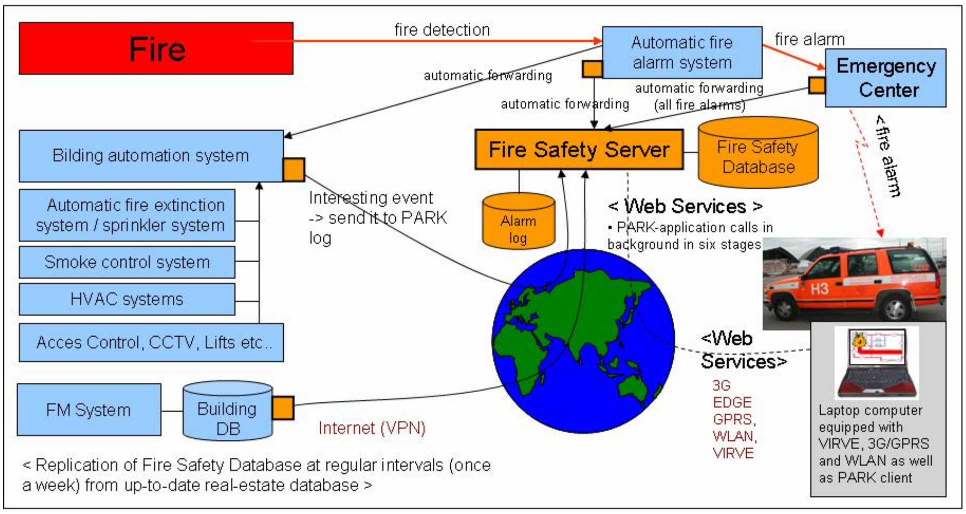

Figure 3. Data communication of disaster management system for authorities – case fire incident.

The main component of disaster management system for people inside the building is presented in Fig. 4.

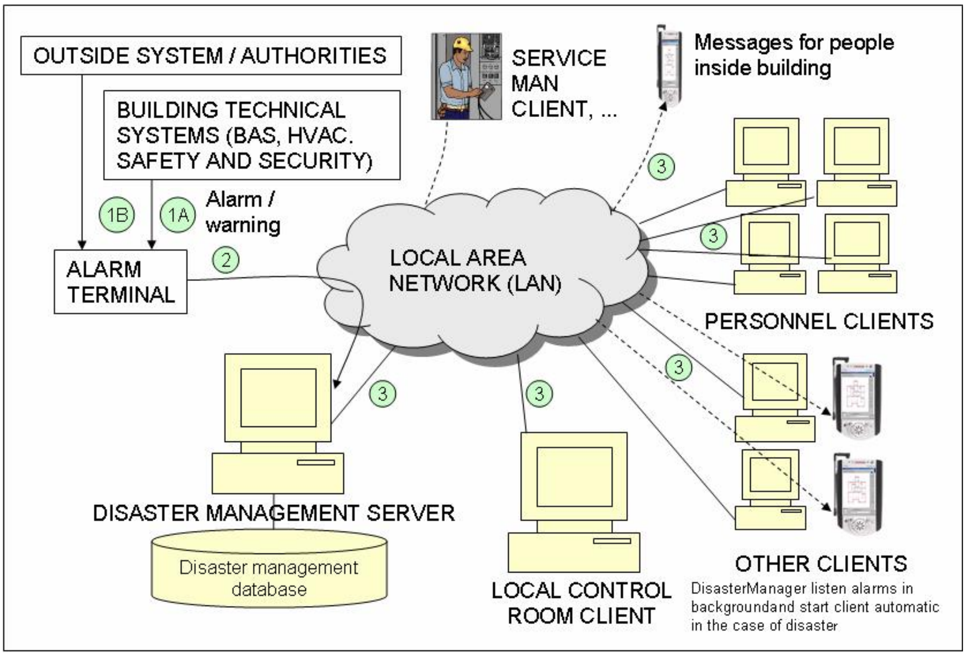

Figure 4. Main component of disaster management system for people inside the building.

The main result of this study was a new prototype for disaster (fire) management.

PROTOTYPE

A new advanced ICT support system has been developed, which reports (displays) focused real time information into the moving rescue vehicle in the case of fire using wireless data transfer. The support system combines the location based real time information about fire and building technical systems like fiery spaces, ventilation system's status, activated loops of the fire-extinguishing system and smoke control system etc. with static information of FM like real estate's layout, floor plans, location and effect areas of systems/equipments, spaces of dangerous substances, valuable spaces, fire sections etc. and reports it to different kind of end users. The context aware system supports different end user groups like fireman, local control room operator and the personnel occupying the building etc.

"Layout" function of the disaster management prototype is presented in Fig. 5. The main idea was to integrate real time information of fire and the facility management information of the location of fire detectors and show it by means of CAD technologies. In this example the part of the building which is on fire is blinking red in the layout picture. Other information included in the prototype are attach routes for fire fighters, rescue ways and the locations of main valves, switches and building technical system centres.

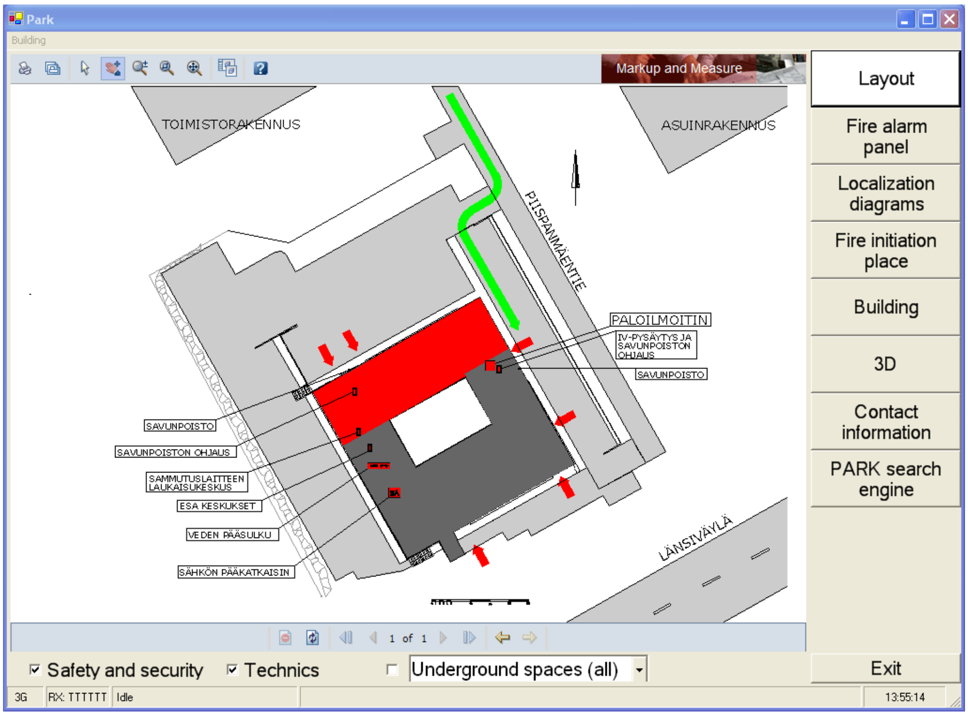

Figure 5. "Layout" function of the disaster management prototype application.

"Fire initiation place" function of the disaster management prototype is presented in Fig. 6. The main idea is to combine the exact place where the fire has started with space information from facility management system and show the result in floor planes. Information included in the prototype are fire sections and how near the fire are to dangerous materials (risks for fire fighters) and valuable spaces for business of the company working in the building. Fire initiation place is coloured red and other selected information is green.

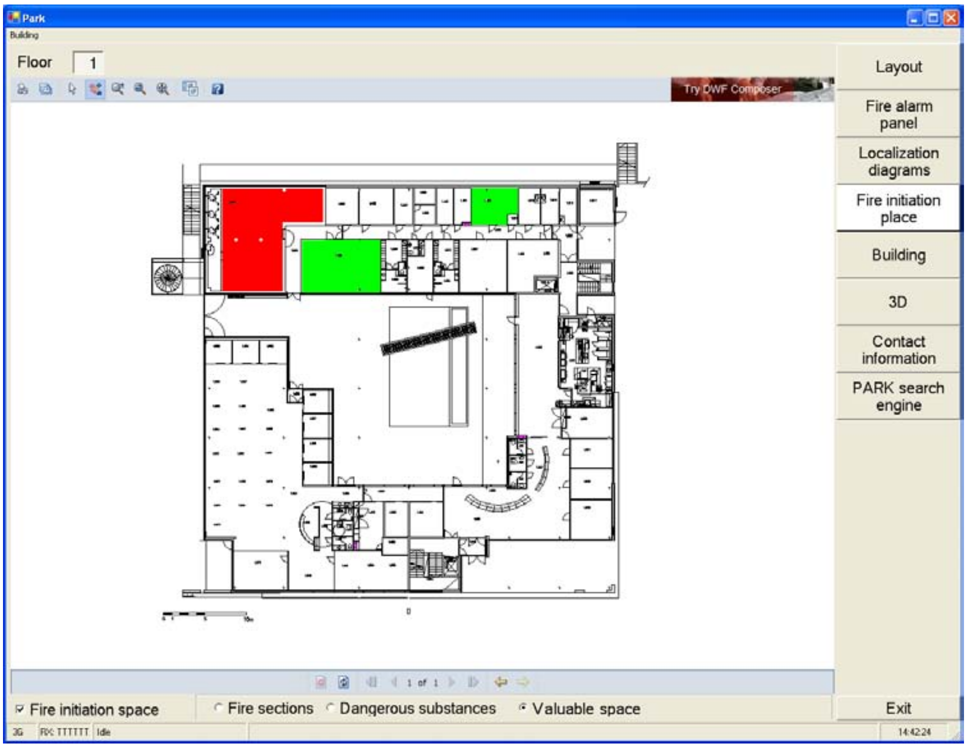

Figure 6. "Fire initiation place" function of the disaster management prototype application.

"Building" function of the disaster management prototype is presented in Fig. 7. This function combines real time information of fire with exact location information and real time status information of building technical system (status information of ventilation, sprinkler, smoke abatement, motorized fire damper etc.) into always up-to-date building floor plans.

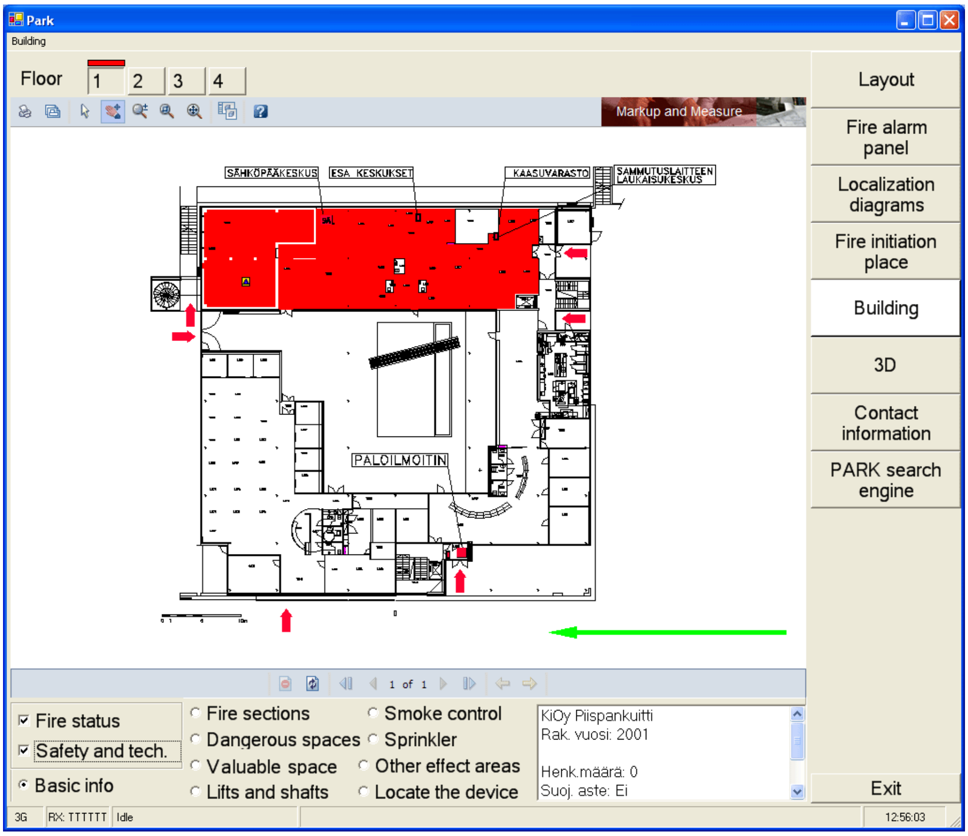

Figure 7. "Building" function of the disaster management prototype application.

“3D” function of the disaster management prototype shows wireframe model of building and combine building real time (fire) and static information (dangerous materials, critical spaces for business etc.) into that 3D model.

The system is presently in test use in several big buildings in Finland.

DISCUSSION

The integration of building information systems enables the development of new kind of applications which utilise any information existing in information space. The disaster management support system developed is a good example of the potential of the systems integration.

Space heating control of an individual dwelling by a fuzzy controller acting on the flow rate of a heating floor

SUMMARY

A lot of complementary solutions to save energy in buildings already exist. If it is well insulated, a building can produce itself a part of its thermal energy consumption, tanks to renewable energy devices such as solar collector. This clean energy mustn't be spoiled; therefore a good control must be applied to its use. The fuzzy control is one of these solutions. We applied it to the control of the heating floor of an individual dwelling. The design and the validation of the controller were carried out in simulation with the software TRNSYS 16.

INTRODUCTION

The integration of renewable energies in a dwelling is a complex process. Many devices are able to produce clean and cheap energy. It concerns electrical energy, domestic hot water and heating. However, this clean energy must be optimized by the consequent control of the actuators using this energy.

Heating floors are one of the most interesting heating devices. They produce a high comfort level to the user and are supplied by a low temperature heating fluid, which facilitate the integration of renewable energies. Energy savings could be made if we could lower their operation level when it is possible during the inoccupation periods in the dwelling. This would optimize the performances of the heating floor and in the same time lower the use of boilers using fossil combustible or electrical energy from the grid.

Since 2005 a partnership between AMPERE and CETHIL and supported by the Region Rhone Alpes carried out a study on the design of a global controller which could optimize the contribution of renewable energies and control the thermal and electrical comfort. Concerning the thermal comfort, the testing of our temperature control procedures requires a reference control to be compared to and appropriate testing conditions. For this reason, we use simulation to test our controller in different buildings. One of these building is the model of a dwelling designed in the process of the Task 26 lead by the International Energy Agency [1]. This model was designed to test the performances of existing solar combisystems, and was chosen for its quality and its simplicity. Our reference controller is a fuzzy controller, one of the most accurate controllers sold to the public. Fuzzy controllers are usually used for office buildings which are occupied during the day and unoccupied during nights and week end. For our dwelling, occupation and inoccupation periods are inverted, which is more unusual. This study will show the interest of this adaptation.

We tested its performances in this house, which we located in Lyon, France.

DESCRIPTION OF THE MODEL

Description of the building

The building we chose is a single family home. Its surface is 140 m² large and it is located on two levels. It was designed to consume 60 kW.hr/m²/year for space heating in Zurich, Switzerland, which represents good thermal performance [1]. It is modelled in TRNSYS 16 with type 56 and the interface TRNBUILD.

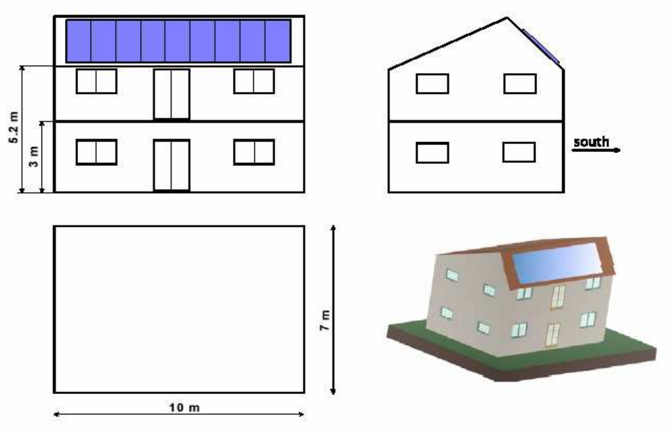

Figure 1: The task 26 dwelling

Windows are double glazing, modelled with type 2001 from the TRNBUILD library.

Table 1: Windows surface

Wall's orientation	North	South	East	West
Windows surface (m²)	3	12	4	4

Table 2: Walls description

Wall	Orientation	Surface [m²]	Conductance [W/m²K]
External Wall	North	50	0.342
External Wall	South	50	0.342
External Wall	West	40.5	0.342
External Wall	East	40.5	0.342
Roof	North	61.4	0.227
Roof	South	25	0.227
Ground	Horizontal	70	0.196
Internal Wall		200	2.686

Description of the thermal energy production systems

For the heating space, we integrated a solar collector and a wood boiler. The surface of the collector is 20 m². Its efficiency is modelled by second order quadratic function.
The boiler was in the first design of the IEA a gas boiler but it will be a wood boiler in our case. Its power is 15 kW, its efficiency is 90%.
The solar collector and the boiler are connected to two loops which supply with hot heating fluid two heat exchangers in a storage tank. This tank is a cylinder tank, it is 1,7 m high with a volume of 0,5 m^3. The tank is heated in priority by the solar collector. Its pump is activated as

soon as the temperature of the fluid exiting the collector is 5°C higher than the tank's bottom's temperature. If the temperature of the tank diminishes lower than 50 °C, the pump of the wood boiler is activated until the temperature of the tank reaches 70°C. The tank also heats domestic heat water.

Table 3: TRNSYS types used for the simulation [2].

System	Type	Details
Solar Collector	Type 1	TRNSYS library
Boiler	Type 700	TESS library
Storage Tank	Type 60	TRNSYS library

Description of the heating floor

The house is heated with a heating floor similar to the floor modelled in the Task 26 [3]. Its surface is 140 m² large, the two stages are supplied with two different loops. It is modelled directly in the definition of the floors of the building. The pipe grid is defined as an active layer of the floor. The pipe spacing from centre to centre is 10 cm, the outside diameter of the pipes is 2 cm. The heating fluid has a 30% glycol fraction, is mass heat is 3.74 kJ/kg. A diverting valve maintains the incoming fluid temperature around 35 °C. The heating fluid is heated in a heat exchanger in the storage tank.

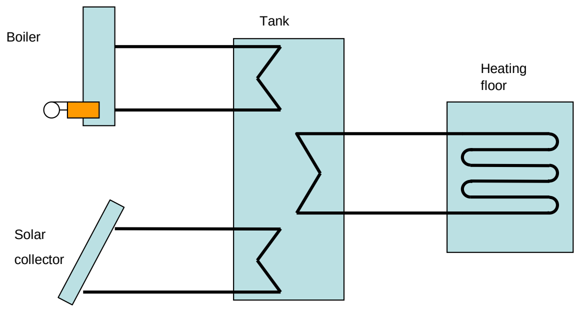

Figure 2: Hydraulics scheme of the dwelling

THE FUZZY CONTROLLER

Principle of fuzzy control

Among the temperature controller available nowadays, we can found the fuzzy controller. Based on fuzzy logic [4], it controls the temperature when the building is occupied and also estimates the necessary time to restart space heating before the end of the inoccupation periods to make sure that the temperature respects the high set point when the next occupation period begins.

Fuzzy logic is a command law which is calculated according the variation of some chosen variable. Considering the case of a single variable e, a grid is realized on the interval $[e_{\min}, e_{\max}]$ defined by the user, which is supposed to be representative of the possible variation of e. We get an ensemble of nodes $\{e_{\min},...,e_i,...,e_{\max}\}$ and sub intervals. To each node e_i corresponds a command value $\mu(e)$, set by the user. For an unspecified e, the command $\mu(e)$ is calculated as following :

$$\text{if } e < e_{\min}, \ \mu(e) = \mu(e_{\min})$$
$$\text{if } e > e_{\max}, \ \mu(e) = \mu(e_{\max})$$

if $e \in [e_i, e_{i+1}]$, then

$$\mu(e) = \mu(e_i)\frac{\mu(e_{i+1}) - \mu(e)}{\mu(e_{i+1}) - \mu(e_i)} + \mu(e_{i+1})\frac{\mu(e) - \mu(e_i)}{\mu(e_{i+1}) - \mu(e_i)}, \qquad (1)$$

In the case of n variables, a *n*-dimension grid is realized and a value $\mu(N_i)$ is set for each node N_i. The command value of an unspecified vector V is the average of each $\mu(N_i)$, taking only the nodes which define the net to which *V* belongs. This average is balanced by the distance of each node N_i to V.

Use of the fuzzy controller in the building

The controller controls the temperature of the building in varying the flow rate of the heating fluid in the heating floor.
The user must first define the periods of occupation and inoccupation in the building. Then he sets the high temperature level for occupation and the low temperature level for inoccupation. The management of inoccupation consists in to steps. The first step consists in turning off the pump of the heating floor, which leads to the descent of the temperature until it reaches the low temperature level. The controller maintains then the temperature of the building around this level. The second step is the restart step. The controller calculates the time when it must produce the maximal flow rate in the heating floor, in order that the temperature reaches the high temperature level at the moment when the occupation period begins. On each time step, the controller calculates the time needed for the temperature to reach the high temperature level. If it is longer than the time before the next occupation period, then the restart step begins and the command is set to its maximum. The restart time is calculated in function of the external temperature and the internal temperature of the building.
The variations intervals are respectively determined between the minimal external temperature which depends of the climate and the high temperature level and between the low and high temperature levels. The restart duration *t* is a linear function of the external temperature T_e, that's why only two nodes are used for the grid on this variable. We use seven no des for the variation of the internal temperature T_i, to guarantee the best precision. The fuzzy function which defines the restart time for each node $(T_{e,j}, T_{i,k})$ with $(j,k) \in \{[1;2],[1;7]\}$ is:

$$t_{(T_{e,j},T_{i,k})} = \alpha \frac{T_{\max} - T_{e,j}}{T_{\max} - T_{\min}}\left(\frac{T_{i,k} - T_{\max}}{T_{\max} - T_{\min}}\right)^3, \qquad (2)$$

We have $T_{\max} = 20$ °C, $T_{\min} = -10$ °C, and $\alpha = 10000$ hr. The two first values are defined by the weather conditions. The last one has been empirically chosen.
For the occupation periods, we also use fuzzy control to calculate in function of the internal and external temperature the best flow rate command for the heating floor which will maintain the temperature of the building around the high temperature level. Seven nodes are used on both variables. The fuzzy function which defines the flow rate for each node $(T_{e,j}, T_{i,k})$ with $(j,k) \in \{[1;7],[1;7]\}$ is :

$$Q_{(T_{e,j},T_{i,k})} = Q_{\max} + \frac{Q_{\min} - Q_{\max}}{6}(j-1) - \beta\frac{(6-k)}{6}Q_{\max}, \qquad (3)$$

For the simulation, we have $Q_{\max} = 700$ kg/hr, $Q_{\min} = 0$ kg/hr and $\beta = 0{,}3$.

STUDY OF THE CONTROLLER'S PERFORMANCES

Description of the simulation

The controller was set with inoccupation periods between 6 A.M. and 7 P.M., from Monday to Friday. The low temperature level is set on 10°C and the high temperature level to 20°C. The real inoccupation periods are between 8 A.M. and 7 P.M., but the inertia of the building is such that the descent step can be anticipated. The flow rate of the heating floor can be set between 0 and 700 kg/hr, the fluid's temperature is set to 35 °C. However, our modelling choice imposes minimal flow rate value in the floor : the floor is divided in a limited number of nets. The lower is the minimal limit, the greater is the number of nets. 250 kg/hr is the lower limit our simulation program can bear.
Furthermore, 200 litres of domestic hot water, temperature 45°C, is produced each day. The simulation takes place in Lyon Bron, France, during the two first week of January. The time step is 6 minutes. We monitored three phenomena: the first one is the evolution of the temperature in the building. To satisfy our performance criterion, the temperature must remain around the high temperature level with a limit of more or less 0,5°C during the occupation periods. The second one is the evolution of the heating power supplied by the heating floor to the building. We will estimate the energy spent to heat the dwelling. The last one is the evolution of the tank temperature and the evaluation of the energy supplied by the solar collector and the boiler.

Results

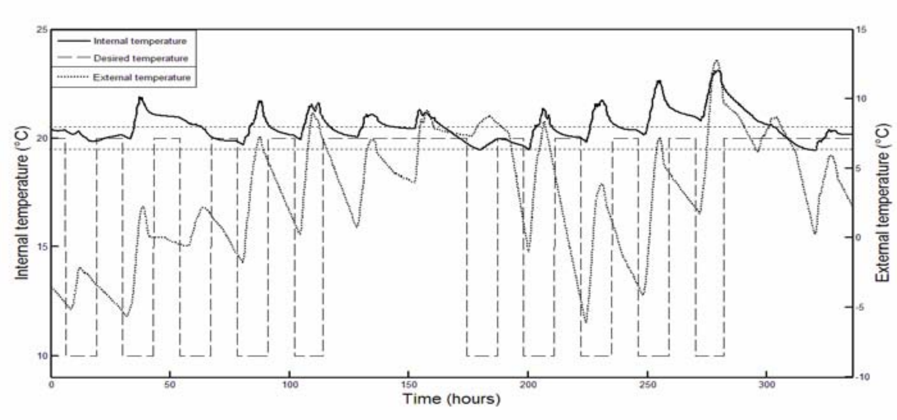

Figure 3: Evolution of the temperature in the dwelling

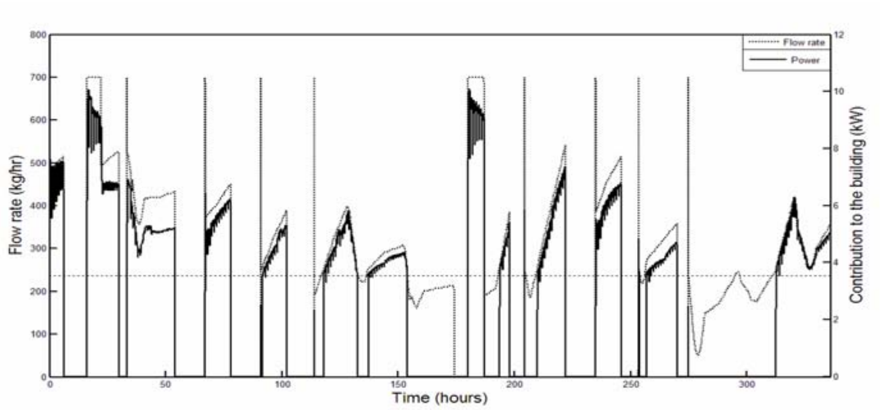

Figure 4: Flow rate and power of the heating floor

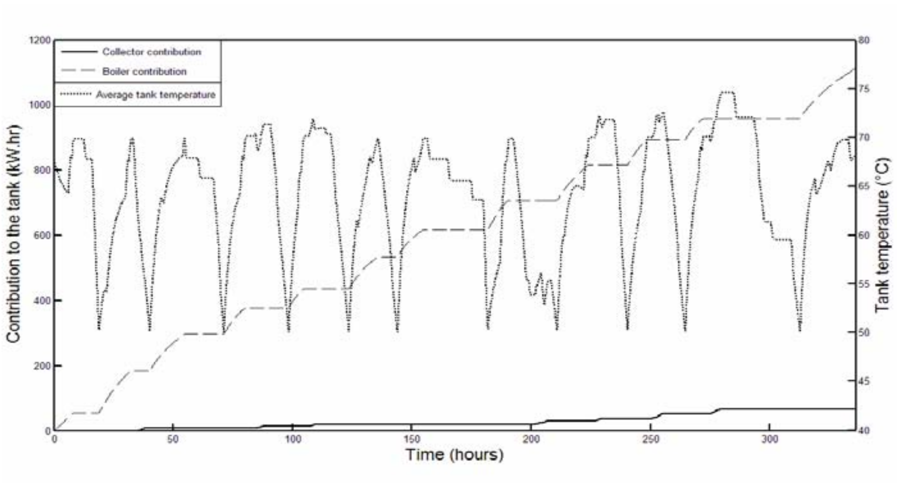

Figure 5: evolution of the temperature of the tank

Analysis

We notice on figure 3 that our criterion is verified during the week, excepted during the first Tuesday and the second Thursday when some overheat can be noticed. The control during the week end is more delicate, the temperature is sometimes too high. We also observe that the temperature doesn't necessarily decrease during the occupation period. The solar gains are sometimes so high that the temperature increases even if the heating floor is turned off. This is the same phenomenon which produces overheats during the week end, since these solar contributions aren't taken into account by the controller during the occupation period. If the temperature somehow decreases during the inoccupation period like during the first and the second Monday, the restart time is well evaluated and the following occupation period begins with a 20°C temperature.

We notice on figure 4 that the heating power given to the building is proportional to the flow rate in the heating floor. This power is null during the inoccupation period, excepted during the restart stage. If the temperature doesn't decrease during the inoccupation period lower than the high temperature level, the restart stage is skipped. The controller actually considers this stage during one time step, that's why we can notice thin flow rate peaks on the beginning of some occupation periods.

The biggest problem of the controller is the fact that it keeps heating the building whereas the temperature is already too high. This is the consequence of the minimal flow rate limit, we have to make sure that the calculated flow rates remains above the limit most of the time, which sometimes leads to overheats.

The total energy contribution of the heating floor to the building is 890 kW.hr

We notice on figure 5 that during these two weeks, the solar gain to the storage tank is low. This could be expected since in this season the solar radiations are weak. We will however notice that the final solar gain is 64 kW.hr and the boiler gain is 1115 kW.hr.

COMPARISON WITH A LINEAR CONTROL METHOD

Control method

Our fuzzy controller passed the test of our criterion, despite some high temperature sometimes and some limitations from our model. We will now compare its performances to a standard linear control.

The flow rate is calculated in function of the external temperature the following way :

$$Q_c(T_e) = Q_{\max}\frac{T_{\max} - T_e}{T_{\max} - T_{\min}}, \qquad (4)$$

$Q_{\max}$, $T_{\max}$ and $T_{\min}$ are empirically determined in order to get the best performances. $T_{\max}$ and $T_{\min}$ delimit the usual variation interval of the outside temperature.
In our case, we respectively chose for those three values =450 kg/hr, 20°C and -15°C.
The goal is to constantly maintain the temperature around the same temperature level of 20°C.

Results

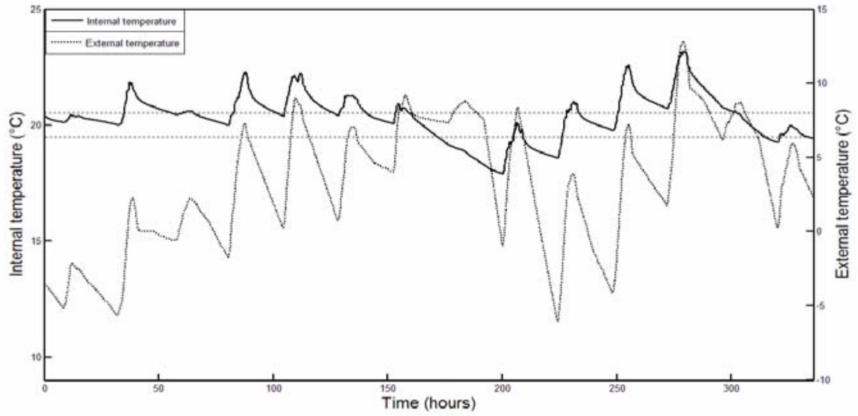

Figure 6: Evolution of the temperature with a linear control

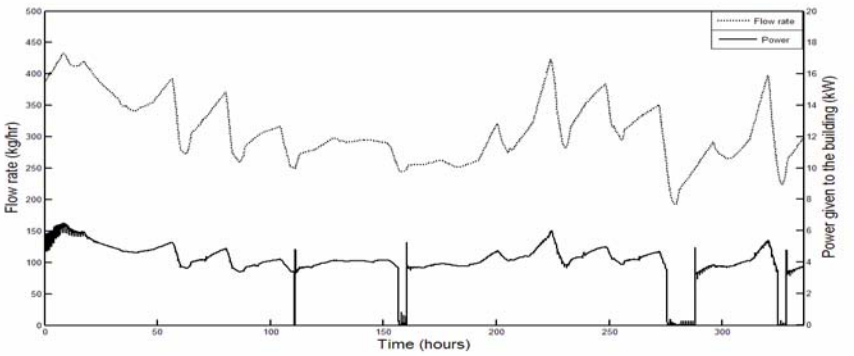

Figure 7: Flow rate and power of the heating floor with a linear control

Analysis

The performance criterion in this case for the temperature control is still to keep the temperature in the $20 \pm 0{,}5°C$ area. But this time, this criterion prevails during the whole simulation, when it only mattered during the occupation period for the fuzzy controller. We can't therefore make a quantitative comparison to determine which controller best respects the criterion but we can somehow make qualitative comparison.
We can see on figure 6 temperature risings on the same moment like on figure 3. The cause of these peaks is the same: the solar contribution isn't taken into account by the controller. However, the amplitude of these peaks is greater with the linear controller. Since the solar contribution happens during the inoccupation period, the fuzzy controller turns the heating

floor off and compensates the solar gain. The linear controller makes no difference and keeps heating while the internal temperature is already too high.
We also notice that the temperature decreases twice below 19,5°C. We can conclude that the fuzzy controller produces a better control than the linear controller.
The calculated flow rate remains between 200 and 450 kg/hr. We can confirm the proportional relationship between the flow rate and the heating power.
The heating power contribution to the building is 861 kW.hr, 3,7% less than the fuzzy controller. The boiler contribution to the tank is 914 kW.hr and the collector contribution is 69 kW.hr.

CONCLUSION

In our study, the fuzzy controller doesn't save more energy than the linear controller.
However, its control is better than the linear controller since it takes profits of the solar gains and the inertia to lower the restart step duration.
The fuzzy controller is a powerful controller but it is limited by its simple rules. It handles well the inoccupation periods, but this capacity doesn't save much energy, because of their short duration. It will in spite of that be our reference to compare the performances of a new controller which we started to design.
Our strategy consists in using advanced automation techniques such as optimal command [5] to improve the exploitation of inoccupation periods and predictive command to better anticipate external gains such as solar gains and internal gains, caused by inhabitants and electric devices. We will also use a state system modelling to anticipate on its behaviour.

SUMMARY

In this paper, we choose to present the generic form of an optimal control law for heating building. To build it, three successive steps are necessary: (i) the first one allows to determine the inside temperature set point that takes into account intermittency and tends to reduce the cost control; (ii) the second that corresponds to the discrete controller design is based on a quadratic mixed criterion “cost and efficency”; (iii) the third corresponds to the design of the virtual sensor. Efficiency of this approach is shown via a numerical example and compared with a Fuzzy regulator (marketed regulator).

INTRODUCTION

Taking into account the intermittency of buildings’ occupation allows saving a significant amount of energy. Many studies are related to saving heating in buildings, because these ones in tertiary sector are only occupied for 30% of time. Today, it is also necessary to work on the residential sector where intermittency exists: dwelling houses being usually empty during the day and may be slowed right down at night.

One way to improve these installations is working downstream of heating sources and defining a strategy to minimize the energy required for heating the dwelling houses. This last one has to take into explicit account of intermittency by stressing the passive contributions and storage in vacant periods. Thus during the day, solar contributions must be exploited as much as possible and energy storage must be optimized in order to use it during evening, when the outside temperature is the less favourable.

An early study in continuous time [1] has already shown the interest of an optimal control strategy (via simulation) [2,3]. In order to take into account technical considerations such as the choice of sampling, we propose to develop in discrete time a similar strategy, based on optimal control for sampled systems. Searching an extremum for the discrete performance criterion leads to a command in the form of recursive equations ready to set up. In [1], a Feed-Forward using direct measurement of outside temperature is also used. To take into account solar contribution, Feed Forward needs an outside sensor and a model of behaviour between solar radiance and inside temperature. This last task is hard to carry out because of the non stationary and non linear feature of solar radiance and also due to solar contributions trough wall and windows. Indeed these last ones show significant difference in term of dynamic behaviour. Thus, we proposed here an elegant solution of this problem.

First, a cost criterion is used to determine the optimal trajectory of inside temperature during inoccupation stage. Searching an optimum of this criterion leads naturally to define the right time to come back to the occupation set point. Thus, a complete profile of temperature set point is built taking into consideration the specific constraints of intermittency (high and low set point).
Second, the structure of the regulator is obtained using a performance criterion composed of quadratic terms related to the quality of the heating control and cost.
Third, a virtual sensor is defined to estimate states required to control the system and the equivalent control that will be delivered by an exact real dynamic Feed-Forward using a direct measurement of disturbances. However, the virtual sensor uses only measurement of inside temperature (call virtual dynamic feed-forward later). It uses an optimal estimator in sense of the minimum variance of estimation error. This step is treated as a deconvolution problem.
Last, to show efficiency of this approach, a numerical example is treated considering only the outside temperature as an outside source. After having presented the cell test (Minibat [4]) and the behaviour model we selected, our new approach will be compared with an existing fuzzy regulator (marketed regulator). To end, we will compare our virtual Feed Forward with an exact real dynamic Feed Forward.

METHOD DEVELOPPMENT

In this part, we choose to present the generic form of the control law. To build it, three successive steps are necessary: (i) the first one allows to determine the inside temperature set point that takes into account intermittency and tends to reduce the cost control; (ii) the second that corresponds to the discrete controller design is based on a quadratic mixed criterion “cost and efficency” [2,3]; (iii) the third corresponds to the design of the virtual sensor [5].

Let us consider the general representation of state of the sampled linear systems, as follows:

$$\begin{aligned} x_{k+1} &= Fx_k + Gu_k \\ y_k^m &= Cx_k + d_k \end{aligned} \qquad (1)$$

With x_k the state vector, u_k the control vector, y_k^m the measurement, d_k the contribution of outside source. F, G and C are matrices with appropriate dimensions.
It is right to consider that the inside temperature of a dwelling is the sum of all sources’ contributions (heating device, outside temperature or solar radiance). Thus the corresponding model d_k will be considered in a first assumption as a white stochastic process, non-zero mean. In this paper, the variance of such process will be considered as constant.

Step 1 – Intermittency and set point profile

In this step, as we are interested in an ideal set point profile, a representation without disturbance must be considered:

$$\begin{aligned} x_{k+1} &= Fx_k + Gu_k \\ y_k &= Cx_k \end{aligned} \qquad (2)$$

The aim is to define the optimal couple (u^*,y^*) for the inoccupation phase respecting specific constraint previously stated. So a quadratic cost criterion is used

$$J_1 = 0.5\left[y_{N_2}^r - y_{N_2}\right]^T Q_{N_2}\left[y_{N_2}^r - y_{N_2}\right] + 0.5\sum_{k=N_1}^{N_2-1} u_k^T R_k u_k \qquad (3)$$

With N_1 and N_2 the first and the last sample of inoccupation phase. R_i and Q_i are matrices respectively definite positive and semi-definite positive. The first term of the criterion is used to find the optimal restart instant. The second allows the determination of the output trajectory that requires the lowest command.

Let us consider now the cost function Φ_k

$$\Phi_k(u_k) = 0.5 u_k^T R_k u_k \tag{4}$$

And the Hamiltonian H_k such as:

$$H_k = -\Phi_k + \beta_{k+1}^T [F x_k + G u_k] \tag{5}$$

with the adjoin state β_k.

Using the Discret Maximum Principe [3], we obtain the minimal control u_k^* :

$$\beta_k = -\frac{\partial H}{\partial x_k} \quad \Rightarrow \quad \beta_k = F^T \beta_{k+1} \tag{6}$$

$$\frac{dH}{du_k} = 0 \Rightarrow u_k^* = R_k^{-1} G^T \left(F^T\right)^{N_2-k-1} \beta_{N_2} \tag{7}$$

Using (7) in (1), some manipulations lead to:

$$\beta_{N_2} = \left(\sum_{k=N_1}^{N_2-1} F^k G R_k^{-1} G^T \left(F^T\right)^k \right)^{-1} \left(I - F^{N_2}\right) x_{N_2}^r \tag{8}$$

with $x_{N_2}^r$ the wished final value of state.

Using (7), (8), we obtain the ideal set point trajectory y_k^* for the inoccupation phase:

$$\begin{gathered} x_{k+1}^* = F x_k^* + G R_k^{-1} G^T \left(F^T\right)^{N_2-k-1} \left(\sum_{k=N_1}^{N_2-1} F^k G R_k^{-1} G^T \left(F^T\right)^k \right)^{-1} \left(I - F^{N_2}\right) x_{N_2}^r \\ y_k^* = C x_k^* \end{gathered} \tag{9}$$

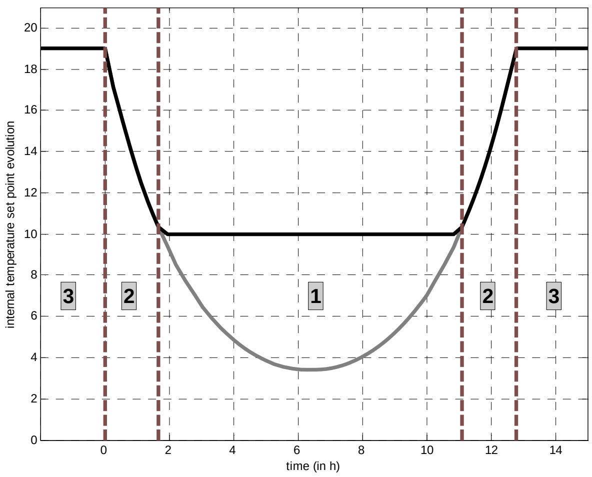

Figure 1: set point trajectory (gray – without constraint, black – with constraint)

Thus, the set point profile without constraint corresponds to a hyperbolic trajectory (9). Taking into account the specific constraint of each phase, the global trajectory of temperature is illustrated Figure 1**.** The evolution is finally composed by 3 parts. In part 2, if a regulator ensures *y**, the corresponding control is equivalent to the lowest *u**. Indeed, the dwelling is considered as a mono-zone space: the input is the heating power and the resulting output is the global inside temperature (considered as homogeneous). This SISO characteristic (Single Input Single Output) leads to a single solution. As illustrated Figure 1, constant set points are used (high and low set point) in parts 1 and 3 according to occupation and inoccupation constraints.

Step 2 – Design of control parameters

From the global set point profile defined in step 1, we are going to treat a pursuit problem in order to design the discrete controller. Thus, let us consider the following criterion:

$$J = 0.5\left[y_N^r - y_N \right]^T Q_N \left[y_N^r - y_N \right] + 0.5\sum_{k=0}^{N-1}\left\{\left[y_k^r - y_k \right]^T Q_k \left[y_k^r - y_k \right] + u_k^T R_k u_k \right\} \tag{10}$$

where y_N^r is the high set point and N is the total number of samples included in the whole cycle.

In order to ensure the reduction of the effect due to the disturbance, a new state z_k is introduced. That leads to an increased discrete representation equivalent to the representation of Johnson into the continuous case [1].

$$\begin{aligned} X_{k+1} &= \begin{bmatrix} x_{k+1} \\ z_{k+1} \end{bmatrix} = F_a X_k + G_a u_k^c \quad \text{with} \quad F_a = \begin{bmatrix} F & G \\ 0 & I \end{bmatrix} \\ Y_k &= C_a X_k \quad \text{with} \quad C_a = \begin{bmatrix} C & 0 \end{bmatrix} \text{ and } G_a = \begin{bmatrix} 0 \\ I\ \mathrm{T_e} \end{bmatrix} \end{aligned} \tag{11}$$

with Te the sample rate, I the identity matrix and subscript “a” to identify the increased representation for control. We introduce the Income function Ω_k defined by:

$$\begin{aligned} \Omega_k &= 0.5\left[X_k^r - X_k \right]^T C_a^T Q_k^a C_a \left[X_k^r - X_k \right] + 0.5\, u_k^{cT} R_k^a u_k^c \\ &\text{with} \quad Q_k^a = \begin{bmatrix} Q_k & 0 \\ 0 & R_k \end{bmatrix} \text{ and } R_k^a = \theta_k \end{aligned} \tag{12}$$

with θ_k a weighting matrix, definite positive and symmetrical.
The optimal value of the criterion is defined by a recurring form of the type:

$$J_k^* = \min_{u_k^c}\left(\Omega_k + J_{k+1}^* \right) \tag{13}$$

Where J_k^* is supposed to be a quadratic form. Thus, we define it as follows:

$$J_{k+1}^* = 0.5\left(X_{k+1}^T P_{k+1} X_{k+1} + 2\lambda_{k+1}^T X_{k+1} \right) \tag{14}$$

With λ_k a adjoin vector and P_k a definite positive and symmetrical matrix. By taking account (11), (13) and (14), the minimum of the criterion (10) with respect to u_k^c is defined as follows:

$$u_k^{c*} = -\left(R_k^a + G_a^T P_{k+1} G_a \right)^{-1} G_a^T \left(P_{k+1} F_a X_k + \lambda_{k+1} \right) = -K_k^c X_k + L_k \lambda_{k+1} \tag{15}$$

As J_k^* is a quadratic form that implies:

$$P_k = \left(F_a - G_a K_k^c \right)^T P_{k+1} \left(F_a - G_a K_k^c \right) + K_k^{cT} R_k^a K_k^c + C_a^T Q_k^a C_a \quad \text{with} \quad P_N = C_a^T Q_{N_1}^a C_a \tag{16}$$

$$\lambda_k = \left(F_a - G_a K_k^c \right)^T \lambda_{k+1} - C_a^T Q_k^a C_a X_k^r \qquad \text{with} \quad \lambda_N = C_a^T Q_{N_1}^a C_a^T X_{N_1}^r \tag{17}$$

Let us note that these two last equations must be solved backward in time. We must take care to solve them before using the controller. The real command of the process is then defined by:

$$u_k^* = z_k \qquad \rightarrow \qquad u_{k+1}^* = u_k^* + T_e\left[L_k \lambda_{k+1} - K_k^c \begin{bmatrix} x_k \\ u_k^* \end{bmatrix} \right] \tag{18}$$

Step 3 – Design of virtual sensor

Considering (1) and step 2, one can notice that the problem is equivalent to use a LQG approach [3]. At this step of design, x_k is required but not available, only the measurement y_k^m is available. Moreover, (1) is a stochastic process, thus, it is necessary to use an estimator to obtain an estimate of real trajectories followed by the states of the system [5]. We remind that our aim is the design of an estimator which estimates both the states and an equivalent contribution of disturbances. Thus, after introducing a deconvolution problem, we summarize a Kalman estimator.

We first define an equivalent system (with equivalent output) in which disturbance is considered as a stochastic unknown input.

$$\begin{matrix} x_{k+1} = Fx_k + Gu_k \\ y_k^m = Cx_k + d_k \end{matrix} \rightarrow \begin{matrix} x_{k+1} = Fx_k + Gu_k + Gw_k \\ y_k^m = Cx_k + v_k \end{matrix} \tag{19}$$

Where w_k is a non zero mean white noise with constant variance and v_k the noise measurement considered as a zero mean white noise with constant variance.
To overcome any estimation bias, we can consider that w_k is the output of a Wiener process generator driven by a zero mean Gaussian white noise with constant variance. That lead to the following representation:

$$\begin{gathered} x_{k+1}^e = \begin{bmatrix} x_{k+1} \\ w_{k+1} \end{bmatrix} = F_e x_k^e + G_e u_k + M_e \omega_k \text{ with } F_e = \begin{bmatrix} F & G \\ 0 & I \end{bmatrix}, G_e = \begin{bmatrix} G \\ 0 \end{bmatrix} \text{ and } M_e = \begin{bmatrix} 0 \\ I\ \mathrm{T_e} \end{bmatrix} \\ y_k^m = C_e x_k^e \text{ with } C_e = \begin{bmatrix} C & 0 \end{bmatrix} \end{gathered} \tag{20}$$

with subscript “e” to identify the increased representation for estimation.
From (20), an optimal estimator in sense of the minimum variance of estimation error can be defined (Kalman Theory []). Thus, in the stationary case, we obtain:

$$\Pi = F_e \Pi F_e^T + M_e Q_\omega M_e^T - F_e \Pi C_e^T \left[C_e \Pi C_e^T + R_v \right]^{-1} C_e \Pi F_e \tag{21}$$

With Π a definite positive and symmetrical matrix, Q_ω and R_k are respective input and measurement noise variance.

$$K_e = \Pi C_e^T \left[C_e \Pi C_e^T + R_v \right]^{-1} \tag{22}$$

With K_e the estimator gain
The “a priori” estimation is defined by:

$$\hat{x}_{k/k-1}^e = F_e\ \hat{x}_{k-1/k-1}^e + G_e u_{k-1} \tag{23}$$

And the “a posteriori” estimation is defined by:

$$\hat{x}_{k/k}^e = \hat{x}_{k/k-1}^e + K_e \left(y_k^m - C_e \hat{x}_{k/k-1}^e \right) \tag{24}$$

Step1 + Step2 + Step 3 = Control law

The final expression of control is as follows:

$$u_k = u_{k-1} + T_e \left[L_{k-1} \lambda_k - K_{k-1}^c \begin{bmatrix} \hat{x}_{k-1/k-1} \\ u_{k-1} \end{bmatrix} \right] - \hat{w}_{k/k} \tag{25}$$

RESULTS

Performances of the new controller are shown thanks to the model [] of the test cell Minibat developed by the CETHIL [4]. This test installation is a 2 identical contiguous area with a controlled climatic environment (temperature, sunning). The rooms dimensions are *3.10 m* $\times$ *3.10 m* $\times$ *2.50 m* (L x l x h). The external jacket consists of standard insulating concrete (Siporex) with *20 cm* thickness and has following dimensions: *7.5 m* $\times$ *4.50 m* $\times$ *3.43 m.* Walls of the cell are composed of agglomerated wood panels of *5 cm* thick, covered with a pressure-sealed plasterboard of *1 cm*. Only the southern wall is equipped with a window of *1 cm* thickness. The floor is made of a concrete flagstone of *20 cm* thickness. A set of runs was carried out with the cell in order to identify its dynamic and static behaviour. A first order continuous model is obtained:

$$F = e^{-\frac{T_e}{\tau}}, \quad G = b\left[1 - e^{-\frac{T_e}{\tau}}\right] \quad C = 1 \qquad (26)$$
$$\text{with} \quad T_e = 1000 \text{ s}, \ \tau = 9564\text{s} \ \text{ and } \ b = 0.008413$$

F, G and C are defined as in (1).

In our case, the outside temperature is the only disturbance considered. The weather data come from the Météonorm station located at Lyon – Bron, France. Simulation runs on two days with occupation range 8h00-19h00

Figure 2 shows results we obtained with a controller using an optimal control strategy combined with a real dynamic Feed-Forward (RFF) when all information are known (states and disturbance). Figure 2 shows also results we obtained with the same kind of control strategy but information needed is estimated with a virtual sensor. It clearly appears that performances of both controllers are quite similar.

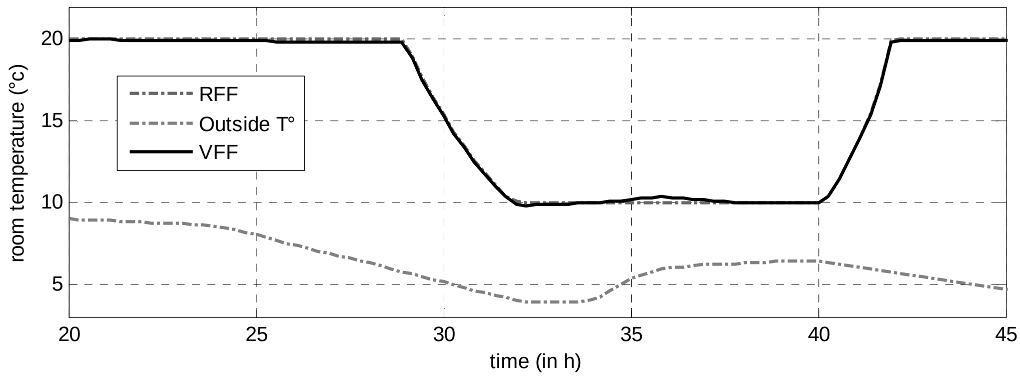

Figure 2 ***: Comparison of our controller (VFF) with an optimal control with all states available and real dynamic feed forward (RFF)***

Figure 3 gives evolution of inside temperature we obtained with a fuzzy controller [6, 7, 8, 9], and our discrete controller. Our new strategy makes it possible to satisfy with a great efficiency the constraints. Let us consider now the first inoccupation phase on Figure 3 and Figure 4. When the inoccupation phase starts, the Fuzzy controller is designed to deliver a constant control whatever external contributions. As a result, this technique spends more energy than necessary. In our case, the control is automatically reduced or stopped when no energy is required and restarts automatically when the low set point is not satisfied. Moreover, for the Fuzzy controller, the time to come back is defined a priori by the operator and the associated control is the maximum control. Thus, room temperature is equivalent to the high set point too much early. As a conclusion, energy expenditure with the Fuzzy controller is more important.

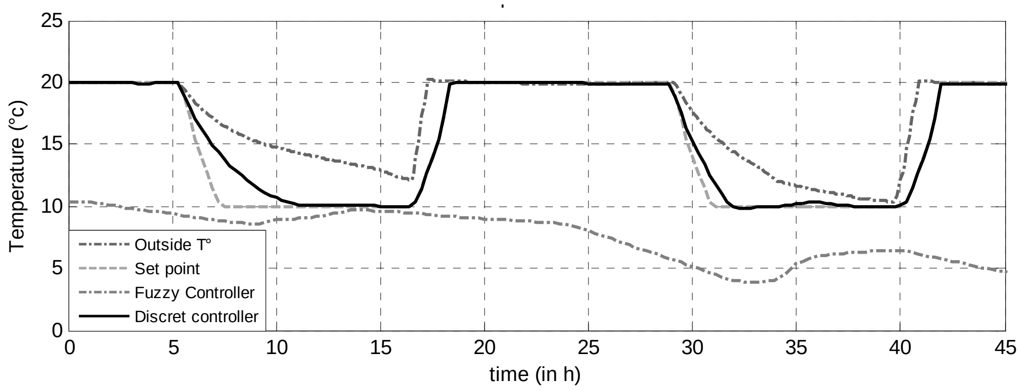

Figure 3 ***: Comparison of our controller (VFF) with a Fuzzy controller during two days (room temperature)***

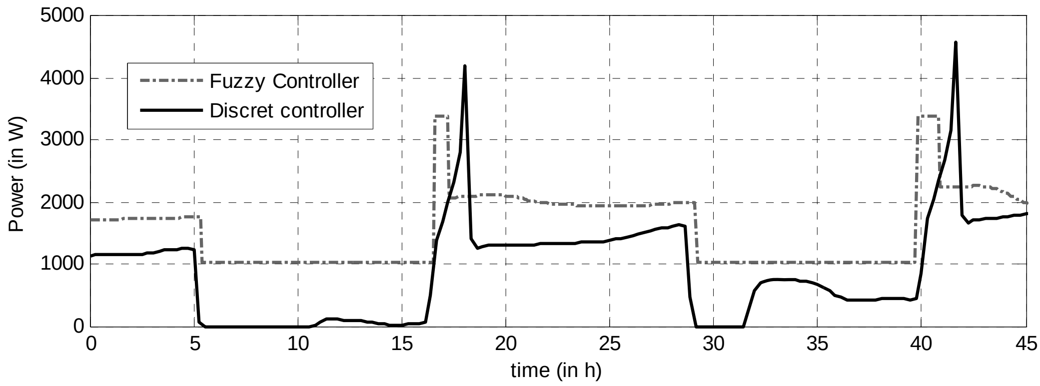

Figure 4 ***: Comparison of our controller (VFF) with a Fuzzy controller during two days (control)***

CONCLUSION

In this article, the synthesis of a discrete controller for the control of the temperature in a building was presented. After introduction, a Cost criterion makes it possible to characterize the specific behaviour to each phase (occupation and inoccupation). Parameters of the control law are next obtained using an optimal control analysis from a Cost-Efficiency criterion. A virtual sensor is then defined to take into account outside contributions from only room temperature measurement. Results of simulations are particularly hopeful and show, in comparison with a fuzzy regulator, the interest to use a model of behaviour of the test cell and more generally of a building. Our controller allows to decrease significantly the amount of energy needed to heat the building.

SUMMARY

In this research, we suggested thermal storage heating and cooling systems by a simplified predictive control for highly insulated office buildings and verified the usefulness of this control technique on the basis of energy conservation and thermal comfort in offices. At first, the calculation procedures of a simplified predictive control were shown. From the viewpoints of energy conservation and thermal comfort, it was very effective to supply heat continuously, such as continuous operation or nighttime operation, in the heating season, and to supply heat intermittently, such as intermittent operation or nighttime operation, in the cooling season.

INTRODUCTION

Recently, bills related to energy conservation were enforced and revised in Japan, and buildings have become highly insulated and air tightened. In contrast with European countries, external insulation has gradually spread around cold districts in Japan, like Hokkaido, where internal insulation has generally been used. However, under the present conditions, even with externally insulated buildings of reinforced concrete, problems related to control techniques such as suspending operations on Saturday and Sunday and overheating room air temperature in the daytime, could not be always solved. From the above, the main purpose of this research is to suggest a newly simplified control technique and to verify the usefulness of this control technique on the basis of energy conservation and thermal comfort in offices. Heating and cooling systems used in this research utilize thermal storage heating and cooling systems consisting of piping laid inside the floor slab and transporting water to pipes with minimal power.

OUTLINE OF BUILDING MODEL AND SIMPLIFIED PREDICTIVE CONTROL

In this research, we postulated a building model and reproduced the thermal fluctuations of an actual building by numerical simulation. This model is of an externally insulated office building that had introduced thermal storage heating and cooling systems, built in Sapporo (Figure 1). The scale of this model was the standard scale of government buildings in Hokkaido (total floor area: 3000 [m^2]), the details of which are as follows: four-storied building, total floor area 3168 [m^2], length of east-west direction 45 [m] and length of south-north direction 17.6 [m]. Concrete volume of this model is shown as the thickness of exterior walls 120 [mm] and slab 150[mm] by adjusting the direction of the depth (z) to a two dimensional model (x-y) in the direction of cross section in each direction. As insulation specifications, EPS external insulation with exterior walls (100 [mm]) and roof slab (150 [mm]) were adopted. Insulation performance became Perimeter Annual Load (PAL) 201 [MJ/m^2 year] (heating PAL 74 [MJ/m^2 year], cooling PAL 127 [MJ/m^2 year]). This value is equivalent to a 30% reduction in the standard value of bills related to energy conservation, and means that this is a very highly insulated building model.

Thermal storage heating and cooling systems are constructed by diverting hot and cold water to cross-linked polyethylene piping (13A) laid inside a floor slab. The depth of piping laid inside the floor slab is 70 [mm], at an interval of 150 [mm]. We have explained a simplified control technique for these systems. We transcribed the simplified control technique suggested in this research into a simplified predictive control, and show the calculation procedures below (Table 1, from a) to d)). Three case studies were done in which the operation methods presumed intermittent operation, continuous operation and nighttime operation (Table 2).

a) Calculation of predictive thermal load: Predictive thermal load was calculated by using mean values for a day of HASP meteorological data. The 2005 calendar was adopted, and thermal load caused by heat gain and ventilation was defined as zero on Saturday and Sunday. When natural room air temperature changed between 22 and 26 [degrees centigrade], this period was defined as the moderate season (*M*). As a result, the maximum predictive heating load became about 1292 [kWh/day] (January 20 (Thursday)) in the heating season (H), and also the maximum cooling load became about 1475 [kWh/day] (July 27 (Wednesday)) in the cooling season (C) (Figure 2).

b) Calculation of equipment capacity of heat source: Equipment required as capacity of heat source for 10-hour intermittent operation or 24-hour continuous operation was calculated by using predictive thermal load. As a result, in the case of intermittent operation, maximum heating and cooling capacity became 153.3 [kW] and 151.9 [kW], and also in the case of continuous operation, 143.1 [kW] and 76.2 [kW] (Figure 3).

c) Calculation of water temperature setting: It was presumed that floor area, which evolved or absorbed heat for heating and cooling, was 3168 [m^2] and ceiling area was 2376 [m^2]. Water temperature setting was calculated to supply predictive thermal load based on the thermal resistance from the center of the pipe to the surfaces of the floor and ceiling.

d) Calculation of approximate water temperature setting: As thermal storage heating and cooling systems were presumed so as to control the constant flow rates of water, water temperature setting repeatedly change throughout the day corresponding to predictive thermal load. However, in order to make it usable as a simplified predictive control, we defined it approximately by the change throughout the year as approximate water temperature setting.

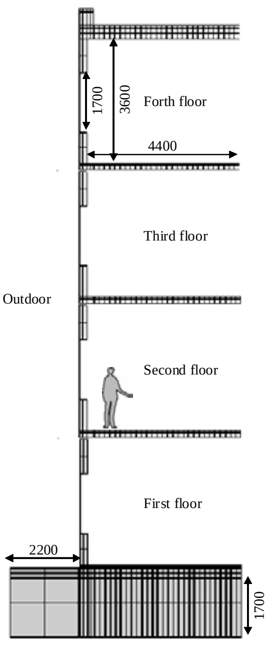

Figure 1. Building model

Table 1. Calculation processes of predictive thermal load

Calculation processes
Predictive heating load [Wh/day] = $Q_1 - Q_2 - Q_3 + Q_4 + Q_5$
Predictive cooling load [Wh/day] = $- Q_1 + Q_2 + Q_3 - Q_4 - Q_5$
Thermal load of walls [Wh/day] = Q_1 = *Siguma* (*Siguma* $K_n \times S_n \times (T_i - T_o)$)
Thermal load caused by solar radiation [Wh/day] = Q_2 = *Siguma* (*Siguma* $S_n \times J_n \times SC$)
Thermal load caused by heat gain [Wh/day] = Q_3 = 87859.2 [W] × 8 [h/day] (9:00 ~ 17:00)
Thermal load caused by infiltration [Wh/day] = Q_4 = 0
Thermal load caused by ventilation (V) [Wh/day] = Q_5
= 0.34 × 12672.0 [m^3/h] × ($T_i - T_{od}$) × 8 [h/day] (9:00 ~ 17:00)
Notes
K_n : Thermal transmittance of n [W/m^2 K], S_n : Area of n [m^2]
J_n : Value of solar radition of n (HASP, 0:00 ~ 24:00) [W/m^2]
SC : Shading coefficient (0.46)
T_i : Room air temperature for design
(Heating season (H): 22 [degrees centigrade], Cooling season (C): 26 [degrees centigrade])
T_o : Mean outdoor air temperature for a day (HASP, 0:00 ~ 24:00)
T_{od} : Mean outdoor air temperature during the daytime (HASP, 9:00 ~ 17:00)
Thermal load caused by exterior walls (W) [Wh/day] = $Q_1 + Q_2 + Q_3 + Q_4$
T_o on Q_1 in the cooling season ⇒ T_{SAT} (Equivalent outdoor air temperature)
87859.2 [W] = 41.6 [W/m^2] × 3168 [m^2] × 2 / 3
12672.0 [m^3/h] = 30.0 [m^3/person h] × 0.2 [person/m^2] × 3168 [m^2] × 2 / 3

VERIFICATION OF ENERGY CONSERVATION

Thermal load caused by exterior walls (W) was calculated from [specific gravity * specific heat * flow rates of water * (water inlet temperature - water outlet temperature)]. Thermal load caused by ventilation (V) was calculated from [specific gravity * specific heat * flow rates of fresh air * (room air temperature - outdoor air temperature)]. As thermal load caused by heat gain was considered heat source, approximate hot water temperature setting was very low. However, when the time to operate thermal storage fell on the time to intake fresh air, approximate hot water temperature setting had not arrived at the expected line even if hot water was heated with equipment of heat source(Figure 4 a), c)). Thermal load caused by exterior walls on January 17 (Monday) became larger than that on other days, so it was confirmed that suspending operations on Saturday and Sunday and continuous operation on weekdays were not reasonable. Therefore, it seemed that it is desirable to control by continuous operation on Saturday and Sunday for minimization of equipment capacity of heat source if it is possible to control by continuous operation on weekdays (Figure 4 c)).

On the other hand, nighttime operation obtained a good balance of heat supply between the time to operate thermal storage and the time to intake fresh air. So it was very effective for the problem of stopping operations on Saturday and Sunday (Figure 4 e), f)). Moreover, concerning the relationship between thermal load caused by exterior walls and differences between outdoor and indoor air temperatures, both showed a positive correlation. However, as outdoor air temperature was too cold in the heating season, thermal load caused by exterior walls on Monday increased about 2 times more than those on other days as a result of suspending operations on Saturday and Sunday (Figure 5). Although energy consumption for heating and cooling throughout the year for 24-hour continuous operation was about 5 % larger than that for 10-hour intermittent operation, it must be considered to have minimized equipment capacity of heat source in CASE2 (Figure 6).

VERIFICATION OF THERMAL COMFORT

In the case of approximate water temperature setting, it was possible that the amount of heat required for a day was surplus or short. Yet, if room air temperature fluctuations could be accepted in the range in which office workers feel comfortable, this control technique may be positioned as a simplified predictive control premised on the permissible range of room temperature fluctuations in highly insulated office buildings. As a result, room air temperature (R) and floor surface temperature (F) during office hours were mostly stable, and the range of room air temperature swings settled at about 1.2 [degrees centigrade] (Figure 7, Figure 8).

Thermal comfort in CASE1 became PPD > 10% (PMV < -0.5) in only the heating season, which was affected by the problem of suspending operations on Saturday and Sunday (Figure 9 a)). In contrast, thermal comfort in CASE2 became PPD > 10% (PMV > +0.5) in only the cooling season, which was affected by the problem of overheating room air temperature in the daytime (Figure 9 a)). When room air temperature surpassed 26.5 [degrees centigrade], PPD increased rapidly, and the maximum PPD reached more than 20% (Figure 9 b)). Thermal comfort in CASE3 was very effective because PPD was not more than the recommended value even if we admit the permissible range of room temperature fluctuations (Figure 9 c)).

CONCLUSIONS

In this research, we suggested thermal storage heating and cooling systems by a simplified predictive control for highly insulated office buildings and verified the usefulness of this control technique on the basis of energy conservation and thermal comfort in offices. Principally, we considered the usefulness of continuous and nighttime operations in these systems. The results of numerical simulations were as follows:

1. The calculation procedures of a simplified predictive control were shown, and when the time to operate thermal storage fell on the time to intake fresh air during office hours, approximate hot water temperature setting had not arrived at the expected line.

2. Suspending operations on Saturday and Sunday and continuous operation on weekdays were not reasonable in the heating season because thermal load caused by exterior walls on Monday increased about 2 times more than those on other days.

3. Energy consumption for heating and cooling throughout the year for 24-hour continuous operation was about 5 %, for example about 4 [kWh/m^2 year], larger than those for 10-hour intermittent operation. However, it is possible to introduce continuous operation, though operation methods should be improved.

4. From the viewpoints of energy conservation and thermal comfort, it was very effective to supply heat continuously, such as continuous operation or nighttime operation, in the heating season, and to supply heat intermittently, such as intermittent operation or nighttime operation, in the cooling season.

SUMMARY

This paper summarises CSIRO's work on intelligent HVAC management techniques, with a particular focus on techniques designed to participate in demand management programmes. Such programmes are of significant interest, seen as a way of reducing expenditure and minimizing energy consumption in electricity systems around the world. CSIRO's aim is to design intelligent HVAC controllers that can enable automated participation in energy demand management programmes, benefiting both the local system owner as well as the electricity business, whilst still considering factors such as occupant comfort. This paper describes our investigations into the application of machine learning techniques towards such a controller. It also summarises our recent experiments trialling demand management techniques (through setpoint variation) in a multi-story building HVAC deployment.

INTRODUCTION

As concepts such as carbon trading, electricity demand management and renewable energy integration become a significant consideration for modern society, there is an increasing focus on more intelligent control of heating, ventilation and air-conditioning (HVAC) plant. At all scales of the HVAC industry, from relatively small residential air-conditioning systems, to large commercial HVAC plant, there is a growing awareness of a need for intelligent, integrated HVAC plant that considers the world around it.

In Australia, a number of recent examples highlight the growing external pressures on the designers, owners and operators of HVAC equipment:

- Air-conditioning systems are being blamed in popular media as one of the causes of demand-related electricity network failures across parts of Australia [1].
- Programmes are being introduced by electricity retailers that are specifically designed to control or limit the energy consumption of air-conditioning units at certain times of the day[1].
- Recognising issues such as those above, standardisation work has already started trying to standardise the interfaces used to control air-conditioning systems [2].

Further, a recent new approach to the operation and management of electricity networks brings even greater challenges, and also opportunities, to HVAC organisations. Part of a wider concept referred to as *distributed energy* (DE), the recent growth in *demand-side* consideration of electricity networks brings a lot of attention towards intelligent load control ~~(or *demand management*), wit~~h local consumer consideration of new factors such as

[1] There are many examples of such programmes, however at this stage they can generally be grouped into two categories- programmes designed to control energy consumption by price signals [3], or programmes that use a physical control technology to directly manage air-conditioner consumption, away from the consumer [4].

electricity network operating condition, electricity unit price, availability of local electricity generation, and short-range weather predictions, as well as more common factors such as operating cost and maintenance issues.

In general, the reason demand-side technologies are of significant commercial, research and regulatory interest is that they are seen to have a number of benefits to electricity systems worldwide. Trials in this area conducted in Europe and the U.S.A have been shown to assist in demand-supply constraint situations, reduce energy consumption, help manage electricity retailer's commercial risks, and assist in the infrastructure investment decisions of electricity network operators. Reflecting such benefits, the U.S.A has recently mandated that distributed energy approaches be encouraged throughout their network [5], other studies have suggested DE type methods are some of the most cost-effective ways to meet peak load growth [6], and new distributed-energy related businesses are beginning worldwide.

Whilst benefits such as increased network stability and reduced financial risk help electricity retailers and network operators, we believe there are two fundamental reasons why demand management should be of interest to HVAC companies:

- Demand-side focussed programmes generally require better HVAC load control, requiring greater sophistication in HVAC operation and control strategies.
- Often, demand management programmes will include a *user-paid* component, where HVAC operators are financially rewarded for taking a particular management action with their plant, thereby facilitating additional income streams for operators of large HVAC plant.

CSIRO's work in this area takes advanced concepts from the artificial intelligence and computer science domains, and applies them to the intelligent control of HVAC plant. Along with optimized end-use efficiency benefits, such technology enables automated participation in energy demand management programmes, improved occupant comfort consideration, and more flexible control of HVAC operating expenditure.

This paper details our work in this area. We first discuss the recent growth in demand management related work, and the implications of this for the HVAC industry. We then detail the technical aspects of our work in this area, discussing CSIRO's technology, and the advanced modelling techniques we are researching for improved HVAC control. Lastly, we consider some results from a recent real-world trial of these types of strategies in a large office building, and discuss the sometimes surprising outcomes resulting from such a trial.

DEMAND MANAGEMENT

Recently, there has been a significant amount of media attention focussing on what is a perceived electricity supply problem in parts of Australia, and indeed many other parts of the world. In short, with aging network infrastructure, a growing peak electricity demand from loads such as air-conditioners, and ever increasing base-load energy consumption, electricity generation and distribution systems are being seen as unable to cope with the demand placed on them. Whilst the traditional solution to such issues has been to build more supply infrastructure, there is an increasing interest in solving these problems from the demand side. For example, consider the peak-load growth issue - addressing this through supply-side augmentation is an incredibly inefficient approach - whilst peak loads can be over double the average base load on a network, they often occur for only a few days per year.

In addition to supply and distribution issues, countries like Australia trade electricity in a relatively volatile energy market, where the price for a unit of electricity can vary from $10 per megawatt-hour, to $10 000 per megawatt-hour, in the space of one day. Such price spikes can represent over 20% of the turnover of our electricity market, but are generally less than 1% of the energy traded.

These relative inefficiencies in our electricity supply systems and economic inelasticities in electricity trading markets can be at least partly addressed by the demand-side solutions embodied in the distributed energy concept- essentially, being selective in when energy is consumed, so as to minimise electricity peaks, and manage financial risks. For the end user, this essentially means that an electricity utility would ask the user to be time-selective in when they consume electricity; assisting the utility in their network operation, and perhaps even helping them deal with unexpected occurrences. Importantly, in using demand-side solutions to address the issues discussed above, we expect the organisations that will benefit most from such solutions (electricity distributors and retailers) to pass such financial benefits on to the end-user.

Considering HVAC systems, demand side benefits are available from more optimal *load* control- fundamentally, in an HVAC system it is possible to reduce electrical consumption by trading off human comfort against the cost of operation of the HVAC plant. Alternatively, it may be possible to simply *shift* electrical consumption, preserving human comfort, by pre-cooling or pre-heating the offices in advance of an electricity price spike, and then allowing the office temperature to drift gradually during a high price period, thereby minimising electricity consumption during expensive periods.

Peak-reducing technologies are not entirely new to HVAC systems. An alternate way to manage peak energy consumption by HVAC plant is to charge ice-tanks in the building during off-peak times, and use the stored thermal energy of these tanks to cool the building during peak times [7]. Whilst effective, these techniques rely on relatively expensive additional plant, and are not well-suited to responding to dynamic, rapidly occurring network contingencies. Existing peak-management techniques that can respond dynamically to changing electricity prices generally rely on a simple load-shed table within a building management system (BMS), and are relatively unsophisticated, removing particular electrical loads once certain thresholds are crossed.

For optimal performance, we believe the HVAC management system should be dynamic and intelligent, responding to changing events, and considering a variety of external factors such as occupancy, human comfort, electricity price, and weather forecast. Further, rather than relying on additional thermal storage plant such as ice-tanks, our system pre-cools or pre-warms a building by taking advantage of the thermal storage inherent to the building fabric itself. Similar attempts to optimise the operating cost of air-conditioning equipment using electricity price signals and the building thermal mass have been attempted previously in at least one other study we are aware of [8]. However, this study used fixed temperature setpoints and the cost function did not consider occupant comfort. Furthermore, it was only possible to minimise either peak loading, electricity cost or electricity consumption but not a weighted combination of these.

An HVAC management system that accounts for all these factors needs to be quite sophisticated- it needs to be able to predict the consequences of a particular action, and decide a long-term HVAC management strategy. Our work in this area is discussed in the following sections.

HVAC PERFORMANCE MODELLING

In evaluating the cost of a particular HVAC control action, it must be determined how many people may be dissatisfied by a particular action, or, how a particular action will affect human comfort. We use the well-cited human comfort metric from Fanger [9] to evaluate how a particular HVAC action will affect human comfort, based on factors such as air temperature, humidity and air velocity.

Clearly, whilst techniques such as Fanger's predict human comfort for various environmental parameters, we need to also obtain a prediction of how these environmental parameters will be affected by a particular HVAC demand management action. Fundamentally, a thermal model of the building is needed. This model should provide some basic time constants of the building- the time to heat up or cool down, with the HVAC plant on or off.

Whilst there is a massive amount of literature available providing thermal modelling techniques for modern office buildings, we have taken a slightly different approach. Wanting our HVAC management technique to be as flexible as possible, we have taken some advanced techniques from the field of *machine learning* to automatically form a basic thermal model of the building, by observing basic building thermal behaviour over time. This field includes the use of techniques such as Neural Networks (NNs) [10] and Support Vector Machines [11], and these have been applied in such diverse fields as renewable power forecasting, financial market prediction, lightning strike forecasting, and fault tolerant robotics.

In this work we have chosen to use Support Vector Machines (SVMs) to learn the features of the thermal model of a room. Essentially, Support Vector Machines can be thought of as a more general version of Artificial Neural Networks. Like Neural Networks, SVMs are a supervised learning technique that can be used for classification or regression. They are "trained" on a particular set of data, this training being the basis for predictions of future data. Ideally these training samples will encompass all possible states of the system, but in reality, this is rarely possible, so the primary aim of supervised learning methods is to build a model that can *generalise* well, that is, it can produce a good model of the system from only a small number of training samples. SVMs take advantage of probability and statistical learning theory to maximise the generalisation ability of their fitted model, and often perform very well with noisy or sparse data sets – an advantage when used for quickly fitting the unfiltered real-time data our system supplies [11].

To simplify the analysis in this early stage of our work here, we have tested the our approach using a cool room, rather than an actual building. This strategy allows us to isolate the thermal behaviour of the room to a relatively small number of inputs and outputs, simplifying the design and analysis of the modelling techniques chosen. The cool room controller system with which our SVM model is used collects several heating/cooling cycles worth of training data, and then fits a model to these samples, essentially finding a characteristic system temperature curve. This model can then be time-stepped into the future, providing accurate temperature predictions of the system.

This behaviour can be seen in figure 1, which shows the training samples, and the predicted and actual temperatures for a period of cool room operation. It is interesting to observe the

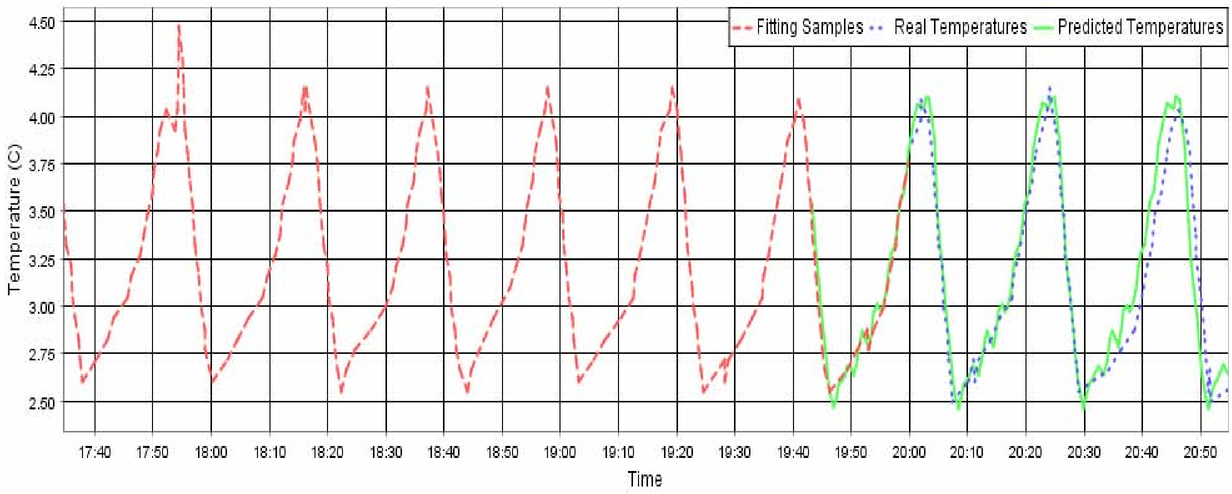

Figure 1: Operation of machine learning technique for cool room thermal model

behaviour of the system at time 17.54, when the cool room door being opened causes a spike in the internal temperature. The learning model was able to identify this sample as having a minor effect, and so the contribution of this training data to the predictive model is minimal. This is a key advantage of SVMs- their ability to intelligently filter outlying data points, and model non-obvious system subtleties like overshoot and leakage which affect the fitting samples.

Whilst these experiments have been run on a relatively simple thermal scenario- the thermal response of a cool room, we believe these results are valid across a variety of scenarios, and are now conducting almost identical modelling experiments in a true office-building setting. We have yet to investigate the performance of the modelling aspects of our work in this office building- the initial aspects of our trial have focussed on the more general impacts demand management approaches such as pre-cooling might have on a building. The results from this trial are very interesting, and sometimes surprising- they are outlined in the following section.

EXPERIMENTAL EXPERIENCES

In order to gain a quantitative assessment of the potential of intelligent demand management techniques, we conducted a variety of demand management experiments on an eleven storey commercial office block in Melbourne, Australia. The experiments were performed during summer 2006/2007 and were specifically designed to assess:

- The effectiveness of a building pre-cool prior to a DSM load shed event; and
- The load reduction, profile and duration achievable using direct adjustment of the building thermostat setpoint.

Experimental Setup

The experimental site is a standard office building comprising eleven floors and a total floor area of around 10555m^2. The HVAC system comprises two chillers (a screw compressor and centripetal compressor with capacities 780 and 600 kW thermal respectively), two boilers (each around 700kW thermal) and eleven air handling units – one on each level. In addition to the main HVAC system, there is a supplementary unit that provides additional cooling on levels 6 and 9 where call centres operate.

For this trial, the demand response was obtained by directly modifying the temperature setpoints of all zones throughout the building. The building automation system was upgraded to allow this to be performed remotely and in response to external stimuli – for example a price peak in the Australian national electricity market. Trials were particularly targeted at hot days (around 35°C) during which times the electricity network is stressed and hence representative of the conditions under which a demand response is typically requested.

In order to allow a full analysis of the building response to the demand reduction trials, additional instrumentation and data logging facilities were added to the building. A full measurement set consisting of:

- all building zone temperatures, around six per level and 68 in total;
- ambient temperature conditions;
- current consumption of each individual chiller;
- current, voltage and power of the total building HVAC system; and
- current, voltage and power of the supplementary systems on level 6 & 9

was recorded every five minutes throughout the summer. This extensive data set has allowed an assessment of both the demand reduction trials and baseline energy consumption as a function of setpoint temperature and ambient conditions.

Experimental Results

A variety of experiments were conducted throughout the trial. Focusing on one particular experiment, which was representative of the others, in figure 2 results can be seen for a 'load reduction with pre-cool' experiment. The figure shows the building setpoint temperature, two zone temperatures and the total HVAC power consumption. This experiment was conducted on Jan 3rd, 2007, which had a peak ambient temperature of 32.8°C and consisted of:

- Starting the HVAC system at 8am with a 22.5°C setpoint (this is normal);
- 2 hour building pre-cool from 11:45am to 1:45pm with 21°C setpoint;
- 2.5hr demand reduction event from 1:45pm to 4:15pm with 24°C setpoint; and
- Reverting to the normal 22.5°C setpoint until the system shut down at 6pm.

In this case, there was a peak load reduction of 35%, and average load reduction of 15%, and a total energy saving of 127kWh.

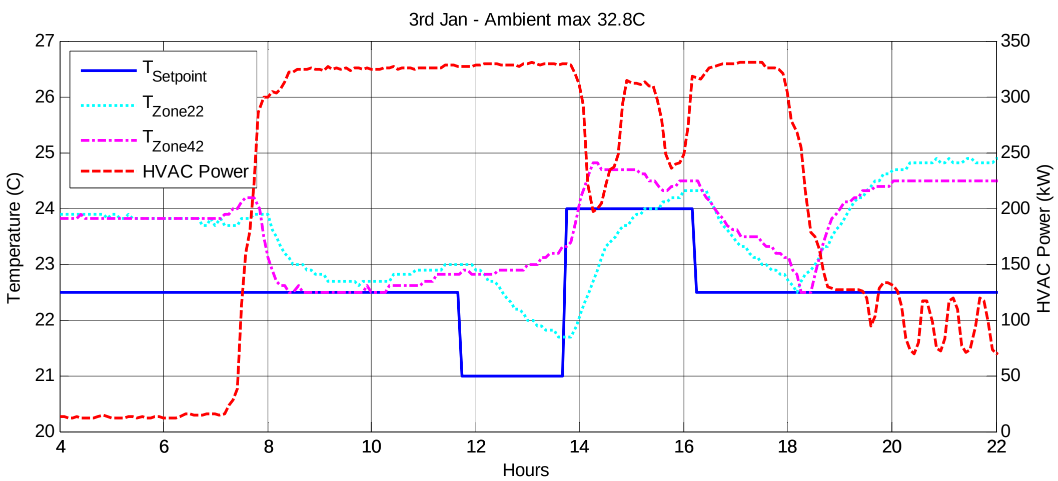

Figure 2: Typical results for a demand response load reduction with pre-cool.

A key observation from these results is that the pre-cool is ineffective when the chillers are already running at full capacity prior to the pre-cool - as is likely to often occur on hot days when load reductions are required. In this case, the pre-cool only serves to redistribute the cooling between zones, providing additional cooling to some, while consequently taking it away from others and resulting in some zone temperature *increases*. This effect can be seen with the two zone temperatures (T_{Zone22} and T_{Zone42}) in figure 2. Clearly, any "intelligent" HVAC management system will need to take into account such behaviours, providing the mechanism for an effective pre-cool that is unachievable with the simple setpoint adjustment used in this experiment.

Other results learnt from this deployment include:

- Following a setpoint change, there is a significant time delay before there is an appreciable change in the building energy consumption. Since the chiller is controlled to maintain a chilled water setpoint, a power reduction does not occur until the zone temperature setpoint change causes the chilled water temperature to drop. In the case of a constrained system, the chilled water temperature can be operating significantly above setpoint and in the case shown in figure 2, it took around 30 minutes from zone setpoint change to peak power reduction.
- It is imperative that a building control scheme is tolerant to fault in sensors/remote units. During the trial, there were typically 5% of sensors providing erroneous data, rising to 10% at times.
- Building power consumption can not be adequately assessed based on aggregate temperature data – it is important that data be intelligently integrated in order to successfully predict behaviour. As an example, in figure 2, the chillers start to pick up load at around 2:30pm specifically to meet the cooling demands of the zones whose temperatures increased during the pre-cool. This behaviour could not have been predicted based on aggregate temperature data.

CONCLUSION

Electricity industries around the world are undergoing significant changes that will have equally significant effects on the end user. In particular, the growing number of demand management initiatives will be of great interest to the owners and operators of large HVAC plant- such initiatives will have important technical *and* financial implications.

Realising this, CSIRO has initiated a significant research programme into intelligent HVAC control systems. Importantly, whilst striving to improve the operation of the HVAC system operating in isolation, we are also designing our strategies to be able to include consideration of the world around them, and thereby participate in demand management programmes.

Our first steps in this area focus on being able to model the thermal performance of a building, and thereby predict the affect of demand management actions on the building and its occupants. Such a prediction is critically important, to enable an HVAC operator to determine the cost and the benefits of a particular operation strategy. Our work in this area differs from traditional modelling techniques, in that we are investigating the performance from so-called "black box" machine learning systems, to form a suitably accurate model of the building, but in a relatively simple, automatic, and financially economical manner.

Whilst the basic principles behind demand management in an HVAC system appear relatively simple- vary the environmental setpoint strategy to change a building's energy consumption, the real-world consequences of such a strategy can be somewhat surprising. The latter part of this paper investigated the real-world consequences of a demand management programme based on peak shifting in a typical office building. Some of the observations made in this trial, such as the varying effects of a changing setpoint on certain zones of a building, were not expected, and need to be kept in mind for any demand management programme under consideration.

Our work in this area is continuing- we continue to enhance our HVAC modelling work, we are experimenting with new hardware platforms for increased granularity data gathering in an HVAC deployment, and we are working on HVAC management strategies that take advantage of this new data. Lastly, we are also looking at the benefits possible through integrating an HVAC system with other loads and generators on site- effectively obtaining a site-wide energy response that can then interact with the demand management programmes mentioned in this paper.

ACKNOWLEDGEMENT

We gratefully acknowledge everyone in CSIRO’s Distributed Energy Management and Control Project’s development and deployment teams, who made a valuable contribution to our work. This project is funded by CSIRO’s Energy Transformed National Research Flagship.

Impact of automation concepts for better performance and monitoring of sustainable energy systems

Alexander Adlhoch, Martin Becker, Roland Koenigsdorff and Hermann Scherer

Biberach University of Applied Sciences, Germany

Corresponding email: becker@fh-biberach.de

SUMMARY

The integration of sustainable energy systems (e.g. earth-to-air heat exchanger (EAHX), solar air collector (SAC) into conventional energy systems is of increasing interest. When more than one of these systems are used simultaneously (e.g. an EAHX and an air handling unit (AHU) with heat recovery) improved automation concepts can help to use environmental energy more efficiently. Consequently, there is also a need of using simulation models not only for building design but also for energy optimisation and management during building operation.

At Biberach University of Applied Sciences a classroom and laboratory building is equipped with different energy systems like an air-handling unit with heat recovery that provides one classroom as a test room. For research and development issues, the external air can be taken directly from the outside or can be preconditioned using an EAHX or a SAC panel. The air can then supply the test room with or without being additionally conditioned by recovering heat from the exhaust air within the air handling unit's cross flow air-to-air heat exchanger. Finally, there is a water-to-air heat exchanger for heating or cooling the air when required.

An advanced automation system controls these facilities with respect to energy efficient operation by taking into account actual weather data or weather forecasting data. The control algorithm applied uses characteristic diagrams which consider energy gains of the EAHX (depending on earth and outside temperature and air mass flow), energy gains of the solar air collector (depending on outside temperature, solar radiation and air mass flow) and fan energy demands (depending on used system and air flow rate).

In a first step the characteristic diagrams were generated by applying simulation models of every energy system to the whole range of relevant conditions. In a next step the diagrams will be adjusted with measured and monitored data, which were collected and achieved during past system operation.

In this paper the corresponding model of an EAHX system is described as an example, and a comparison of simulated and experimentally gained results is discussed.

The impact of improved automation concepts based on such simulation models and measured data during building operation is also described.

INTRODUCTION

The aim of this study is the development of an advanced automation concept for an energy optimised supply of a room with conditioned ambient air by selecting between three options of air preconditioning. These options are: using unconditioned ambient air, preheating of the external air using a solar air collector (SAC), and preheating or precooling the external air using an earth-to-air heat exchanger (EAHX).

At the Biberach University of Applied Sciences a new classroom and laboratory building – “Technikum G” – was built. The building itself serves as a “laboratory-in-a-building” containing a variety of novel facility systems for testing and research purposes. One of these systems is an air handling unit, (Fig. 1), that includes the above-named options for receiving outside air. A detailed description of the building, its energy system and equipment can be found in 1, 2 and 3.

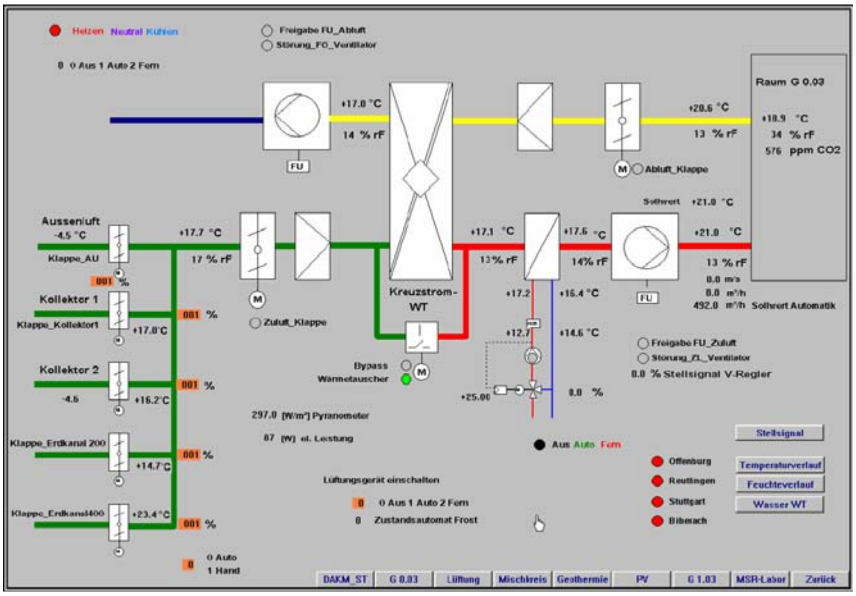

Figure 1. Visualisation of the air handling unit (AHU) of “Technikum G”.

A development environment was built up, using “Technikum-G” as a test facility for validating simulation models, as well as part of this environment. Based on this development environment new control strategies can be developed and tested. There are two possibilities to realise such a control strategy. On the one hand, the decision which air supply is used can be found in an online-simulation, calculating the most energy-efficient way. On the other hand the energy efficiency of each method (by given boundary conditions) can be taken from previous created characteristic diagrams. This paper refers to the latter possibility.

METHODS

To develop and validate overall control strategies for building automation and management an open and flexible development environment is needed. The approach here is to set up this development environment in three levels (Fig.2):

a) **Process with basic control strategies:** the process is represented by the air handling unit (AHU) and the test room G0.03 with standard controllers (e.g. PI controller)
b) **Overall control strategies:** the overall building management system, including the possibility of implementing adaption and optimisation strategies using the development level
c) **Development:** a collection of simulation models and tools to emulate and monitor the real process

All this parts are designed and implemented in a flexible development environment at Biberach University of Applied Sciences. Each level can be coupled to or decoupled from each other level. All parts are in a temporary or permanent data exchange process (offline/online).

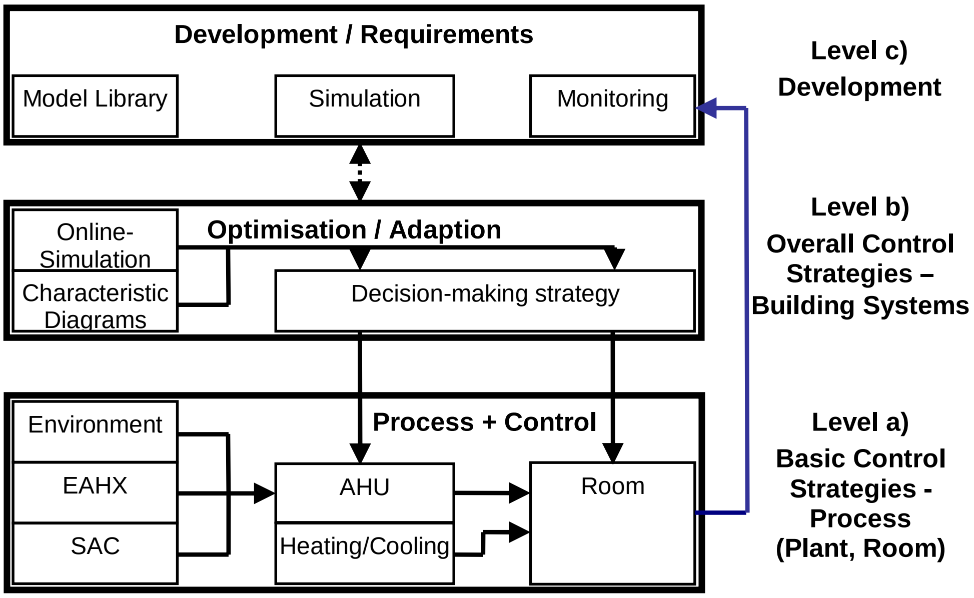

Figure 2. Development environment in three levels.

New overall control algorithms are developed in the overall control strategy level b) in connection with the development level c).
In this context simulation can play different roles:

First, simulation can be used for direct online simulation. In this case simulation runs online parallel to the real process. As a result of the online simulation the decision-making strategy optimises e.g. control parameters of a basic controller (e.g. PI-controller). Therefore a permanent monitoring of the process (plant, room) is necessary.
Second, simulation can be used for building up characteristic diagrams offline. With the help of this characteristic diagrams it is possible to adapt or optimise the basic control strategies in level a) online during operation.
Third, simulation models can be used during design to simulate the process of itself to design and test advanced control strategies in a simulation environment.

Example for Simulation Environment of Process and Overall Control Strategy

Fig. 3 shows an example of implementing level a) and b). In this example the task was to design and implement a damper controller to decide, based on energy criteria, whether to activate the dampers for using direct ambient air, the solar air collector (SAC) or the earth-to-air heat exchanger (EAHX) for preheating or precooling air for the air handling unit (AHU), based on the actual weather data (temperature, solar radiation).
As mentioned before there are two possibilities to realise the control strategy: First, the decision which air supply is used can be found by calculating the most energy-efficient way in an online-simulation. Second, the decision for the most energy efficient condition can be taken from previous generated characteristic diagrams. This paper describes a decision maker based on characteristic diagrams generated by offline simulation of the different sub-systems. This will be discussed later.
To develop an energy management strategy for an energy optimised supply with ambient air, simulation models of the process were built up which includes also all parts oft the air-handling-unit and the classroom G 0.03. In this application the simulation models are used as simulation environment of the process instead of the real process of itself.

Advantage of this approach is the possibility to simulate all interesting scenarios in a short time and under repeatable conditions. However a lower accuracy has to be accepted, as the process can be represented only in a less exact way. Therefore a deviation to measured data exists.

In further work the simulation model will be replaced by the real process and the energy management (as software) controls the dampers and the AHU in "Technikum G". Also the data of the characteristic diagrams – up to now gained by simulation – can be replaced by measured data.

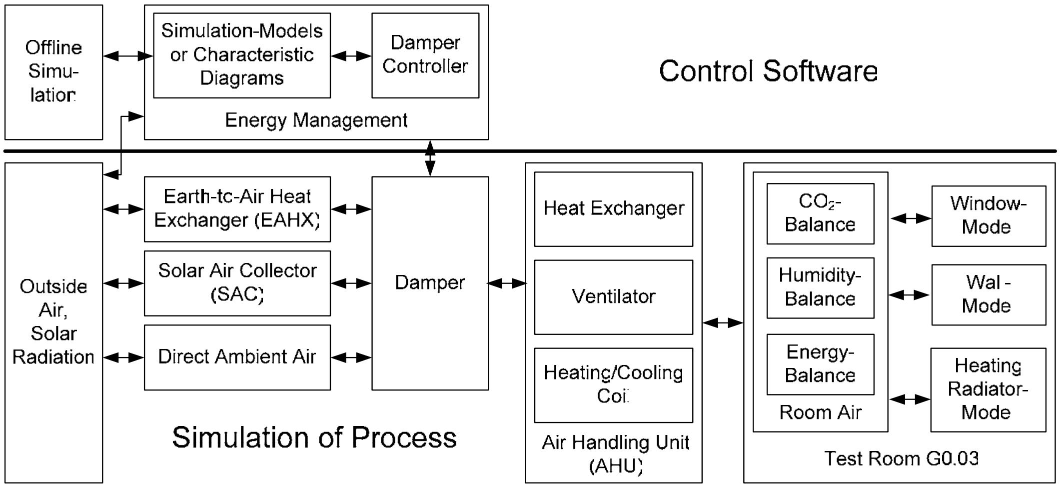

Figure 3. Simulation environment for damper controller development.

The simulation models of the process differ in level of detail. Room, solar air collector and earth-to-air heat exchanger are modelled with detailed physical properties. Heat exchanger, heating/cooling coil and fan of the air handling unit are represented by simple mathematical correlations. If necessary these sub-models will be developed in further work in more detail.

In the following, the sub-system earth-to-air heat exchanger will be discussed in more detail. A description of build-up and evaluation of the solar air collector model can be found in 2, the room model is discussed in 3.

RESULTS OF EARTH-TO-AIR HEAT EXCHANGER (EAHX) MODELLING

Based on preliminary investigations and testing of alternative modelling approaches, the following model of the EAHX was developed and implemented into the development environment (see Fig. 4):
The resistance-capacity model consists of a single air temperature node and several soil temperature nodes arranged along the radial direction from the heat exchanger pipe's centre. Each soil node represents a concentric cylindrical soil layer with a capacity according to the thermal mass of the corresponding soil volume. Heat exchange between adjacent soil nodes takes place by conduction with the innermost node taking part in the heat transfer through the pipe wall to the air. The outer boundary of the system is the undisturbed ground temperature. The air node represents the logarithmic average air temperature within the EAHX pipe. Compared to the soil, the thermal capacity of the air inside the pipe is negligible. Therefore, its temperature is calculated from a steady state energy balance including air flow through the pipe and heat transfer to the pipe wall.

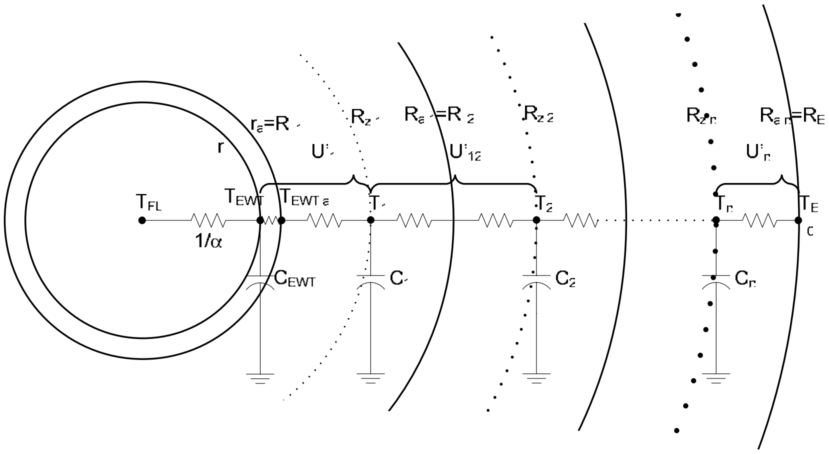

Figure 4. Resistance-capacity model of air-to-earth heat exchanger (EAHX).

During the test of the EAHX model simulations with different parameters were conducted. The results are compared to measured data of the existing EAHX at Biberach University of Applied Sciences. Tab. 1 displays the different parameters used.

Table 1. Different parameters for EAHX simulations.

	Film Coefficient (Air to Pipe)	Consistence of Earth
Test 1	2.90 W/m²K	massive, wet
Test 2	20.0 W/m²K	massive, wet
Test 3	2.90 W/m²K	light, wet

The simulated air outlet temperatures differ about 2 – 4 K from the measured temperatures (Fig. 5). The reason for this deviation is not solely due to the simulation model and its parameter values, but results also from the position of the air outlet temperature sensor which had to be placed within the building at a certain distance from the EAHX outlet.

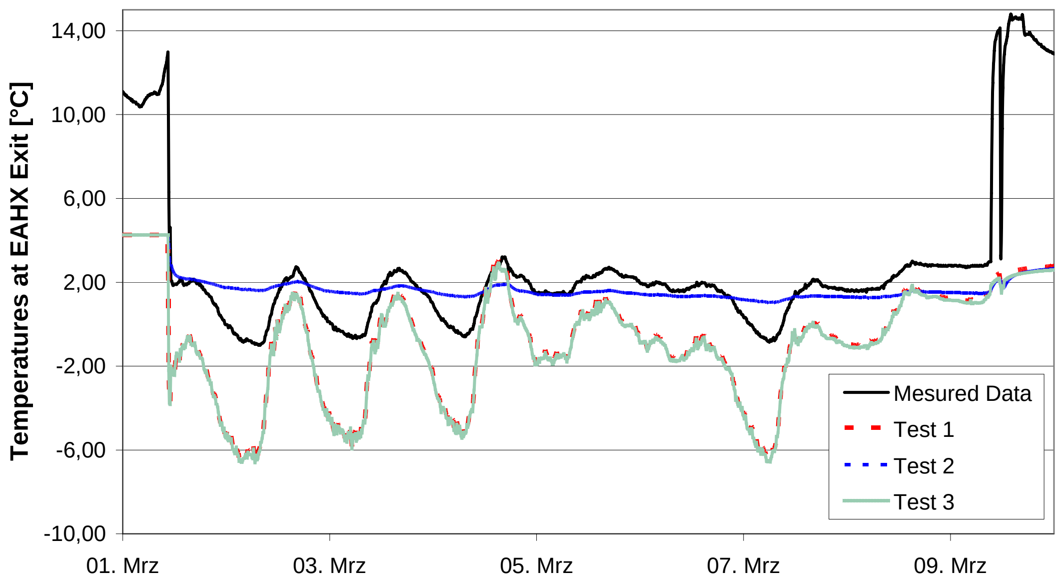

Figure 5. Results of EAHX test simulations and comparison with measurements.

The dynamic behaviour of the EAHX is well reproduced by a chosen film coefficient (air to shell) of 3.5 W/m²K. This value accords to calculations with standard heat transfer coefficient correlations for this particular air flow rate and design. Regarding the aim of developing a control strategy the simulation results are sufficient. Since a control strategy must be able to work properly even when the controlled system deviates from its design point to a certain extend, a moderately inaccurate simulation model is still applicable for testing control strategies.

RESULTS AND DISCUSSION OF THE ENERGY OPTIMISED STRATEGY

To test the abilities of the simulation model as development environment, an energy management strategy including a damper controller was developed. This strategy allows an energy optimised ambient air supply to the AHU by selecting between three options of air preconditioning.
To control the damper the decision criterion is the way to precondition external air with lowest energy consumption. As described before, there are two possibilities to realise the control strategy. The decision which air supply is used can be found by an online-simulation or by using characteristic diagrams. The implemented decision maker (Fig. 6) is composed of the following elementary parts: the characteristic diagrams and the damper controller as a rule based controller, which can be extended by additional features (e.g. weather forecasting, levels of occupancy) in future.

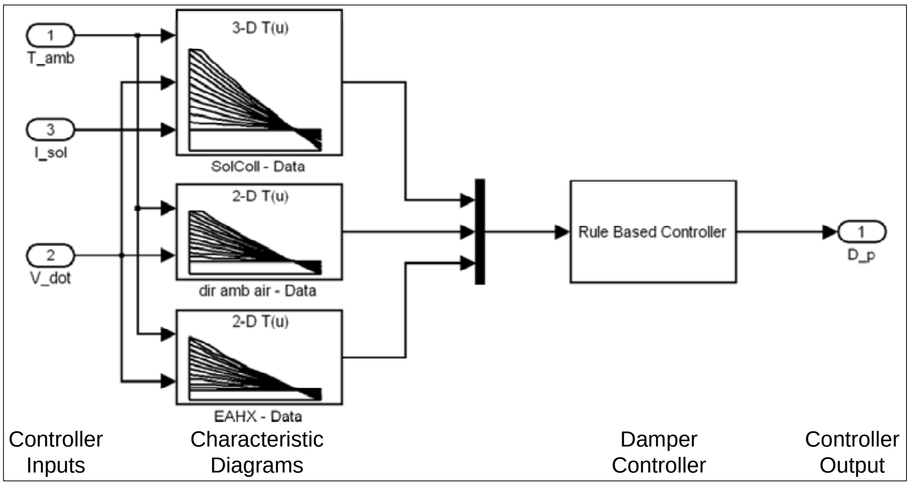

Figure 6. Layout of the energy management block including a damper controller as a rule based controller. (T_amb: ambient temperature, I_sol: incident solar radiation, V_dot: air flow rate, D_p: damper position)

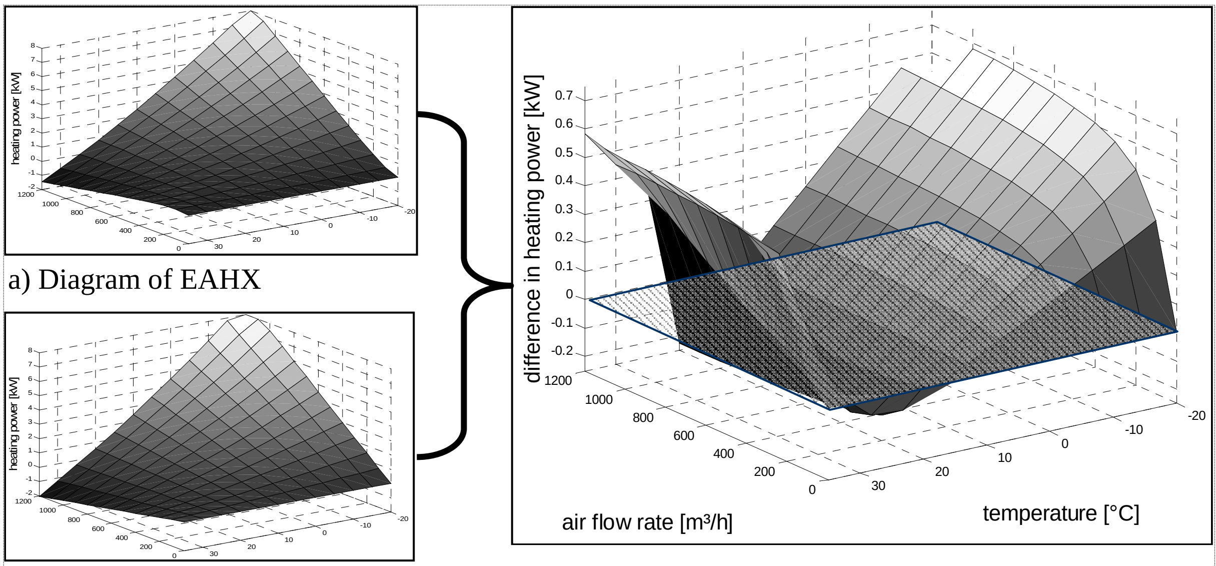
In a first step the characteristic diagrams used within the control system are created by simulation results.
Relation criterion is the heating/cooling demand of the heating/cooling coil to transform the preconditioned air to a supply air of 22°C.
This data were generated as characteristic diagrams for boundary conditions of ambient air from -20 to 35°C (step size 5 K) and air flow rate from 0 to 1200 m^3/h (step size 100 m^3/h) for direct ambient air and EAHX. For the SAC exits a matrix for each of the incident solar radiations on surface (0, 200, 400, 600, 800,1000 W/m^2). Interim values are interpolated during control process.

In Fig. 7 the characteristic diagrams of EAHX (a) and direct ambient air (b) are shown. Also the difference of this values as generated by the decision maker is demonstrated. As result positive values indicate a better efficiency of the EAHX, negative values for direct outside air suction (c).



a) Diagram of EAHX

b) Diagram of direct ambient air

c) Difference of EAHX and direct ambient air

Figure 7. Examples of characteristic diagrams.

The damper controller was also tested within the simulation environment instead of the real process. For first examination this approach is faster than testing the controller directly on the plant. Object of interest is the heating/cooling demand of the heating/cooling coil to transform the preconditioned air to a supply air of 22°C. This is recorded for four cases: uncontrolled air preconditioning using the SAC (1), the EAHX (2) or direct ambient air (3) and controlled air preconditioning using energy management strategy (4). All these tests are simulated with Biberach weather data (first 6 month of 2005, hourly values) and a permanent air flow rate of 500 m³/h.

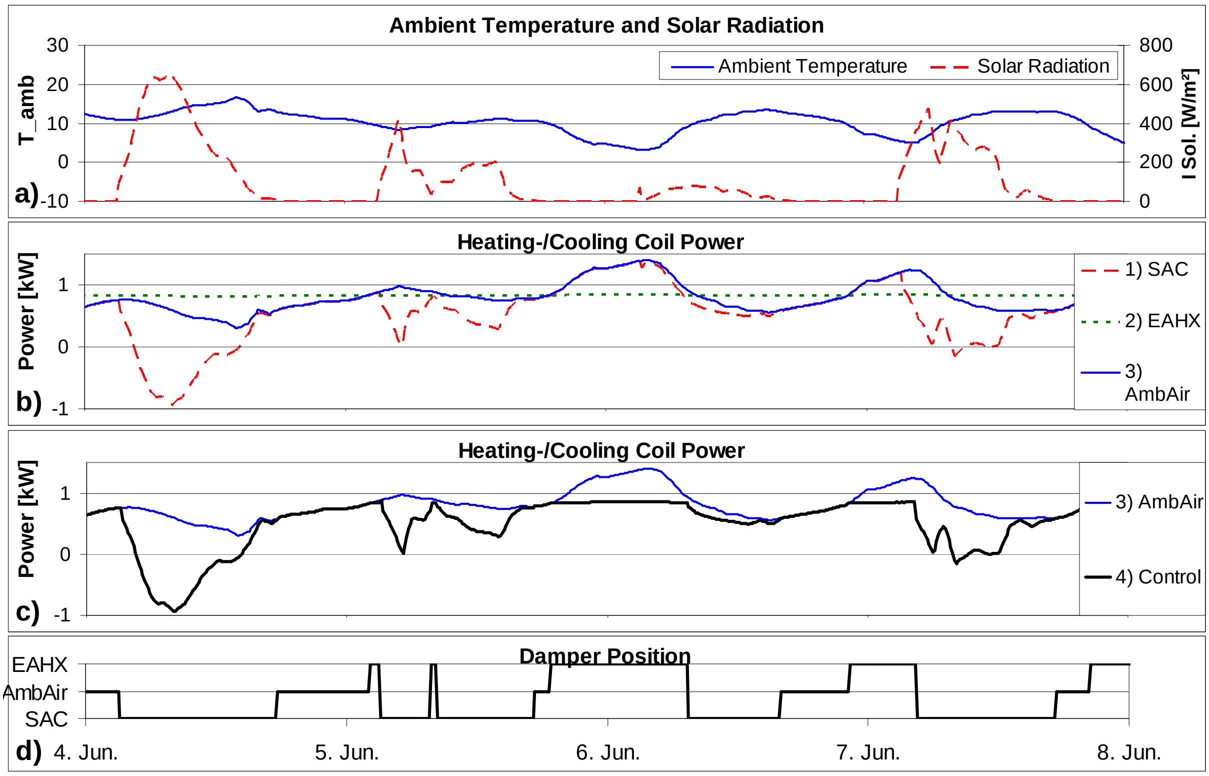


Figure 8. Simulation results without and with energy management strategy.

Fig. 8 shows the simulation results from 4th to 8th June for instance. In Fig. 8a) the boundary conditions measured ambient air temperature and incident solar radiation on SAC surface are given. Fig. 8b) indicates the heating/cooling coil power (negative values means cooling power) for the uncontrolled ventilation strategies. Fig. 8c) shows the heating/cooling coil power of the controlled ventilation strategy and of direct ambient air ventilation in comparison. The corresponding damper positions are shown in Fig. 8d).
The damper controller selects the way of air preconditioning with the lowest energy consumption.

Table 2. Energy demand at heating/cooling coil by different ways of air preconditioning.

	Simulation	Heating [kWh]	Cooling [kWh]	Sum [kWh]
(1)	Solar Air Collector (SAC)	3942	574	4516
(2)	Earth-to-Air Heat Exchanger (EAHX)	3697	0	3697
(3)	Only Ambient Air (AmbAir)	4729	103	4832
(4)	With Energy Management	2423	404	2837

Tab. 2 shows the energy consumption of the heating/cooling coil for the first six month for all the uncontrolled and the controlled air preconditioning. In this example the overall energy consumption of the controlled ventilation strategy is the lowest. However cooling energy demand is higher than in some other cases. This is caused by the fact that in some cases the power demand for cooling is lower than that of heating. In this first approach it is only possible to switch between the three sources. Of course in the real plant the preconditioned air can be mixed. In further work the control strategy has to be enhanced in a way taking into account the possibility of mixed air and will be implemented in the existing plant for test and measurement purposes.

Improving the Possibilities to Monitor Energy Consumption at Home

Sami Karjalainen and Kalevi Piira

VTT, Finland

Corresponding email: Sami.karjalainen@vtt.fi

SUMMARY

Inhabitants have low possibilities to monitor their energy and water consumption. The energy and water meters are typically read only once a year in Finland. The monthly bills are based on estimated consumption, i.e. the consumption of the previous year. A quantitative interview survey with a sample size of 3,094 people was performed to study attitudes and opinions about energy conservation and energy monitoring. The results show that 63% of the Finns think that it is very important or important to improve the possibilities to monitor energy consumption at home. A new prototype for monitoring energy consumption was developed at VTT. It gives occupants real time feedback on their energy consumption and the costs. In addition to the total consumption and costs, the prototype is able to present electricity consumption and costs of each device. The target is to create a system that gives occupants relevant information in a way that is easy to understand. The system is installed in two experimental houses.

INTRODUCTION

Inhabitants have low possibilities to monitor their energy and water consumption. In Finland, the monthly bills are based on estimated consumption, i.e. the consumption of the previous year, because the energy and water meters are typically read only once a year. This means that a household receives an additional bill or is paid after the meters are read. Some households may then get a bad surprise: a newspaper article [1] told about a family that received an additional 1800 € water bill.

Manual reading of energy meters will be replaced with remote reading in future. In Sweden, a new law demand monthly reading of energy meters from 1st of July 2009. Also in Finland and other countries, remote reading of energy and water meters is becoming more and more common. At first, remote reading becomes common in densely populated areas and apartment buildings. Remote reading will make at least some improvement in our possibilities to monitor consumptions.

The aims of our work are to study attitudes and opinions of Finns about household energy conservation and energy monitoring, and to develop a new prototype for monitoring energy consumption.

METHODS

Attitudes and opinions of inhabitants about energy conservation and energy monitoring were studied by a quantitative interview survey with a nationally representative sample. The target group of the study was the population of Finland. The interviews for the survey were carried out by telephone (computer assisted telephone interview, CATI). A random sample of the Finnish population aged between 15 and 74 was selected with quotas set according to gender, age and province. The total number of respondents was 3,094. A well-known Finnish data collection agency (Taloustutkimus Oy) was responsible for the practical realisation of the telephone interviews according to its quality system. The interviews were performed in November and December 2004.

In addition to the quantitative interview survey performed, a new prototype for monitoring energy consumption was developed in this work.

RESULTS OF THE INTERVIEW SURVEY

The results of the interview survey are presented in Figs 1-4. Fig. 1 shows that people think that it is important to save energy at home. 82% of the respondents think it is very important (5) or important (4) to save energy at home. Own strive to save energy is, however, somewhat lower (Fig. 2).

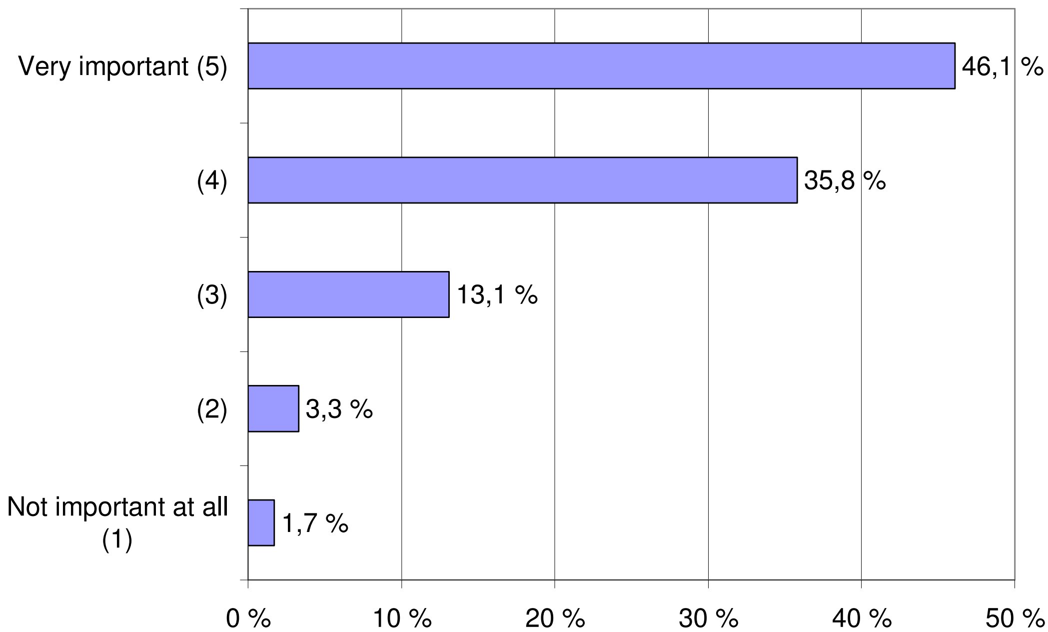

Figure 1. Importance to save energy at home (N=3075, mean: 4.2).

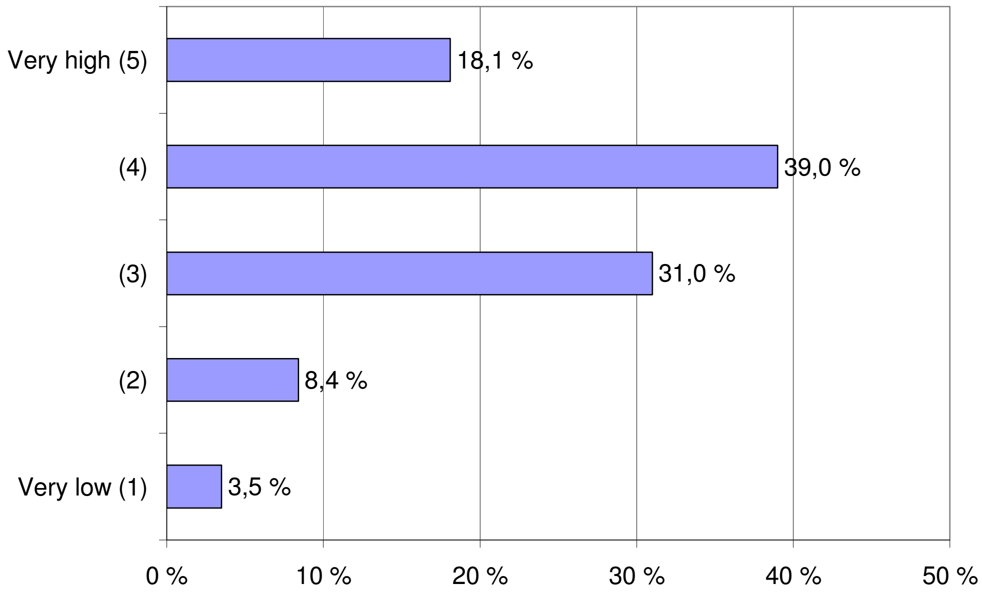

Figure 2. Own strive to save energy at home (N=3067, mean: 3.6).

People think their own actions have an influence on energy consumption (Fig. 3). Mean value is 4.0 in a scale from 1 to 5 (1, very low, … 5, very high).

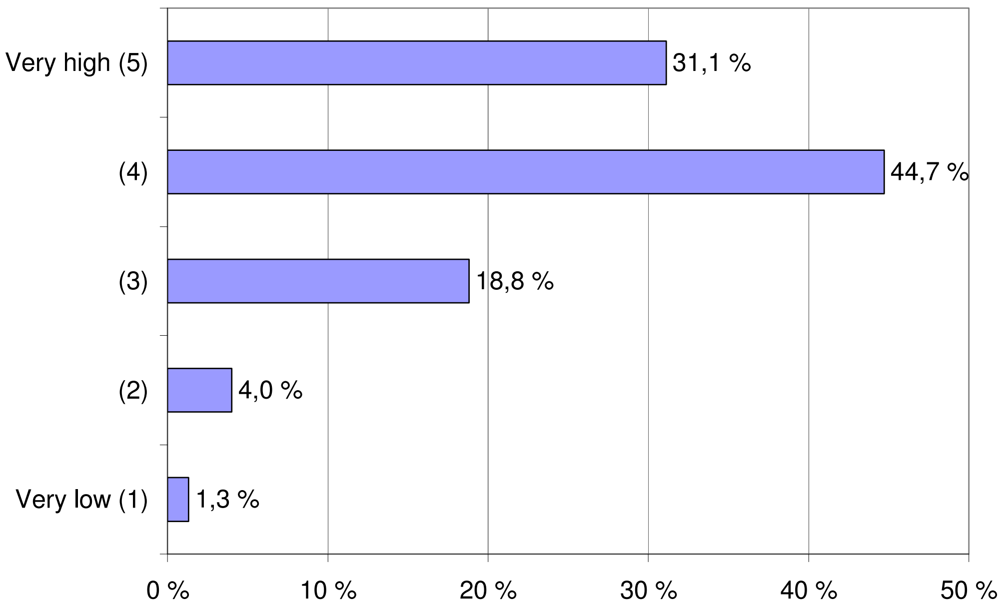

Figure 3. Idea of inhabitants' influence on energy consumption at home (N=3015, mean: 4.0).

Fig. 4 shows that 63% of the Finns think that it is very important (5) or important (4) to improve the possibilities to monitor energy consumption at home. Only 6% think that it is not important at all.

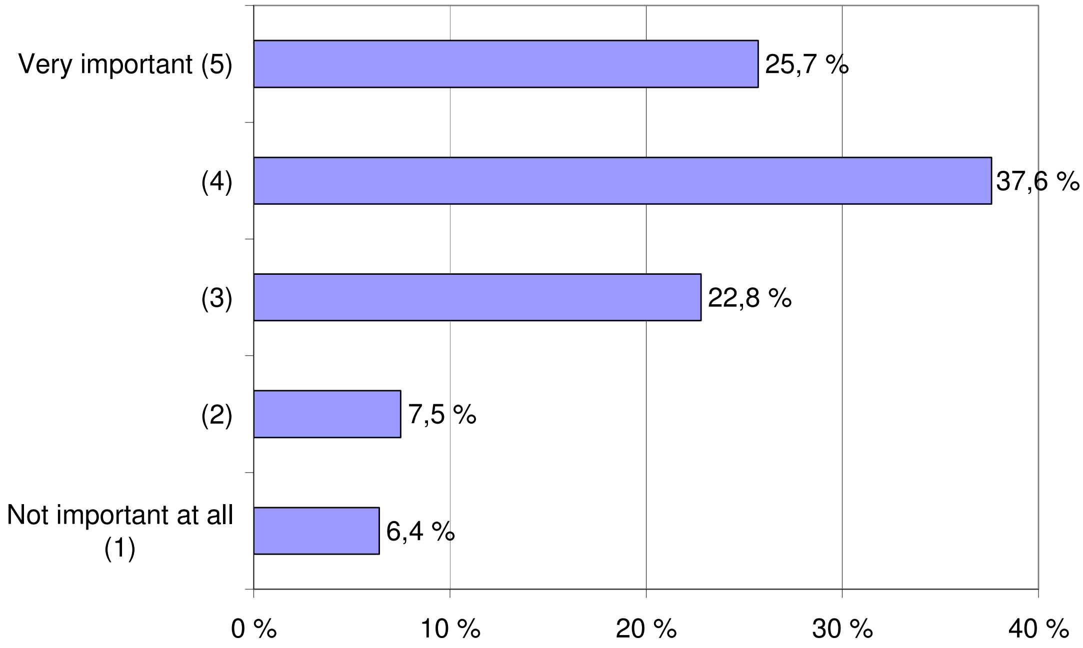

Figure 4. Importance to improve the possibilities to monitor energy consumption at home (N=3008, mean: 3.7).

PROTOTYPE

The results of the interview survey show that it is important to improve the possibilities to monitor energy consumption. A new prototype for monitoring energy consumption was developed in this work. The prototype gives occupants real time feedback on their energy consumption and the costs. In addition to the total consumption and costs, the prototype is able to present electricity consumption and costs of each device. The target is to create a system that gives occupants relevant information in a way that is easy to understand. Main components of the prototype are presented in Fig. 5 and the user interface of the prototype is presented in Fig. 6.

In the prototype two LonWorks technology based electricity meters were connected to a computer that works as a home server. The measured values were true RMS power, reactive power, power factor, true RMS energy, reactive energy, AC frequency, peak demand and computed values of RMS voltage and current. These values were saved in a database (home service book) once a minute.

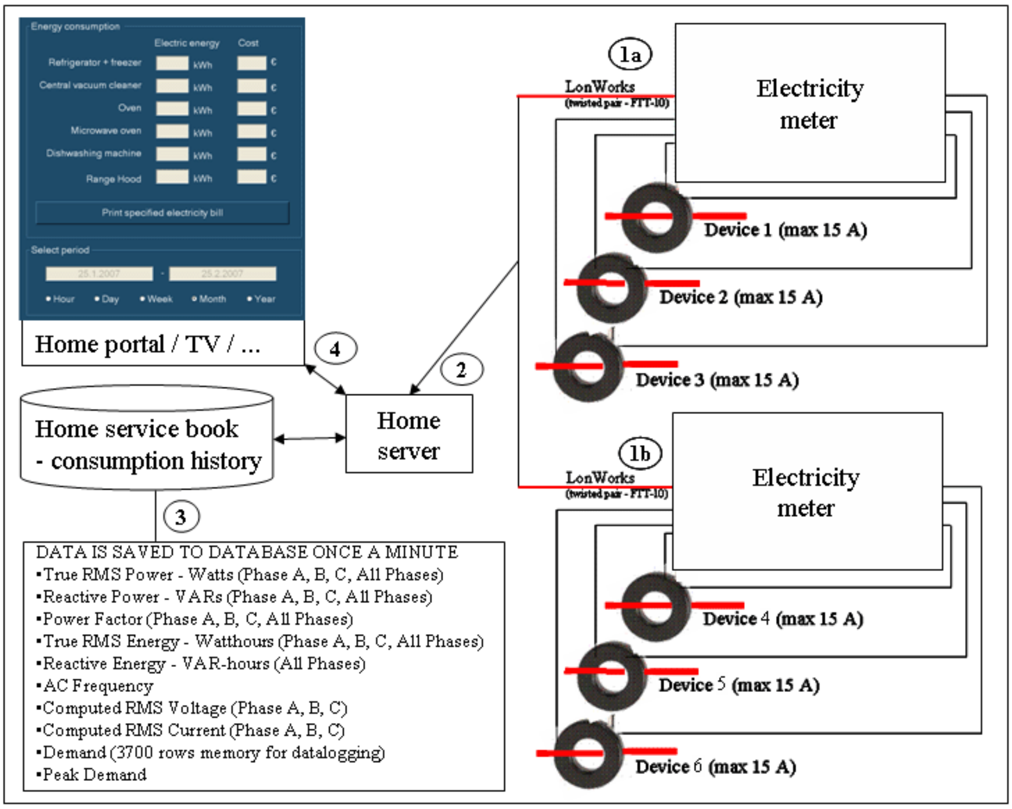

Figure 5. Main components of the prototype for monitoring energy consumption at home.

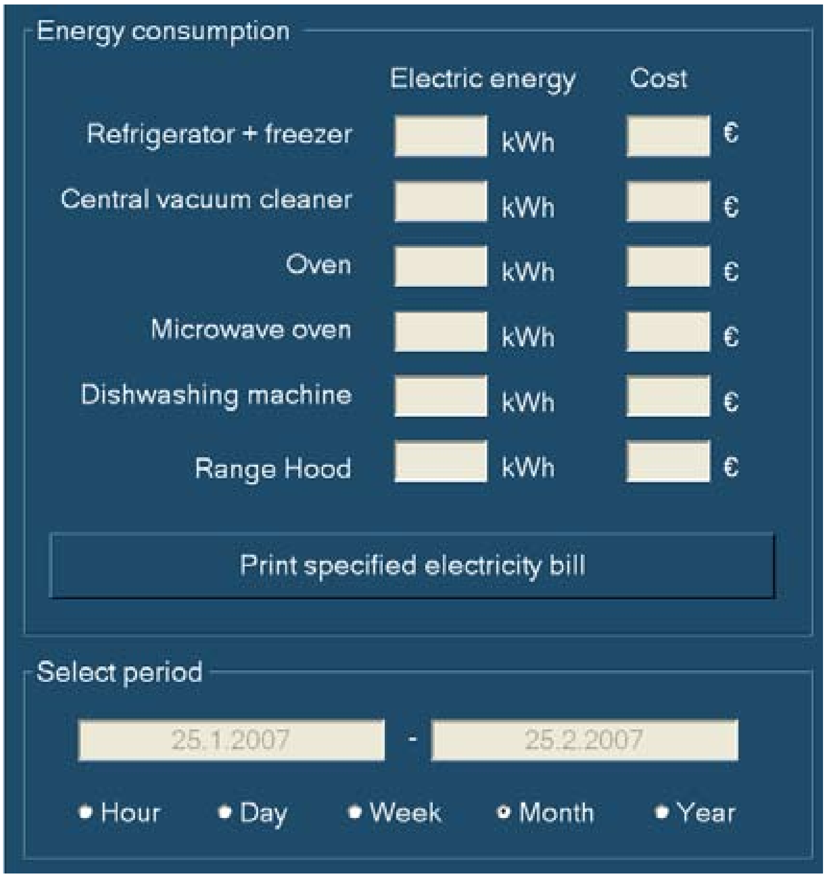

Figure 6. User interface of the prototype for monitoring energy consumption at home.

The user interface in Fig. 6 presents electricity consumptions of kitchen equipment and vacuum cleaner. Depending on the case, it would be very valuable to include also lighting, heating and air conditioning etc.

The prototype system is installed in two houses in Finland, in VTT's experimental low energy house Metop in Espoo and in Work Efficiency Institute's (TTS) experimental house in Nurmijärvi. A study of usefulness of the prototype was performed in Work Efficiency Institute's experimental house with twelve test persons. The participants were between 29 and 84 years old. The test persons think that electricity monitoring system is necessary in future, for example, in the case of selling the house. The user interface of the prototype was found to be clear, and it was easy to monitor electricity consumptions of domestic appliances. The test persons believe that this could affect their use of electricity. A forthcoming publication will present the results of the tests in more detail.

Next the consumption monitoring system will be improved with several new features. The main improvement concerns non-intrusive appliance load monitoring (NIALM) [2-5].

DISCUSSION

Public discussion on climate change and global warming has been very active in Finland in this year and in the end of the previous year. The interviews were performed before that. It is probable that people are currently even more interested in saving energy and monitoring energy consumption.

A review [6] of intervention studies shows that giving people information does not necessarily lead to behavioural changes or energy saving. Instead, according to the review, feedback appears to be an effective strategy for reducing energy consumption. The more frequent the feedback is, the more effective it is. For example, continuous display of electricity consumption was associated with an average saving of 12% in USA [7]. In another study [8], the effects of daily and monthly feedback on gas consumption were compared. It was found that those who received monthly feedback saved less that those who received daily feedback (7.7% vs. 12.3%).

The prototype developed in this work targets energy saving by means of feedback, i.e. by continuously informing how much energy each device consumes and what does that cost. There is clearly a potential to save energy with the system. In this phase, not enough evidence is, however, available, because the system is not installed to any real household yet.

Development environment for model and automation based building management

Martin Becker, Alexander Adlhoch and Hermann Scherer

Biberach University of Applied Sciences, Germany

Corresponding email: becker@fh-biberach.de

SUMMARY

The aim of sustainable building operation and management can be approached considering criteria such as minimized CO_2 emission or reduced energy costs. To consider these points, while also taking into account aspects such as well indoor air quality, improved control and automation strategies are required. One approach is to design decision-making strategies (e.g. for improved energy performance) calculated by an overall building management system that is based on simulation results and which e.g. sets optimised parameters for the local controllers of an energy subsystem for heating, ventilation or cooling.

To design, test and validate new or improved decision-making strategies for a building management system a flexible and open development environment is needed. "Development environment" in this context refers to a collection of simulation models and simulation programs which represent the building and the most important parts of the energy systems within the building, including building control and automation systems. At the Biberach University of Applied Science several building simulation programs (e.g. TRNSYS) and control simulation tools (e.g. Matlab/Simulink, LabView) are connected together in an open development environment.

During the design phase of a building this development environment can be used to simulate all energy subsystems including building control and automation systems. During building operation the development environment can also be used as part of a model and automation based building management system with the aim of optimised control and energy performance.

To test and validate the development environment experimentally a test facility has been set up with different energy systems such as a solar air collector and an air handling unit with a cross-flow heat exchanger. These energy systems supply a classroom which can be used as an experimental test room equipped with different sensors and actuators and a freely programmable room controller.

In the paper the structure of the development environment is described and some examples are presented to show the benefits of model and automation based management systems. The room model and some simulations results are described. Finally the benefits to energy reduction of a CO_2 demand-controlled strategy (DCV) are presented and compared to fixed air change ventilation strategies.

INTRODUCTION

At the Biberach University of Applied Sciences a new classroom and laboratory building was built in conjunction with the new program “Gebäudetechnik / Gebäudeklimatik” (building services engineering / architectural engineering). The building of itself serves as a “laboratory-in-a-building” containing a variety of novel building systems for testing and research purposes. For this reason, the building is named “Technikum G.”, see Fig. 1. A detailed description of the building, its energy systems and equipment, as well as details of the facility can be found in [1] and [2].
In the work described here, an air handling unit (AHU, Fig. 3) together with the classroom G0.03 (Fig.2) as a flexible test room serves for testing of simulation-based building control strategies. The fans of the AHU are equipped with variable frequency drives and dampers are equipped with electric actuators. Ventilation air can be introduced either directly or in a preconditioned fashion by preheating of outside air using a solar air collector, or by preheating or precooling outside air using an earth-to-air heat exchanger, Fig.. 4.

Figure 1. View of “Technikum G”.

Figure 2. Classroom G0.0 3 as test room.

Figure 3. Air Handling Unit (AHU).

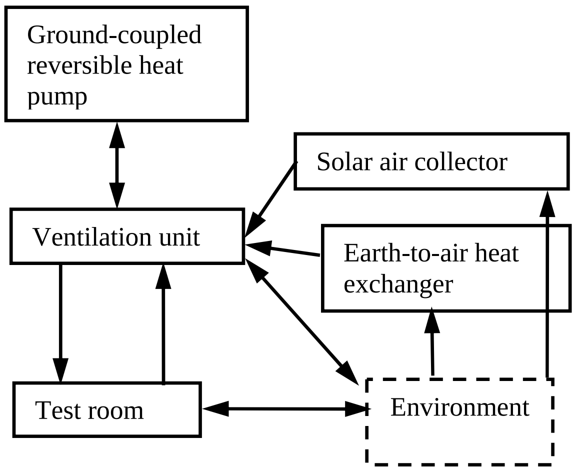

Figure 4. Overview of the test environment [1].

The classroom G0.03 is equipped with a wide range of sensors for measuring temperature, relative humidity, indoor air quality (CO_2, VOC), illuminance, occupancy, and window contacts [1, 2]. Moreover, numerous actuators are provided including ballasts for lamps, dampers for the supply air and a zone valve for heating. All sensors and actuators are connected to a room controller (PLC, programmable logic controller), which is directly connected to the overall building automation system via an Ethernet TCP/IP connection. More than 90 data points in the building are visualized and continuously monitored by the overall building automation system.

MODELING RESULTS

Work has been done and is still in progress to model and simulate all experimental systems in the flexible simulation environment. The approach chosen is to model all components of the air ventilation system, the test room and its facilities including the sensors and actuators. For the purpose of investigating and comparing improved control and automation concepts, there is a high demand for appropriate simulations models.
For maximum flexibility, an open-simulation approach was adopted. A variety of building simulation programs (e.g. TRNSYS), control simulation tools (e.g. Matlab/Simulink, WINFact), and building visualization systems (e.g. LabView, BCON, Wizcon) are implemented while dedicated automation stations (e.g. programmable logic controller) are associated with the various subsystems (air ventilation system, heat pump, rooms) in the "Technikum G". All tools and components are linked together by different communication systems such as the EIB, LON, or Modbus etc. via OPC-Server, [1, 2]. Furthermore work has been done to couple different simulations tools like TRNSYS and Matlab/Simulink, [3].
With this setup, it is possible to develop and test new control strategies in the simulation environment as well as in the test room. Subsequently, improved control concepts can be tested in the actual experimental facility. Moreover, it is possible to visualize and monitor all process data as well as simulation data on a building automation system.
Fig. 5 shows the structure of the simulation models of the test environment as shown in Fig. 4 with the sub-models earth-to-air heat exchanger (EAHX), solar air collector (SAC), air handling unit (AHU) and the model of the test room G0.03 with room air, walls, radiator and windows.

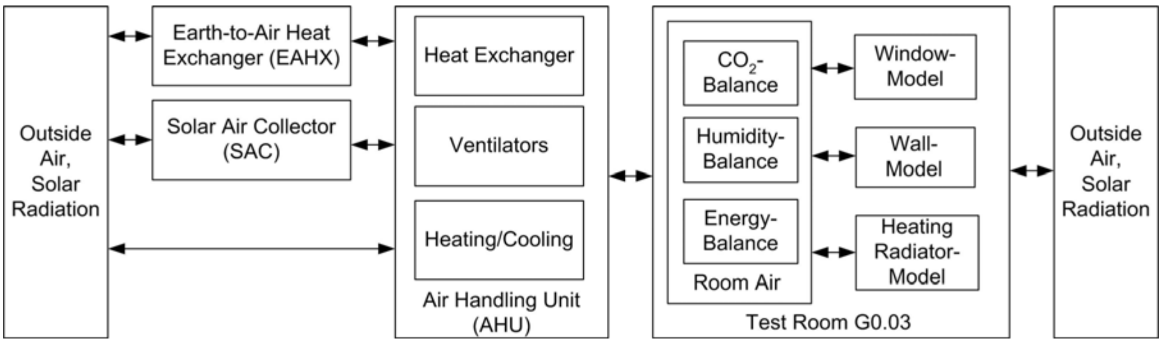

Figure 5. Overview of the simulation models.

In this paper the sub-system "room model" will be discussed in more detail. The sub-systems air handling unit and earth-to-air heat exchanger are described in [4], the sub-system solar air collector is described and discussed in [1]. The idea is to set up a real test room equipped with sensors and actuators as well as a flexible simulation environment for testing new improved room automation concepts and room control strategies which consider not only the room air with room air temperature, operative room temperature and relative humidity but also indoor air quality (CO_2, VOC). Thereby it is possible to investigate and evaluate different room control strategies in terms of energy efficiency, thermal comfort and indoor air quality (IAQ).
In a first approach the simulation model of the test room is developed in a top down way and kept as simple as possible. The main components are the room air, the walls, radiators for heating and windows. Coupling the air handling unit to the room model for air exchange of heated or cooled supply air is also considered. All walls are modeled as equivalent electric R-C circuits. For the air room the temperature is calculated based on the energy balance, the humid air on water mass balance. Additional a CO_2 balance equation is implemented to calculate the actual CO_2 concentration in the room air.

DISCUSSION OF THE ROOM MODEL

The validation of the room model is based on procedures defined by VDI 6020, [5] with two test rooms, standardized boundary conditions and a given set of simulation examples. Because the test room G0.03 is not identical to the test room in VDI 6020 another way had to be found to validate the room model of G0.03. According to this, validation of the room model was conducted in several steps, see Fig. 6.

1. The simulation tool TRNSYS was validated against test procedures based on VDI 6020, [3].
2. Generation of a validation data set. This was done with a simulation model of test room G0.03 in TRNSYS. Data sets are created for four different cases of internal and external gains. For creating this set of data, boundary conditions and constructions elements are chosen equal to the developed Matlab/Simulink model, [5].
3. Validate the room model G0.03 with this data set against the reference model in TRNSYS and weather data of Biberach, [5].

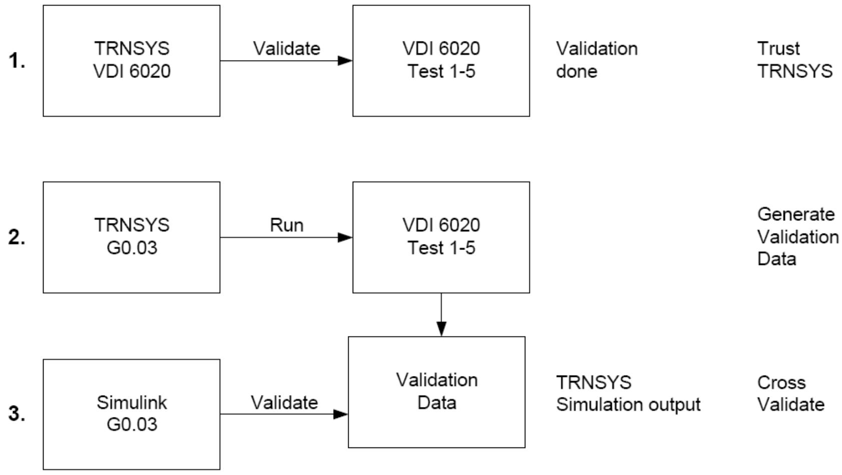

Figure 6. Approach for validation of room model versus VDI 6020, [5] and TRNSYS [6].

The simulation results show in general a satisfying match but also some significant differences. Based on a three day simulation result (Fig. 7) we will discuss some important details: There are only small differences in the dynamic run of the curves. The differences are caused e.g. due to different simulation time steps. The offsets in the air temperature and operative temperature of abut 1 K between the two simulation results can have several reasons. First, in the Simulink model the radiative gains to the construction elements are assumed to be absorbed in the centre of the first wall layer, instead of on their surfaces. Hence the absorbed radiation is subject to a larger heat transfer resistance towards the room air than in the TRNSYS model. The TRNSYS model assumes direct absorption of the radiation in the construction elements surfaces. This leads to lower air temperatures in the Simulink room model due to higher heat losses to the surroundings. Second, in the Simulink model a simplified assumption for radiative exchanges between walls and the surrounding was used. In contrast the TRNSYS model works with a radiative node model.

Conclusion:
With the respect to the aim of developing improved control concepts the quality of the newly developed Matlab/Simulink model turns out to be satisfactory. The final step, the validation of the room model against measured data in the test room G0.03 is still in progress.

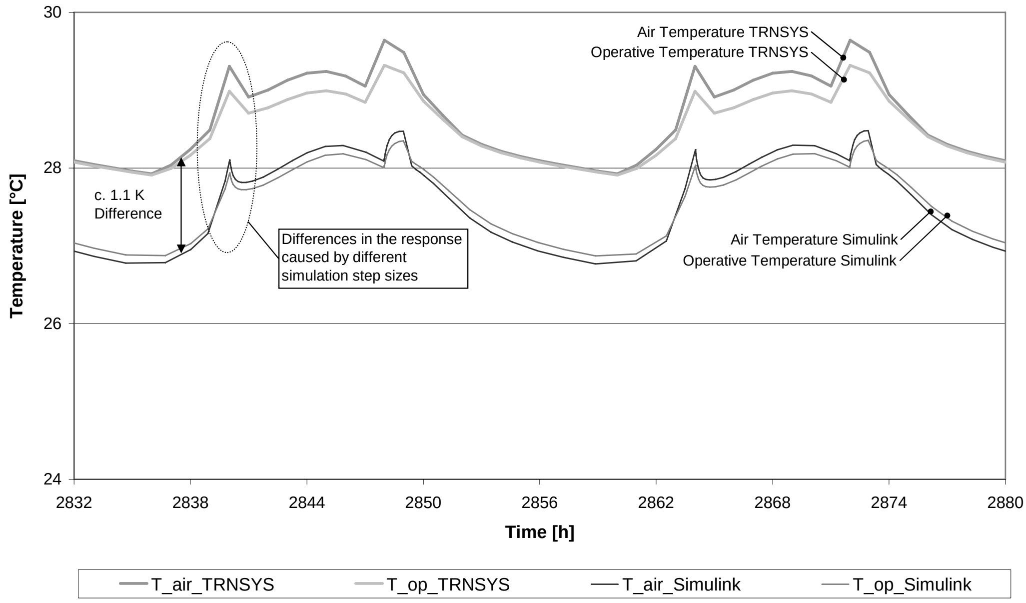

Figure 7. Comparison of test room model G0.0 in TRNSYS and Matlab/Simulink. (T_air: room air temperature, T_op operative room temperature)

DISCUSSION OF CO_2 CONROLLED INDOOR AIR QUALITY STRATEGIES

Based on the presented simulation environment different CO_2 concentration controlled strategies for a classroom were developed, investigated and compared. Two strategies will be discussed in the following.

The volume flow rate of the ventilation air as well as the corresponding air change rate that are necessary to maintain a certain CO_2 concentration mainly depends on the number of people in the classroom. In practice the number of people and their duration of stay in a classroom is rarely the same as the level of occupancy assumed during design. As a result a higher air change rate than necessary is often applied in the classroom which leads to higher energy consumption and higher energy costs. With a required air change rate of e.g. 30 m³/h per person and a CO_2 production of 20 l/h per person the calculated CO_2 concentration in the classroom room G0.03 with an occupancy of 35 people leads to a value of 1000 ppm, based on an air volume rate of 1050 m^3/h and an air change rate of 4.38 1/h respectively.

Fig. 8 shows a typical fixed time schedule for the classroom during the daily operation time from 8.00 to 17.30. The time schedule is defined with three lectures in the morning and two in the afternoon with short 15 minutes breaks and a one hour lunch break. In a first step it is granted that a fixed number of 35 people are in the classroom during the lectures.

As a simulation result Fig. 9 shows the curve of the CO_2 concentration under these conditions. Because the AHU system operates to a fixed time schedule, the CO_2 concentration slowly rises and reaches under these conditions the maximum at 1000 ppm. Because the ventilation system is running continuously during operating time with a fixed air ventilation rate the CO_2 concentration sinks during breaks. At the end of lunch time the CO_2 concentration reaches even the value of the outside air again.

Using a CO_2 sensor as an indicator for well indoor air quality (IAQ) the control task is to limit the concentration to a defined maximum value, e.g. 1000 ppm. This can be achieved by using an AHU system to control the air change rate into the classroom. This strategy in the following is called "CO_2-based demand-controlled ventilation (DCV)". In comparison to a fixed ventilation rate, DCV offers considerable advantages because it considers partial occupancy and the actual air quality conditions in a room. Fig. 10 shows the curve with a DCV strategy under the same scenario as discussed before.

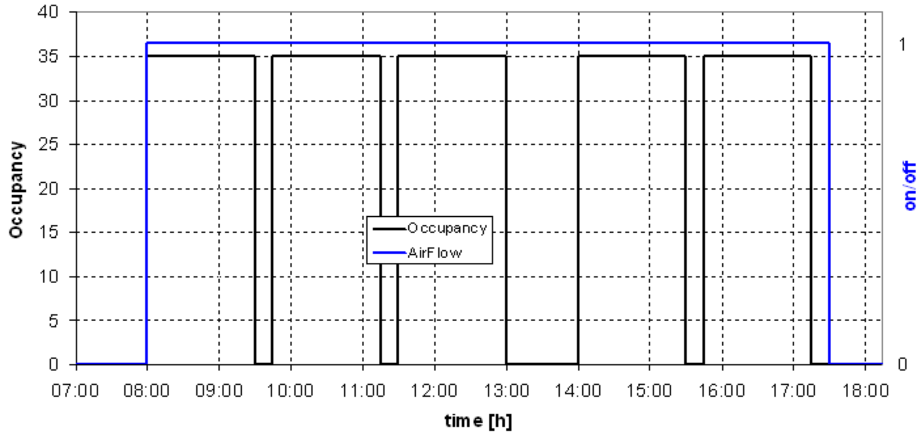

Figure 8. Example for a typical **fixed time schedule** for a daily operation time from 8.00 to 17.30 in the classroom with five lectures per day and an occupancy with 35 people.

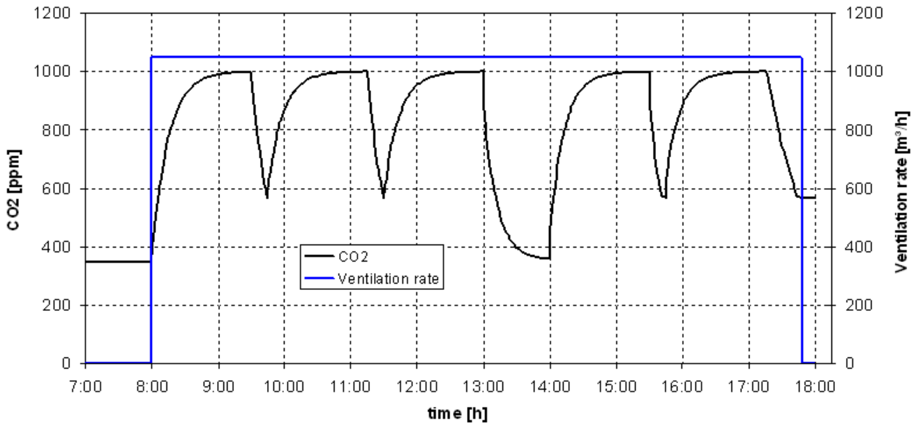

Figure 9. CO_2 concentration in a classroom with a **fixed air ventilation rate** of 1050 m^3/h and the scenario as shown in Fig. 8.

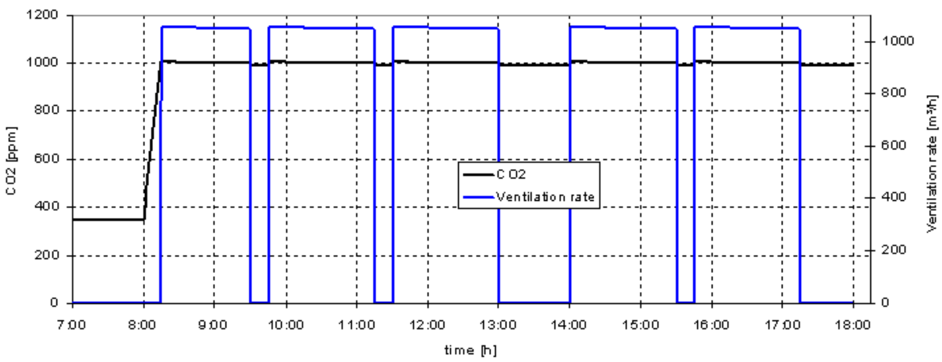

Figure 10. CO_2 concentration in a classroom with a **demand-controlled air ventilation strategy (DCV)** (set point of 1000 ppm) and the scenario as shown in Fig 8.

During usual operation the occupancy is normally not fixed to 35 people, but will be less most of the time. Taking the actual level of occupancy into account improved control concepts significantly reduce energy consumption. Fig. 11 shows a scenario with different levels of occupancy and a cancelled last lecture in the afternoon. Fig. 12 shows the resulting curve of the CO_2 concentration with a fixed air ventilation rate of 1050 m^3/h and Fig. 13 with the demand-controlled air ventilation strategy (DCV). The results in Fig. 13 are based on the same scenario as in Fig. 12. The ventilation control is activated only if the CO_2 concentration reaches the 1000 ppm limit. During breaks the ventilation switches off itself, if no occupancy is detected in the classroom. Nevertheless, during off state a minimum air change rate is supported to supply the room with a minimum fresh air volume.

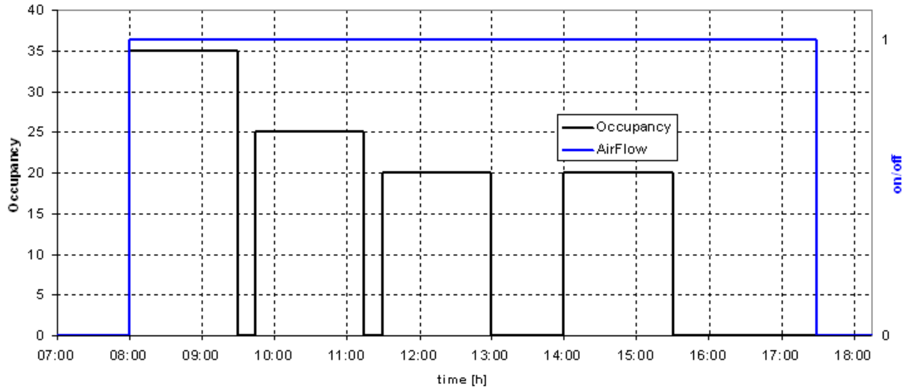

Figure 11. Example for a typical **fixed time schedule** for a daily operation time from 8.00 to 17.30 in the classroom with a **partial occupancy** with people and a cancelled lecture.

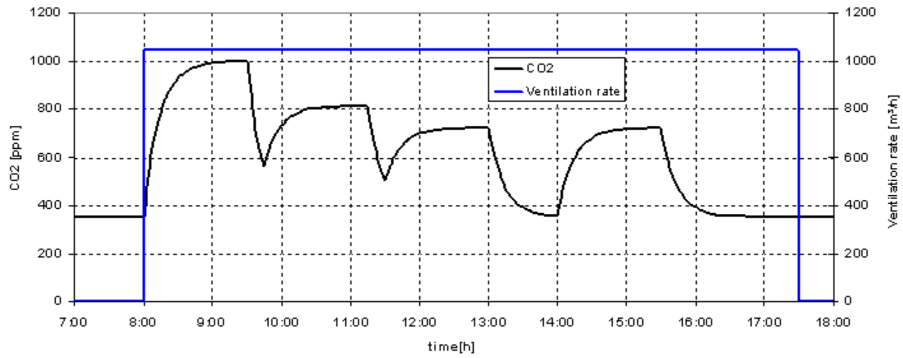

Figure 12. CO_2 concentration in a classroom with a **fixed air ventilation rate** based on scenario shown in Fig. 11.

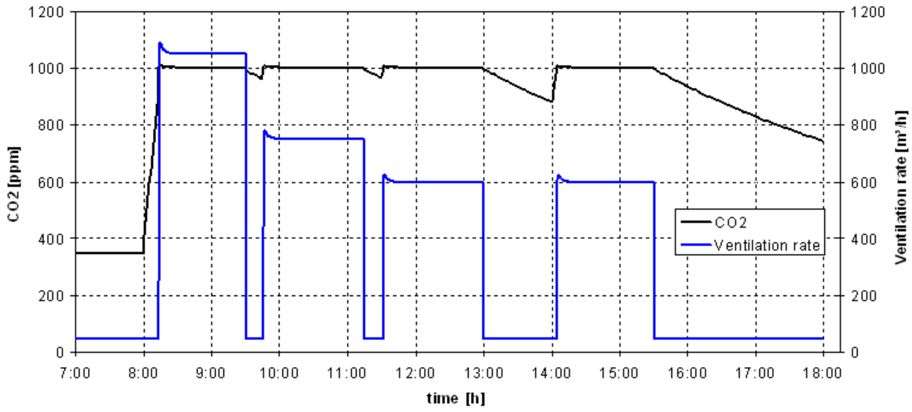

Figure 13. CO_2 concentration in a classroom with **demand controlled air ventilation strategy (DCV)** (set point of 1000 ppm) based on scenario shown in Fig. 11.

The energy consumption due to ventilation is a direct function of fresh air volume. Fig. 14 shows the resulting comparison of the two ventilation strategies shown in Figures 9, 10 and 13. The energy consumption for the demand-controlled ventilation strategy in case of a fixed occupancy of 35 people (Fig.9) is 28% lower and in case of different levels of occupancy (Fig. 13) even 59% lower compared to the fixed time strategy (Fig.9).

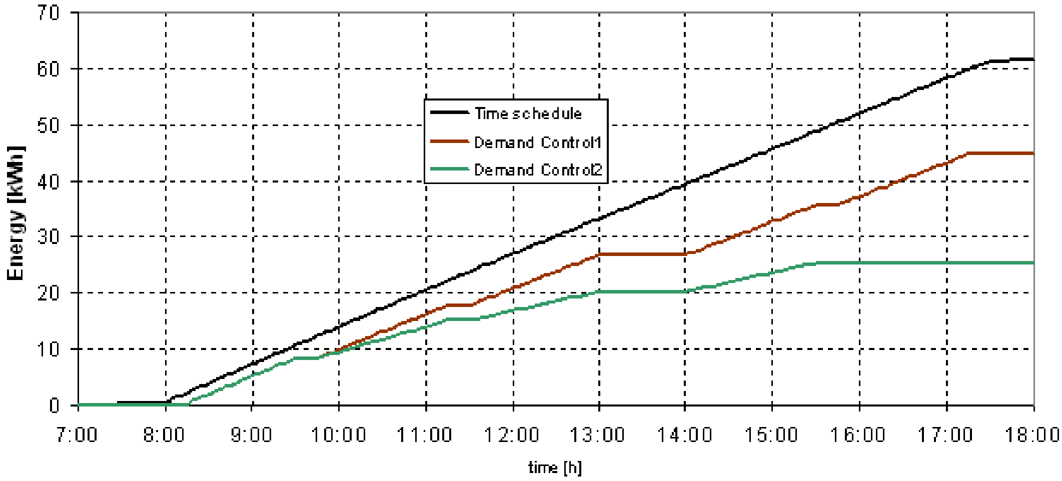

Figure 14. Comparison of energy consumption of the different control strategies based on fixed and demand-controlled air ventilation respectively.

Further work will be done to validate all sub models with data measured in the test room G0.03. Further investigations to improved automation concepts for energy efficient strategies will be carried out by simulations studies and more sophisticated control concepts (e.g. fuzzy control) which can be tested and evaluated in the test environment under real operating conditions.

SUMMARY

The power demands from residential and commercial purposes are increasing due to the life quality improvement. As the charge of power is based on the time-of-use, a proper solution to cut off the bill by reducing power consumption is highly proposed. In order to deliver this solution, it is essential to build up a power consumption model which contains useful information such as power usage during each time period and device type. Consequentially, a residential and commercial energy management system was designed to meet this need. The functions of this energy management system such as meter reading, data collection, reading analysis, energy saving potential and additional functions were tested during this trial. It was found that the system can help a user to reach 10.3% in energy saving. More details related to the trial and the testing results will be shown later in this article.

INTRODUCTION

There are two major factors to influence the residential and commercial power management system and they are the competition between power suppliers and the advance of network technologies. The first factor is because more suppliers are entering the power industry, and the intense of competition is fierce than ever. Hence, each supplier wants to offer users more value-added services such as energy management, home automation, direct load control and real-time pricing program to maintain its own competitiveness. From the report of Cutter Information Corp, the biggest support of home automation will be from the power industry. In addition, the Utility Customer Interface System growth reached 69.7% to 17.8 million sets from 1997-2004 from Frost & Sullivan. It can be seen that the competition of the power industry is the key to accelerate the applications of the information network technologies such as power management and other kinds of value-added services, because these applications can be delivered through the networks of the power suppliers or the other public communication networks.

For the second factor, the pervasion of network technologies which include the growth of communication network, the reduced costs and the appearance of embedded systems, increases the communication functionality and intelligence of devices, and also achieves the integration of separated database systems with networks. This trend can lead the power management for residential and commercial purposes to the next stage. According to the development trend of power management system around the world, new applications and services related to the information network are often delivered with the power management programs. It is believed that the integration of e-life and power management will come true due to the trend. Furthermore, since the competition intensity of power suppliers is getting fierce, services which can offer delicate solutions to users and users who will automatically save power consumption are getting more attention now. In Japan, the Energy Saving Navigator designed by Nado was capable of showing real-time power pricing due to the digital meter with wireless communication function. It was offered to 1700 families to use for two years, and power bill saving could reach 20% in average. The result of home power consumption survey showed that obvious saving can be found after a home energy management system was installed at home.

A “Home Energy Management System (HEMS)” project which is organized by EL Quest Corp, initialized by Panasonic and Hitachi, and supported by Japanese government aimed at applying information technologies onto the field of power management to achieve power saving by increasing users’ awareness. With the full support of the power supply company, this project carried out a multiple home trial involving 300 families in 2002. Within this trial, air conditioner, home appliances, and sensors were covered within the HEMS project, and a total power saving was set to 30%. In Italy, Enel Corp. replaced all the traditional analogue meters by digital meters integrated with LonWorks network technologies and aimed at building up the automatic meter reading system and offering value-added services to the users in 2003. According to the DSM Spotlight reported by the International Energy Agent (IEA), Bundle energy services were also carried out in Finland and the UK in 2003. The bundle energy services include remote energy management, appliance remote repairing, HVAC monitoring and control, and automatic meter reading. The Finland system aimed mainly for apartments, and the UK system offered services to detached houses.

According to the Energy Handbook published by Bureau of Energy, Ministry of Economic Affairs in Taiwan, 206,134.56 million Watts were consumed in 2004, and 19.20% which is about 39,587.86 million Watts were demanded by residential needs. Comparing with the residential needs in 2003, 2004 consumed 440 million watts more and the increasing rate was 1.1%. Comparing the previous recorded data, the power demands from residential and commercial needs increase about 1-5% per year.

Power consumption is found not directly related to the building design, climate difference and members of a family, as it is strongly related to size of a house, numbers of home appliances, the habit to operate the HVAC system and the life style. After analyzing the power consumption of a family, it is found that the numbers of home appliances and lighting devices are not the key factors to cause more power consumption, as it is more related to the using rate, usage and efficiencies of home appliances. Hence, how to choose the right applications and guide users to use them properly can then lead to the reduction of power consumption. In addition, how to deliver power consumption data to the users through the communication channels by integrating information technologies and to offer more value-added services can lead to an effective power management. This research aimed to achieve power demand reduction during the daily life with a power management system by causing users attention and then save power automatically.

METHODS

The function and performance of a set of energy management system was examined based on 100 homes. The energy management system can cooperate with existing devices to offer device management, home security and internet surfing for the purpose of e-life style. The architecture of this system is shown in Figure 1, and the key parts are the central control center, local control center and end user interfaces. The connections in between these three parts are through existing networks such as Ethernet, powerline network, and security network, and the explanation of these three parts can be seen as follow:

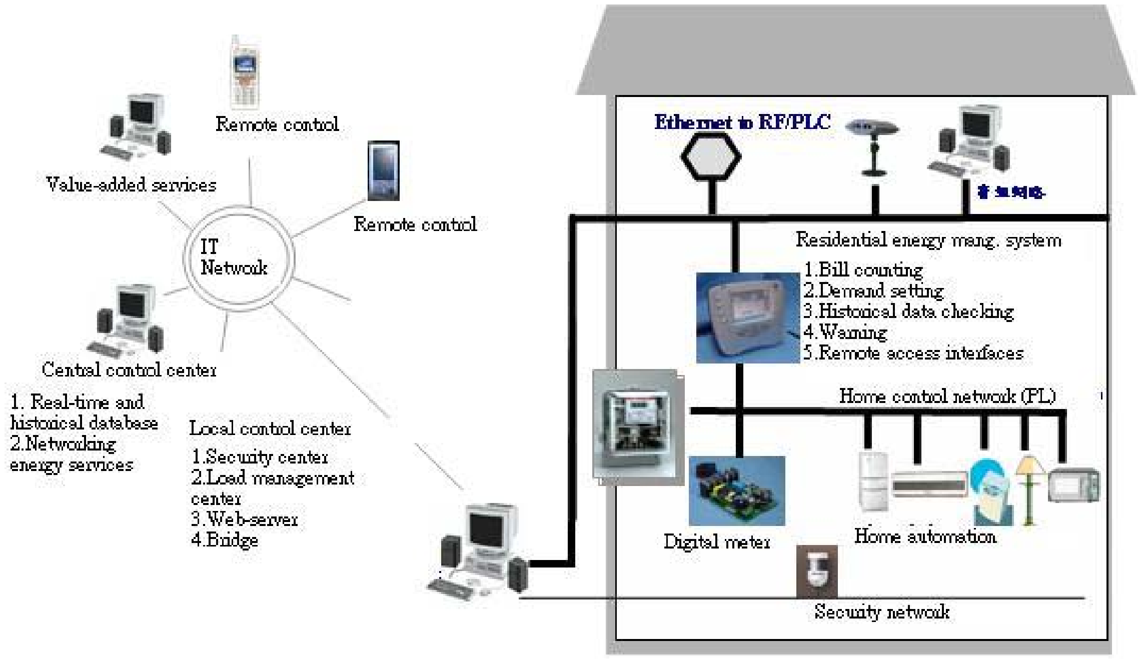

Figure 1: Architecture of residential energy management system

1. Central control center: to offer users services to access real-time and historical data, including power consumption data, data management, load checking and interfaces for vale added services.
2. Local control center: to extend the functions and interfaces from central control center, such as community security gateway, local server, end user device control server, community device management.
3. End user interfaces: to offer users proposed functions such as displaying power consumption data, power bill budgeting and home security.

The aim of this research is at testing and evaluating the function and performance of this energy management system for further promotion, and the testing and evaluating items are:

1. Long term operation testing: to operate this system for 6 months and collect data such as power consumption, historical power usage investigation and system stabilization test.
2. Load analysis: to analyze the collected power consumption data according to the family types.
3. Power saving potential investigation: to compare different power usage modes and find out the potential of power saving.
4. User satisfactory reviewing: to understand the usage of this system and its capability.

RESULTS

1. Energy management operation test

This energy management system includes embedded power meter, energy bill counter and control device and real-time and historical data base. After this system was established, 100 homes including detached houses, apartments, flats and offices were invited to carry out a

long term test, about 6-12 months in Taipei city. Several types of data were collected such as power consumption data, power usage and historical power usage habit.
Figure 2 & 3 shows the installation of power meter, which can collect required data and then send to count the power bill in the energy management system. In addition, this system can also set the desired power usage and warming signal will be sent if the power usage exceeds the desired level.

Figure 2: Energy management system used in this trial

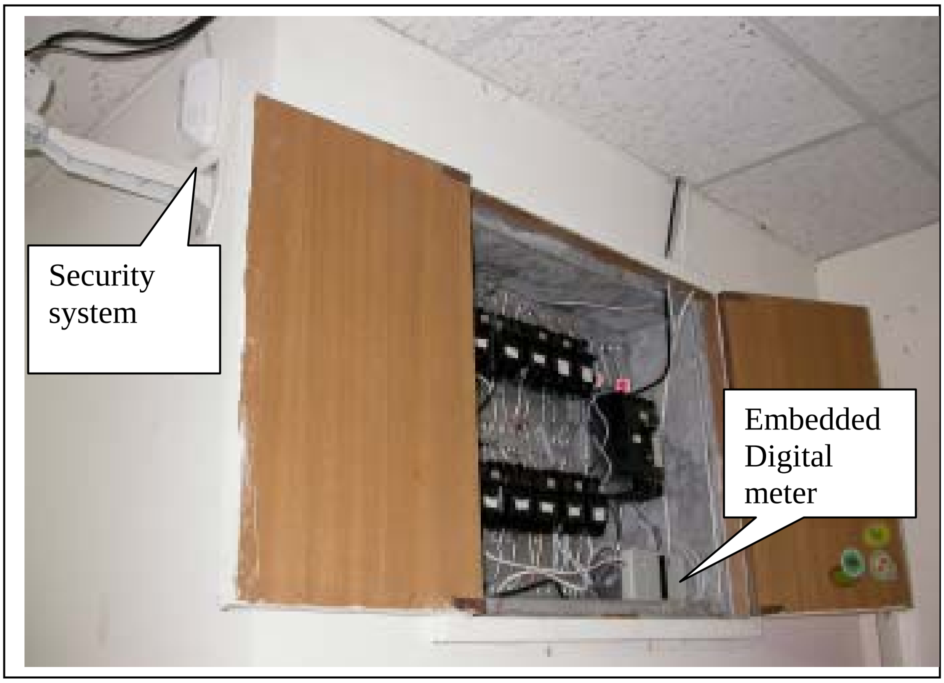

Figure 3: Installed embedded digital meter and security system

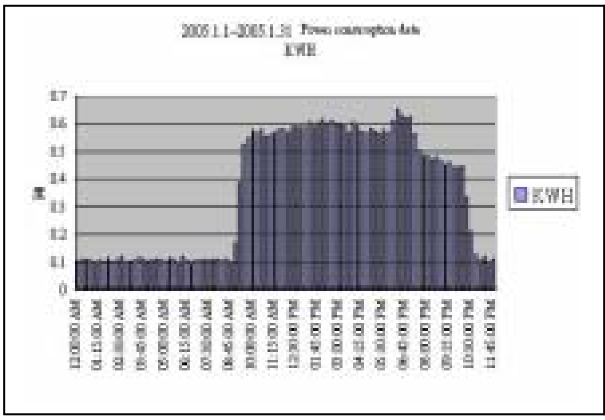
After 6 to 12 months operation, power consumption data collected from different types of home are used for analysis to find out the characteristics. The collected will also be compared with the situation in the previous year to understand the power need per month, and the power saving ratio. Related data such as education level of the users, size of the house, members of the family are also collected to evaluate the potential for further power saving.

General residential power usage characteristic

This energy management system can sample the power demand every 15 minutes. Figure 4 is the power usage of a house (sample A) which also joined the trial. It can be found that the power demand takes place from 9AM to 10 PM, and peak demand appears at 6-7PM. It can also be seen that the demands during week days are higher than weekends in figure 5.



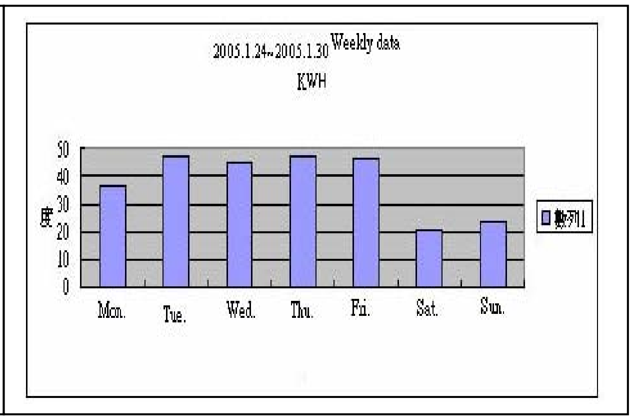


Figure 5: daily power consumption

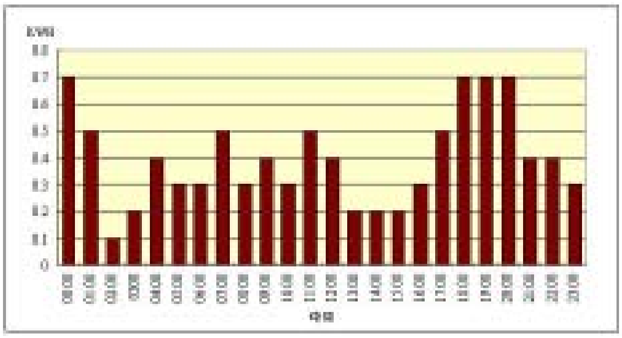
Figure 6: Weekly power consumption

Here shows another example (sample B) by Figure 6 to Figure 9, the peak demand appears from dinner hours to bed hours, and it also shows that the demand during the weekend is higher than weeks. It also shows that the power demand of the Chinese New Year Eve is higher than rest of the February, and the average power demand in August is about 1.4 times in February.



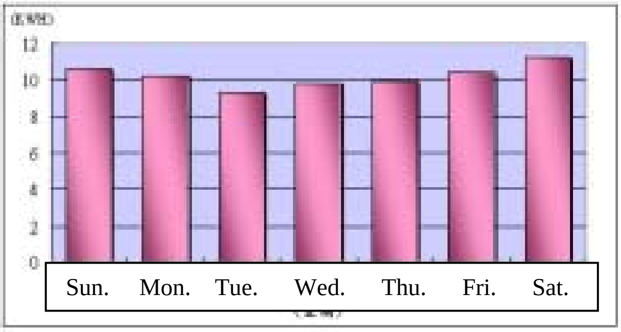


Figure 6: daily power consumption

Figure 7: weekly power consumption

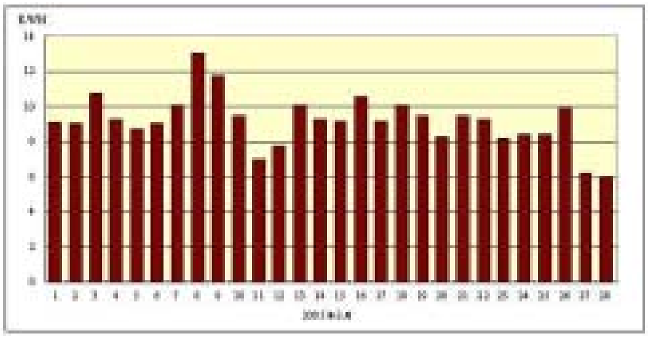

Figure 8: monthly power consumption

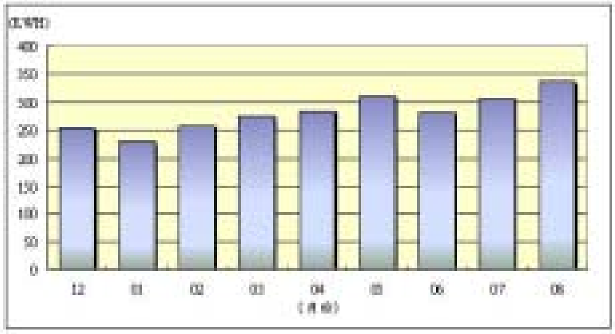

Figure 9:yearly power consumption

In Taiwan, some of the offices are allocated in a building next to an apartment. For Figure 10, it shows the power demand of an office allocated in a building. It can be found that the power demand increases in the office hour, 8AM to 7 PM or 10AM sometimes. The difference of power demand in between week days are not obvious, but during the off office hour and weekend, the demand decreases to minimum for standby power only. Basically this trend matches the demands received by the power supply company.

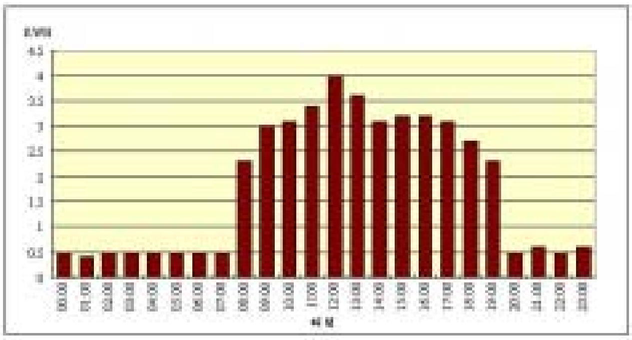

Figure10: Office daily power consumption

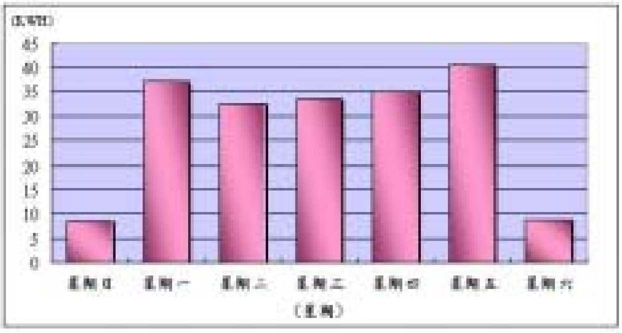

Figure11: Office weekly power consumption

The evaluation of the energy management system

After installing the system within the 100 trial homes, the power saving ratio can be seen from Figure 11&12. In sample A, the ratio is about 1.8% after comparing with the power usage of the previous year: the ratio of sample B is getting better and better. Both samples are showing positive result after adopting the energy management system.

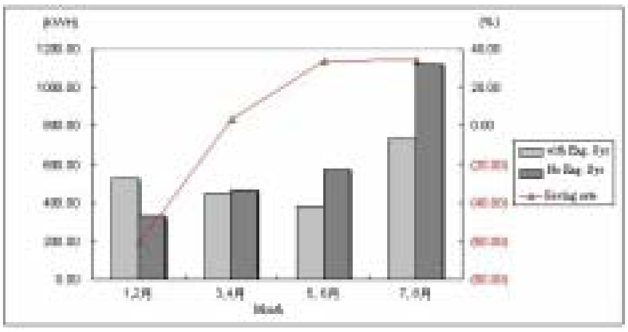

Figure12: power demand reviewing(sample A)

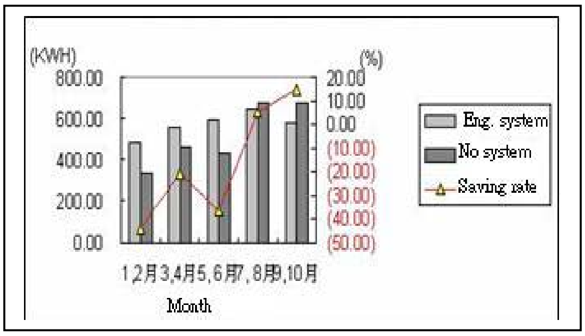

Figure 13: power demand reviewing(sample B)

In spite of the power usage investigation, this research also use questionnaire to understand the changes of the energy management system users to evaluate the potential of power saving. The target of this questionnaire is to understand the usage of the home appliances such as air conditioners, refrigerators, TV sets, dehumidifiers, lighting devices, microwaves, rice cookers and washing machines. In addition, it is also eager to know the satisfactory level and the pricing of this energy management system for further promotion.

Residential power usage analysis:
After the energy management system was installed, users did change many of their power usage habits themselves due to the warming signal. For some issues, users have changed their habits, but the improvement is not obvious, as the saving rate is about 11%. However, some of the issues can save 16-41% after proper advertisements and introduction, such as “cool off the food before put into the refrigerator” and “switch off the light as you don’t need it”. Form the experience of Japan, the issue “unplug or switch off the appliance as it is not operating” can do better power saving than other issues.

Before the energy system was installed, the energy saving issue gets more attention from users that has been awarded with first degree or above by a cross analysis. After the promotion and introduction, users with different education level realized the importance of energy and the users have master degree pay most attention to this issue.

The pricing of the energy management system
After analyzing the questionnaires and interviewing the users, the reasonable price of the energy management system is around NT 16000 dollars. It is roughly the cost of this system and the system has great chance to be accepted by its users. In addition, many users will like to have the system if extra benefits can be provided with this system.

DISCUSSION

This energy management system was tested in a multi-home trial for 6-12 months, and the target is to understand the family power requirement and the potential of power saving. The data of power requirement can be used to manage the power needed or set the contract demand with the power supply company. The power saving achieved by this system is about 1.8% recorded in a detached house, and the saving rare is around 4-21% in community centers. The saving rates recorded in different houses are different, and this can be caused by the difference level of behavior change or change of life style. The found result is quite different from 20% saving rate published by Japan Energy Saving Navigator. To find out the reasons, it can be because of higher energy price of Japan and culture difference. However, this system can actually achieve power saving as it was designed for. Even though the tips for power saving has been published and set inside the energy management system, users did not pay much attention to it, and face to face communicate can achieve better promotion results.

The promotion of residential energy management system requirement further improvement in software and hardware, and it also need some other supporting methods such as promotion through community activities to achieve a better result of saving. In addition, this system should lead users to save energy by changing their behaviors in energy using or add additional functions such as monitoring home power consumption, control the power demand, reduce standby power to extend the functionality of this system.

ACKNOWLEDGEMENT

Many thanks to the Bureau of Energy, Ministry of Economic Affairs in Taiwan, without their support, this project can not be carried out. Also thanks to the member of System Control Laboratory for helping to deliver this paper in time.

SUMMARY

In this paper we present our (possibly controversial) view, as Internet devotees, on the state of Building Automation Systems (BAS's). With one exception, the authors were not BAS practitioners until very recently, when we became engaged in an experiment of building an Internet Protocol (IP) based and open-source based BAS. This work is described in our other paper in these proceedings [1]. Being new to the field we started by studying the BAS state-of-the-art and by familiarizing ourselves with the technological, legal (mostly in the context of intellectual property protection), socio-technical, and business aspects of the BAS industry [2-7].

This paper summarizes our "lessons learned" in two parts. First, we discuss our view of the BAS industry from the point of view of outsiders who are expert in broad aspects of the Internet: IP networks and protocols, Internet-application implementation frameworks, and Internet-related business models, including open source. Second, we take a more critical view in our own work of implementing a BAS based entirely on an Internet technology stack. As a whole, our two papers lie within the genre of systems research.

INTRODUCTION

Digital convergence of communication networks has advanced very far in recent years. Voice and video communications are now well established on IP networks [8], and are quickly becoming as ubiquitous as basic information retrieval and e-commerce services. The global information infrastructure is essentially Internet Protocol based, with all higher layers of network stack, diverse as they are, utilizing the same IP transport layer [8,9].

In contrast, convergence in the field of building automation and control is much slower, to a point that BAS's seem not to be participating in the communication and media exchange convergence. The world of building and process automation is dominated by BACnet/LONTalk [2,3] networks, which, although packet-based, implement a design philosophy alien to IP, with application logic supported by low-level network layers. Web-based interfaces to some of the existing systems and BACnet migration to Ethernet transport are superficial at best. The industrial application development frameworks (ADF's) are mostly proprietary, and carry substantial royalties or even patent protection. We believe that this situation stifles innovation and makes true digital convergence of BAS's an arduous process, with a significant negative economical impact.

In this paper we present our observations of differences between the mainstream Internet technology stack and the approaches adopted by the BAS industry, and we point to weaknesses of the latter as we perceive them. Then, we discuss the architecture of a fully converged BAS system based entirely on open software solutions, with functionality matching typical current BAS ADF's. We believe that he system has the potential to liberate the industry from proprietary solutions and bring BAS's into the mainstream of the digital convergence process.

NOT ALL PACKET NETWORKS WERE MADE EQUAL

Pre-1995, BAS's were closed, isolated, inaccessible, and inward-looking. Faced with the Internet phenomenon, the BAS industry started supporting an interoperability process. BACnet[1] [2] and LONTalk/LONMark [3] were created. Both standards are packet networks. How similar are they to Internet Protocol?

We will focus here on the BACnet standard [4]. Intellectually, we consider BACnet an admirable piece of engineering work and we recognize its superiority over proprietary solutions. However, from the standpoint of the Internet community, the BACnet design is a never-ending source of surprises and conceptual difficulties. One of the differences is the approach to protocol layering: BAS networks define all seven layers of the OSI Reference Model. In the IP world, development moved forward in small, incremental steps. Each protocol was kept simple and designed to do one thing well. Each protocol could have been tested separately, and in fact has been tested until perfection is achieved. With a lower level protocol in place, the Internet Engineering Task Force (IETF) community [8] moved to a higher level, while low-level network engineers were designing carrier networks that could carry IP. This process has been repeated hundreds of times, leading to the current net of compatible, seamlessly interoperable protocols by which anything can be connected to anything, either directly or via a suitable adapter. The history of Internet protocols and of the IETF process is a history of stunning technological success.

BAS networks represent an orthogonal approach. BACnet specification [2,4] is a large library addressing every aspects of the networking system that the working group engineers and their corporate oversight could think of. The complexity of the design seems to reflect a trend to think about interoperability at every single protocol layer, as well as a desire to ensure that the definition will directly support existing products in all their proprietary diversity. The engineers did admirable work by unifying these requirements into a coherent design, but nevertheless the BACnet is an extremely complex design addressing issues that were best left outside of the specification. This, unfortunately, has grave economic consequences. Most devices connected via BACnet are relatively simple, sometimes as trivial as temperature or pressure sensors. The requirements for a BACnet device resulting from the complexity of the network are often far more complex than the sensor itself. We see this as a problem in the world in which wireless sensors can be made as small and ubiquitous as sand particles.

In [1], we describe a moderately complex Personal Environment Module with several sensors and actuators. This module can be purchased with an optional network interface. The cost of the network interface is approximately seven times that of the module itself and rivals the price of a small automobile. The interface designed and built by us following general methodologies perfected by the Internet technology stack can be manufactured for under US$30. This is, of course, anecdotal evidence. However, it is rather obvious that a) manufacturing

[1] Work on BACnet started in 1987. In 1995 BACnet standardization process was taken over by ASHRAE.

BACnet compliant devices is expensive due to the complex network interface, and b) writing fully compliant device drivers is difficult and hence costly.

Other concepts of BACnet that are surprising for Internet community are: a) a fuzzy notion of device address or identifier, b) amount of the state that BACnet devices are required to handle, c) low-level support for sensor and service discovery, and d) a large but closed list of services that the devices are supposed to render on behalf of other network entities.

The first concept hatched and solved by the IP community was device addressing, defined in absolutely unambiguous terms. This was separated from hardware, by simply allowing for two lower layers — data and physical links — with the issue of identifying devices in these layers left outside of the IP concept. This allowed implementation of efficient routing protocols working uniformly across the entire domain, from LANs to the global Internet. Indigenous BACnet routing exists, but it now seems clear that BACnet domains are best connected using IP [7].

The amount of state that network nodes must carry is of paramount importance. It is well known that Internet devices and applications limit it to an absolute minimum. This concept permeates IP networks at all levels, from routers to HTTP-protocol web servers. BACnet devices carry a lot of state, and this *per se* suggests that large BACnet networks cannot ever reach IP robustness and stability. Why would an industry supporting enormous real-estate investments settle for anything but the best?

At the heart of the BACnet specification, there are discovery services, such as “Who-Is” and “Who Has” [10]. The presence of these services forces implementation of a bi-directional client-service model for network nodes (see our comment above regarding amount of state). While various data-link layers may implement discovery services, above the IP layer there are separate, high-level directory services such as Active Directory/LDAP [11,12], or UDDI [13,14] for web services, or NIS [15], to name a few. These services are completely separate from low-level network services and enjoy the reliability of the underlying transport protocols. They also typically use client-server rather than peer-to-peer (P2P) architecture. One could argue that the location of the service in the protocol stack does not matter. However, we have had negative experience with networks that rely on self-discovery, with Sytek/Microsoft NetBEUI/NetBIOS [16] being the most notorious example. NetBIOS is finally being phased out in Microsoft products such as Windows Server 2003, after having caused users grief for over a decade. This aside, we believe that self-discovery of devices is a useful, but not critical feature. Many simple applications do just fine with manual configuration. We are inclined therefore to see BACnet reliance on discovery services as a liability rather than strength.

Discovery services are just few (albeit important) examples of services defined by the BACnet standard. Overall, there are at least 32 services in five categories. In addition, the standard defines multiple types of objects that devices have to support. The overall impression for an outside reader is that BACnet designers were focused on a network that would easily support all possible existing sensors, devices, and applications in the protocol itself, instead of providing the basics and leaving the applications to developers. Again, one can argue that the approach taken is beneficial for interoperability. We remain skeptical. Interoperability is far harder to achieve for complex protocols than for simple ones. Further, any attempt to encapsulate functionality of applications available at a given time is futile, as it invites obsolescence once the standard is defined. BACnet proponents would probably respond that the protocol is extensible, but this is a self-defeating measure: the very mechanism of extensibility and the possible extensions themselves increase the already significant complexity, and the extensions do not guarantee interoperability.

BAS APPLICATION DEVELOPMENT FRAMEWORKS

Let us consider now to the next layer of the technology stack: the application-development frameworks. This is a large and complex field, discussion of which exceeds the space available in this paper by orders of magnitude. The general trend is a division of the market space between a few major players. In our opinion, several vendors were able to attract a very large following for their products, precisely because interfacing to complex BAS networks is difficult. Two frameworks, supported by respective organizations, seem to dominate: a) Niagara Framework [17] and the industrial consortium behind it [18] and b) the OPC (OLE for Process Control) Foundation [19-21] with over 300 members supported single-handedly by Microsoft, as the technology is tied to the Microsoft DCOM. The Niagara Framework is used by many of the largest manufacturers of HVAC equipment. It is a complete software framework and development environment. Recent software releases clearly gravitate towards better integration with the Internet [22], but this is done by layering web services functionality on a rather thick stack of components already dealing with complex BAS networks. Interestingly, the framework description cites “device data unification” as one of core benefits. In other words, the complex networks are now being simplified to a level that applications really need. Of course, there is a price for any of the elements implementing this “standardize-complicate-simplify” seesaw cycle, and the end users eventually wind up paying the bill.

INTELLECTUAL PROPERTY PROTECTION

An additional interesting facet in this thread is that the Niagara Framework is patented in the United States (US Patent # 6,832,120 [23]). This patent is one of a multitude of US Patent and Trademark Office (USPTO) patents for software systems. In the simplest terms, the patent describes a methodology for integration of elements provided either by other vendors or by public standards using a pervasive, well known, and generic software infrastructure. The patent is an example of the recent trend followed by the USPTO for software patents: it is possible to obtain protection for arbitrarily complex systems built from a mixture of generic and widely used modules that do not need to contain any intellectual property of the patent author. US Patent #6,832,120 essentially claims that any software system used for building control that uses the notion of software objects to represent devices infringes on the intellectual property rights of the patent owners. This is a very broad claim that certainly discourages implementation of competitive frameworks.

OPEN SOURCE BASED BAS

The preceding sections should have made it clear that we are not particularly fond of the current state-of-the-art BAS technology. To be constructive, rather than merely critical, we have decided to implement a functional BAS completely from scratch using only pervasive Internet technologies and methodologies. Some aspects of this work have been described in our other paper in these proceedings [1]. Here we would like first to discuss certain recent developments that, in our opinion, justify such work. Next, we will discuss problems and difficulties we have encountered in the design and implementation process.

First, we are strong believers in the open-source phenomenon [24-33]. Before embarking on the implementation, we have searched for an “open” BAS system, or elements thereof [34]. Not only have we failed to find any significant work, but also we have also found it unusually difficult to obtain information about commercial frameworks. In several cases, we were told that access to information is contingent upon a purchase of an expensive membership in a consortium and/or disclosing project goals and details. A study of the “open” projects usually revealed a lack of substance behind publicly stated claims. For a research group immersed in the Internet culture, this has been an unexpected and sobering experience, but also a stimulating challenge.

Our decision to implement a BAS the “Internet way” was reinforced by several technological developments:

Sensors are getting smaller: the “intelligent dust” is no longer a domain of science fiction. BACnet design philosophy does not appear suitable to handle this situation.

There has been profuse development of diverse types of wireless networks: WiFi promises blanket coverage in metropolitan areas [35]; satellite connectivity providing global reach is becoming both affordable and technically straightforward due to availability of Ka band [16] and low-orbit constellations, such as GlobalStar [36]; and mesh networks such as ZigBee [38] provide support for mini-sensors. All these technologies support IP by definition, and can serve as access media for BAS’s.

Construction of pure IP controllers for sensor and actuator devices has become very easy thanks to the availability of miniature, dense, highly reliable components. An HTTP server with processing power sufficient to implement web services is available in enclosures that include an RJ-45 Ethernet jack [39]. This makes the entire TCP/IP stack and a sophisticated application layer available off-the-shelf for any type of sensor assembly

There has been very substantial increase in processing power for embedded applications. Note that the entire concept of LONTalk was built around a Neuron processor [40-42]. Last year, development of ultra low-voltage CPUs such as Intel Celeron M enabled, for the first time, processing power comparable to that of a desktop PC in mobile and embedded platforms. This allows implementation of complex sensing devices. An example of such a complex sensor could be a high-resolution still-image camera capable of real-time image processing, change detection, and object/face recognition, or a video camera/GPS/IMU assembly (where IMU is short for Inertial Measurement Unit)) supporting real-time geo-rectification, object tracking, image stabilization, and feature extraction. Such complex sensor assemblies appear to be outside of what has been envisioned for BACnet domain. For our pure IP-based BAS handling of such devices is as natural as the handling of a temperature sensor.

There has been explosive growth of web services in form of Service-Oriented Architecture (SOA) [43], which at this point ensures that this particular technology will form the foundation of Internet application architecture for many years into the future.

SMART BUILDING SYSTEM

In this section we will briefly look at the way we approached design and implementation of our BAS, based on Internet Protocol (IP) and open-source technologies (for more details see [1]).

System Goals
While researching the feasibility of creating a BAS with IP-based, open-source technologies we focused on building a prototype of the system for Smart Buildings (hence its name: Smart Building System). The system should provide support for the following features:

Heterogeneous sensors and devices: It should be possible to connect arbitrary IP-based sensors and devices to the system with minimal implementation, configuration, deployment, and maintenance effort.

Personalized and dynamic environment: The system should be able to customize environmental properties of the building spaces to align them with the preferences declared by the individuals. Environmental preferences should form an environmental profile of an individual that would 'travel' with the individual across the building space.

Customizable goal-oriented control: The system should be able to apply 'reasoning' to maintain the environmental parameters (temperature, humidity, etc.) of the building within specified parameters. The reasoning logic should be customizable, so that various strategies can be implemented, analyzed, and compared.

Manual administrative control: The system should provide means for the authorized personnel to monitor the status of the system and set the global, overriding goals for the system., means for direct control of specific devices should also be provided.

Potential of integration with IT infrastructure: The system should provide interfaces for embedding it in the larger enterprise IT infrastructure.

Extensibility: It should be possible to add new or replace existing system components using common software engineering skills.

Technology
We decided to base our implementation on the following technologies:

Java 2 Enterprise Edition (J2EE [26]) is used as a general programming platform for most server-side components of the Smart Building System. This choice was not related to Java's being an object-oriented language, but rather due to the following features and properties of J2EE:
a) support for transactional access to the relational database management systems (DBMS) [31]; b) well-defined communication mechanisms such as RMI, HTTP, Web-Services, and JMS [32]; c) mechanisms for accessing directory services such as LDAP [12]; d) J2EE is a set of specifications instead of products; the code is therefore easy to port to various implementations of J2EE; e) Inclusion or integration with technologies that provide scalability, security, and fault tolerance; f) J2EE is widely used as a platform for enterprise software systems; g) a selection of mature open-source implementations of J2EE platform is available.

Architecture
We adopted a modular approach, where the system components can reside on separate IP network nodes. The Smart Building Framework is at the core of the system. It constructs and maintains an up-to-date model, which represents the controlled environment. It allows components of the system to accurately interpret the data gathered from the devices and influence the environment as intended. The Smart Building Framework, which exposes its services

using web services, is implemented using the J2EE platform. It is deployed on a J2EE application server (JBoss [27]) and communicates with a DBMS (Hypersonic [31]). Third-party modules can connect to the Smart Building Framework over the network and access its services via a Web Services [24] application-programming interface (API).

All other system components interact with the Smart Building Framework (including devices) through its set of web services. We have implemented the following essential components:

The *Inference Engine* [25] implements the control logic of the Smart Building System. Refer to [1] for detailed description.

The *Smart Device* is a software wrapper for any real or virtual device that needs to be connected to the Smart Building System. It can be either deployed as a part of the real device software or it can run on a separate network node the real device connects to. Refer to [1] for more detailed description.

The *Administration Interface* provides a graphical user interface (GUI) for monitoring and controlling the Smart Building System. It has tools for defining target environmental parameters for the system (goal-oriented approach), as well as specific device settings (direct device control overriding settings calculated and enforced by the Inference Engine). It is implemented as a Web-based application (Java Servlet, HTML, and JavaScript) that interacts with the Smart Building Framework to access the information about the system state. It is deployed on a J2EE application server (Jboss [27]).

The *Personalization Interface* provides a GUI for regular users of the system. It allows users to specify their environmental preferences that the system tries to enforce. It is deployed on the Jboss [27] J2EE [26] application server.

DISCUSSION

During design and development of Smart Building System we identified the following benefits and drawbacks of our approach.

Benefits

Re-use of existing IT infrastructure: Most of the server-side components of the Smart Building System run on a standard J2EE-compliant application server commonly used in the enterprise. Any relational DBMS can be used. As a result, the server-side components can be deployed and integrated with an existing IT infrastructure. Standard TCP/IP-based networks can be used to connect devices.

Extensibility: Since all components of the system communicate through well-defined interfaces, they can be easily replaced or updated. New components can be created or existing ones modified using well know programming languages (Java) and communication technologies (web-services). A Java API is provided for creating new Smart Devices to simplify development even further. API’s in other languages can be easily created.

Integration with enterprise systems: The systems based on the Smart Building platform can be controlled through a web-services interface. As a result, they become one more element in the SOA [43] palette in the organization.

Support for legacy devices: Adding legacy devices (BACNet, LONTalk) is possible through adapters. Representation of devices in the platform as well as the communication protocol between Smart Device and Smart Building platform are based on BACNet concepts; therefore effort required to develop of an adapter should be reduced.

Blending of real and virtual worlds: Devices connected to the Smart Building Platform can be both real and virtual. This creates the possibility of making other components of the enterprise software infrastructure behave as virtual devices. For example, a corporate calendar can behave as a device that prepares conference room for a meeting before the meeting participants arrive.

Scalability and reliability: Making Web-based and J2EE based applications scalable and fault tolerant is a relatively well-understood field.

Drawbacks

No support for real-time/priority processing: Real-time/priority requirements are not well supported by existing Web-based technologies.

Latency: The Smart Building Framework introduces an intermediate node in the communication between control logic and target devices. Careful capacity planning is required for mission-critical systems

Higher bandwidth/CPU requirement: Protocol overhead for simple communication is significant. HTTP and SOAP add a significant amount of data (impact on bandwidth and processing power). This is mitigated by increasing CPU power.

Security-related effort increased: We do not consider technologies used to build the Smart Building System inherently less secure than the ones used to build existing BAS deployments, but we believe that more tools for exploiting TCP/IP networks and HTTP-based services are available. Therefore security must be a top priority during deployment and maintenance.

Not feasible for small deployments: Smart Building System requires setup of software as well as hardware components. IT skills are required for setup and maintenance.

Complex handling of system state change notifications: This is more of an architectural issue that increases complexity of the code and bandwidth/CPU requirements. Handling notifications in HTTP-based systems is nontrivial. Several approaches are possible to provide this capability:

- *Polling:* The components of the system learn about system state changes by sending requests to the Smart Building Framework periodically. This approach is supported by our current system. It potentially suffers from high (albeit predictable) latency.
- *Web-services [24] (server)/JMS [32] (client):* Components of the system subscribe to the JMS service maintained by the Smart Building Framework and learn about state changes via JMS messages. This approach, which we consider optimal, has been designed, and is being integrated.
- *Web-services (server)/Web-services (client):* The components of the system expose the web service used for notifications, and register it with the Smart Building Framework. The Framework calls the notification web-service, when a specified system change occurs. This approach requires more work, and we plan to implement it in the next version of the system.

ACKNOWLEDGEMENT

This project was supported by funding from Empire State Development Corporation (ESDC) of New York State under Award No: ESDC- R 580, granted to Syracuse University and Syracuse Center of Excellence in Environmental and Energy Systems (SCoEEES). Collab-Worx acknowledges financial help and intellectual leadership of the SCoEEES, without which this study would not have been possible.

Recent Developments and Long Term Test Results for an NDIR CO_2 Sensor Based on Tunable Silicon Micromechanical Infrared Filter

Mikko Laakso, Matti Hohtola, Marko Jalonen and Maria Uusimaa

Vaisala Oyj, Finland

SUMMARY

In carbon dioxide based demand controlled ventilation one of the key system components is the sensor used to measure the CO_2 concentration in the ventilated space. The Non-Dispersive InfraRed (NDIR) technology that is primarily used for CO_2 sensing can provide reliable and stable CO_2 readings for periods well over 10 years, provided that certain inevitable sensor drift mechanisms are compensated for. This paper describes the latest results for an NDIR sensor technology that measures the absolute CO_2 level using a tunable silicon micromechanical infrared filter.

INTRODUCTION

One of the commonly applied Demand Controlled Ventilation (DCV) strategies is to control the ventilation based on the carbon dioxide level in the ventilated area, as the carbon dioxide concentration in a space relatively well represents the person occupancy, and is straightforward to measure compared with other parameters correlating with occupancy. [1,2] Therefore, a key component in a CO_2 based DCV control system is the sensors used to measure the CO_2 concentration in the ventilated space.

For more than a decade the Non-Dispersive InfraRed (NDIR) technology has been the technology of choice for CO_2 sensing in ventilation applications. The basis of the technology is the absorption of IR radiation in gases that follows the well-known exponential behaviour described by the Lambert-Beer equation:

$$I = I_o e^{-\alpha C d} \qquad (1)$$

where

- I_o = intensity of light incident on the sample
- α = absorption coefficient of the gas at the characteristic wavelength [cm^2]
- C = concentration of the gas [$1/cm^3$]
- d = distance the light traverses in the sample gas [cm]

For each measured gas the measurement wavelength must be chosen to match with an absorption band that is characteristic to the said gas. In the case of carbon dioxide the gas features a very strong absorption band at a wavelength of around 4.2 µm. Thanks to the fact that the absorption is strong and the absorption band practically free of interfering gases, CO_2 is one of the gases most commonly measured using the NDIR technology. Figure 1. Depicts the IR absorption spectrum of CO_2.

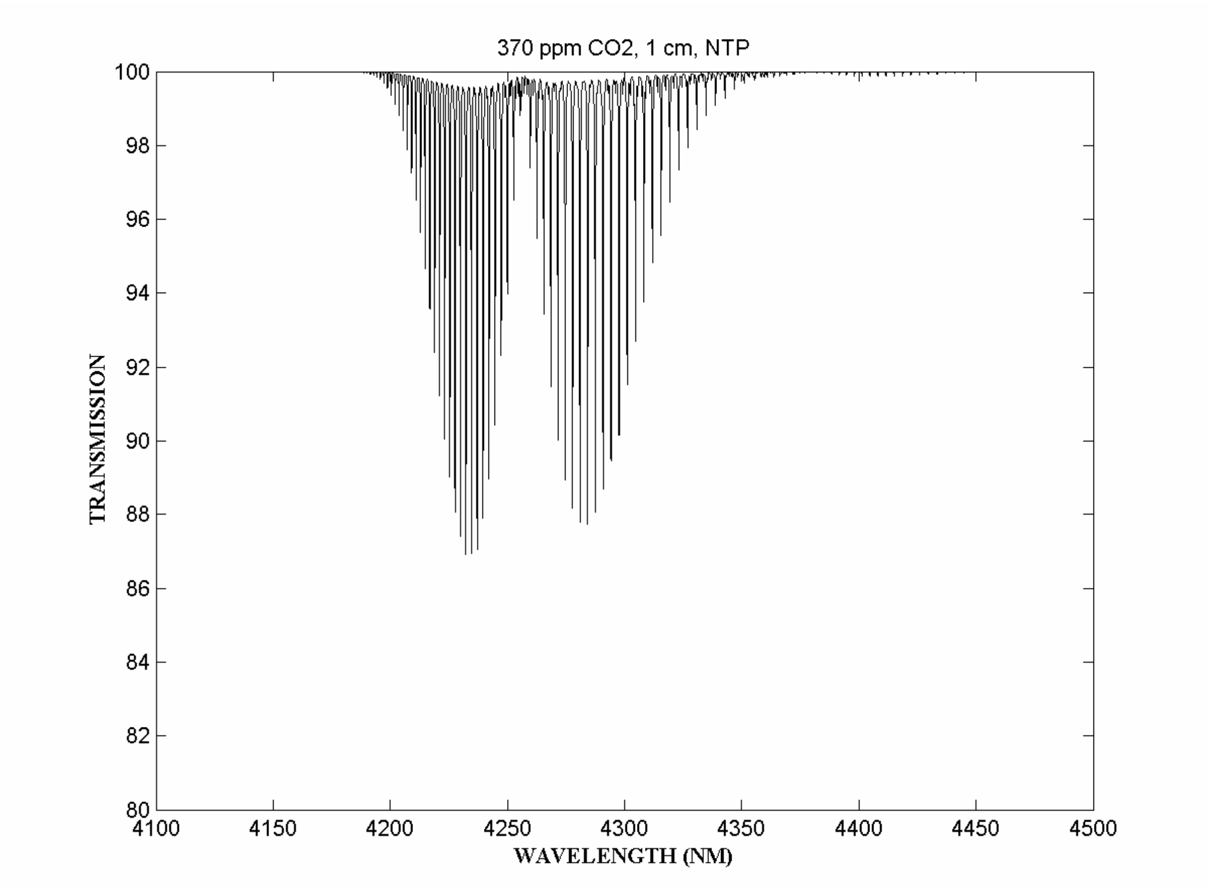

Figure 1. Absorption spectrum of CO_2 in the 4.2 µm wavelength range

Schematically, a typical NDIR based CO_2 sensor for ventilation application consists of three main functional elements: a light source, a measurement channel, and an infrared detector. In most cases the light source is a thermal emitter such as a miniature filament lamp emitting a broad band blackbody IR spectrum, with possible effects caused by absorption in the glass bulb surrounding the hot filament. When considering the long term behaviour of a CO_2 sensor the drift of the lamp intensity over several years is an important drift element that must be compensated for.

The purpose of the second functional element, the measurement channel, is twofold. Firstly, it acts as a light guide and directs light from the light source to the IR detector. Secondly, it acts as a mechanical frame for the sensor, defining the gas volume used for the absorption measurement and providing holes and possible filter elements that are necessary for the sensor to "breathe" with its environment and provide representative measurements. The measurement channel may typically be constructed of injection molded plastic or aluminum, and more often than not contains reflective surfaces used to lengthen or define the optical path of the IR light through the sensor. The optical properties of the measurement channel are crucial for the operation of an NDIR sensor, and may in the long run be affected by corrosion or contamination induced by the operational environment of the sensor.

Finally, an infrared detector is used to measure the intensity of light passing through the measurement channel and the gas therein. The spectral filtering that is necessary for identifying the 4.2 µm absorption band is normally integrated in the detector package in the form of a fixed interference filter or, as in the sensor described in this article, a more advanced tunable filter. Again, any long term drift mechanisms and effects in the sensitivity of the IR detector or in the bandpass characteristics of the filters must be minimized and / or compensated for in order to realize a stable CO_2 sensor.

In practice the different sensor structures and compensation schemes that are being used today in commercially available NDIR CO_2 sensors differ from the simple picture presented above. Dual light sources may be used to compensate for light source aging in a scheme where the second light source is operated only intermittently in order to minimize its aging and hence provide a possibility to use it in correcting for changes occurring in the other parts of the sensor. On the other hand, dual detectors furnished with different filters for measuring the IR transmittance at a CO_2 sensitive wavelength (4.2 µm) and at a reference wavelength typically adjacent to 4.2 µm may be used for compensating long term effects. Finally, software methods and algorithms can be used for post-correcting CO_2 readings from a drifting sensor in applications where the occupancy pattern in a building permits the use of the background CO_2 level at the building location as a baseline reading to which the sensor reading is adjusted, typically at night time.

In this paper we present the operation and latest measurement results of an NDIR sensor technology that uses a tunable IR filter as a means to provide a dual wavelength (CO_2/reference) operation with a single optical path and a single IR detector. The voltage tunable IR filter is made using the Fabry-Perot Intereferometer (FPI) principle, and fabricated on silicon with the methodology of silicon surface micromechanics.

METHODS

Figure 2. depicts the structure of the sensor used in the study. The light source is a miniature filament light bulb, and the measurement channel is constructed of injection molded plastic that is gold plated from the inside to provide a reflective surface which does not age even in

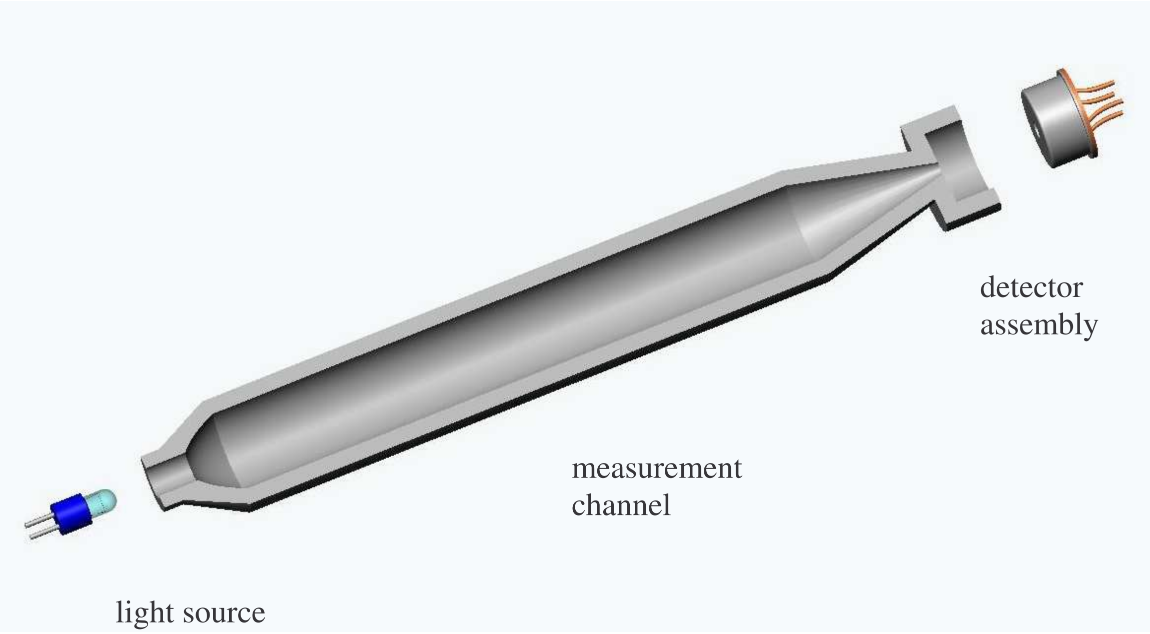

Figure 2. The structure of the NDIR CO_2 sensor used in the study.

harsh environments. The light receiving end of the sensor is built inside a hermetic TO can, which hosts a window for light entry into the can, the tunable FPI filter and an IR sensor. A schematic structure of the detector TO can assembly is presented in Figure 3.

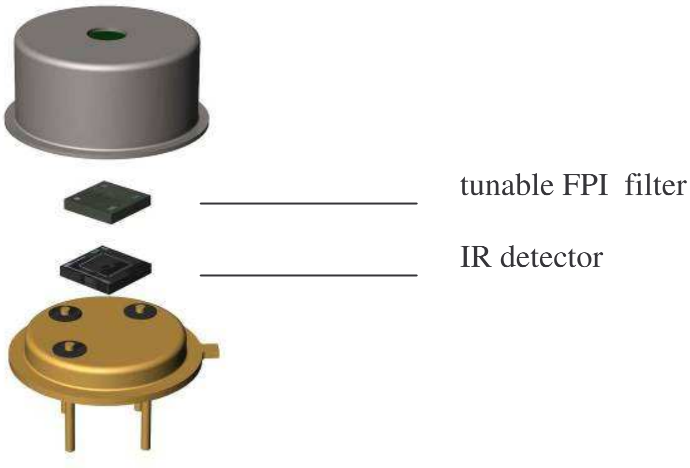

Figure 3. The detector assembly hosting the entry window, tunable FPI filter and IR detector

The tunable FPI filter that is used in the sensor is fabricated on a silicon wafer using silicon surface micromechanics. Figure 4. depicts a schematic structure of the filter.

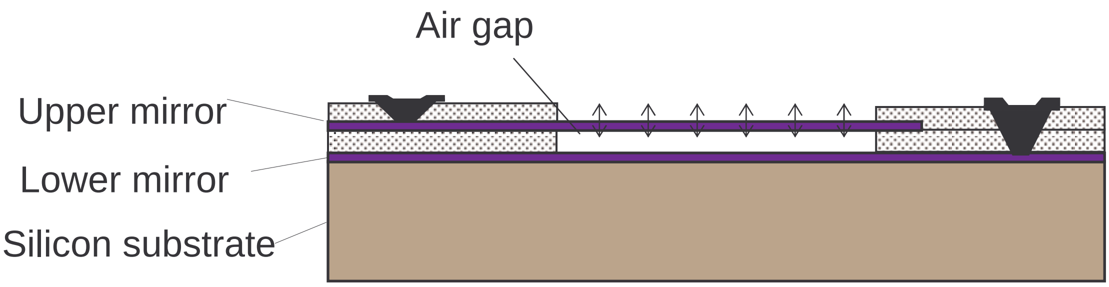

Figure 4. Schematic of the FPI filter used in the sensor

In the component a thin diaphragm is suspended in the vicinity of a silicon substrate to form a narrow air gap. According to the operating principle of a Fabry-Perot interferometer [3] the two closely spaced mirrored surfaces form a bandpass filter whose transmission depends on the distance between the said surfaces. With a judicious choice of the gap dimension the filter can be optimized to operate at the CO_2 absorption wavelength of 4.2 µm. Tuning of the filter is achieved by connecting a voltage across the air gap and displacing the diaphragm electrostatically towards the substrate and hence changing the gap.

For CO_2 sensing the IR transmission through the sensor is measured at the CO_2 wavelength of 4.2 µm and at a reference wavelength near the CO_2 wavelength. The ratio of these two readings is a measure of the CO_2 concentration that is free from many drift mechanisms of NDIR sensors such as light source aging or effects from dust, dirt or even corrosion inside the sensor.

RESULTS

Despite the fact that the operating principle of the sensor in this study inherently compensates drift mechanisms that are caused by for example deterioration of the optical surfaces inside the sensor, for extremely stable measurements it is advantageous to choose the surface coatings inside the sensor in such a way that they resist corrosion. To study corrosion resistance of the coatings we exposed one set of injection molded and gold plated production sensor parts to the following set of accelerated aging conditions, in succession:

1) 3 weeks of dry heat; 90 ^{o}C
2) 3 weeks of damp heat; 90 %RH, 50 ^{o}C
3) salt mist test according to IEC 68-2-11: two cycles of (24 hours of salt mist (5% NaCl, 35 ^{o}C), 24 hours drying (23 ^{o}C))

As a documentation of the results figure 5. shows two plastic parts, one of which is virgin with no aging treatments, the other one after exposure to the aging conditions described above. No effects are visible from the relatively serious environmental tests.

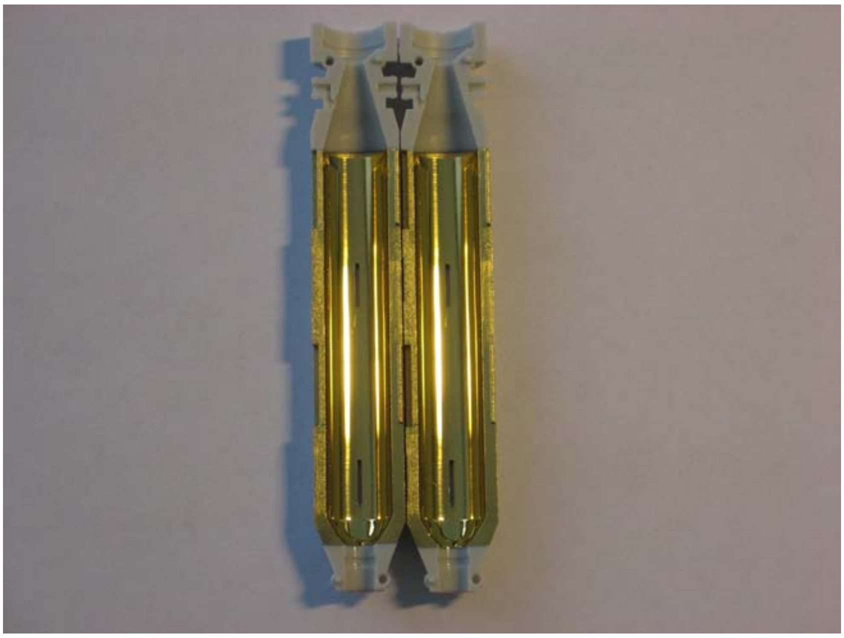

Figure 5. Plastic parts before and after exposure to accelerated aging tests. Part on the left has no exposure, part on the right has been through aging treatments described in the text. No effect is visible.

In assessing the long term stability of an NDIR CO_2 sensor also the sensing algorithm used to extract the CO_2 concentration from the transmitted IR signal(s) is of importance. Furthermore, also the implementation of the algorithm and practical realisation of the whole instrument should be taken into account. Hence for meaningful determination of the long term stability of a sensor structure and technology, a minimum unit for testing is a whole CO_2 transmitter giving out an analog or digital CO_2 signal.

We have installed four preproduction transmitters in an office environment for continuous logging. Data is recorded at 3 am when typically no people are present in the office area. The forced ventilation in the office space is on during office hours and until 8 pm, whereas during night time the mechanical ventilation is off. Figure 6. depicts raw data from the four transmitters from an ~8 month period, as recorded at 3 am daily. The data shows relatively large, +/- 50 ppm, daily variations in the background CO_2 concentration that can be seen in the data from all the devices under test. These can be understood as natural variations in the ambient CO_2 concentration due to natural (photosynthetic activity, soil respiration) and man-made (traffic, energy production) phenomena. Additionally the data would indicate that there has been an effect on the background CO_2 concentration in Helsinki (where the measurements have been made) due to the large forest fires that took place in Russia at the end of August 2006 and had a significant effect on the air quality in Helsinki at the time.

To more accurately assess the long term stability of the devices we applied a correction to the raw data, where the common mode variations that were seen in the readings of all transmitters were compensated in the readings. The resulting common mode corrected data is seen in figure 7.

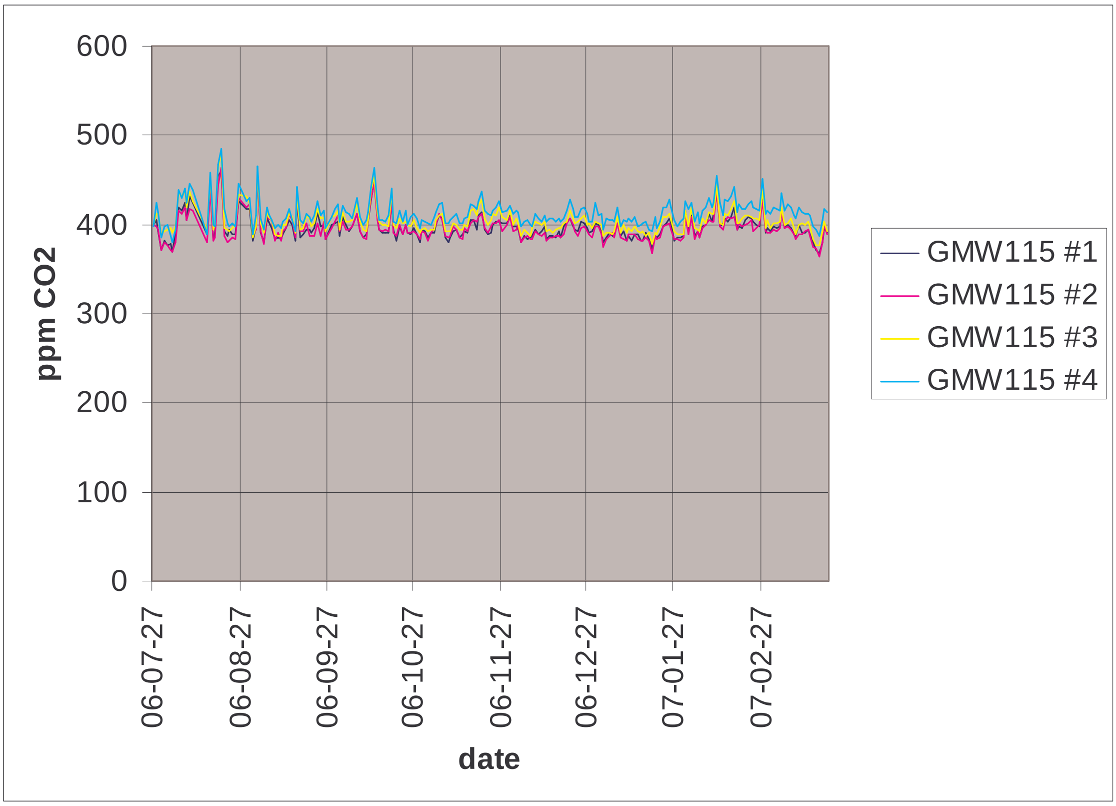

Figure 6. CO_2 readings from the tested units for an ~8 month period, raw data

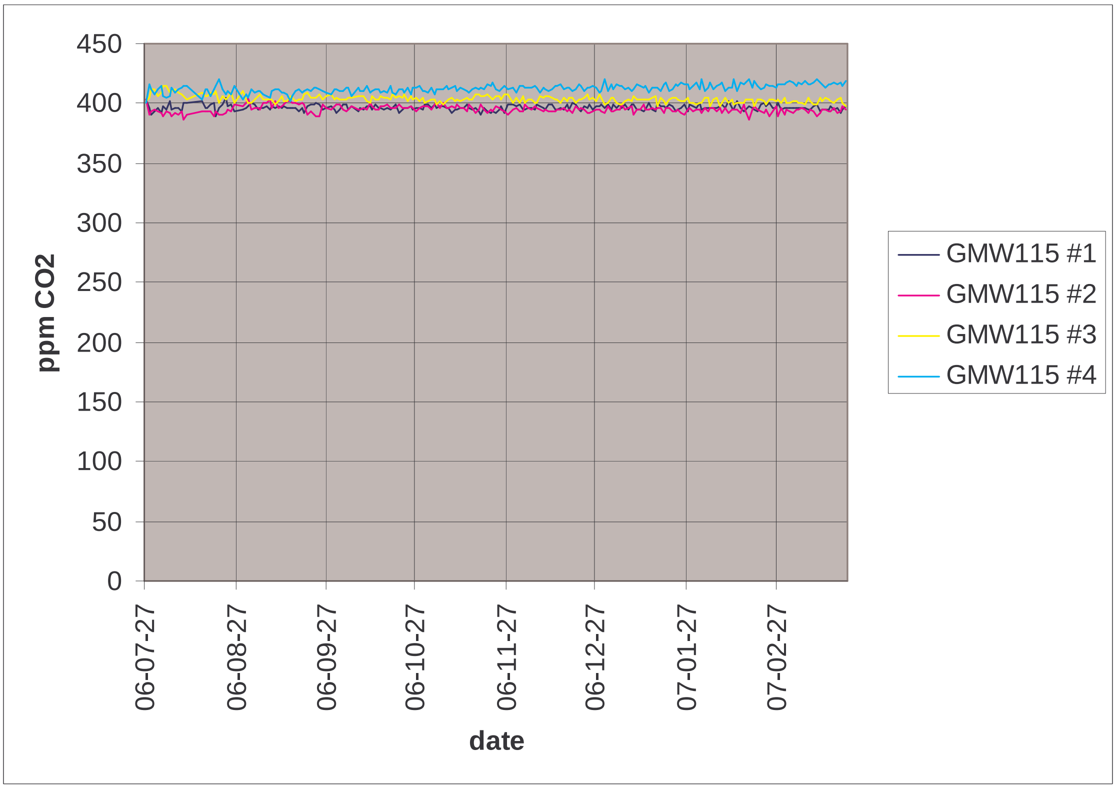

Figure 7. CO_2 readings from the tested units for an ~8 month period, data compensated for variations in the background CO_2 concentration.

In a closer analysis of the data the devices exhibit drift in the readings that vary from 0 ppm (device #1) up to 7 ppm (device #4) over the measurement period. Given a typical accuracy specification for an HVAC CO_2 transmitter (at ambient concentration) of 30-60 ppm, and a long term drift specification for the products in question of 20 ppm/yr, it is to be noted that the drift is well within specified limits and supports the long term use of this type of instruments in Demand Controlled Ventilation applications. A further notion is that in this type of devices the drift phenomena are typically not linear but tend to be faster in the early life of the instrument and then even out in a longer term.

DISCUSSION

Intermediate results from a long term stability study for NDIR CO_2 sensors for Demand Controlled Ventilation applications have been reported. An absolute CO_2 concentration measurement is achieved with a simple sensor structure with no moving parts or software compensation algorithms. In the light of the results presented here the devices show a very adequate performance for the DCV application.

Case study of the shopping centre HVAC systems electrical loads

Andris KrumiHš M.sc.ing., Egils Dzelzitis Dr.hab.sc.ing., Arturs Lešinskis Dr.sc.ing.

Riga Technical University, Latvia

Corresponding email: andris.krumins@lafivents.lv

SUMMARY

This paper reports on energy aspects of the HVAC systems in shopping centre. Presented analysis of the electrical loads shows possibilities to increase energy efficiency of the HVAC systems and to keep desired indoor air quality. This particular case study is done in the shopping centre located in Riga, Latvia, which is 2-floors building with the total area of 22,000 m^2. The shopping centre lighting loads are more than 50 W/m^2, which requires 1.1 MW cooling capacity in summer and just 270 kW heating load in winter.

Building management system (BMS) software stores trendlogs of all HVAC system parameters such as status of fans, fancoils, chillers, pumps and electrical heaters. The analysis of the trendlogs is fulfilled for estimation of energy consumption of the HVAC systems and for optimisation of electrical loads.

INTRODUCTION

The main objective for HVAC and control designers was to maintain 21°C indoor temperature all year round using demand controlled ventilation system (maximum air exchange rate = 1.5) and hydronic ceiling fancoil with cooling / heating system. During summer water is cooled with two chillers, during winter water is heated with electrical heater. There are no air heaters in the air-handling units. The air-handling units maintain supply of air temperature by exhaust air heat recovery and variable air volume by frequency converters. Each of six air handling units serves to an independent zone of the shop. Control is based on CO_2 gas level and temperature analysis. Hydronic cooling / heating system is splited to the same zones for maintaining the same zone temperature. All these systems are controlled from BMS. Premises are open without separated rooms, except some small office rooms on the second floor. Case study of electrical loads is carried out in January 2007 from 7.00 – 22.00, requirements for indoor climate is 21°C.

METHODS

BMS trendlogs are saved to computer as csv files. With application of Microsoft Excel and Microsoft Visual Basic these data are processed and saved as “mat” files for calculation purposes with “Matlab”.

LIGHTING HEAT POWER

The total amount of installed lighting heating power is 50 W/m². Lighting is switched on from 10.00 in the morning and turned off at 22.00. During the night there is a night lighting with heating power of 5 W/m².

AIR HANDLING UNIT ELECTRICAL DATA

Six air handling units are installed in shopping centre.

Table 1. Air handling units data

Air handling unit with the number of zone	Electrical power of supply / exhaust fans, kW	Total pressure, Pa	Air volume of supply / exhaust fans, m^3/h	Temperature efficiency of rotating heat exchanger, %	Humidity efficiency of rotating heat exchanger, %
AHU1	11 /11	891	25000	72	63
AHU2	11 / 11	891	25000	72	63
AHU3	18.5 / 18.5	842	40000	74	66
AHU4	18.5 / 18.5	842	40000	74	66
AHU5	4 / 4	702	10000	73	65
AHU6	4 / 4	702	10000	73	65

Air handling units are equipped with frequency converters. Rotating heat exchangers are rotating proportionally according to necessary supply of air temperature. Air handling units work daily from 7.00 – 22.00 Normally air handling units work with 75% air volume.

AIR HANDLING UNIT CONTROL ACCORDING TO CO_2 LEVEL IN SHOPPING PREMISES

Shopping centre is divided into six zones. Each air handling unit serves to an individual zone. CO_2 gas detectors are located in each zone, except zones 5 and 6, which work from one CO_2.gas detector, air-handling units' assignment is not to allow the CO_2 level increase more than 800ppm. CO_2 trendlogs show, that only in zone 1 and in zone 2 CO_2 increases more 800ppm (figure 1). These zones are located near to the main entrance, and require to be ventilated more than other zones.

Measurements show that CO2 level is a bit various from day to day and it increases more than 800ppm every day in zones 1 and 2. Average calculations of CO_2 gas level in each zone show, that CO_2 increases during the day and ventilation system does not allow it to overreach 800ppm.

From (figure 1) we can analyse that only AHU1 and AHU2 partly work with 100% of air volume because of increased CO_2 level in zones 1 and 2. Zone 1 has increased CO_2 level about 7h a day, and it means that AHU1 works on maximum speed 7 hours a day, 9 hours a day AHU1 uses 70% of its nominal power. Zone 2 has increased CO_2 level about 5h a day, and accordingly AHU2 5 hours a day works on maximum speed, 11 hours a day AHU2 uses 70% of its nominal power. All other air handling units are using just 70% of their nominal power.

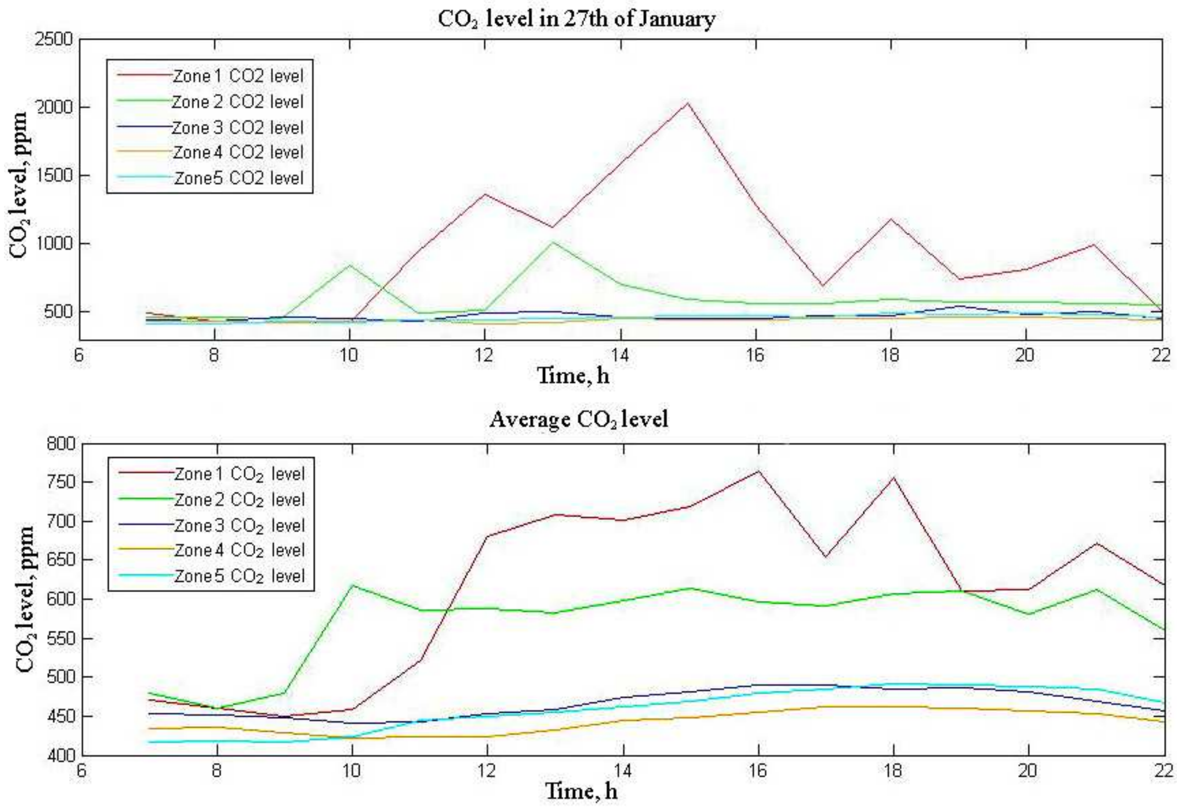

Figure 1. CO_2 gas concentration

CLIMATE IN JANUARY

Climate is measured in shopping centre with relative humidity and temperature sensors. Absolute humidity and enthalpy are calculated [3].

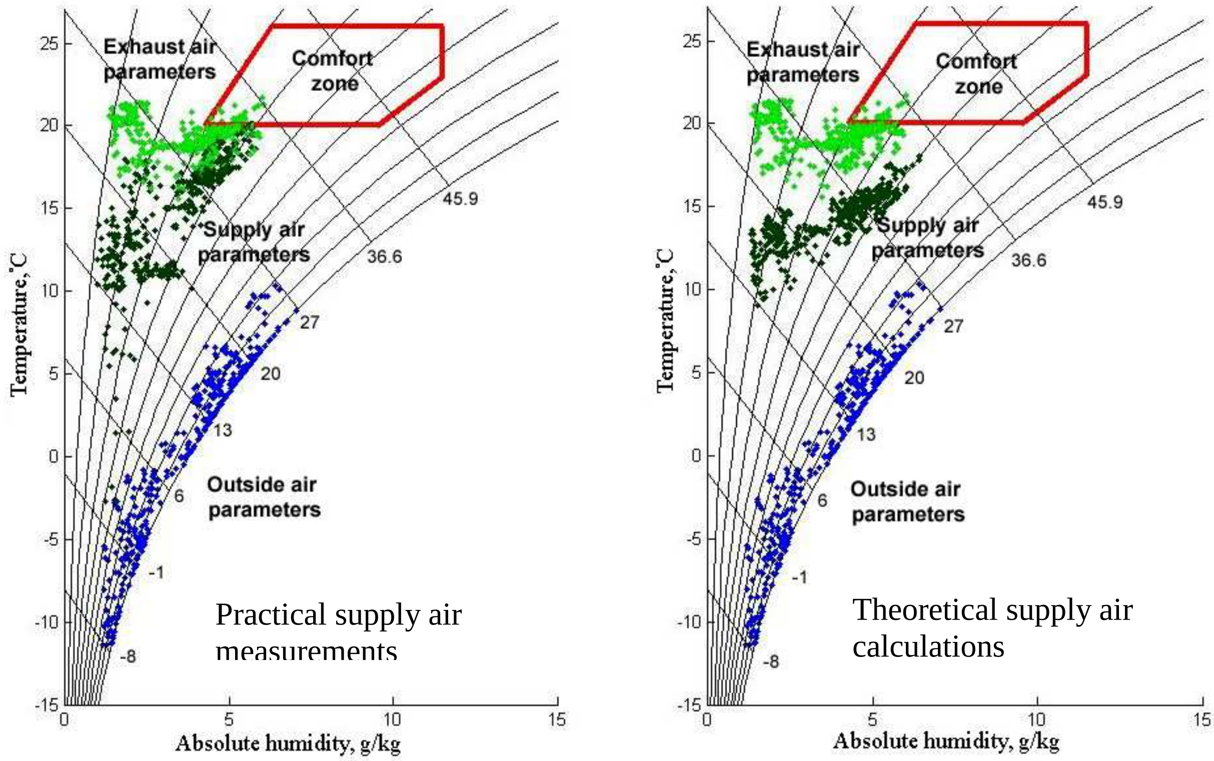

Figure 2. Air handling unit AHU2 supply and exhaust air analysis.

On the left side of Figure 2 there are data from AHU2 measurements (BMS stored trendlogs). Ceilings of premises are 6 m high, chosen air diffusers distribute air evenly, that allows to limit the supply of air temperature of air handling unit to 10 C°. On the right side of Figure 2 there is a theoretical work of air handling unit No. 2. if the speed of heat exchanger wheel is 100%. Such theoretical analyze allows us calculate air handling units effect on cooling the premises. Practically the speed of heat exchanger wheel depends on zone temperature and zone setpoint. Analyze of the average speed of air handling units' heat exchanger wheels is done in Figure 3. Temperature in premises is heated with lighting, cooled or heated with hydronic cassettes. Figure 3 shows, that heating loads are not even in zones. Air handling units No.5 and No. 6. heat exchangers work on maximum temperature efficiency, as zones No. 5 and No. 6 requires heating because of less lighting loads in these two zones. Average exhaust of air temperatures shows that heating capacity of building is enough to keep the necessary supply of air temperature.

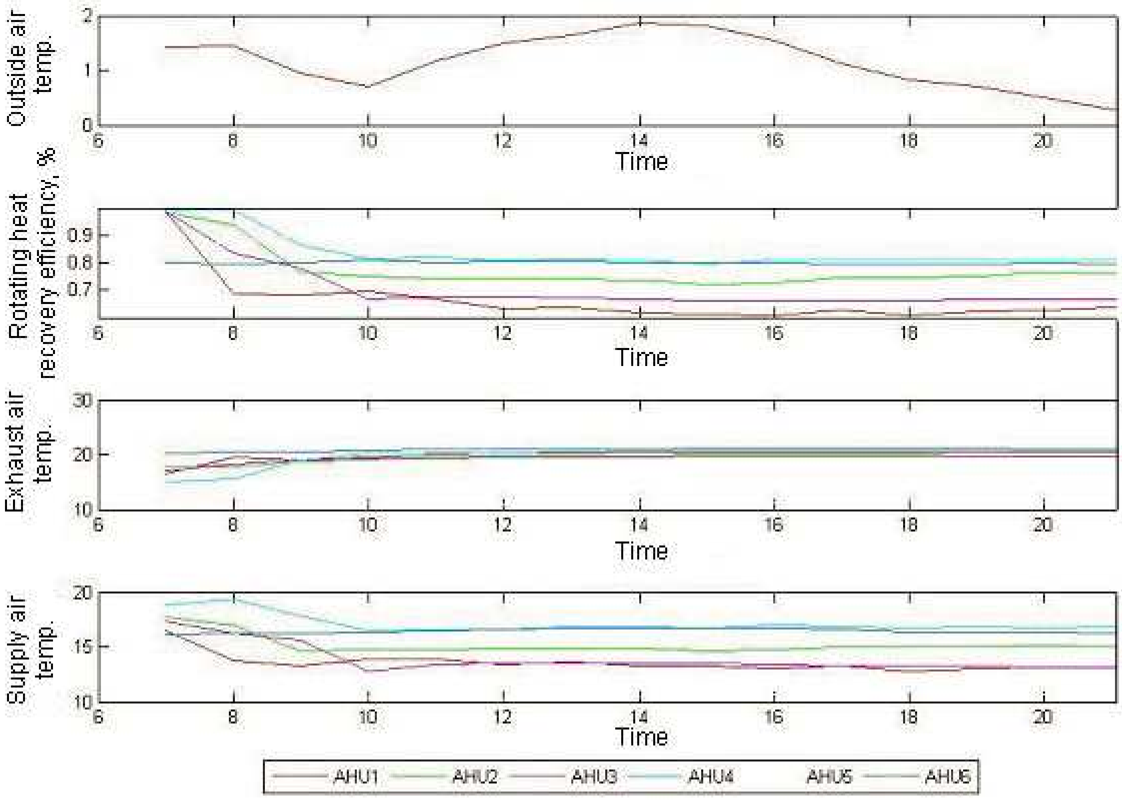

Figure 3. Air handling units average parameters in January.

Air handling units consume just electrical power, as they are not equipped with heating or cooling coils. Also as supply air temperatures are less than exhaust air temperatures, air handling units are cooling premises.

Table 2. Power analysis of air handling units

Air handling unit number	Air volume m^3/h	Electrical power, kW	Cooling power of the unit, kW
AHU1	21 560	15	50
AHU2	20 620	13	48
AHU3	30 000	15	69
AHU4	30 000	15	69
AHU5	7500	3,2	17,2
AHU6	7500	3,2	17,2
Total	**117 180**	**64**	**270**

Average supply and exhaust air temperature and humidity parameters gives information about heat and humidity emission in building premises. We can see (Figure 4) that inside air humidity depends on an outside air humidity, because humidity emission from people is quite small.

Table 3. Average supply / exhaust air parameters

	Average air temperature °C	Average air humidity, g/kg	Enthalpy kJ/kg
Supply air	14,88	3,42	23,61
Exhaust air	19,45	3,76	29,09

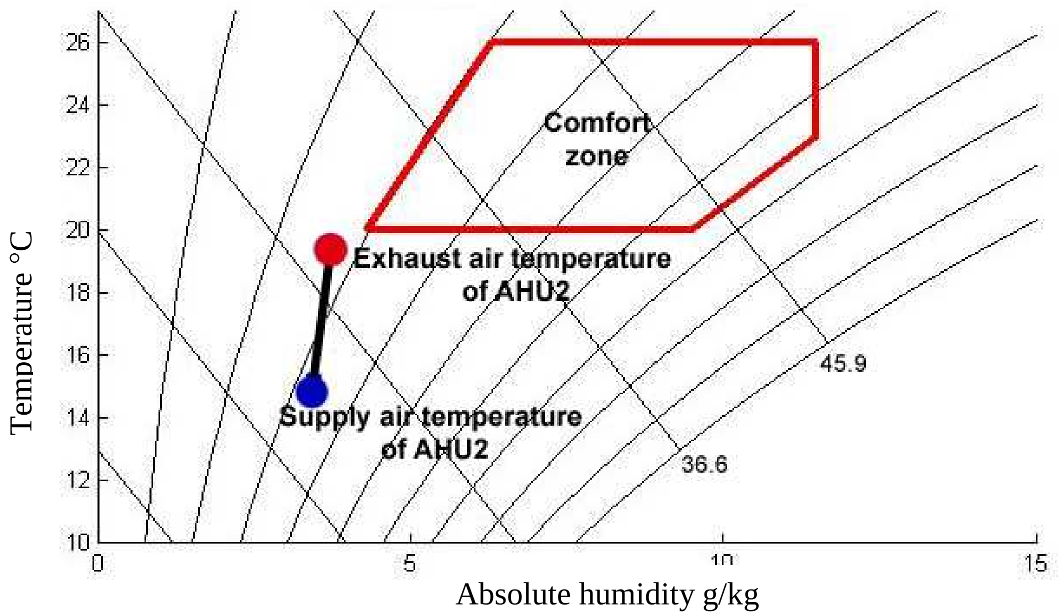

Figure 4. Graphical analysis of supply / exhaust air parameters.

Measured room temperature is a little higher than exhaust of air temperature, because technical rooms are located on the roof, air ducts to roof go through outside. Despite of air ducts insulation, exhaust of air has temperature decrease in 2°C. Such decrease of temperature decreases supply air temperature by 20%. Perfect insulation of building and air ducts could decrease average ventilation system cooling power of premises for 50kW in January.

HYDRONIC COOLING / HEATING SYSTEM

Hydronic system consists of:
Chiller No.1 with free cooling option, cooling power is 820kW (free cooling power is 387kW), electrical power is 315kW ; chiller No.2 without free cooling option, cooling power is 338kW, electrical power is 150kW; Electrical heater is 270kW, 3 steps control. Premises are heated / cooled with 180 units of ceiling cassettes, which are splitted evenly inside the building. Maximum cooling capacity of each ceiling cassette is 7kW.

During winter time, Chiller No.2 is switched off. Chiller No.1 works according to the time schedule from 10.00 – 21.00 if there is a requirement for cooling. Electrical heater is turned on, when there is requirement of heating in some zone. Before turning electrical heater on, Chiller No. 1 is turned off. Control of ceiling cassettes is divided into 6 zones, each zone consist of 30 units of cassettes. Change of speed and temperature control is adjusted from BMS for each zone. Temperature is regulated with one two-way valve for each zone. Theoretically maximum heating capacity of each cassette is 1.5kW, if all cassettes work with the same speed and two way valves are open. Practically heating power of each zone depends on the situation in other zones. Each chiller accumulation tank has its own circulation pump of 5,5kW with electronic control. Pump water flow corresponds to chiller requirements and pump work together with chiller. Three parallel working pumps with frequency converters (each 15kW) are installed after accumulation tank. Control of pumps is done with frequency converters for maintaining necessary pressure difference of 115Pa.

BMS trendlogs shows that to maintain 115Pa it is enough to run just one pump with 33Hz, which corresponds to 61m^3/h.

Cooling / heating power calculations:

$$Q = V \cdot \rho \cdot c \cdot \Delta T \, , \qquad (1)$$

where V is water flow (m^3/h), ρ is water density (1000 kg/m^3), c is water heating capacity (4.18 kJ/kg*K), ΔT is water temperature different between supply and return pipes.

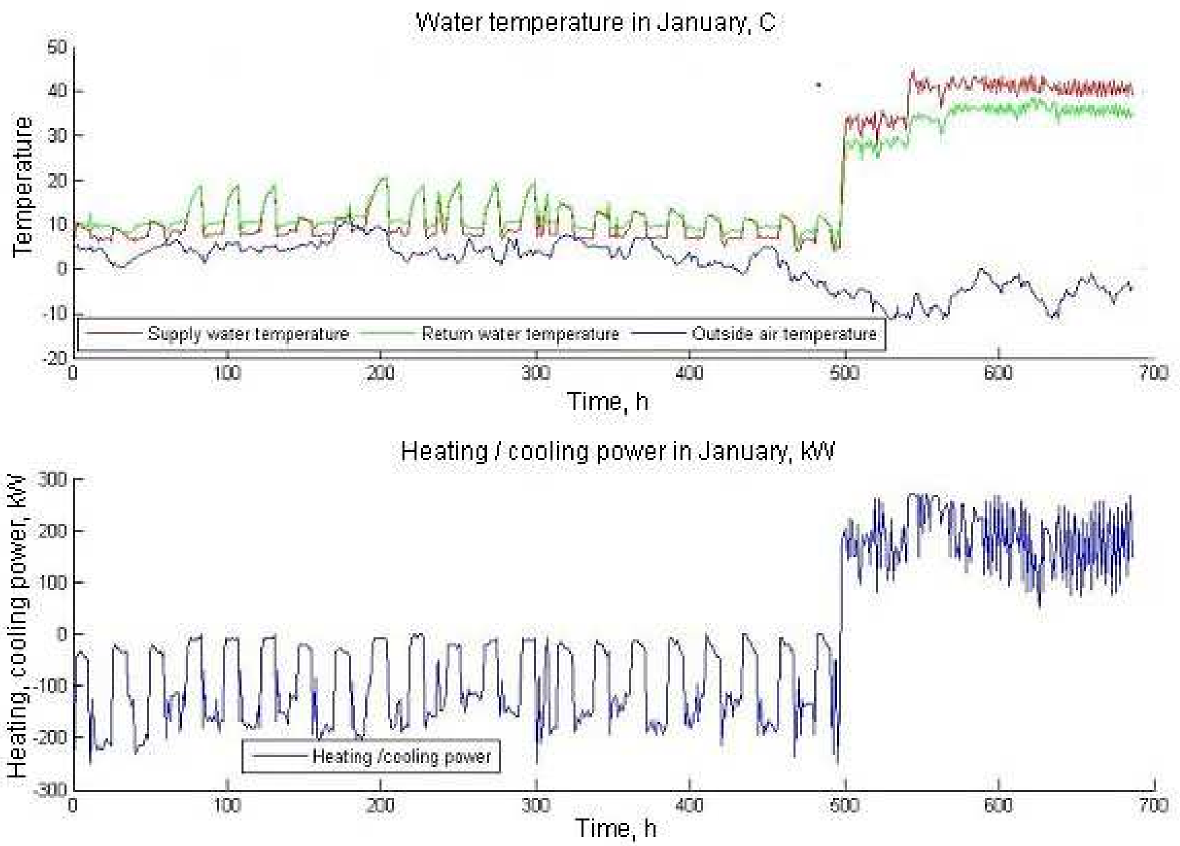

Figure 5. Heating / cooling power analysis in January.

Switching from cooling to heating is done automatically (figure 5), when the outside temperature is less than –5 °C. At this temperature there is a requirement for heating zones No.4-No.6. Shopping centre is heated also during nights. During days heating load is decreased because of high lighting loads.

RESULTS

Results show that it is possible not to use heating coils in air handling units for ventilation of shopping centers with high lighting loads. At least 30% of consumed air handling unit power can be saved with installation of CO_2 gas detectors. During design phase it is not possible to predict number of people in shopping centre, that's why air exchange volume can be higher that necessary. Inside absolute humidity level depends on outside humidity, measured process direction (figure 4) of supply / exhaust air can be used in design of shopping centers ventilation systems. Different lighting loads in building forces to use electrical heater, when outside temperature is below -5°C. Following research will investigate more deeply necessity of switching between cooling and heating. The air temperature in premises is well controlled with air handling units together with hydronic heating / cooling system and the air temperature in premises is distributed almost evenly in all zones of building.

HVAC electrical loads in shopping centre during winter time is about 70W/m².
Practical investigations show, that –5°C is a temperature, where zone 1 and zone 2 still needs to be cooled, but zones 4 – 6 need to be heated. This is the main reason, why it is not possible to keep temperature in premises just with ventilation system therefore fast switching between cooling / heating system is necessary.

CONCLUSION

Control system, which is used for ventilation, air conditioning and heating system automation in shopping centre, is best designed with effective supervision software. Energy analysis cannot be done with temperature sensors, but there are also others requirements for installation of relative humidity transmitters for outside, supply and exhaust airs. Electrical energy meters for air handling units, chillers, electrical heater and lighting electrical consumption with connection to building management system could give very important information for electrical loads.

SUMMARY

The thermal storage systems have as main objective the rationalization of the demand of electric energy, due to the use of it in periods of the low demand, beyond the reduction of the initial investment. One of the means more used for accumulation of latent heat is the ice, due to its bigger capacity of storage of energy in a single volume and also because it always casts in a fixed temperature. The conventional logics of control are widely used in accordance with the necessity of the process. In this work it was used thermal storage with ice bank and it was evaluated the efficiency of the performance of controllers On-off and PID in the control of the temperature of three different environments, after ambient disturbances not measured of thermal load provoked by the variation of the external ambient temperature and/or equipment operation, activities of people and others.

INTRODUCTION

The GREGOR *et al*. [1] showed that the equipment and systems that supply thermal comfort and internal air quality for commercial environments, consume about 42% of the used energy total in the majority of conditional environments, therefore they are the main point in the discussions on energy consumption.

A thermal storage system is that one that exchanges heat with the accumulator mean during the lower demand periods, storing energy at low temperature, “cold”, to be used in the higher demand periods [2].

The ways commonly used for latent heat accumulation are: water-ice and phase change materials (PCM). These ways differ in the amount of stored energy per volume unit, in the temperature in which they store “cold” and “heat”, and in the physical conditions of the stored energy [3].

In the case of thermal storage with ice, the frozen water temperature which flows in the air conditioners is lower, reducing the ventilated air outflow for the environments, consequently reducing the costs of the fans and in the ducts, what it allows an environment humidity reduction and an increase of the comfort and the interior air quality [4].

The main objective of a control system is to make the process operate in a steady way, in accordance with the established values for process conditions and variables [5]. The used control logics can be conventional or not conventional, and the conventional ones are On-off, P, PI and PID types, and they can be very used depending on the process necessity [6].

The buildings thermal automation increases potentiality the energy management, through the supervision graphical screens implementation that provide a general monitoring of the system, resulting in a better control of the energy use and in a higher thermal comfort to its occupants.

Considering what have been showed, the experiment proposes to evaluate the temperature behavior of the rooms 1, 2 and 3, using the PID and On-off control logics with 0,5 ºC band in operational conditions of commercial environments. These environments will be submitted to changeable thermal load, which it's directly related to the external environment, with its occupants and the materials inside the rooms, whose influence in a thermal load increase.

METHODS

In this work the ice bank was used as the thermal storage system, for temperature conditioning of three different environments. Its load was done during the night, when the refrigeration system cooled a propylene-glycol solution that was pumped internally to an immersed coil in a tank with water. Then ice was formed externally on the coil surface, resulting in a mixture of ice and water at 0ºC.

During the day, the water of the tank was pumped to the environments, where the fan-coils were located, which their function was to do the distribution of the "cold", proceeding from the frozen water, in a uniform way to all the environments. The scheme of cooling water coming from the city treatment stations and the distribution of the water frozen to the study environments can be seen in Figure 1.

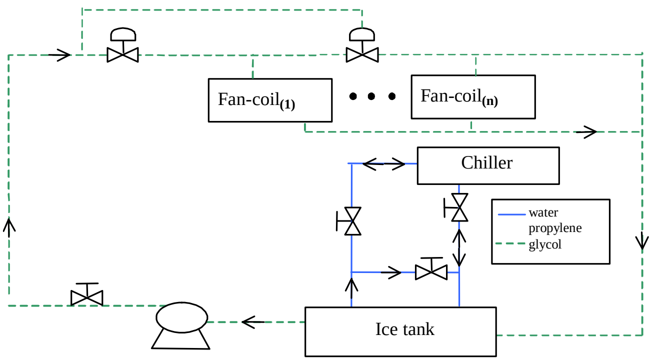

Figure 1 - Schematic diagram of the thermal storage circuit and frozen water distribution.

The temperature of each environment was controlled through On-off controllers with 0,5 ºC band and PID, where those acted directly on the control valve of frozen water outflow. This frozen water is proceeding from the ice tank, and then it's pumped and sent to the study environments, in accordance with the necessity for the desirable temperature maintenance. The PID was tuned by the Ziegler Nichols Reaction Curve method, where it makes step disturbances in the manipulated variable and observes the received reply from the controlled variable.

The On-off controllers evaluation with 0,5 ºC band and PID was made after the ice bank load, with disturbances in the frozen water distribution, then verifying the stabilization of the rooms temperatures around the set-point. These disturbances were performed during the commercial period (8:00 A.M. to 18:00 P.M.) and the imposed thermal load to environments was proceeding from the temperature variation of the external environment, daily activities of the people and equipment.

RESULTS

After the non-measured disturbances with thermal load for all the environments, and both On-off controllers with 0,5 ºC band and PID, it was gotten the internal temperatures behavior for each environment. Figure 2 shows the internal temperature behavior of room 1 under controller PID performance.

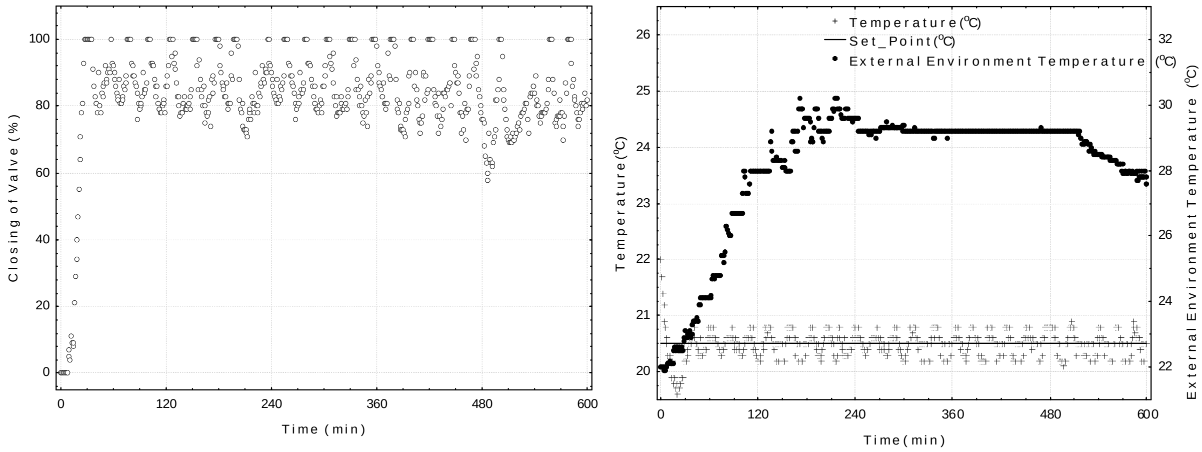

Figure 2 - Internal temperature behavior of room 1 under controller PID performance.

The beginning of the experiment occurred with the definition of the room temperature set-point in a value below the environment value. Thus the controller action, in the beginning of the environment cooling process, was opening the valve until its temperature to reach the desired value. Then the controller modulated the frozen water valve outflow so that the environment temperature was kept around the set-point, even with great variation of the external environment temperature.The Figure 3 presents the internal temperature behavior of room 2 under controller PID performance.

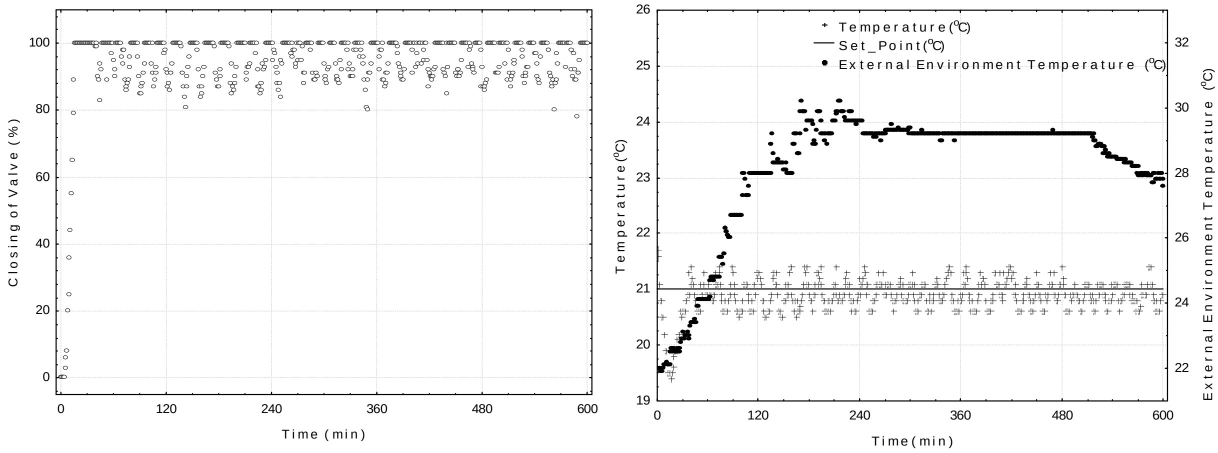

Figure 3 - Internal temperature behavior of room 2 under controller PID performance.

For the room 2 environment the controller performance is also observed so that its temperature reaches the desired initially value. However, there’s a better stabilization around the set-point due to the lower heat variation tax in this environment what it is directly related with lower solar incidence index and consequently lesser control valve modulation.

Figure 4 shows the internal temperature behavior of room 3 under controller PID performance with the respective performance of its control valve, which allows higher or minor frozen water outflow in accordance with the measured error by the controller.

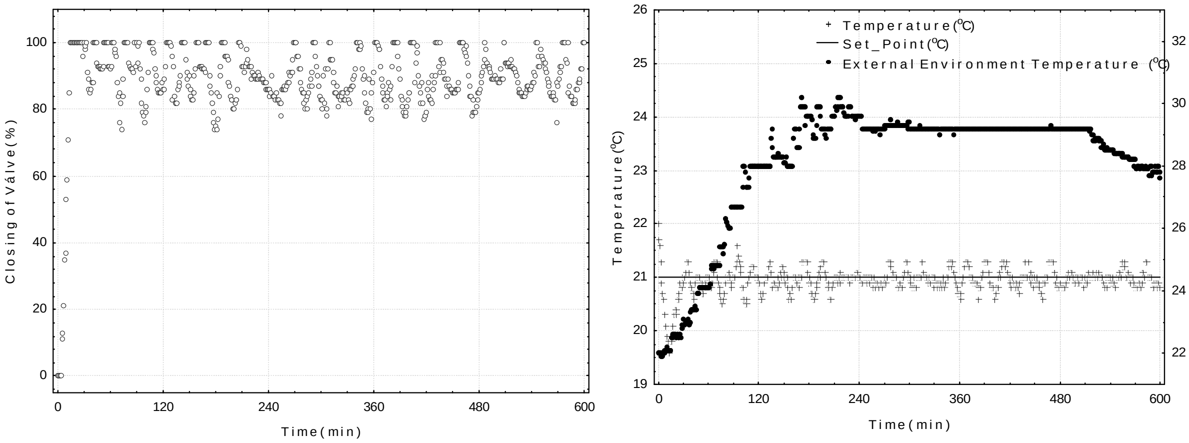

Figure 4 - Internal temperature behavior of room 3 under controller PID performance of.

Initially it was verified the control valve opening with the release of a higher frozen water outflow, occurred in function of the great value of the error (desired value little real value) in the beginning of the process. That caused the reduction of the study environment temperature.

With the reduction of the temperature, the controller compared the desired value (set-point) with the real value resulting in lower error values. In this way, the control valve modulation started to be made thus the temperature of the study environment was kept oscillating around the set-point with small variations, during all the conditioning process. In Figure 5 the internal temperature behavior of room 1 under the On-off controller performance with 0,5 ºC band can be observed.

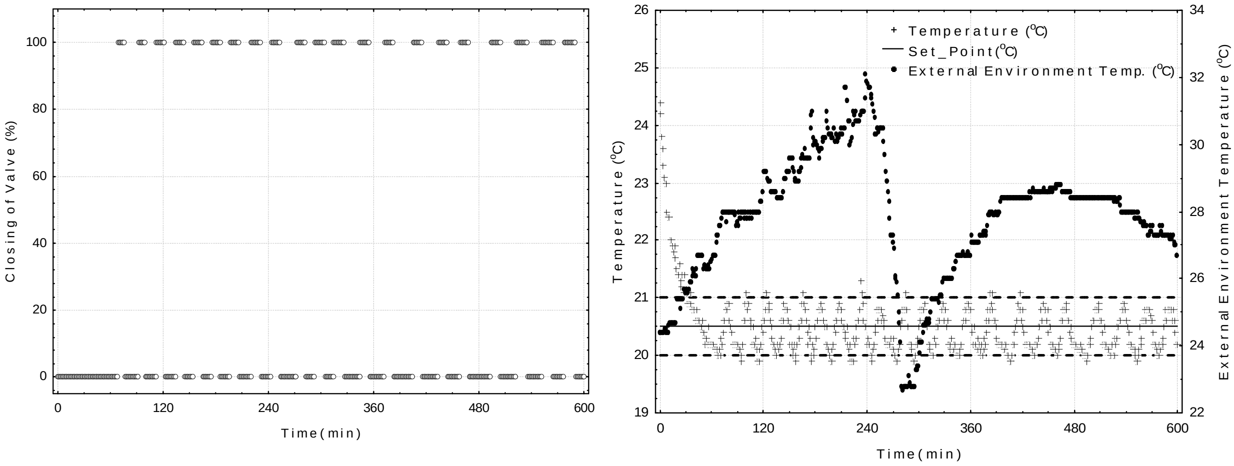

Figure 5 - Internal temperature behavior of room 1 under On-off controller performance with 0,5 ºC band.

It is verified initially that there’s reduction of the internal environment temperature until the desired value and then starts the modulation of the water frozen outflow control valve for the maintenance of the environment temperature around set-point. It can be evidenced that the controller acted in a way to stabilize the set-point between the established band, even with a brusque variation of the external ambient temperature in a certain day period, provoked by a sudden rain. In Figure 6 the internal temperature behavior of the room 2 under On-off controller performance with 0,5 ºC band can be observed.

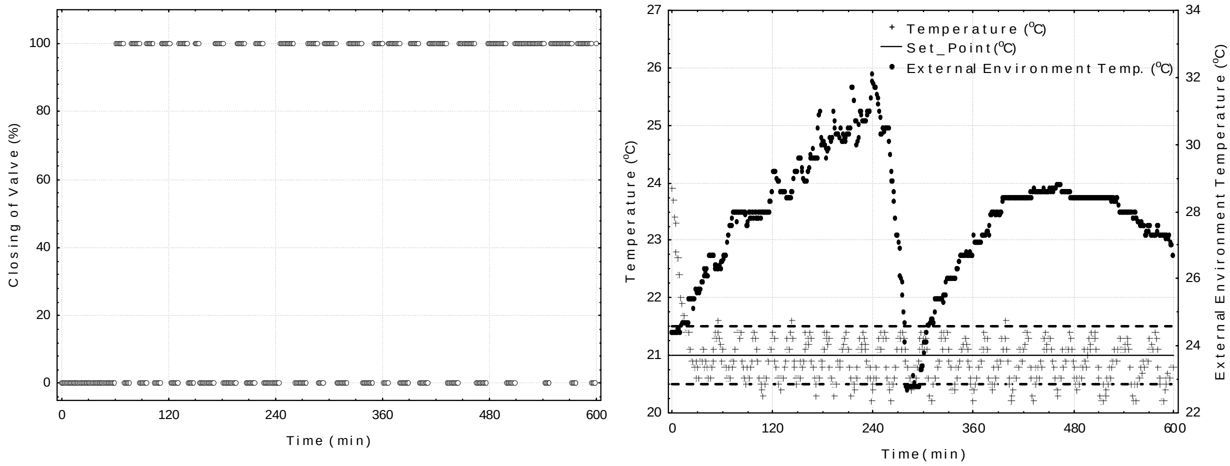

Figure 6 - Internal temperature behavior of room 2 under On-off controller performance with 0,5 ºC band.

For environment 2 it can be evidenced that even with the control valve of water outflow frozen closed during most of the experiment time, there was a higher temperature oscillation of this room comparing to room 1. It happened due to the proper controller, who is on-off type, where the temperature variation can reache values beyond the programmed band (0,5 ºC), and also due to a higher tax variation of the environment temperature, provoked by the greater number of people present. Figure 7 presents the internal temperature behavior of room 3 under On-off controller performance with 0,5 ºC band, with the respective performance of its control valve, that allows the passing of a higher or minor frozen water outflow in accordance with the existing temperature difference.

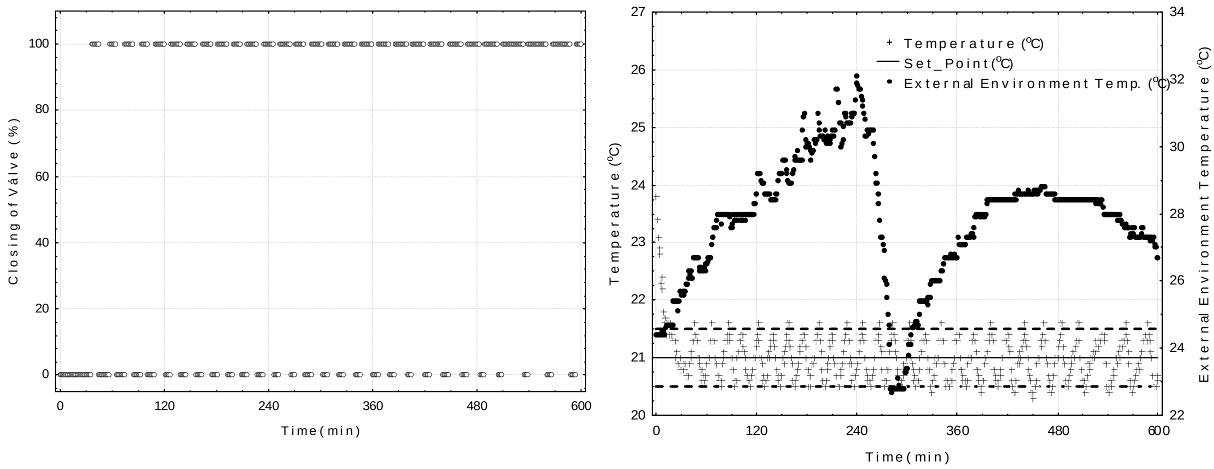

Figure 7 - Internal temperature behavior of room 3 under On-off controller performance with 0,5 ºC band.

It can also be observed for this experiment that in the beginning of the experiment the environment temperature was sufficiently high, needing a faster action of the controller in opening the control valve of frozen water outflow, thus remaining open for a higher time period, when compared with PID controller for the others experiments, that worked with conditions more suave f the internal and external ambient temperature.

DISCUSSION

From the results gotten for both controllers, On-off with 0,5 ºC band and PID, tuned by the Ziegler Nichols Reaction Curve method, can be concluded that those behaved in satisfactory way, keeping the environment temperature around the set-point with small oscillations, what it is perfectly acceptable, because the external environment that supplied most of the thermal load to the study environments that also suffered constants changes provoked by the reduction or increase of the solar light.

Applying a more detailed evaluation of the controllers efficiency as for the presented oscillations, it is evidenced the PID controller superiority, who makes a sharper adjustment around the set-point, keeping the environments temperature more steady, due to the exploitation of the particular characteristics of each action of control, in order to get a significant improve of the transitory behavior and in permanent regimen of the controlled system.

In case that the use of the controllers do not take into account a higher or minor oscillation of the temperature around the set-point (desired value), it's recommended the use of the On-ff controller with 0,5 ºC band, due to its easiness of implementation, lower operation cost during almost all tests period between the stipulated work band in accordance with the upper/lower limits of the control program.

Experimental Analysis of a Multi-zone Control System for Central Heating Plants

L. Cecchinato[1], A. Gastaldello[2], L. Schibuola[2]

[1]University of Padua, Italy
[2]University IUAV of Venice, Italy

Corresponding email: alegasta@iuav.it

SUMMARY

Central heating systems usually are driven by a control which modulates the inlet water temperature as a function of the outside temperature while no information about the actual needs of the different zones of the buildings are taken into account. In this way the maximum heat power is given with the extreme external temperature. A multi-zone control has been developed in order to satisfy the heating loads by considering the real needs. This system can be programmed to maintain different inside temperatures at different time. The control is auto learning and its fundamental aim is to reach the set point temperature as quick as possible, by using the maximum heat power, in order to heat only the air of the zone, without involving too much the building structures.
Thirteen schools of San Donà di Piave, a town near Venice, have been equipped with this system.
The results, presented in this paper, show an important energy saving which can be quantify in terms of a significant reduction of the normalized energy needs and fuel consumption. The energy saving for each school is between 12% an 30%. Obviously also the CO_2 emission is reduced. The economic performance is also very good. The financial analysis shows a pay-back period less then 4 years.

INTRODUCTION

In the interventions to optimize the energy consumption not enough attention is sometimes dedicated to the control system while, often, simple control techniques of the building energy plants can achieve good energy savings. In this paper the attention is focused in central water heating system.
Central heating systems usually are driven by an electronic control which sets the inlet water temperature as a function of the outside temperature while no information about the actual heating loads of the different zones of the buildings are taken into account. In this way the maximum heat power is always given when the design external temperature occurs. Moreover in the oldest buildings, no local controls are installed and all building zones are supplied with water at the same temperature, thus without considering the different local needs and gains. This kind of regulation causes high energy losses and local thermal discomfort conditions. Further, in some plant it is impossible to keep unheated an empty part of a building. Some improvements can be obtained using thermostatic expansion valves, but with these local control devices, no global building energy management can be developed. Better results can be obtained if the building inlet water temperature can be controlled knowing the real loads of the different zones of the building and if there is an auto learning system which can reduce the overall building energy consumption without causing local thermal discomfort [2, 4, 5, 7].

In this paper the performances of the heating plants, obtained in presence of this multi-zone control system and verified during a long period monitoring, are presented and discussed.

METHODS

The system is already on the market and it has been designed to easily set the desired internal thermal conditions by saving as much energy as possible and recording the energy consumption. This remote software system can be installed in every old and new building featured with a central heating plant to control the indoor temperature according to a scheduled plan and to compile the thermal energy bill.
The central unit consists of two main parts: one that interacts with the terminal elements in order to keep the set-point temperature and to count the energy consumption of the thermal zones and the other that drives the central boiler by considering the real energy needs. The central unit can manage up to 60 independent thermal zones but more central units can be linked together to manage buildings with more then 60 thermal zones.
In each thermal zone a converter should be installed to link the thermal zone with the central unit and to drive the terminal elements of the zone. If the temperature of a thermal zone can't be set by the user, only a temperature probe connected to the central unit should be installed, otherwise a local regulator, which is also featured by a temperature probe, to set the personal temperature scheduling should be present. This local regulator has priority in front of the default set point of the central unit. Each terminal element (i.e. a radiator) should be equipped with an electric valve to modulate the heating capacity.
The energy saving is obtained not only by controlling the internal temperature according to the real occupancy and loads of each thermal zone but also by taking "intelligent" decision. In fact this system can learn from the historical behaviour how to keep the set-point temperature without losing energy. For example, if a set-point temperature is reached before the programmed moment, the control system can modify the control constants to improve its accuracy and precision. In the same way, if a set-point temperature should be kept until a certain moment, the system can stop giving power before that moment by using the inertia of the building to keep the desired temperature. Furthermore the system can achieve more energy saving by modulating the water temperature flowing in the terminal element by considering the real heating needs and not on the basis of the outside temperature as the typical regulation method does. In this way, when internal temperature is close to its set-point value, the system operates with a low supply temperature even if the outside temperature is close to the design one.

RESULTS

This system has been installed in all the public buildings of San Donà di Piave, a town near Venice, North-East Italy. The attention in this paper is focused on thirteen schools which were equipped by this system in 1996/1997. The energy consumption data are available from 1991/1992 up to 2004/2005. These data include also the energy consumption for hot water, anyway for these kinds of buildings this energy quota is very small compared to the overall heating energy. The local heating season runs from October the 15th to April the 15th; for each season the heating degree-days (HDD), evaluated for an internal temperature equal to 20 °C, are shown in tab. 1.
In tab. 2 a number is assigned to each building, when a star [*] is present the school includes a gymnasium. The biggest building has a volume of 17701 m^3 while the smallest one has 882 m^3. In the second column, the boiler combustible is indicated: M is for methane and O for oil.

The Normalized Energy Needs (NEN) mean value, evaluated as the ratio between the primary energy annual amount of the fuel needs and the product of the heating degree-days by the building volume, is shown in the third column. The following column shows the weekly heating plant running hours: if a gymnasium is present, its heating hours are indicated after the symbol plus . As the energy consumption depends also on the scheduling of the energy plant finally the ratio between the Normalized Energy Needs and the number of hours is presented in the last column. This ratio is between 0.35 and 0.56 for eight buildings while for the other five buildings is between 2.24 and 3.06.

Table 1. Heating degree-days for the analyzed period

YEARS	HDD
91-92	2432
92-93	2573
93-94	2334
94-95	2353
95-96	2440
96-97	2341
97-98	2293
98-99	2469
99-00	2478
00-01	2225
01-02	2572
02-03	2503
03-04	2537
04-05	2496

The annual heating hours should be intended as a mean value in the monitoring period. In this way the effect due to different scheduling during different seasons can be considered not so significant. A comparison between the average seasonal values during the periods before and after the introduction of the control system is presented in figure 1 for each building.

Table 2. Characteristics of the heating plants of the buildings

N	COMB	NEN [kJ/GGm^3]	h week	NEN/h
1	M	94.31	40	2.36
2*	M	54.31	50 + 78.5	0.42
3*	M	58.67	50 + 86.5	0.43
4	M	79.48	32	2.48
5*	M	65.86	44 + 73.5	0.56
6	M	78.47	35	2.24
7*	M	60.10	50 + 72	0.49
8*	M	63.51	61 + 77.5	0.46
9*	M	48.69	61 + 76.5	0.35
10*	M	58.30	61 + 73	0.43
11	O	95.47	---	---
12	O	122.46	40	3.06
13	O	94.31	40	2.57

The bars in figure 1 show the Normalized Energy Needs mean value for every buildings evaluated before and after the installation of the control system while the line represents the obtained improvement in percentage of the same mean value. The biggest improvement is for building n. 6 (29.5%) while the smallest is for building n. 7 (11.9%), so for each building there is a remarkable energy saving. The biggest value for the Normalized Energy Needs before the control system installation is 138.3 kJ/m^3HDD for building n. 12 while the smallest is 52.4 kJ/m^3HDD for building n. 9. After the installation for the same buildings the values are 106.6 kJ/m^3HDD and 45 kJ/m^3HDD; these values are still the extreme ones. Building n. 9 is also featured by the smallest value for the ratio between Normalized Energy Needs and number of hours; this means that the small value is not due to a partial use of the building but to a good efficiency of the energy plant and to a good building envelope energy quality. It is important to underline that also for this building there is a 12% improvement; this means that, also in presence of excellent performances of the building - plant system, some further energy saving can be achievable by introducing more accurate control system.

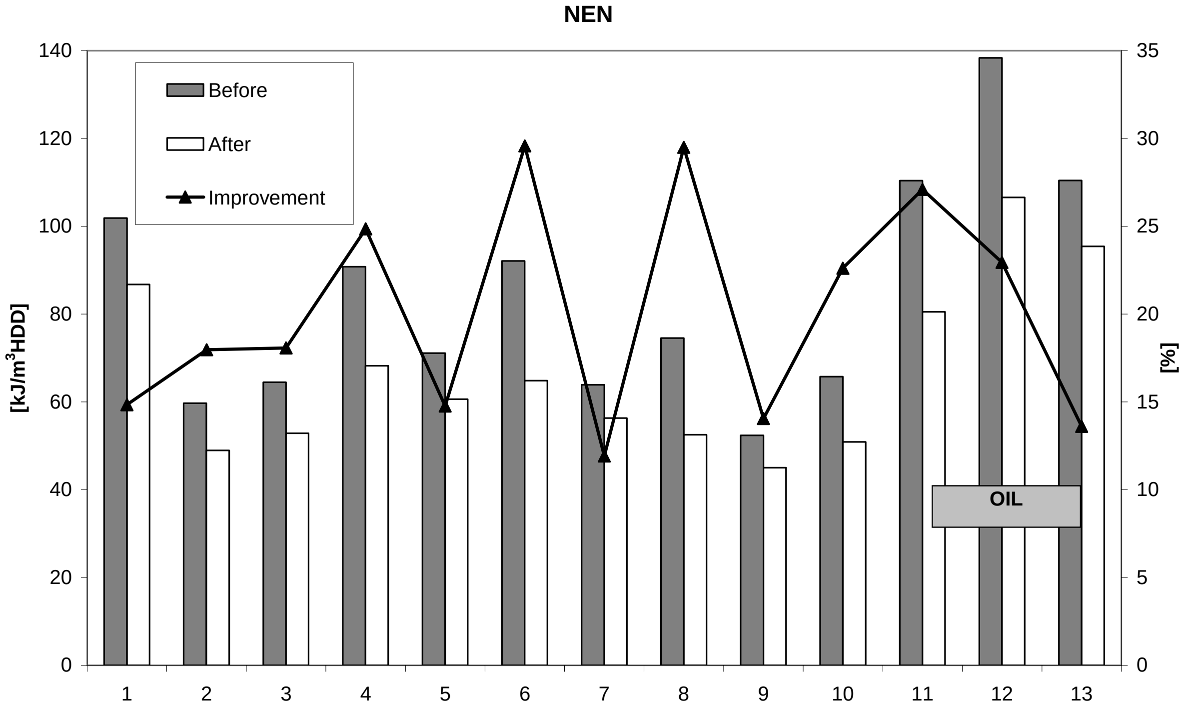

Figure 1. Comparison between average NEN values before and after the installation of the control system and their improvement in percentage for each building

Figures 2, 3 and 4 show the Normalized Energy Needs for each building for each season: the improvement from the 1996/1997 is evident; the trend is almost the same except for the oil boiler buildings.

Figure 5 shows the ratio between the energy consumption and the building size volume, expressed in m^3_{CH4}/m^3 for gas boiler buildings and l/m^3 for oil boiler buildings before and after the introduction of the control system. The line is the CO_2 emission reduction obtained by multiplying the consumption difference by the combustible emission factor (1.8 kg_{CO2}/m^3_{CH4} and 2.7 kg_{CO2}/l_{OIL}). The CO_2 annual reduction for all the buildings is about 180 tons.

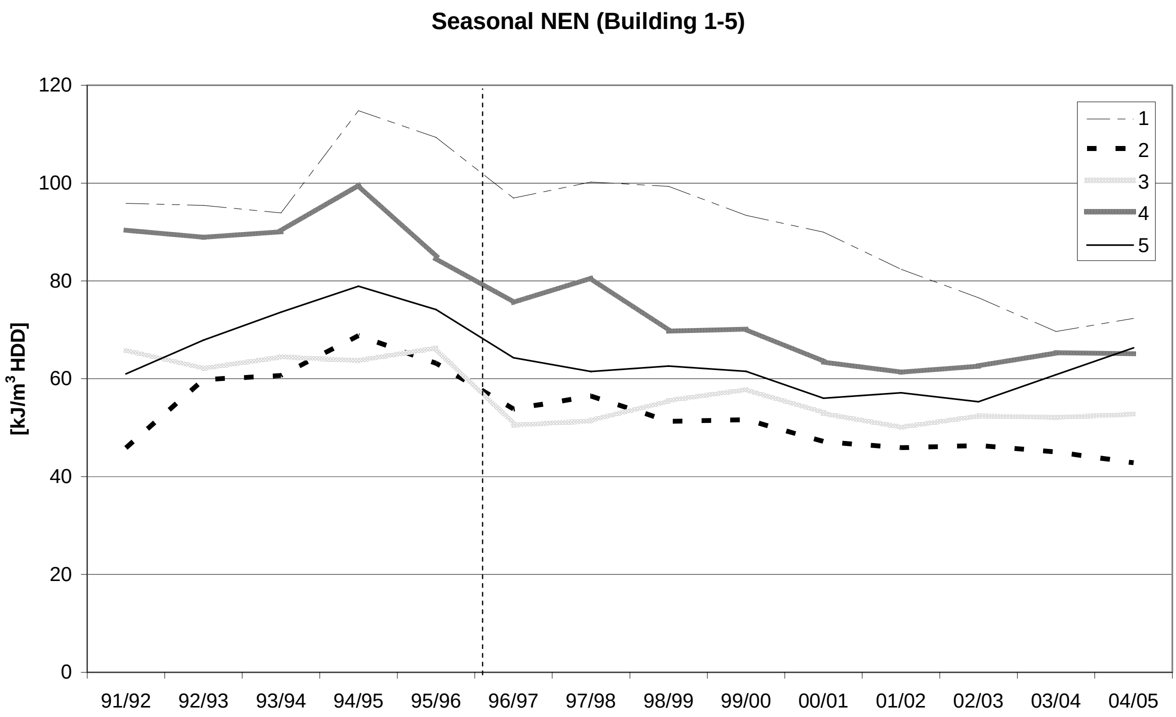

Figure 2. Seasonal NEN for building 1-5.

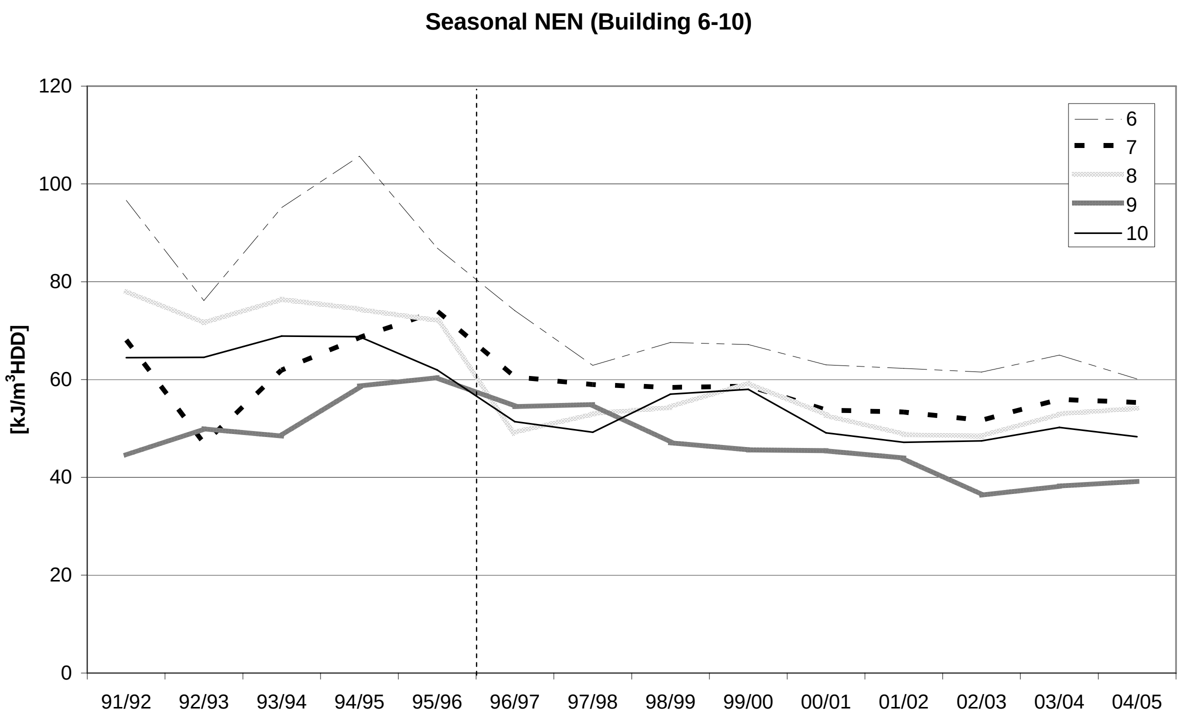

Figure 3. Seasonal NEN for building 6-10.

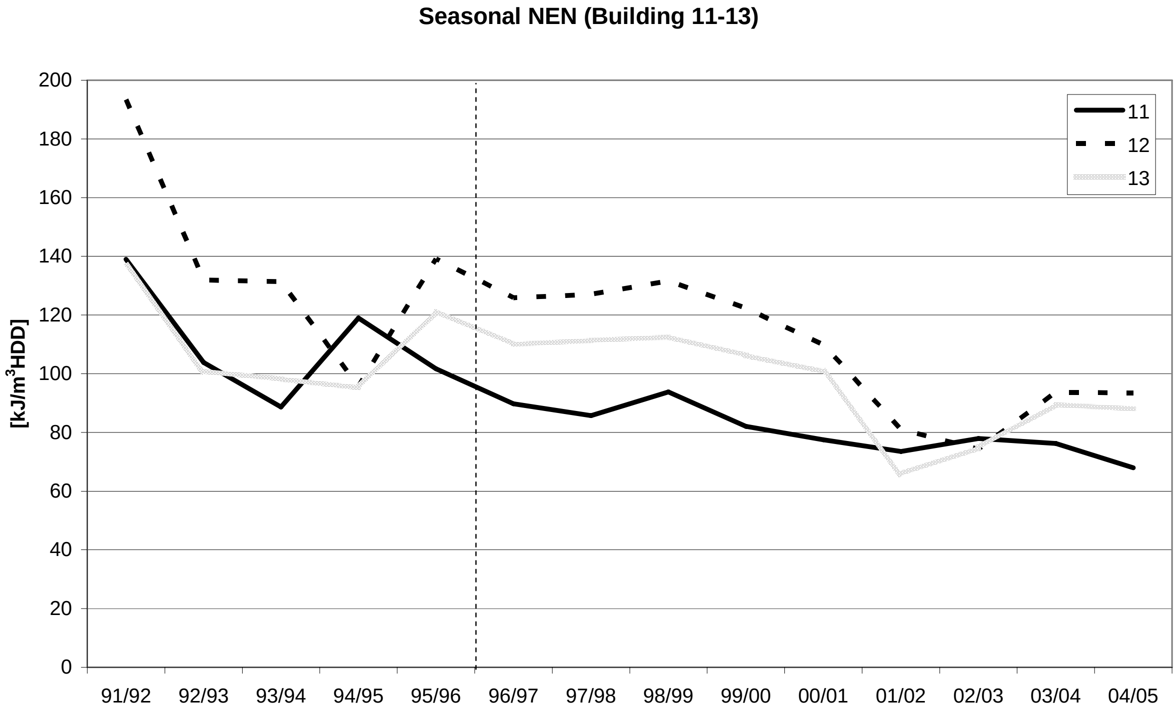

Figure 4. Seasonal NEN for building 11-13

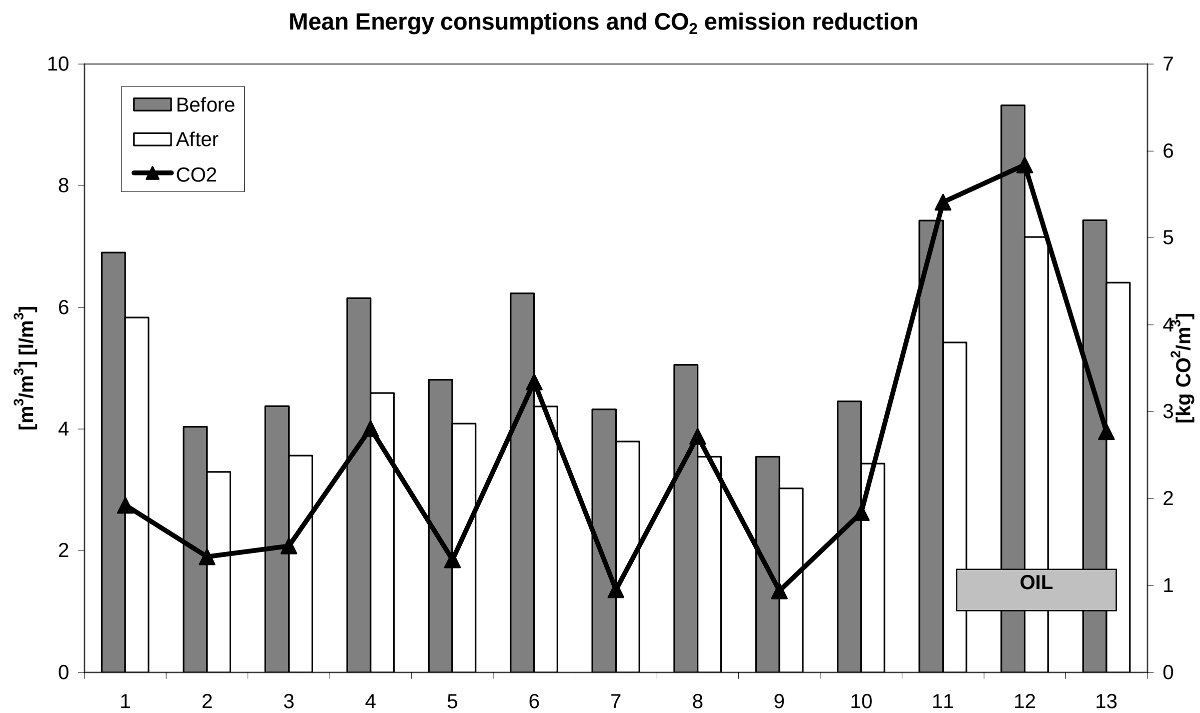

Figure 5. Mean energy consumptions before and after the intervention and CO_2 emission reduction for each building.

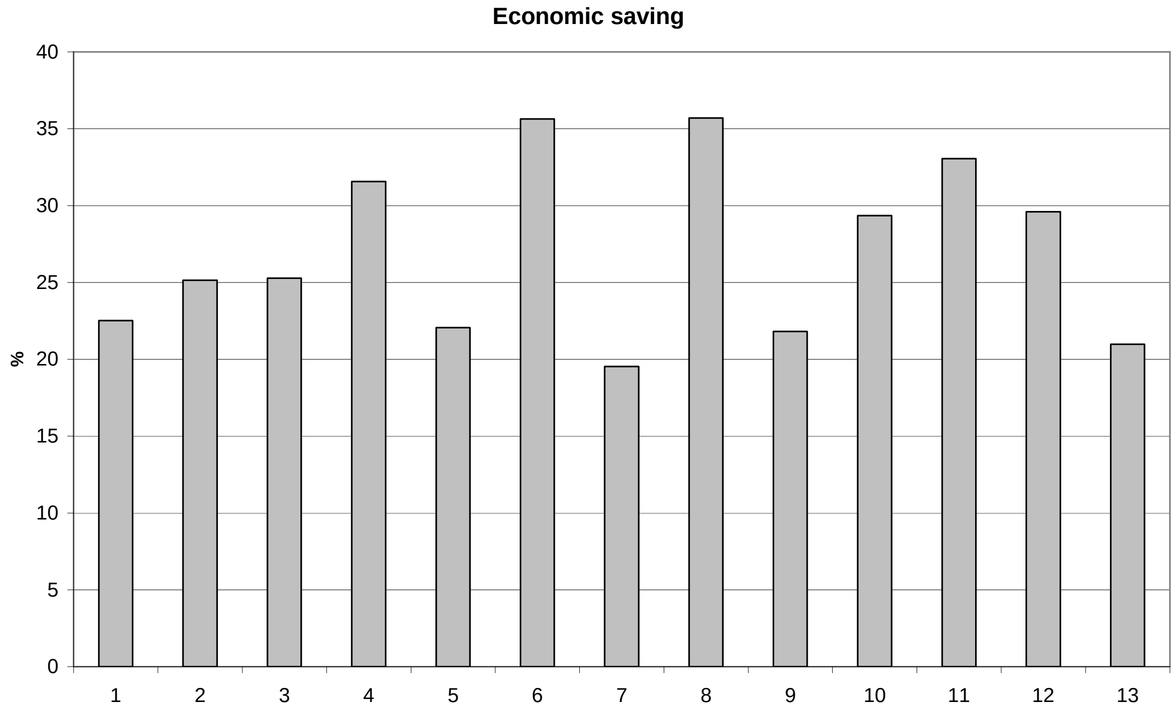

Figure 6. Economic saving in percentage for each building.

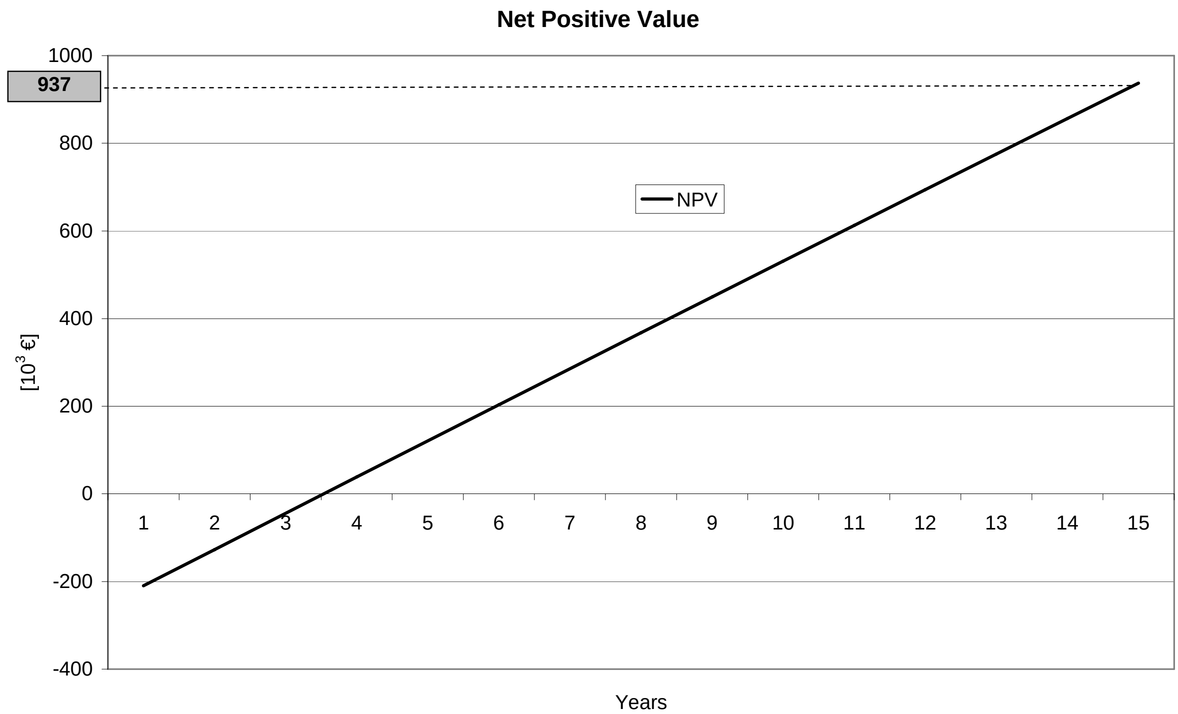

Figure 7. Net positive value of the total investment over 15 years period analysis.

Figure 6 shows the annual economic savings for each building, evaluated by considering the mean combustible reduction before and after the installation at the actual energy costs, which are 0.52 €/m^3_{CH4} + VAT and 0.92 €/l_{OIL} + VAT. It is important to underline that before the installation of the control system the VAT was equal to 20% while now it is equal to 10% as the system allows to obtain a tax reduction for its reduced environmental impact. The economic saving is between 19.5% and 35.7%.

Finally an economic analysis has been done. The cost to install the control system for all the thirteen buildings at the actual value is 293050 € while the annual economic saving for all buildings is 83296 €.

The analysis has been carried on for 15 years with an actual discount rate equal to 3.5% and a 3% inflation rate equal to the annual increment rate of the combustible cost. Figure 7 shows the trend of net positive value (NPV) for the 15 years analysis: the total value is 937197 € and the payback period is about 3.5 years while the internal redditivity rate is 27.7%.

DISCUSSION

A long time monitoring has been carried on to test a new system developed to control the internal temperature of multi-zone buildings equipped with central boiler. This control is auto learning and it is able to take intelligent decisions in order to save more energy as possible. Its fundamental aim is to reach the set point temperature as quick as possible, by using the maximum heat power, in order to heat only the air of the zone, without involving the building structures.

The system has been installed in thirteen schools of San Donà di Piave, a town near Venice. The results show a great energy saving which can be appreciated in terms of normalised energy needs and fuel consumption. The energy saving is between 12% an 30%. The annual CO_2 emission reduction is about 180 tons. The economic performance is also very good. The cost of the system can be approximated around 290000 € and it allows to save about 83000 € per year. Consequently the financial analysis shows a pay-back period less then 4 years and a total net positive value of 937197 € over a period of fifteen years.

A Study on static-pressure control method of VAV System in Intelligent Building

Wei Lifeng

Beijing Institute of Civil Engineering and Architecture, Beijing, China

Corresponding email: cnwlf0501@163.com.cn

INTRODUCTION

As the development of country's economic and the improvement of living-standard in China, there are more and more buildings which are making use of the VAV(Variable Air Volume) Air-Conditioning System to make people comfortable. The Intelligent Building is making use of system integration method to combine with the Intelligence Computer Art, Communication Art, Information Art and Architecture Art in an organic way, which has the characteristics of more subjects, more technologies, high technology synthesis and so on by the automatic monitoring to the equipment, the administration to the information resources and the information service to the user and to their Building's optimization grouping, with reasonableness, safety, high-effect, comfortable, convenient, nimble characteristics to integrate and adapt the information and social demand.

In the 1960s, the Variable Air Volume Air-Conditioning System VAV was born in America. The basic principal of the VAV Air-Conditioning System is simple, which is to satisfy the room's variable load by changing the airflow supplied to the room. As the VAV air-conditioning system is running in partial load most of the time, it can improve the device and system's energy utilization by reducing the ventilator's energy consumption of decreasing the airflow capacity. At present, the usage rate of West Country's VAV air-conditioning system in high Building is surpass 90 percent, however in China, the application of VAV air-conditioning system will be more and more as the serious problem of the High Building's energy consumption. VAV air-conditioning system is composed of AHU, fresh air/exhaust air/supply air/back air duct, VAV BOX, room temperature controller, VAV BOX is the most important part of this system.

VAV AIR-CONDITIONING SYSTEM PLATFORM TASK

The introduction of the system platform

This task's VAV system mainly adopts the WEBCTRL platform as shown in *Fig 1*. Following the agreement of BACnet protocol, under the condition of compatibility of the speed, cost and future frequency width extend ability, ALC corporation's control ware network adopts the structure of three layers, which provide different controller categories including the upper computer machine, router, the controller of I/O nods, integrated controller and the local implement wares and sensors in different layers. The controller of I/O nods is divided into three kinds which is corresponding to the three layer distribution structure, for example, the structure and application of cooling/heating unit, AHU, terminal devices and so on.

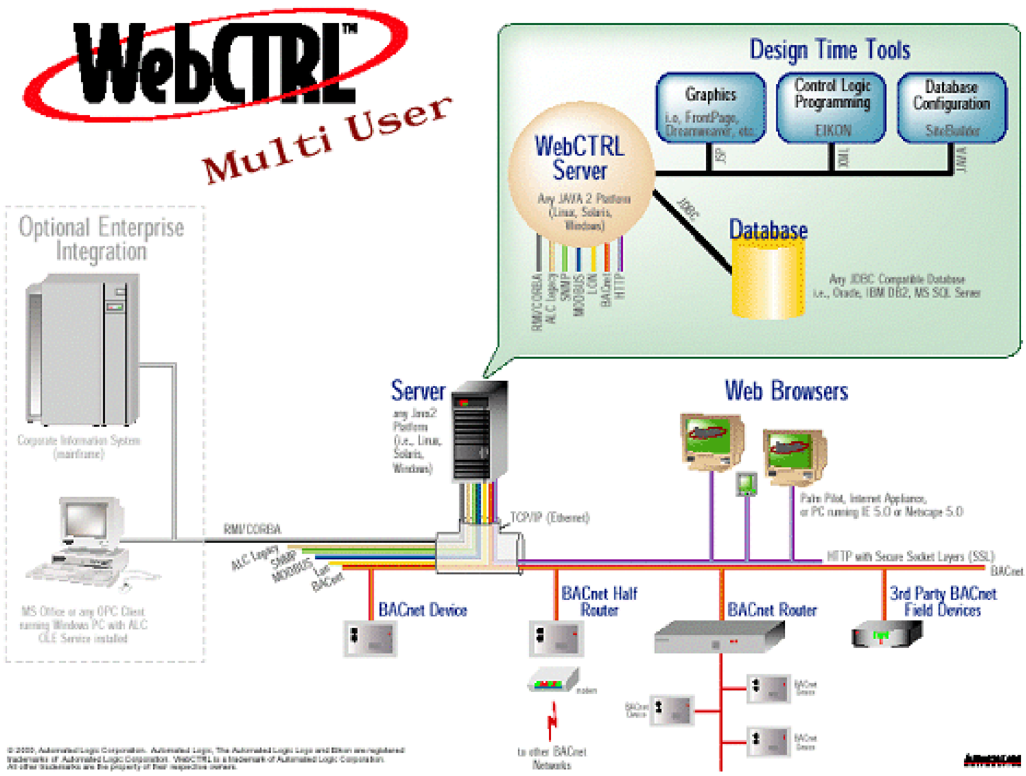

Fig 1 WebCtrl system structure picture

System Software

Building Automation Control System of ALC/WebCTRL^{TM} is composed of four parts:
(1) WebCTRL Server software it takes charge with the various controllers and network station communication as well as data exchange.
(2) SiteBuilder it is the frame tool of the system database that could quickly set up the system structure.
(3) EIKON it is the tool of graphic compiler that is used for compiling device control programs
(4) MS FrontPage2000 and its accessories are mainly used for designing the dynamic graphics and carrying out the controls and data displacements.

Here the compiler tool EIKON is the most advanced graphic compiler in the industry. By clicking the button, it can make complicated control algorithm, diagnosis faults, which can test the performance of the control programs with the real-time or simulative running parameters. EIKON is not adopting line-by-line and abstruse code so that to make the control programs easily understood

System Hardware

The hardwares of the ALC/WebCTRL^{TM}'s Building Automation Control System are as follows:
(1) Network Router LGE
LGE is the high performance net router, which is mainly used for M series, S series, UNI, WebPRTL serial control wares to communicate with the Ethernet. LGE is based on the 10Base-T Ethernet, which is mainly taken charge for the control ware subnet and sending

messages between other net router and the upper computer machine's software WebCTRL Server.

(2) M serial locale control ware
M serial control ware is suit for multi-device control, which is one part of ALC corporation 's WebCTRL™ system. It includes the S serial and U serial control wares. M serial control ware has the firmly structure and separate running ability, which is suit for multi-device application occasion.

(3) S serial locale control ware
S serial control ware is the mainly single control device, which provides the high reliability and strong design that could make the controllers accommodate various conditions, even the roof installation.

(4) Subnet locale control wares
Subnet locale control ware is mainly the U serial control ware, which has two types UNI/16 and UNI/32 at present. They are both the network router that is used for communicating with the BACnet MS/TP standard protocol control wares, which is based on the high 156K baud among the ARCnet Building Automation's communication.

The software's energy-saving device

WebCTRL system has obvious characteristics in energy-saving aspects, which makes the energy-saving devices achieve less energy consumption in a certain degree under the condition of indoor comfortable environment.

(1) Space Temperature Control (STC)
According to the cooling season or heating season, working time or free time and the condition of peak value, it will ascertain the room's temperature control value. And seven kinds of colors will show the room's temperature and PMV.

(2) TOD (Time of Day Scheduling)
Time schedule is to prescribe the building or district under a certain state, for example in the process of being used, set the device's on/off time, make the device run effectively. It can also set separate device or the device group's running schedule. Time schedule has normal, free time super time three kinds of PRI that are convenient for user to manage.
(3)TLO (Timed Local Override)
The Operating System has set the locale super control, which will allow the user to surpass the program control in requiring time and lock the import or export values.

(4) OSS (Optimum Start/Stop)
Optimum Start/Stop is mainly used to complete transition from the free time to working time. Under the normal outdoor condition, optimum start/stop will follow the temperature ascending velocity and the descending velocity of the cooling room considering to the outdoor temperature and enclosure structure's heat-gained and heat-lost coefficient. It will also assure the indoor's PMV and effectively reduce the device's running time.

(5) STO (Source Temperature Optimization)
According to the building's district demand, it will allow the temperature setting value of the cooling/ heating chain's different devices (air-conditioning unit, chiller unit, boiler device) to reset in the user's prescribed scale. The calculation of the practical setting value is processing according to the heating or cooling demand times of the present device or district feedback. In every updating period, STO program will check the network whether each device will absorb the additive heat or cool quantity from their cooling/ heating source.

(6) DL (Demand Limiting)

It will measure the using situation of the building's electric power, which will divide three electric demand grades. According to the electric demand grades to modify the temperature setting value, it will assure the system just to reduce the building's PMV instead of not be paralysis.

(7) DNS (Day/Night Setback

It allows the room's temperature to descend or ascend in a certain pre-establish scale in free time. If it reached any end of the DNS scale, heating (cooling) will start up until the room's temperature return the DNS scale.

THE EXPATIATION OF THE VAV AIR-CONDITIONING SYSTEM'S CONTROL SCHEME

The test condition of the task

This task adopts the typical VAV air-conditioning system control scheme, contrast to the full air-conditioning system, the main characteristic of which is installing a VAV terminal device in each room. This terminal device is actually a valve by which could increase or reduce the airflow supplied to the room in order to achieve separately regulation to various room.

According to the Intelligent VAV control project of this task, its terminal adopts pressure-independent control method, which is lack of plus-pressure ventilator and terminal reheat device. So the hole system only has the summer condition, the main control scheme of this task.

Intelligent temperature sensor will transfer the setting value and measuring value to the locale controller in order to compare the two values of the heat demand or cool demand. Then the airflow control module will calculate the room's airflow set point, and compare it to the actual measured value by the airflow measuring device, regulate the valve's opening and satisfy the room's load request. The valve's minimum opening should satisfy the minimum needs of the room's ventilation, terminal heating or cooling needs and transfer the limit opening value to the upper AHU through the control network. The valve's minimum opening value and the limit opening value are the foundation of resetting supply air temperature. The actual measured value is the foundation of controlling the back airflow of AHU.

Stable static pressure control scheme

At present, the stable static pressure control method is the normally used VAV system control way, which is simple and feasible. However, its fan energy consumption is high so that the terminal valve state's pressure distribution and the static pressure setting value are not easy to set in applicable engineering. Or else it will reduce the energy-saving effect and be likely to appear increscent noise phenomena.

Variable static pressure control scheme

Variable static pressure control method is the best energy-saving way. Although Variable static pressure control method could economize fan's energy consumption in the farthest degree, the control method is very complex and different to carry out because the system has increased the valve-opening sensor, which should be feedback to the static pressure controller through the communication network. The control device provided by the market doesn't offer the variable static pressure control algorithm. As a result, it needs the engineers to compile and debug in the locale case, so the workload is too heavy. Comparing to the stable static pressure control method, this kind of control method also adopts pressure control, which has the same problem of the system stability. This kind of scheme is suit for large-scale public building that adopts Building Automation System.

TRAV terminal regulation scheme

According to the advanced theory abroad, American writer T.B.Hartman has brought forward TRAV (Terminal Regulated Air Volume) control method, which creates comfortable environment by regulating the airflow. Based on the practical airflow demand, TRAV control method adopts more advanced control software to carry out the ventilator control. The concrete control method of this control system is as follows, according to the three VAV terminal airflow's differences between the total measuring value and airflow setting value, it will follow PID algorithm to control the frequency ventilator and ventilator's airflow in the opposite direction and forward feedback.

VAV TERMINAL CONTROL SCHEME

The total airflow control scheme

Based on the pressure-independent VAV terminals, the total airflow control method is a newly simple and feasible control method. According to the relation between the total airflow and ventilator's rotate speed, it can regulate the ventilator's rotate speed. The energy-saving effect is between the stable static pressure and variable pressure method. As the control way does not adopt pressure control, the control system which is a practical fan airflow control way is stable.

The total airflow control method is to calculate the ventilator's demand rotate speed in a certain degree, which is different from the typical feedback control. However, the setting airflow does not immediately set to the satisfied future airflow load (that is stable airflow) after the room's load is changed. Then the setting airflow is the middle control quantum that is gradually stabilized room temperature, which is integrated through room's temperature departure.

As a result, the ventilator's rotate speed of the total airflow control method will immediately regulate to the stable speed and not change after the room's load varies. As a matter of fact, the total airflow control method is a kind of dominating ventilator's rotate speed control method according to the room's temperature departure regulated by the PID controller.

Cooling On Demand scheme

The meaning of Cooling on demand is to carry out the energy-saving control to the cool supply equipment under the satisfying user's cooling on demand. Control system makes use of network control technique, supervises the terminal equipment, cool water user and cool source. And the cooling on demand and using cool time to request are taken on the catenulate delivery, it is shown in *Fig 2.*

Fig2 Cooling on demand control frame picture

Terminal VAV BOX calculates the cooling on demand and the cool time request according to the temperature of the control area and the Opening situation of the valve, transfers it to the superior air-conditioning unit; the air-conditioning unit sets up the supply air temperature according to subordinate cooling on demand, then it ascertains whether or not to start up the air-conditioning unit and suggests using cold time request by the superior cooling source according to the request of the subordinate cooling time; it refers to the real supply air temperature and the duct water valve's opening aperture situation to calculate the cooling demand of the superior cooling source; cooling source makes the statistic of all consumer's cooling on demand and the request of using cooling time, comes to ascertain whether or not to startup a cooling air-conditioning unit, resets the chilled water pump's supply water temperature, or adjusts compression pump again.

Terminal regulate control air volume（TRAV）is to adopt advanced control software to directly control the supply air fan according to the air-conditioning room's working condition, terminal device's real time air-flow demand and air valve's switch state. The concrete control mode is that according to the VAV terminal air-flow's different value between the total measure value and the air-flow's total set point value, it will control the fan frequency transformer and the fan airflow to regulate in the opposite direction feedback on the base of the PID algorithm. It collects VAV terminal device's valve numbers of the full-opened and full-closed, if all valves are full-closed, the fan's frequency transformer will carry out the opposite direction feedback regulation, that is to diminish the frequency of the Frequency Transformer; If at least one valve is full-opened, the fan's frequency transformer will carry out the positive direction feedback regulation. [3] The terminal regulation control theory is shown in *Fig 3*.

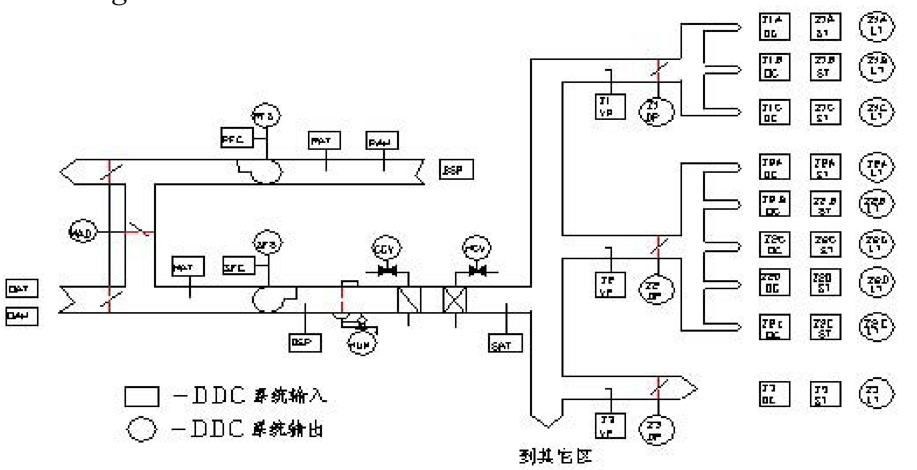

Fig 3 Terminal regulated control theory picture.

Variable supply air temperature control scheme

Here we elementary set the Variable supply air temperature control scheme, the develop control program in our task, the AHU control unit could adopt cooling optimization algorithm:

(1) The initial supply air temperature set value is 12.5℃(summer condition) and the minimum value is 11.5℃ and the maximum value is 22℃

(2) If the 30 percent of the opening of the VAV terminal (Damper value)which is running has reached the maximal opening and continuing 5 min, it will regulate the cold water valve and all terminals of the unit’s service will reduce 0.5℃.
(3) If the 30 percent of the opening of the VAV terminal (Damper value)which is running has reached the minimal opening and continuing 5 min, it will regulate the cold water valve and all terminals of the unit’s service will reduce 0.5℃.
(4) AHU control unit will transit from ir-refrigeration condition to refrigeration condition, the set point’s control algorithm will change from the refrigeration condition set point in a speed of 0.5℃ per minute.
(5) AHU control unit will transit from refrigeration condition to ir-refrigeration condition, the set point’s control algorithm will change from the refrigeration condition set point in a speed of 0.5℃ per minute.
(6) If the supply air temperature is 2.5℃lower than the set point of the supply air temperature(in case of 0.5℃transfer hysteresis) in a continuously 5min, AHU will control it to bring a alarm signal, which will be effective after the ventilator is continuously running for 30 min.
(7) If the supply air temperature is 2.5℃higher than the set point of the supply air temperature(in case of 0.5℃transfer hysteresis) in a continuously 5min, AHU will control it to bring a alarm signal, which will be effective after the ventilator is continuously running for 30 min.

Software testing result

Heat district testing result

Based on the BACnet protocol, this Building Automation Platform software organizes and develops the control algorithm, and carries out software simulation test and physical system’s debugging experiment according to TROX single-duct pressure-independent VAV terminal under the condition of Building Environment and Intelligence Laboratory of Beijing Union University. At the same time, it adopts the ALC Corporation’s U341+ control ware and the test result is shown in *Fig 4*. From the chart, we can see that the indoor temperature’s trend is close to 23.8 after the air-conditioning system setup 20min. And after 55min the result is close to the set point and the dynamic departure reduced markedly. It has proved that the control algorithm is feasible and the algorithm has higher consult values.

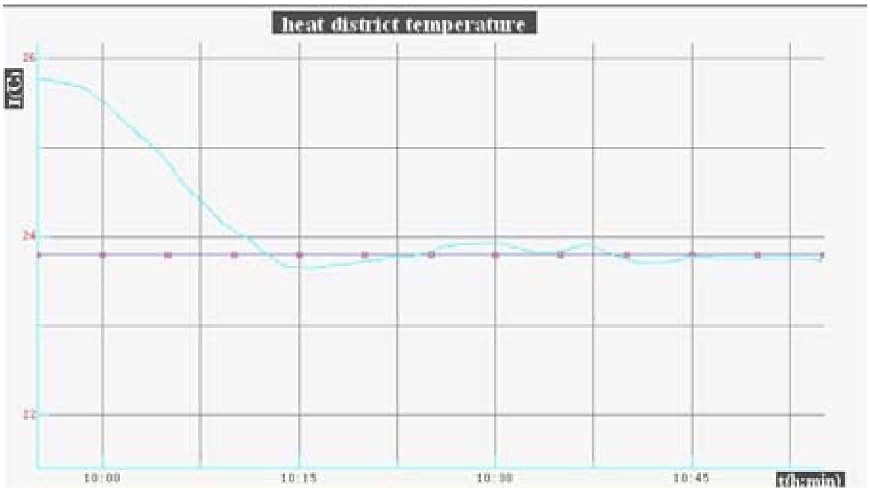

Fig 4 VAV Air-conditioning room's inspecting picture

Airflow and static pressure inspecting result

VAVBox terminal airflow device has measured the variable curve at 14:48-14:58 one day afternoon, as shown in *Fig 5*, of which the airflow is 3250 m^3/h; ventilator static device has measured the variable curve at 14:40-14:48 one day afternoon, as shown in *Fig 6*, of which the mean static pressure is 265pa; the system terminal static pressure device has measured the variable curve at 15:20-15:28 one day afternoon, as shown in *Fig 7*, of which the mean static pressure is 40pa.

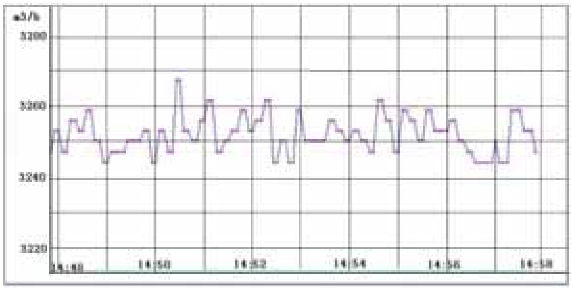

Fig 5 VAVBOX terminal airflow inspecting picture.

Fig 6 ventilator static pressure inspecting picture.

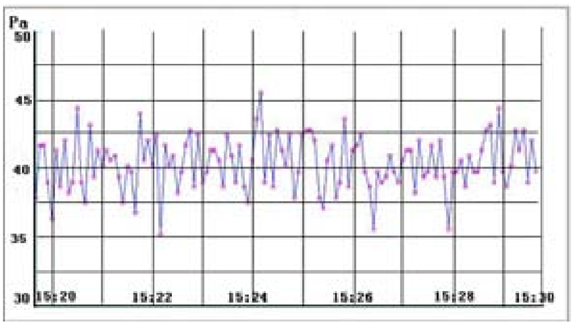

Fig 7 system terminal static pressure inspecting picture

The VAV control system is not only fixing the terminal device and gearshift air fan, but also has the total control system that is made up of some controlling loops. The VAV control system's running condition will be changed following the time varies, which could assure the system's basic demand depending on the Automation Control such as the comfortable room temperature, the sufficient fresh air, the benign airflow and the normal indoor pressure and so on.

The chiller unit's VAV control includes the loops of ventilator control, back-flow fan control, fresh airflow control and so on. We can see that both the VAV air-conditioning system and the control system are combined tightly and indiscerptibly. The main task of the control system is that it could adjust the supply airflow automatically and adapting the variable room load, which can achieve the requests of different function room's different temperature parameters and adjust the ventilator's the rotate speed so that it could reduce the running energy consumption in the air-conditioning system.

CONCLUSION

The automation control of the VAV air-conditioning system in the engineering practice mostly adopts the static pressure control scheme. However, it often exists the problem that super-cooling and super-heating of local district in the Building, the insufficient fresh airflow that dreggy air in the air-conditioning room. From the theoretical analysis, the control tactics principles of the cooling on demand and TRAV have the characteristics of energy-saving and stability, the system demands the fan power is less than the static pressure control system, when the flow drops by the fixed flow's 50%, the request fan power has been fallen below 15% of the fixed power according to this algorithm.

The task has already carried out the software testing and physical system's primary debugging in Building Environment and Intelligence Laboratory of Beijing Union University, testified its feasibility. It can be seen that the control principle and the algorithm have higher reference values. At the same time, it has the practical and immediate significance to improving the running efficiency and reducing energy consumption according to the VAV air-conditioning system's all-around energy-saving and optimal running.

BUILDING INFORMATION MODELING TECHNOLOGY FOR FULLY INTEGRATED DESIGN AND CONSTRUCTION

Gordon Holness, PE ASHRAE Fellow
Consulting Engineer, Detroit, Michigan, USA

Corresponding email: gholness@comcast.net

INTRODUCTION

This paper explores the recent global developments in software and software protocols for Building Information Modeling (BIM) as a tool for fully integrated design and construction. Building Information Modeling is a still emerging technology that has yet to reach its anything close to its full potential. However the technology can already clearly demonstrate its overall benefits in terms of coordinated design, shorter design & construction schedules, significant cost reductions, job site safety improvements and even more sustainable construction programs.

As discussed in this paper, there is a significant amount of work being done worldwide **on software tool & protocol developments** by governmental agencies, non-profit and research organizations, as well as commercial entities, to facilitate and promote BIM technology. Also discussed are the **application software developments** currently underway. The good news is that many, if not most, of these developments are IFC compliant. However there still are many barriers to successful and commercial application.

Clearly BIM modeling has gained wider acceptance in the past two years, particularly in the architectural design side of the profession, but we are far from a fully integrated design process. Research into engineering firms specifically for information related to their experience with Building Information Modeling Programs (i.e. Bentley Microstation, Tri Forma, Factory CAD, Catia, Autodesk Revit, Graphisoft ArchiCAD, etc.) as design and construction tools, does show wider application today. But while we have seen a few companies fully integrate structural design and analysis programs into those architectural models, we have yet to find many companies that are able to demonstrate BIM model tie-ins that can fully integrate HVAC related design programs (such as Load Calculation Programs, Pipe and Duct Sizing Programs, Building Energy Modeling/Analysis Programs - DOE-2, EnergyPlus, BLAST, IBLAST, TRACE 700, etc.).

We have also yet to find many companies that have integrated Building Owning, Operations and Maintenance Programs for Facilities Management. Similarly we have yet to find many companies able to fully integrate natural day lighting design programs (such as Superlite 1.01, LUMEN , doe 2.1 or Radiance 3.4 or illumination design programs such as Autolux, AG132, esp Vision, Autodesk Lightscape, Lightcalc +Art or ALADAN) into BIM models. Yet the spatial planning, modeling and orientation technology imbedded in 3D, 4D & 5D models would seem a logical input data base for such programs and the recipient of the output.

Despite this, the tremendous opportunities for improved efficiency by integration of the design and construction process will continue to drive the technology forward.

OVERVIEW OF BUILDING INFORMATION TECHNOLOGY

The ultimate goal of Building Information Modeling is to assemble a single data base of fully integrated and interoperable information that can be used seamlessly and sequentially by all members of the design and construction team and ultimately by owners/operators throughout a facility's life cycle. The desired result is a BIM model where three dimensional (3D) graphical imaging carries real-time (i.e. immediate and dynamic access) data, and where every line and every object carries real-life intelligent physical and performance data.

The modeling technology can start with direct data transfer from the design calculation software into graphic layouts (for systems such as structural steel, fire protection or other modular elements). Alternatively it can utilize the graphic layouts as direct input to load calculations (such as pipe sizing, duct sizing, etc). Modeling programs can also link to specifications and to manufacturers web sites for data input. Either way, building information modeling technology already extends into fully integrated 4D modeling (adding the fourth time dimension for scheduling or sequencing using programs such as Primavera) and 5D modeling (adding the fifth dimension of cost for estimating and budget control (using programs such as Timberline). The building design development can continue with the provision of automatic bills of material and generation of automatic shop drawings for everything from structural steel to sheet metal duct fabrication, to fire protection and piping fabrication, to electrical cabling and bus duct layouts, etc.

CURRENT TOOL AND SOFTWARE PROTOCOL DEVELOPMENTS

A major key to the success of these efforts is establishing common software protocols. The International Alliance for Interoperability (IAI) at www.iai-na.org. has developed models to address this issue. IAI is a council of the National Institute of Building Sciences (NIBS) at www.nibs.org . The mission of IAI can be found on their Web site, which also provides information on programmable language XML data models for information transfer between disparate software packages (as an example, aecXML is a framework for using an eXtensible Markup Language standard specifically related to technology in architecture, engineering and construction). They also offer comprehensive, intelligent and universal data models through Industry Foundation Classes (IFCs) to IFC.XML2 ISO 10303-28, which incorporate HVAC schemas compatible with ifcXML - IFC2X3 code (ISO 10303-11), as well as data elements that represent entire portions of a building or system. These are used to assemble computer-readable models of the facility that contain all of the information on the parts and their relationship (ISO/PAS 16739). Table 1 Identifies HVAC schema being developed under IAI Project BS-8.

Table 1 - IFC HVAC Extension Under IAI Project BS-8

The main objective of BS-8 was to extend the IFC data model with schema needed to *fully* support the *modeling and simulation* of HVAC components and systems. The pragmatic goal was to *enable rich data exchange* among the various building simulation tools in use today and in the future.	
General Data	**IFC HVAC extension schema for support of *building energy performance simulation***
General and performance specifications of materials General specifications of HVAC and other simulation related equipment, systems and furnishings Performance specifications for the above.	Dynamic load estimation HVAC design HVAC equipment selection Measurement and verification (HVAC view) Building performance metrics (HVAC view) HVAC system and equipment commissioning HVAC system and equipment retrofit HVAC system and equipment physical layout HVAC system and equipment product data (catalogues, external data bases).
Downstream applications	**Processes that are *partially* supported by IFC HVAC extensions**
Other HVAC (design) applications Other building energy performance simulation tools (such as air-flow models) Cost estimating applications Commissioning tools Building operations and maintenance software Code-checking applications Software that serves utility companies Many other types of applications that use HVAC definitions.	Energy code compliance Interference checking Cost estimating HVAC construction documents Construction and installation Procurement Maintenance Operations Fault detection and diagnostics Emergency response Accessibility Utility billing and cost allocation

Even more importantly, IAI's international Council has established the European Integrated Project "InPro" "Open Information Environment for Knowledge Based Collaborative Processes throughout the Life Cycle of a Building"- European Project No. 026716-2.

The US National Institute of Building Sciences (NIBS) has created the National Building Information Model Standard, under their Facility Information Council. The first Version 1.0 is now available for review on their web site www.facilityinformationcouncil.org/. This is in addition to the work being done by the Building Enclosure & Environment Council and the Facility Maintenance & Operations Council. NIBS is working with IAI to develop an overall integrated program developing and expanding IFC component values under the umbrella "building SMART"- www.iai-na.org/bsmart/ . buildingSMART = BIM + IFC and combines BIM technology with Information for the Construction (IFC) global ISO Standard. Target date for the first version was the end of 2006. The annual buildingSMART Conference brings all facets of the industry together to advance the science.

As their web site indicates *"**buildingSMART** is the dynamic and seamless exchange of accurate, useful information on the built environment among all members of the building community throughout the lifecycle of a facility. **buildingSMART** is simply a smarter process for managing the project lifecycle."*

The mission of the National BIM Standard Project Committee as identified in their charter is to improve the performance of facilities over their full life-cycle by fostering a common, standard and integrated life-cycle information model for the A/E/C & FM industry. This information model will allow for the free flow of graphic and non-graphic information among all parties to the process of creating and sustaining the built environment, and will work to coordinate U.S. efforts with related activities taking place internationally.

Of related interest the National Institute for Science and Technology NIST Advanced Technology Program (www.nist.gov/atp) and Standard Reference Data programs (www.nist.gov/srd) are also very supportive of industry research and development in this area. Capital facilities industry cfiXML at www.cfixml.org is a cooperative effort of ePlant Data www.eplantdata.com ; DIPPR a chemical industries alliance and FIATECH are also developing manufacturing industries standard XMLs.
Of particular interest is the work being done by the FIATECH (a non profit consortium supported by NIST and established by the Construction Industry Institute) towards fully integrated and automated design and construction technologies. Their Capital Projects Technology Roadmap (CPTR) www.fiatech.org/projects/roadmap/cptri.htm or www.construction-institute.org/FIATECH addresses many of the critical issues facing the industry. The Projects Technology Roadmap is a cooperative effort of associations, consortia, government agencies, and industry, working together to accelerate the deployment of emerging and new technologies that will revolutionize the capabilities of the capital projects industry. This initiative, led by FIATECH, is open to all stakeholders who are committed to the future success of the capital projects industry. The Capital Projects Technology Roadmap presents their strategy for the capital projects industry in **"Developing a consensus vision for the capital projects industry and a unifying initiative to achieve the vision"**. Table 2 indicates the planned components of project development.

Table No.2 – FIATECH Capital Projects Technology Roadmap

www.fiatech.org/projects/roadmap/jobsite.html

1. Scenario-based Project Planning
2. Automated Design
3. Integrated, Automated Procurement & Supply Network
4. Intelligent & Automated Construction Job Site

6. Real-time Project and Facility Management, Coordination and Control
7. New Materials, Methods, Products & Equipment
8. Technology- & Knowledge-enabled Workforce
9. Lifecycle Data Management & Information Integration

The Internet Standard published by the World Wide Web Consortium www.w3.org offers interoperable technologies for information, commerce, communication and collective understanding. WWW recently released XML schema 1.1 Structures for XML documents. Still further tool technology includes Unified Building Modeling Language UML www.omg.org for specifying, visualizing and constructing the artifacts of software systems and SOLIBRI IFC Optimizer and model checker www.solibri.com for more effective data storage and transmission.

CURRENT COMMERCIAL APPLICATION SOFTWARE DEVELOPMENTS

The first challenge facing private and commercial enterprises in developing integrated information modeling is the reality of the limited size of the marketplace. Unlike basic office software where a word processing program may sell tens of millions of copies, building modeling programs (of far greater sophistication) may sell only a few thousand. The second challenge facing the industry is developing a commonality of program protocols that enable free exchange of data between disparate software systems. These are becoming incredibly complex. Here, the work being done by NIBS and IAI to develop an overall integrated program under the umbrella "building SMART" shows great promise in combining BIM technology with Information for the Construction (IFC) global ISO Standards to ISO/PAS 16793.

One of the biggest recent advances has been the development of open meld protocols that allow the integration of disparate software programs. An example of this is NavisWorks "Jetstream" © 3D Design Review at www.navisworks.com , that has the ability to manage, view and integrate disparate software programs providing real time navigation, collaborative communication and presentation of 3D & 4D Building Information Models.

Certainly the European community, particularly, and to some extent Australia, are further ahead of the USA in the widespread application of BIM. Europe is heavily committed to development of integrated building design technology with extensive work being done in the UK, Norway, Sweden, Finland, Germany and the Netherlands. Programs include Integrated IT Solutions by Nemetschek, NA noiXML whose Vector Works Fundamentals are architectural building programs that can plug into AutoCAD and CATIA, Landmark for site planning and Spotlight for lighting design. (Nemetscheck - Allplan, www.allplan.co.uk/ for architectural design and modeling software). Data Design Systems www.dds-bspco.uk/ has developed mechanical and electrical IFC compliant file systems. Meanwhile Zeit + Raum develops virtual building information models. TELKA develops structural programs. Obermeyer has project model orientated software. Octager has access an viewing technology. Mensch Machine has software for MEP CAD application. Graphisoft www.graphisoft.com ArchCAD 10 encompasses architectural design software and virtual building solutions, which will allow input of files into Energy Plus. Meanwhile EPM Technology, Norway has developed an IFC Model Server to share project model data.

Two of the major players in the architectural/engineering end of building design and modeling are Bentley and Autodesk. Both are collaborating with the buildingSMART initiative.

Bentley Solutions at www.bentley.com has Microstation and Intergraph as the primary products for building design, construction and operation. Recent enhancements include interface with gbXML for energy analysis using Trace 700 and tie into pipe and duct sizing, the latter using ddXML. Their suite of products include Tri Forma as an extension of

Microstation for 3D solid mass modeling geared to plant design. Other products under development include Bentley autoPIPE, Bentley Piping and Bentley HVAC. Also under development is Bentley Facilities for building owners and operators.

Autodesk at www.autodesk.com building solutions include AutoCAD www.autocad.com and Autodesk Revit (Building – Architectural; Structure – Structural Design; Systems Plus – MEP and Buzzsaw – Project Management Tools). Autodesk Building Systems (ABS) and Autodesk Desktop (ADT) are BIM compatible packages. ABS provides the special definition by analyzing CAD layouts identifying internal and external loads orientation, thermal zones etc. It can export to load calculations software such as TRACE and input results back to ABS It can also use the input data from TRACE for auto sizing and scheduling VAV boxes. http:/usaautodesk.com/adsk/servlet/index?siteID=123112&id=6861179

In 2006 Oracle launched a new collaborative Building Information Management Platform (CBIM) at the IAI Building Smart Conference in Munich. The Oracle CBIM www.oracle.com/openworld initiative provides a web accessed enterprise collaboration platform, which makes building information available to architects, project managers, building contractors, subcontractors, operators and facilities management firms from a single source. Oracle is working with Graphisoft to fully integrate building modeling tools with design collaboration, visualization, life cycle management and other applications.

There are even players like the Mayo Foundation (under the Mayo Clinic) are developing Mayo Graphical Integrated Computer Aided Design using MagiCAD software. MagiCAD developed by Program Oy of Sweden is IFC compliant and is used widely in Scandanavia and aimed primarily at duct design and equipment manufacturing, but including HVAC, piping and electrical design and application software (Running on an AutoCAD platform). These have the ability to feed data into Energy Plus using Olof Grandlund/LBNL developed BS Pro Com server middleware (with IFC based 3D RIM).

International Building Performance Simulation Association IBPSA www.ibpsa.org , a non profit organization, is developing building performance simulation specifically aimed at HVAC equipment, air flow in buildings, energy usage, as well as visual and acoustical environments. The annual SIM conference promotes building sustainability and performance through simulation.

Green Building Studio www.greenbuildingstudio.com offers open gbXML schema for direct data exchange offering web based building energy analysis tools integrating data from the BIM into DOE-2, BLAST, TRACE 700, EnergyPlus 1.4, etc. and exporting the results back into the BIM.

Examples of leading edge software for manufacturing and the factory floor are Pro E[6], Factory CAD[7], while for the plant facilities, Unix-based Catia at www.catia.ibm.com. , CC Plant, Tri Forma, Tri-Plan, Bentley Plant Solutions[6], Speedicon , digiPLANT, and autoPLANT, lead the way. These programs can now tackle the more complex elements of equipment layout, HVAC&R design and layout, including piping, sheet metal, equipment, and electrical services. They also are geared to support the complete life cycle from design through construction to operation and maintenance.

Other technologies are emerging, such Ansys CFX 5 computational fluid dynamic software allowing air flow simulation under laminar and turbulent states. Of even greater interest is the development of laser scanning of existing buildings and sites. Programs such as Cyra Technologies www.cyra.com and Leica Geosystems HDS Inc. www.leica-geosystems.com – can record site and as-built conditions and do geospatial imaging and engineering surveys while creating a database file that can be integrated into the building model. Disto laser scanning of existing buildings is tied to USD-M2 www.usdm2.co.uk .

Another interesting development is the work being done by the International Code Council. ICC has unveiled SMART Codes – an interoperable, automated code compliance checking system for checking compliance with the 2006 International Energy Conservation Code. This automatic checking system can yield an inspection check list or provide a 3D virtual walkthrough that tags non-compliant building components.

For a listing of current building systems related software it is worth visiting www.energytoolsdirectory.gov/

BARRIERS TO SUCCESS

The U.S. National Institute of Standards and Technology (NIST) recently published a study that identified and estimated the efficiency losses in the U.S. capital facilities industry resulting from inadequate interoperability among computer-aided design, engineering, and software systems. Although the focus of the study is on capital facilities-commercial/institutional buildings and industrial facilities - it benefits key stakeholders throughout the construction industry. This study - the conception, design, and publicity of which FIATECH was a strong and early contributor to - is based on an earlier report also done by NIST of the cost of interoperability in the U.S. automobile supply chain.

NIST GCR 04-867 estimates the cost of inadequate interoperability in the U.S. capital facilities industry conservatively to be $15.8 billion per year. These cost impacts are of interest to owners and operators of capital facilities; design, construction, operation and maintenance, and other providers of professional services in the capital facilities industry; and public- and private-sector research organizations engaged in developing interoperability solutions.

The construction industry itself is highly fragmented between design disciplines, construction trades, and material suppliers, with wide disparities in operational practices and technological development. Even large engineering companies that would, seemingly, have the resources to apply BIM technology are themselves often internally fragmented by multiple offices and operating divisions. As a result the design and construction industry significantly lags behind other industries (such as manufacturing, petro-chemical and aircraft) in exploiting technological advances.

Unlike the manufacturing industry, with its repetitive mass production processes that allows development of operational techniques to improve efficiency and reduce waste, the construction industry handles one of a kind building programs that are each uniquely designed and developed. It is a dichotomy that the very diversity and fragmentation in the industry, which could more fully benefit from BIM modeling technology, also hinders its development and acceptance. A Construction Industry Institute (CII) study indicates that the level of waste experienced in the manufacturing industry typically averages around 28% while that of the construction industry averages around 57%. Similarly the value added component of manufacturing averages 62%, while that of the construction industry is only 10%. (value added being defined as that component of design or construction team labor and cost that directly adds value for the client) . But it is this very disparity and the industry fragmentation that provides design and construction with such tremendous opportunities for improvement.

ISSUES AND BENEFITS

Of course development and use of all of this technology does not come without cost. Experience on large industrial projects ($75 to $150 million) indicates that currently the added design cost represents a 5% to 10% premium on the Architect-Engineers (A-E) fees (or roughly 0.25% to 0.5% on construction cost). The A-E cost premium can be quite a bit higher on smaller projects. More than offsetting this are all of the cost savings outlined above. Immediate savings of 3% to 7 ½ % have already been seen through improved coordination and reduced conflicts. (The Construction Industry Institute www.construction-institute.org/ analysis indicated a potential of 7% for this element alone). This can only increase as more trades come on board and BIM capabilities, such as shop drawings and quantity take-offs, are realized. Increased use of shop fabrication and elimination of waste is, itself, expected to produce savings of at least 7½ % to 10%. Recent experience in the construction of major automotive plants shows that it is possible to eliminate 20% sheet metal waste, develop programs 15% to 25% faster, reduce RFIs by 50%, eliminate 25% of all change orders and reduce construction cost by 4% to 10%. The greatest potential savings may come from the application of value added and lean construction techniques that BIM enables. Regardless, in the interim, A-Es must convince owners that this added investment justifies increased fees.

Table No.3 – Benefits of Building Information Modeling

- Provide visualization of project
- Build fundamental intelligence into drawings
- Provide a single database of information to meet the needs of all parties.
- A valuable project management tool
- Improve issue tracking process
- Provide seamless flow of information
- Provide automated bills of material Reduce the bidding time and effort
- Automatically provide shop drawings
- Facilitate off-site prefabrication
- Simplify material ordering and site management
- Improve field coordination and significantly reduce interferences
- Reduce change orders
- Save cost and time at every phase of design and construction
- Provide owner with live/intelligent file records Provide electronic links for service and maintenance Facilitate peak building performance throughout a facilities life cycle

BIM can already demonstrate all of the individual elements listed in Table No.3. However it cannot yet achieve all of these benefits incrementally without separate interface. The interoperability of software components is still not there, requiring separate and distinct input and output data. Successful widespread implementation of BIM for fully integrated design, depends upon the ability of architects and engineers, as a design team, to be able to easily input and exchange data. The key then is for the integrated system to be able to continually and dynamically model the building and all of its systems, through daily and seasonal operational cycles. This then allows the “what if” scenarios to be played out utilizing different systems and components and allow them to be evaluated on a first cost, operating cost and life cycle cost basis. We are far from that point.

CONCLUSION

There is no question that the information technology required for these processes is very complex and quite difficult to implement and is straining the limits of designers' current hardware, software, and even staff capabilities. Much more work needs to be done to enable the technology to be applied on a day to day basis and we are still far from having an interoperable system that can enable fully integrated system design. The greatest opportunity lies with fully integrated multi-disciplinary A-Es practices and where BIM integration is being done as a continuum of the design process as well as the construction process.

Building Information Modeling is clearly gaining considerable momentum as the technology evolves and greater interoperability occurs between disparate software systems. The rapidly emerging goals of green building/sustainable design, towards net zero-energy buildings, coupled that with goals for carbon dioxide emissions reduction, will require "whole building" fully integrated design and construction as a dynamic process. BIM can help provide that integration.

Benefits of Building Information Models in Energy Analysis

Tuomas Laine and Antti Karola

SUMMARY

The importance of energy analysis in building design has grown, but it is still mostly done by simple static calculations or estimates. Accurate dynamic simulation software have been available already for decades, but these tools are still not widely used by practitioners in building projects. The main barrier of wider usage of dynamic energy analysis has been the required big manual input work. By utilising BIM as a data source for energy analysis, the data input will be more efficient and the existing data more reusable. Only by using BIM, the verification of thermal performance can truly happen in different phases of the building process. This paper describes a new concept and interoperable software environment for management of thermal performance during the whole building life cycle. Real project experiences also show that BIM based environment allows to use whole building spatial simulation instead of traditionally used zone based models.

INTRODUCTION

The importance of analysing energy performance in building design is growing, because of the increasing awareness of it's role in building life cycle costs and environmental impacts. However, energy analysis is still mostly done by statistical estimates or using simple static calculations.

Dynamic energy simulation softwares have been available already for decades. Commonly known softwares, such as TRNSYS, ESP, DOE-2 and BLAST, have been developed already in 1970's. Also new tools, such as Energyplus and IDA, have been developed for even more accurate thermal simulation. All these tools have been mostly used by researchers, not by practitioners in building projects.

Energy analysis in building design has to meet both the cost and schedule requirements of practical projects. The main barrier of wider usage of dynamic energy analysis methods has been the required big manual input work. Most of the building element specific information needed in energy simulation is described in the building information model (BIM). By utilising BIM as a data source for energy analysis, the data input will be more efficient and the existing data more reusable. It also makes possible to benefit spatial whole building models instead of zone based models often used today in energy simulation. Only by using BIM, the verification of energy performance can truly happen in different phases of the building process. Some of the public building owners, such as in USA [1], Denmark [2] and Finland [3], are starting to demand BIM in their projects, which creates more possibilities to get benefits for thermal analysis.

Other barriers for wider utilisation of BIMs in energy analysis have been the missing interoperable data interface implementations in thermal simulation tools and the lacking guidelines. The Industry Foundation Classes (IFC) [4] provides today an open standard for description and exchange of information within the life cycle of a constructed facility. To use BIM effectively however, and for the benefits of its use to be released, the quality of communication between the different participants in the construction process needs to be improved. The Information Delivery Manual (IDM) by the Norwegian BuildingSMART project [5] is developed to provide the integrated reference for process and data required by BIM by identifying the discrete processes undertaken within building construction together with the information that is required for and results from their execution. There has also been several national projects in different countries, where guidelines for the BIM based design have been developed.

Using BIM is the only practical way to verify energy performance truly in different phases of the building process. The experiences from many BIM based projects show that interoperable energy analysis software is not enough for the management of thermal performance during the building process, but it requires also tools to manage different revisions of BIMs, to compare thermal performance of these revisions and to visualise this by easy-to-understand way. This paper shows the recent developments for concept and interoperable software environment to manage spatial thermal performance. The results show also examples of using BIM based energy analysis in real projects.

METHODS

Thermal performance management can benefit a lot by utilising building information models as a data source for thermal analysis: The data input will be more efficient and the existing data more reusable. The latter is especially important for continuous thermal performance management through the whole building life cycle.

Wider utilisation of BIM requires instructions both to the actual work and to the true understanding of the potential benefits. This paper presents the results of the development of new methods and interoperable software environment to manage spatial thermal performance. The key components in the interoperable software environment are thermal simulation and spatial requirements management, but it supports also building services system modelling and the later phases of building process by linkage to commissioning and facilities management. The Finnish ProIT project [6] has produced guidelines for the BIM based design. The guidelines for building services design [7] are used here to describe the role of thermal performance management in BIM based building process (Figure 1).

The IDM has produced the most detailed guidelines for BIM based energy analysis [8]. It contains both the energy and condition analysis process description and the requirements for information exchange throughout the building process. The IDM process of developing energy analysis throughout the design stages of a project is considered to be divided into 2 key parts:

1. **Speculative**: This is the analysis work undertaken during the programming stage of the project. It is about providing advice on the potential energy performance of a building and its systems to other design roles. The aim of this advisory role is to have an impact on the overall building design, determine the feasibility of concepts in an energy context and to establish energy targets.
2. **Analytical**: This is the analysis work undertaken during the sketch, full concept and coordinated design stages of the project and assumes the availability of geometric information about the building layout. The overall process is the same at each stage of

work, the difference being simply about the extent of the information available and the level of certainty that can be applied to the information.

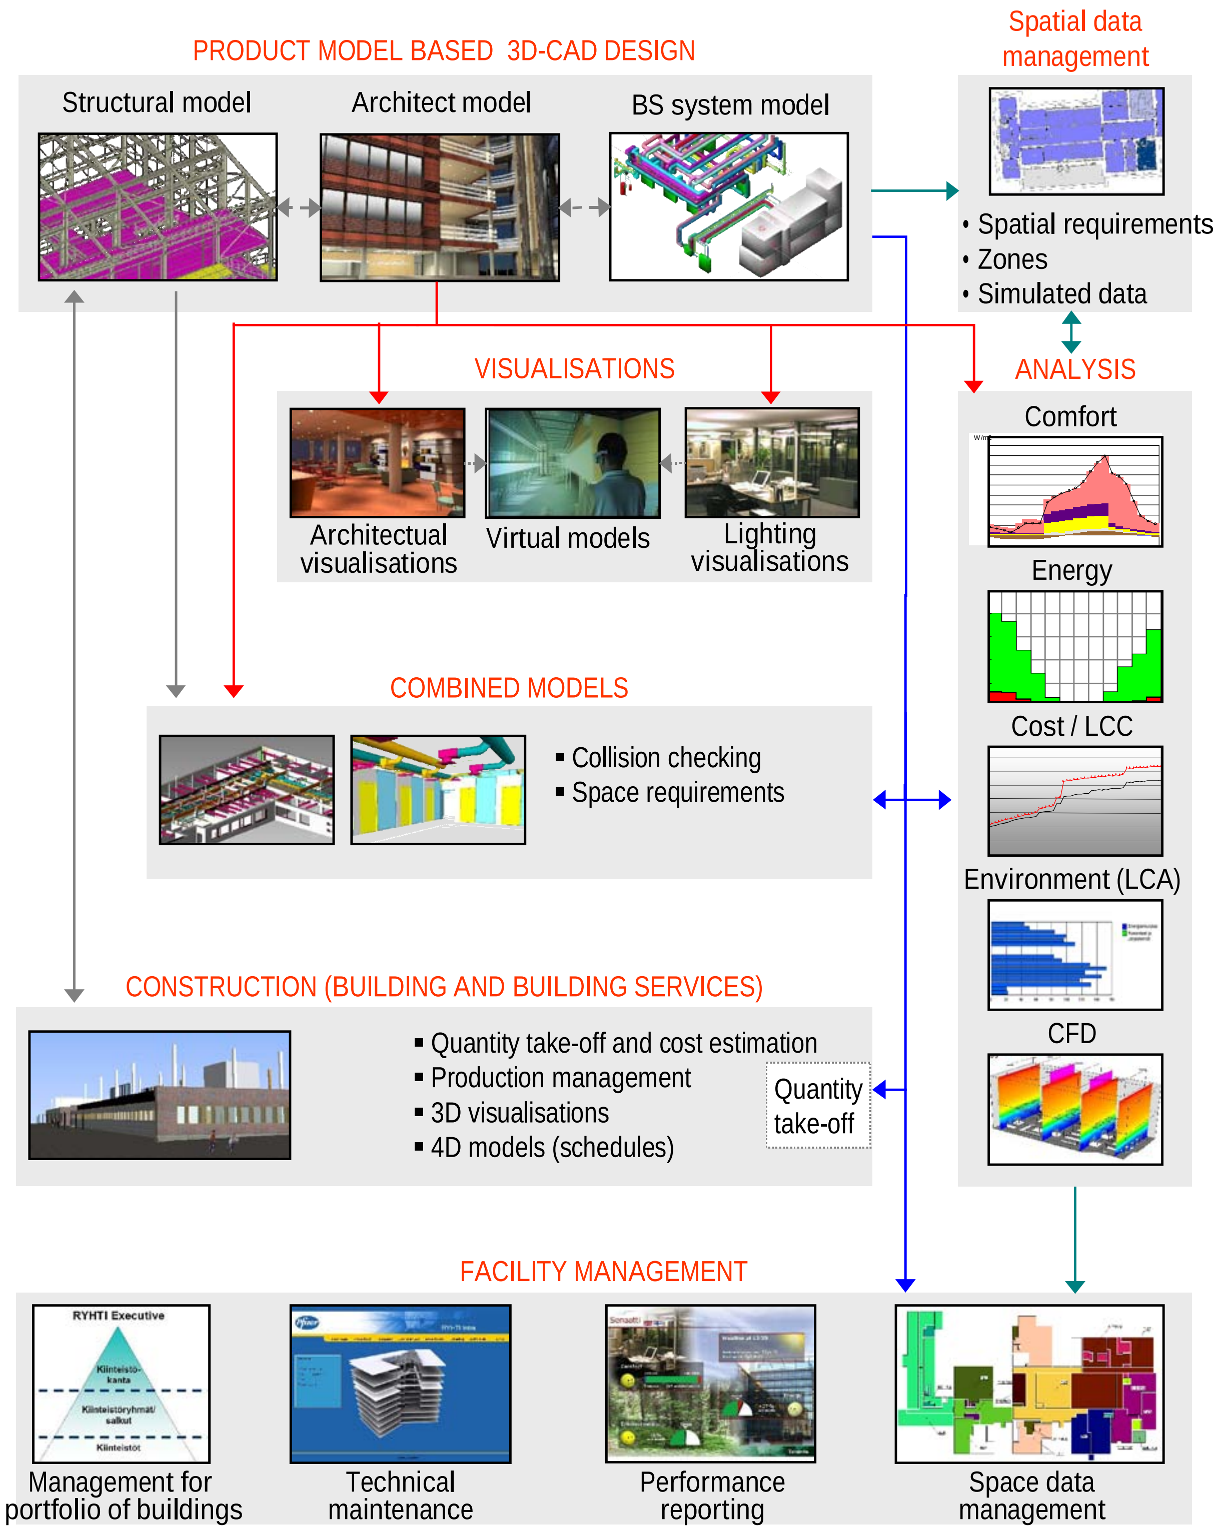

Figure 1. Energy analysis has an important role in the use of building information modelling according to the ProIT guidelines.

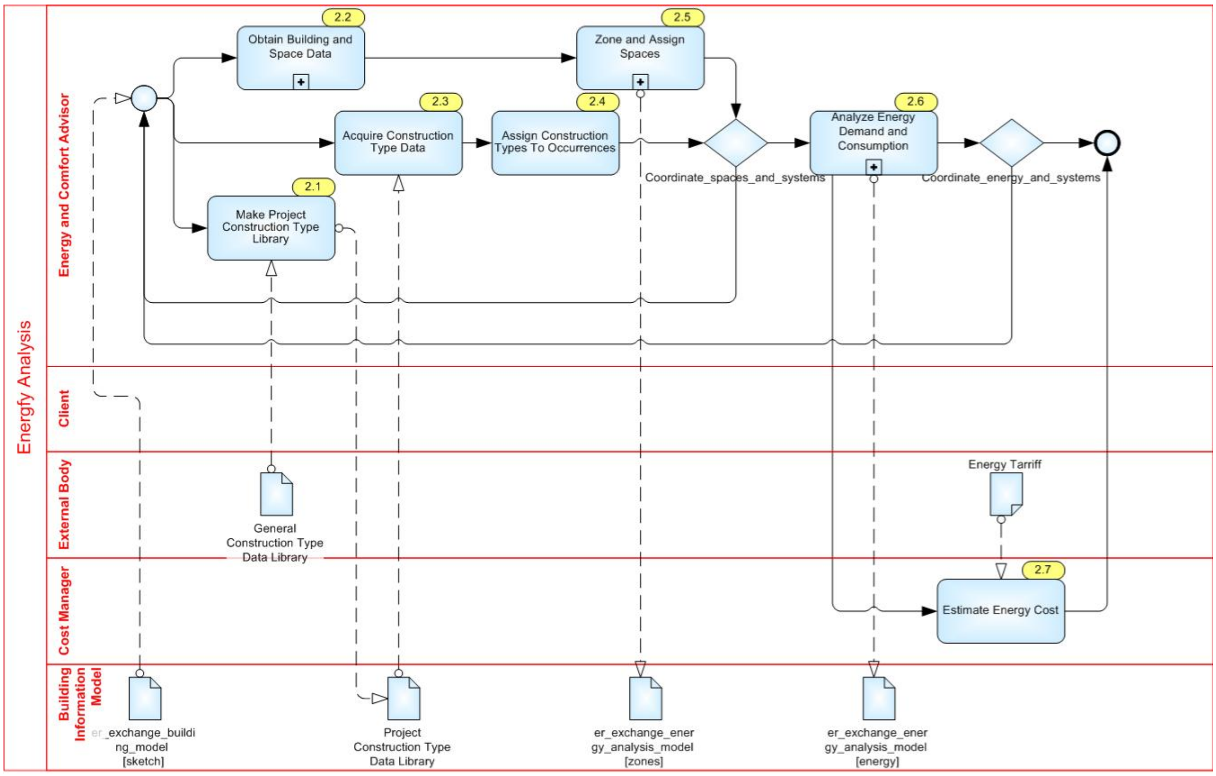

Figure 2. The IDM process map for energy analysis.

RESULTS

The main result of the development was the concept for thermal performance management utilising BIM based environment (Figure 3). The key components in the implementation of the interoperable software environment are energy simulation software RIUSKA [9] and spatial requirements management software ROOMEX. It supports also BIM based building services system modelling and the later phases of the building process by linkage to commissioning and facilities management.

Thermal requirements

Thermal requirements (task 1 in the figure 3) are defined at space type level and so this does not require 3D model of the building. It is necessary to capture client's requirements for different space types, to achieve all the later benefits of BIM based thermal performance management. This task defines both the thermal parameters and the equivalent thermal loads (Table 1). One relevant definition from the electricity calculation viewpoint is also the required lighting intensity.

Utilisation of geometry model

In the utilisation of geometry model (tasks 2 and 3 in figure 3) an architectural 3D model is imported to the environment and validated by automatic checking routines (to report of missing spaces, floors, etc.) and by visual checking (by 3D viewer).

Most of the building element specific information needed in energy simulation is described in the BIM. This includes as mandatory information: spaces with code and name specifications and building structures (walls, windows, etc.) with type definitions. To illustrate the large amount of required building model related data for energy simulation input: As an example a medium size building of 8000 m^2 contains 387 spaces, 295 exterior walls, 912 interior walls, 1439 windows, 760 doors and 57 different type of structures. All this information is needed for spatial level energy simulation, and by utilising BIM this information can be imported to the simulation software. The required information is too much for manual input, which means that traditionally whole building spatial simulation is not practical, and a simplified zone level approach is used instead.

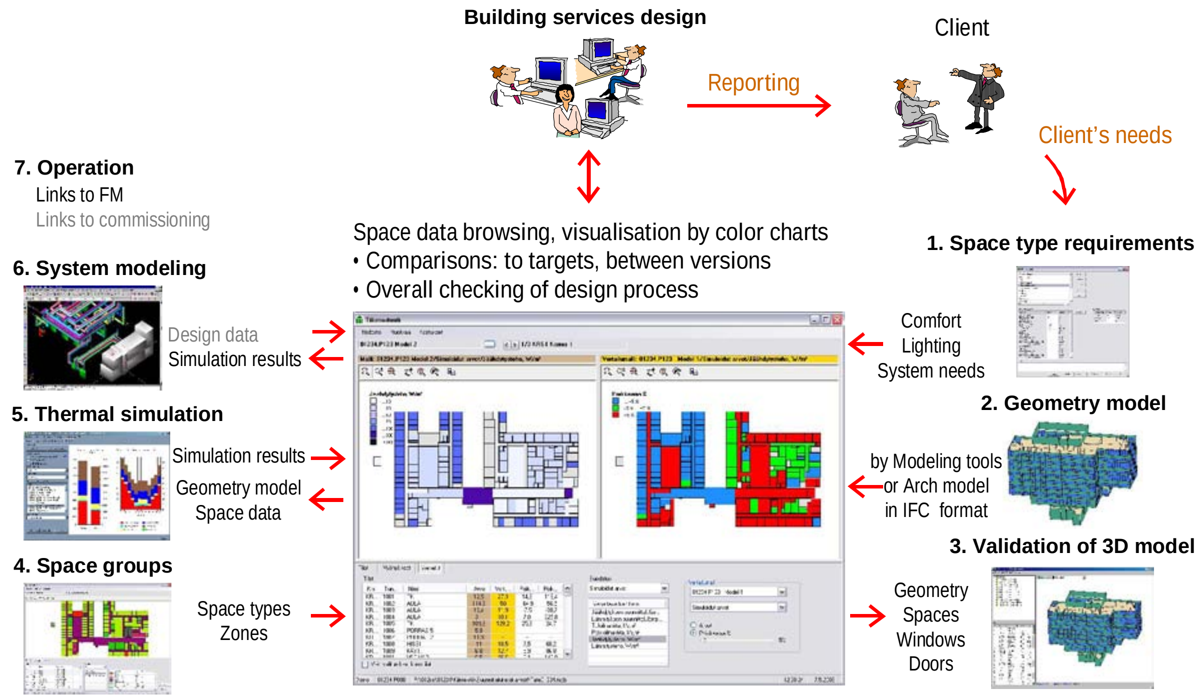

Figure 3. The developed concept for BIM based thermal performance management (the implemented tasks at black, still missing tasks at grey color). The interface in the center shows BIM revision comparison of required thermal parameters against simulated performance.

Table 1. The air quality targets and equivalent loads defined at space type level.

Air quality targets

Attribute	Value	Unit
Indoor temperature, summer	26	°C
Indoor temperature, winter	21	°C
Relative humidity, summer		%
Relative humidity, winter		%
Air velocity, summer	0,25	m/s
Air velocity, winter	0,17	m/s
Carbon dioxide content (CO2)		ppm
Supply air flow	1,5	dm³/s,m²
Supply air flow		dm³/s, per
Sound level		db(A)
Filtering class		EU
Air purity class		P

Loads

Loadtype	Design...	Max value	Unit
People	0,1		p/m²
Lighting	15		W/m²
Equipment	15		W/m²

Sizing val. = Load used in sizing
Max val. = Maximum load

Values of relative humidity are agreed together with the client

Calculated air-flow/person = 15 dm³/s, per

To utilise BIM in energy simulation, IFC model is simplified by pre-processing it. Some format of building objects (Proxys and BREP walls) do not contain the information needed for energy simulation. Figure 4 shows an example from the HITOS project [10], where the biggest part of the architectural BIM was beneficial for thermal analysis to create the required input, but some of the facades were modeled by using BREP format wall objects instead of parametric representation. By visualising the problematic parts (red color) of the model, architect was able to correct the model in the next revision to meet also the requirements of energy simulation.

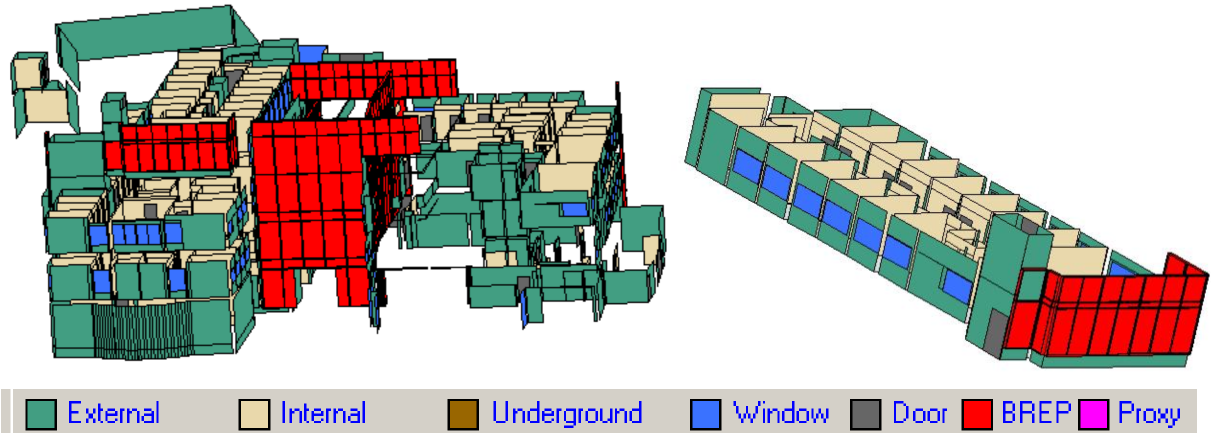

Figure 4. The architectural model of building elements can be imported to energy analysis. It is important to validate that the model meets the requirements of energy analysis.

Space grouping

Space groups (task 4 in figure 3) are created both to define spatial requirements by mapping the space type requirements to actual spaces and for zoning the spaces into different categories, such as air handling unit service areas or lighting control areas. These specifications should be done in the beginning of the building services conceptual design. The same information is needed as input data for energy analysis.

Thermal simulation

In thermal simulation (task 5 in figure 3) the building geometry related data, spatial requirements, loads and air-conditioning and lighting system zones are imported as input data. Additional input, such as usage schedules, HVAC and electrical system specifications and weather data, is defined by using the energy simulation software user interfaces. The simulation results of the spatial thermal performance are exported back to the BIM, allowing performance verification against targets and generation of input data for the HVAC system modelling.

Energy analysis in several projects (Figure 5) has been done by using IDM process descriptions and information exchange requirements. The IDM supports also the creating of energy analysis software specific training material, like the example in figure 6 to describe the required actions in energy analysis to acquire construction type data and assign it to occurrences.

Key requirements for wider use of energy simulation in practical projects are:

- modern user interfaces for practitioners instead of researchers
- efficient data input by reusing the existing information by linkage to BIM and
- using of intelligent data libraries.

Efficient computing is required to move from zone based models to spatial whole building approach. This means also balancing between solver accuracy and efficiency.

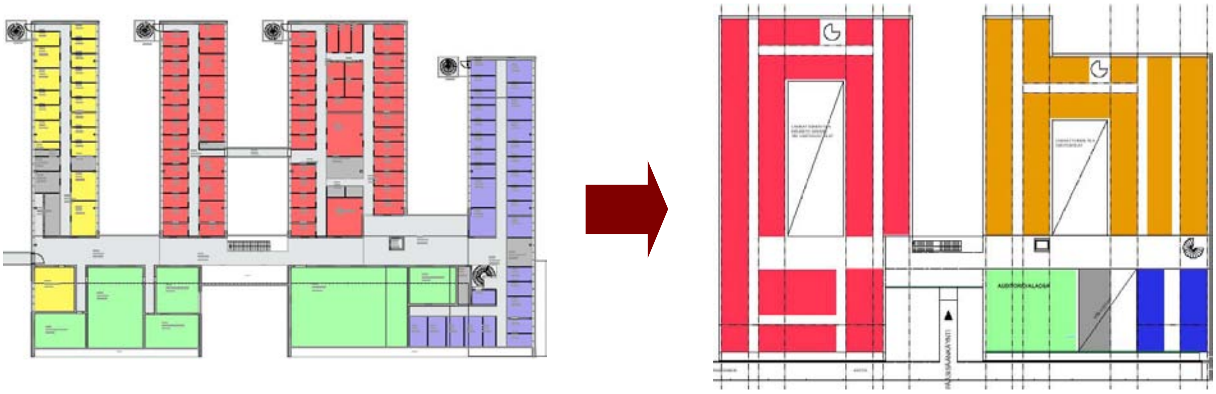

Figure 5. The energy efficiency of the architectural design of the Aurora 2 building [11] was developed during the programming phase by using BIM based energy analysis. From the first solution of cellular office plan with narrow building body (left, a “comb” type of layout), the envelope area was reduced by using glazed inner courtyards for distribution of daylight for the surrounding office spaces (right).

Building services system modelling

The results from thermal simulation can be transferred as starting point to building services system modelling (task 6 in figure 3). The information, such as spatial air flow, heating and cooling needs, is used to select air conditioning equipment for HVAC system model.

Operation and maintenance

Thermal performance management should continue during operation and maintenance phase (task 7 in figure 3). Figure 6 shows an example how the self-reporting building system [12] is used for thermal performance management during operation phase.

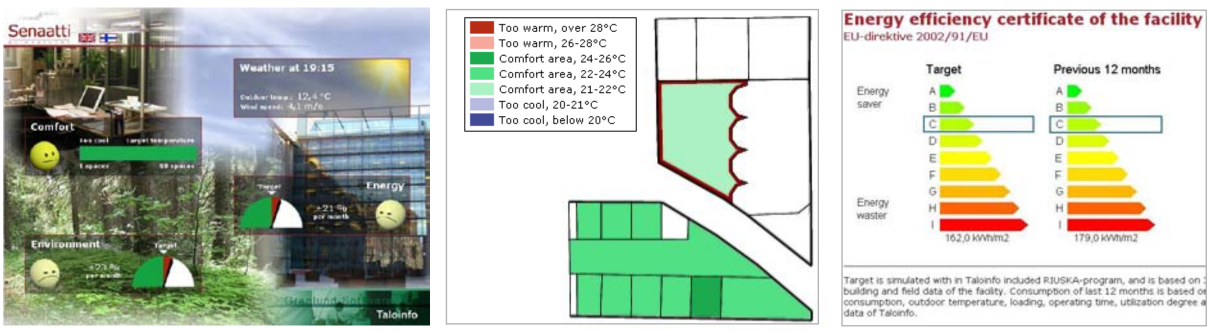

Figure 6. Self-reporting building system for BIM based performance management, including reports for top level performance evaluation (left), spatial comfort requirements verification (center) and on-line energy efficiency certificate (right).

BIM based approach also allows possibility to react on the changes in the use of the building by easy updating of energy and condition targets for monitoring and management systems.

DISCUSSION

The results show potential benefits of utilising BIM based concept in energy analysis: more efficient data input and more reuse for the existing data, possibility to use dynamic energy simulation instead of traditionally used static methods, support to use whole building spatial simulation instead of traditionally used zone based approach. However from the whole building process perspective, the biggest benefit is that by using BIM it is possible to bring continuous verification of energy performance for the whole building life cycle.

The real project experiences also showed, that successful BIM based energy analysis requires BIM revision management with comparison possibilities between different revisions, easy-to-understand visualisations of the thermal performance for clients and architect model validation for energy analysis purposes.

ACKNOWLEDGEMENT

The development of the new concept for spatial requirements management and the interoperable software environment was supported financially by Tekes, the Finnish funding agency for technology and innovation.

SUMMARY

The main challenge for future developments of renewable energy infrastructure is to reach an acceptable price level and a minimized environmental impact. Design tools for renewable energy installations are available on the level of individual installations. The potential for the application of renewable energy installations in the build environment is defined in an earlier phase of development: the design of the energy infrastructure for new build or renovated district areas. Design tools for the energy infrastructure are now lacking: renewable energy installations, tuning demand and supply in a dynamic way and tuning to the decision process. The objective is to develop design tools starting from the existing dynamic tools for single installations. New technological solutions are needed to make renewable energy solutions natural, easy and intuitively understandable for architect and consultants. The paper will discuss the approach to reach these goals.

INTRODUCTION

There is a persistent discrepancy between increasing demands for comfort in buildings and the need to decrease the use of energy. Preservation of energy resources, occupant comfort and environmental impact limitation are the key issues of modern and sustainable architecture. A major portion of primary energy consumption, about 40 %, is due to create thermal comfort in buildings by heating, cooling, ventilating and lighting. During the last decades, the main focus of research in Building Services was on reduction of energy consumption of buildings. The strong focus on the energy reduction led to situations in which health and comfort are endangered.

Integration between end-user and building is the ultimate in the intelligent building concept. “Connecting” the end-user to a building is complex. User-connectivity, the combination of usability and user interface together, is studied and developed further. Information and communication technology connects people and helps them to communicate with the building. Clements-Croome emphased transdisciplinarity and interaction: “Any consideration of intelligent buildings, whether learning, designing or managing them, requires a freedom of thinking which can embrace transdisciplinary ideas and systems. The word transdisciplinary, is a truly holistic and highly interactive concept. Intelligent building strategies are dealing with multiple criteria and attempting to integrate ideas over a wide range of issues [1].”

When the comfort control system is not working adequately, a lot of energy is wasted by too much heating or cooling. As a result of this overshoot indoor temperature is the most common issue in occupants' complaints about thermal comfort.

When design building services traditionally the main attention went to the heating demands. Due to the change in buildings, equipment and out door climate, there is a strongly growing demand for electricity instead of heating, see figure 1. So when designing the focus has to be changed.

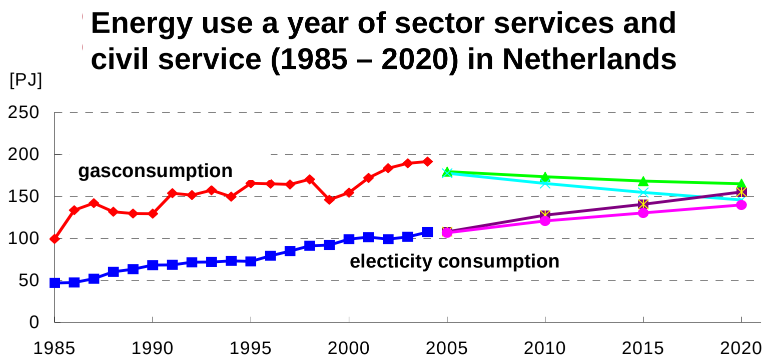

Figure 1. Development gas consumption and electricity demand the next 15 year [2].

Therefore it is important to look at energy reduction especially for this growing demand of a building. In office buildings most of the energy is needed for thermal comfort especially cooling. Present energy efficient technology is not sufficient to further reduce the energy use of buildings. New comfort control technology, such as individual control, offers new possibilities to further reduce energy consumption of office buildings. Dynamic online steering of individual comfort management and building management could save up to 20% of current energy consumption [3]. Misunderstandings and wrong conceptions about indoor comfort and energy use are common. Most office users are not even aware of the fact that they can affect the energy use. The behaviour of building occupants needs to be taken into account as it is responsible for almost half the outcome of planned energy reduction [4].

As until now the user has not been part of the building comfort system control strategy in offices, the energy consequences of the user behavior are not accounted for. New technological development is needed to incorporate the behavior of occupants of buildings.

Such novel control systems should not only improve the energy performance of the building, but should also offer benefits to users (i.e. building operators as well as workers). Comfort management should be linked with improving energy efficiency. Individual comfort management makes it possible to optimize comfort, energy efficiency and costs. This combination would be beneficial for building operators as well as occupants. Therefore in commercial buildings, the inclusion of options for individual comfort management is seen as an important feature to make such systems attractive to end users.

METHODOLOGY

Present control systems for office buildings already make use of new technical possibilities offered by computer networks. A next step in their development is the intelligent connection of the building networks with the Internet. The exploited Web is an interesting and successful storage place of information resources that can be used [3]. Comfort control systems could use dynamic real-time information from the Web about weather forecast, availability of energy and price level of energy. The information of the Web should be combined with information from the Building Management System (BMS) about the users, e.g. comfort demands or comfort preferences of the building occupants.

Agent Technology

Therefore, a new generation of control systems was developed with technology based on agent mediated communication over local networks and the Internet. Intelligent agents are autonomous and intentional pieces of software. These agents are capable of searching and sorting information from the Internet in order to perform certain tasks for the users they represent. Multi-agent systems provide the essential technology for this ICT-infrastructure[3];

- large numbers of actors are able to interact, in competition or in cooperation
- local agents focus on local interests and negotiate with more global agents
- implementation of distributed decision making by the negotiation processes between the different local or more global oriented agents
- communication between actors is minimized to generic information exchange between agents.

Previous work by Akkermans shows that the new Internet agent technology makes it possible to integrate occupants' behaviour with information sources from the Internet [3]. In two projects, SMART (Smart Multi Agent internet Technology) [5] and IIGO (Intelligent Internet mediated control in the built environment) [6] this technology was developed and tested.

Forgiving technology

A different type of technology to incorporate user behaviour, Forgiving Technology, was developed in another project, EBOB, Energy Efficient Behaviour in Office Buildings. EBOB investigated new combined technical and socio-economic solutions to make energy efficient behaviour natural, easy and intuitively understandable for the end-users of refurbished and new offices. Control scenarios for the HVAC systems were derived by analyzing occupants behavior and its effects on comfort and energy use. The EBOB project is an European 5th framework program project with eleven partners from five countries. EBOB ran from 2002 until 2005. The field test was held at Kropman's office at Rijswijk [7].

User representation

The techniques used within SMART/IIGO and EBOB made it possible to use the user representation and combine it with optimalization techniques. The representation of end-users was realized by developing an individual voting system; some results are shown in Figure 2. End-users were represented in the design by Fanger's comfort model [8]. Fanger's model predicts user's evaluations of the indoor climate in buildings. Using Fanger's model, the percentage of dissatisfied users can be predicted for a given set of comfort parameters.
The voting system allowed every user in a thermal zone to enter his vote (warmer/colder) within a voting period (e.g. one hour) while seeing the aggregated voting of other users in his zone at the moment of voting [5].

The users comfort needs dominate this control strategy. The control strategy is based on the description of the user behavior and implemented in a BMS (Building Management System). This BMS was extended with an external real-time information system to improve energy and comfort control. A learning curve is built from the user voting behavior. Responses of the user are interpreted differently depending on the overall trend of the comfort level in the building. Overall voting behavior as a function of the time of day is included in determining the action of the local comfort aspect controllers. Within this system the persistent use of user information is a leading strategy.

To work effectively with methodology, practitioners should learn to work with, and understand, the role of the user in the building design process. The building to be designed takes traditionally the central place in thinking of the design team. But in fact means and goal are mixed up. More and more the insight is growing that it is not the building to be designed that should be central but the needs of the humans for which the building is intended. This leads to a new approach in which the human needs are key aspects that have to be fulfilled, see figure 3.

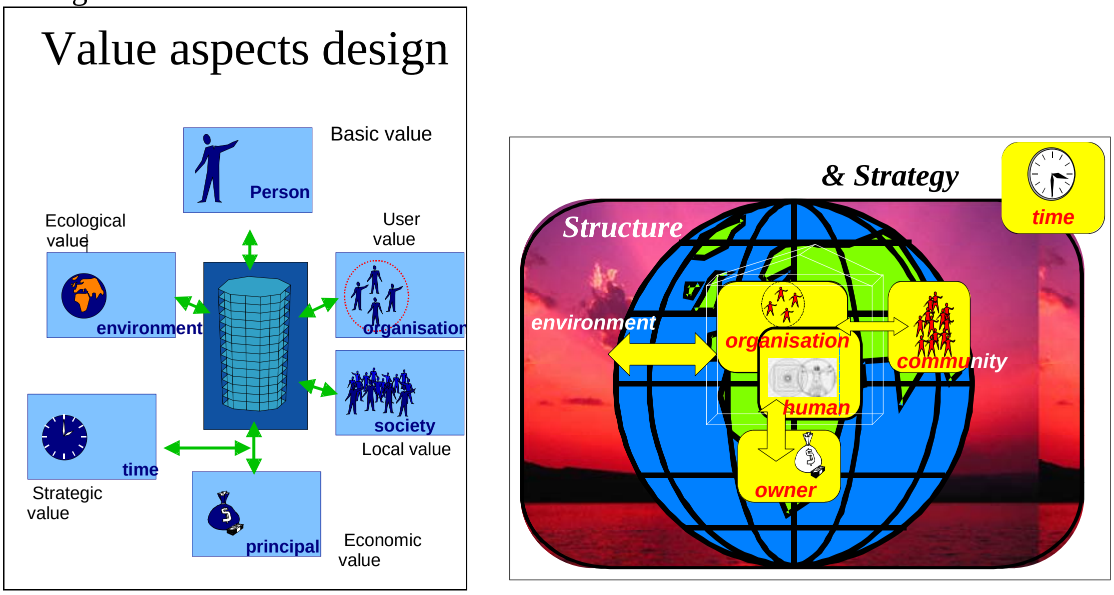

Figure 3: Strategic design, Paul Rutten [9] versus conceptuel representation of user interaction with the built environment

INTEGRAL DESIGN METHODOLOGY

Design is the key discipline that brings systems into being. In the engineering sciences, a lot of approaches have been developed to structure and optimize design processes: concurrent engineering, value engineering, design for manufacturability, systems engineering, quality function deployment, strategic design, etc. To develop our required model of design support, an existing model from the mechanical engineering domain was extended: Methodical Design [van den Kroonenberg [10,11,12] into an Integral Design methodology. The Integral design process can be described at the conceptual level as a chain of activities which starts with an abstract problem and which results in a solution. The original methodical design process is extended from three to four main phases, in which eight levels of functional hierarchical abstraction, stages can be distinguished. Starting by formulating the need, the program of demands is developed and transformed into functions to fulfill. This functional decomposition provides the means for decomposing complex design tasks into problems of manageable size. This functional decomposition is hierarchically so that the structure is partitioned into sets of functional subsystems. Decomposition is done until simple building components remain whose design is a relatively easy task, but each with each own focus, see figure 4.

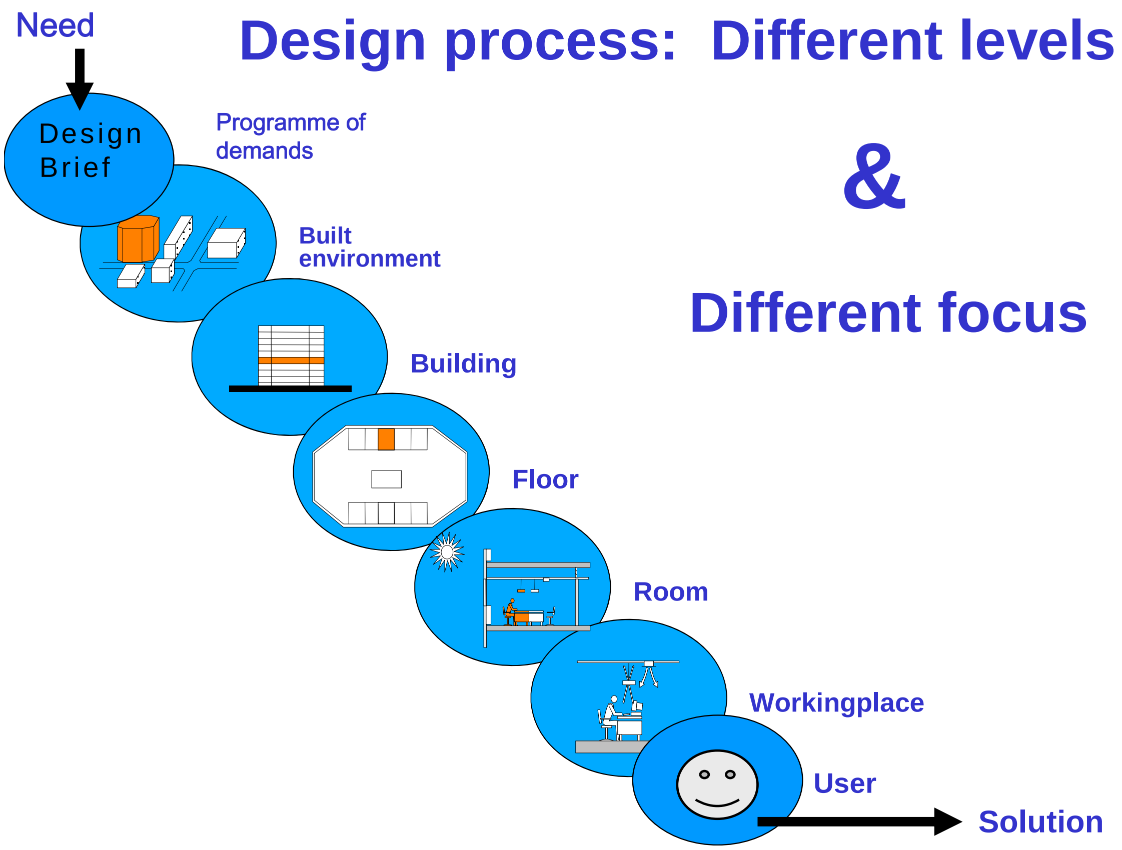

Figure 4: Hierarchical abstraction levels by functional decomposition

Hierarchical abstraction implies the decomposition of information into levels of increasing detail, where each level is used to define the entities in the level above. In this sense each level forms the abstract primitives of the level above. These higher-level terms form condensed expressions of a given relational and/or operational combination of primitives from the level below. Sets of generic components are located at distinct levels of abstraction. The contents of the layers are based on the technical vocabularies in use, technology-based layers or levels. Each layer represents an abstraction of the levels below. For a more extensive description of the models that formed the basis for the notion of technology-based layers see [13]. Separation is made between:
- Information level, knowledge-oriented, representing the "conceptual world".
- Process level, process oriented, representing the "symbolic world".
- Component level, device orientation, representing the "real world".

In addition, a new level is defined [14]: part level, parametric orientation, representing "the specification world". Thus, the four levels of aspect abstraction in the descriptive model of design are:

1. Information Level

This level deals with the knowledge of the systems by experts. One of the essential ideas behind this is that human intelligence has the capability of search and the possibility to redirect search. This information processing is based on prior design knowledge. One of the major problems in modelling design knowledge is in finding an appropriate set of concepts that the knowledge should refer to, or -in more fashionable terms- an ontology [13].

2. Process Level

This level deals with physical variables, parameters and processes. The set of processes collectively determines the functionality of the variables that represent the device properties. Modelling at the functional level involves the derivation of an abstract description of a product purely in terms of its functionality. This abstraction reduces the complexity of engineering design to the specification of the product's desired functionality.

3. Component Level

This level describes the hierarchical decomposition of the model in terms of functional components and is domain dependent. Generic components represent behaviours that are known to be physically realisable. They are generic in the sense that each component stands for a range of alternative realisations. This also implies that the generic components still have to be given their actual shape.

4. Part Level

This level describes the actual shape and specific parameters of the parts of which the components exist. Relevant technical or physical limitations manifest themselves in the values of a specific set of parameters belonging to the generic components. These parameters are used to get a rough impression, at the current level of abstraction, of the consequences of certain design choices for the final result.

Designing takes place in an environment that influences the process, it is contextually situated [15,16]. The context of the model of designing is defined by a "world view". The model of de Vries consists of 3 worlds and is extended by us to four worlds: the real world R, the symbolic world S, the conceptual world C and the specification world M, see figure 5. The Product – Process – Organization model (the PPO model), developed by Friedl [17] represents this "world view". Friedl's PPO model applies and elaborates comparable concepts as introduced in the Building Design Process Model according to Domain Theory [18]. Friedl's
PPO model discerns four essential domains of concern in the design situation:
- 'product domain'
- 'process domain'
- 'organization domain'
- 'context domain'

The relation between the extended model of de Vries and the PPO model is shown in figure 5;

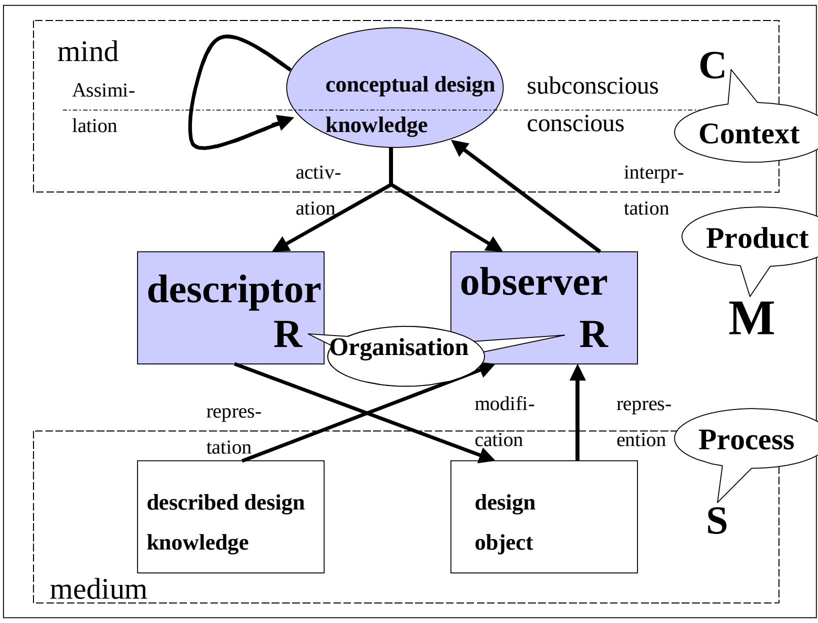

Figure 5: Extended model analytic schematic interaction model of designing

RESULTS & CONCLUSION

By implementing the insight that the user should become the leading factor within the process control, the following symbolic representation of the total process is shown in figure 6.

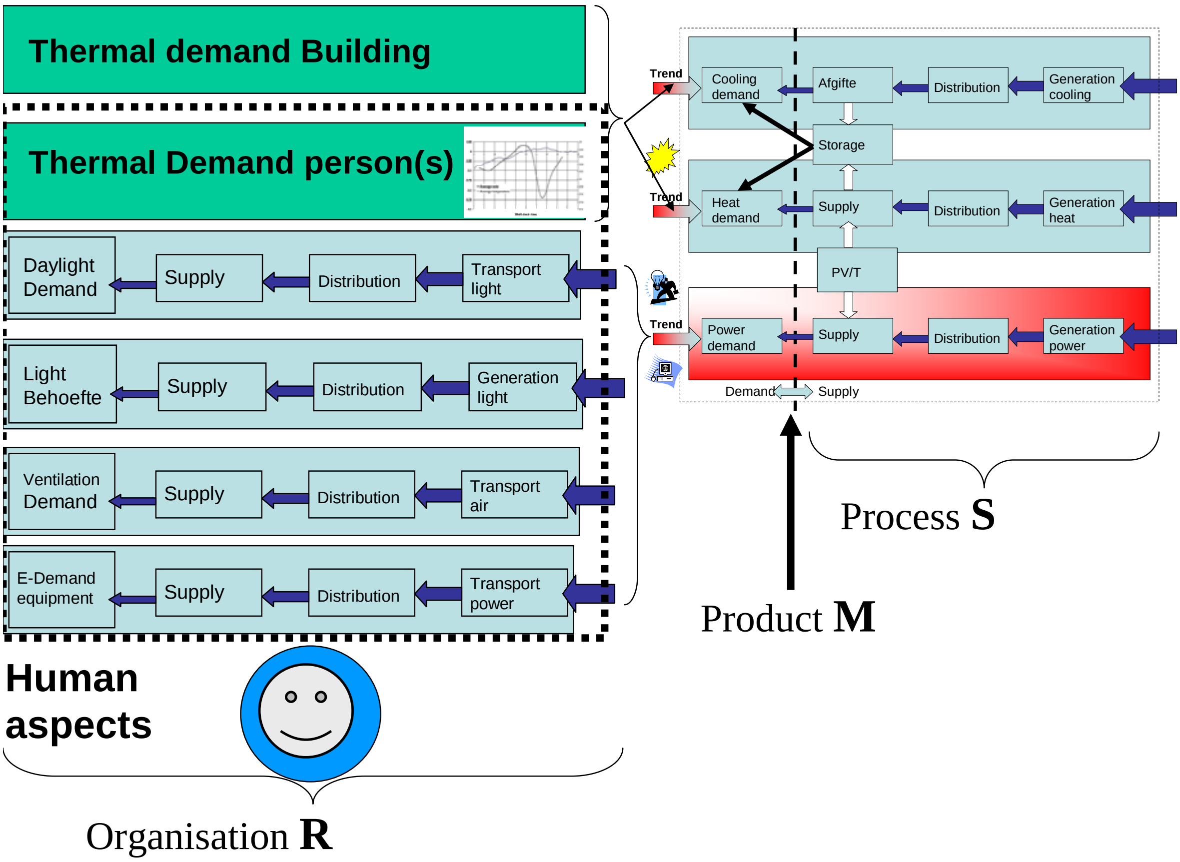

Figure 6; Process representation, the conceptual world C, presenting the context of the information model of energy flows within a building

In order to allow a stepwise approach in which each design decision has well defined implications, four different ontological levels are distinguished for designing energetic process:

* Information Model	* Conceptual World
* Physical Process Model	* Symbolic World
* Functional components Model	* Real World
* Parametric Model	* Specification World

These levels provide a structured framework for an integral design methodology. The benefits of methodical process design strongly depend on the experience of the design team members with the approach and its tools. For the Dutch building Industry workshops ‘Learning by doing’ are organized as part of the professional education of the members of BNA (Dutch Siciety of Architects) and ONRI (Dutch Society of Counsultants).

ACKNOWLEDGEMENTS

SUMMARY

The design of the HVAC and ice rink refrigeration system in an arena is a challenging optimisation task. To ensure that the requirements for the indoor conditions and the ice temperature will be fulfilled, the HVAC and the ice rink systems have to be optimised with the interactivity of each other in mind. This challenging optimisation task is solved with advanced and effective multiphysics and CFD simulation tools. The heat and moisture balance of the arena is solved dynamically with multiphysics tool with 3D simulation of ice rink heat balance. CFD (Computational Fluid Dynamics) is used to support the design of air distribution and indoor thermal conditions. These calculations form the bases for the MEP design solutions where integration of heating, cooling, dehumidification, energy conservation and the use of outside energy resources are optimised to achieve the most economical investment.

INTRODUCTION

Most multipurpose arenas that exist today are usually used for skating in some form, for sport activities or for recreational and leisure purposes. The design of the HVAC and ice rink refrigeration system in an arena is a challenging optimisation task. Ice rink facilities share all the same concerns: energy usage, operation costs and indoor climate. Multipurpose arena design and operation are totally unique and differ in many ways from standard buildings. Each arena should be taken as an individual project. The design solution which functions greatly in the last built arena may not be the ideal solution for another new arena under construction. The project specific requirements for the indoor conditions and ice temperature during events as well as usage of the arena form the boundary conditions for the design project.

The most important to know about multipurpose arenas are to understand their features compared to other kind of buildings. These special features are due to /1/:

- Indoor conditions vary a lot depending on the usage of the arena. In an ice rink high inside temperature differences occur in the same indoor climate, from -4°C to +24°C. At the same time these internal climate zones must be controlled and stay stable. In concert situation there exists also large heat loads from equipment which should also be handled.
- Differences in indoor climate also cause humidity problems that must be under control.
- Air tightness is more important feature of the building envelope than thermal insulation.

The aim of this paper is to present HVAC and ice rink design solutions of the multipurpose arenas. The requirements for indoor conditions, in heat and moisture balance of the arena and ice rinks, CFD simulations and some guidance of HVAC design are presented.

REQUIREMENTS FOR INDOOR CONDITIONS AND ICE TEMPERATURE

The requirements for the indoor conditions and the ice temperature set a basis for design calculations of the HVAC and ice rink piping system in Multipurpose Arenas.
Indoor air design values for multipurpose arenas are presented in Table 1.

Table 1. Indoor air design values for multipurpose arenas /1,2/.

Action	Air temperature		Ice temperature	Max. relative humidity	Heat loads		Min. fresh air intake
	Rink at 1.5 m	Tribune (operative)			Lighting	People	
Hockey	[°C]	[°C]	[°C]	[%]	[W/m]		[dm³/s/ occupant]
- game	+6	+10…+15	-5	70	40	80/spectactor	4…8/spectator
-training	+6	+6…+15	-3	70	20	125/player	12/player
Figure							
-competition	+12	+10…+15	-4	70	40	80/spectactor	4…8/spectator
- training	+6	+6…+15	-3	70	20	125/player	12/skater
Other	+18	+18	-	-	20	80 W/person	8/person

The most of the Arenas are scheduled for an all-year round use with a short break during peak summer conditions. This all-year round use imposes challenges in the design work because of increasing outdoor heat and humidity loads.

In practise, the indoor temperature varies between 10-12 °C above the ice during practice session, to 12-14 °C during competition races. The relative humidity ranges between 40-65% all year around. The temperature in the spectator areas is expected to be slightly higher than above the ice, 14-15°C. The ice surface temperature is in the range of -3..-10 °C. In some cases the ice temperature is wanted to keep much lower than presented in Table 1. It is quite normal that the ice rink is dimensioned at -6°C. The air flow velocity above the ice should not exceed 0.25 m/s.

HEAT AND MOISTURE BALANCE OF THE ARENA AND ICE RINK

Quite often the ice rink piping is built “as the previous ice rink” without thoughtful analyses of the different factors that affects the ice temperature in the arena in question. To ensure that the requirements for the indoor conditions and the ice temperature will be fulfilled the HVAC and the ice rink systems have to be optimised with the interactivity of each other in mind. This challenging optimisation task can be solved with advanced and effective energy simulation, multiphysics and CFD simulation tools.

To establish the expected indoor conditions it is essential that the cold load to the space from the ice surface is taken into account. Vice versa, the ice rink cooling capacity is not possible to be calculated without taking into the account the different heat loads and the indoor conditions, its temperature and humidity. To figure out the complexity of the design work, Figure 1 shows the interactions between different factors.

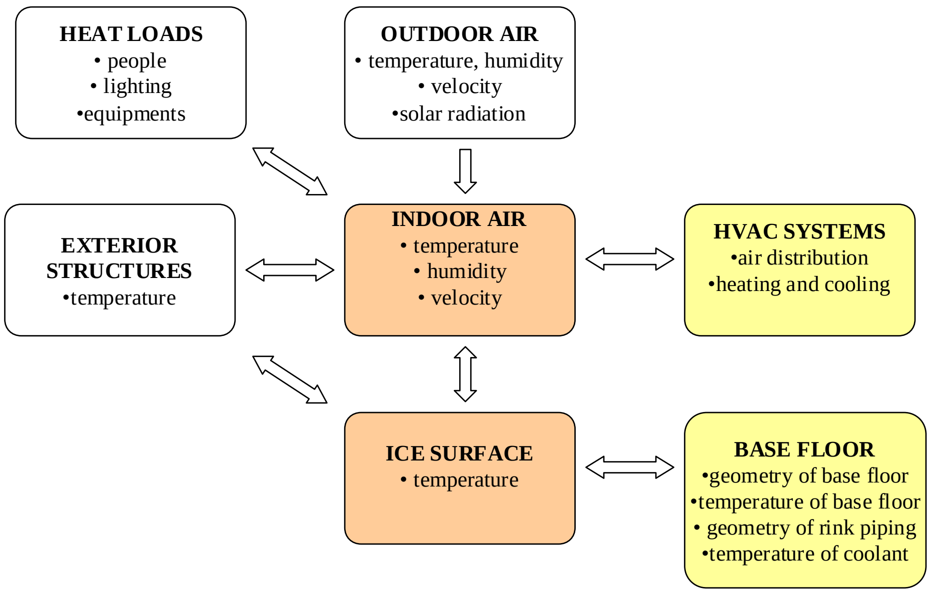

Figure 1. Interactions between different factors in Arena.

As we can see from the figure 1 there are plenty of factors that affect the indoor conditions. These are heat loads from the spectators and competitors, lighting and equipment, infiltrated and conducted outdoor heat loads, the supply air, additional heating load and the cooling load from the ice surface trough conduction and condensation. The people supply air and condensation rate to the ice surface and outdoor infiltration affects in addition the humidity of the indoor air. The moisture from the air condenses on the ice surface and has therefore a drying effect on the indoor air humidity.

Heat balance of the arena is presented in Eq.1.

$$\rho c_p V \frac{\partial T}{\partial t} = Q_{people}(t) + Q_{ligh}(t) + Q_{eq}(t) + Q_{AC}(t) + Q_{\inf}(t) + Q_{str}(t) + Q_{ice}(t)\,, \tag{1}$$

where ρ is the density of the air, c_p heat capacity of the air, V is the volume of the Arena, T is the temperature of the air, t is calculation time and Q is the heat load. The subscript *ligh* denotes lighting, *eq* denotes equipment, *AC* denotes air conditioning, *inf* denotes infiltration and *str* denotes structures.

Equation 2 presents moisture balance of the arena.

$$\rho V \frac{\partial x}{\partial t} = \dot{X}_{AC}(t) + \dot{X}_{aircirc}(t) + \dot{X}_{\inf}(t) + \dot{X}_{people}(t) + \dot{X}_{ice}(t) + \dot{X}_{other}(t)\,, \tag{2}$$

where x is the absolute humidity of the air and $\dot{X}$ moisture content. The subscript *aircirc* denotes circulated air.

The indoor conditions and the heat loads from people, lighting, equipment and building structures as well as the ground floor structure with ice rink piping have a strong effect on the ice surface temperature. In general, the final heat load to the ice surface varies between 155 to

320 W/m² depending on the activity and outdoor conditions. In practise the heat load to the ice is reasonable to keep under 220 W/m². Otherwise, the coolant inlet temperature to the ice rink piping has to be diminished radically down to -18°C to maintain the ice temperature at -6°C. In that case the energy economy of the refrigeration production will deteriorate substantially.

Figure 2 a) presents typical ice rink slab. The heat equation for the ground ice rink slab with boundary conditions for the ice surface, piping and ground are shown in Equations (3)-(6).

$$\rho_m c_{p,m} \frac{\partial T_m}{\partial t} = k_m \nabla^2 T_m \qquad (3)$$

$$k_m \frac{\partial T_m}{\partial y}(y = h) = Q_{conv,a} + Q_{rad} + Q_{cond} \qquad (4)$$

$$k_m \left(\frac{\partial T_m}{\partial y} + \frac{\partial T_m}{\partial y}\right) = Q_{conv,ht} \qquad (5)$$

$$k_m \frac{\partial T}{\partial y}(y = 0) = Q_{ground} \qquad (6)$$

where *k* is the heat conductivity and *h* is the height of the slab. Subscript *m* denotes material in the ground slab, *a* denotes air, *conv* denotes convection, *rad* radiation, *cond* condensation and *ht* heat transfer medium.

In Equation (4) the heat loads are the following:

- Convective load from the ambient air. The convective load depends on the temperature difference between the air and the ice and the heat transfer coefficient of the ice surface.
- Radiant load from the lighting and structures. The ice surface absorbs heat from the surrounding floors, walls, ceiling and lighting.
- Moisture load, condensation from the ambient air. The moisture load is proportional to the convective load and the ratio increases with increasing humidity in the air.

Additional loads, which influence on the ice rink cooling needs are the coolant circulation pumps, slab cooling during ice making, resurfacing and ice building during maintenance intervals and ice building.

To achieve indoor conditions and ice rink slab temperature distribution, the equations (1)-(6) are solved with multiphysics simulation software. In Figure 2 b) show an example of the temperature distribution of the ice rink slab. The geometry of the rink piping and the coolant inlet and outlet temperatures are essential in maintaining the ice surface at a required temperature level.

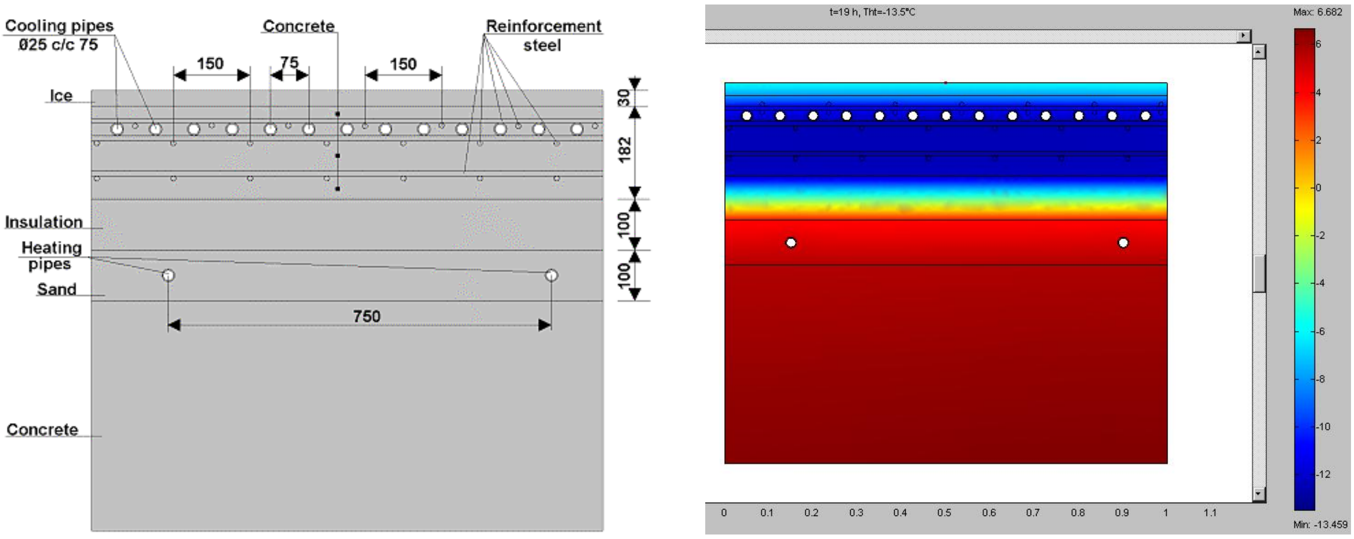

Figure 2. a) The ground floor with ice rink piping system, b) Example of the temperature distribution of the ice rink slab.

INDOOR AIR SIMULATIONS IN MULTIPURPOSE ARENAS

CFD is typically used to study indoor air conditions in spaces where design requirements are high and detailed information on flow field is important. CFD is a numerical calculation method and the realistic modelling of a indoor air environment is not an easy task. Supply air jets, forced and natural convection, and heat sources and sinks cause very complicated 3D flow field. At first, the important properties affecting flow phenomena have to be identified. Then the mathematical model is created and the space is divided into small control volumes. The conservation equations of mass, momentum, and energy are discretized and solved approximately using a numerical method. The accuracy of this calculation depends on the mathematical model, the numerical method, the calculation mesh, assumptions, initial values and iteration convergence. The typical focus is to compare different supply air distribution systems and wall constructions, and heat sources, which affect the indoor air environment. In addition, the results can be used to illustrate HVAC solutions to customers.

The first round of simulations involves individual air supply devices to test and compare operating conditions. The results allow the design team to choose the appropriate devices for each specific location. The device simulation results are compared to air jet theory and to the manufacturer’s profile data and measurements if possible. The simulated supply air jet profiles are then used as boundary conditions in whole arena simulations. The device models and simulation results are then saved to an object library for future projects.

The challenge is to design the supply air distribution so that fresh air flows to fully occupied zones and improves the thermal conditions. Draft, humidity, and temperature levels during different types of events in winter and summer conditions are considered. The benefits of the simulations are that they provide the possibility to try out different air flow device types or supply air systems, such as mixing, displacement, or a combination of both. Usually, first assumptions have to be corrected several times before the target is reached. It seems like a correctly performed CFD simulation is the only calculation method that can capture the indoor air flow field with the accuracy necessary for design purposes. In figure 3 is shown the simulated temperature distribution in arena during the ice hockey and concert events on summer time design day conditions.

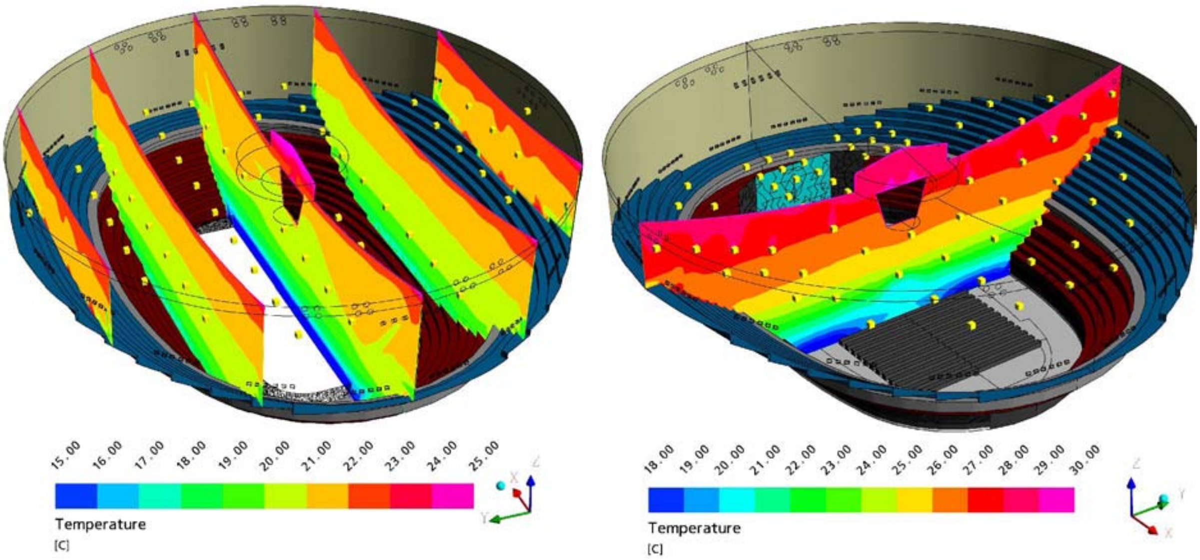

Figure 3. Temperature stratification of the Hodynka Arena in Moscow. On the left-hand side the ice hockey event and on the right-hand side the concert event.

The most challenging aspect in CFD simulations is how to have a realistic simulation results for design purposes. The conclusions should be made with care and compare different models and assumptions with experiments before the realistic results can be reached.

THE HVAC DESIGN

To maintain optimum indoor conditions all year around is a challenging task for the HVAC designer. The usage based on event varies greatly from maximum spectators to home team practice sessions. Then we have a very big open space where the occupied zone is in focus with special consideration to the ice area where a low temperature is a bonus but no condensation or fog build up is appreciated. It is obvious that for the base events such as ice-hockey, concert, small scale PR, ice-hockey practice, maintenance (empty) have to be calculated at winter and summer conditions in order to find out the design air flows and capacities for the these different functions of the air-conditioning units. It is sometimes useful to check with autumn conditions to see if the moisture balance can be obtained. The indoor condition calculations and CFD simulations set basis for HVAC design.

The moisture balance within the design set-points is as important as the temperature balance. The impact of the ice surface is essential to take into account. In cold to moderate climates the maximum air flows obtained for temperature balance are usually sufficient for moisture control. Quite often the spring conditions with ice-hockey game with maximum ventilation air demand and maximum indoor loads gives the design load for cooling. The same is for winter conditions with an empty hall, where optimum indoor conditions are maintained, gives the peak load for heating and autumn for dehumidification. If the skating activity is an yearly activity dehumidification during the summer period has to be calculated as well.

In the arena a heating demand exists as long as we have an ice surface, even during summer period.

Since the arena space itself has usually no outside walls, the only outside surface is the roof. The heat load from sun radiation to the arena is partly connective and partly radiation. The connective heat transmission has a small impact on loads, where as the radiation to the surfaces below are contributing to the total load which has to added to the total load. For some time low emissivity surface materials have been developed to diminish this factor.

The air distribution is one of the most interesting challenges in the design process. There are several parameters to consider in finding the most optimal solution. We want to achieve as low ice surface velocity as possible to keep the connective heat flow to the ice surface at a minimum level. In the spectator area with full seating we have a natural connective vertical thermal flow which will be very decisive for the arena flow pattern. This will create a high degree of stratification which with a displacement supply air distribution is an aim we want to achieve. At the same time a small vertical stratification is also desired to minimise the heating capacity demand and to avoid condensation on envelope structures during small load events such as practice sessions or maintenance periods.

There are very few options to show with design calculations how a solution will work, except with CFD modelling tools. It also gives a chance to test several air flow patterns. The air distribution solution has to selected in detail with the selection of each supply and exhaust air device. Only then is it possibly to find the optimum air distribution in the arena with a CFD simulations method.

It seems reasonable to apply several supply air methods in order to optimise the indoor climate and energy usage. During maintenance or practice periods the solution with vertical induction jets outside the ice surface in a circular pattern seems to have the best possible mixing with the space itself giving a small temperature gradient. At the same time it is possible to avoid the thermal influence of heating or dehumidification during spring and summer conditions. During events with spectators displacement ventilation around the ice rink in combination of active displacement diffuser in the perimeter of the upper spectator area seems to give the best end result.

To maintain a good indoor climate and achieve a low energy usage an advanced control strategy has to be adopted. To keep even indoor conditions at a variety of internal load situations the temperature, relative humidity and CO2 is monitored at several locations in the arena space. Usually CO2 is chosen since it is easily measured and has a rather good correlation with indoor air quality and many standards gives also level limits.
From the event calculations pre-programmed event control strategies can easily be determined.

Even if fire protections is outside the focus of this paper it is on important parameter to consider. The air-conditioning solution at best supports the fire protection solution giving small or no additional HVAC installations.

DISCUSSION

HVAC and ice rink design of the multipurpose arena is challenging optimisation task. The indoor conditions vary a lot according to usage of the hall. Different factors influences indoor conditions. To meet the requirements of energy efficiency and good indoor conditions the influences of the heat loads, ice surface, HVAC system and structures have to take into consideration. The utilisation of the advanced simulation and modelling methods together with multiphysic and CFD calculation tools ensure good background for HVAC and ice rink design.

Virtual indoor environment model for an open-plan office

Hannu Koskela and Raimo Niemelä

Finnish Institute of Occupational Health, Finland

Corresponding email: hannu.koskela@ttl.fi

SUMMARY

3D visualization methods have often been used in order to illustrate a building during the design process. This gives the building owner a better comprehension of the planned premises and improves the possibilities to select between different design options. The quality of the indoor environment is usually not included in the visualizations since it can be only predicted by using specialized software. However, the visualization of e.g. the air temperature, draught rating and contaminant distribution predicted with a CFD model would enable easier comparison of different room air conditioning solutions. Other indoor environment variables such as lighting and acoustics can also be predicted and included in the visualization. In this study, a virtual indoor environment model was created for a part of an open space office. The model is based on common VRML language standard for 3D presentations. It requires no custom software and can be viewed with a web browser plug-in. The model has a menu for user selection of indoor environment variables.

INTRODUCTION

3D visualization methods have often been used in order to illustrate a building during the design process. This gives the building owner a better comprehension of the planned premises and improves the possibilities to select between different design options. The quality of the indoor environment is usually not included in the visualizations since it can be only predicted by using specialized software. However, the visualization of e.g. the air temperature, draught rating and contaminant distribution predicted with a CFD model would enable easier comparison of different room air conditioning solutions.

From the standpoint of the end user it is important to set demands on the environment and to have a clear picture of the quality of the final environment. It is therefore of important to visualize the predicted environment is in such a way that it can act as an interface between the designer and the end user. Furthermore, in the design and construction phases of a building there are many partners who must co-operate with each other. There is therefore a need to enhance the speed and accuracy of the design phase and to improve the communication between different partners.

In the past, 3D visualization has been restricted to special software products and powerful workstations. At the moment, thanks to the requirements set by computer games, all standard computers have some level of hardware support to 3D graphics. This has created new possibilities to utilize 3D graphics for visualization purposes and distribute 3D models as standard documents. Applications like Google Earth demonstrate how 3D models of buildings can be made available through the internet.

A standard format for presenting 3D graphics is important for the distribution of visualization files. VRML format was developed for that purpose already in 1995. It has later been updated to VRML2 in 1997 [1] and to the present X3D format in 2002. It is an open standard designed to present 3D material in the web. VRML models can be viewed with browser plug-ins or special viewer programs that are freely available. There are several possibilities to view the model. The user can walk or fly around in the model or examine it by rotating and zooming. VRML based models have been available in the internet for more than ten years. The popularity of VRML models, however, has been hindered by practical limitations such as limited bandwidth for downloading the models and inadequate power of standard computers.

The aim of this study was to demonstrate the concept of indoor environment visualization by combining several modeling results in one interactive model. The model was created for a part of an open space office by modeling the air flow pattern and indoor conditions by CFD simulation. The model is based on VRML format and has a menu for user selection of indoor environment variables. The study was a part of the Virtual Space 4D project, where several simulation methods were applied in order to model and visualize the indoor environment [2,3].

METHODS

The modeling was done for a part of an open space office located in Helsinki (Figures 1 and 2). The modeled area of 32 m^2 was adjacent to large windows facing southwest. It included two working posts with furniture, PC:s, lamps and two supply air units. The room height was 2.3 m.

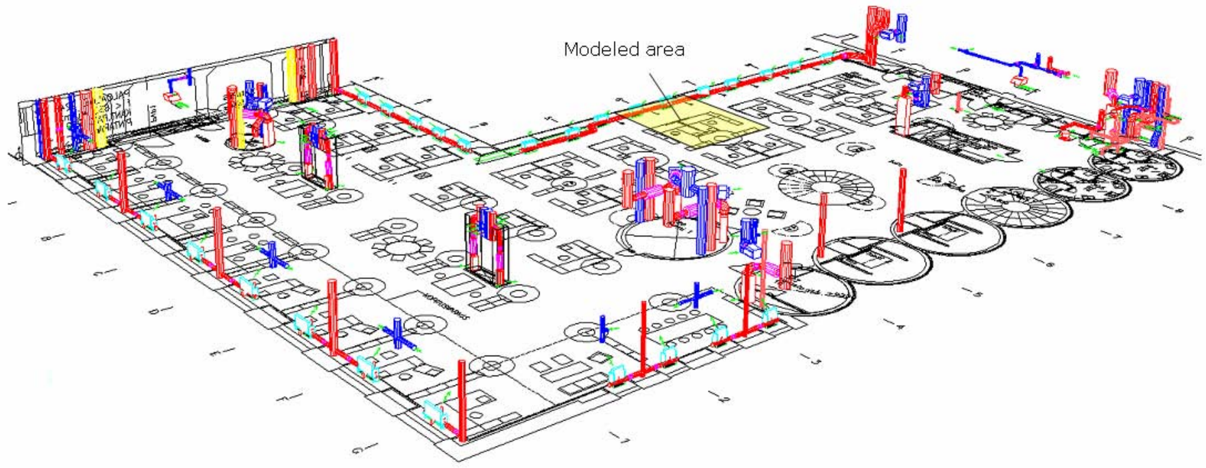

Figure 1. Layout of the open space office from the CAD drawing. The modeled area is shown.

Figure 2. Views from the modeled part of the open space office.

A simplified presentation of the studied area was created for CFD simulation with the pre-processor of the software package (Figure 3). Simplification of the actual geometry is necessary in order to reduce the computational requirements. The persons are presented by cylinders. Heat is produced in the space by the persons, PC:s and lamps. The total heat load was 18 W/m^2 floor area. The modeled situation was an early spring or late autumn day with 0 ºC outdoor temperature. The large window had a surface temperature 4 ºC lower than the room temperature. The heat loads of the model are shown in Table 1. Radiative heat transfer from the heat loads to the room surfaces was calculated separately and is included in the table.

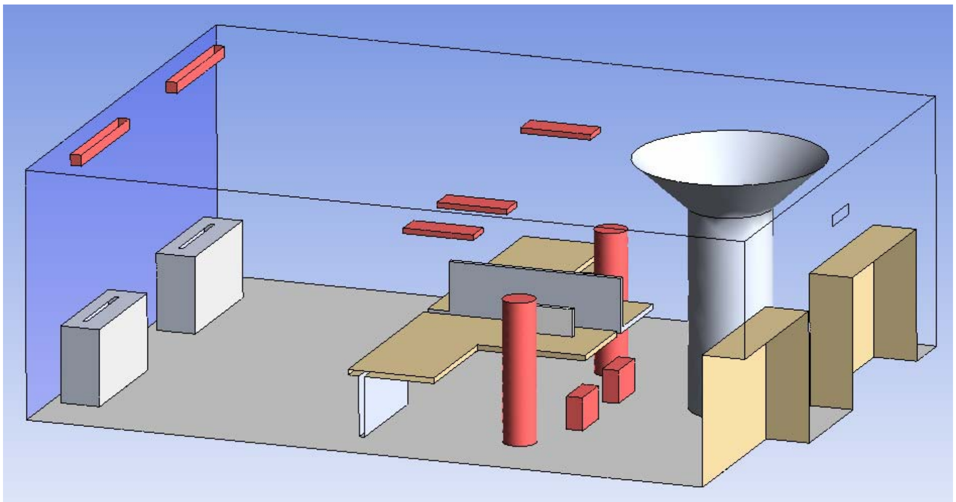

Figure 3. Simplified presentation of the modeled area for CFD-simulation.

Table 1. Heat sources and the distribution of convective and radiative heat loads.

		Convection		Radiation		
Object	Heat power (W)		To objects (W)		To floor (W)	To ceiling (W)
PC + LCD-display 1	100	50 %	50	50 %	30	20
PC + LCD-display 2	100	50 %	50	50 %	30	20
Person 1	100	50 %	50	50 %	25	25
Person 2	100	50 %	50	50 %	25	25
Lamp near working post	110	50 %	55	50 %	20	35
Lamp on the table	48	50 %	24	50 %	10	14
Lamp near the window	28	50 %	14	50 %	7	7
Total heat load	586	50 %	293	50 %	147	146
Window (dT – 4 °C)	–450	75 %	–350	25 %	–50	–50

Supply air as well as heating and cooling were produced by two induction units in front of the window. The supply flow rate was 20 l/s per unit and the flow rate of induced room air was 80 l/s per unit. The inlet boundary condition for the CFD-model was determined from the measured air flow rate and momentum flow rate of the unit. The heating and cooling of induction air was controlled by a room thermostat. In the modeled situation, most of the total head load was compensated by the cooling power of the cold window. Therefore, the induction air was not heated or cooled by the units.

The CFD simulation was carried out by using Ansys CFX 10.0 software. The computational grid was unstructured and had 220 000 nodes. k-ε turbulence model was applied. The spreading of contaminants was visualized by placing carbon dioxide (CO_2) sources above the modeled persons.

Thermal comfort was estimated by calculating draught rating (DR) values from the formula [4]

$$DR = (34 - T_a)(V_o - 0.05)^{0.62}(37 \cdot I_o V_o + 3.14) \qquad (1)$$

where T_a is the air temperature, V_o is the mean air speed (≥ 0.05 m/s) and I_o is the turbulence intensity. I_o is defined as S_o / V_o, where S_o is the standard deviation of air speed (≤V_o). Recommendations for the draught rating are given in the CEN Report CR 1752 [5] for three quality levels: 15 %, 20 % and 25 %.

The omnidirectional time averages of air speed and turbulence intensity were calculated from formulas [6]

$$\frac{V_o}{V_V} = 1 + I_V^{\,2}, \; I_V \le 0.45; \qquad \frac{V_o}{V_V} = \frac{1.596 \cdot I_V^{\,2} + 0.266 \cdot I_V + 0.308}{0.173 + I_V}, \; I_V > 0.45 \qquad (2)$$

$$I_o = \sqrt{(1 + 3 I_V^{\,2}) \frac{V_V^{\,2}}{V_o^{\,2}} - 1} \qquad (3)$$

$$I_V = \frac{\sqrt{\frac{2}{3} k}}{V_V} \qquad (4)$$

where *k* and V_V are the values of turbulent kinetic energy and air velocity magnitude from the CFD results and I_V is the turbulence intensity calculated from *k* and V_V.

RESULTS

The simulation results were analyzed with the post-processor of the CFD software. Following graphical presentations were generated:

- isosurface of draught rating value 15 % (strictest requirement) colored with temperature distribution
- isosurface of draught rating value 30 % colored with temperature distribution
- distribution of draught rating in a plane perpendicular to the window
- visualization of flow pattern by velocity vectors in a plane perpendicular to the window colored with temperature distribution
- isosurface of CO_2 concentration value 680 ppm
- distribution of CO_2 concentration in a plane perpendicular to the window

The visualization results were exported to separate VRML files and one file was exported with only the room geometry. The interactive model was then created manually from the exported files. The visualized environment variables (isosurfaces, contour diagrams and vector field) were copied from the separate files and pasted as individual objects in the file with the empty room. A floating menu was then created manually by utilizing and modifying the selection buttons that were created by the post processor to the exported VRML file. The menu buttons were then programmed to switch on and off the copied visualization objects. The selected items are indicated with red spheres in the menu. The cylinders that represented persons in the simulation were replaced with VRML models of persons in the visualization.

The resulting virtual model can be seen in Figures 4-7 with different selections of the results. The visualization is viewed here with Cortona VRML Client browser plug-in by Parallel Graphics. The viewing mode (walk, fly, examine) can be selected from the buttons on the left.

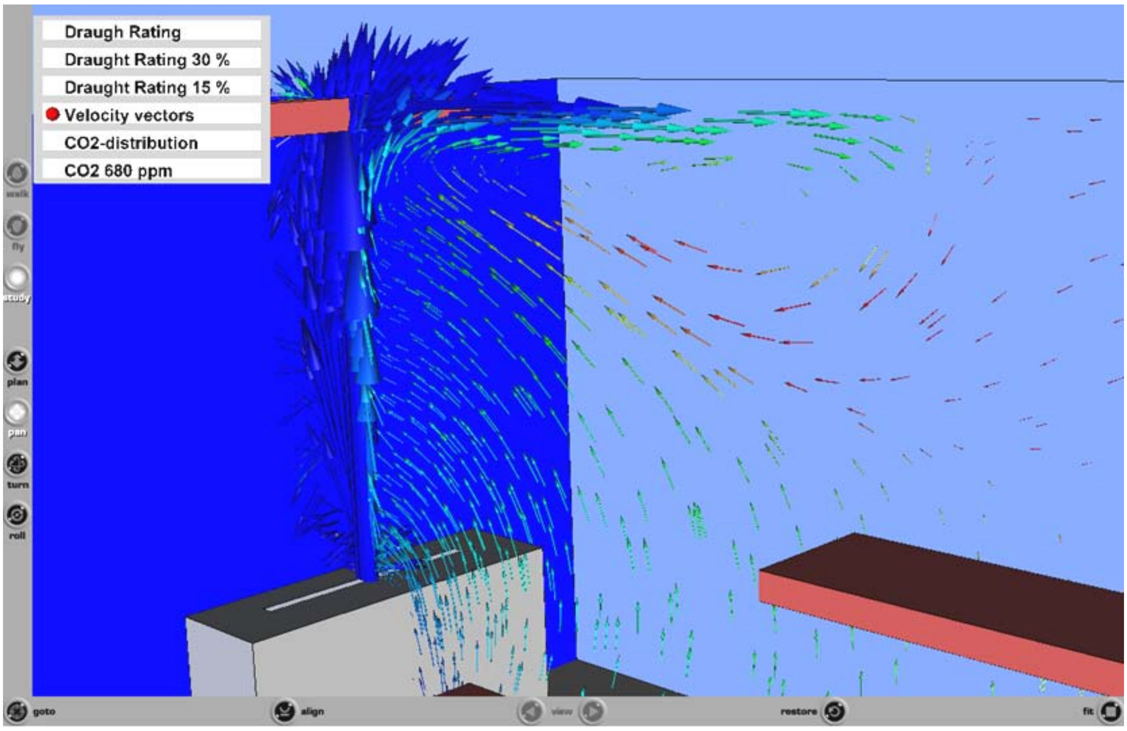

Figure 7. Flow pattern from the induction unit near the window.

DISCUSSION

The concept of virtual indoor environment model was demonstrated in this study by creating an interactive model of an office environment with a user menu for the selection of visualized variables. It represents a first step towards creating a visualization tool for enhancing the interaction between designer and end user in the design process. Such a tool can be useful e.g. in the following tasks:

- setting the user demands for the indoor environment
- visualizing the expected quality of indoor environment to the end user
- selecting between different design options
- showing the benefits of investment to the indoor environment quality
- visualizing the performance of the system in different outdoor and load conditions
- locating the room areas with a risk of discomfort
- finding optimal locations for the working posts

The VRML format offers a standard solution for the visualization of the indoor environment. The model can be equipped with a user menu for the selection of visualization variables. Other functionalities such as animations or sound can be added as well. The model can be distributed and viewed with a standard computer with a browser plug-in. VRML export is available in many modeling and visualization programs. The indoor environment model can be combined with architectural visualization. Modeling results from different applications can be combined in the same model, e.g. lighting visualization or auralization results from acoustical simulation. However, tools are needed for creating VRML models and adding functionality such as user menus or animation into the model. In this project the model functionality was built manually, which is not a practical method.

VRML is not the only available platform for indoor environment visualization. Application specific viewers are one way of distributing 3D models. These have been developed for modeling, visualization or CAD programs by the software companies for viewing the models in 3D format without having to buy and install the actual software product. They are typically meant for only one program and do not accept other formats.

A new proposal for a global standard for the presentation of 3D-graphics called Universal 3D (U3D) has recently been suggested by ECMA [7]. It has also been adopted in the new versions of Adobe Portable Document Format (pdf). It offers a promising platform for distributing 3D-models. The big advantage over specialized viewers is that pdf is a widely used de facto standard format for distributing documents. No installation of software is needed, since most computers already have a pdf reader installed. It remains to be seen, how widely this format will be adopted in the future.

The benefits of 3D visualization are obvious in many fields including the indoor environment. A lot of technical development is still needed for standardizing the file formats, building modeling tools and converters, etc. Multidisciplinary co-operation is also needed to develop the utilization of visualization in the design process in order to design the indoor environment to meet the user's needs.

ACKNOWLEDGEMENT

This study was a part of the Virtual Space 4D project of the CUBE technology program. The financial support of National Technology Agency of Finland is greatly appreciated.

SUMMARY

This paper presents a novel device called a Sense Diary for intelligent buildings. To introduce the new device and its applied system, a brief review of sensor-based systems applied in buildings has been conducted, which is based on current literature and products. The aim of this review is to understand current research and development situation of sensor-based systems that have been developed for all kinds of buildings and their systems across the world, and to further identify specific research tasks for an UK government EPSRC funded project focusing on innovative solutions of building façade systems. For acquiring the knowledge of sensor-based systems for buildings, some target information sources have been subjectively chosen. According to the literature and products review, several key research tasks of a Sense Diary System have been identified and discussed. It is concluded that the proposed Sense Diary and its applied system have advantages by providing daily real-time feedback to the facilities managers on environmental conditions thus improving control and health of occupants.

INTRODUCTION

This paper introduces a novel sensor-based subjective opinion feedback system called a Sense Diary for intelligent buildings. The initiative of this research was led by Clements-Croome in 1990 [1] and is being deployed through an IDCOP (Innovation in Design, Construction & Operation of Buildings for People) research project <http://www.idcop.soton.ac.uk/>, which is funded by the Engineering and Physical Sciences Research Council (EPSRC) in UK.

The EPSRC [2] has been conducting a research programme called Sustainable Urban Environment (SUE) since 2001. The key drivers of the SUE programme are to improve the quality of life of UK citizens, to support the sustainable development and to meet the needs of users of the built environment. The IDCOP is one of 12 research projects involved in current SUE programme, and it aims to develop innovative solutions with respect to the maintenance and refurbishment of existing buildings, specifically to find new ways to improve the performance of building envelopes over the whole building lifecycle [3]. There are two research themes:

- To develop sustainable façade technologies and enhanced methods for building refurbishment, and
- To reduce the consumption of non-renewable resources in a way that is economically viable and socially acceptable.

The research into a sensor-based system is linked to two IDCOP work packages, including embedded sensor systems and system personalisation. The research into a Sense Diary System has been deployed to achieve the following research targets, including

- a prototype of embedded sensors system with focus on occupants' well-being,
- a Sense Diary and its applied system that can be used at either work or residential places to register various degrees of either satisfaction or dissatisfaction by occupants in regard to commonly design environmental factors of buildings,
- to evaluate physical conditions of buildings while a Sense Diary system is used,
- to describe the well-being state of the occupants while they are using a Sense Diary, and
- to power a real-time facilities management process.

According to this deployment, a 4-stage plan has been made, which comprises of

- *A review of sensor-based systems for buildings*,
- *A new prototype of Sense Diary*,
- *The development of the Sense Diary and its applied system*, and
- *An experimental case study*.

This paper focuses on a brief review of current status of sensor-based systems applied in buildings across the world, and a concise introduction of the proposed Sense Diary system to be used for intelligent control of buildings. The review is based on current literature and products relevant to sensors and their applications in buildings and their systems. The aim of this review is to understand current research and development situation of sensor-based systems that have been developed for all kinds of buildings and their systems across the world, so as to further identify specific research tasks for the IDCOP project with focuses on innovative solutions of building envelop systems. For acquiring knowledge of sensor-based systems for buildings, both academic and professional information sources have been subjectively chosen, including *ScienceDirect Navigator* and IEEE Computer Society Digital Library (*IEEE Xplore*) for literature review and *ThomasNet* and *Google* for products review. According to the literature and products review, several key research tasks of the Sense Diary system are identified and discussed. It is concluded that the proposed Sense Diary and it applied system has the advantage in improving well-being and saving energy in buildings.

METHODOLOGY

Figure 1 illustrates a research framework for the review of literature and products and then the development of Sense Diary and its applied system. The research into a Sense Diary system for intelligent buildings has been divided into two stages in terms of related theoretical and methodological contexts:

- *The review stage*: Comprehensive information will be collected from three sources, including academic information sources (such as the *ScienceDirect Navigator*, the IEEE Digital Library, i.e., the *IEEE Xplore* and the *Elsevier EI Compendex*), professional information sources (such as the *ThomasNet*, the *Questex Media Group Sensors* and the *GlobalSpec Search Engine*), and general information sources (such as the *Google*).
- *The development stage*: System analysis and development method will be used to build up the Sense Diary system architecture and to program for a demo system.

With regard to each connection between a preceding stage and a following stage, which is based on a schedule for deploying each research task, a research and development strategy is being set up, which focuses on the products literature review, and the guidance for developing the Sense Diary system.

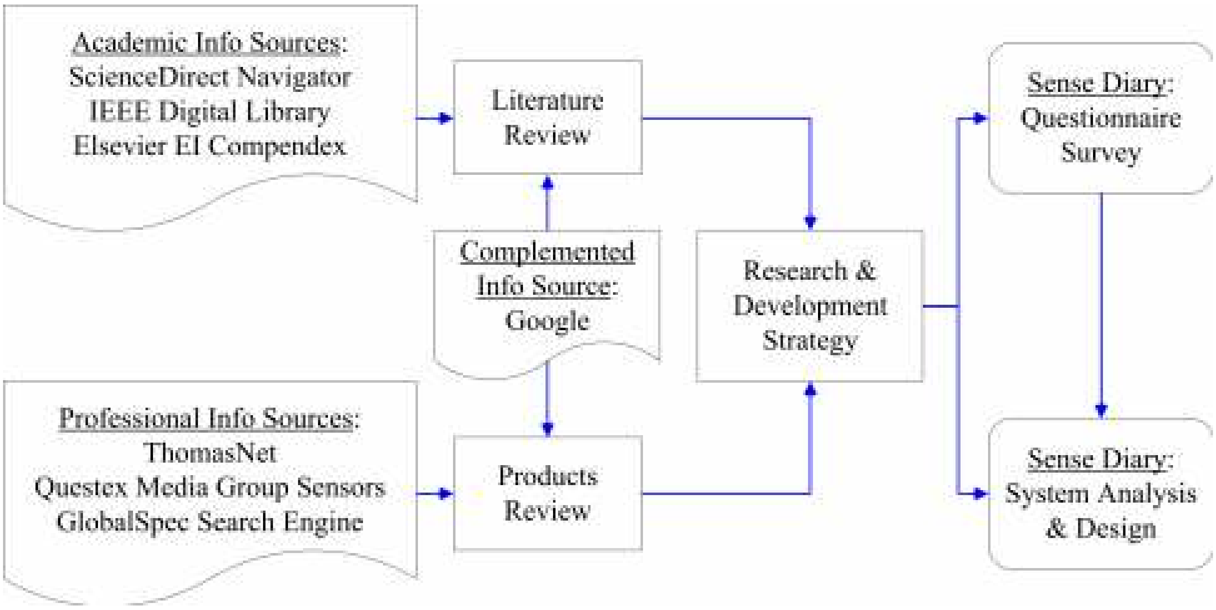

Figure 1: A framework for the research processes.

There are plenty of information sources around the world; however, to select a source of information for literature and products review, two criteria are adopted, depending on whether it is an *original source* of relevant information or whether it is an *authoritative source* of relevant information. Based on these criteria, several online databases have been selected from academic, professional or general information sources (see Figure 1).

LITERATURE REVIEW

Two main kinds of academic literature have been targeted and pursued, including periodicals and books. The reason for this selection is that periodicals can normally provide the most recent information about the review target; while books can give comprehensive information about relevant issues.

According to recent literatures such as the book edited by Gassmann and Meixner [4], the main areas of *sensor-based systems for buildings* cover the following five streams of research and development:

- *energy and heating ventilation & air conditioning* (HVAC) such as self-commissioned heating control system using Artificial Neural Networks (ANN), air-conditioning control, air quality measurement and management, sensor-based management of energy and thermal comfort, sensors in HVAC systems for metering and energy cost allocation, and pressure sensors in the HVAC systems, etc.;
- *information and transportation* such as wireless and M-Bus enabled metering devices, field-bus systems, wireless in-building networks, sensor systems in modern high-rise elevators, and sensing chair and floor using distributed contact sensors, etc.;
- *safety and security* such as life safety and security systems, biometric authentication for access control, smart cameras for intelligent buildings, and load sensing for improved site safety, etc.;
- *maintenance and facilities management* such as maintenance management in industrial installations, and worldwide facility management, etc. and

- *system technologies* such as sensor systems in intelligent buildings, and system technologies for private homes, etc.

The review has shown that modern sensor-based systems based on structured Wireless Sensor Network (WSN) have been applied in facilities management for the energy supply system, the HVAC system, and the safety and security system in buildings. In this regard, the proposed research into a Sense Diary system, which aims to set up an occupancy feedback system to be used at work or residential places to register various degrees of satisfaction/dissatisfaction with commonly design environmental factors, is within the main areas in the research and development of sensor-based systems for buildings, and the unique feature of the proposed Sense Diary system indicates that it is a novel device for aiding facilities management with regard to improving the energy efficiency of buildings and the well-being of occupants.

Davidsson and Boman [5] present a multi-agent system for controlling intelligent buildings. In a de-regulated market the distribution utilities will compete with benefit for the customer in addition to the delivery of energy. They describe a system consisting of a collection of software agents that monitor and control an office building. It uses the existing power lines for the communication between the agents and the electrical devices of the building, such as sensors and actuators for lights, heating, and ventilation. The objectives are both energy saving and increasing customer satisfaction through value added services. Results of qualitative simulations and quantitative analysis based on thermodynamically modelling of an office building and its staff using four different approaches for controlling the building indicates that significant energy savings, up to 40 per cent, can be achieved by using the agent-based approach. The evaluation also shows that customer satisfaction can be increased in most situations. In fact, this approach makes it possible to control the trade-off between energy saving and customer satisfaction (and actually increase both in comparison with current approaches).

PRODUCTS REVIEW

The literature review shows that the research and development of a Sense Diary system for buildings is a creative and innovative practice. However, this practice need to be deployed based on current level of relevant technologies. In this regard, a products review has been conducted, which aims to find out some relevant industrial systems that can be used for reference as follow.

Wireless Sensor Network

A wireless sensor network (WSN) is a computer network consisting of spatially distributed autonomous devices using sensors to cooperatively monitor physical or environmental conditions, such as temperature, sound, vibration, pressure, motion or pollutants, at different locations [6,7]. The development of WSN was originally motivated by military applications such as battlefield surveillance; however, the WSN is now used in many civilian application areas, including environment and habitat monitoring, healthcare applications, home automation, and traffic control [6,8]. The WSN can bring a broad range of diverse applications from house to commercial buildings, from simple system to complex system. The advantage of WSN set up based on wireless network other than traditional wired network can just fulfil the requirements of occupants who want much interior space from the building services systems.

To review current applications of WSN in the built environment, two commercial systems have been identified as good applications. One example is for commercial buildings and the other one is for residential buildings. For the WSN applied in commercial buildings as well as households, the example is GAMMA Building Management System from Siemens [9]; meanwhile, for the WSN applied in residential buildings, the example is the CyberEye system from Sungji [10].

Commercial Initiatives

As the proposed Sense Diary is to be integrated with a local WSN either within a residential building or within an office building, another part of products review goes to control devices; and six set of commercial systems have been reviewed, including

- The Secom building services control station [11], which is a *Building Services Panel* that tenants can use to control the turning on and turning off lighting and air conditioning according to pre-defined time zones.
- The Ambi-Rad SmartCom Control Unit [12], which is designed for warm air heater units and radiant systems and has been designed to consolidate the function of all previous control panels into one unit.
- The Echelon NES system [13,14], which is a state-of-the-art, future-proof smart metering system that brings new features and benefits to every aspect of ones utility's operations - from metering and customer services to distribution operations and value-added business.
- The TAC Satchwell MicroNet [15], which is a modular building management system that is easy to specify, operate, and tailor. It is suitable for small to medium scale operations and is sold through a locally accredited partner network.
- The Microsoft Home [16,17], which simulates a domestic environment including a front door, entry/foyer, kitchen, family room, dining room, entertainment room and bedroom. The Microsoft's technology-laden home of the future aims to feature smart appliances connected by Web services and controlled by tablet PCs or cell phones.
- The Siemens Smart House [18], which is a range of options that enhance the functionality of any home and are easy to use. Once some basic *Standard Fit*, including pre-wired cables for lighting, heating, blinds, surround sound, audio, video, data, voice and living lighting, is installed, then home owners can really make their homes 'Smart' and evolve it as they may change the way of living, and it is also believed that the choice is endless. There are three options below for home owners to choose and match in regard to the level of functionality they require, and the three Siemens Smart Homes options are:
  - The *Silver SMART Home Technology* package includes all the preliminary systems detailed in the *Standard Fit* package,
  - The *Gold SMART Home Technology* package includes *Standard Fit* preliminary cabling, plus all the features in the Silver package.
  - The *Platinum SMART Home Technology* package includes *Standard Fit* preliminary cabling, plus all the features listed in both the Silver package plus Gold package upgrades**.**

As the proposed Sense Diary system aims to develop a new control panel for intelligent buildings control in regard to real-time occupants' opinions, products review has mostly gone to devices and relevant technical platforms that all current systems adopted. Mobile phone and PDA are currently popular intermediaries applied in buildings management systems [17-19]; in addition, touch screen devices are also popularly used in some buildings [19]. For example, mobile phones are used as a controller in Siemens Smart Home [18], and PDA is also used in buildings control [20]. All these information indicates that the intermediary of the proposed Sense Diary system needs to be chosen from these devices or to be embedded into all kinds of these devices.

RESEARCH AND DEVELOPMENT

Strategy

The trend of research and development has been identified through literature and product review, including

- Multi-functional devices and systems based on WSN,
- Such devices need to be based on international standards,
- Such devices need to be with integrative functions,
- Easy to use and to be reliable and energy-efficient.

Although there are some relevant devices using desktop, laptop, PDA and touch screen, the proposed Sense Diary system is new and the idea has a very practical purpose but will contribute to sustainability.

A Sense Diary System

The research into "Embedded Sensor Technology and Occupant Behaviour" aims to help building professionals to further understand building occupancy or use patterns during a period of occupancy time. This study will explore relevant issues related to the Sense Diary System, which is expected to aid managing energy use and monitoring building performance besides assessing occupants' well-being requirements in regard to real-time performance of building services systems and building façade system. In particular, this study aims to identify the occupancy behaviour patterns associated with building use so as to find out a possible relationship among these variables, their carriers and energy use. As a result, a Sense Diary as a prototype intelligent sensor-based device to monitor these variables is introduced, and is to be developed and tested in collaboration with industrial leaders such as Siemens and Echelon, who promote interaction between UK science, engineering and industry.

To facilitate the research going further, the definitions of Sense Diary and its applied system are proposed first based on the idea proposed in the 1980s by Clements-Croome [1,21]. The Sense Diary is a user feedback panel which can be used by building occupants for inputting their opinions about well-being requirements based on indoor environmental status indication and their psychological feelings. The Sense Diary in the format of software can be programmed into different devices such as PDA, laptop, desktop PC and even mobile phone and TV. The Sense Diary within the environment of Ethernet and/or wireless network of the building can exchange data with wired network server and/or wireless network server; various sensor data parameters such as temperature, air quality, light and sound, etc. can be received by the Sense Diary, and Sense Diary can transmit occupants' feedbacks to remote control centre for building services system management or facilities management. The architecture of the Sense Diary System is illustrated in Figure 2.

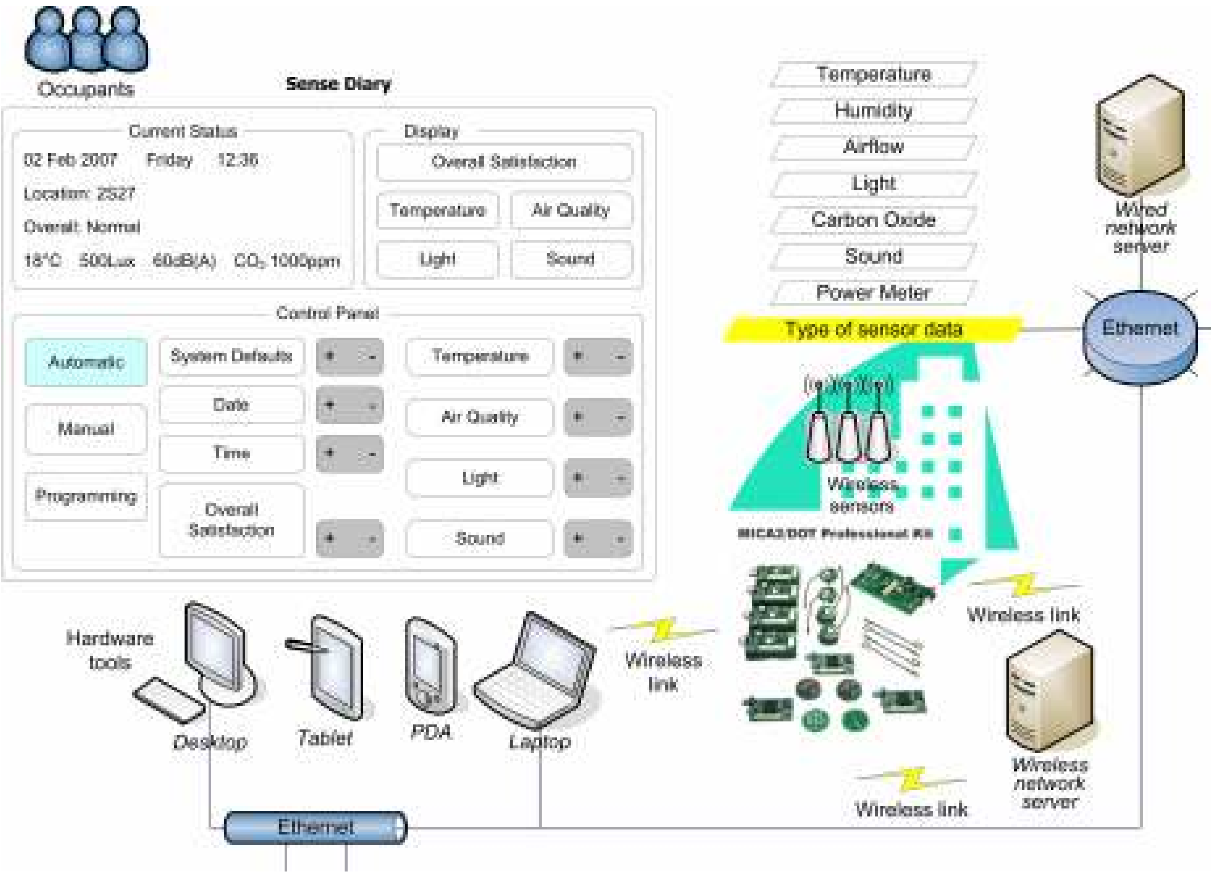

Figure 2: The Sense Diary System [1,21].

DISCUSSION

This paper introduces on-going research into Sense Diary System for intelligent real-time feedback and control to buildings, which can improve energy-saving and well-being. A system diagram about the proposed device has been described, which is based on a comprehensive review of current information from both academic and professional sources. Further research will focus on the collection and analysis of experts' opinions in terms of the design of the proposed device and its integration into diverse buildings management systems; furthermore, a demonstration system is expected to be developed at the end of this research.

ACKNOWLEDGEMENTS

This research is funded by the UK government Engineering and Physical Sciences Research Council (EPSRC). The title of the research project is *Innovation in Design, Construction & Operation of Buildings for People* (IDCOP) (Grant reference number: GR/T04878/01), and the project is being undertaken as part of a project within the EPSRC's *Sustainable Urban Environment* (SUE) programme by three Universities, including University of Southampton, University of Greenwich, and University of Reading. Investigators are Professor A.S. Bahaj, Professor Derek J. Clements-Croome and Dr Keith Jones.

An Intelligent Decision Support System for the Design and Construction of Building Envelopes

Zhen Chen and Derek J. Clements-Croome

University of Reading, UK

Corresponding email: zhen.chen@members.asce.org

SUMMARY

This paper aims to introduce a prototype of an intelligent decision support system, called FacadeChoice system, for decision-making in façade solution evaluation at design stage and façade product selection at construction stage. The prototype of the proposed intelligent system comprises of several assessment tools such as a multicriteria decision-making tool using analytic network process, a façade rating tool, and an intelligent tool using artificial neural network. The integrative use of these tools can enable decision-makers to use a systemic process to deal with problems of building façade systems assessment at either design stage or construction stage. As an on-going research project, this paper does not use case studies to further demonstrate the effectiveness of the proposed system; however, it has been discussed that the adoption of the intelligent system in building façade systems assessment can facilitate the acquisition and reuse of experts' knowledge, which is essential for new buildings. This paper is an output from an on-going research project funded by the EPSRC Sustainable Urban Environment program in UK

INTRODUCTION

Building rating method has been applied in the assessment of either new or existing buildings around the world, and there have been many building assessment systems such as

- BREEAM, Building Research Establishment Ltd., UK;
- CASBEE, Sustainable Building Consortium, Japan;
- LEED, Green Building Council, USA;
- GBTool, International Initiative for a Sustainable Built Environment, Canada;
- HK-BEAM, HK-BEAM Society, Hong Kong, China; and
- IB Index, Asian Institute of Intelligent Buildings, Hong Kong, China.

However, it has also been noticed that all these building assessment systems are not specially designed to evaluate building façade systems. In other words, currently there is not a general buildings façade system assessment tool, and this leads to the research being presented in this paper.

Based on practical experience and theoretical studies of some buildings assessment systems, a new approach to the assessment of buildings façade systems is proposed using a multicriteria decision-making model using Analytic Network Process (ANP) [1] in regard to innovation and environmental sustainability in the design and renovation of building envelopes [2]. To undertake the task, an ANP model named FaçadeChoice was constructed based on a group of Key Performance Indicators (KPIs), and the model was recommended in the design of buildings façade systems for innovation and environmental sustainability. The ANP approach is difficult for practitioners to use according to a number of discussions with professionals from Arup in London. Therefore, an alternative approach integrated with an Artificial Neural Network (ANN) model was put on the schedule of research. In this regard, this paper summarizes the progress of continuing research into the assessment of buildings façade systems.

This paper aims to introduce an intelligent decision support system, called FacadeChoice system, for decision-making in either the assessment of buildings façade systems at design stage or the selection of relevant products at construction stage. The proposed system is an integrative use of several assessment tools, including

- a multicriteria decision-making tool using ANP, which is called FacadeChoice model;
- a façade rating tool, which is called Facade Progress Index; and
- an intelligent tool using artificial neural network, which is called FacadeChoice system.

As an on-going research project, this paper doesn't use case studies to further demonstrate the effectiveness of the proposed FacadeChoice system; however, it has been discussed with both academics and professionals that the adoption of this system in the assessment of buildings façade systems can facilitate the acquisition and reuse of experts' knowledge, which is essential for both new buildings and buildings refurbishment.

METHODS

FaçadeChoice model

The ANP is a general theory of relative measurement used to derive composite priority ratio scales from individual ratio scales that represent relative measurements of the influence of elements that interact with respect to control criteria developed by Saaty [1]; and there are four generic steps in the ANP, including

- model construction,
- paired comparisons between each two clusters or nodes,
- supermatrix calculation based on results from paired comparisons, and
- result analysis for the assessment.

In order to set up an ANP model, a group of indicators has to be defined first as the criteria and sub-criteria for ANP modelling. In this regard, a group of KPIs has been selected for the FaçadeChoice model [3,4] (see Table 1). There are two clusters inside the FaçadeChoice model (see Figure 1), including

- the cluster of Criteria, and
- the cluster of Alternatives.

The model is designed to support the selection of the most appropriate façade solution from two or more alternatives in the process of evaluation, or to make a comparison between a proposed building façade system and a standard/reference building façade system in a same category in the process of assessment. The cluster of Alternatives consists of two nodes in a pilot case study including Façade System A and Façade System B, which are two options of building façade systems under assessment. On the other hand, the Criteria cluster contains six subnets, i.e., the sub-cluster of KPI Group t (t=1~6), which are in accordance with the six KPI groups identified in Table 1, including

- Adaptability,
- Affordability,
- Durability,
- Energy,
- Intelligence, and
- Well-being.

Table 1. KPIs for the assessment of building façade systems

Clusters of KPIs			KPIs to evaluate building façade systems		
No.	Name of Cluster	Score* of Cluster	No.	Name of KPI	Score* of KPI
1	Adaptability		1.1	Maintenance flexibility	
			1.2	Refurbishment flexibility	
			1.3	Environmental impacts	
			1.4	Social impacts	
2	Affordability		2.1	Design cost	
			2.2	Construction cost	
			2.3	Maintenance cost	
			2.4	Refurbishment cost	
			2.5	Demolition cost	
			2.6	Recycling cost	
3	Durability		3.1	Lifespan	
			3.2	Fire protection pattern	
			3.3	Fire endurance	
			3.4	Material density	
			3.5	Structural reliability	
			3.6	Decay resistance	
			3.7	Quality	
4	Energy		4.1	Embodied energy	
			4.2	Energy performance	
			4.3	Renewable energy	
			4.4	Building orientation	
5	Intelligence		5.1	Control strategy	
			5.2	System Integration	
			5.3	Emergency response	
			5.4	Automation	
6	Well-being		6.1	Aesthetics	
			6.2	Daylight absorbability	
			6.3	Indoor daylight comfort	
			6.4	Outdoor daylight comfort	
			6.5	Indoor sound reverberation	
			6.6	Outdoor sound reverberation	
			6.7	Indoor sound absorption	
			6.8	Outdoor sound absorption	
			6.9	Indoor temperature	
			6.10	Indoor relative humidity	
			6.11	Indoor ventilation	
			6.12	Toxicity hazards	

*Note: Below please find scales for scoring with regard to sustainable (environmental, social and economic) issues relevant to People, Products and Processes:
1= Not important, 2= not to moderately important, 3= Moderately important, 4= Moderately to strongly important, 5= Strongly important, 6= Strongly to very strongly important, 7= Very strongly important, 8= Very strongly to extremely important, 9= Extremely important.

On the other hand, Table 1 can also be used to collect experts' opinions in regard to the importance of each KPI in order to set up the FacadeChoice model; and this was conducted through questionnaire survey. For example, in an experimental case study, Table 1 was used to collect information for pairwise comparisons between paired clusters and between paired KPIs.

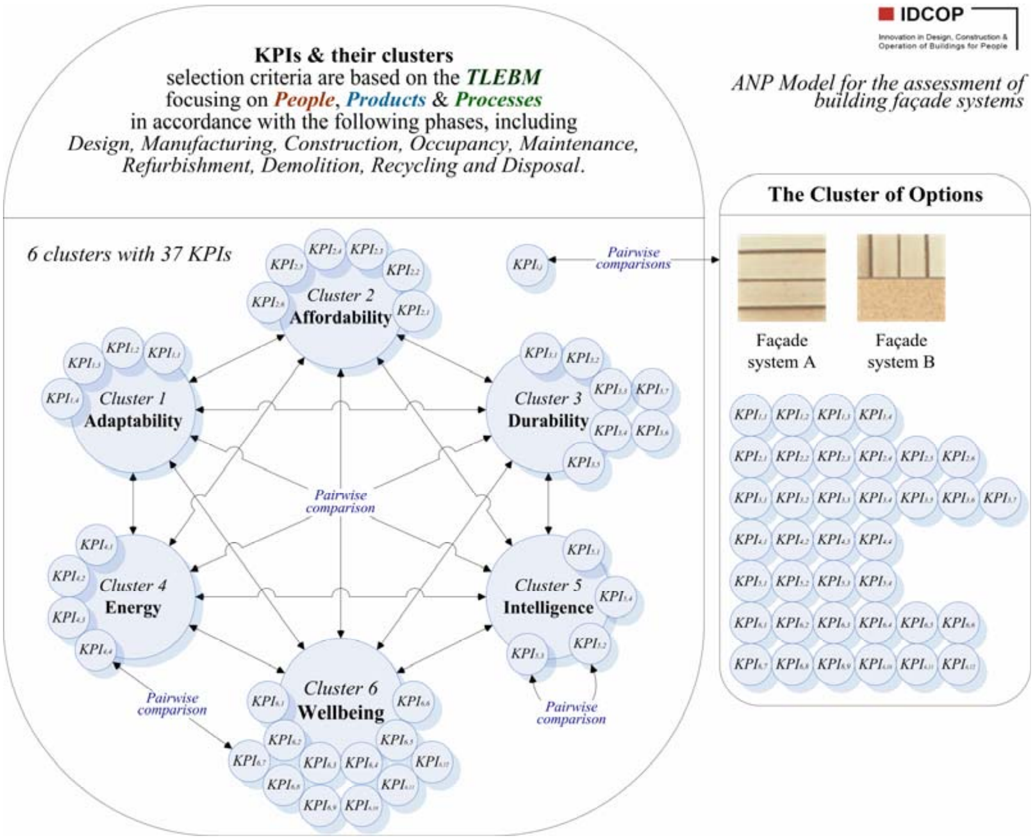

Figure 1. The FaçadeChoice model.

Façade Progress Index

Based on evaluation theories adopted by different building rating methods such as the LEED [5], it has been identified that this kind of method can only be used to evaluate one target building each time; whilst the ANP method can be used to evaluate either one target building or several target buildings [6]. To evaluate more than one building or buildings façade systems together each time, information has to be added to the ANP model in regard to details of a reference building such as a standard building/building façade system in a particular building/building façade system class as well as alternative building/building façade system plans for the same building project. However, after this pilot research into FacadeChoice ANP modelling, it has been noticed that the ANP approach is difficult for practitioners to use through a number of discussions with professionals from Arup in London; instead, it looks that rating method is much easily to be accepted. Therefore, a new rating method, called Façade Progress Index (FPI) (see Equation 1) is proposed.

$$FPI_j = \frac{\omega_{ANP\_j} \times \sum_{i=1}^{n}(w_i \times S_{Gap\_i})}{n \times S_{\max\_Focus}} \times 100\% \quad (1)$$

Where

- FPI_j is the Façade Progress Index of building façade system option j.
- ω_{ANP_j} is the ANP coefficient of building façade system option j, which is the synthesized priority weight of option j base on ANP modeling.
- w_i is the weight of KPI_i based on consensus decision-making.
- S_{Gap_i} is the Gap between current and target scores of each KPI_i.

- S_{max_Focus} is the maximum value of Gap Focus, it is 81.
- N is the number of *KPIs*.

According Equation 1, the ANP coefficient can be calculated based on the result of synthesized priority weight of options from ANP modelling. The reason of this design is that the ANP has been regarded as the most effective and efficient approach to measuring inter-relation among all KPIs, which should not be ignored in multicriteria decision-making.

FacadeChoice system

Although both ANN and ANP have been separately applied for decision-making in relevant areas for a long time, there are few research into an integrative use of ANN and ANP; in addition, it has been noticed that there has been some research initiatives in terms of the integrative use of ANN with multicriteria decision-making area focusing on how to use ANN to define the priorities of indicators for setting up decision-making models [7], and there are also few publications about either applying ANP or an integrative ANP and ANN for multicriteria decision-making purposes. In addition, it has been noticed that, among current publications, the purpose of using ANN and AHP was to use ANN models as the data supplier of AHP models. In this study, the purpose of the integration of ANP, ANN and rating approach is to train an ANN model by using results generated from ANP and the rating approach. It is clear that they are opposite processes in multicriteria decision-making between previous research and this study. As a unique decision-making model, this innovation will make it easy for practitioners to conduct assessment by using valuable expertise accumulated from ANP modeling. Therefore, the proposed FacadeChoice system provides a completely new method for the assessment of buildings façade systems.

The proposed ANN model has three layers, including an input layer, a hidden layer and an output layer. In order to achieve a synergetic effect, the group of KPIs for both FacadeChoice model and Façade Progress Index is used for the input layer; as the group of KPIs, with 37 indicators, does not involve the score of a building façade system, i.e., its value of façade Progress Index (see Equation 1), it is further adopted at the input layer as the 38th input. For the output layer, there is only one output, i.e., the value of the Façade Progress Index of a building façade system under assessment, which can be obtained from ANP modeling and Equation 1.

In order to facilitate the application of ANN, commercial software, i.e. NeuroSolutions is selected, because NeuroSolutions for Microsoft Excel is an efficient add-in that enables users to quickly develop custom neural network models without ever having to leave the Excel environment [8]; and everything users need is all contained within the NeuroSolutions sub-menu of Excel. Therefore it could be much adaptable for users who are familiar with Microsoft Office to use this software for intelligent buildings assessment.

DISCUSSION

This paper presents an integrated approach, called FaçadeChoice system, to the assessment of building façade systems for use at either design stage or construction stage for systems evaluation and selection. The FaçadeChoice system comprises of three components, including an ANP model, Façade Progress Index, and an ANN model. The FaçadeChoice decision-making model can be used to evaluate buildings façade systems. The FaçadeChoice model is developed based on the ANP containing feedback and self-loops among clusters and sub-clusters. 37 KPIs for the model are selected based on literature review and then assembled into the FaçadeChoice model. It was assumed that the FaçadeChoice has advantages over building rating methods as it tackles both values and inter-relationships among KPIs. To facilitate the use of ANP in practice, the Façade Progress Index as a new façade rating approach has been described; and it is believed that the integrative use of FacadeChoice and Façade Progress Index can provide the most reliable support in decision-making on the assessment of buildings façade systems. Finally, results from both FaçadeChoice modelling and Façade Progress Index are integrated with an ANN model in order to facilitate the application of ANP in the assessment of building façade systems.

ACKNOWLEDGEMENT

This research is funded by the UK government Engineering and Physical Sciences Research Council (EPSRC). The title of the research project is *Innovation in Design, Construction & Operation of Buildings for People* (IDCOP) (Grant reference number: GR/T04878/01), and the project is being undertaken as part of a project within the EPSRC's *Sustainable Urban Environment* (SUE) programme by three Universities, including University of Southampton, University of Greenwich, and University of Reading. Investigators are Professor A. S. Bahaj, Professor Derek J. Clements-Croome and Dr Keith Jones. Special thanks to Dr Godfaurd John and Mr Hsieh-Min Loy for their efforts in preparing a part of the research proposal.

Effective Infrastructure Distribution, Implementing An Integrative Concept for Sustainable Office Spaces

Luca Baldini, Forrest Meggers, Arno Schlüter, and Prof. Dr. Hansjürg Leibundgut

Swiss Federal Institute of Technology Zürich, Switzerland

Corresponding email: meggers@hbt.arch.ethz.ch

SUMMARY

Typical infrastructure in office buildings does not facilitate the creation of a sustainable building, effectively using energy, materials, and space. One must recognize that sustainability doesn't only refer to the use of energy, but also to spatial quality, user comfort, and ease of facility management. Different from the commonplace hierarchical systems, our goal is to distribute infrastructure such that highly networked structures arise. Our approach includes the horizontal integration of building infrastructure systems such as air, power, heating and lighting, and the vertical integration of building life cycle stages from design to implementation to management. These vertical processes are continuous, forming a "digital chain." The concept is being integrated into the renovation of the Building Services group office at the ETH Zürich. The office space has tested these concepts while utilizing this new design theory, and will continue to provide data in analysis to support the development of more sustainable office spaces.

INTRODUCTION

Among researchers in the area of building services and technology, it is common knowledge that these services and technologies are in fact the source of two-thirds of global electricity demand. This makes buildings alone responsible for a third of all anthropogenic greenhouse gas emissions [1]. Recent conglomeration of energy demand statistics has shown that when combining the portion of residential, commercial, and industrial energy demand sectors that are related to building operation and construction, buildings are directly or indirectly responsible for over half of the global energy demand [2].

Clearly, the building sector offers an immense opportunity to have an impact on future energy demand. Sustainable design, energy efficiency, ecological design, and natural systems, among many other concepts, have all been developed and used in the creation of buildings to try and address their global impact. Still, although improvements have been made, they have not been integrated into all parts of building construction and usage.

The area of building services is the direct source of energy demand and is not well integrated into the overall design perspective, especially in the important early stages of design. Interdependencies between architecture and building services are not captured. Being aware of these interdependencies is a major step toward developing more sustainable buildings.. This is done through better vertical integration along the design chain and better horizontal integration of building service components. Not only does this directly reduce the energy demand of buildings, but it also eliminates constraints imposed by separately designed infrastructure. The view of the interdependencies provides a larger range of options to improve the indoor space. Europeans spend upwards of 90% of their lives in buildings [3].

Unsatisfying spatial quality leads to less productive users. Removing constraints on spatial quality indirectly improves the sustainability of a structure.

With a holistic and inclusive planning and creation of buildings the palette of available technologies also increases. Instead of a small number of options available for one sector of design, a wide variety of systems can be considered when the entire project can be visualized through a digital design model.

Digital planning technologies gained major importance in the fields of design, construction and facility management over the last decade. However, these fields often remain separated, and information is not communicated between them. In spite of the major economic and environmental impact of building services, the usage of digital technologies in this field is not as thoroughly developed as in other fields of the building industry.

The goal of the project described herein is to define, study, and implement a framework by which seamless design processes and advanced technology can be researched, tested, and implemented in one laboratory, which will guide the creation of more sustainable buildings. In order to achieve this, a methodology was laid out to define this process based on current digital design practices and available technologies. These were applied to the ongoing renovation of the Building Services Laboratory (GT Lab). This was done in part during the real-time design process of the renovation, as well as into the renovation itself to allow future testing and analysis of design techniques and technologies. It is a functioning office space allowing for analysis of the design space from its design phase up to its usage and management. Technologies have been implemented that can be utilized in modeling processes to verify design decisions. The lab provides a system to test various permutations of how a digital chain can be linked together from design phase to operation, thus maximizing the flexibility of all phases and pieces of a building. The methods used in this design concept were applied in a collaborative network of engineers and architects.

METHODS

In the sense of horizontal integration our group picked appropriate, innovative technologies and combined these into a well performing ensemble. Every technology, before being integrated into the overall system, has been carefully chosen based on an educated selection method. The product development and implementation is done in cooperation between the chair and industry. During the selection procedure the aim was always to select technologies that contribute to a comfortable indoor environment. Again, sustainability was considered not just in a narrow, energy related sense, but in a universal sense relating to spatial quality, ease of use, etc.

Heating Ventilation and Air Conditioning (HVAC)

For the method of selection of HVAC components major quality criteria were the exergy efficiency, architectural and spatial aspects, flexibility, and the effectiveness of the ventilation system. Thermodynamic analysis based on the exergy principle has been applied to buildings in order to identify potential improvements of heating systems. The exergy concept classifies energy sources according to their “quality” or potential to do work. It is therefore appropriate to use energy sources of low “quality” to fulfill a low “quality” task such as maintaining a building at a low temperature [4]. Heating systems based on heat pumps are more exergy efficient than systems based on fuel driven burners. By choosing low supply temperatures the operation of heat pumps becomes even more efficient. For that reason the exergy design principles led to the selection of heating and ventilation technologies that are designed to operate with low supply temperatures. In order to minimize the exergy demand of the complete HVAC system, the static heating and the air supply/ventilation must be decoupled from each other. This decoupling exploits the potential energy savings of low ventilation rates without affecting the indoor temperature.

Besides energy efficiency other criterium, such as indoor air quality (IAQ), were not overlooked. Therefore, the use of low ventilation rates required ventilation systems to have high ventilation effectiveness in order to maintain good IAQ. It was decided that the best way to maximize ventilation effectiveness was through a system that comprises of a large number of distributed sensor-controlled exhaust openings, which is based on the displacement principle. Past models and measurements were observed showing that this system achieves high ventilation effectiveness compared to standard systems. The local control characteristics of this kind of system allow the airflow rate to be dynamically adjusted according to the number of occupants being present in a room or a building [5].

The supply air system was matched to this distributed exhaust. The selection of a decentralized air supply was influenced by the potential for enormous space savings and for the flexibility this approach offers compared to hierarchical, centralized systems [6]. Very compact, decentralized supply air units were chosen and optimized in collaboration with industry for integration into the complete ventilation system.

Lighting

Lighting has both a large aesthetic effect as well as a significant impact on energy demand. In this selection method, the spatial and managerial aspects of building sustainability were directly balanced with aspects relating to energy demand. An important criterion was the integration of all lighting elements in the multifunctional ceiling panels which allowed a built-in height of 10 cm only. Also, the artificial lighting was supposed to efficiently complement existing daylighting. In order to define the necessary lighting to meet the required constant amount of 500 lux, model-based lighting simulations were run, comparing different lighting variations. It was found that LED lighting in combination with fluorescent lighting could provide highly controllable lighting with very high efficacy. In order to control the lighting color within the lab and to experiment with different ambient color settings, these LEDs had to be capable to display the full RGB color spectrum.

Power Supply and Distribution

Various supply topologies have been assessed to find the most suitable solution offering the largest flexibility and ease of use. A suitable topology for power distribution was found to be a ring along the boundaries of the space with branching lines that serve the inner part of the ring. This supply structure allows maximum flexibility for the layout of desks. The design also presented an option for new construction. Electrical routing has the potential to be done through ventilation ducting directly integrated into the neutral zone of structural floor elements between steel reinforcements [7]. This integration eliminates the need for either a raised floor or a ceiling plenum. This is not possible for a renovation where an underfloor system is required, but analyzing this system for future implementation was an important consideration in its selection.

Parametric design model

One goal is to expand the digital chain into the fields of building services, starting at the early design stages of a building. The huge impact of technical systems of buildings makes it necessary to consider consequences of building service design already in these early design stages. Performance evaluation has to be integrated into the architectural design process already at an early stage, up to 80% of the decisions most important for the building performance are already made within the first 20% of the design process [8]. Common CAD-Software however does not support an integrated planning approach.

For the design and ongoing research at the GT Lab an approach was chosen based on a parametric building information model. The use of a parametric model provided the capability to design, calculate, and simulate already at very early stages of design and still be able to judge spatial quality. A three-dimensional parametric geometry model was set up. Supply requirements were directly defined in the model database. Every change in geometry or equipment resulted in an instant adaptation in performance data for the selected room cell, floor, or the whole building. The evaluated technical systems are integrated into the model in a schematic. Their dependencies are defined in the database as well as in the resulting geometric model and displayed three dimensionally. Simulations like daylight and artificial light simulations can be directly accessed, comparing light distribution and visual impression with the calculated use of energy of different lighting systems.

System Management Model

It was found that through the use of digital control every system could be addressed and controlled throughout the power network. This included the ability to control everything from ventilation to standby power delivered to a coffee machine. Sensors could be used directly in the same network integrated with the lighting and ventilation systems, which they help steer. Defining a digital power management system realized avenues to reduce control infrastructure and facilitate the optimization of the entire system. The selection method also required a highly flexible system that could be easily modified for research applications, which is provided in the digital control system. This allows for a broader analysis of the digital chain from planning to operation.

The planning model has been furthermore adapted for steering and monitoring purposes within the GT Lab. The distributed systems such as those used in the GT Lab impose a paradigm shift towards the extensive use of management software. Traditional, hierarchical systems of building services like central ventilation for example, rely on centralized control and steering. Distributed components were chosen and implemented at the GT Lab, which lack this central steering component. Instead they are highly networked and act as complex systems, reacting on local and overall conditions. This reaction is based on a large amount of information obtained from sensors and systems including user input to fulfill individual comfort needs. This information has to be synchronized, resulting in control commands created by software-based rules. The actual physical components like the small decentralized ventilation units are inexpensive and energy-efficient, but are not capable of steering the whole topology of units. Therefore, the resulting network of distributed units has to be coordinated by software.

By incorporating sensors monitoring indoor data as well as environmental conditions this network could be steered and controlled to react more sensitively and efficiently. The software would need a digital model of the built environment including geometrical and topological information of the building as well as the applied building service technologies.

RESULTS

Renovation Overview

Within the Building of the Department of Architecture (HIL) one hundred square meters has been selected by the Chair of Building Services to be transformed into a new office space and laboratory. Before the renovation, the existing infrastructure (lighting, sound absorber, air supply/exhaust) was included in a 60 cm high plenum. This means that in this particular case about 1/7 of the actual floor height was occupied by the infrastructure. During the retrofit of the office space the suspended ceiling was completely removed and a raised floor with a height of 17 cm was installed instead. The existing supply air system was substituted with compact decentralized supply air units and a ducting system incorporated in a raised floor. Electrical and IT cables were integrated into the underfloor ducting. The lighting that was previously installed in the suspended ceiling has now been integrated into multifunctional ceiling panels. These panels have a thickness of only ten centimeters and cover about 50% of the ceiling area. They combine the features of static heating with activation of thermal mass, lighting, sound absorption, and also integrated sensor-controlled exhaust openings. The control of all electrical devices is managed with a unique control system. This management system cannot only be used to control the building services but offers a simple and powerful interface for facilities management. A cutting edge microchip attached to the power supply of each device allows a unique way of digital power management. The detailed components of the renovation are described below and how each component is integrated is illustrated in Figure 1.

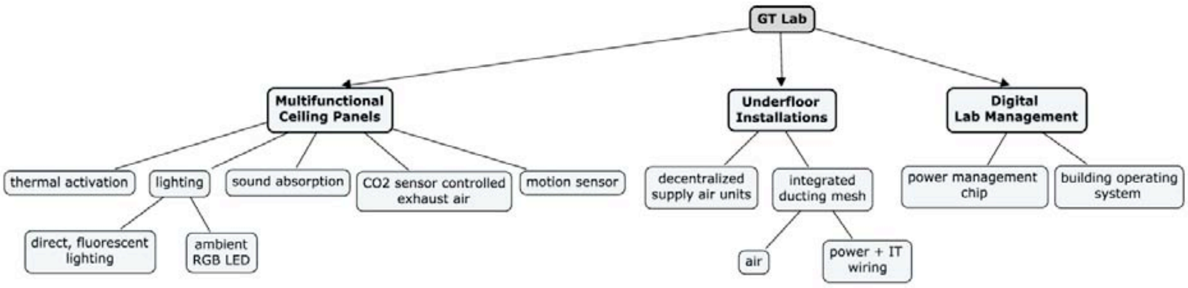

Figure 1: The components integrated into the renovation of the GT Lab.

Underfloor Installations

The fresh air is supplied to the office at a single point below the ceiling. From there two branches of the duct supply air to a U-shaped channel, integrated in the raised floor. This channel is separated into two parts and the airflow of the two supply branches can be regulated, such that different pressure conditions in the two chambers of the channel can be obtained. Since the façade could not be modified and the fresh air comes from the centralized system, the channel was designed to simulate the different pressure conditions that would arise on a buildings façade due to the influence of wind. The decentralized supply air units being installed in the raised floor are connected to the U-shaped channel on their suction side and to another ducting network on their pressure side. The ducting network connected to the supply interconnects the different sides of the channel representing the facades, and allows a regular distribution of fresh air over the entire floor space. For this network a meshed topology is chosen because of its balancing pressure characteristics. The system simulates how the ventilation network can use the wind pressure differences between the facades for air transport and hence to reduce the energy costs.

The supply air ducting network also carries cables (power, data) such that central workstations can be easily connected over a branching line to the main installation built as a ring line along the building façade. Tubing was used with an oval cross section, and newly developed compact decentralized air handling devices make the integration into the floor possible.

Multifunctional Ceiling Panels

The ventilation system with low momentum air supply through the floor and extraction at the ceiling follows the well-known displacement principle [9]. The system designed for the GT Lab utilizes this principle in combination with localized exhaust vents that use sensors to monitor local air quality. This principle of local waste air extraction is often encountered in industries and has been analyzed for buildings [7]. Sensor-controlled exhaust openings with a built-in flap, as proposed by [7] have been integrated into the panels distributed along the ceiling. Air with a higher contaminant concentration can be extracted and the over-all ventilation rate is reduced because of the demand-controlled nature of this system. This system with its autonomous local control characteristics is much simpler and more robust than a conventional system with a master-slave control.

The ceiling panels can be used to cover static temperature control. Hot or cool water in a two-wire system activates the thermal mass of the construction and convectively heats or cools the room air with a power of about 40 W/m^2 within the comfort zone. In modern, well-insulated office spaces it is enough to cover 50% of the ceiling area to meet the heating power requirements. The ceiling panel is covered with a thin, perforated sheet-metal plate that has good sound absorption characteristics. The same area as needed for heating is sufficient to reduce the sound reverberation time to a value below 0.6-0.7 seconds.

The standardized ceiling panels that incorporate the features of heating and sound absorption have been altered and the lighting equipment has been included. Two different kinds of illumination with two different technologies were implemented. Energy efficient fluorescent tubes are used to meet the higher lighting requirement while for the ambient lighting LED technology has been used. The LEDs are mounted 10 cm apart along a 1 m strip, eight of which are integrated into each ceiling panel. The power of a one of the LEDs used is 1.4 W and its luminous efficacy is approximately 40 Lumen per Watt. Compared to a common light bulb with an efficacy of about 18 Lumen per Watt the LED is a clearly superior, and also a rapidly developing technology. The LED lighting has been designed, and each strip can be controlled to compensate for light gradients occurring in the room due to daylight influences. On the other hand it serves as an ambient light providing a convenient atmosphere.

Digital Lab Management

A newly developed chip has been integrated into the lab’s infrastructure. The chip is attached to the power line just before every electrical device connected. The power line is used to carry the control commands to the chip. This transmission method makes it unnecessary to install extra cables to communicate with terminal devices. Because of the unique addressability of each terminal device this technology offers the possibility to implement very effective power management that reduces standby losses almost to zero.

For the management of the ventilation, exhaust air flaps, heat supply, power control chips, lighting, as well as sensor data a "building operating system" is implemented in cooperation with a software company. Therefore the digital chain is extended to actually control physical components seamlessly. All the systems exist in the virtual model as well as in physical reality, and simulation can be directly compared to actual physical operation data. A small server will allow access to all systems via the Internet. A web-based interface enables the user to control and monitor the GT Lab physical environment. Individual lighting schemes can be stored, and global settings for the entire environment are also available. Sensor data is recorded, which includes energy consumption for each device, local CO_2 concentrations, and activity recorded from the motion detector. With the building operating system it will be possible to group systems such as ventilation units individually, simulating the flexible management of space, reacting on changing user needs. No physical replacement of systems is necessary when spatial user requirements change, the system units can just be regrouped within the software model.

DISCUSSION

It has been found that it is possible to create a research space that employs the flexibility to study both horizontal and vertical aspects of design. Analysis can be done on the performance of new technologies for buildings systems while also understanding how these components can be integrated in the design process. By controlling and studying the preliminary design and modeling procedures that can then be implemented into a flexible, yet normally occupied office space, improvements in both physical operation of components can be made along with improvements in the ease of implementation, integration, and management. These last improvements have benefits easily overlooked in a strictly experimental laboratory. The laboratory office is both a normal working environment as well as a laboratory and has realized some unique concepts for a building research environment. In the physical renovation of this space some preliminary analysis of this design process has also taken place.

While many technical results from the laboratory are forthcoming in future research, the current research into the laboratory design provides a valuable description of how more sustainable indoor environments can be created and studied. It does not analyze one area of improvement, but instead allows for an integrated view in the research itself, as all systems are available for study through one digital interface. The use of this digital control system in particular, will contribute to the ability to study the entire system. It also provides a direct link back to the design phase and thus can be used to test preliminary design ideas and models. This is one way in which a digital chain can be maintained for analysis in the lab. As more integrated practices are being pursued for the design , construction, and operation of buildings, this concept presents a method for how these concepts of integration can be incorporated and studied in academic research.

Continued work on the design process is also planned in an expanded renovation of more space within the HIL building where the 100 m^2 lab is located. There is potential for expanded renovation of the adjoining office space, which currently houses the Chair of Computer Aided Architectural Design (CAAD) with whom collaboration studying the digital chain already exists. The entire space would then be designed to house all the chairs under the Institute for Building Technology (HBT). It has also been proposed to work toward a renovation of the entire building using concepts that would be refined in the GT Lab.

The data gathered in the GT Lab will refine the design model to be used in further designs. The direct link between the virtual and physical building model will help to validate virtual simulation results as well as optimize steering operations for the implemented services. Future research will also look at the optimization of the underfloor air distribution and power supply integration. Integrating this ducting into the infrastructure of a building will be studied. It is expected that economics savings will come from space savings, and energy savings will come from more exposed thermal mass.

One of the clearest observations made from the resulting creation of the GT Lab is the tremendous benefit of improving the spatial quality. As the office is situated directly adjacent a space which maintains the former construction, a direct comparison is possible. The higher ceiling and highly controllable lighting has substantially improved the indoor quality.

SUMMARY

The objective of this paper is to develop a method for achieving optimum vertical layout of apartment buildings that can provide proper design alternatives and useful information by its application in order to improve indoor comfort and to verify the efficiency and the validity of the objective method. The result of this research can be used as supporting information to reach an amicable settlement against civil petitions and disputes. This will consequently reduce waste of the time and money, enhance the efficiency of work, and improve indoor comfort.

INTRODUCTION

In Korea, as the social phenomenon of the drift of the population to major cities began to appear from 1970's, a number of high-rise apartment buildings have been constructed in major cities such as Seoul. Following the recent improvements in living standards, there has been growing interest in indoor comfort. Especially, one of the most important issues related to indoor comfort is solar access. These social tendencies have brought about residential environment problems such as violation of solar rights. The number of civil petitions and disputes over solar rights has increased recently. These problems have negatively affected human health, work productivity, thermal comfort, and visual comfort. So, the solar rights analysis system (*HELIOS*) had been developed by research team to evaluate the solar rights of residential buildings, quantitatively (Seong et al., 2006). Furthermore, this solar rights analysis system had been applied to many practical affairs up to recently.

But, as the problems related civil petitions and disputes over solar rights are becoming more complicated and diverse, it is demanded that proper design alternatives should be suggested and active design methods of vertical layout of the apartment buildings should be studied in order to reduce the solar rights violation for neighboring area within the acceptable limits. However, the present solar rights analysis system has some limitations. That is, this system analyzes only the original design condition, and provides only the information on whether violations of solar rights have occurred or not. The information of optimum vertical layout in high-rise apartment buildings to assure the solar rights is deduced from repetitive manual process. To establish alternatives and vertical layout for solar rights assessment, for example, available alternative examined first of all, that experts must participated in. Then, solar rights analysis result about survey buildings is thoroughly examined by an expert. If the results are not acceptable, geometric information is changed and reflected in solar rights analysis system.

If the result of analysis is not satisfactory, the above process is repeated again and again until acceptable result is deduced. These problems bring about economic loss of productivity and efficiency.

For these reasons, this study is intended to develop the method for the optimum vertical layout of the apartment buildings that can provide proper design alternatives automatically and the useful information to improve solar access. The result of this research can then be used to furnish advanced information for an amicable settlement against the civil petitions and disputes, to reduce waste of the time and money, to enhance the efficiency of work, and to improve indoor comfort.

SOLAR RIGHTS AND ASSESSMENT METHODS

Solar rights

The definition of solar rights varies for different localities and situations. In Europe and U.S.A, 'solar right' is generally defined as the occupant's right to unobstructed light from the sun, i.e., the rights to light (Building Performance Research Unit, 1972). In New Mexico, U.S.A, it is considered as a form of property right for renewable energy source, and thus an owner of a real property where a solar collector is installed may claim its solar rights. In Korea, solar rights are generally associated to human health, work productivity, thermal comfort, and visual comfort in apartment buildings.

However, the Korean laws do not clearly stipulate the regulations on solar rights, and so, solar rights are interpreted in various ways based on the theories related to an occupant's solar access. First, solar right is defined as the right to remove an occupant's disadvantages from interference with direct solar access by obstructions (Choi et al., 2000). Since Korea is located in the northern hemisphere, the residents living in the northern site of the building are generally obstructed from solar access if another building is built in the southern site. Based on this definition, the residents living on the northern site of the building can file a formal complaint to the property owner of the southern site as provided in the Korean building code 53 provision. Solar right is also defined as the right to ensure that neighbors have access to natural lighting, ventilation, and field of vision by limiting the height of adjacent buildings. Also, it is defined as the right to ensure sunshine duration for usual residential living in buildings, and also, the right to enjoy high standard of living in terms of health associated with the direct solar radiation. This last definition, in turn, means that a property owner should not infringe upon another property owner's right to direct solar light access when building a new building next to an existing apartment complex.

In Korea, sunshine duration should be maintained consecutively for more than 2 hours in every housing unit during the winter solstice from 9 a.m. to 15 p.m. (during 6 hours). In addition, the distance between each block should be kept to more than 0.8 times of a building's height to the south from the adjacent apartment building. In a densely-populated city with high-rise apartment buildings such as Seoul, it is particularly important to dispute settlements over solar rights for every housing unit in an apartment building. Therefore, an analysis method for assessing the solar rights and a simulation program to quantitatively evaluate the solar rights of each housing unit in an apartment building is necessary.

Assessment methods for solar rights

The analysis methods for solar rights assessment are generally classified as sun-path diagram method (i.e. solar position diagram) (Goswami et al., 1999; Duffie and Beckman, 1991) and shadow diagram method. The sun-path diagram methods can be subdivided into the horizontal sun-path diagram method and vertical sun-path diagram method (i.e. *WALDRAM* diagram method) (Lechner, 2001). The shadow diagram methods can be subdivided into the plan shadow diagram method, the elevation shadow diagram method, the section shadow diagram method, and the perspective (3D) shadow diagram method depending on the point of view. However, only two of the methods can be used to quantitatively compute the sunshine duration for all housing units in an apartment building: the *WALDRAM* diagram method and the 3D SHADOW diagram method. Based on the comparison results (Seong et al., 2006), the *WALDRAM* diagram method was more suitable than the 3D shadow diagram method. In addition, the *WALDRAM* diagram method provided more accurate results, especially in computing the sunshine duration on a specified day. In terms of analysis accuracy, however, the *WALDRAM* diagram method could analyze more dense time interval than the 3D shadow diagram method, and in terms analysis processing time, the *WALDRAM* diagram method required less time than the 3D shadow diagram method, because the rendering process took a long time to make a 3D shadow diagram. Lastly, in terms of the analysis processing steps, the *WALDRAM* diagram method was two steps faster. As such, the *WALDRAM* diagram method was clearly more suitable than the 3D shadow diagram method for assessing the solar rights in apartment buildings.

Method for the optimum vertical layout

In this chapter, we have chosen a real case for vertical layout to develop a method for the optimum vertical layout. According to this case study, we propose a method for the optimum vertical layout in high-rise apartment buildings. An objective for the optimum vertical layout is that all housing units in survey building must be satisfied within acceptable limits for solar rights. In the case study, the survey objects were all housing units in C apartment building 202(i.e. Bldg.202) and obstruction buildings were T apartment buildings 103 & 105(i.e. Bldg.103 & Bldg.105). By figure 1, you can find out the geographical situation.

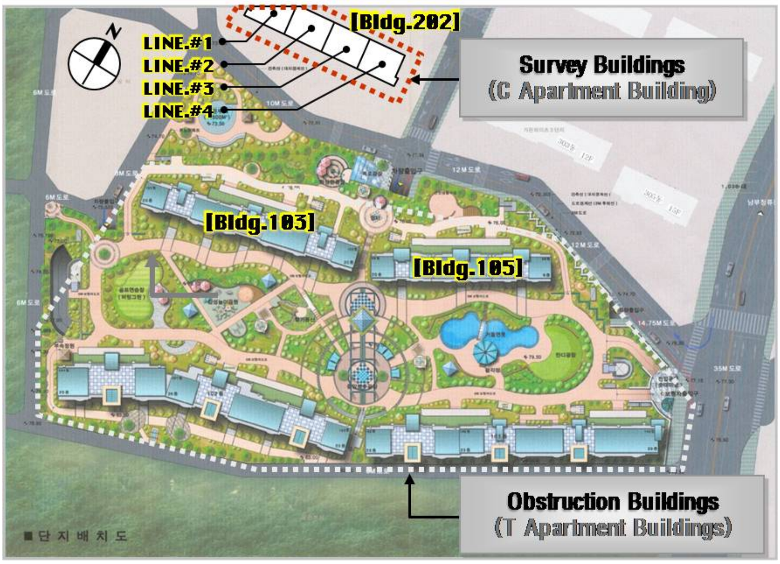

Figure 1. Geographical information of survey building and obstruction buildings

Method of Vertical Layout by Manual Process for Solar Rights

In this chapter, we briefly described the method of vertical layout by manual process for survey objects (all housing units in C apartment building) to assure the solar rights, and discussed some predictable problems in manual process.

(1) Vertical Layout by Manual Process

To find out the process of vertical layout manually, we described the process that our research team executed in the past.

A) In order to deduce alternatives that the solar rights at all housing units in survey building(C apartment building 202, i.e. Bldg.202) can be satisfied within acceptable limits, it is necessary that 1st floor housing units in Bldg.202, which have the worst condition, are investigated first. So, we selected housing units #101, #102, #103, #105(i.e. survey unit #101, #102, #103, #105) in survey Bldg.202, as shown as in figure 1, from the selected survey housing units, and derived the possible alternatives to assure the solar rights at survey unit #101, #102, #103, #105 by repetitively comparing and investigating the *WALDRAM* diagram, which is the result of the many predictable design alternatives.

B) In vertical layout for solar rights, obstruction buildings, which are the vertical layout object, consist of two Bldg.103 and bldg.105. The vertical layout of obstruction buildings should be classified in 3 parts, 103 only, 105only, and 103,105 together.

C) [Design Step.1]: First to know the influence of obstruction Bldg.105 to survey units, we performed the solar rights at survey units against various vertical layout alternatives. The number of cases expected is 24,696,000(all cases which can be generated by product with story numbers of housing lines including story number 0, that is, all cases = 21*21*20*20*14*10). We examined the *WALDRAM* diagram, continuous sunshine duration, and accumulative sunshine duration. We found that obstruction Bldg.105 did not show any improvements in solar rights for all survey units. From this, we can conclude that vertical layout of obstruction Bldg.105 did not have any influence on solar rights improvement and can exclude obstruction Bldg.105 from the vertical layout.

D) [Design Step.2] : By reviewing results of [Design Step.1], and *WALDRAM* diagrams, it is expected that proper alternatives for vertical layout which every survey units could assure the solar rights within the acceptable limits would be deduced through reducing stories of the line number 1(i.e. LINE.#1) and the line number 2(i.e. LINE.#2) in Bldg.103. So we analyzed various expected alternatives in [Design Step.2] by reducing stories of LINE.#1) and LINE.#2. But it turned out that there were no suitable alternatives. However, by reviewing the *WALDRAM* diagram (refer to figure 2) of alternatives, we found that LINE.#1 and LINE.#2 did not interrupt the solar rights in survey unit #105 and the maximum allowable stories for every survey units to assure the solar rights in LINE.#1 and LINE.#2 were 12.

E) [Design Step.3] : By the result [Design Step.1], in order to confirm an additional continuous sunshine duration, stories of LINE.#1, and LINE.#2 should remain as a 12 and we derived several alternatives("Alt.B-105", "Alt.B-106", "Alt.B-107" and "Alt.B-108") by changing the story of LINE.#3 and performed solar rights assessment for all survey units. By comparing the results, we derived the plan that minimizes the loss of story comparing with the original design condition. Results of "Alt.B-105", "Alt.B-106", "Alt.B-107" and "Alt.B-108" are shown as Table 1. "Alt.B-105" and "Alt.B-108" were suitable for every survey units to be satisfied the solar right. The loss of stories in alternative "Alt.B-105" was 24 and the loss of stories in alternative "Alt.B-108" was 22 compared to the original design condition. Finally, among the alternatives ("Alt.B-105" and "Alt.B-108"), we suggested "Alt.B-108" as the best alternative for vertical layout of obstruction buildings (T apartment Buildings). The loss of story "Alt.B-108" was 22 compared to the original design condition.

As above mentioned, by manual process, it needs professional knowledge, complex and continuous analyzing process and lots of time to deduce the alterative through vertical layout.

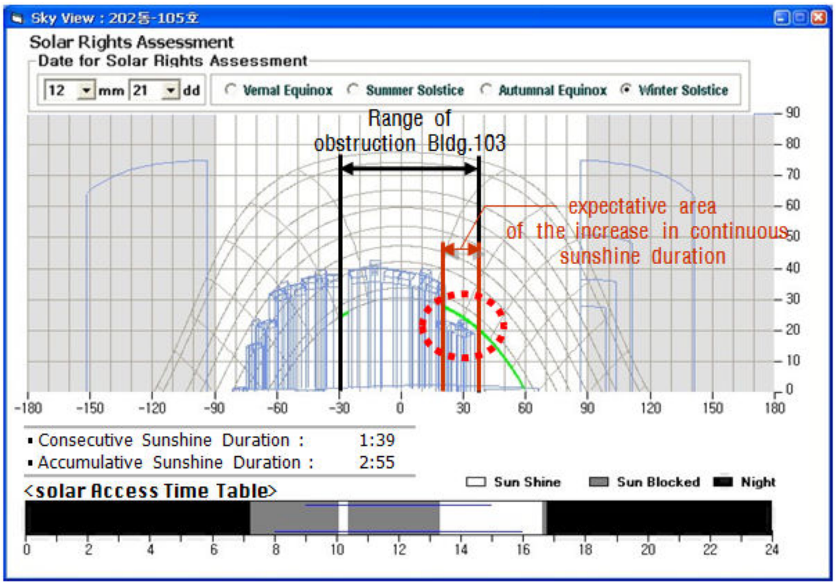

Figure 2. Analysis of *WALDRAM* diagram in [Design Step.2]

Table 1. Results of Vertical Layout by manual process

Designs	Building	Stories						Suitability	Loss*	Remarks
		LINE.1	LINE.2	LINE.3	LINE.4	LINE.5	LINE.6			
Original	Bldg.103	20	20	20	20	20	20	-	-	-
	Bldg.105	20	20	19	19	13	9			
Alt.B-105	Bldg.103	12	12	12	20	20	20	○	-24	-
	Bldg.105	20	20	19	19	13	9			
Alt.B-106	Bldg.103	12	12	16	20	20	20	×	-20	-
	Bldg.105	20	20	19	19	13	9			
Alt.B-107	Bldg.103	12	12	15	20	20	20	×	-21	-
	Bldg.105	20	20	19	19	13	9			
Alt.B-108	Bldg.103	12	12	14	20	20	20	○	-22	Best Alternative
	Bldg.105	20	20	19	19	13	9

(2) Problems of Vertical Layout by Manual Process

We have performed a case study through the methods for the vertical layout by manual process to assure the solar rights in survey units. As above mentioned, a manual process for vertical layout is summarized as follows:

A) Review alternatives step by step;
B) Change stories of LINEs or BUILDINGs in obstruction buildings and reflects the modified geometric information in the solar rights analysis system;
C) Analyze on the basis of reflected data, and estimate the result; and
D) To get the best result, feedback process in analyzing and reviewing should be done continuously.

By a manual process in vertical layout, it not only lowers productivity, efficiency in researching but also requires lots of time and experts. Furthermore, it also includes possibilities of mistakes such as an error of judgment. So, in order to minimize these problems, our research team suggests a methodology in automated vertical layout of high-rise apartment buildings by using computer. This helps us improve the solar rights and the waste of material and business efficiency.

Method for Vertical Layout by General Automation for Solar Rights

(1) Geometric Characteristics of the High-rise Apartment Buildings Design

In order to design proper stories of apartment building, geometric composition elements should be extracted and the hierarchy of the elements needs to be clarified systematically. The elements that compose an apartment building, the hierarchy of the elements and the organic relations are defined as follows:

A) An apartment building (i.e. **[BUILDING]**) is composed of several buildings. A **[BUILDING]** consists of housing unit(i.e. **[UNIT]**), common space(i.e. **[CORE]**) and housing unit line(i.e. **[LINE]**) (See Figure 3)

B) A **[BUILDING]** is composed of multiple **[LINE]**s, and each **[LINE]** comprises the repetitious **[UNIT]**s.

C) The height of an apartment building is determined by the vertical variation of the **[UNIT]** that composes each **[LINE]**. And the **[UNIT]**s, which are distributed uniformly along the vertical line, can be considered as elements of corresponding **[LINE]**.

D) In an arbitrary **[LINE]**, the building geometry cannot be generated if a lower **[UNIT]** does not exist. Therefore, in case of n stories, the elements of universal set "L" are 0, 1, … , n-1, n stories. And the number of possible subsets is n+1 (u_0, u_1, … , u_{n-1}, u_n).

E) A **[UNIT]** is the main space that composes the building and a **[CORE]** is the auxiliary space that serves the main space.

F) The height of a **[CORE]** is determined by the vertical variation of the relevant **[UNIT]**s.

G) In a word, the vertical space of the apartment building is determined mainly by the vertical variation of the **[UNIT]**, which decides the vertical height of the **[CORE]**.

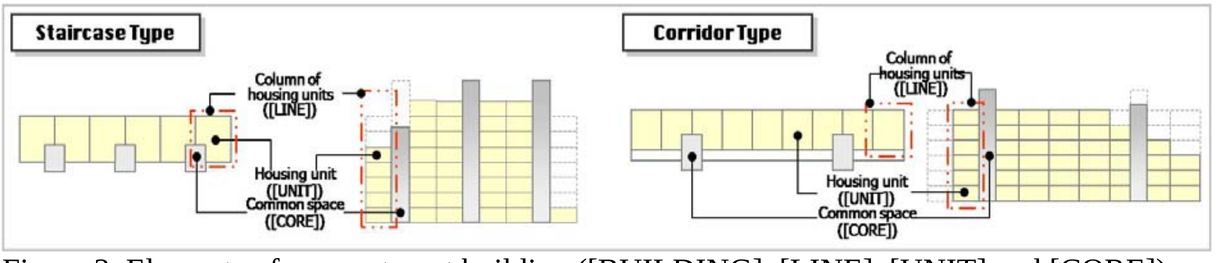

Figure 3. Elements of an apartment building ([BUILDING], [LINE], [UNIT] and [CORE])

(2) Definition of High-rise Apartment Buildings Components

To set plan of method for the vertical layout, the **[CORE]** should be excluded from the building set because it is determined by the **[UNIT]**. It is necessary that the **[BUILDING]** set should be classified by each line that is working equal vertical movement. To sum up, the set of **[BUILDING]**, ***B***, which is composed of several **[LINE]** components, can be defined as in equation (1). Each **[LINE]** set, ***L***, can be defined like equation (2), is located on the same horizontal plane, and composed by several **[UNIT]** elements which are on the same vertical line.

B = {x|x ∈ all **[LINE]**s of housing units in the **[BUILDING]**} = $\{L_1, L_2, L_3, \cdots, L_n\}$ (1)

L = {x|x ∈ all **[UNIT]**s in the **[LINE]**} = {x|x ∈ all stories which can be generated} (2)

$= \{u_0, u_1, u_2, \cdots, u_n\} = \{0_{Floor}, 1_{Floor}, 2_{Floor}, \cdots, n_{Floor}\}$

Where,

B: set of apartment building (**[BUILDING]**)

L: set of housing unit line (**[LINE]**) in the apartment building

u: element of a housing unit in the housing unit line (**[LINE]**)

(3) Algorithm for Vertical Layout by General Automation

Based on elements and sets which are the composition of the apartment defined on the Chap 2, $\boldsymbol{R_B}$ (equation (3))which is the algorithm of possible alternatives of all layer-adjustment about an arbitrary building from the apartment can be defined the subsets of Cartesian product from the given sets like equation (3). When there are many buildings, $\boldsymbol{R_T}$ (equation (4)) that is the set of possible alternatives of all layer-adjustment is able to be defined as equation (3). Figure 4 illustrates this logic in the form of a graph.

$$R_B = L_1 \times L_2 \times \cdots \times L_{n-1} \times L_n \quad (3)$$

$$R_T = R_{B1} \times R_{B2} \times \cdots \times R_{Bn-1} \times R_{Bn} \quad (4)$$

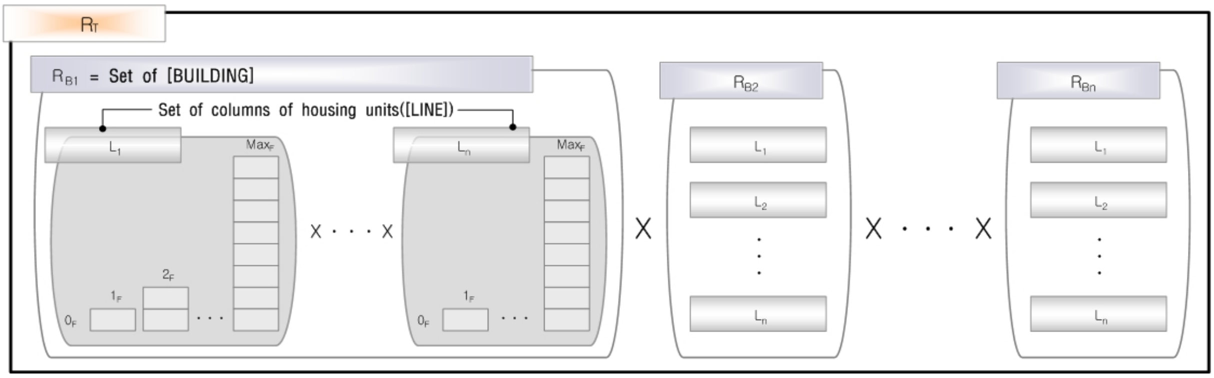

Figure 4. *L* set([LINE[set], $\boldsymbol{R_B}$ set([BUILDING] set) and $\boldsymbol{R_T}$ set

(4) Problems in Method for Vertical Layout by General Automation

Based on equation (4) which is the method of vertical layout by general automation above-mentioned, a total of 85,766,121 alternatives for vertical layout of obstruction Bldg.103 are derived by Cartesian-product of several $\boldsymbol{R_B}$. Considering the processing time of solar analysis system which is available to analyze average 10 cases per a second, it will take a total of 2.4E+03 hours to analyze all vertical layouts. The computers can be inefficient and irrational by simple computerization, and it is necessary to optimize this algorithm setting such as intuition experts can have.

Method for the Optimum Vertical Layout

In this chapter, the method of vertical layout by automation is optimized in a way to set intuition of expert knowledge about the standard sunshine duration and sun-path in the winter solstice.

A) Based on the present standard range, it is necessary to determine whether vertical layout is needed or not about each **[LINE]** to estimate sunshine duration (from 8 to 16). That is, as shown in figure 5, from 8 to 16 o'clock it should be divided into section A(range that vertical layout is necessary) which affects the calculation of sunshine duration and section B and C(range that vertical layout is unnecessary) which does not affect the calculation of sunshine duration. Also, a certain **[LINE]** which is needed vertical layout is necessary to derive information about by what floor has to be proceeded, and a certain **[LINE]** will be how many stories should be designed. Therefore, we defined a factor of "minimum allowable story", that is the minimum story number that is unnecessary vertical layout.

B) In case of section A that may affect the estimation of sunshine duration, it is separated into section A-1(vertical layout is necessary) and section A-2(vertical layout is not necessary) in a boundary of sun-path in winter solstice at *WALDRAM* diagram. Proceeding the vertical layout from the story of original design condition to 0 story in each **[LINE]**s, when all geometrical figure of the **[LINE]** is located blower than sun-path in winter solstice, that is, the story of **[LINE]** which is all geometrical figure of **[LINE]** included in section A-2 is appeared. At this point, the story of **[LINE]** does not affect estimation of sunshine duration at all, and thus it is not necessary to make a vertical layout.

C) On the other hand, a story of certain **[LINE]** in original design condition can be "Minimum allowable story", because **[LINE]** in section B and section C has no effect on estimation of sunshine duration (continuous sunshine duration, accumulative sunshine duration).

D) As mentioned above, the optimization of vertical layout automation is achieved on the basis of above theory. With this in mind, a **[LINE]** set which is defined in equation (2), ***L***, must be redefined as follows. If a certain **[LINE]** is located in section A, a **[LINE]** set, ***L***, is defined as formula (5), and if a certain **[LINE]** is located in section B or C, a **[LINE]** set, ***L***, is defined as formula (6). $\boldsymbol{R}_\mathbf{T}$ (equation (4)) that is the set of possible alternatives of all layer-adjustment is able to be deduced from this set ***L*** that can be redefined using equation (3) and equation (4)

$L = \{x|x \in$ all expected housing unit elements between the original story and the maximum allowable stories, where, the minimum allowable story $\geq 0\}$ (5)
$= \{u_{min}, u_{min+1}, \cdots, u_{Max-1}, u_{max}\}$

$L = \{x|x \in$ an expected housing unit element is the original story$\} = \{u_{max}\}$ (6)

Where,
L: set of housing unit line([LINE]) in the apartment building

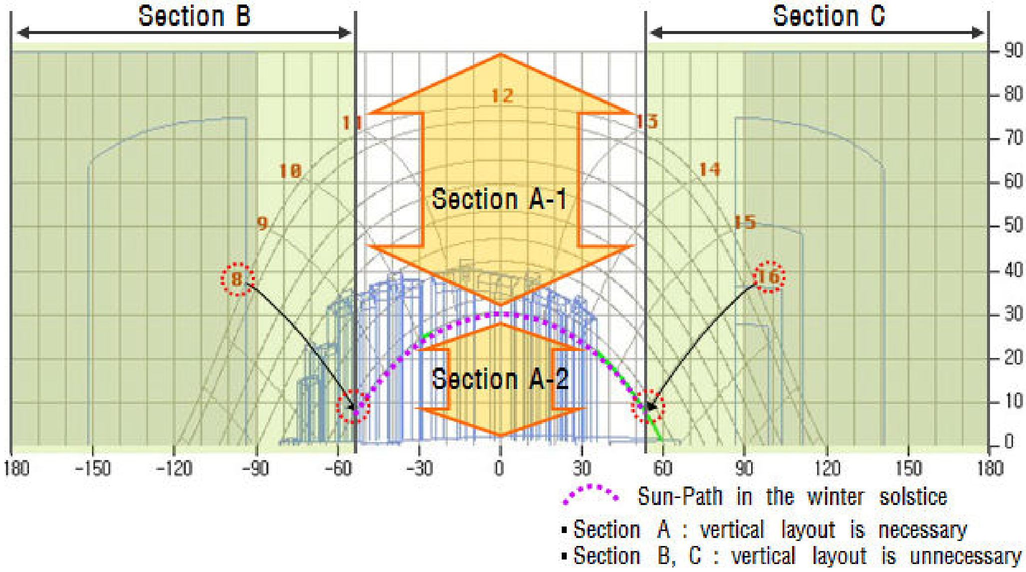

Figure 5. Classification of sections for vertical layout in WALDRAM diagram

VERIFICATION

In order to verify the objectivity of the method for the optimum vertical layout suggested in this study, we compared the results by optimum vertical layout with the results by manual process. We were able to confirm that both methods provided the same results. Also, the comparison of solar rights assessment results (continuous sunshine duration, accumulative sunshine duration and satisfaction of the solar rights) against alternatives between manual process and optimum process for vertical layout verified the accuracy of the method for the optimum vertical layout.

The ultimate goal was to suggest the optimal vertical layout of the obstruction buildings (T apartment Bldg.103 and Bldg.105) in order to assure the solar rights at all survey housing units in survey building (C apartment Bldg.202). With respect to this, however, Bldg.105 was excluded in vertical layout because Bldg.105 was determined to be unhelpful in improving the solar rights or to increase sunshine duration. In original design condition, the obstruction Bldg.103 is 20-storied building that has six [LINE]s. On this condition, the method of general automation generated 85,766,121(=21×21×21×21×21×21) alternatives. Meanwhile, the method of the optimum vertical layout generated 2,665,872(=9×9×11×11 ×16×17) alternatives. In this process, some of them were selected for the comparison in terms of analysis of solar access. The results from those layouts were compared with the results by manual process; in the result, the comparison of cases show the same result.(see Table 2) .

Table 2. Comparison of manual process and optimum process for vertical layout.

Alternatives	Loss*	Analysis results by manual design process				Analysis results by optimum vertical layout			
		Survey unit.#101 in Bldg.202		Survey unit.#105 in Bldg.202		Survey unit.#101 in Bldg.202		Survey unit.#105 in Bldg.202

*** ASD : accumulative sunshine duration (min)

CONCLUSION

The objective of this paper was to develop the method for the optimum vertical layout of the apartment buildings that can provide proper design alternatives and useful information to ultimately improve indoor comfort. In this study, we suggested an automatic optimum model for vertical layout in high-rise apartment buildings as well as to verify the efficiency and the validity of the objective method. To this end, we compared the methods for the vertical layout to protect solar rights through application in cases. The major results of the study are as follows.

(1) The method of vertical layout by manual process entail iteratively a complicated process of analyzing and investigating numerous possible alternatives to find out the best alternative for improving solar rights in survey units. This method considerably needs lots of time and experts. Not only that, it lowers the productivity and efficiency of work and may possibly mistakes in decision and needs some automatic process using computer.

(2) For the automation of vertical layout of high-rise apartment building, the set of alternatives, $\boldsymbol{R}_{\mathrm{T}}$, for vertical layout by automation is defined through the Cartesian product of the defined set ***B***(set of **[BUILDING]**) and set ***L***(set of **[LINE]**) and is shown in equation (4).

(3) For the improvement of inefficiency and absurdity that can arise from simple automation, we have attempted to optimize the method of vertical layout by automation in such a way to set intuition of expert knowledge about the standard sunshine duration and sun-path in the winter solstice.

(4) In the verification of the automatic method for the optimum vertical layout, first, it is expected to reduce in processing time and workforce in comparison with manual method; second, faster processing is expected in comparison with the method of general automation.

SUMMARY

This paper presents the process how CFD was used in the design of Helsinki music centre foyer. The aim was to ensure appropriate thermal conditions in foyer occupied zones. This flow field has very challenging aspects. Supply air jets, heat loads, furniture, stairs, walkways and other objects produce a very complicated 3D flow field. Typical challenge is design the supply air distribution so that the temperature is in appropriate level and fresh air flows equally to the occupied zone without draught risk. A correctly performed CFD simulation is the only calculation method which can estimate the detailed indoor air flow field with proper accuracy for design purposes. The air flow field is solved approximately depending on mathematical model and numerical method. We learn more about air flow behaviour in different situations and this supports the design team to find the appropriate air distribution systems and constructions. The simulation process starts with individual air device simulations. Different air flow quantities and devices are simulated and the effect of air jet flow is estimated. The simulated supply air jet patterns are then used in the foyer calculation model as a boundary conditions. This reduces the number of calculation nodes and saves simulation time. The device simulation models can then be saved to an object library for future projects. This simulation process seems to be a sensible way to model indoor environments and supply air distribution systems.

INTRODUCTION

CFD is a widely used simulation method in industry and it is also an effective design tool for technical building services. We have been using CFD simulations for years to study the flow behaviour of the indoor air environment, and noticed its advantages in the design process. CFD simulations have been quite expensive, but with increasing computer efficiency it is finally reaching the level at which CFD simulation can be used cost-effectively. This paper presents CFD simulation method that was used in the design work on an air distribution system for a Helsinki music centre foyer. The special features of this space are high occupied load, large space volume and a glazed facade. The design team had a great challenge to design the indoor air environment for 1700 people, which are in occupied zones at the same time. In the design process the most important thing is the experience of the design team. The product model based design process and mathematical modelling can support this knowledge. The fact is that correctly performed CFD simulation is the only calculation method that can take account of all the important flow properties affecting the indoor air environment. CFD is used in spaces where design and quality requirements are high and detailed flow field information is important. Air distribution systems, constructions and sources can be compared, and then the results can be used to illustrate HVAC solutions to customers. CFD is a numerical calculation method and the realistic modelling of a room environment is not an easy task. The important properties affecting flow phenomena have to be identified. Then the mathematical model is created and the space is divided into small control volumes. The equations are discretized and solved approximately using a numerical method. The accuracy of this calculation depends on the mathematical model, the numerical method, the calculation mesh, assumptions, initial values and iteration convergence. CFD simulations typically start with individual supply air device simulations. The different models and air quantities are calculated and compared to test the operating conditions. This allows the design team to choose the appropriate devices for specific locations. The device simulation results are compared with the air jet theory [1,2], manufacturer's profile data and measurements if possible. This information is important for evaluation of the simulation results. The point is that a simulated supply air jet pattern can then be used as boundary conditions in the whole foyer simulations, which reduces the number of calculation nodes and saves simulation time. The device models and simulation results are then saved to an object library for future projects. The challenging part is how to take account of all the important parameters affecting the flow field. The furniture and other objects are typically modelled roughly and the occupancy and lighting loads are divided equally to specific areas. In this project the people were simulated as standing or table groups all over the occupied zone. The tables, chairs and people were modelled together as a cubic model, because it seemed to be a reasonable approximation. The complicated 3D flow field includes many parameters affecting the indoor air environment. The supply air jets, furniture, walkways, space geometry and heat sources affect the indoor air behaviour and produce complicated flow phenomena in the space. The approximations were made so that the most important flow characters were captured, and so that mass, momentum and heat balance would be realistic. This is quite challenging because the initial values are approximations as well. That is why the conclusions should be made with care and compare different models and assumptions. The important aspect is how to model this kind of flow behaviour so realistically that thermal conditions and comfort can be estimated with sufficient quality for design purposes.

METHODS

The CFD simulation model of the foyer is shown in Figure 1.

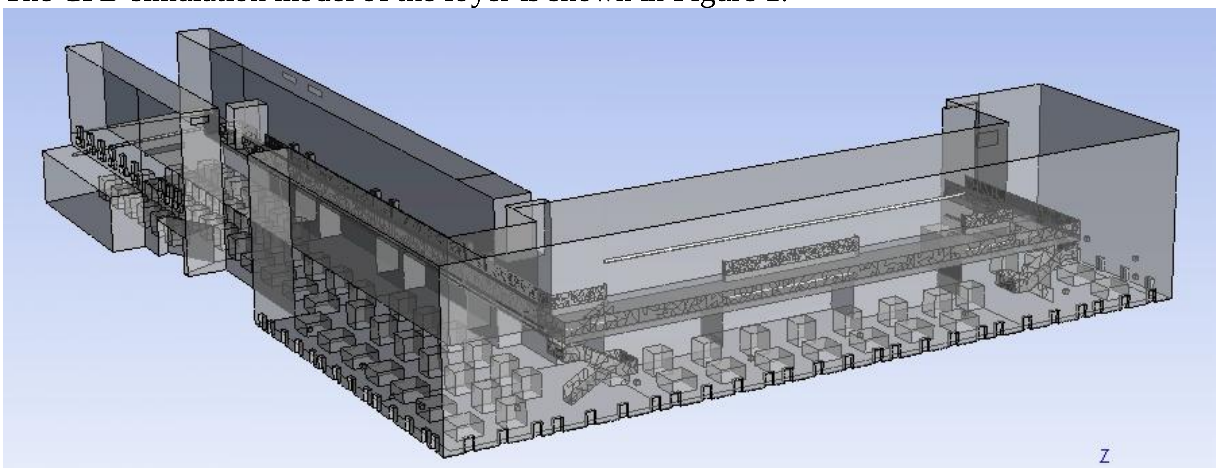

Figure 1. The CFD simulation model of the foyer

The wall geometry was imported to the CFD software from IFC product model generated for this pilot project. The imported IFC geometry was then modified for CFD purposes. After that the air distribution system, walkways, stairs, furniture and other objects were created before the calculation mesh was generated. The supply air distribution system consists of the cooling convectors near the glazed facade, supply air grilles and vortex diffusers located in the interior zone, and low velocity devices in the walkway corridors. Exhaust air grilles were located near the roof zone. The initial values are shown in Table 1.

Table 1. Initial values

Air distribution system, heat loads and constructions			
Foyer	2000 m^2	14 200 m^3	
exterior wall U-value	0.25 W/m^2,K	occupied load	1700x75W
roof U-value	0.16 W/m^2,K	lighting	20 W/m^2
wall temperature	24-39 °C		
glazed facade	total transmittance 28%, U-value 0.78 W/m^2,K		
cooling convectors	glazed facade, 54 units		
supply air grilles	inner wall zone, band installation		
vortex diffusers	inner wall zone, 16 units		
low velocity devices	corridor wall, 6 units		
exhaust air grilles	roof zone		

The lights were located in the corridors and in the facade zone. The occupancy load was simulated as standing and table groups. The heat sources were distributed equally to the surfaces of these cube-shaped models. The supply air devices were simulated individually and the resultant flow patterns were transferred to the foyer model as boundary conditions. The CFD simulation was based on the control volume method. An implicit pressure-based multigrid coupled solver was used [3]. The turbulence model was the k-ε model [4] and the incompressible flow buoyancy was simulated with an expansion factor β=1/T. The atrium foyer was divided into small control volumes using tetra elements. Prismatic elements were located in the boundary layer zone near surfaces. The calculation mesh is shown in Figure 2.

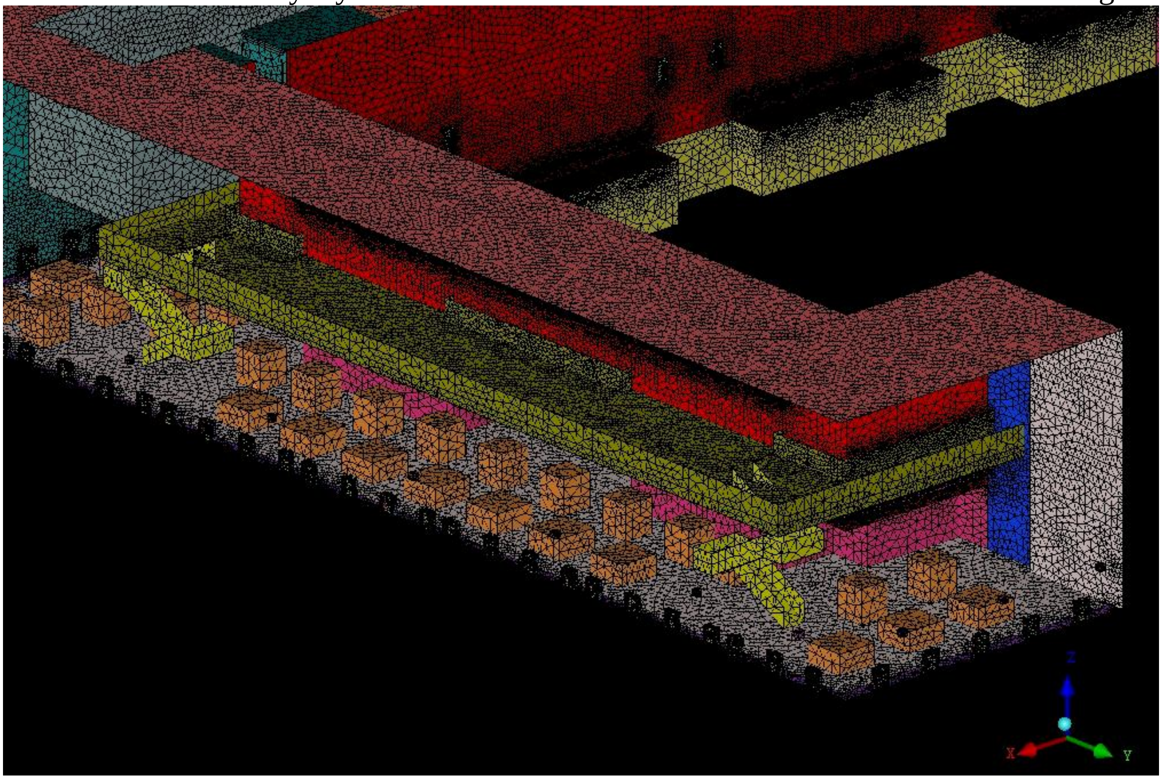

Figure 2. Calculation mesh of the foyer.

The mesh includes 824 593 calculation nodes and 3 271 333 elements. Near the surfaces there were 610 087 prismatic elements in 3 layers.

RESULTS

The results of the device simulations are shown in Figures 3-6. The results of the cooling convector simulation are shown in Figure 3.

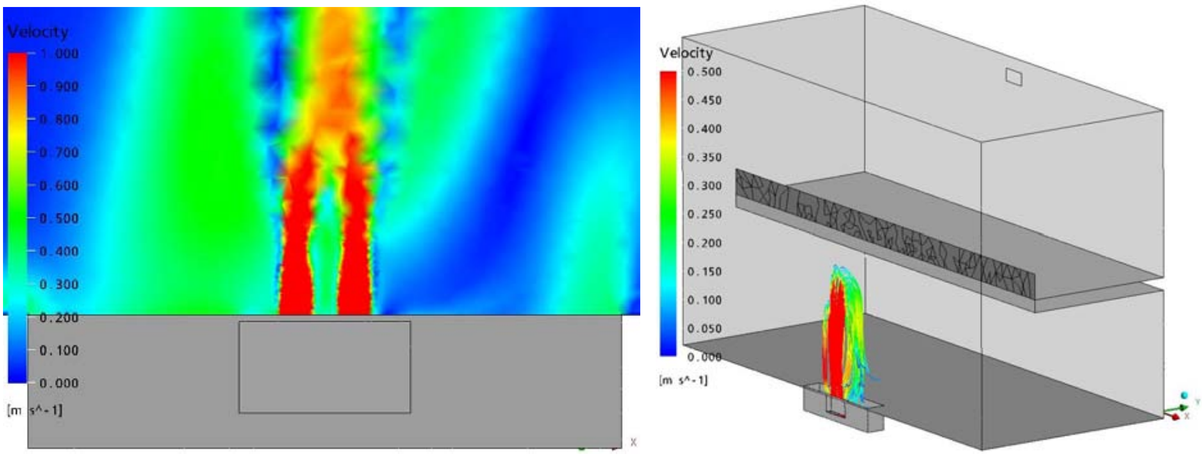

Figure 3. The results of the cooling convector simulation.

The convectors were located in a floor sink near the glazed facade. A simulated flow pattern was utilized in the foyer simulation. The supply air grille simulations are shown in Figure 4.

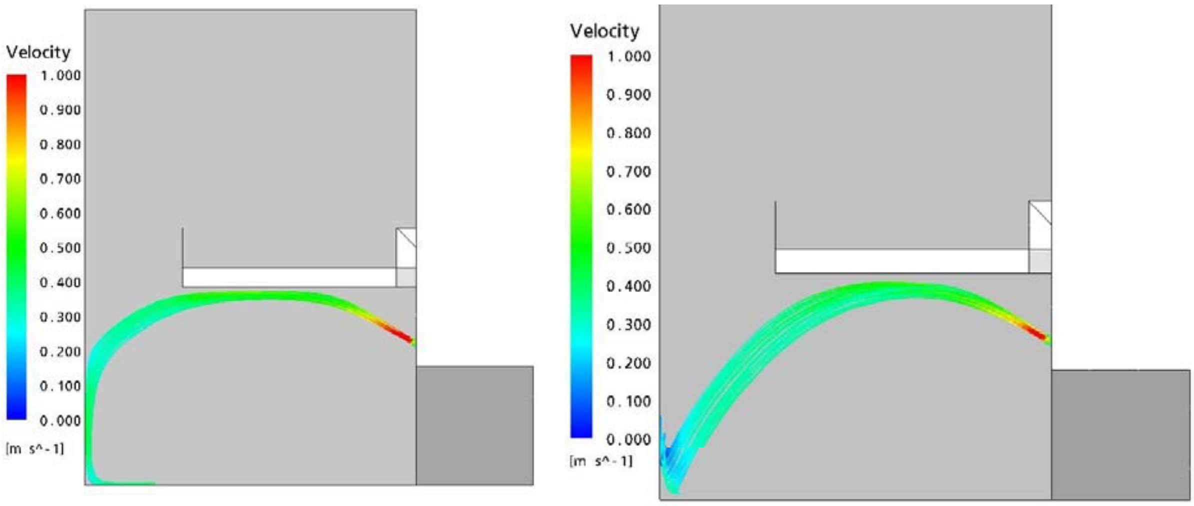

Figure 4. The supply air streamlines from the device simulations.

These devices were simulated in order to estimate the air jet length and how the jet is connected to the walkway roof. The result on the left-hand side was chosen for the foyer simulation, because the air jet seems to connect well to the roof and flows directly to the glazed facade and not to the occupied zone, where it might cause a draught. These devices are located side by side on the wall. For this reason the devices were approximated for the foyer model as a single wide device, see Figure 5.

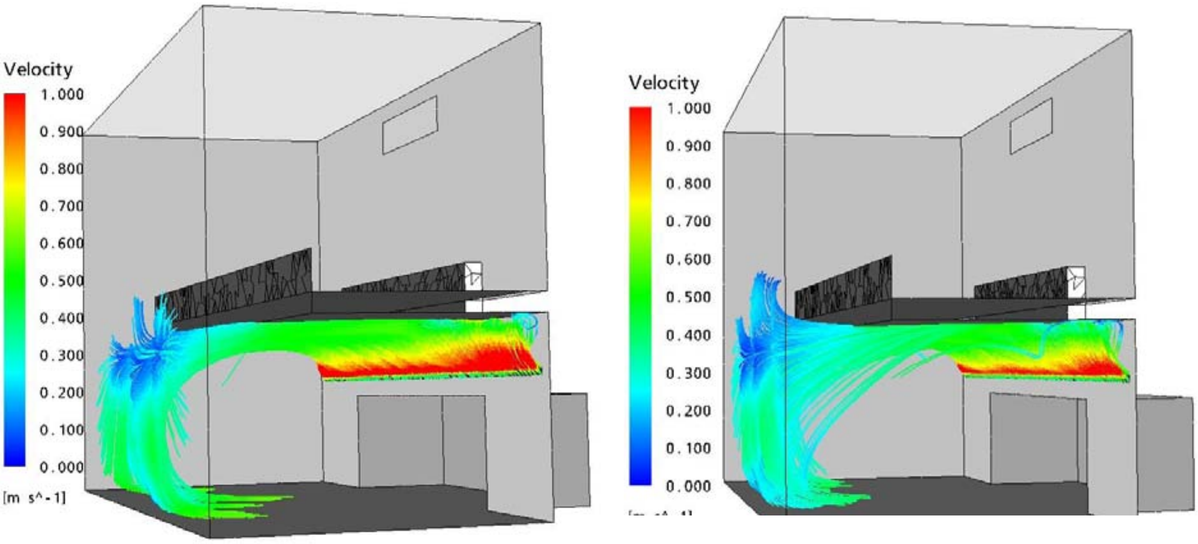

Figure 5. The supply air streamlines from the wide supply air device simulations.

The results of the swirl diffusers simulations are shown in Figure 6.

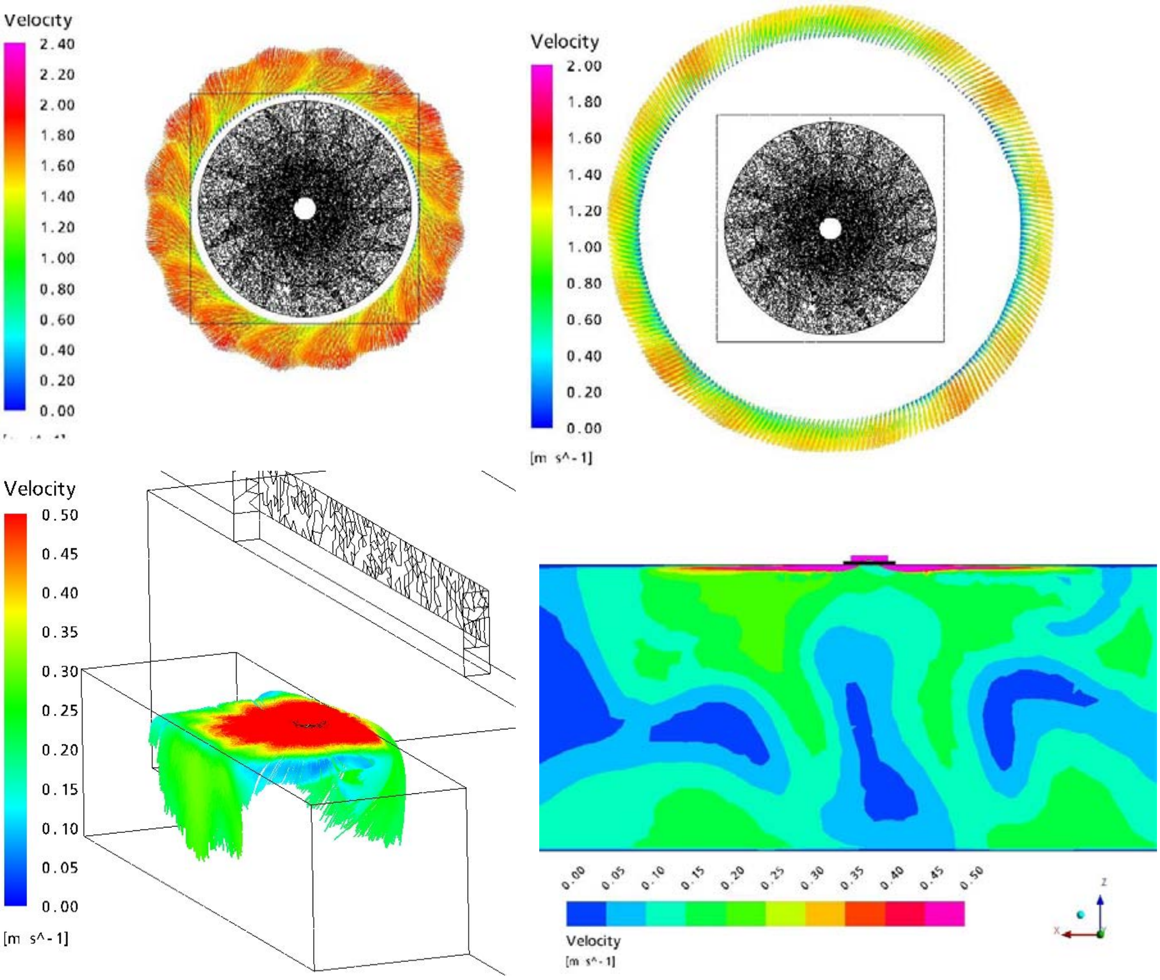

Figure 6. The results of the swirl diffuser simulations.

When the results were compared with the manufacturer's data, they appeared to be in good agreement. The foyer simulation results of the summer design day conditions are shown in Figures 7-10. The results show that the indoor air environment and thermal conditions are reasonable. The cooled air from the convectors near the glazed facade enhance thermal comfort because the air temperature falls and affects the operative temperature [5]. The supply air is distributed so that the temperature in the occupied zone is reasonable, see Figure 7.

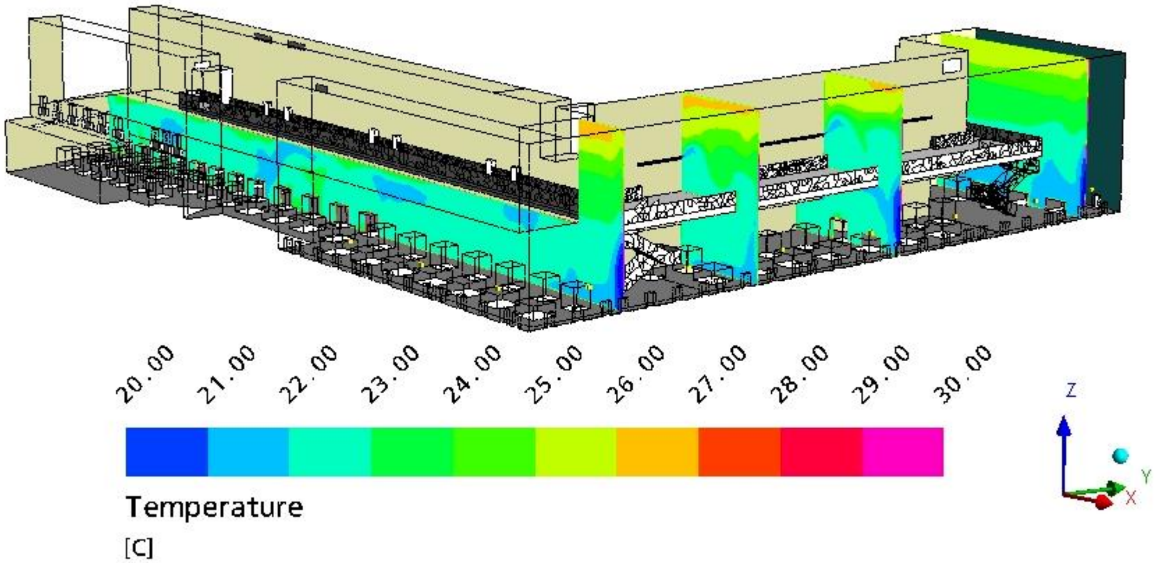

Figure 7. Summer design day temperature distribution in the foyer.

In the occupied zone the temperature is approximately 22-23°C. The temperature is higher close to the roof zone and below 22°C near the air jets. The distribution is quite even all over the foyer. The convector air streamlines are shown in Figure 8.

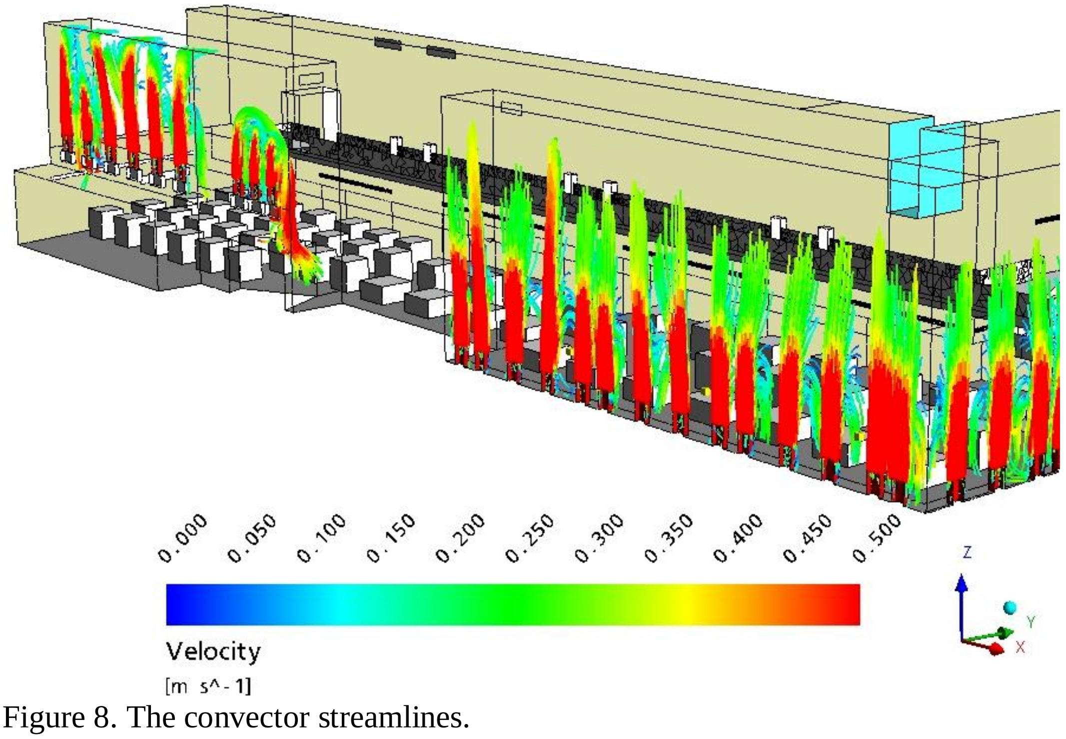

Figure 8. The convector streamlines.

The convector air flows along the glazed facade and it is then mixed with the indoor air. Figure 9 shows the supply air streamlines and velocity distribution. On the 1st floor the jet flows to the glazed facade and the jet length is much longer than on the 2nd floor because it is connected to the roof. The air jet from the cooling convector can be seen near the glazed facade.

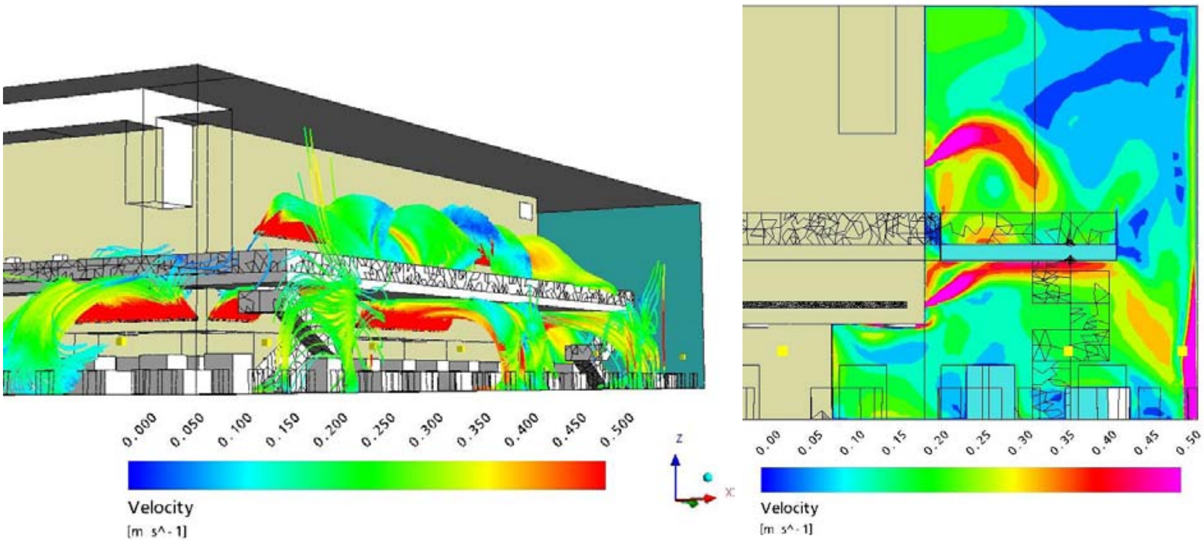

Figure 9. The supply air grille streamlines and velocity distribution.

The velocity profile is shown in Figure 10. The velocity in the occupied zone is mostly below 0.3 m/s.

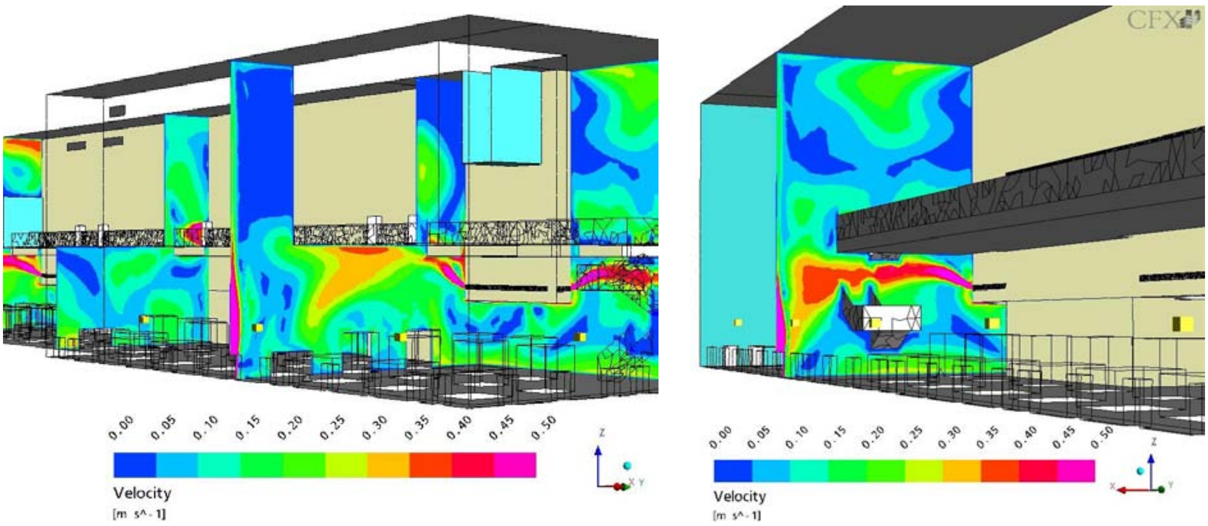

Figure 10. The velocity profile.

On the right-hand side the supply air jet flows directly to the stairs and reduces the thermal comfort in this area. It is recommended that the air jet is not thrown directly to the stairs, where it might produce a draught risk.

DISCUSSION

CFD was used to support the design team to find a functional air distribution system for a music centre foyer. The aim was to ensure appropriate thermal conditions and comfort in the occupied zones. The special features of this space were high occupied load, large space volume and a glazed facade, from where heat flows to the space in summer weather conditions. Air distribution systems, constructions and sources were compared. The individual supply air device simulations seemed to be a sensible way to find appropriate devices for specific locations, because different air flow quantities and devices could be simulated easily and these flow patterns could then be used as boundary conditions in the foyer simulations. This reduces the number of calculation nodes and saves simulation time. The device simulation models can then be saved to an object library for future projects. Approximations were made with the aim of achieving realistic simulation results for design purposes. The mesh should be sufficiently dense to ensure that all the important flow characters can be captured. The mass, momentum and heat balance should be realistic. It should be noted that the initial values are approximations, and for this reason the conclusions should be made with care and compare different calculation models and assumptions. The cube-shaped models for people and the equal distribution of lighting to the roof surfaces seemed to be reasonable approximations. The device simulation results were compared with the air jet theory and the manufacturer's data. This information is important for evaluation of the simulation results. In this study the most important effect on the indoor air environment had the behaviour of the air jet flows.

ACKNOWLEDGEMENT

This study was a part of the pilot project to develop the use of the product model supported by Senate Properties.

SUMMARY

The design of systems has become complex and highly specialized as Air Conditioning becomes involved in virtual with every phase of present human existence. Due to numerous applications and the ever-changing service conditions, it is imperative that we have a balanced system with all components properly selected. The split air conditioning refers to a certain physical arrangement of equipments like indoor and outdoor sections. A practical problem is dealt in this paper taking the computer program into consideration to calculate the loads and performance curves of each component are plotted on the same graph and obtained the balancing point.

INTRODUCTION

Split air conditioning system basically made up of two pieces of equipments (viz. outdoor section and indoor section) that are connected by refrigerant pipe work and control wiring. Each piece of equipment contains half of the refrigeration plant required for the vapor compression cycle (Ref: fig.1). In any system which involves many components working for that system need balance between each other. Two major problems which confront the air conditioning industry are improper system balance and misapplication of equipment. Though the air conditioning system is split into two sections, all the components are connected together in series and the refrigerant flow rate is same through all the components and hence the working capacity of all components in their own conditions must of necessarily be the same.

17. Fan

The present paper deals with four important aspects namely (a) the cooling load calculation using computer program, (b) design and selection of compressor, (c) design and selection of condenser and (d) design and selection of an evaporator.

METHODS:

(a) The cooling load calculation using computer program:

Total heat required to be removed from the space in order to bring it at the desired temperature by the air conditioning equipment is known as cooling load. If the load estimate is not accurate, the system will not perform properly and it will be impossible to meet the customer's requirements no matter how well the individual components are balanced. Any rule of thumb that we may customarily use shall only be used as a means of check. Purpose of load estimation is to determine the size of air conditioning equipment that is required to maintain inside design conditions during periods of maximum outside temperatures. The two main components of a cooling load in a split air conditioning system are as follows:

(i) Sensible heat gain:

When there is a direct addition of heat to the enclosed space, a gain in the sensible heat is said to occur. This sensible heat is to be removed during the process of summer air conditioning. The sensible heat gain may occur due to any or all of the following sources of heat transfer: wall gain load into the building by conduction through exterior walls, floors, ceilings, doors and windows due to the temperature difference on their two sides.

$$Q = U A (T_o – T_i)$$

where

U = Overall heat transfer coefficient
A = Area of the wall
T_o = Outside air temperature
T_i = Inside air temperature
$f_{o,i}$ = outside and inside film surface conductance
K_a = thermal conductance of air space

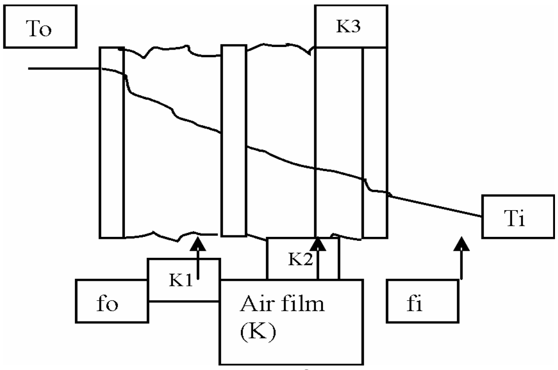

Fig. 2 Heat transfer along the wall.

$$U = \frac{1}{\frac{1}{f_o} + \frac{x1}{K1} + \frac{1}{Ka} + \frac{x2}{K2} + \frac{x3}{K3} + \frac{1}{f_i}} \quad \text{eq - 1}$$

Heat received from solar radiation consists of heat transmitted directly through window glass, ventilators etc. Heat liberated by the occupants which normally called as respiration load is also of this kind only. Heat given off by the lights, motors, machines etc. and heat carried by the outside air which leaks in is also called as air filtration load is to be considered based on openings of the doors under sensible heat gain.

(ii) **Latent heat gain:**

When there is an addition of water vapour to the air of enclosed space, a gain in latent heat is said to occur. This latent heat is to be removed during the process of summer air conditioning. Latent heat gain may occur due to moisture in the outside air entering by infiltration, condensation of moisture from occupants, heat gain due to moisture passing directly into the conditioned space through permeable walls or partitions from the adjoining regions where the water vapour pressure is higher.

Heat gain due to infiltration, due to ventilation, from occupants, from applications, from products and power requirements are to be considered to arrive at the total load on the system. Total cooling load will be the summation of the all four different loads discussed in this paper, outside conditions are 40 C DBT and 28 C WBT, and the required conditions are 21 C DBT and 60% RH and the capacity of the split air conditioning required is 3.79 KW.

(b) **Design and selection of compressor:**

The theoretical power required to drive the compressor may be found by multiplying the actual refrigerating capacity of the compressor in Kilowatts by the theoretical power required per unit capacity for the required operating conditions. The refrigerating capacity of the compressor, in general, decreases as the condensing temperature increases and raising the suction temperature will usually increase the power requirements. For the designed load of 3.79 KW, with the input of compressor ratings supplied by ASHRAE guide, computer will select a 1.5 Hp motor compressor (Model No.E036). The selected compressor ratings are as given below.

Table-1 compressor capacity vs. suction temperature**.**

Capacity of compressor (KW)	2.36	3.06	5.2	6.19
Suction Temperature(K)	279.8	282.6	294.98	298.18

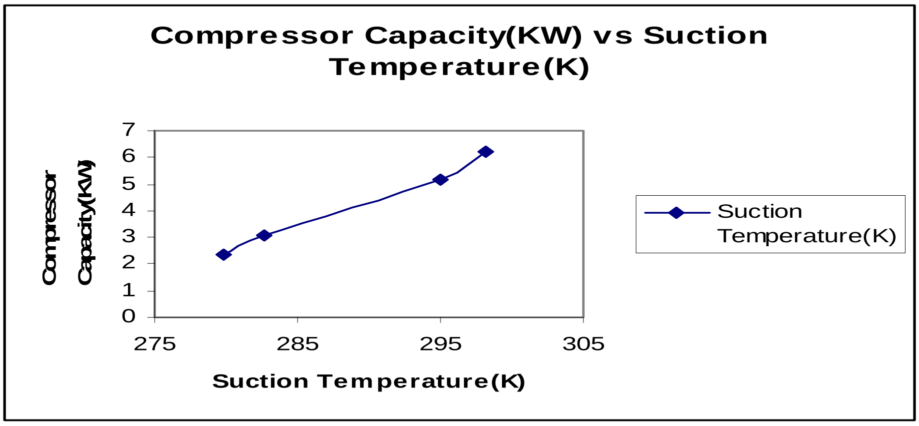

Fig. 3 Compressor capacity vs. saturated suction temperature .

The performance and merits of compressor is as shown in the figure. The reason for selecting this compressor is that it has approximately the right amount of capacity of 294.98 K suction temperature, which is just closer to the balancing point. Refrigerant selected is R-407C and a remote multi circulated air cooled condenser is selected for this requirement. Compressor performance/capacity is plotted on the ordinate and the saturated suction temperature/evaporator temperature on abscissa. Compressor operating conditions are for different condensing temperatures vary from 312K to 333K.

(c) **Design and selection of condenser:**

Capacity of the condensing unit depends upon the capacity of the compressor as the design saturated discharge temperatures depends primarily on the size of the condenser selected and upon the quantity and temperature of the available condensing medium. In this context, the rating and selection of condensing units are practically the same as those for rating and selection of compressors. Remote multi circulated air cooled condensing unit (Model no. STF 812) ratings are based on the saturated suction temperature and design ambient air temperature. Total heat rejection at the condenser includes both the heat absorbed in the evaporator and the energy equivalent of the work of compression. The performance of the condensing unit is as follows:

Table-2 Condenser capacity vs. Saturated suction temperature**.**

Capacity of condenser(KW)	2.9	4.35	6.2	7.85
Saturated Suction Temperature(K)	286.75	293.6	301.56	313.84

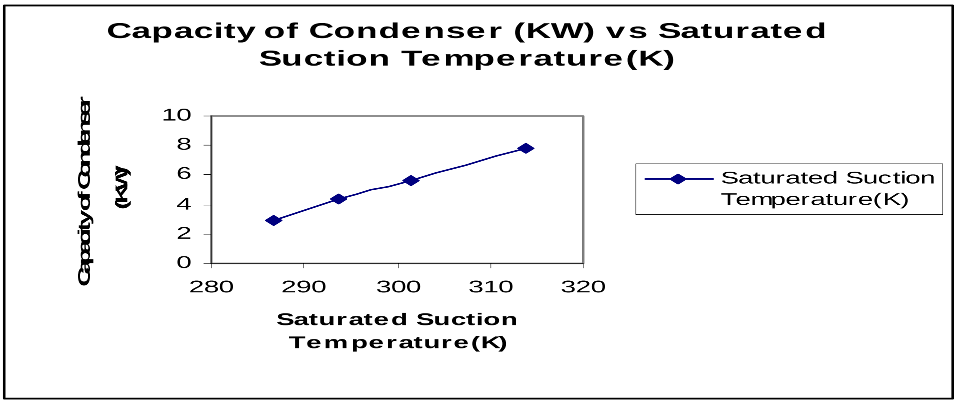

Fig. 4 Condenser capacity vs. Saturated suction temperature.

Condensing unit capacity is taken on the ordinate and the saturated suction temperature difference on the abscissa and the performance curves are plotted in the fig.4

(d) **Design and selection of an Evaporator:**

Once the conditions or the requirements of the air conditioned room are selected, the design and selection of an evaporator from the manufacturer's details is relatively simple. Evaporator temperature difference (TD) is the important aspect in the selection of evaporator and is defined as the difference in temperature between the temperature of the air entering the evaporator, usually taken as the space design temperature, and the saturation temperature of the refrigerant corresponding to the pressure as the evaporator outlet. In practice, the evaporator capacity varies directly with the evaporator TD. For the required TD in lower temperature applications, lesser will be the possibility of frost accumulation in the circuit and will result in better overall system performance. From ASHRAE table, for the required 60% RH and 8 TD, the model selected is BL 2116, whose performance details are mentioned below.

Table-3 Evaporator capacity vs. evaporator TD.

Evaporator Capacity (KW)	0	2.4	3.2	4.01
Evaporator TD(K)	0	4.21	6.4	8.45

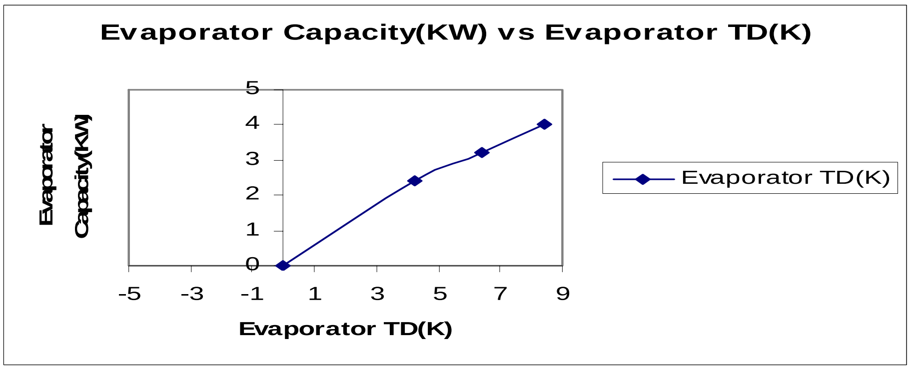

Fig. 5 Evaporator capacity vs. evaporator TD.
While plotting the performance of the evaporator capacity (KW) is on the ordinate and the Evaporator temperature difference (K) on the abscissa.

RESLUTS AND DISCUSSIONS:

It is most scientific and desirable to design and select the whole system of split air conditioning unit though practically not feasible to have a manufacturing endeavor to fabricate innumerable models economically to suit the customer's requirement. It is, therefore, the design engineers who select a proper combination for a particular situation giving the most desirable performance. For the present problem, as discussed earlier, the design load is 3.79KW. For the required conditions from the manufacturer's catalogue, compressor, condenser and evaporator are selected and they need to be balanced in their performance. Hence balance of the components in split air conditioning is observed which is highly desirable. It is also observed that the selection is on basis with selection of standard company. We can compare the balance between compressor and condenser, the compressor and evaporator, condenser and evaporator and the balancing point can be compared in all the cases as nearly 3.80 KW which is very close to our required load of 3.79KW. Finally balancing of all components on a single graph (with different scales) can be seen with the performance curves plotted and the meeting point of all the curves will be very close to the required capacity of the split air conditioning unit of 3.79KW.

PRACTICAL IMPLICATIONS ON THE RESULTS:

In the split air conditioning, for different applications, selection of compressor, condenser and evaporator is an important part of the manufacturer. In wide range of applications, the working conditions of the above equipment should match with practical existing conditions. For this, the present paper is very much required. After careful calculation of each load that are coming into picture at different stages, capacity of compressor, condenser and evaporator are selected using empirical equations. Once capacities of compressor, condenser and evaporator are calculated, we need to go to the catalogue of manufacturer (better to select most genuine manufacturer) and refer to the range of applications at desired conditions. In the present paper, performance curves of individual component are plotted for the combination of two and observed that there exists a common interference of the two superimposing of all the performances of the components, they are passing through a nearly common point closer to the required load. When we select the components like compressor, condenser and evaporator, this after superimposing the performance of individual and obtaining the intersecting point at the required load, then selection will be more appropriate because it has been tested and proved for wide range of applications/working conditions. In the present paper, effort is made for minimum load (3.79 KW) and if the same method is adopted for higher loads and the system is selected with proper balance (after obtaining the performance curves), it will be the best selection of the components in the system and it will be withstanding to any range of conditions that we will apply for the load that is calculated meticulously.

IEA HPP Annex 28 – Uniform testing and seasonal performance calculation of combined operating heat pump systems

Carsten Wemhoener, Thomas Afjei and Ralf Dott

Institute of Energy in Building, University of Applied Sciences Northwestern Switzerland, Muttenz, Switzerland

Corresponding email: carsten.wemhoener@fhnw.ch

SUMMARY

Climate protection targets require the performance assessment of HVAC systems. As basis uniform component testing and subsequent transparent calculation of the seasonal performance factor is needed. Highly-integrated system layouts, however, are not covered by existing testing and calculation standards.
Annex 28 in the heat pump program of the International Energy Agency delivered recommendations for extended testing and calculation of heat pumps with combined space heating and domestic hot water production. Test procedures are an extension of the current heat pump testing for space heating-only and domestic hot water-only mode. Calculation is performed by an extended temperature class approach (bin method). Validation of the calculation method with field monitoring results show a deviation of the seasonal performance factor in the range of ±6%, approving the feasibility of the approach. Implementation of the results in European and national standards has begun in the frame of the EU Building Directive EPBD.

INTRODUCTION

Market boundary conditions

Since the mid of the Nineties of the last century, building directives set tighter limits for the energy consumption of the building leading to the development of low energy buildings with significantly reduced space heating (SH) energy needs, e.g. down to dwellings, which must not require more than 15 kWh/m^{2}a for space heating according to the German passive house standard. This enables to provide the space heating need by reheating of the ventilation air. Domestic hot water (DHW) energy needs reach fractions up to 50% of the total heat energy need. On the other hand, reduced temperature requirements of the heating system lead to new adapted system layouts, and environmentally sound technologies like heat pumps, solar and wood systems have been (re)introduced in the market and have increasing market shares. These developments lead to a generally higher system integration to multifunctional systems, which cover different building needs, in common layout space heating and DHW, often amended by the ventilation function. Currently, additional cooling and space conditioning functions are integrated due to extended comfort requirements.
However, these new system developments are often not covered by existing test procedures and calculation methods. Due to the changing system markets, different stakeholders have strong interest in guidelines to compare the performance of systems under different boundary conditions:

- *Manufacturers* need regulations for providing precise and uniform technical data of their components derived from standard testing.

- Designers need methods to enable a comparison of different heating systems or system layouts in the design process.
- Consumers need a clear indication of environmental impact and energy costs as a guideline for their purchase decision, e.g. by transparent labelling.
- Consultants and policy makers need uniform values to set targets in regulations and directives on the background of climate protection policies. The resulting energy labels or building standards may be based upon the Seasonal Performance Factor (SPF) or primary energy as well as CO_2-emissions, which can easily be concluded from the SPF.

Standarisation work

These needs are addressed by the EU-Directive on the Energy Performance of Buildings (EPBD) [1], which has the target to introduce a Building Energy Certificate, which is displayed in the building and contains the energy consumption of the building and the installed system technologies in terms of primary energy consumption and CO_2-emissions. Moreover, measures to improve the energy efficiency of the building and the system technology are included in the assessment.

As common basis for the building energy certificate the EU has mandated the revision and extension of the current building and system technology standards. Under Mandate 343 a set of standards for the building and the system calculation is currently elaborated in the European standardisation organisation CEN. Most of the standards are almost finished and currently in the final enquiry called formal vote. The introduction of the standards on the national level will probably start by 2008.

With regard to the required component data test standards for domestic hot water appliances are currently to be harmonised based on the EU Labelling Directive. Under the EU Mandate M/324 [2] test standards of household appliances for DHW production are revised. For the harmonisation of the testing common EU reference tapping profiles have been defined in the mandate.

METHODS

The scope of the IEA HPP Annex 28 was the development of test procedure and subsequent SPF calculation method for combined operating heat pump systems for SH and DHW. The nine countries AT, CA, CH, DE, FR, JP, NO, SE, USA participated in IEA HPP Annex 28. Systems found on the market can be distinguished in alternate and simultaneous operating systems. In alternate operating systems the heat pump is switched to either the space heating or the DHW operation. In simultaneous operating systems space heating and DHW energy is delivered at the same time. Most common methods for simultaneous operation are refrigerant desuperheating and condensate subcooling as well as cascade cycle layout. Examples of alternate and simultaneous combined operating systems are shown in Figure 1

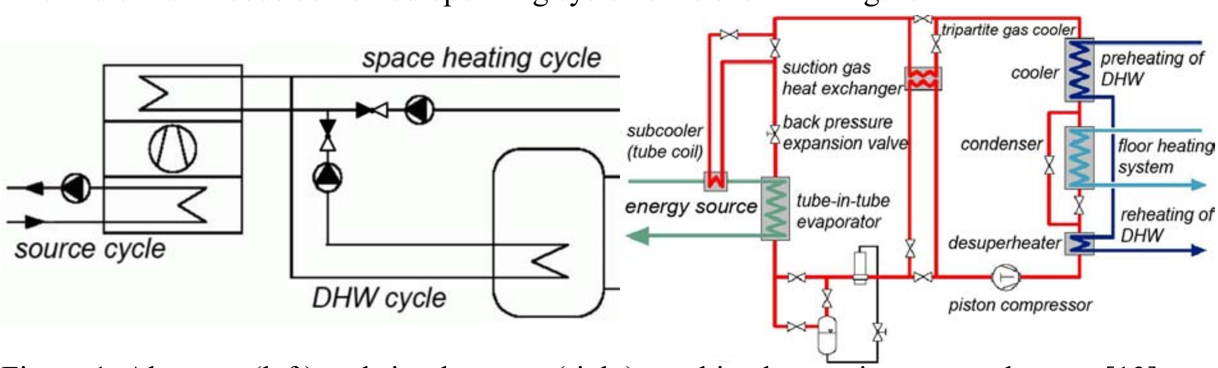

Figure 1. Alternate (left) and simultaneous (right) combined operating system layouts [13]

Ventilation compact units with exhaust air heat pumps have been treated, as well, since they have become very common in low energy dwellings. The accomplished work in Annex 28 comprises the testing of the systems according to existing and extended standards, calculation of the systems and field testing for the validation of the calculation results and to gain experience with the functionality for system optimisation. The following basic definitions have been made for the testing and calculation inline with the ongoing standardisation activities.

Test procedure
In order to uniformly cover the different system configurations on the market, a black box testing is applied, where only the values at the system boundary are used for the calculation, i.e. values, that can be measured outside the unit. This approach enables to abstract from the internal system configuration, which is difficult to consider since it varies a lot from one system to the other. The black box approach is depicted in Figure 2.

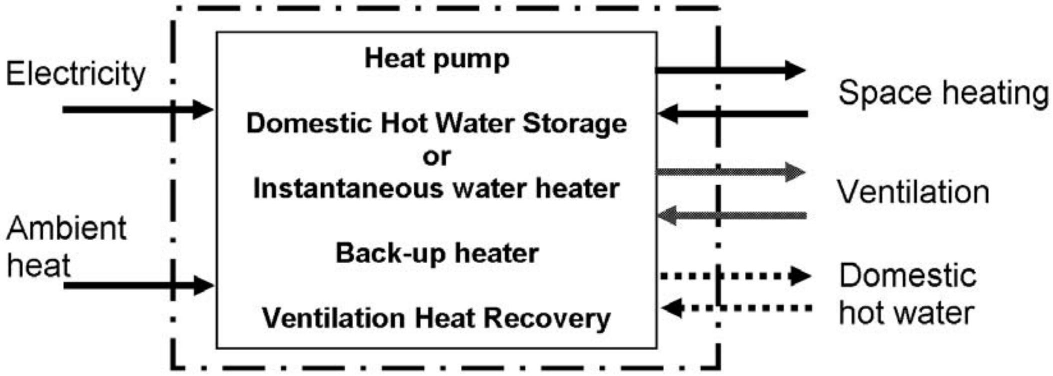

Figure 2. Black box testing as basic principle for the test procedure

Calculation method
Due to the common system testing (generator and storage) and common bivalent system layouts for heat pump systems (heat pump and back-up) the system boundary has been chosen to comprise the generator part with attached storages (both for space heating or domestic hot water) and eventually installed back-up generators. The system boundary in the calculation scheme of the EPBD is depicted in Figure 3.

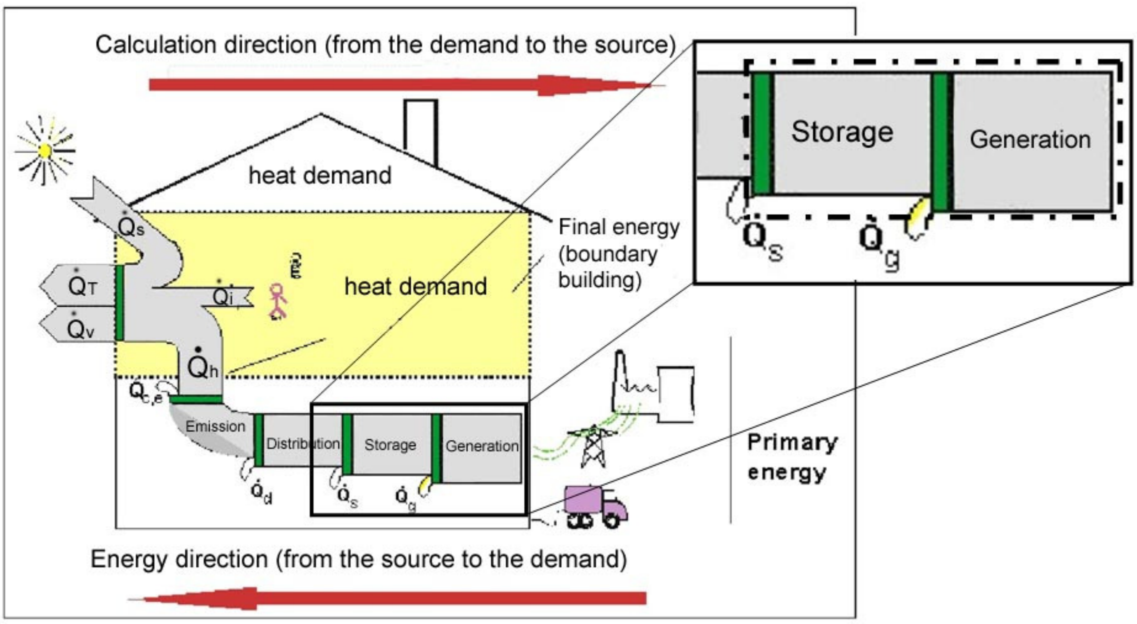

Figure 3. System boundary of Annex 28 in the calculation scheme of prEN 15316-1 [3]

RESULTS

Survey of heat pump markets and state in standardisation (state 2003)

As starting point a market survey of systems and the state-of-the-art in standardisation has been carried out.

Concerning combined operating heat pump systems, markets are different for Europe, North America and Japan. While Europe has mostly alternate combined operating systems on the market, North America mainly uses simultaneous systems with desuperheating for domestic hot water production, sometimes in combination with combined cooling/air conditioning and domestic hot water production, as well. In Japan, a combined alternate system was recently introduced in the market, where a CO_2 heat pump supplies hot water to a storage, which provides water at different temperature levels for floor heating, higher-temperature radiator heating and domestic hot water use.

In all participating countries, standards for the testing of the SH-only and DHW-only operation modes exist. In Japan, the DHW testing refers to the CO_2 heat pump water heaters, so called Eco–Cute systems, which have become very popular since their market introduction in 2002. However, testing for combined operating systems is missing except in the American standards ASHRAE 137 [4] treating the specific case of air-to-air heat pumps with DHW production by desuperheating, which is a common system configuration in the USA and Canada. Concerning the SPF calculation, no common standard for combined operating systems exists, either. For the SH-only mode, temperature class approaches (bin methods) are used in the USA and in some national guidelines in Europe, e.g. ASHRAE 116 [5] and VDI 2067-6 [6].

Evaluation of current European heat pump testing standards

<u>Space heating-only operation</u>

EN 14511 [7] performs steady state testing of the SH-only operation replaced the former standard EN 255-2 [8]. Comparison of the standards showed that resulting COP values according to EN 14511 are in the same range as EN 255, but approx. 4-5% lower due to the changes in the determination of the mass flow rate, which used to be manufacturer given in EN 255-2 and is now determined by a fixed temperature difference in the so-called standard rating point.

<u>DHW-only operation</u>

In contrast to steady-state of EN 14511, EN 255-3 [9] for the test of the DHW operation evaluates a tapping cycle, thus COP-value is derived by averaged evaluation of the energy balance for the tapping. For the determination of the COP DHW tappings of half of the storage volume are repeated, until the energy amount of the tapped hot water is within a 10% range. EN 255-3 is currently under revision in CEN/TC 113/WG 10.

Although comfortable to use, the major draw-back is a very long testing time of about 4 days for a single test point, mainly due to the testing of storage stand-by losses.

Further shortcomings of the EN 255-3, in particular with regard to combined operation, have been identified:

- EN 255-3 does not deliver a DHW output capacity, which is useful to evaluated running time in combined operation.
- EN 255-3 does only deliver one test point for the entire range of possible source and sink temperatures.
- EN 255-3 does not define a DHW outlet temperature, but uses manufacturer controller settings. Consequently, a direct comparison of tested heat pumps is not possible due to differing DHW temperatures.

On the basis of this analysis, modifications are recommended by the IEA HPP Annex 28 to be implemented during the revision of the EN 255-3.

- Storage stand-by losses are not necessary for the COP determination, as the change is about 4% and thereby in the range of the measurement exactness [10].
- Thus, if a heat loss value of the storage is known, testing of storage stand-by losses can be omitted. This can reduce the testing time significantly. If no information on the storage is available, i.e. in highly-integrated systems, the entire EN 255-3 cycle can be performed once, while the COP shall be evaluated for more test points.
- Using the period of the cycle applied for the determination of the COP, an average output capacity can be calculated.

<u>EU tapping patterns for DHW testing</u>
Delivered COP values for EN 255-3 tests using the European tapping profile according to mandate M/324 tend to be lower due to a higher mean temperature in the condenser.
Despite partly small mass flows (EU reference pattern 1), the reproducibility of COP-values is in the acceptable range of 5%, even though it may be problematic to secure the exactness of these small mass flows. Moreover, it is doubtful, if a set of 23 tappings give a more realistic result considering the differences in user behaviour.

Extension of the testing for combined operating heat pumps
Testing of alternate combined operating heat pumps approved that the overall SPF can be calculated based on the test results of the SH-only and DHW-only mode. Therefore, for alternate operating systems, no further testing is required.
For simultaneous combined operating systems, additional testing is to be performed, since the heat pump characteristic may change significantly compared to the SH-only and DHW-only operation. Therefore, the simultaneous combined operation is tested by performing the DHW tapping cycle during the space heating operation. Due to the black box testing, however, only the total electrical energy input to the heat pump can be monitored, so the allocation of the electrical energy to the operation modes is not possible. So the combined operation is evaluated as own operation mode, since in the end, the overall seasonal performance is the relevant characteristic number.

Calculation method
The calculation method is built on an existing temperature class approach (bin method) already introduced in national standards. The principle of the bin method is depicted in Figure 4.
The cumulative annual frequency of the outdoor air temperature is divided into temperature classes (temperature bins). In the centre of each bin, an operating point is evaluated with regard to the heat pump operation at these specific ambient conditions, which is determined by the respective standard component testing, e.g. for SH according to EN 14511 and for DHW according to EN 255-3. The operating point is considered to characterise the heat pump operation of the whole bin. The areas of each bin correspond to heating degree hours based on the meteo data of the site and characterises the energy consumption in the bin. Thus, a weighting of the operating conditions with this energy fraction of the bin and a subsequent summation of all bins delivers the seasonal performance factor. Electrical back-up heaters can also be considered by an evaluation of the respective area in the cumulative frequency diagram, in Figure 4 the area BU.
The overall seasonal performance can be calculated by weighting the single seasonal performance factors with the annual energy needs in SH- and DHW-operation, respectively. Thus, the alternate combined operation can be covered based on existing test standards.

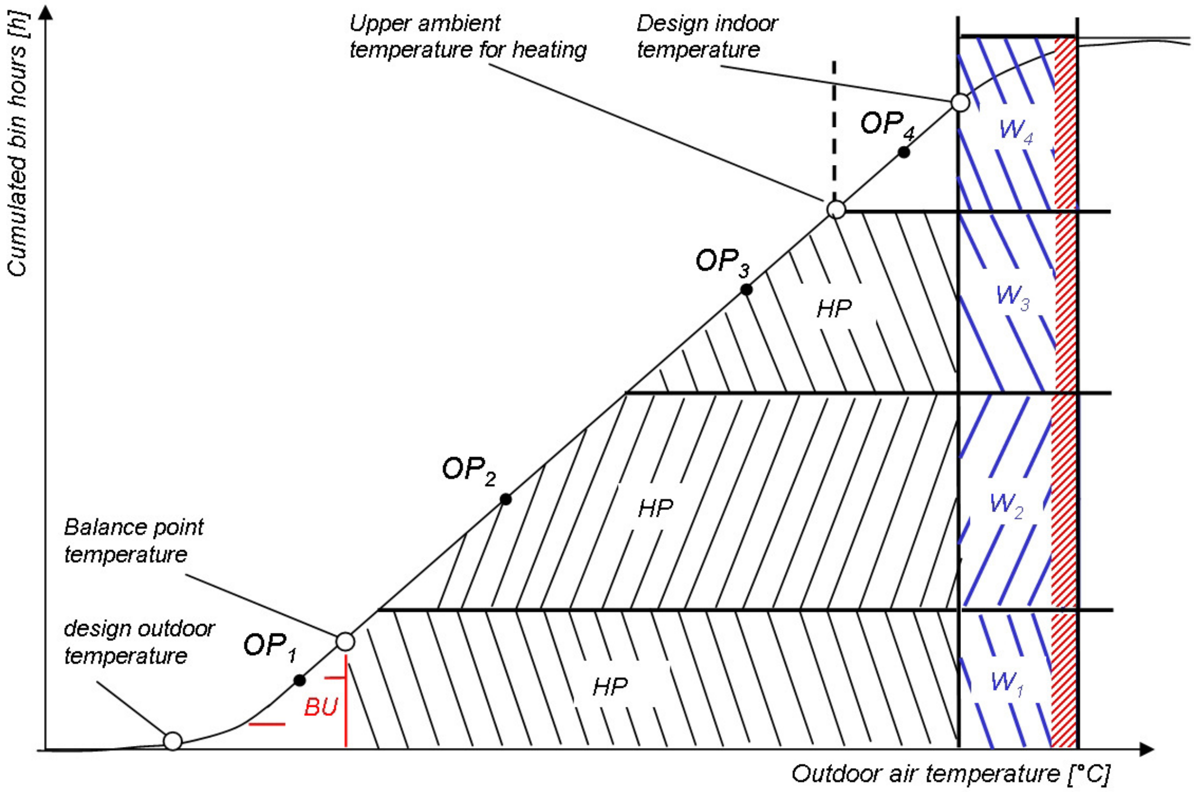

Figure 4. Principle of the bin method for alternate combined operation
(OP – operating point, BU – Back-up, HP – heat pump, W – DHW operation)

In simultaneous combined operation, however, the heat pump characteristic may change significantly. Thus, a third operation mode, the combined operation has been introduced based on the test procedure described above. The estimation, how much combined operation takes place in the bin is done by an evaluation of the running time of each mode, which is determined by the respective heating capacity of the heat pump and the energy requirement in the bin.

The overall seasonal performance can be calculated by the weighting of three operation modes, i.e. SH-only, DHW-only and combined operation.

DISCUSSION

Approximations of the calculation

Obviously, the calculation method implies some simplifications in order to keep the calculation simple. One shortcoming with regard to low and ultra-low energy house may be the redistribution of the energy requirement to the bins, that is only dependent on the heating degree hours and thereby on the outside temperature, while in low-energy dwellings the solar gains may have a higher impact on the energy distribution. This can be considered by an adjustment of the upper temperature limit for heating based on the quantity solar and internal gains as depicted in Figure 4.

Moreover, a shortcoming is that controller layout and controller setting can only be partly taken into account. In particular the energy production in combined operation may also depend on the controller settings for some system layouts. Controller settings for auxiliary components like pumps are often not known in detail and standard situation have to be evaluated. These effects can be taking into account by correction factors for typical control situations depending on the system configuration.

Comparison of calculated values to field monitoring results

To validate the calculation method with real data, field monitoring of pilot plants with combined operating heat pump systems were launched in the framework of the IEA HPP Annex 28. Even though not all types of system configuration could be monitored in field operation, the results of the comparison give a first impression of the exactness of the method.
Three direct expansion ground source heat pumps were evaluated for the SH-only operation. A ventilation compact unit with air-source heat pump and a ground source brine-to-water heat pump with alternate combined operation have been evaluated for the space heating and DHW operation. Differences between the calculation and the measured values are in the range of ±6% for the seasonal performance factor. Considering the simplifications in the approach these values are satisfactory and show the applicability of the method.

Implementation of results

Results of IEA HPP Annex 28 of have been continuously transferred to the respective standardisation working groups of the European standardisation committee CEN. The calculation approach has been implemented in the European draft standard prEN 15316-4.2 [11], which is part of the heat generator calculation standards used in the European Building Directive (EPBD) [1]. The SPF delivered by the calculation method is a basis for primary energy consumption or CO_2 emissions, respectively, which are displayed on the building energy certificate and determine the energy rating of the building.
For the implementation of the EPBD on the national level, Germany has introduced the method on a monthly basis in the pre-standard DIN V 18599 [12].
Results and recommendations for the test procedure are currently implemented in the CEN working group CEN/TC 113/WG 10 for the revision of the DHW test standard for heat pump EN 255-3. A working group committed to heat pump compact units incorporating also the ventilation is currently in constitution as a joint working group the ventilation CEN/TC 113 (Technical committee for heat pump testing) and CEN/TC 156 (ventilation systems). This gives the perspective that uniform testing of the heat pump and ventilation part of integrated ventilation compact units with heat pump can be achieved.
Concerning the international standardisation, the calculation approaches are quite similar, since the bin calculation is also introduced in ANSI/ASHRAE standards, but testing is still different due to different predominating system configurations on the market. Hence, to introduce internationally common standards, mainly the testing standards have to be further unified, i.e. on ISO level.

Information on IEA HPP Annex 28

Further information on IEA HPP Annex 28, workshop publications and related documents can be found on the Annex 28 website at http://www.annex28.net.
The final report of IEA HPP Annex 28 [13] is available at the IEA Heat Pump Centre and can be ordered via Internet on http://www.heatpumpcentre.org, category Publications/Reports.

ACKNOWLEDGEMENT

The authors would like to thank the Swiss Federal Office of Energy (SFOE) for funding and supporting the project.
It has to be emphasised that the IEA HPP Annex 28 is a team work and the results presented above are based on the effort and contribution of each member.
Hence, respect and thanks are expressed to all participants of the IEA HPP Annex 28 for the valuable contributions and for the constructive discussion and co-operation.

Institute of Energy in Building, University of Applied Sciences Northwestern Switzerland, Muttenz, Switzerland

Corresponding email: ralf.dott@fhnw.ch

SUMMARY

Overall energy rating of buildings including installed HVAC systems gets more important due to climate protection as demonstrated in building energy certificates presently introduced in the EU. Multifunctional system layouts for combined space heating, domestic hot water and ventilation, however, are often not covered by current product test standards and calculation methods. In this project consistent testing and calculation of multifunctional ventilation compact units with heat pumps has been elaborated based on present standard testing and calculation approaches. Different comparisons of calculated and field-monitored overall seasonal performance factor accomplished in Annex 28 show deviations in the range of ±6%.
Results are currently implemented in the respective testing and calculation CEN standards in the frame of the EU Directive on the Energy Performance of Buildings (EPBD) and related product testing.
Concerning component optimisation exergy analyses are a useful means, since different loss mechanisms can be quantified on a uniform basis.

INTRODUCTION

Due to reduced energy needs in modern highly-insulated and air-tight buildings, multifunctional system configurations have been introduced in the markets to cover different building energy needs for space heating (SH), domestic hot water (DHW) and ventilation with one unit. However, a system assessment requires standard test procedure and calculation methods, which are presently incomplete or missing for innovative multifunctional system layouts. The assessment is needed for different purposes, on the one hand for the holistic energy rating in the frame of the building energy certificate as currently introduced in the EU based on the Directive on the Energy Performance of Buildings (EPBD). On the other hand, transparent labelling concerning energy consumption/costs and environmental impact is needed to convince consumers to apply environmentally sound technologies.

METHODS

IEA HPP Annex 28 has been accomplished in 2003-2005 as co-normative research project in the frame of the Heat Pump Program (HPP) of the International Energy Agency (IEA). The nine countries AT, CA, CH, DE, FR, JP, NO, SE and US participated in the project. The scope and objective of Annex 28 were the development of

- *comprehensive test procedures* for combined operating heat pumps for SH and DHW with minimum testing requirements
- *subsequent transparent and easy-to-use calculation methods* for the SPF of combined operating heat pumps

as recommendations to standardisation organisations.

Thereby, two types of combined operating heat pump systems have to be differentiated

- *alternate combined operation*, where the heat pump is switched between SH- and DHW operation, and
- *simultaneous systems*, where SH and DHW energy is produced at the same time.

Since ventilation compact units with exhaust air heat pumps have become a standard heating system in ultra-low energy dwellings, they have been included in the scope, as well.
The accomplished work in Annex 28 comprises the

- testing of the systems according to existing and extended standards,
- calculation of the systems and
- field monitoring for the validation of the calculation results and to gain experience with the functionality for system optimisation.

Since test procedures for the SH-only, DHW-only and ventilation system already are in use, existing standards for the single operation modes have been extended to cover highly-integrated system configurations, as shown in Figure 1 and 3.

RESULTS

Results presented here refer to the Swiss national project in the IEA HPP Annex 28 [7] dedicated to the testing and calculation of heat pump compact units and field testing.

Test procedure for heat pump compact units

The testing of ventilation compact units with heat pump comprises

- Assessment of air-tightness (testing for internal and external air leakage)
- Testing ventilation
- Thermodynamic tests
- Acoustic tests
- Filter bypass leakage (optional)
- Operation/Maintenance/Safety (optional)
- Hygienic investigations (optional)

The following description refers to the thermodynamic testing as developed at HLKS of HTA Lucerne, the national Swiss test centre for residential ventilation systems. No European test standard for compact units exists, yet, but only test standards for the ventilation part and test standards for heat pumps for SH and DHW. The test procedure is based on the testing of German Institute of Building Technology (DIBt) and guidelines of the German Passive House Institute (PHI). However, the heat pump has been considered as core component of the compact unit and test points have been chosen based on the European heat pump test standards EN 14511 [2] for space heating mode and EN 255-3 [3] for DHW mode.
Since the operation conditions for the heat pump depend on the heat recovery a combined testing of the heat pump and the ventilation system is advantageous. Consequently, testing of the three basic operation modes deliver the respective characteristics of the component:

- ventilation-only operation (characteristic: temperature change coefficient, fan power)
- combined ventilation and heat pump in SH operation (COP, heating capacity SH)
- combined ventilation and heat pump in DHW operation (COP, heating capacity DHW)

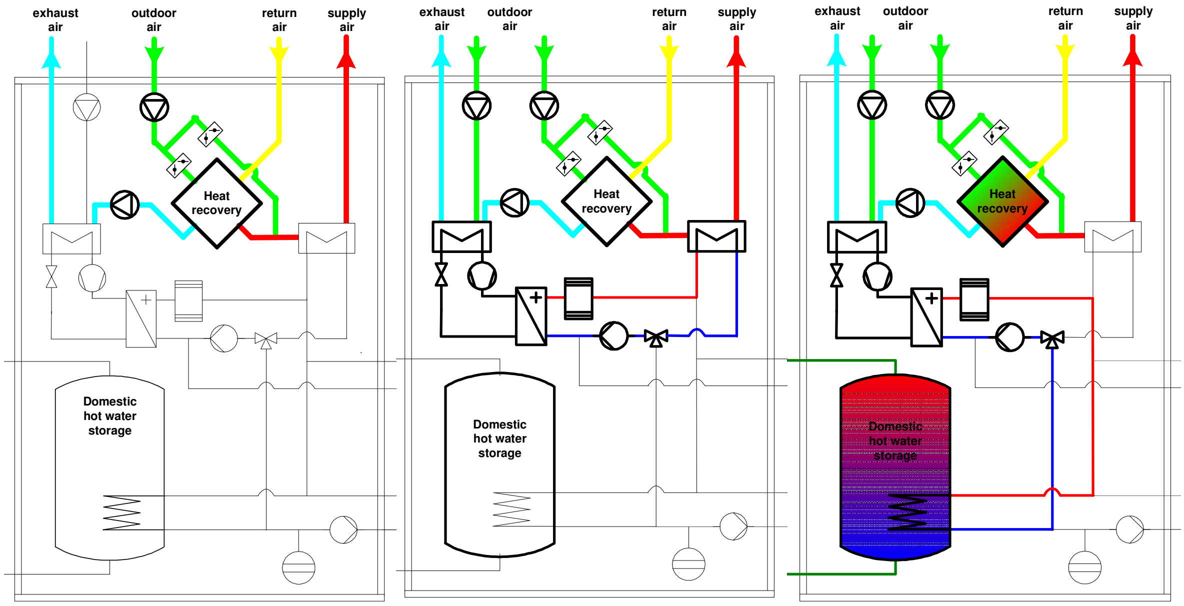

Figure 1. Operation modes for thermodynamic testing of compact units with internal circuit (left: ventilation only, middle: ventilation and SH, right: ventilation and DHW)

Figure 1 shows the different operation modes on the example of a heat pump compact unit with an internal circuit. The active circuit is depicted bold.
The component characteristic depends on the temperatures and the volume flow rates, thus test points of EN 14511 have to be tested for different air volume flow rates to be determined. To characterise the ventilation part including heat recovery unit, the temperature change coefficient and the electrothermal amplification factor are being determined.

Calculation method

The calculation of compact unit with heat pump is based on a temperature class approach (bin method) inline with the proposal for combined operating heat pump systems. Input data of the calculation method are the energy needs of the SH and DHW distribution system, test points of the unit according to the above test method, heating degree hours of the site, the system configuration and control details (e.g. heating curve, balance point).
The cumulative annual frequency of the outside temperature is divided into temperature classes (bins). In the centre of each bin, an operating point is evaluated, where the operation characteristic is known, i.e. at conditions defined in the heat pump testing standard. The operating point is considered to characterise the heat pump operation of the whole bin. The areas of each bin correspond to heating degree hours, which are proportional to the energy need in the bin. Thus, a weighting of COP values at the operating conditions with the energy fraction of the bin and a subsequent summation of all bins delivers the seasonal performance. Electrical back-up heaters and recovered heat by a ventilation heat recovery – only, if not already taken into account in the building energy calculation - can also be considered by an evaluation of the respective area in the cumulative frequency diagram.
For the domestic hot water operation, a similar calculation is performed based on standardised testing results of DHW-testing, e.g. for Europe according to EN 255-3 [3].
The overall seasonal performance can be calculated by weighting of respective operation modes, i.e. space heating-only, domestic hot water-only and combined operation.

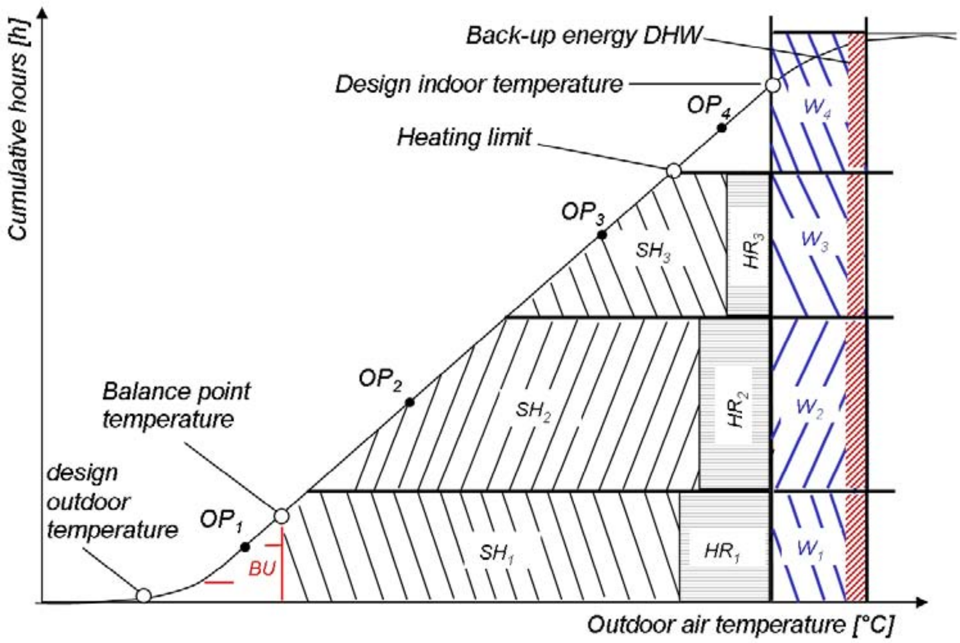

Figure 2. Principle of the bin method for multifunctional system for SH, DHW and ventilation with heat recovery unit (alternate mode) (OP - operating point, BU – back-up, SH – heat pump SH mode, W – heat pump DHW mode, HR – heat recovery unit)

Field monitoring

Calculation results have been compared to field testing results of a compact unit with air-source heat pumps installed in a single family low energy house according to the Swiss MINERGIE® standard. Figure 3 left shows the dwelling and a sketch of the principle system variant of system layouts of ventilation compact units with heat pump. In the investigated pilot plant, the compact unit works with a ventilation heat recovery and floor heating distribution system. A ground-to-air heat exchanger and solar collector are not installed.

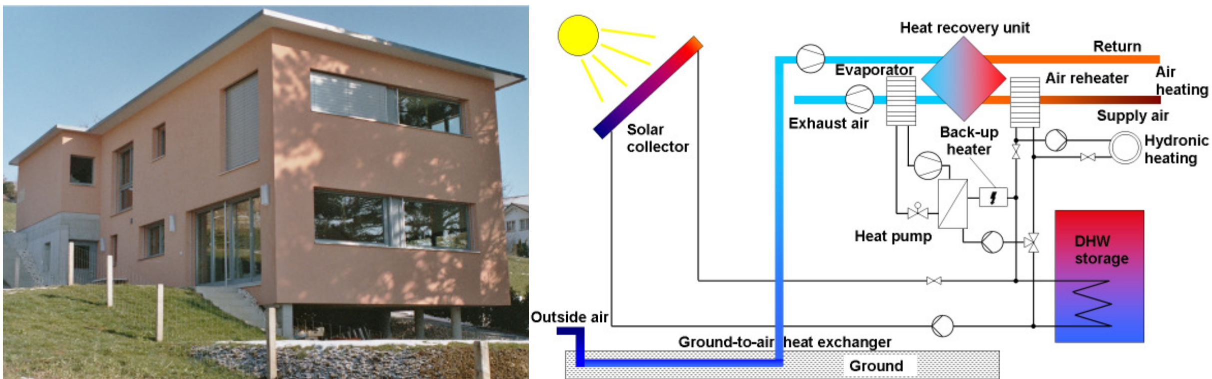

Figure 3. MINERGIE® dwelling for field testing and principle system layout of compact units

The evaluation period of the field testing is April, 26th 2004 to April, 25th 2005.
Figure 4 shows the annual electrical energy consumption of the different components of the compact unit (left) and heat energy consumption (right) for the different building needs. 75% of the electrical energy consumption is used as driving energy for the heat pump compressor, while 20% is used by auxiliaries and only 5% by the electrical back-up heater. Concerning the heat energy consumption, the remarkably low DHW heat energy consumption of only 9% explains the high fraction of SH energy of 83% despite the layout as low energy house.

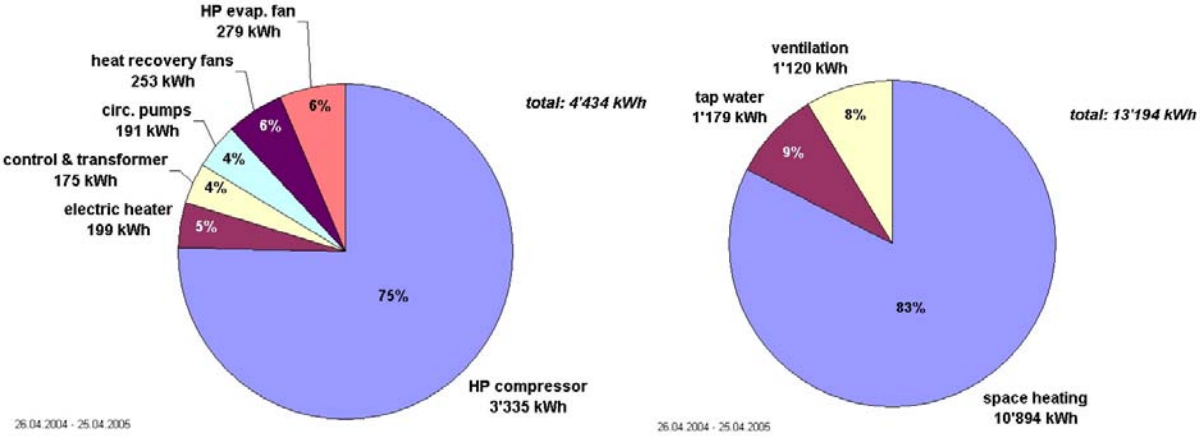

Figure 4. Annual electrical (left) and heat energy consumption (right) of the compact unit

Figure 5 presents the system boundaries used for the evaluation of performance characteristic number for the assessment of a ventilation compact unit with air-source heat pump. The same numbers have been calculated with the calculation method.

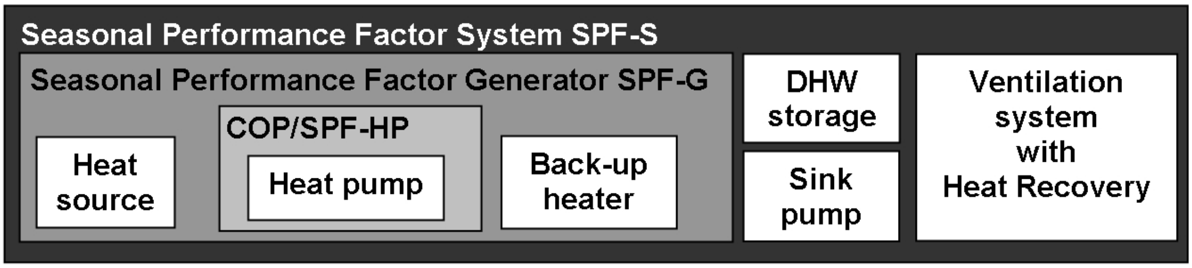

Figure 5. System boundaries for the assessment of the monitored compact unit

The SPF-HP comprises the system boundary according to the European heat pump testing. The Generator SPF (SPF-G) is the ratio of the produced energy of all generators (heat pump, back-up) to the respective electrical energy input and is well suited for the comparison to other heat generators like boilers. The System SPF (SPF-S) is related to the energy need and is calculated as ratio between the used energy (incl. the recovered ventilation energy) and the total electrical energy input to the entire system (incl. auxiliaries and electrical input to the ventilation). Results of the overall SPF for the system boundaries are depicted in Table 1.

Table 1. Monitoring and calculation overall SPF results for a ventilation compact unit with air-source heat pump installed in a low-energy house acc. to Swiss MINERGIE® standard.

	Monitoring (Reference)	**Calculation**	**Difference**
SPF-HP	3.66	3.54	-3.3%
SPF-G	3.42	3.42	0.0 %
SPF-S	3.06	2.96	-3.2%

Exergy analysis

Exergy is defined as the fraction of the energy that can be arbitrarily converted in each of the different energy forms. In all natural processes, exergy is converted to anergy, e.g. by irreversible heat transfer due to finite temperature differences or pressure drop due to friction, which corresponds to an exergy loss. Therefore, the exergy content is a measure of the thermodynamic quality of an energy flow or a process.

An exergetic consideration has been applied to characterise the impact of the temperature requirements of different source and sink systems used in compact units (cf. Figure 3 right) on the performance of a ventilation compact unit.

Pure air heating distribution systems have the limitation that the maximum temperature is restricted to about 50°C. Moreover, to avoid excessive exergy input to the fans, common designs limit the air volume flow to the hygienic necessary. Thus, air heating systems can only be applied in ultra low energy dwellings due to the limited heat capacity of the air and require high supply temperature up to the limit of about 50°C in colder winter periods.
Floor heating systems, on the other hand, have a large surface for the heat emission in the room, whereby supply temperatures below 30°C can be realised. However, additional exergy input for the circulation pump to transport the heat transfer medium is required.
The exergy comparison has been accomplished for an ultra-low energy house under the simplifying assumptions of adiabatic components, negligence of defrosting operation and a constant internal exergetic efficiency of the refrigerant process of ζ=0.5 (exergy losses of compression, refrigerant pipe, heat exchanger friction, expansion) to focus on the exergy losses linked to the source/ sink system periphery. Table 2 shows the boundary conditions used.

Table 2. Boundary conditions and resulting source and sink temperature (HR – heat recovery)

Building	
Ambient temperature [°C]/Indoor design temperature [°C]	-4 / 20
Heat load for the heat pump at ambient temperature [W]	1200
Ventilation system	
Volume flow rate ventilation system [m^3/h]	110
Temperature change coefficient (considered the same for supply and return air path) [-]	0.8
Pressure drop HR, condenser and evaporator [Pa] / air channels (each supply/return [Pa]	80 / 40
Constant fan power [W]/ Pressure drop dependent fan power [W/Pa]	10/ 0.12
Heat pump	
Pinch point condenser air heating [K]/floor heating [K]/Pinch point evaporator both[K]	5 / 2 / 5
Required supply temperature air / floor heating at ambient conditions [°C]	48 / 29
Condensation temperature / Evaporation temperature of the air heating system [°C]	48 / -21
Condensation temperature / Evaporation temperature of the floor heating system [°C]	30/ -23
Pump power of the circulation pump [W]	40

Since the COP of the heat pump can be expressed by the equation

$$\mathrm{COP} = \varsigma \cdot \mathrm{COP_C} = \varsigma \cdot \frac{T_{cond}}{(T_{cond} - T_{evap})}, \qquad (1)$$

where COP_C denotes the Carnot COP, ζ the constant internal exergetic efficiency , T_{cond} the thermodynamic condensation and T_{evap} the thermodynamic evaporation temperature, the COP is proportional to the Carnot COP and thus to the respective temperature levels.
Resulting exergy losses of the air heating are 14% higher than of the floor heating system despite the exergy input to the circulation pump and the evaporation temperature decrease due to the higher anergy extraction in the evaporator in case of the floor heating system, cf. Table 2.
Figure 6 depicts the range of temperature levels in the common components of the compact unit with common source and sink systems. The bold red arrows follow the way of the heat transfer media through the compact unit. Starting at ambient conditions the heat recovery unit raises the exhaust air temperature above ambient level, while in the evaporator it is cooled down by the refrigerant. The evaporation temperature level can be increased by a mix with an additional outdoor air flow or by a preheating of the air in a ground-to-air heat exchanger, which is often installed in order to avoid frosting of the heat recovery heat exchanger. The heat pump makes the main temperature lift from the source temperature level to the required distribution temperature level, and in the emission system the temperature level is reduced first to the room temperature, and then by the heat losses of the room to the ambient level.

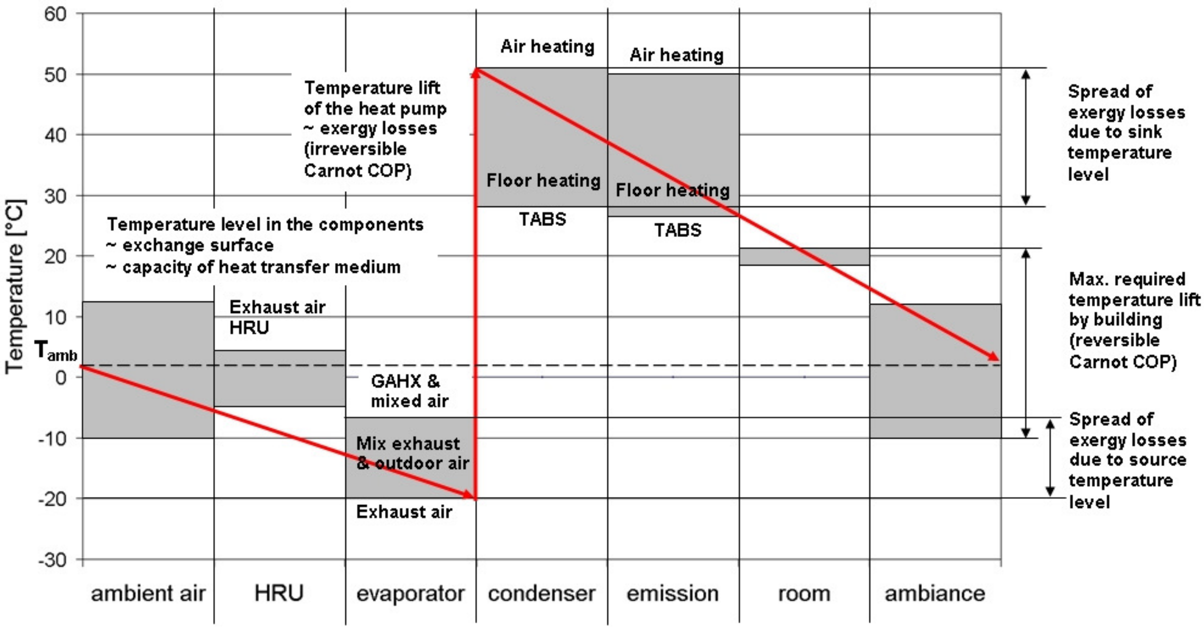

Figure 6. Temperature levels in the single components for compact unit (GAHX – ground-to-air heat exchanger, HRU – Heat recovery unit, TABS – Thermally activated building structures, COP – Coefficient of performance)

The temperature levels and corresponding exergy losses depend on the design of the heat exchangers, since larger heat exchanger surfaces reduce the heat transfer resistance and lead to lower temperature differences for the heat transfer. On the other hand, the temperature levels are also defined by the capacity of the source and the sink heat transfer medium. By the choice of hygienic necessary ventilation air as heating medium, for instance, high temperature spreads are required based to the limited heat transport capacity due to restricted volume flow rate and the heat capacity of the air.

The theoretical minimum required temperature lift for a reversible heat transfer is defined by ambient and indoor temperature (reversible Carnot COP). All limitations of the heat transfer system periphery thus have to be compensated by additional exergy input to the heat pump compressor due to the elevated temperature lift. On the sink side the maximum spread is seen between an air heating and TABS emission system, on the source side between a system with only ventilation exhaust air and a preheating of a higher outside air flow.

The general advantage of exergy analysis is, that the different loss mechanisms, e.g. due to heat transfer or pressure drop, can be quantified on the same basis as exergy loss. However, an exergy consideration gives only the technical viewpoint, and economical consideration may result in a different assessment. Last but not least environmental and comfort issues have to be considered, as well.

DISCUSSION

Simplification in the calculation approach

The calculation method implies the assumption of the redistribution of the energy according to heating degree hours which are only dependent on the outdoor air temperature. The impact of solar and internal gains on the energy redistribution can be approximated by an adjustment of the heating limit based on the quantity of used gains as depicted in Figure 2.

Moreover, controller impact cannot be considered in detail, since often, details are not known. Therefore, controller impact is taken into account by standard settings depending on the system layout, e.g. for the running time of auxiliaries.

Implementation of results

Results of IEA HPP Annex 28 for the heat pump calculation method has been implemented in the European draft standard prEN 15316-4.2 [4] used in the EPBD [1]. As national implementation of the EPBD, Germany has introduced the method on a monthly basis in DIN V 18599 [5].

A working group committed to testing of ventilation compact units with heat pump is presently in constitution as a joint working group of the Technical Committees CEN/TC 113 (heat pump testing) and CEN/TC 156 (ventilation systems). This gives the perspective of uniform testing of heat pump and ventilation part of compact units with heat pump.

Component and system optimisation

Exergy analyses are well suited for a component and process optimisation, since the impact of different loss mechanisms can be quantified on the uniform basis of exergy losses. The exergy analysis of the compact unit shows that any increase of temperature lift by the layout of the source and sink system has to be supplied as additional exergy to the heat pump. Therefore, system layout guaranteeing high source temperature and low sink temperature level lead to a significant reduction of the exergy losses and thus reduces the electrical energy input.

Information on IEA HPP Annex 28

Further information on IEA HPP Annex 28 can be found on the Annex 28 website http://www.annex28.net.

The final report of IEA HPP Annex 28 [6] is available at the IEA Heat Pump Centre. It can be ordered on http://www.heatpumpcentre.org, category Publications/ Reports.

Model of a Reversible Heat Pump for Part Load Energy Based Optimization Design

Elias Kinab, Amélie Fau, Dominique Marchio, and Philippe Rivière

Ecole des Mines de Paris
Center for Energy and Processes

Corresponding email: elias.kinab@ensmp.fr

SUMMARY

With the increase of air conditioning needs in commercial sectors, reversible heat pumps represent a smart solution for energy consumption.
Design and sizing of reversible air conditioning / heating systems are often based on the full load performance, in order to respect thermal comfort at extreme conditions. However, the HVAC industry is switching to designs based on improved seasonal performance at part load.

In this context, this article represents a modeling of a 60 kW reversible heat pump. Detailed models of each component of the system have been developed: a plate heat exchanger (R410A/water), finned tube heat exchanger (R410A /air), two parallel scroll compressors, and an expansion valve. The model simulates the whole cycle after simulating each component separately. Results obtained are validated through tests done on a reference bench machine. Then simulations covering all the climatic conditions and regions of France for a whole year are achieved, helping to model a design of a new reversible heat pump energetically optimized at part load.
This paper will describe the main elements of the model, which has an objective to reduce the annual energy consumption of the reference commercial reversible heat pump by 50%.

INTRODUCTION

Heat pumps have got great interest during the last two decades, due to the increasing attention of the international community towards global environment and energy savings. Therefore, heat pumps are promising efficient solution for buildings air conditioning / heating compared to conventional devices, especially now when electricity production has reached efficiency about 60%.

The paper presents a model developed to assume the steady state characteristics of a commercial reversible air-to-water heat pump. In cooling mode, heat source is the ambient air and heat sink is the water cycle inside the building. Conversely, in heating mode, heat sink is the ambient air and heat source is the water cycle inside the building. Results of the simulations are validated by experimental measures in climatic chamber. Initial validation allows simulating several cases by changing the model parameters, and extrapolating their results to annual conditions in order to design an annually optimized solution. This is coherent with the tendency to introduce energy performance of buildings and HVAC systems not only based on rating conditions but also extended to whole annual building load. This means to calculate a seasonal energy efficiency ratio SEER and seasonal coefficient of performance SCOP.

MODEL DESCRIPTION

The structure of the global model is an image of the vapor compression refrigeration cycle. It is divided into modules representing the different cycle stages for different configurations.

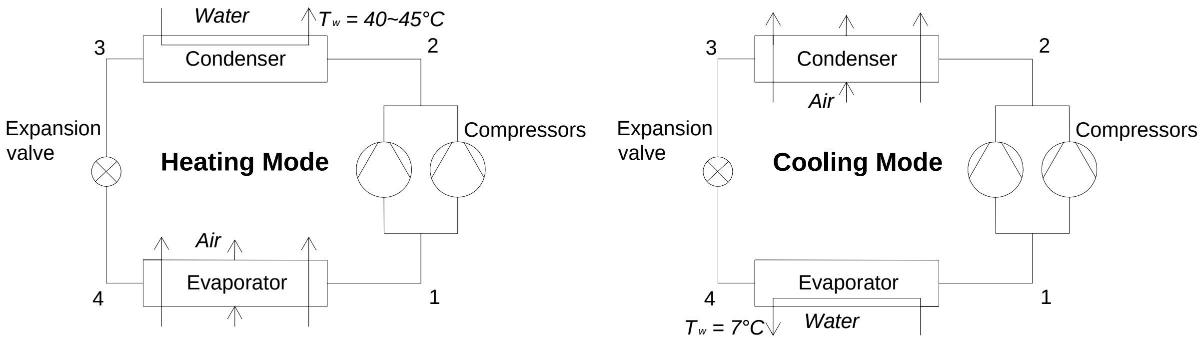

Figure 1: Layout of the vapor compression refrigeration system in heating and cooling modes

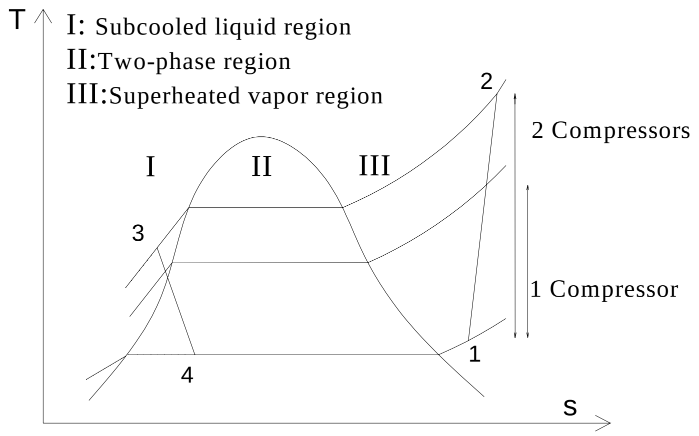


1—2 Compression
2—3 Condensation
3—4 Expansion
4—1 Evaporation.

Figure 2: R410A Vapor compression cycle on T-s diagram

Each module takes its inlet properties from the precedent module, calculates its outlet properties and transmits them to the next one. Details of the equations used are explained below.

The refrigerant used in this study is the R410A (mass fraction: 50% R32 and 50% R125). Calculation of the refrigerant, air, and water thermodynamic and transport properties is performed by correlations formulas written as computer code functions, using thermodynamic properties coming from REFPROP [1] data base. These functions are grouped in a particular module included in the overall source code.

Compressor model

A scroll compressor model is developed from the data given by the manufacturer and measurements carried out in climatic chamber on the whole heat pump. Performance curves are given using two equations fitting the compressor energy suction and the mass flow rate as a function of the evaporating temperature T_e and the condensing temperature T_c,

$$W_{comp} = C_0 + C_1.T_e + C_2.T_c + C_3.T_e.T_c + C_4.T_e^2 + C_5.T_c^2 + C_6.T_e^3 + C_7.T_e^2.T_c + C_8.T_e.T_c^2 + C_9.T_c^3 \quad (1)$$

$$\dot{m} = M_0 + M_1.T_e + M_2.T_c + M_3.T_e.T_c + M_4.T_e^2 + M_5.T_c^2 + M_6.T_e^3 + M_7.T_e^2.T_c + M_8.T_e.T_c^2 + M_9.T_c^3 \quad (2)$$

where C_1- C_9 and M_1- M_9 are constant coefficients.

Compressor calculating module inputs and outputs are:

Inputs		Outputs
Evaporating Temperature Te $[K]$ →	Eq (1)	→ $\dot{W}_{comp}[W]$
Condensing Temperature Tc $[K]$ →	Eq (2)	→ $\dot{m}_{comp}[kg/s]$
$\eta_{global}, \eta_{vol}$ →		→ $(T, h)_{discharge}$

Compressor isentropic efficiency expresses the ratio between the isentropic and real compression work:

$$\eta_{is} = \frac{\dot{W}_{is}}{\dot{W}_{real}} \quad (3)$$

where $\dot{W}_{is} = \dot{m}.(h_{2is} - h_1)$ is the real energy rate absorbed by the refrigerant during compression. Isentropic efficiency is needed to calculate the fluid properties (enthalpy, temperature…) at the compressor outlet. Compressor mechanical efficiency, assumed to be constant, relates real energy rate $\dot{W}_{real}$ transmitted to the refrigerant to power $\dot{W}_{comp}$

$$\eta_{mec} = \frac{\dot{W}_{real}}{\dot{W}_{comp}} \quad (4)$$

Compressor global efficiency expression

$$\eta_{global} = \frac{\dot{W}_{is}}{\dot{W}_{comp}} = \eta_{is} \times \eta_{mec} \quad (5)$$

Compressor volumetric efficiency

$$\eta_{vol} = \frac{V_{real}}{V_{th}} = \frac{v_{asp}.\dot{m}}{V_{th}} \quad (6)$$

where v_{asp} is fluid specific volume at the compressor aspiration [m^3/kg],

V_{th} is displacement volume given by manufacturer [m^3].

Expansion device model

A thermostatic expansion valve (TXV) is considered in the model. TXV is used as rate flow control device, which feeds back the superheat ΔT_{SH}, and adjusts the mass flow to the evaporator in order to maintain a constant superheat preventing liquid refrigerant from entering the compressor.

Inputs are the inlet enthalpy and pressure, the outlet pressure and the superheat ΔT_{SH}. The expansion is assumed to be adiabatic procedure without heat exchange neither work drawn or produced, thus it is an isenthalpic expansion: $h_4 = h_3$.

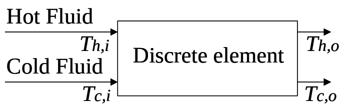
Mass flow rate governing equation depends from the difference of pressure between the condenser and the evaporator $\Delta P = P_c - P_e$, and from the superheat ΔT_{SH}:

$$\dot{m}_{TXV} = k.\Delta T_{SH}.\sqrt{\rho.\Delta P} \quad (7)$$

where k is a coefficient specific to the expansion valve considered.

Heat exchangers models

The air-to-water heat pump studied in this article involves two heat exchangers (HEs): a plate heat exchanger (R410A/water), and a finned tube heat exchanger (R410A/air). These exchangers play the role of condensing or evaporating unit according to the case of cooling or heating mode.
Three types or levels of detail exist for modeling HE depending on the required accuracy on the results: global, zonal or finite elements. In this work, HR are modeled through zonal for every type of HE wherever its working mode: parallel flow, counter flow, cross flow, in a sequence of superheat – condensation – subcooling or evaporation – superheat. However, due to space limitations, only heating mode will be considered to illustrate the different heat exchange stages of the condenser and the evaporator and the calculation procedure.
Discrete elements considered calculate the outlet temperatures $(T_{h,o}, T_{c,o})$, starting by knowing



their inlet temperatures $(T_{h,i}, T_{c,i})$. The calculation is based on LMTD approach:

$$Q = F \cdot UA \cdot LMTD \tag{8}$$

where -Q is the heat flux exchanged [W].
-UA is global heat transfer coefficient [W/K], got from the correlations applied on both sides of the heat exchange process.
- F coefficient for flow type.
-LMTD is the log mean temperature difference defined by:

for parallel flow HE: $$LMTD = \frac{\Delta T_2 - \Delta T_1}{\ln\left(\frac{\Delta T_2}{\Delta T_1}\right)} = \frac{(T_{h,i} - T_{c,i}) - (T_{h,o} - T_{c,o})}{\ln\left(\frac{T_{h,i} - T_{c,i}}{T_{h,o} - T_{c,o}}\right)} \tag{9}$$

for counter flow HE: $$LMTD = \frac{\Delta T_2 - \Delta T_1}{\ln\left(\frac{\Delta T_2}{\Delta T_1}\right)} = \frac{(T_{h,i} - T_{c,o}) - (T_{h,o} - T_{c,i})}{\ln\left(\frac{T_{h,i} - T_{c,o}}{T_{h,o} - T_{c,i}}\right)} \tag{10}$$

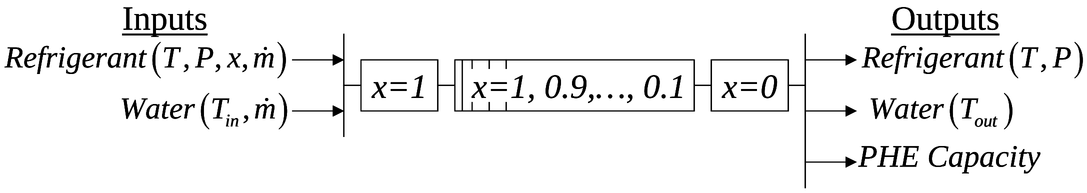
Another expression for the heat flux exchanged between the two fluids:

$$Q = C_c (T_{c,o} - T_{c,i}) = C_h (T_{h,i} - T_{h,o}) \tag{11}$$

where $C = c \cdot \dot{m}$, c is the specific heat [kJ/(kg·K)].
The procedure to solve the set of equations is as follows. An estimate of one of the outlet temperature $T_{c,o}$ or $T_{h,o}$ is taken as initial guess. Then the other outlet temperature and heat flux Q are found with equation (11). Next, a new value of Q is determined using equations (8). If the newly calculated heat flux value matches the previous one, the element computation is complete. Otherwise, Q becomes the new estimate of equation (11) and another computational sequence is performed.

<u>Plate heat exchanger</u>
Since the heat sink in heating mode is the water cycle inside the building, the plate heat exchanger PHE will play the role of condensing unit. During the condensing process, refrigerant passes through three regions: superheated vapor, condensation and subcooled liquid (figure 2). Therefore, modeling of the PHE differs between these three regions through refrigerant quality *x*. Indeed, PHE is divided to superheated zone where *x=1*, subcooled zone *x=0*, and a two-phase zone subdivided to 10 elements where vapor quality *x* is decremented by a value of 0.1 from 1 to 0.

Condenser model inputs and outputs are:



The specified geometry of the PHE includes the number of plates, plate spacing, length and width of the HE. Water side heat transfer coefficient was first taken from the single-phase water to water pre-tests done by Kim [5, 6]. First results lead to use a simple correlation function of Reynolds number and Prandtl number:

$$Nu = 0.386\,\mathrm{Re}^{0.623}\,\mathrm{Pr}^{0.369} \tag{12}$$

where Nusselt number is equal $Nu = \dfrac{h_w \cdot D_h}{k_w}$, k_w represents water thermal conductivity, and D_h hydraulic diameter.

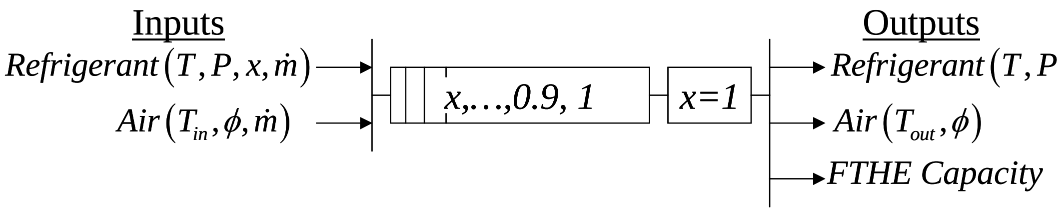
Heat transfer for refrigerant side in PHE [7] depends on refrigerant state: for single-phase flow most correlations that have been proposed by literature are of the form:

$$Nu = C\,\mathrm{Re}^{n}\,\mathrm{Pr}^{m} \tag{13}$$

while for boiling flow, correlations are more complicated like Cooper boiling correlation [6]. Thus, the model uses correlations similar to equation (13) after identifying its parameters by measurements. The parameters C, m and vary with the vapor quality x.

<u>Finned tube heat exchanger</u>

In heating mode, the finned tube heat exchanger FTHE is considered as evaporating unit. As shown in figure 2, refrigerant passes through two regions: evaporation and superheated vapor. Evaporator model inputs and outputs are:



The geometry of the FTHE is specified also, it includes the number of tubes heightwise *N*, the number of tube rows in the direction of the air flow plate *n*, the tube spacing in the direction of air flow S_L and in normal to the direction of air flow S_T, tube inside and outside diameter, spacing between fins *s*, tube length *l*, HE height. Some of these dimensional parameters are shown on figure 3, which is a side cutaway view of the FTHE.

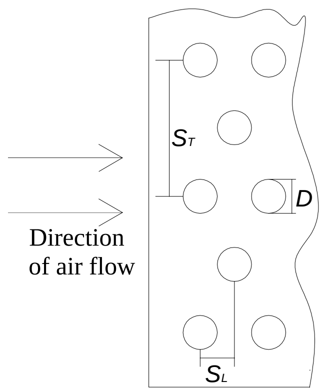


Figure 3: FTHE side cutaway view

Convergence criteria - Main computational loop

First, prior to cycle calculation, initial conditions (air, water) must be specified. Besides, a degree of subcooling must also be specified. Using the ambient temperature, the program generates its initial estimate of evaporating and condensing pressures. A flow chart outlines the model structure and the order of computation in figure 4. The subcooling is compared to the required one. According to the difference between the two values, condensation pressure is adjusted. Then, the mass flow rate calculated by the expansion device model is compared to the mass flow rate obtained by the compressor model. According to the difference, evaporation pressure is adjusted.

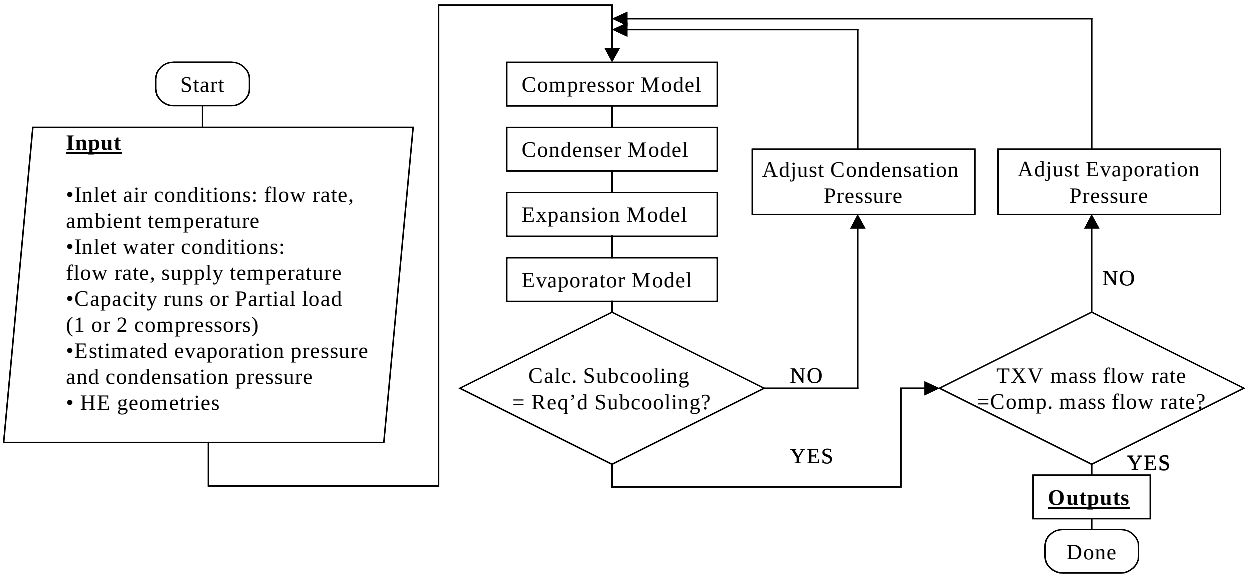

Figure 4: Overall model flowchart

MODEL VALIDATION

Results obtained by the program are validated through tests done on a reference heat pump machine. This test machine is mounted in a climatic chamber where ambient air is maintained at specified conditions of temperature and humidity. Moreover, compensation cycles are conceived to consume the hot and chilled water produced by the system.
The main components of the test machine are: PHE with 64 plates, 2 scroll compressors, FTHE with 24 circuit 3 tube rows and louvered fins, and two thermostatic expansion valves. Temperature and pressure measurement instruments are well distributed on the inlet and outlet of the heat pump components. Compressor mass flow rate is also measured. In addition, flowmeter and air velocity measurement devices are used to determine water and air flow rates respectively.

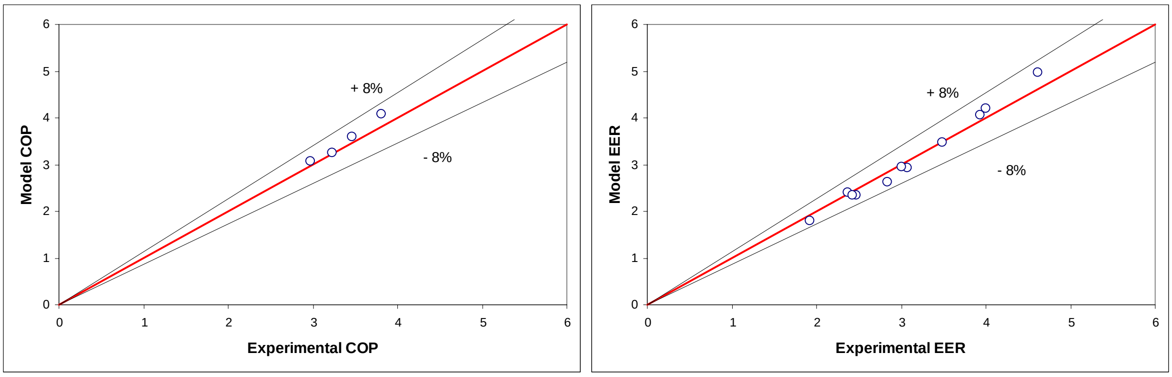
b)



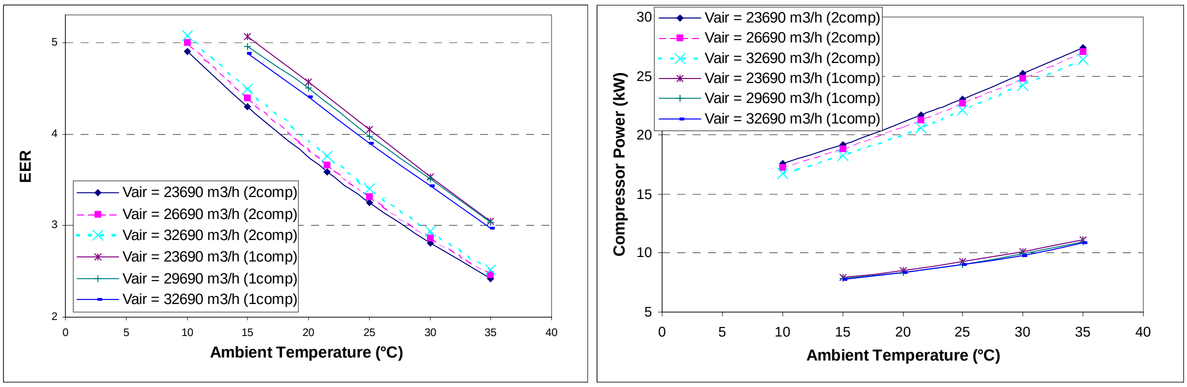
c) d)

Figure 5: Comparison between model and experiments results

Figure 5 shows comparison between the model and the experiments results. The comparison covers partial load and full load charge for a range of ambient temperature. The first plot (5.a) shows results for the power required by the compressor, which is predicted within 5% of error. Compressor mass flow rate (5.b) is perfectly computed by the model with a difference of 2%. COP and EER are predicted within 8% of error.

EXAMPLE OF RESULTS

As an example of the simulations that could be performed, the following figure shows effect of increasing air flow on the FTHE working as a condenser in cooling mode. The simulation was completed for partial load (1 compressor) and full load (2 compressors), it covers a range of temperature from 35°C to 10°C. A benefit of around 7% is noticed at full load and 3% at partial load (6.a), this is due to the decrease of condensation pressure which reduces the power required by the compressor (6.b).



a) b)

Figure 6: Effect of increasing air flow rate on EER and compressor power in cooling mode

In addition, results of simulations serve as tool for evaluating seasonal loads. Figure 7 illustrates reduced load curve for a commercial building in Nice (south east France) function of compression ratio, load and weighting factor. Weighting factor is a percentage expressing the number of functioning hours annually. The curve is divided between partial load 50% (one compressor) and full load 100% (two compressors).

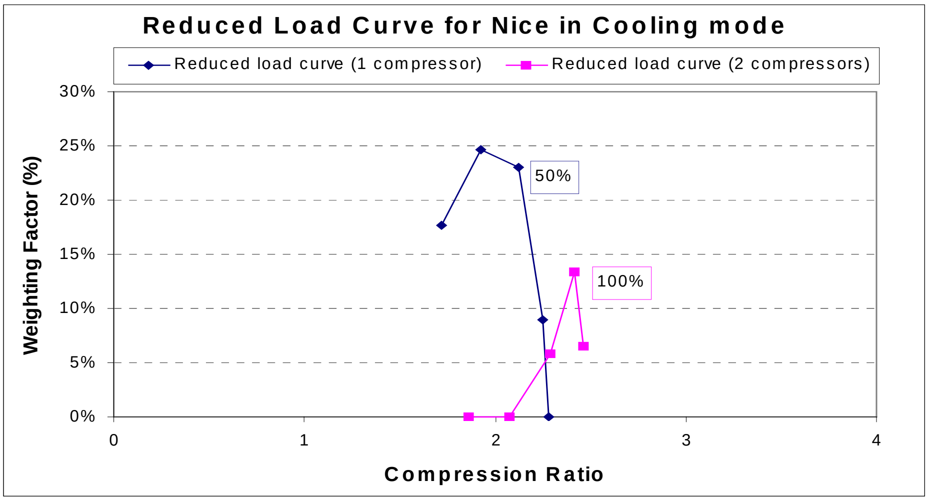


Figure 7: Reduced load curve

CONCLUSION

A vapor compression cycle model has been developed to simulate the performance of an air-to-water R410A based reversible heat pump. The global model is based on first principles and thermodynamics. It includes detailed submodels of the system components: compressor, heat exchangers, and expansion device. The model was successfully tested on a real prototype, it predicts characteristics of the cycle with only a difference of about 5% with the experimental measures. It is able to calculate a complete cycle in a few seconds.

The coupling with the building simulations enables to optimize the reversible when energy consumption has the larger impact, part load and reduced temperature as compared to standard conditions.

Further work will consist in studying different optimization paths for different building and climate conditions.

SUMMARY

The electrical heating in residential sector may be optimized by using mono-fluid heat pumps with direct expansion ground heat exchangers and direct condensing through radiant floors. Such systems are simple and efficient because eliminate secondary fluids (brine, air), circulation pumps, air handlers and fans. This paper presents some design criteria and energy performances of a residential, integrated HVAC system with three direct expansion ground heat pumps and exhaust air heat recovery device. Are presented the main results obtained in a 2-story house during a typical Canadian cold climate heating season. The system seasonal energy performance depends on soil properties, ground heat exchangers depth of burial, and outdoor temperatures and precipitations. The seasonal coefficients of performance of DX ground heat pumps averaged 3.8, while the temperatures of the concrete slab (basement) and wooden floors (1st and 2nd stories) varied around 26°**C** ensuring homogeneous vertical thermal stratification and highly indoor comfort. Improvements of refrigerant circuits and controls allowed avoiding instability phenomenon and improving overall performances and reliability of the integrated HVAC system with direct expansion ground source heat pumps.

INTRODUCTION

Electricity usage for housing heating can be optimized by using ground-source heat pumps (GSHP). The ground is an inexhaustible energy source since it absorbs nearly 46% of the incident solar energy, as well as heat from natural precipitations (rain, melting snow). The well-known indirect GSHP systems use vertical or horizontal ground heat exchangers and water/antifreeze mixtures as geothermal fluid. In spite of their high energy efficiency and contribution to greenhouse gas emissions, the main disadvantages of these systems are relatively high drilling costs, additional energy consumption for geothermal fluid pumping and energy efficiency losses due to thermodynamic irreversibility of intermediate heat exchangers. On the other hand, the direct expansion (DX) heat pumps system with direct condensing inside radiant floors eliminates secondary fluids as brines and air, circulating pumps, air coils and fans. Such geothermal heat pumps have been designed and in-field tested in Eastern Canada where the average solar insulation vary from 50 kWh/m^2 in January to about 180 kWh/m^2 in July and the total heating Degree-Days averages 5 211. The residential system integrates three heat pumps with horizontal DX ground heat exchangers, direct condensing radiant floors for space heating, a central air-conditioning unit with exhaust air heat recovery heat exchanger and a 4-kW electrical back-up heater. The study aimed at determining the influence of soil properties, ground heat exchanger depth of burial and local cold weather conditions on such integrated residential heating/air cooling systems.

SYSTEM DESCRIPTION

A high-comfort 1100-m^2 (total surface area) house with half-buried basement and two stories was equipped with two DX ground-source heat pumps and one make-up air HVAC unit. The 2-story house, located along the Saint Lawrence River (Eastern Canada), is well insulated but exposed to prevailing winds. The nominal heating load, calculated for 21°C indoor and -29°C outdoor temperatures, was estimated at 20 kW of which approximately 12 kW for the basement and the 1st floor, and 8 kW for the 2nd floor. A 4-kW back-up electrical coil provides additional heat during the peak demand periods. The first mono-fluid ground-source heat pump (GSHP #1) supplies heat to the basement and the 1st floor (734 m^2 in total surface) (Figure 1). The horizontal ground-source heat exchanger #1, buried at 0.9 m depth, contains eight refrigerant loops with ½" copper tubes coated with a thin plastic layer and 720 m in total length. Up to 0.8 m depth the soil is sandy and humid, and the ground exchanger is buried at 0.9 m depth in a disaggregate schist soil mixed with a few damp clay. The nominal heating capacity (18.5-kW) of GSHP #1 is dissipated through two parallel, direct condensing heat exchangers. On the basement, the first condenser (260 m of ¾" copper tubes) is inserted inside a 100-mm concrete radiant floor thermally insulated. On the 1st story, the second condenser (350 m of ¾" copper tubes) is installed under a traditional wooden floor, thermally insulated. Precautions were taken to enhance the heat transfer between the refrigerant piping and the wood panels. Each parallel refrigerant circuit contains motorized (SV) and check (CV) valves allowing supplying heat according to each zone heating demand. The second mono-fluid ground-source heat pump (GSHP #2) supplies heat to the 2nd floor (366 m^2). The horizontal ground-source heat exchanger #2, also buried at 0.9 m depth, contains four refrigerant loops with ½" copper tubes and 360 m in total length. The heat pump's nominal heating capacity (7.5-kW) is dissipated through a direct condensing heat exchanger (350 m of ¾" copper tubes) installed under a traditional wooden floor, thermally insulated. The make-up air HVAC unit includes a heat-pipe exhaust air heat recovery heat exchanger with variable speed fans, and a direct expansion, reversible, tri-function ground source heat pump (GSHP #3) with 2.6 kW as nominal cooling capacity. The horizontal DX ground heat exchanger #3 (180 m of ½" copper tubes) is buried at 0.9 m depth. In cooling and dehumidification mode, the "cold" heat exchanger acts as an evaporator and the ground heat exchanger as a condenser. In dehumidification and heating mode, the "cold" heat exchanger operates as an evaporator and the "hot" heat exchanger as a condenser. Finally, in heating mode, the DX ground heat exchanger becomes evaporator and the "hot" heat exchanger - condenser. The electrical humidifier and a 4-kW back-up heating coil respectively provide make-up air humidification to keep the indoor air relative humidity around 50%, and additional preheating during extreme weather conditions in winter.

GROUND DX HEAT EXCHANGERS

All horizontal DX heat exchangers are buried in a compacted gravely, siliceous and damp sand, with little clay content and average thermal conductivity of 1.29W/m.K (Figure 2). The temperature of the disturbed soil was monitored at 150 mm lateral distance from the ID ½" horizontal tubes (T_2). The temperature of the not disturbed soil ($T_{infinite}$) was also recorded at 0.9 m depth, but at 10 m distance, lateral from the ground heat exchanger #1.

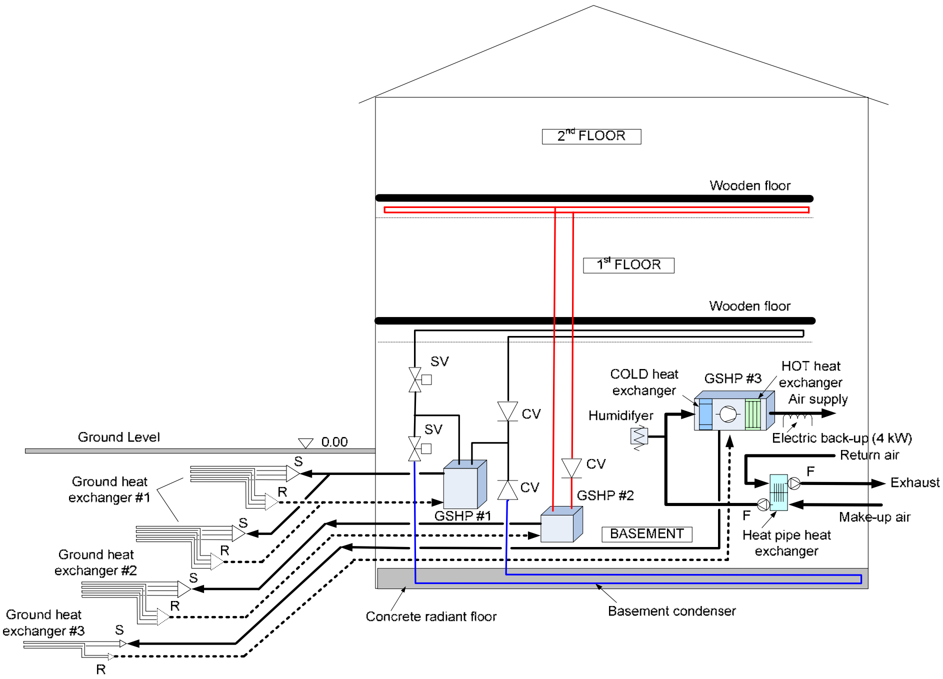

Figure 1.Configuration of the integrated HVAC system
GSHP: ground-source heat pump; SV: motorized valve; CV: check-valve; S: supply header; R: return header; F: fan

With the hypothesis that the temperature is constant along the z axis and that it vary only in radius direction, the conduction heat transfer through an infinite soil cylinder (**r_1** radius) without internal heat sources is given by the Laplace equation:

$$\frac{\delta^2 T}{\delta x^2} + \frac{\delta^2 T}{\delta y^2} = 0 \qquad (1)$$

accompanied by the circle equation: $x^2 + y^2 = r^2$. By neglecting the copper tubes thermal resistance, and under Dirichlet limit conditions ($r = r_0$, $T = T_1$ and $r = r_1$, $T = T_2$), the soil temperature field results in cylinder coordinates:

$$T = T_1 + \frac{T_2 - T_1}{\ln \frac{r_1}{r_0}} \ln \frac{r}{r_0} \qquad (2)$$

where $T_1 = T_0 + 1.5°C$ is the tube wall interior temperature (T_0 – refrigerant saturated temperature).
The thermal flux density results as follows (Fourier hypothesis):

$$\dot{q} = -k\,gradT = \frac{k_{soil}}{r} \frac{T_2 - T_1}{\ln \frac{r_1}{r_0}} \qquad (3)$$

The thermal flux per linear meter of soil (W/m) will be:

$$\dot{q}_L = \frac{\dot{Q}}{L} = \frac{2\pi k_{soil}(T_2 - T_1)}{\ln\frac{r_1}{r_0}} \qquad (4)$$

The heat transfer through horizontal tubes between the refrigerant and the interior wall surface first take place by convective two-phase flow vaporization (zone I) and then by single-phase (vapor) forced convection (zone II). The existing correlations for convective vaporization depend on the fluid properties and the range of operating parameters as regime flow, heat flux, mass velocity, vapour quality, fluid properties and surface geometry. The correlation used for convective vaporization in horizontal tubes with Froude number less than 0.05 superposes the forced convection and the nucleate boiling contributions [**1**]:

$$h_{TP} = Fr^{(0.1-2Fr)} E h_l \qquad (5)$$

where

$$E = 1 + 3000 Bo^{0.86} + 1.12\left[\frac{x}{1-x}\right]^{0.75}\left[\frac{\rho_l}{\rho_v}\right]^{0.41} \qquad (6)$$

is the enhancement factor correlating both void fraction (x) and two-phase heat transfer as a function of Martinelli parameter X_{tt} and of boiling number Bo;
$\mathbf{h_l}$ - the single-phase liquid heat transfer coefficient calculated from Dittus-Boelter equation:

$$h_l = 0.023\left[G\left((1-x)\frac{d}{\mu_l}\right)\right]^{0.8} \Pr^{0.4}\left(\frac{k_l}{d_i}\right) \qquad (7)$$

In the case of nucleate boiling (zone I), the heat transfer coefficient inside the ground DX tubes may also be estimated with the simplified equation:

$$h_{TP} = C\frac{G^{0.1} q^{0.7}}{d_i^{0.5}} \qquad (8)$$

where the constant **C** includes thermo-physical properties of the refrigerant (**0.17** for R22)

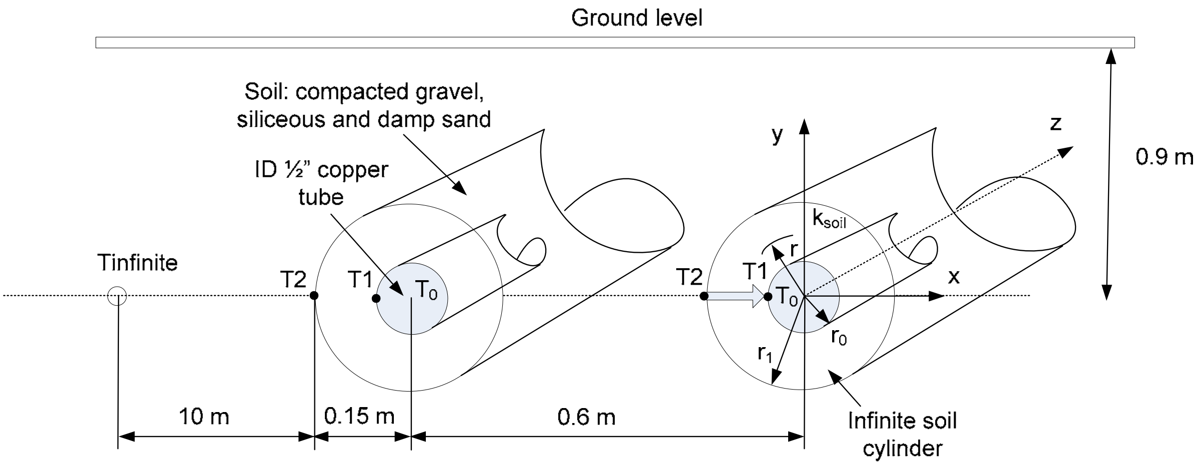

Figure 2.Relative position of ground DX refrigerant tubes buried at 0.9 m depth
T_1: temperature of disturbed soil at 0.15 m from DX refrigerant tubes; k: thermal conductivity; ID: interior diameter; r: cylinder radius; x, y, z: space coordinates

The volume flow rate of refrigerant vapour through the superheating zone II ($\dot{V}_R = \frac{\dot{m}_R}{\rho_R}$) averages 0.00043 m^3/s in each tube of ground DX heat exchangers, and the refrigerant velocity ($w_R = \dot{V}_R / A_R$) results of about 3.65 m/s. The heat transfer coefficient in zone II (134 W/m^2K) was calculated with Mac Adams equation:

$$Nu = 0.023.Re^{0.8}.Pr^{0.4} \qquad (9)$$

where the Reynolds numbers indicate turbulent flows. Table 1 brings together the predicted parameters of the horizontal DX ground heat exchangers.

Table 1.Predicted thermodynamic parameters of DX ground heat exchangers

Parameter	Symbol	Unit	DX ground heat exchanger		
-	-	-	#1	#2	#3
Tube ID diameter	d_i	mm	12.25	12.25	12.25
Tube flow cross section	A_R	m^2	$1.178*10^{-4}$	$1.178*10^{-4}$	$1.178*10^{-4}$
Mass flow	G	kg/m^2s	58	70	70.5
Froude number	Fr	-	0.016	0.023	0.023
Refrigerant velocity	w	m/s	3.65	3.65	3.65
Reynolds number	Re	-	8 052	8 506	8 614
Average evaporating temperature	T_{EV}	°C	-5°C	-5°C	-5°C
Average evaporating pressure	p_{EV}	kPa,a	420	420	420
Average (seasonal) temperature difference ($T_2 – T_0$)	ΔT	°C	6	6	6
Convective vaporization (two-phase flow) heat transfer coefficient (zone I)	h_{TP}	W/m^2K	890	905	907
Forced convective (single-phase flow) heat transfer coefficient (zone II)	h_{II}	W/m^2K	134	134	134

CONDENSERS

All mono-fluid DX ground heat pumps use condensers inserted at 40 mm inside a 100-mm concrete slab (basement) or placed under conventional wooden floors (1st and 2nd stories) (Figure 3). Both concrete slabs and wooden panels are adequately thermal insulated in order to reduce heat losses.

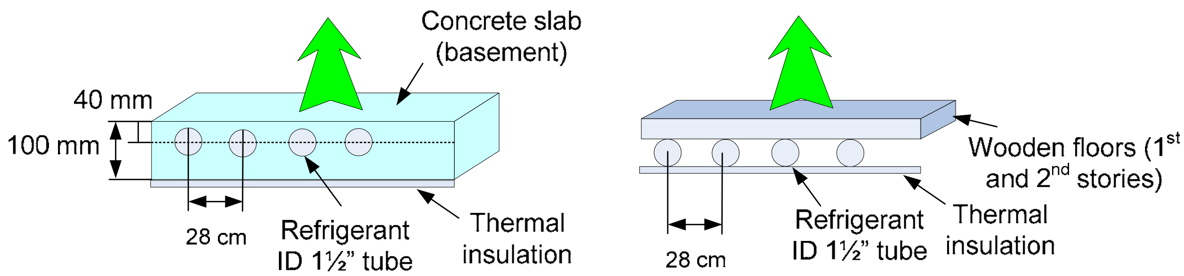

Figure 3.Emplacement of direct condensing tubes on basement (concrete slab), and 1st and 2nd floors (wooden panels)

The condensing heat transfer coefficient in horizontal tubes with stratified flow is given by the following equation:

$$h_c = 0.728 \varepsilon_v^{3/4} \left[\frac{k_l^3 \rho_l (\rho_l - \rho_v) g \Delta h_v}{\eta_l d_i (T_{cond} - T_{wall})} \right] \qquad (10)$$

Where

$$\varepsilon_v = \frac{1}{1 + [(1 - x_v)/x_v](\rho_v / \rho_l)^{2/3}} \qquad (11)$$

is the void fraction [**2**] and x_v – the vapour-phase mass flow fraction.

THERMIDYNAMIC AND COMFORT PARAMETERS

The experiment took place at outdoor weather conditions highly representative for the Canadian cold climate. During the 5-month in-field experience, the total monthly precipitation exceeded the area's usual rainfall by up to 55%. Heavy snow accumulations provided efficient thermal insulation layer during the winter and renewable energy during the spring thaw. Consequently, the average monthly temperature of the non-disturbed soil at 0.9 m depth has never dropped below 0°C, while the minimum temperature of the disturbed soil (T_2) at 150 mm lateral from DX refrigerant tubes averaged -1°C in February, March and April (Figure 4). Generally, the thermal perturbation of surrounding soil has disappeared at a distance of approximately 0.3 m around each horizontal refrigerant tube.

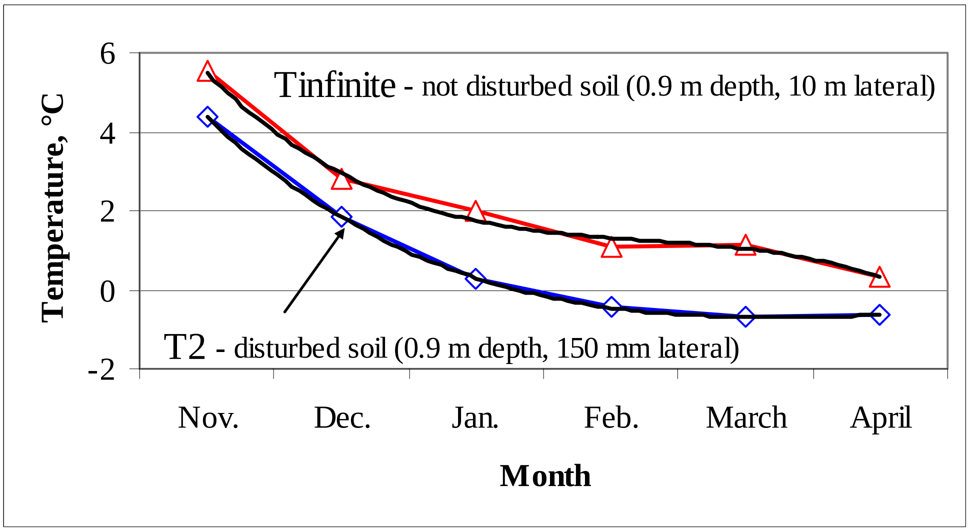

Figure 4 - Temperature profiles of disturbed and not disturbed soil at 0.9 m depth

In winter, the heat pumps #1 and #2 have operated according to typical profiles of such space heating devices. For example, during a very cold and windy night in January (Figure 5), the GSHP #1 supplying the house basement and 1st story, has continuously operated. During the day, the length of on/off cycles varied from three hours to 10 minutes according to the thermostat temperature settings and occupants comfort habits. However, further control improvements would be possible by combining the conventional indoor air temperature control with the radiant floor surface temperatures monitoring. This combined control strategy may be done, for example, on a day/night or a week basis.

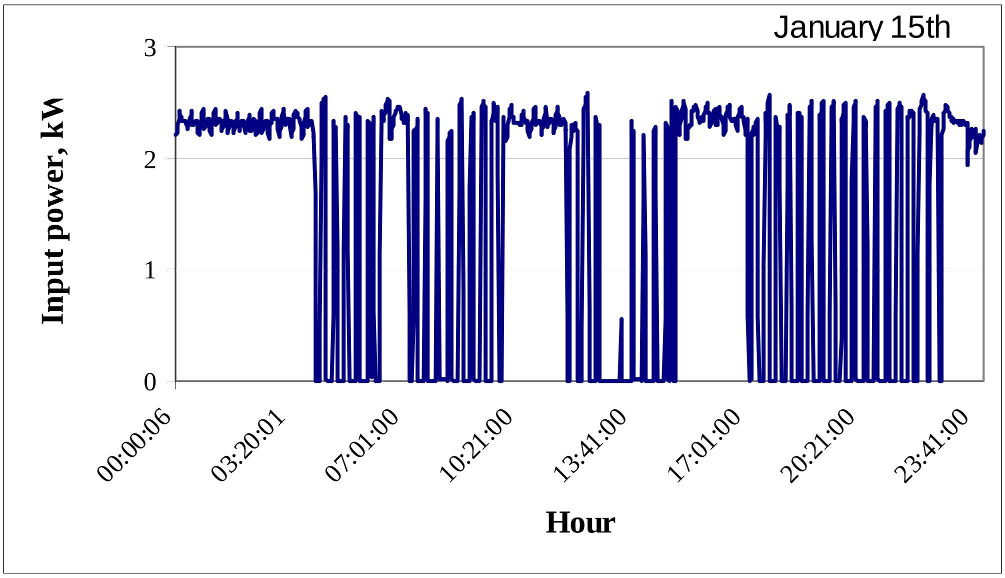

Figure 5 –Operation profile of GSHP #1 (January 15th)

The heat pumps discharge temperatures varied between 100°C and 115°C, while the condensing temperatures averaged 42 to 52°C and the evaporating temperatures were constant at around -5°C during the winter (Figure 6). Higher sub-cooling amounts were obtained with the condenser inserted in the concrete heating floor compared to condensers installed under the wooden floors. However, motorized liquid valves were installed during the tests in order to avoid refrigerant liquid hammers and/or whistling during the compressor shut-down periods. The refrigerant sub-cooling provided efficient operation of the GSHP #1 expansion valve and increased efficiency of its thermodynamic cycle. Such condensing temperatures and sub-cooling, combined to the GSHP #1 running cycles, provided stable temperatures at the basement concrete floor surface of around 26°C. It may be noted that the heating technique using direct condensing coils coupled with wooden floors is not fully developed and should be further improved. Consequently, the average temperatures at the surface of the basement concrete floor have been generally higher compared to those of wooden floors on 1st and 2nd floors. This indicates effective heat transfer and heat storage inside the concrete slab. One of the most significant advantages of radiant floor heating systems is the highly homogenous vertical air temperature distribution. The vertical temperature distribution between the surface of the basement concrete floor and the ceiling was effectively remarkably homogeneous (Figure 7). The average indoor air temperatures during the colder winter month (January) have varied from 20°C (basement) to 22°C (2nd story). During the winter, the make-up air was generally heated by 15 to 17°C through the exhaust air heat recovery heat exchanger (thermal efficiency of 57%), and by up to 13°C through the GSHP #3. The fresh make-up air has left the GSHP #3 at 18°C (December), 23°C (March) and 20°C (April), and the final adjustment of supply temperatures was provided by the back-up electrical heater.

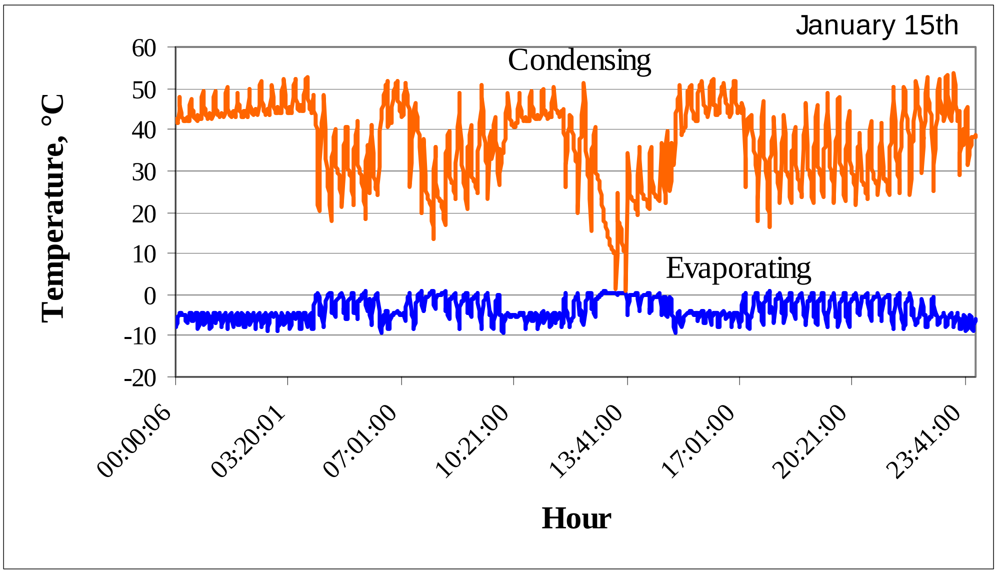

Figure 6 – Refrigerant evaporating and condensing temperatures – GSHP #1 (January 15th)

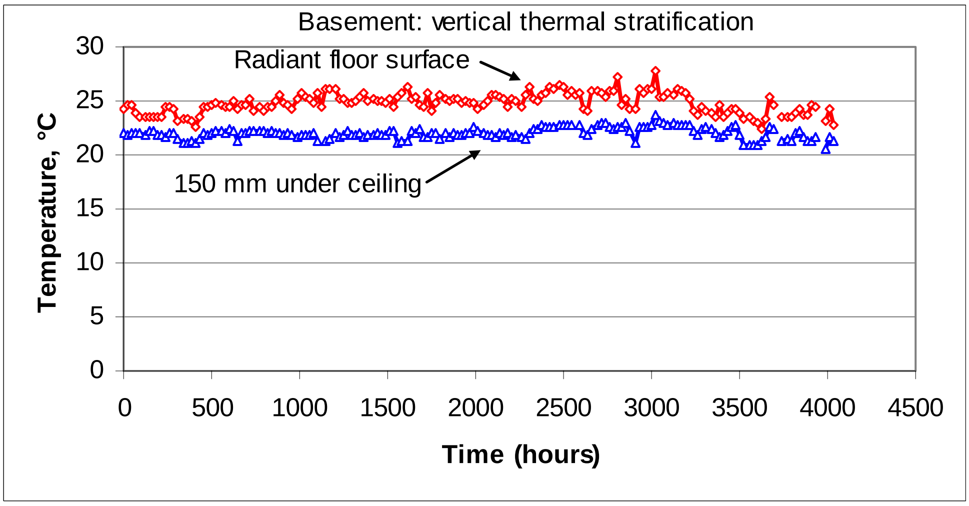

Figure 7 – Radiant floor temperature and indoor air vertical thermal stratification (basement)

ENERGY PERFORMANCES

Between December 1st and April 30th, the GSHP #1 operated 58.6% of the time. This unit has extracted from the ground 15 400 of thermal kWh. The heat pump compressor consumed 5 310 kWh with average compression ratios of 4 and electrical input power of 2.5 kW. The pressure losses through the horizontal ground heat exchanger averaged 0.4 kPa/m. The seasonal energy balance in heating mode of the GSHP #1 system shows that 74.5% of the output energy used to heat the basement and the 1st floor was extracted from the ground and 25.6% was provided by the compressor electrical energy input (Figure 9). The seasonal coefficient of performance (SCOP) of GSHP #1 unit, parameter defined as the total heating energy delivered divided by the total electrical energy input, thus averaged 3.9 (Table 2).

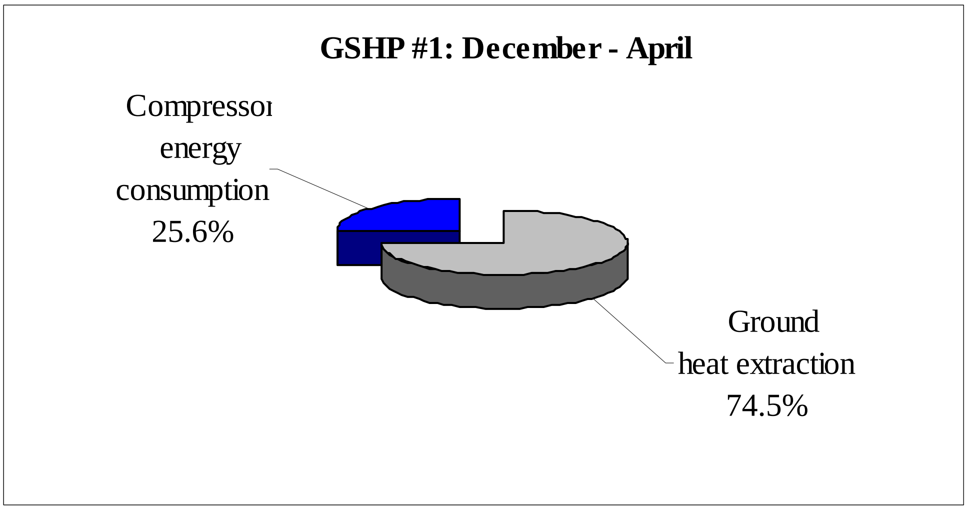

Figure 9 – Energy consumption and ground heat extraction of GSHP #3 (December to April).

The seasonal energy balance of the GSHP #2 unit in heating mode shows that 73.7% of the heating energy was supplied by the ground and the seasonal coefficient of performance (SCOP) was 3.8. This ground source heat pump operated 40% of the time and extracted 7 714 kWh from the ground. Because of temporary breaking of the acquisition system in January and February, no reliable energy data are available for the make-up air preheating system including the GSHP #3. During the entire 5-month heating period, the specific ground thermal capacity (power extraction) respectively averaged 10 W/m (GSHP #1) and 14.8 W/m (GSHP #2). At the same time, the seasonal heat dissipation basement and 1st floor radiant surfaces averaged 20.1kWh/m^2 (basement) and 21.1kWh/m^2 (1st floor). These values correspond respectively to 16 W/m (basement) and 20 W/m (1st floor) of heat flux dissipations per linear meter of direct condensing tubes (Table 2).

Table 2.Seasonal performances of ground DX heat exchangers

Parameter	Symbol	Unit	DX ground heat pump		
-	-	-	#1	#2	#3
Operating time	-	%	59	40	N/A
Ground heat extraction	-	kWh	15 400	7 714	N/A

Average heat dissipation	-	kWh/m^2	20.1	21.1	N/A
Average heat flux dissipation	-	W/m	16	20	N/A

CONCLUSIONS

The integrated HVAC system with ground-source heat pumps and exhaust air heat recovery device has demonstrated its technical feasibility in the Canadian cold climate. Predicted thermodynamic parameters for two-phase convective vaporization and condensation allowed designing optimum length of ground heat exchangers and radiant floor condensers. The space heating DX ground heat pumps have operated with seasonal coefficients of performance up to **3.9** providing high comfort with uniform thermal stratification of the indoor air. The 5-month in-field experience (December and April) showed that the average ground heat flux extractions ranged from 10 W/m (GSHP #1) to 14.8 W/m (GSHP #2) for total operating times of 58.6% and 40% respectively. Further R&D efforts will be done to develop more efficient wood-type radiant heating floors and advanced heat pump strategy controls based on dual (air & radiant floor surface) temperatures monitoring. Installing ground DX heat pumps with individual condensers for each thermal zone instead parallel condensers, optimizing the total refrigerant charge, using natural refrigerants, as propane, and develop reversible DX heat pumps for indoor air cooling and dehumidification, are future R&D objectives for this particular application.

SUMMARY

The air-source heat pump (ASHP) is a convenience and higher energy efficiency rating air conditioner; it can make the best of low-temperature energy sources of the atmosphere circumstance, and has less pollution to the region of use it. The air-source heat pump (ASHP) has energy conservation and environment protection effects; it is a kind of green air conditioning technical. But in northern, northwestern and northeastern of china, the air-source heat pump (ASHP) can not work normally in the period of heating， if it only use outdoor air as low-temperature heat source, the heating quantity of heat pump units decrease greatly, the coefficient of performance (COP) decline rapidly, the outside heat exchanger will been frosted, because of the lower outdoor air temperature.

For solved such issues, authorized by Ministry of Construction P.R.China, the Discussion Group advanced the method of the fresh air handling units in combination with the heat pump units. Make use of the exhaust fully, mix the exhaust and outdoor air, and raise the intake air temperature of heat exchanger, thereby， the heat pump units can work normally in the period of heating.

The Discussion Group analyzed the recent climate condition statistic of Changchun, China, designed the heat pump & fresh air unit, calculated the mix ratio of fresh air and exhaust at the disadvantage of air temperature and calculated heating quantity of the heat pump unit. The data shows that at the time of buildings exhaust is enough, the heat pump unit can work normally in the period of heating in cold and serious cold regions. The Discussion Group will research more about the experiment application of the units in the winter 2006-2007 in Changchun, china.

INTRODUCTION

Now， with the popularization of the decorate, the modern equipment(the computer the printer etc.) and the air condition, as well as the improved hermetic technology in the energy-saving building, the fresh air requirement of air-condition system is shortage or be canceled. It brings on the decline of indoor air quality (IAQ), and the sick building synthesis (SBS). Adjusted and controlled the indoor weather parameter (temperature, humidity, wind speed), provided the fresh air requirement that accord the indoor air quality, it could improve the IAQ. But at the same time it raised the operating energy consumption and increased the operating costs of air condition system, apparently. How to properly handle the relationship between the increased fresh air requirement to improve IAQ and the operating costs of control system are the main issues of air conditioning design. The exploration and research on new systems and new equipment suitable or compatible the thermal comfort, the indoor air quality and the energy conservation are the urgent requirement for sustainable development of energy-saving building field.

The air-source heat pump (ASHP) is a convenience and higher energy efficiency rating air conditioner; it can make the best of low-temperature energy sources of the atmosphere circumstance, and has less pollution to the region of use it. The air-source heat pump (ASHP) has energy conservation and environment protection effects; it is a kind of green air conditioning technique. But in northern, northwestern and northeastern of china, the air-source heat pump (ASHP) can not work normally in the period of heating， if it only use outdoor air as low-temperature heat source, the heating quantity of heat pump units decrease greatly, the coefficient of performance (COP) decline rapidly, the outside heat exchanger will been frosted, because of the lower outdoor air temperature.

For solved such issues, authorized by Ministry of Construction P.R.China, the Discussion Group advanced the method of the fresh air handling units in combination with the heat pump units. Make use of the exhaust fully, mix the exhaust and outdoor air, and raise the intake air temperature of heat exchanger, thereby， the heat pump units can work normally in the period of heating.

The Discussion Group analyzed the recent climate condition statistic of Changchun, china, designed the heat pump & fresh air unit, calculated the mix ratio of fresh air and exhaust at the disadvantage of air temperature and calculated heating quantity of the heat pump unit. The data shows that at the time of buildings exhaust is enough, the heat pump unit can work normally in the period of heating in cold and serious cold regions.

THE PRESENT STATUS OF APPLICATION RESEARCH ON THE AIR-SOURCE HEAT PUMP OVER THE WORLD

Energy prices and each country's energy mix affect the conditions for heat pumps to be competitive with other alternatives. Other important factors influencing how and if heat pumps are used are tradition, knowledge and the condition of existing and new buildings. Research and development, various types of political incentives, requirements for specific minimum levels of energy efficiency and the dissemination of knowledge are all important instruments for encouraging growth of the heat pump. The fact that climate, the condition of building stock, experience of the use of heat pumps and energy mix all vary widely from one country to another. [1]

The new technology of native and foreign air-source heat pump

The new technologies include that the heat pump unit performance ameliorated and advanced (for example screw compressor substituted centrifugal compressor, introduced frequency conversion timing technique, ameliorated configuration and surface performance, adopted electronic expansion valve achieved defrost circulation control, the mistiness nerve net achieved intelligent control, etc.)[2]. Heat pump exploited on the new-style exceeder critical CO_2circle system. New product exploited and extended the scope, include escalating capability for commercial building and use to exhaust heat recovery [3]. Energy storage technology applied [4].

In china, the research of minitype air/air heat pump experimentation technology and heat pump air condition computer simulation technology advance lot of innovation project. Especially, in the research of the heat pump unit worked in cold and serious cold regions.

The localization of air-source heat pump using in cold and serious cold regions

In china, climate condition is a wide variety, roughly be divided into several climate zones: serious cold, cold, hot in summer and cold in winter, very hot (tropical), with variations in humidity depending on whether it is coastal or continental climate. Technological development of Commercial air-to-air heat pumps, to expand the operating temperature range to a lower ambient temperature, has been explored sporadically and is still on going.

Theory and practice indicate that air-to-air heat pump system without any betterment not run well in winter, using it in cold region. The main issues are:

The quantities of heat making through the heat pump system decrease rapidly with outdoor temperature decline, but the quantities of heat requiring of fresh air increase rapidly. When temperature of outdoor is very low, quantities of heat making of the system not satisfy the needs of heating in winter in the region; and then the COP of machine decline rapidly, the compression ratio of compressor increase more, the temperature of exhaust air rise, if the compressor run for a long time in the condition, it will be broken.

If consider the running effect of the heat pump systems, the defrosting veracity is not well. The defrosting criterion not adapted well to the large-scale status in north of china, the phenomena of error defrosting is severity, the time of defrosting is longer, and that can make the indoor temperature greatly fluctuate; the system start up difficultly, the machine will be broken when the system start up or end of defrosting and reheat.

In sum, if only depend on the measures of heat recovery, anti-freezing, and defrosting of the air-source heat pump (ASHP) heat pumps in cold region, the issue of fresh air handling units of centre Air Condition system and heat pump units running by themselves cannot be solved. The effect of technology and economy is not well in cold or serious cold region.

THE STUDY DESIGN CONCEIVED

Analyzed the problems of using air-source heat pump in the cold and serious cold regions; we can say that the temperature and humidity is the main influence.

On the basis of the Japanese experimentation result [2], the frost weather parameter is likely to -12.8 ℃$\leq t_w \leq$5.8 ℃, $\varphi \geq$67%.That means when t_w>5.8 ℃, we can take no account of the frost influence to heat pump; when t_w<5.8 ℃, φ<67%, owing to the air dew point temperature t_{dew} under the heat exchanger surface temperature t_{fe}, it can not frost; when t_w<-12.8℃, because of the low air humidity ratio, it can not frost too.
At present, the Chinese instruction of heat pump engineering design prescribe that the outdoor design temperature in winter t_w=-3 ℃ is the air-source heat pump (ASHP) running lowest-level. In this way, in the region that outdoor design temperature for heating $t_w \geq$-3 ℃, the air-source heat pump can run normally. Or else, the air-source heat pump (ASHP) can not run. In northern, northwestern and northeastern of china, mostly region outdoor design temperature t_w<-3 ℃, that is the reason of the air-source heat pump (ASHP) can not work normally in the period of heating. Now bounded-3 ℃, statistical treatment the weather data of main city in the

cold or serious cold regions of china, quantificational take measures of the air-source heat pump(ASHP) runtime and its proportion of the whole heating period. The table 1 shows the weather data result.

Table1. The weather data of main city in the cold or serious cold regions china

City	Outdoor design temperature for heating t_w(℃)	Hours for heating $T_z(h)$ ℃	t<-3 ℃ hours for heating $T_x(h)$ ℃	t<-3 ℃ hours proportion T_x/T_z ℃	Outdoor design relative humidity (%)
Harbin	-26	4296	3089	71.9	74
Changchun	-23	4176	2879	68.9	68
Shenyang	-19	3648	2205	60.9	44
Taiyuan	-12	3456	1637	48.4	51
Beijing	-9	3096	1287	41.6	45
Jinan	-7	2544	472	18.6	54
Xi'an	-5	2424	208	8.6	67

From the result of the weather data, the air-source heat pump (ASHP) runtime is long (that about 30% heating period) in the serious cold region (Harbin). In the great mass of northern, northwestern of china, the air-source heat pump (ASHP) runtime is at least half of the heating period. If use the outdoor design temperature for winter ventilation to calculate for the system of the fresh air handling units in combination with the heat pump units, the air-source heat pump (ASHP) runtime will even more.

Accordingly, the issue of building heat recovery, prevented frostbite of fresh air handling, advanced the air-source heat pump (ASHP) efficiency in winter, prolonged the building fresh air supply time and the air-source heat pump (ASHP) runtime in winter, would been solved effectively.

THE PROJECT DESIGN OF COMBINATION UNIT IN THE COLD OR SERIOUS COLD REGIONS

Waste heat from various types of central Air Conditioning system of commercial buildings can provide a heat input to absorption heat pumps or compressor heat pumps. Another application is to recover heat from the exhaust air from mechanically-ventilated residential buildings. A requirement for heat recovery is also introduced in northeastern china, and has resulted in increased interest in exhaust air heat pumps in northeastern market.

Load from fresh air is 20%-30% of Air Conditioning. If installed the heat recovery equipment in fresh air handling unit, reclaimed the energy of exhaust air, increased energy-efficient, it would be vital importance measure of energy conservation.

At present, in china, the Air Conditioning design of middling or top grade hotels and office buildings commonly adopt primary air fan-coil system as well as exhaust air system. the energy consumptions of this type of Air Conditioning system is about 20%-40% of buildings, and that the percentage of fresh air load is20%-30 %of total load of Air Conditioning system, thus the energy consumptions of fresh air is 4%-12% of buildings. If the heat recovery efficiency is 60%, the efficiency of energy conservation will be 2.4%-7.2%.

For instance, one building in Changchun, there are 1floor underground, 10floor upside. Underground is park; the acreage is 2850m^2; 1 to 3floors are marketplace, total acreage is8550m^2; 4floor is office and restaurant, the acreage of office is 600 m^2 and 2250 m^2 of the restaurant; 5 to 9floors are hotel, the guest room of hotel is standard for 2 people, total number is 140.According as the standard and criterion, calculated the design quantity of fresh air and its load. The load of fresh air calculated by the equation below:

$$Q_{h,o} = M_o \cdot c_p (t_o - t_R), \quad (1)$$

Where $Q_{h,0}$ is the heating load of fresh air, kW and c_p is the level pressure specific heat, *kJ/(kg· ℃)*， is 1.005 *kJ/(kg· ℃)*. t_0 is the outdoor design temperature for winter ventilation, ℃, the number is－16℃ in changchun and t_R is the indoor design temperature, ℃， is 2 ℃ in the design. M_0 is the design quantity of fresh air, *kg/s*. Table 2 [5] [6] is the result of the design quantity of fresh air and its load calculation. Considered the positive pressure is 5-10*Pa* of the room, the design quantity of exhaust is 90% of the design quantity of fresh air. Considered the negative pressure is 5-10*Pa* of the park, the design quantity of exhaust is 125% of the design quantity of fresh air. Table 3 is the result of the design quantity of exhaust and its load calculation.

In Changchun, in winter, outdoor design dry-bulb temperature for winter ventilation is -16 ℃, wet-bulb temperature is -16.67 ℃, the relative humidity is 68%[7], the room parameter are, indoor dry-bulb temperature as Table3, relative humidity 40%. According to Table3, the losing heat quantity in winter is about1520.77*kW*.if the exit temperature of evaporator is 5 ℃， the recoverable heat quantity of exhaust is about 874.47 *kW*. Thus it can be seen, in air conditioning building, the discharge energy is so large, the heat recovery of discharge energy of air-condition system is very important.

Table2. The result of the design quantity of fresh air and its load calculation

Room	Standard quantity of fresh air($m^3/(h·p)$)	Area (m^2)	Number of people(p)	Design quantity of fresh air (m^3/h)	Load of fresh air (kW)

DESIGN AND SIMULATION OF COMBINATION UNITS

Design combination units base on the part of hotel in the building, the guest room are configured as standard room, total number is 140. The runtime is Am8:00-Pm10:00 and the heat loss of fresh air is95.85*kW* (table2). The design principle of heat pump unit is by the equations below [8]:

The equation of heat loss of fresh air related to the mean air temperature (Q_P):

$$Q_P = Q_W \frac{t_N - t_P}{t_N - t_W}, \quad (2)$$

Where Q_P is heat loss of fresh air related to the mean air temperature, *kW* and Q_W is heat loss of outdoor design temperature for fresh air heating, *kW*, (95.85 *kW*). t_N is the design temperature for fresh air, ℃, (2 ℃) and t_p is the outdoor mean air temperature during heating period, ℃, (-7.9 ℃). t_W is outdoor design temperature for winter ventilation, ℃, (-16 ℃).
The equation of refrigerating effect coefficient of refrigerating medium (*k*):

$$k = \frac{Q_k}{Q_0}, \quad (3)$$

Where Q_k is condensation heat gain of refrigerating medium, *kW* and Q_0 is evaporating heat gain.
The equation of mean refrigerating effect ($Q_{0 \cdot P}$):

$$Q_{0 \cdot p} = \frac{Q_P}{k}, \quad (4)$$

Where $Q_{o \cdot P}$ is mean refrigerating effect.
The equation of evaporator heat gain (Q_0):

$$Q_0 = K_0 F_0 \left[{(t_1 + t_2)}/{2} - t_0 \right], \quad (5)$$

$$Q_0 = \frac{1}{3.6} c_P G_0 (t_1 - t_2), \quad (6)$$

$$Q_0 = \frac{K_0 F_0}{1 + \frac{3.6 K_0 F_0}{2 c_P G_0}} (t_1 - t_0), \quad (7)$$

Where K_0 is evaporator coefficient of heat transfer, $W/(m^2 \bullet ℃)$ and F_0 is surface area of evaporator. t_0 is evaporating temperature, ℃ and c_p is the level pressure specific heat, $kJ/(kg \bullet ℃)$. G_0 outdoor air requirement pass evaporator, *kg/h* and t_1, t_2 are intake temperature and outlet temperature of evaporator.

The design parameter of heat pump unit is: Based on the weather data, calculated the outdoor mean air temperature during heating period t_P=-7.9 ℃ and the heat loss of fresh air related to the mean air temperature Q_P=52.72*kW*. Cryogen is R22; temperature of evaporation (t_0) is -5 ℃; temperature of condensation (t_k) is 40 ℃. Based t_0,t_k, get the refrigerating effect coefficient of refrigerating medium by fig P-h of R22 and equation(2) ,*k*=416.25/194.17=2.14.Calculated mean refrigerating effect,Q_{0P}=52.72/2.14=24.62*kW*, by equation(4). Make certain the outdoor air requirement pass evaporator, the air requirement/ mean refrigerating effect=400$m^3/h/kW$, the outdoor air requirement pass evaporator, G_0=1.29×400×24.62=12703.90*kg/h*,the fact quantity of exhaust is 12600×1.196=15071.77*kg/h*, that means if 85% of fact quantity of exhaust can suffice. Now used 60% of fact quantity of exhaust, calculated the exhaust outlet temperature of evaporator,t_2=8-24.62×3600/1.005×12703.90=1.06 ℃, by equation(6). When the wind speed is 3.5*m/s*, the evaporator coefficient of heat transfer, K0=32.6$W/(m^2\bullet ℃)$. Considered the influence of frost, the safety factor is 0.8, K_0=26.1$W/(m^2\bullet ℃)$. The surface area of evaporator is F_0=85.52m^2 by equation (5). Based on $Q_{0\cdot P}$=35468W, t_0=-5 ℃, t_K=40 ℃, selected reciprocating compressor. The evaporator heat gain, Q_0=1697.39(11+5) =22.07kW. Got the heat gain of compressor from the compressor stylebook, calculated the quantity for heating of condensation, Q_k=22.07×2.4=52.97kW, compare with the heat loss of fresh air related to the mean air temperature Q_P=52.72kW, it is congruence.

The parameter list in table4, the design combination unit construct is figure1.

Table4. The parameter list of combination units

Design quantity of fresh air (m^3/h)	15000	
Heating capacity(*kW*)	123.9	
Input power(*kW*)	20.45	
Power supply	3Ph/380V/50Hz	
Mode of interior side exchanger	High efficiency screw tube with aluminum fin

DISCUSSION

The unit system design was based on the hotel of Changchun, a type city of serious cold regions in northeastern of china. The design accord the design standard for energy efficiency of public buildings, the parameter gist based on the conclusions that have a series of analyzed for a long time. At the standard state, that ensured total load of fresh air and 60% quantity of exhaust, the units can run safety. At the design state, it can prolong time of the heat pump units running about 2625*h*(t<-3 ℃) hours for heating is 2879*h*, under the design parameter -16 ℃,hours for heating is 254*h*). For a year, time of heat pump unit can not run normally only 254h. it can farthest ensured fresh air of building. About running state, the defrosting control technology and assistant heating technology use could prolong running time more. We will deepen the study.

In building with air conditioning systems, the exhaust air of air conditioning systems take away much of heat quantity (in winter) or cold quantity (in summer), recovering exhaust air heat of air conditioning systems, the meaning of energy conservation is vital prominence. The air-source heat pump is equipment with benefit of energy conservation and environment protecting. In practice, the parameters of outdoor air affect the energy efficient ratio and the capability, the using of heat pump is limited by the geography condition. If lead exhaust air of air condition systems to the outdoor exchanger of air-source heat pump, the energy efficient ratio and the capability can be enhanced, and can recover the heat (cold) quantity, achieve the aims of energy conservation.

The centre air conditioning systems can create condign temperature environment and humidity environment, at the same time; it can reduce the concentration of nocuous component through the method of keeping fresh air quantity, and keep the air quality. But the fresh air handling unit of centre Air conditioning systems can't run normally in winter of cold regions, lead to the fresh air handling unit losing the function of supply fresh air. The using of air-source heat pump with exhaust heat recovery is an efficacious method.

The resulting future impact on global environment, development of advanced energy efficient and environmentally friendly technologies is of vital importance for the sustainable development in the foreseeable future.

SUMMARY

This paper presents a study on thermal diffusion of large-scale seawater source heat pump system (SWHP).

SWHP uses seawater as heat source and sink, and discharges the same quantity of water into local oceans after use. The cooling water systems may cause a temperature rise of 3-5℃ above ambient at discharge points which is close to the upper thermal tolerance limit of most marine biota, which would not only have a certain impact on the local marine environment, but also affect the local micro-climate, the local marine life and fishing economy, etc.

Based on Navier Stokes equations and shallow water assumption, non-linear shallow water equations are established in this paper. The two-dimensional numerical simulation research of the flow velocity field and temperature field of the water space where thermal effluent is discharged is done using a case study.

And following an example of Xiaoping Island SWHP project is given. Simulation and description on the discharge of this SWHP project show that, the temperature rise/drop extends to certain area, but the temperature elevation of the influence area is far less than the standard of Grade Ⅰ of Quality Standard for State Oceanic Water.

This paper firstly introduces the hydrodynamic knowledge into HVAC design application, which shows a way to the environmental impact statement of Water Source Heat Pumps.

INTRODUCTION

In the 21st century, the energy issue has become increasingly prominent. The sea water-source heat pump (SWHP) system’s coming into China is a very important significance for the energy efficiency in buildings. Seawater source heat pump technology transfers solar energy captured in seawater which is low temperature and low quality, into high quality energy through the use of heat pump and a small quantity of electricity. At present, there’re only several experimental projects in China, and environmental impact assessment is one of the most important issues to resolve.

SWHP system uses seawater as heat source and sink, and discharges the same quantity of water into local oceans after use. The temperature of the discharge water is higher in the summer than the local water temperature around 10℃, and lower in winter about 3-5℃ than the receiving water body. The discharge temperature elevation of seawater will not only have a certain impact on the local marine environment, but also affect the local micro-climate, the local marine life and fishing economy, etc. When the large-scale application of SWHP systems come into reality in the coastal cities in China for district cooling and heating, these impacts may become particularly prominent.

The above issue can be solved by the thermal discharge research method. Thermal discharge exists in every thermal/nuclear power plant, and researchers have been working on it for tens of years. The method consists of domestic physical and numerical simulation, of which the later is most widely used. What's more, the two are often combined, for the model the model parameters of numerical equation are often obtain from physical tests.

According to different classification method, numerical model can be classified as the near-field model and the far-field model, or the 2D depth-averaged model and 3D mode, and during actual applications these models are developing toward a more sophisticated, visualization and intelligent direction. With the emergence of the sea water-source heat pump system, some new problems need to be considered.

Between the mathematical models studied by scholars at home and abroad, the depth-averaged two-dimensional fluid dynamics model is very effective to solve some problems in the oceans, coasts water level and instantaneous transport, which is widely used in the study of thermal discharge, to predict the temperature distribution of thermal discharge area[1,2].

MATHEMATIC MODEL

Based on Navier Stokes equations and shallow water assumption, non-linear shallow water equations are established. The depth averaged two-dimensional hydrodynamic model, including the effects of earth's rotation, bottom friction, wind shear and surface heat exchange are as follows [3]:

Continuity equation:

$$\frac{\partial \zeta}{\partial t}+\frac{\partial HU}{\partial x}+\frac{\partial HV}{\partial y}=Q \tag{1}$$

Momentum equation:

$$\frac{\partial U}{\partial t}+U\frac{\partial U}{\partial x}+V\frac{\partial U}{\partial y}-fV=-g\frac{\partial \zeta}{\partial x}+v_H\left(\frac{\partial^2 U}{\partial x^2}+\frac{\partial^2 U}{\partial y^2}\right)-\frac{gU\sqrt{U^2+V^2}}{HC_{2d}^2}+\frac{C_d}{H}\frac{\rho_a}{\rho}U_{10}^2\cos\beta \tag{2}$$

$$\frac{\partial V}{\partial t}+U\frac{\partial V}{\partial x}+V\frac{\partial V}{\partial y}+fU=-g\frac{\partial \zeta}{\partial x}+v_H\left(\frac{\partial^2 V}{\partial x^2}+\frac{\partial^2 V}{\partial y^2}\right)-\frac{gV\sqrt{U^2+V^2}}{HC_{2d}^2}+\frac{C_d}{H}\frac{\rho_a}{\rho}U_{10}^2\sin\beta \tag{3}$$

Transport equation:

$$\frac{\partial HT}{\partial t}+\frac{\partial HUT}{\partial x}+\frac{\partial HVT}{\partial y}=\frac{\partial}{\partial x}\left(HK_x\frac{\partial T}{\partial x}\right)+\frac{\partial}{\partial y}\left(HK_y\frac{\partial T}{\partial y}\right)+S \tag{4}$$

U、V depth-averaged velocity in x and y direction; ρ_a density of air ; f Coriolis coefficient, $f=2\omega\sin\psi$, ω angular frequency of the earth, ψ the local latitude; 2D Chézy coefficient, computed by Manning Formula : $C_{2d}=\frac{1}{n}H^{1/6}$, n is the Manning's coefficient; C_d wind drag coefficient; v_H horizontal eddy viscosity; U_{10} averaged wind speed at 10 m above free surface; β the angle between the wind stress vector and the local direction of the grid line x; M_x, M_y source or sink of momentum in x and y direction; T the water temperature; K_x, K_y diffusion coefficient in x and y direction; Q, S the source and sink term.

The heat exchange flux is represented by a bulk exchange formula [4]:

$$Q_{tot} = -\lambda(T_s - T_{back}) \tag{5}$$

with T_s the water temperature at the free surface and T_{back} the natural background temperature, both in ℃. The heat exchange coefficient λ is a function of the surface temperature T_s and the wind speed U_{10}:

$$\lambda = 4.48 + 0.049T_s + f(U_{10})\left(1.12 + 0.018T_s + 0.00158T_s^2\right) \tag{6}$$

$$f(U_{10}) = \left(3.5 + 2.0U_{10}\right)\left(\frac{5.0\times10^6}{S_{area}}\right)^{0.05} \tag{7}$$

Where S_{area} is the exposed water surface in m^2.

The control equations formed by ADI method (Alternating Direction Implicit Method, Leendertse， 1967) are solved on a staggered grid. Each of the dispersed control equation group consists of three unknown variables at adjacent nodes. In the coefficient matrix, all the non-zero elements are arranged along a diagonal matrix. So triangle diagonal matrix algorithm (TDMA) is used for solution.

PROJECT AND COMPUTATIONAL ASPECTS

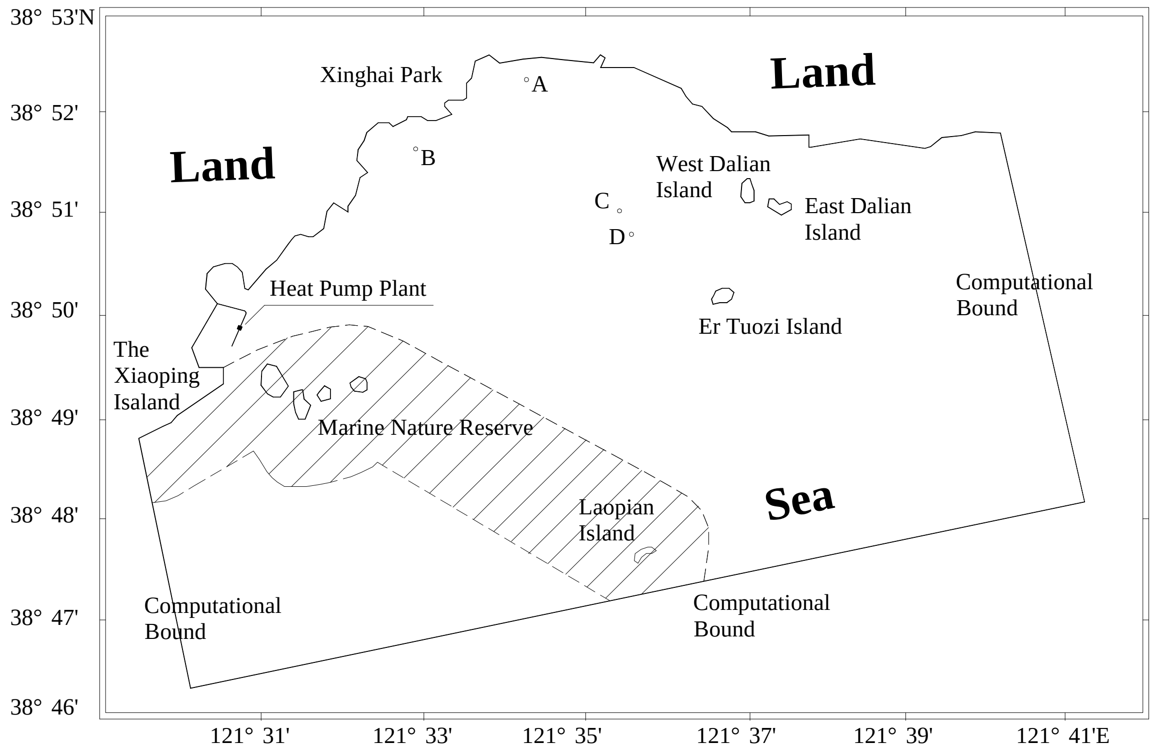

Figure1 Simulation Area and Location of the Project

Using the above method, an example of Xiaoping Island SWHP project is given in this section. This project is located to the Xiaoping Island, at the Huang hai sea of China. The heat pump plant is located at 121°30′34″-121°30′44″E, 38°49′49″-38°49′58″N, on a bulwark of 1300 meters long and L type, see figure 1. The shadow area is the marine nature reserve, which is to be considered not to be affected by this project's discharge.

The design input/output flow and temperature rise/drop at the first stage of this SWHP is as follows:
Heating Season: 1.9 m^3/s, temperature drop 2.5℃
Cooling Season: 1.14m^3/s，temperature rise 10.0℃

RESULTS AND DISCUSSION

24 hours' site tide data of four stations-A, B, C, D（From 8:00, 18th, Apr. to 7:00, 19th, Apr., 2003, sees figure 1）are used for validation of the simulation results. The comparison between the computed and observed results are shown from figure 2 to figure 5。

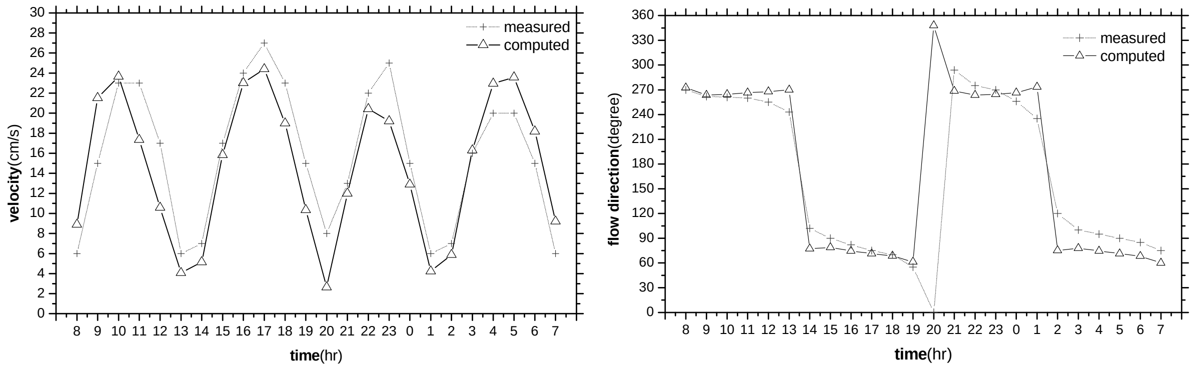

Figure 2 Computed and Observed Velocity and Phase at Station A

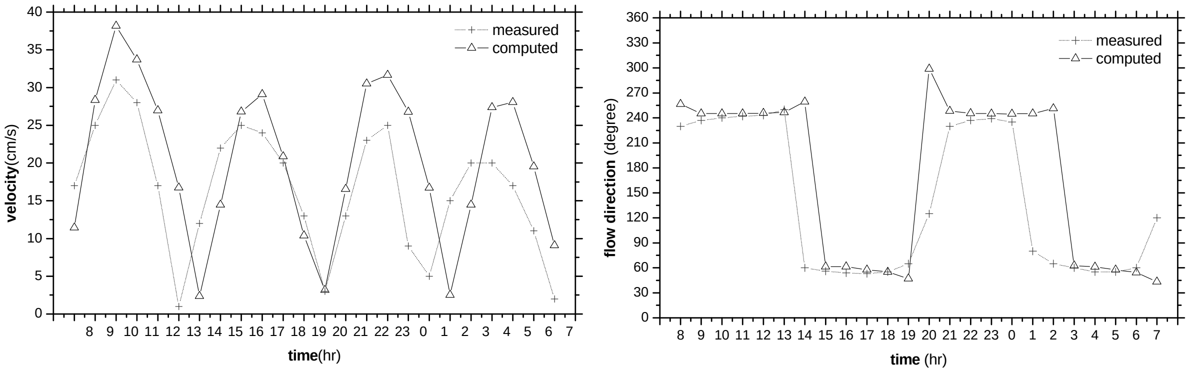

Figure 3 Computed and Observed Velocity and Phase at Station B

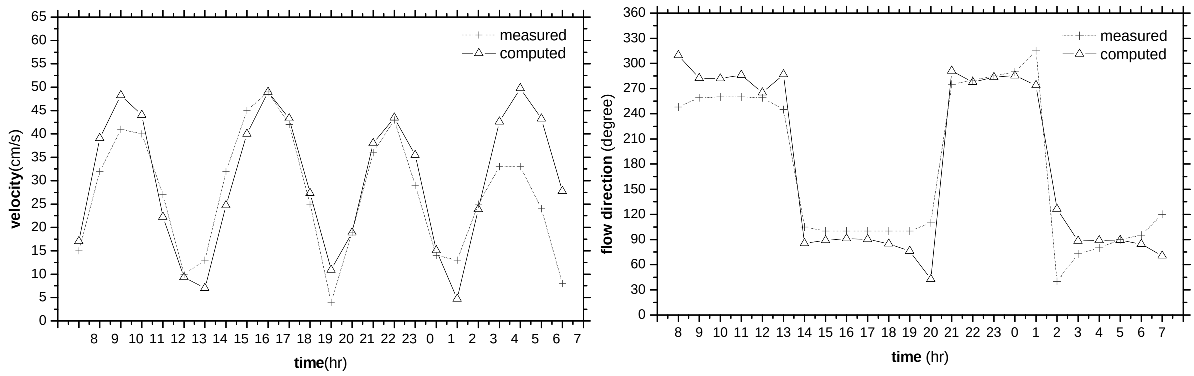

Figure 4 Computed and Observed Velocity and Phase at Station C

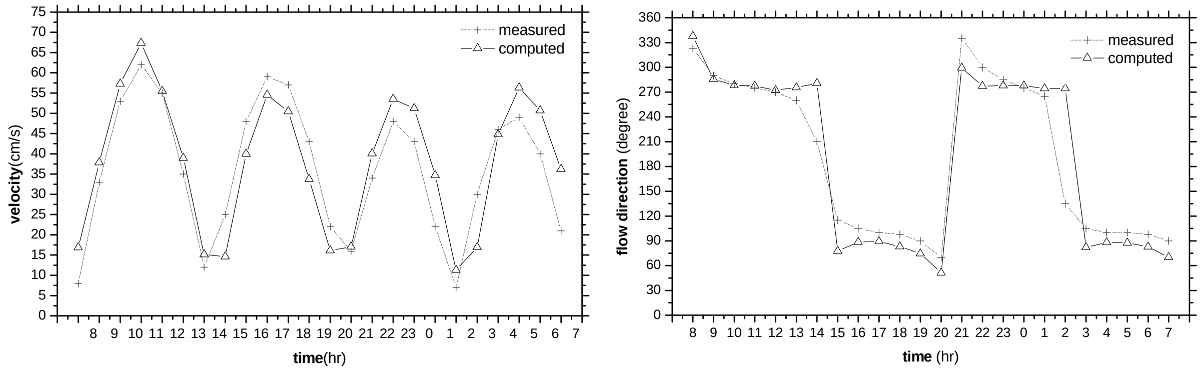

Figure 5 Computed and Observed Velocity and Phase at Station D

It can be seen that the agreement with the observation data is satisfactory. The seawater flows at pulsant turbulence, but the model in this paper is time-averaged and depth-averaged, so large warps of the phase appear at some point of the simulation periods is possible and acceptable, especially when flow direction changes (20:00 at station A for instance). What's more, flow field can be influenced by meteorological parameters-wind, air pressure, temperature etc. The model considers the regular and general instance, so the meteorological effect is ignored.

When the model is validated, transport equation can be used for temperature prediction. Conditions during neap tide and spring tide are simulated. Because of limited space, computed results only during neap tide are given in this paper. Figure 6 shows envelope area of iso-excess temperature during neap tide in summer, and figure7 shows envelope area of iso-excess temperature during neap tide in winter. Both are the worst status during 24 hours' simulation, which means that the temperature rise (drop) absolute value is maximal at the moment.

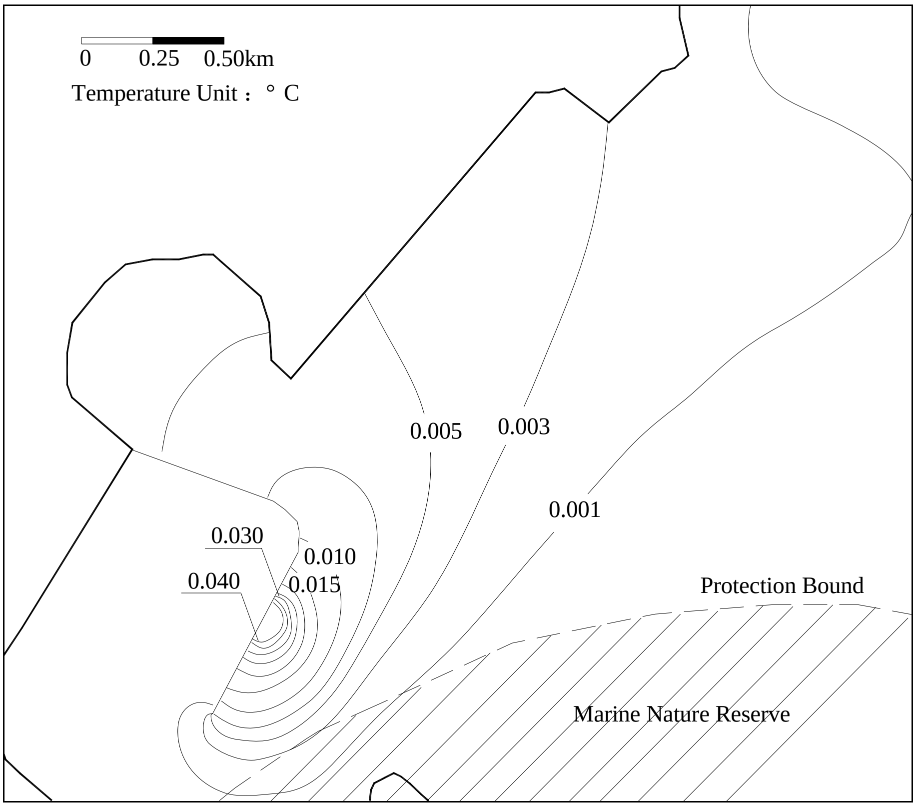

Figure 6 Iso-temperature elevation contours during neap tide in summer

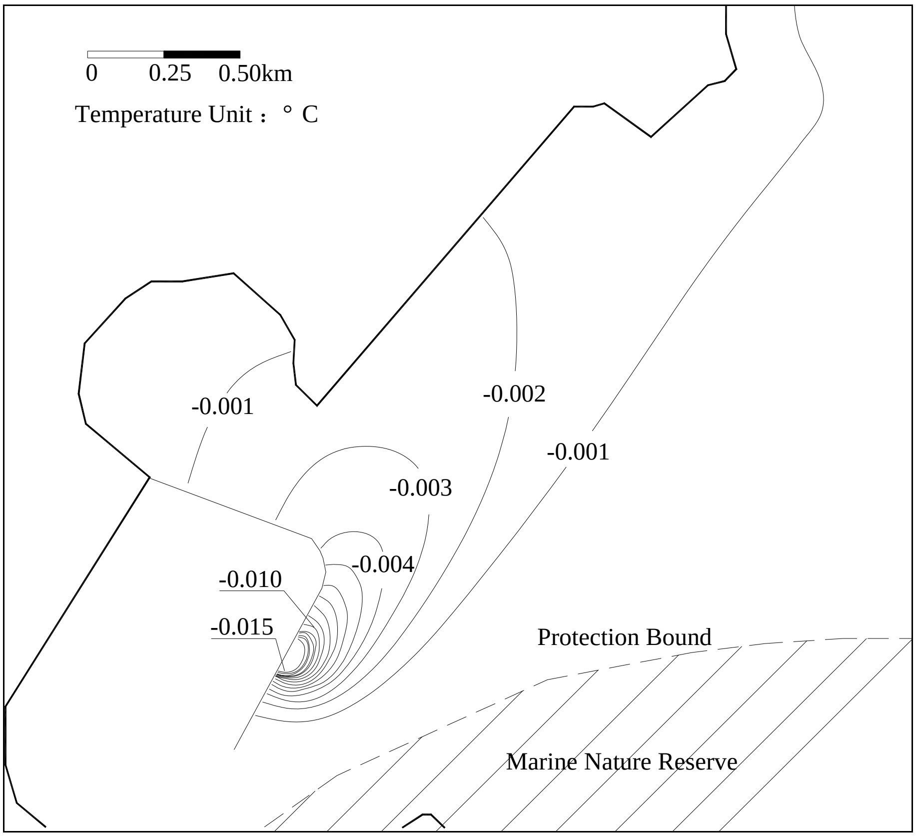

Figure 7 Iso-temperature elevation contours during neap tide in winter

In summer, the temperature rise of 0.003 ℃ would reach the marine nature reserve area (figure 6), and the maximal temperature rise is 0.040 ℃ at the discharge point. In winter temperature drop wouldn't affect the marine nature reserve (figure 7), and the maximal temperature drop is 0.015 ℃ at the discharge point. According to the Quality Standard for State Oceanic Water in China, the temperature change does not exceed prescriptive ranges.

CONCLUSIONS

The paper has presented the depth-averaged two-dimensional fluid dynamics model and its application to a planned SWHP system, which for the first time introduces the hydrodynamic knowledge into HVAC design application. Firstly the model is used for tide simulation, and it demonstrates in general an excellent agreement with the observation data. Then the model is well used for numerical prediction for the influence of temperature changes in the intake (outfall) areas of Xiaoping Island SWHP system.

The model is capable of being used as an environmental impact statement tool to aid in the design and control of SWHP system. It can also be used for the design of some other water source heat pump systems, such as Lake Source heat pump, River Source heat pump, etc.

Design of Heat Pumps Systems using Natural Fluids

Wenling Zhang, Jin-Kuk Kim and Jiří Klemeš

Centre for Process Integration, School of Chemical Engineering and Analytical Science, The University of Manchester, Manchester, UK

Corresponding email:ji.klemes@manchester.ac.uk

SUMMARY

The presentation introduces new mathematical optimisation and design methodology for heat pump systems using natural fluids. A mathematical model is developed to capture thermodynamic and operating characteristics of dual-mode heat pump systems at different ambient temperatures. The multi-period optimisation framework has been developed to perform economic trade-off which minimises operating costs for heat pump, and to determine the capacity of heat pump systems. Case study is presented for demonstrating applicability of the developed methodology. Applications for energy saving in building have been considered.

INTRODUCTION

Due to increasing fuel costs and stricter environmental regulations, heat pump systems have gained great interests in these days as one of practical and realistic solutions in the near future to save energy consumptions as well as to reduce CO_2 emissions. Substituting a conventional boiler with a heat pump may save more than 50% of primary energy, while CO_2 emission from heat pump is lower than other fuel heating methods [1]. The appropriate sizing of system elements for heat pump applications is extremely important in order to achieve minimum cost at maintaining high thermodynamic efficiency. It is well known that the thermal performance of heat pump systems is directly related to its operating conditions, initial and operating costs. For residential air-source heat pumps, operating conditions varies with ambient conditions, which affect the performance of heat pump systems.

Therefore, the heat pump performance at the nominated design conditions should not be only criterion for assessing whether a heat pump is properly designed, as the heat pump is not operated at the design condition for all the time. Various researches [2, 3, 4, 5] have shown the interest the climate conditions on the optimal design of reversible heat pump systems, but there still lacks systematic studies on optimising dual-mode heat pump systems with simultaneously considering non-steady ambient conditions. By following the method [6] which is widely used in practice, a heat pump is selected such that its output balances the heat requirement of the building in most ambient conditions. This 'rule of thumb', however, does not guarantee a minimum cost solution. In this study, the integrated design of heat pump systems has been studied to address seasonal variations of ambient conditions and dual operation mode. First, a mathematical model for heat pump systems at designed conditions and sub-capacity conditions is developed. Then, the impact of compressor and heat exchanger capacity on the system capacity has been investigated to achieve cost-effective balancing the size of components, which leads to the reduction of operating cost. Variables characterising the system performance have been carefully chosen and optimised to improve economic and thermodynamic performance.

Case studies using two natural refrigerants (ammonia and propane) are carried out on the different geographic locations with different heat load, in order to illustrate benefits gained from the developed methodology.

HEAT PUMP SYSTEM MODELLING

The air-source heat pump system for residential heating and cooling normally includes five main components: compressor, indoor coil, outdoor coil, expansion valve and reversing valve (Fig. 1). Through different positions of reversing value, the heat pump system is operated in different modes, i.e. the indoor coil serves as the condenser in the heating mode, while the indoor coil is used as the evaporator in the cooling mode. This means that the heat pump extracts heat from outdoor air in the heating mode and rejects heat to outdoor air in the cooling mode.

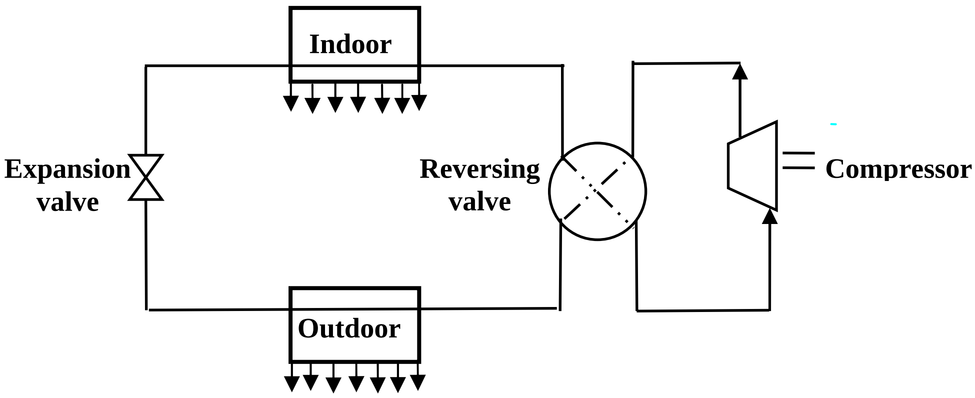

Fig. 1 Heat pump with heating and cooling modes

The important issue in the modelling of heat pump systems is that changes of ambient temperature and its effects on system capacity and power input to the compressor should be properly considered. Actual performance of a refrigeration cycle is different from that of ideal cycle because of the irreversibility occurred, for example, pressure drop of the refrigerant when it flows within the unit and temperature change from isentropic expansion and compression. Isentropic efficiency is a widely used index for efficiency of refrigeration compressors, especially for reciprocating compressors. The heat exchangers (i.e. evaporator and condenser) are assumed to have counterflow streams [7].

Compressor: A map-based method or an efficiency and loss method are mainly used in the modelling for the constant speed compressor. The former one can only be applied to the specified compressor when the performance data of compressor is provided by the compressor manufacturer. It is of higher precision, but difficult to extend to other types. In this study, it is adopted that the concept of the efficiency is used to predict the compressor performance. The compressor power is calculated by:

$$W_{in} = \frac{\dot{m}_r (h_3 - h_2)}{\eta_{isen}} \qquad (1)$$

$$H_{isen} = h_3 - h_2 \qquad (2)$$

where $\dot{m}_r$ is the refrigerant mass flow rate (kg/s), and η_{isen} is the isentropic efficiency.

As reciprocating and scroll compressors are widely used in heat pumps, in this study reciprocating compressor is chosen in the heat pump cycle.

For reciprocating compressor:

$$\dot{m}_r = \dot{V}_P \eta_v \rho_{suc} \tag{3}$$

where the volumetric efficiency η_v is the linear function of pressure ratio between compressor inlet and outlet pressure. There are many different functions to represent isentropic and volumetric efficiencies, but the following two equations are used in this study [8].

$$\eta_v = 98.6 - 5.6\gamma \tag{4}$$

$$\eta_{isen} = 0.109(\ln\gamma)^3 - 0.5247(\ln\gamma)^2 + 0.8577(\ln\gamma) + 0.3727 \tag{5}$$

Evaporator: In vapour compression refrigeration systems, the evaporator is an indirect-contact heat exchanger of the refrigerant and the air. Three equations for heat balance are used to represent the cooling capacity of the evaporator Q_e as following:

$$\begin{cases} Q_e = (UA)_e \Delta T_{e\,mean} \\ Q_e = (FCp)_e \Delta t_e = (FCp)_e (T_{e\,in} - T_{e\,out}) \\ Q_e = \dot{m}_r (h_2 - h_1) \end{cases} \tag{6}$$

where log mean temperature $\Delta T_{emean} = \dfrac{(T_{ein} - T_e) - (T_{eout} - T_e)}{\ln \dfrac{T_{ein} - T_e}{T_{eout} - T_e}}$

Condenser: The modelling of the heating capacity of the condenser Q_c is the same as for the evaporator

Expansion device: The expansion process is treated as isenthalpic.

Overall System: The following heat balance equation is used to link the evaporator, compressor and condenser together.

$$Q_c = Q_e + W = \dot{m}_r (h_2 - h_1) + \frac{\dot{m}_r (h_3 - h_2)}{\eta_{isen}} \tag{7}$$

The required physical properties of refrigerants i.e. enthalpy, density, and equilibrium pressure, can be calculated by the polynomial methods [9] regressed within the certain temperature rang or the commonly used EOS methods [10]. Heat pump efficiency is defined as the useful energy delivered, divided by the energy supplied to drive the compressor. Therefore in the heating mode and cooling mode, coefficient of performance (COP) is calculated by the following equation:

$$COP_{cooling} = \frac{Q_e}{W} \qquad COP_{heating} = \frac{Q_c}{W} \tag{8}$$

OPTIMISATION

The conventional design method for heat pumps are to choose the design condition, such as outdoor condition and indoor comport condition, to calculate heat load. Then sizing for components in the heat pump unit is made to meet heat load at the design condition so that the indoor comfort condition can be maintained. This design condition is referred as the design or balance point. When heat pump is operated at conditions other than at the design point, the heat extracted and rejected through the evaporator and condenser will be changed.

This will break the balance between heat exchangers and compressor, and the refrigerant in the heat pump cycle will adjust its evaporating and condensing temperature to reach a new balance point [9]. Below the balance point, the system has insufficient capacity to meet the demand, as shown in Fig. 2. This deficit should be supplemented from external energy source, such as an electric heater or a gas boiler. Above the balance point, the surplus capacity of the heat pump system can be stored, for example, using water or switching the system off periodically.

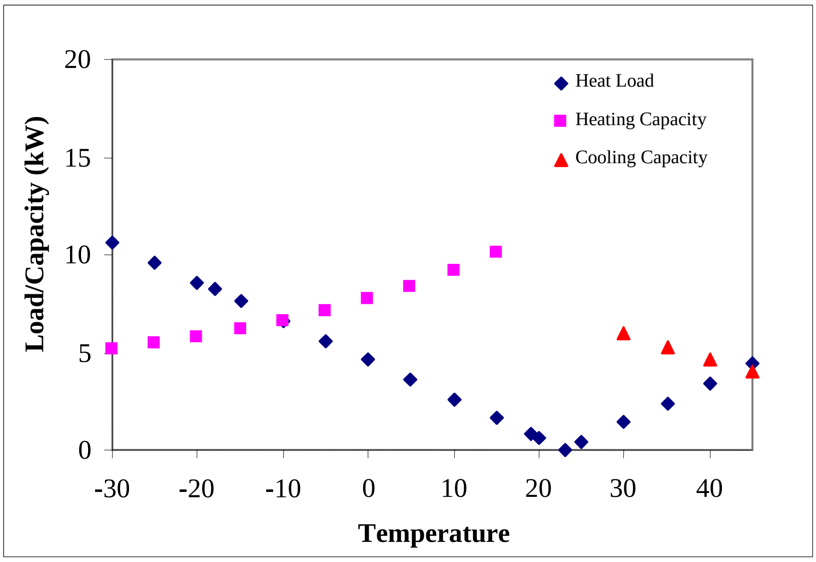

Fig. 2 Variation of system capacity with operating temperature

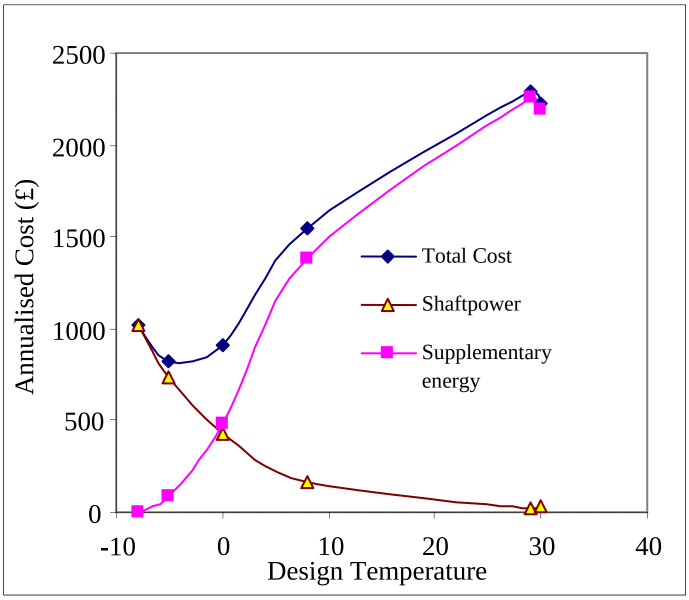

Fig. 3 Annualised energy cost at different design points

Given the geographical location and system on/off switch threshold, the heat pump is to be operated at different ambient temperature and consequently with different capacity and performance. If lower ambient temperature is chosen as the design condition, bigger capacity for heat pump system is required to meet higher heat demand, and less supplementary heating is necessary. On the other hand, the design temperature becomes higher, shaftpower required for compressor becomes less while the need for supplementary heating becomes higher. Fig. 3 shows trade-off between shaftpower and supplementary heating.

Heating and cooling load: The heat pump systems are to meet heating demand in the winter and cooling demand in the summer. Cooling load, Q_{load}^{C}, and heating load, Q_{load}^{H}, are defined in this study as the rate at which heat must be removed from and added to an indoor space so as to maintain a comfortable temperature.

In the heating mode, the condenser capacity Q_c is to meet the heating load, Q_{load}^{H}, while in the cooling mode, the evaporator capacity Q_e is to meet the cooling load Q_{load}^{C}. The general techniques used to calculate the heating/cooling load are TETD/TA method, Transfer Function Method (TFM), 1989 CLTD/CLF Method and Radiant Time Series (RTS) Method [11]. In this study, heat load (heating/cooling) is determined by the simple linear equation of ambient temperatures.

$$Q_{load} = A*[23 - T_a] \tag{9}$$

This is taken from the Canadian Building Digest [12], showing the heat demand of a residential house with modest insulation. Parameter A is 0.2.

Characterising variables of heat pump systems: For the heat pump system as a whole, system capacity is not determined purely by compressor capacity. The evaporator and condenser have their own effects on system capacity as well. Therefore, design variables should be selected carefully to characterise thermodynamic performance of units. In this study two characteristics are chosen to represent for heat exchangers.

Heat transfer capacity, *UA* (kW/K), combines the overall heat transfer coefficient and surface area of the heat exchanger, representing the effect of configuration on heat transfer. When heat transfer capacity *UA* of the evaporator and condenser is increasing, the system capacity is increasing accordingly; therefore the total cost is reduced. In overall, system capacity gain benefits from the increasing of UA of the evaporator and condenser.

Another characteristic of the air-sourced heat exchanger is air-side heat flow capacity, *FCp* (kW/K), which is used to measure how much heat is taken in and out by air flowing through the coils. It is assumed that the specific heat (*Cp*) for air is constant value (1 kJ/kg K) within the working temperature. System capacity is increasing while air side heat flow capacity is increasing, the total cost will be decreased as well.

Overall system performances are collectively influenced by sizing of compressor, evaporator and condenser. The design at minimum cost or high thermodynamic efficiency cannot be simply obtained from heuristics, experiences or engineering judgement. Optimisation should be carried out carefully to obtain the cost-effective design of heat pumps.

Objective function: The objective function is set to minimise annualised cost of shaftpower and supplementary energy cost.

$$\min \quad Cost = \sum_i W(i) \times D(i) \times P \; + \sum_i IH(i) \times (Q_{Load}(i) - Q_c(i)) \times D(i) \times P_{SH} \; + \\ \sum_i IC(i) \times (Q_{Load}(i) - Q_e(i)) \times D(i) \times P_{SH} \tag{10}$$

$$st. \begin{cases} T_{cin}(i) = T_a(i) \\ T_{ein}(i) = T_a(i) \\ IH(i) = 1 \quad if \quad T_a(i) \le 15 \\ IC(i) = 1 \quad if \quad T_a(i) \ge 25 \\ IH(i) + IC(i) \le 1 \end{cases}$$

where i is the index of the set, *IC* and *IH* are the integer variables for cooling mode and heating mode. The optimisation problem is formulated as discrete NLP problem, and the optimisation is solved in GAMS environment using CONOPT solver. It should be noted that in principle the objective function in Eq. 10 can include (annualised) capital cost, and then, economic trade-off between capital and operating costs would be performed during the optimisation.

CASE STUDY – HEAT PUMP HEATING A BUILDING

Fig. 4 shows that the monthly average high and low temperature over the whole year, and how many days at which temperature requiring heating and cooling for the case study. For simplicity in this paper, the case study illustrates the design of heat pump systems using ammonia as a fluid for one geographical location. It should be noted that the method is readily applicable to other fluids (e.g. propane) and other geographical locations with minor adjustments in the model.

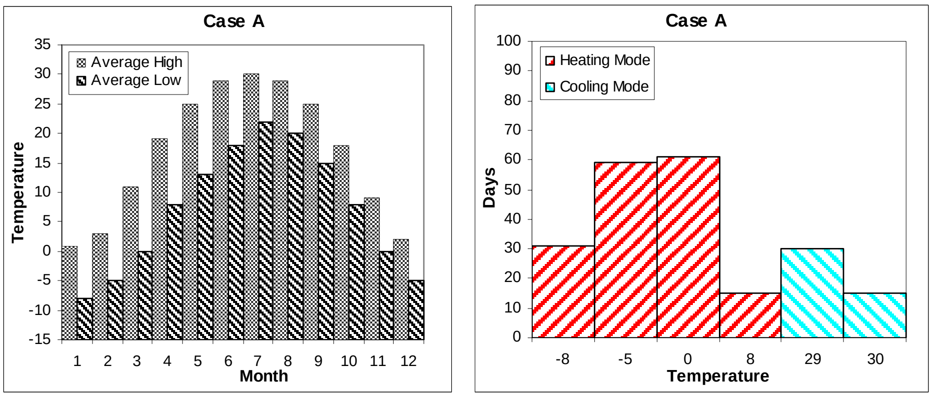

Fig. 4 Climate conditions and discrete multi-period conditions

Two scenarios are considered. Scenario 1 assumes the supplementary heat is provided by the electric heater with 100 % efficiency. Scenario 2 assumes the supplementary heat is provided by the gas boiler with 85 % efficiency. After optimisation, the annual (minimum) operating costs of the heat pump system for Scenario 1 and Scenario 2 are £524.3 and £493.4 respectively.

Fig. 5 shows the heat load and heat pump capacity. In both scenarios the heat pump cannot satisfy the heat demand at lower ambient temperature, which means supplementary heating is employed. COPs and shaftpower requirements at different operating conditions for two scenarios are given in Fig. 6, where COP for the heating mode is decreasing with the increasing of ambient temperature.

Expensive heating source (i.e. electricity in this case study) is used to provide supplementary heating in Scenario 1. Therefore heat pump system with relatively high capacity requiring low supplementary heating is able to achieve the minimum total operating cost, but COP is inevitably sacrificed. It is contrast to the Scenario 2, gas boiler can provide more supplementary heat for the minimum overall operating cost with high system COP.

.

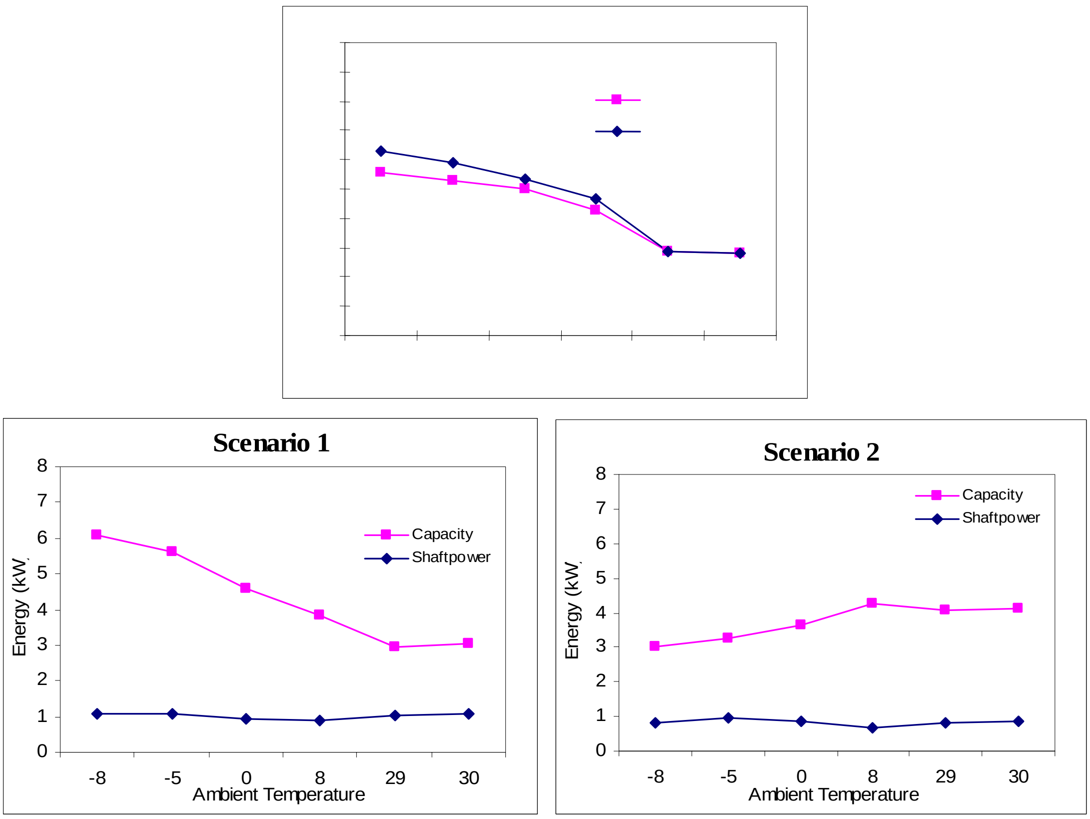

Fig. 6: COP and shaftpower (Fluid: NH_3)

CONCLUSION

In this study, the integrated design and optimisation method for heat pump systems are proposed to improve cost-effectiveness and thermodynamic efficiency of heat pump systems using natural fluids. The optimisation is based on multi-period formulation, in which different ambient conditions and its influences on heat pump performance are evaluated. During optimisation, selection of system capacity and sizing of units in heat pump systems are systematically investigated and screened, as well as economic trade-off between supplementary heating (or cooling) and operating cost for heat pump is performed to minimise annualised operating cost. Dual-mode (i.e. heating and cooling) operation and characteristics are also considered in the modelling and optimisation, which ensures that operating flexibility through dual-mode operation is fully explored in the design stage. The design approach is applied to a case study, which illustrates the developed method is able to bring significant benefits to the design and operation of heat pumps applications for buildings.

SUMMARY

This paper presents a study on thermal diffusion of large-scale seawater source heat pump system (SWHP).

SWHP uses seawater as heat source and sink, and discharges the same quantity of water into local oceans after use. The cooling water systems may cause a temperature rise of 3-5℃ above ambient at discharge points which is close to the upper thermal tolerance limit of most marine biota, which would not only have a certain impact on the local marine environment, but also affect the local micro-climate, the local marine life and fishing economy, etc.

Based on Navier Stokes equations and shallow water assumption, non-linear shallow water equations are established in this paper. The two-dimensional numerical simulation research of the flow velocity field and temperature field of the water space where thermal effluent is discharged is done using a case study.

And following an example of Xiaoping Island SWHP project is given. Simulation and description on the discharge of this SWHP project show that, the temperature rise/drop extends to certain area, but the temperature elevation of the influence area is far less than the standard of Grade Ⅰ of Quality Standard for State Oceanic Water.

This paper firstly introduces the hydrodynamic knowledge into HVAC design application, which shows a way to the environmental impact statement of Water Source Heat Pumps.

INTRODUCTION

In the 21st century, the energy issue has become increasingly prominent. The sea water-source heat pump (SWHP) system’s coming into China is a very important significance for the energy efficiency in buildings. Seawater source heat pump technology transfers solar energy captured in seawater which is low temperature and low quality, into high quality energy through the use of heat pump and a small quantity of electricity. At present, there’re only several experimental projects in China, and environmental impact assessment is one of the most important issues to resolve.

SWHP system uses seawater as heat source and sink, and discharges the same quantity of water into local oceans after use. The temperature of the discharge water is higher in the summer than the local water temperature around 10℃, and lower in winter about 3-5℃ than the receiving water body. The discharge temperature elevation of seawater will not only have a certain impact on the local marine environment, but also affect the local micro-climate, the local marine life and fishing economy, etc. When the large-scale application of SWHP systems come into reality in the coastal cities in China for district cooling and heating, these impacts may become particularly prominent.

The above issue can be solved by the thermal discharge research method. Thermal discharge exists in every thermal/nuclear power plant, and researchers have been working on it for tens of years. The method consists of domestic physical and numerical simulation, of which the later is most widely used. What's more, the two are often combined, for the model the model parameters of numerical equation are often obtain from physical tests.

According to different classification method, numerical model can be classified as the near-field model and the far-field model, or the 2D depth-averaged model and 3D mode, and during actual applications these models are developing toward a more sophisticated, visualization and intelligent direction. With the emergence of the sea water-source heat pump system, some new problems need to be considered.

Between the mathematical models studied by scholars at home and abroad, the depth-averaged two-dimensional fluid dynamics model is very effective to solve some problems in the oceans, coasts water level and instantaneous transport, which is widely used in the study of thermal discharge, to predict the temperature distribution of thermal discharge area[1,2].

MATHEMATIC MODEL

Based on Navier Stokes equations and shallow water assumption, non-linear shallow water equations are established. The depth averaged two-dimensional hydrodynamic model, including the effects of earth's rotation, bottom friction, wind shear and surface heat exchange are as follows [3]:

Continuity equation:

$$\frac{\partial \zeta}{\partial t}+\frac{\partial HU}{\partial x}+\frac{\partial HV}{\partial y}=Q \tag{1}$$

Momentum equation:

$$\frac{\partial U}{\partial t}+U\frac{\partial U}{\partial x}+V\frac{\partial U}{\partial y}-fV=-g\frac{\partial \zeta}{\partial x}+\nu_H\left(\frac{\partial^2 U}{\partial x^2}+\frac{\partial^2 U}{\partial y^2}\right)-\frac{gU\sqrt{U^2+V^2}}{HC_{2d}^2}+\frac{C_d}{H}\frac{\rho_a}{\rho}U_{10}^2\cos\beta \tag{2}$$

$$\frac{\partial V}{\partial t}+U\frac{\partial V}{\partial x}+V\frac{\partial V}{\partial y}+fU=-g\frac{\partial \zeta}{\partial x}+\nu_H\left(\frac{\partial^2 V}{\partial x^2}+\frac{\partial^2 V}{\partial y^2}\right)-\frac{gV\sqrt{U^2+V^2}}{HC_{2d}^2}+\frac{C_d}{H}\frac{\rho_a}{\rho}U_{10}^2\sin\beta \tag{3}$$

Transport equation:

$$\frac{\partial HT}{\partial t}+\frac{\partial HUT}{\partial x}+\frac{\partial HVT}{\partial y}=\frac{\partial}{\partial x}\left(HK_x\frac{\partial T}{\partial x}\right)+\frac{\partial}{\partial y}\left(HK_y\frac{\partial T}{\partial y}\right)+S \tag{4}$$

U、V depth-averaged velocity in x and y direction; ρ_a density of air ; f Coriolis coefficient, $f=2\omega\sin\psi$, ω angular frequency of the earth, ψ the local latitude; 2D Chézy coefficient, computed by Manning Formula : $C_{2d}=\frac{1}{n}H^{1/6}$, n is the Manning's coefficient; C_d wind drag coefficient; ν_H horizontal eddy viscosity; U_{10} averaged wind speed at 10 m above free surface; β the angle between the wind stress vector and the local direction of the grid line x; M_x, M_y source or sink of momentum in x and y direction; T the water temperature; K_x, K_y diffusion coefficient in x and y direction; Q, S the source and sink term.

The heat exchange flux is represented by a bulk exchange formula [4]:

$$Q_{tot} = -\lambda(T_s - T_{back}) \tag{5}$$

with T_s the water temperature at the free surface and T_{back} the natural background temperature, both in ℃. The heat exchange coefficient λ is a function of the surface temperature T_s and the wind speed U_{10}:

$$\lambda = 4.48 + 0.049T_s + f(U_{10})\left(1.12 + 0.018T_s + 0.00158T_s^2\right) \tag{6}$$

$$f(U_{10}) = (3.5 + 2.0U_{10})\left(\frac{5.0\times10^6}{S_{area}}\right)^{0.05} \tag{7}$$

Where S_{area} is the exposed water surface in m^2.

The control equations formed by ADI method (Alternating Direction Implicit Method, Leendertse，1967) are solved on a staggered grid. Each of the dispersed control equation group consists of three unknown variables at adjacent nodes. In the coefficient matrix, all the non-zero elements are arranged along a diagonal matrix. So triangle diagonal matrix algorithm (TDMA) is used for solution.

PROJECT AND COMPUTATIONAL ASPECTS

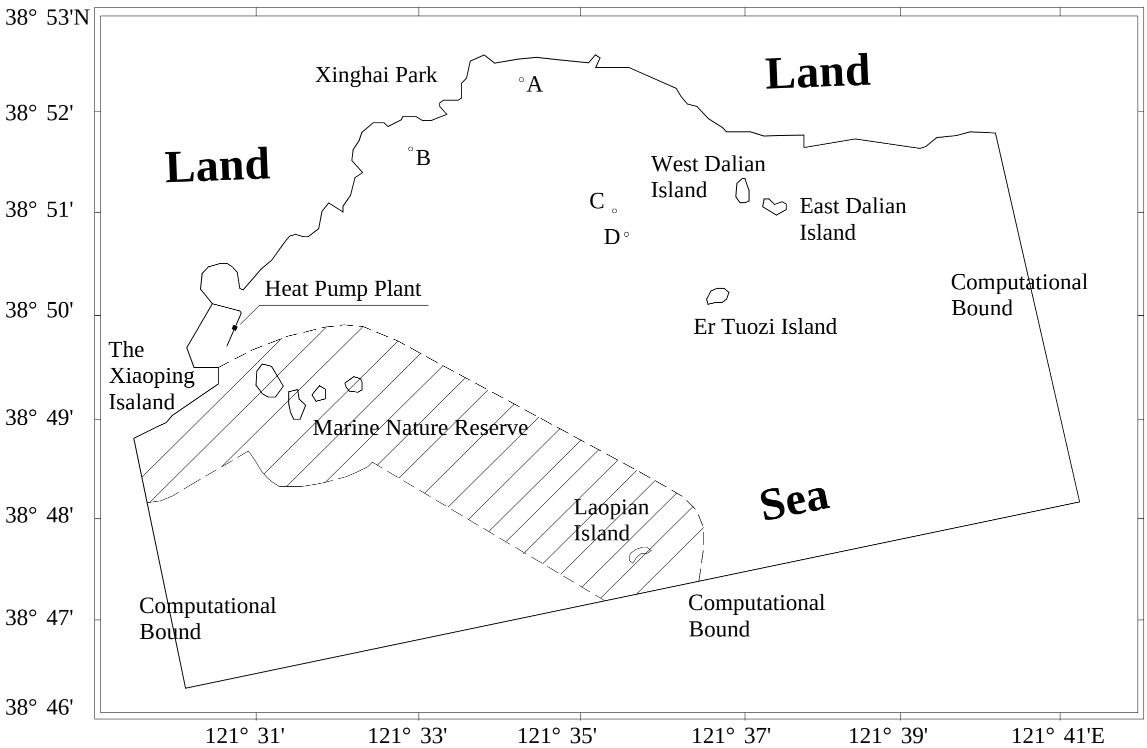

Figure1 Simulation Area and Location of the Project

Using the above method, an example of Xiaoping Island SWHP project is given in this section. This project is located to the Xiaoping Island, at the Huang hai sea of China. The heat pump plant is located at 121°30′34″-121°30′44″E, 38°49′49″-38°49′58″N, on a bulwark of 1300 meters long and L type, see figure 1. The shadow area is the marine nature reserve, which is to be considered not to be affected by this project's discharge.

The design input/output flow and temperature rise/drop at the first stage of this SWHP is as follows:
Heating Season: 1.9 m^3/s, temperature drop 2.5℃
Cooling Season: 1.14m^3/s， temperature rise 10.0℃

RESULTS AND DISCUSSION

24 hours' site tide data of four stations-A, B, C, D（From 8:00, 18th, Apr. to 7:00, 19th, Apr., 2003, sees figure 1）are used for validation of the simulation results. The comparison between the computed and observed results are shown from figure 2 to figure 5。

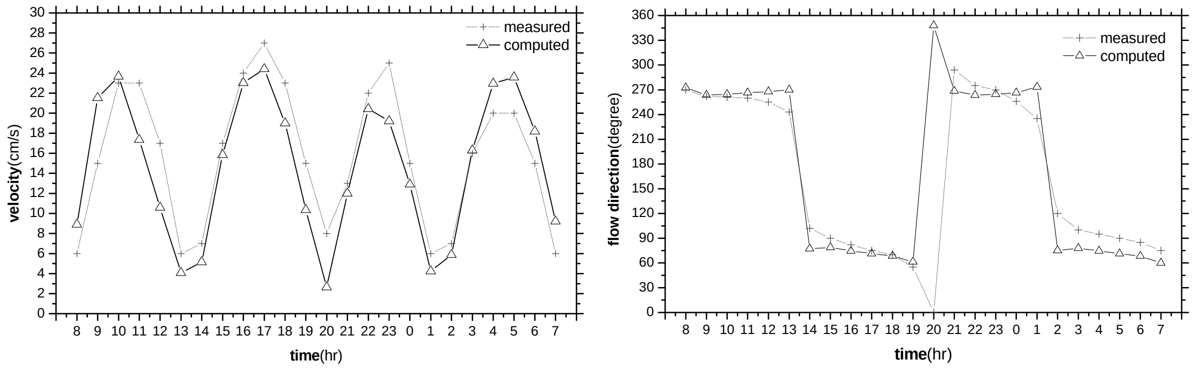

Figure 2 Computed and Observed Velocity and Phase at Station A

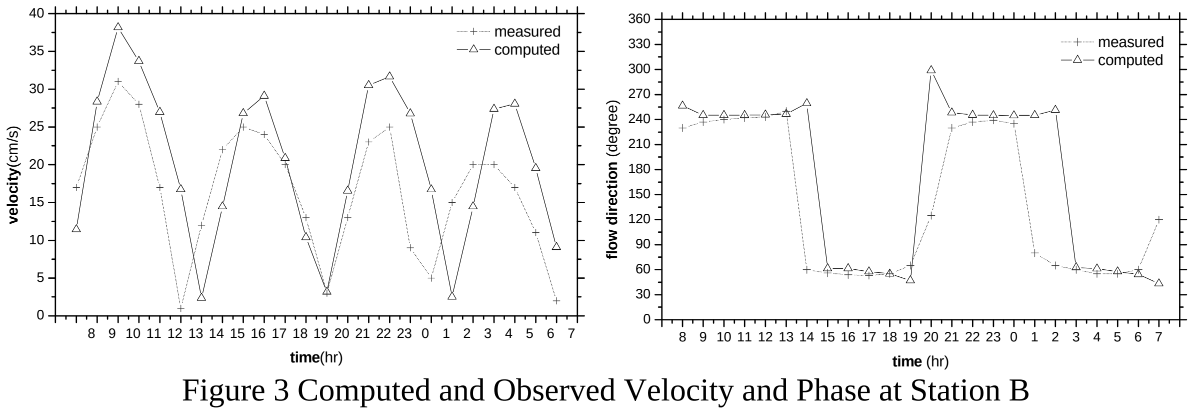

Figure 3 Computed and Observed Velocity and Phase at Station B

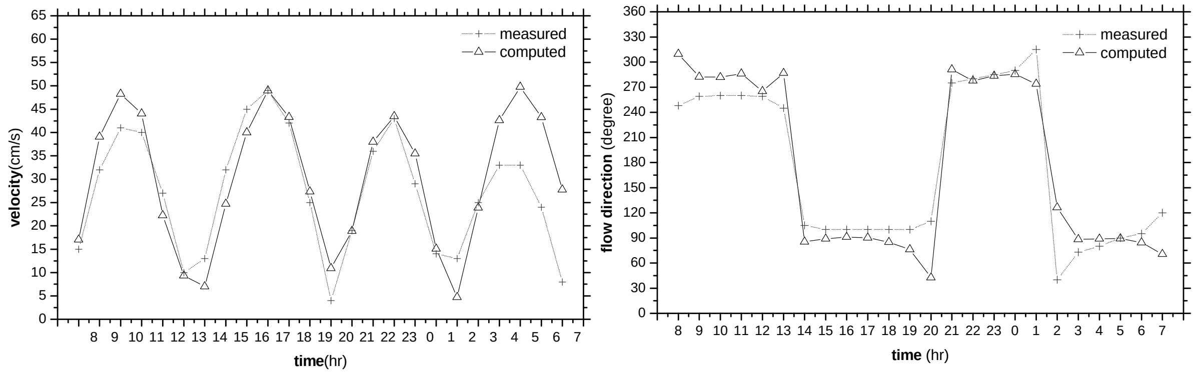

Figure 4 Computed and Observed Velocity and Phase at Station C

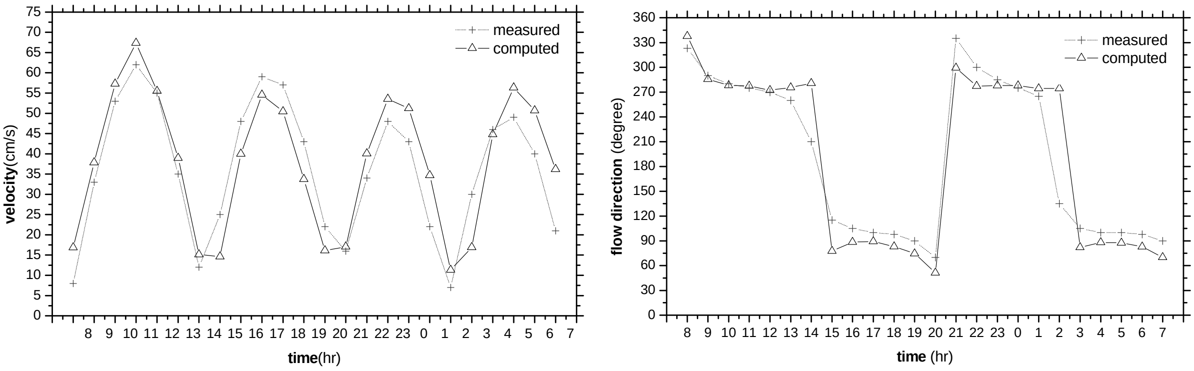

Figure 5 Computed and Observed Velocity and Phase at Station D

It can be seen that the agreement with the observation data is satisfactory. The seawater flows at pulsant turbulence, but the model in this paper is time-averaged and depth-averaged, so large warps of the phase appear at some point of the simulation periods is possible and acceptable, especially when flow direction changes (20:00 at station A for instance). What's more, flow field can be influenced by meteorological parameters-wind, air pressure, temperature etc. The model considers the regular and general instance, so the meteorological effect is ignored.

When the model is validated, transport equation can be used for temperature prediction. Conditions during neap tide and spring tide are simulated. Because of limited space, computed results only during neap tide are given in this paper. Figure 6 shows envelope area of iso-excess temperature during neap tide in summer, and figure7 shows envelope area of iso-excess temperature during neap tide in winter. Both are the worst status during 24 hours' simulation, which means that the temperature rise (drop) absolute value is maximal at the moment.

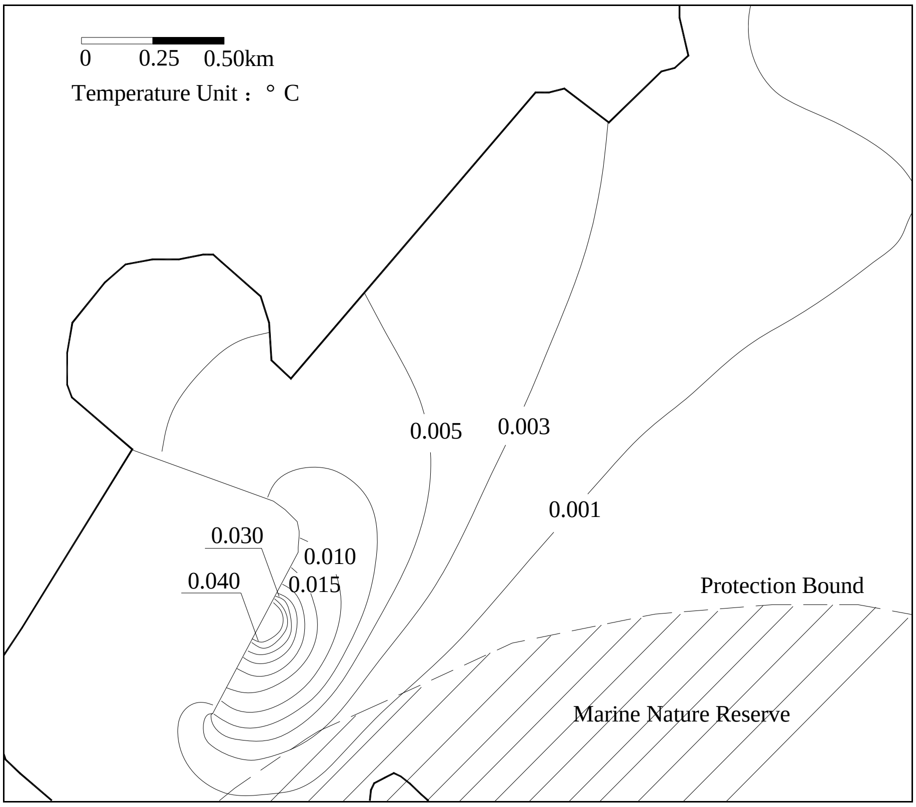

Figure 6 Iso-temperature elevation contours during neap tide in summer

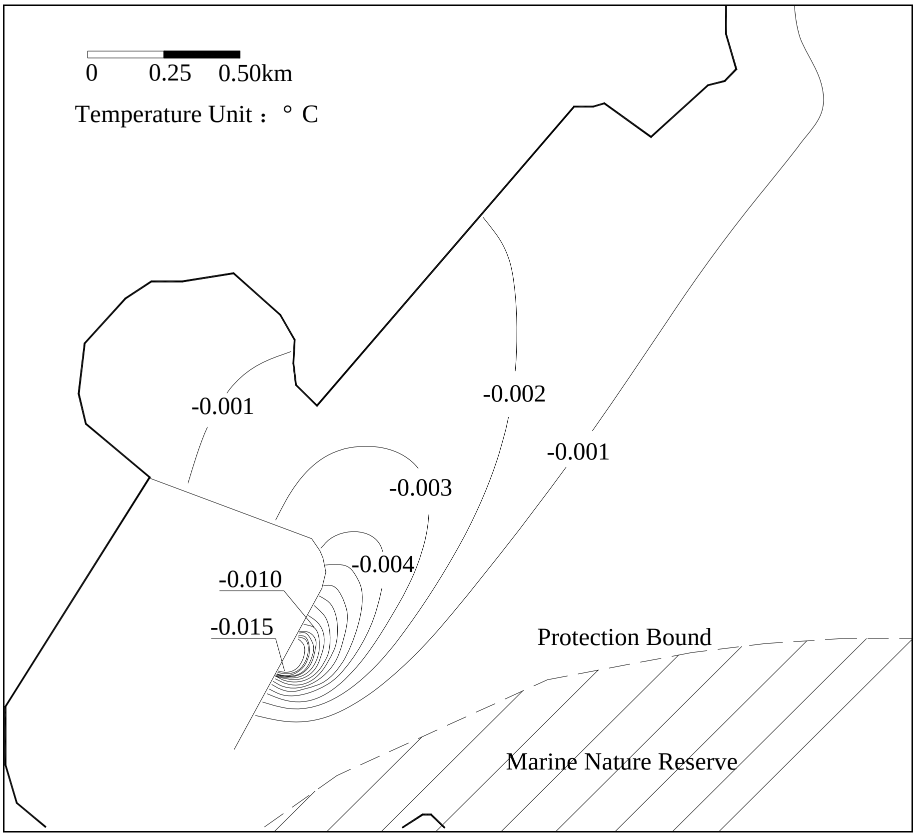

Figure 7 Iso-temperature elevation contours during neap tide in winter

In summer, the temperature rise of 0.003 ℃ would reach the marine nature reserve area (figure 6), and the maximal temperature rise is 0.040 ℃ at the discharge point. In winter temperature drop wouldn't affect the marine nature reserve (figure 7), and the maximal temperature drop is 0.015 ℃ at the discharge point. According to the Quality Standard for State Oceanic Water in China, the temperature change does not exceed prescriptive ranges.

CONCLUSIONS

The paper has presented the depth-averaged two-dimensional fluid dynamics model and its application to a planned SWHP system, which for the first time introduces the hydrodynamic knowledge into HVAC design application. Firstly the model is used for tide simulation, and it demonstrates in general an excellent agreement with the observation data. Then the model is well used for numerical prediction for the influence of temperature changes in the intake (outfall) areas of Xiaoping Island SWHP system.

The model is capable of being used as an environmental impact statement tool to aid in the design and control of SWHP system. It can also be used for the design of some other water source heat pump systems, such as Lake Source heat pump, River Source heat pump, etc.

Exergetic performance assessment of gas engine heat pumps

Arif Hepbasli

Ege University, Turkey

Corresponding email: Arif.hepbasli@ege.edu.tr

SUMMARY

A gas heat pump (GHP) or a gas engine-driven heat pump (GEHP) is a new type of heat pump (one of today's promising new technologies). In evaluating the efficiency of heat pump (HP) systems, the most commonly used measure is the energy (or first law) efficiency, which is modified to a coefficient of performance (COP) for HP systems. However, for indicating the possibilities for thermodynamic improvement, energy analysis is inadequate and exergy analysis, which has been recently widely used in the design and performance evaluation of thermal systems, is needed. This study, which is one of the limited studies, presents exergy analysis and assessment of GHPs aimed at identifying improvement potential. An illustrative example is also presented. The exergy destructions in each of the components of the overall system are determined. Exergy efficiencies of the system components are also derived to assess their performances and to elucidate potentials for improvement.

INTRODUCTION

A gas heat pump (GHP) is a new type of heat pump (one of today's promising new technologies) in which an open type compressor (the core part) is driven by a gas engine. The GHP has been paid more attention in the heating, ventilation and air conditioning (HVAC) field in recent years due to its advantage of reducing the electric consumption in the cooling and heating seasons. Another two distinguished advantages of the GHP are (1) the ability to recover the waste heat released by the engine cylinder jacket and exhaust gas in the heating mode and (2) the easy modulation of compressor speed by adjusting the gas supply. Therefore, the GHP has a different performance from that of the electric driven heat pump, especially in the heating mode [1].

Heat pump is known as a kind of energy saving air conditioning equipment, which is mostly driven by electricity. Current practice is mainly to convert fuel to electric power at a central power plant and reject the waste heat to the environment. The electricity is then transmitted to the heat pump motor, which provides the work input to the heat pump cycle. Significant losses will occur from fuels to work of the heat pumps in such a case. An obvious way to improve overall fuel utilization is to locate the fuel conversion process closer to, where the exhaust heat can be productively used. A combustion engine directly driving a heat pump compressor has about the same overall fuel-to-heat or cooling efficiency as an electric unit. An additional advantage is that the combustion engine's waste heat can be utilized at the site to provide supplemental space heating or water heating. Therefore, GHP will have a high efficiency of fuel utilization. At this time no more than 1/3 of energy consumed in a conventional heat pump is needed in GHP to achieve the same heating effect, as shown in Figure 1 [2,3].

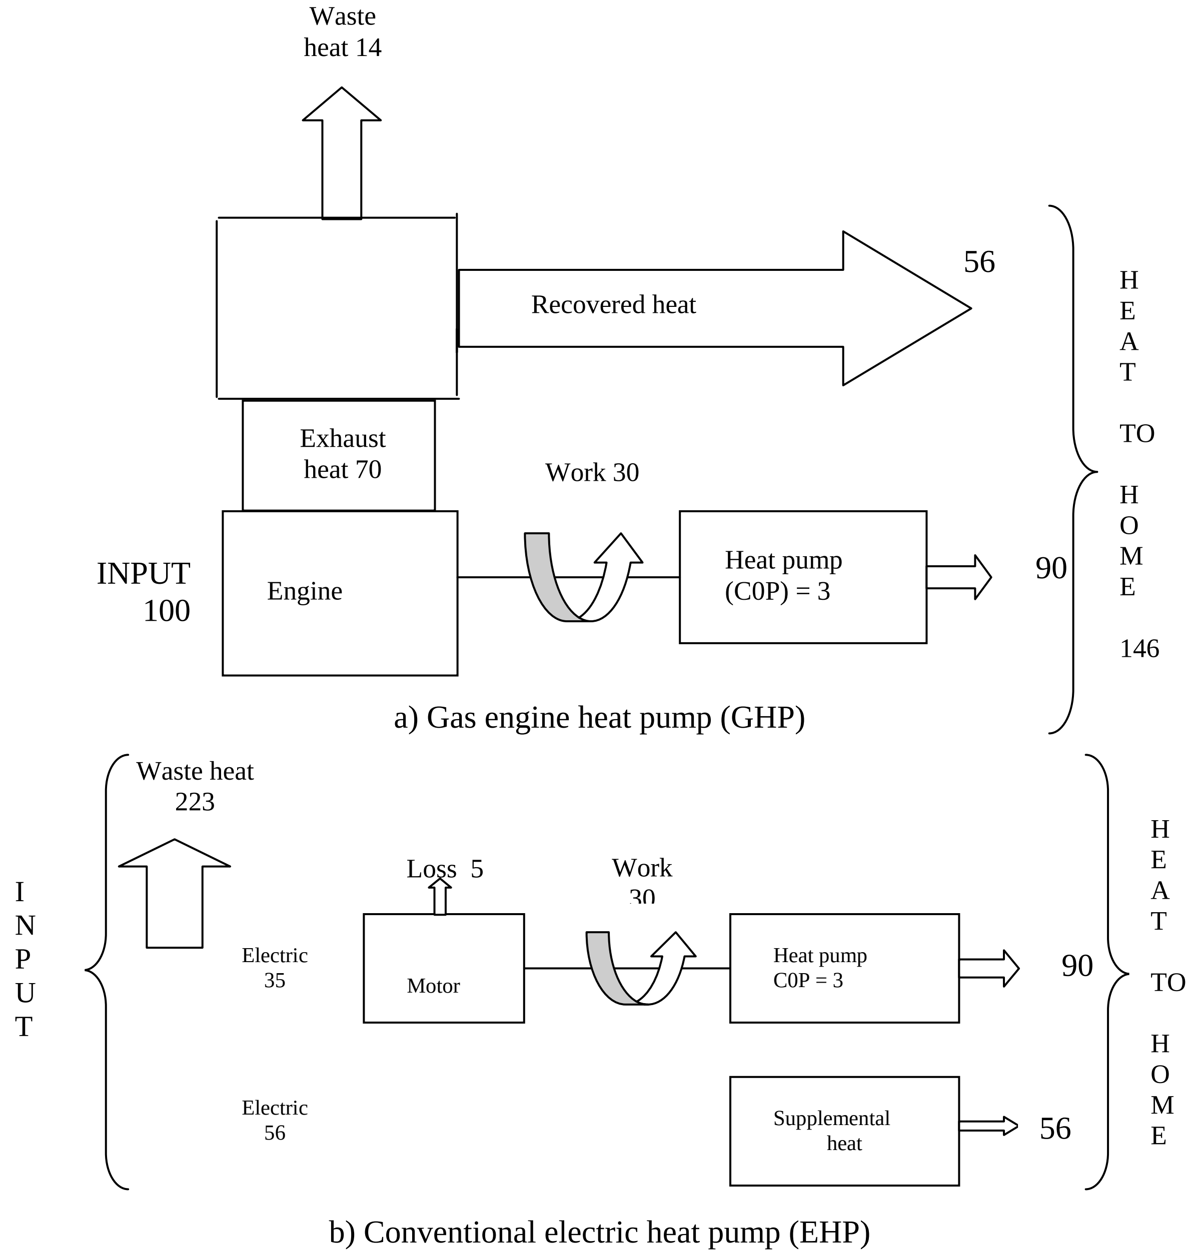

Figure 1. Comparison of energy conversion process between conventional EHP and GHP [3].

GHPs were first launched in Japan in 1987. There were 400,000 units installed worldwide in 2003, with 50,000 annual sales in Japan. The range of gas engine heat pumps, called GHPSplit, are reversible units with capacities 33 kW to 73 kW for heating and 28 kW to 56 kW for cooling [4]. Early examples of GHPs were unreliable, noisy and had a high maintenance requirements. Barriers to their introduction was overcome by research, development and support from gas utilities and governmental organizations [5].

Up to date, various studies on GHPs have been conducted by many investigators. Some of these studies include energetic performance evaluation [1], combination of GHP and water-loop heat pump [3], economic analysis [6,7], cascade fuzzy control [8] and combined refrigeration cycles driven by GHPs [9]. Although various studies on energetic and economic assessment of GHPs have been performed, no detailed studies on exergetic modelling and assessment of GHPs appear in the open literature to the best of the author's knowledge. This has provided the motivation in doing the present study.

METHODS

In the performance evaluation of GHP, energy and exergy analysis methods are used. In this regard, the GHP system may be modeled using the following relations, which are related to the heat pump unit and the whole GHP system. .

General energy and exergy balance equations

General mass, energy, entropy and exergy balance equations are given in more detail elsewhere [10].

The mass balance equation can be expressed in the rate form as

$$\sum \dot{m}_{in} = \sum \dot{m}_{out}, \ (1)$$

where $\dot{m}$ is the mass flow rate, and the subscript in stands for inlet and out for outlet.

The general energy balance can be written as

$$\sum \dot{E}_{in} = \sum \dot{E}_{out} \ \text{or} \ \dot{Q} + \sum \dot{m}_{in} h_{in} = \dot{W} + \sum \dot{m}_{out} h_{out}, \ (2)$$

where $\dot{m}$ is the mass flow rate and the subscript *in* stands for inlet and *out* for outlet, $\dot{E}_{in}$ is the rate of net energy transfer in, $\dot{E}_{out}$ is the rate of net energy transfer out by heat, work and mass, $\dot{Q} = \dot{Q}_{net,in} = \dot{Q}_{in} - \dot{Q}_{out}$ is the rate of net heat input, $\dot{W} = \dot{W}_{net,out} = \dot{W}_{out} - \dot{W}_{in}$ is the rate of net work output, and *h* is the enthalpy per unit mass.

The general exergy balance can be expressed in the rate form as

$$\sum \dot{E}x_{in} - \sum \dot{E}x_{out} = \sum \dot{E}x_{dest} \ \text{or} \ \sum \left(1 - \frac{T_0}{T_k}\right)\dot{Q}_k - \dot{W} + \sum \dot{m}_{in}\psi - \sum \dot{m}_{out}\psi = \dot{E}x_{dest}, \ (3)$$

$$\psi = (h - h_0) - T_0(s - s_0), \ (4)$$

where $\dot{Q}_k$ is the heat transfer rate through the boundary at temperature T_k at location *k*, $\dot{W}$ is the work rate, ψ is the flow (or specific) exergy, *s* is the specific entropy and the subscript zero indicates properties at the dead state of P_0 and T_0,

The exergy destroyed or the irreversibility may be expressed as follows

$$\dot{I} = \dot{E}x_{dest} = T_0 \dot{S}_{gen}, \ (5)$$

where $\dot{S}_{gen}$ is the rate of entropy.

Van Gool's exergetic improvement potentia in the rate form, denoted $I\dot{P}$, is given by [11,12]

$$I\dot{P} = (1-\eta)(\dot{E}x_{in} - \dot{E}x_{out}) , (6)$$

General energy and exergy efficiency relations

The energy-based efficiency measure of electrical HP unit (COP_{HP}) is calculated as follows [13]:

$$COP_{HP} = \frac{\dot{Q}_{cond}}{\dot{W}_{comp,elec}} , (7)$$

The COP for the GHP is calculated from [14,15]

$$COP_{GHP} = \eta_{motor,eff}\, COP_{HP} + a_{motor,u} , (8)$$

or

$$COP_{GHP} = \eta_{mech}\, COP_{HP} + (\eta_{total} - \eta_{mech}) , (9)$$

where $\eta_{motor,eff}$ is the effective (mechanical) efficiency of the gas engine, $a_{motor,u}$ is the share of gas engine useful waste heat in the primary energy utilization, η_{mech} is the mechanical efficiency of the gas engine, and $\eta_{motor,eff}$ is the total efficiency of the gas engine.

The exergetic coefficient of performance of electrical HP unit is calculated by

$$COP_{ex,HP} = \frac{\dot{Q}_{cond}(1 - \frac{T_0}{T_{cond}})}{\dot{W}_{comp,elec}} , (10)$$

The exergy efficiencies of the electrical HP and GHP are obtained, respectively, from

$$\varepsilon_{HP} = \frac{\dot{E}x_{heat}}{\dot{W}_{comp,elec}} = \frac{\dot{E}x_{in,condenser} - \dot{E}x_{out,condenser}}{\dot{W}_{comp,elec}} , (11)$$

$$\varepsilon_{GHP} = \frac{\dot{E}x_{in,condenser} - \dot{E}x_{out,condenser}}{\dot{E}x_{fuel}} , (12)$$

RESULTS

Description of an illustrative example

The general relations given in the previous section are applied to an air/water GHP shown in Figure 2 [6], which is described by Lazzarin and Noro [6] as follows: ''S. Nicola'' HVAC plant in Vicenza, Italy features innovative and significant energy savings characteristics. The nominal cooling power is 275 kW (22 Nm^3/h of natural gas is the nominal fuel consumption), while in heating mode the output power is 380 kW (19 Nm^3/h fuel consumption). These performances are labelled for summer external air 35°C and evaporator input/output 12/7°C; winter external air 10°C and condenser input/output 40/45°C. Heat recovery is taken from the lubricating oil, engine cooling water and partly from the exhaust. The nominal power thus recovered is 109 kW in heating mode and 127 kW in cooling mode, to produce hot water at about 70°C. The energy balance of the system is reported as relative units (primary energy input = 100) and in absolute values (kW) for heating mode. Two hydraulic circuits are provided. The primary one supplies chilled water in summer (7/12°C) and warm water in winter (45/40°C) produced by the heat pump and the secondary one hot water at 70°C given by the heat recovery. The control system is governed by a microprocessor that commands the engine speed regulator and the compressor cylinders chocking.

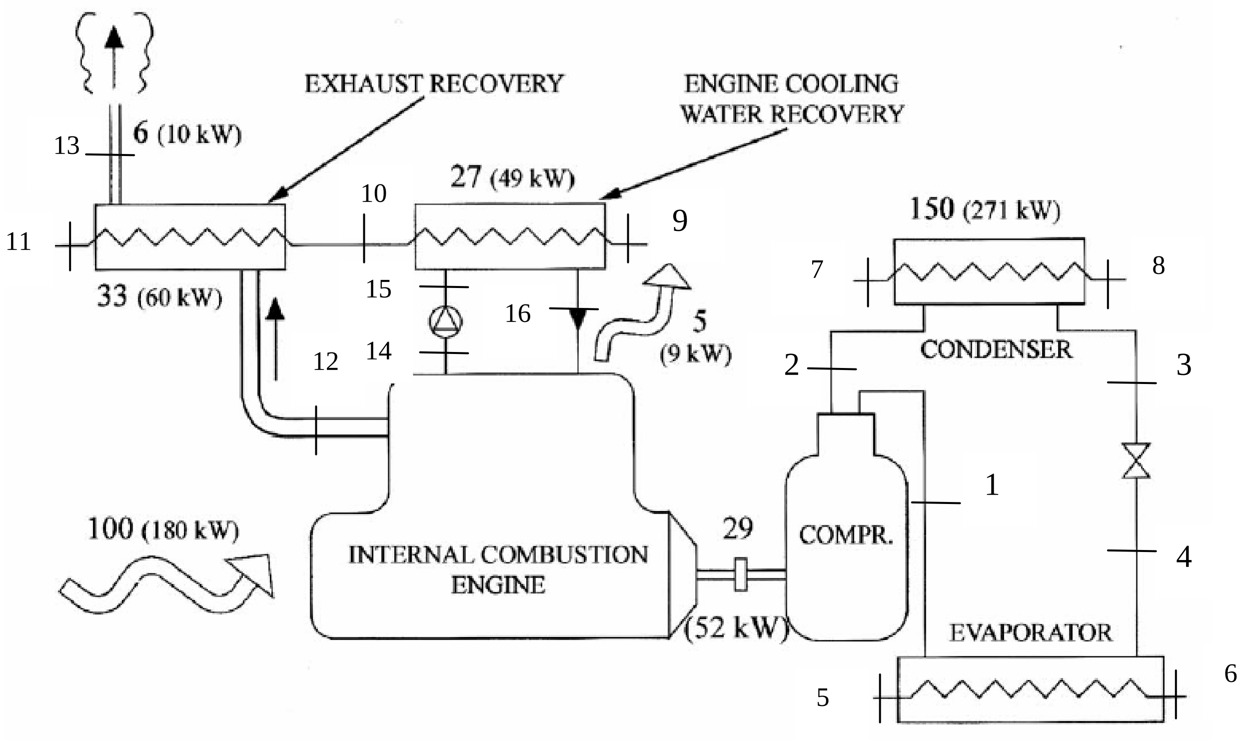

Figure 2. Schematic diagram of the gas engine heat pump studied [6]

Energetic and exergetic assessment of gas engine

The energetic and exergetic evaluation of the gas engine has been given in more detail elsewhere [16], while its exergy efficiency may be calculated using the following relation

$$\varepsilon_{engine} = \frac{\dot{W}_{eff}}{\dot{E}x_{fuel}} \text{ , (13)}$$

where $\dot{E}x_{fuel}$ is the exergy of the fuel, which may be found using the relations given in Ref. [17].

Energetic and exergetic assessment of GHP components

The GHP consists of a HP unit (compressor, condenser, evaporator and expansion valve), a gas engine and heat exchangers (i.e., exhaust recovery and engine cooling recovery), as shown in Figure 2. The energy and exergy balance (exergy destruction) relations for the components of a ground-source HP system have been derived for the author elsewhere [18,19], while they are obtained along with their exergy efficiencies for an air/water GHP shown in this figure as follows:

Compressor (I):

$$\dot{m}_1 = \dot{m}_{2,s} = \dot{m}_{act,s} = \dot{m}_r \text{, (14a)}$$

$$\dot{W}_{comp} = \dot{m}_r (h_{2,act} - h_1) \text{, (14b)}$$

$$\dot{E}x_{dest,comp} = \dot{m}_r (\psi_1 - \psi_{2,act}) + \dot{W}_{comp,elec} \text{, (14c)}$$

$$\varepsilon_{comp} = \frac{\dot{E}x_{2,act} - \dot{E}x_1}{\dot{W}_{comp,elec}} \text{, (14d)}$$

where heat interactions with the environment are neglected.

Condenser (II):

$$\dot{m}_2 = \dot{m}_3 = \dot{m}_r \text{, (15a)}$$

$$\dot{m}_7 = \dot{m}_8 = \dot{m}_w \text{, (15b)}$$

$$\dot{Q}_{cond} = \dot{m}_r (h_{2,act} - h_3) \text{, (15c)}$$

$$\dot{Q}_{cond} = \dot{m}_w C_{p,w} (T_8 - T_7) \text{, (15d)}$$

$$\dot{E}x_{dest,cond} = \dot{m}_r (\psi_{2,act} - \psi_3) + \dot{m}_{w,fh} (\psi_7 - \psi_8) \text{, (15e)}$$

$$\varepsilon_{cond} = \frac{\dot{E}x_8 - \dot{E}x_7}{\dot{E}x_{2,act} - \dot{E}x_3} = \frac{\dot{m}_w (\psi_8 - \psi_7)}{\dot{m}_r (\psi_{2,act} - \psi_3)} \text{, (15f)}$$

Expansion (throttling) valve (III):

$$\dot{m}_3 = \dot{m}_4 = \dot{m}_r \text{, (16a)}$$

$$h_3 = h_4 \text{, (16b)}$$

$$\dot{E}x_{dest,exp} = \dot{m}_r (\psi_3 - \psi_4) \text{, (16c)}$$

$$\varepsilon_{exp} = \frac{\dot{E}x_4}{\dot{E}x_3} = \frac{\psi_4}{\psi_3} \text{, (16d)}$$

Evaporator (IV):

$$\dot{m}_4 = \dot{m}_1 = \dot{m}_r \text{, (17a)}$$

$$\dot{m}_5 = \dot{m}_6 = \dot{m}_{air} \text{, (17b)}$$

$$\dot{Q}_{evap} = \dot{m}_r (h_1 - h_4) \text{, (17c)}$$

$$\dot{Q}_{evap} = \dot{m}_{air} C_{air,p} (T_6 - T_5) \text{, (17d)}$$

$$\dot{E}x_{dest,evap} = \dot{m}_r (\psi_4 - \psi_1) + \dot{m}_{air} (\psi_6 - \psi_5) \text{, (17e)}$$

$$\varepsilon_{evap} = \frac{E\dot{x}_6 - E\dot{x}_5}{E\dot{x}_4 - E\dot{x}_1} = \frac{\dot{m}_{w,prt9} (\psi_6 - \psi_5)}{\dot{m}_r (\psi_4 - \psi_1)} \text{, (17f)}$$

Heat exchanger for engine cooling water recovery (V):

$$\dot{m}_9 = \dot{m}_{10} = \dot{m}_{recovery,w} \text{, (18a)}$$

$$\dot{m}_{15} = \dot{m}_{16} = \dot{m}_{cooling,w} \text{, (18b)}$$

$$\dot{Q}_{cooling,w} = \dot{m}_{cooling,w} (h_{15} - h_{16}) \text{, (18c)}$$

$$\dot{Q}_{recovery,w,I} = \dot{m}_{recovery,w} C_{recovery,w,,p} (T_{10} - T_9), \text{ (18d)}$$

$$\dot{E}x_{dest,engine\ cooling} = \dot{m}_{cooling,w} (\psi_{15} - \psi_{16}) + \dot{m}_{recovery,w} (\psi_9 - \psi_{10}), \text{ (18e)}$$

$$\varepsilon_{HE,cooling,w} = \frac{E\dot{x}_{10} - E\dot{x}_9}{E\dot{x}_{15} - E\dot{x}_{16}} = \frac{\dot{m}_{recovery,w} (\psi_{10} - \psi_9)}{\dot{m}_{cooling,w} (\psi_{15} - \psi_{16})}, \text{ (18f)}$$

Heat exchanger for exhaust recovery (VI):

$$\dot{m}_{10} = \dot{m}_{11} = \dot{m}_{recovery,w}, \text{ (19a)}$$

$$\dot{m}_{12} = \dot{m}_{13} = \dot{m}_{exhaust,gas}, \text{ (19b)}$$

$$\dot{Q}_{exhaust,gas} = \dot{m}_{exhaust,gas} (h_{12} - h_{13}), \text{ (19c)}$$

$$\dot{Q}_{recovery,w,II} = \dot{m}_{recovery,w} C_{recovery,w,,p} (T_{11} - T_{10}), \text{ (19d)}$$

$$\dot{E}x_{dest,engine\ exhaust} = \dot{m}_{exhaust\ gas} (\psi_{12} - \psi_{13}) + \dot{m}_{recovery,w} (\psi_{10} - \psi_{11}), \text{ (19e)}$$

$$\varepsilon_{HE,exhaust\ gas} = \frac{E\dot{x}_{11} - E\dot{x}_{10}}{E\dot{x}_{12} - E\dot{x}_{13}} = \frac{\dot{m}_{recovery,w} (\psi_{11} - \psi_{10})}{\dot{m}_{exhaust\ gas} (\psi_{12} - \psi_{13})}, \text{ (19f)}$$

Circulating pump (VII):

$$\dot{m}_{14} = \dot{m}_{15s} = \dot{m}_{15,act} = \dot{m}_{cooling,w}, \text{ (20a)}$$

$$\dot{W}_{pump} = \dot{m}_{cooling,w} (h_{15,act} - h_{14}), \text{ (20b)}$$

$$\dot{E}x_{dest,pump} = \dot{m}_{cooling,w} (\psi_{14} - \psi_{15}) + \dot{W}_{pump,elec}, \text{ (20c)}$$

$$\dot{W}_{pump,elec} = \dot{W}_{pump} / (\eta_{pump,elec} \eta_{pump,mech}), \text{ (20d)}$$

$$\varepsilon_{pump} = \frac{\dot{E}x_{15} - \dot{E}x_{14}}{\dot{W}_{pump,elec}} = \frac{\dot{m}_{cooling,w} (\psi_{15} - \psi_{14})}{\dot{W}_{pump,elec}}, \text{ (20e)}$$

Relative irreversibility is given by:

$$RI = \frac{\dot{E}x_i}{\dot{E}x_{total}}, \text{ (21)}$$

DISCUSSION

The system considered could not be evaluated using numeric values in terms of energetic and exergetic aspects since they were not available in Ref. [6]. However, the following assessments may be done: Since compressor power depends strongly on the inlet and outlet pressures, any heat exchanger improvements that reduce the temperature difference will reduce compressor power by bringing the condensing and evaporating temperatures closer together. From a design standpoint, compressor irreversibility can be reduced independently. Recent advances in the market have led to the use of scroll compressors. Irreversibilities in heat exchangers (i.e., evaporator, condenser and heat recovery components) occur due to the temperature differences between the two heat exchanger fluids, pressure losses, flow imbalances and heat transfer with the environment. The irreversibility associated with the expansion valve (capillary tube) due to the pressure drop of the refrigerant passing through it.

The only way to eliminate the throttling loss is to replace the capillary tube with an isentropic turbine (an isentropic expander) and to recover some shaft work from the pressure drop.

SUMMARY

This paper assesses the efficiencies and properties of an electric power heat pump (EPHP) system running in dynamic and stable conditions in the heating state with exergy analysis and the whole heating system **C**oefficient **O**f **P**erformance (HS COP). It compares and analyzes the differences of the HS COP, the normal COP of the EPHP set, and exergy loss and exergy efficiency between the stable and the dynamic conditions. With the mathematic models and a case study, it shows that when the devices of the EPHP work in the range of durable strengths, the normal COP of the EPHP set in the dynamic condition is higher than the other one's. It also shows that the HS COP in the dynamic condition, especially the temperature at the evaporator changes with the lower source (or environment) temperature in the EPHP heating system, is higher than the stable one, and it save more energy too.

INTRODUCTION

Generally an EPHP system often runs in stable state. The inlet and outlet temperatures at the condenser and the evaporator are often made steady in engineering [1]. The heating load changes frequently because of the outdoor temperature and lower-level source temperature. So the EPHP works in the part-load conditions. Then whether the running EPHP system benefits in saving energy?

To diagnose an EPHP performance generally uses the first law of thermodynamics. In the other words, **E**ffective **E**nergy **R**ate (EER) and **C**oefficient **O**f **P**erformance (COP) are often taken as standards. However, the whole heating system (HS) can not only use them as judgments. Exergy analysis bases on the first and second laws of thermodynamics [2]. It can analyze energy use from “quality” and “quantity”. And it can reveal how energy has been use and lost. Therefore, exergy analysis points the economic way on energy and the EPHP performance.

DYNAMIC MATHEMATICAL MODEL OF "EPHP" HEATING SYSTEM

Mathematical model of building heating load

The method of calculating the building heating load of the experiment house is simple-stable-state one. The actual heating load $Q_{k,\,j}$ depends on the temperature difference between the indoor and the outdoor. When the indoor temperature keeps 18 ℃, the actual building heating load is related to the outdoor temperature. Therefore, the building heating load can be expressed as:

$$Q_{k,j} = KF(18 - t_w) \quad \text{kW}, \qquad (1)$$

Normal COP mathematical model of a EPHP set

The EPHP COP is defined as:

$$COP_{EPHP} = Q_k / N, \qquad (2)$$

Where Q_k is released heat at the condenser (unit, kW) and N is electrical power input to the compressor (unit, kW). $Q_{k,j} = \xi Q_k$ [3]. ξ is coefficient of heat leak. And it ranges from 0.8 to1. In the paper, ξ is 0.9.

Mathematical model of the HS COP

The HS COP is defined as:

$$COP_{HS} = Q_{k,j} / (N + N_{con} + N_{ev}), \qquad (3)$$

Where N_{con}, N_{ev} are the electrical power inputs to hot water pumps (HWP) at the condenser and the sea water pumps (SWP) at the evaporator, unit, kW.

Electrical power input to the pump model [4] is given by

$$N = \rho GH / 102\eta_{se}, \qquad (4)$$

Where ρ is density of water (kg/ m^3), G is mass flow rate (kg/s), H is lift (m) and η_{se} is pump efficiency. In the paper, density of water is 1×10^3 kg/ m^3; density of sea water is 2.2×10^3 kg/ m^3; HWPs and SWPs lifts are 32m and15m, respectively; HWPs efficiency is 0.78. SWPs efficiency is 0.7.

MATHEMATICAL MODEL OF EXERGY ANALYSIS

Exergy analysis bases on the law of conservation of mass, the law of the energy equilibrium, and the second law of thermodynamics.

Exergy analysis of EPHP set

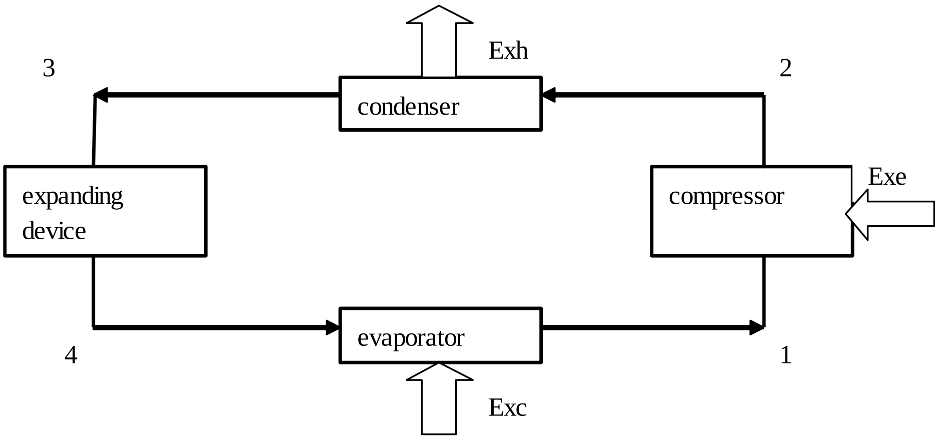

Fig.1. Schematic of an EPHP

Fig.1 Shows an EPHP. The number of the available energy (exergy) entered is equal to the total of the exergy exited and the exergy lost in the system [5].

$$E_{xe} + E_{xc} = E_{xh} + E_{xl} \, , \qquad (5)$$

Where E_{xe}, E_{xc}, and E_{xh} denote exergy at the compressor, the evaporator, and the condenser, respectively; E_{xl} is exergy loss at the EPHP.

When the EPHP works in the heating state, the exergy efficiency (η_{ex1}) is given by

$$\eta_{ex1} = E_{xh} / E_{xe} \, , \qquad (6)$$

Exergy loss of a water pump

When the water flow passes pumps, there are not physical change and chemical change, only raising height. Because pumps consume electrical power on work, exergy loss is same as the electrical power in this process.

For HWPs, exergy loss is $\Delta E_{pc} = N_{con}$.

For SWPs, exergy loss is $\Delta E_{pe} = N_{ev}$.

Exergy analysis in EPHP heating system

The theory is same as exergy analysis in the paper above, the number of the exergy entered is equal to the total of the exergy exited and the exergy lost in an EPHP heating system [6].

$$E_t = E_u + \Delta E \, , \qquad (7)$$

E_t is the total of exergy entered.

$$E_t = N + N_{ev} + N_{con} + Q_{e,j}(1 - \frac{T_0}{T_L}), \qquad (8)$$

Where $Q_{e,j} = \xi Q_e$, ξ is 0.9 in this paper.

E_u is the total exergy used (or exited) in the EPHP heating system.

$$E_u = Q_{k,j}(1 - \frac{T_0}{T_H}), \qquad (9)$$

T_L, T_H are the water average temperatures at the evaporator and the condenser, respectively.

$$T_L = \frac{T'_{w,ev} - T''_{w,ev}}{\ln \frac{T'_{w,ev}}{T''_{w,ev}}}, \qquad (10) \qquad\qquad T_H = \frac{T''_{w,con} - T'_{w,con}}{\ln \frac{T''_{w,con}}{T'_{w,con}}}, \qquad (11)$$

Where $T'_{w,ev}$, $T''_{w,ev}$ are the cold water inlet and outlet temperatures at the evaporator, respectively, $T'_{w,con}$, $T''_{w,con}$ are the hot water inlet and outlet temperatures at the condenser, respectively.

ΔE is the total exergy lost. The rate of exergy loss in the EPHP heating system is given by

$$\eta_{ex2} = \Delta E / E_t, \qquad (12)$$

APPLICATION OF AN EXAMPLE OF MODEL

Assuming the indoor temperature keeps 18℃, the actual heating load is a variable with the outdoor temperature. Using the SOLKANE software calculates the inlet and outlet parameters of the equipment in the EPHP system.

Main conditions in the EPHP running system

The case study chooses a helical-compressor sea water heat pump system (SWHP) (all kinds of the EPHP have the same running theory), uses R22 as refrigerant. The SWHP utilizes the five meters deep sea water as lower-level heat source. The standard working condition of the heat pump is that the condenser releases 879 kW heat; electrical power input to the compressor is 209 kW and energy regulation is stepless from 25% to 100%; the hot water inlet/outlet temperatures at the condenser are 40/45 ℃ and the hot water flow rate is 151 m^3/h; the cold water inlet/outlet temperatures at the evaporator are 9/4 ℃ and the cold water flow rate is 115 m^3/h. In the case, sea water runs into the evaporator directly. The SWP uses the variable frequency pump which maximum flow rate is 200 m^3/h.

Other conditions

The Fig.2 is the meteorological data in Dalian city, China, from 8:00A.M, Jan.1st to 14:00P.M, Jan.10th, 2000 (the time is Beijing time).

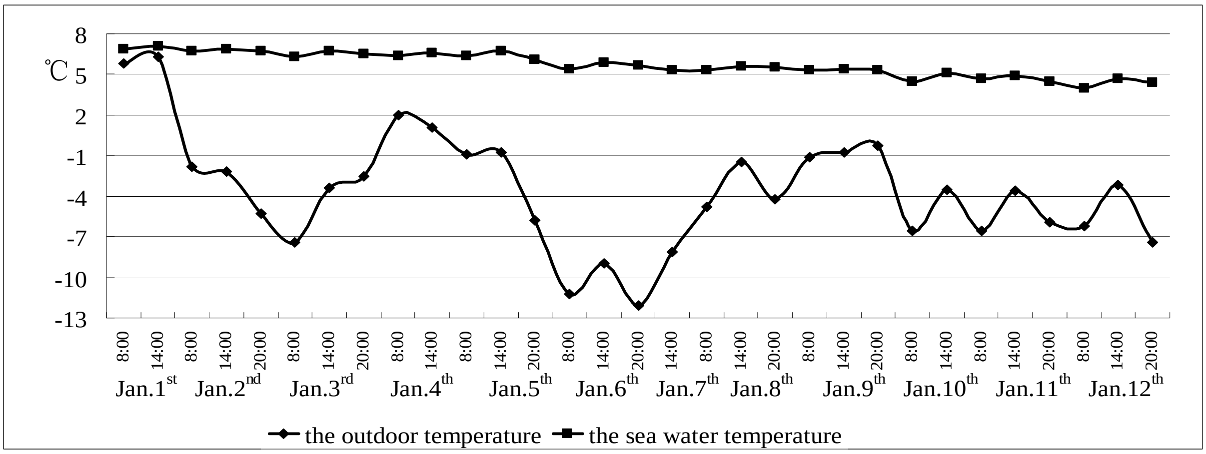

Fig.2 Outdoor air temperature and sea surface water temperatures in Dalian from 8:00A.M Jan.1st to 14:00P.M, Jan.10th, 2000. (The data come from http://www.coi.gov.cn/)

As Fig.2 shows, from 8:00A.M, Jan.1st to14:00P.M Jan.10th, 2000, the outdoor air temperature fluctuated from -12.1 ℃ to 6.3 ℃. The lowest temperature appeared in Jan. 6th. And the sea water temperature fluctuated stably from 4.5 ℃ to 7.1 ℃. Because the sea water temperatures have no difference between the 5 m deep and the sea surface, therefore the sea surface water temperature is used as the sea water temperature in 5m deeps.

Three schemes in the case study

Scheme Ⅰ: the EPHP runs in stable state. Control parameters: the hot water outlet temperature at the condenser is 45 ℃, its flow rate is 150 m^3/h; the cold water outlet temperature at the evaporator is 1.5 ℃.

Scheme Ⅱ: the EPHP runs in dynamic state. Control parameters: the hot water outlet temperature at the condenser is 45 ℃, its flow rate is 150 m^3/h; the cold water flow rate at the evaporator is 200 m^3/h.

Scheme Ⅲ: the EPHP runs in dynamic state. Control parameters: the hot water outlet temperature at the condenser is 45 ℃, its flow rate is 150 m^3/h; the difference temperature between the outlet and the inlet cold water at the evaporator is given by 4 ℃.

RESULTS AND DISCUSSION

Normal Comparison of three schemes

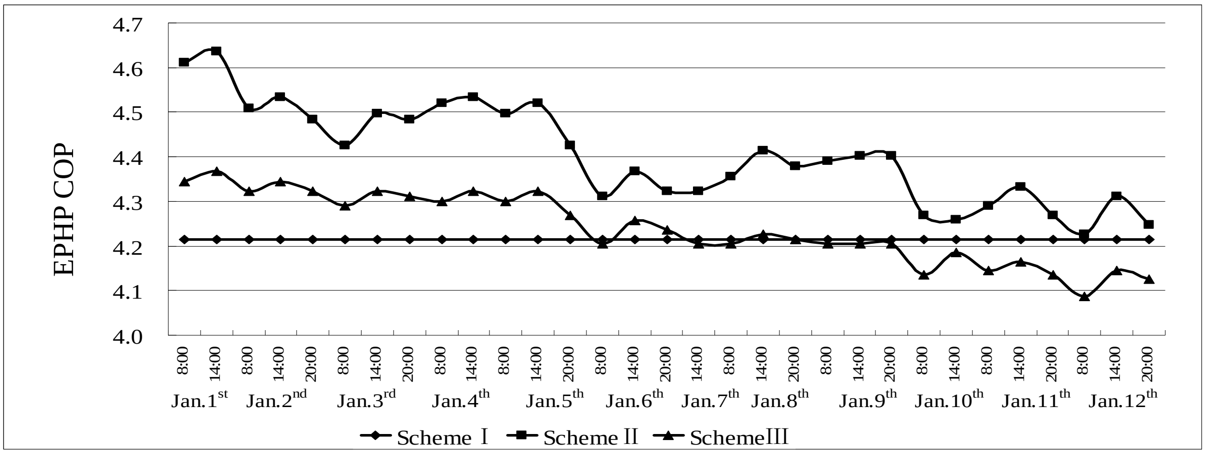

Fig.3. Comparison of normal COPs of three schemes

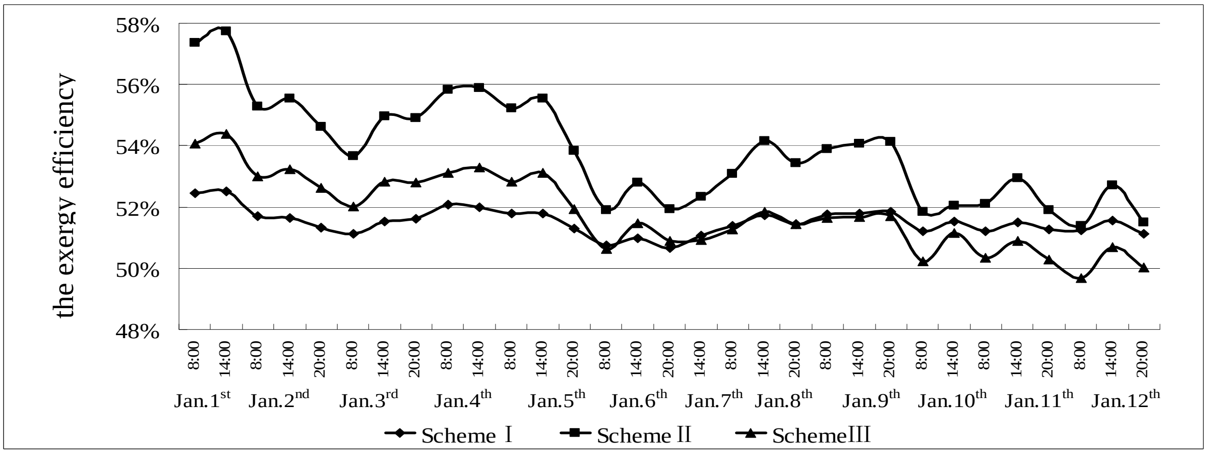

Fig.4. comparison of normal exergy efficiency of three schemes

From fig.3, when the EPHP worked in the way of schemeⅡ, COP, working efficiency, is greater than the others on majority conditions, and the exergy efficiency of schemeⅡ is the best, so obviously the schemeⅡ is the best. The fig.4 shows, for long-term working efficiency and saving energy, the normal COP of an EPHP set could be increased in dynamic state. Comparison of schemeⅡ and schemeⅢ indicates that the normal COP of an EPHP set can be improved better by reducing the heat exchange temperature difference and increasing the cold water flow rate, and the EPHP could recover more available energy from the lower source and decrease the consumption of the high-level energy source and get better working efficiency.

From Jan.10th to Jan.12th in fig. 4, the exergy efficiency of schemeⅢ is the lowest. When the sea water temperature was lower than 5 ℃ after Jan.10th, the refrigerant temperature within evaporator is the lowest. Therefore, the rate of exergy loss and the EPHP normal COP for schemeⅢ are the lowest. At that time, working and the energy efficiencies are both worse.

System comparison of three schemes

Only the EPHP normal COP is better does not mean that the whole EPHP heating system saves more energy. For saving more energy in the EPHP heating system, other equipment connected to the EPHP set such as pumps and expanse regulator should be considered as whole.

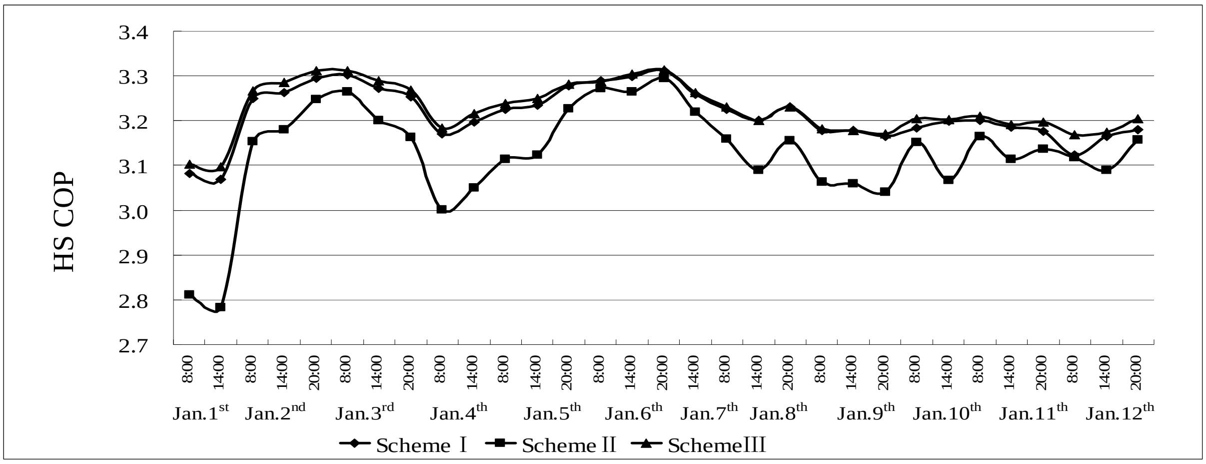

Fig.5. HS COPs Comparison of three schemes

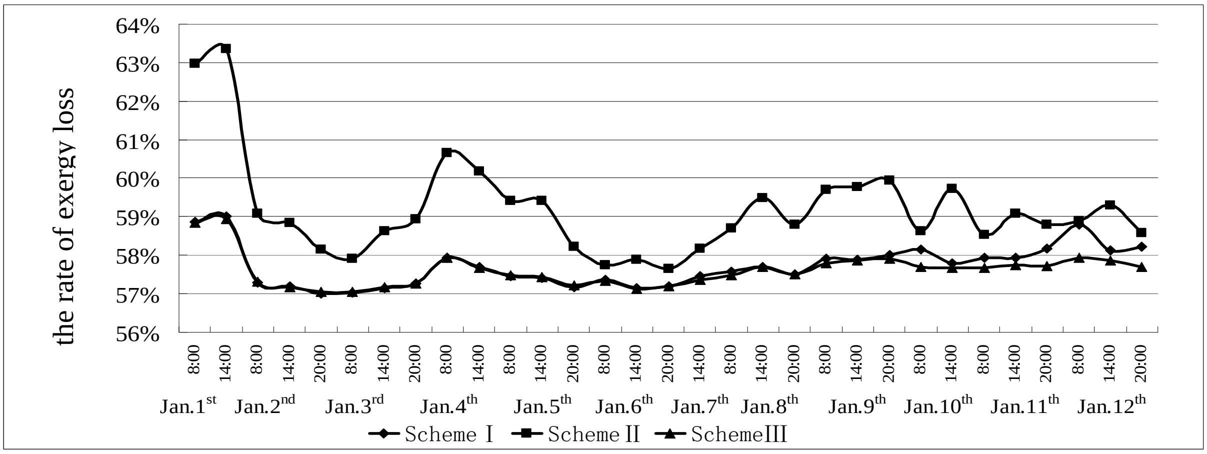

Fig.6. Comparison of the rate of exergy loss of three schemes

From the upper analysis, scheme Ⅱ is the best. However, fig.5 and fig.6 show that the rate of exergy loss of scheme Ⅱ is the highest and its HS COP is the lowest. Although its exergy efficiency of the EPHP set is the greatest, because the cold water flow rate is too much, the exergy loss of the HWP and the SWP are higher. Hence, scheme Ⅱ does not save energy according to the whole EPHP heating system analysis. Therefore fixed cold water flow rate, changed refrigerant temperature with the actual heating load, this kind of scheme does not save energy. It is suggested that engineers should avoid taking the scheme in practical project. In one word, at the same meteorological data, from property comparison of the EPHP set and the EPHP heating system, an EPHP set has the greatest normal COP may not be the best one to check the energy saving and better efficiency when we consider the EPHP set and linked equipment as a whole system. It is suggested that in practical project engineer should not only consider the better normal COP as a standard, sometimes we have to choose lower normal COP in order to save energy of the EPHP heating system and attain an better HS COP.

According to the analysis of the EPHP set, the normal COP and the exergy efficiency of schemeⅢ are the lowest, and it is the worst scheme. However, the HS COP of schemeⅢ is higher than that of schemeⅡ, and the rate of exergy loss in schemeⅢ is lower than in schemeⅡ after Jan.10th. Therefore, according to the analysis of the EPHP heating system, schemeⅢ is the best one. The whole system analysis should be considered to save energy.

From the fig.6, the rate of exergy loss between schemeⅠ and schemeⅢ is very small. It is hard to choose the better one. Hence, it needs to refer to HS COP and the exergy analysis to solve the dilemma. From the fig.5, the HS COP of schemeⅢ is higher than that of schemeⅠ from Jan.1st to Jan.5th and after Jan.10th, so the system could run in dynamic condition. From Jan.6th to Jan.9th, we suggest use the EPHP heating system in stable state because it has advantages in working and management.

CONCLUSION

The paper calculates the energy loss and different normal COP and HS COP results of several EPHP systems running in dynamic and stable conditions.
First, when the devices of the EPHP work in the range of durable strengths, the EPHP COP in the dynamic condition is higher than the other one's. Second, with a case study, it also shows that the HS COP in the dynamic condition, especially the temperature at the evaporator changes with the lower source (or environment) temperature in the HS, is higher than the stable one, and it save more energy too. Finally, using HS COP and the exergy analysis can point out the ways that save energy and improve working efficiency.

SUMMARY

The purpose of this study was to reduce the energy consumption of an industrial air-conditioning system. The energy conservation of an air-conditioning system that supplies low dew point air was investigated and validated experimentally. The consumption of energy was reduced by introducing a heat pump for both heating and cooling of the air at the same time. The authors studied working fluid that is suitable for the heat pump and found that R744 (CO_2) has higher heating performance than R410A and R22. A simulation of the system with a CO_2 heat pump was found to reduce energy consumption by 8.2% at peak conditions and 13.2% at intermediate conditions. The authors also developed a pilot plant that combines dehumidifier and heat pump cycle, and the experimental results indicated a 6.5% energy reduction at peak conditions and a 10.2% reduction at intermediate conditions.

INTRODUCTION

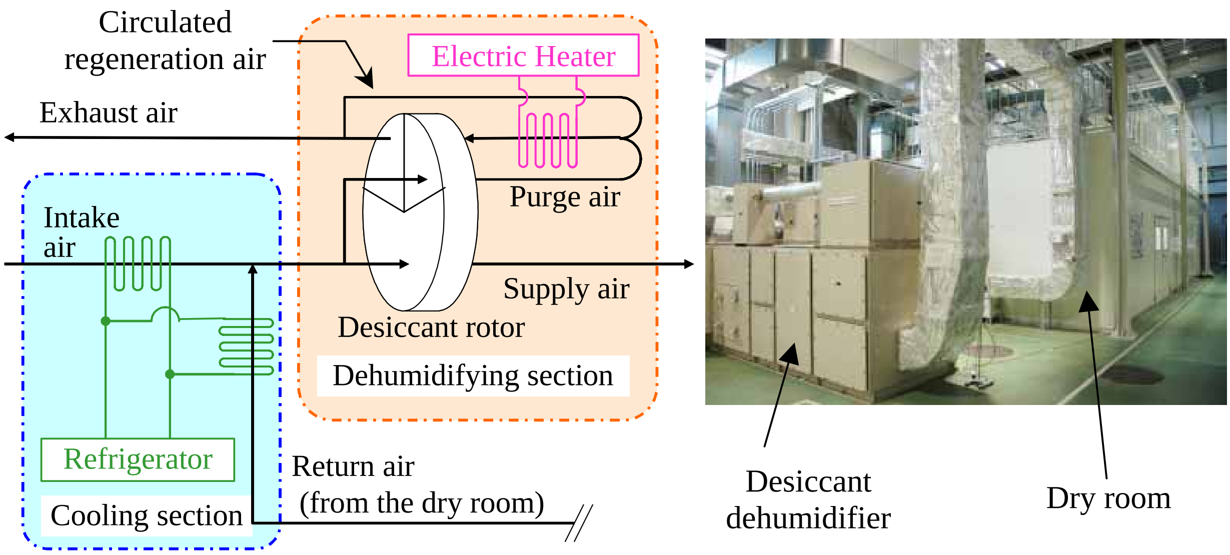
Dry rooms are used when producing electrical and chemical appliances, such as lithium-ion batteries and organic electro luminescence devices. This production process requires extremely low humidity with a dew point of approximately -60 °C. A desiccant dehumidifier is usually used for dry rooms. To provide such dry air, the desiccant must be heated to a higher temperature than a general system. This system requires that the air for the desiccant rotor be heated to over 140°C. Therefore, a lot of electricity is needed for heating the air. This system also has an air-cooling process for intake air and return air from the dry room.

Several studies have been made on the energy conservation of the desiccant air-conditioning system, and some of them have focused on applying a heat pump to both heat and cool the air. Tsay et al. studied the applicability of combining the desiccant cooling system with a heat pump and estimated the system performance [1]. Kato et al. studied the performance of a CO_2 heat pump (CO_2 -HP) with a desiccant air-conditioning system for general air conditioning system [2]. They calculated the behavior of the system and showed a substantial increase in energy efficiency.

In this paper, the authors describe a computer simulation that was carried out to increase the energy saving performance of a desiccant dehumidifier combined with a heat pump. The construction of this system is different from Kato’s one because of the difference of the target humidity. Furthermore, a pilot plant consisting of a CO_2 -HP unit installed with a desiccant dehumidifier was developed. The performance of this system was validated experimentally.

DESICCANT DEHUMIDIFIER FOR A DRY ROOM

Figure 1 shows the basic construction of a conventional air-conditioning system for a dry room and a photograph of a desiccant dehumidifier with a dry room. This system consists of cooling dehumidifying sections. In the cooling section, a refrigerator chills intake air and return air from the dry room. A portion of the moisture in the intake air is removed via the drain. In the dehumidifying section, a desiccant rotor removes the water from the air that was sent from the cooling section and supplies the dry room with the air.



a) b)

Figure 1. Conventional air-conditioning system. a) Basic construction, b) Photograph of system.

This desiccant rotor has three zones, i.e., a dehumidification zone, regeneration zone, and purge zone. In the dehumidification zone, the remaining moisture in the air from the cooling section is removed, and the dew point of the air becomes approximately -60°C. This dry air is then supplied to the dry room. In the regeneration zone, the moisture of the rotor is removed by regeneration air, and a part of this air is circulated to join the purge air at the inlet of an electric heater. The rest of the air is discharged as exhaust air. To make the supply air sufficiently dry, the temperature of the air at the inlet of the regeneration zone must be over 140°C. In the purge zone, the regenerated rotor is cooled by purge air, which is a portion of the air from the cooling section. After cooling the rotor, the purge air is mixed with the circulated regeneration air and heated electrically.

A breakdown of energy consumption of the conventional system appears in figure 2. The electric heater and refrigerator consume a large part of the whole energy, especially during peak conditions. We can see from figure 2b) that the energy reduction of the electric heater is important for this system's energy conservation. To reduce the energy consumed at the heater, the authors focused on applying a heat pump that produces sufficiently high temperature. The characteristics and possibilities of a heat pump cycle and a combined system of a desiccant dehumidifier were then investigated.

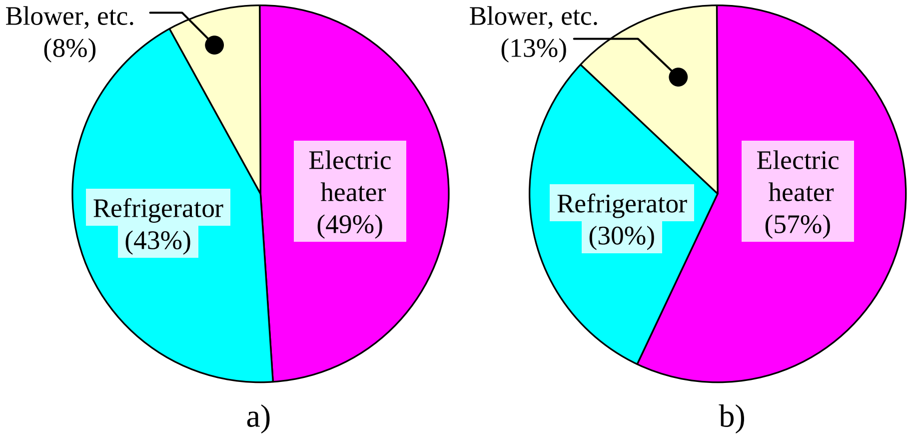


Figure 2. Breakdown of energy consumption of conventional system.
a) Peak (summer) conditions, b) Annual average.

WORKING FLUID OF THE HEAT PUMP

Selecting the working fluid is an important factor for the heat pumps. However, few studies have addressed this matter from the viewpoint of applying heat pumps to a desiccant dehumidifier. Hence, the authors focused on the development of a pilot plant and experimental work. Three kinds of working fluid, which are available on the market, were selected and compared.

Figure 3 shows the theoretical heat pump cycle of each working fluid in a T-h diagram. R410A (R32/R125=50/50 wt%) is presently used in many types of air conditioners. R744 (CO_2: carbon dioxide) was applied for heat-pump water heaters by Endoh et al. [3]. These two fluids were assumed to be available for the target system. Additionally, R22 ($CHClF_2$) was evaluated as a reference. The calculating assumptions shown in table 1 are based on the operating points of the peak conditions.

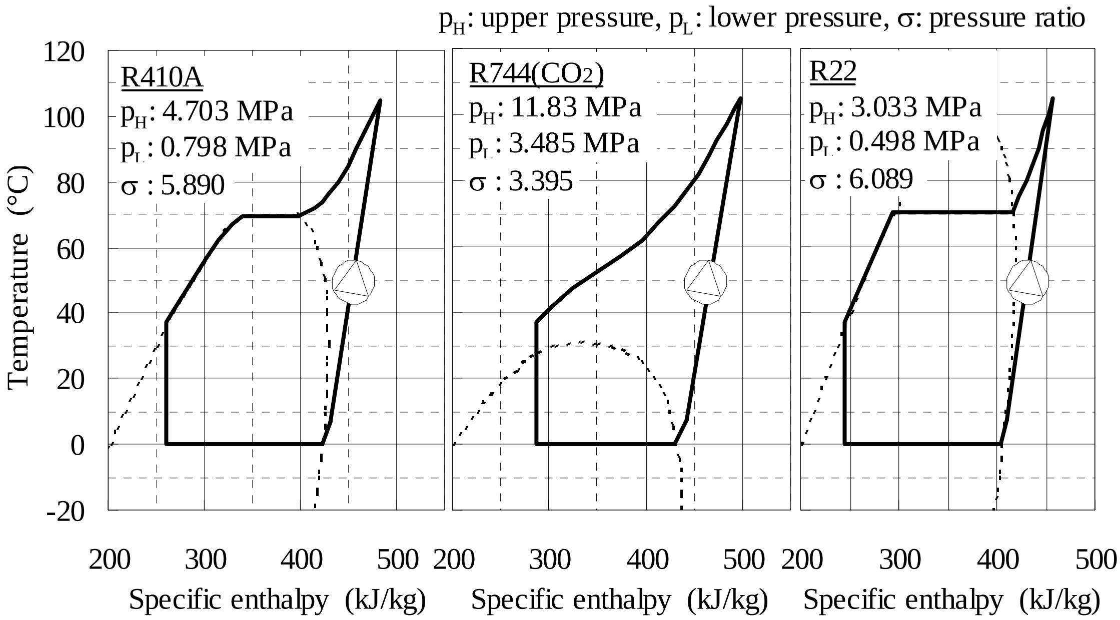

Figure 3. T-h diagram of each working fluid.

The temperature of the inlet air of the electric heater is considerably higher than the ambient air. Consequently, working fluid should have a higher heating capacity in the high temperature domain. That is, in figure 3, the decrease in specific enthalpy after the air was discharged from the compressor outlet (highest point of the T-h diagram) should be big. From this point, R410A and CO_2 have better characteristics than R22 because their shapes in the T-h diagram are not as steep as R22 after the outlet of the compressors.

Table 1. Calculating assumptions of figure 3

Compressor outlet	105°C
Evaporator	0°C
Superheat at the evaporator	7°C
Condenser outlet	37°C

This comparison is represented in figure 4. R22 has the highest value in the theoretical COP (coefficient of performance) of cooling, and the cooling performance of CO_2 is lower than that of the other two substances. The other three characteristics were calculated from the heating capacity when the temperature of the working fluid decreased from 105°C to 75°C. The theoretical COP of heating of CO_2 is obviously better than that of R22 and R410A. These results agree with the aforementioned ones for figure 3.

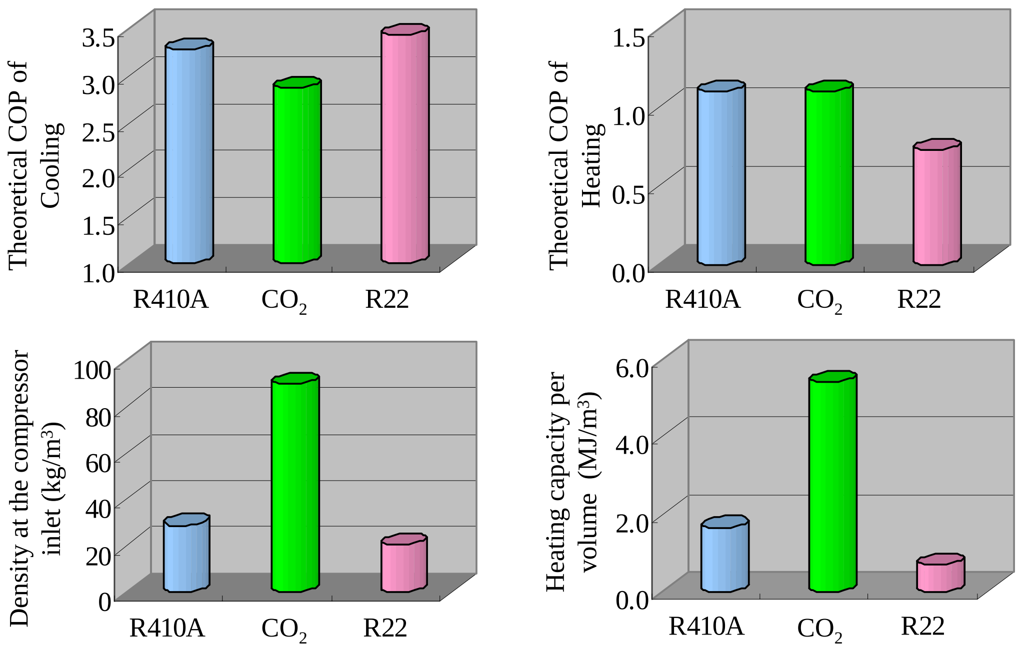

Figure 4. Comparison of working fluids by performance and heating capacity*
(When temperature of working fluid decreases from 105°C to75 °C)

The lower two bar charts present the density of the working fluids and the heating capacity per volume at the inlet of the compressor. The density of CO_2 is considerably higher than that of R410A and R22. This makes the heating capacity of CO_2 more than three times that of R410A and seven times that of R22. This means that CO_2 can miniaturize the components, in particular, the compressor.

The authors selected CO_2 as the working fluid for the heat pump of this system on the basis of these results, namely from the viewpoint of energy saving and practicality. The low global warming potential (GWP) of CO_2 was also taken into consideration.

SYSTEM DESIGN AND COMPUTER SIMULATION

Figure 5 shows the new air conditioning system for the dry room. This system mainly consists of a desiccant rotor, a CO_2-HP, an electric heater, and a refrigerator. The CO_2 -HP is used for both heating regenerating air and cooling return air.

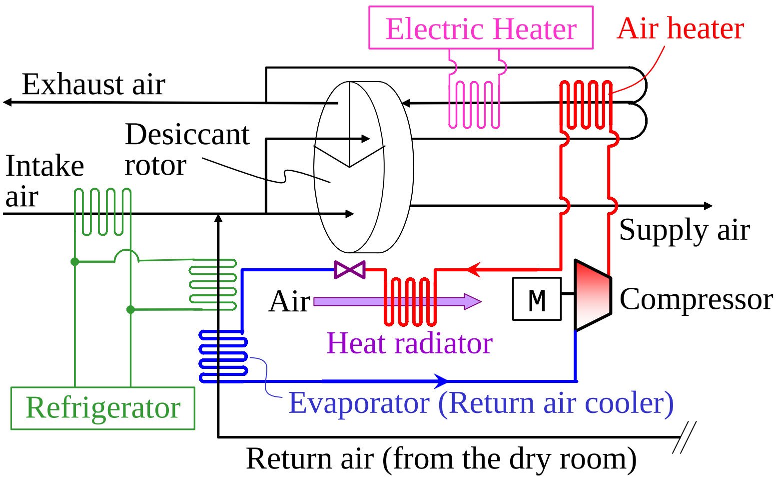

Figure 5. Air conditioning system with desiccant dehumidifier and CO_2-HP.

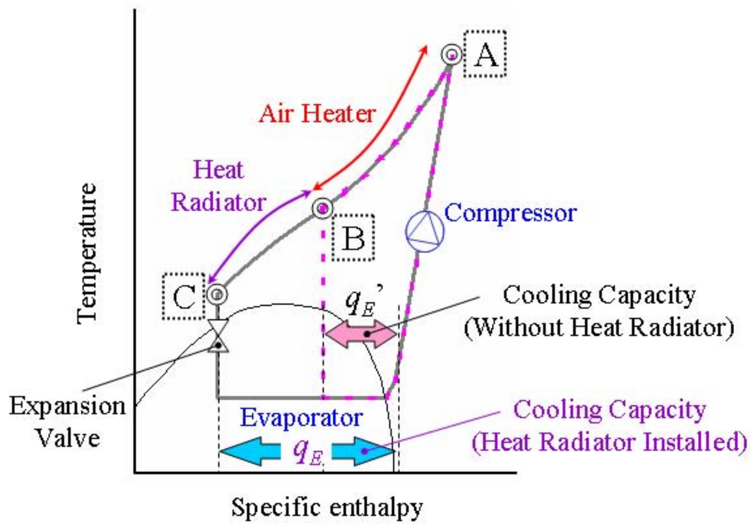

Figure 6. T-s diagram of CO_2 heat pump cycle and effects of adding heat radiator.

A heat radiator is shown in figure 5. It turns on during the cycle to boost the cooling capacity at the evaporator. The effects of the heat radiator can be explained as follows using figure 6. State "A" is the outlet of the compressor. The temperature of the inlet air of the air heater is considerably higher than that of the ambient air. Therefore, if you do not use the heat radiator, the working fluid of state "B" goes directly to the expansion valve. In this case, the cooling capacity would be only "q_E'", which is shown in figure 6. If you put the heat radiator into the heat pump cycle in the position it is in figure 5, the working fluid is cooled by ambient air. Then the inlet state of the expansion valve is state "C". In this case, the cooling capacity is "q_E", which is shown in figure 6.

A computer simulation of the system shown in figure 5 was performed and compared with the conventional system. This simulation was based on the performance data of an actual compressor and heat exchangers of a heat-pump water heater using CO_2 as the working fluid [3]. The ambient temperature was assumed to be 32.0°C at peak conditions and 19.0°C at intermediate conditions, and the return air temperature was assumed to be 25.0°C. The results are in figure 7. The new system, compared with the conventional system, reduced energy consumption by 8.2% at peak conditions and 13.0% at intermediate conditions.

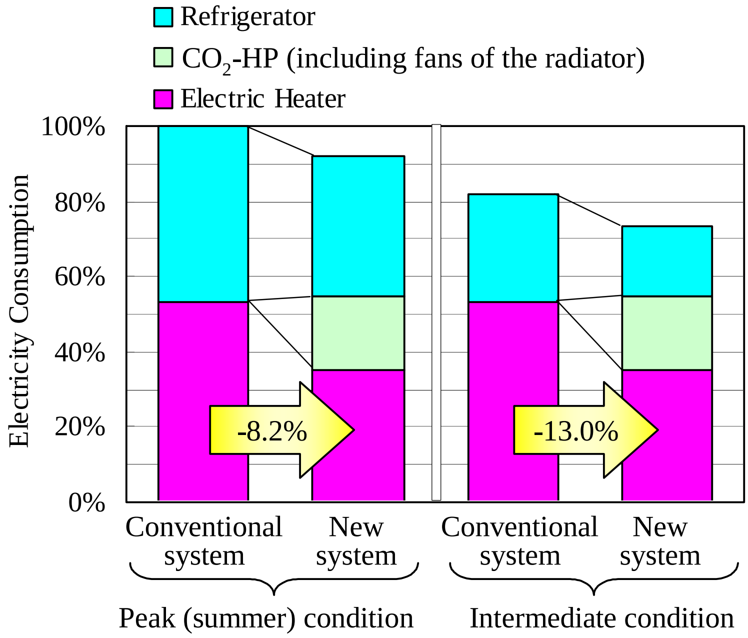

Figure 7. Simulation results of adopting CO_2-HP.

EXPERIMENTAL EVALUATION

A pilot plant, shown in figure 8, was developed by installing the CO_2-HP into a conventional system. This plant can supply 3,000 m^3/h of dry air with a -60°C dew point. The desiccant rotor is 965 mm in diameter and is 400 mm thick. The radiator unit is separated from the desiccant dehumidifier because it will be an outdoor unit when installed for actual use. Figure 9 shows a frontal view of the radiator unit as well as a sectional view of a compressor used in this system.

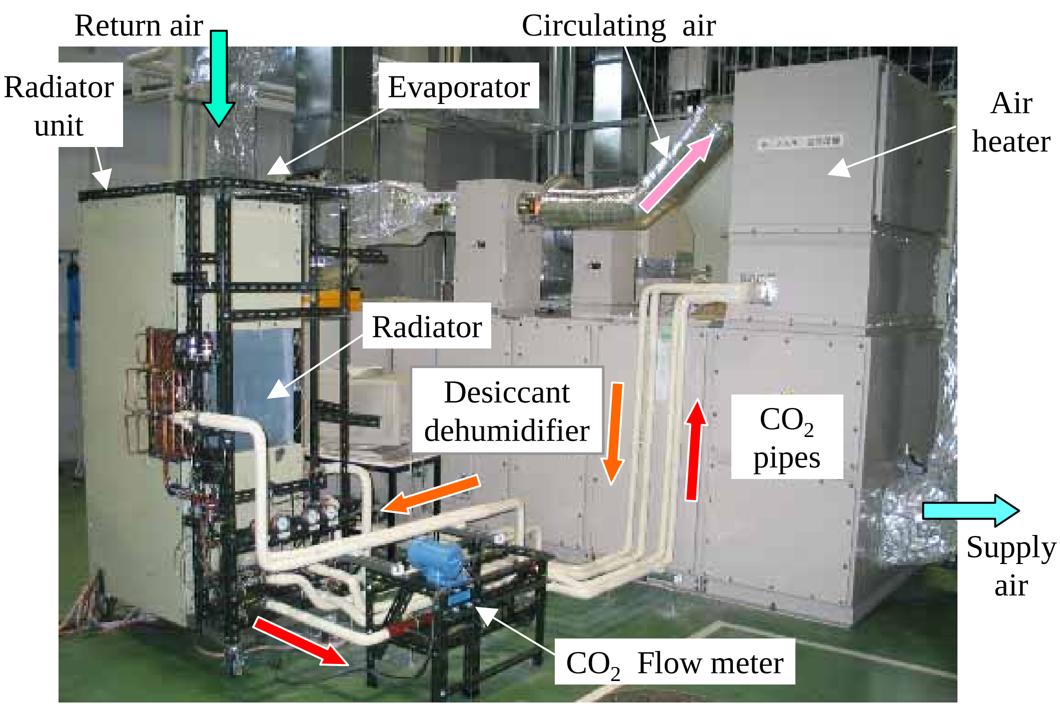

Figure 8. Pilot plant of the system with construction of figure 5.

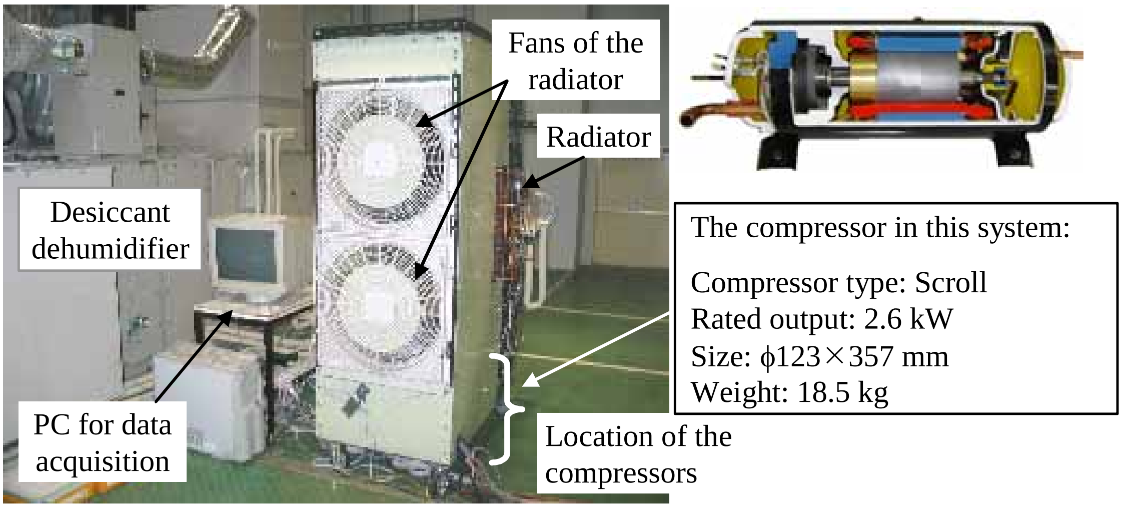

Figure 9. Front view of radiator unit and sectional view of compressor.

The heat pump has two scroll compressors located at the bottom of the radiator unit. They were developed by Endoh et al. [3] and manufactured for CO_2 heat pump water heaters. The specifications of this compressor are also in figure 9. The radiator and evaporator are in the form of a fin-tube heat exchanger.

The experiments were carried out with the same conditions as the aforementioned computer simulation. The results are shown in figure 10. Electricity consumption was reduced by 6.5% at peak conditions and 10.2% at intermediate conditions. Table 2 summarizes the operating conditions of the experiments. The dehumidification obtained at each condition as well as the energy savings were excellent.

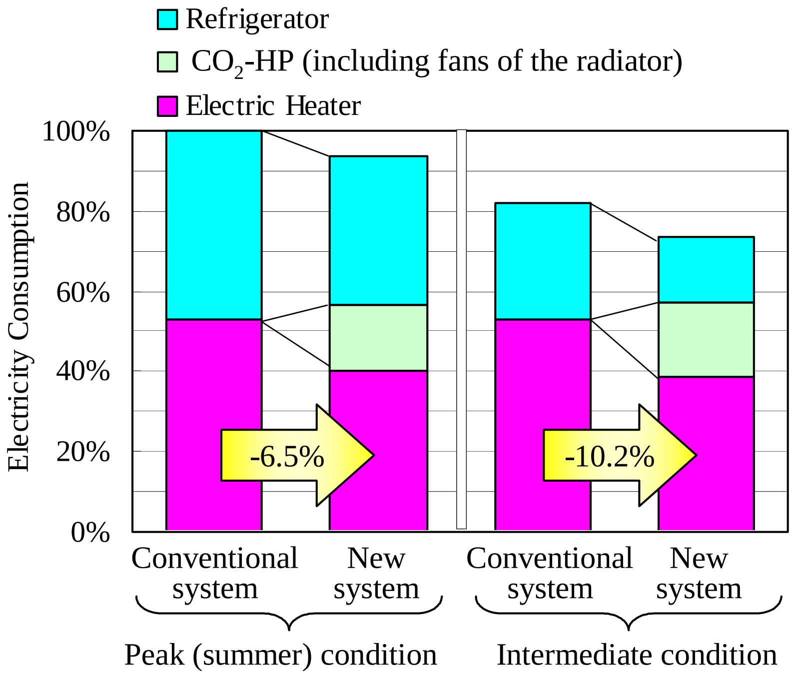

Figure 10. Experimental evaluation of new system.

Table 2. Operating conditions of experiments.

Operating condition		Peak	Intermediate
Ambient air temperature		32.0°C	19.0°C
Return air	Temperature	25.2°C	19.1°C
	Volume flow rate	100%	75.5%
Supply air	Dew point temperature	-60.2°C	-60.4°C
	Volume flow rate	2,946 m^3/h	3,254 m^3/h

DISCUSSION

Combining a heat pump cycle with a desiccant dehumidifier was found to be a practical application of the air-conditioning system for a dry room. The experimental results of the pilot plant demonstrated this. The authors compared CO_2 with R410A and R22 for the working fluid of the heat pump and selected CO_2 because of its superior heating performance and because of environmental issues. The practicality of this system is supported by the fact that the components of a CO_2-HP are already available as the components of a heat pump water heater that uses CO_2 as the working fluid [3].

However, this system can be further optimized. In particular, the matching of the desiccant dehumidifier and CO_2-HP needs further improvement. The heating capacity and evaporating temperature of the CO_2-HP, heat exchanger arrangement, and other aspects are other areas that can be improved. Various applications of the heat pump cycle are being developed, and the performance of compressors and heat exchangers are improving as a result. This study will lead us to applying these technologies of this system and optimizing it.

ACKNOWLEDGEMENT

The authors wish to thank Hitachi Appliances, Inc., in particular the chief engineer, Mr. Masahiko Gommori, for his advice and technical support in the field of CO_2 heat pump applications.

SUMMARY

Based on the weather and groundwater conditions in central China, a computer code has been developed to simulate a residential water-to-water heat pump water heater (HPWH) which practices CO_2 transcrtical cycle; such a modeling is carried out in Engineering Equation Solver (EES). Under the design conditions, the inlet heat source(groundwater) temperature of 17℃,the evaporation temperature of 7℃,the inlet hot water temperature of 17℃,the outlet hot water temperature of 65℃, the compressor power at 3000W, a heating COP of 3.2 is achieved and the optimum high-side pressure is controlled below 8.5MPa which benefits manufacturing materials and operation a lot. The calculation results show that system with internal heat exchanger(IHE) has a 18% increase in COP. Effects of operating parameters on system performance,such as, inlet temperature of heat source, inlet temperature of hot water, compressor speed are also discussed. Compared with the conventional electrical or natural gas fired systems which are now very commonly used in urban districts in China, such HPWH with CO_2 as refrigerant is much more efficient ,energy-saving and correspondingly promising. The simulation results are found to be in reasonable agreements with simulation or experimental results published in the open literature, and offer useful guidelines for prototype design, experiments, and system optimization.

INTRODUCTION

The history of CO_2 commonly used as a refrigerant dates back to the late 1800s. Compared with other natural refrigerants in common use like ammonia, propane, CO_2 is completely harmless. Owing to its non-flammability, non-toxicity even if leaked to the atmosphere, CO_2 was once broadly applied to ships, the kind of unstationary fields. With the technology of the day,the lower critical temperature(31.1℃) and the higher critical pressure(7.37Mpa), CO_2 system had a lower refrigeration efficiency. Additionally, seawater,as the cooling water to evaporator, especially in the tropics approached its temperature to 30℃,therefore further reduced the efficiency of the subcritical refrigeration system, which greatly limited application fields of CO_2. The successfully developed Freons in 1930s suddenly terminated the use of CO_2 as a safe refrigerant. Interestingly, after the CFCs, HCFCs and HFCs were proved to be harmful on atmosphere in different degrees and banned by international agreements, CO_2 revived in refrigeration and heat pump applications. The pioneer researchers, late Professor Gustav Lorentzen looked early upon natural working fluids as the best replacements for the CFCs/HCFCs[1]. In 1992, He [2] and J. Pettersen firstly

proposed the concept ,transcritical cycle where a single-phase gas cooler replaced the traditional two-phase condenser . They considered CO_2 strongly suitable to HPHW because a higher temperature glide at heat rejection in gas cooler is readily available. Petter Neksa et al. [3] have carried out experimental studies on a CO_2 HPWH.Over the past decade,several research groups in Norway,America,Japan,Korea,India,China etc. have made extensive studies on HPWH. In particular,Japan now sells several hundreds thousand CO_2 HPWHs per year. In china, CO_2 application is still in experimental stage.CO_2 also has other unique advantages: compactness due to high operating pressures and accordingly low specific volume, excellent transport properties. The good characteristics make it much fitter for automobile air conditioning which values highly the volume of refrigeration unit[2][4-5].

In order to push the CO_2 application, theoretical system simulation work based on the modern developed computer science plays an important role, providing the true experiment with more guidance, accuracy and economization. But theoretical system simulation on CO_2 is scare in literature.[6] simulated CO_2 mobile air conditioning system.[7] performed simulation studies of CO_2 transcritcal cycle system with air as secondary fluid.[8]reported an simulation of air-to-air air conditioners and heat pumps. A theoretical and experimental study was carried out for a residential brine-to-water CO_2 heat pump system for combined space heating and hot water heating by [9].[10] developed a steady state water-to-water simulation model to evaluate the system performance of a transcritical CO_2 heat pump for simultaneous heating and cooling .Such a system is suitable in diary plants where simultaneous cooling at 4.8℃ and heating at 73.8℃ are required. In the present research, counter flow, pipe-in-pipe heat exchangers are chosen as the configuration of the heat exchangers. After analyzing and comparing in details, the appropriate heat transfer and pressure drop correlations have been used as presented below. According to the present groundwater conditions in central China, it’s such a energy-saving method to use groundwater as the heat source to evaporator, especially in North China where outdoor air at lower temperature is not suitable for low temperature heat source.Under the design conditions,meanwhile considering the national water heater standards, a water-to-water CO_2 transcritical system was designed and simulated to assess the COP, heating capacity, optimum discharge pressure. Effects of operating parameters such as, inlet temperature of heat source, inlet temperature of hot water, compressor speed are also discussed. The simulation models are developed on the following assumptions: compression process is adiabatic but not isentropic; expansion process is isenthalpic; pressure drop on water and connecting pipes, heat transfer with the ambient are negligible; only single-phase heat transfer occurs for both heat source and hot water. The simulation results are expected to offer useful guidelines for prototype design, experiments, and system optimization.

METHODS

Design

As shown in Fig.1, a one-stage CO_2 heat pump water heating system contains four main components and IHE. The corresponding T-s diagram is illustrated in Fig 2.Groundwater at 17℃ is fed as the heat source to the evaporator while city water at 17℃ is supplied as the fluid to gas cooler. Based on the national water heater standards, the hot water temperature at the outlet to gas cooler is controlled at 65℃.Both the heat exchangers are characterized of pipe-in-pipe counter flow type with working fluid in the inner tube and water in the outer annular channel. In the pipe-in-pipe counter flow IHE, hot CO_2 flows through the inner tube and cold CO_2 passes through the outer annular.

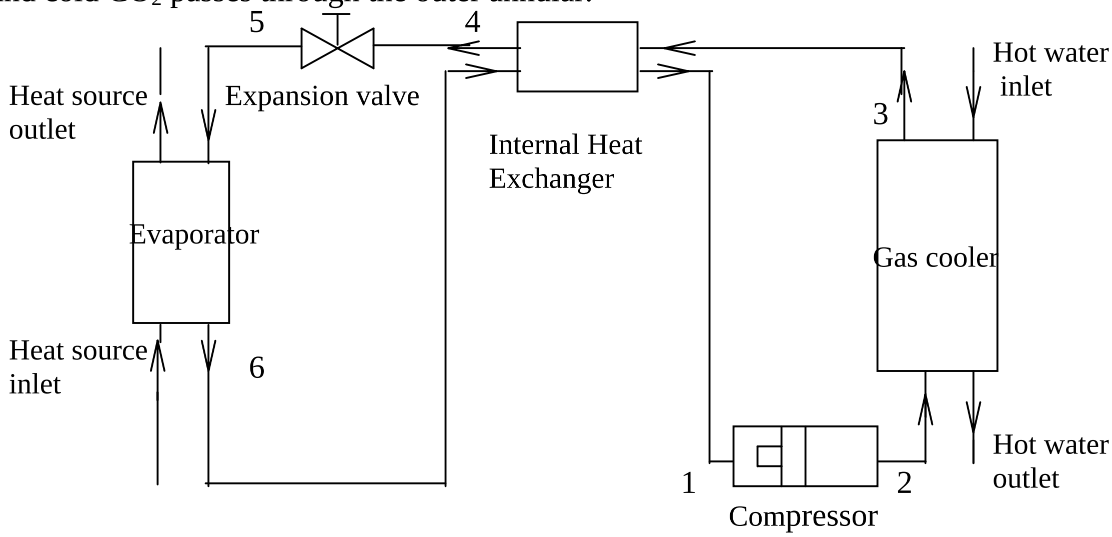

Fig 1. Sketch of a one-stage CO_2 transcritical heat pump system

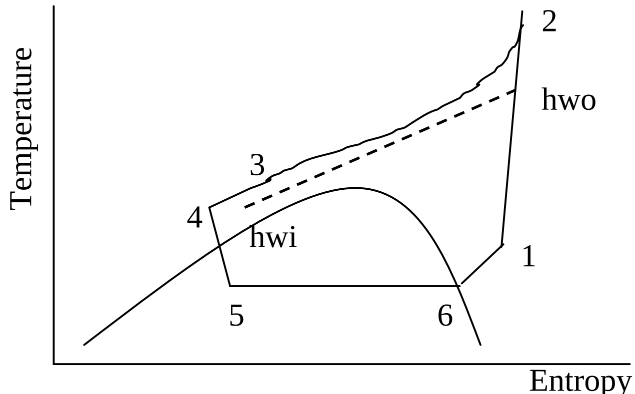

Fig 2 Temperature-entropy diagram for water heating with transcritical CO_2 cycle

is reduced from 4.1 to 2.7 if the hot water inlet temperature increase from 5℃ to 23℃ which spans the city water temperature range during the year in central China.

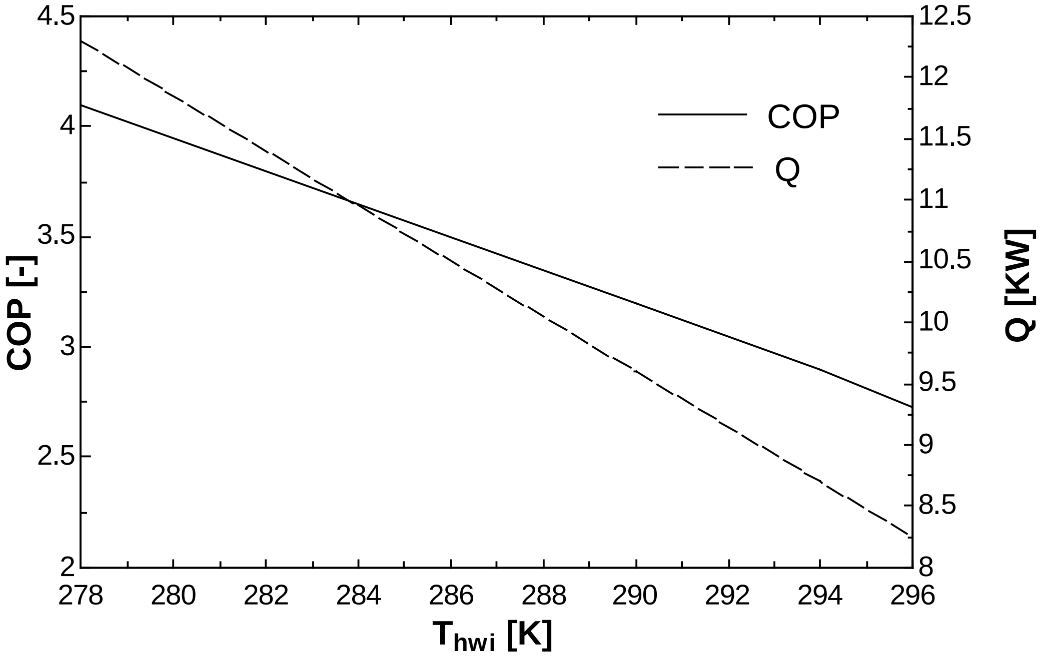

Fig. 3   Simulated COP and Q when varying the hot water inlet temperature

The effect of inlet heat source temperature on system performance is illustrated in Fig.5 .It is obvious that heat source inlet temperature exerts an opposite influence on COP and heating capacity. Considering that certain factors containing artificial recharge affects the temperature of groundwater, a wide temperature scope from 279K to 295K is chosen to model.

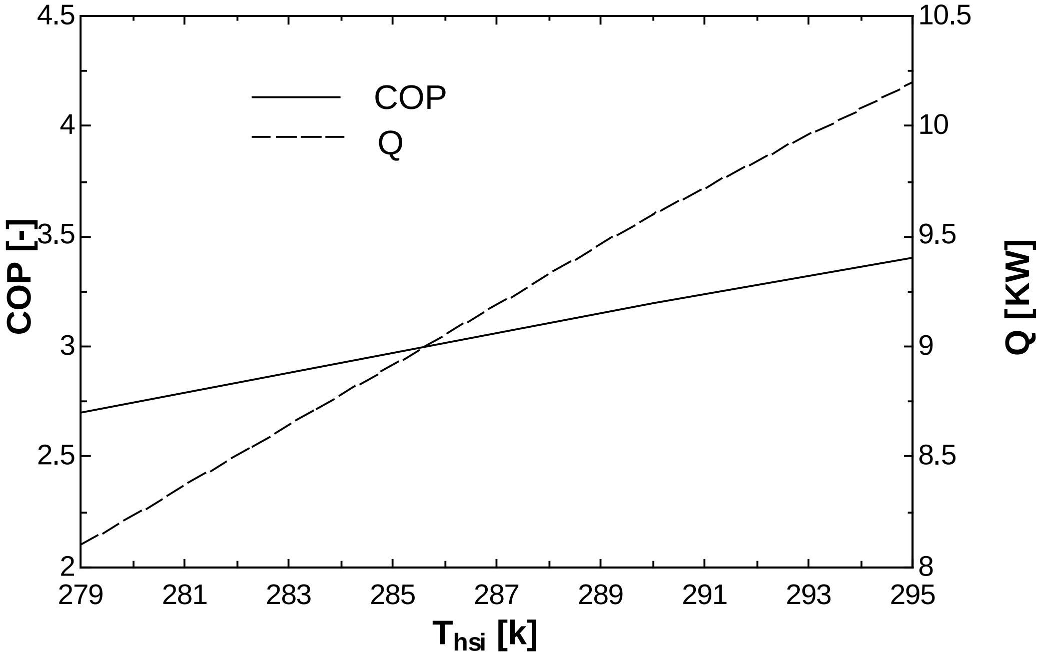

Fig. 4   Simulated COP and Q when varying the heat source inlet temperature

The simulation results reflect that the compressor speed is inversely proportional to system COP and Q.As the compressor speed increases,COP decreases. Rotation of compressor is proportional to compressor work and heating output, but compressor rises more than heating capacity. Consequently, COP falls with the increase of compressor rotate speed. Adding

$$S = \frac{1}{1 + 1.62 \times 10^{-6} E^{0.69} \mathrm{Re}_l^{1.11}} \qquad (12)$$

Secondly, if $\chi > \chi_{cr}$,

$$h_{tp} = \frac{\theta_{dry} h_g + (2\pi - \theta_{dry}) h_{wet}}{2\pi} \qquad (13)$$

Finally, if the tube is dry totally, the heat transfer coefficient is calculated as:

$$h_g = 0.023 \mathrm{Re}_g^{0.8} \mathrm{Pr}_g^{0.4} \frac{k_g}{D} \qquad (14)$$

CO_2 pressure drops are defined by Kim correlation [17] while water by the conventional Dittus–Boelter equation.

A computer code carried out in EES has been developed to design the transcritical CO_2 system for water heating. Due to the sharp variation of refrigerant properties near pseudocritical region, the entire length of the gas cooler was divided equally into n discrete segments to yield accurate simulation results. Energy equations were employed for each segments. Table 1 shows the detail design specifications for the water-to-water CO_2 HPWH.

Table 1 Design specifications for the water-to-water carbon dioxide HPWH

Compressor	Dorin TCS340/4-D:Semihermetics, reciprocating unit,1450rpm input rated power—3000W
Gas cooler	Counter-flow, tube-in-tube, single-pass, copper Length—10m,CO_2 outer diameter/thickness—0.010m/0.001m, water outer diameter/thickness—0.017m/0.001m
Internal heat exchanger	Counter-flow, tube-in-tube, single-pass, copper Length—1.9m, CO_2 outer diameter/thickness—0.010m/0.001m, water outer diameter/thickness—0.017m/0.001m
Evaporator	Counter-flow, tube-in-tube, single-pass, copper Length—3.8m, CO_2 outer diameter/thickness—0.010m/0.001m, water outer diameter/thickness—0.017m/0.001m
Expansion valve	Control high-side pressure

Simulation

Employing the same method as design procedure, a computer code based on EES has been developed to simulate the system. In the present study, simulation results of design conditions and effects of altering parameters (inlet temperature of heat source, inlet temperature of hot water and the speed of computer) on system performance are presented as below.

RESULTS AND DISCUSSION

Design conditions

Under the design conditions, namely, at the inlet heat source(groundwater) temperature of 17℃,the evaporation temperature of 5℃,the inlet hot water temperature of 17℃,the outlet hot water temperature of 65℃, the compressor power at 3000W, a heating COP of 3.2 is achieved and the optimum high-side pressure is controlled below 8.5MPa which benefits a lot for manufacturing materials and operation. A comparison between system with and without IHE was also made, and it was observed that with IHE, the system heating COP can be increased by more than 18%.

altering parameters

Fig. 4 shows the variation of heating capacity and COP when varying the hot water inlet temperature and keeping other parameters constant. It may be observed that the heating COP

frequency converter to constant speed Dorin CO_2 compressor can save energy and increase system efficiency.

4. CONCLUSION

The simulation results presented in the paper show that CO_2 is very suitable for tap water heat pumps. The prediction tends of system performance when altering the operation parameters is found to be in reasonable agreement with experimental data published. Due to the different working conditions, absolute values differ to an acceptable degree. Compared with the conventional electrical and natural gas water heater, the energy consumption of HPWH with CO_2 as working fluid can be greatly reduced. Obviously, the market potential for HPWH with CO_2 as refrigerant in central China is large,which is expected to be pushed by the present study and the further theoretical research , experiments and prototype design.

frequency converter to constant speed Dorin CO_2 compressor can save energy and increase system efficiency.

CONCLUSION

The simulation results presented in the paper show that CO_2 is very suitable for tap water heat pumps. The prediction tends of system performance when altering the operation parameters is found to be in reasonable agreement with experimental data published. Due to the different working conditions, absolute values differ to an acceptable degree. Compared with the conventional electrical and natural gas water heater, the energy consumption of HPWH with CO_2 as working fluid can be greatly reduced. Obviously, the market potential for HPWH with CO_2 as refrigerant in central China is large,which is expected to be pushed by the present study and the further theoretical research , experiments and prototype design.

SUMMARY

A two-stage compression variable frequency air source heat pump has been developed combining variable frequency technology with two-stage compression cycle, and two-control -model with the priority target as coefficient of performance (*COP*) or heating capacity is advanced in this paper. The mathematical model of the heat pump system has been developed and verified with the test data. The simulated optimal intermediate pressure and transition temperature between single-stage and two-stage compression heating condition are given, then the heating capacity, *COP*, and compressor discharge temperature are simulated and analyzed. It can be seen from the simulation results that *COP* of this heat pump system is over 2, the compressor discharge temperature under 120 °C, and the heating capacity can meet the heating load needed when the condensing temperature is 50°C and outdoor air temperature is -20°C.

INTRODUCTION

More and more heat pump systems have been used as the cold source and heat source of air conditioning systems due to their higher efficiency, pollution-free and multi-use. Among all kinds of heat pump units, air source heat pump is the most widely-applied equipment for its low initial investment, convenient maintenance and little influence to ambient. Since 1990's, air source heat pump had been successfully used for building indoor climate in the unconventional heating region of China including the middle and lower reaches of the Yangtze River, south and southwest China. However, when the air source heat pump is used in north China in winter, where the outdoor temperature is very low, there are some problems such as insufficient heating capacity, lower *COP*, and very high compressor discharge temperature except the frost on the outdoor heat exchanger, which block its application in those cold regions.

Besides the auxiliary heat source for the heating supply, much research had been made to solve the heating problems of air source heat pump in cold regions. A new type of heat pump with a kerosene-fired burner was developed to improve the heating capacity and the *COP* [1]. An air source heat pump with an inverter scroll compressor and liquid injection was proposed by Horiuchi [2], which increases the rotary speed under low ambient temperatures and injects liquid refrigerant into compressor to decrease the compressor discharge temperature. Based on the system proposed by Horiuchi, a system with an economizer and vapor injection was developed [3]. A two-stage coupling heat pump system was developed to use air source heat pump to absorb heat from outdoor air and to obtain water of 10-20 ºC, then make higher temperature water for building heating with another heat pump unit [4]. A ternary mixture refrigerant was used to improve the *COP* of heat pump for cold climates by Sami and Tulej[5].

Also a compression/absorption heat pump system was invented by Hulten and Berntsson [6], the waste heat is used to drive the absorption heat pump to get hot air, which is then used as the heat source of vapor compression heat pump, and finally get hot water for heating requirement. The research above has improved the heating performance of air source heat pump for cold climates with different methods.
In this paper, a two-stage compression variable frequency air source heat pump (TV-ASHP) system for cold regions is proposed combining variable frequency technology with two-stage compression cycle. With a variable frequency scroll compressor as the low pressure stage compressor and a fixed frequency scroll compressor as the high pressure stage compressor, the mathematical model of TV-ASHP system with a standard cooling capacity of 16 kW is developed, and the system performance is simulated and analyzed then.

DEVELOPMENT OF TV-ASHP

The TV-ASHP system developed in this paper is shown in Figure 1. The uncompleted intercooling two-stage compression cycle is adopted, and the system mainly includes a low pressure stage compressor, a high pressure stage compressor, an outdoor heat exchanger, an indoor heat exchanger, an intercooler, two throttling devices, a four-way valve, and a solenoid valve. Three work conditions including the single-stage compression cooling, single-stage compression heating and two-stage compression heating can be carried out by controlling four-way valve and solenoid valve and changing the refrigerant flow circuit.

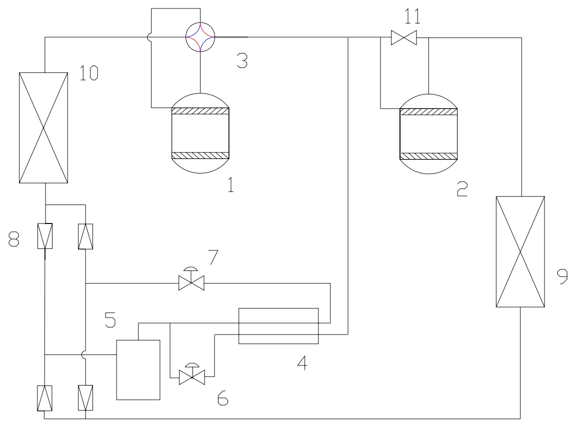

Figure 1. Schematic of TV-ASHP system
1- low pressure stage compressor 2- high pressure stage compressor 3-four-way valve
4- intercooler 5- receiver 6-throttling device I 7- throttling device II 8- one-way valve
9-indoor heat exchanger 10-outdoor heat exchanger 11-solenoid valve

Two-control-mode with the priority target as *COP* or heating capacity is advanced to assure the system higher *COP* when the heating capacity can meet the heating load. That is, when the heating capacity meets the heating load, the system works in the mode of *COP* priority and is kept the optimal intermediate pressure by changing the power frequency of low pressure stage compressor. But if the heating capacity is insufficient for demand, the control mode of heating capacity priority has to be chosen and the power frequency should be adjusted to meet the heating demand. With the TV-ASHP system, the heating capacity is enhanced with two-stage compression and increase of power frequency of low pressure stage compressor together, *COP* is improved with two-stage compression and optimal intermediate pressure by power frequency adjustment of low pressure stage compressor together, and the discharge temperature of high pressure stage compressor is decreased with the two-stage compression cycle, which are used to solve the insufficient heating capacity, lower *COP*, and high compressor discharge temperature in the common air source heat pump systems.

MATHEMATICAL MODEL AND EXPERIMENTAL VERIFICATION

Mathematical model

The mathematical model of TV-ASHP system mainly includes the sub-models of low pressure stage compressor, high pressure stage compressor, outdoor heat exchanger, indoor heat exchanger, intercooler and throttling devices.
The refrigerant mass flow rate and input power of low pressure stage compressor and high pressure stage compressor are fitted with the test data from the manufacturer:

$$\dot{m}_{\mathrm{l}} = \left(0.109 + 0.00305T_{\mathrm{e}} - 0.000253T_{\mathrm{m}} - 0.00000194T_{\mathrm{m}}^2\right)\frac{f - 2.857}{60 - 2.857}, \quad (1)$$

$$N_{\mathrm{l}} = \left(2.13 + 0.02T_{\mathrm{e}} + 0.013T_{\mathrm{m}} + 0.0009T_{\mathrm{m}}^2\right)\frac{f + 2.2}{60 + 2.2}, \quad (2)$$

$$\dot{m}_{\mathrm{h}} = 0.045 + 0.00149T_{\mathrm{m}} + 0.000072T_{\mathrm{c}} - 0.000000208T_{\mathrm{c}}^2, \quad (3)$$

$$N_{\mathrm{h}} = 0.98 + 0.000886T_{\mathrm{m}} + 0.00064T_{\mathrm{c}} + 0.000044T_{\mathrm{c}}^2, \quad (4)$$

where $\dot{m}_{\mathrm{l}}$, $\dot{m}_{\mathrm{h}}$ are the refrigerant mass flow rate through the low pressure stage compressor and high pressure stage compressor respectively, N_{l}, N_{h} are the input power of low pressure stage compressor and high pressure stage compressor respectively, T_{e}, T_{m}, T_{c} are the evaporating temperature, intermediate temperature, and condensing temperature respectively, and f is the power frequency of low pressure stage compressor.
The mathematical models of outdoor heat exchanger, indoor heat exchanger, and intercooler are all the distributed parameter ones.
With the inlet and outlet parameter relationship between every component in the TV-ASHP system, the system model is developed to combine all the sub-models. For the solution procedure, firstly set starting values of evaporating pressure, condensing pressure, intermediate pressure, suction superheat of low pressure stage compressor. Then start the simulation from the suction end of low pressure stage compressor, and call the subroutine of low pressure stage compressor, high pressure stage compressor, outdoor heat exchanger, indoor heat exchanger, intercooler and throttling devices. Finally adjust the assumed starting value of condensing pressure to keep mass conservation of heat pump system, adjust the assumed starting value of evaporating pressure to keep energy conservation, adjust the assumed starting value of suction superheat of low pressure stage compressor to keep momentum conservation of heat pump system, and adjust the assumed starting value of intermediate pressure to keep balanced refrigerant flow rate distribution.

Experimental verification

Figure 2 shows the test bench of TV-ASHP system whose standard cooling capacity is 16kW. The test bench consists of heat pump system, glycol-water system, indoor water system, control system, and measurement system. Three conditions including the single-stage compression cooling, single-stage compression heating and two-stage compression heating can be carried out at different condensing and evaporating temperatures.
The heat pump system is same with the TV-ASHP system shown in Figure 1. A 5HP variable frequency compressor is used as low pressure stage one while a 3HP fixed frequency

compressor is used in high pressure stage. The glycol-water system consists of plate-type heat exchanger, tank, electric heater, pump and flow meter. The mass concentration of glycol in the glycol-water solution is 50%, so the freezing point can be as low as -35 ºC, which can be used to simulate the very low outdoor environment. Indoor water system is constituted with plate-type heat exchanger, water tank, electric heater, pump and flow meter.

The parameters controlled in this test system are the power frequency of compressor, evaporating pressure, condensing pressure, intermediate pressure. The power frequency of low pressure stage compressor is adjusted with the variable frequency controller. The evaporating pressure is adjusted by the glycol-water temperature at outdoor heat exchanger inlet, and the condensing pressure is adjusted by the water temperature at indoor heat exchanger inlet. The intermediate pressure is controlled mainly with the power frequency of low pressure stage compressor.

The parameters measured in this test system include the refrigerant temperatures and pressures at different test points, water temperatures at indoor heat exchanger inlet and outlet, glycol-water temperatures at outdoor heat exchanger inlet and outlet, indoor water flow rate, glycol-water flow rate, compressor power consumption. There are twelve copper constantan thermocouples (measurement precision is ±0.2 ºC) set in the refrigerant circuit to obtain the suction temperature, discharge temperature, refrigerant temperature at the heat exchanger inlet and outlet, as well as the refrigerant temperature at the high pressure inlet and outlet of intercooler. Four voltage-output type pressure sensors with the precision of ±0.1% are used to measure the refrigerant pressures at the inlet and outlet of low pressure stage compressor, the refrigerant pressure at the outlet of high pressure stage compressor and throttle device. The water temperatures and glycol-water temperatures at heat exchanger inlet and outlet are measured with four platinum resistance temperature sensors, whose precision is ±0.1 ºC. The compressor power consumption is measured with the Fluke power meter. Two glass rotor flow meters, calibrated with a calibration cylinder, are used to measure the flow rate of glycol-water solution and indoor water. These sensors above all produce electric voltage or current, which are sent to a data logger and a computer to record the test data.

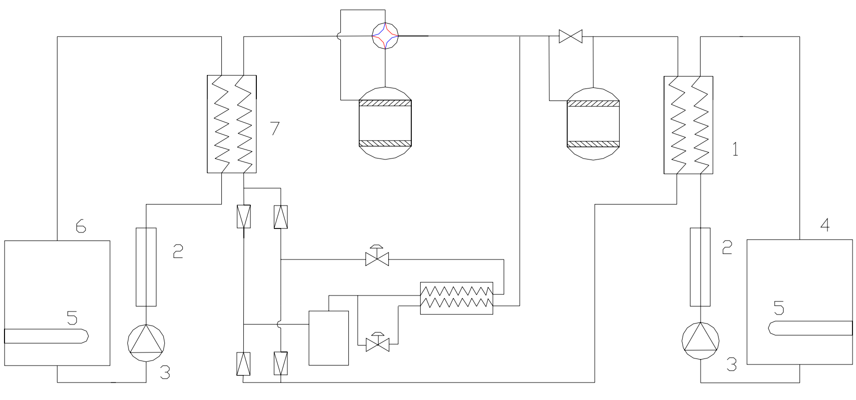

Figure 2. Test bench
1- indoor heat exchanger 2-flow meter 3-pump 4- water tank
5- electric heater 6- glycol-water tank 7- outdoor heat exchanger

Table 1 shows the comparison between the simulated results and test data when the system runs in the two-stage compression heating and the condensing temperature is 50 ºC. It can be seen from Table 1 that the deviations between simulated and measured values of heating capacity and *COP* are less than ±6%, and the simulated results agree well with experimental data.

Table 1. Comparison between simulated and measured results

Evaporating temperature (ºC)	0	-10	-20	-30
Heating capactiy (kW)				
Test data	19.86	16.82	13.4	10.02
Measured results	19.87	16.87	13.9	10.56
Relative error (%)	0.05	0.29	3.57	5.14
COP				
Test data	2.54	2.34	2.1	1.9
Measured results	2.64	2.32	2.14	2
Relative error (%)	3.88	0.85	1.79	5.24

SIMULATION AND ANALYSIS

With the verified mathematical model of TV-ASHP system, the optimal intermediate pressure and transition temperature between single-stage and two-stage compression heating condition are calculated firstly, and the heating capacity, *COP*, and discharge temperature of high pressure stage compressor are simulated and analyzed then.

Optimal intermediate pressure

When the heating capacity meets the heating load and the control mode of *COP* priority is chosen in the two-stage compression heating condition of TV-ASHP system, the optimal intermediate pressure, p_m, is the goal parameter for adjusting the power frequency of low pressure stage compressor. Therefore it is important to learn how much the optimal intermediate pressure is in the different conditions.
The simulated optimal intermediate pressure of TV-ASHP system is shown in Figure 3 when the evaporating temperature is 0 – -30 ºC and the condensing temperature is 50 ºC. The optimal intermediate pressure rises along with the increase of evaporating temperature.

Transition temperature between single-stage and two-stage compression condition

Figure 4 shows the comparison of *COP* in two-stage and single-stage compression heating condition when the condensing temperature is 50 ºC. Here the two-stage compression heat pump system is operating at the optimal intermediate pressure.

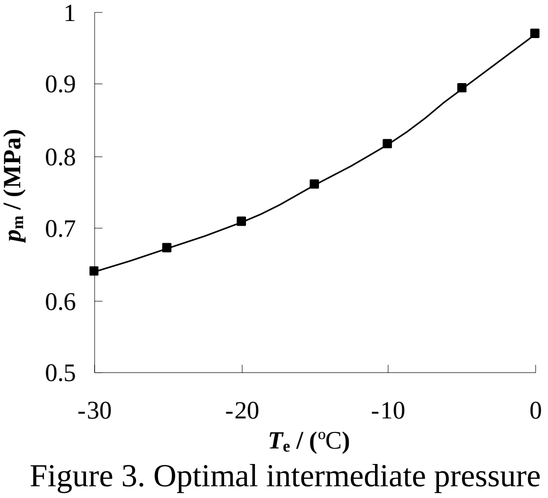

Figure 3. Optimal intermediate pressure

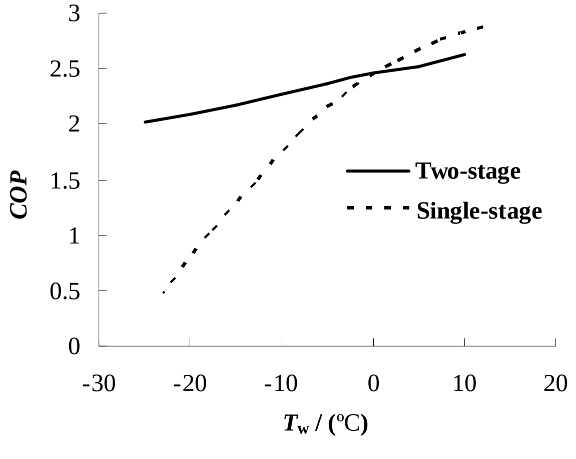

Figure 4. Comparison of *COP*

The *COP* of both two-stage and single-stage compression system goes down along with the decrease of the outdoor air temperature, T_w, but the decreasing rate is more less for two-stage compression system, especially when the outdoor air temperature is lower. As shown in Figure 4, the *COP* of two-stage compression system is equal to that of single-stage compression when the outdoor air temperature is 0 ºC. The *COP* of two-stage compression system is less than that of single-stage compression when the outdoor air temperature is higher than 0 ºC, and larger than that of single-stage compression when outdoor air temperature is lower than 0 ºC. So it can be considered the just temperature to transfer the control modes of the single-stage compression heating and two-stage compression heating when the outdoor air temperature equals 0 ºC. The single-stage compression heating mode is adopted when the outdoor air temperature is higher than 0 ºC, otherwise the two-stage compression heating mode is chosen.

COP in two-stage compression heating condition

The variation of *COP* in two-stage compression heating condition is simulated when the condensing temperature is 50 ºC and outdoor air temperature is 0 ºC, -10 ºC and -20 ºC (Figure 5). When the outdoor air temperature is kept constant and the low pressure stage compressor runs in a higher frequency, *COP* goes down along with the increase of power frequency. And the *COP* goes down along with the decrease of outdoor air temperature at constant power frequency. The *COP* is higher than 2.0 when the power frequency is lower than 70Hz, the outdoor air temperature is -20 ºC, and condensing temperature is 50 ºC.

Heating capacity in two-stage compression heating condition

Figure 6 shows the variations of the heating capacity, Q_c, along with the power frequency of low pressure stage compressor when the condensing temperature is 50 ºC and outdoor air temperature is 0 ºC, -10 ºC and -20 ºC. The heating capacity goes down along with the decrease of outdoor air temperature at constant power frequency. When the outdoor air temperature is kept constant, the heating capacity rises along with the increase of power frequency. So the TV-ASHP system can adjust the power frequency of low pressure stage compressor by the control mode of heating capacity priority to increase the heating capacity besides the improvement with the two-stage compression method when the two-stage compression in optimal condition alone cannot satisfy the heating requirement due to very low outdoor temperature. However, the *COP* goes down a little when the power frequency rises then (see Figure 5).

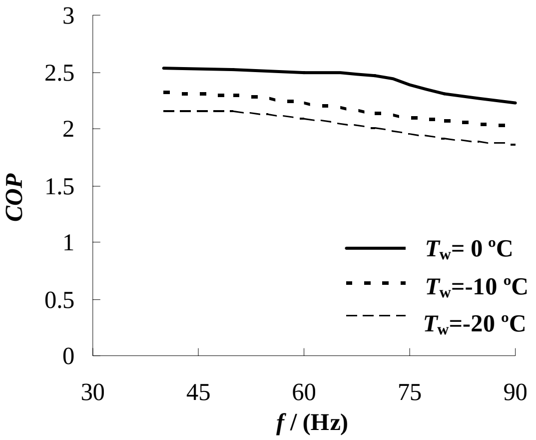

Figure 5. *COP*

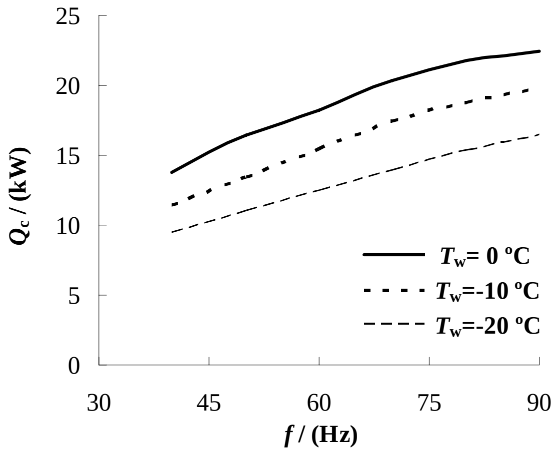

Figure 6. Heating capacity

Discharge temperature of high pressure stage compressor

The variations of the discharge temperature of high pressure stage compressor, T_d, in two-stage compression heating condition along with the power frequency of low pressure stage compressor are shown in Figure 7 when the condensing temperature is 50 ºC and outdoor air temperature is -20 ºC. The discharge temperature increases slowly when the power frequency rises, but doesn't exceed 120 ºC, below which the compressor can operate safely.

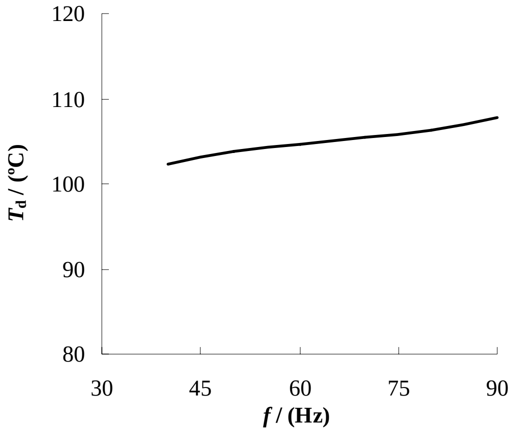

Figure 7. Discharge temperature

CONCLUSIONS

In this paper, a two-stage compression variable frequency air source heat pump has been proposed combining variable frequency technology with two-stage compression cycle, and two-control-mode with the priority target as *COP* or heating capacity has been advanced. The mathematical model of this heat pump system has been developed and verified. The optimal intermediate pressure and transition temperature between single-stage and two-stage compression heating condition have been simulated, then the heating capacity, *COP*, and discharge temperature of high pressure stage compressor have been simulated and analyzed.
It can be seen from the simulation results that *COP* of this heat pump system is over 2, the compressor discharge temperature under 120 °C, and the heating capacity can meet the heating load needed when the condensing temperature is 50°C and outdoor air temperature is -20°C.

Energy Efficient Operation of the Cooling Production System in a Commercial Building Under Hot Climate

Abdelrahman ElSherbini, Ali Hajiah and Gopal Maheshwari

Kuwait Institute for Scientific Research

Corresponding email: asherbini@kisr.edu.kw

SUMMARY

Commercial buildings consume large amounts of energy under hot climates. The efficient operation of air-conditioning systems can lead to important energy savings. This work assesses the potential for savings through efficient operation of the cooling production system in a commercial building under hot climate. The cooling system of the building has a nominal capacity of 3380 Refrigeration Tons (RT) (11900 kW). Analysis of measurements from the building led to the adoption of a more efficient operation strategy for the cooling system. Implemented energy efficiency and conservation measures included: optimizing chilled water distribution, closing flow through non-operating chillers, increasing the loading of chillers, reducing the number of operating pumps and increasing the chilled water supply temperature during non-occupancy and low-demand periods. These measures produced significant improvements in the power rating of chillers and total energy consumption. Daily energy savings of 17% to 40% were achieved by implementing these measures.

INTRODUCTION

Air-conditioning systems operating under hot climates are characterized by high energy consumption. In a country like Kuwait, it is estimated that comfort cooling in buildings accounts for 45% of the annual energy consumption and 70% of the national peak demand for electrical power. Therefore, energy efficient air-conditioning systems are essential for saving energy and for meeting the peak electrical load.

A cooling production system is designed to meet the maximum cooling load during worst conditions to ensure comfort for building occupants. For most of the time, however, the cooling system operates under part-load and/or favorable weather conditions. In the case of cooling systems with centrifugal chillers, part-load operation can deteriorate their energy performance. In addition, the temperature of chilled water leaving the chiller, T_{ws}, affects efficiency. Raising the value of T_{ws} at periods of low cooling demand can improve the performance of the chiller. In hot climates, the efficiency of a chiller with air-cooled condenser is strongly affected by ambient weather temperature. Lower air temperatures lead to reduced condensing temperature and improved efficiency. Thus, the actual efficiency of an air-conditioning system depends on operating conditions.

This work assesses the potential for energy savings through the efficient operation of air-conditioning systems in commercial buildings. The goal of the study is to improve the energy performance of the cooling production system in an office building and estimate the energy savings achieved.

Building and Cooling System

This investigation studied the main office building of the Kuwait Institute for Scientific Research (KISR). The building is an energy-efficient structure with well-insulated walls and roofs and double/triple-glazed fixed windows, meeting the building energy code of Kuwait. It has an approximate air-conditioned area of 23,470 m^2. The air-conditioning system accounts for nearly 70% of the annual electrical consumption of 14,000 MWh.

The air-conditioning system in the building is designed to provide year-round comfort conditions with constant air and chilled water circulation. The cooling production system, commissioned in 1984, consists of ten air-cooled chillers. Every chiller has a 373 kW centrifugal compressor and three condenser fans of 15 kW each, providing a cooling capacity of 338 Refrigeration Tons (RT) (1190 kW cooling). The cooling distribution subsystem has four chilled water pumps (including a standby pump) feeding water to 23 Air Handling Units (AHUs) and 67 Fan Coil Units (FCUs). The major components of the cooling system and their power requirements are presented in Table 1 and a schematic diagram of the cooling system is shown in Figure 1. The building is occupied between 07:30 and 15:00 h, from Saturday to Wednesday.

Table 1. Important features of the air-conditioning system under consideration.

Component	Quantity	Connected Load (kW/Unit)	Total Load (kW)
Chiller (compressor + condenser fan motors)	10 (1+3)	373 +3x15	4180
Chilled water pump	4	75	300
Supply air fans for AHUs	23	0.55-45	258
Return air fans for AHUs	15	0.25-22	114
Fan coil units	67	0.18	12
Exhaust fans		0.18	
Total connected load			4864

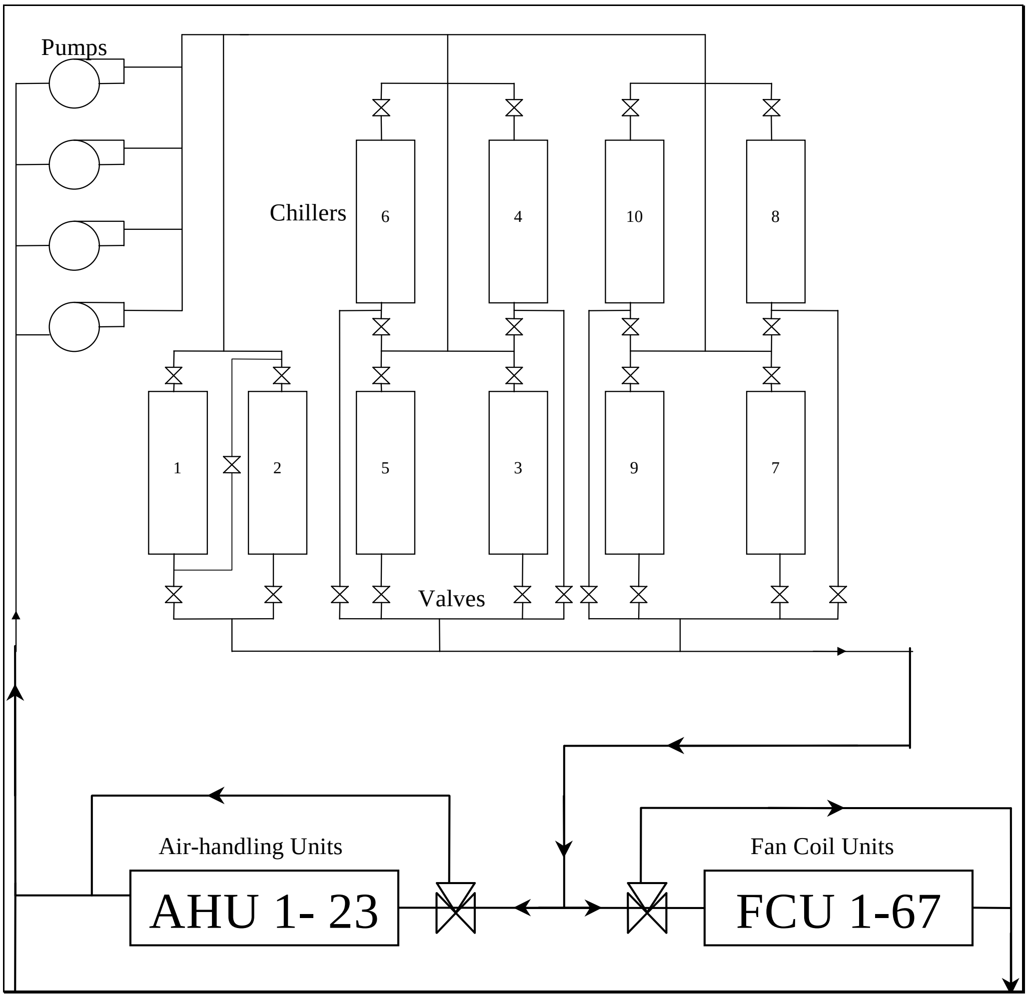

Figure 1. A schematic of air-conditioning system in the building.

METHODS

A key parameter in characterizing the efficiency of a cooling production system is the power rating (PR). The power rating of an air conditioning system and its components is the amount of power needed to produce a unit of cooling (Refrigeration Tons, RT). The power rating of a chiller ($PR_{chiller}$) is determined from

$$PR_{chiller} = \frac{P_{chiller}}{Q_c}, \qquad (1)$$

where $P_{chiller}$ is electric power used by the chiller, and Q_c is the amount of cooling produced. The power consumption of the chiller can be measured by a power meter. The amount of cooling is found from

$$Q_c = q\rho c_p (T_{wr} - T_{ws}), \qquad (2)$$

where q is chilled water flow rate, ρ is density, c_p is specific heat and T_{ws} and T_{wr} are the chilled water supply and return temperatures, respectively. The power rating of the system when chillers and pumps are considered together is

$$PR = \frac{P_{chiller} + P_{pump}}{Q_c}, \qquad (3)$$

where P_{pump} is the power consumed by the chilled water pumps and is related to the number of pumps in operation. Improving the efficiency of the system can be achieved by reducing the power rating of the chillers and the power consumption of the chilled water pumps. The air-distribution system was not considered in this study.

In order to determine *PR* for the cooling production system, the following parameters were monitored: $P_{chiller}$, P_{pump}, q, T_{ws}, and T_{wr}. The ambient temperature was also monitored as it affects the cooling demand of the building and the performance of the chillers. Current transformers and power transducers were used for power measurements. The water flow rate was measured by an ultrasonic flow meter. Chilled water temperatures were determined by high-accuracy Resistance Temperature Detectors (RTDs). Accuracy of temperature measurements was a concern because of the small rise in chilled water temperature (T_{wr} - T_{ws}), which impacts the accuracy of the cooling production in equation (2) and power rating in equations (1) and (3). Ambient temperature and humidity were logged using a weather station. A data acquisition system recorded measurements continuously every 10 minutes.

Analyzed data was used to establish the base-case performance of the cooling production system. The base-case data highlighted the opportunities for energy savings through improved operation of the system. A new operation strategy for the cooling production system was developed and implemented. The performance of the system before and after implementation of the operation strategy was compared to estimate energy savings.

RESULTS

Measurements of chilled water temperatures and flow rates revealed a problem in the cooling distribution system. One of the branches in the constant-flow chilled-water network had high cooling demand, which was originally met by increasing the system flow rate. Other chilled water branches showed low temperature rises, indicating high flow rates. Adjusting the flow rates in the branches according to the cooling demand reduced the total flow requirement and the pumping power. The number of chilled water pumps required during peak summer was thus reduced from 3 to 2. Additional pumping power was saved by removing a pump from operation during non-occupancy and low demand periods. Figure 2 compares the number of chilled water pumps in operation before and after the modification for two days of similar conditions. The figure manifests the reductions in number of operating pumps during occupancy and non-occupancy hours.

Analysis of temperature data showed that the temperature of water supplied to the air handling units (AHUs) was 1 to 3.5°C higher than the temperature of water produced by the chillers. Warmer water returning from AHUs was allowed to flow through non-operating chillers and mix with colder water before being supplied to the building. Cooling the water to temperatures below the supply temperature represented an energy loss. Closure of water flow through non-operating chillers resulted in better matching between the production and supply temperatures of chilled water.

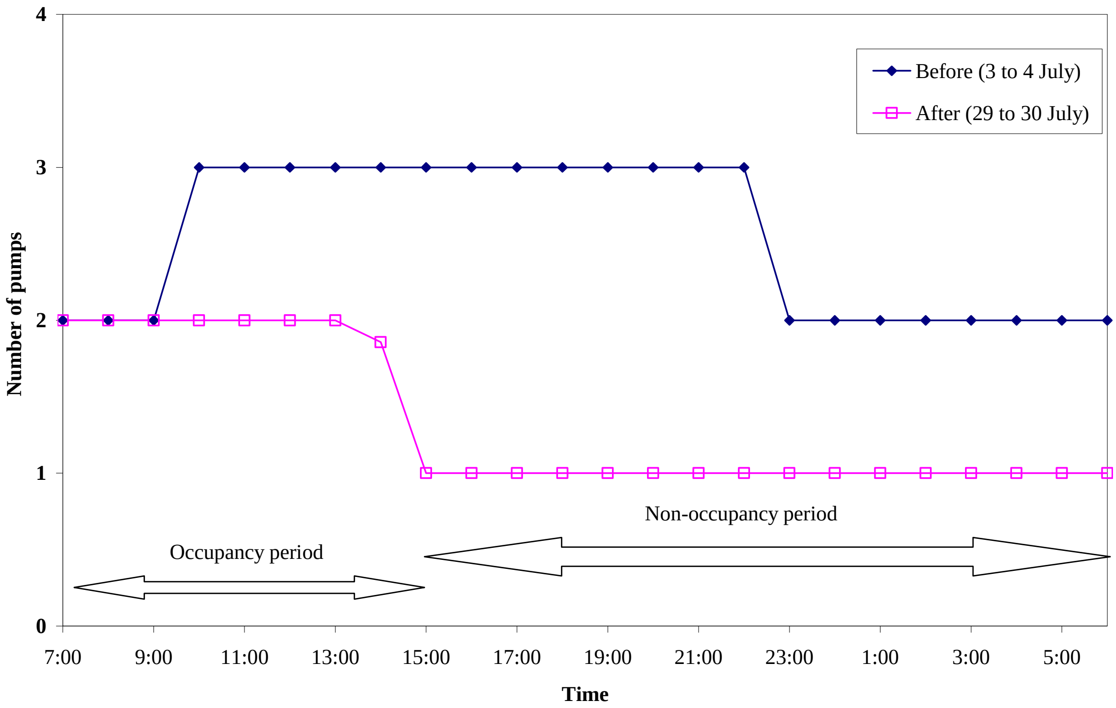

Figure 2. Number of operating pumps before and after optimization for two similar days.

Power measurements showed that chiller loading was low, leading to increased power rating. The loading of the chillers was increased by reducing the number of operating chillers when possible. Although maintenance concerns restricted maximum chiller loading to 70% during the peak summer, average loading was increased from about 55% to 65%.

Daily profiles of chilled water temperature manifested another opportunity for energy savings. The supply temperature of water was higher during the building occupancy hours and lower during non-occupancy hours. Allowing the supply temperature to rise during non-occupancy hours saves energy due to the reduction in number of operating chillers. Moreover, chiller efficiency improves at higher chilled water supply temperatures. The removed chillers were used to pre-cool the building during early morning hours, when weather conditions are milder, leading to better chiller operating efficiency.

Figure 3 shows the profile of chilled water supply temperature before and after optimization for two days of similar conditions. After optimization, the supply water temperature is lower during the occupancy period (7:30 – 15:00h), allowing for improved comfort. During non-occupancy hours, the value of T_{ws} is higher after optimization, as discussed above. Both profiles reach similar temperatures during early morning hours. The impact of increased chiller loading and supply water temperature is manifested in the chiller power rating, $PR_{chiller}$. Figure 4 shows the daily power rating profiles for operating chillers before and after optimization for two days of similar conditions. Although the power rating is high due to chiller age and harsh climate, a significant reduction in power rating was achieved.

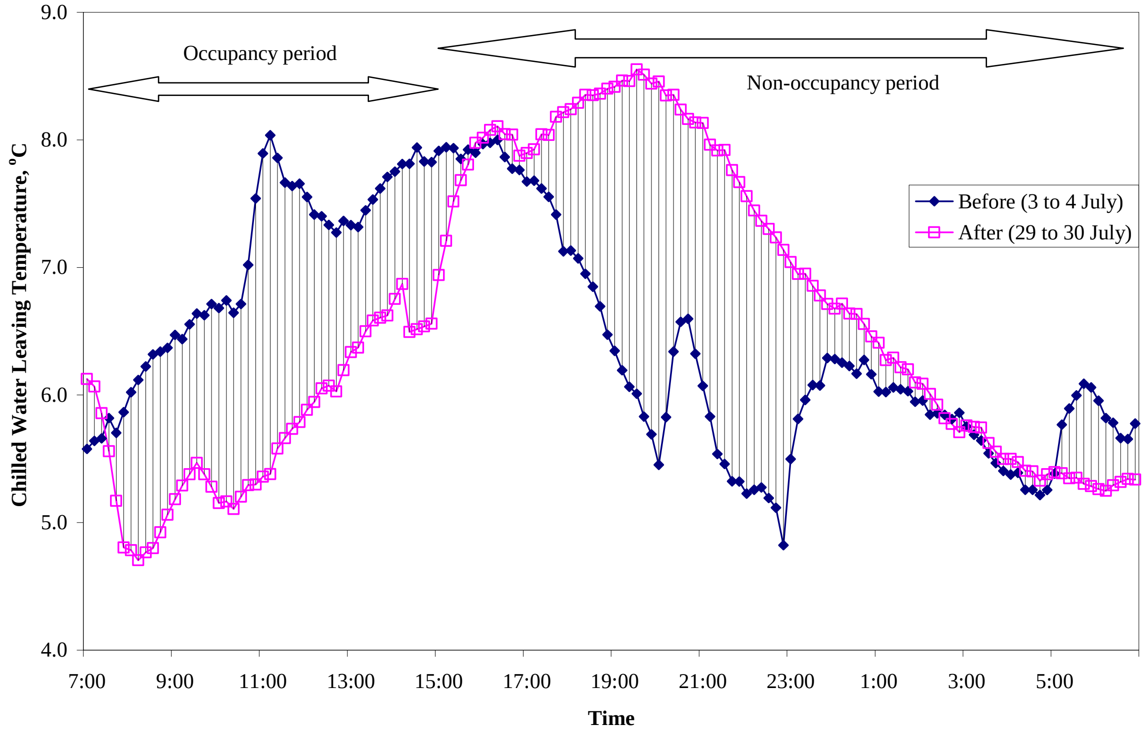

Figure 3. Profiles of chiller leaving water temperature before and after optimization.

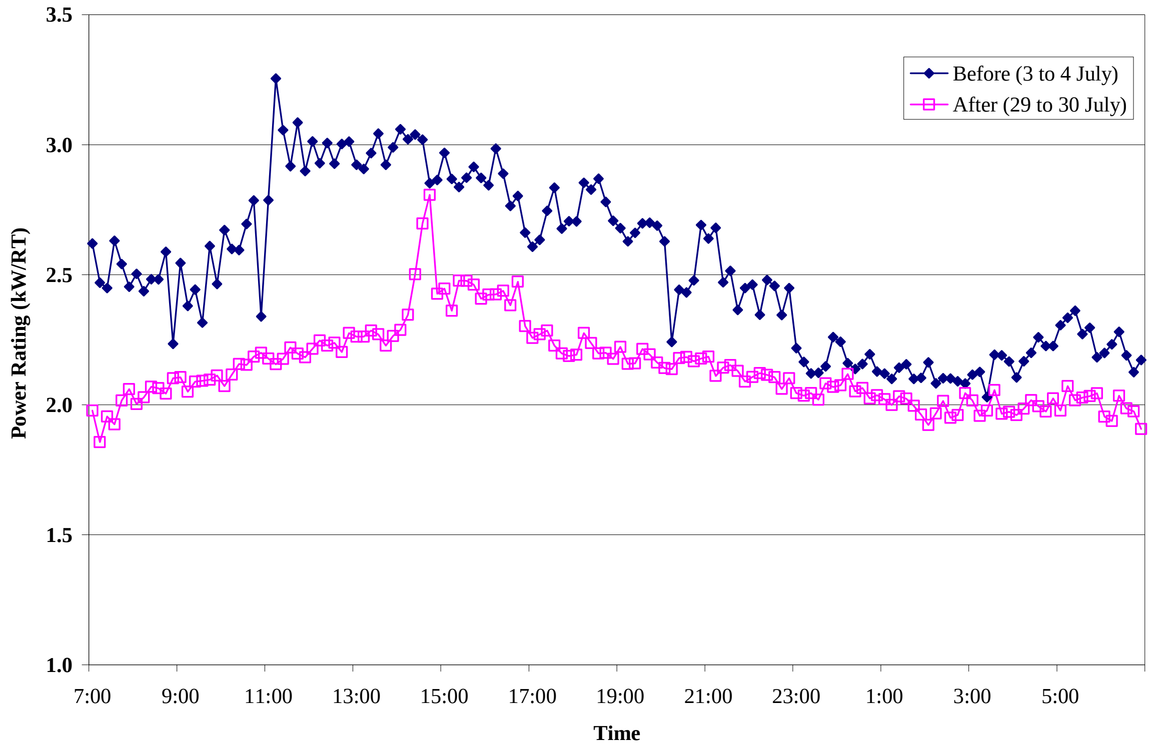

Figure 4. Average power rating (chillers and pumps) before and after optimization.

Table 2 summarizes the comparison results for two nearly identical days before and after optimization. In particular, the table shows a 15% improvement in average chiller efficiency, 43% reduction in daily pumping power, 19% reduction in daily energy consumption, and 14% reduction in peak power demand. The different temperature profiles of Figure 3 resulted in the same daily average chilled water supply temperature.

Table 2. Daily results for two similar working days before and after optimization.

Parameter	Before	After	Remarks
	3-4 July	29-30 July	
Average Ambient Temp, Deg C	36.8	36.0	
Maximum Ambient Temperature, Deg C	43.9	43.9	
Ambient Enthalpy, KJ/Kg	75.7	78.1	
Cooling Production, RTh	14930	14272	4.4 % Reduction
Average Water Supply Temperature, Deg C (non occupancy)	6.2	7.0	11.6 % Increase
Average Water Supply Temperature, Deg C (Occupancy)	7.0	5.7	18.2 % Reduction
Daily Average Chilled Water Supply Temperature, Deg C	6.5	6.5	
Total Energy (non occupancy), kWh	24953	18788	24.7 % Reduction
Total Energy (Occupancy), kWh	12660	11727	7.4 % Reduction
Total Energy, kWh	37613	30515	18.9 % Reduction
Peak power demand, kW	1806	1557	13.8 % Reduction
Average Power Rating, kW/RT	2.5	2.1	15.3 % Reduction
Average Chiller Loading, %	59.5	64.0	7.5 % Increase

Figure 5 shows the daily energy consumption before and after optimization as functions of the daily average ambient temperature. The energy efficiency and conservation measures resulted in daily energy savings ranging from 17% to 40%. Savings were higher for milder weather conditions.

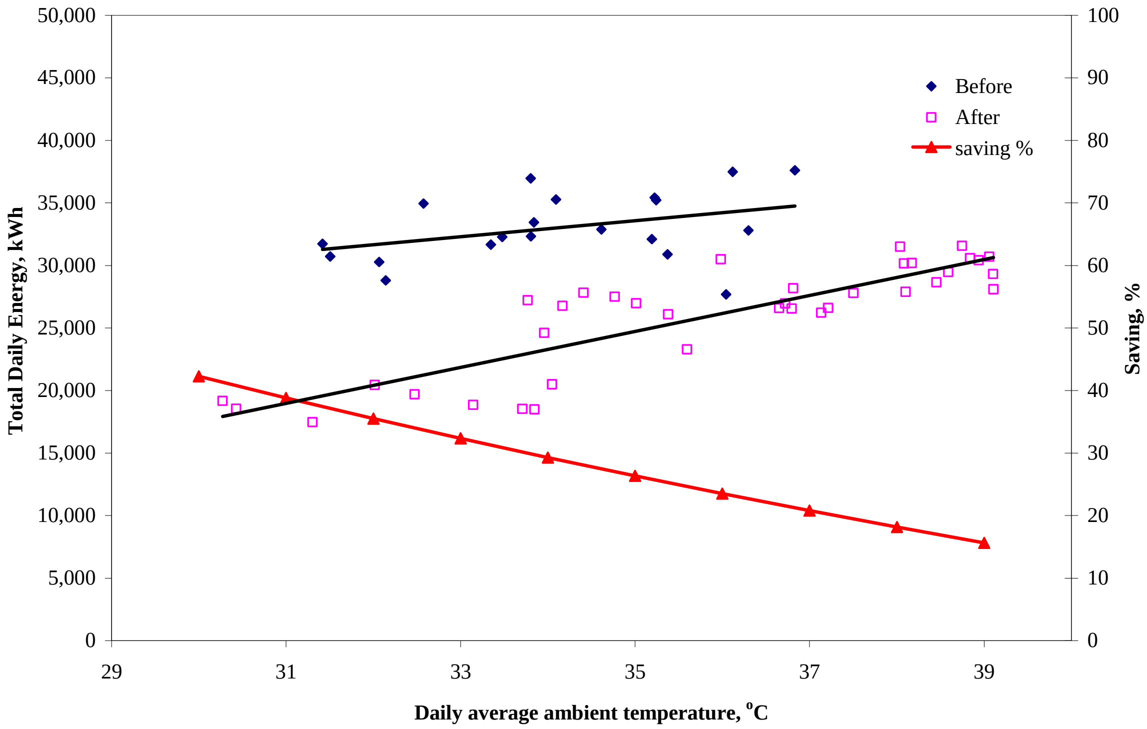

Figure 5. Daily energy consumption before and after optimization as functions of the daily average ambient temperature.

DISCUSSION

Efficient operation of the air-conditioning system in the commercial building under consideration led to significant energy savings. These savings resulted from improving the operating efficiency (power rating) of the chillers and reducing auxiliary power consumed by the chilled water pumps. The chilled water distribution problem is not uncommon in older commercial buildings. Expansions and changes in space usage within a zone can change the cooling load of that zone. In this work, optimization of water distribution improved comfort conditions as well as energy consumption. Similarly, poor chiller loading and other causes of inefficiency are often found in commercial and institutional buildings.

The energy efficiency and conservation measures implemented in this study were focused on operational issues. There are no costs associated with these measures except instrumentation and manpower, which are readily available for many commercial buildings. The implemented energy efficiency measures included optimizing the distribution of chilled water, closing the flow through non-operating chillers, and increasing chiller loading. The energy conservation measures included raising chilled water supply temperatures and reducing pumping power during non-occupancy and low demand periods.

SUMMARY

Energy saving requirements make it imperative to cut CO_2 emissions, reduce energy consumption, and curtail costs at the same time. Life Cycle Management (LCM) evaluations are used to assess the effects of such energy saving efforts. In this study, LCM evaluations were conducted on the air-conditioning chilled water supply system installed as an ESCO facility in the cleanrooms at a semiconductor manufacturing plant. A detailed analysis of the overall system including the pumps, cooling towers, and chillers was conducted to identify the effects of using higher-efficiency absorption chillers and explore optimal mixes of maintenance methods. The analysis yielded quantitative indications of reduced Life Cycle Cost (LCC) and Life Cycle CO_2 ($LCCO_2$) emissions attributed to the use of advanced chillers. The scheme and timing of maintenance practices best suited for specific types of chillers and the degree of cooling water fouling were also identified.

INTRODUCTION

The concepts of LCM that minimize LCC and $LCCO_2$ are becoming permanent parts of modern corporate management. Many existing studies concerning LCM focus on LCA-based environmental evaluation techniques and LCC evaluations. The work done by Actacir[1], Elsafty[2], and others typifies the research conducted on LCC in the chiller air-conditioning sector. These studies are concerned at best with developing comparative evaluations of individual units of equipment, however, and have yet to launch a detailed probe into maintenance-recommended practices.

This study analyzed the effects of using higher-efficiency absorption chillers and explored optimal mixes of maintenance methods from the perspective of LCM evaluations of a chilled water supply system. The following summarizes the major aspects of this study.

- A comprehensive LCM evaluation of the overall chilled water supply system including the pumps, cooling towers, and chillers with regard to the partial load characteristics of the chillers and characteristics of cooling water temperature

- Identification of the optimal methods of maintaining absorption and turbo chillers from the standpoint of optimized LCM, by evaluating how maintenance methods make differences in their effects of energy saving on equipment and in the cost of is equipment.

SUMMARY OF LCM EVALUATION

The chilled water supply system under discussion was installed as an Energy Service Company (ESCO) facility. Because the system is committed to a contractual period of 10 years, both LCC and $LCCO_2$ were evaluated with regard to this period (see Figure 1).

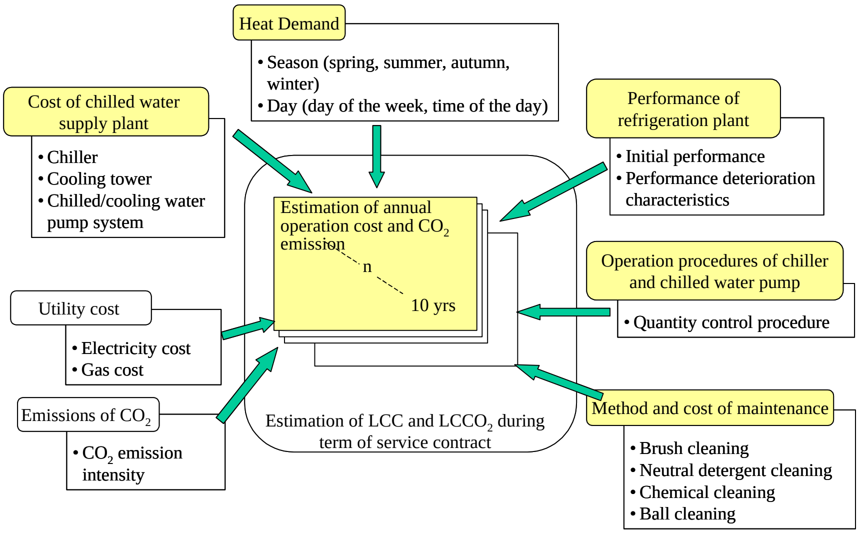

Figure 1. Evaluation system of LCM at refrigeration plant

Estimating LCC

LCC is the sum total of costs for initial equipment installation, operation and maintenance, plus the cost of equipment scrapped. The energy charge is for driving the chillers, cooling towers, and pumps. Annual costs have been evaluated on an NPV (Net Present Value) basis, with an assumed discount rate of 2% per annum.

Estimating $LCCO_2$

The $LCCO_2$ value of a chilled water supply system consisting primarily of chillers is the sum total volume of CO_2 emissions released during system construction and operation, and during the maintenance and scrapping of the chillers.

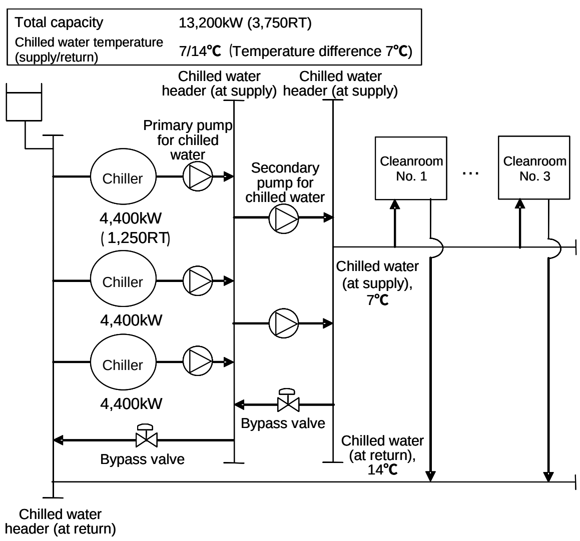

Figure 2. Schematic diagram of chilled water supply system

OUTLINE OF CHILLED WATER SUPPLY-DEMAND SYSTEM

Chilled water supply facility and heat demand

Chilled water is fed to the cleanrooms at the semiconductor manufacturing plant[3]. In the chilled water supply system shown in Figure 2, water is chilled to a temperature of

7°C when supplied and is at 14°C when returned. The maximum and minimum heat demands are 13,050 kW and 4,400 kW, respectively.
Figure 3 shows the heat load demand and annual cumulative time (in hours). The annual demand for heat load is 72.7 x 10^6 kWh. The annual demand for heat load divided by the maximum demand for heat load yields a total-load equipment operation time of 5,570 hours. This plant is running all year-round, with an average load factor as high as 64.5%.

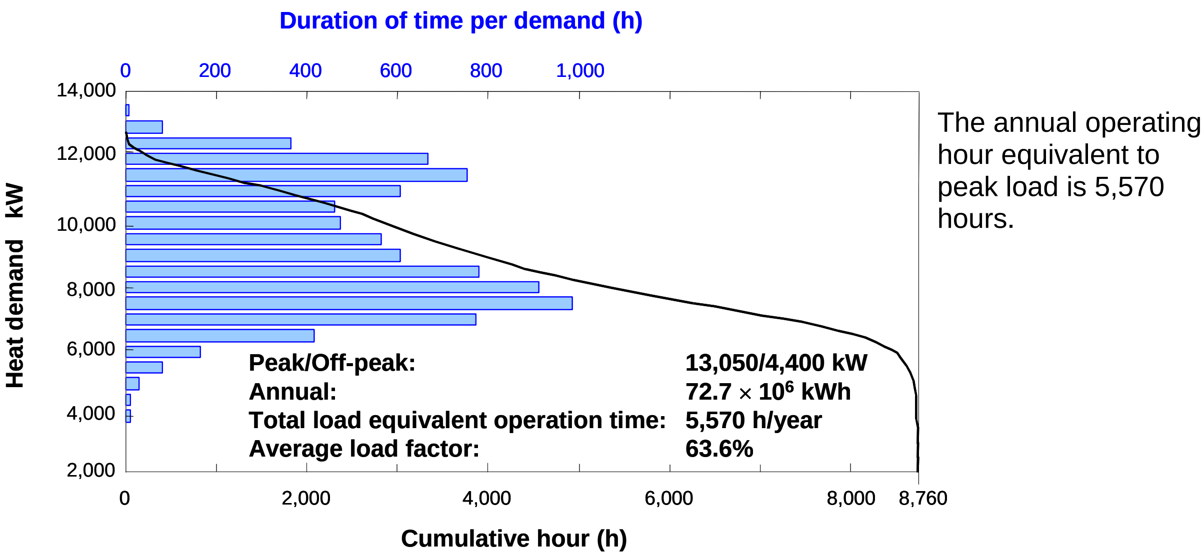

Figure 3. Head demand and annual cumulative time

Performance of chilled water supply system

(1) Turbo chillers

The turbo chiller model using HFC134a as a refrigerant has two-stage economizer and subcooler to achieve higher efficiency. This model conforms to standard specifications and has chilled-water inlet and outlet temperatures of 12°C and 7°C, respectively.

LCM evaluation requires the use of a database covering performance data on chillers working under wide operating conditions; thus we used a cycle simulator for turbo chiller performance data. The coefficient of performance (COP) was then calculated using a chiller load factor between 20% and the maximum load factor, and a cooling water temperature from 12 to 32°C, with and without using a compressor inverter.

Figure 4 plots the results of a simulation performed with cooling-water temperature settings of 24°C and 16°C, in addition to the rated 32°C.

The maximum output exceeds rated capacity in case of cooling water temperature less than 32°C. This characteristic can make the number of chillers to be run reduced.

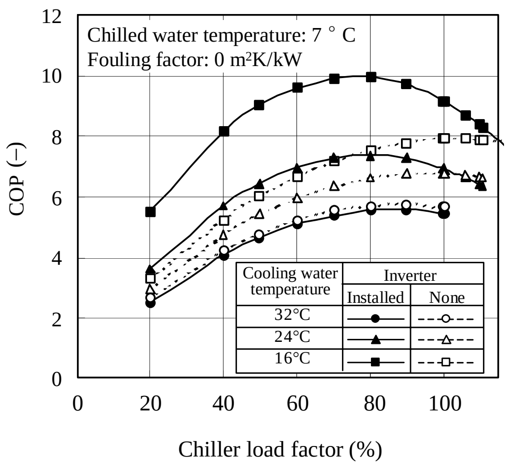

Figure 4. Turbo chiller partial load characteristics

(2) Absorption chillers (steam-driven double-effect/triple-effect)

a. Double-effect absorption chiller

The double-effect chiller (Photo 1) has evaporators and absorbers split into two stages to maintain a heat exchanger temperature difference, and recover heat from condensed refrigerant to achieve a steam consumption rate of 3.5 kg/RT.h and COP value of 1.5 during rated operations.

Photo 1. High efficiency double-effect steam-driven absorption chiller

b. Triple-effect absorption chiller

This study also considered a triple-effect absorption chiller. The first machine, which uses gas directly, achieved a COP value of 1.6 (HHV). We modified performance simulator from gas to steam medium, and an expected steam consumption rate can be 2.81 kg/RT.h and COP value can be 1.87 under rated condition.

Figure 5 shows the partial load characteristics of the double-effect and triple-effect absorption chillers. The COP value of the turbo chiller is converted to primary energy input. The power plant generating efficiency is assumed to be 41.9%.

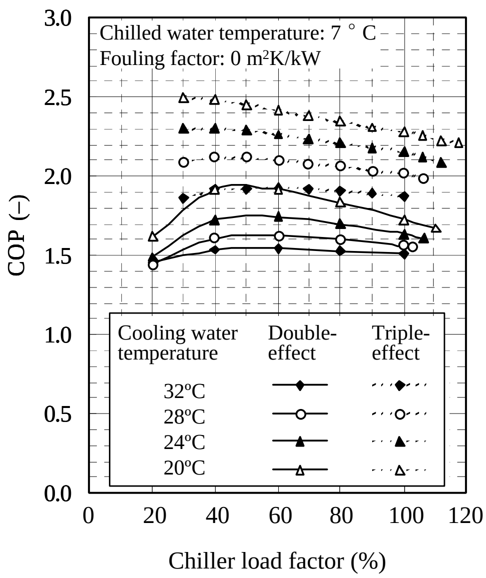

Figure 5. Partial load characteristics of a double-effect absorption chiller (steam consumption rate: 3.5 kg/RT.h) and triple- effect absorption chiller (steam consumption rate: 2.81 kg/RT.h)

Chiller performance effect due to fouled cooling water

Fouled cooling water could impair the heat transfer characteristics of the chiller condenser, resulting in degraded chiller performance. Using the cycle simulator, the chiller performance deterioration associated with fouled water has been determined by calculations (see Figure 6).

Changes in chiller performance without cleaning the CD tube have been calculated based on the assumption that the fouling factor would increase by 0.086 m^2K/kW per year and twice.

The chart reveals quantitative drops in cooling capacity and COP with increases in fouling. The absorption chiller suffers drastic drops in chiller capacity with increased fouling, but its COP only drops slightly.

The deterioration of chilling capacity with the progress of cooling water fouling is more marked on the absorption chiller than the turbo chiller. The rate of reduction in the COP is not much varied among the different chiller types.

Two kinds of cooling water have been selected to be fouled: good and poor. The effect of water fouling upon the condenser was assumed to be 0.86 (m^2K/kW) per year for good-quality water and 1.72 per for poor-quality one.

Cleaning CD tubes and resultant improvements in performance

Brush cleaning (BrC), ball cleaning (BaC), and chemical cleaning (ChC) are typically employed to clean inside the condenser (CD) tubes of turbo chillers. Conversely, cleaning using a natural detergent (NDC) instead of brush or ball cleaning is the preferred method of CD cleaning of absorption chillers. This study has extended its discussions to include four cleaning methods (see Table 1).

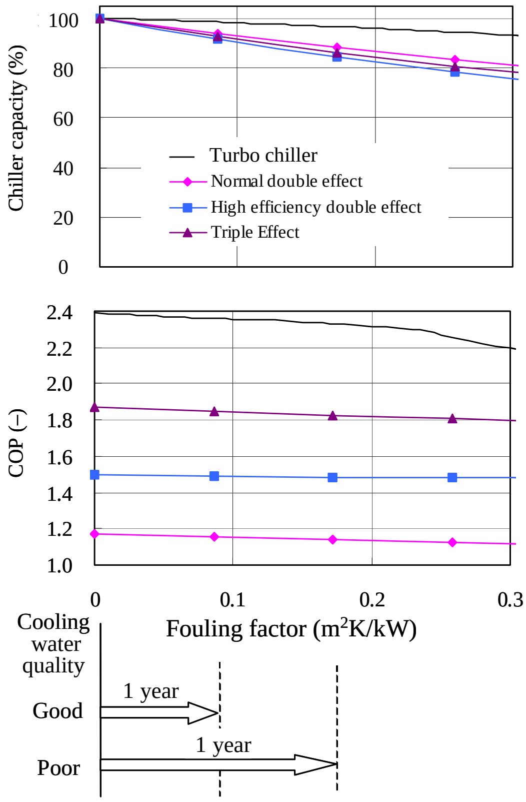

Figure 6. Chiller performance deterioration affected by cooling water fouling

Table 1. Methods of cleaning CD tubes in each chiller and their effects by cleaning methods

Maintenance method	Brush cleaning (BrC)	Neutral detergent cleaning (NDC)	Chemical cleaning (ChC)	Ball cleaning (BaC)
Applied chiller type	Turbo chiller	Absorption chiller	Turbo and absorption chillers	Turbo chiller
Cleaning method	Cleaning inside the CD tubes with a wire brush.	Cleaning inside the CD tubes with a neutral detergent.	Acid-cleaning inside the CD tubes	Inserting spongy balls into the CD tubes to remove contaminants.
Frequency	Once a year	Once a year	Once every several years	Once every several days
Effect (provisional value)	Up to 98% of the COP value obtained one year ago can be recovered.	Up to 98% of the COP value obtained one year ago can be recovered.	The condition of the chiller at initial installation can be restored.	Up to 99% of the COP value obtained one year ago can be recovered.

LCM EVALUATION

Evaluating LCM

1) Method of LCM comparative evaluation

The LCM of three types of chillers has been analyzed over a 10-year period. The following patterns of maintenance were discussed.

- Maintenance is conducted once a year.
- BaC is performed every week.

- At least three years must be allowed to elapse after former ChC practice to minimize the risks of local corrosion on the chiller condenser. (Once ChC is conducted in a given year, no other method of cleaning is employed at the same year.)

2) Method of calculating LCC

The following describes the method of calculating 10-year LCC for the chilled water supply system. The total amount of LCC (or LC) is represented in Eq. (1) as follows:

$$LC = IC + \sum_t \phi_E \overline{E}_E + \sum_t \varphi_E E_E + \sum_t \phi_G \overline{F}_G + DC \qquad (1)$$

where, IC denotes the investment cost, $\overline{E}_E$, the rate of power consumption [Nm^3/year], E_E the contractual demand [kW], $\overline{F}_G$ the gas consumption rate [Nm^3/year], t a 10-year period, ϕ the electric energy charge 7.7 [yen/kWh], φ_E the electric basic charge 1,740 [yen/kW month], and ϕ_E the gas energy charge 35 [yen/Nm^3]. The third term of Eq. (1) is zero for a turbo chiller, because it does not use gas.

3) Method of calculating $LCCO_2$

$LCCO_2$ is determined by summing up the volume of CO_2 emissions calculated from the energy emitted over a 10-year period and that of CO_2 emissions at the time of chilled water supply system initial manufacturing/installation, and scrapping. The total volume of CO_2 emissions of each system is calculated as LE by solving Eq. (2) as follows:

$$LE = E_I + \tau_E \cdot C_E + \tau_G \cdot C_G + E_S \qquad (2)$$

where,
E_I: Volume of CO_2 emissions at chiller manufacturing and installation [t-CO_2]
τ_E: CO_2 emission intensity due to electric power (0.555×10^{-3}) [t-CO_2/kWh]
C_E: Total electric power consumption rate [kWh]
τ_G: CO_2 emission intensity due to gas (2.097×10^{-3}) [t-CO_2/Nm^3]
C_G: Total gas consumption rate [Nm^3]
E_S: Volume of CO_2 emissions at equipment scrapping [t-CO_2]

Table 2 lists the volumes of CO_2 emissions [t-CO_2] at system and scrapping.

Table 2. Volumes of CO_2 emissions at chiller installation and scrapping

Type of chiller		Volume of CO_2 emissions at manufacturing and installation (t-CO_2)	Volume of CO_2 emissions at scrapping (t-CO_2)	Total volume of CO_2 emissions
Turbo chiller		564	60	624
Absorption chiller	Double-effect	345	40	385
	Triple-effect	414	50	464

4) Costs of chillers and maintenance equipment/procedures

Table 3 lists different types of chillers and maintenance equipment (BaC) and the costs incurred to maintain them by chiller condenser cleaning method. The triple-effect absorption chiller supply facility requires the cost of equipment, 1.8 times higher than turbo chillers. Among the four cleaning methods, ChC is most costly.

Table 3. Costs of chillers and their maintenance

Item \ Model		Turbo chiller	Absorption chiller: Double-effect (COP) 1.17	1.3	1.5	Triple-effect (COP 1.87)
Equipment and installation cost (million yen)	Chilled water supply facility (system as a whole)	375	453	466	488	675
	Maintenance equipment (BaC, common use)	+10	-			-
Maintenance cost (million yen/time/system)	BrC	1.5	-			-
	NDC	-	1.8	1.8	1.8	2.4
	BaC	2.4	-			-
	ChC	6.0	6.0	6.0	6.0	6.9

Evaluating the effects of LCM by chiller type and cooling water quality

The LCM values of each chiller associated with differences in water quality were evaluated. Absorption chillers optimize their LCM when serviced by annual NDC, coupled with ChC conducted at four-year intervals, and turbo chillers optimize their LCM when serviced by BaC, coupled with ChC conducted at four-year intervals.

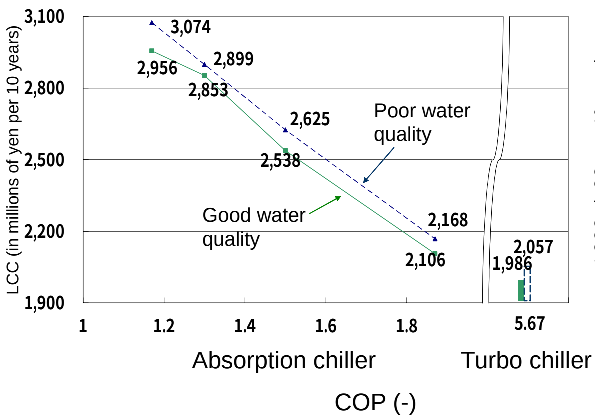

Figure 8. Evaluated effects of LCC by chiller's type

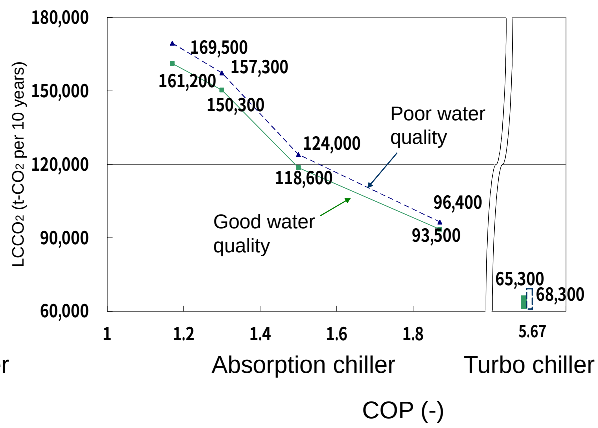

Figure 9 Evaluated effects of $LCCO_2$ by chiller's type

As shown in Figure 8, absorption chillers can reduce their LCC with increases in the COP. Turbo chillers are more cost-effective than absorption chillers. As long as the water is good, the difference between a triple-effect absorption chiller and a turbo chiller remains at about 120 million yen. If the water quality worsens, however, the difference would escalate by 11 million yen. Hence, turbo chillers are more affected by water quality than triple-effect absorption chillers.

As can be seen in Figure 9, turbo chillers are superior to absorption chillers in terms of $LCCO_2$. $LCCO_2$ affected by water quality is almost same as triple-effect and turbo chiller.

Figure 10 shows the relation between LCC and $LCCO_2$ in terms of maintenance and water quality. The arrow marks indicate the direction of an increasing degree of water fouling. LCC/$LCCO_2$ are found to be more noticeably affected by differences in water quality than differences in the maintenance method (standard or optimal maintenance).

Risks imposed by varying energy unit prices

Because the ESCO project is committed to a contractual period of 10 years, the electric power and gas rates are likely to vary in the meantime, resulting in changes in LCC and hence in business economics. Figure 10 presents an evaluation of the cost advantages of triple-effect absorption chillers and turbo chillers against changes in the electric energy charge and gas unit price.

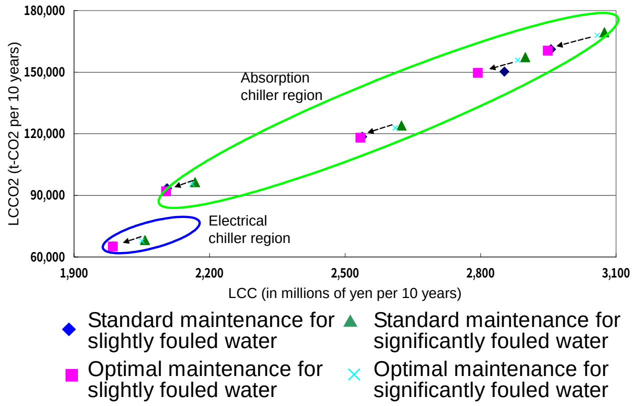

Figure 10. Relation between LCC and $LCCO_2$

In the figure, the upper-left region above the continuous solid line denotes the region in which electric turbo chillers come more advantageous than gas chillers. Figure 11 demonstrates that turbo chillers are more advantageous under the present conditions of review. Moreover, the less the cooling water is fouled, the wider the area where turbo chillers are effective.

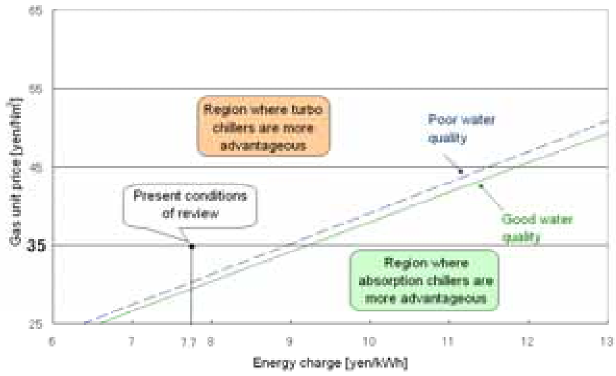

Figure 11. Decision criteria for making energy choices

CONCLUSIONS

This study has conducted an LCM evaluation of turbo, double-effect absorption and triple-effect absorption chillers and, what is characteristic, has demonstrated quantitative measures of reductions in both LCC and $LCCO_2$. Information derived from this study includes:

1) Depending on combinations of cleaning methods and their frequencies, optimal maintenance patterns exist to suit specific refrigerator types.
2) Absorption chillers coupled with neutral detergent cleaning conducted every year and chemical cleaning conducted at 4-year intervals minimize both LCC and $LCCO_2$.
3) Turbo and triple-effect absorption chillers virtually equaled in their evaluation of LCC, but electrical chillers prove better when it comes to minimize $LCCO_2$.

Benchmarking Cooling Efficiency in Server Rooms

Ole Valentin

Birch & Krogboe A/S, Aalborg Department
Sofiedalsvej 9, DK-9200 Aalborg SV, Denmark

Corresponding email: olv@birch-krogboe.dk

SUMMARY

This paper discloses a new set of design guidelines for choosing an energy efficient server room design. Choosing the right server room design can secure very fast money recuperation when selecting a better cooling system than the cheapest available.

The ideal server room has a physical barrier between the hot and cold side. If a physical barrier is not possible CFD-calculations show a large savings potential of electricity for cooling machinery just from choosing the optimal room and server positioning design. With a demand of a specific maximum temperature at the server inlet and a estimated savings potential of 65- 130 Euros/(year*kW*K) and the difference between the best and the worst model design is 8 °C. The servers are consuming 30 kW electricity all year round generating equal amount of heat. The savings potential for this room is 15,600 - 31,200 Euros per year.

INTRODUCTION

Server rooms have large energy consumption thus demanding large cooling effects. The distribution of cooling air was thought essential in order to reduce the power consumption by the cooling machinery for this purpose. When the evaporation temperature of a cooling system is lowered the COP is reduced thus increasing the power consumption for removing the heat from the server room. With a demand of a specific maximum temperature at the server inlet and a estimated savings potential of 65- 130 EURO/(year*kW*K) it was considered essential to be able to control the air flow in the server room avoiding short circuiting of hot exhaust air from the server outlets to the server inlets.

In collaboration with the Danish Electricity Savings Trust, Birch & Krogboe has performed large series of CFD calculations testing the consequences of different common ventilation lay-outs in a small room with 2x3 rack central in the room. The scope of these calculations was creating a benchmarking or an energy classification labelling for server room design. Later the results will be used for guidelines for server room design at the Danish Electricity Savings Trust homepage and will probably be launched late 2007.

Different layout where tried such as fan coils placed in different positions, servers positioned either face to face, face to rear or rear to rear, inlets placed in an elevated technique floor on the server face side and outlets in different positions in the ceiling.

Ideal configuration of server room would be a room with a complete separation of the cold inlet side of the servers and the hot exhaust side and a critical amount of cooling air supplied to the room. Restrictions against mechanical obstructions in the room meant that the exhaust air from the servers had to be guided to the ventilation outlet by the air itself without creating too much short circuiting between the server's outlet and inlet.

Parameters such as air mixing index, scattering and/or enveloping of the hot air, and necessary inlet temperature of the cooling air was derived from the results of the CFD-calculations for different server room arrangements.

METHODS

All calculations were carried out with a commercial general purpose Computational Fluid Dynamics code (CFD). All CFD calculations were steady state, the turbulence model is a Reynolds Average Navier Stokes model the RNG- $k\varepsilon$. 3 different models have been used in a number of variations. Models are processed for 100 iterations. This gives a convenient balance between accuracy and calculation time. The calculations are not fully converged in accordance with the convergence criteria, but solutions are found to be sufficiently precise for a qualitative as well as quantitative comparison between the different setup.

There are 3 basic models, SK2, SK3 and SK4. Each calculation has a name describing what model is used, the orientation of the servers and finally the position of the fan coil/outlet eg. SK2FRS means model SK2 with servers orientated front toward rear (FR) in the two rack lines. The S describes the position of the fan coil outlet at the side of the room. Other positions are at the end of the room (E) and in the ceiling (C).

The SK2 model measures lxwxh 6000x4200x2400. The blue blocks are each 3 racks placed side by side. The racks are wxdxh 1800x1200x2000 mm. Servers are modelled as square tubes, 100x100 mm, passing through the racks. Upper, middle and lower row are active server, each producing 1667 W, total for the servers 30 kW. The air direction kan be selected in both directions through the active servers. The remaining tubes are leaks through the racks where the air is free to pass in any direction. A fan coil can be activated either at the end or at the side of the room, only by the ceiling. Initially airflow through the fan coil are 4 times the airflow through the servers in order to let the temperature difference through the servers be 20 °C and 5 °C through the fan coil/cooling system. Inlet temperature is 20 °C for all calculations. The SK2 model has a calculation grid of 385.330 cells.

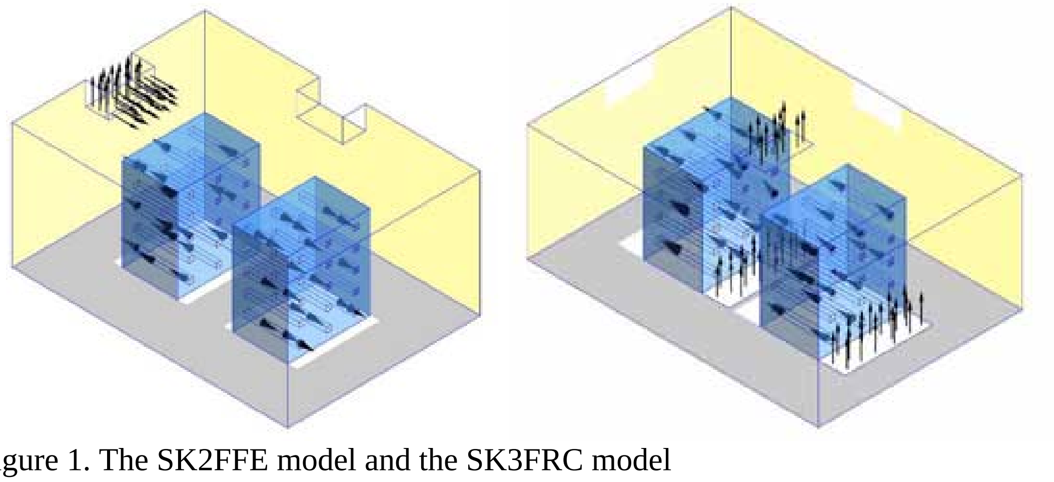

Figure 1. The SK2FFE model and the SK3FRC model

The SK3 model is almost equal to the SK2 model. The fan coil boxes have been replaced with openings in the wall for outlets. A third outlet possibility is situated in the middle of the ceiling. Cooling air inlets are placed in the floor by the front of the servers. The SK3 model has a calculation grid of 332.991 cells.

The SK4 model is similar to the SK3 model having more outlet positions in the ceiling in order to place the outlet opening in the most appropriate position. The model has furthermore a reduced room height, only 2100 mm. The SK3 model has a calculation grid of 407.205 cells.

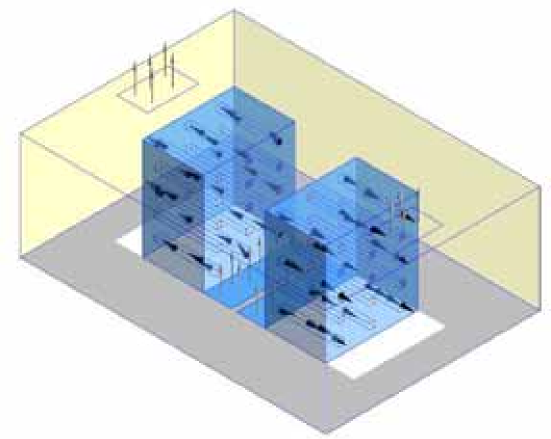

Figure 2. The SK4RRC model

5 main rounds of calculations were carried out:

1. The SK2-model. Fan coil placed at 2 different locations 3 positions of servers in racks (FF front to front, FR front to rear and RR rear to rear), room height 2400mm
2. The SK3-model. Inlet in installation floor by front of servers, outlet at 3 different locations, 3 positions of racks, FF, FR and RR , room height 2400mm
3. The SK4-model. Inlet in installation floor by front of servers, outlet at different locations (ceiling only), 3 positions of racks, FF, FR and RR , room height 2100mm
4. All models. Effect on reduced air volume ratio of cooling air. Inlet in installation floor, outlet at 3 different locations, 3 positions of racks.
5. The SK4FFC-model. Effect on different air volume ratio cooling: servers 4:1 VS 3:1 VS 2:1 VS 1:1; Inlet in installation floor. Racks only FF. Outlet only in ceiling.

All results were checked for all server inlet temperatures, best and worst value chosen, model maximum temperatures, flow speed and flow patterns. From all data was various parameters calculated. The following 3 are the most significant:

The Mixing Index (MI) describing the air quality for the most critically placed server. MI=0 means all server inlet air comes directly from cooling inlet with no mixing af warmer air. MI =100 means a 100 % short circuit where all server exhaust air are led to a server inlet with no mixing of fresh cooling air. The MI is divided in the index classes below:

A	0-4.9
B	5.0-9.9
C	10.0-19.9
D	20.0-29.9
E	30+

The Sub Cooling(SC) gives a direct indication of how much the server room cooling system ha to sub cool the inlet air compared to an ideal system in order to secure all servers in the room are supplied with air below the required maximum temperature. In the ideal system SC is 0 ºC. For increasing values of SC the evaporator temperature and COP of the cooling system are decreasing causing increased energy consumption for the cooling of the server room. In fact the SC is probably the most important index on the server room energy efficiency. The SC is divided in the index classes below:

A	0 - 0.99
B	1 - 1.99
C	2 - 2.99
D	3 - 4.99
E	5+

The overall Energy Class Index is derived from MI and SC and server inlet and mean temperatures and model maximum temperatures. The Energy Class Index is divided into equivalent 5 classes as seen above for MI and SC.

RESULTS

As an example model SK2FFE will be demonstrated thoroughly. Other results will be listed in table 2.

MODEL SK2FFE:

Servers placed front to front. Cooling air enters room by ceiling from fan coil on end wall. Exhaust at the same location from the down side of the fan coil. See figure 1.

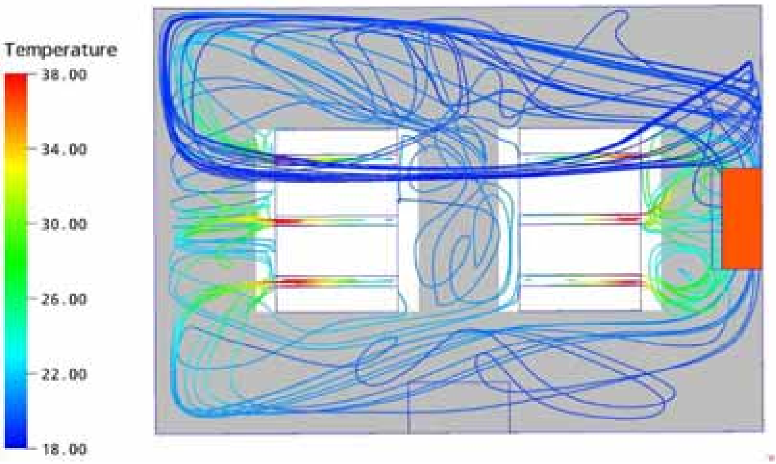

Figure 3. The SK2FFE model seen from above. Fan coil to the right

Table 1. The evaluation of the SK2FFE model

Model	DeltaTmax	Mixing index	Sub cooling	Energy Class
SK2FFE	24.5	17.0	3.4	C

This design gives a substantial mixing of hot air to the servers placed near the outlet of the fan coil. If all servers must have air supply below 20 ºC fan coil have to supply inlet air to the room at maximum 16.6 ºC.

When you have to use a fan coil placed near the ceiling it doesn't matter whether it is placed on the side wall or on the end wall. The significantly best results come from placing the servers front to front. MI 16 – 17 and sub cooling 3.2 – 3.4 °C. All other server configurations give MI 21.5-40.0 and sub cooling 4.3 – 8.0 ºC.

Table 2 Results of initial server room index calculations

MODEL	MIXING INDEX	SUB COOLING	ENERGY CLASS	COMMENT
SK2FFE	17.0	3.40	C	
SK2FFS	16.0	3.20	C	
SK2FRE	40.0	8.00	E	
SK2FRS	23.5	4.70	D

SK2RRS	24.0	4.80	E	
SK3FFE	2.0	0.40	A	
SK3FFC	8.0	1.60	B	
SK3FFS	1.3	0.25	A	
SK3FRE	7.0	1.40	B	
SK3FRC	14.0	2.80	C	
SK3FRS	11.0	2.20	C	
SK3RRE	21.0	4.20	D	
SK3RRC	1.3	0.25	A	
SK3RRS	39.0	7.80	E	
SK4FFC	0.3	0.05	A	
SK4RRC	0.5	0.10	A	

Series of calculations with reduced cooling air or/and increased flow through servers all showed lesser results than the one listed in table 2 when comparing each setup.

One SK4-model (SK4FFC) was chosen in order to examine when a critical change in air supply compared to the air flow through the server racks.

Effect of different air change rates:

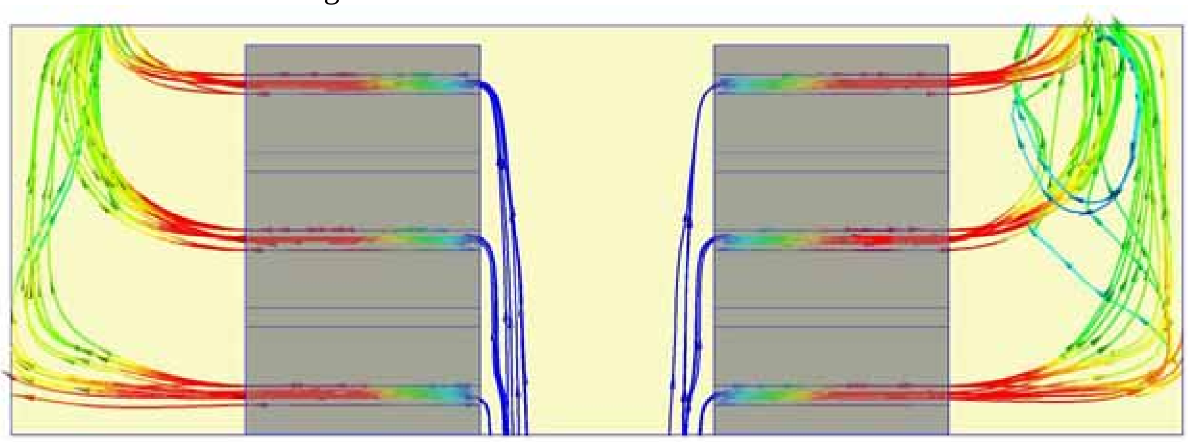

Figure 4 The SK4FFC100 model. Flowlines showing temperature

The SK4FFC100 model has an air change ratio between cooling system and through servers of: 4:1 In this case there is full control with the hot exhaust air which is completely engulfed in an envelope of cold cooling air. MI: 0.25, SC: 0.05°C, Energy Class A.

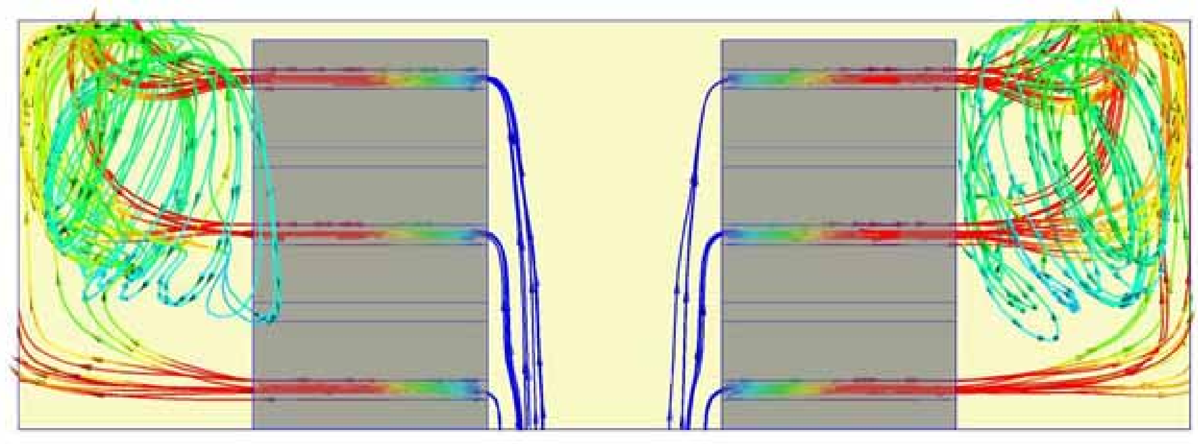

Figure 5 The SK4FFC75 model. Flowlines showing temperature

The SK4FFC75 model has an air change ratio between cooling system and through server of: 3:1 In this case there is control with the hot exhaust air which is partly engulfed in the cold cooling air. The flow patterns show some scattering and mixing but no back flow of hot air to the server inlet side. MI: 0.50, SC 0.10°C, Energy Class A.

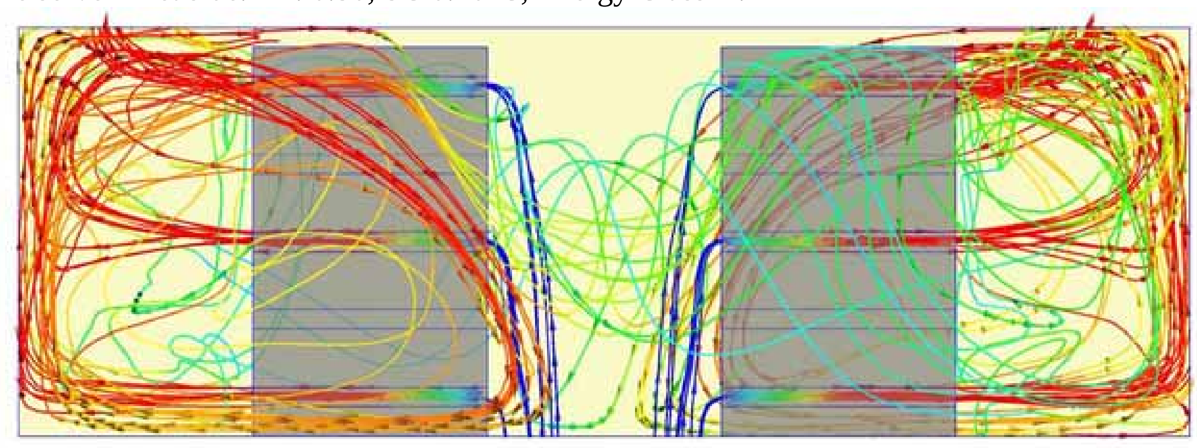

Figure 6 The SK4FFC50 model. Flowlines showing temperature

The SK4FFC50 model has an air change ratio between cooling system and through server of: 2:1 In this case there is control with the hot exhaust air which is no longer engulfed in the envelope of cold cooling air. The flow patterns show scattering of the hot air and. It is primarily the servers by the edges of the rack that receives premixed thus warmer air.MI: 3.0, SC 0.6°C, Energy Class B.

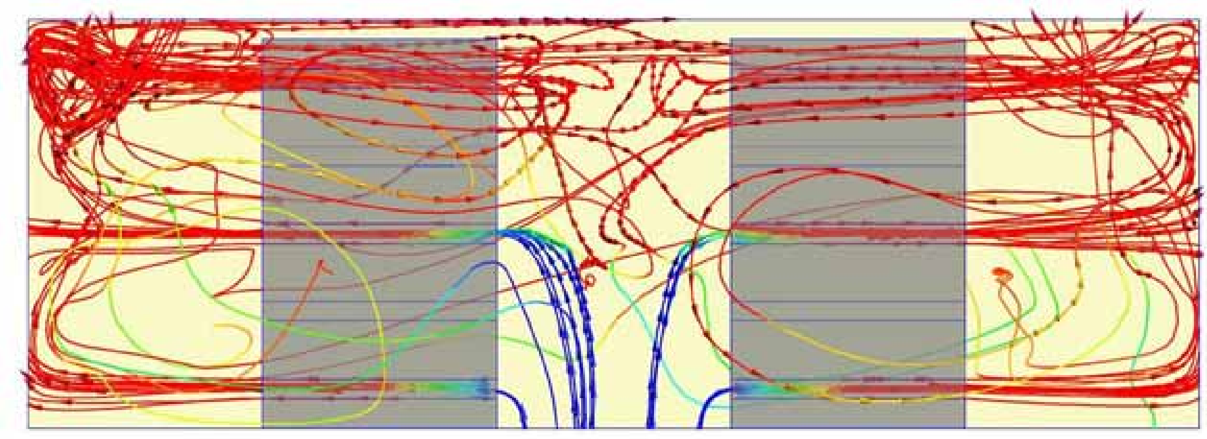

Figure 7 The SK4FFC25 model. Flowlines showing temperature

The SK4FFC25 model has an air change ratio between cooling system and through server of: 1:1 In this case there isn't cold air upper half of the servers. The hot exhaust air is traveling freely between the 2 exhaust sides. There is outspoken scattering and mixing of the hot air and most servers receives premixed thus warmer air.MI:80, SC 16.8°C, Energy Class E.

Open rooms with a narrow space above the racks needs a supply of cooling air at least 2 - 3 times the air flow through the servers giving a holding pressure large enough to keep the exhaust air from mixing and getting to the server intake side. For this air ratio to work it is necessary to have physical barriers between the intake and the exhaust side of the servers.

DISCUSSION

From the results of the CFD-calculations it is now possible to setup some basic guidelines for selecting the optimal server room design.

It is always better to build up a server room with an installation floor and concealed ceiling and this way guide your cooling air inlet and outlet to the optimal position as close to the server than building a server room with fan coils for cooling. If it's impossible to separate the intake and exhaust side physically it should be attempted to have as little room above the rack as possible and reduce the number of gaps in the rack. Demand for cooling air increases with increased opening areas between the two sides.

If you are forced to use fan coils, it is better to have some open space above the racks. When having a fan coil placed near the ceiling it can be at either side or end wall. The servers just have to be placed front to front for the most efficient cooling. MI 16 – 17 and sub cooling 3.2 – 3.4 °C. All other server configurations give MI 21.5-40.0 and sub cooling 4.3 – 8.0 ºC.

Table 3 Comparing model results

	MI-range	SC-range
SK2	16-40	3.2-8.0
SK3	1.3-39	0.25-7.8
SK4	*	*

* SK4 models seem to be better than SK3- models. This has only been tested for a few configurations.

Comparing model SK3 and SK4 can also be used to optimize the cooling air flow rate. It is possible to control and guide the exhaust air from server to room outlet in an SK4 setup with as little as half the flow rate of a SK3 saving half the power consumption for ventilating the cooling air.

With a demand of a specific maximum temperature at the server inlet and a estimated savings potential of 65- 130 EURO/(year*kW*K). As the difference between the best and the worst model design is 8 °C, and the server room is emitting 30 kW all year round, the savings potential for this room is 15,600 - 31,200 Euro pr. year. Further savings can be found if the system can operate at a higher temperature. This gives exactly the same savings pr. °C. If the system can be designed to use fresh air for free cooling during periods with outdoor temperature below the inlet set point even more electricity for cooling can be saved.

About the model it has been created in a well verified General Purpose CFD code from one of the leading vendors. The models have all been checked for grid independency. Though full convergence was not reached, 100 iterations brought the calculations very close to the convergence criteria. Measurements of server inlet temperatures were taken 1cm from inlet of tube inside the tube. Thus best mixing index 0.25 equals ideal 0.00. Comparative testing is a future challenge, but will probably not give any substantial deviation from the CFD-results.

No free cooling considered since it was the mere room design that was the scope of this work.

SUMMARY

Geo Power System [1] [2] uses the geo thermal heat from the very shallow area of the underground temperature down to 5 m depth. Though the conventional Geothermal Heat Pump system uses the deeper soil like 30 to 100 m from the ground, because of the slow heat transfer in the soil, the temperature of 3 to 5 m depth is warmer in winter and cooler in summer than the average temperature of the site. This system is more efficient and lower cost. Now this system was introduced in Japan for more than 600 buildings including 27 large size facilities. This paper explains the system and the typical performance data of the house, kindergarten and the office.

The test in Canada was done in Ottawa with Natural Resources Canada for the application to the different climate from Japan.

INTRODUCTION

The temperature profile of the underground

The annual temperature profile of the underground is shown in Fig.1 and one day profile in summer is in Fig.2.

The temperature below 6m is constant as the average ambient temperature of the site and at 3 to 4m below the ground level is lower in summer and higher in winter than the average temperature because of the slow heat transfer of solar energy from the sun.

In western part of Japan, we have investigated and worked with Yamaguchi University and applied this character in this system for efficient and cheaper heat exchanger of house ventilation air.

Fig.2 one day temperature profile in summer
30 °C air in summer can heat exchange with shallow soil of 15 °C and installation cost can be cheaper because of the digging cost can be reduced by auger drilling down to 5 m is easy comparing with the cost down to 30 m or 100 m depth from the ground.

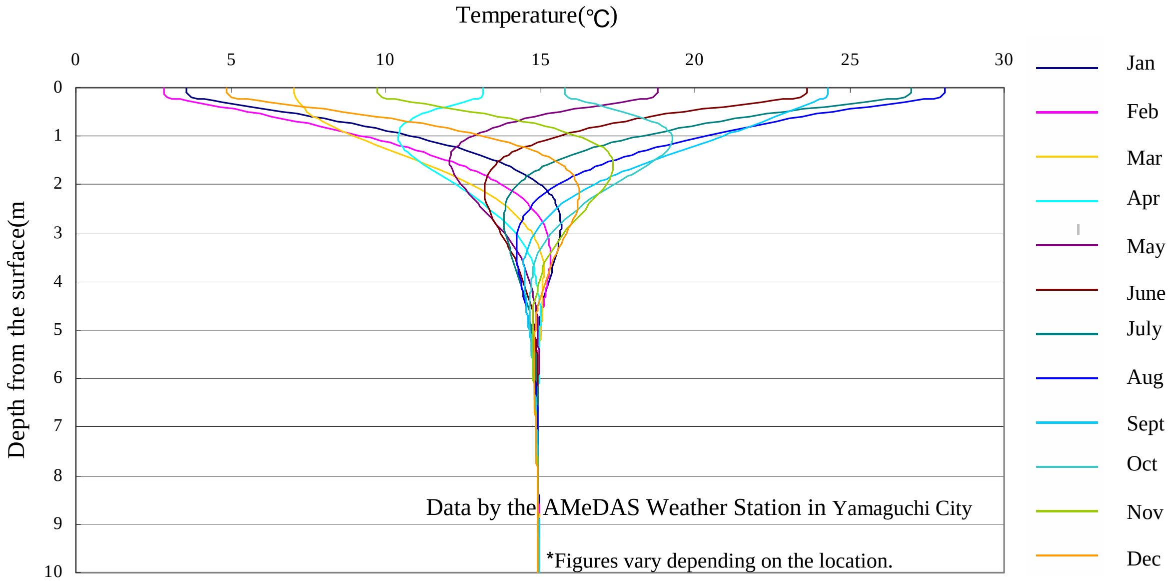

Fig.1 Underground Temperature Profile (all year).

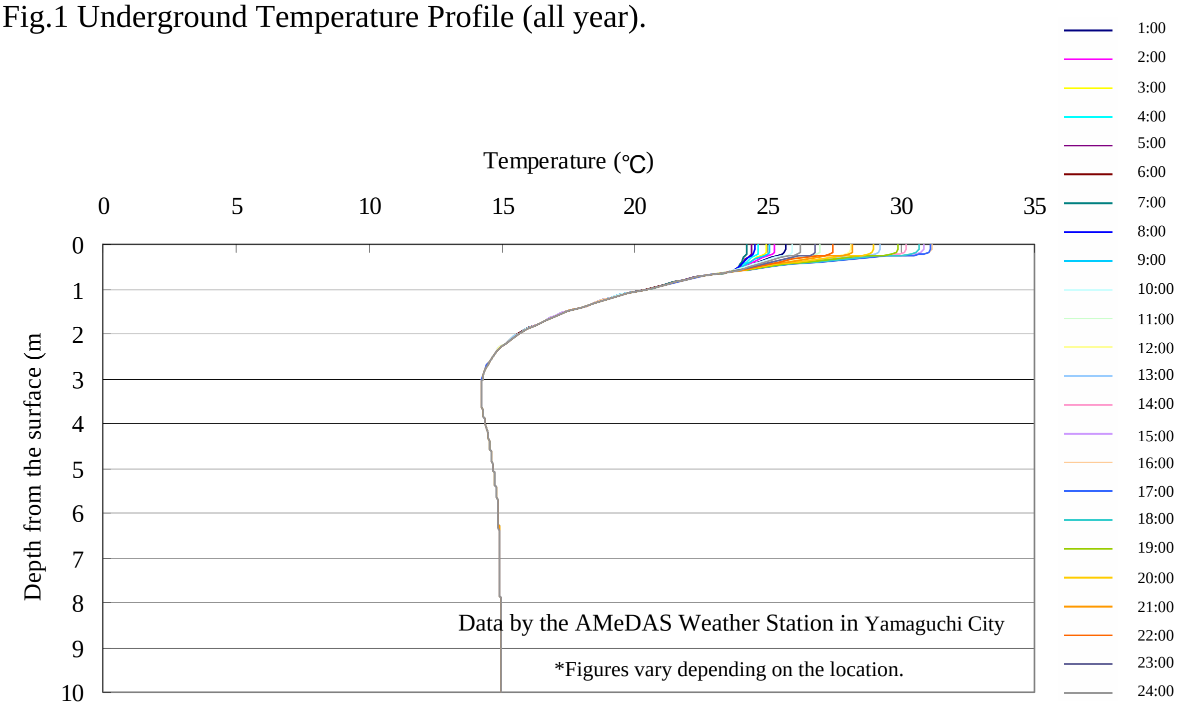

Fig.2 Underground temperature Profile(one day in summer).

METHODS

Description of the system

The system is shown in Fig.3 System Flow.

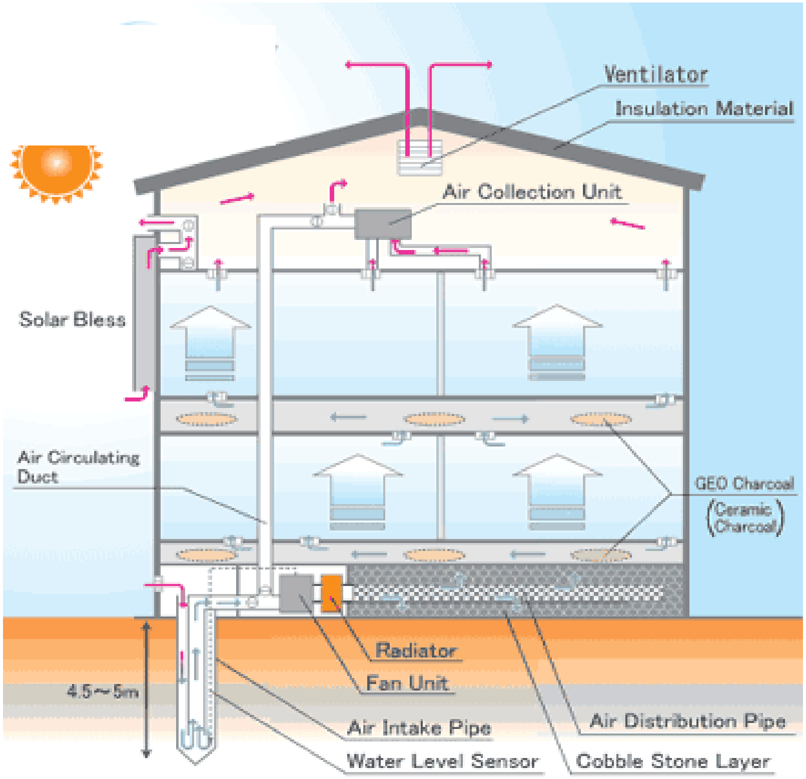

Fig.3 System Flow.

The system is a three in one system combining the effectiveness of three factors namely, Geothermal Energy + Air Circulation + Ventilation. The ground heat collecting double pipe is vertically installed down to 5m at the perimeter of the building and the cobble stone layer is arranged under the first floor board for heat sink. The outer pipe is good for heat transfer and the inner pipe is for insulation by plastic material. When the well water is available at site, radiator (fin-tube heat exchanger) is installed for further effective use of thermal heat.

For typical domestic houses in Japan, 250 mm diameter and 5 m length of aluminum pipe is used for outer pipe and the 150 mm polyethylene for inner pipe. The room air can be circulated or vent depending on the temperature and the circumstance.

Demonstration Tests in Yamaguchi, Japan

The temperature profile of the show room in Yamaguchi city, Yamaguchi Pref. Japan was taken by Yamaguchi University in summer 2003 and the efficiency was confirmed even 32°C air can be cooled to 22°C by this system. The graph is shown in Fig.4 Temperature profile at demonstration house in Yamaguchi Japan.

Though this is not so cool as the air conditioner, it is good for health reducing energy consumption and avoid over cooling.

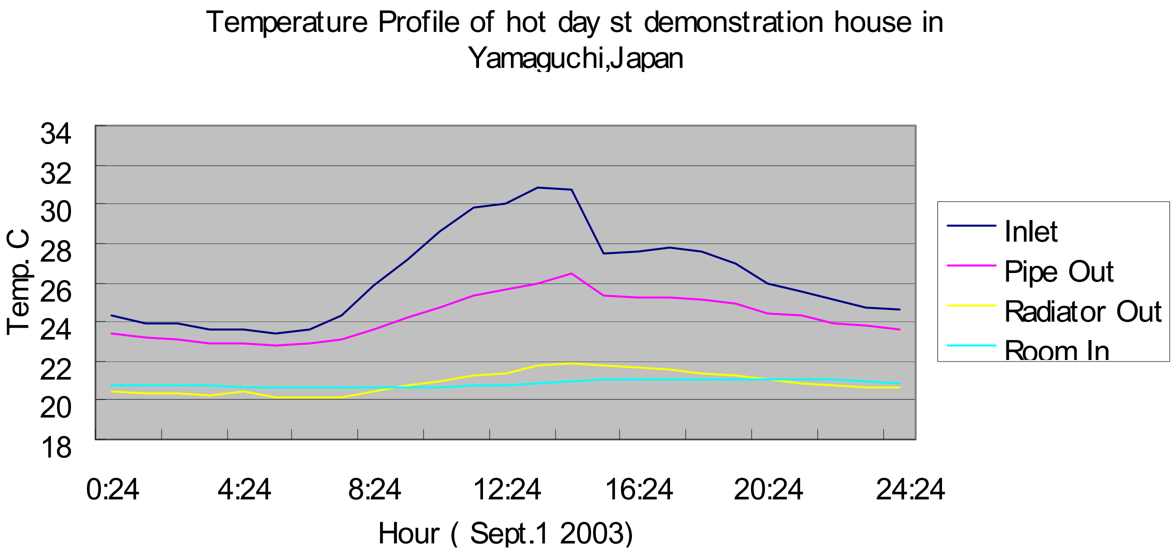

Fig.4 Temperature profile at Demonstration house in Yamaguchi, Japan.

RESULTS

Tests in Ottawa, Canada

In order to have an overseas performance of very hot summer and very cold winter, the agreement was made to comprehensive tests in Ottawa Canada with Natural Resources Canada (NRCan) for one year. The effect to the ground soil was also tested.

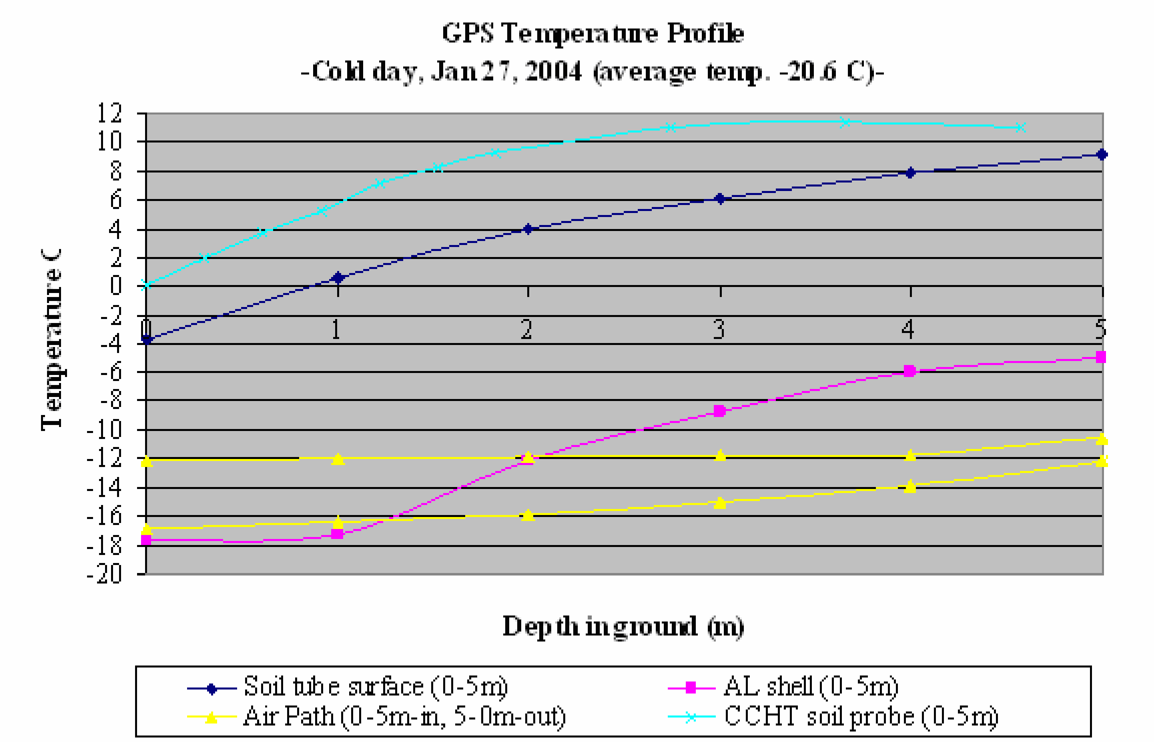

Fig.5 Cold winter day in Ottawa.

The performance at a kindergarten in Shiga, Japan

With a subsidy of the Ministry of Environment, the kindergarten in Shiga, Japan installed 44 pipes and 11 radiators for their rooms of 2637 m2 by July 2005. Fig.7 and 8 show the temperature profile of one day in winter /summer. They enjoyed the energy saving consequently reduction of CO_2 emission and running cost saving as shown in Fib.9 ,10 and 11.

In a cold in winter of 0 to 1°C of outdoor temperature, Room-In Temperature of air is almost constant and Room Temperature varied in a day from 12 to 15C.

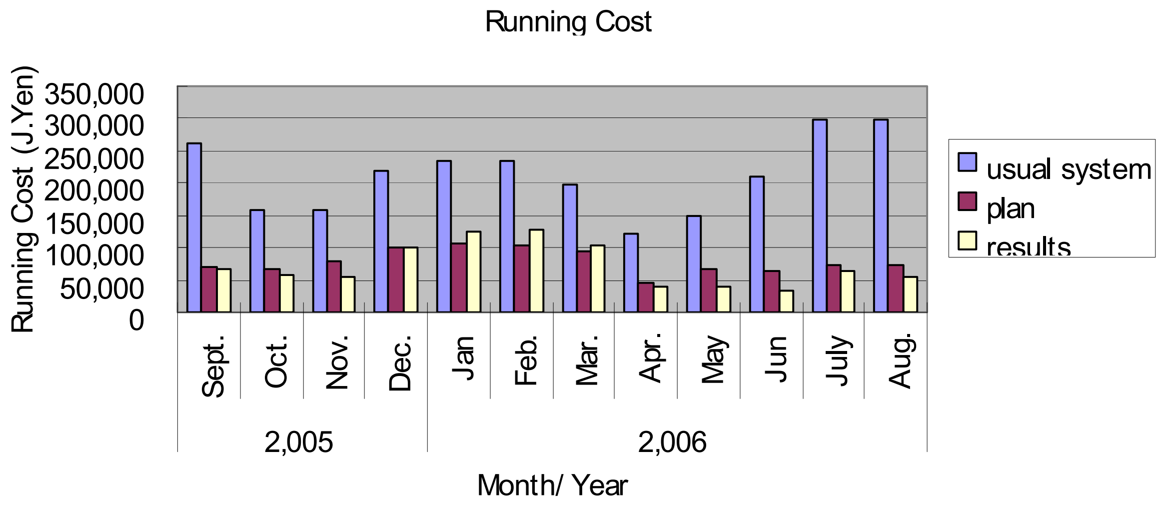

Fig.11 Running cost at a kindergarten in Shiga, Japan.

DISCUSSION

Comfortable life is not synonymous with healthy life. Symbiotic society of healthy environmentally friendly society helps to create genial personalities.

The wastes of electricity due to the excess use of air-conditioners and overuse of fossil fuels have accelerated of CO_2 in the atmosphere, worsening global warming.

More and more children have autonomic nerve dysfunctions, causing them to be unable to sweat, because of the excess use of air-conditioners. Deterioration of autonomic nerve functions can impair the natural functioning of human body temperature regulation and cause other function disorders.

The kindergarten which installed this system enjoyed the absent rate decrease of the gardeners.

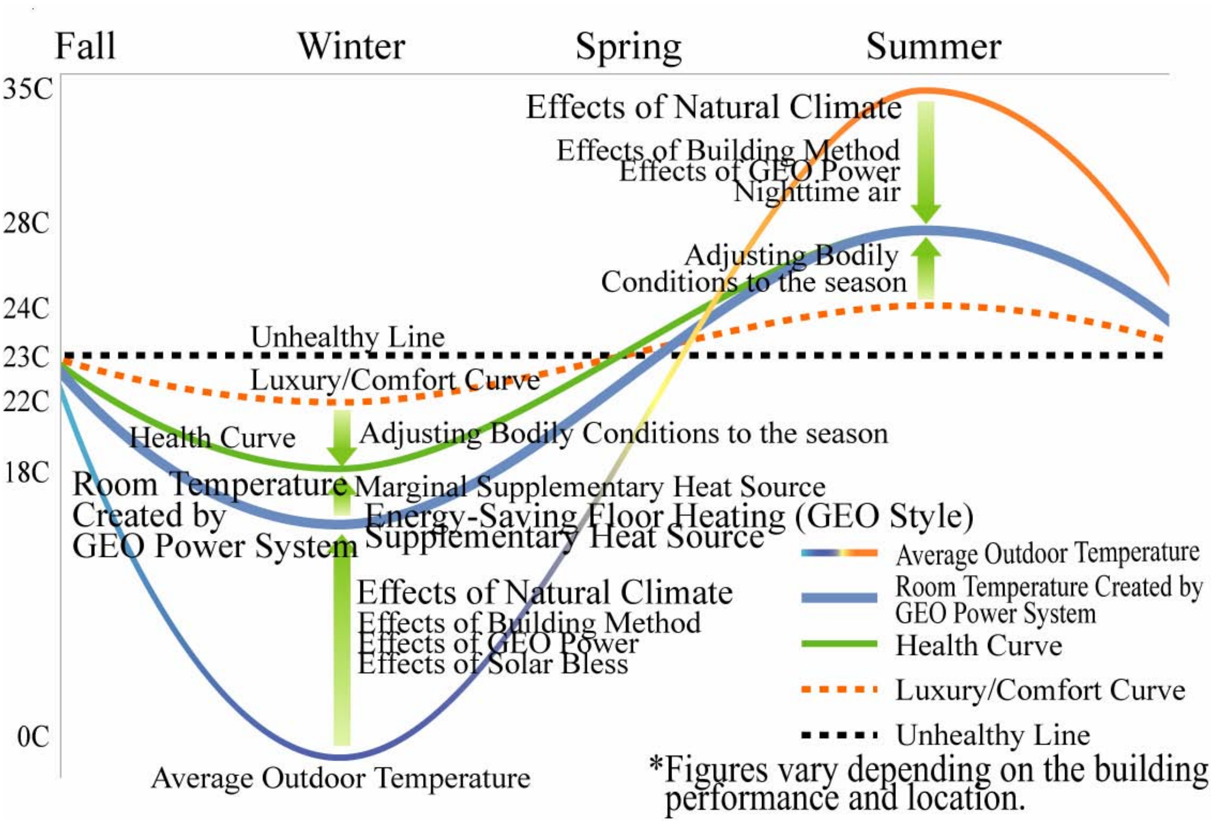

Fig.12 Health Curve shows the temperature profile for a year.

SUMMARY

A ventilation and air conditioning system using the ground heat was developed as one of techniques using renewable energy. In the system, vertical double pipe type of heat collector is used. We developed a code, which is able to solve unsteady three dimensional heat conduction equation, heat balance equation at the ground surface and heat transfer equation from the heat collector to the ground simultaneously, to predict the performance of the heat collector. Main results are as follows: the outlet air temperature of the heat collector becomes higher /lower at most 7^{o}C than the inlet air; the performance of the heat collector increases with the length of the heat collector and increases with the heat conductivity of the soil; continuous operation of the system over a year contributes to improvement of the performance of the heat collector both in winter and in summer.

INTRODUCTION

Every country including Japan needs to reduce CO_2 discharge. To achieve it, many techniques using renewable energy are being developed now. As one of such techniques, have been developed ventilation and air conditioning systems using the ground heat. Sekine et al. [1,2] carried out feasibility studies of ground source heat pump system and they tried to reduce initial cost by using cast-in-place concrete pile foundations of building as heat exchangers. Hamada et al. [3] proposed a heat pump system with improved underground heat exchanger which is set up by no-dig method. They showed that the COP of the system was higher than ordinary air source heat pump. Tsukidate et al. [4] investigated the heat collection performance of single U tube of 75 meters and Martin et al. [5] discussed maintenance cost of geothermal heat pump. Hashimoto [6] developed a new ventilation system using geothermal heat. The heat collector of Hashimoto's system is made of double pipe with inner polyvinyl pipe of 0.15 meter diameter, the outer aluminum pipe of 0.25 meter diameter and 5 meter length. It is buried vertically up to five meter depth in the ground. The purpose of our study is to develop a code predicting the performance of the heat collector of the ventilation and air conditioning system developed by Hashimoto and to examine the effect of several factors on the heat collector performance.

To predict the performance of the heat collector, we need to know the outlet air temperature of the heat collector, so we develop a model to predict the outlet air temperature. The model should include heat balance equation at the ground surface, unsteady three dimensional heat conduction equation for the ground and equation for the temperature change of the air flowing in the heat collector. The three equations must be solved simultaneously. We also discuss the effect of several factors, such as the outer diameter of double pipe, the length of the heat collector, the heat conductivity of the soil etc., on the heat collector performance.

VENTILATION AND AIR CONDITIONING SYSTEM USING GROUND HEAT

The ventilation and air conditioning system using ground heat is described in detail in Part 1, so we mention the system briefly. The outside air is taken into the heat collector and is supplied into the room through heat storage room filled with crushed stones as shown in Figure 1 [7]. The outside air flows into the heat collector from the upper annular space and flows into the inner pipe through many holes on the wall of the inner pipe near the bottom and flows out of its upper end. The outside air is heated in winter and cooled in summer by the ground while flowing down in the annular space of the heat collector. Heated air or cooled air contributes to reducing the energy for heating and air conditioning.

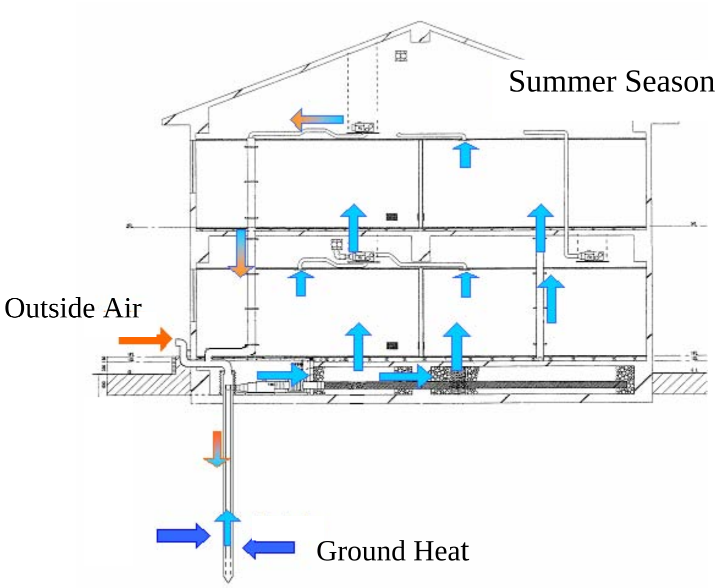

Figure 1. Ventilation, heating and air conditioning system using ground heat.

PREDICTION MODEL OF OUTLET AIR TEMPERATURE OF THE HEAT COLLECTOR

Unsteady heat conduction equation

Unsteady three dimensional heat conduction equation is expressed by equation (1),

$$\frac{\partial T}{\partial t} + a\left(\frac{\partial^2 T}{\partial x^2} + \frac{\partial^2 T}{\partial y^2} + \frac{\partial^2 T}{\partial z^2}\right) - S = 0\,, \quad (1)$$

where T is the soil temperature, t is time, a is thermal diffusibility of the soil, S is the source term and x, y and z are the coordinates.

Heat balance equation at the ground surface

Influence factors on the heat balance at the ground surface are solar radiation R_S, effective radiation R_N, convection heat transfer H, latent heat transfer E and heat transfer from the ground surface to soil Q_G. The heat balance equation is expressed by equation (2) using these factors (see Figure 2),

$$Q_G = R_S - R_N - H - E \,. \quad (2)$$

When calculating Q_G from equation (2), we used measured values of R_S and R_N and predicted values of H and E which are calculated using atmospheric stability scale of Monin-Obukhov.

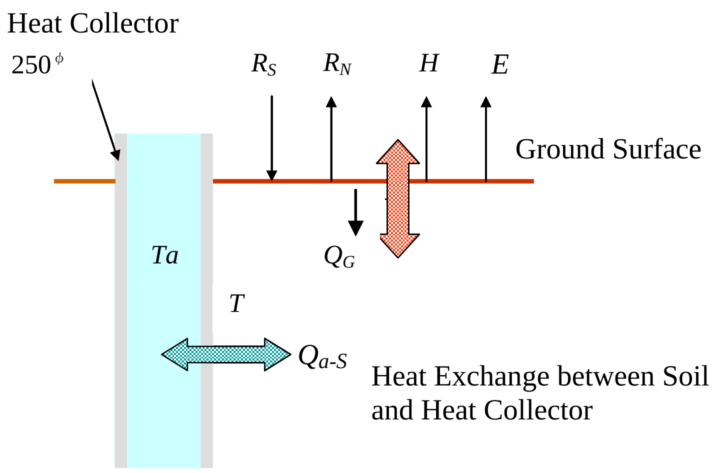

Figure 2. Heat balance at the ground surface and heat exchange between soil and heat collector.

Equation of temperature change of the air flowing in the heat collector

An equation for the temperature change of the air in the heat collector is expressed by equation (3)

$$\rho_a C_{pa} V_a \frac{\partial T_a}{\partial z} = -Q_{a-S} \,, \qquad (3)$$

where ρ_a is the density, C_{pa} is the specific heat, V_a is the flow rate, T_a is the air temperature, $Q_{a\text{-}S}$ is the heat transfer from the air in the heat collector to the ground and subscript a means the air.

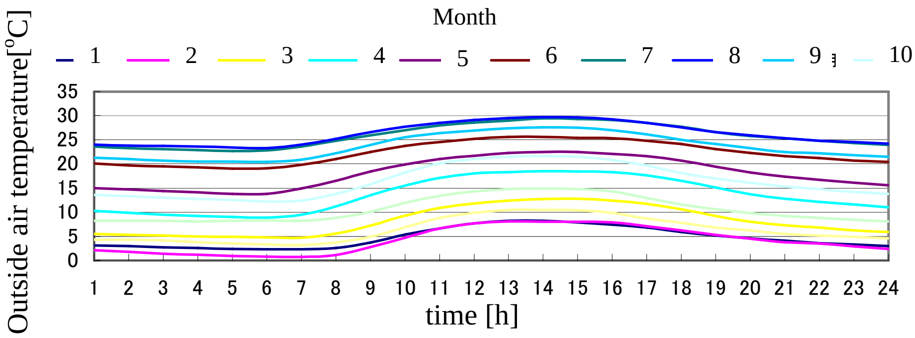
Computational method

The temperature in the ground, the downward heat transfer from the ground surface and the air temperature in the heat collector depend on each other, so the three equations (1), (2) and (3) must be solved simultaneously. Here, we calculate the temperature of the ground T, the downward heat transfer from the ground surface Q_G and the air temperature T_a by iterative computation method.

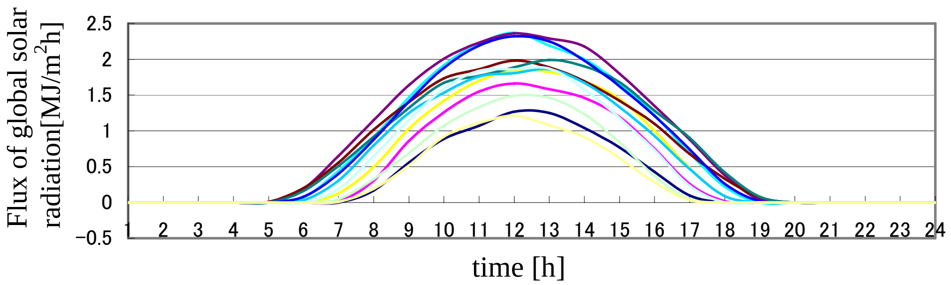
We applied free slip condition to the boundary condition of the temperature at the ground surface and the heat flow from the surface to the ground was taken into consideration as heat source of the control volume just under the ground surface. The same method was applied to the boundary between the outer surface of heat collector and the soil.

Computational conditions

The weather conditions are necessary for the above calculation. Here, we used measured values of the outside air temperature, solar radiation, effective radiation, absolute humidity and the outside air velocity. As an example, we show standard data of the outside air temperature and the solar radiation in Figure 3.



(a) The outside air temperatures.



(b) Solar radiation.

Figure 3. Weather conditions.

Heat transfer coefficient on the inner wall of the outer pipe is calculated using an empirical equation applied to well developed turbulent flow in pipe and Reynolds number in the annular space was calculated with hydraulic mean radius. We assumed that the air in the inner pipe is thermally insulated from the air in the annular space.

RESULTS

Annual change of ground temperature

Annual change of ground temperature from January to December is shown in Figure 4. The result is when the heat collector does not exist. The ground temperature near the ground surface changes widely with month but the temperature in the depth more than five meters hardly changes and is kept at nearly constant temperature. It is well known that the temperature of the deep ground is nearly equal to the local average air temperature, that is, the temperature of the deep ground is higher than the outside air temperature in winter and lower in summer. This is the reason why energy saving is possible by using ground heat to ventilation, heating and air conditioning system.

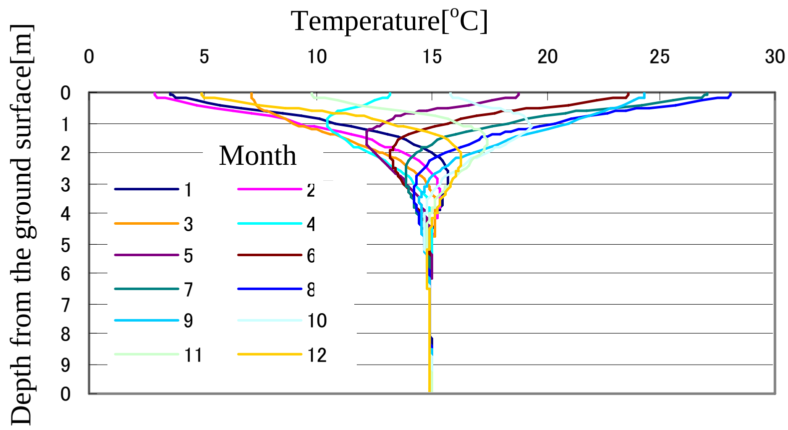


Figure 4. Annual temperature change in the ground.

Outlet air temperature of the heat collector

Calculated outlet air temperature was compared with measured temperature to examine the accuracy of the prediction model. The calculated temperature agreed well with the measured temperature as shown in Figure 5.

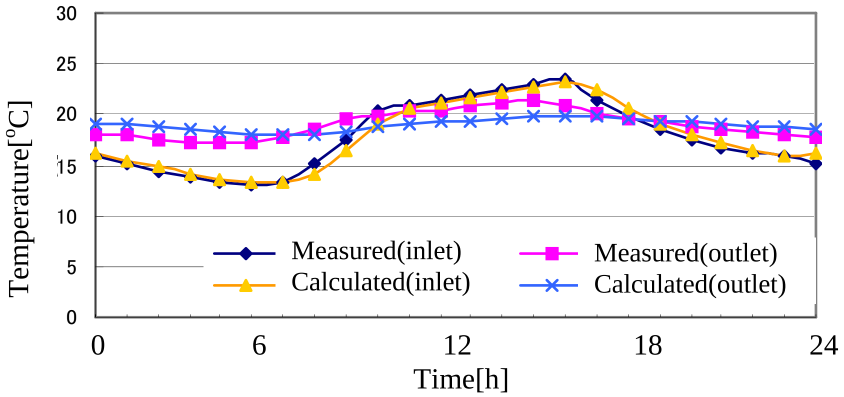

Figure 5. The inlet air temperature and the outlet air temperature of the heat collector.

Figure 6 shows calculated annual change of the outlet air temperature of the heat collector. The outlet air temperature changes with the outside air temperature and becomes at most about 7 ^{o}C higher than the inlet in winter and at most about 7 ^{o}C lower in summer. Here, the inlet air temperature is assumed to be equal to the outside air temperature.

The temperature of the soil in the surroundings of the heat collector is affected by the heat flow from the heat collector to the soil and it is expected that the soil temperature increases gradually with time in summer and decreases in winter. Figure 7 shows the change of the temperature distribution in the surroundings of the heat collector from July 10th to August 30th. We can see that the region of high temperature is expanded in August 10th. And the outlet air temperature of the heat collector increases gradually with time as shown in Figure 8 because of the raise of soil temperature.

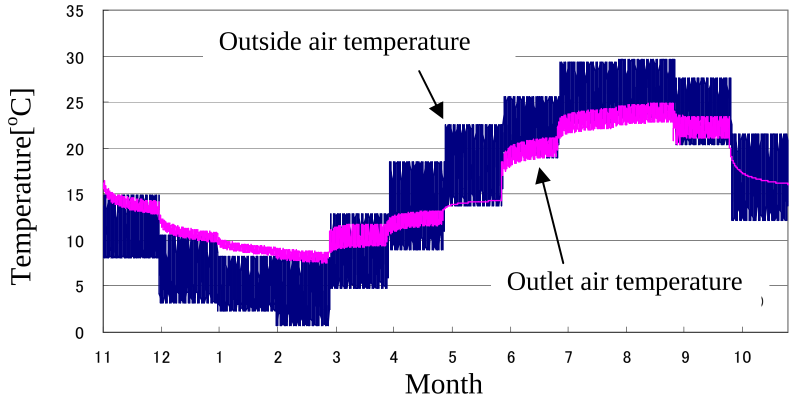

Figure 6. The outside air temperature and the outlet air temperature of the heat collector.

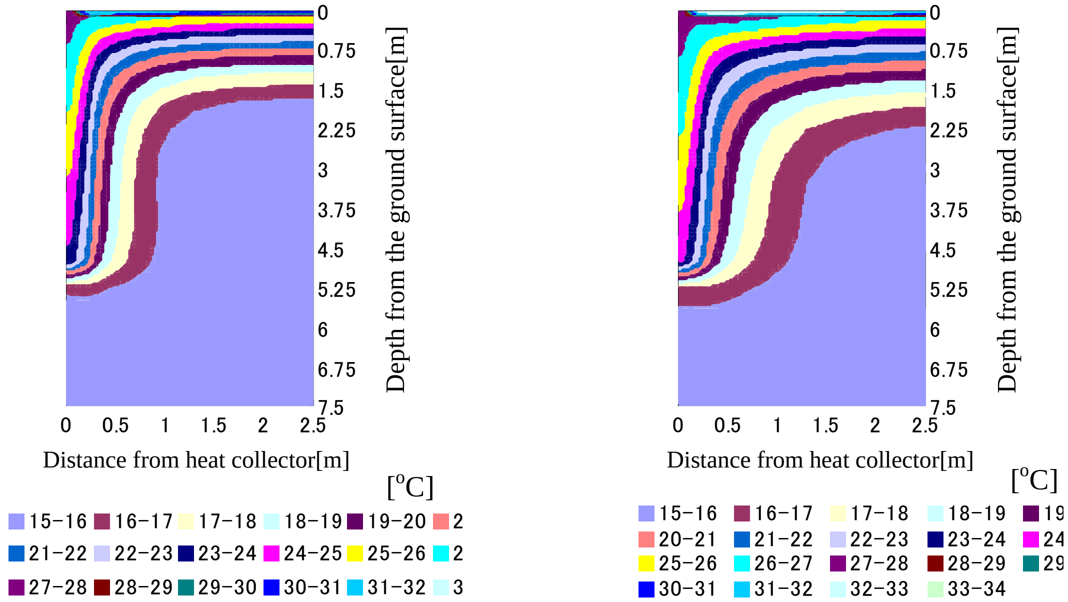

July 10th August 30th

Figure 7. The soil temperature in the surroundings of the heat collector.

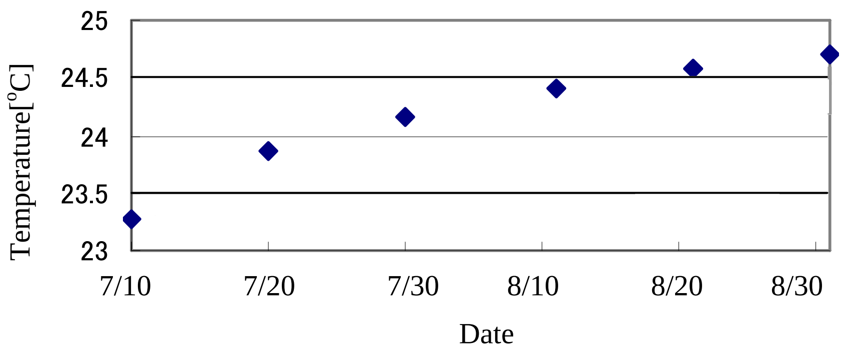

Figure 8. The change of the outlet air temperature of the heat collector.

Effect of pipe size on the performance of heat collector

It is expected that the performance of the heat collector increases with the diameter of the outer pipe and the length of the heat collector because heating/cooling surface area increases. The computation results showed the same inclination as expectation, that is, the quantity of collected heat increases with the outer pipe diameter and increases with the length of the heat collector as shown in Figures 9 and Figure 10. The heat collection performance of the heat collector of 400mm outer diameter increases by about 3% in winter and about 9% in summer comparing with the standard heat collector of 250mm outer diameter. The heat collection performance of the heat collector of 10 meter length increases by about 61% in winter and about 86% in summer comparing with the heat collector of 5 meter length.

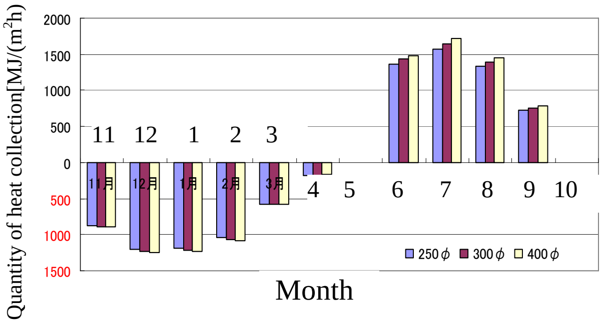

Figure 9. The effect of the pipe diameter.

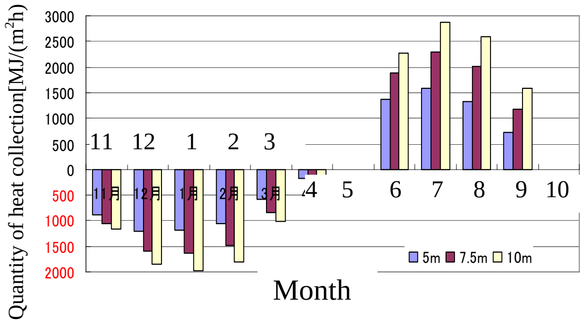

Figure 10. The effect of the pipe length.

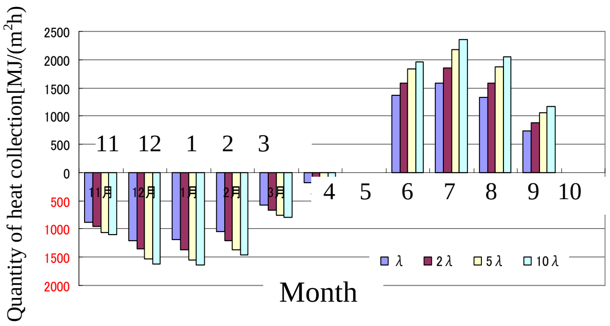

Figure 11. The effect of the heat conductivity.

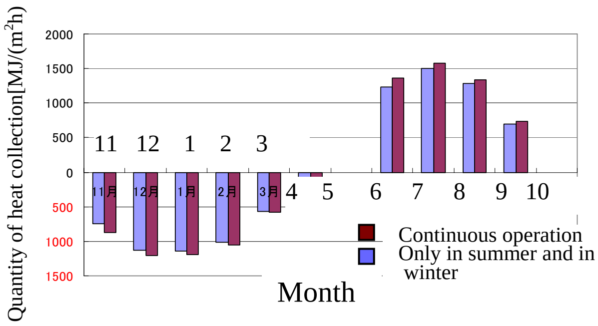

Figure 10. The effect of operation condition.

Effect of heat conductivity of soil

Here, we consider the case when the soil in the peripheral region of the heat collector, from 2 meter depth to 6 meter depth and within 0.5 meter distance from the center of the heat collector, is replaced by the material with the heat conductivity higher than the soil. The result is shown in Figure 12. The heat collection performance increases by about 36% in the case of 10 λ in winter and increases by about 51% in summer comparing with in the case of λ.

Effect of continuous operation of the system

The soil in the surroundings of the heat collector is heated in summer and is cooled in winter by operation of the system, so it is worth to examine the influence of continuous operation of the system on the heat collection performance. Here, we consider the two cases. One is when the heat collector is continuously operated all over a year and the other is when the operation of the system is limited to only in summer and in winter. As you can see from Figure 13, the quantity of collected heat is larger both in winter and in summer in the case of continuous operation over a year than in the case of the operation limited only in summer and in winter.

CONCLUSIONS

To predict the outlet air temperature of the double pipe type of heat collector buried vertically in the ground, we developed a code which can solve unsteady three dimensional heat conduction equation, heat balance equation at the ground surface and heat transfer equation from the heat collector to the ground simultaneously. We examined the heat collector performance and the following results are obtained: (1) the outlet air temperature becomes higher /cooler at most 7^{o}C than the inlet air; (2)the performance of the heat collector increases with the length of the heat collector; (3) the heat collector performance increases with the heat conductivity of the surroundings of the heat collector; (4) Continuous operation of the system over a year contributes to increase of the heat collector performance both in winter and in summer.

ACKNOWLEDGEMENT

SUMMARY

In 2003 a new advanced biotechnology laboratory building was opened at the Ghent University. Very high standards were demanded for the HVAC-installation.

The refrigeration system consists of two large electrical chillers cooled with two cooling towers and the possibility to use free cooling with a plate heat exchanger and the cooling towers if outside air temperatures allow it.

An energy survey was made of the whole building from 2003 to 2006, with special attention being paid to the refrigeration equipment. Measurements showed a strong rise in energy use of the campus, after start-up of the building. Several measures were introduced to reduce energy use and related heat dissipation.

The performance of the chillers was monitored. Measurements show that performance of the free cooling is disappointingly low. This is caused by bad design and suggestions are made for amelioration

Secondly, it was noted that the cooling towers used a lot of water. This was due to the way the towers were operated to give minimal energy use in the HVAC-system and ensure the performance all time of the year. An analysis of the water consumption is made.

INTRODUCTION

In November 2003 the Fiers-Schell-Van Montagu research building was inaugurated at the Ghent University campus Ardoyen. The building was named after the pioneers in biotechnical research at the Ghent University. The building houses the research departments of Molecular Biomedics and Plant System Biology, both being part of the Flemish Interuniversitary Institute for Biotechnological Research (VIB). Research in the building is done on cancer, virology, cell analysis, … The research groups use very advanced techniques and laboratory appliances. Very high requirements are set for the indoor air quality and conditions, to provide optimal growing conditions for the cells and plants studied.

The building consists of two laboratory wings (east and west wing) of rectangular shape, 36 m wide and 3 floors high. In front of the laboratory wings a main building is situated as shown on Figure 1. Each laboratory wing is divided in three sections. The central section contains the laboratory equipment with high power density (up to 80 W/m²), such as ultra freezer and laminar flow tables. The central part is surrounded by corridors. The left and right hand side of the wings consist of laboratory modules for about 10 people each, where manual laboratory operations are performed and small offices are available.

Figure 1 - Lay-out of the VIB-Building

There are 300 people working in the building, with a total ground surface of 13000 m², of which 8000 m² (60%) is used for laboratory facilities. Figure 2 shows the measured electricity use of the building during 2004. The average value is about 500000 kWh/month, resulting in a power density of about 53 W/m².

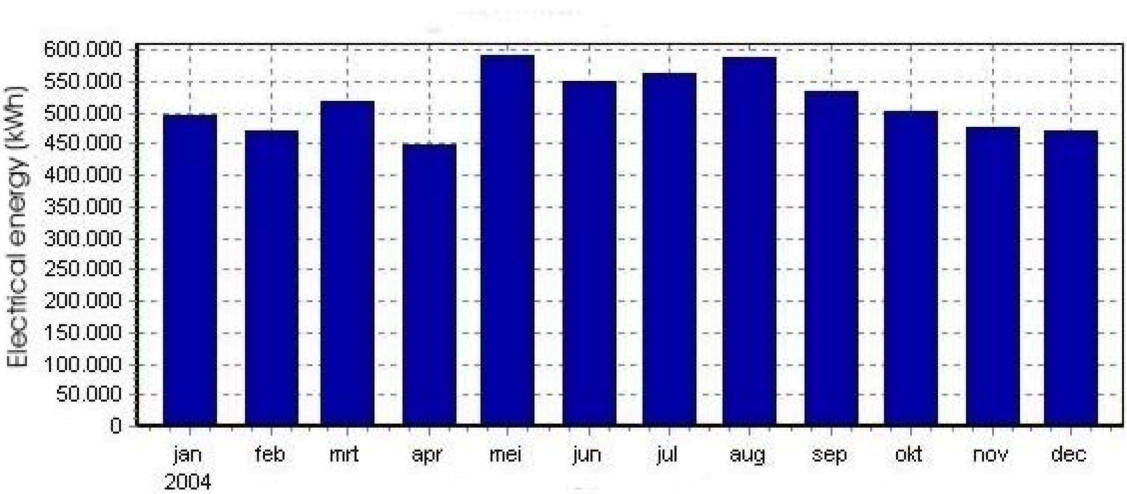

Figure 2 - Energy use of the VIB-Building (2004)

The building HVAC system consists of several pulsion/extraction groups for each wing and for the main building. Temperature and relative humidity control is set to 18°C/RH>30% in summer and 21.5°C/RH>30% in winter. Heating is provided by natural gas fired condensing boiler units and humidity is controlled by vapour injection, being produced by a small gas fired steam boiler. Cooling is done with an ice-water circuit, providing ice water at 7 °C.

Local units are used to provide high indoor air quality requirements for certain laboratory modules. They use fresh air coming from the central system, mix it with room air and condition it within very narrow margins.

MAIN COOLING SYSTEM – FREE COOLING OPTION

Figure 3 shows the layout of the main cooling system. The air conditioning units in the building use a 7/12 regime, delivering ice water at maximal value 12°C to the cooling plant. The cooling plant has two screw compressor cooling machines of 1139 kW and 600 kW cooling power. The cooling machines have a priority setting for the smaller machine. The bigger cooling machine only operates at high cooling load conditions. Both machines are coupled to cooling towers with 1425 kW and 710 kW thermal power respectively. Water flow rate to the towers is controlled by a three way valve. All pumps are constant flow rate pumps. The cooling tower fans are frequency controlled. Readings of the frequency controller set-point in the building management system can be translated into the electrical power use of the fans during operation. To this purpose controller settings and power use were logged over a certain period.

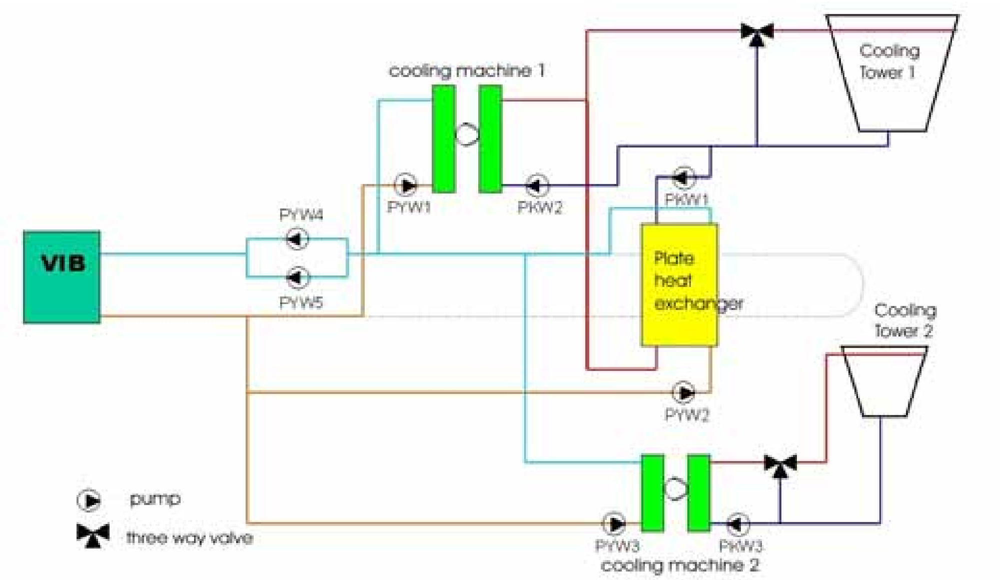

Figure 3 - Main Cooling system lay-out

Next to the cooling machines a plate heat exchanger was installed in order to be able to use the bigger cooling tower directly in free cooling mode during winter. The ice water is directed to one side of the heat exchanger while an extra pump circulates the cooling tower water over the other side. A part of the cooling water flow rate can be circulated over a by-pass in this case (dotted line). Free cooling is started by the building management system when the outside wet bulb temperature drops below 6°C.

In this paper the performance of the cooling system is studied both working in normal and free cooling mode. To this end data supplied by the building management system was used as well as measurements done with temperature loggers mounted on the piping and electrical power measurements on pumps and compressors.

MEASUREMENT RESULTS

Smaller cooling machine performance

Measurements were done during two periods: January 10 to 21 2005 and during April and May 2005. During winter only the smaller cooling machine is active. In Figure 4 measurement results are shown. Thermal power was determined by:

$$\dot{Q} = \dot{m}_{water} c_{p,water} \left(T_{evaporator,in} - T_{evaporator,out} \right)$$

Electrical power was directly measured on the compressor. On the right hand side axis the COP is shown for the cooling machine and for the installation including pumps and fans. The cooling machine is constantly turned on during the measurement period. During weekends less cooling is needed. During night time very little difference is seen in electrical power use. The small peaks in power use are caused by water sanitation twice a week during which the water is heated to an extreme value during a short period. After this the cooling machine has to run at full power to reach operational values again. COP of the cooling installation varies from 3 to 4, which is in fact lower than promised by the supplier. If pumps and fans are included COP drops to 2.

Figure 5 shows the temperatures of the water flows entering and leaving the condenser and evaporator of the smaller cooling machine. Day time variation of the ice-water temperature can again be clearly seen. Water coming from the cooling tower is at a constant temperature of 25°C. At the end of the measurement period displayed strange.

Oscillations can be observed in the temperature curves. As the outside air temperature during the end of the period climbed above 26.6 °C, the bigger cooling machine started to take over. In Figure 6 the energy use and performance of the cooling machine is again shown. Now a COP of 6 is reached, peaking to 8. (For the installation including fans and pumps COP drops to 5 and 4). If the cooling machine is running in part load, poorer performance is clearly seen.

Free cooling mode

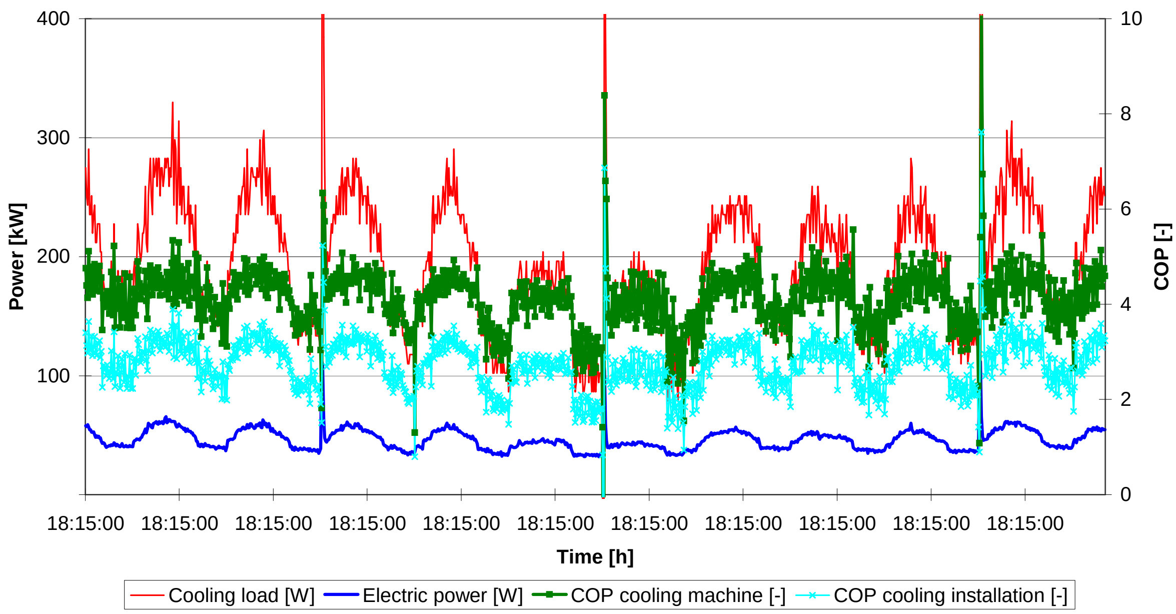

Figure 4 - Smaller cooling machine performance (January 2005)

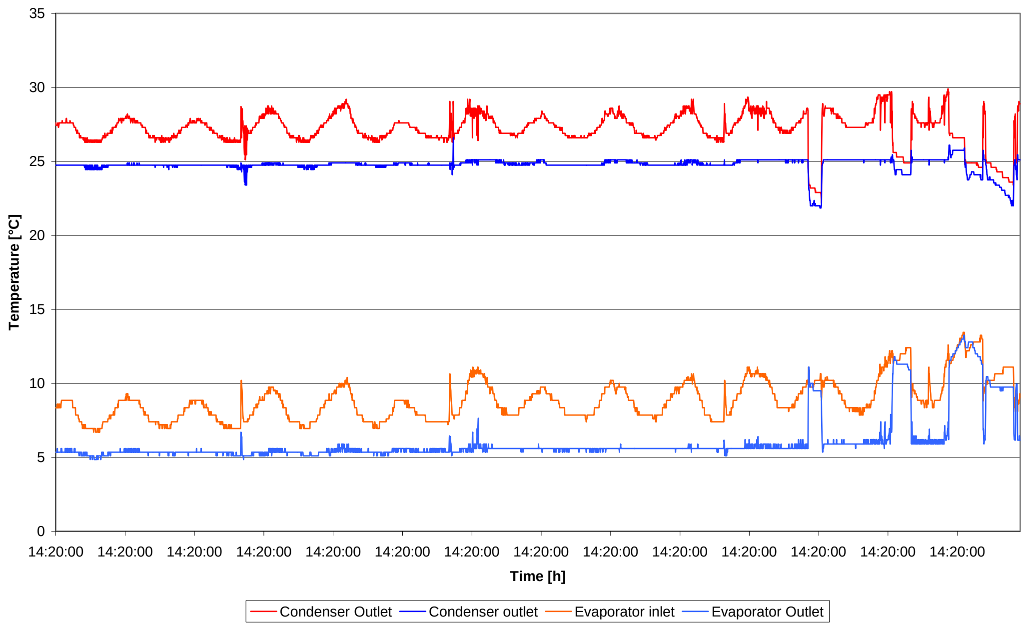

Figure 5 - Temperature measurements in smaller cooling machine (April-May 2005)

During the last week of February 2005 and the first week of March 2005 weather conditions were favourable for using free cooling. The inlet and outlet ice-water temperature are registered by the building management system. Because the pumps have a constant flow rate regime, the flow rate could be measured once, with an ultrasonic flow meter. The heat extracted from the building could thus be determined by:

$$\dot{Q}_{extracted} = \dot{m}_{ice-water} c_{p,water} \left(T_{ice-water,in} - T_{ice-water,out} \right)$$

The electricity used to operate the free cooling is coming from the pumps and the cooling tower fans. COP for free cooling is then given by:

$$COP = \frac{\dot{Q}}{P_{pumps} + P_{Fans}}$$

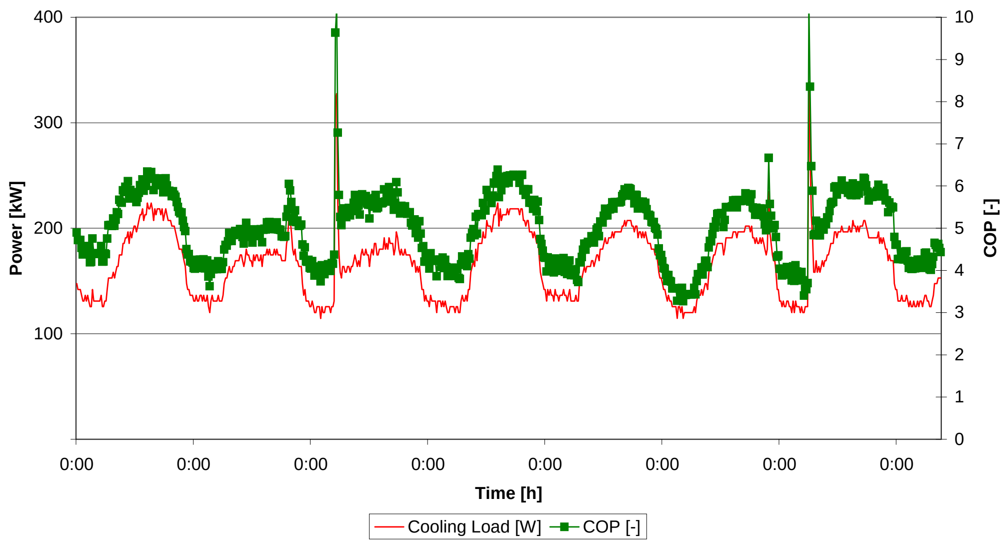

Figure 7 - Performance of the Free Cooling system

Figure 7 shows thermal capacity and COP of the free cooling mode. The COP of free cooling is approximately two times as large as for the cooling machine. It is striking to notice that the COP varies between 4 and 6, which is low compared to values found in literature [1]. The plate heat exchanger was designed to deliver 1307 kW of thermal power (building full load cooling conditions). During times when free cooling is possible, cooling load is a lot less, only 200 kW. The whole ice-water flow rate is nevertheless sent through the heat exchanger. This causes the temperature change of the ice water to be small (1°C or less, compared to 4°C in design) and the effectiveness of the heat exchanger under this condition to be only 0.37, as shown in Figure 8. Furthermore the cooling water for the heat exchanger is coming from the larger cooling tower. Again this causes the fan and pumping power to be too large, as the tower is oversized. Free cooling performance this way, does not reach the desired performance.

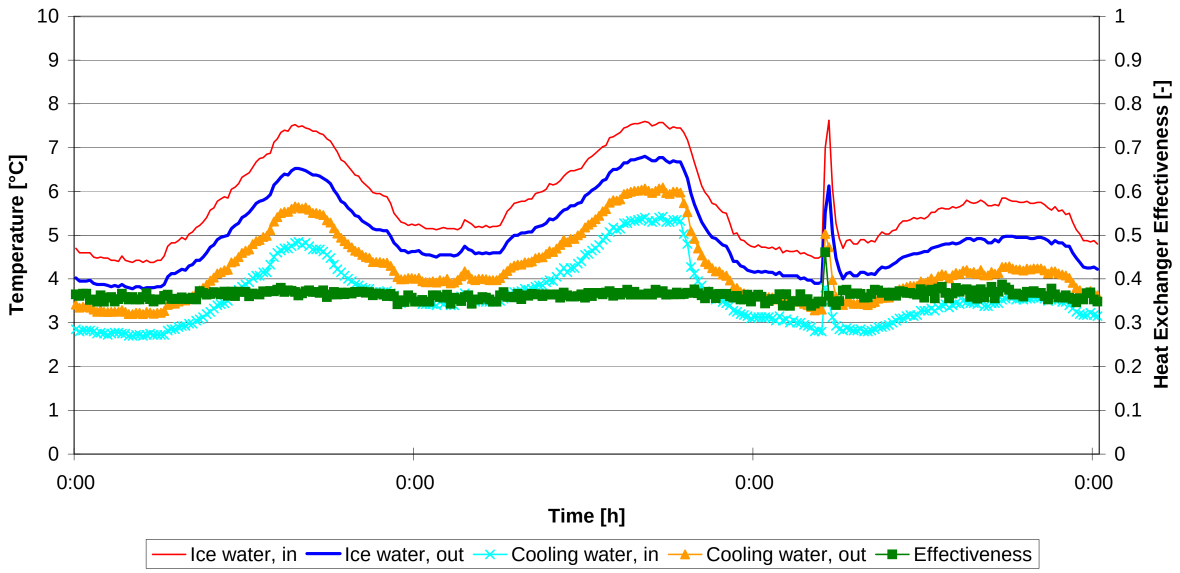

Figure 8 - Temperature measurements over the plate heat exchanger

Simulations and free cooling mode ameliorations

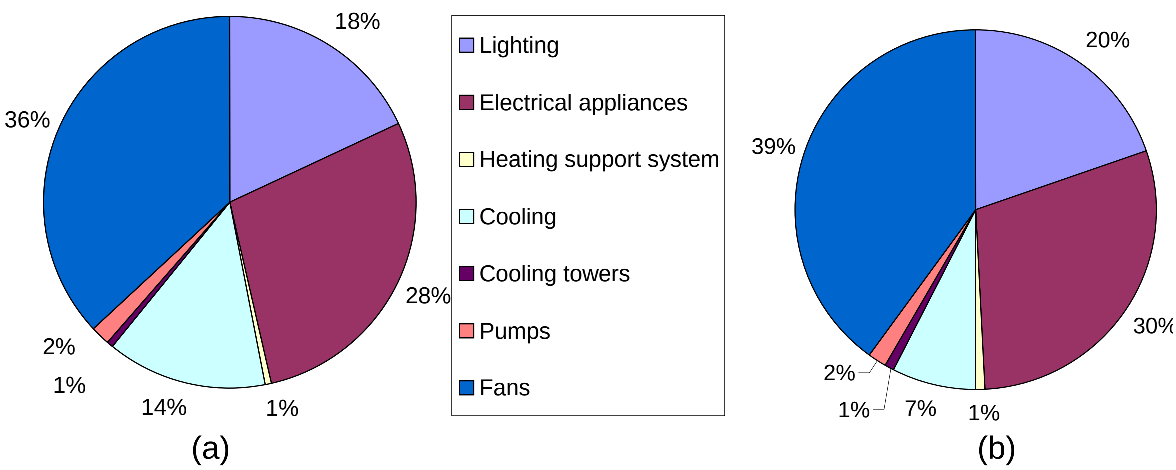

Figure 9 – Energy use in the VIB building (a) with free cooling (b) with free cooling (COP=10)

Using DOE_V6.2 a simulation model was constructed of the VIB-building. The model was calibrated with the data of the energy use during 2004. Total monthly electricity use could be predicted within a margin of 5%.

Figure 9 (a) shows the electrical energy use distribution of the building when no free cooling would be present. As expected, the fans of the HVAC-system are the main users of electricity. Second largest use for electricity goes to the electrical appliances, representing more than a quarter of the total use. This is more than for office buildings, because of the large laboratory facilities in the building. Finally cooling represents 14% of the total use.

If a three-way valve would be introduced in the ice-water system before the heat exchanger, only a part of the flow rate can be sent over the heat exchanger and mixed with an uncooled flow. This way the temperature drop of the cooled ice water would go up, resulting, after mixing, in the same ice-water temperature going to the building. Doubling the temperature change (using half the flow rate) would result in doubling the heat exchanger effectiveness.

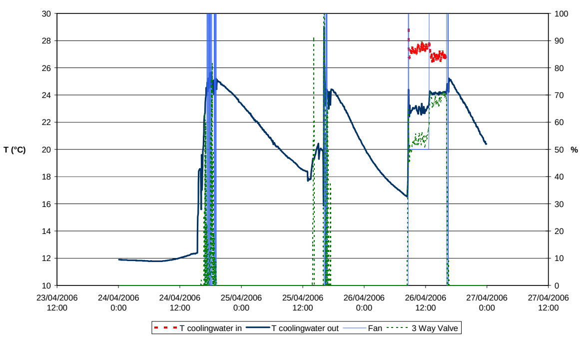
A resulting measure would be the reduction of flow rates at the cooling tower side. This could be done by installing frequency controller on the pumps. Finally the smaller cooling tower should be used. This will increase performance again. These measures will result in a COP of 10 for the free cooling system.

Simulations of the building showed that with a COP of 10 for free cooling the energy use for cooling could be strongly reduced (Figure 9 (b)). This could, also from simulations, result in a reduction of energy use of 80 000 kWh per year (about 1.25% of the total electricity use).

WATER USE

From April to August 2006 a second measurement campaign was conducted focusing on the water use of the cooling towers. Figures 10 and 11 show results for the smaller cooling tower.

In the month of April the cooling power is about 600 kW. In the morning of April 26 the cooling power is about 12% higher than in the afternoon. Water flow rates are also shown. Even with lower water flow rate a high cooling power is measured. The cooling towers are well sized. Evaporation loss lies between 0.5 and 0.9 m³/h. Note that evaporation loss is lower during the regime with higher water flow rates (afternoon of April 26). A lower cooler power is measured, meaning less evaporation occurs.



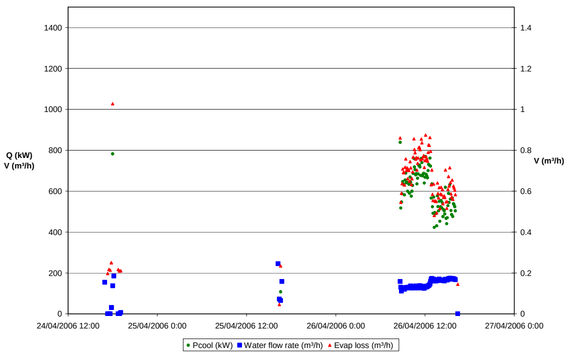


Figure 10: Cooling Tower 1, Cooling power, water flow rate and evaporation loss, April 2006

From 3 to 11 July 2006 a hot summer spell occurred. The cooling tower is thus running at full load most of the day. (Figure 11). July 4 at noon the water temperature after the chiller reaches a maximum value of 32 °C. The water is then cooled to 27 °C, as was given in the specifications of the constructor. From July 7 on the outside temperature goes down. Evaporation loss reaches 1.8 m^3/h at the maximal cooling load and drops to 1.2 m^3/h at lower loads. The water flow rate over the cooling tower is proportional to the power (10 drop in power results in 10% drop in flow rate), but the evaporation losses over the tower reduce a lot more. With lower air temperatures the water is less cooled by evaporation, and more by direct convective transfer.

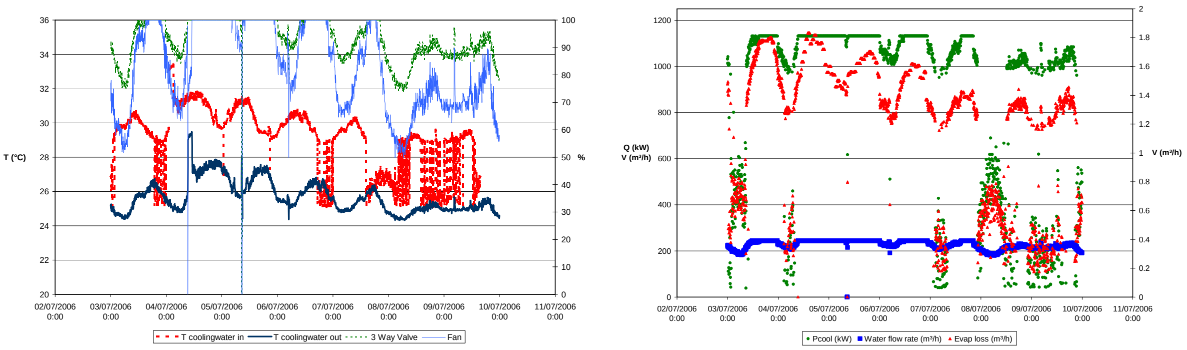

Figure 11: Cooling Tower 1, Cooling power, water flow rate and evaporation loss, July 2006

CONCLUSION

A measurement campaign was conducted on a high performance laboratory building. Special attention was paid to the free cooling system included.

Measurements showed that the free cooling system was badly sized during design. This causes the free cooling performance of the installation to be lower than expected.

By taking simple measures, the energy savings of Free Cooling could be easily doubled in the future.

Water consumption of the tower is not negligible. In general it is according to the specifications of the constructor.

A precise rating method for energy performance of vapour compression chillers serving commercial buildings

F. W. Yu, K. T. Chan

The Hong Kong Polytechnic University, Hong Kong

Corresponding email: befwyu@polyu.edu.hk

SUMMARY

This study aims to develop a new method to specify precisely the coefficient of performance (COP) of vapour compression chillers under part load conditions. Most chiller manufacturers currently specify a chiller COP based on standard rating conditions given in the (Air-conditioning & Refrigeration Institute) ARI standard 550/590. The COP calculated at such conditions is applicable for certain US conditions and is not appropriate for specifying the part load performance of chillers operating in parallel and working in any given climate zone. The ton-hour distribution of office buildings and hotels in Hong Kong was considered to indicate the unique operating conditions of chillers with specific number and capacity. Using the simulation program TRNSYS 15, a thermodynamic model was developed to determine the COP of air-cooled chillers under part load conditions. Results of this study highlight the need to use a set of part load performance curves with the working range of condensing temperature to describe precisely a chiller COP under various operating conditions.

INTRODUCTION

Vapour compression chillers are commonly used to provide cooling energy in air-conditioned buildings but with considerable electricity consumption. One possible way to reduce the electricity demand for commercial buildings is to select chillers with a high COP which is defined as the cooling capacity in kW over chiller power in kW. With regard to the performance rating of air-cooled chillers, most chiller manufacturers currently specify a chiller COP based on standard rating conditions given in the ARI standard 550/590 [1]. The full load conditions refer to an ambient temperature of 35^{o}C, a chilled water flow rate of 0.043 L/s per kW cooling capacity and a chilled water supply temperature of 6.7^{o}C. Considering that chillers in a chilled water system tend to operate at part load for most of the time, rating conditions were established for part load operation under which the part load ratios of a chiller ranging from 0.33 to 1 are related directly to outdoor temperatures ranging from 12.8 to 35^{o}C. Based on these part load rating conditions, the integrated part-load value (IPLV) was developed to express the part load performance of chillers. IPLV is defined as the sum of the chiller COPs at part load ratios of 0.25, 0.5, 0.75 and 1, multiplied by weighting factors of 0.12, 0.45, 0.42 and 0.01, respectively. The determination of the weighting factors is based on the average of buildings and climate conditions in 29 US cites.

Air-cooled chillers used in the EU countries may comply with the Eurovent certification programme for liquid chilling packages [2]. Regarding the Eurovent's part load ratings, chiller part load ratios ranging from 0.25 to 1 are related directly to outdoor temperatures ranging from 20 to 35^{o}C. A European seasonal energy efficiency ratio (ESEER), equivalent to

IPLV, was established for the universe of buildings and climates in the EU. In the calculation of ESEER, the weighting factors multiplying the chiller COPs at part load ratios of 0.25, 0.5, 0.75 and 1 are 0.23, 0.41, 0.33 and 0.03, respectively. It is worth ascertaining whether an IPLV or ESEER can present the part load performance of chillers working in any climate zone and running at various combinations to meet the changing building cooling load. The ARI standard 550/590-98 White Paper reminded that for a specific building in a certain climate zone, using the rated COP and/or IPLV would not come up with optimal selection of chillers. A whole year energy simulation is the more accurate way to compare chiller performance under all possible load conditions.

At present there are no alternative rating methods to deal with diverse operating conditions under the multiple chiller arrangement and to gauge the COP of chillers working in any given climate zone. In connection with this, standards for chiller performance requirements used in eight places [2,3-9] specify only the minimum allowable levels for the full load COP which vary from 2.7 to 3.2. Yet the COP of modern air-cooled chiller products at the full load conditions is in a range of 2.8 to 4.2 which, in most cases, exceeds the minimum COP levels. This suggests that the current standards are incapable of encouraging the use of highly efficient chillers. Only the ASHRAE and Canadian Standards Association standards [3,5] consider the minimum IPLV levels for chillers at part load operation. Yet the IPLV may fail to represent the actual part load performance of chillers. Indeed, the IPLV given by chiller manufacturers is higher than the full load COP, which contradicts the part load COP data monitored in existing chiller plants [10]. The discrepancy between the IPLV and actual part load COP is mainly due to a situation where the ARI rating conditions assume the drop of ambient temperature at each % load reduction and do not consider at what level the evaporating temperature and condensing temperature are set. As far as air-cooled chillers are concerned, the condensing temperature can hover by various degrees above the outdoor temperatures ranging between 13 and 35^{o}C. For any given combination of chiller loads and outdoor temperatures, the chiller COP can vary with the condensing temperature floating at different values based on head pressure control. It remains to be ascertained how the variation of the condensing temperature influences the specification of chiller COP.

In view of the pitfalls of the current performance rating methods, the aim of this paper is to illustrate a more precise rating method to specify the COP of air-cooled chillers under part load conditions. The ton-hour distributions of an office building and a hotel were used to explain the diverse operating conditions of chillers when working in parallel to meet the building cooling load. Drawing on a sophisticated thermodynamic model for air-cooled centrifugal chillers [11], the interaction between the chiller COP, part load ratio, condensing temperature and outdoor temperature was investigated. Results of this study will provide guidance on how to formulate a set of part load performance curves with the working range of condensing temperature to describe precisely a COP under various operating conditions. Engineers, manufacturers and researchers will better understand how the chiller COP curves help determine a chiller performance benchmark for buildings in any climate zone.

METHODS

Evaluation of hourly building cooling loads and chiller loads

The simulation program TRNSYS 15 [12] was used to calculate the hourly cooling loads of a reference office building and an existing hotel in Hong Kong throughout the year. The office building is widely employed to study the average energy performance of local office buildings. The hotel is the representative of the trade and has average characteristics in terms of the number of guestrooms, total floor area and annual electricity consumption in kWh per unit floor area of the building in m^2. Table 1 summarizes key information about the buildings and their air-conditioning systems. Detailed features of the buildings and their simulation procedure were described elsewhere [11]. It was assumed that every piece of air side equipment is capable of delivering the cooling energy to meet the cooling demand for the thermal conditions specified in each air-conditioned area. The hourly local weather data in 1989 were used because 1989 was the test reference year which is considered representative of the prevailing weather conditions in Hong Kong in building energy analysis.

Table 1. Key information about the office building and hotel.

Building	Office	Hotel
Total air-conditioned area (m^2)	42,840	45,540
Building operation schedule	11 hrs/day, 5.5 days/wk	24 hrs/day, 7 days/wk
Total business hours per year	3131	8760
Total cooling hours per year	2834	8152
Annual cooling energy (kWh)	7,423,883	17,692,414
Peak cooling load (kW)	6,389	4,753
Chiller plant details Total capacity installed (kW) Number and type of chillers Nominal capacity per chiller (kW) Chilled water distribution system Number and type of chilled water pump Rated power of each pump (kW)	 6,744 6 air-cooled centrifugal chillers 1,124 Single-loop pumping system with a differential pressure by-pass pipe 6 constant speed 31.3	 5,000 5 air-cooled centrifugal chillers 1,000 Single-loop pumping system with a differential pressure by-pass pipe 5 constant speed 16.8
Air side system details Type of air handling units Chilled water flow control	 Variable air volume 2-way valve	 Variable air volume 2-way valve

As Table 1 illustrates, the total capacity of the chiller plants was designed to meet the peak cooling load and equally sized chillers were installed to operate in parallel to meet the changing building cooling load. Chiller sequencing was implemented so all the chillers were operating at the same part load ratio, and no additional chillers started to operate until each of the running chillers was carrying full load. Tables 2 and 3 show the schedules of staging chillers and ranges of chiller part load ratios for the office building and hotel. The part load ratio (PLR) of each operating chiller is given by the building cooling load divided by the number of chillers staged and their nominal capacity.

Table 2. Schedule of staging chillers and ranges of chiller part load ratios for the office building.

Building load ratio (BLR)	Number of operating chillers and their capacity (kW)	Total capacity of operating chillers (kW)	Step	Chiller part load ratio (PLR)
$0<BLR\leq 0.17$	1 x 1124	1124	1	$0.29\leq PLR\leq 1$
$0.17<BLR\leq 0.34$	2 x 1124	2248	2	$0.5\leq PLR\leq 1$
$0.34<BLR\leq 0.51$	3 x 1124	3372	3	$0.67\leq PLR\leq 1$
$0.51<BLR\leq 0.68$	4 x 1124	4496	4	$0.75\leq PLR\leq 1$
$0.68<BLR\leq 0.85$	5 x 1124	5620	5	$0.80\leq PLR\leq 1$
$0.85<BLR\leq 1$	6 x 1124	6744	6	$0.83\leq PLR\leq 0.95$

Table 3. Schedule of staging chillers and ranges of chiller part load ratios for the hotel.

Building load ratio (BLR)	Number of operating chillers and their capacity (kW)	Total capacity of operating chillers (kW)	Step	Chiller part load ratio (PLR)
0<BLR≤0.21	1 x 1000	1000	1	0.21≤PLR≤1
0.21<BLR≤0.42	2 x 1000	2000	2	0.5≤PLR≤1
0.42<BLR≤0.63	3 x 1000	3000	3	0.67≤PLR≤1
0.63<BLR≤0.84	4 x 1000	4000	4	0.75≤PLR≤1
0.84<BLR≤1	5 x 1000	5000	5	0.80≤PLR≤0.95

To avoid presenting a huge set of hourly building cooling loads and chiller loads, the temperature bin method used to determine IPLV was followed to compile the load data in the form of ton-hours. For each temperature bin, the ton-hours represent the total number of equivalent full-load hours, which was determined by adding all hourly loads expressed as ratios of their peak value. The interval of each bin was set at 2.8°C and there were ten bins with temperatures ranging from 7.2 to 35°C to cover all hourly outdoor temperatures found in 1989. With regard to the four bin groupings to evaluate the four weighting factors of IPLV, the 1st temperature bin of 32.2–35°C is for the design bin, 2nd to 5th bins from 21.1–32.2°C for the peak bin, 6th to 9th bins from 10.0–21.1°C for the low bin and 10th bins below 10.0°C for the minimum bin. For each bin group, the weighting factor, average load ratio and average entering condenser air temperature (i.e. outdoor temperature) were computed. These three parameters were used to judge if the IPLV formula is suitable for local applications.

Four building operation categories (Groups 1 to 4) are defined in the ARI standard 550/590 to generate four separate IPLV formulas (see Table 4, where A is COP at 100% load, B is COP at 75% load, C is COP at 50% load and D is COP at 25% load). The office building and hotel generally comply with the building operation categories of Group 3 and Group 1, respectively. Group 2 and Group 4 were considered here by applying airside economizers to the hotel and the office building, respectively, when the outdoor temperature is below 18.3°C, instead of 12.8°C shown in Table 4. The level of 18.3°C is adequate for deciding free cooling based on local weather conditions and is the base temperature for calculating cooling degree days.

Table 4. Building operation categories and IPLV formulas given in ARI standard 550/590.

Group	Building operation category	IPLV formula
1	24 hrs/day, 7 days/wk, -17.8°C and above	IPLV = 0.009 A + 0.309 B + 0.413 C + 0.269 D
2	24 hrs/day, 7 days/wk, 12.8°C and above	IPLV = 0.012 A + 0.423 B + 0.565 C + 0.0 D
3	12 hrs/day, 5 days/wk, -17.8°C and above	IPLV = 0.015 A + 0.409 B + 0.392 C + 0.184 D
4	12 hrs/day, 5 days/wk, 12.8°C and above	IPLV = 0.018 A + 0.501 B + 0.481 C + 0.0 D

Determination of the COP and operating data of air-cooled chillers

A thermodynamic model was developed using TRNSYS 15 to determine the operating variables of an air-cooled centrifugal chiller with characteristics shown in Table 5. The chiller capacity is comparable to that used in the chiller plants of the two buildings. Details about the development of the chiller model were given in Ref. [11]. The model was verified using a wide range of operating data and the performance data in chiller specifications. It considered the mass balance of refrigerant and energy balance at the evaporator, and the real process phenomena, including the capacity control of the compressor, variations in the overall heat transfer coefficients of the evaporator and condenser at part load. An algorithm was included to compute the number and speed of condenser fans staged based on a set point of condensing temperature. The model was sophisticated enough to study the steady-state behavior of chiller COP at various combinations of chiller loads and outdoor temperatures when different strategies for controlling the condensing temperature were present.

Table 5. Details of the chiller model.

Refrigerant type	HFC-134a
Nominal capacity (kW)	1266
Evaporator component	
Type	Shell-and-tube flooded
Evaporating temperature (^{o}C)	5
Temperature of supply chilled water (^{o}C)	7
Temperature rise of chilled water at full load (^{o}C)	5.5
Nominal chilled water flow rate (kg/s)	55.1
Compressor component	
Number and type	One hermetic centrifugal compressor; constant speed
Capacity control	Inlet guide vanes; controlled at 25–100% full capacity
Condenser component	
Designed condensing temperature (^{o}C)	50 at an outdoor temperature of 35^{o}C
Number and type of condenser fans	3 constant speed fans
Nominal heat rejection airflow (m^3/s)	118; each fan provides 39.3 m^3/s
Type of expansion valve	Orifice plate

RESULTS AND DISCUSSION

Ton-hour distribution of building cooling loads and chiller loads

Based on simulation results of hourly building cooling loads and chiller loads, the ton-hours distributions were constructed for the office building and hotel, as shown in Figure 1. The distributions generally follow an irregular "hill" shape. Based on local weather conditions, the number of total cooling hours is highest (604 hrs for office; 1890 hrs for hotel) at the bin of 26.7–29.4^{o}C with the average of 28.1^{o}C. This results in the highest ton-hours in all the operation categories, regardless of the building cooling load or chiller load. The building load means the chiller load when a single chiller is installed in a chiller plant. At a given temperature bin, higher ton-hours would mean a higher frequency of chiller operation at near full load. It is found that the multiple-chiller arrangement is a direct approach to prolonging the operation of the chillers at higher loads. The ton-hours distributions could vary a lot, depending on the type of building and its operating hours, the use of free cooling, and the chiller plant design with respect to the number and capacity of chillers. Based on the vague relationship between the ton-hr and outdoor temperature, it is questionable to gauge the real part load COP by the IPLV formula with a specific set of part load rating conditions.

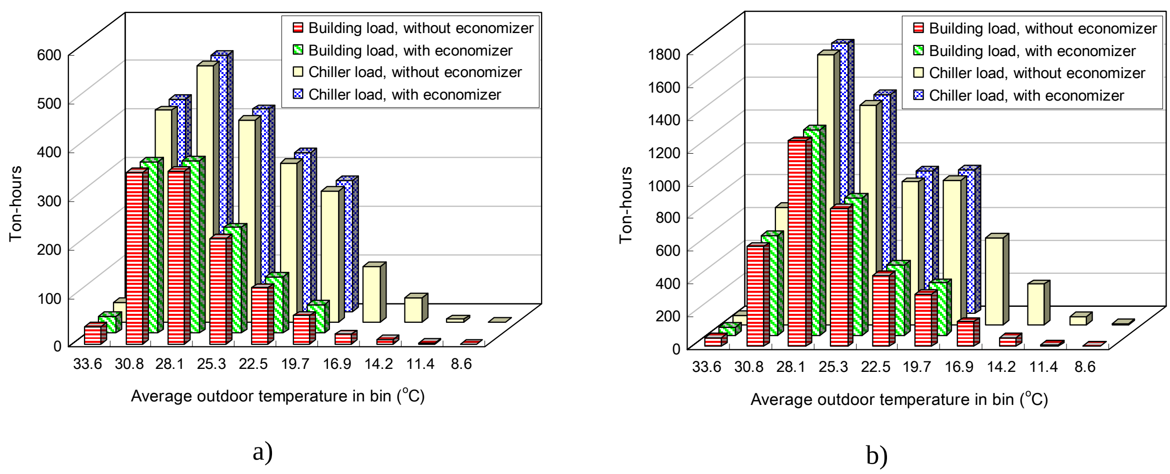

Figure 1. Ton-hour distribution of building cooling loads and chiller load. a) office building, b) hotel.

Critique of using the IPLV formula

The parameters used to create the IPLV formula were evaluated for the buildings with different operating characteristics and chiller plant designs. The results of the parameters are summarized in Table 6. At each bin group, the average outdoor temperature varies slightly at different categories of load and operation and the average load ratio changes widely (0.78–0.91 for design bin; 0.51–0.85 for peak bin; 0.12–0.70 for low bin; 0.09–0.41 for minimum bin). This confirms the inadequacy of using a specific set of part load ratings (stated in the ARI and Eurovent standards) to present the diverse combination of outdoor temperatures and chiller loads. Furthermore, it is insufficient to consider only four loading conditions (25%, 50%, 75% and 100% of full load) to present an IPLV. It is important to ascertain COPs at the peak bin with part load ratios of 0.51–0.85 because this loading range accounted for over 72% of the total ton-hours based on the weighting factors calculated. The ton-hrs at above 80% full load accounted for only 0.9–3% of the total ton-hours. This weakens the importance of using a full load COP to specify minimum chiller performance requirements. The accuracy of using IPLV to present the actual part load performance of chillers relies heavily on assessing the prominent ambient and load conditions and adjusting the weighting factors from time to time in response to various building features and chiller plant designs. It is worth considering other performance rating methods to account for diverse operating conditions of chillers.

Table 6. Parameters of IPLV formulas for the office building and hotel

Parameter	Building load, without economizer		Building load, with economizer		Chiller load, without economizer		Chiller load, with economizer

Significance of using a set of part-load performance curves

Based on a verified model for air-cooled centrifugal chillers, the interaction between the COP and operating variables was analyzed. Figure 2 shows how the COP at various operating conditions can be described precisely by a set of part load performance curves when the chiller operated under head pressure control (HPC) or condensing temperature control (CTC). HPC means that the number of condenser fans staged is kept minimal to control the condensing temperature by various degrees above 45°C. CTC, on the other hand, means that the condensing temperature hovers closely above the outdoor temperature by staging all condenser fans as much as possible to minimize the sum of compressor power and condenser fan power. Existing rating methods consider only the correlation between the COP, chiller part load ratio (PLR) and outdoor temperature. The part load COP curves show the importance of specifying the working range of condensing temperature in order to reflect the possible range of chiller COP at any given operating condition or combination of outdoor temperatures and part load ratios. It is possible to judge the superiority of part load performance with the reduced condensing temperature. As no specific link between the outdoor temperature and chiller load is considered, such curves are generic to compare the part load performance of chillers working in any given climatic zone and chiller plant design.

A set of part load COP curves with the working range of condensing temperature not only helps engineers to better understand the chiller COP at various operating conditions, but also enables plant operators to verify whether their chillers can operate with the specified performance. The condensing temperature is generally monitored. The part load ratio of the chillers will be ascertained if the flow and temperature difference of chilled water across each chiller are measured. The chiller power is typically monitored in terms of % full load ampere. Any decline in the COP of the chillers due to deficient operation can be assessed by comparing the measured COP with the nominal COP given from the part load COP curves.

Given the ARI's part load ratings, ARI performance curves were constructed for HPC and CTC. Each of these curves fails to explain how the chiller COP can rise with a decrease in the outdoor temperature or condensing temperature at a given part load ratio. The ARI performance curves also give imprecise information about the uniqueness of maximum COP at the PLR of 0.75 for HPC and 0.4 for CTC for all ambient conditions. The optimum loading points for maximum COP, in fact, are different, depending on the outdoor temperatures.

CONCLUSIONS

This paper demonstrates how to specify precisely the COP of air-cooled chillers under various operating conditions. An analysis on the ton-hour distribution of typical local chiller operation categories showed that ARI's part load rating conditions are incapable of presenting diverse operating conditions of chillers working in parallel to meet the changing building cooling load. A set of part load performance curves should be developed to show how the chiller COP varies at different condensing temperatures for any given combination of outdoor temperatures and part load ratios. It is expected that such curves are applicable to presenting the part load performance of water-cooled chillers when the outdoor temperature is replaced by the entering condenser water temperature which depends on the ambient wet bulb temperature and the working approach of cooling towers. It remains to be seen how to foster chiller manufacturers to provide their products with specific sets of part load performance curves. It also remains to be investigated how to specify the upper limit of condensing temperature to state the minimum chiller COP at any given part load condition and hence to boost the part load performance of chillers. If minimum allowable COPs at part load conditions are established, a pragmatic chiller performance benchmark can be formulated for buildings in any climate zone.

Modelling of a heating and cooling plant coupled to a hotel using HFC or CO_2 as a working fluid. Comparison of the performances.

Paul Byrne, Jacques Miriel, Yves Lenat

SUMMARY

Since ozone depleting substances were banned, HFCs have become the most common working fluids in refrigeration devices. However, these greenhouse gases are responsible for global warming and are likely to be banned by European directives. Interest is now being turned towards natural fluids such as CO_2. The Heating and Cooling Plant (HCP) is intended to produce domestic hot water (DHW) and to heat and cool residential and smaller office buildings. The HCP presents a special design of the refrigeration circuit and an innovative defrosting system. Two HCPs (CO_2 and HFC) coupled to a hotel have been modelled using TRNSYS software. Simulations show that CO_2 is less efficient. Nevertheless, this working fluid seems to be well suited to the operation of the HCP, because it enables to produce DHW at 55°C and because the high amount of energy recoverable by subcooling increases the efficiency of the defrosting system.

INTRODUCTION

Many buildings have simultaneous needs in heating and cooling. Typically, during summer, they face needs in cooling and in domestic water heating. During in-between seasons, from March to May and from October to November, rooms facing north have to be heated and rooms facing south have to be cooled, especially in buildings with significant glazed surfaces. In winter, only heating is required. The Heating and Cooling Plant (HCP) [1] is intended to satisfy the needs for domestic hot water production, space heating and cooling all year round and uses a special defrosting technique.

This article describes an innovative defrosting system for a Heating and Cooling Plant. This machine is coupled to a hotel whose needs in domestic water heating are quite substantial. It is assumed that the system uses either a hydrofluorocarbon (HFC) or carbon dioxide as a working fluid. As the two machines are quite similar, only the carbon dioxide type is described in this paper. Then annual simulations are run using TRNSYS software [2] for both plants and the results are compared and analyzed.

THE HEATING AND COOLING PLANT

Three heat exchangers

The CO_2 HCP (figure 1) has three heat exchangers: a condenser and an evaporator that heat and cool two water tanks for space heating and cooling and an exchanger that works either as a condenser or as an evaporator on ambient air to adapt production to needs. This last exchanger evacuates any excess cold produced in a heating mode and any excess heat produced in a cooling mode.

Three operating modes

The HCP works in three modes: a heating mode using the water condenser and the air exchanger as an evaporator; a dual mode preparing hot and cold water using the water heat exchangers; and a cooling mode using the water evaporator and the air heat exchanger as a secondary condenser. The cooling mode also integrates the production of domestic hot water by using the top part of the water condenser as a primary condenser.

An innovative defrosting technique

The water condenser is divided into three parts. The top part is used for domestic water preparation, the middle part is dedicated to the production of hot water for space heating and the lower part is connected to the cold water tank. During winter, this feature enables the storage of heat in the cold tank. The HCP alternates between heating mode and dual mode. In heating mode, the heat exchangers involved are the air evaporator and the three parts of the water condenser. The temperature of the cold tank rises to a maximum of 15°C. The fins of the air evaporator become frosted. The HCP then changes mode to operate in the dual mode. In this mode the fan of the air heat exchanger stops. The water evaporator and the top and middle parts of the water condenser are now involved. This allows for better COP by working on water as a source on both sides. A second advantage of the circuit design is that the defrosting system is automatic: after passing through the water condenser for domestic hot water production and space heating, the working fluid enters the air heat exchanger at a temperature around 35°C and is subcooled by exchange with the frosted fins. The cycle finishes on dual mode until the cold tank temperature decreases back to 5°C. Then the HCP switches back to heating mode and so on.

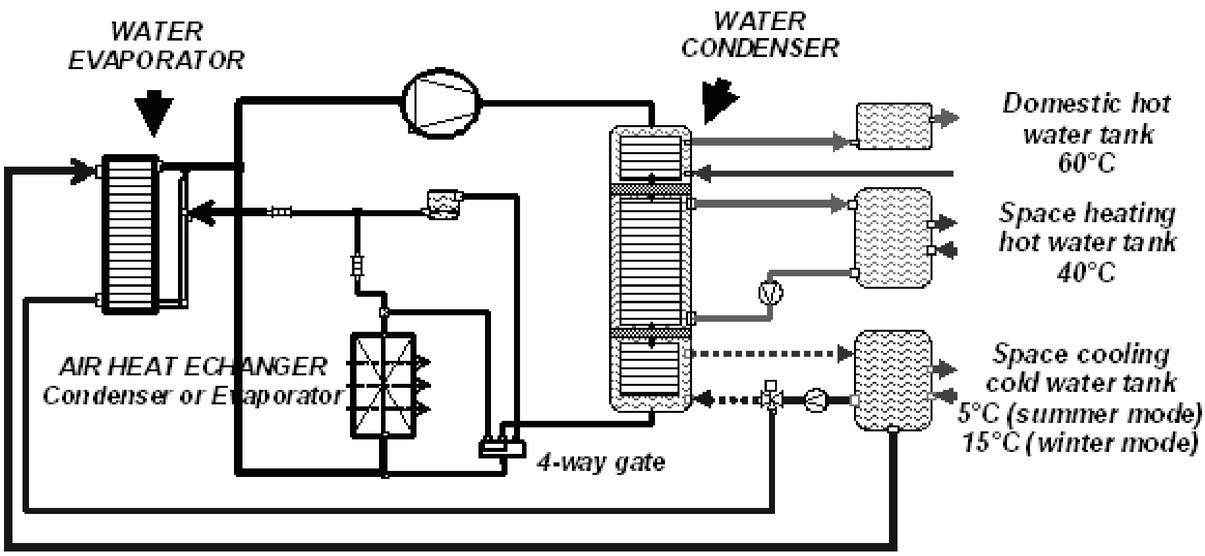

Figure 1. The Heating and Cooling Plant working with CO_2 as a working fluid

THE REFRIGERANTS

R407C

The choice of the refrigerant is linked to three criteria: performance, cost and security and environmental regulations.

Table 1. Characteristics and properties of some refrigerants

Fluid	CFC-12	HCFC-22	HFC-134a	NH_3 R-717	C_3H_8 R-290	CO_2 R-744
Natural substance	No	No	No	Yes	Yes	Yes
Molar mass (g/mol)	120,92	86,48	102,03	17,03	44,10	44,01
Volumic refrigerating capacity at 0°C (kJ/m^3)	2740	4344	2860	4360	3870	22600
ODP	1	0.05	0	0	0	0
GWP (100 years)	7100	1500	1200	0	0	1
Flammable?	No	No	No	Feebly	Yes	No
Toxic?	Feebly	Feebly	Feebly	Yes	No	No

Table 1 shows the most common fluids used until now in refrigeration. R12 is a chlorofluorocarbon (CFC) and R22 is a hydrochlorofluorocarbon (HCFC). Because of their impact on the ozone layer (Ozone Depletion Potential ODP $\neq 0$), the sale of devices using these substances was banned in Europe in 2000 for CFCs and in 2004 for HCFCs [3] [4]. Widely used in mobile air-conditionning systems, R134a is one of the best performing HFCs however it has a high Global Warming Potential (GWP = 1200). Therefore these refrigerants are also likely to be banned in future by the European directive on F-gases. R407C is a HFC mostly used in heat pumps and air-conditionning for residential applications. Its GWP is 1503.

Carbon dioxide

According to Gustav Lorentzen, author of "Revival of carbon dioxide as a refrigerant" [5], CO_2 is today's best natural refrigerant as a substitute for HFCs. CO_2 is quite performant when used in transcritical cycles (Fig. 2). In such cycles the major problem is dealing with high pressures. Indeed for CO_2, low pressures are around 40 bars and high pressures can reach 120 bars. During heat rejection, the pressure of the refrigerant is above its critical value (73.8 bar for CO_2). This implies that there is no drastic change of phase at heat rejection. When the temperature decreases, supercritical gas progressively turns to supercritical liquid. The temperature of the fluid at the compressor outlet is between 70 and 100°C. The gliding temperature obtained at the heat rejection side enables the production of hot water at different temperatures as required for the HCP (Dosmestic hot water at 60°C and space heating water at 40°C). Producing DHW with a HCP R-134a would have required an auxiliary heater. The CO_2 transcritical cycle seems to suit residential and office applications selected for the HCP. Besides, the defrosting technique can also benefit from the good thermodynamic properties of supercritical carbon dioxide because of the high amount of energy created by subcooling.

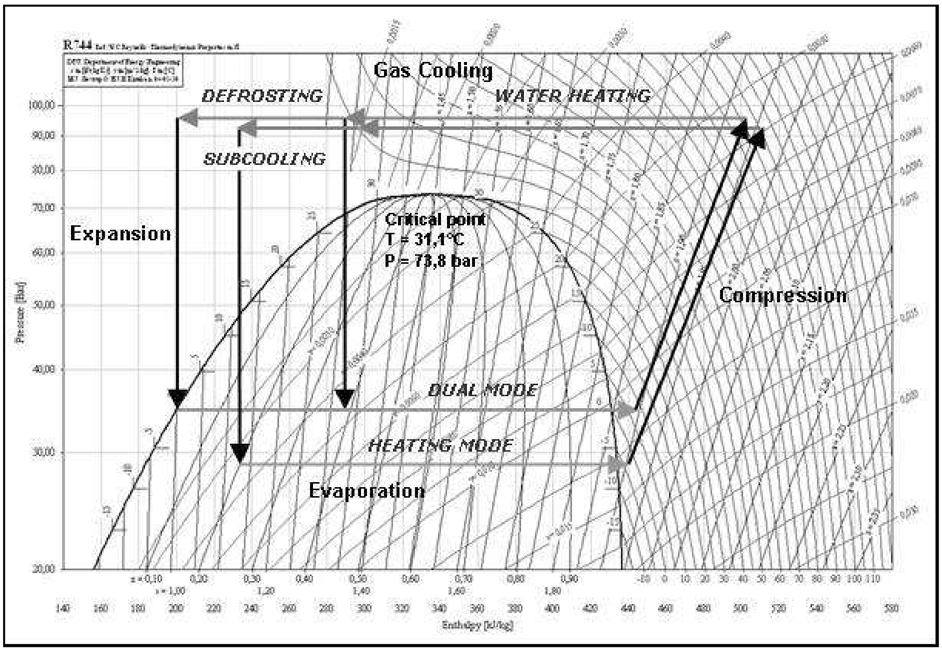

Figure 2. Transcritical cycles of carbon dioxide on the Mollier diagram

MODELLING HYPOTHESES

Building model

The building model is a hotel of 45 rooms where domestic hot water consumption is quite significant. Thermal zones, wall compositions, glazings, solar protections, ventilation et occupancy and light schedules are defined using the building module of TRNSYS so as to calculate the hotel's daily needs in heating and cooling. The simulations are run using a weather data file from Paris.

Heating and cooling plant model

The components of the system are also modelled using TRNSYS software. Simulations calculate the heating and cooling capacities and the coefficients of performance for the three operating modes (heating, cooling and dual mode) according to the ambiant temperature. The HCP is supposed to have a heating capacity of 100 kW in the heating mode for the base temperature of Rennes (-6°C). This capacity corresponds to a maximum operating time of 10 hours during the coldest day the year.

Operating strategy

The HCP is designed to work mainly in the dual mode as this is the most efficient. Then it works in the heating or the cooling mode depending on the needs of the building. When heating, the HCP alternates between the heating and dual mode. The cold tank temperature increases in the heating mode and decreases in the dual mode between 5 and 15°C. Time ratios were previously calculated in order to take into account the alternation of the two modes in the heating sequence with and without frosting (Equations 1 and 2). These ratios were supposed constant and are reported in Table 2. The ratios are different with and without frosting because when appearing the defrosting capacity is added to the heating capacity. To balance the higher heating capacity, the cooling capacity increases as well. Therefore the cold tank temperature decreases more quickly from 15 to 5°C.

$$r_{DM-noF} = \frac{dual\ mode\ time\ without\ frosting}{time\ of\ the\ heating\ sequence} \tag{1}$$

$$r_{DM-F} = \frac{dual\ mode\ time\ with\ frosting}{time\ of\ the\ heating\ sequence} \tag{2}$$

Table 2. Time ratios in heating sequences

Time ratio	CO_2	R407C
r_{DM-noF}	0.28	0.15
r_{DM-F}	0.25	0.12

A third time ratio was calculated to estimate the time of frosting conditions during each day of the year (Equation 3).t is assumed that frost appears when the ambient temperature is beyond 7°C.

$$r_{T<7°C} = \frac{Number\ of\ hours\ with\ T_{amb} < 7°C}{24} \tag{3}$$

Operating times per mode

Dual mode is the first mode until the minimum need is satisfied (Equation 4). The right-hand member is due to the alternation between dual and heating mode during a heating functioning.

$$t_{DM} = \min\left(\frac{q_h}{Q_{hDM}}, \frac{q_c}{Q_{cDM}}\right) + \left[r_{T<7°C}.r_{DM-F} + \left(1 - r_{T<7°C}\right).r_{DM-noF}\right] \times \left[\frac{q_h}{Q_{hHM}} - \min\left(\frac{q_h}{Q_{hDM}}, \frac{q_c}{Q_{cDM}}\right)\right] \tag{4}$$

where q_h is the daily need in heating, q_c, the daily need in cooling, Q_{hDM}, the heating capacity in dual mode and $_{HM}$ stands for heating mode.

In heating mode, the real operating time is the time needed to cover all the heating needs minus the dual mode time (Equation 5).

$$t_{HM} = \frac{q_h}{Q_{hHM}} - t_{DM} \tag{5}$$

In cooling mode, the real operating time is the time needed to cover all the cooling needs minus the time dedicated to cooling of the dual mode (Equation 6).

$$t_{CM} = \frac{q_c}{Q_{cCM}} - \min\left(\frac{q_h}{Q_{hDM}}, \frac{q_c}{Q_{cDM}}\right) \tag{6}$$

where $_{CM}$ stands for cooling mode.

Coefficients of performance

The daily and annual coefficients of performance are calculated in proportion to the operating times.

RESULTS AND DISCUSSION

Building simulation

The annual simulation of the 45-room hotel (Figure 3) shows the evolution of heating and cooling needs all year round. Annual needs amount to 25322 kWh in DHW production, 68640 kWh in space heating and 30146 kWh in cooling. Paris is situated in a temperate climate where heating needs are higher than cooling needs. It can also be pointed out that during in-between seasons heating and cooling needs appear simultaneously. During summer the plateau in the heating curve corresponds to the hot water production that is nearly constant. From the end of April to the end of October hot and cold productions are simultaneous during at least a few hours day.

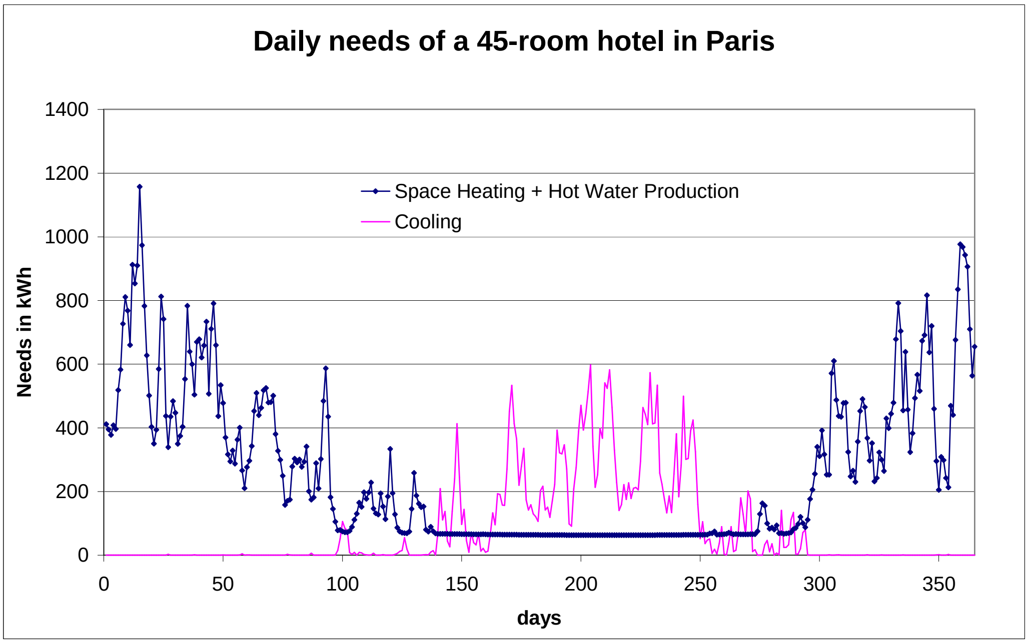

Figure 3. Evolution of daily needs in heating and cooling of a 45-room hotel in Paris

Operation times

Operation times per mode to satisfy the needs of the building are calculated and reported in table 3. Performances of carbon dioxide being lower the total operation time is greater. The weaker cooling capacity of CO_2 implies an increase in the cooling mode time whereas in heating mode the weaker performances are balanced by an increase in the dual mode. This is due to the better time ratio between dual and heating mode during winter. These values show that in spite of its poorer performance CO_2 as a working fluid better suits the modal operation technique of the heating and cooling plant.

Table 3. Comparison of the operation times per mode

Operation times	R407C	CO2
Dual mode	134.7 h	244.4 h
Heating mode	543.5 h	513.0 h
Cooling mode	127.2 h	291.1 h
Total	805.4 h	1048.6 h

Coefficients of performance

These graphs on figure 4 show clearly that CO_2 has a lower COP for space heating and cooling than any HFC. The curves record a serious increase during in-between seasons, and summer especially for R407C. For carbon dioxide the performances in cooling are not as good as in heating. So when cooling demands are important, the average COP goes down. Annual COPs are near their value in winter because the operation times are higher in the heating period for the climate of Paris.

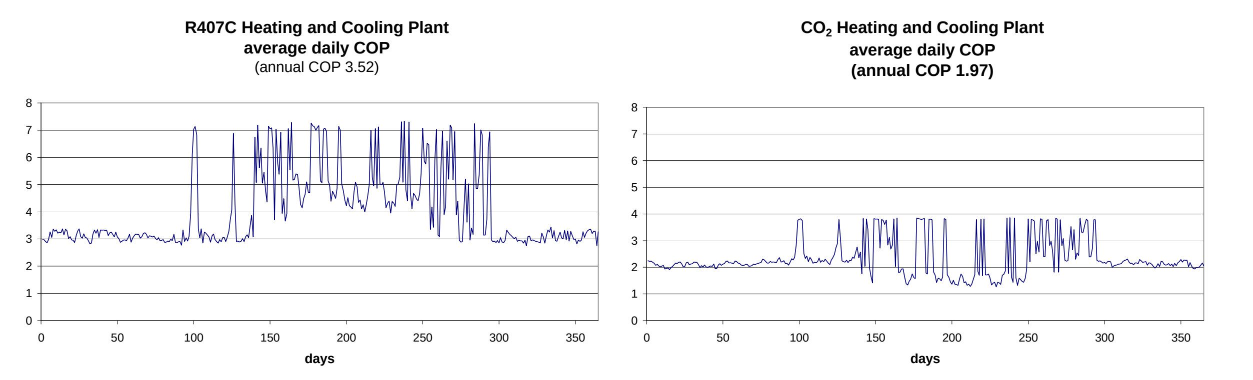

Figure 4. Comparison of daily coefficients of performance between R407C and CO_2

In addition the results of the HCP can be compared to the ones of a classic reversible heat pump (Table 4). The decrease of the performances due to carbon dioxide is less for the HCP than for the reversible heat pump. By another way, replacement of a standard heat pump by a HCP leads a better increase with carbon dioxide than with a HFC.

Table 4. Comparison of annual COPs of HCPs and reversible heat pumps

Fluid	R407C	CO2	Decrease
Reversible Heat Pump	3.18	1.58	-50.4%
Heating and Cooling Plant	3.52	1.97	-43.9%
Increase	10.7%	25.1%	

CONCLUSIONS

Today, HFCs are the most efficient “secure” fluids on the market. Unlike these greenhouse gases, carbon dioxide is environmentally friendly but is about 50% less efficient. CO_2 technology needs more development to be competitive in space heating and cooling applications. Nevertheless its thermodynamical properties allow domestic hot water production. It is an option to explore for the CO_2 HCP. The new defrosting technique for heat pumps noticeably increases average performance in heating mode, and increases more with high subcooling capacity.

The model presented here show how this Heating and Cooling Plant can satisfy the needs in heating, cooling and domestic hot water production of a hotel of 45 rooms situated in Paris. The HCP records better annual performances by between 10 and 25% and could even be improved with carbon dioxide for lower cooling needs obtainable in Northern countries such as Finland.

Theoretical Studies And Experimental Research Regarding The Evaluation Of Energetic Consumptions During The Production Of Menial Refrigeration

Dragos Hera and Anica Ilie

Technical University of Civil Engineering, Romania

Corresponding email: anica@eits.mediasat.ro

SUMMARY

The present paper brings out to knowledge the results of the studies and the experimental research, carried out during a project belonging to the National Program of Excellency Research, regarding the evaluation and analysis of energy consumptions during the production of menial refrigeration in Romania.

The authors analyze the refrigerating equipment categories and present the graphic evolution in time of afferent energy consumptions (time versus energetic consumption).

Also, specific consumption indexes, for the manager refrigerating equipment used in Romania, are being defined and determined, both theoretically and experimentally. The equipment mentioned previously is either used for producing alimentary refrigeration or for producing ventilation refrigeration.

In order to define the specific consumption index, one must keep in mind: the type if the refrigeration equipment, the type of the refrigerating agent which was used, the effect of the exploitation conditions and the manufacturer.

Furthermore, we present studies and analysis regarding the improvement of energy consumptions during the production of ventilation refrigeration, by using heating pumps and the heating pump on the whole-refrigerating equipment.

INTRODUCTION

Within a national research project of Energsys Excellence, along with the energetic rehabilitation analysis of the menial consumers’ charging systems, with either thermal or electrical energy, in Bucharest, the energetic consumption for the production of menial refrigeration and the refrigeration used in the comfort air-conditioning, were theoretically and experimentally analyzed, as well.

Lately, a continuous rise of the electric energy’s consumption which insures the alimentary menial refrigeration, has been noticed. We are witnessing a continuous change in Terra’s climate, Romania being affected, as well, by the atmosphere warming, and with this, the home air-conditioning becoming more of a necessity.

THE ENERGETIC CONSUMPTION'S EVOLUTION FOR THE MENIAL REFRIGERATION AND FOR THE AIR CONDITIONING IN ROMANIA

The energetic consumptions' for menial refrigeration

Using the statistic data, given by specialized institutions, we distinguished graphically the evolution in time of the equipments' categories used in the menial refrigeration (refrigerators, freezers, combines) represented by the cooled volume encountered with a frequency of more than 95% among the menial consumers. We must add the fact that in 1975, refrigerators were represented by one door refrigerators, in 1985, refrigerators with freezer and combines, made in Romania, begin to be used (Arctic and R12), and, by 1990 numerous major equipments in producing menial refrigeration start to be commercialized (Zanussi, Electrolux, Indesit, Gorenje, etc), with thermodynamical performances and with various effects on the medium. If, in the beginning, the commercialization was accessible enough, allowing also equipments using refrigerants forbidden by the Montreal Protocol, after it's ratification by Romania (1993) only refrigerating equipments with ecological working fluids have been imported (R134a, R600).

In figure 1, we can observe a continuous volume rise of the cooling volume for the menial consumption. Simultaneously, because of the increased comfort and the need of a more reduced specific energy's consumption, the population turns to more advanced equipments (with larger volumes, but more efficient), a contribution to this being brought by the energetic labeling of these equipments. More and more used are the refrigerators with more efficient equipments (compressors, heat exchangers), in search of placing them within the energetic classes A and A+.

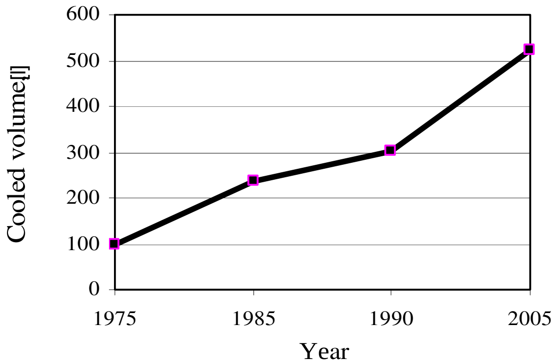

Figure 1: The required cooled volume vs. year.

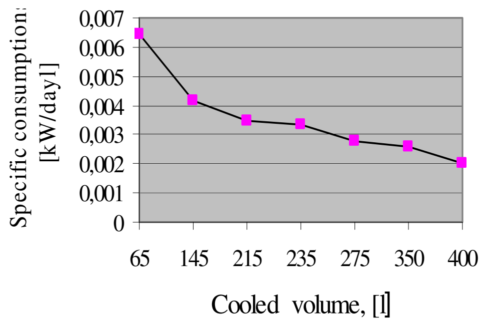

Figure 2: The variation of the energy specific consumption vs. cooled volume.

In figure 2 one can notice a drop of the specific energy's consumption (W/l). The highest specific consumptions correspond to the more reduced volumes (65….1251), a characteristic of the less advanced Romanian equipments (ARCTIC-the old generation). Along with the rise of the cooled volume (the ones used lately being the equipments with higher volume), but also with the use of advanced equipments, one can observe a continuous diminish of the specific energy consumption.

Tables 1, 2 and 3 present equipments for domestic cold used in Romania, remarking different technical characteristics, due to the used frigorific fluid (The best being those with R 600), as well as to the construction (refrigerators with one door, with two, as well as combines).

Energetic consumptions for air conditioning

For home air conditioning, the corresponding rise of the electrical energy consumption is even more spectacular, being almost absent before 1990 and reaching today to a point with air conditioning installation in almost 50% of homes. This phenomenon is due to the continuous rise of the air’s temperature in summer, on one hand, and to the comfort conditions inside the houses, which are higher by day, on the other hand. Considering the importance of electric energy consumption for building air conditioning out of the total of menial consumptions, we consider adequate the analysis of these individual consumptions, as well as the necessity of their reduction by adopting new design solutions and new exploitation techniques. Two systems for comfort ventilation inside buildings are being used: systems with direct evaporation (split, multisplit) and systems with indirect cooling with secondary refrigerant (chiller and fan coils).

Systems with direct evaporation

For small cooling capacity (for a surface of 25÷120m2), the system which imposed itself is the one with direct evaporation, with one or more inner units. Studies and experimental researches regarding the performance of the systems with direct evaporation (Table 4) show their electric energy consumptions (Pc), in various working conditions: ambient air temperatures, evaporation temperatures (t0) and condensation temperatures (tC), of the common refrigerating agents used in installations (R134a, R404A, R410A).

Table 4: COP for air conditioning systems with direct evaporation .

$t_{amb.}$, [°C]	t_{int} [°C]	t_0, [°C]	t_C, [°C]	Q, [kW]	R 134a		R404A		R410A	
					Pc, [kW]	COP, [-]	Pc, [kW]	COP, [-]	Pc, [kW]	COP, [-]
30.00	20.00	8.00	45.00	9.60	2.24	4.29	2.52	3.81	2.43	3.95
32.50	20.00	8.10	47.50	9.60	2.42	3.96	2.76	3.47	2.65	3.61
32,50	20.00	8.30	50.00	9.60	2.61	3.68	3.02	3.17	2.89	3.32
37.50	20.00	8.40	52.50	9.60	2.81	3.42	3.31	2.90	3.15	3.04
40.00	20.00	8.60	55.00	9.60	3.01	3.19	3.62	2.65	3.43	2.80

Romania, as a country in progress, has benefited up until this year of facilities regarding the Montreal Protocol exigency, and so, in the present study the only refrigerant taken into account is R134a, as it is the most often used at this moment. The average electric consumption for homes' air conditioning was calculated for a functioning period of 10 hours a day, having as a result the data in table 5.

Table 5: The performance of air-conditioning systems with direct evaporation.

Living space	Living surface	Technical features of cooling plants		Average consumption of electrical power
	[m²]	Cooling capacity, [kW]	COP, [-]	[kWh/24h]
Studio flat	25	1.5	4,61	3,25
Apartment 2 rooms	40	2.4	4,61	5,2
Apartment 3 rooms	60	3.6	4,61	7,81
Apartment 4 -5 rooms	80-120	4.8 – 7.2	4,61	10,4…15,61

Indirect cooling systems (with secondary refrigerant).

In conditions identical to the ones of the direct cooling (the same spaces, the same inner and outer temperatures and the same functioning period), the cooling capacity and the driving electrical power are presented in table 6.

Table 6. The performances of air conditioning systems with secondary refrigerant.

No.	Living space	Living surface	Technical features of cooling plants		Average consumption of electrical power
		[m²]	Cooling capacity, [kW]	COP, [-]	[kWh/24h]
1.	Studio flat	25	1.5	3,77	3,98
2.	Apartment 2 rooms	40	2.4	3,77	6,37
3.	Apartment 3 rooms	60	3.6	3,77	9,55
4.	Apartment 4 -5 rooms	80-120	4.8 – 7.2	3,77	12,73…19,1

It is clearly seen that the systems with a direct cooling are more economical (the electric consumption is reduces with 18%). Nevertheless, the systems with indirect cooling are being used due to the advantages given by: the possibility of using ammonia, the most advanced, the cheapest and most ecological refrigerant; it uses a low quantity of refrigerant with a favorable influence over the ambient; the possibility of being used in district cooling systems.

Both systems have evolved towards variants with reversible functioning (insuring both the air conditioning and the building heating) or with heat recovery, which improve more and more their performances.

SPECIFIC INDICATORS

Further, we present the experimental data for the specific indicators, for the production of menial refrigeration and air conditioning, using the most customary refrigerant (R134a).

Menial refrigeration

Table 7. Energy consumption for the production of menial refrigeration.

No.	Living space	Cooling volume of refrigerator, [l]		Average consumption of electrical power, [kWh/24h]	Specific consumption [10^{-3} kW/(day,l)]
		Refrigeration	Freezing		
1.	Studio flat	228	20	0,71	2,87
2.	Apartment 2 rooms	322	70	0,89	2,37
3.	Apartment 3 rooms	425	99	1,17	2,22
4.	Apartment 4 5 rooms	522	165	1,43	2,08

The average energy consumption was calculated for certain equipments presented in tables 1, 2, 3 in accordance with the size of the menial consumer.

Air conditioning energy consumption (working time 10 hours/day)

Direct evaporation systems

Table 8. Specific air conditioning indicators with direct evaporation systems.

No.	Living space	Type of air conditioning unit	Cooling capacity, [kW]	Electrical power, [kW]	Average consumption of electrical power [kWh/24h]	Specific consumption [kW/(m2,zi)]
1.	Studio flat	Monosplit	1,5	0,325	3,25	0,13
2.	Apartment 2 rooms	Bisplit (2 UI)	2,4	0,47	4,7	0,1175
3.	Apartment 3 rooms	Multisplit (3 UI)	3,6	0,72	7,2	0,12
4.	Apartment 4-5 rooms	Multisplit (4-5 UI)	4,8 – 7,2	0,94….1,37	9,4…13,7	0,1175.... 0,114

Indirect cooling systems with secondary refrigerant

Table 9. Specific air conditioning indicators with indirect cooling systems.

No.	Living space	Cooling capacity, [kW]	Electrical power, [kWh/24h]	Average consumption of electrical power [kWh/24h	Specific consumption kW/(m2,zi)]
1.	Studio flat	1,5	0,398	3,98	0,159
2.	Apartment 2 rooms	2,4	0,572	5,72	0,143
3.	Apartment 3 rooms	3,6	0,855	8,55	0,1425
4.	Apartment 4 -5 rooms	4,8 – 7,2	1,12….1,68	11,2…16,8	0,14

From the data in tables 8 and 9, one can observe that the specific indicator has higher values in the case of the indirect evaporation with cca 21%, in rapport with the direct evaporation; the same dropping tendency can be observed in the case of the specific indicator's value the same as the decrease of the cooled volume.

DISCUSSION

The data regarding the energy consumption for the production of menial refrigeration and air conditioning are specific to Romania today.

Between the years 1975 and 2005, it has been canned a. ascending evolution of the cooled volume for menial refrigeration, determined by the continuous rise of the lifestyle. The specific consumptions for the production of menial refrigeration have canned a continuous drop determined by the increase of equipment's performances.

The air conditioning has also canned major increases and determined, at the same time, the electric energy's menial consumption rise.

The average energy consumption necessary to the air conditioning depends on the volume of the cooled space and on the cooling system type.

Nevertheless, in spite of their reduced electric consumption of the air conditioning system with direct evaporation, they are not recommended.

NOMENCLATURE

- UI – interior unit;
- COP -coefficient of performance.

A 95% More Efficient Telecom Cooling System

Dieter Többen and Michael Gräppi

Dr. Eicher+Pauli AG, Bern, Switzerland

Corresponding email: dieter.toebben@eicher-pauli.ch

SUMMARY

Reduction in investment of over 100 million Euros reduction and more than 5 million Euros per annum in operating costs for cooling telecom systems, combined with a higher level of cooling availability and in particular of the telecom technology; these are the consequences of a very special paradigm change in the cooling of telecom systems. The use of the new cooling system will enable Swisscom alone to make savings of around 70,000 MWh in electricity throughout Switzerland, with investments being reduced by more than 100 million Euros. The sustainability can also be seen in the drastic reduction in refrigerant quantities and generally lower material flows. However, the solution strategies are not only attractive to other telecom providers but also offer valuable input for future computer centre cooling systems.

INTRODUCTION

Because of ageing, the existing cooling systems used in Swisscon telecommunications centres and remote units are having to be replaced. Replacing the air-conditioning systems in the more than 1,000 centres will give rise to costs of € 180 million for the whole of Switzerland. In addition, the current high operating costs will be reduced by a not-inconsiderable amount. The rapid development in the field of telecommunications technology demands more flexible and more low-cost cooling systems.

These are the driving forces behind the start-up of the Mistral projects which are aimed at the development and implementation of new telecom cooling systems. The requirements were as follows:

- adherence to the required air-conditioning levels
- simplicity of the system
- value for money
- flexibility in changeover
- modularity, expandability
- redundancy in the case of higher thermal loads and high availability
- energy savings
- minimal environmental pollution
- easy operation and maintenance
- adherence to the Swisscom safety specifications

The Project Team has already accumulated three years experience from the design, pilot and test phase and implementation of the innovative indoor temperature control systems. To-date, implementation has been carried out in around 150 control rooms and most of these have been operating for several years.

BASES

The ETSI guidelines (European Telecommunications Standard Institute) form the basis for cooling telecom system control rooms throughout Europe. These define normal and extreme ranges. A distinction is drawn between two profiles of requirements depending upon the importance of the telecom equipment. These are the **ambient classes 3.1** and **3.6** in accordance with the ETIS standard 300 019-1-3 [1]. In practice the 3.1 requirements apply almost exclusively for all telecommunications installations at Swisscom.

Control rooms for the **ambient class 3.1** (see Figure 1) are defined in the ETIS standard.

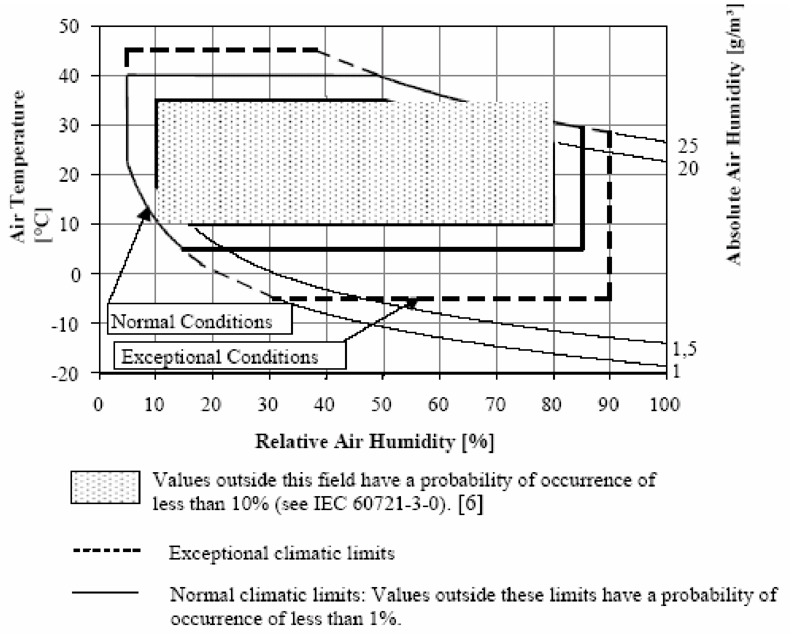

Figure 1. Climatogram for Class 3.1: Temperature-controlled locations.

Swisscom aims to achieve an average annual temperature of < 26°C in order to extend the service life of the telecom systems and to maintain the comfort for the employees at a high level. However, higher levels over a short period (a couple of hours per year) have no affect on the service life and are readily accepted by the users.

In order to provide a full picture at this point we show Figure 2 for rooms in the **ambient class 3.6**. It defines the standards for control rooms which have high temperature requirements.

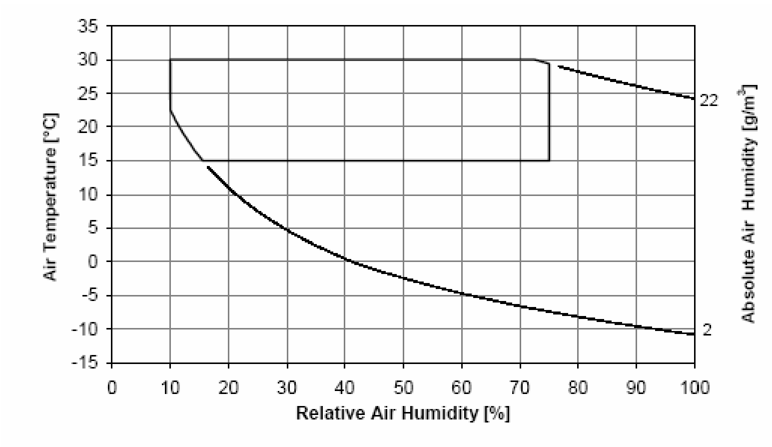

Figure 6: Climatogram for Class 3.6: Telecommunication Control Rooms

Figure 2. Climatogram for Class 3.6: Telecommunication Control Rooms.

The relationship between availability and room air temperature is shown in the graphic below. The warmer the average room air temperature the higher the relative error rate with the telecom installations. One of the specifications was consistent or even improved availability. The current average room temperature of 26°C was therefore taken as a basis.

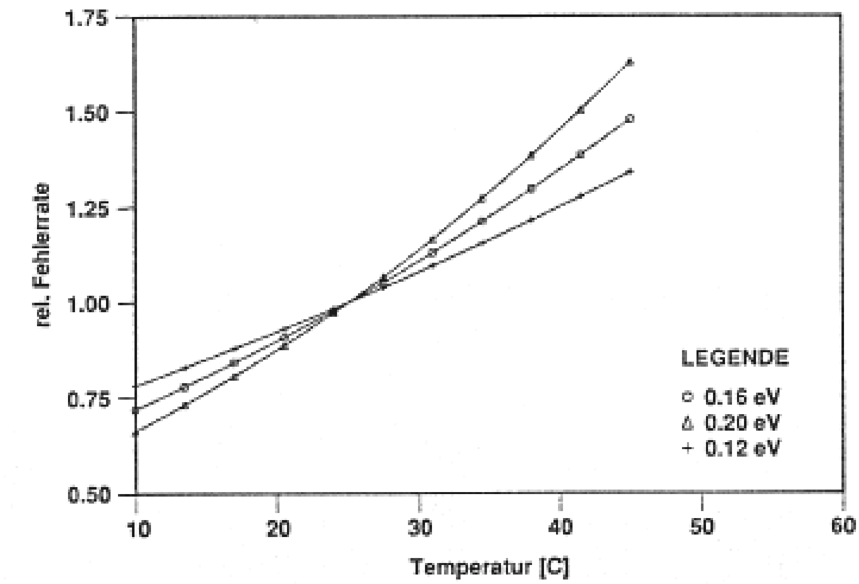

Figure 3 Relative failure rate of exchange depending on room air temperature for error activation energy of 0.12, 0.16 and 0.20 eV respectively [2]

FUNCTION / PRINCIPLE

The approach for an efficient solution is to tackle the root cause of the problem.
The heat that escapes above the rack is extracted as close as possible to the source and evacuated directly out of the room. This hotspot extraction prevents the hot air from the racks having any effect on the room at all.

Thanks to the direct evacuation of the heat only a minimal portion becomes active in the room through thermal radiation and so this can be ignored. This means in turn that at most we will achieve the external temperature in the room by supplying non-cooled outside air for the fresh air supply. There is however the added factor of the influence exerted by the building mass. At night, as the outside air cools, the ventilation reduces the temperature in the room and of the building mass and the storage effect of the mass has a positive effect on the development of the room temperature.

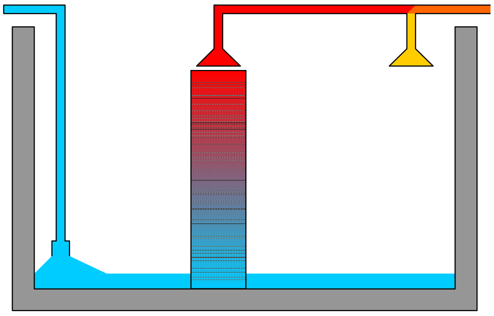

Diagram 1 This sketch of the principle shows the simple function method, the hotspot extraction is fitted above the rack. The fresh air supply using the outside air is carried out via screens with filters.

Depending upon the specific thermal load and type of application, there are a number of different systems from which to choose. The most frequent solutions typically selected are those with two exhaust fans.

Table 1. Description of ventilation principle

Ventilation principle	**Thermal load[W/m^2]**	**Description**
Mistral	Up to 680	2 outlet air fans each with 50% of the air volume flow with hotspot extraction and fresh air supply above ground via screens and filters. 50% redundancy

Photo 2 Mistral outlet 2V

Photo 3. Hotspot extraction

RESULTS

Readings clearly demonstrate that the systems are functioning superbly. The results from last Summer, a genuine 'hot' Summer in Switzerland with extreme climatic conditions, are shown below.

Meteorological data

The daily mean temperatures reached in July 2006 are the highest since the Swiss Meteorological Institute (SMA) began taking systematic records in 1864. If we look at the annual external temperature graph 2005/2006 from the SMA in Bern-Liebefeld we can see an exceptional density of high external air temperatures in July 2006. The highest reading was 33.7°C. The annual mean temperature of the external air is 8.9°C, this reflects quite a hot year for the Swiss Mittelland region.

Readings in a solid room with thermal load of 300 W/m²

Diagram 4 shows a Mistral system in a Swisscom telecommunications centre near Bern. The system is able to maintain the mean room air temperature over the course of the year at 24.8°C. In Summer, peak levels of 33°C were recorded over a period of 21 hours, 12 K below the permitted maximum in accordance with the ETIS ambient class 3.1 (Figure 1). The target, low average annual temperature is therefore maintained.

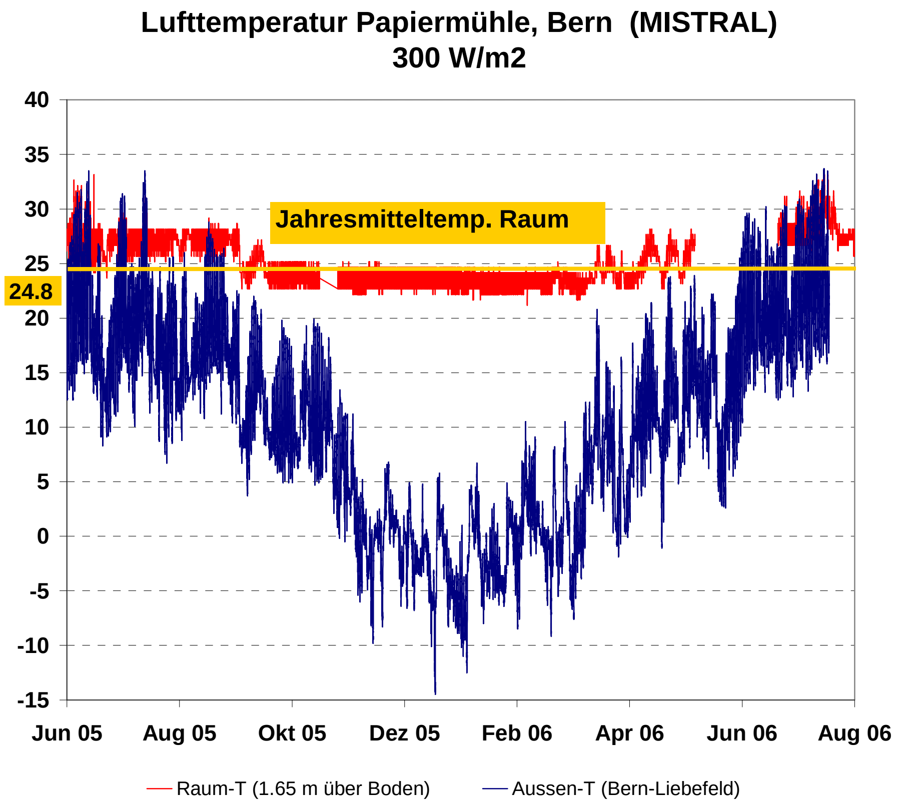

Figure 4. Graph of annual temperature at the Bern plant.

Table 2. Sum frequency temp.

t_{Room} [°C]	Number of hours [h]	Percent [%]
>34	0	0
33	21	0.3
32	37	0.5
31	67	0.9
30	113	1.5
29	151	2.0
28	869	11.6
27	744	10.0
26	457	6.1
25	701	9.4
24	1800	24.1
23	2359	31.6
22	150	2.0
<21	0	0

The sum frequency table for the room temperature using the example of the paper mill in Bern illustrates the distribution throughout the whole year. Over 55% of the hours in the year are at a temperature level of 23-24°C. Temperatures above 30°C account for just 3.2%. Therefore when we talk about “temperature peaks” we mean just a few hours per year. The room air temperature hardly, if ever, exceeds the outside air temperature. It is therefore clear that the optimum thermal load extraction was not achieved but the building mass helps to keep the levels very low.

Readings in a lightweight construction cabin with 108 W/m²

Diagram 4 below shows a Swisscom Mobile outside unit in Lavigny (Vaadt). The room air mean temperature in the Summer months is 27.1°C, the figure throughout the whole year is approx. 23.5°C.

The mobile rooms differ from the Fixnet rooms in terms of their construction. The mobile cabins have virtually no building mass. The result of this is that there is almost no activation effect by the building mass and so the temperatures are slightly higher than at the solid construction locations. However, since the hotspot extraction was able to be implemented to better effect here the levels achieved are once again very satisfactory.

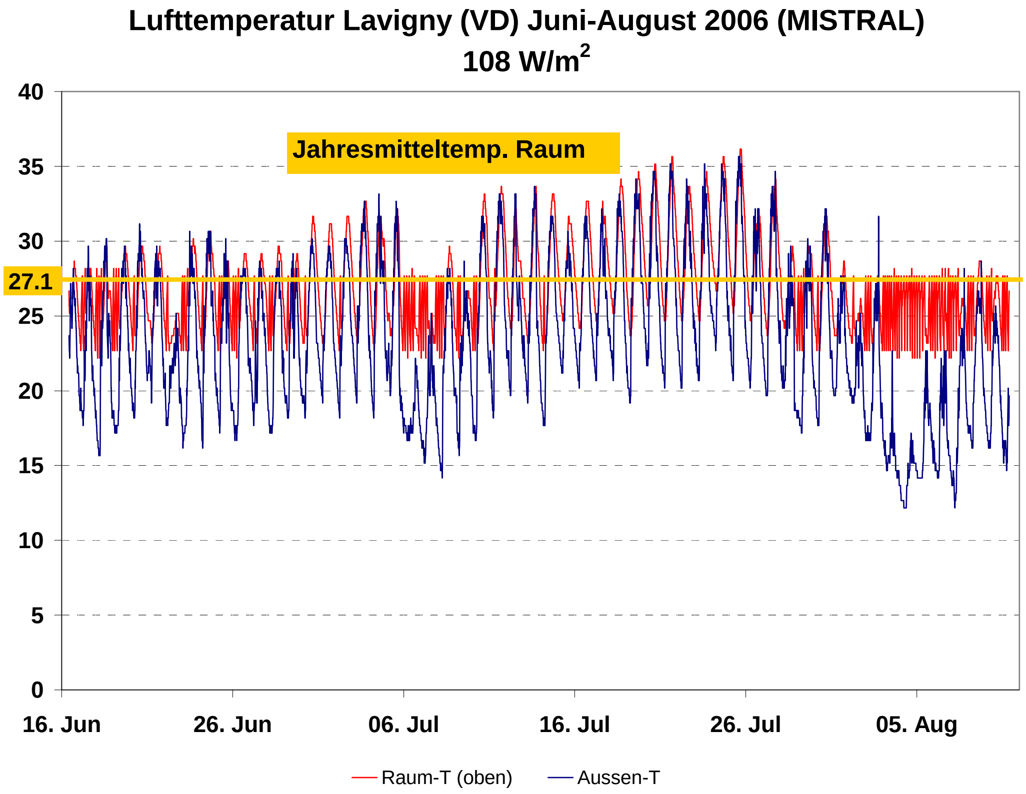

Figure 4. Graph of 3 months temperature
Mistral mobile

Operating experiences in Summer 2006

An independent temperature monitoring system is fitted in all Swisscom Fixnet's operating control rooms. In the hot Summer of 2006 the incoming temperature error messages were recorded and statistically evaluated over a period of three months. The task was to determine the relationships and frequency between the new and original systems on the basis of these error messages. 144 alarms were received, 10 of which were triggered by new systems. These 10 alarms occurred in a total of 4 rooms and were able to be traced back to incorrect thermal load data or operator error. There was therefore clear evidence that the system reliability is very high and is functioning properly.

Rooms with thermal loads up to 680 W/m2 had been previously implemented successfully using this system.

Humidity

Under the guideline (see Figure 1) the room humidity requirement of 5-85% relative h. must be met. The upper figure is quite safe since the air in the room is warmed up (except when outside temperatures are high) and so no relative humidity can be achieved in this area. On hot days the outside air humidity in Switzerland is never above 70% so here again, as the readings demonstrate, the upper figure can never be achieved.

What appears more critical is not to fall below the 10% relative humidity. The Mistral Team tested this at one of the highest telecommunications centre in Switzerland on the Säntis, 2503 metres above sea level. The readings in the room and all others which have been measured show figures of min. 10% relative humidity and have therefore never fallen below the lower limit.

Summary of the results

The field readings and experiences prove that the telecommunication control rooms can be successfully cooled to a functional temperature level without any problems using mechanical ventilation.

At annual mean temperatures of 24-25°C this can be easily maintained, as can the specifications in accordance with ETSI 3.1. The peak temperatures are limited to a minimal period and are clearly below the limits set by the ETIS standard. The requirements in terms of room humidity are met without exception.

There were no climate-related failures of the telecom systems in the 2006 hot Summer.

KEY FIGURES

A number of key figures should illustrate the potential that lies in this cooling system for telecommunication control rooms:

The imminent replacement investment for the outdated cooling systems for the whole of Switzerland, without Mistral, is € 180 million. This also means savings on maintenance in the sum of € 2 million and energy costs in the sum of € 4 million.

- 80% lower investment costs than conventional cooling systems (for new Systems)
- 80% lower maintenance costs
- 95% lower electricity costs

The total energy consumption per annum will be reduced by 70GWh after full implementation at existing and new planned sites at Swisscom.

OUTLOOK

Telecom operators in other European countries have already expressed significant interest in the new system. Belgacom from Belgium is already in the process of planning pilot projects. This publication is intended to draw the attention of specialists in the field of air-conditioning to this subject. The market potential in Europe alone is enormous and the potential gain for the environment more than considerable.

DISCUSSION

The impressive features of the system are not only its simplicity but its economic and ecological advantages. Combined with the improved availability and low maintenance operation, it is a showpiece of simulation-aided modern planning results.

The publication of this solution is however also intended to initiate a process of discussion and review. Many experts are still insufficiently familiar with the opportunities offered by natural cooling, many are unable to envisage the functionality of the simple solution.

However, the range of uses for this simple solution is not limited purely to cooling telecommunication installations. Depending upon the outside climatic conditions we can envisage being able to achieve the same levels as those in a computer centre. Faced with the knowledge gained from these results the IT equipment manufacturers should consider how much is needed that their items of equipment also can be cooled by using this system. Computer centre operators and the environment will feel the result of this change.

ACKNOWLEDGEMENT

We would like to take this opportunity to express our thanks to Swisscom for their active support and providing the resources for the realisation of this project.

ABSTRACT

Understanding the nature and thermodynamic behavior of sound waves and the attempt to harness the effect as a useful heat engine is called Thermoacoustic's. Thermoacoustic refrigerators utilize no environmentally hazardous gases. They use inert gases which are both readily available, inexhaustible, and completely environmentally benign! And, because they can utilize waste heat as an energy source, they are extremely environmentally friendly. In addition, since thermoacoustic refrigerators do not use the compressors, lubricants, sliding seals and after gismos present in vapor compression refrigerators, the thermoacoustic refrigerator should more reliable.

An inexpensive demonstration model of thermoacoustic Refrigeration system is built from a loudspeaker unit (Ahuja) of 90W with glass tubing and aluminum plug. The digital thermometers were used for recording the temperature and its variation along the resonator tube. The results were achieved after running the system for 40-50 minutes and were analysed.

INTRODUCTION

Understanding the nature and thermodynamic behavior of sound waves and the attempt to harness the effect as a useful heat engine is called Thermoacoustic's. A thermoacoustic refrigerator uses the thermoacoustic effect to remove heat with sound. A thermoacoustic prime mover uses heat to create sound. Thermoacoustic effect is the conversion of heat energy to sound energy or vice-versa. Utilizing the thermoacoustic effect, refrigerator can be developed that uses Acoustic energy as a source to remove heat with no moving parts.

In the mid 1990's the production of CFC's refrigerants (Freon mainly) was banned by the Montréal protocol. The CFC's are the major player in the depletion of ozone layer. In addition, CFC's are nasty green house gases. While the recent HFC and HCFC replacements are less harmful, they will still be major contributors to the greenhouse effect and there is concern over possible health hazards for many of the newer chemicals. In addition, since both HFC's & HCFC's are expected to be banned early in the 21st century, an entirely new refrigeration technology needs to be developed.

Thermoacoustic refrigerators utilize no environmentally hazardous gases. They use inert gases which are both readily available, inexhaustible, and completely environmentally benign! And, because they can utilize waste heat as an energy source, they are extremely environmentally friendly. In addition, since thermoacoustic refrigerators do not use the compressors, lubricants, sliding seals and after gismos present in vapor compression refrigerators, the thermoacoustic refrigerator should more reliable.

An inexpensive demonstration model of thermoacoustic refrigeration system is built from a loudspeaker unit (Ahuja) of 90W with glass tubing and aluminum plug. The digital thermometers were used for recording the temperature and its variation along the resonator tube.

Principle of working

The thermoacoustic refrigeration cycle is illustrated in Fig. 1 & 2. As the motion of the sound wave causes a gas parcel in the stack to move left towards the closed end of the tube. The pressure increases and the gas is compressed. The compressed gas parcel is now hotter than the nearby stack wall so it dumps heat to the cooler stack, thus shrinking in volume. As the standing wave continues through its cycle the parcel is pulled back to the right where the pressure is lower. The rarefied parcel is now cooler than the nearby stack wall so it absorbs heat from the warmer stack wall and expands. The cycle repeats with the net effect of a small amount of heat being moved a short distance along the stack from the colder towards the hotter end. Thus significant amount of heat is moved from one end of the stack to the other.

(A) Heat Pump or Refrigerator,
(B) Heat Engine or PrimeMover.

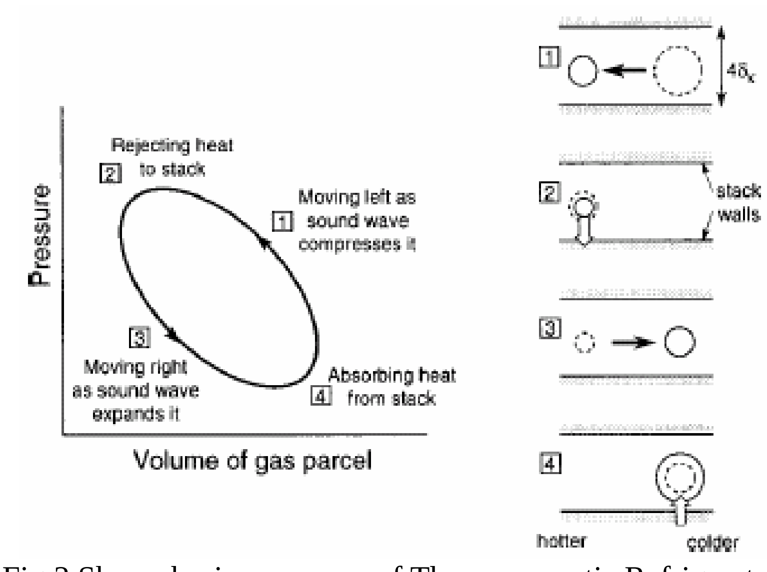

Fig:2 Shows basic processes of Thermoacoustic Refrigerator.

Literature Review

Advances in the development of thermoacoustic engines and acoustical compressors require an understanding of extremely intense sound fields (acoustic Mach numbers of order one) in resonators that are not cylindrical. Nonlinear effects such as harmonic generation, waveform distortion, and nonlinear frequency shift are to be investigated with a one-dimensional model[5]. All properties of the flow field throughout the resonator are to be calculated numerically. To estimate energy losses in the resonator, we have to consider the gas flow in the boundary layer along the walls of the resonator in the linear approximation and match it to the nonlinear solution in the volume. Energy loss due to turbulence is to be evaluated by introducing a model for eddy viscosity.

An analytical study is to be conducted of the thermoacoustic effects induced by the interaction of a strong acoustic field with a rigid boundary such as that in a thermoacoustic engine. With the sphere as a representative object, it has been found that the acoustic field can create a spatially periodic heating and cooling pattern on its surface just as in the stack of a thermoacoustic engine[10]. The thermoacoustic effects are generated primarily in the narrow Stokes boundary layer region on the sphere and are diffused and convected over the remaining part of the fluid domain.

Pressure oscillations in a sound wave is accompanied by temperature oscillations. In the presence of a solid boundary, the heat transfer from the oscillating gas to the solid boundary causes dissipation of the acoustic energy. This results in the attenuation of the sound wave[3]. This thermal-relaxation dissipation process has a negative effect on the performance of thermoacoustic heat pumps and engines. A simple analytical model describing the interaction between an acoustic wave and a solid boundary is presented. The effect of the solid material and gas type on thermal-relaxation dissipation is analysed. The main result of this model is that the choice of a solid material with the smallest possible heat capacity per unit area in combination with a gas with the largest possible heat capacity per unit area minimises the thermal-relaxation dissipation. From the different combinations solid-gas used in the calculations, the combination cork-helium leads to the lowest thermal attenuation of the sound wave. In this case, the heat transfer from the gas to the wall less damps the temperature oscillations. However, because of the porosity of cork that may cause some problems, it is suggested that the combination of polyester-helium can be used in practice to minimize the thermal-relaxation losses.

Thermoacoustically driven thermoacoustic refrigerator powered by solar thermal energy has been successfully built and tested by Jay A Adeff[14]. A 0.457 m diameter Fresnel lens focuses sunlight onto the hot end of a 0.0254 m diameter reticulated vitreous carbon prime mover stack, heating it to 475°C, thereby eliminating the need for the most troublesome component in a heat driven prime mover, the hot heat exchanger. The high intensity sound waves produced by the prime mover drive a thermoacoustic refrigerator to produce 2.5 watts of cooling power at a cold temperature of 5°C and a temperature span of 18°C.

Experimental set-up

The thermoacoustic refrigerator demonstration model described in this paper is of the standing wave variety, and consists of a half/quarter-wavelength resonator with an open-closed tube, driven by a loudspeaker unit of 90W. This is the easiest resonator shape to build, Since the primary purpose of this apparatus is to demonstrate the action of an acoustic refrigerator.

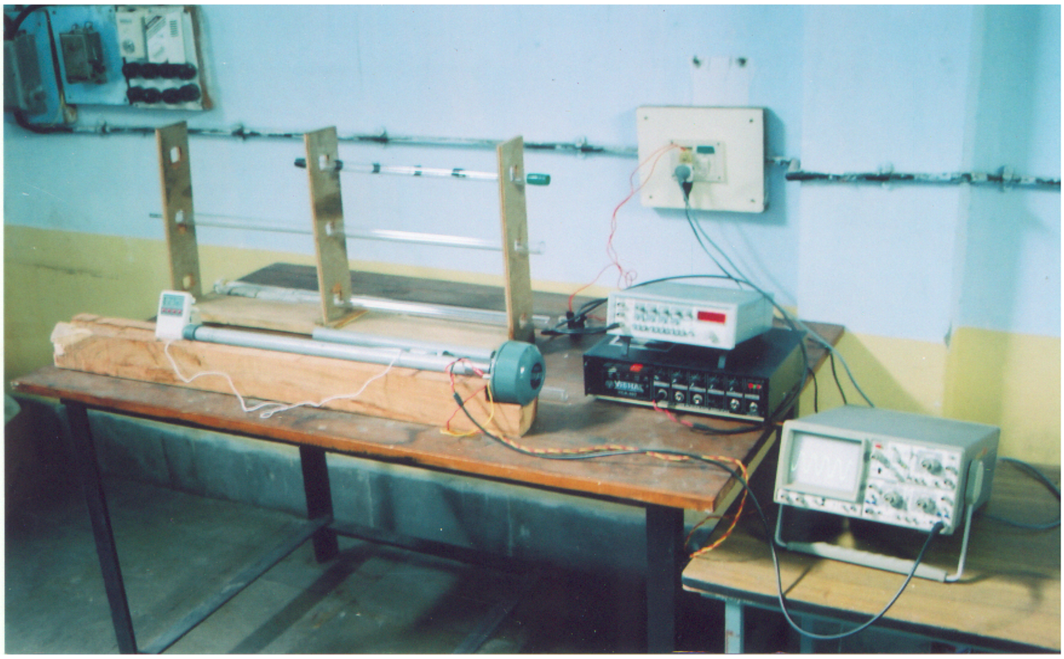

Fig:3 Experimental Set-up. Acoustic Driver, Amplifier, Function Generator, Cathode Ray Oscilloscope, Resonance Tube and digital thermometers etc.

The resonator for this refrigerator was made up of a 1m length of glass tubing with an inner diameter of 20 mm. The length defines the resonance frequency of the system. The loudspeaker (Ahuja Unit) was driven by a frequency generator producing a sine wave through a 90W audio amplifier and a 1.2-inch diameter o-ring was used to provide a seal around the edge of the speaker. An aluminum plug was milled to fit snugly into the end of the tube, forming the closed end. The resonator for this refrigerator was made up of a 1m length of glass tubing with an inner diameter of 20 mm. The length defines the resonance frequency of the system. For recording the frequency and amplitude of the wave, Cathode Ray Oscilloscope was used. Digital thermometers were used for recording the temperature at each node – antinodes points. The pressure amplitude inside the resonator tube was not measured but was obtained following the ideal gas equations. The power to the speaker was varied and increased until a second harmonic became audible indicating that the system was becoming non linear. The most important part of an acoustic refrigerator is the stack, which consists of a large number of closely spaced surfaces aligned parallel to the length of the resonator tube. The stack for this apparatus was constructed from photographic film around a central spindle so that adjacent layers of the spirally wound film provide the stack surfaces, so that air could move between the layers along the length of the stack parallel to the length of the resonator tube. If stack layers are too far apart the gas cannot effectively transfer heat to and from the stack walls. If the layers are too close together viscous effects hamper the motion of the gas particles.

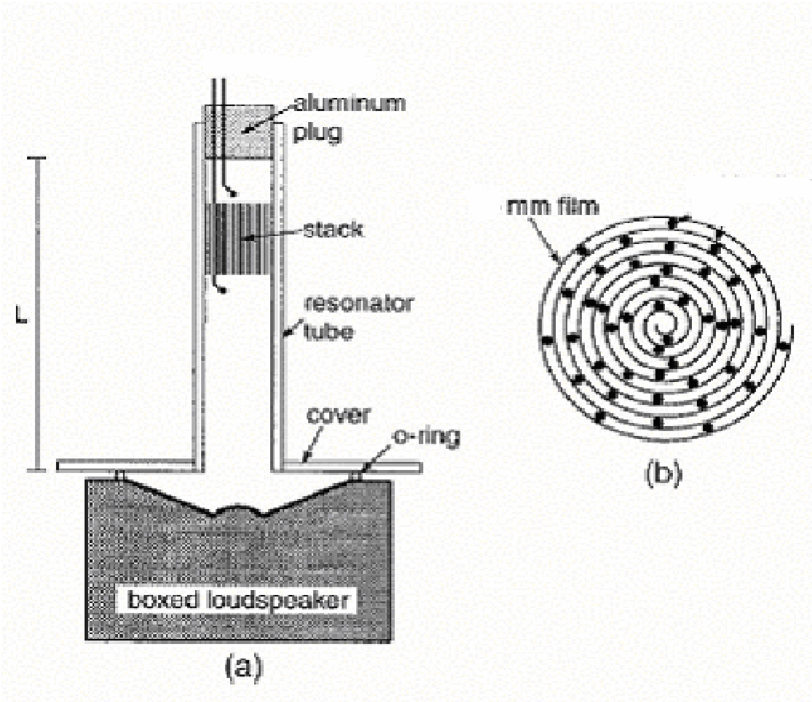

Fig:4
(a) Schematic diagram of the prototype of Thermoacoustic Refrigerator model,
(b) Cross section of the stack showing how the film layers were separated.

Experimentation

Initially water was poured in the tube and the loudspeaker was turned on by setting the frequency of the acoustic wave. The working substance used for this setup is the inert gas called air, which is alternatively compressed and expanded in the tube due to generation of the sound waves. The acoustic waves which are longitudinal waves, standing waves are set in the resonator tube. Standing waves causes the gas particle to oscillate back and fourth parallel to the walls of the resonator tube. The alternating compression and rarefaction of the gas causes the local temperature of the gas to oscillate due to adiabatic nature of sound waves. As there is alternatively compressions and rarefactions existing in the resonator tube the temperature difference is obtained due to the pressure amplitude of the of the acoustic wave. As there is 90degree phase lag between the oscillations of the pressure and velocity inside the tube, the water poured in the tube swirls at the junction of acoustic pressure amplitude (antinodes).

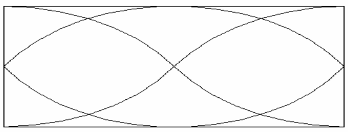

Fig:5 Pressure & Velocity, variation in the resonance tube.

Thus heat is transferred to the water medium and the gas gets cooler causing refrigeration effect. The temperatures were recorded before and after the points of water swirl i.e. at the nodes and antinodes of the acoustic waves. It was observed during experimentation the maximum temperature difference of 22^{o} was achieved and the lowest temperature achieved with the demonstration model was found to be 14^{o}.

The results obtained while experimentation, were plotted and the nature of the curve has been studied.

The Fig.6 shows the comparative study of the temperature variation in the resonance tube along the length at various frequencies. It is observed that maximum temperature is attained at the low frequencies, since the wavelength of the acoustic wave is longer and the occurrence of the nodes and antinodes is clearly defined.

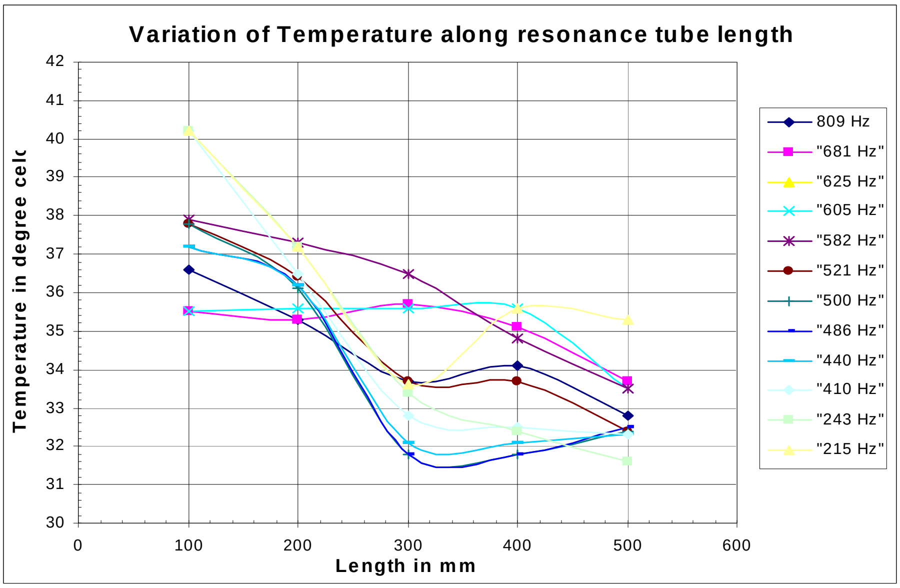

Fig: 6.

The Fig.7 gives the comparative study of the maximum & minimum temperature variation in the tube indicating room for the refrigeration effect. The maximum & minimum temperature in the tube occurs in the frequency range of 200-400Hz and this is the range one has to concentrate his studies for the achievement of the fruitful results for causing refrigeration effect.

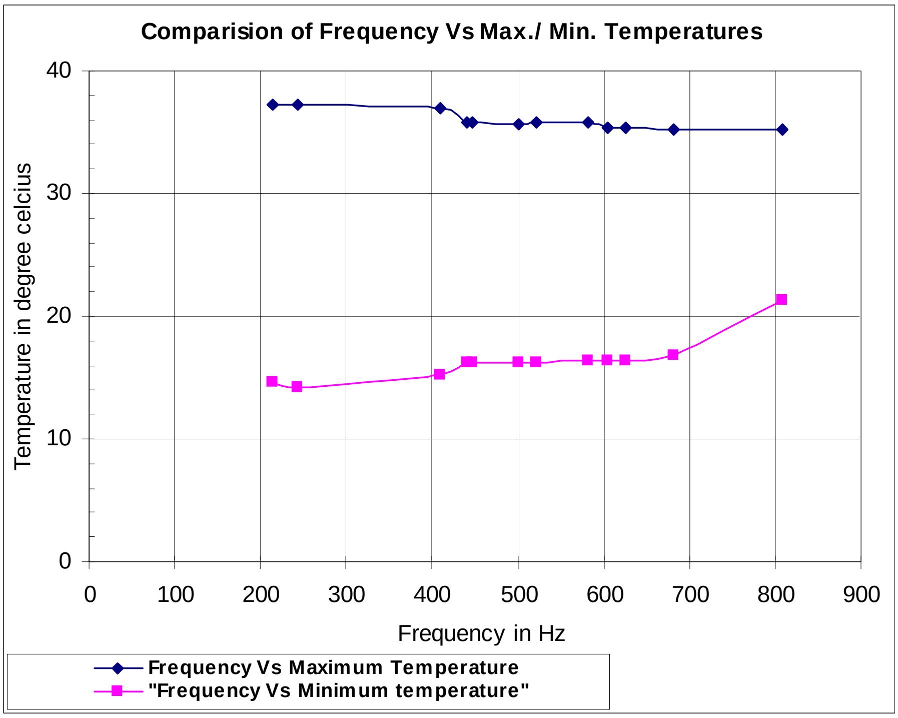

Fig:7.

CONCLUSION

The Experimental data implies that the frequency of acoustic wave is of great concern in the performance of the thermoacoustic refrigerator. The frequency range of 200 – 400 Hz. Could be used to achieve the commercially viable unit. The results obtained in this paper with the experimental setup developed can be used as a guideline for further development of the system in this field.

Thermal Flux Sampler for Onsite Performance Evaluation of VRV System

Tatsuo Nobe and Yusuke Haga

Kogakuin University, Japan

Corresponding email: nobe@cc.kogakuin.ac.jp

SUMMARY

This paper reports an alternative technique to evaluate onsite performance of Variable refrigerant volume (VRV) multiple indoor units connected air conditioning systems. The newly-devised Thermal Flux Sampler gathers and merges the blowing flow at multiple measuring points on the exhaust grille of outdoor unit into a single typical point using a sampling tube. The system coefficiency of performance is calculated from the amount of heat discharge and the electric power consumption of compressor and whole system. Because enthalpy and airflow velocity are greatly different in each part of exhaust grille face, sampling air is collected by tubes from twenty points on the grille face, and representative enthalpy and airflow velocity are measured at the merging point. The practical operating conditions of the VRV system installed in a certain building were investigated by using this technique. Though the investigation period was one week of summer, there was much time when the VRV system was operating by the very low load overwhelmingly.

INTRODUCTION

VRV systems of the multi-unit type especially are now showing remarkable popularity. VRV systems used to replace central air-conditioning systems in small-scale buildings and be added to compensate for inadequate central air-conditioning systems. Recently in Japan, however, VRV systems have been applied even to main air-conditioning systems in office buildings having total floor areas of the 100,000 m^2 class and are replacing central air-conditioning systems. Central air-conditioning systems were improved by research and development to realize an indoor environment of higher accuracy. Meanwhile, VRV systems have gradually achieved performance equivalent to central air-conditioning systems while featuring easy design and construction, individual operability, and individual controllability. By gaining complicated functions through this process, VRV systems became a “black box” beyond the understandings of facility designers and users.

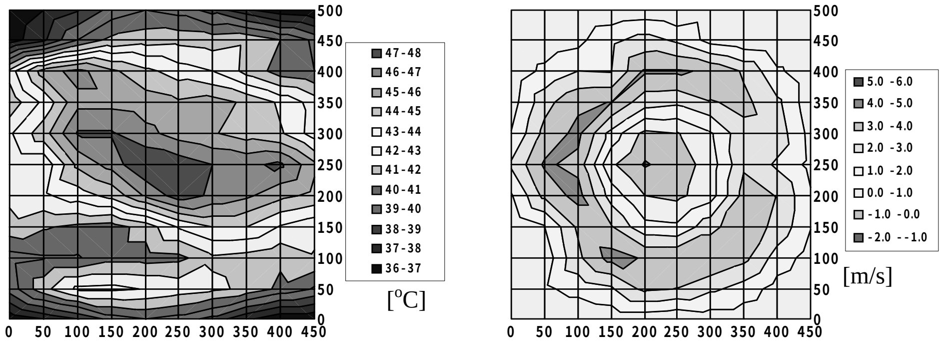
Also, in evaluating the energy performance during actual operation, it is very difficult to understand VRV behaviors because each indoor unit shows complicated operation. A bench test in a laboratory is also difficult. Therefore, we cannot avoid saying that VRV is a “black box” in terms of not only functionality but also performance. To solve this problem, the authors developed a technique of easily evaluating VRV behaviors in actual operation as an outdoor unit that doesn’t require entering a room. This paper introduces the basic concept of this evaluation technique and the results of an experimental application to a VRV system in operation.

In recent Japan, where VRV systems are spreading remarkably, we have been seeing many studies to verify various performance factors. The authors compared the evaluation technique of measuring the blowing flow from an indoor and outdoor unit by transverse equipment with a heat balance technique using a calorie box [1].

METHODS

Properties of blowing flow from outdoor unit

Figure 1 shows the temperature distribution and the airflow velocity measurement of the blowing flow from the outdoor unit on the exhaust grille face. Since the blow-off air is the swirling flow appearing immediately after the axial flow fan, the scalar wind velocity, vector wind velocity, and air temperature are not uniform. Therefore, the conventional technique of measuring typical points by inserting a rectification duct into the exhaust grille face has low accuracy of measuring the amount of heat discharge. To accurately calculate the amount of heat discharge from the outdoor unit, therefore, it may be necessary to measure the exhaust at multiple points of the exhaust grille simultaneously.



a) b)

Figure 1. a) Temperature distribution and b) airflow velocity on exhaust grille face.

Configuration of thermal flux sampler

It is very difficult to maintain many anemometers outdoors for a long time because of the economic burden and equipment weather resistance. To solve these problems, the authors attempted to realize simple and long-time continuous measurement by devising a thermal flux sampler that gathers and merges the blowing flow at multiple measuring points on the exhaust grille into a single typical point using a sampling tube.

Figure 2 shows the configuration of the thermal flux sampler. The thermal flux sampler consists of 20 sampling tubes, an interval adjustment plate, and a merging section. By moving the interval adjustment plate, the sampling points can be rearranged according to the size of the exhaust grille. The choke valve is installed at each sampling tube to adjust the sampling air volume.

Heat discharge from outdoor unit

When the thermal flux sampler is used, the amount of heat discharge from the outdoor unit to the atmosphere can be calculated by Equation 1.

$$Q = \gamma \times C_p \times v'' \times S'' \times (t'' - t_0) \times \alpha \times \beta \times \sin \overline{\theta} \times \frac{x_t}{x''}, \qquad (1)$$

Where Q is the quantity of exhaust heat from outdoor unit [kW], γ is the specific weight [kg/m^3], C_p is the specific heat [kJ/kg K], v'' is the airflow velocity of merging section [m/s],

S'' is the area of merging section [m^2], t'' is the air temperature of merging section [K], t_0 is the suction air temperature of outdoor unit [K], α is the constant of airflow velocity ratio tuned by the choke valve, β is the constant ratio of representative area of grille face for cross section of sampling tube, $\overline{\theta}$ is the average composite angle of grille face and airflow [^{o}] (approximately 50^o with the following case), x_t is the total airflow volume of all sampling tubes [m^3/s], and x'' is the airflow volume of measuring point [m^3/s].
These details and the verification of the measurement accuracy were mentioned in another paper [2] of the poster session.

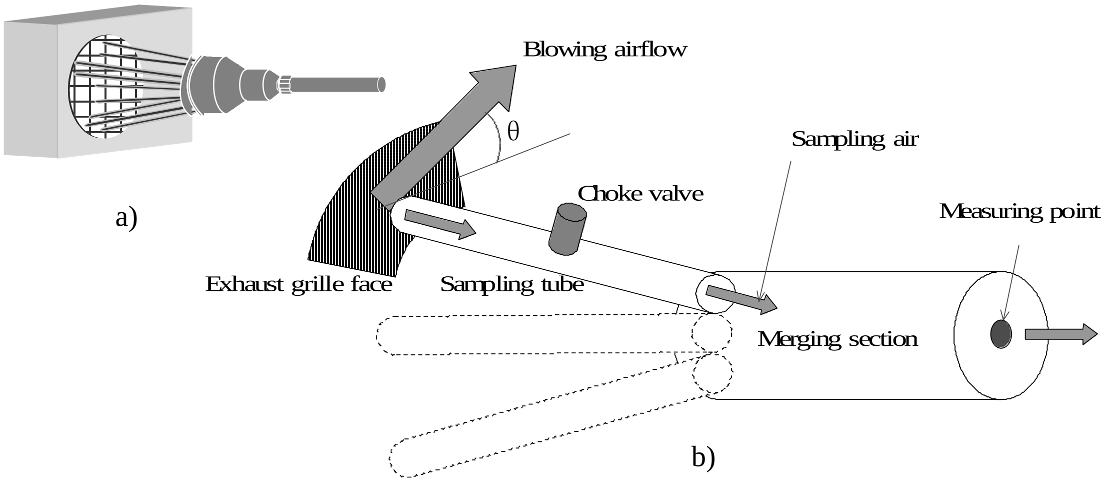


Figure 2. a) Configuration and b) Concept of Thermal Flux Sampler.

EXPERIMENTAL APPLICATION TO VRV SYSTEM IN OPERATION

Outline of object system

Using this thermal flux sampler, the authors evaluated a VRV system in operation. From August 31 until September 5, 2005, an actual VRV system was measured at a laboratory building of a university in the suburbs of Tokyo. Table 1 lists the system facilities. The VRV system is a heat pump for both cooling and heating and the compressor of the outdoor unit is controlled by an inverter. Seven indoor units are connected to the single outdoor unit. Since the experiment was conducted in summer, the VRV system was in cooling mode.

Table 1. System facilities.

Designation		Specifications
Electric Source		3Φ 200V
Refrigerant		R-22
Cooling capacity		56.0 W
Heating capacity		63.0W
Rated COP	Cooling	2.64
	Heating	3.44
Indoor unit		4-way ceiling mounted cassette unit

Measurement items

This VRV system had four fans in the outdoor unit. The thermal flux sampler was installed at the exhaust grille of each fan and the wind velocity and air temperature were measured at the

merging section (Figure 3). The power consumption was measured for the outdoor unit system and the indoor unit system. For the outdoor unit system, the power consumption by the compressor was also measured. The intake air temperature and the amount of solar radiation were also measured.
To calculate the amount of heat produced at the outdoor unit, the power consumption by the compressor was subtracted from the amount of heat discharge measured by the thermal flux sampler. To calculate the system COP, the amount of heat produced by the outdoor unit was divided by the power consumption of both the outdoor and indoor units.

Figure 3. Thermal flux samplers mounted on VRV system.

RESULTS

Figure 4 shows the outdoor air temperature and the amount of solar radiation in the experimental period. The weather was generally fair throughout the experimental period. From the evening of September 4 until September 5, a typhoon caused torrential rain.
Figure 5 shows the load factor appearance frequency. The load factor was calculated with the rated cooling performance of the outdoor unit as 100%. Despite the great cooling load in summer, the load factor rarely became 50%, and usually was up to 20%.
Figure 6 shows a change of the system COP at every five minutes of system operation during the experimental period. Figure 7 shows the system COP by day. The poor system COP of this VRV system is partially attributable to the power consumption of about 300 W in the standby state.
Figure 8 shows the load factor appearance frequency and the system COP in the experimental period. Where the load factor is low, the system COP is also low.

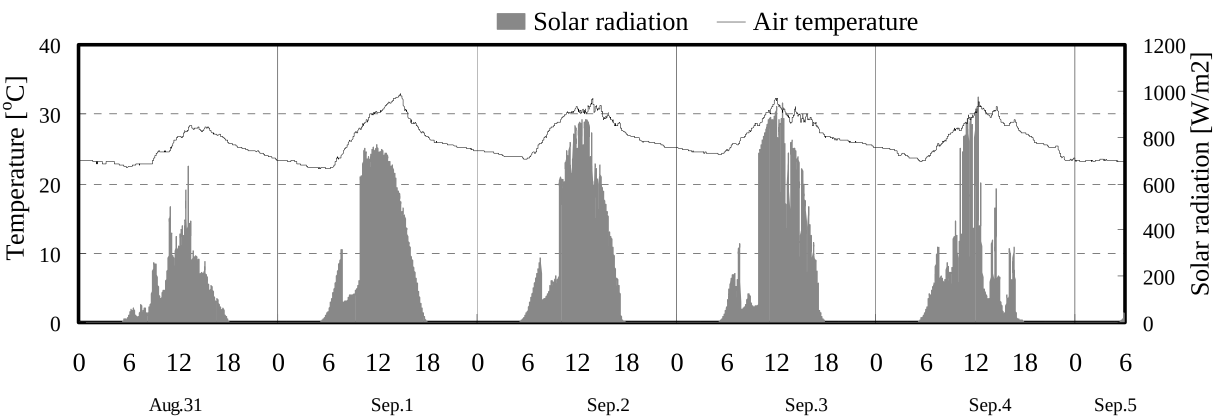

Figure 4. Outdoor air temperature and amount of solar radiation in experimental period.

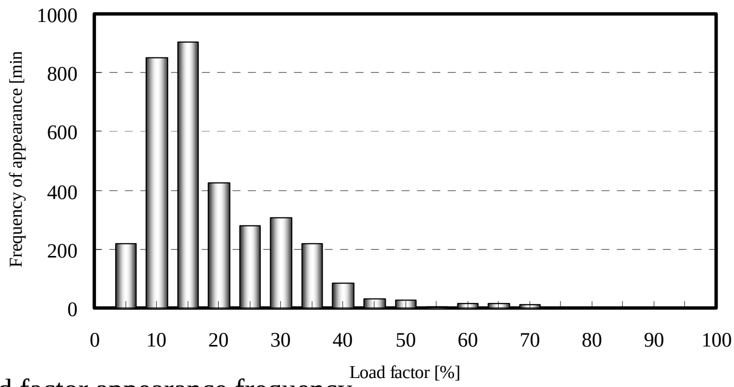

Figure 5. Load factor appearance frequency.

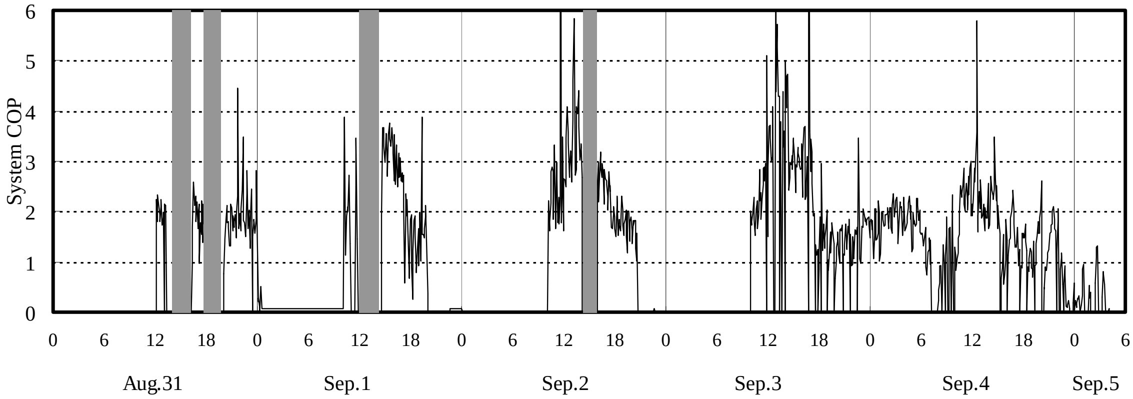

Figure 6. System COP at every five minutes.

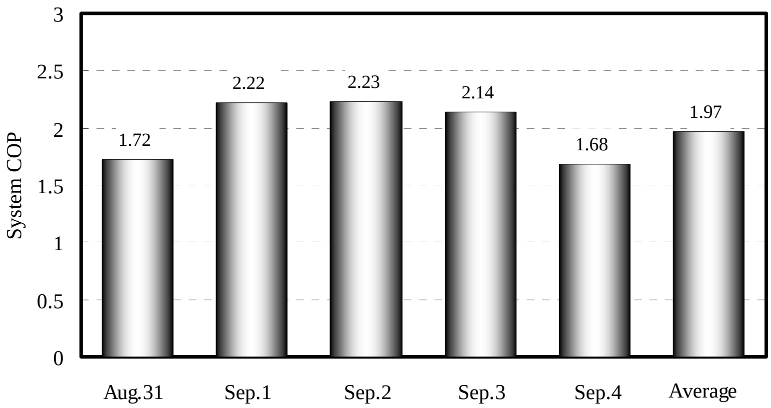

Figure 7. System COP by day.

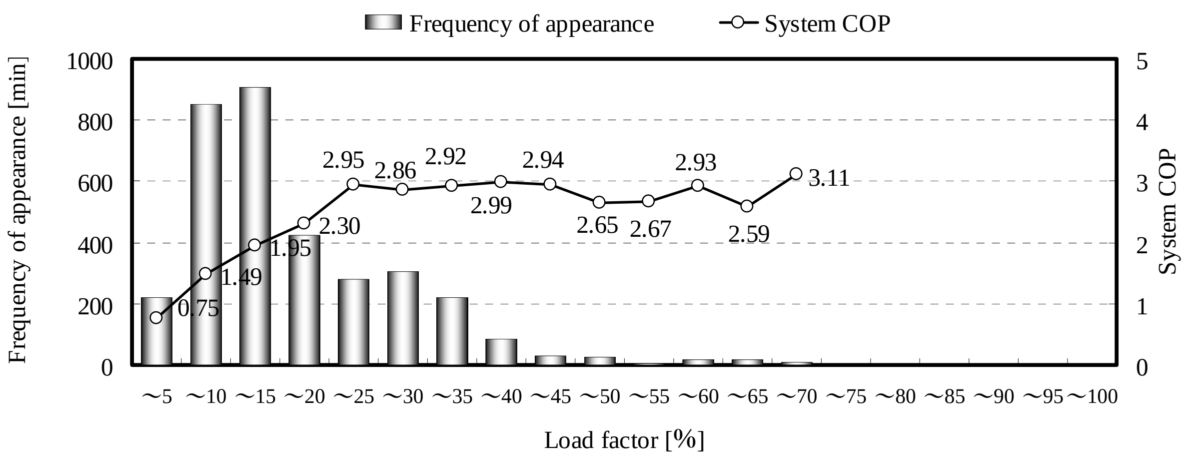

Figure 8. Load factor appearance frequency and system COP.

DISCUSSION

The authors developed a technique of continuously measuring VRV system operation status easily by measuring the amount of heat discharge from the outdoor unit with the thermal flux sampler. The results of an experiment using the sampler, however, clarified several points.

One result is that the sampler is susceptible to external wind velocity. At the end of the sampler merging section, a spherical windshield is attached to reduce the influence of dynamic pressure by the outdoor wind velocity. For stable measurement, however, further improvement is necessary.

The second problem is about the power consumption measurement. To measure the power consumption by the compressor of the outdoor unit, a precise watt-hour meter is necessary on the secondary side of the inverter. We need to consider the logic of estimating the power consumption by the compressor from that by the entire outdoor unit.

The VRV system evaluated using the thermal flux sampler was found to have a very small load factor despite the cooling peak in summer. Compared with central systems, unitary systems tend to have excess facility capacities. Therefore, VRV systems are expected to show no COP decrease even under extremely small loads.

ACKNOWLEGEMENT

The authors gratefully acknowledge Prof. S. Kametani of Tokyo University of Marine Science and Technology for his support.

SUMMARY

This paper reports the accuracy of a measurement device for evaluating the actual performance of a variable refrigerant volume (VRV) system. A newly devised thermal flux sampler can be installed on an outdoor unit easily and measure the exhaust heat quantitatively. An experiment was conducted in a room-type calorimeter chamber to verify the accuracy of the thermal flux sampler. The accuracy was verified by measuring the energy efficiency of the test unit by three measuring methods: the heat balanced method, the improved duct inserted method and the sampler method. In a cooling condition, the average mean error of the sampler method and the improved duct inserted method was 12% and 19%, respectively, in comparison to the results of the heat balanced method.

INTRODUCTION

It is important to understand the actual performance of VRV (variable refrigerant volume) multiple indoor units connected to an air-conditioning system (herein referred to as the “VRV system”) to optimize its practical operation. The VRV system in air-conditioning systems is noted for its easy installation and convenience. However, the on-site performance of the VRV system is not clear, because the performance is evaluated in a static condition according to Japan Industrial of Standard (JIS) rules. Thus, it is necessary to investigate a practical evaluation method of the VRV system in actual operating conditions. Therefore, a technique to evaluate on-site performance was examined and a sampling system for the quantity of exhaust heat from an outdoor unit was developed. In this paper, an experiment was conducted in an environmental chamber to verify the accuracy of the newly devised thermal flux sampler.

CONCEPT OF THERMAL FLUX SAMPLER

Air distribution of outdoor unit

Figure 1 shows the air distribution on the air outlet of an outdoor unit. The air distribution was investigated in detail and yielded the following results [4], [7]:

1. The exhaust air temperature and airflow are greatly different in each part of the air outlet of the outdoor unit.
2. The airflow distribution of the outdoor unit is concentric circular.
3. The airflow is exhausted as rotational flow. Thus, it is necessary to consider the vertical angle of the airflow.

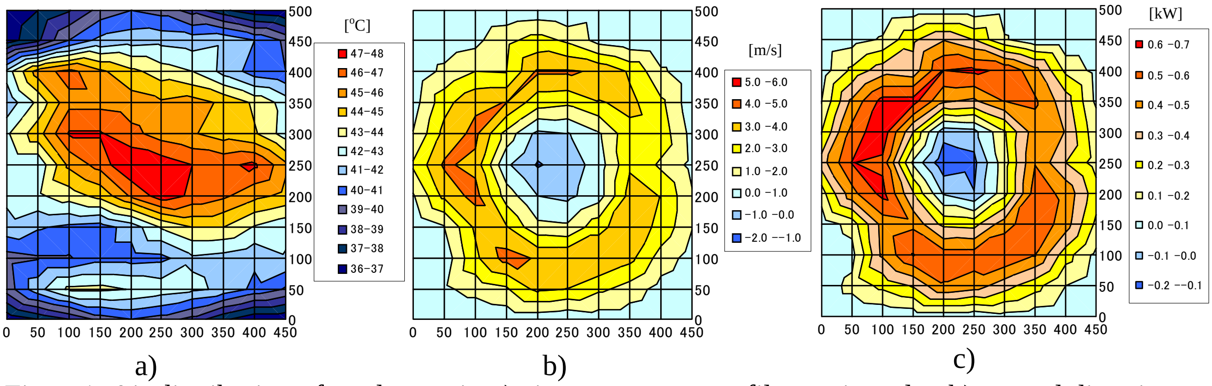

Figure1. Air distribution of outdoor unit: a) air temperature profile on air outlet, b) normal direction profile airflow on air outlet, c) exhaust heat profile on air outlet

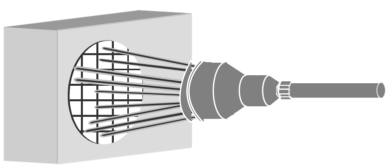
Characteristics of thermal flux sampler

The thermal flux sampler is a sampling device that samples the exhaust heat from an outdoor unit. An illustration of the thermal flux sampler is shown in Figure 2. The quantity of exhaust heat is identified from the thermal flux of the measurement point in the merging section of the thermal flux sampler. Since the air distribution is greatly different in each part of the air outlet, the exhaust airflow is measured in twenty parts. The sampling air is collected by conduits and the representative air temperature and airflow velocity are measured in the merging section.

Calculation formula for the thermal flux sampler

The exhaust heat calculation formula for the thermal flux sampler is shown in Equation (1). The thermal flux of the representative area was calculated in Equation (2).The quantity of exhaust heat from outdoor unit is the total of the thermal flux of representative area (Equation (3)).The thermal flux of each conduit is shown in Equation (4).Thus, Equation (5), the quantity of exhaust heat from outdoor unit is deduced from Equation (2), (3) and (4). Furthermore, v_n / v_n' becomes a constant by adjusting the ratio of airflow velocity from the representative area to outlet of each conduit. Moreover, S_n / S_n' becomes a constant by dividing the measurement area equally. If the heat loss of airflow that passes conduits is negligible quantity, t_n and t_n' are equal and the ratio of $(t_n - t_o)$ and $(t_n' - t_o)$ is a constant. Furthermore, v_n / v_n' and S_n / S_n' are replaced with α and β. Thus Equation (5) is substitute for in Equation (6). Where $\bar{\theta}$ is the average of composite angle grille face and airflow. The thermal flux of the measurement point in the merging section is calculated in Equation (7).It is the total of thermal flux of all conduits. This is shown in Equation (8).The quantity of exhaust heat from outdoor unit is deduced from Equation (6), and (8). Moreover, Equation (1), the quantity of exhaust heat by using this method is deduced to compensate the air volume reduction in process of merging section from inflow entrance of conduits.



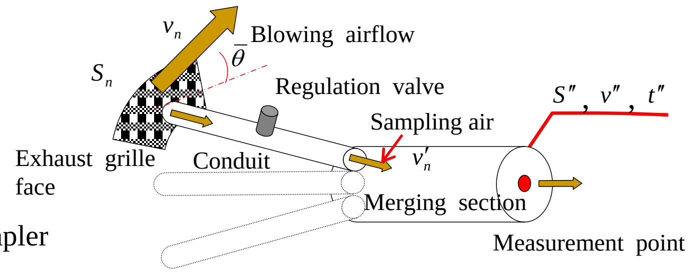


Figure2. Illustration of the thermal flux sampler

$$Q = \gamma \times C_p \times v'' \times S'' \times (t'' - t_o) \times \alpha \times \beta \times \sin\bar{\theta} \times x_t / x'' \quad (1)$$

$$q_n = \gamma \times C_p \times v_n \sin\theta_n \times S_n \times (t_n - t_o) \quad (2)$$

$$\sum_{n=1}^{20} q_n \fallingdotseq Q \quad (3)$$

$$q'_n = \gamma \times C_p \times v'_n \times S'_n \times (t'_n - t_o) \quad (4)$$

$$Q = \sum_{n=1}^{20} q_n = \sum_{n=1}^{20} q'_n \times \frac{v_n \sin\theta_n \times S_n \times (t_n - t_o)}{v'_n \times S'_n \times (t'_n - t_o)} \quad (5)$$

$$Q = \alpha \times \beta \times \sin\bar{\theta} \times \sum_{n=1}^{20} q'_n \quad (6)$$

$$q'' = \gamma \times C_p \times v'' \times S'' \times (t'' - t_o) \quad (7)$$

$$q'' = \sum_{n=1}^{20} q'_n \quad (8)$$

γ : Specific weight [kg/m3]

C_p : Specific heat [kJ/kg K]

v'' : Airflow velocity of merging section [m/s]

S'' : Area of merging section [m2]

t'' : Air temperature of merging section [K]

θ_n : Composite angle of grille face and airflow [°]

v_n : Airflow velocity of measurement area [m/s]

v'_n : Airflow velocity of each conduit outlet [m/s]

S_n : Representative area for measurement point [m2]

S' : Cross section of each conduit [m2]

v'' : Airflow velocity of merging section [m/s]

x_t : Total air volume of all conduits [m3/s]

x'' : Air volume of merging section [m3/s]

t_0 : Suction air temperature of outdoor unit [K]

Q : Quantity of exhaust heat from outdoor unit [kW]

q_n : Thermal flux of representative area [kW/m2]

q_n : Thermal flux of each conduit [kW/m2]

q'' : Thermal flux of merging section [kW/m2]

Components of thermal flux sampler

Figure 3 shows the components of the thermal flux sampler. The thermal flux sampler is composed of conduits, two supporting plates of conduits and a merging section. The each conduit is fitted into a regulating valve to adjust the pipe flow velocity. The measurements points of the airflow and air temperature are shown in Figure 4. The representative area reflects the vertical airflow profile and was divided into concentrical and equal circles. The supporting plates are equipped to keep the position of these measurement points. Moreover, it enables to correspond to various fan sizes of outdoor units by adjusting the mutual distance.

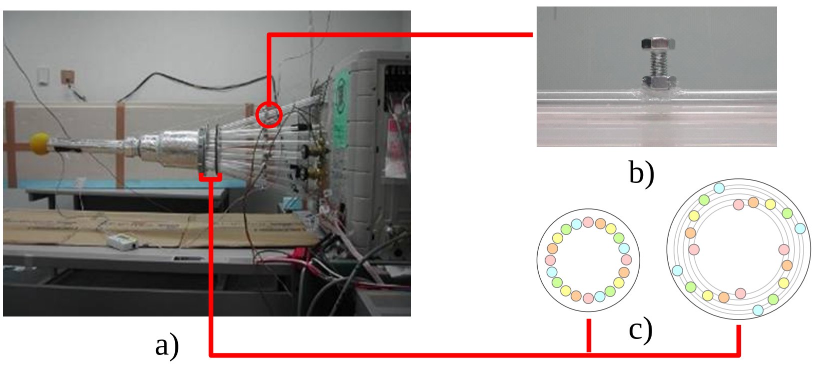

Figure3. Components of the thermal flux sampler: a) overall view, b) regulation valve of the conduits, c) supporting plates of the conduits.]

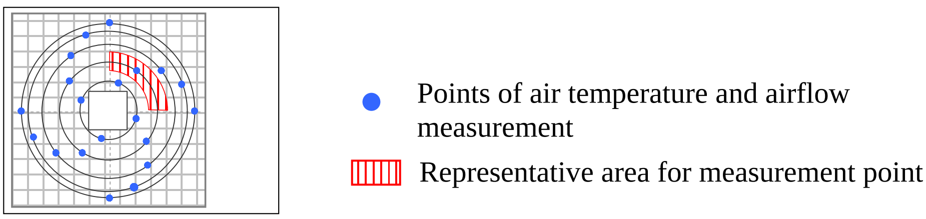

Figure4. Points of air temperature and airflow measurement

Experiment apparatus

Figure 5 shows the calorie meter chamber and position of the test unit. The experiment was conducted in a room-type calorimeter chamber owned by Kogakuin University. Table 1 shows the specification of the calorie meter chamber. It has a pair of chambers (room A and room B) which has glass windows on the south side. There is a thermal buffer zone that does not include the glass windows. The dimensions of the chamber are length 5.5 m, width 4.1 m, and height 5.9 m. Each chamber is equipped with an air-conditioning system to conduct a comparative experiment under different thermal conditions, and the thermal buffer zone is also equipped with six air-conditioners. Thus this chamber is able to supply a thermal load quantitatively by controlling the air-conditioning. In this experiment, the glass window on the south side was covered with outside shutters to exclude the influence of disturbance.
Table 2 shows the specification of the test unit. The test unit is a packaged air-conditioner, which is split type. In this experiment, it was experimented by alternately using the indoor unit: a 4-way ceiling-mounted cassette unit and a ceiling-suspended cassette unit. Thus, we installed the test unit in each chamber and used room A as the outdoor side and room B as the indoor side.

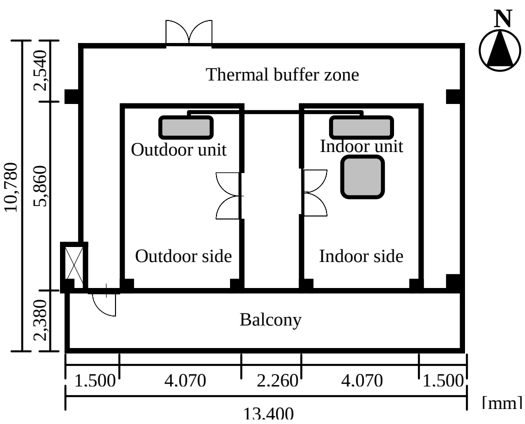

Table1. Specification of the calorie meter chamber

Designation	Specifications
Refrigerator	Air cooling chiller (45 kW)
Heater	Electric heater (40 kW)
Cool bath	FRP sandwich panel (3 cubic meter
Heat bath	Monocopue steel (2 cubic meter)
Outdoor air conditioning unit	Air volume (1000 cubic meter/h)

METHODS

Experimental conditions

The experimental conditions are shown in Table 3. There are fourteen experimental conditions which are based on the measurement conditions set by the JIS [1], [2] and [3] Table 4 shows the conditions of the supply air to the indoor side. It was decided to become the indoor side conditions of Table3 with the indoor unit operated. Thus, these values were calculated in consideration of the sensible heat factor (SHF) and the supplied thermal load to the indoor unit. The standard of the supplied thermal load to the indoor unit was decided based on the cooling and heating capacity of the outdoor unit.

Heat balanced method

The quantity of generated heat from the indoor unit was determined by the heat-balanced method. The heat balanced method is the way to determine the capacity of the test unit from the supplied thermal load when the generated heat from the indoor unit and the supplied thermal load to the calorimeter chamber are balanced. Thus, this method can identify and measure the generated heat from the indoor unit as the supplied thermal load to the calorimeter chamber. The supplied thermal load to the indoor side was calculated from the mean value of the supplied thermal load before the test unit operated and the supplied thermal load after the test unit operated. The supplied thermal load before the test unit operated was determined as the mean value of one hour before the test unit operates [6].

Improved duct inserted method

The quantity of exhaust heat from the outdoor unit was measured by the improved duct inserted method. We installed the rectangular duct on the air outlet of the outdoor unit and measured the quantity of exhaust heat. The quantity of exhaust heat was calculated from the airflow velocity and the difference of the exhaust air temperature and suction air temperature in the cooling condition. In the heating condition, the quantity of exhaust heat was calculated from the airflow velocity and difference of the exhaust air enthalpy and suction air enthalpy because a latent load is generated. Figure 6 shows the points of measurement of the outdoor unit. The exhaust air temperature was measured at three points in the rectangular duct, and the suction air temperature was measured at five points on the back side of the outdoor unit. The point of the airflow velocity measurement was determined by examining the airflow distribution on the air outlet of the rectangular duct [5].

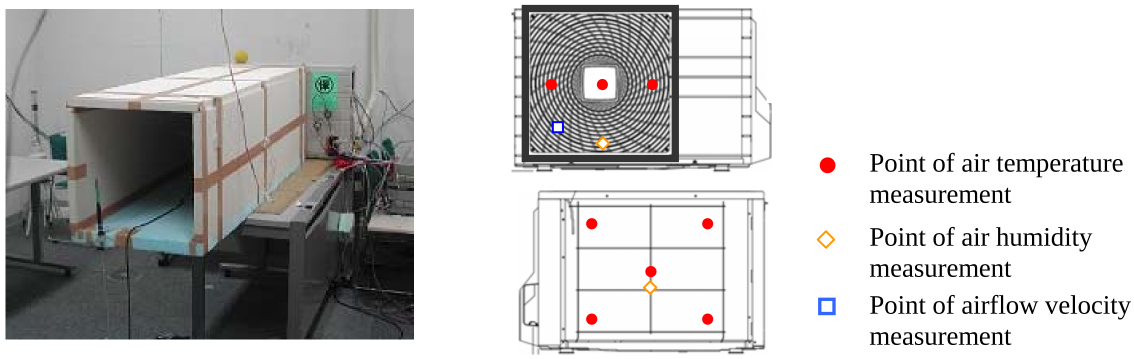

Figure6. The improved duct inserted method: a) experimental situation, b) points of measurement

Sampler method

Figure 7 shows the experimental setup of the Sampler method. The quantity of exhaust heat from the outdoor unit was measured by the Sampler method. We installed the thermal flux sampler on the air outlet of the outdoor unit and measured the quantity of exhaust heat. In the cooling condition, the quantity of exhaust heat was calculated from the airflow velocity, the exhaust air temperature and the suction air temperature. In the heating condition, the humidity of the exhaust air was measured and the quantity of exhaust heat was calculated from the airflow velocity, the exhaust air enthalpy and the suction air enthalpy.

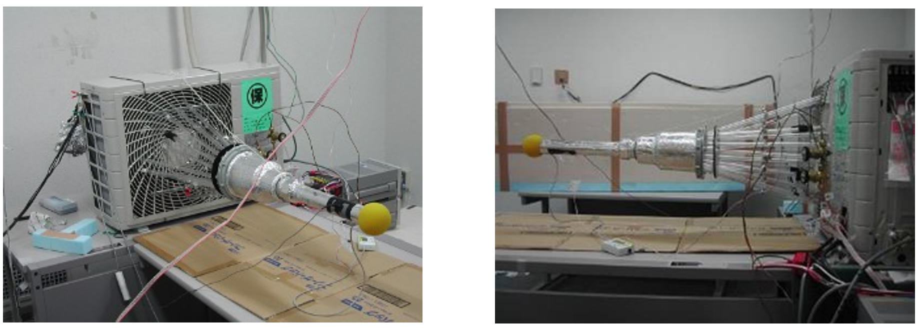

Figure7. Experimental setup

EXPERIMENTAL RESULTS

The accuracy of the thermal flux sampler was verified by comparison with the system coefficient of performance (herein called the “system COP”) that was measured by the three measuring methods, including the Sampler method. The experimental results of the three methods become approximately the same theoretically. The system COP is calculated from the quantity of generated heat from the indoor unit and the electricity consumption of the entire system. Thus, for the case of the Sampler method and improved duct inserted method,

the quantity of generated heat from the indoor unit is identified from the quantity of the exhaust heat and the electricity consumption of the compressor.
Figure 8 shows the system COP ratio based on the experimental results of the heat-balanced method. The system COP ratio is calculated with the experimental result of the heat balanced method as 100%. Figure 9 shows the average mean error of system COP ratio. The experimental results of the three kinds of methods were approximate. However, compared to the results of the heat balanced method, the average mean error of the Sampler method was 12% and that of the improved duct inserted method was 19% in the cooling condition.
In the heating condition, the experimental results are shown in Figure 10 as a reference, because the experiments were conducted in just one thermal condition.

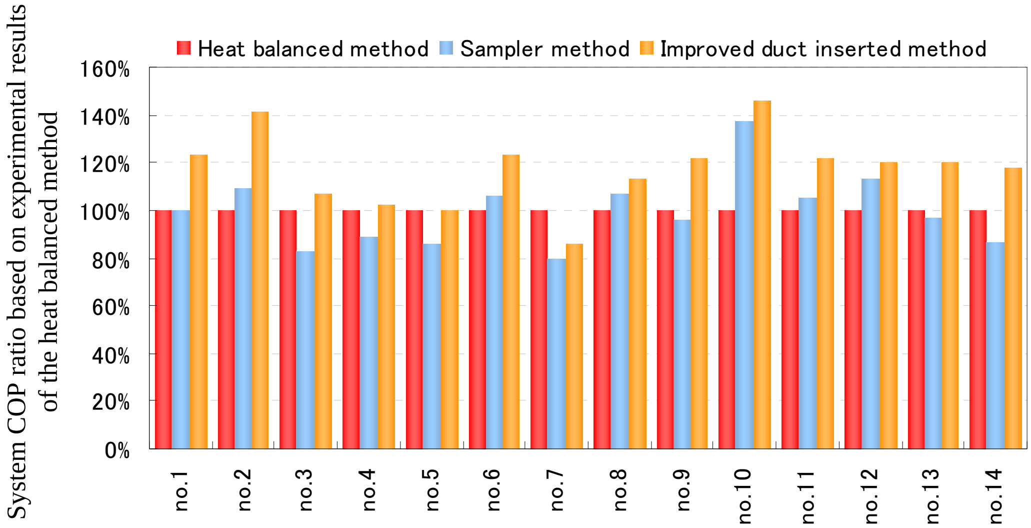

Figure8. System COP ratio based on experimental results of the heat balanced method

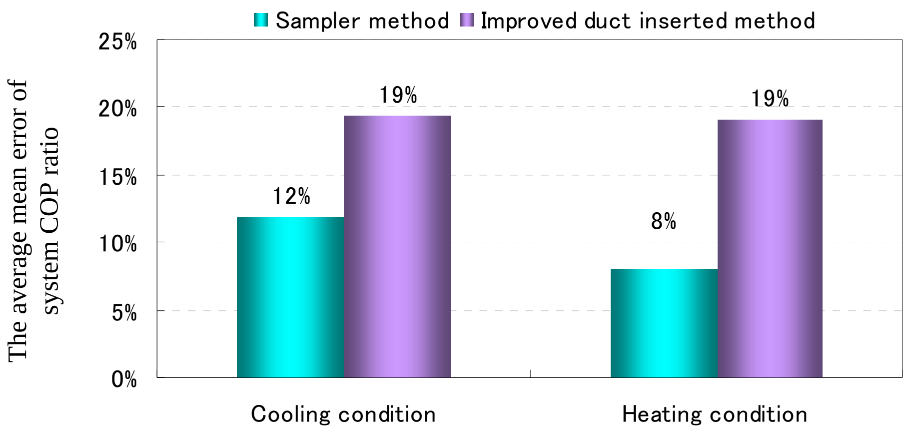

Figure9. The average means error of the measurement results based on the heat balanced method

DISCUSSION

In the cooling condition, in comparison to the results of the heat-balanced method, the average mean error of the Sampler method was 12% and the improved duct inserted method was 19%. Though the improved duct inserted method determined the point of airflow measurement by investigating the air distribution on the air outlet of the rectangular duct, the average mean error was 19%. This shows that it is difficult to measure the quantity of exhaust heat at a point of the representative airflow measurement. On the other hand, the average mean error of the Sampler method was 12% and it was shown that this method is effective.

ACKNOWLEDGEMENT
The authors would like to appreciate Prof. Kametani(Tokyo University of Marine Science and Technology) and Mr.Yumoto for their assistance in the experiment. This research is partly supported by Academic Frontier Project for Private Universities from Ministry lf Education, Culture, Sports, Science and Technology.

SUMMARY

An analytical model is developed of an optimized small scale refrigeration system using vapor compression, with application to the cooling of electronic components populating a Printed Circuit Board (PCB). The author's previous study [1] evaluated a vapor compression system using an off-the-shelf compressor, focusing on the thermal feasibility of non-optimized mechanical refrigeration system and on-chip system-level incorporation. Investigation focuses on the miniaturization of evaporator micro-channels, fitting smaller packages. The design takes into account the miniaturized system components, optimized to address the appropriate power dissipation ranges. R-134s refrigerant is used, providing the best COP/feasibility ratio, suitable for microelectronics applications [2].

Various micro-channel designs are considered. The efficiency is evaluated for various structures; the optimal design is compared to designs using mechanical compression cooling. The advantages of the optimized design are highlighted, establishing a performance vs. size relationship for vapor-compression refrigerators, to serve as the basis for enhanced cooling of future miniaturized refrigeration applications.

INTRODUCTION

One of the main concerns of the microelectronics industry is the increased heat flux reached by the individual components, leading to failure or faulty operation. It is widely recognized that the current cooling techniques using fans, baffles, heat sinks, heat spreaders, will cease to satisfy the projected thermal requirements of the power systems. Several alternative active cooling methods incorporating liquid cooling, Thermoelectric Coolers (TEC's) or phase change techniques, have been extensively explored before, yet the application of classic refrigeration has not been considered to a significant extent, due to the large size constraints.

The present work fills this gap, proposing a miniaturized refrigeration system, designed to fit the existing microelectronics, with efficient cooling and minimal associated costs. The advantage of the proposed method is the sub-ambient cooling of the junction, leading to increased operating speeds of the processors (maintained thus at fairly constant temperatures), also to the increased overall reliability and component feasibility.

Studies over the past several decades acknowledged that vapor-compression refrigerators have been the leading refrigeration technology at the macroscale [3]. Additional studies [4 – 6] provided an enhanced understanding of the heat transfer and multi-phase related flows and boiling processes in smaller scale systems with micro-channels.

The performance of *miniscale* vapor compression refrigerators, however, has not yet been experimentally demonstrated, although recent theoretical studies [2, 7 and 8] have presented an overview of refrigeration alternatives for microelectronics cooling, and indicated that at temperatures near room temperature and above, a vapor compression refrigerator may compete successfully with a high efficiency thermoelectric cooler.

The objective of the study is threefold: 1) To evaluate a baseline vapor compression refrigeration design with a given overall size and cooling power; 2) To provide a comprehensive comparison between various miniaturized evaporator designs incorporating micro-channels, and 3) To extract meaningful performance factors and identify the evaporator design with the best performance.

FUNCTIONAL DESIGN FOR A VAPOR COMPRESSION REFRIGERATION SYSTEM

The author's previous study [1] has focused on evaluating the overall thermal performance of a miniaturized vapor compression system (Fig. 1) for a given overall size and cooling power, without the individual performance optimization of the system components (evaporator, condenser, compressor). This study focuses on the optimization of the compression system elements, starting with one of the most critical components, the evaporator.

The evaporator makes direct contact with the package to be cooled, and enhancing its thermal performance will eventually lead to lower junction temperatures, with associated reliability and operating benefits for the microelectronic component. The evaporator uses micro-channel heat exchangers. The functional schematic with the evaporators (E1, E2) placed on top of each package/component, is presented in Figure 1.

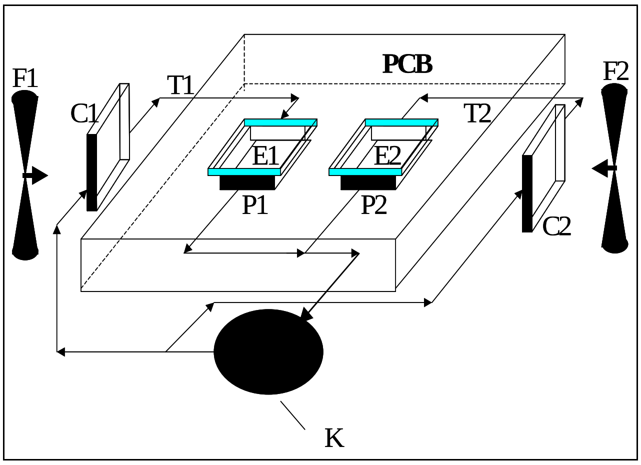

Figure 1: Overall Refrigeration System (w/PCB and packages)

COMPONENT SIZE OPTIMIZATION

The Evaporator

As seen in Figure 1, the evaporator is in direct physical contact on one side with the heat dissipating component (package), and is thermally insulated (in order to minimize heat losses) on the other side. The evaporator can be made relatively small, due to the good thermal coupling between itself and the heat load (i.e., the package). Aluminum is the material of choice for the evaporator in this study, due to its high thermal conductivity and manufacturing/processing convenience.

As it is, the heat transfer rate is limited only by the conductive coupling, which can be made very efficient using a high-conductivity heat spreader (e.g. an inverted exposed pad package) and thermal interface material at any solid/solid junctions. The conceptual schematic is shown in Figure 2, with the evaporator consisting of a micro-channel structure in contact with the package.

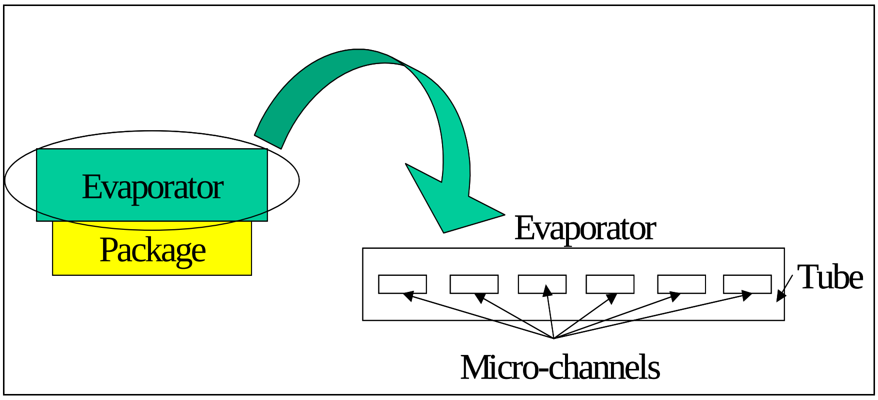

Figure 2: Evaporator/Package Stack-up

It is desired to optimize the evaporator structure/geometry, the number of micro-channels and the effective surface area available for the heat transfer. The inputs are: the evaporator rate of heat transfer (Q_o), T_o, T_{pi} (package initial temperature), T_{pf} (package final temperature), also V_o (volumetric flow rate of vapor at state 1 – compressor entrance).

<u>Evaporator Micro-Channels Structure/Array</u>

For a micro-channel with a hydraulic diameter D_h, the volumetric flow rate is described by:

$$V_o = N\, u\, (\pi\, D_h^2)/4, \qquad (1)$$

Where: N = no. of micro-channels, u = vapor velocity. The number of micro-channels can be easily determined:

$$N = 4\, V_o/(\pi\, u\, D_h^2), \qquad (2)$$

<u>Evaporator Heat Transfer Surface Area</u>

The basic relationship used for the calculation of the surface area is derived from the global heat exchanger governing equation:

$$Q_o = K\, A_o\, \Delta Tmo, \qquad (3)$$

With: Q_o = evaporator heat power, K = overall heat transfer coefficient, A_o = evaporator surface area, ΔT_{mo} = average temperature difference between the package and evaporator refrigerant.

$$\Delta T_{mo} = (T_{pi} - T_{pf})/ln[(T_{pi} - T_o)/(T_{pf} - T_o)], \qquad (4)$$

The overall heat transfer coefficient K can be expressed as:

$$K = [1/\alpha_o + R_{tc} + R_{tw}]^{-1}, \qquad (5)$$

Where: α_o = the vaporizing process s heat transfer coefficient, R_{tc} = thermal contact resistance and R_{tw} = evaporator's wall thermal conductive resistance.

The vaporizing process heat transfer coefficient α_o is further calculated using one of the classical flow boiling correlations, with total vaporizing of the refrigerant at evaporators' exit, followed by vapor super-heating.
The analytical formulation was suggested by Schrock and Grossmann, further modified by Chaddock and Noerager [9]:

$$\alpha_o = \alpha_{mf} F, \qquad (6)$$

where α_{mf} = convective heat transfer coefficient for single-phase flow, and

$$F = 1.85\ [B_o\ 10^4\ (1/X_{tt})^{0.67}]^{0.62}, \qquad (7)$$

$$B_o = q_o/(rG), \qquad (8)$$

$$X_{tt} = [(1\text{-}x)/x]^{0.9}\ (\rho_v/\rho_l)^{0.5}\ (\mu_l/\mu_v)^{0.1}, \qquad (9)$$

With: q_o = heat flux (W/m^2), r = latent heat (J/kg), G = mass flow rate (kg/m^{2}s); x = vapor quality (value of 0.8).

The single-phase heat transfer coefficient α_{mf} may be calculated with the convective heat transfer correlation inside the tubes [10].

RESULTS

A total of 6 evaporator (with micro-channel heat exchangers) structures have been evaluated, with the final purpose to identify the smallest available design with the highest efficiency, able to fit existing microelectronic components. The first case (Design 1) evaluated below is connected to the baseline overall mechanical compression refrigerator design presented in detail in the previous paper [1].

REFRIGERATION SYSTEM DESIGN FOR PRACTICAL MICROELECTRONICS APPLICATIONS

Evaporator - Design 1

The simulation was based on a practical microelectronics application dissipating a total power of ~ 100W. This could apply to a single or an array of power microelectronic packages. In order to design the evaporator, the following inputs are needed (Table 1):

Table 1: Inputs for Evaporator Design

Q_o (W)	T_o (°C)	T_{pi} (°C)	T_{pf} (°C)	V_o (m^3/hr)	D_h (m)	U_o (m/s)
100	10	120	20	0.14	1.54E -06	3.5 - 5

Using the analytical correlations from the previous paragraph, the optimal dimensions of the evaporator are extracted, leading to N = 6 micro-channels. The micro-channels are arranged inside the tube as described in Figures 3 and 4.

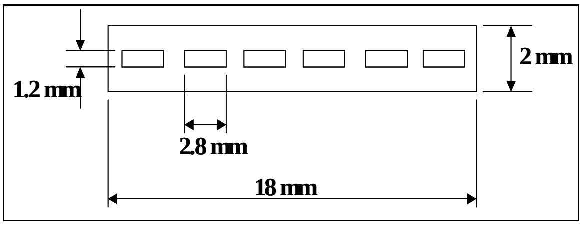

Figure 3: Evaporator Cross-Section.

The other dimensional values are: $\Delta T_{mo} = (T_{pi} - T_{pf})/\ln[(T_{pi} - T_o)/(T_{pf} - T_o)] = 41.7K$; K = 8260 W/m^{2}K; A_o = 2.9E –04m^2; A_o = L l (where L is the tube length and l is the tube width); hence, L = 1.61E-02m. A summary of the main results is provided in Table 2.

Table 2: Results – Design 1

Overall K	So	Tm	Qo
w/m2K	mm2	k	w/m2
8262.96	289.8	41.7188	99.90

The design details are consistent with the specifications provided by evaporator manufacturing companies. The final evaporator configuration is presented in Figure 4.

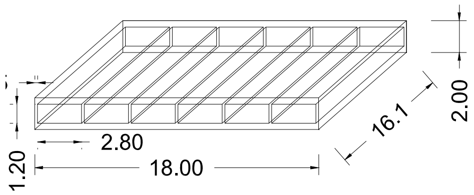

Figure 4: Evaporator – Design 1.

It is the intent to further miniaturize the system and identify the evaporator design with the smallest specific size which provides the best cooling performance.

Ideally, the evaporator should fit the exposed pad of the power package, since being slightly larger than the package could lead to significant reduction in the cooling efficiency. Several designs are further evaluated to reduce the overall size and yet maintain the efficiency at high levels.

Evaporator - Design 2

A similar procedure is used for all the following designs, to calculate the optimal size of the micro-channels for a specific hydraulic diameter and power dissipation.

In the second design, the hydraulic diameter is reduced to 1 mm, and the overall system size is maintained as before at 18 x 16.1 x 2 mm. The individual size of the micro-channels has reduced (Fig. 5). The units in Figs 5 – 8 are millimeters.

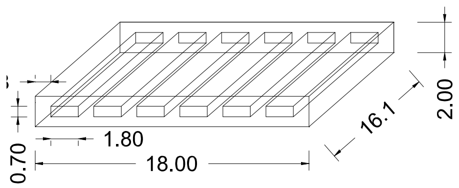

Figure 5: Evaporator – Design 2.

Equations 1 – 9 are used again to calculate the equivalent overall heat transfer coefficient. The value in this case is about twice compared to the first case, thus the increased cooling power (~ 190W) for this case. A summary of the heat transfer coefficient, area available for cooling, and cooling power are summarized in Table 3.

Table 3: Results – Design 2

Overall K	So	Tm	Qo
w/m2K	mm2	k	w/m2
15796.05	289.8	41.72	190.98

Evaporator - Design 3

In the third case, the hydraulic diameter is further reduced to 0.5 mm, while maintaining the overall size as in the previous cases. Keeping the same number of micro-channels (a total of six), will lead to smaller micro-channels dimensions (Fig. 6).

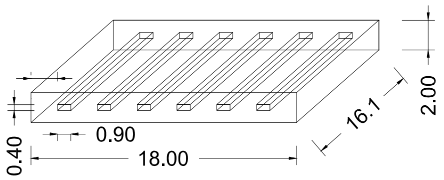

Figure 6: Evaporator – Design 3

The results of the study are summarized in Table 4 and indicate that the overall heat transfer coefficient is even higher than for the first two cases, at ~ 44700 W/m2K. For the same overall size of the evaporator, when using smaller micro-channels, the effective overall heat transfer coefficient (K) increases. In this case, the cooling power reaches almost 540W.

Table 4: Results – Design 3

Overall K	So	Tm	Qo
w/m2K	mm2	k	w/m2
44706.88	289.8	41.72	540.51

The last two cases focus on two evaporator designs with reduced overall dimensions.

Evaporator - Design 4

Compared to the previous designs, the overall size of the system for design 4 has changed to 6.8 x 6.8 mm, and maintained the smaller 0.5 mm hydraulic diameter.

By reducing significantly the size, the evaporator will fit better on top of the inverted exposed pad power package, providing also a better thermal contact. However, by maintaining the same hydraulic diameter as in case 3, the overall heat transfer coefficient will remain unchanged.

Following the same calculations as before, the cooling power in this case is ~ 85W, and this is satisfactory for power packages operating at 100% duty cycle. The new evaporator schematic is presented in Figure 7, while the new results are included in Table 5.

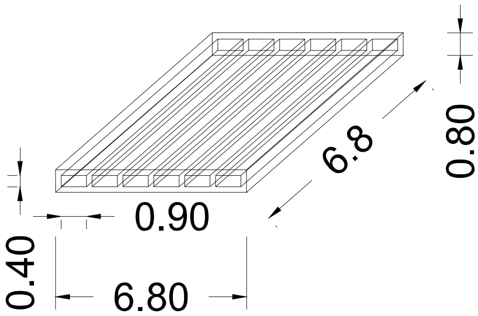

Figure 7: Evaporator – Design 4

Table 5: Results – Design 4

Overall K	So	Tm	Qo
w/m2K	mm2	k	w/m2
44706.88	46.24	41.72	86.24

Evaporator - Design 5

In the last case, the size is further reduced to 6.1 x 6.1 mm, with the hydraulic diameter still at 0.5 mm. The micro-channels will be more compact in this design, with the schematic presented in Figure 8.

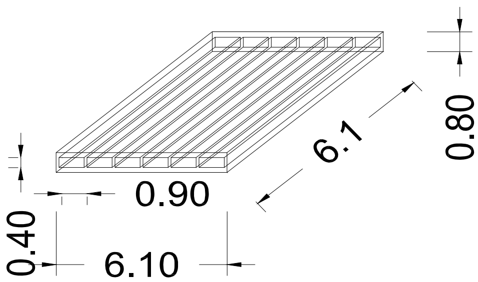

Figure 8: Evaporator – Design 5

Again, as the hydraulic diameter is the same as for the previous two cases, the overall heat transfer coefficient (K) is the same. However, due to the reduced overall size of the evaporator compared to previous cases, the cooling power is much smaller and reaches ~ 69.4 W. Results summarized below.

Table 6: Results – Design 5

Overall K	So	Tm	Qo
w/m2K	mm2	k	w/m2
44706.88256	37.21	41.7188	69.4010219

EVALUATION STUDY

The results are summarized in Table 7. The size, overall evaporator surface and volume, the cooling power as well as the micro-channel overall surface (S_{mch}) are reported for each case. The micro-channel overall surface area is decreasing with the decrease in the overall evaporator size.

Table 7: Summary - Various Designs

Design	A (mm)	B (mm)	H (mm)	L (mm)	l (mm)	D_h (mm)	S (mm^2)	V (mm^3)	Q_o (W)	S_{mch} (mm^2)
1	2.8	1.2	2	18	16.1	1.54	289.8	579.6	99.9	467.35
2	1.8	0.7	2	18	16.1	1	289.8	579.6	190.9	303.47
3	0.9	0.4	1.2	18	16.1	0.5	289.8	347.76	540.5	151.73
4	0.9	0.4	0.8	6.8	6.8	0.5	46.24	36.99	86.24	64.08
5	0.9	0.4	0.8	6.8	6.8	0.5	36	28.8	69.4	57.5

The impact of the hydraulic diameter on cooling efficiency for same size designs (Cases 1 –3) is presented in Figure 9. The cooling power decreases with the increase in hydraulic diameter, due to the decrease in the overall heat transfer coefficient.

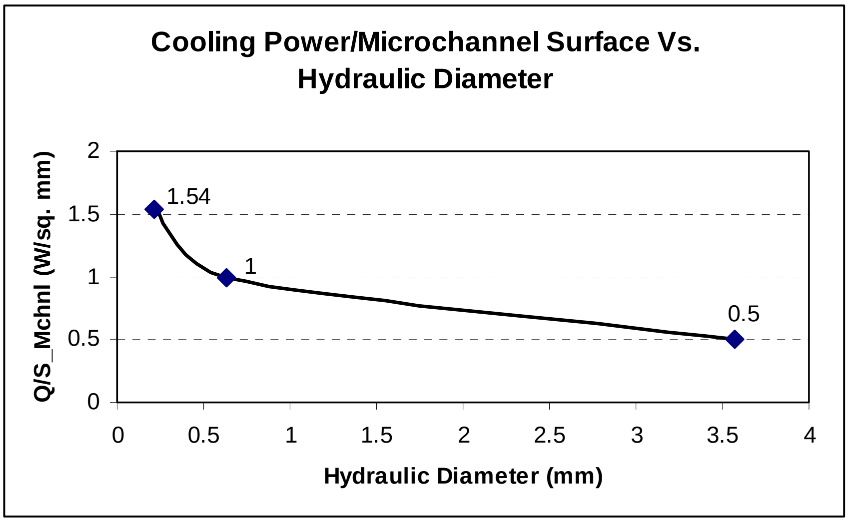

Figure 9: Cooling power variation with hydraulic diameter for same overall volume (Designs 1 - 3)

Furthermore, the cooling power varies almost linearly with the evaporator volume for the same hydraulic diameter (as seen in Figure 10). This is due to the fact that the heat transfer coefficient is the same, but the available surface area for heat transfer increases linearly with the increase in volume.

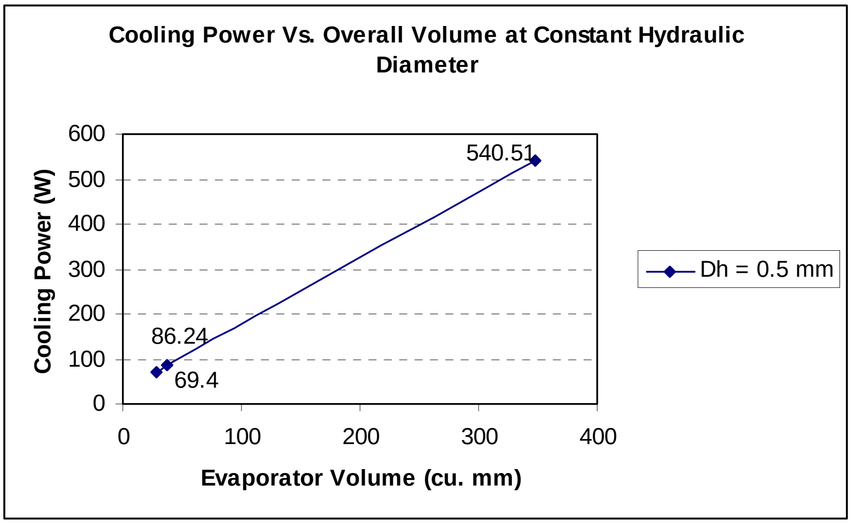

Figure 10: Cooling power variation with evaporator volume for same hydraulic diameter (Designs 3 – 5)

It is desired to have an optimal ratio between the overall heat transfer coefficient (closely related to the micro-channel hydraulic diameter) and the contact surface area between the evaporator and package. Figure 11 shows the ratio for cases 1 – 5.

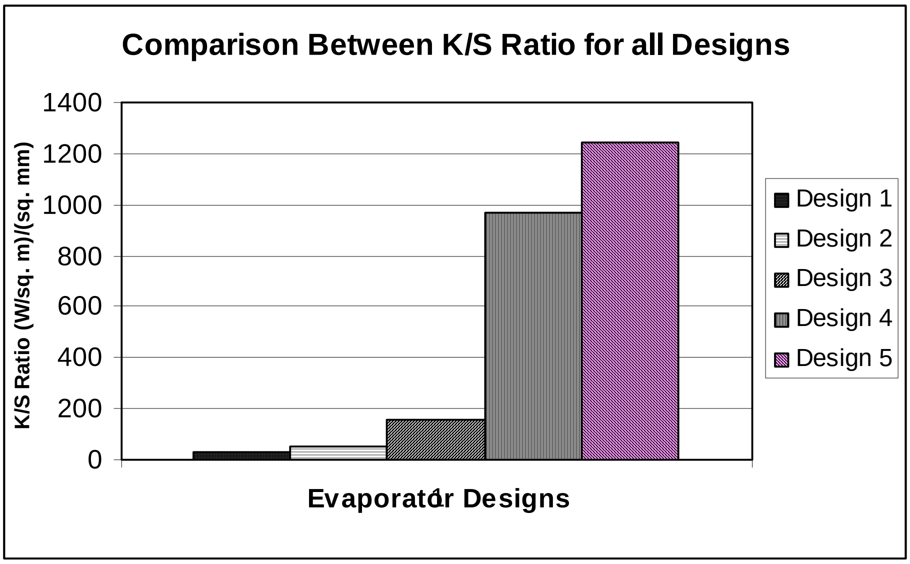

Figure 11: Comparison Between Evaluated Cases

Based on the values summarized in Table 7, the smallest design evaluated (Design 5) is the best of all, as the cooling power per micro-channel surface area is the highest.

Also, Figure 11 indicates that Designs 5 is the most efficient as the heat transfer coefficient divided by the contact surface area is the highest, thus validates the concept that the most compact evaporator will provide the most efficient mini-scale cooling.

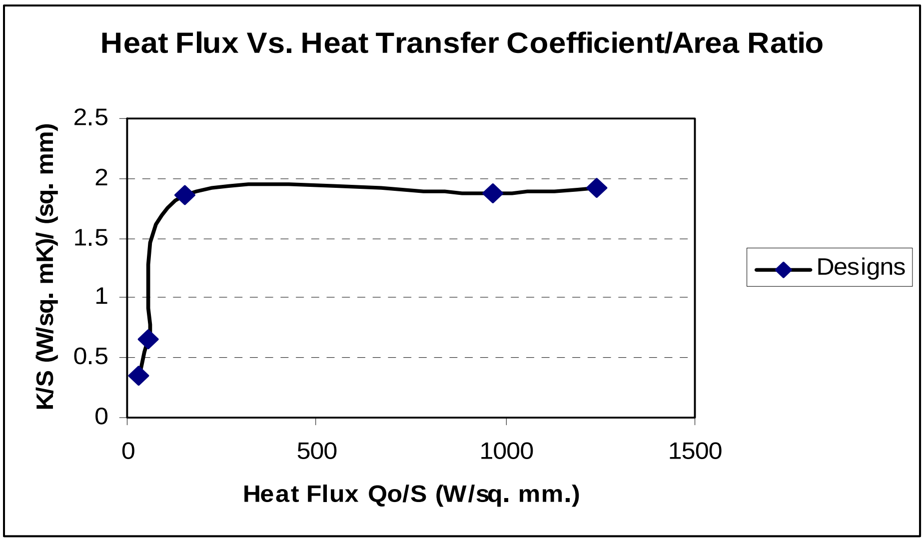

Figure 12: Heat Flux Vs. Heat Transfer Coefficient Ratio

Finally, Figure 12 shows the steep increase of the heat flux when increasing only slightly the heat transfer coefficient to area ratio, and then reaches asymptotically a constant value for the smaller hydraulic diameter micro-channel designs. This indicates that the system will reach a peak in its thermal performance that cannot be further improved by decreasing the hydraulic diameter, which controls both K and S.

NAMES AND UNITS

P Power (W)	Q Rate of Heat Transfer (W)	T Temperature (ºC)	u Refrigerant Velocity (m/s)
m Mass Flow Rate (kg/s)	V Volume Flow Rate (m^3/s)	p Pressure (N/m^2)	h Specific enthalpy (kJ/kg)

CONCLUSIONS

An analytical model of the evaporator design is developed using the R-134a refrigerant. Various micro-channel designs are considered while miniaturizing the evaporator to be incorporated in the vapor compression system. The efficiency of the proposed system is evaluated for various structures, and the optimal design is further identified and compared to previous designs using mechanical compression cooling. The advantages of the optimized refrigeration design are highlighted, establishing a performance vs. size relationship for vapor-compression refrigerators, to serve as the basis for the enhanced cooling of future miniaturized refrigeration applications.

A Comparison Between Refrigerants Used In Air Conditioning

Derya Özkan, Özden Agra and Özlem Çetin

University of Yildiz Technical University, Turkey

Corresponding email: tumer@yildiz.edu.tr

SUMMARY

It's clearly known that growing dimensions of the hole on ozone layer has very important damages and effects on living creatures today. Investigations show that refrigerants that commonly used in air conditioning have great impacts on damage of ozone layer. For this reason, researches on alternative refrigerants to be used for air conditioning are still continuing. In this study, performance of different refrigerants like R600a, R134a, R290, R1270, R32, R22, and R152a, in vapor compression refrigeration cycles and heat pumps was investigated. Analyses was made on the ideal vapor compression refrigeration cycle and a second cycle which was created by adding subcool and superheat regions on the first one. While evaporation temperature is changing between -40 °C and – 10 °C, condensation temperature Tcond = 40 °C is constant for 2,2kW of cooling load. Also a comparison between refrigeration performance and variation on compressor power was carried out at different evaporation temperatures of different refrigerants.

INTRODUCTION

Natural elements such as carbon dioxide, air, water and ammonia have been used as refrigerants in cooling systems which started being developed at the second half of 19th century. During the following century, chlorofluorocarbons and hydro chlorofluorocarbons have replaced some of these elements and have seen heavy use. [1] However, as a result of the dispersal of these elements into the atmosphere, several environmental problems such as damages on the atmosphere and the greenhouse effect have occurred. Especially the ozone layer which protects living beings from the harmful rays of the sun, is being damaged as the chlorine atoms are released from the structure of cooling elements and start damaging the weak ozone molecules.[4] The problem that is the destruction of the ozone layer has gained worldwide significance and countries have united to find a way to prevent it. With the Montreal Protocol that has been signed by 43 countries in the year 1987, the production and usage of CFC class refrigerants which also include R12 have been gradually constrained. Aside from the countries that have signed the protocol, other countries have set up new law regulations regarding the import, export and production of these refrigerants. It was expressed by medical authorities that there was an increase in the number of several clinical diseases with the growing of the holes in the ozone layer. As a result of the studies that were carried out about this issue which is highly important for environment and human life, it was found out that the CFC group refrigerants have got a great potential of damaging the ozone layer. Many alterative refrigerants were invented to be used instead of these harmful refrigerants and the researches for developing new are still taking place. The refrigerants that are used as replacement for the HFC's are R134a, R404A, R407A, R410A, R22, and hydrocarbons (propane and butane) and ammonia. Propane could also be used, with an acceptable degree of risk, for car air conditioning, again provided that appropriate precautions were taken. Some tens of thousands of car air conditioning systems have been ‘‘unofficially’’ converted to operate on propane by private individuals in USA and Australia. [5]

In this study, the thermodynamic analysis of the R22 refrigerant, the pure refrigerants R134a, R32 and R152a as well as the easy-to-obtain, cost efficient, environment-friendly natural refrigerants R290, R1270 and R600a have been carried out in a single phase steam compression cooling cycle. The mass flow rate, compressor power and COP changes of the aforementioned refrigerants have been shown as graphs. While evaporation temperature is changing between -40 °C and – 10 °C, condensation temperature Tcond = 40 °C is constant for 2,2kW of cooling load. Analyses was made on the ideal vapor compression refrigeration cycle and a second cycle which was created by adding subcool and superheat regions

THE COMPARISON OF THE THERMODYNAMIC STATISTICS OF COOLING LIQUIDS

While designing air conditioning and cooling systems, refrigerants that do not damage the ozone layer or cause global warming should be preferred instead of those that have the same physical features but have harmful effects.

Table 1. Refrigerants of thermodynamics property

REFRIGERANTS	MOLAR MASS (KG/KMOL)	SATURATED TEMPERATURE(^{0}C)	T_C (^{0}C)	P_C (BAR)	TLV (PPM)	LFL (%)	DELTA h_{comb} (MJ/Kg)	ODP	GWP (100 YEARS)	ATMOSPHERIC LIFETIMES (YEARS)
R600a	58,112	-11,670	134,67	36,4	800	1,8	49,4	0	~20	-
R134a	102,03	-26,074	101,06	40,593	1000	0	4,2	0	1300	14,6
R290	44,096	-42,090	96,675	42,471	2500	2,3	50,3	0	~20	-
R1270	42,080	-47,690	92,420	46,646	375	2	-	0	2	-
R32	52,024	-51,651	78,105	57,820	1000	13,3	9,4	0	650	5,6
R22	86,468	-40,810	96,145	49,900	1000	0	2,2	0,04	1500	12,1
R152a	66,051	-24,023	113,26	45,168	1000	3,1	17,4	0	140	1,5

The R22 refrigerant which is used as an alternative to CFC-included refrigerants, has got a low ODP value and thus, its use is permitted until the year 2030. As a result, a refrigerant that has similar thermodynamic properties could be an alternative to R22. As Table 1 shows, taking into account the Global Warming Effect (GWE), the Ozone Depletion Coefficient and the other statistics, the R134a could be an alternative to R22. However, the fact that R134a has a relatively high global warming effect requires an alternative to be found for this refrigerant too. The hydrocarbons like R600a, R290 and R1270 are good alternatives to R12, R22 and R502 since they do not damage the ozone layer much and they have a very low greenhouse effect. Even though their high rate of flammability prevents them from being used commonly, the propane-butane and propane-isobutene mixtures are good alternatives to R12 in house-type coolers. Most of the refrigerants that are to be compared against one another in a simple coolant cycle are chosen from hydrocarbons in this study too.

THEORETICAL ANALYSIS

This study has been carried out on a compressed vapor cooling cycle which runs on -30 °C evaporation temperature and 40 °C condensation temperature and which has been designed for a no-frost refrigerator. The saturated and boiling steam properties of refrigerants R22, R134a, R32, R152a, R290, R1270 and R600a to be analyzed have been taken from the Refprop 7.0 software.

h_{2g} (kj/kg)	627,68	445,332	663,982	676,495	627,395	464,802	589,98
h_3 (kj/kg)	297,03	256,41	307,82	305,01	275,61	249,65	271,35
h_4 (kj/kg)	297,03	256,41	307,82	305,01	275,61	249,65	271,35

Taking the cooling capacity of the evaporator as 2.2 kW's, the various mass flow rates, compressor works and condenser capacities have been calculated for different refrigerants and the COP values have been acquired. Thus,

Q_l= 2,2 (kW)

the mass flow rate of the liquid to travel through the cooling cycle is calculated as:

$$m = Q_l / (h_1 - h_4)\ (kg/s), \qquad (1)$$

The work done by the compressor has been calculated at Equation 3, by taking the isentropic efficiency as (0,80).

$$0{,}8 = (h_1 - h_2) / (h_1 - h_{2g}), \qquad (2)$$

$$W_{comp} = m\ (h_{2g} - h_1)\ \ (kj/s), \qquad (3)$$

The condenser capacity has been calculated according to Equation 4.

$$Q_k = m(h_{2g} - h_3), \qquad (4)$$

Cooling performance COP;

$$COP = Q_l / W_{comp}, \qquad (5)$$

has been calculated at Equation 5.

The change in the compressor power has been compared in Figure 2 by changing the evaporation temperature of the refrigerants in use between -10 °C and – 40 °C. The increasing compressor power is a parameter that decreases the COP. It is understood from the figure that for all the cooling liquids, the compressor power decreases linearly with an increase in the evaporation temperature. It is shown that R290 requires more compressor power than the other refrigerants at evaporation temperatures lower than -20 °C, while R152a requires less. It is also shown that R 32 requires more compressor power than the other refrigerants at evaporation temperatures higher than -20 °C, while R 22 requires less.

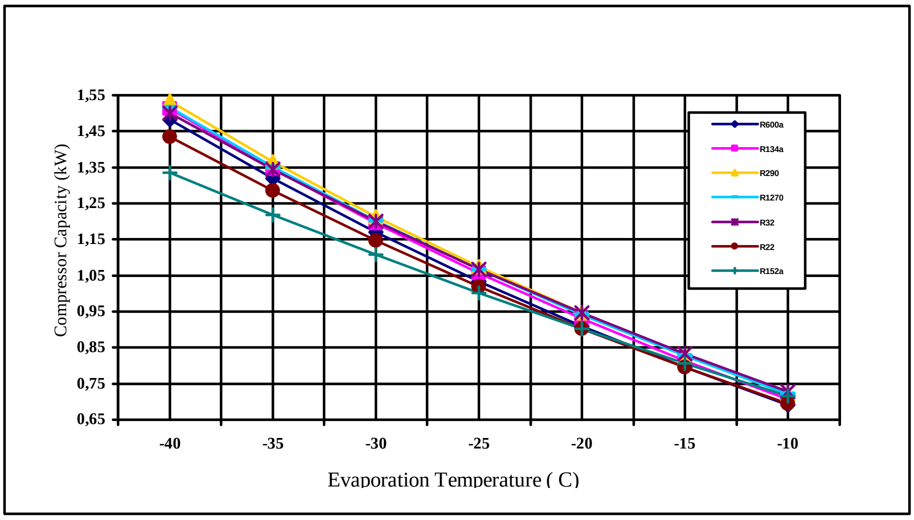

Figure 2. Effect of evaporation temperature changes of refrigerants on compressor capacity

Figure 3 shows the change of the mass flow rate of refrigerants along with the changing evaporation temperatures, for 2.2 kW's of cooling capacity. And for all the refrigerants, mass flow rate decreases linearly with increasing evaporation temperature. The highest mass flow rate between the temperature range of -40 °C and -10 °C is R134a liquid's, while the lowest is the R1270's. Having a low mass flow rate with in the system is a parameter that reduces the cost of operating.

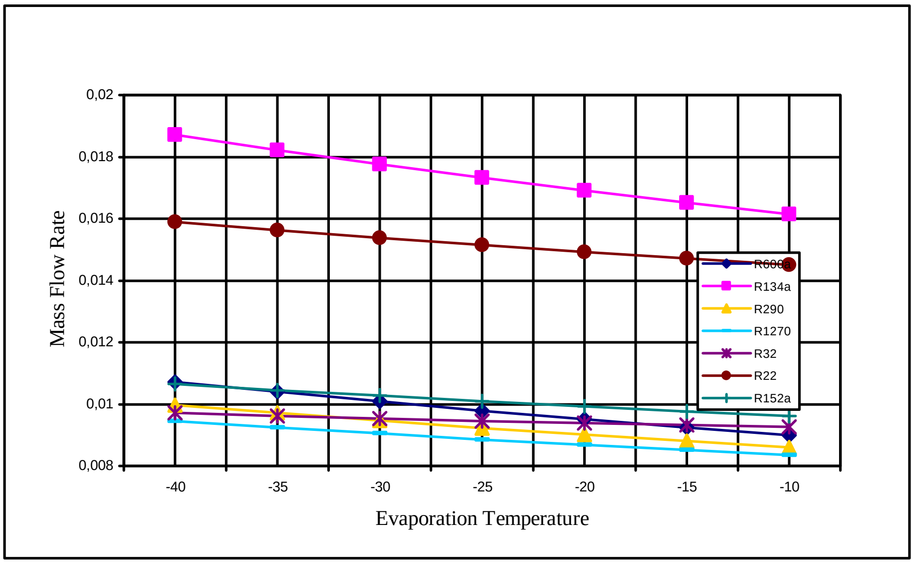

Figure 3. The mass flow rate changes of refrigerants with the changing evaporation temperatures, for 2.2 kW's of cooling capacity

Figure 4 shows the change of the cooling performance (COP) of refrigerants for a cooling cycle with a cooling load of 2,2 kW and with a -30 °C evaporation temperature and 40 °C condensation temperature. According to the figure, it is seen that the COP of R 152 a is the highest while the COP of R 290 is the lowest.

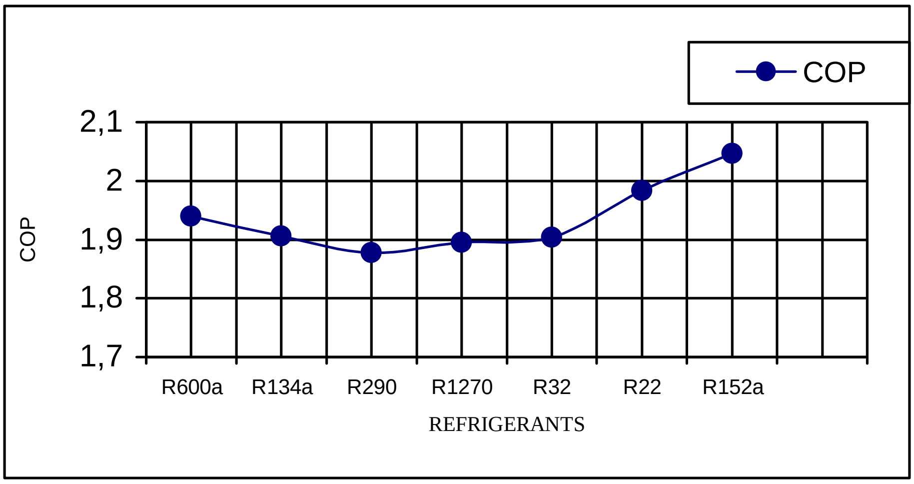

Figure 4. The change of the COP of refrigerants for a cooling cycle

The COP of R 22 has been considered to be 100% in Figure 5 and the comparison for the COP's of the rest of the alternative refrigerants has been made. It was seen that the performance of R 152 a is better than R 22, while the others are worse.

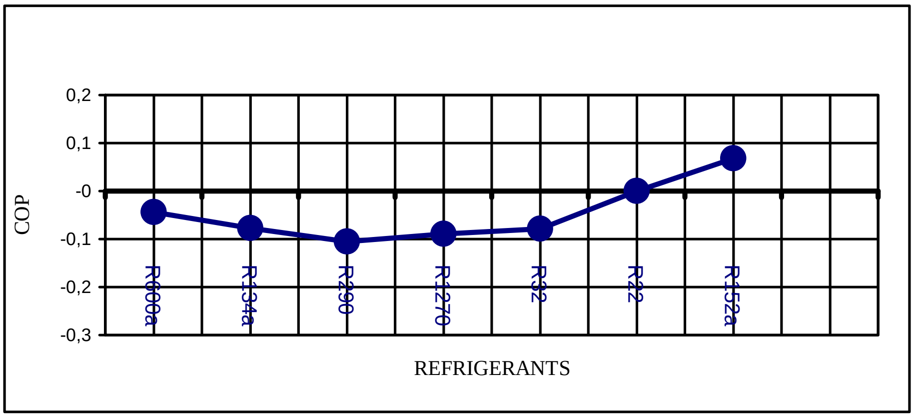

Figure 5. The comparison between R 22 COP and alternative refrigerant's COP's

Figure 6 shows the COP changes of the refrigerants chosen for this work between 40 °C condensation temperature and -40 °C to -10 °C evaporation temperature. In the refrigerants R600a, R134a, R290, R1270, R32, R22 and R152a, the COP increases with increasing evaporation temperature. But this increase is varying upon the refrigerant used.

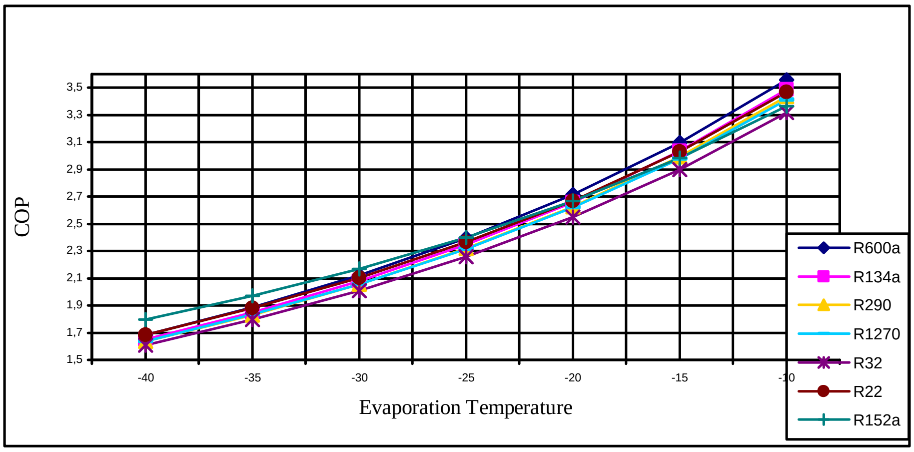

Figure 6. The change of the COP of refrigerants with the changing evaporation temperatures

From this graph it is possible to conclude that the COP value of R 152a is high for evaporation temperatures below -25 °C and the COP value of R 600a is higher than the rest of the refrigerants between -25 °C to -10 °C evaporation temperatures and that it can be preferred to the other refrigerants within this temperature range.

The cooling performances of refrigerants have been tested by making 7 °C of subcooling is made within the condenser and 7 °C of superheating in the evaporator.

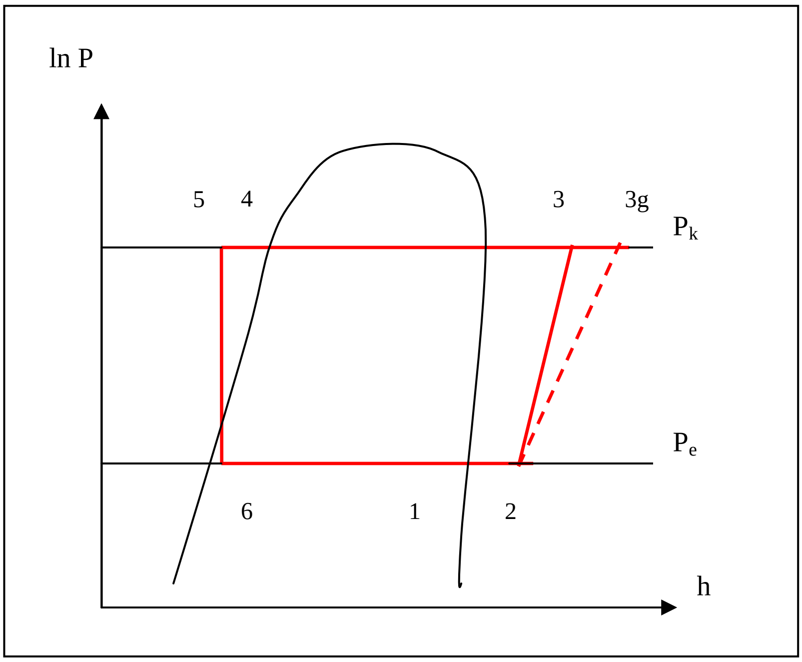

Figure 7. lnP-h diagram of ideal vapor compression cycle by making subcooling and superheating

Table 3: Refrigerant's enthalpy value

Refrigerants / Enthalpy	R600a	R134a	R290	R1270	R32	R22	R152a
h_1 (kj/kg)	515,21	380,32	540,22	548,17	506,27	392,69	485,55
h_2 (kj/kg)	525,45	385,79	551,03	558,17	513,1	397,78	492,24
h_3 (kj/kg)	618,27	439,61	653,57	664,49	613,78	457,7	578,49
h_{3g} (kj/kg)	641,475	453,065	679,205	691,07	638,95	472,68	600,0525
h_4 (kj/kg)	297,03	256,41	307,82	305,01	275,61	249,65	271,35
h_5 (kj/kg)	279,34	246,07	287,71	285,3	261,01	240,45	258,32
h_6 (kj/kg)	279,34	246,07	287,71	285,3	261,01	240,45	258,32

For the situations that 7 °C of subcooling and 7 °C of superheating has been made, the amount of heat that the evaporator is going to absorb is found out by equation 6.

$$Q_{l2} = m\,(h_2 - h_6), \qquad (6)$$

Taking into account the isentropic efficiency of the compressor, the work expanded by the compressor has been calculated for various refrigerants for the 2nd cooling cycle that has sub cooling and superheating.

$$0{,}8 = (h_2 - h_3)\,/\,(h_2 - h_{3g}), \qquad (7)$$

$$W_{comp} = m\,(h_{3g}-h_2)\ \ (kj/s), \qquad (8)$$

Condenser capacity has been calculated at equation 9

$$Q_k = m\,(h_{3g}-h_5), \qquad (9)$$

COP has been calculated at equation 10

$$COP = Q_{l2} / W_{comp}, \qquad (10)$$

Figure 8 shows the COP values for the refrigerants that work within the ideal vapor compression cooling cycle and the comparison of these COP's for the 7 °C subcooling and 7 °C superheating cooling cycle situations.

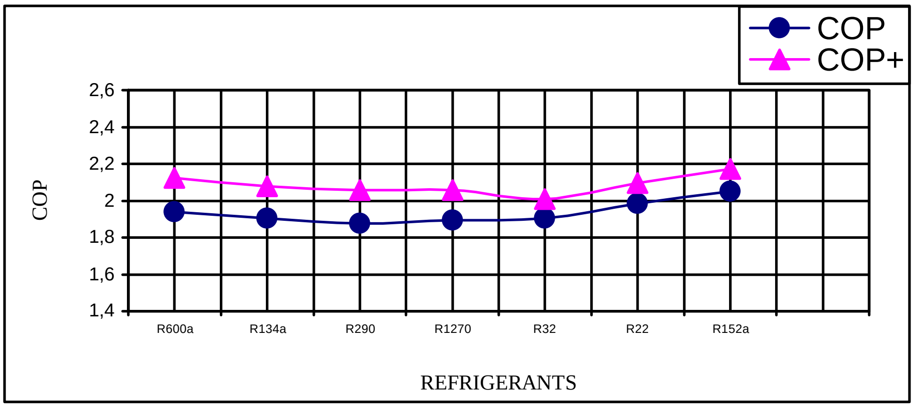

Figure 8 Comparison between COP and COP+.

The increase in the COP has been calculated by applying subcooling and superheating to the vapor compression cooling cycle. The increase rate of the COP's of the refrigerants have been shown to be different. Figure 9 shows the COP increase rates for different refrigerants. According to this, R600 has the greatest increase and R152a has the least.

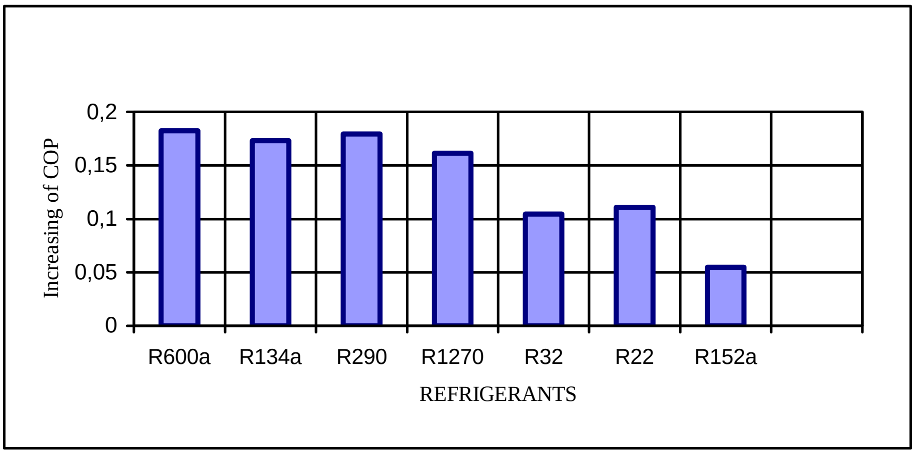

Figure 9. Comparison of COP increase rates of refrigerants by applying subcooling and superheating

RESULTS

Within this study, the different thermodynamic properties of refrigerants R600a, R134a, R290, R1270, R32, R22 and R152a have been analyzed. And in the modern day world which ozone destruction is very important, it is very interesting to find out that the R152a that belongs to the hydro fluorocarbon (HCF) group has an ozone damage rate of zero-to-none. In addition to this very important feature of it, its effect on the global warming is only 2% of the effect of R12. R152a is an alternative at heating pumps for R12 and R500. It also works well with mineral oils. R152a is not flammable and it is odorless. It shows no poisonous properties. Thus, there is no need for the modification of the compressor in the cycle of the cooling system that this refrigerant is used in. The hydrocarbon based refrigerants used in the study have high flammability and this prevents their fields of use to be limited. Although they can be used on their own, they can also be used as mixtures of each other. Propane-isobutene and propane-butane mixtures can be used as alternatives to R12 in house type cooling systems. They can be used together with oils that could be used together with R12. In addition to the fact that among the hydrocarbons, Propane is cheap and easy-to-obtain, its cooling capacity per volume is around 35-50& higher than R12's, and these facts make this coolant a possible alternative for R12.

Further in this study, the condensation temperature (T_c = 40 °C) has been taken as a constant for 2.2 kW of cooling load and the evaporation temperature (T_e) has been changed between -40 °C and -10 °C. It was seen that for all the refrigerants, the mass flow rate and the compressor power increase while the COP values decrease, with increasing evaporation temperatures. It can be concluded that the COP value of R 152a is high for evaporation temperatures below -25 °C and it is advisable to use this refrigerant rather than the others at these temperatures while the COP value of R 600a is high for evaporation temperatures between -25 °C and -10 °C and it is advisable to use this cooling liquid rather than the others at these temperatures.

As a conclusion of the study, the comparison of COP's for the vapor compression cooling cycle situations and the situations that superheating and subcooling have been carried out. It was found out that superheating and subcooling are elements that increase the COP but this increase rate varies depending on the type of refrigerant used. The COP increase for the R600a, R290 and R1270 type refrigerants which belong to the hydrocarbon family is higher. The increase of COP means energy savings. This shows that the hydrocarbons might be the choice for alternative refrigerants in the future.

SUMMARY

A new promising integrated design method for thermally activated building systems (TABS) and their control is presented. In contrast to the conventional iterative design method of TABS, which is based on iterative dynamic model simulation studies, the new approach is a more straight-forward calculation process. The new design method is less time-consuming and enables more insight into the potential of TABS. For example, it shows the limitation of TABS application and points out when additional auxiliary heating or cooling devices have to be installed. It is based on lower and upper bounds for the heat gains that have to be estimated within the design process.

KEYWORDS: control, thermally activated building systems (TABS), concrete core conditioning, integrated design, unknown-but-bounded

INTRODUCTION

A research project on the control and design of thermally activated building systems (TABS) [1], [2] has been started in May 2004 [3], [4]. This paper presents one selected result: A TABS design method for building automation and HVAC design engineers.
It is well known among TABS designers that TABS cannot be designed and sized like other HVAC systems. The design and sizing of an HVAC system and its control is usually done in two steps. In a 1st step the HVAC system is designed and sized using a static model for full load operation. The 2nd step is the design of its control, where sometimes dynamic models are used. If the HVAC system is a TABS this approach is not appropriate. This has two reasons. The temperatures in a TABS usually never achieve steady-state conditions. The dynamic behavior has therefore to be considered. This requires dynamic instead of static models. The second reason is that the dynamic behavior of the temperatures depends also on the control. Therefore the control should be taken into account when designing and sizing the TABS. Thus it should not be designed afterwards in a second step. That’s why a TABS and its control should be designed and sized in an integrated way. This is well known among designers of TABS. A frequently heard argument is that simulations have to be performed to design and size TABS. And for such simulations it is necessary to assume some kind of control.
This paper presents a new promising integrated design method for TABS and their control based on [3], [4]. In contrast to the conventional integrated design method of TABS, which is based on iterative dynamic model simulation studies, the new approach is a more straight-forward calculation process. It is based on lower and upper bounds for the heat gains that have to be estimated within the design process.
The first section of the paper will describe how the new integrated design method has been developed. The second section gives an overview of the resulting new integrated design method. A design example will illustrate the method in the third section.

DEVELOPMENT OF THE INTEGRATED DESIGN METHOD

In this section it is outlined how the integrated design method has been developed. It has been designed together with the control algorithms.

The following questions Q1 to Q4 have guided the design process essentially:

Q1 How to switch automatically between heating and cooling a TABS using the outside air temperature information?
This question has been motivated by often heard statements as: The switching between heating and cooling of TABS must be done by hand. Automatic solutions switch too frequently which causes waste of energy. Or automatic solutions based on outside air temperature dependent switching lead to comfort problems.

Q2 How to control rooms with different specific heating and cooling loads?

Q3 What are the advantages and disadvantages of water flow on/off control and how should it be done?

Q4 Is it possible to use room temperature feedback control, and if yes, how should it work and what is the benefit?
This question has been motivated also by often heard statements as: The self-regulating effect is sufficient to control the room temperature, no conventional room temperature feedback controller is necessary. Conventional room temperature feedback controllers do not work because the system to be controlled does react very slowly.

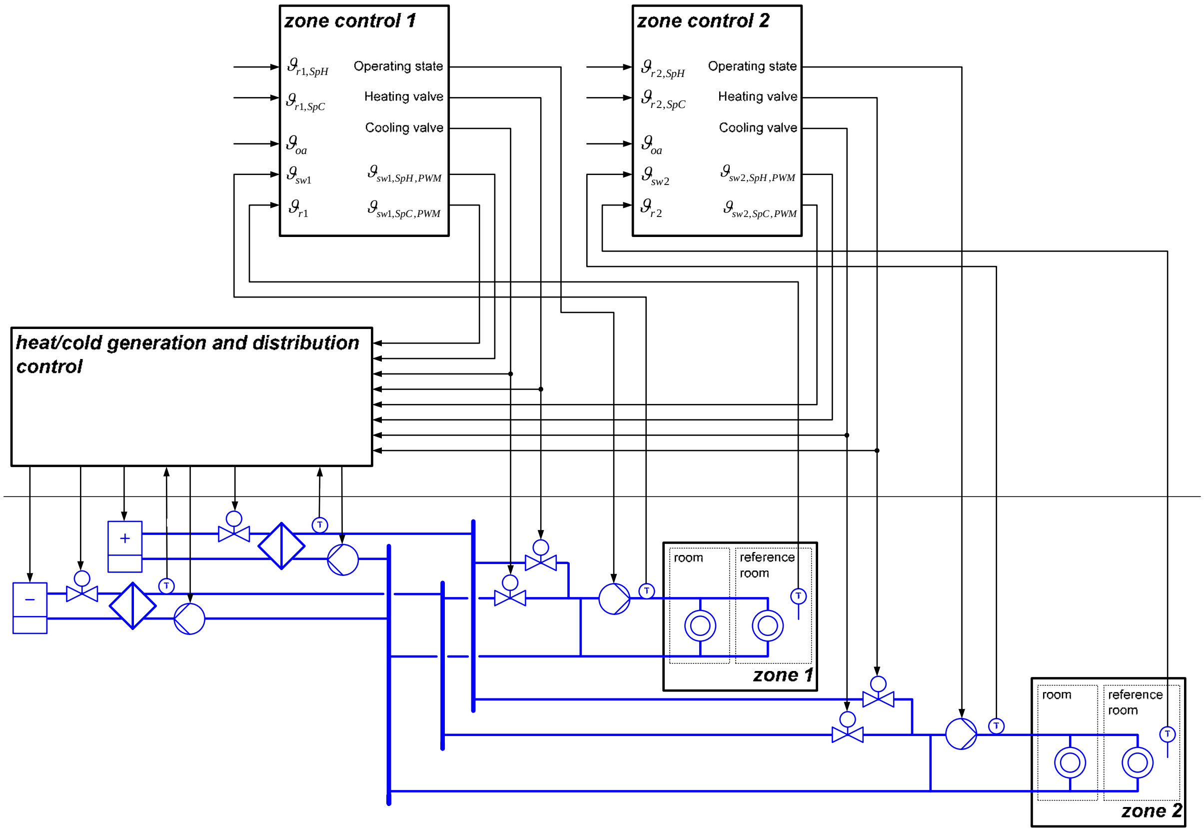

Figure 1: The overall TABS control concept, including heat/cold generation and distribution

Development step 1:

Question Q1 has been addressed first. It led also to an answer of question Q2. In order to find an answer to Q1 only one zone has been considered, e.g. zone 1 in Figure 1. It has been assumed that no room temperature sensor in a reference room is available. Thus the zone controller (Zone control 1 in Figure 1) has only two sensor inputs, the supply water temperature ϑ_{sw} (also called flow temperature) and the outside air temperature ϑ_{oa}. The zone controller acts on the zone heating and the zone cooling valve and it includes a supply water temperature feedback controller with the set-points $\vartheta_{sw,SpH}$ for heating and $\vartheta_{sw,SpC}$ for cooling. The zone controller has also the room temperature heating set-point $\vartheta_{r,SpH}$ and the room temperature cooling set-point $\vartheta_{r,SpC}$ as inputs, which define together the room temperature comfort range.

Development step 2:

In order to find a solution to the problem expressed in question Q1 it has been started with a related problem which is easier to solve, as it is recommended by G. Polya in his famous little book on how to solve problems [8]. The related problem is a special case: the outside air temperature dependent switching between heating and cooling for a system where the *outside air temperature and the heat gains vary only slowly*. This allows us to use a static model to solve the problem. It has additionally been assumed that all rooms of the zone are identical and have the same heat gain $\dot{q}_g$, which allows us to assume that all rooms have the same room temperature ϑ_r. This problem can be formulated mathematically as follows (**problem 1**):

Static model (cf. Figure 2):

$$\dot{q}_w = \frac{1}{R_{l,f}} \cdot \left(\vartheta_r - \vartheta_{oa}\right) - \dot{q}_g \tag{1}$$

where $\dot{q}_w$ is the TABS heating or cooling power and $R_{l,f}$ the thermal resistance of the façade.

$$\dot{q}_w = \begin{cases} 0 & \textit{if no heating and no cooling is required} \\ \dfrac{1}{R_t + \tilde{R}} \cdot \left(\vartheta_{sw} - \vartheta_r\right) & \textit{if there is heating or cooling demand} \end{cases} \tag{2}$$

where $R_t + \tilde{R}$ is a thermal resistance characterizing the TABS between the supply water temperature and the room temperature.

Known:

$R_{l,f}$, $R_t + \tilde{R}$, $\vartheta_{r,SpH}$, $\vartheta_{r,SpC}$, ϑ_{oa} and $\dot{q}_g$.

Determine:

When is it required to heat and when is it required to cool, and if either of them is required, what is the required supply water temperature ϑ_{sw}, such that $\vartheta_{r,SpH} \le \vartheta_r \le \vartheta_{r,SpC}$ and $\left|\dot{q}_w\right|$ is minimal.

Result:

Heating is required if $\vartheta_{oa} \le \vartheta_{oa,LmH}$ where $\vartheta_{oa,LmH}$ is the heating limit and

$$\vartheta_{oa,LmH} = \vartheta_{r,SpH} - R_{l,f} \cdot \dot{q}_g \tag{3}$$

$$\vartheta_{sw} = \vartheta_{sw,SpH} = \vartheta_{r,SpH} + \frac{R_t + \tilde{R}}{R_{l,f}} \cdot \left(\vartheta_{r,SpH} - \vartheta_{oa}\right) - \left(R_t + \tilde{R}\right) \cdot \dot{q}_g \tag{4}$$

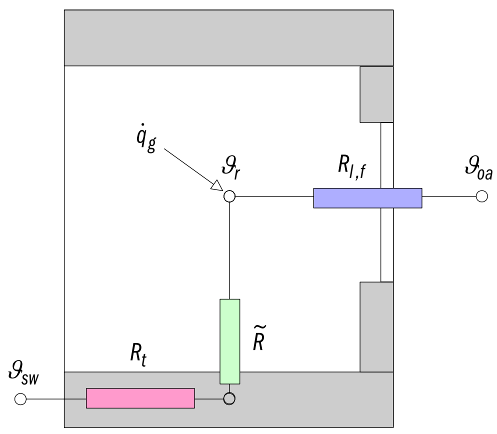
Cooling is required if $\vartheta_{oa} \ge \vartheta_{oa,LmC}$ where $\vartheta_{oa,LmC}$ is the cooling limit and

$$\vartheta_{oa,LmC} = \vartheta_{r,SpC} - R_{l,f} \cdot \dot{q}_g \tag{5}$$

$$\vartheta_{sw} = \vartheta_{sw,SpC} = \vartheta_{r,SpC} + \frac{R_t + \tilde{R}}{R_{l,f}} \cdot \left(\vartheta_{r,SpC} - \vartheta_{oa}\right) - \left(R_t + \tilde{R}\right) \cdot \dot{q}_g \tag{6}$$

Neither heating nor cooling is required if $\vartheta_{oa,LmH} \le \vartheta_{oa} \le \vartheta_{oa,LmC}$.

The result is illustrated by Figure 3. HC is the heating curve and CC the cooling curve.



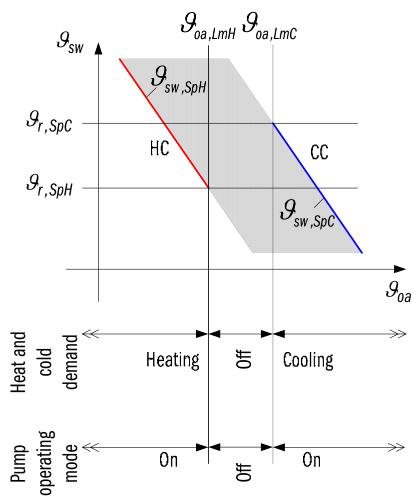


Figure 2 (left): Static building and TABS model

Figure 3 (right): Heating curve (HC) and cooling curve (CC) for known heat gain $\dot{q}_g$

Development step 3:
A next step was to solve another related problem which is a little more difficult. It has been assumed that the heat gain $\dot{q}_g$ in the room is not known but only a lower bound $\dot{q}_{g,lb}$ and an upper bound $\dot{q}_{g,ub}$ of it are known. That means $\dot{q}_{g,lb} \le \dot{q}_g \le \dot{q}_{g,ub}$. This reflects one of the following situations:

- the designer of a controller is uncertain on the value of the heat gain,
- the heat gain in a room is varying very slowly, in a non predictable way and cannot be measured
- the rooms of the zone have different specific heat gains

This more difficult problem (**problem 2**) can also be solved with a static model.
Depending on $\Delta\dot{q}_g = \dot{q}_{g,ub} - \dot{q}_{g,lb}$, which we call the heat gain span, three cases can be distinguished, as can be seen in Figure 4. Case (a): if the heat gain span $\Delta\dot{q}_g$ is small, the solution is similar to that of problem 1. There exists an outside air temperature interval in which certainly neither TABS cooling nor TABS heating power is required. Case (b): for medium heat gain span $\Delta\dot{q}_g$, the heating and the cooling curve overlap, i.e. there exists an outside air temperature interval in which – with knowing only the outside air temperature – it is not possible to determine whether there is heating or cooling demand or no power demand at all. Nevertheless, the supply water temperature feedback controller is able to automatically do the correct action (lowering ϑ_{sw} if it lies above the cooling curve, rising ϑ_{sw} if it lies below the heating curve or water circulation only if ϑ_{sw} lies between heating and cooling curve). Case (c): for large heat gain span $\Delta\dot{q}_g$, it is not possible anymore to maintain comfort for all heat gain situations as the heating curve lies above the cooling curve! In certain cases, the integration of a control loop (with room temperature sensors) may solve the problem. But in most cases, this situation can only be handled by using auxiliary heating or cooling systems and/or additional sensors (not outlined here).
The solution of the problem 2 supplies us with formulas which can be used to calculate the parameters of the heating and cooling curves. The solution leads also to a switching algorithm which can be used in the zone controller to switch between heating and cooling.
The model used so far, where the uncertainty of the heat gains is characterized by bounds, in system theory is called an unknown-but-bounded model. That's why the resulting method to design the TABS and its control has been called **unknown-but-bounded method**.

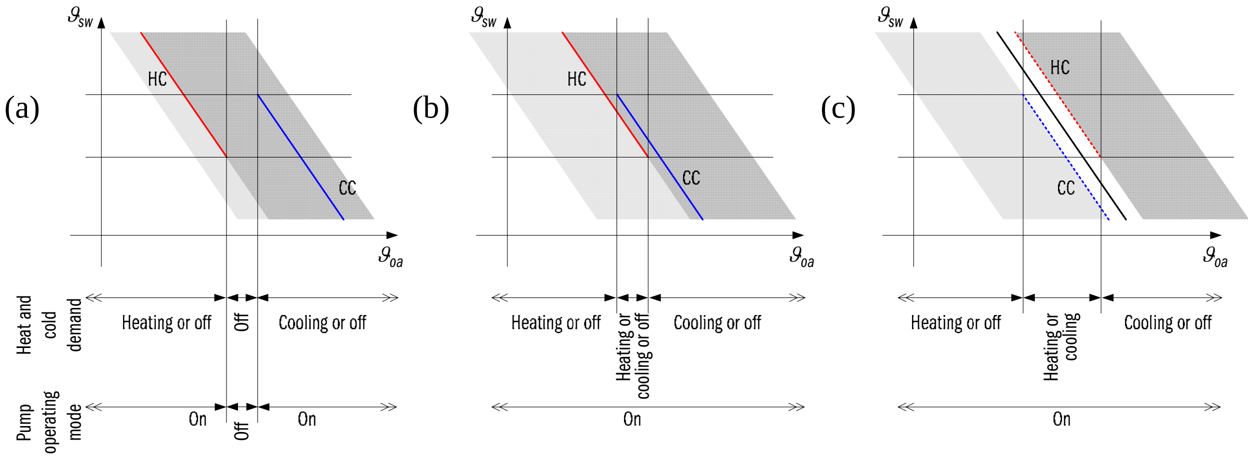

Figure 4: Heating curve (HC) and cooling curve (CC) for different heat gain spans $\Delta\dot{q}_g$

Development step 4:
The problem solved so far differs from the real situation mainly in two points:

- Daily variation of the outside air temperature
- Daily variation of the heat gains. For example considerable internal heat gains during the occupancy time from 08:00 until 18:00 in an office building at weekdays. This usually leads to daily variation of the lower and the upper bound of the heat gains.

It is easy to cope with the first point. Because of the large thermal inertia of TABS it is reasonable that the zone controller takes the average $\overline{\vartheta}_{oa}$ of the past 24 hours of the outside air temperature instead of the actual value ϑ_{oa} to determine the supply water temperature set-point. This averaging of the outside air temperature leads to a slowly varying variable.
To cope with the second point – the daily variation of the heat gain bounds – is more difficult. It has been solved by calculating an equivalent lower bound $\dot{q}_{g,elb}$ and an equivalent upper bound $\dot{q}_{g,eub}$ of the heat gains, which replace $\dot{q}_{g,lb}$ and $\dot{q}_{g,ub}$ in step 3 and which can be used instead of $\dot{q}_g$ in the formulas (4) and (6) to calculate the heating and the cooling curves. To calculate these equivalent bounds a linear dynamic model of TABS and room is used, which represents the dynamic thermal behavior . Further details are given in [5].
What has been done so far in the four steps is the derivation of a first base control strategy for a zone controller – called in analogy to EN 12098-1 “outside temperature compensated flow temperature control” – and of a method to calculate its parameters. Additionally a solution of how to group and assign rooms to zones has been found. Also a method to tune the heating and cooling curves during the first phase of operation has been developed, based on [9].
Development step 5:
Looking for an answer to question Q3 has lead to an option of the base control strategy – called “pulse width modulation” – and looking for an answer to question Q4 has lead to a second option – called “room temperature feedback control”. Finally other base control strategies – e.g. the “outside temperature compensated return temperature control” – have been derived, again with the two options mentioned above. The base control strategies together with the two options altogether lead to a set of control strategies among which a designer may choose [6]. Additional control strategies have been derived for the case where additional auxiliary heating or cooling devices are used.

OVERVIEW OF THE INTEGRATED DESIGN METHOD

The integrated design method is represented by the flow chart in Figure 5. Steps 1 to 6 in this chart represent the straight forward design part. Step 7 is recommended to be performed, when the result of step 6 leaves doubts whether the resulting comfort will be accepted (see example in the next section). A prototype of a design tool which supports to design a TABS and its control according to this method has been developed.

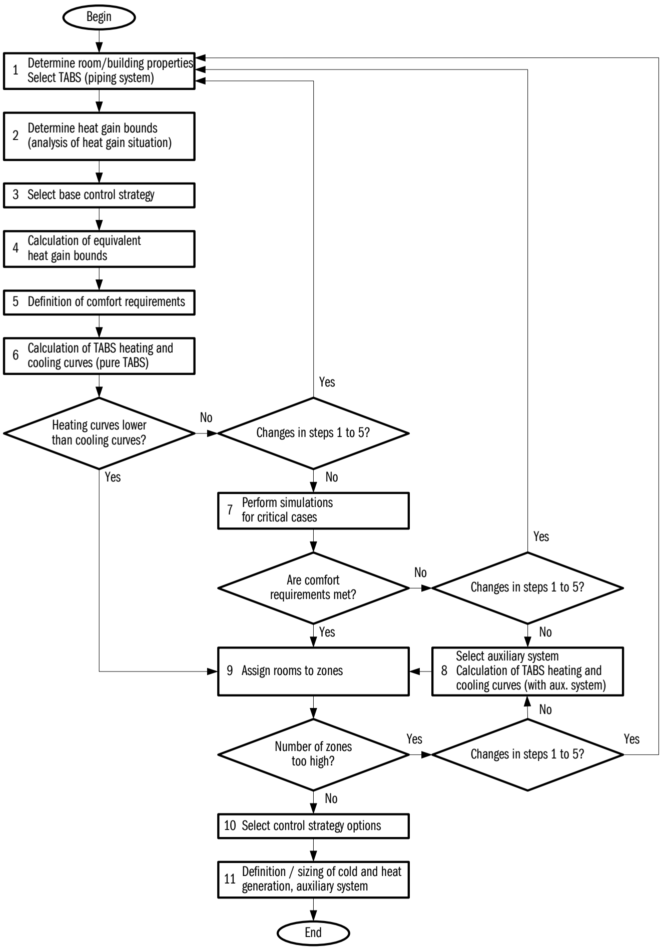

Figure 5: Flow chart of the integrated TABS design method

AN EXAMPLE (Design steps according flow chart in Figure 5)

Design step 1: "Determine room/building properties, select TABS (piping system)"

Table 1. data of the rooms

		Room 1 (normal office)	Room 2 (corner office)
Space length, width, height		6 m x 6 m x 3 m	6 m x 6 m x 3 m
Façade	Orientation	West	West / South
	Area	18.0 m^2	36.0 m^2
	Overall U-Value	0.65 W/m^2K	0.65 W/m^2K
	Glazing fraction façade	42 %	42 %
Additional internal Wall (light)		36 m^2	36 m^2
Natural air change		0.1 h^{-1}	0.2 h^{-1}
Ventilation according to indoor air quality requirements (no cooling/heating by ventilation assumed)			

Table 2. data of the TABS configuration (valid for room 1 and 2)

TABS covering fraction (floor area)	80 %
Thickness concrete slab	250 mm
Pipe spacing	200 mm
External/internal pipe diameter	20/15 mm
Specific supply water mass flow rate [a)]	15 $kg/(h\ m^2)$
Fictitious TABS thermal resistance (R_t) [a)]	0.08 $(m^2\ K)/W$
Thermal resistance of flooring (carpet)	0.125 $(m^2\ K)/W$

[a)] in terms of floor area covered by tabs

Design step 2: “Determine heat gain bounds (analysis of heat gain situation)”

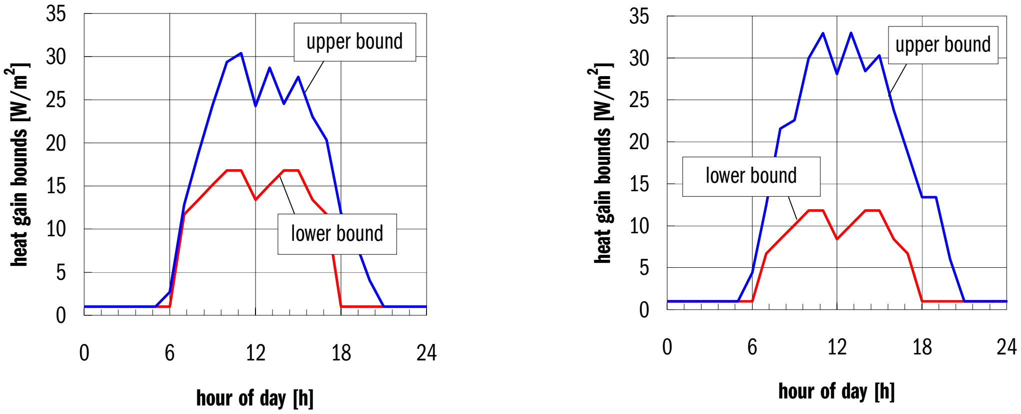

Figure 6: Heat gain bounds for room 1 (left) and room 2 (right), valid for week days

Design step 3: “Select base control strategy”

Here, “outside temperature compensated flow temperature control” is selected.

Design step Step 4: “Calculation of equivalent heat gain bounds”

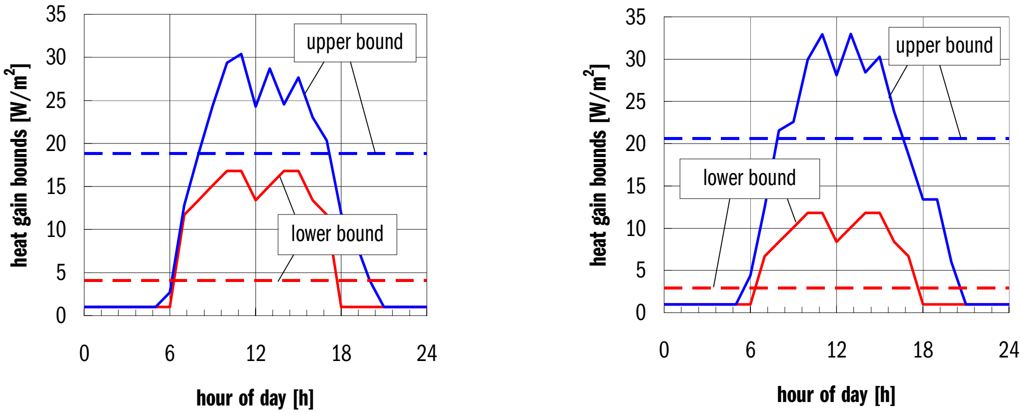

Figure 7: Equivalent heat gain bounds for room 1 (left, dotted lines) and room 2 (right, dotted lines), valid for week days

Design step 5: “Definition of comfort requirements”

Here, a comfort according to [7] is defined (see comfort range in Figure 9).

Design step 6: “Calculation of TABS heating and cooling curves (pure TABS)”

Results (Figure 8) show that room 2 is just at the limit to the critical case (c) in Figure 4.

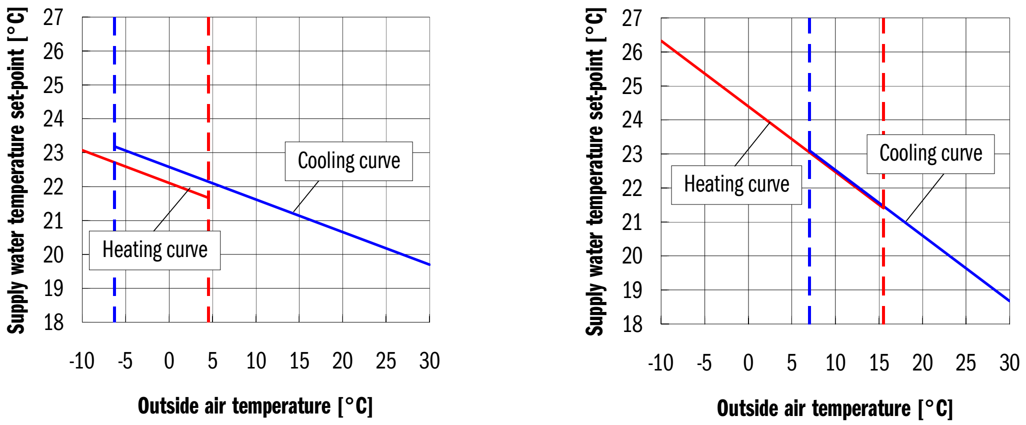

Figure 8: Heating and cooling curves for room 1 (left) and room 2 (right), valid for week days

Design step 7: "Perform simulations for critical cases"

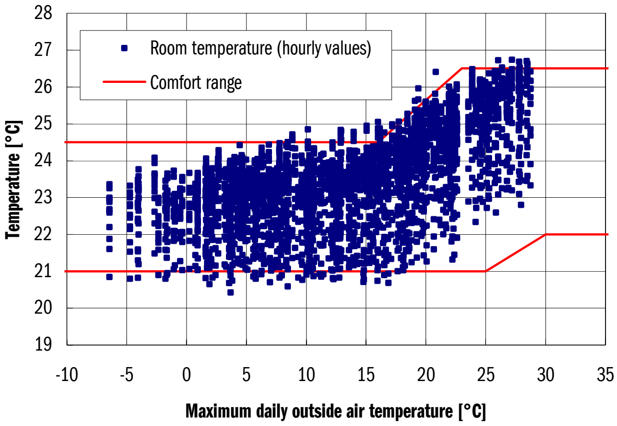

Figure 9: Simulated room temperatures for room 2 (whole-year simulation)

CONCLUSIONS

The new design method is less time-consuming and enables more insight into the potential of TABS. For example, it shows the limitation of TABS application and points out when to install additional auxiliary heating or cooling devices. Additional to the conventional iterative TABS design, the new design process also includes the direct calculation of the parameter values for the underlying base control strategy.
Further details of the method can be found in the design and commissioning handbook which will be published in the frame of our work.

ACKNOWLEDGEMENT

The partial funding of the project by the Swiss Confederation's innovation promotion agency CTI and the input of the project steering committee are gratefully acknowledged.

SUMMARY

The hollow-core slabs can be used actively as a cold and heat storage by conducting supply air through the cores to the space. TERMA project (2004-2006) developed several concepts to integrate thermal mass of hollow-core slabs and air-conditioning systems to meet the requirements of energy efficiency and good indoor conditions. The development was done by using advanced modelling and simulation methods. Thermal behaviour of the hollow-core slab integrated to ventilation was also measured in laboratory. Simulation models were validated against these measurements. The basic strategy for thermal mass utilisation during cooling season is cooling down the slab during unoccupied time by night ventilation to decrease the day time cooling need in the room. By active use of thermal mass of hollow-core slabs the indoor temperature can be reduced at least 2ºC. The active use of thermal mass showed 4..10% savings in heating energy, 46..47% savings in cooling energy and 12..23% savings in fan energy compared to systems traditional systems with passive use of thermal mass.

INTRODUCTION

The thermal mass of the building has a big influence on the energy consumption of the building and indoor temperatures. The present European trend is that the heating and cooling energy consumption is more and more emphasised as a basis for the standards and design work .

Passive use of the building mass has been studied widely. The passive use of thermal mass showed energy savings potential of 4..7% in heating energy and 42..52% in cooling energy /1/. Total energy saving potential can be increased by active utilisation of the building mass. Recently in active utilisation it has been focused on the night ventilation and air circulation trough hollow cores in hollow core slabs. According to Hietamäki et al. /2/ in general night cooling decreases cooling power 40% and cooling energy 20%. With active night ventilation trough hollow core slabs has been decreased 15% cooling energy need.

The hollow-core slabs can be used actively as a cold and heat storage by conducting supply air through the cores to the space. TERMA project (2004-2006) developed several concepts to integrate thermal mass of hollow-core slabs and air-conditioning systems to meet the requirements of energy efficiency and good indoor conditions. The main basis was in Finnish office building. The objective was to achieve 10 % reduction in heating and at least 20% reduction in cooling energy consumption compared to recent calculated level of passive effect of thermal mass.

The development was done by using advanced modelling and simulation methods: spatial level dynamic energy simulations for a whole building, detailed 3D thermal modelling of the hollow-core slab and computational fluid dynamic simulations for indoor conditions. Thermal behaviour of the hollow-core slab integrated to ventilation was also measured in laboratory. Simulation models were validated against these measurements. In the end the LCC survey and design guide were done for developed concepts.

The main objectives of this paper are to present modelling and simulation methods and measurements which have been used to find out the potential concepts. The most potential concepts are presented as well as theirs' influences to the indoor comfort and energy consumption.

METHODS

In the beginning of the TERMA project state-of-the-art study of existing systems was done /3,4/. The project continued with study of possible integrated concepts /5/. According to the preliminary studies the development was focused on the integrated hollow-core slabs and air-conditioning system. Figure 1 shows the development of the TERMA concept.

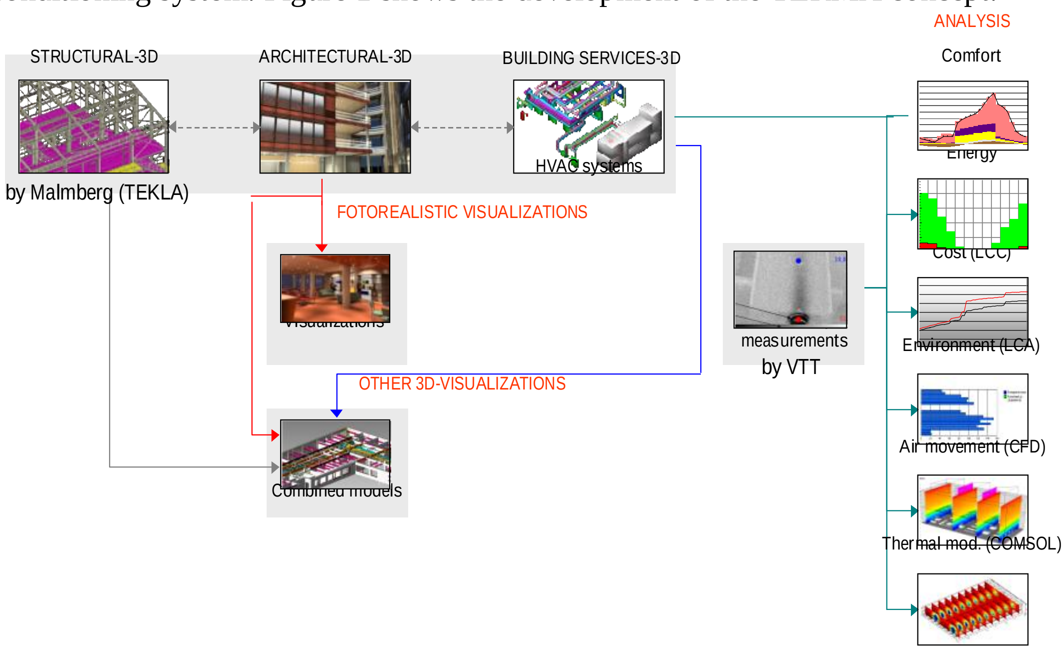

Figure 1. The development of TERMA concepts of utilising advanced modelling, analysis and measurements in TERMA project.

The analysis of the integrated hollow-core slabs and air-conditioning system concepts were done with multiphysic program /6 /. The purpose of the calculations was to determine dynamically in one day period the effect of the air circulated in hollow-core slab to the indoor temperature in south and north faced office rooms in summer conditions. The changing variables were the routing of the air in the slab cores, the temperature of the air conducted to the cores and the supply air temperature from the cores to the room.

The simulations results were indoor temperature, supply air temperature to the room space after core, the temperature distribution of the hollow-core slab and heating and cooling effect of the hollow-core slab to the room space. Figure 2a presents simulated hollow-core slab and 2b the connection between room model and hollow-core slab.

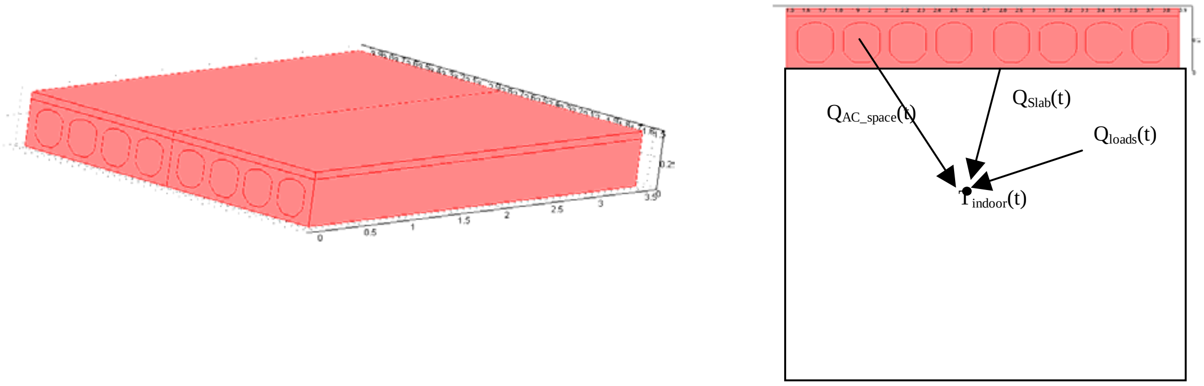

Figure 2. a) Simulated hollow-core slab. b) Connections between hollow-core slab and room model in the multiphysics model.

The energy consumption and heating and cooling needs for office building with different integrated concepts were defined with dynamic energy calculation program /7/ and multiphysics simulation program (Figure 3) /8/.

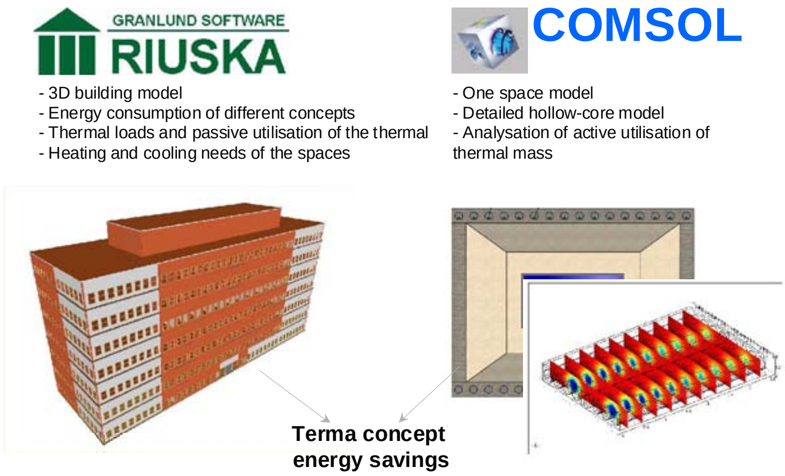

Figure 3. Calculation of the energy consumption and heating and cooling needs.

The energy consumption of the different concepts were compared to typical variable volume air conditioning system (VAV system) and cooled beam system (CB system).

The laboratory tests of the hollow-core slab were performed. The objectives of the tests were to measure and estimate the thermal behaviour of hollow-core slab. One hollow of the hollow-core slab was used as supply air duct of the ventilation system. The inlet supply air temperature was varied like outdoor air temperature in hot summer day (24 h sinus wave model, Tmin=12°C, Tmax=25°C) /9/. The ambient temperature was 20°C. The size of the hollow-core slab was 1200 mm(width) x 400 mm(height) x 10000 mm (length). The measurements were done with two nominal air flows 20 dm³/s and 40 dm³/s in one core. Figure 3a presents the location of the measurement points and figure 3b measurements at 8 m distance.

The multiphysics model was validated against the laboratory tests.

CFD simulations were performed to ensure indoor comfort in different integrated concepts /10/. The aim of the CFD simulations were to estimate office indoor air flow field on summer design day conditions in case the hollow-core slab were used.

RESULTS

The multiphysic model was validated against laboratory tests. Figure 5 shows as an example the temperature comparison of the supply air conducted trough the hollow-core slab in simulations and tests.

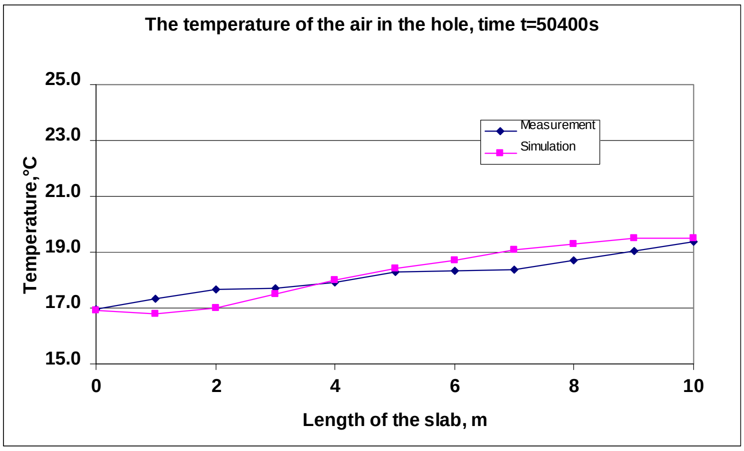

Figure 5. Simulated and measured supply air temperature.

After the multiphysics model was validated, the analysis of the integrated hollow-core slabs and air-conditioning system concepts were performed for 24 different concepts /6/. Figure 6 shows an example of temperature distribution of the hollow-core slab in case where supply air was conducted trough two holes to the space.

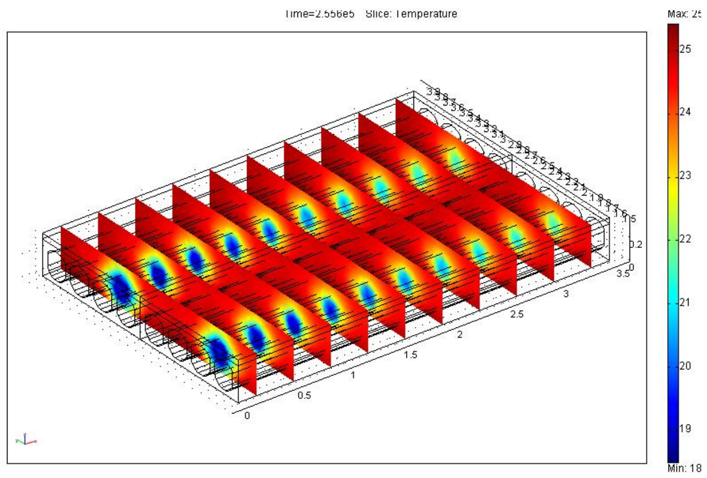

Figure 6. The temperature of the hollow-core structure at midnight.

The results showed that the best indicator for the efficiency of the hollow-core slab as a heat storage is indoor temperature. Even, if the supply air is brought trough one hollow at outdoor temperature the indoor maximum temperature can be dropped 2.2°C. If the air flow is doubled and conducted trough one hollow, the drop in indoor temperature is 6°C in south faced room. By increasing air flow and number of the cores as air channels, indoor temperature can be dropped even 8°C. In north faced room, the indoor temperature can drop from 29.8°C to 24.1°C by using hollow-core slab and increasing air flow. All in all, the excess cooling power is needed at least south faced rooms to achieve indoor temperature 24°C. However, the required cooling power is smaller than in case the hollow-core is not used.

The laboratory tests showed that during the summer night hollow-core slab preheats the incoming cool supply air from +9 °C to +14 °C. Hollow-core slab stores 40 - 70 % of the total cooling energy of supply air. Average storing capacity is 25 W/m² (supply air flow is 40 dm³/s) and 14 W/m² (20 dm³/s) (slab area 12 m²). Less supply air preheating is needed in air handling unit. Most of the time the slab preheats the supply air enough. During the hot summer day hollow-core slab cools down the incoming hot day time supply air from +29 °C to +23 °C. Hollow-core slab stores 60 - 95 % of the excess heat load of hot supply air. Average storing capacity is 20 W/m² (40 dm³/s) and 9 W/m² (20 dm³/s).

Minimum surface temperature of the hollow-core slab in cooling case was +16 ... +19 °C. Lowest temperatures were measured near the supply air inlet of the hollow-core and straight above the hollow-core used as air duct. Surface temperatures do not create any condensation problems or uncomfortable thermal conditions. Even more uniform temperature distribution was measured when extra surface slab was used.

For the full utilisation of the thermal mass it is recommended to use at least two hollow-cores per slab as supply air ducts.

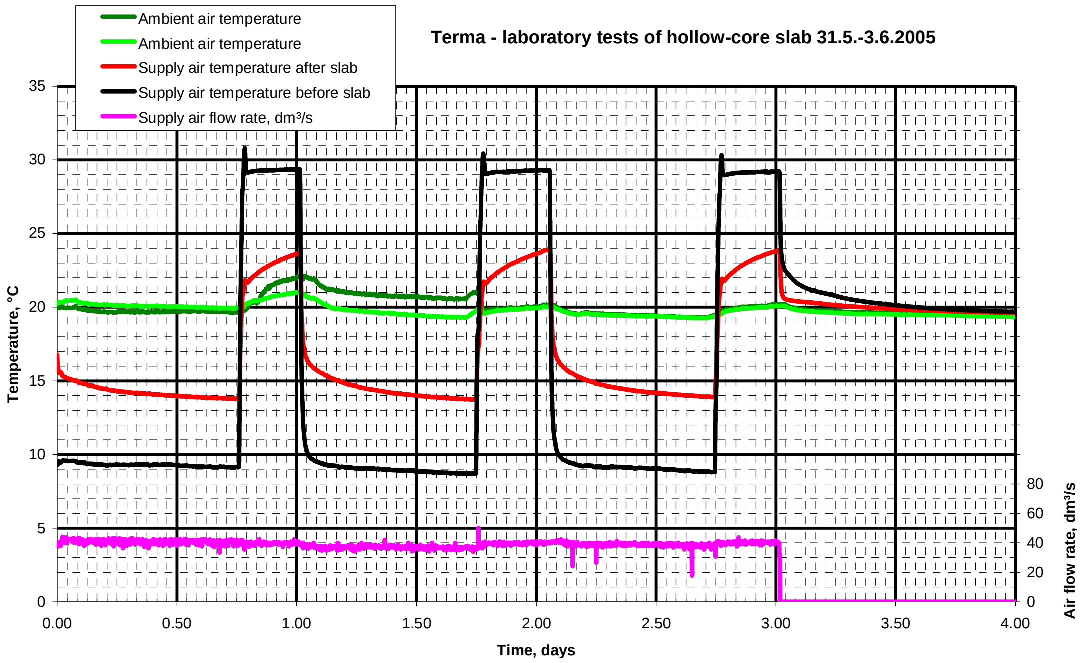

Figure 7. The air temperatures of the hollow-core slab, air flow rate 40 dm³/s, one core as air duct.

After multiphysics simulations and laboratory tests the main TERMA concepts were fixed /11/. TERMA concept utilises thermal mass by air circulation. Both supply and exhaust air distribution and additional night time forced air circulation can be integrated to utilise hollow-core concrete slab (Figure 8). The basic strategy for thermal mass utilisation is:

- *Cooling season*: the slab is cooled down during unoccupied time by night ventilation or forced air circulation to decrease the day time cooling need in the room.
- *Heating Season*: the ventilation air need to be heated less mechanically when the supply air is reheated in the slab by day time heat gains.

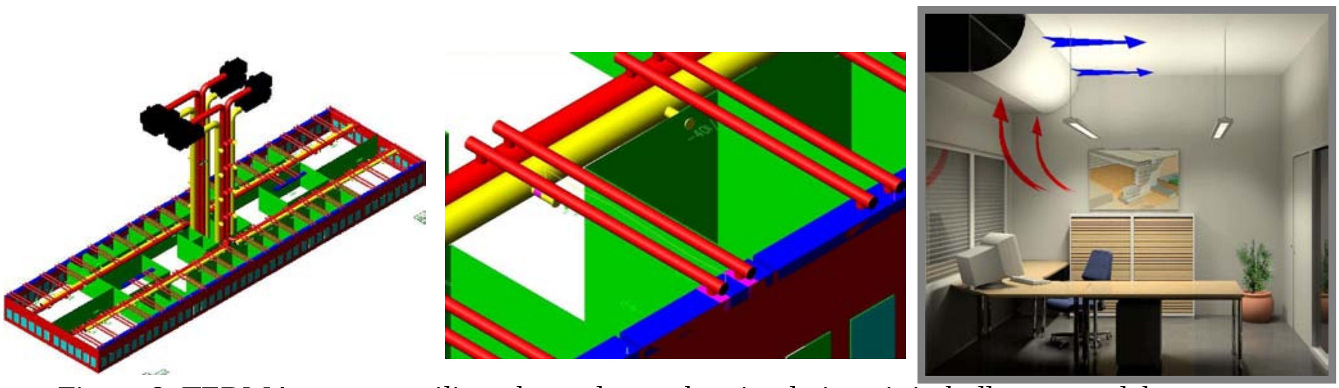

Figure 8. TERMA concept utilises thermal mass by circulating air in hollow-core slabs.

The concepts are divided in four main concepts (TERMA Alfa, TERMA Beta, TERMA Gamma and TERMA Future) which are presented in Figure 9. The characteristics of the different concepts are also presented as well as potential level of energy savings.

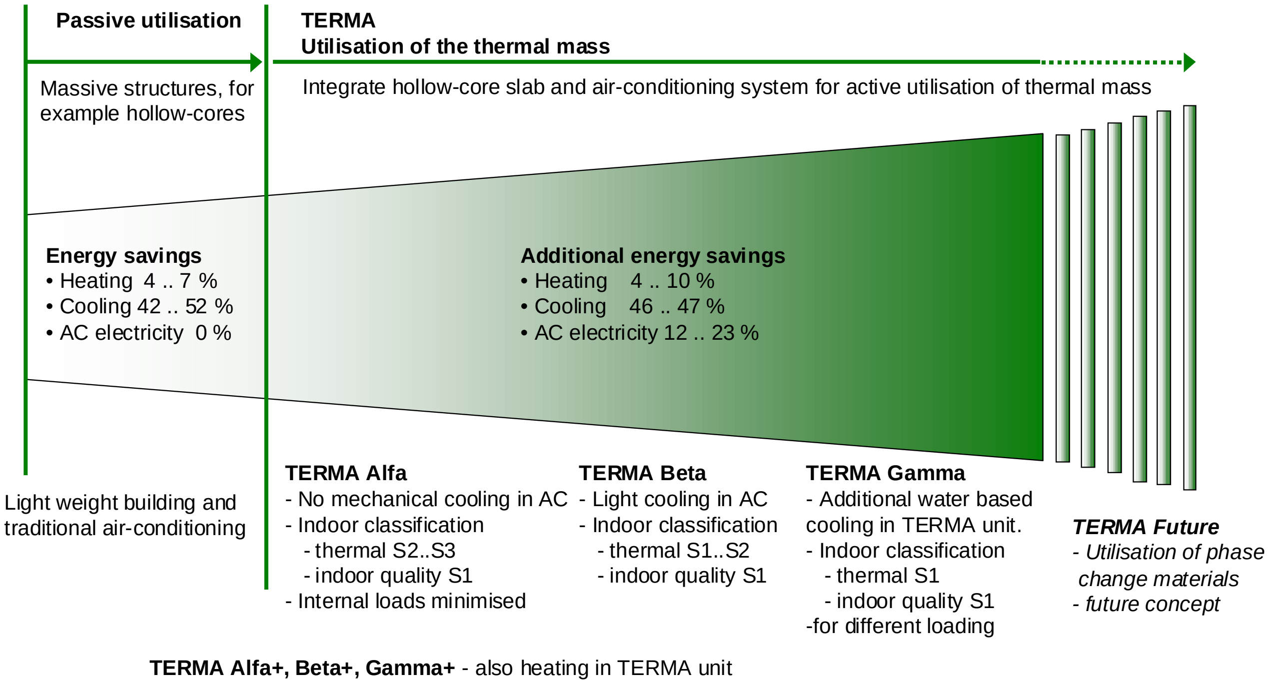

Figure 9. TERMA concepts to fulfil different requirements of building use and indoor comfort.

CFD simulations were used to confirm good thermal comfort for critical parts of occupied zone by using different TERMA concepts. Figure 10 shows the indoor conditions in TERMA Gamma system /10/.

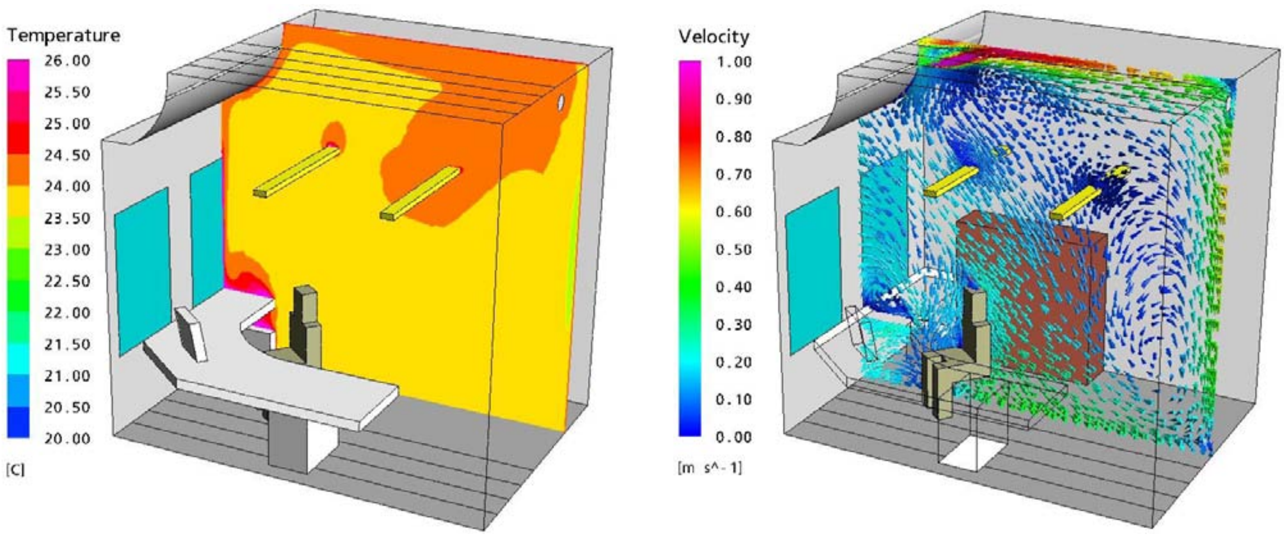

Figure 10. Indoor conditions in TERMA Gamma concept.

TERMA concepts save cooling energy almost 50% (46-47%) compared to traditional variable air volume (VAV) system or cooled beam (CB) system, Figure 11. The saving potential in fan electricity is 12-23% which is indirectly related on cooling, because of smaller air flows in TERMA concepts than in other systems. The heating of the supply air is reduced appr. 10%

and total heating energy of the building appr. 4% compared to traditional AC systems, VAV and CB system /8/.

	VAV	TERMA β	CB	TERMA γ
Cooling electricity	16,5	8,9	24,0	12,6
Fan electricity	164,4	127,4	89,2	78,8
Air ventilation heating	218,6	197,0	181,7	163,8
Space heating	276,3	276,3	297,7	297,7

Figure 11. The energy consumption of the office building.

DISCUSSION

The basis of the concept development in TERMA was in advanced modelling and simulation analysis and laboratory measurements. The simulation models were validated against laboratory measurements. Therefore, the reliability of the hollow-core slab multiphysics simulation was improved considerably. The modelling and simulation gave a good background for development of the new TERMA concepts. The results of the project were good. Four different concepts which integrate thermal mass of hollow-core slabs and air-conditioning system were developed and almost 50% of cooling and 4..10% of heating energy savings potential were recorded.

ACKNOWLEDGEMENT

TERMA project was the development project of PARMA Oy and financially supported by TEKES, the Finnish funding agency for technology and innovation. Companies Olof Granlund Oy and Magnus Malmberg Oy, and VTT Technical Research Centre of Finland conducted research and development of TERMA concepts.

SUMMARY

This paper summarises the work of the LowEx co-operation /1/. The aim was to promote rational use of energy by encouraging the use of low temperature heating systems and high temperature cooling systems of buildings. These systems can use a variety of fuels and renewable energy sources. Energy is used efficiently while providing a comfortable indoor climate. Exergy defines the quality of energy and is a concept for designing and assessing different heating and cooling systems. Application of exergy analysis into buildings has not been common before. Low exergy systems are defined as heating or cooling systems that allow the use of low valued energy as the energy source. In practice, this means systems that provide heating or cooling energy at a temperature close to room temperature.

Low exergy systems successfully combine both traditional and innovative new approaches. Research shows that people living in houses with low exergy systems are very satisfied with indoor environment quality. The demonstration projects, in turn, show the wide variety of possibilities to apply low exergy heating and cooling systems in buildings. The Guidebook, which was the final product of LowEx cooperation, is meant to help engineering offices, consultants and architects in their search for energy efficient heating and cooling systems that can provide the occupants with comfortable, clean and healthy environment. In addition, some background information is offered for real estate builders, building maintenance managers, political decision makers and the public at large.

INTRODUCTION

The necessity for an increase in the efficiency of energy utilisation in buildings is obvious and indisputable. Heating, cooling and lighting appliances in buildings cause more than one third of the world’s primary energy demand. Thus, the building stock contributes as a major actor to the energy related environmental problems. “Energy saving” and emission reduction are both affected by the energy efficiency of the built environment and the quality of the energy carrier in relation to the required quality of the energy. Taking into account qualitative aspects of energy leads to introduction of the exergy concept in comparison of systems, which was the key idea of LowEx research programme. LowEx, the international low temperature heating systems research programme (IEA ECBCS Annex 37), was part of the International Energy Agency’s (IEA) Energy Conservation in Buildings and Community Systems programme (ECBCS). The aim of the programme was to promote rational use of energy by encouraging the use of low temperature heating systems and high temperature cooling systems of buildings. In Annex 37 these systems were called low exergy (or LowEx) systems.

Exergy is energy, which is entirely convertible into other types of energy. High valued energy such as electricity and mechanical workload consists of pure exergy. Energy, which has a very limited convertibility potential, such as heat close to room air temperature, is low valued energy. Low exergy heating and cooling systems allow the use of low valued energy, which is delivered by sustainable energy sources (e.g. by using heat pumps, solar collectors, either separate or linked to waste heat, energy storage etc.).

Future buildings should be planned to use or to be or to be suited to use sustainable energy sources for heating and cooling. One characteristic of these energy sources is that only a relatively moderate temperature level can be reached, if reasonably efficient systems are desired. The development of low temperature heating and high temperature cooling systems is a necessary prerequisite for the usage of alternative energy sources. The basis for the needed energy supply is to provide occupants with a comfortable, clean and healthy environment.

EXERGY CONCEPT

What we really should start talking about, because this is what we actually mean, is “saving exergy” and “exergy consumption”. One reason for using the exergy approach and not just settling for the primary energy approach is that it is physically more correct to talk about exergy than energy consumption and production. It is a fact that the term exergy is an unknown term even for scientists not to mention “people on the street”. In order to make this term less strange we need to first of all start talking more about it and stop using the term energy when we actually mean exergy.

In Figure 1 are shown a large enclosure with adiabatic boundaries containing a lot of air at the initial temperature of Ti and a small container of fuel. It is furthermore supposed that the fuel burns in air, heating the surrounding air and environment so that there is a slightly warm mixture of combustion products and air in the final state. It is obvious that the total quantity of energy in the enclosure is the same as in the initial state. But the combination of fuel and air in the initial state has a greater potential to be useful than the warm mixture in the final state. The fuel can be used in a device to generate electricity, do work or heat rooms. But the uses for the slightly warm combustion products are much more limited. It can be stated that the initial potential has been destroyed to a large extent.

The same fact, that there is an energy quality, can be illustrated by another example evident for us from our experience in daily life (Figure 2). It is obvious that 100 kJ electricity stored in a 12 V / 2.3 Ah car-battery is more useful, easier to transform into something useful for us, than the same amount of energy stored in 1 kg water at a temperature of 43 °C in an ambient temperature of 20 °C. The electricity is suitable for running a machine, like a computer, operating a light bulb of 40 W for 42 min or at least heating 1 kg of water with 23 °C. The 100 kJ heat contained in the 1 kg water is only suitable for washing our hands or doing the dishes. It becomes clear that there is a difference between the types of energy. By introducing the term exergy we appreciate the fact that energy manifests itself by its quantity and its quality.

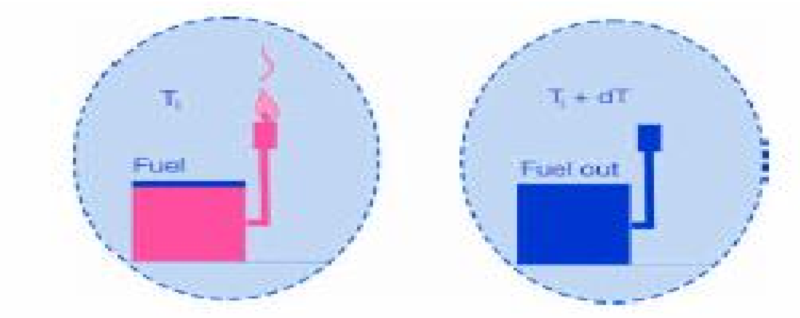

Figure 1. Combustion of fuel in air as an example to show the difference between energy and exergy analysis.

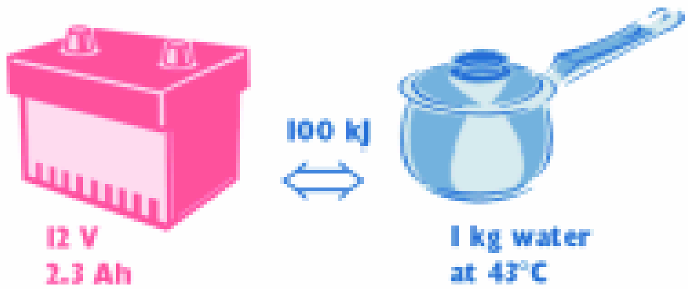

Figure 2. Both systems contain the same amount of energy but not the same amount of exergy.

Despite the efforts made to improve energy efficiency in buildings, the issue of gaining an overall assessment, and comparing different energy sources still exists. Today's analysis and optimisation methods do not distinguish between different qualities of energy flows during the analysis. An assessment of energy flows from different sources is first done at the end of the analysis by weighting them with the primary energy factors. The primary energy factors necessary for the calculation are not based on analytical ground or thermodynamic process analyses, yet they have been derived from statistical material and political discussion. In the theory of thermodynamics, the concept of exergy is stated to be the maximum work that can be obtained from an energy flow or a change of a system. The exergy content expresses the quality of an energy source or flow. This concept can be used to combine and compare all flows of energy according to their quantity and quality. Exergy analysis is commonly used in, for example, the optimisation processes of power stations. This method can be applied to buildings, as well. Most of the energy is used to maintain room temperatures at around 20 °C. In this sense, because of the low temperature level, the exergy demand for applications in room conditioning is naturally low. In most cases, however, this demand is satisfied with high quality sources, such as fossil fuels or using electricity. Exergy analysis provides us with additional information on where and when the losses occur. It helps us to see in which part of the energy chain the biggest savings can be achieved. The need for energy saving is based on the will to reduce the effects of our actions to the environment.

Exergy consumption within the human body becomes higher in a cold environment due to larger difference in temperature between the human body and its surrounding space and also becomes higher in a hot environment mainly due to sweating. It is interesting that the thermally comfortable condition is provided with the lowest exergy consumption rate within the human body. This suggests that rational heating and cooling systems in buildings would work well with low exergy consumption under a condition in which we humans consume as low amount of exergy as possible. That is, we may be able to establish both thermal comfort and low-exergy consuming systems at the same time.

The lowest human body exergy consumption occurs at thermally neutral condition. Figure 3 shows a new relationship between the human body exergy consumption, thermal comfort (PMV*=0), room air temperature and mean radiant temperature. The lowest exergy consumption rate emerges at the point where the room air temperature equals 18 °C and mean radiant temperature 25 °C. This suggests that the use of radiant warm exergy is more effective than the use of convective warm exergy for a heating purpose to realise both thermal comfort and as low exergy consumption within the human body as possible. Such a built environment can be provided by a moderate radiant heating system combined with passive heating strategies, for example, good thermal insulation and suitable thermal exergy storage capacity of building envelopes, solar thermal exergy gain through properly insulated window glazing and others. It is interesting to see that, from the exergetic point of view, there is an optimal combination of room air temperature and mean radiant temperature which results in thermally neutral conditions, namely PMV*=0, although, from the conventional energetic point of view, there are many combinations of room air temperature and mean radiant temperature.

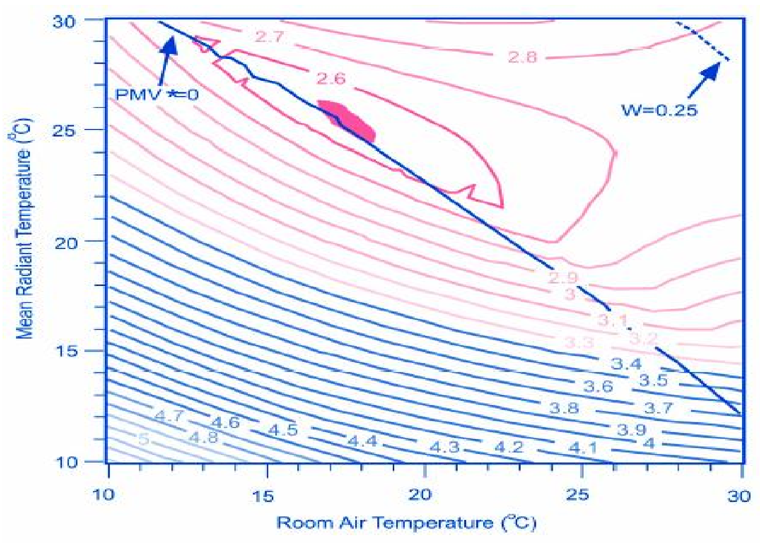

Figure 3. The relationship between exergy consumption within the human body (W/m^2), room air temperature, and mean radiant temperature. The solid line descending from the upper left corner to the lower right corner indicates thermally neutral conditions (PMV=0). The broken line in the upper right corner is skin wetness up to the amount which most people find tolerable (W=0.25). There is an optimal combination of room air and mean radiant temperatures which results in the lowest exergy consumption and thermal comfort.*

EXERGY ANALYSIS TOOLS

To increase the understanding of exergy flows in buildings and to be able to find possibilities for further improvements in energy utilisation in buildings, pre-design analysis tools were produced during the Annex 37 work. It was recognised the importance of developing a simplified tools to visualise why low exergy systems would be advantageous in some energy chains compared to high exergy systems. These tools should be easy to use and show the exergy flow through a system or energy chain (see Figure 4).

LOW EXERGY TECHNOLOGIES AND SYSTEM CONCEPTS

For future buildings, a minimum of energy at a very low level of temperature difference between the system and the room should be used for thermal conditioning. In this way a maximum of high quality energy (exergy) could be saved. The big efforts made in the field of energy saving in buildings by constructing well-insulated and tight envelopes, sufficient window shading and the use of thermal storage result to a much better usage of the energy. But there is still a big saving potential left. To make the energy use in buildings even more efficient, new low temperature heating and cooling systems are required. The components and systems presented show a step further in this direction. The Guidebook, which was the final product of LowEx cooperation, consists of sixtytwo information sheets, which describe the technologies; their basic principles, technical risks and benefits, advantages, limitations and state-of-art (commercially available, prototype or innovative concept). The idea was to give a quick overview of the possibilities and limitations of the technologies. Some system concepts, which are compiled with these components are also presented.

In recent years system solutions have appeared where heating and cooling is carried out in a holistic system solution where the energy use is planned in a wider and more general perspective. An example of this is the Sensus® building services system (Figure 5). The exergy consumption of the Sensus ® system is lower than in comparable high-standard systems, which also decreases environmental impact during use. Office ventilation employs a Sensus® ventilation unit connected to the Sensus panels with a three-pipe network. The ventilation units utilise surplus heat collected from the rooms with the cooling water system for the heating of intake air whenever heating is needed for the intake air. This conserves heating exergy. The ventilation machine also has an efficient rotating heat collector for the exhaust air (over 70 % heat efficiency). The Sensus® ventilation unit utilises outdoor air for cooling the cooling water for the rooms when outdoor temperature is sufficiently low (under +12–14 °C). This free cooling carried out with ventilation units operates alongside mechanical cooling when necessary. It has a considerably longer annual period of utilisation (over half of the year' s working hours) than conventional free cooling. This lowers the electricity consumption of cooling unit in the Sensus® system in comparison with conventional solutions.

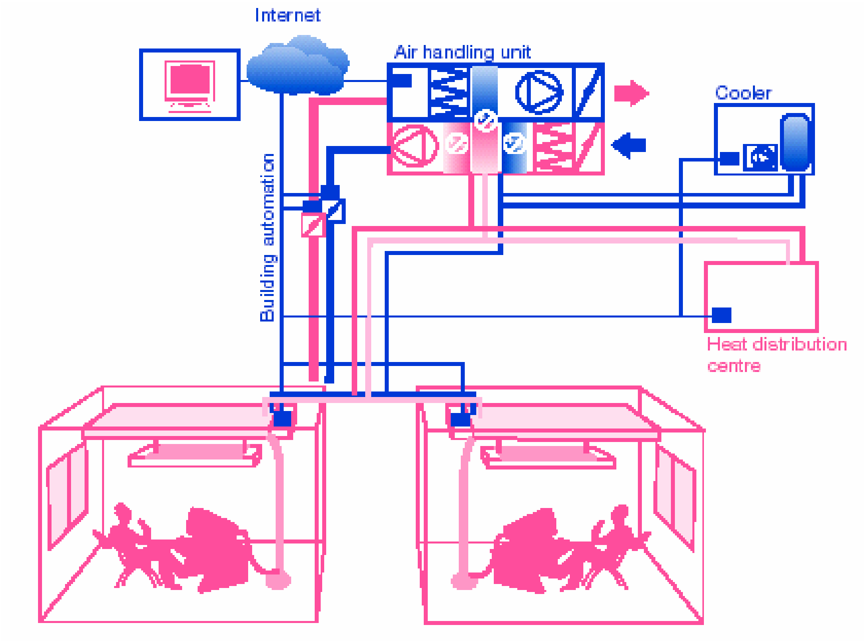

Figure 5. The Sensus system solution.

EXPERIENCES FROM CASE STUDIES

The case examples of the LowEx programme show the wide variety of system applications. They also demonstrate the flexibility of the systems with regard to the energy source. There are 30 examples of LowEx systems in dwellings and offices, but also in a museum, a church and a concert hall. Findings from cases show that the application of LowEx systems provides many additional benefits besides energy supply, such as improved thermal comfort, improved indoor air quality and reduced energy consumption.

One of the critical success factors for the implementation of, for example, low temperature heating systems in residential buildings is the way these systems are viewed and accepted by the occupants. An occupant survey was conducted in the Netherlands in October 1999 among 409 households with these systems. Occupants were asked about their opinion of the indoor climate in terms of whether or not it had improved in relation to the indoor climate in their previous dwelling. Notable was the very positive score for floor and wall heating. Although low temperature heating systems are very well accepted and appreciated, there are some negative aspects and disadvantages that should be taken into account and solved. These are, for example, system controllability per room (floor and wall heating) and the size, design and installation of low temperature radiators. The study shows that lowering the temperatures for heat distribution systems, besides the possibilities of savings in energy supply, gives additional benefits such as:

- thermal comfort increases in many respects (greater share of radiant heat transfer, less temperature gradients, better floor contact temperature, less draught and air turbulence);
- the indoor air quality is also positively influenced (less dust singe and house dust mites, less stuffiness and odours through lower air temperature, less suspended particles);
- in addition to the ability to use low valued energy, savings are gained from better performances of boilers and heat pumps, less piping heat loss and less ventilation losses.

Other benefits might occur, like avoidance of burning risk, extra space due to the absence of radiators, avoidance of mould growth, etc. It can therefore be concluded that LowEx systems are not only preferable from an exergy point of view, people also seem to appreciate the “softer” heat and coolness of the LowEx systems much more than the traditional heating and cooling solutions.

CONCLUSIONS

Exergy defines the quality of energy and is an important tool for designing and assessing different heating and cooling systems. Low exergy (or LowEx) systems are defined as heating or cooling systems that allow the use of low valued energy as the energy source. In practice, this means systems that provide heating or cooling energy at a temperature close to room temperature. Low temperature heating systems or high temperature cooling systems that are suitable for office buildings, service buildings and residential buildings, can use a variety of fuels and renewable energy sources. These systems use energy efficiently while providing a comfortable indoor climate. They should be widely implemented now in order to create possibility to use sustainable energy sources in the near future.

The classical exergy analysis enables to pinpoint the location, to understand the cause, and to establish the true magnitude of waste and loss. Exergy analysis is therefore an important tool for the design of thermal systems since it provides the designer with additional information on where and why the losses occur. The designer can then proceed forward and work on how to improve the thermal system. Application of exergy analysis into buildings has not been usual before. Exergy analysis can also be applied to human body to find optimal thermal conditions. Studies show that the lowest human body exergy consumption occurs at thermally neutral condition. Exergy consumption within the human body becomes higher in a cold environment due to larger difference in temperature between the human body and its surrounding space and also becomes higher in a hot environment mainly due to sweating. These findings suggest that heating and cooling systems may also work well in such conditions where the lowest amount of exergy is consumed by those systems. That is, we may be able to establish both thermal comfort and low-exergy consuming systems at the same time. The human body exergy analyses have now just started to articulate why LowEx systems are essential for creating rational and comfortable built environment.

There are currently many LowEx technologies available. Low temperature systems successfully combine both traditional and innovative new approaches to heating. Usually the heat is transferred into the room through air or liquid circulation systems and the same system can often be used for both heating and cooling. Research shows that people living in houses with low temperature heating systems are very satisfied with ambient indoor air quality. In particular, thermal comfort levels are considered to be higher than in houses with a traditional heating system. Residents also experienced a reduction in draughts and dust, and reported fresher air in houses with low temperature heating systems. By using low temperature heating systems the room temperature can be decreased by a few degrees, which is more energy efficient and healthier for occupants. Low temperature heating systems are sustainable because they are flexible. These systems are not bound to any one energy source and fuel switching does not entail excessive cost. Low temperature systems can utilise a variety of sources of heat including district heat, biofuel, solar energy, gas, oil or electricity, and so the user is not constrained by choices made in the planning phase.

Thorough planning and expert implementation are prerequisites for an appropriate and functional system. System flexibility will be dependent on the choice of appliances and overall system design, which can be difficult and expensive to change after installation. Low temperature heat distribution systems have an operating life of at least 30-40 years during which time the user benefits from the economic advantages offered by flexibility of fuel choice. The life cycle costs of a low temperature heating system are about the same as of a traditional system. Although the initial investment might be slightly higher, the system offers increased flexibility in terms of fuel choice and increased energy efficiency. For example the efficiency of solar heating is considerably higher in a low temperature heating system than in a traditional one.

The demonstration projects show the wide variety of possibilities to apply low exergy heating and cooling systems in buildings. The application of LowEx systems provides many additional benefits besides energy supply such as: improved thermal comfort, improved indoor air quality and reduced energy consumption. These aspects should be further promoted to increase the application of LowEx systems for heating and cooling of buildings. The building regulations and energy strategies should take the quality of energy into account more than today. Wide application of LowEx heating and cooling systems in buildings will create a building stock, which will be able to adapt to use of sustainable energy sources, when desired. Without this ability, the transfer towards an energy-wise sustainable world will be delayed for decades.

The Guidebook, which was the final product of LowEx co-operation, is meant to help engineering offices, consultants and architects in their search for energy efficient heating and cooling systems that can provide the occupants with comfortable, clean and healthy environment. In addition, some background information is offered for real estate builders, building maintenance managers, political decision makers and the public at large. The Guidebook is available as a CD-rom version and also freely available on the internet (http:// www.lowex.net/).

A Combined Low Temperature Water Radiator and Floor Heating System

SUMMARY

Space heating load is decreasing in modern Finnish apartments due to better construction of building envelopes (lower U-values for the construction and more tight envelopes) and use of heat recovery in the ventilation. The decreasing load for space heating makes it possible to develop a new combined low temperature water heating system. Such a system includes both radiators in rooms and floor heating in bathrooms. The nominal supply and return water temperatures are 45 ºC and 35 ºC, respectively.

In this study, the performance of an apartment building connected to a combined low temperature water heating system is determined by using dynamic building performance simulation. The results are compared with those for two conventional radiator and floor heating systems. The simulation results show that the combined low temperature water heating system performs well and it is comparable to the other conventional heating systems. It supplies the studied zones by the needed space heating energy and is able to maintain the zones in the required temperature levels showing significantly less temperature fluctuation compared to the floor heating system. This system appears to have the benefits of the two combined systems. The required primary energy for the combined low temperature system is low due to the use of district water heating. The system is also suitable for other types of low temperature heat sources, such as heat pump solutions.

Keywords: low temperature, water radiator, floor heating, heating energy

INTRODUCTION

A common heating system in Finnish apartment buildings is a water radiator system which operates by district heating water. The supply and return water temperatures are 70 ºC and 40 ºC, respectively, at an outdoor air temperature of –26 ºC, which are the design temperatures for southern parts of Finland. The supply water temperature is outdoor air temperature compensated; i. e. the supply water temperature increases as the outdoor air temperature decreases. In typical Finnish buildings, floor heating is expected in bathrooms and toilets. As the supply water temperature is too high for direct use in floor heating, a secondary circuit with a mixing valve is one option to lower the operating temperature. However, this arrangement is expensive and is not practically used. Another option is to use electrical floor heating. Major disadvantages of this method are high consumption of the primary energy and its On/Off switching.

Heat losses are becoming low in modern Finnish apartments due to lower U-values for the construction and more tight envelopes. Besides, heat recovery units, which recover heat form exhaust air, are increasingly used nowadays. All these factors result in a decreasing load for space heating. This situation leads to thinking about developing a new combined low temperature water heating system which includes both radiators in rooms and floor heating in bathrooms. The nominal supply and return water temperatures are 45 ºC and 35 ºC, respectively, at an outdoor air temperature of –26 ºC for southern parts of Finland. This system is simple, easy to install and expected to perform well compared with conventional systems. The application of such a system is mainly in apartment buildings and also possible in detached houses.

The objective of this study is to determine the performance of an apartment building connected to a combined low temperature water heating system by using dynamic simulation. Indoor air temperatures and required heating energy for the building will be compared with simulation results for two conventional radiator and floor heating systems.

Description of the Building

In this study, three flats in a third floor of a four storey residential building is investigated. Fig. 1 shows the building floor plan. The flats have concrete construction with medium heaviness. The U-values (W/m^2K) of the external wall and windows are 0.25 and 1.4, respectively. These values are in accordance with the Finnish National Building Code C3 of 2003 [1]. Good air tightness of the building is considered: the air leakage value n_{50} is 1.0 l/h.

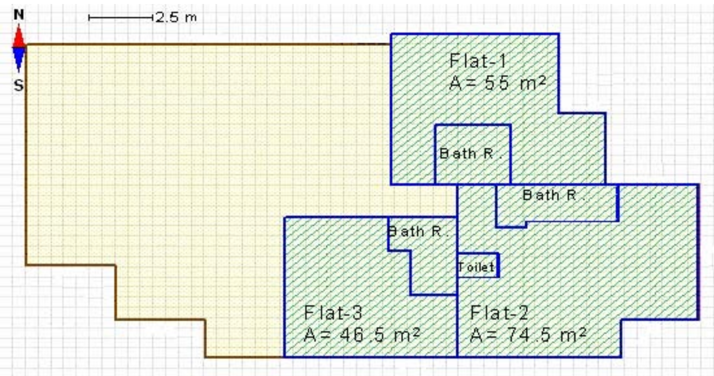

Fig. 1. Floor plan of the studied flats.

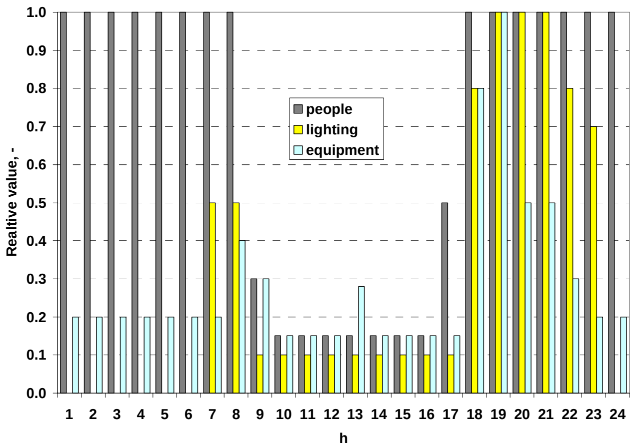

Fig. 2. Relative profile of the internal heat gains.

An hourly profile of internal heat gains (from people, lighting and equipment) for one day is assumed, which is based on averaging more detailed ones for working days and weekends. The relative profile is shown in Fig. 2. The number of occupants in each flat is: 2 in Flat-1, 3 in Flat-2 and 2 in Flat-3. The mean internal heat gain for Flats 1, 2 and 3 is 6.76, 7.80 and 6.07 W/m^2, respectively.

HVAC Systems

Three heating systems are investigated in this study and as indicated in table 1. For System 1, water radiators with conventional water temperature levels are used in the rooms and electric floor heating is used in the bathrooms. For System 2, water floor heating with conventional water temperature levels is used in all zones (rooms and bathrooms). The combined low temperature water system is used in System 3 which comprises water radiators in the rooms and water floor heating in the bathrooms. It is to note that bathrooms in this study refer to toilet rooms as well.

Table 1. Heating systems.

	Rooms	**Bathrooms**
System 1	Water radiators (sizing temperatures: supply/return = 70/40 ^{o}C)	Electric floor heating (Sizing power = 100 W/m^2)
System 2*	Water floor heating (max. water supply temperature is 40 ^{o}C)	Water floor heating (max. water supply temperature is 40 ^{o}C)
System 3	Water radiators with combined low water temperature levels (sizing temperatures: supply/return = 45/35^{o}C)	Water floor heating with combined low water temperature levels (max. water supply temperature is 45 ^{o}C)

* According to the temperature control in the rooms: System 2A is on the indoor air temperature at 21 ^{o}C and System 2B on the floor surface temperature at 24 ^{o}C.

The selected water radiators in the rooms for Systems 1 and 3 is PURMO-Compact type 11 (height = 400 mm and width = 1400 mm) [2]. The number of water radiators in each flat is: 3 in Flat-1, 4 in Flat-2 and 2 in Flat-3. The sizing of the water floor heating system is based on a maximum water temperature drop of 10 ^{o}C and a maximum heating power of 50 W/m^2. The supply water temperature, to the radiators and/or the floor heating, is outdoor air temperature compensated and as shown by Fig. 3.

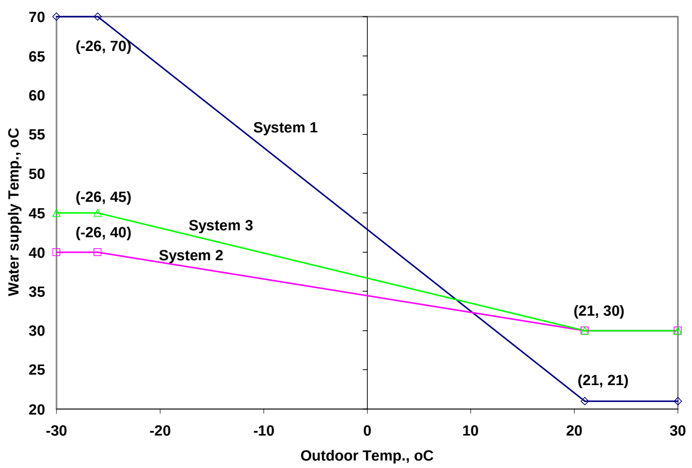

Fig. 3. Hot water supply temperature as a function of outdoor air temperature.

The temperature control inside the rooms is on the indoor air temperature at a set point of 21 ^{o}C. In addition to this control, the all-flat water floor heating investigates another possibility of control which is according to the floor surface temperature at a set point of 24 ^{o}C (System 2B). For the bathrooms, the temperature control is on the floor surface temperature at a set point of 27 ^oC. This temperature keeps the floor surface warm and produces drying effect on the bathroom's floor surface. To reach this temperature, the minimum water supply temperature to the floor heating in Systems 2 and 3 is set at 30 ^oC and as indicated by Fig. 3.

Each flat is connected to one air handling unit (AHU) which comprises two fans (supply and exhaust). The supply fan brings in fresh air from the outdoor. There is a heating coil in each AHU which heats air to a supply temperature of 17 ^oC. The exhaust fan drives the exhaust air through a heat recovery exchanger before it is discharged outside the building. The heat recovery exchanger heats up the air before it passes across the heating coil. The efficiency of the heat recovery is assumed equal to 0.6. The hourly air change rates (ACH) for Flats 1, 2 and 3 are 0.75, 0.69 and 0.89 1/h, respectively.

Normally, there is no cooling system in Finnish apartment buildings (neither inside the rooms nor in the AHU). Instead a window opening action in each room is implemented when the indoor air temperature exceeds 26 ^oC. The building location is in Helsinki. The hourly weather file for 1979 is considered.

METHOD

The performance of the building and the HVAC system is evaluated using the IDA Indoor Climate and Energy 3.0 program (IDA ICE 3.0) [3]. It is a whole-building simulation program with climate processor and simultaneous airflow and heat transfer dynamic simulation. The program can be used for the simultaneous performance assessments of all issues fundamental to a building design: shape, envelop, glazing, HVAC systems, controls, light, indoor air quality, comfort, energy consumption etc. The accuracy of the IDA ICE 3.0 was assessed through the IEA solar heating and cooling programme, Task 22, sub Task C [4]. In addition to heat transfer between adjacent zones, IDA ICE 3.0 calculates air flow through vertical openings and leaks between the zones.

Simulations are carried out to find the indoor air and floor surface temperatures of the rooms and the required energy for space heating for the studied flats. For this purpose the flats are divided into zones. Due to the different heating systems implemented for each zone, the bathroom and the toilet room are considered as separate zones than the rest of the flat which is taken as another zone.

RESULTS

Fig. 4 shows the hourly simulation results for the temperatures of Flat-2 zone (excluding the bathroom and toilet zones). Figs. 4A- 4D display the air temperature which show that it is affected by the characteristics of the implemented heating system. Fig. 4C is the air temperature duration curves and Fig. 4D is the room air temperature in the first week of January. From these figures, it is noticed that using the floor heating system (Systems 2A and 2B) results in higher fluctuations of the indoor air temperature (Fig. 4B) compared with the water radiator system (Systems 1 and 3) (Fig. 4A) which are more stable. This is due to the slow action of the floor heating system because it heats up the floor mass first, and from which heat transfers to the room air. The air temperature with System 2B is higher than with System 2A because the control in the former case is on the floor surface temperature at 24 ^oC, while for the latter case it is on the air temperature at 21 ^oC. For the two systems which use water radiators: the air temperature with the combined low temperature system (System 3) acts in a similar way to that with the conventional high temperature system (System 1). There is only a slight temperature drop between the two cases which is due to the lower inlet water temperature to the radiators for System 3. However, the air temperature inside the rooms is still in the acceptable temperature range (> 20 ^{o}C), which is even better than that for the water floor heating system (Systems 2A and 2B) as the duration curves inform.

Figs. 4E and 4F show the floor surface temperature of the Flat-2 zone. The temperature fluctuations with the floor heating system (Systems 2A and 2B) can be clearly noticed. The higher temperature levels are for System 2B. The floor surface temperature control for System 2B is set at 24 ^{o}C with ± 0.5 K band and as shown by these figures. For the water radiator systems (Systems 1 and 3), the room floor surface temperature follows that for the air temperature and as can be noticed from the results for the first week of January (Fig. 4F).

Fig. 5 shows the air and floor surface temperatures of the bathroom of Flat-2. The floor surface temperature control is set at 27 ^{o}C (with ± 0.5 K band). The proposed combined low temperature systems (System 3), as well as the other systems, appear to operate well in the required temperature range. However, using the electric floor heating (System 1), the floor surface exhibits more temperatures >27.5 ^{o}C (Fig. 5A). The reason could be the higher power rating of the electric floor heater (100 W/m^2) compared with that for the water floor heating (maximum is 50 W/m^2). The systems using water floor heating (Systems 2 and 3) work closely as indicated by the floor surface temperature duration curves (Fig. 5D). This can also be realised from the air temperature inside the bathroom (Figs. 5E and 5F), with higher values for System 2B as before.

The required energy for space heating of the three flats is indicated in Table 2. It is consisted of heating energy to the flats, which covers heating energy to the radiators and floor heating in the rooms and bathrooms, and energy to the heating unit in the AHU. To see the distribution of the heating energy, let us consider System1: the total required space heating energy is 8852 kWh. The heating energy to the AHUs is 2547 kWh (29% of total) and 6305 kWh to the flats (71% of total). This latter is consisted of 2889 kWh (32% of total) by the radiators in the rooms supplied by district heating water and 3416 kWh heating energy to the bathrooms (39% of total) supplied by the electric floor heaters. It is to note that the bathroom heating energy demand is a considerable percentage of the total energy, especially when we know that the bathrooms area is about 16% of the total flats area. This heating energy is used for bathroom heating and it also flows to other adjacent zones due to bathroom’s higher temperature. The conclusion is that the warm floor surface of the bathroom has its expense in terms of heating energy. This is valid for the other studied systems as well. For System 2B, the heating energy to the flats is 11% higher compared with that for System 1, while it is close for the other systems (1, 2A and 3). This is due to the implemented control on the room’s floor surface temperature in System 2B. The heating energy to the flats in Systems 2 and 3 (to the radiators and floor heating) is all supplied by district heating water. The AHU heating coils for all the systems work with district heating water. There is 10% reduction in the heating energy for the AHU in System 2B compared with that for System 1, which is due to higher amount of recovered heat from the exhaust air. As a resultant, the total required space heating energy is close for all the studied systems as there is a only a slight difference (-3% to +5%) form that for System 1.

Besides, table 2 indicates the required primary energy for the studied systems. Typical conversion factors for CHP are implemented to calculate the primary energy from the space heating energy (0.5 for district water heating and 2.0 for electric heating). The latter is applicable for the bathrooms floor heating in System 1. This produces a dramatic increase in the required primary energy for this system with respect to the other systems. The required primary energy for the combined low water temperature system (System 3) is at the lowest level of the investigated systems as appears from the results in table 2.

Table 2. Required energy for the three flats.

	Space Heating Energy (kWh)				Primary Energy (kWh)			
	Flats	AHUs	Total	Ratio to system 1	Flats	AHUs	Total	Ratio to system 1
System 1	6305	2547	8852	1.00	8277	1273	9550	1.00
System 2A	6118	2479	8597	0.97	3059	1240	4299	0.45
System 2B	7024	2291	9315	1.05	3512	1145	4657	0.49
System 3	6108	2460	8568	0.97	3054	1230	4284	0.45

CONCLUSIONS

The simulation results indicate that the combined low temperature water heating system can keep the three studied flats in an acceptable temperature range. Despite of its low water supply temperature (max. 45 ^{o}C), the water radiators can still fulfil the thermal requirements inside the rooms by keeping the air temperature > 20 ^{o}C. Besides, it is capable of maintaining the bathroom floor surface within the required temperature levels. Such a system gathers the benefits of the two combined systems.

The space heating energy provided by the combined low temperature system is comparable to those provided by the other two systems (water radiators with conventional water temperature in the rooms and electric floor heating in the bathrooms, and water floor heating with conventional water temperature in all zones). The required primary energy for the combined low temperature system is at the lowest level of the investigated systems. It is also revealed that bathroom floor heating energy is a significant amount of the total energy heating demand.

The combined low temperature water heating system could be used with decentralised low temperature water production units serving a certain number of buildings. It could also be connected with primary district water heating networks operating with conventional high supply temperatures. In this case, better use of the thermal potential of the primary district heating water could be made which allows lowering its return temperature. This would result in increase of the efficiency of the heat generation plant.

SUMMARY

Due to the increasing use of embedded, hydronic systems for heating and now also cooling of buildings there has been a need to revise the existing European standard EN1264-part2 for floor heating. At the same time a new set of standards EN15377 for these systems has been developed in relation to the many CEN-standards developed for implementing the Energy performance of Buildings directive.
The EN1264 standard series [1,2,3,4,5] have been revised as testing and prove standards for floor heating. A new part is now included for other surfaces (ceiling, walls) and also for cooling. The standard presents a test method either by calculation or by experimental testing. In this way the heating-cooling capacity can be tested under standardized conditions and used for certification.
The new standard EN15377 [6,7,8] includes calculation method for design and dimensioning of embedded radiant heating and cooling systems. For some systems the same calculation methods as in EN1264 is used for design and dimensioning. For other system types not covered by EN1264 new calculation methods are included. A separate part is dealing with systems (TABS) embedded directly in the building mass (slabs). This part shows how to take into account the dynamic behavior of the system.

INTRODUCTION

Formatted: Bullets and Numbering

The new standard for embedded, water based surface heating and cooling systems, EN15377 consists of the following parts:

— Part 1: Determination of heating and cooling capacity

— Part 2: Design, dimensioning and installation

— Part 3: Optimizing for use of renewable energy sources and dynamic considerations

In Part 1 the steady state heating and cooling capacity is determined calculation in accordance with design documents and a model. The calculation models are listed in prEN1264 part 2 and 5 and in EN15377-1. In the case of special constructions and if necessary, the determination of thermal performance by calculation is combined with a test method according to EN1264-2.
The heating-cooling capacity is given as a function of the temperature difference between room and mean water temperature.
The surface temperature and the temperature uniformity of the heated/cooled surface, nominal heat flow intensity between water and space, the associated nominal medium differential temperature and the field of characteristic curves for the relationship between heat flow intensity and the determining variables are given as the result.
The standard include several methods like general Finite Difference or Finite Element methods, simplified calculation methods depending on position of pipes and type of building structure. The simplified calculation methods are specific for the type of system. The standard is for

systems which are calculable in accordance with EN1264 part 2 and part 5. The simplified methods include certain boundary conditions, which must be met before the given method is applied.

CONCEPT OF THE METHOD TO DETERMINE THE HEATING AND COOLING CAPACITY

A given type of surface (floor, wall, and ceiling) delivers, at a given average surface temperature and room temperature (operative temperature θ_i), the same heat flow intensity in any space independent of the type of embedded system. It is therefore possible to establish a basic formula or characteristic curve for cooling and a basic formula or characteristic curve for heating, for each of the type of surfaces (floor, wall, and ceiling), independent of the type of embedded system, which is applicable to all heating and cooling surfaces.
Two methods are included in this standard:
Different simplified calculation methods are included in for calculation of the surface temperature (average, maximum and minimum temperature) depending on the system construction (type of pipe, pipe diameter, pipe distance, mounting of pipe, heat conducting devices, distribution layer) and construction of the floor/wall/ceiling (covering, insulation layer, trapped air layer, etc). The simplified calculation methods are specific for the given type of system, and the boundary conditions listed in the standard must be met. In case a simplified calculation method is not available for a given type of system, either a basic calculation using two or three dimensional finite element or finite difference method can be applied or a laboratory testing in combination with a calculation may be applied according to EN1264
Based on the calculated average surface temperature at given combinations of medium (water) temperature and space temperature, it is possible to determine the steady state heating and cooling capacity. If proved certificated values for the specific thermal output shall be used, generally EN 1264 part 2 and/or Part 5 apply.

HEAT EXCHANGE COEFFICIENT BETWEEN SURFACE AND SPACE

The relationship between heat flow intensity and the temperature difference between room and average surface temperature (θ_i - $\theta_{S,m}$) is given by equations (1) to (4)) depending on the type of surface (floor, wall, ceiling) and whether the temperature of the surface is lower (cooling) or higher (heating) than the space temperature.

Table 1 - Total heat exchange coefficient (combined convection + radiation) between surface and space, recommended max/min surface temperatures and heating capacity by 20 °C room temperature and cooling capacity by 26 °C room temperature for cooling (EN15377-1, Olesen et. al. 2000 [10]).

		Total heat exchange coefficient W/m².K		Acceptable surface temperature °C		Maximum capacity W/m²	
		Heating	Cooling	Max. Heating	Min. Cooling	Heating	Cooling
Floor	Perimeter	11	7	35	19	165	42
	Occupied Zone	11	7	29	19	99	42
Wall		8	8	~40	17	160	72
Ceiling		6	11	~27	17	42	99

Floor Heating and Ceiling Cooling $\quad q = 8{,}92\ (\theta_i - \theta_{S,m})^{1{,}1}$ (1)

For other types of situations the following relations shall be used:

Wall heating and Wall cooling:	$q = 8\,(\lvert \theta_i - \theta_{S,m} \rvert)$	(2)
Ceiling Heating:	$q = 6\,(\lvert \theta_i - \theta_{S,m} \rvert)$	(3)
Floor cooling:	$q = 7\,(\lvert \theta_i - \theta_{S,m} \rvert)$	(4)

SIMPLIFIED CALCULATION METHODS FOR DETERMINING HEATING AND COOLING CAPACITY OR SURFACE TEMPERATURE

Two types of calculation methods can be applied according to the type of system:
One method is based on a single power function product of all relevant parameters developed from the finite element method (FEM). Another method is based on calculation of equivalent thermal resistance between the temperature of the heating or cooling medium and the surface temperature (or room temperature).
A given system construction can only be calculated with one of the simplified methods. The correct method to apply depends on the type of system, A to G (position of pipes, concrete or wooden construction) and the boundary conditions listed in the standards.

Universal single power function according to EN1264-2.

The heat flux between embedded pipes (temperature of heating or cooling medium) and the space is calculated by the general equation:

$$q = B \cdot \prod_i (a_i^{m_i}) \cdot \Delta\theta_H \qquad (\mathrm{W/m^2}) \qquad (5)$$

where:

B a system-dependent coefficient in $W/(m^2 \cdot K)$. This depends on the type of system and on the heat exchange coefficient

$\prod_i (a_i^{m_i})$ the power product, which links the parameters of the structure (surface covering, pipe spacing, pipe diameter and pipe covering).

The heat flow density is proportional to $\Delta\theta_H$ where the heating /cooling medium differential temperature is:

$$\Delta\theta_H = \left| \frac{\theta_V - \theta_R}{\ln \dfrac{\theta_V - \theta_i}{\theta_R - \theta_i}} \right| \qquad °C \qquad (6)$$

Where: θ_i = Room operative temperature, °C
Θ_V = Supply water temperature, °C
θ_R = Return water temperature, °C

Thermal resistance methods

The heat flux between embedded pipes (temperature of heating or cooling medium) and the space or surface is calculated using thermal resistances. The concept is shown in Figure 3.
An equivalent resistance, R_{HC}, between the heating or cooling medium to a fictive core (or heat conduction layer) at the position of the pipes is determined. This resistance includes the influence of type of pipe, pipe distance and method of pipe installation (in concrete, wooden construction, etc). In this way a fictive core temperature is calculated. The heat transfer between this fictive layer and the surfaces, R_i and R_e (or space and neighbor space) is calculated using linear resistances (adding of resistance of the layers above and below the heat conductive layer).
The equivalent resistance of the heat conductive layer is calculated in different ways depending on the type of system. This calculation method, using the general resistance concept, is given in for the following two types of systems shown in figure4 (Type E and F) and figure 5(Type G).
The equivalent resistance of the conductive layer may also be determined either by calculation using Finite Element Analysis (FEA) or Finite Difference Methods (FDM) or by laboratory testing according to prEN1264-2.
The heating and cooling capacity are in some of the described calculation methods determined directly (see EN1264 part 5).
In other calculation methods, the average surface temperature is determined and the heating and cooling capacity is calculated according to:

$$q_{des} = h_t (| \theta_{s,m} - \theta_i |)$$

For evaluation of the performance of the system – and when calculating the total heating and cooling power needed from the energy generation system (boiler, heat exchanger, chiller, etc.) – the heat transfer at the outward (back) side shall also be considered. This heat transfer shall be regarded as a loss if the outward side is facing the outside, an un-conditioned space or another building entity, and it depends on the temperature difference between the pipe-layer as well as the heat transfer resistance to and the temperature in the neighbor space or outside.

EN15377- PART 3: OPTIMIZING FOR USE OF RENEWABLE ENERGY SOURCES

The aim of this standard is to give a guide for the design of water based embedded heating and cooling systems to promote the use of renewable energy sources and to provide a method for actively integrating the building mass to reduce peak loads, transfer heating/cooling loads to off-peak times and to decrease systems size. A section in the standard describes how the design and dimensioning can be improved to facilitate renewable energy sources. Peak loads can be reduced by activating the building mass using pipes embedded in the main concrete structure of the building (**T**hermo-**A**ctive-**B**uilding-**S**ystems, TABS). For this type of systems, the steady state calculation of heating and cooling capacity (part 1 of this standard) is not sufficient. Thus, several sections of this standard describe methods for taken into account the dynamic behavior. The proposed methods are used to calculate and verify that the cooling capacity of the system is sufficient and to calculate the cooling requirements on the water side for sizing the cooling system.

Thermo Active Building Systems (TABS)

A Thermo-Active-Building-System (TABS) is a water based heating and cooling system, where the pipes are embedded in the central concrete core of a building construction. The heat transfer takes place between the water (pipes) and the concrete, between the concrete core and the surfaces to the room (ceiling, floor) and between the surfaces and the room.
The peak-shaving is the possibility to heat and cool the structures of the building during a period in which the occupants may be absent (during night time), reducing also the peak in the required power (Figure 6). In this way energy consumption may be reduced and lower night time electricity rate can be used. At the same time a reduction of the size of cooling system including chillier is possible

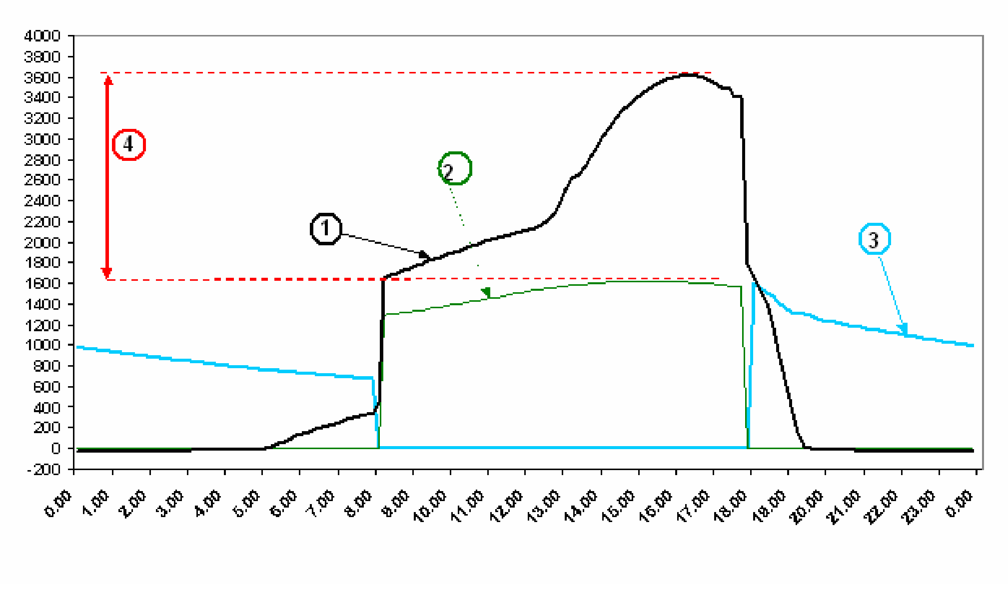

Figure 3 – Example of peak-shaving effect (X-axes: time; y-axes: cooling power W)
1) heat gain, 2) power needed for conditioning the ventilation air, 3) power needed on the water side, 4) peak of the required power reduction

The performance and dimensioning of TABS can be done by full dynamic building simulations with commercial programs including calculation models for embedded pipes. (Olesen and Dossi, [9]). The standard includes a more simplified calculation method. Besides the standard includes diagrams like the one shown in Figure 7 [12]. This simplified diagram give the relation between internal heat gains, water supply temperature, heat transfer on the room side, hours of operation and heat transfer on the water side. The diagrams correspond to a concrete slab with

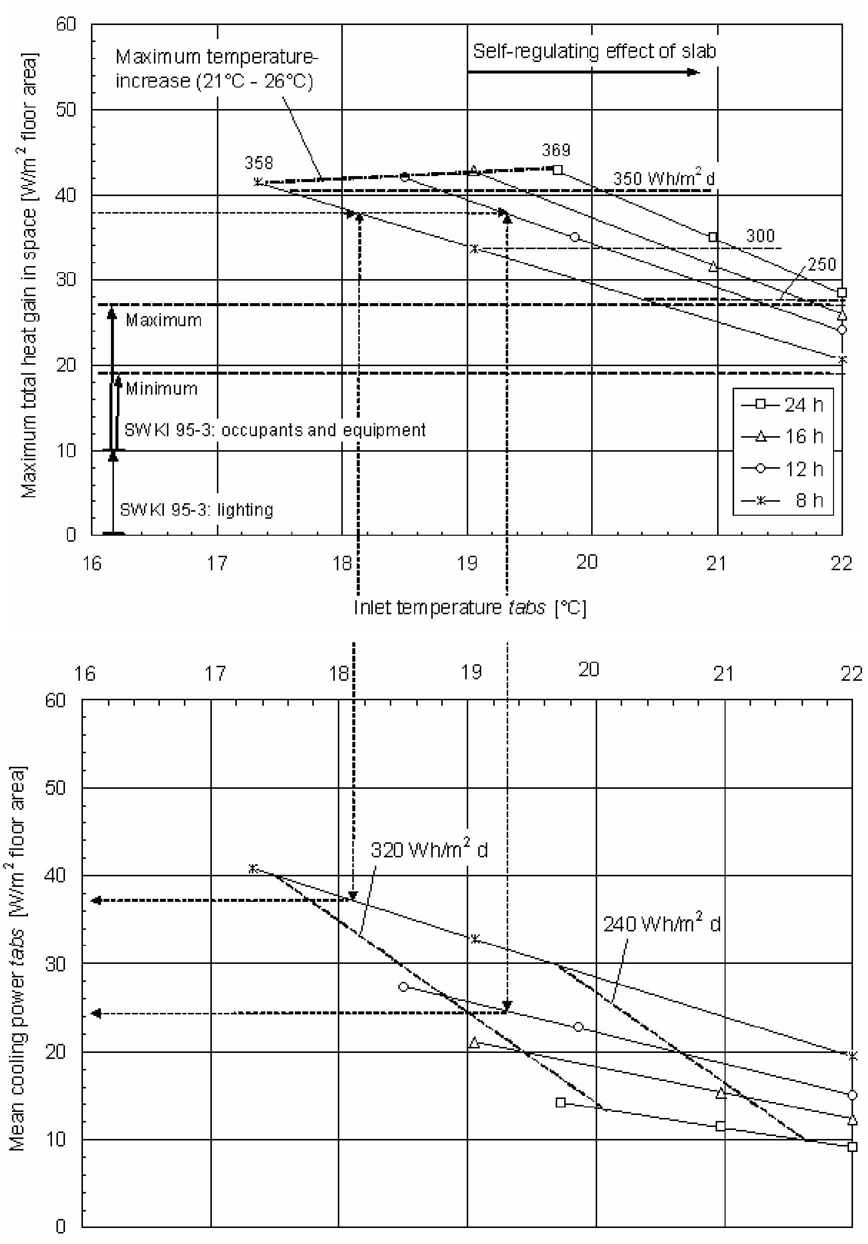

Figure 5 – Working principle of TABS (Koschenz and Lehmann [12]

raised floor (R=0.45 m^2K/W) and a permissible room temperature range of 21 °C to 26 °C. The upper diagram shows on the y-axis the maximum permissible total heat gain in space (internal gains plus solar gains) W/m^2 , and on the x-axis the required water supply temperature. The lines in the diagram correspond to different hours of operation (8h, 12h, 16h, and 24h) and different maximum amount of energy supplied per day Wh/m^2 d . The lower diagram shows the cooling power W/m^2 required on the water side (for dimensioning of chiller) for thermally activated slabs as a function of supply water temperature and operation time. Further, the amount of energy rejected per day is indicated Wh/(m^2 d). The example shows, that by a maximum internal heat gain of 38 W/m^2 and 8 hour operation, a supply water temperature of 18,2 °C is required. If, instead, the system is in operation for 12 hours, a supply water temperature of 19,3 °C is required. In total, the amount of energy rejected from the room is app. 335 Wh/m^2 per day. The required cooling power on the water side is by 8 hours operation 37 W/m^2 and by 12 hours operation only 25 W/m^2. Thus, by 12 hours operation, the chiller can be much smaller. The total heat rejection on the water side is app. 300 Wh/m^2 per day.

SUMMARY AND DISCUSSION

This paper presents a new and a revised European standard for the calculation of heating and cooling capacity for hydraulic, radiant surface heating and cooling systems. Different "simplified" calculation methods, depending on the type of construction, have been presented. In contrast to radiant heating and cooling panels, where the heating/cooling capacity must be determined by testing in a standardized test room, the determination for embedded systems is based on calculations. Besides the included "simplified calculation methods," the standard also allows the use of finite difference and finite element methods. The manufacturers of radiant heating and cooling systems can use the standardized calculation methods to develop diagrams relating water temperature and space temperature to the cooling-heating capacity. This will avoid unnecessary testing of systems.

Besides the new standard includes a part describing methods to take into account the dynamic effects of thermally activated building systems (TABS), where the pipes are embedded in the main building structure (concrete slabs or walls), to activate the building mass.

SUMMARY

Studies indicate that a high ventilation rate with fresh air supply directly from outdoors gives better thermal comfort conditions, less SBS (Sick Building Syndrome) symptoms and increased work productivity. The drawbacks with a high ventilation rate in natural or exhaust ventilated buildings are normally increased energy use for heating and cold air draught. Such problems may be minimized with ventilation radiators, radiators where cold ventilation air is brought directly from outdoors through a wall channel into the radiator where it is heated before entering the room.

This paper discusses advantages with ventilation radiators in comparison to those of traditional heating systems. Focus has been on energy aspects and thermal comfort. The main conclusions are that ventilation radiators may give a stable and uniform thermal indoor climate. The high thermal gradient between cold ventilation air and the radiator surface inside the ventilation channel also makes the ventilation radiator more efficient than other systems. A method to vary indoor climate on a daily basis according to where people stay is proposed for additional energy savings with ventilation radiators. The deductions were based on results from CFD simulations in a well validated office model.

INTRODUCTION

A CFD (Computational Fluid Dynamics) model of an office room was made to simulate and investigate thermal climate and energy aspects with different heating systems. The goal of the project was to find ways to improve the thermal efficiency of water-based space heating, mainly radiators, and adapt them to low systems temperatures. Low-temperature heating, either by heat pumps or district heating systems, have several positive environmental and economical aspects. Some of them are more efficient energy use, decreased thermal losses in distribution and improved thermal comfort [1-3].

During the study interaction between heating and ventilation systems proved to be an important factor for controlling the thermal climate. Cold draught tends to be the largest hazard, especially in low-temperature systems. The reason is because low temperature systems such as floor and wall heating have weak buoyancy power to counteract cold down-flow from air inlets and windows. With ventilation radiators, on the other hand, the ventilation air is already heated to room air temperature when it enters the room after passing through the radiator. This secures stable indoor climate. The ventilation radiators even proved to perform better in terms of thermal efficiency compared to the other heating systems tested. That is why the focus of the project turned to the evaluation and development of ventilation radiators.

There are still great possibilities for improvement. This paper deals with experiences from the study and explains some advantages with ventilation radiators that can be utilized further in the future.

PRINCIPLE OF VENTILATION RADIATORS

A ventilation radiator is a combined ventilation and radiator system where cold ventilation air passes through the gap between the radiator panels before entering the room. The mean temperature gradient, $\Delta\theta_m$, between the radiator surface and the passing air is larger than in other low temperature radiator systems, just as the heat transfer coefficient, k. The radiator efficiency is improved as heat is more easily extracted from the radiator surface. Figure 1 shows the principle of a ventilation radiator.

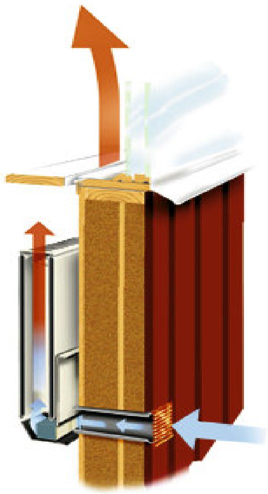

Figure 1. Illustration of a ventilation radiator

Cold ventilation air (blue arrows) enters a gap in the wall because of pressure differences between outdoors and indoors. The air stream is directed between the parallel radiator plates and rises as it is pre-heated to room air temperature.

Because of high efficiency with ventilation radiators (the product of parameters on the right hand side of Equation (1)) the temperature difference between incoming and outgoing water in the radiator circuit, $\Delta\theta$, automatically becomes larger. The water leaving the radiators, $\theta_{\text{water, out}}$, may theoretically achieve temperatures similar to that of the room air where the radiators are placed, or even lower, depending on the mass flow rate, $\dot{m}$, inside the circuit. This is impossible with conventional radiators and very interesting in terms of energy savings and environmental aspects.

$$\dot{m} \cdot c_p \cdot \Delta\theta = k \cdot A \cdot \Delta\theta_m , \qquad (1)$$

where c_p and $\Delta\theta$ are the specific heat capacity of water and temperature difference between water entering and leaving the radiator, $\theta_{\text{water, in}}$ and $\theta_{\text{water, out}}$. The terms on the right hand side, k and A, are the total heat transfer coefficient and the area of the radiator surface, respectively. The mean temperature difference, $\Delta\theta_m$, is given below.

$$\Delta\theta_m = \frac{\theta_{\text{water, in}} - \theta_{\text{water, out}}}{\ln \dfrac{\theta_{\text{water, in}} - \theta_{\text{air}}}{\theta_{\text{water, out}} - \theta_{\text{air}}}}, \qquad (2)$$

where $\theta_{\text{water, in}}$, $\theta_{\text{water, out}}$ and θ_{air} are the water temperature in and out of the radiator and the temperature of ambient air.

METHODS

A CFD model was made as a reproduction of a real life test lab where Olesen et al measured thermal comfort [4]. Even the characteristics of building materials and heating and ventilation systems were replicated. The room, which resembles an office, had an exhaust ventilation system and a window, but no furniture. It was exposed to an outdoor climate similar to that of a normal winter day in Stockholm, Sweden. A sketch of the office is shown in Figure 2 below. The same model was used in two previous studies at the KTH School of Technology and Health. These papers are referred to for more details of the model and simulations [5,6].

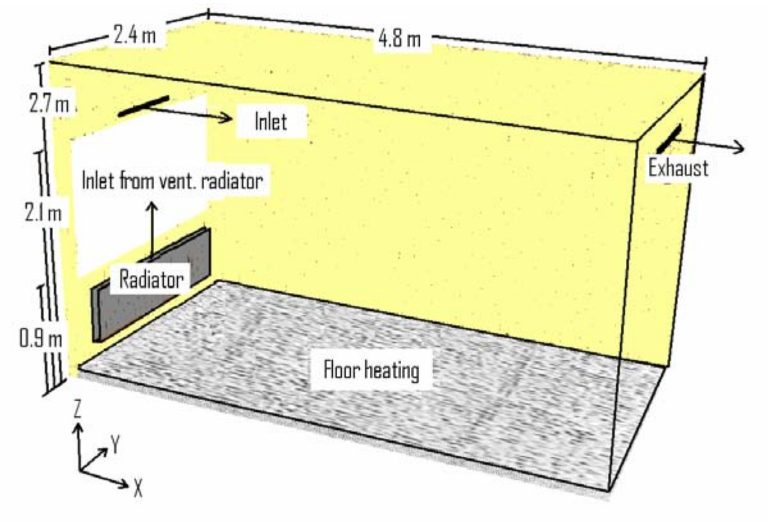

Figure 2. Sketch of the CFD model

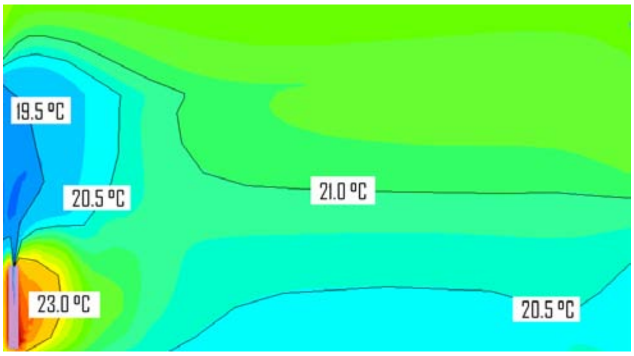
About 450 W of heating power was needed to heat the room to a desired comfort temperature. Different heating systems were tested, among them ventilation radiators and a conventional radiator. All radiators had the same size. The heating systems were initially adjusted to give a comfort temperature of 21.0 °C at 1.1 m above floor level in the centre of the room. This did not necessarily mean that the thermal climate was similar for all cases. The aim of the study was to map differences in thermal climate and compare the performance of each heating system. The thermal comfort results were evaluated according to recommendations in ISO 7730:1994, an international standard that specifies conditions for thermal comfort [7].

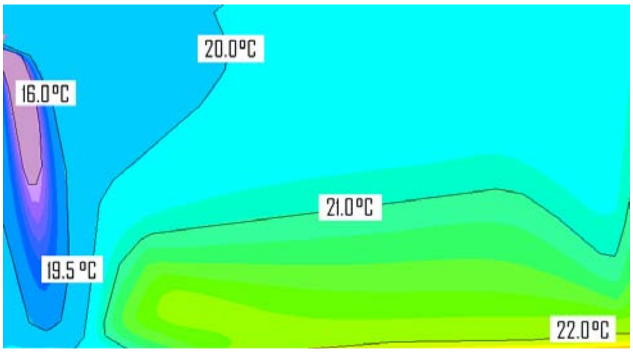
The water flow situation inside the heat emitters was not reproduced. Instead a fixed mean temperature was set for the whole heated surface. This simplification was made to make the CFD simulations less complicated even if a certain margin of error would occur according to theory. In reality the temperature variations over heated radiator surfaces are in linear relation to $\Delta\theta_m$, the mean temperature difference of water entering and leaving the radiator. The size of $\Delta\theta_m$ and the margin of error depend on the mass flow through the radiator. Higher mass flow means more uniform surface temperature.

RESULTS

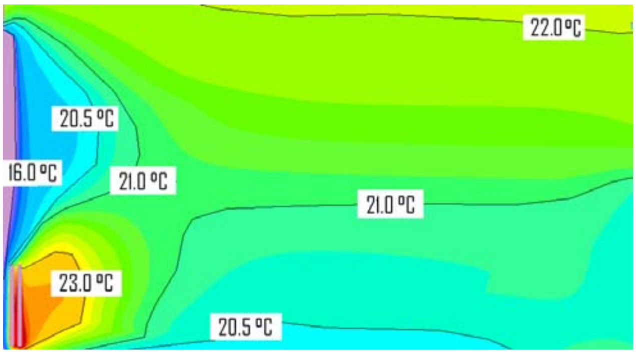
Figure 3 displays simulated thermal comfort results with different heating methods. Comfort temperature is, like the more commonly used operative temperature, a variable used to obtain an understanding of the perceived thermal climate. It considers the balance between radiant heating or cooling and the draught-induced air temperature effects on the perceived air temperature. Table 1 shows various data achieved during the simulations with three different ventilation radiators and a conventional radiator.



Ventilation radiator A, surface temp. 34.5 °C



Floor heating, surface temp. 26.0 °C



Conventional radiator, surface temp. 42.3 °C

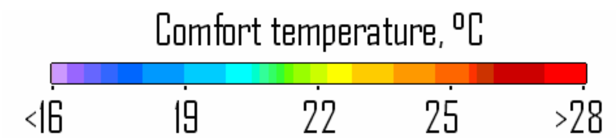


Figure 3 a-c. Comfort temperature with different heating methods

The illustrations are from the XZ plane at Y = L/2. Cold areas are represented by blue colours, while the warm areas are shown in red.

Table 1. Simulation results

	Vent. radiator Case A	Conventional radiator	Vent. Radiator Case B	Vent. Radiator Case C
Temperature of heated surface, °C	34.5	42.3	38.0	34.5
Comfort temp. at Z = 1.1 m and X = L/2, °C	21.0	21.0	21.0	23.2
Flow rate of ventilation air, l/s	7.0	7.0	7.0	3.0
Channel width in ventilation radiators, m	0.015	-	0.04	0.015
Air temp. at Z = 1.1 m and X = L/2, °C	21.3	20.8	21.4	23.8
Total heat output from radiator, W	435	483	445	335
Conv. heat output between panels, W	230	138	196	155
Total heat transfer coefficient, W/(m^2·°C)	9.6	6.7	7.8	8.8
Mean air speed in ventilation channel, m/s	0.93	-	0.35	0.4

DISCUSSION

The following discussion is based on simulation results from our low temperature heating project.

THERMAL COMFORT

Because the ventilation air had already been heated to about 18 °C before entering the room no areas inside the room had problems with cold air draught when using the ventilation radiator in case A. The temperature gradients between floor and ceiling, and between the walls, became smaller than with the other systems for the same reason. Small temperature differences in the room resulted in less air movements caused by buoyancy forces.

RADIATOR EFFICIENCY

The total heat transfer coefficient was 9.6 W/($m^2 \cdot$°C) for the ventilation radiator used in case A and 6.7 W/($m^2 \cdot$°C) for the conventional radiator. It is obvious that a large thermal gradient between radiator walls and cold air in contact with the panels boosts convection heat output. The convection heat emitted from between the radiator panels was 67 % higher for the ventilation radiator compared to the conventional radiator.

In case B and C adjustments were made to the ventilation radiator. The heat transfer coefficient decreased considerably when the channel width was enlarged or the air velocity was decreased in the ventilation channel. As expected from theory the degree of turbulence inside the ventilation radiator was crucial for the heat output. No radiator with convection fins were tested in the study.

THERMAL RESPONSE TIME

The heat output from a ventilation radiator is strongly dependent on the air temperature and air velocity of air passing in the ventilation channel. As a consequence a ventilation radiator has super-short response time and regulates its heat output automatically according to the ventilation rate in the room or changes in outdoor climate. In other water-based heating systems the need for manual adjustments of valves is much greater and the response time is much longer.

EXAMPLE:

When the outdoor temperature and the temperature of air entering the ventilation channel decrease the thermal efficiency of the ventilation radiator automatically increases simultaneously. The ventilation radiator emits more heat as the need for heat in the building increases.

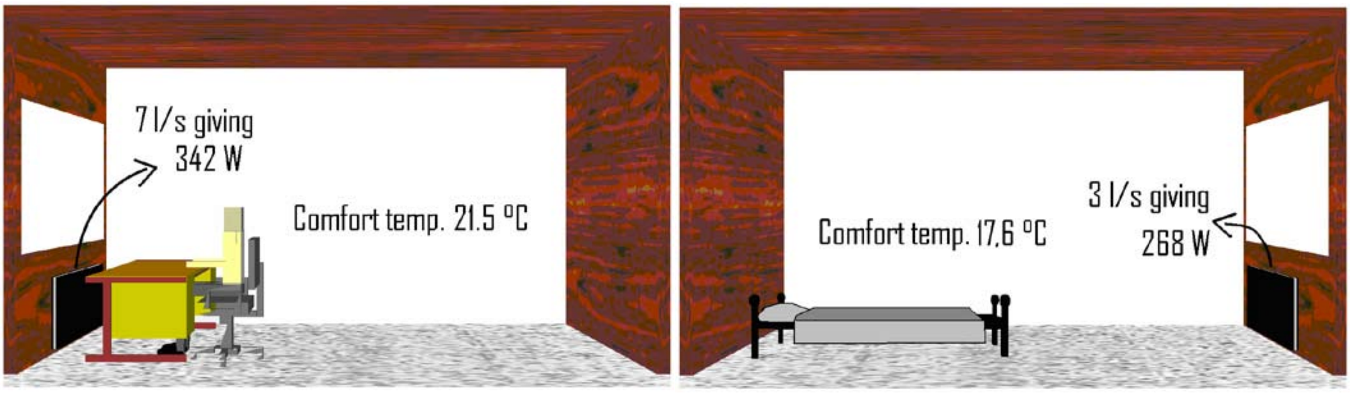
A WAY TO CREATE A DYNAMIC HEATING AND VENTILATION SYSTEM

The super-short response time of ventilation radiators way be used to create a dynamic heating and ventilation system where the radiator heat output is controlled by the ventilation rate in the room.

EXAMPLE:

The ventilation rate in different parts of a house is varied automatically on a daily basis depending on where people tend to stay, sleep and where fresh air and heat is needed. The heat output from the ventilation radiators increases and decreases in perfect synchrony with the variation in ventilation rate. All the time a desired thermal climate is kept where people stay. In the rooms where there are no people the ventilation rate is lower. Here the ventilation radiators do not emit as much heat, but still the room temperature is kept at an acceptable level. This renders energy savings. The example is illustrated in Figure 4.

Day



Night

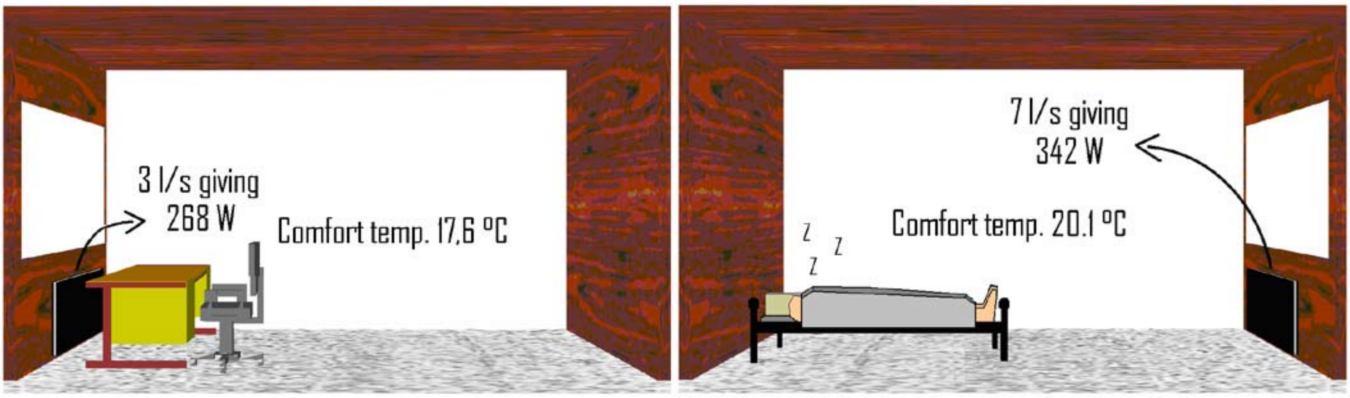


Figure 4. A dynamic heating and ventilation system with ventilation radiators is shown above

The ventilation rate was changed according to where a person stayed. Each illustration shows ventilation air flow, corresponding heat output from the radiator and comfort temperature in the centre of the room at Z = 1.1 m. The upper illustrations show the situation during daytime, while the lower illustrations show the same at night. Heat emitted by the person, 93 W when the person did office work and 70 W when sleeping, was included in the estimations. The radiator had a constant surface temperature of 31.7 °C.

CONCLUSIONS

The thermal climate proved to be more stable and uniform with ventilation radiators than with floor heating and the conventional radiator. Because the ventilation air was pre-heated before entering the room a high ventilation rate could be kept without any hazard of cold draught, even if the temperature of the supply air was below freezing. With conventional heating systems cold draught is often a major problem in wintertime, especially in naturally or exhaust ventilated buildings.

The ventilation radiators had higher thermal efficiency than the conventional radiator. In practice this means that a lower water temperature may be kept in the radiator circuit with the same heat output. This results in energy savings in heat production and distribution. Even more energy may be saved if the short reaction time of ventilation radiators is used to balance the need for heating and ventilation on a daily basis.

The ventilation radiator with the narrowest ventilation channel between the radiator panels had a larger total heat transfer coefficient and thus a better thermal performance than the other ventilation radiators. The reason was higher air velocity and a more turbulent flow inside the channel. This knowledge may lead to development of ventilation radiators with design differing from that of traditional radiators. It is likely that new types of slim double panel ventilation radiators attached close to the wall may be interesting both in terms of energy usage and visual aspects. To find the ideal geometries for increased convection heat output the degree of turbulent air flow in the ventilation channel should be optimized in relation to pressure losses and noise. This process should include calculations that show whether convection fins would be functional to have inside the ventilation channel.

Modeling of Heating Systems and Radiators in Combined Simulations

Ralf Gritzki, Alf Perschk, Markus Rösler and Wolfgang Richter

TU Dresden, Germany

Corresponding email: gritzki@tga.tu-dresden.de

SUMMARY

In this paper different approximation levels for the simulation of heating systems and radiators in a test chamber are presented and evaluated. It is shown that for more complex radiator types a detailed combined simulation including CFD should contain an appropriate model of the heating system. In addition, the level of approximation depends on the target of the calculation, e.g. thermal comfort or energy consumption, and on the geometrical complexity of the investigated radiator, respectively. Therefore a simulation tool was created which provides the ability to handle each desired level of approximation from simple tempered panels up to the fully coupled geometrical radiator models including internal heat conduction and water flow. Results of the calculations regarding the three different approximation levels are compared with each other as well as with experimental data in order to show the quality of the developed models.

INTRODUCTION

Combined simulations consisting of thermal building simulation, simulation of the technical equipment, and computational fluid dynamics (CFD) are very useful to get numerical data about thermal comfort, air quality, and energy consumption of rooms and buildings.
Although this kind of simulation is known to be already detailed there are still some options for advanced modelling. In case of technical equipment in rooms, it can be approximated on different levels. The main goal of our investigations was to generate a simulation tool which provides for the possibility to increase the level of approximation up to the fully modelled radiator configuration, including three dimensional heat conduction, geometrically highly resolved radiation, and in addition the internal water flow.
By means of the fully coupled simulation tool developed for this purpose one should be able to investigate geometrically very complex radiator models, both under standard conditions as well as under the dynamic conditions of real practical applications. The tool could especially be used to substitute the construction of different radiator prototypes and in this manner can yield enormous cost savings.

METHODS

Overview about the simulation tool

The designed simulation tool consists of three highly coupled program parts to assure that all relevant physical and technical aspects for the simulation of radiators are considered. In detail it consists of the thermal building simulation code TRNSYS® [1], the indoor air flow simulation code ParallelNS [2], and the commercial CFD code Fluent® [3]. Fluent® is applied for

simulation of the interior of the radiator, ParallelNS for the air flow calculation, and TRNSYS® for the radiation, the heat conduction of the surrounding faces, the controlling and the technical equipment.
Due to the coupling within the transient simulation process these three single codes together result in a very complex simulation tool which is able to satisfy the demands of practical applications, like radiator test chambers. In the following section the three modules and the coupling algorithm are described in more detail.

Modules

Thermal building simulation and control - TRNSYS®

TRNSYS® was developed at University of Wisconsin, Madison (USA). It is a commercially available simulation tool with modular structure, especially designed for the evaluation of the transient performance of thermal energy systems. The modular and to some enhancement open structure allows to extend the available modules, or to add new features, respectively. Based on version 14.2, the program was developed at TU Dresden as the building simulation unit for combined simulations, see [4], [5]. It can communicate with different CFD programs via PVM (Parallel Virtual Machine), in order to get detailed information about the convective heat transfer or about parameters of technical equipment.

Airflow and coupling - ParallelNS

The CFD code ParallelNS is used for the simulation of the indoor air flow, e.g. in the simulated test chamber. It is a research code developed at Göttingen University and Dresden University of Technology. Based on the Reynolds-averaged Navier-Stokes equations for incompressible non-isothermal fluids two turbulence models, a k-ε model and a φ-f-k-ε model are used for calculating the effects of turbulence. In the case of the k-ε model special care is devoted to the heat transfer at rigid walls by applying especially developed boundary layer approximations. This is of great importance for the investigations in terms of energy consumption. Moreover it is possible to consider a wide variety of additional transport equations, like the equation of age of the air or mass transport equations, respectively [6].
The discrete model was created by means of a stabilized Finite Element method, based on linear tetrahedron elements. Using this method one gets some advantages for specifying boundary conditions at openings, for details see e.g. [7] or [8]. The code itself can be parallelized very easily by a non overlapping domain decomposition method based on the public domain software package PVM. The same feature is applied for the interaction with the thermal building simulation program and also with the radiator simulation in Fluent®. Because ParallelNS has already applied PVM for domain decomposition, it now represents the master part of the whole coupled simulation tool.

Water flow and radiator - Fluent®

In case of fully coupled problems including the extended radiator model, the radiator itself is completely modelled and simulated by use of the commercial CFD code Fluent®. Fluent® is a finite volume code which allows for the calculation of a huge variety of flow types like non-isothermal unsteady compressible flows or flows with highly temperature dependent properties, as for instance the water flow in radiators. Moreover it is possible to simulate solid parts with thermal conduction within the flow field which are calculated together with the flow solution and are required to simulate the metal parts. Due to the ability to handle hybrid mesh types it is possible to model very complex three dimensional geometries, thus also the interior of multi-section radiators, see example I. The coupling with the building simulation was done by means of the implemented user programming interface, the so called “user defined functions” (UDF). Therefore the ability to exchange data via PVM was implemented in the UDF-code. For more information see the Fluent® user manual [3].

Coupling algorithm

The complete coupling algorithm works transient, according to the type of successive approximation. Because there are no inner iterations inside each time step between the different simulation tools the algorithm can bee seen as an explicit time integration procedure. Concerning this matter and in order to avoid divergence problems it is important to be careful when defining the size of the main time steps (in TRNSYS®).
The main program which is responsible for the entire data transfer between the three simulation codes is ParallelNS. At first, ParallelNS starts and initialises the thermal building simulation code. After a period of time of “stand alone” simulation within TRNSYS® the coupling with the air flow solver ParallelNS starts, in order to generate useful initial values. The coupling itself works across the transfer of boundary condition (BC) values at predefined BC interfaces. To ensure a realistic approximation of the interaction among the wall faces of the surrounding walls and the flow field, all the walls are split into a number of such BC interfaces. For the flow solver, the BC interfaces are additionally further refined to gain more stability due to the use of mean BC-values.

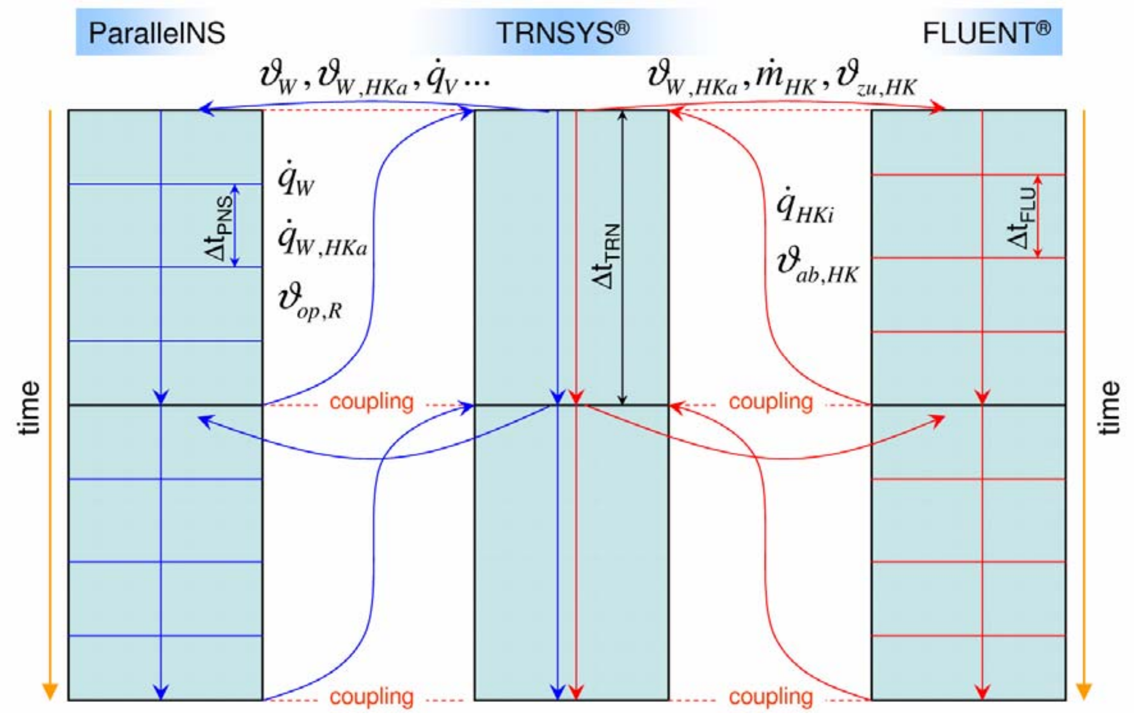

Figure 1. Overview of the coupling algorithm in the fully coupled case.

The chronological operating sequence of the BC-exchange now works as follows, see fig. 1. At first TRNSYS® sends an exchange vector of temperature- and other BC-values to ParallelNS. Using these values ParallelNS performs a transient flow field calculation, until it reaches

the next coupling time. When the coupling time is reached (next TRNSYS® time step), the flow solver calculates the desired heat fluxes at the BC-interfaces and sends them back to TRNSYS®. Now TRNSYS® starts its calculation (energy balances) for the current time step and sends the resulting temperature values for the next time cycle back to ParallelNS. More detailed information about the coupling algorithm can be found in [9].
If the fully coupled radiator model is enabled, ParallelNS simultaneously starts the radiator calculation based on the Fluent® model. Hereby the geometrical resolution of the radiator surfaces is much higher than the resolution of the surrounding walls. This is important in order to ensure the correct temperature distributions in the investigated radiator models. The temporal coupling for this level of approximation can also be seen in fig. 1. A special feature is that the whole radiator model is surrounded by a very thin layer of TRNSYS® BC-faces. The exchange of boundary conditions now takes places between Fluent® and TRNSYS® at these faces. The same TRNSYS® faces also exchange BC-values with the surrounding air flow model, so they get exchange vectors from both sides. The energetic balance for the radiator faces (including radiation) then is calculated in TRNSYS® taking into account both exchange vectors.

RESULTS

Introducing remarks

To illustrate the capabilities and the quality of our simulation tool we modelled two different radiator types, a multi-section radiator and a simple fluted radiator in a test chamber under standard conditions complying to EN 442 [10] in order to investigate their standard heat output. In addition, for the fluted radiator we used three different levels of approximation. The results are finally compared with each other and with measurement data from the radiator specifications, respectively.

Configuration of the simulated test chamber and the radiator models

The modelled test chamber has the overall dimensions of L x W x H = 4 m x 4 m x 3 m, see also fig. 2. The investigated radiator model is, as postulated in [10], located centered in front of the backside of the chamber, 0.1 m above the floor and 0.05 m away from the backside. All walls of the test chamber except the backside are controlled tempered walls. The materials and the wall constructions correspond to the guidelines in [10]. The sensor point for the temperature control (red point) is located in the middle of the test chamber at a height of 0.75 m above the floor.
Our model of the test chamber is equipped with two different control loops. One loop controls the tempered walls in order to keep the temperature at the measure point at a constant value of 20 °C. In the fully coupled case (I and II) the other loop controls the water influx against the radiator outflow temperature. In the simplified cases (IIA, IIB) the second loop controls the outflow temperature and mass flux of an internal radiator model in TRNSYS®. In our investigations we used constant inflow temperatures of 75 °C and required outflow temperatures of 65 °C.
The simulations were performed unsteady on a workstation with two processors until steady state conditions were reached.

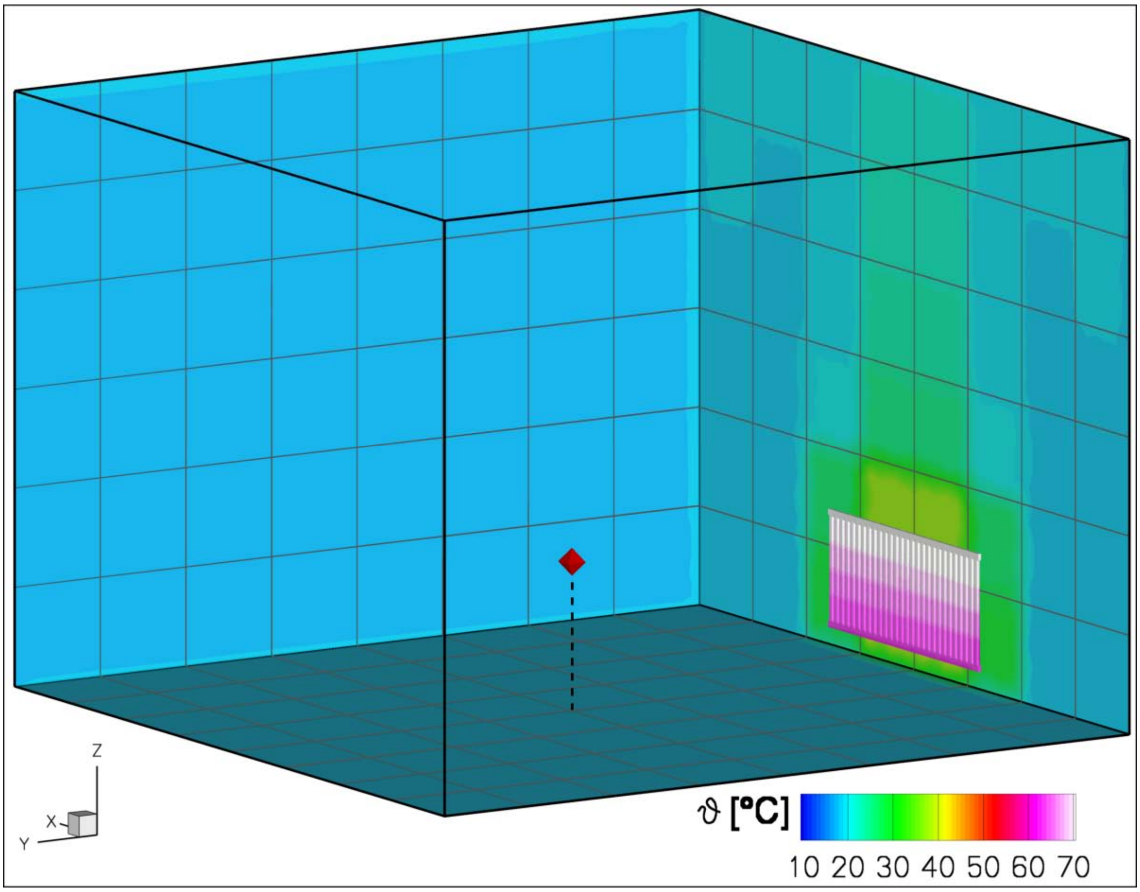

Figure 2. Geometry of the modelled test chamber with radiator and controller location.

For the discretization of the boundary condition exchange and the radiation exchange the test chamber walls are divided into small tiles (0.5 m x 0.5 m), see fig. 2 again.
In case of the fully coupled simulations the radiators are also divided into a large amount of very small tiles (up to 4000 BC faces are possible). This way their real geometry and their real physical behavior, especially in respect to the radiant and the convective heat transfer and the temperature distribution are reflected, see fig. 3.

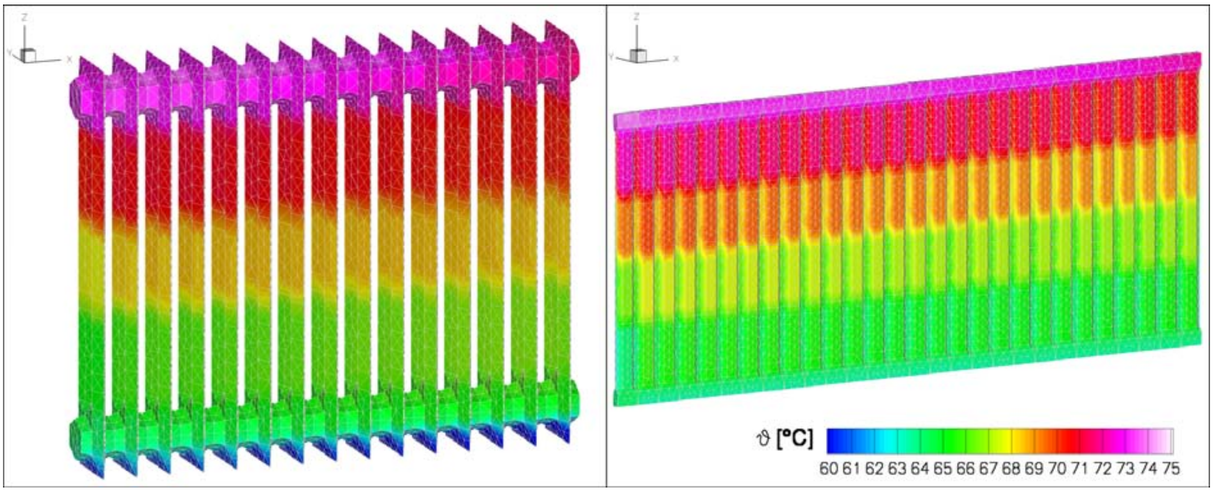

Figure 3. Wall temperatures and surface grids of the fully coupled radiator models.

Figure 3 shows the two investigated fully coupled radiator models (I and II) along with their temperature distributions in the steady state. The water inflow is located at the upper left side while the outflow is located at the same lower side.
In case of the simplified radiator models IIA and IIB, see fig. 4, the whole radiator shell has only two unique surface temperatures (front and back) which are results of the averaged radiant and convective heat transfer between the test chamber and the internal radiator model in TRNSYS®. The only difference between the two cases IIA (fig. 4 left) and IIB (fig. 4 right) is the higher geometrical resolution of IIB which leads to more realistic values of the averaged convective heat transfer. The calculation of the radiation transfer in both cases stays the same.

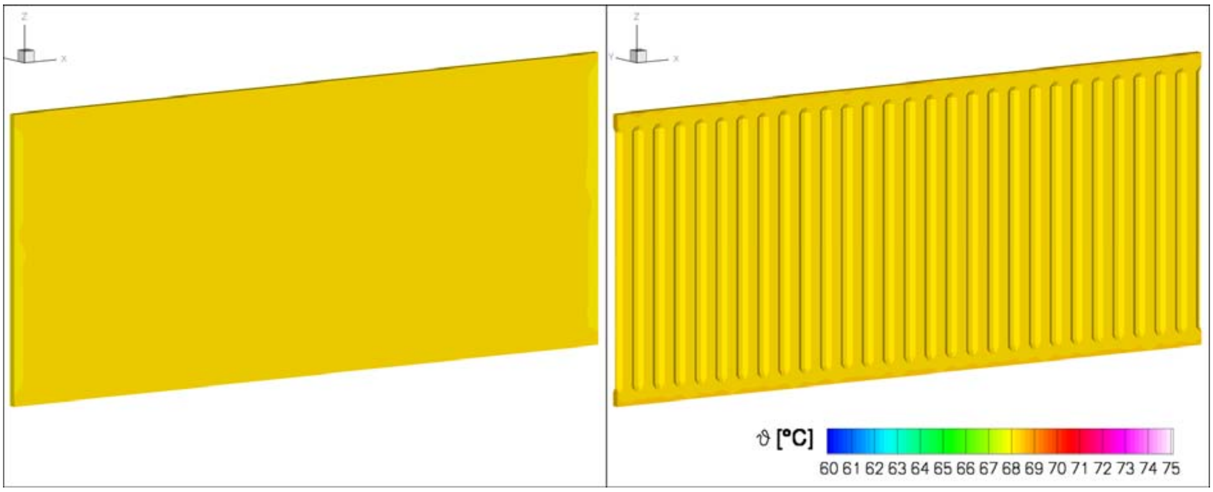

Figure 4. Geometry and wall temperatures and of the simplified radiator models IIA (left) and IIB (right).

Example I – Multi-section radiator model

The main results of the fully coupled simulation of radiator model I are resumed in table 1. Also shown in table 1 are measurement data of the radiator given by the manufacturer.

Table 1. Integral simulation results for radiator model I.

	ϑ_v [°C]	ϑ_r [°C]	Mass flux [kg/h]	Thermal output [W]
Simulation	75.00	65.00	70.02	815
Reference	75.00	65.00	69.68	810

Results regarding the thermal behaviour of the radiator, especially the value of the thermal output are in very good agreement with the standard values given by the manufacturer. The temperature distribution of the radiator, see fig. 3 left, meets the expectations. Due to the low main velocity and the high temperature differences between the fluid and the wall temperatures a nearly uniform vertical temperature stratification arises. Because of the high increase of the flow cross-section after the intake a very smooth distribution of the inflowing water across the radiator sections and hence the visible uniform temperature distribution arises.
The good results confirm the needs of such a complex geometrical model, especially in case of the radiation exchange. Using our simplified radiator model we were not able to predict the correct radiation exchange between the different sections of the radiator.

Example II - Fully coupled fluted radiator model

The simulation results for model II also very well match to the reference values from the manufacturer. The temperature distribution in fig. 3 right again shows the accuracy of the thermal behaviour of our model. In addition, the good results in both cases, I and II, illustrate that for such radiator models with moderate water flow velocities, like I and II, a vertical sectioning of 3 to 5 pieces is sufficient to obtain a very good agreement with the available reference data.

Table 2. Integral simulation results of radiator model II.

	ϑ_v [°C]	ϑ_r [°C]	Mass flux [kg/h]	Thermal output [W]
Simulation	75.00	65.00	81.10	945
Reference	75.00	65.00	80.64	938

Example IIA and IIB - Simplified and geometrical expanded fluted radiator model

Results of simulations of the simplified radiator models in terms of thermal output are resumed in table 3. The data are compared to the reference values from measurements and the values form the fully coupled model. It shows that the results of both detail levels also fit very well to the desired standard values. Here the model IIB with the more complex geometrical resolution even reproduces the standard thermal output as good as the fully coupled model.

Table 3. Comparison of the thermal output for different approximation levels, model II

	Model II	Model IIA	Model IIB	Reference
Thermal output [W]	945	971	932	938
Mass flux [kg/h]	81.10	83.40	80.06	80.64

The results allow the statement that the simplified models and the fully coupled model are on a par if the geometry of the radiator is simple enough, like it is in example II. This result is of great importance for the use of simplified radiator models because most of the investigations like studies of energy consumption of different building types etc. are done based on simplified radiator models.

DISCUSSION

The results of our investigations clearly show that the designed simulation tool is very well suited to reproduce the measured radiator parameters. The differences between measured and simulated thermal output in all investigated cases are less than 5 %. Considering the complexity of the model, these results seem to be very good. In case of standard radiators with simple geometry (model II) the investigations show that our radiator model implemented in TRNSYS® can be used to predict very reliable data of thermal output. Here the higher geometrical resolution (IIB) and the associated more realistic convective heat transfer yields increased quality of the results with comparable calculation effort.

Nevertheless the simplified radiator models are not able to predict the correct behavior of geometrically complex radiators, like the one in case II. Thus the fully coupled model is a very useful simulation tool for the design of complex and new radiator models.

The Economy of Heat Cost Allocation and Temperature Control in Multiple Unit Dwellings

Arne Jönsson

Mid-Sweden University, Härnösand, Sweden

Corresponding email: arne.jonsson@miun.se

SUMMARY

Heat cost allocation is primarily not a method to save energy. It is a way to give the households the temperature they are willing to pay for. The condition that gives the highest reduction of costs from heat cost allocation is at a high marginal cost of temperature. At a high marginal cost there will not be any reduction of the average indoor temperature at the introduction of heat cost allocation. The reduction of costs comes when the households who prefer a high indoor temperature gets the temperature they are willing to pay for. The reduced costs 114 SEK/yr dwelling in buildings built after 1980 and 262 SEK/yr dw in buildings from before 1975 in Sweden should be compared with the cost for meters, reading and administration 334 SEK/yr dw. (8 SEK = 1 USD)

INTRODUCTION

This is a theoretical analyse based on microeconomics. It compares MU-dwellings with heat cost allocation and temperature control that gives a collective indoor temperature, the same temperature in all dwellings, with systems that gives individual temperatures.

Heat cost allocation in homes with individual control and individual heat metering, individual temperature metering and collective allocation was described in [1] and [2]. The use of a fixed part and a variable part for heat cost allocation after heat quantity was not included. This gives a to low indoor temperature. A fixed part (grundkosten) and a variable part (verbrauchskosten) are used in Germany [3]. The fixed part there is between 30 –50 % of the sum of all costs for heating including cleaning and maintenance of the heating system. A paper about the fixed and the variable part is presented at this conference.

METHODS

The systems with individual temperatures are assumed to have the marginal cost of temperature that corresponds to the heat loss to the outdoor air and a cost for indoor temperature that is close to the cost for the heat loss to the outdoor air. This gives the same cost for an increase of the indoor temperature for both owner and household.

In figure 1 the supply water temperature, t_s is controlled after the outdoor temperature, and the heaters are chosen to give the same temperature in all dwellings. The cost of heat is distributed to the households after their share of the buildings dwelling area. Since all households get the same temperature the cost of cold will be high for the households who want a high indoor temperature. This normally gives a higher indoor temperature than if the households could chose individual indoor temperatures.

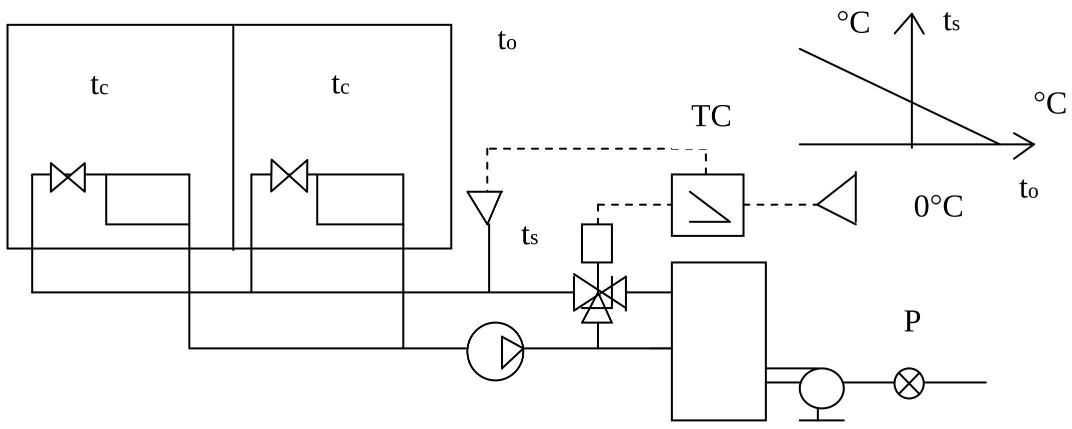

Figure 1. Heating system with a collective temperature, t_c.

The households in a building have different demand curves according to figure 2. The t* is normally distributed with t^*_m = 21.65°C, k = 0.004 (1/°C^2). DI' (SEK/h hh) (8 SEK = 1 USD) is the disposable income per hour and household [4] and [5]. The standard deviation s* = 1.3°C. s* is based on measurements from Swedish SU-dwellings in [6].

To get the demand curve for a collective temperature the individual demand curves in figure 2 are added vertically and divided by the number of households. This gives figure 3.

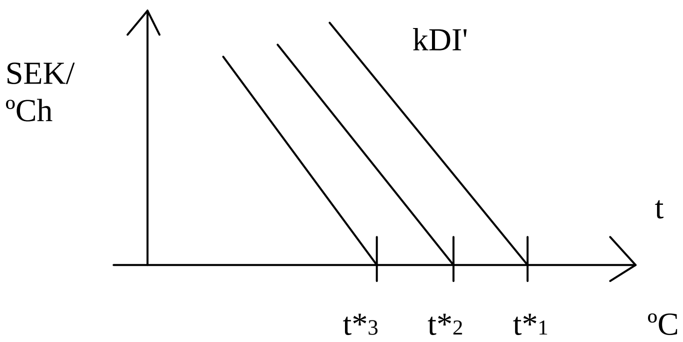

Figure 2. Demand curves for indoor temperature for different households.

The demand curve for a collective temperature in figure 3 goes up to the highest preferred indoor temperature among the households. At a low price of temperature the highest temperature demand will be satisfied. The horizontally marked area is the cost of heat and the diagonally marked area CC(t_c) is the average cost of cold for the households.

If individual heat cost allocation is introduced with the heating system in figure 1 then the indoor temperature is controlled with the valves on the heaters.

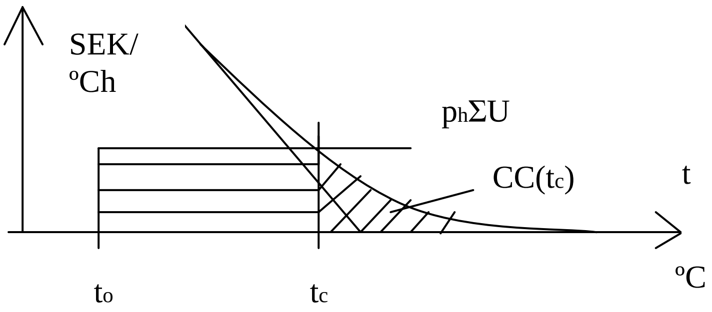

Figure 3. Demand and supply curve for a collective temperature, t_c.

Heat cost allocation systems that gives the marginal cost of temperature that corresponds to the heat loss to the outdoor air is heat metering with a suitable fixed and variable part and indoor temperature metering with the specific heat demand (W/°C) for the heat loss to the outdoor air.

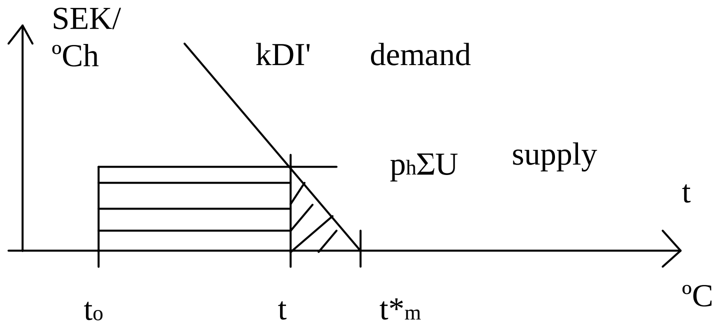

Figure 4. Demand and supply curve for the average of individual temperatures, t.

The supply curve in figure 3 and 4 is $p_h\Sigma U$ where p_h is the price of heat to the dwellings (SEK/kWh) and ΣU is the specific heat loss for a dwelling to the outdoor air (W/°C). t^*_m is the average of the highest demanded temperatures. The horizontally marked area is the average cost of heat and the diagonally marked area is the cost of cold for a household.

Before individual temperatures are introduced a collective temperature in figure 3 is used and after the average indoor temperature in figure 4 is used. The reduced costs RC are figure 4 subtracted from figure 3. The resulting area is shown in figure 5.

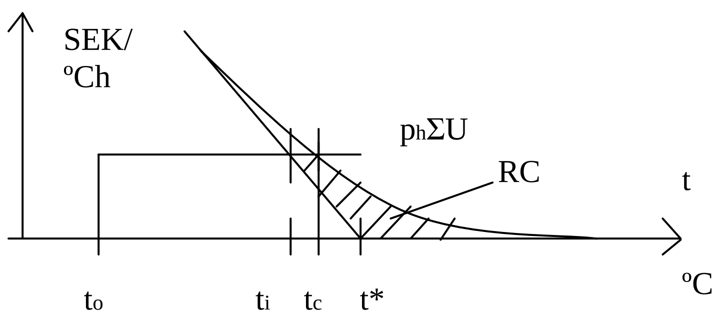

Figure 5. Area, RC representing both the reduced cost of cold and reduced cost of heat when individual temperatures, t_i are introduced. The collective temperature before is, t_c.

$$RC = CC(t_c) + p_h \Sigma U(t_c - t_i) - \frac{k \cdot DI'}{2}(t^* - t_i)^2 \qquad (1)$$

The diagonally marked area in figure 5 or equation 1 represents the reduced cost when the heat cost allocation system is changed from a collective temperature to individual temperatures. The average of the individual temperatures t_i is lower than the collective temperature t_c. The cost reduction is both reduced heat cost and reduced cost of cold. The area RC represents a change from a perfect collective indoor temperature to perfect individual temperatures meaning that they follow the theory. In reality the temperatures are slightly higher than both t_i and t_c. In order to find the perfect collective temperature the owner must know the demand curves of the households. If individual temperature control is used then some households will not control their indoor temperature witch will increase the average.

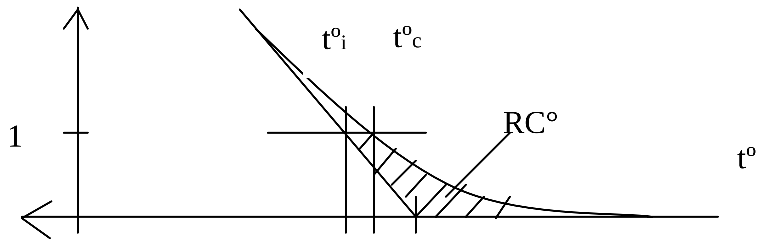

Figure 6. Dimensionless reduced costs, RC° when individual temperatures are introduced in a building with a collective temperature.

Dimensionless area RC° representing reduced costs when heat metering is introduced equation 2. The area CC in figure 3 must be calculated numerically so in order to make the calculations universally valid the axis are normalised. The dimensionless cost of cold for a collective temperature $CC(t_c)$ was shown in [7]. Dimensionless indoor temperature equation 3, individual indoor temperature $t°_i$ equation 4 and standard deviation s equation 5. The dimensionless indoor temperature and corresponding collective temperature, marginal cost, marginal cost of cold and the area that gives the cost reduction are given in table 1.

$$RC° = CC°(t°_c) + t°_i \cdot (t°_c - t°_i) - \frac{{t°_i}^2}{2} \qquad (2)$$

$$t° = \frac{t^* - t}{s} \qquad (3)$$

$$t°_i = \frac{p_h \cdot \Sigma U}{k \cdot DI' s} \qquad (4)$$

$$s = \sqrt{s^{*2} + {s_b}^2} \qquad (5)$$

The temperature in the dwellings in a building with the heating system in figure 1 follows a normal distribution with s_b = 0.8°C according to an estimate from measurements in [8]. s_b depends on the accuracy of the design and balancing of the heating system.

Reduced costs with heat metering equation 6 (SEK/h). To get the cost per year multiplie with the length of the heating season τ (h/year).

$$RC = RC^{\circ}\left(t^{\circ}_{i}\right) \cdot p_{h}\Sigma U \cdot s \qquad (6)$$

Table 1 Dimensionless average of individual, t^{o}_{i} and collective temperature, t^{o}_{c} marginal cost of cold, MC^{o} cost of cold, CC^{o} and cost reduction, RC^{o} at the introduction if individual temperatures.

t^{o}_{i}	t^{o}_{c}	$MC^{o}(t^{o}_{i})$	$CC^{o}(t^{o}_{i})$	$RC^{o}(t^{o}_{i})$
2.0	1.99	2.01	2.50	0.50
1.8	1.79	1.82	2.12	0.50
1.6	1.58	1.62	1.78	0.50
1.4	1.36	1.44	1.47	0.49
1.2	1.15	1.26	1.20	0.48
1.0	0.90	1.08	0.97	0.47
0.8	0.65	0.92	0.77	0.43
0.6	0.35	0.77	0.60	0.39
0.4	0.00	0.63	0.46	0.33
0.2	-0.50	0.51	0.35	0.23
0.0	-2.00	0.40	0.25	0

The highest cost reduction from individual heat cost allocation is at high t°_{i} or when the marginal cost of temperature is high in relation to the disposable income. These economic conditions means that the indoor temperature with collective temperature is low and that the indoor temperature will not be reduced at the introduction of individual heat cost allocation. The reduced costs is from the reduced cost of cold for those who want a high indoor temperature.

At low t°_{i} or at a low price of energy and a high disposable income the indoor temperature will be high with collective heat cost allocation and the temperature reduction at the introduction of individual heat cost allocation will be high. The value of the temperature reduction will be low since the heat has a low price.

RESULTS

The economic evaluation is for one building with MU-dwellings built before 1975 and for one built after 1980 in Sweden. The U-values and the ventilation were reduced after the energy crisis. The dwelling area is 70 m^2/dw.

The economic data for the household refers to 1992. The average disposable income for a house-hold in a multiple unit dwelling were 135.000 SEK/yr hh. The disposable income per hour is DI' = DI/8760 = 15 SEK/h, hh. The length of the heating season 6000 h/yr. The price of heat p_h = 0.5 SEK/kWh (including tax).

The standard deviation $s = (1.3^2 + 0.8^2)^{0.5} = 1.6$°C

The investment in equipment for temperature registration and heat metering is 1500 SEK/dw. It can be used for 10 years and the interest rate is 4 %. The factor of annuity is 0.123 /yr and the cost 184 SEK/yr. To read the heat meters costs 75 SEK/yr dw. The heat cost should be calculated and added to the rent. This is an additional 75 SEK/yr dw. The total cost for heat metering and cost allocation is 334 SEK/yr dw.

Table 2. Heat loss from MU-dwelling to outdoor air.

		Built after 1980		Built bef 1975	
	Area m^2	U $W/m^{2o}C$	ΣUA W/ºC	U $W/m^{2o}C$	ΣUA W/ºC
Wall	31	0.3	10	0.8	25
Roof	70	0.2	14	0.6	42
Window	10	2.0	20	3.0	30
Ventilation		25 l/s	30	30 l/s	36
Sum		ΣU W/ºC	74	ΣU W/ºC	133

Table 3. The average temperature with individual heat cost allocation, t_i and the collective temperature t_c with collective allocation in a MU-dwelling.

Built	$t^o{}_i$	t_i ºC	t_c ºC	RCº	RC SEK/yr
Before 1975	0.69	20.54	20.85	0.41	262
After 1980	0.38	21.03	21.73	0.32	114

The reduced costs 262 SEK/yr dw in buildings before 1975 and 114 SEK/yr dw in buildings after 1980 should be compared with the cost for meters, reading and administration 334 SEK/yr dw. Metering cost more than the cost reduction from metering. The cost of the control work from the households is not included.

DISCUSSION

A high marginal cost of temperature makes the households reduce their indoor temperature due to the cost. The reduction will be high at low disposable incomes. If a collective indoor temperature is used, the same temperature for all households, then the indoor temperature is highly reduced for those who preferes a high indoor temperature. Then the value of individual heat cost allocation will be high since everybody can have the temperature they are willing to pay for. The marginal cost of temperature is high if the price of heat is high and if the buildings are poorly insulated. Poorly insulated buildings are used in warm and mild climates. Individual temperatures can be expected were there are long mild winters.

Individual heat cost allocation benefits from badly designed and badly balanced heating systems that don't give the same temperature in all dwellings and from different indoor temperature preferences among the households.

The Use of a Fixed Part and a Variable Part in Heat Cost Allocation after Heat Quantity in Swedish Multiple Unit Dwellings

Arne Jönsson

Mid-Sweden University, Härnösand, Sweden

Corresponding email: arne.jonsson@miun.se

SUMMARY

This is a theoretical analyse based on microeconomics. It analyses heat cost allocation methods after measured heat quantity for MU-dwellings in a building with an owner who byes or produces the heat that is sold to the households.

A MU-dwelling loses heat to the outdoor air and exchanges heat with surrounding dwellings. The owner can use less heat to increace the indoor temperature than the household it self. The household must pay for heat transfer to other dwellings. This makes an increase in the indoor temperature more expensive to the household than to the owner. The households will have a to low indoor temperature. To compensate this only a part of the measured heat quantity is sold. The rest of the heat cost for the building is distributed to the households after dwelling area. In Swedish MU-dwellings 60-80 % the fixed part should be distributed after area and 20-40 % the variable part sold after measured quantiy.

INTRODUCTION

The influence of the marginal cost on the consumed quantity of a goods has been known from economics for hundreds of years, but it has seldom been used to analyse heating of buildings. The use of a fixed part is to reduce the marginal cost of indoor temperature or to make a temperature increase cheaper. This paper suggests how the fixed part should be calculated to give indoor temperature the marginal cost that corresponds to the heat loss to the outdoor air.

[1] called heating in MU-dwellings a semi-collective goods. Semi means that the acces to the indoor temperature is limited to the membes of the households. [2] used economics to analyse individual metering of hot water in MU-dwellings. [3] presented the economics of heating. The occupants sets their thermostats to the temperature where marginal cost equals marginal value of indoor temperature. He investigated the economic differences between a common temperature and individually chosen temperatures in two apartments and used the theory for public goods to find the best common indoor temperature in a building with two dwellings. [4] used economics to investigate low indoor temperatures in low income households.

The demand curve for indoor temperature in Swedish MU-dwellings was determined by [5] as a straight line and in SU-dwellings by [6] and [7]. Heat cost allocation in homes with individual control and individual heat metering, individual temperature metering and a collective temperature was described in [8]. The use of a fixed part and a variable part for heat cost allocation after heat quantity was not included in [8]. A fixed part (grundkosten) and a variable part (verbrauchskosten) is used in Germany [9]. The fixed part there is between

30-50 % of the sum of all costs for heating including cleaning and maintenance of the heating system.

METHODS

A household in a MU-dwelling produces indoor temperature whith heat and insulation. The household balances the cost of heat or cost of temperarure horizontally marked in figure 1 and the cost of cold diagonally marked against each other. The household choses the indoor temperature where the marginal cost of heat is equal to the marginal cost of cold. The marginal cost of heat is the cost of a temperature increase.

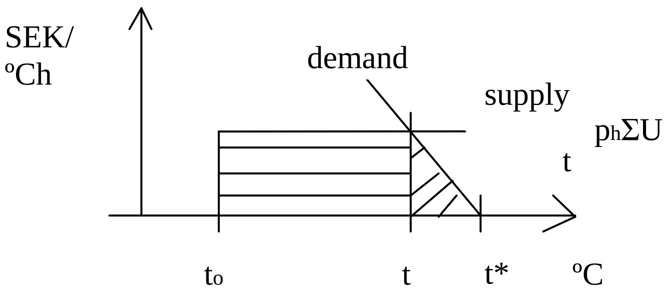

Figure 1. Demand and supply curves for indoor temperature. Indoor temperature, t. Outdoor temperature, t_o. Highest indoor temperature the household is willing to pay for, t*.

The MU-dwellings are in a building with an owner who byes or produces the heat that is sold to the households after meassured heat quantity. A MU-household in a building loses heat to the outdoor air and exchanges heat with surrounding dwellings. The owner can use less heat to increate the indoor temperaturre in a dwelling than the household it self. This makes an increase in the indoor temperature more expensive to the household than to the owner. The household must pay for heat transfer to other dwellings, but the owner only pays for the heat that goes out to the outdoor air. Heat to other dwellings repleaces heat from the heating system. The households will have a to low indoor temperature if the household pays for the heat after measured quantity.

In this case it is possible for the owner to reduce the price of heat to the household or to sell only a part of the measured heat quantity. The ideal is to make the cost of a temperature change the same as for the owner. This will increase the indoor temperature and well beeing for the households. To cover the cost of heat to the building the owner must increase the rent so his economy isn't affected. It is important that the cost of a goods or serivce is the same to all users in the society so the alternatives can be optimised against the same price. This is for the period during the year when heating is neccesary in all dwellings in the building. Three heat cost allocation methods are analysed.

The same cost for a temperature increase for both household and owner

Q is heat quantity to the building in figure 2 (W). Q_1 is the measured heat quantity (W) to dwelling 1. ΣQ_i is the sum of measured heat quantities to the n dwellings. ΣU_1 equation 1 is the specific heat demand of dwelling 1 (W/°C) for heat to outdoor air. q outdoor air rate for ventilation (m^3/s). ΣU_{12} is the specific heat exchange between dwelling 1 and dwelling 2 trough internal walls (W/°C) equation 2.

$$\Sigma U_1 = \Sigma UA + q \cdot \rho \cdot c_p \qquad (1)$$

$$\Sigma U_{12} = \Sigma UA_{int} \qquad (2)$$

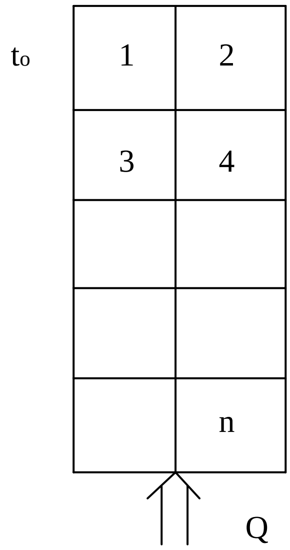

Figure 2. Building with n MU-dwellings. t_o outdoor temperature ºC.

The heat loss to outdoor air (W) from dwelling 1, equation 3. All rooms in a dwelling have the same temperature.

$$\Sigma U_1 \cdot (t_1 - t_o) \qquad (3)$$

The heat loss from dwelling 1 to outdoor air and to other dwellings Q_1, equation 4.

$$Q_1 = \Sigma U_1 \cdot (t_1 - t_o) + \Sigma\Sigma U_{1i} \cdot (t_1 - t_m) \qquad (4)$$

t_m average (weigthed) temperature in dwellings surrounding dwelling 1 (ºC). $\Sigma\Sigma U_{1i}$ is the specific heat exchange between dwelling 1 and surrounding dwellings trough internal walls (W/°C) equation 5.

$$\Sigma\Sigma U_{1i} = \Sigma U_{12} + \Sigma U_{13} + \Sigma U_{14} \qquad (5)$$

If equation 4 is differentiated with respect to t_1 and the variable share (1-Φ) times the heat demand for the household to increase the indoor temperatue is put equal to the differentiated heat demand for the owner equation 3. Then $(1-\Phi_1)$ can be solved equation 6. The fixed share Φ_1.

$$(1 - \Phi_1) = \frac{\Sigma U_1}{\Sigma U_1 + \Sigma\Sigma U_{1i}} \qquad (6)$$

If Q_1 $(1-\Phi_1)$ is sold to the houshold at the market price of heat p_h (SEK/kWh), (1USD = 8 SEK) or the price of heat is reduced to $(1-\Phi_1)$ p_h then it will be equally expensive for the household and the owner to increase the indoor temperatue in dwelling 1 but the owner will not cover his cost for heat. The measured heat quantity to dwelling 1 will still depend on the temperature in surrounding dwellings, t_m but the fixed part will reduce the influence.

Since this is a reduction in marginal cost for the household a higher indoor temperature will be used by the household. There is another variable share for dwelling 2.

The same cost for a temperature increase for both household and owner that covers the cost for the owner

If the price of heat or the sold quantity of heat is reduced then the owner must increase the rent to cover his costs.

The heat to dwelling i, Q_i is divided in two parts with the fixed share Φ_i for dwelling i in equation 7.

$$Q_i = \Phi_i \cdot Q_i + (1 - \Phi_i) \cdot Q_i \qquad (7)$$

All heat that the owner byes or produces Q will be sold to the households according to equation 7 and 8.

$$Q = \Sigma Q_i = \Sigma \Phi_i \cdot Q_i + \Sigma (1 - \Phi_i) \cdot Q_i \qquad (8)$$

Each household pays p_h (1 - Φ_i) Q_i as the variable part. The rest of the heat $\Sigma\Phi_i Q_i$ is equally divided between the n dwellings since they have the same area. This is called the fixed part and it is included in the rent.

The marginal cost of indoor temperature now depends on the number of dwellings n in the building so a new Φ_1 analog to equation 6 have to be derived. .

Household 1 pays for the heat quantity Q_{p1} according to equation 9.

$$Q_{p1} = \frac{\Sigma \Phi_i \cdot Q_i}{n} + (1 - \Phi_1) Q_1 \qquad (9)$$

The new Φ_1 should make the differential of Q_{p1} with regard to t_1 equal to ΣU_1 according to equation 3. This makes the marginal cost for the household in dwelling 1 equal to the marginal cost for the heat loss to the outdoor air. Q_1 from equation 4, Q_2 - Q_4 are analog to equation 4 and inserted in equation 9. Dwelling 2, 3 and 4 have heat exchange with dwelling 1.

If Φ_1 to Φ_4 are approximately equal then Φ_1 can be calculated from equation 10. This approximation is probably a better method than to use the same average Φ for all dwellings. Different Φ makes the marginal cost equal to the marginal cost for the heat loss to the outdoor air for every dwelling.

$$\Phi_1 = \frac{\Sigma\Sigma U_{1i}}{\Sigma U_1 \cdot \left(1 - \frac{1}{n}\right) + \Sigma\Sigma U_{1i}} \qquad (10)$$

Compared to the fixed share from equation 6, equation 10 gives a higher fixed share. It will be higher in buildings with a few dwellings.

The same cost for a temperature increase, the same cost for heating for both household and owner and that covers the cost for the owner

This is not possible with heat quantity measurement since the heat to other dwellings depends on the temperature in the surrounding dwellings and on the heat transfer properties to the other dwellings equation 4.

Heat quantity measurement will give a reduced cost for the household if heat from internal heating systems or free heat are used in the dwelling. But the variable part will reduce the part of the free heat that reduces the cost.

A cost allocation system that gives the same cost for a temperature increase, the same cost for heating for both household and owner that covers the cost for the owner is indoor temperature measurement and calculation of the heat to the outdoor air from the dwelling with equation 3. This system can not register the free heat.

Example

The heat to and from a MU-dwelling can be shown as function of the indoor temperature in a diagram figure 3. The dwelling get heat from heaters and depending on the indoor temperature exchanges heat with other dwellings. The dwelling also get heat from its occupants, from lighting, refrigerators etc. This is called free heat. If the heaters in the dwelling is shut of it will get the indoor temperature t_b. At higher temperatures the heaters are used. At the indoor temperature t_m there is no net heat exchange with other dwellings and at higher indoor temperatures heat is lost to other dwellings.
The line representing heat loss to the outdoor air starts in t_o. At t_b the line is thick. This part shows the heat power that a dwelling pays for if the marginal cost of temperature is for the heat loss to the outdoor air. The horizontal thick line shows the fixed part.

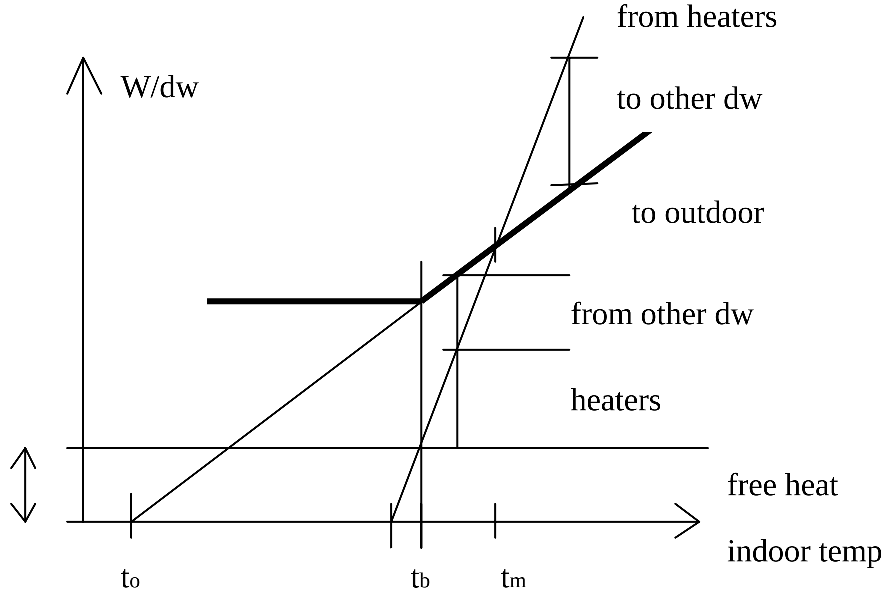

Figure 3. Heat to and from a MU-dwelling with free heat.

The heat from the heaters is more sensible to the indoor temperature than the heat loss to the outdoor air. If the heat from the heaters should be used for cost allocation then it must be corrected with Φ so the heating cost follows the cost for heat loss to the outdoor air, from t_b and up to higher temperatures. At the lowest possible temperature t_b the household pays the fixed part of the buildings heating cost.

RESULTS

Calcualtion of the fixed share Φ that gives the same cost for a temperature increase for both household and owner in Swedish MU-dwellings built before and after the energy crisis.

Table 1 Heat loss from a MU-dwelling to outdoor air trough different building elements.

Element		Built after 1980		Built bef 1975	
	Area m^2	U $W/m^2 ºC$	ΣUA W/ºC	U $W/m^2 ºC$	ΣUA W/ºC
Wall	31	0.3	10	0.8	25
Roof	70	0.2	14	0.6	42
Window	10	2.0	20	3.0	30
Ventilation		25 l/s	30	30 l/s	36
Sum		ΣU W/ºC	74	ΣU W/ºC	133

Table 2 Heat exchange between MU-dwellings $\Sigma\Sigma U_{1i}$

	Area m^2	U $W/m^2 ºC$	ΣUA W/ºC
Wall	41	2.5	102
Floor	70	1.5	105
Sum		$\Sigma\Sigma U_{1i}$ W/ºC	207

The ΣU_1 from table 1 and $\Sigma\Sigma U_{1i}$ from table 2 in equation 6 gives the Φ in table 3. If the building have preheated supply air then the heat demand for ventilation in table 1 is excluced.

Table 3 Fixed share Φ that fullfills the same marginal cost for both owner and household. In a MU-dwelling according to table 1 and 2. Variable share (1- Φ).

	Built after 1980	Built before 1975
Exhaust ventilation	74 %	61 %
Supply and exhaust vent	82 %	68 %

The Φ that gives the same cost for a temperature increase for both household and owner and that covers the cost for the owner to be used with equation 9 will be higher than in table 3 depending on how many dwellings there are in the building.

To calculate a Φ for all dwellings in the building that gives the same cost for a temperature increase for both household and owner and that covers the cost for the owner more data for the building must be known, but the fixed share will be of the same magnitude as in table 3. The fixed share used in Germany is between 30-50 %.

DISCUSSION

Well insulated buildings where the dwellings have a small heat loss to the outdoor air needs a high fixed part to reduce the marginal cost of temperature. The heat exchage with the outdoor air is a small part of the total heat exchange for a MU-dwelling. Small not so well insulated buildings needs a low fixed part since the heat exchage with the outdoor air is a big part of the total heat exchange for the dwelling.

More numeric calculations and data are necessary to find the fixed part for all equaly sized dwellings that cowers the cost for the owner. More research is necessary to find the best fixed part in a building with dwellings that differs in size.

SUMMARY

A prefabricated deck system made of laser-welded steel sandwich panels (LSP), up to now only used for decks in shipbuilding, shall be improved for the use in buildings. Beneath other items like fire safety, acoustics and vibrations here the thermal performance is of particular interest. Due to the very low weight the thermal inertia is very low. For compensation of this property this deck element was designed with an integrated piping system for simulating the thermal behaviour of a heavy construction, furthermore the characteristic of a heating and cooling ceiling could be reached, depending on the supply temperature.

Prototypes of these new deck panels were produced and implemented into the research building of the Institute of Steel and Light-weight Constructions, RWTH in Aachen. A detailed scientific programme was performed to work out the thermal capabilities of these elements using a detailed monitoring system, heat meters and infrared surveys. In parallel numerical investigations were made (FEM-calculations and TRNSYS-simulations) to compare the results and to show further steps for improvements.

The investigations show interesting results: The manufacturing must be properly performed to get sufficient thermal contact from pipes to the ceiling, the response time is low due to the low mass, and the benefit for the indoor climate of light-weight constructions is high with acceptable additional costs.

INTRODUCTION

The deck element in the scope of this investigation is a laser-welded steel sandwich panel (LSP) with vertical webs in a Vierendeel system. Figure 1 shows this element, which is originally used for decks in shipbuilding, and gives the range of dimensions, in which this panel is available, the maximum span amounts 10 m. The column indicated with “RWTH” shows the dimensions of the elements used for testing in the RWTH Modular Research Building (see below). The very low depth could only achieved by penetrating the laser-weld beam from the outside. These deck elements have a high stiffness at a very low mass. These properties make the panels interesting for highly prefabricated construction systems.

	from [mm]	to [mm]	RWTH [mm]
Width	500	3000	1800
Length	1000	10000	5400
t	2	10	3
p	120	120	120
hs	40	100	80
ts	3	4	4

Figure 1: Laser welded steel sandwich panel with upper deck plate, vertical webs and lower deck plate (left), dimensions of laser-welded panels (right)

One problem of having this very low mass is the missing thermal inertia, therefore a solution to compensate this disadvantage was developed and tested. A steel pipe meander was integrated in the panel to create a heating / cooling ceiling resp. a thermally activated building component (Figure 2). The denomination is not clear-cut, on one hand, the hydronic system is integrated in a structural component similar to a concrete core cooling, on the other hand it behaves like a cooling ceiling

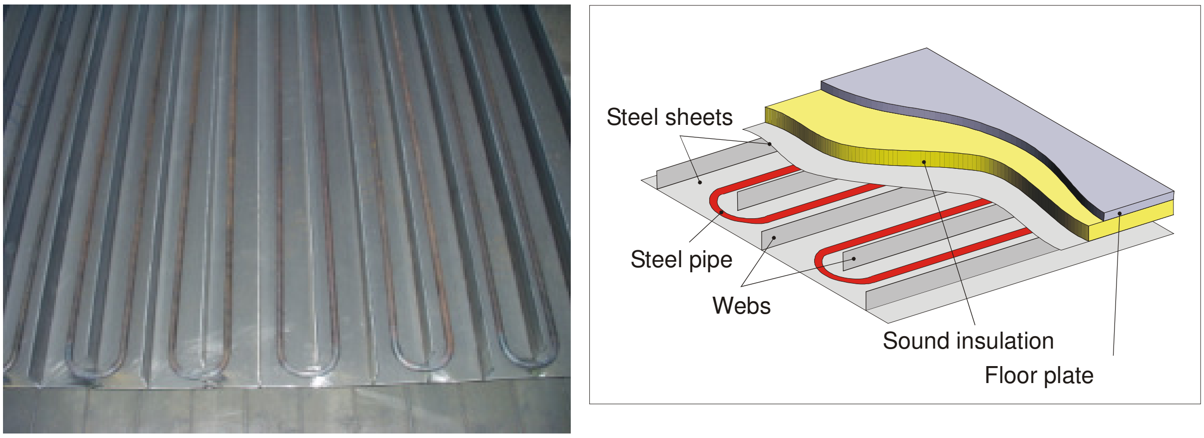

Figure 2: Integration of steel pipes in the steel deck system (left: steel pipes in the module before welding the upper steel sheet, right: principle of the completed deck system)

IMPLEMENTATION AND TESTING OF THE DECK SYSTEM IN A RESEARCH BUILDING

In 2005 the Institute of steel and light-weight construction, RWTH Aachen University, in collaboration with the german association IFBS (Industrieverband für Bausysteme im Metallleichtbau, Düsseldorf), erected a research building using light weight, prefabricated components made of steel. Drawings of the building are given in figure 3, figure 4 shows the erection and figure 5 the completed building. One objective of this research building is the measurement of the thermally activated LSP. The test room in the center of the ground floor is equipped with these elements.

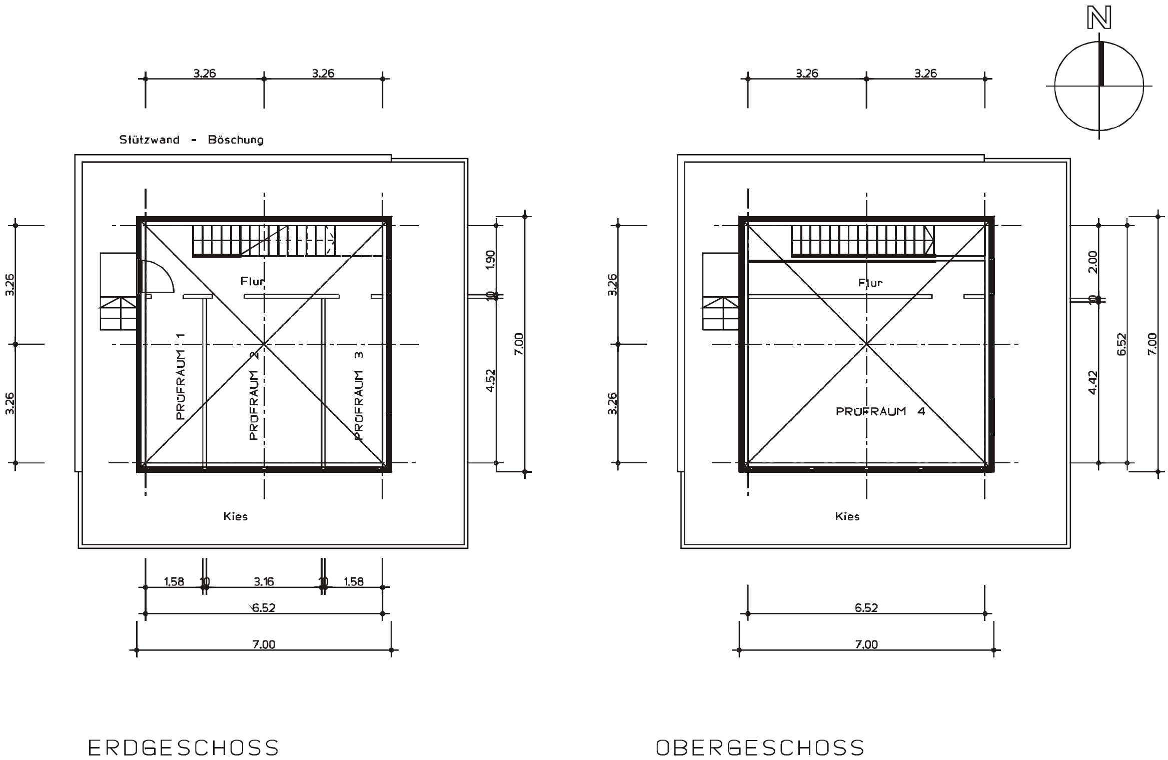

Figure 3: Ground plan of modular research building (left: ground floor, right: upper floor)

Figure 4: Erection of Modular Research Building

Figure 5: Modular Research Building, elevation North-West (left), South-East (right)

TESTING EQUIPMENT FOR DECK SYSTEM

The two active deck elements are feeded by a refrigerated circulator, providing pre-heated or pre-cooled water. Various valves are integrated in the circuit to allow different running modes (only one panel active or both in parallel or serial connection). Each panel has a heat meter for measuring volume flow and the consumption of heat resp. coolth (figure 6). Additionally heat flux plates and an infrared camera were used to get more reliable data by using different measurements at once.

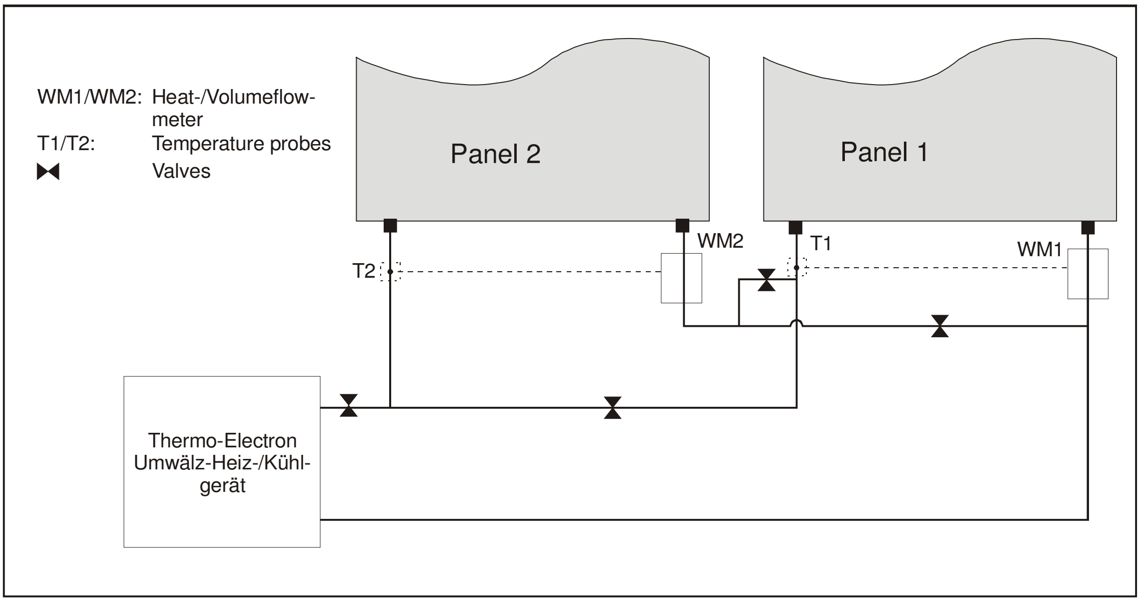

Figure 6: Sketch of testing set-up

Measurements were made for heating and cooling, due to the lack of space only the cooling results are presented (further results: see [4]). Figure 7 shows the specific cooling power depending on the mean temperature difference water – room. In the diagramm results taken from the heat meters and by heat flux meters in combination with infrared surveys are shown. Results between ca. 30 and more than 45 W/m² were measured at temperature differences between 6 and 8 K (room – mean water temperature).

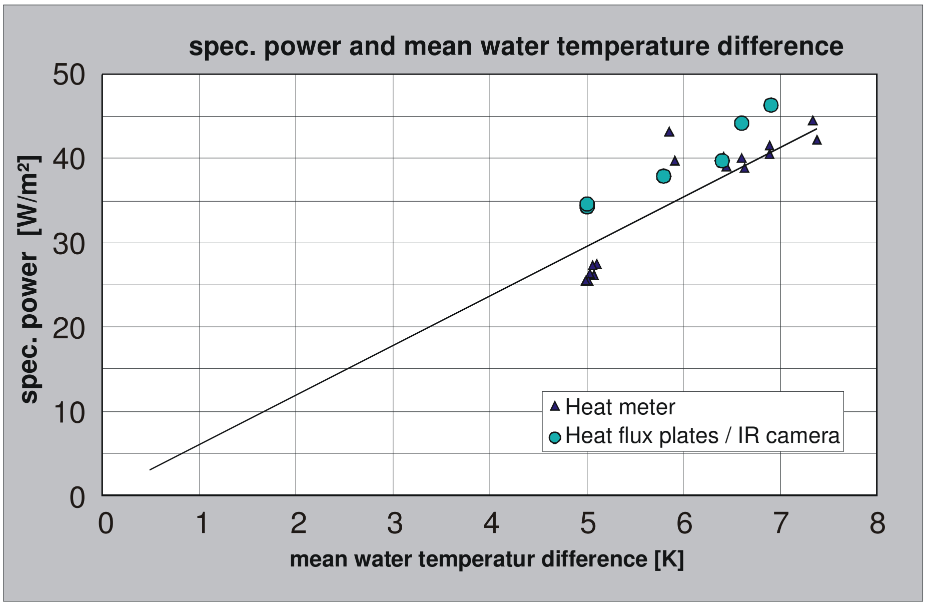

Figure 7: Measured cooling power of active deck element, cooling mode

An infrared survey from the ceiling were taken to get detailed information about the temperature distribution (figure 8). The view on the lower side of the panels shows some remarkable aspects: The steel pipes are sticked-welded to the lower deck plate of the section every 100 cm, these positions can be identified as “cold spots”, here is a good thermal contact guaranteed. In between the contact is more or less random – in some parts there is good contact also between the welded points, but in the majority part the temperature is higher – the thermal contact is not sufficient.

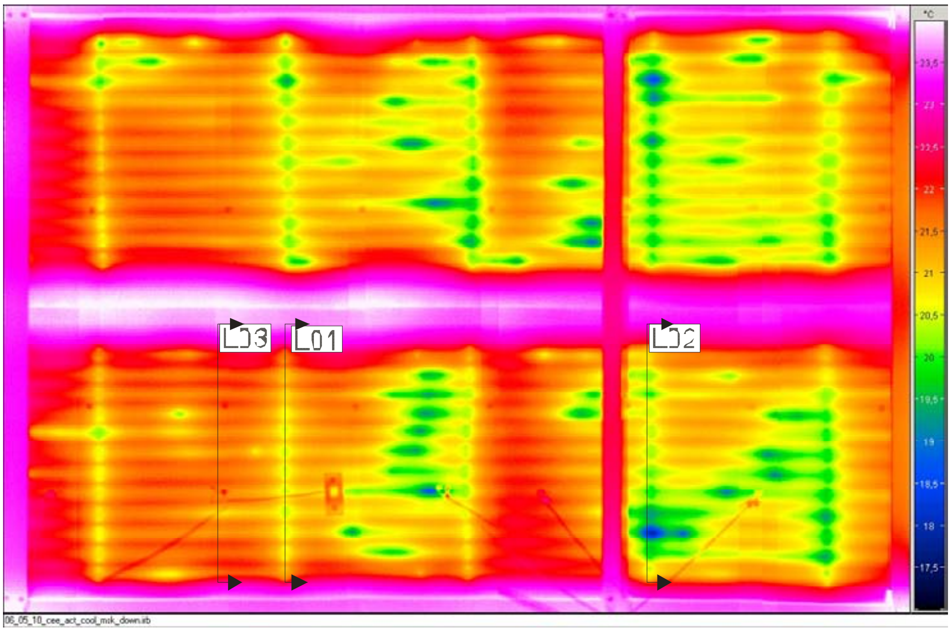

Figure 8: Infrared survey of active deck element, cooling mode (view underneath the steel slab)

FEM-CALCULATIONS

The tested deck element was also numerically investigated. A representative sectional model was used for a FEM-study. Two different cases were considered: The pure LSP with the pipe and a complete deck system including insulation and floor plate (figure 9). These two variations were tested in the research building, too.

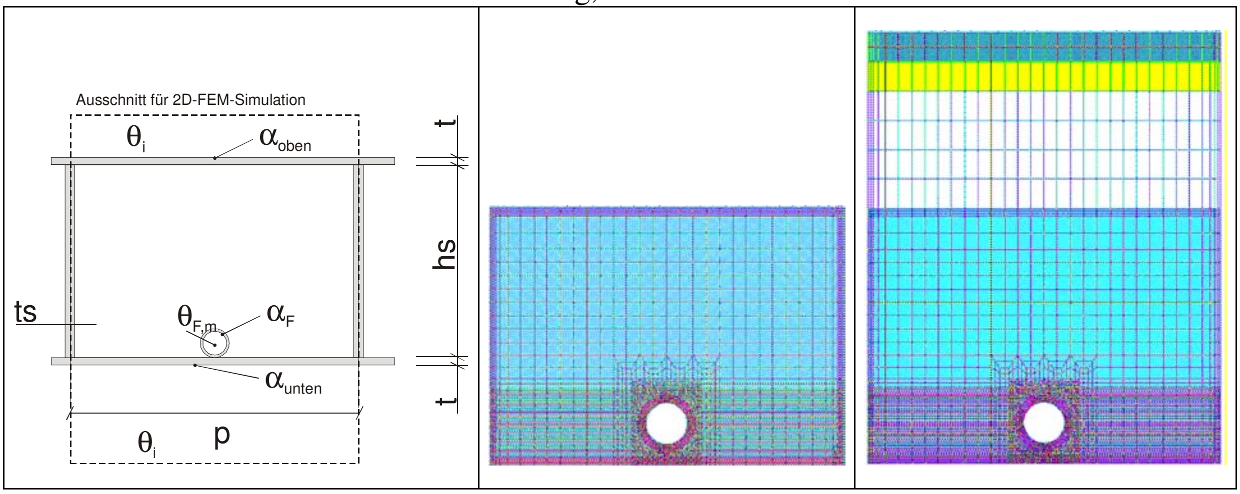

Figure 9: FEM-model of thermally activated LSP (left: sketch with boundary conditions, mid: FEM-model without flooring, right, FEM-model with insulation an floor plate)

The following boundary conditions were taken into account [2],[3]:

Mean water temperature $\theta_{F,m}$:	18 °C
Room temperature θ_i:	26 °C
Heat transfer coefficient α_{top}:	6.7 W/m²K
Heat transfer coefficient α_{unten}:	$8.92\ (\theta_i - \theta_{F,m})^{0.1}$ W/m²K
Heat transfer coefficient water/pipe α_F:	200 W/m²K

Figure 10 shows the results of the FEM-calculations. Without insulation a part of the coolth reaches the floor, the ceiling temperature is about 20 °C, the floor approx. 22 °C. If the insulation and floor plate is added, nearly all coolth is transferred by the ceiling (temperature 19 – 20 °C), the floor temperature is close to the room temperature.

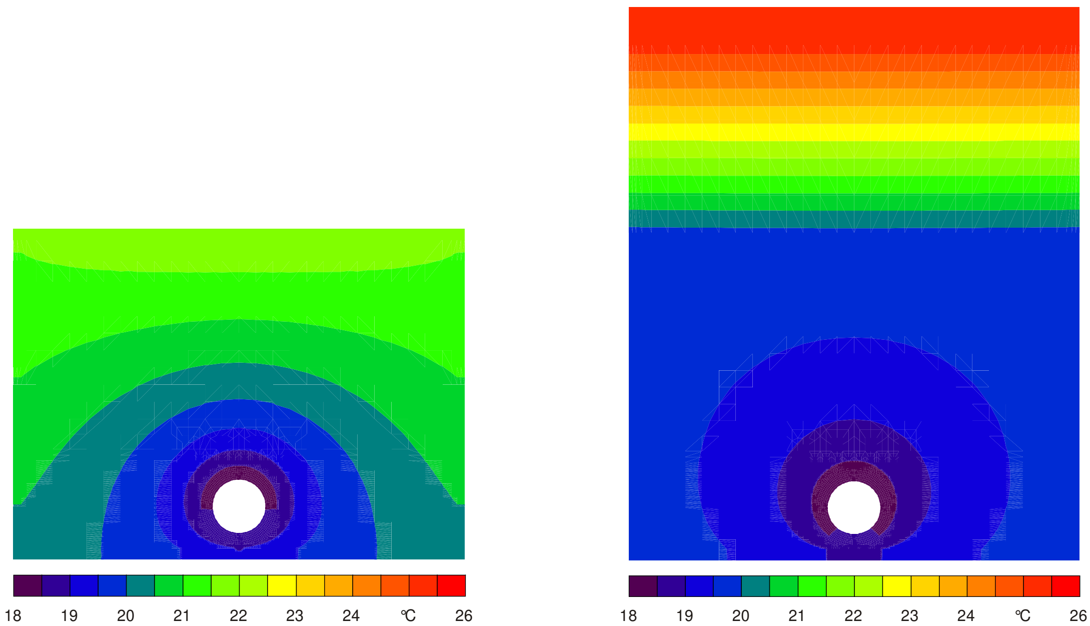

Figure 10: Results FEM-calculation (left: without flooring, right: with insulation and floor plate)

Based on these results the cooling power for various temperature differences was calculated (Figure 11); the diagram shows additionally curves for existing cooling ceilings, furthermore the measured results as shown in Figure 7 are marked. The FEM-results show a high performance of the thermally activated LSP, on the other hand, the measured results are significantly lower. This difference was studied in detail by an analysis of the IR-survey and a variation of the FEM-calculations (Figure 12).

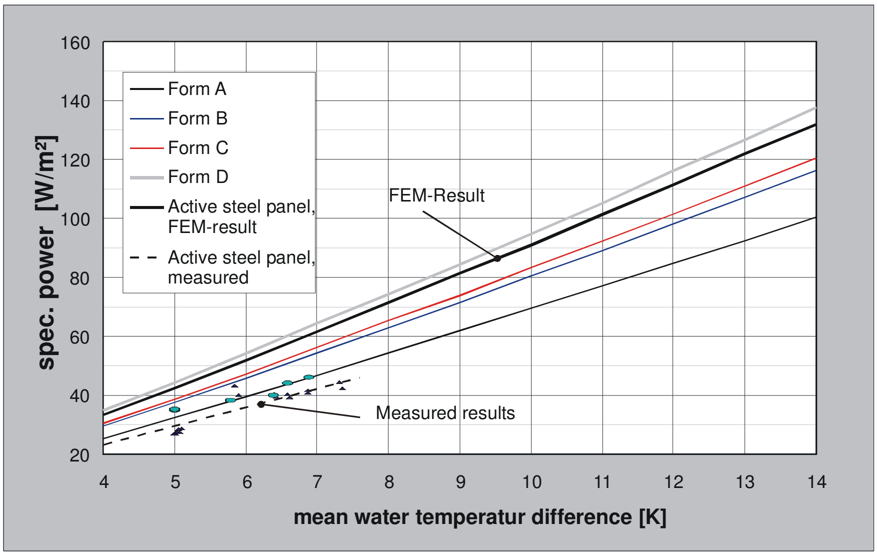

Figure 11: FEM-result (thermally activated LSP with insulation and floor plate), in comparison with conventional existing cooling ceilings (Form A to D, [1]) and the measured results

The comparison of Figure 12 shows, that very small air gaps between the pipe and the sheet lead to a significant loose of performance. The measured section L3 is close to the calculated result for a 1 mm air gap, on the other hand the measured cold spots (see L02) reach the temperature

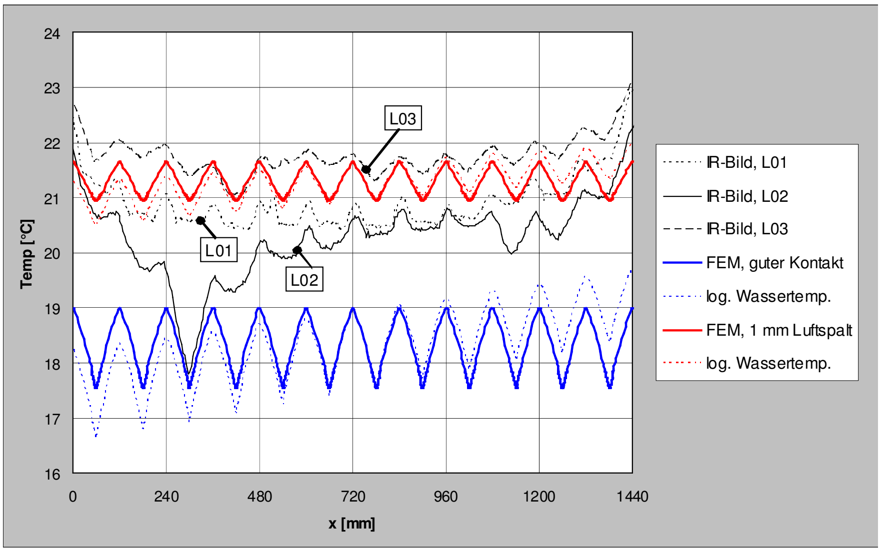

Figure 12: Comparison of FEM-results (good contact and 1 mm air gap) and sections of the IR-survey (as marked in Figure 8)

RESULTS

The thermal activation of a laser-welded steel sandwich panel is possible. The thermal performance was tested by measurements and in parallel investigated with numerical calculations. The theoretical performance is very good, a specific cooling power of 70 W/m² by a mean temperature difference water – room of 8 K was calculated, which is in the top range of existing cooling ceilings. The measured results are lower, a value of ca. 48 W/m² at the same temperature difference can be extrapolated from the measurements. The main reason for this deviations was identified: The steel pipes have good contact to the lower steel sheet only at the fixing points, in between frequently an air gap exist, whereas small gaps (1 mm) lead to a significant loss of power

DISCUSSION

Generally the deck system “LSP” presented in this paper has the potential for a high cooling performance, as the FE-calculations show. To reach this value in practice, the contact between pipe and sheet has to be worked out carefully. The punctual stitched welds lead to unwanted decrease of the cooling power. A continuous welding or other techniques (glue, thermal paste, e.g.) to improve the thermal contact will bring the practical results closer the calculated values.

ACKNOWLEDGEMENT

The investigations has been carried out with a financial grant of the Research Programme of the Research Fund for Coal and Steel within the project EEBIS - Energy Efficient Buildings through Innovative Systems in steel (RFS - CR – 03017). The Modular research building was supported by IFBS (Düsseldorf, D), the laser-welded steel sandwich panels by Meyer Werft (Papenburg, D). These funds are greatly acknowledged.

SUMMARY

In many countries, a radiant heating system is gaining much popularity due to its high comfort level, energy efficiency, improved IAQ and so on. A lot of studies have suggested that the supply water temperature of a radiant heating system be modulated by a heating curve, which is a linear function of outdoor temperature. The heating curve, however, has been determined by an operator's experience or a tedious trial and error approach. This study aims at deriving a heating curve to determine supply water temperature based on heat loss of a building and a heat flow model of the floor structure. To evaluate the derived heating curve, TRNSYS simulation and a mock-up experiment were conducted. The results show that the developed heating curve provides optimum water temperature enough to keep the indoor environment comfortable. This study would be able to provide an algorithm for the outdoor reset controller of a radiant floor heating system.

INTRODUCTION

The goal of a radiant heating system is to supply heat at the same rate at which the building loses heat, thereby keeping the indoor environment stable and comfortable. To achieve this purpose, outdoor temperature reset control is widely applied to the radiant heating system. The main principle of the control strategy is to modulate the supply water temperature according to the heating curve or reset ratio, which means the relation between supply water and outdoor air temperature. Although a lot of studies have been conducted to evaluate and improve the performance of outdoor temperature reset control, there has been little research on the determination of heating curve or reset ratio.

Adelman proposed a heating curve based on supply water design temperature and supply water starting temperature, which corresponds to the coldest and mildest outdoor condition, respectively [1]. But he did not explain how water design temperature and water starting temperature should be calculated.

MacCluer used a reset ratio determined by U-value of the wall, thermal resistance of the slab and heat transfer coefficient of floor surface [2]. But the detailed floor structure was not considered in the calculation of a reset ratio. Leigh conducted several experiments on the outdoor temperature reset control and other control methods of a radiant floor heating system. In the experiment, a reset ratio was estimated based on design conditions and thermal characteristics of the building. But the reset ratio was adjusted by performing several pre-tests before the experiments [3].

Gibbs recommended that auxiliary control strategies be combined with outdoor reset control for the multi-zone control [4]. In the research, a reset ratio was set constant but the method to calculate the reset ratio was not described specifically.
Liao et al compared the energy consumption and control performance of the heating system with different heating curves. It was pointed out that the performance declines significantly if a heating curve is not determined properly [5]. The method of determining a heating curve, however, was not explained definitely. Zhang argued that outdoor reset control requires a good relation between zone load, outdoor temperature and supply water temperature. And it was emphasized that the absence of accurate knowledge of such a relation could result in either overcorrection or poor control [6].

In most residential buildings, however, a heating curve is determined by an operator's experience or time-consuming trial and error procedure. This makes supply water temperature determined incorrectly, with heating load, thermal characteristics of a building and heat flow from the radiant heating floor ignored.

The objective of this study is to derive a method to determine a heating curve which considers heating load of the building and heat flow from radiant heating floor. The result of this study could help to determine optimum supply water temperature for the enhancement of indoor thermal environment.

FACTORS OF A HEATING CURVE

Heating load is the first factor to influence the heating curve of a building. As it is general that the building is under steady-state when heating system is operated continuously, heating load can be expressed as follow:

$$Q_{load} = \sum_{exterior} U_i A_i (T_{set} - T_{out}) + \sum_{interior} U_j A_j (T_{set} - T_{ad,j}) + V_{air}(T_{set} - T_{out}) \quad \text{(W)}, \qquad (1)$$

where first two terms in the right side of the equation are heat loss through exterior walls and interior walls respectively. And the last term is heat loss by infiltration or ventilation. Solar gains and internal heat sources were not included so that the gains could act as a safety factor.

The second factor of a heating curve is heat flow from the radiant heating floor. Heat flow is determined by various parameters of floor structure such as pipe spacing, thermal conductivity and thickness of the screed, thermal resistance of surface covering and so on. According to EN 1264, heat flow between embedded pipes and the space is calculated by the general equation as follows [7]:

$$Q_{panel} = A_f B \prod_i (a_i^{m_i}) \Delta\theta_H \quad \text{(W)}, \qquad (2)$$

where A_f is an area of heating surface, and B is a system coefficient dependent on system type and the heat exchange coefficient (for floor heating, B=6.5W/m^{2}K). $\prod_i (a_i^{m_i})$ is the power product which links the parameters of the floor structure (surface covering, pipe spacing, pipe diameter and pipe covering) . $\Delta\theta_H$ is heating medium differential temperature determined by following equation.

$$\Delta\theta_H = \frac{T_{sup} - T_{ret}}{\ln \dfrac{T_{sup} - T_{set}}{T_{ret} - T_{set}}} \quad \text{(K)}, \qquad (3)$$

where T_{set}, T_{sup} and T_{ret} are room air temperature, supply water temperature and return water temperature, respectively.
In other words, heat flow from the radiant heating floor is proportional to $\Delta\theta_H$ and $B\prod_i (a_i^{m_i})$ can be considered as a heat transfer coefficient for the surface of a radiant heating floor. Figure 1. shows the factors influencing the heating curve of a building.

DERIVATION OF A HEATING CURVE

If a building is maintained steady-state with continuous heating, heat output from the floor is equivalent to heating load. And if downward heat flow is restricted with insulation and the lower space is heated, as in a multi-family house, heat output from the floor is also equivalent to heat discharged by hot water in the embedded pipe, which is calculated as follows:

$$Q_{water} = m_w \cdot c_{p,w} \cdot (T_{sup} - T_{ret}) = m_w \cdot c_{p,w} \cdot \Delta T \quad \text{(W)}, \qquad (4)$$

where m_w is a mass flow rate of hot water (kg/s), $c_{p,w}$ is a specific heat capacity of hot water (J/kgK), ΔT is a temperature drop of hot water (K).
Combining equation (2), (3) and (4), supply water temperature T_{sup} can be calculated as

$$T_{sup} = T_{set} + \alpha \Delta T \quad \text{(K)}, \qquad (5)$$

where α is a coefficient dependent on the geometry and thermal property of the radiant floor, expressed as following equation.

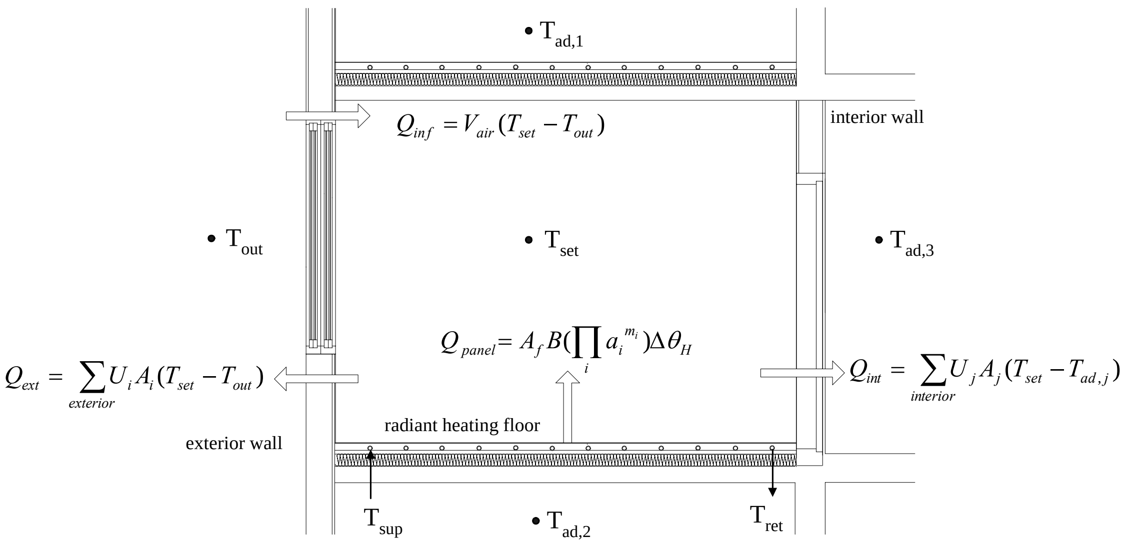

Figure 1. The factors related with the heating curve of a building

$$\alpha = \frac{1}{1 - \exp\left(- \frac{A_f B \prod_i (a_i^{m_i})}{m_w \cdot c_{p,w}} \right)} \qquad (6)$$

On the other hand, ΔT in equation (5) can be obtained by combining equation (1) and (4). Thus ΔT can be replaced with following equation (7).

$$\Delta T = \frac{(\sum_{exterior} U_i A_i + V_{air})(T_{set} - T_{out}) + \sum_{interior} U_j A_j (T_{set} - T_{ad,j})}{m_w \cdot c_{p,w}} \text{(K)} \qquad (7)$$

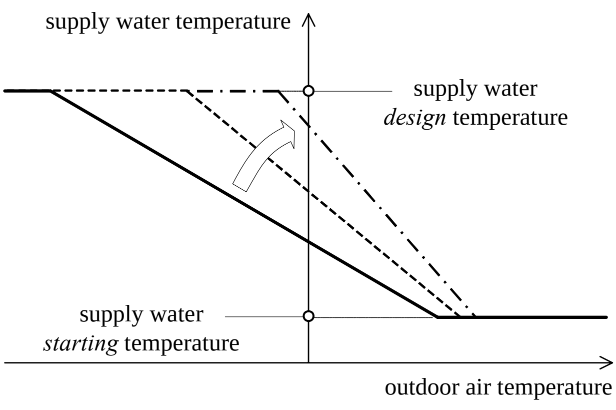
Putting equation (7) into equation (5) and arranging the equation with regard to T_{out} gives a final result, that is, a heating curve expressed as a linear function of outdoor air temperature.

$$T_{sup} = -\left(\frac{\alpha(\sum_{exterior} U_i A_i + V_{air})}{m_w c_{p,w}} \right) T_{out} + \left(1 + \frac{\alpha(\sum_{all} U_i A_i + V_{air})}{m_w c_{p,w}} \right) T_{set} - \frac{\alpha}{m_w c_{p,w}} \sum_{interior} U_j A_j T_{ad,j} \quad (8)$$

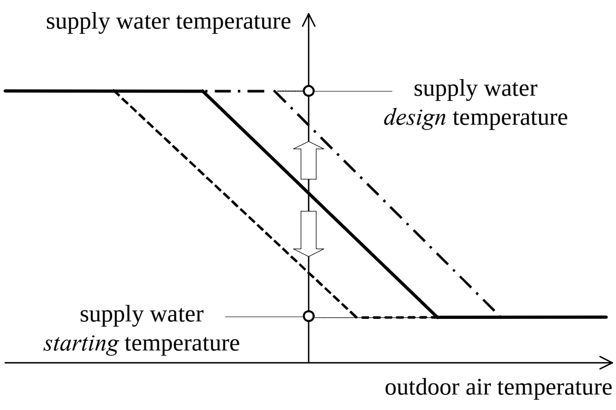
According to equation (8), the slope of heating curve gets steeper as the heat loss of a building becomes larger as described in Figure 2. a). On the other hand, the change of set temperature and adjacent room temperature tends to shift up or down without changing the slope of the heating curve, as illustrated in Figure 2. b).

EVALUATION OF THE DERIVED HEATING CURVE

In order to examine whether the derived heating curve can assure optimum supply water temperature, a simulation and a mock-up experiment were conducted. The analyzed building, located in the vicinity of Seoul, Korea, consists of two test chambers equipped with radiant floor heating system as illustrated in Figure 3. A radiant floor structure conforms to Type A in EN 1264, which has pipes inside the screed.

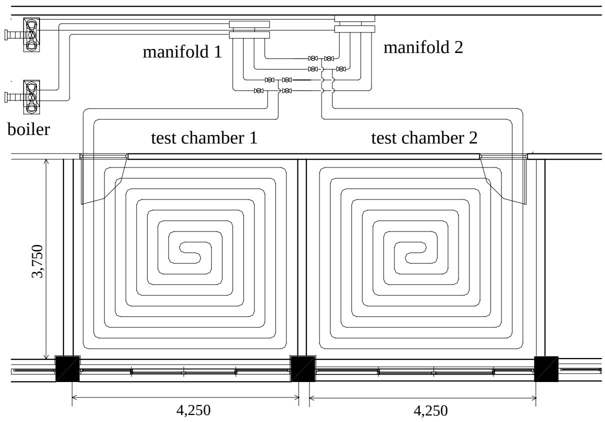


a) the change of heating curve slope

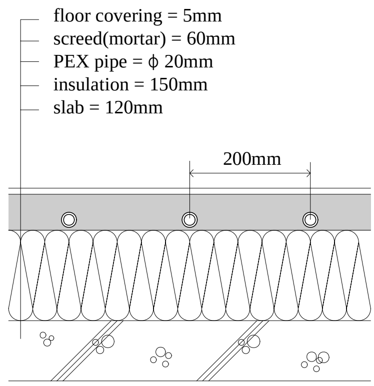


b) the shift up or down of heating curve

Figure 2. The characteristics of a heating curve



a) The plan of test chambers



b) floor structure

Figure 3. Test chambers for the mock-up experiments

Simulation Analysis

Based on the thermal properties and design condition of the chambers, heating curve was estimated as T_{sup} = -0.887T_{out}+43. In order to analyze the performance of the chamber with the estimated heating curve, a TRNSYS type which can modulate supply water temperature according to a heating curve was developed. The type receives an outdoor air temperature, calculates water temperature with the heating curve and transfers water temperature to the active layers of the analyzed thermal zone. But it does not receive the feedback from the room because outdoor temperature reset control is basically open-loop control algorithm.

The simulation was performed for the whole winter season using standard weather data of Seoul. The effect of internal heat sources was not taken account into the simulation. Figure 4 and Figure 5 describe the simulation result for the whole season and coldest 3 days, respectively. Although the heating system did not receive a feedback from the room, room air temperature was kept at set temperature, 23℃, by just modulating supply water temperature according to outdoor air temperature. Figure 5 shows the performance of the heating system more clearly. Room air temperature is maintained stable without much fluctuation, as in a conventional on/off control heating system. Thus it can be said that the derived heating curve can assure the optimum supply water temperature to keep the heated space comfortable.

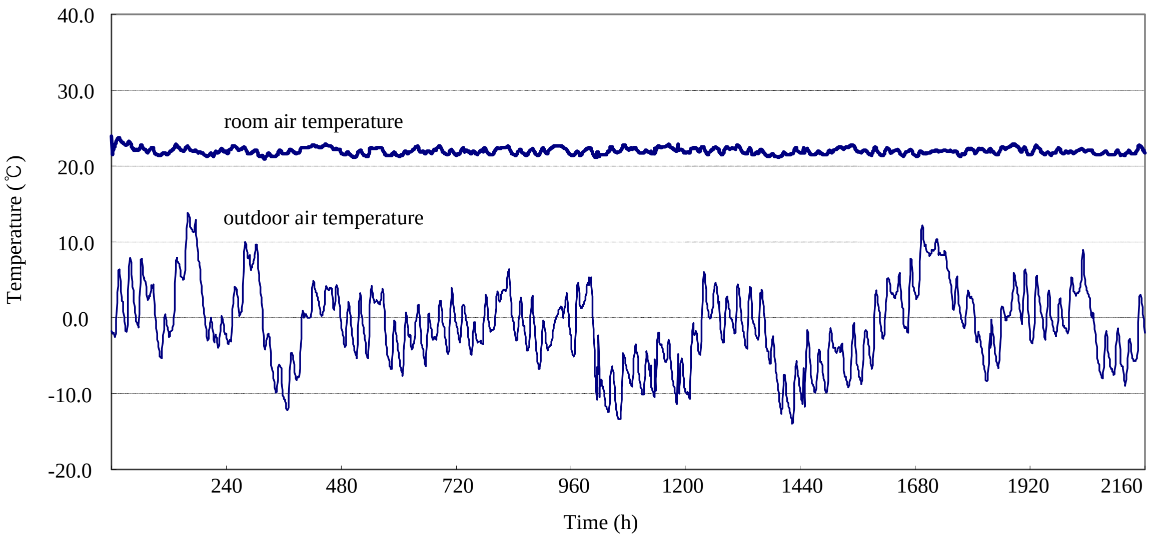


Figure 4. Simulation result for the whole winter season

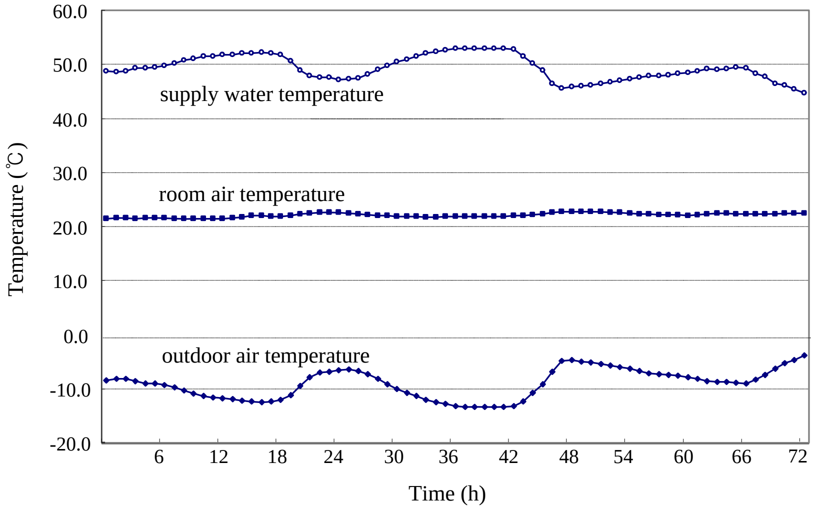

Figure 5. Simulation result for the coldest 3 days

Mock-up Experiment

For the purpose of more accurate evaluation, a mock-up experiment was performed. The derived heating curve was applied to the aforementioned test chambers. The chamber, water distribution system and control instruments used in the experiment are presented in Figure 6. As it is the main purpose to analyze the relation between outdoor air temperature and supply water temperature, a sun shade device was installed on the windows of a chamber.

a) a test chamber　b) gas-fired boiler　c) distribution system　d) control devices

Figure 6. Equipments for the mock-up experiments

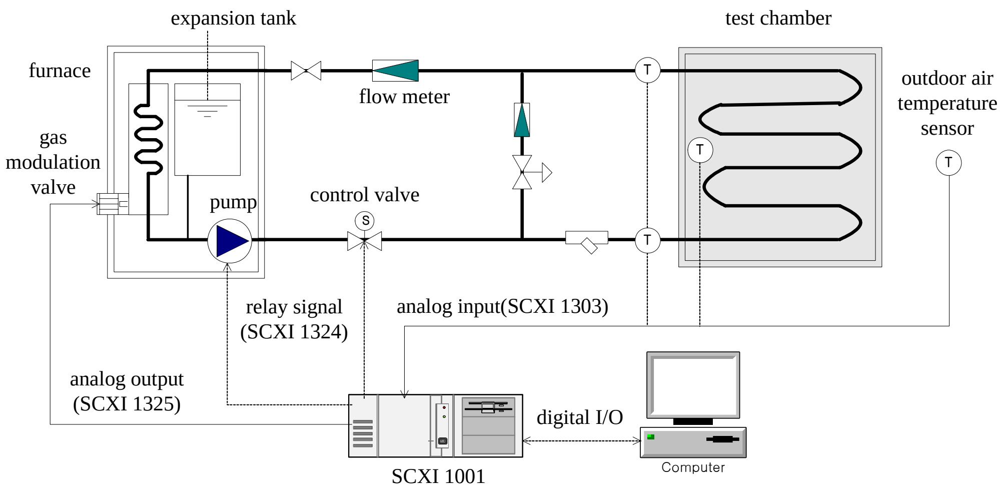

Figure 7. The schematic diagram of the instruments

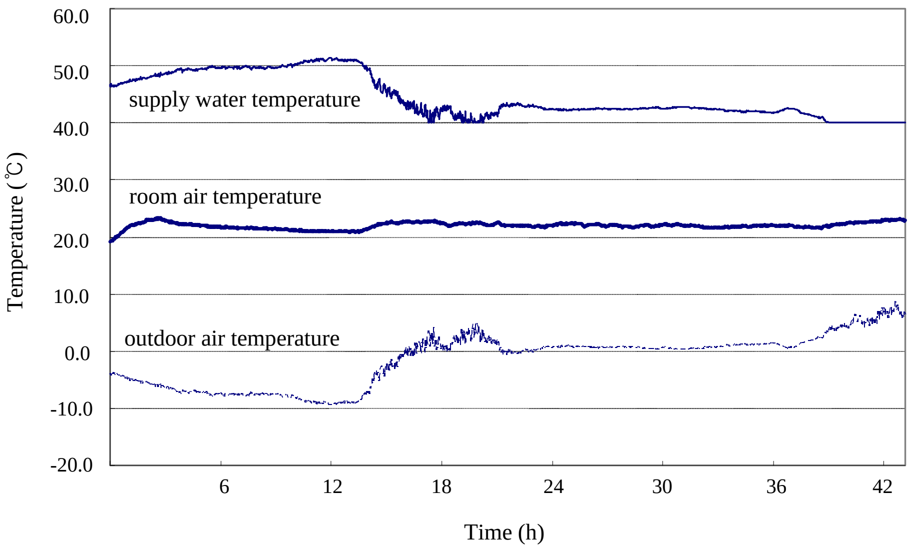

Figure 8. The result of a mock-up experiment

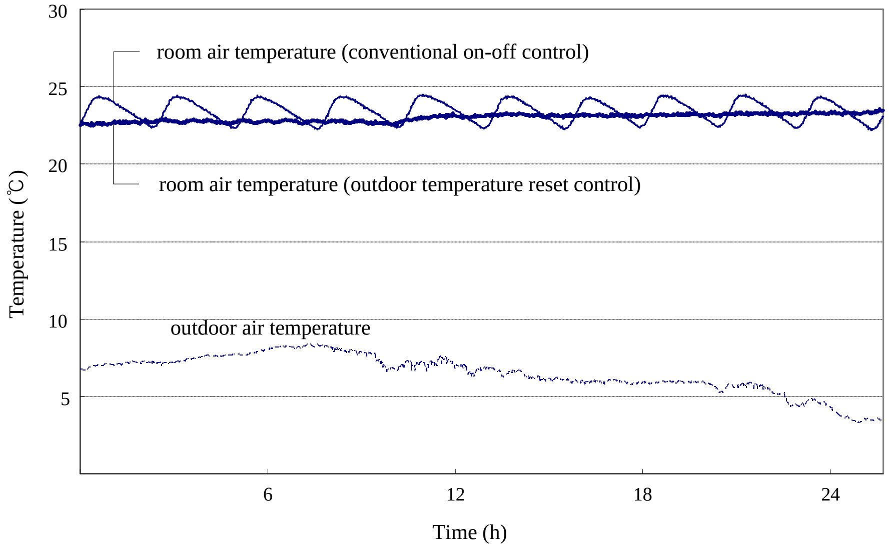

Figure 9. The comparison with a conventional on-off control

To modulate the supply water temperature, the firing rate of a gas-fired boiler was proportionally modulated with the analog input and output devices (NI SCXI-1001). Figure 7 describes the schematic of the equipments for the mock-up experiment. Supply water temperature was calculated by a heating curve, but maximum and minimum temperature were constrained to 80℃and 40℃ respectively for the purpose of preventing an overheating or flue gas condensation in a boiler.

Figure 8 shows the results of the experiment to examine whether the derived heating curve results in a good control of room air temperature. With the modulation of supply water temperature, room air temperature was maintained at averagely 23.1℃, with slight difference with set temperature, 23℃. Moreover, overshoot and/or undershoot, which occur frequently in conventional on/off control, were not observed in the experiment as shown in Figure 9. In conclusion, the derived heating curve can assure the optimum supply water temperature which can supply heat at the same rate at which the building loses heat.

CONCLUSIONS

In this study, a method to determine heating curve of a radiant heating system was proposed and evaluated. The heating curve could be expressed as a linear function of outdoor air temperature. It was also found that the slope of a heating curve varies with the heat loss of exterior walls and air change rate of the room. And set temperature of the room and adjacent room temperature would shift up or down of a heating curve.

The results of a simulation and a mock-up experiment show that the derived heating curve yields an optimum supply water temperature enough to keep the room stable and comfortable. The room air temperature was maintained closely at designed set temperature, without any feedback from the room. It can be said that the modulation of water temperature according to the derived heating curve provides as much heat as the building loses.

This study, however, assumes no solar gain and internal heat source. Those gains might result in slight increase of the room air temperature because they provide additional heat to the room. Thus it is proper to use outdoor reset control in combination with an auxiliary control to prevent additional heat supply. Outdoor temperature reset plus on-off control can be a good alternative. In addition, this study assumes that the heating system operates continuously and the room is under steady-state. Thus a heating curve should be modified so that it can cope with the dynamic condition such as an initial boost-up operation, a recovery from deep setback and so on.

Despite of those limitations, this study can be said to be significant because it provides a basic strategy to determine optimum supply water temperature, which considers heating load and the floor structure of a building. The results can be applied to the outdoor reset control algorithm of a heat exchanger or a boiler for a radiant heating system.

SUMMARY

In Heerlen, the Netherlands, warm and cold water volumes from abandoned mines is used for heating and cooling of buildings, based on a low exergy energy infrastructure. The combination of low temperature heating and cooling emission systems, advanced ventilation technologies and integrated design of buildings and building services provide an excellent thermal comfort and improved indoor air quality during 365 days/year, combined with a CO2 reduction of 50% in comparison with a traditional solution.

INTRODUCTION

Abandoned and flooded mines have a high potential for geothermal utilization as well as heat cold storage of water volumes in remaining underground spaces. The use of heat and cold from mine water is one of the important aspects of rational and sustainable utilization of post mining infrastructure and may bring positive socio-economic results, social rehabilitation and improved health for communities living in European areas with (former) mining activity. In Heerlen, the Netherlands, the redevelopment of a former mining area, including a large scale new building plan, is being realised with a low exergy infrastructure for heating and cooling of buildings, using mine water of different temperature levels as sustainable source. Mines have large water volumes with different temperature levels. In Heerlen the deeper layers (700 – 800 m) have temperatures of 30 – 35^0 C; shallow layers (200 m) of 15- 20^0 C. These water volumes can be considered as heat/cold storage as well as geothermal sources. Most crucial however is that these sources provide low valued energy (low exergy). As on the demand side heating and cooling for buildings also require low valued energy the intended design strategy is to realise the climatisation of the buildings in this pilot directly by mine water. The combination of low temperature emission systems with advanced ventilation technologies and integrated design of buildings and building services provide an excellent thermal comfort for 365 days a year, including sustainable heating and cooling and improved indoor air quality. This sustainable energy concept gives a reduction of primary energy and CO_2 of 50% in comparison with a traditional concept (level 2005).The project is funded by EC Interreg IIIb, the UKR program of the Dutch ministry of Economic Affairs and the EC FP6.

THE ENERGY CONCEPT

The mine water energy concept in Heerlen is in principle as follows. Mine water is extracted from different wells with different temperature levels. In the concession of the former ON III mine (location 1 Heerlerheide) mining took place to a level of 800m. In this concession the warm wells (30^{0}C) can be found. In the former ON I mine (location 2 Heerlen SON) mining took place to a level of 400m and here the cold wells are situated. The extracted mine water is transported by a primary energy grid to local energy stations. In these energy stations heat exchange takes place between the primary grid (wells to energy station) and the secondary grid (energy station to buildings). The secondary energy grid provides low temperature heating (~ $35^0 - 40^0$ C) and high temperature cooling (16^0 - 18^0 C) supply and one combined return (20^0 - 23^0 C).

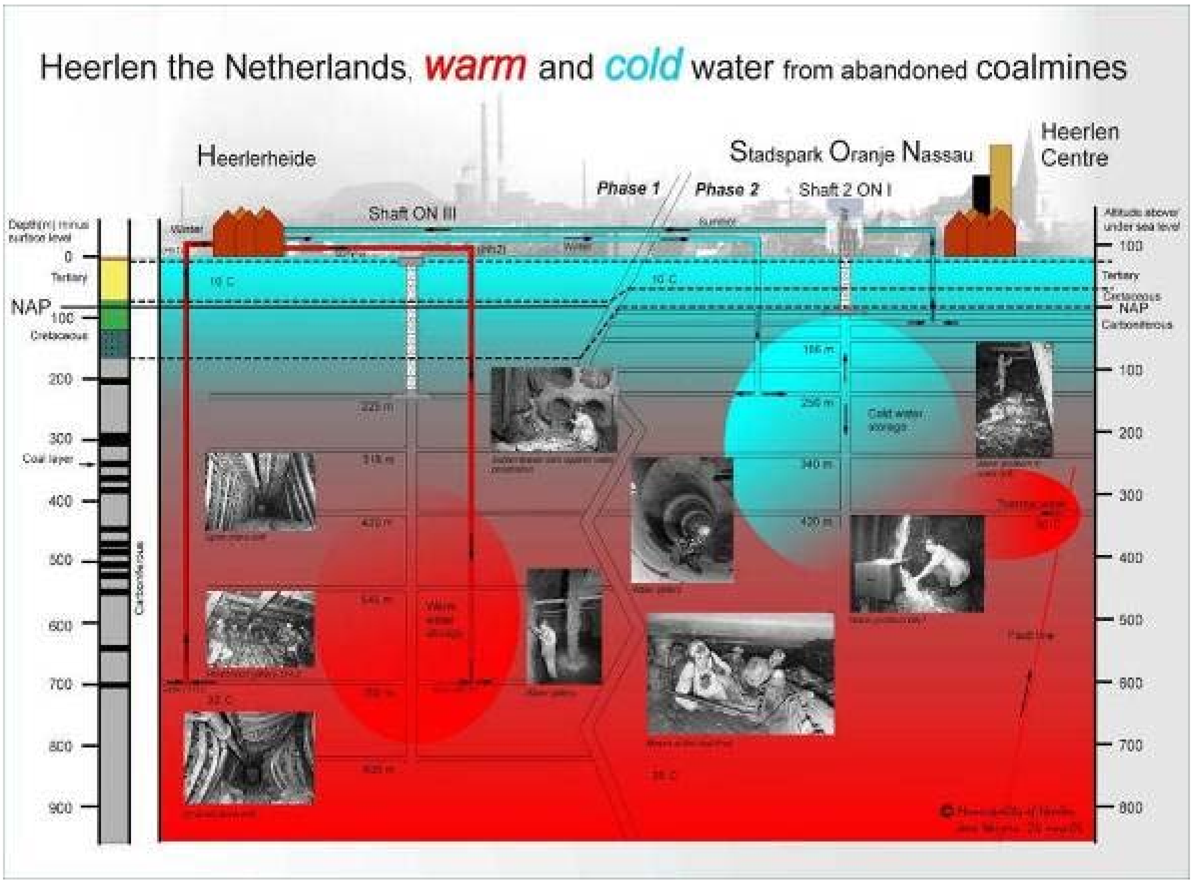

Figure 1. Schematic cross section of the underground conditions of the ON I and ON III mines

The two locations 1 and 2 are connected by a pipeline. Warm water is partly transported from location 1 to 2 and, visa versa, cold water is partly transported from location 2 to 1. Return water of 22 to 23^0C is transported to an intermediate well (400m). The temperature levels of the heating and cooling supply are “guarded” in the local energy stations by a polygeneration concept existing of heat pumps in combination with gas fired boilers and CHP on (preferably) on biomass in combination with local storage tanks. The (biomass fired) CHP provides the electricity to power the heat pumps but also the higher temperature levels (65 – 70^0C) for domestic hot water and peaks during extreme conditions. As, by this integral approach, the demand profile of DHW is almost equal to electricity, the CHP can be designed in the most economic and energy efficient way. The surplus of heat in buildings (for example, in summer, cooling, process heat) which can not used directly in the local energy stations can be lead back to the mine water volumes for storage. If necessary local sub-energy stations in buildings for preparation of DHW by heat pumps, small scale CHP or condensing gas boiler, depending on type of building and specific energy profile. The total system will be controlled by an Intelligent Energy Management System including telemetering of the energy uses/flows at the end-users. A scheme of the total concept is given in figure 2.

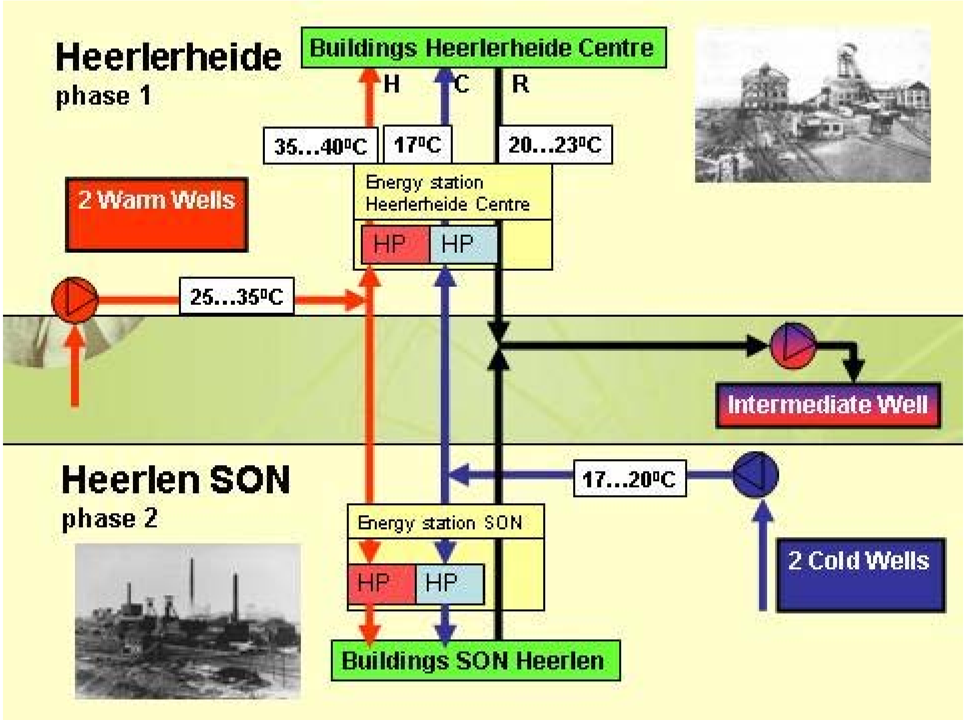

Figure 2. Schematic view of the energy concept in Heerlen, connection of the wells and energy stations

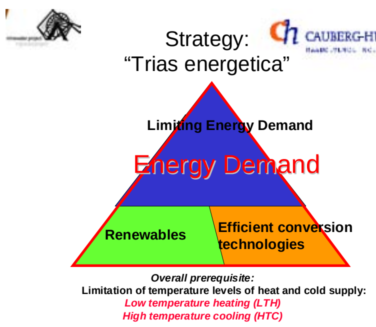
INTEGRATED DESIGN APPROACH VERSUS TRADITIONAL APPROACH

The present development of energy efficient buildings in an increasing way requires an integral design approach. A couple of decades ago energy efficient design and building mostly focussed on improving a certain technique or apparatus. Nowadays an energy efficient building, supported by an energy efficient installation, has to be combined into one integrated energy efficient concept with an optimal performance in terms of indoor climate, thermal comfort, user's satisfaction etc. This asks for an integral design approach in which well balanced choices are being made. This means that in sustainable building projects it is crucial to consider the design and realization of the sources, the heat generation (especially with non-traditional solutions such as heat pumps, cogeneration, heat/cold storage) distribution and emission together including all possible interactions with the building, building properties and building users. Only this approach can lead to a set of well defined performance criteria concerning energy performance, sustainability, indoor air quality, thermal comfort (365 days/year, winter and summer conditions), and health. Next to it is necessary to have specific emphasis on investments and energy exploitation, as well as communication to the end-users. A traditional approach is often based on partial optimization of the different disciplines. An integrated approach will achieve a total optimization, taken into account all disciplines and their interaction. Basis is a set of unambiguous well defined performance criteria. The design strategy applied in this approach is the so called Trias Energetica. It is a three step approach that gives a strategy to establish priorities for realising an optimal sustainable energy solution. The approach is introduced in 1996 by Novem the Netherlands and has been further worked out by the Technical University of Delft the Netherlands, containing the following steps:

Step 1: Limitation of energy demand
Step 2: Maximising share of renewables
Step 3: Maximising efficiency of using fossil fuels for remaining energy demand

With as overall prerequisite: limit the temperature levels of heat and cold supply (conform 2nd law of thermo dynamics)



In general the heating and cooling of buildings can be realized with very low valued energy, with medium temperatures close to required room temperatures. The better the building properties (extreme high thermal insulation, suitable emission systems) the closer the temperatures of heat an cold supply can be to room temperatures. In order to utilise these extreme moderated temperatures for heating and cooling the buildings must comply to a number of boundary conditions such as:

- Limitation of heat losses ($U_{envelope} < 0.25$, $U_{windows} < 1.5$)
- Limitation of ventilation losses and peaks by air tight building (n50 < 1.0), mechanical ventilation with heat recovery or state of art demand controlled hybrid ventilation systems
- Limitation of solar and interal gains to limit cooling loads, integrating shading and sun blinds in architectural design
- Application of combined low temperature heating and high temperature cooling emission systems, (thermally activated building components, floor and wall heating).

Technologies for low temperature heating and high temperature cooling are available on the market an are described for example in the IEA Annex 37 Guidebook (www.lowex.net)
For some functions higher temperatures will be necessary such as domestic hot water. Also lower temperatures can be necessary for certain functions (high cooling loads for some types of buildings, some processes, etc.). Another aspect to be taken into account is that the use of geothermal energy and heat/cold storage as such does not cover electricity use/sustainable electricity generation. Therefore additional sustainable solutions have to be taken into account. Sustainable electricity generation can be realized by cogeneration (such as biomass CHP). This combination can also deliver higher temperatures for DHW.

THE DEMONSTRATION LOCATIONS

1 Location Heerlerheide Centre:

This plan is situated on the concession of the ON III pit in a relatively deep mined area with warm wells (30 – 35^0). The plans include the following activities for ***new buildings:***

- 33.000 m^2 (330) dwellings (single family dwellings and residential buildings)
- 3800 m^2 commercial buildings
- 2500 m^2 public and cultural buildings
- 11500 m^2 health care buildings
- 2200 m^2 educational buildings

The first new building and construction activities in Heerlerheide Centre have started in 2006. The total plan will be realised between 2006 and 2008. All planned buildings will be connected to the energy supply (heating and cooling) from mine water. All these buildings are planned in a very compact area which is very favourable for energy distribution. The building location is situated between two potential wells. This means that the length of the transport lines between the wells and the energy station is limited. Next to it, the planned building functions require heating as well as cooling. The location of the wells has been determined as a result of geological research. The drilling of the wells took place from February to June 2006. The two warm wells and the primary net (i.e. the connection between the two wells) was completed in June 2006, followed by a successful testing in July. The energy supply includes the building of an energy station and a small scale distribution grid from this station to the buildings. In the energy station the mine water is brought to the necessary heating and cooling levels by heat pumps. In order to facilitate the process and to guarantee all real estate developers, involved in this building plan, the delivery of energy to the buildings the main investor, Housing Corporation Weller, is realising the exploitation of the energy supply, including the building and construction of the energy station and distribution grid. The liberalised energy market in the European Union makes it possible for housing corporations to exploit the energy supply for their buildings. It is important to realise, that with minor modifications this energy supply can also be functional and operational without the application of mine water. In that case the heat pumps will be connected to closed loop ground heat exchangers (separate bore holes). Although this option is less energy efficient in comparison with the use of mine water as source this will be still much more energy efficient then the traditional option with condensing gas-fired boilers and electrical cooling devices for air-conditioning.

	Old situation Heerlen, location Heerlerheide	New situation

Figure 3. Impression of location 1 Heerlerheide

2 Location SON (Stadspark Oranje Nassau)

This area is situated on the concessions of the ON I pit. This is a relatively shallow mined area (200 – 400 m) with cold and intermediate wells. There for this area is connected with a master connection to the warmer wells in the ON III area (Location Heerlerheide). Cold form the ON I area is transported to Location Heerlerheide Centre. The development of Stadspark Oranje Nassau has a strategic significance for the social and economical rehabilitation of Heerlen. This plan will offer an opportunity to improve the image of Heerlen, to develop new economical opportunities and to enhance and stimulate the existing (but poorly functioning) activities inner city of Heerlen. This plan will be realized in combination with sustainable mobility and accessibility. The total programme contains the realisation of approximately 100.000 m^2 of new buildings (offices, shops, residential, school and a hotel) and the renovation of a large existing office building (43.500 m^2) of the Dutch Central Office of Statistics.

3. Location Heerlen centre ABP head office

This location concerns the retrofitting of the ABP head office of 41.000 m^2. ABP is the pension fund for employers and employees in service of the Dutch government and the educational sector. The total building envelope is retrofitted to a level better then the current Dutch Building Decree values for new buildings. The minewater is used for comfort heating and cooling (i.e. low temperature heating and high temperature cooling in all offices). The ABP building will have a direct connection to the minewater wells and will have its own energy station to provide the required temperature levels for the distribution net. The energy station will have heat pumps. The emission systems in the offices are climate ceilings. Special glazing will be used to limit solar radiation in summer; this makes it possible to use high temperature cooling (in most of the time direct from minewater).

Maankwartier (Moon Quarter)

Renovation of the CBS office

Figure 4. Impressions of location 2 Stadspark Oranje Nassau (SON)

BALANCING SUPPLY AND DEMAND SIDE

For the elaboration of the final energy concepts following questions should be answered:
- total heating and cooling demand, how to control and limit this demand
- the target values for percentage of renewables in total energy demand
- what is the available amount of renewable energy form mine water (i.e. how much water can be extracted) and other renewables
- what is the most efficient conversion technology for the (not sustainable) back-up system.

This input is necessary for the integrated design process including building, sources and energy systems, distribution and emission systems. An important tool for the assessment of this process and balancing demand and supply side is the so called energy profile of a building, expressed in a so called load-duration curve, based on dynamic calculations (using TRNSYS) of the energy demands of the buildings. This curve is a profile representing the energy demand over a total year, including heating and cooling. This curve also provides a good indication of the maximal capacities for heating and cooling as well as the balance between heating and cooling demand. Important for balancing the supply and the demand side is the tuning and balancing between the cold and heat sources, in this case, the deep (warm) and shallow (cold) wells. This assessment takes place in relation to the required temperature levels, the yearly extracted volumes and the energy demands of buildings; this in relation to the available water volumes in the reservoirs. The load duration curves give important information about:
- the balance between cold and heat demands,
- the effect of optimisation (for example limiting heat losses by thermal insulation or heat recovery, etc.)
- the way how to limit the installed capacity of heat pumps, CHP and other heat generation, and , on the other hand, how to increase the number of operation hours, in combination with storage, to increase the efficiency and to decrease investment costs. Also thermal impact on the ground is made visible and can be assessed.

In order to establish a balance between the rational use of energy needs on the building side and the renewable energy supply a total annual heat-load duration curve of the total building plans in Heerlerheide Centre and SON is calculated by dynamic simulations with TRNSYS. In figure 5 the heat-load duration curve for Heerlerheide (location 1) is shown.

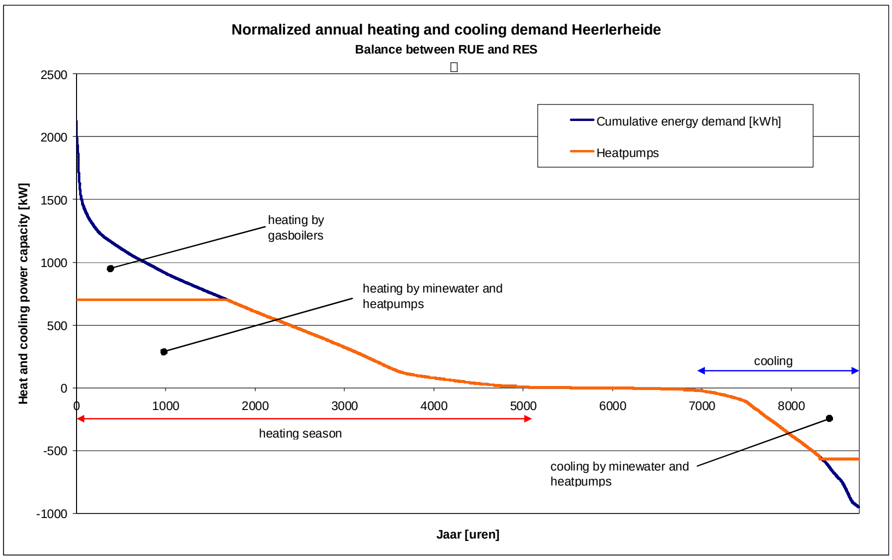

Figure 5. Load-Duration Curve for location 1 Heerlerheide

FEASIBILITY BY PRIVATE ORGANIZED ENERGY EXPLOITATION

Despite the rather high level of investments for the energy installations and buildings measures this concepts is economically feasible by private organized energy exploitation. In this case, the main investors will also organise the energy exploitation, i.e., in separate private owned Energy Exploitation constructions). These private organized companies can use lower internal interest rates, 6 to 8% instead of the usual 15% of utilities and district heating companies. The main reason is that profits from selling energy is not considered as core business. By establishing connection fees for heating and cooling and avoiding a gas infrastructure on building/dwelling level, as well as avoiding extra cooling installations, these constructions offer possibilities for economical sound energy exploitation. Economical benefits will also occur because of the integrated design and especially combining heating and cooling in the same emission system (i.e. floor heating and cooling, thermally activated building components etc.). Using these combined emission systems avoids the investment costs for a separate cooling system

CONCLUSIONS

Abandoned and flooded mines can be reutilized for a new sustainable energy supply for heating and cooling of buildings. The minewater project in Heerlen shows that temperatures of 28 – 30 ^{0}C can be found at 700 m and 16 -17 ^{0}C at 200 m. These temperatures can be used for heating and cooling of buildings if these buildings are very well insulated, have energy efficient ventilation systems and have emission systems suitable to operate with moderated temperatures like floor heating or concrete core activation. Despite the rather high investment costs such projects can be economical profitable avoiding additional cooling systems and by integrated design and if energy exploitation is organised by the investors.

ACKNOWLEDGEMENTS

The Minewater project is funded by the European Commission and the Dutch Ministry of Economic Affairs. These fundings are gratefully acknowledged.

Energy Performances Of A Radiant Floor Heating System Supplied By Solar Collectors With Ventilation Stream Heating By An Air To Air And An Air To Water Heat Exchanger

SUMMARY

The energy analysis of a heated space with a radiant floor plant supplied by hot water provided by a storage system charged by a field of solar collectors, has been evaluated. A suitable control strategy has been evaluated to reduce thermal inertia effects. Given an external air-change ventilation flow rate must be provided, a system using two heat exchangers has been used: the first an air to air heat exchanger that uses the expulsion air from the heated space as hot fluid, and a second air to water heat exchanger that uses the outlet water from the radiant floor. The whole system has been studied by dynamic simulation code TRNSYS, to evaluate interaction between the devices and, overall, the contribution of the solar source on plant performance by the solar fraction, varying the collectors' surface and the storage system volume.

INTRODUCTION

Energy consumption in the building field is anything but ignorable considering that today, in the European Community, such a voice concurs a percentage higher than 40%. Some recent community directives [1], promote the energy consumption reduction in the winter heating of buildings. This result is obtainable by means of multiple solutions such as efficient building insulation of opaque surfaces, a wise choice of glass surfaces, the adoption of high efficiency thermal energy production, the use of low temperature energy distribution systems, powered by a supply coming from a field of solar collectors. The latter solution assumes greater value for houses situated in localities with cold climates, whose requirements for thermal energy for heating are considerable compared to other energy requirements of the building.
Among the various types of thermal energy distribution systems used for heating areas, radiant floor heating systems are those which permit the best direct use of solar radiation as a primary energy source. In fact, the floor surface temperature must be moderated so that a relatively low temperature fluid can be used which is obtainable from the solar source with elevated efficiency [2]. Another advantage deriving from the use of radiant floor heating systems lies in the reduction of winter energy requirements. The increase of average temperature radiating within the area permits the attainment of the same operative temperature with lower internal air temperatures, with a consequent reduction in transmission and ventilation losses through the building shell. On the other hand, radiant floor systems, compared to traditional ones, are characterised by notable thermal inertia, therefore the adoption of control systems which take into account this peculiarity is necessary [3]. In this article, thermal performance of radiant floor heating systems powered by an storage system

which receives energy from a field of solar collectors, with preheating of the ventilation airflow obtained by exploiting the building exiting airflow from an air to air exchanger and, successively, the exiting flow rate from the radiant floor in a second air to water exchanger are evaluated.

DESCRIPTION OF THE BUILDING USED IN THE SIMULATION

The building is considered as being for office use, it has a regular parallelepiped shape, with the longest side being 16m, and the shortest being 6m and a height of 2.75m. The walls of the largest surface area are North and South facing. On each external wall and triple glazed window is present having a global loss coefficient equal to 1.8 W/m²K and a solar gain coefficient of 70%. The glazed surfaces are respectively 8.8 m² for the south facing wall, and 3.3 m² each for the remaining three exposures. The total glazed surface area is therefore 22 m² while the total opaque dispersant is equal to 291 m². In Tab. 1 the thermal properties of the various opaque components of the building shell are reported. The thermal transmittance values are 0.198 W/m²K for the vertical walls, and 0.146 W/m²K for the covering floor and 0.207 W/m²K for the floor placed on the ground.

Table 1. Layers thermal characteristic of opaque walls.

	Thickness	Conductivity	Density	Thermal Resistance
	m	W/mK	Kg/m^3	m²K/W
Plasterboard	0.018	0.9	1800	0.02
Mineral wool with moisture stop	0.125	0.048	11	2.60
Mineral wool rigid support	0.063	0.035	100	1.80
Air gap	0.03	-	-	0.18
External surface bricks	0.075	-	650	0.28
Wooden beams and battens	0.045	-	850	0.25
Covering material in tile-concrete	0.055	-	1800	0.03
Floor covering material	0.01	1	1800	0.01
Light Concrete	0.09	1.2	1800	0.08
Heavy concrete	0.10	1.2	2000	0.08
Rigid panel insulating	0.10	0.035	37	2.85
Ground floor loose stone foundation	0.50	-	2000	0.28

In order to determine the internal energy gains it is supposed that the building is used as an office with a number of people equal to 12, present from 08.00 to 13.00 and from 14.00 to 18.00, from Monday to Friday, who work with the same number of computers. For each person a sensible load of 65W is estimated and a latent load of 55 W [4]; each computer transfers a sensible load of 80W. The lighting plant is active from 8.00 to 18.00 and causes a thermal flux equal to 5 W/m², for a sensible load of 480 W. Finally, with regards to ventilation, for each occupier an air-flow rate of 11 l/s was estimated [5].
The radiant floor properties are as follows [6]:

- pipes in polymeric material with k=0.33 W/mK, internal diameter of 0.01 m and a tube pitch of 0.15 m;
- light concrete layer with a thermal conductivity equal to 1.2 W/mK and a thickness of 0.1 m, covering material floor with k=1 W/mK and a thickness of 0.01 m.
- an inlet flow rate equal to 1191 kg/h;

DESCRIPTION OF THE HEATING SYSTEM

The plant of the system considered is reported in Fig. 1. The inlet flow rate of the radiant floor is taken from the storage tank which receives energy from the collectors field. In the case in which the temperature of the storage system is higher than that requested, a mixing by means of valves 1 and 2 is carried out to reach the desired temperature. In the case that the temperature is lower, an auxiliary system intervenes by means of the commutation of valves 3 and 4. The auxiliary system is situated parallel to the storage system, in such a way that the water flow feed is supplied either by the storage tank or by the auxiliary system. This planning configuration avoids the temperature of the water flow produced by the auxiliary system being conveyed to the storage system.

To reduce losses due to ventilation, a system which employs two heater exchangers is used. In the first exchanger, the external airflow is heated in counterflow of the expulsion airflow from the indoor environment; the second also in counterflow, uses the flow rate exiting from the radiant floor before this returns to the storage tank or auxiliary system. The sizing of the heat exchanger was carried out imposing a global thermal exchange coefficient so that for both 50% efficiency was obtained.

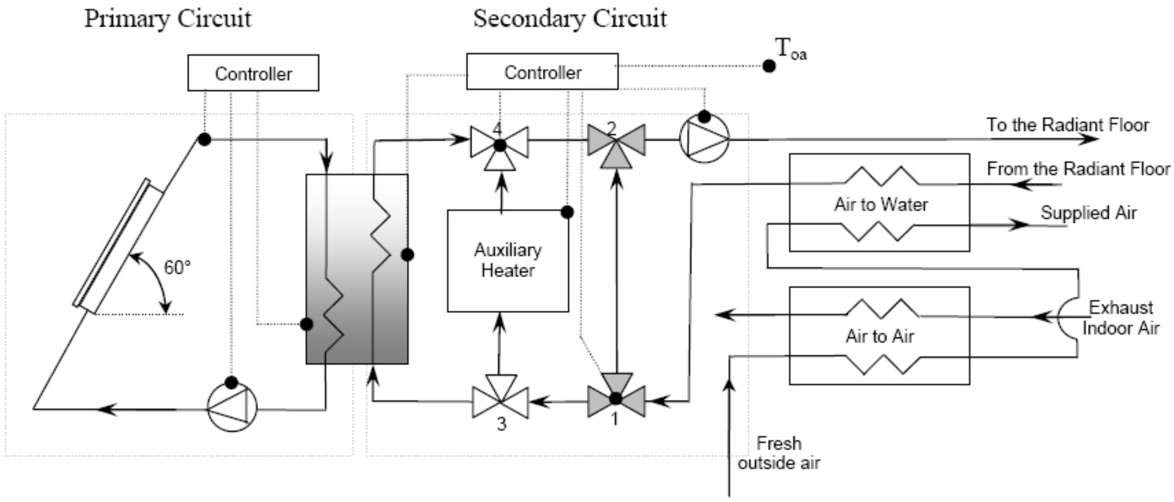

Figure 1. Plan of the solar plant for building heating.

SIMULATION CODES AND CONTROL STRATEGIES

The whole system was studied using the TRNSYS simulation code [7], which consents detailed simulation in a dynamic conditions to evaluate exchange mechanisms relating to the collector surface, storage tank, radiant floor and the indoor volume to be heated.

Moreover, the considered dynamic simulation environment has permitted the study of a adequate control strategy, with the aim of a rational use of the thermal level of the storage tank and the optimisation of the thermal performance of the radiant floor, otherwise penalised by excessive thermal inertia. In order to evaluate the energy performance of the entire system, the building was situated in three different localities in Europe having different climatic characteristic: Helsinki, Copenhagen and Munich.

The hourly values of solar radiation and external air temperature used in the simulations were generated by means of a special TRNSYS subroutine, starting from corresponding average monthly data of the locations considered, in such a way as to generate a metrological year type (TMY) [8]. For the average monthly temperature and horizontal solar radiation values for the considered locations, those contained in the European Solar Radiation Atlas (ESRA) [9] were used. The values of diffuse and beam radiation on the horizontal plane were obtained by Reindl relations [10], which use the solar height angle and index cloudiness. The projection of such components on the field of collectors and on the building walls was carried out using the isotropic sky model [11]. The average monthly values of external air temperature and solar radiation on the horizontal plane during the heating period relating to the three considered locations are listed in Tab. 2.

Table 2. Average monthly daily values of external air temperature (T_{OA}) and of solar radiation on the horizontal plane (HSR) .

		Sep	Oct	Nov	Dec	Jan	Feb	Mar	Apr	May
Helsinki	T_{OA} [°C]	10.0	5.9	-0.1	-4.2	-6.9	-6.1	-2.4	3.6	10.4
	HSR [kWh/m²]	2.16	1.00	0.03	0.12	0.24	0.89	1.96	3.68	5.27
Copenhagen	T_{OA} [°C]	14.0	9.4	5.3	2.5	0.0	0.2	2.1	7.0	11.8
	HSR [kWh/m²]	2.67	1.43	0.66	0.32	0.47	1.08	2.02	3.81	5.07
Munich	T_{OA} [°C]	14.4	9.7	3.3	0.8	-1.0	-0.9	4.2	7.7	12.6
	HSR [kWh/m²]	3.37	2.11	1.14	0.74	0.96	1.79	2.73	3.94	5.03

Given that the function of the solar collectors is prevalently in winter, the inclination angle of the collectors field is 60° for all three locations, to maximise the solar radiation incising on the collector field. The latter are characterised by the following efficiency expression:

$$\eta = 0.7847 - 4.4894 \cdot \frac{T_m - T_{oa}}{G} - 0.027 \cdot G \cdot \left(\frac{T_m - T_{oa}}{G}\right)^2 , \qquad (1)$$

with G (W/m^2) solar radiation, T_{oa} external air temperature, and T_m average water temperature in the collector field.

CONTROL STRATEGIES

In radiant floor heating systems, due to elevated thermal inertia, the type of control which must assure reduced plant response times and avoid thermal discomfort conditions assumes great importance. The methodology used is the control of the inlet temperature combined with a traditional ON/OFF type control, on the inlet flow rate in the case of overheating of the indoor environment (T_{ia}>22°C), due to eventual free energy gains, and its restoration when the temperature goes below a determined limit (T_{ia}<20°C).

The inlet temperature depends principally on the external air temperature, which in the heating period represents the prevalent external constraint on the heated area. Such a control takes into account the effects linked to floor thermal inertia, since the temporal delay with which the floor inlet temperature variation is carried out on the area is comparable with that with which a variation in external air temperature manifests itself within the building by means of dispersing walls. Therefore, no predictive estimate of the feed temperature is necessary, such a criteria is much truer as to the thermal inertia of the floor, and of the same entity of the external dispersing walls. The inlet temperature is that which guarantees an internal air temperature of 20°C in the least favourable conditions, in the absence of solar radiation, and is made to depend linearly on the external air temperature. Imposing the condition that the floor must not transfer thermal power when the external air temperature is 20°C , the law which determines the feed temperature assumes the following expression:

$$t_{INLET} = k(20 - t_{OA}) + 20, \qquad (2)$$

where t_{OA} is the external air temperature while k constant factor depends uniquely on the average global transmittance of the building's dispersing walls. For the structure taken into consideration, the value of variable "k" assumes the value -0.2183.

In order to improve the control function and minimise floor response times, the control relation (2) was further corrected multiplying it by a secondary function, linked this time to the internal air temperature. The logic is based upon the possibility of correcting the inlet temperature obtained from (2) with a minor unit coefficient when the internal air temperature passes a temperature of 20°C, thus making it unnecessary to increase the floor's thermal power, even when the external environment has a relatively harsh temperature, and of using a greater unit coefficient if the internal air temperature is lower than 20°C, in such a way as to render the plant response more rapid when the internal air temperature conditions are unfavourable. The relation used for evaluating C.C. corrective factor in function of the internal air temperature t_{IA} is the following:

$$C.C. = -0.11 \cdot t_{IA} + 3.2 \qquad (3)$$

Using relation (3), the feed temperature results as being 40% higher compared with that necessary determined by (2) if the internal air temperature is around 16°C, it is almost equal to that calculated with (2) if the internal air temperature is around 20°C, while the C.C. corrective factor is equal to about 0.8 if the internal air temperature is near 22°C. Combining relations (2) and (3), the real radiant floor feed temperatures assume the form:

$$t_{INLET} = [k(20 - t_{OA}) + 20] \cdot (-0.11 \cdot t_{IA} + 3.2) \qquad (4)$$

The use of relation (4), determines the raising of the inlet temperature of the radiant floor during the first hours of the day, in which the internal and external air temperatures assume relatively low values, limiting the plant's slow response at the moment of turning on. For such a reason, the implemented control strategy also foresees an attenuation operation at night and at the weekends, to avoid internal air temperatures going down too low. The attenuated operation was rendered necessary also to avoid too high feed temperatures which derive from the use of (4), whose field of application is effectively reduced to the internal air temperature range 16÷22°C. The attenuated operation starts when the internal air temperature goes below 16 °C. In such a case, the radiant floor feed temperature is 25°C, in order to exploit the thermal level of the tank and end at the reaching of 18°C.

RESULTS OBTAINED FROM THE SIMULATION

In Fig. 2, the hourly trends of the internal air temperature, of water in the storage tank, of the requested inlet temperature and of the inlet flow rate to the supply terminals for a period of 48 hours (7^{th} and 8^{th} of February) for Helsinki, are illustrated.

Feed temperature modulation, with values lower than 25°C avoids interruption of the plant feed thus permitting the exploitation of the storage tank even with low temperatures, is to be highlighted. Moreover, in some hours of the day, the inlet requested temperature is lower than the tank water temperature, and in the remaining hours the flow rate is provided entirely by the auxiliary system and the temperature foreseen by (4). Naturally, when the temperature in the tank is greater by less than 1°C compared to that requested, the recycling and extraction flow rate are nil because the airflow feed is prepared entirely by the auxiliary system with the aim of equipping the control system with minimum hysteresis.

In Fig. 3, for the same period, the temperature rise undergone by the ventilation airflow as an effect of heat recovery, is illustrated. The air to air exchanger is always in use, from 8.00a.m. to 6.00p.m., given that the exchange air flow must always be guaranteed during office opening hours. Heat recovery assumes a revealing role: for example at 8.00a.m. on the first day the external air temperature of -7.3°C was raised to +6.3°C. The second heat exchanger is only operative when the radiant floor plant is in use: in this specific case, since the return temperature from the radiant floor is slightly lower than 35°C, the air temperature undergoes an increase from +6.3°C to +17.2°C,. Such a recovery amply reduces load entity induced by ventilation airflow.

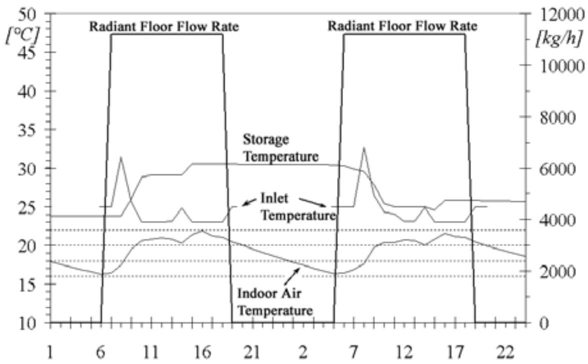

Figure 2. Trends of indoor air temperature, storage tank water, inlet temperature, flow rate to supply terminals (7th and 8th of February, Helsinki)

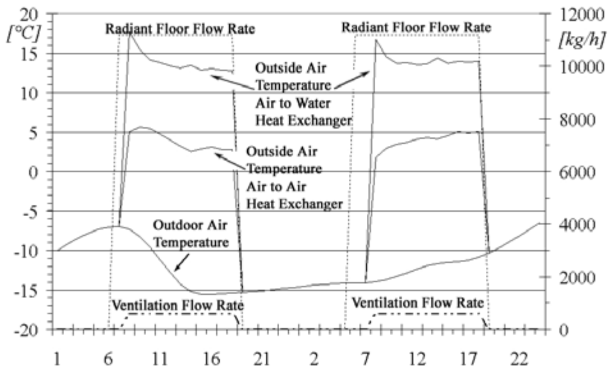

Figure 3. Ventilation flow rate temperature profiles (7th e 8th February, Helsinki).

In Tab. 3, for the three locations examined and for the entire heated period, which goes from September to May, the percentages of thermal energy requirements provided by the radiant floor (F_1), of the air to air exchanger (F_2) and of the air to water exchanger (F_3) are reported. It is possible observe how the percentage of thermal requirement recovered takes on important values, with a greater weight for the air to air exchanger which works continuously for 10 hours per day.

Table 3. Required seasonal energy for heating and seasonal fractions provided by the radiant floor (F_1), from the air to air exchanger (F_2), and the air to water exchanger (F_3).

	Heating Demand	F_1	F_2	F_3
	[GJ]	[%]	[%]	[%]
Helsinki	42.220	44.1	38.2	17.7
Copenhagen	29.053	39.1	44.9	16.0
Munich	27.255	36.4	48.7	14.9

In Fig. 4 seasonal energy provided by the storage tank, by the auxiliary, by the radiant floor, and by the two heat exchangers varying according to the collectors surface for an accumulated volume of 4 m^3 is reported for the city of Munich. It is possible to observe that both the energy provided by the radiant floor and that provided by the two heat exchangers are independent of the collectors surface, while energy provided by the fluid to the floor and to

the air to water exchanger is the sum of the energy provided by the storage tank and the auxiliary. The contribution in terms of energy provided by the tank is a high percentage.
In Fig. 5 trends of the average seasonal temperature of fluid present in the storage tank, and the efficiency of collectors, varying the collectors surface for an accumulated volume of 4 m^3 are reported. It is possible to observe that the average seasonal water tank temperatures increase with an increase in the collectors surface, with higher values for Munich due to a higher insolation level and lower for Helsinki which, in addition to having lower insolation, presents a greater thermal requirement. The average thermal efficiency of the collectors has, as a consequence, a decreasing pattern with the collectors surface, even if it does not alter very much for the three considered locations. Energy provided by the storage tank is reported in Fig. 6. Rising values are encountered with the collectors surface and strongly linked to incising solar energy. The best values are obtained for Munich which has greater insolation.
Finally, in Fig. 7, trends of the requirement fraction provided by the solar source which result as growing with the collectors surface and storage volume, are highlighted. In such a calculation, energy recovered in the air to air exchanger is not considered, in that it is not influenced by the feed system. The greater solar fraction values were obtained in Munich, reaching a value of 0.73 for a 40 m^2 collector surface and a storage volume of 4 m^3. For Copenhagen, the solar fraction varied from a minimum of 0.22 (S=10 m^2, V =1 m^3) to a maximum value of 0.52 (S=40 m^2 e V=3 m^3). Lower values were encountered in Helsinki, due not only to lower insolation, but also to a higher thermal requirement. For such a location the maximum solar fraction value resulted as being equal to 0.36.

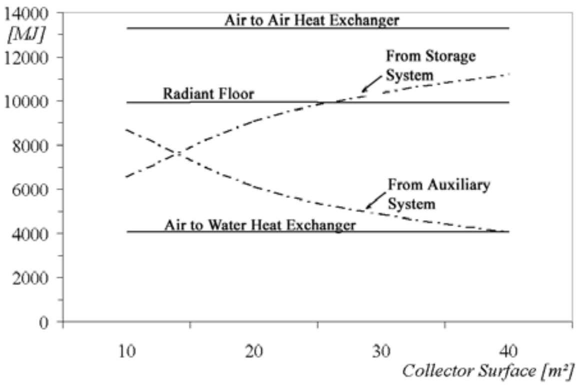

Figure 4. Seasonal energy provided by the storage tank, by the auxiliary, by the radiant floor, and by the two heat exchangers varying according to the collectors surface (Munich V=4 m^3).

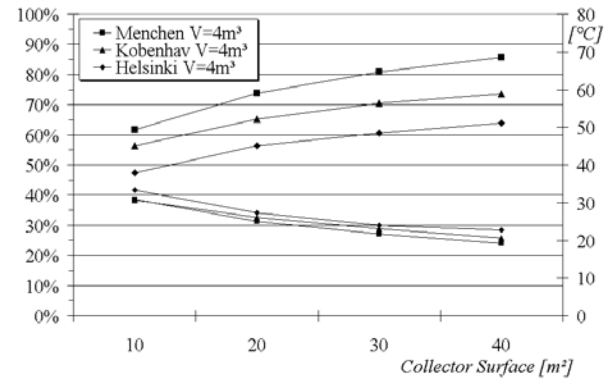

Figure 5. Storage tank average seasonal temperature trend and collectors' average efficiency.

CONCLUSIONS

The thermal performance of radiant floor heating systems supplied by a solar system were identified. The ventilation flow rate to the indoor environment is heated in two successive phases, the first using the air feed expelled from the indoor and the second with the feed exiting the radiant floor. The plants provide heating for areas used as offices in Munich, Copenhagen and Helsinki. This type of plant requires an efficient control system which assures the use of energy available from storage even when the temperature level is low, while thermal comfort conditions within the building are acceptable.
These plant configurations permit, by means of thermal recovery, the obtainment of significant and higher requirement fractions than those provided by the radiant floor.
The results obtained can be summarised as follows:

Winter requirements are delivered to the indoor environment by the radiant floor in the following percentages: 36.4% for Munich, 39.1% for Copenhagen and 44.1% for Helsinki, from the air to air heat exchanger in a percentage including between 38,2 for Helsinki and 48,7 for Munich, and finally from the second air to water exchanger a percentage slightly variable between 14,9% and 17,7%. The requirement fraction provided by the solar source principally depends upon available solar energy, the collectors surface and storage volume.
For collectors surfaces variable from 10 to 40 m^2 and storage volumes between 1 to 4 m^3 the solar fraction resulted as being variable between 0.32 to 0.72 for Munich; from 0.22 to 0.54 for Copenhagen and from 0.13 to 0.34 in Helsinki. Such results demonstrate that obtainable solar contribution with such plants, even in non Mediterranean climates, represents a non negligible fraction of the winter heat requirement.

SUMMARY

The present study investigates the type of temperature sensor that best represents the operative temperature, i.e., the type of sensor that will integrate the influence of air and mean radiant temperature in the same way as a person. Size, shape and colour of the sensor will have an impact on the relative influence of air and mean radiant temperature in a space.
In an experimental chamber different combinations of air temperature and radiant heated or cooled surfaces were tested. Several types of sensor (flat, sphere, ellipsoid, half-sphere, grey, black, white) were used to measure the operative temperature. Besides comparing the type of sensor, the influence of the sensor position in the room was experimentally investigated. The results show that a grey sensor of 3-5 cm diameter is the best size. The best shape, however, depends on the position of the sensor in the space.

1. INTRODUCTION

Several indoor environmental parameters influence the thermal comfort condition for the occupants. In all existing standards for the indoor environment the requirements for the thermal environment and the room temperature are given by using the operative temperature as reference. (ISO EN 7730 [1], EN 15251 [2]).
The present paper analyses how the measured room temperature varies as a function of position and type of temperature sensor. The influence of sensor type and position in the room was studied in a test chamber with different combinations of heated and cooled surfaces.

The room temperature sensor (or thermostat) represents the first element of a heating/cooling system control loop and is therefore significant for the quality of the control. The operative temperature is defined as the uniform temperature of an enclosure where a person would exchange the same amount of heat by radiation plus convection as in the actual non-uniform environment [1]. Thus the sensor should represent the same ratio of heat exchange as the person. The operative temperature can be expressed as:

$$t_o = \frac{\left(h_c \cdot t_a + h_r \cdot t_r\right)}{\left(h_c + h_r\right)} \quad , \qquad (1)$$

where t_o is the operative temperature, t_a is the air temperature, t_r is the mean radiant temperature (°C), h_c is the convective heat exchange coefficient, and h_r is the radiant heat exchange coefficient for a person (W/m^{2}K).
In practice, in most cases where air velocity is small (<0.2 m/s), or where the difference between mean radiant temperature and air temperature is small (<4 °C), the operative temperature can be

calculated with sufficient approximation as the mean value of air and mean radiant temperature [3]:

$$t_o = \frac{(t_a + t_r)}{2}, \qquad (2)$$

This means that air temperature and mean radiant temperature are equally important for the level of thermal comfort in a space and therefore they have the same influence in providing acceptable thermal conditions.
In particular the mean radiant temperature, and consequently the operative temperature, are not evenly distributed and vary according to the location in the room. With radiant surface heating and cooling systems, the mean radiant temperature depends strongly on the surface temperatures of the heated/cooled surfaces, but also on the angle factors between the human body (position of occupant) and the room surfaces, as well as on the emissivity of the surfaces [4].
Therefore if the operative temperature is measured by a sensor, the result will be influenced not only by the position, but also by the shape, size and colour of the sensors.
Among commercially available sensors a grey coloured, ellipsoid-shaped (light grey, 160 mm long, 54 mm in diameter) has angle factors and projected area factors equivalent to the human body [4]. An approximation could be the use of spherical, half spherical and flat plane sensors.
By means of theoretical calculations and experimental testing, this project investigates how representative the temperature measured by the different shaped sensors and in different positions, is of the person's operative temperature in the centre of the room. The paper gives recommendations on positioning the sensor in a room and the type of sensor that is appropriate for radiant surface heating and cooling systems.

2. METHODS AND RESULTS

A theoretical calculation method was used to investigate the influence of sensor size, while an experimental set-up was used to test the influence of a sensor's colour, shape and position.

2.1 Influence of the sensor size

To measure the operative temperature directly, it is necessary to use a sensor with a diameter that will be influenced by the air temperature and mean radiant temperature equally as a person. By transformation of Equation (1) we obtain the following expression of the operative temperature, including the influence of the ratio of radiative/convective heat loss:

$$t_o = \frac{1}{1+\left(\frac{h_r}{h_c}\right)} \cdot t_a + \frac{1}{1+\left(\frac{h_c}{h_r}\right)} \cdot t_r, \qquad (3)$$

$$\left(\frac{h_r}{h_c}\right)_{sensor} = \left(\frac{h_r}{h_c}\right)_{person}, \qquad (4)$$

where h_c for a person was calculated based on ISO EN 7730 [1], Vogt et. al [7] and Mitchell (1974) [8], for a sphere according to ISO EN 7726 [4, 9] and for a plate according to [10]. The relative influence of the air temperature (a – weighting factor [1, 4, 6, 7, 8, 9]) can be calculated as a function of the temperature difference (Δt) by natural convection (see Figure 1) or air velocity (v_a) by forced convection (see Figure 2) and compared for sensors of different dimensions.

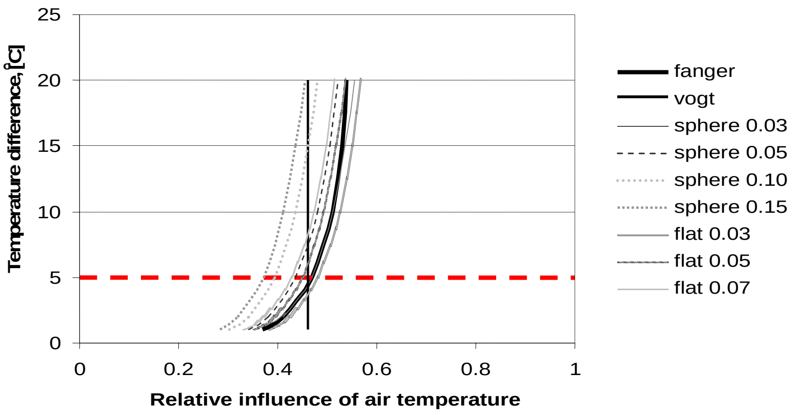

Figure 1. Comparison for natural convection.

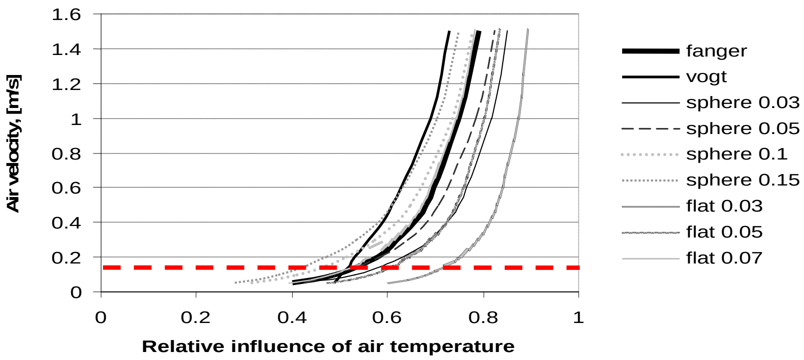

Figure 2. Comparison for forced convection.

The optimal size of the sensor depends on air velocity and Δt, and there is no general optimal size that represents a person's operative temperature. There is also disagreement concerning the convective heat loss for a person [5, 7]. In moderate indoor thermal environments the air velocity is normally lower than 0.15 m/s and the temperature difference between air- and mean radiant temperature is lower than 5 K. For such boundary conditions a diameter between 0.03 and 0.05 m for the sphere, and a length between 0.04 and 0.07 m for the flat shape may suffice (the one used in the present experiment had 3 cm). The lower the air velocity the smaller the required sensor.

2.2 Influence of colour

Three coloured sensors (black, grey, white) and one polished aluminium flat sensor were used in the experiment. The sensors were first exposed to a radiant ceiling (about 42 ^{o}C). The results in Figure 3 show that the colour of a sensor is not important when exposed to long-wave infrared radiation. A polished sensor, however, will reflect more of the radiation and show less influence. In the present test the polished sensor showed a 1 to 2 K lower temperature, depending on the position to the heated ceiling. Room sensors or thermostats may often be exposed to short-wave radiation from direct or diffuse sunlight. This was tested in another experiment. The sensors were exposed to short-wave radiation produced by a high temperature sun-spot lamp. The sensors' direction to the lamp was changed from a perpendicular (position 1 a), 45^{o} angle (position 1b) and a 90 ^{o} angle (position 1c). The results in 4 shows that the colour and finishing of the sensors had a significant influence on the temperature reading. The lowest effect was on a white and a polished sensor; the highest was on the black sensor. The highest differences (approximately 6 K between black and white) appeared when all sensors were placed 3.5 m from the lamp and faced front perpendicularly to the lamp. By turning around the horizontal axis from the perpendicularly facing position (0°) to parallel with the radiation from the lamp (90°), sensors receive less short-wave radiation and the influence decreases. In a real room the angle of the short-wave sun radiation varies during the day. Generally, a grey sensor gives intermediate results between black and white (see Figures 3 and 4), but closer to the black, and the polished sensor gives results very close to the white, especially when the sensors face the light source directly.

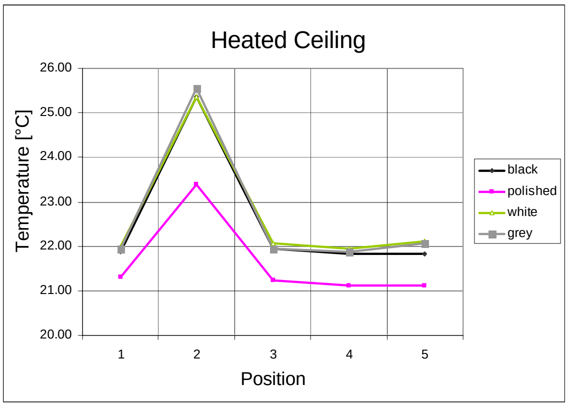

Figure 3. Sample of measured temperatures for flat sensors exposed to heated ceiling

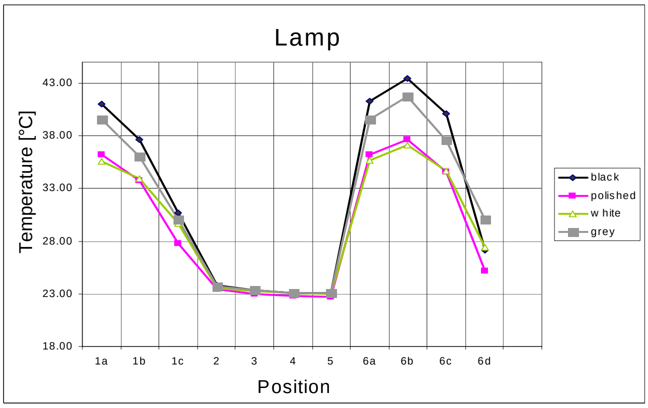

Figure 4. Influence of sensor colour when exposed to sun-lamp at different angles.

2.3 Experimental test of sensor shape and position

The experimental part was completed in a test room (see Figure 5). The tests included experiments with cooled and heated surfaces at different surface temperatures and sensors positioned at different room locations and directions (Figure 6). The experimental room was equipped with a heated/cooled window, heated/cooled ceiling, heated/cooled wall, heated floor, and combinations.

The operative temperatures were measured at 1.1 m height, to simulate the centre of the standing human body. This parameter was estimated by an ellipsoid-shaped sensor (assumed as reference, see Figure 7), a spherical sensor of 4 cm diameter (optimum diameter for use indoors [11] see Figure 8), a half spherical sensor of 4 cm diameter (see Figure 9) and four flat circular sensors of 3 cm diameter. They were made of aluminium plate and painted with black, grey and white colour and one was in polished material. The wall surface temperature was measured with surface temperature sensors.

All sensors were calibrated in a special chamber (with uniform and equal air t_a and wall temperature, placed inside an insulated polystyrene box of 3 cm in five steps (20, 25, 30, 34, 38 °C) and consequently the correction regression lines were developed.

Water-cooled panels (down to 10 °C, sizes of 0.8 m*2 m and 0.8 m*2 m) and electrical heating foils (up to 43 °C sizes of 0.6 m*1.25m and 0.6m*1.75 m) were installed in the test room in order to create significant differences between air- and mean radiant temperature and a high radiant asymmetry. The surface temperatures exceeded the standard values in order to be sure that the results will always be applicable for cases in the comfort range.

The air temperature in the test room was controlled by piston flow through a perforated floor in the range (19-21 °C).

2.4 Test results

The measurement was taken with the different sensors at different room locations at the same height (1.1 m). The results of the measurements with the different sensors are shown in Tables 1 and 2.

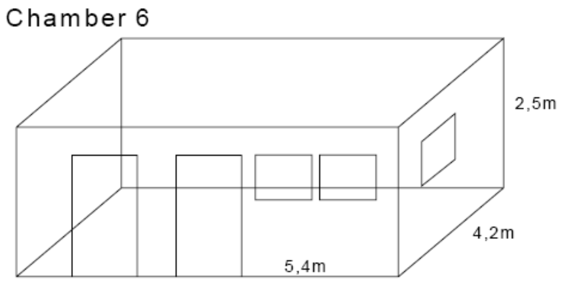

Figure 5. Test room, climate chamber 6 [12]

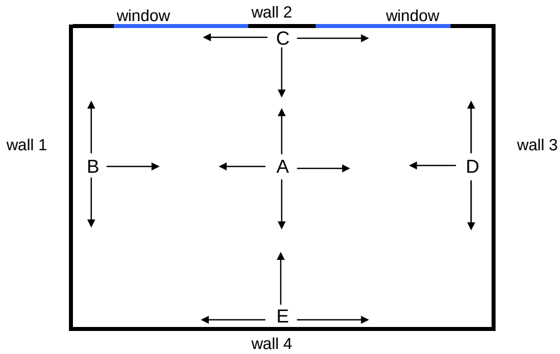

Figure 6. Position and direction of sensors in room test.

Figure 7. Ellipsoid-shaped sensor

Figure 8. Spherical sensor

Figure 9. Half-spherical sensor

Figure 10. Air temperature sensor

The radiant temperature asymmetry is used to describe the non-uniformity of the radiant environment by floor and ceiling heating. The difference between air and mean radiant temperature is also used to describe the non-uniformity. Table 1 shows the results for all sensors in the centre. This comparison is thus influenced only by the type of sensor and not the position. For typical conditions, the floor and the ceiling temperatures were respectively 29.2 °C and 42.4 °C, generating a maximum horizontal radiant temperature asymmetry of 18.8 °C for a heated ceiling. The maximum vertical asymmetry of 8.1 °C was found in the test with a heated wall combined with a cooled wall.
Even if in some cases the radiant temperature asymmetry was quite big the difference between operative and mean radiant temperature were in only two cases higher than 1K (heated ceiling, cooled wall/heated wall).
Table 2 shows the difference between the reference operative temperatures in the centre compared to the measured sensor temperatures in different locations. This is influenced by both the difference in sensor type and position. Table 2 also includes the measured air temperature at the different sensor locations.

Discussion

In terms of thermal comfort, it is preferable to control the room temperature as a function of the operative temperature in the area occupied by people. The positioning of the room temperature sensor in the occupied area may also save energy of 3 to 5% [16] as opposed to positioning the sensor on the wall, and the variations in the room temperature due to the control are smaller.

Other authors have shown the advantage of operative temperature control for maintenance of human comfort compared to air temperature control [13, 14].
In general, a high radiant asymmetry results also in a large difference between air and mean radiant temperature. The results show that using a sensor that is influenced by the radiation gives much better results than just using the air temperature.
Looking at Table 1 for the measurements in the centre, it can be seen that in all cases the sphere will give the best approximation. This difference is in all cases less than 0.5 K except for cases 8 (cooled wall/heated wall) and 2 (cooled windows), where it is respectively 1.7 K and 0.9 K. This is not surprising as the projected area factor for the sphere is closest to the ellipsoid. In the present tests the ellipsoid was in an upright position (standing person), which means a higher influence from the vertical radiation (walls) than from the horizontal radiation (floor-ceiling). This also explains why the greatest difference for the sphere is found for cases 2 and 9.
There is no clear difference between using a half-sphere and a flat sensor. In most cases the difference between the sensors and operative temperature (ellipsoid) were less than the difference between air- and operative temperature.
The results in Table 2 show also in most cases relatively small differences between the different sensors and the reference operative temperature in the centre. However, the sphere in general is not better than the flat and the half-sphere. In most cases the difference between local air temperature and operative temperature in the centre is bigger than the difference between the other sensors and the operative temperature. If positioned close to a heated or cooled wall, the sphere will over-evaluate the influence of the wall. The same is true if the half-sphere or flat sensor faces the heated-cooled surface.

				half sphere	-0.2	-0.2	-0.2	

The room sensor should be placed either on an interior wall (half-sphere, flat) or preferably in the occupied zone (all wireless, sphere) of the room. Since the effects of the weather (solar radiation) often affect the area nearby windows, and often people are even positioned close to windows in rooms, it is recommended to position the room sensor approximately 1-2 m from a window at a height of 0.6 to 1.1 m since this height represents a sitting/standing person
Since solar radiation often causes an increase in the temperature in a room, it is beneficial if the room sensor (preferably grey coloured) is affected by solar radiation as soon as possible. A further advantage comes with wireless room sensors that can be installed (placed) in accordance with the room furnishings (furniture, shelves, pictures, etc.).

				half sphere			-0.2			-0.1

CONCLUSION

The investigations show the advantage of taking into account the thermal radiation in a room, when controlling heating and/or cooling systems according to the operative temperature.

A sensor size (flat, sphere, half-sphere) about 3 to 5 cm will be influenced by radiant and convective heat exchange in a similar way as a person.
For long-wave radiation the colour of the sensor is not important.
For short-wave radiation such as sunshine, a black sensor will overestimate and a white or reflective sensor will underestimate the influence of the radiation. A flat grey or similar colour is recommended.
The influence of the sensor shape depends on the position of the sensor. If the sensor can be positioned in the centre of the room the best shape seems to be a sphere.
As a room thermostat is most often positioned on a wall, the sphere will overestimate the influence of the wall close to the sensor. In this case, a half-sphere is a better shape.
The half-sphere and the flat sensor give in many cases similar results; however, the half-sphere gives values closer to the operative temperature in the centre.
The influence of the sensor shape and position may be up to 2 K in environments where the difference between air and mean radiant temperature is less than 3 K.

SUMMARY

A Thermo-Active-Building-System is a modern sustainable efficient cooling system with pipes installed in the structural concrete slabs of multi-storey buildings. Due to the high thermal mass the accumulation or releasing of heat may occur at different times with respect to the heat load. The issue is how much of the concrete slab will actively be involved in the accumulation of energy. The paper shows the results of dynamic FEM analysis on how deep the room drifting temperatures of 6K penetrate into the concrete structure covered by various floor types (no covering, tiles, wood, acoustic insulation, raised floor). The fluctuations decrease exponentially with the depth while the attenuation ratio and time delay hardly depends on the floor type. Generally, the effective slab thickness is 15 cm, 10cm for wall. The vertical position of pipes should be considered approx. 7,5cm from ceiling surface according to operational mode (heating or cooling) and floor type.

INTRODUCTION

The modern architecture and building design follow the sustainable development by applying of energy efficient building systems. Requirements for insulation of building envelope increase in order to reduce the energy demand in winter however may thus increase cooling needs in summer especially by high internal load. Thermo-Active Building System (TABS) is a cooling system with pipes usually installed in the structural concrete slabs of multi-storey buildings. TABS performs as a heating or cooling elements fully integrated into the main building structure. Due to the high thermal mass the accumulation or releasing of heat may occur at different times with respect to the heat or cooling load (occupancy, sun radiation) [1]. Asynchronous operation of the conditioning system and thermal loads results in energy savings, shifts the fraction of loads to night time and reduces (shaves) the daytime peak load. The simulations [2] already showed how a TABS with 25 cm thick ceiling slab covered by the carpet dynamically behaves. The issue is how much of the concrete slab will actively be involved in the accumulation and release of energy during daily or weekly room temperature and load variations. Therefore it is important to investigate how deep the room drifting temperatures penetrate into the concrete structure, and the paper provides the analysis on this issue using computational method.

METHODS

The paper provides a dynamic software Finite Element Method (FEM) analysis [3] of the concrete structure exposed from the room side by drifting temperatures that follow the sinusoid curve (1) in range from 20 °C to 26 °C:

$$y = 23 + 3 \cdot \sin\left(\frac{2\pi \cdot x}{24}\right), \quad (1)$$

where x is the time [h] and y is the temperature [°C].

The results of the simulation will show the ability of penetration of drifting room temperature in various depths of a concrete structure. Heat transfer was modelled according to following two-dimensional thermal conductance equation:

$$div(a.gradT) = \frac{\partial T}{\partial t}\ , \qquad (2)$$

where dt is time and dT is temperature.

The thermal properties of the concrete structure without floor surface covering and with a thermal insulation was treated by mathematical model represented by heat transfer equation (2) in the investigated domain - the rectangle representative part of the slab 1m x 1m - given as the 2D section and with Newton boundary condition on the surface of a slab. The bulk temperature is considered as a periodic function (1).The simulation was carried out for four commonly used floor structures (Figure 1, Table 1) with different thermal resistance of surface covering ($R_{\lambda,B}$): no floor surface covering (ceramic tiles), with a light carpet of 1 cm thickness, with an acoustic/thermal insulation of 2 cm and 4 cm thickness was analyzed.

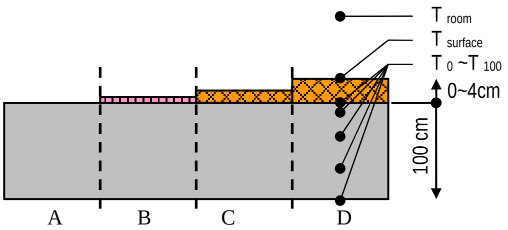

Figure 1. Simulated cases with a concrete and floor structures with reading points

Table 1. Parameters for calculated cases

Calculation case	A	B	C	D
Type of floor structure	No covering	Carpet (1 cm)	Rockwool (2cm)	Rockwool (4cm)
$R_{\lambda,B}$ [m^{2}K/W]	0	0,1	0,5	1,0
ρ [kg/m^3]	-	300	35	35
λ [W/m.K]	-	0,1	0,04	0,04
C [J/kg.K]	-	1000	1200	1200
Case corresponds to	No covering, Ceramic tiles	Light carpet, Wooden (floor) parquets	Floor with an acoustic insulation layer	Raised floor

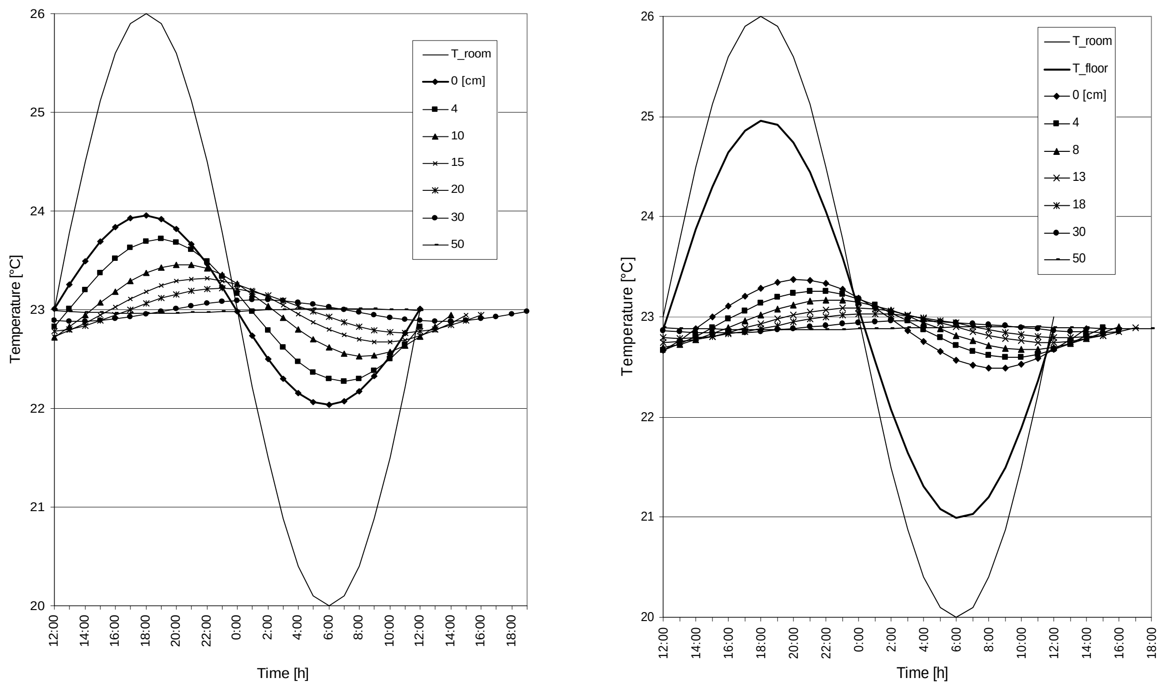
An issue was to select the constant value of total heat transfer coefficient (h_t, [W/m^{2}K]) as the software is not capable of dynamic recalculation of ht value per each time step separately.

Although the h_t may vary during the day, in our simulation h_t changes periodically according to sinusoid periodicity, in range of 6 - 11 depending on the position of the surface (wall/ceiling/floor) and temperature difference between surface and space (if there is heating or cooling).The value h_t of 8 belongs to wall heating and cooling, h_t 11 corresponds to floor heating and ceiling cooling, 7 to floor cooling and 6 to ceiling heating [4].

By periodic drifting room temperatures difference between surface and space is sometimes positive, and occasionally negative. It means that a surface performs partially as a cooling and partially as a heating element related to the room environment temperature. The h_t dynamically changes all the time in range approx. from 6-10. The h_t constant input value was finally chosen to 8.0 W/m^{2}K that covers with sufficient approximation all of available system types and boundary conditions.

RESULTS

The temperature fluctuations decrease exponentially with the depth of the concrete structure (Figure 1), while the attenuation ratio hardly depends from the $R_{\lambda,B}$. It is obvious that the accrued time delays of fluctuations can be observed by all of simulated cases but the most by raised floor structure (Figure 2). The conclusion will follow the assumption that the effective thickness of a concrete slab should be lower than such a concrete layer depth were the 10% of room temperature fluctuations is achieved.



a) b)

Figure 2. Daily temperature fluctuations inside a concrete structure. a) without surface covering, b) with acoustic insulation

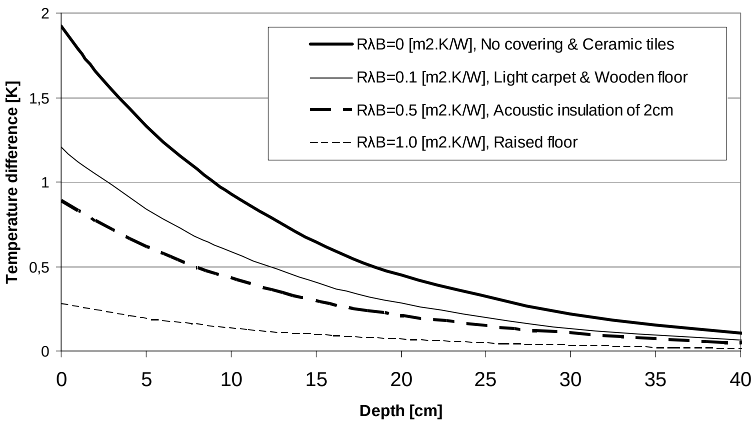


Figure 3. Temperature difference (fluctuation) between daily maximum and minimum temperature in horizontal concrete layers as a function of depth and floor surface covering.

DISCUSSION

However the floor surface coverings may differ in buildings and even from a room to another one. In residential buildings the acoustic insulation should be applied in order to keep the entire privacy. No surface covering floor structure is mostly used in non-residential, storage or industrial spaces. In domestic spaces occupied by persons (apartments and one-family houses) the wooden floor or ceramic tiles are usually used. Although the carpets may perform as a significant indoor pollution source they are still quite popular in some countries, though it might cover the room floor area just partly. The raised floor construction creates in office spaces creates a hollow trapped air layer that is available for leading the electric and IT cables, HVAC water distribution pipes or fresh air ducts, etc. Occasionally in some of the countries are room acoustic issues solved with a small additional acoustic insulation layer on ceiling of $R_{\lambda B}$=0,1. The higher is $R_{\lambda B}$ the lower is the effect of room temperature fluctuations on the mean slab temperature (Figure 1) and thinner part of a concrete layer is available for the heat exchange under the day cycle.

The results of the simulation may be concluded for three significant groups of cases with relatively low $R_{\lambda B}$=(0~0,1; case A B), relatively high $R_{\lambda B}$=(0,5~1,0; case C D) and the case with ceiling slab of thickness more than 150 mm. The ceiling slab with a low $R_{\lambda B}$ should not be of higher thickness then 10~15cm and the hydronic pipes should be located in mean slab level. A thicker slab might dispose higher thermal mass capacity, but it does not really matters, as the slab core would most likely be thermally passive. For cases with a high $R_{\lambda B}$ it is recommended to place the TABS pipes should be positioned closer 7,5~10 cm (or even less) to the ceiling surface in order to be included to heat transfer process following daytime cycle. The active slab thickness is approx. 10~15cm, and in any case should not exceed 20cm.

The height or extended column distance of a building may however sometimes affect sizing of load bearing structure. In this case the ceiling slab may be estimated to even more than 20 cm thickness. As such a slab will mostly not be fully activated it is reasonable to put hydronic pipes closer to the surface with lower $R_{\lambda B}$, usually ceiling surface up to 7,5 cm. Here the application of the raised floor structure comes suitable. This kind of construction is especially favourable by ceiling cooling system as the h_t achieves quite high value of 9-11. Even in case when a small acoustic ceiling insulation is applied.

The effective thickness of a thermally activated concrete slab is recommended to be 15 cm. The vertical position of pipes should be considered according to operational mode (heating or cooling), thermal resistance of floor covering and if a thin acoustic ceiling arrangement is present. The trend of last 10-15 years used to be of a build up the TABS with the slab from 20 to 30 cm thickness [1]. The recent simulations showed that there is no reason to dispose with so high building thermal mass as it is not effective from the point of daytime cycle. Naturally, it might be reasonable for long term heat storage (accumulation). But if for some reason the slab is too thick, the pipes should keep the position recommended above.

The paper describes an idea of an effective slab thickness from the point of view of the potential in all of its structure mass – even in the mean slab level - to be included into the heat exchange inside the room. It means that the whole slab is actively involved in the heat exchange under daily or weekly varying loads. On the other hand the study does not claim that the slab of a recommended thickness (10 - 15cm) is able to store certain amount of heat e.g. sufficient to cover high cooling loads just by using of night operation.

The accuracy of the results might be influenced by at least three facts. The h_t value was selected as a constant value because of the software imperfection; however, in reality h_t varies dynamically all the time. In a real room the fluctuations do not follow the same curve day after day but rather vary in the amplitude and the temperature drifts usually achieve in most of the days up to 4 K. Nevertheless the chosen sinusoid curve approximates the tendency quite well, because an extreme case was chosen for. By following this approach all of results should certainly be in range of those cases achievable under real - also extreme - boundary conditions.

SUMMARY

A research project on the control and design of thermally activated building systems (TABS) has been started in May 2004. This paper presents one selected result after three years of work: A comprehensive TABS zone control strategy with a modular concept consisting of maximally four parts which allows creating four different control strategies.
The (mandatory) first part of the comprehensive control strategy is an outside air temperature compensated supply water temperature control based on an unknown-but bounded approach to cope with uncertainties and variations in the heat gains during operation.
The (optional) second part of the comprehensive control strategy is an algorithm for room temperature feedback control. With this part, room temperatures are controlled in an energy-efficient way. The algorithm also corrects wrong parameter settings of the other control parts.
The (optional) third part of the comprehensive control strategy is a pulse-width modulation (PWM) module for intermittent operation of the recirculation pump. The intermittent operation is used to save pump energy, but it is also applied to benefit from low-cost energy sources such as free-cooling during the night or electrical energy in low tariff phases.
The (mandatory) fourth part of the comprehensive control strategy is a standard sequence controller to control the zone supply water temperature within the according setpoint range.
In simulations, all four control strategies are applied to TABS and the simulation results are analyzed regarding comfort criteria and energy efficiency.

KEYWORDS: control, thermally activated building systems (TABS), concrete core conditioning, performance bound

INTRODUCTION

Thermally activated building systems (TABS) have emerged as an energy efficient and economical way for cooling and heating of buildings. They integrate the building structure in the overall energy strategy of the building as energy storage. The dynamic thermal behavior of building elements such as structural floors and slabs is exploited to provide either cooling by radiant and convective energy absorption from the space, or space heating by the release of stored energy. In contrast to radiant cooling by suspended ceiling panels, peaks in energy demand are flattened and the actual cooling is shifted in to the colder night time [1], [2].
So far, control is implemented downstream in the design process. The specification of control algorithms is difficult because of the large thermal inertia of the system and because of the challenge to comply with comfort requirements in different rooms with different heat gains within the same hydraulic zone. Various control approaches are presented (see [3]-[9]), but they often have disadvantages due to different approaches for cooling and heating, too frequent switching between heating and cooling, the need for manual switching between heating and cooling mode as well as the need for manual adjustment of parameters. In [10],

[11], an unknown-but-bounded approach is presented to cope with uncertainties and variations in the heat gains during the design phase. In [12], [13], an integrated design process for TABS and its control is given based on the unknown-but-bounded approach.
This paper presents possible additions to the base control concept described in [12] which leads to a modular control concept. This concept can be adapted to different TABS plants and thereby increase the energy efficiency, the comfort and/or the commissioning and operation effort. The concept has been developed in the frame of a research project on which was reported the first time in [10].

OVERALL CONTROL CONCEPT

The presented control concept is one part of an integrated process that additionally consists of TABS design (planning of HVAC system and its control), commissioning of TABS and optimization during operation. In the TABS design, the base TABS zone control strategy is used (mandatory parts, see [12]). This base control strategy can be extended by optional control parts to improve comfort and/or energy efficiency depending on given requirements and installations. The result is a modular control concept for a TABS zone which – by configuration – can be adapted to different TABS plants. Besides the control of the zones, also the heat and cold generation and the distribution have to be controlled. In this paper, only the TABS zone control is described in detail.
In Figure 1, the overall control concept is shown for a TABS plant with two zones. Two zone controllers (see next chapter) act on the zone circulation pumps and the zone heating and cooling valves. Together with the zone supply water temperature setpoints $\vartheta_{sw,SpH,PWM}$ and $\vartheta_{sw,SpC,PWM}$, these signals can also be used to set up a demand dependent control of the heat and cold generation and distribution as indicated in Figure 1.

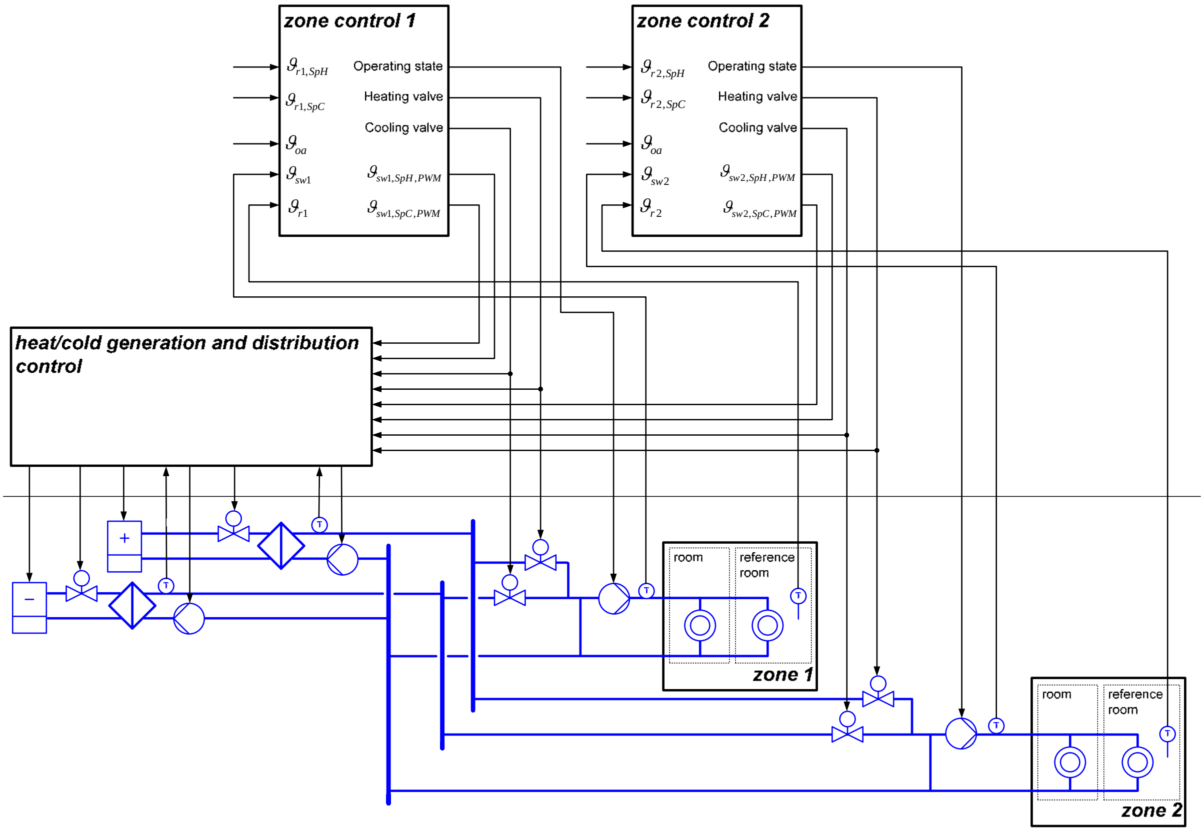

Figure 1: The overall TABS control concept, including heat/cold generation and distribution

ZONE CONTROL

In Figure 2, the modular TABS zone control is given in more detail. If an optional part is not needed or required, only the feed-through indicated by dotted arrows in the corresponding control part function block has to be realized. The functionalities of the four control parts are explained below.

1. Outside temperature compensated supply water temperature control (mandatory)

This core control part determines a supply water temperature setpoint range [$\vartheta_{sw,SpH}$, $\vartheta_{sw,SpC}$] as a function of the mean outside air temperature of the last 24 hours $\overline{\vartheta}_{oa}$ and the current room temperature setpoint range [$\vartheta_{r,SpH,FB}$, $\vartheta_{r,SpC,FB}$]. For that purpose, the so called heating and cooling curves are used. The heating and cooling limits serve to identify the operating mode depending on $\overline{\vartheta}_{oa}$ (see e.g. Figure 2). In order to define initial parameters of this control part, an unknown-but-bounded design process can be used [12].

2. Room temperature feedback control (optional)

If one or several room temperatures ϑ_r are measured in the controlled zone, a room temperature feedback control part can be added to the zone control. Room temperature feedback control has the following advantages (+) and disadvantages (–):

+ Comfort can be improved if heating and cooling curves are wrong placed or if the intermittent zone pump operation is inaccurate due to modeling errors (see part 3).
+ Energy efficiency can be increased when room temperatures are controlled making full use of the room temperature comfort range. This also leads to less frequent switching between heating and cooling demand of the zone.
+ Commissioning and tuning effort can be reduced since the feedback control corrects settings that are wrong (to a certain extent).
– Since TABS react slowly, only a day-to-day compensation is promising, an instant correction can not be achieved through the TABS.
– The placement of the room temperature sensor is critical: The measured temperature should be meaningful during the whole operation.
– If the zone consists of more than one room, the measured temperature has to be a reference temperature for the whole zone or several sensors in different rooms are used.

Since TABS react slowly, only day-to-day room temperature compensation is promising, an instant correction can not be achieved with TABS. A possible implementation of room temperature feedback control by two standard PID controllers is outlined here: The task of controller 1 is to keep the room temperature ϑ_r above the lower room temperature setpoint $\vartheta_{r,SpH}$ and the task of controller 2 is to keep the room temperature below the upper room

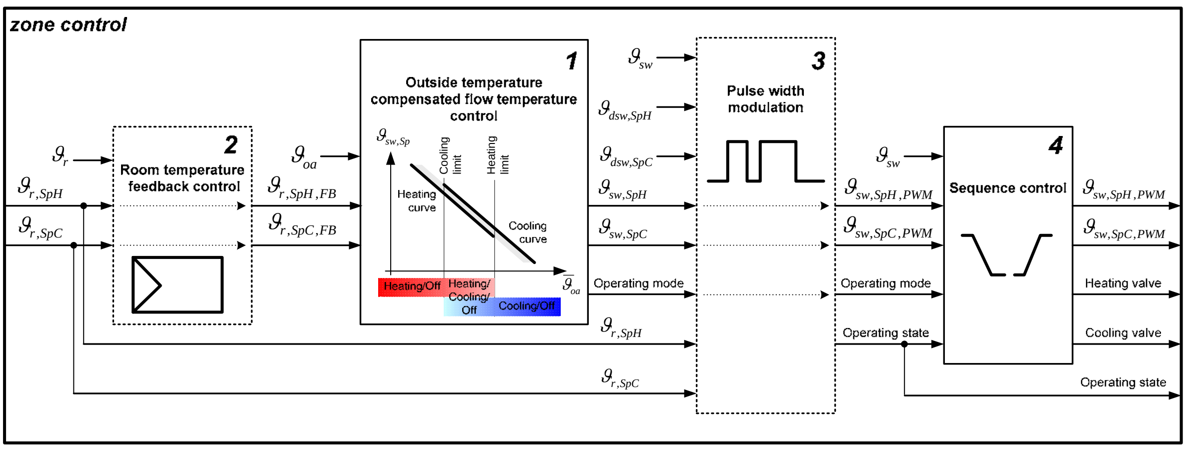

Figure 2: Scheme of the modular zone control (mandatory parts with solid frame, optional parts with dotted frame)

temperature setpoint $\vartheta_{r,SpC}$. The controlled variable for the P- and I-part of the controllers are the minimal (for controller 1) and maximal (for controller 2) room temperature of the last 24 hours. The controlled variable for the D-part of the controllers is the average room temperature of the last 24 hours. The controller outputs are limited (e.g. [-5K, 5K]) and added to $\vartheta_{r,SpH}$ and $\vartheta_{r,SpC}$ so that a corrected room temperature setpoint range [$\vartheta_{r,SpH,FB}$, $\vartheta_{r,SpC,FB}$] results. Controller 1 operates with $\vartheta_{r,SpH}$ while the setpoint of controller 2 is modified to cope with exceptional days when less internal heat gains are present (e.g. weekend).

3. Intermittent operation of zone water circulation pump (optional)

The control parts presented so far are based on continuous operation of the zone water circulation pumps. An additional third control part (see Figure 2) can be added to operate the zone water circulation pump intermittently which has the following advantages (+) and disadvantages (–):

+ Energy efficiency can be increased by reducing the operation time of the zone circulation pumps.
+ Energy efficiency can be increased by moving zone circulation pump on-times to time intervals where heat and cold can be delivered efficiently, e.g. free-cooling during nights.
+ Energy costs can be reduced by moving the on-time of the zone circulation pumps to time intervals where energy can be delivered at lower cost, e.g. using low tariff of the electrical energy to operate chillers and heat pumps.
+ Investment costs can be reduced by smaller dimensioning of the chiller when using it during the day for the air conditioning system and during the night for the TABS.
− The achievable comfort level generally decreases with intermittent operation of the zone circulation pump. During off-times, no heat is exchanged to the water circuit. This has to be compensated by lower or higher supply water temperatures during on-times, respectively, which reduces the self-regulating effect.
− The control of zone supply water temperatures for intermittent operation is more critical since turning the zone pumps on and off is heavily disturbing the control system.
− Intermittent operation can lead to more switching between heating and cooling demand than necessary.

A possible implementation of the intermittent operation control part is presented here: A pulse width modulation (PWM) approach is used to determine pump on- and off-times depending on the current operating mode. The pump operating mode (on or off) and the according supply water temperature setpoint range [$\vartheta_{sw,SpH,PWM}$, $\vartheta_{sw,SpC,PWM}$] are calculated based on a physical TABS model (see Figure 3). The same model then can be used to shorten or prolong pump on-times whenever the supply water temperature ϑ_{sw} is not kept within its setpoint range due to control errors or limitations of the heating/cooling system. Before starting an active heating or cooling process, an idle running operation is applied (the water circulates in the zone with zone valves closed). If after a specified idle operation time, the measured supply water temperature is within the range [$\vartheta_{sw,SpH}$, $\vartheta_{sw,SpC}$], the model based calculation is redone so that – whenever possible – no active heating or cooling process is necessary. To increase energy efficiency (or to reduce energy costs), on-time intervals are placed where heat or cold is expected to be delivered more efficiently (or less expensive).

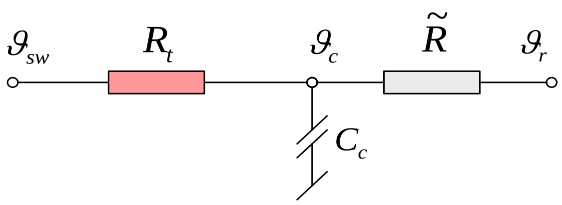

Figure 3: TABS first order model used for control of intermittent operation of zone water circulation pump

The values of the fictitious TABS thermal resistance R_t (between ϑ_{sw} and the concrete core temperature ϑ_c of the concrete core thermal capacity C_c) and the thermal resistance $\tilde{R}$ (between ϑ_c and ϑ_r) of the model in Figure 3 can be calculated according to [12]. The model then allows calculating turn-on ratios between on-time Δt_1 and the period length Δt for given supply water temperature setpoints. The simplified result for the turn-on ratio in the heating cases is given in (1), a similar equation is found for the cooling case. To calculate a non-simplified result, a calculation procedure as described in [15] can be applied.

$$\frac{\Delta t_1}{\Delta t} = \frac{1}{1 + \dfrac{\vartheta_{sw,SpH,PWM} - \vartheta_{sw,SpH}}{\dfrac{R_t}{R_t + \tilde{R}}\left(\vartheta_{sw,SpH} - \vartheta_{r,SpH}\right)}} \tag{1}$$

A simplified result for the turn-on ratio in the heating case for varying supply water temperatures is given in (2). This equation is used to shorten or prolong pump on-times whenever the supply water temperature is not controlled within its setpoint range.

$$\frac{\Delta t_1}{\Delta t} = \frac{\dfrac{1}{\Delta t}\displaystyle\int_{t=t_0}^{t_0+\Delta t_1} \vartheta_{sw}(t)dt - \dfrac{R_t}{R_t + \tilde{R}} \cdot \left(\vartheta_{sw,SpH} - \vartheta_{r,SpH}\right)}{\vartheta_{sw,SpH} - \dfrac{R_t}{R_t + \tilde{R}} \cdot \left(\vartheta_{sw,SpH} - \vartheta_{r,SpH}\right)} \tag{2}$$

4. Sequence control of zone supply water temperature (mandatory)
A standard sequence controller that controls the supply water temperature ϑ_{sw} (the according setpoint range is [$\vartheta_{sw,SpH,PWM}$, $\vartheta_{sw,SpC,PWM}$]) is acting on the heating and cooling valves. Depending on operating mode and operating state one or both sequences are disabled and the respective valve is closed.

RESULTS: CASE STUDY WITH DIFFERENT ZONE CONTROL TYPES

A simulation case study was made to compare four different TABS zone control strategies:
- control strategy 1 includes control parts 1, 4
- control strategy 2 includes control parts 1, 2, 4
- control strategy 3 includes control parts 1, 3, 4
- control strategy 4 includes control parts 1, 2, 3, 4

The simulated zone only contains one room; key figures of the room and the TABS configuration are given in Table 1 and Table 2 (see reference building in [12]).
Whole-year simulations for all four control strategies were carried out in a Matlab/Simulink simulation environment. Outside air temperature and solar heat gains were derived from local meteorological data for Zurich/Switzerland. The used individual heat gains of persons, equipment and lighting are based on the Swiss standard [14]. Room temperature setpoints $\vartheta_{r,SpH}$ = 21 °C and $\vartheta_{r,SpC}$ = 26 °C were used for the whole year. Other main control parameter values were determined in an unknown-but-bounded design process for the defined zone as described in [12], [13]. Here two major heat gain situations were differentiated: workdays and weekends; for both situations dynamic lower and upper heat gains were specified. This ultimately leads to the heating and cooling curve parameter values for weekdays and weekends. The design process also produces parameter values for the heating limit (13.1 °C) and the cooling limit (-1.2 °C).
In Figure 4, an example of the TABS zone control is shown for control strategy 4 for one week in summer: In the top diagram, it can be seen that $\vartheta_{r,SpC}$ is increased by control part 2

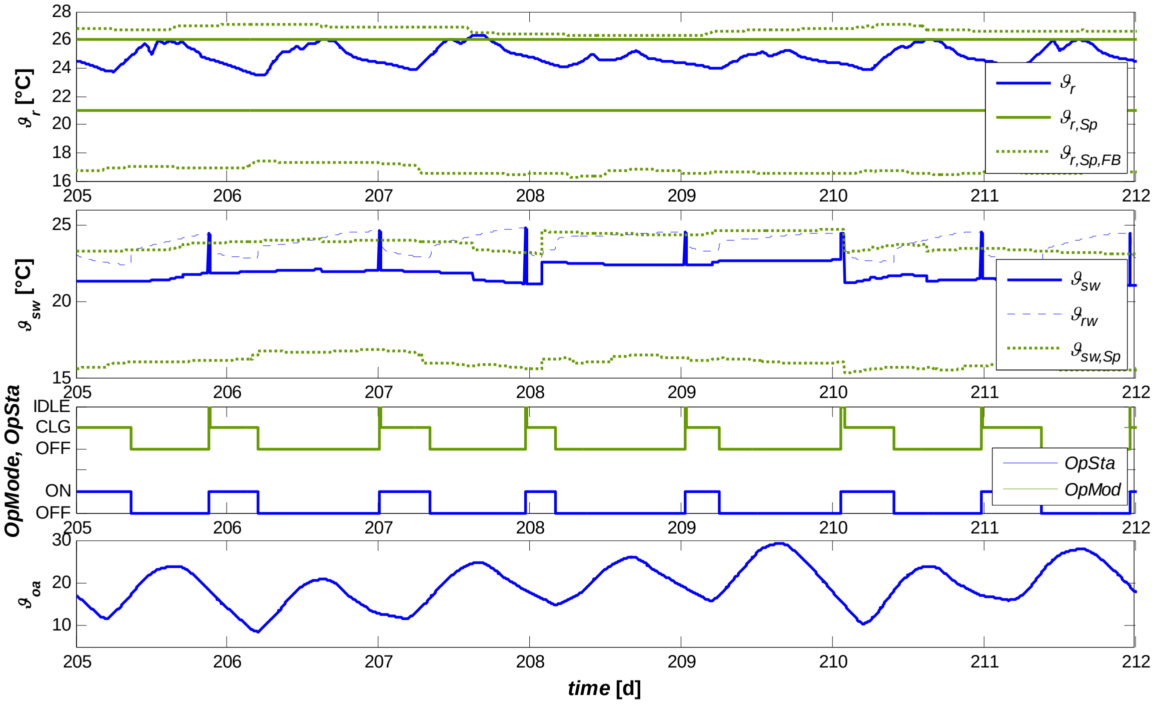

Figure 4: Example of zone control for control strategy 4 in summer

due to heat gains lower than the specified upper bound. The upper supply water temperature setpoint is then calculated by control part 1. Control part 3 lowers this setpoint and reduces pump on-time. The turn-on times are moved within the cooler nighttime. At the beginning of each cooling period, the zone is operated in idle operation to check if cooling is necessary. The resulting room temperatures for all control strategies are given in Figure 5. Figure 6 shows the heating and cooling energy demand, zone water circulation pump turn-on times as well as hours where the needed supply water temperature was lower than the outside air temperature. Figure 6 also contains performance bound energy demands which are calculated by optimal control with full knowledge of the controlled model and actual and future inputs.

Table 1. data of the simulated room

Space length, width, height		6 m x 6 m x 3 m
Façade	Orientation	West
	Area	18.0 m^2
	Overall U-Value	0.65 W/m^{2}K
	Glazing fraction façade	42 %
Additional internal Wall (light)		36 m^2
Natural air change		0.1 h^{-1}
Ventilation according to indoor air quality requirements (no cooling/heating by ventilation assumed)		

Table 2. data of the simulated TABS configuration

TABS covering fraction (floor area)	80 %
Thickness concrete slab	250 mm
Pipe spacing	200 mm
External/internal pipe diameter	20/15 mm
Specific supply water mass flow rate [a)]	15 kg/(h m^2)
Fictitious TABS thermal resistance (R_t) [a)]	0.08 (m^2 K)/W
Thermal resistance of flooring (carpet)	0.125 (m^2 K)/W

[a)] in terms of floor area covered by tabs

DISCUSSION

Since the parameter values of the control strategies are based on the exactly known simulated zone and since the boundaries of the heat gains have been specified reasonably, the open-loop room temperature control of strategy 1 is almost ideally in terms of comfort (see Figure 5). An added room temperature feedback control (strategy 2) is reducing the energy demand a little, but also – in a tolerable amount – the comfort. In this scenario, the main advantage of the feedback control is not apparent.

Application of PWM control (strategy 3) results in less pump turn-on times (47 %, see Figure 6), but increased heating and cooling energy demand. That is because the self-regulating effect is lower compared to a continuous operation (where supply water temperatures are closer to the room temperature), and therefore the control tends to compensate more than necessary (room temperatures stay within the comfort range for the whole year). Control strategy 4 with PWM and room temperature feedback control is able to avoid this: heating and cooling energy demand is similar to strategy 2 with similar comfort. Here, the PWM is done in a way so that during summer the on-times are moved to the colder night time in order to benefit more from free cooling (i.e. use of a dry cooling tower). To illustrate the resulting control behavior, Figure 6 shows the numbers of hours for which the outside air temperature was larger than the supply water temperature. During that time, the cooling demand cannot be satisfied by a dry cooling tower alone.

The presented control concept is one part of an integrated process consisting of TABS design (planning of HVAC system and its control), commissioning of TABS and optimization during operation. A modular control concept is used to handle different requirements and installations in a simple manner. Further details of the method can be found in the design and commissioning handbook which will be published in the frame of our work.

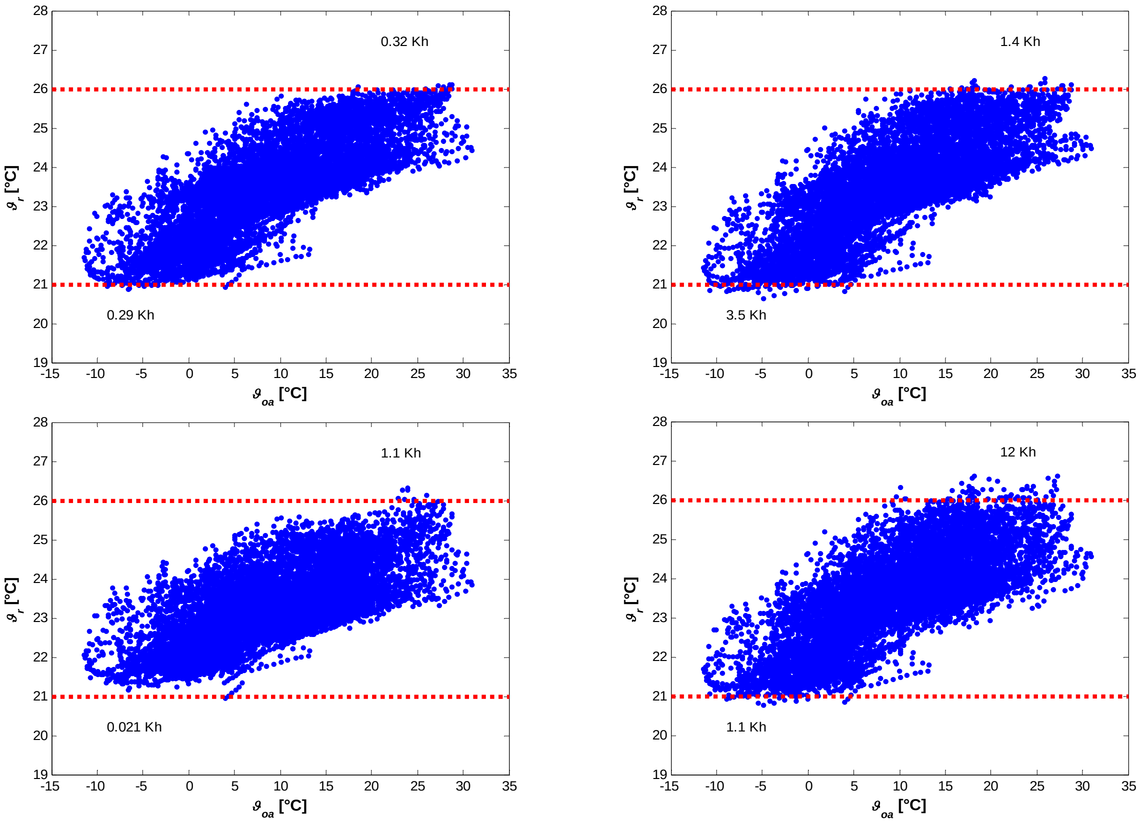

Figure 5: Whole-year simulation room temperatures (hourly values) for control strategies 1 (above left), 2 (above right), 3 (below left) and 4 (below right), room temperature setpoint violations are given within the figures

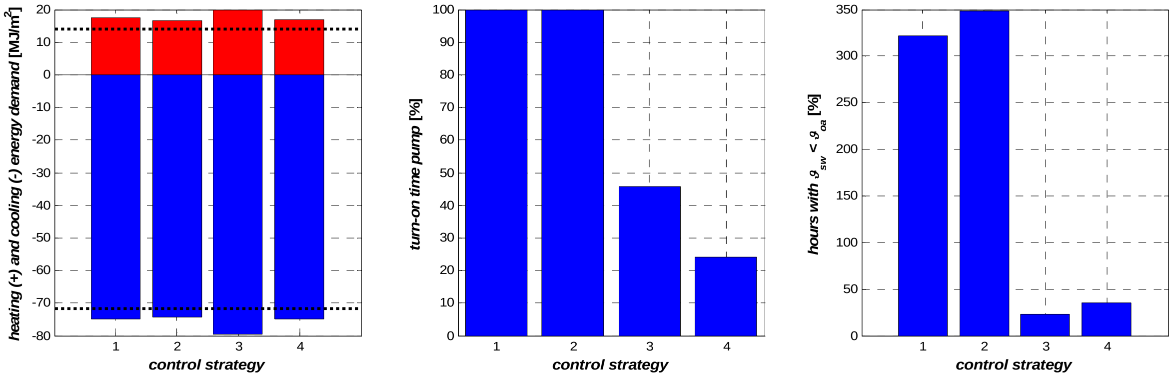

Figure 6: Whole-year simulation heating and cooling energy demand (left) with performance bound (dotted lines), pump operation time (middle) and hours where the supply water temperature was lower than the outside temperature (right)

ACKNOWLEDGEMENT

The partial funding of the project by the Swiss Confederation’s innovation promotion agency CTI and the input of the project steering committee are gratefully acknowledged.

SUMMARY

The tendency towards better insulated and energy friendly ventilated buildings leads to an ever decreasing building heat load. On the other hand, the installed boiler size is not altered. Often this is due to requirements of the coupled domestic hot water production, or worse, due to the superstitious belief that larger means better.
Correct sizing of the boiler can not only reduce the heating system investment cost, but also lower the energy consumption, and maybe even improve the thermal comfort.
For this study, a simulation model has been set up in which the boiler's output capacity is varied and the resulting heating system evaluated for both thermal comfort and energy consumption. The simulations are performed for two natural gas boilers, i.e. a high efficiency and a modulating, condensing one. The performance of the boilers sized following the European standard design heat load calculation [1], is compared to the results of the broad range of thermal output capacities.
As expected, oversizing leads to increasing primary energy consumption, especially in the case of the High Efficiency boiler due to its inadequate control system and high skin losses. The heat load calculation from the European standard is not far from the optimum, but it overestimates the necessary reheating power after night set back.

INTRODUCTION

As the thermal resistance of a building enclosure increases, the impact of any additional thermal insulation on energy economy decreases. This physical law forces countries with tough insulation requirements to turn to Energy Performance Regulation (EPR). EPR not only evaluates thermal insulation, but also takes into account the energy efficiency of ventilation, lighting, hot water production and heating systems as well as the benefits of passive and active solar energy [2]. A great unknown in such a vast corpus of possibilities is the heating installation's efficiency. The efficiency should be determined on the building scale, so that interactions between heating system and building are included. By defining the overall efficiency as the ratio of the net heat demand of the building and the total energy consumption of the boiler, control losses are included, but also the partly recovering of distribution and boiler losses can be assessed.
Since the net heat demand is a theoretical consumption minimum, and can not be measured like the real energy consumption, TRNSYS 16.1 is used to simulate different types of boilers, different boiler controls as well as different emission controls in houses with varying insulation quality [3]. It is shown that the boiler size has an important influence on the efficiency of the heating system.

The estimation of the required thermal power is not evident. Standard calculation methods have been developed. However, as Corrado [4] and Wouters [5] state, standardization, and as a consequence simplification, of the heat load calculation must be done carefully. In this paper the boiler size is assessed to maximize the heating system efficiency while maintaining the indoor thermal comfort. This result is then compared to the boiler size as determined by the European standard procedure [1].

METHODS

The building is a compact terraced house with an outer volume of 446 m³ and an exterior surface of 226 m². The heated ground floor (level 0) has an area of 63 m². The day zone, which comprises the kitchen, hall and living room, has a floor area of 50 m². Its set temperature during the day is 21°C, the implemented night set back allows a temperature decrease down to 15°C. The first floor (level 1) includes a hall (14.3 m²), two bed rooms (16.3 m² and 19.3 m²) and the bathroom (6.6 m²). This last zone has a set temperature of 24°C during the day and 21°C during the night. The bed rooms are not heated. The upper floor (level 2), partly under the sloped roof, comprises a study (14.1 m²), a storage room (4.8 m²), the third bedroom (21.5 m²) and the upper part of the hall (16 m²). The study and hall are both heated as the day zone, while the other rooms on this floor are not heated. The boiler, however, is located in the storage room and thus indirectly heats this volume.
The average U-value of the building envelope is 0.8 W/m²K, which leads to a net annual energy demand for space heating equal to 11 573 kWh. The heat emission system consists of low temperature radiators and thermostatic radiator valves (TRVs). The ventilation is modelled as non-forced natural ventilation as described in the Belgian standard NBN D50-001 [6].
The building as described above is modelled in TRNSYS 16.1. A detailed description is available in [7]. The low temperature radiators are modelled on Type 72 from IEA Annex 10 and numerically optimized by Kummert [8]. They are dimensioned according to the technical reports of the Belgian Building Research Institute [9]. Each radiator is equipped with TRVs. In the framework of IEA Annex 10, a simplified TRV-model has been developed by Ast [10]. It is a lumped capacitance model of the temperature sensor including the (relatively small) thermal resistance of the casing and the (larger) thermal resistance between sensor and water. Further refinements and measured data have allowed to develop a representative model of a programmable TRV in TRNSYS.
The boiler models for both the condensing and the high efficiency gas boiler are elaborate refinements of the TESS-boiler model ([11] and [12]). The input data is based on test data and a static boiler EES model developed by Lebrun [13]. The TRNSYS boiler models can be regarded as a combination of an ideal heater and a lumped capacitance model. The ideal heater, the burner, is immediately turned on or off as requested by the boiler control logic. The heated water then ‘passes’ the capacitive element. This part also models the heat losses through the boiler’s envelope. The boiler’s water exhaust temperature, leaving the capacitance, is thus lower than the burner’s water outlet temperature.
The boiler’s control logic can be set to an on/off regime or to a modulating regime so that the Part Load Ratio (PLR) can vary between 25% and 100%. The high efficiency boiler is modelled as a non-modulating system. It is turned on if the TRVs allow water flow. If the water exhaust temperature exceeds the maximum water outlet

temperature, the boiler is turned off again. Obviously, this working regime leads to frequent cycling. The condensing boiler can modulate to a quarter of its maximum thermal power. The latter is equipped with an external temperature compensated control. If the requested PLR becomes lower than 25%, this boiler will have to cycle as well.
The boiler is switched off during night set back. However, during day time, the boiler is required to maintain its operation temperature, since it is coupled to TRVs which can always demand heat.
The simulations are performed with varying boiler sizes. Firstly the thermal power as calculated based on the European standard is determined for four reheat time periods, i.e. the heating system is turned on one, two, three or four hours before the set temperature has to be reached. This leads to four surplus powers for intermittent heating (Table 1) and thus four boiler sizes as shown in Table 2. Secondly, a range of power levels from 3 kW to 30 kW is simulated. Auxiliary power, thermal capacity, as well as the thermal transmittance of the boiler envelope varies proportionally. The reheat time is set to one hour for this range.
The European standard EN 12831 [1] specifies a method for calculation of the design heat load of either a heated space or an entire building. The focus in this paper is on dwellings, heated with a central heating system. The European standard calculation for the total building design heat load ϕ_{HL} is[1]:

$$\phi_{HL} = \sum \phi_{T,i} + \sum \phi_{V,i} + \sum \phi_{RH,i} \quad (1)$$

where $\phi_{T,i}$ indicates the transmission heat losses of the heated spaces, excluding the heat transferred towards other zones inside the building, $\phi_{V,i}$ indicates the ventilation losses of the heated spaces excluding heat transferred in the building and $\phi_{RH,i}$ indicates the reheat capacities of the heated spaces required to compensate for the effects of intermittent heating.
The building is considered as a whole, therefore, internal heat transmissions are not taken into account. The EN 12831-standard aggregates the transmission losses through this building envelope to be 4.2 kW. The ventilation losses are calculated based on the volume flow rates for natural non-forced ventilation [6]. This results in a design heat loss for ventilation equal to 3.0 kW. For the surplus due to intermittent heating, a cold winter day is considered: the simulated temperature drop during night set back amounts to 3°C, averaged over the building zones. The thermal power to compensate for intermittent heating, as a function of the reheat time for a 3°C temperature drop is given in Table 1.

Table 1: Surplus in thermal power due to intermittent heating after a 3°C temperature drop

Reheat time (h)	1	2	3	4
Surplus for intermittent heating (kW)	3.8	1.9	1.4	1.1

Summing up the thermal loads due to transmission, ventilation and intermittent heating, results in the design heat load. To determine the necessary thermal power of the boiler, the emission and control efficiency have to be taken into account [14]. That means a division by a factor 0.97. A safety margin is applied to calculate the thermal

[1] The simplified calculation method can be used as the restriction on the air exchange flow rate, n_{50} being lower than $3h^{-1}$, is fulfilled.

power of the boiler, i.e. the power is multiplied by 1.1. Table 2 shows the resulting thermal power levels.

Table 2: Total thermal power as a function of reheat time, according to the European standard [6].

Reheat time (h)	1	2	3	4
Thermal power to install(kW)	12.6	10.4	9.8	9.5

The thermal comfort is determined based on an adapted weighted temperature excess method. This method is developed to assess overheating and is based on the Predicted Mean Vote (PMV)-model as developed by Fanger [15]. The aim of this paper, however, is to evaluate the thermal comfort for varying boiler sizes. Therefore only 'underheating' periods during the heating season will be included, i.e. when the indoor temperature does not reach the set value of the heated room during day time. The Weighted Temperature Subceeding hours (WTS) method is defined as follows:

$$PMV_i > -0.5 \rightarrow WF_i = 0 \qquad (2)$$

$$PMV_i \leq -0.5 \rightarrow WF_i = \frac{\sum PPD_i}{10.16} \qquad (3)$$

Where i indicates the zone and WF the hourly weighting factor. When the PMV is higher than -0.5, or put otherwise, when is predicted that less than 10% of the people judge the room too cold, the weighting factor equals zero. In the other case, when more than 10% thinks it is too cold, the factor is directly proportional to the Predicted Percentage of Dissatisfied (PPD). Finally, the WTS-hours are calculated as the sum of these hourly weighting factors during the whole heating period.

The energy consumption of the whole heating installation will be assessed. The circulation pump's working regime is determined by the boiler's working load; therefore, pump's energy consumption should be included. The energy input of the heating installation consists of natural gas (gas_{cons}) and electricity ($elec_{cons}$). As the energy consumption is expressed in primary energy (PE_{cons}), a conversion factor for electricity (f_{conv}=2.5 [16]) is used:

$$PE_{cons} = gas_{cons} + f_{conv} \cdot elec_{cons} \qquad (4)$$

The overall efficiency is then defined as the ratio of the net energy demand of the building and the total primary energy consumption. The boiler efficiency can be defined as the ratio of the useful boiler output, i.e. the increase of energy of the water flowing through the boiler, and its primary energy consumption. The Higher Heating Value (HHV) is used throughout this paper.

RESULTS

As this paper focuses on both the indoor thermal comfort and the energy consumption, Figure 1 and Figure 2 show these variables as function of the boiler output capacity for both the high efficiency and the condensing gas boilers. Figure 1 shows that the indoor climate is acceptable for a heat output of at least 8 kW. The indoor climate is not influenced by oversizing the boiler. The effect of oversizing, however, can be seen in the increased energy consumption (Figure 2) and is mainly due to decreasing boiler efficiencies (Figure3). The effect is much more pronounced for non-modulating high efficiency boilers with a fixed water outlet temperature.

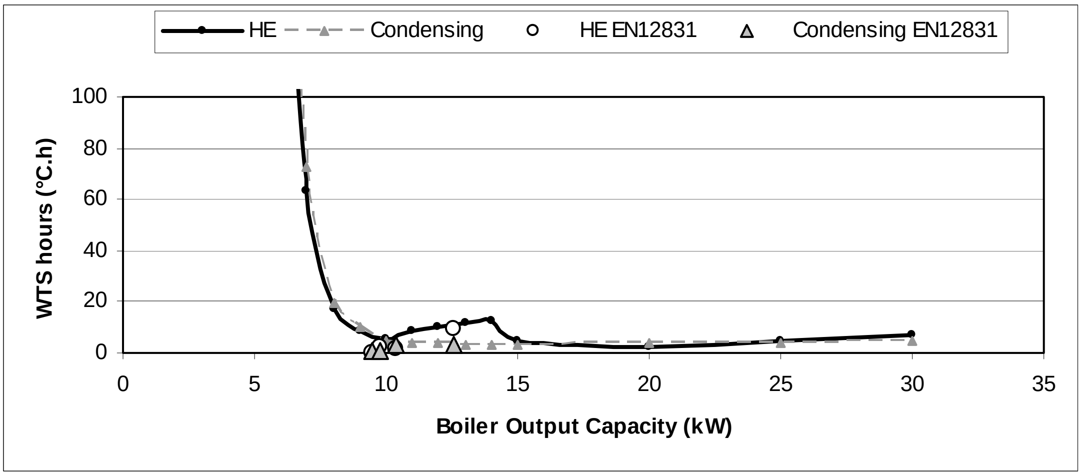

Figure 1: Weighted Temperature Subceeding hours versus the boiler output capacity for High Efficiency and Condensing boilers. The EN12831-cases are the boiler sizes determined by the European heat load calculation code with reheat times from one to four hours.

Figure 2 shows that the electricity use is low compared to the consumption of natural gas, so the effect on the primary energy use is limited. The higher electricity consumption for lower thermal power is due to increasing working time. For increasing boiler size, the cycling frequency increases (as shown in Figure 4), the number of working hours decreases and thus the auxiliary electricity consumption lowers as well. This effect counterbalances the growing ventilator power due to increasing boiler size. The modulating boiler can additionally profit from lower part load ratios and thus lower ventilator consumptions.

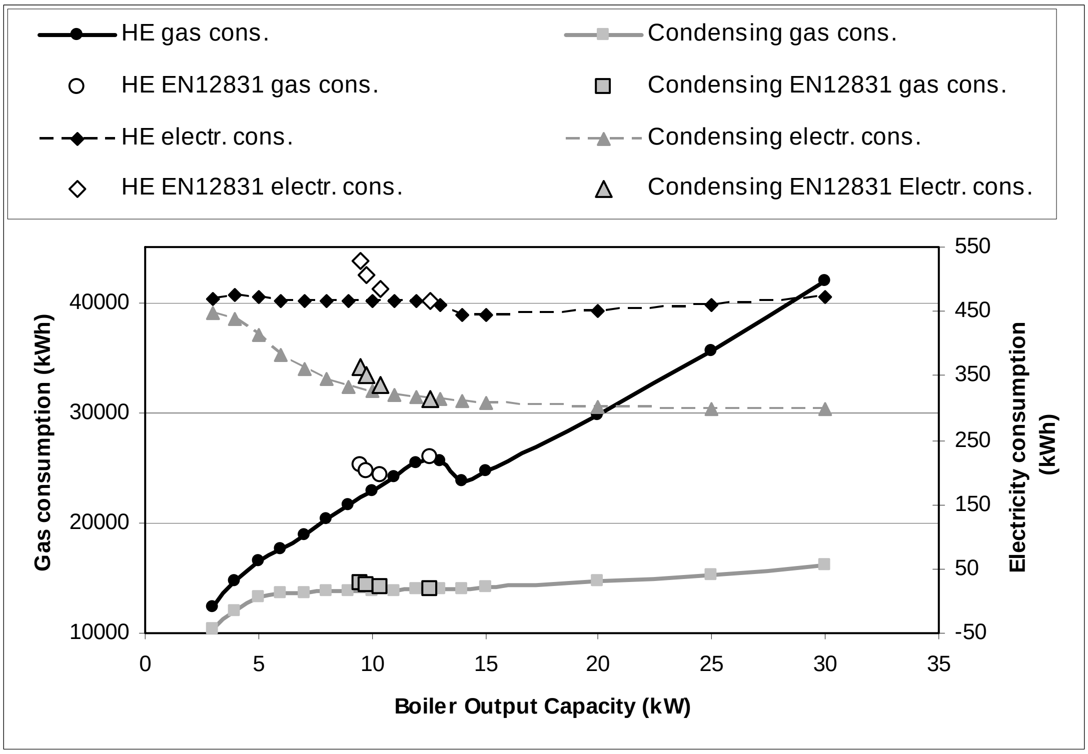

Figure 2: Gas and electricity consumption versus the boiler output capacity for both the High Efficiency on/off boiler and the Condensing modulating boiler.

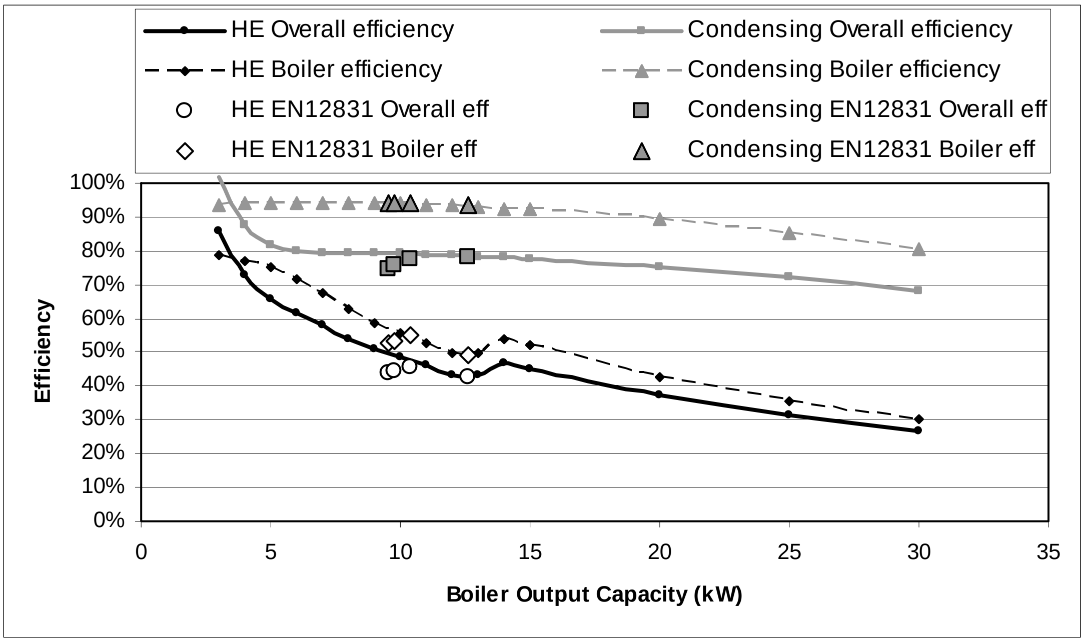

Figure 3: Overall efficiency (net heat demand / primary energy consumption) and boiler efficiency (net boiler output / primary boiler consumption at HHV) versus the boiler output capacity for both boiler types.

The decreasing boiler efficiency is correlated to the increasing cycling frequency. For boiler sizes under 6 kW, the cycling is limited. As Figure 4 shows, the boiler temperature stays below expectations despite almost continuously being switched on. The energy consumption and overall efficiency for these very low boiler output capacities are however not meaningful, since the boundary condition, a minimal indoor comfort, is not reached. The net heat demand is even bigger than the energy consumption in the case of a 3kW boiler. Therefore results below 8 kW should be neglected as a solution, but they are still visualised to show the trends.

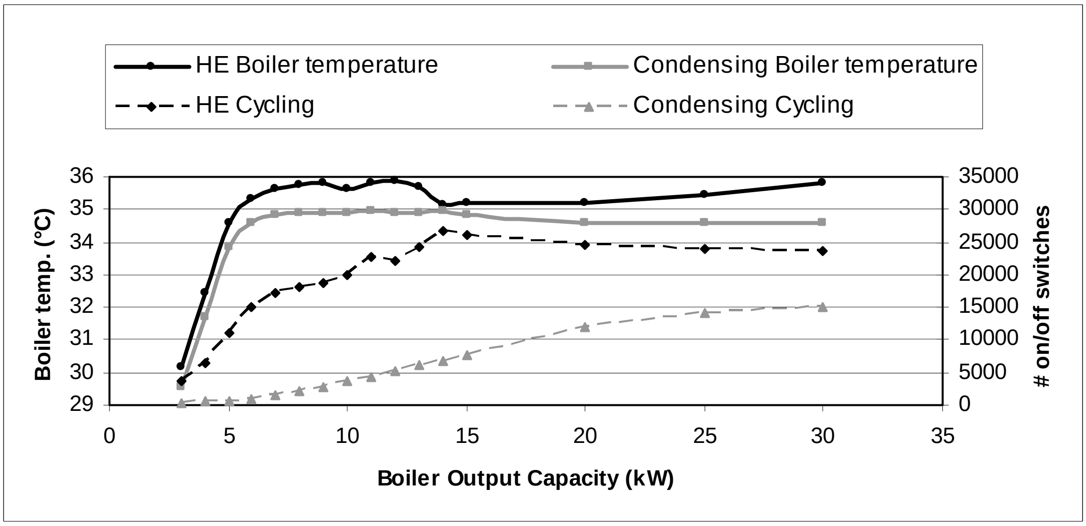

Figure 4: Boiler temperature and number of on/off switches versus the boiler output capacity for both boiler types.

Increasing the boiler size leads to more satisfying indoor conditions and a stable boiler temperature, but also implies a higher cycling frequency. The tendency of this

curve, though, changes for the different boiler types when further increasing the power. The high efficiency boiler, which is a non-modulating system, shows a maximum cycle frequency for thermal sizes slightly above the required heating power, around 15 kW. Modulating, condensing boilers with variable outlet temperature will smoothly tend towards the curve for non modulating systems, as extreme oversizing leads to a comparable working regime.
The results for the four boiler sizes as determined based on the European standard [1] diverge at the lowest boiler output capacities. This is due to the corresponding reheat times of one to four hours, while for the simulations of the range of boiler sizes one hour reheat time is used in all cases. The simulations show that this short reheat time is large enough during most of the heating season, except for a short period in winter. As a result, the increase in night set back time implies only a slightly better thermal comfort (Figure 1), but mainly a higher gas and electricity consumption (Figure 2). A temporary increase of the reheat time, or even adapted winter clothing could offer the same comfort but at a much lower energy consumption.
Deviant behaviour for boiler sizes of around 15 kW can be observed: lower thermal comfort (Figure 1), lower average boiler temperatures (Figure 4) and higher boiler efficiency (Figure 3). The main reason is that the oversizing results in frequent cycling, easily reached maximum temperatures and thus average boiler temperatures that are rather low (Figure 4). This effect is more pronounced during spring and fall. Lower temperatures allow more fume gas heat to be recovered and thus higher boiler efficiency, as can be seen in Figure 3. The modulating capacities cause much smoother curves for the condensing boiler.
Considering both thermal comfort and primary energy consumption, a thermal power from 9 kW to 11 kW leads to the best option, given the boundary conditions, i.e. in the case of the considered terraced house equipped with the specific heating system.

DISCUSSION

Oversizing does not influence the indoor thermal comfort, but leads to increase of primary energy consumption. However, there is a pronounced difference between boiler types. The condensing boiler can maintain its high efficiency quite well, due to low envelope losses, the ability to modulate its power down to 25%, and an outdoor temperature compensated boiler temperature which reduces the boiler temperature and thus skin losses even more.
The High Efficiency boiler with its simple on-off control, at the other hand, shows increasing difficulties to offer a constant water temperature to the TRVs with increasing boiler size. The boiler is required to cycle more and more, which leads to higher boiler temperatures and thus higher boiler losses. This is combined with a constant useful heat output and thus fast decreasing boiler efficiency. For these boilers a central room thermostat would offer a better solution, since this control allows the boiler to cool down between short intervals of (larger) heat demand.
The building heat loads calculated following the European standard only slightly overestimate the boiler size. However, the additional thermal power for intermittent heating seems difficult to predict. The corresponding reheat time is often overestimated, decreasing the overall efficiency. To put it otherwise, the heat load calculated for a reheat time of 4 hours suffices to heat up the building in slightly more than one hour.

Heat loss in distribution system influence on energy requirement from heating station

Raymond Riise, Bjørn Reidar Sørensen and Bjørnulf Jensen

SUMMARY

The objective of the study was to verify the assumption that heat loss in the distribution system would increase the boilers intermittence, and hence increase the final energy requirement. To verify the assumption, a model for selecting boilers in an energy flexible heating system is used to calculate the final energy requirement. The study shows a rather considerable increase in the energy consumption due to increased intermittence and reduced system efficiency. The result of the study demonstrates the importance of locating the distribution system in the building so that as much as possible of the heat emission from the distribution system can be recovered.

INTRODUCTION

Predicting the energy consumption for building heating purposes is important for several reasons. For instance when selecting boiler based on lowest running cost in an energy flexible heating system or when energy budgets are calculated.

It was assumed that when taking into account the relative heat loss in the distribution system in central heating system, the boilers intermittence would increase and hence the boilers efficiency would decrease making the final energy requirement increase.

The objective of the study was to verify this assumption and increase the awareness of this effect on the final energy requirement and the total running cost.

METHODS

To investigate whether the heat loss in the distribution system have any influence on the final energy requirement a model for selecting boilers in an energy flexible heating system is used.

Relative heat loss, L_d

Parts of the heating system located in unheated spaces must be insulated to reduce undesirable heat losses. Suitable insulation classes can be selected from The European Standard EN 12828 [1]. When calculating which insulation class to be used for the distribution system three critical factors must be defined; the heating period for which the heating system is operating, the water- and surroundings temperatures and the fraction of heat emission considered wasted, f_a. When all these three factors are determined the operational parameter I can be calculated. Based on the value of I the corresponding recommended insulation class can be obtained from EN 12828, Annex C. The maximal thermal transmittance (W/m·K) corresponding each of the insulation classes from 0 to 6 can then be calculated for each heat pipe based on EN 12828. The total heat emission, L_e, for the entire distribution system can then be found by adding up all the heat emission from each pipe. L_e depends on temperature difference between water and ambient temperature, the pipe dimension and length of the pipe and the insulation of the pipe.

The relative heat loss from the distribution system, L_d, must not be confused with the relative heat emission from the distribution system, L_e. The relative heat emission is defined as the total heat emission from the adequate insulated distribution system, while the relative heat loss is defined as the fraction of the relative heat emission that is considered as wasted. The relative heat loss, L_d, will then be:

$$L_d = f_a \cdot L_e \quad (1)$$

Final energy requirement, Q_f

To demonstrate the effect of L_d on the final energy requirement a model building is constructed, and the final energy requirement is calculated. Riise, Jensen Sørensen [2] describes a method for calculating and selecting boilers in an energy flexible heating system based on lowest running cost.

The final energy requirement, Q_f, can be calculated when the total heat demand and the efficiencies of each boiler are known

$$Q_f = \frac{Q_d}{\eta_l} \text{ (kWh)} \qquad (2)$$

where:

Q_d total energy requirement to the heating system (kWh)
l the boiler in question
η_l efficiency of boiler l ( )

[2] presents a set of equations to find the efficiency as a function of the heat demand from the heating system for an intermittently controlled boiler. These equations have been modified to take into account relative heat loss due to inaccurate control, L_{con}. Heat loss due to inaccurate control will probably cause an increase in the final energy requirement.

$$\eta_l = \frac{Q_{out}}{Q_{inst}} \cdot (I_l + 1) \qquad (3)$$

The intermittence rate can be obtained by using equation (4)-(7) as follows:

$$I_l = \frac{N_l - 1}{\frac{N_l}{I_{l,\max}} + 1} \qquad (4)$$

$$N_l = \frac{Q_{inst} \cdot \eta_{l,\max}}{Q_{out}} = \frac{Q_{\max}}{Q_{out}} \qquad (5)$$

$$\begin{aligned} I_{o,\max} &= \frac{1 - L_{eg} - L_r - L_d - L_{con}}{L_r + L_g + L_d + L_{con}} \\ I_{e,\max} &= \frac{1 - L_r - L_d - L_{con}}{L_r + L_d + L_{con}} \end{aligned} \qquad (6)$$

$$\begin{aligned} \eta_{o,\max} &= 1 - L_{eg} - L_r - L_d - L_{con} \\ \eta_{e,\max} &= 1 - L_r - L_d - L_{con} \end{aligned} \qquad (7)$$

where

η_l	mean efficiency for the boiler in question ( )
Q_{out}	heat output from heat system (kWh/h)
Q_{inst}	gross installed boiler capacity (kWh/h)
Q_{max}	maximum heat output from heat system
I	intermittence rate ( )
N	help variable
I_{max}	maximum intermittence rate ($\eta=0$) ( )
η_{max}	maximum operating efficiency for unit ($I=0$) ( )
L_{eg}	relative exhaust gas heat loss ( )
L_r	relative radiation and convection heat loss for boiler surface ( )
L_d	relative distribution heat loss ( )
L_g	relative heat loss caused by air draught at boiler off time ( )
L_{con}	relative heat loss caused by inaccurate control ( )

The heat loss from each boiler must be obtained from calculations, measurements or given by the boiler manufacturer. The heat loss from distribution system must be calculated for each case. It is assumed that L_{con} will be affected by the size of f_a in the calculation of L_d. The effect of L_{con} on the total energy consumption is not a part of the study. Neither is the calculation of f_a.

When the efficiency for each boiler have been calculated for the time step in question, it is a simple matter to determine the final energy requirement, Q_f, Q_f ca be found by combining equations (2) and (3) for that time step:

$$Q_f = \frac{Q_d}{\eta_l} = \frac{Q_d}{\frac{Q_{out}}{Q_{inst}}\left(I_l + 1\right)} \text{ (kWh)} \qquad (8)$$

This approach is not widely used in cases where the selection of boilers is done manually, but it have become more and more common in automated heat stations where a control unit selects the optimal boiler based on lowest running cost.

Calculation / simulation model

A model building is used in a simulation case based on [2], with modified to account for L_{con}. Building data is shown in table 1, and necessary external data (outdoor temperature and energy prices) are displayed in figure 1 to figure 3.

Table 1. Building data for model building used in simulation case

Type of building	Office building
Indoor set-point temp	17°C
Area	3100 m^2
Volume	9900 m^3
Infiltration rate	0.3 h^{-1}
Total heat transfer incl. infiltration	3258 W/K
Heat demand domestic hot water	5 W/m^2
Heating period	365 days, due to production of domestic hot water.
Air specific heat capacity	0.35 $Wh/(m^3K)$
Airflow rate	20.000 m^3/h
Heat recovery efficiency, ventilation	0.75
Operating time ventilation	0600-1600 (Monday-Sunday)
Oil boiler gross installed capacity	400 kW
Electric boiler gross installed capacity	350 kW
External temperature	Daily maximum and minimum temperature given by Norwegian Meteorological Institute. Location Narvik. Year 2005.
Electricity prices	Hourly electricity prices given by Nord Pool ASA. Figure 2 shows average daily prices for 2005 including transmission charges, EURO/kWh, from local power grid owner, Narvik Energi AS.
Oil prices	Approximately marked price for fuel oil for 2005. For simulation purposes it is assumed different prices for each month of the year. Figure 3 shows prices for each month used in the simulation example.
Lower calorific value	10 kWh/litre
Specific oil boiler losses	$L_{eg} = 0.085$ $L_r = 0.035$ $L_g = 0.02$ $L_e = 0.045 - 0.063$ [1] $L_d = 0.000 - 0.045$ [2] $L_{con} = 0.05$ [3]
Specific electric boiler losses	$L_r = 0.025$ $L_e = 0.045 - 0.063$ [1] $L_d = 0.000 - 0.045$ [2] $L_{con} = 0.000$ [3]

1) The total heat emission from the distribution system depends on the insulation class defined in European Standard EN 12828. The insulation classes reflect the fraction of the heat emission considered wasted, f_a, from 0.0 to 1.0. A low fraction of the heat emission wasted allows a lower insulation class and hence a higher total heat emission from the distribution system since a larger share of the emission will benefit the building for heating purposes.

2) The total heat loss depends on the magnitude of f_a. Wigestad, Dokka, Pettersen and Myhre [3] suggest that all non direct-acting heating systems will have a relative distribution heat loss, $L_d = 0.05$ of all delivered heat from the heating station. In this study L_d is determined based on equation (1).

3) Wigestad, Dokka, Pettersen and Myhre [3] suggest $L_{con} = 0.05$ for oil fired boilers and $L_{con} = 0.0$ for electric boilers.

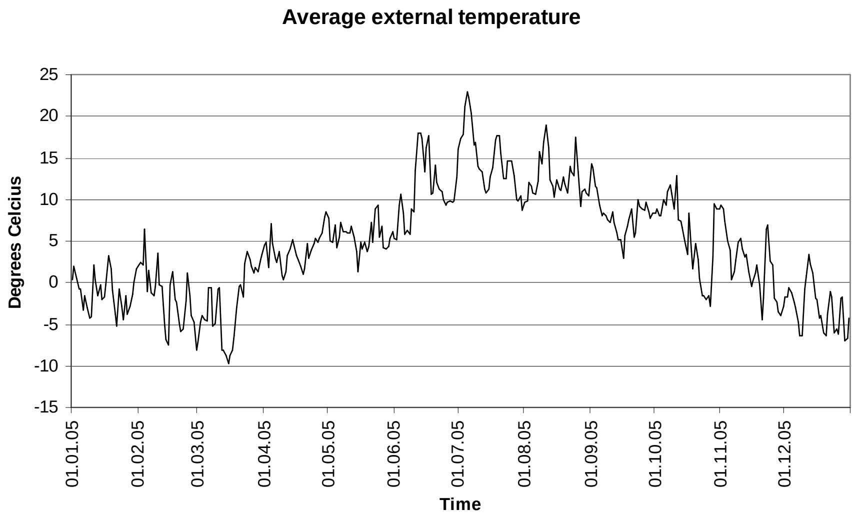

Figure 1. Average outdoor temperature in Narvik 2005 used for simulations.

RESULTS

f_a, heat emission and heat loss

Total heat emission and heat loss depends on the fraction of heat emission from the distribution system considered wasted. Table 2 shows the connection between f_a and total relative heat loss from the distribution system and heat recovered from the heat emission for the model building together with the corresponding operational parameter, ***I***, and insulation classes.

Table 2. Relation between f_a and L_d

f_a	Operational parameter	Insulation class [1]	Relative total heat emission, L_e [2]	Relative heat loss (waste), L_d [3]	Relative heat recovered	Final energy requirement (kWh)

[1)] From EN 12828
[2)] Total heat emission from the distribution system relative the gross installed capacity.
[3)] Total heat loss for the distribution system relative gross installed capacity, $L_d = f_a \cdot L_e$

Table 2 demonstrates the effect of f_a on the total heat emission from the distribution system, and the fact that a higher share of the heat emission recovered for building heating purposes allows a higher total heat emission compared with a situation where all the heat emission is considered as waste.

Final energy requirement

Figure 4 shows the increase in final energy requirement from the heating station with different values of f_a, For this particular case the increase in energy requirement is 8.4 % with a f_a 0.5, and 15.4 % with a f_a 1.0.

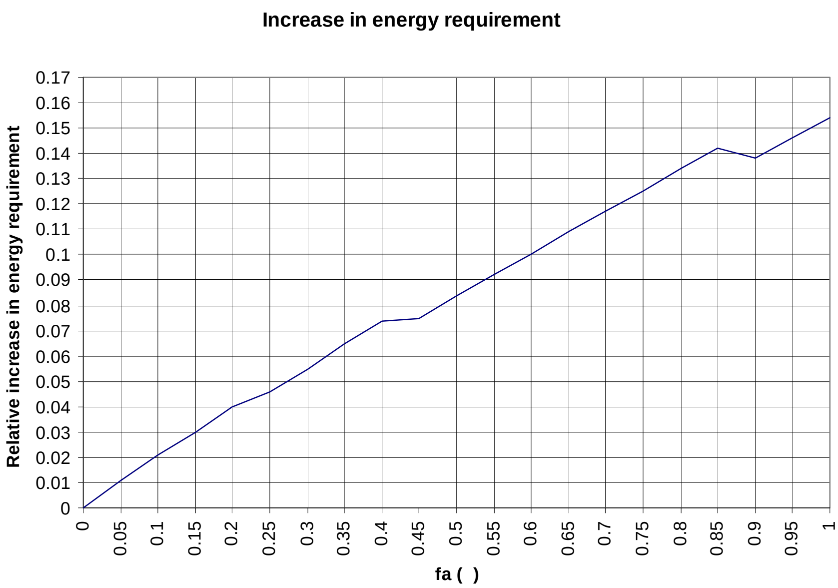

Figure 4. Relation between f_a and increase in energy requirement from the heating station.

It is also possible to investigate the effect on the final energy requirement if the considered value of f_a is incorrect. For instance, if f_a is assumed to be 0.10, but the actual f_a is 0.4. Then the final energy requirement will be approximately 6.3 % higher than calculated. In this case f_a 0.10 gives insulation class 1, and f_a 0.40 insulation class 3. If insulation class 1 is used instead of class 3, with f_a 0.4, the final energy requirement will be approximately 1.1 % higher than if insulation class 3 is used.

Intermittence rate

The reason for this relative high increase in the energy requirement can be identified by examining the intermittence, I, for the different cases. For $f_a = 0.05$; $I_{max,oil}$ is 5.15 with a boiler efficiency 0.27 and $I_{max,el}$ is 11.8 with a boiler efficiency 0.64. For $f_a = 1.00$; $I_{max,oil}$ is 3.8 with a boiler efficiency 0.23 and $I_{max,el}$ 7.3 with a boiler efficiency 0.42. A closer study of the result of the boiler selection shows that the electric boiler is the predominant under existing conditions.

System efficiency

The result of the increase in the energy requirement is also visualized by the mean system efficiency as shown in figure 5.

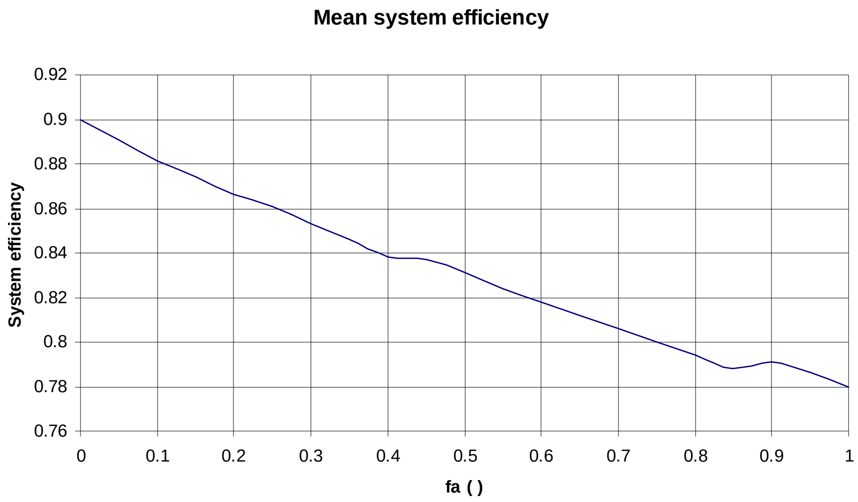

Figure 5. Mean system efficiency.

DISCUSSION

The results of the study show that the location of the distribution system in the building can be vital to the energy consumption, and hence the energy cost. Following the minimum insulation requirements, it is evident that to design the distribution system in such a way that as much as possible of the heat emission from the distribution system can be recovered for building heating purposes is preferable. If it is not possible to reduce f_a one should consider the possibility to exceed the minimum insulation requirement in EN 12828. The study has not considered the effect of an increase in the insulation thickness or quality.

Further it is not considered how the heat loss from the distribution system will affect the control of the heating system. It can be difficult to control the system correct if undesired heat loss from the distribution system is allowed to enter heated spaces in the building. EN 12828 recommends that an undesirable increase of room temperature of more than 2 K should be avoided.

To reduce undesirable heat loss, insulating the distribution systems is important. However, this study shows that it is not sufficient just to focus on the maximum thermal transmittance from the distribution system. The effect of heat losses from intermittent controlled boilers should also be considered.

SUMMARY

This paper compares pressure independent balancing and control valves (PIBCV's) to traditional – pressure dependent – control valves.
Traditional valves are subject to changes in differential pressure that occur during normal operation. These pressure fluctuations cause deviations in the room temperature and change the control response. In practice this results in unpredictable control behavior and the inability to control small flows.
In contrast, pressure independent valves eliminate these fluctuations. As shown by calculations, laboratory tests and measurements in a real life installation, removing the differential pressure from the control equation results in significantly improved room temperature control. Additionally the PIBCV also automatically limits the flow to the designed flow rates at all load conditions, thus increasing the pump efficiency. Preventing overflows will also increase the performance of boilers and chillers because temperature differences over the terminal units will be in accordance with the design specifications.

INTRODUCTION

This paper is focused on control valves for fan-coil units (FCU), chilled ceilings & beams, air-handling units (AHU) and similar terminal units (TU). Most water based HVAC systems apply control valves to control the flow through heat exchangers. The flow is adjusted according to the difference between the set and the real temperature and normally this adjustment is achieved by de- or increasing the valve opening.
According to system demands, experience and personal preference the system designer has several choices with regards to valves like fast opening, linear or equal percentage, and control strategies like on/off, chrono-proportional or modulation.
Engineers worldwide use only a few different methods for sizing valves which are all derived from the same background. These methods range from assuming a fixed differential pressure (for example the 35kPa rule) or to limiting the minimum authority (for example a>0,25), while the selection of the valve characteristic is based on expectations of the performance (for example: Equal percentage are expected to be better then linear valves) or according to the characteristic of the terminal unit and the control authority of the valve.
The article's goal is to show the differences in performance between traditional control valves and pressure independent balancing and control valves (PIBCV's).

METHODS

In order to put a value to the performance of the control valve (provided there's adequate temperature control) we need to mention the study performed by Federspil et al [1] where the main findings after extensive complaint analysis were that 77% of all claims were of a thermal nature. Subsequently a model was developed to show the relation between temperature deviations and temperature change rates. According to this study any excessive temperature deviation is penalized by costly claim handling. The study goal didn't include Indoor Air Quality (IAQ) that could also negatively influence the working environment and add considerable costs. This study proves the benefits of adequate temperature control: The number of claims will double when the average temperature is 1K above ideal (23°C) and if we increase the standard temperature deviation from 0,5 to 2K. The cost of these claims could then be as high as 10%, compared to the total energy cost for the installation.

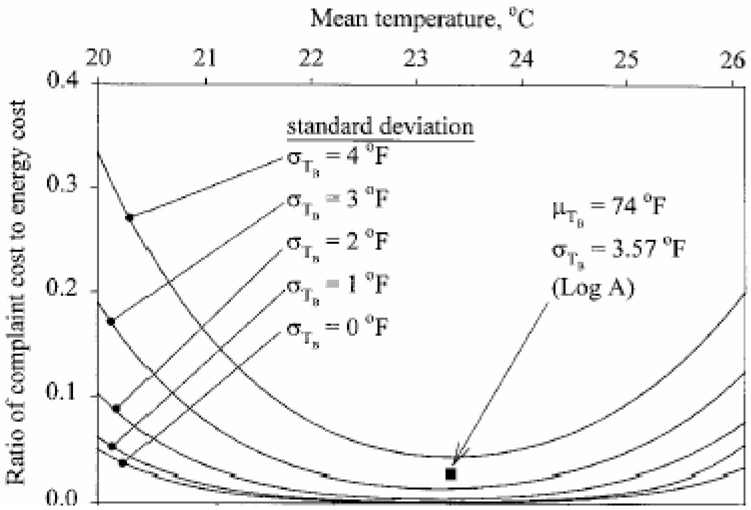

Figure 1: "Cost of complaints relative to cost of energy during summer in Huston" [1] in relation to room's mean temperature and its deviation .

One of the methods to select a control valve (CV) is described in Recknagel [2] where the main goal to design a CV is to compensate for:

- Un-linear characteristic of heat exchanger (terminal unit)
- The increase of the differential pressure when the valve closes (described by the valve authority)

The procedure of the valve selection is summoned in following graph (figure 2).

The last graph shows that the selection of a valve characteristic depends on the characteristic of the heat exchanger and the authority of the control valve. This means that for water-air heat exchangers (a typical factor a is between 0,15 to 0,3) an equal percentage valve should be selected, while for water-water heat exchangers (typically >0,5) a linear valve is preferable. However in between lines we need to accept a deviation from the ideal situation. Furthermore, the valve characteristic combined with that particular valve's authority will cause different gains at different loads. In order to provide a stable control of the temperature, the correct P-band needs to be defined. A higher deviation from the ideal selection would result in a bigger P-band, meaning more deviation from the required temperature.

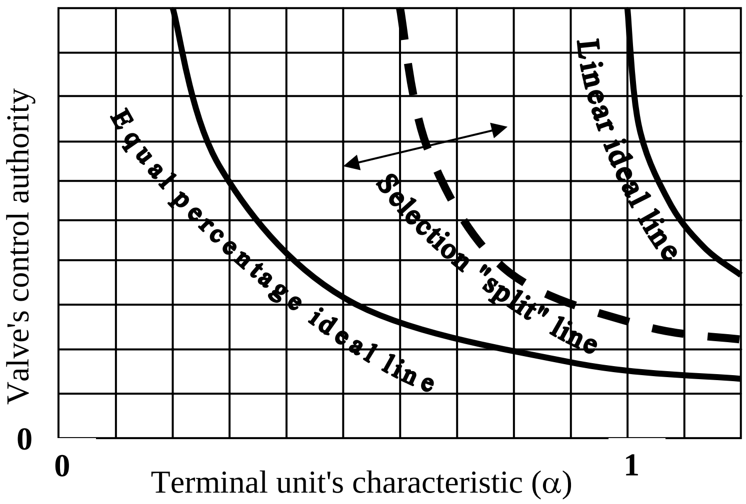

Figure 2: Selection criteria for control valve characteristic [2].

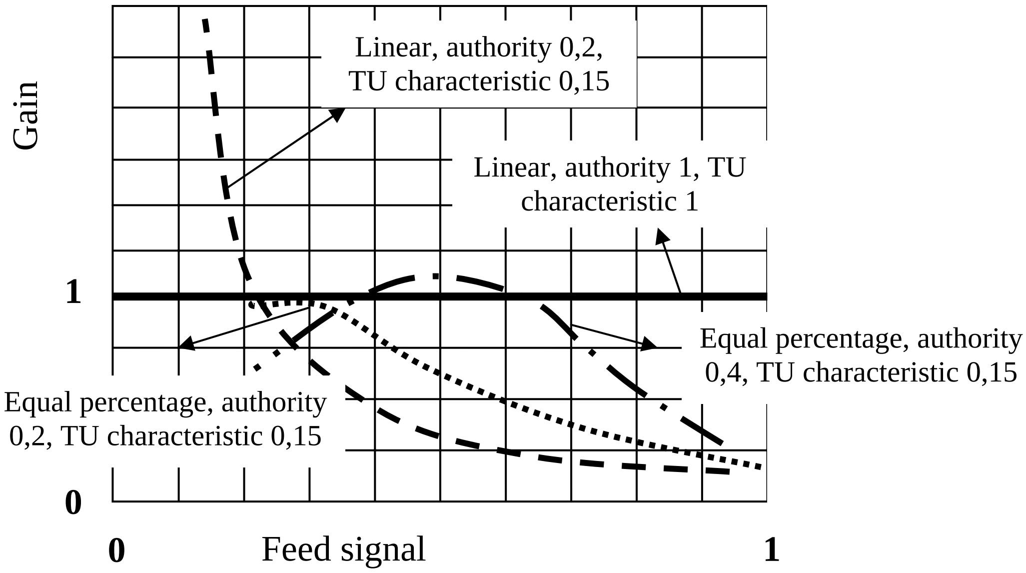

Figure 3: Gain for different valve types, TU characteristic and control authorities [2] .

Another issue is the ability of the control valve to control small flows. This is an issue especially with equal percentage valves where the ratio between the lowest kv that still complies with the equal percentage characteristic and the highest kv value (Kvs) is defined as the control ratio. This is typically between 25 to 100, meaning that stability can be obtained between 4% and 1% of the nominal kvs values respectively. On figure 3 we can see this phenomenon as the gain curve for equal percentage valve ends on 10% of the signal where valve characteristics change so gain increase in step. Detail definition of control range is defined by standard IEC 534-2-4 [3]. For example at a pressure change ratio (authority) of 0,1 and a control ratio of 1:50 we can only control emissions higher than 30%! For linear valves this is less of a problem because at lower valve positions their characteristic will stay linear or very close to linear, more or less indefinitely.

<u>The aforementioned methods assume that the valve under consideration is the only one in the system, meaning that the only change of the available pressure is caused by the valve itself.</u> When we consider control valves in a typical secondary system for FCU’s, chilled beams or AHU’s that is not the case. Since there will be many TU’s in a system, there will also be

many valves controlling the flows through the TU's. Changing the flow through one particular valve will have consequences for the available differential pressure of all other valves. This means that in a realistic situation we would need to consider all the possible gains (as depicted on figure 4) between minimal authority (a=design dp / pump head) to authority 1. The fact that any change of flow through one TU will change the flow through all the other TU's means there are constant interferences with the temperature control loop of the TU's. In effect this causes the valves to constantly adjust their positions to the ever changing available pressure, that results in changing flow – emission and at last temperature (figure 4). PIBCV's don't have these problems. Changes of flows in TU's will not result in a change of flow for any other TU. This means that by using PIBCV's the only interference to the temperature loop is a change in the demand (load). In most of the systems the load is changing slowly compared to the fast changes in available pressure. Systems with PIBCV's are therefore much easier to control than systems with traditional control valves.

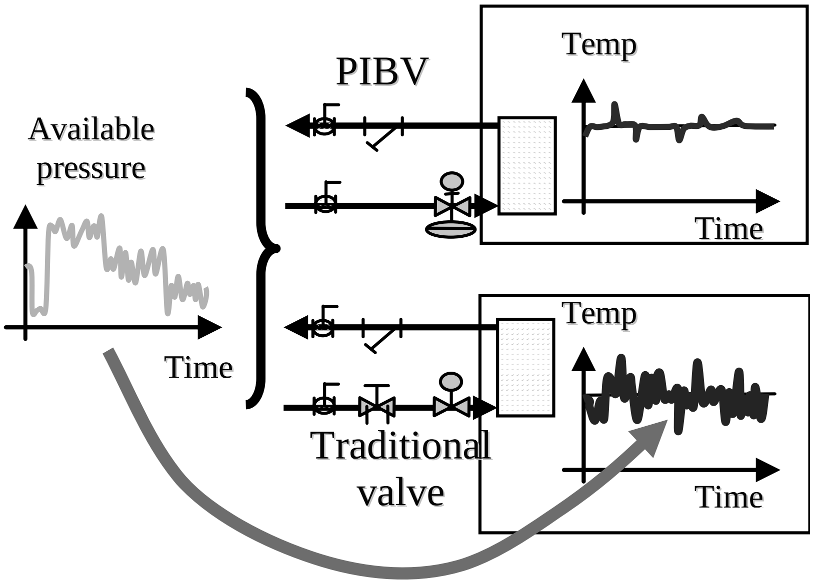

Figure 4: Changes of available pressure causes changes of flow – emission – temperature in case of traditional valve.

RESULTS

In order to research the ability to control small flows of different types of control valve a special test was performed where the control valve had to control the flow while the available pressure was changed. This is similar to conditions where the available pressure changes while the load remains constant. There were 3 valves exposed to the test: a linear valve, an equal percentage one (both kvs 1,6 m3/h) and a PIBCV on flow setting 450 l/h (the maximum for this size).

A comparative test was performed on the same test stand with the same actuator and with the same PI controller with the same settings. The PI-controller was set to realize 100 l/h and the pump was gradually increased and then decreased to zero available pressure. The results are depicted on figure 5. The linear valve is stable only at low pressures when it has a high authority. The equal percentage valve can control the flow up to 150 kPa of available differential pressure over the valve. Above 150 kPa the valve has to go below the minimum Kv-value as defined by the control ratio and this causes unstable control. The actuator on the pressure independent valve only needs to correct for the P-band deviation of the differential pressure controller, a mechanical controller inside the PIBCV.

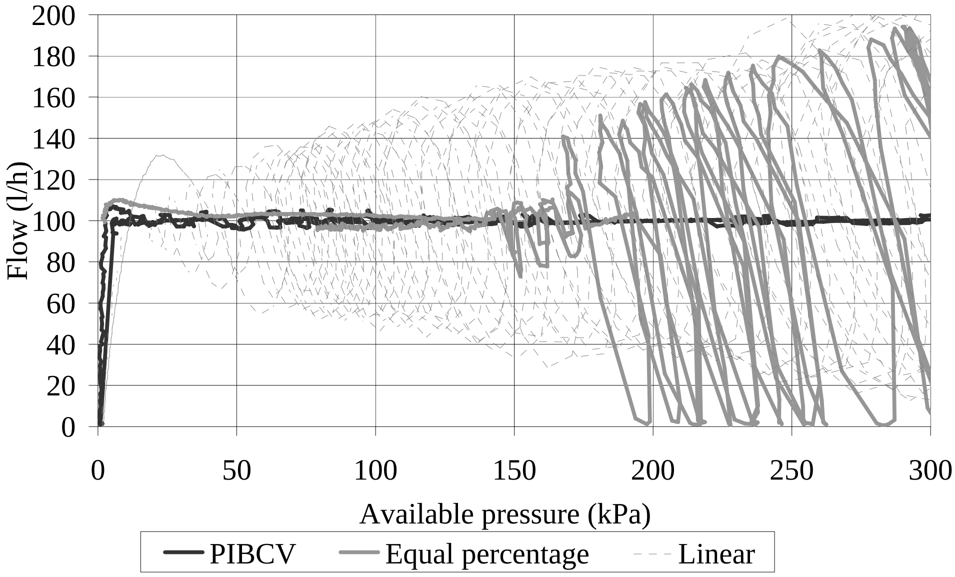

Figure 5: Performance comparison test.

In order to compare equal percentage CV’s and PIBVC’s measuring and monitoring of a real life installation was done. The installation was situated in an office-building in Amsterdam and for the purpose of the test two small offices were measured. The offices were next to each other, on the same floor and with the same orientation so the demand was comparable. The temperatures on the FCU inlet & outlet were measured. In one office an equal percentage valve was originally installed. In the other office we have exchanged the valves for PIBCV’s. The situation was monitored for 6 months and measurements stored on a temperature logger. Figure 6 depicts the temperature behavior in the morning hours when the load in both rooms was comparable (outlet temperature from FCU is similar). In the room with the equal percentage valve the outlet temperature from the FCU was changing considerably as opposed to the room with the PIBVC. At this time the valves were operating under low load conditions causing the equal percentage valve to operate below its range-ability as defined by its control ratio (1:100) and sizing (valve was sized for 10 kPa and max flow of 450l/h – resulting in kvs1,6). There are reasons to claim the sizing was not adequate. The sizing calculations assumed that balancing will provide the same available differential pressure for all CV’s in the system because the maximum flow was the same on all units. Above mentioned presumption is realistic if the balancing was perfect. However, balancing is done at the construction site with time consuming iterative and complicated methods, based on measurements of differential pressures across balancing valves or fixed orifices. Balancing valves ore often mounted on unsuitable places like behind elbows or other disturbances. Those are definitely not lab-conditions and significant deviations of the actual pressure and consequently flow can be expected. Manual balancing valves are used to achieve flows as close as possible to the design quantities, where pre-assumptions on CV sizing are long forgotten or probably unknown. It is noteworthy that manual balancing valves only provide proper flow limitations at design conditions, which means all the valves fully open. In any other hydronic condition (partial loads) they are not functional and only adding to the pump head or reducing the CV’s authority.

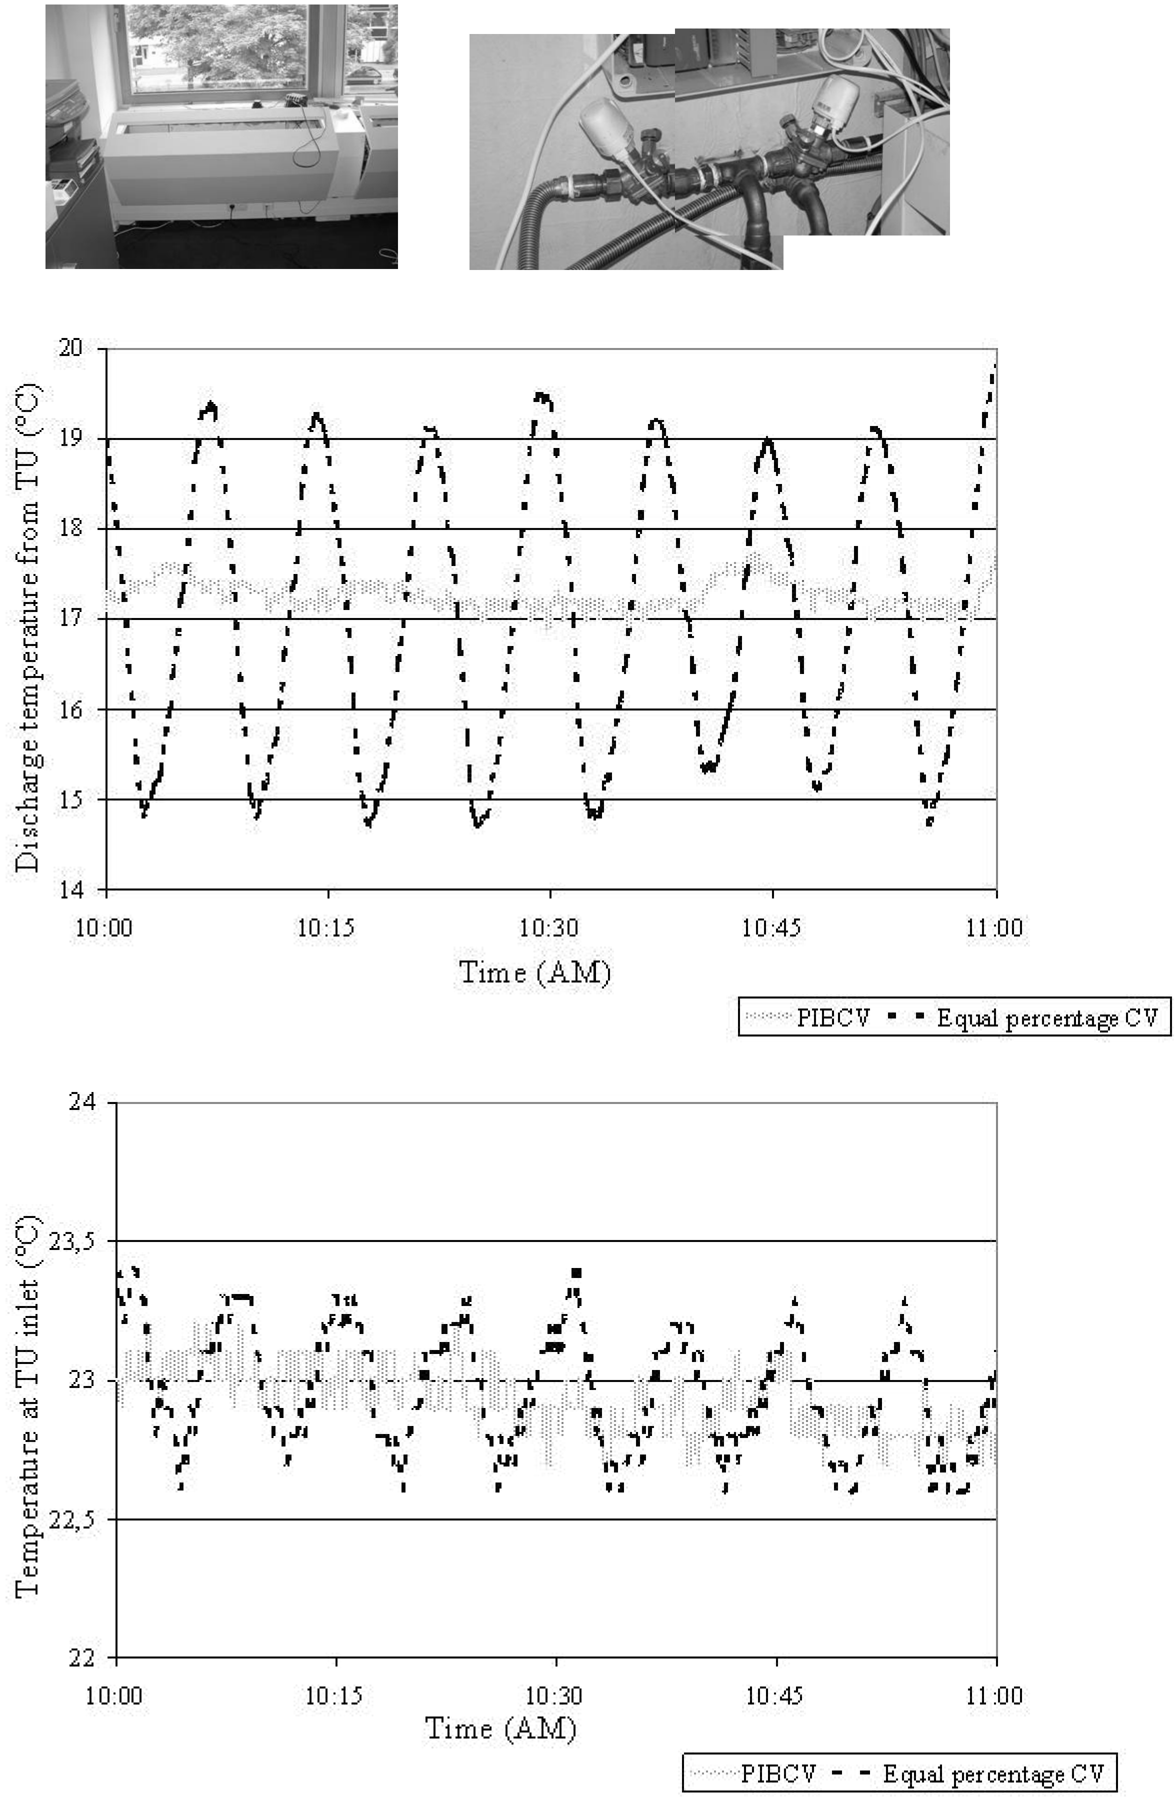

Figure 6: Real site comparison test – installation pictures and temperature on inlet and outletof TU.

DISCUSSION

It's impossible to compensate for a poor performing hydronic system with control software or by other electronic means. In order to provide well-being indoors and efficient transfer of energy between source and terminal units, control valves need to be sized with care and the balancing has to be performed correctly. An alternative to traditional control valves would be a pressure independent balancing and control valve that is prone to fewer disturbances and has a practically unlimited range-ability. Because PIBCV's also perform a flow limiting function there will be no overflows. This increases the efficiency of pumping and also benefits the chiller or boiler because the proper differential temperatures are maintained. Additionally, the PIBCV can be adapted to the characteristic of any heat exchanger because is has a control authority of 1 so the adaptation to the heat exchanger can be made by means of actuator/ controller signal transformation.

Pressure Surges in Drinking-water Installations

Franz-Peter Schmickler[1], Tobias Ausländer[1] and Jan van Wersch[1]

[1]University of Applied Sciences Münster, Münster (Germany)

Corresponding email: schmick@fh-muenster.de

SUMMARY

The new guidelines, for example the new EN 806, and new perceptions of water hygiene force more better dimensioning of pipes for potable water. The results are often smaller diameters of the potable water tubes and smaller hot water boilers.

On the other hand pressure surges are more often observed. This report will try to declare these effects by different methods: First a test stand for the measurement of pressure surges and evaluation of drinking water armatures is presented. The investigation of the armature technology especially of fast closing armatures shall help to improve new realizations and optimizations for the building services and engineering supply.

At second the theory is introduced: A new technical guideline about this topic, the VDI 6006 „pressure surges in drinking-water installations, causes and preventions”[2], treats for the first time in Germany. It addresses itself to planners, but also consultants and manufacturers of sanitary-technical products and plants.

At last the connections are discussed. While new installation methods demand smaller pipe diameters, these demand increases the pressure surges. Thus a compromise between drinking water hygiene and technically necessary piping dimensions must be found. If the compromise should not be found, the search for technical solutions for the reduction of these effects has to be strengthened. So the closing time must be affected in such a way that a very short term closing is no longer possible. Perhaps also pressure impact absorbers are a solution, which must be examined before however also under hygienic aspects.

INTRODUCTION

The pressure surge is a phenomenon that can be observed more frequently. Its effects are not only the well-known noise problems, what disturbs particularly in house building, but also technical problems in the attachment of the pipes. These effects can be force incorrect and inadvertent responding of technical safety devices. In the last years theses phenomenons are observed more often as in further times.

Obviously there is a (new?) problem in drinking water installations of today. The question is why this problem is increased.

Sanitary engineers of today have only one theme to discuss: The water hygiene. New guidelines, for example the new EN 806, and new perceptions of water hygiene force more better dimensioning of pipes for potable water. This means in most cases smaller diameters of the potable water tubes and smaller hot water boilers.

Hygiene problems are no theme of today anymore in this well engineered installation systems. But now the pressure surge occurs as a new problem.

The pressure surge is a phenomenon which is not trivial. There are a lot of influences on it. One of the important facts is the diameter and length of the tube to the armatures. The armatures themselves are responsible too.

METHODS

To examine the problems of pressure surge – which are discussed briefly in the introduction - two proceedings are possible. On the one hand theoretical considerations should be cared about, on the other hand around practical examinations have to be made. Both methods are presented here briefly.

THEORATICAL BACKGROUNDS

The pressure surge in water installations depends on the medium itself, the velocity of the pressure surge and the variation of the drinking water velocity.

The highest value of the pressure surge (the so called Joukowski-surge) Δp_{max} is calculated:

$$\Delta p_{max} = \rho \cdot a \cdot \Delta v \qquad \text{in Pa} \qquad (1)$$

where is:

ρ density of water in kg/m^3 (about 1.000 kg/m^3)

a velocity of the pressure wave in m/s

Δv variation of the velocity in the drinking water pipe in m/s (at Δp_{max}: variation of velocity to 0).

The velocity of the pressure wave a depends on the elasticity of the medium. However in installation systems the pressure wave a is influenced by the elasticity of the medium and by the elasticity of the pipe material.

$$a = \frac{1}{\sqrt{\rho\left(\frac{d_i}{s\,E_R} + \frac{1}{E_W}\right)}} \qquad \text{in m/s} \qquad (2)$$

where is:

d_i inner diameter of the pipe in m

s thickness of the pipe in m

E_R elasticity modul of the pipe material in N/m^2

E_W elasticity modul of the drinking water in N/m^2

For example in copper pipes the following pressures are theoretically possible, when the final armature is closed suddenly. The values depend on the flowing volumes and the diameter of the pipes (fig.1)

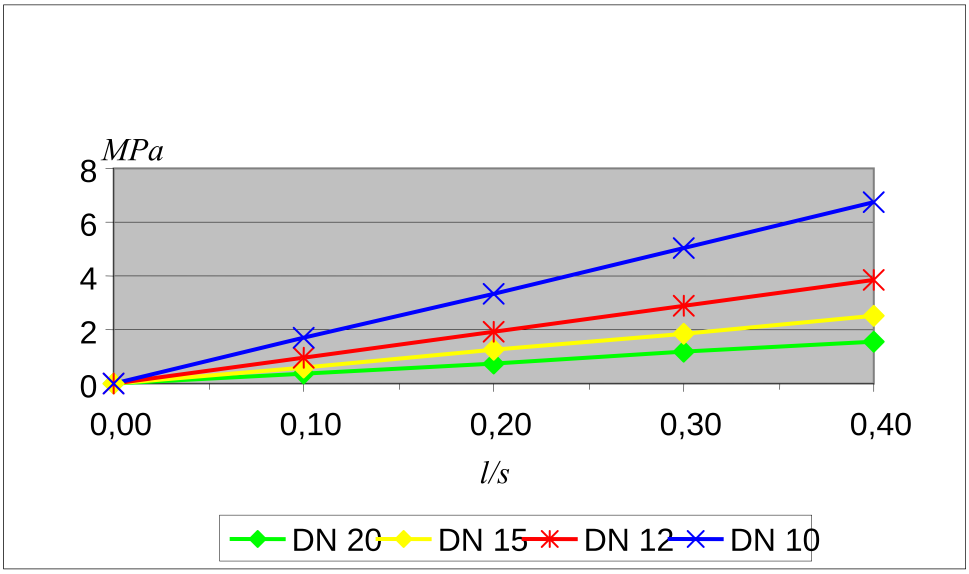

fig.1: maximum pressure surge in relation to the inner pipe diameter for copper pipes (remark: 1 MPa = 10 bar). [2]

There are a lot of other effects, which can not be declared mathematically. Some examples (Table 1):

table 1.: relevant parameters [2]

parameters	influence on pressure surge
volume velocity	++
water temperature	0
shut down time of the valve	++
length of the pipe	+
bent pipe, angle pipe	0
T-distribution	+
diameter	+
drain back valves	+
fixation at the building	0
flexible connection	+
material of pipe	++
++: heavy influence +: influence 0: nearly no influence	

MEASURING OF PRESSURE SURGE AND EXPERIMENTS

To compare reality with theoretical values the idea of experiments were born. in former times industries have made a lot of tests with their valves and armatures. You have to use oszillographes to measure peaks of pressure which was expensive und complicate. The results of these experiments were used to improve their products. Nobody was interested in the installations of the buildings.

In a first step at our university we started to build a multifunctional test plant. In a diploma work [3] this test plant was concepted, built and first experiments were done. The concept is that different armatures and valve and different pipes (concerning the length and material and diameter) can be tested and compared with each other.

Figure 2 shows the scheme and figure 3 a photo of the test plant. In the first step copper pipes are built in. Pipe 1 has a length of 5 metres; pipe 2 has a length of 50 metres. The installed copper pipes have a diameter of DN 15 or d_i = 13 mm.

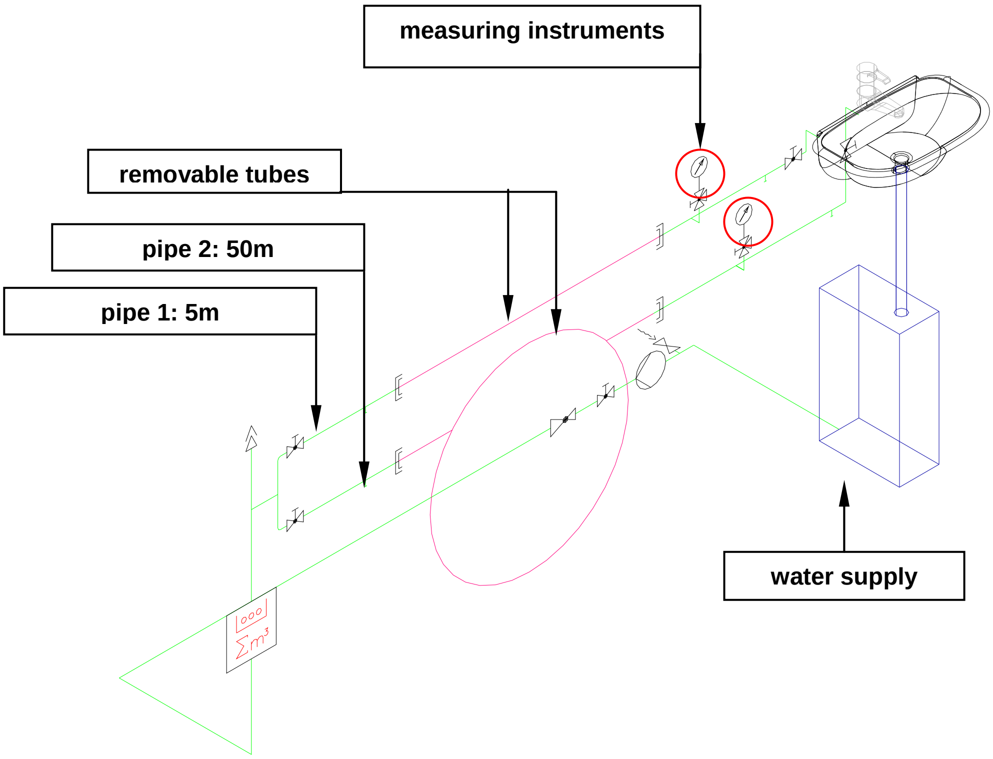

Fig.2: test plant to measure pressure surge [3]

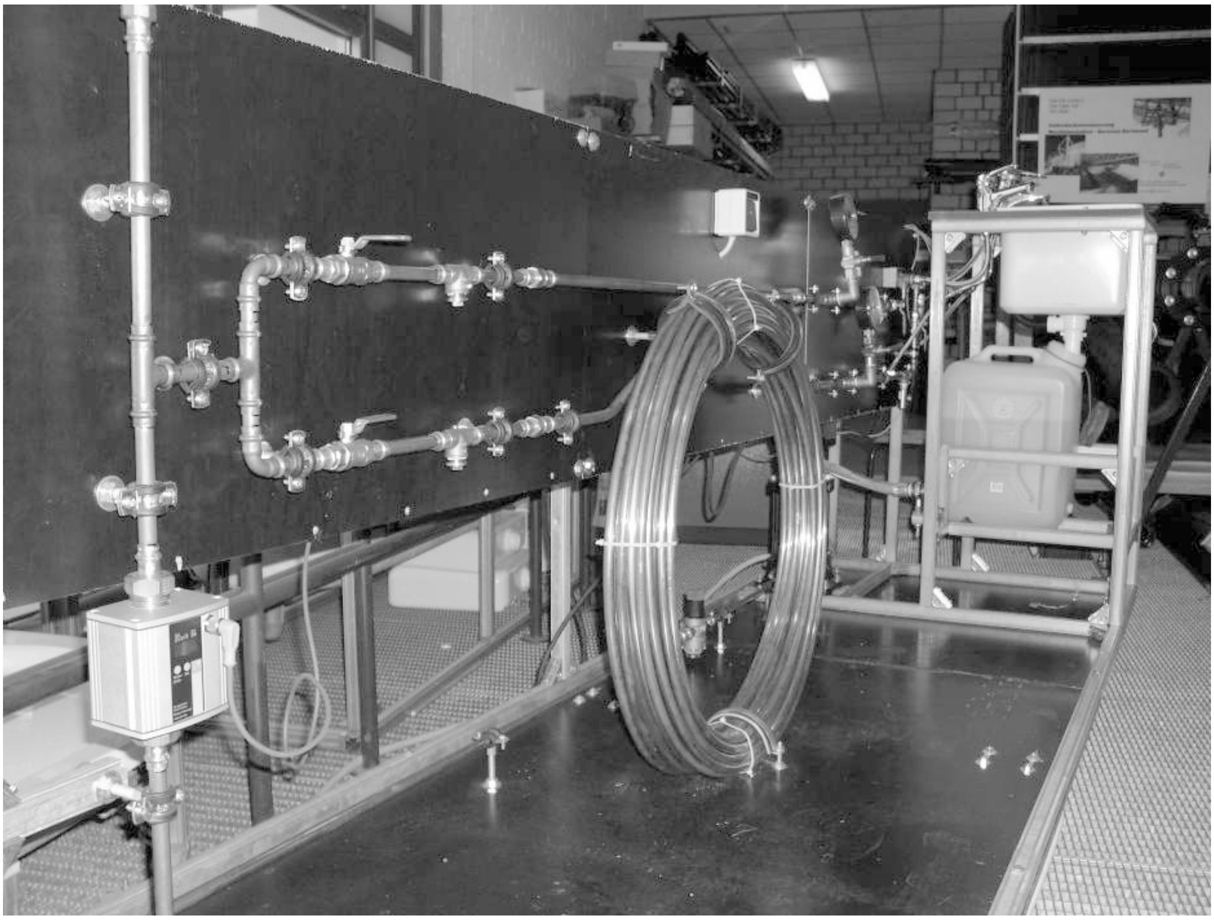

fig. 3: photo of the test plant to measure pressure surge [3]

There are a lot of details which had to be regarded: for example the measurement equipment or the measurement of the volume velocity. All these details are described in [3].

One problem, which is not solved until now, is the replayability of the shut down time. A second work at our university will deal with this theme and I hope that we will have results in about one year. Here in this report first results and the possibilities of this test plant shall be introduced.

RESULTS

First of all figure 4 shows the normal measurements while closing a normal armature (a so called one lever armature). In all following examples the armatures are closed fast and in an usual way. There were not unusual closings by beating on the armature or so on.

Hammering on the armature will cause very high pressures (up to 50 bar). The consequence will be a destroyed test plant. Our first results show, that pressure peaks about 20 bar are normal. Our technical rules, for example the EN 806, describe however that all components of drinking water installation system have to be built for a maximum of 10 bar.

A real test measurement is listed in figure 5. You see that we have a very high resolution in measuring pressure and that it is no problem to measure very short times.

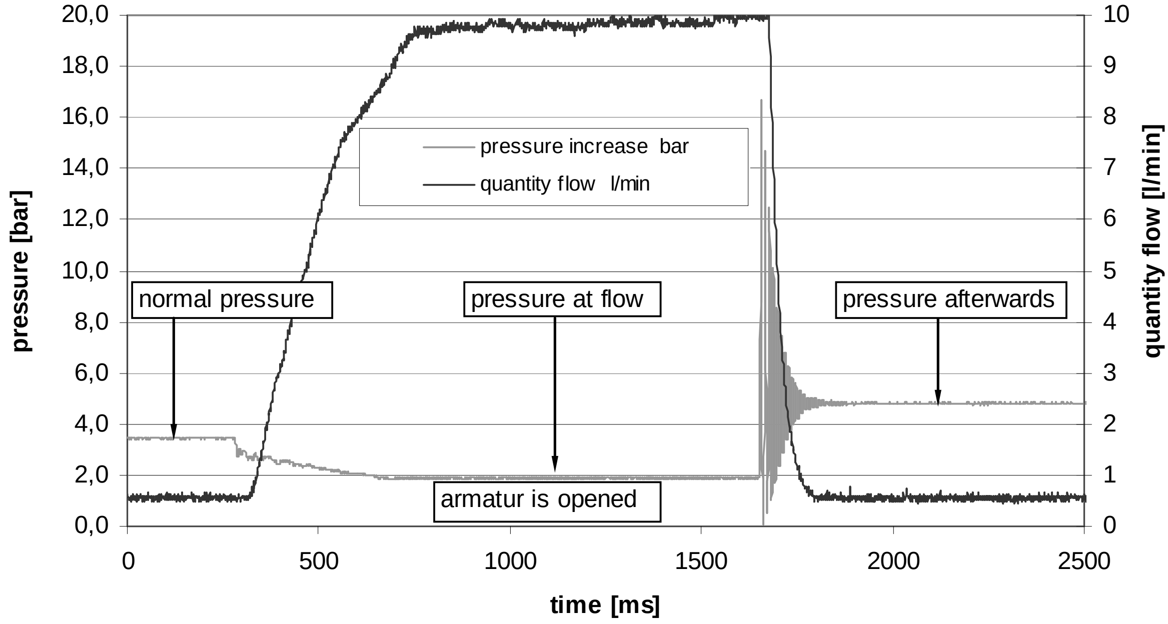

fig. 4: principle measurement result [3]

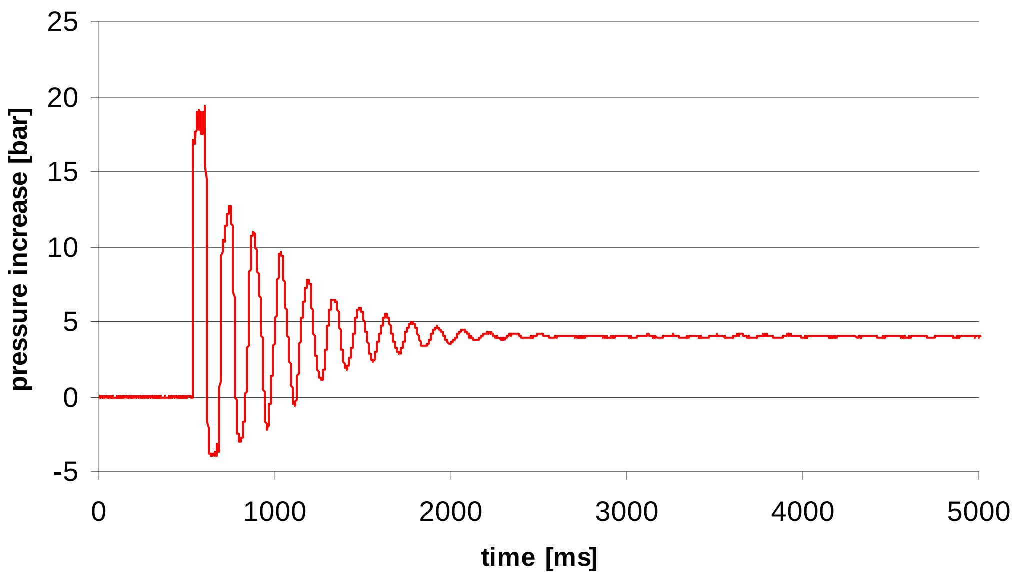

fig. 5: test measurement of a pressure surge [3]

There are some further results which could be observed:

- there are no big differences between two different armatures (different manufacturers)
- a very big difference makes the length of the pipes
- our installation elements had no problems with the pressure surges. The question is if there will rise up problems after longer times.

- longer pipes produce higher pressure surges
- higher normal pressure cause higher flow rates at the armatures. Higher peaks of pressure surge are the consequence.
- the pressure wave has times where the minus peak is near vacuum.

DISCUSSION

Considering the measurements it is not further astonishing that pressure surges cause some noise. Our materials and sanitary products are so good, that defects are seldom. Often pipes´ diameters are reduced to an absolute minimum to avoid hygienic problems. These small pipes with high water velocities force pressure surges.

On the other hand there is much to do in future. Is there the possibility to deaden the surges by constructing special armatures or valves? Is this theme only problem of loud noise, which can be insulated acoustically? Are there new problems by having vacuum at short times?

The thematic is very interesting and the VDI guideline 6006 [2] is a very good help for all civil engineers and experts because – at least in Germany – the occurring pressure surges are becoming more and more. Probably the phenomena will engage us for the next years.

SUMMARY

The effects of different flow regimes on water quality and formation of biofilms were studied in a pilot scale drinking water distribution system consisting of two parallel 100 m loops of copper and composite plastic (polyethylene, PE) pipes. The increase in water flow velocity from 0.03 m/s to 0.3 m/s increased significantly the formation of biofilms in both materials. Small changes in water flow disturbed the balance of sediments and biofilms in the pipes, which was seen as an increase in turbidity and the number of bacteria in water. Also, pressure shocks in water flow detached biofilms and sediments increasing the concentrations of metals, bacteria and particles in water. Water stagnation in pipelines increased the concentration of copper in outlet water of copper pipes and microbial numbers in outlet waters of both copper and plastic pipes.

INTRODUCTION

Drinking water distribution system affects microbiological and chemical quality of drinking water. For example, the concentrations of metals and bacteria in water may increase in distribution system. Typically most critical part of the system is household plumbing [1]. Most of the microbial biomass in drinking water distribution system is in biofilms growing on the inner surfaces of water pipes [2, 3]. Several factors, including disinfection, water microbiological quality, temperature, microbial nutrients and water hydraulic regime, affect the growth of biofilms.

With aging of pipes, soft deposits accumulate to the pipelines. These deposits consist of organic and inorganic matter and several metals [3, 4]. Deposits in pipelines originate mainly from water, corrosion products of pipelines, and particles and chemicals are derived from water treatment processes [5]. Changes in water flow can detach sediments and biofilms to drinking water and thus deteriorate the quality of water [4, 6]. This may be seen as an increase in water turbidity, concentrations of metals and bacteria [4, 6].

Typically household plumbing is constructed with copper or plastic pipes. In Kuopio, we have built a pilot scale drinking water distribution system with copper and plastic pipes. With this research environment several research projects have been realized to study the effects of pipeline materials and water flow regime on drinking water quality and formation of biofilms.

METHODS

Pilot distribution system

The pilot scale distribution system consist of two parallel 100 m loops of 10 mm (ID) copper and two parallel 100 m loops of 12 mm (ID) composite (polyethylene-aluminum-polyethylene) plastic tubings (PE). Distribution system was built in a year 2002. Drinking water can be produced in a pilot scale waterworks or taken from the munucipal water distribution system of Kuopio City. In the pilot waterworks lake water is chemically coagulated with ferric sulphate, and further purified using flotation and rapid sand filtration. Finally water hardness, alkalinity and pH were adjusted with lime and carbon dioxide and water was chlorinated with NaOCl (0.5 Cl_2 mg/l) and UV-disinfected (approximately 70 mWs/cm^2). However, when the water reached the pilot distribution system, concentration of active chlorine was decreased below 0.05 mg/l. Purified water was collected into a 4 m^3 stainless steel tank before pumping to the pilot distribution network, which explained the consumption of chlorine.

Effects of flow rate

The effects of water flow velocity on the formation of biofilms and water quality were studied by increasing the flow rate with water circulating pumps gradually from 0.2 l/min to 1.3 l/min corresponding the flow velocities of 0.04 m/s, 0.09 m/s, 0.17 m/s and 0.28 m/s in 10 mm copper pipes and 0.03 m/s, 0.06 m/s, 0.12 m/s and 0.19 m/s in 12 mm PE pipes [7]. With these flow rates the water flow was still laminar (Reynolds numbers were below 3000). Water samples were collected immediately after the increase the water flow rate, and water quality was then followed for three weeks. Biofilm samples were taken after each three week period [7].

Pressure shocks

The effects of pressure shocks on water quality were studied by producing the pressure shocks by compressed air valves placed at the ends of the pipes [8]. The valves halted the water flow for few seconds very rapidly. Before pressure shocks water flow in the pipes was 1 l/min (i.e. flow velocity in copper pipes was 0.21 m/s and in PE pipes 0.15 m/s). Water samples were collected before and after the pressure shocks. First pressure shock was done after 4 weeks of constant water flow (1l/min). Subsequently, pressure shocks were done 2 weeks, 1 week, 4 days, 3 days, 2 days and one day after previous pressure shock. Between the pressure shocks water flow was constant [8].

Water stagnation

The effect of water stagnation on the water quality was studied with experiment where the pilot distribution system was programmed to stagnate water for different times [9]. Stagnation times were 15h 40 min, 4 h, 2h, 1h, 40 min and 40 min. This program was run daily for four months. After each stagnation period, water was pumped for five minutes with the flow rate of 2.6-3.2 l/min (correspond the flow velocities of 0.55-0.68 m/s). Water samples were collected during the flushing and analysed form microbiological and chemical parameters. Water samples were collected nine times during the four month experiment.

Analyses

Concentration of iron was analysed with HACH DR/2010 spectrophotometer (Loveland, Colorado, USA) according to the manufacturers´ instructions. Total copper was analysed using the bicinchoninate method with HACH DR/2010 spectrophotometer. Turbidity was analysed with WTW Turb 555IR turbidimeter. Heterotrophic plate counts (HPC) were analysed with a spread plating method on R2A-agar (Difco). R2A-agar plates were incubated for 7 days at 22 °C before colony counting (cfu). Total numbers of bacteria were analysed with an acridine orange direct counting method. Stained bacteria were enumerated at 1000x magnification under blue excitation using an Olympus BX 51 epifluorescence microscope (Olympus Co. Ltd., Japan) equipped with an ocular grid. The number of particles was analysed with online particle counter (Pamas Water Viewer, WV-IMU, Pamas BmbH, Germany). The particle counter separated the number of particles per milliliter into 8 size classes ranging 1-1.5, 1.5-2, 2-5, 5-8, 8-15, 15-25, 25-50 µm and particles over 50 µm.

The growth of biofilms is analysed with biofilm collectors, which consists of 15 cm (copper) and 20 cm (PE) pieces of pipes. Biofilm collectors were installed in different parts of the pilot system. During sampling, the biofilm collector pipes were closed by ball valves before disconnecting and removed with the water inside the tube. Biofilms inside the collector pipes were removed by shaking with sterile 2 mm glass beads. Detached biofilms were analysed for heterotrophic plate counts, content of ATP and total number of bacteria, and results were normalized to the amount of surface area (cm^2). Total number of bacteria and heterotrophic plate counts were analysed as described above. The content of ATP was measured with a Bio Orbit 1251 luminometer (Turku, Finland) using ATP Biomass Kit HS (BioThema AB, Sweden).

RESULTS

We have found with the pilot distribution system that copper pipes decreased the number of bacteria in water for first six months, but thereafter copper had minor negative effect on the occurrence of bacteria [10]. These experiments also showed that microbial community structure was different in biofilms growing in copper and plastic pipes [10]. New plastic pipes had ability to release phosphorus to water for the first weeks after they were taken in use [10].

Flow rate

Increase in the flow rate of water increased the formation of biofilms in both copper and plastic pipes [7]. In copper and PE pipes the increase in flow velocity from 0.2 l/min to 0.8 l/min increased the total number of bacteria in biofilms on average by 13- and 15- fold, respectively [7]. Content of ATP in biofilms of copper pipes was on average 4 times higher with flow rate of 1.3 l/min than with the flow rate of 0.2 l/min. Corresponding difference with the PE pipes was 7-fold. Increase in the flow rate increased temporary turbidity and number of bacteria in water [7] by detaching biofilms and sediments from the inner walls of pipes. However, although the number of bacteria in biofilms increased with increasing flow rate, the microbial numbers in water did not increase [7].

Pressure shocks

Pressure shocks detached biofilms and sediments. This was seen as elevated concentrations of iron, copper, particles, bacteria and turbidity in water [8]. Immediately after pressure shocks the concentration of iron was on average 2.5 times higher than before pressure shocks in both pipeline materials (Fig. 1). In copper pipes the concentration of copper in water was on average two times higher immediately after the pressure shock than before pressure shock [8]. Time between the pressure shocks did not affect the amount of metals released to water. The numbers of HPC were in copper pipes 19 times higher and in PE pipes 15 times higher immediately after pressure shocks than before pressure shocks (Fig. 2).

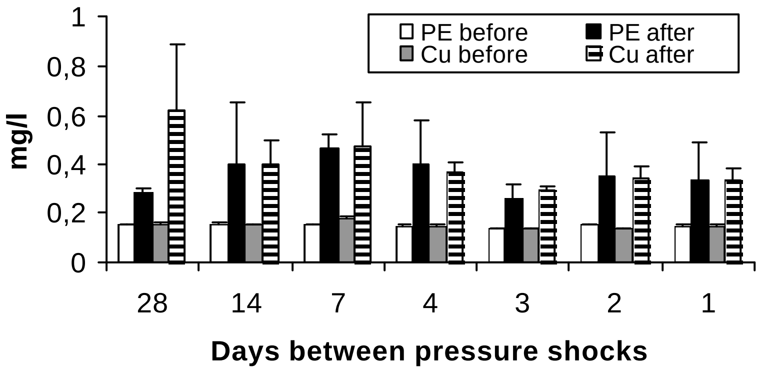

Figure 1. The effects of pressure shocks on the concentration of iron in drinking water in copper (Cu) and plastic (PE) pipes.

.

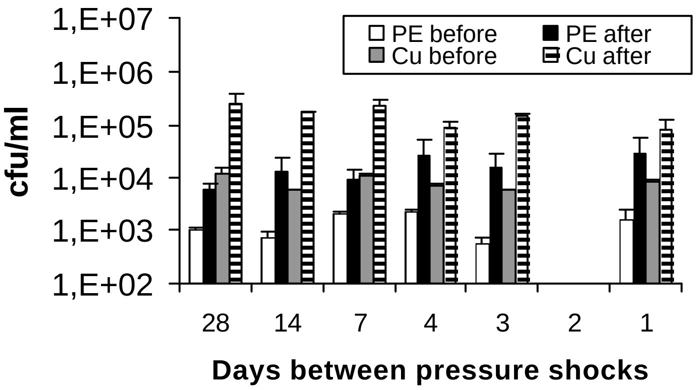

Figure 2. The effects of pressure shocks on the numbers of heterotrophic bacteria in drinking water in copper (Cu) and plastic (PE) pipes.

Water stagnation

Water stagnation in pilot distribution system increased the concentrations of copper and number of bacteria in water [9]. There was only minor increase in the copper concentrations after the stagnation time of four hours (Fig. 3). The number of bacteria (HPC) in water increased linearly up to the longest stagnation time of 15h 40 min (Fig. 4). A regression model showed that the number of bacteria in copper pipes increased on average 4400 cfu/ml/h and in plastic pipes on average 1400 cfu/ml/h [9].

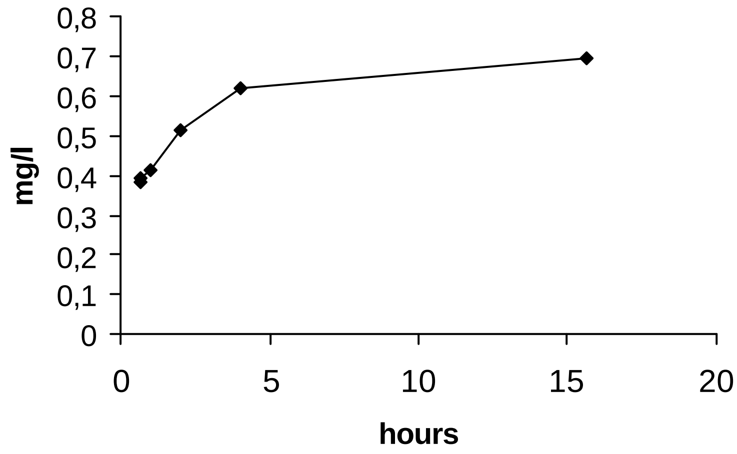

Figure 3. Concentration of copper in water after various stagnation times in copper pipes.

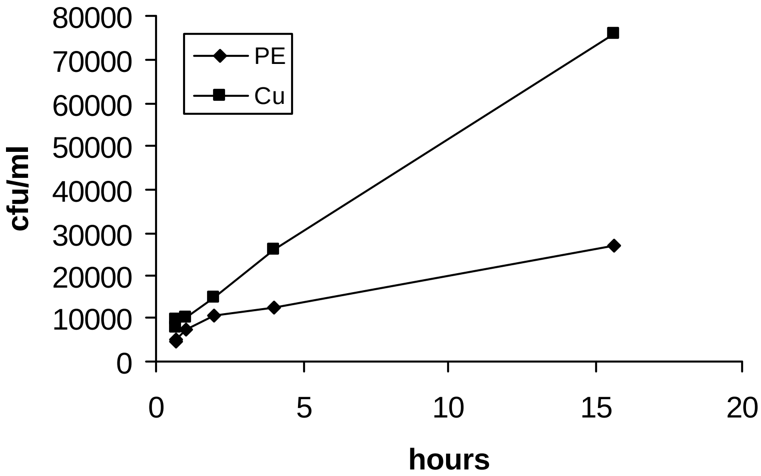

Figure 4. Numbers of heterotrophic bacteria in water after various stagnation times in copper (Cu) and plastic (PE) pipes.

DISCUSSION

The pilot scale drinking water distribution system has shown to be very valuable in studies for the interactions of piping materials, water flow characteristics, biofilms and occurrence of microbes in drinking water. The experiments with this system soon showed that the formation rate of biofilms and their microbial community structure differ between plastic and copper pipes [10].

Our results show that the increase in water flow rate increases number of bacteria in biofilms as found also in some previous studies [11, 12]. The increased biomass and activity in biofilms is also reflected in changes in the consumption of microbial nutrients in water [7]. Increase in the consumption of the nutrients in conjunction with the increased microbial numbers in biofilms are evidence of the enhanced mass transfer of the nutrients in biofilms at the higher flow rates, i.e. the growth of biofilms is mass-transfer limited, as has been proposed previously [12, 13]. Flow rates in our studies have been fairly low. It has been proposed that to remove biofilms and sediments from the pipeline, flow velocities should be higher, like 0.7 - 4 m/s [14, 15].

The balance of sediments and biofilms in pipelines is very sensitive for any disturbances in water flow. When water flow slightly increases, the balance is disturbed and a resuspension of sediments and biofilms occur. This can be seen as elevated concentrations of bacteria and turbidity in water [7]. When stronger pressure shocks are produced with compressed air valves, the number of bacteria increase over ten fold and the concentrations of metal also highly increase. So, biofilms and deposits in pipelines contain not only bacteria, but also copper, iron and microbial nutrients which can be released to water [4, 16].

Iron can be originated from the accumulated coagulation chemicals in the distribution system and copper from Cu-particles from the pipe surface, or be a result of microbially influenced cuprosolvency [17]. The accumulation time of sediments (i.e. time between pressure shocks) does not significantly affect the detached mass of metals or bacteria [8]. This indicates that the system recovers rapidly (less than one day) after the pressure shocks.

The concentration of copper in water is affected by stagnation of water in distribution system [9, 18, 19]. In our case even though stagnation increased the copper concentration in water, it still was clearly below the parametric value of 2 mg/l set by European Union drinking water directive [20], and did not increase significantly after four hours stagnation.

Stagnation of water increases the number of bacteria in water in both copper and plastic pipes [9]. Stagnation times of 16 hours can result to 6-10 times higher numbers of bacteria (HPC) in water than a shorter 40 minutes stagnation. In contrast to the copper concentration, the increase in the concentration of culturable bacteria has been linear [9]. The laboratory experiments have shown that there is only minor microbial growth in water during 16 hours incubation [9]. These results support the earlier conclusions that biofilms are the key sites for microbial growth in drinking water distribution systems and represent the critical source of bacterial biomass to water [2, 21].

To sum up, the studies with the pilot system show that the number of bacteria and metals in drinking water are strongly affected by disturbances in flow regime and stagnation of water in the pipelines. Thus effect of stagnation should be considered carefully when planning a sampling strategy for drinking water microbiological quality control in drinking water distribution systems or designing the piping systems.

SUMMARY

A research project on the control and design of thermally activated building systems (TABS) has been started in May 2004. This paper presents one selected result after three years of work: Decision guidance and recommendations for HVAC design engineers regarding how to select an energy-efficient hydraulic piping topology for TABS.
The hydraulic piping system in TABS basically can be separated in a heating and cooling generation part, a distribution part and the consumer part which consists of several individually supplied zones. The heating and cooling demand of the zones is different from zone to zone and time-dependent. In this paper, two hydraulic piping topologies commonly used for TABS are analyzed in terms of energy consumption, resulting thermal comfort and understandability:
1) Injection circuits (in all zones) with one common return pipe for all zones
2) Injection circuits (in all zones) with separate return pipes for every zone
The paper presents a comparison between both topologies, using a realistic example, for which the piping topology has a considerable impact on the energy consumption. The example also shows the difference between the two piping topologies on the understandability and that it may have an impact on the comfort.
For the chosen realistic example, hydraulic piping topology 2) delivered better results.

KEYWORDS: HVAC design, hydraulic piping topology, thermally activated building systems (TABS), concrete core conditioning

INTRODUCTION

In this paper, two hydraulic piping topologies commonly used for TABS are analyzed in terms of energy consumption, resulting thermal comfort and understandability:
1) Injection circuits (in all zones) with one common return pipe for all zones (see Figure 1)
2) Injection circuits (in all zones) with separate return pipes for every zone (see Figure 9)
A common return pipe is generally selected for cost considerations.
Today, multiple flow pipes with various supply water temperature levels are often led to the TABS registers. The appropriate temperature levels can be selected (room or register assigned to a zone) with the help of a manual valve per zone during commissioning or changes in room use. In [1],[2] the corresponding implemented plants are described. The paper presents a comparison between the two topologies, using a realistic example, for which the choice of the piping topology has a considerable impact on the energy consumption. The example also shows the difference between the two piping topologies on the understandability and that it may have an impact on the comfort.

The dynamic whole-year simulation for this example will show that the topology with common zone return pipes (topology 1) has a considerable larger energy consumption than the other topology. The simulation will also indicate that the increased energy consumption comes from the fact that the circulated water must be cooled 360 days a year. The result is surprising at first glance and raises the following questions: Why? What is the behavior for a hydraulic topology with separate zone return (topology 2)?
We answer these questions and give the reasons in this paper by analyzing typical stationary load situations and whole-year simulations. We illustrate the different behavior of TABS with common and separate zone return as a matter of principle. Finally, we compare the energy demand of both investigated topologies.
The effect of the hydraulic piping topology on the energy demand and comfort with TABS was examined in the frame of a research project on which was reported for the first time in [3], [4].

1ST HYDRAULIC PIPING TOPOLOGY: COMMON ZONE RETURN

Figure 1 illustrates a typical hydraulic topology from a TABS, consisting of two zones with injection circuits with primary valves and a common zone return flow.

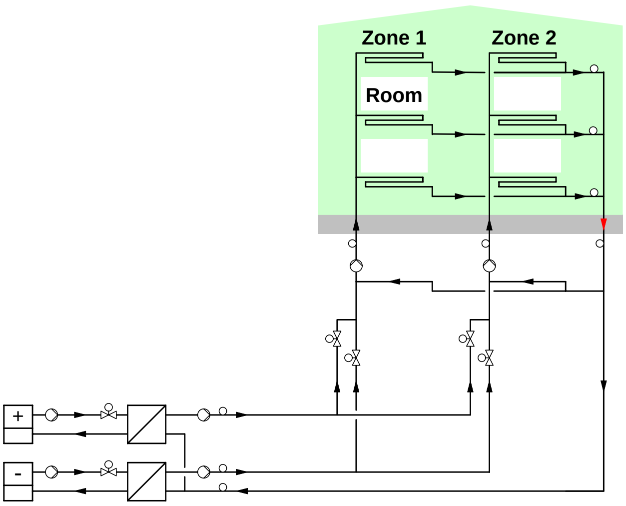

Figure 1: TABS hydraulic piping topology with common return pipe

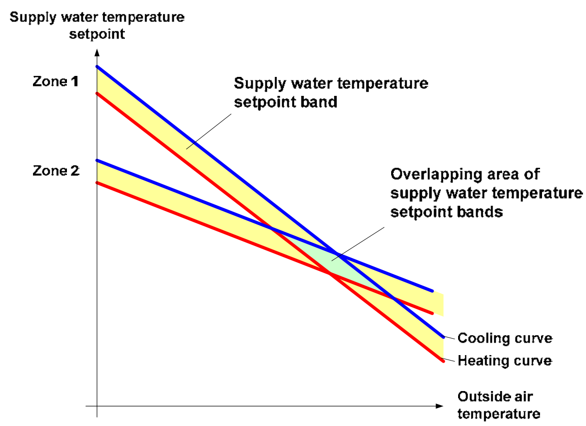

Figure 2: Supply water temperature setpoint bands for a two-zone plant, limited by heating and cooling curves

Supply water temperature setpoints are determined by using heating and cooling curves for each zone as outlined in Figure 2. In general, the curves or the resulting supply water temperature setpoint bands differ by their width and their slopes. Depending on the shape of these supply water temperature setpoint bands, there exists an outside air temperature range where the two supply water temperature setpoint bands overlap.
In [4], [5], [6], [7], an integrated design process for TABS and its control is given based on a so-called “unknown-but-bounded” approach. This approach allows – among other things – to determine adequate supply water setpoint bands.

Analysis of a stationary load situation

The following explains the behavior based on a typical stationary load situation in winter. Figure 3 and Figure 4 illustrate the supply and return water temperatures typically found during the winter: The supply water temperature for zone 1 must be at least 26°C and the temperature for zone 2 may be at most 23°C. The water cools by 0.5K in both zones, in other words heat is provided to the rooms.

At an equal volumetric water flow rate through zones 1 and 2, the common return water temperature corresponds to the mean of the zone return water temperatures, i.e. 24°C. The supply water temperature must be heated to 26°C for zone 1 and cooled to 23°C for zone 2 to achieve the desired supply water temperatures.

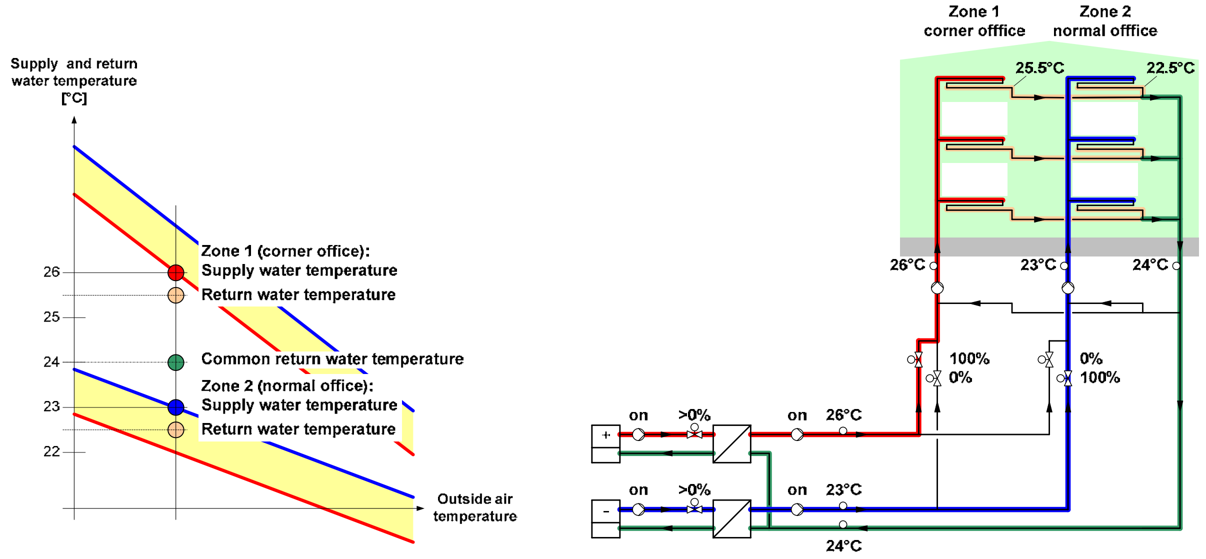

Figure 3 and 4: Temperature ratios and valve settings for common zone return during winter

The common return water temperature is higher than the supply water temperature setpoint for zone 2. The setpoint for zone 2 therefore cannot be achieved by admixing common return water to the supply.

- Although both zones have heat demands, in addition to heating also cooling is required to achieve the desired setpoints.
- If cold generation is blocked for this typical winter situation, the supply water temperature for zone 2 would be too warm and as a result, the room temperatures would exceed the room temperature cooling setpoint, i.e. thermal comfort cannot be achieved.

Analysis of a whole-year simulation

Two equal-sized offices, a corner and a normal office are assumed (see Table 1 and Table 2).

Table 1. data of the simulated zones (cf. [6])

		corner office	normal office
Space length, width, height		6 m x 6 m x 3 m	6 m x 6 m x 3 m
Façade	Orientation	West / South	West
	Area	36.0 m^2	18.0 m^2
	Overall U-Value	0.65 W/m^2K	0.65 W/m^2K
	Glazing fraction façade	42 %	42 %
Additional internal Wall (light)		36 m^2	36 m^2
Natural air change		0.2 h^{-1}	0.1 h^{-1}
Ventilation according to indoor air quality requirements (no cooling/heating by ventilation assumed)			

Table 2. data of the simulated TABS configuration, valid for both offices (cf. [6])

TABS covering fraction (floor area)	80 %
Thickness concrete slab	250 mm
Pipe spacing	200 mm
External/internal pipe diameter	20/15 mm
Specific supply water mass flow rate [a)]	15 kg/(h m^2)
Fictitious TABS thermal resistance (R_t) [a)]	0.08 (m^2 K)/W
Thermal resistance of flooring (carpet)	0.125 (m^2 K)/W

[a)] in terms of floor area covered by tabs

The corner office has twice the ratio of outside walls compared to the normal office. Construction, use and weather conditions correspond to a typical TABS building in the Zurich area (Switzerland). The same simulation set-up as described in [6] was used.

Refer to Figure 5 below, we assumed an outdoor temperature dependent comfort range according to SIA 382/1 [8]. During winter, the comfort range is between 21°C and 24.5°C, during summer between 22°C and 26.5°C. Pursuant to [6], [7], the supply water temperature setpoint band is influenced by the room temperature comfort range, among others: the wider the comfort range, the wider the supply water temperature setpoint band. As an example, refer to simulation results during the summer (Figure 7): the wide room comfort range during summer implies a wide supply water temperature setpoint band.

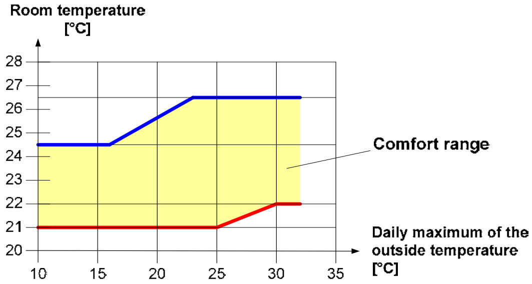

Figure 5: Room temperature comfort range according to Swiss national standard [8]

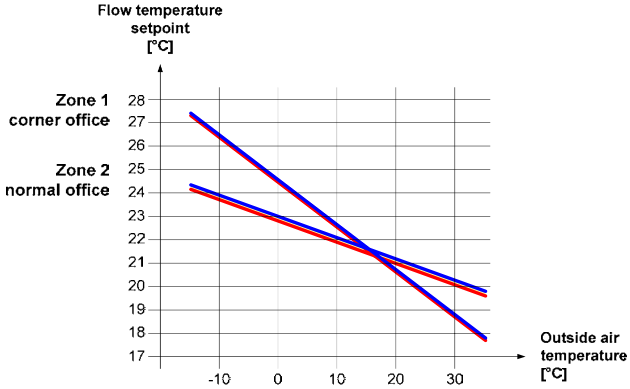

Figure 6: Heating and cooling curves for zone 1 (corner office) and zone 2 (normal office)

For the corner office and the normal office heating and cooling curves according to Figure 6 were determined. Due to the larger fraction of façade heating and cooling demand in corner offices is larger than in normal offices: This results in steeper heating and cooling curves than for normal offices. The heating and cooling curves were defined per the "unknown-but-bounded approach", which is described in [4], [5], [6], [7].
Since the heating and cooling curves are quite different for the two offices, separate zones have to be defined (see Figure 6).

The simulation results are recorded for a whole year, with days 180 to 270 representing summer. Simulation results are shown in Figure 7. Most of the time, the common zone return water temperature (green) is higher than the setpoint band for zone 2. As a result, cooling (magenta, negative value) is needed during most of the year to control the supply water temperature within the setpoint band.

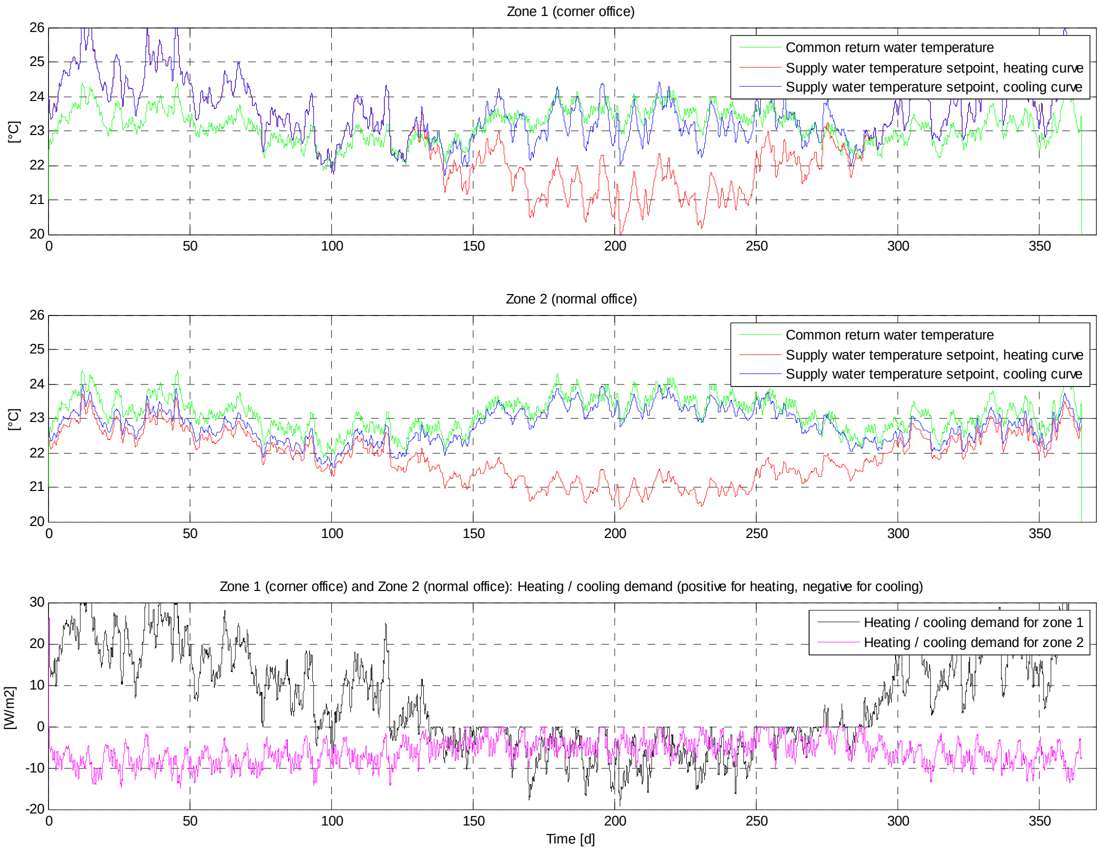

Figure 7: Whole-year simulation results for a TABS with common zone return

2ND HYDRAULIC PIPING TOPOLOGY: SEPARATE ZONE RETURNS

Analysis of a stationary load situation

Figures 8 and 9 illustrate supply and return water temperatures as typically found during the winter: The supply water temperature for zone 1 must be at least 26°C and the temperature for zone 2, 22°C. Water cools off by 0.5K in both zones, i.e. heat is provided to the rooms. The distribution supply water temperature is heated to the highest demanded supply water temperature (i.e. demand-controlled), or per zone 1 to 26°C. For zone 2, cooled off zone return water is mixed to achieve the setpoint (refer to Figure 9).

The setpoint for zone 2 can be achieved by mixing the distributed hot water with its own zone return water.

- Requires only heat to cover zone demand.
- Cold generation can be blocked for this typical winter situation.

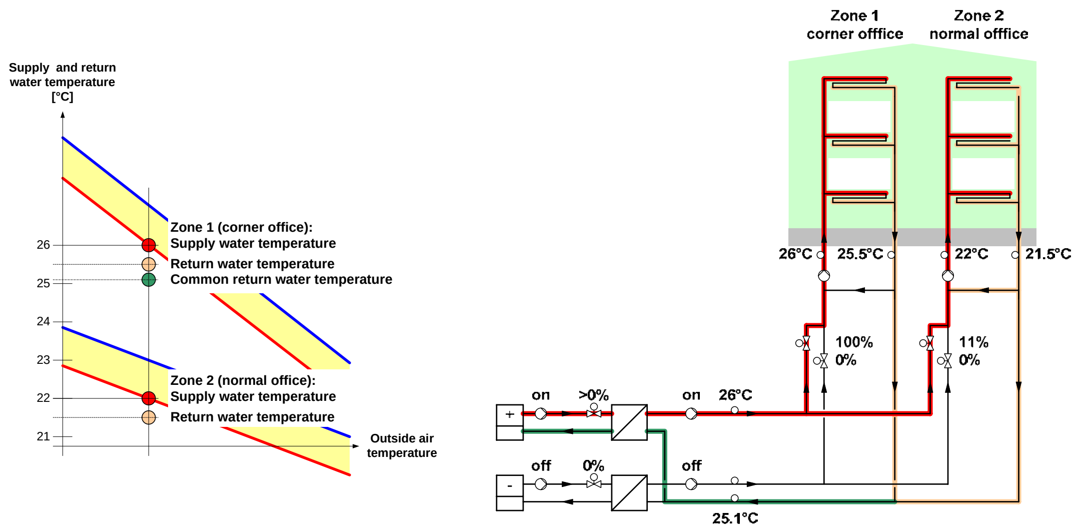

Figure 8 and 9: Temperature ratios and valve settings for separate zone returns during winter

Analysis of a whole-year simulation

In Figure 10, simulation results are presented when using the 2nd hydraulic piping topology. Here, the same simulation set-up was used as for the simulation with the 1st hydraulic piping topology (see Figure 7).

The simulation confirms the expectations: cooling is in winter only required during few days (magenta, positive value).

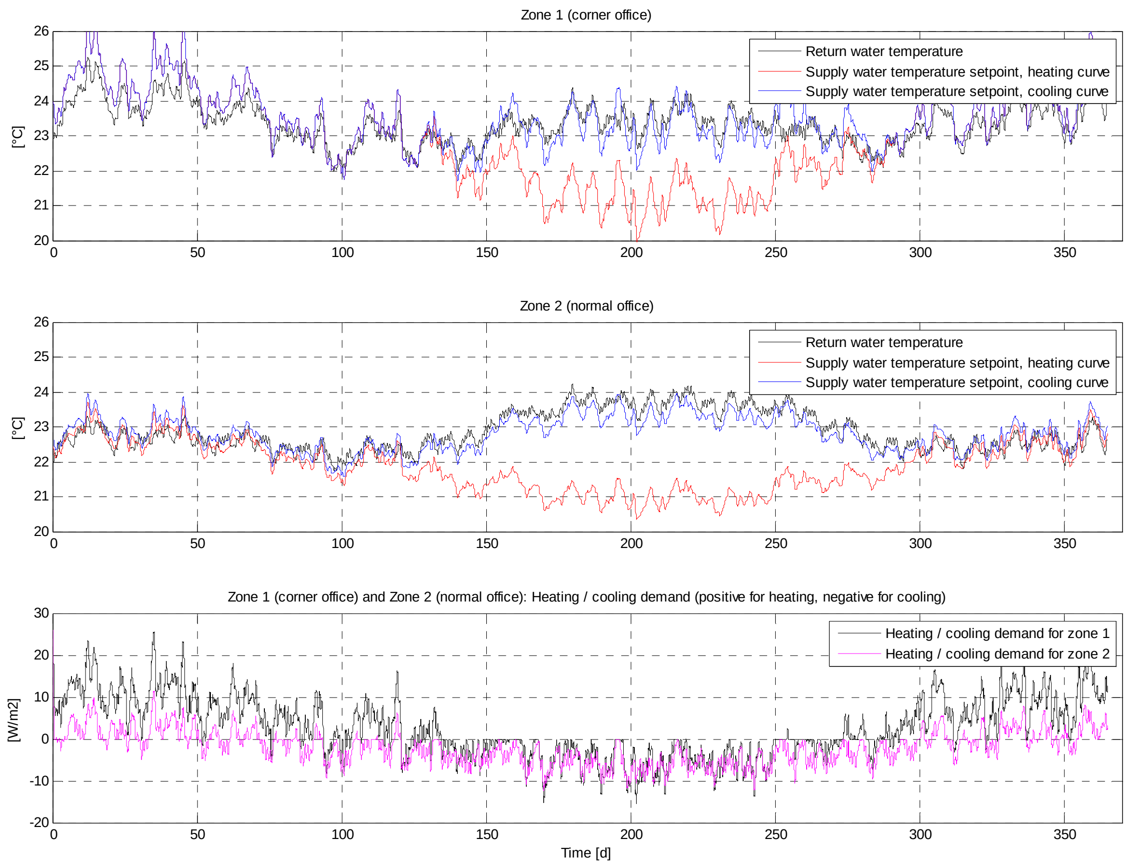

Figure 10: Whole-year simulation results for a TABS with separate zone returns

DISCUSSION

We found the following for hydraulic topologies with common zone return:
Decisive for current heating and cooling generation demand is not the TABS demand (what the room absorbs or is extracted from the room), but rather the actual position of the common zone return water temperature in relation to the supply water temperature setpoint bands of the zones:

1. If it lies between the zone supply water temperature setpoint bands pursuant to Figure 11 (cf. also Figure 2), cold water is required to achieve the zone supply water temperature setpoints below the common return water temperature and hot water above it. In other words, heating and cooling demand for the zones is not directly dependent on the TABS demand and therefore difficult to interpret. If, for example cold generation is incorrectly blocked for a typical winter situation (expected heat demand only), the supply water temperature setpoints below the common zone return water temperature can no longer be achieved. As a consequence, rooms in this zone may be too warm and the anticipated room comfort may no longer be maintained.
2. If it lies within the zone supply water temperature setpoint bands pursuant to Figure 11, a heat exchange may take place between the zones.

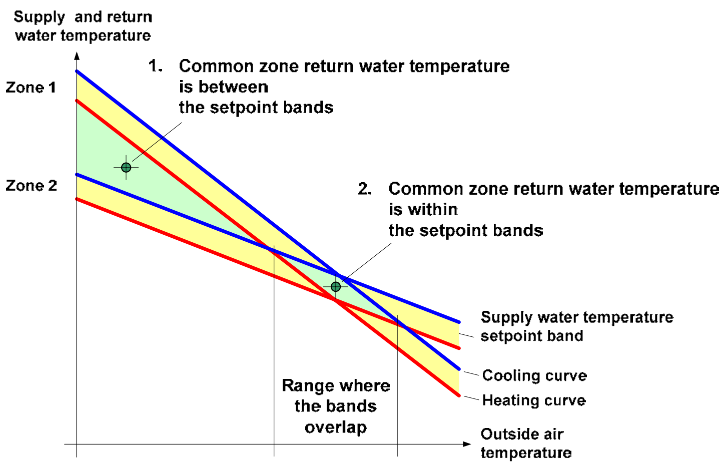

Figure 11: Common zone return water temperature between the supply water temperature setpoint bands (1.) and within the supply water temperature setpoint bands (2.)

The whole-year simulation resulted in the following for generation demand:

- 28 % less heat demand and 30% less cooling demand per year were required for the hydraulic piping topology with separate zone returns compared to the topology with a common zone return!

Depending on the shape of the supply water setpoint bands, an outside air temperature range results where the supply water setpoint bands overlap. The longer the real outside air temperature does stay outside of this outside air temperature range (over the year), the larger the potential energy savings by using a piping topology with separate zone return pipes compared to a piping topology with a common return pipe. If the potential is really exploited then depends on the load situations of the zones and the sizes (floor space) of the different zones (see [1]).
If the common zone return water temperature lies not within the zone supply water setpoint bands during a major part of time, we recommend separate zone return pipes based on current findings. This does result in higher investment costs, but lowers energy consumption,

increases understanding of operational behavior and improves room comfort. If separate zone return pips are installed and multiple flow pipes with various temperature levels are led to each register, (manual) valves for supply and return water have to be installed and they have to be switched so that supply and return are connected to the same zone.
As the present investigation is based on the specific assumptions concerning building characteristics, heat gain situation, proportion between normal and corner offices etc., the presented results strictly speaking are valid for the chosen example only. For situations with strongly deviating parameters results and conclusions may be different.
The presented results in this paper can be transferred to other systems than TABS and also to systems with different heat and cold transfer medium like air conditioning systems. Whether or not different hydraulic topologies provide additional benefits is the subject of further examinations for this research project.

ACKNOWLEDGEMENT

The partial funding of the project by the Swiss Confederation's innovation promotion agency CTI and the input of the project steering committee are gratefully acknowledged.

The New Three Pipe System: Presentation And Evaluation of its Applications in HVAC Technology

Aristidis Afentoulidis & Merima Zlateva (Assoc. Prof. PhD)

Msc Naval and Mechanical Engineer - HVAC consultant – Greece
PhD Candidate, Tech. Univ. Sofia – Bulgaria

Corresponding email: aris@hydronic.gr

SUMMARY

The purpose of the present article is the presentation and evaluation of the new three pipe system which composes a new methodology and style of building hydronic networks in HVAC technology. The basic characteristics of the new system are as follow :

1. Applicable to all hydronic HVAC networks
2. Innovative and patent pending
3. Obtains rational energy use and saving
4. Simply, stable, easily planned and constructed
5. Experimentally and practically proved

The presentation and evaluation of the new system will take place through the presentation and the analysis of a 3 step procedure of building and optimizing a heat hydronic network. The standards of optimizing are set to a very high level, so that a network will be produced, characterized by simplicity, stability and rational energy use during its function. It will be proved that the new three pipe system is able to obtain such high energy and functional standards based only on its nature, form and hydraulic behavior.

INTRODUCTION

In the hydronic network building there are many styles and methodologies applied, each one with different results in positive and negative features imputed to the network.
The constant primary flow network obtains good authority and functionality of the control valves, negligible interference in the network but it involves energy waste and adaptation inability between produced, distributed and consumed heat power.
The variable primary network on the other hand, generally presents a good adaptation of produced and consumed heat power but it involves interactive phenomena which decrease the stability and functionality of the whole network and leads to energy waste and low efficiency. Furthermore the use of more than one production units with the aim to fit the production power to the variable consumed needs, is deterrent in efficiency and success due to the many instabilities which appear by the use of primary – secondary network, like reverse flows, interactivity and control complexity. The proposed new three pipe system is an effective combined form of the variable and constant primary flow network styles, keeping their benefits and minimizing their drawbacks.
The system in its primary form, presented in fig. 1, composes of two loops, the primary and the secondary. The primary loop is normally the heat production and distribution loop, where as the secondary is the consumption one. The terminal units are installed across the distribution pipes of the secondary loop, each one with a local circulator. A central circulator is also installed in the main pipes to compensate for friction losses in them.

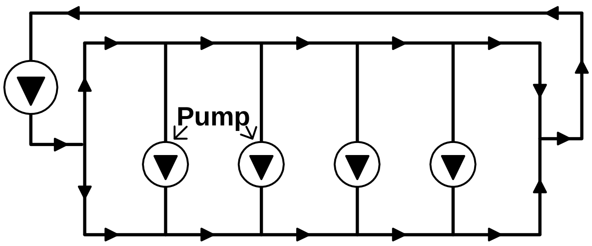

Fig. 1 New three pipe form

The new and innovative feature of the system is that the terminal units function between two central supplies. This has the effect that the initial pressure at the beginning and at the end of each terminal unit pipe is exactly the same so leading to negligible interference between them. The advantages of the proposed system are many and significant. The new three pipe system is applicable in every hydronic HVAC network from small and simple to large and complex, showing rationality in energy use, simplicity and stability in heat control, negligible interference and significant functional stability.

NETWORK ANALYZING & RESULTS

Initial data of the network :
The aim is the planning of a network with 7 consumers (terminal units) with a heat power overall of 248 KW.
The heat power choice of each terminal unit was chosen at random. A random choice was also the determination for the total resistance coefficient of each terminal pipe but in each case adapting to reality.

Table 1. Initial data

Consumer	**1**	**2**	**3**	**4**	**5**	**6**	**7**	**Total**
Power (KW)	25	32	40	20	38	50	43	248
ΔT (K)	15	15	15	15	15	15	15	
Supply (m^3/h)	1.43	1.83	2.29	1.15	2.18	2.86	2.46	14.2
C (Resist. Coeff.)	10270	6870	4770	14370	5050	3300	4300	
ΔP (Pa)	21000	23000	25000	19000	24000	27000	26000	

A production unit of 260 KW heat power was chosen with a prospective ΔT=15.74 K.
The heat power in the terminal units is proportionally adjusted, though in the production units it is constant and the units function in on-off mode.
The mathematically solution of the system takes place based on the theory of the loops and branches, where $\Delta P = C * V^2$, V (m^3/h), H (Pa), C (Total resistance coefficient of the branch).
All the networks under investigation and comparison are at the same length for comparison clarity and efficiency.

The rules to be obtained by the optimized network are the follows :

Rule 1 : The distribution flow is adapted to the terminal units flow.
Rule 2 : The proper flow supply is always obtained by the minimum head of the circulators.
Rule 3 : The produced heat power is adapted to the consumed one.
Rule 4 : Maintenance of equality between production and consumption supply temperature and the proper direction of flows without reverse flow.
Rule 5 : Interactivity between the terminal units is less than 5 %.
Rule 6 : The production units are controlled on their activation by rationality and simplicity.
Rule 7 : Maintenance of constant flow supply in the production units.

First approximation of planning the network

The simplest form of the network applying the new three pipe form is shown in fig. 2.

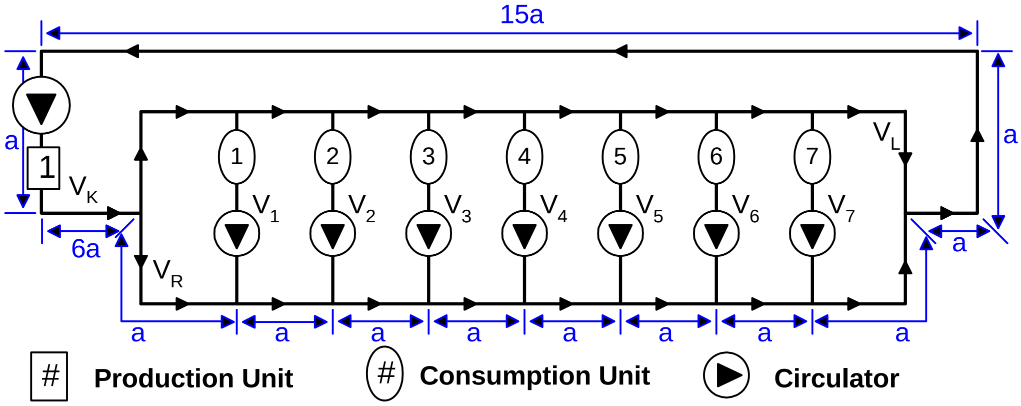

Fig. 2 First stage 3pipe network

Where a=4.5, the total resistance coefficient of the pipe parts. The heat power of the production unit <1> is assumed to be 260 KW.
The emitted heat power through the terminal units has been adjusted via the control of the speed of the local circulators and the totally distributed flow supply in the network is adjusted via the control of the speed of the central circulator.
The characteristic curves of the circulators are :

- Type A : $H=n^2*37708-n*8497*V-781*V^2$
- Type B : $H=n^2*49772-n*8604*V-755*V^2$
- Type C : $H=n^2*56309-n*3786*V-595*V^2$
- Type D : $H=n^2*59995-n*10252*V-543*V^2$
- Type E : $H=n^2*56351+n*670*V-172*V^2$

V (m^3/h), H (Pa), n (Speed coefficient 0 - 1)

Evaluation

The system and its equations is solved 3 times, see table 3. The first solution refers to full power emission through the terminal units. The second solution refers to partially power emission of the leading four terminal units and exactly at 1/3 of their nominal value. The third solution refers to partially power emission of the leading six terminal units and exactly at 1/3 of their nominal value. The criterion of adjusting the speed of the central circulator is the approach of zero flows in the passive bypasses, V_R, V_L, procedure which takes place via flow switches.
On the preset rules of optimization, the results are as follows :
(<**S**> : Satisfy, <**NS**> : Not satisfy)

Rule 1 : <S> The distribution flow is adapted to the terminal units flow. The surplus V_R, V_L is negligible.
Rule 2 : <S> The proper flow supply is always obtained by the minimum head of the circulators.
Rule 3 : <NS> The produced heat power is adapted to the consumed one.
Rule 4 : <S> Keeping maintenance of equality between production and consumption temperature and proper direction maintenance in flows, without reverse flows.
Rule 5 : <S> Interactivity between the terminal units is less than 5 %.
Rule 6 : <-> The production units are controlled on their activation by rationality and simplicity.
Rule 7 : <NS> Keeping maintenance of constant flow supply in the production units.

<u>Second approximation of planning the network</u>

In this form (fig. 3) an added separate three pipe cluster for the production is formed.

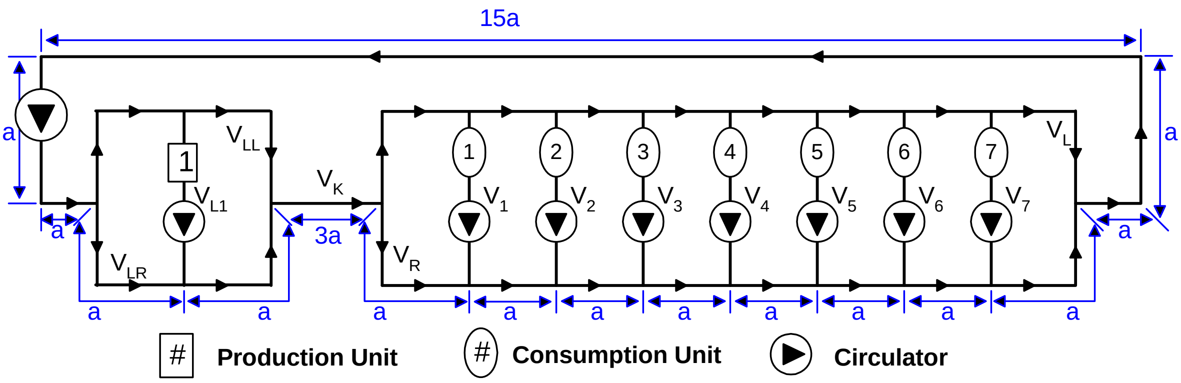

Fig. 3 **Second stage 3pipe network**

The local circulator of the production unit <1> is of type <E> and is determined to function with constant speed by a RPM coefficient of n=0.81. As concerning the rest of the circulators, table 2 is valid.
The criterion of adjusting the speed of the central circulator is the approach of zero flows in the passive bypasses in the consumption cluster, V_R, V_L.
Through this procedure of planning the network, a constant flow supply in the production unit is obtained, an essential fact for cooling applications. However a variable flow supply through the production unit, if allowed by the manufacturer, could be also obtained by the use of variable speed production unit circulator.

Table 4. Solving the system

	V_1	V_2	V_3	V_4	V_5	V_6	V_7	V_K	V_{L1}	V_{LR}	V_{LL}	V_R	V_L

	n_1	n_2	n_3	n_4	n_5	n_6	n_7	n_K					
RPM Coefficient	0.32	0.29	0.30	0.29	0.32	0.29	0.94	0.46					

Evaluation

The system is solved again 3 times, see table 4. The first solution refers to full power emission through the terminal units. The second solution refers to partially power emission of the leading four terminal units and exactly at 1/3 of their nominal value. The third solution refers to partially power emission of the leading six terminal units and exactly at 1/3 of their nominal value.

On the preset rules of optimization, the out coming results are as follows :
Rule 1 : <S> The distribution flow is adapted to the terminal units flow. The surplus V_R, V_L is negligible.
Rule 2 : <S> The proper flow supply is always obtained by the minimum head of the circulators.
Rule 3 : <NS> The produced heat power is adapted to the consumed one.
Rule 4 : <S> Keeping maintenance of equality between production and consumption temperature and proper direction maintenance in flows, without reverse flow. The reverse flows in the production cluster (V_{LR} , V_{LL}) do not affect the supply temperature.
Rule 5 : <S> Interactivity between the terminal units is less than 5 %.
Rule 6 : <-> The production units are controlled on their activation by rationality and simplicity.
Rule 7 : <S> Keeping maintenance of constant flow supply in the production units.

Third approximation of planning the network

In this form (fig. 4) three production units are installed in the production cluster.

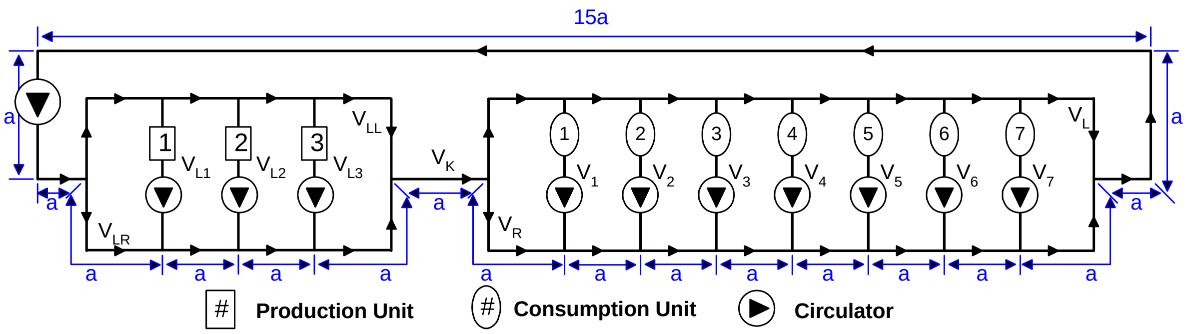

Fig. 4 Third stage 3pipe network

There will be used 3 production units, of total heat power 260 KW, in order to obtain adaptation between produced and consumed heat power in the network.

Table 5. Production unit data

Production Unit	**1**	**2**	**3**	**Total**
Heat power (KW)	60	100	100	260
ΔT (K)	15	15	15	
Flow supply (m^3/h)	3.44	5.73	5.73	14.90
C (resistance coefficient)	1000	400	400	
ΔP (Pa)	11833	13133	13133	
Circulator type	D	C	C	
RPM coefficient (n)	0.92	0.98	0.98	

All the production unit local circulators function with constant speed, determined by the relevant RPM coefficient as in table 5.
The emitted heat power through the terminal units has been adjusted via the control of the speed of the local circulators and the totally distributed flow supply in the network is adjusted via the control of the speed of the central circulator.
The criterion for adjusting the speed of the central circulator is the approach of zero flows in the passive bypasses in the consumption cluster, V_R, V_L, a procedure which takes place via two flow switches.
To continue, two points should be specified, firstly how the variable emitted heat power is determined and secondly by which procedure the production units will be activated.
Many and different procedures are proposed and applied for this purpose, as for instance through the measurements of flow supply temperature, temperature differences, return temperature etc, procedures with different results in success, accuracy, complexity and rational energy use. By the use of the new three pipe system, the proposed procedure of determining the emitted heat power is simple and new. It should be used only the already known RPM coefficient of the central circulator, which corresponds to the flow supply distributed in the network and which is equal to the flow supply through the terminal units, in fact analog the emitted heat power.

Table 6. Production unit activation rules

RPM Coefficient (%)	**0 – 20**	**20 – 35**	**35 – 60**	**60 – 75**	**75 – 100**
Production unit	1	2	1 + 2	2 + 3	1 + 2 + 3

Table 7. Solving the system

	n_1	**n_2**	**n_3**	**n_4**	**n_5**	**n_6**	**n_7**	**n_K**							
RPM Coefficient	0.32	0.29	0.30	0.29	0.32	0.29	0.94	0.45							
Active units (1+2)	**V_1**	**V_2**	**V_3**	**V_4**	**V_5**	**V_6**	**V_7**	**V_K**	**V_{L1}**	**V_{L2}**	**V_{L3}**	**V_{LR}**	**V_{LL}**	**V_R**	**V_L**
Flow (m^3/h)	0.47	0.61	0.76	0.38	0.72	0.95	2.46	6.89	3.43	5.71	0	-1.98	-0.27	0.08	0.46
	n_1	**n_2**	**n_3**	**n_4**	**n_5**	**n_6**	**n_7**	**n_K**							
RPM Coefficient	0.32	0.29	0.30	0.29	0.32	0.29	0.94	0.45							

Evaluation

The system is solved again 3 times, see table 7. The first solution refers to full power emission through the terminal units, where all 3 production units function. The second solution refers to partially power emission of the leading four terminal units and exactly at 1/3 of their nominal value. This solution procedure is made in two steps, firstly while all production units are functional, the RPM coefficient of the central circulator is determined and secondly the system is solved again maintaining only the proper production units functional, which in this case are the <2> & <3>, while n=0.68.
The third solution refers to partially power emission of the leading six terminal units and exactly at 1/3 of their nominal value. This solution procedure is made again in two steps, firstly all production units are functional and the RPM coefficient of the central circulator is determined and secondly the system is solved again maintaining only the proper production units functional, which in this case are the <1> & <2>, while n=0.45.
During the whole procedure of defining the active production units, it was determined in the background, that the relationship between the RPM coefficient and the distributed flow supply is linear proportional, a valid assumption in most of the cases. However this relationship could be set more precisely in each particular application.

On the preset optimization rules, the out coming results are as follows :
Rule 1 : <S> The distribution flow is adapted to the terminal units flow. The surplus V_R, V_L is negligible.
Rule 2 : <S> The proper flow supply is always obtained by the minimum head of the circulators.
Rule 3 : <S> The produced heat power is adapted to the consumed one.
Rule 4 : <S> Keeping maintenance of equality between production and consumption temperature and proper direction maintenance in flows, without reverse flow.
Rule 5 : <S> Interactivity between the terminal units is less than 5 %.
Rule 6 : <S> The production units are controlled on their activation by rationality and simplicity.
Rule 7 : <S> Keeping maintenance of constant flow supply in the production units.

CONCLUSIONS

The satisfaction of all rules of optimization by the new three pipe system, a normally dimensioned and easily planned and constructed network, opens new scientific and applicative ways in the hydronic HVAC technology.
Actually the simultaneous satisfaction of the above rules by using the known primary – secondary network style would not be feasible [1].
Furthermore the use of the new three pipe system comprises an invitation and challenge to the industry on producing more efficient variable speed circulators and proper flow switches.
For the fulfillment of the presentation, it should be focused on two more points.

1. The adjustment of the emitted power by the terminal units could take place by the use of two or three way control valves, though the local circulators would be of constant speed. In this case the satisfaction of the rule 2 would be partial, concerning only the central circulator.
2. The new three pipe system, by its negligible interference and rational energy use comprises a hydronic solution applicable mainly in constructions based on collectors, where the wide distances of the network are covered by the terminal unit pipes. By its use in wide spread networks, where the wide distances of the network are covered by the central pipes as for instance in district heating or cooling networks, a further financially and hydraulically investigation should be done.

SUMMARY

Because central heating (CH) boilers represent a considerable amount of the total energy consumption in the European Union (EU), initiatives have been taken by the European commission to phase out boilers with poor efficiency from the market. To fairly judge boilers, efficiency tests carried out by different laboratories have to be conform. Tests carried out in the past between different laboratories on the contrary have showed that this is not the case. In this paper the possible methods that are used to carry out the efficiency test on gas-fired boilers are analysed. Trough uncertainty and sensitivity analysis the factors that have the largest influence on the efficiency results are determined for the different cases.

INTRODUCTION

Even a few percent rise in efficiency of a boiler represent a considerable reduction in energy use due to the number of boilers sold on the EU-market. This knowledge led to a number of European initiatives to phase out boilers with poor efficiency from the market. As a result the efficiency requirements for central heating (CH) boilers have become more stringent. Efficiency requirements in connection with CE-marking of gas-fired boilers are mentioned in the directive 92/42/EEC. Nowadays there are also a few other European directives that are important for CH boilers and their performance. The energy performance of buildings (EPB) directive 2002/91/EEC resulted in many countries in new minimum requirements for boiler efficiency. The present version of directive 2005/32/EEC on the eco-design of the energy-using products (EuP) obliges the labeling of central heating (CH) boilers in eight categories. This situation has increased the importance of a high measurement-quality.

The European standards for gas-fired boilers [1] [2] [3] are frequently used by the laboratories which are certified to measure the efficiency of boilers e.g. when performing CE-label testing. But the standards permit different interpretations and give the laboratories a large degree of freedom. Looking at the requirements for the uncertainty of the efficiency measurement in the standards, only large limits for the individual measurement equipment of the input parameters and a maximum absolute uncertainty in the efficiency measurement of 2% is stated. So it is left to the laboratories to fix the measurement uncertainties in the measurement of the input so that the desired uncertainty on the efficiency is achieved. Also, too little details on the preferred measuring method and equations to be used to calculate the efficiency are recorded in the standards. Laboratories are free to choose which method and equations are used to determine the efficiency of the boiler. Also little is mentioned on the boiler stability during the measurements. This is nevertheless an indispensable requirement for a correct result.

A fair judgment of the CH boilers can only be achieved when the measured efficiency of different laboratories on the same boiler agrees and if the efficiency measurement is of a high quality. If not the risk of wrongful labeling of boilers is unacceptably high. This is a recent issue, seeing the only discrimination that was previously made was between boilers who did and did not satisfy the requirements for CE-marking. The new European directive divides the CH boilers into 8 label categories. This will lead to more discussions as each category covers a small range of the efficiency (typically 3 till 4%). Differences in the measured efficiency between different laboratories can lead to a different classification of the boiler.

In 1991 efficiency measurements were carried out on the same boiler by different laboratories [4]. This study led to the following conclusions: a reproducibility of 4% for the full load efficiency test and 6% for at the 30% part load test. The reproducibility (R) is the value below which the absolute difference between two single test results obtained with the same method on identical test material may be expected to lie within a specified probability of 95% under different conditions like apparatus, operators and laboratories. These observed differences are considerable when compared to the small ranges proposed for the labeling of boilers.

A number of laboratories have already joined forces in a network named LABNET. The aim of this collaboration is to investigate the problems that occur when testing CH boilers and in particular the non conformity of the obtained efficiency results. A document (Good Laboratory Practice or GLP) [5] detailing the appropriate testing rules, was established based on the investigations carried out by and the experience of the partners in the project. The most significant proposals to improve the quality of the efficiency measurements stated in the GLP are: stability criteria to verify the stability of the boiler, corrections for ambient conditions such as ambient temperature and atmospheric pressure and which equations to use for the determination of the total uncertainty of the efficiency. The impact of the GLP has been verified by again comparing the efficiency results of different laboratories [4] [6]. The results showed clear improvements: a reproducibility of 2.5% for the full load test and 5.9% for the 30% part load test.

At part load the results are still not satisfactory. The remaining difference may be attributed to differences in measuring instruments and the methods that can be used to carry out the efficiency test. The most difficult part in determining the total uncertainty of the efficiency measurement is determining the separate uncertainty factors of the measured input parameters. Research done by LABNET has shown that not all the laboratories have a clear idea about these uncertainties. A number of laboratories underestimate the measurement uncertainty due to insufficient knowledge of the different uncertainty sources. A first step to the improvement of the quality of measurement is to have the laboratories realize the importance of the uncertainty in their measurements. Sometimes the procedures are not sufficient, e.g. a calibration frequency that is too low. Taking into account that the standards and GLP are not obligatory, larger differences can be expected between the different testing laboratories, as not all participated in the comparisons.

BOILER EFFICIENCY

To execute the efficiency measurement the boiler is connected to the primary side of a heat exchanger (Figure 1). Some laboratories measure the output capacity of the boiler by measuring water mass flow rate (Q_{wp}) and water temperatures before and after the heat exchanger (*Tp1* and *Tp2*) in the primary water circuit of the heat exchanger. The efficiency (η) can then be expressed as:

$$\eta = \frac{Q_{wp}.(h_{p1} - h_{p2})}{Q_g.Hi}, \qquad (1)$$

where h_{p1} and h_{p2} are the water enthalpy before and after the heat exchanger, Q_g is the gas mass flow rate and Hi is the gross calorific value of the gas used. Other laboratories measure the output capacity of the boiler by measuring water mass flow rate (Q_{ws}) and water temperatures before and after the heat exchanger (*Ts1* and *Ts2*) in the secondary water circuit of the heat exchanger and taking into account the extra heat losses in the secondary circuit and heat exchanger (*L*). The efficiency is calculated with:

$$\eta = \frac{Q_{wp}.(h_{s2} - h_{s1}) + L}{Q_g.Hi}, \qquad (2)$$

where h_{s1} and h_{s2} are the water enthalpy before and after the heat exchanger. The goal of this paper is to examine the main differences between these two methods and to determine which method gives the highest quality of measurement. The main input factors that have an influence on the variation of the efficiency have to be determined.

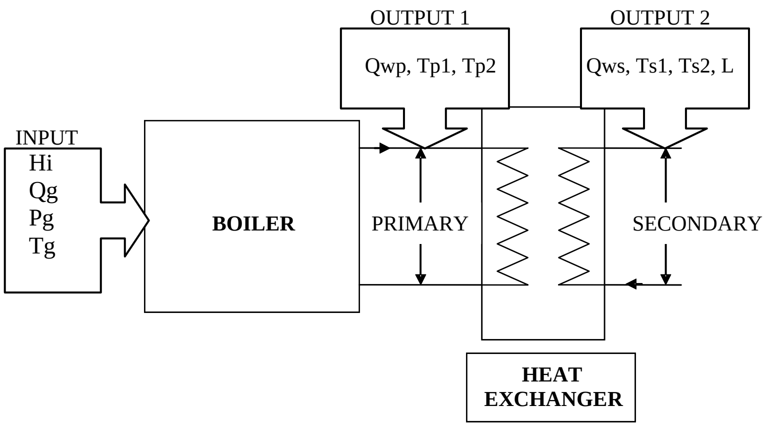

Figure 1. Different measuring methods

The main reason for laboratories to measure in the secondary water circuit is a reduced impact of the uncertainty of the water temperature measurement because of the larger temperature difference before and after the heat exchanger. As this uncertainty is an important factor in the total uncertainty, it leads to a reduced total uncertainty on the efficiency. This is especially important for the part load test because these tests have the smallest temperature difference (for part load typically in primary water circuit: 7°C, for the secondary water circuit: 20°C). This study is restricted to gas-fired CH boilers up to 70kW because firstly most of the tests in laboratories are carried out on such boilers and secondly because the biggest differences in efficiency measurements occur for relatively small boilers.

METHOD AND RESULTS

First of all the uncertainty analysis [4] of two different laboratories is compared to each other. Laboratory 1 performs measurements in the primary water circuit while laboratory 2 measures in the secondary water circuit. The different measuring instruments and procedures used are taken into account. The first laboratory calibrates the temperature difference between the two water temperature measuring probes and this calibration is carried out before and after the efficiency test on the boiler. The second laboratory calibrates the water temperature probes separately and with a smaller calibration frequency. For both laboratories four cases are

considered in order to investigate the possible differences between the laboratories and the proposed used methods:
1) measuring on the primary water circuit and separate calibration of the water temperature probes
2) measuring on the primary water circuit and calibration of the water temperature difference
3) measuring on the secondary water circuit and calibration of the water temperature probes separately
4) measuring on the secondary water circuit and calibration of the water temperature difference

During the analysis a normal distribution is assumed for the input parameters and a level of confidence of 95% is taken. The uncertainty analysis is carried out for both the laboratories for a measurement on a boiler of 28kW. The results are presented in Figure 2. Table 1 gives an idea of the part (in % of the total uncertainty on the output) of each important input parameter in the uncertainty of the efficiency.

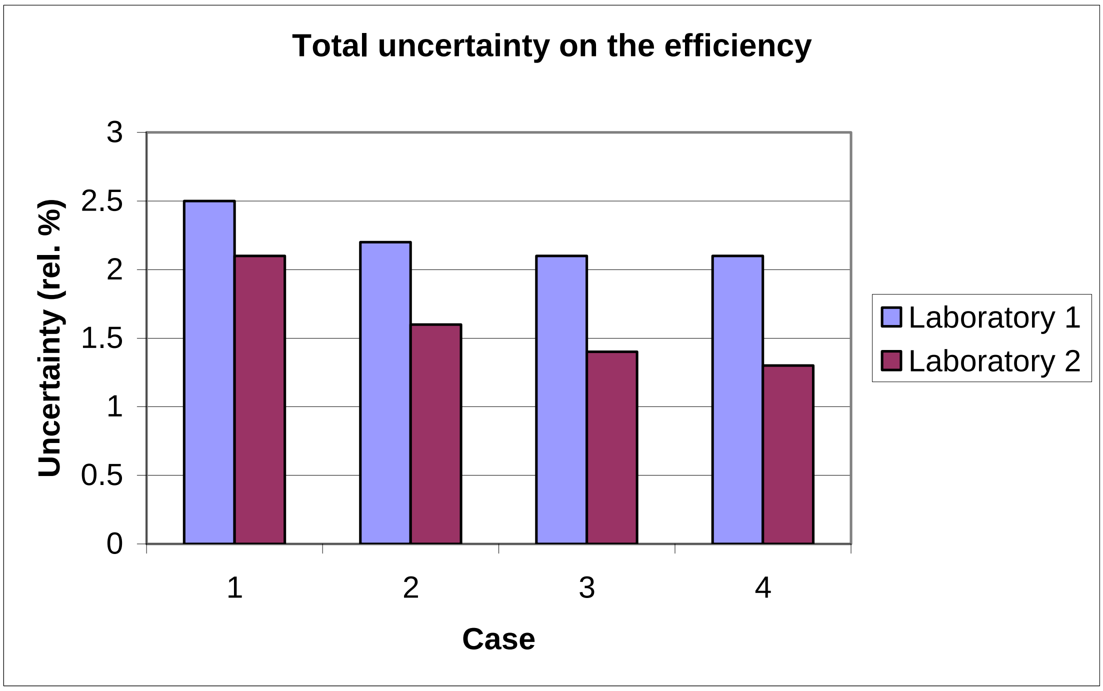

Figure 2. Results of the uncertainty analysis: total uncertainty on the efficiency

Looking at the same method (Figure 2) there is a clear difference in the total uncertainty results obtained by the two laboratories. The most important reasons for this are the uncertainty of the calorific value (Hi) and of the gas pressure (Pg) (as can be seen from Table 1). The uncertainty on the calorific value of the gas used is large for the first laboratory because of the use of natural gas for the efficiency test while the second laboratory uses gas from bottles (99.5% CH_4). In the first laboratory the calorific value of the natural gas is measured with a chromatograph a few times during the measurement. An uncertainty factor because of the unincorporated variation of the calorific value during the test has to be taken into account and also the error due to calibration of the chromatograph is considerable. This is not the case for the second laboratory which only has to take into account the uncertainty stated by the certificate of the bottle. The uncertainty on the gas pressure has to be taken into account for the first laboratory. The gas flow is measured with a volumetric flow meter so a correction has to be applied to convert the flow rate from measurement conditions (real gas temperature and gas pressure) to reference conditions (0°C and 1013.25 mbar). The most important reason for the large impact of the uncertainty of the gas pressure is the drift between calibrations. The second laboratory uses a thermal mass flow meter and no correction has to be applied. This results in a smaller total uncertainty.

Case	Input parameters	Laboratory 1	Laboratory 2
Case 1	Qg	14.55%	17.66%
	Hi	27.52%	2.08%
	Pg	17.31%	0.00%
	Qw	12.23%	9.33%
	Tp1	13.43%	36.11%
	Tp2	12.91%	34.22%
Case 2	Qg	17.75%	44.29%
	Hi	33.57%	6.95%
	Pg	14.92%	0.00%
	Qw	21.11%	23.41%
	ΔT	9.69%	20.83%
Case 3	Qg	19.67%	54.24%
	Hi	37.21%	6.39%
	Pg	23.41%	0.00%
	Qw	15.91%	27.58%
	Ts1	1.57%	5.19%
	Ts2	1.57%	5.19%
Case 4	Qg	20.11	59.02%
	Hi	38.04%	6.95%
	Pg	23.93%	0.00%
	Qw	16.27%	30.01%
	ΔT	0.98%	2.49%

Table 1. Part of the important input parameters in the total uncertainty of the efficiency

Looking at the results of all the cases for one laboratory (for example laboratory 2), it can be seen that the total uncertainty improves both by calibrating the temperature difference between the probes (case 2) or by measuring on the secondary water circuit (case 3) opposite to case 1. A large improvement compared to case 1 is obtained by both the laboratories when measuring in the secondary circuit using separately calibrated temperature probes (case 3). Calibrating the temperature difference between the probes (case 4) offers no significant improvement compared to case 3. The differences between the observed cases are smaller for the first laboratory because of the smaller contribution of the water temperatures in the total uncertainty on the efficiency (table 1).

Comparing the methods that are presently used by the laboratories, measuring in the secondary water circuit clearly offers a better result. This is the result of the differences mentioned in the sections above. It can be concluded that the best way to work is according to case 3. Due to the continuing improvement of boiler efficiency and better insulation of buildings, boilers with a smaller capacity will appear on the market. For these boilers the efficiency measurement at part load can not be done on the secondary circuit due to the small secondary water flow. Measuring on the primary side (case 2) then provides a solution to reduce the uncertainty value. Further reduction of the uncertainty of the efficiency is only possible through careful study of the input factors.

In the next part of the paper a sensitivity analysis is carried out for a condensing boiler of 24kW input capacity. The mathematical model is based on the general equations to calculate boiler efficiency taking into account the corrections for ambient conditions mentioned in the GLP. A distinction is made between measuring on the primary and the secondary water circuit. Also the cases of full load or part load are studied. For the sensitivity analysis we use a variance based method, the method of Sobol [8]. The sensitivity parameters used to investigate the model are:

$$S_i = \frac{V[E(Y \mid X_i)]}{V(Y)}$$

$$S_{Ti} = \frac{E[V(Y \mid X_{-i})]}{V(Y)} \qquad (3)$$

The first parameter S_i represents the first order sensitivity index. $V(E(Y \mid X_i))$ is the variance of the expected value Y, if we were able to learn the true value X_i. If S_i agrees with a high value, the corresponding input parameter X_i is very important for the total uncertainty of the efficiency. The second parameter S_{Ti} represents the total order sensitivity index. $E(V(Y \mid X_{-i}))$ is the expected output variance that would remain unexplained if only X_i were left free to vary over its uncertainty range. Orthogonal input parameters are supposed to simplify the determination of the conclusions. When the total index is zero, the input parameter has no influence on the total uncertainty.

The accepted variations of the input parameters are set to the allowed variations mentioned in the standards or to values based on user experience in testing of gas-fired boilers.

In figure 3 the five most important first order sensitivity parameters are represented for the different cases studied. In all the cases the water temperatures measured to calculate the corresponding enthalpies are by far the most important. When measuring on the secondary water circuit the importance of the water temperatures is decreased as expected. Also the gas pressure has an influence on the efficiency and this influence is higher when measuring at the secondary circuit. The importance of the parameters used in the corrections mentioned in the GLP is rather small. The large value of the sensitivity parameter for Tp2 when measuring on the primary circuit at part load can be explained by the knowledge that the possible variation of Tp1 allowed by the standards is smaller at part load than at full load while the variation of Tp2 is left at the larger value.

In figure 4 the most important second order sensitivity parameters are represented. It is clear that these parameters are much smaller than the sensitivity parameters of the first order. Comparing the appearing interactions, it can be seen that the second order parameters corresponding to the water temperatures appears more when measuring at part load, this because the influence of the water temperatures is larger at part load than at full load. The sensitivity parameters corresponding with the gas temperature and water temperatures are also important for most of the cases.

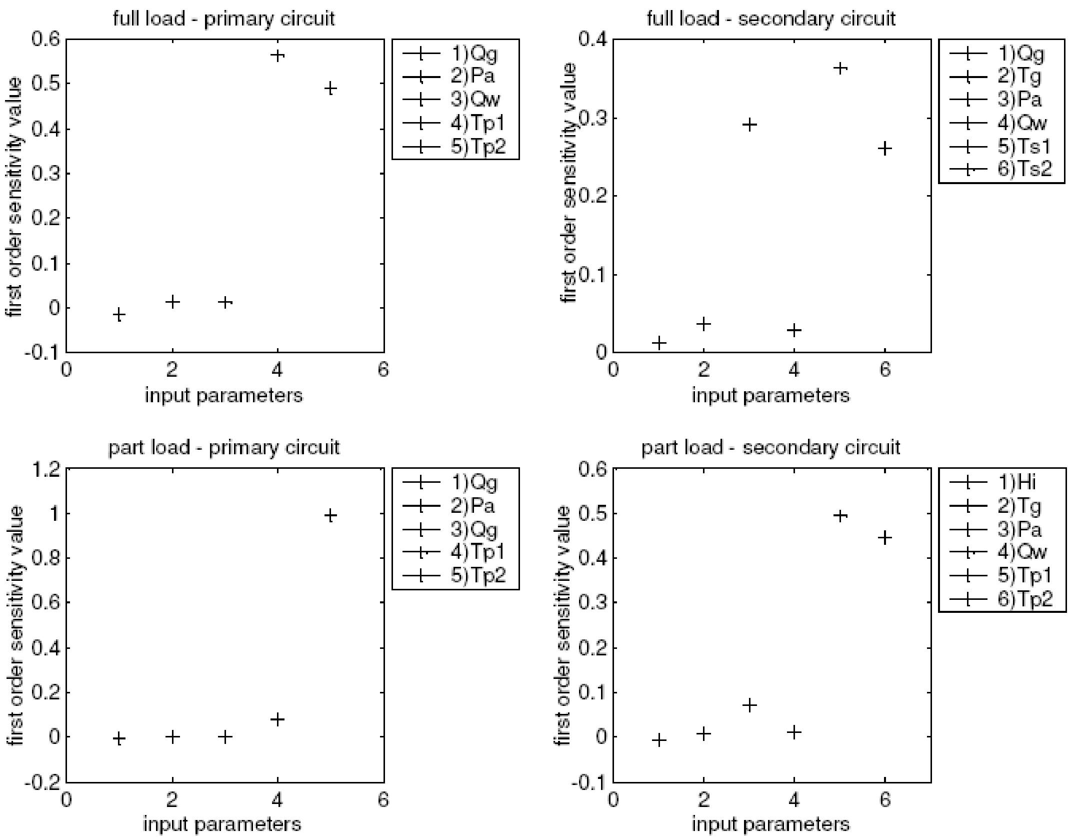

Figure 3. Most important first order sensitivity factors

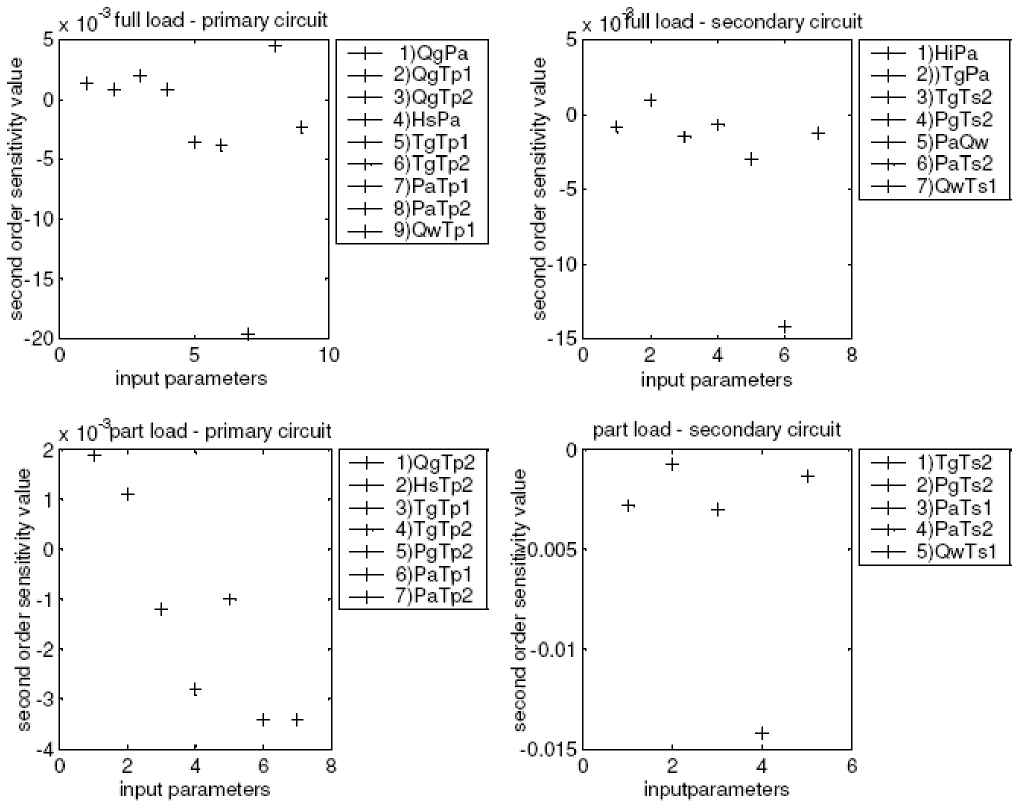

Figure 4. Most important second order sensitivity parameters

CONCLUSIONS

Out of the uncertainty analysis it can be concluded that five input parameters are important for the uncertainty in the efficiency measurement: water flow, calorific value, water temperatures and gas pressure. The measurement on the secondary water circuit with separate calibration of the water temperature probes seems to be the highest quality measurement. Measuring on the primary circuit with calibration of the temperature difference can be a good substitute when the boiler has a small capacity.

The sensitivity analysis of the efficiency measurement showed that especially the water temperatures are an important factor in the variation of the efficiency result. Also the atmospheric pressure and water flow have a non negligible effect on the efficiency.

SUMMARY

The aim of this project was to study 1) the materials in contact with drinking water 2) the quality of drinking water in Finland and 3) the interactions of materials and water. The study was based on scientific literature, reports and surveys. The main materials in distribution networks in Finland are polyethylenes, cement mortar, and polyvinylchloride. In water supply systems of buildings the main materials used are copper, brass, galvanised steel and polyethylenes. Drinking water quality in Finland is high in respect of the Drinking Water Directive (98/83/EC) and national legislation. However, especially groundwater in Finland, has low pH and are soft, so it is aggressive for materials.

INTRODUCTION

The quality of drinking water is dependent on many factors *i.e.* raw water (ground water vs. surface water), water purification technology and distribution systems. Drinking water flows days or even weeks in the distribution network before arriving to consumer's tap. Drinking water and materials in contact with it are in a complex interaction, which can result in deterioration of water quality and/or the deterioration of materials (Figure 1). The interactions between water and the materials in distribution systems in contact with drinking water are influenced *f.e.* by the quality of water, the characteristics of the materials, microbial activity in biofilms and corrosion. The main basic mechanisms in interaction of drinking water and materials are l) leaching of substances from materials 2) corrosion and 3) microbial actions in biofilms. Increasing temperature increases reaction rates and microbial activity. Also increasing flow rate can raise the corrosion rates or increase microbial activity.

Higher concentrations of substances leach from brand new materials, whereas the leaching gets slower when time passes by. All materials can leach out substances under unfavourable circumstances. Leached substances can affect the aesthetic or health related quality of water and microbial growth.

Corrosion is an electrochemical reaction, where the metal is oxidized and the metal ions migrate in to the water. In uniform corrosion, metal corrodes evenly, but in localized corrosion only in small areas. Amounts of metal ions that may have an effect on human health can only result in uniform corrosion. Biocorrosion is a form of corrosion where microbes themselves corrode materials or create circumstances where corrosion is likely to occur [1].

Biofilms are formed on surfaces of materials in distribution systems and water supply systems in buildings because of microbial activity. Most of the microbes in biofilms are not dangerous to human health. On the other hand, pathogenic bacteria are protected in the biofilms against disinfection chemicals. Biofilms can also cause technical and aesthetic problems in drinking water quality. [2]

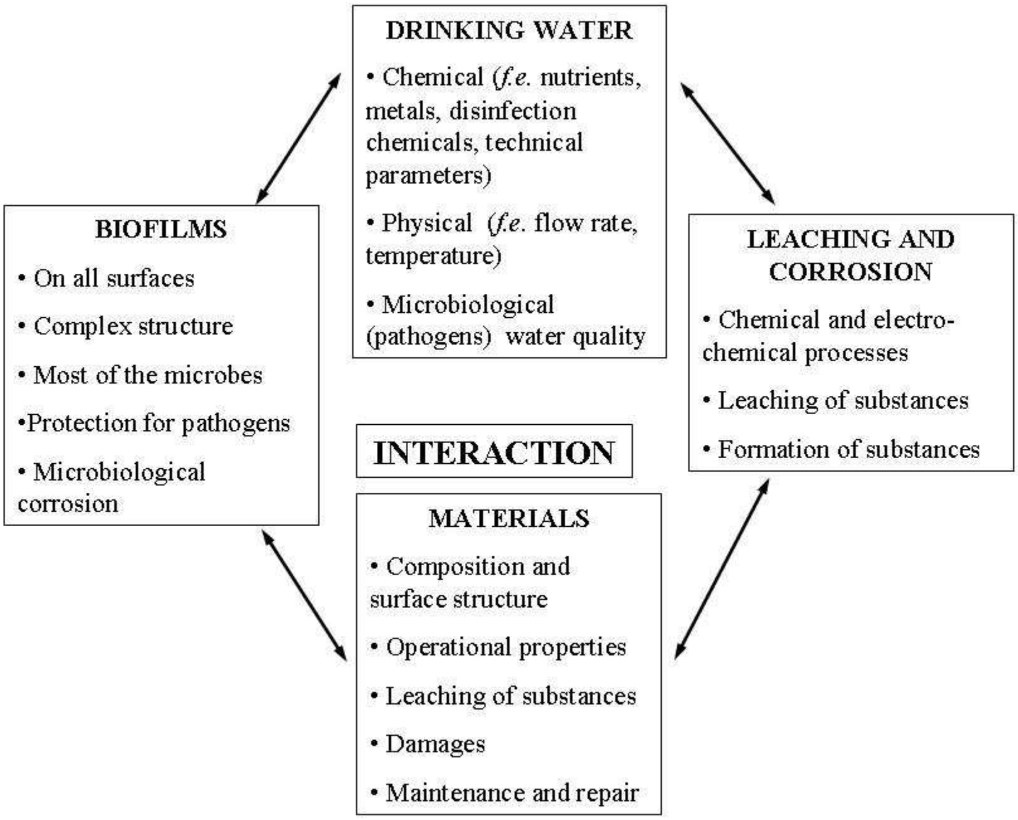

Figure 1. Interactions of drinking water and materials in contact with the water.

Information on materials and the quality of drinking water is needed in the preparatory work of the forthcoming mandatory European acceptance system for products that are in contact with drinking water, EAS (European Acceptance Scheme). The aim of EAS is to promote safer products for human health in drinking water distribution.

The aim of the studies was to gain information on a) the materials in contact with drinking water and b) the quality of drinking water in Finland. This information is needed in understanding the interactions between materials and drinking water.

METHODS

Materials in contact with drinking water in Finland

The information sources for the study on materials and their properties used in Finnish water distribution systems and water supply of buildings were scientific literature, surveys (10 companies and 48 waterworks), interviews and manufacturers'/importers' web pages. The study defines all the materials that are in contact with drinking water in Finland, their structure, composition, manufacture, use, fittings and the interaction phenomena between materials and water. Also materials in hot water systems in buildings were studied.

The waterworks that responded to the survey accounted 56 % of the water supply and 50 % of the population in Finland. Their networks consist 18 % (15 000 km) of the water distribution lines in Finland. [3]

Quality of drinking water in Finland in years 1984-2006

The drinking water quality in Finland was reviewed in the second part of the study. The study is based on published reports, surveys to waterworks (76 in number) and scientific publications containing data mostly from years 1984-2006. [4]

This study presents 72 parameters of which 48 are included in the Finnish legislation of drinking water and Drinking Water Directive (98/83/EC). The other 24 parameters are essential in estimating the technical quality of water and in the preparation work of EAS. The quality information of Finnish drinking water was compared with those obtained from Sweden and Norway.

RESULTS

Materials in contact with drinking water in Finland

The study showed that different products with different materials include pipes, fittings, valves, coatings, gaskets from the starting pipeline at the waterworks to the consumer's tap. Materials used are metallic, plastic, cementitious and rubber materials. The compositions of metallic materials are well known, since they contain metals in certain proportions. Plastics and rubbers compose of polymers and additives. In plastics, the principal group of additives is stabilisers. Also cementitious materials usually contain additives. Substances that can leach from materials altogether are mostly metals, cement or organic/inorganic additives. Nearly all of the materials that have been installed in the past are still being installed and in use. Products and their materials are in contact with drinking water for decades.

Mainly used pipe materials and their proportions (%) in our survey in distribution networks were high density polyethylene (HDPE) 28.6, ductile iron 22.5, polyvinylchloride (PVC) 17.2, grey cast iron 10.4, other plastics 9.6, low density polyethylene (LDPE) 3.2 and asbestos cement 2.8. Also steel, middle density polyethylene (MDPE) and stainless steel are in use. Materials that are no longer installed as pipe materials are grey cast iron and asbestos cement. Nowadays, practically all metallic pipes in new installations are coated, mainly with cement mortar. 15 materials that are being installed in contact with drinking water were identified as pipe, fitting or valve materials.

The main pipe materials in water supply systems in buildings in Finland are copper, galvanised steel and polyethylenes, but exact proportions are not known. The installation of galvanised steel pipes ended in the 1970's and the material was only used in cold water plumbing. Nowadays installed pipe materials are mostly copper, crosslinked polyethylene (PEX) and composites in which the material in contact with drinking water is either PEX or PE-RT (polyethylene of raised temperature resistance) (Table 1). Fittings are usually made out of brass or plastics (*e.g.* polyamide, polyacetal).

Table 1. Materials that are being installed in contact with drinking water in Finnish buildings. Coating and gasket materials are not included.

MATERIAL	**PRODUCT**			
	pipes	**fittings**	**valves**	**other**
Metals				
Galvanised steel				x
Stainless steel	x	x	x	x
Copper	x	x		
Brass		x	x	x
Aluminium				x
Ductile iron				x
Bronze			x	x
Red Brass		x	x	
Plastics				
Crosslinked polyethylene (PEX)	x			
PE-RT	x			
Glass reinforced plastic (GRP)				x
Polyamide (PA)				x
Polyacetal (POM)				x
Polyethene terephtalate (PET)				x
Polycarbonate (PC)				x
Polyphenylene oxide (PPO)				x
Polyphenylsulfone (PPSU)		x		x
Polypropylene (PP)	x	x		x
Styrene acrylonitrile (SAN)				x

There are 12 coating and gasket materials that are being installed altogether both in the distribution networks and in buildings. Usually plastic and always cementitious materials are used as coatings and rubbers mainly as gasket materials. The principal coating materials are cement-mortar (only in distribution networks), bitumen (only in distribution networks), epoxides, polyesters and polytetrafluoroethylene. Bitumen is no longer being installed into contact with drinking water. Coating is mainly used in the distribution networks. Principal gasket materials being installed in water supply systems in buildings are ethylene propylene diene monomer rubber (EPDM), fluoro rubbers, chlorobutyl rubber (CIIR), nitrile rubber (NR) and polytetrafluoroethylene (PTFE).

Quality of drinking water in Finland in years 1984-2006

The study on the quality of Finnish drinking water contained parameters requested in Drinking Water Directive and parameters important for EAS preparatory work. The parameters in the study were presented in main themes: 1) microbes, 2) nutrients, 3) metals, 4) chemicals and organic compounds, 5) non-metals, 6) parameters affecting technical quality of water and 7) radioactive compounds.

The study shows that microbes requested in the Drinking Water Directive have been adequately reported and drinking water is of high hygienic quality.

Results on microbial nutrients showed that concentrations of nitrogen compounds have been below the regulatory limit values. The amount of organic carbon is high in Finland, as the concentration of total organic carbon is generally 2 mg/l or more. The concentrations of phosphorus have not been widely reported, even though phosphorus is the microbial growth limiting factor in Finland.

The metals and non-metals requested in the Drinking Water Directive have been adequately reported and the concentrations have generally been below the regulatory limit values. However, high concentrations of iron and manganese have caused technical and aesthetical problems, which have been more obvious in well water than in water delivered by waterworks. In certain areas, fluoride concentration in water has also exceeded the limit value. Some metals such as molybdenum, zinc and tin are interesting in respect of EAS, but data available is very limited.

The technical variables of drinking water affect the corrosive properties of water and consequently the service life of distribution systems. Variables of this type are pH, alkalinity and hardness and concentrations of chloride and sulphate ions. The study showed that pH values in waterworks have been within regulatory limit values (6.5-9.5), whereas ground waters are more acidic (Figure 2). Concentrations of chloride and sulphate ions have been according to the Drinking Water Directive, and Finnish waters are soft (hardness 0.6 mmol/l). The capacity of water to resist the change of pH, alkalinity, has been low (1 mmol/l). The information available indicates that the quality of drinking water in Sweden and Norway is similar to that in Finland. According to the building regulations, the materials used in water supply systems in buildings should not lessen the quality of water for health. However, there are no specific instructions for water quality that may restrict the use of certain materials.

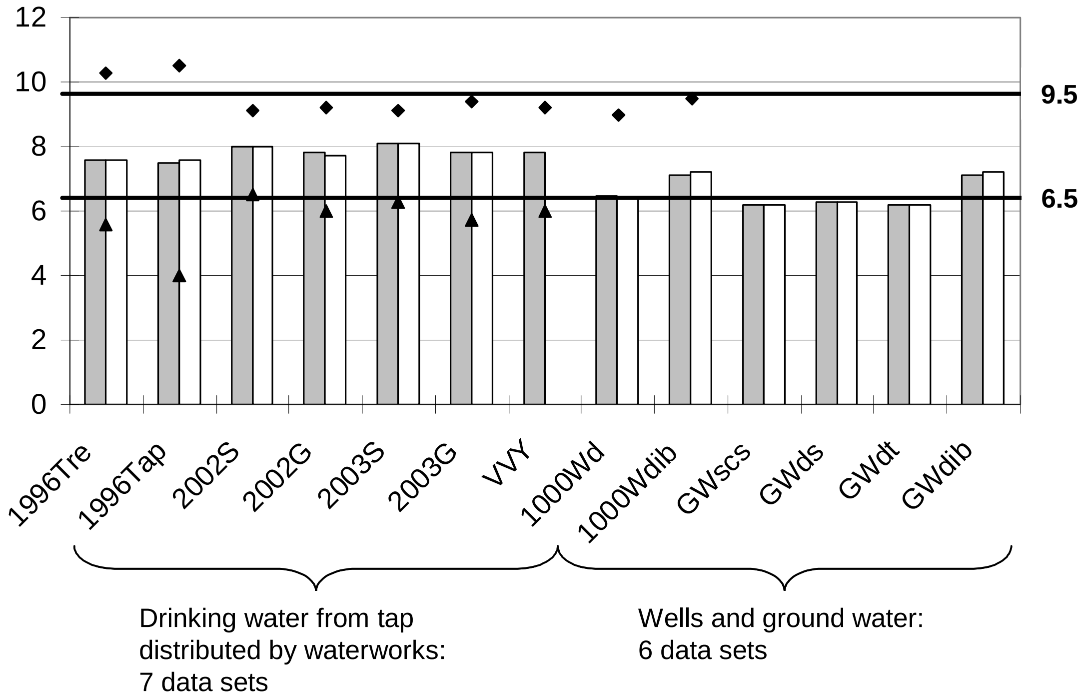

Figure 2. pH values in Finnish drinking waters from waterworks, wells and groundwater. Data originates mostly from years after year 1996. Average (grey column), medium (white column), maximum (♦ mark) and minimum are shown (▲mark). The acceptable regulatory limits are 6.5-9.5.

DISCUSSION

There are numerous different materials used in both distribution network and water supply systems in buildings in Finland. The interactions in the water supply systems in buildings are strongly dependent on the phenomena in the distribution networks. Materials used in Finnish distribution networks and water supply systems in buildings are not likely to have health effects except in some special cases. The area of the material in contact with drinking water is essential. Leaching from pipe materials can be slow, but the amount can be much higher because of the large contact area in pipes. The reactivity of the materials should also be considered. Materials with small area in contact with drinking water can leach out substances or diffuse harmful substances from outside of the system in much higher rates than pipe materials with large surface area. In buildings, the hot water systems can increase the reaction rates compared to cold water lines and the distribution network. Also the surface to volume ratio is considerably larger in the pipelines of buildings compared to distribution network.

Information on drinking water quality with health-related parameters is available and the water quality is high, whereas technical parameters are not taken into account as much. Water quality can differ dramatically within different geographical area of the country, which can influence the service life of materials used in pipes and accessories.

Still the knowledge of lifetime exposure to slow leaching of certain substances is weak. Also risks related to microbial growth and the effects of leaching substances on it need more research. Flushing of installed pipelines is essential not only from a technical aspect, but also from a health related point of view. It is necessary to remove the substances that might have leached from materials and impurities in water.

As a conclusion, the main interactions of materials and drinking water are: leaching of substances from materials, corrosion and microbial activities in biofilms. Further work within interactions of materials and drinking water will contain *e.g.* studies on a) damages of pipe materials and b) less studied water quality parameters. The information is needed whether the Finnish drinking water quality should be enhanced to be less aggressive for the materials used or should the use of materials in case of certain water quality be restricted to avoid the migration of harmful substances to water.

Seismic Protection of Fire Sprinkler and Other Mechanical Systems: Best Practices from Turkey

Eren Kalafat

SUMMARY

Earthquakes are non-predictable natural disasters. Nobody can foresee a coming earthquake and escape from its consequences. What can be done is to observe happened earthquakes, collect empirical data and analyze these data for estimating effects of future earthquakes. This is the basis for seismic protection of our living spaces.

Today engineers can design buildings depending on expected seismic forces. However, an unacceptable mistake is to neglect the importance of seismic restraint for non-structural systems. This is crucial especially for fire sprinkler pipes, fuel lines, emergency and energy systems etc. Without having a functioning mechanical and electrical system there will be no fire protection, no energy supply, no communication and no health services.

This paper includes basic information about earthquakes and examples of seismic restraint design and applications for some selected buildings in Turkey; an office, a shopping center and a residence. Followed buildings codes are IBC 2003 and Turkish Code 1997.

INTRODUCTION

The purpose of this paper is to point out the importance of seismic protection for mechanical and electrical systems in buildings and facilities. These systems are the essential bases for a building and/or facility to be functional after and sometimes even during an earthquake. There is no scientific hypothesis in this work. Instead, this work first covers basic information about earthquakes and how they affect our buildings; then shows the empirical calculations of seismic forces and a comparison between the Turkish Local Code and the International Building Code; and finally demonstrates ways to keep our mechanical and electrical systems safe. The ultimate purpose of this work is to support the awareness for importance of seismic protection for non-structural systems in buildings.

Seismic forces can be calculated thru globally accepted building codes. The most widely used building code today is IBC (International Building Code) which has joined the previous ones (UBC, BOCA etc). Except Japan, almost the rest of the world is using IBC when dealing with non-structural seismic design. The reason is that many local codes (including Turkish Code) are technically weak in terms of seismic protection for mechanical and electrical systems. Once the seismic force assumed to act on a mechanical component (piping, equipments etc) is calculated, the next step is to make the necessary precaution. This can be done either by fixing it to the structure in an experienced and accepted way or by restraining it with help of specifically designed and manufactured seismic hardware (snubber, isolator, steel cable, bracket etc). In both cases, it is a must to calculate the forces and design protection system.

EARTHQUAKES AND DAMAGES ON MECHANICAL SYSTEMS

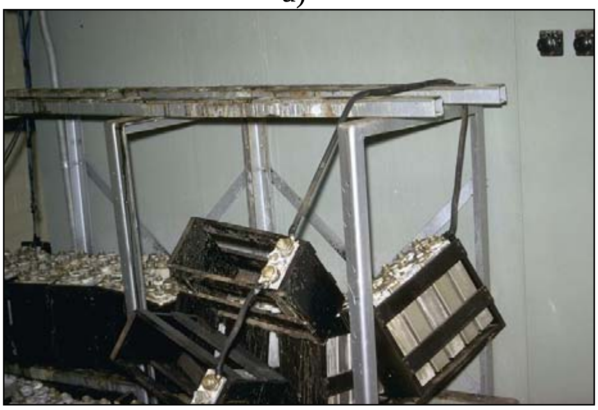
Earthquakes are non-predictable natural disasters caused by three reasons: volcanic action, collapse of an underground hole, or a ground layer motion which is called “tectonic action”. The first 2 are not as critical as the last one, since these happen seldom and affect rather smaller areas. Tectonic earthquakes, on the other hand, are more critical because of their strong and devastating effects on wide areas.

During an earthquake, a building can stand still if it has been constructed properly. But can we use that building after the earthquake? The answer of this question can only be “yes”, unless the building is still functional. This means, a building is useless without electricity, heating/air conditioning, water supply, etc. There is a more important question: How can we save lives during and right after an earthquake? Is it enough to make a building stand still after the seismic activity? What if a small fire has started? Will there be people to stop that fire? Or will we depend on our automatic fire sprinkler system to stop this little fire? What if our sprinkler piping has been damaged by the earthquake? A bunch of people will be trying to escape from the building and that small fire and/or smoke can easily cause deaths.

The above paragraph shows a very possible situation. But if we have a fire sprinkler system, strong enough to resist the seismic forces, we don’t need to be afraid of these kinds of situations. The same is for all mechanical and electrical systems. We have to consider the non-structural aspects when constructing our buildings and facilities. If we don’t, the followings can happen:

a)

b)



c)

d)

Figure 1. Examples of earthquake damages; a) A sheared pipe, b) A broken sprinkler head, c) Collapsed emergency battery racks, d) Ripped body of a chiller by the connected pipe.

BUILDING CODES AND SEISMIC FORCES

Just like the weather forecasts, seismic forces can not be known exactly. Instead, these can be calculated with empirical formulas, based on observations on past earthquakes. A very detailed formula can be found in IBC 2003 (Equation 1),

$$F_p = \frac{0{,}4\, a_p\, S_{DS}\, W_p}{\frac{R_p}{I_p}} \left(1 + 2\frac{z}{h}\right) \qquad (1)$$

where F_p is the design seismic lateral force, a_p is the component amplification factor, S_{DS} is the design spectral response acceleration at short periods, W_p is the component operating weight, R_p is the component response modification factor, I_p is the component importance factor, z is the height in structure at point of attachment of component, and h is the average roof height of structure.

The formula in the local Turkish Code 1997, on the other hand, is much less detailed, thus weak (Equation 2),

$$f_e = w_e A_0 I \left(1 + \frac{H_İ}{H_N}\right) \qquad (2)$$

where f_e is the design seismic lateral force, w_e is the component operating weight, A_0 is the ground acceleration, I is the building importance factor, $H_İ$ is the height in structure at point of attachment of component, and H_N is the average roof height of structure. In addition to this, there is a statement in the local Turkish Code to double the calculated force for fire suppression systems, emergency energy systems, and boilers of central heating systems.

Sample calculations

A sample seismic force calculation for a rigidly mounted transformer can be found below. The design lateral seismic force has been calculated both per IBC 2003 and Turkish Code 1997.

Physical characteristics of the sample equipment (same for both calculation methods):
W_p : Operating weight of the equipment (is equal w_e in Turkish Code);
taken as *5.000 kg*
z : Height in structure at point of attachment of component (is equal $H_İ$ in Turkish Code);
taken as *30 m* (assuming the *10*th floor of a building with *3 m* floor height)
h : Average roof height of structure (is equal H_N in Turkish Code)
taken as *45 m* (assuming the building has *15* floors with *3 m* floor height)

Parameters of IBC 2003 calculation (taken from tables in IBC 2003):
F_p : Design seismic lateral force; this will be the result of the calculation
a_p : Component amplification factor; taken as *1* for rigid mounted equipments
S_{DS} : Design spectral response acceleration at short periods; taken as *1,1* for Istanbul
R_p : Component response modification factor; taken as *2,5* as a moderate value
I_p : Component importance factor; taken as *1* for non-critical equipments

$$F_p = \frac{0{,}4\, a_p\, S_{DS}\, W_p}{\frac{R_p}{I_p}}\left(1+2\frac{z}{h}\right) = \frac{0{,}4\cdot 1\cdot 1{,}1\cdot 5.000}{\frac{2{,}5}{1}}\left(1+2\cdot\frac{30}{45}\right) = 2.053\, kgf$$

Parameters of Turkish Code 1997:
f_e : Design seismic lateral force; this will be the result of the calculation
A_0 : Ground acceleration; taken as *0,4* for Istanbul
I : Building importance factor; taken as *1* for non-critical buildings

$$f_e = w_e A_0 I\left(1+\frac{H_i}{H_N}\right) = 5.000\cdot 0{,}4\cdot 1\cdot\left(1+\frac{30}{45}\right) = 3.333\, kgf$$

Assuming a circulation pump with the same physical characteristics of the sample transformer is vibration isolated. In this case, the result of Turkish Code does not change, whereas the result of IBC multiplies by *2,5* since we have to take the a_p value as *2,5* for vibration isolated equipments.

Assuming a fire pump with the same physical characteristics of the sample transformer, which shouldn't be vibration isolated. This time we come up with *3.080 kgf* in IBC, since we have to take the I_p value as *1,5* for life safety equipments. On the other hand, the result is *6.666 kgf* in Turkish Code, since the Turkish Code says double the force for life safety equipments.

Table 1. Seismic force comparisons between IBC 2003 and Turkish Code 1997.

NON-STRUCTURAL EQUIPMENT	**Seismic Force (kgf) Per *IBC 2003***	**Seismic Force (kgf) per *Turkish Code 1997***
Transformer (non isolated)	2.053	3.333
Circulation pump (vibration isolated)	5.133	3.333
Fire pump (non isolated)	3.080	6.666

As seen in the above sample calculations, IBC 2003 gives more accurate results compared to Turkish Code 1997. The reason is that, there are more parameters in the IBC formula. It is obvious that a less detailed formula will give less detailed results. This, at the end will give either too low or too high results.

SEISMIC RESTRAINT DESIGN

Seismic restraint design for mechanical systems can be split into 2 groups:
1) Floor mounted, suspended or wall mounted equipments.
2) Suspended pipes, ducts, electrical cable trays etc.

Floor mounted equipments can either be rigidly mounted to the floor or to concrete pads or they can be mounted on vibration isolators with snubbers or directly on seismic isolators. If there is a need for vibration isolation (for a chiller for instance), rigid mounting cannot be done. If the equipment needs to be restrained, it is less expensive to use seismic isolators instead of using 2 different hardware, open springs and snubbers. Suspended equipments can also either be rigidly restrained if there is no need for vibration isolation or they can be hanged with vibration hangers and also restrained with seismic cables. Wall mounted equipments rarely need vibration isolation. Thus it is enough to rigidly mount them to the wall with anchors strong enough to resist the calculated seismic force.

Suspended pipes, ducts and electrical cable trays are critical, since those are subject to sway and damage both themselves and other systems close to them. Therefore, it is a must to brace these systems. The bracing (called seismic bracing, sway bracing or cable bracing) is a matter of design. The non-structural seismic engineer has to determine the points of bracing on a layout drawing. Many building codes (including IBC) and standards (including SMACNA) directs to put lateral bracing at each 12 meters and longitudinal bracing at each 24 meters. However, depending on the installation conditions, these distances can be less. In other words, seismic cable bracing points must be determined depending on seismic calculations.

Figure 2 shows a general concept of determining the cable bracing points on a pipe/duct/ electrical cable tray layout system. It also shows an alternate way of bracing (45° angles) instead of having lateral (transverse) and longitudinal braces separately. The installation details of seismic cables can be seen in Figure 3.

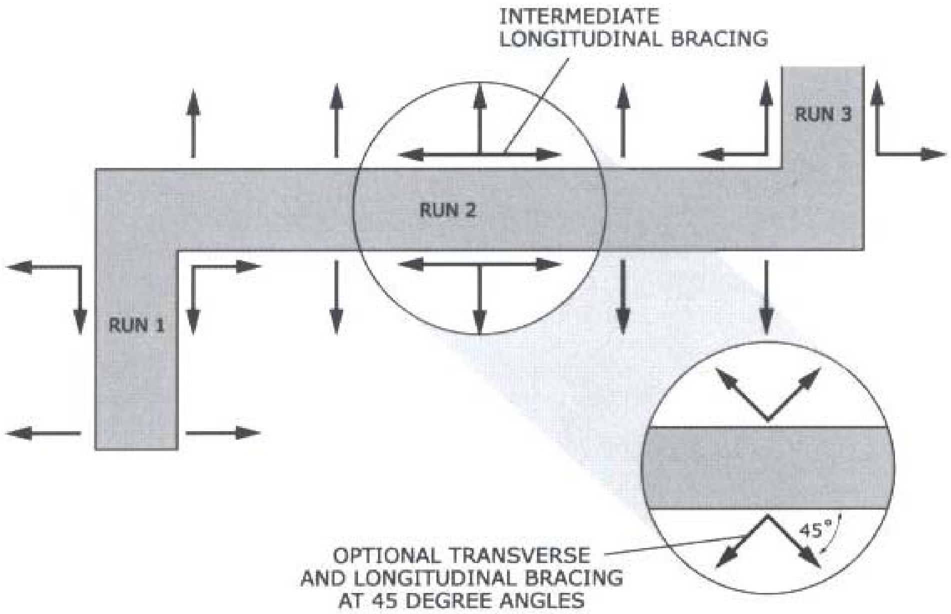


Figure 2. Seismic cable bracing for suspended pipe/duct/electrical cable tray lines.

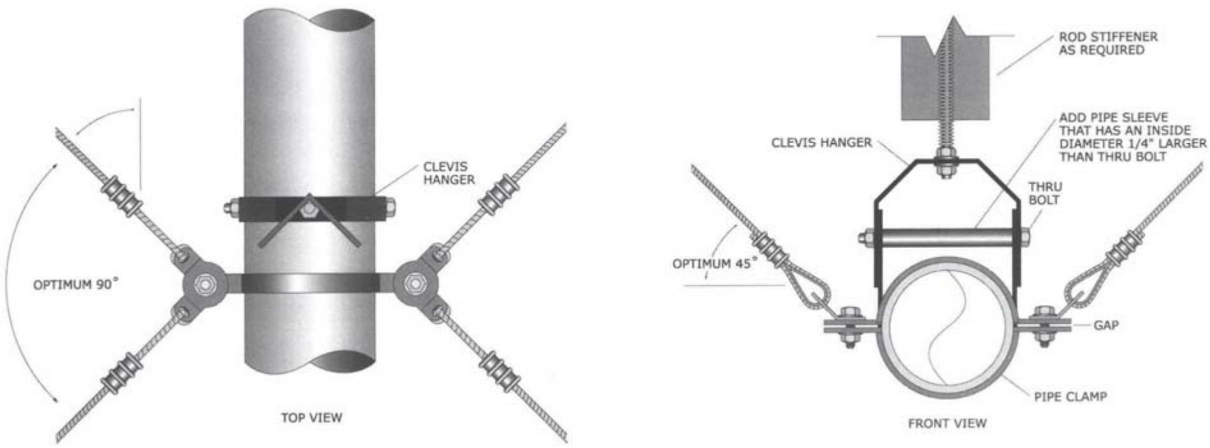

Figure 3. Seismic cable bracing details for suspended pipes.

SEISMIC RESTRAINT APPLICATIONS FROM TURKEY

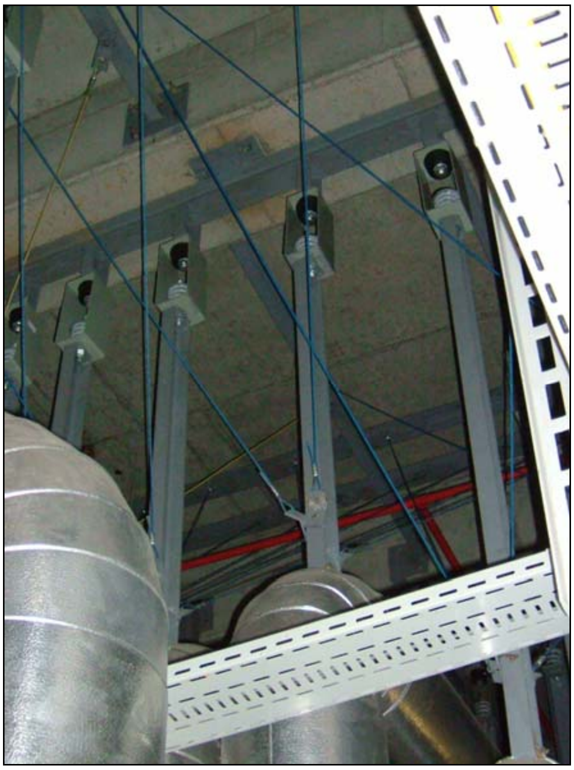
Tekfen Tower – Office Building: This is a 32 floor high class office building. The main HVAC equipments are located on top of the building right over a VIP office floor. This made it difficult to avoid vibration and noise. In order to achieve this, all equipments have been vibration isolated by using seismic isolators (Figure 4) and all pipe supports have been installed with vibration hangers and seismic cables (Figure 5).

a)

b)

Figure 4. Applications of seismic isolators in Tekfen Tower for; a) Pumps, b) Boilers.

a)



b)

Figure 5. Applications of seismic cables and vibration hangers in Tekfen Tower.

Kanyon Levent – Shopping Center: This is a building complex of shopping center, office tower and residence blocks. The main HVAC equipments have been vibration isolated with seismic isolators (Figures 6a) and pipes have been braced with seismic cables (Figure 6b).

a) b)

Figure 6. Applications of seismic isolators (a) and seismic cables (b) in Kanyon Levent

Sisli Plaza – Residence Tower: This is a premium class residence tower. All main HVAC equipments have been vibration isolated with seismic isolators and pipes have been braced with seismic cables. A seismic brace layout drawing of fire sprinkler system is shown in Figure 7.

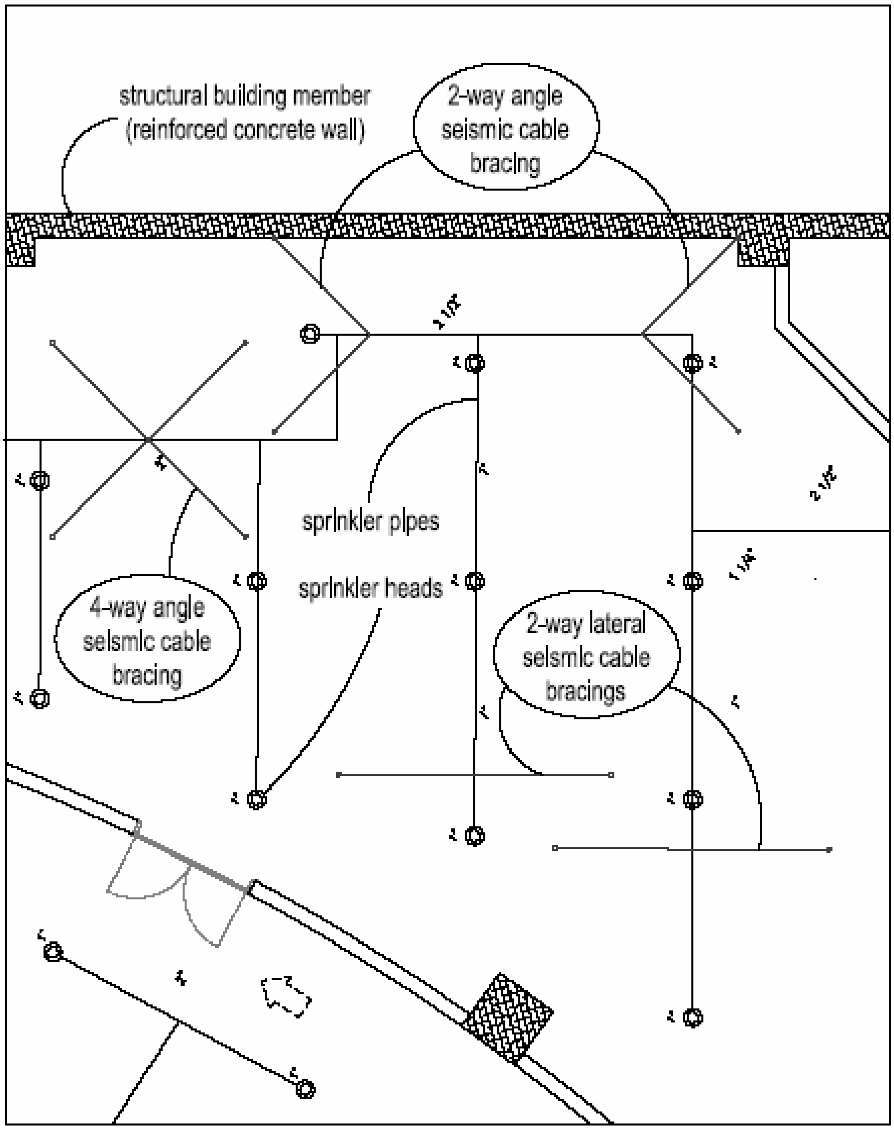


Figure 7. Seismic cable bracing layout drawing for Sisli Plaza Residence.

CONCLUSION

Seismic protection of mechanical and electrical systems in our buildings and facilities is crucial in terms of human life safety in the first place and also minimizing the costly damages. It is a matter of non-structural seismic engineering, which must be done by following the local and international building codes. It should also be done by professional non-structural seismic engineers. Finally, a necessity is to use certified seismic products only. These are the guidelines for the construction industry including the project owners, designers and consultants, contractors, control engineers and all other decision makers.

This issue is also very important for the code writers including government officials, university professors and managers of non-profit organizations. The weaknesses in local codes (for instance the Turkish Local Code) in terms of non-structural seismic protection must be taken into consideration carefully. Necessary precautions should be determined in the local codes and standards. As for Turkish code writers, the global level of awareness for seismic protection of non-structural systems should be reached.

ACKNOWLEDGEMENTS

Many thanks to my father Ceyhan Kalafat, PM of Tekfen Tower, for giving me my first job; my ex-boss Olgun Sonmez and Werner Stebner, VP of Amber/Booth, for opening me a door in seismic world; Robert E. Simmons for my training, to my colleagues Sarper Arun, Erkan Selek, Murat Kantarci, Okan Sever and others for being in my team; Prof. Mustafa Erdik, Prof. Abdurrahman Kilic and Prof. Ahmet Arisoy for their academic support; Celal Okutan, the founder of TTMD, and all other TTMD and MMO workers for their support.

Heat recovery from raw sewage - An alternative for thermal energy supply in cities

Urs Studer

Rabtherm AG, Switzerland

Corresponding email: info@rabtherm.com

THE IDEA

- It is high time that we start recovering and re-using waste heat from industry and households. On a comprehensive view, waste heat could cover at least 30 % of our heating and cooling energy requirements. Today heat is being recovered from exhaust air and used on a very large scale. In many countries this is even governed by regulations. But what happens to waste water? Out of sight, out of mind.
- This was the starting point of the idea to utilize these resources, an idea resulting in the Rabtherm® Energy System. RABTHERM stands for heat recovery and utilization from untreated waste water. On leaving a house, the sewage has an average temperature of over 25°C and in the sewage system an annual mean of 15°C (summer 20°C, winter 10-12°C). Sewage is a continuously renewed source on a relatively high temperature level. With modern heat pumps one can transform this to a useful temperature of 65°C, high enough for hot water production and for the heating of newly constructed houses → heat pump COP's between 3.1 and 5.2, in special cases up to 6.2.
- The heat present in the waste water from residential buildings, trade and industry should therefore be utilized decentrally, i.e. locally, where it is generated, with a heat exchanger in the sewers and a heat pump. The temperature level is higher than that of most of the other natural renewable energy sources. The system can be used for heating and hot water in winter, and for cooling (air conditioning) and hot water in summer.
- The idea is not new but so far heat has been extracted practically only from purified waste water downstream of sewage works. However, since many sewage works lie at the periphery or outside residential areas, with large distances to the heat consumers, this strategy is uneconomic.
- Previous obstacles to the utilization of untreated water directly in the sewage system have been:
  - possible detriment to the biological purification stage in the sewage works, which are designed for a temperature of 8-13°C.
  - lack of a suitable heat exchangers which when installed in the drain channel, cannot lead to blockages.
  - → Today, these problems have been technically and economically solved, and the system is accepted by the authorities, i.e. Rabtherm®can now be marketed. The maximum cooling of the entire waste water on the way to the sewage works will in no case exceed 0.5 K.
- Contamination of the sewage channel and therefore the heat exchanger leads to a decrease in heat exchanger efficiency of up to 40%. (soiling with biomass film) Patented systems to solve this problem.

THE DEVELOPMENT

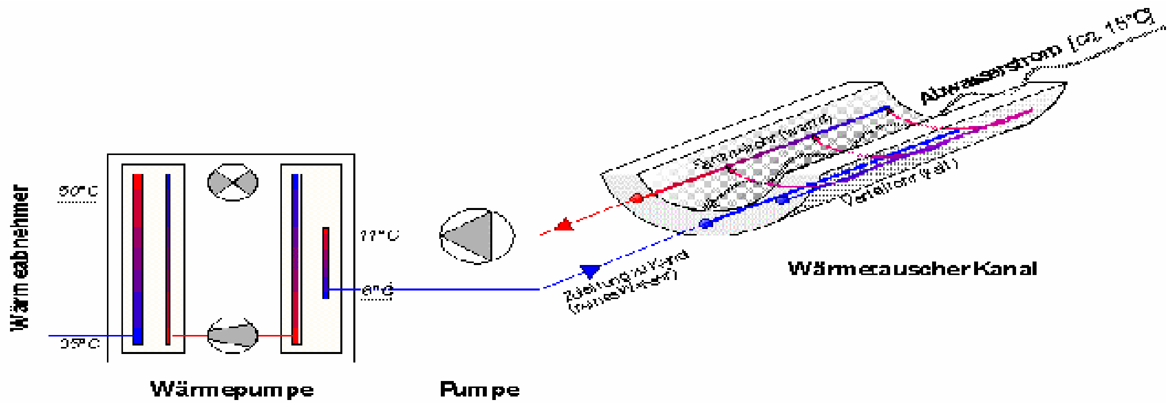
- The idea now had to be developed and brought to market in an economic manner.
- For this purpose, a trend analysis was required, e.g.
  - what is demanded by the energy market?
    → economical and/or ecological products
  - how are other technologies developing?
  - how fast is the political situation changing? (climatic changes, CO_2, fine dust)

  The trends were quite clear .
  - Electricity prices will drop .
  - Oil and gas prices have a tendency to rise .
  - Energy price surcharges or eco-taxes cannot be avoided sooner or later
- The expected result of the development process was that the local, decentralized utilization of the continuously available, renewable ambient energy by means of Rabtherm systems is
  - economic and
  - ecological / environmentally friendly.
- The goal was to develop a simple, robust and low-cost system. This required special efforts in the following areas:
  - Hydraulics, heat transfer
  - Materials
  - Joining technique
  - Design, installation

  The above objective has been achieved and led to patents. The know-how gained during this process represents a decisive lead over any competition.

THE PRODUCT (TECHNOLOGY)

- Working principle of the Rabtherm waste heat utilization system



Wärmeabnehmer .... user
Wärmepumpe .... heat pump
Pumpe .... circulation pump
Wärmetauscher Kanal .... heat exchanger sewage channel
Zuleitung zu Kanal (reines Wasser) .... connecting pipes (tap water)
Verteilrohr (kalt) .... distribution pipe (cold)
Sammelrohr (warm) .... collection pipe (hot)
Abwasserstrom [ca. 15°C] .... sewage

In the heat exchanger heat is extracted from the waste water and fed to the heat pump via the intermediate medium. The latter (pure water), circulating between heat pump (heat generation) and heat exchanger (heat utilization, heat extraction), is fed through the plastic pipe to the heat exchanger at the start of the cycle. The distributor pipe individually feeds each of the 1 to 3 m long heat exchangers. The intermediate medium warmed in the heat exchangers is then collected in the collector pipe and returned to the heat pump.

For summer cooling, the heat pump is hydraulically reversed, using the waste water as heat dump.

preassembled Rabtherm® - heat exchanger elements

- The specific extraction power of the heat exchanger is approx. 2-9 kW per metre heat exchanger (depending on the sewage flow rate, the flow speed or gradient and the degree of contamination). This rate can increase to 15 kW with pressure pipes. From 1 m3 of waste water (the contents of 5 bathtubs), the heat exchanger can extract 2-3 kWh of energy.
- Criteria for the application of Rabtherm systems.
  - sewage channel diameter > 400 to 500 mm
  - sewage flow average rate > 12 l/s
  - length of heat exchangers 9 m (min.) to 200 m (max.)
  - heating or cooling power output min. 80 kW
  - distance from sewage channel to user max. 150-300 m
  - heating temperature max. 70°C
- The heat exchanger is cemented into the sewage channel and is designed for a service life of at least 50 years.
  Corrosion, erosion / wear, leak tightness, channel maintenance and cleaning are some of the factors that because of the strict quality assurance criteria, had a decisive influence on choice of material, design, product (welding) and assembly / installation. Parallel to quality assurance, all possible damage repair scenarios have been established following the principles of "analysis-find-repair".
- The maintenance of the sewage channels with the integral heat exchanger requires no special effort. Blockage of the channels is impossible and they are cleaned with conventional equipment. The heat exchanger is dimensioned to withstand this treatment

Rabtherm Wülflingen (CH).

Trockenwetterrinnen Rabtherm Leverkusen (D) Dry weather channels.

THE MARKET

- After it had been recognized and proved that the system
  - makes good sense energetically, inasmuch as it has already been included in many urban energy plans
  - is economically feasible, in contrast to many other forms of alternative energy
  - brings ecological benefits with comparable or lower energy production costs than with energy from fossil fuels the question of markets and customers was considered.
- Who is interested in Rabtherm?
  - The heat consumer (user)
    . Rabtherm replaces the conventional heat energy supply with gas or oil by an environmental superior technology utilizing the waste heat from households that generates heat at economically comparable prices
    . The customer gets the same benefits (heat) at a comparable or better price, but in an ecological manner.
  - Who are the consumers?
    . Towns and cities with roughly 5'000 inhabitants upwards.
    . Communal co-operatives and consortia
    . Industrial enterprises with a significant fraction of consumption for space heating
    . Private building owners
    . The public sector
      . Rabtherm helps the public sector to
      . improve ecobalances
      . achieve energy policy goals
      . guarantee security of energy supply.
      → To supply 100 apartments with heat from waste water, the effluent from 300 apartments plus trade and infrastructure is required. To generate one kWh of heat, about 420 litres of waste water are needed.
      . Employment.
      . Rabtherm can generate around 30'000 man-years of work (up to 3'000 jobs).
- Who are our partners in the market?
  - Consulting engineers for the acquisition, study and planning of installations

   – Contractors for the installation, maintenance and operation of installations. Contractors are e.g.
      . Electricity utilities .
      . Municipal works .
      . Industrial enterprises

Contractors finance the construction of the installations and sell the energy generated. Electricity utilities and municipal works are highly interested in this lucrative second or additional source of income.

- What does Rabtherm cost?
   – Installations
      . CHF 1'800.00 - 2'500.00 per connected residential unit (€ 1170-1620)
      . CHF 500.00 -700.00 per kW of connected useful power (€ 325-455)
   – Heat exchangers
      . CHF 1'600.00 - 2'100.00 per m of heat exchanger (€1070-1360) .
      . The heat exchanger as an element, uninstalled, costs approx. 6-10% of the overall installation.
   – A sensitivity analysis predicts with high probability an improvement of profitability by over
   – 20%, influenced by
      . the price of electricity
      . the price of oil
      . investment costs
      . technological improvements (heat pump)

- How and where will Rabtherm® be employed?
   – The Rabtherm technology should be examined in the case of
      . renovation of large sewage channels .
      . renovation of large central heating or cooling works .
      . new sewage channels .
      . larger central heating or/and cooling works in the vicinity of larger sewage channels
- Market potential
   – Towns and cities
   – over 500'000 inhabitants 60 to 120
   – 200-500'000 inhabitants 27-60, equal to approx. 12'000 apartments
   – 100-200'000 inhabitants 20-27
   – 40-100'000 inhabitants 12-20
   – 15-40'000 inhabitants 5-12
   – 5-15'000 inhabitants 1- 5
      . Switzerland 2500
      . Germany 25000
      . Europe 120000
      . world 400000
- Existing and running installations 17 in Switzerland, Germany, Austria
- Installations in building or planning stadium over 100 in Switzerland, Germany, Austria, France, Ukraine, USA

ECOLOGY

- Rabtherm installations reduce the CO2 emissions over those from conventional plant by 50-80% (ecological benefit)Rabtherm installations reduce also the amount of primary / conventional energy.
- CO_2-output with the 17 running plants is reduced by 6000 tons.
- Rabtherm systems produce no fine dust like diesel engines and wood burning plants.

WHAT IS THE PRACTICAL SEQUENCE OF EVENTS IN THE PLANNING OF A HEAT UTILIZATION SYSTEM FROM UNTREATED SEWAGE?

- By means of a check list, a site can be roughly assessed for acceptance or rejection.
- Next the following procedure is scheduled .
  - Fundamental decision by the
    . sewage channel operator
    . sewage works operator
    . community
  - Analysis, site or feasibility study with data on the drainage system and heating furnaces. The studies contain the results of the local examination of sewage channel data (incl. condition) and furnace data, calculations of heating power and profitability, and cost estimates for the investments.
  - Clarification with the users or those to be connected .
  - Project with consulting engineers and contractor .
  - Execution and operation by contractors under long-term heat supply contracts.

Even with generally sinking heat demand, the Rabtherm technology, used in the district heating networks of city agglomerations, has an excellent chance of success, also in towns with an existing remote heating network.

ASSESSMENT / CONCLUSIONS

- The success of waste heat utilization from the public sewer system is based upon the following corner-stones

1. Profitability
2. Financing
3. Public interest
4. Ecology

- Profitability .
  - The heat production costs with a Rabtherm system are 5-20% lower than for conventionally generated heat.
  - The profitability increases when the installations are used in summer for cooling
  - Financing . by contracting
  - Public interest

  - Compliance with goals of energy and environmental policies
  - Creation of jobs
- Rabtherm Systems have an excellent outlook Future R&D can bring another 30% of improvement in quality, price and economy

Low energy cooling

Simulation And Optimization of a Solar Absorption Cooling System Using Evacuated Tube Collectors

Jean Philippe Praene, Alain Bastide, Franck Lucas, François Garde and Harry Boyer

Université de la Réunion, France

Corresponding email: praene@univ-reunion.fr

SUMMARY

Summer air conditioning represents a growing market in commercial and residential buildings. Solar energy is a very interesting energy source because of its advantages. Instead of a compressor system, which uses electricity, an absorption cooling system needs only heat produced by a solar collector plant. Furthermore, Reunion Island has a high solar energy potential. The yearly average solar-radiation and is 5.4 kWh/m²/day. This paper presents a solar-powered, single stage, absorption cooling system, using a water–lithium bromide solution. The first part of this work deals with the dynamic modeling of an evacuated tube collector used for the simulation of heat production. In a second part, simulation and optimization of the system has been investigated in order to determine the optimum of solar collector plant surface, storage tank volume and nominal capacity of the absorption chiller. A new building code was added under TRNSYS16, to have dynamic coupling between building loads and cooling production.

INTRODUCTION

Reunion Island is a French overseas department located in the southern hemisphere characterized by a tropical humid climate. Conventional energy will not be enough to meet the continuously increasing need for energy in the future. In this case, renewable energy sources will become important. Solar energy is a very important energy source because of its advantages (insulation > 5 kWh/m²/day in Reunion Island). Of share our insularity an orientation towards renewable energies is today a perennial solution to obtain certain energy independence, cf. Figure 1.

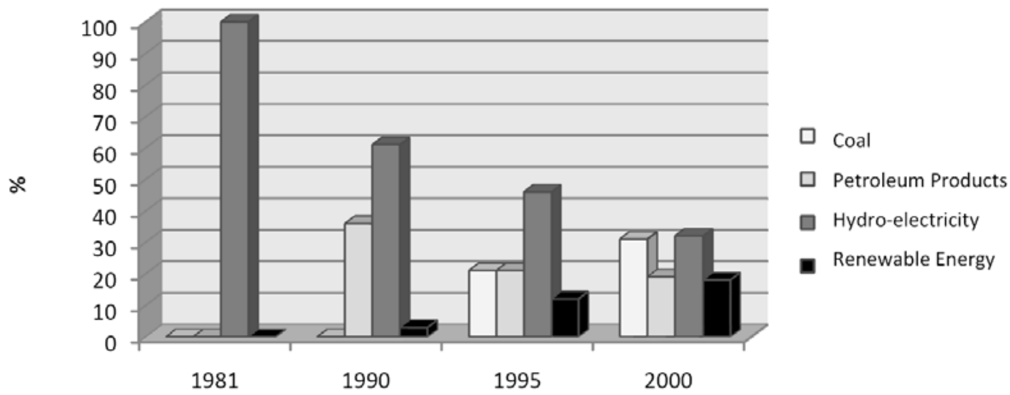

Figure 1. Evolution of the repartition of energy production in Reunion.

The building remains at the present time the most consuming sector in electricity. Under our latitudes, one of the most important demands for electricity relates to the air-conditioning of the buildings during the summer (period active of November 1 to April 30). Thus solar cooling system are particularly interesting as it is an application in which the demand for cooling energy closely matches the availability of solar energy, both in seasonal and the daily variations. One of the many categories of solar cooling systems is the solar absorption cooling. As no CFCs are used, absorption systems are friendlier to the environment. The possibility of cooling system using solar energy was initiated by the technological developments in the solar field, [1]. Absorption air-conditioning systems are similar to vapor compression air-conditioning systems, but differ in the pressurization stages. In general an absorbent in the low pressure side absorbs an evaporating refrigerant (H_2O). The most usual combinations of chemical fluids used include lithium bromide–water ($LiBr–H_2O$), where water vapor is the refrigerant, and ammonia–water ($NH_3–H_2O$) system where ammonia is the refrigerant, [2]. The electric quantity of power consumed by the pump is almost negligible. One needs nevertheless a contribution of heat, cf. Figure 2.

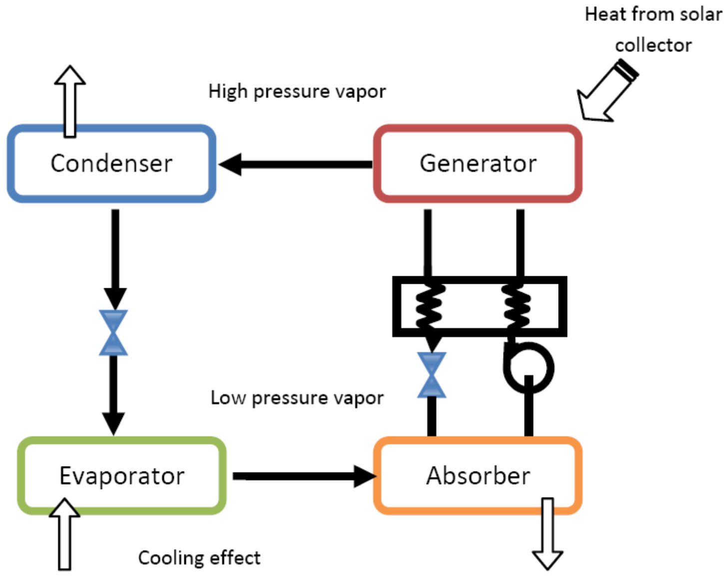

Figure 2. The basic principle of the absorption cooling system.

The single effect absorption chillers require for their operation a hot water temperature on the level of the generator of 80°C - 150 °C. Moreover, the temperature of cooling water must lie between 7°C and 43°C, [2]. The higher limit is founded in order to limit the differences in pressure between the generator and the absorber and the condenser and the evaporator. The lower limit makes it possible to avoid the crystallization of lithium bromide which is carried out at low temperature.

An European research program, IEA Task 25, was set up in 1998, in order to study these installations. Two approaches are classically used within the framework of this working group. The first consists of the establishment of real pilots, one counts at the present time an about sixty systems installed,[3]. The second consists to simulate and optimize existing or future systems via various codes. It is within the framework of second axis that this article is registered. The objective of this present work is to model the behaviour of the future installation at the Civil Engineering Department. Solar collectors represent the heart of the performances and the investments (~ 57%) of the installation. Thus, a good prediction of the performances of the solar loop is particularly judicious. The first part of this study was first interested in the dynamic modeling of the solar collectors. Then a coupling between the various components under TRNSYS has been investigate.

METHODS

There are three types of solar collectors which can be used within the framework of solar cooling: flat-plate, parabolic and vacuum collectors. Necessary heat for absorption chiller will be produced by evacuated tube collector. The literature contain numerous works on the modeling of solar collectors. These models developed have different levels of complexity. Usually, solar collectors are described by stationary models, considering the collector working under steady-state conditions. These approach are generally based on the work of Klein, [4].

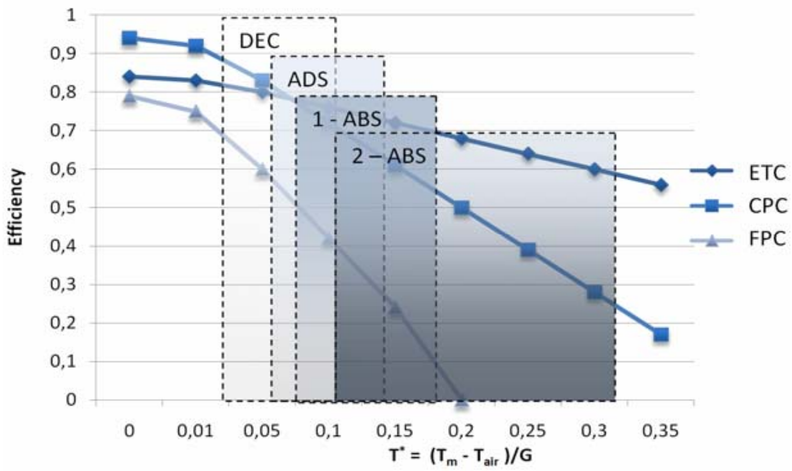

Figure 3. Comparison of Evacuated tube / compound parabolic / flat-plate collector for Desiccant / Adsorption / Absorption cooling systems.

A dynamic approach is more interesting in several cases: control strategies, dynamic testing procedures, coupling with others elements, particularly, in predicting the behaviour of collectors for short time step. The model developed corresponds to direct flow collector. The starting point of the model is a mathematical description proposed by Kamminga, [5]. The model consists of three nodes corresponding to the fluid, the absorber plate and the transparent glass cover. It is considered that the temperature of the fluid is a function of x. The fluid is moving in a single channel with the velocity u, along x-axis, see Figure 4.

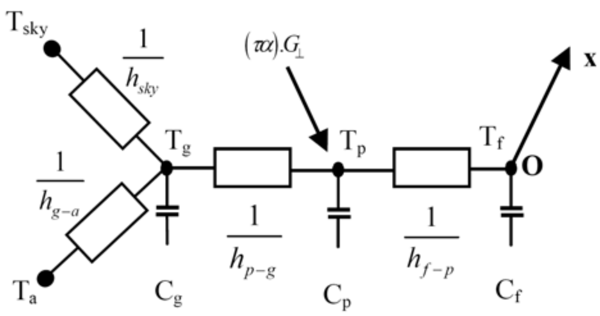

Figure 4. Thermal networks of the ETC model

The details of the model developed and elements of validation associated have been previously described by Praëne, [6]. A comparison between model forecast and measurements is presented in Figure 5. The simulation is carried out at the minute time step. A new type has been created under TRNSYS, in order to coupling with the rest of the solar cooling system.

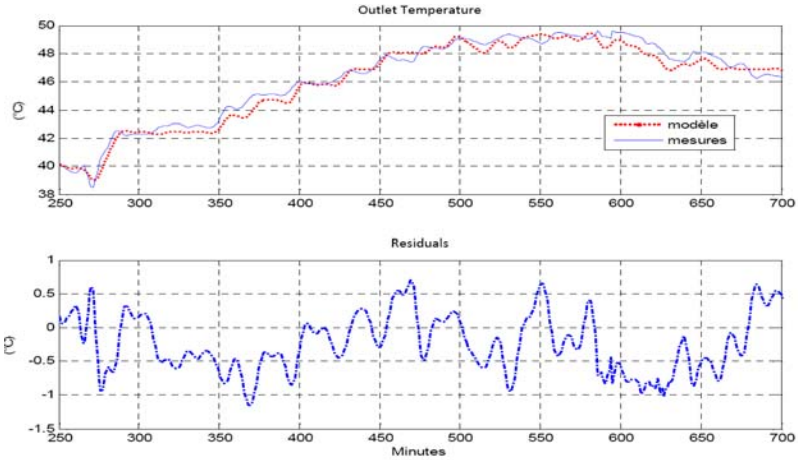

Figure 5. Simulation of the outlet temperature of the solar collector model.

The thermal behavior of the building was initially simulate over a whole year in order to observe cooling period. We used for that CODYRUN, [7], a thermal building code translated under TRNSYS to replace the TYPE56, this code has good accuracy for short time step. We evaluated over one year the level of comfort inside the classrooms and the building load to calibrate the absorption chiller refrigerating power.
We first simulate the evolution the inside classroom air temperature under natural ventilation during one year. The first condition of comfort is fixed for a temperature lower than 25°C. The graphic at Figure 6 shows that period spreading out May to October offers conditions of comfort. This period approximately corresponds to the southern winter.

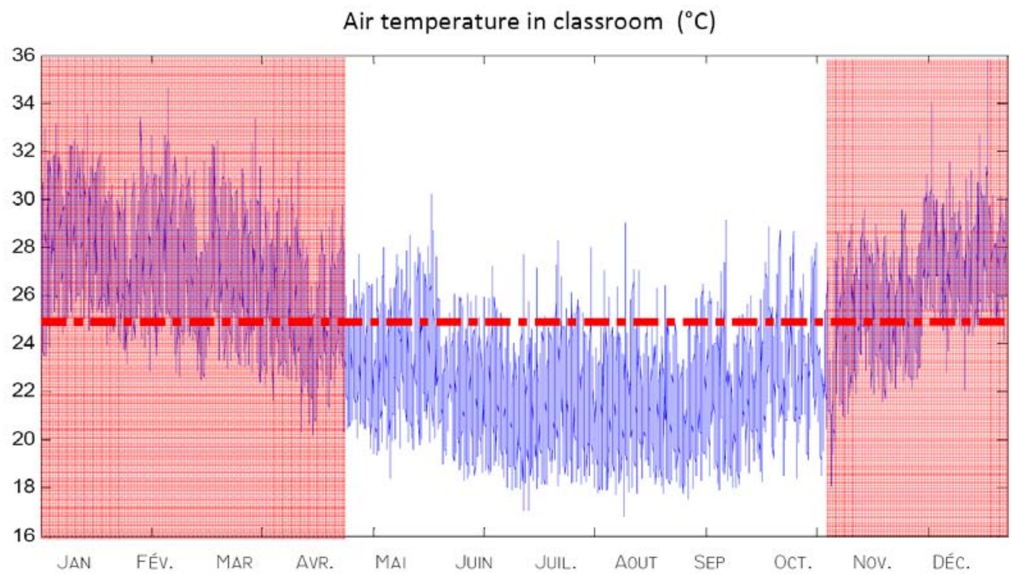

Figure 6. Yearly evolution of air temperature in classroom.

Many researches were carried out by the researchers in order to create simplified tools of indication of comfort, [8], [9]. We were thus based on the computation results of these indices of comfort within the framework of our simulations over the past year, in order to determine the building loads in relation to the indices of comfort. The starting point for the definition of the levels of comfort is based on the value recommended of PMV* (Predicted Mean Vote). That involves values of $-0.5 < PMV^* < +0.5$. In what concerns us, one is interested only in the positive part of this equation, which accounts for the requirements in air-conditioning. The evolution of the PMV*, according to Figure 7, comes well to confirm the zone of natural comfort which one has on the level of the building. This indices is particularly interesting because it considered the influence of air temperature and relative humidity.

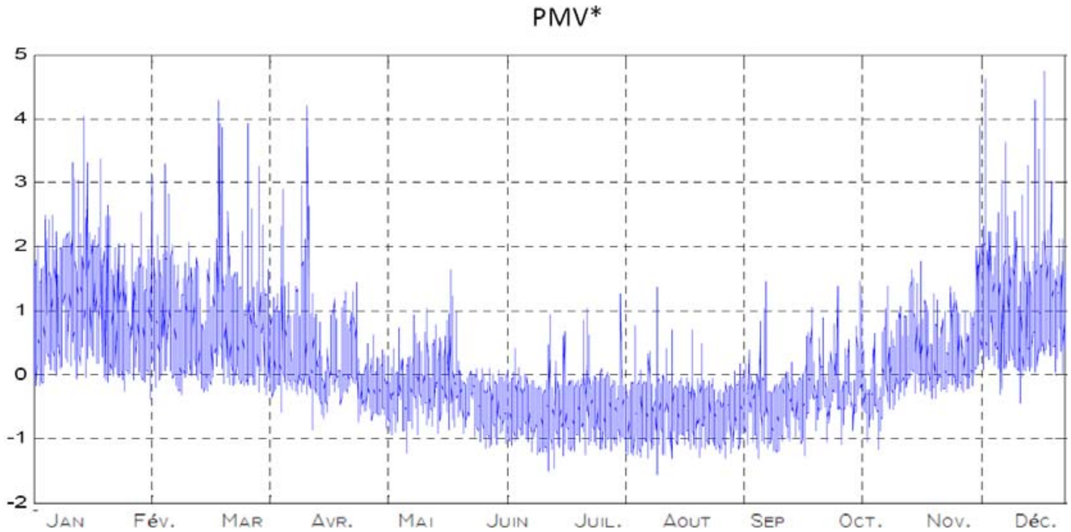

Figure 7. Yearly evolution of PMV* inside the classroom in natural ventilation condition.

The period from November to April corresponds to the period with maximum needs of solar cooling system. In order to evaluate the building, a sequence of January has been used. An air temperature of 25°C and humidity of 55% are fixed as comfort criteria to dimensioning the air-conditioning system, cf. Figure 8.

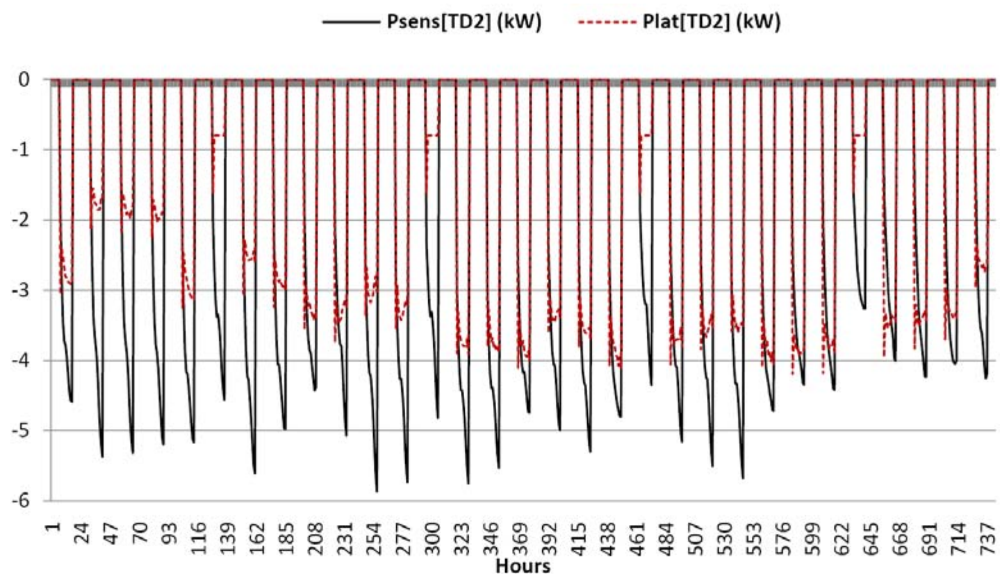

Figure 8. Sensible and latent power called by the classroom TD2 during January.

The maximum cold power called y the building is 9.5 kWf. This peak occurs after midday that is due to the accumulation of the walls inertia of the building and consequently restitution of this heat. Thus, for the four classrooms of the Civil Engineering Department, an absorption chiller of 35 kWf is necessary.

RESULTS AND DISCUSSION

This section presents the principal results obtain under TRNSYS16 for simulation of the global solar absorption cooling system. This program consists of the use of several "subroutines" which represents the components of the system described by ordinary or algebraic equations. Two types were added to the models existing under TRNSYS. It is about the model of simulation of the building and the model of vacuum collector. The useful surface area of collector used during simulation is 60 m ². The storage of hot water uses Type 38. That corresponds to a vertical roll of 800 L made up of copper insulated thermically with polyurethane. We consider a use of the machine with absorption without additional contribution of a contribution of auxiliary heat. We chose a sequence of January, to carry out our simulation, see Figure 9.

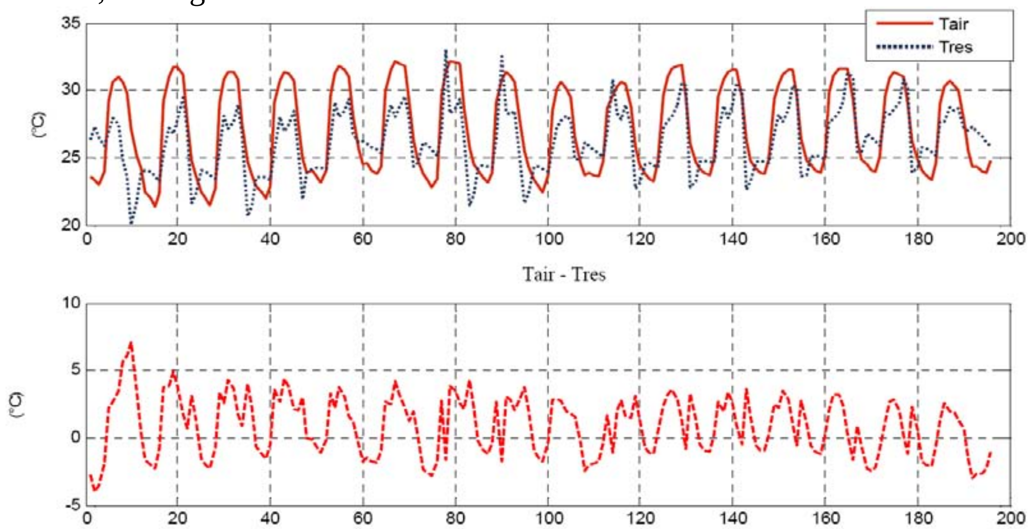

Figure 9. Comparison between resultant temperature (Tres) in classroom and outside temperature (Tair).

The average temperature in classroom is 27°C during the day. There is difference about 4°C between inside and outside air temperature.

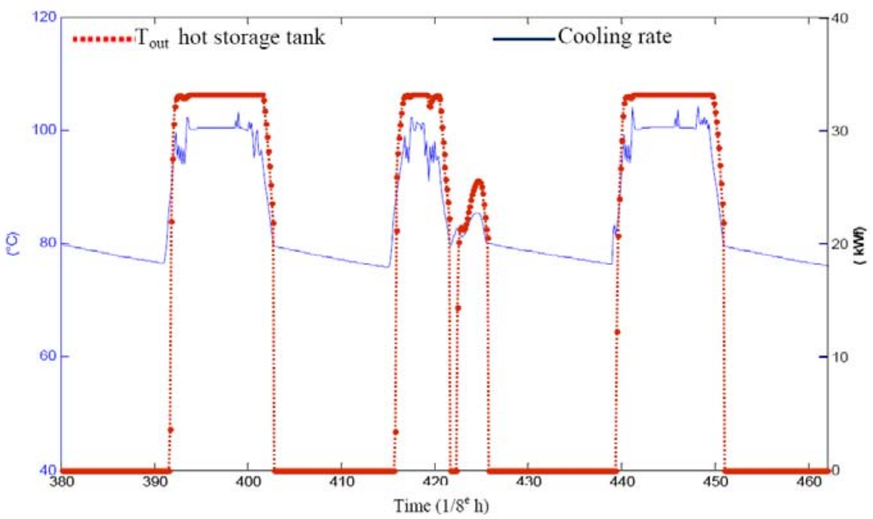

Figure 10. Evolution of cooling rate of the absorption chiller and outlet temperature of hot water storage tank.

The absorption chiller works without additional contribution of a contribution of auxiliary heat. As we can see on Figure 10, the 60 m² of ETC is enough to meet the minimum temperature of 80°C for the generator.
One of the most important points from an economic point of view of a solar cooling plant is the solar loop. The field of solar collectors accounts for approximately 60% of the total investment (in particular if it is vacuum collector). So it is important to dimension in a first place the needs for the building then the total surface of the field of solar collectors. Three points go in general to the decision of the field of solar collectors:
Ec onomic constraint: Budget dedicated to the project
Spa ce constraint: surface available for the solar field
Weather constraint: averag e numbers of good days during the hot period.
Also, it is important to quantify the influence of the elements of the solar loop, of as much we are in the case of an operation of solar cooling, without auxiliary contribution.

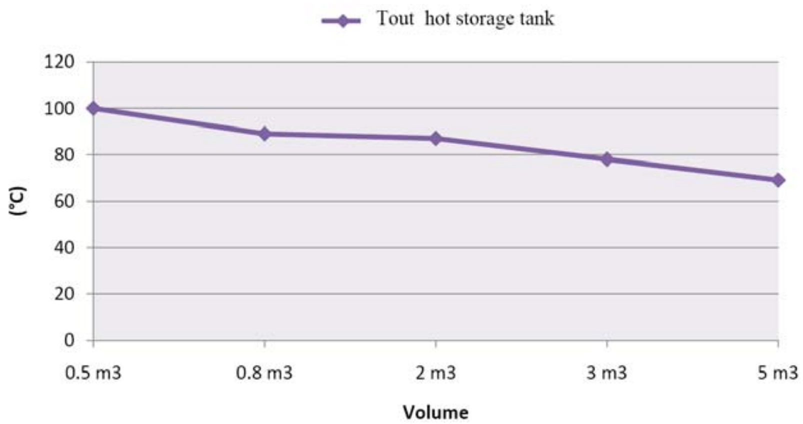

Figure 11. Effect of volume tank on the outlet of hot water temperature.

Many tests have been investigated to evaluate the sensitivity of the machine performance for different volume of storage tank, see Figure 11. For a volume superior than 2.5 m^3, the outlet temperature is lower than 80°C, thus the cold production will stop. Storage volume plays a dominating part because it has a buffering effect to the abrupt weather variations and makes possible to continue the hot water supply of absorption chiller The total solar collector area is the most important point (performance and economy). Several area of solar collectors have been tested (Figure 12.)

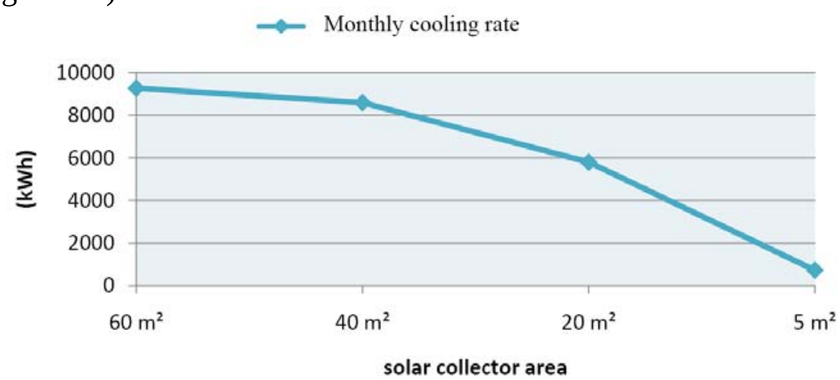

Figure 12. Energy production for different solar collector areas.

The effect of solar collector is evaluated against the energy from absorption chiller. The cooling rate from 60 m² to 40 m² is near. This production reaches to low value for a solar area less than 20 m². Thus, to have continuous condition for cold production a collector area of 60 m² is required.

CONCLUSION

The aim of the current work was to present a method of using solar energy for the air-conditioning. The system is modeled with the TRNSYS program. For the requirements in cooling for our classrooms, an optimum of the components consists of the use of 60m ² of vacuum solar collectors associated a storage tank of 0.8 m^3. We also fixed the nominal capacity of the absorption chiller with 33 kWf. The final objective of this work was to set up a simulation tool representing a solar cooling plant. This environment will be used as basic support with the simulation of various configurations. Theses simulations have been used to dimensioning an installation in our university. The cooling plant will be setup on may June 2007, in order to be in function at the beginning of summer in November 2007.

SUMMARY

Feasibility study of solar-assisted desiccant cooling system (SDCS) in Hong Kong has been conducted, by comparing the two major approaches – the outdoor air (OA) scheme and the mixed air (MA) scheme. In the former, desiccant cooling would fully make use of OA to satisfy the required cooling load. In the latter, MA from the pretreated OA and the return air would be mixed and supplied for cooling purpose. In principle, the latter may be better due to the enthalpy conservation from the return air. However from the year-round simulation study by using TRNSYS, it was found that the OA scheme would provide better cooling and energy performance under the typical meteorological year of Hong Kong. The system design of SDCS would depend on the local climatic conditions, and the extent of solar irradiation, air temperature and humidity should be considered thoroughly in the study.

INTRODUCTION

Hong Kong has the sub-tropical climate, featured with long hot and humid summer and temperate climatic conditions for half a year. Air-conditioning for comfortable indoor environment is therefore indispensable. Owing to the fact that air-conditioning and refrigeration becomes the biggest electricity "consumer" in Hong Kong [1], different measures of energy conservation and management have been implemented, in order to reduce energy consumption without sacrificing thermal comfort. Electrically driven compression refrigeration systems have been applied for a century, commonly found at homes, work places, industrial facilities and transportation. Due to the environmental impact of burning fossil fuel and non-stopping climbing of oil price, alternative energy sources other than fossil fuel generated electricity are being explored. Solar energy is definitely welcome if feasible technology for air-conditioning and refrigeration is available. In the recent years, there is encouragement from the government to seek for potential applications of renewable energy in Hong Kong, particularly to make use of solar energy [2]. Solar heating is a well-known technology, no matter using the flat plate collectors or evacuated tubes. However solar cooling has little mention, since it is a blooming technology even in Europe, USA and Japan, where research and development works are still ongoing [3,4]. The prominent advantage to utilize solar energy for building air-conditioning is the coincidence of solar irradiation availability and building cooling demand. In this study, the application potential of solar cooling in Hong Kong was perceived through suitable simulation methodology.

SOLAR COOLING IN CONTEXT

The basic principle of solar cooling is to apply the heat acquired from solar collectors for the thermally driven system, so that chilled water or conditioned air can be produced for air-conditioning purpose. From the latest research works [5-7], active solar cooling can be categorized in the following ways:

a. Solar-electric refrigeration: PV-operated compression cycle (compressor driven by a direct current motor)

b. Solar-thermal refrigeration
   i. Solar mechanical compression cycle (using Rankine cycle to drive a conventional compressor)
   ii. Absorption (note "ab") refrigeration
   iii. Adsorption (note "ad") refrigeration
   iv. Steam jet cycle (a novel cycle driven in 200°C)

c. Solar-thermal air-conditioning
   i. Solid desiccant cooling
   ii. Liquid desiccant cooling

In active solar cooling, the solar-electric refrigeration and solar-thermal refrigeration have the focus on the development of new types of chillers for refrigeration purpose. In solar-thermal air-conditioning, conditioned air with both design temperature and humidity is directly provided to indoor space. As incorporated with the desiccant adsorber, the humidity control can specifically handle the required latent load. Therefore its dehumidification performance would be commonly better than the conventional cooling coil.

SOLAR-ASSISTED DESICCANT COOLING SYSTEM

For the solar-assisted desiccant cooling system (SDCS), the core part is the sorbent component. Currently, both solid and liquid sorbents are available, like silica gel and lithium chloride respectively. Although the liquid desiccant cooling has feature of thermal storage in the regenerated liquid sorbent, the choice of the hygroscopic sorbent is limited, since the sorbent would be carried over into indoor space by the conditioned air. For the solid desiccant cooling, the processes of adsorption and desorption of moisture by solid sorbent are stable, that is more suitable to directly apply upon the conditioned air. Desiccant wheel is commonly used as the solid sorbent component. SDCS also includes the heat recovery unit, direct evaporative coolers, solar collectors and auxiliary heater, as shown in Figure 1. A typical psychrometric cycle in summer is also presented.

In principle, the adsorption or desorption process is adiabatic, but the wave propagation effect during the regeneration process of desiccant wheel would cause deviation from the theoretical process. Solar air collector is a common choice for SDCS. Since it can be directly coupled to SDCS for handling the regeneration air, and instantly make use of thermal gain without the need of thermal storage. Solar air collector is effective when the cooling load profile is in line with the availability of solar irradiation in day time. The heat recovery unit is used to conserve the sensible heat and pre-cool the outdoor air. The evaporative cooler EC1 would cool down the supply air up to the humidity level capable of tackling the space latent load.

Another evaporative cooler EC2 is installed to cool down the return air, for furnishing better sensible heat extraction at the heat recovery unit.

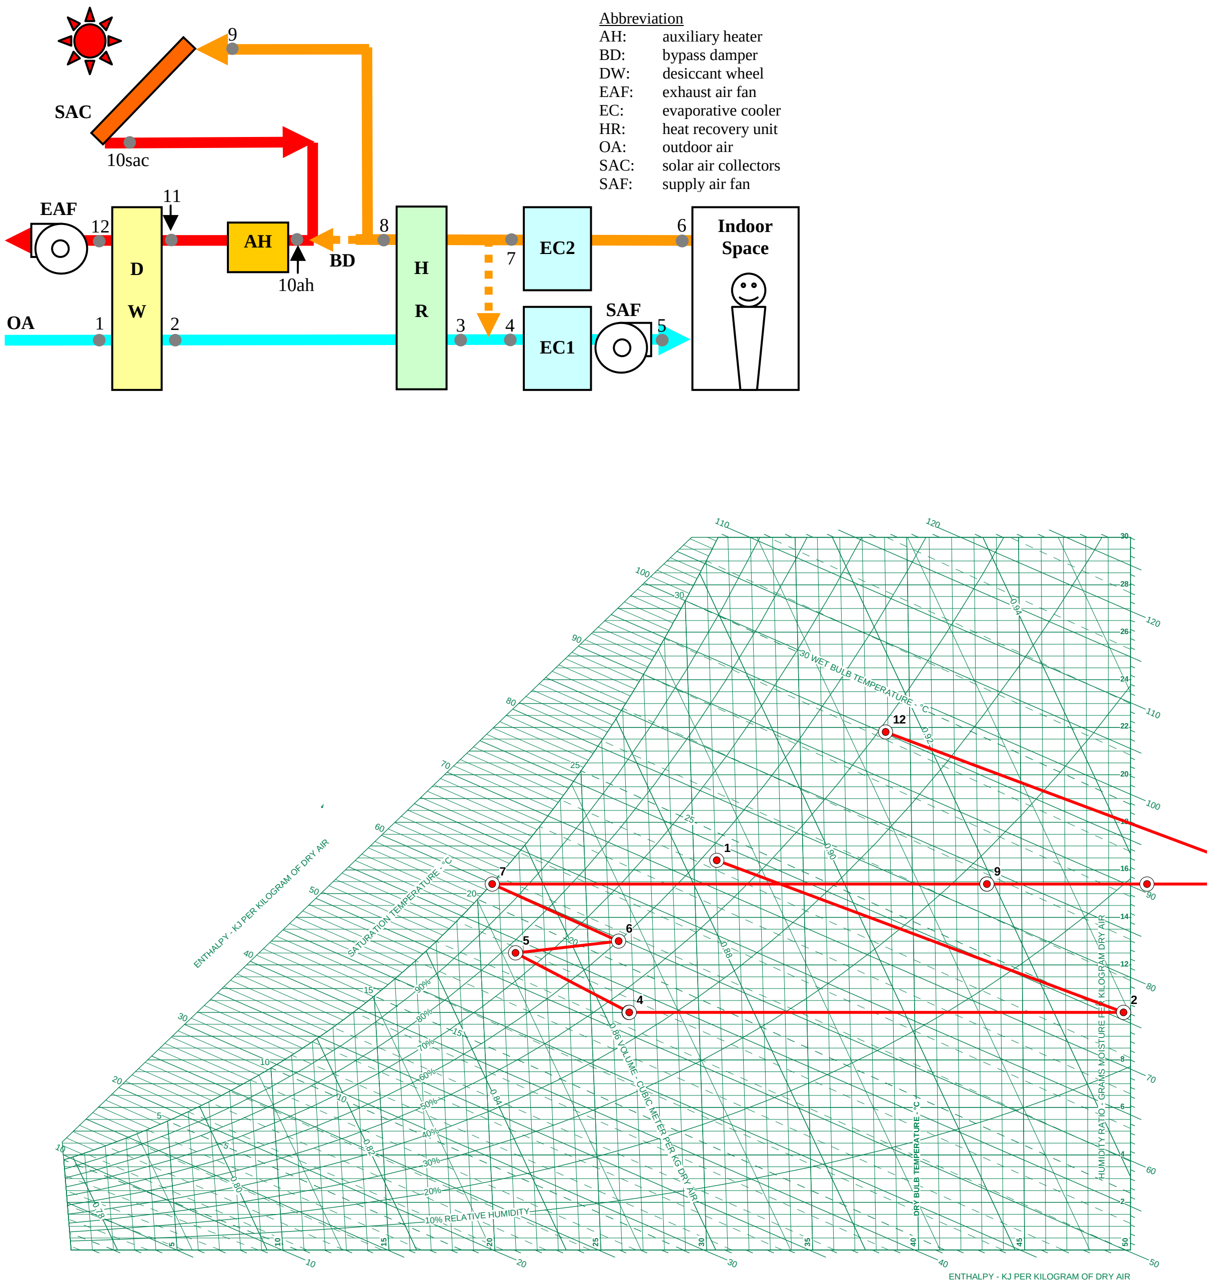

Figure 1. Schematic diagram and typical psychrometric cycle of solar-assisted desiccant cooling system in the summer.

The European countries have practical experiences in the system design and installations of SDCS [4]. Generally SDCS has the outdoor air (OA) scheme and mixed air (MA) scheme. In the former, desiccant cooling would fully make use of the OA to fulfill the required cooling load. In the latter, the MA from the pretreated outdoor air and the return air would be mixed for cooling purpose. Therefore the OA scheme would have larger sizes and higher capital costs of equipment components, since the amount of full OA is involved, while the MA approach would have smaller equipment sizes thus lower initial costs due to smaller amount of OA required. It seems that the latter can have the advantage of enthalpy conservation from the return air, but the cooling performance of the former may be better due to larger amount of conditioned air being produced. This would depend heavily on the local climatic conditions, particularly the solar irradiation, air temperature and humidity. As a result, simulation model was built for in-depth study between these two schemes. Moreover in each scheme, the regeneration air for the desiccant wheel can be either from the return air leaving the heat recovery unit, or a separate outdoor air stream. In summary, there are altogether four alternatives for the system design of SDCS as follows:

A. OA scheme with return air for regeneration (Figure 2a);
B. OA scheme with separate outdoor air for regeneration (Figure 2b);
C. MA scheme with return air for regeneration (Figure 2c); and
D. MA scheme with separate outdoor air for regeneration (Figure 2d).

Figure 2. Four alternatives for system design of solar-assisted desiccant cooling system

DEVELOPMENT OF SIMULATION MODEL

In order to have an in-depth study and comparison for these four alternatives, simulation model of SDCS was built by using TRNSYS 16.01 [8], with the support of the component models from TESS [9]. The desiccant wheel model could determine the regeneration air inlet temperature based on the humidity ratio set point. The heat recovery unit model had the sensible effectiveness of 0.8. Each evaporative cooler model could vary its saturation efficiency between 0 – 100%. Each fan model was the variable speed type, and its power was adjusted from the rated power according to the flow change. The solar air collector model was an un-glazed type that passed the air behind the absorbing plate. It had the absorptance of 0.947 and emissivity of 0.85. The auxiliary heater model was electric type with efficiency of unity. In Hong Kong, the energy cost of electricity and that of town gas are comparable, so the electric heater was designed for system and operation simplicity. The Hong Kong Typical

Meteorological Year [10], which was in the EnergyPlus / ESP-r format (*.epw), was adopted in this simulation model.

In order to understand the effectiveness of the cooling performance of SDCS, it was designed to provide air-conditioning for function area with commonly high cooling intensity, therefore a seminar room located on the top floor was selected for simulation purpose. It had floor area of 213 m^2 and 3.82 m high. There were four external walls and a flat roof. The wall-fenestration ratio was 0.4 to 0.6. The internal and external shading factors of fenestration were 0.8 and 0.2 respectively. The internal heat gains included 120 persons seated at rest and 13 W/m^2 artificial lighting with 30% convective part. The daily air-conditioning period was from 08:00 to 18:00 to suit the solar availability.

According to the local design practice, the rated mass flow rate and rated power of the variable supply air fan were 3.47 m^3/s and 4.63 kW respectively, with the flow range from 30 to 100%. The rated flow rate of the variable exhaust air fans would depend on the alternatives, ranged from 1.04 to 3.47 m^3/s. The rated power of the exhaust air fans EAF1 and EAF2 were 2.89 kW and 5.79 kW respectively. The power of heat recovery unit and evaporative cooler were 0.19 kW and 0.034 kW respectively. The capacity of the electric auxiliary heater was 100 kW. The set point of the desiccant dehumidification was 0.01 kg/kg. 100 m^2 solar air collectors with tilt angle of 22°C were installed on the roof directly above the air-conditioned space.

Control scheme was included for year-round operation in response to different climatic conditions and changing heat gains. There were free cooling mode and desiccant cooling mode. Free cooling with adjustable fan speed of supply and exhaust air fans was implemented when the outdoor temperature was higher than 5°C. When the outdoor temperature was higher than the room temperature 24°C, desiccant cooling was called in and the supply air temperature was set at 13°C. Bypass control was applied whenever there was no thermal gain at the solar air collectors. The entire plant and energy simulation model was developed in a total energy approach, with the consideration at the equipment level, system level and operation level, in order to reflect the effectiveness of SDCS in different seasons in Hong Kong. The general cooling performance and year-round energy consumption of this simulation model was validated with a similar project in Freiberg of Germany [4].

RESULTS AND DISCUSSION

For the four alternatives, the simulation results for comparison are summarized in Table 1 and introduced below.

Table 1. Year-round simulation results of the four alternatives.

Alt	Annual electrical consumption (kWh)	Annual thermal gain (kWh)	Average solar fraction	Hour percent out of comfortable temperature	Average COP
A	154,417	17,166	0.15	15.0%	1.07
B	225,417	33,348	0.14	17.5%	0.51
C	79,167	13,207	0.20	79.4%	-0.45
D	103,599	28,181	0.25	78.8%	-0.41

The *annual electrical consumption* is the year-round electrical energy consumption of all the involved components of SDCS, including the fans, evaporative coolers, heat recovery unit, desiccant wheel, and electric auxiliary air heater. The *annual thermal gain* is the year-round thermal energy acquired by the solar air collectors during the operation of SDCS. The *average solar fraction* is to compare the solar fraction of the thermal gain from solar air collectors Q_{sac} to the heat generated from the auxiliary heater Q_{ah}. The monthly average solar fractions were determined first, then the year-round average value SF_{avg} was found as follows:

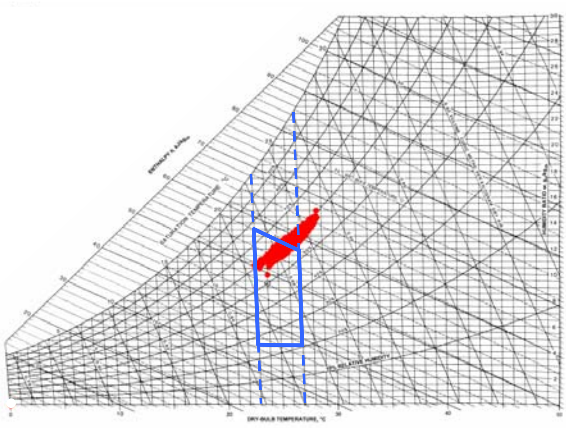
$$SF_{avg} = \frac{\sum_{i=1}^{12} Q_{sac,i} / Q_{ah,i}}{\sum_{j=1}^{12} j} \qquad (1)$$

The *hour percent out of comfortable temperature* is to consider the effect about thermal comfort. In this study, the upper limit of 27°C of the summer comfort zone from ASHRAE [11] is used to check against the room air temperature. The percentage was based on the annual air-conditioning hours. The hourly COP (coefficient of performance) of SDCS is defined as follows:

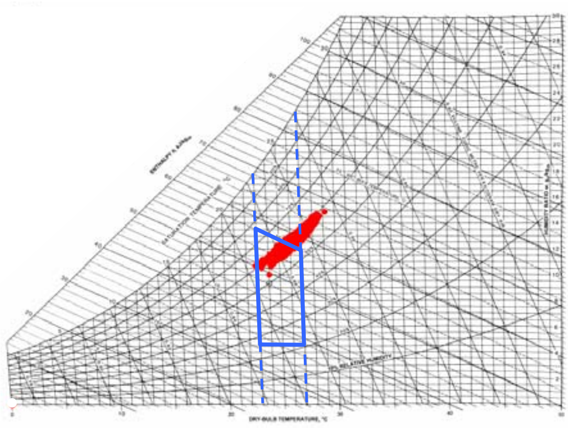
$$COP = \frac{\dot{m}_{\text{supply}}(h_{\text{outdoor}} - h_{\text{supply}})}{Q_{\text{in}}} = \frac{\dot{m}_{\text{supply}}(h_1 - h_5)}{Q_{\text{sac}} + Q_{ah}} \qquad (2)$$

where $\dot{m}_{\text{supply}}$ is the mass flow rate of supply air for the conditioned space, h_{outdoor} or h_1 is the outdoor air enthalpy, h_{supply} or h_5 is the supply air enthalpy, Q_{in} is the total thermal energy input that is the sum of Q_{sac} and Q_{ah}. The monthly average COP was determined, then the year-round average COP.

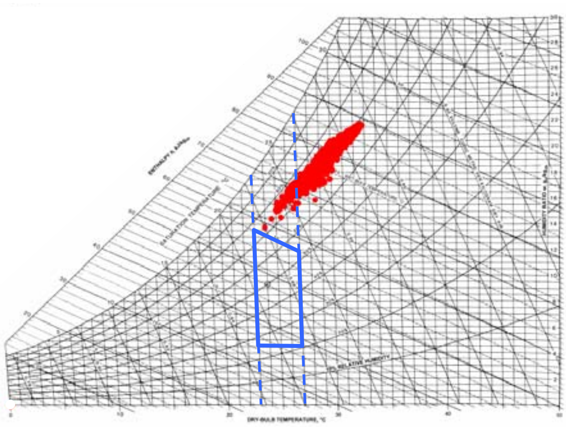
In addition to the results in Table 1, the room conditions during the air-conditioning hours are plotted in red spots on the psychrometric chart. The ASHRAE summer comfort zone is encompassed by blue solid lines.



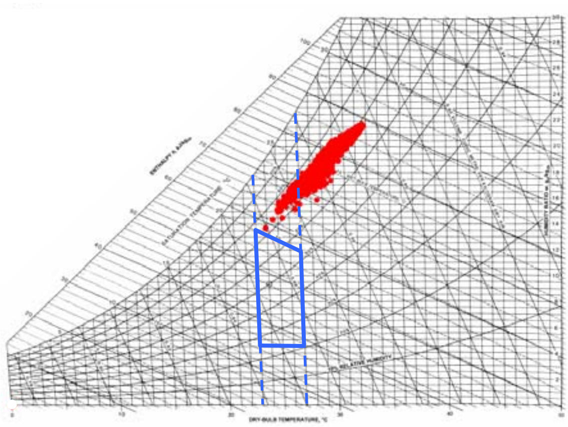
(a) Alternative A



(b) Alternative B



(c) Alternative C



(d) Alternative D

Figure 3. Room conditions during the air-conditioning hours throughout a year for the four alternatives.

From Table 1, it seems that Alternative C had the lowest annual electrical consumption among different system designs. But with regard to the other results, particularly Figure 3(c) and (d), both Alternatives C and D could not generally provide the required comfortable conditions for the air-conditioning area. It accounted to 79.4% and 78.8% of air-conditioning hours higher than the comfortable upper limit of 27°C. These two alternatives were the MA scheme, although they had relatively high average solar fraction due to better thermal gain from 30% OA passing the same area of solar air collectors. But such flow rates of process air and regeneration air were not enough to provide the necessary cooling effect for the space loads. Therefore only about 20% of the room temperature was satisfactory in a year. In addition, the average COP of both Alternatives C and D were negative in Table 1, implying that h_{outdoor} was lower than h_{supply} from Eq(2). This shows that the enthalpy of MA was even worse than that of the OA, and the room condition was not comfortable enough in most of the time.

As a result, only Alternatives A and B would be under consideration. Both of them were designed based on the OA scheme. From Table 1, it is obvious that Alternative A was advantageous over Alternative B due to lower annual electrical consumption, greater average solar fraction, smaller hour percent out of comfortable temperature and better average COP. The annual thermal gain of Alternative A was less than that of Alternative B, but it did not have contradiction to the result that Alternative A had a better solar fraction. It was because Alternative A applied the return air with higher temperature for regeneration in desiccant wheel (Figure 2(a)), while Alternative B used the OA with lower temperature for the same purpose (Figure 2(b)). Therefore the thermal gain in Alternative A would be less hence the demand of auxiliary heating for regeneration was also less, and the solar fraction was eventually higher. Consequently, Alternative A, the OA scheme of SDCS with return air for regeneration had the best overall performance in view of energy and cooling effect.

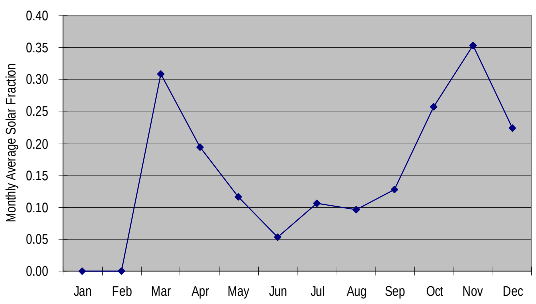


Figure 4. Profile of monthly average solar fraction in different months.

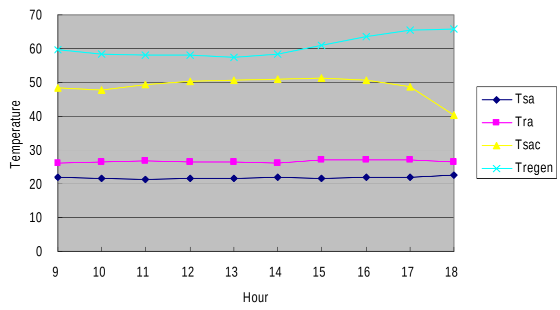

Figure 5. Temperature profiles of supply air T_{sa}, room air T_{ra} , solar air collector outlet T_{sac}, and regeneration air T_{regen} on a typical summer day.

For Alternative A, an in-depth performance appraisal was made. Figure 4 shows the changing profile of monthly average solar fraction. It is noted that the solar fraction was high around March and November, which are the spring and autumn in Hong Kong. The weather and cooling load of these two months were moderate, so the solar contribution could be more significant. For the local summer period from May to September, the solar fraction was low, between 0.05 to 0.13. This indicates that auxiliary heating was necessary in summer in order to achieve the design humidity set point for desiccant cooling purpose. Figure 5 illustrates the temperature profiles of supply air, room air, solar air collector outlet and regeneration air on a typical summer day. For both the supply and room air, their temperatures are fairly constant throughout a day, around 22°C and 27°C respectively. The outlet temperature of solar air collectors and regeneration temperature were around 50°C and 60°C. The temperature difference was accomplished by the auxiliary heater, this shows again the need of auxiliary heating in the summer time.

CONCLUSION

Although there are many solar cooling applications in the European and western countries, the system design should be carefully examined for local use based on the climatic conditions. In this study, the outdoor air scheme was found more suitable than the mixed air scheme for the solar desiccant cooling system (SDCS) in Hong Kong, and the system configuration of return air for regeneration was more effective. The average monthly solar fraction and COP were 0.15 and 1.07 respectively. Owing to the sub-tropical climate featured with hot and humid summer in Hong Kong, auxiliary heating was necessary in order to achieve the design performance of SDCS. Although the application potential of solar air collectors in Hong Kong was generally assured, there were 15% air-conditioning hours exceeding the comfortable temperature limit for the air-conditioning area with high cooling load intensity. This problem can be firstly handled by the other choices of solar collectors, like the flat plate collectors or evacuated tubes, and it would be studied in the next stage. Total solar cooling solution would be pursued to prevent from using auxiliary cooling.

SUMMARY

In the desiccant dehumidifier using adsorbent such as silica gel and zeolite, moist outdoor air is dehumidified by the adsorbent, and the damped adsorbent needs to be dried (regenerated) by giving heated air. Utilizing solar thermal energy as a heat source for the regeneration of the adsorbent leads to large energy conservation. We aim to develop the high efficiency desiccant dehumidification system using solar thermal energy. For this development, we investigated numerical analysis method of heat and moisture transfers in desiccant wheel in order to carry out the optimal design of this desiccant system. In this paper, the heat and water vapor transfer phenomena inside a desiccant wheel were formulated, and the algorithm of numerical calculation for the formulated equations was investigated. Its validity was checked by comparing the calculation results with the results of the repeated adsorption-desorption experiment for a fixed desiccant wheel (the wheel is not rotating), and with the experiment using an actual desiccant machine (the wheel is rotating). With regard to the numerical calculation targeted at the repeated adsorption-desorption experiment, the periodic change in moisture content was accurately reproduced by the calculation. However, with regard to the actual desiccant machine, this numerical analysis could not accurately predict the air temperature after passing through the desiccant wheel, although it could evaluate the amount of dehumidification fairly well.

INTRODUCTION

In Japan, solar heat systems have been introduced in mainly detached houses. In fiscal 2002, the quantity of these amounted to 740,000 kL in crude oil equivalent. The scheme for achieving the goals of the Kyoto Protocol [1], which was approved at a Cabinet meeting in April 2005, also includes the aim to further promote the introduction of solar heat systems. In order to achieve the goals, it is necessary to promote the use of solar systems for the public buildings, housing complex, and industrial fields, and so it is imperative to develop the technology for application in these fields. In order to spread the heating and the hot water supply systems that utilize solar heat, it is one key to find how to use the excessive solar heat during summer and spring/autumn seasons, and we started on a research project of “the floor heating & cooling, ventilation, and hot water supply system using solar heat” (Fig.1). For this system, we are developing a wheel-type solid desiccant air-conditioning system (Fig. 2) using this excessive solar heat. In the desiccant system that uses absorbents, such as silica gel and zeolite, outdoor moist air is dehumidified in absorbents, and heated up by adsorption heat, to become low-humidity high-temperature air, and then it passes sensible heat exchanger and evaporative cooling, to be supplied as cool and dry air. By utilizing solar heat as the heat source for regenerating (dehumidifying) the damped absorbents, it is possible to gain a great degree of the energy-saving effect. In addition, this is not dehumidification by the dew condensation method, and so it is possible to inhibit the growth of mold and fungi. As mentioned above, the desiccant system is an air-conditioning technology attracting people's attentions as an environmentally-friendly air-conditioning system from the perspectives of energy saving, air quality, and chlorofluorocarbon issues. But for the popularization of this system, we need to pursue higher efficiency, miniaturization, weight reduction of devices, the methods for utilizing solar heat effectively, and the technique for post-cooing at low energy costs.

In this study, in order to develop a high-efficiency desiccant system utilizing solar heat, we are examining the pre-cooling technique of the adsorbing part of the desiccant wheel, unique post-cooling methods, and the application of new adsorbing materials. We are also intended to optimize a variety of parameters that influence the performance of the desiccant system. There are a large number of parameters that determine the performance of a desiccant system—desiccant material's moisture adsorption/desorption characteristics, size of the wheel, air volume, process/regeneration splitting ratio, rotation speed, temperature of regeneration, void ratio, and the degree of pre-cooling. Therefore, it costs an enormous amount of time and labor to discover the desirable combination of parameters.

In this circumstance, we developed a technique for numerical analysis of heat and moisture transfers, considering the rotation of a desiccant wheel in order to carry out the optimal design of a desiccant system. The heat and moisture transfer phenomenon inside a desiccant element was formulated, and the algorism of numerical calculation for the formulated equations was investigated. First, we measured the equilibrium moisture content, which is used as the input value of the adsorption/desorption characteristics of a desiccant material for numerical calculation. Secondly, in order to confirm the validity of the numerical analysis method, we compared the results of the experiment of repeating the adsorption and desorption when a wheel is fixed with the results of the numerical calculation, and then compared the results of the measurement in the actual desiccant machine and the results of the numerical calculation that took the rotation of the wheel into account.

TRANSPORT EQUATIONS OF HEAT AND WATER VAPOR INSIDE A DESICCANT ELEMENT

As shown in the left diagram of Fig. 3, a parallelepiped infinitesimal volume is taken from the wheel and modeled, as shown in the right diagram of Fig. 3. Considering the balances of water vapor and heat quantity inside this infinitesimal volume, the three transport equations (1), (4), and (5), as shown in Table 1, can be obtained. Equation (2) indicates that the moisture content of a desiccant material changes due to the water vapor transfer on the desiccant material's surface. Equation (3) is based on the assumption of local equilibrium in which the relation between the absolute temperature and moisture content of the desiccant material's surface (adsorption/desorption phase) instantaneously follows the adsorption isotherm. This formulation was conducted with reference to the theory of simultaneous transfer of heat and water vapor proposed by Matsumoto and Hokoi et al.[),)]. The adsorption isotherm of Equation (3) varies significantly according to materials, and so in this study, we measured this for the target desiccant wheel.

MEASUREMENT OF THE EQUILIBRIUM MOISTURE CONTENT OF A DESICCANT WHEEL

The experimental apparatus and measuring methods adopted in this study follow the JIS's method for measuring the equilibrium moisture content of building materials [2] and the Environmental Standards of the Architectural Institute of Japan [3].

Fig. 4 shows the experimental apparatus. This apparatus is composed of a temperature-controlled bath, an air control unit, which automatically adjusts the mixing ratio of dry air and saturated air to a specified relative humidity and sends air to the measurement chamber, and an air handling unit (AHU), which supplies the air with steady temperature to the temperature-controlled bath. The weight change of the desiccant wheel during moisture adsorption or desorption was gauged by an electronic balance, and the dew-point temperature of the influx/outflux air was measured by a chilled-mirror dew-point thermometer. The temperature inside the temperature-controlled bath was measured by a PT100.

Firstly, a desiccant wheel with a diameter of 150 mm and a thickness of 100 mm was put into an oven, and dried sufficiently at 110 degrees Celsius, and then the reference dry mass was measured. Next, the desiccant wheel was put into the measurement chamber, air with a specified relative humidity of 10% was supplied, and measurement was carried out until the desiccant wheel reached the constant weight (equilibrium state). The relative humidity was increased in a stepwise manner, and the above weight measurement was conducted (adsorption process). After the specified relative humidity was increased to 95%, the relative humidity was decreased in a stepwise manner, and the above weight measurement was conducted until the specified relative humidity reached 10% (desorption process).

Fig. 5 shows measurement results of the equilibrium moisture content. Here, the moisture content higher than 45%RH for 70 degrees Celsius condition was not measured because the measuring limit of dew-point temperature was 50 degrees Celsius, and so the humidity limit was 45% in the 70 degrees Celsius condition. This has no problems because the relative humidity of the air inside the actual desiccant wheel never becomes higher than 45 %RH in the high-temperature condition.

Under the 25 degrees Celsius condition, the moisture content during the desorption process was higher than that during the adsorption process, under the medium humidity condition (20%RH-80%RH). This hysteresis phenomenon, which is commonly seen in porous materials, was observed. In addition, when the ambient temperature was set to be 70 degrees Celsius, the moisture content became lower than that under the 25 degrees Celsius condition, for the same relative humidity. This indicates that the relation between relative humidity and equilibrium moisture content varies according to temperature.

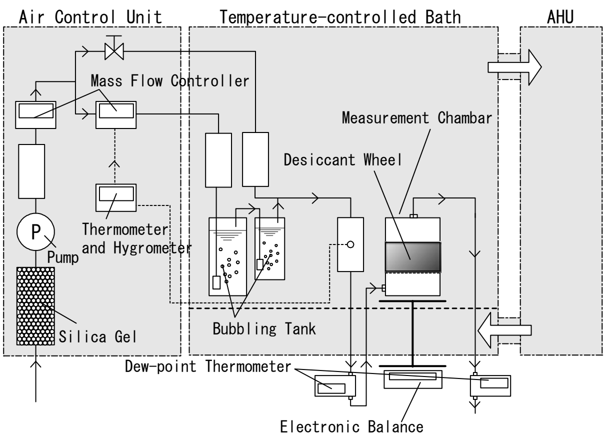

Figure 4. Experimental apparatus for measuring the equilibrium moisture content

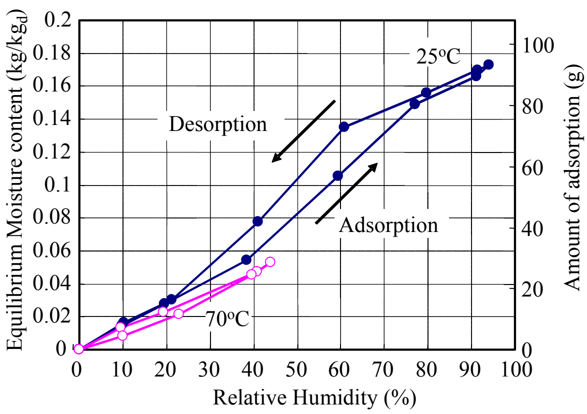

Figure 5. Adsorption isotherm

ALGORITHM OF NUMERICAL CALCULATION

The five equations shown in Table 1 are solved, to obtain the five unknown quantities: X_a, X_b, θ_a, θ_d, w. This algorithm is such that each variable is set at an initial value, Equations (1), (4), (5), and (2) are solved through time evolution, to obtain the values of X_a, θ_a, θ_d, w at the next time step, and then a convergent calculation between Equations (2) and (3) is carried out to determine w and X_b. If the explicit method was used to solve Equations (1), (4), and (5), it is necessary to discretize time extremely finely in order to obtain stable solutions, and so the full-implicit method is adopted in this study. Namely, each of Equations (1), (4), and (5) is solved with TDMA (tri-diagonal matrix algorithm) [4] and then a convergent calculation is conducted between Equations (2) and (3), to determine provisional values of X_a, X_b, θ_a, θ_d, w at the next time step. Using these updated provisional values, the above procedures are repeated with the Gauss-Seidel method [4] until convergence, to determine the values at the next time step. When the values at the next time step are determined, the time step proceeds to the next one. The control volume method is used for the discretization of space, and the upwind scheme is adopted for the advection term [4].

Fig. 6 shows the graph drawn by converting the horizontal axis in Fig. 5 from relative humidity to absolute humidity. The curves in Fig. 6 correspond to the function $f(X_a, \theta_a)$ in Equation (3). Here, the moisture content was defined as the average values of the adsorption and desorption processes, and the unmeasured temperature condition was obtained through the interpolation based on the measurement results at 25 degrees Celsius and 70 degrees Celsius. In the numerical analysis for the Equation (3), the temperature and the absolute humidity on the desiccant surface θ_d and X_b are substituted into the function that was produced by approximating adsorption isotherms in Fig. 6 with a quartic function, to obtain moisture content w in the Equation (3).

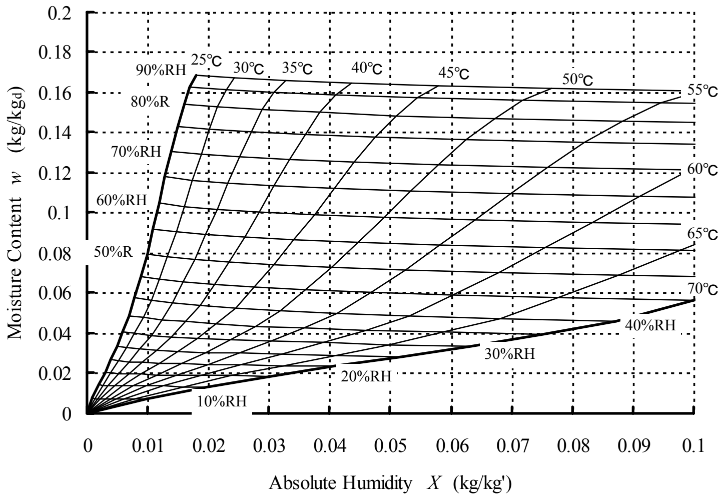

Figure 6. Adsorption isotherm used for the calculation

VALIDATION OF NUMERICAL CALCULATION

In order to check the validity of the formulated equations and the numerical calculation method for solving them, the repeated adsorption-desorption experiment was conducted for comparison. Fig. 7 shows the experimental apparatus. In the experiment, the air of 25 degrees Celsius and 70 degrees Celsius were supplied to a desiccant wheel by turns every two minutes, by operating manual dampers. The desiccant wheel with a diameter of 150 mm and a thickness of 100 mm was fixed so as not to rotate. The air volume was adjusted to 100 m^3/h with an orifice flow meter. In order to insulate heat, glass wool was wrapped around the Y pipe, the straight pipe, and the orifice. The desiccant wheel was placed on an electronic balance, separated from the straight pipe and the chamber box. The both sides were covered with lightweight, thin vinyl film, so as to prevent air leakage and not to receive loads from the both sides as much as possible. The mass of the desiccant wheel was measured with the electronic balance, and the dew-point temperatures at the upstream and the downstream of the wheel were measured with the chilled-mirror dew-point hygrometer.

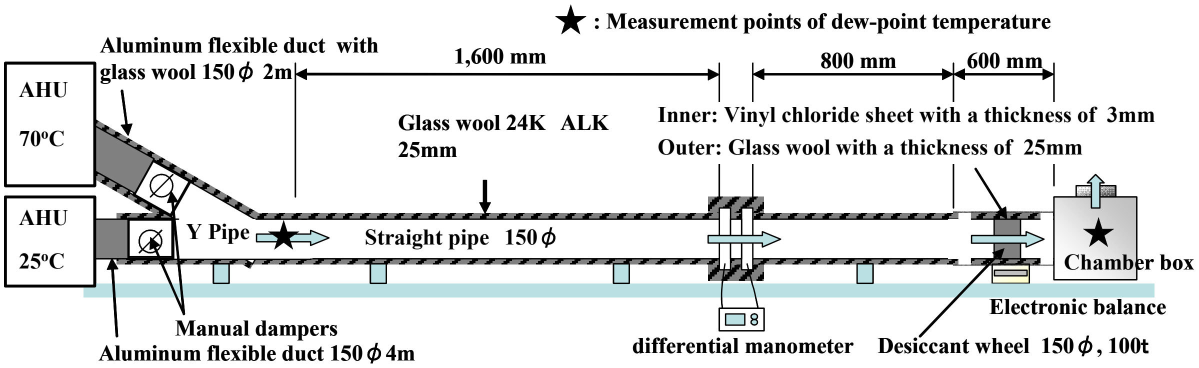

Figure 7. Experimental apparatus for repeated adsorption-desorption experiment

Table 2 tabulates properties used for the numerical calculation. For the computational grid, the 100 mm-thick element was divided equally into 20 parts, and time interval was set at 0.1 seconds.

Fig. 8 shows the calculation result of the moisture content after it reached periodic steady state, with the experimental result. The calculation reproduced the periodic change of the moisture content with the repeat of adsorption and desorption, and the calculated moisture content was within the range of the variation of the experimental data, as a whole.

Table 2. Calculation conditions

$\varepsilon = 0.71$ $\rho_d = 988$ (kg/m^3) $\alpha = 60$ (J/sm^2K) $\rho_a = 101.3/((\theta_a + 273)*0.287*(1+1.61*X_a))$ (kg/m^3)

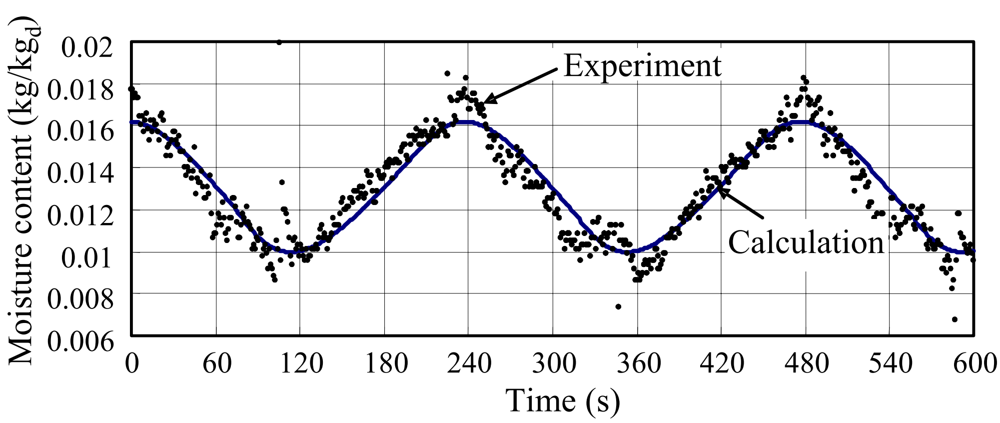

Figure 8. Periodic change of moisture content

NUMERICAL CALCULATION METHOD CONSIDERING THE ROTATION OF A WHEEL

Calculation method

As shown in Fig. 9, the wheel is segmented into each element in the rotational direction, and the above-mentioned numerical calculation is carried out separately. Each segmented element is rotated, and the flow direction and the influx temperature and humidity are switched, according to whether it is located at the adsorption side or the desorption side. By averaging the outflow temperature and humidity of all elements located at the adsorption side, it is possible to obtain the temperature and humidity of the air that has been dehumidified through the wheel at each time step. Until this averaged temperature and humidity become steady, the calculation is continued while rotating the wheel.

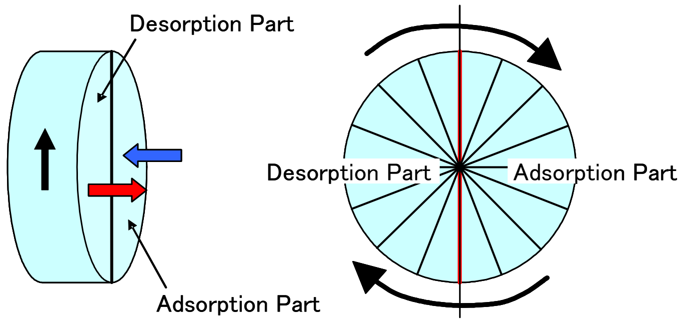

Figure 9. Calculation method for rotating desiccant wheel

Validation of Calculation method

In order to validate the numerical calculation method considering the wheel's rotation, we compared the calculation results with the experimental results for an actual desiccant machine. The actual desiccant wheel had a diameter of 300 mm and a thickness of 100 mm. Table 3 shows the experimental condition. For the inflow boundary conditions of the temperature and the humidity at the process side and the regeneration side, the measurement values were used. The air volume was set at 100 m^3/h, and the rotation speed was set at 30 RPH.

Fig. 10 plots the calculated result and measured result on a psychrometric chart. The air temperature that has passed through the wheel increased from 30 degrees Celsius to 54 degrees Celsius in the experiment, while the calculated temperature became 49 degrees Celsius, which was about 5 degrees lower than the experimental value. The absolute humidity after passing through the wheel was 0.01 kg/kg' in the experiment, while the calculated one was 0.0093 kg/kg'; these values are almost the same. Namely, the amount of dehumidification was evaluated quite accurately by the calculation. As for the regeneration side, there was also some difference in temperature between the experimental and the calculated results, but the results of the absolute humidity were almost the same. With regard to the discrepancy in temperature, this calculation method did not take the heat transfer among the segmented elements into account, but in actual wheels, it is considered that there is heat transfer at the boundary surface between the regeneration and process sides. This is expected to be improved by considering the heat transfer at the boundary surface between the regeneration and process sides in the model of the numerical calculation.

Table 3.
Calculation conditions

Geometry of desiccant wheel	300φ×100 t
Inflow Condition of process air	Temperature 30 K Absolute humidity 14.7 g/kg'
Inflow Condition of regeneration air	Temperature 70 K Absolute humidity 10.7 g/kg'
Air volume	100 m^3/h
Rotation speed	30 RPH

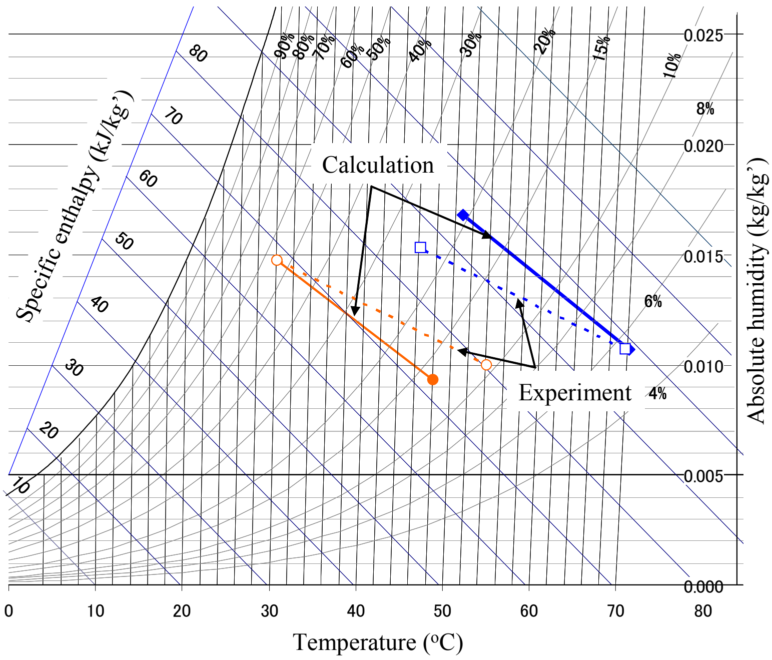

Figure 10. Comparison between calculated results and experimental results for an actual desiccant machine

CONCLUSIONS

The heat and water vapor transfer phenomena inside a desiccant wheel were formulated, and the algorithm of numerical calculation was investigated. Its validity was checked by comparing the calculation results with the results of the repeated adsorption-desorption experiment and the experiment using an actual desiccant machine. With regard to the numerical calculation targeted at the repeated adsorption-desorption experiment, the change in moisture content was accurately reproduced. However, the comparison with the experiment using an actual desiccant machine indicates that this numerical analysis could not accurately predict the air temperature after passing through the desiccant wheel, although it could evaluate the amount of dehumidification quite accurately. The prediction of air temperature is expected to be improved by considering the heat transfer at the boundary surface between the regeneration and process sides in the model of the numerical calculation.

SUMMARY

The objective of this study was to evaluate the underlying physics and controlling parameters for designing a Controlled Active Mass (CAM) system. The purpose of such a system is to obtain a good thermal indoor climate and facilitate the use of energy sources with low environmental impact. The CAM system will be designed to cover the cooling demands for controlling the internal heat gains in a typical-sized office room for one person. The CAM unit will be constructed as a tank filled with water in which the level and temperature can be controlled depending on demand. Compared to other cooling systems such as passive cooling beams, the system should only be used when there is a cooling demand in the office. We also expect that the CAM system will be possible to achieve more energy savings and better indoor climate compared to other active mass systems.

INTRODUCTION

Office buildings are often subject to substantial temperature variations during the day, with the building's structure acting as an active energy storing mass. Appropriate selection of massive construction materials permits the building's energy storage behaviour to reduce the energy demand of the building.

For many years, there has been an interest in using the heat capacity of different building materials to reduce temperature fluctuations and thus improve the indoor climate and reduce energy use. IEA Annex 37 [1] “Low-exergy Systems for Heating and Cooling of Buildings” has investigated increased use of low-temperature heating systems and high temperature cooling systems in what are known as low-exergy systems. Today, there are a number of different thermally active construction elements available. Examples include the “Thermodeck”, where ventilation air passes through holes in concrete slabs that act as heat stores [2], and embedded water pipes in a flat-slab floor that works as a heat accumulating mass [3]. Similarly, there are systems for cooling buildings where water pipes have been cast into the concrete building elements in floors, ceilings or walls [4, 5, 6, 7].

IEA Annex 44 [8] “Integrating Environmentally Responsive Elements in Buildings” is concerned with various building components known as Responsive Building Elements (RBE). RBE is defined as “a building construction element that assists to maintain an appropriate balance between optimum interior conditions and environmental performance by reacting in a controlled and holistic manner to changes in the external or internal conditions and to occupant intervention”. It concentrates on five specific RBEs that seem to have the most promising potential for improvement and good take-up in the building sector: Advanced Integrated Façades, Thermal Mass, Earth Coupling, Dynamic Insulation Walls and Phase-

Change Materials. This report concentrates on thermal mass, and so does not discuss the other types further here.

Thermal Mass can be utilized in both passive and active ways. In passive thermal mass systems, the thermal energy is stored directly in the building structure hence the mass cannot be altered. When the thermal mass, such as roofs and external walls, is directly exposed to the ambient air, it is classified as external thermal mass. If it is exposed to the indoor air, it is referred to as internal mass. For good performance of passive systems, the mass should have a high heat capacity, such as that of a typical massive concrete structure, or with inner walls inside the building's thermal insulation. Compared to a building with a low thermal capacity, such a design can show an annual energy saving of about 5-10 %.

Active thermal systems, on the other hand, and known as Thermo-Active Building Systems (TABS), consist of thermally massive structures incorporating ducts or pipes for circulation of thermal-energy-transferring media. This permits the flow and the temperature of the thermal mass to be changed to suit demand, and allows the supply of energy to or from the building to be controlled. In this way the thermal mass becomes active instead of passive, and the effect of the thermal mass can be controlled.

The thermal mass of buildings is affected by ambient temperature variations as well as by temperature variations inside the building. Temperature variations over the day can be used to supply heat to (for cooling the building), or abstract it from (for heating the building), the thermal mass. These are the most important variations that the thermal mass has to cope with. Short and more fluctuating temperature variations during the day are also reduced by the thermal mass.

The objective of this study was to evaluate the underlying physics and controlling parameters for designing a Controlled Active Mass (CAM) system. The purpose of such a system is to obtain a good thermal indoor climate and facilitate the use of energy sources with low environmental impact and low exergy value. This paper will describe the definition of a CAM system and some of the underlying theory of the design process.

THEORY

The energy storage capacity of the thermal mass will work together with other energy transfer processes in the office building. Heat is gained or lost in the office through heat conduction through the building envelope, thermal radiation through windows, ventilation through openings and infiltration/exfiltration through leakage. The following subsystems are included in the office; outdoor air, building envelope, furniture, the CAM system itself, ventilation air, room air, person, computer, lights and other equipment.

Thermal mass

The building envelope, furniture and equipment in the building all contribute to thermal mass. The energy that is supplied or stored in the thermal mass will be transferred to the room air and affect the thermal climate in the building. Depending on the shape, volume, location, thermal load etc., the thermal mass will affect the indoor air differently. There are three parameters that mainly govern energy transfer from the thermal mass to the indoor air: the convective heat transfer coefficient on the surface of the thermal mass, the thermal diffusivity within the thermal mass and the specific energy storage capacity of the thermal mass.

By expression the time scales for these parameters, we can quantify how the different parameters will influence the energy transfer from the thermal mass to the room air.

The building envelope is affected by the outdoor air and contributes to the thermal mass. Temperature variations in the outdoor air will penetrate the building envelope, to a depth and at a rate that depends on the physical properties of the wall. The penetrating depth δ, of the temperature variations with frequency omega into the building envelope, is described as:

$$\delta = \sqrt{\frac{2\kappa}{\varpi}} \ ;$$

where κ is the thermal diffusivity (thermal conductivity /(density*specific heat)) of the building envelope. The effective thermal mass is either equal to the thickness of the wall d or the penetration depth δ. If the penetration depth is less than the wall thickness, then the effective thermal thickness is equal to the penetration depth.

Furniture inside the building contributes to passive thermal storage. Furniture with volume $V_{Furniture}$ and surface area $A_{Furniture}$ can be lumped into a sphere with radius d as:

$$d = 3V_{Furniture} \,/\, A_{Furniture}$$

Time scale for thermal diffusion within the thermal mass:

$$\frac{d^2}{\kappa}$$

Here d is a characteristic length of the thermal mass and κ is the thermal diffusivity of the building envelope. This is the characteristic time scale for thermal diffusion to affect mass temperature.

Time scale for convective heat transfer at the surface of the thermal mass:

$$\frac{\rho \ C \ V_{Active}}{S_{Active} \ h}$$

Here ρ is the density and C is the specific heat capacity of the air surrounding the thermal mass, V_{Active} is the volume of the thermal mass, and where S_{Active} is the surface area of the thermal mass. The heat transfer coefficient h can be found from different empirical expressions, such as the type of convection (forced, mixed or natural) at the surface of the thermal mass, and whether the surface is horizontal or vertical [9, 10]. This is the time scale for convection to affect mass temperature.

In this study the thermal mass is an active system, in which the thermal storage mass and its temperature may be varied by changing the water in the CAM tank.

Time constant for charging

$$\tau = \frac{V_{Active}}{q_W}$$

Here V_{Active} is the volume of the thermal active mass and q_w is the volume flow rate of the water filling of the CAM. This is the time it takes to charge the tank with new fresh tap water.

Temperature variations
The temperature of the outdoor and indoor air will affect the heat transfer to the thermal mass and the temperature of the incoming ventilation air will also influence the system and the thermal comfort in the office.

The outdoor air temperature T_a is described by a mean temperature T_0 with amplitude of variation of outdoor temperature ΔT_a, and frequency ϖ [Hz].

$$T_a(t) = T_0 + \Delta T_a \cos(2\pi\varpi t)$$

The characteristic time scale for variation of the outdoor temperature is the *forcing time scale* $1/\varpi$.

There are different parameters and physical phenomena that affect the indoor air temperature in the office.

Time scale for ventilation
The building must be ventilated with fresh supply air to achieve a good indoor air quality. For a room with volume V and ventilation flow rate q, the time scale for the ventilation can be expressed by the nominal time constant for the ventilation:

$$\tau_n = \frac{V}{q}$$

The time it takes to replace the air within the room is at least twice the nominal time constant.

Time scale for mixing within the room

$$\frac{V^{1/3}}{U}$$

Where U is a characteristic velocity which can be set equal to the velocity that is not experienced as a draught, say 15 cm/s, and V is the ventilation flow rate.

Time scale for convection to affect interior temperature

$$\frac{\rho\ C\ V}{S\ h}$$

where S is the room surface and ρ, C and V are properties of the thermal mass in the office building envelop. This corresponds to the energy transfer between the exterior and the indoor air.

Ratio between scales
By using the above defined time scales, we can find relationships between them and also how the different energy transfer processes are affected by each other. We can, for example, quantify how changes in outdoor air will affect the thermal energy transfer of the thermal mass.

The ratio $\frac{\varpi\rho Cd}{h}$ of the time scale for convection at the surface to the forcing time scale indicates whether there is time for significant energy to be transferred to the thermal mass before the outdoor temperature changes appreciably.

The ratio $\frac{d^2\varpi}{\kappa}$ of the time scale for diffusion to the forcing time scale indicates whether there is time for temperature variations to penetrate the thermal mass before the outdoor temperature changes appreciably.

Evaluation of the occupants' thermal comfort situation

To ensure that the CAM system creates good thermal comfort in real conditions, it is essential to focus on the occupants in the system, using thermal comfort evaluation methods originating from people. It is their comfort requirements that finally decide what type of design that will succeed in the long run. It is consequently very important to use comfort evaluation methods that are based on human reactions, and not just temperatures of surfaces and air.

It can be quite difficult to communicate the combined effects from different heat losses to and from individuals. It is therefore very useful to convert these values into something easier to understand, such as the PMV index [11, 12] for whole-body evaluation and the equivalent "experienced" temperature (t_{eq}) [13, 14]. The intentions in this study are to look at how both whole body and local influences of the positioning of the CAM system affect the subjective experience of thermal comfort.

DEFINITION AND PLANNED EVALUATION OF CAM

Here follows the definition and application of the Controlled Active Mass (CAM) system. The methods that will be used to evaluate the CAM system in an office room are presented together with the CAM variables that will be evaluated.

Definition of the CAM system

The purpose of the Controlled Active Mass system is to reduce the need for cooling in offices and at the same time to provide a good indoor climate. CAM can be seen as a combination of active and passive thermal mass systems, with which both the thermal mass and the temperature can be varied. While the CAM installation transfers cooling energy to the office area it can be seen as a passive system, since there is no media flowing in the system. On the other hand, when there is an increased need for cooling in the office, the water in the system can be replaced by new cold water to increase the cooling capacity. CAM thus becomes an active system that can be controlled depending on demand from the occupants of the building. The CAM system allows us to change both the mass and the temperature during the day. The thermal mass is changed by varying the level of filling.

The CAM system will contribute to a better thermal comfort in two ways: by reducing temperature fluctuations, due to an even distribution of cooling in the office, and also through permitting the cooling load to be changed to suit weather conditions and seasons, which will give a more adaptable thermal comfort. Many office buildings have a high cooling demand due to solar radiation through glazed facades and through transmission through walls during the summer. It may therefore be necessary to have a central cooling system connected to the ventilation unit for achieving a comfortable supply temperature. The purpose of the CAM system is not to replace the central system but rather to meet the cooling need for internal heat loads such as computers, lighting, occupants etc.

The thermal mass will be constructed as a tank filled with water, the level of which can be varied depending on demand. The temperature of the water in the tank can also be controlled and varied by changing the water in the tank with new fresh tap water. The temperature of the water in the tank can thus be altered between room air temperature and the temperature of the incoming tap water which, for Swedish conditions, varies between 4 °C and 12 °C, depending on the season and type of water source. The temperature of the incoming water to CAM must however be higher than the dewpoint of the office air in order to avoid condensation.

Application of CAM

During the evaluation the CAM system will be placed in a test room with dimensions 2.6*3.7*2.8 m (*W***L***H*), as shown in Figure 1 below. The test room corresponds to a typical-sized office room for one person. The room is well insulated, and is located inside a large test hall with a normal indoor climate, so that the climate inside the test room is not influenced by its surroundings. There are therefore no transmission losses through the test room envelope.

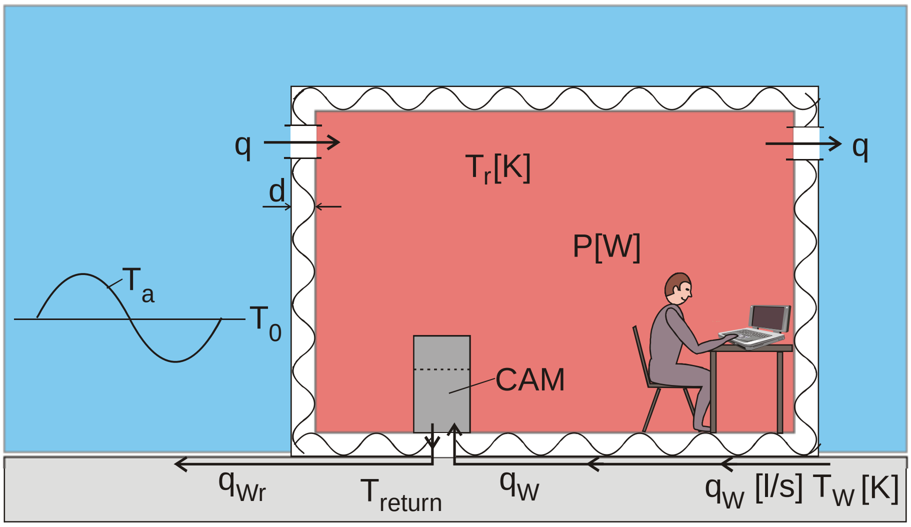

Figure 1. Test room for evaluation of CAM

In this study the CAM system will be designed to cover the cooling demands for controlling the internal heat gains from occupants, computers and lighting. For this specific case, this gives a total cooling requirement of 284 W in order to control the internal heat loads in the room. The occupant for the measurements will be simulated using a mannequin. The internal heat loads affecting the room during daytime in normal working hours, which means that cooling is needed only during these hours. The room is ventilated with a low-velocity inlet device located 2.4 m above the floor, with the exhaust opening located in the opposite wall.

Methods to be used for evaluation of CAM

Experiments and simulations will investigate how CAM will affect the thermal comfort in the room and energy-saving potential. Temperature and air velocity distributions in the office will be measured. Temperature measurements will be made using thermocouples and infrared thermograph. The velocity and turbulence levels in the room will be measured using sensors located around the mannequin and CAM. The air flows in the room will also be visualized using smoke. Measurements will also be used to determine boundary conditions that should be used as input for the simulations. The measured results will also be used for validation of the calculated values.

Simulations will be made to achieve a detailed description of the temperature and velocity distribution in the whole office room. Computational Fluid Dynamics (CFD) will be used for the numerical predictions. The same cases that have been evaluated will be simulated and a detailed comparison between the calculations and the measurements will be made. Some extra additional cases will be performed using CFD to evaluate the potential with CAM and its influence on the indoor climate.

CAM variables to be evaluated
How the CAM system influences the air movements in the office and thermal climate has to be examined. This will be made from various approaches, including the position of the CAM unit, its temperature, the amount of water in it, and when the water should be changed. When performing the CFD calculations the size, shape and the total cooling load will also be evaluated.

For the experimental evaluation, one geometrical configuration of CAM system will be examined, i.e. the volume, size and shape will be constant. In order to change the cooling capacity of CAM, both the temperature and the amount of water will be changed. Performance might also be affected by the position of the CAM unit, and so the experiments will also investigate the effect of different locations on the thermal climate in the office. It is important that the cooling need of the office should be fulfilled, but the unit should also improve occupants' thermal comfort.

DISCUSSION

CAM can be viewed as a cooling sink that should balance the thermal loads of occupants and equipment in the office. Compared to other cooling systems such as passive cooling beams, the system should be used only when there is a cooling demand. However, passive beams provide cooling all day, even though the demand may have decreased. Another advantage is that with CAM one can predict where the chilled air is released to the room and draught problems might be avoided. With beams, the airflow is more unstable and harder to predict, and draught problems might arise.

An evaluation of the CAM system is interesting, as we expect that it should be possible to achieve energy savings and better indoor climate than from other active mass systems. Compared with traditional active systems, such as systems with embedded pipes or ducts, the thermal mass is placed directly in the room, thus giving a more direct energy transfer. There is also no continuous drive energy requirement needed to transfer the energy into the building, since the cooling in the tank is exchanged only when there is a demand.

In real use of CAM systems the best solution must also take into account possible different prices for cooling and heat energy during the day or year. It is also important to know the working time schedule and the heat load from lighting, equipment, occupants etc.

Indirect evaporative cooling: performance evaluation based on the system's effectiveness

Marijke Steeman, Arnold Janssens and Michel De Paepe

University of Ghent, Belgium

Corresponding email: Marijke.Steeman@UGent.be

SUMMARY

Indirect evaporative cooling (IEC) is an interesting passive cooling technique in which the extracted air is cooled by means of adiabatic humidification. By passing over an air/air heat exchanger this air cools down the supply air. A clear interaction can be observed between the relative humidity of the extracted air and the thermal comfort realized in the building.

Using data from measurements carried out in a non-residential building which makes use of this cooling technique, the influence of the room moisture balance on the thermal performance is investigated. Furthermore, dynamic simulations based on the system's effectiveness were performed using the multizone building simulation program Trnsys, in order to evaluate different parameters affecting the performance of IEC.

INTRODUCTION

The relative humidity in a room is influenced by moisture sources (people, cooking …), ventilation with outdoor air, infiltration and the exchange of moisture with walls and furniture. Hygroscopic materials such as wood and textile are able to dampen out relative humidity variations [1] [2]. Nevertheless the uncertainty of many parameters (material data, available surface …) makes it difficult to assess the relative humidity variations well and as a result most building simulation programs, e.g. Trnsys, predict the relative humidity in a simplified way [3] [4].

In indirect evaporative cooling the thermal performances depend on the indoor humidity. In the installation the return air passes over the wet side of an air/air heat exchanger (Figure 1). By adiabatic humidification the air stream is cooled. At the same time fresh air flows over the other side of the heat exchanger and cools down. This method differs from direct evaporative cooling in which the supply air stream is directly humidified. By humidifying the return air the dry bulb temperature of the supply air can be lowered without increasing its humidity ratio. In this way a more comfortable indoor climate can be obtained.

In figure 2 the states of both airstreams during the process are schematically presented making use of a Mollier chart. During humidification, the return air follows lines of equal wet bulb temperature until saturation, while the horizontal lines indicate the cooling of the supply air.

Typically, an IEC installation can operate at different stages. When the outdoor air is fresh enough in summer, the air flow rate is increased and the air is used for free cooling. As soon as the outdoor air temperature is too high, the fresh air is adiabatically cooled by moistening the heat exchanger. In some installations, active cooling is present to contribute to lower the temperature of the supply air, if the desired indoor temperature is not yet reached [5].

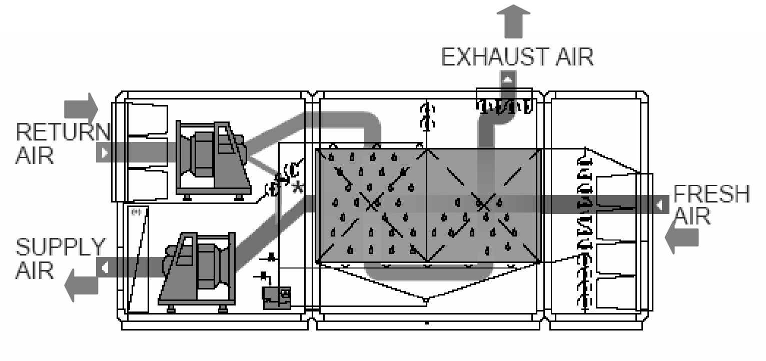

Figure 1. Indirect evaporative cooling [5]

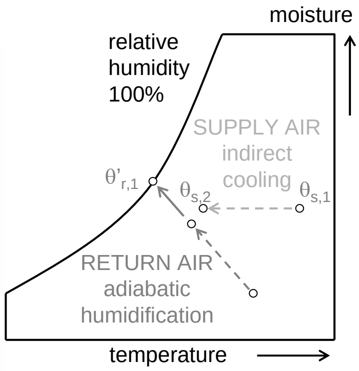

Figure 2. State of the airstreams in IEC

This paper focuses on evaluation of the system's performance. First, making use of measurement data the relation between the indoor humidity and the cooling performance is established. After, dynamic simulations will be used to evaluate various parameters influencing the thermal performance of the technique.

METHOD

A. Experimental study of hygrothermal interaction

The relative humidity of the return air plays an important role in the performance of IEC because it is moistened in the installation. Measurements carried out in non-residential building in Oostende (Belgium) where IEC was applied showed that a linear relation exist between the amount of cooling of the supply air and the difference between the dry bulb temperature of the supply air entering and the wet bulb temperature of the return air leaving the heat exchanger (Figure 3). The smaller this latter temperature difference, the less the fresh air can be cooled because saturation is reached faster when humidifying the return air. This can as also be seen in the Mollier chart (Figure 2).

The effectiveness ε of an indirect evaporative cooling system can be defined. It describes its thermal performance and is given by:

$$\varepsilon = \frac{\theta_{s,1} - \theta_{s,2}}{\theta_{s,1} - \theta'_{r,1}} \quad (1)$$

In Eq. (1) $\theta_{s,1}$ and $\theta_{s,2}$ are respectively the temperature of the supply air entering and leaving the heat exchanger. $\theta'_{r,1}$ is the wet bulb temperature of the return air entering the heat exchanger. The effectiveness thus compares the actual temperature difference realized by IEC with the maximum possible difference.

Calculated from the measurements the effectiveness of the IEC installation in Oostende is on average 82.5 %. The studied system contains a cross flow heat exchanger with total width of 900mm, a length of 1950mm and is made out of polypropylene. The maximum air flow rate of both the supply and return fan is 7100m³/h.

It should be noted that the measured points on figure 3 do not intersect the origin. It shows that a small temperature change occurring in the return air flow will not be perceived by the supply air flow. We assume that this should be explained by the heat resistance of the heat exchanger's walls and the water film that has to be overcome.

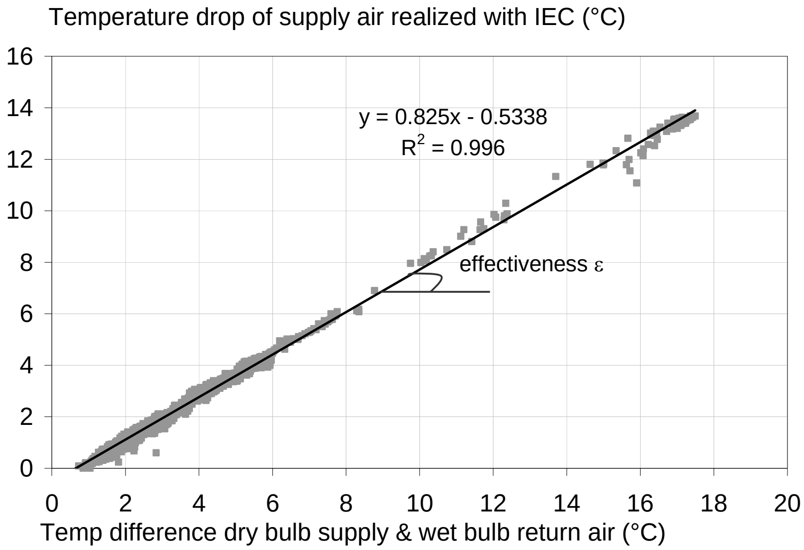

Figure 3. Interaction between indoor humidity and thermal performance (Oostende, 18/07/06 - 22/07/06)

B. Simulation model

The definition of the effectiveness can be used as a first step in studying the performance of an IEC system. As the performance of the installation depends on wet bulb temperature of the return air, the indoor temperature realized using IEC is defined both by the room heat and moisture balance. Therefore in Trnsys [4] a simple model assuming a constant effectiveness was built, which calculates the temperature of the supply air using Eq. (1) in every time step. The model has the advantage to be able to predict the indoor thermal comfort, without the need of numerical models that require a large calculation time.

As a case study, a small office model was designed (Figure 4). The office has a floor surface of 15m² and a height of 2.8m with one window of 3m² facing west, being the most disadvantageous orientation. No shading is present. The office is occupied during the office hours (08-16h) by one person (seated and light writing), who has a heat production of 120W/person (65W dry and 55W latent heat) and a moisture production of 0.07kg/h [4][6]. Apart from this, internal gains due to office equipment (140W/pc) and lights (10W/m²) are introduced.

The office is built up from a traditional heavy construction. Only the west oriented wall is an external wall, all the other boundaries are assumed to be adiabatic. For the floors and ceilings only the layers that are the most important for the storage and conductance of heat, are modelled. There is no lowered ceiling or raised floor taken into account. Due to symmetry, only half of the construction is modelled for the interior walls. For the exterior wall, the whole construction is taken into account. Tables 1 and 2 show the construction details as well as the window and material properties used.

To model the moisture buffering the simplest model from Trnsys, assuming the indoor air is lumped, is used. Buffering in the plastered walls and ceilings and in some basic furniture was taken into account [2] and the capacity ratio was calculated to be 5.

In the office model also a control system was introduced:

Day control:	Ti < 21°C	Heating setpoint 21°C (07-17h)
		Hygienic ventilation air change rate (07-18h)
	Ti > 25°C	IEC (07-18h) until Ti < 22°C: Cooling air change rate
Night control:	Ti < 16°C	Heating setpoint 16°C (17-07h)

The airflow rate for cooling is derived from cooling load calculations [7]. The hygienic ventilation rate is calculated for one person to be 36m³/h to meet the minimal ventilation requirements to obtain an IDA 2 – class in non-residential buildings [8].
Simulations were run for the entire year using a 15 min - timestep. The outdoor climate from Uccle was used in which the air temperatures have a return period of ten years [9]. The summer period extends from 01May to 30September. Weekends are not taken into account as we wanted to include all hot summer days.

C. Saved cooling demand and indoor comfort

It is possible to calculate the cooling demand Q_c, that should be delivered by an active top cooling e.g. a ventilo-convector placed in the office, in order to accomplish a maximum indoor air temperature of 26°C during all office hours.

$$Q_c = 0.34\, nV(\theta_i - 26°C) + \frac{h_{ev}\rho_a\, \xi\, nV}{3600}(p_i - p_{sat}(\theta_i)) \quad (2)$$

In Eq. (2) h_{ev} is the latent heat of evaporation (2.5 10^6 J/kg), n is the cooling air change rate (h^{-1}), V is the office volume and ξ is the specific vapour capacity of air (6.1 10^{-6}kg/kg/Pa). As the heat exchanger can be bypassed in the described installation (Figure 1), thus allowing free cooling with outdoor air, the cooling demand that is saved using IEC in comparison to free cooling can be calculated:

$$Q_{c,saved} = Q_{c,FreeCooling} - Q_{c,IEC} \quad (3)$$

The indoor summer comfort is evaluated using the Adaptive Temperature Limits Indicator (ATG) which takes into account the thermal adaptation of occupants to the indoor climate [10] [11]. The method differs between alpha and beta - buildings. The evaluation of the beta building is more severe and is used for our office model. It assumes occupants cannot affect the indoor climate e.g. by use of opening windows). The ATG method divides thermal comfort into three levels. It is required that a building meets the standard level B which corresponds to 80% thermal acceptability to have a 'good' indoor thermal comfort in the period studied. Levels A and C correspond respectively with 65% and 90% acceptability.

In figure 5 the evaluation of the indoor climate using this method is shown for a specific simulation case as an example. On the horizontal axis the running mean outdoor temperature is presented $T_{e,ref}$, which is derived from the external temperature from the current day and that of the three preceding days. The vertical axis shows the indoor operative temperature $T_{i,o}$.

Figure 5 shows that in this specific case a good indoor comfort is expected at average outdoor temperatures. During some hot days ($T_{e,\,ref}$> 21°C), some peaks can be found in the indoor climate, during witch the comfort criteria are not fulfilled.

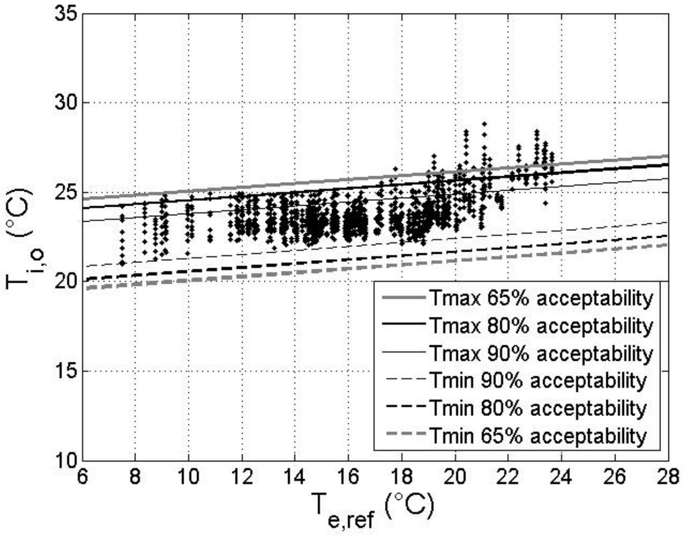

Figure 5. Indoor comfort evaluated using the ATG – method for a beta building with an IEC system: effectiveness 85% and cooling air change rate 7h^{-1} (1May-30Sept: 08-16h).

RESULTS

The cooling air change rate was calculated to be 9h^{-1} (equals 380m³/h). Simulations, assuming an IEC installation with a constant effectiveness of 85%, are compared with simulations in which the heat exchanger in the IEC installation is bypassed (free cooling). Furthermore a case, in which no cooling at all is present, is shown. In this case the hygienic ventilation was working constantly during the office hours.

In figure 6 the percentage of the office hours in which respectively an indoor class A, B and C is obtained, and, in which the IEC/free cooling is working, are given. The cooling demand, which is saved making use of IEC instead of free cooling, is calculated with Eq.(2) and (3).

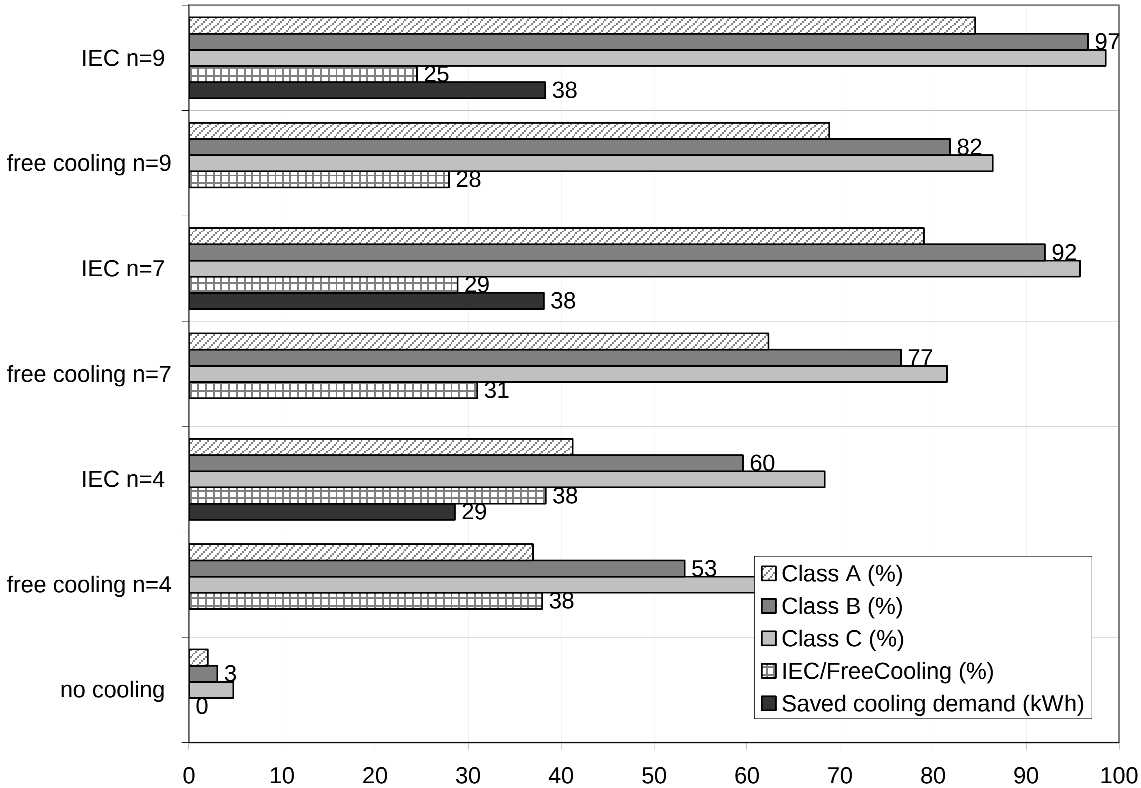

Figure 6. Influence of air change rate on indoor comfort and saved cooling demand

We can conclude that a sufficiently good indoor climate is obtained when applying IEC with a cooling air change rate of 9h^{-1}: during 97% of the occupancy hours the climate is situated in class B. By lowering the cooling air change rate respectively to 7h^{-1} and 4h^{-1}, this value drops with respectively 5% and 37%. The comfort obtained by using IEC is always better than when applying only free cooling. No cooling at all only 3% of the time good comfort is predicted. The saved cooling demand decreases when lowering the air change rate. In case of a cooling air change rate of 7h^{-1} 38 kWh can be saved, while 6.5 kWh would still be necessary to obtain an indoor temperature of maximum 26°C during all the office hours. Free cooling and IEC work for almost the same time in the respective cases.

Apart from this, other parameters influencing the thermal performance of IEC are evaluated. Starting from an IEC system which has an effectiveness of 85%, figure 8 shows which parameters have been changed in the different cases. In all the cases the cooling air change rate is $7h^{-1}$, other parameters are kept constant.

- Changing the systems effectiveness only has a small influence on the performance of IEC. The obtained comfort and the cooling demand saved are similar for an effectiveness equal to 70%, 85% and 95%. Logically, an installation with a higher effectiveness will perform slightly better, as lower supply temperatures can be obtained.
- Increasing the indoor moisture production has a large influence on the room's moisture balance. One person produces about 0.07 kg/h moisture at rest, but other gains such as bathing, washing, … can be introduced (e.g. in health care). Enlarging the intern gains to 2.5kg/h, the time in which comfort is situated in class B reduces with about half. Furthermore, IEC is working 10% of the time more. Apart from a sensible part, also a latent part is present in the cooling demand, being respectively 82% and 18% of the total cooling demand (102kWh).
  In this case the cooling demand for IEC is larger than when applying free cooling. This can be explained by the large internal moisture production, for which the wet bulb temperature of the return air will be larger than the outdoor air temperature. This means the outdoor air will be heated by the heat exchanger instead of cooled which results in higher supply temperatures. In practise the heat exchanger may be bypassed in these situations to allow free cooling with outdoor air.
- Doubling the moisture buffering capacity has almost no influence on the systems performance. This can be explained by the fact that moisture buffering does not have a large effect on the average relative humidity, but rather dampens out the variations. This is also concluded in [2] by experiments.
- In case the office is built up from a light construction the comfort decreases with 6% of the time (class B). The saved cooling demand is in this case 51kWh, compared to 38kWh in case of a heavy construction type. At the other hand, IEC is active during 4% of the time more. Construction and material details can be found in Table 1.

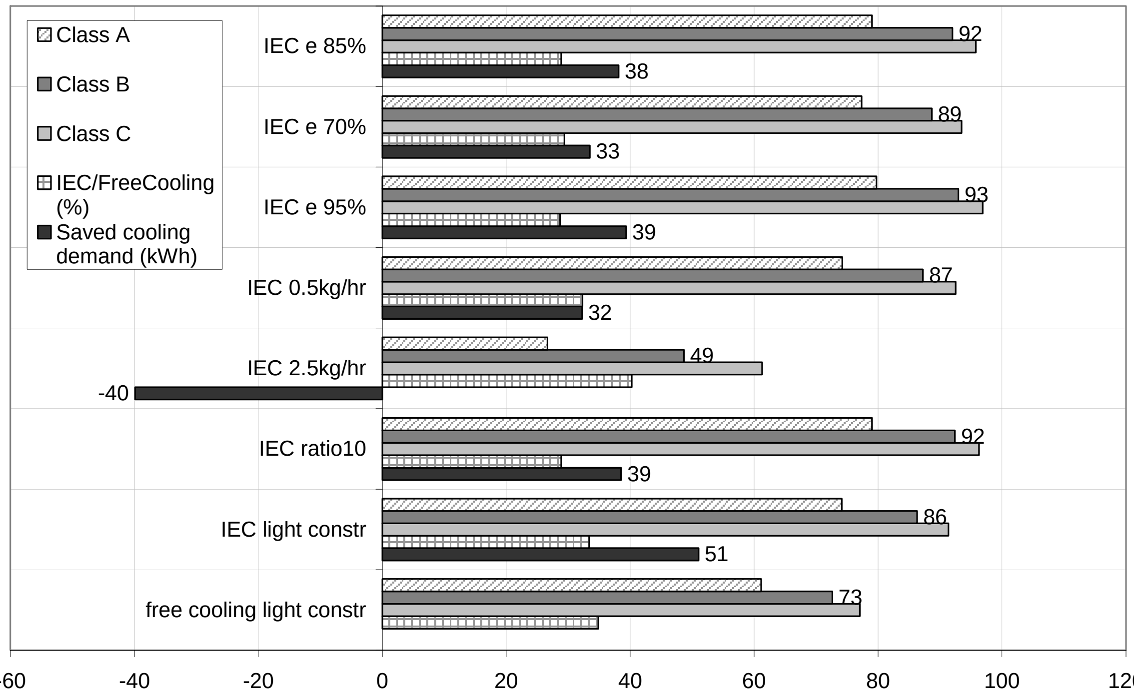

Figure 7. Influence of effectiveness, indoor moisture production and buffering, and construction type on indoor comfort and saved cooling demand ($n=7h^{-1}$)

CONCLUSION

Indirect evaporative cooling is an interesting passive cooling technique in which the thermal performance depends mainly on the indoor humidity. The evaluation of measurement data shows that a linear relation exists between the temperature drop of the outdoor air and the maximum cooling amount that is possible with IEC. Dynamic simulations based on the system’s constant effectiveness showed that the knowledge of the indoor moisture balance is essential to predict the performance of indirect evaporative cooling well.

The indoor moisture production has the most important influence on the system’s thermal performance. On the other hand, the amount of moisture buffering material in the room rather influences the stability of the climate and does not have a large effect on the performances of IEC. Furthermore the moisture balance is also determined by the ventilation air change rate. Lowering the cooling air change rate decreases the established indoor comfort. In the studied installation, varying the system’s effectiveness had only a limited influence on the obtained thermal comfort. Applying the technique in a building with a light construction will reduce the comfort but increases the energy saved in comparison to free cooling.

SUMMARY

This paper presents the study of the desiccant based cooling system in the laboratory. The main purpose of the study is to determine the performance of desiccant system components. Also, using some results from the experimental works, preliminary parametric investigation in TRNSYS had been done. The investigation is centered on the application of the system in different climatic conditions. The results showed the dependence of the desiccant system upon the performance of its components and the climatic conditions.

INTRODUCTION

Desiccant based dehumidification and cooling system is envisioned as an alternative to the refrigerant based cooling system. The main advantage of the desiccant based system is that it can be directly operated using renewable thermal energy sources compared to the refrigerant based which is electrically operated. Several studies are on-going for the application of desiccant system in actual situations. This paper presents the studies conducted in our laboratory regarding this technology. The study is focused on the performance evaluation of the system components including some preliminary modeling and parametric investigations.

EXPERIMENTAL FACILITY AND EVALUATION

Experimental Facility

The thermal conversion facility was constructed to simulate the outdoor and indoor air conditions. The main purpose of the said facility is to test and investigate the performance of the desiccant based system. The experimental facility has a physical set-up shown in Figure 1. It has two controlled chambers in which Chamber A is used to simulate the outdoor air condition and Chamber B for the indoor air condition. The first chamber (A) has temperature range from -10^{0}C to 40^{0}C with accuracy of 2%. The humidity could be varied depending on the needed condition. The accuracy of maintaining the set-value of the air humidity content is within 10%. For Chamber B, the operating temperature range is from 10^{0}C to 40^{0}C with accuracy of within 1%. The air humidity content could be varied as in Chamber A. Its accuracy is within 1%.

The technical description of the facility as shown in Figure 2.The source of raw air for both controlled chambers is from ambient air. It is forced to flow into the chambers by fans. If the temperature set-value is lower than that of the ambient air, air cooling operates. On the other hand, if the set-value of the needed air temperature is higher than that of the ambient, air heater operates. Seemingly similar is the situation for maintaining the air humidity content. If the ambient air humidity is high, dehumidification process operates. And when the ambient air humidity content is lower compared to the set-value the humidifier operates. The conditioned air is mixed in the controlled chambers before supplying it to the testing chamber. The testing chamber is located between the two controlled chambers. The air is moved from the chambers into the testing chambers using fans attached to the ducting system. In the testing chamber any kind of air handling unit and heat exchanger can be tested and evaluated. For this study, the desiccant system was evaluated.

Experimental Evaluation of Desiccant System

The main components of the desiccant based system consist of desiccant dehumidifier, heat recovery wheel, desiccant heater and evaporative cooler. The performance of the whole desiccant cooling system is dependent on the performance of its components. To determine the performance of its components, the performance evaluations of the desiccant wheel and heat wheel were under taken.

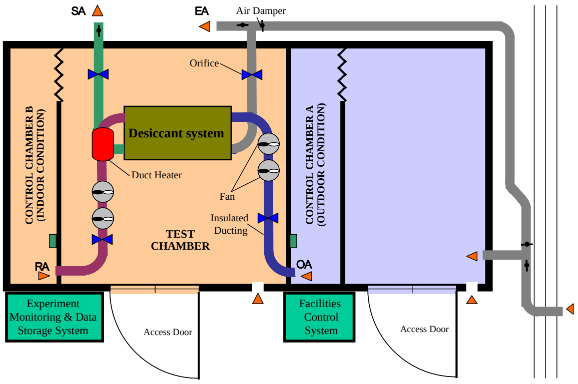

Figure 1. Experimental Facility.

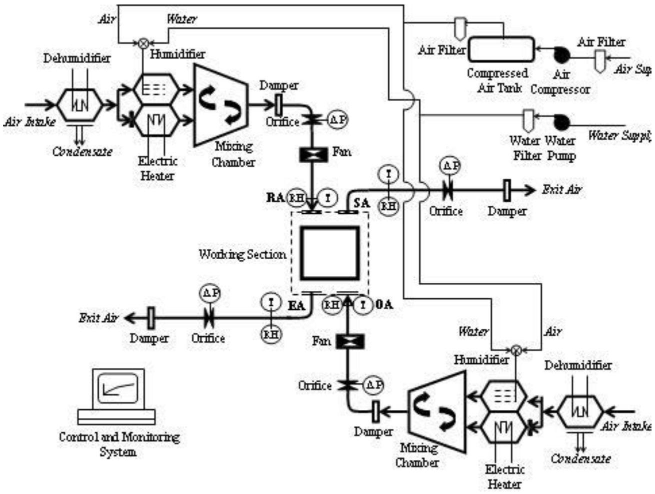

Figure 2. Technical description of the experimental facility.

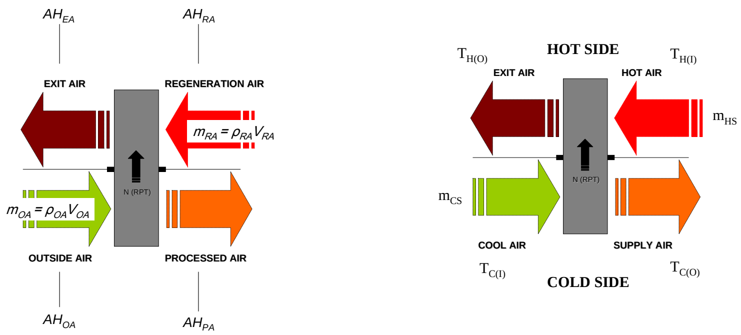

Figure 3. The schematic diagram of the desiccant wheel (left) and heat wheel (right).

Desiccant Wheel Evaluation

The desiccant wheel subjected to evaluation is a Silica-Gel coated wheel. It has 300mm external diameter with 100mm depth. The parameters considered for the evaluation were the rate of volumetric flow, the regeneration temperature and the wheel rotational speed. The considered flow rates were $100m^3/hr$ and $200m^3/hr$. The regeneration temperatures applied were 60^0C, 70^0C and 80^0C. For $100m^3/hr$ the wheel rotational speeds were 5, 10, 15, 20, 25, 30, 35, 40, 50 & 60 RPH and for $200m^3/hr$ the rotational speeds were 5, 10, 20, 30, 40, 50, 60, 70, 80 & 90 RPH. The selection of different wheel speed for the different flow rates was based on the initial test run that as the flow rate increases the optimum speed of the wheel increases. Figure 3 shows the schematic diagram of the wheel and the governing performances were based on NREL testing manual [1]. Based on the manual, the dehumidification performance of the desiccant wheel is based on moisture removal capacity or MRC. It is expressed as,

$$MRC = m_{OA}(AH_{OA} - AH_{PA}) \tag{1}$$

The amount of moisture removal capacity or sorption rate is the same at the regeneration side moisture regeneration rate which is the moisture removal regeneration (MRR) expressed as,

$$MRR = m_{RA}(AH_{EA} - AH_{RA}) \tag{2}$$

To evaluate the characteristic and performance of the experiment, the moisture mass balance (MBB) determined the quality of gathered data and thus the MBB is a checking factor and expressed as,

$$MMB = \frac{MRC}{MRR} \tag{3}$$

For acceptable accuracy of gathered data, the ratio of MMB should be within 0.5 to 1.5. To be within the limits of acceptable accuracy improvements of the experimental conditions and instrumentations are highly necessary. And the nomenclature, m_{OA} and m_{RA} are the mass flow rates (outside air and return air), kg/s. *AH* is absolute humidity content of air, g/kg. *OA*, *PA*, *EA* and *RA* are the outside air, processed air, exit air and return air.

Heat Wheel Evaluation

The evaluated heat wheel is coated with Silicone-Acrylic Compound. The physical appearance and dimension of the wheel is the same as the desiccant wheel. However, the main purpose of the heat wheel is for sensible heat recovery only. In the evaluation, the moisture content of the air was not considered. To create temperature difference between the two counter flowing air streams in the wheel faces, air stream at cold side was maintained at 25^0C and the air stream at hot side 50^0C. For properly designed heat exchanger, variation of air streams temperature was found to have no effect on its performance. Therefore only these two temperatures were considered and the schematic diagram of the heat wheel is shown in Figure 3.

The other parameters used in the evaluation were the volumetric flow rates and the wheel rotational speed. The considered flow rates were $100m^3$/hr and $200m^3$/hr. The wheel rotational speeds were 2.5, 5, 10, 15 and 20 RPM. And, the performance evaluation of the heat wheel was based on its effectiveness in transferring sensible heat shown as [2],

$$Eff_{Average} = \frac{m_{CS}(T_{C(O)} - T_{C(I)}) + m_{HS}(T_{H(I)} - T_{H(O)})}{2m_{Minimum}(T_{H(I)} - T_{C(I)})} \quad (4)$$

For the nomenclature, the $Eff_{Average}$ is the average effectiveness of the heat wheel. The m_{CS} and m_{HS} are the mass flow rates (hot and cold sides), kg/s. $T_{C(I)}$ and $T_{C(O)}$ are temperature of air in the cold side (inlet and outlet), ^{0}C. $T_{H(I)}$ and $T_{H(O)}$ are temperature of air in the hot side inlet and outlet, ^{0}C. And, $m_{Minimum}$ is the minimum flow rate of either cold or hot side, kg/s.

EXPERIMENTAL RESULTS AND DISCUSSION

Desiccant Wheel

Using equations 1, 2 and 3 in analyzing the gathered data and plotted below (Figure 4), the results show that the wheel performance is basically dependent upon its rotational speed. In the case of $100m^3$/hr the optimum speed is 30RPH and for the $200m^3$/hr flow rate the optimum speed is 50RPH. Meaning for the same type and dimension of wheel, increasing the flow rate will also increase the optimum wheel speed. The optimum speed is the same for different regeneration temperature. However, as the regeneration temperature increases, the moisture adsorption increases. At optimum speed, for the case of $100m^3$/hr, the increase of moisture adsorption rate from 60^0C to 70^0C is 13% and from 70^0C to 80^0C the increase is 6 percent. In the case of $200m^3$/hr flow rate the increase of adsorption rate from 60^0C to 70^0C is 14% and from 70^0C to 80^0C the increase is 5%. So, the amount of the regeneration temperature is another factor in the effectiveness of desiccant dehumidifier in moisture adsorption. However, the increase of moisture adsorption rate becomes lower as the regeneration temperature becomes higher. Based on the moisture mass balance presented in Figure 4 the gathered and analyzed data are within the range of 0.95 to 1.05. Thus experimental evaluation is within the accuracy imposed by NREL.

Heat Wheel

For the heat wheel the results of the experimental study are presented in Figure 5. For $100m^3$/hr flow rate, the effectiveness approached 81% for wheel speed of 20RPM and for the $200m^3$/hr the effectiveness approached 69% at 20RPM. Based on the results, the performance of the heat wheel is dependent on the wheel rotational speed and on the amount of flow rate. Results show that the wheel can be operated at 20 RPM as maximum rotational wheel speed.

MODELLING AND PARAMETRIC INVESTIGATION

Modeling

Preliminary modeling of the desiccant based system was implemented in TRNSYS [3]. Standard components were used such as the desiccant dehumidifier, the heat wheel and evaporative coolers. In the TRNSYS, the model of the desiccant dehumidifier is based on the analogy between the heat transfer of the sensible heat exchanger and of the desiccant heat and mass transfer. The input parameters of the model are the two effectiveness values proposed by P.J. Banks which is discussed in TRNSYS Manual. In this study, experimental results of the performance of the desiccant wheel were available. However, it could not be used directly to the model of the desiccant wheel. Thus the comparison between the experimental performance of the desiccant wheel and the model in TRNSYS was done through series of trials in finding the two effectivenesses that can have almost similar result to the experimental works. In the future study, this limitation will be addressed later. The modeling of heat recovery wheel is based on the sensible heat transfer from two streams of air in different temperatures. The actual effectiveness from the experimental work was used in the model. For the evaporative cooler, the modeling was based on effectiveness in reducing the dry bulb temperature to the maximum of its web bulb temperature. Based on the study cited by Daou, et al. 2006 [4], the maximum effectiveness of direct evaporative cooler is 90% and of the indirect evaporative cooler 80%. These parameters were used in the modeling since the current experimental set-up did not include experimental investigations in these devices. In general, the above considerations were used in the modeling and parametric investigation. Thus some deviations occurred in the results when compared with the experimental works.

Figure 6 shows the schematic diagram of the experimental unit which was under experimental investigation. This set-up was also used for comparison with the modeling done in TRNSYS. As stated above, since the model of the desiccant wheel in TRNSYS has no provision for direct comparison with experimental results, series of trials had been done. The finest trials that can be reached are presented in Table 1. Based on the results, the comparisons are within 10 percent. However, some points such as of points 2, 3 and 7 of the relative humidity content, the results are more than 10 percent. These points are in the desiccant wheel. As stated above, since the TRNSYS desiccant model cannot have direct comparison with the experimental results, higher deviation in these states was expected. This is the limitation of TRNSYS and should be subject for more improvements to arrive at a good agreement between the experimental and the simulated results. Considering this limitation, some parametric investigations were done for testing the capability of the model when applied in different conditions.

Simulation

The parametric investigations for the application of the desiccant cooling system was implemented in different climatic conditions; for temperate climate - little bit warm and humid, for the Mediterranean - warm and humid and, of the tropical climate - relatively hot and humid for all-year-round. Table 2 shows the temperature and relative humidity for the countries representing the three different climatic conditions used in the study. Two models of the desiccant cooling system were used for the investigation: the standard desiccant cooling system shown in Figure 7 and, the desiccant cooling cycle with pre-cooling of outdoor air prior to the desiccant wheel shown in Figure 8.

PARAMETRIC INVESTIGATION RESULTS AND DISCUSSION

Using the performance data, stated above, regarding the comparison between the experimental results and modeling and, applied in different climatic conditions the results are presented in Table 3. Based on the presented results the standard desiccant cycle can operate effectively in temperate and Mediterranean climates. However, for the Mediterranean climate, the needed regeneration air temperature (RegA) is high, more than 100^0C. For tropical climate, the standard cycle cannot operate and supply comfortable air condition since the sensible load of air is higher even though the air latent load is lower. On the other hand, the cycle with pre-cooling may attain the same capability in temperate and Mediterranean climates and comparable to standard cycle with lower supply air and regeneration temperature (only small difference). However, in the tropical areas, the system is still short of supplying comfortable air condition as shown in the condition of the supply air temperature. But, by using much more efficient pre-cooling devices such as borehole heat exchanger, absorption chiller and others, the system performance could be further improved as shown in graphical presentation, Figure 9.

Based on this presentation, the desiccant adsorption process increased when the air temperature entering the desiccant wheel decreased. Thus cooling the outdoor air to near saturation may increase the dehumidification performance of the desiccant wheel. However, further study should be done to determine the over-all performance of the system.   Some research works conceptualized the pre-cooling effect intended for hybrid desiccant cooling system [5].

SUMMARY AND CONCLUSIONS

Experimental works and some parametric investigations were conducted. Based on the results, the performance of the desiccant cooling system is dependent on the intrinsic and

SUMMARY

Indirect evaporative cooling an efficient and cheap way to reduce the heat load in a building. For an innovative small scale evaporative cooler (400 m^3/h) a model is made to predict the outlet temperature and cooling capacity for different environmental conditions in order to estimate the seasonal heat load reduction. The cooler is a compact counter flow heat exchanger with louver fin geometry on either side; the secondary side is coated with a water absorbing material. Due to the direct evaporation from the surface and the counter flow operation outlet temperatures below the wet bulb temperature can be achieved. The model uses Chilton & Colburn approximation for the evaporation, an approximation for the j-factor as found by Chang and Wang. The resulting model is based on estimated geometry properties and predicts the outlet temperature for given inlet conditions an airflow rates. The model predicts an over performance of the output temperature. For the inlet temperature below 24°C there a 20 % overshoot of the model, for higher inlet temperatures the overshoot is less than 10%.

INTRODUCTION

The demand for cooling increases due to higher comfort demand, compact way of building, higher internal heat load ect. For small scale building as primary schools, small utility buildings a demand for a simple way of cooling is desirable. Evaporative (adiabatic) cooling is an energy efficient way of cooling, though it has a drawback that with increasing outdoor humidity the cooling capacity decreases. In this paper a performance model for an indirect evaporative cooling is described. The purpose of the model is to use it in order to predict the effective cooling performance for use in building performance studies.

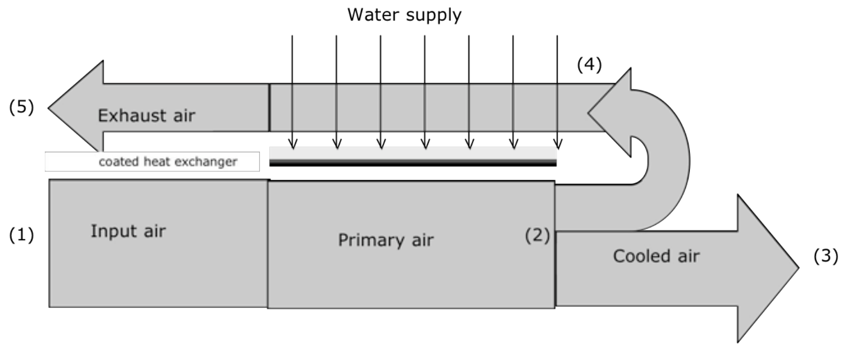

Figure 1. Schematic operation of the indirect adiabatic cooler

Operation

The main advantage of indirect adiabatic cooling is that the water content of the cooled air is not increased. The studied cooler is an innovative design where efficient use is made of counter flow geometry and of direct evaporation of water from the separating wall. The principle operation is given in fig.1.

On the primary side of the heat exchanger outside air (1) is cooled to outlet conditions. About 1/3rd of the air (2) is fed back to the secondary side (4). The secondary side of the heat exchanger has a hygroscopic coating, saturated with water. With regular intervals (typically 10min.) fresh water is sprayed onto the coating. Due to the direct evaporation from the wall a counter flow operation the outlet temperature (3) approximates the dew temperature of the inlet air. The secondary outlet air (5) is exhausted to the environment.

Construction

The heat exchanger consists of fin geometry according to Figure 3. The copper fins (primary and secondary) are glued back to back on a thin plastic foil. The separation plates between the fins achieve construction stability. This results in a very lightweight heat exchanger that after service life easily can be replaced.

Objective.

Measurements of the performance of the cooler have show that the outlet temperatures of the cooler are very near the dew point of the inlet air. This performance is due to the effective counter flow operation and the direct vaporization of water from the coated fins. In order to get insight in the performance of the cooler a model is made to relate the convective heat transfer on the primary side to the combined heat and mass transfer on the secondary side. The mathematical model can be used to enhance the performance of the cooler for different configurations and also can be used to predict the performance of the cooler

METHOD

The main principle of the cooler is the evaporation of water on the secondary side. The heat transfer consists of a convective part and a mass transfer part due to the evaporation. An enthalpy balance is set up for a surface element in the heat exchanger (Figure 2).

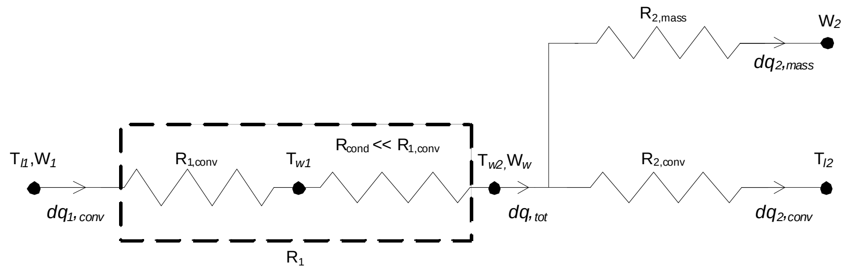

Figure 2. Model of the enthalpy exchange for a surface element of the heat exchanger.

In order to find a solution for (1) approximations have to be found for the convective heat and convective mass transfer coefficients h_c, h_m.

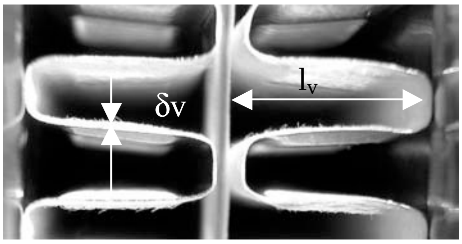
$$d(T_1,T_2,w_1,w_2)\ of\ dq_{tot} = f(\underbrace{\dot{V}_1,\dot{V}_2}_{\text{Operational Flows}}, \underbrace{A_c,A_m}_{\text{constrution}}, \underbrace{T_1,T_2,w_1,w_2}_{\text{Proces variables}}, \underbrace{\rho_l,c_{pl},c_{pw,g},c_{pw,f},h_{fg}}_{\text{material properties}}, \underbrace{h_c,h_m}_{\text{process parameters}}\ \underbrace{T_{w2},w_w}_{\text{other variables}}) \quad (1)$$

Chilton-Colburn correlation.
The heat exchanger is build up with louvered fins according to figure 3. For an estimate of the mass convection coefficient h_m the Chilton-Colburn analogy in a boundary layer is used and expressed in the dimensionless Colburn factor j_c. [1]

$$\frac{Nu}{\mathrm{Re}\,\mathrm{Pr}^{1/3}} = j_c = \frac{1}{2} f \qquad for \quad 0.5 < \mathrm{Pr} < 2 \quad (2)$$

The friction factor *f* and the Colburn factor j_c are supposed to be only a function of the Reynolds number.
The Reynolds number based on the hydraulic diameter of the canals gives *Re* = 570 and suggest a laminar flow. Though to the louvers on the fins flow through the fins leads to a turbulent flow, a so-called "low Reynolds-number turbulent flow" [2].
In the paper "A generalized friction correlation for louver fin geometry" by Chang e.o. [3] experimental correlations are given for a different arrangement of fins and louvers. For this study a general approximation from [3] is used to estimate j_c.

$$j_c = C_{jc}\,\mathrm{Re}^{-n} = 0.425\,\mathrm{Re}_{Lp}^{-0.496} \qquad (3)$$



$l_v = 8$mm
$\delta_v = 0.05$ mm
k_v=401 W/mK

Figure 3 Fin geometry of the heat-exchanger

From (3) an expression fort the heat-transfer coefficient h_c can be derived:

$$h_c = \frac{C_{j_c}\left(\frac{\mu_l c_p}{k_l}\right)^{1/3}}{\left(L_p/k_l\right)}\left(\frac{L_p}{\mu A_k}\right)^{1-n}\left(\dot{m}\right)^{1-n} \qquad (4)$$

For the given configuration with A_k=0.0048m^2, L_p= 1mm, and the general properties of air this gives:

$$h_c = 344\cdot\dot{m}^{0.505} \qquad (5)$$

According to Chilton-Colburn j_m=j_c and from (6) h_m can be expressed in h_c (7)

$$\frac{Sh}{ReSc^{1/3}} = \frac{Nu}{RePr^{1/3}} \Rightarrow h_m = h_c\frac{D_{AB}}{k_l}\underbrace{\left(\frac{k_l}{c_{pl}\rho_l D_{AB}}\right)^{1/3}}_{Lewis\ number} \qquad (6,7)$$

With ((5) follows an estimate for h_m:

$$h_m = 9.46 \cdot 10^{-4} \;\Rightarrow\; h_m = 0.325 \cdot \dot{m}^{0.505} \qquad (8)$$

Assumptions and simplifications.
With the found heat and mass a heat coefficients a heat and mass balance can be derived. The material properties of water and air (Table 2) are assumed to be constant over the length of the heat exchanger. The thermal resistance R_{cond} (figure 2) is assumed to be negligible to the convective heat resistances.
The effective conducting surface is based is based on the number of fins, the length and an estimated fin efficiency according to [4].

$$\eta_v = \frac{\left(tanh\left(ml_v\right)\right)}{ml_v} \quad \text{with} \quad m = \sqrt{\frac{2h_c}{k_v \delta_v}} \qquad (9)$$

With a length of the exchanger of 0.48 m, 108 (two sided) fins, height l_v=0.008 m A_v=1.66 m^2 and with a fin efficiency according to (9) the effective surface can be expressed as a function of h_c.

$$A_{lc} = \eta_{lv} A_v \approx -1.5 \cdot 10^{-3} h_c A_v = -2.49 h_c \qquad (10)$$

The fins are coated only on one side so $A_{lm} = \frac{1}{2} A_{lc}$.

The temperature drop due to the thermal resistance of the wetted coating is neglected. Assumed is that the humidity at the boundary of secondary side is saturated. The capillary resistance of the coating is also neglected.

Model.
The resulting model is a set of 3 coupled (11,12,13) witch can be numerically solved with boundary conditions (14,15,16).

$$\frac{dT_1}{dx} = -\underbrace{\frac{1}{\rho_l \dot{V}_1 (c_{pl} + w_1 c_{pw,g})}}_{Constant} \left(\frac{(T_1 - T_2)}{\frac{1}{A_{1c}h_{1c}} + \frac{1}{A_{2c}h_{2c}}} + \frac{\frac{1}{A_{2c}h_{2c}}}{\frac{1}{A_{1c}h_{1c}} + \frac{1}{A_{2c}h_{2c}}} \cdot \frac{(w_{w2} - w_2)}{\frac{1}{A_{2m}h_{2m}h_{fg}}} \right) \qquad (11)$$

$$\frac{dT_2}{dx} = -\frac{1}{\rho_l \dot{V}_2 (c_{pl} + w_2 c_{pw,g})} \left(\frac{(T_1 - T_2)}{\frac{1}{A_{1c}h_{1c}} + \frac{1}{A_{2c}h_{2c}}} - \frac{\frac{1}{A_{1c}h_{1c}}}{\frac{1}{A_{1c}h_{1c}} + \frac{1}{A_{2c}h_{2c}}} \cdot \frac{(w_{w2} - w_2)}{\frac{1}{A_{2m}h_{2m}h_{fg}}} \right) \qquad (12)$$

$$\frac{dw_2}{dx} = -\frac{1}{\rho_l \dot{V}_2 (h_{fg} + c_{pw,g} T_2)} \frac{(w_{w2} - w_2)}{\frac{1}{A_{2m}h_{2m}h_{fg}}} \qquad (13)$$

$$T_1(0) = T_{1,in}\ ;\ T_2(1) = T_{1,uit} \qquad \text{and} \quad w_2(1) = w_{1,uit} = w_{1,in} = w_1(0) \qquad (14,15,16)$$

The equations are solved with Matlab® the used routines are collected in [9].

Results

Figure 4 shows the heat transfer along the length of the exchanger. The secondary air enters from the right. |At first the latent heat transfer (2) is also used to cool the secondary air, the sensible heat transfer (2) is negative. Due to the vapour transfer along the total length of the heat exchanger a good performance is achieved. The latent heat transfer is about 2 times larger than the sensible heat transfer.

DISCUSSION

The model gives a good insight in the principal operation of the cooler, although based on experimental approximation for fin geometry; the model gives a reasonable approximation of the performance. The found model gives (Table 2) an over estimation of the temperature drop of max. 20%. The neglect of: heat conductance through the wall, the moisture transport through the coating all causes an overestimation of the cooling effect. For the lower inlet temperatures (<24 ° C) the secondary air over the total length is staying close to the saturation line, when the air at the surface is not fully saturated, as was assumed, this will have a significant effect on the cooling performance. The neglected R_{cond} of the wall will also lead to an increase of error at lower temperature.

To improve the model for the lower temperature range the thermal conductance of the wall and the vapour transport through the coating should be incorporated in the model.

Another thing was not accounted for in the model, is or the long term the saline deposition could lead to an extra thermal barrier. The manufacturer claimed on basis of endurance test that the deposition does not affect the water transport in the coating.

ABSTRACT

The objectives of this work are: to evaluate and optimize a method of operation of a combined system of energy recovery for air conditioning systems by means of one configuration in series of three devices, semi-indirect evaporative cooler of ceramic tubes, which recover sensible and latent energy, using the refrigeration effect by evaporation of water transmitted through its porous ceramic structure to a non saturated airflow, or by the sensible cooling of air by water flow. Heat-Pipes heat recovery battery and an air-air Heat Pump, which allow low temperature residual energy recovery. Experimental design methodology was used in test beds. This combined system will allow reducing investment cost in air conditioning equipment, to lower energy consumption of the buildings and reduce CO2 environmental impact in emissions using less HCFCs.

INTRODUCTION

In 2002 The European Union approved a directive on Energy Performance Building EPBD, one of its specific sections being the introduction of new technologies of air conditioning systems, more energy efficient such as the one proposed in the research project developed, that allows, by means of combination of a system of semi-indirect evaporative cooling to gain heat, a battery of Heat Pipes HP and a Heat Pump HPu to reduce the energy consumption in the thermal conditioning of buildings.

The application of the combined system studied, in addition to preparing the air with high energy efficiency and obtaining a suitable level of comfort in areas allows a configuration of tri recovery, recovering energy of the airflow of the return or expulsion, and therefore to reduce final energy consumption. One of the problems associated to systems of evaporative cooling is proliferation of legionella; in our semi-indirect evaporative system primary airflow does not take place, since the matter exchanged is made from pores of the ceramic material towards the primary airflow avoiding aerosols, as a result of the gradient of water steam concentrations between surface and air. In addition to being a system of highly energy efficient system, allows a reduction in the environmental impact by reducing use of coolants like, HCFCs, and producing less CO2. The study of the behavior of the combined system was conducted in winter and summer conditions, analyzing the different characteristics that might have air in different climate conditions.

Figure 1 shows the experimental installation, its main components numbered, corresponding to climate chamber (1), Air Treatment Unit (ATU) or, simulator of conditions of outer air (2), SEC (3), Heat Pipes HP (4) and Heat Pump HPu (5).

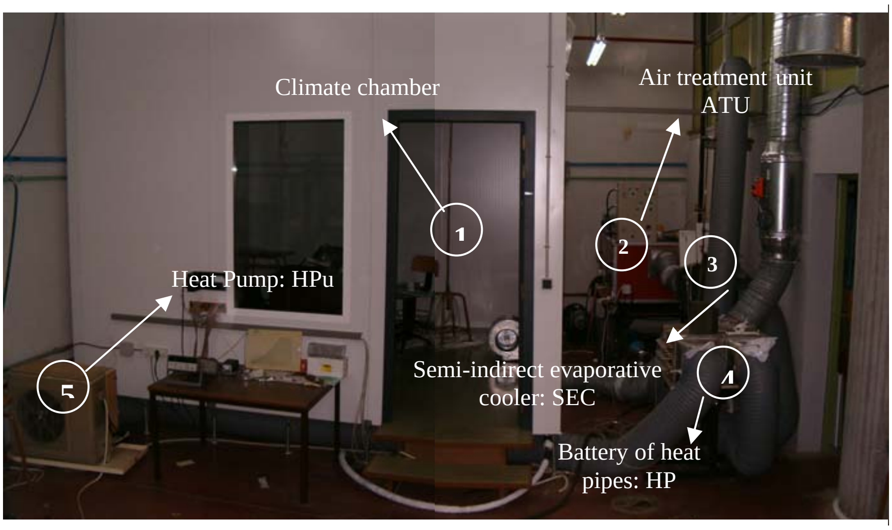

Figure 1.Experimental installation.

EXPERIMENTAL TEST BED, SENSORS AND DATA ACQUISITION

The experimental test bed of the combined system, shown in figure 1, consists of ceramic semi-indirect evaporative cooler equipment SEC, a battery of heat pipes HP and an air-air heat pump HPu linked by means of one recovery configuration to obtain air conditioning comfort on the premises and obtain energy recovery.

The Air Treatment Unit ATU prepares the air to simulate different climate conditions, that can be included in some of the climate conditions analyzed summer in tropical climate (hot air and high specific humidity) and continental summer (hot air and low relative humidity).

The outside air supply (primary current) flows through the SEC where it comes into contact with the ceramic surface, becomes humid, and as the ceramic surface is a porous material, part of the water is transferred to the primary air producing cooling by heat and mass transfer. In crossed current and by the interior of the SEC the return air (secondary current) from the premises is put in direct contact with water in counter flow, producing cooling by heat and mass transfer. Part of the water returns to the tank from where it returns to be pumped to the evaporative cooling system. However another part of the water can cross the porous structure coming into contact with the outdoor air.

The process in the SEC ceramic pipes not only produces cooling in the water, also in the secondary air flow, and in addition, humidifies the latest. This cooled airflow is used in condensation stage of the battery of heat pipes HP, where the primary air supply from the SEC is subjected to further to cooling, this time sensible cooling, with no variation of specific humidity. Figure 2 shows the components of the recovery system.

After the Semi indirect Evaporative Cooler in serial configuration, the primary air is cooled in crosscurrent in a heat pipe battery. The chamber return air, after the adiabatic cooling process, is used in the condensation stage of the heat pipes HP and on its exit, goes to the outer unit of the heat pump HPu, used in the final thermal conditioning of climate chamber used to develop the experimental tests.

Evaporative
cooler of
ceramic pipes
SEC

Heat Pipes recovery system HP.

Outer Unit of the heat pump HPu (left) and inner unit (right)

Figure 2.The components (SEC, HP and HPu) placed in the recovery process.

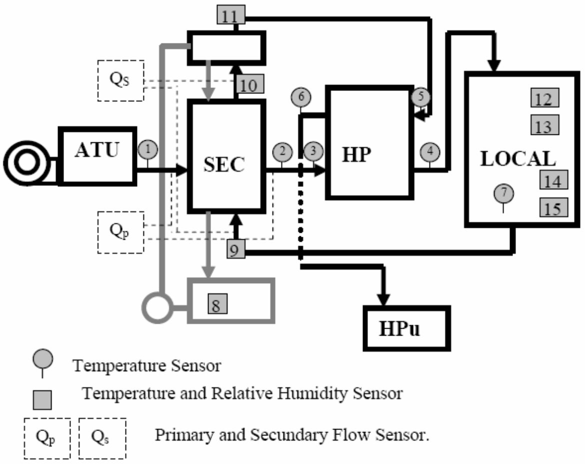
The last stage of energy recovery of the return air flow is to pass through the outer unit of the HPu that operates as, a condenser and is connected to the exhaust duct leaving from the HP battery. The inner unit of the air-air HPu, allows us, to obtain comfort conditions in the chamber.

Finally, the recovery system consists of taking advantage of the higrothermal characteristics of the return air using three processes in series, the evaporative cooler SEC that takes advantage of the cold water of on adiabatic cooling process with the return air, the HP system, that takes advantage of the cooling capacity of the air from the adiabatic cooling process itself and HPu system, since the power characteristics of the return air before being expelled, are usually more favorable for the outer unit that the outside air itself.

In the implementation of the recovery system in the air conditioning system, the installation control system must decide on the direction of the airflows, to optimize system power recovery, determining the most favorable operation conditions based on the specific temperature and humidity characteristics of the air flows involved in the recovery process.

For the measurement of the variables in all the points of the installation, we decided to use platinum resistance sensors, the humidity sensors, differential pressure sensor water flow, and air volume nozzle. The configuration of the sensors in the test bed is shown in figure 3.

A data acquisition system transforms the tension signals from pressure sensors, RTDs, humidity sensors, etc. into numerical values for subsequent later graphical representation and numerical analysis. The data acquisition, shown in figure 3, will receive the information from the sensors described in the previous section, and the software of the data logger “MOCIL” designed by us will be used in the experimental test bed recuperator.



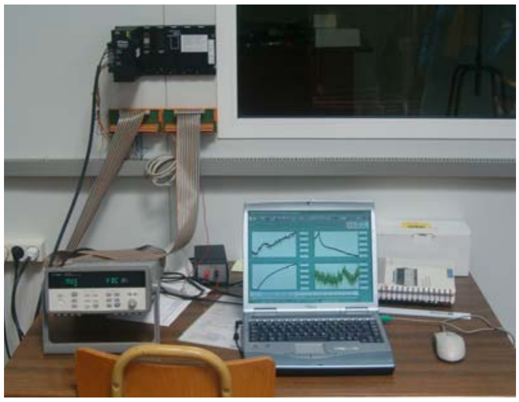


Figure 3.General scheme of the distribution of the sensors and the acquisition system used.

EXPERIMENTAL MEASUREMENTS AND ANALYSIS OF RESULTS

In the present study “design of experiments” methodology has been chosen to develop the experimental stage, using as control factors those variables that are anticipated, will affect the behavior of the recovery systems energy analyzed SEC, HP and HPu. The factors that have been analyzed in the complete design of factorial experiments are those that can be controlled in the experimental device, and which affect the functional characteristics of the equipment. These factors are:

Outer air temperature. Levels:

T1 5 ºC T2 10 ºC T3 15 ºC T4 20 ºC T5 C 25 ºC
T6 30 ºC T7 35 ºC T8 40 ºC T9 45 ºC

Outer Air flow. Levels:

V1 300 V2 400 V3 500

Outer air humidity. Levels:

The hygrometric conditions of the installation, established as its base are those of the laboratory, establishing three levels from the base conditions to the upper level. NH1 conditions base, NH2 base + 3 g w /kg d.a. and NH3 base + 6 g w /kg d.a.

Water flow:

Experimental tests have demonstrated the convenience of evaporating a litre of water each 300 m^3 of air. Provided we remain in that ratio the water volume does not have any appreciable impact. For this reason for all our tests we decided to maintain this constant value at 150 l/h.

Once the corresponding factors and their levels have been determined, we considerate making an experimental design table, ensuring that all the levels of all the factors have been assayed with all the levels of the remaining factors the same number of times. The number of tests agrees with the product of the number of levels of the factors, and in addition it is necessary to guarantee the repeatability between experiments.

The experimental results must be treated so that the required characteristics can be calculated to be able to explain the behavior of the recovery systems involved in the process of the case study.

Different characteristics have been analyzed. As an example we show only total heat flow for all the combined system and latent heat for the SEC. The analysis of the different characteristics is made in two stages. Having presented the first average values of the levels of each factor and their interactions, which establish the behavior of the characteristic with the factor, the contribution of the factors and interactions using ANOVA variance analysis will subsequently be verified.

Sensible heat for SEC+HP set.

Figure 4, shows two graphs and a table. The graph on the left shows the results corresponding to the average values of the characteristic for the different levels from the individual factors. The graph on the right corresponds to the interaction of both factors, temperature x volume finally table 1 shows the evaluated values and contributing percentage with the variance analysis.

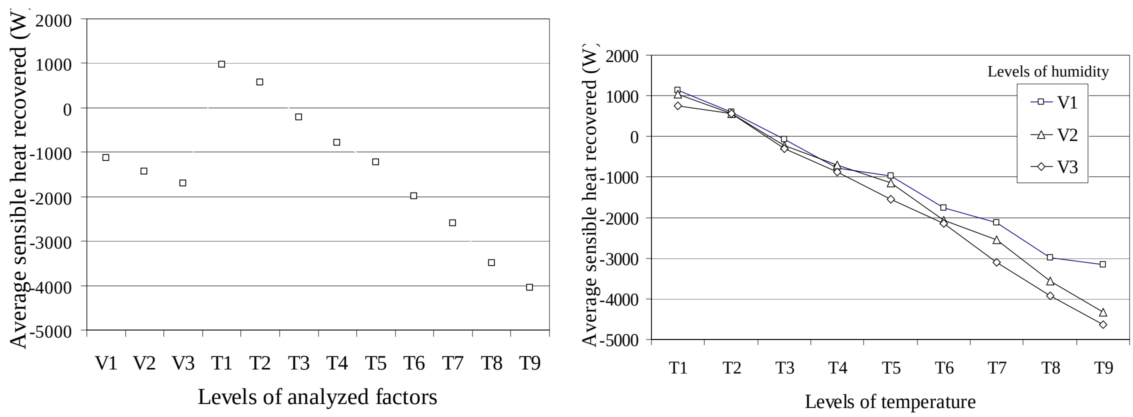

Figure 4. Graph for the levels of the analyzed factors (left) and the interaction of volume x temperature (right).

Table 1 ANOVA for the sensible heat characteristic.

Factors	gdl	SS	V	%
V	2	1453205.1	726602.5	1.91
T	8	73561119.0	9195139.9	96.69
VxT	16	1065784.6	66611.5	1.40
Total	26	76080109.0	2926158.0	100.00

The results from the table give an idea of the behavior of the device with respect to the characteristic:

Air volume. The recovered energy is slightly proportional to the air volume, but varies very little with this factor. It is the least contributing factor with a percentage in variance analysis to close to 2%. The slight change between the different levels in volume causes the global exchange coefficient, to remain constant.

Temperature. As happens in the other heat exchangers systems, when increasing the temperature difference between the outer air and the return air the amount of recovered sensible heat is greater, since the flow interchanged between the currents is directly proportional to the difference of its temperature, and is the factor that contributes most to the characteristics with a percentage close to 97%. In addition, the first graph allows us to see how in the proximities of level 3 temperature (T3), corresponding to 15 ºC, exchange between heating and cooling mode takes place in our device, we can also see in our characterization how positive values change to negative values, lineally becoming increasingly negative at higher temperature level. This fact can be very interesting when internal loads are considered.

Interaction double Temperature x Flow. Its study corroborates the analysis of the individual factors. It can be seen how as temperature and volume increase, sensible energy recovered increases. Interaction between the factors does not appear, the evolution of the energy recovered with respect to the three volumes having an almost parallel behavior.

Contributions of the recuperators SEC and HP separately.

The contributing percentage of each piece of SEC and HP equipment can be analyzed separately on the analyzed characteristic (sensible heat). However, in this case it is evident that SEC contributes more as it has greater thermal gradient between the currents that exchange energy. Figure 5 shows the total HP and SEC equipment sensible heat values compared to volume and temperature. Table 2 shows ANOVA for the recuperators separately.

SEC behavior in cooling mode.

In the second design of experiments, humidity factor level has been tested, and addition the temperature factor is analyzed only in summer conditions. As in the previous example figure 6 presents the graphs and the tables of the average values obtained for each level of the analyzed factors and the double interaction. Table 3 contains the ANOVA where error is included as the contributions associated to the higher order interactions.

Error	16	431728.76	26983.05	7.02
Total	44	6152668.30	139833.37	100.00

The behavior of the device with respect to the characteristic can be seen by observing the results presented:

Humidity level. An increase in humidity can even cause condensation in input air (dehumidification). Therefore it is felt that the system may be applied in tropical climates. When the relative humidity in the input air is low, water evaporation from the outer surface of the ceramics occurs and the treated current is humidified.

Air volume. It has no significant impact. Therefore under the analyzed conditions, it does not contribute to the result of the characteristic.

Temperature. Evaporation is determined by the gradient from partial pressure of the water steam between the surface of the pipes and the primary air. Therefore, when outer air temperature increases, if the constant specific humidity remains stable, relative humidity is reduced. Therefore the exchanged latent heat is greater when the evaporation capacity from the humid surface increases. It can be seen how for the higher humidity value and lower temperature (greater analyzed relative humidity), condensation takes place on the outer surface of the ceramic pipes.

CONCLUSIONS

The main conclusions to be drawn from this work are:

1. The recovery system combining SEC/HP /HPu allows energy exchange between the return current and the outer airflow, reducing consumption of thermal adjustment in all air, air conditioning systems.
2. The SEC recovery system eliminates the possibility of ventilated air contamination, as there is no mixture between the two currents that take part in the exchange process, the structure of the ceramic filter itself acting as a filter. This is why possible contamination from legionella that might appear in the primary air flow by water diffusion in the air, is avoided when no aerosols are formed.
3. The characterization of the SEC – HP equipment has been developed using experimental design techniques, making a complete factorial design, analyzing how they affect the factors considered input air volume, input air temperature and humidity level and the double interactions raised for each characteristic of the case study. Its contribution has been authenticated by means of variance analysis of results obtained. The factors analyzed in the design experiments, have allowed us to characterize the behavior of the SEC/ HP recovery equipment.
4. The efficiency of ceramic evaporative cooling like direct evaporation greatly depends on the ceramic pipes, since in the mass of water exchanged with the main airflow capillary diffusion of the water in the porous wall of the pipes also contributes. The controlling mechanism of the cooling process is due to convective mass diffusion of water through the ceramic pipe fillings.
5. The HP battery behaves like a “thermal shock absorber”, stabilizing temperature oscillations the airflows which cross the system of energy exchange system.

SUMMARY

The present report concerns mathematical simulation of coupled heat and mass transfer in the heat exchangers used in air conditioning units for the purpose of evaporative air cooling. Heat and mass transfer model based on the one-dimensional transfer model has been developed for thermal calculations of indirect evaporative cooler performance. On the basis of numerical investigations of "classical" heat exchangers designs the new design of air cooler is proposed. The original arrangement of matrix makes possible to realise two-stage indirect evaporative air cooling under combined parallel-counter air flow conditions and raise the degree of air cooling and thermodynamic perfection of this unit at the expense of efficient phase change heat utilisation. The received results show high efficiency of indirect evaporative air cooler under combined parallel-counter airflow conditions and offer scope for estimation of optimum operating conditions range variations and suitable climatic zones for the proposed unit.

INTRODUCTION

Keeping a safe and clean environment is currently becoming a more and more serious problem. One of the possibilities to decrease the pollution is the reduction of conventional energy consumption on behalf of more environmental friendly solution such as the increasing of renewable energy share in the total primary energy structure. Evaporative air cooling is recognized as a key demand-side "opportunity technology", which offers compelling energy, economic development and environmental benefits at the expense of utilization of thermodynamic unbalance of the atmospheric air.

In the case of direct evaporative cooler, the air stream to be cooled is in direct contact with a liquid water film and cooling is accomplished by the adiabatic heat exchange between the air stream and the liquid water film. The evaporation of water in the air stream leads to reduction of dry-bulb temperature and increasing absolute humidity of the supplied air. In general, the maximum possible reduction in air dry-bulb temperature depends on the difference between the dry-bulb and the wet-bulb temperature of the air stream. The direct type is simple but introduces moisture into the air-stream while cooling it adiabatically. In many applications, however, the increase of humidity in a supply air stream is not desirable. A promising way to increase the thermal performance of evaporative cooling systems is to decrease the dry-bulb temperature of the air at constant absolute humidity. Such kinds of processes can be realized with the help of indirect evaporative air coolers (IEC) [1–7].

Conventional integrated IEC has two distinct air passages, one named as the primary and the other as the secondary air passage. The primary air is usually outdoor air that is supplied to the room after it has been cooled by the air in the secondary air passages through the heat transfer surface . The secondary air can be either outdoor air or room exhaust air. The surface of the secondary air passage is moisturized, so that heat and mass transfer takes place between the wet surface and the secondary air. The dry primary air stream passes through the heat exchanger and uses the cooled wet secondary stream as its heat sink. Thus, IEC involves sensible cooling of the 'primary' air by an evaporatively cooled secondary air stream. As a result, the temperature of both streams decreases. The two air streams never mix or come in direct contact.

Traditionally, the heat exchanger type employed for IEC is a plate heat exchanger. The evaporative cooling of the wet stream takes place within the IEC itself along the wet passages. Then, the humidified air is dumped into the atmosphere.

There are many construction designs of combined IEC, improving of which goes in the following directions [6–9]:

- application of multistage cooling process within the confines of one unit;
- using capillary porous plates as a structural material for the heat transfer matrix, allowing moisture to fully cover the surface of the secondary channels at the minimum value of water consumption;
- implementation of rational combined management of airflows conditions, allowing to lower the temperature level of the received cold (air coolant);
- searching optimum operating conditions and suitable climatic zones for IEC on the basis of using the modern methods of polyoptimization.

Taking into account that there are merits and demerits for each type of heat exchanger, researches should be carried out not only for the developed air coolers, but also for heat exchangers, realizing "traditional" management of airflows conditions (Fig. 1). Such kind of research allows one to estimate an overall performance of new IEC and their conformity to the predicted purposes and to determine suitable climatic zones of their rational application.

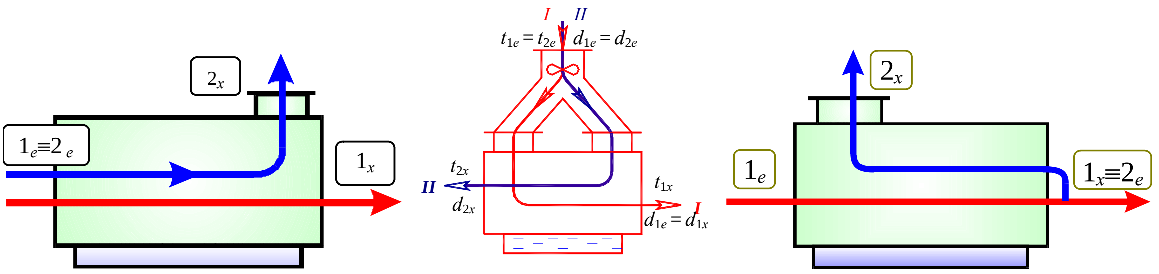

Figure 1. Schematic diagrams of typical IEC designs. a) Direct-flow, b) Counter-flow, c) Regenerative heat exchanger [6].

However, the substantiation of potential efficiency of heat and mass transfer process and rational performance of the considered units calls for a detailed theoretical study. With this purpose mathematical model of heat and mass transfer was developed for the combined IEC on the base of differential equations of the α-model [4, 5, 10]. It is necessary to note, that mathematical modelling of heat and mass transfer in modern IEC appears rather complicated [1–5, 11]. First of all, it is connected with an increase of the number of airflow passages and, consequently, the problem order.

The present paper is concerned with mathematical simulation of coupled heat and mass transfer in the units, used in air conditioning for the purpose of indirect evaporative air cooling.

METHODS

In many problems, including the said one, an engineer is not interested in receiving thermodynamic variables distributions normal to the heat exchanger plate surface, but bulk average values. Therefore, we gave preference to a one-dimensional transfer model (α–model) [4, 5, 10]. In this case, air stream in matrix passages is considered as a gaseous fluid flow with constant temperature and mass transfer potential in direction normal to plate surfaces, which are equalled to bulk average values.

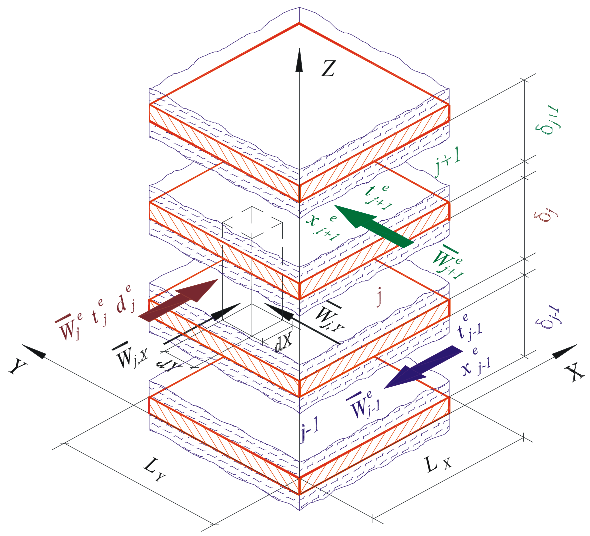

Figure 2. Schematic diagram of multichannel plate IEC.

Now, let us formulate a number of assumptions, concerning the peculiarities of examined heat and mass transfer processes and taken as the base of developed model in the most universal case (Fig. 2):

- driving force of mass transfer is a gradient of absolute humidity of air;
- kinetic properties of air flow and water film are constant, equalled to bulk average values;
- longitudinal molecular diffusion of water vapor in air and longitudinal heat transfer at the expense of thermal conductivity are negligible;
- no wall, air and fluid thermal and moisture diffusivity in the flow directions;
- unrestricted number of passages – n;
- consumed water rate corresponds to sufficient evaporation and keeping up the material of plates in hygroscopic saturated condition, that causes the following water film to air flow heat capacity rate ratio $\overline{W}_w / \overline{W} << 1$;
- the passage walls are impervious to mass transfer;

According to the assumptions of α–model combined heat and water vapour transfer in in the j^{th} passage of the plate IEC is described by partial differential equations of energy and mass balances developed for the air stream

$$\left(\overline{W}_X / \overline{W}\right)_j \frac{\partial t_j}{\partial \overline{X}} + \left(\overline{W}_Y / \overline{W}^e\right)_j \frac{\partial t_j}{\partial \overline{Y}} =$$

$$= \mathrm{NTU}_{j,j-1}\left(t_{wj,j-1} - t_j\right)\left[1 + \left(\frac{c_g}{c_p}\right)_j (\sigma/\mathrm{Le})_{j,j-1}\left(d_{wj,j-1} - d_j\right)\right] +$$

$$+ \mathrm{NTU}_{j,j+1}\left(t_{wj,j+1} - t_j\right)\left[1 + \left(\frac{c_g}{c_p}\right)_j (\sigma/\mathrm{Le})_{j,j+1}\left(d_{wj,j+1} - d_j\right)\right], \qquad (1)$$

$$\left(\overline{W}_X / \overline{W}\right)_j \frac{\partial d_j}{\partial \overline{X}} + \left(\overline{W}_Y / \overline{W}^e\right)_j \frac{\partial d_j}{\partial \overline{Y}} =$$

$$=\left(\mathrm{NTU}\cdot\sigma/\mathrm{Le}\right)_{j,j-1}\left(d_{wj,j-1}-d_{j}\right)+\left(\mathrm{NTU}\cdot\sigma/\mathrm{Le}\right)_{j,j+1}\left(d_{wj,j+1}-d_{j}\right)\ , \qquad (2)$$

and equations, describing conditions of energy flow rate continuity on the phase boundary

$$\left(\overline{W}^{e}_{j+1}/\overline{W}_{\mathrm{o}}\right)\mathrm{NTU}_{j+1,j}\left[\left(t_{wj+1,j}-t_{j+1}\right)+\left(1/c_{pj+1}\right)\left(H_{fg}\sigma/\mathrm{Le}\right)_{j+1,j}\left(d_{wj+1,j}-d_{j+1}\right)\right]+$$

$$+\left(\overline{W}^{e}_{j}/\overline{W}_{\mathrm{o}}\right)\mathrm{NTU}_{j,j+1}\left[\left(t_{wj,j+1}-t_{j}\right)+\left(1/c_{pj}\right)\left(H_{fg}\sigma/\mathrm{Le}\right)_{j,j+1}\left(d_{wj,j+1}-d_{j}\right)\right]=0\ , \qquad (3)$$

$$\left(\overline{W}^{e}_{j-1}/\overline{W}_{\mathrm{o}}\right)\mathrm{NTU}_{j-1,j}\left[\left(t_{wj-1,j}-t_{j-1}\right)+\left(1/c_{pj-1}\right)\left(H_{fg}\sigma/\mathrm{Le}\right)_{j-1,j}\left(d_{wj-1,j}-d_{j-1}\right)\right]+$$

$$+\left(\overline{W}^{e}_{j}/\overline{W}_{\mathrm{o}}\right)\mathrm{NTU}_{j,j-1}\left[\left(t_{wj,j-1}-t_{j}\right)+\left(1/c_{pj}\right)\left(H_{fg}\sigma/\mathrm{Le}\right)_{j,j-1}\left(d_{wj,j-1}-d_{j}\right)\right]=0\ , \qquad (4)$$

where j = 1..., n – the number of the channel (air stream), (j, j–1), (j, j+1) - the indexes describing interrelation between the j^{th} air stream and water film on the plate surfaces of the j^{th} passage, accordingly adjacent to (with) the $(j-1)^{\text{th}}$ and $(j+1)^{\text{th}}$ channels, $\overline{W}_{\mathrm{o}}$ - heat capacity rate of the base air stream, W/ K.
Derivation of the energy balance equations for water films (3), (4) is carried out on the base of the following additional assumptions: temperature difference across the plate and water film on the plate has been assumed to be negligible because of the small thickness of the plate (Bi<<1) and liquid film ($\overline{W}_{wj,j+1} << \overline{W}_{j}$ $\overline{W}_{wj,j-1} << \overline{W}_{j}$), and, hence, the local temperature of water film can be taken to be the same as the local temperature of the plate

$$t_{wj,j+1}=t_{wj+1,j}\ ,\ t_{wj,j-1}=t_{wj-1,j}\ . \qquad (5)$$

Thus, the set of simultaneous equations, describing heat and mass transfer in IEC, includes n differential equations of energy and mass balances for the air streams (1)¸ (2), n the algebraic equations of energy balance for water films (3)¸ (4) and n conditions for local temperature of water films (5). To derive the solution the set of equations (1)–(5) is supplemented by the non-linear empirical relation between absolute humidity of saturated air over liquid film and its temperature $d_{w,sat}=f\left(t_{w}\right)$ [12], the boundary conditions, establishing initial thermodynamic parameters values of exchanged air streams on the entries to appropriate channels of IEC. Taking into account the big variety of IEC construction designs and characters of plate mouisturizability , the boundary conditions should be taken up for each type of heat exchanger separately. The above formulated nonlinear boundary problem is nonlinear and can not be solve on analytic way. Therefore simultaneous integration of the equations set (1)–(5) with proper boundary conditions was made by numerical methods. Numerical simulation was executed with the help of the one-step fourth-order Runge-Kutta method, distinguished by sufficient accuracy and stability at the decision of similar type problems. The values of local plate temperature t_W satisfied by equation (3) and (4) were determined on each step of integration by means of Wegstein's iteration method used for solving general nonlinear equations of the form $t_W = f(t_W)$. The described algorithm was realised in digital computer program including 14 modules. The computer program evaluation tests were performed with the help of calculations of different variants, describing problems with familiar analytical solutions [4, 5, 9]. The accuracy of numerical method was checked by computing the identical variants on various space-time domain grids. Convergence test showed that the optimum number of grid nodes and, consequently, the minimum time of computation within the given tolerance of accuracy (0,5% thermal and mass balance error) was reached at the step size of 0,02 in the direction of axis $\bar{X}$.

RESULTS and DISCUSSION

On the basis of numerous calculations it was established that combined heat and mass transfer in the investigated IEC is characterised by complex and diverse temperatures and humidity profiles, which depend upon the combinations of thermodynamic, hydrodynamic and other factors.
The established distribution of air streams and water film thermodynamic parameters in the direction of primary airflow (Figs. 3, 4) necessitates the need to take into account the changes of plate temperature. Largely it concerns to regenerative IEC, in which changes of water film temperature reach (6–11)°C (Fig. 3.*b*) and to a lesser degree – to direct-flow IEC, where these changes are in an interval (1÷5) °C (Fig. 3.*a*).

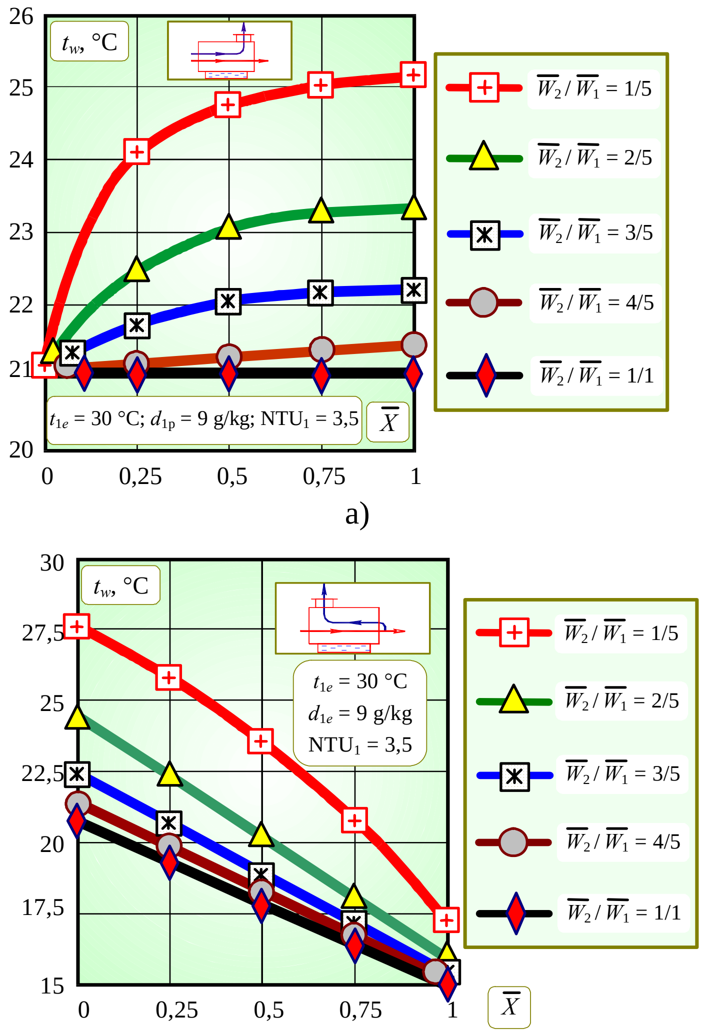

Figure 3. Effect of heat capacity rate ratio $\bar{W}_2/\bar{W}_1$ on the liquid film temperature distribution in the direction of primary airflow for two IEC construction designs.

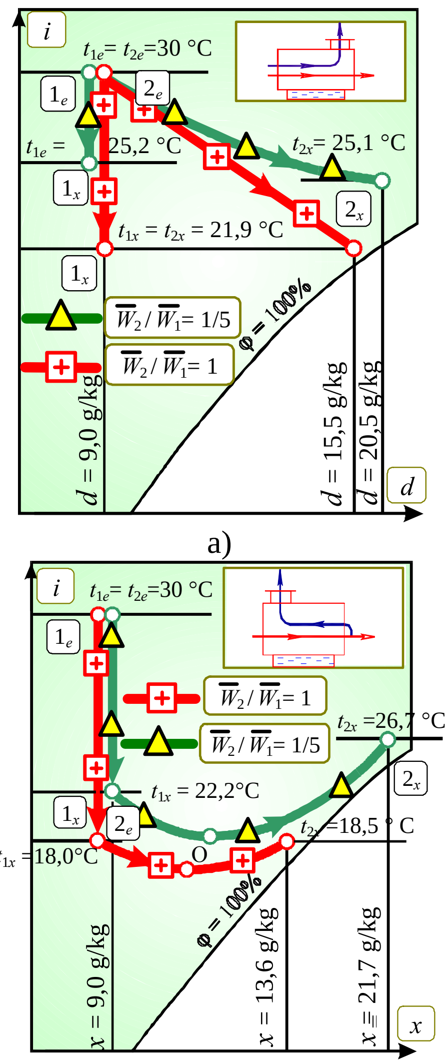

Figure 4. Paths for the ‘primary’ and secondary air streams on the *i-d* chart for two IEC construction designs.

In the case of the regenerative type of IEC the degrease of water film temperature in the direction of primary airflow allows the lowering of the temperature of the received cold (see Figs. 3.*b*, 5).

As shown in the Fig. 4, combined heat and mass transfer in the investigated IEC differs substantially in the case of direct-flow and regenerative type. The character of heat and mass transfer in counter-flow IEC needs special discussion.

The analysis of temperature distribution in secondary counter-flow passages brings out the existence of two particular heat and mass transfer areas (2_e-O and O-2_x in Fig 4.*b*). The air temperature decreases when the secondary air stream enters the channel (2_e-O), reaching a minimum value at a certain distance from the entrance, and then going up in the remainder of the channel (O-2_x). This can be explained as follows: the high values of temperature and absolute humidity differences at the entrance of secondary counter-flow channels (2_e-O) cause intensive water evaporation and secondary airflow cooling as a result. At the same time liquid film temperature t_w gradually increases because virtually constant sensible heat flow from adjacent primary air stream begins to exceed the evaporative cooling effect. Therefore, the temperatures of the secondary air stream t_2 and water film t_w at a certain distance from the flow inlet become equal (point O in the Fig. 4.*b*). As a result of water film heating on the terminal parts of the plate the temperature of liquid film t_w becomes higher then airflow temperature t_2. Thus combined heat and mass transfer process at the exit part of secondary counter-flow channels is characterised by the change of sensible heat exchange direction.

Figure 5 compares the thermal performances of three investigated IEC models for the ranges of heat capacity rate ratio $0 \le \overline{W}_2 / \overline{W}_1 \le 1$.

The received dew-point temperature effectiveness functions of dimensionless operating parameters (Fig. 5.*a*) are the most advantageous for the regenerative model of IEC. However, from the point of view of cooling capacity Q such construction design of IEC are worse then direct-flow and counter-flow heat exchangers (Fig. 5.*b*).

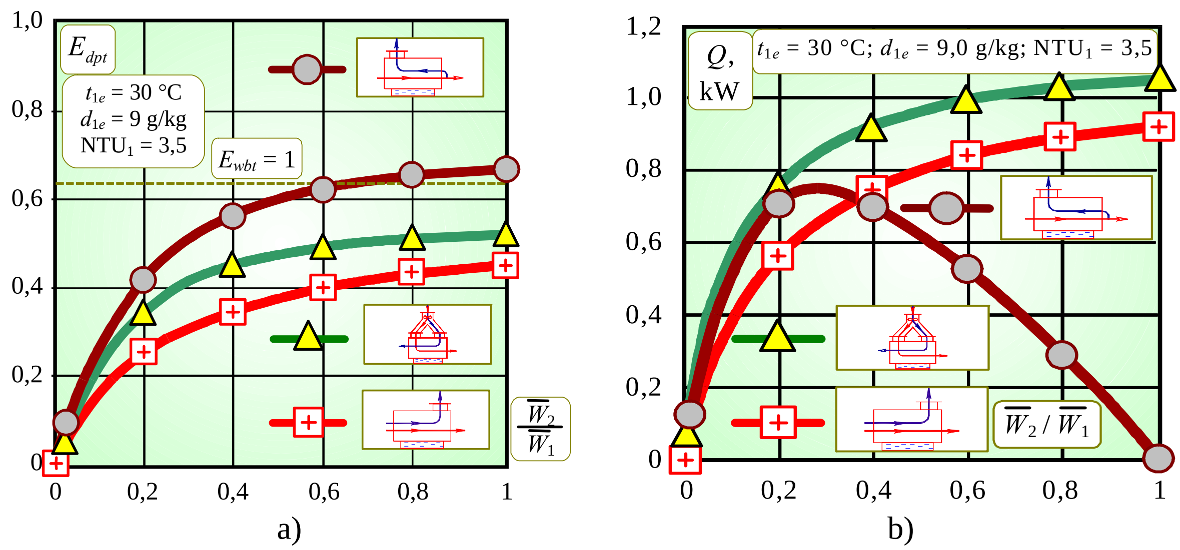

Figure 5. Influence of heat capacity rate ratio $\overline{W}_2 / \overline{W}_1$ dew-point temperature effectiveness E_{dpt} and cooling capacity Q for three IEC construction designs

According to the above specified characteristics of the heat and mass exchange processes the new construction of heat exchanger (Fig. 6) was proposed [7]. This construction – owing to the rational implementation of the combined management of airflow conditions (direct-flow

and counter-flow) – results in the following advantages of two-stage cooling process: effective heat and mass exchange at the entrance areas of plates at the parallel airflow conditions bundle and regenerative counter-flow on the terminal parts of the matrix.
The heat exchanger contains shell 1, pallet 2, suction branch for total airflow 3, and downstream fairings for primary 4 and secondary 5 airflows. Heat transfer bundle of a regular structure located in package 1 is composed of capillary porous plates 6, one side of which is covered by moisture-resistant coating. Plates are arranged so that they form alternate "*dry*" 7 and "*wet*" 8, 9 channels for passing to total ***I*** and secondary ***II***, ***III*** airflows consequently. There are dividing partitions 10 for organising necessary directions of airflows.

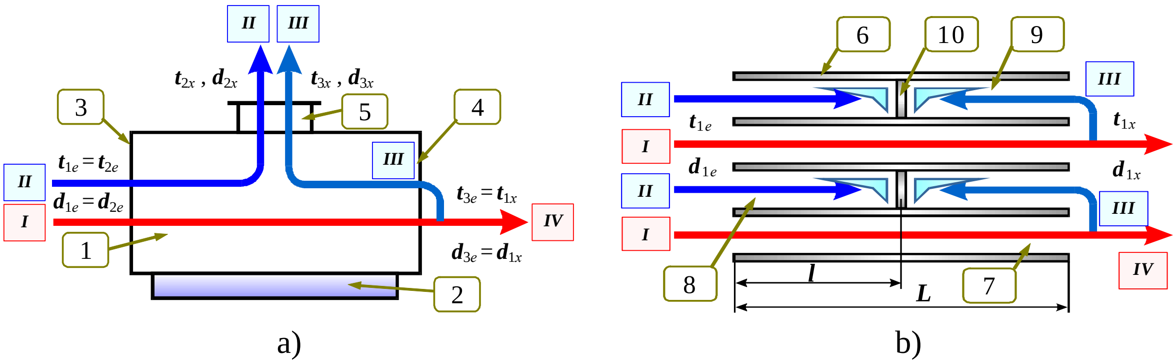

Figure 6. IEC under combined airflow conditions [7]. *a*) Front view, *b*) Top view.

The air cooler works as follows. Outside air enters the heat exchanger through suction branch 3 and then is divided on parallel secondary ***II*** and total ***I*** airflows, the first of which, passing through the "*wet*" channels 8, causes liquid film to be cooled by evaporation and then is discharged through downstream fairing 5 into the atmosphere. The total airflow ***I*** is cooled in "*dry*" air passages 7, formed by moisture-resistant surfaces of plates 6, due to its heat exchange with secondary airflows ***II*** and ***III*** passing through "*wet*" passages, and on the exit from downstream fairing 4 is divided on the primary ***IV*** and secondary regenerative ***III*** airflows. The primary airflow ***IV*** is delivered to air conditioned space, and secondary countercurrent airflow ***III*** (after the cooling of water film via evaporation in channels 9) is discharged through downstream fairing 5 in atmosphere.
The increasing of the air cooler capacity in comparison with the regenerative indirect evaporative air cooler [6] becomes possible due to the reduction of the secondary regenerative airflow consumption without decreasing total airflow temperature difference.
Optimising these distributions with the help of mathematical response surface models offered scope to determine rational performance characteristics of this IEC and the variation range of optimal operating conditions (1,5 <NTU_1< 2,5; 0,8<$\overline{W}_2/\overline{W}_1$ < 1; 0,14 <$\overline{W}_3/\overline{W}_1$ < 0,27; 0,4<$\bar{l}$< 0,55).

NOMENCLATURE

c_p = specific heat of the air, J/(kg dry air·K); c_g = specific heat of the water vapor, J/(kg K); d = absolute humidity of air (air humidity ratio), kg/kg dry air (g/kg dry air); E_{dpt} = $\left(t_{1e}-t_{1x}\right)/\left(t_{1e}-t_{1dpt}\right)$ = dew-point temperature effectiveness, dimensionless; G = air mass flow rate, kg/s; F = heat and transfer area of matrix, exposed to an air stream, m^2; H = latent heat of phase change, J/kg; i = specific enthalpy of the air-water vapor mixture, J/(kg dry air); l = length of parallel airflow zone, m; $\bar{l}=l/L_X$ = relative length of parallel airflow zone, dimensionless; L_X = plate length in X direction, m; L_Y = plate length in Y direction, m; Q =

heat flow rate, W/m^2; t = temperature, °C; w = speed of air flow m/s; $\overline{W}$ = heat capacity rate = ($G\, c_p$), W/ K; X = axial coordinate along the plate in the direction of primary airflow, m; $\overline{X} = X/L_x$, $\overline{Y} = Y/L_y$ = relative coordinates, dimensionless; α = sensible heat transfer coefficient, $W/(m^2{\cdot}K)$; β = mass transfer coefficient, $kg/(m^2{\cdot}s)$; φ = relative humidity, percent; σ = mouisturizability of plate (σ = 0,0 : dry; σ = 1,0 : completely wet), dimensionless.

NONDIMENSIONAL COMPLEXES

NTU = number of heat transfer units = $(\alpha \cdot F)/(G \cdot c_p)$; Le = Lewis number = $\alpha/(\beta \cdot c_p)$.

SUBSCRIPTS

dpt = dew-point temperature; *e* = state of air stream at the entrance of passage; *fg* = vapor-liquid; *g* = water vapor; *p* = at constant pressure; *sat* = saturation state; *x* = state of air stream on the exit of passage; *w* = surface of plate; 1 = primary airflow; 2 = secondary parallel airflow; 3 = secondary regenerative counter-airflow.

SUMMARY

The continuous rise of electric power rates worldwide and environmental issues related to the ozone layer depletion have increased the interest in natural gas cooling technologies over the last years. One of the most promising techniques consists of evaporative cooling aided by solid desiccants. Although silica-gel has been primarily used in such systems, the requirement of encompassing a greater variety of climatic conditions has led to the development of new materials with selective adsorption properties, some of them being able to adsorb more than one chemical species at the same time (co-sorption). Accordingly, the present work analyses the influence of the isotherm shape of different adsorptive materials over the dehumidifying capacity of a desiccant wheel. A mathematical model for the desiccant wheels is developed, and the governing equations for heat and mass transfer are solved employing a totally implicit finite volume technique. The adsorption isotherms are represented by a general equation characterized by a separation factor R, the variation of which allows the behavior of three different materials (silica-gel, molecular sieve and 1M) to be simulated. The results show that the separation factor R has a great influence over the dehumidifying effectiveness, for a given regeneration temperature.

INTRODUCTION

The adsorption phenomena occur in almost all solid-vapor interfaces, but its effects are negligible unless the solid possess certain properties that allow a great affinity with the vapor. For instance, the internal area of 1 cm^3 of silica-gel is estimated to be 400m^2. The average size of the porous is also of great importance, as it is the factor which determines the size of the molecules to be absorbed. The structural integrity in face of the continuous thermal inversion is also a factor to be considered. One of the earliest works devoted to the dehumidification modeling was performed by Bullock and Trelkheld [1], and used a predictor-corrector method to solve a quite simplified model. Maclaine and Cross [2] presented a characteristics potential method, which allowed the coupled problem to be solved in an analogous heat transfer problem. Jurinak, Mitchell and Beckmann [3] proposed alternative design options combining evaporative coolers and desiccant wheels, expanding the range of applicability of such equipment. Zheng and Worek [4] used an explicit finite difference scheme to solve the governing equations, using experimental data for the silica-gel heat of adsorption and isotherm shape. Zhang, Dai and Wang. [5] presents a very accurate model for the cyclic adsorption, which however involves too many parameters. They also provide the experimental data for the heat of adsorption used by the present simulation. The present work uses a totally implicit finite volume technique to solve the non-dimensional governing equations, which contains less parameters when compared to previous efforts. It also proposes the use of a generalized equation for isotherm shape [6], which can be set to represent a particular material (silica-gel, molecular sieve 13 or 1M) by choosing an appropriate value for the separation parameter R. Desiccant wheels consist of a porous disc impregnated with hygroscopic material, which by definition attract and retain water vapor. Figure 1 shows a schematic of a desiccant wheel, operating between two air streams. At the "cold side", a fresh air stream (process air) is forced through the wheel, giving up its moisture to the hygroscopic material and leaving the wheel at a much lower humidity ratio. As the wheel rotates, the hygroscopic material eventually switches to the regeneration stream, where hot air from a hot source is forced through the wheel, drying the hygroscopic material and dumping the water vapor back to the atmosphere. As depicted in Figure 1, the porososity pattern is not random, but formed by small channels, evenly distributed throughout the disc. Each channel has a structural layer (usually aluminum) and an adsorptive layer, above which the air flows.

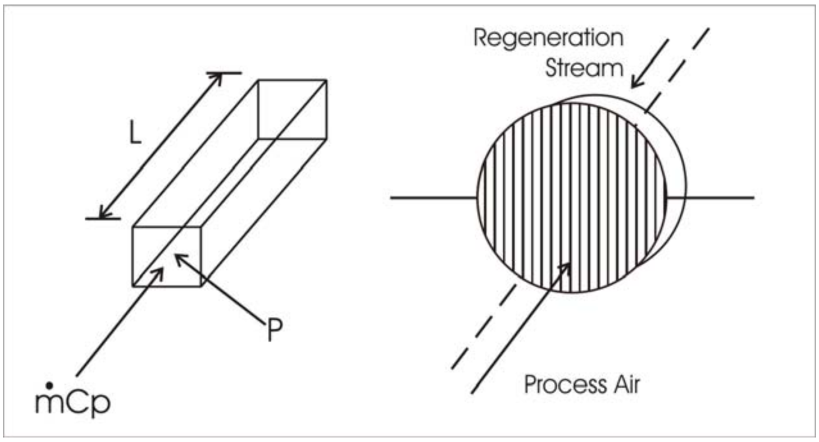

Figure 1: Schematic representation of a desiccant wheel

METHODS

An element of the channel of length Δx, in the direction of the flow, as shown in figure 2, is considered.

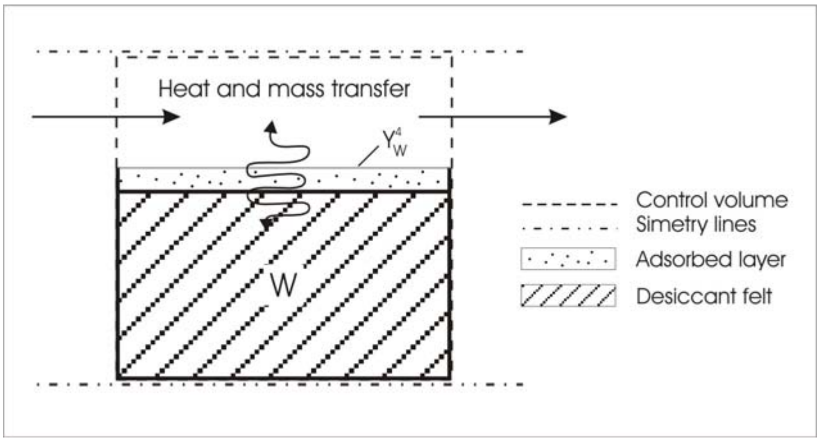

Figure 2: Elementary Control Volume

Some simplifying assumptions are necessary to the establishment of a mathematical model:

1) The flow is hydrodynamic developed.
2) The heat and mass transfer coefficients are constant along the channel.
3) Energy and mass storage within the air are negligible when compared to the solid.
4) Uniform temperature and concentration values in the direction perpendicular to the flow.
5) Symmetry lines represent perfectly adiabatic and impermeable surfaces.
6) Thermal and mass resistances are negligible in the direction perpendicular to the flow.
7) Thermal and mass resistances are infinite in the direction of the flow.

Assumption (1) is reasonable because of the low viscosity of air and the (small) ratio between the air channel height and length. Assumption (2) holds because the flow is usually laminar in the range of interest, whereas assumption (3) reflects the smaller thermal and mass capacitances of air when compared to those of the hygroscopic material. Assumption (4) reflects the typical dimensions of desiccant wheels, in which the channel length is usually a hundred times greater than the channel height and the desiccant layer. Assumption (5) reflects the homogeneity of the porous media, and both assumptions (6) and (7) are consequences of assumption (4).

Accordingly, applying a mass balance to the elementary control volume shown on Figure (2), enclosing both the flow channel and the hygroscopic material,

$$\underbrace{\rho_1\,\Delta x\;b\,a_1\,\frac{\partial Y^*}{\partial t_A}}_{\substack{transient\\ within\,the\,channel}}+\underbrace{f\;\rho_w\,\Delta x\;b\,a_w\,\frac{\partial W}{\partial x}}_{\substack{transient\\ within\,the\,solid}}+\underbrace{\frac{\dot{m}_1}{n}\left[\left(Y^*+\frac{\partial Y^*}{\partial x}\Delta x\right)-Y^*\right]}_{net\;\;flux}=0 \qquad (1)$$

in which

ρ_1 = *density of air*

Δx = *elementary length*

b = *channel and solid width*

a_1 = *channel height*

Y^* = *air absolute humidity*

W = *solid humidity content*

ρ_w = *density of solid*

f = *solid void fraction*

t_a = *time*

using the following definitions

$$\dot{m}_1=\rho_1\,a_1\,y_{AF}\,u_1\,n$$

$$m_w=\rho_w\,a_w\,x_{AF}\,y_{AF}\,n$$

one obtain

$$\dot{m}_1 \left[\frac{1}{u_1} \frac{\partial Y^*}{\partial t_A} + \frac{\partial Y^*}{\partial x_A} \right] + \frac{f\ m_w}{x_{AF}} \frac{\partial W}{\partial t_A} = 0$$

The mass transfer between the solid ant the air stream is given by

$$f\ \rho_w\, b\, \Delta x_A\, a_w \frac{\partial W}{\partial t_A} = 2h_y\, b\, \Delta x_A \left(Y^* - Y^*{}_w \right)$$

or

$$\frac{f\ m_w}{n\ x_{AF}\ y_{AF}} \frac{\partial W}{\partial t_A} = 2\, h_y \left(Y^* - Y_w^* \right) \tag{2}$$

in which

m_w total mass of desiccant in the wheel
n number of channels
x_{af} length of the wheel
h_y mass transfer coefficient

Applying a mass balance to the control volume shown on Figure (2), enclosing both the flow channel and the hygroscopic material,

$$\underbrace{\rho_1\, \Delta x_A\ y_{AF}\ a_1 \frac{\partial H_1}{\partial t_A}}_{\substack{transient \\ within\ the\ channel}} + \underbrace{\rho_w\, \Delta x_A\ y_{AF}\ a_w \frac{\partial H_w}{\partial t_A}}_{\substack{transient \\ within\ the\ solid}} + \underbrace{\frac{\dot{m}_1}{n} \left[\left(H_1 + \frac{\partial H_1}{\partial x_A} \Delta x_A \right) - H_1 \right]}_{net\ \ flux} = 0$$

or

$$\dot{m}_1 \left[\frac{1}{u_1} \frac{\partial H_1}{\partial t_A} + \frac{\partial H_1}{\partial x_A} \right] + \frac{m_w}{x_{AF}} \frac{\partial H_w}{\partial t_A} = 0 \tag{3}$$

The heat transfer between the solid ant the air stream is given by

$$\underbrace{\rho_1\, b\, \Delta x_A\, a_1 \frac{\partial H_1}{\partial t_A}}_{\substack{transient \\ within\ the\ channel}} + \underbrace{\frac{\dot{m}_1}{n} \left[\left(H_1 + \frac{\partial H_1}{\partial x_A} \Delta x_A \right) - H_1 \right]}_{\substack{net\ enthalpy \\ flux}} = \underbrace{2h_y\, b\, \Delta x_A \left(Y^* - Y_w^* \right) \frac{\partial H_1}{\partial Y}}_{\substack{heat\ released\ due\ to \\ adsorption}} + \underbrace{2\, h \left(T_w - T_1 \right)}_{\substack{heat\ transfer \\ between\ air\ and \\ solid}}$$

$$\frac{\dot{m}_1}{n b} \left[\frac{1}{u_1} \frac{\partial H_1}{\partial t_A} + \frac{\partial H_1}{\partial x_A} \right] = 2\, h_y \left(Y_w^* - Y^* \right) \frac{\partial H_1}{\partial Y} + 2\, h \left(T_w - T_1 \right) \tag{4}$$

in which

$$H_1 = aT_1 + Y^* \left(d + cT_1 \right) \tag{5}$$

$$a = 1.0046465\, KJ / Kg\, ^\circ C \quad d = 2467.4304\, KJ / Kg$$

$$c = 1.8837122\, KJ / Kg\, ^\circ C$$

Equations (1) through (4) are transformed into equivalent dimensionless forms after extensive algebra,

$$\frac{\partial Y^*}{\partial x^*} = Y_w^* - Y^* \quad (6)$$

$$\frac{\partial W}{\partial t^*_{h,c}} = \lambda_2 \left(Y^* - Y_w^* \right) \quad (7)$$

$$\frac{\partial T_1}{\partial x^*} = T_w - T_1 \quad (8)$$

$$\frac{\partial T_w}{\partial t^*_{h,c}} = \left(T_1 - T_w \right) + \lambda_1 \left(Y^* - Y_w^* \right) \quad (9)$$

where h and c refer to the hot and cold periods, respectively, and

$$\lambda_2 = \frac{C_{wr}}{f\left(\frac{\partial H_1}{\partial T_1}\right)} \qquad \lambda_1 = \frac{Q}{\left(\frac{\partial H_1}{\partial T_1}\right)}$$

The heat of adsorption Q is expressed in terms of the latent heat h_v and is experimentally obtained [5] as

$$Q = h_v \left(1.0 + 0.2843\, e^{-10.28W}\right) \quad (10)$$

We have now four equations (6) to (9) and five unknowns, Y^*, Y, W, T_1 and T_w . The missing equation is the adsorption isotherm, which relates the humidity content of the hygroscopic material, its temperature and the humidity ratio of the air layer in equilibrium with the solid,

$$W = W\left(T_w, Y_w^*\right) \quad (11)$$

with boundary conditions are given by

$$T_1(0,t^*) = T_{hin} \qquad ,0 < t^* < P_h^* \quad (12)$$

$$Y_1(0,t^*) = Y_{hin} \qquad ,0 < t^* < P_h^* \quad (13)$$

$$T_1(x_f^*, t^*) = T_{cin} \qquad ,P_h^* < t^* < P^* \quad (14)$$

$$Y_1(x_f^*, t^*) = Y_{cin} \qquad ,P_h^* < t^* < P^* \quad (15)$$

and the periodicity conditions are given by

$$T_{wc}(x^*, P^*) = T_{wh}(x^*, 0) \quad (16)$$

$$W_c(x^*, P^*) = W_h(x^*, 0) \quad (17)$$

The adsorption isotherm (Eq.11) is specific for each hygroscopic material. Simonson and Besant [6] suggest that although the humidity content W is a function of both temperature and relative humidity of the air layer, its dependence on the later is much stronger than on the former. Accordingly, a variety of adsorptive materials can be represented by

$$\frac{W}{W_{\max}} = \frac{1}{(1 - R + \frac{R}{RH})} \tag{18}$$

in which

W_{max}	maximum humidity content of the solid
R	separation factor
RH	relative humidity of the air layer

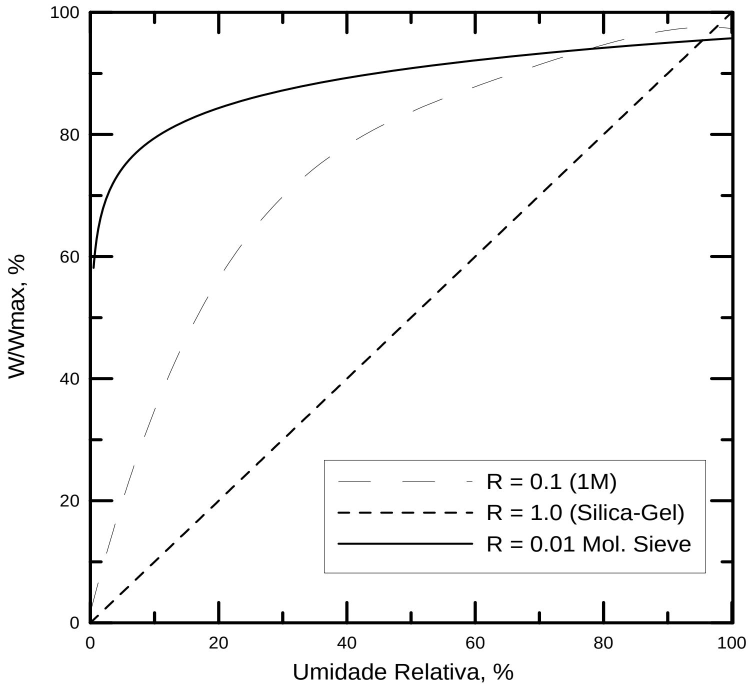

Figure 3: Generalized Adsorption Isotherm

The separation factor R can be adjusted so as to make the curve a fair representation of selected hygroscopic materials, as illustrated in Figure (3). The definition of effectiveness for a desiccant wheel is not as straightforward as it is in heat exchangers. In a desiccant wheel both heat and mass are being exchanged, and mass and heat transfers have opposite directions. Taking the regenerative stream (hot period) as an example, one would note that its temperature decreases as it flows through the channel, which tends to decrease its enthalpy. However, the hot stream is also humidified as it flows, which causes its enthalpy to increase. Moreover, both fresh air and the regeneration streams are supplied by ambient air, so they should have the same inlet humidity ratio (i.e., $Y_{hi} = Y_{ci}$). Accordingly, results are expressed by the dehumidification effectiveness given by

$$\varepsilon_d = \frac{\left(Y_{ci} - Y_{co}\right)}{\left(Y_{ci}\right)} \tag{19}$$

The domain was discretized using a finite-volume technique, using a fully-implicit formulation for the transient terms and an upwind formulation for the convective terms. Since both initial mass and temperature distributions are not known a priori, an iterative procedure, which compares the initial fields with the fields calculated at 360° is required. The enthalpy flux of the inlet streams must equal the average enthalpy flux of the outlet streams, as otherwise the wheel wouldn't be operating in a cyclic condition. The heat balance error HBE given below was found to be smaller than 0,1% for all simulations carried out.

$$HBE = \frac{\dot{m}_h\, h_{hi} + \dot{m}_c\, h_{ci} - (\dot{m}_h \frac{1}{p_h}\int_0^{p_h} h_{ho}\, dt^* + \dot{m}_c \frac{1}{p_c}\int_0^{p_c} h_{co}\, dt^*)}{\dot{m}_h\, h_{hi} + \dot{m}_c\, h_{ci}} \qquad (20)$$

RESULTS

Figures (4) and (5) show the influence of the adsorptive material selection over the effectiveness of dehumidification for two regeneration temperatures. For both cases the best performance is obtained for R=0,1 (1M). For a moderate value of the regeneration temperature (90°C), silica-gel exhibits a better performance than molecular-sieve, whereas for a higher regeneration temperature (160°C) the results are reverted. This result is consistent with the fact that molecular sieves are much stronger adsorbents than silica-gel, and thus require higher regenerative temperatures for desorption to take place. Interesting to note that a relatively weak adsorbent like silica-gel might not be indicated because of the relatively low capacity of removing humidity. Conversely, a strong adsorbent such as a molecular sieve might not be recommended as well, because an excessively high affinity to the water vapor might result in an uncompleted desorption, compromising the cyclic operation of the desiccant wheel. Accordingly, a moderate value for the separation factor seems to be the best choice. The existence of an optimum value of NTU can be explained by considering that an excessively long channel will result in continuous cooling of the regenerative stream with subsequent resorption of the water vapor. The order of magnitude of the optimum value for NTU is consistent with independently obtained results [7].

Optimisation and Cost Analysis of a Lithium Bromide Absorption Solar Cooling System

Georgios A. Florides and Soteris A. Kalogirou

Mechanical Engineering Department, Higher Technical Institute, Nicosia, Cyprus.

SUMMARY

This paper presents the optimisation of the various components of a lithium bromide (LiBr) absorption solar cooling system such as the type, slope and area of solar collector and storage tank size. The collector types considered are the flat plate, compound parabolic and evacuated tube collectors. The optimisation is based on an energy benefit analysis, i.e., the amount of useful energy collected against the life cycle cost of the solar system. The above analysis considers the current prices for fuel and equipment costs, which have increased greatly during the last 5 years. A solar absorption system consisting of a lithium bromide-water unit, a solar collector and a storage tank is modelled with the TRNSYS computer program using a typical meteorological year (TMY) for a hot climate (Nicosia, Cyprus). For this analysis a typical house is modelled for a full year. The solar system can be used during summer to provide part of the heat required by the absorption unit and during winter to provide part of the heating load. The results indicate that due to the present high cost of fuel a large part of the building load can be covered with solar energy.

INTRODUCTION

Solar energy is in abundance in Cyprus. In summer, mean monthly temperatures for Nicosia at 14.00 hours in July, are 35.4°C with the temperature sometimes reaching 43°C. Therefore, there is a need to lower the indoor temperature considerably in order to be able to provide comfort. Solar cooling of buildings seems to be one of the most attractive solutions. This is an application in which the demand for cooling energy closely matches the availability of solar energy, not only to the seasonal but also to the daily variation.

Many researchers have developed solar assisted absorption refrigeration systems. Most of them have been produced as experimental units and computer codes were written to simulate the systems. Relevant studies are shown in [1-4].

The objective of this paper is to model a complete system, consisting of a number of solar collectors, storage tank, a boiler and a LiBr-water absorption refrigerator, which will cover a typical house load during the whole year. Conclusions are drawn by comparing the economics of the system between the years 2001 and 2007 when there was a dramatic change in the fuel price.

For this analysis the typical house indicated in Fig. 1 is considered. The house thermal load is minimised by considering an insulated roof, insulated walls, double glazed windows, internal shading and night ventilation (3 ach) in summer. The above factors were studied and found to be economically viable [5]. The double-walls are made of 0.10 m hollow brick and 0.02m plaster on each side and a layer of 0.05 m insulation in between. The roof is constructed from fair-faced 0.15 m heavy concrete, 0.05 m polystyrene insulation, 0.07 m screed and 0.004 m asphalt, covered with aluminum paint of 0.55 solar absorptivity. The above construction requires an annual cooling load at 25°C of 17,600 kWh with a peak load of 10.3 kW and an annual heating load at 21°C of 3,530 kWh with a peak load of 5.5 kW.

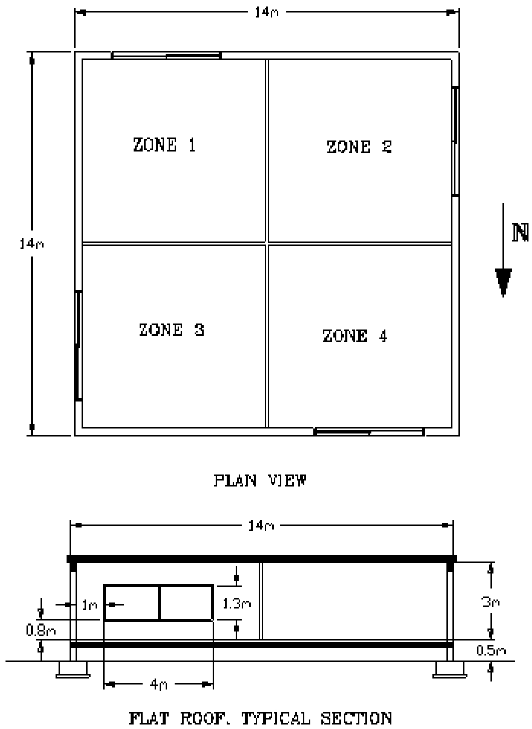

Fig. 1 Model house

The TRNSYS program is used to model the complete system (house load estimation with solar powered heating and absorption cooling), together with the weather values of a typical meteorological year (TMY) file for Nicosia, Cyprus.

The solar powered system consists of an array of solar collectors, boiler, storage tank, 11 kW absorption cooling unit, pumps and thermostats.

Using this approach a system optimisation is performed in order to select the right equipment, i.e., the collector type, the storage tank volume and the collector slope angle and area. The collector area is decided by performing an economic analysis of the system. Also the long-term integrated system performance and the dynamic system behaviour is evaluated and an economic comparison is made between the years 2001 and 2007.

CHARACTERISTICS OF AN 11 KW WATER-LIBR ABSORPTION CHILLER

The characteristics needed in TRNSYS deck file are the generator load, the mass flow of the heating water to the generator heat exchanger and its input and output temperatures. Referring to previous work [6] the calculated 11 kW unit characteristics are as shown in Table 1. Also other parameters needed for the TRNSYS input file were calculated based on this previous work.

THE COMPLETE SYSTEM CHARACTERISTICS

The complete system besides the absorption refrigerator consists of a number of solar collectors, a thermally insulated vertical storage tank, a conventional boiler and interconnecting piping. A schematic of the system showing also the simulation program information flow is shown in Fig. 2.

The system was modelled with the TRNSYS simulation program. The program consists of many subroutines that model subsystem components. The type number of every TRNSYS subroutine used to model each component is also shown in Fig. 2.

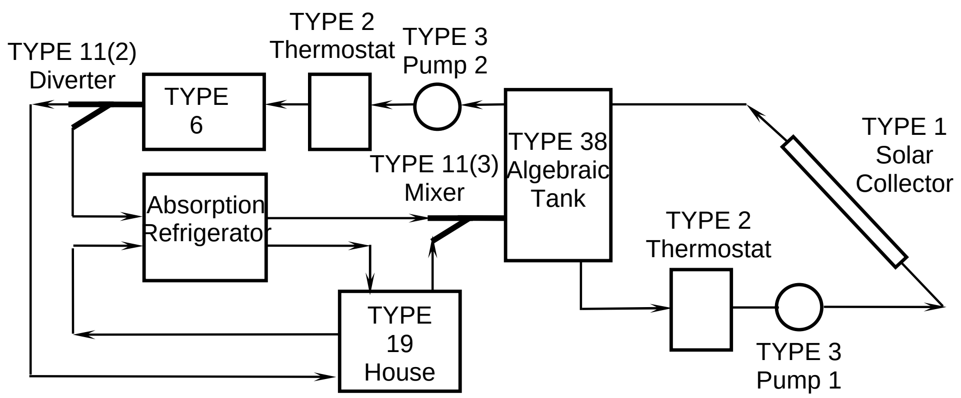

Fig. 2 Circuit diagram and TRNSYS types used for modelling the system.

The construction and type of the solar collectors is important and relevant to the operation and efficiency of the whole system. Three types of solar collectors, modelled with TRNSYS Type 1, are evaluated in this study as follows:

Flat Plate Collectors: These are predominantly used for domestic hot water production. The external casing of the collectors considered in this study, which are manufactured locally, is made of high corrosion resistant galvanised steel sheet, sprayed with aluzinc paint. The casing is covered with a 4 mm thick single glass and sealed with a rubber gasket. The absorber plate is made of copper. High radiation absorption is achieved by the use of black fine matt finish on the copper surface, which has a high absorption coefficient. The underside of the absorber plate and the side casing are well insulated to reduce conduction losses with 50 mm and 30 mm fibreglass insulation respectively. Each flat plate collector consist of 12 evenly spaced parallel copper pipes, 15 mm in diameter, embossed by semi-circular grooves formed in the flat plate absorber.

Conventional flat plate collectors are developed for use in sunny and warm climates. During cold, cloudy and windy days their performance is greatly reduced. Furthermore, condensation and moisture can cause early deterioration of internal materials resulting in reduced performance and system failure.

Compound Parabolic Concentrating Collectors (CPC): These collectors use curved reflecting surfaces to concentrate sunlight onto a small absorber area. CPC’s are used for higher water temperature applications than the flat plate collectors. Such a focusing collector performs very well in direct sunlight but, depending on the concentration ratio, does not perform well under cloudy or hazy skies because only a few rays are captured and reflected onto the absorber. A compound parabolic collector system can work either as a stationary system, or it can track the sun. In stationary systems, much of the sunlight that hits the concentrator's reflector often misses the absorber. Tracking devices allow the collector to follow the sun's movement across the sky. This ensures that the concentrator always faces toward the sun. Such systems are usually employed for higher temperature applications. Since residential applications only require medium temperatures, stationary systems are usually employed. Stationary systems are also less expensive and are easier to install and maintain. Concentrating collectors work best in climates with a high amount of direct solar radiation as in Cyprus.

Evacuated Tube Collectors: These collectors are highly efficient, made of an absorber pipe enclosed within a larger glass tube. The absorber pipe may also be attached to a black copper fin that fills the tube (absorber plate). The space between the glass and the absorber is evacuated. Only radiant heat is transmitted from the absorber pipe to the outside of the collector and in this way the efficiency of the collector is substantially increased.

The tubes are usually mounted into a manifold and the heated liquid is either used directly or circulates through a heat exchanger and gives off its heat to water. The coated surface of the absorber pipe has high absorption (> 92 %) of solar radiation and low emittance (< 6 %) for the infrared heat radiation. The absorber coating also has high resistance to long-term vapour condensation and high operating temperature.

The performance of the system employing these three types of collectors is investigated in order to select the most suitable for the present application. The final selection is made by considering the financial viability of the system.

Hot water is stored in a TRNSYS Type 38 tank. The vertical cylinder construction is made of copper and is thermally insulated with polyurethane. Also the tank is protected by a galvanised outer shell 0.6 mm thick.

The backup boiler (TRNSYS Type 6) is assumed to have a maximum heating rate of 18 kW and a set upper temperature of 93°C.

A number of thermostats (TRNSYS Type 2) are also used in order to control:

a. The flow to the solar panels, allowing the fluid to circulate only when the temperature of the fluid returning from the collectors to the storage tank is higher than that of the fluid delivered to the load; and

b. The operation of the boiler, allowing the boiler to operate only when the temperature of the fluid delivered to the load is below an optimum value. In this case the boiler will keep the water temperature delivered to the absorption cooler always above 85°C.

SYSTEM OPTIMISATION AND ENERGY FLOWS

A number of simulations were carried out in order to optimise the various factors affecting the performance of the system. The parameters considered are as follows:

The collector slope angle: The solar heat gain from the system for various collector slope angles was examined. The optimum angle in the Cyprus environment is:

i. 25°-30° for the flat plate collector
ii. 30° for the compound parabolic collector, and
iii. 30° for the evacuated tube solar collector

This is due to the solar altitude angle, which for the latitude of Cyprus (35°) can reach to 78° during noon in June. Also, because of the load characteristics, with the total cooling loads being about 6 times bigger than the heating loads, the optimum angle should be such that the collectors are absorbing greater heat during summer.

Storage tank size: This factor also plays a role in the optimisation of the system. Simulations show that for all three types of collectors, a smaller tank size results in slightly less energy consumption by the boiler and slightly less energy collected by the solar collectors.

The storage tank size is therefore decided only from the length of time intervals between firing the boiler. Between these intervals the tank should be able to supply the system with the needed water mass flow at the correct temperature in the summer. As it results, when the storage tank size is small the temperature in the cylinder cannot be kept above 85°C for long periods of time.

Assuming that the boiler is firing every 12 minutes, which may be a reasonable interval, the optimum storage tank size needed for the system would be:

i. 0.8 m^3 for the flat plate collector
ii. 0.6 m^3 for the compound parabolic collector and
iii. 0.6 m^3 for the evacuated tube solar collector

Finally the effect of the collector area is evaluated against the boiler heat required. As it is expected the greater the collector area the less the boiler heat needed as indicated in Fig. 3 and the more the collected heat as indicated in Fig. 4.

To determine the optimum collector area the cost of the solar system must be compared against the fuel saved due to its use. The cost of the various types of collectors is shown in Table 2.

Table 2 Cost of solar collectors

Collector type	2001 Cost (€/ m^2)	2007 Cost (€/ m^2)
Flat plate collector	186	220
Compound parabolic collector	305	370
Evacuated tube collector	425	460

The economic method used, is the life cycle analysis [7]. For solar systems the following equation can be used:

System annual cost = Extra mortgage payment + Maintenance cost – Extra fuel savings

– Extra electricity savings – Extra tax savings (1)

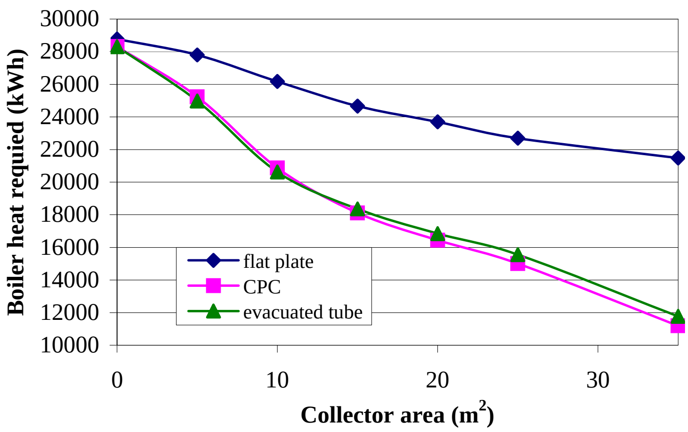

Fig. 3 Effect of the collector area on the boiler heat required by the system

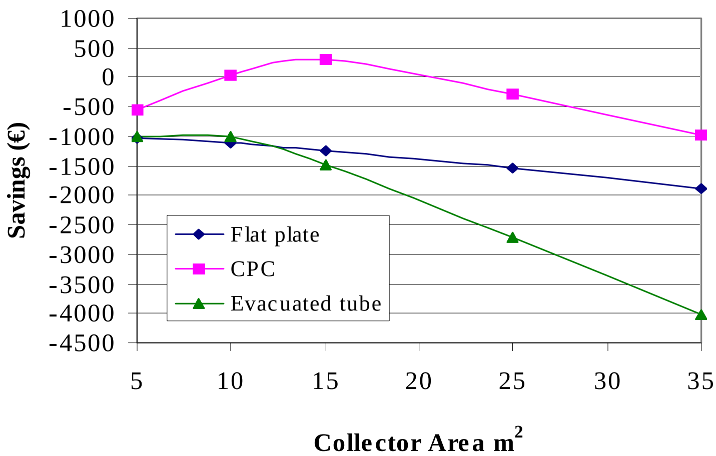

Fig. 4 Effect of the collector area on the collector heat gain

The scenario considered is that 30% of the initial cost of the system is paid at the beginning and the rest is paid in equal instalments in the next 10 years. The evaluation is based on the price of the diesel in 2001, which was € 0.29 per lt and the current price which is € 0.73 per lt.

The results of the economic analysis are presented in Fig. 5. As it is observed the only economically viable solution in 2001 was to use the CPC with a collector area of 15 m^2. The flat plate collector and the evacuated tube collector were not suitable for this application then due to the low price of fuel.

Now, in 2007, the situation has changed and CPC and evacuated tube collectors can be used economically as indicated in Fig. 6.

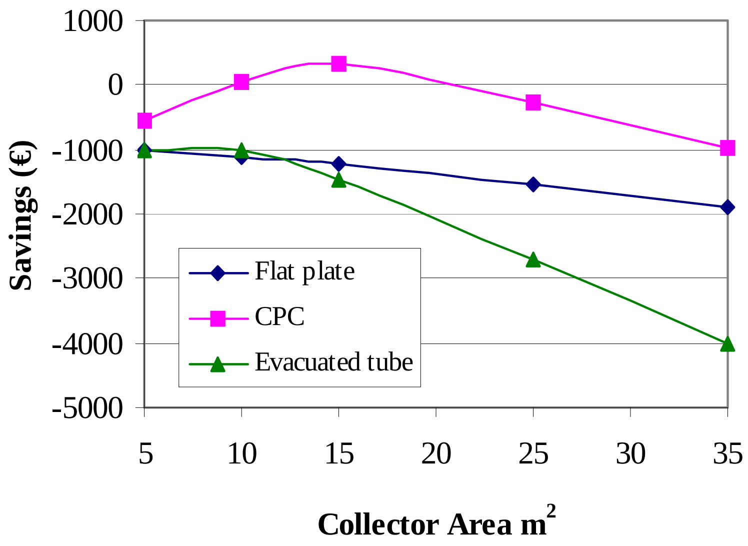

Fig. 5 Collector area against life cycle savings in € for a fuel price of €0.29 per lt and a 20 year period.

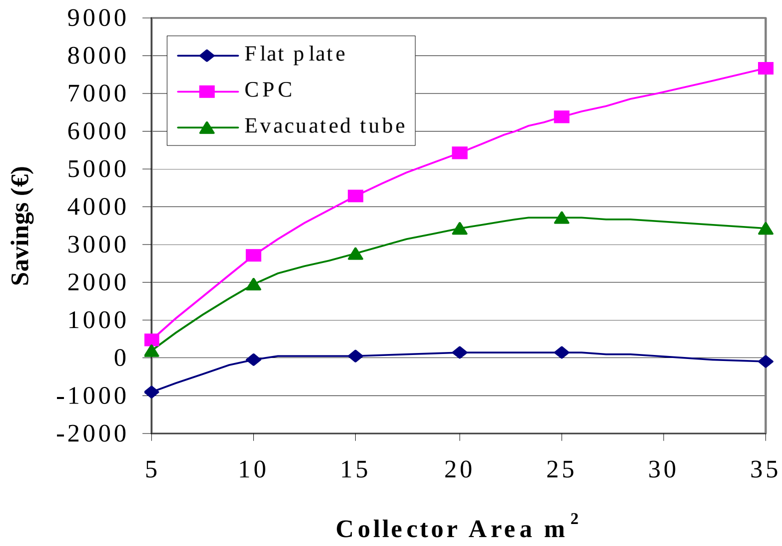

Fig. 6 Collector area against life cycle savings in € for a fuel price of €0.73 per lt and a 20-year period.

SYSTEM LONG-TERM PERFORMANCE AND ECONOMIC ANALYSIS

The specifications of the final system obtained from the optimisation study are shown in Table 3.

The energy flows of the system are shown in Figs. 7 and 8 for the years 2001 and 2007 respectively. The cooling load of the building reaches a maximum monthly value of 4200 kWh (in July), whereas the maximum monthly heating load occurs during January and is equal to 1250 kWh. The heat required from the conventional boiler is also shown in the above figures. The maximum monthly load supplied by the solar system is 1500 kWh and as can be seen from the difference of the curves for the cooling load and boiler heat, nearly all collector heat can be utilised for cooling or heating purposes.

Table 3 The final optimum system in 2001 and 2007

Item	Year 2001	Year 2007
Collector type	CPC	CPC
Collector area	15 m^2	35 m^2
Collector slope	30°	30°
Storage tank size	600 lt	600 lt

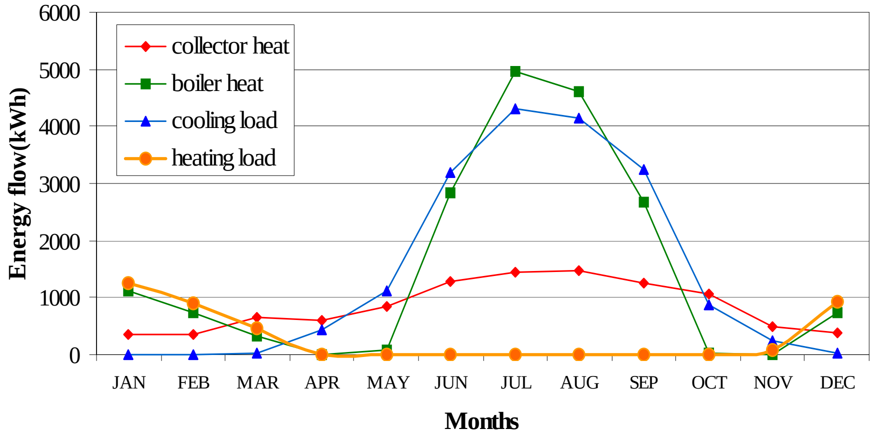

Fig. 7 System energy flows for 2001

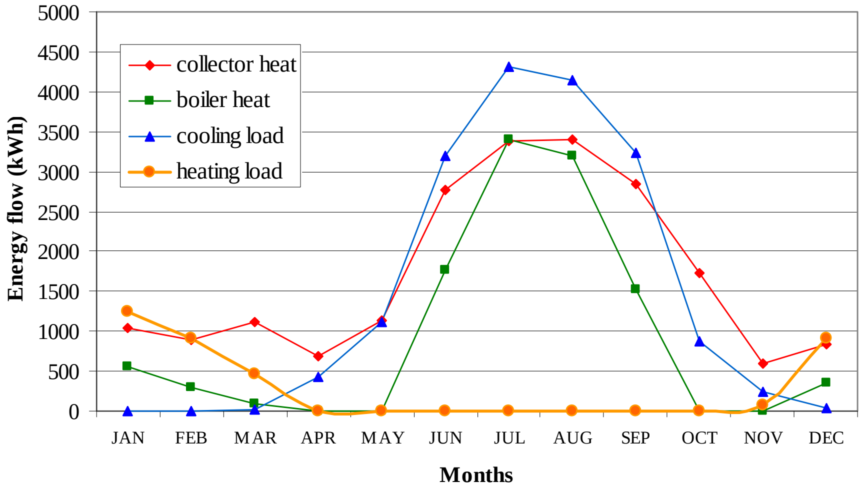

Fig. 8 System energy flows for 2007

The annual cooling load of 17,600 kWh is covered with a total supply of 15,220 kWh of boiler heat, supplemented by 8500 kWh of solar heat, offered by the solar system. The annual heating load of 3530 kWh is covered with a total supply of 2880 kWh of boiler heat and 1500 kWh of solar heat.

In 2001, the total life cycle cost of a complete system comprising the collector and the absorption unit, for a 20-year period was €22,700 with an estimated price for the absorption unit together with its accessories equal to € 8,140. In order to have the same total life cycle cost the price of the absorption unit together with its accessories should not be higher than € 3,400. This could be possible only when absorption units were mass-produced.

Today (in 2007) the final optimum system, as obtained from the complete system simulations, consists of 35 m^2 compound parabolic collectors. The only limitation is the available area on the house roof, which cannot be completely blocked. The price of diesel in 2007, which is € 0.73 per lt indicates that it is economical to replace about 20,000 kWh with solar energy collected with 35 m^2 of CPC and the life cycle savings of such a system are € 7,700. The total life cycle cost of a complete system comprising the collector and the absorption unit, for a 20-year period is € 38,200.

CONCLUSIONS

The final optimum system for 2007 as obtained from the complete system simulations, consisted of 35 m^2 compound parabolic collector tilted at 30° from horizontal and 600 liters hot water storage tank. The typical insulated house considered, requires an annual cooling load at 25°C of 17,600 kWh with a peak load of 10.3 kW and an annual heating load at 21°C of 3,530 kWh with a peak load of 5.5 kW. This annual load could be met by using about 28,100 kWh of boiler heat. The price of diesel in 2001, which was € 0.29 per lt indicated that it was economical to replace about 10,000 kWh with solar energy collected with 15 m^2 of CPC and the life cycle savings of such a system were € 320. The life cycle savings for the present system and 2007 fuel price (€ 0.73 per lt) give life cycle savings of € 7,700. The increase of the cost of fuel compels consumers to move to other energy forms in order to meet their needs. So gradually renewable energy forms can economically replace part of the fuel energy as the fuel price increases.

The Effects of External Fluids Parameters on the Performance of District Heat Water Driven Absorption Chillers

Dianjun Zhang and Olli Seppänen

Helsinki University of Technology, Espoo, Finland

Corresponding email: dzhang3@ifc.org

SUMMARY

District heating and cooling plays a great role to improve CHP plants efficiency and reduce global warming gas emission to meet Kyoto Protocol. DH energy driven absorption cooling can balance the production of heat and power in CHP plants, and reduce the summer power peak load caused by huge cooling load of building air conditioning systems. All fluids loops related to chillers have a great influence on the chillers' performance. With a simulation program developed by the author, the paper studies and simulates their effect on chillers operation so as to find the solutions to improve its performance.

1. INTRODUCTION

In some European and Asian countries, district heating (DH) systems are commonly used due to the cold winter [1], but summer cooling by separate summer electric power driven compression chillers. Two sets of system means big initial investment for building air conditioning. The integration of building cooling with existing heating systems sounds a nice solution to provide building air conditioning round the year.

District heating and cooling plays a great role to improve CHP plants efficiency and reduce global warming gas emission to meet Kyoto Protocol [2]. DH energy driven absorption cooling can balance the production of heat and power in CHP plants [3], so as to reduce the summer power peak load due to the huge cooling load of building air conditioning systems. In addition to the impacts of chillers' design on their performance, all fluids loops related to chillers have also big influence on the performance. This paper studies and simulates the effect of the factors below on the performance of DH water driven absorption chillers [4].

a. Diluted water/lithium bromide solution flow
b. Cooling water temperature
c. Chilled water outlet temperature
d. Chilled water inlet temperature
e. Driving water inlet temperature to chillers
f. The temperature drop of driving water through chillers
g. Driving water flow
h. Chillers' operating output

2. SIMULATION

One simulation program is developed by the author with EES (Engineering Equation Solver) as the platform which was developed by F-Chart Software [4]. EES is mainly designed for thermodynamics and heat transfer simulations, which has been extensively used as the platform for other further simulation programs development.

LG low temperature water driven absorption chiller is taken as the prototype for the simulation [5]. Figure 1 presents the single effect absorption chiller's (SE ACC) model. The nominal chilled water capacity is 1000kW$_c$.

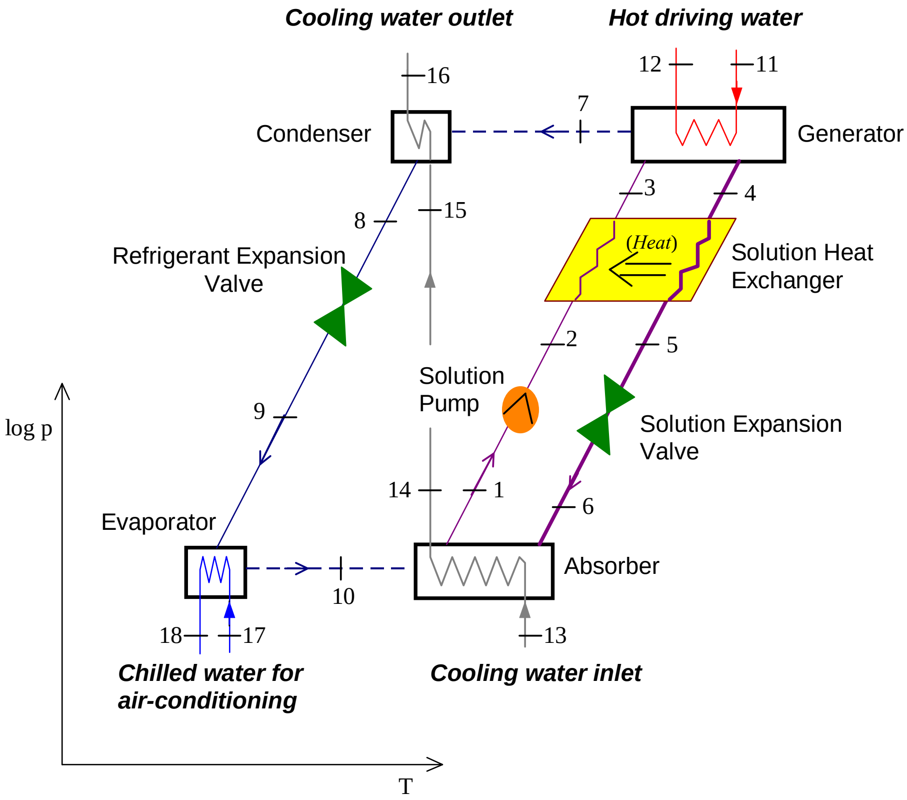

Figure 1 SE ACC model

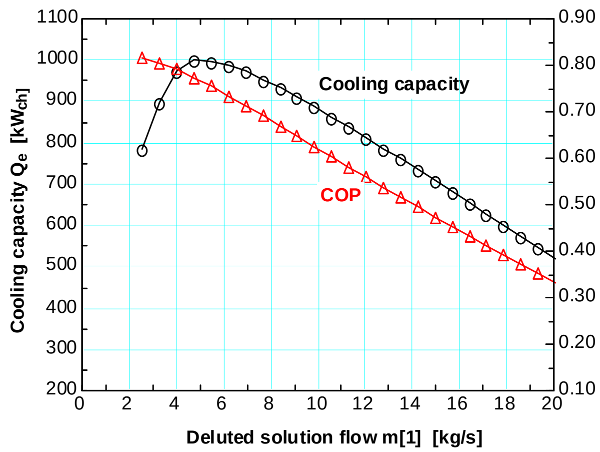

Figure 2 The impact of diluted solution flow on chillers' performance.

2.1 Diluted water/lithium bromide solution flow

Normally, SE ACCs in the market have constant diluted solution flow rate, i.e. constant flow of solution pump is installed. However, diluted solution flow rate has a strong effect on the performance when other parameters keep constant shown in Figure 2. There is a maximum value when diluted solution flow at 6kg/s, depart from that, the cooling capacity is lower.

Simulations show that the diluted solution flow at which cooling capacity reaches it maximum value, called as optimised diluted solution flow (ODSF) changes when other 6 external temperature changes. As driving water temperature increases and cooling water temperature decreases, ODSF goes up so that maximum cooling capacity is higher; whereas, when driving water temperature decreases and cooling water temperature increases, ODSF goes down resulting in a lower cooling capacity. Therefore the diluted solution pumps should be speed-controlled to meet the ODSF at different external temperature.

2.2 Cooling water temperature

Cooling water temperature has a great influence on chillers' performance. Maintaining driving water temperature, chiller's cooling output and COP increase as the decrease of cooling water temperature, shown in Figure 3. When cooling water temperature decreases from 31^{o}C at design mode to 25^{o}C, and driving hot water temperature keeps at 88/78^{o}C, cooling capacity of the chiller increases from 1000kW to 1526kW, and COP goes up from 0.691 to 0.755; on the contrary, if cooling water temperature increases from 31 to 35^{o}C, cooling capacity decreases from 1000kW to 440kW linearly, and COP goes down from 0.691 to 0.57.

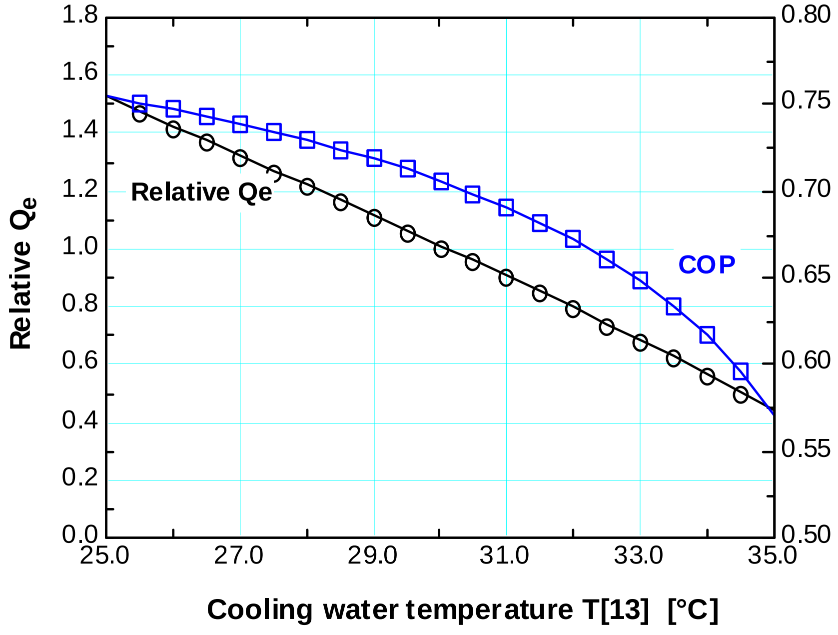

Figure 3 Cooling water temperature VS Chillers' performance

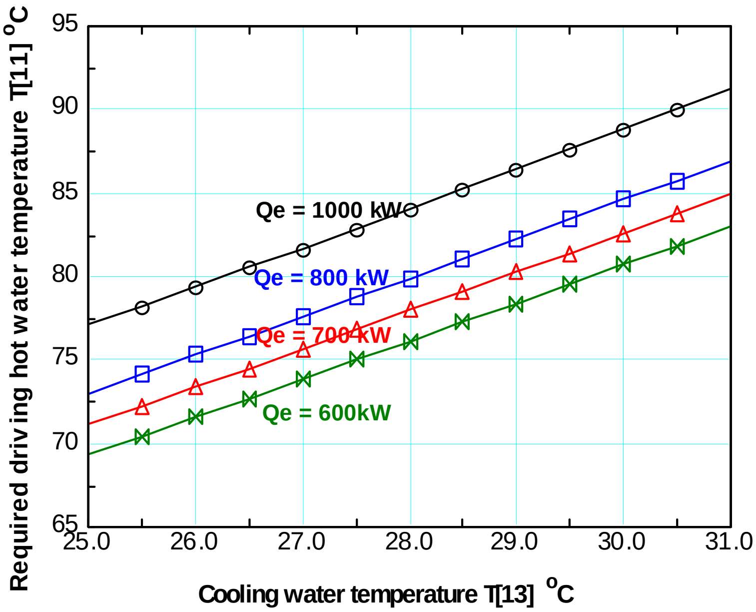

Figure 4 Cooling water temperature VS driving hot water temperature

It is obvious that cooling production of the chiller decreases 11.8%, i.e. 118kW when cooling water temperature has 1°C increase.

At design mode, the cooling water temperature at 31/36°C, but if cooling water temperature drops to 25°C by some ways, for instance heating swimming pool water with cooling water, the required driving hot water temperature can be decreased considerably shown in Figure 4. When cooling water is 25°C, it is possible to reduce the driving hot water temperature from 88 to 77°C that is very suitable for DH system in summer. As the decrease of chiller's capacity, the required driving hot water temperature decreases correspondingly. When chiller capacity is kept as 800kW, the required driving water temperature is 85 and 73°C when cooling water temperature are 30 and 25°C respectively.

Since the benefits of lower cooling water temperature, and its effective influence on chillers' performance, the solutions to reduce cooling water temperature have to be found.

2.3 Chilled water outlet temperature

The simulation results when change chilled water temperature are shown in Figure 5 and 6, under certain amount of chiller output, increase chilled water temperature level can improve chiller's performance and reduce required driving water temperature.

Increasing chilled water temperature results in the higher heat transfer potential of evaporator, i.e. greater temperature difference between refrigerant and chilled water. When keeps other parameters, increased chilled water temperature causes higher chiller output. While keeps the certain amount of chiller output, driving energy input decreases, thus COP goes up.

Refer to Figure 6, DH supply water temperature entering to chiller generator keeps at 88°C and chilled water output at 800kW_{ch}, when chilled water outlet temperature increases from 8°C to 14°C, driving water exit temperature will decrease from 76.2°C to 66°C, as the result it can return to DH network directly, and driving water flow decreases from 22 to 11.8kg/s.

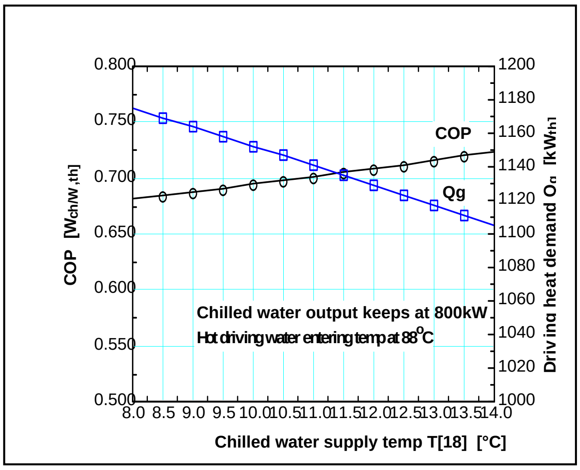

Figure 5 Chilled water temp vs chiller COP and driving heat demand

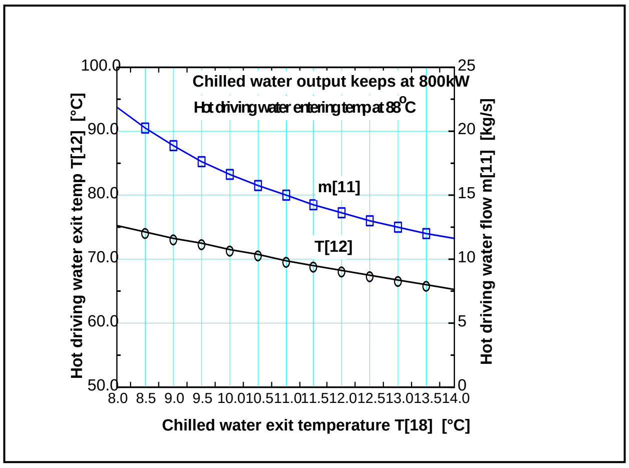

Figure 6 Chilled water temperature vs driving water exit temperature and flow

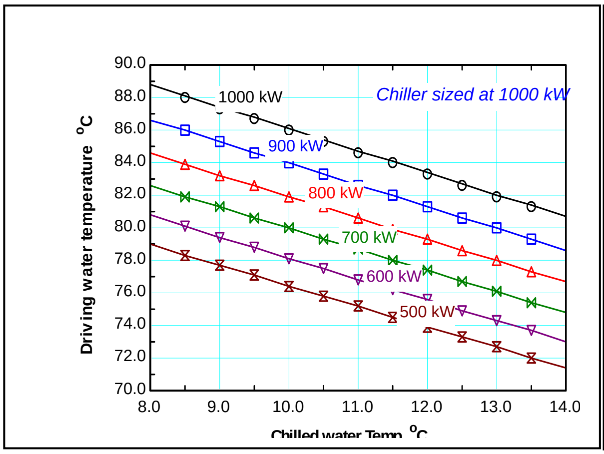

Figure 7 Driving water temperature VS chilled water temperature at different chillers output

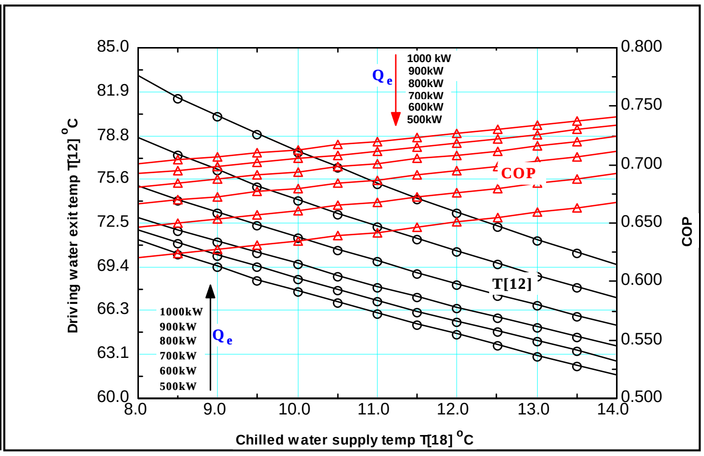

Figure 8 Driving water exit temperature and COP VS chilled water temperature at different loads

Figure 7 shows the results of how chilled water temperature influences the required driving water temperature when chiller's output varies with the chiller sized at 1000 kW. If the chiller runs at its full capacity 1000kW, the required driving water temperature decreases from 88 to 80.7°C when chilled water temperature increases from 8 to 14°C. When the chiller's output is 500kW, the required driving water temperature decreases from 79 to 69.5°C corresponding the same range of increase of chilled water temperature.

When driving water temperature keeps at 88°C, the driving water exit temperature and COP values at different chiller's output are illustrated in Figure 8 if chilled water temperature increases from 8 to 14°C. With the increase of chilled water outlet temperature, the driving water exit temperature decreases. the driving water exit temperature goes down as the reduction of chiller's output.

Figure 9 presents the chiller's output at increased chilled water outlet temperature. When the outlet temperature rises from 8 to 13°C, the chiller output increases from 884 to 1195kW, and COP increases from 0.691 to 0.743.

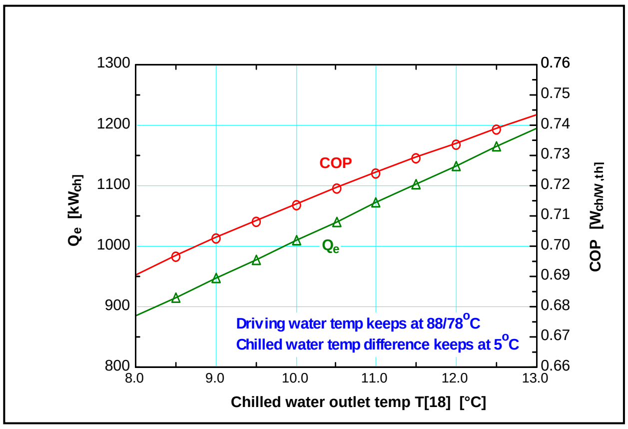

Figure 9 Chilled water outlet temperature VS COP and chillers' output

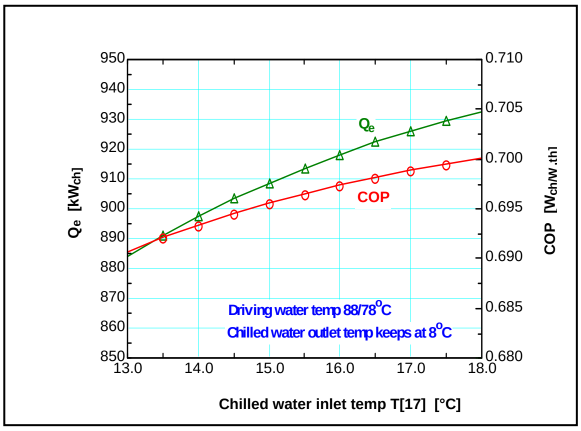

Figure 10 Chilled water inlet temperature VS COP and chillers' output

2.4 Chilled water inlet temperature

Chilled water inlet temperature impacts chillers' performance as well. Shown in Figure 10, keep chilled water outlet temperature at 8^{o}C, but increase chilled water inlet temperature, the chilled water output and COP goes up. When the inlet temperature rises from 13 to 18^{o}C, the chiller output increases from 884 to 933kW, and COP increases from 0.691 to 0.7.

To increase of chilled water outlet temperature has much stronger influence on chiller's output and performance than that of chilled water inlet temperature does.

2.5 Driving water temperature to chiller

Keeping all other parameters at design mode, the influence of driving water temperature on chillers' performance is simulated, and the results are shown in Figure 11 and 12 for driving water temperature drop at 5^{o}C and 10^{o}C, respectively. If driving water temperature drop keeps at 5^{o}C, when driving water temperature decreases to 75^{o}C, chilled water output decreases to 365kW. If driving water temperature drop keeps at 10^{o}C, the minimum driving water temperature is 78^{o}C when the chilled water output is only 311kW. The chiller output is more sensitive to driving water entering temperature than exit temperature.

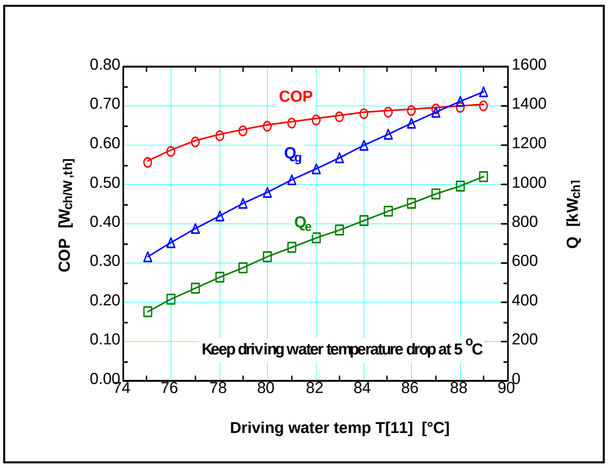

Figure 11 Driving water temperature VS COP & chiller output and driving heat demand in case of driving water T drop at 5^{o}C

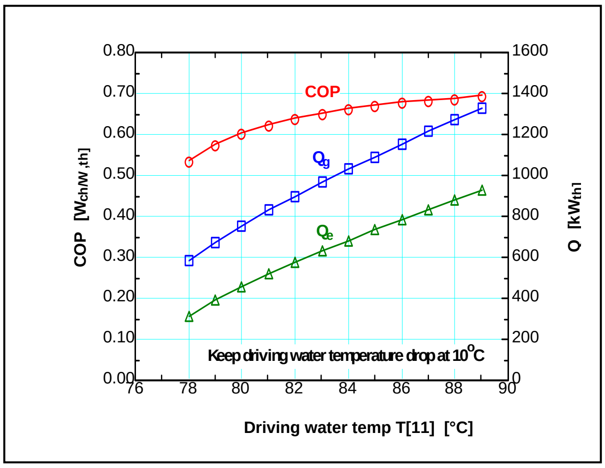

Figure 12 Driving water temperature VS COP & chiller output and driving heat demand in case of driving water T drops at 10^{o}C

2.6 The Temperature drop of driving water through chillers

It is found that driving water temperature drop through chillers' generator impacts its performance. Maintaining driving water temperature at 88°C and other parameters, to simulate the influence of variable temperature drop, the results are shown in Figure 13.

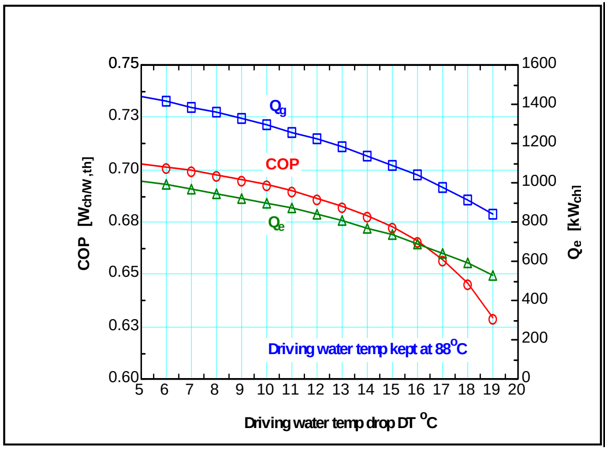

Figure 13 Driving water temp drop VS performance **[Chiller sized at 1000kW when the drop is 5°C]**

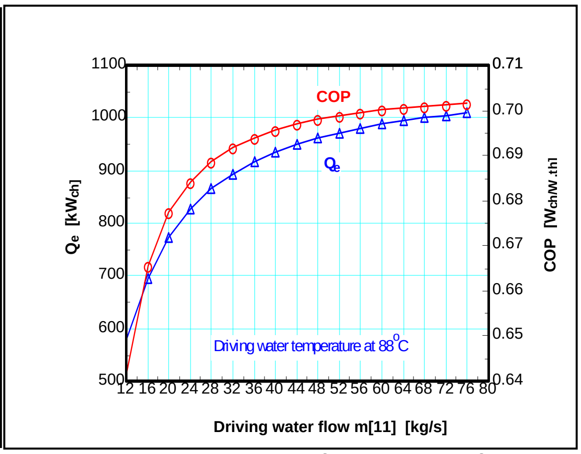

Figure 14 Driving water flow VS performance

If driving water temperature drop increases, the performance of chiller depreciates. When it rises from 5 to 19°C, chiller's output decreases from 1000kW to 527kW, and COP from 0.703 to 0.629.

2.7 Driving water flow

Figure 14 gives the correlation between driving water flow and chillers' output when other parameters are kept as constant. The higher of driving water flow, the better of performance. Figure 15 presents the change of driving water exit temperature as the flow varies.

When driving water flow is small, to increase the flow can bring a big rise of chillers' output and COP. But as the continuously increasing, the effect becomes weak.

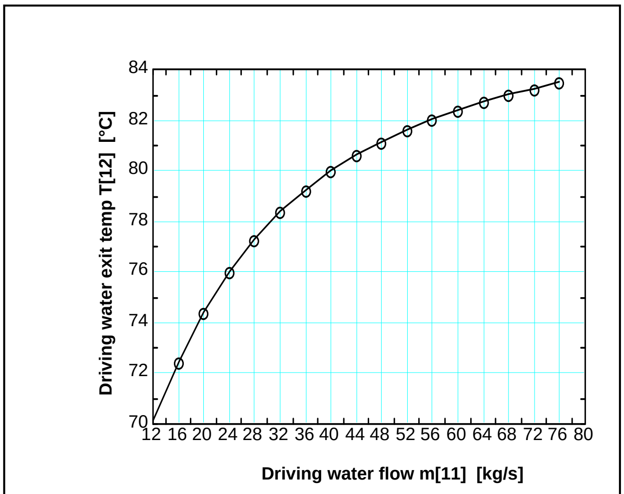

Figure15 Driving water exit temperature VS driving water flow

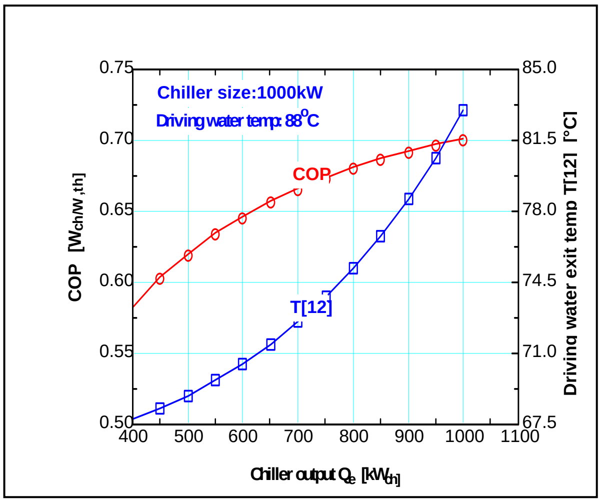

Figure 16 Chiller performance VS its operating output

2.8 Chillers' Operating Output

For the chiller sized at 1000kW at 88/83°C, as its operating output changes, the performance varies as well, Figure 16 gives the simulation results.

When its operating output goes down from 1000kW to 400kW, COP value drops from 0.7 to 0.583, but the driving water temperature drop increases. As the result, the performance depreciates as the decreasing operating output.

3. CONCLUSIONS

Simulation is the basis for manufactures to optimise their products, for designers to design a perfect district cooling station, for operators to run the station in an economical manner. The simulations implemented in this paper give the hints how the external fluids and their parameters influence the cooling capacity and performance of certainly sized absorption chillers.

Diluted solution flow has strong effect on the performance of chillers. When external fluids parameters vary, the optimised diluted solution flow at which maximum cooling capacity is reached will change as well. As the facts of the varied external fluids parameters, the solution pumps should be speed-controlled to reach the optimised performance of chillers.

Absorption chiller's performance can be improved through the following solutions:

- Control diluted water/lithium bromide solution flow
- Lower cooling water temperature;
- Higher chilled water temperature;
- Higher driving water temperature;
- Lower driving water temperature drop through chillers' generators;
- Higher driving water flow;
- Operate chillers at high output.

SUMMARY

The process of developing environmentally friendly and sustainable building structures is an interdisciplinary task. Only with a close teamwork of people from different building related disciplines, is it possible to face the challenge of solving the real life problems involved in an integral planning process. The construction of the ZUB is an example of what today's state of the art of technology for low energy demand and sustainable building can look like.
Planned as an example of a low energy building, the new office of about 1300 m^2 is attached to an existing preserved building and consists of three different main parts: one for exhibitions and events, one for offices, and an experimental part for different kinds of research in innovative building techniques and building services. A special focus was given to the realisation of a sustainable cooling concept, using a renewable energy source: the coolness of the ground underneath the building.

During the first two and a half year long intense monitoring period, about 1300 points of data were recorded in the entire building, the achievements have been proven and optimisations based on the measurements have been made. Results and findings from the intense measurements and from an additional three year long measurement period have also been collected. The project offers an opportunity to obtain actual proof and quantify the achievements of a good sustainable building. In addition, it highlights today's possibilities in the field of energy conservation design.

INTRODUCTION

Building a sustainable building is an interdisciplinary task, in which a close teamwork of people from all different building related disciplines is needed to face the challenge of answering the real life problems of this process. That is one reason for the foundation of the Centre of Sustainable Building at the University of Kassel, Germany. However, not only building research and the development of integrated planning processes in the field of building are conducted within the walls of the centre. Moreover, the centre is a platform for the fast implementation of research results into practical building processes. It offers a variety of different services in research and development, and in education for all kinds of people who are interested in building (professionals and non-professionals). Furthermore, public relation activities are carried out at the ZUB to present ideas for better, more efficient and reliable building while having the smallest possible impact on the environment. The building of the ZUB is an example of what today's state of the art technology of low energy demand and sustainable building can be like [1],[2],[3].

---

[*] Zentrum für Umweltbewusstes Bauen in Kassel, Germany. (The Centre for Sustainable Building)

In modern and energy efficient office buildings, there is interaction between the architectural design, the construction of the building envelope, and the building services equipment. These factors combine to integrally influence the resulting indoor climate. During the project presented here, these interactions have been identified. By optimising all factors, it is possible to secure a comfortable indoor environment by consuming only a minimum amount of energy.

THE BUILDING CONCEPT

The office building of the Centre for Sustainable Building is situated at the University of Kassel, in an old urban neighbourhood. The new building of the ZUB closes a gap in an ensemble of old houses. An atrium, used as a gap of light, containing the entrance zone and the staircases, joins the old brick building of the Faculty of Architecture to the modern concrete construction, thus combining old and new.

Figure 1. The office building of the Centre for Sustainable Building in Kassel, Germany [4].

The ZUB office building consists mainly of three different parts: one part for exhibitions and events, one part for offices and an experimental part for different kinds of research in innovative building techniques and building services concepts. Some space, with non-shaded conditions, has been provided for test equipment on the flat roof.

The building envelope construction

The load bearing skeleton in reinforced concrete consists of round pillars with 5.40 m spaced between them and flat concrete slabs for the floor/ceiling construction. The U-value of the exterior concrete walls, with 30 cm of polystyrene insulation, is 0.11 W/m^2K, and triple glazing with a U-value of 0.6 W/m^2K and a g-value of 0.48 have been chosen for the mainly south facing large window area. The minimal frame-fraction of the wooden façade construction helps to reduce heat losses. Furthermore, the problem of thermal bridges has been diminished by carefully planning all joints and details. Good thermal insulation is mandatory in achieving minimal heating energy demand for the entire building.

Table 1. Main building facts

		Building part	U-value
Volume	6882 m^3		
Net floor area	1348 m^2	Exterior walls	0.11 W/m^2K
Main floor space	830 m^2	Roof	0.16 W/m^2K
		Windows	0.80 W/m^2K
Area/volume ratio	0.34 m^{-1}	Wall/floor against ground	0.26 W/m^2K
		Mean U-value	0.32 W/m^2K

The high insulation standard has dramatically reduced the energy demand. For the ZUB building, the calculated heating demand according to the WSVo'95 (old German energy code) turned out to be 25 kWh/m^2a, which is 27% of the limiting value. The heating demand according to the new and actual German energy code EnEV is 21.3 kWh/m^2a [2].

These higher standards caused, on one hand, some more initial costs but, on the other hand, some special savings became possible. One example of this is that it was possible to reduce the size of the building equipment. Finally, the costs of the ZUB building were in the range between a commonly built and a low cost office building, according to the German building costs index [5]. Also, the other buildings examined during the named research program, the EnBau program, show the same cost structure as commonly built offices in Germany.

Table 2. Building costs per net floor area of the ZUB building compared to different German standards

	ZUB	Low cost [5]	Common [5]	Advanced [5]
Construction	768.50 €/m²	772 € /m²	979 € /m²	1284 € /m²
Services equipment	300.60 €/m²	151 € /m²	268 € /m²	408 € /m²
Building costs	1069.10 €/m²	923 € /m²	1247 € /m²	1692 € /m²

THE SUCCESSFUL BUILDING SERVICE SYSTEM CONCEPT

During the planning phase, there was already an emphasis on a good interaction between the used building construction and the chosen building service systems. A lot of passive and natural means were utilised for the heating, cooling and ventilation of the building, and it was possible to reduce the use of building service equipment to a minimum. The results of the evaluation from the concomitant scientific research program, as shown in the figure, point out the success of the concepts which have been executed.

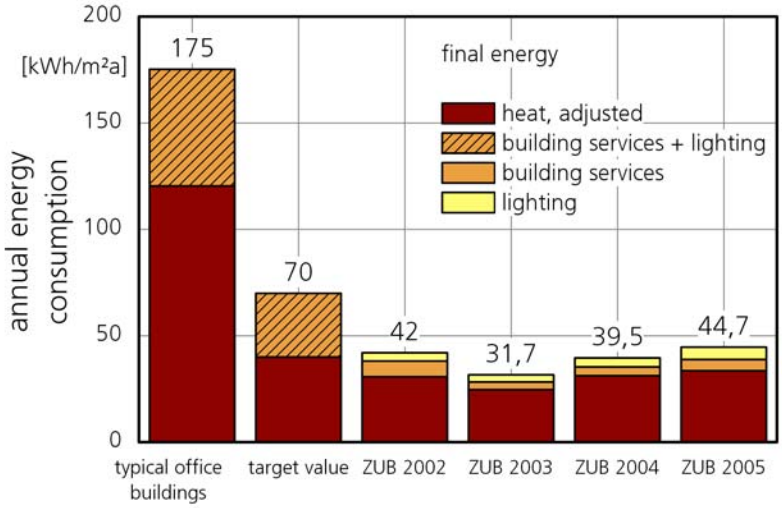

Figure 2. Specific annual energy consumption for heating, building services and lighting of the ZUB building compared to the target values of the German research program EnBau and to existing typical office buildings [6].

The central points of the outlined achievements are the good insulation standard and the utilisation of aligned building service equipment, which is described in its three most important parts: heating and cooling, ventilation and lighting.

Soft heating and cooling with thermally activated building constructions

All office rooms and the lecture hall of the ZUB building are equipped with a surface heating and cooling system, with thermally activated building constructions. On all floor slabs, conventional floor heating has been installed in addition to the activated ceilings. This has been done for research purposes in order to test and verify different regulation strategies. The pipes of the ceiling systems are laid about 15cm apart, directly on the lower reinforcement layer. Each office room is equipped with a separately regulated heating/cooling circuit in the ceiling and in the floor slab. Via a regulation of the mass flow of the heat carrier, water, an individual energy supply and demand controlled heating and cooling is possible. In the case of heating, the systems are supplied with district heating, which is available from the neighbouring university building (see Figure 1).

Figure 3 . The pipes of the thermally activated slabs directly on the lower reinforcement layer

The main general difference between the other radiant systems and thermally activated building construction, as used in the ZUB, is the possible asynchrony of the operation of the conditioning plant and thermal loads, i.e. the slab has the opportunity to store heat or cool at different times, with respect to thermal loads.

The main advantages for the thermally activated constructions are the following [7]:

- the thermal load is distributed in a longer period, which leads to lower peak loads, thus allowing the use of conditioning plants of reduced sizes
- the possibility to use two radiant surfaces leads to more uniform conditions in the conditioned space and better thermal comfort conditions
- the buildings have reduced dimensions in relation to buildings with suspended ceilings
- it is possible to use conditioning plants suitable for temperatures close to room temperature, i.e. heat pumps, condensation boilers, solar collectors, or ground heat exchangers as used in the ZUB
- for cooling purposes, the night over-ventilation can be used as well
- low installation costs and low operation costs are possible.

The use of thermally activated systems on the other hand requires the following [7]:

- active thermal slabs are used in multi-storey buildings with a central plant
- attention has to be paid in the case of raised floors, while the ceiling surfaces have to be free from obstacles (no suspending ceilings can be used, which could cause difficulties for the room acoustics)
- the design of this type of radiant systems is very critical; adequate solar radiation screens are needed as is good thermal insulation of the envelopes, which has to be lower than 1 W/m^2 K and better than 0.6 W/m^2 K, the transmitting insulation (shading elements). The ZUB building is a good example which shows how these challenges can be met.

A great glazing fraction of a façade, such as that of the south facing façade of the ZUB , leads to an increased demand in cooling if no highly efficient sun shading is installed. This has been done in the ZUB by installing external blinds. To reach particular comfortable indoor conditions, the thermally activated constructions are also used as a soft cooling system. The operational temperatures for these systems are relatively low for heating (27°C) and high for cooling (20°C). This fact allows for the possibility of using renewable cooling sources, e.g. the coolness of the ground under the building. In the ZUB, a so-called ground heat exchanger has been installed.

The ground heat exchanger

The utilisation of low water supply temperature (of 25 – 40°C) for in the case of heating and high temperatures (16 – 20 °C) for cooling, makes it possible for renewable energy sources to be used in the system. In cooling conditions, it is possible to use renewable energy sources as well, for example ground heat exchangers (as used in the ZUB) or rain water ground accumulators. Due to the high thermal inertia, the thermally activated building constructions can even be loaded during the night.

Similar to the construction of the activated floor slabs, there are pipes in the bottom slab of the building. Via thermal contact to the ground, the flowing water inside the pipes is cooled and via the circulation, it is supplied to the ceiling and floor systems in the office rooms. Measurements have shown that the ground heat exchanger works with a calculated COP of 23, in comparison to a normal mechanical cold production with COP’s of about 3.5. The system used in the ZUB is about 6.5 times more energy efficient than a conventional cooling system. A common German office building uses about 30 kWh/m²a primary energy for the climatisation (cooling) of the office spaces [5]. In this figure, the energy use for the pumps is not included. In the ZUB building approximately 5300 kWh of cooling is delivered per year to the offices, using approximately 270 kWh of electricity for the pumps. The primary energy use turns out to be 0.6 kWh/m²a for the cooling.

The cooling power, which can be utilised at low operational costs, is not arbitrarily adaptable. It depends strongly on the temperature and water flows (moisture) of the ground. For very dry grounds, the cooling potential could be worn out after a few weeks as the ground temperature rises and only a very limited cooling power can be used. In the case of flowing ground water, it is possible to use greater cooling power and rooms can be cooled more intensively.

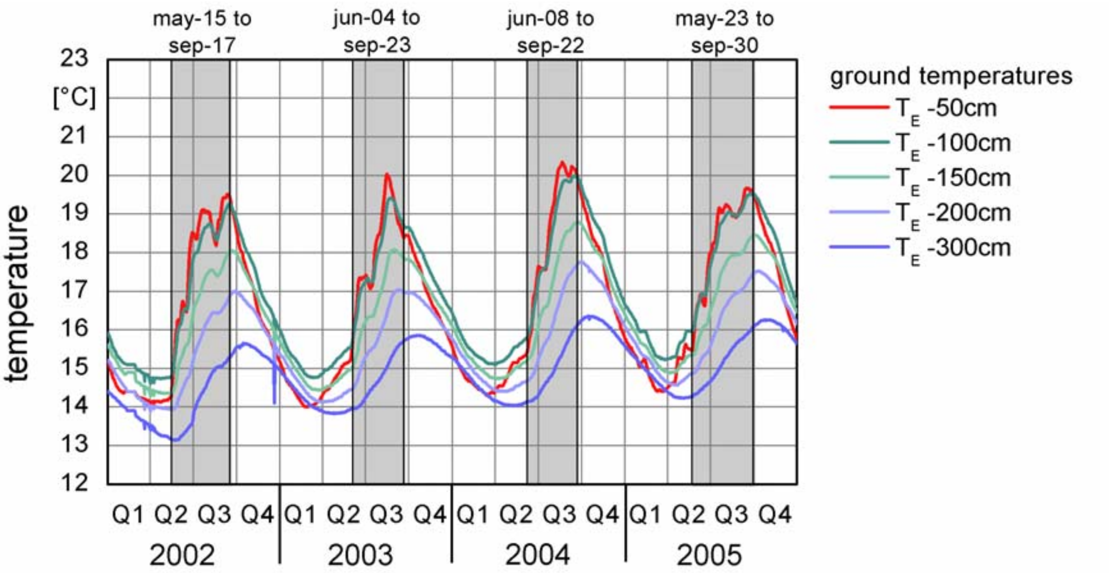

Figure 4. Measured temperatures in the ground below the ZUB building, which is used as the heat sink for the cooling system.

As shown in the figure, the ground temperature rose slightly from the cooling season in 2002 to 2004 by about 1K/a in 3m below the ZUB. This trend was stopped in the later cooling seasons, the ground temperature returned to the same values after cooling during periods. The management of the cooling source works.

Thermal conditions in the ZUB offices

A main concern during the course of the project was the question whether or not the limited power output of the thermally activated constructions would be sufficient to cover the demands.

Simulations showed that a constant cooling power of about 8 W/m^2 is reasonable for the ZUB. The maximum measured cooling power was 40 W/m^2 and the maximum heating power was 80 W/m^2, which is also shown in the following figure. These values are in the same range as indicated in the literature [7].

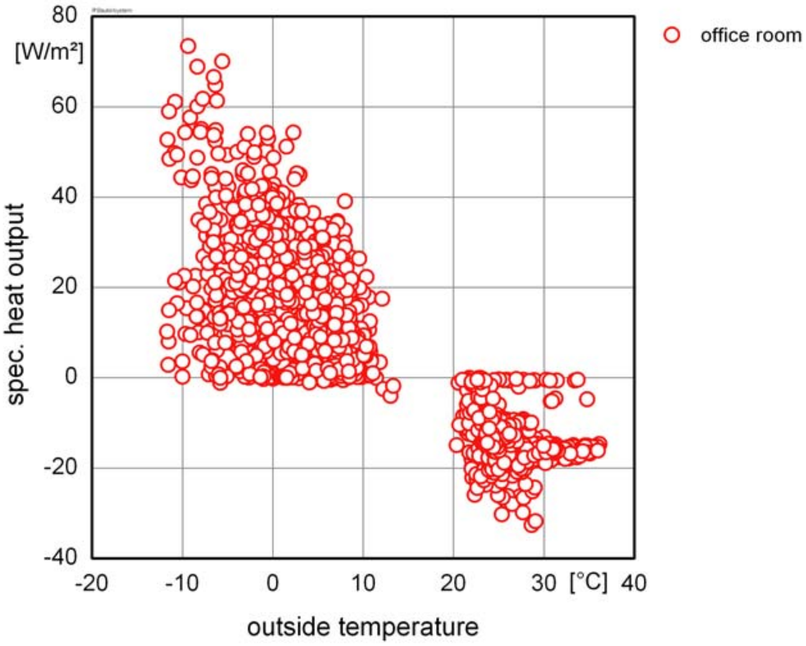

Figure 5. Measured specific heating and cooling power of an office room in the ZUB

With these values, thermal comfort could be secured during the measurement period. The overheating hours, hours with room temperature above 26°C, could be diminished by using this system up to only 125 h or 4% of the occupancy time in a representative office room during the “summer of the century” in 2003. An intensive study on the comfort conditions in the ZUB based on questionnaires showed that the occupants were very pleased with the conditions in the building and accepted the slight changes in room due to the heating, cooling and ventilation system. This is proof of the excellent thermal comfort of the ZUB building.

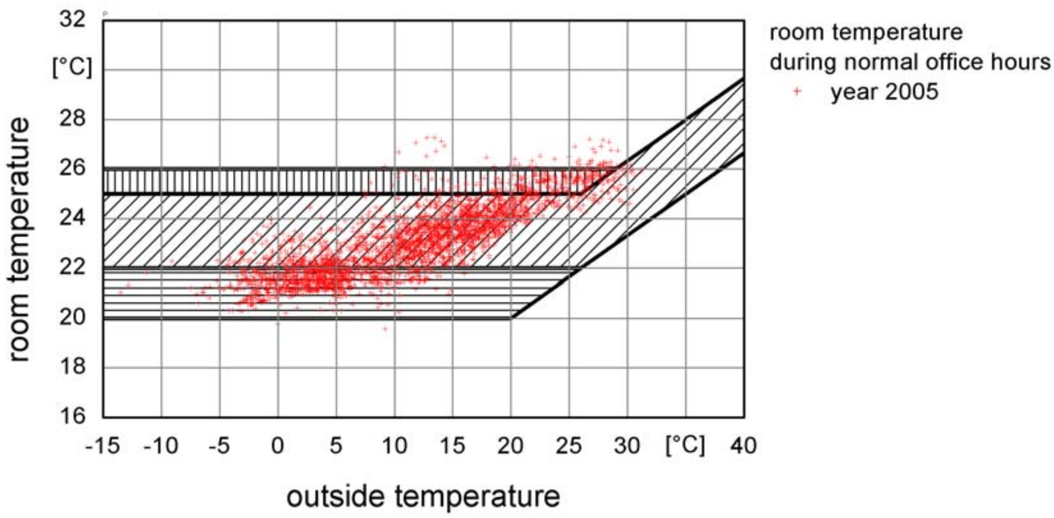

Figure 6. Measured room temperatures in an office room in the ZUB depended on the comfort ranges given in the German Standard DIN 1946 part 2 for the year 2005.

CONCLUSIONS

The project of the ZUB building is actual proof that high demands on commercial buildings with regard to energy efficiency in heating and cooling, as well as a rational use of electricity, can be met. The first two year long intensive monitoring period provides evidence for the fact that if all crafts are integrated into the planning and building process in a holistic manner, it is possible to build houses which are trendsetting in the sense of energy efficiency and indoor comfort. The combination of a high insulation standard and the solar optimised orientation of the building, with thermally activated building constructions for heating and passive means for cooling, are the framework for energy optimised buildings in Northern (European) climates. The use of the ground heat exchanger, which is especially expedient when external and internal load from machines, computers and persons can be reduced, shows a very high acceptance and a high energy efficiency. By using external sun shadings and energy saving office equipment, good indoor thermal comfort can be reached at all times.

SUMMARY

Since the heat wave of 2003, summer thermal comfort in buildings and more particularly in residences for the elderly has become in France one of the major concerns of building owners. Hence they have been requesting for finer thermal simulation studies. Within the framework of a care home project for dependent elderly people, two ventilation systems have been studied: a double-flow system with possible adiabatic indirect evaporative cooling and a buried-pipe system coupled to a double-flow-type blowing network.

The building model studied has been defined using TRNSYS software. Simulations were carried out using the annual weather data file of Toulouse (south of France). The performance analysis in terms of energy consumption and thermal comfort (evaluated by a number of hours of overheating) of the double-flow and buried-pipe systems is carried out over the whole year and seems favourable compared to the results of a basic simple-flow ventilation system.

INTRODUCTION

In France, since the heat wave of summer 2003, the thermal study for new buildings has become finer especially in the case of care homes for dependent elderly people. Now, this type of building has to satisfy the new French thermal regulations (RT 2005) in terms of energy consumptions for space heating and thermal comfort during summer and in-between seasons (between winter and summer and between summer and winter). These regulations also encourage not to use cooling systems in order to reduce summer temperatures. This study compares the performances of different ventilation systems. A double-flow system using an air heat exchanger to recover the heat of the extracted air in winter and equipped with an adiabatic indirect evaporative cooling system in summer, and a buried-pipe system are studied and compared to a reference solution, which is a simple-flow ventilation system. The 45-bedroom care home for elderly people is situated in Toulouse (south of France).The thermal simulations are run using TRNSYS software.

DOUBLE-FLOW VENTILATION SYSTEM

Description of the system

The ventilation box (figure 1) is composed of a blowing fan, an extraction fan, a static heat recovery exchanger and a lost water humidifier placed on the extraction side. This feature is only working during summer. An electronic gate commands the cold water (CW) that flows on a web weaved in polyester threads. The excess of water is evacuated through a siphon. The box is also equipped with dampers controlled by an on-off system that allow the by-pass of the exchanger in the hotter seasons.

Thus outside air can follow three ways: a preheating in winter through the heat recovery exchanger, an indirect adiabatic cooling in summer and a direct blowing with no previous treatment when the exterior and interior conditions are favourable during the in-between seasons (free cooling).

The conditions of operation of the double-flow system are detailed in Table 1. To avoid any conflict in the regulation strategy and to limit short sequences, the laws of control integrate a hysteresis of 1°C on set temperatures.

Table 1. Operation modes of the double-flow ventilation system

Period	**Temperature conditions**	**Air treatment type**
Winter	Tamb ≤ 17 °C	outside air preheating
Winter	Tamb > 17 °C	Direct ventilation
Summer	Tin > 22 °C et Tamb > Tint	Indirect evaporative cooling
Summer	Tin ≤ 22°C	Free cooling

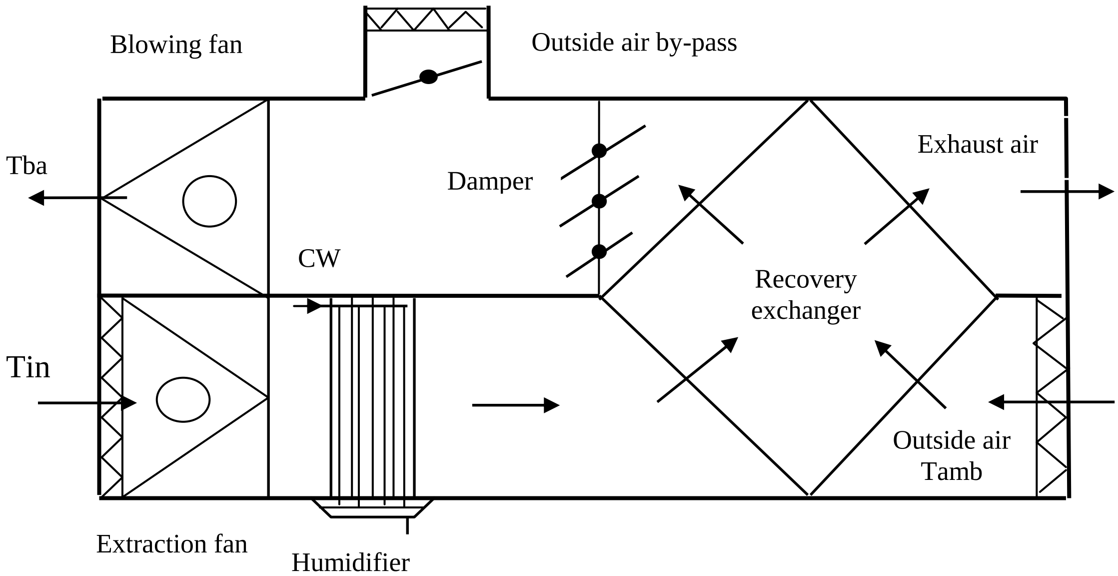

Figure 1. Double-flow ventilation box

Outside air preheating

In winter, the outside air is preheated through the heat recovery system by exchange with the exhaust air. Considering the efficiency ε of the exchanger and an increase of 0.4°C by passing through the fan, the supply air temperature is given by equation 1:

$$T_{sa} = T_{amb} + \varepsilon \times (T_{in} - T_{amb}) + 0{,}4 \qquad (1)$$

Where T_{sa} is the supply air temperature, T_{in} is the inside temperature and T_{amb} is the ambient temperature. The mean value of the efficiency is estimated at 0.75, which corresponds to measurements already carried out on mechanical double-flow ventilation systems [1]. For ambient conditions of 21°C and 50% of relative humidity and exterior conditions of 5°C and 80%, the supply air temperature is 17.4°C. The evolution of the air characteristics is represented on figure 2.

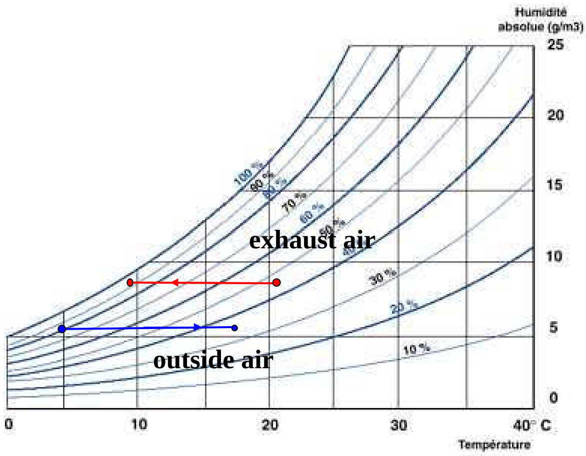

Figure 2. Evolutions in outside air preheating on the psychometrics diagram

Direct ventilation, free cooling

During hotter seasons, the building can be ventilated directly. The dampers of the ventilation box enable the outside air to by-pass the recovery exchanger. The fan slightly increases the temperature of the air (0.4°C in equation 2). Depending on the temperature levels inside and outside, this operation mode can lead to a direct refreshment of the building (free cooling).

$$T_{sa} = T_{amb} + 0{,}4 \qquad (2)$$

Indirect adiabatic evaporative cooling

In summer, when the inside temperature goes over 22-23 °C and the outside temperature is even higher, the double-flow system can work as a cooler. Exhaust air is adiabatically cooled through the humidifier following a wet-bulb isotherm. The temperature of the exhaust air decreases by around 6°C. Then in the static exchanger the outside air is refreshed by the humidified and cooled exhaust air. The evolution of the characteristics of the supply air and the exhaust air are represented on figure 3.

The value of the humidifier's efficiency ε_h is estimated at 0.9 and the lost water flow is around 15% of the evaporated water in the air flow. These values correspond to mean values measured on this type of systems [1]. The characteristics of the outside and exhaust air are given by equations 3, 4 and 5.

$$\varepsilon_h = \frac{(\omega_{hea} - \omega_{in})}{(\omega_{sat} - \omega_{in})} = 0{,}9 \qquad (3)$$

$$T_{wb,in} = T_{wb,sat} = T_{wb,hea} \qquad (4)$$

$$T_{sa} = T_{amb} + \varepsilon \times (T_{hea} - T_{amb}) + 0{,}4 \qquad (5)$$

hea, wb and sat in subscript mean respectively humid exhaust air, wet bulb and saturation. For example, if the inside temperature is 25°C and the outside temperature 30°C, the humidified air temperature is 19°C and the supply air temperature is 22.2°C.

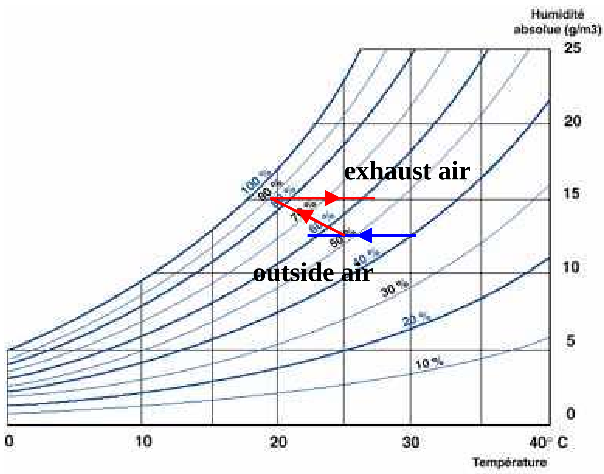

Figure 3. Evolutions in indirect evaporative cooling on the psychometrics diagram

BURIED-PIPE VENTILATION SYSTEM

Description of the system

The buried-pipe system enables air preheating in winter and also air cooling in summer. It is connected to a blowing network similar to the one used in a double-flow ventilation system. The exhaust air is extracted from the technical premises by several air outlets linked to a fan of a simple-flow mechanical ventilation system.

The buried pipes are in polyethylene. Their diameter is 184 mm and their thickness 5 mm. They are placed in parallel and between 1.8 and 2 m deep. The distance between the tubes is around 2.5 m. The air flow per pipe is 240 m^3/h. The length of the tubes is 50 m with a slope of around 2% in order to evacuate the possible condensates. The air inlet is raised at 1 meter over the ground and is equipped with an anti-rain system and a grate fine enough to prevent dead leaves, rodents and insects from entering.

A direct inlet in the blowing network by-passes the buried-pipe system depending on the inside and outside temperatures. The ventilation box is composed of two dampers (Figure 4). The regulation system enables a continuous functioning of the buried-pipe system all year round (Table 2). In winter when the ambient temperature is lower than the ground temperature, the buried-pipe system preheats the outside air. During the in-between seasons when the ambient temperature is higher than the ground temperature, the buried-pipe system is by-passed. The supply air is then directly blown in the premises. This operation mode can also be used in summer to provide direct refreshment (free cooling). When the inside temperature is near 22°C and the ambient temperature is higher than the ground temperature, the buried pipe system is used to cool the outside air efficiently before being blown in the building.

Table 2. Operation modes of the buried-pipe ventilation system

Period	Temperature conditions	Air treatment type
Winter	Tamb ≤ Tground	Outside air preheating using the buried-pipe system
Winter	Tamb > Tground	Direct ventilation
Summer	Tin ≤ 22°C	Direct ventilation
Summer	Tin > 22 °C Tamb ≤ Tground	Direct ventilation
Summer	Tin > 22 °C Tamb > Tground	Refreshment using the buried-pipe system

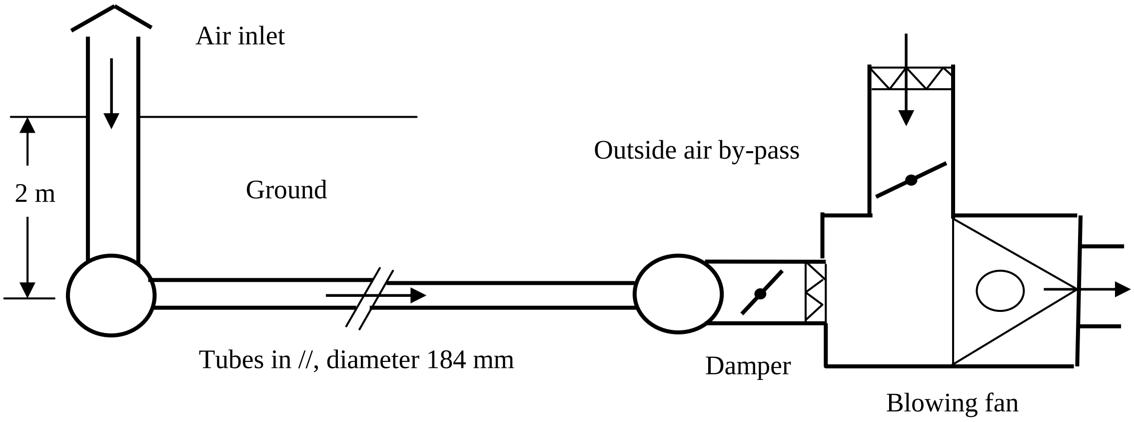

Figure 4. Sketch of the buried-pipe system

Temperatures of supply air

In direct ventilation or free cooling, the supply air temperature is given by equation 2 that takes in account a slight increase in temperature passing through the fan. When the outside air flows in the pipes the air temperature is given by equation 6 that is valid for heating and cooling. The outlet temperature is function of the length of the pipes l and of the overall heat transfer coefficient U between the air and the ground.

$$T_{sa} = T_{ground} + \left| T_{amb} - T_{ground} \right| \times e^{-\frac{Ul}{q_m C_{air}}} + 0{,}4 \quad (6)$$

Where q_m is the air flow rate and C_{air} is the air specific energy. The ground temperature varies in a sinusoidal way [3]. The minimum temperature is in February (10.1°C) and the maximum in September (19.2°C).

BUILDING CHARACTERISTICS AND SIMULATION CONDITIONS

Description of the care home for elderly dependent people

The care home for elderly dependent people has 45 bedrooms and is composed of a building of three levels with the main frontages towards north and south and a second building on one level where are located a reception, two offices, a restaurant, a leisure room and a care room. The building with heavy floors and an interior isolation is considered having average inertia.

The building has 7 bedrooms on the ground floor and 19 on each upper level. Each bedroom has a surface area of 20 m² and is led into by lifts and staircases. The bedrooms are nearly equally distributed between north and south.

The windows are equipped with double glazing argon-filled and with low-emissivity coating (low-e). Overhang shadings and interior Venetian blinds limit direct solar gains. In every zone it is simulated that the Venetian blinds are shut down when the solar radiation is over 500 W/m² and are put up under 400 W/m². The rooms are assumed to be occupied continuously from 21:00 until 7:00 in the morning. The light gain is taken equal to 5 W/m² from 21:00 to 23:00 every evening. During all the heating period, the temperature is maintained at 21°C. Each room includes a bath room, where is placed the ventilation outlet. Ventilation is continuous in the whole building and corresponds to 1350 m^3/h that is 30 m^3 per hour and per room.

The common part of the building (reception, administration and restaurant) communicating with the room part has a surface area of 250 m² and counts three frontages towards north, west and south. This part of the residence is occupied every day of the year from 7:00 to 21:00. The restaurant welcomes 60 persons every day from 8:00 to 9:00, from 12:00 to 14:00 and from 18:30 to 20:30. During the rest of the time the occupants and the staff are supposed to be in the other common rooms. The artificial light gains are 10 W/m² when natural lighting is not sufficient and between 7:00 and 21:00. The two offices are equipped with computers. The common part of the building has a discontinuously occupancy with intermittency of heating and ventilation. Heating and ventilation are cut from 21:00 to 7:00 during the night. During the day, the total ventilation flow is 1080 m^3/h and is produced by a second ventilation set. During the heating season, the daytime set temperature is 21°C.

Electric power of the fans

Table 3 shows the powers of the blowing and extraction fans depending on the type of ventilation. Because of the use of the exchanger and its filters the double-flow ventilation fans have higher powers. Concerning the buried-pipe system, the blowing fan power is the same as for the double-flow system and the extraction fan power is more or less the same as for a simple-flow ventilation system.

Table 3. Electric power of the fans

	Simple flow	**Double flow**	**Buried-pipe**
Bedroom area Qv = 1350 m^3/h			
Blowing fan	-------	600 W	600 W
Extraction fan	350 W	600 W	350 W
Common area Qv = 1080 m^3/h			
Blowing fan	-------	500 W	500 W
Extraction fan	270 W	500 W	270 W

Simulation tool

Thermal zones, wall compositions, glazed surfaces, solar protections, ventilation systems, occupancy and lighting schedules have been defined using the multi-zone model of the transient simulation program TRNSYS [5]. The simulation has been run with an hourly weather data file from Toulouse (south of France). Depending on the ventilation type (simple-flow, double-flow or buried-pipe) different features are compared: the energy consumptions during the heating season, the temperatures in each zone in order to evaluate a number of hours of overheating and eventually the number of hours of functioning per mode (outside air preheating, direct ventilation or free cooling and refreshment).

COMPARISON OF SIMULATED PERFORMANCES

Heating energy consumptions

The simulations run with the climatic data of Toulouse enable to calculate the heating energy consumptions for each system and to evaluate the economy done using outside air preheating compared to a basic simple-flow solution. The energy consumptions are counted separately for the common area and for the bedroom area of the building where the operating is different as far as heating and ventilation are concerned.

Table 4 shows that the two double-flow ventilation systems with heat recovery exchanger are the most performing and enable to save 32626 kWh compared to a simple-flow system. The registered energy economy using a buried-pipe system is 6207 kWh. For outside air preheating, it is to say that the buried-pipe system is of very little interest.

Table 4. Thermal energy consumptions for heating

	Simple flow	**Double flow**	**Buried-pipe**
Bedroom area Energy consumptions in kWh	81949	57919	77311
Common area Energy consumptions in kWh	19965	11369	18396
Total consumptions in kWh	101914	69288	95707

Annual electric energy consumptions of the fans

The values of table 5 show that the double-flow ventilation system with heat-recovery exchanger has the higher electric energy consumption of the fans. Compared to a simple-flow solution, the annual over-consumption of the whole building raises 11180 kWh. In the same conditions, the over-consumption of the buried-pipe system is 7810 kWh.

Table 5. Annual electric energy consumptions

	Simple flow	**Double flow**	**Buried-pipe**
Bedroom area Energy consumptions in kWh	3066	10512	8322
Common area Energy consumptions in kWh	1380	5110	3935
Total consumptions in kWh	4446	15622	12257

Comparison of the operation times per mode

For the bedroom area of the care home and for the double-flow and the buried-pipe ventilation system, table 6 gives the number of hours of functioning per mode: outside air preheating, direct ventilation or free cooling and outside air cooling. This table confirms that in winter, with the chosen operating strategy and the relative temperature levels of the ground and the ambient air, the buried-pipe system is less performing than the double-flow system.

Table 6. Number of hours of operation per mode

	Outside air preheating	**Direct ventilation**	**Cooling**
Double-flow	4585	2702	1473
Buried-pipe	3441	3846	1473

Comparison of the temperature levels during summer

Table 7 shows the number of hours for which the inside temperature is above 27°C for the three studied types of ventilation and for three zones of the building.

Table 7. Number of hours of overheating

	Simple flow	**Double flow**	**Buried-pipe**
Bedroom area			
Zone at the north	314	110	3
Zone at the south	646	316	70
Common area			
Leisure room	607	249	93

A double-flow ventilation system with indirect evaporative cooling enables to divide by 2 or 3 the number of hours of overheating depending on the thermal zone concerned. A buried-pipe is very efficient in summer: the overheating risk in the care home is really limited.

CONCLUSIONS

This simulation study enables to validate that a double-flow ventilation system using a heat recovery exchanger between the exhaust air and the outside air is very performing as far as energy economy is concerned. Nevertheless the fans have to be carefully chosen. These equipments can lead to a subsequent energy over-consumption. A buried-pipe ventilation system has poor performances when preheating outside air. However it seems to be very efficient to cool premises in summer. When lowering the maximum temperatures, the internal summer comfort is improved, which is a critical subject concerning care homes for elderly people.

This work will be implemented by the study of the performances of a buried-pipe system coupled to a double-flow ventilation system. This solution could preheat efficiently the outside air in winter and maintain coolness in summer with no air-conditioning system. It is also seen as a lead to evaluate the performances of this system under other weather conditions and to study in a more precise way the electric energy consumptions of the fans.

The research of French organization CSTB (Scientific and Technical Centre of Buildings) in the area of buried pipes should soon lead to new regulations of dimensioning and implementation to limit sanitary risks around legionella in condensates and radon radiations.

Passive Downdraught Evaporative Cooling, Humidity Control and Water Resources: defining strategies using Traditional Chimney as Case Study in Portugal

Ana Cláudia Martins de Melo and Manuel Correia Guedes

Instituto Superior Técnico, Universidade Técnica de Lisboa, Portugal

Corresponding email: acmmelo@hotmail.com

SUMMARY

Passive Downdraught Evaporative Cooling (PDEC) towers applied indoors produce high rates of humidity (RH) that should be controlled not exceed 70% inside the tower and the room in order to reduce risk for public health and fabric detioration. An experiment using PDEC on an existing fabric in a hot-dry area of Portugal, combined with Computer Fluid Dynamics (CFD) and a Thermal Model (TM) indicated excessive production of RH inside the tower and besides windows, where risk of condensation is higher due to solar radiation from glass. Some recommendations are proposed to reduce the excessive RH production according with fabric constrains in order to prevent from Legionella, condensation, microbiological growth and fabric deterioration, such as treatment of water system and maintenance of the PDEC tower.

INTRODUCTION

PDEC originates from the vernacular architecture of the Middle East [1] and it has been the object of great interest worldwide since 70´s energy crises. Several experiments have been carried out to extend its effectiveness to both outdoors and indoors for uses such as domestic, offices and refurbishments.

The device consists of single or multiple towers equipped with a water/vapor supply placed on the top. During the constant injection of water, droplets descend through the tower and conditions close to saturation along its length. Cool air descends the tower and exits at its base where it is delivered to the adjacent spaces.

The concept is based on the relatively large amount of energy required to convert water from its liquid to gaseous form within a local thermal imbalance with subsequence differences in air density. This leads to the movement of air from a zone of high pressure, where air is hot and less dense (top of the tower) to a zone of lower pressure, where air is colder and denser (bottom of the tower). The physical process occurs when water evaporates within a stream of ambient air without a supply of external heat, resulting in the drop of the Dry Bulb Temperature (DBT), increase of the RH while the Wet Bulb Temperature (WBT) remains approximately constant. The capacity of air to hold vapour is indicated by its DBT and RH. Traditionally, the temperature drops to 2-3 ^{o}C above WBT [2]. This phenomena is the result of the principle of latent heat of vaporization that is the amount of “hidden energy” that is required to convert a unit of mass water from its liquid to its gaseous/vapour phase. The transfer of heat energy from ambient air to water to support the phase change is the process that reduces ambient air temperature. The latent energy required to evaporate more water is supplied by the surrounding air, so the later is cooled.

PDEC is specially useful in hot-dry climates and it has several advantages: it is an adiabatic process because there is no addition or extraction of energy (heat) from the system, therefore, it can be completely passive; it supplies ambient air with moisture raising the RH levels, thus improving the thermal comfort and reducing problems resulting from low RH; it is a quite flexible system that can be easily adapted to new and existing constructions.

Regarding refurbishments, a PDEC shower system was introduced and tested on an existing brick chimney traditionally used for summer ventilation throw “chimney” effect in the southeast of Portugal. This experiment included measurements that indicated RH, T and Air Speed (AS) values inside both PDEC and room. In order to validate and complement data collected from experiment it was created a TM according to building fabric. A CFD model was also created and combined with the TM to evaluate predicted Air Movement (AM), AS, T and RH beside all the room geometry and fabric, including chimney.

METHODS

The chimney object of the case study is located on the first floor of, a small cultural centre from the 19th century located in Moura (38º13N:07º13W). The use of these chimneys was particular successful in obtaining cooling by stack effect.

a)

b)

Figure 1 a) Location of Moura b) photo of the exterior of the chimney

Construction details include internal and external walls 60 cm thick, made from adobe and finished with lime.

The chimney has a cylinder shape measuring 4,8 m in height (measured from the floor of the room) and 0,9 m in diameter. It is located on the first floor adjacent to a room with approximately 19 m² floor area and 63 m³ of volume. The room has tree old wooden doors (two interior and one exterior), and one north-facing window with single glazing and aluminum frame. The chimney walls are in adobe, 0,30 m thick. On the upper limit there are a few openings. There is no lime rendering on it.

An evaporative system project within the chimney was designed according to the experiments made by Givoni and Pearlmutter et al. It included a single shower placed 4,5 m high above floor plan, with coarse water. The water was provided from an existing tap on the exterior that could be easily controllable. The water flow rate was 10,5 l/min.

The measurements took place in the 6th of August, every hour, between 11:30 and 15:30. The room’s exterior and interior atmospheric conditions are registered on row 1 and 2 of Table 1. The drop of temperature and relative humidity registered at 12:30 is due to a breeze.

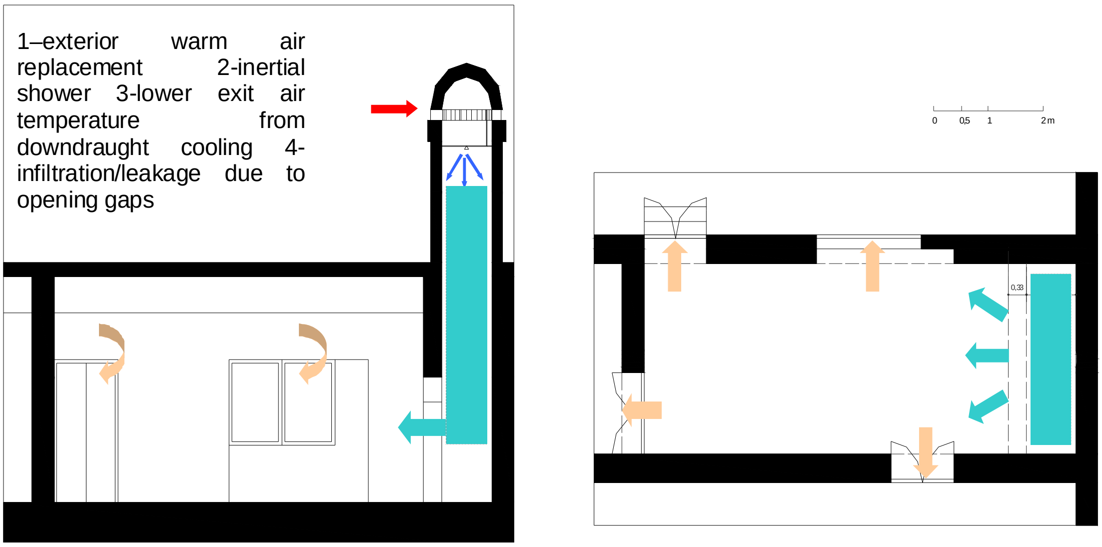

Figure 2: Section and Plan of the chimney and adjacent room (not on scale)

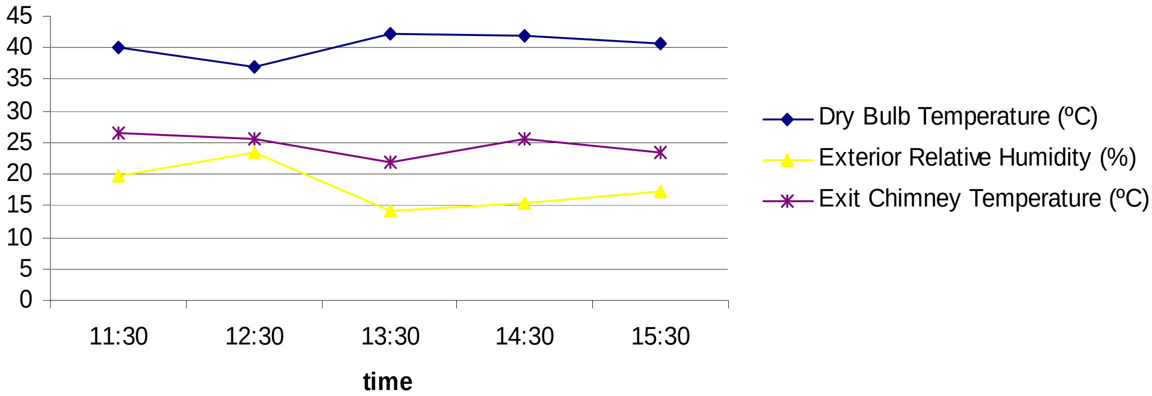
Water did not circulate continuously in order to avoid flood problems and the shower operated for only a few minutes. Also, PDEC configuration ended up being less detailed than initially thought. Testing conditions were not ideal, especially due to the use of course instead of fine spray.

RESULTS

Results show that after the shower system was activated, both exit air temperature and RH were not stable on the measured periods. Temperature ranged from 22 ^{O}C to 26.6.^{O}C and RH from 62 % to 95.5 %. Graphic 1 shows that there is a relation between temperature and RH: a higher humidity corresponds to lower exit air temperature. According to Graphic 2, room conditions after PDEC are very close to saturation, i.e., air cannot hold more moisture. Also, line of enthalpy is not absolutely constant, therefore WBT changes slightly.

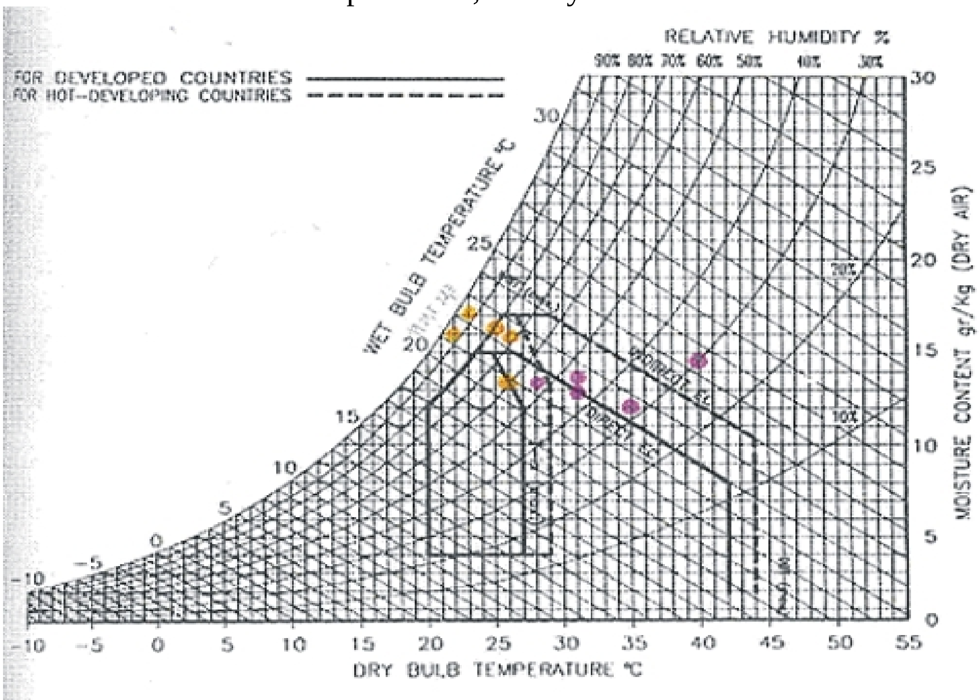
Exterior Temperature, Relative Humidity and Interior Temperature



Graphic1: Measurements

When Moura´s chimney PDEC was activated, it produced very high values of relative humidity (more than 90 %), especially in the first minutes of operation. Such high humidity can lead to surface condensation, creating the risk of mold growth or other moisture problems.

Therefore, temperature depression of the chimney should be controlled so that relative humidity should not exceed 70 % in all zones [3]. It is important to note that although PDEC was activated every hour thus not providing continuous cooling, results are quite similar to those observed on other experiments, namely Givoni´s.



Graphic2: Givoni´s psychometric chart.

Also, water particles did not fully evaporate before reaching the ground. People placed near the chimney could easily get wet from not evaporated water droplets. Evaporation depends upon droplet diameter and length of time water stays within the air stream. Therefore water droplet should be small enough or the distance from the sprays to the openings great enough to guarantee total evaporation. Since height of the shower could not be maximized because cooling source was placed on the top of it, a fine spray mist of water (like filtered micronisers) should have been used instead.

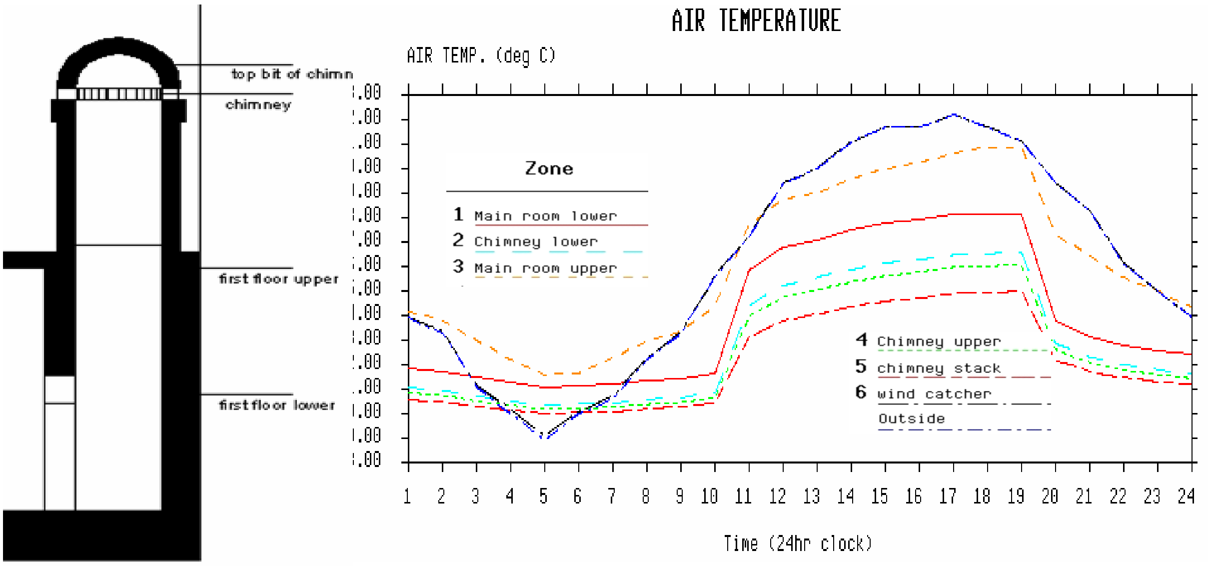
Finally, exit airflow of 0.7 m/s rate was far above than the 0.25 m/s recommended avoiding unpleasant draughts [4].

Since field-testing had several limitations to produce valid data, it seemed important to create a thermal and a dynamical model of the PDEC tower and adjacent rooms to investigate cooling performance of the system. There are few programs that allow a PDEC simulation because there is the need to recognize top-down airflows and driven forces. PDEC are often described as “reverse chimneys” because the column of cool air falls.

However, internal conditions can be reproduced according to an occupancy pattern (number of users of the space/building, heat gains from people, machinery, etc) and physical properties of the construction (envelope, heat losses from envelope, etc) in a thermal model of the PDEC chimney and adjacent room. This model can be combined with a CFD program that analyses how airflow rates from PDEC supply coolness into the adjacent room. CFD does not simulate cooling systems where driven forces and cooled air occur in the same pressure zone, therefore heat transport does not correspond to air movement inside the cooling chimney. The downdraught evaporative cooling should be on the bottom of the tower. A CFD can be very efficient to ensure that exit AS, T and RH are precisely distributed within a space. This is especially important to identify eventual stagnant zones where air does not flow.

THERMAL AND COMPUTER FLUID DYNAMICS (CFD) MODEL

TAS 8.4 was used to create a TM model.



Graphic 3: TAS output data.

AMBIENS is a CFD two dimensional Cartesian grid system, in which a transversal “slice” 1m tick including exit air from chimney, was modeled. The grid represents the computational cells that will be the basis of the simulation. Building elements were not placed reproducing reality thus maximizing output information to better understand indoors thermal comfort. Therefore window and outlets (corresponding to doors gaps) are placed in the same plan, although this does not happen in any 1m slice.

Features represented are:

a) one window b) one cooling source (air inlet) c)two door gaps (air inlet and air outlet)

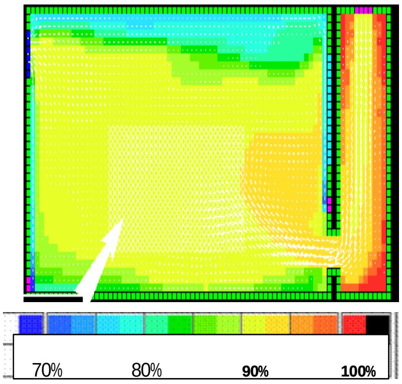
Note that inlet air volume should equal outlet air volume.

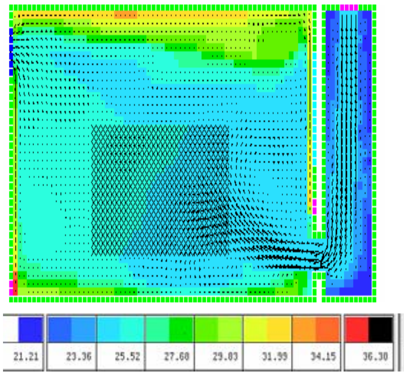
Definitions of modeling included:

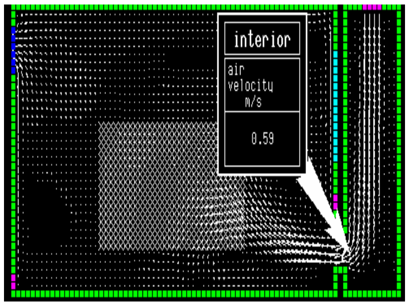
a) each pixel is equivalent to 0.1m height or width and 0.1 m² area b) 4 pixels for each opening, equivalent to 0.41 m² assuming 2.5 m² in reality

Input data for modeling included:

a) 63 m³ of room volume b) 2 ACH of infiltration, equivalent to 0.035 m³/s of Airflow Rate in the whole room, therefore 5.83 x 10 -3 m³/s in the “slice” c) air speed of 1 pixel equivalent to 0.0075m/s at 0.6m/s or 8 pixels at 0.3m/s i.e., “slice” volume divided by area of each pixel d) 0.6m/s definition of exit air speed, either 4 pixels







Interior: air velocity 0.59 m/s

Figure 3 : Relative Humidity

Figure 4 : Temperature

Figure 5 : Air Speed

Temperature surface (obtained from TAS thermal model) included: roof - 34^{o}; floor - 31^{o}C; walls - 32^{o}C ; window - 40^{o}C.

DISCUSSION

According to AMBIENS model, there is an excessive production of humidity inside the chimney (between 90% and 100%). Junctions of chimney walls and ground are especially affected and water particles that did not fully evaporate before reaching the ground can warmer situation on the bottom PDEC tower. Air beside a window has a higher RH than the rest of the room, excluding the chimney since its surface has a higher temperature. (Figure 3). Here risk of condensation is higher. However, air is distributed in a very satisfactory way within the room, and door gaps are important to help extract "old" air.

Exit air openings can play an important role defining water flow rate. Results suggest that a system with a flexible size opening could be used to deliver the exact amount of cooling required, although this is not practical. Results also show that even though thermal comfort benefits from reducing on exit air speed, increase of temperature penalizes it. By reducing the water flow rate by 2.5l/min, exit air temperature will increase 1^{o}C.

Regarding ventilation supply, the system is efficient since 25 people require approximately 13 ACH (assuming 8l per person per second), and the system can supply 38 ACH.

Simulation data suggests that humidity produced inside traditional chimney PDEC can represent a problem to public health and building maintenance:

- Risk of diseases (such as pneumonia) associated with production of Legionella;
- Condensation produced inside the tower will create corrosion and fabric deterioration;
- Risk of sedimentation/deposition of solids (organic and inorganic) in tower surfaces.

Therefore some recommendations can be made according to limitations of the building fabric, namely architecture form:

- Placement of an exhaust (like a fan) on the opposite side of the of the PDEC tower to extract "old" air thus renewing the air and creating a replacement cycle;
- Placement of an microbial bio film on all tower surfaces in contact with water, since these films can consume certain inhibitors and prevent access of inhibitors [5];
- Water particles that did not fully evaporate before reaching the bottom of the tower should not be induced again to feed the PDEC system before being previously filtered and heated to a temperature above 55ºC to inhibited microbiological growth . Then, water temperature should be lowered and then induced in the system again;

- All pipe system and water reservoirs (such as to collect particles that did not fully evaporate before reaching the ground) should be in copper since it is inhibitory to support the growth of Legionella and other bacteria [6];
- Water should be previously treated before feed PDEC system. It is suggested disinfectants such as chlorine and bromide or ultra-violet light. Sea water could also be used since surviving of Legionella is limited by both salinity and warmer temperature [6];
- Pipe installation should avoid any contact between main and PDEC water supply system to avoid contact between different types of water and filtration;
- Maintenance and cleaning of the PDEC system should be at least twice a year;

However PDEC is a specific technique can help reducing the impact of global warming thus providing thermal comfort in building and occupants.

In *2004 the* annual temperature of Portugal increased 0.6 ºC[7] and *recent studies predict* that the *dry condition will affect 1/3 of the Portuguese territory* [8]. The spectrum of buildings and urban areas that can use these techniques is wide enough: it can be applied both in indoors and outdoors, new buildings and refurbishments, all scales and type of buildings with architectural expression according to the occupants and buildings aesthetical form. The benefits affect several areas:

- Indoors temperature can reach 24 – 30 Cº, and HR 40-70 %, when outdoors conditions can reach 40-45 Cº and 15-20 % RH whenever EC systems are applied. It can improve occupant's thermal comfort, allowing the use of natural elements such as ventilation;
- PDEC techniques can help reaching Kyoto Protocol objectives that in Portugal should be reduction in 27% the emission of pollutants in the period 2008-2012 [9]. In Portugal, in the period 1990-2003 the residential and commercial sectors registered an increase of 100% of emission of polluents into atmosphere mainly due AVAC systems[10]. Measures promoted by European Community and Portuguese governments obliged the use of renewable energies in all sectors, including buildings [11].
- In PDEC, all white waters can be recycled and re-used. Typically a shower consumes 20-40 litters and a bath 50-100 liters [12]. To provide a cooling power of 3 Kw, a PDEC system can consume 40 litters of water a day that represents a small percentage of residual domestic water [13]. The Department of Water Resources recommends the recycling of residual waters in semi-arid or arid in the world, especially from domestic sources. In Israel, it represents 70% [14] of total residual water. In Portugal, residential is the second sector that consumes more water (8%) and the majority of it goes to flush toilets, showers and baths, with an efficiency of only 58%[14].
- Compared to conventional air-conditioning systems, evaporative cooling techniques can represent a significant reduction of energy consumption and money savings. The European Programme Energy Manage promoted the application of an evaporative cooling system in an office building in Malta. It was proved that it reduced energy consumption in 48% and CO_2 emissions in 28 152 kg compared with a building that used electrical cooling. It represented money savings of £ 3·080/year [15].

PDEC should always be considered as a part of a cooling strategy that may include high thermal mass or proper shading. These techniques may be high or low tech, according to the cooling power required in the building/outdoor area or the capital costs involved in the construction/maintenance of the system. Quality of the water piping system and treatment of deposited water can be considered the higher financial investment in PDEC solutions.

SUMMARY

The underground pipe system (UPS) cools the intake outdoor air through the underground pipe before supplying it to the indoor space, so that the cooling load of the air-conditioning system of the building can be obviously reduced. In this paper, a quasi-three-dimensional heat transfer model was developed, which was made up with a two-dimensional unsteady heat transfer model of earth and a one-dimensional fluid model of air. The total heat transfer process was considered when the condensation happened on the pipe wall during the calculation. Moreover the model was validated by the comparison between simulated result and measured data of a built project applied UPS. By means of this model, the earth-to-air heat exchanging process was simulated and the effect of the pipe parameters, such as the length， depth of burial and ventilation velocity of underground pipe system, on the cooling/heating capability was analyzed. The simulated result was also used to direct the design, operation and management of the UPS.

INTRODUCTION

Underground Pipe System (UPS) utilizes the energy accumulating in the soil to cool or heat outdoor air, and then supplies it into rooms. The system can ameliorate indoor environment and save energy. Moreover its air-conditioning efficiency is limited by outdoor climate, structure of underground pipe, operating schema, etc. Therefore the mathematic model which can be used to simulate the earth-air heat exchange process accurately is a very important tool for engineering design.

In most studies of the earth-air heat transfer models, the models can be separated into two kinds: one is steady models; the other is unsteady model. A steady model based on the assumption of constant heat flux and half-infinite object heat transfer was simple and fit for engineering design [1]. Another steady model utilized the empirical equation which was regressed by the measurement data [2]. The unsteady model includes regression model, finite difference model and finite element model. Some researchers introduced the finite difference model to solve the 3-dimension unsteady sensible heat transfer process, and analyzed the influencing factors of operating effect [3][4]. Furthermore, a 3-dimension finite-element model, which can judge whether moisture will condense on the wall of UPS, was developed to depose the simulation of total heat transfer process while the air went through the underground pipe [5].

In this field great progress has been made, however the present models still don’t satisfy the requirements. The steady models mentioned above can’t predict the temperature variation during the operation of UPS. The 3-demintional models required a lot of computations, so it was hard to accomplish annual simulation of UPS due to the complex computations. There is still dearth of accuracy, general and swift computation model to direct the design of UPS projects.

In this paper, a quasi-three-dimensional heat transfer model was developed, which was made up with a two-dimensional unsteady heat transfer model of earth and a one-dimensional fluid model of air. By means of this model, the effect of the pipe parameters, such as the length, depth of burial and ventilation velocity of underground pipe system, on the cooling/heating capability was analyzed. The simulated result can also be used to help the designers to determine the structure and the operation scheme of the UPS.

METHODS

2.1 Numerical simulation model

The heat & mass exchanging process can be predicted by a quasi-three-dimensional model, which assumes that heat transfer of soil along the direction of pipe can be ignored. For the z basic calculate surface in Figure 1, energy balance equation of soil and air are respectively presented as:

$$\frac{\partial t_{soil}}{\partial \tau} = a\left(\frac{\partial^2 t_{soil}}{\partial x^2} + \frac{\partial^2 t_{soil}}{\partial y^2}\right) \qquad (1)$$

and

$$V \rho_{air} \frac{\partial i_{air,z}}{\partial \tau} = G \cdot (i_{air,z-1} - i_{air,z}) + dQ \qquad (2)$$

where t_{soil} is temperature of soil(˚C), τ is time(s), a is thermal diffusivity(m^2/s), V is volume of air for a basic grid(m^3), $i_{air,z}$ is air enthalpy of computational unit in Z coordinate axis(kJ/kg), ρ_{air} is density of air(kg/m^3), G is fresh air volume(m^3/s), and dQ is heat transfer quantity between air and earth(W).

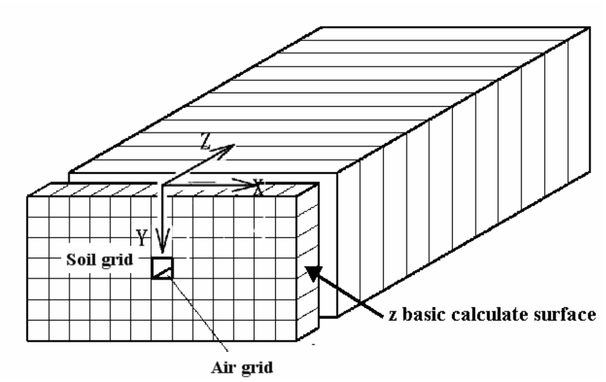

Figure 1. Grid division for numerical simulation

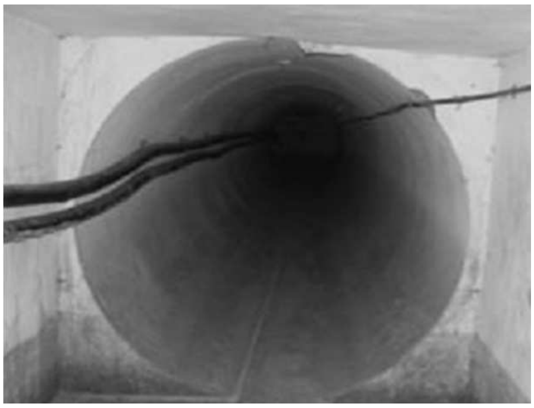

Figure 2. Cross-section of the UPS

Because latent heat exchange may exist between air and earth, dQ can be calculated by Eq.(3) for only sensible heat exchange or by Eq.(4) for total heat exchange.

$$\begin{aligned} dQ &= \sum_{j=1}^{J} hF_{Z,j}(t_{b,Z,j} - t_{k,Z}) \\ &= \sum_{j=1}^{J} hF_{Z,j}(t_{b,Z,j} - i_{k,Z} + 2500 \cdot d_{k,Z}) \end{aligned} \qquad (3)$$

$$dQ = \sum_{j=1}^{J} h' F_{Z,j} (i_{b,Z,j} - i_{k,Z}) \qquad (4)$$

where j is No.j earth-to-air heat transfer surface, h is convective heat transfer coefficient (w/(m^2.˚C)), h' is convective mass transfer coefficient (kg/(m^2.s)), $F_{Z,j}$ is area of earth-to-air heat transfer surface of computational unit Z (m^2), $t_{b,z,j}$ is surface temperature of the pipe of No,j surface, $t_{k,Z}$ is air temperature in the pipe of computational unit Z, $i_{k,Z}$ is saturated enthalpy corresponding to temperature of pipe wall(kJ/kg), $d_{k,Z}$ is absolute humidity of air (kg/kg). Finite difference method is applied to solve the problem, and temperature and humidity of air extracted from the UPS can be achieved.

2.2 Experimental Measurement of a UPS

To validate the availability of numerical calculation model, the airflow velocity, inlet and outlet air temperature and humidity of a UPS was measured. The experimental result would be compared with the simulation result.

The Building applied UPS system is in Beijing. The shape of cross-section of the UPS is shown in Figure.2. Table.1 reveals the main parameters of the system. The experiment time was from Jul.15th, 2002 to Aug.18th, 2002. The system operated from 7:00am to 19:00pm everyday.

Table 1. Parameters of an UPS in a college in Beijing

Length	Diameter	Material of pipe wall	Burial depth	Mean annual temperature of soil surface
250m	1.4m	Steel concrete	3m	13.1 ˚C

2.3 Effect of factors of UPS

Based the heat transfer model, the effect of different parameters, such as length, burial depth, airflow velocity and operating mode of UPS, on air-conditioning performance was investigated. The outdoor air temperature and humidify data from Jul.7th, 2002 to Jul.9th, 2002 were selected as computational conditions (Figure.3). The cross-section size of pipe is 1m×1m. In the system, only one pipe was buried under the ground.

RESULTS

3.1 Measurement result of UPS

The airflow velocity and temperature in the outlet of the UPS was measured. When the system was running, the wind speed maintained at about 3 m/s (Figure.4). Figure.5 shows the comparison between the measured outlet temperature and the simulated temperature; the outdoor temperature is also presented in the figure. From Jul. 17th to Jul. 29th, the measured data accorded with the simulated data on the whole. The average temperature which was measured in the outlet was 20.3˚C; and the computed temperature was 20.6˚C, which was 0.3˚C higher than the measured data.

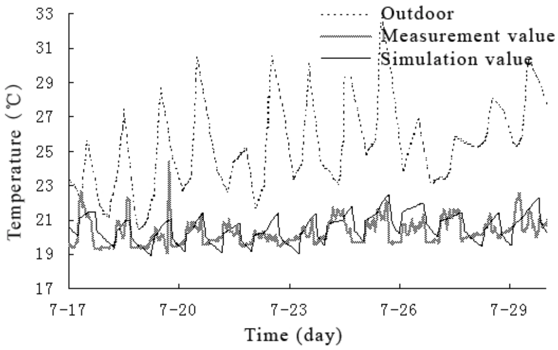

Figure 5. Measured and simulated air temperature

3.2 Influence of UPS parameters on the operating effects

3.2.1 Length of UPS

As the calculated examples, the depth of burial of pipe was 3.5m; the air velocity was 3m/s, the length was 50m, 100m, 200m and 300m respectively. The outlet air temperature, desiccation and cooling capacity are shown in Figure.6. When the length increased, the outlet temperature decreased; and the desiccant and cooling capacity rose. The amplitude of temperature fell after the outdoor air went through the system. The outdoor air can be cooled down below 26˚C by a 50m long pipe, and below 22˚C by a 300m long pipe (Figure.6a). For example, the maximal desiccant capacity of a 300m long pipe was 2~3g/kg (Figure.6b); its maximal cooling capacity reached 30~40kw (Figure.6c); and its average daily cooling duty was 340kWh (Figure.6d).

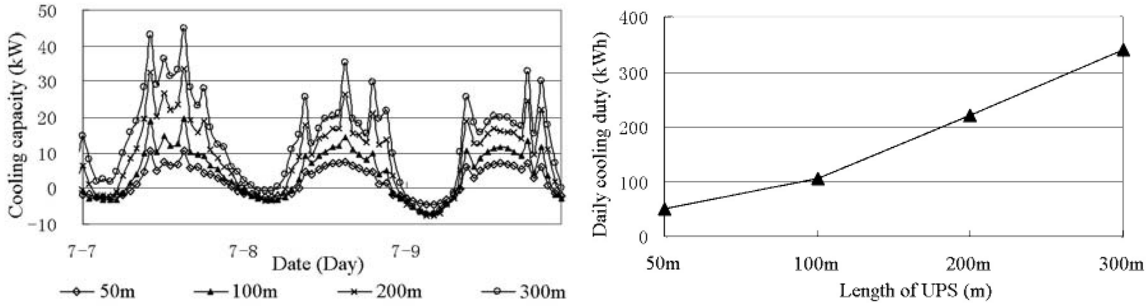
b. Desiccant capacity of UPS

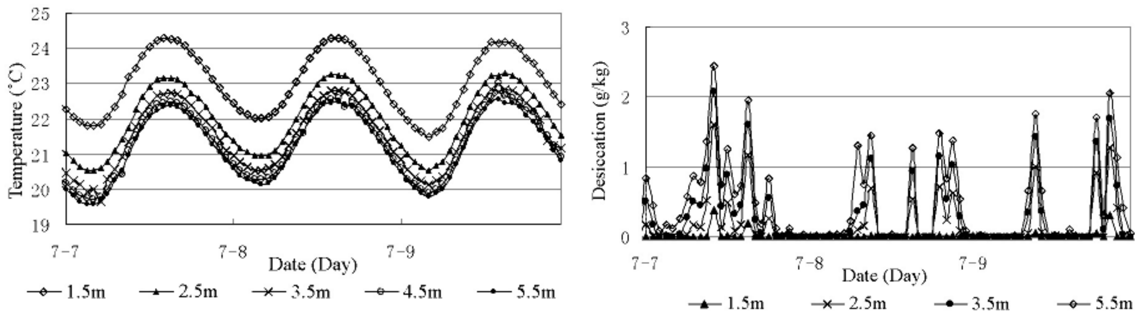


c. Cooling capacity of UPS d. Average daily cooling duty of UPS

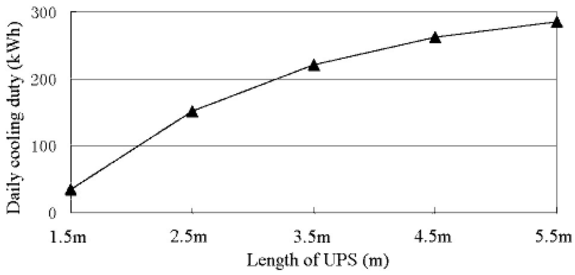
Figure 6. Influence of different length of UPS

3.2.2 Burial depth of UPS

In the simulation, the length of pipe was 200m; airflow velocity in the pipe was 3.5m/s; burial depth was 2.5m, 3.5m, 4.5m, 5.5m respectively. Figure.7 shows the variation of outlet air temperature, desiccant capacity and average daily cooling duty of the UPS.



a. Outlet air temperature of UPS b. Desiccant capacity of UPS



c. Average daily cooling duty of UPS

Figure 7. Influence of different depth of UPS

3.2.3 Airflow velocity of UPS

The simulated UPS was 200m long, 3.5m deep from the ground. The airflow velocity in the pipe was 1m/s, 3m/s, 5m/s and 7m/s respectively. The lower the velocity was, the lower the outlet air temperature was (Figure.8-a), the higher the desiccant capacity was (Figure.8-b), and the smaller the average daily cooling duty was (Figure.8-c). When the wind speed was 1m/s, the outlet air temperature was in the range of 18~21˚C. And the maximal desiccant capacity can reach 4g/kg.

3.2.4 Operating mode of UPS

In this case, the length of pipe was 200m; the burial depth was 3.5m; the airflow velocity was 3m/s. The system was operated in the two different modes: One was running continuously, the other was only operated at 8:00~18:00 daily. The outlet air temperature and cooling capacity are shown in Figure.9.

DISCUSSION

In this study, a heat transfer model was developed to predict the operating effects of UPS. The influence of UPS parameters on outlet air temperature, desiccant and cooling capacities and average daily cooling duty was investigated.

4.1 Length of UPS

The simulated data indicated that the underground pipe system (UPS) can dehumidify outdoor air in summer, if the system is long enough. When moisture is removed from air, the heat transfer capability between air and pipe wall is enhanced. In this paper, while the length of UPS was greater than 100m, the air intake can be cooled below its dew-point temperature; and then heat transfer process was stronger due to desiccant capacity of the pipe. The average daily cooling duty increased by 12kWh as the length of pipe was lengthened by 10m. Beside these, while the length was less than 100m, the system had less dehumidification capability and less cooling effect than longer system; an increment of 10kWh in the average daily cooling duty associated with a 10m increase in length.

4.2 Burial depth of UPS

As a result of our simulation, when the burial depth was 1.5m, the UPS had little dehumidification capability; the moisture content of air change little while it went through the pipe. When the burial depth increased to 2.5m, the desiccant and cooling capacity rose significantly. However the cooling capability increased slowly as the burial depth was deeper than 3.5m. As the deeper the burial depth was, the more expensive the project cost was; it is likely that the optimum burial depth of UPS was 3~4m.

4.3 Airflow velocity of UPS

The average daily cooling duty increased as the airflow velocity increased, because the coefficient of heat transfer of pipe was positively proportional to the velocity 0.8-power. The increment of velocity led to the growth of the cooling capacity. Moreover while the velocity increased, the outlet air temperature rose; and the desiccant capacity decreased. It is because heat exchange increased slower than the flow rate of air, as the velocity increased the unit mass heat transfer of the air decreased; the air temperature in the pipe increased. So the latent heat exchange part is shortened, and the unit mass desiccant capacity decreased. Accordingly, if the airflow velocity is low in UPS, the system has lower cooling capacity and application effect. In contrast if the velocity is too high, the outlet air temperature and humidity is excessively high; thus the supplied air has little air-conditioning effect. For the UPS with specific length, there should be an optimal range of the airflow velocity in which the system operate effectively and economically. This optimal velocity would rise when the length of the pipe increase.

4.4 Operating mode of UPS

When the UPS ran in the intermittent mode, the outlet air temperature was 1˚C lower than that in the continuous mode. Because the quantity of heat absorbed by the pipe wall in the daytime can be transfer to the deep soil when the system stopped operating at night, the temperature of the wall was lower. Thus the cooling capacity of system rose by 40 percent in the intermittent mode relative to that in the continuous mode. Therefore the rationalized design can improve the cooling capacity of the system effectively.

This paper only used the pipes with some specific size as the calculated examples to obtain the results. If the pipe parameters are changed, the quantitative results should be varied. But the qualitative conclusions presented in the paper are still available.

CONCLUSIONS

Based on the experimental investigations and numerical simulations presented in this paper, the following conclusions may be made:

a) The quasi-three-dimensional heat transfer model was developed to predict the heat and mass transfer process between air and soil. It was verified by experimental measurement and can be used to direct the design, operation and management of the UPS.

b) The cooling capacity and the length of UPS were positively related. The increment of cooling capacity of longer pipe was greater than that of short pipe, when the length increase by the same distance.

c) The deeper the burial depth was, the higher the cooling capacity was. However the cooling capability increased slowly as the burial depth was deeper than 3.5m. It appeared that the optimum burial depth of UPS was 3~4m.

d) While the airflow velocity rose, the quality of heat exchange increased; the outlet air temperature and humidity went up also. A UPS with specific length should have an optimal velocity at which the cooling effect and economical efficiency can be performed. The optimal velocity was positively related with the length of system.

e) In the intermittent operating mode, the cooling capacity was increased by 40% than that in the continuous operating mode.

In the development of the paper we considered that the comprehensive analysis of the factors investigated hereinbefore should be presented to discover the interrelationship among these factors. To study the economical efficiency of UPS is also among our future research goals.
