Figure 7 Eurovent-Certification database: example of data for certified air conditioners of capacity less than 12 kW in 1996

The auditor should find less barriers as possible during the procedure: the TG 8 “How manufacturers could help the unfortunate energy auditor”, intended to manufacturers, explains how a component can be used as measuring device is an inexpensive way just adding measurement points in catalogues and how they can help audit improving the documentation of the equipment and their nomenclature. TG 10 and the AUDIBAC tool can one more time support the decision of the auditor to investigate some opportunities on the base of the previous successful case study presented in the database.

ECONOMICS OF RENOVATION AND INSPECTION

When does decision take place? Saving running costs, reliability, what are the decision factors? How to give an energy efficiency orientation to the renovation of AC? The new factor is the EU inspection: the ways to implement it have been investigated. How to integrate it in the life cycle of a plant? TG 9 “How to integrate Energy Efficiency and AC inspection with full benefit in the structures in place” explores the relations between the AC actors and defines the different interests and how to combine it in the effort for the energy efficiency. The aspects of certification and training of inspectors are faced, showing the possibilities in some country. Discussion about inspection has be animated also grace to the estimation of the energy and economic saving of the inspection implementation in main EU AC market countries: figures for an engineer and a craftsman inspection has been presented in many international meeting arousing a new discussions and interest.

DISSEMINATION ACTIVITIES

All along the project the group developed dissemination activities at international and national level. On one hand we combine internal workshops with open national dissemination meeting with professionals of the host country: this allowed us to meet national problems and situations peculiar for each country and to add on the view point of the professional (installers, manufacturers, operators etc). This allowed also to have a more clear idea of the

level of dissemination of the new inspection and certification measures in countries were the measures are not yet applied (no country implemented the AC inspection measures in the 2006, all asked for three years of delay).
On the other hand the group met an international public participating actively to international events and conferences, promoting results and tools all along their development (AICARR congress 2006, ICEEB 06, Klimaforum'06 etc.).
All the presented papers and posters are available on the AuditAC project web site and can be freely downloaded. The group was in charge to deliver also periodically a newsletter (6 in total all along the project) about the development of the project and about the Directive implementation, author outside the project has been invited to cooperate and intervene about EPBD or other EU project EPBD related. Each country was responsible to create a contact list and deliver the newsletter to the national list.

CONCLUSIONS

AuditAC was part of the IEE projects to support the EPBD implementation and success. The objectives more than support the inspection were to develop the audit procedures for the AC, due to the lack of methodologies and tools. On one hand several tools and actions has been prepared to reduce the barriers to the audit promoting successful Case studies of AC audit and disseminating the contents of the audit procedures in order to motivate the owners and manager to face the investment for the AC renovation for energy efficiency. Moreover, a series of tool wants to help the auditor into the procedure to make shorter and efficient the procedure. Deliverables in form of document (Technical guides for owner and auditors), programmes (Tools), disseminating tools (Training Package). The material is freely downloadable on the project site that will be kept operative for two more years after the end of the project (December 2006).

Taking flexibility into account in designing beam systems

Risto Kosonen and Maija Virta

Halton Oy, Finland

Corresponding email: risto.kosonen@halton.com

SUMMARY

In a modern office environment, balance is sought between working as individuals and the interaction between employees. It must be possible to appropriately combine various work methods, which means that partition walls and workstations should be flexibly adaptable, in order to best match the business model of each customer. The adaptability of office space is one of the central premises in designing a beam system. The systems must adapt to changed loads and partition wall locations. For a room system, adaptability means taking changes in the supply air flow, cooling effect and throw pattern of the supply air device into consideration. It must be possible to adjust the air flow supplied by the room device, which enables managing the maximum and average velocity in the occupied zone and thus reducing the risk of a draught.

INTRODUCTION

Recent studies have clearly proven the correlation between indoor air quality and the work performance of employees [1, 2]. Similarly, it has been demonstrated that the thermal conditions of the room have a significant impact on the productivity of work [3, 4]. Employee salaries and the potential change in productivity amount to many times the cost of a building technology system. The studies indicate that an investment in a better indoor environment is a profitable one, even with very minor productivity changes [5].

In addition to the indoor environment, the functionality of the workspace significantly affects the productivity of employees. Often a compromise must be made among the needs of the employee, team and organisation when arranging workspaces. Addressing the interaction and privacy needs of employees, both of which are important considerations in organisations, is particularly challenging. In general, it can be stated that, from the perspective of dispersing silent information (views, experiences, intuitions), fully autonomous workspaces do not support the business models of most companies. On the other hand, reducing the autonomy afforded by individual workspaces reduces acoustic privacy, which disturbs concentration.

Organisational changes in most companies are continuous and require flexible changes in work methods and workspaces. The traditional one-person office areas, or cells, and open offices, or hives, seen in traditional offices are today changing into spaces that are more suited to team work, referred to as dens or clubs (Table 1) [6]. In addition to this, information technology contributes to independence of time and location, transforming offices more into meeting places for sharing information. The office space must be utilised efficiently, and therefore a dedicated workstation is no longer deemed necessary for a worker who spends only a few hours a day at the office. Working at several workstations and at customer sites is becoming more common.

Table 1. Adapting space types and business processes in office buildings.

Space	Interaction	Autonomy	Operation	Example
Hive	low	low	customer service	call centre
Cell	low	high	support tasks	financial administration
Den	high	low	team work	media
Club	high	high	expert work	consultancy

The supply air flow required in office buildings is relatively low (1.5–2 l/s per m^2), with the exception of meeting rooms and similar spaces. On the other hand, cooling (50–70 W/m^2) is required for attaining a good indoor environment. A beam system offers the possibility of achieving the above objectives within economical life-cycle cost limits. Therefore, the beam system has become the most common system in office buildings. It should be borne in mind that the various systems should be applied according to the requirements in each space. For example, variable air systems should be selected for meeting rooms and displacement ventilation for auditoriums and common spaces. Thus can an optimal overall solution be obtained with respect to expenses, energy use and environmental impact [7].

This paper discusses the flexibility requirements imposed by changing office processes for a beam system and covers certain solution models that help to improve the adaptability and flexibility of the system as well as the indoor conditions in the room.

FLEXIBILITY IN A BEAM SYSTEM

In Scandinavian design, ventilation beams are typically installed without a suspended ceiling in the room space, in the longitudinal direction. The basis for the system is the column spacing (e.g., 8.1 m), which can accommodate three one-person office rooms or two larger rooms (Fig. 1). This is possible because the beam is located at the side of the room instead of in the middle of the room module.

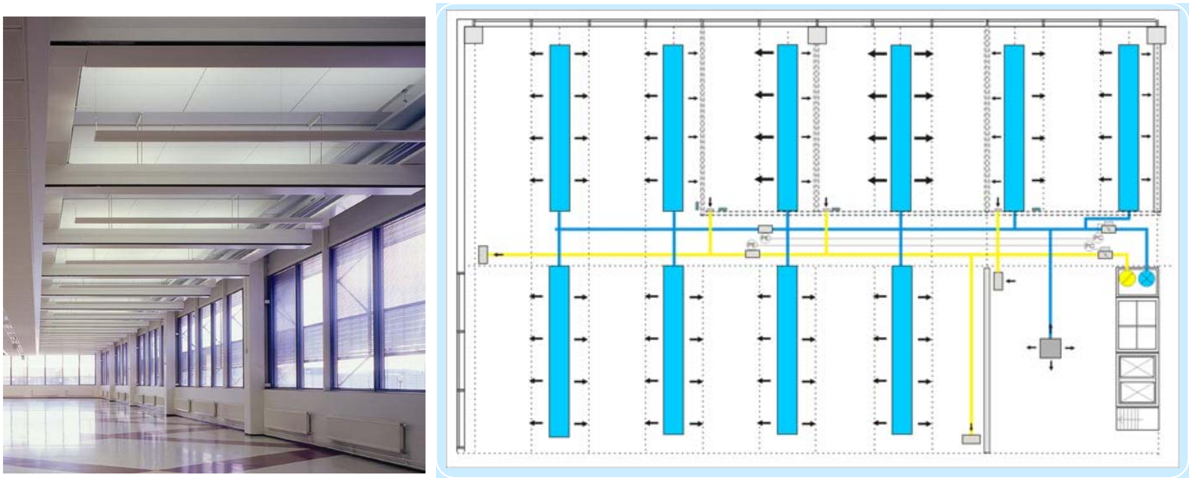

Figure 1. Typical Scandinavian office building module division.

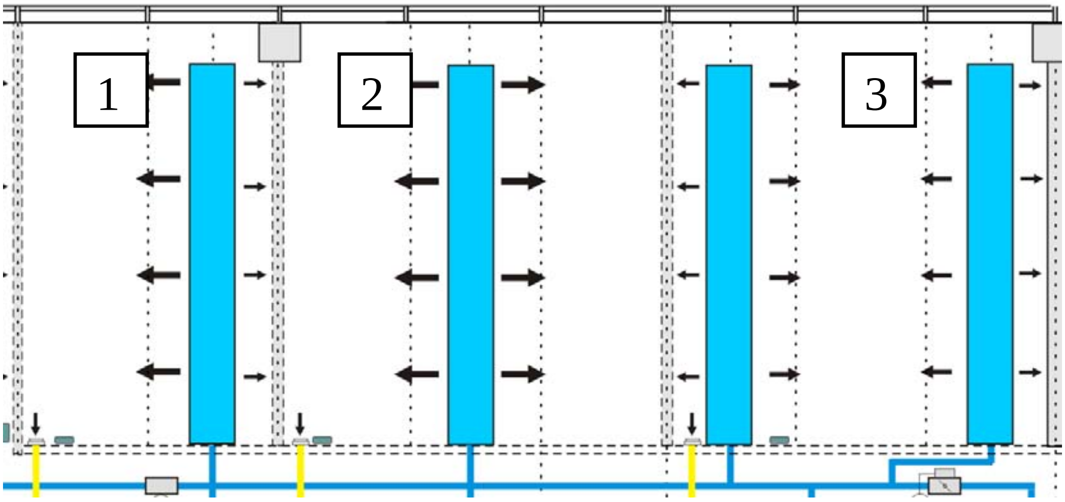
The ventilation ductwork should be designed for constant pressure, which enables demand-based air flow control in meeting rooms. Pressure adjustment is implemented per zone or by individual ventilation device. It should be taken into consideration in the management of air flows in a meeting room that the pressure level in a beam system is 60–

100 Pa and the pressure level of a typical variable air system (MIV) is considerably higher than this. The variable air unit installed in the system must operate at the pressure level of the beams.

When the location of partition walls changes, the size of the room space and the supply air flow of the room device change as well. The typical office module division can result in three different cases: 1) one room device produces supply air for one room module, 2) it does so for 1.5 room modules, or 3) two room devices provide the required supply air flow for 1.5 room modules (Fig. 2). For maintaining a constant supply air flow (2 l/s per m^2), an adjustment range of 15–30 l/s is required of the room device. This range increases to 15–40 l/s if it must be possible to convert a one-person office room into a meeting room.



Room / Beam	Space Type	Primary airflow rate			
		Nozzles	HAQ	Total	
1 /	Office	15 l/s	5 l/s	20 l/s	2 l/s,m2
2 /	Office	15 l/s	15 l/s	30 l/s	2 l/s,m2
3 / Unit A	Office	15 l/s	0 l/s	15 l/s	2 l/s,m2
3/ Unit B	Office	15 l/s	0 l/s	15 l/s	2 l/s,m2
3 / Units A &B	Meeting room	15 l/s	0...45 l/s	15...60 l/s	6 l/s,m2

Figure 2. Impact of room module division on the office and meeting room air flow.

Ready adaptability of air flow and space arrangements also increases the need to manage air distribution such that it reflects the various space solutions. It must be possible to reduce the total air flow from a beam in situations where, for example, the room device is close to a partition wall and the distance of the workstation from the wall is short (Figure 2: room module 1). It should also be noted that, owing to individual differences between people, some people perceive even low air velocities as a draught. This means an increased need to manage the individual room conditions.

It is important to remember that the majority (70–80%) of the air flow distributed to the room is recycled indoor air induced by the ventilation beam through the thermal exchanger to obtain the required cooling effect. The supply air flow provided by the fans is only 20–30% of the total air flow. This means that if the supply air flow is 2 l/s per m^2, the volume of air continuously recycled in the room is 8 l/s per m^2. Therefore, an efficient way of managing room space air velocities is to reduce the induction ratio of the room device to an appropriate level. Figure 3 presents the principle of operation for the induction ratio adjustment in a ventilation beam.

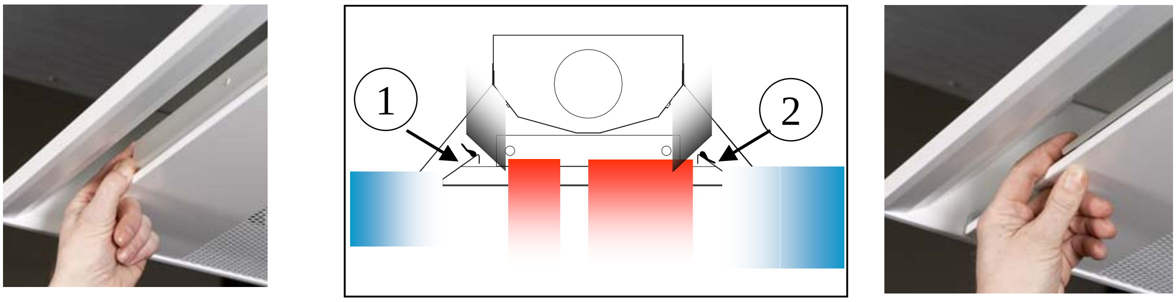


Figure 3. Principle behind induction ratio adjustment: 1) induction ratio adjustment on and 2) induction ratio adjustment off.

Figure 4 presents the impact of the induction ratio adjustment on the flow range of a CFD-simulated example room. The simulations indicate that induction ratio adjustment allows for reducing air velocities in the proximity of a window wall and at floor level. In Figure 4, induction adjustment is used on both sides of the beam. In practice, only one-sided induction ratio adjustment can be used, which lowers the effect of induction ratio adjustment on the room temperature.

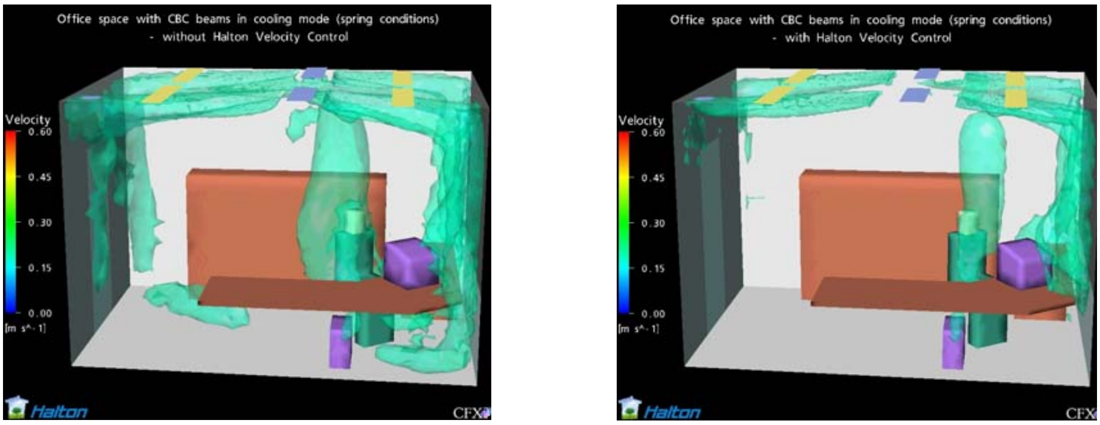

Figure 4. Impact of two-sided beam induction ratio adjustment on the air velocity for a sample room (threshold velocity: 0.25 m/s) and its temperature. Left: Induction ratio adjustment off. Right: Induction ratio adjustment on.

Case-studies carried out in laboratories examined the significance of induction adjustment in a situation where beams installed in a suspended ceiling were perpendicular to the window. According to the measurements made, induction adjustment could significantly reduce air velocities in the proximity of the employees (Fig. 5) [8].

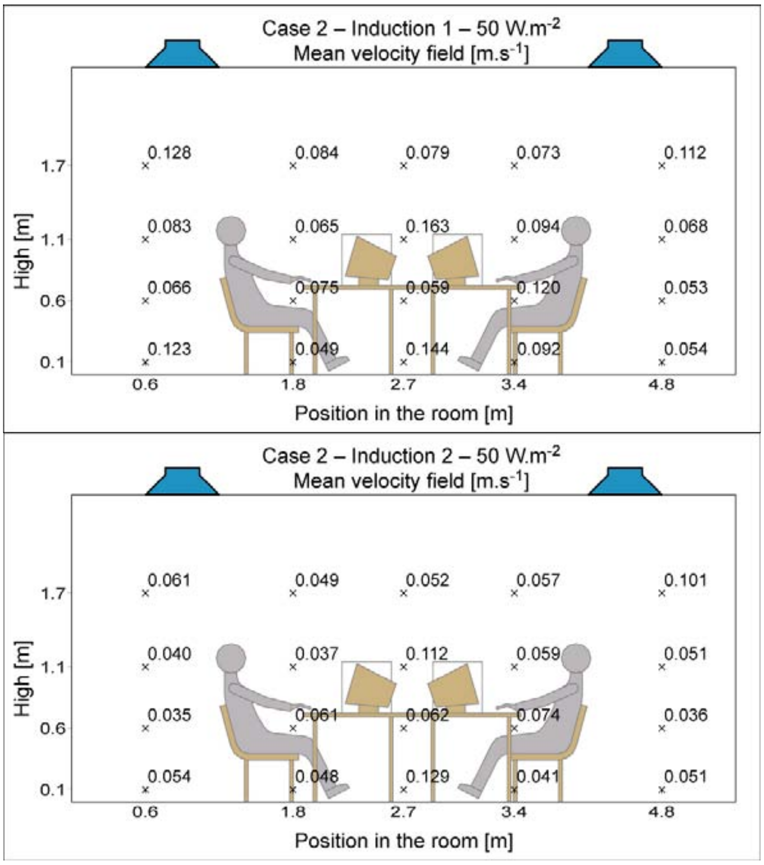

Figure 5. Impact of induction ratio adjustment on air velocity in laboratory tests.
Top image: Induction ratio adjustment off. Bottom image: Induction ratio adjustment on.

Induction ratio adjustment simultaneously affects air velocity and the cooling effect of the room device (by 5–15%). Depending on the design solution, the cooling effect of the room device can be decreased or increased on site depending on the induction adjustment position in the design situation. In comparing induction adjustment to adjusting the water flow in the beam, it can be determined that, when the goal is to reach the same air velocity, water flow adjustment results in a greater change in the cooling effect than induction adjustment does [9].

In addition to the maximum air velocity, induction ratio adjustment can reduce the average room air velocity. Figure 6 presents the impact of induction adjustment in a sample case on the average and maximum velocity [10].

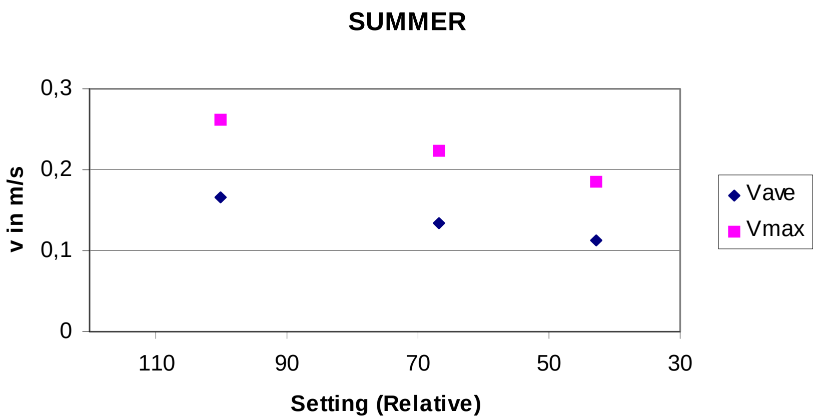

Figure 6. The impact of the total air flow supplied in the room on the maximum and average air velocity in the occupied zone as a function of the relative change of the induction ratio adjustment.

DISCUSSION

In a modern office environment, balance is sought between work performed by individuals and in interaction between employees. It must be possible to appropriately combine various work methods, so partition walls and workstations should be flexibly adaptable if they are to best meet the business needs of individual customers.

Adaptability of office space is one of the central requirements in the design of a beam system. The systems must be adjustable to address changed loads and partition wall positions. In design of a room system, this flexibility means taking account of supply air flow, cooling effect, and supply air device throw pattern changes. In addition, adjustability entails requirements concerning room automation, actuators and sensors. It must be possible to adjust the air flow supplied by the room device, which enables managing the maximum and average velocity in the occupied zone and thus reducing the draught risk.

IAQ and Energy Performance of the newly developed Single Coil Twin Fan air-conditioning and air distribution system – Results of a Field Trial

S.C.Sekhar, Yang Bin, K.W.Tham and David Cheong

Department of Building, National University of Singapore

Corresponding email : bdgscs@nus.edu.sg

SUMMARY

The Single Coil Twin Fan (SCTF) system is a newly developed air-conditioning and air distribution system that aims to deliver enhanced IAQ as well as save energy. The fundamental principle of this system is based on "demand ventilation" and "demand cooling", which is achieved in the individual occupied zones through localized temperature and carbon dioxide sensors positioned in the respective return grilles. The conditioning of the two air streams is achieved by a single compartmented cooling coil, which provides ease of control of the chilled water flow through the coil. Following a successful pilot study on a small-scale laboratory project in 2003 with an estimated energy saving potential of around 12%, a field trial of the SCTF system was embarked upon that involved an office floor area of about 2500 m^2 in a newly constructed office building within the campus of National University of Singapore. This paper presents the IAQ and energy data in this office area served by the SCTF system.

INTRODUCTION

The Single Coil Twin Fan (SCTF) concept involves two variable air volume (VAV) systems employing one compartmented cooling and dehumidifying coil [1, 2]. A schematic diagram of the SCTF air-conditioning and air distribution system is shown in Figure 1. The fresh air is conditioned in the "fresh air" compartment of the air handling unit (AHU) and distributed to the various VAV boxes that form part of the air distribution network. Each of these F/A VAV boxes is controlled by its own localized carbon dioxide (CO_2) sensors, which will ensure an adequate ventilation (F/A) provision at all times. As the main purpose of the F/A VAV box is to ensure adequate fresh air quantity based on occupant density, it helps in achieving energy conservation in the event of reduced occupant loads.

The return air from the various zones of the same distribution network is conditioned in the "recirculated air" compartment of the same AHU and distributed to a separate set of the various VAV boxes. Each of these R/A VAV boxes is controlled by its own localized zone thermostats, which addresses diversity in cooling loads, and consequently helps in achieving significant energy savings at part load operating conditions resulting from non-occupancy related factors. The conditioned Fresh Air and the conditioned Recirculated Air travel in parallel ducts and do not mix until just before the supply air diffusers in the mixing chamber of the modified VAV box. The compartmented coil achieves the required psychrometric performance of the two separate air streams throughout the operating range based on the concept of two VAV systems but one cooling coil.

DESCRIPTION OF BUILDING USED FOR FIELD-TRIAL

The building that is adopted for the field-trial of the SCTF system is a newly constructed low-rise office building located within the university campus. One half of the 3rd floor of this building, approximately 2,500 m^2, is used as the test-bed for the new air-conditioning and air distribution system. The SCTF system was installed in early 2005 and it has been in operation since June 2005. A schematic layout of the relevant portion of the 3rd floor of the building is presented in Figure 2. The office layout in Figure 2 comprises a combination of individual office rooms, low-level office cubicles, conference room, meeting rooms and open plan spaces. The return air is ducted from the various zones to the AHU room. The design cooling capacity of the compartmented coil was 86 kW for the F/A compartment and 233 kW for the R/A compartment, thus giving a total cooling capacity of 319 kW. The design F/A and R/A flow rates were 5,400 cmh and about 60,000 cmh respectively.

CONCEPTUAL DESIGN OF SCTF SYSTEM FOR THE BUILDING

The basis of design of the SCTF air distribution system is as follows:

- All the temperature thermostat and CO_2 sensors are duct mounted near the return air grille of the concerned occupied zones
- Every individual office room has its own temperature thermostat and CO_2 sensor
- All meeting rooms and conference rooms have their own temperature thermostat and CO_2 sensors
- The open plan areas are divided into clusters of imaginary thermal zones as shown in Figure 2. For each open-plan zone, a set of temperature thermostat and CO_2 sensor is to be provided that will control the requirements of R/A and F/A respectively

MEASUREMENT METHODS

As this is the first installation of the SCTF system on a large scale in a real building, it was important to measure the IAQ and energy performance of the system. Several experiments were conducted, during which the following measurements/data were obtained:

- Continuous measurements of CO_2, CO and TVOC at the sampling locations 1 through 5. Locations 1 through 4 are in the open plan office zones and location 5 is in an individual office room, as indicated in Figure 2. A multi-gas monitor, based on the photo-acoustic infra-red principle, is used for these measurements.
- Continuous monitoring of indoor air temperatures and relative humidity at the sampling locations 1 through 5. These are obtained using HOBO data loggers.
- Actual count of the occupancy rate in the open plan office areas at half hourly intervals during the experiment involving the dynamic response study
- Readings (frequency, hz) of the Variable Speed Drive (VSD) of both the “Fresh Air” and the “Recirculated Air” fans during the dynamic response study
- Compartmented cooling coil energy consumption obtained from Building Automation System (BAS) data, involving continuous measurements of chilled water supply and return temperatures to the coil and the chilled water flow rate.

RESULTS AND DISCUSSION

The IAQ and energy results are discussed and are based on the measurements obtained during the different interventions.

Continuous IAQ monitoring - Zone CO_2 set points at 700 ppm, (13th – 17th Nov, 2006)

The carbon dioxide, carbon monoxide and TVOC levels are plotted in Figures 3 through 5 respectively. The indoor temperature and RH levels are plotted in Figures 6 and 7 respectively. The concentration levels of indoor pollutants are generally within recommended Threshold Limit Values (TLV), which are also indicated in Figures 3-7 [3]. As the CO_2 set point in the zones is 700 ppm, the indoor CO_2 levels are of the order of 700-800 ppm during the normal operating hours of the day (Figure 3). The CO plot in Figure 4 reveals that the CO is well within the TLV of 9 ppm and that there are no sources of CO inside the building. It is observed from Figure 5 that the TVOC levels drop from an overnight build-up of 3.0-3.35 ppm to around 2.0-2.4 ppm when the AHU is started in the early morning. This clearly shows the increased dilution effect of a higher ventilation provision. During normal operating hours when the zones are occupied, the ventilation provided is able to maintain the indoor TVOC levels in the range of 1.8-2.4 ppm. The indoor temperature and humidity levels during normal operating hours are in the range of 20-23 °C (Figure 6) and about 50-58% RH respectively (Figure 7).

The total bacteria count and total yeast and mould count were obtained at the selected sampling locations and were generally within recommended Threshold Limit Values of 500 CFU/m^3. The Total Bacteria Count ranged between 70 and 370 CFU/m^3 and the Total Yeast and Mould count, which do not have any indoor source, were quite low in the range of 18-26 CFU/m^3.

The dynamic response of the SCTF system to varying set point requirements of CO_2 in the various occupied zones is seen from Figures 8. These experiments were conducted at two different set points of CO_2, - 500 ppm and 1000 ppm respectively. It is seen that the occupancy rate in the open plan office areas is about the same in both cases and that the indoor CO_2 level ranges between 500 and 750 ppm through the day when the CO_2 set point is 500 ppm. When the CO_2 set point is 1000 ppm, the indoor CO_2 level ranges between 520 and 800 ppm. Whilst the indoor CO_2 levels reached in both cases is quite similar and that the case involving CO_2 set point of 500 ppm is only marginally lower than that of 1000 ppm, it is seen that the fresh air fan operates at a higher frequency during 500 ppm set point of CO_2, implying the dynamic response capability of the system to provide more fresh air. It is to be noted that the CO_2 set point of 500 ppm is very close to ambient CO_2 levels, which typically ranges around the 400 ppm level in Singapore. A high recirculation rate of almost 90% further exacerbates the problem in the context that the design fresh air is only about 10% of total air flow.

Energy Measurements

The compartmented cooling coil energy consumption, expressed in terms of coil capacity (kW) at different time intervals, is presented in Figure 9. It is seen that the measured coil capacity is about 160 kW and this compares with the design capacity of 319 kW. It was also observed that the ΔT across the chilled water supply and return temperatures is rather high (about 9 °C) and the chilled water modulating valve was generally about 30% open. It is to be noted that fan energy consumption was not included in these measurements.

CONCLUSIONS

This paper presents the field data for IAQ and energy of a newly developed air-conditioning and air distribution system, called the Single Coil Twin Fan (SCTF) system. The results presented indicate that the SCTF system is able to provide adequate ventilation in a typical large office premises, based on "demand ventilation" and "demand cooling" in the individual occupied zones. The study has produced a clear demonstration of the dynamic response of the SCTF system. The thermal comfort parameters also indicate superior performance of the SCTF system, particularly in terms of the indoor RH levels, which is attributable to the enhanced dehumidifying performance of the compartmented cooling coil.

SUMMARY

Present study is devoted to specifying the optimization of use of air-cooled vs. water-cooled cooling systems based on the climatic region classification. It proposes affecting design criteria's, which could be implemented in HVAC Uniform code for Middle East, and especially for the Egyptian HVAC and Energy codes. It yields selection criteria's for typical size ranges, where a water-cooled cooling systems are more economical than air-cooled systems and vise versa. This concept has impacts on energy efficiency and conservation. Study is concerned to the field survey, and energy analysis of non-residential buildings in Egypt, covering seven main climatic regions, on which, each region shall be defined for specific cooling system configurations. One of the conclusions is that for newly designed projects, located almost in all Egyptian climatic regions, with any cooling capacities ,could be designed based on water-cooled system with minimum initial and running cost taking into consideration the availability of different water sources in Egypt.

INTRODUCTION

Energy demands in buildings require clear identification of the energy measuring factors with potential verification of each factor in terms of energy saving and the economic revenue [1]. First, factors those required for comfort control and are easy to implement by codes. Second, factors that based on promoting changes in needs and habits of occupants, equipment, operating schedules and control of temperature settings. Third, those factors that are related to the Electro-Mechanical systems, which are the most effective terms on total energy, use and demands [2]. Field surveys, theoretical analyses and parametric runs were performed on different building types in Egypt [3]. Most of these analyses were related to the first group of factors. While, economic evaluations of cost impacts versus anticipated benefits were carried out by the local authorities [4]. The second group of factors has been preliminary treated, since these factors require adaptations in the habits of occupants. Finally, third group of factors was considered since these factors have strong potential on global energy efficiency without affecting citizen's habits. Egypt country was elected as a base case in present study.

Climatic Classifications

Egyptian climate as a sample case considered as Hot and Dry climate while the north region adjacent to Mediterranean Sea is hot and humid climate due the effects of sea [5]. Bioclimatic classifications based on temperatures, humidity and solar heat gains, for Egypt show main seven regional climates [6] on which human biological and physiological impacts were studied by many investigators to evaluate, and justify the acceptable human comfort limits [7]. Climatic Regions are indicated in Figure 1 .

Region [1],
Mediterranean Sea climates.
22-to-28^{O}C dbt & 50-to-80%RH
Region [2],
Upper and Lower west desert.
30-to-38^{O}C dbt & 40-to-60%RH
Region [3],
Upper Egypt valley at Sudan borders.
30-to-45^{O}C dbt & 15-to-40%RH
Region [4],
Southern-Upper Egypt valley.
31-to-42^{O}C dbt & 20-to-55%RH
Region [5],
Northern-Upper Egypt valley.
30-to-40^{O}C dbt & 30-to-55%RH
Region [6],
Delta Region.
22-to-37^{O}C dbt & 45-to-65%RH
Region [7],
Sinai, Red Sea Zone.
23-to-41^{O}C dbt & 17-to-50%RH

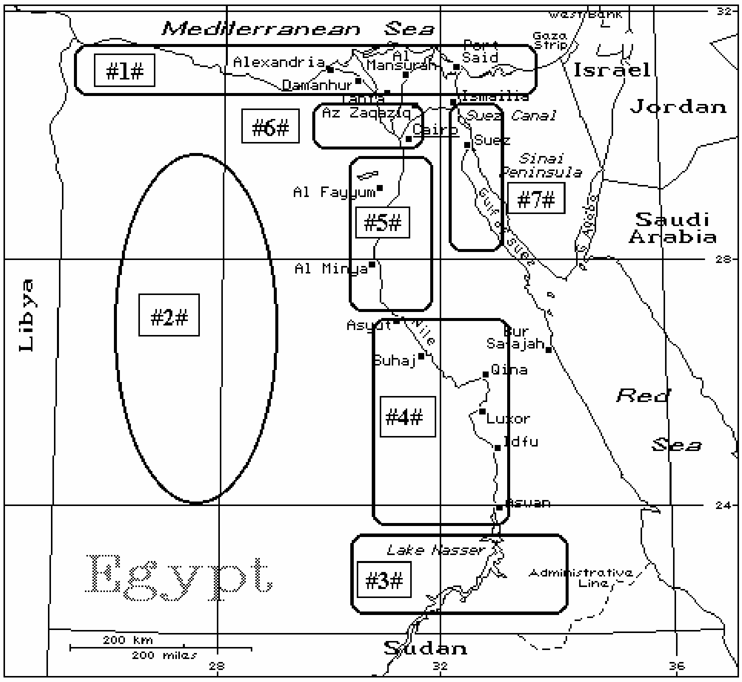

Figure 1. Climatic Regions Classifications in Egypt at Average Summer Conditions

Heat Release Concept

In dry coolers ambient air is used to remove heat by convection process, while in wet coolers heat removal achieved by ambient air in combination with water in evaporation processes. Where, heat release is a function of the wet bulb temperature, WBT, of ambient air and of air capacity for vapor transport. In a Hot & Dry climate, WBT is usually much lower than dry bulb temperature, DBT. Accordingly, lower effective heat sink temperature can be achieved with wet coolers than with dry coolers [8]. On the other hand, wet coolers require water feed & drainage systems, water treatment, filtration units, piping between cooling units and towers, and extra controls leading to additional complexity, together with installation and maintenance costs, that make it less acceptable and less economical than dry coolers. In Egypt cooling towers are not considered for installations smaller than 1500 kW [2].

Thermal load characteristics survey and common practices in Egypt [3] demonstrated ranges of required air-cooled cooling equipment capacities, especially when these equipment are located at ambient DBT over 45^{O}C with the presence of sandy storms. Figure 1 shows real energy efficiency ratios, EER's of in-service air cooled cooling units starting from ARI-Conditions and up to 48^{O}C outdoor operating conditions representing different locations in Egypt. Fitted curves listed in Figures 1 & 2 represent the following different cooling systems that have same cooling capacities, operating schedules and indoor conditions:

[A], Water cooled reciprocating or screw chillers ranged from 70kW-to-525kW nominal cooling capacities, new installations, sand filters and chemical treatment were utilized in condenser side, and operating at 80%-to-100% full loads.
[B], Water cooled reciprocating direct expansion units ranged from 17kW-to-100kW nominal cooling capacities, new installations, sand filters and chemical treatment were utilized in condenser side, and operating at full loads.

[C], Water cooled reciprocating or screw chillers ranged from 70kW-to-525kW nominal cooling capacities, old installations, sand filters and chemical treatment were not utilized in condenser side, and operating at 80%-to-90% full loads.
[D], Water cooled reciprocating direct expansion units ranged from 17kW-to-100kW nominal cooling capacities, old installations, sand filters and chemical treatment were not utilized in condenser side, and operating at 90% full loads.
[E], Air cooled reciprocating direct expansion units that are new &/or have five years old installations, operating at 80%-to-100% full load covering nominal cooling capacities from 17 kW-to-67 kW..
[F], Air cooled reciprocating water chillers that have five years old installation, operating at full load covering nominal cooling capacities from 17 kW-to-525 kW.

Figure 2 show that air-cooled cooling systems that ranged from 17 kW to 525 kW, When operated at tropical outdoor temperatures and with presence of sandy storms will have a new cooling ratings and performances lower than that listed in the original catalogues [2,8]. This means losing sensible cooling capacities and increase power consumptions significantly, On the other hand, the figures show that water cooled units have a stable cooling capacities as its operation principles are based on evaporative cooling that is affected only by wet bulb temperature. Wet bulb temperatures are almost stable and ranged from (22 ^{O}C-to-26^{O}C). Figure 3 shows actual behavior in term of the coefficient of performances, COP's of the same cooling systems compared with ARI-Conditions and up to 48 ^{O}C. Both Figure 2 and 3 show that water-cooled systems have good sustainability in hot and dry climate as they consume low energy up to 0.88 kW/T.R (1.0 T.R=3.5 kW cooling) ,when utilizing evaporative systems rated at 90% or more saturation efficiency [1].

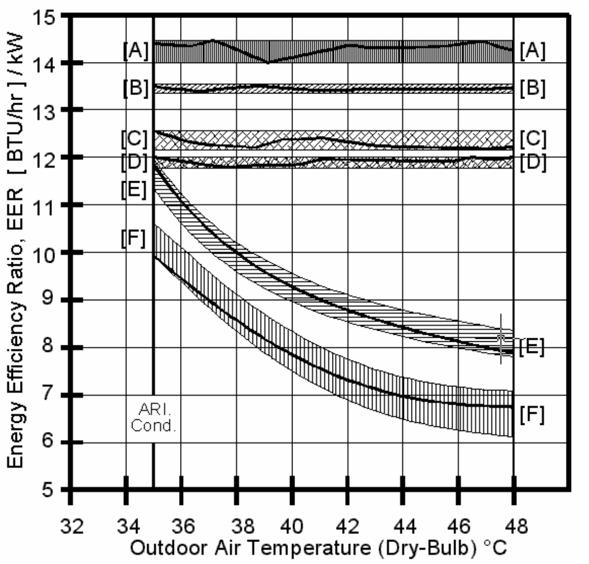

Figure 2, Changes in EER with increase of outdoor DBT compared with ARI-Conditions

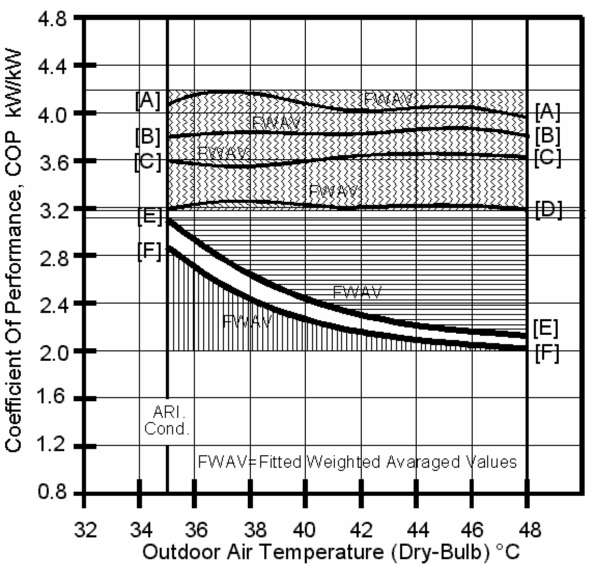

Figure 3, Changes in COP with increase of outdoor DBT compared with ARI-Conditions

Comparative Study Standardization

As this study primarily presents an economic evaluation of air-cooled and water-cooled systems, a number of assumptions are used to make the investigation more manageable and appropriate; the more important assumptions can be summarized as:

- In air-cooled units; the study covers direct expansion and chilled water systems for 100% loading units in operation up to 900 kW, 255 TR cooling capacity.

- In water-cooled units; the study covers direct expansion and chilled water systems for 100% loading units in operation range 500-to-3500 kW, 140-to-1000 TR cooling capacity.
- Ambient Conditions, dry bulb temperatures ranged from $39^{O}C$ to $42^{O}C$, & Wet Bulb temperatures ranged from $23^{O}C$ to $26^{O}C$.
- Indoor Conditions, dry bulb temperatures ranged from $24^{O}C$ to $26^{O}C$, & Relative humidity ranged from 45% to 55%.
- Systems Conditions, All units utilize refrigerant R-22 using Reciprocating or Screw compressors types while, water cooled types over 2000 kW, 570 TR cooling Capacity utilize centrifugal compressors.
- Supply air temperatures from direct expansion units are not more than $10^{O}C$.
- Supply/Return water temperatures in hilled water systems $6\ ^{O}C$ /$12\ ^{O}C$.
- Analyses for the life cycle cost, and maintenance do not consider any interest or inflation rates for simplification purposes and render the study consistent with other approaches and also due to the lack consistent projections for interest and national inflation rates.
- Annual operating costs consist of the cost of the electricity, water use and operation, maintenance charge per year of operation.
- Annual consumption of electricity and water are estimated on the basis of an equivalent full load operation of plant over a specified number of hours of operation per year.

Comparative Study Methodology

This study involves the evaluation of life cycle cost of air-cooled and water-cooled direct expansion and chiller plants of various sizes up to 3500 kW, 1000 TR. The cost analysis is performed in terms of customer [CI] and national [NI] cost indexes. Customer cost index reflects all expenses born by individual property owner the capital equipment of the chiller plant, installation, operation and maintenance over specific life time, and includes the new charges for installation and connecting the electrical capacity required by the plant. While national cost index reflects all expenses for equipment and labor at national level to install, operate and maintain cooling plant over same life time. It is rather similar to customer cost index except that the annual operating cost is estimated on the basis of the national cost for producing electricity and water as per the following governing equations:

$$CI = \{[CC+I]/TR\}+\{([LT]*[AC]+[NC]*[ER])/TR\} \quad \textbf{Eq.1}$$

$$NI = \{[CC+I]/TR\}+\{([LT]*[AC])/TR\}+\{[ER]*[CAE]\} \quad \textbf{Eq.2}$$

$$[AC]_{\text{air cooled}} = [ER*TR*HRE*EC]+OP+MC \quad \textbf{Eq.3,}\ \text{Customer}$$

$$[AC]_{\text{air cooled}} = [ER*TR*HRE*EN]+OP+MC \quad \textbf{Eq.4,}\ \text{National}$$

$$[AC]_{\text{water cooled}} = [ER*TR*HRE*EC]+[W*TR*HRE*WC]+OP+MC \quad \textbf{Eq.5,}\ \text{Customer}$$

$$[AC]_{\text{water cooled}} = [ER*TR*HRE*EN]+[W*TR*HRE*WN]+OP+MC \quad \textbf{Eq.6,}\ \text{National}$$

Where:

I	Installation cost **(L.E)**
CI	Customer cost Index **(L.E)**
CC	Capital equipment Cost **(L.E)**
TR	installed cooling capacity **(TR)**
LT	Life Time of equipment **(Years)**
AC	Annual operating Cost **(L.E)**
NC	New connection fee per kW Capacity **(L.E/kW)**
ER	Electrical Requirement per unit (T.R) capacity **(kW/TR)**
HRE	Equivalent hours of operation per year at full load **(h/yr)**
EC	Electricity Cost to customer **(L.E/kWh)**
W	Water consumption rate per unit (T.R) capacity **(l/h/TR)**
WC	Water Cost to customer **(L.E/m^3)**
OP	Cost of operator per year **(L.E)**

MC Maintenance Cost per year (labor + spare parts), **(L.E)**
CAE Cost of installing additional electrical capacity **(L.E/kW)**
EN National cost for producing electrical energy **(L.E/kWh)**
WN National cost for producing domestic water (**L.E/M^3)**

It is evident that accurate evaluations of customer and national cost indices requires detailed and accurate information of all the component costs that contribute on life cycle cost. This information was provided by HVAC contractors, equipment agents and consultants.

ENERGY ANALYSIS

a. Air-Cooled Units are available in one size of up to 800 kW, 255 TR in single packaged units. The majority of the units on the market are driven by reciprocating or screw compressors, one or more compressors per unit, for most installations in the range of 350-to-1750 kW, 100-to-500 TR . An analysis of the packaged units available on the market reveals a kW/TR requirement, excluding the chilled water pump and the air side, as shown in Figure 4. The figure indicates that the electrical requirements fall between 1.40-to-1.70 kW/TR.

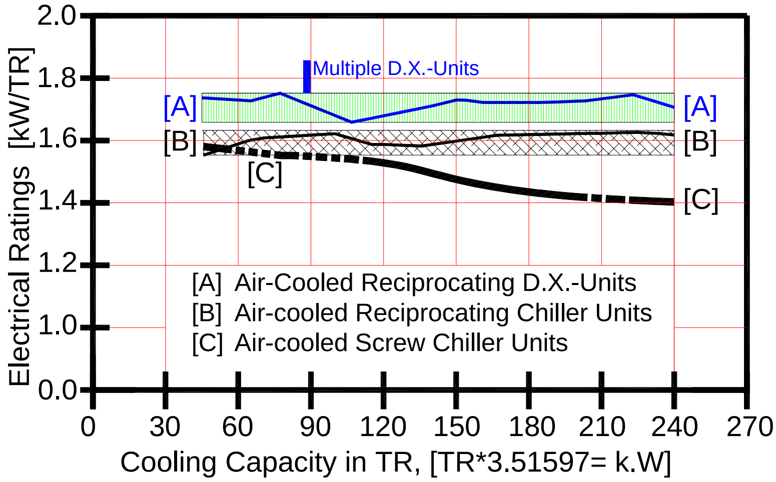

Figure 4, Electrical Average Ratings of Air-Cooled Units

b. Water-Cooled Units are available in sizes of up to 2000 kW, 570 TR in packaged units.

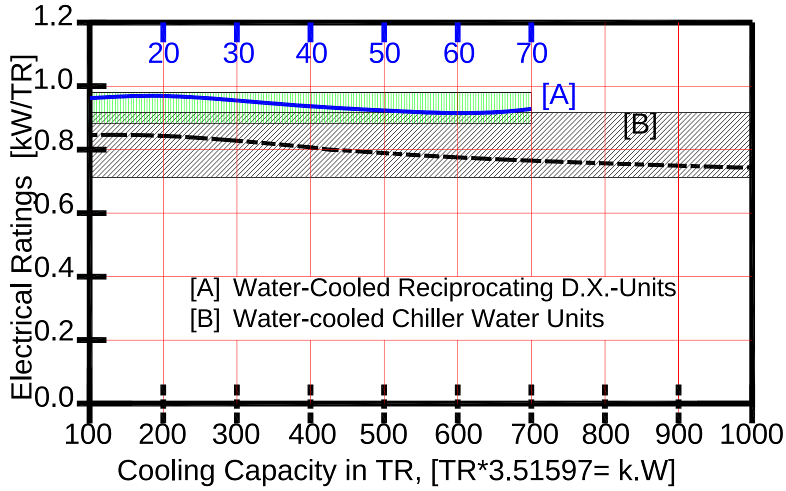

Figure 5, Electrical Average Ratings of Water Cooled Units

Reciprocating or screw compressors are used in the small size units while centrifugal compressors are common in the large size units. Due to the diversity in the type and size of compressors and other components, the electrical requirement of the cooling plant is expected to vary accordingly.

Cooling plant components that require electricity are primary the compressor, the condenser water pump and cooling tower fan. These components in water-cooled units are rather detached physically and operationally and their sizing is somewhat site dependent. Collected data reveal a spread in the energy requirements of the D.X or chiller only, as shown in Figure 5. The kW/TR requirement falls generally between 0.80-to-0.90, kW/TR. There is a tendency for the kW/TR requirement to drop with the increase in the size of the chiller though this drop is rather insignificant.

c. Cooling Towers have similar analysis of electrical requirements of the cooling tower fans for cooling towers of 350-to-7000 kW, 100-to-2000 TR in capacity gives the spread in results as shown in Figure 6. It is observed that the kW/TR requirement is around 0.1 kW/TR for 750 kW, 215 TR capacities, and falling off to 0.094 kW/TR for a 3000 kW, 850 TR capacity unit. These values are common for the usually utilized induced draft cooling tower design.

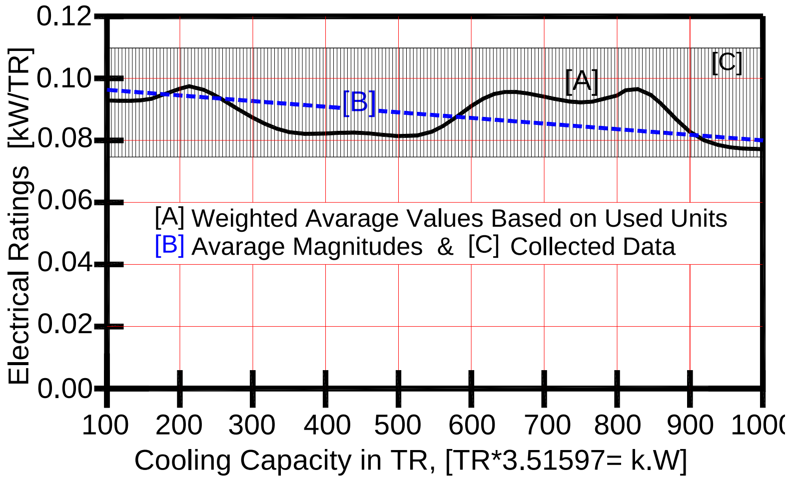

Figure 6, Electrical Approximated Ratings of Wet Cooling Towers

d. Water Pumps are strongly site dependent, the location of the cooling tower relative to cooling unit and the extent of piping, its size and number of bends, valves, etc. between the two units dictates the size of pump required. It is expected that there would be a very wide variation in the sizes and the electrical requirements of pumps for different installations. A review for the past ten years installations revealed a spread in the kW/TR requirement between 0.05 and 0.17 a generalized value for condenser water pump requirement could be within 0.10 kW/TR.

COST ANALYSIS

Capital **C**ost of **A**ir-cooled **U**nits in sizes of 150 KW, 40 TR and higher is shown in Figure 7. The values quoted in the figure are contractor price figures for packaged units delivered to site. The prices are for the packaged units with its air-cooled condenser, electrical panel and cabling. Figure 6 shows that, for chillers with reciprocating compressors in the capacity range of 150-to-530 kW, 40-to-150 TR, the capital cost ranged from 500-to-700 L.E/kW, 1750-to-2500 L.E/TR.

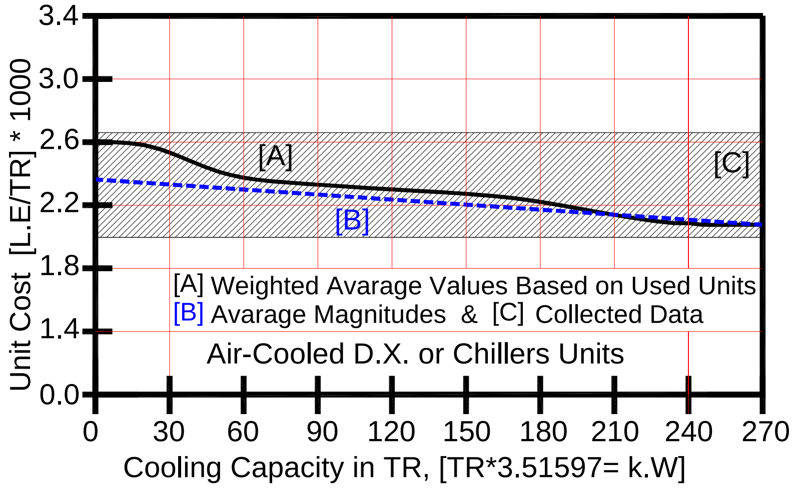

Figure 7, Predicted Cost per Cooling Capacity for Air-Cooled Packaged Unit

Capital **C**ost of **W**ater-Cooled **U**nits figures delivered to site are in Figure 8 The cost figures are for individual packaged units in the capacity range of 150-to-3000 kW, 40-to-850 TR. Installations of large capacities (3000 kW, 850 TR & up) and even those in the mentioned capacity range usually consist of a number of packaged units appropriately chosen to have a competitive L.E/TR cost. It can be observed from Figure 6 that there is a wide scatter in the cost figures, with the average values showing a distinct drop in the L.E/kW cost with the increase in capacity of the packaged unit. This cost starts at around 500 L.E/kW, 1750 L.E/TR for a 350 kW, 80 TR unit and drop off to around 350 L.E/kW, 1225 L.E/TR for units in the 1700-to-3500 kW, 485-to-1000 TR range.

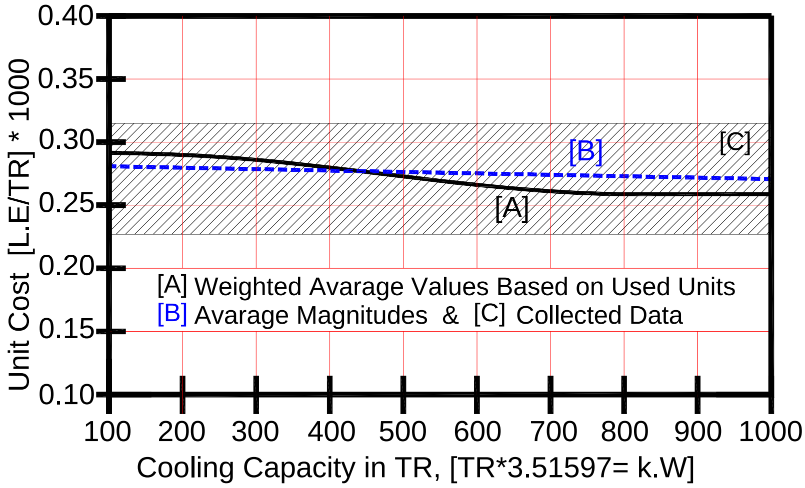

Figure 8, Predicted Cost per Cooling Capacity for Water-Cooled Packaged Unit

Capital **C**ost of **C**ooling **T**ower depends on the type of cooling tower specified for the installation. Capital cost for cooling tower is shown in Figure 9. The figure shows a variation in capital cost from around 125 L.E/kW, 440 L.E/TR for a 350 kW, 100 TR installations to around 100 L.E/kW, 350 L.E/TR for sizes 2800 kW, 800 TR and over. Pump cost varied between 10-to-25 L.E/kW, 35-to-88 L.E/TR, Piping cost has greater variations, from 20-to-65 L.E/kW, 70-to-225 L.E/TR. Other capital equipment costs are water treatment and filtration units that varied around 25 L.E/kW, 88 L.E/TR.

Water-cooled Units require a built-in space as opposed to air-cooled units, which are mounted directly on the roof. This space is normally provided or a separate plant room built, then the expense could add some 30-to-50 L.E/kW, 100-to-175 L.E/TR to the total installation cost of water-cooled units. This cost is not considered in the analysis.

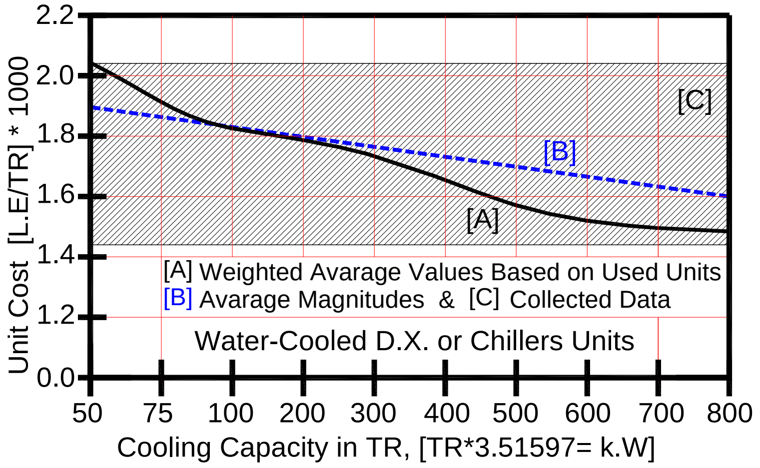

Figure 9, Predicted Cost per Cooling Capacity for Wet Cooling Towers

Installation & commissioning cost is difficult to determine with any certainty and vary among contractors and different installations. This is because some contractors include it within the capital cost or consider it as a certain percentage of the equipment cost. It is deduced that the cost of the installation and commissioning of air-cooled chillers is in the range of 30-to-50 L.E/kW, 100-to-175 L.E/TR. Installation size should have little effects on cost since large capacity installations would be made up a number of packaged units with each unit requiring the same amount of effort in installation and commissioning. A similar analysis for water-cooled units reveals that the cost for installation of all the components of the plant and its commissioning is in the range of 60-to-70 L.E/kW, 210-to-245 L.E/TR for large capacity installations.

POWER AND WATER COST

In Egypt, the energy consumption for residential and commercial private buildings contributed with 35% of the total energy generated [3] the larger portion of this energy was consumed in the cooling processes. Therefore, the residential and tertiary sector is one of the most energy intensive sectors. Nevertheless; the new buildings will be constructed in accordance with new energy efficiency codes. Energy consumed by the older buildings themselves is very high. Heat losses in buildings are caused, not only by low standards building materials and construction, but also by poor insulation of heat and lack of energy efficiency awareness that presents the main reasons for high energy consumptions in residential buildings and describes the traditional methods that have been employed to achieve energy conservation in residential sector. The running cost relating to the electricity and water used by cooling units over a one year period is estimated according national cost. The water consumption in water-cooled units is estimated to be 0.013 m^3/hr/TR for make-up water, while cost of air-cooled units could be similarly obtained, taking into considerations that water cost is subsidized by government.

CONCLUSIONS OF THE RESULTS

Simple analysis of air-cooled units and the effect of various parameters on their respective costs were carried out using simple parametric analysis with the ratio $(CI)_{\text{air cooled}} / (CI)_{\text{water cooled}}$ & $(NI)_{\text{air cooled}} / (NI)_{\text{water cooled}}$. It is observed from analyses that the capital equipment and installation costs represent a small fraction of the CI and NI. Thus, the variation of cost with cooling capacity should have insignificant effect on the analysis as indicated in Figure 10.

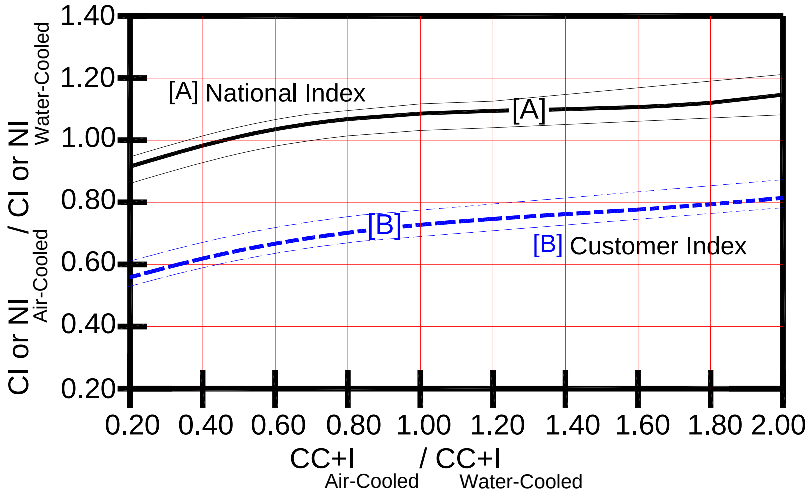

Figure 10, Effects of capital and installation costs on the customer and national index

There is a general consensus among contractors that air-cooled units are cheaper to operate and maintain, there is no clear idea of the actual cost. The figures obtained showed large variations. This is because operation and maintenance contracts are not based on the equipment only but also on site conditions. Also, contracts are usually awarded for the operation and maintenance of the total HVAC system and often these contractors for labor only with the spare parts to be paid by the customer according to use.

Study on Running Performance of a Split-type Air conditioning System Installed on a University Campus in Suburban Tokyo

Toru Ichikawa [1], Anna Won [2] and Satoshi Yoshida [2]

[1] Tokyo Gas Co, Ltd.
[2] Yokohama National University, JAPAN

Corresponding email: toithi@tokyo-gas.co.jp

SUMMARY

Split-type air conditioning systems, or heat pump systems with multiple indoor and outdoor units, are becoming very popular for room cooling and heating of small or middle-sized non-residential buildings in Japan. However, their running performance is yet to become known due to the difficulty of measuring actual amount of heat transferred by the system. Mixed irregular flow of vapor and liquid refrigerant has prevented building engineers from obtaining accurate amount heat flow between indoor and outdoor units. The study introduces an alternative method to calculate heat transferred by the system from air volume and enthalpy measured with simple sensors attached to the indoor units. Experimental results on a national university campus in suburban Tokyo showed unexpectedly low COP values both in summer and winter mainly due to the prevailing low partial load factors under 20-30% of the system capacity.

INTRODUCTION

The recent rise in environmental problems and deteriorating state of the earth combined with approaching deadline for public commitments to reduce CO_2 emissions and increasing energy consumption at private sector has intensified the importance of developing and promoting methods for conservation and efficient use of energy.

In this situation, recently, split-type package air conditioners (PACs for short) have been rapidly spreading from the aspect of cost saving and convenience and installed even in the buildings with several tens of thousand square meters of floor area in major Japanese cities. From the aspect of energy efficiency, however, it is suspected that their high rating COP based on the Japanese Industrial standard does not represent actual values in use. It is also suggested that PACs may constitute a primary source of heat island, because unlike centralized air-conditioning systems equipped with cooling towers which primary discharge latent heat, PACs exclusively discharge sensible heat into the urban canyon directly rising its air temperature. PACs efficiency therefore is also a primary interest from the aspect of urban environment. In order to obtain some knowledge to these pending questions, this research has tried to measure energy efficiency of a typical PAC under actual operating environment. The results will help us in designing and installing PACs in a better way.

METHODS

A multiple type package air conditioning unit installed on a national university campus in west suburb of Tokyo has been chosen for measurement. Multi point measurement method is applied to examine its efficiency in daily operation. Summer measurement was conducted with the indoor setting temperature of 27℃, and winter measurement with the temperature of 24℃ (February 14 through 16), 22℃ (17 through 19) and 20℃ (February 20 through 22). Throughout measurement, airflow was set at “strong” mode while wind direction was set “no swing with middle low angle” blowout position. Weather information of measurement periods are provided in table1 and 2.

MEASUREMENT CONTENTS

(1) Indoor thermal environment
In order to measure indoor temperature distribution, 15 representing points were designated each with three vertical measurements making up 45 altogether as shown in Figure 1.

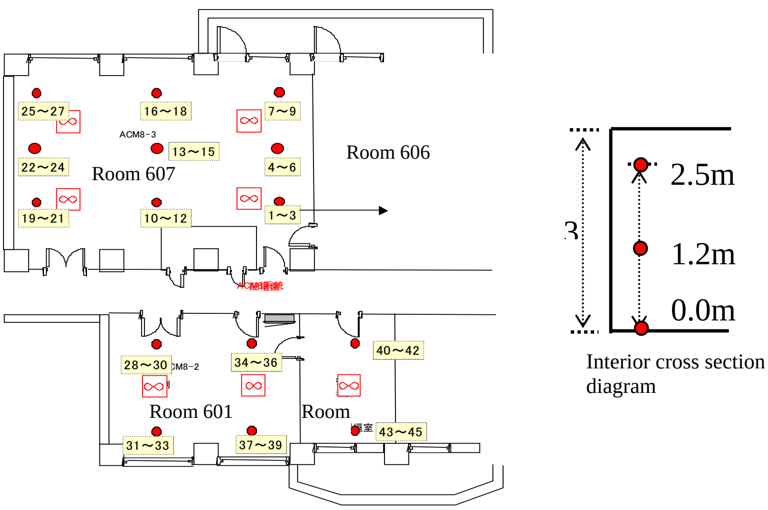

Figure 1. Horizontal and vertical location of thermo-hygrometers installed around indoor units

(2) Thermal flow at Indoor units
Dry bulb and wet-bulb temperature of the inlet and outlet airflow were measured at all of 7 indoor units with thermocouple and data logger (Figure2) while air velocity was measured

with the traverse developed for this study. Heat exchange quantity was then calculated by multiplying inlet and outlet temperature difference and air volume calculated by the air velocity distribution described later. In addition, outdoor temperature, humidity, solar radiation, wind direction, wind velocity, atmospheric pressure and precipitation were measured with a Davis Weather Station.

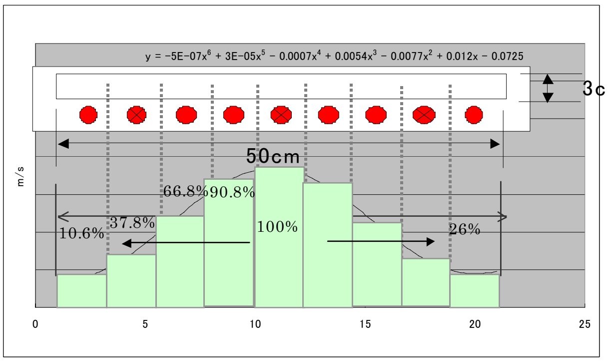
Power current	Cooling	67.6/72.1A
	Heating	59.3/65.1A

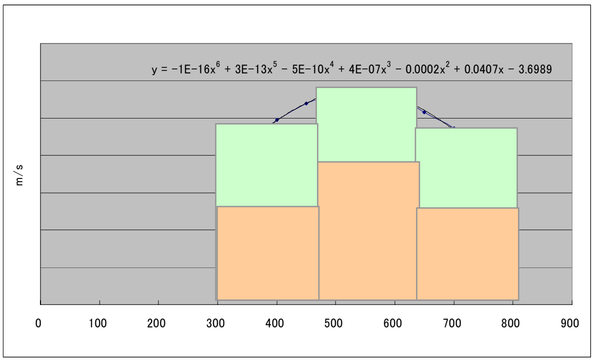
(3) Electricity consumption by outdoor and indoor units
Electricity consumption of 7 indoor units, 4 outdoor units and their control systems were measured every minute by attaching clamp watt meters to the power line.

Specification of measured PAC is shown in table 4 and 5. The rated COP on the specification is 2.64 for cooling and 2.90 for heating.

RESULTS

(1) Airflow calculation
Airflow volume was calculated by airflow distribution model (Figure 3) based on 3 dimensional velocity distribution measured by the traverse unit equipped with measuring devices developed by professor Shigeki Kametani of Tokyo University of Marine Science.





(a) (b)

Figure 3. Wind velocity Ratio of air outlet(a) and inlet(b)

Wind inlet and outlet velocity distribution measured by the traverse were expressed with an approximate curved line which gives a wind velocity ratio at a random point to the central point. Using the curve, mean wind velocity of each measured point and its representing area was calculated and applied to thermal flow calculation. A sum of the calculated airflow volume was adjusted to match the rated volume for “strong wind” mode.

(2) Result of summer measurement
Outside air temperature, humidity and electricity consumption of indoor and outdoor units throughout summer measurement are shown in Figure5 and 6. Room temperature is shown in Figure 7 for reference.

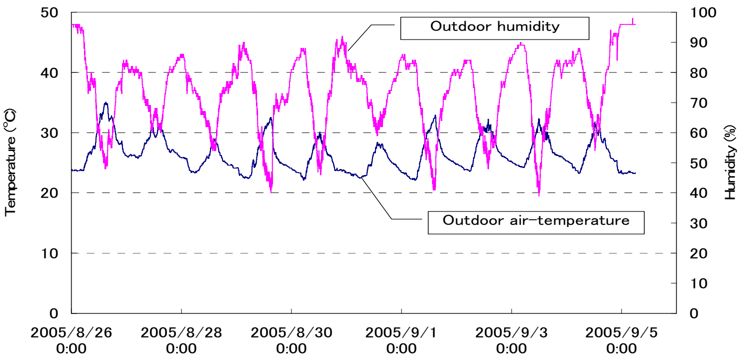

Figure 5. Outside air temperature and humidity (summer measurement)

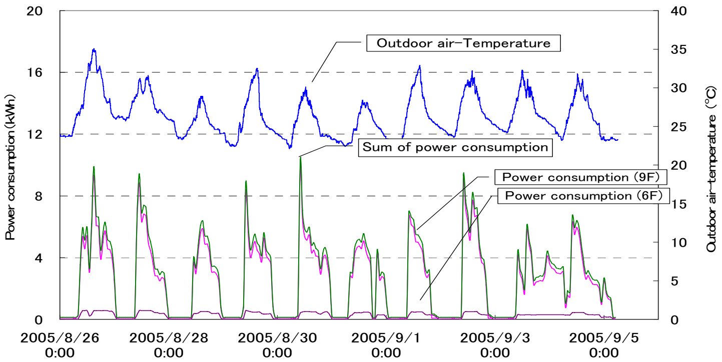

Figure 6. Electricity consumption (summer measurement, indoor: 6F, outdoor: 9F)

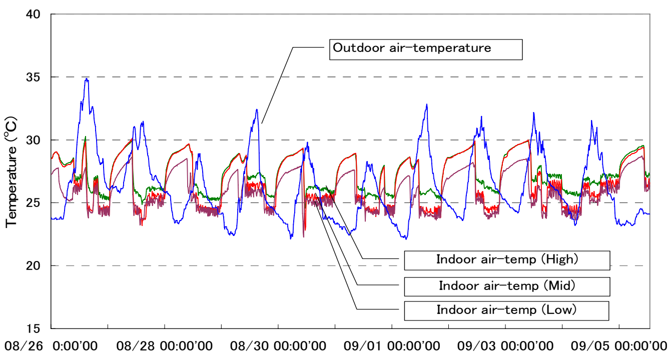

Figure 7. Outside air and room temperature (summer measurement)

The change of COP during operating time (10am-9pm) in summer measurement is shown in Figure 8. Measured COP was considerably lower than rating COP (=2.64).

COP was calculated by the following formula.

$$\mathrm{COP} = \frac{\text{Heat exchange quantity}}{\text{Electric power consumption of indoor and outdoor units}} \qquad (1)$$

= 715.806 [kWh] / 411.382 [kWh] = 1.74 (10am-9pm, August 26-September 5, 2005)

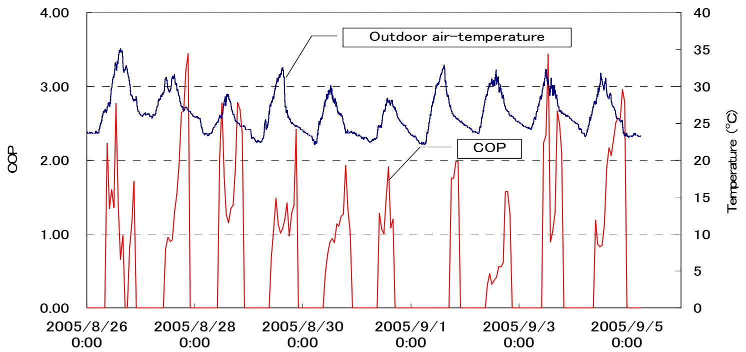

Figure 8. Change of COP (summer measurement)

Figure 9 and 10 show distribution of load factor. Most of the load is concentrated under 30% of PAC's capacity.

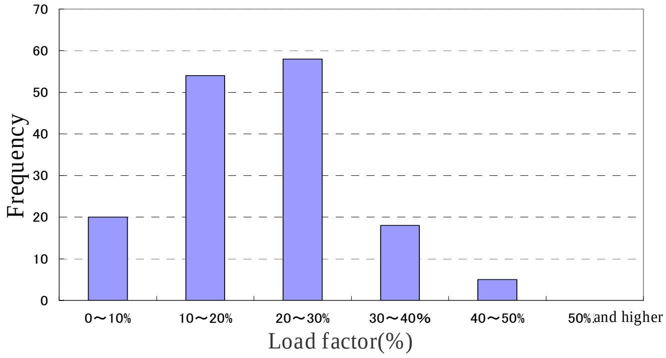

Figure 9. Frequency distribution of load factor (summer measurement)

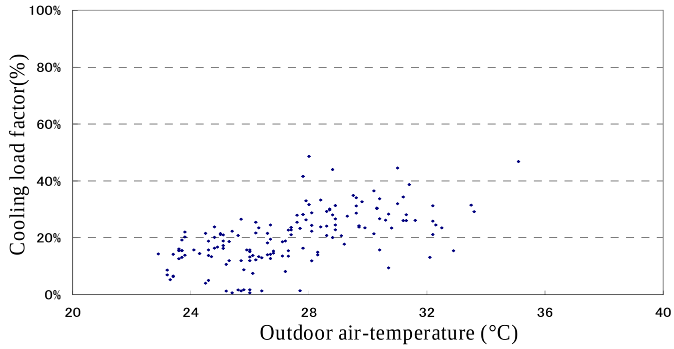

Figure 10. Relation between outside air temperature and load factor

(3) Result of winter measurement

Outside air temperature, humidity and electricity consumption of indoor and outdoor units throughout winter measurement are shown in Figure 11 and 12. Room temperature is shown in Figure 13 for reference.

The change of COP during operating time (10am-9pm) in winter measurement calculated by formula (1) is shown in Figure 14. Measured COP was quite lower than rating COP (=2.90).

COP= 92.700 [kWh] / 153.898 [kWh] = 0.60 (10am-9pm, February 14 - 22, 2006)

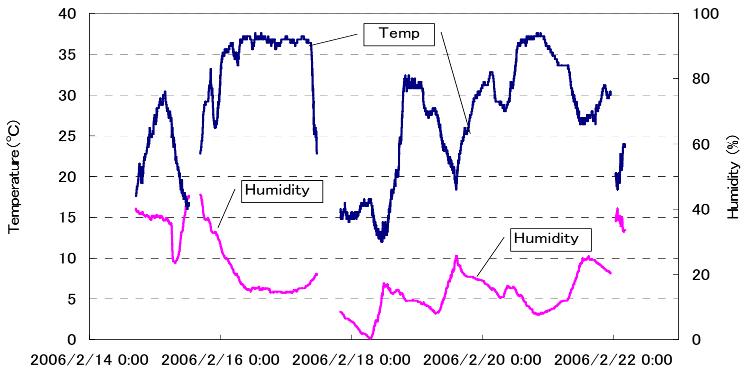

Figure 11. Outdoor air temperature and humidity (winter measurement)

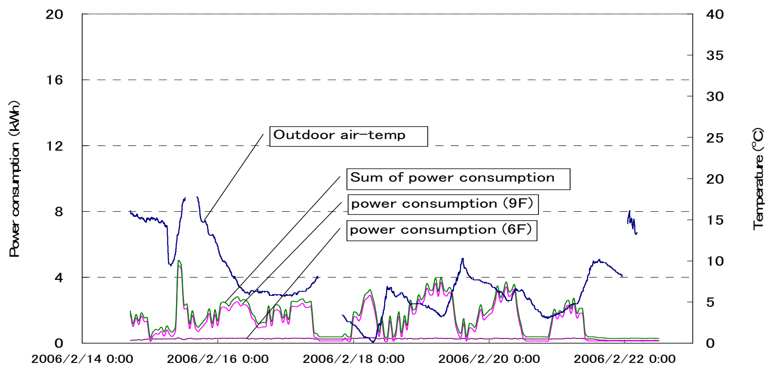

Figure 12. Electricity consumption (winter measurement, Indoor : 6F, outdoor : 9F)

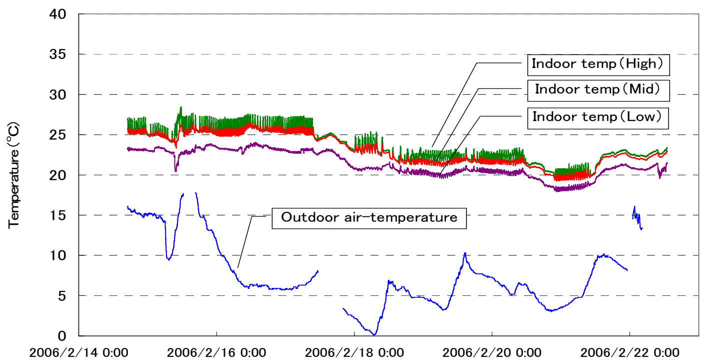

Figure 13. Outdoor air and room temperature (winter measurement)

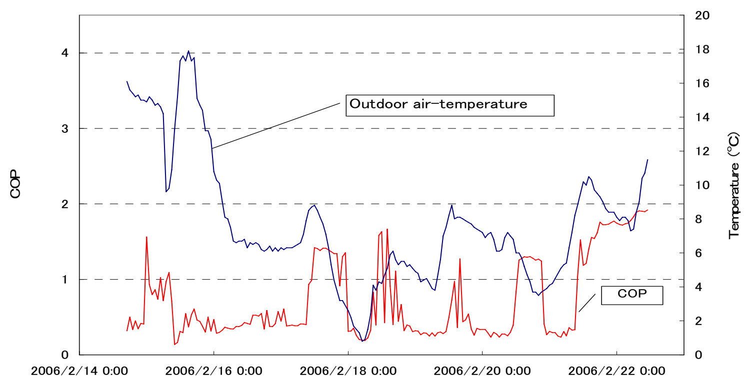

Figure 14. Change of COP (winter measurement)

Distribution of load factor during winter measurement is shown in Figure 15 and 16. Most of the load is concentrated under 20% of PAC's capacity. Load Factor was lower in winter because relatively high outdoor air temperature prevailed during measurement and the inevitable problem of excess heating capacity for a PAC designed to meet maximum summer peak load has come to the surface.

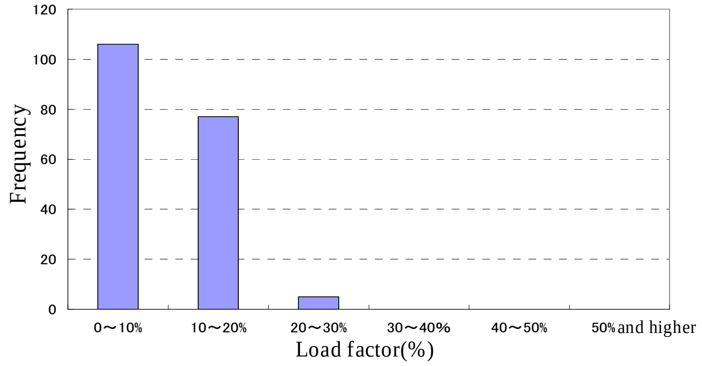

Figure 15. Frequency distribution of load factor (winter measurement)

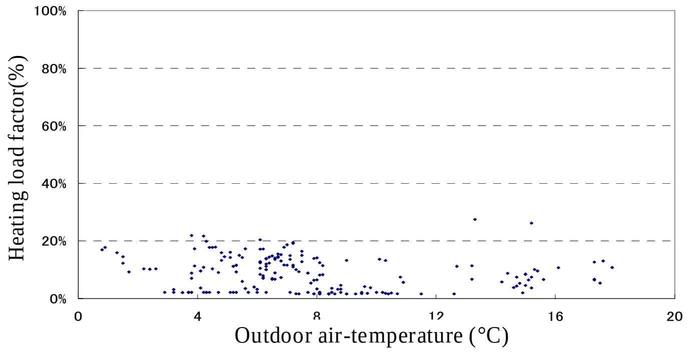

Figure 16. Relation between outdoor air temperature and load factor (winter measurement)

DISCUSSION

In this study energy efficiency of a PAC under actual operating environment was measured by the "multi point measurement method". The result revealed considerably low COP for cooling and very low COP for heating in comparison with their rated values. It also became clear that PAC's capacity far exceeding actual load is causing operation under extremely low load factor which prevents it running at expected efficiency. In addition, if global warming worsens, imbalance between summer and winter load will become greater, creating even lower partial load operation for heating. To solve these problems, accurate load calculation with reliable software is required. And also, a technological breakthrough to integrate PAC's heat load into fewer number of outdoor units to operate them at higher load factor is expected.

R&D Case: New Holistic Air Conditioning System

Heikki Mäki

Are Oy, Finland

Corresponding email: heikki.maki@are.fi

SUMMARY

A new air conditioning system was developed to combine low energy consumption, good indoor conditions and competitive investment costs. Computer simulation was utilized to develop the system operation and dimensioning principles and design tools. The generated HVAC-solution comprises several functions, which are usually separate. It takes care of heating, cooling, ventilation, illumination and electric distribution of the rooms. The integrated system operates with low temperature heating and high temperature cooling principles. Internal heat loads are utilized efficiently in heating. An advanced free cooling process with outdoor air is used in cooling. The system has been build in several office buildings. The measured energy consumptions and indoor conditions fulfill the strict target values. The user satisfaction is high. The work and results showed that simulation is an efficient and reliable tool for system development and design. Low consumption, good conditions and a competitive price level can be combined.

INTRODUCTION

The HVAC, control and electrical systems, which maintain indoor conditions, are usually separate due to historical and commercial reasons. They function typically quite independently. The goal was to develop a new building services system, which integrates various functions and thus improves energy efficiency and indoor conditions of office and public buildings. Further the design methods and practical solutions were to be generated to make the system as a commercial product. The final task was to measure the system performance in a real building and compare it to the theoretical values.

The main objectives of the development project were set already in the year 1996. Good indoor conditions, low energy consumption and competitive investment costs were self-evident goals for the new system. The fourth goal, low environmental impact, was fulfilled through the low energy consumption.

METHODS

System simulation was chosen as the development method due to the large variety of different operating situations during the four climate seasons of the Nordic climate. Scientific university owned and commercial simulation programs were studied. The programs, which were found were either very laborious or too superficial. Finally a simulation environment, which was still under development was chosen. The Royal Institute of Technology in Stockholm was creating a program named IDA [1] [2] with the assistance of Helsinki University of Technology.

The development procedure was straightforward. New system and control principles were innovated. The systems were programmed in IDA and their operation in different outdoor conditions were studied by simulation. Finally simulations throughout the year were carried out. As a whole over one hundred simulations were done before all system properties were defined. A Finnish reference building "HVAC-2000" was used in the models. The building is an imaginary office building designed for research purposes. Several new HVAC-equipment models were created to make the system simulations possible.

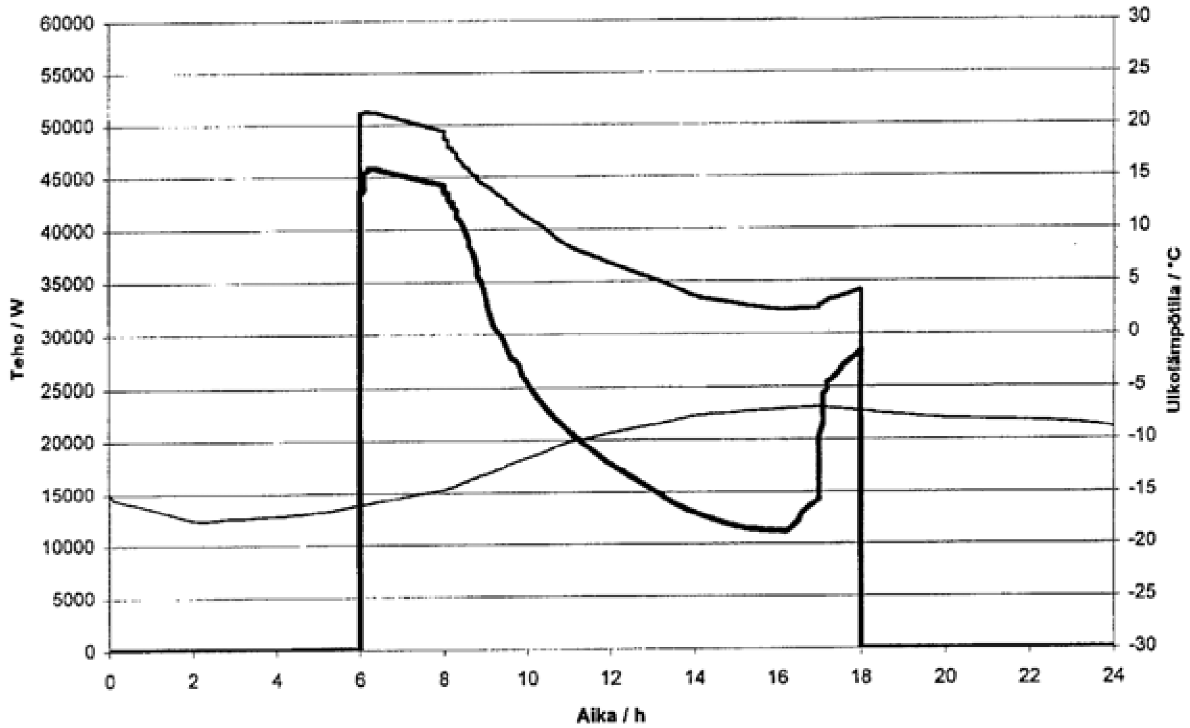

Figure 1. The operation and performance of the new system under development were compared to a conventional HVAC-system by simulation. As an example the heating power need (W) of an air conditioning unit during a winter day is shown. Uppermost curve is a conventional unit and the lower curve is the new system unit. Third curve is outdoor temperature (°C) [3].

The new system operates with low temperature heating – high temperature cooling bases, which is called also low exergy principle [4]. The air heating and cooling coils and fluid heat exchangers operate with very small temperature differences compared to the conventional systems. The behavior of these coils was studied theoretically and with laboratory measurements [3]. The results were programmed in the coil simulation model as initial values.

RESULTS

System principles

Modern office houses require long periods of time simultaneous heating and cooling in cool and moderate climates to maintain comfortable indoor temperatures. Cooling is often needed already in below zero outdoor temperatures. The excess heat from room cooling is discarded

out and at the same time heat is brought in the HVAC-unit and in the rooms, which need heating.
The heating and cooling energy saving principle of the system is simple in the new system. The excess heat from room cooling is not rejected out but brought in the HVAC-unit where heat is needed. The HVAC-unit cools simultaneously the cooling water of the room units with cool outdoor air (free cooling). This reduces the energy consumption of mechanical cooling.

Large heat exchange surfaces are needed in heating and cooling devices of the low exergy systems due to the small temperature differences available. Hence the same devices are used both in heating, free cooling and mechanical cooling in the HVAC-unit and in the room units. The total heat exchange surface is not larger than in conventional systems, which have separate units for heating and cooling. This makes the new system also commercially competitive.

The system has only three pipes to the room units, the heating, cooling and return pipes. Using the common return pipe would increase the energy consumption in conventional systems. In the new system this decreases the consumption, because the return heat is utilized.

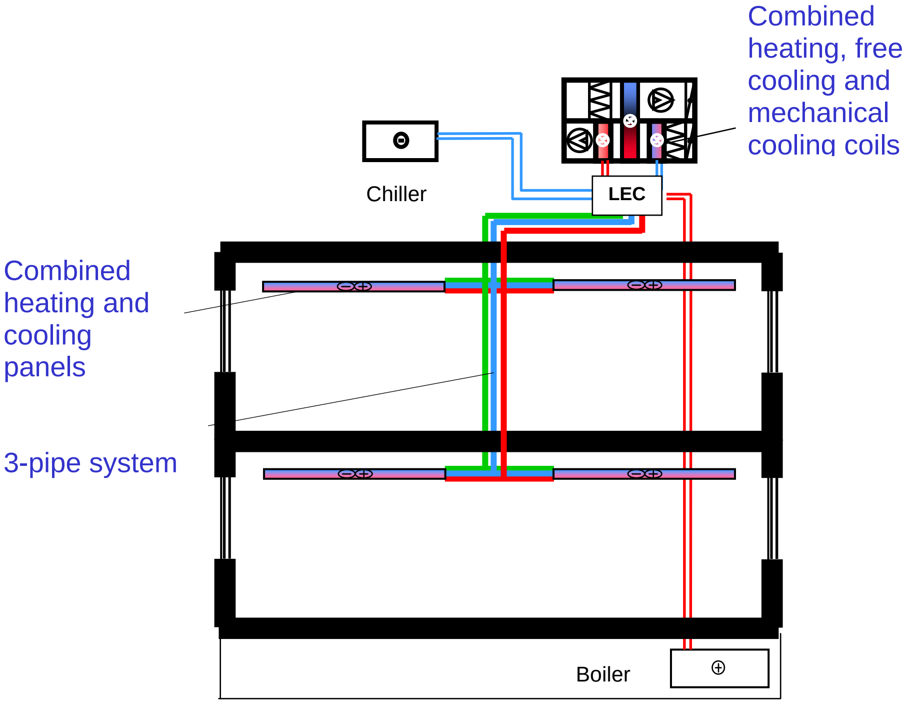

Figure 2. The system has less components than traditional HVAC-systems. The same devices perform several functions. Low energy center LEC transfers heating and cooling energy inside the building reducing the need of external energy [5].

System verification, energy consumption and indoor conditions

The system follow up with the building energy management system show that energy recycling inside the building and free cooling operate practically throughout the whole year. Free cooling is needed in the spaces with high internal heat loads and good thermal insulation even when the outdoor temperature is very low in the winter. On the other hand the new type of free cooling operates nighttime even during the warmest seasons cooling the building structures and reducing the daytime cooling need.

The studies [6, 7] compare the measured and the theoretical system operation with each other in a large pilot building. The studies show that the system operates as designed. The free cooling produces over 70% of the total yearly cooling need.
Measured heating energy consumptions of several buildings equipped with the new system are 25%-40% lower than the average values in buildings of similar type and age (comparison data by Association of Finnish local and regional authorities and by local district heating companies).

The studies [6, 7] show that measured indoor conditions fulfill the design target level S2 of the Finnish indoor classification [8]. Conditions are within the best class S1 about 90% of the time. An international research Hope [9] studied the possibilities and means of combining good indoor environment and low energy consumption. The indoor conditions in a building equipped with the new system was ranked best among eight Finnish office buildings by the users.

DISCUSSION

The project showed, that system integration brings about advances compared to conventional separate systems. Excellent indoor environment, low energy consumption and competitive investment cost is combined in the new holistic HVAC-system.

HVAC-system simulation is often considered mainly as a research implement for scientists. The project proved that simulation is an efficient tool for developing practical solutions and for verifying system function in real use.

Individual HVAC-equipments and units are factory made and tested. Their properties are well known. However total HVAC-systems are designed and build without testing their function as a whole. System dimensioning is made in the extreme steady state design conditions. Operation in other conditions is not examined. Hence system simulation, testing, verifying and follow up in a larger scale would reduce the total energy consumption of the building stock along constructing new and renewing old buildings.

ACKNOWLEDGEMENT

The main development project was done by the HVAC-laboratory of Helsinki University of Technology and Energy laboratory of Lappeenranta University of Technology. The project was funded partly by Tekes.

Thermal climate requirements and the effects on environmental performance of comfort cooling systems

Katarína Heikkilä

Chalmers University of Technology, Sweden

Corresponding email: Katarina.Heikkila@chalmers.se

SUMMARY

There is a lack of knowledge of how significantly various indoor climate criteria affect the overall environmental performance of air-conditioning systems. The purpose of this study is, therefore, to investigate the relation between environmental performances of four types of air-conditioning systems and five various criteria on indoor thermal climate. Furthermore, the relation between the specific fan power (SFP) factor and the overall environmental performance of the systems studied is investigated. The annual operating energy of each of the systems is modelled for the five indoor thermal climates. The environmental performance is evaluated by the life cycle assessment (LCA) method, including weighting by EPS 2000d.

INTRODUCTION

Elevated requirements on the thermal climate in offices imply increased cooling loads, and to round the year operation of air-conditioning systems even in rather cold climates. This trend leads to an extended energy use, which consequently affects negatively the environmental performance of air-conditioning systems since energy use often is the main contributor to the overall environmental impacts. There is a lack of knowledge of how significantly the indoor climate criteria affect the overall environmental performance of these systems. Heikkilä and Lindholm [1] show no significant difference in environmental performance of a particular air-conditioning system designed for the most usual requirements on thermal climate. However, that study is based on one air-conditioning system operating in one particular office building. The purpose of this study, therefore, is to investigate the relation between environmental performances of several types of air-conditioning systems and various indoor thermal climate criteria. Furthermore, the relation between the specific fan power (SFP) factor and the overall environmental performance of the systems studied is investigated.

METHOD

The analysis is based on different case studies focused on environmental evaluation of four types of air-conditioning systems. For each of the systems, the annual operating energy is calculated for five different indoor thermal climates. The demanded operating energy, as well as the airflow volumes that correspond with the various thermal climates, are estimated by the software application ‘The heat balance of buildings’ [2], known as BV^2, which is a software commonly used in the design practice in Sweden. The different requirements on thermal quality (TQ) are summarized in Table 1. The TQ1, TQ2, and TQ3 criteria represent requirements that are frequently used in Sweden; the more extreme requirements are represented by TQmin (low requirements) and TQmax (high requirements).

Table 1. Criteria for the thermal indoor climate used in the analysis

Criteria for the indoor thermal climate	t_{air}		
	Minimum	Set point	Maximum
TQmax	20 °C	21 °C	22 °C
TQ1	23 °C	24,5 °C	25,5 °C
TQ2	22 °C	24,5 °C	26,5 °C
TQ3	21 °C	24,5 °C	28 °C
TQmin	20 °C	24,5 °C	35 °C

The buildings and the air-conditioning systems

The systems included in this analysis are designated as a bore-hole based system, a traditional system, an air-and-water system, and an all-air system. The bore-hole based system and the traditional one are alternatives designed for the same building designated as *Medicinaberget*. This three-storeyed building, detailed described in Heikkilä [3], has a total net area of 1920 m^2, which is divided into cell offices. The air-and-water and the all-air systems are alternatives for another office building known as *Arendal*. This building is six-storeyed, and the total area of 17 000 m^2 comprises an office landscape with work places of 12 m^2; for more details, see Heikkilä and Fahlén [4]. Both buildings are situated in Göteborg, Sweden.

In the *bore-hole based system*, the heat surplus is lead off from offices by an all-air system that comprises an air-handling unit and an air-distribution system. This system is controlled by a variable airflow volumes (VAV) control strategy, and operates for 11 hours (7 am to 18 pm) each working day, 5 days a week. The cooling energy is supplied by a bore-hole based heat pump system, which supplies 33 % of the cooling energy required. The rest of the cooling energy is supplied by free cooling directly from the ground.

The *traditional system* includes an air-handling unit and an air distribution system, of the same size and composition as the bore-hole based system, but the cooling energy is supplied by a vapour compression chiller. The chiller is designed to cover the whole cooling loads. The operating time and control strategy are the same as in the bore-hole based system.

The *air-and-water system* consists of an air-handling unit, a vapour compression chiller, an air distribution system and a water distribution system. The operating energy is determined for a constant airflow volume (CAV) operation, but with differentiation between the airflow volume during the night and during the day. The CAV strategy is chosen taking into account the limitation of the program that does not enable VAV operation for an air-and-water system.

Similarly, the *all air system* contains an air-handling unit, a vapour compression chiller and an air distribution system. The operating energy is determined for VAV control strategy.

The environmental evaluation

The environmental performance of the systems is evaluated by the life cycle assessment (LCA) method, taking into account the whole life cycle of the system: the production, the user, as well as the disposal stages. The impact assessment is performed by the weighting methodology EPS 2000 default method [5]. For purposes of this analysis, however, the results are normalized with respect to the environmental impact of the all-air system for *Arendal* that affects the environment with the highest environmental burden among the four systems studied.

The environmental performance is studied for two different scenarios:

In *Scenario A*, the specific fan power (SFP) factor is the same for all variations of the indoor thermal criteria; the SFP factor describes the efficiency of operation of fans and is given in kW/(m^3/s). The size of the air-handling unit in this scenario changes with each TQ class due to the various airflow volumes required. In *Scenario B*, the desired indoor thermal climate is met by operation of the same size of air-handling unit originally designed for the TQ2 class; i.e. the SFP factors in this scenario vary with the different airflow volumes required in the various TQ classes. Table 2 summarizes the demanded airflow volumes for the four systems included in this analyses that correspond with the various TQ classes.

Table 2. The airflow volumes of the four different systems that correspond with the various TQ classes

Criteria for the indoor thermal climate	Design air flow volume l/(s.m^2)				
	Bore-hole based system	Traditional system	Air-and-water system		All-air system
			Night	Day	
TQmax	4,5	4,5	1,6	2,3	5,4
TQ1	2,8	2,8	1,6	2,3	3
TQ2	2,5	2,5	1,6	2,3	2,7
TQ3	2,1	2,1	1,6	2,3	2,3
TQmin	1,2	1,2	1,6	2,3	1,2

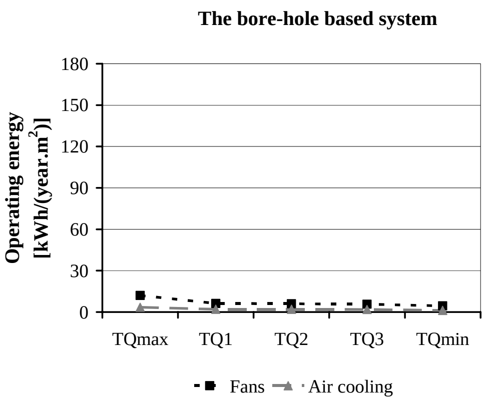
The environmental evaluation of the bore-hole based system and the traditional one is based on results of the LCA study described in Heikkilä [3]. The environmental performance of the air-and-water system and the all-air system refers to the study of Heikkilä [6] which, for the purposes of this analysis, was complemented with environmental impacts related to the disposal stage since the original case does not include this phase. Furthermore, *Scenario A* implies that the size of air-handling system varies for the various TQ criteria. The environmental impacts related to the various sizes are modified (enlarged or reduced) in accordance with the ratio of the actual system to the system from the reference case. The reference size of the air-handling units is that originally designed for the for the TQ2 class.

RESULTS

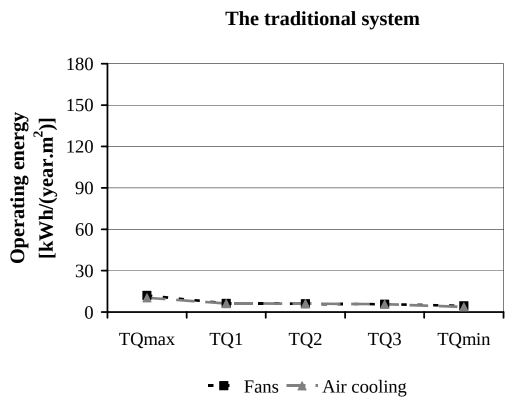
Operating energy of the various systems

Figure 1 shows the variation of operating energy of the four systems with the different TQ criteria in *Scenario A*; i.e. the SFP factor is the same for all TQ criteria.

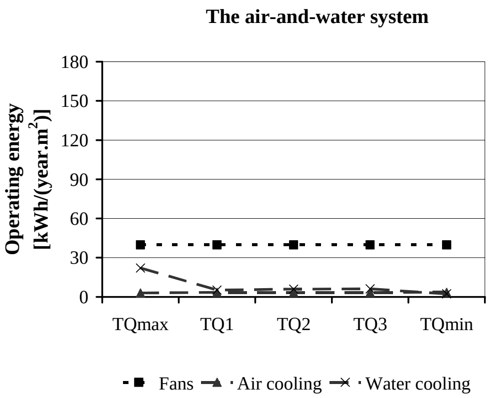
Basically, the range of the variations of the total operating energy for fans, air- and water cooling varies with the different systems. For all TQ classes, the total demand of operating energy for systems in *Medicinaberget* is small compared to the systems in *Arendal*, mainly due to the efficiency of fans operation. Fans are the main users of the operating energy in all systems. The systems in *Medicinaberget* work in accordance with SFP of 1,1 kW/(m^3/s), the SFP factor for the systems in *Arendal* is 2,5 kW/(m^3/s). The cooling systems are the minor contributors to the total energy use, and the amounts of the required energy are affected by the specific design of each system. For example, the bore-hole based system requires only 1/3rd of demanded energy due to the possibility to use ‘free cooling’ energy directly from the ground, which is not possible in the traditional system.



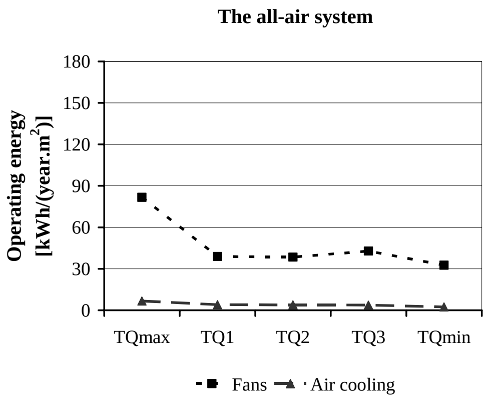
a)



b)



c)



d)

Figure 1. Operating energy of the four air-conditioning systems with the same SFP factor: of 1,1 kW/(m^3/s) for a) the bore-hole based system, and for b) the traditional system; and of 2,5 kW/(m^3/s) for c) the air-and-water system, and for d) the all-air system.

Figure 1 shows, furthermore, the effect of the various thermal climate criteria: the energy demand increases with the higher requirements. The increase is moderate for the usual range of the thermal indoor climate criteria, TQ1 to TQ3, but more marked for the two extreme classes. The most significant increase of energy demand is for operation of fans to achieve TQmax criteria. In *Scenario A*, the SFP factor remains the same for all the TQ classes and systems respectively, therefore, the increased energy amounts are related to the extended operation of the systems, as well as to increased airflow volumes corresponded with the higher TQ criteria (see Table 2). Only the air-and-water system distributes the same amount of airflow volume for all TQ classes since the increasing demand of cooling energy is supplied by the water system. However, the tendency in increase of energy demand with higher TQ classes is different for the all-air system shown in Figure 1d), which requires more energy for operation of fans in TQ3 class compared to TQ2 class. This can be explained by an increased demand of night cooling during the periods of year with the highest outdoor air temperatures, which leads to more extended operation of fans.

Figure 2 presents the operating energy for the different systems calculated in *Scenario B*; i.e. the systems operate with the same size of air-handling unit, which leads to various SFPs. The trend in increase of operating energy with higher requirements on the thermal climate remains also in *Scenario B*, but the increase is more rapid in the TQmax due to the less efficient fan operation. Moreover, the air-and-water system shown in Figure 2 c) operates in both scenarios identically; this system maintains a constant airflow volume in all TQ classes, and the increased cooling demand is supplied by the water cooling system.

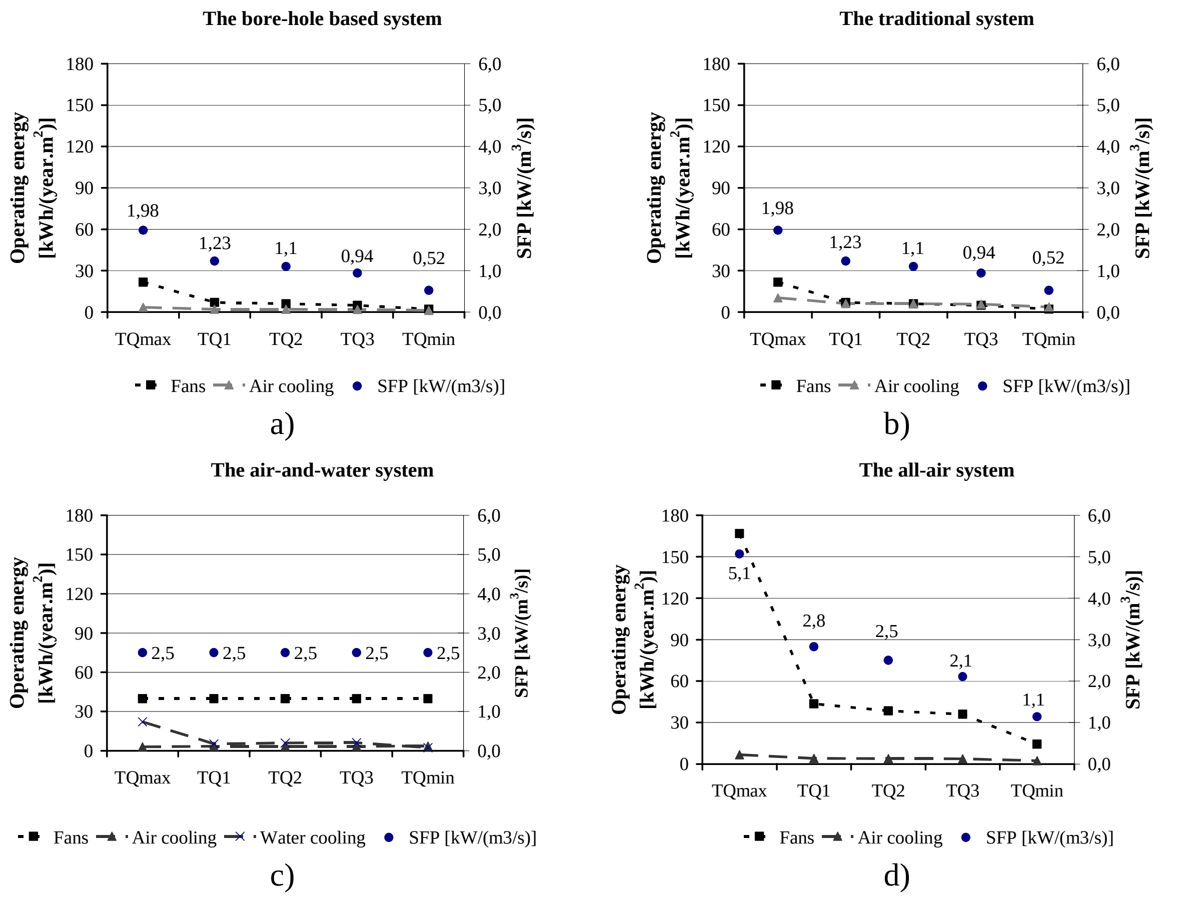


Figure 2. Operating energy of the four air-conditioning systems with various SFPs for a) the bore-hole based system, b) the traditional system, c) the air-and-water system, and for d) the all-air system.

Environmental performance

Figure 3 shows the environmental performances of the four systems in *Scenario A*, i.e. the SFP factor is assumed to be the same for all TQ classes and system respectively. The unbroken line, which is linked to the secondary y-axis, shows the demanded airflow volumes for each of the TQ classes. The total environmental performance of the different systems varies with the type of the air-conditioning system. Also the specific design and the particular preconditions affect the total environmental performance; for example, the total environmental impacts of the alternative systems for *Medicinaberget* is lower compared to the systems for *Arendal*.

For all the systems studied, the total environmental impacts increase with the higher requirements on TQ climate. The increase is moderate within the interval of TQ1 to TQ3 classes, but more rapid for the TQmax and TQmin classes. The operating energy contributes the most to the total environmental impacts as well as to the increasing trend.

The environmental impacts related to the material stage, represented by component materials and EoL treatment, follow the increasing trend for the higher TQ classes. The increase is most obvious for the TQmax class due to the increased airflow volume, with the exception of the air-and-water system that operates with a constant airflow volume for all TQ classes.

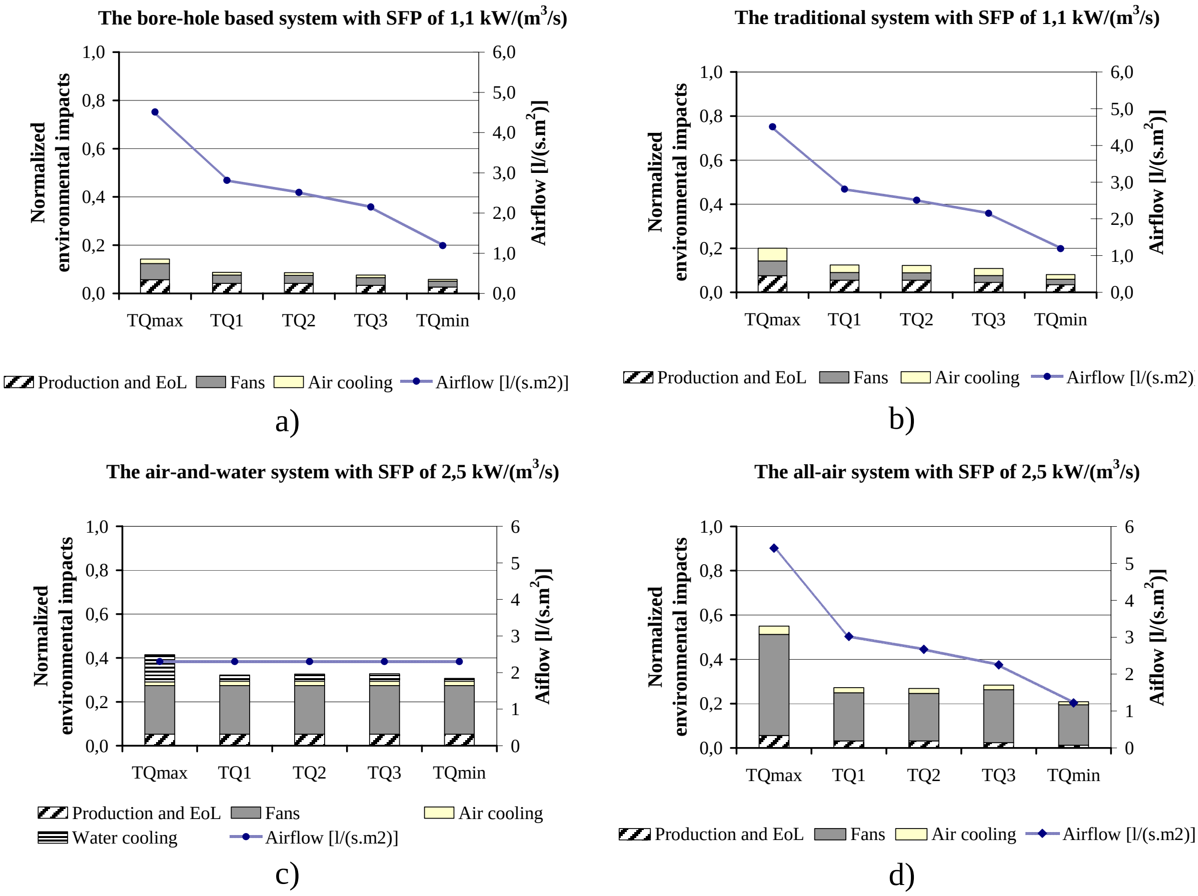

Figure 3. Environmental impacts of the various systems with the same SFP of 1,1 kW/(m^3/s) a) for the bore-hole based system, and for b) the traditional system; and of 2,5 kW/(m^3/s) c) for the air-and-water system, and for d) the all-air system.

However, the proportions between the contribution of the materials stage and the user stage to the total environmental impact differ for the alternative systems in *Medicinaberget* and *Arendal*. In the alternatives for *Medicinaberget*, in the bore-hole based and the traditional systems, the material stage contributes with 38 to 45 % (see Figures 3 a) and b)). These systems are designed taking into account specific requirements on a low energy use to maintain the desired indoor climate; especially, the bore-hole based system can be considered as an exceptionally energy efficient system. The average total environmental impact of these systems is about 50 to 65 % lower compared to the systems designed for *Arendal* which are more traditional air-conditioning systems. The corresponding contribution of the material stage of *Arendal* systems, the air-and-water and of the all-air systems, is 6 to 17 %, see Figure 3 c) and Figure 3 d).

Figure 4 presents the environmental performance of the four systems in *Scenario B*; i.e. the systems operate with the same size of air-handling unit in all TQ classes which leads to different SFPs. Also in this scenario, the trend in increase of environmental impacts with a higher TQ class remains, but it is more marked especially for the all-air system, see Figure 4 d). For all systems, the highest environmental impact is related to TQmax class. The main contributor to the environmental impact is the user stage as a result of a less efficient fan operation; for the SFP factors see Figure 2.

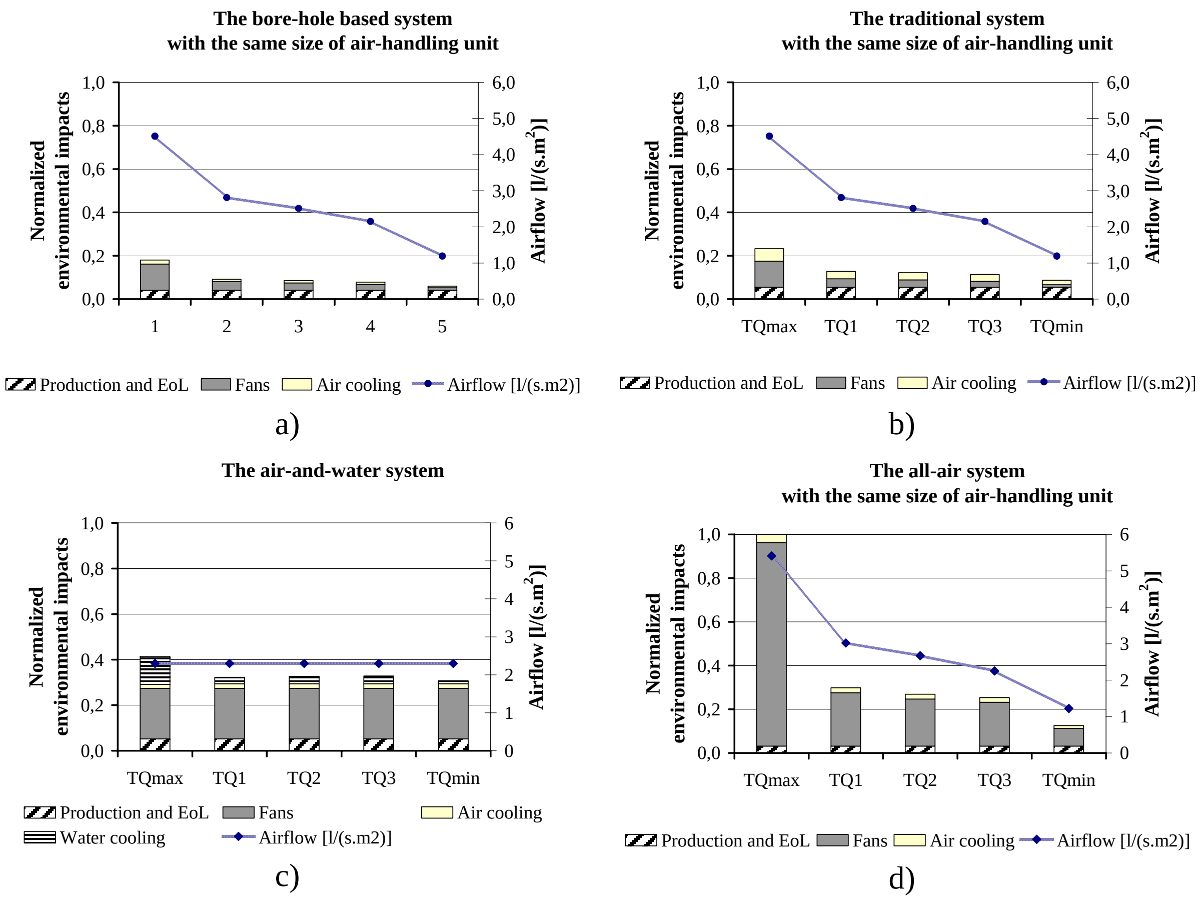

Figure 4. Environmental impacts of the various systems with various SFPs for
a) the bore-hole based system, b) the traditional system;
c) the air-and-water system, and for d) the all-air system.

The difference in contribution of the materials stage to the total environmental impacts between the systems designed for *Medicinaberget* and those for *Arendal* is even more marked in the *Scenario B*. For example, for the TQmin to TQ1 classes, the material stages in *Medicinaberget* systems contribute with 50 % in average; in *Arendal* systems, the corresponding contribution is about 15 %. The environmental performance of the air-and-water system is the same as in *Scenario A*. In both scenarios, this system operates with the same conditions for each of the TQ classes.

DISCUSSION AND CONCLUSIONS

In this study, the environmental performance of four types of air-conditioning systems was investigated, as well as their environmental performance in relation to various indoor thermal climate criteria. Table 3 presents the total normalized environmental impacts (EI_{Norm}) for the various TQ classes, and the corresponding SFPs. The results are based on several assumptions for the estimation of operating energy, as well as of the environmental performance. However, the same assumptions were made in all cases; more refined assumptions would, therefore, have only negligible impact on the proportions of the results.

Based on the results, the following observations can be made: for each of the different systems, there is not a significant difference in environmental impacts within the range of TQ1 to TQ3 criteria. The various TQ criteria affect significantly the amount of the demanded operating energy; the effect on the material stage is moderate. However, each decrease of the environmental impacts related to the material stage, however, contributes positively to the total environmental performance of all systems. The results, moreover, indicate that within the range of TQ1 to TQ3, the SFP factor could be used as an indicator of the predicted environmental performance. As shown in Table 3, the environmental performance within this range does not vary significantly. For TQmin and especially for TQmax, the environmental performance can differ more compared to the range of the most usual TQ requirements. To keep the environmental impacts as low as possible, it is not recommended to use a SFP factor higher than 2,5 kW/(m^3/s).

Table 3. Normalized environmental impacts (EI_{Norm}) of the four systems studied for various TQ classes in *Scenario A* and *Scenario B*

	Bore-hole based system		Traditional system		Air-and-water system		All-air system	
	SFP	EI_{Norm}	SFP	EI_{Norm}	SFP	EI_{Norm}	SFP	EI_{Norm}
	[kW/(m^3/s)]	[-]	[kW/(m^3/s)]	[-]	[kW/(m^3/s)]	[-]	[kW/(m^3/s)]	[-]
Scenario A								
TQmax	1,1	0,14	1,1	0,2	2,5	0,41	2,5	0,55
TQ1	1,1	0,09	1,1	0,12	2,5	0,32	2,5	0,27
TQ2	1,1	0,09	1,1	0,12	2,5	0,33	2,5	0,27
TQ3	1,1	0,08	1,1	0,11	2,5	0,33	2,5	0,28
TQmin	1,1	0,06	1,1	0,08	2,5	0,31	2,5	0,21
Scenario B								
TQmax	1,98	0,18	1,98	0,23	2,5	0,41	5,1	1
TQ1	1,23	0,09	1,23	0,13	2,5	0,32	2,8	0,3
TQ2	1,1	0,09	1,1	0,12	2,5	0,33	2,5	0,27
TQ3	0,94	0,08	0,94	0,11	2,5	0,33	2,1	0,25
TQmin	0,52	0,06	0,52	0,09	2,5	0,31	1,1	0,13

The results presented in this paper do not diverge from the results of previous studies of the author [1]. The highest criterion, TQmax, implies the highest environmental impact. The requirements on the indoor climate should, therefore, be established at appropriate levels to reflect the real demand in each particular case, taking into account the environmental performance of the air-conditioning system. Communication of the environmental consequences of the desired indoor climate to the commissioner of a building project or future owner is also essential.

SUMMARY

The paper describes an approach to calculate primary energy demands for air conditioning systems. These values are not attached to specific types of air conditioning systems but to the use of the air conditioned space. In a first step the minimum for the primary energy demand is calculated on the basis of ideal thermodynamic processes. In a second step an analogue calculation is being made for real processes. A comparison between both shows the range of possible primary energy demands. From that a fixed value can be derived for future limitations of the primary energy demands of designed air conditioning systems, which has to be proved during the approval design.

INTRODUCTION

The “Energy Performance of Buildings Directive” (EPBD) requires an energetic evaluation of buildings and their technical systems. In Germany, an “Energy saving directive” exists since 2002 for buildings and heating systems including domestic hot water systems. This directive follows former legal limitations, which were first introduced in 1976.
New aspects in EPBD are the air conditioning systems and the lightning systems.
This will be a legal requirement for the design and building approval. During the approval design of VAC-system a calculation has to be done for the energy demand of the designed system and that then has to be compared with legally given maximum values for the demand. In Germany, these maximum values are given by the new “Energy saving directive”. This regulation is based on the German Standard DIN V 18599. The maximum values insofar are derived by a “reference-building method”.
For the evaluation of the energy demand of VAC-Systems exist so far no appropriate technical rules. In order to force energy conservation, a limitation of the energy requirement for VAC-systems is necessary.
The research project shows by an example a new way to get energetic characteristic values to evaluate the energy demand of VAC-systems.

METHOD

Ideal Thermal Processes

For each case, there is one defined theoretical process for the VAC-system. This process has the minimum energy demand. It is called the ideal process. Figure 1 shows a psychrometric chart with a set point area for the supply air temperature and humidity. This set point area (S) was transformed out of the room conditions, considering the loads.

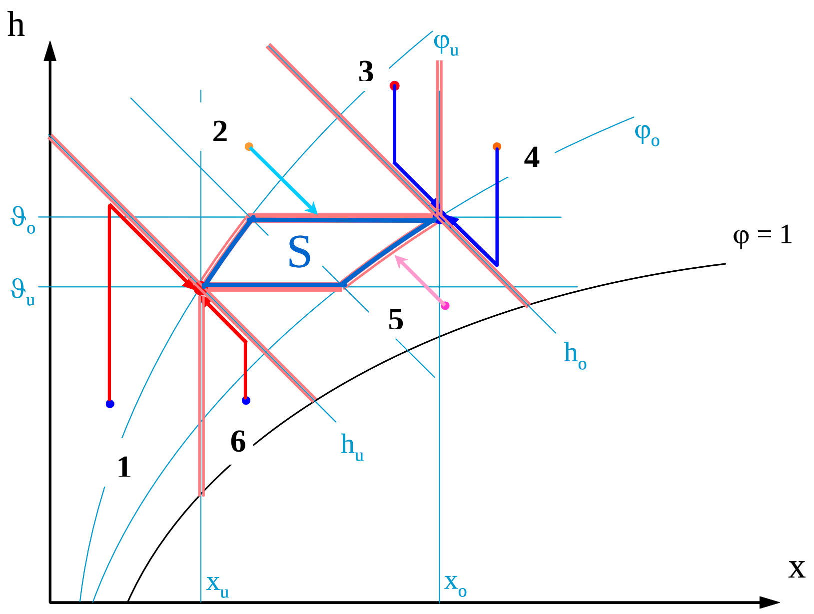

Figure 1: Ideal thermal process

For each outside air condition there is one way to this set point area with minimal energetic effort, neglecting whether this is technically possible nowadays. Within the ideal process, the following thermodynamic processes are possible:

- heating with constant absolute humidity
- cooling with constant absolute humidity
- isenthalpic humidification
- isenthalpic dehumidification.

Using one or a combination of these processes it is possible to get to the boundary of the set point area with a minimal enthalpy difference [1]. These ways are also shown in Figure 1. Each condition is described by:

- air temperature
- relative humidity
- enthalpy
- absolute humidity

where u indexes the lower end of the set point area and o the upper end.

The individual thermodynamic processes have to be applied under the following conditions:

S: no conditioning
1: heating plus isenthalpic humidification
2: isenthalpic humidification
3: cooling plus isenthalpic humidification
4: cooling plus isenthalpic dehumidification
5: isenthalpic dehumidification
6: heating plus isenthalpic dehumidification

For the above conditions, it is possible to calculate the enthalpy difference for each outside condition. The integral of these differences over one year gives the yearly accumulated enthalpy differences H_H and H_K for heating and cooling.

$$H_{H,\,ideal} = \int_a (h_u - h)dt \qquad \forall h < h_u\,, \tag{1}$$

$$H_{K,\,ideal} = \int_a (h - h_o)dt \qquad \forall h > h_o\,. \tag{2}$$

Multiplied with the appropriate primary energy factor f and the air mass flow $\dot{m}$ this gives the yearly primary energy demand

$$Q_{a,th,ideal} = \dot{m}(H_{H,ideal} \times f_H + H_{K,ideal} \times f_K) \tag{3}$$

and related to a floor space A_F

$$q_{a,th,ideal} = \frac{Q_{a,th,ideal}}{A_F}\,. \tag{4}$$

Ideal Air Transport

It is not possible to define a theoretical minimum analogue to the thermal one for the air transport. Therefore assumptions have to be taken. These are shown in Table 1. The assumption is, that we have a minimal pressure drop over the necessary components but no pressure drop in the duct system, resulting in an overall pressure drop Δp .

Table 1: Ideal Air Transport

components	**pressure drop in Pa**	
	supply air	**extract air**
filter	120	120
heating coil	10	-
cooling coil	20	-
humidifier	2	-
attenuator	12	10
heat recovery unit	80	80
sum air handling unit	**244**	**210**
air duct	0	0
sum system	**244**	**210**

Furthermore it is assumed, that the fan has an efficiency η of 1.
The resulting yearly primary energy demand then is

$$Q_{a,el,ideal} = \frac{f_{el}}{\rho}\int_a \left(\frac{\dot{m} \times \Delta p}{\eta}\right)dt \tag{5}$$

and related to the floor space A_F

$$q_{a,el,ideal} = \frac{Q_{a,el,ideal}}{A_F} \tag{6}$$

The total primary energy demand for the ideal process related to the floor space then is

$$q_{a,ideal} = q_{a,th,ideal} + q_{a,el,ideal}\,. \tag{7}$$

Real Thermal Processes

Each case for an air conditioning system can be dealt with by various different types of systems, for example for a system as shown in Figure 2 different heat recovery, different humidification, different control strategy etc. Figure 3 shows one example for such a real process. This real process takes into consideration the enthalpy-humidity-characteristics of the real apparatuses assumed, but each modelled for ideal behaviour. In the shown case it is assumed to have a recuperative heat recovery, an air washer and a direct humidification control.

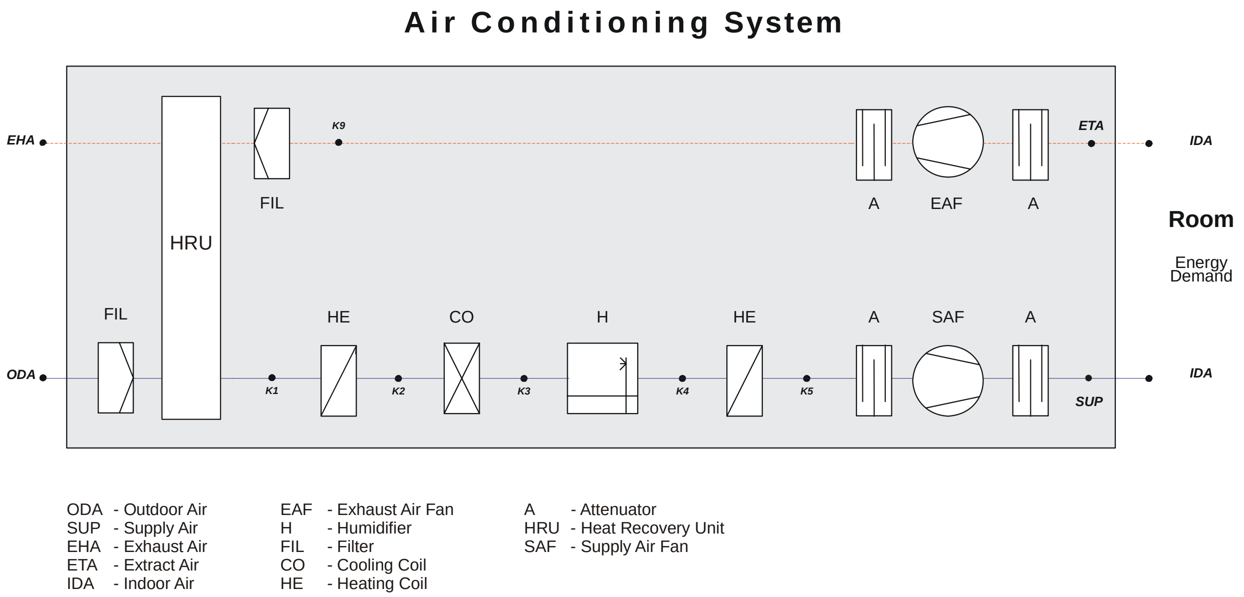

Figure 2: Real Air Conditioning System

Analogue to the calculation for the ideal process, the accumulated enthalpy differences, the absolute and the related primary energy demand can be calculated.

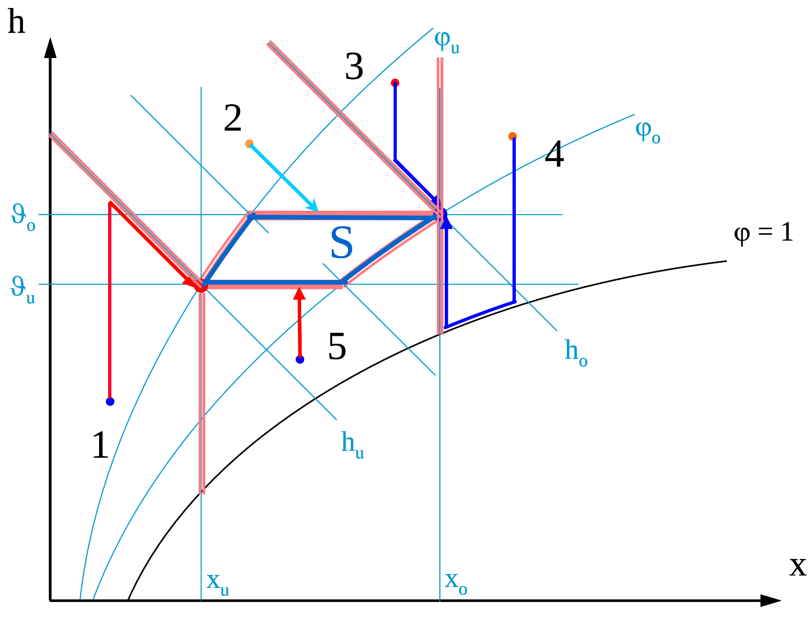

Figure 3: Real Thermal Process

Real Air Transport

Table 2 shows the range for real pressure drops on components and duct systems for typical German VAC-systems. These are the basis for the calculation of the primary energy demand for the air transport of the real systems.

Table 2: Real Air Transport

components	pressure drop in Pa					
	supply air			extract air		
	min.	common	max.	min.	common	max.
filter	120	149	200	120	149	200
heating coil	10	77	160	-	-	-
cooling coil	40	186	400	-	-	-
humidifier	15	134	300	-	-	-
attenuator	40	61	100	40	61	100
heat recovery unit	80	192	370	80	192	370
sum air handling unit	305	799	1530	240	402	670
air duct	250	643	1800	200	607	1500
sum system	555	1442	3330	440	1009	2170

The total energy demand for the real system then is the sum of the thermal plus the air transport demand.

Values for the limited Primary Energy Demand

The calculation of the energy demands for various real systems gives an idea for the range of energy demands for a specific use of a space. The quality coefficient g gives an energetic evaluation for each specific system related to the ideal process:

$$g = \frac{q_{a,\,real}}{q_{a,\,ideal}}. \quad (8)$$

A calculation of this quality coefficient then uncovers one problem. The ideal primary energy demand does not take into account any energy recovery. Because energy recovery is good practice in Germany, it is pragmatic to calculate a quality coefficient g^* on the basis of corrected ideal primary energy demand $q^*_{a,ideal}$ for which we decided to take into account a controlled recuperative heat recovery system, with a maximum recovery rate of 0,85.

$$g^* = \frac{q_{a,\,real}}{q^*_{a,\,ideal}}. \quad (9)$$

The evaluation of air conditioning systems follows the development of requirement, described in German Standard VDI 2067 [2], from the building with its envisaged use and the loads which arise from this and the climate, through benefit transfer (heat, cooling, conditioned air etc.), distribution and to the heating and cooling generation system. Since none of these subsystems – benefit transfer, distribution, generation – can be achieved perfectly, an additional energy effort occurs in each case.
This together with the typical reference energy requirement for the building and its use gives the total energy requirement applicable to the generating system. Figure 4 shows the requirement development in buildings.

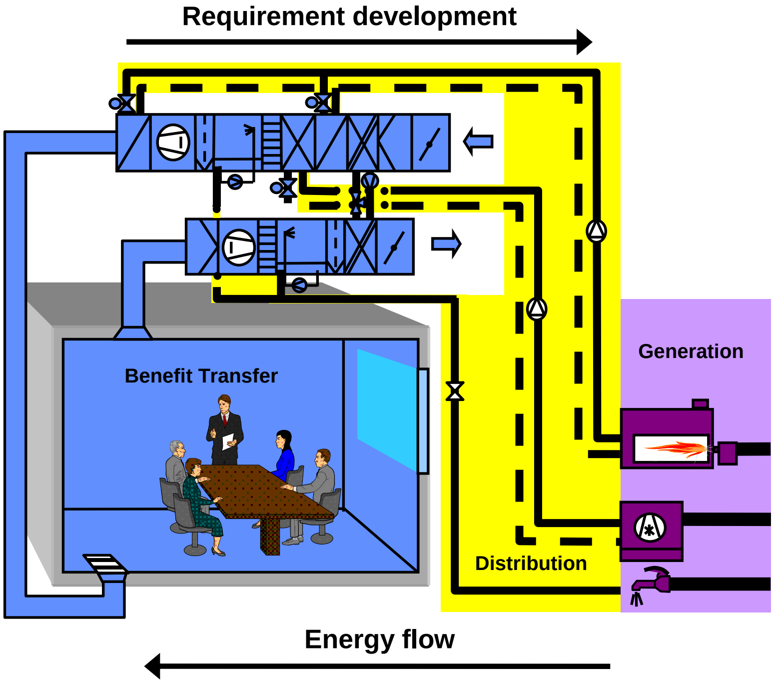

Figure 4: Requirement development (from VDI 2067)

The subsystems of benefit transfer are defined as followed:

- Air handling
- Air transport
- Air conditioning

To evaluate air conditioning systems in this research project only the subsystems air transport and air conditioning are discussed.
In a first step the Reference energy requirement of the room and its use has to be calculated. This value is the input for the requirement development and the energy demand of the benefit transfer than is calculated in a second step. The energy demand here is electrical energy, heating and cooling energy. It has to be evaluated by primary energy factors to compare the different types of energy.
The primary energy demand is a sum of electrical energy for the air transport and thermal energy for the air conditioning like described before.

EXAMPLE AND RESULTS

The paper shows the evaluation method on a typical example for the use of air conditioning systems. We choose here as an example a typical office room with the geometrical details shown in Figure 5. The typical use of the office space is described in Table 3 including all information about set point conditions, weather data, infiltration and the use.

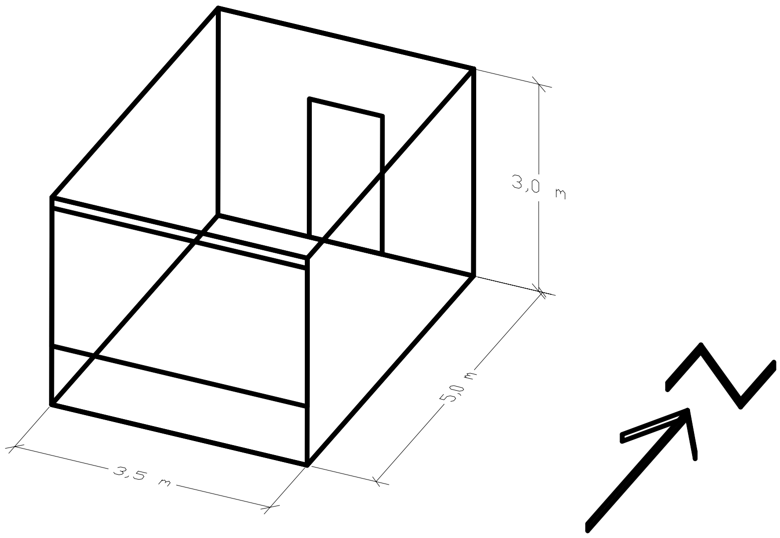

Figure 5: View of the Office Room

Table 3: Example case: Office Room

Utilisation	Standard office from VDI 2067-11, medium-heavy building			
Size	L x W x H = 5m x 3,5m x 3m, A_{window} = 7m²			
Orientation	South, clouding factor b = 0,5			
Weather Data:	Test Reference Year: TRY05			
Utilisation Time	Mo – Fr: 7:00 – 17:00	t_{util} = 2607 h		
Operation Time	Mo – Fr: 6:00 – 18:00	t_{op} = 3129 h		
Requirements	Summer Time:	$\vartheta_{Ra,o} \leq 26°C$	$\varphi_{Ra,o} \leq 65\%$	
	Winter Time:	$\vartheta_{Ra,u} \geq 22°C$	$\varphi_{Ra,u} \geq 45\%$	
Internal Gains		**Heat Gains**		**Substance Gains**
		Convection [W]	Radiation [W]	Humidity [g/h]
	1 Person	50	25	60
	1 Personal Computer	117	23	0
	Ligting (10 W/m²)	70	105	0
	2 Plants	0	0	30
Infiltration	$n = 0{,}2\ 1/h$ is equivalent to $\dot{m}_{inf} = 52{,}5\ m^3 \times 0{,}2\ 1/h = \underline{\underline{10{,}5\ m^3/h}}$			

Figure 6 shows calculated quality coefficients g^* for an office space, with design parameters as given in Table 3.

It can be concluded, that real systems for that purpose show quality coefficients in the range of **2,9…13,2.** The examples shown are pretty good types of systems, because they have up to date energy recovery and direct control. Thereby a decision can be taken to limit future systems to those showing a quality coefficient for example up to **9,5**.
If in the future any new type of system may be invented, it is only necessary to change the maximum quality coefficient for a specific use of a space.

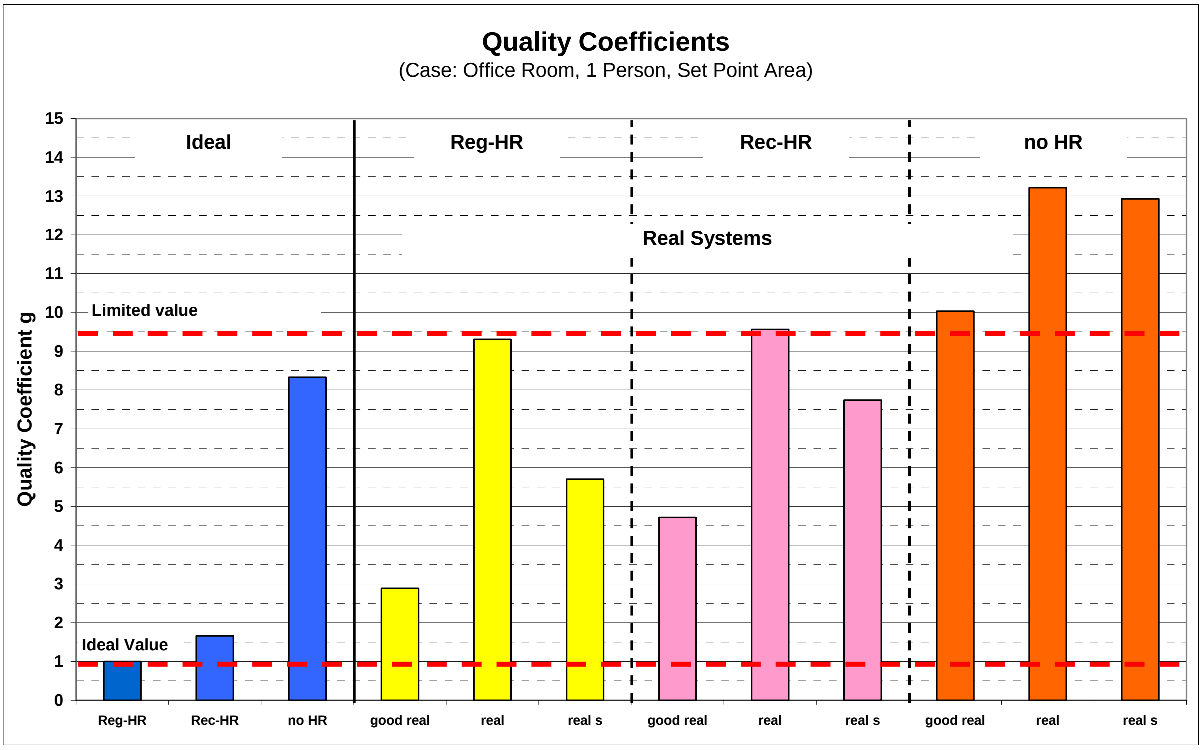

Figure 6: Quality Coefficients for an Office Room with 1 Person

DISCUSSION

It is shown, that by the developed method, values for limited energy demands for VAC-systems can be derived. The method does not take into account any designed specific type of VAC-system, i.e. it does not benchmark a designed system.
The derived limitations are based on the size and the use of the space.
This method should be considered for future application in general to implement a legally given energy demand for VAC-systems.

ACKNOWLEDGEMENT

The project was supported by Arbeitsgemeinschaft industrieller Forschung (AiF-Nr. 13975N). We thank for that.

SUMMARY

Thermal comfort has always been an ambiguous concept. Any public policy has to understand and respect first the functionalities demanded by the user for equipment and space, and establish the link between those expectations and environmental objectives. Premature judgment would lead to problems when coming to public policies aiming to regulate HVAC. Using fans and moving air in a room is a way people may choose to improve their individual Summer comfort. This study characterized the benefits of comfort fans in term of comfort in summer and investigated if comfort fans could be a real alternative to compressor based systems in France.
By using experimental measurements of air speed along with building simulations with free temperature and humidity evolution, it was made possible to access inside climatic conditions when using a comfort fan. An optimized approach was then defined to describe comfort fan operating and compute the electric consumption. For the purpose of assessing the benefits of fans in terms of comfort and comparing it to air conditioners, a discomfort index based on Fanger indices was defined. It appeared that occupants using comfort fans would face about 10% of discomfort hours during occupation and that comfort fans can suppress about 60% of discomfort by consuming four times less energy than a split system.

INTRODUCTION

In Europe, some environmental agencies and associations consider compressor based air conditioning as useless energy consuming appliances and promote environmentally friendly cooling products without compressors. Considering that public policies have to understand and respect first the functionalities demanded by the user for equipment and space, and establish the link between those expectations and environmental objectives, this study aims to characterize the benefits in term of summer comfort of the air movement created by a comfort fan in French climates. The conditions in which ventilation can provide a reliable level of comfort and can be an alternative to compressor based cooling systems are investigated. After defining and presenting general concepts of comfort fans, a literature review is proposed regarding fans, comfort and energy savings.

Comfort fans

Using fans and moving air in a room is a way people can choose to improve their individual summer comfort. Air moving appliances aiming at cooling people like desk fans, pedestal fans or ceiling fans will be called “comfort fans” in this study. By generating air movement close to the body, comfort fans increase convection and evaporation and by this way individual summer comfort without lowering the room temperature. In fact, the inside temperature is even likely to increase since the comfort fan motor generates heat.

Comfort fans and thermal comfort

Numerous human thermal comfort studies have been carried out to analyze and quantify the positive and negative effects on thermal comfort of air flows and in particular of airflow due to comfort fans. As in ASHRAE standards [1], thermal consequences of air movement in cold ambiances that cause drafts and local discomfort have been often emphasized. This does not form a part of this study which aims at evincing the potential cooling benefits of air flows in Summer conditions, assuming the local discomfort is avoided.

First of all, potential cooling benefits of air flow in summer are presented in several standards. In the ASHRAE and ISO standards [1] [2], the summer thermal comfort zone is extended by increasing the air speed. For instance, the 2004 ASHRAE standard proposes, in summer conditions, to relate the comfort temperature to the air speed and the difference between the mean radiant temperature and ambient temperature [1]. However, air speed is reduced to very low level (0.8 m/s) in order to avoid disturbance like paper flying and drafts and the elevation of air speed must be adjustable and controlled by affected occupants. This kind of approach consisting in expressing the cooling sensation (temperature rise in °C) of uniform air flow according to the air speed can also be found in many research works like for example those of Szocolay [3].

All this is based on comfort indices developed by Fanger [4]: the PMV ("Predicted Mean Vote") and the PPD (Predicted Percentage of Dissatisfied). These indices mainly depend on six parameters, four ambiance ones (air temperature, mean radiant temperature, air velocity, relative humidity) and two concerning people (physical activity, clothing thermal resistance). In order to predict thermal sensations, Fanger assumed that, in comfort conditions, the human thermal balance must be null which leads to a first formula. It means that the individual exactly looses the heat produced by the metabolism. In addition, Fanger realized experiments in climate chambers to correlate metabolism with mean skin temperature and sweating. In more details, the PMV equation assumes that deviations from the human thermal balance vary with thermal comfort vote. A PMV equal to zero represents the optimum comfort when the thermal balance is null and this index can vary from –3 (cold) to 3 (hot). It is also possible to predict the reaction of individuals thanks to the PPD index that aims at calculating the expected number of thermally dissatisfied people in a group according to the PMV. PMV and PPD are used in several standards where comfort zones are often defined by limiting the PMV between –1 and 1 (ie less than 10% of unsatisfied people according to the PPD). In a further study [5], Fanger stated that the quantitative influence of air velocity is in good agreement with PMV and PPD equations.

Regarding comfort fans whose air flow is not uniform several studied have been carried out based on human experiments. Arens [6] showed that the cooling effect of personally controlled fans was approximately 1°C by 0.1 m/s increment of air speed. This study was carried out under specific factors, mainly air temperature from 24°C to 31°C, activity level of 1.2met (sitting in activity) and clothing equivalent to 0.5clo (summer light clothes). Furthermore, Arens [6] compared his results from experiments to results obtained with Fanger's indexes and found that they were close with a 5% difference. Effects of ceiling fans on the summer comfort zone have also been studied by Roshles [7] in experiments gathering eight subjects. They considered that air movement was pleasant up to 1 m/s at 29.5°C and the turbulence of the flow was a beneficial aspect. A study carried out by Konz [8] aimed at comparing fixed fans with oscillating fans. The exposed subjects preferred oscillating fans to fixed ones. A second set of experiments consisted in exposing the subjects to air movements at different angles to the front of the body. It appeared that angle was not a significant parameter in terms of thermal comfort. Another documented effect of air movement is the human response to the power spectrum of the turbulent airflow provided by a comfort fan. In fact, like other receptors contained in the skin, heat receptors are sensitive to some stimulation frequency ranges and have peak response at certain frequencies. Thus, Oelsen [9] determined that human thermal receptors had a significant peak in response around 0.5 Hz in cool ambiances and related velocities at a 0.5Hz gust frequency to equivalent uniform air speed for identical cooling sensations (discomfort in this case). For example, a mean air speed of 0.4m/s at a 0.5Hz frequency will provide the same cooling sensation as a uniform airflow of 0.6m/s. This kind of experiments has been also processed in hot ambiances where the human thermal response to the cooling sensation of air movement has a significant peak around 0.4 Hz [10].

Comfort fans and energy savings
In the United States, efforts are triggered off to quantify the potential energy savings of comfort fans (mainly ceiling fans) and try to improve their efficiency. Regarding energy savings, simulation studies have demonstrated that using ceiling fans can lead to energy savings or wasting in comparison with air conditioners according to set point chosen by end-users. For example, according to James [11], using ceiling fans combined with raising a home's temperature 1.1°C (2° F) will generate about a 14% net savings in annual cooling energy use (subtracting out the ceiling fan energy and accounting for internally released heat). This savings drops to 2.6% with a 0.56°C increase in set point and to a negative 3.7% savings with only a 0.28°C increase in set point. If the thermostat is not adjusted at all for fan use, cooling energy use may increase by 15%. Comfort fans can theoretically extend the natural ventilation season when the air conditioner is not used, allow for higher thermostat set points when the air conditioner is used and therefore should lead to energy savings. However, James [11] mentions that a survey of 400 households in Florida does not indicate cooling energy savings due to ceiling fans because of inappropriate thermostats settings. It was not investigated if this result could be explained by an insufficient level of comfort provided by ceiling fans. Regarding the improvement of fan efficiencies, ceiling fans have been already studied. For example, Schmidt [12] and Parker [13] have presented new designs of ceiling fans based on the improvement of motor and blade efficiencies.

METHODS

This study aims at assessing comfort benefits and electrical consumption of air moving devices and comparing them to other cooling appliances. From the bibliography previously presented, Fanger's indices (PPD and PMV) appear very relevant to assess the global thermal feeling (without drafts and asymmetries) of individuals and notably to take into account air movement benefits. These indices require a full knowledge of indoor conditions along with information regarding people like clothing or metabolic rates. As a result, the first step consists in simulating a house to define typical indoor conditions. Several sets of simulations have been carried out with different climates and different appliances. Available typical indoor conditions along with characteristics of appliances are treated with Matlab in order to provide the PPD index and consumption all over the summer period. An approach has been defined to calculate and determine the number of discomfort and operating hours for fans.

Simulations
From characteristics of the French building stock and from information of the year 2000 regulation defining energy performance requirements for buildings, a typical house has been defined. This house is supposed to be representative of the up-to-date residential building stock. Main geometrical and thermal characteristics are described in Table 1 and Table 2. In addition, assumed occupant usages are specified (occupation profiles, lighting control, installed equipments), an examples is reported in Table 3. Occupant usages are typical of a French family and are not representative of sedentary people usages (offices, rest-homes).

Table 1. Geometrical characteristics

Total area	136m²
Average Height	2.5 m
Windows-to-wall ratio	7.8% of the vertical area
Living room	34m²
Bedrooms	51m²
Kitchen	17m²
Lavatories	9m²
Circulations	25 m²

Table 2. Main thermal characteristics

Window solar factor	0.6
Light transmission rate of windows	0.6
U value for windows	2.45 W/m².K
U value for external walls	0.6 W/m².K
U value for the roof	0.25 W/m².K

Table 3. Example of occupant usages characteristics in the living room

Nominal occupation	Four occupants
Occupation profile From Monday to Friday	
This two storey residential house has been simulated fist with free temperature and humidity evolution and then with an air conditioner with the ConsoClim software. ConsoClim is an energy calculation software that was developed with the aim of reducing the large amount of inputs as much as possible and using input data which are easily available by designers such as data found in manufacturer's catalogs [14]. Consoclim uses hourly weather data to compute hourly energy consumptions and hourly loads. In this study, climatic files of 1999 are used for three cities: Trappes [48.5N-2.2E]; Rennes [48.1N-1.4W]; Pau [43.1N-0.2W].

Determination of devices characteristics

Airflows of a pedestal comfort fans has been measured by means of a hot-wire anemometer in a 30m² room. Since asymmetries are not taken into account in this study, only a global assessment is needed and air speed average has been computed at given distances from the fan. Some experimental values are presented in Table 4. The consumption has been set to 50 W which is the manufacturer value. It is assumed that when the fan operates, the load has to be increased by 50W due to heat production. Furthermore one comfort fan of this type can ventilate up to two occupants and therefore when a room is occupied by more than two people, additional fan is required. When assessing comfort, the potential speed interval that can be provided by this pedestal fan will be between 1.2 and 3.3 m/s. This means that occupants are located between 0.9m and 1.5m from the fan.

Table 4. Pedestal fan characteristics

Type	Distance to measurement	First speed [m/s]	Second speed [m/s]	Third speed [m/s]	Electrical input
Pedestal fan	0.9m in front	1.8	2.5	3.3	50W
	1.5m in front	1.1	1.6	2.3	50W

In France, air conditioners are often present in only one room of the house. In this study, it is presumed that a Split system is installed in the 30m² living room. This air conditioner has been sized and fills the summer load of this room (the set point is 25°C when the room is occupied). Then existing models were looked for and performances given by manufacturers were used for the simulations. As a result, characteristics are different according to the city. The EER varies from 2.63 to 3.27 that can be considered as energy efficient products in the European market. Main characteristics are given in Table 5.

Table 5. Split systems characteristics

Cities	EER	Nominal frigorific power [W]	Nominal electrical input [W]
Trappes	3.27	2750	840
Pau	2.63	3890	1480
Rennes	3.27	2750	840

Data processing:
This subsection aims at explaining how to assess the comfort obtained with comfort fans and air conditioners over French cooling season in a typical French house. The PPD index is used to assess the comfort feeling. For air conditioner, a temperature set point has been chosen and the PPD is then processed for an air speed of 0.4m/s, a clothing rate of 0.7clo and a metabolic rate of 70W/m² that corresponds to a seated subject in activity or a stand subject at rest.
When it comes to calculate the PPD for the pedestal fan, the problem becomes more complicated since the provided comfort is partial and occupants are considered to adjust their clothing and fan speed to maximize the comfort feeling. An approach to reproduce occupant behaviors has been investigated and programmed with Matlab.
First of all, the PPD calculations depend on the metabolic rate that is set at 70W/m² and on several factors that are provided by building simulations with free evolutions of temperature and humidity: pressure, relative humidity, ambient temperature and mean radiant temperature. Other remaining factors (air speed and clothing) are directly under occupant action and as a result occupant behaviors must be defined to access these values and compute the PPD index. From indoor conditions and air speed of 0.1m/s (no air moving device), the PPD is minimized by selecting the most appropriate clothes that are associated to thermal resistances. It means that occupants are assumed to look for the clothes that generate the best thermal feeling. In a second time, if the reached PPD is higher than 10%, occupants face a discomfort feeling and will try to improve it by switching on the pedestal fan. As a result, if the PPD is higher than 10%, a second minimization is computed by selecting the best fan speed (from 1.1 to 3.3m/s). This 10% value has been chosen to distinguish between comfort hours and discomfort hours because this value has been selected in standards ([1],[2]) to define the thermal comfort zone. To conclude, the obtained PPD is not necessary lower than 10% but it corresponds to the best combining between clothing and ventilating. This approach is an optimized approach since the first optimization relies on clothing and that the comfort fan is not used if a cloth modification is enough to reach a PPD lower than 10% (Figure 1).

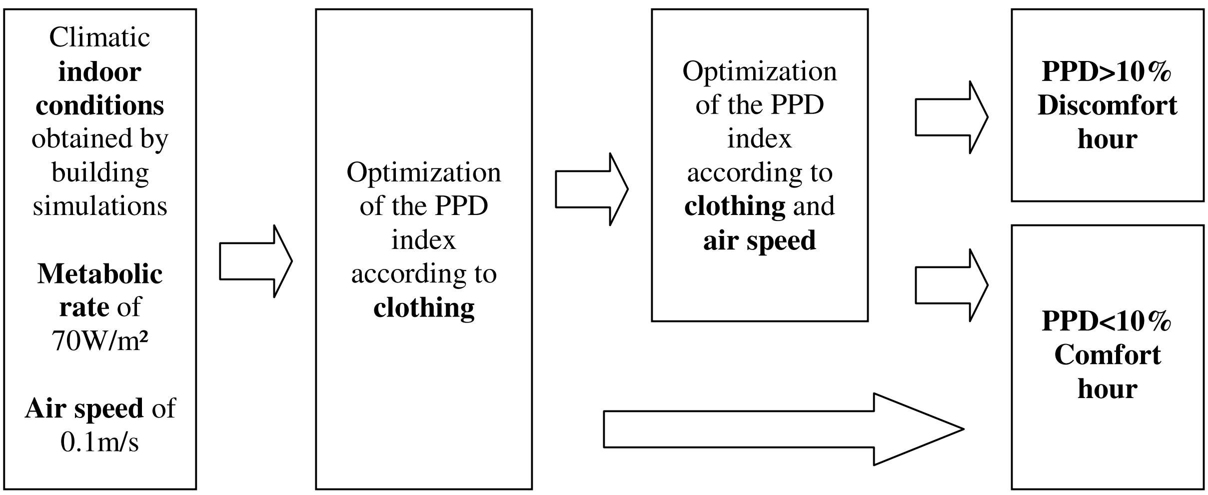

Figure 1. Approach to calculate the PPD index and determine the number of discomfort and operating hours for comfort fans

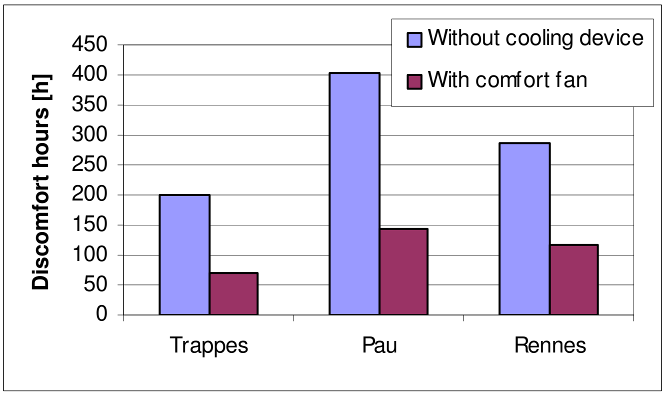
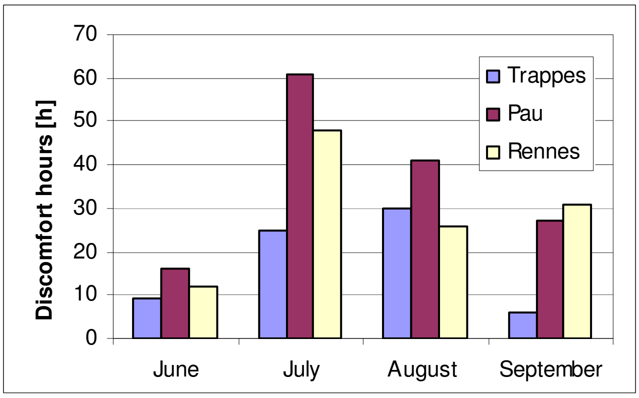
RESULTS

The typical French house previously defined has been simulated for three cities in two configurations: free evolutions of humidity and temperature and air conditioning. Results are given in this section regarding comfort assessment and consumption calculations.

Comfort assessment:
As for international standards, it has been considered that the thermal comfort zone corresponds to a PPD lower than 10% ([1],[2]). Thus, a discomfort hour is defined as an hour during which the calculated PPD is higher than 10%. The number of discomfort hours has been calculated in the three cities (Trappes, Pau and Rennes) for the two types of systems (Split system and pedestal fan) over the summer period from May to September (Figure 2a). When an air conditioner is used, there is no discomfort hour. With a comfort fan, occupants would have to face from 70 discomfort hours in Trappes to 145 in Pau, which correspond respectively to 6.4% and 13.3% of the occupation time. It is also noticed that by using a comfort fan, occupants can reduce the number of discomfort hours by more than two compared with a room without cooling device. With a comfort fan, discomfort hours depend on outdoor conditions and are more present on July and August (Figure2b). Note that French people usually leave for holidays during these two months.



a)



b)

Figure 2. a) Number of discomfort hours over the summer period for every studied city,
b) Number of discomfort hours every month for every studied city by using a fan

Consumption calculations:
The electrical consumption that is often considered as the main environmental impact has been calculated over the summer period for both the pedestal fan and the split system in the three studied cities.

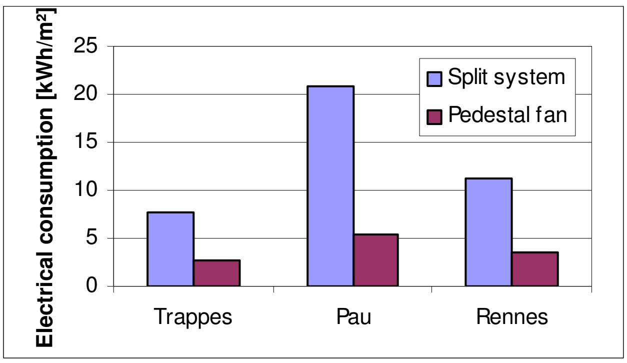


Figure 3. Electric consumptions in the studied cities

The electrical consumption varies from 7.7kW/m² in Trappes to 20.8kW/m² in Pau for air conditioners and from 2.7 kW/m² to 5.5 kW/m² for the studied pedestal fan. In Trappes, a pedestal fan will consume 2.8 times less then a Split system, 3.8 times less in Pau (Figure 3) but both appliances do not provide the same level of comfort.

The benefits of fans in terms of cooling are very dependent on climatic conditions. It turns out that in some cases comfort fans can be considered as good alternatives to air conditioners if occupants are wiling to accept some discomfort hours (less than 15% in the worst cases).

DISCUSSION

The French house previously defined has been simulated for three climates in two ways: free evolutions of humidity and temperature and air conditioning. In order to compare comfort fans to other cooling appliances, the relationship between improvement of summer comfort and consequences in terms of environmental impact is analyzed and a comfort index is proposed for this purpose. Finally, the cost of comfort is used as a second step of unification.

Improvement of summer comfort and consequences in terms of environmental impact

In order to state if comfort fans can be a relevant alternative to compressor based systems for cooling, an analyze of gains in terms of summer comfort and consequences in terms of environmental impact must be done. For this purpose, two different indices must be selected to assess both comfort and environmental impacts. Since the electrical consumption often appears as the main environmental impact, this will be kept as environmental index. In opposition, a unified comfort index is required to compare different cooling solutions. RAC provide total cooling by changing humidity and temperature whereas comfort fans only provide partial cooling by increasing the air speed. An index like the “discomfort degree hours” [15] cannot field this problem since with it a comfort fan is considered as not improving comfort. As a first step of unification, it is proposed to define discomfort as the integral of PPD in respect to a reference value over the summer period (1). In this way, the number of discomfort hours is taken into account along with the amplitude of the discomfort. As for comfort standards, the reference value is fixed to 10%.

$$\mathrm{I} = \sum \int \left[PPD_{occ}(t) - 0.1\right]^{+} .dt \,, \qquad (1)$$

where PPD_{occ} is the PPD index in occupation.

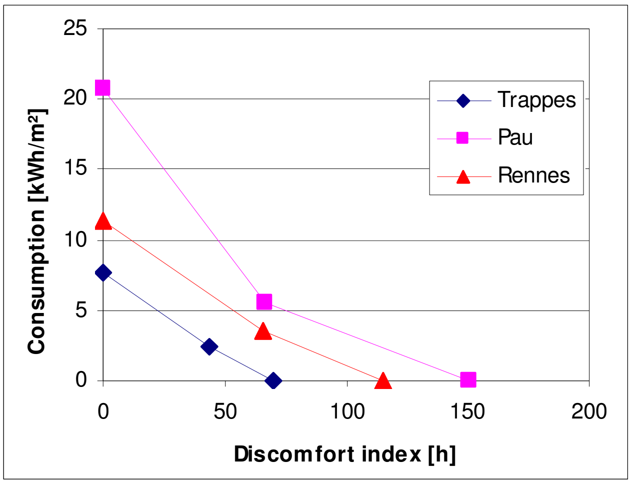

Figure 4. Electric consumption according to the discomfort index in the three studied cities

This index is calculated for three configurations (split system, pedestal fan, no cooling appliance) in the three cities (Figure 4). Results are similar for the three cities, between 40% and 65% of discomfort is suppressed by using a comfort fan. An air conditioner will suppress all of it consuming around 3 or 4 times more energy than a fan.

Comfort cost

As a second step of unification, the cost of comfort has been studied. The concept, presented by Barroso-Krause [15], is based on the acknowledgement that there is a given level of discomfort below which the end-user would try to install or change a cooling system in accordance with what he can afford. As a result, it is relevant to focus on what the costumer has to pay to improve comfort. A raw evaluation consists in only taking into account the purchase cost: 50€ for a fan, 1000€ for a Split system. To assess the gains in comfort, the discomfort index previously defined is used. These gains are defined by device discomfort indices normalized by the index calculated without cooling device. Results are given for the three cities and three configurations (no cooling appliance, comfort fan, air conditioner) in Table 6. Results are similar for the three cities, between 40% and 65% of discomfort is suppressed by spending 50 euros but one have to spend 1000 euros to suppress all of it.

Table 6. Costs according to comfort gains

Cooling devices	None	Comfort fan			Air conditioner
Cities	All	Trappes	Pau	Rennes	All
Gain in comfort [%]	0	37	65	43	100
Cost [€]	0	50	50	50	1000

Methods to compute environmental impact and comfort of fans have been created in such a way that at the end fan performances can be compared to a split system. It appears that occupants using comfort fans would face about 10% of discomfort hours during occupation and that comfort fans can suppress about 60% of discomfort by consuming four times less energy than a split system. In some cases, fans can be considered as good alternatives to air conditioners if occupants are wiling to accept some discomfort hours. Additional simulations should be performed to analyse other cooling appliances (evaporative coolers…) and to study other sectors (office, rest-homes). The discomfort cost should also be computed in a more comprehensive way (electricity bill).

SUMMARY

For the prototype of the local air conditioning of the working places named PERMICS (Personal Microclimate System) the air velocity and turbulence intensity at horizontal air inlets were analyzed. The velocity field was visualized with smoke. Based on findings from visualization the measurements were made with new technology of the hot-wire anemometer named HW3D-ED. Experimental analysis has been supplemented by a numerical simulation of the velocity field on the air terminal device and in the breathing zone using a commercial CFD package, software PHOENICS. Simulation results using three two-equation turbulence models: standard k-ε, RNG k-ε and Chen k-ε model were compared with measurements results. Findings show complex inlet profile at inlets and small difference between measurements and simulations and also between selected turbulence models. Conclusions from visualization, measurements and simulations are need for further simulations with equivalent diameter of the inlet with uniform velocity and turbulence intensity profile to achieve comparable results of the velocity field from simulations with measurement results.

Keywords**:** personalized ventilation, air distribution, horizontal air jet, turbulence models

INTRODUCTION

What is thermal comfort? Thermal comfort is that condition of mind which express satisfaction with the thermal environment [1]. While this definition has its merits, it cannot be easily translated into physical parameters because thermal comfort depends on many parameters (ambient temperature, clothing, body constitution, health, age of individual, activity, lighting, noise in environment, odours, individual psychological conditions, etc.).

The energy crisis of the 1970's was responsible for an approach which emphasized energy savings. The results of such an approach were decreased volume flow rates of fresh air into building and thus worse indoor air quality than before the crisis. At the same time, more and more interior pollutants were making their appearance. New building materials, furniture, laser printers, photocopiers, detergents, as well as people themselves and their activities (odours, respiration, perfumes…) represent numerous sources of pollutants that are potential health risks. Taken together, this can lead to Sick Building Syndrome (SBS) [2].

Studies carried out in Slovenia [3-5] show that people are dissatisfied with the indoor environment, especially in mechanically ventilated buildings [6]. Another finding shows the significance of psychological factors in the evaluation of indoor environment parameters [7-10]. The conclusions gleaned from these studies indicate the need for new, more qualitative systems of ventilation or air-conditioning of the indoor environment. Such systems should have a local inlet of air with the possibility of local regulation of key parameters of thermal environment. We could achieve satisfactory thermal comfort parameters for any subject with such a system and have better air quality at the same time.

Studies show that displacement ventilation is very useful in achieving good air quality, especially when we have heated sources of contaminants [11]. At the same time it could be problematic from the point of view of draught and a large vertical temperature gradient [12, 13]. Analysis has also shown that up to 50% of occupants may still be dissatisfied with the thermal environment and air quality in buildings using displacement ventilation [14]. Nevertheless, local ventilation or local air-conditioning has numerous advantages and can assure good air quality and thermal comfort in the majority of case [15-21].

The concept and development of a system for local air-conditioning of workplaces PERMICS is based on an analysis of other local air-conditioning systems and on measurements from local air cleaning devices [22, 23]. PERMICS is an individual unit for a single work area which makes air distribution possible at the work area and is designed for use in offices with several employees in one room. The PERMICS concept is analogous to creating smaller, separate "rooms" within each work area with individually regulated microclimate conditions. The system is not designed for heating or cooling large areas due to the draught risk from larger amounts of air or lower air temperatures [23]. A sensor could also be mounted for sensing the presence of a person at the desk and it could then regulate the table lamp and close the air inlets of PERMICS. PERMICS is designed to be connected to the central air-conditioning system. There are several methods of connection. A duct with fresh air in a double floor connected to PERMICS by a flexible duct is one possibility. Elements for air distribution are located within the microclimate zone. Figure 1 shows the scheme of PERMICS. An office desk with dimensions 800 x 1600 mm with height 765 mm was supplemented with a partition wall at a height of 800 mm above desk level. The PERMICS duct connecting the system to the central air duct is located on the back side of the partition wall. The duct is then separated into two parts which both lead to the elements for air distribution. The system is hydraulically balanced with a built in trap.

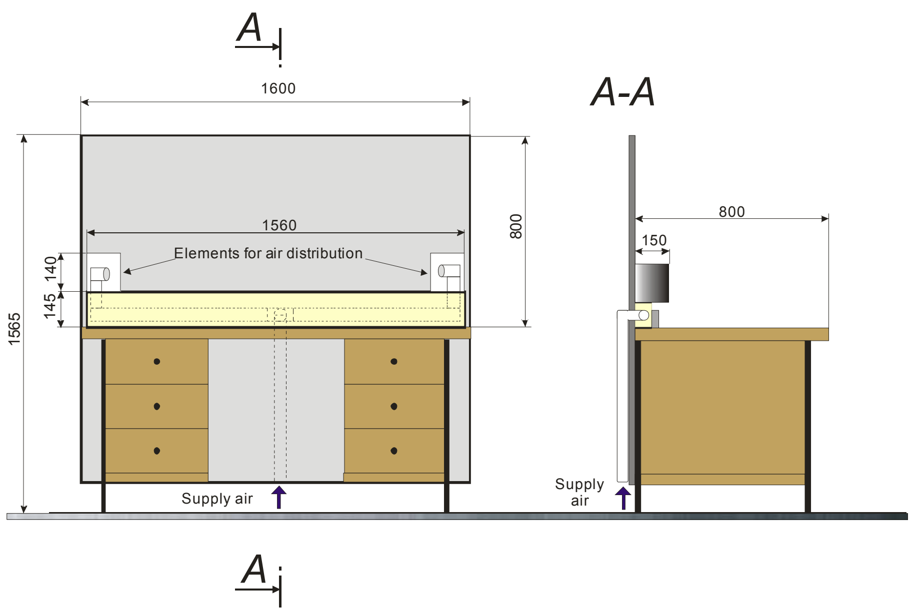

Figure 1: Scheme of PERMICS.

METHODS AND RESULTS

The velocity field at the inlets of PERMICS was visualized with smoke at isothermal inflow of 9.5 l/s of fresh air. Inlet angle of the air distribution element of PERMICS was 45° (Figure 3, right). Line laser was used as source of light. Picture was taken with analogue camera. We found complex inlet velocity profile at the air inlets. Figure 2 shows inlet velocity profile at 6 different times.

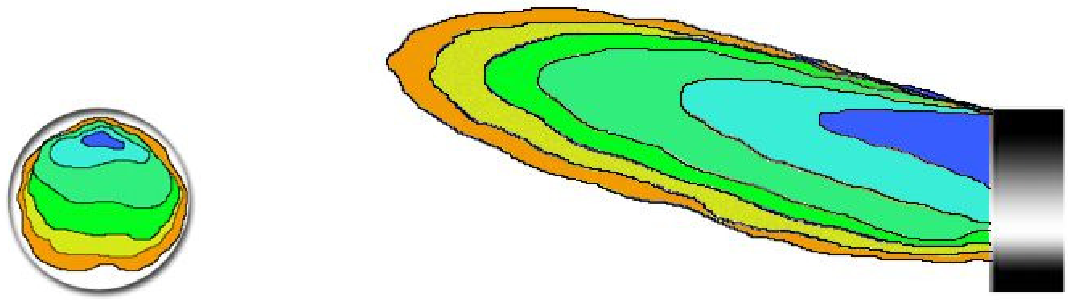

Figure 2: Jet in transverse and in longitudinal section from the visualization.

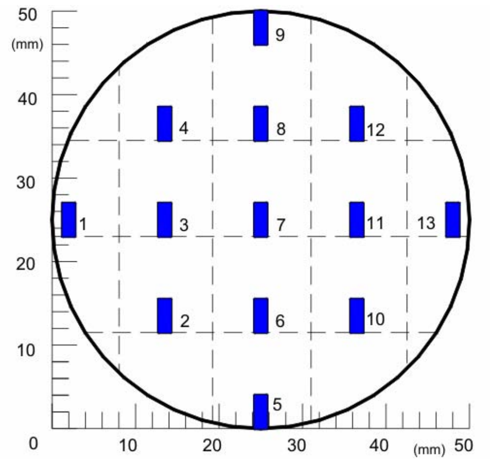
Based on the findings from the visualization the measurements were made with hot-wire anemometer HW3D-ED. The anemometer is result of our research and development. Figure 3 shows 13 defined measurement points at the inlet of PERMICS. Sensor of the anemometer was positioned at least 0.5 mm accurately. This error is not essential for the visualization of the velocity field with Kriging method [24].



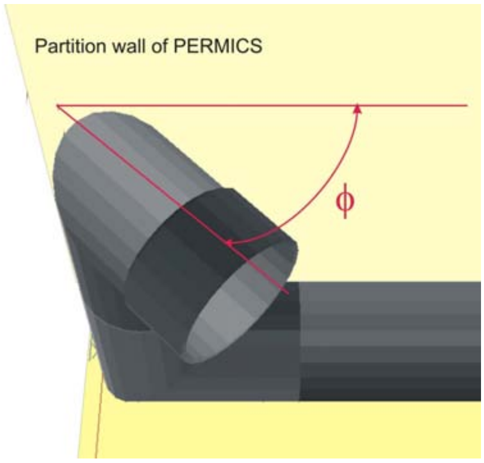


Figure 3: Measurement points at inlet (left) and inlet angle ϕ (right).

Figure 4 (above left) shows measurement results of the air velocity distribution at cross-section of the left air inlet. The results are in accordance with findings from the visualization. We got large gradients of the velocity at the cross-section of the air inlets because of the construction of supply ducts of the PERMICS.

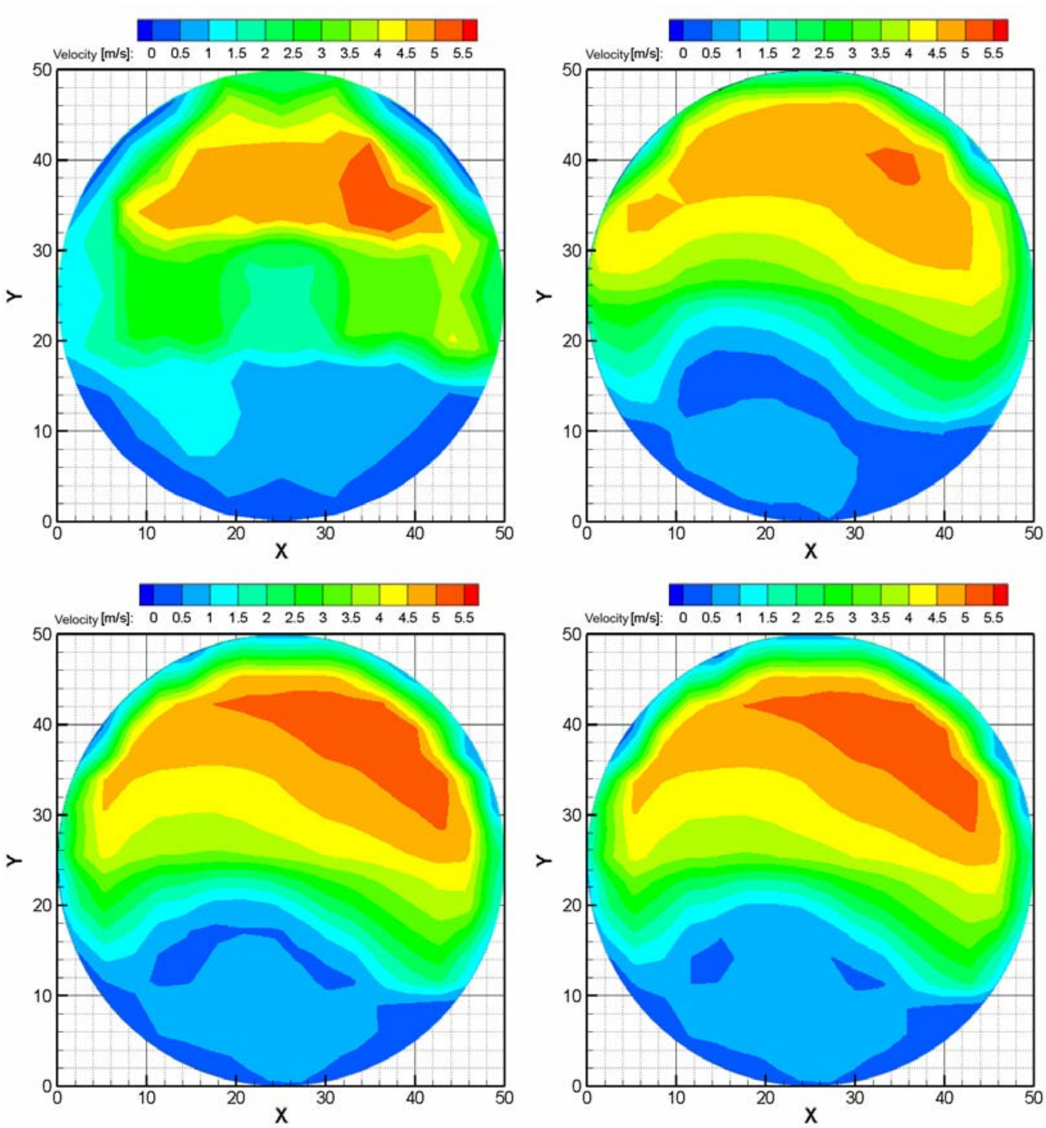

Figure 4: Air velocity distribution at cross-section of the left air distribution element of PERMICS. Above left measurement results, above right results of simulation with standard k-ε model, below left results of simulation with Chen-Kim k-ε model, below right results of simulation with RNG k-ε model.

CFD model was made for the above described setting of the inlets. Adiabatic steady state model of the left air inlet was made with mesh of 76x92x85 cells (Figure 5) and real geometry of the air distribution element and supply duct. Inlet of 4.75 l/s of air with 295K and with 5% turbulence intensity were described at the inlet in the domain (at the straight part of the pipe). Standard k-ε, RNG k-ε and Chen k-ε turbulence model were used for turbulence modeling because of the NOKFOS principle (NObody Knows FOr Sure) [25]. Figure 4 shows measurement and simulation results of the velocity distribution at the left air inlet of PERMICS. There is very accurate prediction of the velocity distribution from the simulation irrespective of chosen turbulence model. Turbulence intensity from simulations was also compared with the measurement results. There are no big differences in prediction between selected models, but all models have higher prediction of turbulence intensity than was measured out. This verification shows that numerical model could be used for optimization of the inlet angle of the air distribution element.

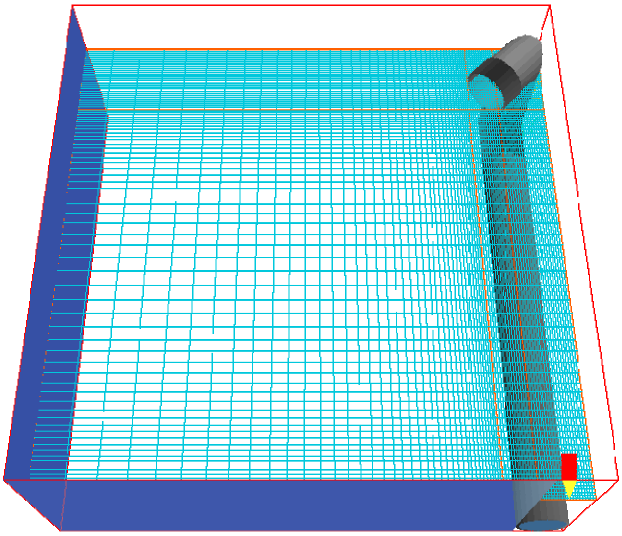

Figure 5: CFD model of the left air distribution element.

CONCLUSIONS

Experimental validation of the simulations shows that we have accurate prediction of the velocity field from the simulations so the CFD model could be used for optimization of the inlet angle of the air distribution element. But we also found very complex inlet profile of the velocity and turbulence intensity at the inlets of the PERMICS, which could not be easily described as the boundary condition for the simulations of the whole microclimate zone of the PERMICS. So the further simulations of PERMICS must be made with equivalent diameter of the inlet with uniform velocity and turbulence intensity profile to achieve comparable results of the velocity field from simulations with measurement results in microclimate zone of user of PERMICS.

SUMMARY

Analysis of operation of a prototype system for local air-conditioning of working places, named PERMICS-LOS1 (Personal Microclimate System) was made based on measurements of air velocity field, using a hot-wire anemometer and of tracer gas concentrations with decay method. The emphasis of the experimental analysis was on design and effectiveness of the air terminal device in terms of air distribution using also visualization technique. Analysis of system operation was made for different operating regimes of personalized ventilation, where changes of air quantity (volume flow) and direction of supplied air in the breathing zone were applied. Experimental analysis has been supplemented by a numerical simulation of the velocity field on the air terminal device and in the breathing zone using a commercial computational fluid dynamics (CFD) software PHOENICS. Performed analysis of operation of personal ventilation system has verified our expectations in terms of the importance of proper air distribution device design on achieving greater effectiveness of the system.

Keywords: personalized ventilation, air distribution; CFD simulation; vertical air inlet; ventilation effectiveness

INTRODUCTION

In the last years indoor air quality and the importance of providing a healthy and comfortable environment for the occupants of closed spaces has been drawing more and more attention. People have become aware of the term *sick building syndrome* (SBS) [1] and building-related health complaints which represent significant health problems, such as headaches, allergies and fatigue. Room air, which is in majority of ventilated buildings normally supplied by a mixing or displacement ventilation systems, is at the time when it is inhaled by the occupants already polluted by different indoor air contaminants. These are generated by numerous pollutant sources such as building materials and equipment, electrical appliances, detergents, as well as people and their activities themselves. That is the reason for bad indoor air quality which has an economic impact, caused by decreased productivity of employees, absence of work, as well as consequently higher health care costs [2-4].

A new approach for the future air-conditioned environments based on philosophy of excellence was proposed by Fanger [5]. He suggested narrowing the air-conditioned space from the whole room space to a local space of the occupants' breathing zone and proposed a novel personalized air (PA) system which would serve gently a small amount of cool and clean air close or directly into the breathing zone of each individual without causing a draught.

Results of different studies carried out in Slovenia [6-13] were presented in the last research of effectiveness of personal ventilation system [14]. The conclusions gleaned from these studies indicated the need for new, more qualitative systems for ventilation or air-conditioning of indoor environment. In previous research [14] such system with a local inlet of air with a possibility of local regulation of key parameters of thermal environment was analysed. Measurements and simulations of system operation showed that personalized ventilation system is very effective in terms of ventilation efficiency. Furthermore a new index of relative decrease of tracer gas concentration in the first minute of system operation *dC(1)* was defined. The connection of this index with the velocity field and with the ventilation effectiveness parameters was discovered that could be used for direct measurement of ventilation efficiency in a shorter time.

In present paper we report findings of measurements, visualizations and numerical simulations of operation of a new personalized ventilation system for working places, named PERMICS-LOS1. Development of this prototype system was mainly based on a local air-conditioning system PERMICS (Personal Microclimate System), developed in previous research [14,15] as on analysis of other personalized air systems [16-20] and on measurements from local air cleaning devices [21,22]. A novel system is designed as individual unit for distribution of personalized air directly into the breathing zone of the occupant at a single working place and is appropriate for offices with several employees. Therefore it is not designed for heating or cooling of large areas due to possibility of draught from larger amounts of air at lower temperatures. System is designed for use in conjunction with a total-volume ventilation and air-conditioning and makes possible to customize the environment to individuals' preferences by allowing the adjustments of direction, flow rate and temperature of the personalized air. At the stage of development of the system predictions were made to achieve better ventilation efficiencies in the breathing zone with smaller amounts of fresh air than with previous PERMICS system.

METHODS

Air terminal device of PERMICS-LOS1 consists of a desk grille with dimensions of 225mm × 75mm with two freely adjustable grilles, mounted on a horizontal surface of an office desk with dimensions of 800mm × 1600mm and height of 765mm respectively as shown on schemes in Figure 1 and Figure 2. Such position of a desk grille is suitable for working places equipped with personal computer when usual arm position pattern on a keyboard does not interrupt airflow, because a desk grille is located between the arms of sedentary person. Adjustable grilles enable adjustments of direction of personalized air flow which is basically orientated vertical directly to the breathing zone of the occupant or towards the occupant's body. The appropriate inclination of adjustable grilles in respect to vertical position is from 45° to 0° (vertical position) while at greater inclinations from vertical position the air jet is strongly affected by the side pods of desk grille housing.

Air terminal device (desk grille) can be connected with a supply duct for fresh air of an air-conditioning system in several different ways, for example by a flexible duct from the wall or floor at the back side of an office desk as one possibility. System can also be equipped with a sensor for sensing the presence of a person at the desk which turns system on or off.

For the purpose of the analysis a seated manikin behind an office desk was used to simulate a sitting occupant at work. A manikin was during the testing procedure in an upright position with a nose height of 1.10m. In the first stage of experimental analysis the appropriate amount of supply fresh air at isothermal conditions and the proper inclination of adjustable grilles were tested using a visualization technique with a smoke. For the tested specification it was found that the suitable amount of inlet air was between 1.50 and 3.50 l/s and the inclination angle of adjustable grilles between 15° and 35° from vertical position. Inside these operating conditions the system is expected to be working effectively.

Figure 1: Scheme of PERMICS-LOS1.

Based on findings of visualization, measurements of velocity field and turbulence intensity on the desk grille were made for several different operating conditions in the range of proposed operating conditions using a hot-wire anemometer HW3D-ED with the uncertainty ±0.882% of measured value [15]. Hot-wire probe of the anemometer was positioned on inlet surface at different points along the width of the grille between two adjustable grilles as presented in Figure 3 with accuracy of positioning of at least 0.5mm. Furthermore additional velocity and turbulence intensity measurements were performed at the manikin's nose and in the breathing zone above the desk grille.

Figure 2: Horizontal desk grille geometry

As a part of the analysis measurements of ventilation efficiency of PERMICS-LOS1 using a tracer gas technique in the test chamber with a tracer gas carbon dioxide (CO_2) were made.

Used measuring technique was decay, or tracer step-down method [23-25]. CO_2 concentration was measured using a system for CO_2 measurements with infrared absorption sensor at four locations, namely in fresh supply air, at the air terminal device, at the manikin's nose and at the outlet from the test chamber.

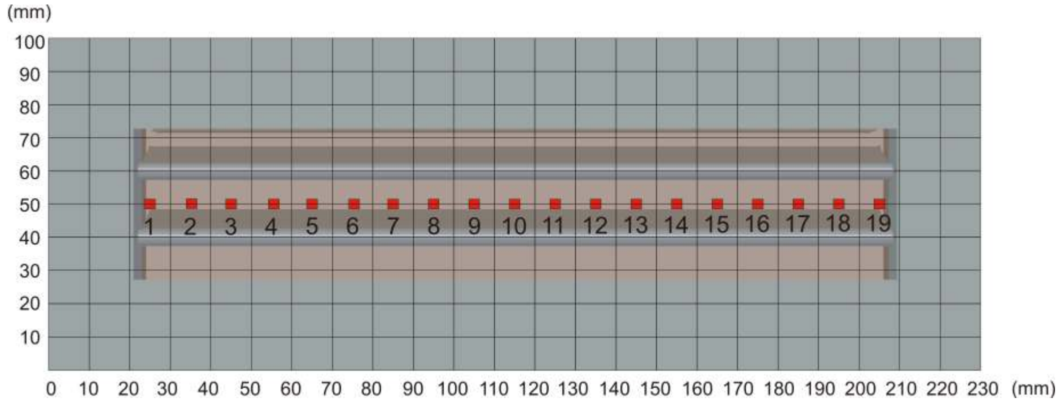

Figure 3: Measurement points of hot-wire probe on a desk grille.

For a described personalized ventilation system two different numerical simulations were performed using a commercial CFD package CHAM PHOENICS. The first one was a 2D simulation of velocity and turbulence intensity field on the horizontal desk grille with mesh of 327×131 cells. This simulation served as a basis for a 3D simulation of velocity field in the breathing zone for a PERMICS-LOS1 positioned in a room with a seating manikin behind the desk with mesh of 71×54×55 cells. For both simulations an adiabatic steady state model was made to satisfy isothermal conditions of air jet similar to those, assured during measurements.

RESULTS

Measured results of the air velocity profile on a surface of a desk grille for maximal proposed amount of 3.50 l/s of air are presented in Figure 4. The velocity gradient at the boundary region is well seen as are slight fluctuations of velocity and consequently of turbulence intensity. These variations in velocity are caused by flow direction lamellas, positioned under both adjustable grilles. The results are in accordance with expectations as the low turbulence intensity at the inlet is assured by an additional element for a laminar flow.

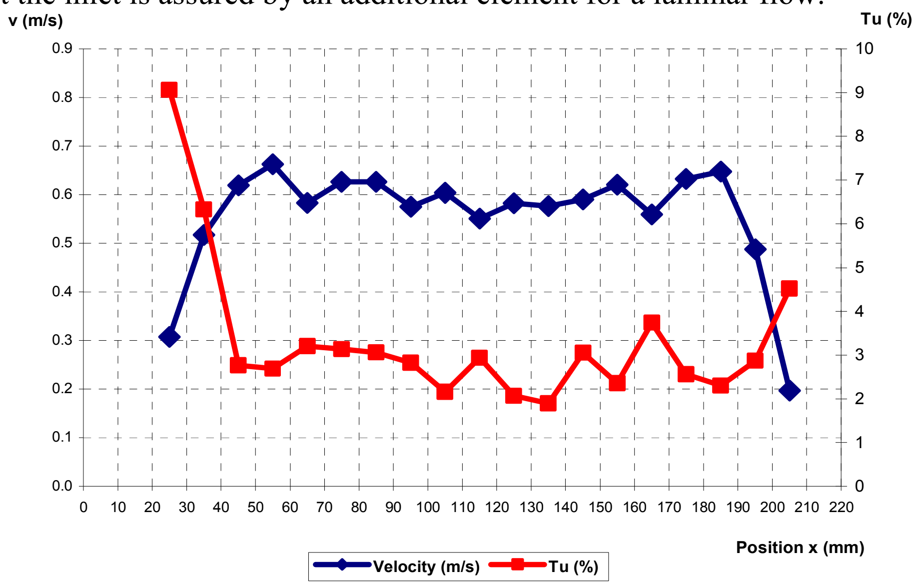

Figure 4: Velocity and turbulence intensity profile in measurement points on desk grille.

In 2D numerical simulation both standard k-ε and Chen-Kim k-ε models were used for turbulence modelling. There were no important differences discovered between two models at the 2D level that would have significant influence on a velocity and turbulence intensity field result. On the other hand for the 3D simulation of velocity field in the breathing zone significant differences were discovered between tested turbulence models. Current findings, similar to previous results of CFD simulations [15,26], confirmed that Chen-Kim k-ε model is the most suitable for this case.

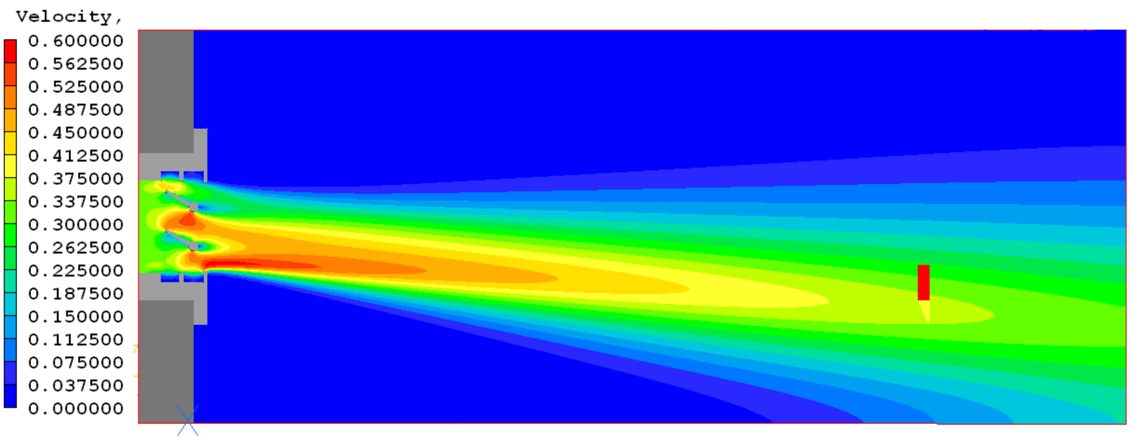

Figure 5: Results of air velocity field simulation on a desk grille.

Figure 5 represents 2D simulation results for an air velocity profile on a desk grille with the usage of Chen-Kim k-ε model for an inlet described with 3.50 l/s of air with 295K and with 5% turbulence intensity with the inclination angle of two adjustable grilles set to 30°. Velocity field at the cross section over simulated air jet at the distance of 0.4m from air inlet on a desk grille is shown in Figure 6.

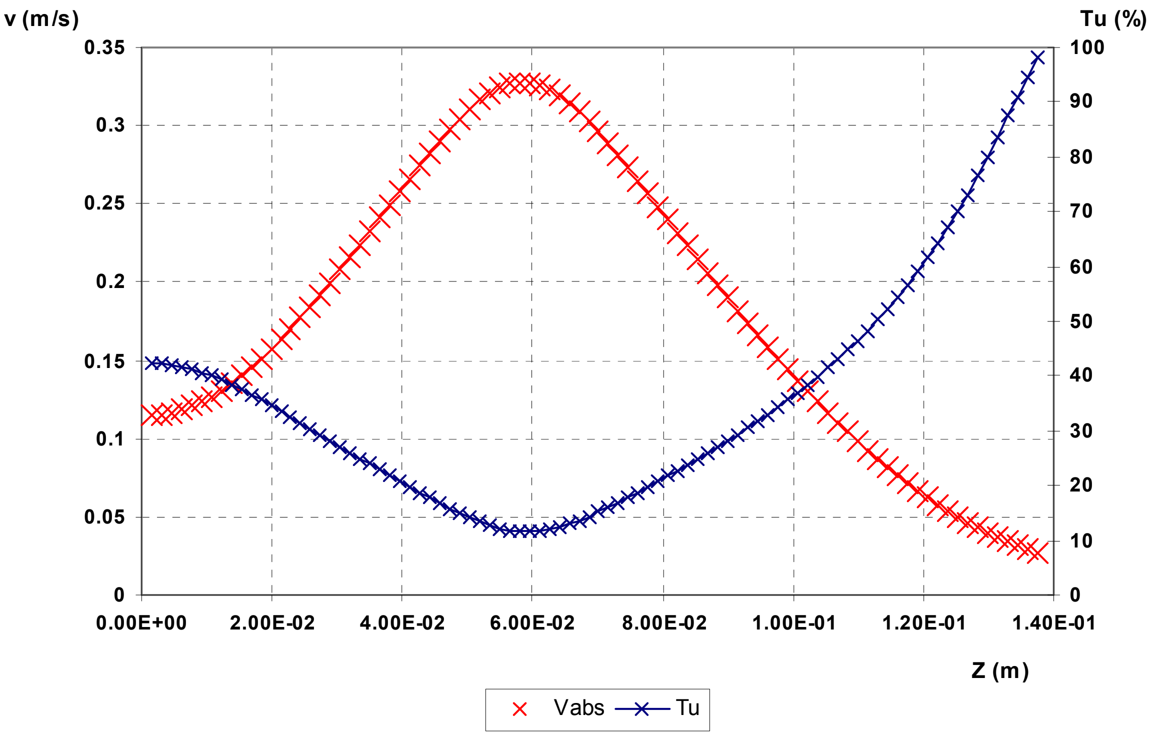

Figure 6: Velocity and turbulence intensity profile at the distance of 0.4m from air inlet on a desk grille.

Velocity field results in the breathing zone of steady-state 3D numerical simulation for isothermal inflow of 3.50 l/s of air with 295K through a desk grille with the angle of inclination set to 30° are presented in Figure 7. Air velocity at the nose level for this case with a maximal proposed amount of air is just under 0.25 m/s, while in other cases with smaller amounts of air, velocities in the breathing zone are consequently lower. Similar is with induction rate of ambient air which is higher at higher amounts of air and vice versa.

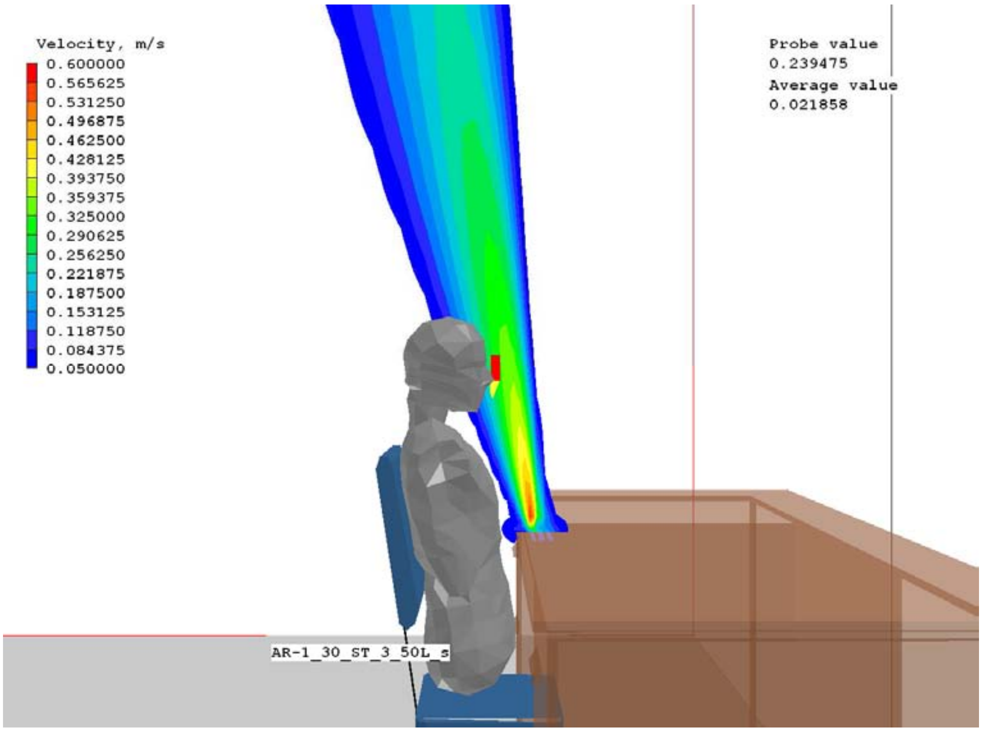

Figure 7: Air velocity distribution in the breathing zone of steady-state 3D simulation for isothermal conditions.

Beside presented results of measurements and simulations of air velocity field on a horizontal desk grill and in the breathing zone of the occupant which were as already mentioned acquired for a case with a maximal amount of air, measurements and simulations were made also for smaller amounts of personalized air in combination with different operating conditions of the system.

Comparison between results of velocity measurements in the breathing zone and at the manikin's nose with results of steady-state 3D simulation for the same operating conditions of PERMICS-LOS1 shows very accurate prediction of air velocity distribution with simulations. Some differences are found between measured and simulated results of turbulence intensity, where there is a higher prediction of turbulence intensity significant for simulation. These findings are important, because they show that it could be possible to optimize the operation of the system not only with measurements but also with simulation tools. However, additional measurements and simulations will be necessary to develop the appropriate numerical model that would be reliable enough for optimization process.

Results of ventilation efficiency measurements show the importance of operating conditions, especially in terms of applying the right air jet orientation and the proper amount of fresh air. It was found that for the same air jet orientation a smaller amount of more laminar air flow assures equal or even higher air quality parameters as a larger amount with higher turbulence level. This is due a reason that there is no actual mixing of air in the laminar flow case as fresh air pushes old air out of the breathing zone and there is less induction rate. The rate of induction is besides dependent also of the width of the air jet at the head level.

CONCLUSIONS

Results of the analysis of ventilation effectiveness of personalized ventilation system PERMICS-LOS1 show that the design of the air terminal device in terms of air distribution is crucial for achieving higher ventilation efficiency in the breathing zone of the occupant. The most influencing parameters are beside the amount of fresh air also the right orientation of air jet and velocity distribution in the breathing zone. Accordingly to measured and simulated data, ventilation efficiency is very dependent of the position of adjustable grilles of the air terminal device and also of the amount and the turbulence intensity of distributed air, while higher amounts of air not necessary assure better air quality in the breathing zone and can also cause a discomfort for the occupant due to draught. Modifications of air terminal device should be considered to achieve wider and thus more uniform air jet in the breathing zone. Further measurements of velocity field and ventilation efficiency, including numerical simulations are necessary for better understanding of the influence of air distribution, especially air jet width on the amount of personalized air in the breathing zone.

An experimental investigation of a passive chilled beam system in sub-tropical conditions

SUMMARY

Chilled beam systems are effective in providing good indoor environmental quality (IEQ) in an energy efficient manner. However, chilled beam systems are not common in sub-tropical climates where the requested cooling capacity is much higher than in temperate climates. This paper reports the findings of physical testing undertaken on a simulated office environment when the maximum cooling capacity was 122 W/m². Tests were also undertaken for higher theoretical heat gains (up to 164 W/m²). The mock up test environment included a 3.6m x 3.6m zone, representing a perimeter zone of an office building in a semi sub-tropical southern hemisphere climate. The purpose of the test was to measure the internal temperature distribution and air velocities for different heat gains and also for changes in internal layout. The test results are referenced to recognised standards for occupant comfort, particularly ISO7730. The conducted measures show that the air velocities in the occupied zone were below 0.25 m/s in all tests and the draft rates were below 20 % in nearly all measured points. The location of the workplace also did not have any effect on the air velocities within the space. This shows that passive beam system, including cooled mechanical ventilation, is possible to cover the requested cooling capacity in sub-tropical conditions without any draft.

BACKGROUND

<u>Chilled Beam Application</u>

The application of passive chilled beams in HVAC (Heating Ventilation and Air Conditioning) design for office spaces has been reasonably commonplace in Europe with examples of the application spanning over the last couple of decades. A common design encompasses a combination of ventilation air, distributed by mechanical means to a ceiling (or floor) mounted diffuser, and mechanical cooling via the passive chilled beam element located above a perforated ceiling. The passive beam element (battery type) itself is essentially a series of water tubes with fins attached to increase heat transfer to the air. Cooled water circulates through the beam. Airflow across the beam is driven by the natural buoyancy effects from air cooling through the beam element. Other solutions are active chilled beams where the room ventilation air is integrated into the room unit. This study is focussed on passive chilled beam systems.

Historically the majority of the application of passive chilled beams has been confined to certain room load densities (typically 50 to 80 w /m²). This is likely to be a symptom of the actual design loads encountered in such European regions. Much research has been undertaken in relation to the performance of various combinations and types of chilled beam products for these load scenarios. Zboril et al [1] investigated the air distribution for active beams with internal loads ranging from 50 to 80 w/m². A paper by Fredriksson et al [2] investigates the effect of the location of internal loads on the airflow and finds that the air plume under the beam can be affected by the placement of internal heat sources. It also identifies that air velocities under the beams can fluctuate. The study does not include the presence of mechanical ventilation air.

Other research, including information published by Rehva [3], recommends benchmark limits of capacity for passive chilled beams for “optimum heat loads” to 80 W/m² (watts per square metre of floor area) with a maximum of 120 W /m². These reports equate this to a specific chilled beam capacity of <150 W/m (Watts per linear metre of beam) when the beam is in an occupied zone, and up to < 250 W/m when installed in a non occupied zone. These limits have been established on the basis of air velocities and particularly draft within the space. The guide states that these values should be used as reference values and special attention should be given to room air velocities for higher heat loads. It is noted that these limits are based upon tests with no additional influences from room ventilation systems.

The performance of battery type passive chilled beam systems, in combination with cooled ventilation air and higher internal heat gains has limited research. This is of particular interest in semi tropical climates, including parts of Australia, where internal gains are higher than Europe due primarily to higher ambient temperatures and solar intensity. Perimeter office room sensible design gains can often reach 120 W/m² (or higher), even with relatively high performing double glazed facades.

The application of chilled beam HVAC design for office buildings is gaining popularity in Australia due to its potential of reduced energy consumption in comparison with traditional all-air variable air volume or constant air volume systems. Local regulation and market expectation is also increasing emphasis on energy efficiency in office building designs. Due to the limited application, the performance of chilled beams for higher heat loads (greater than 80 W/m²) is of great interest.

Of course the application of passive chilled beam systems for higher heat load spaces is not limited to spaces with higher fabric loads. Spaces with higher internal gains (e.g. call centres, TV studies etc) could make inference from this study.

<u>Thermal Comfort</u>

An assessment of thermal comfort includes consideration to a number of influences, which can be measured and quantified. These include Dry bulb temperature, humidity (or moisture), radiant temperatures (exposure) and air velocity (or draft). Much study has been undertaken on the interrelation of these items. This study aims to reference standard ISO 7730 standard (1990) which identifies a basic guideline for thermal comfort. This considers the temperature gradient in the room and also the room air velocities as follows (for summer cooling):

Draft rating (DR): < 20 (for category B space. For category C space this is <25)

Vertical air temperature difference: <3°C from foot to head when sitting or standing.

In general terms the differentiation between category B and C relates to the estimated Percentage of People Dissatisfied (PPD), with B targeting less than 10% and C targeting less than 15%. For general office type spaces category B is considered the appropriate target.

The equation for the determination of draft rating can be found later in this report. In general terms the draft rating takes consideration of both the local air turbulence and dry bulb temperature.

METHODS

The experiment was conducted at Halton Research Center. A test room (L *x* W *x* H = 3.6m *x* 3.6m *x* 3.3/2.8m) was used to simulate a real office. In the test room, two passive beams (CPT-105-605-2600/2400) were installed above the perforated false ceiling (3195 mm from the floor level). Three light fittings (each: 2x28 W/T5) and a swirl diffuser (TSR-160) were installed in the false ceiling at the level of 2800 mm from the floor level. The gross free area of the ceiling panels was 37 % and the perforation holes were 5mm. Close to the window wall, there was arranged an additional opening (300 mm) to improve the buoyancy effect, Fig. 1.

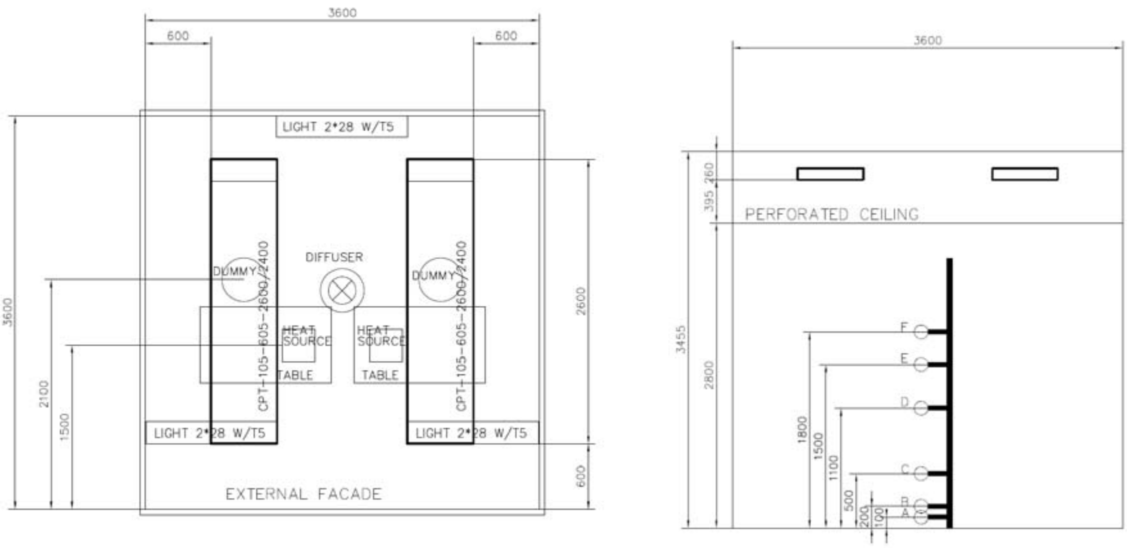

Figure 1. Simulated office (workplace layout 1) and the cross-section of the room space.

In the basic case of 122 W/m^2, the heat loads are: two computers (260 W), two dummies (150 W), light fittings (168 W), warm window surface (35.0 ^{o}C and ~ 600 W) and an electrical foil (400 W) (size of 3.6 m x 1.5 m close to the window) on the floor. The used airflow rate and supply air temperature of the swirl diffuser were 35 L/s (2.7 L/s per m^2) and 13 ^{o}C. The inlet water temperature of the chilled beams was 15 ^{o}C. The requested cooling capacity was arranged by modulating water flow rate of the chilled beams. The room air temperature was in the test cases between 23.5- 24.7 ^{o}C.

Two higher cooling capacity 153 W/m^2 and 164 W/m^2 were also studied. In the case of 153 W/m^2, two extra computers and dummies were installed. The highest cooling capacity (164 W/m^2) was arranged from the case of 153 W/m^2 by increasing the heat gain of the dummies. In this study, there was also analyzed the effect of the location of the workplaces on the performance of the passive chilled beam system. One additional case without false ceiling was measured to analyze the effect of the perforated ceiling panels on the air distribution. The studied cooling capacities and office layout cases are shown in Table 1.

Mean air velocity, air temperature and turbulence intensity were measured within the occupied zone at the locations of 0.1m, 0.2m, 0.5m, 1.1m, 1.5m and 1.8m above the floor. The measurement grid consists altogether 16 locations (altogether 96 points), Fig. 2.

Air flow velocities were measured with velocity sensor type Sensor HT 412 having accuracy ± 1 % of readings. The room air temperature, inlet water temperature, supply and exhaust air temperatures were measured with temperature sensors of type PT100 class A. The water flow rate was measured with Krohne Electromagnetic Flowmeter IFC010 with accuracy less than ± 1% of the readings. The airflow rate was measured with differential pressure transmitter Furness Controls FCO33 with accuracy less than ± 0.5% of the readings.

Table 1. Studied heat load and workplace layout cases.

Case	Room air (^{o}C)	Water flow rate (l/s)	Heat loads (W/m^2)	Workplace (WP) layout:
1	23.5	0.094	122	1:WP in the middle
2	24.1	0.094	122	2:WP close to the side wall
3	24.0	0.094	122	3:WP close to the window
4	23.4	0.094	122	1:WP in the middle (no ceiling panels)
5	24.7	0.196	153	1:WP in the middle
6	24.1	0.250	164	1:WP in the middle

For measuring of velocity, temperature and turbulence intensity 6-channel low-velocity anemometer HT 400 was used. The used 6 omni-directional velocity probes have spherical velocity sensor with a diameter of 2 mm, ensuring a fast response. The temperature sensor is shielded against radiation. Instantaneous values of velocity and temperature are measured simultaneously. Measurements of velocity and temperatures were time averaged over 180 s.

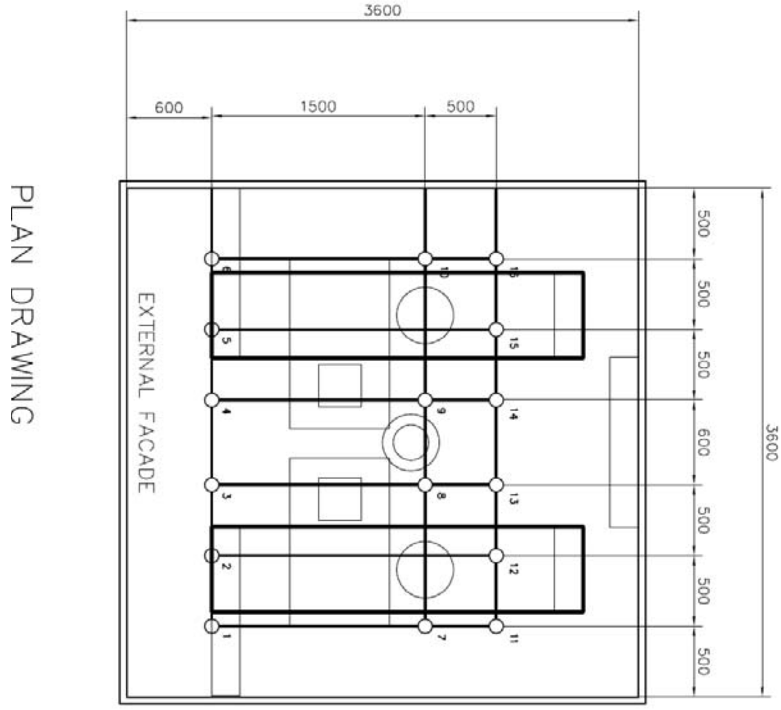

Figure 2. Measurement grid of the conducted experiment when workplaces are in the middle.

RESULTS

In Fig 3, there is presented the measured air velocity, temperature, turbulence intensity and draft rate profiles for test case 1. The measured velocity profile depicts that the air is well mixed over the whole occupied zone. Even with a heat gain of 122 W/m^2, the maximum air velocity was only 0.20 m/s. Also, the draft rate values were acceptable level.

Figure 3. Measured air velocity, temperature, turbulence intensity and draft rate in case 1.

Changes in office layout did not have any effect of the performance of the air distribution. This is seen in case 2 &3. The maximum air velocity was 0.20 m/s when the workplaces were located in the middle of the room , close to the side wall or close to the window. Also when the false ceiling was removed, the air velocities did not increased. In fact, the maximum velocity slightly reduced.

When the cooling capacity was increased from 122 W/m^2 to 153-164 W/m^2, the maximum air velocity was increased to value of 0.23 m/s. Also, the draft rate values were acceptable level: only in the couple of points DR- index was higher than 15 %. It should be noted that the typical limit of air velocity is set to 0.25 m/s during cooling season. Thus, the studied chilled beam concept fulfills this international standard threshold for the air velocity even when the cooling capacity was very high 150-160 W/m^2.

Table 2. Measured air velocities and draft rate (DR) in the test cases.

DISCUSSION AND CONCLUSIONS

Several tests were performed in order to establish the draft and heat gain performance of a mock up passive chilled beam installation under a number of scenarios. In summary these scenarios included:

- Adjustment of internal heat gains from 120 W/m² through to 164 W/m² (all cases);
- Adjustment to the internal layout of equipment, desks and people (case 2&3);
- Adjustment to the water flow rates delivered to the passive chilled beams in order test for increased capacity;
- Removal of perforated ceiling (case 4);

The results identify that within the range of these tests the draft rate (DR) could be maintained below 20 (with one reading at 21 for case 1) which would indicate compliance with ISO7730 For a category B building. More specifically the following was observed.

The removal of the perforated ceiling produced minimal difference to the draft and temperature performance for the internal heat gain loads at 120 W/m². Similarly, increasing the internal gains to 164 W/m² (case 6) resulted in broadly equivalent performance in terms of draft. At first glance this appears to be in contradiction to established limits of performance for battery type passive beam products. However further review indicates that the influence of the mechanically introduced air supply via swirl outlet diffusers has a profound effect on the air flow within the space. This can be illustrated by the smoke test demonstrations where it is apparent that the air movement is driven from these diffusers.

Similarly, adjustments to the internal layout of equipment produced little effect on the air movement. This could be attributed to the relatively small load as a percentage of the simulated fabric and lighting gains, which were fixed.

In all cases, the whole volume is fully-mixed as demonstrated by the measured velocities and from smoke tests. There is not any location in the occupied zone that exhibited excessively high velocities. Also the maximum velocity is approximately 2-times higher that average velocity in all cases.

Temperature distribution across the height of the room in all cases is significantly less than the 3°C target. Again the fully mixed environment is reason for this.

In conclusion it is apparent that the total performance is a combination of the influence of the cooling elements, air diffusion and thermal plumes of heat gains (although in this instance the affect of thermal plume was limited to changes in internal layout, which resulted in negligible affect). Focusing on the performance of a chilled beam element in empty space will not give the total view. All elements should be analysed concurrently. In cases where heat gains are high (> 80 W/m²) , this is required. Analysis could be undertaken using full-scale mock-up or with CFD simulation. However special attention should be made to the boundary conditions and modelling of heat gains to achieve an accurate result.

These tests found that under certain conditions a combination of cooled air supply through swirl outlet diffusers, and battery type passive chilled beams can provide room sensible cooling capacities of 120 W/m² and potentially up to 164 W/m² without exceeding the requirements of ISO7730 for occupant comfort for category B office buildings. It is believed that the mechanically introduced air supply plays a significant role in the resultant air velocities within the space. The extent of influence of this is likely to be dependant upon the diffuser selection and airflow rate and this should be given due consideration. The tests presented did not compare different diffuser types so quantifying the effect of this may be the subject of further study.

SUMMARY

Task/ambient air-conditioning (TAC) system allows a user to control his microenvironment flexibly by setting the local supply air outlet and control device near his working location. Present researches show that this system can improve human thermal comfort remarkably. With the help of numerical simulation, the paper mainly studies the temperature and PMV (Predicted Mean Vote) values both in working and ambient area. The results show that the air temperature in front of body is lower than in the back of body, and the lowest temperature is in the head region. And PMV values both in working and ambient area can be kept within the range of -1~+1 by proper combinations of supply air temperature and volume. Finally some detail suggestions on local supply air parameters are given to keep PMV values in the whole working area within -1~+1, and those in the ambient area below +2, and also the temperature difference between the head and the feet levels in the ambient area less than 3℃ under the background air temperature at 28℃. It would be fascinating to further study on the mechanism of asymmetrical air parameters for human thermal comfort.

INTRODUCTION

TAC system is an air-conditioning system that has the air outlets and control devices set together near working stations so that workers in working area could control their individual environment flexibly. Current researches on TAC system show that it not only can improve human thermal comfort and indoor air quality, but also has the advantage and potential of lowering energy consumptions [1-3]. Desktop TAC system can supply air directly to breathing zone by air outlet mounted on desktops and provides each user with control devices for their local environment adjustment. In recently ten years, many scholars have been dedicated their effort to the TAC technology, mainly focusing on human thermal comfort and air quality with much achievement obtained [2-5]. One of the differences between TAC system and traditional system is that parameters such as temperature and air velocity around a human body are non-uniform. So characteristics of environmental parameters distribution of TAC system should be well studied in order to solve its thermal comfort problem. In this paper, the room airflow and environmental parameters distribution within work stations under different supply air parameters of TAC system have been studied using the CFD software of PHOENICS.

METHODS

I. Air-Conditioning System Arrangement

Eight work stations isolated by separation boards are set in the air-conditioned room dimensions, 7.5m×5.6m×3.6m. The overhead air delivery background air-conditioning system is adopted with ceiling mounted return air grilles far away from supply air outlets whose dimensions are 12cm×14cm.

Since the cooling load comes from the indoor facilities and human bodies in an inner zone of a large office building, only the indoor heat sources are considered in this study. The cooling load includes eight computers, eight workers and four fluorescent lamps where the heat capacity of a computer is 300w, a human body 60w, and a light 40w. And a human body is simplified to a cube. The supply air temperature of the background air-conditioning system is set at 20℃ and the amount of air supply is calculated by maintaining the indoor air temperature at 28℃ according to the following formula:

$$G = \frac{Q}{\rho c_p (t_n - t_o)} \quad (1)$$

where G is supply air volume flow rate, m^3/h; Q is cooling load, W; ρ is air density, kg/m^3; c_p is specific heat, $kJ/(kg\cdot K)$; t_n is the calculation temperature of indoor air, ℃; t_o is the supply air temperature, ℃.

II. The Basic Air Turbulence Model[6-7]

Usually, control equations describing air motion can be written in the following universal pattern:

$$\frac{\partial(\rho\phi)}{\partial t} + \nabla\cdot\left[(\rho V\phi) - \Gamma_\phi grad(\phi)\right] = S_\phi , \quad (2)$$

where Φ is dependent variable; ρ is air density; V is the vector of air speed; Γ_Φ is the coefficient of air diffusion; S_Φ is the source term of Φ; t is air temperature.

Continuation equations, momentum equations and energy equations can be gotten for the different meaning of Φ in the study.

For continuation equations:

$$\Phi=1; S_\Phi=0; \Gamma_\Phi=0 \quad (3)$$

For momentum equations:

$$\Phi=u \quad (4)$$

$$S = -\frac{\partial p}{\partial x} + \frac{\partial}{\partial x}\left(\mu_{eff}\frac{\partial u}{\partial x}\right) + \frac{\partial}{\partial y}\left(\mu_{eff}\frac{\partial v}{\partial x}\right) + \frac{\partial}{\partial z}\left(\mu_{eff}\frac{\partial w}{\partial x}\right) \quad (5)$$

For energy equations:

$$\Phi=T \quad (6)$$

$$\Gamma_{\phi} = \frac{\mu}{P_r} + \frac{\mu_t}{\sigma_T} \quad (7)$$

$$S_{\Phi}=0 \quad (8)$$

In the above equations, P_r is for air pressure; μ_{eff} is for equivalent viscosity; μ is for laminar air dynamic viscosity; μ_t is for turbulent air dynamic viscosity; σ_T is for turbulent Prandtl number.

It is usually impossible to solve the above partial differential equations directly except for some very simple cases. So numerical methods have been used, which include finite difference method, finite element method, border element method and finite analysis method where the last three methods have gained much progress by dissolving some difficult problems on fluid flow and heat convection. As the finite difference method still prevails over the others because of the mature level, easiness of putting into practice and broadness of application fields, the finite volume method—one of finite difference method—is adopted in the study.

III. The Meshing Model

Much more nodes and smaller meshes should be arranged around human bodies, computers, and air supply grilles due to the relatively sharper gradient of temperature and velocity around them. The total number of calculating meshes to 130,340 at the end of the model meshing stage.

IV. Working Modes of Simulation

All twenty five working modes are selected for simulation, in which there are five air supply volumes in combination with each of five different temperatures. All the working modes are listed and numbered in table 1.

Table 1. Different working modes for simulation

Air supply temperature (℃)	Air supply volume (m^3/h)				
	20	40	60	80	100
14	A_1	A_2	A_3	A_4	A_5
16	B_1	B_2	B_3	B_4	B_5
18	C_1	C_2	C_3	C_4	C_5
20	D_1	D_2	D_3	D_4	D_5
22	E_1	E_2	E_3	E_4	E_5

RESULTS

I. Comparison of Simulation and Field Test

A TAC system is set up in an environment controlled chamber according to simulation conditions. Twelve testing points are set within the working area, and four points are set in the ambient area at different heights for the air temperature and velocity measurement.

Multi-functional instruments are used to measure air temperatures and velocities. The temperature measurement range is -20℃~+70℃ in accuracy of ±0.4℃, and velocity measurement range is 0~5m/s in accuracy of 0.03m/s+4%m.v. Figure 1~3 show the testing and simulating results only at the height of one meter due to the restriction of the paper length. It can be seen from the figures that the temperature and velocity distribution between testing and simulating results are similar at the largest temperature difference of 4.05% and the biggest velocity deviation of 0.07m/s.[9]

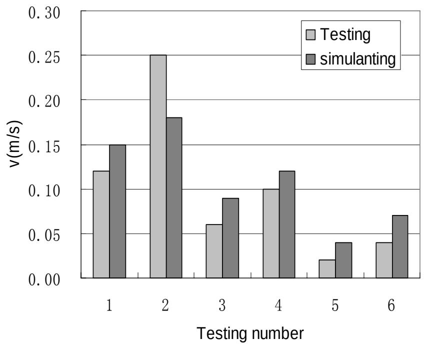

Fig.1. Air velocity comparison in working area

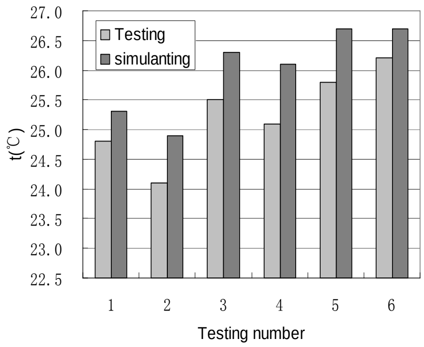

Fig.2. Air temperature comparison in working area

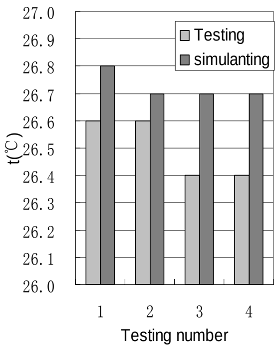

Fig.3. Air velocity comparison in ambient area

II. Temperature Distribution around a Human Body

Comparisons have been made between the mean air temperature in front of body (at the height of 0.6m~1.2m) and that in the ambient area (below the height of 2.0m) under different working modes by means of numerical simulation method. Refer to figures 4-7. [9]

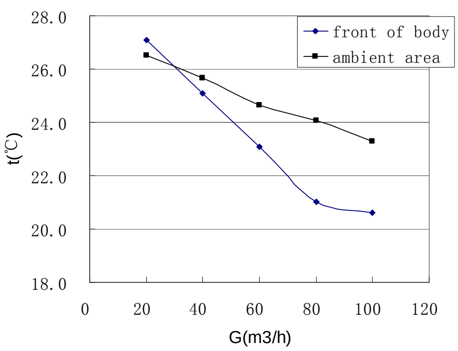

Fig.4. Mean air temperature variation with different air supply volumes at 16℃

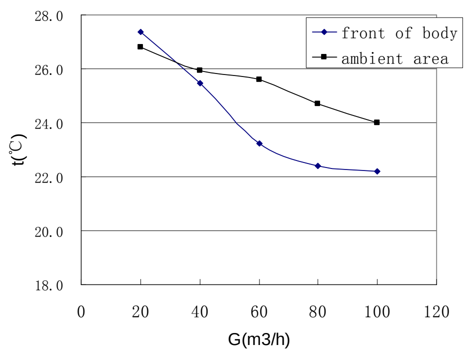

Fig.5. Mean air temperature variation with different air supply volumes at 18℃

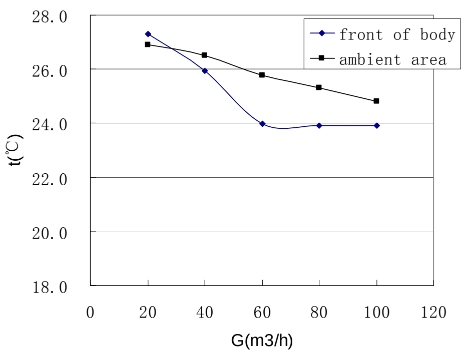

Fig.6. Mean air temperature variation with different air supply volumes at 20℃

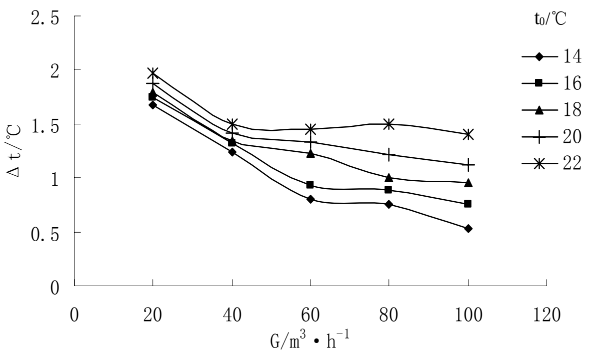

Fig.7. Mean air temperature differences at head and feet levels in ambient area at different working modes

It can be seen from figure 4~6 that air temperatures in front of body are slightly higher than in ambient area when the supply air volume flow rate is 20m^3/h because of the heat flow coming from heat sources which mainly located in the working area. As the supply air volume reaches 40m^3/h, the air temperatures in front of body become lower than those in the ambient area. Moreover when the supply air temperature is at 14℃ or 16℃ and the supply air volume is below 80m^3/h, the air temperatures in front of body will drop dramatically as the supply air volume increases. And the tendency that the air temperature in front of body lowers as the supply air volume increases will be slowed down when the supply air volume is over 80m^3/h. But when the supply air temperature is at 18℃, 20℃ or 22℃, for turning point of the tendency, the supply air volume flow rate is about 60m^3/h. It is also found that the lower the supply air temperature, the lower the mean air temperature in the working and ambient area under the same supply air volume. And when the supply air temperature is set at 14℃, the mean air temperature in front of body will drop to below 20℃, but when the supply air temperature is raised up to 22℃, the mean air temperature in front of body will only drop to 25℃ under the same supply air volume. Though the mean air temperature difference between the front body and the ambient environment can reach as high as 3℃ at a relatively lower supply air temperature, this temperature difference will drop to some 1℃ at a higher supply air temperature.

Figure 7 shows the air temperature differences between the head and the feet levels in the ambient area with different supply air volumes under the five supply air temperatures. It can be seen from figure 4~7 that all the air temperature differences between the head and the feet levels in the ambient area under the twenty five working modes are kept within 2℃. So under calculation conditions, thermal discomfort can be avoided in spite of the large vertical temperature gradient in the ambient area. It can also be found that the air temperature differences between the head and the feet levels will lower as the supply air volume increases at the same supply air temperature, but after the supply air volume reaches 60m^3/h, the temperature difference basically remains unvaried. [9]

III. PMV Distribution

PMV is a thermal environment index established by P.O. Fanger on the basis of thermal comfort equation after he collected thermal sensation data of 1396 American and Danish subjects. The difference between PMV and other thermal environment indexes is that the PMV value is the occupants' mean vote for a thermal environment based on ASHRAE's classification on thermal feeling instead of a certain equivalent temperature. [10] The index values of the ASHRAE's classification on thermal feeling are from 1 to 7, and these values minus 4 are the PMV index values, that is from -3 to 3, in which zero means neutral feeling (thermal comfort), values below zero stand for cool feeling, and values above zero stand for warm feeling.

It is confirmed that human thermal comfort can be improved by modification of the supply air temperature or volume or both from the simulation calculation in the working area. As can be seen from figure 8 and 9 that although the background temperature remains at 28℃, a slightly cool feeling (PMV<0) can still be felt at relatively low supply air temperature with large amount of supply air, but thermal feeling will become warm (PMV>0) when the supply air temperature is raised up to 22℃. So it can be predicted that in a relatively high ambient air temperature, human thermal comfort can be improved effectively by environmental parameters difference around a human body produced by a local air supply system.

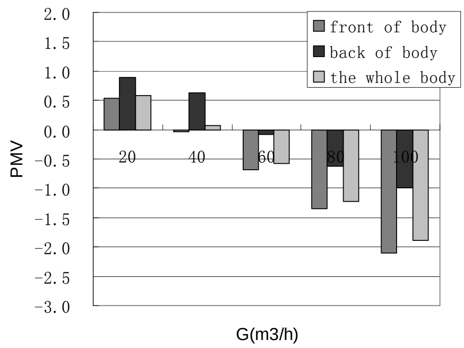

Fig.8. Human thermal comfort at supply air temperature of 16℃

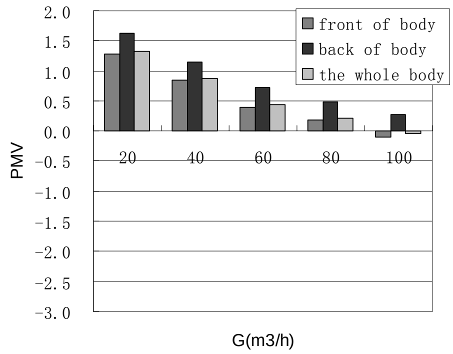

Fig.9. Human thermal comfort at supply air temperature of 22℃

The relationships among the thermal feeling of the whole body in the working and ambient area and the local supply air temperature and volume in all the twenty five working modes are drawn in figure 10 and 11 according to simulation calculations. It is found that PMV values can be kept from -1.0 to +1.0 in most working modes, and the highest PMV value is +1.4 while the lowest is -0.9 in the ambient area at all working modes. So a person will feel neither too cool nor too warm within working area or ambient area.

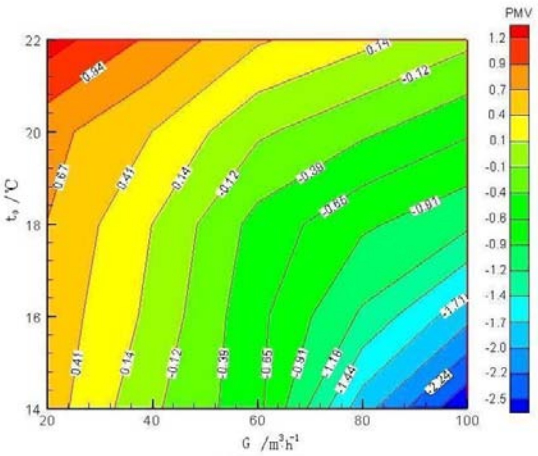

Fig.10. Thermal feeling of the whole body in working area with different supply air temperatures and volumes

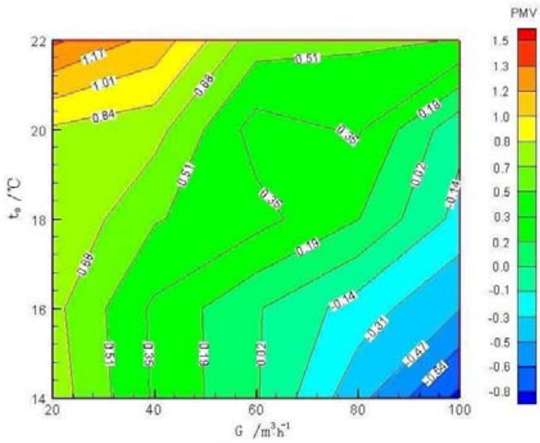

Fig.11. Thermal feeling of the whole body in ambient area with different supply air temperatures and volumes

DISCUSSION

I. The air temperature in the head region is apparently lower than in other areas in the desktop TAC system, but at the lower level of the room, the air temperatures around a human body have no distinct differences from that in ambient area.

II. The maximum mean air temperature difference between the front body and the ambient area is 3℃ under different supply air temperatures and volumes in all working modes.

III. The PMV values can be kept in a range of -1 ~ +1, in working and ambient area under different combinations of supply air temperatures and volumes. The prediction could be made that even at a relatively high ambient air temperature, human thermal comfort will be improved effectively by changing the environmental parameters around the human body through produced a local air supply system.

IV. The following suggestions on supply air parameters of desktop TAC system should be achieved in order to keep the PMV values in the working area between -1 and +1, and the ambient area below +2, and also the temperature differences between the head and the feet levels in the ambient area is less than 3℃ when the indoor air calculation temperature of the ambient air-conditioning system is 28℃: The supply air volume should be 20~60m^3/h if the supply air temperature is 14℃ or 16℃; The supply air volume should be 20~80m^3/h if the supply air temperature is 18℃; The supply air volume flow rate should be 20~100m^3/h if the supply air temperature is 20℃; And the supply air volume should be 40~100m^3/h if the supply air temperature is 22℃. It would be better to set the supply air volume at 40~60m^3/h for energy efficiency.

ACKNOWLEGEMENT

We should greatly thank to the National Natural Science Foundation of China (NSFC) for its financial support (No. 50678030).

Evaluation and rating of building performance

A Systematic Method for Improving Indoor Environment Quality through Occupant Satisfaction Surveys

Tarja Takki[1] and Maija Virta[2]

[1]Indoorium Oy, Finland

SUMMARY

A systematic method for assessing and improving indoor environment quality (IEQ) is developed for existing and occupied office buildings. The method begins with an occupant satisfaction survey that is directed to everyone working in a building. The structure of the questions follows a pattern that offers valuable information of the technical reasons leading to dissatisfaction. The questions assess satisfaction with the following IEQ areas: office layout, office furnishings, thermal comfort, indoor air quality, lighting, acoustics, and building cleanliness and maintenance.

A database of 25 office buildings in Southern Finland has been collected. The average value of all indoor environment factors in these 25 buildings is 0,85 in scale from –3 to +3. This average value can be used as a benchmark value to compare workplaces to each other. Office layout, office furnishings, lighting and cleaning have received higher scores than thermal comfort, air quality and acoustics. Also the variation between buildings has been bigger in thermal comfort, air quality and acoustics. These are also the areas where most of the technical problems have been found. In each building the occupant perception map lays the foundation for auditing and evaluating the indoor environment quality and for locating the possible technical problems.

INTRODUCTION

Well-being of people and environmental issues are some of the major concerns of our European societies today. Several hundreds of thousands of people die too early due to environment in Europe each year. Increased hospital admissions, extra medication and millions of lost working days are not only a financial issue but above all they influence the quality of our everyday life. [1]

People in modern societies spend most of their time (90%) in indoor spaces such as at home, work, school and in vehicles. Improving the quality of indoor environment enhances well-being and productivity of people. Prevention of dissatisfaction created by poor indoor environment and disoperation of technical systems needs to be our aim.

There are many effects of inappropriate indoor environment quality, like increased need to keep breaks during work, decreased concentration or fatigue. In extreme cases problems can lead to absence from work due to permanent or temporary health effects like headache, eye, skin, throat or nose irritation, thermal stress, allergy or asthma. [2]

Productivity of work is one of the most important factors influencing the profitability of business. Often other factors like cost of work or material are determined by external reasons. Good indoor environment improves productivity quicker than changes in working habits or skills, especially if indoor environment has not been in focus before. In a typical company operating in office environment 90 % of total company costs consist of employees' salaries. The rest of the costs include workplace related investment and running costs. International research has proven a development of 2-10 % in workers' productivity, when indoor environment has been improved. [3]

Indoor environment can create dissatisfaction and health problems for users due to various reasons. Often the reason is the performance of technical systems. In many cases technical problems are local and that is why it is difficult to find and locate them. Occupants complain about too hot or too cold temperatures during summer, too hot or too cold temperatures during winter, draughts from ventilation system, stuffy or stale indoor air or lack of sound privacy in open plan offices. At the same time average physical measures (e.g. room air temperature) and average occupant satisfaction may show high comfort.

When occupant satisfaction for thermal environment is known, the indoor climate category can be specified based on CEN Standard prEN 15251 (draft) "Criteria for the Indoor Environment including thermal, indoor air quality, light and noise", published in 2005 [4]. This standard specifies the three categories of indoor environment that shall be selected for a space to be conditioned (see Table 1 for recommended criteria and categories for the thermal environment).

Table 1. Recommended criteria and categories for the thermal environment according to CEN prEN 15251

Category	Thermal State of the body as a whole		Local Discomfort			
	Predicted percentage of dissatisfied PPD [%]	**Predicted Mean Vote PMV [-]**	**Percentage of dissatisfied due to draft DR [%]**	**Percentage of dissatisfied due to temperature difference [%]**	**Percentage of dissatisfied due to warm of cool floor [%]**	**Percentage of dissatisfied due to radiant asymmetry [%]**
A	**< 6**	**-0,2 …0,2**	**< 15**	**< 3**	**< 10**	**< 5**
B	**< 10**	**-0,5 …0,5**	**< 20**	**< 5**	**< 10**	**< 5**
C	**< 15**	**-0,7 …0,7**	**< 25**	**< 10**	**< 15**	**< 10**

Occupant satisfaction with the average thermal conditions can be translated to performance of workers (Fig. 1). That could be used as a tool to estimate the potential productivity improvement and furthermore to calculate the total investment potential.

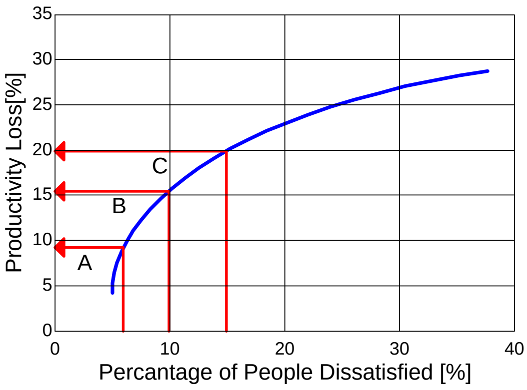

Figure 1. Linkage between percentage of dissatisfied people for thermal comfort (%) and productivity loss (%) [5].

METHODS

A systematic method for assessing and improving indoor environment quality (IEQ) is developed for existing and occupied office buildings. The method begins with an occupant satisfaction survey [6] that is directed to everyone working in a building. The structure of the questions follows a pattern that offers valuable information of the technical reasons leading to dissatisfaction. Questions focus on the human experience of indoor environment, not leading respondents directly to problems or symptoms. By using the occupant satisfaction survey all comments, also the silent comments, can be collected and taken into account when deciding on improvement actions. The questions assess satisfaction with the following IEQ areas: office layout, office furnishings, thermal comfort, indoor air quality, lighting, acoustics, and building cleanliness and maintenance.

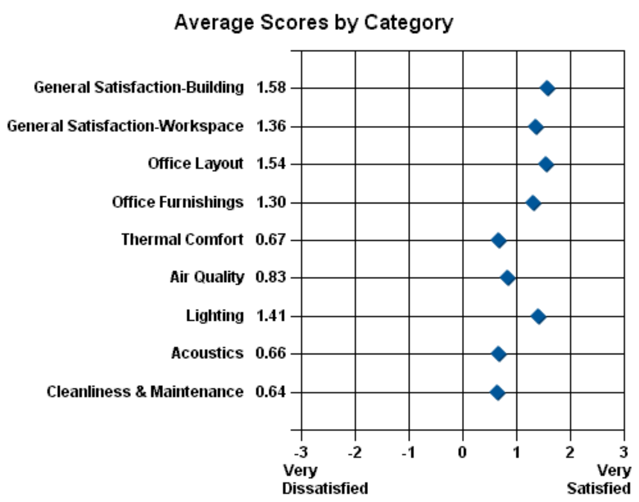

Figure 2. Average occupant satisfaction survey results normally show good values in many areas of indoor environment. [6]

Average satisfaction values between different evaluation areas (Fig. 2) do not vary as much as the local values between different areas of a building. This is why it is important to analyze results not only at building level, but also to locate the possible dissatisfaction more exactly into floors and facades. This helps to allocate actions to specific areas where they are needed. Furthermore, if the exact problems have been localized it is often possible to optimize the

HVAC-system so that both the energy usage of the system and the dissatisfaction of users can be reduced at the same time (e.g. when users complain too cold room air during summer). Table 2 presents an example of an occupant perception map.

Table 2. Occupant perception map (% of dissatisfied people) on different floors and facades helps to identify and locate indoor environment problems.

		All	2nd floor	3rd floor	4th floor	5th floor	6th floor	North	South
General satisfaction	Building	3%	3%	0%	0%	13%	7%	3%	0%
	Workplace	5%	3%	6%	0%	29%	0%	0%	14%
Office furnishings	Comfort	10%	15%	12%	8%	0%	6%	7%	0%
	Adjustment	10%	9%	15%	9%	0%	13%	10%	14%
Thermal comfort		26%	36%	12%	58%	0%	35%	19%	43%
Air quality		20%	39%	12%	8%	25%	12%	10%	43%
Lighting	Quantity	9%	15%	6%	25%	0%	0%	0%	29%
	Quality	12%	12%	12%	17%	13%	12%	16%	0%
Acoustic quality	Sound level	16%	15%	21%	33%	13%	6%	10%	43%
	Acoustic privacy	32%	21%	36%	58%	25%	35%	16%	57%

As an example, we can calculate the productivity improvement potential of e.g. thermal environment presented in Table 2. There 26 % of the personnel are dissatisfied or very dissatisfied with the thermal environment. 25 % of the personnel also think that the present conditions interfere significantly with their ability to get their job done. If the quality level of indoor environment is improved to class A (CEN prEN 15251), the improvement in performance according to scientific studies is 5.8 %. Total monetary benefit for increasing the productivity of 100 people is € 290.000 per year with annual labor cost of € 50.000 per person. Total possible investment for improving thermal conditions is € 1.680.900 with five years of repayment time and 3.0 % of interest rate.

A technical analysis requiring multidisciplinary knowledge is conducted in building areas where more than 30 % of respondents are dissatisfied. Systems creating and maintaining indoor environments consist of many components that are usually provided by different companies. Cross-scientific team of people representing various aspects of technical services conducts the technical analysis in the building. Improvement actions are determined based on the results of the survey and the technical analysis.

Sometimes technical problems are more complicated to solve, especially if there are any doubts of local thermal conditions e.g. drought. In those cases a full-scale mock-up can be built into laboratory conditions to find a technical solution. Another option is to use CFD simulations, but then it is critical to know the real boundary conditions of the specific terminal unit and the heat loads in the room space.

RESULTS

A database of 25 office buildings occupying 5200 people in Southern Finland has been collected. The smallest building was with 30 occupants and the largest building occupied 1200 people. The average value of all indoor environment factors of all 25 buildings is 0,85 in scale from –3 to +3. The highest average value has been 1,24 and the lowest 0,42. This average value can be used as a benchmark value to compare workplaces to each other (Fig. 3).

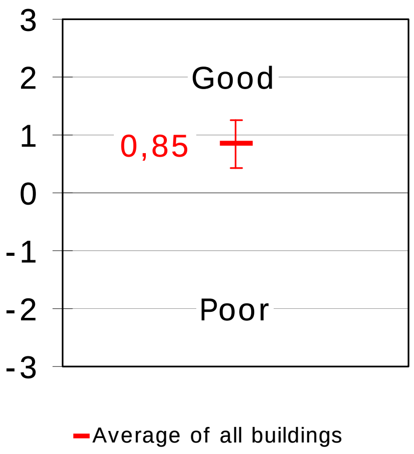

Figure 3. The average value of all indoor environment areas of all 25 studied buildings can be used as a benchmark value to compare workplaces to each other.

When searching technical improvement areas in buildings it is more valuable to present each indoor environment area separately. The evaluation of a building does not necessarily describe the magnitude of problems, because in occupants' evaluation the scale of different elements varies. Office layout, office furnishings, lighting and cleaning have received higher scores than thermal comfort, air quality and acoustics. The average values of each indoor environment area in the database of 25 buildings are in descending order:

- Lighting 1,25
- Building in general 1,23
- Office furnishings 1,22
- Office layout 1,20
- Workspace in general 1,12
- Cleaning 1,03
- Technical maintenance 0,97
- Indoor air quality 0,83
- Thermal comfort 0,49
- Acoustics 0,18

Also the variation is bigger in thermal comfort, indoor air quality and acoustics (Fig. 4). These are also the areas where most of the technical problems have been found. Occupants in office buildings complain mostly about:

- Too cold temperatures,
- Draughts from ventilation system,
- Stuffy or stale indoor air,
- Cold radiation of windows,
- Lack of sound privacy in open plan offices and
- Poor quality of cleaning service.

The typical technical reasons have been:

- Non-balanced ductworks or pipe works,
- Diffusers, which do not have a proper throw pattern
- Chilled beams, which are out of optimum operation range
- Lack of planning in room acoustics

- Operation of building management system.

All the analyzed buildings have typical Scandinavian room systems: chilled beams and mixed flow systems.

Sometimes reason has been a device failure, but too often it is just a change in office layout or change in usage of space. Changes have been completed in furniture and wall layout, but no adaptation of technical systems has been made. Also the combination of air diffusion, warm or cold window surface and layout of office furnishings may create unexpected airflows in the space.

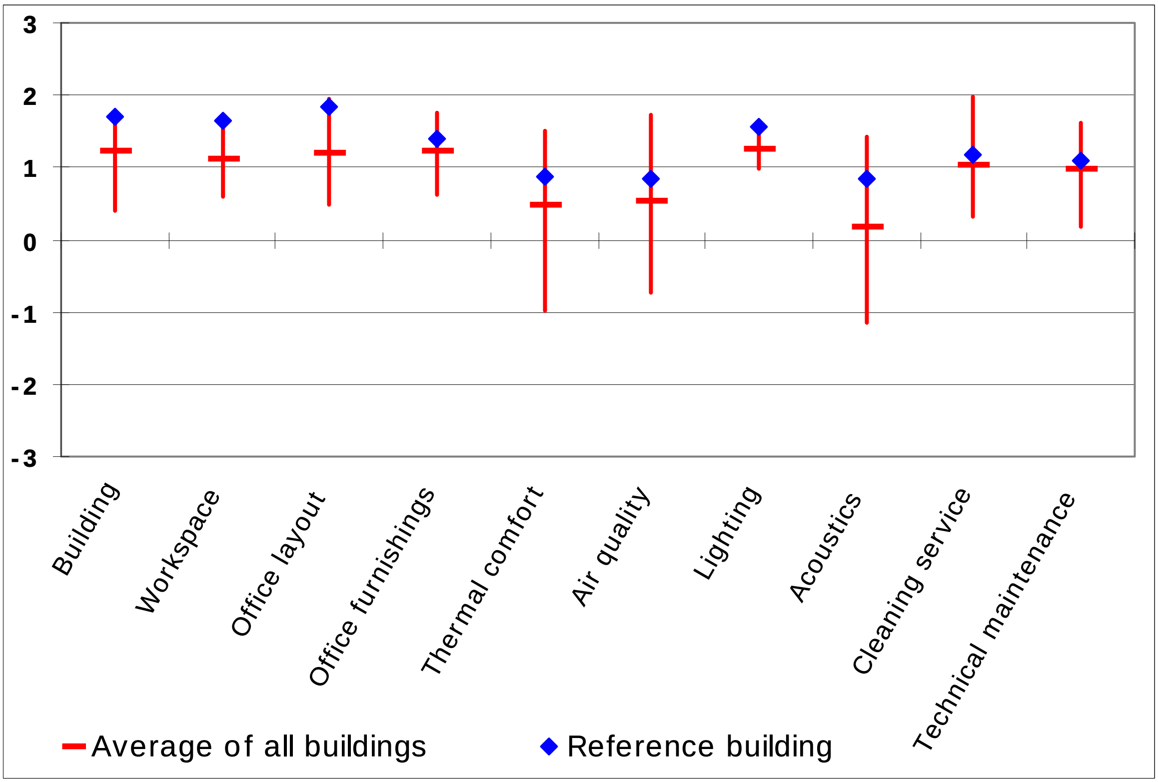

Figure 4. The average values and variations of each indoor environment area concerning 25 studied buildings.

In each building the benchmark values (Fig. 4) in association with occupant perception map (Table 2) lay the foundation for auditing and evaluating the indoor environment quality and for locating the possible technical problems.

DISCUSSION

The average value of occupant satisfaction survey (mean value of all indoor environment areas) can be used as a benchmark value when comparing workplaces to each other. It could also be the basis of indoor environment rating of buildings in the future and become a part of a holistic building labeling, where the mandatory part is energy labeling (based on Energy Performance of Buildings Directive). However, it is challenging to draw detailed conclusions of technical problems from the average occupant satisfaction only. There are several buildings, where serious problems related to indoor environment have been found in some parts of building even when the average satisfaction has shown excellent conditions.

The reason why office layout, office furnishings, lighting and cleaning get generally speaking higher scores than thermal comfort, air quality and acoustics can not be specified based on this material. Maybe people are more aware of thermal comfort, air quality and acoustics and that is why they are more critical about them. Or the other more likely option is, that the quality of thermal comfort, air quality and acoustics are poor in office environment. Technical problems found in all cases, where dissatisfaction is high, favors the latter assumption. However more research is needed in this area before any final conclusions can be drawn.

CONCLUSIONS

Occupants are an important source of information about indoor environment quality. Even though physical measures describe (numerically accurately) parts of the indoor environment only the perceived quality determines the functionality of the space to workers. People create the outcome of the work and therefore indoor environment's only purpose is to support the human performance and wellbeing. It is essential to measure the perception of people towards different indoor environment factors and in different parts of a building in order to find and correct the problems that affect human performance most. Even when the average satisfaction shows high scores there may exist major problems in some parts of the building. Occupant perception map is a beneficial tool to systematically solve the indoor environment related problems.

Many different vendors create thermal comfort, air quality and acoustics and therefore the end result is nobody's responsibility. There are no companies providing integration services to enable a satisfactory indoor environment within thermal conditions, air quality and acoustics. A more holistic approach of indoor environment development and maintenance is needed in order to provide satisfactory workplaces for people to perform at their best.

ACKNOWLEDGEMENTS

Building Energy and Environmental Performance tool BEEP

Development of a method to compare the true energy efficiency of buildings

Prof. Brian Cody

Graz University of Technology, Austria

Corresponding email: brian.cody@tugraz.at

SUMMARY

Regulatory devices for the energy efficiency of buildings currently in use, including the new EU "Directive on the Energy Performance of Buildings" [1] and especially the methods currently proposed in the various member states to determine and judge the energy performance of buildings as required by this directive deal only with energy demand and not with energy efficiency. This paper proposes a method which allows the true energy efficiency of a building design to be determined and thus a real comparison of various building design options. Energy efficiency is understood here as the relationship between the quality of the internal thermal environment in a building and the quantity of energy consumption required to maintain this environment. The proposed method takes into account the interrelationship between energy demand and internal environment and the calculated BEEP value is an indicator for total Building Energy and Environmental Performance.

INTRODUCTION

The true meaning of energy efficiency must take into account the internal environmental conditions as well as the energy demand required to maintain them. In fact, I propose that it is the relationship between the quality of the internal environment in a building and the quantity of energy consumption required to maintain this, which defines the energy efficiency of a building, at least in a thermal sense. The economic importance of the relationship between thermal comfort and productivity is becoming increasingly recognized [2]. The real challenge in energy efficiency is achieving a good indoor environment with a low energy demand. Prospective tenants and buyers of buildings should know what they are getting – a certificate with an energy demand rating means little if information about the quality of the associated internal environment is not made available. The current one-sided approach with concentration on energy consumption can lead to situations whereby seemingly high energy efficiency is only being achieved on paper. If the indoor environment is not acceptable, systems will be adjusted or new systems added to achieve a better environment at the cost of higher energy consumption. A method is needed which allows both energy demand and indoor environment to be quantitatively appraised to allow a real comparison between various options.

METHODS

The goal of the study was to develop a chart which allows the energy efficiency of various building designs to be plotted and thus compared. In order to measure the energy efficiency of the considered options it is necessary to relate the quality of the internal environment to the energy use necessary to maintain this. It is proposed here that the quality of the internal environment be indicated by the number of hours whereby comfortable conditions are not achieved; this in turn is measured by determining how many hours the "Predicted Percentage Dissatisfied" (PPD) is greater than 10%. PPD is the percentage of people likely to be dissatisfied with the thermal environment [3]. In the ISO 7730 a PPD value of less than approx. 10% is recommended [4].

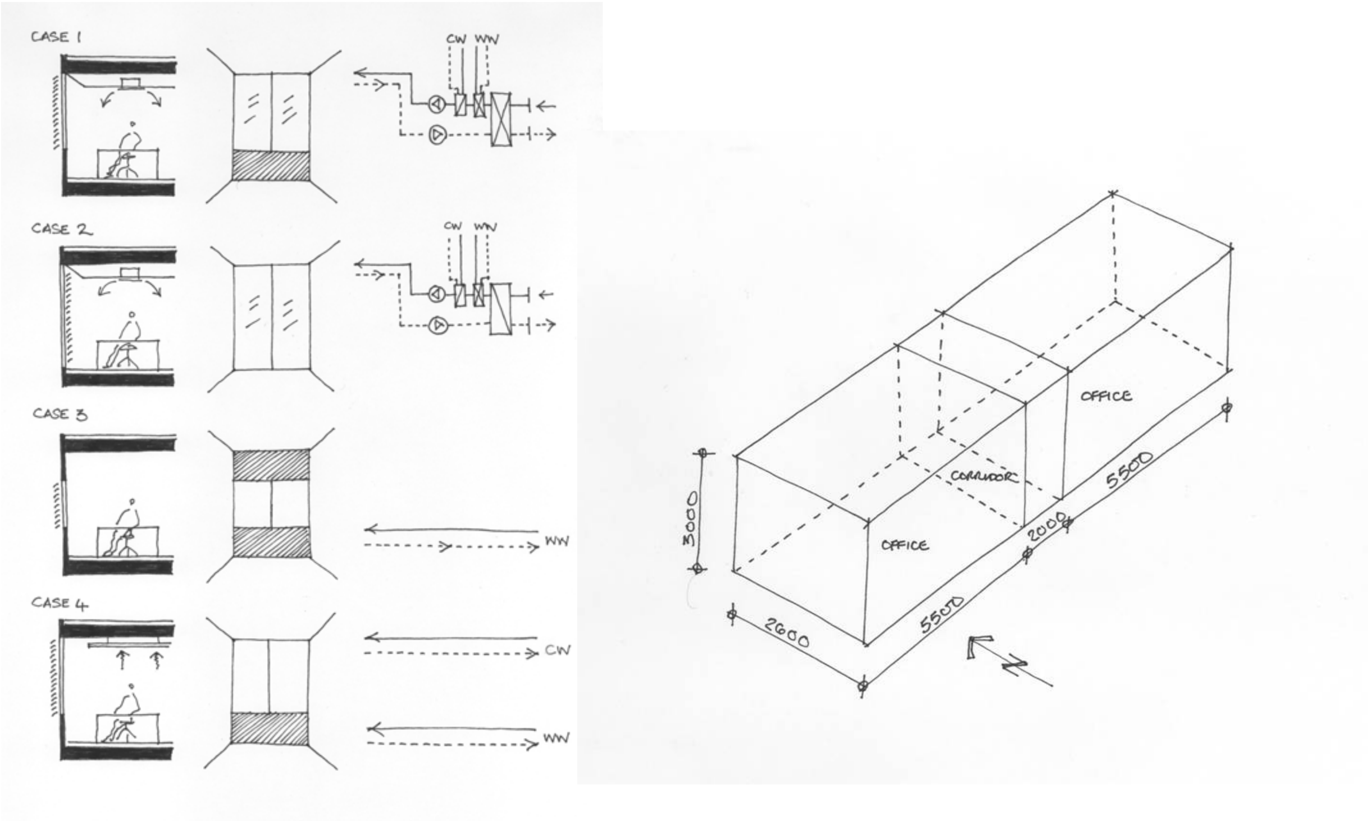

Figure 1. Design options and model geometry

In a second step four design options for a hypothetical office building were examined using dynamic thermal simulation and plotted on the chart as a means of testing the suitability of the proposed method. The options examined are various design alternatives for a hypothetical office building in Vienna city orientated with main facades east and west (see figure 1). The first design option has facades with approx. 70% window area and external blinds and is air-conditioned with non-operable windows. The second is fully glazed with a highly selective solar control glass and internal shading devices. It is also air-conditioned with non-operable windows. The third building has 40% window area, external blinds, operable windows and is heated only. Exposed concrete slabs and night time ventilation are used to limit summertime temperatures. The fourth building has façades with approx. 70% window area and external blinds, exposed concrete slabs, night time ventilation, comfort cooling and natural ventilation. For the thermal simulations a representative slice of the building as shown in figure 1 was used. The following assumptions were made:

- office hours from 9 am to 5 pm
- room setpoint in summer 24°C
- room setpoint in winter 22°C (reduced to 16°C at night)
- normal office internal loads (1 Person per 14 m², 15 W/m² machines, 15 W/m² lights)
- window frame 10%
- no humidification in winter
- supply air condition 20°C all-year round

- no ventilation in the corridor
- ventilation system in operation from 8 am to 6 pm
- nighttime ventilation from 12 pm to 6 am, May to September, assumed constant at 1.5 ac/h
- a constant air change rate of 2 ac/h is assumed for the natural ventilation options
- % window to wall is based on internal wall area (seen from office)
- internal walls are assumed adiabatic

To assume a constant air change rate of 2 ac/h for the natural ventilation options is a simplification and could potentially lead to overestimation of both heating demand in winter and summertime overheating. However cross-checking of the results with previous detailed studies into natural ventilation of offices [5] shows that the results correlate well with previous results based on more complex models. Due to the uncertainties associated with occupant behavior in naturally ventilated buildings it was felt that this approach was adequate for the present purpose. For details on the various design parameters used for the four options see table 1.

Table 1. Parameters

	Alternative 1	Alternative 2	Alternative 3	Alternative 4
Window Area as % of indoor wall area	73%	100%	40%	73%
Window U-Value	1.3	1.5	1.5	1.3
Glass g-Value	62%	36%	62%	62%
Glass light transmission	80%	66%	80%	80%
Operable windows	no	no	yes	yes
Solar Shading Position	external	internal	external	external
Solar Shading Control Value	200 W/m²	200 W/m²	200 W/m²	200 W/m²
Wall U-Value	0.3		0.5	0.3
Suspended ceiling	yes	yes	no	no
Cooling	yes	yes	no	yes
Ventilation	mechanical	mechanical	natural	natural
Air change rate	2.5 ac/h	2.5 ac/h	2 ac/h	2 ac/h
Dehumidification	yes	yes	no	no
Heat Recovery efficiency	70%	50%	none	none
Heating Unit Capacity (W/m²)	70	70	70	70
Cooling Unit Capacity (W/m²)	50	50	0	50
Nighttime ventilation	no	no	yes	yes

Heating and cooling loads were calculated using dynamic thermal simulation software. Fan energy was calculated based on 3 W per l/s of supply air, typical for conventional ventilation systems currently installed in European buildings. Lighting energy was estimated using a simple method developed by the author, which uses calculated daylight factors and annual external light availability data to roughly estimate the hours when electrical lighting can be expected to be in use. The primary energy demand thus calculated represents roughly 90% of the total primary energy demand of an average office building (excluding computers, office machines etc.). Items such as domestic hot water, pumps and lifts are not included.

RESULTS

Figure 2 shows the BEEP chart which was developed to allow the energy efficiency of various building designs to be plotted and thus compared. The x-coordinate of a given point represents the primary energy demand of the building design for heating, cooling, lighting and fans and the y-coordinate the percentage of occupied hours in a year with PPD > 10% as an indication of the comfort level achieved.

It is proposed that energy efficiency is expressed as the relationship of the number of hours with comfortable conditions to the primary energy demand necessary to maintain this condition. This is called the BEEP value and is calculated thus:

$$BEEP = \frac{NOH(100 - N)}{100PED} \qquad (1)$$

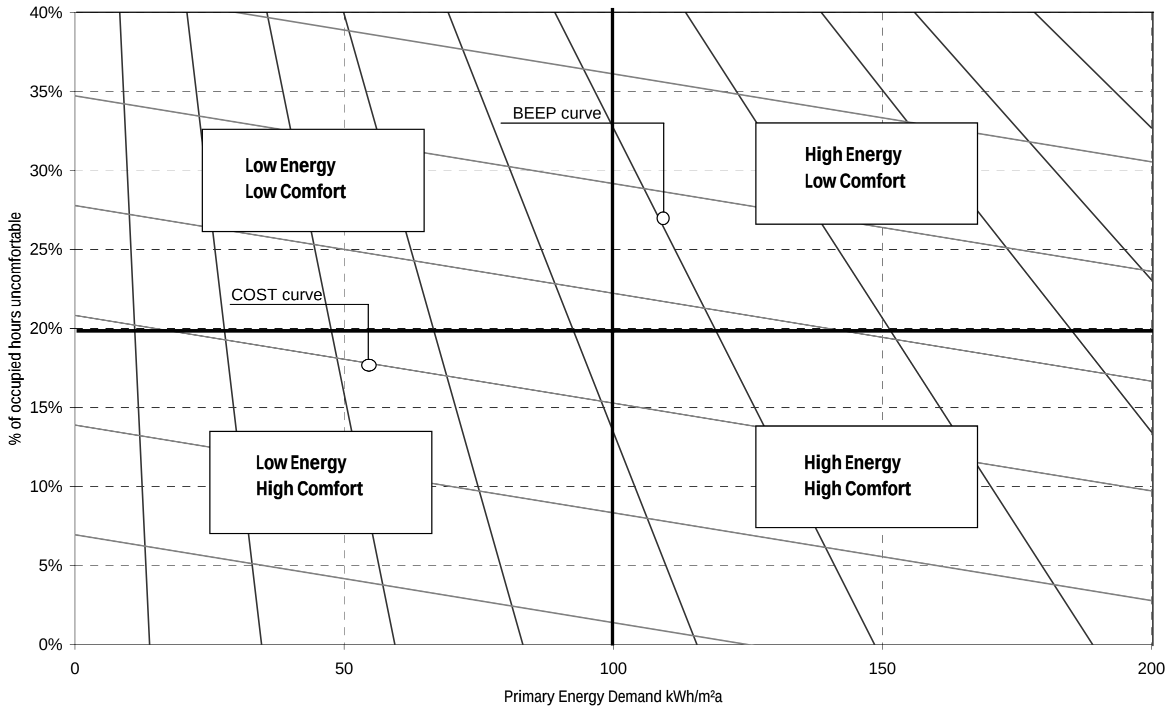

Figure 2. BEEP Chart

where BEEP is the Building Energy and Environmental Performance in hours comfortable per kWh/m²a, NOH is the number of occupied hours in a year, here assumed to be 2080, PED is the primary energy demand for heating, cooling, fans and lighting in kWh/m²a and N is the % of occupied hours with non-acceptable internal environmental conditions (PPD > 10%). To allow a comparison of the economic or financial implication of the considered options in operation it is proposed to sum the energy costs and the effect of the loss of productivity due to poor internal conditions and use this as an indicator of the economic cost of the various options.

$$COST = (EC)(PED) + (PL)\frac{(SC)(N)}{10000} \qquad (2)$$

where COST is measured in €, EC is the cost of a unit of primary energy in EUR/kWh, here assumed to be 0.04 €/kWh, SC are the staff costs and are assumed here to be EUR 7200/ m²a (€12 000 (Salary+overhead+profit) x 12 months / 20 m²) and PL is the assumed loss in productivity in % for the time when PPD is higher than 10%. It is assumed here that a 1% loss in productivity occurs whenever the PPD is greater than 10%. It should be noted that this is probably a gross underestimation of the effect of poor comfort on productivity. The assumption that the loss remains at 1% regardless of how high the PPD is, is also of course a simplification and probably an underestimation of the effect. Roelofsen states values of approx. 3% productivity loss at 10% PPD rising to nearly 20% at 60% PPD [6]. However for the purpose of providing an indicator such as proposed here for use in the comparison of options, it was felt that it may be better to initially underestimate this effect. As the results will show, even a constant value of 1% weighs in heavily when compared to energy costs. Further research should be undertaken into the application of the available data on productivity loss dependent on comfort in a method such as proposed here.

The resulting BEEP chart can be thought of as comprising four areas as shown in figure 2. The goal of building designers should of course be the bottom left area. Often decisions are between the bottom right and the top left areas. Obviously the top right area is to be avoided. Lines connecting BEEP points with equal values are called BEEP curves. Buildings which lie on the same BEEP curve may be said to be equally energy efficient. Lines connecting COST points with equal values are called COST curves. Buildings which lie on the same COST curves may be thought of as having similar economic implications in operation. The higher the BEEP value is, the higher the energy efficiency of the solution. A lower COST value means lower costs in operation. 100 kWh/m²a was taken as the boundary value between high and low energy solutions. This is the value used to define a low energy building in a governmental support program for energy efficient building in Germany [7]. A value of 20% of the occupied hours uncomfortable was chosen as the boundary value between high and low comfort. While this may seem high, one must remember that a large proportion of office buildings in Europe have no passive or active cooling and will thus be probably uncomfortable for large portions of the summer. Obviously these values are to some extent by nature arbitrary and will need to be adjusted after further research work. Table 2 shows the results of the dynamic thermal simulation of the four design options described above, including the BEEP values, which were calculated as described above. The primary energy value obtained from the simulation of the representational slice was multiplied by a factor of 0.85 to convert the value to kWh per m² total floor area of the building. This factor is based on typical values for the relationship between office and total floor areas and between energy demand in the office areas and in the other areas of the building.

Table 2. Results

	Energy Demand	**Comfort**		**BEEP**
	Primary Energy kWh/m²a	Hours PPD>10%	% of occupied hours	Value
Alternative 1	110	13.0	0.6%	19
Alternative 2	150	615.0	29.6%	10
Alternative 3	100	564.0	27.1%	15
Alternative 4	87	174.0	8.4%	22

Figure 3 shows the break-down of the primary energy demand for the various options. In figure 4 the four alternative solutions are plotted on the BEEP chart. When the alternative solutions are ranked in terms of both BEEP value and COST values the results are surprising when compared with a ranking done on intuition. Interestingly, alternative 1 can be seen to have a higher BEEP value and therefore a higher total energy and environmental performance than alternative 3, which may not have been apparent before being plotted on the BEEP chart. From an economic point of view alternative 1 can be seen to be by far the most efficient, also not immediately apparent before plotting on the BEEP chart. Before finalizing a decision, capital costs and the costs of system maintenance etc. would of course need to be considered. Alternative 2 is the worst type of solution; high energy and low comfort. In terms of costs in operation alternative 2 and 3 are similar, also an unexpected result. Of course the capital costs associated with alternative 2 will be higher. Alternative 4 is a low energy high comfort solution and has the highest BEEP value. Considering that alternative 1 will also be more expensive in terms of initial costs than alternative 4 and that the absolute energy demand of alternative 4 is considerably lower than alternative 1, alternative 4 may be judged to be the best solution. The relatively large percentage of time however, whereby the internal environment is not comfortable, needs to be considered. On the other hand, many solutions exist for low energy high comfort buildings which may be expected to perform considerably better than alternative 4. Note also that if natural ventilation was reduced in winter and increased in summer the comfort performance of alternative 4 (and alternative 3) could be expected to improve (see assumption above for natural ventilation). In other words there is potential with alternatives 3 and 4 to improve comfort and energy performance by optimizing natural ventilation strategies. Note that whilst the energy demand from the alternatives 3 and 4 are similar, the total performance of alternative 4 as measured by the BEEP value is significantly higher.

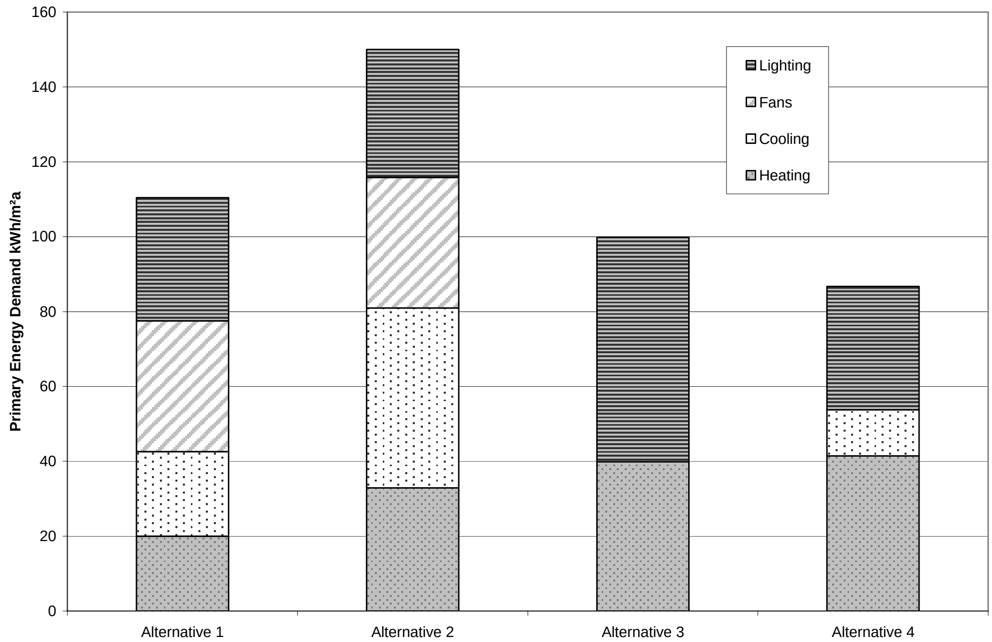

Figure 3. Primary energy demand of the various options

An interesting question poses itself with regard to alternative 3. What would happen, if the building was upgraded at a later stage with a cooling system to improve comfort? This option was also simulated and the result is shown in figure 4 as point 3´. The cooling system is the same as that used in alternative 4. It can be observed that although comfort is significantly improved and the BEEP value is also improved (slope of the improvement curve is steeper than the BEEP curves), the total energy and environmental performance is still less than for alternatives 1 and 4. The energy demand of the upgraded alternative 3 is very similar to 1, yet the attained comfort level significantly lower. This result demonstrates that the BEEP value in such a case should be calculated for both the present condition and the condition after an upgrading to include systems which provide a certain minimum level of comfort.

DISCUSSION AND CONCLUSIONS

The method presented here outlines an approach which could form the basis on which further work could be carried out with the ultimate goal of developing a comprehensive way of comparing the energy efficiency of building design options. The examples here were used as a means of initially testing the method. The results obtained are not intended in any way to provide conclusions on the appropriateness of the various design solutions studied. The results do indicate however that we need to compare options comprehensively and understand energy efficiency not as energy use alone but as the relationship between energy use and value in terms of the quality of the internal climate achieved. This should be part of a total approach in which capital and running costs, functionality and architectural quality etc. of the various options are also compared with one another. The economic curves are primarily displayed to indicate tendencies and to show the vast difference between the energy and economic efficiencies (demonstrated by the different slope of the curves). An increase in energy cost would change the slope of the economic curve and it is interesting to note, that based on the data considered here, the energy price would need to increase by a factor of approx. 15 before the slopes would roughly coincide and decision making based on total energy and environmental performance and decision making based on cost would lead to the same solution. It must be remembered that capital costs have not been factored-in. The goal of any design should be a high BEEP value positioned in the bottom left area. Note that the higher the BEEP number, the steeper the curve; i.e. large differences in comfort and small differences in energy demand.

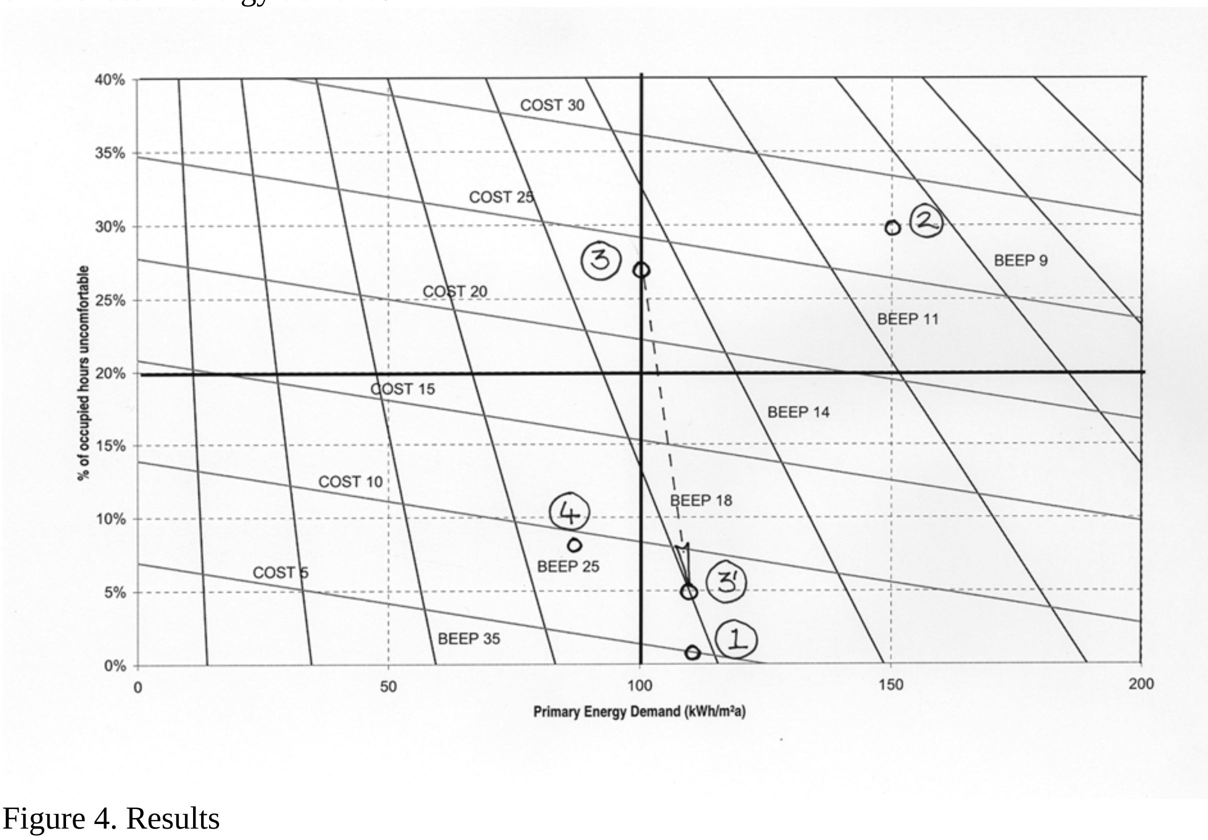

Figure 4. Results

The proposed tool could be developed to be put in use not only as a means of demonstrating the energy efficiency of building designs at the planning permission stage (similar to the energy certificate as required by the new EU directive) but also as a design tool to compare various options during the design stage. Items such as energy production (photovoltaic, wind energy, solar cooling) and system configurations such as underground fresh air ducts are not considered in the illustrated case studies but could and should be included in the final planning instrument. A more complex instrument can be imagined whereby the x-axis is represented by total primary energy demand over the total life cycle of the building (including embodied energy etc.) with the y-axis representing the total internal environment achieved including factors such as air quality, lighting levels and acoustics but also psychological issues such as daylight, operable windows etc. The capital costs could be factored into the economic curves.

Contemporary engineering design firms use dynamic simulation to design buildings as standard procedure. It seems questionable, whether the right approach is to develop spreadsheets for energy calculations for the production of energy certificates, which is what is happening all over Europe right now, instead of accrediting commercial dynamic simulation software programs. Further research is necessary to determine the range of appropriate values in the BEEP chart and to produce BEEP charts for different applications. A series of charts could be produced for different building uses (office, apartments etc.) for various climatic regions. Further research should also look at ways to measure comfort which would be appropriate to be used in such an approach. The simulation software used in the study here calculates the PPD value for the centre point of the room. It should be investigated further whether this relatively primitive indicator is adequate for the intended purpose or alternatively whether a better one could be employed. Further research on the exact nature of the relationship between PPD and performance would also be valuable. Future work could also improve the complexity of the natural ventilation model (see above). Note also that research has shown that comfort perceptions in naturally and mechanically ventilated buildings are different [8]. This aspect has not been considered yet in the approach used here.

The upgrading of alternative 3 with cooling shows the danger of the current methods concentrating only on energy demand; a seemingly low energy building may after upgrading to rectify comfort problems be less energy efficient than a relatively conventional fully air conditioned building. In terms of conserving energy or possibly even from an ecological point of view, concentrating on reducing energy demand is possibly a legitimate approach but is it really sustainable? Achieving sustainability is complex and consideration of the economic and social aspects may mean that conserving energy at the expense of a lower quality of internal environment is not the most sustainable approach.

SUMMARY

This paper describes the production of the Customer Advising Tool (CAT), a piece of software to help assess the potential for reducing the cooling demand of Office buildings, as required by Article 9 of the EPBD. It is a practical tool aimed at use by building owners, inspectors and auditors as part of the Inspection and Audit process. The tool was developed by the authors as part of the IEE AUDITAC project.

The tool is based on a mixture of monitored and modelled data, and this paper presents the tool's development, concluding with how the inputs and outputs are simplified down to those required to provide a focus to the on-site inspection and audit.

It is anticipated that many Member States will refer to the tool as part of their support for implementing Article 9. The tool can be downloaded from, or used at, the following website: http://www.cardiff.ac.uk/archi/research/auditac/advice_tool.html

INTRODUCTION

Article 9 of the European Energy Performance of Buildings Directive (EPBD) is concerned with reducing the energy consumption of Air Conditioning systems in buildings. The second paragraph of Article 9 states *"This inspection shall include an assessment of the air-conditioning efficiency and the sizing compared to the cooling requirements of the building. Appropriate advice shall be provided to the users on possible improvement or replacement of the air-conditioning system and on alternative solutions"*.

The practical reality for the auditor/assessor in meeting Article 9 is that they have a limited timescale in which to assess/estimate the performance of both a building and its A/C systems. Within this timescale it is likely that the assessment of the A/C systems will occupy the majority of the time. A quick and easy method of assessing the effect that the building and its usage is having on the A/C system cooling demand is therefore required to minimise the time and effort spent on this task.

The purpose of this paper is to provide details of the recently published AUDITAC Customer Advising Tool (CAT) [1]. This tool has been designed to provide information, in a form accessible to a building owner or assessor, on which aspects of the Building Fabric and Operation are likely to be having the largest effect on the cooling energy demand imposed on the building's Air Conditioning systems, and therefore which areas are most likely to provide the greatest potential for reducing this demand. The tool also provides an indication of the percentage change in cooling demand that would occur through variation of aspects of the building design or operation. It is important to note that the tool is a **holistic** design tool, i.e. it considers the overall cooling demand resulting from the **interactions** between all the criteria and parameters specified.

It is important to note that the CAT has been derived using data from Offices, but it is believed that the basic findings should be generally applicable to any situation that matches those described in the CAT input sections.

The nature of cooling demands in buildings
Modeling, monitoring and other studies on cooling in buildings and building services by the authors [2,3,4,5,6,7,8,9,10,11,12,13,14,15,16,17] and other researchers, have shown that those factors which have a significant effect on a building's heating and cooling demands are relatively few.

The heat transfer mechanisms within buildings are the familiar ones of radiation, convection and conduction. These mechanisms will transfer energy into or out of a building depending on the following main factors:

- Time of day, week, year.
- Ambient weather conditions.
- Design of the building, its services, and its location with respect to overshadowing, exposure, etc.
- Building use, i.e. occupancy type, hours of use, layout.
- Internal conditions provided in the building.
- Effectiveness of building services controls

The CAT considers these aspects in terms of their effects on the cooling demand of buildings. The data presented by the CAT is obtained purely from modeling, but the results have been compared with previous measurements and monitoring to provide a few points of reference. The CAT presents the findings from the work in a manner that is of use to the assessor in meeting the requirements of Article 9.

The design of the CAT uses the extensive experience of the authors in assessing the energy performance of buildings and A/C systems to minimise the information an assessor needs to obtain to use the tool. It does this by asking only for information that can be used to estimate, and make improvements to, the building cooling demand.

Within the context of the CAT, the factors noted above which affect the cooling and heating demand in buildings can therefore be simplified into various criteria and parameters that the assessor can establish for each building.

Not all of the criteria and parameters identified as important were able to be assessed through modeling, primarily due to time and resource constraints. Details are given later in this paper. The other limitation of the CAT is that it has not been possible to model all the possible permutations of the criteria and parameters. This is again due to the impossibility of achieving this in the time with the computing resources available. Therefore the CAT modeling has used a technique of varying some of the individual **parameters** around an **average** value that is considered by the authors to represent the best compromise of all the possibilities available for that parameter. Nearly all the possible permutations of the **criteria** assessed have been modeled however.

Use of the Customer Advising Tool

The authors consider that the CAT will be used primarily at the pre-audit stage of an inspection. At this stage the CAT can usefully identify the main aspects of the building and its operation which might be further studied onsite by the assessor in their search for potential means in reducing the building cooling demand.

While the CAT cannot consider the detail of the individual buildings to be inspected, its ability to holistically consider the interaction of some of the main contributors to building cooling demands is a major assistance in writing Inspection Reports.

DETAILS OF THE PARAMETERS AND CRITERIA USED IN THE CAT MODELING

The basis of the CAT modeling is an open-plan cube of dimensions 10m x 10m x 2.4m. This cube is shown in Figure 1 as part of a 9 cube square. Once each layout is generated, inter-zonal adjacencies between each cell are calculated, making it possible to discern for each side whether it is adjacent to another cell or exposed to external conditions. Windows of the appropriate size are then automatically inserted into each exposed facade element.

The apparently low ceiling height reflects the authors' desire to approximately model the effect of occupancy on the reduction of internal volume in the space (taken as about 20%), and hence the reduction in ventilation air needed to achieve the required air change rate.

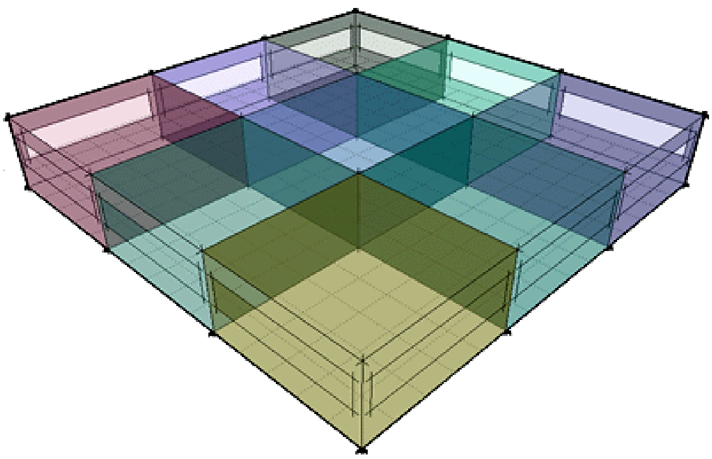

Figure 1. Basic cube model, shown as the deep plan 30m x 30m layout.

The various combinations of the basic cubes and their properties were modeled in the ECOTECT software programme [18] and exported to the EnergyPlus building energy modeling software [19] to be run with the various combinations of criteria and parameters required to meet the purposes of the CAT.

Descriptions of the individual criteria and parameters modeled which are applied to the permutations of this basic cell model are discussed in more detail below, along with the ranges over which each criteria or parameter was modeled. The descriptions also consider how an assessor might go about classifying each for a building.

CAT criteria

For the CAT, **criteria** are deemed to be those elements of the building design or operation that are known to have an influence on the heating and cooling demands, but are realistically unlikely to be altered simply to try and reduce heating and cooling demands.

***Plan depth*: The ratio of floor area to total external facade area.** A shallow plan will normally allow daylight and natural ventilation to be used over the entire floor area. A deep plan will usually be fully mechanically ventilated. The choices available and modeled for this criterion are shallow plan (10m x 10m); medium plan (20m x 20m); and deep plan (30m x 30m)

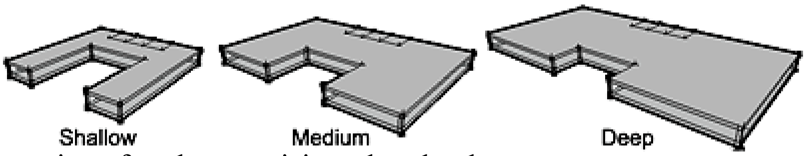

Figure 2 - Three options for characterising plan depth.

Glazing ratio: The glazing ratio represents the percentage of the exposed external vertical facade area of the building that is considered to be a solar aperture. This is typically a glazed area having some transparency to both visible light and solar radiation. Variations in glazing ratio were modeled using windows of the same sill and height but with different widths relative to each wall surface such that the ratio of glazed area to total vertical façade area represented 20%, 40%, 60%, 80% and 90%.

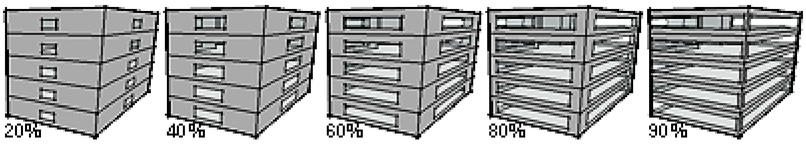

Figure 3 - Values for characterising facade glazing ratio.

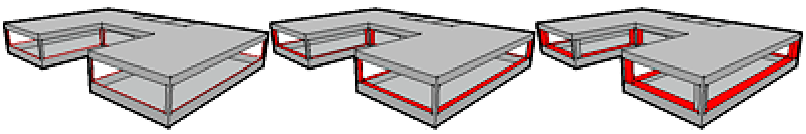
Thermal mass: In order to consider the effect of thermal inertia on building performance, it is necessary to define this criterion which is based on the amount of internally exposed thermal mass. A building with significant amounts of masonry or concrete visible would usually be classed as heavyweight, whilst a building which is predominantly suspended ceilings and lightweight partition walls would usually be classed as lightweight. The choices available and modeled for this criterion are lightweight, mediumweight and heavyweight.



Lightweight *Medium weight* *Heavyweight*

Figure 4 - Three levels of internally exposed thermal mass**.**

Weather locations: The city location/region modeled by the CAT which is most likely to reflect the weather conditions to which the audit building will be subjected. Regional variations in climate were considered by using average annual weather data sets for a range of locations throughout Europe in the calculations. The choices available and modeled for this criterion are Vienna (Austria), Berlin (Germany), Madrid (Spain), Paris (France), London (UK), Athens (Greece), Rome (Italy), Lisbon (Portugal) and Stockholm (Sweden). These were modeled to allow a choice of climatic zones.

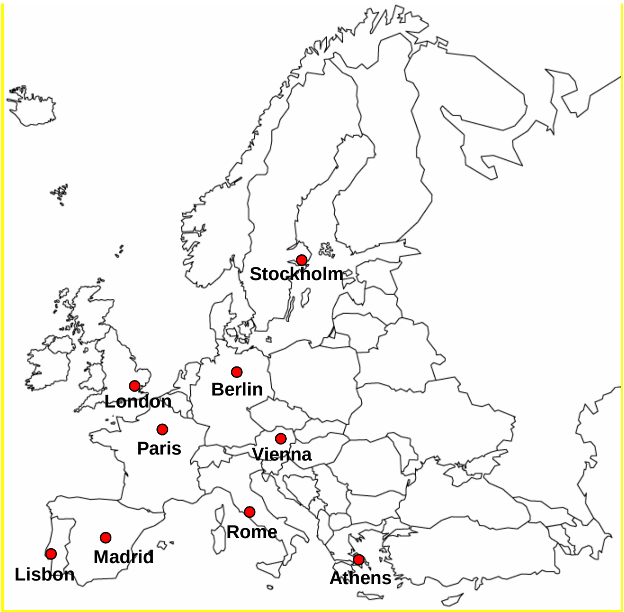


Figure 5 – Map of European weather locations modeled in the CAT.

***Internal layout*:** This reflects whether the building is predominantly cellular offices or open plan. *The CAT currently considers the building to be comprised of 10m x 10m open-plan cells as noted earlier. These options are not available in the model yet.*

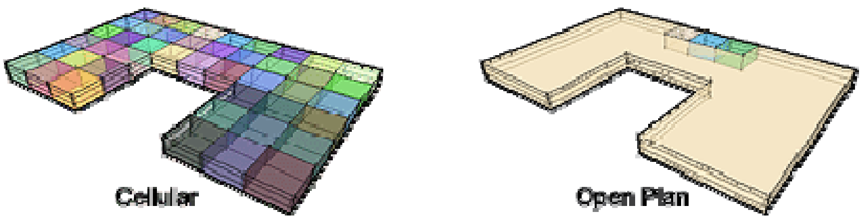

Figure 6 – The two extremes of internal layout.

***Building form*:** This reflects the effect of building form on issues such as self-shading and ventilation rates. *Only the square form has been modeled for this criterion.*

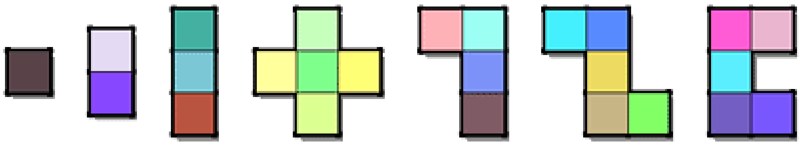

Figure 7 – Examples of simple cell layouts.

***Multiple storeys*:** Due to the number of runs involved, work to include the effects of multiple storeys has not yet been included in the CAT. However, the strategy to do so has been carefully considered. To represent buildings with any number of storeys, it is necessary to simulate ground floors (which may be underground or in direct contact with foundations) separate from top floors (which may have an exposed roof or be in direct with a ventilated plant room directly above) separately from mid-level floors (for which thermal transfer through the floors and ceilings is likely to be negligible).

Moreover, self shading of windows on lower floors may be quite pronounced in some of the plan layouts making it necessary to model the floors above. Whilst it would be possible to generate and test a series of multi-storey versions of each plan layout, as shown in Figure 8, the resulting number of runs becomes prohibitive.

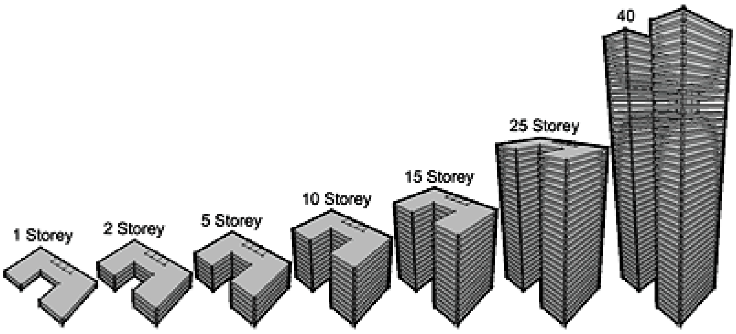

Figure 8 - Simulations should allow choice of any number of storeys.

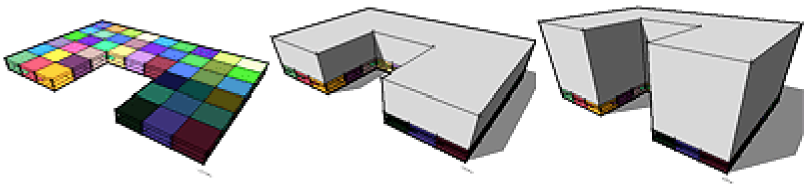
A proposed solution was to generate 3 models for each plan layout. The first, representing a top storey, would be assigned an adiabatic floor (to simulate insignificant heat flow to the zones below) and an exposed roof. The second, representing a mid-level storey, would be assigned both an adiabatic floor and an adiabatic ceiling (to simulate insignificant heat flow to zones both above and below) with an additional non-thermal zone generated above to simulate any self-shading effects. The third model, representing the ground storey, would be assigned a ground-connected floor and an adiabatic ceiling, as well as a much larger non-thermal zone above. The different models are illustrated in Figure 9 below.



Top floor *Mid-level floor* *Ground-floor*

Figure 9 - The three models required to simulate multi-storeys

This way, by simply performing three runs, it is possible to represent any number of storeys by adding the energy demand of the ground and top floors to a number of mid-level floors equal to [storeys-2]. This assumes that the self shading effect on the mid-level floor represents the average over all floors. Figure 10 illustrates the theoretical assembly of this building.

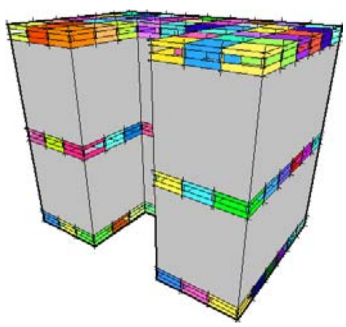


Figure 10 - Assembling a multi-storey building from the 3 models.

Single storey buildings, with both an exposed ceiling and a ground-connected floor must be represented by an additional and separate fourth run based on a model with both a ground-connected floor and an exposed ceiling. *Only this single storey building has been modeled for this criterion in the CAT to date.*

CAT Parameters

Parameters are defined as those elements of the building design or operation that are known to have an influence on the heating and cooling demands, and are potentially able to be altered by the assessor or building owner.

***Fabric U-value*:** This refers to the overall surface-averaged thermal conductance of the opaque elements in the external building envelope. This includes the roof as well as facades. The effects of this parameter have been modeled between 0.1 and 4.0 W/m^{2}K. The average value used for this parameter is 0.5 W/m^{2}K.

***Window U-value*:** This refers to the overall surface-averaged thermal conductance of the windows and transparent elements in the external building envelope. The effects of this parameter have been modeled between 0.5 and 6.0 W/m^{2}K, where the most insulating transparent element available would have a U-value of around 0.5 and single glazing would have a U-value of around 6.0. The average value used for this parameter is 3.0 W/m^{2}K.

***Solar Heat Gain Coefficient (SHGC)*:** This is the fraction of incident beam (direct) solar radiation that enters the building through the transparent elements, such as windows. This includes the transmitted solar radiation and the inward flowing heat from the solar radiation that is absorbed by the glazing. The effects of this parameter have been modeled for SHGC's ranging from 0.1 to 0.9, where 0.1 is highly shaded, (i.e. little solar gain), and 0.9 means no effective shading. The reduction from 1.0 is simply due to the normal properties of glass. The average value used for this parameter is 0.5.

***Air change rate (infiltration only)*:** This refers to the uncontrolled exchange of air between internal spaces and outside air due to gaps in the building fabric linked to design details. This value is given as the number of complete air changes per hour. The effects of this parameter have been modeled between 0.1 and 4.0 ac/hr, where a well detailed, well-sealed building would be around 0.1 and a very leaky, shallow plan building in an exposed and windy location would be around 4.0 ac/hr. The average value used for this parameter is 0.5 ac/hr.

The tool does not specifically include a parameter for varying the **ventilation** air change rates, as it was deemed that this would be set by the building owner to meet the ventilation and cooling demands of the building. However, in tightly sealed buildings, the effects of modifying the ventilation rate can be approximated by adding the infiltration and ventilation rates together. This sensitivity analysis could be useful if a change from using air as the heating and cooling transport medium to recirculation A/C systems with separate fresh air supply were being considered.

***Internal Gains (W/m^2)*:** This refers to the contribution of small power, lighting and people loads per metre squared floor area. The effects of this parameter have been modeled between 10 and 160 W/m^2, where 10 W/m^2 represents a very low density of occupation and equipment use, and 160 W/m^2 would represent a very high density of equipment and occupancy, such as a business call centre. The average value used for this parameter is 40 W/m^2.

***Hours of use of the heating and cooling systems*:** This parameter refers to the effect of running the systems continuously or over the working week only (assumed 08:00 to 18:00 in this system). *The effects of optimum start/stop have not been assessed.*

***Variation in heating and cooling setpoints*:** The CAT assumes a heating setpoint of 21°C and allows the cooling setpoint to be varied between 21 to 25°C in 1°C intervals. *It does not allow the effect of varying the heating setpoints to be assessed.*

***Variation in occupancy, equipment and lighting schedules*:** This parameter refers to the effect of intermittent or continuous occupation, equipment or lighting schedules. The CAT assumes an 08:00 to 18:00 schedule for all these parameters including the HVAC equipment. *The effects of various combinations of continuous and intermittent schedules of these parameters have not been assessed.*

***Spatial distribution of cooling loads*:** This reflects the possibility of moving the cooling loads within the space to minimize the cooling demands on the A/C system. *Only evenly distributed loads are currently considered by the CAT.*

System Parameters

In order to accurately compare heating and cooling energy, as well as calculating potential carbon emissions savings, the relative efficiency of the plant and equipment used to supply the building's heating and cooling demand must be specified or estimated. These values are usually very difficult to obtain with any accuracy so it is necessary to test the likely range in the building being assessed to estimate the sensitivity of any recommendations to reasonable variations in these figures. These are defined in this work as *system parameters* and include the following for both the heating and cooling systems if present in the building.

Heating System Efficiency (SCOP)

This defines the Seasonal Coefficient Of Performance (SCOP) for the equipment used to provide space heating within the building. This is given as the annual average ratio of total heat output compared to total energy input to the equipment. A good condensing boiler based system would expect to achieve a SCOP of around 0.9, whereas an old cast-iron boiler based system might struggle to reach 0.6.

***Cooling System Overall Efficiency*:**

This is the overall annual ratio of the cooling energy demand met by the installed cooling system, divided by the total energy input to the cooling system. It includes auxiliary energy consumption as well as the chiller energy consumption. It is important to note that this is NOT the Energy Efficiency Ratio (EER) for the equipment used to provide comfort cooling within the building. A low rating (0.3 - 0.6) would apply to an inefficient system, and a high rating (>2.0) to an efficient system. An average performance is likely to be 1.0 - 1.5.

Countries with high cooling demands are likely to see better overall efficiencies than countries with low cooling demands, as the chiller energy demand in hot countries will be a greater proportion of the overall cooling system energy consumption.

Fuel Carbon Emission Factor

The amount of carbon dioxide emitted through the consumption of 1 kilo-Watt hour of fuel used. This is given as a value between 0.0 for totally renewable energy and 0.43 kgCO2/kWh for delivered grid electricity - although allowance is made in the CAT for values up to 0.60.

For countries other than the UK the appropriate Grid delivered electricity factor should be used. Refer to the International Energy Agency (http://www.iea.org) for further information.

DISCUSSION

Interpreting the outputs from the cat

Once the building assessor has entered values for each of the above criteria and parameters (or accepted the default values offered) the CAT then searches its database to find the output graphs that match these values.

Figure 11 shows an example output graph.

Output graphs present the PERCENTAGE change in heating and cooling demands that would occur for a given change in an individual parameter, along with an estimated overall change in carbon emissions. The value assigned to each parameter is shown by the vertical green line on each graph, and the percentage changes in the Y-axis are relative to this value.

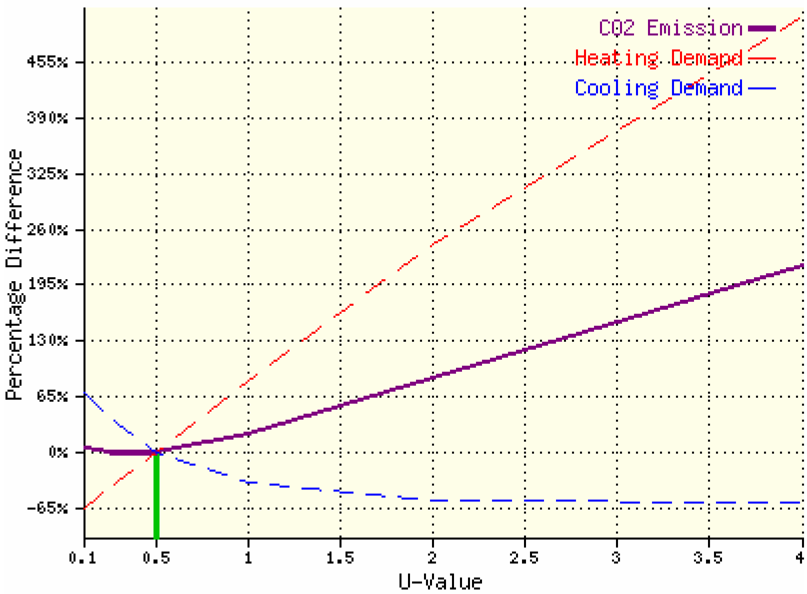

Figure 11. Example output graph showing the percentage change in heating and cooling demand achievable by varying the building fabric U-value from the input value (0.5).

A positive percentage increase shows an increasing demand for heating or cooling, and increasing carbon emissions. A negative percentage shows a reduction in these values.

The carbon emissions line is used as a proxy for assessing whether the proposed parameter changes might adversely affect the heating demands. The carbon emissions estimates are derived using the heating and cooling system parameters entered on the input screens, so it is important these are as accurate as possible, but they are still only estimates as the values entered will vary with time of year and actual demands on the systems.

In this example the graph shows that from a carbon viewpoint the current fabric U-value is probably the optimum for the combination of criteria and parameters chosen. Had we increased the U-value to 2.0 then from the graph we would have potentially achieved around a 60% reduction in the cooling demand, but the heating demand would have risen 250% and the overall carbon emissions around 100%.

The assessor would therefore not need to consider this as a potential area for improvement in the on site survey. This graph also shows the importance of considering the building and occupancy holistically. Had the heating impact not been considered then it would have appeared that we would need a less insulating U-value than currently installed.

The output graphs are viewable as both annual and monthly graphs for each parameter, so that the seasonal variation of the loads due to a given parameter can be assessed. At present the CAT does not allow the assessment of dynamic parameter changes in one run, e.g. using moveable shading to alter the SHGC only through the months requiring cooling. However the assessor can run a series of different parameter values which would give him the same information.

CONCLUSION

This paper has provided an overview of the derivation of the CAT, a tool which shows how a building's basic design and operation might affect the cooling demands placed on an A/C system used in the building, and how these demands might potentially be reduced through altering aspects of the buildings design or operational parameters.

MINERGIE-P® – A Building Standard of the Future

Stefan Mennel, Urs-Peter Menti and Gregor Notter

University of Applied Sciences of Central Switzerland, Lucerne (HTA)

Corresponding email: stefan.mennel@hta.fhz.ch

SUMMARY

Already 20 years ago, Gro Harlem Brundlandt stated «I believe the time has come for higher expectations, […] for an increased political will to address our common future» ([1], p. 13). Indeed reading the newspapers one could get the notion that finally politicians (at least in Europe) are re-thinking those lines.
This paper presents the low-energy label for buildings MINERGIE-P® launched in Switzerland end of 2002. MINERGIE-P® demands a decrease of the heat demand by 80%. Solutions are shown of how to comply easily with these demands that appear severe on first sight. Furthermore the historical and political necessity to act is outlined and put into perspective.
Of utmost importance regarding MINERGIE-P® is not only the massively decreased heat demand. The used technologies and appliances furthermore guarantee a high indoor air quality and the long-term conservation of building value. This is easily communicated and in the meanwhile broadly accepted by banks offering better conditions for real estate mortgages.

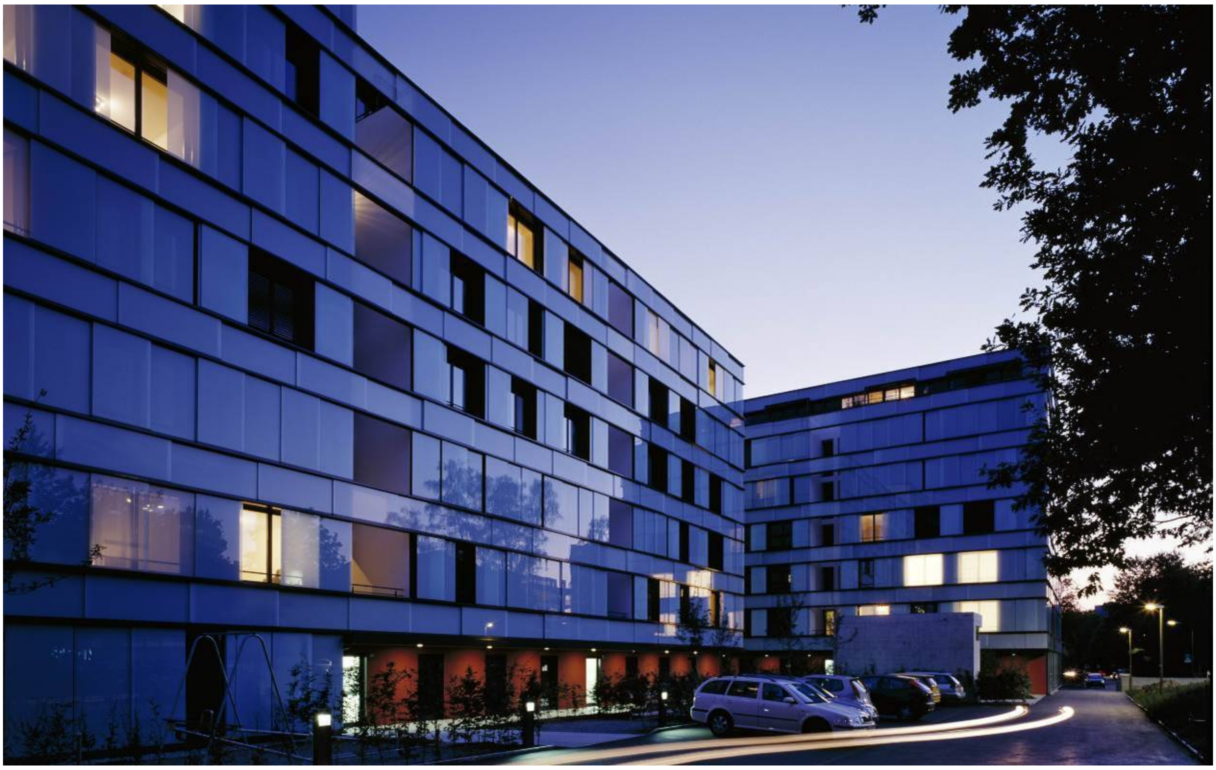

Figure 1. Multiple-family dwelling offering 90 apartments close to Zurich designed to comply with the demands of MINERGIE-P®. (Picture courtesy of Senn BPM, Switzerland)

INTRODUCTION

At the moment of writing, energy consumption and cutting down on CO_2 output are highly pressing matters (and hotly debated at least in the European Community). One of the central points to get the matters at hand under control is of course the augmentation of today's energy efficiency. This is especially true for buildings. Nowadays it is possible using existing technology to reduce consumption for heating by 80%.

In Switzerland energy calculations are standardised since 1988. More and more the legally allowed energy consumption is reduced according to the energy label MINERGIE and the still more rigorous label MINERGIE-P (harmonised with the German *Passivhaus* of Dr. Wolfgang Feist). In the paper presented the historical and political background of MINERGIE-P as well as the demands imposed by MINERGIE-P are illuminated. The paper presents both precise values of energy consumption and the consequences for low-energy buildings.

MATERIALS

Not only the European Performance of Buildings Directive (EPBD) postulates steps towards a more efficient way of handling our resources. NOVATLANTIS in cooperation with the SIA (Swiss Society of Engineers and Architects) and the BfE (Swiss Federal Office of Energy) map out in [3] the need to realise the so-called "2000-Watt society". The thought which stands behind this programme is the realisation that the worldwide average energy consumption in 1990 equalled 17,5MWh/y which amounts to a constant power consumption of 2000W per person. As could be shown in [4], 2000W in the long run guarantee a sustainable development covering all three aspects of sustainability. The authors postulate a "window of energy consumption". Thus it shall be ensured that we are not «compromising the ability of future generations to meet their own needs» ([1], p. 24).

This "window of energy consumption" takes the energetic poverty line of economic development to define the minimal possible energy consumption whereas the maximum is defined by the amount still compatible with our planet's ecological equilibrium. Lastly the distribution of consumption among consumers serves as an indicator of social stability. The industrialised countries obviously still need to take large steps to make this idea come true whereas the developing countries mostly lie well below the consumption of 2000 Watt per capita (Fig. 2).

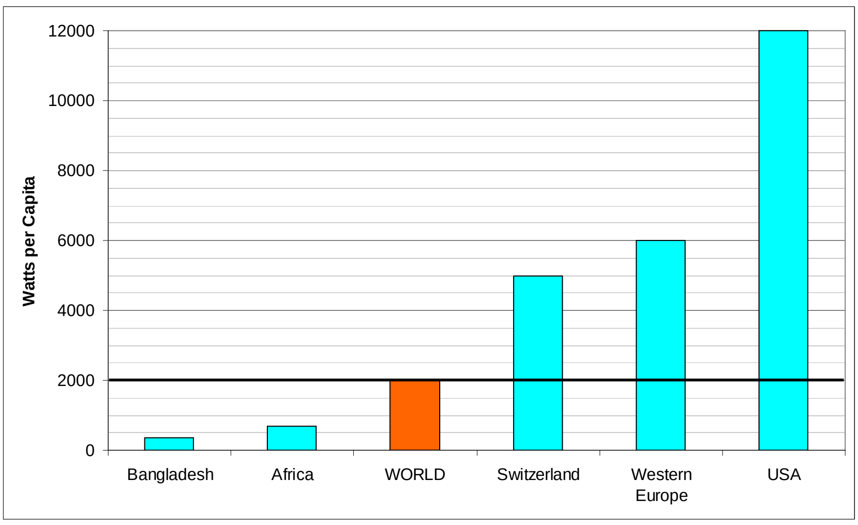

Figure 2. Comparison of the energy use per-capita in selected areas. Adapted from [5].

The association MINERGIE®, which is financially sponsored by the Swiss Federal Government as well as by the Cantons (cf. Federal States), took up those ideas in 2002, and the standard complies with them. It generated the building energy standard MINERGIE-P® which adopts mainly the ideas of *Passivhaus* elaborated by Dr. Wolfgang Feist during the 1990's in Darmstadt/D [6 and 7]. The differences between *Passivhaus* and MINERGIE-P derive mainly from the different standardisation in Germany and Switzerland. In addition, there are always different (political) points of view on the conceptual design of the optimal low-energy houses, of course. Here MINERGIE pursued perspicuously the following ideas:

- High living comfort due to surfaces of uniform temperatures,
- High indoor air quality due to mechanical ventilation,
- Better noise control since it is no longer necessary to open windows,
- Low energy consumption (not first but equal among others, see below),
- Long-term conservation of building value due to less structural damages such as caused by mould,
- Viable with a minimum of extra cost (less than 10% to 15%),
- Feasible with technology that is proven and existing.

It is of utmost importance to follow the idea of MINERGIE closely. Quite obviously the name derives from MINimal enERGIE (spelled with "ie" instead of "y" in German). The central focus of the MINERGIE agenda is not so much the absolute minimal use of energy but providing the comfort expected today at the lowest possible energy consumption. Otherwise one could just lower the room temperature to 16°C and thus generate energy savings of up to 25%! Another important point concerns the reasonable use of proven technology. It is not the goal to provide a playground for prospective technologies but to define a standard that can be met easily using existing technology and appliances.

Yearly the Swiss Federal Office of Energy (BfE) provides up-to-date data on energy usage [8]. Fig. 3 shows clearly the sectors featuring the highest potential for energy saving being traffic and housing. At the time, housing in particular offers a realistic fulcrum to start cutting down energy usage. This is the starting point for the definition of MINERGIE-P.

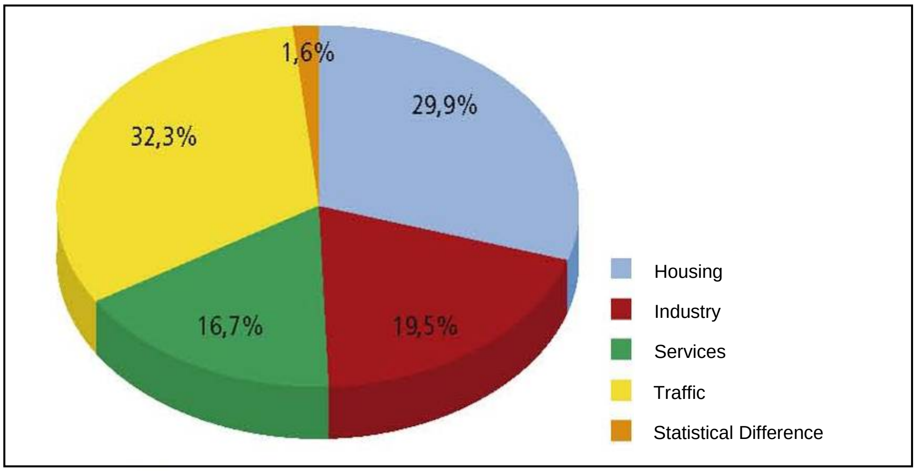

Figure 3. Energy use divided into sectors. From [8] p. 5.

In 1988 the SIA published its normative paper SIA 380/1 [9]. For the first time a standardised mathematical method was created to provide information on the predicted energy use of houses and moreover to demand a certain upper limit of energy use (as has recently been imposed by the EPBD). Thus the energy flows for the heating period were characterised and divided into heat flow due to transmittance (loss), heat flow due to airing and leakage (loss), heat flow due to persons and electricity (internal gain), and heat flow due to solar radiation (external gain), whereupon the difference between total loss and total gain, of course, needs to be provided by an additional heating system as shown in Fig. 4.

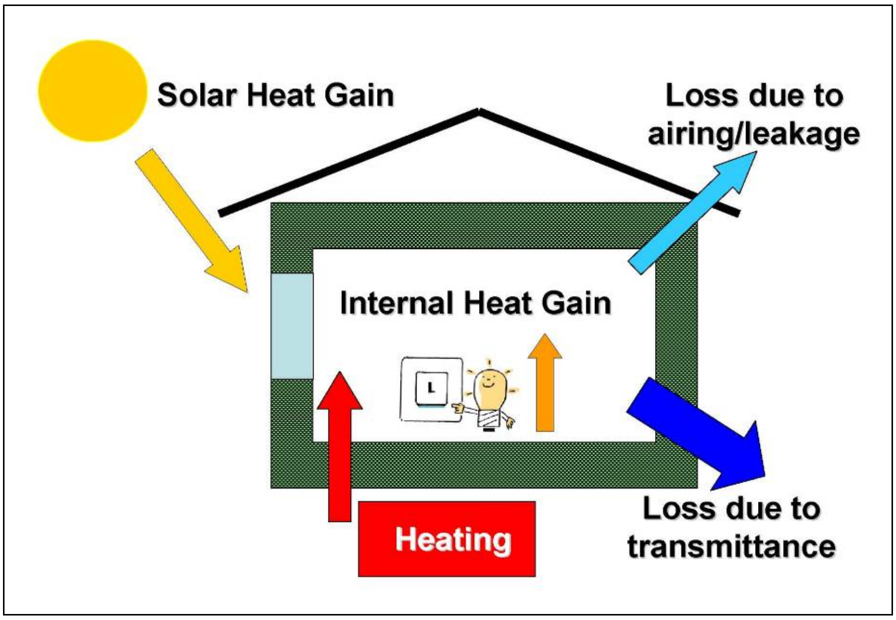

Figure 4. Energy flows following [9].

Obviously, one attempts to minimise losses and maximise gains for buildings that should consume as little energy as possible. Consequently the package of measures includes:

- Very well insulated walls (U-values ≤ 0.15W/m^{2}K, tending towards 0.10W/m^{2}K),
- Very good windows, consisting of three panes (U-value transparent ≤ 0.6W/m^{2}K, U-value including frame ≤ 0.9W/m^{2}K, total solar energy transmittance ≥ 0.5),
- Minimised thermal bridges and therefore a homogenous heat insulation of the building envelope,
- Highly airtight outer shell ($n_{50} \leq 0.6h^{-1}$ – air change rate at 50Pa pressure difference),
- Controlled ventilation using high performance heat recovery.

Moreover the building's main façade should face southeast to southwest featuring a minimum of 30% transparency of the outer shell. These orientations provide massive solar gains even in winter so that windows facing these directions contribute to the reduced heat demand. Windows in façades to other orientations and above all to the northwest to northeast produce losses and should therefore be quite small. (These statements are true for average Swiss meteorological conditions as in [10].)

Very often architects and energy engineers underestimate the importance of the realisable gains and concentrate on minimising the losses. This will never suffice to comply with the label MINERGIE-P. Indeed one could state that the "P" stands for "passive solar gains". Every factor that reduces those gains in any way (shading, skyline, and regulation) increases the heat demand considerably. The second most and often ignored point concerns thermal bridges. Common houses may feature a considerable amount of thermal bridges with losses of almost 5% of the heat demand. After having eradicated a good part of losses due to transmittance, thermal bridges (even in very well constructed and thought-through buildings) add up to 10%. If proper construction to avoid thermal bridges is neglected, the associated loss can increase considerably! Thus the ambitious goal of saving a very good part of the heat demand compared to standard houses may be missed.

RESULTS

To give the reader an idea of the dimensions we are talking about, we take an ordinary Swiss single-family detached house of $200m^2$ total area. The area in Switzerland is always measured grossly therefore including structural components as well. All the statistical energy values are based on this so-called energy reference area (ERA) and looked at over a whole year. The outer surface of the house amounts to $400m^2$ thus resulting in a ratio of thermal exposed area to ERA of 2 ([11] describes the ERA as "conditioned space" and does not explicitly specify a ratio of ERA to enveloping, thermally exposed surface). The annual energy consumption allowed by law amounts to $75kWh/m^2_{ERA}$. MINERGIE-P allows 20% of the legal energy consumption. This means that only $15kWh/m^2_{ERA}$ per year might be used as maximum heat demand. This is the primary of four conditions. The German energy label *Passivhaus* also allows $15kWh/m^2$ but measures the area differently (net instead of gross).

Second, the demand of energy including hot water production, auxiliary energy for pumps and ventilation including weighting factors must not exceed $30kWh/m^2_{ERA}$. Weighting factors always hold a political component and shall not be discussed here. Table 1 shows the weighting factors of MINERGIE together with those of *Passivhaus* and SIA to give an idea of the different points of view. All those weighting factors try to take into account the conversion between secondary energy (i.e. the amount of energy delivered to the property) and primary energy (i.e. the energy including losses due to extraction, transport, and the like).

Table 1. Weighting factors to express the conversion from primary to secondary energy

Heat producer	*Passivhaus* (D)	MINERGIE (CH)	SIA (CH)
Heating oil	1.08	1.0	1.1
Natural gas	1.07	1.0	1.1
Wood (any form)	1.01	0.5	0.1
Electricity	2.97	2.0	2.9

The Swiss mathematical method to calculate the energy demand standardises not only the internal gains, ventilation rates, and room air temperatures but also the demand of heat for production of hot water for sanitary purposes. The amount is referred to the ERA. Thus the examined single-family house needs $13.9kWh/m^2_{ERA}$ or a total of 2778kWh per year. This is enough to heat 130 litres of water from 10°C to 60°C per day. Assuming typical values for ventilation ($150m^3/h$) and auxiliary purposes ($1.5kWh/m^2_{ERA}$), Table 2 provides an overview of the energy demand so far.

Table 2. Overview to the energy demand

Energy demand by	Demand [kWh/m^2_{ERA}]	Form of energy	Weighted energy
Heating	15.0	Heat (wood)	7.5
Sanitary hot water	13.9	Heat (wood)	7.0
Ventilation	3.0	Electricity	6.0
Auxiliary energy	1.5	Electricity	3.0
Total			23.5

Of course, the exact values may vary as well as the way to produce the energy for heating and hot water. At the same time the presented values represent the typical case of a MINERGIE-P single-family house.

The second to last condition involves that the outer shell must be very airtight. Air tightness is determined by applying a pressure difference of 50Pa and measuring the air change rate.

MINERGIE-P requires an air change rate below $0.6h^{-1}$ at 50Pa (average of both overpressure and vacuum). Taking into account the consumption of electricity, the last condition demands that all domestic appliances hold the European energy label A, and A^{+} for freezers, respectively.

Statistical interpretation of 100 Swiss MINERGIE-P houses

As a matter of course the statistical interpretation of all realised MINERGIE-P houses are of interest. The following figures show the evolution of the label, which was launched at the end of 2002 (Fig. 5). Furthermore the heat production systems (Fig. 6) as well as the heat distribution systems (Fig. 7) are shown and give a distinct idea of the most common solutions to both challenges. All values are based on the last statistical review of mid-February 2007.

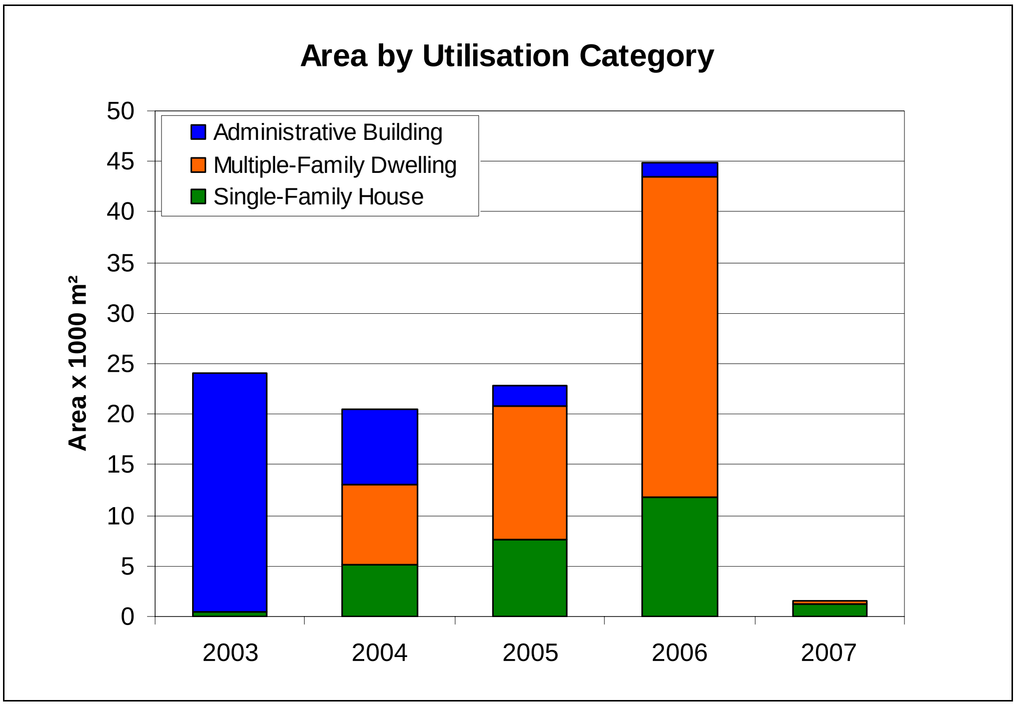

Figure 5. Evolution of area certified each year as MINERGIE-P.

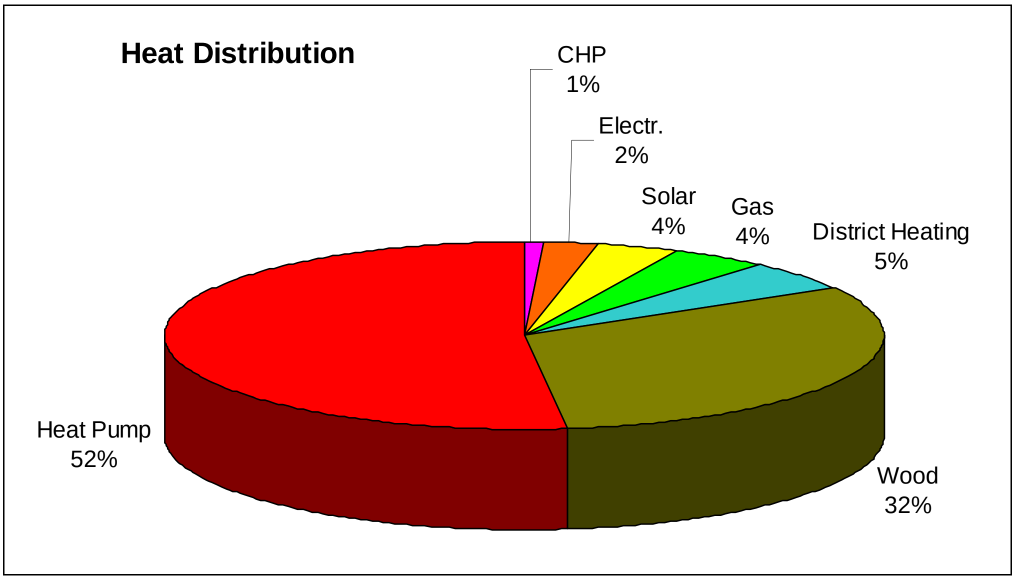

Figure 6. Statistical interpretation of used heat production systems.

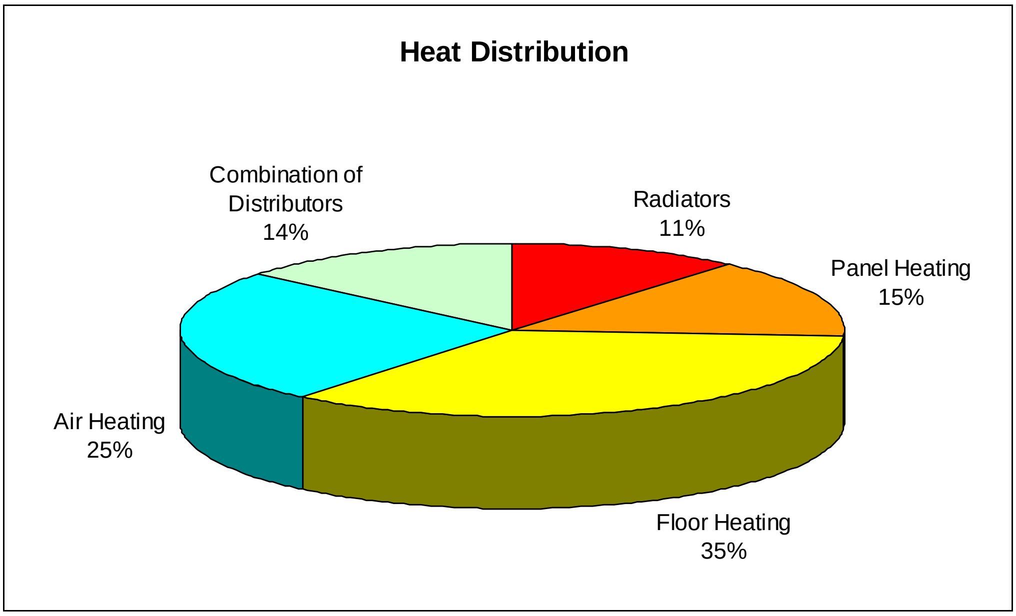

Figure 7. Statistical interpretation of used heat distribution systems.

DISCUSSION

The energy label MINERGIE-P presents a valuable way of classifying energy-efficient buildings. The perspective lies both on energy saving and, in particular, presenting an excellent comfort providing high indoor air quality and minimising the risk of structural damages due to mould and the like.

It could be shown that using proven technologies and appliances of today's state of the art one can decrease the heat demand by 80% without taking any risks. Furthermore, the importance of realising feasible energy savings could be shown. In particular the housing sector, which consumes roughly one third of the energy in Switzerland, still holds a huge potential to reduce the massive output of CO_2.

Experience shows that the presented standard can easily be communicated not only to energy-interested pioneers or idealists but to the broad public as well. The astonishing evolution of the still young label is demonstrated by the increasing rate of newly built living area with the high MINERGIE-P standard. Recently the better conservation of building value even convinced several banks to offer better conditions for home mortgages.

The complete success of all MINERGIE energy labels presents a prime example of an effective marketing strategy. (To date there are four energy labels assigned by MINERGIE – compare [12].) MINERGIE as a brand has consistently been built up over the last years. Without the tireless work to establish the vision of energy saving buildings in the minds of both the public and politicians, in Switzerland population and building industry would probably still be waiting for «an increased political will to address our common future» ([1], p.13).

ACKNOWLEDGEMENT

We thank Alfred Moser for his highly estimated advice and his invaluable editing work. Furthermore Franz Beyeler appertain sincere thanks for his tireless work to establish MINERGIE as the unique brand it is now. To conclude, we thank Patricia Bürgi for her dedication and the always pleasant cooperation.

BGP index: an approach to the certification of building global performance

Franco Cotana and Michele Goretti

University of Perugia, Italy

Corresponding email: goretti.unipg@ciriaf.it

SUMMARY

In order to improve life quality into buildings, the present paper proposes a certification model for indoor total comfort.

The first part of the paper concerns energy certification of buildings, with attention to energy efficiency, renewable sources, heating and air-conditioning. In the second part of the paper certificate concept is extended to factors which contribute to ideal requirements into buildings: acoustics and lighting, use of water, safety and technology are studied according to standards. Finally, an overall building quality certificate is proposed, based on indexes concerning specific performances. Every index is assigned a weight to characterize different contributions to Building Global Performance (BGP) index, which expresses total indoor quality. Weights are estimated according to objective criteria. Measurements and provisional models allow to analyse and classify a private flat as a case study. A reliable approach is shown to improve indoor environments and to support comfortable and sustainable buildings.

INTRODUCTION

Human activities impose a long time stay into buildings, where high comfort must be guaranteed: such a condition comes from a combination of different elements, such as thermal, hygrometric, acoustic, lighting, safety and technological factors.

According to Directive 2002/91/EC [1] and to national or regional procedures, energy certification of buildings assumes remarkable importance in order to rationalize the use of energy sources and to reduce costs and pollution.

The improvement of indoor life quality is due to many other factors too, which contribute to global well-being. In the present paper noise protection is studied according to Italian decree DPCM 5 December 1997 [2], which concerns building systems and acoustic insulation of façades, walls and floors. Suitable artificial lighting and natural light into buildings enhance indoor comfort; at present, Italian standard UNI EN 12464-1 [3] disciplines lighting of work places, while UNI 10840 [4] defines criteria for natural light into schools. Attention must be paid also to rational use of water: the installation of specific equipments can reduce considerably domestic water consumption, thus improving building performances. As concerns electrical, gas and water systems, they must be provided with protection devices and automatic control stop in case of leaks, according to Italian law 5 March 1990, n. 46 [5] and respective decrees; safety of persons, instead, can be upgraded by means of control and alarm devices. Finally, technology optimizes functionality and well-being into buildings with automation and communication systems.

The aim of the present paper is to propose a model of certification extended to building global performance, concerning all main aspects in an independent and objective way. Experimental measurements were carried out in order to analyse a private flat as a case study, considering use of rooms, building components and consumption bills.

METHODS

Indoor global performance

Quality of buildings means an appraisal of overall indoor comfort. Assessment indicators of single contributions were proposed and a global index was defined to classify new and existing buildings, referring to total performance: the model of building global certification was then applied to a case study.

ENERGY CERTIFICATION OF BUILDINGS

Building needs energy to condition indoor climate. Requirements based on primary energy consumption allow to have a coherent evaluation of energy efficiency of adopted systems. The energy performance of a building must be estimated with a methodology based on a general framework, which was defined by Directive 2002/91/EC [1]. Construction, sale and rent of a building need a certificate of energy performance for owner and purchaser: the purposes of certification are to estimate and to compare buildings, in order to make energy performance part of the appraisal, together with dimensional and aesthetic considerations.

Therefore, as household-electrics, also buildings must be provided with a coloured label, that identifies 7 classes of energy performance, where "A" means low consumptions/high efficiency while "G" means high consumptions/low efficiency. The aim is to estimate all energy contributions (heating and cooling, hot water, ventilation, lighting systems and renewable sources) thus pursuing high quality buildings. "Building Energy" index is defined according to energy certification: each class of energy performance (from G to A, Table 1) is assigned a value from 1 to 7.

Table 1. Classification of energy performance for residential buildings.

Annual specific primary energy consumption (kWh/m^2year)	Energy performance class	"Building Energy"
< 50	A	**7**
50-70	B	**6**
70-90	C	**5**
90-110	D	**4**
110-130	E	**3**
130-150	F	**2**
> 150	G	**1**

Energy certification procedures

Building energy requirements can be simulated by implementing calculation codes. General and climatic data, composition of opaque structures (walls and floors), transparent elements (windows) and exposure of building must be defined. Energy performance was studied for 3 different Italian cities (Perugia, Milan and Bolzano) which defined energy certificates, in order to evaluate the energy efficiency of the same building in such different places (Table 2).

Table 2. Main differences among examined energy certification procedures.

Energy performance	Perugia	Milan	Bolzano
Building shell	Yes	Yes	Yes
Heating system	Only 75%	Yes	No
Hot water	Yes	Yes	No
Plant efficiency	Only for hot water	Both for heating and hot water	No

Acoustic insulation

Noise sources can determine uncomfortable acoustic conditions into buildings. Partitions obstacle noise transmission, due to material mass. Mass increment doesn't represent a feasible method to achieve high acoustic well-being into rooms, so it is necessary to study building acoustics. In order to assess indoor acoustic quality, "Building Acoustics" index is proposed: it is evaluated by means of 7 classes of acoustic performances for 5 acoustic requirements into buildings, according to Italian decree D.P.C.M. 5 Dicember 1997 [2]. As concerns existing residential buildings, the limits imposed by decree for each parameter are assumed as central values of the scale, that was obtained by steps of 3 dB (+ 3 dB is equivalent to doubling of sources) both in increasing and decreasing sense: each acoustic requirements is assigned a score from 1 to 7, as specified in Table 3. Regarding noise insulation indexes R'_w (partitions) and $D_{2m,nT,w}$ (façades), acoustic comfort improves for increasing values, while the very contrary is the case of acoustic pressure levels L'_{nw} (floors), $L_{AS,max}$ and L_{Aeq} (systems); "Building Acoustics" index is calculated as arithmetic mean of obtained values.

Table 3. Classification of acoustic requirements for existing residential buildings.

	1	2	3	4	5	6	7
R'_w	< 41	41-44	44-47	47-50	50-53	53-56	> 56
$D_{2m,nT,w}$	< 31	31-34	34-37	37-40	40-43	43-46	> 46
L'_{nw}	> 72	69-72	66-69	63-66	60-63	57-60	< 57
$L_{AS,max}$	> 44	44-41	41-38	38-35	35-32	32-29	< 29
L_{Aeq}	> 44	44-41	41-38	38-35	35-32	32-29	< 29

Artificial lighting and natural light

Ranges of medium illuminance *E* according to visual tasks, limits for direct dazzle of light sources and suitable chromatic features of lamps are important to have comfortable lighting conditions. Natural light into building depends on site, exposure, windows, adjacent buildings and landscape natural elements. Correct exposure to sun is necessary to use natural lighting into buildings. Day lighting medium factor FLD_m is defined according to (1):

$$FLD_m = \frac{E}{E_0}, \qquad (1)$$

where E is room medium illuminance and E_0 is sky medium illuminance (5000 lux).

"Building Lighting" index concerns indoor artificial lighting and natural light. The assessment of artificial lighting is carried out by identifying 7 classes, for typical rooms into residential buildings (bedroom, kitchen, bathroom, living-room/access area) based on E medium values according to use. Maximum and minimum values (in lux unit) recommended by technical literature and standards are assumed as extreme values and the central range is divided into equal parts (Table 4). Natural lighting, instead, is evaluated by identifying 7 classes of FLD_m, for each room. The minimum value imposed by Perugia Building Regulations (2%) is assumed as inferior limit, while, on the basis of experimental measurements and technical literature advices, superior limit is fixed equal to 22%. The scale is obtained by dividing the range between 2% and 22% in equal parts and each class is assigned a score from 1 to 7 (Table 5). "Building Lighting" index is calculated as the arithmetic mean of the indicators, concerning artificial lighting system and natural light, into each room. If rooms of the same kind are present (for example, 2 bedrooms), the lowest value is considered cautiously.

Table 4. Classification of artificial lighting performance for residential buildings.

	1	*2*	*3*	*4*	*5*	*6*	*7*
Bedroom	< 50	50-70	70-90	90-110	110-130	130-150	> 150

Rational use of water

Waste of water, for washing and other uses, can be reduced by specific devices or effective options, such as systems for the recovery of rain water. "Building Water" index evaluates the rational use of water taking into account the presence of water saving equipments listed in Table 6. Index may varies from 0 to 7 and each device increases the value by 1 point, except toilet with double key or stop key flush (2 points), because it guarantees higher water savings.

Table 6. Classification of water saving performance.

Rational use of water	Presence	Value
Water saving tap	Y/N	1/0
Flow controller tap	Y/N	1/0
Flow controller shower	Y/N	1/0
Low water consumption toilet	Y/N	1/0
Double key/Stop key flush toilet	Y/N	2/0
Rainwater tanks	Y/N	1/0

Safety into buildings

Safety of systems is basic in the appraisal of indoor quality: a building can't be comfortable if first of all it is unable to protect people from the risks caused by dangerous or obsolete plants. Safety is also protection from outside, so alarm and video-surveillance systems may prevent to enter someone's property illegally and contribute to satisfy the growing need of safe buildings. "Building Safety" index estimates safety into buildings, both of systems and people; it can be equal to 0 or assume a value between 4 and 7. The safety of electrical, gas and water systems, disciplined by Italian law 5 March 1990, n. 46 [5] and respective decrees, was assumed as absolutely necessary: if minimum law prescriptions are respected, the index assumes value 4 (medium safety degree). The presence of safety devices to protect people increases index value by 1 point (Table 7).

Table 7. Classification of safety performance.

Safety parameter	Presence	Value
Properly done system (certificate) + IMQ, CEI or equivalent brand + Magnetothermal switch + Differential switch + Earthed system + Aeration hole + Gas/Steam aspiration hood	Y/N	4/0
Video screen entryphone	Y/N	1/0
Alarm system	Y/N	1/0
Signalling to Police force or private vigilance service	Y/N	1/0

Technological devices

High quality habitability and functionality of buildings depends more and more on available technological systems. Integration of services affects positively indoor well-being. "Building Technology" index estimates the technological level into rooms and can assume values from 0 to 7. Each device listed in Table 8 increases by 1 point the index minimum value.

Table 8. Classification of technological performance.

Technological devices	Presence	Value
PC/Internet/ADSL	Y/N	1/0
Sensors	Y/N	1/0
Automatic lighting/curtains	Y/N	1/0
Parabolic antenna	Y/N	1/0
Hi-Fi/Wi-Fi	Y/N	1/0
Auxiliary devices (transducers, interface circuits)	Y/N	1/0
Residential gateway	Y/N	1/0

Building Global Performance index

"Building Global Performance" (BGP) index is defined by giving each indicator a weight. In order to attribute the weight fitting every index, different criteria were examined and the one based on costs was preferred, which seems to assure the greatest objectivity; therefore weights are calculated on the basis of cost analysis. Average costs to be supported in order to equip new or existing buildings with materials and devices which can guarantee high performance, quality and comfort are estimated in about 54% of the total costs of construction works (Table 9), according to Italian market general data. The weights given to the indexes were obtained by comparing single contributions to total percentage 54% (Table 9).

Table 9. Index weights according to Building Global Performance (BGP).

Index	Contribution	Percentage on total costs	Weight
Building Energy	Thermal insulation/energy performance	20%	37%
Building Acoustics	Acoustic insulation	15%	28%
Building Lighting	Natural light/artificial lighting system	5%	9%
Building Water	Water saving equipments	7%	13%
Building Safety	Safety devices	3%	6%
Building Technology	Technological devices	4%	7%
BGP	*Total*	*54%*	*100%*

Case study

A private flat in Perugia (Umbria Region, Central Italy) was assumed as a case study and an example of global certification was given. The examined flat is sited in a residential building that was built in the early Seventies (Figure 1). The occupants are 2 students. Independent heating system is fed by a boiler, having nominal thermal power of 24 kW; fuel is natural gas. Indoor temperature can be regulated by a thermostat. The system works both for heating and production of hot water. The flat has a volume of 161,7 m^3; the area is equal to 56,7 m^2. External walls are 29 cm thick (1,5 cm external and internal plaster, 2 layers of 12 cm bricks separated by 2 cm of mortar). The walls that separate the examined flat from the adjacent ones are 15 cm thick (12 cm bricks and 1,5 cm coat of plaster). The floor thickness is 30 cm and dividing walls into the flat are 10 cm thick.

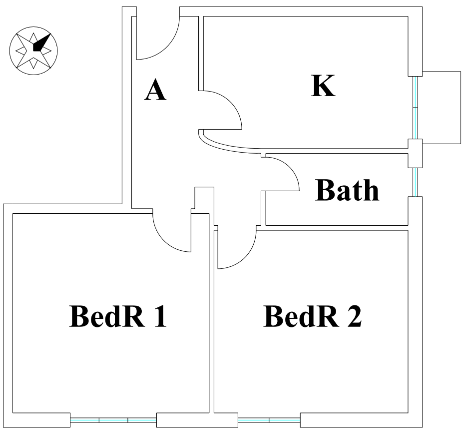

Figure 1. Plan of examined flat.

RESULTS

Building energy performance

According to calculations, the flat was assigned “E” class, with annual specific consumption of primary energy equal to 126,13 kWh/m^2year (86,90 for heating; 0,00 contribution from renewable sources; 39,23 for hot water). The examined procedures classify the flat in the same category: differences among obtained values of energy consumption, however, is due mainly to the methodology of calculation, the contributions to be considered and the climatic zones (average temperatures). In order to compare the specific energy performance of the building shell, the values to be considered are 115,87 kWh/m^2year for Perugia, 102,72 kWh/m^2year for Milan and 106,80 kWh/m^2year for Bolzano. Finally, the value obtained as simulated energy consumption of the case study has a good agreement with the study of real energy consumptions of the same flat as concerns the bills (126,75 kWh/m^2year).

Case study “Building Energy” index, defined by “E” class, obtained 3 points (Figure 2).

Building acoustic performance

Italian and international standards UNI EN ISO 140 [6] and 717 [7] were applied to carry out measurements and calculations (Table 10). According to Table 11, “Building Acoustics” index for the examined flat obtained 2,0 points (medium; Figure 2).

Table 10. Case study acoustic performance.

Acoustic parameter	Measured value	Unit
R_w	37	dB
$D_{2m,nT,w}$	33	dB
$L'_{n,w}$	74	dB
L_{ASmax}	47	dB(A)
L_{Aeq}	33	dB(A)

Table 11. Classification of case study acoustic performance.

R'_w	1						
$D_{2m,nT,w}$	1						
L'_{nw}		2					
$L_{AS,max}$	1						
L_{Aeq}					5		

Building lighting performance

According to standards UNI EN 12464-1 [3] and UNI 10840 [4], artificial lighting and natural light were measured (Tables 12 and 13). "Building Lighting" index for the case study equals 3,8 points (medium-low), as shown in Figure 2.

Table 12. Case study lighting performance.

Room	Natural light	Artificial lighting	Unit
Bedroom	1030	109	lux
Kitchen	1235	168	lux
Bathroom	783	83	lux
Access area	145	66	lux

Table 13. Classification of case study lighting performance.

Artificial lighting	Bedroom				4			
	Kitchen	1						
	Bathroom			3				
	Access area		2					
Natural light	Bedroom						6	
	Kitchen							7
	Bathroom					5		
	Access area		2					

Other building performances

The flat obtained a low value of "Building Water" index, equal to 2 (only water saving tap and flow controller tap are present). Also "Building Technology" index obtained 2 points (flat equipped with PC/Internet/ADSL and sensors/thermostat). Finally, as alarm and signalling devices are unavailable, case study has "Building Safety" index equal to 4 (Figure 2).

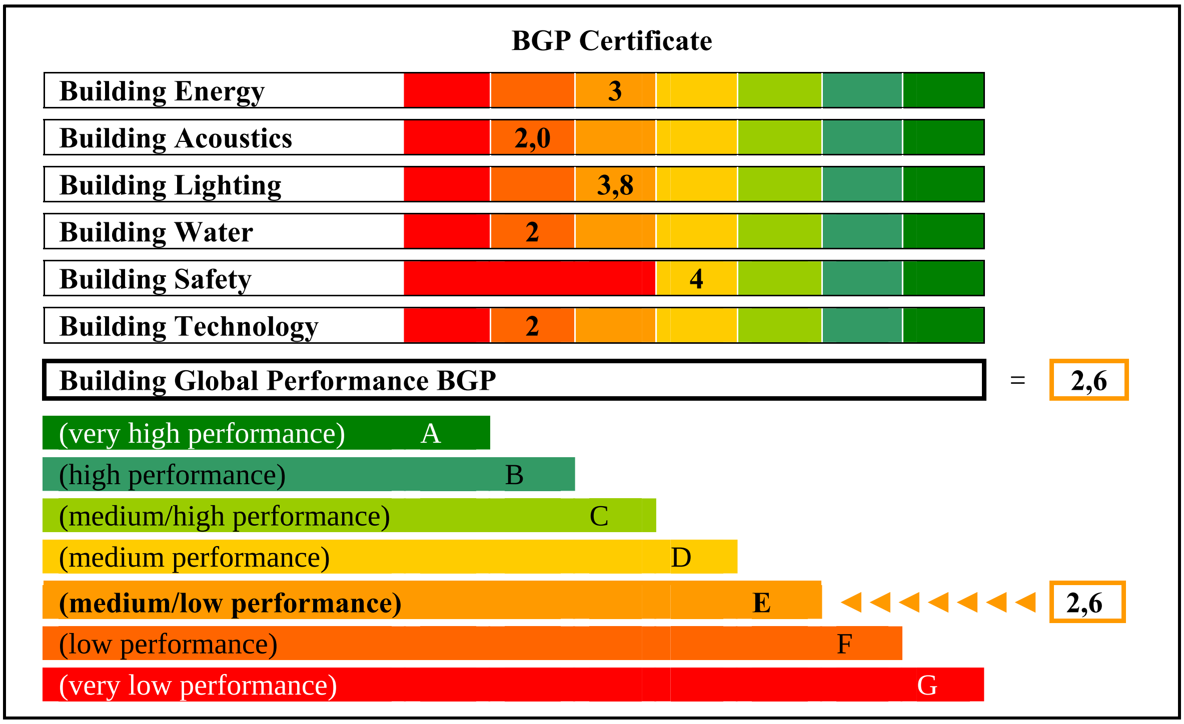

Figure 2. BGP certificate: results of application to the case study.

Building Global Performance index

All required input data were processed to calculate BGP index: the calculation gives back the values of all indicators as a certificate (Figure 2). Case study obtained BGP = 2,6 (low-medium performance), in tune with the appraisal of the occupants.

DISCUSSION

A new instrument for indoor quality certification was proposed: “Building Energy”, “Building Acoustics”, “Building Lighting”, “Building Water”, “Building Safety” and “Building Technology” indexes were defined to determine “Building Global Performance” BGP.

As a validation, the assessment of a private flat in Perugia (Umbria Region, Central Italy) was carried out. Energy certification was analysed according to different methodologies: total energy consumptions of the flat, calculated according to Perugia Building Regulations, are equal to the ones obtained by studying actual energy consumptions, thus demonstrating the reliability of such a procedure. Weights were assigned to indexes on the basis of cost analysis; actually costs were estimated with approximation, so a combination of mentioned analysis and further assessments, even subjective evaluations (such as statistical preferences of people), may improve the model. Being comfort a personal feeling, there are different perceptions, but it must be attempted to satisfy the greatest number of persons. The assessment could be integrated with other peculiar features, such as architectural quality of buildings. BGP index could be measured to test existing buildings or it could be predicted to evaluate new buildings, according to standards.

The purpose of the present paper is to put in evidence the advantages that would be obtained by pursuing building overall quality. High performances are expensive, however the increment of building cost is amortized thanks to lower consumption and optimal comfort.

Quality and saving must be pursued by builders and planners in order to guarantee high indoor habitability, functionality and efficiency and to perform sustainable buildings.

Using fractional experimental designs to establish multi-parametric expressions for energy consumption of commercial buildings

Sila Filfli, Dominique Marchio

Center for Energy and Processes-CEP, Ecole des Mines de Paris, France

Corresponding email: sila.filfli@ensmp.fr

SUMMARY

The large advancement in the market of building materials and of HVAC systems leads to a wide variety of technical solutions that can be employed to build an efficient low energy commercial building.

The comparison between different combinations of parameters representing the main elements of the envelope, lighting management and solar blinds, office automation, plug consumptions and efficiency of the HVAC system is always of special interest to building owners and HVAC design engineers; however, such a study is rarely totally accomplished because of the time required.

The paper describes a fast method for organizing simulations through the use of fractional factorial designs. The method permits reduction of the number of simulations needed to cover all combinations of influent parameters.

The reduction result shows that it is feasible and quick to determine mutli-parametric models for a large range of building types. As a result, consumption can be calculated bypassing steps of projects description, sizing of components and running the simulations. The precision of such multi-parametric models is established by comparison with full simulation.

INTRODUCTION

The purpose of the project is to build a large library of analytical multi-parametric models giving the consumption as a function of key parameters of typical building/system.

The project is addressed mainly to engineers and commercial buildings design departments who aim to obtain optimized solutions quickly and to identify the impact of main choices on total yearly energy consumption.

In a first time, the description of French commercial sector, mainly for offices and hospitals, has been established. It permits to draw up a representative typology of these buildings [1] [2]. On the basis of this typology, geometrical description and different values or scenarios necessary for accomplishing the simulation are defined [3][4]. Simulations are then carried out with ConsoClim [5], a building energy simulation software package. Its particularity is that systems models [6] require simple and available parametric inputs and are coupled to the building model.

The variables predominantly affecting energy consumption are then listed. The high number of possible simulations needed to cover all the variation of variables in addition to the organization of a huge quantity of results was initially the main reasons for introducing experimental design notion.

METHODS

The aim of the method is to obtain maximum information with a minimum number of simulations. For a defined problem, various solutions can be tested, evaluated and compared. A systematic organization of simulations helps to analyze the results and decreases the risk of errors at the same time.

The experimental designs are essentially based on multi factorial experiments and on the use of multiple regressions besides variance analysis while treating the results. Their application supposes a good knowledge of the studied phenomenon before realizing the tests. This has to be accompanied by the ability to detect the parameters most likely to influence the system operation [7]. It is necessary to represent the diversity of powerful energetic technical solutions already present on the market, then to be able to establish a correspondence between the chosen solutions and a level of the cluster parameter representing the variety of these solutions.

If the number of considered parameters and the number of their levels are very high, the solution consists in reducing the number of levels and/or factors followed by control of the precision of obtained results. When defining the design of experiments, a preliminary step is to study the linearity (or not) of variables in order to set the number of levels.

Figure 1. Choice of number of levels: 2 levels on the left (linear evolution), 3 levels at least on the right (non linear evolution)

COMPLETE FACTORIAL DESIGN

Factorial design or complete factorial design is to experiment all the possible combinations between the levels of the variables. The number of combinations is a product of the numbers of levels of the factors. [8]
In the study we considered 13 variables for office building application, they are:

Table 1. Low and high values of the considered variables – building/system

	Variables	Level	
		Level (-1)	Level (+1)
U_{op}	Insulation of ceiling and walls (opaque)	0.2, 0.4 W/m^2/K	0.3, 0.6 W/m^2/K
U_{bay}	Characteristics of glazed surfaces	2 W/m^2/K	3 W/m^2/K
Ori	Orientation	Glazed facades N/S	Glazed facades E/W
MSP	Management of solar protection as a function of natural lighting	Occupant not so reactive	Occupant very reactive
Off_Aut	Mode of management and effeciency of office automation equipments	15 W/m²	7.5 W/m²

Light	Management and efficiency lighting	Interrupter 18 W/m²	Interrupter + graduator 10 W/m²
Iner	Inertia level	light	heavy
Perm	Permeability	1.2 $m^3/(h.m^2)$ under 4 Pa	2.4 $m^3/(h.m^2)$ under 4 Pa
Vent	Ventilation	Reduction in flow rate during occupancy -30%	Normal flow rate during occupancy
Aux_Eff	Fans and pumps efficiency	0.87	0.52
Boil_Eff	Boiler efficiency	0.98 (70°C), 1.08 (40 °C)	0.89 (70°C), 0.88 (40 °C)
Dist_Ins	Insulation of distribution network	0.14 W/m.K	0.28 W/m.K
EER	EER Chillers - Split ,VRV (EER/COP)	3.3 - 4.2/4.5	1.9 - 1.8/1.95

This paper presents an application of the method to a small area office building (1000 m^2) existing in the industrial suburban zones and simulated in the climatic region of Paris; for other cases see [11]. The selected system for this article is made of a chiller for cooling, gas boiler for heating, air-handling unit for fresh air, and 4 tubes fan coil units (domestic hot water is not taken into consideration). The HVAC system is described from market real devices after sizing all the needed elements in cooperation with engineer design departments. Simulations are realized to check the consumption tendency between the levels of each variable (the linear response justifies keeping only two levels). The variables used in the experimental design are centered and reduced. To pass from a variable, A, to the reduced centered variable, x, the formula is:

$$x = (A-A_0)/\Delta_A \quad (1)$$

Where A_0 is the central value of the interval [- 1, +1], expressed in current unit, Δ_A being the variation between the average position of the variable and the domain extremity.

Figure 2a (left) gives consumption while passing from the basic case (all variables at level –1) to another case – each time one variable passes to level 0 (central value of the interval [- 1, +1]) then on the level (+1). The value obtained is compared with the calculated value at level (0) obtained from a linear regression.

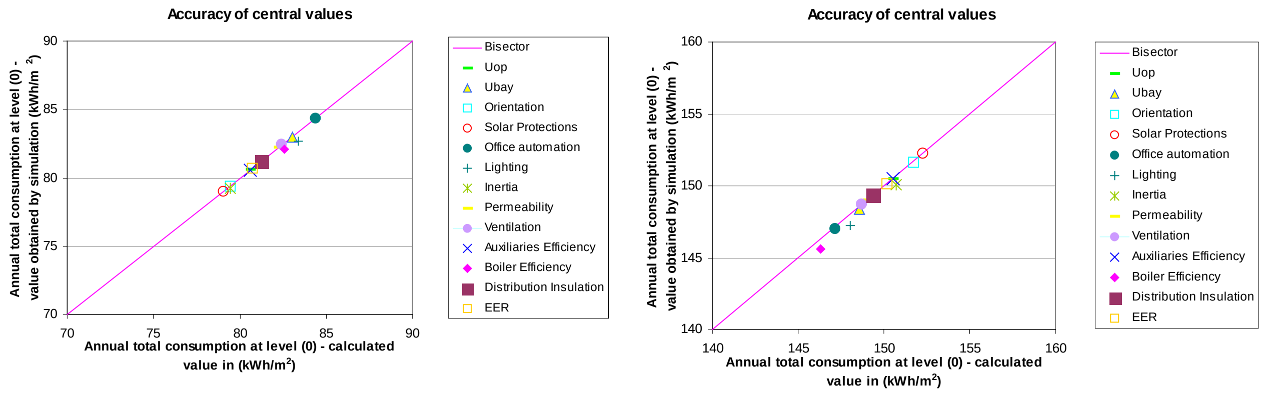

Figure 2. Precision of the assumption of the answer (consumption) linearity

Figure 2b (right) is obtained by the same principle, this time starting from a basic case where all the variables are at the high level (+1). For each simulation, a variable passes to the level (-1) then to the level (0). The variation obtained with the calculated values is negligible.

To carry out a 2^{13} complete factorial design, 2^{13} simulations have to be done. Each simulation gives an answer y_i. The answer is represented by a matrix-column [Y] including 2^{13} lines. The mathematical model associated to the 2^{13} design contains 2^{13} unknowns: one constant, 13 principal effects and 2^{13} - 13 – 1 interactions.

The effects are represented by a matrix-column [A] constituted of 2^{13} lines. The matrix of calculation of coefficients X contains a number of lines equal to the number of answers y_i that is 2^{13}, and as many columns as there are unknown factors i.e. 2^{13}.

Matrix X is thus a square matrix (2^{13}, 2^{13}). It is reversible, we can write:

$$Y\,(2^{13}, 1) = X(2^{13}, 2^{13})\,A\,(2^{13},1) \qquad (2)$$
$$A = X^{-1}Y \qquad (3)$$

The researched model is constituted from 13 parameters of Table 1. The matrix representation usually employed in experimental designs is replaced by YATE notation [13]. The variable is multiplied by the level it takes (-1 or +1); the interaction between two variables or more is represented by the product of their levels. So the simplified writing of the model becomes (Refer to table 1 for nomenclature):

C_{tot} (kWh/m^2) = M_{tot} + U_{op} + U_{bay} + Ori + MSP + Off_Aut + Light + Iner + Perm + Vent + Aux_Eff + Boil_Eff + Dist_Ins + EER + all interactions of the 1st order (= 78 interactions) (4)

M_{tot} is the average and C_{tot} is the total yearly consumption. This model considers that the interactions of 2nd order and above are negligible, which is validated by comparing the results of the model to the "real" answer: that of the simulation.

In this study, the energy ratios refer to total energy consumption (lighting, heating, cooling, plug loads and auxiliaries) without considering specific areas of the building such as data processing centers. Conversion into primary energy is given by applying the French rules [10] ratios (2.58 for electrical energy and 1 for gas energy).

The number of simulations needed to accomplish such a model is: 2^{13} (13 variables with 2 levels each) or 8192 simulations. This number is huge in terms of results and organization. As mentioned in the introduction, the methodology is to be applied to two main commercial sectors: offices and hospitals represented by five types of office buildings and two types of health buildings. The building/system matrix is representative of the real park in France and each system is sized per climatic region. With this model of the park, just for the small area building analyzed in this paper we have: 5 HVAC systems, 2 climatic regions i.e. 10 times 8192 simulations. The time for a series of 8192 simulations is around 820 hours with a relatively powerful computer. These figures show that complete factorial design is not a realistic solution. For us, it is only a reference set of results to compare with the fractional factorial design or fractional design presented below.

FRACTIONAL DESIGN

The fractional design is a "fraction" of the factorial design; it is an orthogonal subset of combinations of the complete factorial design. Its main advantage is revealed in the significant reduction of the number of simulations and therefore rapidity in giving reduced models.
Nevertheless, the reduced number of experiments makes it impossible to determine all coefficients of the multi-polynomial model related to the complete factorial design. The

reason is that the number of coefficients is higher than the number of experiments. In fact, the fractional design makes it possible to determine the sum of certain coefficients identified by the complete factorial design; these coefficients are called “aliases”.

A half-design is less expensive in terms of simulation number than a complete one, but this profit is offset by an ambiguity in the estimation of effects [13]. However, when building fractional designs, it is necessary to alias as much as possible the principal effects with interactions of a higher order, these latter being in general negligible.

To simplify the application of fractional designs, we use the Taguchi method or Taguchi tables [15]. The construction of an experimental design according to the method of Taguchi is based on two principles [9]:

1- the use of tables, facilitated thanks to linear graphs, provides the mode for filling the matrix.
2- considering the actions of 2nd order negligible except in particular cases.

Some interactions are immediately neglected when physical reasons deem it possible; for example, the interaction between the boiler efficiency and the EER is null. On the other hand, there are some interactions that cannot be neglected:

- interactions between the thermal transmittance of the glazing and the internal contributions or lighting for a largely glazed building (thus strong internal contributions and lighting),
- interaction between the boiler efficiency and the insulation of the distribution for a significant length of the network; etc.

The reduction of the number of interactions considered leads to a reduction of the degree of freedom of the model and consequently the number of experiments to be realized. The first order interactions, which are considered significant, are kept. The influence of this choice is then evaluated.

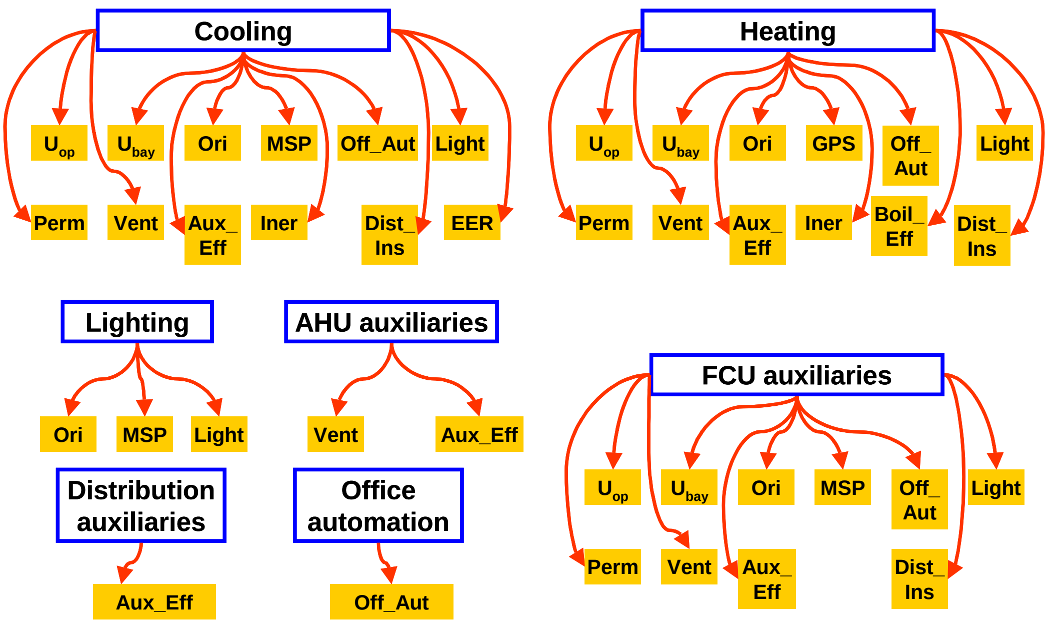

Figure 3. Variables that have an effect on the consumption of each sub model

Selection of the most significant interactions requires advance experience in the building/system simulation. To avoid this expertise requirement, we suggest the establishment of different models representing categories of annual consumption (figure 3). The addition of these elementary models of subparts constitutes the total consumption. The variables that influence each category of consumption are the following:

The global model is then composed of sub-models (Refer to table 1 for nomenclature):

$$C_{cool}\ (kWh/m^2) = M_{cool} + U_{op} + U_{bay} + Ori + MSP + Off\_Aut + Light + Iner + Perm + Vent + Aux\_Eff + Dist\_Ins + EER.Perm + EER.U_{bay} + Perm.U_{bay} + EER.Off\_Aut + Perm.Off\_Aut + U_{bay}.Off\_Aut + EER.Aux\_Eff + EER.Light + Perm.Light + U_{bay}.Light + EER.MSP + Off\_Aut.Light + EER.Ori + EER.Uop + EER.Iner \quad (5)$$

$$C_{heat}\ (kWh/m^2) = M_{heat} + U_{op} + U_{bay} + Ori + MSP + Off\_Aut + Light + Iner + Perm + Vent + Aux\_Eff + Dist\_Ins + Boil\_Eff.U_{op} + Off\_Aut.U_{bay} + Ubay.Light + U_{bay}.Perm + Boil\_Eff.U_{bay} + Off\_Aut.Light + Off\_Aut.Perm + Boil\_Eff.Off\_Aut + Light.Perm + Boil\_Eff.Light + Boil\_Eff.Iner + Boil\_Eff.Perm + Boil\_Eff.Vent + Boil\_Eff.Aux\_Eff + Boil\_Eff.Dist\_Ins \quad (6)$$

$$C_{Light}\ (kWh/m^2) = M_{Light} + Light + MSP + Ori + Light.MSP + Light.Ori + MSP.Ori \quad (7)$$

$$C_{Aux\_AHU}\ (kWh/m^2) = M_{Aux\_AHU} + Vent + Aux\_Eff + Vent.Aux\_Eff \quad (8)$$

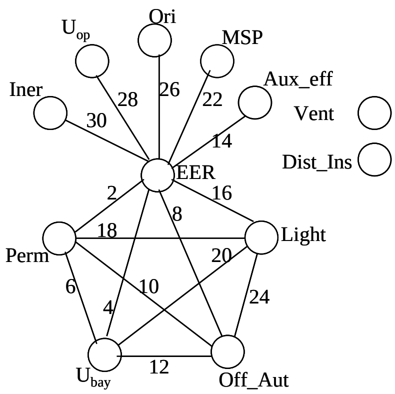
$$C_{Aux\_FCU}\ (kWh/m^2) = M_{Aux\_FCU} + U_{op} + U_{bay} + Ori + MSP + Off\_Aut + Light + Iner + Perm + Vent + Aux\_Eff + Dist\_Ins + U_{op}.Aux\_Eff + Iner.U_{bay} + Perm.U_{bay} + U_{bay}.Aux\_Eff + Iner.Off\_Aut + OFF\_AUT.Aux\_Eff + Light.Aux\_Eff + Iner.Aux\_Eff + Perm.Aux\_Eff + Vent.Aux\_Eff + Aux\_Eff.Dist\_Ins \quad (9)$$

$$C_{Aux\_Dist}\ (kWh/m^2) = MA_{ux\_Dist} + Aux\_Eff \quad (10)$$

$$C_{Off\_Aut}\ (kWh/m^2) = M_{Off\_Aut} + Off\_Aut \quad (11)$$

To find the table of Taguchi adapted to the model, two criteria must be validated [11]: criterion of the degrees of freedom and criterion of orthogonality.

We give an example for the cooling sub-model. The number of degrees of freedom is 28 (12 variables, 15 interactions, 1 for average). The number of experiments should be equal to or higher than 28. The PPCM between disjoined orthogonal actions is (4,8,16) = 16. The Taguchi table $L_{32}(2^{31})$ is then chosen - 32 simulations, 31 columns that can be assigned to variables or interactions [14] - with a resolution plan IV, i.e. variables of order 1 are aliases of interactions of order 3, and interactions of order 2 are aliases with other interactions of order 2.
The associated linear graph given by Taguchi has been adapted to our model [11]. The most significant variable in the model of cooling is obviously the EER.



RESULTS

The total consumption C_{tot} is deduced from the sub models distinguishing gas and electricity.

$$C_{tot}\,(kWh/m^2) = C_{cool}\,(kWh/m^2) + C_{heat}\,(kWh/m^2) + C_{Light}\,(kWh/m^2) + C_{Aux\_AHU}\,(kWh/m^2) + C_{Aux\_FCU}\,(kWh/m^2) + C_{Aux\_Dist}\,(kWh/m^2) + C_{Off\_Aut}\,(kWh/m^2) \quad (12)$$

The results of the reduced model have been compared with the reference simulations (32 in the case of cooling). The precision is in the interval of $\pm$ 0.5%.
Neglecting some interactions may influence the results precision; this latter improves systematically when more interactions are taken into consideration. In the selected example, we also compared the results of the additive model (12) with the results of a complete factorial design (4).
In other words, we compare the model obtained by 112 simulations (32 for cooling, 32 for heating, 8 for lighting, 38 auxiliaries and office automation (without counting identical simulation) with the model obtained by 8192 simulations. The precision is shown in figure 4.

Table 1. Average deviation (with respect to the complete model) is 0.66 (kWh/m^2)

	-1 % ≤ Deviation ≤ 1 %	-3 % ≤ Dev.< -1 % 1 % < Dev.≤ 3 %	-5 % ≤ Dev. < -3 % 3 % < Dev. ≤ 5 %
N° of simulations (total = 8192)	6840	1330	22
%	83.50 %	16.24 %	0.26 %

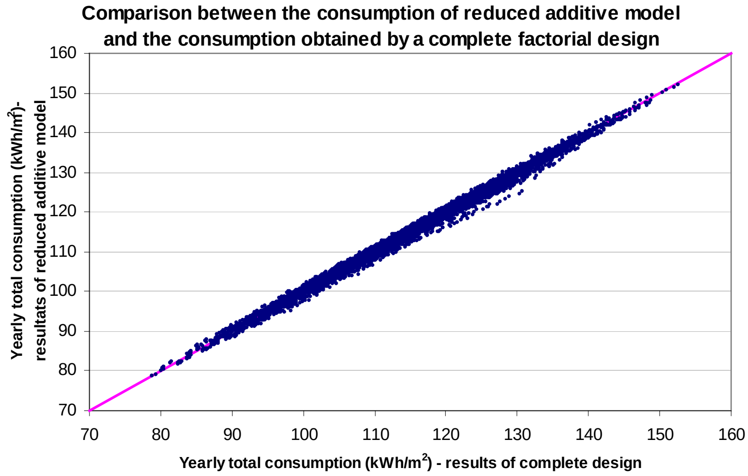


Figure 4. Precision of reduced model with respect to complete model

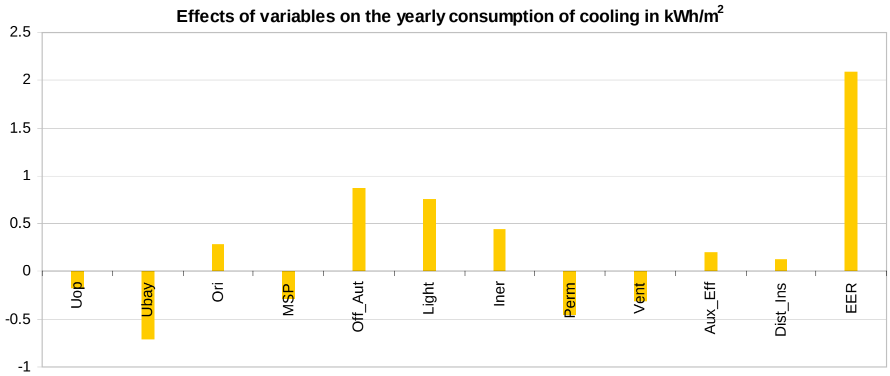
Typical results like effects of the elements are deduced for each model, we give that of cooling as an example.



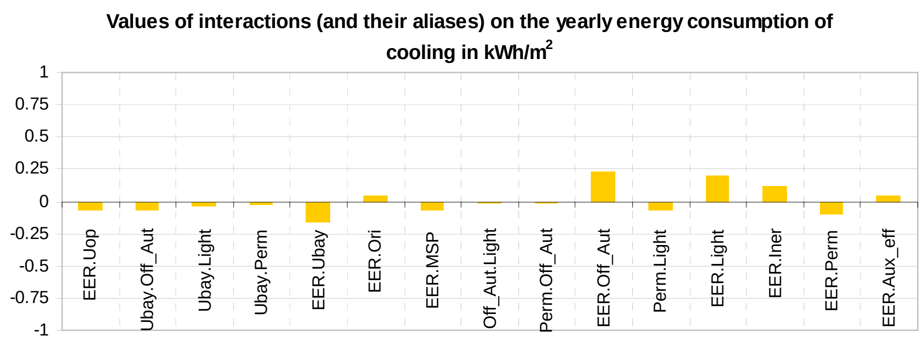


Figure 5. Example of effects and interactions values for cooling model, average = 7.8 kWh/m^2

DISCUSSION

It has been shown that the reduction of the number of simulations does not have an important influence on the quality of the answer, granted precaution with significant variables and interactions. The time requirements for running and, more importantly, preparation of simulations are greatly reduced when compared up to the factorial design. Evidently, the preparation of the fractional plan must be carried out with firm knowledge of the method. The user must be attentive while launching simulations of validation. This method is applicable to all types of buildings and systems in all sectors. The multi-parametric model is useful for an economical optimization when disposing of cost libraries of different technical solutions.

Environmental Assessment of a Low-Energy House

Roman Rabenseifer

Department of Building Construction, Slovak University of Technology, Bratislava, Slovakia

Corresponding e-mail: rabens@svf.stuba.sk

SUMMARY

The paper shows the life cycle of a low-energy detached house from the viewpoint of CO_2-emissions. It compares the energy use in the course of its service life in relation to energy input necessary for its assembly and manufacturing of single building products. The service life is described using both the standardized calculation methods for energy balance of buildings and the open software tools, e.g. esp-r, as well. The input data related to embodied energy are based on information originating from selected recent works on life cycle analysis. The paper discusses the limits of the building envelope improvements in terms of thermal insulation thickness and the sense of the building environmental assessment.

INTRODUCTION

The European countries, the economy of which is based on export of industrial products and services and completely dependent on imports of fossil fuels, systematically support the improvement of energy efficiency of buildings. They do it in two basic ways:

- Normatively and legislatively, using restrictions in order to ensure the basic quality of buildings from the viewpoint of energy effectiveness, e.g. by requiring more and more improved and detailed investigation of the future energy demand for heating and hot water preparation and by suitable systems of criteria,
- Motivating, using various state and communal programs, usually the aim of which is the effective use of energy from fossil fuels and the development of alternative and ecological energy sources (solar radiation, water, wind).

These two basic instruments focus almost entirely on building performance after its assembly on the building site. Explained in terms of the life cycle of a building, the mentioned policy does not take into consideration the energy needed either for production of the building materials or for assembly of a building or for its dismantling. The main argument for this exclusive concentration on the service life of a building is that 40% of the total energy consumption is caused by operation of the buildings. The remaining 60% fall on industry and transportation, whereas 20% out these 60% are supposed to be caused by production of building materials, building processes, renovation and dismantling of the buildings. The following case study wants to show that this argumentation is no longer valid for buildings built in compliance with existing standards or even in a low-energy way. As the energy supply needed for the operation of such buildings is quite low, a significant rise of the building industry portion within this imaginary scheme should be a consequence. In this context several questions occur, e.g.:

- Whether the perception of buildings as power plants using renewable sources of energy is justified in relation to energy inputs and CO_2-emissions,
- Whether the currently used energy demand calculations should not be complemented by information on energy inputs needed for building assembly and manufacturing,

- Whether alternative and lasting (sustainable) building materials would be a kind of solution and what is the optimal insulation of the building envelope,
- Whether the energy savings by building industry in the course of manufacturing could lead to other architectural solutions than so called “low-energy design”,

and

- Whether it is possible in the design phase to consider the questions of CO_2-emissions due to the life cycle of buildings at all?

The presented study tries to find answers to the above questions. However it does not reserve the right either on completeness or absolute correctness. It is far more an attempt to realize to which extent the so called low-energy design (in the sense of highly insulated building envelope) is meaningful and where is the limit to the overflow of material – and related production energy and financial resources.

METHODOLOGY

The crucial problem of the presented comparison of CO_2-emissions due to the expected building operation on the one side and due to the built-in energy on the other side was the gathering of reliable data regarding the CO_2-emissions due to the production of building materials. Usually, the building industry does not record information on kilograms or tons of CO_2-emissions per building product, e.g. brick or window. Under circumstances these values could have been derived from the annual reports of single companies, if they had been at our disposal and had included the CO_2-emissions and the number of products per year. Unfortunately this was not the case. Therefore, some research in the libraries and on the internet was necessary. This effort showed that there had been serious research on this topic done, particularly in the German speaking countries. From a number of serious sources first of all the use of information in the Austrian Ökologischer Bauteilkatalog [1], the German Ökologische Bilanzierung von Baustoffen und Gebäuden [2] and on the website www.architektur.tu-darmstadt.de/ee [3] was made. The majority of the relevant values in all three cited publications are identical. Where differences occur (mostly steel, iron and aluminium based products) the newer information was taken. The necessary energy input for the production of building materials used for the assembly of the case study building and the related CO2-emissions were calculated using the PEI (Primary Energy Input [MJ per unit of material or product]) and the GWP (Global Warming Potential [kgCO_2-eq. per unit of material or product]) values in the cited publications. Unlike the notion PEI, which is quite comprehensible, the notion GWP should be explained at this point. The GWP represents not only a production of single CO_2-emissions but also other greenhouse gases that contribute to the global warming as well and have the same impact as comparable amount of CO_2-emissions, e.g. methane, NO_x or particles. Hence, it is more the measure of all relevant greenhouse gases converted and added up to CO_2-equivalent emissions [1].
The energy demand for heating (operation) of the case study building was calculated using the software esp-r - a kind of open software for integrated building simulation [4]. Just for the verification purposes also a calculation according to the German energy conservation decree EnEV2004 [5] was performed – primarily in order to get a plausible initial range of heating power for esp-r model and as a kind of reference. The calculations were based on climate data for Berlin. The resulting calculated annual energy demand was converted into primary energy demand and following CO_2-emissions using the conversion table published in “Der österreichische Gebäude-Energieausweis – Energiepassport” written by Professor Panzhauser et all [6]. However, the same conversion coefficients are introduced in esp-r, too. Of course, only the fossil-fuels-based CO_2-emissions were traced. As a primary energy source for heating the natural gas delivery was taken into account.

CASE STUDY

The construction of detached houses (up to 120 m^2) and apartment buildings (having flats with up to 80 m^2) is in Germany and many other countries, e.g. Slovakia very often supported by the state under the fulfilment of certain conditions. One of these conditions represents the compliance of the project with the building regulations, e.g. the minimum thermal resistances of the main building envelope components, the highest allowed transmission heat loss (thermal-coupling coefficient (H_T')) of the entire building envelope and maximum heat or even primary energy demand. The figs. 1 and 2 show the floor plans, the cross section and the characteristic elevation of the family house in consideration, the basic versions of which meet the above mentioned standard requirements both for Germany and for Slovakia as well. The basic versions were the heavy one (brick masonry combined with thermal insulation) and the lightweight one (thermally insulated timber frame-work). Each of the basic versions was then modelled and simulated with four other combinations of the thermal insulation thicknesses according to the table 1.

Tab.1. Combinations of building envelope elements modelled

		Brick house					**Lightweight house**				
Mean U-Value:	[W /(m2K)]	0.41	0.32	0.30	0.29	0.28	0.41	0.32	0.30	0.29	0.28

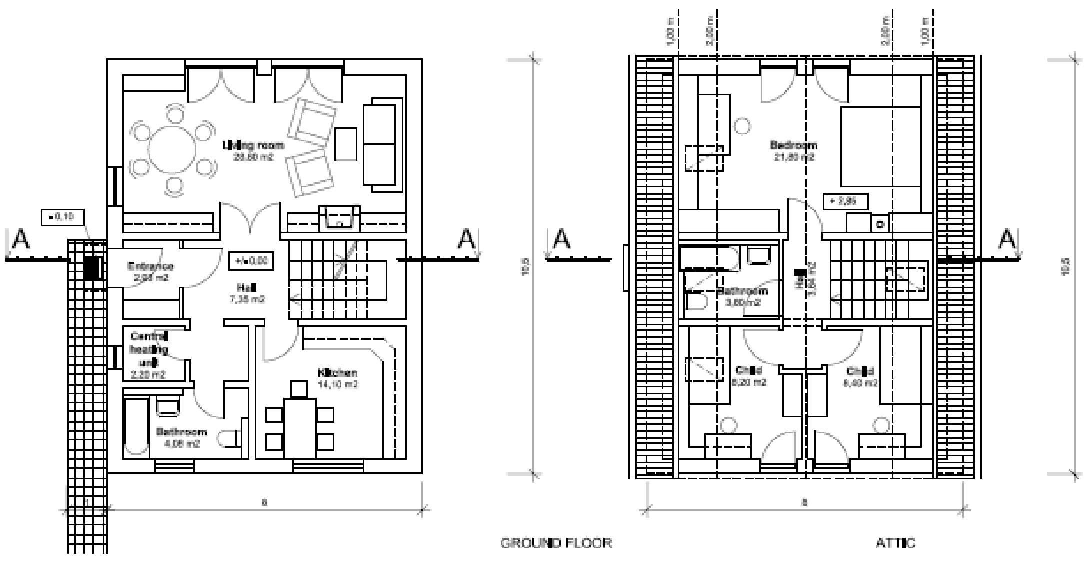

Fig.1. Floor plans of the investigated detached house

The U-values of the windows remained in all calculations the same. The simulations were performed using esp-r. The fig. 3 introduces pictures of the one zone model of the case study house generated by the Radiance [7] module within esp-r. The ventilation heat losses were set to 0.5 air change per hour. The heat gains are represented by occupant sensible ones only (fig. 4). They stand also for heat gains due to equipment and light in order to keep the model as simple as possible. The required indoor air temperature was set to 20°C and an ideal zone heat control was chosen.

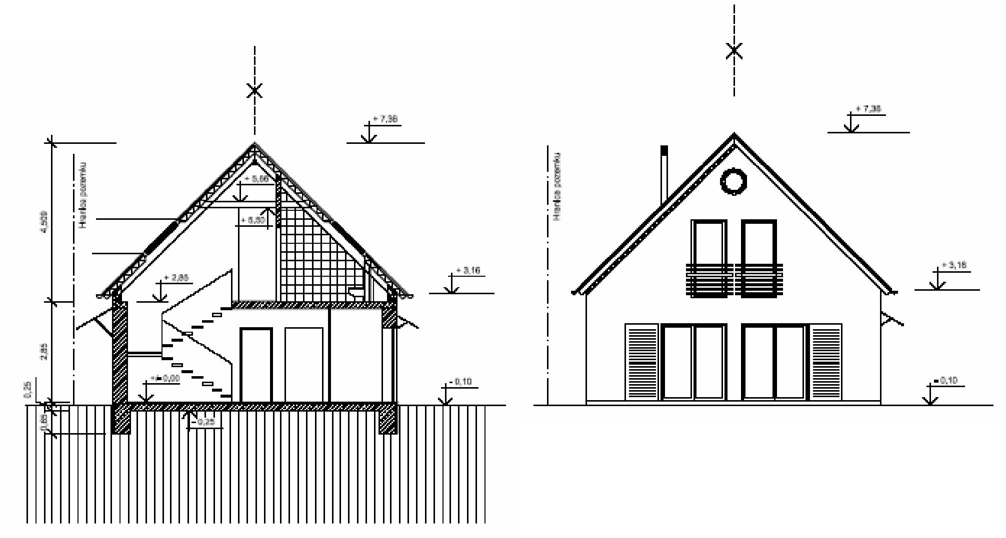

Fig.2. An elevation and the cross-section of the investigated detached house

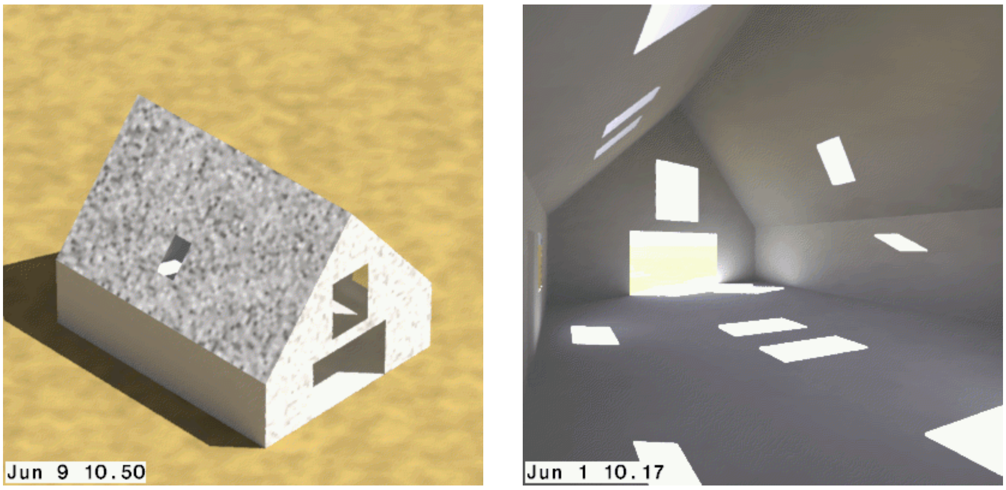

Fig.3. Visualization of the one zone model of the case study house

In addition to the simulation of the heat energy demand an ecological balance model (fig.5) for each of the 10 combinations (5 for each basic version) has been set up and the PEI and GWP values calculated. In the balance models the transportation of final products from the factory / the selling place to the client and the processes at the building site, e.g. the production of shuttering, the formworks or the use of machines were not considered.

Fig.5. Ecological balance model of one of the 10 combinations in tabular form

INTERPRETATION OF RESULTS

The diagram 1 shows the comparison of the CO_2-emissions due the energy demand for heating between the heavy (also called "brick house") and lightweight variant of the case study house (the compared bars are always for the same mean U-Values of the building envelope). The brick house performs slightly better due to the higher thermal capacity. This difference would be probably higher if the ceiling between ground floor and attic was simulated. Unlike this information, which is already quite known, the diagram 2 explains the relationship between the improvements of the mean U-values by increasing the heat insulation thicknesses on one side and the reduction of energy demand for heating on the other side. It is quite obvious that the linear reduction of the heat energy demand is achieved by the geometrical increase of the heat insulation thickness. Somewhere between the mean U-Values 0.30 and 0.32 W/(m^{2}K), which corresponds to approx. 17.5 cm of thermal insulation of the brick house and approx. 21 cm of the lightweight house, stops then the rational increase of the thermal insulation thickness. Just to compare: for the improvement of the mean U-Value from 0.41 to 0.32 W/(m^{2}K) and the reduction of heat energy demand in the range of 1500 kWh/a 5 cm of an additional thermal insulation is necessary. But the next increase of the thermal insulation by 5 cm brings about the improvement of the U-Value by just 0.02 W/(m^{2}K) and the reduction of heat energy demand in the range of 300 – 400 kWh/a. This leads to the conclusion that the efficiency of the increase of the thermal insulation thickness has its economical and also ecological limits as it will be obvious from further diagrams. They can be quite well established using the computer simulation tools.

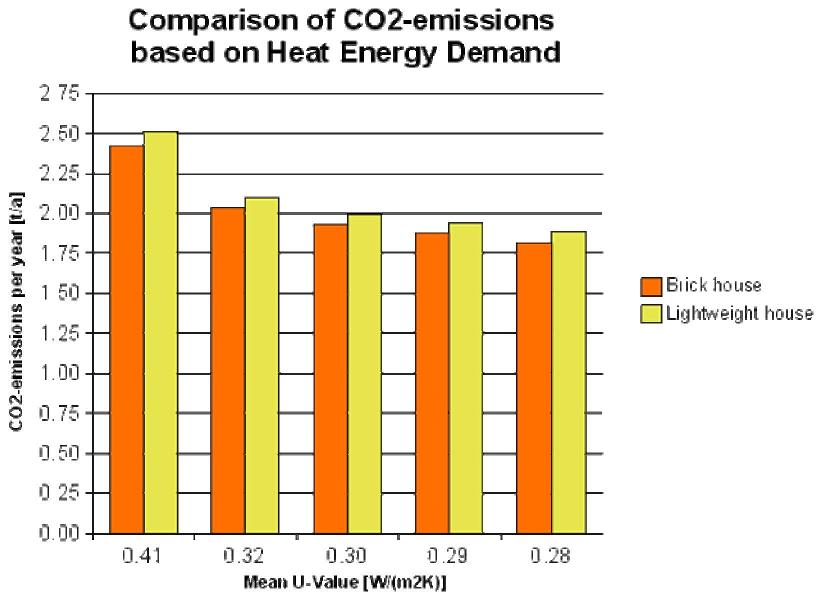

Diagram 1. Comparison of the CO_2-emissions based on energy demand for heating against the mean U-value of the heavy ("brick house") and lightweight variant of the building envelope.

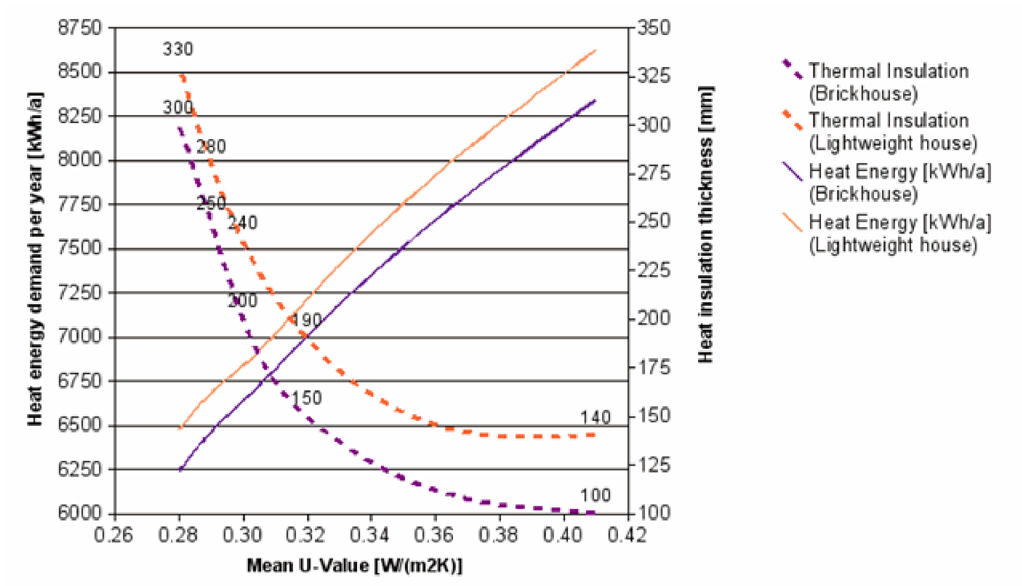

Diagram 2. The effect of the mean U-value improvement in dependence on heat insulation thickness upon the heat energy demand reduction.

Diagram 3 is a summary of the performed study and depicts the increase of the CO_2-emissions due to the building and operation of the case study house for both the heavy (B – brick house) and the lightweight (LW) variant as well. For each variant 5 modifications of the thermal insulation thickness (in diagram represented by the mean U-values) were examined. The starting values of the lines are the calculated GWP values due to the fabrication of the construction material and building products. The inclination of each line is then caused by the annual CO_2 output due to the building operation.

Looking at it two basic information can be deduced:

– The improvement of the mean U-Value, and hence the thermal insulation thickness, under 0.32 W/(m^{2}K) does not have significant effect on CO_2 reduction within the first 25 years of operation. On the other side the GWP value due to the fabrication of construction material and building products can increase in case of heavy construction by up to 16 % and in case of lightweight construction by about 30 % for the U-Value of 0.28 W/(m^{2}K) against base variant (U-Value = 0.41 W/(m^{2}K)). Provided that the building operation is based on renewable energy sources these lines would be shallower and closer to constant value. Therefore it might have sense to introduce a reasonable system of limitations on the initial GWP values due to the fabrication of construction material and building products. This would likely have positive effects on:
  - Larger use of environmentally friendlier construction material and building products,
  - Increasing the moral obligation to use renewable energy for building operation.

– The lightweight variant seems to perform environmentally better than the heavy one. It is then purely the question of expected building service life and material durability that is to consider primarily when doing the decision between heavy and lightweight variant.

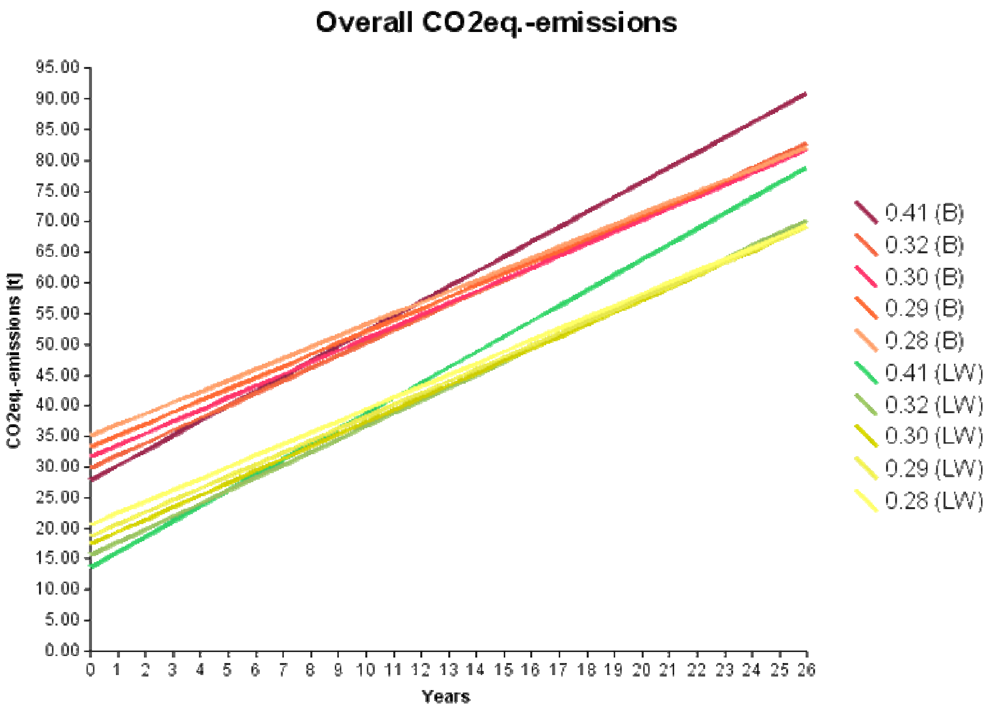

Diagram 3. The CO_2-emissions due to manufacturing and operation of the case study house calculated in dependence on time for both the heavy (B – brick house) and the lightweight (LW) modifications of the building envelope (represented by the mean U-values).

CONCLUSIONS

The current exclusive focusing on the energy efficiency of the building operation leads to heavy insulated building envelopes and to the utilization of alternative renewable energy sources (mostly on a decentralized basis). In principle this trend is right as the good insulated building envelope is a basic precondition for efficient use of energy, regardless if it comes from conventional or renewable sources. However, as the above case study tried to show the increasing the thickness of thermal insulation and the improvement of the mean U-value are effective to certain extent only. Then it becomes a kind of useless overflow that just cost investment money. Providing that the building envelope is optimized and the use of renewable energy sources is made, the third way to improve the environmental harmlessness of the buildings is to use materials and products the production of which is as much CO_2 free as possible. In order to do this a kind of environmental product declaration for buildings (EPD) should be introduced as a complementary measure to energy passports of buildings that are being prepared at the present. In fact the work and first discussions on EPDs for buildings have already started, too [8]. As the energy passports are quite complex matter and a subject to strong criticism the author's opinion is that the EPD's should exclusively cover the period of the building's life cycle prior to its commissioning. The other option would be an EPD that would consist of the energy passport and of some other document that would describe the environmental quality of the building manufacturing before its commissioning. Whatever the decision will be, there is a lot of reliable information on the environmental quality of building products and materials already available. It can help progressive architects to assess and optimize the design quality from both points of view - the building operation and the building manufacturing as well. Perhaps, as a consequence, a new architectural style based on optimally insulated buildings supplied from central green power plants could originate.

ACKNOWLEDGEMENTS

At this time I would like to express my warmest thanks to Professor Hanno Ertel from Institute of Building Products, Building Physics and Design (IBBTE) at Stuttgart University, who kindly provided me with all necessary information, working place and encouraged my efforts, and Ms. Anna Braune from Institute for Building Physics (IBP) of the same University, who gave me an established insight into GABI and explained many questions. This work was supported by the German Scientific Society, the Slovak Science and Technology Assistance Agency under the contract No. APVT-20-042202, and the Marie Curie Actions of the EC.

A voluntary scheme for certification of indoor environment and energy use

SUMMARY

Specialist researchers, property owners, builders and building managers have together developed a quality assurance (QA) management scheme that considers indoor environment and energy use. The primary objective of quality assurance is to work towards continuing improvements and to encourage those concerned to perform measures that otherwise would not have been considered, and to ensure that energy improvements are not introduced at the expense of indoor environment conditions. The QA scheme therefore aims to be flexible so that it can achieve the primary objective independently of the building's category or the management organisation. The new QA scheme's flexibility has successfully been tested in three different buildings; a school building, an office and an area of multi-family houses.

INTRODUCTION

To achieve the intended results of building, managing and using a property requires knowledge, continuity and communication, which can be assured by a dynamic and flexible quality assurance management scheme. Such a voluntary scheme focusing on high quality indoor environment has been developed during the 1990s and been successfully applied to schools, offices and multi-family houses [1]. Clients have been very satisfied with the scheme and its results in terms of an improved indoor environment, with fewer complaints from the building users [2, 3].

However, new emphasis on energy conservation (such as in the European Energy Performance in Buildings Directive [4], has added new demands for energy improvements as well. On the other hand, a reduction in energy use is appropriate only if it does not adversely affect the indoor environment. In order to avoid a one-sided focus on either good indoor environment or energy efficiency that might result in mutually adverse effects, the building sector requested that the QA scheme should be extended to consider energy use as well.

Specialist researchers, property owners, builders and building managers have therefore jointly developed the QA scheme with the objective of including energy efficiency assurance [5]. The scheme has been extended to a labelling scheme for the total building performance of both indoor environment and energy use. It includes methods and routines to control the indoor environment and energy use by using occupant questionnaires, the building monitoring systems or other methods during operation. A third party certifies the energy and indoor environment and makes annual inspections. To ensure that the scheme's rules are accepted, and that they are needed by the building sector, the scheme has been approved by a committee consisting of representatives of private and municipality property owners. However, the main target group of the end results is the occupants. It is important to occupants to know that their potential home or workplace building has a healthy indoor environment with minimum use of energy. The new QA scheme for both indoor environment and energy use is now ready to be applied in practice.

The system covers the planning, design, construction, commissioning and operation phases, and it would be natural to perform a performance analysis of all phases of the extended scheme. However, to do so, considering both the indoor environment and energy use, would have required a very long trials period. In order to obtain a first relatively quick evaluation, the extended scheme was applied to buildings which formed a special case in that their indoor environments had already been certified with the QA scheme. They therefore needed only the additional element of QA of their energy schemes. The pilot buildings were chosen in order to represent a wide range of building categories and property manager organisations. The pilot projects are a school building, an office and an area of multifamily houses.

DESCRIPTION OF THE QUALITY ASSURANCE SCHEME

The primary objective of the scheme is to work towards continuing improvements and to encourage clients, builders, architects, administrators and occupants to perform measures that otherwise would not have been considered. This requires quantified and measurable goals, action plans for measures, and management systems during operation.

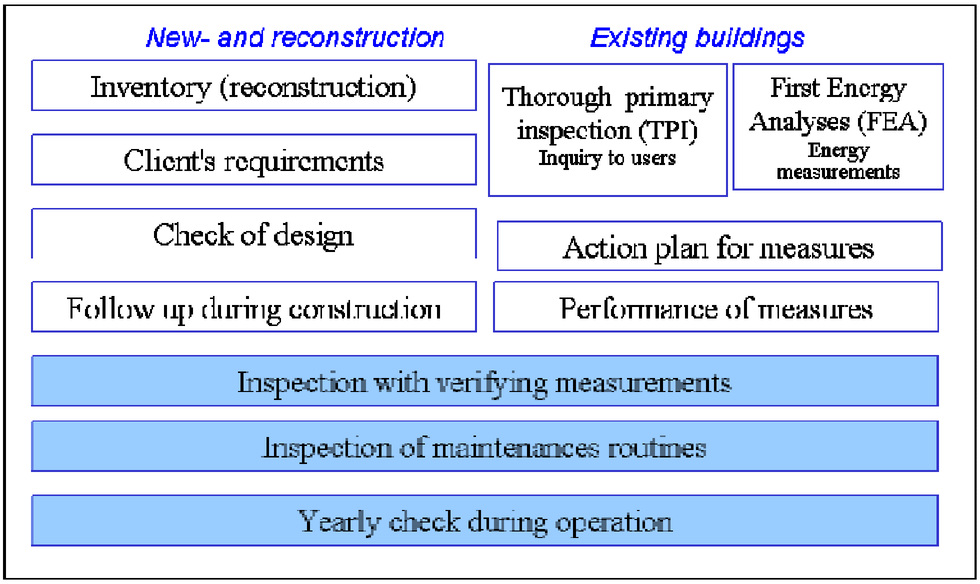

Figure 1. Illustration of procedures for quality assurance of indoor environment and energy use.

Cooperation between all parties, from scientists and public authorities to designers, contractors, managers and users, is important for the end results. All need to listen to, and to learn from, each other. Good indoor environment and efficient use of energy can be achieved by creativity, planning and layout design, choice of materials, general designs and detailed and overall designs of systems for heating, ventilation, electricity and water supply. This QA scheme makes sure that the requirements set out in legislation, standards or common codes of practice are fulfilled as intended. An independent third party supervises, evaluates and checks that the requirements are fulfilled. Measurements show that the performance requirements have been met. Occupants' perceptions of the indoor environment are evaluated with the help of questionnaires, while energy use is evaluated with energy measurements or energy bills. The QA system includes new building and reconstruction work, as well as improvements of existing buildings, and covers the entire process, from planning and design, through the construction stage to final use and operation. The certification is based on ISO 9000 procedures, is illustrated in Figure 1 and described in SPCR 114E [6].

Additional elements for energy use

Certification work for existing buildings begins with a first energy analysis (FEA), which consists of an inventory of the actual property with its actual energy status, energy aspects and energy performance [7]. This can be done by examining construction drawings, operational follow-up programs, control systems or other documentation; inspections, interviews with staff and additional measurements. It is recommended that this should be carried out in conjunction with the TPI (Thorough Primary Inspection) of the indoor environment, particularly with respect to visual inspection and interviews with staff.

The results of the FEA are then used to set objectives to be achieved, including a performance measurement specification of how the comprehensive targets should be measured and checked. The QA scheme considers the fact that each building project is unique, and therefore the annual energy use target will be set on the basis of the building's current condition and its associated limitations, rather than on the basis of a specific predefined figure. For new construction, or major reconstruction, the primary limitations relate to building use and climate, while minor reconstruction and existing buildings also have limitations due to design.

The next step is to draw up an action plan for measures and carry them out in order to reach the set targets. Experience shows that successful energy efficiency in a building will be maintained only if the building is efficiently managed, operated and maintained, with all parties steadily improving their performance and with the results regularly monitored. This means that the energy target must be regularly monitored and reviewed, and the QA scheme is therefore based on a management system modelled on a Swedish standard (SS 62 77 50, [8]). The standard includes comprehensive routines for energy management for any organisation and has therefore been refined and customised to fit the building sector.

DESCRIPTION OF THE PILOT PROJECTS

The pilot projects are a school building, an office and an area of multifamily houses.

The Sjöbo School

The main classroom building of Sjöbo School (originally built in 1959) was rebuilt in 2001 and 2002, complemented by new building of the gymnasium, kindergarten, teachers' staff rooms etc. In total, the school consists of six buildings, with a floor area of 6673 m^2. The indoor environment element of the QA scheme was employed during the planning, design, construction and commissioning stages, and after some months of operation the school indoor environment was certified. As far as energy use is concerned, the school should perform quite well, since all buildings were rebuilt or newly built, with new building envelopes and HVAC systems. However, the focus of this project was to introduce the extended QA scheme in order to ensure retention of good building performance rather than (primarily) to improve energy use.

Figure 2. The Sjöbo school.

The Elektra Office

The Elektra building was built in 1894 for Borå's steam engine-driven power station. In 1970, it was converted to office premises. After the last refurbishment in 1990, the building presents a modern impression, while at the same time reminding us of older days with its large windows and small chimney towers. The 2100 m^2 interior was certified according to the indoor environment QA scheme in 2003. The owner and property manger is the town's district heating company, with good knowledge of energy efficiency measures and therefore already having clear ideas about how to improve the energy performance, with respect to the building's age, during the extension of the QA scheme to cover energy use.

Figure 3. The Elektra office.

The Högsbohöjd area with multifamily houses

The Högsbohöjd district consists of 14 multi-family houses with 940 apartments and a total area of 57 817 m^2. The district was built during 1959 to 1961 and was totally renovated in 1992. Part of the buildings were certified according to the indoor environment QA scheme in 2001, and the last building in 2006.

Figure 4. The Högsbohöjd district with multifamily houses.

TARGET DETERMINATION AND SPECIAL CONSIDERATION FOR EACH PILOT PROJECT

The three pilot projects are very different in their character regarding building categories and property manager organisations. They also had different additional aims with the introduction of the QA scheme and ways of working during the introduction.

The Sjöbo School

The property manager, based in the municipality and responsible for management of the Sjöbo school, worked very hard with getting all parties involved in the management process with several meetings between the principal, the operation staff at the school (caretaker, cleaner, etc.), teachers' and occupants' representatives and the municipality property manager. Besides this series of regular meetings with standing agendas, two consultants had been engaged to help with computerisation of the building management system, installation of new sensors and instrumentation equipment and commissioning the building control system. One of the main measures that was introduced was time-control and demand-control of the ventilation system in the kindergarten and the gymnasium. This required special consideration on how the ventilation should be controlled while the indoor environment was kept at a high level, which is described in Wahlström et al. [9].

The FEA showed that the annual energy use of district heating was 121 kWh/m^2, and that of electricity was 59 kWh/m^2. The target was a 10 % reduction during the first year, and 15 % after two years, while the use of electricity should not exceed the previous level. After one year, the first target was met for district heating, while electricity use had also been reduced by a few percentage points.

The Elektra Office

The property management structure for the Elektra office is a very flat organisation for management of the building, and it was simple to introduce a management system with rules and responsibilities since there was already an environmental management system. At the same time, it was very easy to monitor the energy performance, since the office consisted of only one building. The building owner had, however, an additional aim with the introduction of the management system, which was to analyse how energy use could be controlled using the company's own internet-based statistical monitoring tool. Monthly and yearly energy performance was evaluated with the internet tool, in the form of graphs and alarms for easy follow-up, during the introduction of the QA scheme.

The work involved in the Elektra building consisted of replacement of the building control system, modifications to the ventilation, heating and cooling control system, and calibration of sensors. The target for energy performance was set at a 15 % reduction in heating energy, a 7 % reduction in electricity use, and a 10 % reduction in cooling energy use during the first year.

The Högsbohöjd district with multifamily houses

The property manager for the Högsbohöjd district wanted to work in a different way with both organisational and target set-up. The main approach with their energy reduction work was to first consider and work with the buildings that had the highest energy use, and thus also the highest potential for energy improvements. This enabled the current year's investment costs to be used where they gave the most benefits. Targets were therefore set up for all 14 buildings together, instead of an individual target for each building, but with the limitation that the energy use was not allowed to increase in any building. An action plan for work was set up with the following main features; adjustment of heating, replacement of windows, insulation of windows, insulation of attics, hot water metering and improving the airtightness of the building envelope. However, what was not defined was in which building the various measures should be performed. Each year, a few buildings with the highest energy demand will be examined in order to decide which energy measures would be of most benefit to that particular building.

Today, the Högsbohöjd district has an average specific district heating demand of 169 kWh/m^2, and has set a target of 149 kWh/m^2 for the whole area by 2010. Electricity use is 21 kWh/m^2, and the target here is prevent any increase by 2010.

The organisation for management of the Högsbohöjd district consists of a chief property manager, based in the head office, and staff known as local landlords who deal directly with daily maintenance within the buildings. If anything acute happens that need to be dealt with immediately, the owner has a contract with a service company. The local landlords check the energy performance every month and report deviations directly to the chief property manager. At yearly evaluations by the chief property manager, buildings with high energy use are selected for further investigation by energy auditors. This can also be the case if a local landlord has recognised a large monthly deviation. The energy auditors examine the selected buildings and give suggestions for necessary improvement or remedial work.

RESULTS AND DISCUSSIONS

New demands for energy improvements must not be allowed to draw attention away from the indoor environment. The preliminary results from the pilot projects show that this can be done by using a practical and flexible quality assurance scheme, intended to design and maintain a good indoor environment and efficient energy use.

The primary objective with the QA scheme is to work towards continuing improvements and encourage property managers, administrators and occupants to perform measures that otherwise would not have been considered. The QA scheme aims to be flexible so that it can be used for different building categories, different organisational structures and different parts of the building process. This report describes application of the QA scheme to buildings that already employ the indoor environment management scheme, but in three different kinds of pilot projects.

The results show that the QA scheme is really flexible. For each pilot project it was possible to introduce quantified and measurable goals, action plans for measures and management systems during operation with authorities, responsibilities and awareness for all actors within the process. All pilot projects have already shown, with their new targets and action plans for work, that they are moving towards improved energy performance. The projects have also led to a significant improvement in the systematic work related to the controlling energy use, while at the same time maintaining a good indoor environment.

The main target group of the end results is the occupants. It is important to occupants to know that their potential home or workplace building has a healthy indoor environment with minimum use of energy.

The next step is to test the flexibility of the QA scheme during planning, design, construction and commissioning of different building categories.

ACKNOWLEDGEMENT

The authors would like to thank the building management department of Borås City Council, Bostads AB Poseidon and Borås Energi och Miljö. We gratefully acknowledge financial support from FORMAS (the Swedish Research Council for Environment, Agricultural Sciences and Spatial Planning) and BIC (the Swedish Construction Sector Innovation Centre).

Simplified methods to evaluate energy use for space cooling in the energy certification

Alessio Gastaldello and Luigi Schibuola

University IUAV of Venice, Italy

Corresponding email: luigi.schibuola@iuav.it

SUMMARY

Both on European and national scale, standards are now being drawn to extend to summer air conditioning the evaluation of energy requirement in building-plant systems. To this aim different simplified methods have been taken into account, anyway all similar to the utilization factor method already used for the winter season.
The results obtained by the application of these methods in the case of typical buildings are therefore compared here with those from a dynamic simulation of building-plant system by means of comprehensive computer programs like Energy-Plus. The analysis points out the possibilities but also the limits of these simplified methods.

INTRODUCTION

Comprehensive software programs to simulate building energy performances in dynamic conditions are available today for professional purpose. But the use of simplified methods is still diffuse and recommended or sometimes even compulsory in various national standard. Also in the new European standard [1], in draft , for the calculation of energy use for space heating and cooling are foreseen both quasi-steady state methods and dynamic methods. At national level it may be decided which of these methods is or are allowed to be used. Eventually depending on the purpose of the calculation and the complexity of building. With regard summer air conditioning, the actual tendency is to elaborate a simplified approach similar to the one used for heating requirements calculation and based on the utilization factor method. For example this method is already present in the standard EN 832 [2]. Naturally the application of this technique to the more complicated summer case is destined to increase the problems, the doubts and the criticisms which have appeared over the winter calculation. The possible application of the utilization factor method for the cooling calculation is therefore discussed here on the basis of the comparison with the results obtainable with the EnergyPlus program [3] . This is a dynamic simulation program of the building-plant system based on the most popular features and capabilities of BLAST [4] and DOE-2 [5] programs. Its development is supported by the US Department of Energy and actually it can be considered one of the most reliable software codes for building energy simulation.

THE APPLICATION CASES

For our investigations about summer requirement evaluations some typical application cases have been analysed . As the fundamental aim is to investigate the influence of the heat gains on the simplified calculation of the cooling needs, we have concentrated our attention about office buildings normally characterized by greater heat fluxes than dwellings. Three buildings with different shapes have been considered: a single unit, an horizontal serie of units and a vertical serie. The three buildings are sketched in figure 1. One of the largest façades is always South oriented. The conditioned volume is respectively 432 , 10368, 9720 m^3 for the three buildings. Typical envelope structures have been assumed , for example brick walls well insulated as required by the current Italian laws. Double glazing 6+13+6 mm uncoated, clear and air filled with a thermal transmittance of 2.71W/m^2K and a SHGC=0.70. Further details can be found in [6]. Three different amounts of external glazing have been considered: 10%, 50% and 100% of the external surfaces for the single unit, 20%, 50% and 100% for the horizontal and vertical volume. The air conditioning can be continuous or intermittent, from 7 am to 7 pm. (12h).

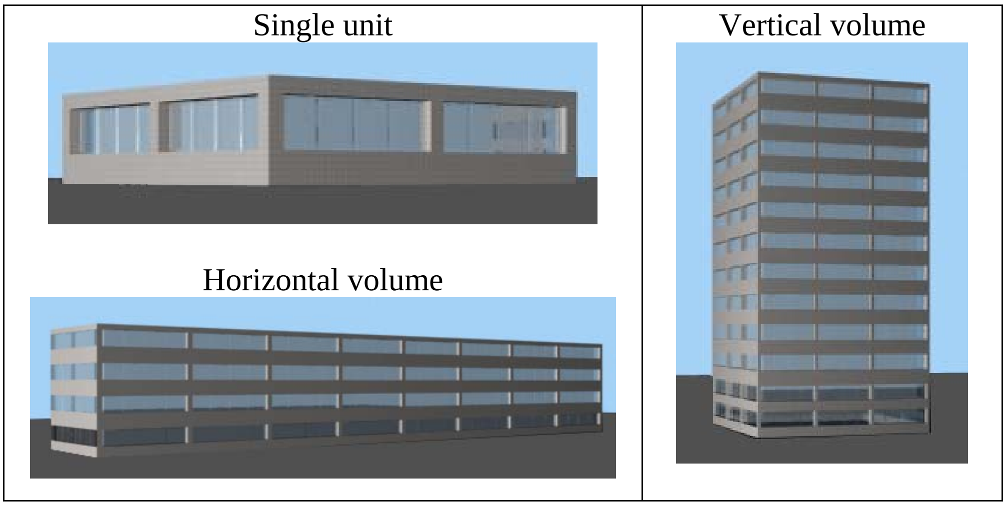

Figure 1 A view of the analysed buildings

Forced ventilation equal to 2 vol h^{-1} is present only in the period from 7 am to 7 pm. Internal heat gains for persons (maximum 1 person 10 m^{-2}), lighting (maximum 20 W/m^2, fluorescent) and different maximum electric machine gains (computers): 12, 48 W/m^2. Typical daily

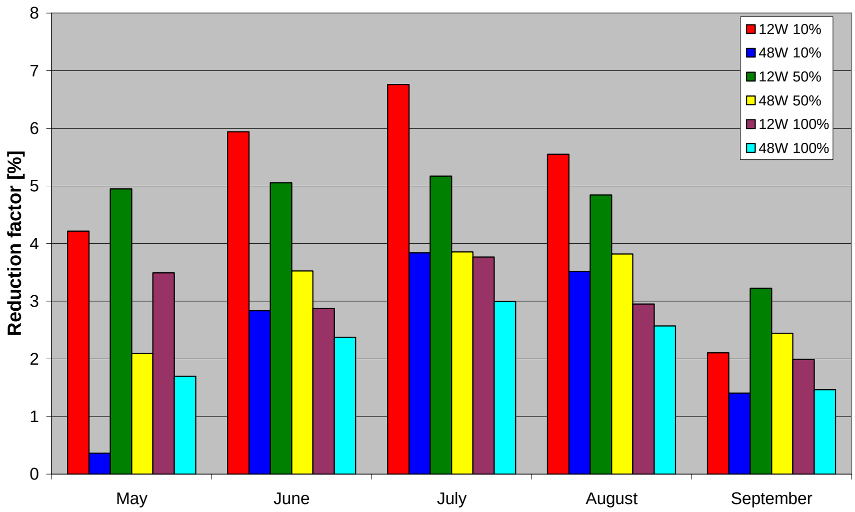

Figure 2 Percentage reduction of the cooling needs with intermittent instead of continuous air conditioning for the single unit in Venice with various electric gains and glazed quota.

scheduling for office buildings are foreseen. The indoor air design temperature is 26°C, a standard value in Italy. The air conditioning period analysed is from May to September (5 months). The procedure to calculate energy requirement for humidity control will not be discussed here even if latent loads normally have an important effect on overall plant performance. In fact hygrometric load calculation is normally easier to do by a mass balance on the indoor air. The following considerations will refer only to sensible load estimation whose determination is undoubtedly more critical. For the simulation the weather of two different localities in Italy: Venice and Palermo have been utilized. They are assumed representative of the climate in the central and southern part of Europe.

In figure 2 the percentage reductions of the seasonal cooling needs with the intermittent instead of continuous air conditioning are presented in the case of single building with different internal electric gains and external glazed surface ratios. Unlike the winter case, the passage from continuous to intermittent plant operation does not cause noticeable differences in the seasonal requirement because the heat gains are normally concentrated on daytime. In this first phase of the analysis therefore, we have concentrated the attention on the plant continuous working case. All the results presented are referred to the continuous cooling.

THE UTILIZATION FACTOR METHOD

The monthly heating requirement for each zone Q_h of a building is calculated using the following correlation:

$$Q_h = Q_l - \eta_u \cdot (Q_{si} + Q_i) \qquad (1)$$

where:
Q_l is the total heat loss, sum of transmission and ventilation losses (J)
Q_{si} is the solar gain through fenestrations (J)
Q_i is the internal gain (J)
η_u is the utilization factor of the heat gains
The utilization factor is a reduction factor for the heat gain introduced to take into account of the dynamic behaviour of the building. The parameters having the greatest influence on the utilization factor are:
- the gain/loss ratio γ which is defined as:

$$\gamma = \frac{Q_{si} + Q_i}{Q_l} \qquad (2)$$

- the time constant τ which characterizes the internal thermal inertia of the heated space:

$$\tau = \frac{C}{H} \qquad (3)$$

where C is the effective internal thermal capacity (J/K).
The utilization factor η_u is then calculated with the following equations:

$$\eta_u = \frac{1-\gamma^{\alpha}}{1-\gamma^{\alpha+1}} \qquad \text{if } \gamma \neq 1 \qquad (4)$$

$$\eta_u = \frac{\alpha}{\alpha + 1} \qquad \text{if } \gamma = 1 \qquad (5)$$

where α is a numerical parameter depending on the time constant τ.

$$\alpha = \alpha_0 + \frac{\tau}{\tau_0} \qquad (6)$$

The values of α_0 and τ_0 are provided by the standard.

THE APPLICATION TO AIR CONDITIONING

In analogy with winter calculation the review of the standard EN 13790 proposes the evaluation of the cooling requirement Q_c. In the summer period the heat gains become the fundamental cause of the air conditioning needs, instead the quantity Q_l due to transmission and ventilation normally reduces the cooling load. In fact, in the European climate the average monthly temperature of the outdoor air is lower than the indoor design temperature which is for example in Italy equal to 26°C. Therefore for each zone and in the case of continuous air conditioning, at the present time the standard suggests the following equation:

$$Q_c = (Q_{si} + Q_i) - \eta_u \cdot Q_l \qquad (7)$$

where η_u becomes an utilization factor for heat losses and it is calculated again as a function of γ and τ with different values α_0 and τ_0.

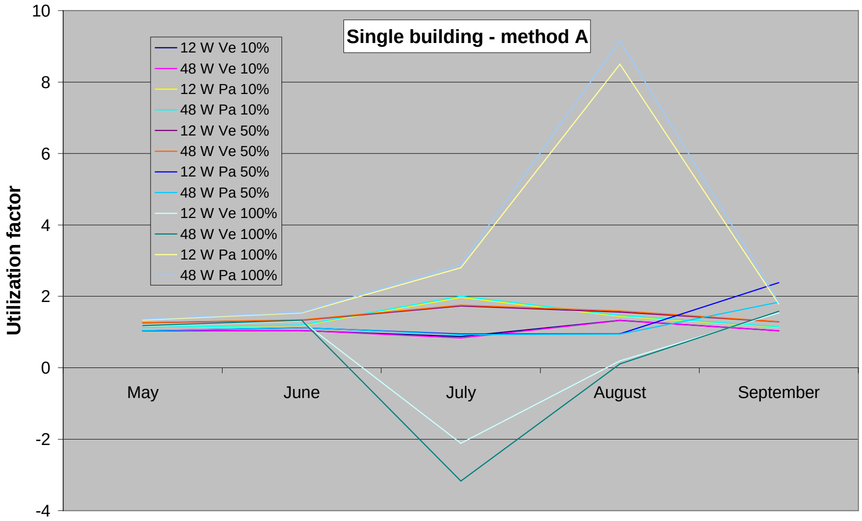

Figure 3 Utilization factors with method A for the single unit in the various cases

If these losses are negative (γ <0) the utilization factor will have the value one and consequently the negative losses are totally added as gains. By this procedure η_u can be less o equal one. An investigation on this procedure, here called method A, is carried on, starting, on monthly basis, from the cooling demand Q_c , heat losses Q_l and heat gains (Q_i + Q_{si}) obtained by dynamic simulation with EnergyPlus program. In this way it is possible to calculate the corresponding utilization factor necessary with method A in order to obtain the same Q_c . In the figures 3, 4, 5 this utilization factor is reported for the three considered buildings respectively and for the different localities, internal gains and glazed quota.

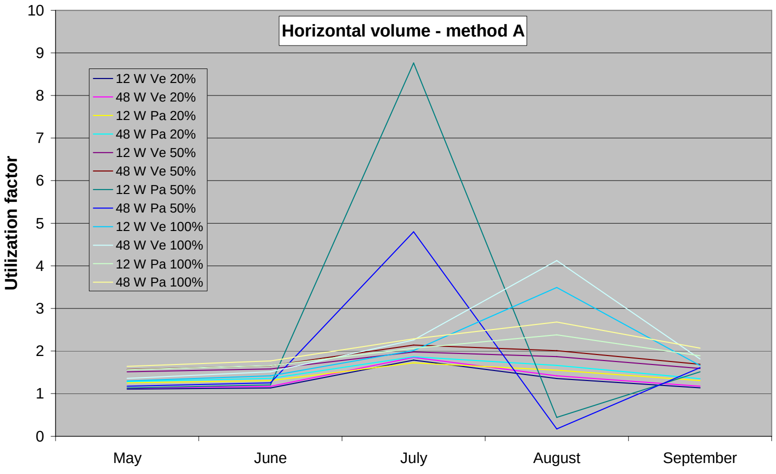

Figure 4 Utilization factors with method A for the horizontal volume in the various cases.

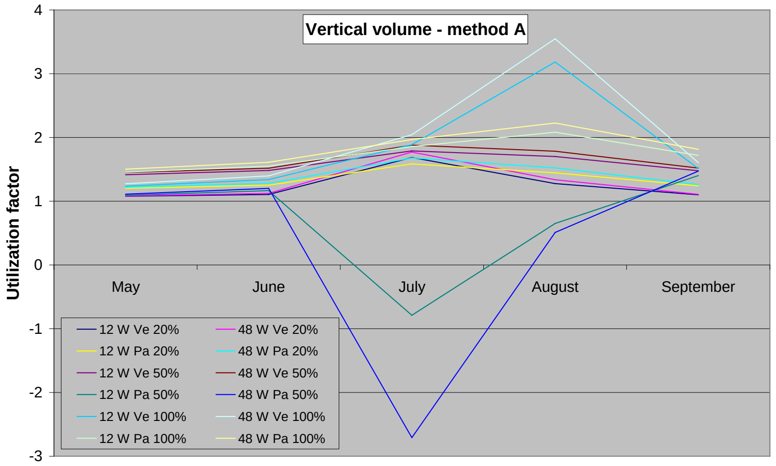

Figure 5 Utilization factors with method A for the vertical volume in the various cases.

An extreme variability of the utilization factor can be noted and this fact involves the difficult to introduce a simple correlation able to calculate a correct value for the equation (7). Besides it is often strongly greater than the unit. This is because normally only a fraction of the heat gains contributes to the cooling requirements while a considerable quota is lost to the surroundings. Indeed this conclusion is not a great novelty for people familiar with cooling load calculations by dinamic simulation. The transfer function method from ASHRAE [6] foresees reduction coefficients for the various types of heat gains. The necessity to reduce also the heat gains is the reason of the utilization factors greater than one. In the same way when sometimes the heat losses are negative (i.e. in Palermo) the procedure can need negative values of $\boldsymbol{\eta_u}$. We can conclude that especially in presence of remarkable solar contributions and smaller effect of free cooling connected with heat losses there is the necessity to introduce an utilization factor for the heat gain. Another method (here called method B) is then proposed and based on the following equation:

$$Q_c = \eta_u \cdot (Q_{si} + Q_i) - Q_l \qquad (8)$$

where η_u becomes again an utilization factor for heat gains. For sake of simplicity an utilization factor of the heat losses is here neglected. The effort is to maintain a simple correlation like in the winter procedure. A verification of the method B is presented in the figures 6,7 and 8 in the various cases. We can appreciate in this case the moderate variability of the values. In this way it is justified to consider eventual approximations or errors anyway of limited amount. The use of only one utilization factor for the heat gains seems to be able to

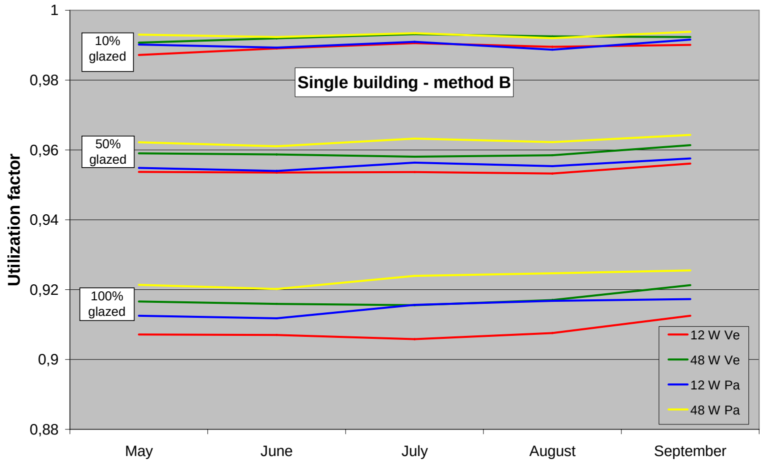

Figure 6 Utilization factors with method B for the single unit in the various cases.

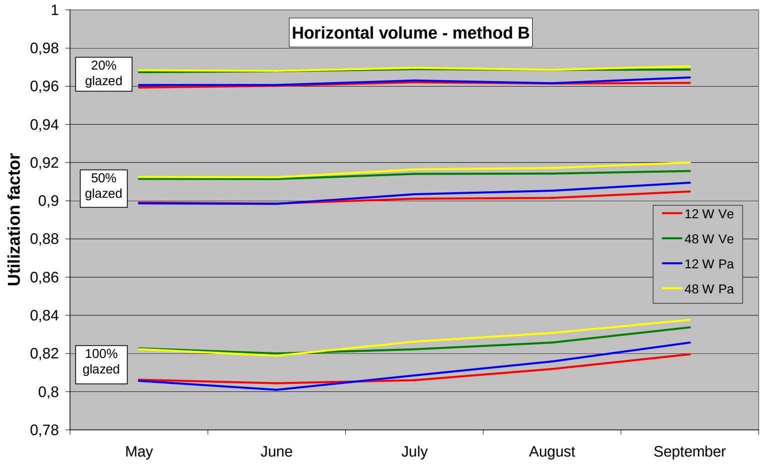

Figure 7 Utilization factors with method B for the horizontal volume in the various cases.

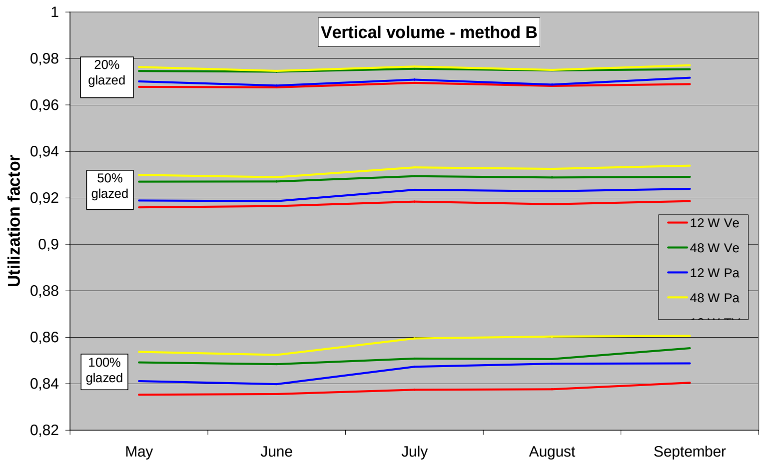

Figure 8 Utilization factors with method B for the vertical volume in the various cases.

control in a correct way the effect of both the heat fluxes and contributions. In addition the figures show a greater influence of the percentage glazed quota than the internal gains on the values of utilization factors. It means that the solar contributions deeply influence the η_u In particular we find, as foreseen, a significant reduction of the utilization factor by increasing the glazed quota i.e. the solar flux. On the contrary it is quite logical that an internal electric gain (computer, electric machines) becomes immediately a convective cooling load and then it is completely added to the cooling needs. The variability of η_u regards therefore especially the solar gain. For this reason a third method (here called method C) is here analysed where the utilization factor is referred only to the solar contribution like presented in the following formula:

$$Q_c = \eta_u \cdot Q_{si} + Q_i - Q_l \qquad (9)$$

A verification of the method C is presented in the figures 9, 10 and 11 in the various cases.

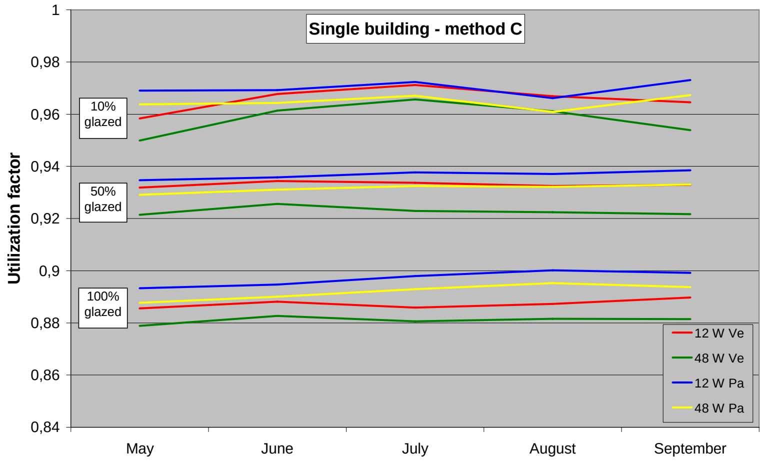

Figure 9 Utilization factors with method C for the single unit in the various cases.

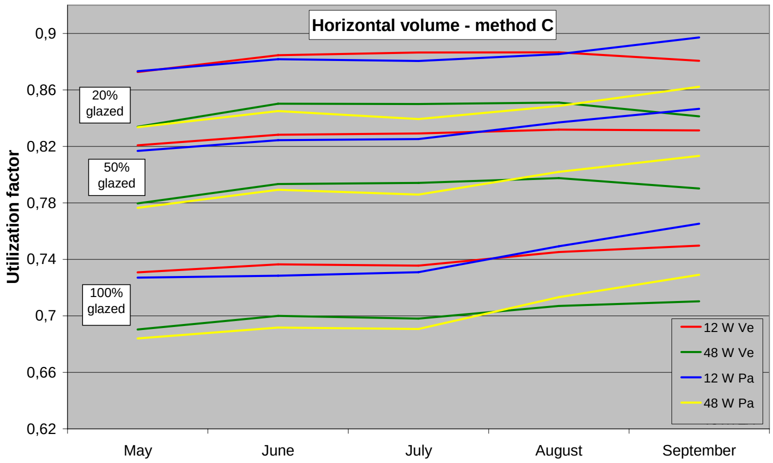

Figure 10 Utilization factors with method C for the horizontal volume in the various cases.

The application of the method C points out a better sensibility of η_u to the influence of the amount of glazed quota and therefore to the parameter γ . This fact confirms the correct interpretation of a reduction of the utilization of the heat gain only referred to the solar contribution which is absorbed first by the internal surfaces and later partially transferred to the internal air as a cooling load. This mechanism is influenced by the thermal inertia of the structures and the heat loss coefficient of the room. Besides, for the same glazed quota, the figures show that the utilization factor increases lightly in presence of less internal gains. Also with method C therefore, it is correct the research of a correlation to calculate η_u where the ratio γ still contains all the heat gains.

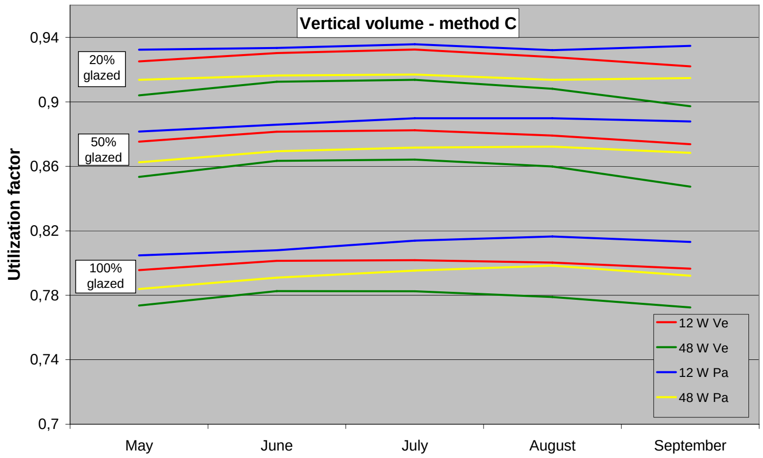

Figure 11 Utilization factors with method C for the vertical volume in the various cases.

DISCUSSION

The analysis confirms the possibility of a simplified estimation of building cooling requirement based on the utilization factor method likewise the procedure to calculate heating energy use. But in the cooling case the utilization factor must be referred to the free heat gains which are the fundamental heat fluxes which determine the air conditioning need. Instead in summer heat losses permit often a free cooling, but they are normally modest. Therefore a reduction coefficient of their influence on the cooling load is not the best way to take into account also the more significant reduction of the heat gains. The results of the dynamic simulation suggest the introduction of an utilization efficiency referred only to the solar contribution. It seems to be possible to evaluate it by an algorithm equal to that one already used for heating calculation as a function of the parameters γ and τ. But new correlations to calculate them will have to be elaborated and verified by an extended data base of simulation results with different building characteristics, use and climatic conditions.

Planning Healthy Buildings – A Swiss Label that Insures Quality

Reto Coutalides[1], Udo Heinss[1], Philipp Thalmann[1] and Samuel Koller[1]

[1]BAU- UND UMWELTCHEMIE Beratungen + Messungen AG, Leutholdstr. 12, CH-8037 Zürich

SUMMARY

The following article presents a method that outlines how to effectively construct buildings that emit only minimal concentrations of harmful airborne substances. The conception and implementation of a label that certifies the ambient air quality of newly constructed and renovated buildings by carrying out accredited, post-construction air quality evaluations, will touched upon as well. In addition, a certified building of Swiss Life, Zurich will also be profiled.

INTRODUCTION

Even in Switzerland today, it is common for health complaints to arise in newly constructed buildings due to excessive levels of ecological contaminants. Sometimes these new buildings must be shut down for decontamination work. This was the case of a newly renovated school building in Zurich that was found to have formaldehyde values ranging between 190 and 311 $\mu g/m^3$ in no fewer than 10 of its classrooms. In an even more recent case, stemming from 2006, a school building of wood construction was found to be emitting maximum formaldehyde concentrations of 381 $\mu g/m^3$ [2]. In each of these cases, adverse health effects resulted. Pupils and teaching staff alike complained of eye and throat irritations. The publication Innenraumklima - which was produced in collaboration with the Swiss Federal Office of Public Health and a number of Swiss building authorities – documents 18 separate cases of complaints, complete with detailed laboratory readings and materials data [1]. As a direct result of these cases, the Planungsleistung Innenraumklima (Indoor Air Quality Service IAQS) was developed [3]. The IAQS has established concrete performance levels (in accordance with performance model SIA 112) [4], that are to be adhered to throughout each planning phase in an effort to optimise indoor air quality. In addition: performance targets, decision making protocol and impending documents of the building developer as well as a performance itinerary for the planner are precisely outlined. With the help of spreadsheets which, as templates, can also be presented electronically, relevant influences on indoor air quality can be determined, controlled and thus minimised. In addition, an agreement could be made concerning the target values to be achieved by construction's end and consequences if not achieved. Requirements on ambient air quality driven by target values are also included. The label, GI Gutes Innenraumklima, is the logical development and further enhancement of such target requirements. A two year test phase was initiated to show whether and how such target values might be achieved, and thus promoted, in an actual construction situation. The present work will illustrate the findings of our investigations both into building projects that followed the protocol of the IAQS as well as projects that took no special measures to optimise indoor air quality. Furthermore, the certification of one building with the GI Gutes Innenraumklima will be presented.

METHODS

For VOC (volatile organic compounds) test measurements, the substance TENAX TA with accompanying thermodesorption was used as a carrier material/substrate. Identification and quantification were done via gas chromatography/high resolution mass spectrometry (GC/MS) in accordance with VDI 4300, page 6 [5] und ISO 16000-6 [6]. VOC encompass all TENAX TA absorbable and identified substances within the given retention periods between n-Hexane and n-Icosane. The identified substances that register above the maximum, per substance stipulated value are accounted for (2-10 $\mu g/m^3$). Any unidentified signals registering above 10 $\mu g/m^3$ are also accounted for. Through the application of gas chromatic separation, the concentration of individual compounds, each found within the parameters of its own compound range and each exhibiting its own characteristic marker (response factor) will be evaluated through external standards. Moreover, the peak area of each unidentifiable compound will be taken under observation. Through the use of a characteristic marker of the reference compound, Toluene, equivalent concentrations of the as-yet-unidentified compound can be calculated. The target values for individual substance classes cannot be superseded, even if the exigency TVOC $\leq$ 1000 $\mu g/m^3$ has been met. Substances that have neither been identified nor ordered into a specific class cannot exceed 15% of the TVOC. If the stated final concentration does exceed 15%, then the reason for this must be clarified. Substances which are found but are not yet on the list must be individually studied and evaluated. In this regard, protocol must be conducted in analogy to the derivation of the target values.

Aldehyde Measurements

DNPH cartridges were used as aldehyde carriers. Analysis was done according to VDI 3484, page 3 [7]. Identified and listed substances above the limit of determination of 5 $\mu g/m^3$ were taken into account.

Particulate Matter Readings

Measurements were taken using a particle measuring device that operates on the basis of scattered light measurements, a laser and photodiodes or a system of measurement capable of achieving the same values. Measurements were conducted long enough for a stable reading of each measurement point to be achieved - at least 10 minutes per reading. A stable reading was defined as the average value of the last five minutes of the measurement. The measurement was conducted under isokinetic conditions.

Germs Measurements and Identification

Measurements were done using an impacter device with a mass flow meter. In the air delivery stream there is an impaction volume of at least 100 litres per minute (in exceptional cases, where the air delivery stream is weak - <100 litres per minute - the impact volume may be reduced to 50 litres). TSA, DG18, MEA and DRBC were used as culture mediums. The measurement was conducted under isokinetic conditions. Identification was done to at least the genus level. The specification of results was done in cfu/m^3 of ambient air. Moreover, individual petri cultures are to be in cfu/m^3 of ambient air and the average germ count of the cultures DG 18, MEA and DRBC in cfu/m^3 must be presented.
The label GI Gutes Innenraumklima also defines the standard building inspection procedure for conducting air quality evaluations. In office and large residential buildings, at least 2 of a construction project's building units or at least 10 % of all building units up to a total of 100

units must be inspected. For office, industry, administration, school and health services buildings, the surface area of a building unit ranges in size from 10 m^2 to a maximum of 200 m^2 of net space. For buildings consisting of more than 100 units, the number of units to be measured will be established according to a gradation scheme determined by the certification authority. In office and residential buildings, all interior surface materials must be considered. Evaluation readings collected from the inspected building space must comply with the established target values for TVOCs as well as every other individual substance and class of substance. If individual readings are too high, the building unit in question may be reassessed within 30-100 days after the final day of construction. If air handling systems are present, the stream of supply-air serves as the point of measurement: the number of supply-air readings is determined by the number of listed hazardous chemical and organic substances. Of these supply-air readings, 20 % must check for germs and particulate matter. The stream of supply-air from every building segment that makes up a building unit must be tested at least once during the evaluation.

Target Values

Target values had to be determined for harmful chemical substances as well as airborne germs and particulate matter found in the supply-air of existing air handling systems. For reasons of practicability and general acceptance in the field, the general scope of investigation has been limited to these three category groupings. Reliable target values for harmful chemical substances cannot be derived strictly from statistical target values, as was done by Schleibinger [8]. Weeks and months after a building's completion, measured values are much higher than statistical values reported by Schleibinger, making these as resulting target values wholly impracticable. It was important then to select and focus on target values that would help minimise the risk of complaints from both a respiratory hygiene as well as a toxicological viewpoint; and, those values needed to be both relevant and attainable for building developers. In the work at hand, we have gravitated toward the pragmatic method of using already existing and established values. Above all, existing RW-I-values (reference value) [9] or other established indoor air guidelines like WHO guidelines will be drawn from. In the event that no data was available, 1/100 of the Maximale Arbeitsplatz Konzentration (MAK) values, respective to 1/100 threshold limit values (TLV) were selected. In the case of a few compounds, low values of LCI (lowest concentration of interest) were also chosen as orientation markers in order to establish target values. Furthermore, where available, odour threshold limits have also been taken into account. This was especially the case with regard to the higher aldehydes (C_7-C_{10}), for which no RW-I-values exist. Because odour threshold values tend to differ widely depending on the literature consulted, a number of different sources have been drawn from and the respective plausibility of each source cross-examined. It is well understood by the authors that odour threshold limits are to be used with the greatest caution. Furthermore, existent testing criteria, guidelines and odour threshold limits have been a useful source - where available - for the establishment of target values. Because odour threshold values tend to differ widely depending on the literature consulted, a number of different sources have been drawn from. Wolkoff suggests, for instance, that with new olfactory methods, odour threshold values for many VOCs could well be placed lower than they presently are [10]. This would also have an effect on the relation of target values to the compounds which are ultimately based upon odour threshold limits. And certainly not least of all, there exists the problem that substance mixtures will indeed exhibit different olfactory characteristics from those same substances when analysed in their pure, individual forms. Yet, in practical experience, in spite of all of these difficulties, one must rely upon orientation values that pertain to ambient air which enable one to evaluate the myriad complexities of building construction and at the same time to make meaningful statements about ambient air quality upon construction's end. In an effort to achieve this goal, and with regard to [11] for the various substance classes, maximum values were defined. Highly reliable data has been tabulated and presented (see tables 4 and 5). From the individual representatives of these substance classes, the target value was deduced as being half of this value when no lower RW-I-values, respective of other values, were available (see above). And thus, the target value for Toluene is 300 $\mu g/m^3$, and that of Naphthalene: 5 $\mu g/m^3$ (RW-I-value 2 $\mu g/m^3$). Bearing in mind that complaints of noxious air quality and building-related health problems occur with the greatest frequency within the first few months of occupants settling into a newly constructed building and that concentrations of malodorous chemical compounds are most intense during this initial period, it should be made clear that it is necessary to achieve threshold limits within the 30 to 100 day period following the last day of a building's construction (including all final touch ups). If tests are conducted beyond this 100 day period, certification can no longer be granted. Under normal conditions - barring some kind of serious and unexpected ecological mishap - the measured values will attenuate further in the ensuing months. In buildings with low energy consumption (i.e. Minergie-Standard) [12], it is now common to install mechanical handling systems to insure adequate levels of air exchange. It is not altogether unusual for these systems to prove insufficient at the outset putting a negative strain on the supply-air. In addition to the standard inspection for chemically harmful substances, it becomes necessary in such cases to test for particulate matter as well as the level of airborne germs in the supply-air. Established target values for biological air pollutants delimit the concentration densities for bacterial, as well as fungal spores present in the stream of supply-air. These values are based, in part, on the results of the German ProKlima-Projekt [13] as well as on our own appraisals of 25 properly functioning air handling units (ACUs).

Table 1. TV (target values) for particulate matter and airborne fungal spores for the label

Parameter	TV	Unit
Bacteria	≤190	cfu/m^3
Thermoactinomyces	0	cfu/m^3
Molds	≤120	cfu/m^3
Particle class		
Particulate matter >2 µm	≤10	particles/litre
Particulate matter >0.75 µm	≤150	particles/litre

Target values for aldehydes and VOCs are listed in Tables 4 and 5.

Concerning particle concentrations, target values will be specified for two relevant particle sizes. Achieving the prescribed target readings can only be accomplished if the air is being handled by a fully operational ACU that has been equipped and maintained in accordance with SIA Norm 382/1 [14] filters. Our own readings, taken from 20 ACU systems, show that these target values are practicable. If the filter performance is too low or if its performance is compromised by an influx of additional particles to the supply-air stream, the stipulated values will be exceeded.

Certification

The label GI Gutes Innenraumklima certificates ambient air quality after standard building inspection procedure evaluations. It defines the requirements of the ambient air quality including germs and particulate matter concentrations of the supply-air stream. The certification authority defines the requirements of the measuring points and also the scheduling and realisation of the inspection evaluations. The label will be awarded by the swiss certification authority for construction materials S-Cert AG [15].

RESULTS

Aldehyde readings show (Table 2) that the detected values in buildings in which there was no IAQS implemented are significantly higher - in the case of almost every listed compound - than in those buildings where there was IAQS implemented during construction. Tests were conducted 30-100 days after the last construction date in buildings where consultation was used and 1-30 weeks in buildings without IAQS. In the case of VOC measured readings in buildings without IAQS were found to be markedly higher than in those structures that had undergone IAQS (table 3). The median of the 37 buildings (n=48) without building consultation was found to be 1302 µg/m^3 for TVOC (95 Percentile 4512 µg/m^3). These results are considerably higher than those found in buildings with IAQS (Median 698 µg/m^3, 95 Percentile 2338 µg/m^3).

Case Study

The headquarters Swiss Life office building in down town Zurich, consisting of 9’589m^2 of office space on each floor, was completely renovated. The building was first stripped down to a bare, skeletal structure. After that, the floor work, non-supporting partition walls, suspended ceilings, all interior surfaces and numerous installations were newly reconstructed. The work was optimized with the help of the IAQS and the use of on-site, ecological consultants was made.
In the project development phase, materials and construction methods were scrutinized to evaluate the potential adverse impact of emission levels. This was made possible through the early selection of building material types. Adequate airing-out periods were also made an integral part of the construction time-frame.
During the construction phase, the implementation and inspection of ecological planning specifications to be adhered to by the contractor played a crucial role. Wherever possible, materials were selected or prescribed on the basis of the relevancy of their emission labelling. Contractor’s bids were carefully considered and building products and on-site construction methods were regularly controlled. Eight weeks after the final day of construction, readings were taken. During that eight-week interval, offices not equipped with air handling equipment were manually aired out once daily in strict accordance with a pre-arranged building ventilation plan. The air ventilation equipment on the executive floor was kept operational until one day before readings were taken. In the following table, the readings for each individual room are presented. For a complete and successful evaluation, each room had to fulfil the target values. The maximum shows that this was indeed the case for every room.

Table 4. Final measurements for aldehyde, 8 weeks after the last day of construction. 13 rooms were analysed, measurements in µg/m^3. SD: standard deviation, TV = Target Value

DISCUSSION

The VOC and aldehyde target values listed in tables 4 and 5 are derived from real and pragmatic test measurements that have been carried out on actual buildings. They should not, however, be taken as universal examples of ambient air quality, as they refer to newly constructed buildings which in general give off higher levels of harmful contaminants. With today's building techniques, it is not only possible to achieve these target values but to reduce them to even safer levels through lending careful attention to relevant IAQS criteria during the planning such as the use of low-emission building materials, air handling systems and ecologically sound construction methods. Meeting or improving upon derived target values incites us to consider more deeply the care and attention we should be granting the use of low-emission materials both in the planning and execution phases of a building project. Success in meeting the required certification standards helps minimise the risk of complaints or lawsuits from building occupants. This work demonstrates that through clear and careful planning and implementation, achieving target values is feasible. The selection of to-be-tested VOCs was made after close scrutiny of the compounds presented in the VDI of 4300 listed compounds [5]. This list was supplemented further by a number of additional compounds: (n-1-Methyl-2-pyrrolidinone (TV: 40 $\mu g/m^3$), Decamethylcyclopentasiloxane (TV: 250 $\mu g/m^3$), 2-Butanone oxime (TV: 100 $\mu g/m^3$), n-Decylaldehyde (TV: 10$\mu g/m^3$) 2-Decenal (TV: 2 $\mu g/m^3$). The list of aldehydes selected for testing, is identical with those compounds enumerated in table 4. An extended list of target values and measured VOCs is published in [16]. In an academic effort to assess the hygienic air quality of newly constructed buildings, a more theoretical path is sometimes taken by which hyper-efficient, ecological show rooms are set up using emissions-certified materials [17]. Our practically-minded intentions have taken us in a different direction; because in the end, the completed building with all of its shortcomings and imperfections is the more relevant object and it is the one requiring evaluation and certification. The advantage of swaying in favour of the practical side is that the inevitable imponderabilities of the building industry: such as frequent changes of contractor, additional subcontractors - who may avoid the use of approved materials - do not end up taking you completely by surprise. Experience shows that the optimisation of the indoor air quality the evaluation and certification thereof is well within the realm of feasibility without the need for legally imposed limit values of hazardous compounds. Moreover, new product formulations alter the spectrum of hazardous substances trapped in our non-ambient air and fresh discoveries concerning photochemical reactions in indoor space make it periodically necessary to reshuffle the selection of compounds that are to be verified.

The weight of experience has shown that by making and communicating the timely decision to have the indoor air quality of your building project evaluated and to certify it with a label has positive effects on the entire planning process. By relying on indoor air quality planning with regard to both newly-constructed buildings as well as renovation projects, it is possible to construct buildings that give off very low concentrations of hazardous substances even directly after the last day of construction. The budgetary implications of ecological consultation with respect to the illustrated case studies - including the end-of-construction building evaluations - runs modestly in the neighbourhood of 0.1 to 0.2 percent of the total building costs. In the case of the Swiss Life building, this amounted to <60 Cents/m^3 of building volume according to SIA 416 [18].

We have noted further that every effort made and communicated on the building developer's behalf to improve the living quality of future occupants produces in the latter a courteous attitude which is good at the best of times and invaluable in those potentially difficult times when relations between renter and rentee become strained. As a direct result of this constructive phenomenon, the Swiss Reinsurance Group has made it their standard practice -

with positive effect- to include the label of certification as part of each new occupant's building reference documentation package.

SUMMARY

In order to reduce the energy consumptions, it is urgent to be focused on existing buildings. The answer is how to determine priorities of interventions on a building to be renovated. The traditional method consists in carrying out a great number of tests and quantifying profits obtained with each solution or combinations of solutions. Our object is to optimize the number of tests to be realized by use of the method of the experimental design concepts which is applied to draw up decisional flow charts of interventions on a building built before 1975. Software Nemrod [1] is used for the experimental design concepts. This stage carried out, the plans are applied by the means of the software Trnsys [2] giving as output the requirements.

INTRODUCTION

Existing buildings consumption is estimated at 60% more than the new buildings.
To determine rehabilitation works on the building, it's possible to vary a lot of parameters. Nevertheless, a mathematical method making it possible to reduce the number of simulations for what is strictly necessary to make a decision, thus allowing a saving of considerable time, was selected in order to draw up a decisional flow chart in term of interventions on the building. It is the methodology of the experimental designs. These experiments determine the influence of such or such factor of the building on the performances of the latest. Two experimental design concepts must be carried out separately according to the weather for two localisations. Identified elements are the following: windows, frontages, roof, ventilation and floor.
On a reference building built before 1975, the method of the experimental design concepts is applied to draw up decisional flow charts of interventions on the existing buildings according to a share of the typology of the building but also of the climatic conditions.
Thermal air flow modelling of building is integrating in TRNSYS via TRNFLOW [3] which is the integration of the multi-zone air flow model COMIS (Conjunction of Multi-zone Infiltrations Specialists) into the thermal building module of TRNSYS (Type 56).
The required objective is the reduction of a factor four of the requirements in winter.

METHODS

The reference building is described first, to know requirements in winter in Type 56. On this building the method of the experimental design concepts is applied by supposing that the lower limits correspond to the building not renovated. Responses are given for requirements. On those responses, the weight of elements is studied for two weathers.

The period of heating considered is spread out from October 1 to April 31.

Reference building

Reference building built in 1966 (Figure 1) is given by [4]. It's made of three floors: Basement, Ground floor (Dining room, services rooms, Rooms 1 at 3) and a stage (rooms 4 and 5, attics 1 and 2 and cupboards) on 120m² of liveable area with single glasses. The roof slope's is 45°. Building description is given in Tables 1 and 2.

Services rooms	North	3,5	3,05
Bedroom 4	West	1,75	5,55
Bedroom 5	East	1,75	5,55

Assumptions of simulation

The building is divided in several thermal zones in Type 56 as saw above (Figures 1 and 2):

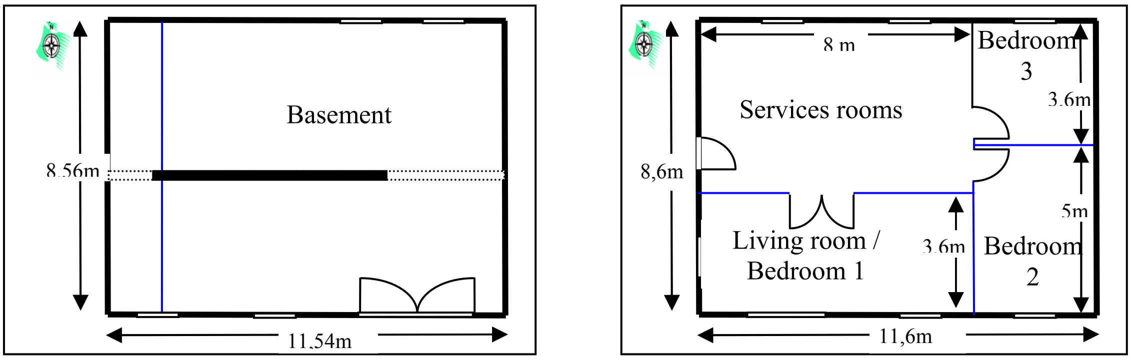

Figure 2: Basement and ground floor plans

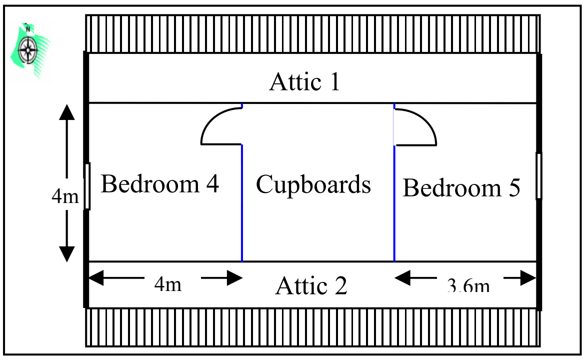

Figure 3: Stage plan

Choice of convective heat transfer coefficients: Inside walls convective heat transfer coefficients are calculated by TRNSYS software in Type 56. For other vertical walls, default values are retained: 3 W/m².K for front wall and 17,8 W/m².K for back wall.
For slope surfaces like roof, result is carried out via an input related to an equation computed convective heat transfer coefficients described above. Brau [5] allows calculating them for outdoor surfaces and shows what h_{out} can express (1):

$$h_{out} = 3{,}89 \cdot \left(\frac{v_m}{l}\right)^{\frac{1}{2}} \quad [\mathrm{W/(m^2.°C)}] \qquad (1)$$

where v_m is the wind speed [m/s] and l the length considered [m].
For front surfaces, convective heat transfer coefficients for slope walls are the same as the one proposed by TRNSYS in roof Type (usable only with the mono-zone building) result from ASHRAE Handbook of Fundamentals : $h_{i,45}$ = 9 W/m².K.

Ground Temperature: In order to approach reality as well as possible, the temperature of the ground is modelled by a specific type (Type 77) which represents the sinusoidal evolution of the temperature over the year. A parameter of this model is the average temperature of surface which is typically the annual average of the temperature of the air to the place considered: it's 10,15°C for Lille et 14,8°C for Marseille.

Internal loads: Internal loads results of the Concerto study were retained [6] for the summer and for the winter they are based on French thermal requirement RT2000 (4 W/m²).

Air flow model: Wind pressure coefficients, cp, are defined for a building reference high of 7,5m. Wind prevailing is supposed North direction, rather frequent situation in France, for a wind profile: "Open terrain with isolated obstacles" [3].

Orme, Liddament M., Wilson A. [7] provide cp for ratios width/height of building equal to 1 or 2. This report/ratio is worth approximately 1,35 for the building of reference. We thus carry out a linear interpolation in way as well as possible of bringing us closer reality.
TRNFLOW takes the difference between the data weather and the data of site into account and uses a law of power to express the wind speed on the building level at the reference height. In TRNFLOW, it is necessary to define a factor of opening equal to 0 for a door or a closed window and to 1 for a door or a completely open window. It thus proves useful to differentiate the strategies from natural ventilation by the opening of the windows in winter and summer. The interior doors are supposed to be half open with during all the period of simulation. A strategy of opening is defined for each period for the windows giving on the outside: 10 min per day during the cold season.

Existing building diagnostic

Thermal air flow modelling of the not renovated building gives results of requirements for various weathers (Lille and Marseilles). Heated area is 120m². Attics, basement and cupboard are not heated.
Heat requirements found simulating this existing building are 320kWh/m².year for Lille and 183kWh/m² year for Marseille.

According to climatic zones, priorities of interventions will not be the same ones. In winter, one will seek to reduce the requirements in heating in the zones located in North of France. In France the announced target value for obtaining the factor four is 80kWh/m² for water heat and heating. The order of magnitude of the calculated requirements corresponds to reality. This factor results in approximately 80kWh/m² at Lille and 50kWh/m² at Marseille.
By which skew is it possible to reach these values?

EXPERIMENTAL DESIGNS CONCEPTS ON THE BUILDING BUILT IN 1966

Experimental designs concepts help to draw up interventions priorities on the building by the analysis of the weights of the various building elements.
It's a mathematical method allowing reducing simulations number for what is strictly necessary to make a decision, saving of considerable time. It is selected in order to draw up a decisional flow chart in term of interventions on the building. For further information on methodology of the experimental designs, the reader will refer to lesson of Fürbringer [8].
An experimental design is carried out for a given reference building, in a fixed configuration. It is clear that for similar buildings (morphology, situation) the results found could be exploited. Nevertheless, the main object of the step is to propose a methodological approach replicable on any building.
Elements building influence is now studied on the following answers: heating requirements in winter.
It is necessary to carry out different experimental designs according to the period considered (hot period or cold period). Thus the analyzed answers are distinguished. In the same way, the studied factors intervals will be indicated according to the desired answer. However, intervals corresponding to the not renovated building will be identical. Cold period is considered in this study.
Seven factors are analyzed corresponding to 5 building elements. Thus, for the window the insulation and the capacity to generate heat are studied.
High factors selected levels summary correspond at low energy label of France [9].

In an experimental design, the *sifting* makes it possible to know the weights of the levels of the factors on the answers. This study type makes it possible to find the few factors active, quantitative or qualitative, among a great number of factors in a limited number of experiments. The factor weight represents the importance of the answer variation due to a change of factor level.
The experiment matrix is indicated and the twelve following experiments (Figure 4) are carried out, Xi are the various factors:

N° Exp	X1	X2	X3	X4	X5	X6	X7
1	1	1	1	-1	1	-1	-1
2	-1	1	1	1	-1	1	-1

Figure 4. Experiment matrix

Next, answers vectors are indicated in the experiment matrix. At the end of this stage Software Nemrod provides several types of exits of which the graphic study which makes it possible to analyze various factors effects on 1966's building.

Experimental designs in cold period

In cold period, the transmission coefficient and solar gains will seek to be increased. For ventilation, the lower limit corresponds to the not renovated house with all its defects of sealing. In the old buildings, one supposes indeed that ventilation is carried out by the defects of sealing. The upper limit represents here a system with recovery of heat. This parameter corresponds at infiltrations. For low level, infiltrations maximum are indicated in Table 3 for all zones and null for high level (completely blocked up building).

Table 3. Definition of ventilation in experimental design concepts

Period	Old building: Level 0		Renovated building: Level 1	
	Lille	Marseille	Lille	Marseille
Cold period	188 kg/h	142 kg/h	0 kg/h	0 kg/h

For walls solar absorptance, accent was related to the choice of the coating in particular on the importance of surfaces colour and texture (Table 4).

Absorptance	Abs. factor	α		Level 0	Level 1

RESULTS

Various factors weights are given for cold period for Lille and Marseille weathers.
In the figures analyzing the effects of the factors on the answers, the latter are indicated as follows:

b1: Thermal transmission of windows
b2: Solar factor of windows
b3: Thermal transmission of walls
b4: Thermal transmission of roof
b5: Thermal transmission of basement floor
b6: Ventilation
b7: Absorptance of walls.

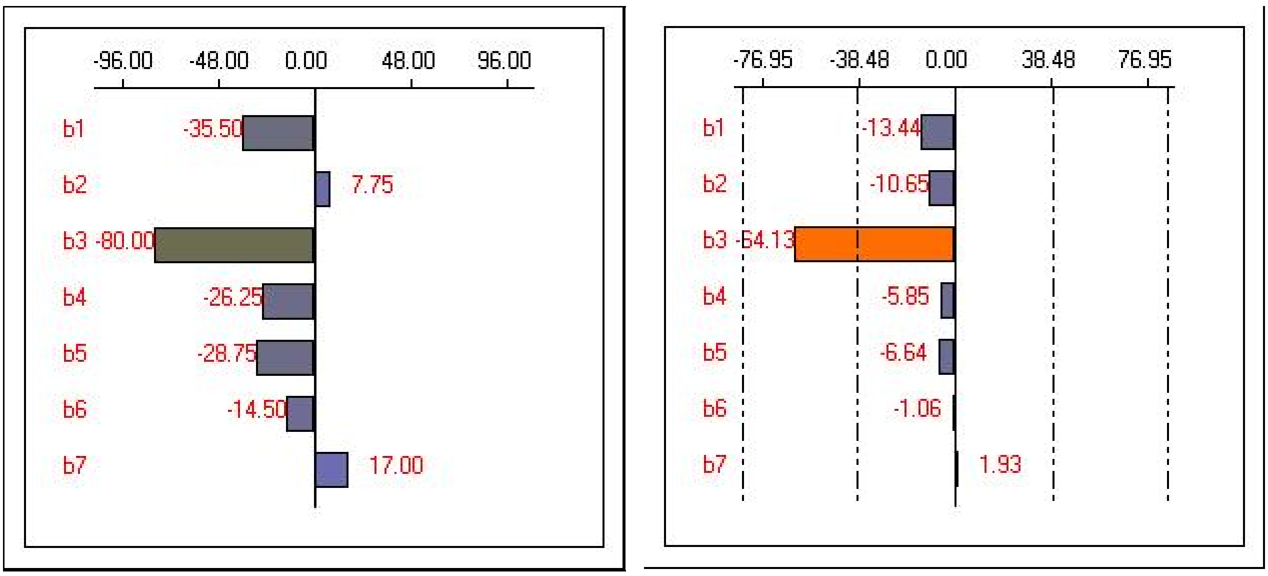

Figure 6. Effects Graphic study of the response "Heating requirements" in Lille (left) and Marseille (right)

DISCUSSIONS

Experimental design result analysis give decisional flow charts in terms of interventions on the building below:

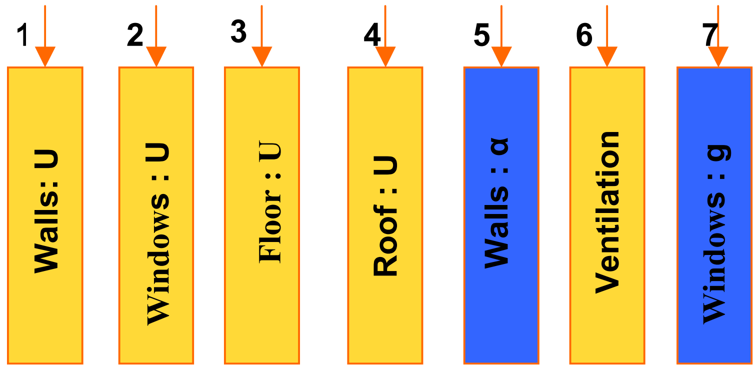

Figure 7. Decisional flow chart in terms of interventions for Lille

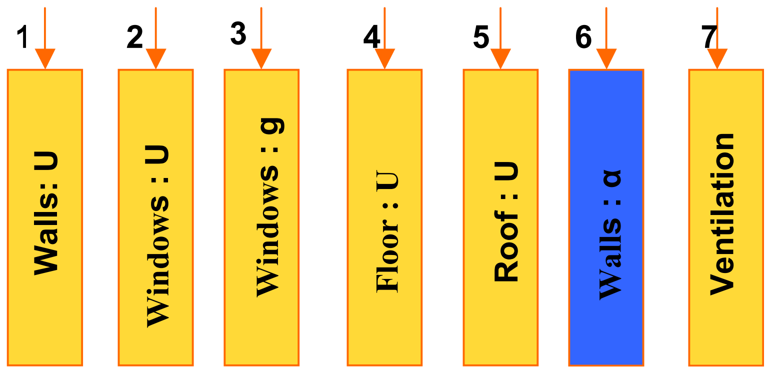

Figure 8. Decisional flow chart in terms of interventions for Marseille

Decisional flow charts, in terms of interventions in the building, are different according to the geographical localization.
For Lille and Marseille, the main priority is the improvement of wall insulation followed by thermal transmission of windows (U).
For Marseille, the other factors have a negligible influence.
In both cases, the wall absorption operates negatively on requirements. This result is not surprising since when this coefficient decreases (vertical surfaces are brighter when walls are painted), solar radiation is absorbed less. The high limit corresponds rather to an improvement of comfort during summer.
Ventilation improvement has more impact in Lille (cold city) than Marseille (Mediterranean city).

In the two cities, the floor insulation decreases the heat requirements with a higher impact in Lille where the ground temperature is lower (approximately 10°C against 15°C in Marseille).
A similar influence appears for the roof. Note that this element is often cited as a main intervention priority on the building. In our study, the reference building has 5 cm of roof insulation, which explains its position in the decisional flow chart.
The solar factor has a negligible influence in Lille, while in Marseilles it is the third parameter after the wall and window insulation.
The singularity of the method lies in the fact that, by defining an existing building through a mathematical methodology, it is possible to determine the intervention priorities which are not always those recommended in literature [10]. Each old building is a unique case due to the

building materials used for its construction and its geographical location and thus must be regarded as such.
At this stage, it would be interesting to reflect on what the influence of these factors in terms of summer comfort improvement would be?

Thermal Effect of 'Changing Clothes Function' of Building with Changeable Thermal Property of Wall Surfaces

Yukio Ishikawa

Mie University, Mie, Japan

Corresponding email: ishikawa@arch.mie-u.ac.jp

SUMMARY

To realize a desirable building environment by saving energy and low global emission, the author has been investigating passive systems in buildings where the environment is controlled biomimetically and autonomously by simulating the physiological functions of human and other organisms. An environmental harmonized "Biomimetic Building", which simulates the environment physiology mechanism of a human body and human wisdom for environment symbiosis, has been developed. This paper describes the regional variation of thermal effect estimated theoretically of the "Changing Clothes Building (CCB)" whose roof and wall surfaces can, depending on the season, autonomously change their thermal properties, such as absoptivity and emissivity. The simulation results showed the remarkable thermal effectiveness and the desirable changing mode of the thermal properties of the "CCB" for various regions in Japan. The saving energy effects due to the "changing clothes function" in the typical detached house in Japan were 7 to 32% in house sensible heat load and 6 to 24% in house total (sensible and latent) heat load as compared to the "Non Changing Clothes Building (NCCB)". The effect in hot weather regions became remarkably bigger than the one in cold weather regions.

INTRODUCTION

To realize a desirable building environment by saving energy and low global emission, it is important to learn more about physiological function of organisms and human wisdom for environmental symbiosis and control. Our idea of "Biomimetic (creature imitative) Building", where the environment physiology mechanism of the human body and other creatures are compared and applied to the environment symbiosis and control, has been developed. This paper describes the regional variation estimated theoretically, in summer and winter, of the thermal effectiveness of the "Changing Clothes Building" whose roof and wall surfaces autonomously change their thermal properties, such as absorptivity and emissivity.

THE "CHANGING CLOTHES BUILDING"

The "Changing Clothes Building (CCB)" changes autonomously; the thermal properties of the building surface become low solar absorptivity with high emissivity (selective emission surface) in summer and become opposite (selective absorption surface) in winter. According to the building surface temperature, these functions are fulfilled by the following ways. One way is transforming the "thermo sense transformation material" or "bimetal" with different thermal properties on both sides of the fin plates, one side of which is a selective emission surface and the other selective absorption, set to the building. The other way is using the torque of the shape-memory alloy to rotate the fin plates with different thermal properties on both sides or the cylinder with different thermal properties on each half of the circumference set to the building. The walls and roofs are now under development and the thermal effects are examined experimentally.

SIMULATION OF THERMAL EFFECT

The room temperature and heat loads of the "CCB" are theoretically estimated and its thermal effect is studied by comparing the results between the "Changing Clothes Mode (CCM)" and "Non Changing Clothes (usual) Mode (NCCM)" of the "CCB".

Analysis method and algorithm

The method adopted is of calculating multi room temperature, heat load and ventilation rate with the use of simultaneous non linear equations of room heat balance, room air rate balance, wall outer and inner surface heat balance, with room temperature, room pressure, wall outer and inner surface temperatures for each room set as unknown quantities, which is shown in literature [1,2]. As for the heat conduction calculation of the wall, the finite difference method (implicit scheme) is used.

Simulation model

A detached house was taken up as a simulation model. The plan and elevation views are shown in Figure 1, the building material specifications in Figure 2, and the schedules of various items in Figure 3. The areas taken up were Sapporo(43°4′N, 141°21′E) as a cold weather region, Tokyo(35°39′N, 139°41′E) and Osaka(34°41′N, 135°30′E) as mild weather regions, and Naha(26°12′N, 127°41′E) as a hot weather region, and the Standard year of expanded AMeDAS weather data 1981-2000 for each area were used. The "flat plate thermo sense transformation material" or some others set to the wall surface will express the change of surface thermal properties. In the simulation, 8 ideally changing modes were set as shown in Figure 4. Mode A is "Non Changing Clothes", which means thermal properties do not change through the year; solar absorptivity(a) is set at 0.9, emissivity(ε) at 0.9.

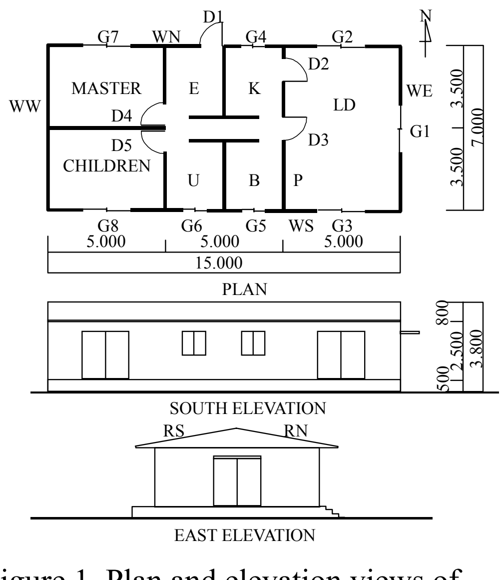

Figure 1. Plan and elevation views of detached house

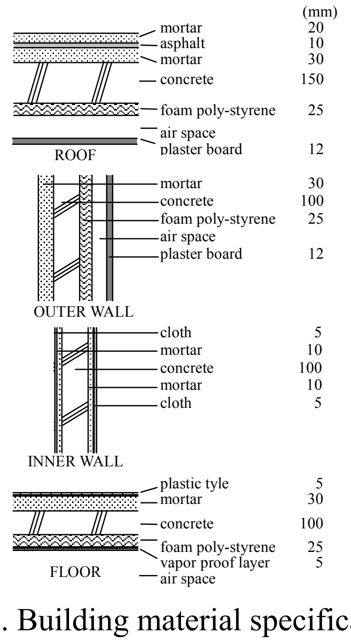

Figure 2. Building material specifications

The modes from B to H are "Changing Clothes", where the thermal characteristics are assumed to vary linearly between set two temperatures high and low. The properties of materials considered, solar absorptivity(a) is set at 0.2-0.9, emissivity(ε) at 0.2-0.9. From mode B to D, the set high and low temperatures become higher gradually. Mode E has a wider range of set temperature. The variation of the surface thermal properties can be fulfilled by rotating the cylinder and by changing a sunward surface ratio of selective emission to selective absorption (Figure 5 a)). The modes from F to H are also "CCM", where the thermal properties are assumed to change at a certain temperature, which can be fulfilled by rotating and turning over the flat plates with different properties between front and back surfaces (Figure 5 b)). From mode F to H, the set temperature becomes gradually higher. Both air-conditioning case (all rooms air-conditioned) shown in Figure 3 and un-air-conditioning case (all rooms un-air-conditioned, i.e. natural room temperature calculation case) were investigated, and in the former case, the room set temperature and humidity were

Figure 5. System examples to fulfill "changing clothes function"

27ºC, 60% in the cooling period, and 20 ºC, 40% in the heating period. In the heat load calculation, the cooling period is set to be July-September in Sapporo, June-September in Tokyo and Osaka, and May-October in Naha, while the heating period November-April in Sapporo, December-March in Tokyo and Osaka, and December-February in Naha.

Simulation results

As one example of the examination results in each area, Figure 6 shows the monthly average natural room temperature in LD room in each mode. Table 1 shows the difference in the average natural room temperature between the “Non Changing Clothes Mode (NCCM)” and each “Changing Clothes Mode (CCM)” where the difference of room temperature is expressed; $\text{temperature}_{NCCM}$ – temperature_{CCM} in the cooling period and temperature_{CCM}– $\text{temperature}_{NCCM}$ in the heating period. In every room for all the regions, the difference in the average natural room temperatures between the “CCM” and “NCCM” is the greatest in mode B (in the cooling period) and mode D (in the heating period), meaning the “Changing Clothes” effect is significant, while mode D is the smallest in the cooling period, and mode B in the heating period. Table 2 shows the saving energy effect of the house total annual heat load (cooling load + |heating load|) in the air-conditioning case in each “CCM”, where the saving energy effect is expressed; (heat load_{NCCM} – heat load_{CCM})/ heat load_{NCCM}. Figure 7 shows the house total monthly and annual heat load in mode A, “Non Changing Clothes” and in the minimum mode of total heat load of the “CCB”, mode G in Sapporo and Tokyo, mode F in Osaka and Naha. Table 2 shows the saving energy effect in the cooling period becomes the most evident in mode B (84.4% in sensible heat load (SH)) and mode F (62.3% in total heat load (TH)) in Sapporo, in B (36.4% in SH) and F (27.7% in TH) in Tokyo, in B (35.8% in SH) and F (30.9% in TH) in Osaka, and in B (31.2% in SH) and F (25.6% in TH) in Naha.

It also shows the saving energy effect in the heating period becomes the most evident in mode D (5.7% in SH) and mode D (5.7% in TH) in Sapporo, in D (14.7% in SH) and D (11.6% in TH) in Tokyo, in D (10.3% in SH) and D (10.3% in TH) in Osaka, and in D (37.7% in SH) and D (37.6% in TH) in Naha. On the contrary, in the cooling period, the effect becomes the least in mode H (in SH) and mode D (in TH) in Sapporo, in D (in both SH and TH) in Tokyo, in D (in both SH and TH) in Osaka, and in D (in both SH and TH) in Naha, while in the heating period, in mode B (in both SH and TH) in Sapporo, in B (in both SH and TH) in Tokyo, in B (in both SH and TH) in Osaka, and in B (in both SH and TH) in Naha. As the result, the most effective mode in saving energy all through the year is mode D (7.2% in SH) and mode G (6.3% in TH) in Sapporo, G (15.8% in SH) and G (13.9% in TH) in Tokyo, G (16.2% in SH) and F (14.0% in TH) in Osaka, and F (31.9% in SH) and F (23.5% in TH) in Naha. On the other hand, the least effective mode all through the year is mode B (in both SH and TH) in Sapporo, B (in both SH and TH) in Tokyo, B (in both SH and TH) in Osaka, and D (in both SH and TH) in Naha.

Consideration

As for the "Changing Clothes Mode", the biggest saving energy effect all through the year was mode D and G in Sapporo, mode G in Tokyo, mode G and F in Osaka, and mode F in Naha. Mode B and F have a great effect in the cooling period; solar absorptivity is small while emissivity is big even from low surface temperature. Mode D is effective in the heating period; solar absorptivity is big while emissivity is small from high surface temperature. The annually effective modes are, on the whole, mode D in the cold weather, mode G in the mild weather and mode F in the hot weather, which means, in cold weather regions in Japan, the most effective mode in the heating period is considered as annually effective, while in hot weather regions, the effective one in the cooling period is.

DISCUSSION

This paper describes the thermal effect of the "changing clothes function" of the "Changing Clothes Building" whose roof and wall surfaces can autonomously change their thermal properties, such as solar absorptivity and emissivity. The regional variation of thermal effect and the desirable changing mode of the thermal properties of the building wall surfaces has been demonstrated, by estimating room temperature and heat load when the thermal properties vary according to various modes changed and by comparing the results obtained from the modes non-changed ("Non Changing Clothes Mode"). The results showed the remarkable thermal effectiveness of the "CCB". The annually effective modes in Japan were, on the whole, mode D in cold regions, mode G in mild regions and mode F in hot regions. The saving energy effect due to the "changing clothes function" in the typical detached house in Japan was 7 to 32% in house sensible heat load and 6 to 24% in house total (sensible and latent) heat load as compared to the "Non Changing Clothes". The effect in hot weather regions became remarkably bigger than the one in cold weather regions.

ACKNOWLEDGEMENT

The author would like to express his sincere thanks to Mr.Hironori Ohashi, research assistant, Graduate School of Engineering, Mie University, for his kind assistance in the execution of the simulation study.

Corresponding email: vishal@iiit.ac.in

SUMMARY

A multiple film based daylight control system for window has been developed to maintain the illuminance level at task plane. The developed system consists of three films with a visual transmittivity (Tvis) range of 0.159 - 0.015 and a 2x55W dimmable compact fluorescent lamp (CFL) fixture. The system works on the principle of feedback control, which records the changes in light intensity with the help of photosensor placed on the ceiling and facing the task plane and accordingly adjusts the film-position as well as the control voltage of dimmable CFL to maintain the task plane illuminance within a tolerance of -10%, +20% of setpoint. Optimized use of solar illuminance saves energy used for the task lighting for the period from 8:00 to 19:00, which was found to be about 70%. The paper describes the design, implementation of the proposed system and the preliminary results for task light illuminance and energy savings achieved in laboratory setup.

INTRODUCTION

Window in a building provides daylight, ventilation and the outside view. A well designed fenestration system usually provides sufficient daylight during the day but it suffers with the problems of glare and heat. Usual glare control strategies deploy blinds or curtains which are not automated and require frequent manual intervention, hence most of the time these systems are kept closed [1]. Moreover, these systems block the outside view and cause lighting energy consumption when they are controlling the excess daylight [2]. Every household and firm spends about 20% of its annual energy budget for lighting purpose [3], [4]. Thus a need arises to develop smart light-controllers [5] for windows which not only maintain a constant light intensity in the room within the comfort levels of the occupants but also decrease glare and maintain outside view for the room. Field studies for such control systems have been done as discussed in [6], [7]. Emerging technologies such as electrochromic windows [8] satisfy the purpose of glare protection and clarity of outside view but they are expensive. The proposed system is not only cost-effective compared to electrochromic windows, but also provides the constant task lighting with the tolerance of -10% to +25% of setpoint with minimized glare.

The controller system was built and installed at the Center for IT in Building Science at International Institute of Information Technology, Hyderabad. The setup consists of a single room with a door, three windows and three twin lamp fluorescent fixtures along with a 2x55W dimmable CFL fixture. The system consists of three films of varying visual transmittivity, joined with each other at ends forming a long sheet and rolled over two rollers. By rolling both the rollers, the system can cover the window with different type of films and thus controlling the amount of daylight entering into the room. If required illumination at task plane is not being satisfied by sun light even after placing the most transparent film then the system can top up the task plane illuminance by operating dimmable CFLs. A graphical user interface has been provided on mobile phone, using which user can set the comfort value of task plane illuminance.

This paper describes the design and implementation of proposed system and the preliminary results of energy saving as well as the clarity of outside view achieved in laboratory setup.

METHODS

Laboratory setup

A room of the dimensions 5m x 10m with ceiling height of 4m was instrumented and configured to test the multiple film based daylight control system. The room consists of three windows W1, W2 and W3; and three fluorescent fixtures T1, T2 and T3 and a 2x55W dimmable CFL fixture with a control voltage range of 0-10V shown in figure 1. The CFL fixture has been placed at a distance 1.3m from ceiling and 1.7m from task table above W2 at a distance of 0.305m from the vertical wall containing W2.

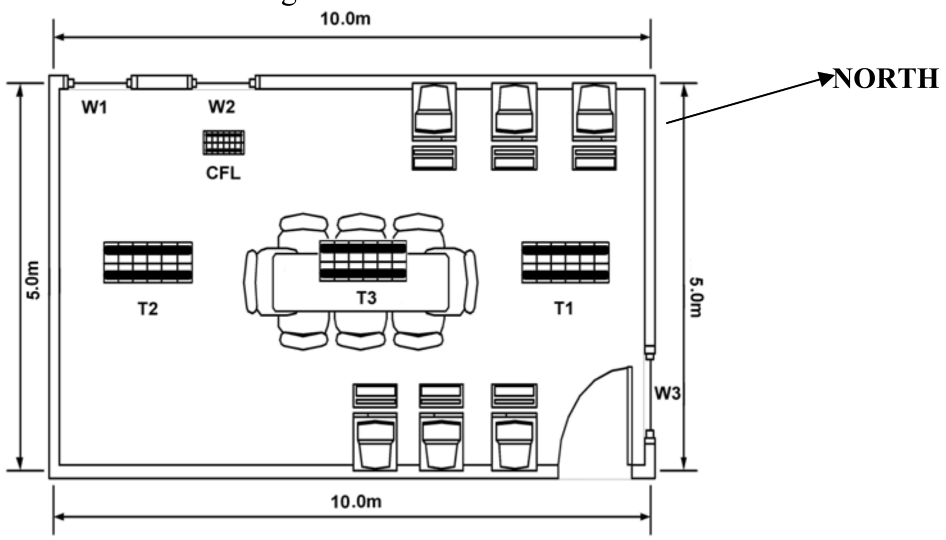

Figure1: Experiment room layout

Hardware setup

A National Instrument's data acquisition card (DAQ) PCI-6229 [9] was used for the setup, which has 32 analog input, 4 analog output channels and 4 digital ports.

The sheet of three films was rolled on two rollers. These rollers were connected to gears whose direction and duration of rotation was controlled by stepper motors. The sheet consisted of three tinted films each of varying transmittivity. The darker film was attached below the lighter one to provide less sun light at level of eyes [10].

A lux meter was placed at the centre of the task table which was used to monitor the actual illuminance on the table. A photosensor was installed in between two dimmable CFLs. The downward-facing, shielded photosensor sends out a proportional signal in response to the illuminance level within its field of view. The sheet used for daylighting control consisted of three different films each of different Tvis. Transmittivity of the three films comprising the controller are 0.159 (Film A), 0.055 (Film B), 0.015(Film C).

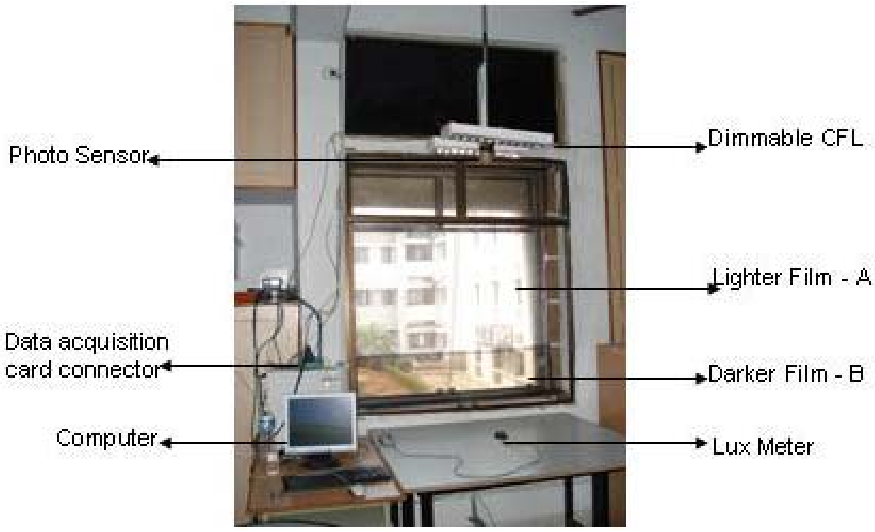

Figure 2: Photograph of installed system

Control Algorithm

System is designed to maintain the total illuminance from the artificial lights and daylight within the setpoint illuminance range and to block direct sun by adjusting the sheet position and control voltage of dimmable CFL.

Four correlations were required to determine the daylight and electric lighting contributions to the task plane illuminance in the space, where the average of illuminance at four points on task plane at a distance of 0.30m, 0.60m, 0.90m, 1.20 from window W2, I_{avg}, was used as the benchmark as suggested in [11]:

1. Correlation between lighting power consumption (W) and I_{avg}, electric lighting only.
2. Correlation between photosensor signals (V) to I_{avg}, electric lighting only.
3. Correlation between photosensor signals (V) to I_{avg}, daylight only.
4. The ratio of measured task plane illuminance to measured illuminance by photosensor as M factor [12] for any given instant in time for all three films.

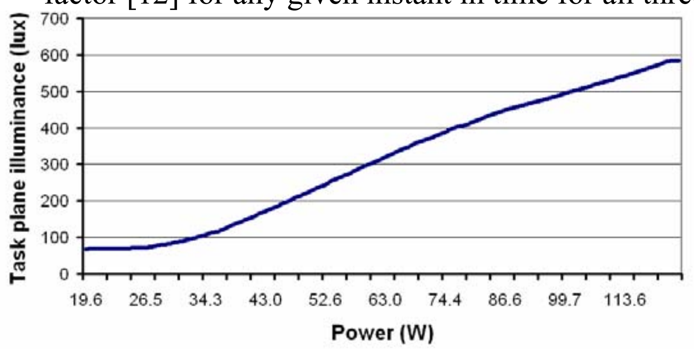

Figure 3: The correlation between electrical power consumption (W) and I_{avg}, electric lighting only. This shows the average task plane illuminance measured at night by varying control voltage of dimmable CFL.

Formula (1) calculated from night calibration is used to calculate the illuminance caused by artificial lighting during the experiment by using the control voltage given to the dimmer

$$y = 0.1711x^4 - 4.2481x^3 + 34.541x^2 - 39.846x + 78.923 \quad R2 = 0.9999,$$
$$y = \text{Task plane illuminance, } x = \text{Control voltage to dimmer of CFL} \tag{1}$$

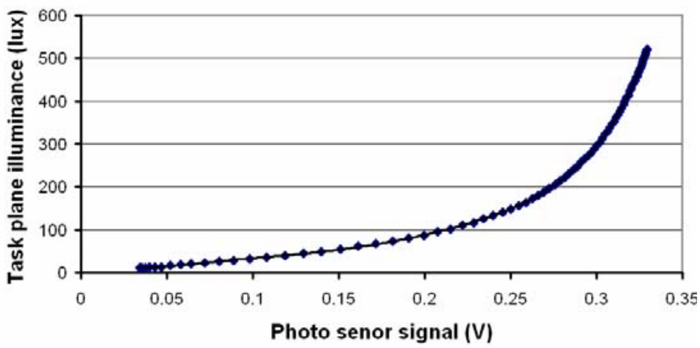

Figure 4: Correlation between photosensor (V) to I_{avg}, electric lighting only, with photosensor on top and lux meter on table.

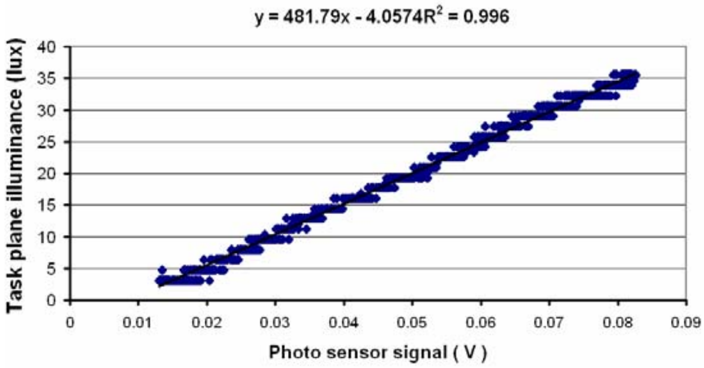

Figure 5: Correlation between photosensor (V) to I_{avg}, electric lighting only, with both the sensors on top. The correlation shown in Fig. 4 has photosensor output in the range from 0V to 0.35V and gives a non-linear relationship with task plane illuminance. But it was observed that during the experiment photosensor output remains in the range of 0V – 0.1V. To get more accurate readings in this range both photosensor and sensor of lux meter were kept on the top, downward facing. This correlation gives the formula (2), which is used to convert photosensor output to Lux within this range.

$$\text{Lux} = 481.79^{*}\text{voltage} - 4.0574 \tag{2}$$

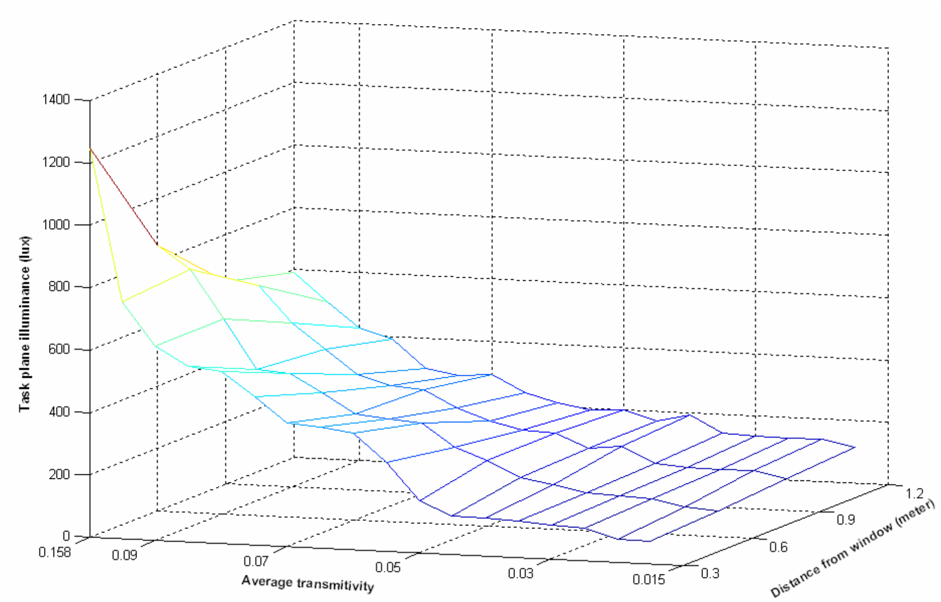

Figure 6: Correlation between photosensor signals (V) to Iavg, daylight only. This shows that the light distribution is uneven as lower film is darker than upper film, hence average light distribution has been considered.

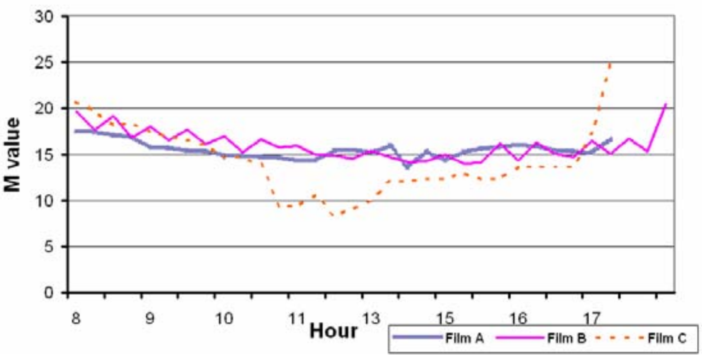

Figure 7: The ratio of measured task plane illuminance to measured illuminance by photosensor considered as M factor for any given time instance for all three films. This shows how M factor changes for different films at different times of the day. During the experiment the task plane illuminance was calculated by multiplying the lux output calculated from formula (2) with this M factor for Film A, which changes every hour.

The algorithm which has been implemented using in Lab VIEW is as follows:

1. Output of photosensor in voltage is converted to Lux using formula (2).
2. Multiply photosensor reading of illuminance by M factor for that time of the day to get task plane illuminance.
3. Calculated task plane illuminance is compare with user setpoint. If it is not in the tolerance range of -10%, +20% of setpoint then appropriate signals are sent to rotate motor and to change the signal voltage of dimmable CFLs.

The main objective of the controller is to attain the setpoint as quickly as possible. The illuminance output of dimmable CFL can be maneuvered quickly and with much ease as compared to the tinted film positioning. Thus by varying the signal voltage by 0.2V, the CFL output is set as the primary light source till the task plane illuminance comes in the tolerance range of setpoint and till this point of time, the film is the secondary light source. The signal voltage is changed with a small value so as to avoid the fluctuations. Once the tolerance range has been attained, the film is made the primary light source by slowly changing dimmer voltage and repositioning the film until end of sheet comes. The end of sheet has been detected by the amount of time for which film is rotating in a direction. If end of sheet is reached on either side of the film and the instantaneous light intensity is not within the tolerance range, then the dimmer voltage is adjusted to provide the light intensity within the range of setpoint.

Graphical user interface on mobile phone

A graphical user interface has been provided on the mobile phone using which user can change the setpoint of task plane illuminance as shown below in Fig. 8. The GUI has been developed for phones supporting Symbian[13] series by using symbian C++. User can eneter the value of setpoint either using key pad or value can be incremented or decremented with help of joystick. After enetring the setpoint when user presses the "Done" key, the value of setpoint gets tranfered to computer via bluetooth.

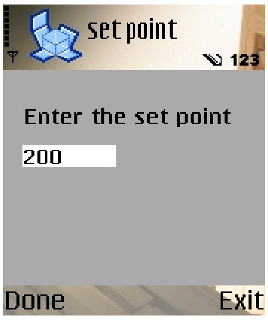

Figure 8: Graphical user interface on Mobile Phone to change the setpoint

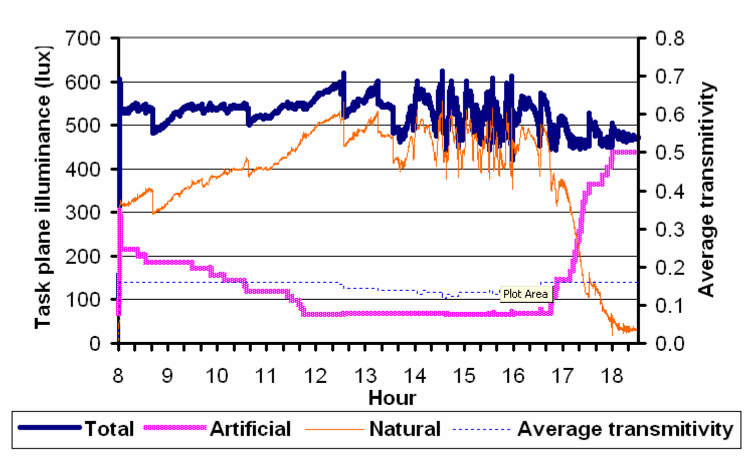
RESULTS

Reference Case

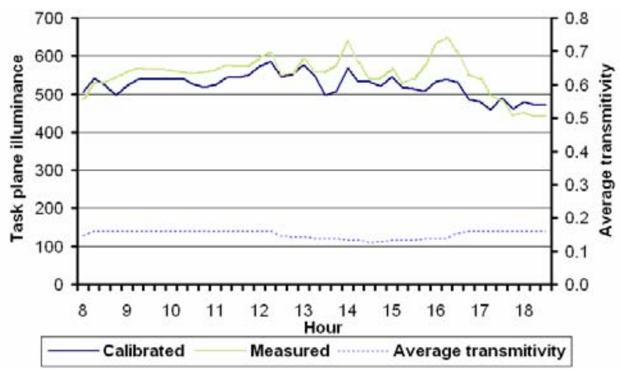
In the Reference case, the control voltage of dimmable CFL was at its maximum to achieve the setpoint of 500 lux, which consumes 124W power. The other three fluorescent tubes were also in their ON state and the W1, W2 and W3 were kept covered with opaque blinds to avoid the glare caused by the daylight and to determine the power consumption by the artificial light sources.

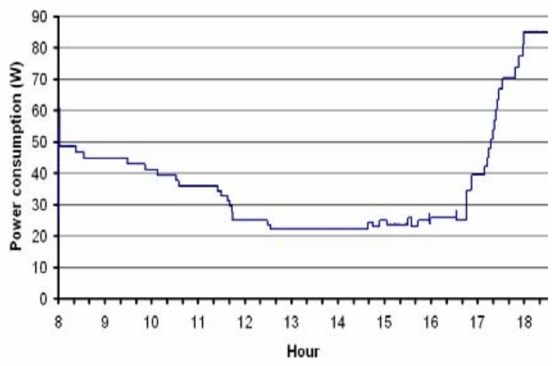
Monitored Data

The objective of the controller was to maintain the light intensity of the room within the tolerance range. The test value of the illuminance was set at 500 lux which maintained task light in the range 450-600 lux. During the test three fluorescent fixtures T1, T2 and T3 were kept ON and windowsW1 and W3 were kept covered with opaque vertical blind. It was found that the controller was able to maintain the task plane illuminance within the designated range for over 99% of the test time.



a)





b) c)

Figure 9: (Plotted with reading at every 10 seconds)

(a) Task plane illuminance for different timings during the experiment on a typical day
(b) Difference between calibrated and measured task plane illuminance
(c) Power consumption during the experiment by dimmable CFL. The average power consumption was 36.7W and reference case power consumption was 124W. Hence about 70% task light saving was achieved.

DISCUSSION

Controller Performance

The controller was tested on three aspects. First, how effectively can it maintain the room intensity within the tolerance range of setpoint, second, how much task lighting energy was saved and finally, the controller was evaluated by the user feedback as to whether it caused any type of discomfort. It was observed that the system was able to maintain task plane illuminance within the tolerance range for over 99% of the test duration irrespective of the local and global solar radiation intensity. Secondly, as explained in Fig. 9(c), about 70% task light saving was achieved with the base case of CFL being lit at the maximum intensity. Finally, user feedback was taken on comfort aspect achieved by the controller. It was found that the initial algorithm maneuvered the dimmer voltage in the large steps and this caused user some amount of discomfort. The algorithm was then refined to employ a ramp function for the dimmer voltage. The second point of discomfort was caused by the noise of the rollers maneuvering the sheet.

This noise was minimized by keeping the sheet and rollers in between the two pans of the double glazed window.

Conclusion

Multiple film based automated day lighting control system is a cost-effective solution for smart fenestration systems which not only provides dynamic sunlight control with glare reduction but also saves energy. As the sheet is in between the two pans of the double glazed window by using reflective films, the amount of heat entering the room can be reduced. The corresponding tests have to be performed to give the savings of air-conditioning in the room. The technology has potential to be used commercially. Pilot studies will help refine the technology.

AKNOLEDMENT

We wish to acknowledge research students in the Center for IT in Building Science, Murari Hari Babu and K. Niranjan Reddy for their assistance during the hardware setup and preparing figures.

Daylighting and thermal analysis of an obstructed double skin façade in hot arid areas

Neveen Hamza, Abdalla Gomaa, Chris Underwood

Northumbria University, Newcastle Upon Tyne, UK

Corresponding author: n.hamza@northumbria.ac.uk

SUMMARY

In recent years, there has been an increasing number of publications on the thermal and daylight performance of double skin facades in moderate climates. However, there is a scarcity of research on how different configurations of the cavity and its height can lead to an impact on internal cooling/ heating loads and the availability of daylight indoors in hot arid climates. This paper looks at comparing surface temperatures and daylight distribution between a continuous double skin façade over six floors and a corridor double skin façade (dividing the cavity by floor height) in a hot arid climate (Cairo-Egypt). A CFD code is used to predict the behaviour of air flows. RADIANCE software is used to test indoor luminance levels. Results indicate that there are no major differences in terms of surface temperatures between the two configurations, luminance levels are different in distribution but in both cases average luminance levels seem to provide adequate daylight levels indoors.

INTRODUCTION

Glass is a material with a huge innovative potential, offering the possibility of a completely transparent building envelope. Glass facades are seen not only as a symbol of financial prosperity but also as a reflection of organizational transparency. Although glass has not yet achieved its optimum thermal performance compared to traditional heavy insulated opaque technologies, its daylight transmittance and its effect on human well being can not be ignored.
The transfer of façade technologies to the Middle East can be traced back to 1888 [1] observing that in Egypt 'Today people have abandoned old ways in construction in favour of European style because of its more pleasant appearance and reduced building costs'. Since the 1970's it is observed that many major cities in the Middle East have aspired to increasing the glazed areas on facades. In Cairo, Dubai, Bahrain and Jeddah, although in hot arid climates, it is accepted that glazed facades would lead to increased cooling loads and energy consumption. The availability of air conditioning systems coupled with cheap electricity supply, and difficulty of cleaning and maintaining traditional systems of shading (wooden shutters or concrete louvers) drove design away from vernacular forms of providing solar shading.
Within this context it is prudent to look into the possibility of applying double skin façades as an architectural technology in hot arid climates before it is transferred -from European and North American countries to the Middle East, without an in-depth study of its impact on cooling load demand, daylight and human well being.
Reviews of simulation studies on double skin facades in hot arid climates [2],[3] and [4] and in moderate climates [5],[6],[7] [8] claim that the exterior leaf acts as a first line of defence against direct solar radiation passing through the internal leaf into rooms; trapped heat in the

double skin cavity is expected to induce natural buoyancy as a mean to reduce elevated air temperatures away from the inner building skin. This may result in additional reduction of conductive heat gains through the inner façade layers into the occupied space. Kim etal [9] suggested a double skin façade with fixed blinds as a refurbishment option for an existing single skin façade to reduce summer cooling loads and provide a more visually comfortable indoor environment in Seoul Korea. Hamza [10] predicted, that compared to a single skin façade with a 40% window-wall ratio and clear glazing, an 18% reduction in cooling loads maybe achieved if an absorptive tinted glazing is used on the outer leaf of a continuous cavity double skin façade configuration. Further analysis using CFD, validated the effect of buoyancy and the solar shading properties of a continuous double skin façade with a tinted glazing on the outer skins in a hot arid area [11]. This work departs from previous attempts by studying the thermal and daylight performance of a corridor double skin façade configuration where a walkway, inlet and outlets air vents at each floor level are included. In this paper, the term obstructed cavity is also used to express the configuration of a corridor double skin façade whenever reference to the interruption to the air flow, due to the walkways, within the cavity is made.

METHOD

In this work, two software packages are used to test the thermal (CFD) and daylight (RADIANCE) performance of a corridor double skin façade. The three dimensional CFD modelling provides a framework to study the performance of a double skin cavity as a full conjugate problem of the heat transfer. This conjugate problem involves coupling of ray tracing and radiation models in conjunction with the conduction-convection coupling through the domain. The three dimensional CFD modelling is used to study the thermal performance and the behaviour of the buoyancy driven flow in a corridor double skin façade, where the air flow is obstructed at each floor level by a walk way.

The metal walkway consists of longitudinal slots that run the length of the façade with 50% openings. The walkway is used for maintenance and cleaning but is also expected to reflect daylight deeper into the room while allowing air flow by buoyancy between floors. An inlet and outlet is provided at each floor level to augment the airflow in the cavity. Figure 1, explains the configuration of the continuous and obstructed double skin facade used in both software analysis.

The purpose of using a CFD code is to analyze the solar radiation through the intermediate air cavity in which buoyancy-driven flows augment turbulent mixed convection. The temperature of the air in the cavity is influenced by many interlinked factors such as solar radiation, outside temperature, wind speed and direction, type of glazing, and time. A finite volume discretization method of standard k-ε model using body-fitted coordinates and a SIMPLEC-based solution algorithm of the velocity-pressure coupling were used with a segregated solver. The momentum and energy equations were solved by the power-law and second order upwind scheme respectively. The PERSTO scheme was used in pressure interpolation. A ray-traced solar model is coupled with long wave radiation tracing to solve the complete solar and radiation fields as well as the convection and conduction. The contribution presented here is a conjugate heat transfer modelling used to simulate as near to actual conditions to predict the thermal performance of a corridor double skin façade configuration on an East and West orientation. The three dimensional model domains are cast over three computational zones; wind (external) zone with solar radiation entering the outer skin of tinted glass; buoyancy-driven air cavity zone with convection and transmitted solar radiation; and an internal zone with a brick solid wall and clear glazed windows of 40% window to wall ratio.

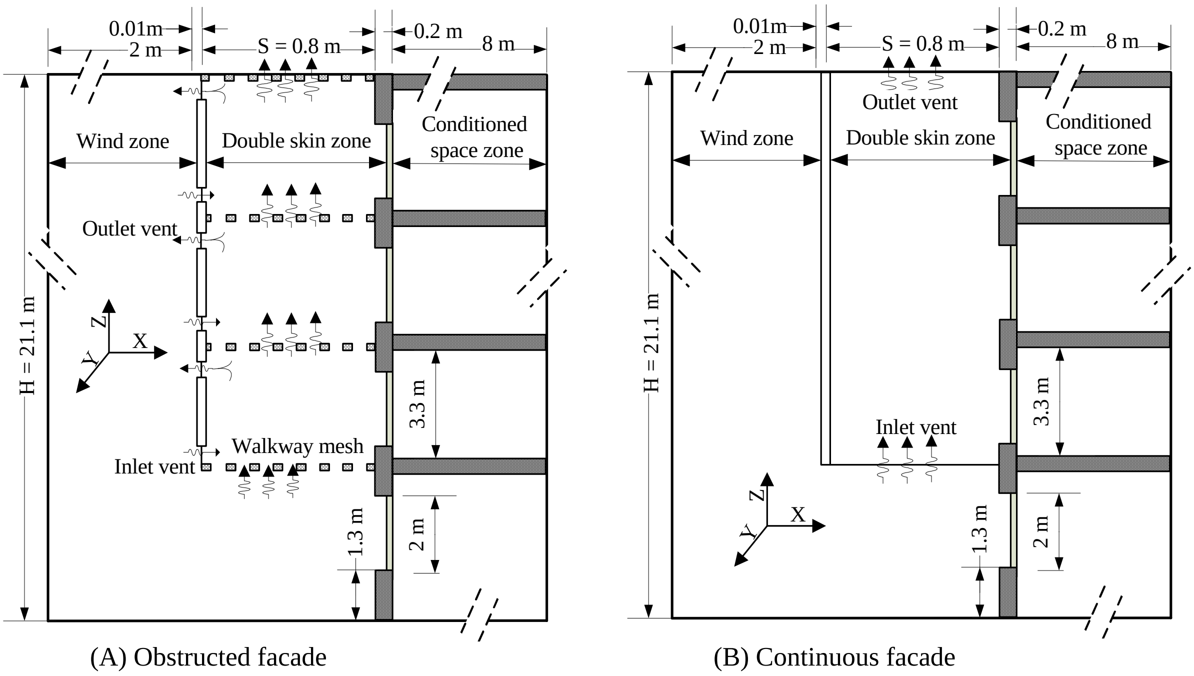

Figure (1) Schematic diagram of the computational domain fields

The heat gain due to direct solar, heat radiation and convection through the inner glass layer over time is presented. The length of the cavity is assumed to be 30m and of height 21.1m. The walkway is 50% solid, the voids are to maintain a vertical air flow between floors (Figure 1-A)

The boundary condition of the outside air temperature, wind speed and solar inputs over the time are adapted according to field data of ASHRAE. After some initial refinements to the mesh strategies to obtain reasonable accuracy, the grid system of 93*68*105 (674,340 grid points) is chosen. The values of the convergence criteria were less than 10^{-5} for all parameters. The governing equations are solved using FLUENT-6.2.16 CFD code. The turbulent flow through the double skin cavity is governed by mass, momentum and heat transfer equations. Steady state natural convection flow in the double skin cavity can be represent by the following equations;

$$\frac{\partial}{\partial x_i}\left(\rho U_i \varphi\right)=\frac{\partial}{\partial x_i}\left(\Gamma_\varphi \frac{\partial \varphi}{\partial x_i}\right)+S_\varphi \qquad (1)$$

Where φ represents the flow variable such as velocity, pressure, temperature and turbulent parameters. Boussinesq approximation model was adapted to obtain faster convergence criteria in solving the free convection governing equation, in which the Boussinesq approximation of $\rho=\rho_1\left(1-\beta\Delta T\right)$ is accurate for such kind of applications.

SOLAR RAY TRACING AND RADITION MODELS

The solar ray tracing model is used to calculate radiation effects from the sun's rays that enter a computational domain. Solar calculator was used to compute solar beam direction and irradiation for a given time, date, and position. These values are used as inputs to the solar ray tracing algorithm in relation to the sun direction vector, direct normal solar irradiation at

earth's surface, diffuse solar irradiation on vertical and horizontal surface and ground reflected (diffuse) solar irradiation on vertical surface.
The direct normal solar irradiation is computed using the ASHRAE Fair Weather Conditions method. At the earth's surface, the direct solar irradiance E_{DN}, is represented by

$$E_{DN} = \frac{A}{e^{\left(B/\sin\theta\right)}} \qquad (2)$$

The values of *A* and *B* vary during the year due to seasonal changes in the dust and water vapour content of the atmosphere [12]. The solar ray tracing algorithm is used to predict the direct energy source that results from incident solar radiation. The resulting heat flux that is computed by the solar ray tracing algorithm is coupled with the calculation via a source term in the energy equation. A two-band spectral model is used for direct solar illumination and accounts for separate material properties in the visible and infrared bands. A single-band hemispherical-averaged spectral model is used for diffuse radiation. Opaque materials are characterized in terms of two-band absorptivities. A transparent material requires specification of absorptivity and transmissivity in the visible and infrared portions of the spectrum. A P1-radiation model (equation 3) is coupled with the solar ray tracing model to deal with emission from surfaces, and the reflecting component of the primary incident load through the computational domain;

$$q_r = \frac{1}{3\left(a+\sigma_s\right)-C\sigma_s}\nabla G \qquad (3)$$

BOUNDAY CONDITIONS

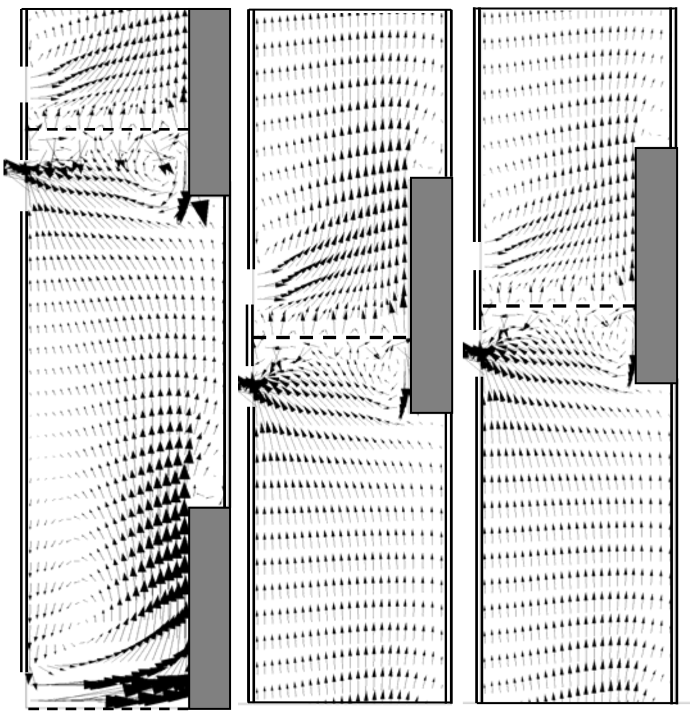
Cairo is located on latitude (30.13^o), longitude (31.4^o), time zone relative to GMT (GMT+2). The double skin façade configuration is studied on the East and West orientation. The ambient temperature and the wind speed are applied according to the local climate field data of ASHRAE [13]. The buoyancy effect was activated and the gravity is set to -9.81m/s^2 with z-direction.

In order to minimize the solar radiation through the double skin cavity, the outer glass skin is absorbing glass (0.01 m thickness) of transmissivity (τ = 0.45) and absorptivity (α = 0.49) at zero incident radiation angle. The inner skin glass (windows covering 40% of the inner facade) is clear glass (0.006 m thickness) of transmissivity (τ = 0.78) and absorptivity (α = 0.15) at zero incident radiation angle. Glazing optical properties are dependent on incident angle, which were varied as the incident angle increases from 0^o to 90^o. The conditioned space is assumed at constant temperature of 22^{o}C.

RESULTS AND DISCUSSION

The flow field of the obstructed double skin cavity is complicated, where in each floor there are two perpendicular inlets (walkway mesh and the side inlet vent) and two perpendicular outlets (walkway mesh and the side outlet vent). A further complication is the expansion and contraction of the flow field due to changes in the cavity's cross section. The double skin façade is built starting from the 1st floor leaving the ground floor as a single skin configuration; this is to reduce the possibility of fine dust rising into the cavity. . The flow field of the obstructed double skin cavity for the 1st, 2nd and 3rd floors on the 21 of June is illustrated in Fig. (2). Air is induced into the cavity from two inlets on the 1st floor (walkway mesh and the side inlet vent), this explains the higher mass flow rate at the bottom of the cavity. The CFD simulations indicate that the air flow through the inlets forces the air into the cavity horizontally till it meets the brick wall then it moves vertically into the cavity. At the zone where the walkway, inlet and outlets are in close proximity in intermediate floor levels (2^{nd} to 6^{th} floors) a turbulent flow is created with a reverse flow nearer to the inside brick wall. CFD simulations predict that the mass flow rate decreases within the cavity height, this is expected due to the presence of the walkway which affects the airflow between floors. The local tracing of the air velocity and temperature through the cavity at different level is illustrated in Fig. (3). At the walkway, the flow velocity is small (0.2 m/s) and then increases to a maximum (0.4 m/s) aided by the inlet flow. As the flow moves vertically on each floor level it expands to the full depth of the cavity in front of the glass decreasing the air velocity at mid floor level height. The flow then contracts as the cavity depth decreases which leads to increases in velocity aided by buoyancy and the outflow vent. However, the variations in air velocity are small. CFD simulations predict that air velocities in the continuous cavity reach a maximum of 0.8 m/sec [2]. It could be concluded that although the air velocity in the cavity is slightly slowed down by the presence of the walkways, this effect has been offset by the introduction of the inlet and outlets at each floor level.

The prediction of the heat fluxes passing through the inner skin (windows) which impact the cooling load of the building for both the West and East orientation are illustrated in Figures (4 -5). These heat fluxes are the transmitted part of the sun ray passing indoors (direct solar). The longwave radiation exchange between the inner surface of the inner skin and the interior of the conditioned space is generated due to the temperature difference (ranged from 8 ^oC at 6 am to 20 ^oC at 4 pm). The convective heat transfer is generated between the conditioned air and the inner surface of the inner skin.



(A) 1^{st} floor **(B) 3^{th} floor** **(C) 4^{th} floor**

Figure (2) Flow vector through the double skin cavity

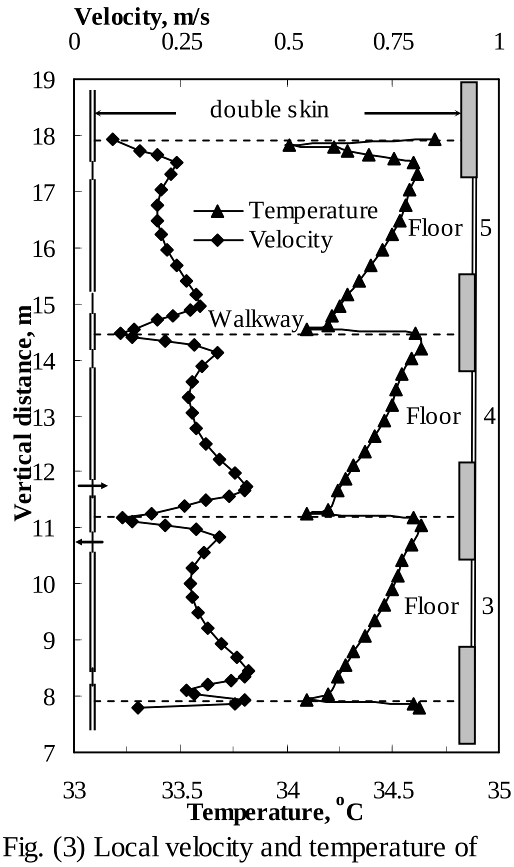


Fig. (3) Local velocity and temperature of floors No. 3, 4, 5 at mid of x and y axes

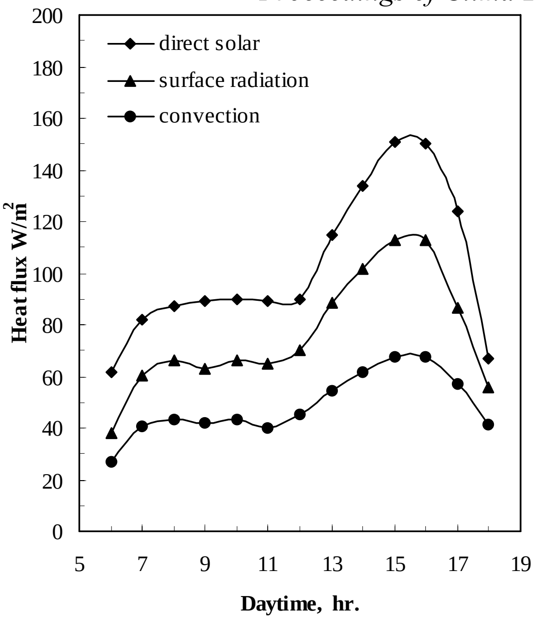

Figure (4) Radiation, convection and direct solar heat fluxes passing through the inner skin that impact the cooling load of the west building

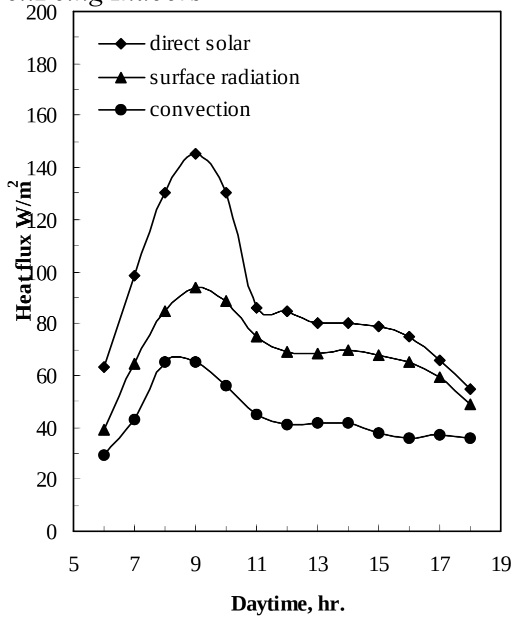

Figure (5) Radiation, convection and direct solar heat fluxes passing through the inner skin that impact the cooling load of the east building

Results indicates that compared with surface radiation and convection through the inner façade, direct solar radiation dominates the heat gain. For example, at 4 pm on the West building orientation, the direct solar heat flux = 150 W/m^2 while surface radiation heat flux = 113 W/m^2 and the convection heat flux = 68 W/m$^{2.}$ Direct solar heat flux is 25 % and 62 % higher than the radiation and convection heat fluxes indoors respectively.

Daylight simulations on the East and West orientations are simulated using RADIANCE software Figure (6). The view point is taken at the corner of the room as one of the poor locations in terms of daylight. It is observed that the luminance levels on the back wall tend to be similar in the case of the obstructed cavity and the continuous cavity. This is due to the deep room configuration of the room where only reflections from the other room surfaces would illuminate this surface. Luminance levels are tested on both orientations at direct and diffuse solar radiation incidence. Luminance levels and the distribution of daylight indicate minor value differences for both orientations and therefore the Lux grid is only presented for the West orientation.

During direct solar radiation hours for both façade configurations luminance levels beside the window area exceed 10,000 Lux which will require the use of blinds to control excessive glare on the work surfaces. Reflectance from the walkway leads to stripes of sharp contrast between light and shade in the area nearer to the window. On the floor level the walkways decrease the luminance levels than the continuous cavity leading to a darker indoor environment with an average of 150 Lux on the working planes during diffuse hours. This may lead to offsetting any benefits from the walkways decreasing surface temperatures within the cavity, as it necessitates the use of artificial lighting to provide the required maintained luminance levels. However, the walkways reflect higher daylight onto the ceilings than those in the case of the continuous cavity, this may give a better psychological effect. It is understood that changing the depth of the room and the position of the walkways and their material may lead to different results; therefore this is an area for future research.

Figure 6: A comparison of illuminance levels on East and West orientation between a continuous and obstructed double skin façade configuration

Figure (7) compares the variations of temperatures between a continuous and an obstructed façade at mid of X-Z and X-Y planes at 2p.m on the East orientation on the fourth floor, the graph indicates that the air temperature of the continuous cavity is about 1.5 ^{o}C higher than that of the obstructed cavity. Compared to the continuous cavity, the obstructed double skin façade experiences a turbulent flow at outlet and inlet levels. The ambient air which induced through inlet vents leads to a minor reduction of temperatures in the cavity and on the surface temperatures of the brick. The absence of this cooling effect in the continuous double skin configuration leads to increasing the surface temperature of the glass facing the cavity by about 1.5^{o}C. Figure (8), explains the higher surface radiation and convection heat gain of the continuous type generated from the inner surface of the inner skin, compared to the obstructed configuration.

In the case of the obstructed double skin cavity, the effective factor affecting the flow rate is the wind pressure and its direction aided by the buoyancy effect due to temperatures in the cavity being higher than ambient. In the case of the continuous double skin, the mass flow rate is higher due to trapped heat over the height of the cavity assisting the buoyancy effect as higher temperature differences between the cavity and ambient temperatures.

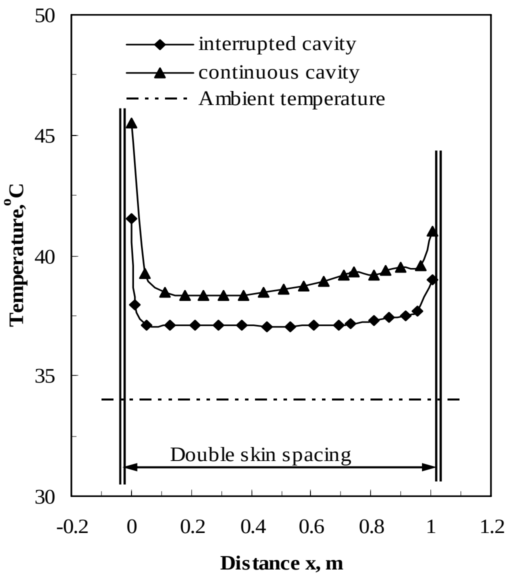

Figure (7) Temperature variation through double skin width of the continuous and obstructed cavity

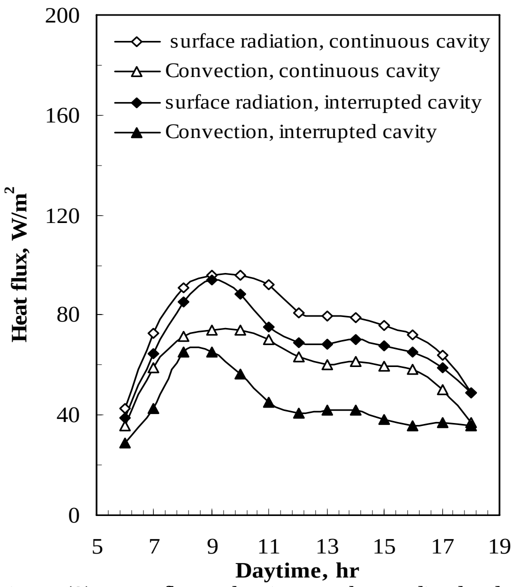

Figure (8) Heat fluxes that impact the cooling load through the inner skin of the continuous and obstructed double skin cavity

CONCLUSIONS:

In this work a comparison between the thermal and daylight performance of a continuous and an obstructed cavity of a double skin façade configuration is undertaken.

Both double skin façade configurations seem to perform similarly in reducing direct solar radiation indoors. Direct solar radiation in hot arid climates is the main contributor to increasing cooling loads. From a thermal point of view, CFD results indicate a turbulent air flow at the inlet, walkway and outlet zone. This turbulence leads to a minor back flow within the cavity that helps in reducing inner surface temperatures by about 1.5^{0}C, the significance of this reduction on cooling loads needs to be researched in future studies.
From a daylight perspective, during direct solar radiation hours, very high luminance levels in the window area will necessitate the use of blinds indoors. However, during diffuse solar

radiation, at view points away from the main daylight area, it is predicted that the obstructed double skin façade will further decrease the daylight levels on the work plane to an average of 150Lux (compared to a 250 Lux in continuous facades). The reduction in day light levels will lead to switching on of electrical lights to provide the minimum of 300Lux required for office work [15]. Simulation results in both façade configurations predicts more than adequate luminance levels [300 Lux] in the main daylight area (6m depth).Further research is needed to test the impact of using different glazing types on the exterior façade and optimizing daylight performance in the obstructed double skin façade.

Modeling the Heat Gain of a Window With an Interior Shade, How Much Energy Really Gets In?

ABSTRACT

Not long ago the ASHRAE Technical Committee on Load Calculation, TC 4.1, had a "bake off" of sorts between different peak air-conditioning load calculation schemes and programs. One of the outcomes of this exercise was the realization that practitioners and software developers make largely different assumptions about how solar energy absorbed by window glass and by window shades contributes to the room solar heat gain. For unshaded glass windows there is general agreement [ASHRAE Handbook of Fundamentals, 2005]. For a shade however, there were two extremes in the models—one assumes that the shade rejects most of the solar energy that it does not transmit, logical if the shade is highly reflective and the glass highly transmissive, the other assumes that all radiation absorbed by the shade is immediately convected into the room.

Suffice it to say that we are not the first to derive and present the fundamental equations of this heat transfer problem. What we have done is to avoid any simplifying assumptions in formulating the problem while allowing that some physical constants, convection coefficients in particular, are not well known and need to be parameterized. We whet the readers' appetite by revealing that for a glass/shade system where the glass was 22% transmissive and the shade 52% transmissive, the total heat gain to the room from this window assembly was nearly half of the incident radiation. Of course "It all depends!"

INTRODUCTION

Not long ago the ASHRAE Technical Committee on Load Calculation, TC 4.1, had a "bake off" of sorts between different peak air-conditioning load calculation schemes and programs. One of the outcomes of this exercise was the realization that practitioners and software developers make largely different assumptions about how solar energy absorbed by window glass and by window shades contributes to the room solar heat gain. For unshaded glass windows there is general agreement [ASHRAE Handbook of Fundamentals, 2005]. For a shade however, there were two extremes in the models—one assumes that the shade rejects most of the solar energy that it does not transmit, logical if the shade is highly reflective and the glass highly transmissive, the other assumes that all radiation absorbed by the shade is immediately convected into the room.

Suffice it to say that we are not the first to derive and present the fundamental equations of this heat transfer problem (see [McCluney and Mills, 1993, and Duffie and Beckman, 1991]). What we have done is to avoid any simplifying assumptions in formulating the problem while allowing that some physical constants, convection coefficients in particular, are not well known and need to be parameterized. We whet the readers' appetite by revealing that for a glass/shade system where the glass was 22% transmissive and the shade 52% transmissive, the total heat gain to the room from this window assembly was nearly half of the incident radiation. Of course “It all depends!”

OBJECTIVE

The objective of this study was to model the true solar heat gain of glass and shade. Older, rough calculations have assumed that a 50% opaque shade will reduce the solar heat gain through the glazing by something just less than 50%. One of the less well understood parts of these estimates is the energy convected from the glass and shade into the room.

The model developed under this study provides an accurate and complete calculation scheme to support the performance of a shade having various transmissivities and absorptivities. The absorptivities are important for the calculation of solar interaction between the inside surface of the glass and shade and to determine the temperature of the shade facing the occupants in a room. More importantly, inside and outside surface convection coefficients can be varied to establish limits on how they impact solar heat gain.

BACKGROUND

We know that if a porous shade is suspended between the inside surface of the glass and the adjoining room, the solar radiation will be reduced. However a detailed model is required to address several issues. These include: How much energy is reflected between the outer surface of the shade and the inner surface of the glass and what happens to this energy? How much energy is re-radiated back into the room through the shade? How much energy is convected from the glass and shade into the room.

THE MATHMATICAL CALCULATIONS

The model developed permits the parametric evaluation of the window/shading characteristics including: The effect of different transmissivities of the shade. The surface temperature of the glass with the shade in place. The surface temperature of the shade in the cavity. Convection coefficients, both inside and outside.

Note that in the model the effects of the sash and frame have been excluded. However, ASHRAE Standards 90.1 and 90.2 and national Energy Codes require that fenestration ratings be determined in accordance with NFRC (National Fenestration Rating Council) procedures. These procedures (NFRC 200 for solar heat gain coefficient) explicitly rate the entire fenestration product including the frame, sash, and glass. See the NFRC website at www.nfrc.org for further information.

Modeling Incident solar radiation (this section is presented for the sake of completeness)

The solar constant, G_{sc}, is the energy from the sun, per unit time, received on a unit area of surface perpendicular to the direction of propagation of the radiation, at mean earth-sun distance, outside of the atmosphere. Measurements of the constant were made with high altitude aircraft flights, balloons, and spacecraft [Thekaedara et.al. 1971 and 1976]. Later, spacecraft and rocket flight data were reported [see Hickey et.al, Wilson et.al., and Duncan et al.] and led to the adoption of the value of 1367 W/m^2 for the solar constant by the World Radiation Center. We will use this value to calculate the beam, diffuse and reflected radiation on the exterior of a window.

The distance from the earth to the sun varies with time of year. Hence the extraterrestrial radiation, G_{on}, measured on the plane normal to the radiation on the *n*th day of the year is given by:

$$G_{on} = G_{sc}(1 + 0.033\cos\frac{360n}{365}) \qquad \text{Eq.[1]}$$

Clear sky radiation on the earth's surface can be estimated by calculating the atmospheric transmittance for beam radiation, $\tau_{batmos,}$ from a method presented by Hottel [Hottel, 1976].

$$\tau_{batmos} = a_o + a_1 \exp(-k/\cos\theta_z) \qquad \text{Eq[2]}$$

θ_Z = solar zenith angle, a_o=0.3887, a_1=0.5496, k =0.3176, (for mid-latitude winter)
Liu and Jordan, 1960 formulated an empirical relationship for diffuse radiation for clear days:

$$\tau_{datmos} = \frac{Gd}{Go} = 0.271 - 0.294\tau_b \qquad \text{Eq[3]}$$

where G_o=$G_{on}(\cos(\Theta_z))$.

As an example, for a clear day on December 21st in Los Angeles[1], the above formulations yield: τ_{batmoa}=0.6938 –atmospheric transmittance beam radiation, τ_{datmos}=0.0670 –atmospheric transmittance diffuse radiation, G_{on}=1411 W/m^2 –extraterrestrial normal beam radiation, G_{cnb}=979.3 W/m^2 –normal beam radiation at the earth's surface, G_o=761.5 W/m^2 --extraterrestrial beam radiation on a horizontal plane, G_{cd}=94.59 W/m^2 –diffuse radiation at the earth's surface.

Beam and Diffuse Radiation Transmitted and Absorbed

Figure 1 shows a schematic of the glass and porous shade system. The arrows are a symbolic representation of the short wave energy, accounting for radiation, transmitted, reflected, and absorbed. The diagram is for beam radiation but a similar accounting applies to diffuse radiation.

"Abs" denotes the fraction of absorbed short wave energy for the glass or shade on each successive reflection. The portion of the incident beam short wave energy that is ultimately absorbed by the shade, Abs_{bss}, is:

$$Abs_{bss} = \tau_{gb}\alpha_{ss} \sum_{n=0}^{\infty} [\rho_{ss}\rho_{gd}]^n = \frac{\tau_{gb}\alpha_{ss}}{1-\rho_{ss}\rho_{gd}} \qquad \text{Eq[4]}$$

τ_{gb}=short wave transmittance of the glass (a function of incidence angle, θ), α_{ss}=short wave absorptance of the shade, ρ_{gd}=diffuse reflectance of the glass[2]

---

[1] We use this example location and date throughout the paper a representing a hot winter climate when south sun will be at a maximum. Also, accounting for cloudy weather is possible using the model provided but since the paper is motivated by and concerned with peak load calculation we have not considered cloudy days in our example.

[2]Brandemuehl and Beckman have shown that the effective incidence angle for isotropic diffuse radiation is approximately 60 degrees. [Brandemuehl and Beckman, 1980]. integration performed using manufacturer's data shown in the next section produced results that agree to within 1% of the Brandemuehl/Beckman results.

The incident radiation on the inside of the glass is diffuse radiation reflected from the shade. Optical properties for diffuse radiation for the glass can be determined for isotropic radiation by integration over all angles of incidence. This was done using glass properties from a manufacturer and shown in the next section of this report.

Similarly, the short wave beam radiation fraction absorbed by the glass, Abs_{bg}, is:

$$Abs_{bg} = \alpha_{gb} + \tau_{gb}\alpha_{gd}\sum_{n=0}^{\infty}[\rho_{ss}^{n+1}\rho_{gd}^{n}] = \alpha_{gb} + \frac{\tau_{gb}\alpha_{gd}\rho_{ss}}{1-\rho_{ss}\rho_{gd}} \qquad \text{Eq[5]}$$

where variables are as defined before and α_{gb}= beam absorptance of the glass (a function of incidence angle, θ), α_{gd}= diffuse absorptance of glass. Equations 4 and 5 also apply for diffuse radiation Abs_{dss} and Abs_{dg}, but τ_{gb} is replaced with τ_{gd} and α_{gb} is replaced with α_{gd} (see footnote 7).

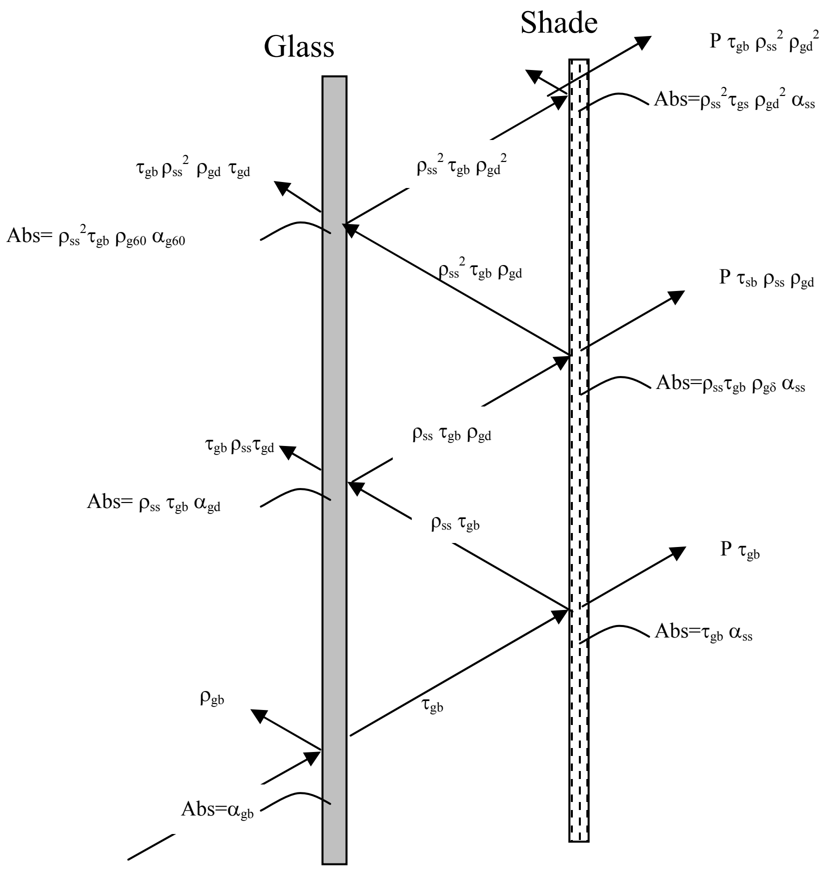

Figure 1. Short wave energy flows.

We can now do a short wave energy balance:

$$\dot{Q}_{gs} = \left[G_{cnb}\cos\theta Abs_{bg} + G_{cd}Abs_{dg}\right]^{3} \qquad \text{Eq[6]}$$

$$\dot{Q}_{ss} = \left[G_{cnb}\cos\theta Abs_{bss} + G_{cd}Abs_{dss}\right] \qquad \text{Eq[7]}$$

[3] We assume a uniform diffuse short wave field. This is accurate except for the lower floors where the diffuse radiation is a mix of diffuse sky radiation and ground reflected radiation. We have ignored ground reflected radiation in this analysis but its inclusion would be straight forward.

P = porosity or open fraction of the shade (this is the transmittance of the shade), $\dot{Q}_{gs}$ and $\dot{Q}_{ss}$ are the short wave radiation absorbed by the glass and shade respectively. Some of the radiation reflected from the shade is reflected again by the glass and then transmitted through the shade to the room. Referring to Figure 3 the quantity is:

$$\dot{Q}_{refin} = G_{cnb}\cos\theta\left[\frac{(P * \tau_{gs})}{(1 - \rho_{ss} * \rho_{sd})} - P * \tau_{gs}\right] + G_{cd}\left[\frac{(P * \tau_{gs})}{(1 - \rho_{ss} * \rho_{sd})} - P * \tau_{gs}\right] \qquad \text{Eq[8]}$$

Glass Properties

Data has been obtained for a heat absorbing glass. This product represents an application where total heat gain might be significantly higher than intuition may suggest because its transmissivity is so low. We will begin our analysis with this product but will move on to others. Figure 2 shows the transmittance, absorptance, and reflectance for the glass as a function of incident angle. In general, these properties can be characterized as functions of the cosine of the incidence angle, Θ. An incidence angle modifier can be defined as the ratio of the property at angle of incidence Θ to the property at normal incidence.[4] For example:

$$K_{transmittance} = \frac{\tau_{\theta}}{\tau_{n}} \qquad \text{Eq[9]}$$

Plots of incidence angle modifiers for transmittance, absorptance, and reflectance versus $\frac{1}{\cos(\theta)} - 1$ are shown in Figure 3. Curve fits are shown for transmittance and reflectance – the fits are generally excellent. The equations for the trend lines can be used to calculate transmittance and reflectance for any angle Θ less than 80 degrees and, since $\tau+\alpha+\rho=1$, the absorptance can be calculated. For a winter design day at noon in Los Angeles, Θ is 22.6 degrees.

[4] The incidence angle modifier (IAM) has its roots in the experimental characterization of solar collectors. The definition used here is a slight modification of the IAM used with solar collectors.

Figure 2. Optical properties of heat absorbing glass.

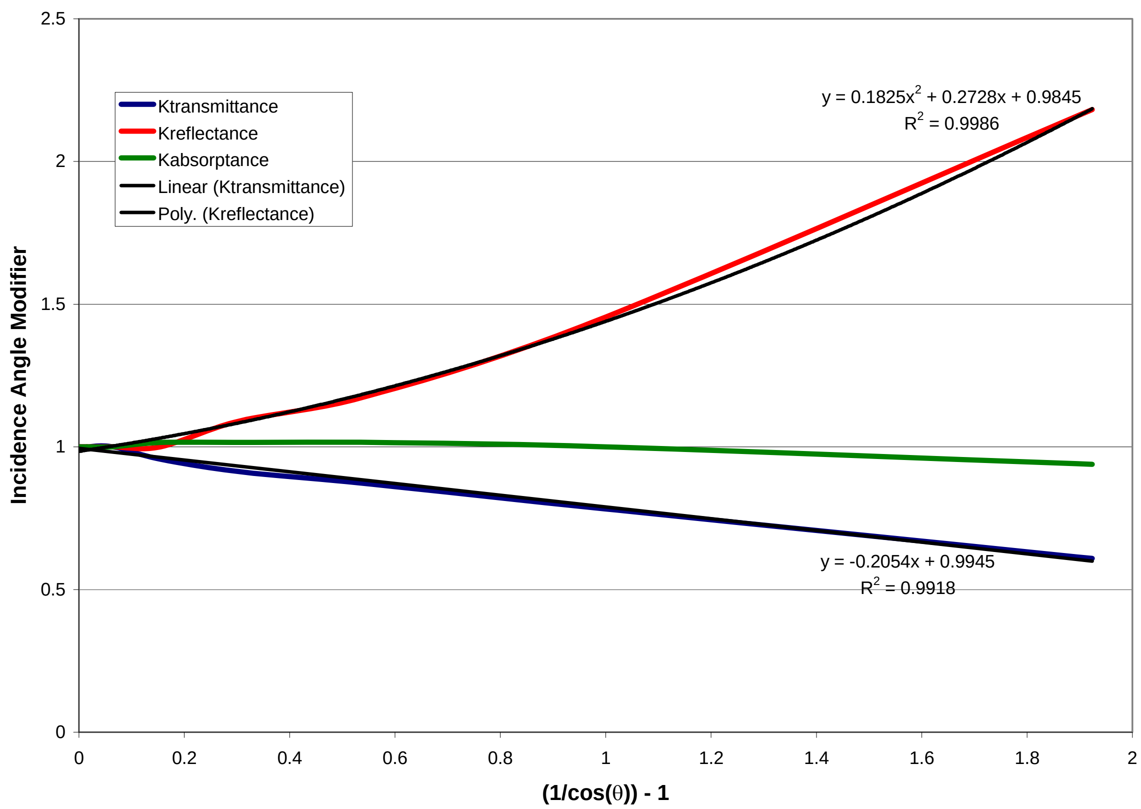

Figure 3. Incidence angle modifiers versus (1/cos(θ)) – 1)

Long Wave Radiation Exchange

The long wave radiation exchange between the glass and the shade can be characterized by treating the problem as one of gray body radiation exchange with essentially the same geometric interpretation as for short wave radiation. The interior is assumed to behave like a cavity and hence a black body. The long wave radiation heat exchange between the glass and shade can then be written as:

$$\dot{Q}_{glsl} = \frac{\varepsilon_{ssl}(1-P)\varepsilon_{gl}\sigma(T_g^4 - T_s^4)}{1-(1-\varepsilon_{gl})(1-P)(1-\varepsilon_{ssl})} \quad W/m^2 \text{ into the mesh} \qquad \text{Eq[10]}$$

where σ =Boltzman constant = 5.670E-08 $W/m^2\text{-}K^4$ and T_g and T_s are the glass and shade temperatures in degrees Kelvin. Note that the conductivity of the glass and shade are sufficiently high that their temperatures can be assumed to be locally uniform. Similarly,

$$\dot{Q}_{slgl} = -\dot{Q}_{glsl} \quad W/m^2 \text{ into the glass} \qquad \text{Eq[11]}$$

The long wave radiation from the interior to the glass is:

$$\dot{Q}_{igl} = \frac{P\sigma(T_i^4 - T_g^4)}{1-(1-\varepsilon_{gl})(1-P)(1-\varepsilon_{sl})} \quad W/m^2 \text{ into the glass} \qquad \text{Eq[12]}$$

The glass also exchanges long wave radiation with the outdoors. Assuming that all the surroundings are at the outdoor temperature, the long wave radiation received by the glass from the outdoor environment is:

$$\dot{Q}_{ogl} = \varepsilon_{gl}\sigma(T_o^4 - T_g^4) \qquad \text{Eq[13]}$$

Similarly, the radiation from the interior to the shade can be written as:

$$\dot{Q}_{isl} = \frac{P(1-\varepsilon_{gl})(1-P)\varepsilon_{sl}\sigma(T_i^4 - T_g^4)}{1-(1-\varepsilon_{gl})(1-P)(1-\varepsilon_{sl})} + (1-P)\varepsilon_{sl}\sigma(T_i^4 - T_s^4) \qquad \text{Eq[14]}$$

Hence the total incoming long wave radiation for the glass is:

$$\dot{Q}_{gl} = \dot{Q}_{ogl} + \dot{Q}_{slgl} + \dot{Q}_{igl} \qquad \text{Eq[15]}$$

and for the shade:

$$\dot{Q}_{sl} = \dot{Q}_{glsl} + \dot{Q}_{isl} \qquad \text{Eq[16]}$$

Convection

Heat is transferred from or to the glass and shade by convection to the interior air and outdoor air. For the glass, heat flow in by convection is:

$$\dot{Q}_{gc} = h_i * (T_i - T_g) + h_o * (T_o - T_g) \qquad \text{Eq[17]}$$

where h_i=interior convective heat transfer coefficient W/m^2-K (5 was used initially)[5], h_o=exterior convective heat transfer coefficient W/m^2-K (15 was used initially). For the shade:

$$\dot{Q}_{sc} = h_i 2(1 - P)(T_i - T_s) \qquad \text{Eq[18]}$$

Total Heat Balance

We now note that the heat flows for long and short wave radiation and for convection have been defined as being into the glass and shade. Since the sum of the energy into the glass and into the shade has to be zero in steady state, some flows will have a negative sign indicating that the heat flow is out of the material. The overall grand total heat balance for the glass is:

$$\dot{Q}_g = \dot{Q}_{gs} + \dot{Q}_{gl} + \dot{Q}_{gc} = 0 \qquad \text{Eq[19]}$$

For the shade:

$$\dot{Q}_s = \dot{Q}_{ss} + \dot{Q}_{sl} + \dot{Q}_{sc} = 0 \qquad \text{Eq[20]}$$

(As a reminder, all flows and heat balances are based on a unit area of the exterior façade, i.e. one square meter of glass adjacent to one square meter of shade)

The total radiant heat flow transmitted and reradiated into the room is:

$$\dot{Q}_{gainrad} = -\dot{Q}_{isl} - \dot{Q}_{igl} + P(G_{cnb}\cos(\theta)\tau_{gs} + G_{cd}\tau_{gd}) + \dot{Q}_{refin} \qquad \text{Eq[21]}$$

The total heat flow into the room caused by radiation and convection from/to the glass and shade is:

$$\dot{Q}_{gaintot} = \dot{Q}_{gainrad} - h_i(T_i - T_g) - \dot{Q}_{sc} \qquad \text{Eq[22]}$$

Engineering Equation Solver

The model, as defined by the above equations, was implemented in Engineering Equation Solver (EES), a tool for solving simultaneous equations, especially those involving solar energy relations and thermodynamic properties [Engineering Equation Solver, 2005].

GENERAL RESULTS

The results are from a simulation of a south facing room on a hot winter day in Los Angeles (outside temperature 35 ^{o}C, 95 ^{o}F). This illustrates how the model can be used. The glass in this example was assumed to be oriented vertically and facing due south. However, any tilt or azimuth angle can be explored using the EES model. Energy flows for the glass/shade ensemble were enumerated for this day and are shown in Figure 4 below.

The figure shows that about 45% of the incident radiation becomes a heat gain to the room. This occurs even though the transmittance of the glass is about 0.22 and the transmittance of the shade is 0.53. The long wave radiation and energy convected into the room from the glass and shade contribute significantly to the heat gain (in addition to what is transmitted directly). Multiple reflections between the shade and glass, sometimes not considered in simple models, also impact heat gain, both directly and as they affect the surface temperatures of the glass and shade.

---

[5] Convection coefficients from the ASHRAE Handbook of Fundamentals were used as starting points but the ASHRAE values are higher than those used because they include equivalent radiant transfer, which is handled explicitly in this model. See ASHRAE Handbook of Fundamentals. Even taking this into account both these coefficients may be high and we will return to this issue later.

This study also evaluated the affects of shade "porosity," the fraction of open area of the shade or its transmissivity. Their impact was evaluated using parametric tables. Figure 5 shows the variation of glass and shade temperature with variation of porosity. For the shade, more energy is absorbed with decreasing porosity but there is a simultaneous increase in energy convected off of the shade due to the increased surface area of the shade material. The glass, on the other hand, receives more reflected radiation from the shade at low porosity causing a very slight increase in glass temperature. However, the glass temperature is most strongly influenced by its high absorptance in the solar spectrum.

Figure 6 shows the total heat gain to the room and the radiant heat gain versus shade porosity. The relationship is very nearly a straight line ranging from about 415 to 520 W/m^2 (130 Btu/hr-ft^2 to 166 Btu/hr-ft^2). At the lower end, heat transfer to the room is dominated by convection from the glass and shade and by long wave radiation transfer. At the upper end, direct solar gain plays a more important role. Long wave radiation from the glass to the room also increases as the glass "sees" more of the room and less of the shade. The glass absorbs a large fraction of the incoming radiation and hence is hot, causing long wave radiation to go into the room and promoting convective transfer from the glass to the room.

Some observations are in order. First it is important to say that the heat absorbing glass used in our model represents a rather extreme case – it really is a solar collector. That said, we note from figure 4 that 45% of the heat gain to the room is convected from the glass and shade. Further more, we used table 22 of chapter 31 of the 2005 ASHRAE Handbook of Fundamentals to find the solar heat gain coefficient and the interior attenuation coefficient and to calculate the fraction of incident radiation that would become heat gain. For a shade transmissivity of 0.2 the result was 0.29. The model described above predicts 0.43.

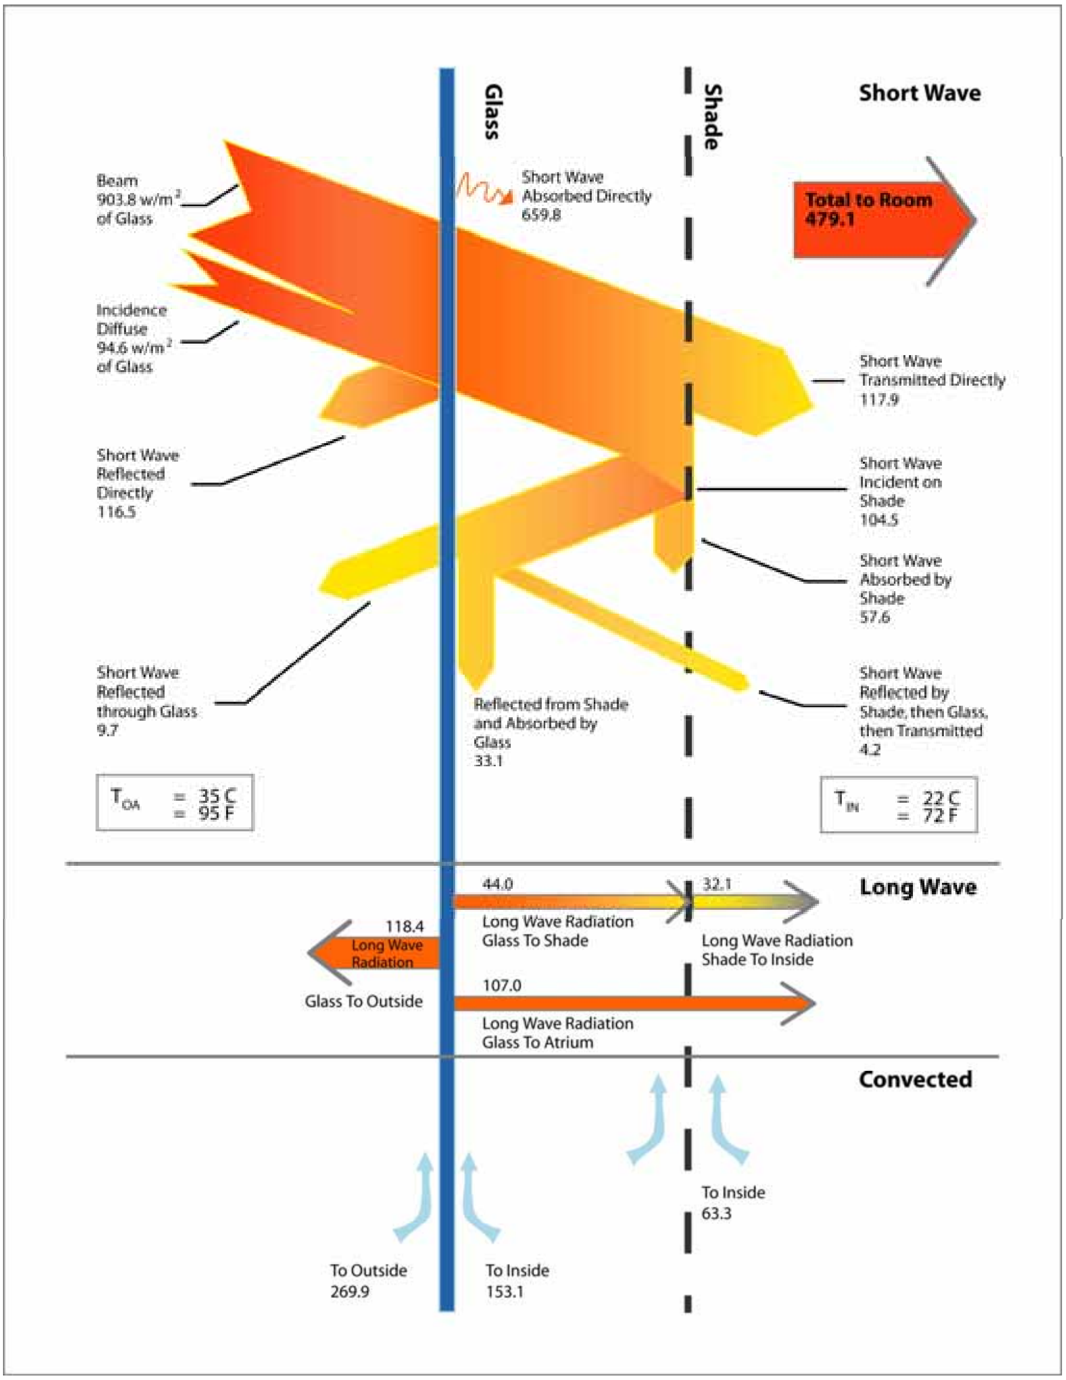

Figure 4. Energy flows occurring in the glass/shade system.

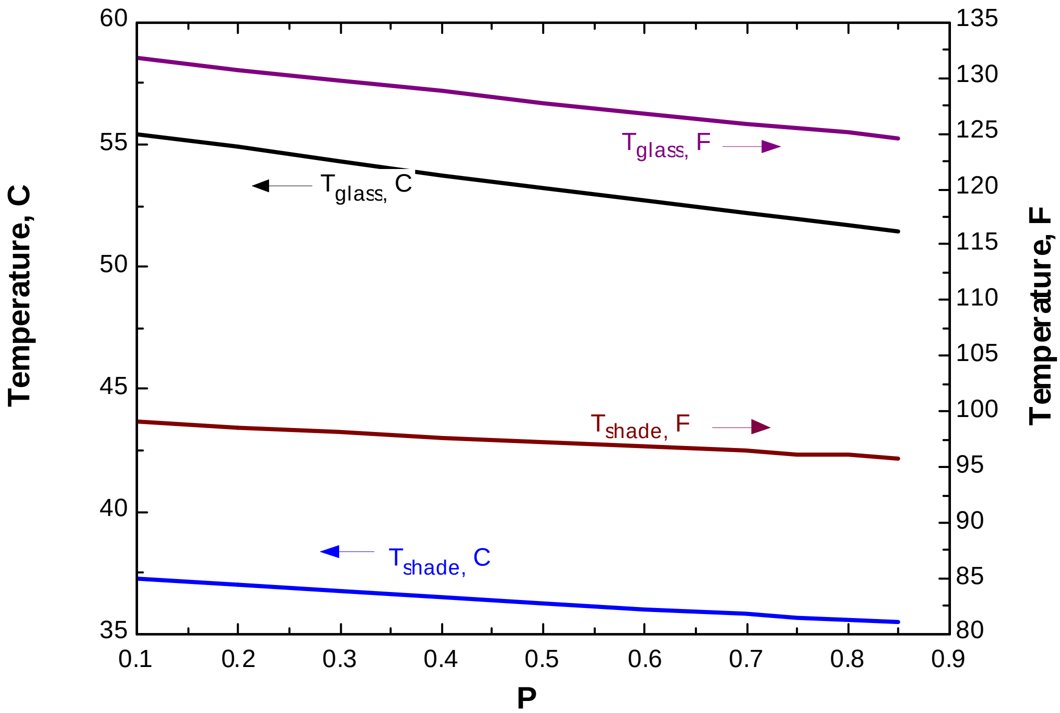

Figure 5. Glass and shade temperature versus shade porosity (transmittance).

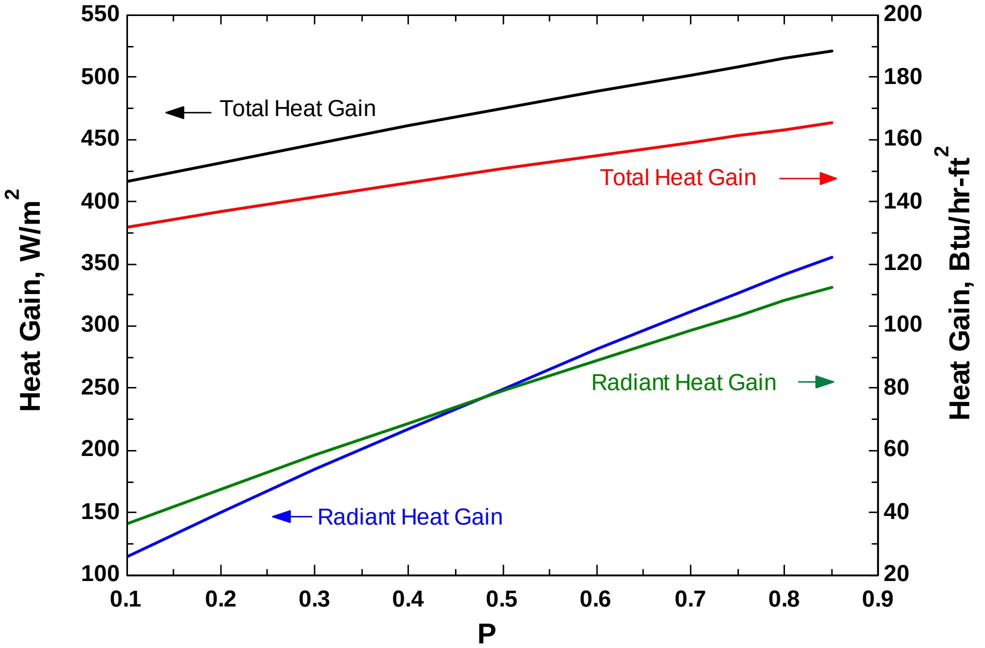

Figure 6. Total heat gain through façade versus shade porosity (transmittance).

Convection coefficients

We next explore the impact of convection coefficients on total solar heat gain. As a reminder, the properties of the glass and shade are:

	Glass	Shade
Transmissivity	0.23	0.53
Reflectivity	0.11	0.22
Absorptivity	0.66	0.25

We deal first with the outside convection coefficient. Yazdanian and Klems [1994] measured the convection coefficient on their test facility for a first floor window and determined that it varied from 2-20 W/m^2-K over 0-10 m/s (0-45 miles per hour). Keeping 5 W/m^2-K for the inside convection coefficient, the variation in heat gain due to variation in outside convection coefficient can be calculated and is shown in figure 7.

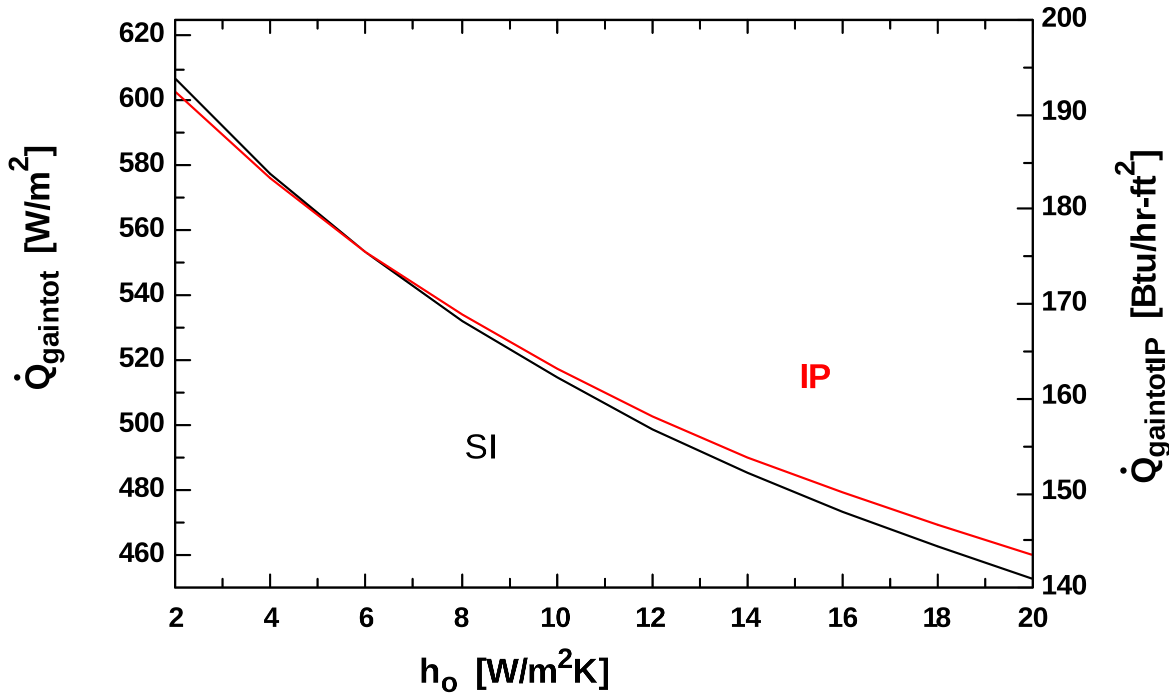

Figure 6. Heat gain versus outside convection coefficient.

How does figure 7 illuminate us. Firstly, we are reminded that the model we have developed is for *total* heat gain through a glass/shade system. In the dark, at night, there would be heat gain from a hot outdoors to a cool room and a low convection coefficient would reduce the heat gain. However, when the glass is hotter than the surroundings, wind (and a high outside convection coefficient) helps reduce the heat gain to the room even when it is hot outdoors and cool indoors.

In this example with heat absorbing glass, the worst case scenario is not when the exterior film coefficient is high (i. e. a high speed wind) but when the air outside the glass is still. Methods that try to separate conduction/convective heat gain due to temperature difference through a window from solar heat gain seemed doomed or at least impractical. Ditto for schemes that try to combine convection and radiation at the inside or outside surface.

Figure 7 shows that heat gain to a room caused by the sun can vary by 50% depending on how much energy absorbed by the glass is swept to the outdoors. How about convection off the inside of the glass and shade? Fisher and Pederson [1995] and Spitler in referenced work show that the inside convection coefficient off interior walls ranges between 2 and 5 W/m^2-K. If, for the sake of consistency, we assume that the outside convection coefficient is 15 W/m^2-K, what happens when we vary the inside coefficient? Figure 8 below shows the result.We varied the inside coefficient from 2 to 10 W/m^2-K because the glass and shade could be hotter than other room surfaces, promoting convection. The variation is 45%.

We now compare heat absorbing glass with 1/8 inch clear glass in the figures below. Figure 9 shows the total heat gain to the room for each glass/shade system. The clear glass is more transmissive and the glass/shade system admits more heat to the room. It is not quite as simple as it may seem however as figure 10 reveals the temperature of the glass and shade for the two glass/shade systems. For the heat absorbing glass/shade system, the glass is hotter than the shade. For the clear glass/shade system the opposite is true, the shade is hotter than the glass. From the point of view of convective heat gain, most comes from the glass in the first case most comes from the shade in the second case.

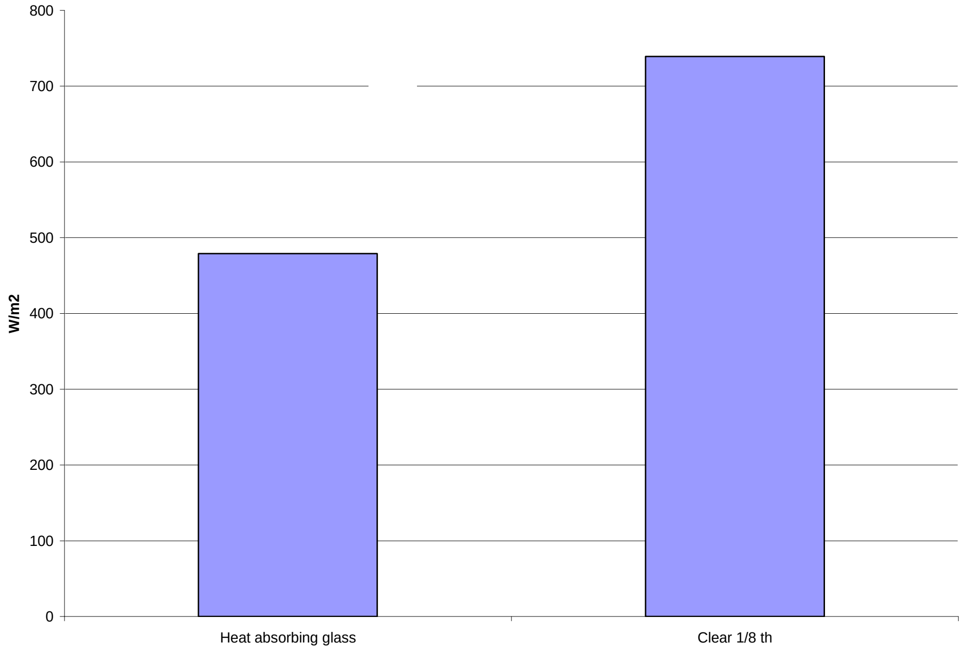

Figure 7. Window heat gain for heat absorbing and clear glass

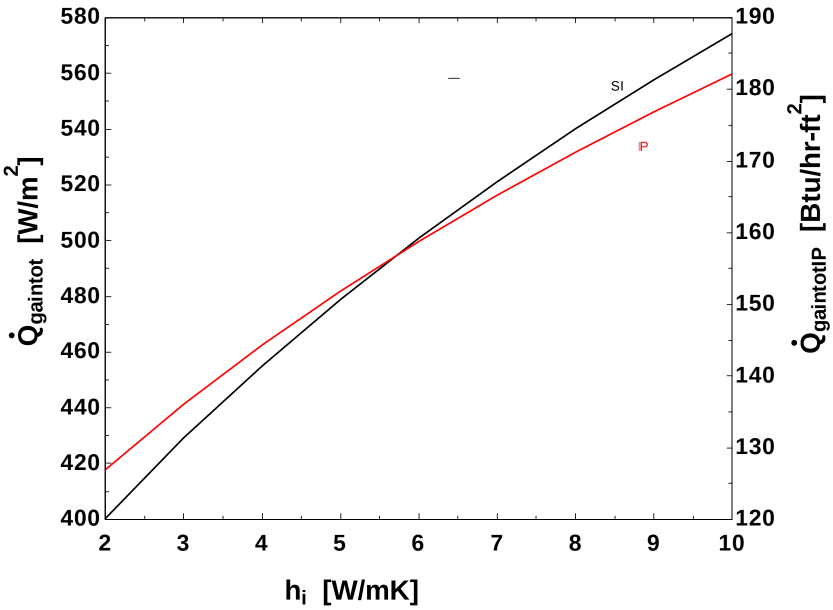

Figure 8. Window heat gain versus inside convection coefficient.

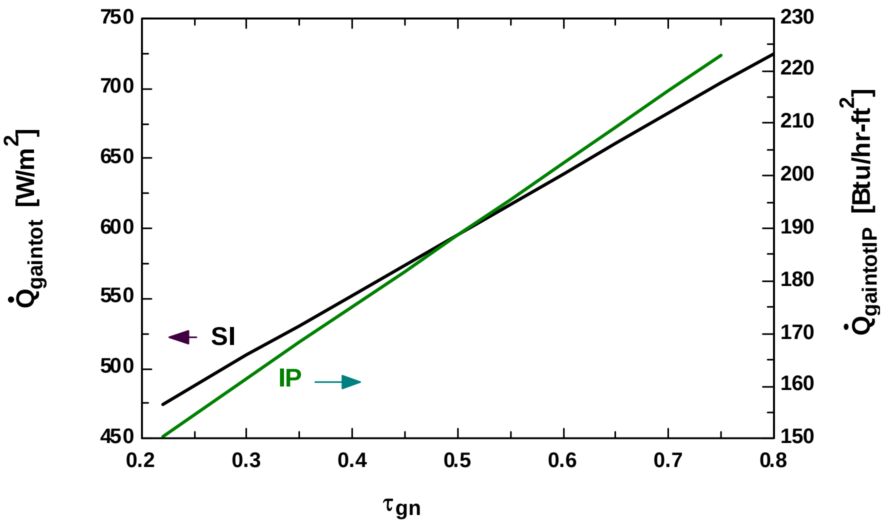

Figure 11. Solar heat gain versus glass transmissivity, reflectivity of 0.11, shade transmissivity of 0.53.

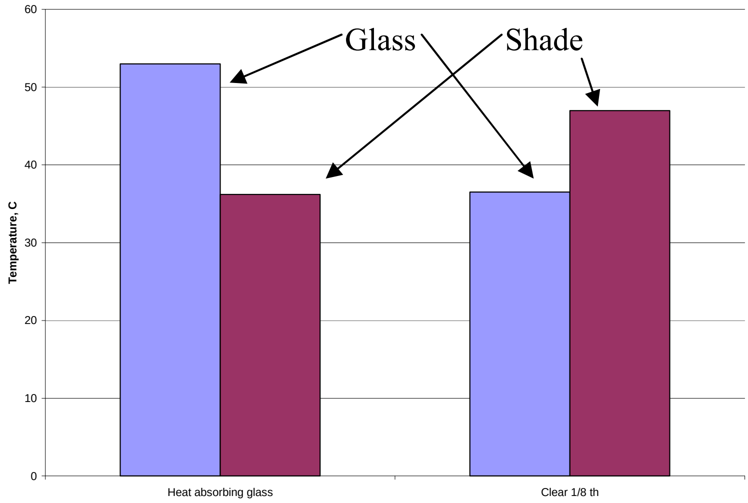

Figure 8. Temperature of glass/shade systems.

Finally, figure 11 shows the impact of the variation of transmissivity of the glass from 0.23 to 0.80, keeping the reflectivity of the glass at 0.11 and the shade tranmissivity at 0.53. The relationship is linear.

CONCLUSIONS

Modeling results lead to the following conclusions:

For the baseline glass/shade system studied here, the temperature of the glass and shade vary with shade transmisivity, the glass varying from 51.4 to 55.5 C (124.6 to 131.8 F) and the shade changing from 34.4 to 37.6 C (95.8-99 F).

Again for the baseline glass/shade system, the heat gain through the south façade varies almost linearly with shade transmisivity, ranging from about 416 W/m^2 (132 Btu/hr-ft^2) to about 521 W/m^2 (165 Btu/hr-ft^2) as the transmissivity varies from 0.1 to 0.85.

The transmissivity of glass and a shading device do not, by them selves, define the solar heat gain into the room. The reflectance of the glass is equally important. Long wave radiant exchange and convection from the glass and shade to the room are significant components of heat gain.

For the hot winter condition studied, the *solar heat gain* is predicted to be 480 W/m^2 (152 $Btu/hr\text{-}ft^2$). The contribution of this heat gain to the *cooling load* should be calculated using the load calculation methods described in the ASHRAE Handbook of Fundamentals, 2001.

FURTHER WORK

ASHRAE is currently sponsoring work to develop more complete models and verify them experimentally.

ABSTRACT

Ventilated façades have become an increasingly employed feature in the design of low energy buildings over recent years in that they offer the attractive features of a conventional glass façade but without the thermal disadvantages. These façades consist of a double skin surface, the outer layer of which is of toughened glass, and the inner layer of which usually comprises conventional double-glazing, behind which is the occupied space.

The cavity formed by the outer and inner layers is ventilated, and frequently contains a blind. This blind, together with the cavity ventilation, provides a means to control the heat transfer across the façade, in terms of solar gain transmission and recovery of heat lost from the interior.

A three-year project, funded by the UK's Engineering and Physical Sciences Research Council (EPSRC), has investigated the thermal and airflow performance of ventilated façades. A series of parametric experiments have been performed using the Large Scale Solar Simulator at Loughborough University. Results from these experiments have been used to validate models of airflow and thermal behaviour developed at De Montfort University. Advice on practical application and industrial practice has been provided by Arup Research and Development and IT Power. The result of the research is an improved understanding of the thermal and air flow behaviour of such ventilated double skin façades.

The effects of external conditions, solar irradiation and exterior air temperature, on double skin façades with differing internal characteristics are presented and analysed in this paper. In particular, the effect of the blind blade angle on cavity temperatures and ventilation air flows will be reported, together with an outline of the guidance that is now emerging to assist designers of such façades.

INTRODUCTION

Detailed measurements of the thermal performance of building elements are essential in the validation of models used for performance prediction. A collaborative project funded by the UK's Engineering & Physical Sciences Research Council (EPSRC) has recently been completed. The focus of this project was a detailed investigation of the performance of double skin façades, which are an increasing feature of many commercial and public buildings. Such façades typically consist of an outer layer of toughened glass, a double glazed inner layer and a ventilated cavity that frequently includes a solar control device, typically a venetian blind [1]. An objective of this research was to measure and provide a comprehensive data set detailing air and surface temperatures, together with air flow rates, so as to provide a practical resource for further research and for use by building designers.

Facilities for providing detailed measurements of such building façade elements under controlled conditions are hard to find. Most testing to date has been conducted outdoors where there is little or no control of the key environmental factors [2, 3]. Further development and characterisation of double skin façades requires good control of the test conditions, not only of the solar radiation striking the façade surface, but also of the thermal environments that affect the façade surfaces both externally ('outdoors') and internally ('indoors'. Such a facility is available at Loughborough, and has been used to provide the experimental results reported here. Key characteristics of the specially designed Large Scale Solar Simulator, are also presented.

Prior to carrying out the detailed tests, wide ranging consultation with the designers and manufacturers of building façades was undertaken. As a result, the more conventional façade element comprising a single storey 'box-window' was selected for investigation [1]. In this respect, a full sized double skin façade incorporating a sun-shading blind was constructed and installed in the solar simulator for investigation of its performance . As the majority of practical installations of the double skin façade utilise natural ventilation, the work has concentrated on this more challenging situation of buoyancy-driven flow in the façade cavity.

This paper describes details of the experimental conditions, together with the characteristics of the test facility and the tested façade element. Test results showing façade temperatures and airflow profiles and how they depend on the climatic conditions and the blind blade angles are presented.

THE LARGE SCALE SOLAR SIMULATOR AND THE DOUBLE SKIN FAÇADE

Large Scale Solar Simulator

Numerous details of the simulator have been reported in Mei et al[4], but are given again here for convenience. The large scale solar simulator installed at Loughborough University essentially provides a source of artificial solar radiation of acceptable spectrum and uniformity for irradiating a test element surface. In addition, the simulator provides for two separately conditioned thermal environments on either side of the test element. In this way, the thermal behaviour of building-integrated test elements, as if bounded by 'outdoor' and 'indoor' environments, can be effectively addressed. The solar radiation is provided by fifteen Sol 1200 lamps manufactured by Honle UV(UK) Ltd. The lamps are capable of producing a natural sunlight spectrum to D65 standard, at an air mass ratio of 1.5, and can deliver an irradiance upon a test surface of up to 1000W/m² with a uniformity to within ±10%. A combination of mesh attachments can be used to reduce the 1000W/m² peak irradiance value in steps of 200W/m² down to a minimum of approximately 200W/m², without spectral alteration.

The solar simulator is designed to test elements up to 2.5m in length and 1.5m in width. It is also possible to ventilate the test element both on its front face (to simulate wind) or through an internal cavity within the element, as required. This can consist of natural or mechanical convection, depending upon the nature of the element being tested.

The environment that adjoins the front irradiated surface of the test element corresponds to the 'outdoor' ambient condition. Air conditioning of the test laboratory space was used to maintain the required outdoor ambient environment within the temperature range 12°C to 30°C. The environment that adjoins the rear of the tested element corresponds to the 'indoor' ambient condition, such as a room or office. A rectangular shaped enclosure attached to the rear of the test element was used to produce the rear environmental conditions. The air and mean radiant temperatures within the rear enclosure are mostly maintained equal in the tests reported here but can be independently controlled if required. Air can also flow through the rear enclosure if required so as to generate known heat transfer conditions.

The solar simulator facility has been designed specifically for testing multifunctional façade elements but can also be used for other, more conventional, components such as solar thermal collectors, curtain walls, roof lights and for PV applications. Fig 1 shows the arrangements of the lamps in the solar simulator.

Fig. 1 Large Scale Solar Simulator, showing lamp array.

THE TEST FAÇADE AND ITS COMPONENTS

The test façade element was custom-built using materials and dimensions that closely resembled a typical single-storey ('box-window') commercial façade design. To facilitate experimental testing and access, both the inner and outer skins of the façade were constructed as door assemblies. The outer skin of the designed double skin façade is a single glass door which is 144cm wide and 206cm high comprising an aluminium frame and 12mm thick toughened clear glass. The glass area is 128cm × 191cm. The outer skin of the façade was designed to be opened and closed for easily installing the measurement devices and for changing the blind positions. Air leakage was minimised by sealing the façade doors with rubber strip seals. Both the air intake and exhaust of the double skin façade are designed as a commercial grille arrangement to permit air flow through the façade cavity. The grilles are of height 24cm and width 145cm. Each grille has three spaces for air ingress and egress, each space being 4.5cm high. In commercial façades, wire meshes are installed horizontally at the bottom and top of the façade cavity to prevent birds getting into the façade. These are included in the customised test section for authenticity of design. The size of the mesh 'hole' is 2.5cm square.

The façade inner skin consists of another door, fitted with double glazing housed within an aluminium frame. The glazing cross section comprises two panes of low-e toughened clear glass each 6mm thick, separated by an air cavity of width 16mm. The dimensions of the inner skin are 138cm × 200cm and the glass area is 122cm × 185cm. Fig 2 shows photographs of the constructed double skin façade where the outer skin can be opened for installing measurement devices.

SUN-SHADING BLINDS

The sun-shading devices commonly used in practice and installed for these experiments are Venetian type blinds, These were purchased from the Krülland Company in Germany. This type of blinds can be motor driven. The blinds tested are made of aluminium and the blade width is 8cm (total blind dimensions 2.1 m high by 1.45 m wide). The colours of blinds selected for testing were white (reflectance = 0.762), and dark brown (reflectance = 0.079). In Fig 3. both colours of blinds can be seen in the cavity of the double skin façade.

MEASUREMENTS

TSI air velocity transducers, based on anemometry, were selected to measure air velocities within the ventilated cavity. The TSI Omni directional Model 8475 offers accurate measurements at low velocities from 0.05 to 0.5m/s and is suitable for unknown or varying flow direction. The accuracy of Model 8475 is ±3.0% of reading over the temperature range 20°C to 26°C, outside this range, and within temperature compensation range, an additional reading error of 0.5% per °C must be added to the measured values.
Cable to the connector

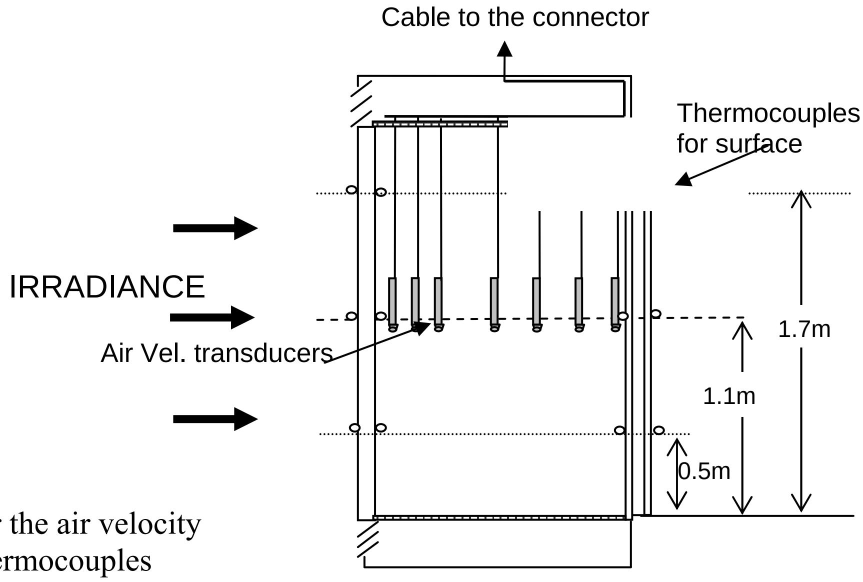

Fig. 4 Positions for the air velocity transducers and thermocouples (side cross-sectional view of cavity)

Seven such air velocity transducers were used for the measurements, and to each velocity transducer a calibrated type-T thermocouple was attached to provide co-located airflow and air temperature data. The transducers were suspended vertically in the cavity with the probes facing the upward air flow. For most of the experiments, the transducers were located at the middle height of the façade cavity (1.1m from the bottom of the façade). The distribution of air velocity transducers and thermocouples can be seen in Fig. 4.

In total, twenty two T-type thermocouples were used to measure the façade surface temperatures and the cavity air temperatures. For measuring the surface temperatures, twelve thermocouples were attached to the glass and covered with thermocouple pads to shade the thermocouples from the direct solar radiation. Pad emissivities matched that of the surrounding surface. For measuring the cavity air temperature, seven thermocouples, were attached to the air velocity transducers; the thermocouples were located about one centimetre distance downstream of the velocity transducer probe head.

A Kipp & Zonen CM3 pyranometer (0-2000W/m² = 0-0.5V) connected to the data logging system was used to measure the radiation on the façade outer skin surface. Table 1 gives the measured irradiance values corresponding to the nominal irradiance values which can be selected by choice of mesh in front of the lamps.

Table 1 Measured irradiance corresponding to nominal irradiance.

Nominal	800W/m²	600W/m²	400W/m²	200W/m²
Measured	715W/m²	540W/m²	360W/m²	187W/m²

In the experiments, the nominal irradiances were varied from 200W/m² to 800W/m² by changing the mesh attachments. However, in all results, the measured irradiance values were used and quoted.

The data acquisition and logging (DAQ) system for the Large Scale Solar Simulator is PC based and employs National Instruments (NI) Labview software, with two internally fitted NI data acquisition boards.

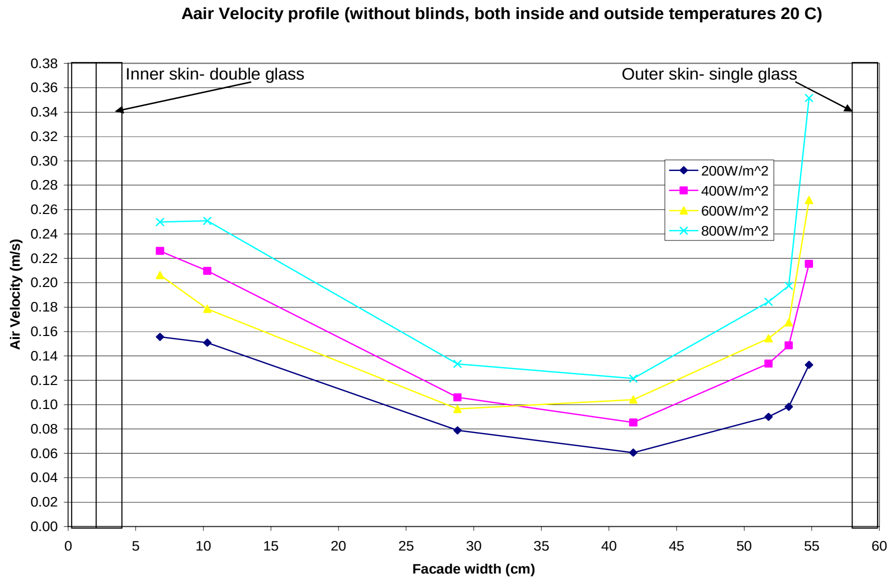
EXPERIMENTAL RESULTS

Test without blinds

Testing of the double skin façade without blinds was performed over a range of controlled climate conditions.

Tests have been carried out under the following measured irradiance values: 187W/m², 360W/m², 540W/m² and 715W/m² For each irradiance, three values for the test room air temperatures (‘outdoor’ air temperature or T_{room}) were set: 12°C, 20°C and 30°C, respectively. A total of twelve environmental conditions were tested for the double skin façade. The plenum air temperature (‘indoor’ air temperature, or T_{box}) was set to 20°C for all the experiments. The cavity width was fixed at 550mm for all experiments. Typical results are shown in Fig. 5 for profiles of the air velocity and façade temperatures (surfaces and cavity air) at four irradiances and at 20°C for both 'indoor' and 'outdoor' conditions. It is evident that the cavity air velocity and façade temperatures increase with increasing values of the irradiance. It is also clear that the air speed is faster nearer the surfaces of the glazing that bound the cavity.

In order to better see the impacts of varying conditions, air velocity and façade temperature were plotted as a function of the irradiance for each data set as shown in Fig. 6. It appears that the increase of the air velocity and the local façade temperatures are more or less directly proportional to the irradiance. For both air velocity and temperature, each set of data gives slightly different gradients.



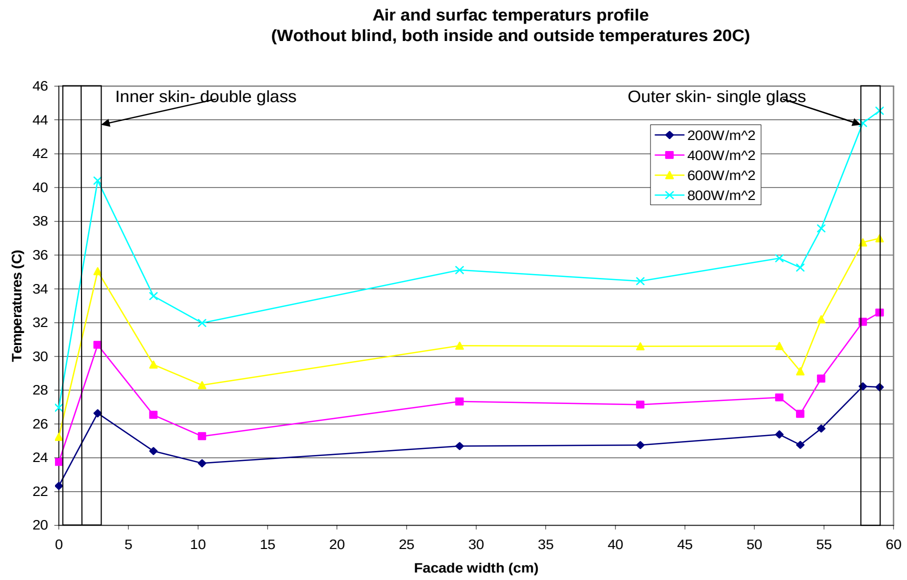


Fig. 5 The profile of the air velocity and the façade temperatures across the façade cavity

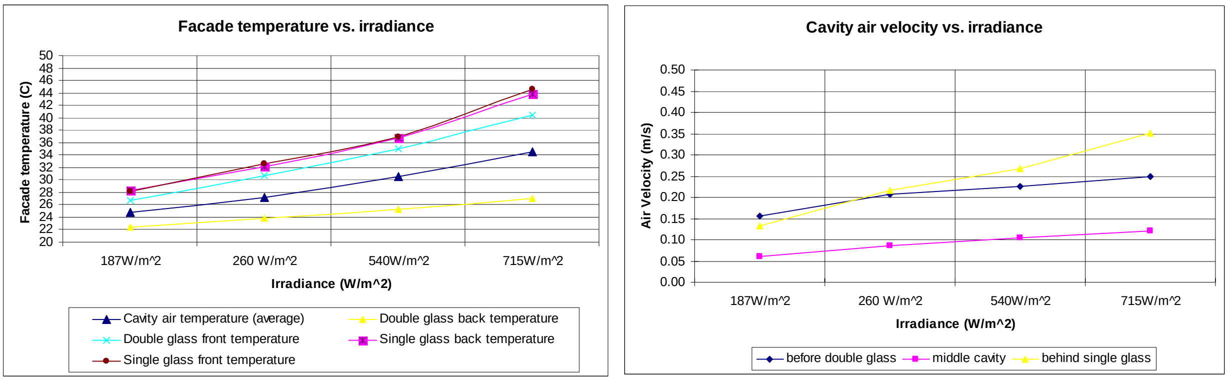

Fig. 6 Façade temperature and cavity air velocity increase vs. solar irradiance; Both 'outdoor' and 'indoor' air temperatures are fixed at 20°C.

In a similar manner, the effect of 'outdoor' temperature on the cavity air velocity and façade temperature is shown in Fig. 7. In this graph, the comparison of the air velocities in the cavity and the temperatures of the façade (surfaces and cavity air) for three different temperatures of the 'outdoor' air at a fixed irradiance of 715W/m² are presented. Façade air velocity and façade temperatures appear to be proportional to the 'outdoor' air temperature.

It is noticed that the double glass back temperature (inner skin back) was dominated by the controlled 'indoor' temperature which was at 20°C. Therefore, for the effects of either irradiance or outdoor air temperature, the double glass back temperature tends to be low with only small gradients evident. From Figs. 6 and 7, it also can be seen that the cavity air velocity was affected strongly by the irradiance rather than the outdoor air temperature.

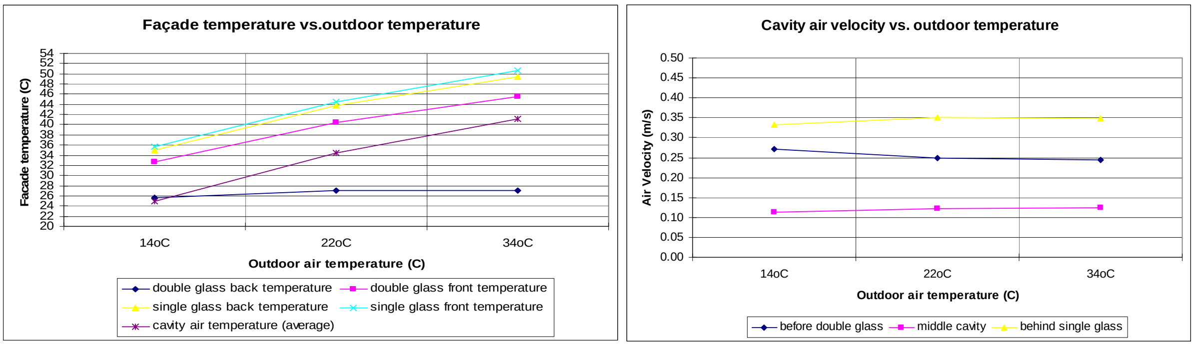

Fig. 7 Façade temperature and cavity air velocity increase vs. outdoor temperature; the irradiance is set at 715W/ m²

TESTS WITH SUN-SHADING DEVICE (BLINDS)

Tests with the blinds within the cavity of the double skin façade were performed to investigate several effects, including the effects of blind blade angle on cavity airflow and thermal behaviour. The angle of the blind blade is an important factor for the heat transfer through the façade cavity, and data on observed behaviour is needed based on parametric testing in controlled conditions. These data are presented in this paper.

The tests for the effects of blind blade angles were carried out at the fixed conditions of 715W/m² irradiance and 20°C temperature for both 'indoor' and 'outdoor' situations. The blind colour is white and the blind was located at one third of the cavity width as measured from the outer skin. The blade angles were set at 0, 30, 45, 60 and 90 degrees, where 0 and 90 degrees relate to the blinds being fully open or fully closed, respectively. In Fig. 8, the measured air velocities of the cavity and the façade temperatures are displayed as profiles across the cavity width for the blind blade angles. In Fig. 9, the cavity air velocities and the façade temperatures are plotted as a function of the blind blade angles. As the blind effectively separates the façade cavity into two vertical chambers, the effect on the cavity air velocity and the façade temperatures will be considered as two parts: in front of the blind and behind the blind. From both Fig. 8 and 9, it can be seen that the temperatures of the façade surface and cavity air in front of the blind increase as blind blade angle increases until the fully closed position is reached (90 degrees), as well as the surface temperature of the blinds themselves. Behind the blind, the temperatures for the surface and the cavity air decrease as blind blade angle increases. It is clear that with the blade at 0 degrees (fully open), more radiation energy transfers to the back chamber and causes the higher temperature in the chamber behind the blind. When the blade is at 90 degrees (fully closed), the blind absorbs more radiation energy and its surface temperature rises. At the same time, the blind reflects more energy to the front chamber and the single glass (outer skin) to increase the temperature of both the air and the surfaces.

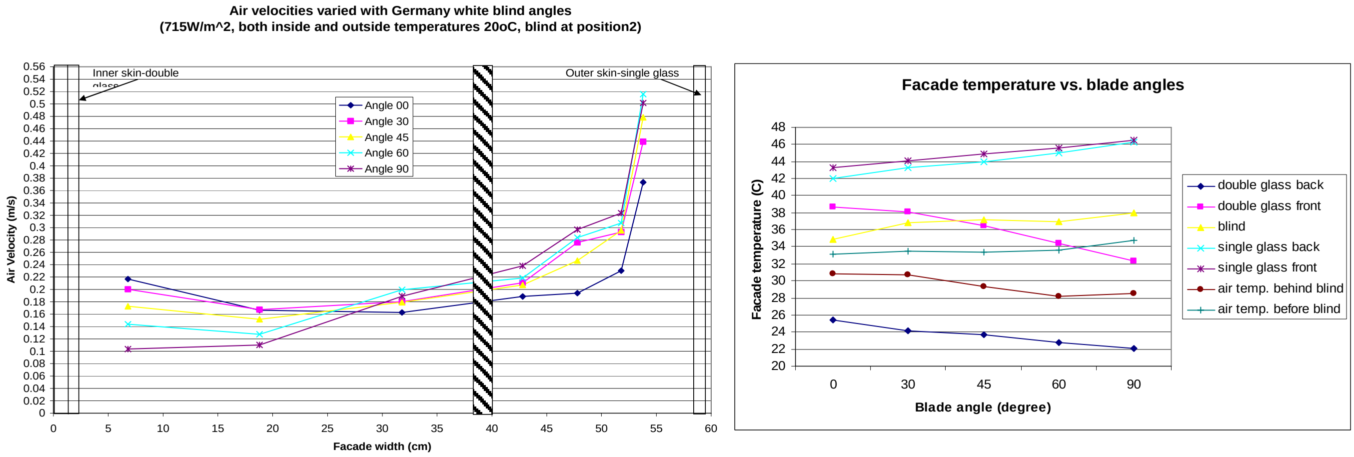

Fig 9. Façade temperatures and cavity air velocity vs. blind blade angles

CONCLUSIONS

An outline description has been presented of a new facility installed at Loughborough University for the testing and development of building ventilated façade elements. A series of parametric experiments have been carried out for testing the performance of these façades under controlled conditions using a large scale solar simulator.

One series of tests involved a section of double skin façade with a common type of solar shading device (venetian blinds) located between the two skins. Test results for the air flow and façade temperatures have been presented. The effects of the irradiance and outdoor air temperature were shown to affect the air velocity and façade temperatures, and thus the façade thermal performance. Furthermore, the effect of the blade angles of the shading device located in the naturally ventilated cavity was presented . The presence of the shading device within the cavity can be considered to separate the cavity into two vertical chambers, in front of and behind the blinds. It is concluded that the blinds have a significant influence on the thermal and airflow performance of the façade. If the sun-shading device is fully closed, the 'front chamber' of the cavity and the shading element itself will have higher temperatures than if it is opened. In contrast, the temperatures behind the sun-shading device will be higher if the sun-shading device is fully opened. Whilst these findings might at first sight appear intuitive and unremarkable, it is important to note that the behaviour has been related parametrically to specific changes in conditions, has revealed trends in performance, and thus constitute a useful data resource, as well as being an important aid to designers. These findings were obtained under well-controlled conditions in an experimental facility that incorporates a representative section of double-skin façade. This facility remains available for further testing across a wide range of parameters (blind colour and position within cavity, cavity width), and these will be reported in due course. It is further concluded that the large scale solar simulator is a valuable facility for testing the solar thermal performance of building components and can provide realistic and meaningful results.

ACKNOWLEDGMENTS

This work is part of a project funded by the UK's EPSRC. The authors express their gratitude for this funding, as well as for advice provided by ARUP Research and Development and IT Power.

SUMMARY

Because we spend most of our time in enclosed spaces, demand in thermal comfort of buildings rose increasingly and then energy consumption correspondingly is increased, aggravating the pollution of natural environment. Integrating phase change materials (PCM) into building walls is a potential method of reducing energy consumption in passively designed buildings. A wallboard new PCM material is experimentally investigated in this paper to enhance the thermal behaviour of light weight building internal partition wall. The experiments are carried out in a full-scale test room MINIBAT (3.10m x 3.10m x 2.50m) which is completely thermally controlled. The external temperature and radiative flux from spotlights dynamically simulate a summer and mid-season repetitive days. The tests concern walls with and without PCM material under the same external conditions. The PCM allows reducing the room air temperature fluctuations, in particular when overheating occurs.

INTRODUCTION

Because we spend most of our time in enclosed spaces, demand in thermal comfort of buildings rose increasingly and then energy consumption correspondingly is increased, aggravating the pollution of natural environment. Integrating phase change materials (PCM) into building walls is a potential method of reducing energy consumption in passively designed buildings. This tendency is confirmed by the numerous papers which a review can be found in [1]. However, there is a strong need for experimental data to evaluate the capacity of PCM to stabilize the internal environment (and thus minimise energy consumption) when there are external temperature changes and solar radiations in case of light weight buildings: that is the purpose of our article.

The use of PCM materials in building envelop is subject to considerable interest in the last decade. Their main interest is that they can store latent heat energy, as well as sensible energy. As the temperature increases, the material change phase from solid to liquid. The chemical reaction being endothermic, the PCM absorbs heat. Similarly, when the temperature decreases, the material change phase from liquid to solid. The reaction being exothermic, the PCM desorbs heat.

The main disadvantage of light weight buildings is their low thermal mass. Obviously, they tend to large temperature fluctuations due to external cooling or heating loads. Using PCM material in such buildings can decrease the temperature fluctuations, particularly in case of solar radiations loads. This have been proved in several numerical studies [2], [3], [4], [5].

A new product has been achieved by the DuPont de Nemours Society: “Energain ™”it is constituted of 60% of PCM, of which the temperature of fusion has been chosen to 22°C. The figure 1 shows the experimental heat capacity measured by differential scanning calorimetry

system. The figure 2 presents the experimental thermal conductivity. This product is like a polymeric membrane, relatively flexible, of 5 mm thickness.
The use of PCM in the building is a relatively old concept that could be ever exploited really because of the inherent difficulties of setting such materials. The novelty in this case is constituted by encapsulation of an important quantity of active matter in a thermoplastic polymer that, after transformation in a relatively thin membrane, permits a practical installation in all type of envelope of the building.
In order to show the efficiency of this PCM made of a 5 mm thickness, we have made a comparative measurement in our experimental cell MINIBAT. Very few experimental data under controlled external conditions exist. These one make it possible to be used as reference for numerical simulations, mainly in the case of solar radiations.

The first part of our article presents the experimental test cell. The experimental set-up simulates a complete day with dynamical effects, and the climatic conditions can be reproduced. The second part presents the results of a summer and a mid-season day and a comparison is made between the case with PCM and the case without PCM. The results show a good improvement in thermal comfort for the case with PCM wallboards.

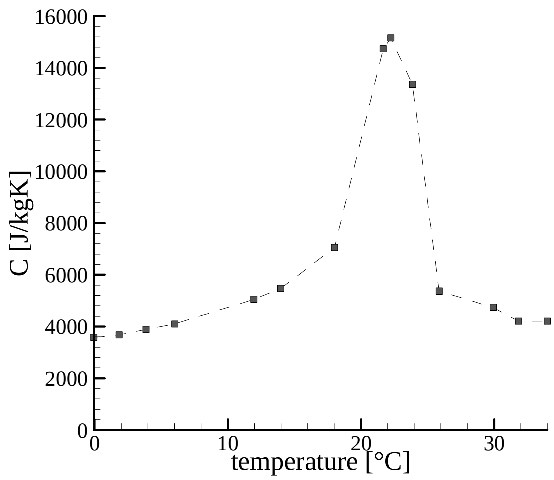

Figure 1: Experimental PCM material heat capacity measured for several temperatures

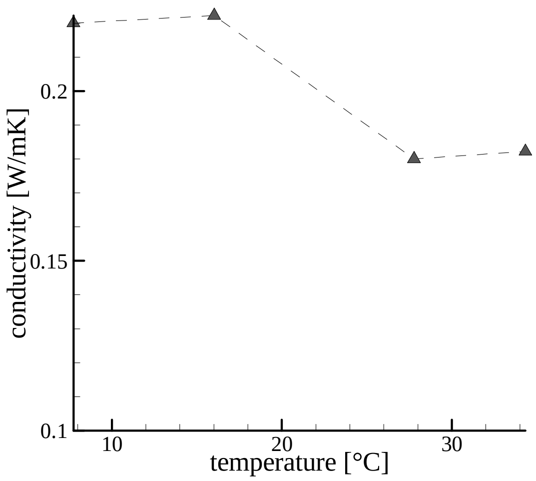

Figure 2: Experimental PCM material thermal conductivity measured for several temperatures

PRESENTATION OF TEST CELL MINIBAT

The experimental cell MINIBAT, presented figure 3, is composed of two identical parts which dimensions are 3.10mx3.10x2.50m respectively to (x, y, z). We will use in our study only the cell 1 which will be called experimental test cell. In our studies, cell 2 is not distinct from the thermal guard because the communication door between these two entities is open. The composition of the walls is given in table I. Three of the walls (which location are given figure 4) have been covered with PCM material for the tests. The glazed façade separates the cell from a climatic chamber whose temperature is controlled and can vary between -10°C and 40°C. A thermal guard allows keeping the five others faces at a constant temperature, which can vary between 5°C and 30°C. During our tests, the thermal guard temperature was kept constant at 19°C.

A battery of 12 spotlights, of 1000W each one, makes it possible to simulate an artificial sunning (gas-discharge lamps with metal halides which spectrum is similar to the sun one). The spotlights are placed on 3 horizontal lines (see figure 4), each line being tilted of an angle α: for line A α=0°, for the line B α=25° and for the line C α=50°. The radiative flux thus created penetrates in the cell via the glazed wall. The control makes it possible to dynamically control the temperature of the climatic chamber as well as the entering level of radiative flux, by the means of the number of lit spotlights.

(17) climatic chamber air treatment system; (18) test room air treatment system

Figure 3: Experimental test cell MINIBAT

All the faces temperatures are measured using thermocouples of resolution ±0.4°C, each face with 9 thermocouples. The temperatures of the climatic chamber and the various parts of the thermal guard are measured using Pt100 probes of which the resolution is of ±0.3°C. The globe temperature is measured using a thermocouple inside a black ball centred in the experimental cell. The temperature of the air is measured using shielded Pt100 probes: the first one is positioned at the middle of the room and at a height of 85cm (the soil being at height 0cm); the second one is at a height of 170cm. The various levels of radiative fluxes are measured using a pyranometer.

Table I: Composition of the existing walls

Wall	Material	Thickness (mm)
Floor	concrete	200
Wall	plaster plate wood plate	10 50
Ceiling	plaster plate insulated material wood	10 55 25
Glazed facade	glass	10

The acquisition of the various parameters is done by the means of a multiplexer-multimeter connected to a PC. The control of the whole of the apparatuses, except control, is made using software LABVIEW. The time step chosen between two series of measurement is 10mn and the duration of each test is three days.
The tests presented in this article correspond to a summer test, for which the temperature of the climatic chamber varies between 15°C and 30°C and a mid-season test, with climatic chamber temperature varying between 10°C and 20°C. The climatic chamber temperature (T_{cl}) and the radiative fluxes (E) are shown for the two test cases on figures 5. We can notice the good repeatability of the controls of the climatic chamber temperature and lighting of the projectors.

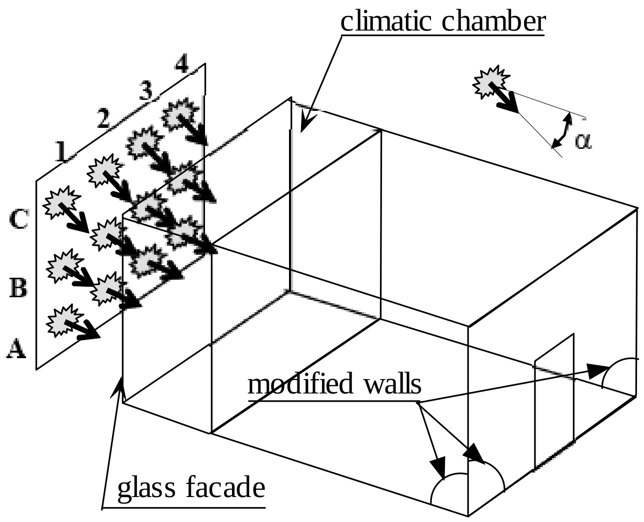

Figure 4: Isometric diagram of the climatic chamber with the projectors and location of the 3 modified walls

In conclusion, the experimental methodology permits us to obtain a complete boundary conditions description and the temperature inside the test cell, all the values being dynamically measured.

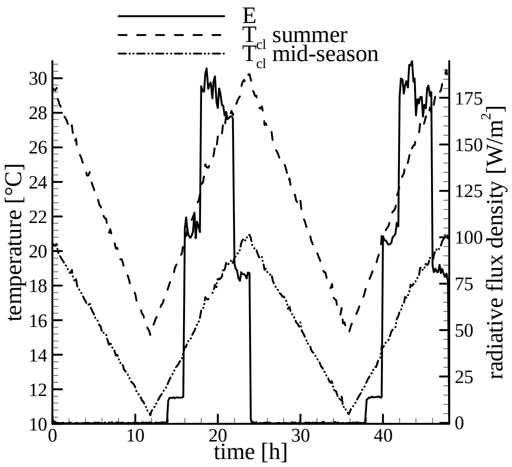

Figure 5: Experimental conditions for the summer and mid-season cases

RESULTS

Summer case

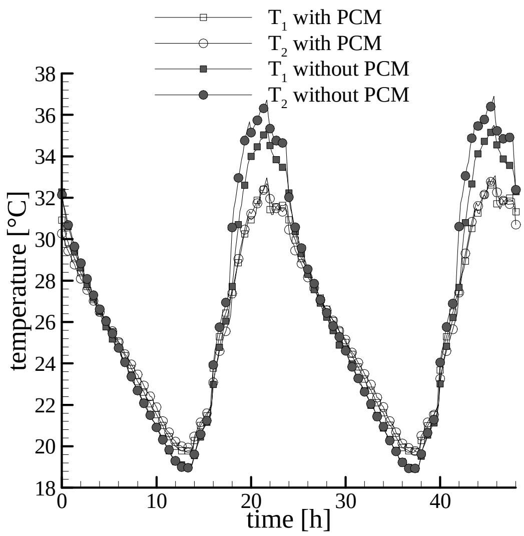

Figure 6: Room air temperatures T1 and T2 measured respectively at a height of 85 cm and 170 cm – Summer case

The results concern the temperatures mesured during the two experiments with and without PCM. The figure 6 shows the evolution of the air temperatures for the two different height positions (85cm and 170cm). The differences between the two cases tested concern mainly the temperature evolution maximum and minimum. With PCM, the maximum temperature maximum is about 32°C when without PCM this value is about 36°C. Concerning the minimum temperature minimum, the differences between the two cases is about 1°C, the PCM case being higher than without PCM (20°C with PCM and 19°C without PCM). The gain concerning the air temperature is clearly shown for the summer case. It is interesting to note that a thermal stratification exists in the case without PCM (a difference of 1°C for the temperature maximum between the two probes) which doesn't happen for the PCM case. This is mainly due to higher natural convection effects because of the lower vertical walls temperatures. This improves the thermal comfort and has never been observed before.

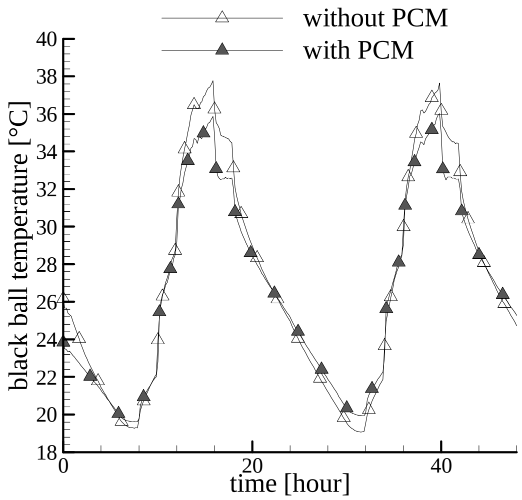

Figure 7: Globe temperatures for the cases tested – Summer case

The figure 7 shows the evolution of the globe temperature measured with a thermocouple in a black ball. The main difference concerns the maximum temperature maximum which is lower of about 2°C for the PCM case. This measure shows that the PCM material enhanced the thermal comfort for which the globe temperature is an indicator.

Concerning the time delay between the cases with and without PCM material, the figures 6 and 7 shows a phase difference (measured at the temperatures profiles maimum and minimum) of about 1 hour. The PCM material can stock-destock energy (the effect being the decreasing of temperatures fluctuations) but canot prevent the radiative effects more than 1 hour.

Mid-season case

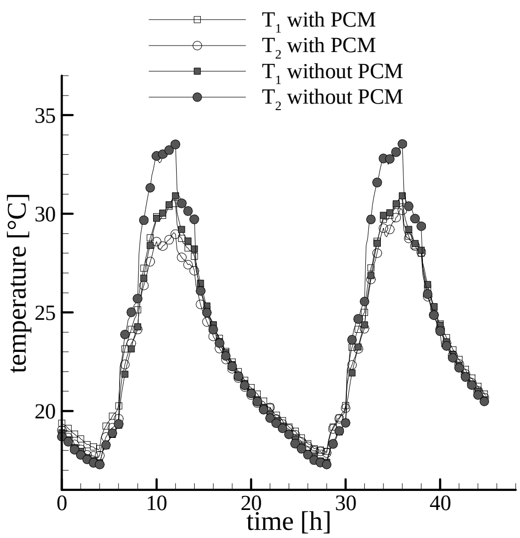

Figure 8: Room air temperatures T1 and T2 measured respectively at a height of 85 cm and 170 cm – Mid-season case

The figure 8 shows the evolution of the air temperatures for the two different height positions (85cm and 170cm. With PCM, the temperature maximum is about 28°C when without PCM this value is between 31°C and 34°C. The gain concerning the air temperature is obvious for the mid-season case. It is interesting to note that the thermal stratification is more important than for the summer case and once more, this stratification doesn't exist for the room with PCM wallboards.

The figure 9 shows the evolution of the globe temperature measured with a thermocouple in a black ball. The main difference concerns the maximum temperature maximum which is lower of about 2°C for the PCM case

Concerning the time delay between the cases with and without PCM material, the figures 8 and 9 show a phase difference (measured at the temperatures profiles maximum and minimum) of about 1 hour. The PCM material can stock-destock energy even during mid-season.

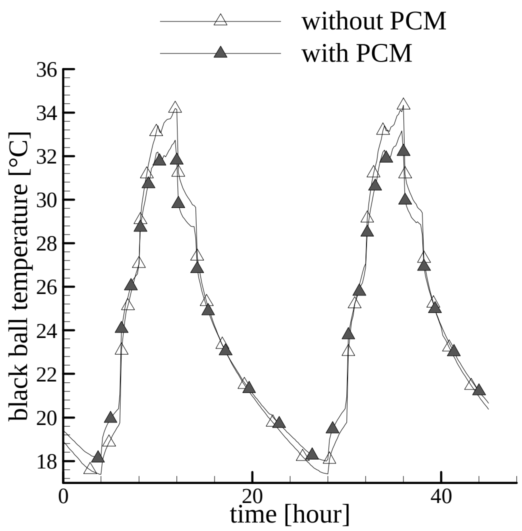

Figure 9: Globe temperatures for the cases tested – Mid-season case

DISCUSSION

In this article experiments are carried out in a test cell and in controlled external conditions with solar contributions which is new in the literature.

According to the comparisons presented in this paper, the PCM composite walls allow to enhance the thermal comfort of the room in the summer case. The maximum air temperature is decreased by about 4°C and the minimum increased by about 1°C. This free regulation is obtained only by using PCM material. Another notable effect is the natural convection enhancement, allowing to have a better mixing concerning the air in the room and decreasing the thermal stratification.

The globe temperature evolution confirms the enhancement of the thermal comfort because of the PCM used.

Further investigations are needed in order to have more results concerning various external conditions. The winter case is actually our subject of interest. For that case, we hope a reduction of the heating energy consumption with the use of PCM materials. These results will be used to validate numerical codes for the prediction of energy consumptions of such systems.

Optimization Of Double Skin Facades For Buildings: An Office Building Example In Ankara-Turkey

Dr. Ibrahim Cakmanus

Society of Turkish HVAC and Sanitary Engineers, Turkey

Corresponding email: ibrahim.cakmanus@tcmb.gov.tr

ABSTRACT

There are about 16 millions building in Turkey. The total energy consumption of these buildings is approximately 3.48×10^5 GJ. The energy consumption of the office buildings having HVAC systems can be stated as 150 kWh/m^2.year.Turkey is in the warm climate band and the day time outside air temperature in summer (May ~ September) is about 30°C. Parallel to the increasing comfort demands, energy consumption also increases. These factors make the necessity for increasing energy efficiency of buildings apparent.

In this study, a life cycle analysis is introduced for an office building having double skin obtained by dressing a second glace façade to the two main façades and for the situation of natural ventilating and night cooling in summer. In according to the results from the analysis, approximately 45% energy saving is possible by this application. Consequently the energy use will be reduced from 203 kWh / m^2.year to 106 kWh / m^2 year.

Keywords: Existing office building, natural ventilating, optimization, simulation, thermal comfort

1. INTRODUCTION

Starting from the year of 1970, increasing researches in the world on the energy efficiency have resulted in a number of new standards and regulations. In addition, Kyoto protocol against global warming and ozone layer depletion is taking effect more seriously all over the world. At this connection, both the energy efficient design of new buildings and increasing the energy efficiency in existing building turned to the one of the leading issues of construction sector. The retrofit projects having the harmony between renovation and energy efficiency are more attractive than those having these processes separately [1]. In this study a life cycle analysis has been made for an existing office building situated in a complex of a public institution. The two principal façades (back and front façades) of this building is planned to be dressed by two glass skins and a cost-benefit analysis has been conducted for the double skin construction obtained, for the situation that natural ventilating and night-time-cooling was used in summer.

2. EXISTING CHARACTERISTICS OF THE BUILDING

2.1. Architectural Characteristics

a) Building working areas: Normal floors of higher blocks: 900 m^2/floor (14 floors exist), Ground floors (ground, 1st and 2nd floors) : 2.800 m^2/floor, Basement floors (3 floors): 4.300 m^2/floor,	b) Net usable area: 34.000 m^2.

The external view and the normal floor plan in higher block of the building are shown in Figure 1 and 2.

Figure 1.External view of the building.

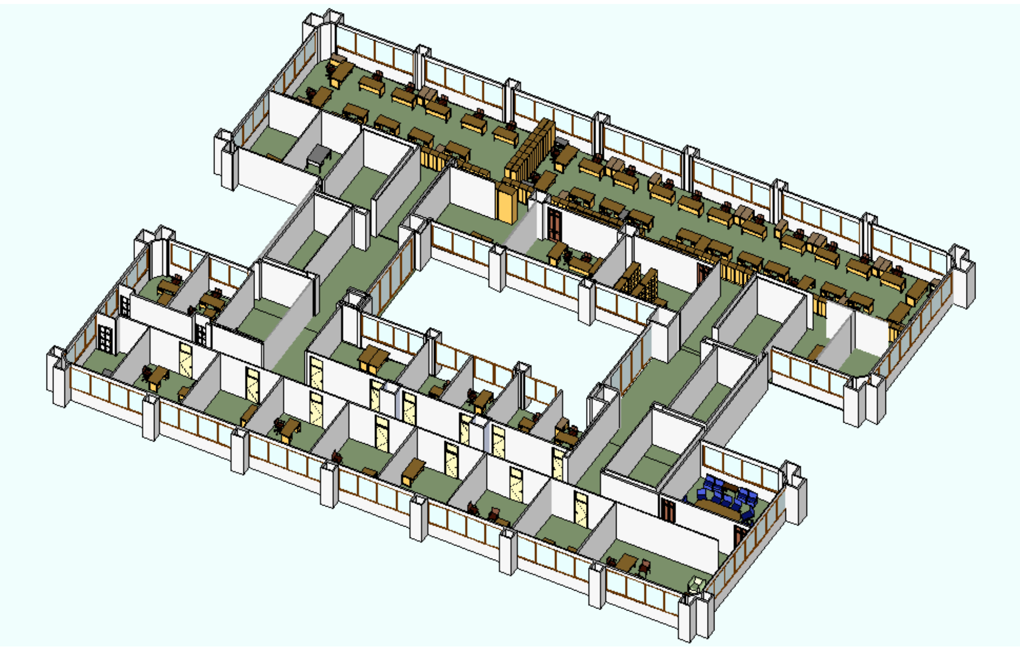

Figure 2 the sample floor plan for upper sections of the building.

As it can be seen in Figure 2, the floors have been oriented as open and closed offices. The natural ventilating is considered as single-sided ventilating in the offices facing to the principle façades.

2.2. Building Façade

The building has been oriented in southwest-northeast axis. The basic façades for heat gains areas are given in Table 1:

Table1 The external surface areas basis for heat gains.

Directions	Glass area (m^2)		Cement(wall) area (m^2)	
	Per Floor	Total	Per Floor	Total
SW	80	1120	120	1680
NE	80	1120	120	1680
NW	55	770	65	910
SE	55	770	65	910
TOTAL		3780		5180

The façade of the existing building has been constituted by clear glasses (solar transmittance ε=%100 and over all U coefficient= 4.0 W/m^2K) with alumina frame. In this case, the heat gains in winter and the heat losses in summer are high.

2.3. HVAC Systems

Since, the building has been got into operation on 1988 and HVAC systems had been based on the old and out-dated technologies; these systems have completed their life-cycles. The second and lower floors of the building, are heated/cooled by the air, supplied by the air-handling units. These systems are the constant flow, variable temperature, single zone systems. Consequently they create inefficient and uncomfortable spaces. The 4th and upper 14 floors; are heated / cooled by a two-pipe fan-coil system and there is no possibility of outside air supply. For this reason, there always are internal air quality problems in the building. Furthermore, the two-pipe fan-coil system provides insufficient comfort for transient seasons.

In sunny winter days and particularly in southwest façades, the temperatures, rise in the extent that it can disturb the comfort levels in the offices. Also in summer; the electrical energy consumed by the fan-coil system is much more than normally required. This is because the façades are not protected against solar radiation.

2.4. Annual Energy Consumption

The energy consumption (readings from the meters) to meet the heat gains/losses and their monetary values are given in Table 2 (as the average of the years between 2002~2005).

Table 2a The actual annual utility (natural gas, electricity) consumption rates of the building.

Item	Type of Consumption	Consumption Rate	Unit Price (EU)	Total (EU)
1	Electricity	8.000.000 kWh/year	0.11 EU/KWh	880.000
2	Natural gas	635.000 m^3/yıl	0.30 EU/ m^3	190.500
TOTAL				1.070.500

40% of natural gas and 30% of electrical energy in Table 2a, are used in the buildings other than this building. Thus the natural gas consumption of the building is (0.6x635.000=) 381.000 m^3/year and the consumption of electrical energy is (0.7x8.000.000=) 5.600.000 kWh/year. The distribution of energy consumption is determined, checking the nominal powers, numbers, operating times, and annual energy consumption of the devices using electricity. The data given below have been based on;

			Remarks
Annual heating period	=	1600 hrs	
Annual cooling period	=	1600 hrs	(for comfort purposes)
Heat value of natural gas	=	11 kWh/m^3	
Energy equivalent of natural gas consumed in boilers	=	4.191.000 kWh	(381.00 m^3x11 kWh/m^3 =)
Annual electrical energy consumption for auxiliary heating equipments	=	425.000 kWh/year	burners, fans, pumps etc
Total energy consumption for heating	=	4.616.000 kWh/year	(4.616.000 + 425.000 =)
Unit energy consumption for heating	=	136 kWh / m^2	(4.616.000/ 34 000 =)

The electrical energy consumption of the building (rounded values) is given in Table 2b.These values are calculated taking into consideration of metered values, the powers and the operating times of the equipments. As apparent from the Table 2b, 2.282.000 kWh/year energy is consumed by comfort cooling systems (chilled water cooling units, circulating pumps, cooling towers etc). This is approximately 40% of the total energy use in the building.

The total heat gains from solar radiation and the internal loads is 3.880.000 kWh/year. Then, the overall COP of the cooling system can be estimated as (3.880.0000/2.282.000 =) 1.7. And the unit energy consumption for cooling will be (2.282.000 kWh/yıl/34.000 m^2 =) 67 kWh/m^2yıl. Thus, the total unit energy per m^2 for heating and cooling is (136+67=) 203 kWh/m^2. Since the uncontrolled, single glass fenestration with alumina frames having no shading features and inefficiencies in HVAC systems, this figure of unit energy consumption is significantly higher.

Table 2b Distribution of electrical energy consumption by sources.

System	Electrical energy consumption (kWh/year)	(%) of total
Comfort cooling system	2.282.000	40.7
Continually operating cooling system (EFT, DATA Execution etc)	1.133.000	20.2
Heating systems (electrical)	425.000	7.6
Plumbing systems	170.000	3.1
Illumination	340.000	6.1
Elevators	250.000	4.4
Aspirators	500.000	8.9
BIM, PC, copy, printer, fax, telephone centrals	400.000	7.2
Others	100.000	1.8
TOTAL	5.600.000	100

3. Basic DATA For The Calculations

3.1. Climatic Characteristics

The outside temperatures between May-September through which natural ventilating is possible, are shown in Figure 3 and the wind velocities (m/s) for the same period in Figure 4 [2]. As can be seen, Ankara in summer is hot and dry in day times and cool in night times. For these characteristics of the city, night-cooling and natural ventilating seems to be possible.

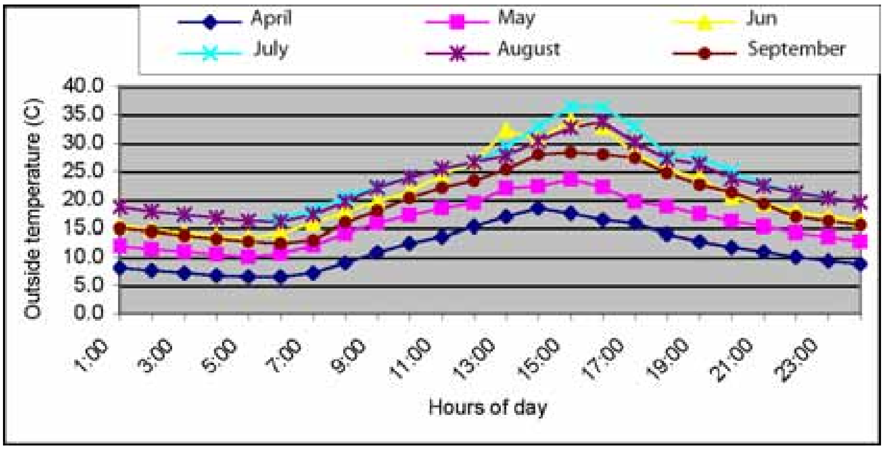

Figure 3 The average dry bulb temperatures between April~September [2].

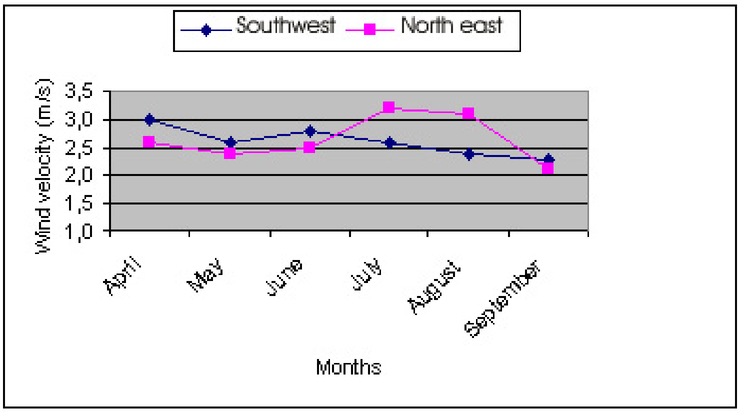

Figure 4 The average wind velocity between April~September [2].

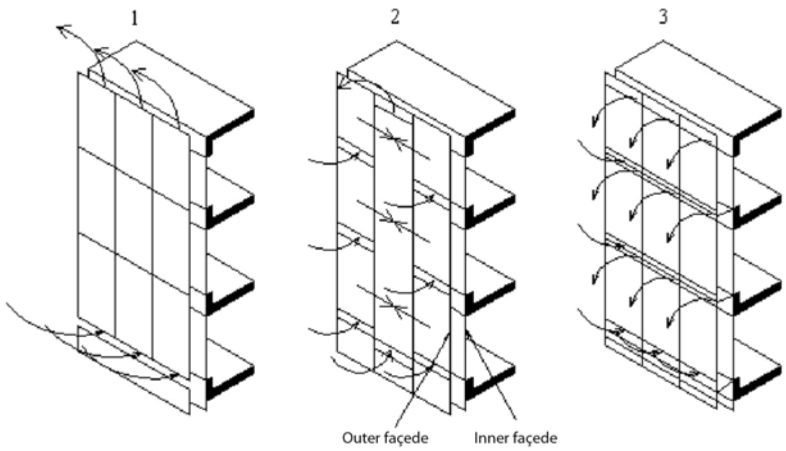
3.2. Heat Losses/Gains And Ventilating

In the calculation of heat losses and gains the glass characteristics, the U values, inside (23°C) and outside temperatures given in Table 3 are used. The wind velocities from Figure 4 and 10 m^3/hm^2 natural ventilating air are considered. In addition, 12 W/m^2 for peoples, 10 W/m^2 for illumination and 8 W/m^2 for electrical devices heat gains are assumed [3, 4].

4. Double Skin Façade Systems

To reduce the energy consumption, it is considered to dress the secondary glass façade for the two main façades of the building. For the natural ventilating, mainly three alternatives shown in Figure 5, are taken into considerations. For the first alternative, the air flow is provided along the entire façade. For the second alternative; the air is taken from the openings arranged for the individual floors and exhausted from the upper floor. For the third alternative, the air is introduced in each floor separately and exhausted from the same floor, again separately. In all of the alternatives, to reduce the mechanical cooling system operation time, in addition to natural ventilating the dampers on the glass façade will be leave open all night long for night-time cooling. In winter, the air between the two façades will be trapped and an additional insulation will be obtained. Furthermore, in suitable weather conditions, natural ventilating will also be possible during day-times. [5].



Type 1 *Type 2* *Type 3*

Figure 5 Alternatives for ventilating in two skin building [5].

4.1. Dressing A Second Glass-Skin To The Building

Mainly two measures have been considered for the building: (1) changing the glasses in the façades of the building, and (2) substitution of the old HVAC systems with new and more efficient systems. But, since the building is occupied and there are peoples working in the offices, it will be very difficult to renew the glasses with the low-e fenestration and insulated frames. For this reason and since this application will not be as effective as desired, instead of changing the glasses, it has been preferred to dress another glass skin to the main facades. Thus, the building will have an external inoperable glass skin and an operable inner skin (double skin façade). The glass characteristics of additional Low-e glass skin shown in Table 3.

Table 3- Physical characteristics for alternative glasses [6].

Type	Total transmittance	Shading coefficient	Heat transfer coefficient (U) EN 673 (W/m^2K)	Unit costs (EU/m^2)
6+12+6* mm clean heat-glass (tempered)	0.69	0.81	2.8	50,00
6+12+6 mm low-E haet glass (tempered)	0.59	0.63	1.8	65,00
6+12+6 mm low-E comfort glass (tempered)	0.40	0.56	1.7	80,00
* 6+12+6= glass tichkness+ air gap+glass tickhness				

The unit prices for the glasses include carrier profiles (frames) and mounting workmanship. These additional costs are constant for all alternatives and valued as 150 EU/m^2.

4.2. Second Façade Options

The second skin that can be dressed into the this building may be 10 configurations as shown in Figure 5. Theese options are listed in Table 4. The total glass area of the two façades of the building is 3780 m^2 and approximated costs of the system including frames also, shown in the table. Since the number of dampers and automatic controllers etc is lesser, the type 1 is least expensive Type 2 is moderately expensive and type 3 is most expensive system (Figure 5).

Table 4. The façades options used in life-cycle analysis.

Option number	**Façade type**	**Arrangement of double skin elements**	**Shading coefficient (SHGC)**	**Heat transfer coefficient (W/m^2K)**	**Estimated investment cost of second façade (EU)**
1	Existing situation (no second skin)		1.00	4.00	0,00
2	Second skin: 6+12+6 mm clear glass *(Figure 5, type 1)*		0.81	2.80	756.000,00
3	Second skin: 6+12+6 mm clear glass *(Figure 5, type 2)*				770.000,00
4	Second skin: 6+12+6 mm clear glass *(Figure 5, type 3)*				795.000,00
5	Second skin: 6+12+6 mm insulated glass low-E *(Figure 5, type 1)*		0.63	1.80	775.000,00
6	Second skin: 6+12+6 mm low-e insulated glass *(Figure 5, tip 2)*				792.000,00
7	Second skin: 6+12+6 mm low-e insulated glass *(Figure 5, type 3)*				826.000,00
8	Second skin: 6+12+6 mm low-e comfortal glass *(Figure 5 ,type 1)*		0.56	1.70	791.000,00
9	Second skin: 6+12+6 mm low-e comfortal glass *(Figure 5, type 2)*				817.000,00
10	Second skin: 6+12+6 mm low-e comfortal glass *(Figure 5 ,type 3)*				835.000,00

5. Analysis for Natural Ventilating

The performance of natural ventilating is dependent to the outside air conditions. Not to cause discomfort and energy losses, the dampers will be controlled by BAS's (Building automation systems). The calculations related with natural ventilating are as below.

5.1.1. Effective Pressures

5.1.1.1. Pressure Differences Caused By The Wind

The average air velocity (m/s) on building façade can be estimated by [7];

$$U_h = U_{met}\left(\frac{\delta_{met}}{H_{met}}\right)^{a_{met}}\left(\frac{H}{\delta}\right)^{a} \qquad (1)$$

Where;
U_{met} is the meteorological air velocity (m/s), H_{met}= 35 (mid plane of the building); the meteorological exponent α_{met}=0.33 (from ASHRAE), flow exponent α_{met}=0.22, meteorological wind depth δ_{met}=460m, wind depth δ=850m (assumed) . The pressure caused by wind velocity can be estimated by;

$$\Delta P_{wind} = \rho_a C_p \frac{U_h^{\,2}}{2} \qquad (2)$$

Where ρ_a is the outside air density (kg/m^3), C_p is the local wind coefficient given by ASHRA as;

$$C_p = C_s - C_{\text{int}er} \qquad (3)$$

C_s is taken as -0.3 and C_{inter} is assumed to be -0.2 [7].

5.1.1.2. Pressure Differences Caused By Temperature Differences (Chimney Effect)

There will be a pressure difference originated by the density difference between the hot and cold air. The difference caused, by density differences of the air, can be estimated by the equation below [7];

$$\Delta P_s = \rho_i g T_{\text{int}} (H - H_{neut}) C_d \frac{T_{\text{int}} - T_{out}}{T_{out}} \qquad (4)$$

Where ρ_i *i*nternal air density (kg/m^3), H_{neut} height in reference to the neutral axis of the building (m), H *a*verage height of the building (m), T_{int} inside air temperature (°C), T_{out} outside air temperature (°C), C_d total wind coefficient. It is between 0.63 ~0.82 and here taken as 0.63.

5.1.1.3. Total Pressure Difference

This pressure difference is obtained by adding the dynamic pressure difference and heat affected pressure differences each other and can be stated as;

$$AP_t = \Delta P_{wind} + \Delta P_s \qquad (5)$$

5.2. Air Flow Rate

The air flow rate in single sided ventilating through the windows can be estimated by the formula below [8];

$$V_i = C_d A_i \left(\frac{2\Delta P_t}{\rho_a} \right)^{1/2} \qquad (6)$$

Where V_i air flow rate (m^3/s), *i* number of openings, A_i opening area (m^2), ΔP_t total pressure drop (Pa), ρ_a density of outside air (kg/m^3).

The total air flow rate (m^3/h) can be estimated as;

$$V_{i-tot} = \sum_{i=1}^{n} V_i \qquad (7)$$

Air change rates for offices can be estimated dividing the air flow rates to the total space volume.

$$n = \frac{V_{i-tot}}{V_{tot,space}} \qquad (8)$$

Where n air change rate (1/h), V_i-t_{ot} total air flow rate (m^3/h),
$V_{tot.space}$ total volume of spaces (m^3).

6. Heat Transfer Between The Surfaces Of The Spaces And The Ventilating Air

During natural ventilating, heat transfer is between the surfaces of hot internal space and cold outside air. In other words, ‘cold’ is stored in the space walls and elements. This stored ‘cold’ is transferred to the warm air in the space and thus, less operation time for the mechanical cooling system is achieved. The heat energy transferable to the ventilating air can be estimated by the equation below;

$$Q = hA(T_S - T_{out}) \qquad (9)$$

Where A the area of the surfaces swept by the ventilating air (m^2), h overall heat transfer coefficient (W/m^2K), T_s surface temperature of space elements (°C), T_{out} temperature of outside air (°C).

When the ventilating commences, since the space temperature is gradually reduced; T_s is a time dependant characteristic. These temperatures for the months of natural ventilating and night-cooling are given in Figure 3.   It is difficult to determine the effects of the temperature of the elements such as tables, chairs, etc and an accurate h value for the space components.

The only solution for the issue seems to model via CFD techniques and use approximate values for the coefficients mentioned above. For most of the engineering purposes, the approximate value of h is sufficiently acceptable. For example, in free convection; h value can be evaluated as 6~30 W/(m^2.K) [9]. Despite that there is a wind and/or chimney driven ventilating; h value has been taken as 10 W/m^2K as a safely approach.

7. Life Cycle Analysis

An optimization process is needed for minimizing the life cycle for options in Table 4. This optimization process will aim to reach a, minimal total cost value which is the addition of investment costs and operation costs. The target function used for the minimization of life-cycle costs (20 years) is;

$$C_T = C_{fi} x CRF + (C_{en} + C_{maint}) = \min \qquad (10.1)$$

The limitations are;

$$E < E_1$$
$$PPD < \%10 \qquad (10.2)$$

where ;
Where C_T present value of annual life-cycle cost (EU/year), C_{fi} initial cost of the façades (EU), E annual energy consumption (kWh/ year), E_1 annual allowable energy consumption (kWh/m^2year), C_{en} present value of annual energy cost for life cycle period (EU/year), C_{maint} present value of annual maintenance cost (EU/year), PPD Predicted Percentage Dissatisfied (%), CFR capital recovery rate for life-cycle of the building. CRF can be estimated as follows;

$$CRF = \frac{i(1+i)^n}{(1+i)^n - 1} \qquad (10.3)$$

Where i average annual interest rate (%), N life expectancy of the system (year).

The influence of the glass and façade types on investment and energy costs has been defined; considering different options for glasses. Similarly influence of different combinations has also determined. During the optimization process, it is considered that the PPD have to be lower than 10%. Investment cost of each option includes; material per m^2 (fenestration, frames, grilles, automatic control system etc), workmanship, transportation, auxiliary equipments etc. To define the energy costs during life-cycle period; it is needed calculating the energy costs for the heat losses/gains and converting them to present values. Annual energy costs of the options have been calculated as the product of the unit energy price and the annual energy consumptions estimated by Carrier E-20 (Hourly Analysis Program) software. After the investment and operating costs of the options defined, the optimal one has been found using a PC software based on Revise Simplex method [10].

8. Conclusions

In the Equation (10.3) assuming the annual interest rate (i) 4% and the life-cycle period 20 years. CRf is obtained from the Equation (10.3) as 0.0726. Then Table 7 has been designed solving the Equation (10.1) for every option. From the Table, it is apparent that the most suitable option is number 8 having 4.7 years recovery period for the investment. While natural ventilating improves inside air quality; night-cooling provides energy conservation reducing wall temperatures. As a consequence of these measures, the energy consumption of the building is reduced from 203 to 106 kWh/(m^2.year). In fiscal terms, this means 228.000 EU/year (485.000-257.000=) and for the life-cycle of 20 years 4.560.000 EU/year [values rounded]. The value that has to be invested, calculated as 791.000 EU. On the other hand air change is calculated as 3.5 change/hour during the natural ventilating season.

Table 7 Costs from the life-cycle cost analysis.

Alternative no	**Façade type**	**Initial cost of second skin (EU) (1)**	**Annual operating cost (EU/yıl) (2)**	**Annual total cost (EU/year) (3=1xcrf+2)**	**Simple recovery period (Year) (4=1/(485.000 – 3)**

SUMMARY

Due to high-rise residential buildings and extension of balcony, to resolve discomfort of indoor-environment and the problem which energy consumption increases, high-rise residential buildings, coming natural ventilation and decreasing expense of an air-conditioning system., enable envelope system to be developed.

The object of this study is to present the improvement on envelope of high-rise residential buildings to reduce heating and cooling load. To improve the environmental performance of envelope, it is necessary to modify envelope vent system and ensure intermediate space.

In this study, the shape of vent in high-rise residential buildings has been inspected, and the survey about the environmental conditions related to the envelope of high-rise residential building has been conducted. Environmental measurement has been done to examine out door air quality for natural ventilation.

INTRODUCTION

The envelope of building is, horizontally and in section, one of project factors different from other building around on surface and mainly decoration and also from a variety of weather conditions such as solar radiation, warm and cold internally protects residential environment of house so that it is evaluated as one of the important function maintaining uniform house-environment

In Korea, balcony section of high-rise residential buildings is apt to be extended as front-glass on case of high-rise residential building. While the window glass provides not only, unit residents of natural lighting and view, but also is essential for psychological aspect, attaching to outdoor. It increases heating and cooling load for much heating acquisition in summer caused by high overall heat transmission and much heat losses in winter

Also it is reared up that the problem of comfort for a resident and window opening in case of high-rise building which high window pressure exists. Especially the seriousness comparatively appears on the side of natural ventilation in the building being so for mechanical ventilation. The most problem is difficult to open window because of high window pressure outside in case of high-rise building.

Not only most of high-rise buildings to resolve that ventilation problem have the equipment of mechanical ventilation, but also come to minimize window size as possible as opening. But the induction of the mechanical ventilation increase needs for mechanical-cooling as decreasing the probability of natural ventilation through window frame.

Now even though the envelope of high-rise residential building comparatively is less than architecture regulation related to building height and structure, as the curtain wall of older high-rise office is selected without any other improvement, For matching residence that the envelope performance needs to be improved, through those above, it is supposed to think of indoor-environmental performance of high-rise residential buildings.
In this study, on the basically step of improvement project of envelop about building in order to reduce the energy of high-rise residential building, To catch on problems of high-rise building now we had posed a survey about residents of older high-rise residential building. Also practicing natural ventilation through outdoor-air, as a plan of reducing heating and cooling load, it had measured environmentally whether natural ventilation of high-rise residential building now brought in or not.

PROPOSED APPROACH

The survey of preexistence envelope of high-rise residential buildings

The curtain wall involved in the department of envelope about high-rise residential building is largely classified by the department of window and wall having glass. As the performance of those two parts, it is decided that the performance of curtain wall about two parts above is.
It is practiced that the survey at Youido, Yongsan-gu, Gangnam-gu, Yangcheon-gu in Seoul in the country ranged in high-rise residential buildings, total 15 areas is. After practicing survey of envelop pattern, survey target building have applied most of the curtain wall. A part of curtain area divided frame have been using.
In order to resolve the uncomfortable problem of indoor-environment caused by high-rise tendency of residential building, balcony extension and the problem of increasing energy consumption, we had focused shape of vent in the purpose of improving envelope performance of high-rise residential building as easy as natural ventilation and saving heating and cooling expense.
Vent pattern as well as vent area is major one of factors deciding vent quantity, due to that, it is decided that induction quantity of opening air is. Therefore having investigated vent opening-pattern of high-rise residential building's envelope, we have gained the actual condition of opening-air induction.
Shape of vent is applied by most of top-hinged out swing window type except low-floor department of T- high-rise residential building at Youido and that is adopted by casement type, T-low-floor department at Youido.

The simulation of preexistence envelope of high-rise residential buildings

Even though shape of vent is important not to be able to ventilate directly caused center core structure, as we have known that the area and opening-angle which ventilation window occupies are small, It is evaluated that this is to reduce the risk of the accident caused the fall and excessive wind-pressure because of wide opening-area.
In case of top-hinged out swing window type, as ventilation volume is 2600 m^3/h such as simulation conclusion, a chart above, while it satisfies 1240 m^3/h, encouragement ventilation volume, because the ventilation volume is comparatively smaller to be lower than different opening-method, natural ventilation to the cooling of the open air is enough carried out. In order to resolve that, in case of top-hinged out swing window type, transforming the tall and width of window, it can correct faults. But we have known imperfection of ventilation performance that opening-angle is not big. (Figure 1, Figure 2)

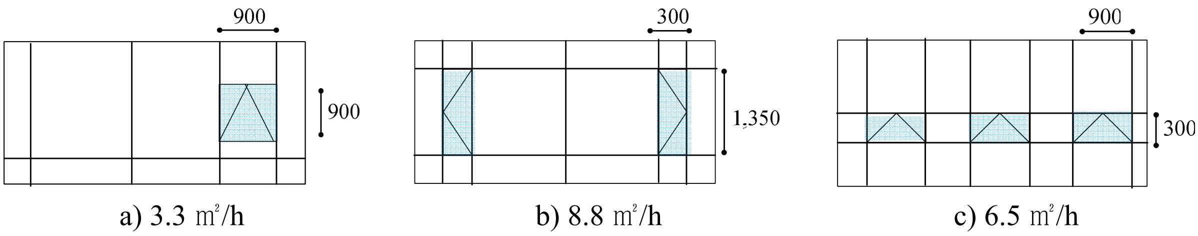

Figure 2. Amount of ventilation according to window area and type (unit:mm)

FIELD SURVEY

Survey outline

To get gist of envelope of high-rise residential building influences indoor-environment performance we had posed survey and deep interview related to environment performance for the envelope of high-rise residential building complex. Through it, after catching on environment performance how the resident in the high-rise building complex feels in their life, eliciting the problem, we got the improvement outline.

The building, which is surveyed in this study, is a complex in Seoul, Korea. It consists of the lower podium for commercial shops and higher stories for residential building. Although it is a complex, the commercial zone and the residential zone are separated from each other. This study focuses mainly on the higher stories for residential building. To increase the reliability of survey, people of the survey is selected that in the building the height and window of a household gives a steady distribution. The survey is carried out to a high-rise residential building in Seoul. To increase the reliability of survey, people of the survey is selected that in the building the height and window of a household gives a steady distribution. The residential building has 37 floors above ground and 6 underground, which located in the metropolitan Seoul .The envelope is composed of AL.Curtain wall +24mm Lowe pair glass and the general characteristics are like Table 1. Fig. 3, Fig. 4 and, Fig. 5 is the typical. The items of survey are composed of factors for thermal, indoor; lighting, sound environment and the details are like Table 2

Table 1. Building description

Location	Seoul, KOREA
No. of floor	37 floors
Height	111.63M
Use	Residential
Envelope	AL.Curtain wall +24mm Low–e pair glass

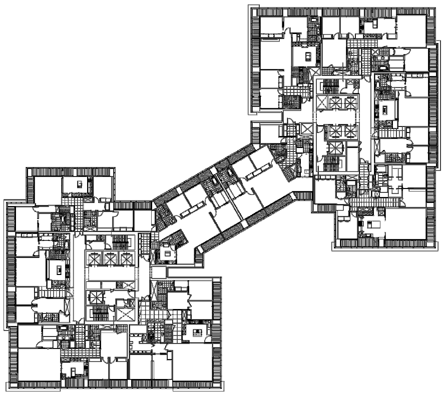

Figure 3. Typical floor plan of the survey building

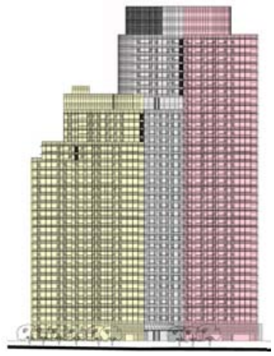

Figure4. Elevation of the survey building

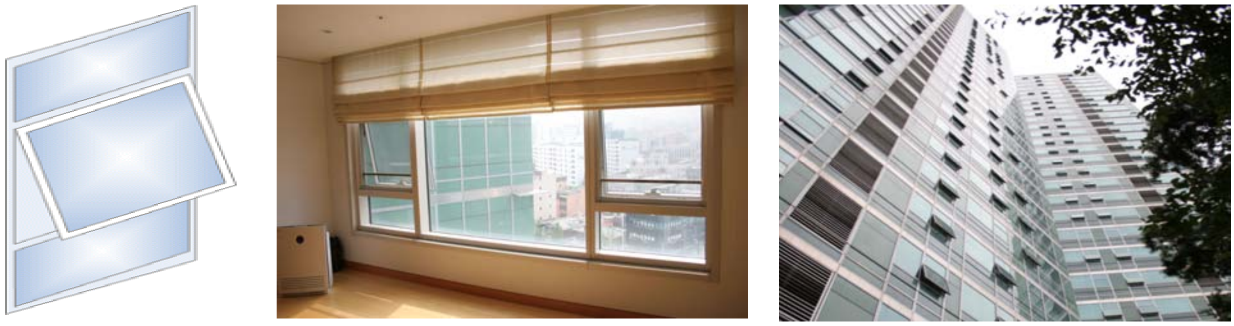


a) Window type b) Interior Envelope c) Exterior Envelope

Figure 5. Envelope of the survey building

Table 2. Composition of resident question item

Classification	Item
Thermal environment	Thermal ,Humidity, Condensation ,Type of sunshade, Purpose of sunshade Frequency sunshade, operation time, Heating and Cooling expense
Indoor air environment	Draft and effect of outside wind, To use availability of ventilation facilities, opening method of windows and doors and opening -area, Frequency of natural ventilation, Satisfaction of natural ventilation, Satisfaction about IAQ
Lighting Environment	Type of sunshade, purpose of sunshade, frequency to use shade, vibration of sunshade, appearance of glare and effect
Sound Environment	Outdoor noise influence, Sound insulation performance of window

Survey result and discussion

Because of the survey conclusion about a resident, the air tightness drops of envelope. heat and environment problem such as water leak and infiltration occurrence, airflow speed and the deficiency of natural ventilation, comparatively smaller of opening area of window, so people feels psychological stuffy. The arrangement of the problem at a part of envelop of high-rise residential building is like Table 3.

1) Natural ventilation performance through outdoor air

Taking a complex of a tendency of high building, cooling load have increased, the increase of cooling load has been aggravated by envelope utility of high curtain wall which the rate of glass area is high. But because of the problem of wind pressure and security, decreasing Opening area of ventilation window, ventilation volume has decreased.

Table 3. Classification and composition of resident question item

Classification	phenomenon	Diagnosis
Thermal environment	Heating and Cooling Load	· Glass area rain because is high excessive inflow of one thing · Buffer zone delete by balcony extension
	Water leakages and infiltration	· Envelop airtightness decline
	Cold draft	· Heat-loss occurrence caused envelop in winter · Envelop airtightness decline from balcony extension · Disability of heating in extended space of balcony
Indoor Air environment	Decrease of air speed	· Small of opening square of ventilation window · Difficult to feel air sense of a resident · Even though more than standard of average ventilation volume, feeling deficiency · When the speed of air speed outside is up, window is suddenly locked
	Deficiency of natural ventilation	· Disability to ventilate directly as a center core structure · Decrease of cooling effect of open air as opening area of decreased ventilation window · Cooling load and period increase caused natural ventilation decrease
	Deficiency of psychological opening sense	· Small of visible opening area · Psychologically stuffy and discomfort not to feel air-flow · Unpleasant of top-hinged out swing window type and sliding type about the apartment of older finest shape
Lighting environment	Ineffectively operation of shade	· Do not operate after establish shading device · Shading device e does not warmer ability
Sound environment	Satisfaction of need condition for a resident	· Sound interception by tree on lower floor · Do not problem caused distance attenuation effect of noise on higher-floor

In that case, not to get cooling effect of open air, lengthening cooling period, it badly influences directly to energy utility quantity. Therefore, it is required that in the middle, until open-air cooling comes enough, the design of open-mouse to be able to make enough ventilation quantity is.

2) Increasing air speed

A resident of high-rise building complex appears to want to feel air sense through induction of open air. This tendency was more prominent to the resident who had lived in plate-type block having experience of cross ventilation before living in a high-rising complex. Therefore, need introduce outdoor air at the higher air current speed than present within scope that do not cause the uncomfortable. On the other hand, low stories part and upper floor part can do opening area measure differently because outside wind pressure gives and is difference in the air current speed.

3) Psychological openness

The residents wanted to feel well ventilated psychologically unconcerned in amount of ventilation. The high-rise residential building that was resident question target was measured

was satisfying required amount of ventilation and indoor air quality.. However, a window was not opened widely compared with a window of plate-type block and the size of the window was quite small so the residents might feel uncomfortable psychologically
Instead of installing the top-hinged out swing window system in the building, careful consideration of various type and combination of ventilation window system which may give a resident visible wide open space would be required to solve out this problem.

4) The Insulation

Since the space of balcony has been renovated as one of residential space after the extending the balcony was legalized by a law, it gives an effect to temperature conservation of interior space because of the sunshine through the window has bad insulation ability.
In winter season, it may cause discomfort for residents because of cold draft and the damage of interior material because of a condensation around of the window. In the case of summer, it may cause the outstanding air conditioning cost because of the room temperature increase and gives a problem with envelope with weak thermally.
Because the existing balcony acted like intermediate space environmentally, we could check plan that reduce heat road by introducing intermediate space at curtain wall of high-rising residential building. Besides, the insulation ability of envelope is decided by a mixture of glass during manufacture process, the type of interior window and exterior window, the width of intermediate space, the way of unlocking the ventilation window and area of those, and so on. Consequently, a choice of envelope would be determined in many ways and totally considered in any conditions.

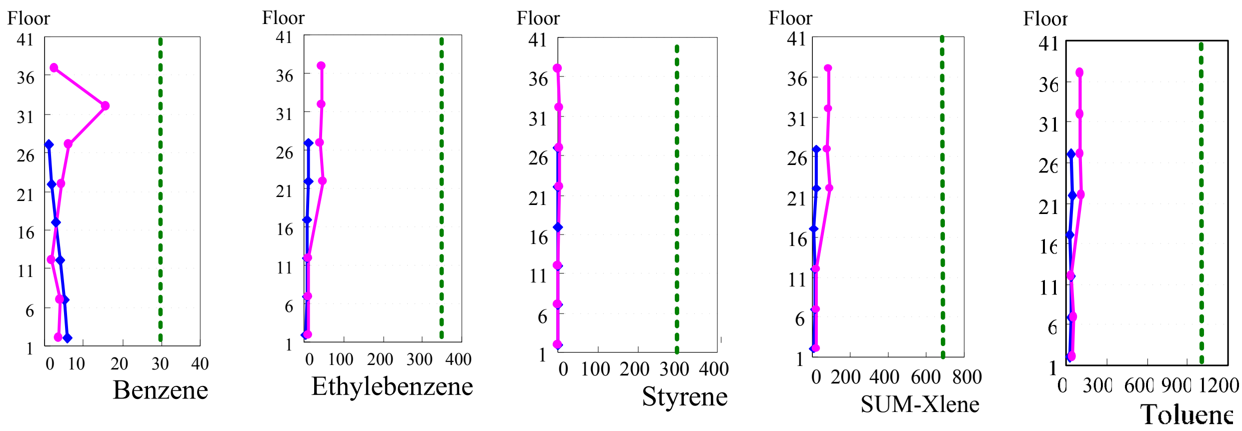
MEASUREMENT OF THE OUTDOOR AIR

Measurement outline

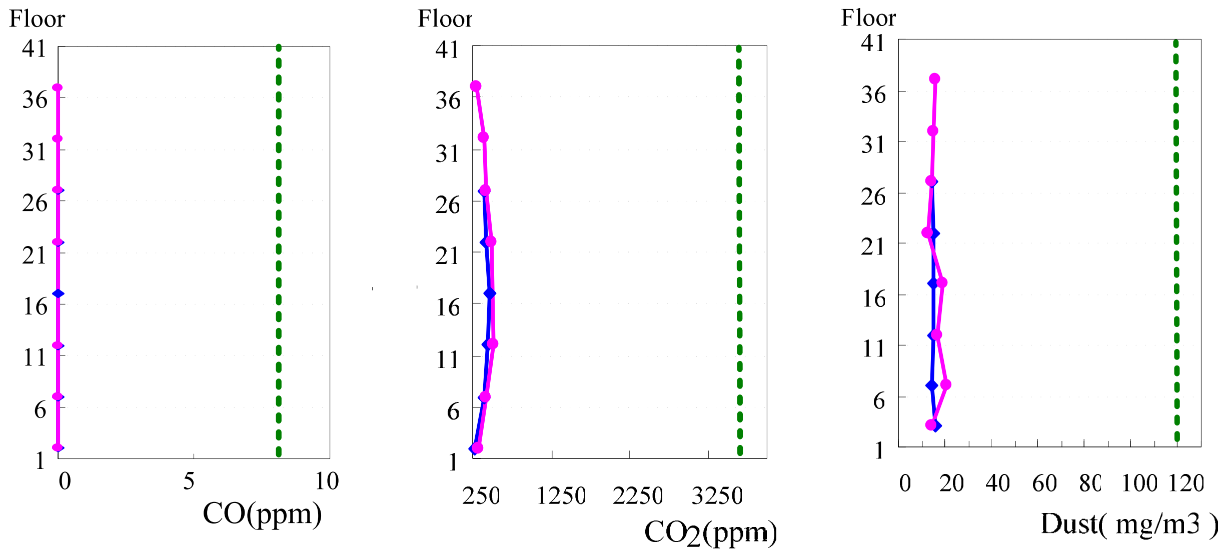
Need to examine propriety of outdoor-air introduction so that can reduce air conditioning cooling load by natural ventilation extension application, and I measured cleanliness of outdoor air for this.
Stand-by status by height measured each about 40heights of story (120m) air contaminant concentrations from same native place vent 5 floors interval with west exposure of A high-rise residential building two coppers located downtown in Seoul

Measurement result and discussion

Pollution level of outside spot results of measurements outdoor air of high-rise residential building estimates that it is possible to appears by thing which do not reach greatly and introduces outdoor air into indoor without special device for natural ventilation do acceptable level.
Since it had lower degree than legal air pollution level around both high stories and low stories of the building, the air pollution doesn't matter with the height-level of building.



a) VOCs Concentrations



b) CO, CO_2. Dust Concentrations

Figure 6. Outdoor-air contaminant concentrations measured data by heights

CONCLUSION

In this study, it includes the contents, such as the survey of residential people and extensive interview with the purpose of drawing up a plan in architectural environmental approach for prospective problem with envelope system which can be occurred by increasing the number of the high-rise residential building.

It aims to bring out proper choice of envelope material for the high-rise residential building which needs to maintain good insulation system especially in this country which has distinctive four seasons, and to give a suggestion to improve the insulation system which can economize in energy in this high population density city. Considering the plan that introduce double-skin façade system in the high-rise residential building which can do natural ventilation efficiently as reduce wind pressure and solve buffer zone by balcony extension.

Studies on Energy Storage Capacity of a Spherical Encapsulated PCM Using Eutectic Salt as Phase Change Material

Karthik.P, Ranjit prakash. S and Kalaiselvam. S

Anna University, India

Corresponding email: kalai@annauniv.edu

SUMMARY

The need for higher productivity to match the growing competition has forced employers to look for better Indoor Work Environments. Since most of the buildings are being air conditioned, the Heating Ventilating and Air Conditioning (HVAC) systems account for nearly 40% of total building energy consumption. To reduce this energy consumption Thermal energy storage systems (TES) were developed. The Latent heat thermal energy storage (LHTES) systems using water/ice are commonly used for peak shifts in electrical demand. To maintain a temperature below 0°C, the water/ice storage system is not suitable, but for a HVAC application the chiller requires a temperature below 0°C. In TES systems, phase change materials (PCMs) have attracted a great interest as thermal storage materials because the thermal energy is stored in them with high density and it is also possible to maintain below 0°C. This research uses Sodium nitrate along with nucleating agent (borax), freeze point depressant (ethylene glycol) and thickening agent (propylene) as a eutectic mixture in PCM. The percentage of composition of these selected phase change materials are Sodium nitrate 33%, ethylene glycol 27%, borax 22% and propylene 18 %. The numerical studies are conducted to determine the maximum storage capacity of the eutectic mixture and also the influence of the nodule size on TES.

INTRODUCTION

Thermal energy storage systems are used during periods of low cooling demand. To store the cooling energy, the chill storage media such as water, ice, or a phase change material are used. Thermal storage systems using latent heat of phase change material has the advantages of high storage density and heat retrieval at constant temperature during phase change. The storage application involves a 24-hour or alternatively, weekly or seasonal storage cycle depending on the system design requirements. It is proved that the cool storage technology is an effective means of shifting peak electrical loads as part of the strategy for energy management in buildings [1]. It is also considered as a useful tool to reduce the size of refrigeration machinery and air conditioning by means of spreading the daytime load over a 24-hour period. PCMs are used for various heat storage applications since 1800s, but they are recently used as cool storage media. Most of the PCMs for cool storage are inorganic salt hydrates and mixtures of salt hydrates. They are employed due to their high latent heats of transition, high densities and low cost. The experimental results using stearic acid as phase change material showed that the melting stability of PCM is better in the radial direction than in the axial direction. [2]. Ze-shao et al [3] introduced a new style cool storage scheme with high temperature water for air-conditioning. The capital cost of the cool storage system with paraffin waxes as phase change material indicates that the cool storage system not only saves energy and other operating costs but also saves a significant fraction of the initial capital costs

[4]. The manganese (II) nitrate hexahydrate, with melting point from 15°C to 25°C is used as a new PCM for the TES cooling system [5]. It was also found that the modulation of melting point and reduction of super cooling can be made by dissolving small amounts of salts in the material.

METHODOLOGY

To determine the maximum storage capacity of the eutectic mixture, this research uses sodium nitrate along with additives as suitable PCM, because of their desirable properties such as lesser degree of super cooling, high density, large heat of fusion and stability for repetition of melting and solidification. Additives such as nucleating agents, freeze point depressants and thickening agents are added along with sodium nitrate to attain the required temperature. Nucleating agent, borax is used to stabilize the refreeze temperature. The freeze point depressant, ethylene glycol is used to provide greater cooling capacity and the thickening agent, propylene is used to overcome separation and degrading problems. The eutectic mixture is considered in nodular form for this analysis and the heat storage capacities of PCM nodules of different size are compared.

SYSTEM DESCRIPTION

An air-conditioning system is simulated with a chiller of capacity 1.7 kW and heater of 1.8 kW, connected to the storage system of height 0.52m, diameter 0.484m, and volume 0.0956 m^3 is shown in figure 1. The cold fluid (ethylene glycol) and hot fluid (hot water) are circulated to transfer stored thermal energy in the system. The coriolis flow meter and RTDs are to monitor the mass flow rate and temperature of cold and hot fluids respectively. To pump the cold and hot fluids into the storage tank, 1.5 kW capacity pumps are connected across the chiller and heater units. Cold fluid of -6°C from the chiller enters into the storage tank and absorb heat from the hot fluid and leaves at -3°C. Hot fluid at 15°C from heater rejects heat to the cold fluid and leaves at 11°C. In the storage tank 60% of volume is filled with spherical nodules, where the PCMs are packed and remaining 40 % is filled with a heat transfer fluid (ethylene glycol).

NUMERICAL ANALYSIS

The simulation is fast becoming a substitute to real time experimentation trends where the stakes involved are too high to implement. For this model the type of analysis is thermal transient non-linear. The material properties such as conductivity, density and enthalpy are specified for the PCM, ethylene glycol, and water .Figure 2 shows the volume of the tank considered for analysis. In the storage tank, 60 % of the volume is filled with spherical nodules and remaining 40 % is filled with heat transfer fluid. The fluid acts as medium to accommodate the expansion and compression of phase change material during heat transfer. The modelled storage tank is symmetrical about x-y plane; hence the heat transfer characteristics are similar in the plane. To reduce the complexity, a portion of the storage tank is considered for analysis.

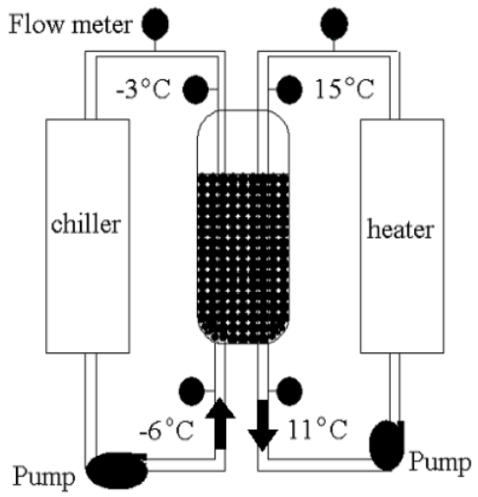

Figure 1. Experimental setup.

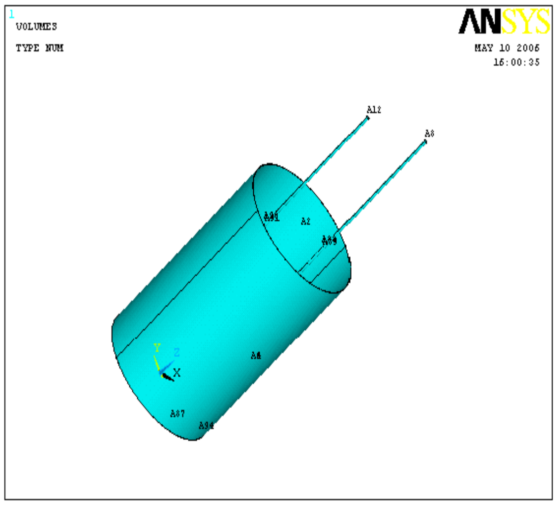

Figure 2. Volume of the tank considered for analysis.

RESULTS AND DISCUSSION

The characteristics of thermal energy storage system like heat transfer capacity of the nodules in the storage tank and the time required to attain steady state phase change temperatures are examined to predict the influence of nodule size. The various nodules considered are of diameters 77mm, 88mm, and 98 mm. Figure 3 shows the temperature profile of the storage tank with nodules of size 77mm. It shows that the temperature of the nodule of diameter 77mm and the heat transfer fluids are of uniform temperature of -3.8°C. To attain a required steady state temperature, the system requires duration of 3100 seconds, which is less than the available commercial eutectic salts.

The time required to obtain a steady temperature is shown in figure 4. It shows for the first 3100s the temperature of the PCM is gradually reduced and attains a steady state temperature. Further increase in cooling does not have any effect in PCM; hence it attains a complete phase change, i.e. it solidifies completely. Figure 5 shows the breaking point where the complete phase change occurs for the particular mixture of PCM. It shows that the temperature drops continuously until a complete phase change occurs.

Similarly the analysis is performed for the other two nodules of diameters 88 mm, 98 mm. The temperature contour plots for the nodule diameters 88 mm, 99mm are shown in figure 6 and figure 9 respectively. The time taken to attain complete phase change in nodule of size 88 mm is 12000 seconds as shown in figure 7 and figure 8. In the case of nodule of size 98 mm the time taken to solidify completely is 23000 seconds as shown figure 10 and figure 11.

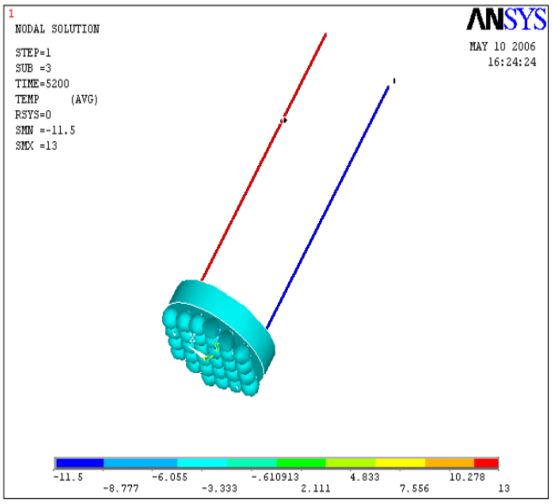

Figure 3. Temperature profile for the nodule of size 77mm.

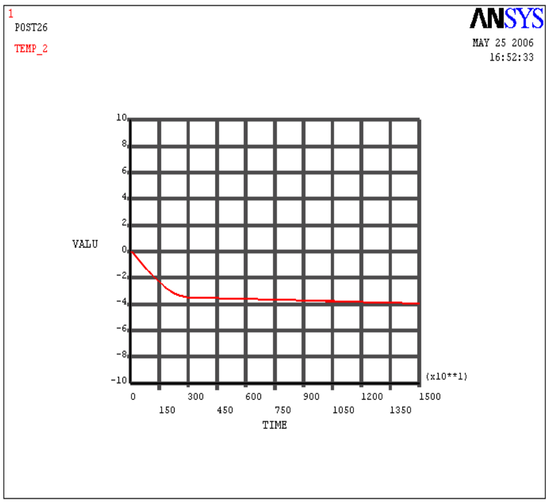

Figure 4. Steady temperature for the nodule of size 77mm.

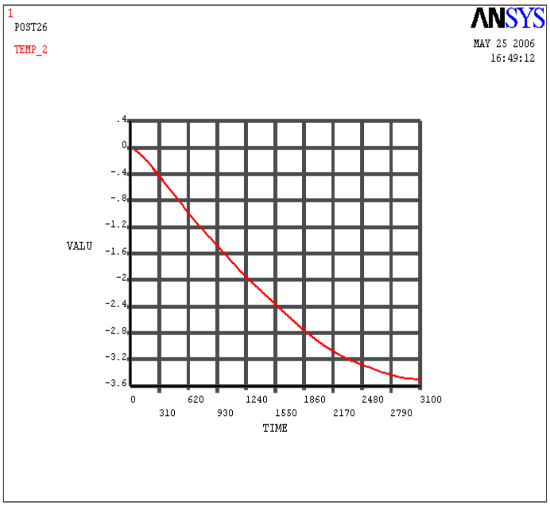

Figure 5. Phase change breaking point for the nodule of size 77mm.

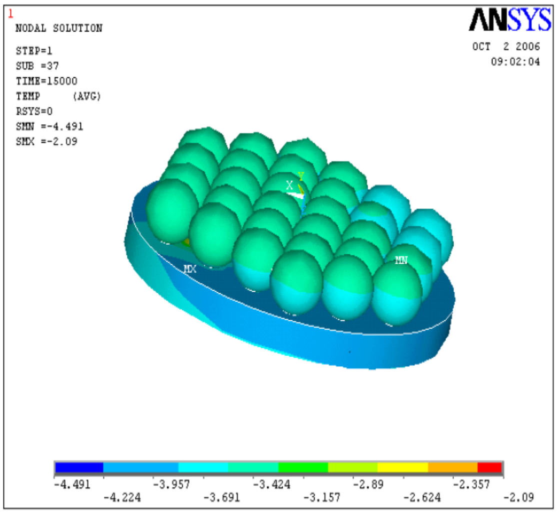

Figure 6. Temperature profile for the nodule of size 88mm.

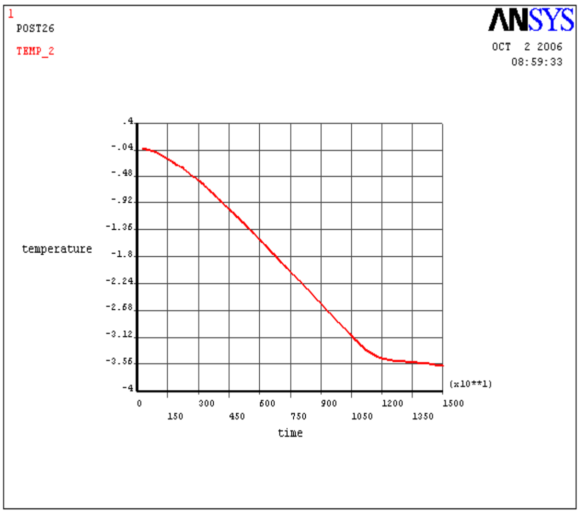

Figure 7. Steady temperature for the nodule of size 88mm

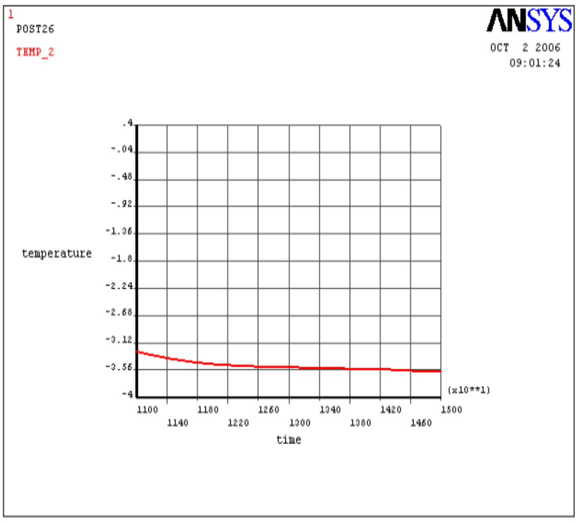

Figure 8.Phase change breaking point for the nodule of size 88mm

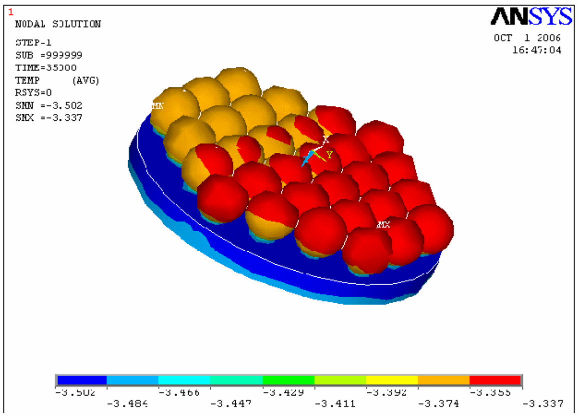

Figure 9. Temperature profile for the nodule of size 98mm.

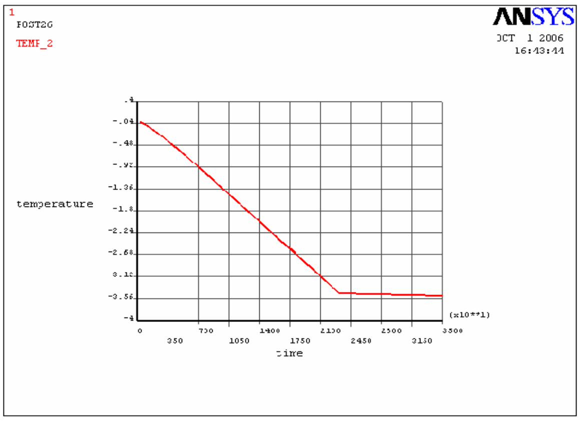

Figure 10.Steady temperature for the nodule of size 98mm.

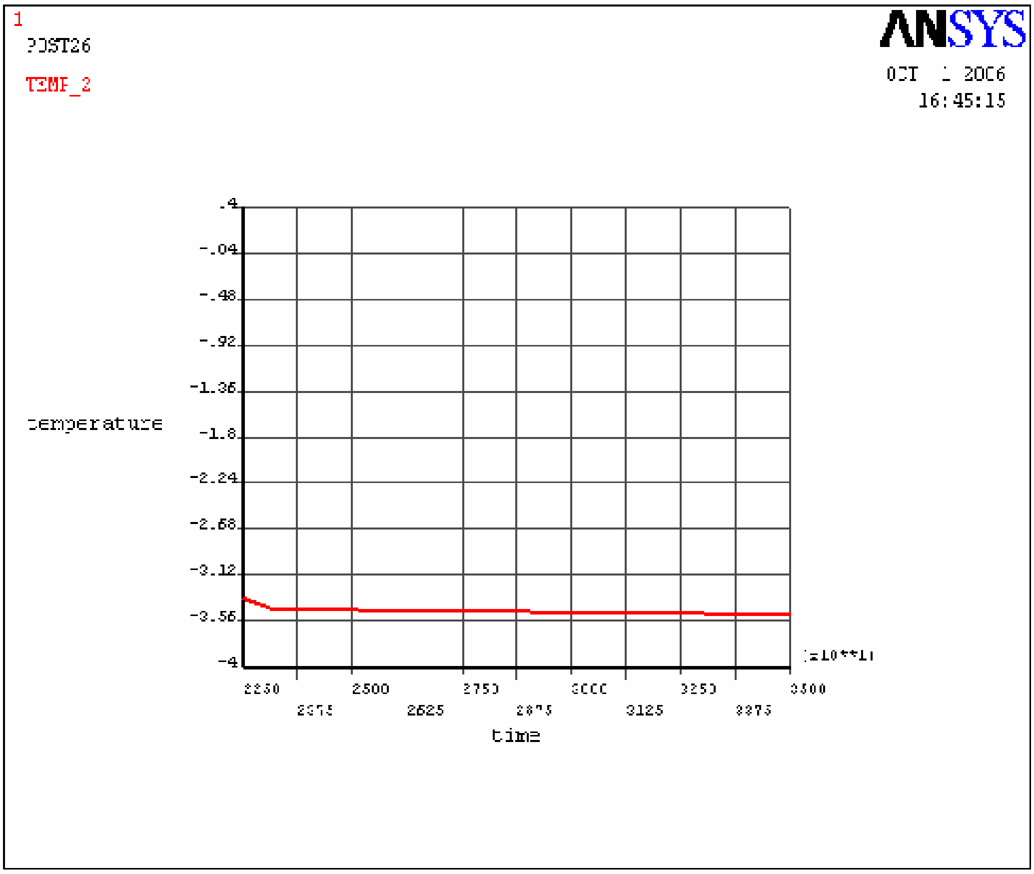

Figure 11. Phase change breaking point nodule of size 98mm.

CONCLUSIONS

The study on thermal energy systems depicts that to obtain a steady state temperature of -3.8°C, this eutectic mixture requires continuous cooling for 3100 seconds, 12000 seconds, and 23000 seconds for nodules of diameter 77 mm, 88 mm, and 98 mm respectively. The heat transfer capacity of nodules of diameter 77 mm, 88 mm and 98mm are 47.66 kWh, 45.369 kWh and 45.01 kWh respectively. Hence the results indicate that the reduction in nodule diameter leads to lesser time for attaining a steady state. It also indicates that heat transfer decreases with increasing nodule diameter.

SUMMARY

Venetian blind can have a major impact on building energy use and occupant's comfort. But manual or motorized Venetian blind has limitations in meeting occupant's needs and in reducing energy consumption. These limitations can be overcome by the automatic control of the Venetian blind. This study aims to analyze the control method of commercially used automated Venetian blind and to evaluate the environmental performance of this type of blind. The environmental performance of an automated Venetian blind was evaluated by a real-scale experiment and occupant's response in summer. The enhancement of environmental performance by the application of an automated Venetian blind was confirmed.

1. INTRODUCTION

Recently, cooling loads through the building envelope has greatly increased with the increase of glass area in office buildings in Korea. Windows provide occupants with daylight, direct sunlight, visual contact with the outside and a feeling of openness. While it is desirable to introduce sunlight for natural lighting over a given constant level, the radiation heat of the sun has to be determined to allow its entrance or not according to the weather conditions. The radiation heat from the sun reduces the heating load in the winter season but increases the cooling load during the summer season. Due to the characteristics of solar energy, which is comprised of light and heat, solar energy is not easy to control; that is, daylight introduction and excessive heat isolation have to be considered at the same time. In addition, excessive sunlight will cause glare problems in an office space, which are a major complaint by occupants. These glare problems must also be taken into consideration.
In office buildings, since the reduction of the opening ratio and the design of the windows orientation are restricted from the design perspective, Venetian blinds are generally used to control the incoming solar radiation. Venetian blinds are better than roll blinds because they can be controlled to slat angle as well as to occlusion index.
Venetian blinds can greatly affect building energy use and occupant comfort, so it is important to control Venetian blinds properly according to the change of the external weather condition for enhancement of indoor environment. But previous studies have shown that in reality, occupants rarely change the position of the manual or motorized Venetian blind [1] [2] [3] [4] [5] [6] [7]. The manual or motorized Venetian blind has limitations in meeting occupant's needs and in reducing energy consumption. To overcome these limitations, the Venetian blind must be controlled automatically. The use of the automated Venetian blind,

controlled automatically by sensors according to the external weather condition, would be more effective than the manual or motorized Venetian blind. During times of peak solar gain, such a blind can reduce cooling loads and overheating. Under cloudy conditions, or in winter, it can be withdrawn to allow daylight and useful solar gains to enter the building, so that the building can reduce its dependence on electric lighting and heating requirement. To achieve this condition, the blind should be properly controlled. Otherwise, unwanted solar gain may enter the building and increase the cooling load. Occupants may experience glare from the sun and be unable to operate the shading to alleviate it.

This study aims to analyze the control method of the commercially used automated Venetian blind and to evaluate its environmental performance in comparison to the manual or motorized Venetian blind. The environmental performance of the automated Venetian blind was evaluated by a real-scale experiment and occupant's response in summer. Finally, the potential of energy savings and comfort enhancement by use of the automatic control was confirmed.

2. BLIND TYPE AND OPERATION SURVEY

A blind can be categorized into manual, motorized and automated according to its control method. The manual blind is the simplest type of blind without a motorized device. It is controlled directly by the occupant and used generally in modern buildings. But the occupants control the manual blind only when they feel discomfort [8]. In fact, manual blind control has problems because occupants do not control the blind until they feel discomfort such as glare and solar radiation. The motorized blind that can be controlled by a remote controller, and in some buildings, computer are used to control motorized blinds. Though the motorized blind can be controlled easier than the manual blind, it is operated inefficiently in real situations. According to the operation survey of actual motorized blinds, though it is able to control the motorized blind in central control room, central control is not used by the occupants need and 82.6% of all motorized blinds do not move, as shown in Tables 1 and 2. Also, the occlusion index of the stopped blind is usually, almost opened (0 ~ 20%) or closed (80 ~ 100%), as shown in Table 3. An automated blind is automatically controlled by sensors according to the external weather condition to enhance environmental performance.

A motorized blind requires higher initial cost than a manual blind but does not produce better environmental performance. Therefore, the application of automated blind is necessary.

3. EVALUATION EXPERIMENT ON ENVIRONMEMTAL PERFORMANCE BY AUTOMATED BLIND

3.1 Outline

The effects of commercially used automated blind on thermal and visual environment performance and comfort are compared with those of conventional manually operated blinds. The product specification of an automated blind used in this experiment is presented in Tables 4 ~ 6. In the test room, located on the top floor of a building in Seoul National University, Korea, evaluation experiments were conducted to measure the energy saving effect and occupant comfort enhancement for the month of August 2006.
Two test rooms of dimensions 5.8m x 4.8m x 2.7m with the same architectural planning were used to reproduce the same conditions. Each room was equipped with an internal Venetian blind of same material and color, and the blind in one room was manually controlled and that in the other room automatically controlled, as shown in Figure 1 and 2. Various instruments were installed inside and outside the rooms to measure and analyze the various environments, as presented in Table 7.

3.2 Method

In order to investigate the effect of the automated blind on the environmental performances of the rooms in the summer season, experiments were conducted for four cases, as presented in Table 8. In test room 1, the energy saving mode and comfort mode, which were controlled by an outdoor illuminance sensor, were selected. When in the energy saving mode, it was set up to shut out the solar radiation at the maximum level within the control range (see Table 5), and in the comfort mode, the slat angle was controlled to cut off direct daylight (although allowing some daylight to enter), in consideration of the working hours of the occupants and the comfort factor (see Table 6).

4		Motorized*		

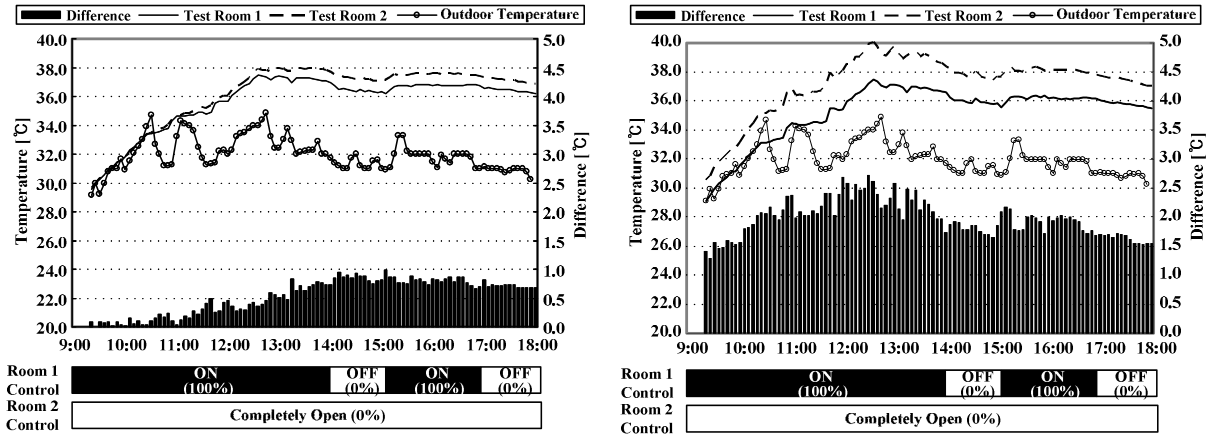
* Occlusion index 75%, Slat angle: 90°

For the set up of the compared blind, three model cases were selected, in which the blind was completely open (occlusion index: 0%), the blind was completely close (occlusion index: 100%, Slat angle: 90°), and the blind was motorized (occlusion index: 75%, Slat angle: 90°), respectively. The latter case represented the results of the blind operation survey. In cases 1 and 2, the characteristics of automatic control in terms of energy consumption in comparison with those of the extreme case of manual control were verified by comparing temperature and workplace illuminance. In cases 3 and 4, the conditions (with and without automatic control) were compared by PMV measurement and workplace illuminance, and a questionnaire was conducted four times per day(10:00, 12:00, 14:00, 16:00) to investigate their characteristics with regard to comfort. For each case, the experiments were conducted from 09:00 AM to 18:00 PM, without artificial lighting.

4. EXPERIMENT RESULT AND DISCUSSION

4.1 Case 1 : energy saving mode vs. completely open

Case 1 was conducted on August 12th. On this day, the sky was fairly clear but became rather cloudy from 13:00 ~ 14:00. The temperature of the interior zone of the test room is shown in Figure 3 a).
The temperature in test room 2 was higher than that of test room 1. Because solar radiation was effectively shut out in the energy saving mode, the temperature in test room 1 was lower than test room 2 by a maximum of 1.0℃. For the perimeter zone, which is directly subject to solar radiation, the temperature difference was greater. In Figure 3 b), the perimeter zone temperature of test room 1 was lower than that of test room 2 by a maximum of 2.7℃.



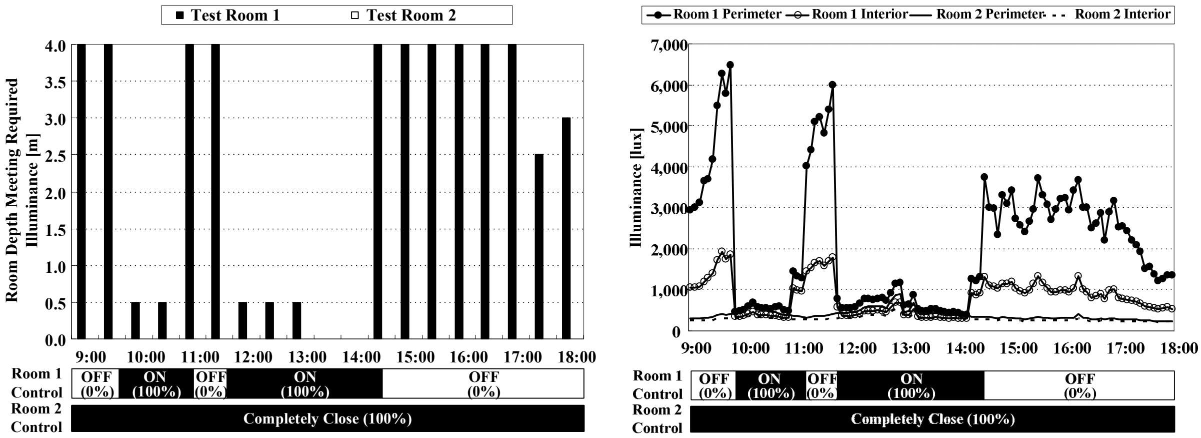
a) Interior zone b) Perimeter zone

Figure 3. Temperature profile of case 1.

In conclusion, the rise in room temperature was effectively reduced by the automated blind. In particular, in the perimeter zone, the automated blind effectively shut out solar radiation to reduce temperature rise. Especially, on clear summer day, the cooling load by the excessive solar radiation can be minimized through the appropriate automatic control of blind.

4.2 Case 2 : energy saving mode vs. completely close

Case 2 was conducted on August 16th. The sky was cloudy all day. There was little temperature difference between the two test rooms. Therefore, though the blind was fully opened a few times during the experimental period in response to the external weather condition, the cooling load of test room 1 was slightly higher than that of test room 2, but the lighting energy of test room 1 could be saved by introducing daylight.
The room depth meeting the required illuminance profile at the workplace in the two test rooms are shown in Figure 4. Compared to test room 2(completely close), which needed artificial lighting “on” whole day, test room 1 could satisfy the illuminance criteria(≥500lux) during most of the experiment period without artificial lighting because daylight was introduced. So the lighting energy of test room 2 was saved.
Consequently, the overall energy consumption, including cooling and lighting energy consumption, could be reduced by using the automated blind. In addition, the automated blind provided an open field of vision and a view of the outside scenery.



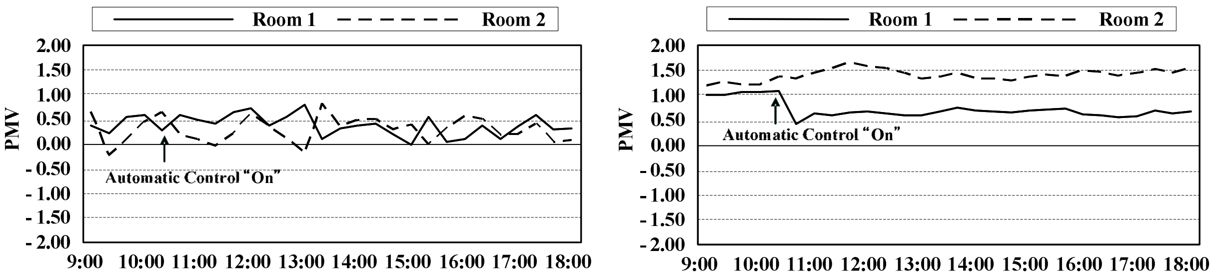
a) Room depth within satisfied range b) Workplace illuminance profile

Figure 4. Analysis of the satisfied range and measured workplace illuminance of case 2.

4.3 Case 3 : comfort mode vs. completely open

Case 3 was conducted in August. The sky was clear.

A representative comfort indicator PMV was measured in two test rooms to determine the degrees of comfort of the two test rooms, as shown in Figure 5. In the interior zone, since both rooms were air-conditioned continuously and the PMV meter was installed away from the influence of solar radiation, the difference in the measured values was insignificant, and largely satisfied with the comfort criteria (-0.5 < PMV < +0.5) of the ISO. However, in the perimeter zone, which is directly subject to the influence of solar radiation, the PMV measured in test room 2 remained constant between 1.2 and 1.6, which indicated a discomfort environment. However, the PMV in test room 1 fell by about 0.5 at 10:30 when the blind began to be controlled, and as a result, enhanced the degree of comfort.

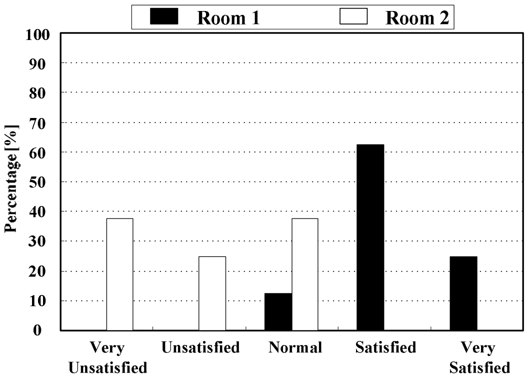


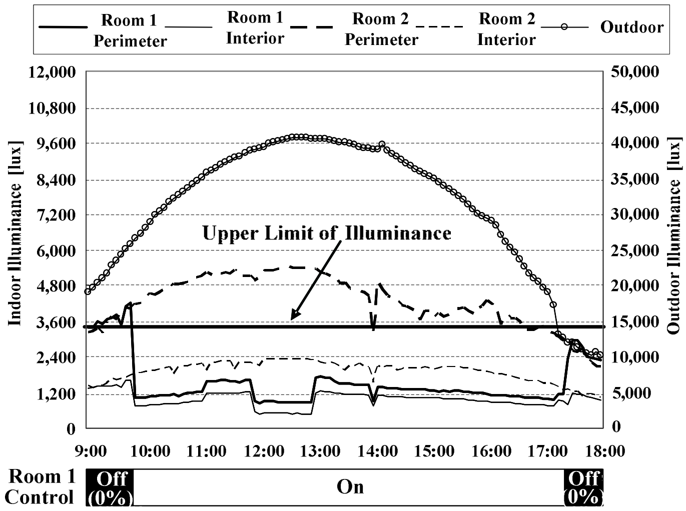
a) Interior zone b) Perimeter zone

Figure 5. PMV profile of case 3.

With respect to the overall operation of the blind, 87.5% of the subjects in test room 1 were satisfied, while 62.5% of those in test room 2 were dissatisfied due to the rise in temperature resulting from solar radiation as shown in Figure 6 a). With respect to workplace illuminance, both test rooms showed illuminance of higher than 500lux during entire experiment period, but in test room 2, the illuminance exceeded the recommended upper limit (3,340lux [9]) during most of the experiment period as shown in Figure 6 b). Test room 1, which was operated in the comfort mode, was maintained within the recommended value because slat angle was controlled to cut off direct sunlight but allow daylight to flow in.

Since the experiment had been conducted during a period of hot weather and clear sky, solar radiation must have had great impact on the result. Consequently, the degree of direct radiation and direct light should be appropriately controlled with a blind to protect the occupants from glare and to improve comfort.





a) Overall satisfaction b) Illuminance profile

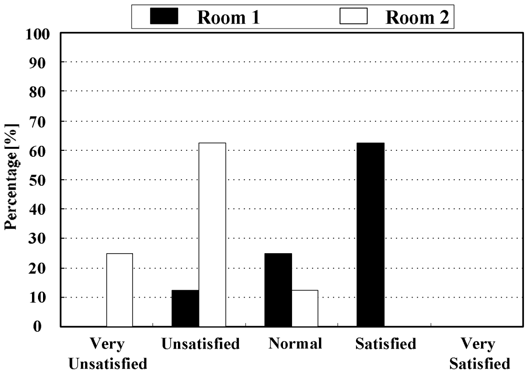
Figure 6. Subject response and illuminance profile at workplace of case 3.

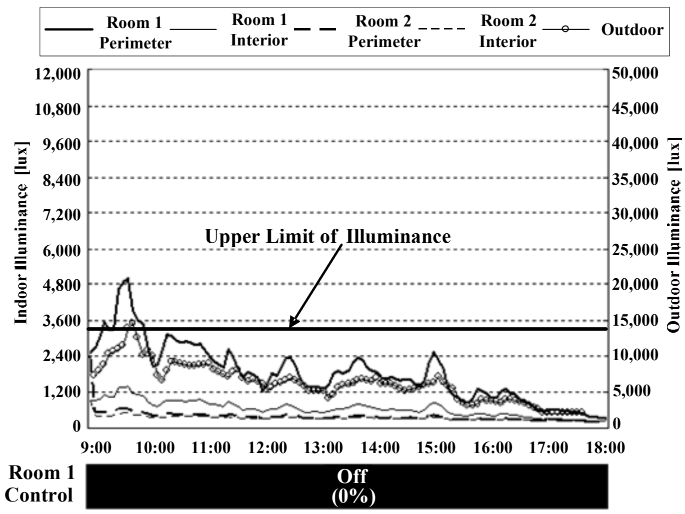
4.4 Case 4 : comfort mode vs. motorized

The experiment was conducted on August 29th, a cloudy day with rainfall starting from the late afternoon. Motorized blind condition was determined based on the operation survey results. Since the weather was cloudy and no significant influence from solar radiation was likely to be felt, no significant difference of PMV was observed due to the constant air conditioning, and the ISO comfort criteria were largely satisfied in both interior and perimeter zones.

With respect to the overall operation of the blind, subjects in test room 1 were satisfied since optimal illuminance could be obtained by automatic control, while subjects in test room 2 were dissatisfied with the brightness, since the blind kept shutting out the daylight greatly during the cloudy weather as shown in Figure 7 a).

With respect to workplace illuminance, test room 1 showed illuminance of higher than 500lux during most of the experimental period , but test room 2 under 500lux, as shown in Figure 7 b). Test room 1 was able to introduce more daylight by automatic control of the blind reflecting the outdoor weather condition.





a) Overall satisfaction b) Illuminance profile

Figure 7. Subject response and illuminance profile at workplace of case 4.

Based on the questionnaire and measurements, visual comfort could be improved without additional lighting by introducing daylight selectively with the automated blind in accordance with the prevailing weather conditions. Additionally, it was judged that an open field of vision could be provided by automatic control.

5. CONCLUSION

In this study, control methods of commercially used automated Venetian blind were analyzed and improvement effects of environmental performance were proven through the experiments on energy saving and comfort.

In the energy saving mode, cooling load was reduced more than that with the fully opened window because blind blocked solar radiation according to established conditions under the clear sky condition. In overcast sky, the blind allows daylight to enter according to established conditions and so it can reduce the lighting energy and minimize the cooling load increase, simultaneously. In the energy saving mode, in which the blind is only fully opened or closed, the modification of the occlusion index and slat angle is not considered. Therefore, we need a control method that can consider the lighting and cooling energy saving simultaneously by proper control of the occlusion index and slat angle.

In the comfort mode, the slat angle is controlled to cut off direct sunlight and this reduces the discomfort from excessive solar radiation and direct sunlight. Also, in this mode, daylight can be introduced to supply a feeling of openness to the occupant. Because modification of the occlusion index is not considered and modification of slat angle is limited to two times per day in the comfort mode, a more detailed and delicate control method which can consider the control of occlusion index is necessary.

The control method discussed in this paper is operated only through external weather condition sensing. But the purpose of blind control is to improve indoor environment, so a more effective and enhanced control method which can reflect indoor environment needs to be developed by sensing internal factors such as workplace illuminance, indoor temperature etc.

The University of the Basque Country, Alameda Urquijo s/n, 48013, Bilbao, Spain

Correspondence e-mail: bckurpem@ehu.es

ABSTRACT

The trend to reduce energy losses through enclosures (walls and windows) is an increasingly important part of improving the energy efficiency of a building. Adequate window design and orientation can reduce the heating and cooling requirements of a building.

An optimization process was undertaken for a single-zone building envelope, based on the climate of the Basque Country and using a parametric study of annual heating requirements, according to glazing type and orientation. Two software were used in the analysis: WINDOW 5.2 for window thermal performance and TRNSYS 16 for building thermal simulation.

The results of the study were applied to the case of a single-family dwelling to predict energy savings for heating, based on the recommended window type for each orientation.

INTRODUCTION

Windows play a key role in the energy efficiency of both residential and commercial buildings. At least one-fourth of domestic heating requirements in OECD countries (Muneer T. et al, 2000) are considered to be the result of energy losses through windows. In recent years, major efforts have been made to improve the thermal behavior of windows using various technologies, such as low-emissivity (low-E) coatings, inert gas fill, insulating edge spacers, low-conductivity frames, etc. This approach has led to windows with a thermal transmittance as good as a wall.

Energy consumption in buildings depends largely on the type of building, whether residential or commercial. In the latter case, 90% of the heating and cooling is linked to losses and gains through the façade, particularly through windows, which are the most sensitive to heat flows. Energy requirements are a function of various factors such as climate, building location, season of the year, and operational and functional conditions.

This study analyzes the influence of window type on heating requirements for the climate of the Basque Country. To accomplish the objective, two simulation tools were used: WINDOW 5.2 to determine the thermal performance of window systems and TRNSYS 16 to simulate the heating requirements of the building envelope.

NOMENCLATURE	
A	Area (m^2)
c_p	Specific heat (J/kg-K)
g	Solar heat gain coefficient
R	Thermal resistance (m^2K/W)
R_{fsol}	Solar reflectance of the exterior-facing surface of the glazing system
R_{bsol}	Solar reflectance of the interior-facing surface of the glazing system
R_{fvis}	Visible reflectance of the exterior-facing surface of the glazing system
R_{bvis}	Visible reflectance of the interior-facing surface of the glazing system
T_{sol}	Solar transmittance
T_{vis}	Visible transmittance
U	Thermal transmittance or U-factor (W/m^2K)
α_1	Absorptance of the first pane in the glazing system, counting from the exterior-facing surface
α_2	Absorptance of the second pane in the glazing system, counting from the exterior-facing surface
α_3	Absorptance of the third pane in the glazing system, counting from the exterior-facing surface
ρ	Density (kg/m^3)

DESCRIPTION OF BUILDING ENVELOPE AND STANDARD WINDOWS

The building envelope considered is similar to the one described in ANSI/ASHRAE Standard 140/2004, consisting of a single-zone enclosure of 8.0 m x 6.0 m x 2.7 m, fitted with two windows of 3.0 m x 2.4 m, as shown in Figure 1. The thermophysical properties of the materials used for the model are listed in Table 1, which correspond to the configuration of the high-mass enclosure described in the ANSI/ASHRAE Standard 140/2004 mentioned above.

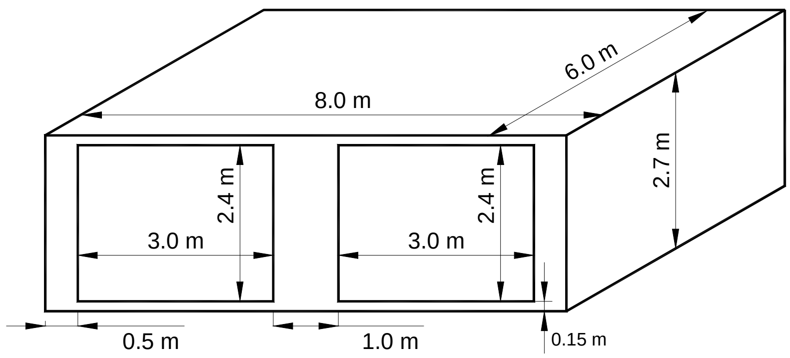

Figure 1. Simulated building envelope for determination of heating requirements

Tables 2 to 4 show the characteristics of the various types of windows and glazing used in the study. The coating position is indicated by numbering the pane surfaces from exterior-facing to interior-facing. The effect of varying the glazing was analyzed, while using the same PVC frame for all windows. Double-pane glazing (Type 1) was taken as a reference. The window Type 2 is a double-pane glazing with a low-E coating and a high solar gain (0.72). Type 3 is a double-pane glazing with low-E coating and a moderate solar gain(0.61) and Type 4 is a double glazing with low-E coating and a low solar gain (0.40), spectrally selective. When compared to tinted glass, this glazing system has the property of greater visible transmittance (in this case, 0.70). A common measure of the efficiency of spectrally selective glass is given by the light-to-solar ratio. This is the visible light transmission divided by the solar heat gain coefficient for the glazing system.(in this case, 1.76, with a maximum possible ratio of 2).

Low-E coatings reduce radiative heat transfer. If a lower conductive-convective heat transfer in the air-gap is also desired, then gases with a lower thermal conductivity than air can be used, as occurs with windows Type 5. If heat flow through the system is to be further decreased, triple glazing with two low-E coatings and a low-conductance gas can be used; this is the configuration chosen for the window Type 6 .

BUILDING ENVELOPE MODELING AND SIMULATION TOOL

The energy analysis of the building envelope was performed using TRNSYS 16, a transient simulation software of thermal systems created by the Solar Energy Laboratory of the University of Wisconsin. The TYPE 56 multi-zone model was used for both the model envelope and the single-family dwelling.

The most important heat flows considered in this TYPE are a long-wave radiative exchange with the exterior environment, a convective heat exchange and a fraction of absorbed solar radiation. There is also a transient heat exchange through the wall layers, modeled using transfer functions (Mitalas and Stephenson, 1971). Long-wave radiation heat exchange between the interior surfaces of the building envelope are estimated using the star network method implemented by Seem (1987).

The TRNSYS software allows importing a file with the optical data and thermal and solar properties of windows from the WINDOW (LBNL) software. The WINDOW calculation procedure (Finlayson et al., 1993) used to obtain an overall window property is based on computing an area-weighted average of the properties of each component of the window (ISO 15099). The total heat flow through a glazing system can be divided into the heat loss flow depending only on temperature difference and the heat flow depending on the intensity of the short-wave radiation.

SIMULATION OF MODEL ENVELOPE

The simulation was performed using climatic data from two Basque cities: Bilbao (43.30º N, 2.93º W) and Vitoria (42.51º N, 2.40º W). The climate of Bilbao is a temperate oceanic climate, whereas Vitoria has a temperate continental climate. The mean annual ambient temperature is 14.3ºC for Bilbao and 11.2ºC for Vitoria, whereas the mean annual irradiance of global horizontal radiation is 146 W/m^2 and 164 W/m^2, respectively. Since the TRNSYS building model requires hourly data to estimate energy requirements, Meteonorm 5.1 (Meteotest, Edition 2003) was used to generate files with typical meteorological year data for the cities under consideration.

The building envelope operating conditions described in ANSI/ASHRAE Standard 140-2004 were used, i.e. continual infiltration throughout the year of 0.5 air changes per hour, an internal gain of constant sensitive heat of 200 W, with a 60% radiant fraction and 40% convective fraction. A temperature setting of 20ºC for heating was used as a control strategy to estimate energy requirements.

Based on the results obtained, an analysis was then carried out to analyze the sensitivity of annual energy requirements to the following factors: type of glazing and orientation. The effect of window orientation was analyzed by turning the building envelope in steps of 90º, such that the only wall with windows was oriented toward the north, south, east and west. The heating season is considered to be from October to May. The heating requirements for the cases studied according to orientation are shown in Tables 5 and 6.

Table 5. Heating requirements according to orientation and window type (kW.h) for Bilbao

	Type 1	**Type 2**	**Type 3**	**Type 4**	**Type 5**	**Type 6**
N	2493.28	1915.78	1908.07	2112.7	1718.94	1594.17

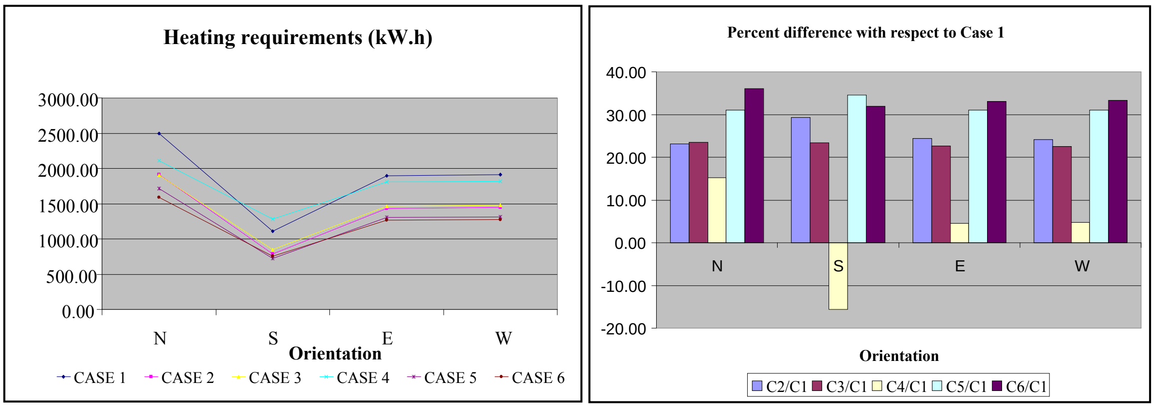
Table 6. Heating requirements according to orientation and window type (kW.h) for Vitoria

	Type 1	**Type 2**	**Type 3**	**Type 4**	**Type 5**	**Type 6**
N	4026.20	3202.44	3196.80	3466.45	2893.81	2696.41
S	1904.77	1346.13	1485.83	2234.19	1274.49	1353.61
E	3072.65	2376.32	2450.00	2934.62	2206.13	2152.26
O	3117.02	2404.50	2472.00	2954.25	2227.40	2158.40

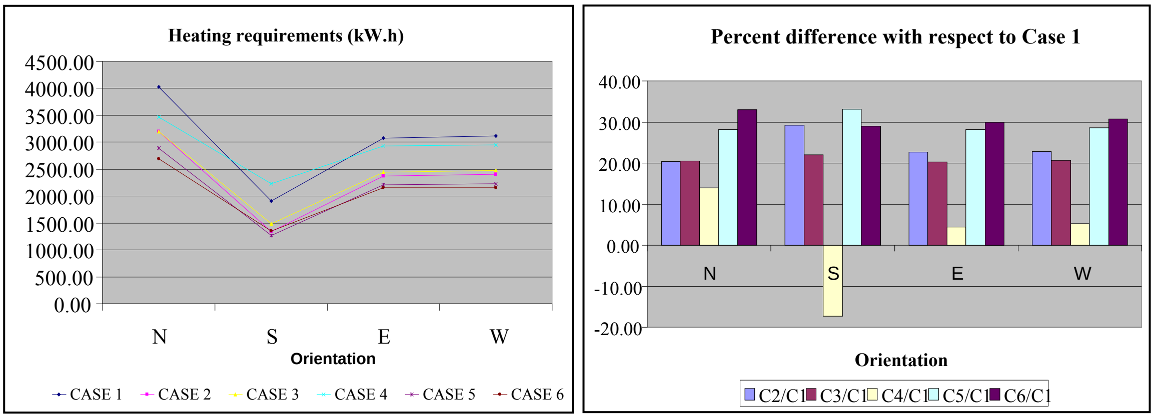
Type 1, which corresponds to an uncoated double-pane glazing, was taken as the reference case, and the heating energy savings obtained by replacing this by other glazing types were then analyzed. The conclusions obtained for the Basque cities were similar, since their climates are not much different. Figures 2 and 3 show the results obtained for Bilbao and Vitoria, respectively.

When replacing the reference glazing with low-E double glazing Type 2, the heating requirement decreases in all directions, particularly the southern direction, with a 29% decrease for Bilbao. Therefore, the glazing Type 2 is appropriate for the climatic zone of the Basque Country. In the southern direction, this pane works well in winter, since it is low-E glass with high solar heat gain. Its high longwave infrared reflectivity bounces the thermal radiation, which originates in the space, back into the space. This also true for glazing Type 3.



(a) (b)

Figure 2. For Bilbao: (a) heating consumption for each window type, (b) % differences with respect to Type 1.



(a) (b)

Figure 3. Vitoria: (a) heating consumption for each window type, (b) % differences with respect to Type 1.

COMMENTS

If low-E double glazing Type 3 is used, the heating requirements are lower in all directions considered, making this an appealing option. However, in the southern direction, the effect is less noticeable than with glazing Type 2, because Type 3 has a moderate solar gain (0.61) with a lower solar transmittance (0.53). For both Bilbao and Vitoria, the heating requirements are lower with windows Type 2 than Type 3, except on the northern side. Therefore, glazings Type 2 are recommended for all orientations, and glazings Type 3 are strongly recommended for the northern direction.

If a double-pane glazing is replaced by a spectrally selective glazing (Type 4), somewhat higher heating requirements are obtained on the southern direction and the savings are minimal on the other sides, since the solar heat gain (solar factor of 0.40) is lower. This type of glazing is adequate, particularly in climates where cooling is required. Spectrally selective coatings, which are not only highly reflective in the far infrared, but also in the near, are not recommended for these locations, which require heating during part of the year.

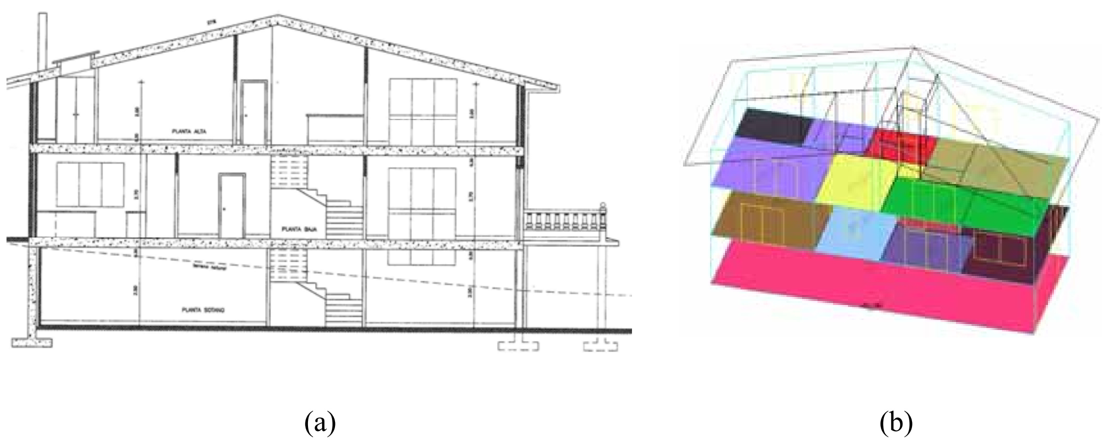
The glazing Type 5 is a version of glazing Type 3 in which the air gap is replaced by a gas of a lower conductivity. In addition to reducing radiation heat exchange, this approach reduces heat transfer by conduction-convection with the low-E coating. This type of glazing results in considerably lower heating requirements than those achieved with uncoated double glazing and similar to those obtained with triple glazing with low-E coatings. In particular, 31% savings is achieved for Bilbao in the northern, eastern and western directions, and 34% in the southern direction.

Triple glazing Type 6 represents a good option from the energy point of view, since it decreases the heating requirements considerably, achieving 36% savings in the northern direction and 32% in the southern for Bilbao for the model envelope.

ENERGY SAVINGS IN A SINGLE-FAMILY DWELLING

A heating consumption study of a single-family dwelling located in Bilbao was conducted by varying the glazing type. Figure 4 shows the single-family dwelling that was simulated. The window with glazing Type 1 was taken as a reference. Considering a mean system efficiency of 70%, the heating requirements were determined by performing the following simulations: with windows Type 1, with windows type 3 for northern orientation and type 2 for all other orientations and with windows Type 5 for all orientations

The results are shown in Table 7. The savings obtained when replacing the reference window with others are lower than when doing so with the ASHRAE envelope. This is primarily due to the fact that the model envelope has large windows and its walls are better insulated. In addition, whereas in the physical model, the effect of glazing surfaces has been analyzed for each orientation separately, in the actual case, a combination of glazing areas in the various orientations was used. Replacing Type 1 by a combination of Type 2 and 3 according to the orientation, 9.1% savings in heating requirements were obtained. When Type 5 was used, similar savings were achieved.



(a) (b)

Figure 4. (a) Cross-section of the simulated home, (b) thermal areas defined for Trnsys

Table 7. Results obtained when varying window types in a single-dwelling home.

	Heating consumption, kW.h	**%**
Type 1	16984.04	
Type 2/3	15440.26	9.09
Type 5	15432.61	9.13

CONCLUSIONS

Double glazings Type 4 are not interesting from the heating viewpoint. In south-facing windows, there is a loss with respect to the glazing taken as the reference. In other directions, the savings that would be produced are insignificant compared to other low-E windows.

Cases of interest for the climate of the Basque Country are glazings Type 2 and 3, e.g., low-E glass of 0.155 and 0.066, with high and moderate solar gain, respectively. With these panes, the heating requirements decrease for all orientations, making them truly of interest for our climate conditions. In the southern, eastern and western directions, glazing Type 2 is prefered, whereas Type 3 is prefered for the northern direction, due to higher longwave reflectivity. Therefore, these types of glazing are suitable for residential buildings. In this study, 9% savings was obtained by using a combination of glazings Type 2 and 3.

Type 5 is similar to Type 3, in which the air-gap has been replaced with argon, thus decreasing the conductive-convective exchange. This represents a slight improvement over Types 2 and 3, but may be important in the case of large windows, depending also on the type of enclosure.

The application of the results to the actual case confirms the trends observed with the model envelope. The extent of percent savings will depend on the specific characteristics of the building, in particular, the relative area of glazing surface and the inertia and insulation of the enclosure.

Natural Convection Heat Transfer in a Saltbox Roof with Eave in Winter Day Conditions

Ahmet Koca, Hakan F. Oztop and Yasin Varol

Firat University, Turkey

Corresponding email: ysnvarol@gmail.com

SUMMARY

In this study, a numerical analysis has been performed to examine the natural convection heat transfer and flow field inside a saltbox roof with eave in winter day conditions. This analysis is important for applications since it shows the effective parameters on natural convection heat transfer. The governing equations of natural convection in streamfunction-vorticity form were solved using central difference method to obtain flow and temperature fields inside the roof. Also, the Successive Under Relaxation (SUR) technique was used to solve linear algebraic equations. Results are presented by streamlines, isotherms and local and mean Nusselt number by using effective parameters as Rayleigh number, aspect ratio of the roof, and length of eave. The results indicated that both eave length and aspect ratio can be used as control parameter for heat transfer.

Keywords: *natural convection, saltbox roof, eave*

INTRODUCTION

Natural convection is formed in some parts of buildings due to temperature difference between cold and hot surfaces. The roof is an important part of the building because it protects the building from the environmental effects. Natural convection heat transfer occurred inside the roof due to temperature difference which depends on the climate such as winter or summer.

Natural convection heat transfer analyzed in differentially heated square or rectangular enclosures in earlier studies due to simplicity of numerical solution [1]. However, the number of study about partially heated enclosures is very limited and they investigated mostly for square cross sectional geometries [2-4].

Researchers the natural convection in roofs using different numerical techniques for triangular cross-sectioned roofs (Gable roofs) were investigated by different researchers. Asan and Namli [5] investigated the laminar natural convection heat transfer inside the triangular roof with different aspect ratio in winter day boundary conditions. They observed that, both aspect ratio and Rayleigh number affect the heat transfer inside the roof. Tzeng et al. [6], Akinsete and Coleman [7], Holtzman et al. [8] and, recently, Ridouane et al. [9] investigated the laminar natural convection inside the triangular cross-section enclosure which is applicable for roof geometry of building at different constant temperature or constant heat flux boundary conditions. On the other hand, Varol et al. [10,11] investigated the natural convection in different roof shapes including Gambrel and Saltbox roofs. They observed that natural convection flow fields strongly depend on the geometrical shape and thermal boundary conditions of the roof. Moukalled and Acharya [12] analyzed the natural convection heat transfer in a trapezoidal roof with baffles that located at the top and bottom of the wall. They indicated that baffles are effective parameters on thermal field inside the roof.

The main purpose of the present study is to analyze the flow and thermal fields inside the saltbox roof with eave in winter day conditions. According to knowledge of the authors and literature review given above, laminar natural convection heat transfer has not been investigated yet for partially heated roofs. Thus, the present study will be the first attempt in that area and it will help the designers and constructers from the energy saving point of view.

The photo and physical model of the saltbox roof with eave and the boundary conditions is shown in Figure 1 with coordinate system. It is considered that the inclined surface and eave have constant cold temperature. Also, room ceiling (bottom surface of the roof) has constant hot temperature to simulate winter day boundary conditions. The vertical boundary has adiabatic with height, H. Thus, total length of the bottom of roof (L) can be calculated by adding the length of room ceiling (B) and the length of eave (E). An aspect ratio can be defined as the ratio of the height of the roof to the length of bottom wall (AR=H/L) which can be changed according to climatical conditions.

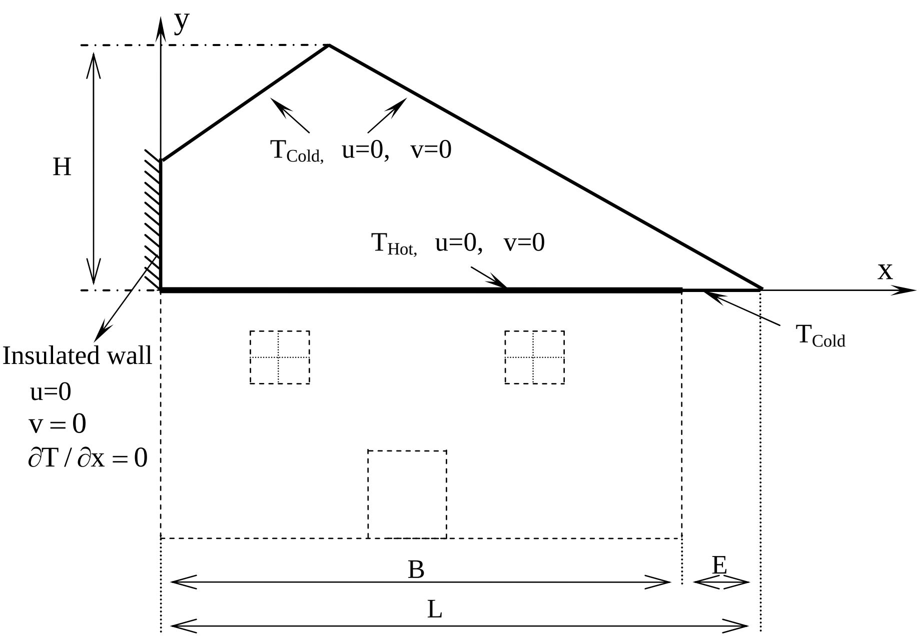

Figure 1b. Physical model

GOVERNING EQUATIONS AND NUMERICAL SOLUTIONS

The governing equations of natural convection (Eqs. 1-3) are written in streamfunction-vorticity form for laminar regime in two-dimensional form for steady, incompressible, and Newtonian fluid with Boussinesq approximation. It is assumed that radiation heat exchange is negligible according to other modes of heat transfer and the gravity acts in vertical direction.

$$-\Omega = \frac{\partial^2 \Psi}{\partial X^2} + \frac{\partial^2 \Psi}{\partial Y^2} \tag{1}$$

$$\frac{\partial^2 \Omega}{\partial X^2} + \frac{\partial^2 \Omega}{\partial Y^2} = \frac{1}{Pr}\left(\frac{\partial \Psi}{\partial Y}\frac{\partial \Omega}{\partial X} - \frac{\partial \Psi}{\partial X}\frac{\partial \Omega}{\partial Y}\right) - Ra\left(\frac{\partial \theta}{\partial X}\right) \tag{2}$$

$$\frac{\partial^2 \theta}{\partial X^2} + \frac{\partial^2 \theta}{\partial Y^2} = \frac{\partial \Psi}{\partial Y}\frac{\partial \theta}{\partial X} - \frac{\partial \Psi}{\partial X}\frac{\partial \theta}{\partial Y} \tag{3}$$

The employed non-dimensional variables are given as

$$X = \frac{x}{L},\quad Y = \frac{y}{L},\quad \Psi = \frac{\psi\,Pr}{\upsilon},\quad \Omega = \frac{\omega (L)^2\,Pr}{\upsilon},\quad \theta = \frac{T - T_{cold}}{T_{hot} - T_{cold}}, \tag{4}$$

$$u = \frac{\partial \psi}{\partial y},\quad v = -\frac{\partial \psi}{\partial x},\quad \omega = \left(\frac{\partial v}{\partial x} - \frac{\partial u}{\partial y}\right),\ Ra = \frac{\beta g (T_{hot} - T_{cold}) L^3\,Pr}{\upsilon^2},\ Pr = \frac{\upsilon}{\alpha}. \tag{5}$$

Boundary conditions for the considered model are depicted on the physical model (Figure 1(b)). In this model, boundary conditions as

On all solid walls, $u = v = 0$

On the adiabatic wall, $\frac{\partial T}{\partial x} = 0$

On the bottom wall, $0 < x < B$, $T=T_{Hot}$, $B \le x \le L$, $T= T_{Cold}$

On the inclined wall, $T= T_{Cold}$

Local and mean Nusselt numbers are calculated via Eq. 6 a and b, respectively.

$$Nu_x = \left(-\frac{\partial \theta}{\partial Y}\right)_{Y=0}, \qquad Nu = \int_0^B Nu_x\,dx \tag{6 a.b}$$

Governing equations in streamline-vorticity form (Eqs. 1-3) are solved through finite difference method. Algebraic equations are obtained via Taylor series and they solved using Successive Under Relaxation (SUR) technique, iteratively. The central difference method is used for discretization procedure. The detailed solution technique is well described in the literature [13]. The convergence criterion, 10^{-4}, is chosen for all depended variables and value of 0.1 is taken for under-relaxation parameter. Some grid tests are made between 34x23 and 352x235 to obtain optimum grid dimension. The test results showed that 214x143 grid dimension is enough for calculations.

RESULTS AND DISCUSSION

A numerical simulation is performed for a saltbox attic with eave for winter season. Different parameters such as Ra number, eave length and aspect ratio (AR) of the attic were tested to see the effects of these parameters on natural convection.

Figure 2 shows flow field (by streamline, on the left) and temperature distribution (by isotherms, on the right) for different Rayleigh numbers and E=6%, AR=0.6. Both AR and eave length represent real values which is used in architecture. In the case of small Ra number ($Ra=10^4$), conduction mode of heat transfer is dominant to convection and almost parallel temperature distribution is formed. For both $Ra=10^4$ and 10^5, two circulation cells are formed in different rotation directions. However, multiple cells are obtained for the highest Ra number, namely $Ra=10^6$ (Figure 2c). At this value of Ra number, plumlike temperature distribution is observed. However, for all values of Ra number, at the intersection point of bottom wall and eave, isotherms are stored due to higher temperature difference.

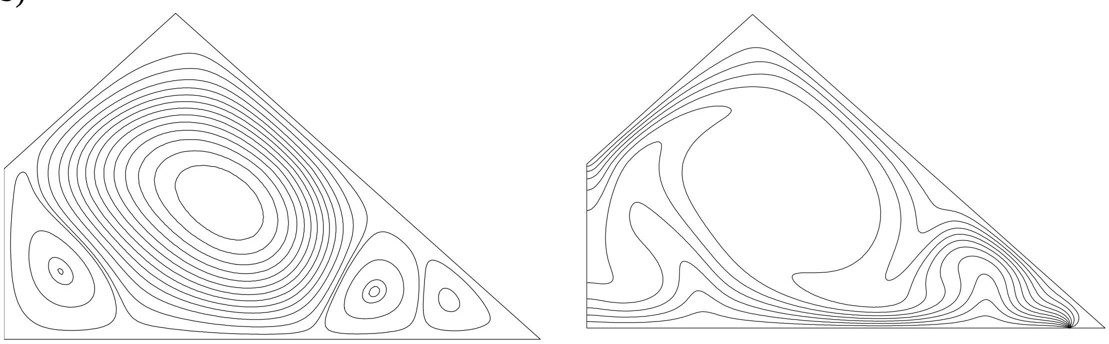
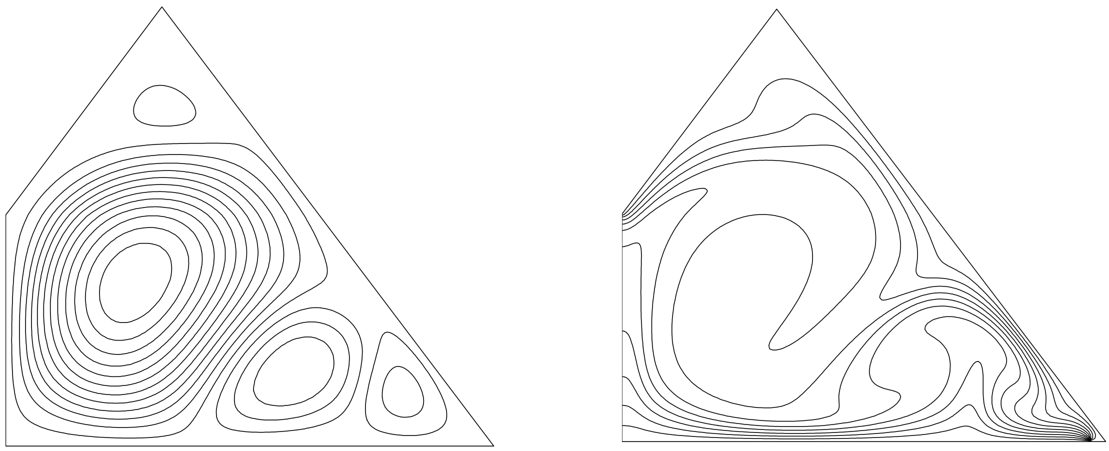
b)



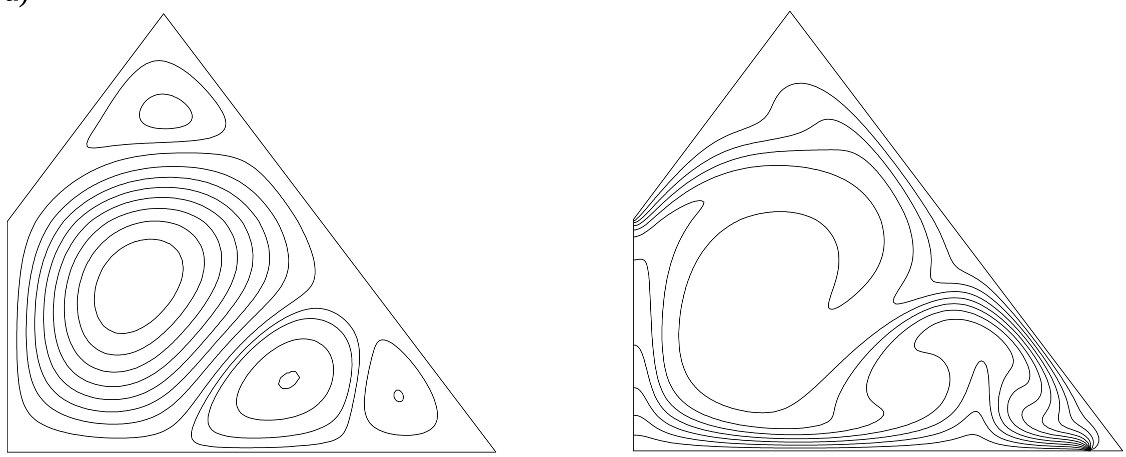
c)

Figure 2. Streamlines (on the left) and isotherms (on the right) at E=%6, AR=0.6, a) $Ra=10^4$, b) $Ra=10^5$, c) $Ra=10^6$

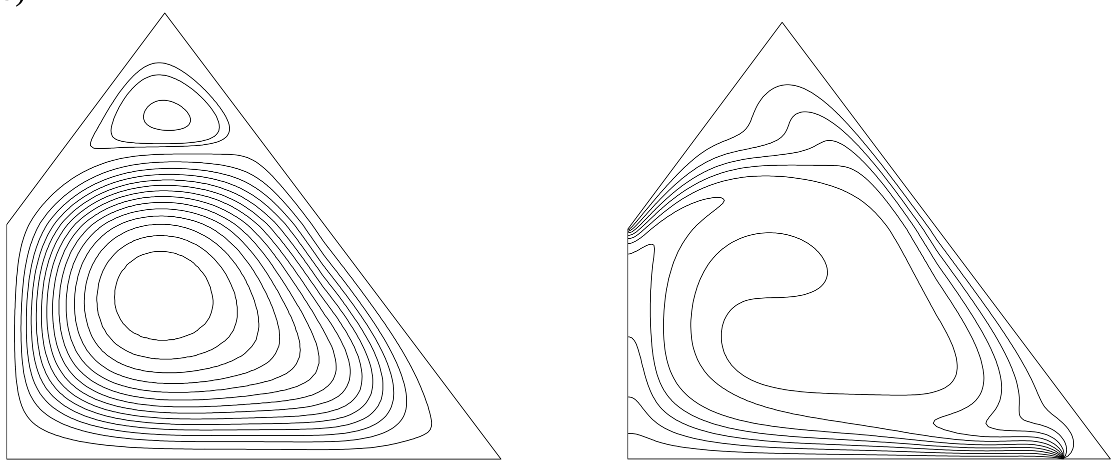
Figure 3 is presents the flow and temperature distribution for AR=0.9 and Ra=10^6 to show the effects of eave length. As can be seen from the figure, length of eave affects the isotherms and streamlines due to length of heated and cooled part of the bottom wall are changed. Strong plumelike distributions are observed for isotherm. Even, they show mushroom shaped distribution near the right corner. It means that strong convection is occurred. For the highest value of eave, two cells are formed which one of them locates to the top of the triangle like region and the other forms almost at the middle of enclosure (Figure 3(c)).



a)



b)



c)

Figure 3. Streamlines (on the left) and isotherms (on the right) at AR=0.9, Ra=10^6, a) E=3%, b) E=6%, c) E=9%

The results of mean Nusselt number are shown in Figures 4 (a) and (b) for different aspect ratios and eave lengths, respectively. Figure 4(a) shows that heat transfer decreases with increasing AR. However, conduction mode of heat transfer is dominant to convection at lower Ra number ($Ra<10^4$). It enhances with increasing Ra number due to domination of convection mode of heat transfer. Mean Nusselt number decreases with increasing eave length due to decreasing heater surface. It means that eave makes negative effect on heat transfer inside the roof. Variation of local Nusselt number with Rayleigh number and eave length is shown in Figure 5 and 6, respectively. In these figures, results are presented for both inclined and bottom surfaces. As can be seen from the Figure 5 (a) that results of local Nusselt numbers are close to each other due to domination of conduction mode of heat transfer along the bottom wall. However, higher values were obtained for $Ra=10^6$. At this value of Rayleigh number, local Nu number shows wavy variation. The highest Nu number was formed at the intersection point of eave and ceiling due to high temperature difference. Local Nusselt number shows similar variation along the inclined surfaces except intersection point of eave and ceiling. The variation of local Nusselt number for different eave length is shown in Figure 6 (a) (along the bottom surface) and 6(b) (along the inclined surface). As can be illustrated in Figures, length of eave directly affects the peak point of local Nusselt number due to changing of location of maximum temperature difference. Higher values were obtained due to increasing of heater surfaces.

CONCLUSIONS

Steady state flow field by natural convection in a saltbox roof with eave for different aspect ratios has been numerically studied. Based on the findings in this study, we conclude that heat transfer regime is conduction for lower Rayleigh numbers. Heat transfer increases with increasing of Rayleigh number with domination of convection mode of heat transfer. Due to geometrical shape of the roof at least double circulation number was formed. It is observed that number of cells is strongly depending on eave length and Rayleigh number. Higher heat transfer was formed for lower aspect ratios. Similarly, smaller eave length enhances the heat transfer.

Effects of Geometrical Shape of Roofs on Natural Convection for Winter Conditions

Ahmet Koca, Hakan F. Oztop and Yasin Varol

Firat University, Turkey

Corresponding email: ysnvarol@gmail.com

SUMMARY

In the practical applications, roofs of buildings can be in different shapes depending on architectural design of building or climate. Some of these building roofs can be classified as gambrel, saltbox and gable roofs. In the present study, we investigated the natural convection heat transfer and fluid flow inside the gambrel, gable and saltbox roofs for winter boundary conditions. With this aim, the identified roofs are compared with each other from the heat transfer and flow field point of view. Effects of Rayleigh number also tested in each type. Results are presented with streamlines, isotherms, local and mean Nusselt numbers. It is aimed that this study will help for designer to show more efficient ways of saving energy.

Keywords: *natural convection, roof, winter conditions*

INTRODUCTION

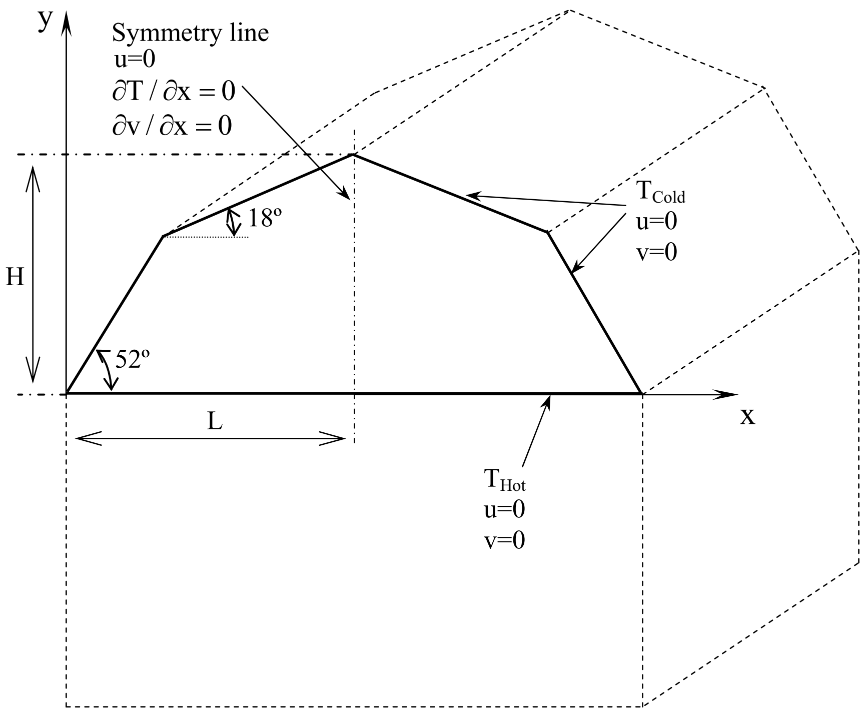
Roofs protect the building from environmental effects such as rain, snow and wind or particle matter in air. It also prevents the heat losses from environment to the room and vise versa. One can see different types of roofs as gambrel, gable, saltbox, and shed roofs etc. in urban or rural areas. These types of the roofs are chosen according to decorative view or type of the building. Both winter and summer day conditions natural convection heat transfer occurs inside the roof due to buoyancy forces and temperature difference between ceiling of the room and sloping wall of the roof.

Investigation of the natural convection heat transfer and fluid flow inside the roof is important to save energy and reduce to heating or cooling load of the building. Thus, cost of energy of the building will be decrease. Natural convection in roofs is analyzed mainly for gable roofs in the literature. Asan and Namli [1,2] investigated the natural convection heat transfer in gable roofs for both summer and winter day boundary conditions using finite difference techniques. They indicated that both aspect ratios of the roof and temperature boundary conditions are important parameters on temperature and flow fields inside the roof. Varol et al. [3] made a numerical solution for gambrel roofs for both summer and winter conditions. The same method applied the solution of natural convection inside the Saltbox roofs [4] and shed roofs with or without eave in summer conditions [5]. Natural convection in trapezoidal enclosure with offset baffles investigated by Moukalled and Acharya [6]. They tested the effects of baffle on buoyancy-induced flow and thermal fields in the trapezoidal shaped attics. They observed that conjugate baffles make important effect on natural convection and can be used control parameter for heat transfer.

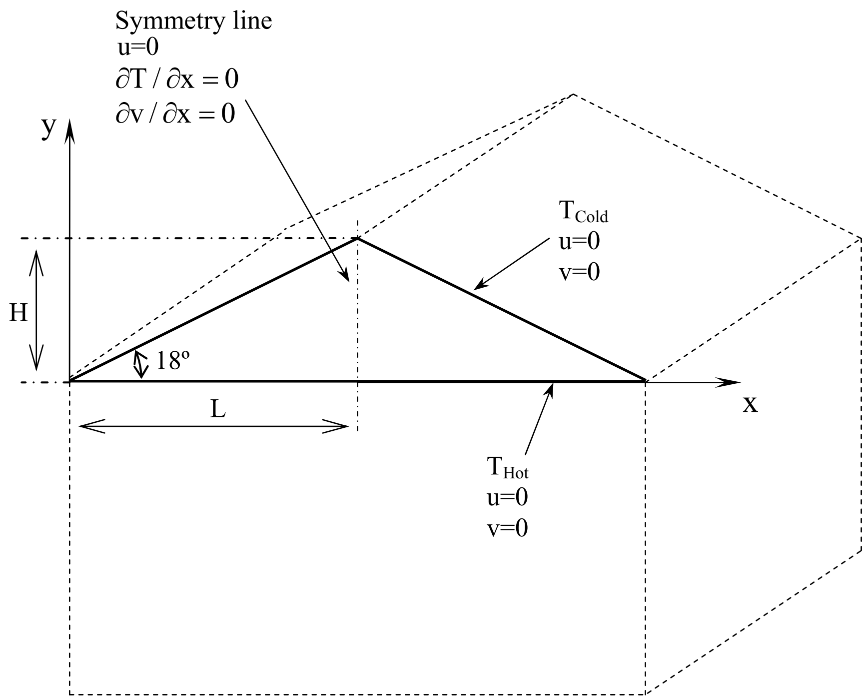
The main purpose of this study is to examine the natural convection heat transfer in the different types of the roof. These roofs are chosen as gambrel, gable, saltbox and compared with each other from the heat transfer point of view. The bottom area of the roofs is equal in each type to compare occurred heat transfer in the roof.

DEFINITION OF TREATED ROOFS MODELS

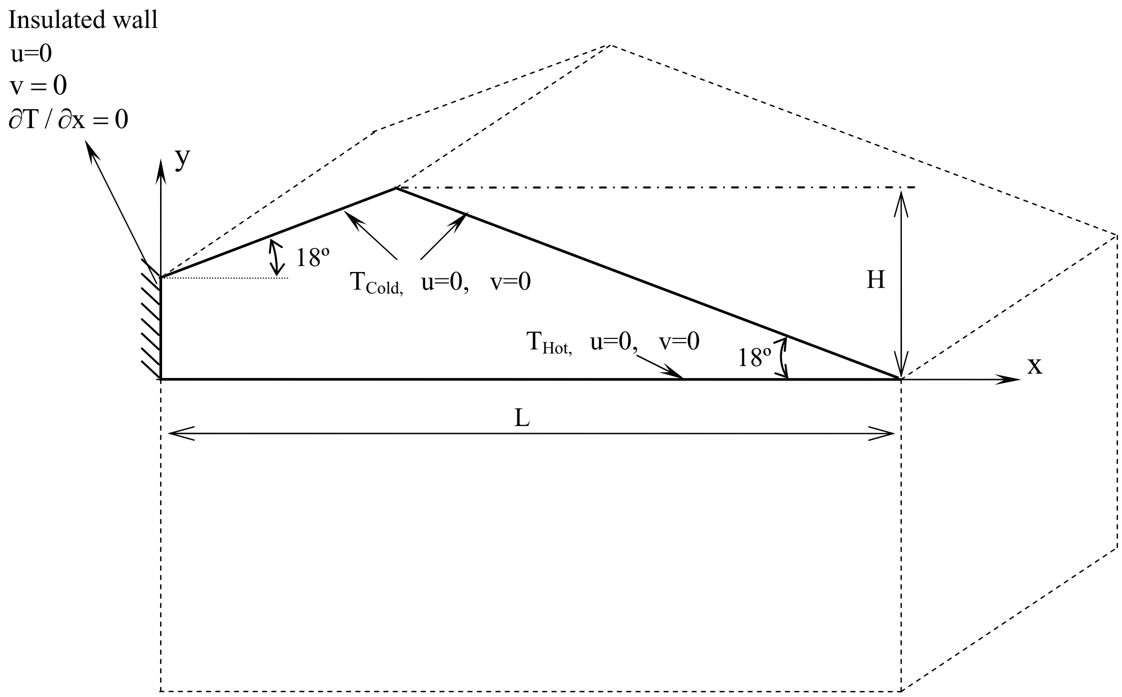
Three different roofs models were chosen to compare the effects of roof shape on temperature and flow field of natural convection. Figure 1 shows physical models for treated roof types. Inclination angle is the most important parameter for a roof which is chosen based on meteorological data of the region. To compare roof types in this study, inclination angle of roofs are chosen according to climate of the East Anatolian region of Turkey. Thus, main inclination angles are chosen 52^o and 18^o for gambrel, gable and saltbox roofs, respectively. Comparisons are performed depends on winter conditions. Thus bottom wall (ceiling of the room) behaves as heater and temperature of the inclined wall is colder than that of bottom wall.



a)



b)



c)

Figure 1. Different types of roofs a) Gambrel roof, b) Gable roof, c) Saltbox roof

Left part of the roof according to symmetry line was chosen as computational domain in each type except saltbox roof. Two-dimensional, steady-state and laminar solution were accepted. Further assumption was made that flow is incompressible and Newtonian. Thus, governing equations can be written as follows:

$$X = \frac{x}{L}, \quad Y = \frac{y}{L}, \quad \Psi = \frac{\psi \, Pr}{\upsilon}, \quad \Omega = \frac{\omega (L)^2 \, Pr}{\upsilon}, \quad \theta = \frac{T - T_c}{T_h - T_c} \tag{1}$$

$$u = \frac{\partial \psi}{\partial y}, \quad v = -\frac{\partial \psi}{\partial x}, \quad \omega = \left(\frac{\partial v}{\partial x} - \frac{\partial u}{\partial y} \right), \quad Ra = \frac{\beta g (T_h - T_c) L^3 \, Pr}{\upsilon^2}, \quad Pr = \frac{\upsilon}{\alpha}. \tag{2}$$

Based on the dimensionless variables above governing equations (stream function, vorticity and energy equations) can be written as

$$-\Omega = \frac{\partial^2 \Psi}{\partial X^2} + \frac{\partial^2 \Psi}{\partial Y^2} \tag{3}$$

$$\frac{\partial^2 \Omega}{\partial X^2} + \frac{\partial^2 \Omega}{\partial Y^2} = \frac{1}{Pr} \left(\frac{\partial \Psi}{\partial Y} \frac{\partial \Omega}{\partial X} - \frac{\partial \Psi}{\partial X} \frac{\partial \Omega}{\partial Y} \right) - Ra \left(\frac{\partial \theta}{\partial X} \right) \tag{4}$$

$$\frac{\partial^2 \theta}{\partial X^2} + \frac{\partial^2 \theta}{\partial Y^2} = \frac{\partial \Psi}{\partial Y} \frac{\partial \theta}{\partial X} - \frac{\partial \Psi}{\partial X} \frac{\partial \theta}{\partial Y} \tag{5}$$

The numerical method used in the present study is based on finite difference method to discretize the governing equations (Eqs. 3-5) and the set of algebraic equations are solved using Successive Under Relaxation (SUR) technique. The solution technique is well described in the literature [7,8] and has been widely used to solve natural convection equations. The convergence criterion 10^{-4} is chosen for all depended variables and 0.1 is taken for under-relaxation parameter. The present solutions are compared with the known results for triangular shaped roofs from the open literature. As indicated in the Figure 2, it was observed that these results of the present code are in very good agreement with the literature [2,9,10].

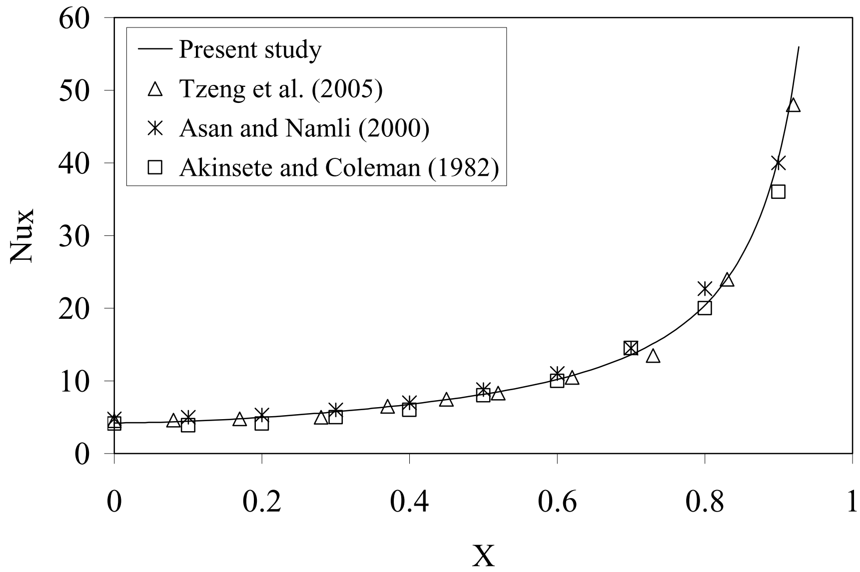


Figure 2. Comparison of obtained results with literature.

As indicated above, the problem is defined for winter boundary conditions. The physical boundary conditions are illustrated in the physical model (Figure 1) and they can be defined as follows:

On the inclined surfaces, u=v=0, $T_U = T_{cold}$ (6)

On the bottom wall, u=v=0, $T_B=T_{hot}$ (7)

On the symmetry line, u=0, vertical wall, u=0, $\partial T/\partial x = 0, \partial T/\partial x = 0$ (8)

Calculation of the local Nusselt number was performed by

$$Nu_x = -\left.\frac{\partial \theta}{\partial Y}\right|_{y=0} \tag{9}$$

RESULTS AND DISCUSSION

Numerical analyses of natural convection temperature and flow fields for different types of the roofs have been performed in this study for different Rayleigh numbers. Streamlines and isotherms are shown in Figure 3 for different type of roofs in winter conditions at $Ra=10^6$. Thus, the bottom area of the roofs is chosen as equal. As can be seen from the figure, double circulation cells were formed in type of saltbox roof. However, in other types of the roofs single cell was obtained.

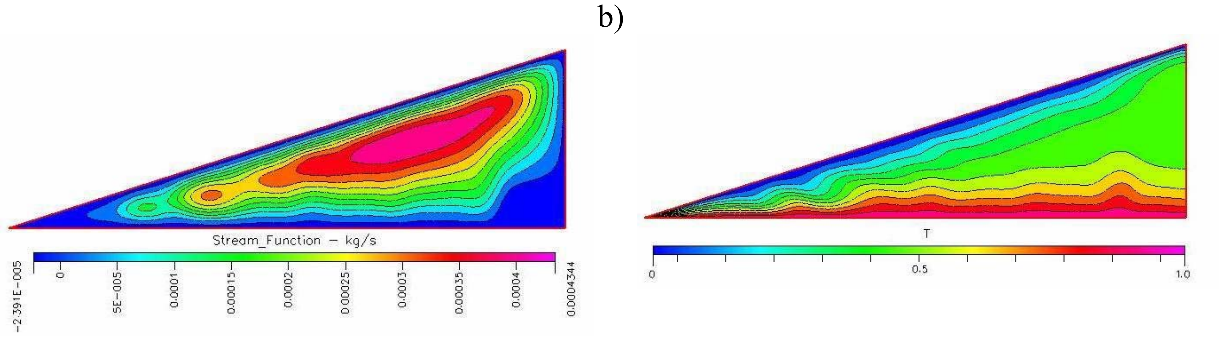
b)



c)

Figure 3. Flow field by streamline (On the left) and temperature distribution by isotherms for winter day conditions at $Ra=10^6$ a) Saltbox, b) Gambrel, c) Gable

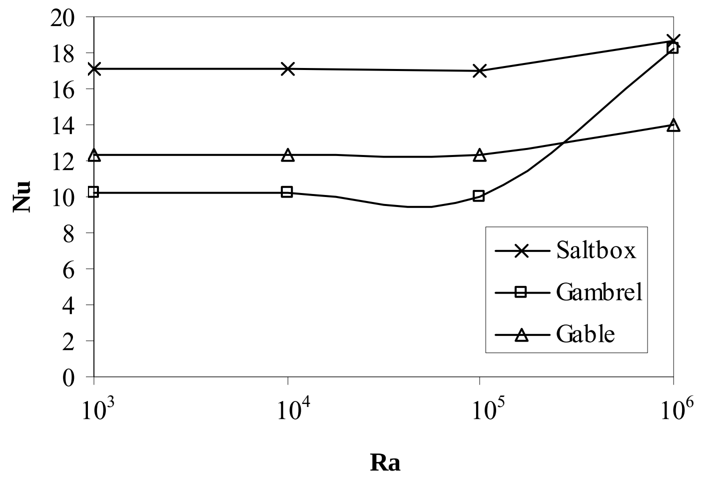


Figure 4. Variation of mean Nusselt number with Rayleigh number for different types of the roof

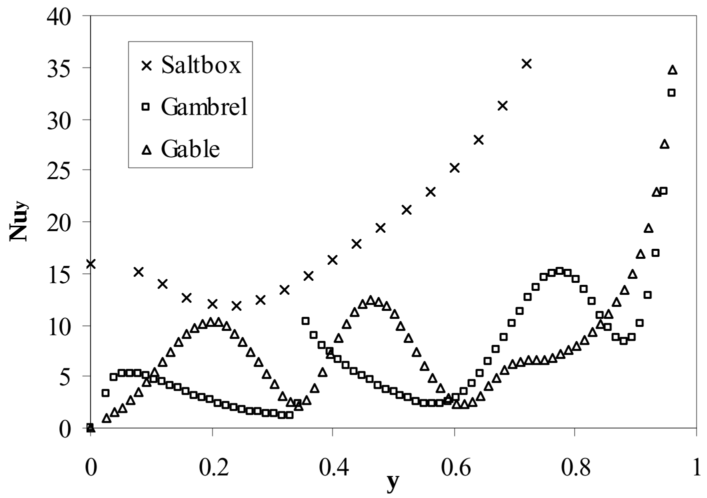

Figure 5. Variation of local Nusselt number along the heated wall at $Ra=10^6$

Figure 4 shows the mean Nusselt numbers which defines the overall heat transfer. They have given for different types and Rayleigh number. As can be seen from the figure, heat transfer mode is mainly conductive at low Rayleigh numbers. Thus, mean Nusselt number becomes constant with increasing of Rayleigh number up to 10^5. For higher Ra numbers, mean Nusselt number increases with increasing of Ra number due to domination of convection mode of heat transfer. The figure shows that, the highest mean Nusselt number is obtained when saltbox roof is chosen due to strong flow strength. It is interesting result that when gambrel roof was chosen same values of mean Nusselt number was obtained between saltbox and gambrel roof at the highest Rayleigh number. Figure 5 presents the local Nusselt number over heated wall of roofs. Thus, variation of local Nusselt number can be comparable for different types of the roofs. Figure presents that, local Nusselt number shows almost sinusoidal shaped variation for gable roofs and its value smaller than that of saltbox roof. Again, gambrel roof shows wavy variation but its value is smaller at the left corner due to long distance between hot and cold walls. Variation shows monotonically increasing for saltbox roof and highest local Nusselt numbers are obtained for this type of roof.

CONCLUSION

Temperature distribution and flow fields of natural convection are presented for three types of the roofs using a numerical technique. It was observed that single cell was formed for gable and gambrel roofs but double circulation cell was formed for saltbox roof. It means that the flow strength is higher for these types of the roof. The lowest heat transfer was performed for gambrel roof at the low Rayleigh numbers. On the contrary, almost same values are formed for both saltbox and gambrel roofs at the highest Rayleigh number.

Calculating the Heat Transfer of Wall Structures in Non-stationary Cases

József Vajda

University of Pécs, Pollack Mihágy Faculty of Engineering, Hungary

E-mail: vajdaj@witch.pmmf.hu

Summary

In order to get an accurate knowledge of the energy consumption of buildings and of comfort parameters inside of closed rooms depending on the time, we developed a mathematical model. Based on Fourier's differential equation, this mathematical model allows us to calculate the instantaneous heat loss, the amount of the heat flow stored in the wall between the two time values, and the plotting versus time of the temperature generated on the contact surface of a double-layer wall structure. In addition to the outside temperature, in the mathematical model we can take into account the radiation intensity reaching the external wall structures by way of sun radiation, as well as the plotting versus time of these meteorological characteristics. The boundary conditions of the developed equation system, which consists of 5 equations, can be determined on the basis of meteorological databases or our own measurements.

Introduction

For an accurate knowledge of the energy consumption of buildings and of comfort parameters inside of closed rooms depending on the time the development of mathematical models is necessary in the field of building structures and thus in the field of wall structures as well, which models enable the necessary calculations to be performed on a scientific basis but in a simple way and using relatively short CPU time. The results of these calculations are expected to provide the following numerical data both in winter and summer modes:

- The function describing the changing versus time of the heat loss in winter, and of the heat load in summer of the rooms, taking into consideration the thermal energy stored in the wall structures for some time.
- The values of the internal surface temperature of the wall structures, which allow us to evaluate the given room's thermal comfort if we know the other comfort parameters (air temperature, air velocity, humidity, clothes, activity level).

All of these calculated values should be determined with the knowledge of what we can regard the two most important meteorological variables, namely the outside temperature and the radiation intensity during any given day.

Methods

Calculating the heat transfer of wall structures in non-stationary cases is based on Fourier's differential equation. In addition to the necessary material characteristics (c: specific heat, ρ: density and λ: thermal conductance), this equation contains, as its last component, the effect of a heat source (E, in W/m^3), which allows us to also take into account the solar radiation reaching the wall surface.

$$c \cdot \rho \cdot \frac{\partial t}{\partial \tau} = \frac{\partial}{\partial x}\left(\lambda \cdot \frac{\partial t}{\partial x}\right) + \frac{\partial}{\partial y}\left(\lambda \cdot \frac{\partial t}{\partial y}\right) + \frac{\partial}{\partial z}\left(\lambda \cdot \frac{\partial t}{\partial z}\right) + E\,, \quad (1)$$

On the basis of this equation, and taking into consideration other factors as well, we can formulate an equation system consiting of 5 equations, two of which are differential equations that allow us to solve the equation system numerically if we choose the right steps.

The the equation system's unknown values, which have to be determined in relation to any given time period, are as follows:

- the value of the instantaneous heat loss: $\dot{Q}$,
- the heat flow stored in the wall between two time periods: $\Delta\dot{Q}$,
- the surface temperature of the internal wall structure: t_{iw},
- the temperature at the point of contact of the brick wall and of the heat insulation on its external surface: t_c.

In order to solve the equations, we need to know the meteorological characteristics, as well as the plotting versus time of the surface temperature of the external wall structures – out of these characteristics, the changing of the radiation intensity and of the air temperature for the given day was taken from an appropriate meteorological database [1], while the changing of the surface temperature of the external wall structures was determined by measurement.

Results

In order to define the mathematical model, we have used a double-layered wall structure that contains a brick structure capable of storing heat, and an outer heat insulation. Further, in relation to heating, we applied the following presumptions:

- By the wall's heat loss we mean the heat flow arriving at the internal wall structures, whose instatntaneous value, at the time of $\tau = 0$ is $\dot{Q}_0$.
- The heat flow stored in the wall in between the 1st and 2nd time period is: $\Delta\dot{Q}_1$.
- The heat flow on the external wall structures is the difference between the two quantities above, that is $(\dot{Q}_0 - \Delta\dot{Q}_1)$.

The mathematical model consists of the following equations:

$$\begin{aligned}\Delta\dot{Q}_1 = {} & \frac{c_1 \cdot \rho_1 \cdot \Delta x_1}{6 \cdot \Delta\tau} \cdot \left[\left(t_{iw1} + t_{c1}\right) - \left(t_{iw0} + t_{c0}\right)\right] + \frac{c_2 \cdot \rho_2 \cdot \Delta x_2}{6 \cdot \Delta\tau} \cdot \left[\left(t_{c1} + t_{ew1}\right) - \left(t_{c0} + t_{ew0}\right)\right] + \\ & + \frac{\lambda_1}{3} \cdot \frac{\left(t_{iw0} - t_{c0}\right)}{\Delta x_1} - \frac{\lambda_2}{3} \cdot \frac{\left(t_{c0} - t_{ew0}\right)}{\Delta x_2} + \frac{I_r \cdot a}{3} + \frac{\alpha_i}{3} \cdot \left(t_{i0} - t_{iw0}\right) - \frac{\alpha_e}{3} \cdot \left(t_{ew0} - t_{e0}\right)\end{aligned} \quad (2)$$

$$\dot{Q}_0 = \alpha_i \cdot \left(t_{i0} - t_{iw0}\right), \quad (3)$$

$$\dot{Q}_0 = \frac{c_1 \cdot \rho_1 \cdot \Delta x_1}{6 \cdot \Delta \tau} \cdot \left[\left(t_{iw1} + t_{c1} \right) - \left(t_{iw0} + t_{c0} \right) \right] + \frac{c_2 \cdot \rho_2 \cdot \Delta x_2}{6 \cdot \Delta \tau} \cdot \left[\left(t_{c1} + t_{ew1} \right) - \left(t_{c0} + t_{ew0} \right) \right] +$$
$$+ \frac{\lambda_1}{3} \cdot \frac{\left(t_{iw0} - t_{c0} \right)}{\Delta x_1} - \frac{\lambda_2}{3} \cdot \frac{\left(t_{c0} - t_{ew0} \right)}{\Delta x_2} + \frac{I_r \cdot a}{3} + \frac{\alpha_i}{3} \cdot \left(t_{i0} - t_{iw0} \right) + \frac{2 \cdot \alpha_e}{3} \cdot \left(t_{ew0} - t_{e0} \right) \quad (4)$$

$$t_{c0} = \frac{\lambda_1 \cdot \Delta x_2 \cdot t_{iw0} + \lambda_2 \cdot \Delta x_1 \cdot t_{ew0}}{\lambda_2 \cdot \Delta x_1 + \lambda_1 \cdot \Delta x_2}, \quad (5)$$

$$\Delta \dot{Q}_{j+1} = \dot{Q}_{j+1} - \dot{Q}_j, \quad (6)$$

The indexes used in the equations indicate the following:

1 and 2	the values of the brick wall and the heat insulation
iw and ew	internal and external wall structures
c	contact point between the brick wall and the heat insulation
i and e	internal and external
r	radiation
0, 1, j	time periods and running index

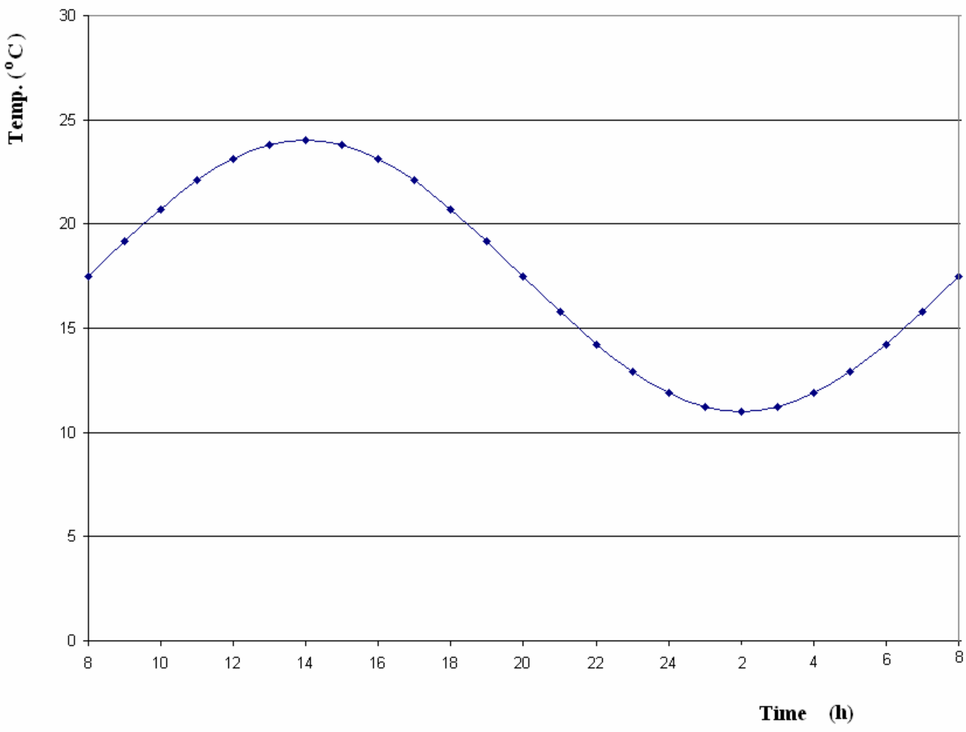

Figure 1. Daily outside temperature fluctuation in Hungary during the month of September

Figure 1 shows the external temperature characteristics of the month of September in case of clear weather. While analyzing the meteorological data, we found that, given Hungary's climate conditions, the average daily temperature measured at 8 am in the morning is the same in the case of clear or cloudy weather. In view of this fact, we determined the following equation for the plotting versus time of the temperature during a given day:

$$t = t_m + A \cdot \sin \frac{2 \cdot \pi}{24} (\tau - 8), \quad (7)$$

Where t_m is the average daily temperature, while A is the amplitude of the daily temperature fluctuation.

Figures 2 and 3 show the daily temperatures measured on the internal and external surfaces of the wall structures facing East. (The wall structure was made of 30 cm wide perforated bricks, plastered on both sides.) The daily fluctuation of the radiation intensity is described on the basis of curves that connect the time periods with the same or similar radiation intensity [1], Figures 4.

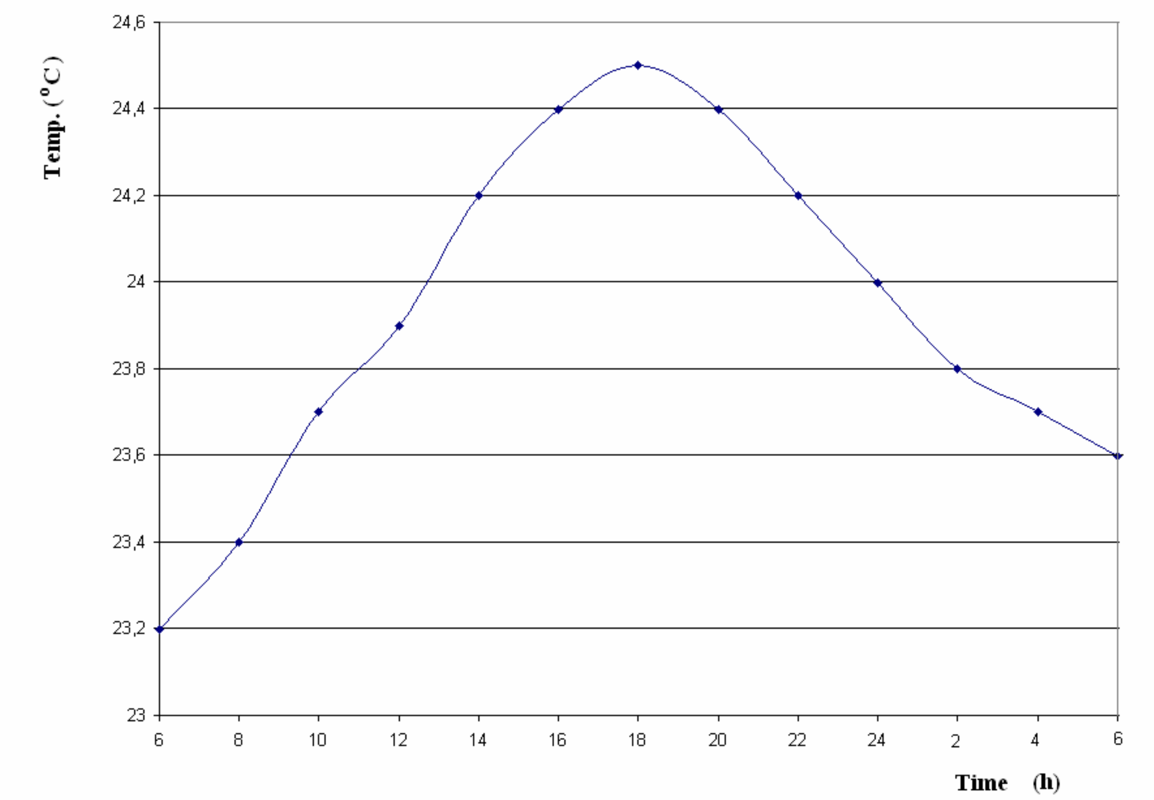

Figure 2. Daily surface temperature fluctuation on the internal wall surface of the wall structure facing East, measured in September 2006

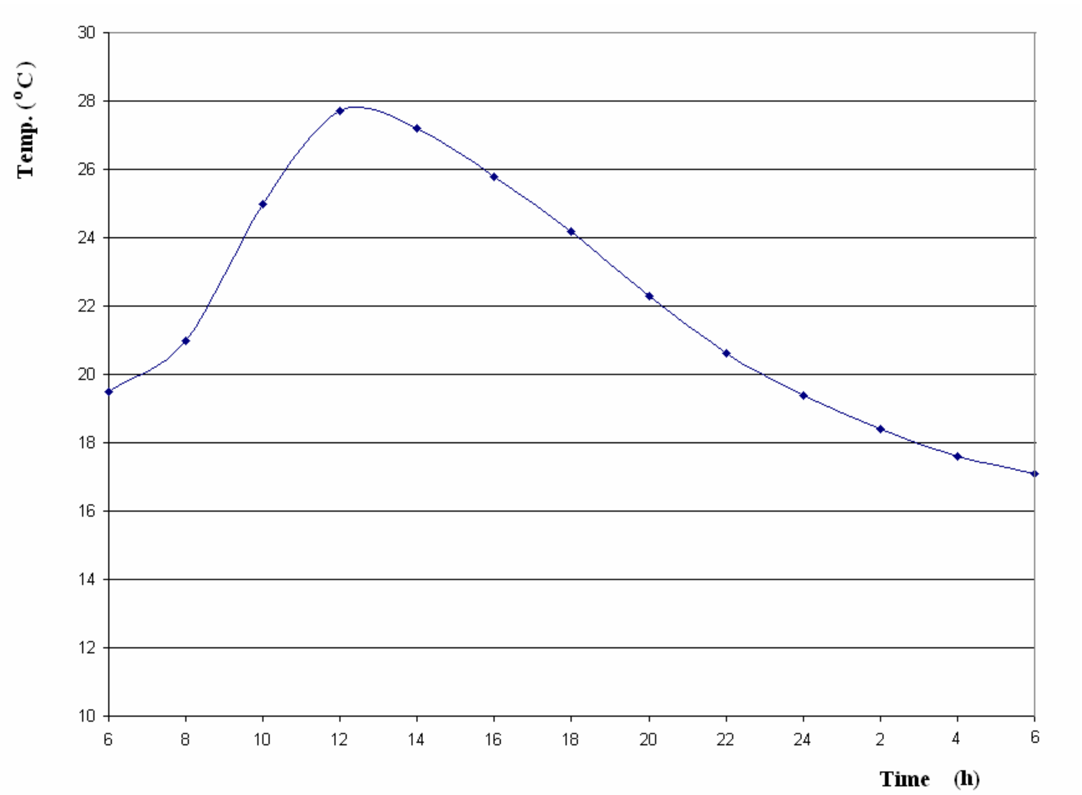

Figure 3. Daily surface temperature fluctuation on the external wall surface of the wall structure facing East, measured in September 2006

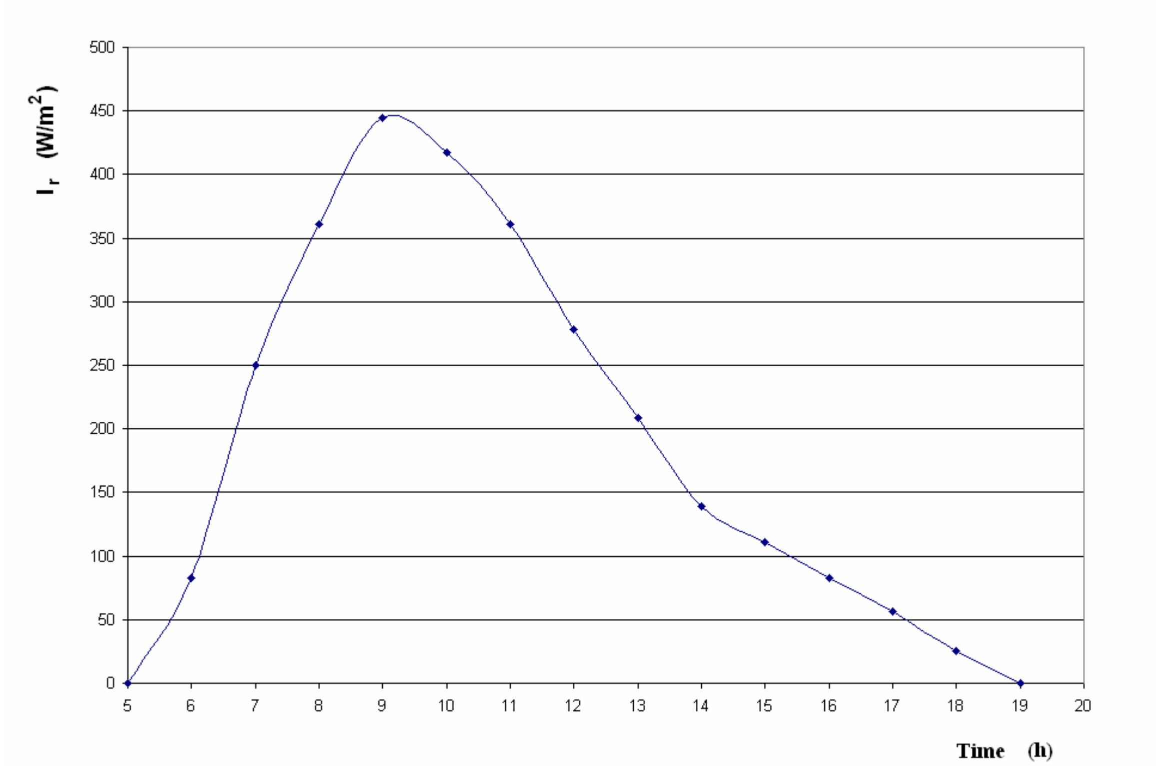

Figure 4. Daily fluctuation of radiation intensity in Hungary, on an average day in September

Discussion

To sum up the research work, we can draw the following conclusions:

- The equation system defined in (2) – (6) can be solved if we know the boundary conditions as defined on the basis of measurements and meteorological databases. The equation is best solved by applying a computer algebra system. When recording the $\Delta\tau = 1$ hour interval, we need to write down a total of 122 equations for one day, which allows us to define the unknown factors.
- From the measuring results of the internal and external wall surface temperatures the damping effect of the brick wall becomes quite obvious: while on the external wall structures we can detect approximately 11 °C daily fluctuation, this value on the internal wall structures is only 1,2 °C.
- As shown in Figures 2 and 3, after a cooler night (in comparison to the preceding nights), the value of t_{iw} will not drop to the value of the previous period's, but will increase to a small extent (approximately 0,3 °C). This temperature difference will be covered by the thermal energy that had been previously stored in the wall structure.

Sustainable Approach to Healthy Buildings Indoor

Santosh Ghosh

Centre for Built Environment Kolkata, India

Corresponding email: sghoshcbe@hotmail.com

SUMMARY

Concepts of sustainability in buildings and cities are many and there are various programmes for healthy cities and researches on indoor air quality. Wellbeing indoors depend on external factors also. The fourth skin or microbiosphere above the building envelope has not been studied well. Sustainable building or green building is being designed but such building functions well only in sustainable cities and often indoor air quality is creating sick building syndrome. Concepts of solar envelope or shadow umbrella are new thinking with the study of urban geometry and bioclimatic design coming from tradition provides new solution with modern tools. Micro urban climate can be controlled with understanding of indoor and outdoor conditions of building envelope.

INTRODUCTION

There are growing concepts of sustainability in buildings and cities. There are multiple definitions, musrhoom concepts and parameters. These can be grouped into (a) broader aspect of environment, ecology, city and region, and (b) buildings and structures. The first group includes concepts like ecological footprint, factor four, green and brown agenda, life cycle assessment, environmental justice, ecoware etc. and the second group includes bioclimatic design, green building, recycling and regeneration, sick building syndrome, dematerlisation, ecovillage, zero emission etc. [1]. The concept of sustainability has widened from the original definition in the report of Burndtland commission. There are various programmes and projects . environmental management plan, healthy cities programmes, sustainable cities etc. Often these are uncoordinated and inside-out or outside-in i.e. relation between building and city is not well defined. A building is part of physical and nonphysical urban systems. Performance of building depends on sustainability triangle with socio¬economic, physical-technical and environment-ecological parameters. There is considerable amount of research on indoor air quality and there is growing research on outdoor environment but interaction between indoor and outdoor under different conditions in cities has not been researched well. The paper deals with these aspects. Wellbeing indoors depend on external factors as well. In a city often standards and criteria are given for environmental health, preventive health, safety health, reproductive health and health care for special groups etc. The management of healthy buildings and surrounding environment depends on occupants/users also.

THE FOURTH SKIN

The human skin is protected by clothing and apparel which are second skin and they live within a building envelope which is third skin. Now buildings are affected by external factors like pollution of air, water, noise, climate . sun, wind and other factors like natural disaster, sanitation, construction fault etc. On the other hand emissions from air conditioning, kitchen exhaust, disposal of waste etc. from buildings affect surrounding buildings. Mosquitos grown in overhead drinking water tanks have affected communities with malaria is many tropical countries. Heat island in highdensity development has effects on microclimate. There are now legal court cases in USA on the effect of perpetual shadows of tall buildings on surrounding low buildings. There is much knowledge and development on the thrid skin i.e. building envelope . façade, wall, roof, protective devices from sun, wind, ventilation, climate etc. together with energy saving devices but inside is also affected with sick building syndrome for the users.

There are now certain common aspects which are studied and results are applied in sustainable healthy buildings . use of renewable or less energy, recycling of waste or zero waste, recycling of water, use of recycled building materials, use of indoor greenery etc.

The invisible fourth skin of micro biosphere requires studies as this regulates health and wellbeing also. A new science of sensasory ecology provides new knowledge.

A safety pin reinvented from the Roman times is a multifunctional tool, strong and durable and yet it is made of very small amount of recyclable material. A Bedouin tent is a sustainable shelter. It can be moved, it can be closed, its height can be adjusted and it can be fixed according to movement of sun and wind and it can be folded and taken away in the desert on the camel back A building does not have the same advantages. It requires a holistic approach, from fragmented approach to integrated approach. In the cities building rules for construction are often not derived from townplanning zoning regulations. Despite huge investments the cities have become un-sustainable and buildings unhealthy. In old paradigm there was belief that the dynamics of the whole could be understood from the properties of the parts but in the new paradigm the properties can be understood only from dynamics of the whole [2].

The science of ontology comes here for consideration. Ontology is defined as an .explicit specification of conceptualization, ontology is a description of the concepts and relationship. [3]. It is defined as formal and explicit specification of a conceptualization[4]. In other words an ontology is a structured collection of unambiguously defined concepts. It is a knowledge management and sustainability has many ambiguous concepts. In computer simulated model, indoor-outdoor correlation can be established and ambiguities can be removed.

SUSTAINABLE BUILDINGS

A discusion on some aspects of indoor air pollution will be relevant though it is not intention of this paper. The main part is sustainable building and construction. There are many green codes. Sustainable building has minimum adverse effects on the built and natural environment, it reduces resource and energy consumption, prevent pollution, enhances natural environment etc. Out of principles of sustainable buildings and green buildings has come Environmental Architecture and its five principles are [5]

- Healthful Interior Environment
- Energy Efficiency
- Ecological Benign Materials
- Environmental form
- Good design

From this a concept of Ecological Building has developed with major areas in environmental building fabric with building technology and sustainable urban design concerning land form, microclimate, land use, site design, transportation, infrastructure efficiency, on site energy

resource etc. [6]. .Reduce, reuse, recycle, reintegrate, repair, restore, refurbish etc.. are new paradigms. Takashi Kawanaka, of National Institute for Land and Infrastructure, Tsukuba, Japan conducted research and developed formula for resource and energy-conscious urban planning [7] Out of 31, two sets of formula can be quoted.
Formulae for urban vegetation . A network of green spaces in urban areas, promote planting of tall tree in each lot, promote roof planting, promote the covering the building walls with vegetation.

Fromulae for construction in urban areas . utilize the advantages of accumulation in urban areas, larger buildings save more energy, consume less cement and steel, maximize the service life of buildings, Assess life cycle, Co2, Recover and dispose chloofluor carbous, (CFC) at steady rate.

European Charter for solar energy in architecture and urban planning was drafted in March 1996 in Berlin. It emphasised new thinking in the design of buildings and urban spaces. The charter states that the form of the urban and landscape structure need to be governed by the following factors [8].

- Orientation of street and building structures to the sun
- Temperature control and use of daylight in the public realm
- Topography (land form, overall exposure , general situation)
- Direction and intensity of wind (alignment of streets, sheltered public spaces, sytematic ventilation, cold-air corridor).
- Vegetation and distribution of planted areas (oxygen supply, dust consolidation, temperature balance, shading and windbreaks).
- Hydrogeology (relationship to water and waterway system) With the concept of sustainability in construction and public buildings, green accounting or environmental auditing becomes the new criteria. Such accounting is becoming an essential process before and after the construction and after a period when occupants users can react. Sustainability is now from paradigm to measurement. The use of Life Cycle Assessment (LCA) as a dignostic tool for determining the environmental health of production process including input, output, resources used and waste generated, use of energy, water etc. has been recognised in many evaluations including US Green Building Council.s assessment. Various evaluation rating have been adopted such as LEED . leadership in energy and environmental design and BREAM Building research environmental assessment and management. The LEED building rating systems are based on erosion and sedimentation control, alternative transport, the reduced site disturbances, storm water management, landscape, water use reduction, innovative waste water technologies, optimum energy performance and renewable energy system, building storage, building reuse, construction waste management, recycled content, carbon dioxide monitoring, thermal comfort, daylight and views, innovation in design etc. Many projects have been certified according to a rating system. The Royal Institute of British Architects[10] has given guidelines on key indicators of sustainability which are land and ecology, materials, community energy, health and water. The American Institute of Architects. Sustainability Task Force has also identified 10 measures on similar aspects including landuse and site ecology, bioclimatic design etc. [11]. Sustainable buildings function well in sustainable cities.

Sustainability is not new and it is in every religious texts. Accordingly to Buddhism, all outer and inner phenomena, the mind and its surrounding environment are understood to be inseperable and interdependent, human beings, society and nature are interconnected. According to Hinduism there is soul in every plant and animal and in the religious text it is said, .I am pervading the universe. All objects in the universe rest on me as pearls on the thread of a garland.. In the Hinduism, the creation is the result of union of humanity (Purush) with nature (Prakrity). The World Council of Churches said, the integrity of creation has a social aspect which we recognise peace with justice, and an ecological aspect which we recognise in the self-renewing, sustainable character of natural ecosystems. The Orthodox Church says that the humanity ought to perceive the natural order as a sign and sacrament of God. In other religions similar thinking is there [9].

INDOOR AND SICK BUILDING SYNDROME

The whole healthy building system can be subdivided into several components (a) Indoor air quality, building related diseases and human response (b) Indoor climate (c) Design and operation of healthy buildings (d) Materials systems and technologies for healthy buildings (e) Policies and practice issues in creating healthy buildings in all subitems [12].

Indoor environment depends on airquality, ventilation, thermal comfort, noise and visual comfort. Many traditional architecture was solar sensitive and buildings were designed accordingly. Attention is now diverted to occupants/users. reaction in indoor environment. Sick Building Syndrome is an increasing phenomenon.

Sick Building Syndrome (SBS) is a situation in which building occupants experience acute negative physical and mental effect that is linked to time spent in a contaminated and overcrowded area. According to the World Health Organisation SBS may be diagnosed if greater than 20 percent of building occupants complain symptoms of sickness, irritation, infection etc. The ventilation standard has been revised to provide a minimum of 15cfm of outdoor air per person.

In recent times energy saving and various measures in green buildings have been adopted but WHO pointed out energy efficient but sick buildings often cost society far more than it gains by energy saving and peoples. confidence in the effectiveness of health and building authorities may be seriously harmed if sick building becomes a common phenomenon [13]. The causes of Sick Building Syndrome are (a) Inadequate ventilation (b) Chemical contaminants indoor and outdoor and (c) Biological contaminants and solutions may include (1) Pollutant source removal or modification (2) increasing ventilation (3) Air cleaning (4) Education and communication [14].

There are many hazardous indoor pollutants. In the beginning of the 20th Century there were 50 materials to construct a building, now there are 55000 with half of them synthetic [15]. There is increasing asthma in UK. Home dustmite, dampness etc. which are associated with respiratory diseases, surrounding environmental conditions and changing of air temperature, moisture generation and ventilation rates are also responsible [16]. In developing countries, about 50% of people use solid fuels (wood, coal, dung etc) for cooking resuting high incidence of respiratory diseases [17].

THE SOLAR ENVELOPE & SHADOW UMBRELLA

According to Dr. Ralph Knowles, for solar sensitive healthy buildings the shape and size of buildings will change and a concept of solar envelope has been developed by research at MTT and at Univ of Southern California, USA [18]. Orientation of streets, placement of greenery and water bodies, control of radiation and pollution, reduction of heat island effect and many other healthy measures can provide the fourth skin for a healthy building. The Solar Envelope is proposed as a zoning device to gurantee access to sunshine now and in the future. It is an imaginary contanier to regulate development within limits. It does not shadow surrounding buildings but there is assured solar access with a new design strategy.

Urban geometry affects heat island which is a dome of stagnant warm air at the heavily built up areas of cities. Emmanuel writes that the urban geometry of a city is characterized by a repetitive element called urban canyon.a three dimensional space bounded by street and buildings thus restrict the view of skydome and gives multiple refections of solar radiation and restricts the free movement of air. [19]. Emmanuel developed concept of shadow umbrella to reduce radiation in outdoor environment which is based on urban massing, use of water and vegetation.

BIOCLIMATIC DESIGN

Shadow umbrella is part of bioclimatic design Traditionally tropical passive solar architecture adopted bioclimatic design.wind catchers, courtyards, plantations, water, shading devices etc. The symbiotic relation between indoor and outdoor is seen in many historic area. The bioclimatic design eliminates heat islands and enhances windflow and aerodynamics. Offices, shopping centres and other places visited by large number of people have large parking areas and many mechanical devices, a bioclimatic environment creates buffer and reduces sick building syndrome. Bioclimatic design in green building does not mean design with greenary. It is solar sensitive environment and greenery which help to promote healthy environment by converting carbondioxide into oxygen which is to be incorporated. Architectural solution for healthy indoor is a result of implementation of ecological principles. According to Dr. Giovani bioclimatic design can control climate at micro-urban scale with understanding of indoor and outdoor conditinos of building envelope [20].

CONCLUSION

The fourth skin or microbiosphere around building envelope has not been studied properly. A healthy and sustainable building and its indoor air quality has symbiotic relation with outdoor. Sick building syndrome can be avoided. Astudy of urban geometry with concepts like solar envelope and shadow umbrella is needed. Bioclimatic design is recommended to develop healthy buildings.

Energy efficient building design

The ASHRAE GreenGuide: One Means of Establishing a Link between Sustainable Design Practitioners

John Swift[1], Thomas M. Lawrence[2]

[1]Cannon Design, Boston, MA USA
[2]University of Georgia, Athens, GA USA

Corresponding email: JSwift@cannondesign.com

SUMMARY

The paper discusses the newly revised ASHRAE GreenGuide, particularly as it relates to the topic of indoor environmental quality. The updated Guide includes a new chapter on LEED Guidance for Mechanical Engineers and a new chapter on building systems Impact on the Local Environment- both indoor and outdoor. This chapter is intended to describe how HVAC systems interact with the building indoor and outdoor environment, and includes (among others) sections dealing with indoor environmental quality, cooling tower systems and chemical water treatment, acoustics, and the science of designing healthy buildings. One of the more useful concepts in the Guide is the inclusion of “Green Tips”, which are sidebar summaries of specific technologies that can be used to design a high-performance (green) building. Three building specific Green Tips are discussed, with particular emphasis on topical areas related to indoor air quality concerns.

INTRODUCTION

The ASHRAE Green Guide (Guide) [1] is a primary reference for mechanical engineers working on high performance building projects in the United States. The original edition of the Guide was released in January of 2004, and the second edition was introduced at the U.S. Green Building Council’s Greenbuild Conference in Denver, CO, USA in November, 2006. The Guide is intended to be a living document and the process is in place to maintain this with new editions that will contain updated material.

The Guide is not intended as a complete compilation of all interactions that buildings, and heating, ventilation and air-conditioning (HVAC) systems in particular, have on and with the environment. Many of the issues are common knowledge as being important to “green” building design among engineers and lay people alike; such areas as energy consumption, location of buildings and the construction process are prime examples. The Guide is primarily intended to convey ideas on how to improve buildings and their systems. There are, however, some areas that are either not intuitively obvious as being potential impacts of HVAC systems, or are items that are some may not consider to be truly “sustainability” issues. While not being the sole target market, the Guide is written such that practitioners in the early stages of their career will particularly benefit.

Regardless of your definition of sustainability or the various labels and compartmentalization, it is assumed that the reader of the Guide is interested in designing buildings and their systems that provide for the needs of the occupants while minimizing the their adverse impacts. Therefore, the chapter on local environmental impacts provides examples of several areas that the HVAC engineer may not initially think are important when minimizing environmental impacts, but truly are significant.

This paper discusses the importance of continuing to build a link between ASHRAE, REHVA and other global building engineering design associations. Important differences in the integrated design process will be identified from a U.S. perspective. The issues will be evaluated and discussed with the goal of working toward the optimization of the high performance building design process globally. The example presented for this discussion is the Second Edition of the ASHRAE Green Guide.

What is New to the GreenGuide

The updated Guide includes a new chapter on LEED Guidance for Mechanical Engineers and a new chapter on building systems Impact on the Local Environment- both indoor and outdoor. This chapter is intended to describe how HVAC systems interact with the building indoor and outdoor environment, and includes (among others) sections dealing with indoor environmental quality, cooling tower systems and chemical water treatment, acoustics, and the science of designing healthy buildings. One of the more useful concepts in the Guide is the inclusion of "Green Tips", which are sidebar summaries of specific technologies that can be used to design a high-performance (green) building. Some of the chapters from the First Edition have been reorganized in an attempt to more accurately mirror the path that an actual project would take from Pre-Design to Post Occupancy. Content has been added and edited in all of the chapters, with significant updates in the subject areas of Building Automation Systems, Renewable Energy Options, combined heat and power and ground-source heat pump systems. The Second Edition also provides a more global perspective with a specific section titled "International Perspective", along with SI/IP dual units provided for all.

METHODS

Developing a guideline on Indoor Environmental Quality (IEQ) intended for a broad audience while still technically sufficient can be a difficult task. One weakness of the original edition of the Guide was a lack of information on IEQ, and this has been corrected with the new second edition. This section first presents a summary of the IEQ information content in the new Guide and how it relates to other chapters within the Guide. Next, a description is given of three examples on how information contained in the Guide can be applied.

The terms indoor environmental quality (IEQ) and indoor air quality (IAQ) are sometimes confused as being one in the same. In reality, *IEQ* is a broader, more encompassing concept which includes *IAQ* as one of the key factors. Other areas are also considered key to providing good overall IEQ, such as:

- Air quality and ventilation
- Thermal comfort
- Acoustics and noise
- Lighting levels
- Visual perception
- Building materials and envelope

When considering indoor air quality, the outdoor environment can have a negative impact on the building HVAC and the indoor environment, or vice-versa depending on the specific situation. Location of outdoor air intakes near a known contamination source (such as a loading dock with potential idling engines) can seriously degrade the indoor air quality by introducing, rather than removing, contaminants. Similarly, building exhausts can contaminate the local area near the exhaust discharge, making this air unsuitable for human exposure or re-intake into the building. Chapter 44 of the 2003 ASHRAE Applications handbook [2] (Building Air Intake and Exhaust Design) contains more information on this topic.

Assuming no contamination of the local air surrounding the building, then good indoor air quality is possible by providing adequate ventilation and distribution within the space; for example if the design met the requirements as specified in ASHRAE Standard 62.1 [3].

Similar to lighting levels, thermal comfort affect the occupants and overall building indoor environmental quality. Thermal comfort of the occupied space is covered in Chapter 7 of the Guide. The interaction with the local environment has minimal impact on thermal comfort.

The acoustical environment can also be an important factor in determining good indoor environmental quality. Sound and vibration are the often unheralded contributors to occupant comfort and health that should be an integral part of green building design and should not be forgotten. While noise is not always an obvious problem, human productivity and performance can be impacted by the acoustical environment.

Adequate lighting levels are required for the building occupants. Lighting levels required vary according to the design purpose of the room or building zone. The local environment, in the form of trees, landscaping or other buildings, can influence the lighting that may enter the space and hence affect the lighting levels inside. Lighting and its impact on HVAC load determination is discussed in more detail in Chapter 6 of the Guide.

This is another area that influences how a person perceives the indoor environmental quality. Rarely would the HVAC system interact with visual perception of the indoor space, with one possible aspect being exposed ductwork. Any HVAC system interaction with visual perception will likely be dealt with by the project architect. The Guide addresses these issues in Chapter 4.

Recent years have seen a marked increase in recognition of the impact that building materials (envelope, furniture, paints, flooring, etc.) have on indoor air quality. This was the primary reason for changes to the ASHRAE Standard 62.2 outdoor air ventilation requirements to include an allowance for the building area and not just total number of occupants.

The indoor air quality can be negatively affected by off-gassing of chemicals building materials or chemicals used during the construction or fabrication of the components. The LEED program contains a number of credit point items that related to reducing the introduction of potentially harmful materials into a building environment. It also describes methods to help ensure that key HVAC components, such as ductwork, do not become contaminated during construction and act as a source of indoor pollution after occupancy.

Focusing on the Indoor Air Quality concept and how the Guide can assist in advancing the latest design concepts that optimize air quality, several example are given indicating how the Guide would be used.

The first example presented is how “green” practices can be applied in general to laboratory buildings. Building-specific ‘Green Tips’ have been included in the Second Edition of the Guide. The Green Tip for Lab Buildings indicates a number of design concepts for consideration as they relate to IEQ issues.

The second example is a summary of the Green Tip for Healthcare Facilities, and the final example is a similar compilation of techniques as applied to the specific design challenges of a university student residential facility. The strategies outlined can also be applied to hotels and multi-unit residential complexes, including luxury condominium developments.

RESULTS

Example 1: Laboratory Buildings

One of the user friendly features of the Green Guide are the Green Tips. If used, these tips can help the designer make informed decisions on what systems may be properly integrated on a specific project. These tips also allow the engineer to identify benefits and costs in order to work with the constructors and the owner to implement concepts that best suit the needs and ideals of the project.

Building-specific Green Tips have been included in the new Second Edition of the Guide. The Green Tip for Laboratory Buildings focuses on safety, energy and occupant comfort considerations. The following design concepts are given for consideration as they relate to IEQ issues:

Safety

1. Fume hood design and associated air distribution and controls must be designed to protect the users and the validity of the laboratory work.
2. Pressurize rooms consistent with the ASHRAE Laboratory Design Guide and any other code required standards. Utilize building pressurization mapping to develop air distribution, exchange rate and control strategies.
3. Optimize air exchange rates to ensure occupant safety while minimizing energy usage.
4. Chemical, biological and nuclear storage and handling exhaust and ventilation systems must be designed to protect against indoor pollution, outdoor pollution and fire hazards.
5. Intake/ exhaust location strategies should be modeled to ensure that lab exhaust air is not reintroduced back into the building air handling system.

Energy Considerations

1. Heat recovery for spaces served by air handling units with 100% outside air capability or over 50% outdoor air component. The Guide contains several Green Tips associated with air-to-air energy recovery covering heat exchange enthalpy wheels, heat pipe systems and run-around systems.
2. Utilize variable air volume (VAV) systems to minimize air exchange rates during unoccupied hours.
3. Consider low flow fume hoods with constant volume controls where this concept can be properly applied.
4. When appropriate, consider decoupling outdoor air conditioning from the space loads by using chilled beams.

Occupant Comfort

1. Air systems should be designed to allow for a collaborative working environment. Acoustic criteria should be adhered to in order to maintain acceptable levels of noise control.
2. Day light and views should be considered where lab work will not be adversely affected.

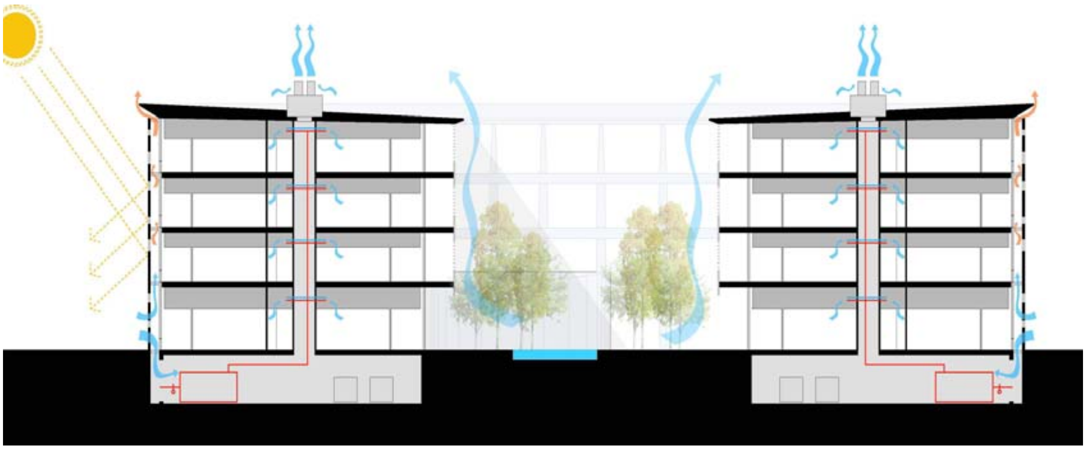

Figure 1. Conceptual diagram indicating optimization of indoor air quality and minimization of cooling loads for a proposed project in Algeria.

Example 2: Healthcare Facilities

Healthcare facilities are infrastructure intensive and include many different types of spaces. The HVAC systems for these different types of spaces must be designed to address the specific needs of the spaces being served. The first considerations should always be safety and infection control. In addition, optimizing energy efficiency and positively affecting the patient experience should also be important design team goals. A summary of the key points contained in the Guide's Green Tip for healthcare facilities is given in the following topical sections.

Safety and Infection Control

1. Consider HEPA (high-efficiency particulate air-filter) filtration for all air handling equipment serving the facility.
2. Consider air distribution and pressurization strategies in operating and trauma rooms that balance air flow zones from most clean to least clean. The order of zone cleanliness starts at the operating and thermal plume location at the patient, then moves to the zone around the doctors, the zone around the room, and then the zone outside of the room.
3. Pressurize rooms consistent with American Institute of Architect (AIA), ASHRAE or other local or national codes and guidelines.
4. Provide air exchange rates in excess of AIA guidelines in operating rooms, intensive care units, isolation rooms, trauma rooms, and patient rooms.
5. Redundancy of equipment should be designed for fail-safe operation and optimal full and part load energy efficient operation.

6. Intake and exhaust location strategies should be modeled (computational fluid dynamics or wind tunnel) to ensure no re-introduction of exhaust into the building.

Energy Considerations

1. Heat recovery for spaces served by air handling units with 100% outside air capability.
2. Utilize VAV systems in non-critical spaces working in conjunction with lighting occupancy sensors.

Occupant Comfort

1. Acoustics of systems and spaces must be designed with patient comfort in mind.
2. Daylighting and views should be provided but design to minimize the HVAC load impact of these benefits.
3. Provide individual temperature control of patient rooms with capability of adjustment by patient.
4. Building pressurization relationships/ odor issues should be carefully mapped and addressed in the design and operation of the building.

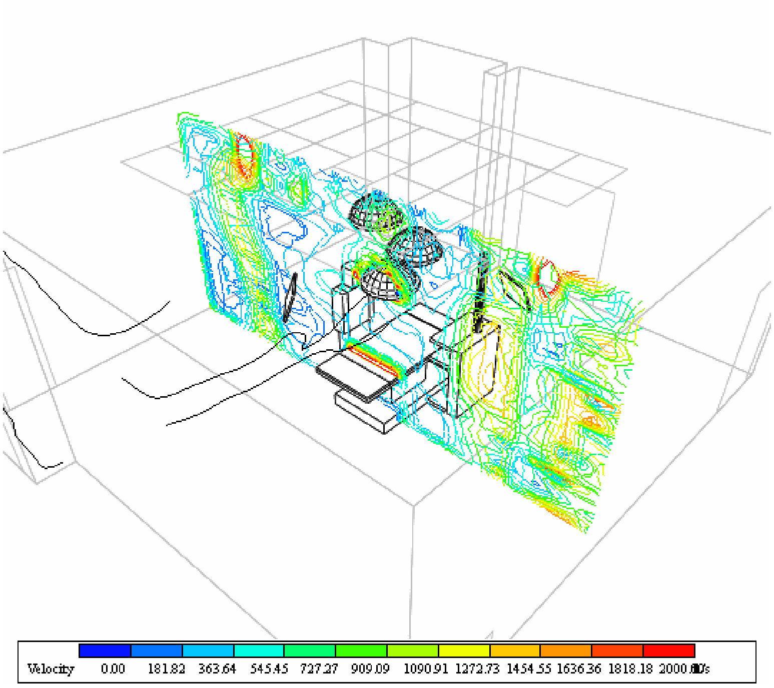

Figure 2. CFD results showing particle path tracing in an operating room. (UMass Memorial Lakeside Addition, Worcester, MA, USA)

Key Elements of Cost

1. HEPA filtration costs are significant in both first cost and operating cost. The engineer should work closely with the infection control specialists at the healthcare facility to determine cost/ benefit assessment of the filtration strategies.
2. Heat recovery strategies should be assessed using life cycle analyses. All components of the strategy must be taken into account, including the negative aspects, such as adding fan static pressure, and therefore, using more fan energy, when heat wheel or heat pipe strategies are considered.

Example 3: University Residential Facilities

Student residence halls are made up primarily of living spaces (bedrooms, living rooms, kitchen areas, common spaces, study spaces, etc.). Most of these buildings also have central laundry facilities, assembly/ main lobby areas, and central meeting/ study rooms. Some of these spaces also include classrooms, central kitchen and dining facilities. The strategies outlined below can also be applied to hotels and multi-unit residential complexes, including luxury condominium developments.

Energy Considerations

1. Heat recovery for spaces served by air handling units with 100% outside air capability serving living units (exhaust taken from toilet rooms and supply air to occupied spaces).
2. Utilize VAV systems or induction systems for public spaces.
3. Investigate methods to provide natural ventilation or hybrid natural ventilation strategies, as appropriate to the local climate. An example airflow path of such is given in Figure 2.
4. Utilize electronically commuted motors (ECM) for fan coil units.
5. Utilize ground source heat pumps where feasible.

Occupant Comfort

1. Systems should be design to appropriately control noise in occupied spaces.
2. Daylight and views should be optimized while minimizing load impact on the building.
3. Consider providing occupant control in all bedrooms, which will be a balance of cost impact with improved indoor environmental quality.

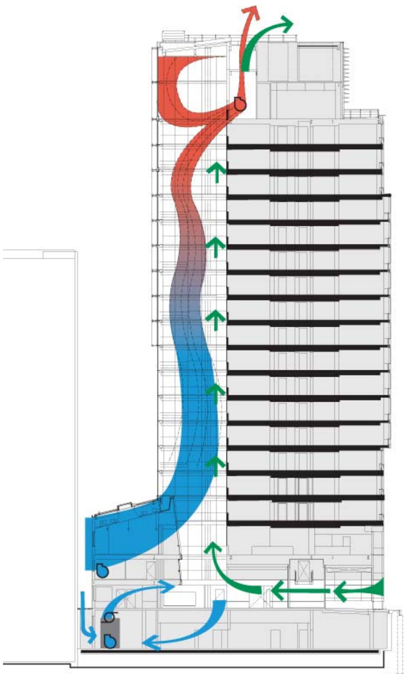

Figure 3. Path of natural ventilation in high-rise atrium which also optimizes views while minimizing solar gain (Suffolk University Residence Hall, Boston, MA, USA).

Key Elements of Cost

1. While there is a premium to be paid in first costs for ECM motors, many utility companies have energy rebate programs that make this concept viable, even on projects with tight budgets.
2. Heat recovery strategies should be assessed using life cycle analyses. All components of the strategy must be taken into account, including the negative aspects, such as adding fan static pressure, and therefore, using more fan energy, when heat wheel or heat pipe strategies are considered.
3. Hybrid natural ventilation strategies could be utilized using operable windows, properly designed vents using venturi effect to optimize natural airflow through the building, and shut down of mechanical ventilation and cooling systems during ambient temperature ranges between 15 and 17 C. This will save significant operating costs. The costs of the operable windows and vents will need to be weighed against the energy savings.

SUMMARY

Indoor air quality is influenced by all of the inter-related aspects of building design. The ASHRAE Green Guide is a valuable tool for mechanical engineers striving to meet the goals of resource use optimization and a comfortable, healthy indoor environment through an integrated design team approach.

Workshop Integral Design Methodology

Perica Savanović and Wim Zeiler

Technische Universiteit Eindhoven (TU/e), The Netherlands

Corresponding email: p.savanovic@bwk.tue.nl

SUMMARY

Integral design shows high promises to reduce failure costs and to improve design quality. Based on this assumption, the Royal Institute of Dutch Architects (BNA), the Dutch Society for Building Services (TVVL) and Delft University of Technology (TUD) started a research project on Integral Design in year 2000, which resulted in a series of workshops for architects and HVAC consultants. This project was succeeded by new research within the Knowledge Centre Buildings and Systems (KCBS), in which Eindhoven University of Technology (TU/e) and the Netherlands Organization for Applied Scientific Research (TNO) cooperate. The ongoing research utilizes workshops, in which already over 220 professionals from BNA and the Dutch Association of Consulting Engineers (ONRI) participated, for development and evaluation of integral design methodology in the domain of sustainable comfort systems. Both workshops and 'integral design methodology' are used as part of the education programme for continuous BNA-ONRI professionals' personal development.

This paper presents theoretical background for knowledge sharing and knowledge creation within building design teams, implemented in form of 'ID(Integral Design)-methodology'. Additionally, development of workshop experimental setting for measurement of its effects is described.

INTRODUCTION

The present situation in building (design) practice, where "it is hard for building partners to give a collective good answer for variety of questions from the society" [24], is determined by large number of different and often mutually influencing factors that require a broad approach on a variety of levels. For improvement of this situation, changes on three levels are needed:

1. process level – in order to improve design process to fit all involved design disciplines;
2. product level – to improve the end product (building as a whole, as well as its parts);
3. culture level – to bridge the gap between 'Design' and 'Engineering' worlds, in case of building design specifically between architects and (building services) consultants.

To realize all these three aims, an integral approach, as defined by Quanjel and Zeiler [24], is needed: "Integral approach represents a broad view on the world around us that continuously needs to be adapted and developed from sound and documented experiences that emerge out of interaction between practice, research and education. This integral approach can eventually lead to integral process, team and method – all the required conditions for design of the end product." [24]

For such high ambition, a true culture change, it is not enough to just 'prescribe' new ways of doing things. History shows that of design processes through prescriptive methods is not sufficient for large scale design problems/situations [6]. This is partly due to a design problems' peculiarity, being described as 'ill-structured' [30] or even 'wickedness' [25].

The prescriptive methods are often based on experiences of the researchers who develop them. These experiences are either recognized, and as such considered 'open doors', or not recognized and turned down. Jjust reading about design methods is not enough to really get grip on the real philosophy behind them. Designers have to be thought and trained how to work with design methods in order to be able to implement them. Because one has to endure himself that something is indeed worthwhile pursuing, a 'learning by doing' course is used in our pursuit for culture change in building design practice. Insights acquired from observing this implementation have to subsequently be used for further improvement of design methods.

DESIGN PROCESS

Our aim is to improve conceptual design (process level) by defining an 'integral design (ID) methodology' that increases potential for creation of integral building designs (product level). We assume that positive results on these two levels, which we try to demonstrate in our research, eventually will trigger and support culture change in building design practice. For this to happen, continuous implementation of achieved results in the setting of research-education-practice triangle is crucial. Besides research and development goals, this is the major function of workshops.

The main reasons for focusing on design process instead on design product level are because of *subjectivity of* design task *interpretation* and of design (as product) *evaluation*. (A representation of any stage in design development, from initial sketches, models and drawings to prototypes and final spatial objects is considered 'design as product'.)

It is known that designers/architects tend to reinterpret initial program of requirements [15], being it in rational (through analysis) or intuitive way (by framing design situation) [21,29]. However, in both cases this reinterpretation can't be considered objective. Moreover, a designer often makes different interpretations of the same design assignment each time he/she is confronted with it again. In these types of situations it is hard to compare design results (as products) which are based on different interpretations, even though the designer might be the same. We therefore argue that objective comparison concerning integration aspects within building designs, made by *different* designers, is not possible. Even in case of independent experts' deployment, the measurements regarding evaluation of integral designs remain subjective [9].

Design solutions and design problems are evolving together [29]. Because of this duality, initial requirements and subsequently required essential design information often change according to the in time increased insights about design task. Within traditional design process organisation types some disciplines that have to provide parts of this information at the start of design process, simply aren't there. Instead, one must try to find this information using reference books, databases, case studies etc. However, information always has to be *transformed* into design, and this requires certain skills, which we regard as *implicit* design knowledge. Implicit knowledge is coupled to actual person/designer (looking at design from different viewpoints…), while information is discipline based. Considered separately from persons and their skills, information could also be described as a special form of knowledge. In this sense, a certain discipline can indeed be characterized by *explicit* knowledge that it represents. The previous are the reasons why we focus on term knowledge instead on information. Besides, the emphasis on availability of information implies that precise (objective) definition of design task is needed. Moreover, it indicates that objective definition of design task is possible, which in the past proved as a pitfall leading to defining designing as purely rational (scientific in classical meaning) activity [18,22].

DESIGN (TEAM) KNOWLEDGE

In contrast to clients, constructors and managers, design team's disciplines posses *object design knowledge*. 'Object knowledge' is knowledge on the characteristics and properties of artefacts and their materials [33]. Van Aken's distinction between object, realization and process design knowledge proves to be very helpful in explaining what we are trying to do: integrate *explicit* discipline based 'object design knowledge' through implementation of 'process design knowledge' (represented in our case by developing 'ID-methodology').

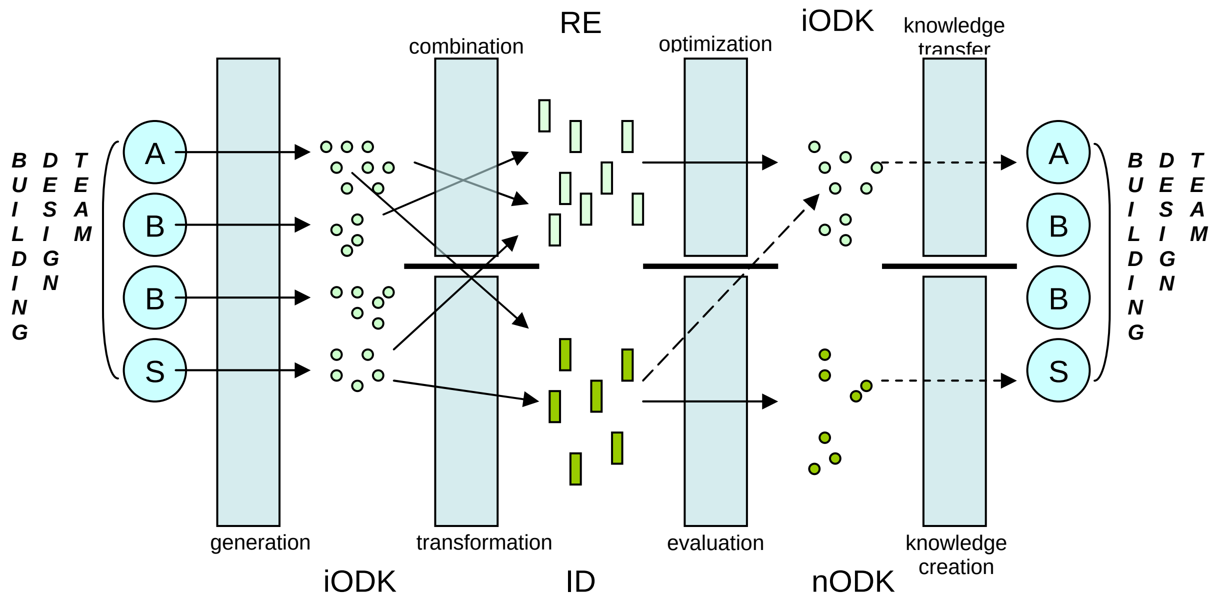
To be able to relate knowledge of different disciplines, we have adopted the view of designing as *the* most central activity in engineering [20]. However, it has been confirmed [28] that at present most of building design team disciplines actually don't act as designers during (traditional) design processes – meaning that there exists an artificial separation between 'design' (as a generalist; architect's) and 'engineering' (as a specialist; consultant's) activity. This duality forms an obstacle that has to be overcome. If we consider relations between different disciplines within design teams as a form of social system, the question is if (in our case design) activities can be imposed on 'design team system' through external (meaning outside intrinsic design activities) management. Certain approaches suggest that each system, if we look at its constituting entities, can only *organize itself* [1] – resulting in what is called emergent behaviour [17]. In order to enhance building design processes, communication between various disciplines has to be improved. Currently, cooperation between design disciplines is unsatisfactory; better organization of building design process is necessary [13]. Communication between different members of a design team is generally a notoriously difficult problem, especially at the early stages of design process [10]. It is important to stress that communication in the first place needs to be transparent; not only internally for design teams themselves, but also for external stakeholders. Communication within groups can generally be discerned in social-emotional and task neutral [2]. Similar distinction is made in literature on design teams, where distinction between task and team work, or content and process activities has been made [11,32]. In our 'ID-methodology' development we are primarily interested in task related communication. Given the fact that in our setting design teams have restricted amount of time to work on design tasks, we assume that this will automatically lead to more task related communication. Some research results support this assumption by showing that time pressure prevents teams from engaging in 'social niceties' [8].

KNOWLEDGE TRANSFORMATION

Besides communicating object design knowledge to each other, design team members/disciplines have to be able to use it for designing. Theoretical background on how design knowledge could be transformed into integral design concepts is found in "C-K theory" [14]. C-K stands for concept-knowledge relation. This theory defines design as a process generating co-expansion of two spaces, space of concepts C and space of knowledge K: "A design concept is a proposition that can not be logically valued in K... Concepts are candidates to be transformed into propositions of K, but are not themselves elements of K (properties of K can however be incorporated into concepts)… If a proposition is true in K, it would mean that it already exists and that we know all that we need about it (including its feasibility). Design would then immediately stop. There is no design if there are no concepts.

Without the distinction between the expansions of C and K, design disappears or is reduced to mere computation or optimization." In our view, optimization through merely (re)combination of already existing object design knowledge leads only to redesign (Figure 1, RE).

We focus on possibility of expanding concept space with integral design concepts (Figure 1, ID) and on producing new object design knowledge (Figure 1, nODK). A concept not being true or false (within K), the design process aims to transform this concept and will necessarily transform K [14]. At the end of process of generation and integration of concepts, transformation of existing object design knowledge within design team into new object design knowledge takes place, allowing design team members to acquire new insights in this 'learning by doing' approach.



A – architect
BP – building physics consultant
BS – building services consultant
SE – structural engineer
iODK – initial 'object design knowledge'
nODK – new 'object design knowledge'
RE – redesign (concepts)
ID – integral design (concepts)

Figure 1. Combination vs. transformation, knowledge transfer vs. knowledge creation; 'ID-methodology' design model

In our case K is defined by initial object design knowledge that participants bring into design team (iODK). Making this knowledge *explicit* enables designers/participants to use it for creation of design concepts. What we are curious about is if these concepts are *integral* (ID), some would even call them innovative, or just plain combinations (RE). The problem regarding innovative concepts / knowledge is that they are mostly related to the present state-of-art. We, on contrary, are focusing only on *knowledge within design team itself*. Now, if we assume that communication aspect can be measured, for example using Bales' Interaction Process Analysis categorization [2], the question is how we can measure (design) knowledge? Our operational definition is the one of only explicitly presented/communicated object design knowledge. Implicit knowledge is considered not directly transferable to other design team members and, as such, isn't treated as a research subject. If we were concerned how designers utilize implicit knowledge, in other words if we were researching *individual* design thinking, it would indeed be one of the essential aspects. Instead, we are interested in how explicit object design knowledge is transformed/integrated within building design *teams*, assuming that different design disciplines are (on average) of the same standard, because of their similar level of education and daily practice.

The essential aspect of design (thinking) is often referred to as creativity [7]. Although we are aware of significance of creativity in design thinking, we are not interested in how this process is unfolding, but if, when and how often it takes place within building design teams setting. People can be credited with creativity in two senses, described as P-creativity and H-creativity: P stands for psychological and H for historical [4]. The P-creativity represents creation of ideas which are new to the person that 'comes up' with them, whether this person immediately realizes their significance or not. These ideas are 'new' no matter how many other people may have had the same ideas already. H-creative ideas are fundamentally novel with respect to the whole of human history, and people usually have them in mind when they're speaking of 'real' creativity and 'real' innovative proposals. In case of design teams we consider transformation of object design knowledge, introduced by different design team disciplines, as design teams' P-creativity process. In other words, with application of 'ID-methodology' we are concerned how to stimulate design teams to produce, for themselves new, integral concepts. Seen in this way, *design within our integral approach represents realisation of potential for creation of new object design knowledge through integration of discipline based explicit object design knowledge into integral design concepts*.

By observing if proposed 'ID-methodology' for building design teams enhances emergence of integral design concepts (ID), we can say that (within specific context of a particular design team) potential for creation of new object design knowledge is realized. This new knowledge increases the possibility of arriving to 'satisficing' final solutions in subsequent design phases of a given situation (within specific design team, regarding given design task and using 'ID-methodology'). *The number of integral design concepts produced by design team is then the measure for this potential.*

INTEGRAL DESIGN METHODOLOGY SETTING

A suitable environment for integration of activities of a building design team is believed to be workshop setting. The workshops are seen as a self-evident way of working for designers, that occurs both in practice as during their education. They are however not predominant way of working in practice, where most of time different disciplines work separately. The actual designing, in the full design team line-up happens only occasionally and mostly at the very beginning of the project. Even then the purpose of (workshop) meetings is often just to get better acquainted with each other. Besides full design team line-up there are a number of other advantages of workshops with regard to standard office situations, while at the same time retaining practice-like situation as much as possible: the possibility to gather a large number of professionals in a relatively short time, repetition of the same assignment and comparison of different design teams and their results. The openness of participants for new methods is also bigger than during daily routine, something that can't be emphasized often enough.

Until now 12 workshops involving design teams were organized, with more then 220 participants. In all except one, workshop participants worked as design teams. A total of 65 teams were observed / worked with. The development of workshop setting was also a 'learning by doing' process. Instead of making a theoretically 'optimal' configuration, the approach we used was rather adaptive. Starting with 'standard' practice-like building team setting for the first sessions in 2001, workshops have evolved to two full-day series. The first workshops were organized during 'Integral Design' project [23,24] that was conducted by the Dutch Society for Building Services (TVVL), the Royal Institute of Dutch Architects (BNA) and Delft University of Technology (TUD), which involved mainly architects and building services consultants. The main focus of that project, which was initiated in 2001 and ended in 2003, was to raise the awareness of different disciplines about each others positions and problems in relation to building design. During this project a total of seven workshops were organized. The first one was an explorative session, which confirmed suitability of workshops for integration of activities of a building design team. Based on this result a workshop concept was developed in which the participants, members of BNA and TVVL, had to change their roles. The architect acted as building service consultant and vice versa. The awareness of position and needs of 'the other' was believed to be most evident if one had to play the role of 'the other'. A series of six identical workshops provided us with an important, and at the same time very surprising insight that either the level of knowledge about not only 'that other', but also about one's own field of expertise, was generally not that high; at best, it couldn't be understandably communicated to the other party in design process. This left us with conclusion that a way for structuring and confronting the respective (object design) knowledge of design disciplines needs to be found.

Hugely oversimplified, these were the most important conclusions regarding direction of further development of 'Integral design' workshops. Much more information is available in Quanjel's report [23], which unfortunately is only available in Dutch.

The basic framework for structuring knowledge of design team members was found in 'Methodical design' [34], a model which is problem oriented and distinguishes, based on functional hierarchy, various abstractions and/or complexity levels during different design stages and design phase activities. This framework proved its potential within (mechanical) engineering domain [3], and makes it possible to explicitly think and act on a specific abstraction level. A distinguishing feature of 'Methodical design' is the use of morphological overviews, both for the overall description of design stages as for separate design activities. Morphological overviews were first used by Zwicky [38], and are listed as one of 'Design methods' in the book by the same name [19]. Jones states that "morphological charts are intended to force divergent thinking and to safeguard against overlooking novel solutions to a design problem", and that "experienced designers in mechanical and structural engineering have quickly learned to use it with enthusiasm and success in areas in which they have some knowledge of problem structure and feasibility." The fact that workshop participants are also experienced designers is the main reason we assume that also within field of building design this method can be applied. Since, according to 'integral approach', the basis for culture change is formed by relation research-education-practice, we also implement findings from workshop based research into master education program within Department of Architecture, Building and Planning at TU/e. As such, we were able to confirm one of other Jones' statements: "graduate design students who have tried the method have found considerable difficulty in defining *functions*" [28].

Emphasis on working with functions is based on experienced designers' preference for function-oriented strategy [12], instead to phase-oriented that is often recommended by (engineering) design methodology [22]. Besides, definition of functions during interpretation of design task makes it possible to assess client's needs on a higher, but better workable, abstraction levels than program of requirements (which is often too detailed) provides. Based on definition of functions, various design complexity levels can be separately discussed and, accordingly, possible solutions generated. This way interaction with the client is aided, and at the same time design process is structured. The process of continuous interpretation and solution feedback transparently narrows field of possible solutions leading to well thought-out integral building concepts, while actively involving the client in design process [26].

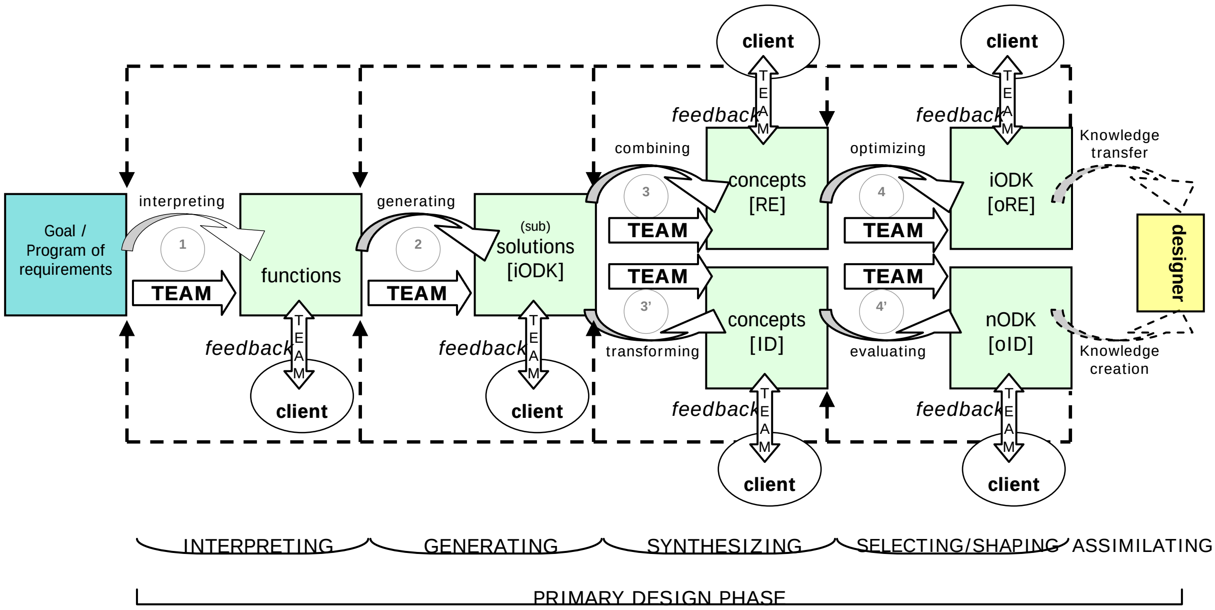


Figure 2. 'ID-methodology' design model; continuous feedback between design team and client additionally structures design process.

Using morphological overviews as a design tool all interpreted functions (step 1, Figure 2) and all generated (sub) solutions (step 2, Figure 3), represented by 'chunks' of object design knowledge, can be structured. During following activity (step 3/3', Figure 2), it is important to understand that integration of initially presented discipline based design object knowledge is something different than plain combination of (sub) results from various abstraction levels. Combination can only lead to redesign (RE), while in literature much referred designer's 'creative leap' is needed for integral concepts (ID). This is the major step in understanding how to work with morphological overviews, and needs 'designerly' [5] attitude. Because concept integration involves *transformation* of design knowledge (C-K theory), it requires design thinking / creativity. Contrary to redesign, the connections design team (members) make between presented (sub) solutions / design aspects in order to produce ID-concepts are subjective, design task and context dependent. Therefore, they cannot be objectified and/or rationalized. This is the reason why 'ID-methodology' can't be automated, even though the structure of morphological overviews makes it very tempting to try (Figure 3).

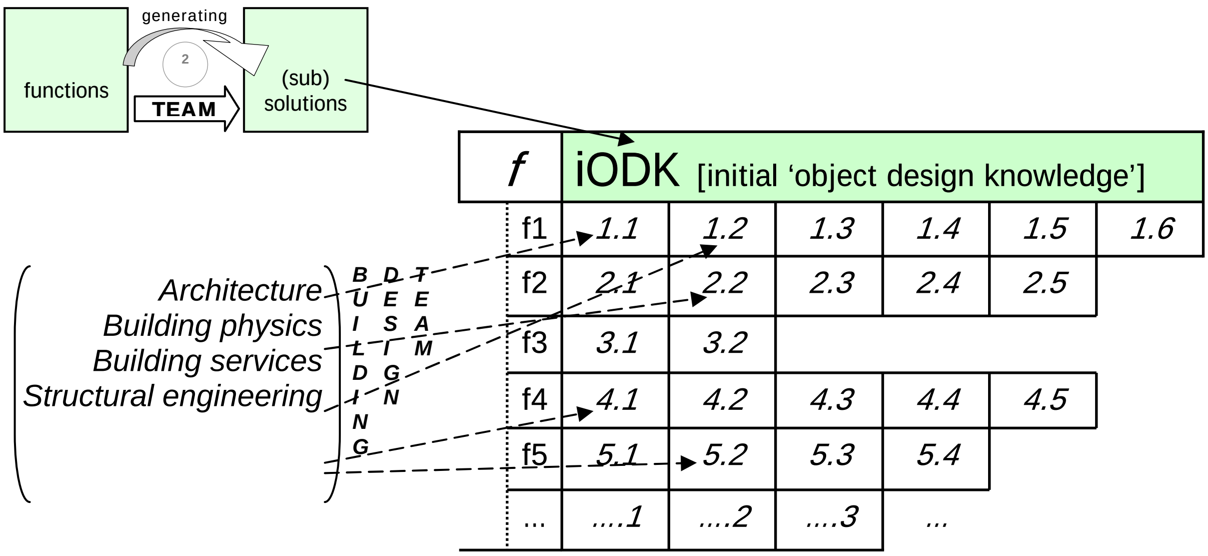

Figure 3. Morphological overviews show the initially available object design knowledge

The essence of 'ID-methodology' is strict separation between synthesising design proposals, being it RE or ID concepts, and selecting suitable ones. This selection step, which once again emphasises importance of interaction between design team and client, represents extension of methodical design model [34] as introduced by Zeiler [37].

DISCUSSION

'Integral design (ID) methodology', based on a reductive (positivism) framework [18,22,31,34] for design teams, in which concepts and knowledge (C-K) [14] constructs (phenomenology) [29] of individual designers are structured, provides suitable ground for creation of conceptual integral building designs. Subsequently, these integral concepts provide potential for creation of new (object design) knowledge. We have tried to build up this chain of reasoning as much as possible on our own observations of design teams during series of workshops with professionals. The development of workshop setting mirrors developments of 'ID-methodology'. Because we don't want this methodology to be yet another set of rigid prescription methods, but a flexible framework that most designers could fit to their own needs and ways of working, we have tried to modify and reduce it to a complexity level that would satisfactorily meet these needs. Taking into account that a fairly large number of new elements were introduced: workshop setting, design team configuration, methodical design, pressurised timeframe, forced client feedback, sustainable comfort systems, new design tasks and above all abstract thinking, a statement from W. Ernst Eder [18], made during one of design conferences, warns: "'If you have to use a new method, under time pressure, on a new problem – you will guaranteed fail!". Bearing this in mind, our framework was largely simplified (instead extended, as was initially expected). The only remaining tool, morphological overviews, however proved to be sufficiently suitable for 'learning-by-doing' explanation of integral approach involving 'ID-methodology'. They do require abstract thinking, for which an adaptation phase and a certain amount of training is needed, but they do provide framework for self-organization of design teams.

Modelling and optimization of multi-energy source building systems in the design concept phase

Vincenzo Corrado, Enrico Fabrizio and Marco Filippi

Dipartimento di Energetica (DENER), Politecnico di Torino, Torino, Italy

Corresponding email: enrico.fabrizio@polito.it

SUMMARY

A growing interest has been addressed to multi-energy systems in buildings that involve the integration of different energy sources to cover the thermal and electrical loads of the building. A modelling approach to multi-energy systems in buildings based on the concept of hybrid energy hub is presented. The model has been customised to be used in the concept phase of the building design, either as a system simulation tool or as a system design optimization tool. Given the prices of technologies and of energy-wares, under a certain set of constraints it is possible to determine the configuration that minimises the capital cost, the primary energy consumption or the life-cycle cost. This approach allows avoiding a burdensome simulation and ranking of a set of different systems. In the end, an application on a case study is provided.

INTRODUCTION

The energy system of a building is the complex of building plants that transform primary (chemical, thermal, solar, wind) and secondary (electricity, hydrogen) energy-wares into energy used to cover the building energy demand.
In recent years a growing interest has been addressed to zero energy homes or buildings that produce more energy than that they consume. The efforts to attain this goal have produced a progressive integration of renewable and conventional energy sources. This means that new technologies, such as solar plants, biomass plants, geothermal heat pumps, co/tri-generators, fuel cells, are spreading rapidly.
The application of these technologies leads to a sort of building that can be referred to as a multi-energy source building, since the thermal, cooling and electrical loads are covered by a mix of energy sources, at least one of them renewable. The aim is to design and manage such systems with the best efficiency [1].
It is necessary to investigate the coupling between a building, characterized by energy demand profiles for heating, cooling and electricity, and a system, characterized by production profiles (solar, wind, electricity, etc…). The study of the integration of different energy sources in buildings has to be the foremost in order to fully exploit the energy savings potential of renewable sources.
Being conscious that the degree of the design effort is greater during the program pre-design and schematic design phases [2], it is of a great importance to concentrate the research activities on the elaboration of a methodology to model and optimize the coupling between energy demand and energy supply in a building at the design concept phase.

MULTI-ENERGY SOURCE BUILDING SYSTEMS

Several examples of multi-energy source building systems can be found in literature, combining cogeneration with solar energy (both thermal and PV) and with wind energy [3], exploiting geothermal and solar energy through solar assisted heat pumps [4], combining CHP with absorption chillers and desiccant cooling [5], exploiting solar energy to produce both heating and cooling [6], exploiting wind energy through a fuel cell stack [7].
One of the main problems of a multi-energy system [8] is the mismatch between energy supply and energy demand. This is especially true for renewable sources. This problem, as for the plants that exploit solar energy to produce cold [6], is usually dealt with the integration of a storage. Typical storage mediums are water (refrigerated or ice), ground, PCM or hydrogen. As an example, in the wind fuel cell hybrid energy system described in [7] electricity surplus provided by a wind turbine is utilized to produce hydrogen that is used, later when necessary, in a fuel cells stack, which also represents a cogeneration system.
The objectives of multi-energy systems are the followings [8]:

- to reduce the primary energy consumption;
- to produce energy on site;

It is out of doubt that in the near future this kind of systems will be used both for new buildings and for renovations.

MULTI-ENERGY SOURCE BUILDING SYSTEM MODELLING

The presented modelling approach to multi-energy systems in buildings is based on the concept of hybrid energy hub, which was developed by Andersson, Fröhlich, Geidl *et al.* [9,10] to model and optimize the multi-carrier energy network of the future [11].
The building is modelled as an energy system that is supplied with different energy carriers and must meet heating, cooling and electrical loads. The coupling between the sources (inputs) and the loads (outputs) is established by a coupling matrix that depends on the technology and on the conversion efficiencies of systems and plants installed. Within the same modelling approach, different levels of complexity are possible depending on the input data and on the coupling matrix entries.
With reference to the optimization of a multi-energy source building system in the design concept phase, the data selected to model flow and conversion of energies within the hub are the design power P and the annual (or seasonal) energy E. Each energy carrier is identified by a superscript (e.g. *e* for electricity, *t* for thermal). The subscript identifies the demand (*out*) or the supply (*in*).
The coupling between energy demand and energy supply can be written as

$$\mathbf{E}_{in} = \mathbf{D}\,\mathbf{E}_{out}$$

where $\mathbf{E}_{in}$ is the vector of energy inputs $[E^e_{in}, E^t_{in}, \ldots]^T$, $\mathbf{E}_{out}$ is the vector of energy outputs $[E^e_{out}, E^t_{out}, \ldots]^T$ and $\mathbf{D}$ is the coupling matrix which depends on systems and plants installed and on their conversion efficiencies.
The same relation can be written for design power, assuming design efficiencies instead of mean seasonal efficiencies.
Each matrix entry d^{ab} accounts for both connection and conversion efficiency between energy carriers. A value of d^{ab} equal to 0 means that no connection between the energy carrier a and energy carrier b is provided by the hub; a value of d^{ab} equal to 1 means that all power of energy carrier a flows into energy carrier b without conversion losses.

Multi-energy source building system modelling application procedure

The application procedure to model a multi-energy source building system is the following:

1) identify the set of available energy sources and the set of building loads;
2) identify the components that can be used to cover the building loads, given the set of energy sources available: this can lead to two different approaches:
   2.1) a *generic hub* which takes into account all conversions (and the relative components) that energy sources can undergo before covering the loads;
   2.2) a *tailored hub* which takes into account only the conversions (and the relative components) that are of practical application and of interest to the building owner;
3) identify all the parameters (such as efficiencies) that can model the performance of the components both at the design condition and at operational conditions, and assign to them a numeric value;
4) define the costs of the energy-wares and of the technologies adopted;
5) perform an optimization to select the best multi-energy system.

MULTI-ENERGY SOURCE BUILDING SYSTEM OPTIMIZATION

Several criteria can be adopted to optimize a multi-energy source building system. Some of them are the followings:
- reduce the running costs;
- reduce the capital costs;
- reduce the amount of energy consumed in a period of time;
- maximize the efficiency of the system (both in terms of energy and of exergy);
- reduce the environmental impact of the building and services;
- maximize the use of natural resources that are available at no cost.

The most appropriate optimization criterion for the design concept of a multi-energy source building system in the design concept phase seems to be the economic approach. It has been adopted in the case study presented. Two different procedures can be outlined.
The first one is based on the net present value calculation. The procedure steps are the followings:

1) set a reference configuration (converters, allowable conversions, power flows, design powers of the converters) of the system;
2) set the period (number of years) for the investment analysis;
3) determine the capital cost difference and the running cost difference between alternative scenarios and the reference case;
4) calculate the net present value for each scenario based on capital and operational cost differences over the fixed period.

As regards the design alternatives, usually after a greater capital cost in the first year, savings on running costs are expected. The optimal scenario is the one that has the greater net present value (this comparison can be done if all net present values are calculated assuming the same period of time. The determination of the internal rate of return (IIR) is also useful.

The second procedure tends to minimise a yearly cost based on the sum of one year running costs and of the investment costs divided by the years of expected life of each component. This procedure can be implemented without defining a reference configuration of the system. In any case, the lifetime of components installed must be defined in order to compare capital and running costs.

APPLICATION TO A CASE STUDY

The methodology presented has been applied to the design of the energy system serving the Valcasotto castle in Piedmont.
A tailored energy hub procedure has been carried out as follows:

1) The available energy sources are: wood (*w*), LPG and electricity (*e*) from the network; the building thermal and the electric load are to be covered. Four demand scenario (the first one considering thermal energy only) have been identified in terms of design power $\mathbf{P}_{out}$ and annual demand $\mathbf{E}_{out}$ and are reported in Table 1.
2) The converters that can be used to cover the building loads are a wood boiler (WB), a boiler (B), an internal combustion engine (ICE) and a steam turbine (ST). The internal combustion engine and the steam turbine provide both electricity and heat. The heat-power ratios are respectively 1 and 2. The internal combustion engine is fed either by wood through a wood gasifier (WG) or by LPG. The steam turbine is considered to be an ensemble of a wood boiler and a steam turbine. The schematic representation of the energy hub considered is designed in Figure 1. The ε coefficients represent the load fractions covered by a certain converter (the superscript identifies the energy carrier, the subscript the converter): for example ε^{t}_{WB} represents the fraction of the thermal load covered by the output of the wood boiler.
3) The efficiencies η of the components (divided into thermal and electrical for cogeneration converters) are reported in table 2 including both design efficiencies and yearly mean efficiencies.

Table 1. Components of $\mathbf{P}_{out}$ and $\mathbf{E}_{out}$ vectors (respectively in kW and MWh/year)

Energy	Scenario 1		Scenario 2		Scenario 3		Scenario 4	
	$\mathbf{P}_{out}$	$\mathbf{E}_{out}$	$\mathbf{P}_{out}$	$\mathbf{E}_{out}$	$\mathbf{P}_{out}$	$\mathbf{E}_{out}$	$\mathbf{P}_{out}$	$\mathbf{E}_{out}$
Thermal	1857	6169	1284	4267	929	3085	573	1902
Cooling	0	0	0	0	0	0	0	0
Electricity	0	0	573	1902	929	3085	1284	4267

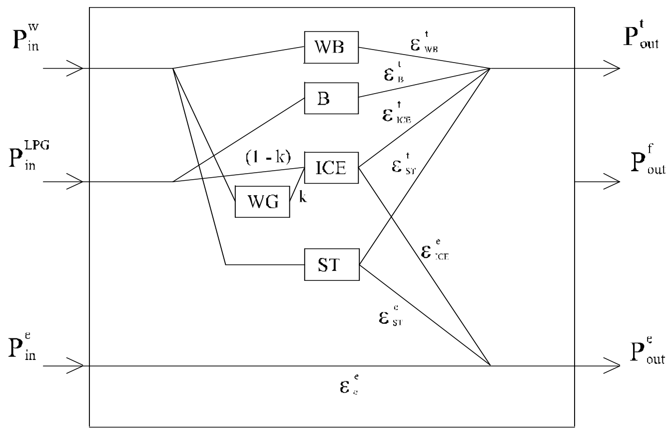

Figure 1. Schematic representation of the Valcasotto tailored energy hub

Table 2. Design efficiencies and mean annual efficiencies of the converters

Design efficiency		Mean efficiency	
η_{WB}	0.75	η_{WB}	0.65
η_{B}	0.95	η_{B}	0.85
η_{WG}	0.75	η_{WG}	0.65
η^{t}_{ICE}	0.40	η^{t}_{ICE}	0.30
η^{e}_{ICE}	0.40	η^{e}_{ICE}	0.30
η^{t}_{ST}	0.60	η^{t}_{ST}	0.45
η^{e}_{ST}	0.30	η^{e}_{ST}	0.23

After having defined the efficiencies of each converter η (for example η^{t}_{ICE} is the thermal efficiency of the internal combustion engine) the input powers at the entrance port of the hub can be determined summing up the contributions of each converter as follows:

$$
\begin{aligned}
P^{w}_{in} &= \frac{1}{\eta_{GCL}}\varepsilon^{t}_{WB}P^{t}_{out} + \left(\frac{1}{\eta^{t}_{ST}}\varepsilon^{t}_{ST}P^{t}_{out} + \frac{1}{\eta^{e}_{ST}}\varepsilon^{e}_{ST}P^{e}_{out}\right)/2 + \left(k\frac{1}{\eta^{t}_{ICE}\eta_{WG}}\varepsilon^{t}_{ICE}P^{t}_{out} + k\frac{1}{\eta^{e}_{ICE}\eta_{WG}}\varepsilon^{e}_{ICE}P^{e}_{out}\right)/2 \\
P^{LPG}_{in} &= \frac{1}{\eta_{B}}\varepsilon^{t}_{B}P^{t}_{out} + \left((1-k)\frac{1}{\eta^{t}_{ICE}}\varepsilon^{t}_{ICE}P^{t}_{out} + (1-k)\frac{1}{\eta^{e}_{ICE}}\varepsilon^{e}_{ICE}P^{e}_{out}\right)/2 \\
P^{e}_{in} &= \varepsilon^{e}_{e}P^{e}_{out}
\end{aligned}
\tag{1}
$$

Assuming a linear correlation between inputs and outputs, this can be rewritten in a matrix form as

$$
\begin{bmatrix} P^{w}_{in} \\ P^{LPG}_{in} \\ P^{e}_{in} \end{bmatrix} = \begin{bmatrix} \frac{\varepsilon^{t}_{WB}}{\eta_{WB}} + \frac{\varepsilon^{t}_{ST}}{2\eta^{t}_{ST}} + k\frac{\varepsilon^{t}_{ICE}}{2\eta^{t}_{ICE}\eta_{WG}} & 0 & \frac{\varepsilon^{e}_{ST}}{2\eta^{e}_{ST}} + k\frac{\varepsilon^{e}_{ICE}}{2\eta^{e}_{ICE}\eta_{WG}} \\ \frac{\varepsilon^{t}_{B}}{\eta_{B}} + (1-k)\frac{\varepsilon^{t}_{ICE}}{2\eta^{t}_{ICE}} & 0 & (1-k)\frac{\varepsilon^{e}_{ICE}}{2\eta^{e}_{ICE}} \\ 0 & 0 & \varepsilon^{e}_{e} \end{bmatrix} \begin{bmatrix} P^{t}_{out} \\ P^{f}_{out} \\ P^{e}_{out} \end{bmatrix}, \tag{2}
$$

where the products $\varepsilon^{e}_{ICE,ST}P^{e}_{out}$ and $\varepsilon^{t}_{ICE,ST}P^{t}_{out}$ are related, in the case of a cogenerator, by the relation

$$
\varepsilon^{t}_{ICE,ST}P^{t}_{out} = \varepsilon^{e}_{ICE,ST}P^{e}_{out}\frac{\eta^{t}_{ICE,ST}}{\eta^{e}_{ICE,ST}}, \tag{3}
$$

that must be included as a further equation to (3) in order to model the hub performance. The optimisation of the hub can be performed by minimizing the objective equation

$$
C_{y} = f\left(\mathbf{E}_{\mathrm{in}}, \mathbf{P}_{k}\right) \tag{4}
$$

which takes into account the energy costs in a period of time and the capital cost of the converter devices installed. It is therefore necessary to determine the design power of each converter $\mathbf{P}^{k}$ and then (5) can be rewritten as:

$$\min C_y = \min\left(c^{\mathrm{w}} E_{\mathrm{in}}^{\mathrm{w}} + c^{\mathrm{LPG}} E_{\mathrm{in}}^{\mathrm{LPG}} + c^{e} E_{\mathrm{in}}^{e} + \frac{c_{WB}\, P_{WB}}{y_{WB}} + \frac{c_{B}\, P_{B}}{y_{B}} + \frac{c_{ICE}\, P_{ICE}^{e}}{y_{ICE}} + \frac{c_{WG}\, P_{WG}}{y_{WG}} + \frac{c_{ST}\, P_{ST}^{e}}{y_{ST}} \right) \quad (5)$$

where cost for energy consumed c, costs of converters (in terms of design power) c_k are resumed in tables 3 and 4. The expected number of years is fixed to 20 years for each converter. The minimisation of this yearly cost function has been performed by means of a commercially available reduced gradient method algorithm.

The problem is then to find the values of ε that minimize the cost function

$$\varepsilon_i^{\alpha} : \min \quad f\left(\mathbf{E}_{\mathrm{in}}, \mathbf{P}_{\mathrm{k}}\right)$$

under the constraint of the hub:

$\mathbf{E}_{\mathrm{in}} = \mathbf{D}\ \mathbf{E}_{\mathrm{out}}$; $\mathbf{P}_{\mathrm{in}} = \mathbf{D'}\ \mathbf{P}_{\mathrm{out}}$

$\mathbf{E}_{\mathrm{in}} \geq \mathbf{0}$; $\mathbf{P}_{\mathrm{in}} \geq \mathbf{0}$

and the constraints relative to the ε coefficients:

$$0 \leq \varepsilon_i^{\alpha} \leq 1 \ \ \forall\, \alpha \qquad , \forall\, i \in \{GCL, GC, ME, \ldots\}$$

$$\sum_i \varepsilon_i^{\alpha} = 1 \ \ \forall\, \alpha$$

$$\varepsilon_{ME,TV}^{t} P_2^{t} = \varepsilon_{ME,TV}^{e} P_2^{e} \frac{\eta_{ME,TV}^{t}}{\eta_{ME,TV}^{e}}$$

Table 3. Cost structure c of the energy wares

Energy-ware	[€/kWh]
Wood	0.014
LPG	0.060
Electricity	0.150

Table 4. Cost structure c_k of the energy converters

Energy converter	[€/kW]
Wood boiler	200
Boiler	100
Wood gasifier	50
ICE	900
Gas turbine	1100
Electricity	100

The results of the optimization of each scenario are shown in figure 2.

The model can be used to simulate, for a given demand scenario, other hub structures. In the case of scenario number 2, it is possible to determine the primary energy that must be supplied using the internal combustion engine feed by gas via the wood gasifier or the internal combustion engine fed by LPG instead of the wood gasifier and the steam turbine. This can be done by fixing the values of coefficient ε instead of letting them to freely change as in the optimisation. Those two alternative scenarios simulated are presented in figure 3 and it can be verified that the resulting values of C_y are higher than that of the optimized configuration.

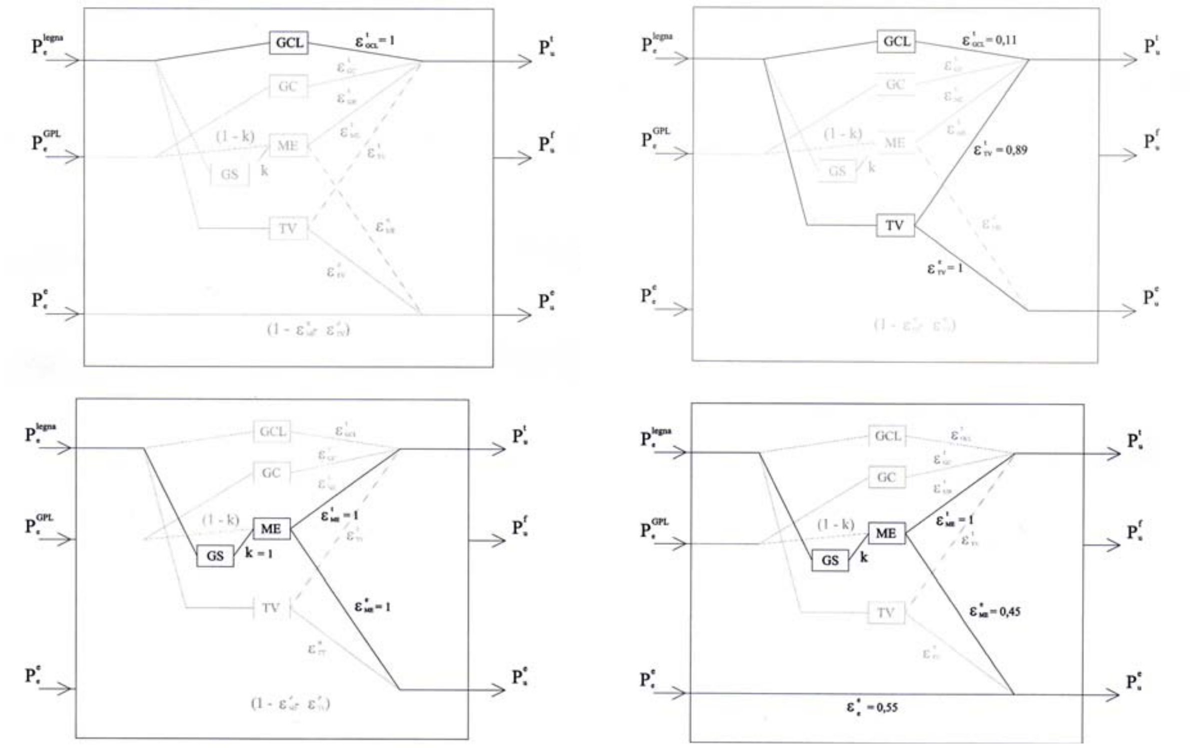

Figure 2. Schematic representation of the Valcasotto tailored energy hub optimized for four different demand scenarios (1 to 4 from right to left)

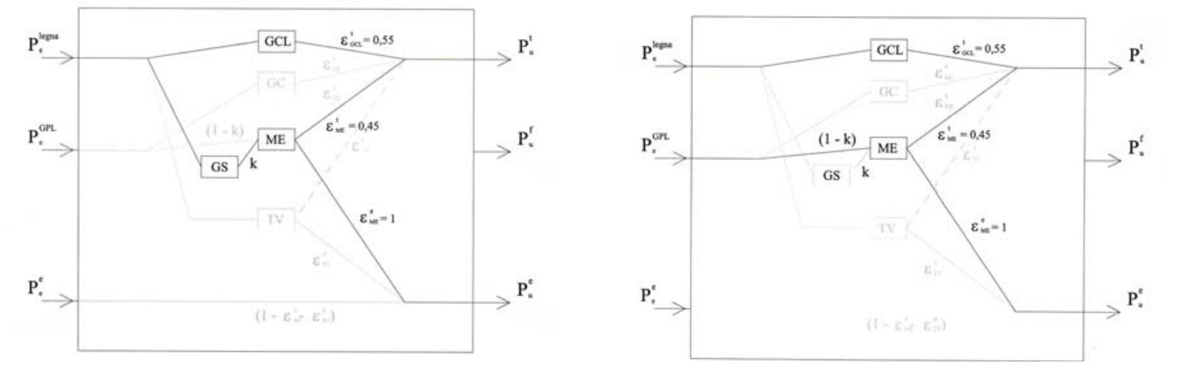

Figure 3. Schematic representation of two further simulation of the Valcasotto tailored energy hub for the second demand scenario

DISCUSSION

A modelling approach to multi-energy systems in buildings has been presented. It is based on the concept of the hybrid energy hub has been customised to be used in the design concept phase. The model is quite simple and allows analysis to be performed in presence of design power and annual or seasonal energy demand data only.

Such a model meets the requirements of simplicity that characterize the design concept phase, but a factor of uncertainty is represented by the choice of the values of the efficiencies. Values of mean seasonal efficiencies greatly affect the results and appropriate values of these properties are difficult to determine *a priori* and must be based on the consultant experience. Further research activity is currently carried out to overcome this drawback; values of efficiencies dependent on design power installed and on the part load ratio may be integrated into the model.

Integral approach for adaptable indoor comfort; Building and occupants follow the sun

Wim Zeiler

Technische Universiteit Eindhoven, The Netherlands

Corresponding email: w.zeiler@bwk.tue.nl

SUMMARY

The focus on the needs and drives for adaptation of the building automatically leads to changing needs and demands of the occupants of the building. Building should really take care of its occupants and show adaptable behaviour and reaction to the changing outdoor environment during the day. Design for adaptability should start with the occupants needs for comfort and indoor air quality. These are partly influences by the changing environmental forces as wind and sun. Weather predictions and the aggegated voting of users about their thermal comfort, should be the leading parameters to adaptable comfort and the adaptable building.

INTRODUCTION

Building design is a fascinating ,it starts with a blank sheet and ends with a building with spaces and materials. Since the future is unknown, it is only possible to paint scenarios, possible futures, buildings have to meet. A building usually has to comply with more demands than mentioned in the list of specifications, for example because they were overlooked by the client, or necessary changes during the design process. In the continous analysis, there are hard to quantify demands, such as comfort, beauty, social acceptance and safety. The designers has to pay due attention to all aspects, how trivial or unexpected they may seem.

Inappropriate formation of the design team may result in ineffective designprocess and solutions. Many problems emanate from a lack of integration between architectural design and design of indoor climate. After the industrial revolution, the natural relationship between design, construction and the built environment disappeared and has been replaced by a complex system of decision making, complex legislation, a subdivision of a whole integrated building into subsystems and disciplines in the construction process.

METHODOLOGY

The making of the built environment has become complex. In the conceptual design phase, in order to create conditions that assure a built environment that gets better, the ingenuity of the whole design team existing of different disciplines should be used, not only architecture. The quality of the team should be combined with a well considered process of decision making. Techniques are selected and put together by a team in an integral design process. In addition to the application of proven construction methods, the integral approach demands an attitude of openness and appreciation of the other participating disciplines and their positions.

This approach makes it possible to combine and develope different kind of aspects in interaction to each other. During the design proces participants and their decisions are structured at several levels of decision-making; the infill-level, the support-level and tissue-level. On each level there has to be made a balance between the performance of supply and demand for the building during the life-cycle. The basis of this *'level-thinking'* is that of the Open Building [1]. As often such new ideas take a long time before being implemented. The Osaka Gas NEXT 21 Project in Shimizudani, Tennoji-ku, Osaka City, Japan, realized in October 1993 is a very nice example of the realisation of the open building approach, see figure 1.

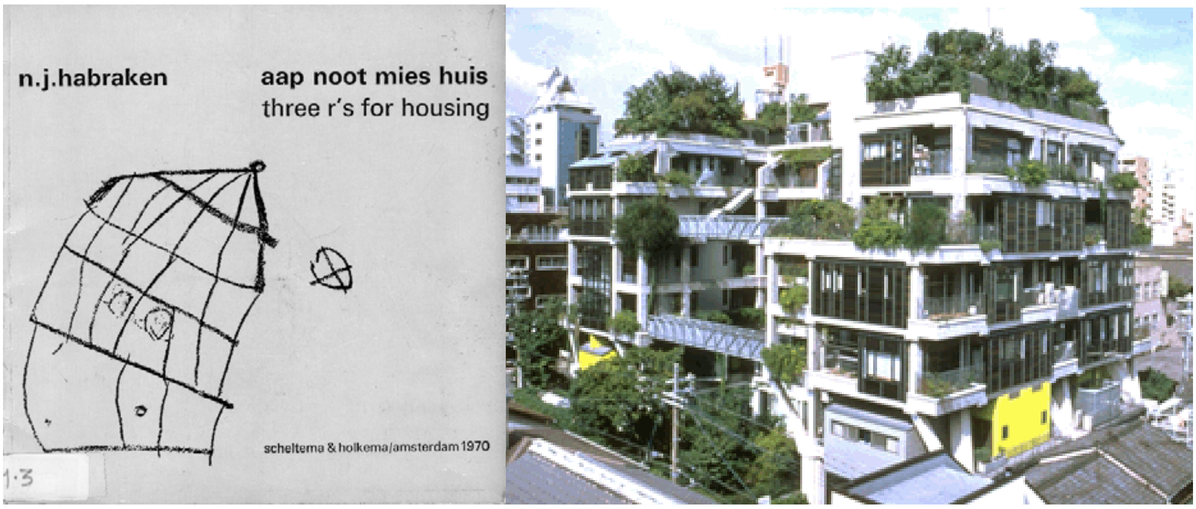

Figure 1: Publication by Habraken, NEXT project interesting realisation of the ideas

Open building is primarily intended as an organised way of responding to the demands of diversity, adaptability and user involvement in the built environment. In open building the built environment is approached as a constantly changing product engendered by human action, with the central features of the environment resulting from decisions made at various levels.

A central idea in Open Building is to respond to the various needs of individual users through the phasing of the design and implementation process. In order to provide prospective occupants with the opportunity to influence their building, the elements decided by the occupants must be easy to change. Thus adaptability is not merely a means for modifying the dwelling during use; it is first and foremost a strategy for enabling the fulfilment of individual wishes without compromising. Thinking in levels is the basic Open Building principle.

Techniques are available to help further organize the complexities of environment as a subject into its component part and wholes. Dissecting a subject into its intrinsic parts and then shifting to how those parts are organized into a whole, allows access to content as well to the way parts connect and, therefore, to a full definition. To characterize connections a hierarchy is needed to out line sequence and progression and to illustrate part-whole relationships.

During design support, it is important to transfer the essentials of the proposed structures and mechanisms, without overloading other member of the design team with unwanted details. This information control can be achieved by use of abstraction. So far, many building teams have been sending their partners detailed drawings, thus relying on the addressees to make the necessary abstraction themselves. With the increasing use of product information models, it is now possible to incorporate multiple abstraction levels in the design representation. Abstraction is the mapping from one representation of a problem to another, which preserves certain desirable properties and reduces complicity [2]. Abstraction is the selective examination of certain aspects of a problem. The goal of abstraction is to isolate those aspects that are important for a particular purpose and suppress those aspects that are unimportant [3]. This enables representations to take an appropriate (abstract) form that matches the needs of the design specialist, thus saving much time and confusion.

Throughout the different levels of abstraction, the description of the building design gradually becomes more and more detailed. The various levels of abstraction should be considered as representations of a particular view on the total information available for a design.

This integrated design model must:

- be able to distinct related information,
- support distinctions related to the different levels of abstractions (views) by being structured into corresponding sub-models,
- ensure the satisfaction of consistency and completeness constraints linking different levels of abstraction in the design process.

Methodical Design [4,5,6] can be described at the conceptual level as a chain of activities which starts with an abstract problem and which results in a solution.The original methodical design process is extended from three to four main phases, in which eight levels of functional hierarchical abstraction can be distinguished, see figure 2.

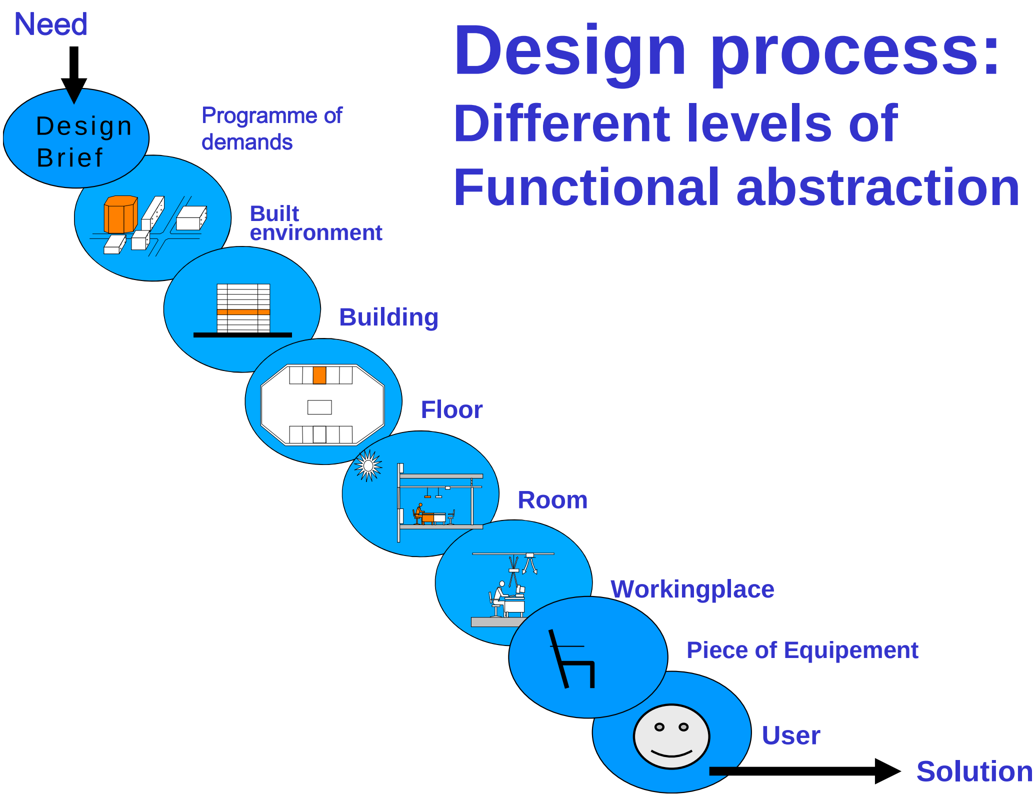

Figure 2: Functional Hiearchy Methodical Design

Hierarchy can be used as a simplifying organizational tool to order and relate the parts of a subject in range-large to small most important to least, etc., used in a neutral sense where all parts are unique and important. Hierarchy theory in this way, frees minds from the analytical mode without requiring them to reject it and provides, as well, glilmpses of a wider, more diverse world. Hierarchies suggest an interplay between parts and wholes and between the two basic modes of thinking:

- Analysis: separation of a whole into its component parts, the examination and study of each part;
- Synthesis: the composition or combination of parts or elements so as to form a whole.

This organizational structure provides a way to study and design complex issues. With regard to the built environment the parts human, built and natural environments can be analysed separately and then synthesizing the parts together to form a composite definition to obtain more meaning like a word integrated into a phrase and then into a sentence.

To work effectively with methodology, practitioners should learn to work with, and understand, the role of methodology in the building design process. Often means and goal are mixed up. More and more the insight is growing that it is not the building to be designed that should be central but the needs of the humans for which the building is intended.

FOLLOW THE OCCUPANTS NEEDS

For about 40 years there is an evolution of thinking and research in this way, strongly related to the integration of disciplines in proces and product. The most important new idea is taking man in his environment as the departure point, variable and criterion. The comfort of the occupants becomes leading.

The first guidelines for thermal comfort in the Netherlands were developed in the late seventies and eighties. They were based on the theory of Fanger and resulted in the PMV-PPD relationship, which predicts the percentages of dissatisfied occupants. Extensive field research however by de Dear showed that people have various adaptation mechanisms with most important people's expectations of the building's climat, based on the actual outdoor temperature. New thermal comfort models based on the human adaptability were developed over the past years. Applying adaptive thermal comfort, a distingtion was made between different types of buildings, usage and climatic circumstances. An important feture to distinguish between the differences here is the possibility of individual control [7].

The representation of situations with multi end-users, multi-individual control, was realized by developing an individual voting sytem. This voting system implied that every user in a thermal zone could enter his or her vote, warmer or colder, within a voting period, e.g. one hour, while seeing the aggregated voting of other users in his zone at the moment of voting.

The new user behaviour control strategy was implemented in a BMS(Building Management System). This BMS was extended with an external real-time information system to improve energy and comfort control.

To further enhance comfort and at the same time reduce energy consumption of buildings, new control technology is needed. Technology in which the end-user behaviour and preferences are integrated into a responsive ambient surrounding. Improvement of the energy consumption is made possible by agent-based systems for energy management in buildings, as well as new possibilities occur to enhance individual comfort of occupants.

On this philosophy, design teams can develop buildings with contrastful attributes for temperature, wind, humidity, daylight and smells. Buildings similarly gain a contrastful microclimate that changes in accordance with the time and the outdoor conditions, as well as a more pleasant interior, a space that will endure longer than we may imagine.

INTEGRAL APPROACH

The search for a building that functions better within its surroundings forces architecture into every closer company with engineering. These buildings take advantage of the prevailing climatic conditions in combination with the familiar physical principals of natural draught, sunlight, wind, precipitation etc. The climatic conditions of the location are highly determinative for the form of the building, thus producing a climate-related and regionally distinctive architecture. Intensive collaboration with technical consultants takes place from the outset in these designs.

In 2000, the Royal Institute of Netherlands Architects, BNA, TVVL and the Delft University of Technology have participated in a research project called Integral Design. Observations in the construction industry show a fractionated process by different parties achieving their own aims, working on the same building. Different cultures and different traditions, many times conflict with the common aim of completing the building. The initiators of the Integral Design project had the vision that breaking the barriers of different trades may be the first step to a better built environment. It was named Integral Design and unfolded ways to implement, investigate, teach and learn the integral approach (2). The Integral Approach in relationship to Integral Design has to deal with different scale-levels and different 'kind' of aspects. To give the range of aspects which are related to the Integral Approach, not in the way to give a definition, in the way of describing, shows the interweaving meachism between the several apsects and the area and approach which belongs to the word 'Integral'[8]

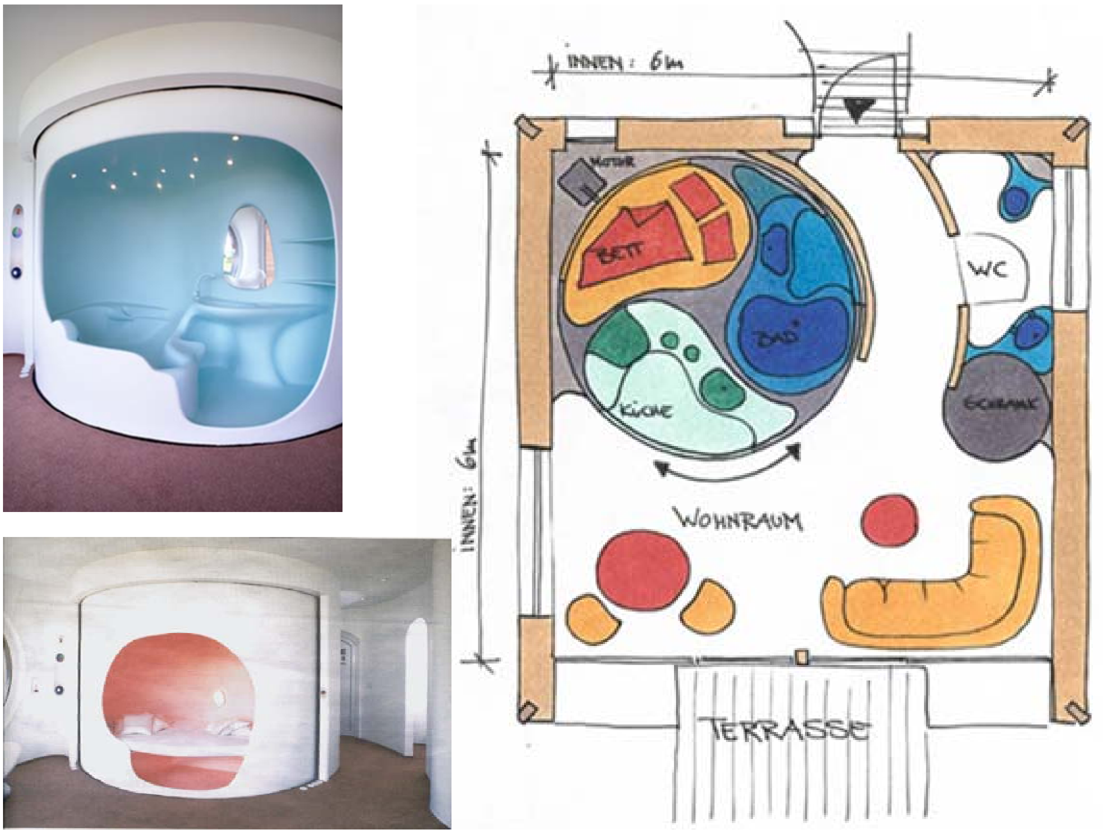
The 'umbrella-aspect' is the flexiblity and bandwidth in process, designmethodology, constructionmethodology and facility-management. The integral approach will guide, interdependent to the value-frameworks, will control and correct and will leave room to the specific method or sollution for the several participants during the total process.

The Integral Approach is conceptual and therefore inhabits the several 'specific methods' such as for instance Strategic Design, Sustainable Design and LCA-Design. The Integral Approach is related to the longer term for different (time, site, process and program) settings; a sustainable approach [9][10], [11].

The integrated building design process is one which considers all aspects of a building, its environment and life cycle, and is undertaken by a team which includes all relevant professionals and stakeholders working together throughout the process rather than sequentially and independently.

INTERNAL ADAPTABILITY

Internally, structures satisfy and symbolize human spatial needs, wants and values; externally they provide and symbolize a protective envelope, an interrelationship with the outside environment. The external enclosure can be considered the “third skin” of the human body and its comfort (light, fresh air, optimum temperatures, etc.) is based upon human senses and either provided for by natural means (windows for light, solar energy for heat, shade for cooling, etc.) or by artificial means (electric lights, heating, air conditioning, etc.). The project ‘rotor haus’of Colani shows how internal adaptability of use of specific functional rooms is possible. Nevertheless because of the major influences of the sun, outside adaptability is more important in relation to energy and esthetics.



Picture 1 Rotorhaus, L.Colani, 2004

OUTSIDE ADAPTABILITY: ADAPTIVE BUILDINGS TO THE SUN

The external character of a building form is shaped not only by internal requirements, but also by fitting a building to its elusive environmental context. Designing with local climates and sun orientation, with similar construction methods and materials, can increase human comfort and reduce energy consumption. Building, indeed, must consider and respond to its built environmental context but also to its natural environment. Technologies should resolve conflicts between what the natural environment provides and human needs, sustenance and comfort.

To let the building react on the thermal comfort demands, it is effective to let the building react to the path of the sun. By letting rotate the building, its sun protection or both, with the turn of the sun the heat of the sun can be left outside the building or when needed let into the building. Differnet solutions were already realised in built projects. But there are more solutions to make buildings adaptive to the sun and the comfort needs of the occupants. Some of the realized projects show completely different ways of solution.

Figure 3. Draai test woning ECN Petten 2002, Waterwoning H.Hertzberg, Middelburg 2002 and Heliotropp, Rolf Dish, Freiburg, 1994

Figure 4: Gemini Haus, Erwin Katenegger, Steiermark, Oostenrijk, 2001

Figure 5: Ellesse International, Perugia, Italië,

If a building is a working whole, a system, we can distinguish subsystems: the load bearing construction, the envelope, inner partitions, HVAC and MEP installations and many more, as can be seen clearly in figure 4 the Gemini Haus designed by Erwin Katenegger and built in Steiermark, Oostenrijk, 2001. Instead of such a drastic and complete approach there are also solutions which are less drastic e.g. the headquater of Ellesse International in Perugia. In this project only the sunprotection is moving around the building and following the sun. Still the effect of such an adaptation to the sun gives a interesting dynamic architectural appearance. It is no longer a dream; A building that can anticipate on an unknown future consisting of building parts with different cycles of change, co-ordinated, yet uncoupled, designed by different disciplines, collaborating in a team, serving the client as well as the end user.

CONCLUSION

For the focus on the needs and drives for adaptability building comfort a process aproach is needed in which the thinking of the architect designer is linked in the design-process itself with the engineer. Support both parties with information on the tasks and decisions of the other party and at the same time supplying an explanation of this information will greatly enhance understanding performance of combined efforts. The structuring of the communication of the process between architecture and consultants is based on abstraction, for instance the exchange of abstract descriptions of a design. Through the different levels of abstraction, the building model is gradually described in an increasingly more detailed manner. Thus decomposing complex design-tasks into manageable size problems.

The integrally working design team not only designs the building, it designs the design process as well. Continuous adaptation of the design and final decision making need to be balanced. Thus the design process is cyclical, spiralling up towards the final plan. The plan with its focus on internal and outside adaptability also determines the possibilities and impossibilities of construction, maintenance and management, It is therefor important to inform and hear the construction partners and the parties .responsible for running the building. It is quite likely that a certain team will never operate again in the same configuration. It is therefor advisable to report on and evaluate the process in order to gain from the accumulated experience and techniques applied.

ACKNOWLEDGEMENTS

The research is embedded in the KCBS (Knowledge Centre Building Systems TNO-TU/e) . The current proposal fits within the research theme “Sustainable energy systems”. One of the objectives of this theme is to provide tools, knowledge and procedures for integrated design processes which lead to innovative applications of comfort systems for building designs with a balanced attention to the value systems of the building occupants, building owner, society and environment.
KCBS, Kropman and the foundation PIT support this research

Energy Autarky of the Monte Rosa Cabin – A Challenge for the Building Services Engineering Concept

Urs-Peter Menti, Iwan Plüss and Stefan Mennel

University of Applied Sciences of Central Switzerland, Lucerne (HTA)

Corresponding email: umenti@hta.fhz.ch

SUMMARY

Close to Zermatt (Switzerland) the new Monte Rosa mountain cabin is going to be built in 2008 at 2810 metres above sea level. This hut is designed to accommodate 120 mountaineers. Furthermore, it is going to mark a milestone in high alpine building presenting an attractive, unconventional architecture combined with both a surpassing comfort and a high degree of energy autarky of over 90%.

Of course several measures have to be taken to achieve such a high degree of autarky while always keeping a limited budget in mind. Apart from the technical systems, which are based on existing technology (combined heat and power unit, photovoltaics, thermal collectors), there will be an innovative wastewater treatment and, first and foremost, an ingenious energy management. Only an optimised operation taking into account external conditions such as weather forecast and anticipated occupancy schedules is likely to achieve the demanding goal of the high degree of autarky. Detailed thermal simulation is used on the one hand to dimension the building services engineering systems and on the other hand to develop the best energy management strategies.

This is a joint project of the Swiss Alpine Club (SAC) together with the Swiss Federal Institute of Technology in Zurich (ETH), while the energy strategy and building services technology concepts are worked out by the Centre for Integral Building Technology (ZIG) at the University of Applied Sciences of Central Switzerland, Lucerne (HTA).

Figure 1. The new Monte Rosa cabin amidst impressive glaciers showing the Matterhorn in the background (computer visualisation by ETH).

INTRODUCTION

The new Monte Rosa cabin is planned in the context of the 150-year anniversary of the ETH in a joint project with the SAC. The hut is situated 2810 metres above sea level amidst pure nature, surrounded by the Gorner, Grenz, and Monte Rosa glaciers and about 10 kilometres away from the world-known health resort Zermatt. The Monte Rosa cabin is one of the best-known and most visited alpine huts of Switzerland and the starting point for several mountain hikes.

For this new building the engineers aim high. The mountain cabin shall offer an unheard of comfort for such a mountain shelter. Rooms will be heated and mechanically ventilated, the hut will be supplied with enough fresh water such that the visitors can enjoy a hot shower and the wastewater is going to be purified on-site to be reused as greywater. All of the above-average comfort shall be provided without negative effects on the hut's required energy supply. Indeed the hut will feature an energy autarky of 90% meaning that 90% of needed energy is obtained locally from renewable sources.

The concept worked out in detail by HTA incorporates technologies and procedures by which the high requirements concerning comfort, energy demand, and autarky can be achieved – all the time bearing in mind that the budget is limited. Thermal simulations turned out to be of crucial importance to both reach the high planning confidence and permit to establish that the set goals can be achieved.

This paper offers an overview of the aims, the approaches, and the proposed solutions to building services engineering.

METHODS

The simulation package IDA ICE 3.0 [1] is used to set up a very detailed simulation model both of the building and the energy and building services system based on the formulation of the energy strategy and building services engineering concept described below. This model takes into account the climate data, the geometry, the physical properties of the building envelope, all components of energy supply and building services, as well as the thermal loads of persons, equipment, and lighting. The entire system, room temperatures and conditions, as well as the energy flows are being calculated dynamically using hourly steps over a whole year.

These simulations pursue three main aims:

- Represent the actual project status,
- Identify the important factors and system sensitivity on these,
- Optimise the building envelope, the building services, as well as the operation (energy management).

At the same time the investment costs are calculated in a second computing model since the cost is a dominant factor for project realization. This second computing model integrates the investment costs and finds how the energetic aim of 90% autarky are reached at the lowest cost.

Starting from the first design solution, different scenarios with varying exterior conditions are calculated to analyse the stability and robustness of the technical solution examining:

- How does the system react to changed climate conditions (e.g. fewer sunny days than expected)?
- How does the system react if the number of visitors exceeds expectations?
- How does the system react to the failure of single components (system redundancy)?

The following chapter comments on the results of the first phase of the project "Definition, dimensioning, and optimisation of both energy and building services technology". The second phase of the project "Energy management" is currently subject to ongoing work at the HTA.

RESULTS

Water

Water supply and wastewater treatment are top-ranking questions considering the hut's location far away from any infrastructure [4]. On top, the water demand surpasses the average demand of mountain shelters due to the elevated comfort requirements of the cabin (hot water showers, toilets with water flushing).

The calculations show that even using water saving devices, 219 m^3 of fresh water are needed annually. This amount can only be won by catching the melt water around the hut. At the same time it is essential to take into account that melt water accumulates primarily during the summer months (typically during two months only). Therefore the melt water needs to be collected and stored until the next summer. Should the water tank not be built high enough above the hut, a booster pump is necessary. Although the quality of this water is quite good in general, it cannot be directly used as drinking water.

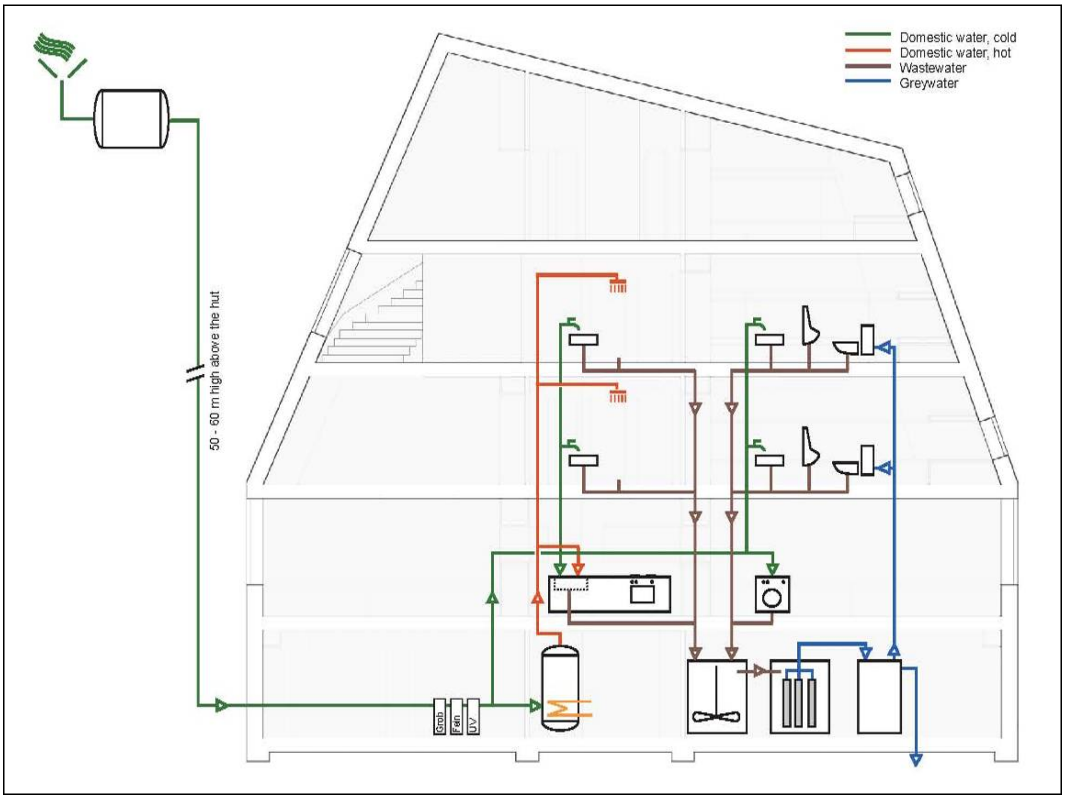

Figure 2. Concept of water supply and wastewater treatment.

After suitable treatment the melt water is used for showers, for cooking, for personal hygiene, and laundry. The toilets are flushed with greywater that originates from the wastewater treatment system. This system is new for such sites and based on the principle of microbiological sewage plants [2]. Tests on the nearby mountain *Hohtälli* show very promising results.

The water balance presents itself as follows:
Supply water: 219 m^3/a, thereof 120 m^3/a hot water
Greywater: 100 m^3/a
Wastewater: 320 m^3/a

Figure 3 shows the water demand prediction over the year, the expected melt water volume, and the resulting water level at the water tank. Clearly recognisable are the weekends with high water demand and the peak weekends with the maximum demand (about 3500 l/d which equals 30 litres per guest). Well recognisable is the fact that the critical phase of storage is reached in early summer just before the melting begins. Depending on the effective water level at the water tank it is generally necessary to save water in spring, which is easily and most effectively done by shutting off the showers.

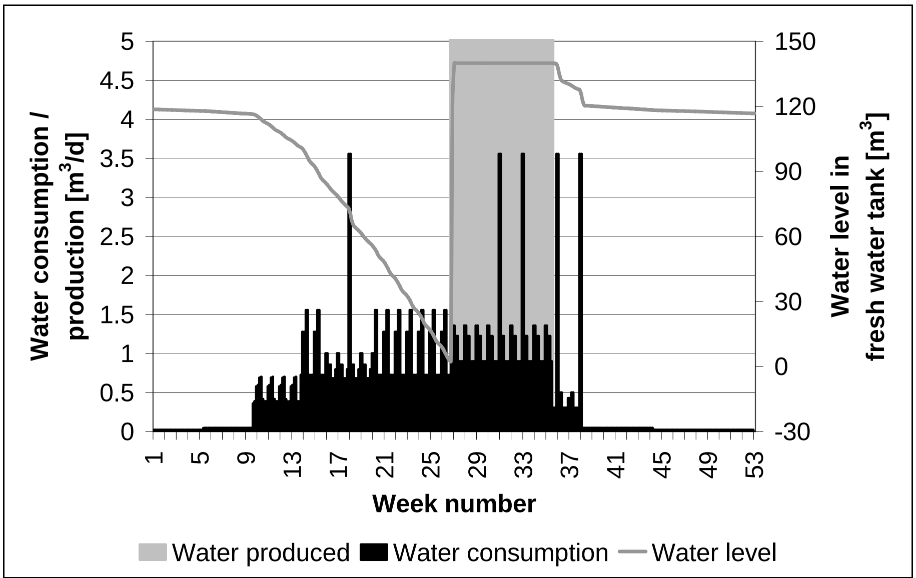

Figure 3. Water supply (20m^3/d during summer) and use, water level at the water tank.

Another point of importance concerns frost protection of the water tank since it will be placed outside the hut. Using good insulation and covering the water tank several metres high with soil solves this problem. In addition, the water tank will be heated during winter by the excess electricity from photovoltaics so that the water temperature will never fall below 5 °C.

Energy

For the needed electricity and heat energy there are photovoltaics (about 84 m^2) and thermal collectors (about 56 m^2) available, respectively. Optionally, a wind generator could supplement those facilities. Although no manufacturer could be found to date who would guarantee its operation at this exposed site. Solar energy can cover 90% of the energy demand not counting cooking, which in a later phase could be covered by solar energy as well. A combined heat and power unit (CHP) powered by gas or rapeseed oil serves as a backup and to cover the demand during peak hours. Both a hot water storage tank of 6000 litres (4500 litres for heating and 1500 litres for sanitary hot water) and batteries having 184 kWh capacity buffer the occurring differences between heat supply and heat demand.

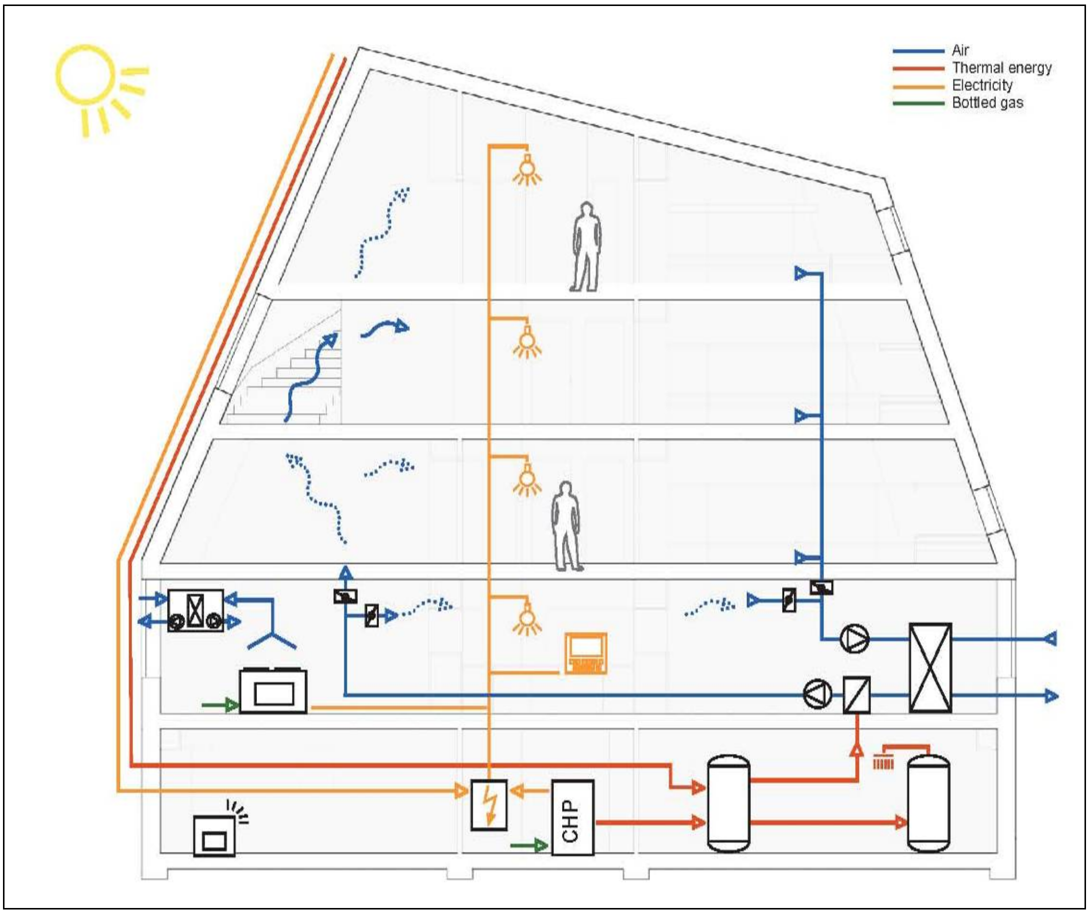

Figure 4. Basic scheme of energy and building services technology.

Building services technology
The cabin will be mechanically ventilated, which is a novelty for mountain shelters. The mechanical ventilation serves two purposes: First it helps to avoid structural damage mainly by mould (the risk is quite high since the building envelope is designed to be extremely airtight) and second, it ensures a basic thermal comfort for the occupants. At the same time the building will be heated by air. The supply air is blown into the open staircase and the exhaust air is drawn off the rooms. After heat recovery, the air is blown outdoors. During the operation of the hut (beginning of March till end of September) the internal heat loads (i.e., persons, equipment, and lighting) together with passive solar gains suffice to ensure the required air temperature of 5 - 20 °C, whereas the target value lies at 15 °C.

The dynamic simulations of the building services technology show that with the chosen concept it is necessary that especially during winter time, in the absence of the warden, the combined heat and power unit, is switched on to ensure the temperature of 5 °C to avoid freezing of piping. The buffers will be charged to 100% while they get uncharged during the few peak weekends when the CHP is used for the production of electricity.

The above described dimensioning of different parts of the facility is based upon elaborate dynamic simulations. Those simulations served to optimise, amongst others, the following parameters:

- Size of batteries and hot water storage tank,
- Optimal division of the available area into photovoltaics and thermal collectors,
- Clarification of whether an improvement of the building envelope or the augmentation of the area of thermal collectors (or the hot water tank) is more cost-effective.

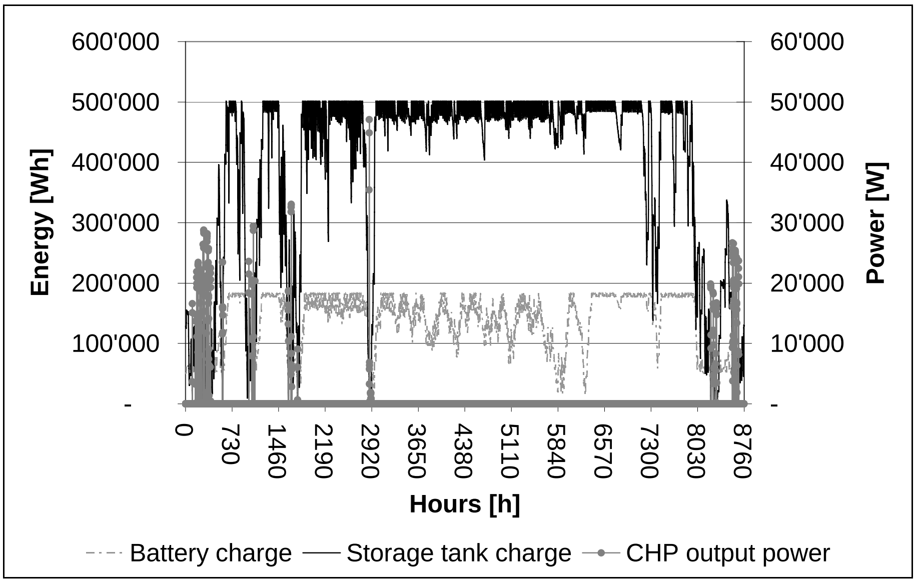

Figure 5. Results of simulations: State of charge of batteries and hot water storage tank, net total power production (heat and electricity) of CHP.

Figure 6 shows an example diagram for this optimising process. For different fractions of a certain total area covered by thermal collectors one can read off the possible degree of autarky on the ordinate. The abscissa hereby displays the total area covered by both photovoltaics and thermal collectors.

The figure shows that to reach a degree of autarky of 90% and using the best ratio of photovoltaics and thermal collectors one would need at least 125 m^2 total covered area. The concept of HTA proposes to cover up 140 m^2, taking into account the local situation.

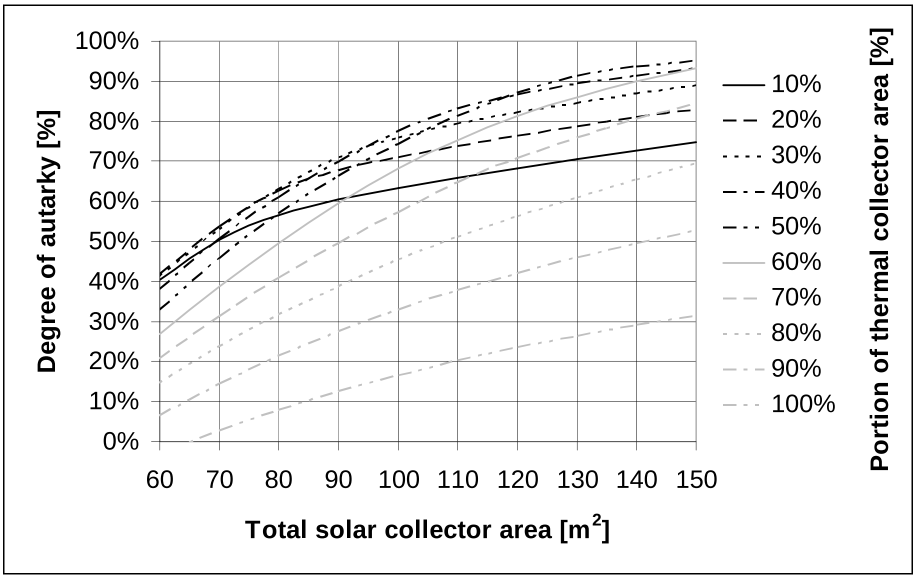

Figure 6. Optimisation of the total area covered with collectors and the resulting degree of autarky. The different curves represent the portion of thermal collectors to the total collector area.

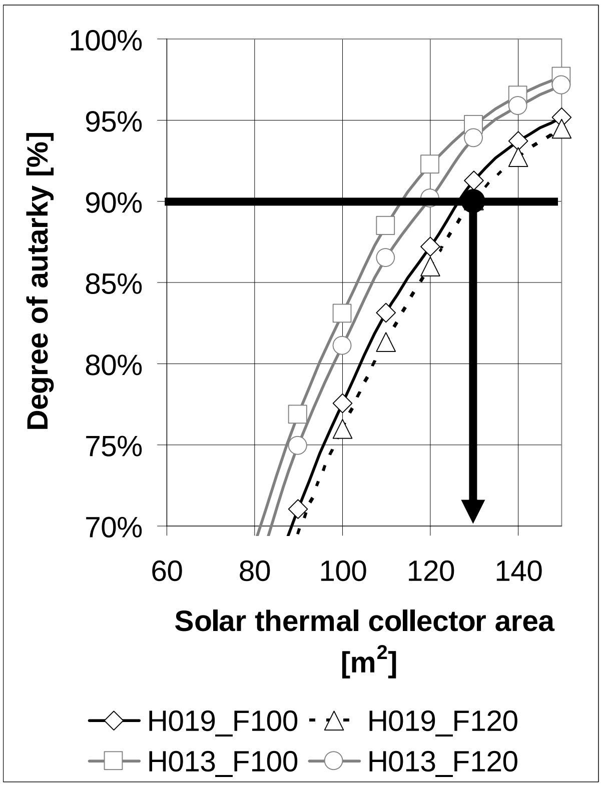
Another optimising process concerns the building envelope (U-value of opaque parts and windows) and the area covered by thermal collectors taking into account the investment cost (see Fig. 7). The figure shows clearly the interrelationship of the area covered by thermal collectors and four different qualities of U-values of the façades. The right figure shows distinctively that even using a comparatively bad building envelope (U-value opaque 0.19 W/m^{2}K, U-value windows 1.2 W/m^{2}K, code 'H019_F120') the investment cost for the building services would not increase much. In contrast, building a good façade (U-value opaque 0.13 W/m^{2}K, U-value windows 1.0 W/m^{2}K, code 'H013_F100') would increase primarily the building envelope cost. Therefore one reaches a better cost-benefit ratio planning a "poor" building envelope and increasing the area covered by thermal collectors.



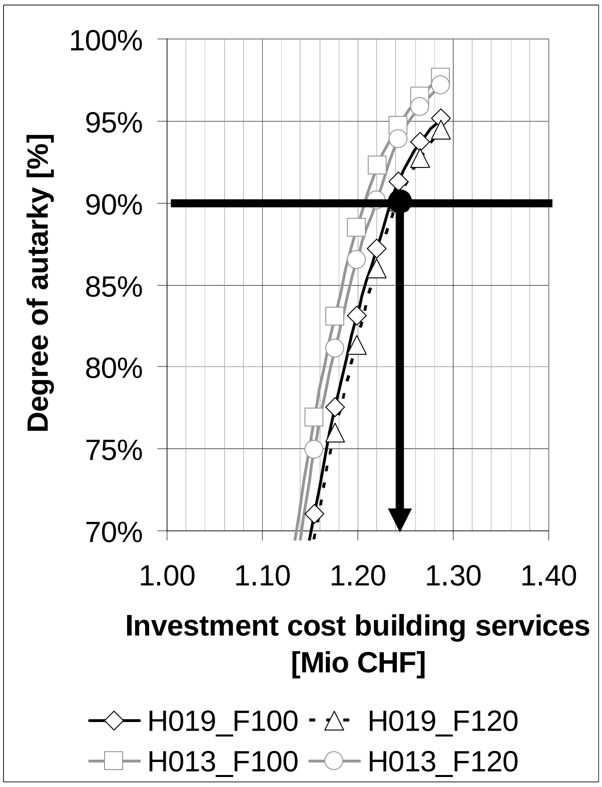


Figure 7. Optimisation among total area covered by collectors, the quality of building envelope ("H019_F100" etc.), investment cost for building services, and degree of autarky.

DISCUSSION

The part "energy and building services technology" for the new Monte Rosa cabin shows that it is certainly possible to reach an extraordinarily high degree of autarky at absolutely affordable investment costs. It is vital that because of the remote location only proven and robust systems are employed. No unproved equipment or sophisticated gadgets will be installed because one cannot take any chances at a hard-to-reach, remote location as an alpine cabin in the middle of the mountains. Despite the reliability of the employed systems (photovoltaics, thermal collectors) it is paramount to provide redundancy and therefore plan a backup system to ensure full security of supply. Furthermore, the paper shows that energy is just the second largest challenge in the conceptual design of such a building. Much more demanding is the supply and recycling of water since, after all, wastewater cannot be disposed of untreated as is quite common nowadays [3, 4].

One important insight will affect the next steps of the project: The presented concept will reach the desired degree of autarky with a clever optimised energy management. This energy management system incorporates the weather forecast and expected occupancy schedules to allow an optimal management of both batteries and hot water storage tank. This is also important to guarantee an optimal operation of the wastewater treatment system. The wastewater tank should be emptied before the peak weekends so that the energy-intensive treatment system can be operated at off-peak times when free electricity is available. Further dynamic simulations will focus on the development of such algorithms for the building automation system and the energy management as well as their validation. Another crucial element is going to be the investigation of sensitivities and the analytical testing of different scenarios to determine the robustness of the planned energy strategy and building technology concept.

ACKNOWLEDGEMENT

We thank Prof. Meinrad K. Eberle and his team at ETH Zurich for the possibility to be working on this interesting and innovative project and the inspiring cooperation. We also thank the Swiss Alpine Club, SAC, for the constructive cooperation. Last but not least we thank all entrepreneurs who supported us so far in the development work providing information and sharing their operating experience.

Energy Savings in Blocs of Flats Due to Individual Heat Metering

Florin Iordache and Vlad Iordache

Technical University of Civil Engineering of Bucharest, Romania

Corresponding email: fljord@instal.utcb.ro

SUMMARY

The installation of thermostatic valves and cost allocators represents the main modernization measure of the heating installation. In this study we determined theoretically and experimentally their effects upon the energy savings. Their adaptive behavior to the dynamic climatic conditions leads to 15% energy savings. Further on, the people reduce the indoor temperature in order to reduce the price of the energy. This effect represents another 9%, leading to a total of 24% energy savings. The north apartments need 15% more thermal energy than the south oriented apartments. The installation of these devices raise un other problem, the measures to correlate the heat production to the heat need.

INTRODUCTION

The modernization of the heating and hot water installations from blocs of flats in Romania is an operation that has started in 2000. The main operations consists in the installation of heat meters on the branch pipes of the two installations, the installation of individual water meters in bathrooms and kitchens and the installation of thermostatic valves with cost allocators for each radiator. These modernization measures offered the consumers the possibility to deal with the thermal consumptions as goods.

The paper presents a comparison, both theoretically and experimentally, of the heat consumption of a bloc of flats before and after the installation of thermostatic valves. The paper also presents o comparison between the heat consumptions of the north oriented apartments and the south oriented ones. The objective of the paper is to identify the consequences of this modernization measure.

The paper presents the description of the building, the theoretical model, the experimental protocol, the results, discussions of the results and the implications upon the actual district heating.

METHODS

Building description

The analysis was carried out on a bloc of flats (basement, ground floor and 10 more levels) composed of four stairwells with four apartments on each floor of a stairwell, in Bucharest Romania. The front wall of the building is north oriented, meaning that 80 apartments are north oriented and other 80 apartments are south oriented. The central heating installation of the building was gradually modernized:

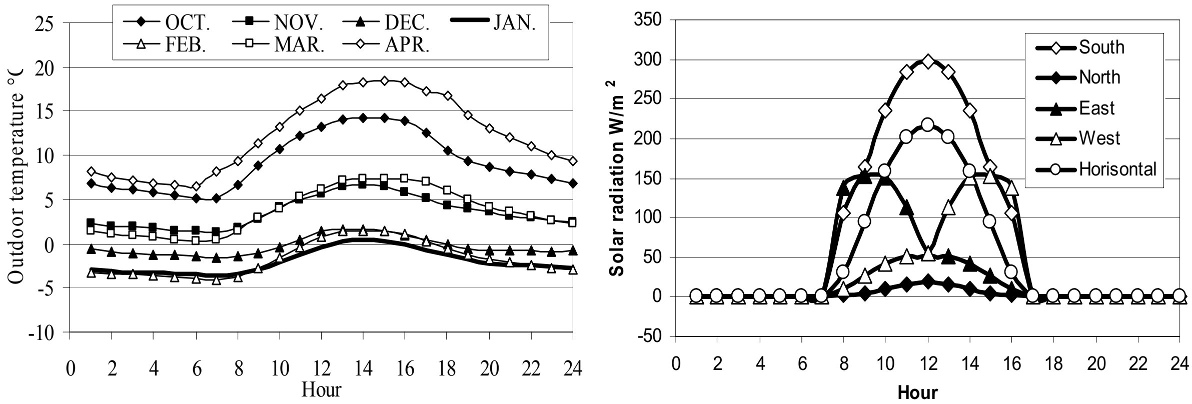
- heat meters were installed on branch pipes of heating and hot water installations, in 1999,

- individual water meters were installed, in 2004,
- thermostatic valves and cost allocators were installed in the 2005 summer.

Both the theoretical and the experimental analysis were carried out during the cold season, considered from October till April.

Theoretical approach

Theoretic evaluation of the heat consumption was carried out in two situations: with and without thermostatic valves installed. In the first case, we considered that the set point of the thermostatic valves was 20°C. The outdoor climatic database for Bucharest (temperature and solar radiation) corresponds to an average intensity of the cold season. The database was composed of 30 similar days for each month, but different from one month to another (Figure 1).



a) b)

Figure 1. Variation of climatic parameters: a) temperature, b) Solar radiation

The evaluation of the heat loss of the building represents the sum between the transmission heat loss through building envelope elements and the heat loss due to outdoor air infiltration.

In the second situation (no thermostatic valves), the unsuited temperature of the hot water in the heating installations generate a raise of the indoor temperature. The dynamic heat transfer calculus was based on the hypothesis of constant temperature inside the walls. The thermal behavior modeling of the radiators was achieved by means of stationary relations. We considered that the global thermal transfer coefficient of the radiator depends on the hot water temperature entering the radiator. Thus the temperature of the hot water at the end of the radiators is the result of the complex thermal transfer phenomenon building – heating installation.

The outdoor temperature used for the calculus cumulates both convective and solar radiation heat transfer phenomena (Equation 1 for heat transfer through walls and Equation 2 for heat transfer through windows).

$$t_{EO} = \frac{\alpha_a}{\alpha_o} \cdot I + t_o \qquad (1)$$

$$t_{EO} = \frac{\alpha_a \cdot \tau}{\alpha_o} \cdot I + t_o \qquad (2)$$

where t_{EO} is the equivalent outdoor temperature, t_o is the outdoor temperature, α_o is the outside convective thermal transfer coefficient, α_a is the absorption coefficient of the outside wall surface, $(\alpha_a \cdot \tau)$ is the absorption-transparency coefficient and I is the solar radiation.

The heat consumption represents the time integration of the heat flux during the cold season. The heat consumption was calculated in both situations of the installation: with and without thermostatic valves.

Experimental approach

The first type of recordings is the heat consumption of the entire building, measured for several years on the branch pipes of the heating and hot water installations.

The second type of recordings is the individual heat consumption due to the installation of the thermostatic valves before winter 2005-2006. These heat consumptions were estimated by means of the monthly recordings of the cost allocators and the indoor temperatures.

RESULTS

Theoretical approach

The theoretical approach is based on the hypothesis that the occupants of the apartments do not modify the position of the thermostatic valves; thus the initial setting of the valves corresponding to a 20^{o}C indoor temperature becomes permanent.

The heat consumption of the apartments with thermostatic valves is:

- similar to that of the apartments without thermostatic valves during evening and night period (20:00-07:00), whatever the orientation of the apartment,
- smaller than that of the apartments without thermostatic valves during morning and midday period (07:00-20:00), whatever the orientation of the apartment (Figure 2).

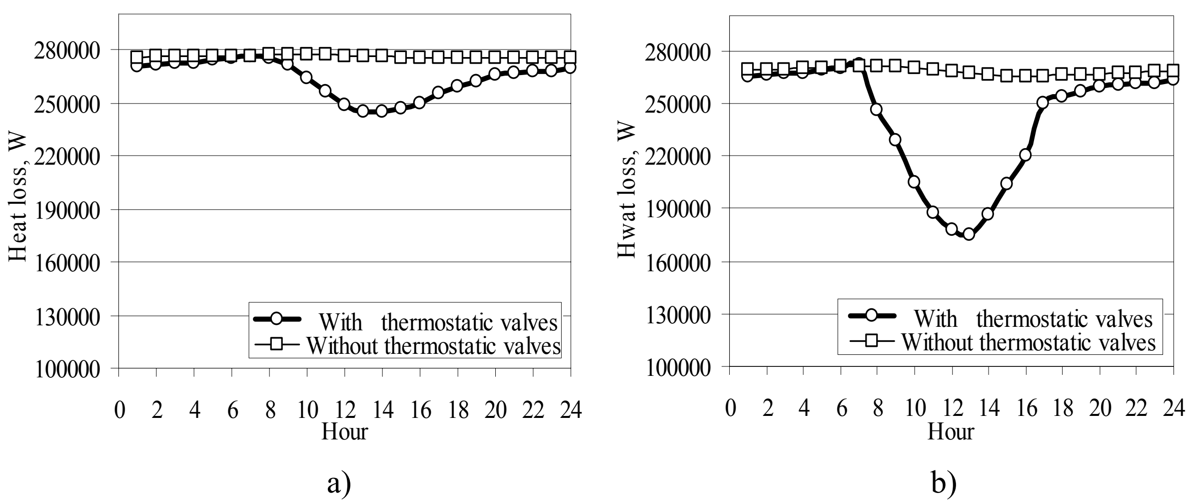


Figure 2. Daily variation of the heat losses of the apartments on a) NORTH b) SOUTH side of the building, for an average day on JANUARY

Comparing the heat loss of the north and south oriented apartments we note that:

- the simple valves do not adapt according to heat gains, and the heat losses is almost similar whatever the orientation,
- the thermostatic valves react to heat gains and lead to important energy savings (Figure 2).

The integration of heat losses during the winter season (October – April) lead to the values of the heat consumptions (Table 1).

Table 1. Specific heat consumption

Orientation	with thermostatic valves (kWh/m^2.an)	without thermostatic valves (kWh/m^2.an)
SOUTH	**105,176**	**127,561**
NORTH	**120,323**	**132,338**

The following conclusions can be drawn from this analysis:

- In the case of simple valves, there is only a very small difference (3.7%) between the heat consumptions of north and south sides of the building. This value is due to different solar radiation between the two sides of the building.
- In the case of thermostatic valves, north oriented apartments present a 14,4% higher heat consumption that the south oriented apartments,
- In the case of south oriented apartments, the thermostatic valves generate a 21.3% energy saving compared to the simple valves,
- In the case of north oriented apartments, the thermostatic valves generate a 10% energy saving compared to the simple valves,

The same specific heat consumption index was calculated for the entire building in the two situations (with and without thermostatic valves). In the case of simple valves the heat consumption is 129.95 kWh/m^2an, while in the case of thermostatic valves it is 112.75 kWh/m^2an.

We conclude this analysis with the remark that this modernization measure (installation of thermostatic valves and cost allocators) lead to 15% energy savings.

Experimental validation

Before the installation of the thermostatic valves and cost allocators, the evaluation of the heat consumptions of the north and south oriented apartments is not possible, thus this paragraph presents only two aspects:

- a comparison of the heat consumptions of the north and south oriented apartments for the winter 2005-2006, and
- a comparison of the recorded heat consumptions of the same building between the winters 2004-2005 (the thermostatic valves were not yet installed) and 2005-2006 (the thermostatic valves were installed), in order to experimentally establish the effect of the thermostatic valves.

The recorded heat consumption of the north oriented apartments are, obviously, higher than for the south oriented apartments (Table 2). The recorded thermal energy savings of the north oriented apartments compared to the south apartments considering the entire cold season (14,74%) is almost equal to the theoretic result (14,4%). This represents a good validation of the theoretic model.

Table 2. Heat consumption comparison between north and south oriented apartments

Month	Heat consumption, %		Reduction, %
	NORTH	SOUTH	
nov. 05	53,74	46,26	14,97
dec. 05	53,25	46,75	12,99
jan. 06	52,71	47,29	10,87
feb. 06	53,23	46,77	12,9
mar. 06	53,15	46,85	12,59
apr. 06	56,04	43,96	24,13
cold season	**53,69**	**46,31**	**14,74**

In the case of the second analysis, we mention that the two cold seasons were characterized by different climatic conditions, leading to an improper comparison of the heat consumptions (Table 3).

Table 3. Temperatures and specific heat consumptions for winters 2004-2005 and 2005-2006

Month	Winter 2004-2005 without thermostatic valves			Winter 2005-2006 with thermostatic valves		
	t_o ºC	t_i-t_o ºC	ϕ kWh/m^2	t_o ºC	t_i-t_o ºC	ϕ kWh/m^2
November	7.4	12.6	22.36	5.8	14.2	19.84
December	3.06	16.94	27.58	2.7	17.3	24.95
January	2.18	17.82	29.91	-2.2	22.2	25.08
February	-0.4	20.37	31.89	0.6	19.4	22.21
March	5.3	14.7	23.21	6.4	13.6	18.41

In order to surpass this inconvenient, we compare the heat consumptions divided by the indoor-outdoor temperature difference (Figure 3).

The heat consumptions for the 2005-2006 winter are smaller then those of 2004-2005 winter with 12% (December) up to 33% (January). We can conclude that the installation of the thermostatic valves generate an average value of 24% thermal energy saving during the cold season. The difference between the experimental result (energy reduction of 24%) and the theoretic result (energy reduction of 15%) is probably due to human behavior; people tend to modify the indoor temperature in order to accord the thermal comfort to the desired cost.

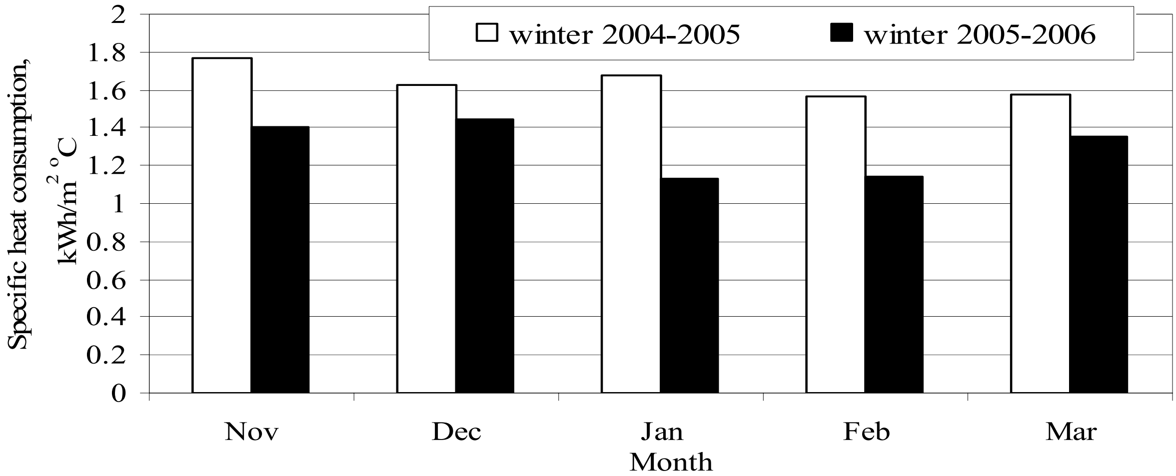

Figure 3. Specific heat consumption comparison between winters 2004-2005 and 2005-2006

DISCUSSION

The theoretical and experimental research followed two objectives. The first is to determine the effect of the thermostatic valves installations upon the thermal energy consumption. The theoretical simulation shows that there is a 15% energy savings while the experimental work showed a 24% energy savings. The 9% difference is probably due to the initial hypothesis for the theoretical model, that indoor temperature is constant 20^{o}C, while in reality people tend to reduce the indoor temperature in order to reduce further more the expenses. The second objective is the comparison of the heat consumption of the apartments oriented north and those oriented south. The advantage of the thermostatic valves is that they can adapt the water flow and by consequently the heat consumption according to the heat gains. We obtained a 14.5% energy savings of the south oriented apartments compared to the north oriented apartments.

Both analyses show the advantages of this modernization of the heating installation, the installation of thermostatic valves and cost allocators. However, if they represent a very important and economic measure for the consumers, the thermostatic valves have a major impact upon the heat producer.

In today’s conditions of rising price of thermal energy, the lack of individual control of heat consumption leads to the impossibility of payment from the consumer. Many district heating company were obliged to stop the thermal energy delivery. Thus the installation of thermostatic valves becomes not only a modernization measure but also a necessity. Another influence of the thermostatic valves consists in the running strategy of the heat production. If before, there was a constant production of heat, and the entire district heating was functioning this way, now the thermostatic valves present a dynamic thermal energy need. The district heating company from Bucharest, RADET, is now confronted with this aspect of correlation between the heat production with the dynamic heat need. The national research project ENERGSYS was developed in order to find the suitable measures to adapt the heat production to the variable heat need.

ACKNOWLEDGEMENT

We acknowledge the contribution of the district heating company of Bucharest, RADET SA, and TECHEM to the present study.

SUMMARY

A workshop was held in the fall of 2006 for the purpose of developing courses related to "Energy Efficient Integrated Sustainable Design for the Built Environment" for university, college, and vocational schools. The objectives of this workshop were to determine the key elements for students to know related to integrated energy efficient sustainable design; to identify specific learning objectives for each of those elements; and to identify resources available to use in these courses. The workshop was attended by a selected interdisciplinary group of well recognized engineering, architecture and building science professors, representatives of related professional organizations and national laboratories, and individuals working with the US DOE Building America teams. This paper presents a listing of the key topics identified and the learning objectives related to each of those topics.

INTRODUCTION

Sustainability and energy efficiency are topics which are covered in wide variety of different college courses in America. They are now being widely taught though community colleges, professional organizations' continuing education programs, and general university and adult education programs. The basics however traditionally have been in the curricula of architecture, engineering and building science programs.

The accreditation board for professional degree programs in architecture is the National Architectural Accrediting Board which "… is committed to the provision of effective professional architectural education through the establishment and application of accrediting procedures …" and "… strives to foster an educational foundation that prepares students who are both broadly and professionally educated for the profession of architecture." [1] For the purpose of accreditation, NAAB indicates that graduating students must demonstrate an understanding or ability in 34 different areas. Most relevant to the purposes of this paper is "#15 Understanding of the principles of sustainability in making architecture and urban design decisions that conserve natural and built resources, including culturally important buildings and sites, and in the creation of healthful buildings and communities." Similar references are also made to the areas of: site conditions, environmental systems, building envelope systems, building systems integration, building materials and assemblies, construction cost control and comprehensive design.

Specific references to sustainability are not as explicitly described in the accrediting body in the field of engineering, ABET. This group indicates in the program outcomes and assessment that a school undergoing accreditation must demonstrate that their students attain an ability, understanding, recognition, or knowledge in eleven different areas. The one related to the area of sustainability indicates that students must demonstrate "(c) an ability to design a system, component, or process to meet desired needs within realistic constraints such as economic, environmental, social, political, ethical, health and safety, manufacturability, and sustainability."[2]

In a meeting of land grant institution teachers and researchers discussing energy efficient residential construction it was recognized that there many different approaches and materials used to discuss energy efficient sustainable design. During the breakout session it was also recognized that there was a pressing need for a systematic discussion to share ideas and basic concepts between the various educational disciplines, professional organizations and research teams. This discussion needed to determine the knowledge base of what was needed by students as to the key elements of integrated sustainable design, to develop curriculum related to these key elements, and to identify the resources used in the delivery of these courses.

METHODOLOGY

In order to address the needs identified, a workshop was held in the fall of 2006 for the purpose of developing courses related to "Energy Efficient Integrated Sustainable Design for the Built Environment" for university, college, and vocational schools. The objectives were to determine the key elements for students to know related to integrated energy efficient sustainable design; to identify specific learning objectives for each of those elements; and to identify resources available to use in these courses. Although the topic was considered to be applicable to all building sectors, it was determined that the first focus should be on the low-rise residential market. The workshop was attended by an interdisciplinary group of 30 selected well recognized engineering, architecture and building science professors, representatives of related professional organizations and national laboratories, and individuals working with the US DOE Building America teams.

RESULTS

The interdisciplinary group met for a 3 ½ day intensive workshop and identified the key elements of knowledge which a student should know in this area. While the extent of the courses might vary between the professional degree programs (such as architecture or engineering) and the two-year associates degree programs; the key elements remained the same. It was thought that these key elements could be used as the basis for the first course on energy efficient sustainable design for the built environment and were therefore laid out as separate modules. Depending upon the level of instruction (i.e. professional design instruction such as engineering versus a technical school) the modules could be modified to suit the needs of the audience. Each one could be the topic of a one day adult education workshop, one-week instructional modules in an introductory course, or serve as the basic outline for an entire semester in an advanced course.

The underlying learning objectives for each of the modules were then identified.

Seventeen modules were identified and learning objectives for each were developed. The modules and the topics contained and learning objectives for each are given below.

Module 1. Setting the Stage for a Sustainable Energy-Efficient Built Environment – The Context of Energy Issues and Building Solutions

- Define terms of building science, ecological systems, economics of consumption
- Relate building science perspective, ecology, social science
- Explain historical energy and environmental issues related to buildings

- Compare site and source energy
- Examine the health, safety and comfort issues in buildings
- Examine the general context for building solutions (The goal of net-zero energy green home with durability.)
- Explain a basic overview of the sufficiency of alternative energy (total solar flux and wind availability)
- Examine cash flow to homeowners
- Demonstrate ability to find, evaluate and synthesize knowledge regarding building performance and sustainability
- Define Business case – career opportunities
- Explain appropriate technology and systems (and how to research them with every lesson)
- Define interconnections / inter-relationships among building systems

Module 2. Introduction to Sustainable Design & Building Performance
Learning Objectives:
- Recognize that a building works as a system
- Learn about the roles of air, heat, water, and vapor flows
- Recognize the importance of climate-specific design details
- Understand the issues on health, IEQ and productivity.
- Building performance and relations to overall sustainability
- Differentiate between the available fuel choices and characteristics
- Recognize roles, responsibilities and respect of the participants in design and construction

Module 3. Site Related Flows: Air, Heat, Water, Vapor
Learning Objectives:
- Comprehend specific issues related to pressure- and temperature-induced flows
- Grasp the significance of water flows and their roles in building details related to the drainage plane and other building elements
- Recognize the need to manage relative humidity and prevention of condensation
- Understand the air change rate and its relationship to above concepts

Module 4. Building Materials and Their Properties
Learning Objectives:
- Understand building material porosity and the impact it has on properties, such as wetting and drying, capillarity action
- Understand and be able to use:
  - Vapor perm ratings
  - Air perm ratings
  - R-values/U-values – all materials, including glazing
- Understand the difference between individual material properties and assembly performance
- Understand the impact of mass and phase change materials
- Recognize the life span of materials and their embodied energy
- Understand the need for waste reduction, regionally appropriate and ecological materials

Module 5. Climate and Designing with Nature

Learning Objectives:

- Understand the importance of climate-appropriate design
- Recognize relationships among temperature, precipitation, and construction techniques
- Learn about hygro-thermal regions and how design and construction details vary across them
- Understand building details related to seismic conditions, hurricane-resistance, wind, corrosion and other climate-specific factors that affect structural durability
- Understand solar geometry, daylighting, natural ventilation
  - Understand building geometry related to the local environment
  - Understand daylighting performance in building design
  - Understand shading devices in building design
  - Understand building designs that utilize natural ventilation

Module 6. The Process of Building Design, Systems Engineering, Commissioning

Learning Objectives:

- Understand air leakage control through design details and blower door testing
- Understand HVAC design and integration issues as well as testing protocols
- Gain competence in performance of building commissioning and management of commissioning records
- Understand the role of design details, specifications, and trade contractor scopes of work with respect to quality and high performance
- Understand diagnostics techniques and reports

Module 7. Site: Drainage, Pest Control, Landscaping

Learning Objectives:

- Understand the role of site grading and water run-off
- Understand management of termites, rodents, and other pests
- Understand proper placement of vegetation, mulch, and other decorative land cover
- Comprehend soil properties and soil conditioning
- Know native vegetation and the role of irrigation and reduction of water usage

Module 8. Foundation: Moisture Control and Energy Performance

Learning Objectives:

- Understand foundation construction techniques essential for the prevention of moisture and soil gas entry
- Understand the contribution of the foundation system to overall building energy performance
- Understand climate-specific use of alternative foundation insulation systems

Module 9. Building Envelope: Moisture Control and Energy Performance

Learning Objectives:

- Learn roof and wall assembly materials and techniques essential to water management (including flashing)
- Learn roof and wall assembly materials and techniques essential to air infiltration
- Learn roof and wall assembly materials and techniques essential for the prevention of vapor intrusion and drying of interstitial spaces
- Learn climate- and design-specific use of alternative glazing systems

- Understand selection criteria and application details of cavity and attic insulation materials
- Understand alternative approaches to vapor retarder and house wrap systems
- Understand the energy and lighting implications of alternative window treatments
- Gain an appreciation and understanding of the dual roles of weather barrier and energy performance

Module 10. Mechanicals/Electrical/Plumbing: Systems Engineering, Energy Performance, Occupant Health, Safety, Comfort, and Envelope/Mechanicals Management, Part I
Learning Objectives:
- Understand equipment and duct issues
- Understand integration of mechanical system design and architectural design
- Understand best practices of selection and installation of mechanical equipment
- Understand efficiency standards and appliance ratings
- Understand the importance of plug loads, appliances and lighting systems
- Understand the principles of the systems for
  - Space temperature conditioning (heating and cooling systems)
  - Hot water distribution
  - Duct layout
  - Controls and monitoring
  - Pollutant source control
  - Evaporative cooling

Module 11. Mechanicals/Electrical/Plumbing: Systems Engineering, Energy Performance, Occupant Health and Safety, Comfort, and Envelope/Mechanicals Management, Part II
Learning Objectives:
- Understand applicable ASHRAE ventilation Standards (ASHRAE 62.2)
- Understand backdrafting issues, combustion gas management, and sealed combustion systems
- Understand proper placement and penetration sealing of electrical wires, plumbing pipes, and HVAC ducts
- Understand the role of indoor relative humidity in building performance and the conditions-based need for dehumidification/humidification
- Understand the basics of alternative heating systems
  - Dual fuel heat pumps
  - Wood burners and fireplaces
- Understand on-site generation systems
  - Photovoltaic and wind
  - Solar thermal
  - Combined heat and power (CHP)
  - Fuel cells

Module 12. Energy codes/standards, Building Simulation and Tools, Measurement and Prediction
Learning Objectives:
- Understand applicable energy codes, standards and best practice recommendations
- Demonstrate the ability to use tools to analyze buildings and make design decisions (energy, environment, etc.)
- Know how to measure performance and make adjustments.

Module 13. Field Issues: Construction Management, Building Codes, and Other Regulatory Matters

Learning Objectives:

- Understand practical matters that affect implementation of design details, specifications or purchasing requirements, and scopes of work including construction labor issues and homebuyer concerns
- Understand code enforcement and zoning ordinance issues that may obstruct the construction of high performance housing and effective counter strategies
- Understand the impact of codes/standards on building performance and sustainable design
- Understand local public policy; Impact of policy, regulation and enforcement
- Be aware of the processes of policy development and change
- Understand contracts and contract law

Module 14. The Business Case, Communications and the Community Scale Perspective

Learning Objectives:

- Understand valuation methodologies for building performance and sustainable design
- Gain communications skills / tools to achieve effective team functioning
- Value the ability to use peers as a resource not a competitor
- Understand the relationship between single building & site land use, infrastructure and ecological impacts
- Learn about utility systems and interconnections
- Comprehend rate structure, base and peak usage
- Understand time-of-day usage and electrical marginal dispatch
- District heating and cooling
- Transportation – people, waste, water and energy

Module 15. Putting it all Together: Experiential Learning in the Field / Office

Learning Objectives:

- Through a partnership with a high performance builder, shadow a construction manager for an assigned time during a one-week period
- Be able to apply the principles to
  - Case studies
  - Performance verification studies
- Analyze examples given in videos

Module 16. Homeowner Education (Communicating with the Consumer)

Be able to communicate the following with the consumer

- Tax incentives
- Financing & insurance
- Occupant lifestyle impact
- Energy improvement mortgages
- Commissioning, punch lists, owner manual
- Operation and maintenance
- TED
- Selling energy efficiency
- Home energy audits
- Cleanliness of the job site

Module 17. Conclusions, Implications, Directions of Future Research
Learning Objectives:
- Highlight and review materials covered and studio and field experiences
- Understand current research issues regarding high performance buildings
- Understand need for life long learning
- Reflection

The resources to be used in the modules were also identified in the workshop. This material will be expanded upon in another workshop to be held in the summer of 2007.

SUMMARY AND CONCLUSIONS

A workshop with faculty and building industry leader participants was held to develop university and community college courses related to the design of energy efficient and sustainable buildings. The objective was to determine the key topics and the elements of these topics which need to be taught and to develop the learning objectives for each of the segments. Courses were developed to be taught at the architectural and engineering schools, at community colleges and vocational schools, and for general education in colleges, universities and general adult extension education. The topics and learning objectives for each of the topics are presented in the paper.

ACKNOWLEDGEMENT

The workshop which provided the input for this paper sponsored by the US Department of Energy and the National Association of State Universities and Land Grant Colleges.

SUMMARY

Various means of improving the energy efficiency of commercial buildings while preserving and/or improving their internal environmental quality have been extensively studied. In the recent past, the Gas Technology Institute (GTI), produced several of such studies oriented exclusively to identifying the benefits of applying various energy efficiency technologies to different types of commercial installations in the U.S.A. and also in Europe. Independently, these involved technologies for desiccant dehumidification and/or systems of combined heating, cooling, and power generation, (CHP). The applications and their performance were simulated by internally developed programs such as the Building Energy Analyzer, using the DOE2.1E computational engine. Studies identified potentials of targeted application of combined technologies in comparison to using the traditional building heating, ventilation, and air conditioning equipment.[1]

The latest study, which is the subject of this paper, expands on the previous ones. Authors compare the economics of investing either in installing the energy saving mechanical equipment, such as CHPs and solar thermal cooling, or applying the modern means of improving the building envelope and reducing internal loads. As in previous studies the results were found to be “case specific”, yet for the assumed installations the preferred ways of improving a building performance were identified and are reported in this paper. This has been accomplished for the specific case of selected buildings on the campus of the University of Hawaii, yet the implications can be valid for other locations with similar climatic conditions.[2]

INTRODUCTION

In a renewed effort of making the American economy less dependent on foreign oil several approaches to improving the efficiency of power conversion systems are getting higher attention again. One of those is the concept of co-generation, a concept that over a half century of its modern evolution went through a series of names and modifications. Currently, most often labeled as combined heat and power systems, they usually incorporate various kinds of natural gas-fired prime movers and electricity generators in a configuration with equipment providing air conditioning and heating services. A solid wheel desiccant dehumidification of the indoor air, powered by heat recovered from a CHP system found to be attractive in many applications.

One of the original objectives of the Gas Technology Institute previous studies was to determine the economical value of CHP systems and their contribution to energy savings in commercial building applications. In a broader spectrum, that study was aimed at finding the benefits of recovering heat for space heating/domestic hot water, desiccant dehumidification, and absorption cooling for five specific building types, considering climatic conditions and local utility rate structures of several U.S. cities.[1]

Subsequently, these studies were expanded to cover other means of improving the energy efficiency of commercial buildings while improving their economics, such as those shown later in this report. While these additional studies were carried out for one location only, (i.e. the University of Hawaii at Manoa), the results can be considered as providing an important guidance in the process of implementing energy conservation measures for all locations with similar climatic conditions, and as such are presented here.

BACKGROUND AND OBJECTIVES

Energy is a key factor in the success of Hawaii's economy. Efficient use of Hawaii's indigenous and sustainable energy resources can reduce the state's high dependence on imported oil, increase local economic development, and reduce the potential negative economic impacts of oil price fluctuations.

As a major research university, the University of Hawaii presented an ideal setting to research energy savings by way of viable technologies and strategies that can be used to reduce energy consumption and cost while increasing energy self-sufficiency.

The Hawaiian Electric Company, (HECO) owns and operates oil-fired power plants that produce electricity for the island of Oahu. Crude oil used in the plants is imported primarily from foreign sources and then locally refined. Naphtha, a byproduct of refining process is converted by the Gas Company, (TGC) to clean-burning synthetic natural gas (SNG). Utilizing the SNG displaces the need to import additional barrels of oil. Consequently, one of the targets of GTI's study was to evaluate ways to maximize the use of this indigenous energy sources.

The following collection of energy-efficient and sustainable technologies and strategies were evaluated in terms of how much energy could be saved annually and the economic feasibility of implementation:

- SNG-fired reciprocating engine for combined heat and power (CHP) - using waste heat for domestic hot water, and absorption cooling.
- SNG-fired reciprocating engine-driven vapor compression chiller with engine heat recovery for domestic hot water production. No power production.
- Solar cooling based on the application of medium-grade heat (approximately 180°F) thermal collectors driving absorption chillers.
- Energy-efficiency strategies recommended in the local Hawaii Model Energy Code (HMEC).

In this paper we concentrate on the issues of recommended Energy-efficiency strategies as the represented the most economical means of improvements.

BUILDING SELECTION

Based on the results of evaluating the existing campus buildings it was decided to develop prototypical models that closely resemble typical existing structures as well as new buildings projected to be built on Manoa campus as well as West Hawaii and Hilo. The prototype models were then used to determine appropriate methods for targeting and applying energy-efficient strategies and technologies.

Below is a summary of the characteristics for the three models:
1. Dormitory - Twelve-story, 65,300 square-foot facility with three independently characterized zones (dormitory wings, common area, and kitchen and laundry). The zones are cooled by a central plant consisting of an electric water-cooled centrifugal inlet-vane controlled chiller. The dormitory wings make up 60% of the occupied space and the common area 35%. The kitchen and laundry area makes up the remaining 5% of the space. Building glazing is 25%.
2. Lab/Class/Office - Four-story, 93,100 square-foot facility with three independently characterized zones (classroom/office, lab/shop, and mechanical). The zones are cooled by a central plant consisting of two electric water-cooled centrifugal inlet-vane controlled chillers. The classrooms and offices make up 60% of the occupied space and the labs and shops 35%. The mechanical area makes up the remaining 5% of the space. Building glazing is 25%.
3. Library – Four-story, 135,000 square-foot single-zone facility. The facility is cooled by a central plant consisting of two electric water-cooled centrifugal inlet-vane controlled chillers. The HVAC system is configured to maintain an appropriate humidity level for library material. Building glazing is 50%.

BUILDING ENERGY MODELING

Building Energy Analyzer (BEA) computer energy modeling tool was used to generate energy and economic models for each of the building case-studies. BEA consists of hour-by-hour computer simulation models for various building types, heat and power generation equipment, and HVAC equipment. Within the BEA models, equipment (e.g. lighting, HVAC, etc.) and building parameters (e.g. wall material, window designs, roofing, etc.), energy rates, and geographical weather data can be defined for specific applications.

BEA forecasts and reports annual hour-by-hour heat and power loads along with hour-by-hour fuel requirements. GTI enhanced the software for this study with solar thermal analyses module.

BEA uses weather data from the typical meteorological year (TMY2) data sets derived from the 1961-1990 National Solar Radiation Data Base (NSRDB). The building model data streams are typical for weather during the TMY2 time span.

Alternative Energy-Efficient Technologies

As an alternative to CHP, a collection of energy-efficient technologies and strategies, based on the Hawaii Model Energy Code (HMEC), was applied to the prototypical building models to determine energy reductions and associated cost benefits. Technologies and strategies that were considered in the analysis are as follows:

<u>HVAC</u>

- Application of an economizer cycle (although typically not used in Hawaii) that takes advantage of free cooling using outside air. The system selects outside air to condition building if its enthalpy is lower than that of the building comfort set point.

- Reduced cold-deck temperature from 55°F to 50°F (the lower limit on supply air temperature) for greater humidity reduction and lower air flows and fan power. This does not apply to the Library as the building was already designed for 50°F.
- Minimal HVAC system oversizing – Oversizing was reduced from 20% (often a rule-of-thumb) to 5%.
- Addition of a desiccant wheel dehumidifier with enthalpy relief air heat exchanger. The base system is a standard gas-fired reheat system. The alternative implements an enthalpy wheel system that provides both sensible and latent heat exchange between the relief air and outdoor air. A desiccant wheel with gas-fired regeneration is also used to remove excess latent heat from outdoor air entering building.
- Addition of variable frequency drives (VFDs) on fans and pumps to control flows at partial loads – The air handling and cooling tower fans and the chilled water pump are configured with VFDs.
- Substituting standard electric centrifugal or screw chillers with an engine-driven centrifugal or screw chiller and engine heat recovery to hot water supply of the traditional heating system.

<u>Lighting</u>

- Increase lighting efficiency from ASHRAE standards to HMEC standards (roughly 30% to 50% reduction in watts per square foot).

<u>Shading</u>

- Reduced glazing percentage by 25% to account for overhang wall and window shading and radiant barriers that may be implemented on the buildings.

DISCUSSION OF RESULTS

Figure 1 and 2 show energy and cost savings respectively for the different energy-efficient technologies and strategies that were modeled for the dormitory building. Each of the technologies and strategies is represented by a multi-color bar that shows the contributions from gas and electricity. The individual bars are laid over one bar that is the width of the chart and represents the baseline model without any of the energy-efficient technologies applied. The "T" symbols indicate the change in gas levels relative to the baseline model.

In addition, all of the energy-efficiency strategies were collectively applied and the resulting scenario was titled "Collective EE" as shown in the figures.

Tables 1 through 3 show annual utility cost savings for the dormitory and the other two buildings; lab/class/office building and library, respectively.

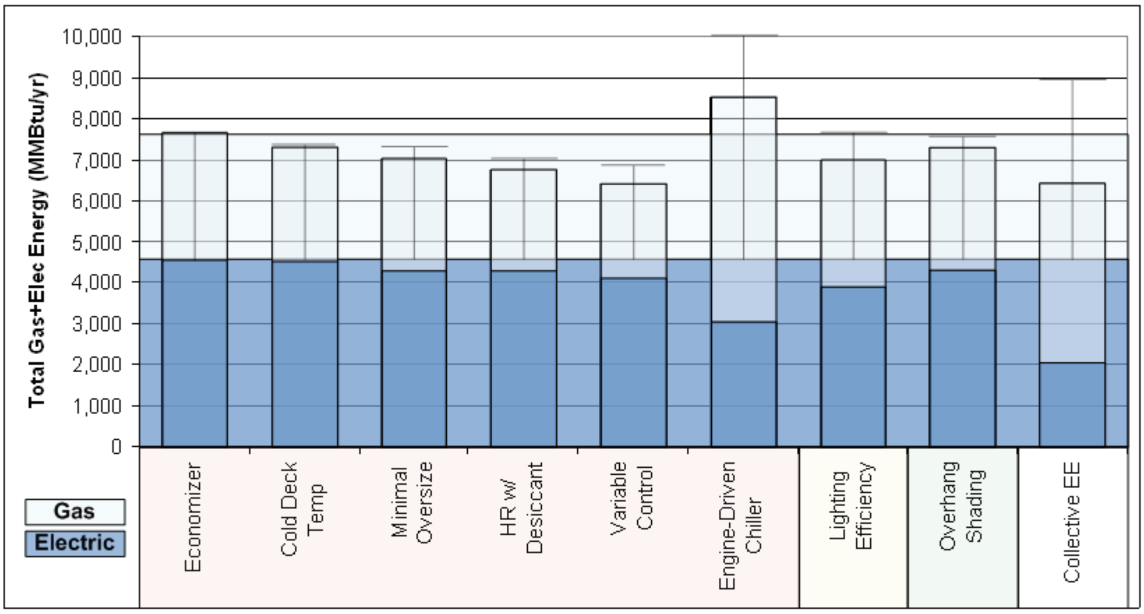

Figure 1 – Annual Energy Savings from Energy Efficient Technologies at the University of Hawaii (Dormitory).

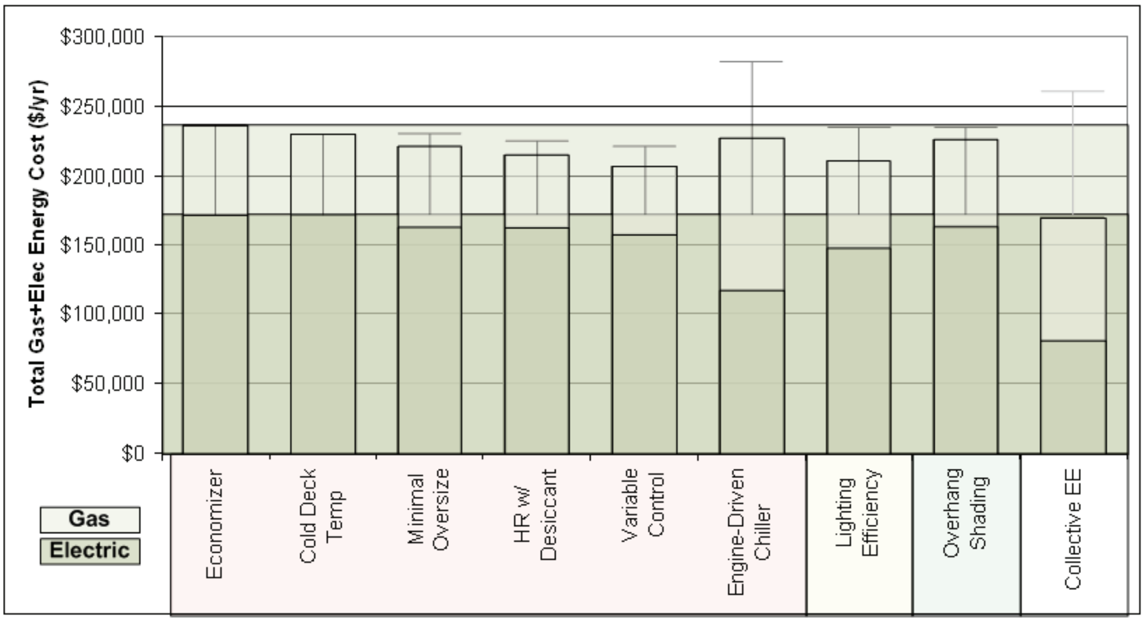

Figure 2 - Annual Cost Savings from Energy Efficient Technologies at the University of Hawaii (Dormitory).

Table 1 – Energy-Efficient Technology Savings (Dormitory).

Technology/Strategy	% Cost Savings	Annual Savings on $236,000/yr*
Economizer	0%	$0
Cold Deck Temp	3%	$6,000
Minimal Oversize	6%	$15,000
HR w/ Desiccant	9%	$21,000
Variable Control	12%	$29,000
Engine-Driven Chiller	4%	$9,000
Lighting Efficiency	10%	$24,000
Overhang Shading	4%	$10,000
Collective EE	28%	$66,000

Table 2 - Energy-Efficient Technology Savings (Lab/Class/Office).

Technology/Strategy	% Cost Savings	Annual Savings on $450,000/yr*
Economizer	0%	$0
Cold Deck Temp	4%	$18,000
Minimal Oversize	6%	$27,000
HR w/ Desiccant	16%	$74,000
Variable Control	18%	$82,000
Engine-Driven Chiller	8%	$36,000
Lighting Efficiency	5%	$22,000
Overhang Shading	2%	$9,000
Collective EE	31%	$138,000

Table 3 - Energy-Efficient Technology Savings (Library).

Technology/Strategy	% Cost Savings	Annual Savings on $460,000/yr*
Economizer	0%	-$1,000
Minimal Oversize	10%	$46,000
HR w/ Desiccant	1%	$2,000
Variable Control	23%	$107,000
Engine-Driven Chiller	3%	$13,000
Lighting Efficiency	12%	$52,000
Overhang Shading	7%	$32,000
Collective EE	29%	$133,000

To put these results into the perspective of the other two evaluated energy saving measures, it's suffice to say that none of the considered systems (i.e. particularly those of CHPs and solar thermal cooling technologies considered as retrofits to existing buildings) could match the savings of the most of the above discussed energy efficiency measures. Consequently, also their return on investment would not warrant their deployment.

Summary of the important results for the alternative energy-saving strategies is as follows:

- An economizer cycle has almost no effect on energy consumption, thus no effect on energy cost for all the three modeled buildings.

*These are the assumed operating costs for prototype buildings with the base equipment as originally designed.

- In some cases, HVAC equipment may be oversized to account for extreme weather conditions that may seldom occur, or just due to the rule-of-thumb engineering. The model indicates that over-sizing the equipment by 20% as opposed to only 5% could cost about $15,000/year. This is caused by inefficiencies of partial loading of the equipment and unnecessary pumping and fan power consumption during non-extreme weather conditions. However, variable speed fans and pumps can more than compensate for the additional cost of oversizing by reducing the excessive flows. In fact, the model indicates that equipping the HVAC system with VFDs could save $29,000/year even if the HVAC system is 20% oversized.
- An engine-driven chiller consumes more energy than an electric centrifugal chiller as shown in Figure 1. However, an engine-driven chiller with heat recovery to domestic hot water can reduce the annual cost as shown in Figure 2.
- Collectively, energy-efficient technologies and strategies could reduce annual energy cost for a prototypical dormitory by almost 30% while increasing the consumption of clean-burning gas by over 40% and reducing the consumption of electricity by 55%. Similar values are shown in Tables 2 and 3 for the two other buildings.
- As with the dormitory, the best cost savings for the Lab/Class/Office ($82,000/yr) comes from installing VFDs on the fans and pumps. The savings from VFDs are still based on a 20% oversized system. However, a 5% oversized system with VFDs also reflects significant savings ($68,000/yr).

CONCLUSIONS

The following are the most important conclusions of this study:

- Collective implementation of energy-efficient technologies, such as engine-driven chillers, fluorescent lighting and HVAC strategies could reduce annual energy cost for prototypical UH facilities by as much as 30% while increasing the consumption of clean-burning gas by over 50% and reducing the consumption of electricity by up to 50% at some UH facilities. As such they could be very effective.
- At least 70% to 90% of recoverable heat from power generation must be recovered in a manner that directly displaces heat from the heating source, for CHP systems serving individual UH prototypical facilities to fall within a 5-year payback range. CHP host facilities must present the proper criteria in terms of persistent heat loads, operating hours, and sufficient size to optimize the return offered by CHP. At the University of Hawaii Manoa campus, such facilities are a challenge to identify.
- Solar thermal cooling is not as yet feasible, given the current electric rates, cost of solar panels, and cost of absorption chillers. A significant subsidizing would be needed for implementation.

ACKNOWLEDGEMENT

This program was carried out as a collaborative effort including the Gas Technology Institute (GTI), The Gas Company (TGC), the University of Hawaii (UH), the City and County of Honolulu, and the State of Hawaii's Department of Business, Economic Development & Tourism (DBEDT). It was developed under the auspices of GTI's Sustainable Energy Planning Program. The project report outlines the feasibility of sustainable energy applications utilizing energy-efficient technologies and strategies at the University of Hawaii

Manoa Campus. The authors would like to thank GTI for allowing using the results of this project for this paper.

SUMMARY

In the world of design and engineering, gaps of knowledge between these disciplines are recognized. The learning capacity of the building industry – as well as in other industries – is becoming a main issue, also within Architect-organizations. To link the parts of the knowledge-triangle practice, education and research forms the basis for possible solutions – within the context of the building design-engineering. This context can be represented by the Product-Process-Organization model. This integral approach is the basis for integral solutions, by structuring knowledge of design and engineering within the design team.

A model for structuring knowledge on different abstraction levels is found in Methodical Design, a system theory based on the combination of the German design school (Pahl, Beitz and others) and the Anglo-American school (Archer, Krick, Jones and others). Methodical Design is a problem oriented model based on functional hierarchy, which can be applied on several levels of abstraction and makes it possible to link these levels of abstraction with the phases in the design process itself.

This paper describes the research methodology, based on Methodical Design, as used in a doctoral design related to practice and the 6th European framework research project EURACTIVE ROOF-er. The research methodology – as quasi-experimental design – uses the structuring method of the Methodical Design to investigate how this specific design method and associated design tools can support the collaboration between designers and engineers.

INTRODUCTION AND PROBLEM DEFINITION

Roofs play a special role in buildings. Their value and impact often significantly surpass the cost ratio they represent in the total investment cost of the building. Traditionally, roofs have a protecting function and their basic design has changed little over hundreds of years. Nowadays however, they are increasingly used as preferred location for mounting additional functions such as photovoltaic systems, roof lights, ventilation devices, insulation and safety devices. The roof will contain more and more aspects which are strongly related with the comfort of the building as a whole. Looking in a wider context, the build environment is dominated by the circumstances related to energy use. As results of Global Warming become more and more prominent, it is necessary to look for new ways to save more energy and to generate more sustainable energy for the comfort in the building environment. [24, 25]. In current building design primarily the façade, as the most prominent building component, is used as integral part of these sustainable comfort systems. This integral approach is lacking for the roof, where these systems are mostly treated like add-on components to the already completed conceptual building design.

Until now the roof was not actively developed to meet the new demands. Active Roofs should change this. Active Roofs is the concept related to this change: the possibility or need to change the culture, process and or product related to the roof. Active roofs, with the described possibilities, implicate a more active role in the process for the roofer and roof-advisor. An active attitude of the total roof-culture is needed in order to design and construct innovative and better roofs. The approach needed for the development of these knowledge and skills is integral as defined by Quanjel and Zeiler [8]. Integral design is meant to overcome, during design team cooperation, the difficulties raised with the early involvement of consultants. This is achieved by providing methods to communicate the consequences of design steps between the different disciplines at early design stages. Related to the specific field of the roofer this means the direct connection of construction /user- and design-related knowledge. A domain-related methodology, therefore has a large group of different users with different backgrounds, which will influence the set up for methods and tools.

The actual state is that there is a gap exists between solutions and application in design practice of active roofs (EURACTIVE ROOF-er, 2005). Roof design and roof engineering with all its existing – traditional – and new functions and applications are most of the time handled like separate and add-on aspects. As complexity and scale of design processes in architecture and in building services engineering increase, as well as the demands on these processes with respect to costs, throughput time and quality, traditional approaches to organize and plan these processes may no longer suffice [26]. This implies defining a process methodology that acts as a “bridge” between architectural elements such as shapes and material on the one hand, and the aspects of indoor climate issues such as overheating and ventilation on the other; an integral approach where all design members have shared understanding – with their own background – on the project [27].

Offering design teams and product developers an appropriate methodology will result in decision support for integral roof-design, within the setting of the primal design. Therefore a decision supportive methodology, within the integral design approach of active roofs, is developed. This implies defining a design methodology that acts as a “bridge” between architectural elements such as shapes and material on the one hand, sustainable energy use and the aspects of indoor climate issues such as overheating and ventilation on the other.

The active-roof design and -engineering, as an integrated product development task, involves solving a design problem. Design problems are a special type of problems and have the following characteristics [28]:

- design problems tend to be large and complex, have both logical and creative components and are wicked
- actors search for a solutions of the design problem within a certain solution space, this solution space is undetermined and the available information is incomplete, since project specifications are never complete or without ambiguity; design problems are therefore ill defined and/or ill structured
- during the design process, actors iterate between design problem and its solution(s)to support the decision making process for these generated design/engineering solutions
- design problems are open ended; it is often not clear when actors have solved the design problem; there is also not one best solution for solving the design problem

Given these characteristics, a methodology to support the design team during the development of the building design is of great importance to clarify the problems and to structure possible solutions. To support the design of large-scale, complex design processes, such as one has in the building industry, a method is presented based on the Methodical design methodology; a matrix orientated approach used in the mechanical engineering domain. Thesis of the research is that, through the use of the characteristics of the Methodical Design, an appropriate support tool is available for Collaborative Design Teams.

WORKING PRINCIPLE

The Methodical Design method is based on system theory and a combination of ideas of the German design school of Pahl, Beitz and others[11, 12, 13, 14, 15, 16] and the Anglo-American's,Archer, Greogory, Krick, Jones and others [17, 18]. Methodical Design combines German and Anglo-American process model approaches. Methodical Design is a problem oriented model based on functional hierarchy, which can be applied on several levels of abstraction and makes it possible to link these levels of abstraction with the phases in the design process itself [19, 20, 21, 22].

The essential element in this model is the design process [21]. The characteristics of the design process can be split up into those related to: strategies, stages and activities. Within the setting of Methodical Design several design-support tools are used: the morphological overview and the Kesselring-method [29]. These are practical tools to structure several functionalities, generate and select possible solutions and can be used for different aspects and abstraction levels.

Due to these characteristics, the methodical approach can accommodate the different subjective interpretations of the requirements, inherent to the design team approach. By structuring the requirements, within each complexity level, the development of the shared understanding in the design team is encouraged. More insight by the design-team-members of different possibilities, from the different requirements, can generate more possible solutions. Through iteration cycle of interpretation-generation steps the set of requirements is continuously refined, and with it also the design solution proposals. The research is focused on the added value of the introduced design-tools, as part of the Methodical Design, within the collaborative design team for the preliminary design-phase.

The research methodology, as quasi-experimental design, uses the structuring method of the Methodical Design. This method can be applied on several levels of abstraction and makes it possible to link these levels of abstraction with each other. By using 4 different levels of abstraction as formulated as functionalities of the problem – integral design / collaborative engineering / sustainable comfort systems / active roofs – the research has a clear framework. Within each level of abstraction - though the research is about developing a methodology for design collaboration - the approach for developing edge conditions and possible approach is the same. This is applicable as well for the research methodology as for the design methodology. For each level the approach (analyze / generate / select / modify) is similar, the development will be different.

Within the Methodic Design, the relationship of the several functionalities and steps can be shown in the scheme below (fig. 1.). In order to structure the research for each level of abstraction (integral design / collaborative engineering / sustainable comfort systems / active roofs) there will be a problem definition / working principle to develop solutions / choice of developed solutions / shape of chosen solution (blue arrow) – for all the functionalities related (vertical column / green arrow).

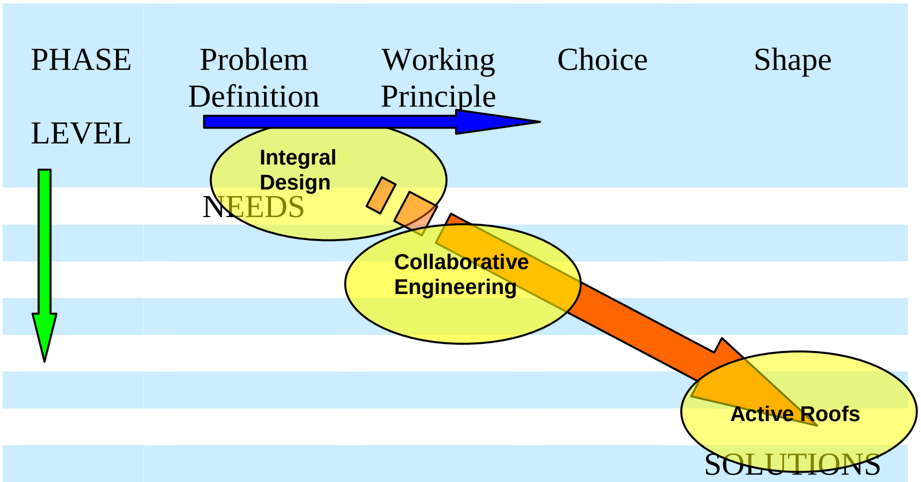

Figure 1. The modular system of hierarchical abstraction as basis of the research methodology

As shown in figure 1, the problem definition generates the working principle for the research methodology. For each level of abstraction within the defined research topic, the several stages and their specific functionalities / needs have to be taken into account. These stages will be described in this paragraph.

The integral approach of the research methodology means different viewpoints on the same topic [8]. For this research the two main viewpoints are that of the designer – the architect – and the engineer – the roofer. By using different typologies of quasi experiments – case studies, scenario's and design task workshops – comparing, verifying and clarifying these experiments, also on research level the different viewpoints are used. By using quasi-experiments, step by step a next – more concrete abstraction level – will be analyzed and verified in order to get a clear view on the influence of the several functionalities / needs related to the specific abstraction level (Integral Design / Collaborative Engineering / Sustainable Comfort Systems / Active Roofs).

Before investigating solutions of 'bridging the gap between architects and roofers, the research will start with investigating the needs and knowledge which causes this gap of design solutions and application engineering.
Therefore the following analysis is made:

- needs in primal design phase for designers / architects
- supply / knowledge from engineers / roofers
- analysis of the differences and similarities between needs and skills of both disciplines

By analyzing all these aspects, an overview of which functionalities are necessary for possible design decision tools to support the participants (architect and roofer) in the setting of collaborative engineering, will be generated.(fig. 2)

Through this first step a further analysis of the roof engineering / installer industry is possible, to develop a model of competence profiles. This model will show which steps are necessary, as a path to success, for creation of appreciation for this specific industry on different levels in the context of collaborative engineering: organization / process / product-level. To have a

reference with practice the competence profile of the façade engineering / installer industry, as a successful path-to-success, is used.
Next step is to set up functionalities related to design- and engineering aspects and generate them in a database useful for both architects and roofers. Related to the different users, two different menus are developed to search and combine the knowledge needed, to design and/or engineer an active roof. The database will be developed in a web-based-setting to facilitate the different users with the needed knowledge, related to design and engineering active roofs.

From the practice, case studies are used to show which kind of problems are there in the traditional design process for roofs and facades, as part of the total building design, in relationship with engineering aspects.

Three different projects will be analyzed (to prove the assumption of the problem);

- comparison of traditional process and collaborative process-approach
- SWOT-analysis with focus on communication and information sharing
- in relationship with architectural concept product/system requirements and technical facilities
- determine criteria of specialist interaction aspects of collaborative design and engineering
- feed-back for aspects of a competence-model and aspects engineering knowledge supply for roofers in the design process

The designed competence profile will be used to set up several, process-based scenarios, used for testing and modifying the data-base-structure as part of Methodical Design methodology. The experiments for testing will redefine the data-base-structure and give a more precise view on the influential and important aspects and functionalities of the knowledge needed in the primal design/engineering phase. Through these steps more precise aspects which are necessary for using more optimal the Methodical Design Tools and Database, can be developed. (fig. 3)

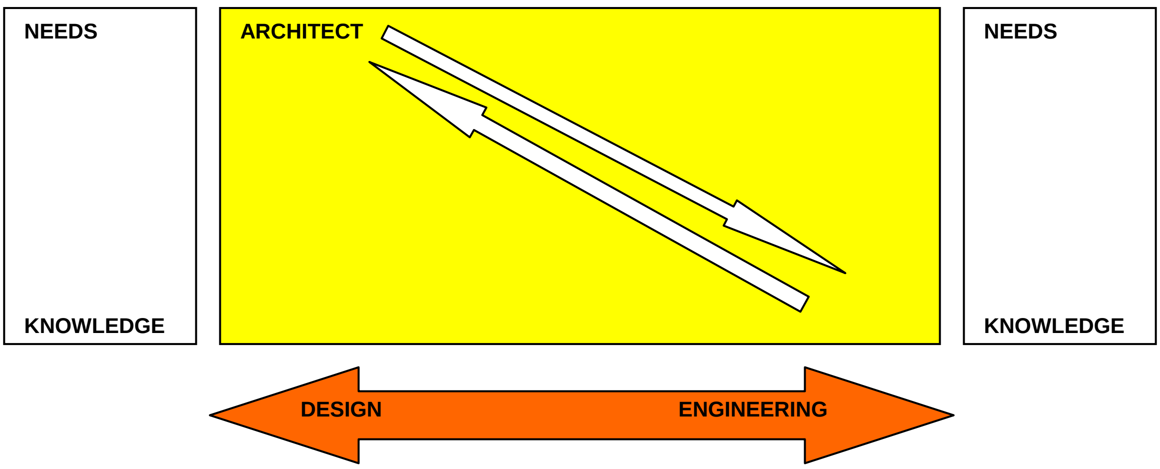

Figure 2. Relationship of needs and knowledge of architect and roofer, from engineering to design

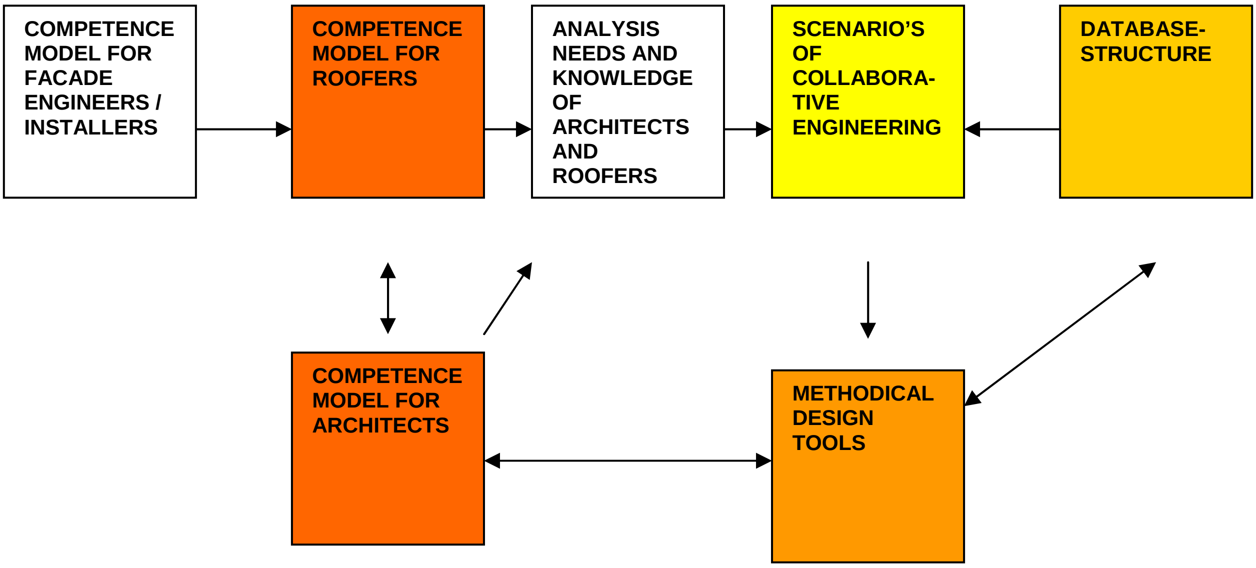

Figure 3. Process scheme for designing / engineering active roofs

Crucial point by using the experiments, in relationship to the 'theoretical model of the Methodical Design, is the connection to a 'realistic model which is part of the design-practice. For constructive implementation / exchange of knowledge within the design process there are 3 main different possibilities of knowledge exchange / generation:

- reflection in action [30]: which connects the design situation in interaction with a framework for the several disciplines
- shared knowledge – heterogeneous engineering [31, 32, 33]: a process of aligning cognitive and social-political elements to create and realize a good design
- 'bricolage' [33, 34, 35]: the use of situational resources tendering with the resources at hand.

The setting which is chosen is that of 'the reflexive practice [32, 36]. This setting has characteristics which makes it, comparing to the other two possibilities, a realistic setting which we can use to verify and validate our theoretical model of Methodical Design. It is a setting which inhabits characteristics to, as in a design-process, have a rational feed-back on the former design-steps and design-decisions and to support the next design-steps and – decisions in a realistic setting with several disciplines.

Mostly the verification of a new methodological concept is done by experiments with student groups (novices) [37] or with design groups within one company [38]. The relevance of the research methodology for practical use in a realistic setting is improved by using experienced designers and participants (professionals), as there is a major difference in approach between novice and experienced designers [39, 40].

CHOICE / SELECTIOIN PHASE

With the found functionalities from the Working Principle – in relationship to the use of the Database-structure and Methodical Design – the scenarios for a serial of quasi experiments will be set up and modified. This is a set up for a prescriptive method to develop appliances for supporting the collaborative design- and engineering-process in combination with engineering knowledge supply.

The quasi experiments will have the focus on the following aspects:

- communication between the design- and engineering solutions for active roofs
- generation of more possible design / engineering solutions for active roofs
- the use of the support decision tool to generate these design / engineering solutions

The same format, related to the Methodical Design, will be used for the set up of the quasi experiments as well for the verification and clarification.

The quasi experiments will be build up in a step by step format with alterations on the group setting (collaborative engineering), group tasks (use of sustainable comfort systems, design /engineering active roofs). The experiments will have the format of design task workshops and/or master classes related to design tasks. The same methodology used on the level of research as a whole is also used on the other abstraction levels within the research; in this case the quasi experiments and the verification of these quasi experiments. (fig. 5.) As example, related to the setting of Collaborative Design and the use of the Database and / or Methodical Design tools we can define the following functionalities / needs related to these quasi experiments:

- situation of the design-team without the use of database or methodical design tools
- situation of design team by using database or methodical design tools, without training
- situation of design team by using database or methodical design tools, with training

The experiments will be done in a serial with feed-back; comparison / selection of the type of experiments as the use of several verification methods as well as the results of the quasi experiments itself. The specific functionalities and results of the experiments will be verified with the use of different verification-methods.

SHAPING PHASE AND DISCUSSION

By using the Kesselring-method a comparison of the different abstraction-levels can be made, finally through the quasi experiments to optimize the experiment and the introduced tools for communication / knowledge exchange. Realization and functioning of the most successful generated tools can be improved. Based on the found and verified functionalities / needs for each abstraction lever an overview of the most successful support tools and scenario's can be generated as part of the developed methodology. Further improvement and research topics for 'how to get there can be evaluated. Through this iteration process more insight in the knowledge exchange of architect and roofers is generated and requirements for the support tools will become clear and can be modified when the circumstances change – the modifying phase. Within a wider range of the EURACTIVE ROOfer project this iteration process can be used for developing the use of the Database structure and the Methodical Design Tools training-set up by the several Collaborative Design team-members for the Active Roof Design [41].

The actual phase of the described research methodology is the selection-phase for defining and applying the case-studies and quasi-experiments. Final results of the research methodology are:

- insight into the needed knowledge / skills of designers (architects) and engineers (roofers) in designing Active Roofs, as part of the total building design

- development of design-decision tool(s), within the setting of Collaborative Design teams, which can structure the needed knowledge from the different design-team members in order to design/engineer these Active Roofs

ACKNOWLEDGEMENTS

TVVL, BNA and TU Delft have supported the Integral Design project. KCBS, Kropman bv and the foundation “Stichting Promotie Installatietechniek (PIT)” support the research.

SUMMARY

The application of a ventilation system in a new building is a multidimensional complex problem that involves both quantifiable and non-quantifiable data e.g. energy consumption, indoor environment, building integration and architectural expression. This paper presents a structured method for evaluating the performance of a ventilation system in the design process by treating quantifiable and non-quantifiable datasets together. The method is based on general morphological analysis and applies cross-consistency assessment to reduce the problem complex, thus treating the multi-dimensionality, the uncertainty and the subjectivity that arise in the design process on a sound methodological and scientific basis. Using a distance analysis of the shared values, the solution scenarios may be plotted relative to each other, which provides the designer with an illustrated 'space of solutions'. Herein the designer may view multiple ventilation solutions and navigate between them, evaluate the differences and choose a suitable ventilation system in terms of energy consumption, indoor environment and architectural quality.

INTRODUCTION

Analysing problem complexes like choosing the ventilation system for a new building presents the engineer and the architect with a number of methodological difficulties. The issue involves both quantifiable and non-quantifiable variables that are intercorrelated and due to the early stage in the design phase information is incomplete, missing or undetermined.

In this contribution we use morphological analysis to decompose and structure the problem complex into both objective (technical) and subjective (architecture) variables while treating incomplete information in a structured manner. One of the advantages of morphological analysis is that such combinations are valid. General morphological analysis has mainly been used for socio-technical problems [1] but also in a building related context e.g. to improve the comfort of various ventilation concepts [2].

Here we couple morphological analysis with cross-consistency assessment and a distance analysis to establish the feasible 'space of solutions' for different ventilation concepts within different building envelopes. This process is time-consuming but we have automated it by implementing it in a simplified yet fully dynamic building simulation program BuildingCalc [3] programmed in Matlab [4].

In the Methods section we describe the requirements and general theory for the method while illustrating it with a limited example. The results section contains the results and the xx at last we discuss the consequences that may be derived from the method and results.

METHODS

The methods section contains a chronological description of the methodological approach: establishing the building requirements, generating the morphological box, performing the cross-consistency analysis and the evaluation criteria and tools. Xx example

Requirements

The requirements for the ventilation system are specified in prEN15251 [6] and we use these to establish the initial design criteria for the ventilation system. In prEN15251 the ventilation and thermal comfort criteria are specified for different building types. The criteria are given as intervals in three categories I, II, and III for different building types. Thus we require initially the building owner to specify the use of the building, the desired category of indoor climate, the type of materials to establish the building pollution and the overall placement of the building on the premises to establish external shadows and prevailing wind conditions.

Table 1. The overall requirements specified by the building owner. Data is obtained from prEN15251 [6] and Danish Building Regulations [7].

Building type	Indoor climate category	Building pollution (no smoking)	Total vent. rate [l/s/m^2]	Temp. range [°C]	Energy frame [kWh/m^2]	External shadows	Wind conditions
Single office 18m^2	I	very low (0.5 l/s/m^2)	1.5	21.0-25.5	95.5[1]	None	Good enough for nat. vent.

Morphological analysis

The background for general morphological analysis is to identify and investigate the total set of relationships or configurations contained in a problem complex.

The morphological analysis was developed by Fritz Zwicky and is described in [5]. It is used to structure *messes*, which are complex issues without well-defined form, into problems of unambigiuous form and dimension.

In this contribution the morphological analysis is used to generate a problem matrix that enables us to decompose the problem complex into sets of functional subsystems. The decomposition is carried out hierarchically and continues until arrived at simple building functional components that can be described with a single variable. There are no formal requirements that the variables are of the same unit; technical, aesthetical and architectural elements, known or hypothesized, are treated together to create a space of solution for the designers. Hence the method is flexible xx the example which is used here does not encompass all ventilation variables or dimensions possible.

[1] At a heated floor area of 3000 m^2.

The decomposed problem is put into a 'box' which is depicted as a chart in Table 3. The dimensions and variables are listed in the left columns and the values are listed in rows. The combination of variables with arrays of values makes up the morphological box.

To start the morphological analysis we need to:

1. Identify the *aspects* of the problem complex. Aspects are also referred to as *dimensions* because they represent the sides in the n-dimensional morphological box. In Figure 1 comfort, energy and building characteristics, and aesthetics are chosen as dimensions.
2. Each dimension is governed by a set of variables. E.g. comfort is achieved through fresh air supply and the ability to cool or heat when necessary (Figure 1).
3. Each variable may attain a well-defined range of values or conditions. In practise the ranges are discretized on the basis of a user perception of low, medium and high values.[2] Thus uncertain or hypothesized values are represented on a backwards traceable methodological basis.

Table 3 illustrates the morphological chart. The imaginative values (high, medium, low) are exchanged with real numbers that *we* regard as representing high, medium and low values. The chart has been reduced for the purpose of illustration and to reduce computation time. Thus the parameters in Table 2 are fixed.

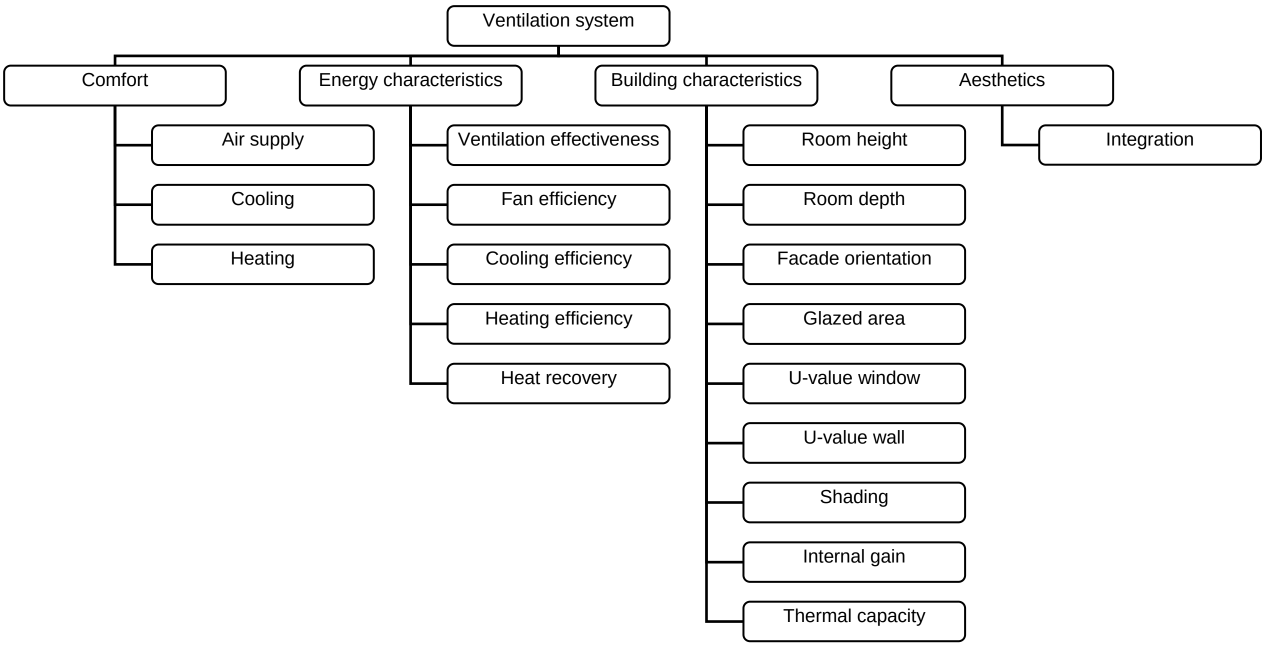

Figure 1. The problem complex decomposed into dimensions and variables.

Table 2. Fixed and excluded values from the morphological chart in Table 3.

Depth of room	Average U-value of window	Average U-value of wall	Façade length	Façade orientation	Min. shading factor
6 m	1.4 $W/(m^2K)$	0.15 $W/(m^2K)$	4 m	South	0.2

Four system/user profiles have been specified: working hours, outside working hours, heating season and outside heating season.

[2] The exact number of discrete values is user defined.

Table 3. Example of a morphological box for a ventilation system in a building. The greyed out areas represent the reduced problem which is used in CCA in Table 4.

Dimensions	**Variables**	**Values**			
Comfort systems	Ventilation 1 Supplied air* [l/s/m²]	Natural **calculated**	Fan-assisted **1.5-3.0**	CAV **3.0**	VAV **1.5-7.5**
	Ventilation 2 Supplied air* [l/s/m²]	Natural **calculated**	Fan-assisted **1.5-3.0**	CAV **3.0**	VAV **1.5-7.5**
	Cooling 1 Max cool. power [W]	Mech. increa-sed vent. rate **calculated**	Night cooling **calculated**	Cooling unit **10**	Chilled beams **30**
	Cooling 2 Max cool. power [W]	Mech. increa-sed vent. rate **calculated**	Night cooling **calculated**	Cooling unit **10**	Chilled beams **30**
	Heating 1 Max heat. power [W]	Radiator ∞	Heating coil **10**	Heat pump **10**	
	Heating 2 Max heat. power [W]	Radiator ∞	Heating coil **10**	Heat pump **10**	
Energy characteristics	Vent.effecness [-]	Low **0.7** (natural)	Medium **0.9** (mixing)	High **1.3** (displacemnt)	
	Fan efficiency SFP** [kJ/m³]	Low **0** (no fan)	Medium **1** (extract only)	High **2**	Very high **2.5**
	Cooling efficiency COP† [-]	Low **1** (cooling w/ outdoor air)	Medium **3**	High **4**	
	Heat recovery [%]	Low **0** (no heat rec.)	Medium **65**	High **85**	
	Heating efficiency [-]	Medium **1** (waterbased)	High **3** (heat pump, COP)		
Building characteristics	Room height [m]	Low **2.5**	Medium **3**	High **3.5**	
	Glazed area [%]	Low **25**	Medium **40**	High **60**	Very high **80**
	Internal gain [W/m²]	Low **10**	Medium **25**	High **40**	
	Thermal capacity [kJ/(m²K)]	Light **144**	Medium **288**	Heavy **432**	Very heavy **576**
Aesthetics	Integration of vent. system	Visible	Somewhat visible	Invisible	

* 'Supplied air' is the required minimum by prEN15251 during occupancy. Some of the systems (CAV, VAV) may be able to supply additional air (for cooling purposes). The user defines the desired ventilation ranges of the systems.

** SFP: annual average specific fan power. A measure of the efficiency of the ventilation fans and the pressure loss in the system.

† COP: annual average coefficient of performance. A measure of the efficiency of the cooling system.

Cross-consistency assessment

After the initial setup and definition of the dimensions of the problem, we apply cross-consistency assessment (CCA). This is to accomplish two things: eliminate the illogical or normatively unwanted configurations and to detect *input garbage*. Input garbage consists of vaguely defined problems, terms or variables with no clear meaning or with more than one meaning etc. If anything is insufficiently defined or described one must go back to the morphological box and redefine or refine input. Table 4 demonstrates the cross-consistency assessment derived from the morphological box in Table 3. All values are pairwise compared by the user for logical incompatibility (denoted by I) or because they are normatively unwanted (denoted by U). The remaining blank intersections are valid combinations.
It is important in the cross-consistency assessment to focus on each value pair to avoid biased assessments that unintentionally exclude value combinations that may be perfectly compatible but are incompatible on a normative basis. In general only strictly illogical combinations should be excluded.

If the intersection between two values is marked all the configurations containing the value couple is excluded from the simulation. For an n-dimensional morphological box this leaves xx

Table 4. The CCA matrix from the morphological chart in Table 3. 'I' denotes illogical value pairs, 'U' unwanted value pairs based on a normative judgement.

Examples of questions for assessing the CCA matrix: useraction related xx:

- Is it possible to have a building scenario where a cooling coil in the second cooling system coexists with a night cooling system in the first cooling system? Obviously this is possible. Hence no marking is used.
- Is it possible to have an efficient heat recovery of 85 % and a specific fan power of zero? This is illogical, so the pair is marked with an I.
- Is it possible to have a room height of 2.5 m together with a natural ventilation system? This is a possibility, but the litterature states that natural ventilation performs better if the room height is 3 m xx. Hence an U is used because the user assesses that on a normative basis this particular combination is unwanted.

Evaluation criteria

The morphological approach generates a large number of configurations or scenarios as depicted on Figure 2. We evaluate the scenarios on the basis of total energy consumption, indoor climate (PPD-hours) and annual total cost. For electrical appliances a primary energy factor of 2.5 is used [7].

PPD-hours are calculated from the annual sum of hourly values of predicted percentage dissatisfied [8]. Local discomfort is not considered and relative humidity and air velocity is fixed to 50% and 0.15 m/s respectively. The ventilation rate is not considered as we assume that the minimum ventilation requirements are always meat.

Total costs are based on the sum of the annualized constructing and yearly running costs of the ventilation system.

Distance analysis

One of the most important goals in visualising data is to provide the viewer with a sense of distance between the plotted points. While it is straight-forward to plot scenarios based on two criteria, e.g. energy consumption and PPD-hours, the designer is not provided with the overall picture. With a large number of dimensions (>3), it is very difficult to visualise distances unless the data can be reduced to 2 or 3 dimensions. Hence a dimension reduction is necessary. Metric multidimensional scaling (MDS) is a set of statistical methods that address this type of problem. The methods are available in a toolbox in Matlab and we use them to plot the selected scenarios relative to each other to obtain an instant sense of the distances between them. The interscenario distances are not Euclidean but the *configurational* or technical distances, or more precise the pairwise dissimilarities between the scenarios. I.e. a technical distance of 1 between two configurations indicates that they have been produced from the same set of values except for 1 value that has been replaced by its horizontal neighbour in the morphological box.

It is evident that a certain amount of distortion has to be tolerated when a multidimensional dataset is reduced to two or three dimensions. In typical MDS applications an investigation into the significance of the error is conducted via Kruskals Stress criterion ref xx (stress1) where values are excellent below 0.1 and unacceptable above 0.15. The stress1-value on Figure 4 is 0.12. If the criterion is exceeded the user must reduce the number of selected configurations or raise the number of depicted dimensions from 2 to 3.

RESULTS

In this section we show the results that may be obtained using the method. The initial requirements established by the fictive building owner are shown in Table 1. A total of 248,832 scenarios was simulated with BuildingCalc taking approximately 80 minutes on a laptop with a Pentium M processor running at 1.86 GHz and 1 GB of RAM.[3]

In Figure 2 all the configurations derived from Table 3 and Table 4 have been simulated and depicted with respect to energy consumption and PPD-hours. With the BuildingCalc tool it is possible to pick the most interesting configurations, typically with respect to low energy consumption and low PPD-hours. Figure 3 depicts the predominant value settings of the 30 selected configurations. With the predominant values as starting points it is possible to reformulate the morphological box and resimulate with refined values.

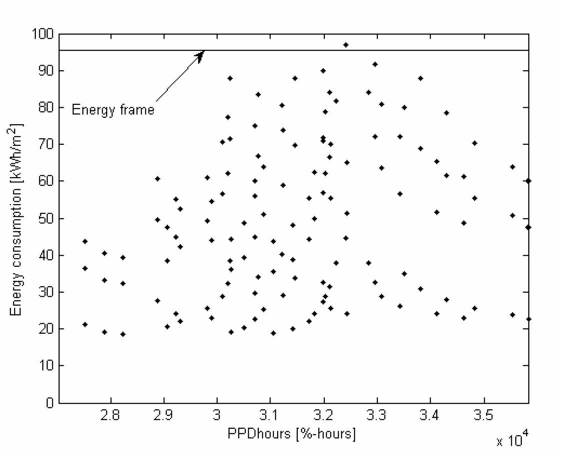

Figure 2. The distibution of ventilation configurations produced via the morphological box.

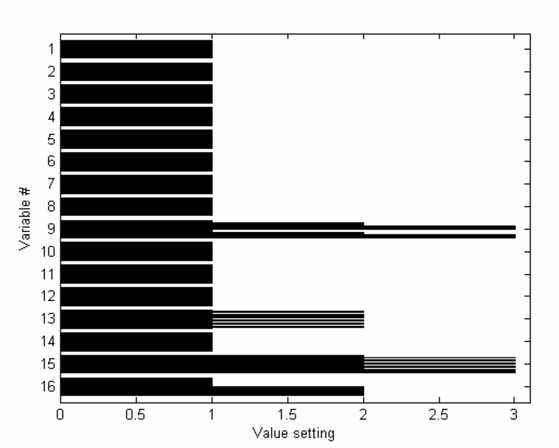

Figure 3. Predominant values for the 30 selected configurations. The variables are numbered consecutively as in Table 3.

Establishing a linear correlation between bubble size and total costs we use the MDS method to plot the selected scenarios relative to each other in
Figure 4. We may navigate between them and explore their similarities simply by clicking on the points with the mouse.

[3] Only a part quantity of the total number of configurations requires lengthy thermal simulation time.

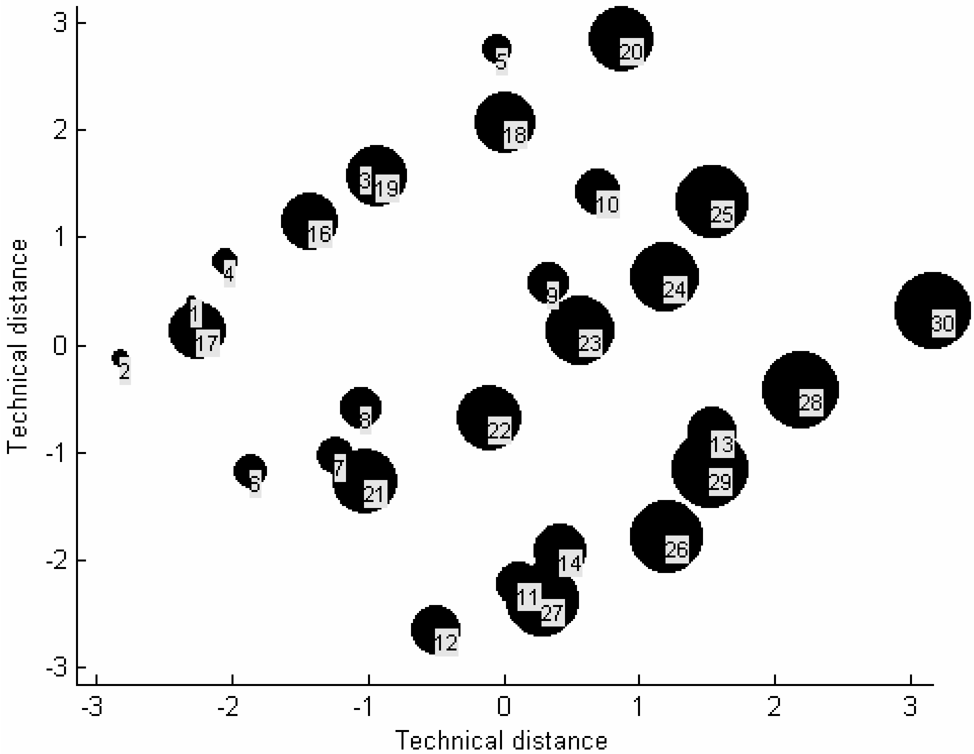

Figure 4. The relative technical distance between the 30 selected scenarios. Bubble Size xx

xxThe distances between the points are the distances expressed in terms of 'technical distance'. Two points closely spaced represents two ventilation scenarios that are very similar to one another. The MDS method visualizes the morphological chart to the engineer and he is able to distinguish between multiple scenarios because their visual distance is a measure of their similarity. Thus
Figure 4 illustrates a space of solutions, where it becomes clear that scenario 3752 xx is better than 2030 if 3758 is not entirely suitable to the engineer or the architect.

DISCUSSION

The method described in this paper offers a deep insight into the problem complex of choosing a suitable ventilation system for a building. The morphological approach exempts the engineer from generating biased scenarios and by coupling the morphological analysis with cross-consistency assessment we ensure that the subsystems are unambiguously defined. The method is fully scaleable to the needs of the user and it allows for treating quantifiable and non-quantifiable datasets parallelly while remaining backwards-traceable. However the method also requires a certain amount of skills and practise to be able to setup the morphological box, cross-assess and iterate, but the procedure helps to keep out garbage input and to decompose the problem complex correctly.

The MDS method is limited to a certain number of configurations and dimensions, but it provides an excellent visualization and overview of the feasible configurations to discuss among engineers and architects in the design phase.

Energetic Sustainability Assessment about Passive Solar Systems by a Finite Differences Code

Giorgio Galli, Cesare Antonio Muceli and Rosaria Ippolito

Department of Technical Physics, University of Rome "La Sapienza", Italy

Corresponding email: giorgio.galli@uniroma1.it

SUMMARY

The use of bioclimatic solutions in architecture has been for a long time in Europe a consolidated procedure, especially developed in northern countries. In the last years, in Italy too, It has been followed through a good policy to increase the construction of buildings equipped with solar energy harnessing system; many architectural competitions expressly ask for passive solar architectonic solutions. In this study, It has been assessed the energetic performance of a solar passive building by a finite differences code (TRNSYS).
Many tests and simulations have been carried out on a residential building, changing the configurations of the building envelope and transparent or opaque surfaces.
It has been calculated the thermal performance of a south-facing building, in which the façade, chancing configuration, is made up of opaque wall and windows, or a completely transparent surface, testing many kind of glasses (direct gain sunspace) or small sunspaces against a thermal storage matt wall.
Thanks to these final results, It has been possible to make some considerations about different kinds of proposed passive solar solutions, picking out the more convenient ones as to their energy performances and appropriate lighting and thermal indoor comfort.
This work would arise a contribution about:

- a correct way of bioclimatic design, by using transparent insulating materials,
- new kinds of direct gain sunspaces, that allow energy saving of 50%,
- sustainable energy use of building envelope.

INTRODUCTION

New Italian law about energetic saving (D.Lgs n. 192 of 19 August 2005), impose to equipping new constructions of energetic certification, exposed as a simple label to the door of the building (figure 1).
The normative system develops new limits more restrictive than previous laws (L. n° 10 of 1991) fixing transmittance acceptable maximum values, relatives to 2006 and to 2009, for the building envelope components, that new constructions will have to respect.

Figure 1 – Energetic label

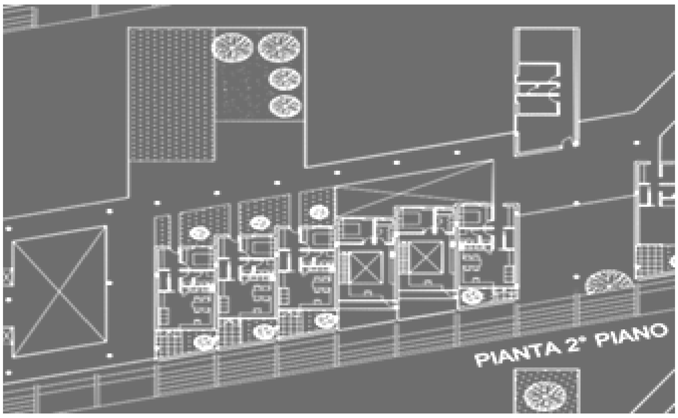

Figura 2 – Detail of the studied plan

In the light of this new laws, object of this work is the energetic behavior of a bioclimatic residential building, characterized from a very particular facade exposed to south (figure 2-3).
Various configurations of this architectonic element have been assumed: the “traditional” one, made of masonry and rectangular windows, the passive solar solution with attached sunspaces to a thermal storage wall, and an other one, made of a completely glazed façade and characterized with “innovative” type glasses (low emissivity triple glass with interstices in krypton) with very low thermal transmittance values (U=0,4 W/m ² K).

METHODS

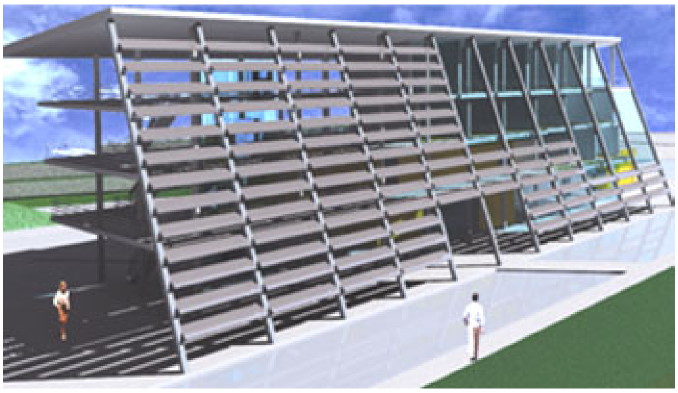

Figure 3 – View of the southern facade

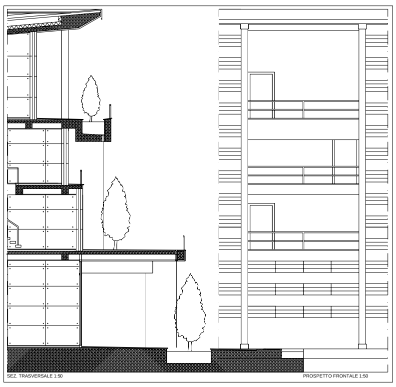
Thanks to a thermal transient simulating software (TRNSYS), it has been possible to calculate the inner temperatures of lodgings and the energetic requirements of the building envelope during the winter period. In order to obtain the temperatures data, the simulations have been carried out supposing a building lacking in heating system, moreover to achieve results about energetic requirements, It has been studied the binomial *building - heating system*, regulated to work every time the dwellings inner temperature falls below 21°C. The final scope has been that to estimate and to confront the behavior of these new transparent materials in relation to passive solar solutions, as classic sunspaces, wide dealt about.
The energetic requirement has been analyzed in the winter time, that is the period in which in Rome is allowed working of heating system, (from 1 November to 15 April, equivalent to 166 days, for a total of 3984 annual hours).

STUDIED CONFIGURATIONS

1. Building with standard windows



Picture 1. Section and front of the building with standard windows

The figures 4, 5, 6 and 7 represent the temperatures and the energetic requirements of the residential construction assuming the southern facade as an opaque wall with standard window. The thermal transmittance of the external walls is U=0,48 W/m² K , the type of window instead is made of double glass with U=2,8 W/m²K and transparency G=75%. Heating system enters in action when the room inside temperature gets below 21°C:

analyzing the temperatures diagrams It is easy to note that with this type of structure the temperature is always under the 21°C, that means that the building has a high thermal dispersion, in winter time about 137 GJ/year.

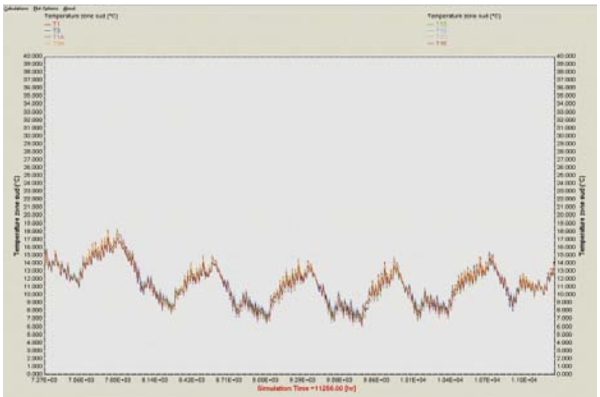


Figure 4 – Diagram of T [°C] of the southern zones of the building.

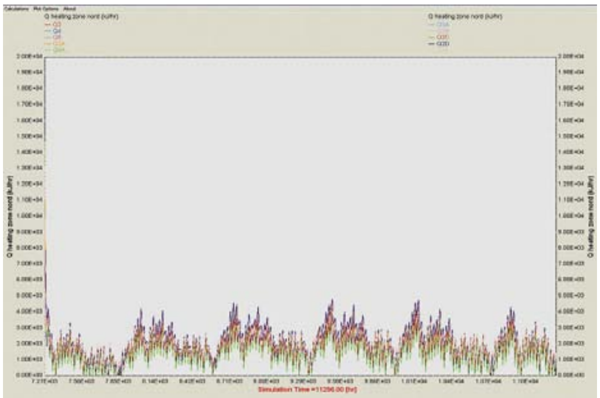

Figure 5 – Diagram of T [°C] of the northern zones of the building

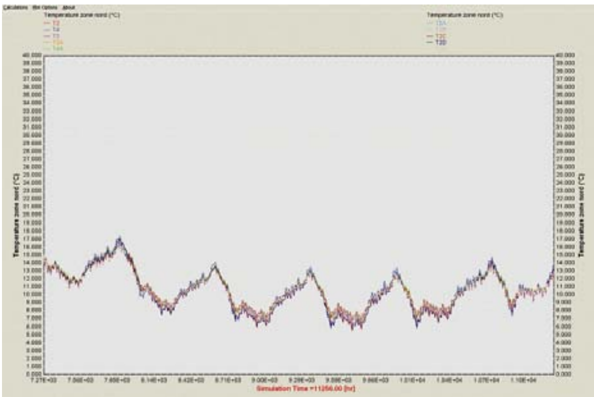

Figure 6 – Diagram of Q [kJ/hr] of the northern zones of the building

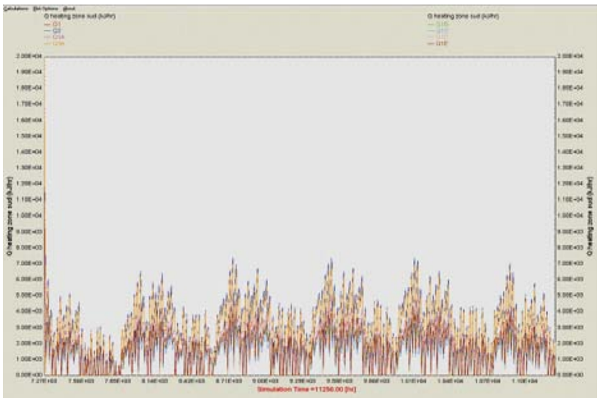

Figure 7 – Diagram of Q [kJ/hr] of the southern zones of the building

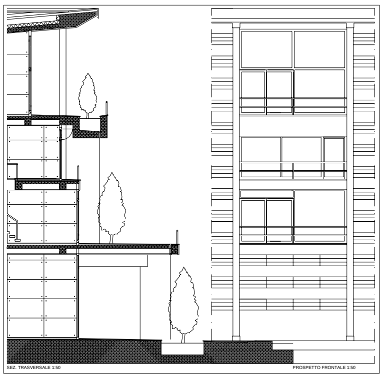
2. Building with a completely glazed southern façade

The external walls thermal transmittance is U=0,48 W/m²K, instead for southern facade, many types of glass have been analyzed with different values of thermal transmittance (U) and transparence (G).

The represented diagrams in figures 8, 9,10 and 11 regard the temperatures and the energetic requirements of the residential structure supposing to use triple glazed panels made of an extra-clear glass on which it is applied, by vacuum packed cathode pulverization, a low emissivity noble metals powder. These transparent innovative materials have the skill to achieve very high values of luminous transmission G=60% and thermal insulation, thanks to those noble metals powder characteristics and krypton gas of which It is filled up with (U=0,7 W/m² K).



Picture 2. Section and front of a building with whole glazed facade

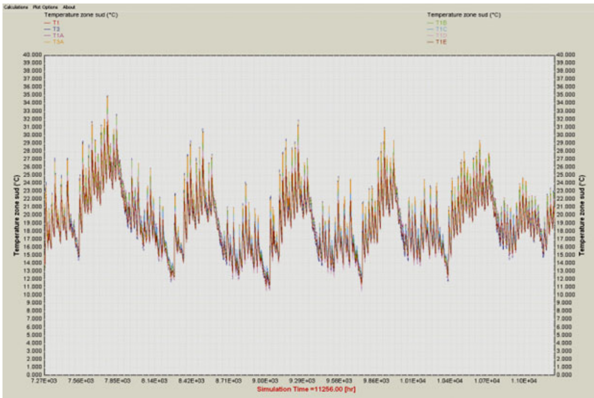


Figure 8 - Diagram of T [°C] of the southern zones of the building

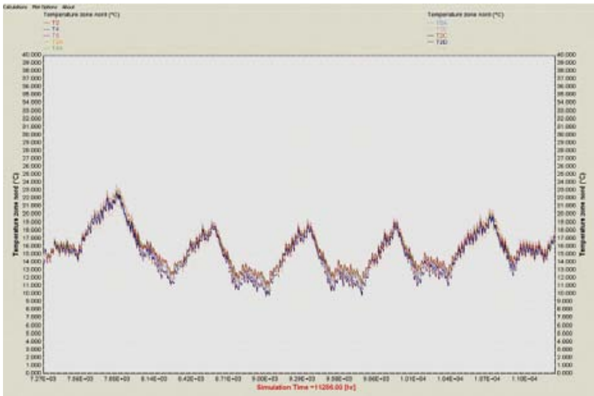

Figure 9 - Diagram of T [°C] of the northern zones of the building

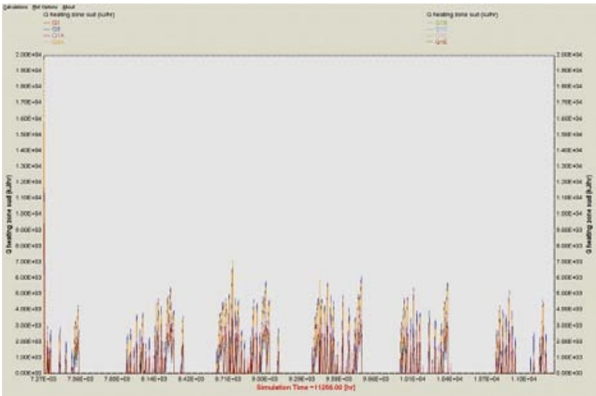

Figure 10 - Diagram of Q [kJ/hr] of the southern zones of the building

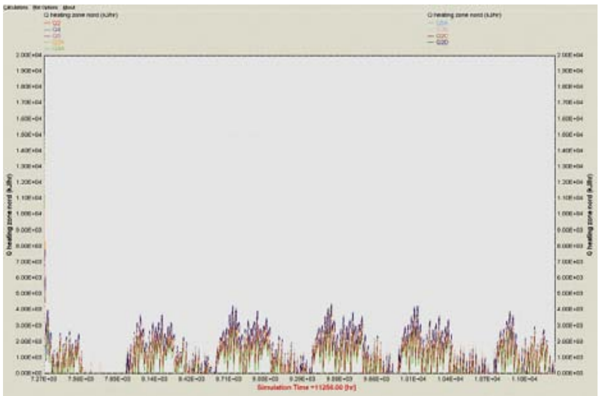

Figure 11 - Diagram of Q [kJ/hr] of the northern zones of the building

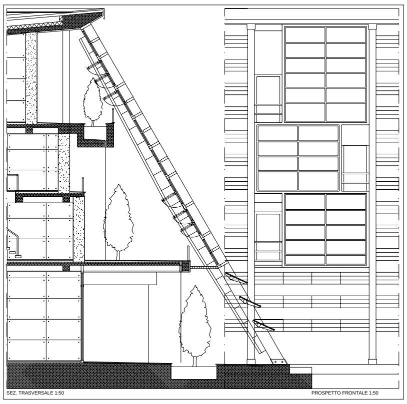
Making use of a single glass, for southern glazed façade, would involve high energetic requirements, because of its transparence value (G=85%), that lets great part of the solar radiation in, with consequent excessive elevation of the inner temperatures on day, while during night, because of its high thermal transmittance value, whole accumulated heat in daytime is leaked out, making go down the temperature one. Instead, in an other studied case, using glasses with lower transmittance and transparence values, energetic requirements diminish, saving energy about 1/3 as regards use of a single glass. Every time the glass transparence value is less than 60%, the energetic requirements increase because the solar radiation cannot go through the almost completely opaque glass and directly irradiate all rooms to rise indoor temperature. The energetic requirement of this solution, made of low emissive triple glass, is lower than the other transparent ones, that is 57 GJ/year (Table 1).

Table1. Building Energetic requirements in proportion to U and G values

Type of glass	**U-values**	**G-values**	**Q Tot. GJ/year**
single glass	U=5,8 W/m²K	G=85%	147
double glass	U=2,8 W/m²K	G=75% (air)	82
double glass	U=1,3 W/m²K	G=64% (argon)	61
double glass	U=1,1 W/m²K	G=63% (krypton	65
triple glass	U=0,8 W/m²K	G=50% (krypton)	70
triple glass low-E	U=0,7 W/m²K	G=60% (krypton)	57
triple glass low-E	U=0.4 W/m²K	G=40% (krypton)	79

3. Building with window and sunspace attached to a thermal storage wall.

The figures 12, 13, 14 and 15 describe temperatures and energetic requirements of the residential building, supposing that southern facade is made of a wall with a standard window and a sunspace attached to a storage wall. The applied heat transfer coefficient of all opaque walls is U=0,48 W/m ² K. For sunspace inclined surface has been analyzed the same transparent configurations already used for studied case 2. The use of a single glass in sunspace southern inclined wall is more convenient than the other types of glass, because of its transparence G=85% allows to have a great thermal gain on the storage wall and all accumulated heat by day can be released by night-time hours. Glasses with smaller transmittance and transparency values increase the energetic requirements, because of reasons already explained before, therefore the storage wall absorbs less heat and the inside room temperatures are lower. The diagrams in figure 12, 13, 14 and 15 regard the configuration with the most convenient type of applied glass (table 2), that is the single one with U=5,8 W/m² K and G=85%: in this case the building energetic requirements are about 102 GJ/year.



Picture 3. Section and front of the building with window and sunspace attached to a thermal storage wall.

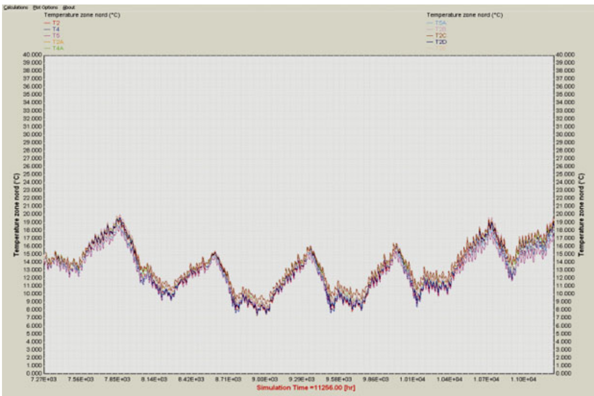


Figure 12 - Diagram of T [°C] of the southern zones of the building

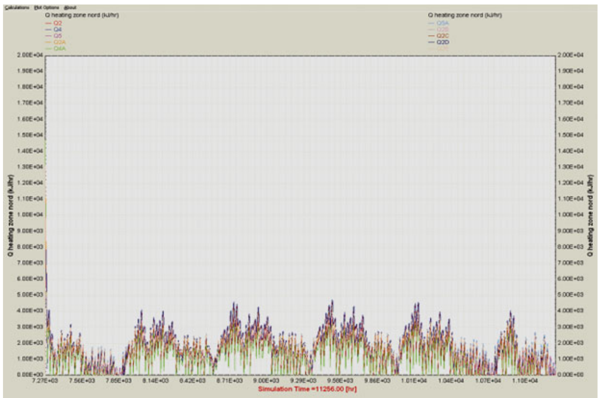

Figure 13 - Diagram of Q [kJ/hr] of the southern zones of the building

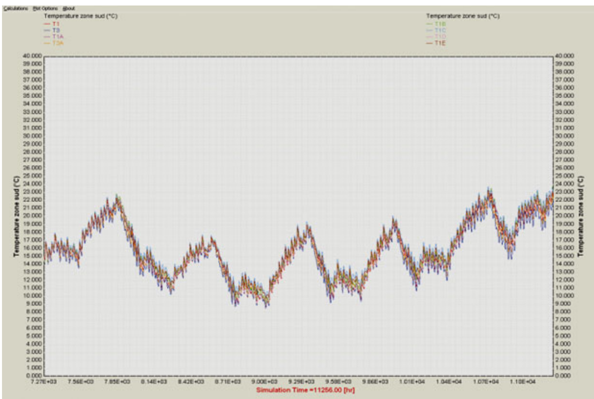

Figure 14 - Diagram of T [°C] of the northern zones of the building

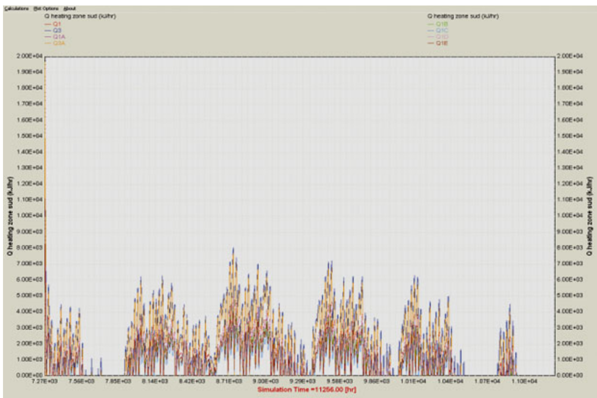

Figure 15 - Diagram of Q [kJ/hr] of the northern zones of the building

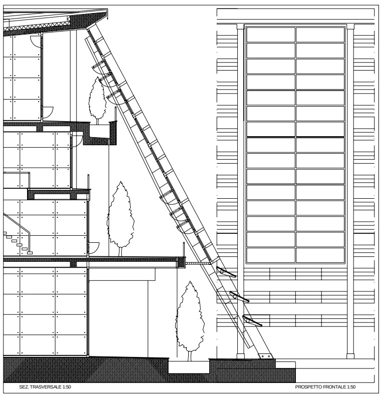
Table2. Building energetic requirements in proportion to U and G values

Type of glass	**U-values**	**G-values**	**Q Tot. GJ/year**
single glass	U=5,8 W/m²K	G=85%	102
double glass	U=2,8 W/m²K	G=75% (air)	106
double glass	U=1,3 W/m²K	G=64% (argon)	109
double glass	U=1,1 W/m²K	G=63% (krypton	109
triple glass	U=0,8 W/m²K	G=50% (krypton)	123
triple glass low-E	U=0,7 W/m²K	G=60% (krypton)	114
triple glass low-E	U=0.4 W/m²K	G=40% (krypton)	132

4. Building with sunspaces attached to a glazed wall

In this other studied case, It has been simulated the building configuration, applying to inclined surface the triple low emission glass, instead to glazed wall behind the sunspace, the use of single glass has been very advantageous, because of its high U-value, heating all adjacent rooms. Many configurations have been analyzed (table 3) and the most energetically sustainable solution has been represented in Figures 16, 17, 18 and 19.: applying triple low emissivity glass, characterized by U= 0,7 W/m^2 K and G=60%, the energetic requirements are about 94GJ/year.



Picture 4 - Sunspaces attached to a glazed wall

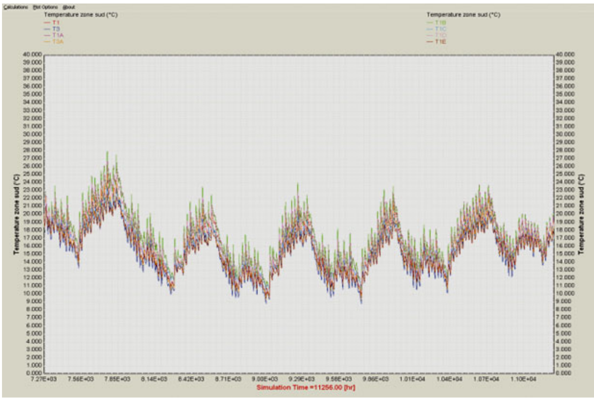


Figure 16 - T [°C] of the southern zones

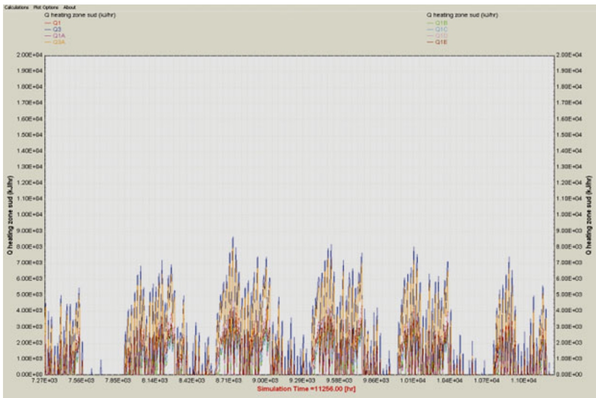

Figure 17 - Q [kJ/hr] of the southern zones

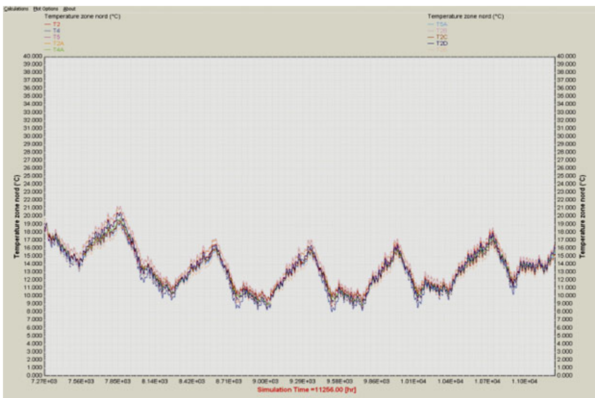

Figure 18 - T [°C] in northern zones

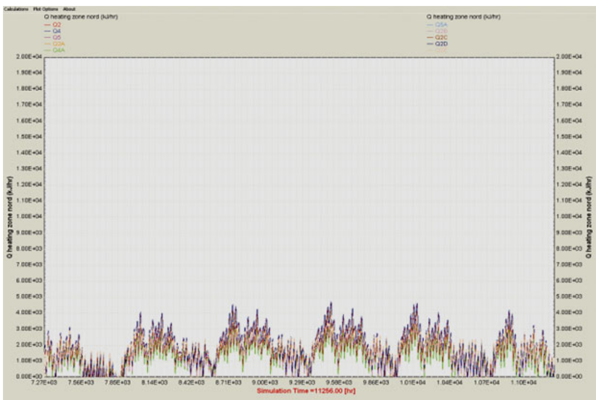

Figure 19 - Q [kJ/hr] in northern zones

Table 3. Building energetic requirements in proportion to U and G values

Type of glass	**U-values**	**G-values**	**Q Tot. GJ/year**
single glass	U=5,8 W/m²K	G=85%	133
double glass	U=2,8 W/m²K	G=75% (air)	110
double glass	U=1,3 W/m²K	G=64% (argon)	96
double glass	U=1,1 W/m²K	G=63% (krypton	97
triple glass	U=0,8 W/m²K	G=50% (krypton)	105
triple glass low-E	U=0,7 W/m²K	G=60% (krypton)	94
triple glass low-E	U=0.4 W/m²K	G=40% (krypton)	112

DISCUSSION

Comparing the several solutions represented in tables 4 and 5, the results are that It is possible to get the best energetic performance, in a southern façade, by employing a triple low-E glass filled of krypton to a whole glazed wall configuration . Therefore, this architectonic solution is the only one that fulfills all new restrictions of D.Lgs 192/2005; in fact its energetic requirement value is less than utmost allowable one in *D climatic zone* of Rome.

Table 4. Energetic requirements of building envelope in winter time

Building characteristic	F.E.P. GJ/year
Traditional windows double glass	137
Southern whole glazed façade(triple low-E glass)	57
Sunspace attached to a storage wall	102
Sunspace attached to glazed wall (triple low-E glass)	94

Table 5. Energetic requirements of building envelope in winter time
ex D. Lgs 192/2005 related to D climatic zone

Building characteristic	F.E.P. kWh/m^{2}year (49.9 max value)
Traditional windows double glass	84.5
Southern whole glazed façade(triple low-E glass)	35.8
Sunspace attached to a storage wall	62.9
Sunspace attached to glazed wall (triple low-E glass)	58.1

The results of the façade made of window and sunspace attached to a thermal storage wall have not been so appreciable. This solution demands less primary energetic requirement than that made of rectangular windows on an opaque wall, but compared with the whole glazed facade, this one presents twice as much annual consumption.
Therefore in any case, this study puts in evidence that all more classic configurations used in the bioclimatic architecture, as sunspace attached to a storage wall, are less convenient than solutions that employ innovative transparent materials, that in fact They do not fulfill italian law parameters.

Complex Building Automation
Energy Efficient New Construction of Hagen Sparkasse by Klaus auf der Springe

THE PLANNING TEAM

In mid-2002 the Friedberg architects' bureau Bremmer, Lorenz, Frielinghaus, which had been successful in the architecture competition, was commissioned to plan the new construction of the main branch of the Hagen Sparkasse (savings bank). The Sparkasse had already decided to demolish the 22-storey 1970s office block known for miles around as "Langer Oskar". Redevelopment of the Hagen landmark was not economically viable and instead its spectacular blowing up was to open the door to technical progress. To complete the planning team Skiba Ingeniurgesellschaft für Gebäudetechnik from Herne, which in the meantime has merged with THS Consulting GmbH, Gelsenkirchen, was commissioned with the planning of all the internal technical facilities, including the extensive media installations and the preparation of an integrated facility management and operating plan. The planning team was rounded off with structural planners, sound insulation experts, a fire safety consultancy company and the EGS-plan engineering company for energy, structural and solar technology. The project management for the building was assumed by DBB, Deutsche Bautec Baumanagement GmbH based in Mainz, which originated out of DAL Bautec.
In collaboration with our engineering bureau, EGS-plan drew up the integrated energy plan for the new building, which in addition to the necessary requirements for the shell of the building also had a strong influence all the building's internal technical systems. As the Sparkasse was incurring high energy costs because of the ageing technical systems and façade of the existing building, the client had placed particular value on the economic operation of the new building, without impairing the convenience, amenities or the attractiveness of the building. The use of natural resources formed apart of further considerations, was discussed together with the clients and led to the overall design of the building approved for further planning.

THE STRUCTURE OF THE NEW BUILDING

A five-story building was erected on an area of around 125 m × 50 m. The basement acts as an underground garage with 145 parking spaces and is also used as a storage area, strong-room and for the archives. It also contains the heating and cooling control systems. On the ground floor, in addition to the elliptical entrance and the cash machine areas accessible

outside opening hours, is the expansive customer foyer over 20 m in height with consultation desks, privacy and waiting zones.
An events area, the conference and events room, a Mediterranean-style restaurant and integrated VIP area, a coffee bar, an atrium with a glass roof (22 m high) as well as five shop units make up the remaining space.

In addition to offices, the Sparkasse's conference rooms are located on the first floor. The conference room above the main entrance has been designed in a particularly exclusive manner, taking on the shape of the main entrance. The second to fourth floors are predominantly used as offices, with the Sparkasse's casino also being located on the 4th floor. The Sparkasse offers offices to rent on the floors 1 to 4 of the southwest wing of the building.

INTEGRATED ENERGY CONCEPT

In addition to the user requirements in terms of functionality and convenience, the integrated consideration and planning of a building also includes the subsequent operating costs of the building. In regard to the economic viability of the investment and the subsequent operating and maintenance costs, the drawing up of a sustainable energy concept plays a central role in planning.

In the discussions between all the parties involved in the planning the following objectives were defined:

– Window ventilation rather then mechanical ventilation,
– Air-conditioning or cooling as an exception,
– Reduction in heating and cooling costs,
– As much use of daylight as possible
– Individual room regulation,
– Use of natural resources,
– High level of sound-proofing from outside as the building is located directly adjacent to several bus stops.

The concept also included training of the building users in order to harmonise their expectations and behaviour with the new building.

BUILDING SHELL

In the initial phase of consideration decisions on the building shell were made.

First decision: the office will have box windows, which in the case of rooms facing the street will also have a “deflector pane” for sound-proofing reasons. This deflector pane effectively reduces the noise of arriving and departing buses but still allows the windows to open for natural ventilation as narrow gaps between the deflector pane glass and the facade allow air to be exchanged.

The glass-covered area of the customer foyer, the events area and the inner atrium as well as the entrance area designed as a glass facade are constructed with different qualities of glass in order to create optimum thermal insulation conditions and a feeling of comfort in the interior.

VENTILATION

The building was divided into zones with different ventilation concepts.

The principle of natural ventilation before mechanical ventilation was taken into account in the offices.

Offices adjoining the customer foyer area or the atrium are provided with displacement ventilation via air outlets integrated into the lower sections of cupboards. The air drifts through the room and is directed via sound-proofed facade ventilation elements into the customer foyer/atrium.

The total quantity of air in the offices in conjunction with the adjoining customer foyer and atrium take is balanced out via shutters for natural and/or mechanical ventilation and venting of these areas depending on the weather.

An extensive ventilation shutter control system in the façade and glass roof also ensure pleasant temperatures in the customer foyer and atrium.

A weather station records climatic data, wind strength and direction so that the necessary shutters can be opened for optimum ventilation of the foyer without draughts being felt or rain coming in. Depending on the assigned individual room settings of the offices and customer foyer, the optimum shutter opening is set. However, there are areas in the new Sparkasse building that require mechanical ventilation and venting in the interests of user comfort, in particular the conference rooms in which many people are frequently expected, but also in the gastronomic areas of the restaurant, coffee bar and casino. These areas are mechanically ventilated, whereby of course ventilation devices with heat recovery integrated as circulatory composite systems are used. The ventilation controls are located on the roof behind a technical membrane.

SMOKE EXTRACTION

As well as the ventilation plan, smoke extraction forms an integral part of the installation technology and the associated natural ventilation and venting, particularly in the customer foyer. As part of the integrated planning of the building a concept was developed in collaboration with the fire safety consultancy company Lorenz that makes use of the existing ventilation and venting technology as far as possible.

This means that the ventilation and venting shutters, as well their control systems, assume an important dual function in extracting smoke from the customer foyer. If the event of a (hopefully never to occur) incident the weather station data is also used, but this time for the purpose or extracting smoke from the foyer as quickly as possible. Here the key is not an absence of draughts, but opening the façade and roof shutter so allow the greatest possible movement of air. At the same time the opening of shutters that could cause banked-up pressure in the foyer must be avoided. In accordance with the fire safety plan, in addition to the corridor areas from which smoke must be extracted, there are three smoke extraction zones – the atrium, events area and inner courtyards. Smoke is extracted from the atrium via smoke-heat removal windows (SHR windows) in the roof, which are also used for natural ventilation and venting. Electric doors to the shop area which in the event of a fire alarm in the atrium can be opened by way of a fire alarm system (FAS) contact within 90 seconds serve to provide an additional air flow, and at the same time the FAS controls the closure of the roller grilles in front of the doors. The partition wall to the events area should be closed or remain closed, the ventilation and air-conditioning switch of and the natural ventilation and venting shutter close. The SHR windows in the roof of the atrium are arranged in such a way that groups can be formed in various areas so that depending on the wind direction and strength at least two of the four areas can be opened. The specifications were determined for each flow situation. A similar smoke extraction plan applies in area 2, the events area. Here, the shading systems must be moved into the “open position” in the event of a fire.

Smoke is also extracted from the inner courtyard via SHR windows in the roof that are used for natural ventilation and venting. Here, electrically operated additional flow openings in the outer façade provide additional flow and these can also be opened within 90 s by way of an FAS contact. The partition wall between the atrium and events area as well as the smoke extraction openings in these areas must be closed in the event of a fire alarm in the inner courtyard, the ventilation and air-conditioning systems switch off and the natural ventilation and venting shutter close.

HEATING, COOLING, BUILDING ELEMENTS ACTIVATION SYSTEM

Via the comprehensive building elements activation system provided in the office floors a basic temperature equalisation of the building is achieved. As a three-pipe system the building elements activation system can be used for both heating and cooling. However, in order to keep to the principle of optimising energy use cooling has been largely dispensed with. Therefore it is permissible for office temperatures not to be kept constant throughout the day in the summer months as is the case with cooling ceilings, but to fluctuate in accordance with changes in the outside temperature. If this basic temperature equalisation is inadequate the building is heated by heaters. The offices have individual room regulators which in addition to radiator valve regulation provide important room data to the building process control systems. Evaluation of this data optimises the deployment of building element activation. In the entrance hall, customer foyer, consultation desk area, events area and conference area underfloor heating/cooling is built in in combination with a double floor as a three-pipe system. The consultation, training and board rooms are also supplied via a three-pipe system, though in connection with single room regulation, cooling ceilings and cooling sails. Depending on the recorded room and weather station data the building component activation system is charged during the night. The cooling machines are designed for acyclic use by the consumers, i.e. not all consumers can be cooled at the same time. The system was optimised to use the building element activation system at night, whereby a basic load through constant consumers of cold, e.g. the dataprocessing and server rooms was added.

The cooling system allows the following four operating modes:
1. Normal operation
2. Heat coupling to the three-pipe system
3. Free cooling operation 1,
4. Free cooling operation 2.

As the various operating modes can change smoothly from one to another, the operating management for automatically selecting the relevant operating mode has been optimised to this use.

Normal operation is activated at external temperatures of over 20 °C . It is defined in that free cooling operation is not possible due to too high external temperatures and no more heat is being requested by the building element activation three-pipe system.

At external temperatures below 20 °C heat energy is required for the three-pipe system (operating mode heat coupling). Free cooling operation 1 (external temperatures below 14°C) is a combination of free cooling operation with simultaneous operation of the cooling machines. It is primarily intended for concrete core cooling, but also for the "server room" cooling cycle. Due to the hydraulic design of the installation as a dual-circuit system and the by-pass regulation on the cooling machines, simultaneous operation of the cooling machines and free cooling can be achieved.

Free cooling operation 2 is classic free cooling operation, without simultaneous cooling machine operation. Free cooling is triggered at external temperatures of below 7°C or if the specified value of the flow temperature of the "server room" cooling circuit exceeds the external temperature by more than 5 K.

ROOM AUTOMATION

For room temperature regulation and control of solar protection, daylight and artificial lighting use the building the building will have a bus-capable room automation system as a result of the system architecture based on the LON Mark standard.

The full functionality of the room automation stations is shown on the central building control system. The individual room management system allows individual necessity-related regulation of thermal by each room user with simultaneous minimum energy requirements. The integration of all room functions, in particular the combination of heating, ventilation, climate control with daylight utilisation, lighting, solar protection, access control and safety systems is also possible.

The solar protection system has variously shaped and coated panels which in the upper section direct light into the room. Depending on the position of the sun the panels are automatically moved into the optimum position so as to provide protection from the sun at the same time as continuing to guarantee optimum utilisation of daylight. By way of a daylight measuring sensor, which not only transmits the light intensity, but also the elevation and azimuth to the room automation devices, depending on room occupation the lighting, solar protection and, where available, also antiglare systems are moved into the optimum position. The solar protection system also minimises external heat gain or, in winter, serves to enable solar energy to be used for room heating.

The following take place via the bus interface
– individual, group and zone control of the individual rooms,
– energy requirement signalling to energy production and distribution systems,
– individual use with the start-up and service software,
– individual adaptation to changing room conditions and
– access to every information point of the connected regulation and control devices.

Local operation is via room controls. Programmable are functions such as, for example:
– remote control and display via LonMark on LON bus,
– manual recording of room use via room controls, or automatically via presence recorders
– recording of variables, e.g. by way of window contacts (energy block),
– regulation of the room temperature in heating and/or cooling operation and air exchange (comfort operation),
– reducing or increasing the room temperature when not in use (stand-by operation)

– individual allocation of timer programs,
– if necessary integration of all room functions including the combination of heating, ventilation, and climate control regulation with lighting and solar protection
– rapid warming or cooling,
– free night cooling,
– morning purging,
– summer/winter compensation.

RECORDING CONSUMPTION AND ENERGY MONITORING

In order to be able to monitor the ambitious targets of optimised building operation, the Sparkasse Hagen has decided to use remote-readable metering devices and to commission EGS-plan with monitoring the energy for two years.

In addition to the advantage of allowing easy-to-understand running cost accounting with the tenants through extensive measurements and meter data, the measurements recorded by the central building control system are to be evaluated in collaboration with all those involved and used for further optimisation of installation operation and energy use. In this way both the operator and user can see the sustainability of the planning and optimisations.

Of course, the optimisation phase assumes the collaboration of users and operators. But caution is required as measures not accepted by the users will rapidly lead to dissatisfaction with the building. Eagerly awaited therefore is the first building data which after the introductory phase of the extensive building control systems should provide information about the achieved level of economic viability and user comfort.

Facts and technical data

Heating:
2 gas condensing boilers each with approx. 790 kW modulating, distributed to 20 heating circuits

Cooling:
3 cooling machines as screw-type compressor each with 438 kW cooling output at 139 kW compressor output distributed to 26 cooling circuits including 3 pipe system

Sprinkler system:
CEA/VdS-tested sprinkler system with side wall sprinklers as wide-angle nozzles in the offices, umbrella sprinklers and mist sprinklers in the other areas, pump output 90 kW.

Argon gas extinguishing systems:
For the archives, server rooms, back-up rooms, central distribution rooms data-processing with automatic fire alarm system and a fire early detection system.

Sanitary installations:
Fountains for the customer foyer, greenery in the atrium and entrance, sanitary fittings in various qualities.
2 fat separators

Ventilation and air-conditioning:
12 ventilation control systems with fresh air supply and outgoing air of 6000 m^3/h to 45,000 m^3/h with heat recovery and smoke extraction function
2 fat separators for the gastronomy areas and canteen
Garage CO- and smoke extraction system
Jet ventilators for garage smoke extraction and CO control

High voltage electricity
2 transformers 10 kV/400V each with 1000 kVA for bank operation
1 transformer 10 kV/400V with 1000 kVA for tenants
1 mains back-up system 700 kVA
1 no-break power supply system 240 kVA
2 no-break power supply systems 11 kVA
2 no-break power supply systems 7 kVA
2 no-break power supply systems 5 kVA
4 low-voltage main distribution frames (2 secure supply, 1 normal mains supply, 1 tenants' supply)
Security lighting system 35 kVA wit 15 sub-stations in function preservation
50 differently equipped sub-distribution frames

Telecommunications and IT installations:
DP network FTTO with mini-switches in the offices, designed completely as an optical fibre network
ISDN telephone system with 400 users
Camera system in accordance with accident prevention guidelines
Break-in alarm system partly class “C” with certificate
Fire alarm system with push button alarms, optical smoke alarms, smoke extraction systems
Venting installation
Access monitoring system with time recording
Emergency exit controls
Security cell DP certified in accordance with ECBS (European Certification Board Security Systems), quality class R60D; type-tested in accordance with EN 1047-2

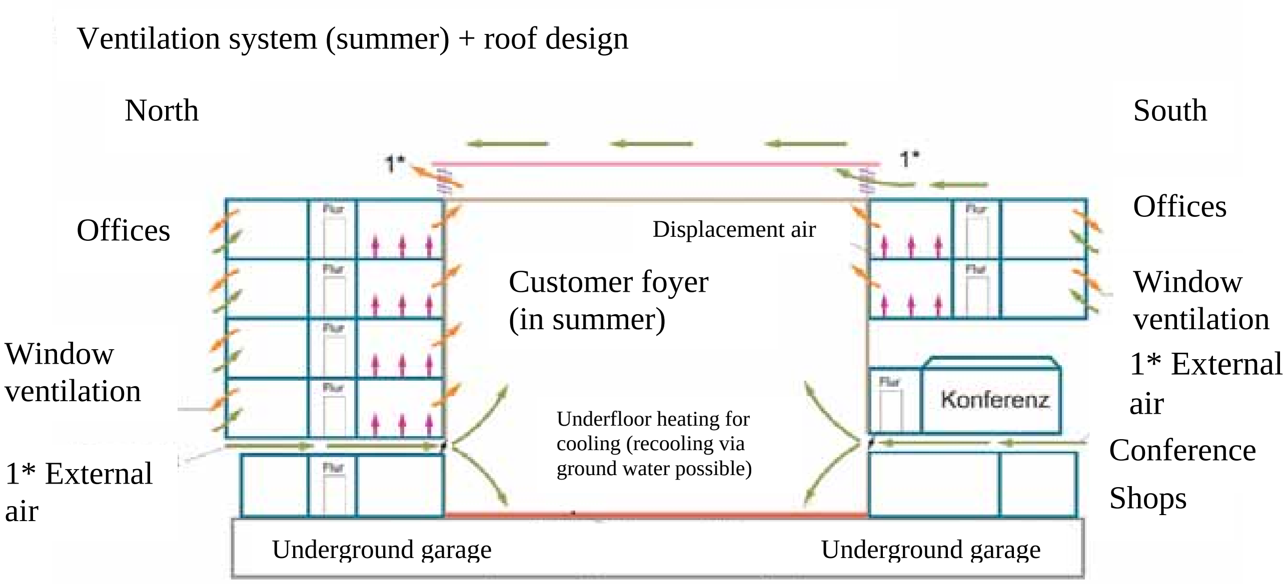
Media technology:
PA systems, including amplifiers, mixing panels, loudspeakers
Stage lighting systems
Plasma screens
Interactive information points (Infopoints)
Screens
Projection systems with uplighting and rear projection systems
Movable ceiling stands
Light rails
Light scanners
Control systems
AV cupboard
Transportable camera system
Training system
Conference system
Touch screen
Monitors

Software

Measuring, control and regulation systems, central building control:
Control system with 2 servers, ODBC interface to other systems
2 operating stations
1 touch screen at atrium reception
Individual room control systems LON
9 information centres
approx 12,000 data points hardware
Weather station
Consumption data recording via LON

1 New building Sparkasse Hagen

2 Large customer foyer with “functional roof”



1* Shutter control of the external air and outgoing air via the roof façade depending on the temperature, CO2 volume in the customer foyer, wind speed and wind direction

3 Ventilation

SUMMARY

Novi Sad is capital administrative center of the Province Vojvodina, one of two towns with active oil refinery crossroad of transit traffic artery and until recently – great industrial town! In this paper are presented data of imission for basic pollutant matters in the air of the town, microclimate and health condition of children and adult population according to permanent reports of health services for preschool, schoolchildren and physician in primary health care (general population) for the period 2002-2005. Climate changes (increased temperature, relative humidity change in the air etc.), then endangered urban air quality, have influenced the increase of specific morbidity from respiratory diseases in vulnerable population categories. Results of the paper indicate to monitoring set up towards specific pollutants followed by bio-indicator analysis. In further period, multidisciplinary studies can enable to become a part of some European project of environmental effect analysis to population health.

INTRODUCTION

Climate change is a new and rapidly developing topic of scientific inquiry and health risk assessment [1]. Anthropogenic **climate** change signifies that for the first time the aggregate **global** impact of humankind exceeds the physical and ecological limits of the biosphere [2]. The potential consequences of this and other **global** changes (including stratospheric ozone depletion, loss of biodiversity, worldwide land degradation, and depletion of aquifers) are wide ranging [1,3,4].

The aggregate environmental impact of humanity has begun to change some of the earth's great biophysical systems. Such human-induced systemic environmental change is unprecedented. Some health effect are related to climatic and weather variability, while others are connected to climatic changes [5,6,7]. Changes in frequency of temperature extremes and stagnation periods increase episodes of thermal stress and air pollution.

There has been a clear worldwide warming trend. Global temperatures have increased by amount 0.6 ^{o}C in the last 100 years. In Europe the warming trend is slightly greater, 0.8 ^{o}C [3,7]. Increases in minimum temperatures have been far than changes in maximum temperatures, and the observed temperature rise has been the most marked during the winter period [3,7].

The effects of climate change go beyond the gradual spread of disease [8,9]. Extreme events such as floods, droughts and heat waves are likely to increase under global warming and will challenge our ability to manage health risks and test the resilience of our infrastructures in many areas, including health service delivery. In 2003, Europe experienced summer temperatures that were unprecedented in the instrumental record. In France, over 14 000 more deaths were reported during the August heat wave than were typical for that time of year, and the total for Europe was in the region of 20 000. In Paris, the number of deaths increased by 140% over usual figures. The modest climate change that occurred between the mid-1970s and the year 2000 is estimated to have caused the annual loss of over 150 000 lives and 5 500 000 disability-adjusted life-years" [9,10].

Exposure to ambient air pollution has been linked to a number of different health outcomes, starting from modest transient changes in the respiratory tract and impaired pulmonary function, continuing to restricted activity/reducing performance, emergency room visits and hospital admissions and to mortality [4].

For the first time in history, the economic activity of the human population has become so vast that it is beginning to change the gaseous composition of the lower and middle atmospheres. This is now called human induced global climate change (HIGCC), which in turn will have a significant impact on a future generation of children [11]. Why the children have at high risk? Because: Children breathe more per unit body weight than adults; have smaller airways and lings; has a different rate of toxification and detoxification; time spent outdoors; increased ventilation with play and exercise; high prevalence of asthma and other diseases; high ruts of acute respiratory infections [4].

Which population groups are at high risk, also? Undoubtedly the elderly people, with cardio respiratory disease. When compared with healthy people, those with respiratory disorders (such as asthma or chronic bronchitis) may react more strongly to a given exposure, either as a results of increased responsiveness to a specific dose and/or as a results of a larger internal dose of some pollutants than in normal individuals exposed to the same concentration. Increased particle deposition and retention have been demonstrated in the airways of people suffering from obstructive lung disease [4,11-13].

Ussually, the air pollution problems are associated with oil and heating oil furnaces, industrial facilities with dirty technologies and motor vehiclecs [3,4,14-17].

METHODS

Since 1967 Institute of Public Health, Novi Sad - Department of Hygiene and Environmental protection follows-up everyday presence of basic and some specific pollutant matters in the outdoor air of the city. Air sediments, are continually followed during 30 days/12 months at 20 localities in the city, accordingly to our legal regulations and recommendations [17,18].

Data on the number of diseased from respiratory infections at adults, registered in the General practice of Health Center, preschool and school children at regarding Dispensaries, are acquired from the Department of Social Medicine, Institute of Public Health, Novi Sad. Climate data (2002 -2005) are acquired from the Meteorological Center - Novi Sad. [17,18].

Statistical data processing is performed with SPSS for Windows, graph presentation with Harvard & Graphics program and the whole text - in text processor Microsoft Word for

Windows. In the paper are applied descriptive statistic parameters: mean value, standard deviation (SD), minimum and maximal values, variation coefficient (CV).

RESULTS

Air-sediment is analyzed in the period 1989-2005 at 20 localities in Novi Sad (Figure 1a), and in details for the period 2002-2005. The highest average monthly values are registered in May and June (within recommended values) for each investigation year. Maximal value of total aero-sediment quantity was: in 2002 – 1332.9 mg/m^2/day in May (mean annual value: 158.8; C_{98} 500; SD 135.1; CV 85.09); in 2003 – 874.41 mg/m^2/day in June (mean annual value:174.8; C_{98} 710; SD 147.4; CV 84.34); in 2004 - 1567 mg/m^2/day (mean annual value: 169.5; C_{98} 541.1; SD 154.52; CV 91.15) in June and in 2005 – 778.7 mg/m^2/day in May (mean annual value: 778.7; C_{98} 452.9; SD 110.29; CV 69.61). According to localities, values above recommended values are registered in the parts of the town with the greatest building activity.

The lowest pH is determined in February 2003 (2.6), and then in 2005 (3.0), also determined in the winter period. Survey of the average annual values pH is presented in the Figure 1b. Although our regulations do not have limited concentrations for calcium, sulfate, chloride and nitrate in air-sediment, we still present them in order to have general view of the air quality (Figure 1c). These results are presented to enable the view of “acid rains” in this territory.

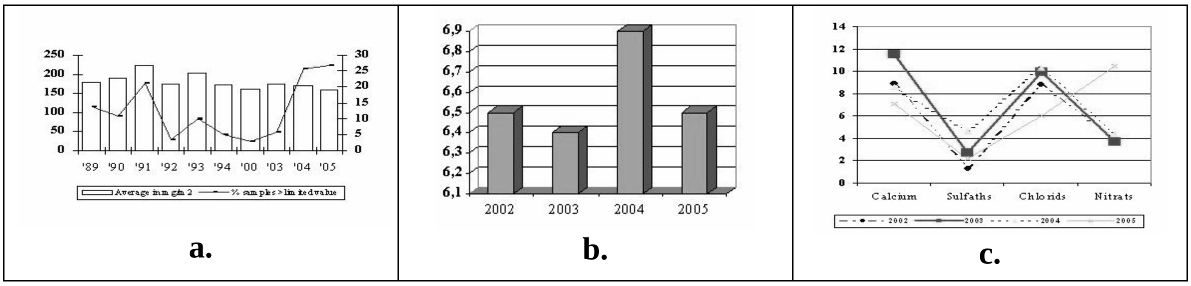

Figure 1. a) Average Concentration of air-sedimentation in the capital town of Vojvodina, Novi Sad, in the period 1989 -2005, b) Outdoor pH in the city of Novi Sad in the period 2002 - 2005, c) Content of calcium, sulphates, chlorides and nitrates in the air-sediments, in the period 2002-2005 (mg/m^2/day).

In Figures 2a, 2b, 2c and 2d are presented climate parameters: temperature, relative humidity, atmospheric pressure and air circulation velocity by localities during the period 2002-2005 [17,18]. Volume of temperature peaks ranged in this sequence: in 2002 from – 11.6 to 30.4^{0}C; in 2003 from –15.7 to 31^{0}C: in 2004 from – 8.8 to 28.1^{0}C; in 2005 from –2.0 to 36.2^{0}C. Increase of daily maximal temperatures is evident (from 28.1 to 36.2^{0}C) as well as change in minimal temperatures (from –15.7 to –2.8 ^{0}C). Average air circulation velocity ranged from 2.6 to 2.2 m/s, while minimal air humidity ranged from 5.9 to 7.1 %. Atmospheric pressure was standard for city area in investigated period (from 1006 to 1008 mbar).

Specific morbidity from respiratory diseases at pre-school and schoolchildren and adult population in Novi Sad is presented in Figures 3a, 3b and 3c. The following registered diseases are analyzed (2001-2005): Pneumonia (N^o 169; numbers* from: Int. diseases clasif.-10, Federal Institute of Public Health, Savremena administracija, Belgrade; 1996), *Bronchitis acuta et bronchiolitis acuta* (N^0 170*), other diseases in upper part of breathing system (N^{0}174*), *Tracheitis ac., Emphysema* and other obstructive lung diseases (N^{0}175*) as well as

Asthma bronchiale ($N^0$176*), which is base on medical documentation (routine evidence and reports of health services for health care of preschool and school children as well as General medicine service). There is evident increasing number of the following diseases: *Bronchitis ac. et bronchiolitis ac.* (N^0 170*); *Tracheitis ac., Emphysema* and other obstructive lung diseases ($N^0$175*) during analyzed period at all three population categories, which can be in correlation to urban air quality and climate changes.

DISCUSSION

Air pollution in urban areas is a major concern for environmental health in Europe, especially the effects of particulates [19-22]. The dissemination and concentration of air pollutants (both particles and gases) depend on the prevailing weather conditions air current, temperature variation, humidity and precipitation. Large, slowly moving anticyclones may cover an area for several days, are a week or more, and give rise to conditions that readily allow pollutants to accumulate. Predicting the impact of climate change an average local air pollution concentration is therefore very difficult.

Exposure to thermal extremes cause direct: altered rates of heat and cold - related illness and death; as An altered frequency and/or intensity of other extreme weather events cause direct: deaths, injuries, mental disorders, damage to public health infrastructure [12].

Several recent studies have observed that elderly people are especially vulnerable to heat-related illness [21]. By the year, 2025 the population of adults aged ≥ 60 years will increase by 37 million (50%) [22]. The population vulnerable to thermal stress will therefore increase, and climate change will represent an additional burden on this population. Meta-analyses by Martens [23,24] estimated that an increase in global temperature of 1^{o}C could reduce winter cardiovascular mortality in Europe.

Climate change effects on population health will reflect the conditions of the ecological and social environments in which humans live. Projections on future climate change in Europe are derivate from global climate model experiments [24,25]. An overall increase in average annual temperatures is projected, and thus increase is likely to be greater in high latitudes than in mid-latitude Europe. Summer temperatures will increase more than winter temperatures. In general, continental regions may become dryer while maritime regions may become wetter.

Air pollution (AP) is associated with increased upper and lower respiratory symptoms in children; may increase bronchitis and cough and aggravate asthma symptoms; it is uncertain whether current levels of ambient AP (traffic - generated air pollution) contribute to cancer development in children. Does air pollution influence the development of the lung? Studies of lung in children suggest that: living in areas of high air pollution is associated with lower lung function; long-term air pollution is associated with lower rates of lung function development.

Particulate matter and acid aerosols seem to be the main agents of acute effects all-cause mortality in European cities [26]. In most epidemiological studies on air pollution effects, temperature is treated as a confounder. There is some evidence of a physiological synergistic effect between high temperatures and pollutants [2,4,7, 9-13].

The regional "negative" effect of sulfate aerosols in central Europe could offset some of the time-dependent 'positive' effect of carbon dioxide on climate warming [26,27]. The local effects of aerosols on precipitation patterns are also highly uncertain [27-29].

Our previous investigations indicated to correlation of respiratory and malignant diseases not only in Novi Sad but also in the widen area of AP Vojvodina and the country as well. Influence of basic pollutant matters originating from the communal air ambient (sooth, SO_2, NOx) and correlation with some microclimate parameters (temperature, velocity and relative air humidity) gave positive association [14,16,17,27-29].

ACKNOWLEDGEMENT

The author is grateful to all colleagues participating in all phases of project activity, which is partially financed by Novi Sad municipality – Department for environment protection.

SUMMARY

Near-extreme solar irradiance, ambient dry-bulb and wet-bulb temperatures are fundamental data for determining the peak building cooling load. Design solar irradiance has been separately and independently selected by both ASHRAE and CIBSE. This may result in over-estimated cooling loads, and in turn over-sized air-conditioning systems. Hence, a statistic method based on probability theory and heat transfer principles was developed for rational selection of the three coincident design weather data used for calculating peak cooling loads in a building with thermal lag less than one hour. The new method was applied to historic weather records of 25 years in Hong Kong to rationally generate design weather data. These data were compared with those produced by the traditional method. Results show that traditional design solar irradiance, dry-bulb and wet-bulb temperatures may be significantly overestimated when a room or building faces east, south and west. Generating sequences of three coincident weather variables for heavy buildings is also discussed.

INTRODUCTION

Near-extreme weather conditions, including dry-bulb temperature, moisture content and solar irradiation, are essential and fundamental data for the design of building air-conditioning systems [1,2]. They simultaneously act on a building, and are driving potentials of heat transfer though building envelope and direct mass exchange by infiltration and ventilation. Near-extreme coincident design weather conditions are required in determining the peak cooling load for sizing air-conditioning systems [1,2]. Improper design weather conditions may lead to oversized or undersized HVAC system, which will result in unnecessary extra capital cost and low part-load efficiency or frequent failures in providing sufficient cooling. Even a small difference in the design temperature and solar irradiance may have significant economic implications. Hence, coincident solar irradiation, dry-bulb and wet-bulb temperatures should be properly selected.

Engineering design involves a trade-off between maximizing system reliability and minimizing cost [3]. The probability of failure in meeting the required load is expressed as the ratio of the number of hours that the capacity would fail to meet the load to the total operating hours. This probability is call as risk factor here, which is the complement to the system reliability, and equals the difference of one subtracted by the system reliability. It is highly desirable that the design method and the associated design data can help optimize this trade-off. Several professional institutes have revised their design guidelines to incorporate probabilistic design concepts or reliability into design. For instance, the American institute of

Steel Construction Load and Resistance Factor Design specifications and the European and Canadian structural design specifications have been revised [3].

Many researchers have made valuable contributions to the development of weather design conditions in the past decades. ASHRAE has launched a number of research projects, such as ASHRAE RP-754 [4], RP-828 [5], RP-890 [6], and RP-1171 [7]. These ASHRAE research project were aimed at providing, improving and rationalizing the fundamental weather data for HVAC system design.

Thom [8] developed a statistical method for proper selection of outdoor design dry bulb temperatures in winter for heating system sizing. The method took into account the probability that the system could fail to meet the actual load. He found five design dry bulb temperatures with different cumulative probabilities. HVAC engineers may select reasonable design temperatures, based on their experience, for various types of buildings to properly size the system to match the capacity reliability required. Holladay [9] analyzed design weather data from three sources: Summer Weather Data 2.5 percent, the Guide 2.5 percent and Common Use. He found that large differences existed among these data for some locations. He developed a simple weighted average equation for determining the design dry bulb temperature.

Colliver et al [4] statistically determined near-extreme dew-point temperatures and mean coincident dry-bulb temperatures using a 30-year set of hourly weather data from 239 US and 143 Canadian locations. They found that humidity ratios computed from the design extreme dew-point temperature and mean coincident dry bulb temperature is greater, on average, than those from the design extreme dry bulb temperature and mean coincident wet bulb temperature. Colliver et al. [5] further developed criteria and procedures for statistical analysis of weather data and generated sequences of near-extreme weather records for four design parameters. The four parameters are high and low dry-bulb temperature, high dew-point temperature, high enthalpy level, and low wet-bulb depression. They determined four different extreme sequences for each parameter for the 0.4%, 1.0% and 2.0% annual frequencies of occurrence. Colliver et al [6] also analyzed historical weather data to produce annual frequency-of-occurrence design dry-bulb, wet-bulb, and dew-point temperatures with mean coincident values at the design conditions. Their analysis showed that the design dew-point directly derived from coincident dry-bulb and dew-point temperatures had a much higher humidity than that generated from coincident dry-bulb and wet-bulb design conditions.

Mason and Kingston [10] indicated that the use of separately selected coincident dry-bulb and wet-bulb design temperatures would lead to computed cooling loads much higher than actual loads. ASHRAE [1] and CIBSE [2] presented two forms of coincident design dry-bulb and wet-bulb temperatures; one is the dry-bulb temperature at a certain cumulative frequency of occurrence associated with the mean coincident wet-bulb temperature; and the other is the wet-bulb temperature at a certain cumulative frequency of occurrence associated with the mean coincident dry bulb temperature. These coincident design weather data are well applicable to systems the thermal time constant of which is less than one hour [5].

Chen et al [11] pointed out that the dry-bulb temperature at a certain percentile of occurrence together with the mean coincident wet-bulb temperature may not indicate the frequency of occurrence of the cooling load. This is because the defined percentile may not equal the real probability of occurrence of coincident dry-bulb and wet-bulb temperatures. Hence, they developed a statistical method for rational selection of coincident design dry-bulb and wet-bulb temperatures. These design weather conditions allow engineers to do risk-based air-conditioning design when the effect of solar irradiation on the peak cooling load is negligible. Their study shows that the rationally derived coincident dry-bulb and wet-bulb temperatures could be largely different from the traditional ones.

Generally, solar irradiation should have a significant contribution to building cooling loads, especially for passive or active solar cooling buildings [12]. From the above literature review, however, it can be seen that less attentions have been paid to the design solar irradiance. The current design solar irradiance data do not simultaneously occur with the coincident dry-bulb and wet-bulb temperatures for air-conditioning system design. Therefore, this study is first aimed at developing a method for rational selection of coincident solar irradiation, dry-bulb and wet-bulb temperatures. The second objective is to apply this novel method to historical hourly weather data observed in Hong Kong to generate the coincident design weather conditions. These selected design weather data can be used to design an air conditioning system that can match system reliability desired for a building with thermal time constant less than one hour.

THEORETICAL METHOD

For a building or room whose thermal lag is less than 1 hour, hourly cooling load $Q(k)$ may be expressed by [1]

$$Q(k) = \sum_{j=1}^{n} (UA)_j (t_e(k) - t_{rc}) + m_o c_{pa} (t_{db}(k) - t_{rc}) + m_o h_l (W_o(k) - W_{rc})$$
$$+ A_{wd} (IAC) [SHGC(\theta(k)) E_D(k) + < SHGC >_D \; E_{dt}(k)] \qquad (1)$$

where n is the number of external envelopes; k is discrete time, hr; A_{wd} is window area, m^2; A is the area of external envelope components of a building or room, m^2; h_l is air latent heat, 2430×10^3 J/kg; c_{pa} is the sensible specific heat capacity of air, 1010 J/(kg °C); E_D is direct irradiance, W/m^2. E_d is diffuse sky irradiance, W/m^2; E_{dt} is diffuse irradiance, $E_{dt} = E_d + E_r$, where E_r is ground-reflected irradiance， W/m^2; E_t is total solar irradiation incident, W/m^2; *IAC* is inside shading attenuation coefficient; *SHGC* is direct solar heat gain coefficient as a function of incident angle θ; $<SHGC>_D$ is diffuse solar heat gain coefficient; t_{rc} is presumed constant room air temperature, °C; U is the overall heat transfer coefficient of walls, roofs or windows W/(m^2·K); m_o is outdoor air mass flow rate introduced into room, kg/s; W_o is outdoor air humidity ratio, kg/kg; W_{rc} is presumed constant room air humidity ratio, kg/kg; θ is incident angle, °; n is the total number of external envelope components of a building or room; t_e is sol-air temperature, °C and its calculation may be referred elsewhere [1]. In the small range of near extreme weather conditions, outside air humidity ratio may be approximately expressed by $W_o(k) = w_1\, t_{wb}(k) + w_0$, where w_o and w_1 are constants; t_{wb} is outdoor air wet-bulb temperature, °C.

The number of building characteristic parameters in Equation (1) may be reduced by the following methods. Figure 1 shows how the diffuse solar gain coefficient $<SHGC>_D$ varies with *SHGC*(0) in the normal direction for all glazing and window systems listed in ASHRAE Handbook [1]. It can be seen from Figure 1 that $<SHGC>_D$ is approximately equal to *SHGC*(0) since their relation can be expressed by

$$< SHGC >_D = SHGC(0) - 0.063 \approx SHGC(0) \qquad (2)$$

SHGC ratio is defined by

$$r_{SHGC}(\theta) = \frac{SHGC(\theta)}{SHGC(0)} \qquad (3)$$

which is the ratio of *SHGC* at any incident angle to *SHGC*(0) at the normal angle. Analysis of all the glazing and window systems listed in ASHRAE Handbook [1] shows that *SHGC* ratios vary similarly at most of the incident angles with the upper and lower limits. Therefore, all the glazing or window systems listed in ASHRAE Handbook [1] are classified into three classes: I, II and III based on the ratio of $SHGC(\theta)$ to *SHGC*(0). Table 1 shows the average SHGC ratio values at different solar incident angles.

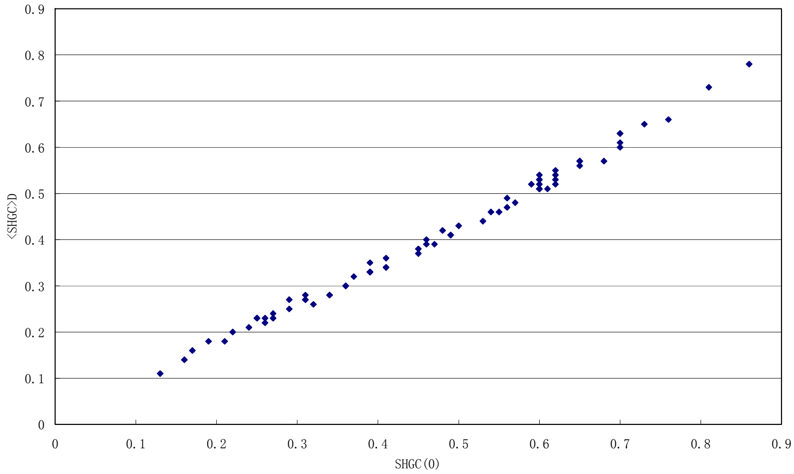

Figure 1 Relation between $< SHGC >_D$ and $SHGC(0)$ of glazing

Table 1 SHGC ratio values at different solar incident angles

Glazing classes	$r_{SHGC}(\theta)$					
	Normal	40°	50°	60°	70°	80°
I	1.0	0.980	0.940	0.920	0.80	0.50
II	1.0	0.955	0.900	0.855	0.70	0.40
III	1.0	0.920	0.860	0.785	0.60	0.30

Application of the above simplifications to Equation (1) yields

$$Q(k) = [\sum_{j=1}^{n}(UA)_j + m_o c_{pa}]t_{db}(k) + m_o h_l w_1 t_{wb}(k) + \frac{\alpha}{h_o}\sum_{j=1}^{n_w}(UA)_j E_t(k)$$
$$+ A_{wd}\,(IAC)\,SHGC(0)\,[r_{SHGC}(\theta(k))E_D(k) + E_{dt}(k)] + C_o \qquad (4)$$

where

$$C_o = m_o h_l w_o - \left[\sum_{j=1}^{n}(UA)_j + m_o c_{pa}\right] t_{rc} - m_o h_l W_{rc} - \sum_{j=1}^{n_{rf}}(UA)_j \frac{\varepsilon \Delta R}{h_o} \qquad (5)$$

where n_w is the number of building opaque envelopes and n_{rf} is the number of roof types; t_{db} is outdoor air dry-bulb temperature, °C; h_o is heat transfer coefficient by long-wave irradiation and convection at outer surface, which is equal to 17 W/(m^2 °C); ΔR is difference between long-wave irradiation incident on surface from sky and surroundings and irradiation emitted by blackbody at outdoor air temperature, W/m^2; $\varepsilon\Delta R/h_o$ = 4 for horizontal surface, =0 for vertical surface; α and ε are the absorptivity and emissivity of the exterior surface of building opaque envelope, respectively.

C_o in Equation (5) is constant when building design and required indoor air conditions are known. It does not impact the selection of design weather data, and hence will not be considered in the statistical analysis of weather data. Only those terms associated with solar irradiance, dry-bulb or wet-bulb temperature will be analyzed. They can be combined into a single index, which may be called as equivalent weather temperature. Neglecting the constant term and rearranging Equation 6 yields

$$T_e(k) = t_{db}(k) + at_{wb}(k) + bE_t(k) + c[r_{SHGC}(\theta(k))E_D(k) + E_{dt}(k)] \qquad (6)$$

with

$$a = \frac{m_o h_l w_1}{\sum_{j=1}^{n}(UA)_j + m_o c_{pa}} \quad , \quad b = \frac{\alpha}{h_o}\frac{\sum_{j=1}^{n_w}(UA)_j}{\sum_{j=1}^{n}(UA)_j + m_o c_{pa}} \quad , \quad c = \frac{A_{wd}(IAC)\,SHGC(0)}{\sum_{j=1}^{n}(UA)_j + m_o c_{pa}} \qquad (7)$$

Coefficients *a*, *b* and *c* in Equation (6) are constant for a given building or room. It can be easily observed from Equations (7) that these coefficients only depend on building design parameters and some constants. Therefore, they reflect the thermal characteristics of buildings, and describe the effect of wet-bulb temperature and global solar irradiance incident on opaque and transparent envelope on cooling loads, respectively. In addition to the three weather variables, the *SHGC* ratio and $r_{SHGC}(\theta(k))$ in Equation (6) also varies with time. Nevertheless, the annual distributions of the *SHGC* ratio are fixed for a building or room with one external envelope in a given orientation. Thus, the selection of coincident weather conditions should only depend on the building characteristic parameters, *a*, *b* and *c* as well as glazing types, and the required capacity reliability for a building or room with one external envelope in a given orientation.

NEW DESIGN WEATHER CONDITIONS

Air-conditioning system design should aim to optimize system reliability and cost. Coincident design weather data to be selected should allow engineers to design an air-conditioning system that can satisfy the target system reliability or risk. Examination of Equations (4) to (6) indicates that the variation of cooling loads is proportional to the equivalent weather temperature. This means that the percentile of coincident solar irradiance, and dry-bulb and wet-bulb temperatures should be equal to the capacity risk of air-conditioning systems designed with the corresponding weather data.

The Hong Kong Observatory observes dry-bulb and web-bulb temperatures, horizontal global solar irradiance as well as other weather parameters hourly at latitude 22º18 ʹN and longitude 114º10 ʹN [13]. The hourly weather records of 25 years from January 1979 to December 2003 were used for statistic analysis of the peak cooling loads of different buildings. The hourly horizontal global irradiance was first decomposed into direct and diffuse irradiance using the formula given by Lam and Li [14]. The horizontal irradiance can then be converted to the vertical surfaces in eight orientations: north (N), northeast (NE), east (E), southeast (SE), south (S), southwest (SW), west (W) and northwest (NW), using the method given in ASHARE Handbook [1].

Building characteristics largely impacts the selection of design weather data. It can be fully described by the three building characteristic parameters *a*, *b* and *c*, as well as glazing type. In addition to these three parameters, three classes of glazing are also taken into account. However, no windows were considered on the roof at this stage.

Table 2 shows a sample of coincident design weather data for buildings with the same building characteristic parameters *a* (0.60), *b* (0.03) and *c* (1.00), and glazing class III for the percentile or risk factor of 1.0. The combination of different coincident weather conditions may result in the same cooling loads [11]. In the other words, there are many equal cooling loads occurring at different weather conditions, month, day and time. The design conditions given in Table 2 represent the statistic center of them, which means most of the equal cooling loads occur in or around the design conditions shown in Table 3. Note that the 21st of each month can be used as the design day on which the peak cooling load is calculated, following the ASHRAE method [1].

Table 2 Coincident design weather data derived by the new method for Hong Kong

	Glazing class = III, *a* = 0.60, *b* = 0.03, *c* = 1.0, Risk factor = 1.0%								
Orientations	N	NE	E	SE	S	SW	W	NW	H
Equivalent temperature (°C)	215	324	444	531	589	675	667	501	72
Dry bulb temperature (°C)	29.9	29.4	25.3	20.5	20.6	22.5	28.9	29.8	31.3
Wet bulb temperature (°C)	25.9	25.8	21.3	15.5	15.1	17.4	24.3	25.4	26.4
Beam irradiance (W/m^2)	28	158	244	322	388	466	457	327	828*
Diffusion irradiance (W/m^2)	155	166	185	203	205	194	181	160	
Month	6	7	10	12	12	11	7	5	7
Hour	15	11	10	11	12	15	16	16	13

Table 3 shows coincident horizontal design solar irradiance, and dry-bulb and wet-bulb temperatures generated by the traditional and new methods for the percentile or risk factor of 0.4 and 2.0. The building characteristic parameters *a*, *b* and *c* that were used for generating Table 3 are respectively equal to 1.0, 0.03 and 1.0, and window glazing was class III. It can be seen that the rational design solar irradiance decreases with the increase of risk factor on the horizontal surface. The design solar irradiance is kept constant for all the risk factors because the traditional calculation of design solar irradiance does not depend on both the risk factor and the other weather parameters. Difference between the traditional and rational design solar irradiances is negligible at the percentile of 0.4, but about 19.5% at the percentile of 2. Difference between the traditional and rational design dry-bulb temperature is about 1.5 °C and the wet-bulb temperature 0.6 to 0.8 ºC.

Table 3 Comparison of traditional and new design weather data on horizontal surface

Risk factor	0.4%			2.0%		
Glazing class III *a*=1.0, *b*=0.03, *c*=1.0	Dry temp	Wet temp	Solar irradiance	Dry temp.	Wet temp.	Solar irradiance
Traditional	33.0	27.1	907	32.2	26.8	907
Rational	31.5	26.5	895	30.6	26.0	759

Table 4 shows the coincident design dry-bulb and wet-bulb temperatures generated by the two methods for a building with a = 0.60, b = 0.03, c = 1.00, glazing class III and risk factor = 1.0%. These design weather data are used for calculating the peak cooling load through vertical building envelopes in different orientations. The 'Month' shown in the table means that in the indicated month, the peak cooling load occurs for that vertical envelope in the given orientation. Careful examination of Table 4 shows that all the traditional design dry-bulb and wet-bulb temperatures are overestimated as compared to the rationally derived design temperatures. Difference between the dry-bulb and wet-bulb design temperatures generated by the two methods is generally very large for the vertical envelope in most of the orientations, especially in the east, southeast, south, southwest and west. The traditional design dry-bulb and wet-bulb temperatures could be more than 6 ºC higher than the two rationally derived design weather temperatures.

Table 4 Comparisons of traditional and new design dry-bulb and wet-bulb temperatures

Orient.	Month for Peak Load	Traditional		Rational	
		Dry temp.	Wet temp.	Dry temp.	Wet temp.
N	6	32.1	26.7	29.9	25.9
NE	7	32.6	26.9	29.4	25.8
E	10	29.9	24.8	25.3	21.3
SE	12	24.0	20.4	20.5	15.5
S	12	24.0	20.4	20.6	15.1
SW	11	27.0	22.1	22.5	17.4
W	7	32.6	26.9	28.9	24.3
NW	5	30.8	26.0	29.8	25.4

Note: a = 0.60, b = 0.03, c = 1.00, glazing class III and risk factor = 1.0%

DISCUSSION

New near-extreme coincident design solar irradiance, dry-bulb and wet-bulb temperatures have been generated using the novel method given in the second section. It can be seen from the model described by Equations (1) to (7) that the annual percentile of coincident design weather data is now statistically equal to the capacity risk factor of air-conditioning systems designed with the corresponding design weather conditions. This allows engineers to design air-conditioning systems that match the target system reliability probably required by the client. In the other words, the use of these outdoor design weather data will result in consistent sizing air-conditioning systems in different conditions.

Comparison between the traditional and rational design weather data shows that all the traditional data are higher than the rational ones. These differences are significant in many cases, especially when a room or building faces east, southeast, south, southwest and west. The current design solar irradiance could be more than 19% higher than the rational value. The current design coincident dry-bulb and wet-bulb temperatures could be more than 6 ºC higher as compared to the newly generated design dry-bulb and wet-bulb temperatures. This will significantly impact the peak latent as well as sensible cooling load.

The new method can also tell us when the peak cooling load occurs, and hence HVAC engineers can avoid calculating 24 hour cooling loads on one design day in each month of the year. This significantly simplifies the design cooling load calculation.

Although the new design weather data can be used only for direct determining the peak cooling load in a building with a thermal lag less than one hour, the new method provides a basis for the further generating coincident design weather data for any buildings.

Based on the principle of the new rational method, all the independent heat sources may be described with the discrete Fourier series [15]. Cooling load, Q_{cl}, due to these sources can be computed by

$$Q_{cl} = \sum_{i=1}^{4} \sum_{n=-N}^{N} H_i(j\omega_n) u_{n,i}(j\omega_n) \exp(j\omega_n t) \qquad (8)$$

where H_i is Fourier transfer function with respect to any heat source, $u(j\omega_n)$ is the coefficient for each harmonic (ω_n), t is time, n is the harmonic number, and $j = \sqrt{(-1)}$. The amplitude and phase angle of the complex transfer function represent the heat transfer level and thermal lag of building envelopes. Like building characteristic parameters a, b and c in Equation (7), the amplitude and phase angle of transfer functions fully represent the physical characteristics of medium and heavy buildings. Therefore, the selection of sequences of three coincident design weather variables fully depends on these parameters. Similar to Table 2, sequences of the design weather data can be uniquely determined by glazing type, building characteristic parameters, and desired risk factor.

SUMMARY

Sitsang belongs to cold Region in china and heating energy consumption in winter is very large. There is fairly scarce petrochemical energy, and that the oxygen content in plateau section is lower, which makes combustion become insufficient, so the cost of conventional energy is considerably high. However, compared with other regions in china, the best advantage of Sitsang is that it possesses abundant solar energy resources. According to climate conditions and energy resources in Sitsang, the paper studied passive solar houses heating system using EnergyPlus software, which is capable of rapid and detailed analysis of energy consumption in buildings, and analyzed carefully such influencing factors as architecture plan layout, the thermal resistance of envelope, the window shading coefficient, area ratio of windows and walls and indoor heat mass. Sufficiently considering the heat gain, heat loss and heat storage, the paper presented the optimum design proposal. The analysis on annual energy consumption and indoor thermal environments is performed. The results showed that when the structure was composed of well thermal insulation materials the solar energy can completely satisfy the heating demand in winter in Sitsang.
Key words: solar building; passive solar heating; sustainable energy

INTRODUCTION

Current situation of energy sources in Sitang

In Sitang, petrifaction energy used in building heating are mostly transported from other areas, so the cost of energy sources is very high. The local resident of rural heat mainly though sapless grass and dried cow-dung and the local resident of urban heat though different ways on the basis of the local circumstance. For example, the north of Sitang(Nangqen) is close to Qinghai and the cost of transporting coal is lower, so the boiler of burning coal for heating is adopted in Nangqen. In other areas, since environmental protect and the higher cost of transporting coal, the boiler of burning coal is restricted. The Sitang area processes pipe laying, petroleum is used for heating. However, the lower content of oxygen in plateau area leads to combustion insufficient, which reduces the efficiency of boiler. Decreasing consumption of conventional petrifaction energy sources not only saves hard-earned resource but also helps to protect environment. The environment resource of Sitsang is rare and weak, so the traditional mode of treatment after pollution is absolutely unallowed.

Main Characteristics of Climate in Sitsang

The cities of Lhasa、shiagatse、Nangqen belong to cold or freezing regions in china according to the standard of climate regionalization in architecture (GB50178-93),. The outdoor temperature of the winter in Sitsang is not tremendous different with other cold or freezing regions regions. The characteristic of climate is that the relative humidity is greatly low. The outdoor design relative humidity is respectively 28% and 27% in Lhasa and shiagatse. Because Sitsang is in low latitude and high altitude region, and atmosphere is rarefied, the content of dust and water is low, so the transparence of atmosphere is fairly high. In most areas of Sitsang, the total yearly solar radiation is 6000～8400MJ/m2. The total yearly solar radiation of Lhasa is 8170MJ/m2, and that of Chengdu and Shanghai, which is same latitudinal, are respectively 3687 MJ/m2 and 4375 MJ/m2. The solar radiation of Lhasa is greatly intense. According to criterion of SDM and SMM, Sitsang belongs to the optimal climate region of solar energy heating.

Traditional buildings in Tibet plateau

It can be seen from the traditional building layouts in Tibet plateau that all the designers take the use of solar energy into consideration. The main used rooms of these buildings such as offices, guest rooms are disposed in the south, while the secondary rooms such as storerooms, public toilets are placed in the north. Some buildings just possess rooms towards the south whereas gallery exists in the north, which plays the role of buffer action in heat transfer. The area ratio of window to wall of the external wall of room towards the south is usually greater than 0.4. Solar radiation coming into rooms through window makes these rooms be worthy of the name of greenhouses (direct heat gain passive solar building). Taking good advantage of solar energy is further considered in some buildings. For instance, all the south chambers of a certain hospital are hybrid passive solar house, i.e., the upper glazing of the south external wall directly receives solar radiation heat and the outside surface of the lower solid wall is napped, blacked and closed by a single clear glass, which is treated as solar heat gathering board. The air gap, between the wall and glass, is remained. In addition, the upper and the lower of the wall has ventilating orifices which can be switched off, such that the indoor air flow is natural convection in the air gap and thus absorb solar radiation heat. According to the introduction of the owners, the indoor temperature can be improved in the range of three to five degree Celsius.

Although the designers take the use of solar energy into consideration in the region, the indoor thermal environment doesn't meet the requirements. This is attributed to the poor thermal performance of the building envelope in the region. At present, wall materials of buildings in the region are mostly concrete blocks and rock materials, generally the concrete brick building blocks with a thickness of 200 millimeters produced at local are adopted, whose heat preservation is just better than clay bricks with a thickness of 120 millimeters. Its corresponding heat transfer coefficients greatly exceed the limit thermal conduction value required by civilian building energy economy design standard (the portion of heating supply dwelling buildings). Windows of the buildings mostly use metallic frame single glazing, such as new aluminum alloy frame in recent years and earlier steel frame for buildings.

From the above mentioned situation, we can conclude that the heating supply design in Tibet plateau cannot be completely processed according to conventional heating system in cold region. The design idea also cannot be focused only on heating system design. Three following problems must be solved one by one:With begin to, improving the heat preservation performance of the buildings and reducing heat dissipation of the outside enclosure structures; Then, make good use of the local resource advantages and solar energy (direct and indirect);Finally, optimizing heating design schemes and choosing the most optimal heating system.Only so completely considering heating problem in given environment at plateau can meet the demands of indoor heat comfort environment for occupants and at the same time reduce the conventional petrifaction energy consumption.

This paper mainly considers the using potential of passive solar buildings in the region. The research on direct heat gain passive solar building is conducted through using building energy consumption simulation software EnergyPlus, analyzing the difference of indoor thermal environment of direct heat gain passive building in the region at various external wall constructures.

SELECTION OF THE DYNAMIC ENERHY SIMULATION PROGRAM

The building dynamic energy simulation can compute buildings energy consumption established on mathematical model. These programs can compute hour-by-hour based on 8760 hourly weather data and simulate building indoor thermal environment and energy consumption. In last twenty years, the software of the building dynamic energy simulation has developed father fast. There are about 100 kinds these softwares, in which DoE-2 and EnergyPlus are applied usually. Because doe-2 mainly is used to calculate the heat extraction (heat-addition) rate and air temperature of a room in given conditions, Doe-2 solves these problems by a two-step process. In the first step, the air temperature is assumed to be fixed at some reference value. Instantaneous heat gains (or losses) for the room are calculated based of this constant temperature. Various types of heat gains, such as solar radiation entering through windows, energy form lights, people or equipment, and conduction of energy through the walls, are considered. The cooling (heating) load for a room is calculated for each type of instantaneous heat gain. At the end of the first step, the cooling loads from the various heat gains are summed to provide a total cooling load for the room. In the second step, the total cooling load for a room, along with data about the HVAC system attached to the room and a set of air-temperature weighting factors, is used to calculate the actual heat-extraction rate and air temperature.

In DOE-2, there are two general assumptions made with all weighting factors. The first is that the process modeled can be represented using linear differential equations. Therefore, non-linear processes such as natural convection and radiation must be approximated linearly. The second general assumption is that the weighting factors are constant (that is, they are not functions of time or temperature). This requires system properties, such as film coefficients and the distribution of incident radiation on surfaces, be represented by average values over the time of interest. Both assumptions limit the application of the Doe-2 program. In most case, the DoE-2 is still a valid tool and will continue to be applied in various environments. However, the user should be caution, when used for passive solar buildings or other buildings with heavy construction and for buildings where solar energy provides a large part of the load.

In order to overcome the obvious shortcomings of DOE-2, the EnergyPlus was developed, which had its roots in both the DOE-2 and BLAST. Many of the simulation characteristics have been inherited from the legacy programs. There are also some new features of the EnergyPlus, such as integrated simultaneous solution, Sub-hourly time steps, heat balance based solution, etc. The new features of integrated simultaneous solution and heat balance based solution make the Energy plus can be used to analyze the passive solar building, so the EnergyPlus is selected to use.

Model and Parameter

Simulation Model

Passive solar building is one of the easiest and the most effective modes of heating supply in winter, especially in Tibet plateau where solar energy is abundant. Currently there are mainly three using modes of passive solar building, such as direct heat gain, Trombe Wall, additional solar chamber. Among these three class passive solar buildings, both additional solar chamber and Trombe Wall need to add components at the south of the buildings, which result in difficulty at construction phase and high cost. While direct heat gain mode only considers window area of the south of the building and sunshade in summer, which has less matter at construction phase and a lower cost. Consequently, this paper is mainly on the research of direct heat gain passive building. The Building studied in this paper is showed in the Figure 1, which is the typical layout of the building in the Sitang. The middle standard room is chose in the research.

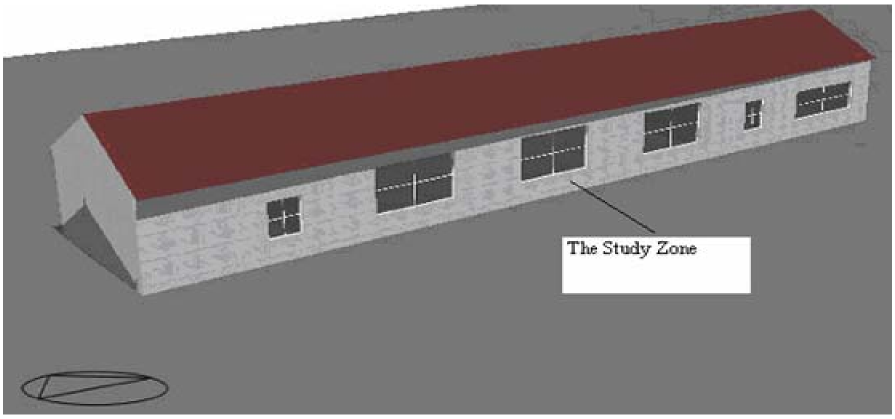

Fig. 1 Simulation model of building

Thermal Design Parameter

In order to compare the indoor thermal environment of the traditional resident building with the new passive building, two different work conditions are simulated. The one is the traditional resident building; the other is new direct gain passive solar building.

The different constructions of traditional and new building envelope are showed in table 1-4. There isn't thermal insulation layer in traditional building construction.

Table 1 Thermal parameter of external window

External window		specification	SHGC	U-Value W/(m2K)
Traditional	Single Clear	4 m	0.858	6.2
New	LowE Double	CLEAR +Air+ LowE (4+12+4)	0.631	2.0

Simulation result and discussion

In order to study the potential of passive solar building in Lasha regional, the object room is calculated and analyzed. Compare to the indoor thermal environment of the traditional building and that of new reconstruction passive solar building in the heating season. The results are showed in the Fig.2-3 (the radio of window and wall is 0.5). Fig.1 shows the compare results when the outside condition is bad (such as the outside temperature and solar radiation is low).

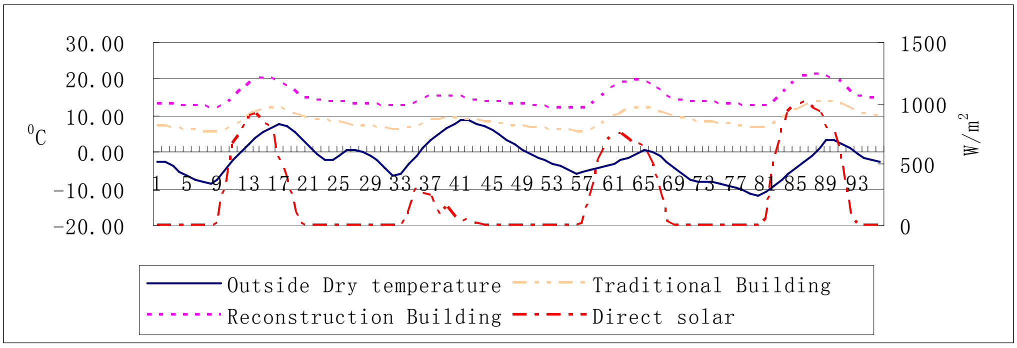

Fig.2 The mean operative temperature of two buildings when the outside condition is bad

Fig.3 shows the compare results when the outside condition is better (such as the higher outside temperature and solar radiation).

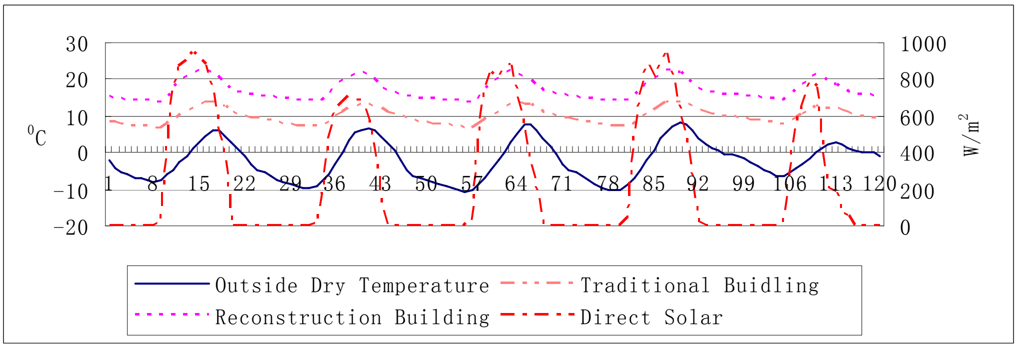

Fig.3 The mean operative temperature of two buildings when the outside condition is better

From the Fig.2-3, we know that no matter what the outside climate is, the traditional building indoor thermal environment is poor, the maximum value of the mean operative temperature is 10 ^{0}C, the minimum is 5 ^{0}C. This can't satisfy the thermal comfort requirement. When the building envelope is insulated, the indoor thermal environment is greatly improved. The value of the mean operative temperature is between 13~20 ^{0}C. In order to exploit potential of using passive solar heating in this regional, the key design parameters (such as the area radio of window to wall, the U-value of external wall) of direct gain passive solar are studied. The analyzing results are showed below.

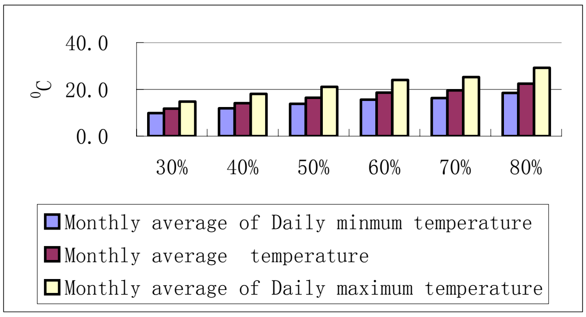

Fig.4 The mean operative temperature of building at different area radio of window to wall

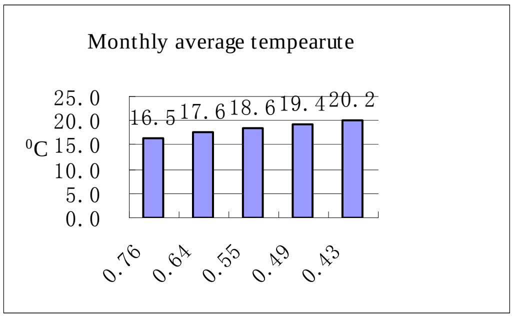

Fig. 5 indoor monthly average temperature at different U-value of external wall

From the Fig.3, we know when the monthly average temperature, monthly average temperature of daily maximum temperature and monthly average temperature of daily minimum temperature are considered together, the value of southern area radio of window to wall should between 0.5%~60%. When the radio is above 60%, the monthly average maximum temperature of each day exceed 24 ^{0}C and the people in this room will feel overheat. When the radio is less than 50%, monthly average temperature is below 16 ^{0}C, which can't satisfy the requirement of thermal comfort.

The fig. 5 gives indoor monthly average temperature at different U-value of the external wall, when window-wall radio is 60%. The U-value changes from 0.76 to 0.43.

From fig.5, we know that when the U-value of external wall is 0.55 and the monthly average operative temperature is about 18 ^{0}C, the U-value is reasonable.

Based on the above analyze, the area radio of window to wall should be 60% and the U-value of external wall should be 0.55. At this case, the yearly operative temperature is calculated and the coldest and hottest month results are showed in Fig6-7.

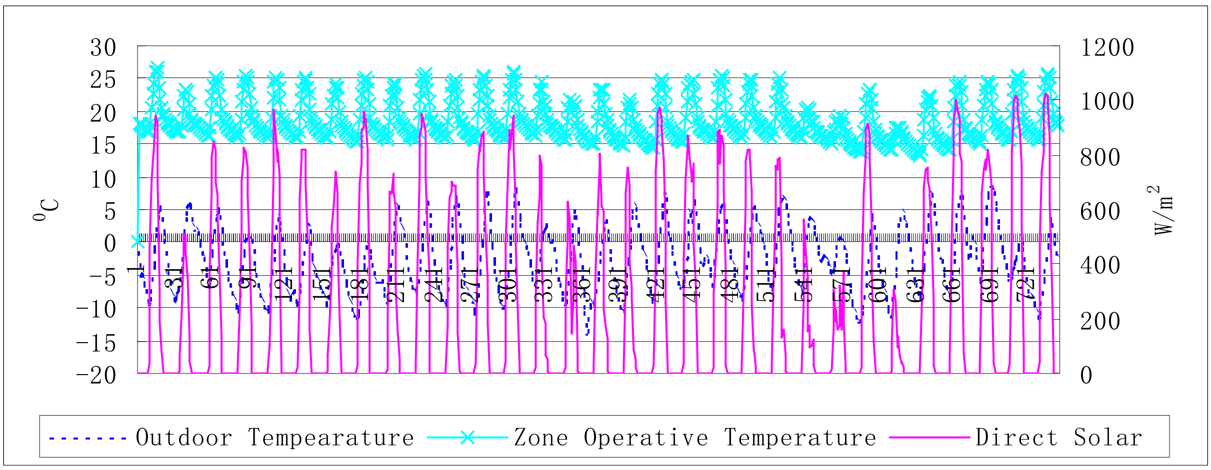

Fig.6 the operative temperature of the coldest month

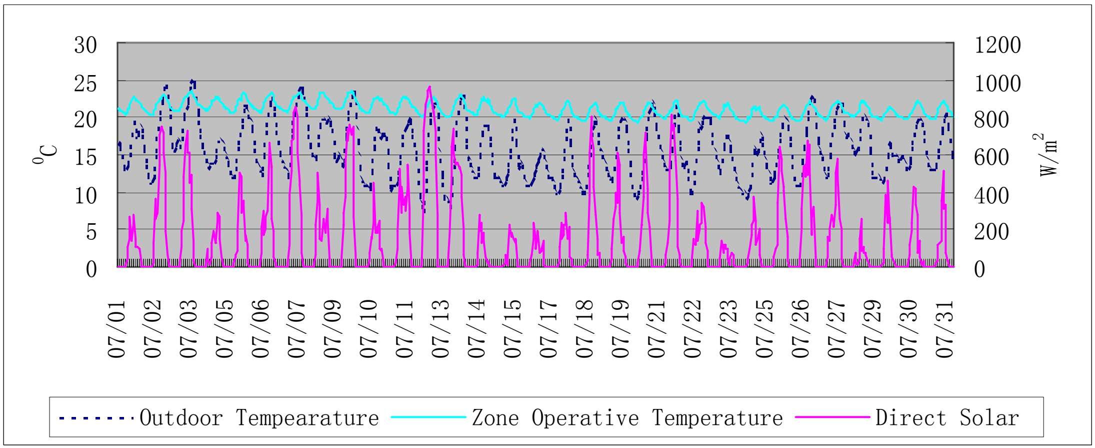

Fig.7the operative temperature of the hottest month

From the fig.6, we know that the operative temperature of the room is 15~25^{0}C at most time and the time of temperature below 15^{0}C or above 25^{0}C is very short. This means that the indoor thermal environment is satisfied and the overheat conditions or clod is not serious.

Because outside temperature of Lasha isn't very high in summer, the maximum outside temperature is about 25^{0}C, so the overheat condition isn't serious in summer. The figure 7 shows the indoor operative temperature variety in summer, the operative temperature is between 20~25 ^{0}C. This shows that the overheat condition isn't serious.We can know that the direct gain passive solar building with reasonable thermal design can provide a satisfied indoor thermal environment without consuming any petrochemical energy in LaSha.

Conclusion

Based on the above analyze, we can draw the conclusion that when the direct passive solar building is optimally designed, it can provide a satisfied indoor thermal environment in winter without consuming any petrochemical energy and the overheat condition isn't serious in summer. This show that the direct gain passive solar building should be applied on a large scale. The utilization of solar energy for building heating can reduce the petrochemical energy consuming and protect the zoology environment.

Assessing thermal comfort of dwellings in summer using EnergyPlus

Irina Bliuc, Rodica Rotberg and Laura Dumitrescu

"Gh. Asachi" Technical University of Iasi, Romania

SUMMARY

The simulation of a building as a whole offers an image of its behaviour, reflecting the complex relation established between the outdoor environment factors, the building characteristics, the use by its occupants, and the parameters which intervene in satisfying the comfort criteria. This paper gives an overview of the use of building simulation in Romania. It focuses on summer comfort.

INTRODUCTION

In specific climatic conditions (cold winters and hot summers), the housing fund of Romania, characterised, to a great extent, by a low level of insulation and high occupancy, is a great consumer of energy. Mention should be made that in the social mass housing units the energy is consumed exclusively to heat the space during winter time, the use of air conditioning plant not being the preferred choice. As the thermal climate rehabilitation measures are focused on saving the energy consumed for heating, the preoccupation for achieving comfort during summer time by passive measures appears as markedly topical.

Knowledge concerning the thermal climate parameters, their influence on the occupants and the influence of buildings and systems is today relatively known and established in international standards. Energy consumption of buildings depends significantly on the demands for the indoor environment, which also affects health, productivity and comfort of the occupants. The indoor environment is mentioned in prEN 15251 :2005 Criteria for the indoor environment including thermal, indoor air quality, light and noise. This standard presents IEQ (Indoor Environmental Quality) performance demands that can be used as input or default value for energy calculations, energy evaluations and building quality labeling.

One of the issues that is addressed in prEN 15251:2005 is the maximum allowable upper temperature in summer. For naturally ventilated buildings with a high degree of occupant control (e.g. access to operable windows and no strict clothing policy) the standard allows for the use of an adaptive criterion.

THERMAL COMFORT : MODELS AND CRITERIA

The environmental parameters that constitute the thermal environment are: temperature (air, radiant, surface), humidity, air velocity and personal parameters (clothing together with activity level). Criteria for an acceptable thermal comfort (PMV-PPD index) are evaluated by Fanger model. In the Fanger model the optimum internal condition for a building (i.e. one in which occupants will report comfort) is correlated exclusively to parameters referring to conditions which are internal to the building (mentioned above). Standard ISO 7730 is based on the steady state Fanger model of human physiology. The Predicted Mean Vote is strongly dependent on metabolic rate and clothing insulation. In the technical report 1752 (CEN 1998), are proposed 3 categories of thermal environment.

Table 1. Three categories of thermal environment. Percentage of dissatisfaction due to general comfort and local discomfort (ISO EN 7730, 2005, CR 1752, 1998.),[1]

Cate-gory	Thermal state of the body as a whole		Operative temperature °C		Max. mean air velocity m/s	
	PPD %	PMV	Summer (0,5 clo) Cooling	Winter(1 clo) Heating	Summer(0,5 clo) Cooling	Winter(1 clo) Heating
A	< 6	-0.2 < PMV < + 0.2	23,5 – 25,5	21,0 – 23,0	0,18	0,15
B	< 10	-0.5 < PMV < + 0.5	23,0 – 26,0	20,0 – 24,0	0,22	0,18
C	< 15	0.7 < PMV < + 0.7	22,0 – 27,0	19,0 – 25,0	0,25	0,21

For the last years several new CEN standards have been developed (e.g. USA – ASHRAE 55 2004 and the European draft pr EN 15251 which proposed Adaptive Comfort model based on comfort survey in the field.

The Adaptive Comfort model was proposed by Nicol and Humphreys. It states that people in real, naturally ventilated buildings, tend to adapt their comfort requirements to the prevailing outside temperatures. This model takes into account that people in real life situations are not functioning at constant conditions; instead they vary their activities, posture, metabolic rate and clothing according to the climate and its variations. Thus, the optimum indoor temperature (i.e. one at which occupants will report comfort) varies with the history of outside temperatures; in particular, it has a strong correlation with the average external temperature in the last few days. The adaptive principle is: if a change occurs such as to produce discomfort, people react in ways which tend to restore their comfort. They do this by making adjustments to their clothing, activity and posture, as well as to their thermal environment. The set of conceivable adaptive actions in response to warmth or coolness may be classified into five categories:

1. regulating the rate of internal heat generation
2. regulating the rate of body heat loss
3. regulating the thermal environment
4. selecting a different thermal environment
5. modifying the body's physiological comfort conditions

Design values for the indoor operative temperature as a function of mean monthly outdoor air temperature for buildings without mechanical cooling systems are shown in figure 1:

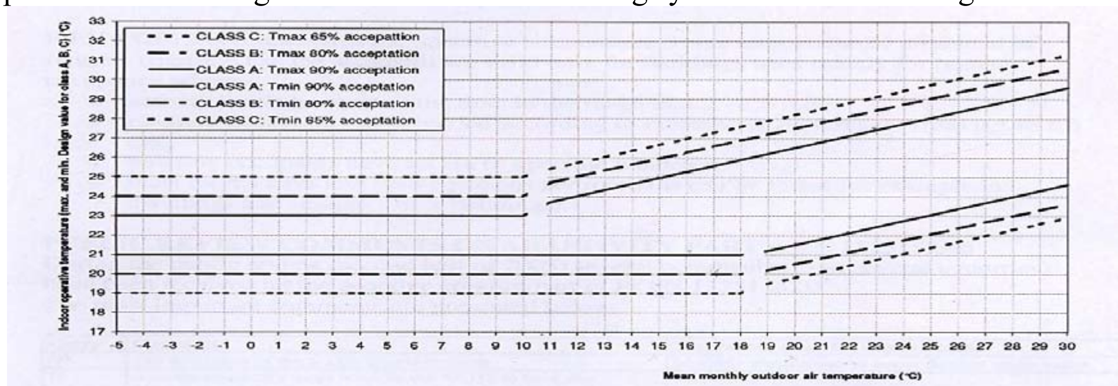

Figure 1. Design values for the indoor operative temperature, [2]

Four categories of adaptive thermal comfort are identified in prEN 15251:2005:

- Categories A: Thermal environment of the building meets the criteria of category A when the room temperature in the rooms representing 95% of the occupied space is not more than 3% of occupied hours a year outside the category A temperature limits.
- Category B: Thermal environment of the building meets the criteria of the category B when the room temperature in the rooms representing 95% of the occupied space is not more than 3% of occupied hours a year outside the category B temperature limits.
- Category C: Thermal environment of the building meets the criteria of category C when room temperature in the rooms representing 95% of the occupied space is not more than 3% of occupied hours a year outside the category C temperature limits.
- Category D: A building belongs to the category D if it does not meet the criteria of category C.

CASE STUDY

The building was modeled in EnergyPlus simulation environment. The main purpose is describing the thermal performance of the building from the viewpoint of external gains and losses (climate) and internal casual gains and losses. The building was modeled with 3 geometry thermal zones (fig. 2). All zones are virtually mutually ventilated by circulating air to keep uniform indoor environment in the entire building. Natural ventilation takes places through operable exterior windows and interior doors in all zones. In addition to natural ventilation, there are cracks in all exterior and interior walls. Cracks in the exterior walls allow infiltration of outside air into the zones. The location of the building is the city of Galati, in July. There was used a Weather File, with Rain Indicators. The occupation set up is the numeric representation of the way, the house is occupied and used by their residents. The important data are: number of occupants (3 in zone A, 2 in zone B), schedule of occupancy, the internal maximum ventilation ratio, and the schedule of weather, the openings (windows and doors, the ventilation set point 21^{o}C). The working hours are from 9.00 to 17.00. The wind pressure coefficient data are taken from literature,[3] for a simple rectangular building shape, surrounded by buildings of equal height. Hourly schedules with 24 schedule events are used for building parameters like window opening. These schedules are reused for all days of the simulation period.

EnergyPlus is an energy analysis and thermal load simulation program,[4]. It calculates the energy required to maintain each zone at a specific temperature for each hour of the day. A zone is an air volume at a uniform temperature plus all the heat transfer and heat storage surfaces bounding or inside of that air volume.

The building model must:

1. Determine heat transfer and heat storage surfaces ;
2. Define equivalent surfaces ;
3. Specify surfaces and subsurface (windows, doors, etc) construction and materials ;
4. Compile surface and subsurface information.

People, lights, equipment, outside air infiltration and ventilation all constitute internal gains for the thermal zone that are described as a peak level with a schedule for each hour.

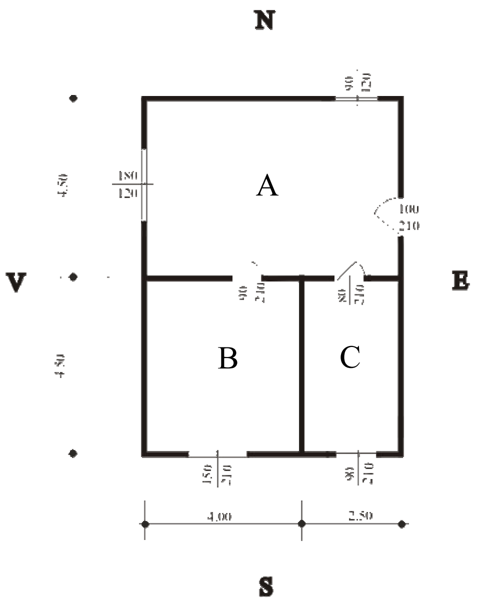

Figure 2. Test house

RESULTS, COMMENTS

By running the Energy Plus program there have been obtained data referring to the parameters which influence the comfort level. There have been considered such factors as indoor air temperature (fig.3), relative humidity (fig.4). The variation in time of the PMV index is shown in fig.5. and infiltrations (fig.6). On the bases of this information, it was possible to analyse the extent to which the comfort exigencies are met as against the Fanger and Adaptive model.

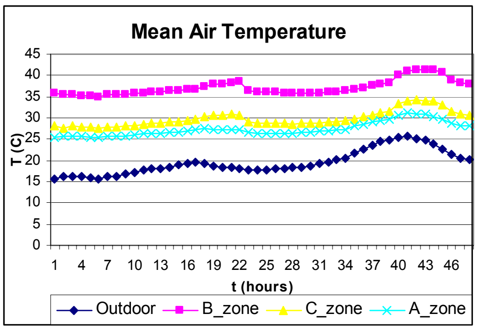

Figure 3. Mean Air Temperature

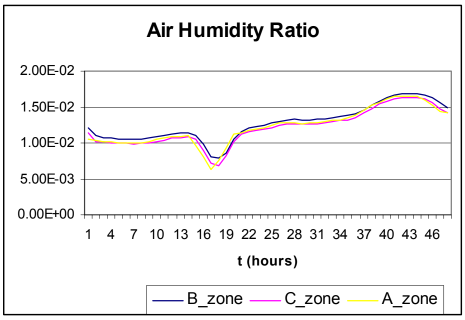

Figure 4. Air Humidity Ratio

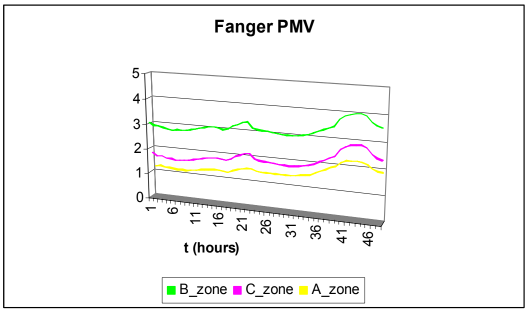

Figure 5. Fanger PMV , Simulation I

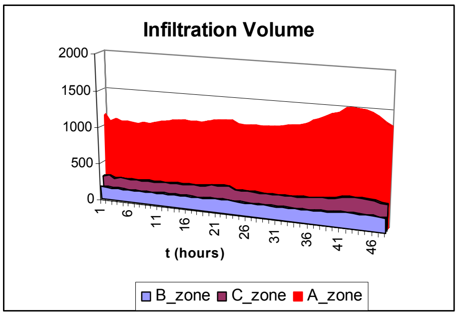

Figure 6. Infiltration Volume

It can be seen from fig.5 that the PMV index for the 3 zones varies between 1, 2, and 4, which means that not even the minimum conditions, for class C of comfort, are met. The least favourable situation is found in zone B, with double exposure.

The Adaptive Model: The operative temperature values for the 3 zones have been calculated and compared to the optimum ones recommended by the Adaptive Comfort Model (table 2, Simulation I). In the given situation the comfort criteria for zone A are satisfied, while in zone C the operative temperature values are relatively near the design ones. The research was resumed for a situation where passive measures were used in view of improving the comfort, such as: replacing glazing (table 2, Simulation II) in zone B and using blinds. The results obtained by running EnergyPlus are shown below:

Table 2. The operative and recommended temperature's values

Outdoor Temp	Design Value	Simulation I Zone operative values			Simulation II Zone operative values		
		A	B	C	A	B	C
17.8	24.7	24.4	33.1	26.2	23.1	23.8	25.0
18.0	24.7	24.4	33.0	26.2	23.1	23.8	25.0
18.1	24.8	24.4	33.0	26.1	23.1	23.8	25.0
18.3	24.8	24.5	32.9	26.1	23.2	23.8	25.0
18.4	24.9	24.5	32.9	26.1	23.2	23.9	25.0
18.8	25.0	24.7	32.9	26.2	23.4	24.0	25.0
19.2	25.1	24.8	33.0	26.3	23.6	24.2	25.2
19.7	25.3	25.0	33.1	26.5	23.8	24.4	25.4
20.1	25.4	25.2	33.2	26.7	24.0	24.7	25.6
20.5	25.6	25.4	33.4	26.9	24.2	24.9	25.8
21.8	26.0	26.0	33.7	27.2	24.9	25.5	26.2
22.7	26.3	26.5	34.2	27.8	25.4	26.1	26.8
23.5	26.6	26.9	34.5	28.2	25.8	26.5	27.2
24.4	26.9	27.4	34.9	28.6	26.4	27.0	27.7
24.8	27.0	27.8	35.2	29.0	26.7	27.3	28.0
25.3	27.1	28.8	37.1	30.9	27.7	28.5	30.1
25.7	27.3	29.1	37.9	31.5	28.1	29.0	30.6

The values presented in table 2, Simulation II, show that the comfort criteria are satisfied, over the simulation time, according to the adaptive model in the three zones, as follows:

Zone A – 100%
Zone B – 83.3 %
Zone C – 66 %

If a difference of 0.2 ^{0}C against the designed value is accepted.

The Fanger Model,[5]: The values of PMV index (fig.7) which vary between 1 and 2.5 for zone A orientated in the most favourable position, show that not even in this situation the minimum comfort criteria (class C) are met.

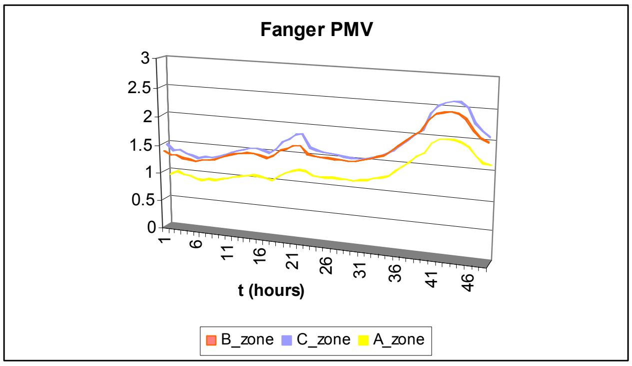

Figure 7. Fanger PMV, Simulation II

CONCLUSIONS

This paper gives an overview of the use of building simulation in Romania. It focuses on summer comfort. Summer comfort,[6] depends on the characteristics of the building envelope; in particular, the transparent components and the materials play a relevant role. In summer time, most of the cooling loads depend on the solar gains, coming from the transparent surfaces of the building. The analysis presented in this paper gives some useful information, concerning energy simulation of buildings. Transparent components deeply affect the energy balance of the building. The simulation of a building as a whole offers an image of its behaviour, reflecting the complex relation established between the outdoor environment factors, the building characteristics, the use by its occupants, and the parameters which intervene in satisfying the comfort criteria.

The Adaptive Comfort Model constitutes an instrument of realistic assessment of the quality of the indoor environment from the point of view of comfort in the naturally ventilated buildings, thus contributing to saving energy in air conditioning. Applying simple passive measures with minimum costs may led to achieving a summer time comfort which is acceptable even in dwellings of low surfaces and high occupancy degree.

EULEB - European high quality Low Energy Buildings

Jörg Schlenger, Helmut Müller

University of Dortmund, Chair for Environmental Architecture, Germany

Corresponding email: Joerg.Schlenger@Uni-Dortmund.de; Helmut.Mueller@Uni-Dortmund.de

SUMMARY

The European research project "EULEB – European high quality Low Energy Buildings" intends to provide information about good examples of energy efficient buildings in use, in order to reduce prejudices and lack of knowledge of many key actors of the building market. Therefore, a multilingual CD and website was produced, containing detailed information about 25 buildings from all over Europe including measured data about energy consumptions, construction costs, comfort and user acceptance. 150.000 copies of the CD resulting from this work have been disseminated in the beginning of 2007 through European magazines reaching the target groups of architects and engineers as well as investors and property developers all over Europe. Furthermore, all information is available on the website www.EULEB.info
The project was performed by a European consortium of five Universities and a European umbrella organisation and it was partly funded by the "Intelligent Energy Europe" programme.

INTRODUCTION

The energy consumption in Europe is rising from year to year. The replacement of limited fossil fuels by renewable energies is proceeding slowly. As a result, the reduction of CO2-Emissions is proceeding slowly, too.

The building sector plays an important role in the total energy consumption. In order to tap this potential for energy savings and reduction of CO2-emissions the energy-efficiency of buildings has to be improved as soon as possible.

One important measure to achieve these goals is the legislation for new and existing buildings. With the European "Energy Performance of Buildings Directive" (EPBD), which has to be turned into national laws by the European member states, an important step into this direction has been done.

But unfortunately energy efficient buildings are sometimes facing prejudices and image problems resulting from bad examples from the past. Many people mistrust the real energy efficiency in use, the quality of architecture, the user comfort and the cost effectiveness. Other people just have concerns about energy efficient buildings as a result of lack of information.

These prejudices and the lack of information can be reduced and eliminated by providing information and detailed data of existing good examples to key actors of the building market. With a collection of 25 European high quality low energy buildings and detailed information about their architecture, their building concept, their measured energy performance and their building costs, EULEB helps to improve the image of energy efficient buildings and supports the implementation of the EPBD.

PROJECT TEAM

The EULEB project team consists of five European Universities of which the University of Dortmund coordinated the project and one international association. The Universities are represented by different institutes, which are working in the field of energy efficiency of buildings. They have formed a successful research and teaching network in which several projects already have been performed. The excellent knowledge of the team's national building stock allowed a detailed identification of buildings from the five largest European countries.

The sixth partner was REHVA, the Federation of European heating and air-conditioning associations. REHVA is a 43 year old umbrella organisation, representing 30 member associations of European experts for building services. Thus, REHVA has direct contact to about 110.000 key actors of the European building market. They supported the project with the expert knowledge and their network which was used for disseminating the results.

SELECTION OF BUILDINGS

A total of 50 public buildings have been identified, predominantly from the countries where the University Partners are situated. To cover the large variety of climatic conditions in Europe, buildings from the very far north (Scandinavia) as well as from the very south of Europe, (Mediterranean countries), were included. Out of the identified buildings, there had to be a selection of five buildings per University Partner for further examination.

For the selection of buildings a simple evaluation system was designed. In this first step, each building was evaluated concerning its qualification to the project. Seven categories (such as quality of architecture, energy consumption, availability of monitored data etc.) with different weightings were used in this subjective evaluation methodology. Low ratings in some of the criteria had to lead to a direct exclusion of a project (for example lack of monitored data).

After having evaluated the 50 identified buildings, a ranking of the buildings identified by each partner could be established, showing which buildings fulfilled the overall criteria best. This process led to the selection of 25 buildings from all over Europe.

SELECTED INFORMATION

The EULEB project should address to different target groups, namely architects, engineers, investors and property developers. All these groups have a very different knowledge background as well as different interests in terms of building information. As EULEB could never satisfy 100% of the different interests in all details, the challenge was to provide a basic set of general building information. A number of details should address the different target groups and raise the user's interest to search for more information.

Besides the different building use, the locations of the buildings from all over Europe result in a large variety of differences of the buildings´ boundary conditions, especially in terms of climate. Therefore a visualisation of the buildings locations with reference to the climatic zones of KOEPPEN was used to introduce the user to the influence of locations on the building design and building energy consumption.

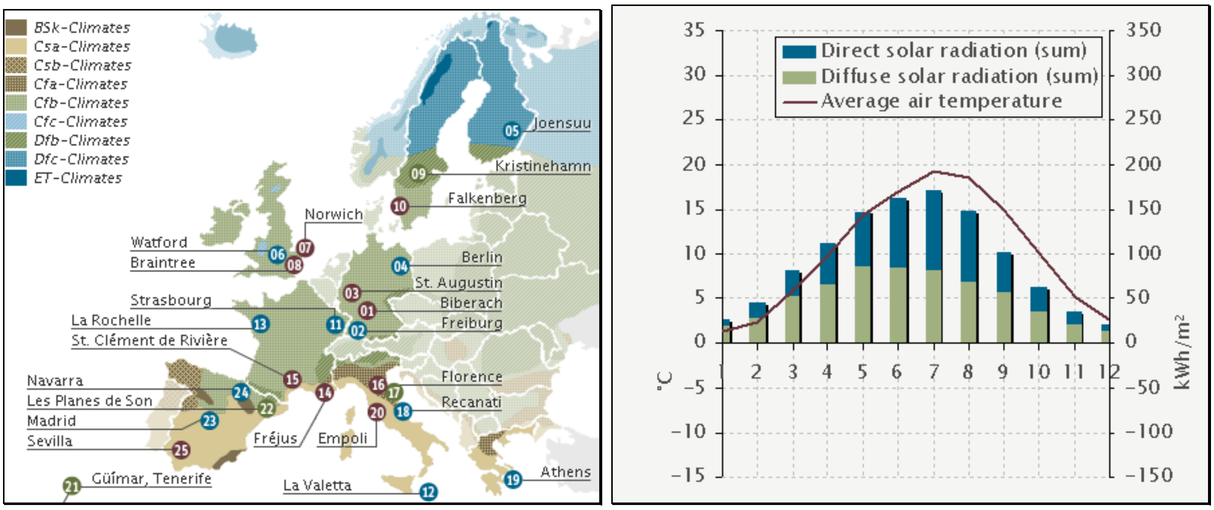

Figure 1. Locations and climatic zones of selected buildings and example of climatic data in EULEB

Each building presentation starts with some general information about the exact building name, location address, relevant persons involved in the design and construction, information about the buildings´ areas and volumes etc. These information are accompanied by images (external and internal views) and plans (site maps, floor plans, elevations and sections) visualising the architecture of the building. To visualise the appearance and the atmosphere of the buildings, short professional video clips provide extra impressions beyond the static images and plans.

The climatic conditions are described in more detail by statistical diagrams and some figures, like the ASHRAE classification [1] which relates the climate to the energy consumption of buildings. The next sections give general descriptions of the building construction including the thermal quality of the building envelope and the general energy concept and technical systems.

Special features of the building concept, which are significant for the energy efficiency of the building, are described and visualised in more detail. These features have been grouped to the categories Insulation, Solar control, Lighting, Heating, Cooling, Ventilation, Materials, Renewable energies, Co-Generation and Rainwater use.

The energy performance of the buildings is evaluated with measured energy consumption. Where available, the consumption is separated by fuel type (electricity, gas, oil etc.) and load type (heating, cooling, ventilation, lighting etc.). This allows giving a detailed overview on the building's energy performance and calculating the respective partly and total primary energy consumptions. All values are related to the building's usable floor area and compared with national average and standard values where available.

The real building costs have been documented in relation to the usable floor area of the building. Where available, the total costs are divided by cost categories and national average costs for a similar building have been used for comparison.

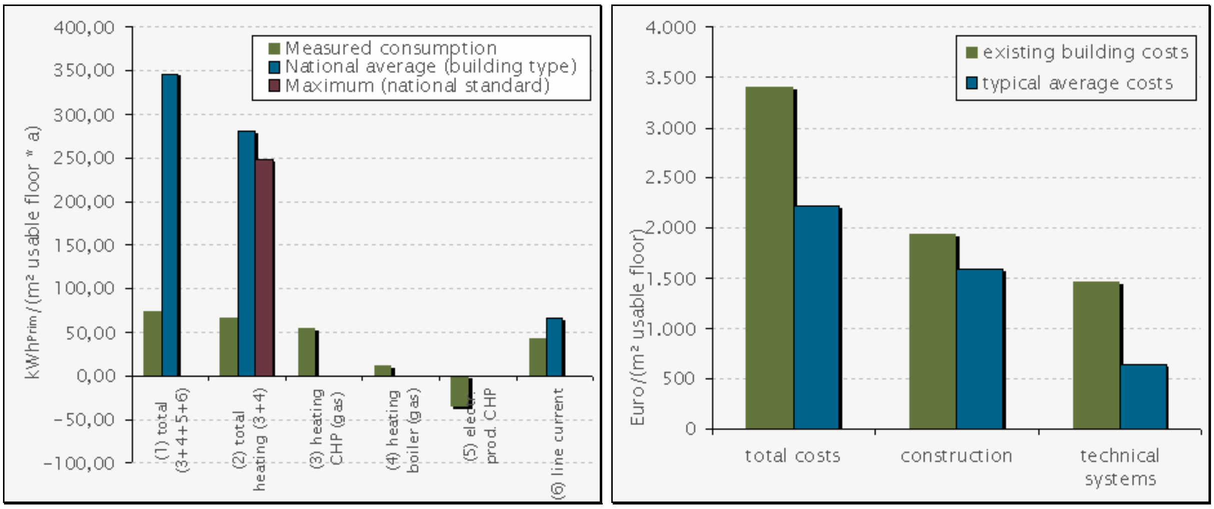

Figure 2. Example of Energy performance and construction costs in EULEB

The visual comfort has been measured by luminance pictures, which have been taken and processed for all buildings in the curse of the EULEB-project. They give an impression of the luminance and possible glare effects in a typical room of the building.

In order to evaluate the quality of the buildings, user acceptance studies have been performed in all 25 buildings. Using a simple questionnaire with 12 questions concerning temperatures, air quality, lighting, comfort, user influence, architecture etc. allowed creating a detailed evaluation and an overall user acceptance.

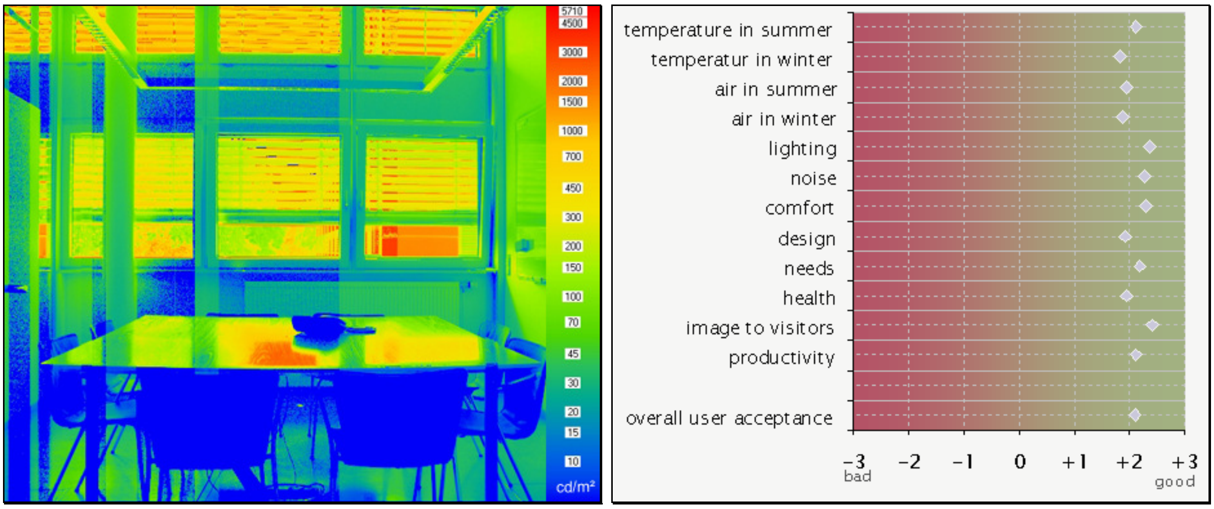

Figure 3. Example Visual comfort expressed by luminance pictures and results of post occupancy studies in EULEB

Based on the building data described above, the “Benchmarking” section provides a comparison of the building costs, the energy performance and the user acceptance of all 25 buildings. These characteristics depend on many variables such as building use, climatic conditions etc. which have to be taken into account. Thus, in EULEB the buildings have been grouped according to building type and climatic zone. Although this of course does not take into account all relevant parameters (user influences, etc.) a rough comparison could be established.

With this compilation of building data, the general and specific interests in terms of design, technical details, energy performance and costs of the target groups Architects, Engineers and Property Developers have been addressed as much as possible.

COMPARISON OF BUILDINGS

The comparison of different buildings generally is a very sensitive process as many different boundary conditions like the use of a building, the climatic background etc. Still then, other factors like the occupants' behaviour will have influences on the results and are very difficult to separate.

In the EULEB project, the 25 buildings have been compared in the section "Benchmarking" in the three main categories "Economy", "Energy" and "Quality". The buildings have been grouped by building type and by climatic zone. The climatic zones have been defined according to the ASHRAE-classification system [1]. This method takes into account the heating and cooling degree days of a certain location and thus takes into account a building's energy demand resulting from climatic conditions.

The Economy-Benchmarking shows a significant variance of the total building costs, within one building type and on climatic zone. But discounting some extreme values, general statements can be found: The total building costs for office buildings constitute generally about 1400 and 2100 €/(m² usable floor area). For the educational buildings this value generally reaches between 1000 and 1500 €/(m² usable floor area).

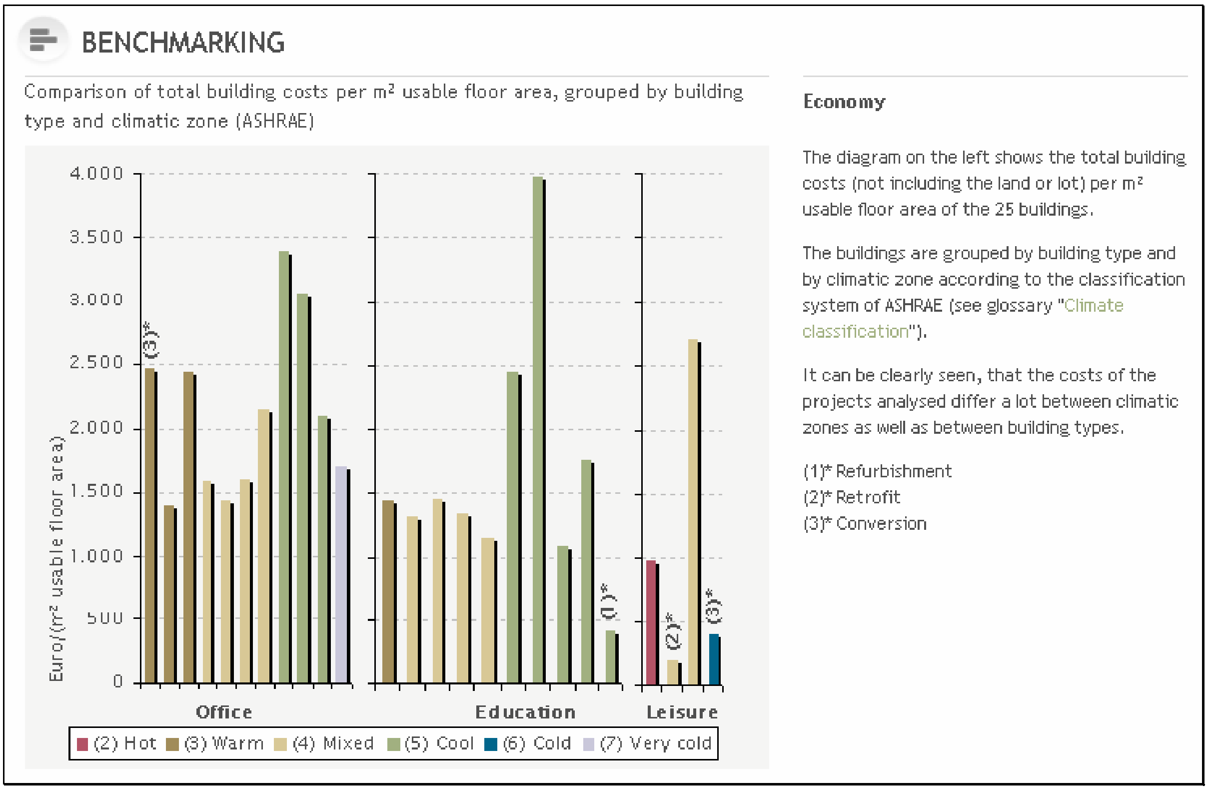

Figure 4. Comparison of building costs in EULEB

Comparing the energy consumptions of the 25 buildings again brought a significant variance even within one building type and climatic zone. But again, a general statement could be, that for example for all three building types, a total primary energy consumption between 100 and 220 kWhPrim/(m² usable floor area) can be achieved.

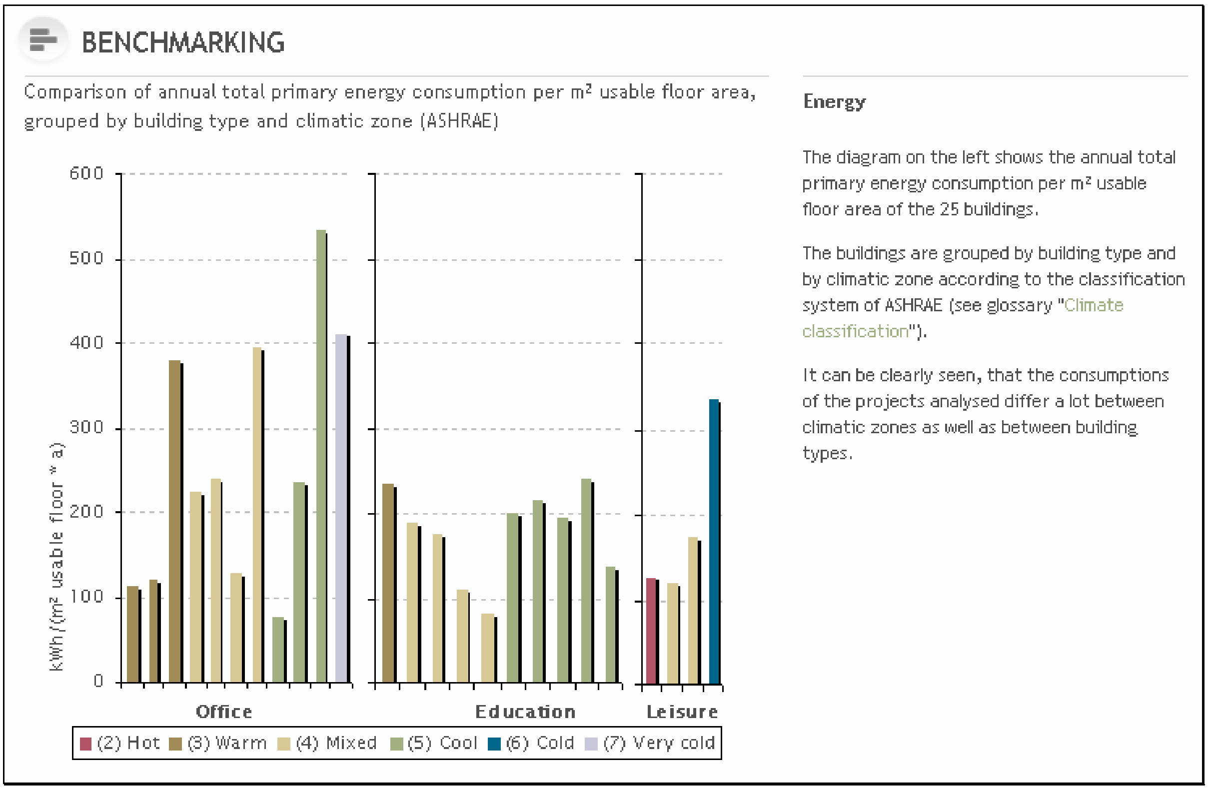

Figure 5. Comparison of energy consumptions in EULEB

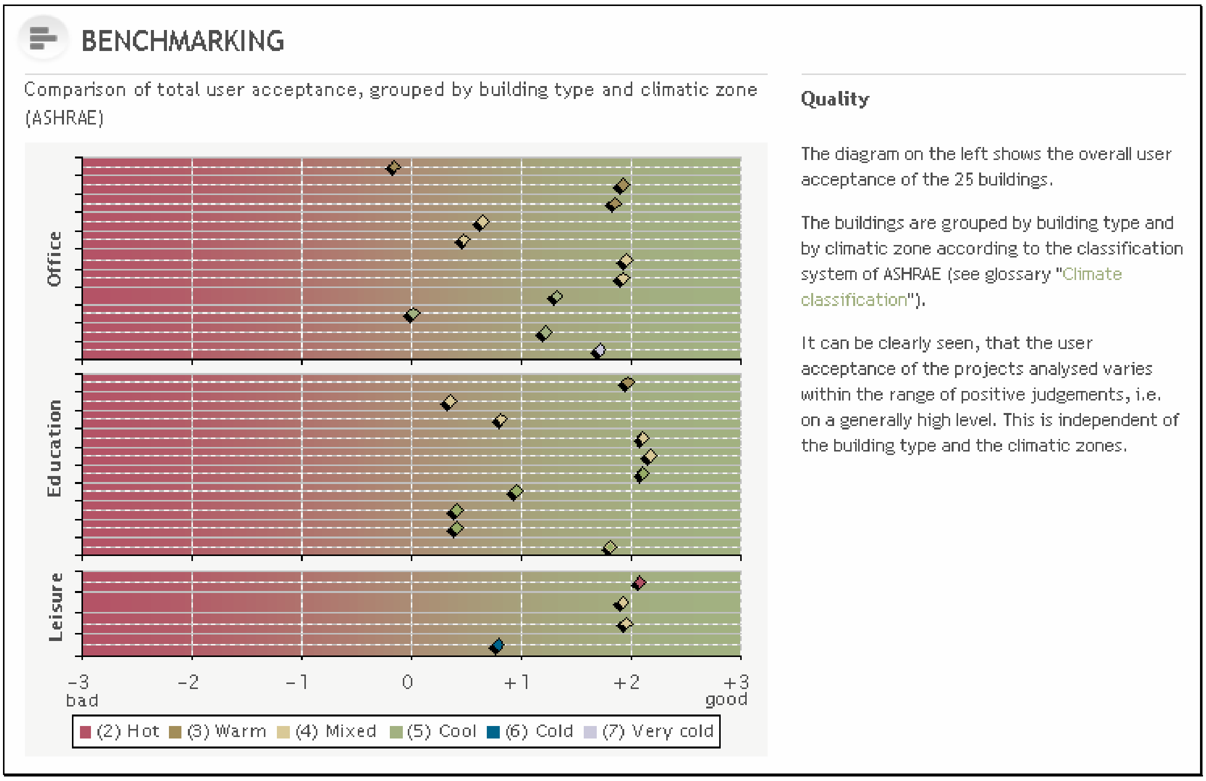

Figure 6. Comparison of overall user acceptance in EULEB

The overall user acceptance has been compared in the Quality benchmarking diagram. Generally positive results are obvious, independent of the building type and the climatic zone.

Energy efficient service buildings with ecofacility: support for planners and building developers

Gerhard Hofer [1] and Margot Grim[1]

[1]Austrian Energy Agency, Austria

Corresponding email: gerhard.hofer@energyagency.at

SUMMARY

The construction of a building with an optimized thermal and energy performance and an accordingly low energy demand does not necessarily require higher investment costs. The decisive factor is an interdisciplinary and foresighted – an Integrated Energy Design. Although this integrated approach prolongs the design process and increases the planning budget, in return the construction time and the subsequent costs such as energy and operating costs are significantly reduced. A qualitative (using checklists) and quantitative assessment (calculation of heating and cooling demand, building energy simulation) is essential for the identification of flaws in the design. In order to ensure the longevity of the quality of design beyond the realisation of the project, guarantee models can be applied. This is a model of a “slim” integrated planning process, but applying this concept step by step should help to overcome the introduction barriers. The ecofacility consulting services should be the first step.

INTRODUCTION

Newly built service buildings - such as office buildings, shops, hotels or schools - with a final energy consumption exceeding 400 kWh/m²/yr are still common. However, several examples exist which prove that service buildings with a final energy consumption of less than 40 kWh/m²/yr are equally feasible [1].

What is the reason for this considerable disparity in energy consumption levels? Although the use of innovative technologies certainly plays an important role, an even more decisive factor is the choice of an integrated design approach. An approach that focuses not only on the appearance and functionality of the building, but also accounts for its energy performance during the utilisation period. Decisions made at an early design stage, such as those concerning the shape and orientation of a building, have a crucial impact on the building’s future energy consumption [2]. Only an integrated design process at this early stage allows for optimisation in as many areas as possible (architecture, function, building code, comfort, investment costs and operating costs). For a timely identification of areas for possible improvements, a regular assessment of the draft according to certain criteria becomes necessary at the end of every planning stage. At the first design stage – the predesign stage – the main assessment criterion is the net energy demand; later – when the installations have been chosen – the final energy demand becomes relevant. Additionally, an analysis of total investment and running costs is possible with the help of a life-cycle cost estimation.

Concerning life-cycle costs, it is widely recognised that 80% of operating, maintenance and repair costs of a building are already determined during the first 20% of the entire planning process – i.e. during the predesign and design stage [3] (see Figure 1). In the subsequent stages, the chance to lower these costs decreases.

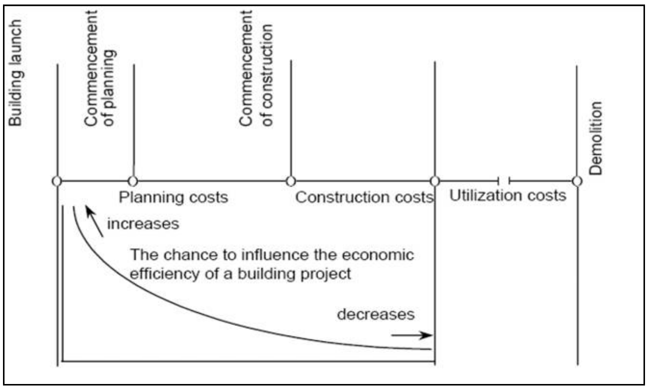

Figure 1: Chance to influence the economic efficiency of a building [3]

The same concept applies to the energy demand of a building: the earlier the energy demand of the building is taken into account and optimised during the design stage, the bigger the chances for success. Due to the fact that at this stage of the design process the amount of time and money invested is still relatively low, redesign is still feasible and financially insignificant. An integrated energy design process and regular assessment provide the basis for a quick and efficient completion of the project, less construction defects and lower repair costs – and therefore help maintaining low investment and repair costs [4].

In the course of implementing the Energy Performance of Buildings Directive (EPBD) on a national level, every member state incorporates minimum standards for the energy performance of buildings in their national building codes. As soon as the implementation process is completed, new buildings as well as existing buildings that are subject to major renovation will have to comply with certain thermal and energy performance criteria. Thus, building developers have to take low energy demand for buildings into account in future.

How can the construction of an energy efficient building be realised? How can real estate developers be supported to fulfil the requirements of national implementation of EPBD? How can the theoretical concepts of integrated energy design, life-cycle cost analysis and optimisation of thermal and energy performance of new buildings be put into practice and become part of the standardised construction process of building developers? How can clients make sure – especially at the project initiation stage and during predesign – that an energy efficient service building is built in the end?

ecofacility, the programme of the Austrian Climate Protection Initiative “klima:aktiv” aims at increasing energy efficiency in private service buildings, has developed a standardised consulting process to achieve these goals. The ecofacility consulting services help building developers to incorporate energy efficiency as a key factor into the planning process right from the beginning. The aim is to design buildings that can operate with minimal energy consumption, i.e. with minimal heating and cooling demand. The better the building envelope is adapted to climatic conditions and the function of the building, the lower the energy demand [5]. The choice of installations should be based on the estimated energy demand. This way, it is guaranteed that the installations fit the building and that investment costs are not increased by the installation of unnecessary and oversized equipment. In addition, indoor environmental quality must not be neglected; simple measures such as allowing for individual indoor temperature regulation by opening the windows raise the comfort level of the building occupants.

METHOD: CONSULTING SERVICES FOR BUILDING DEVELOPERS

The ecofacility consultants make sure that the future energy demand of a building is taken into account at every planning stage – from the first draft to detailed design – and especially at the early design stage. The best results can be achieved when the consulting activities take place within the framework of an integrated energy design process under independent guidance. However, the consultation is based on a modular concept so that the right service can be provided at every stage of the process.

Definition of goals

At the beginning of the whole design process, it is necessary to determine the energy criteria the building has to meet during the utilisation period.
At the beginning of the design stage of a building project, the client usually has only a rather vague and general idea of his objectives. Therefore, it is essential to translate the client's vaguely stated wishes and goals (strategic goals) into clear and measurable requirements[6,7]. These requirements form the basis of the entire design process and can be used in the design competition or the design bid (see Figure 2).

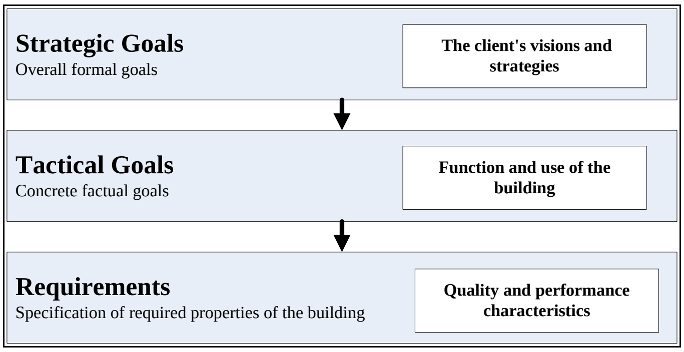

Figure 2: Process of defining requirements [6]

The requirements have to contain criteria, target values and indicators. They can be very general in nature and specify only maximum values of final or primary energy demand, or they can specify in detail maximum values of energy consumed by heating, cooling, lighting, etc. Some requirements even fix details such as minimal U-values for building components, obligatory installation of an exterior shading system, avoiding the installation of a chiller, etc. In addition to the requirements, an assessment method has to be defined which makes it possible to check at every design stage if the decisions made meet the requirements [8]. This specification of requirements combined with an assessment procedure makes it possible already at the initial planning stage to check the compliance with energy efficiency criteria. At the beginning of the design stage, it is necessary to find out which innovative or energy efficient options are available for the building in question. The number of options is determined by some basic decisions concerning e.g. the location or shape of the building which have to be made or are already made when design activities start. If the location of the building has already been chosen, it can be determined whether e.g. the prevailing winds allow for a movable exterior shading system or the noise level allows for natural ventilation.

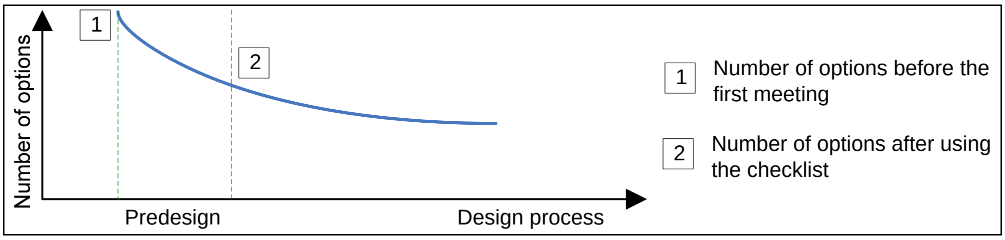

Figure 3: Reducing the number of options with the help of a checklist (Source: Austrian Energy Agency)

The development of comprehensive concepts and a closer look at different options often reveal conflicting goals. Finding an optimal solution which resolves these conflicts allows for significant energy savings, but only if this is done at a very early stage of the design process [9].
In addition, it is necessary to define which of the requirements are mandatory and which of them may still be changed in the course of the optimisation process [9,10]. A list of questions which is discussed with the client in the first meeting assists this process of defining requirements (see Figure 3).

Assessment of building energy performance during predesign

During the predesign phase, the architectural concept is assessed with respect to the estimated energy consumption. Based on the first sketches and drafts, several observations are already possible: e.g. whether a shading system is necessary to lower the cooling demand or the installation of a chiller is required. Afterwards, suggestions for improvements of the preliminary draft as regards thermal and energy properties are submitted that aim at a reduction of the total energy demand. Possible ways to lower the cooling demand or to even avoid the installation of a chiller are the reduction of the amount of glazed surfaces (e.g. by adding a parapet) or the installation of solar control glazing.
This assessment of building energy performance is carried out with the help of two tools:

- Calculation of the heat and cooling demand of the building: the net energy demand is calculated in order to determine whether an improvement of energy efficiency is advisable or not an absolute necessity.
- Qualitative analysis of the preliminary draft based on a standardised checklist: the checklist covers various aspects of energy efficient building practice. The draft is evaluated according to every aspect in the checklist, and – if necessary – suggestions for improvements are noted. The checklist covers the following aspects: shape of the building / architectural concept, orientation of the building / the sections of the façade, compactness of the building, number of internal rooms, effective thermal mass, thermal protection, thermal bridges, summer thermal protection (window-wall ratio, shading systems, orientation of the glazed façades), orientation of the office spaces, passive solar energy use, daylighting and ventilation. The online information site provided by ecofacility (http://tool.ecofacility.at) offers property developers and contractors an overview of the main aspects that determine the thermal and energy properties of the building.

The above two procedures are included in the ecofacility report on the preliminary draft which is presented to the client and serves as a basis for further detailed design of the building.

Assessment of thermal and energy properties during the schematic and detailed design phase

During design development and detailed design, the ecofacility consulting services offer an in-depth analysis: An hourly simulation of the building's thermal and energy performance simulates possible realisations of the building and its installations, including internal and external influences and their synergies. These simulations help in spotting flaws in the design and make sure that the energy performance of the building and its installations are optimised. Based on the results of the different simulations, the estimated energy costs of the building can be calculated. For the calculation of the life-cycle costs, additional operating costs such as maintenance, repair and cleaning costs are estimated and, together with the energy costs, added to the investment costs.

Guarantee models for the operational phase

To ensure that the quality of the design process is entirely reflected in the construction and operation of the building, various guarantee models can be applied, depending on the project delivery method (single product contractor, general contractor, total contractor or integrated system provider). Similarly to Energy Performance Contracting projects, the guarantee models apply to energy costs / energy consumption and quality of realisation. The ecofacility consultations support clients with the integration of these guarantee elements into the contract.

COLLABORATIONS

In order to increase the know-how and thus continuously improve the services, ecofacility collaborates with several EU projects. The project "Network for the Promotion of RTD results in the field of Eco-building technologies, small Polygeneration and renewable heating and cooling technologies for buildings" (PEP-NET) within the Sixth Framework Programme of the European Community for Research, Technological Development and Demonstration is developing technology profiles for energy efficient office building, creates dialogue platforms between planners, technology developers and manufacture and makes pilot studies to support building developers when applying innovative products. In the framework of "Integrated Energy Design in Public Buildings" (INTEND), an "Intelligent Energy – Europe" project, several countries compare their processes for thermal and energy performance optimisation of service buildings, assess other concepts and develop common approaches. In the course of the EIE project KeepCool, the promotion-project of 'sustainable cooling' in the service building sector", extensive documents and checklists concerning summer comfort have been developed in the last few years which are now used in the consulting process.

CONCLUSION

The Integrated Design Process is a minimum requirement for developing energy efficient buildings in the tertiary sector. Taking many aspects into account, starting from the first planning phase is the key for optimising the building. But on the other hand, professional office building developers often don't have enough time and resources to apply such a comprehensive approach in the planning phase. These developers need support in every planning stage, edited on their specific requirement, in order to develop energy efficient buildings. Ecofacility developed a consulting service process for building developer. This service is modular in order to be applied in every planning stage. This approach should support to overcome the introduction barriers in applying more comprehensive planning strategies like integrated planning. However, this is not an broad integrated planning process, but applying this concept step by step is for the target group of real estate developer in the tertiary building sector more realistic.

SUMMARY

A global methodology is developed to optimize concepts for extremely low energy dwellings, taking into account energy savings, environmental impact and financial costs over the life cycle of the buildings. Energy simulations are executed with TRNSYS. The ecological impact is evaluated through a life cycle inventory of the whole building, whereas costs are evaluated through a cost-benefit analysis. The multi-objective optimization problem is solved with a combination of genetic algorithms and the Pareto-concept. Firstly the optimization methodology is presented. Subsequently the main results are presented and a hierarchy of cost-effective energy saving measures is derived. Finally the impact of economic parameters, such as price evolutions and discount rate is discussed together with the strengths and weaknesses of extremely low energy buildings from an economic point of view.

INTRODUCTION

Since the oil crisis of the early seventies energy consumption in buildings is a hot item. During the first years most research focused on the reduction of transmission losses, later also on the optimization of passive solar gains. The next step was the search for better performing heating systems and the reduction of ventilation losses through heat recovery systems. From the early nineties on, the interest shifted towards the overall sustainability of buildings, taking into account the environmental impact over the whole life cycle of the building [1].

Currently extremely low energy dwellings are in the picture, ranging from passive houses [2,3] over zero energy houses [4-6] to energy autarkic buildings. The latter often is considered as the ultimate objective for sustainable buildings [5]. Though, these concepts assume the application of a good many technologies resulting not only in much more embodied energy and pollution, but also in more resources and higher costs. Although these buildings have much smaller energy consumption during the usage phase, the projects hardly ever show clearly if the global balance of energy, ecology and cost is finally positive.

An important tool for evaluation and quantification of environmental impact is life cycle assessment (LCA) [7]. Traditionally LCA is mostly concerned with materials, components and product design and rarely buildings as a whole are subject of a detailed LCA. Furthermore, LCA is mainly used as an instrument to quantify in- and outflows and environmental impact, but lacks to be an instrument to optimize decision making [8-11].

Optimization of a building as a whole is also a complex problem due to the amount of parameters and variables, the non-linear relations and second order effects. During the two last decades evolutionary computational optimization techniques, which are adaptive methods inspired by the genetic processes of biological organisms, have been receiving increasing attention for their potential for such complex problems [12]. One of their main advantages is that they do not have much mathematical requirements about the optimization problem [12]. However, application in building related engineering is rare until now [13-15].

So, the current trends for sustainable buildings lack an underlying scientifically based methodology to develop and evaluate dwellings that are optimized for energy, ecology and costs. The development and implementation of such a methodology is presented here. Basic principle is a well-founded evaluation of the environmental impact and financial cost during the whole life cycle of the building and its installations, by coupling LCA and cost assessment with advanced optimization techniques. This results in concepts and guidelines for globally optimized extremely low energy building concepts.

METHODOLOGY

The developed methodology consists of three main pillars. The first pillar concerns the multi-objective evolutionary optimization strategy. The second pillar consists of databases for LCA and investment costs whereas the third pillar concerns the building energy simulations.

Reference dwellings and energy saving measures

The objects for optimization are residential buildings. In order to obtain representative results for Belgium, a number of reference dwellings are designed following the statistical average of the Belgian residential sector [16]. To include the compactness, being the proportion of heated air volume and heat loss area, as a parameter, five typologies are defined, resulting in five references dwellings: one terraced dwelling, one semi-detached house, two individual dwellings (one with a simple square plan and one with a fragmented plan) and an apartment flat. To assess the impact of the energy saving measures, the non insulated version of the dwellings is defined as the reference situation. The geometry of each reference dwelling is fixed. Only the glass area per room can vary in order to include its impact on net heat demand and summer comfort. The thermal capacity is included by incorporating both light weight (wood frame) and massive variants (cavity wall and massive wall with outer insulation).

The parameters for optimization are related to energy saving measures applied to both the building envelope and the heating system. The optimization itself is performed in two steps. In the first step only envelope-related energy saving measures are considered. Insulation measures are taken for the roofs, attic floor, façade and ground floor. The insulation thickness in each envelope component can vary from zero to a maximum and different types of insulation material can be applied. Table 1 gives the maximum applicable insulation thickness per envelope component, as well as the applicable materials.

A large number of different glazing types is considered with a U-value varying from 2.8 W/m²K to 0.4 W/m²K and a g-value varying from 0.76 to 0.21. Different types of window frames are considered, such as frames of wood, PUR, PVC and/or aluminium with a U-value varying from 6 W/m²K to 0.65 W/m²K (passive house frames). Summer comfort can be affected by adding movable internal or external shading with an opaque fraction of 0 to 100% and/or by choosing one of four ventilation scenarios for extra summer or night ventilation.

These ventilation scenarios are combined with four levels of air tightness, ranging from the average of new built dwellings [17] to the passive house standard for air tightness.

Table 1. Maximum insulation thickness and applicable materials per envelope component

Envelope component	Maximum thickness [cm]	Applicable materials
Flat roof	30	MW, PUR, CG
Sloped roof	40	MW, PUR, EPS, XPS, CF
Attic floor	40	MW, PUR, EPS, XPS
Façade massive variant	30	MW, PUR, EPS, XPS
Façade light weight variant	30	MW, CF
Floor	15	MW, PUR, EPS, XPS

Legend: MW = mineral wool; PUR = polyurethane; CG = cellular glass; EPS = expanded polystyrene; XPS = extruded polystyrene, CF = cellulose fibre

In the second step, the measures on the building envelope are combined with system-related measures. This includes systems for distribution, emission, production and storage of heat, natural and mechanical ventilation systems with or without heat recovery, systems for local electricity production and control systems. Traditional systems, such as high efficiency or condensing boilers, are considered, but aim of the research was also to focus on more innovative technologies, such as heat pumps, cogeneration of heat and power, different levels of heat recovery of ventilation losses, combination of mechanical ventilation with heat recovery and integrated electrical heater and renewable solar energy systems.

Multi-objective optimization

To deal with the large number of parameters and variables that are involved, the evolutionary optimization method of genetic algorithms (GA) is selected. The algorithm starts from a set of individuals called a population, in which each individual, called a chromosome, represents a possible solution to the problem. Solutions from one population are selected to create a new population. Solutions that are selected (=parents) to form new solutions (=offspring) are selected according to their fitness, which means the more suitable they are for the problem, the higher their probability to be selected for reproduction [18]. This normally leads to a new and improved population. Applied to the reference buildings, each potential variant of these buildings is represented unequivocally as a set of parameters, joined together in a string of values. This string forms the chromosome, in which each value represents one parameter, being the insulation thickness, glazing type, type of sun shading, glass area, etc. for a particular building design. The fitness of a solution depends on its primary energy consumption, net present value and global warming potential.

To deal with the multiple objectives that need to be optimized simultaneously, the Pareto concept is selected [19-21]. This concept treats all objectives equally during optimization and deduces the trade off between them by determining the non-dominated solutions. A solution is non-dominated if no other feasible solution exists that decreases one objective without causing simultaneously an increase in at least one other objective. For two objectives this results in a curve of non-dominated solutions (Pareto-curve), for three objectives in a surface of non-dominated solutions (Pareto-surface). For each solution in a population the Pareto score equals the number of solutions in the population by which the solution is dominated. Non-dominated solutions have score 0. Constraints, such as summer comfort and insulation standard, are treated through a penalty function. If one or more constraints are not met, a penalty is added to the Pareto score, proportional to the violation of the constraint. With the

Pareto concept all information on the objectives is maintained during the optimization process and weighting of the objectives can be postponed to the decision making process.

Life cycle inventory for buildings

A life cycle inventory (LCI) database for building-related materials and components is established to provide the ecological input in the optimization process. It also allows an analysis of the relation between the energy savings realized with extremely low energy buildings and the embodied energy needed to create these buildings.

As the optimization process aims at developing building concepts that are not only globally optimized, but also satisfy boundary conditions for indoor comfort and IAQ, the LCI does not focus on materials or building components, but considers the building as a whole. However the very long lifetime of buildings makes hypotheses on processes of the end phase highly uncertain and even unrealistic. Moreover, most buildings undergo several refurbishments during their lifetime, often resulting in thorough modifications. Therefore not the whole life span of the building is considered, but only the impact of one generation. This results in the scenario that the building is designed and constructed and then used and maintained by one generation during 30 years. Thus the phases of extraction, production, transport, usage and replacement are taken into account, whereas the end phase of the building is not considered.

The LCI is mainly limited to an inventory of energy flows and emissions. No impact indicators are calculated, except for the global warming potential. For each phase, LCI models are developed for materials, components and systems and aggregated data are calculated based on LCI data from the ecoinvent2000 database [22]. The energy consumption and CO_2 emissions during the usage phase are determined with dynamic building simulations with TRNSYS. The input data for ventilation and infiltration are calculated with COMIS. The weather data are hourly average data for the Test Reference Year of Brussels, Belgium. Summer comfort is evaluated with the method of weighted temperature exceeding hours according to [23]. Finally the sum of energy flows from all phases and the corresponding emissions form the optimization criteria for energy (total primary energy consumption) and ecology (total global warming potential). A sensitivity and uncertainty analysis is performed on the LCI building model. It showed that the sensitivity for errors and the propagation of errors is limited and that the errors of the different input data neutralize each other somehow. A more detailed description and discussion of the LCI building model can be found in [24].

Cost assessment

The economic impact of the building concepts is integrated in the optimization model through a cost-benefit analysis for a private building owner. Several economic criteria are calculated, such as investment cost, yearly energy cost and cost savings, total and net present value, static pay back time, etc. However, only one cost criterion is incorporated in the optimization process. As in the first step no assumptions are made on the heating system, no energy cost can be calculated yet. Therefore the initial investment cost serves as cost criterion in this phase. In the second phase all costs can be calculated. For this phase the net present value (NPV) serves as optimization criterion, to be able to extract the economically viable solutions.

All cost data for materials, components and systems are based on up to date (from 2005) price information and include working hour cost and VAT. Mostly a discount rate of 4% is adopted, but as the real discount rate is uncertain, different scenarios have been analyzed: a discount rate of 2%, 4% and 8%. Energy prices are based on private consumer prices for Belgium for May 2006. For the energy price evolution three scenarios are adopted based on [25]: low (+0%), medium (+2%) and high (+3 to 4% depending on the energy carrier).

RESULTS

Figure 1 presents the results for the individual dwelling with simple plan, with all variants analyzed during the optimization process in grey and the final optimal solutions in black. For each variant the total primary energy consumption over 30 years is given together with the corresponding NPV over 30 years. The results are valid for a low energy scenario.

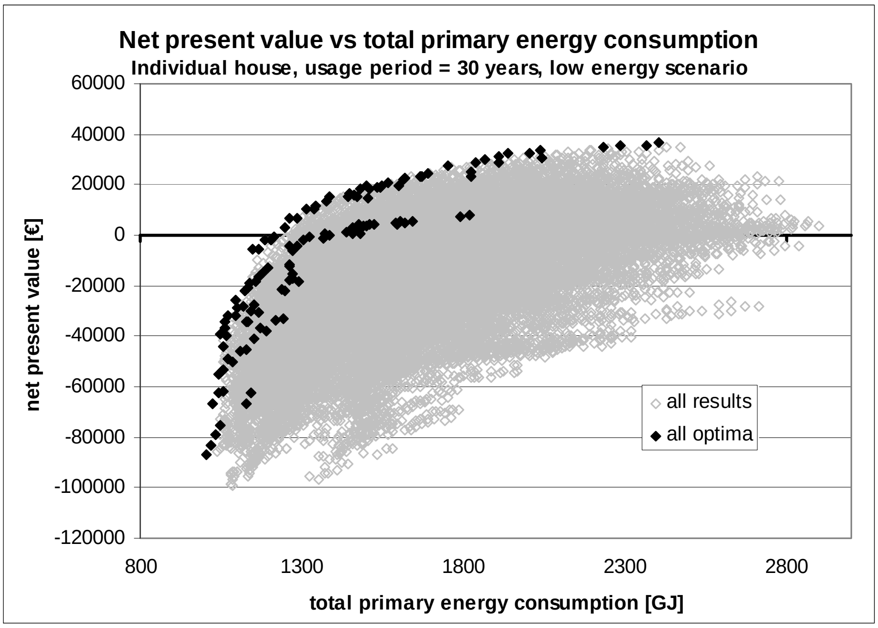

Figure 1. Globally optimized solutions for the individual dwelling

Some optimal solutions seem to be suboptimal as solutions exist with higher NPV for the same total primary energy consumption. This misleading visual effect is caused by the fact that the optimisation process considers three objectives, whereas the figure only shows two of them. Thus the optima in figure 1 are a 2D projection of that 3D trade off front, which does not coincide completely with the 2D trade-off curve.

Obviously the optima with a positive NPV are of most interest, as they are economically viable, even in the improbable case that the energy prices remain constant. Similar results are found for the other reference dwellings. Table 2 presents a summary of the results for all reference dwellings. Cost results are valid for the low energy scenario and a discount rate of 4%. Most values are expressed per m³ heated air volume (energy related values) or per m² heated floor area (cost related values). The insulation level in Belgium is expressed as a K-value, that depends on the mean U-value and the compactness. Therefore table 2 also gives the legal maximum for the mean U-value per reference dwelling.

Figure 2 presents the initial extra investment cost for the energy saving measures on the building envelope and installations as a function of the yearly energy cost. The graph is valid for the terraced house, but similar results are found for the other reference dwellings.

Table 2: Summary of the results for the global optimization of all reference dwellings

	Terraced house	**Semi-detached house**	**Individual house**	**Architectural house**	**Flat, centre**
Number of optima economically viable	79 16	138 48	125 62	36 15	35 17
Insulation level $U_{mean, optima}$ [W/m²K] $U_{mean, legal}$ [W/m²K]	K15-27 0.20-0.37 0.60	K13-34 0.15-0.40 0.52	K13-40 0.14-0.43 0.48	K13-20 0.13-0.20 0.45	K9-38 0.15-0.69 0.90
Net energy demand [MJ/m³,a]	15-90	15-90	25-100	30-55	< 40
Total primary energy consumption over 30 years [MJ/m³]	2000-4500	2240-4650	2230-5330	2500-3700	1300-2500
Total GWP over 30 years [kg/m³]	90-330	100-290	95-330	120-230	100-190
Extra investment cost [€/m² floor area]	40-500	80-800	3-840	100-720	50-340
Yearly energy cost [€]	300-880	300-900	300-1000	300-650	130-510
TPV over 30 years, low energy scenario [€/m²]	1100-1300	1000-1600	1000-1700	1000-1500	800-1050
NPV over 30 years, low energy scenario [€/m²]	(-260) - 60	(-360) - 300	(-500) -200	(-200) - 400	(-160) - 70
Static payback time [yrs]	9 - 50	3 - 57	(-4) - 62	2 - 23	(-3) - 35

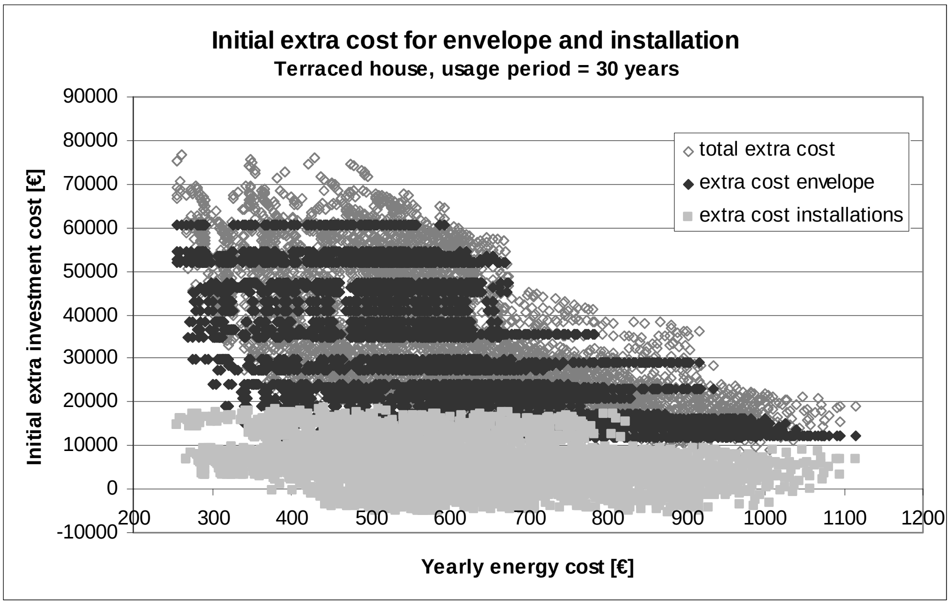

Figure 2. Terraced house: extra investment cost for building envelope and installations

DISCUSSION

Without any insulation the terraced house with a heated volume of 446m³ and a heat loss area of 220m², has a yearly energy cost of ca. 1600€. To halve the yearly energy cost, a total extra initial cost of at least 8.000 to 9.000 € is needed, consisting of 12.000€ extra cost for the building envelope and a negative extra cost of -3.000 to -4.000€ for the installation due to smaller dimensions of the installation. Further decrease of the yearly energy cost leads to an exponential increase of the initial extra cost. To realize an extremely low energy variant of this house with a yearly energy cost less than 300€, an extra cost of 60.000€ is needed for the highly insulated building envelope (U_{mean} = 0.14W/m²K) and 20.000€ extra for the installation (heat pump and mechanical ventilation system with heat recovery), compared to the non-insulated version. Similar results were found for the other reference dwellings. As table 2 shows, the NPV over 30 years for these variants is negative and thus, these variants are not economically viable.

Of importance however is that large cost and energy savings can be realized, also with economic viable concepts, if the hierarchy of energy saving measures is respected. This hierarchy is derived from the results and consists of the subsequent steps of most cost-effective energy saving measures:

1. Firstly invest in a good insulation level with good air tightness and a well designed natural ventilation system. The economic optimal insulation level lies far beneath the legal Flemish insulation requirement ($U_{mean, optimal} \approx$ 0.3-0.4 W/m²K ↔ $U_{mean,legal}$ = 0.5-0.6 W/m²K for compactness of 1.5 to 2m)
2. Secondly select a well performing heating system, at least a high efficiency boiler or condensing boiler with variable water temperature. Combined with the economic optimal insulation level, this represents the overall economic optimum. If the budget is available, a heat pump can be a good alternative, as it has a better energy performance. However due to its higher investment, it is beyond the economic optimum.
3. Finally, if for any reason, further decrease of the energy consumption is needed, heat recovery of the ventilation losses, a solar driven system and/or CHP is an option. However, although these measures improve the energy performance of the building, none of them is not economically viable over 30 years.

Analysis of energy price evolutions and discount rates showed that the economic optimum not only remains economic viable for all analyzed cases, the optimal combination of measures is also independent of these cost scenarios. Also the hierarchy of energy saving measures appeared to be independent of these scenarios. Obviously the economic viability of some measures, such as the application of heat pumps or mechanical ventilation with heat recovery, will depend on the cost scenarios, but in contrast to what sometimes is assumed, none of the scenarios causes a shift in the hierarchy of energy saving measures.

Concepts for extremely low energy dwellings have been determined for all reference dwellings, but none of them appeared to be economically viable for the current energy prices or discount rates. Only in case of much higher energy prices, some of these concepts will become cost-effective over 30 years. However, the largest barrier for all these concepts is the extremely high investment cost. Without financial support or incentives, these concepts will be limited to a minor part of consumers with a high environmental consciousness that is willing to invest such a large budget in an extremely energy saving house.

ACKNOWLEDGEMENT

The research was funded by the Flemish government through IWT, the Institute for the Promotion of Innovation by Science and Technology in Flanders.

SUMMARY

In this paper insight is given in the potentials for energy efficiency and renewable energy sources, specifically when applied to the built environment in the Netherlands. To this end, an analysis is presented of the building stock development from now to 2050 and building concepts and scenarios for a mid-century energy-neutral built environment in the Netherlands. Special attention is given to the potential of energy management systems in buildings.

1. INTRODUCTION

Our world is strongly on the move. The climate changes. More and more uncertainty exists concerning the energy supply. The discussion is no longer about the need to contemplate the future of energy supplies but about the way we can meet the future energy demand in a sustainable way. Both national and international policies are developed in the climate field and people devote themselves to energy transition.
In the Netherlands more than one third of the energy is used in the built environment. Insulation of buildings, more efficient comfort installations and local production of sustainable energy have strongly improved the energy performance of buildings in the previous decades. The potential for even better energy performance however has still not been exhausted. The urgency to bring all measures for improvement of the energy performance into action, and thereby connecting to nationally and internationally pursued policy, increases.
The Dutch research institutes TNO and ECN have started the strategic cooperation Building Future (BF) in the field of energy in the built environment in order to jointly give an impulse to this transition. Both institutes believe that by the middle of this century energy neutrality in the Dutch built environment can be reached, provided that the developments to this end are tackled energetically.

2. SCENARIO ANALYSIS

2.1. The scenario analyses tool

To assess the potentials of technological developments use is made of a scenario-analysis tool. Specific details about this tool can be found in [1].
The energy consumption profile of the Dutch built environment in 2000 is illustrated in Figure 1. The figure illustrates the distinct difference between residential and non-residential buildings: in residential buildings 65% of the total primary energy is used for heat (for space heating and domestic hot water), whereas in the non-residential sector electricity is dominant (52%). It is interesting to note that, although the total primary usage associated with the non-residential sector is lower than that of the

residential sector, the average energy per m^2 floor area is much higher in the non-residential sector. This is illustrated in Figure 2.

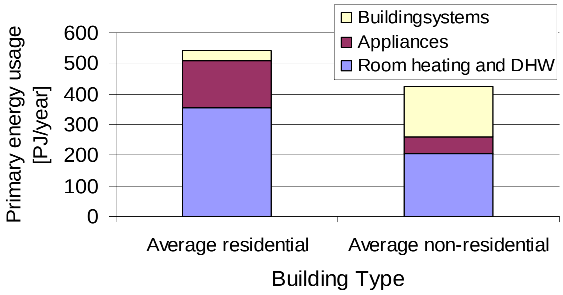

Figure 1. Building energy consumption profile for the built environment in 2000

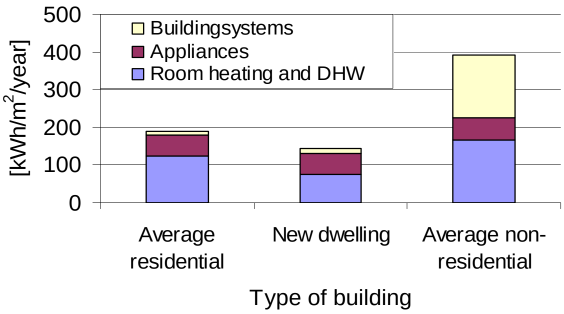

Figure 2. Building energy usage in 2000

Figure 2 shows that in the non-residential sector the higher primary energy usage per m^2 floor area is, for the main part, due to the larger amount of energy used for building systems (mainly HVAC and lighting).

3. ENERGY IMPACT MEASURES

3.1. Breakthrough technologies

In order to bring about the sought for transition to an energy neutral built environment, implementation of measures are considered which comply with the following philosophy:

1. Maximum demand reduction. With respect to buildings this implies measures such as:
   a. optimal insulation of the building envelope, minimal infiltration
   b. use of heat recovery on ventilation air and domestic hot water
   c. use of energy efficient appliances (A-label, energy conservation lamps)
   d. avoid standby losses of electrical appliances
2. Optimised use of renewable energy (RE), implying:
   a. optimal use of passive renewable energy such as solar heat, daylight and natural ventilation
   b. high-efficient renewable energy production, for instance from (high temperature, vacuum) solar collectors (possibly in combination with a μ-Organic Rankine Cycle (μ-ORC)), PV(T) panels, (small scale) windturbines
   c. balance demand and supply of renewable energy, both in energy sort (heat or electricity, temperature or power) and in time
   d. make use of (compact) energy storage, either local or using grid-connected / community systems
3. Technologies which make efficient use of fossil energy sources such as:
   a. heat pump (compression, sorption, magneto-caloric or thermo-acoustic)
   b. μ-Combined Heat (Cold) and Power Generator (μ-CH(C)P), stirling driven or using fuel cells (SOFC/PEMFC)
   c. community systems for instance using waste heat from waste processing plants

4. ENERGY IN THE BUILT ENVIRONMENT

4.1. Business as usual

Future energy consumption of the built environment mainly depends on the development of the building stock, but also on global and national developments, such as climate change, national turnover / economy and policy-effectiveness. The building related modifications influencing energy consumption involve construction of new residential buildings, demolition, renovation, extensive maintenance and installation replacement.

Taking all these developments into account, future energy consumption according to the 'Business As Usual' scenario can be outlined [2], [3].
Figure 3 illustrates that the expected total primary energy consumption in the building sector remains approximately 1000 PJp per year. Two significant trends contribute to this stabilization. Due to improved building insulation and more efficient comfort installations, gas consumption is expected to decrease. On the other hand, residential electricity consumption increases, mainly due to increasing cooling needs and increased use from household appliances (HHA). A growing number of ICT related applications contribute to increasing electricity consumption in the non-residential sector.

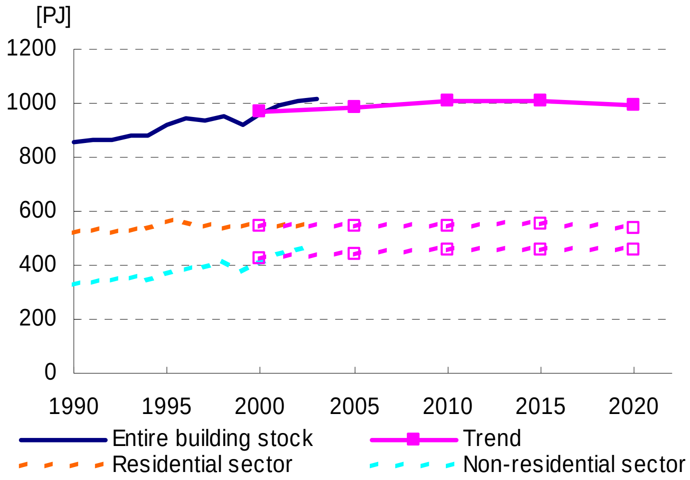

Figure 3. Total annual primary energy consumption in the building sector according to the 'Business As Usual' scenario.

4.2. Building Future scenario

The research program of Building Future (BF) aims at reducing the total net energy usage of the built environment to energy-neutrality around the middle of the century. To this end several technological and non-technological developments have to be undertaken linked to the building stock improvement moments.
To assess the potential of measures with the scenario tool first the effect of the measures separately is examined:

- Replacement of heating installations (every 15 years) including compact heat storage and thus reducing the energy for heating and domestic hot water (DHW), by 50% overall through system replacement, will result in a reduction of 130 PJ/year by 2050.

- If from 2015 onwards all new to build residential buildings would be energy-neutral a reduction of 65 PJ would result by 2050.
- Even if from 2015 onwards the introduction of net energy producing residential buildings would be taken on (starting at app. 4.5 GJ/year/building), a maximum reduction of 80 PJ/year could result by 2050.
- On the other hand, when all effort is directed towards renovation, for instance by implementing renovation packages that will reduce the demand for heat and DHW by a factor 4 and additionally integrate Renewable Energy (RE) from the sun in the building, the total reduction will not exceed 145 PJ/year by 2050. With a more modest package, but compared to current best practice still ambitious, consisting of only 50% reduction in demand for heat and DHW, a reduction of approximately 70 PJ/year by 2050 results, which is in the same order as the variant with energy neutral new buildings.
- Reduction of energy used by HHA by 2% per year from 2015 onwards might result in a total reduction of 145 PJ/year by 2050.

The above findings illustrate that, if an energy neutral built environment is to be reached, focus on only one of the building stock developments will not suffice; all the building stock improvement moments have to be used and a reduction of the user-related energy (HHA) should be accomplished as well. The required combination of measures (which are interrelated) for the residential sector is listed in table I.

Table 1. Impact of developments in residential sector on energy consumption [%] compared to the original situation according to BF scenario.

Mutation	Heat (%)	Electricity (%)	RE (kWh/a)
- new buildings	-40/year	-	4000
- renovation	-75	-20	2000
- maintenance	-15	-20	-
- installation replacement	-50	-50	-
- household appliances	-	-2	-

On top of these measures, the total energy consumption of the non-residential sector should decrease from 0% in 2010 up to 5% per year in 2025. This decrease in fact implies the same trend in energy consumption as for the residential sector. Most of the targets listed, albeit ambitious, can be achieved with introduction of the required building concepts around 2015, using existing technologies and technologies currently under development.

If all of the abovementioned measures are set in place the resulting development of the net energy usage of the built environment is depicted in Figure 4. Note, that the effect of the separate measures can not simply be added to obtain the result for the combination of measures, since some are interrelated. Figure 4 illustrates that building related measures (for new to build residential buildings and the existing stock) are not sufficient to reach energy neutrality. Also reduction of user related energy (HHA) and measures on district level (yellow line) should be introduced.

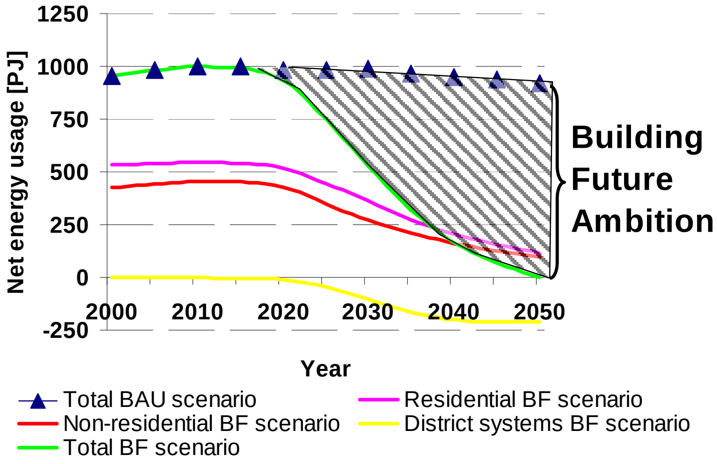

Figure 4. Development of net energy usage in Dutch built environment.

The effect of the Building Future scenario in terms of CO_2 emission directly related to residential buildings and user related electricity, is an emission reduction from 31.4 Mton in 2000 to 5.5 Mton in 2050. This implies an 83% reduction of building related energy for the residential sector with respect to the reference year 2000. With respect to Business as Usual in 2050 it implies a 2.5 times higher reduction of Mton CO_2.

5. BUILDING CONCEPTS AND KEY TECHNOLOGIES

The above conclusions on required ambitions for building concepts set the R&D agenda for Building Future. Energy management systems play an important role.

5.1. Building concepts

In the previous sections it is shown that in order to reach an energy-neutral built environment in the Netherlands around mid-century, there is a demand for building concepts with a higher (energy) ambition level than currently available. These ambition levels are the set point for a number of building concepts for residential buildings and non-residential buildings and are based on expected availability of technology in the year 2010, with estimated payback times of the complete concepts of approximately 15 years. In all concepts a strategy is used in which as a first step the energy demand is reduced as much as possible, in line with PassivHaus targets. The second step is to fulfil the need for energy wherever possible with renewable energy sources and, thirdly, using fossil fuels if still needed in an energy efficient way. As an example a short description is given of a concept for residential retrofit:

- Increasing the insulation levels of walls, floor and roof to R_C=7.5 m^2.K/W. Windows are replaced by triple glazing U=0.6 W/m^2.K.
- Improving the air tightness to 0.6 air changes/hour at 50 Pa.
- Heat recovery from ventilation air by using either a central balanced system or decentralised solutions like a facade integrated HVAC or a window-frame integrated system (new development).
- Application of external shading to prevent overheating.

As a reference case a typical Dutch terraced house of the late sixties is selected, since the major part of the housing stock currently up for renovation resembles the building characteristics of this type. The aim is to reduce the total energy demand for gas and electricity 'on the meter' to one quarter of the existing energy end-use before renovation. This means that besides building related energy (heating, domestic hot water, ventilation, lighting, etc.) also building related measures to reduce energy consumption of household appliances have to be taken into account. In addition to the reduction of the energy demand for space heating, described above, the following measures are incorporated:

- Heat recovery for DHW from the (renewed) shower
- Installation of intelligent sockets designed to minimise standby losses of HHA
- Heat recovery and storage connected to water distribution system of dish water and washing machine
- Replacement of standard boiler by a micro-Combined-Heating-Cooling-Power-generator micro-CHCP operating in combination with a solar collector.

The energy usage before and after renovation are illustrated in Figure 5.

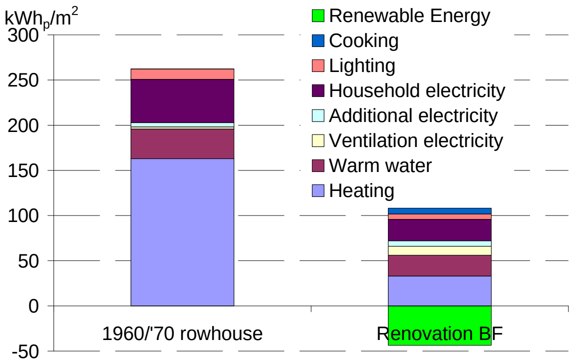

Figure 5. Energy usage before and after renovation.

5.2. Energy Management systems

Recent research has shown that the technical savings potential of advanced control systems in the whole Dutch built environment is estimated to be in the order of 190 PJ of primary energy per year (19% of the total energy usage of the Dutch built environment) and 12 Mton CO_2 emission reduction per year.

In table 2 and 3 below the estimated savings potential of some of the most promising control measures for the residential buildings and office buildings are shown. In addition to environment-adaptive control also user-adaptive and user-educational control is taken into account. User-adaptive control is characterized by adaptation of control to the behaviour and the preferences of the user. User-educational control goes a step further and aims to influence the behaviour and the preferences of the user, for example by providing feedback on the consequences of the current behaviour.

The estimates for the savings potential in the residential sector are based on model calculations for a typical Dutch terraced house built in the 70s. The estimates for office buildings are based on literature and practical experiences. They are calculated for office buildings built in the 80s. Both types of buildings are to be renovated shortly. To arrive at an estimate for the total savings potential the applicability of these measures in the current building stock has been taken into account. [4]

Table 2. Technical savings potential of advanced control measures in the residential sector.

control measure	savings potential per dwelling (GJ_p/a)
environment-adaptive	
irradiation control with solar shading	2.3
user-adaptive	
presence-based control of ventilation	3.0
window-closure-based control of space heating	0.3
disconnection of appliances in standby-mode	7.2
presence-based control of space heating	4.6
user-educational	
feedback on ventilation behaviour	1.9
general feedback on measured energy use	2.6
influencing hot water use to match available solar heat	0.4

Table 3. Technical savings potential of advanced control measures in office buildings.

control measure	savings potential per m^2 (MJp/m^2)
environment-adaptive	
daylight-dependent control of lighting	23
summer night ventilation, (incl. heat load reduction)	20
irradiation control with solar shading	14
user-adaptive	
presence-based control of ventilation	210
presence-based control of lighting	23
disconnection of appliances in standby-mode	41
user-educational	
improving operation and maintenance through monitoring	359
close windows during heating	20

From the tables it is clear that user-adaptive and user-educational control measures represent a large potential in addition to current state-of-the-art control measures (including environment-adaptive control). In the residential sector user-adaptive control measures represent two-thirds of the estimated savings potential, whereas user-educational control measures account for one-thirds of this potential. In office buildings the majority of the potential is covered by improved operation and maintenance through continuous monitoring. Presence-based ventilation also has a large per m^2 contribution, but in most of the situations where it is applicable this is already applied.

In addition to the use of advanced control systems for the reduction of primary energy use, it is also possible to introduce demand response in the built environment. This does not directly lead to the reduction of the primary energy use, but it will be necessary in future electricity grids with a high penetration of intermittent, renewable energy sources. In the residential sector there is a significant potential for demand response by shifting the electricity demand of various appliances: 34 PJ electricity demand response per year.

These figures indicate the large energy saving potential of energy management systems. At TNO and ECN, research is focussed on developing energy management systems, ranging from environment-adaptive, user-adaptive up to user-educational. First experiences in the latter category have been acquired in the EU-FP5 project EBOB (Energy Efficient Behaviour in Office Buildings [5]), see Figure 6. The effect of the system in an office building situated in Sweden, showed that more than 50% energy saving could be accomplished on indoor climate systems, with the major part on the heating system.

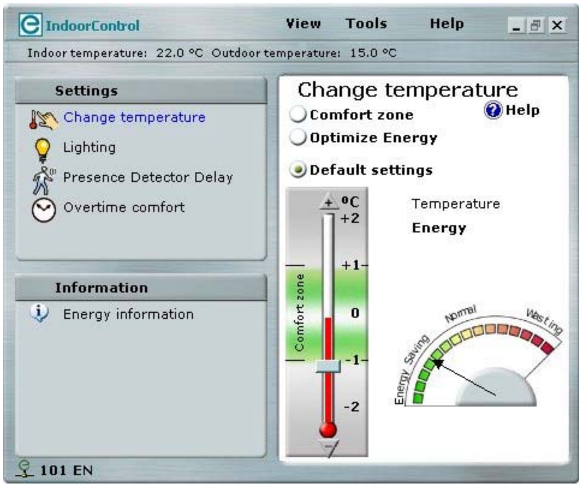

Figure 6. User Interface, providing feedback on comfort and energy.

6. CONCLUSIONS

The developments concerning the built environment indicate that in a 'business as usual' scenario, the energy usage will not decrease although a great potential for reduction exists. This potential can only be achieved by bringing about a transition to a sustainable energy system in the built environment, borne by all responsible parties.

From the Building Future scenario, associated with this transition, it can be deduced that all available measures for improvement should be used. This implies making best practice (such as Passivhaus measures), common practice and developing necessary technologies for essential concepts such as energy producing new residential buildings and factor 4 renovation concepts.

Potentially successful concepts incorporate technologies for building related and user related energy reduction as well as integration of renewable energy technology and intelligent energy management systems.

SUMMARY

This study investigated the impacts of lifestyle in terms of family patterns, life schedules and climate factors upon household energy consumption, as well as to unfold the main causes of household energy consumption under various climatic lifestyles. Based on the findings of the previous studies, it was assumed that space heating, cooling, lighting and entertainment/media equipments usages are the major lifestyle and climate related sources of household energy consumption. Based on these aspects, together with the typical life schedules of different occupation groups, climatic data and typical family patterns, lifestyles related household energy consumptions were calculated for Hokkaido (cool temperate climate), Saitama Prefecture (temperate climate) and Kogoshima Prefecture (varies from temperate to sub-tropical climates) of Japan, for years 2005, 2010, 2015, 2020 and 2025. The results confirmed that regional basis lifestyles in terms of family patterns, life schedules and climate factors are significant in dictating the household energy consumption trends.

INTRODUCTION

The Intergovernmental Panel on Climate Change (IPCC) has predicted a rise in the average global surface temperature of about 2°C between 1990 and 2100, and the average sea level is also projected to rise by about 50cm over the same period [1]. The projected climate changes are expected to result in significant adverse impacts on ecological systems and socio-economic sectors. In view of the continued rise of greenhouse gas (GHG) concentrations in the atmosphere, which may lead to dangerous interference with the climate system, the United Nations Framework Convention on Climate Change (UNFCCC) sets an ultimate objective of stabilizing GHG concentrations in the atmosphere. Under the Kyoto Protocol, the participating developed countries are committed to reduce their GHG emissions on an average of about 5% by the target years of 2008 to 2012 [2].

GHG emission is closely related to energy consumption. Based on the projection by the International Energy Outlook 2006, world carbon dioxide emission from the consumption of fossil fuels is expected to grow at an average rate of 2.1 percent per year from 2003 to 2030 [3]. The world CO_2 emission from the consumption of fossil fuels is predicted to increase from less than 20,000 million metric tons in 2003, to more than 40,000 million metric tons by 2030, as shown in Figure 1. Hence, in handling GHG emission issue, energy consumption should firstly be looked into.

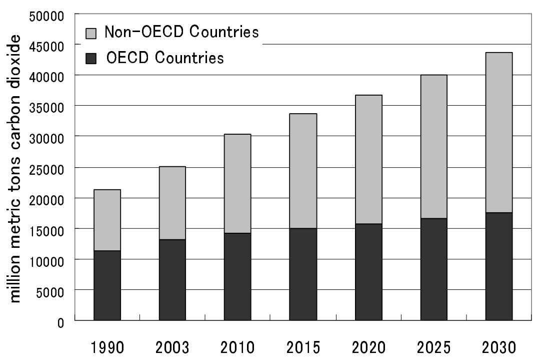

Figure 1. World CO_2 emissions from energy use, 1990-2030 [3]

In response to the above issues, the present authors had previously undertaken a study to investigate the urban energy consumption trends [4]. The said study was based on an integrated approach to investigate the embodied urban energy consumption over a period of 50 years using the System Dynamic model (SD model). The study found that household energy consumption and lifestyle aspects are among the significant factors in dictating the overall urban energy consumptions trend. The current study is a continuous work from the previous investigation and it was focusing on understanding of the interrelations between household energy consumption, lifestyle and climate factors.

In Japan, there are a number of existing researches on household energy consumption and lifestyle. However, little has been done in cogitating about the effects of lifestyle in terms of family patterns and life schedules of family members on household energy consumption. In view of these shortfalls, the purpose of this study is to shed new light on the impacts of lifestyle (in terms of family patterns and life schedules) and climate factors (under different climate zones of Japan) upon household energy consumption.

In most the previous studies on lifestyle and household energy consumption, questionnaire survey and long-term on-site monitoring/measurement methods were commonly used. Despite the better accuracy of data, the disadvantages of these methods are that they are very costly and time consuming. This study thus stressed to estimate the lifestyle related household energy consumption using on the existing life schedule data, which is low cost and time saving, and yet able to provide reasonably accurate estimate of energy consumption. The objectives of the study are to understand the effects of family pattern, life schedule and climate aspects on household energy consumption.

METHODS

The climate of Japan is predominantly temperate, but due to the large north-south extension of the country, the climate varies strongly in different regions. Generally, northern Japan is experiencing cool-temperate climate, central Japan is temperate, while southern Japan is under sub-tropical climate. In order to understand the differences in domestic energy consumption patterns under different climatic characteristics, the case study was divided into three parts according to the climate zones i.e. Hokkaido for cool-temperate zone, Saitama Prefecture for temperate zone, while Kagoshima Prefecture is experiencing climates that varies from temperate to sub-tropical. (cf. Figure 2).

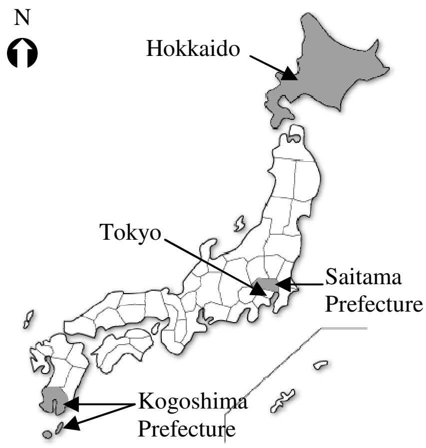

Figure 2. Locations of case study areas

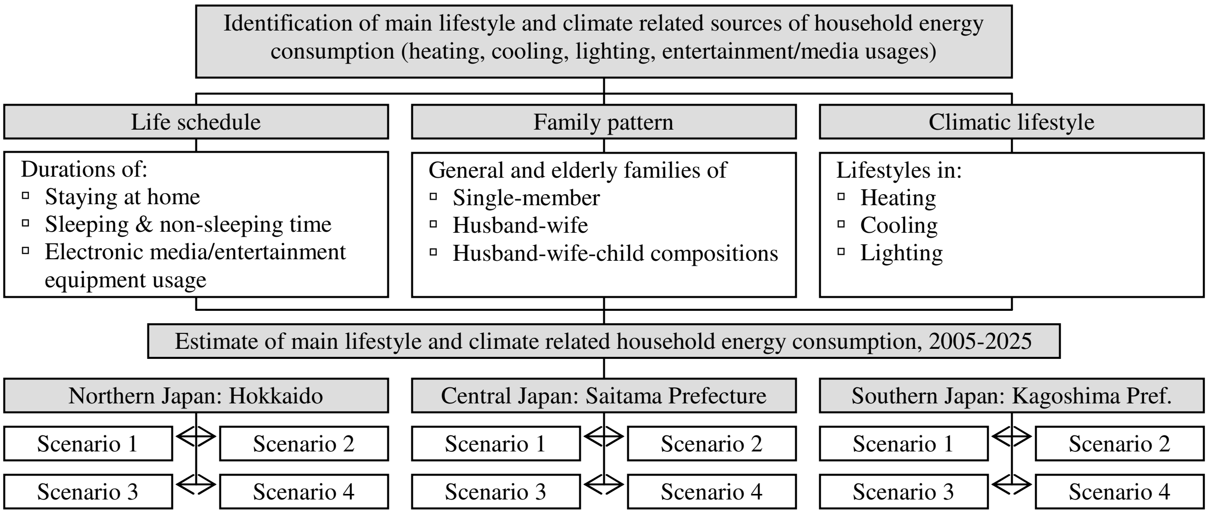
Figure 3 outlines the study methodology of the current investigation. From the literature review, it was pointed out in the previous studies [5,6,7] that space heating, cooling, lighting, electronic entertainment/media equipments and hot water supply are the major sources of household energy consumption. The current study adopted these factors as the major lifestyle and climate related sources of household energy consumption, however, hot water supply was excluded in this study due to absence of life schedule data on this aspect (hereinafter, household energy consumption by space heating, cooling, lighting and entertainment/media equipments shall be referred as ‘lifestyle related household energy consumption’).



Note: Details of Scenarios 1, 2, 3 and 4 are described in Table 1.

Figure 3. Study methodology

As mentioned above, the purpose of this study was to investigate the impacts of life schedule, family pattern and climate factors on household energy consumption. For this reason, detailed analysis had been carried out on these three aspects.

For the life schedules, typical life schedules of people of different occupation groups (working groups, housewives, retirees, students, children below schooling age) were identified based on the life schedule survey by the Japan Broadcasting Corporation in 2005, on 12,600 respondents throughout Japan [8]. In this study, the extracted data include the average durations of time staying at home, sleeping & non-sleeping times and for media/entertainment equipment usages (television, radio, CD/MD/cassette player and video).

Based on the above life schedule data and climatic information (sourced from the Japan Meteorological Agency and National Astronomical Observatory of Japan), as well as other relevant studies [5,7] together with necessary assumptions, typical trends of heating, cooling, lighting and media/entertainment equipment usages under the three climate zones were determined.

For family pattern, based on the projection by the Japan National Institute of Population and Social Security Research, cf. Figure 4, it was predicted that by the year 2025, about 79.5% of the families in Japan would be in the categories of single-member family (i.e. 1 person), husband-wife family (i.e. 2 people) and husband-wife-child family (i.e. 3 people) [9]. Also, it was projected that the proportion of population age 65 and above will increase from 19.9% in 2005 to 24.4% in 2025, and 35.7% by 2050 [10]. Based on this information, this study focused on these three family groups and the elderly family groups for the estimate and analysis of household energy consumptions.

Figure 4. Japanese family patterns [9]

Based on the above data and assumptions, typical lifestyles related household energy consumptions were estimated for Hokkaido, Saitama Prefecture and Kagoshima Prefecture, for years 2005, 2010, 2015, 2020 and 2025. The projections were carried out according to the official household projection data of each region [10]. The assumptions for energy consumption rates were based on the typical energy consumption rates of the relevant household electrical appliances in Japan, as well as reference to the household energy consumption survey carried out by the Architectural Institute of Japan (AIJ) [5].

The projections for lifestyle related household energy consumption were carried out for four scenarios as described in Table 1. Under these projections, it was assumed that there is no change of energy efficiency and no extra energy saving effort as compared to the present trend.

Table 1. Projection scenarios

Scenarios	Descriptions
Scenario 1	Projection based on the existing typical lifestyles and the official population projection statistical data [10].
Scenario 2	Instead of the official household projection data, it was assuming that the proportion of family groups in year 2005 to be remained unchanged over the projection period, while population growth was based on the official projection data [10] as in Scenario 1, and other factors as per Scenario 1.
Scenario 3	Instead of being housewives in the traditional Japanese families, this scenario assumed that the proportion of working women would be increased, while other factors as per Scenario 1.
Scenario 4	It is assuming that the average daily working hours of the working groups would be reduced by 1 hour over the projection period, while other factors as per Scenario 1.

RESULTS

Before presenting the analysis results, it is necessary to describe the trends of population and household growths in the three chosen case study areas. The 2005 populations of Hokkaido, Saitama Prefecture and Kagoshima Prefecture were about 5.7, 6.9 and 1.8 millions respectively. Projection by the Japan National Institute of Population and Social Security Research shows that the population of Hokkaido and Kagoshima Prefecture will gradually drop over the next 20 years, while in Saitama Prefecture, the population will slightly grow until 2015 then decrease gradually [10], cf. Figure 5.

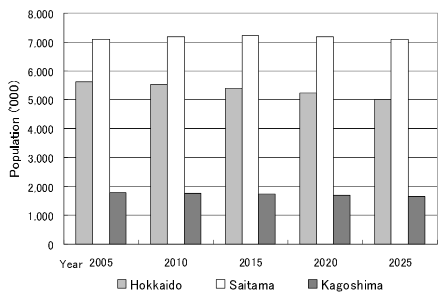


Figure 5. Population projections for Hokkaido, Saitama Prefecture and Kagoshima Prefecture [10]

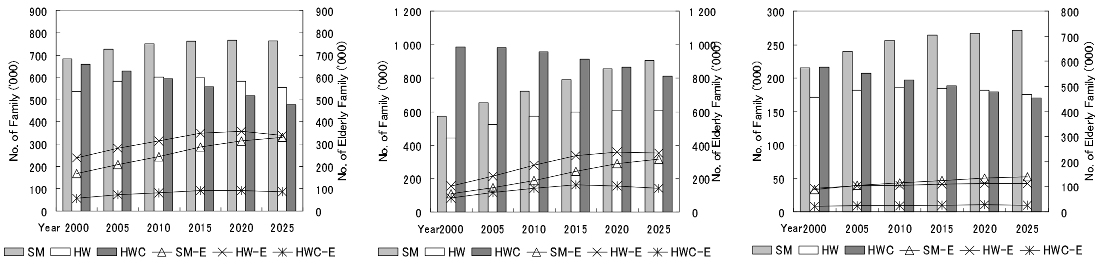
In the next 20 years time, as shown in Figure 6, the number of single-member families (SM) and husband-wife families (HW) will increase steadily, while the number of husband-wife-child families (HWC) will continue to drop in all these three regions. It must also be noted that the proportion of elderly families are projected to increase significantly, particularly in the single-member family and husband-wife family sectors. Projection shows that the family pattern in Japan is moving towards small family's direction, whereby the single-member families and husband-wife families will constitute more than 50% of the overall Japanese families by the year 2025.

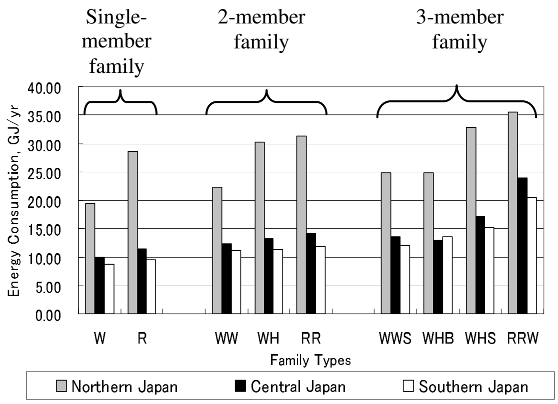


Hokkaido   Saitama Prefecture   Kagoshima Prefecture

SM: single-member family, HW: husband-wife family, HWC: husband-wife-child family, SM-E: elderly single-member family, HW-E: elderly husband-wife family, HWC-E: elderly parent husband-wife-child family

Figure 6. Household growth trends of Hokkaido, Saitama Prefecture and Kagoshima Prefecture, 2000-2025 [10]

Figure 7 illustrates the calculation results of the typical lifestyle related household energy consumption (per household per year) of different family patterns in northern, central and southern Japan. Validation of results has been done by comparison with the residential energy consumption survey conducted by AIJ [5]. This data were used as the basis for the analysis in this study. This figure indicated three energy consumption trends that worth mentioning, (1) households with retirees or housewives generally consume more energy due to longer hours staying at home, (2) northern Japanese households generally consume more energy due to space heating and lighting needs, and (3) the bigger the family, the higher the energy consumption is expected but the per person energy consumption rate is obviously less.



W: working, R: retiree, WW: both working, WH: working husband & housewife, RR: both retirees, WWS: working parent & schooling child, WHB: working husband, housewife & child below schooling age, WHS: working husband, housewife & schooling child, RRW: retiree parents & working child

Figure 7. Typical lifestyle related household energy consumption for each family

Figure 8 presents the calculated results of total lifestyle related household energy consumption for Hokkaido, Saitama Prefecture and Kagoshima Prefecture (for all households of each region) under **Scenario 1**. This scenario serves as the reference case for Scenarios 2, 3 and 4. Despite the expected continuous decrease of population in Hokkaido and Kagoshima Prefecture, the total lifestyle related household energy consumption increases until 2015 and 2020 respectively. For Saitama Prefecture, the population is expected to drop after 2015, cf. Figure 5, but the total lifestyle related household energy consumption will increase until 2020. The increase of energy consumption despite population drop is mainly attributed to the reduction of family sizes and growth of elderly households. The calculated results also show that energy consumption in Hokkaido is higher compared to the southern regions. It is basically due to energy consumption for heating. Similar findings were also showed in the residential energy consumption survey carried out by AIJ [5]. Another reason of higher energy consumption in the northern regions was the energy consumption for lighting. In Hokkaido, generally more than half of a year the sunset time is earlier than 6.00pm, while in Kagoshima it is only about 3 months.

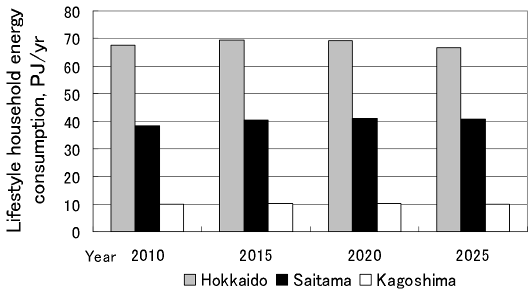


Figure 8. Lifestyle related household energy consumption under Scenario 1 (*based on official household projection data*)

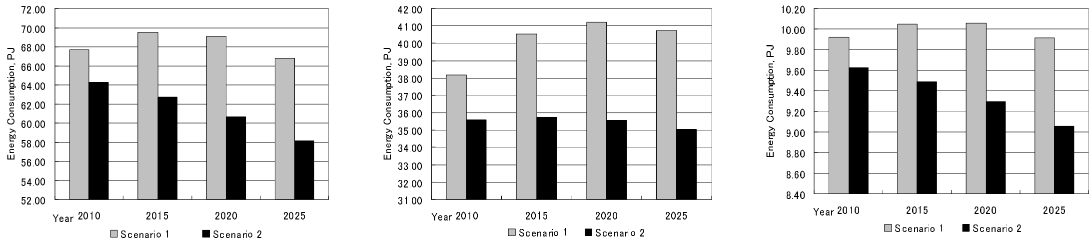
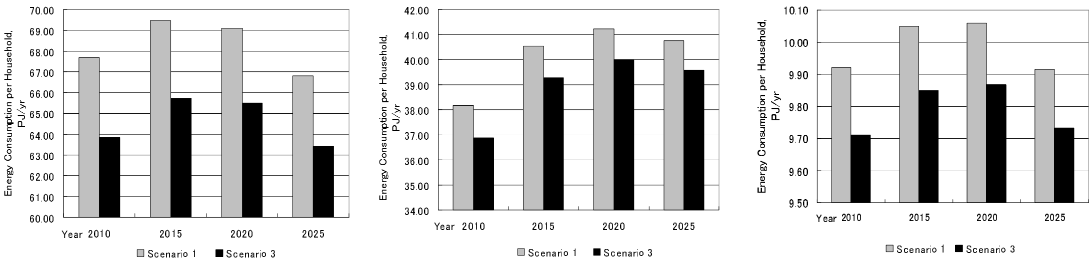
Figure 9 shows the calculated results of **Scenario 2** in comparison to Scenario 1. Under Scenario 2, the energy consumption was calculated based on the assumption that the 2005's family pattern (the proportions of each family group) will remain unchanged over the projection period. It is obvious that the energy consumption would be significantly reduced if there is no change of family pattern. Under the official household projection, the shares of single-member families and husband-wife families will significantly increase in future (cf. Figure 6). The reduction of family size results in higher energy consumption because of higher per-person energy consumption rate and increased number of households/residential units. The result concludes that family size has inverse relation with household energy consumption. In the case of Hokkaido, under Scenario 1, the energy consumption increases until 2015 but under Scenario 2, the energy consumption consistently drops over the projection period. The huge different of energy consumption under Scenarios 1 and 2 in Hokkaido was because of drastic drop of husband-wife-child families and significant increase of the share of single-member families under Scenario 1.



Hokkaido Saitama Prefecture Kagoshima Prefecture

Figure 9. Lifestyle related household energy consumption under Scenario 2
(*assuming that the family pattern of year 2005 remains unchanged*)

It was indicated previously in Figure 7 that households with housewives generally consumed more energy because of longer hours staying at home. **Scenario 3** attempts to validate this statement. Under this scenario, energy consumption was calculated based on increased proportion of working women (reduced proportion of housewives), which results in shorter duration of energy usage for heating, cooling and lighting. As shown in Figure 10, regardless of energy consumption at the workplace, increased proportion of working women will reduce the household energy consumption.



Hokkaido Saitama Prefecture Kagoshima Prefecture

Figure 10. Lifestyle related household energy consumption under Scenario 3
(*increased proportion of working women*)

Scenario 4 calculates the lifestyle related household energy consumption under assumption of reduced working hours. The Japanese Government is presently encouraging people to reduce working hours and spend more time with family at home. This scenario investigates its impact on household energy consumption if the average working hours of the working groups were reduced by one hour per day. The calculated results obtained (cf. Figure 11) shows that reduced working hour will result in increase of household energy consumption. It is because longer hours at home mean spending more household energy, particularly on space heating, cooling and lighting.

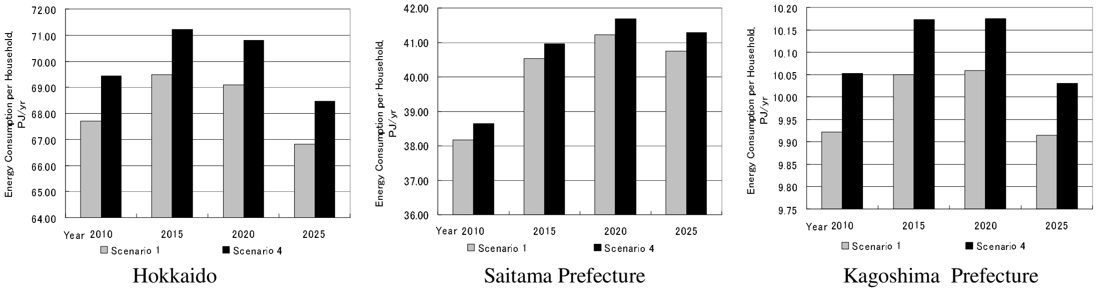


Figure 11. Lifestyle related household energy consumption under Scenario 4
(*reduced working hours*)

DISCUSSION

From the above results, it can be inferred that lifestyles in terms of life schedule and family pattern, and climate factors have significant effect in predominating over the household energy consumption trends.

In most of the previous studies on lifestyle and household energy consumption found in literature, the focuses were put on the energy saving potential by practicing energy saving smart lifestyle in term of the usage of energy consuming household appliances. However, it is difficult to get long-term cooperation from all households. For example, in the survey conducted by AIJ [5], the respondents were not practicing energy saving lifestyles in most of the aspects in household daily life.

Besides the aforementioned lifestyle aspect, there are also some other aspects of lifestyle that have indirect effect on household energy consumption. This study pointed out that lifestyles in terms of life schedule and family pattern do have significant impacts on household energy consumption. The longer time staying at home results in higher energy consumption, this is even more notable in the northern regions where long hours heating and lighting are necessary. Hence, the higher proportions of housewife and retiree population, who tend to spend more time at home, implying higher household energy consumption.

In terms of family pattern, smaller family size results in higher per-person energy consumption. In Japan, the family sizes are getting smaller and smaller (cf. Figure 4), as mentioned earlier, smaller family size is expected to result in higher household energy demand. The situation is worse when the smaller family size coupled with the rapid increase of retired elderly who consumes more household energy due to longer duration at home. Hence, in order to reduce energy consumption for space heating/cooling and lighting, it is deemed necessary to encourage the usage of smaller power space heating/cooling and lighting equipments. Besides improvement of energy efficiency, it can also be achieved by having smaller and enclosed partitions/room in the residential buildings (particularly the living room and dining room), so that same space heating/cooling and lighting effect can be achieved with smaller power equipments. Also, in term of lifestyle, the family members should be encouraged for shared usage of space heating/cooling and lighting by spending more times in the common spaces such as living room, particularly during evening time when most of the family members are at home.

Another aspect of lifestyle that has significant impact on household energy consumption is the climatic lifestyle. This study indicated that households in the northern regions of Japan (cold region) generally consume more energy in comparison with the southern regions (warmer region). As mentioned above, the main reasons are energy requirements for heating and lighting. Thus, as part of the efforts to reduce the energy consumption in the northern regions, it is necessary to reduce the heating and lighting requirement by passive design measures such as introducing solar radiation in winter through windows facing south, double glazing windows, airtight building, direct solar radiation for lighting, etc. for the residential buildings in the cold regions. Besides, it is also important to reduce the energy consumption for heating and lighting by introducing higher energy efficient heating and lighting equipments.

Although this study has effectively pointed out the importance of some aspects of lifestyle in household energy planning, it must also be noted that there are some limitations with this study. Firstly, fixed energy consumption rates were applied for the projections of future energy consumptions. So it may not reflect the actual amount of future energy consumption. Secondly, the household energy consumptions were calculated based on the typical life schedules and energy consumptions of household appliances and climatic data. Thus, it may not represent the actual energy consumption of each household. However, in this study, the main purpose is to understand the energy consumption trend rather than predicting the future energy demand. Hence, the results were deemed sufficient to illustrate the possible future household energy consumption trends. Nevertheless, these limitations will be taken into consideration in the future studies.

This study based on the case of Japan is deemed important as Japan is often used as a model for development in other Asian countries, hence the findings will have implications beyond Japan. Japan is now experiencing social change such as aging society and shrinking family sizes. This study found that these social changes will indirectly result in increased household energy consumptions. It is believed that the existing developing countries will also experience similar social change in future, which will eventually affect the household energy consumption trends. Hence, it is vital to take these aspects into consideration in their long-term energy planning.

SUMMARY

The energy utilization of a country can be evaluated using exergy analysis, which is a way to a sustainable development, to gain insights into its efficiency. The authors have conducted various studies on analyzing the energy utilization efficiencies of Turkey and extended here these studies by dealing with the investigation of the thermodynamic parameters in the Turkish residential-commercial sector (TRCS). These parameters are determined for the components of the TRCS in an attempt to assess their individual performances and are also compared to each other, while the analysis is done based on the actual data. The present study has clearly indicated the necessity of the planned studies towards increasing exergy efficiencies in the sector studied and especially the critical role of policymakers in establishing effective energy-efficiency delivery mechanisms throughout the country.

INTRODUCTION

Thermodynamic analysis including exergy analysis method is a powerful tool, which has been successfully and effectively used for estimating energy utilization efficiencies of countries. Based on the earlier studies conducted on the sectoral energy and exergy analysis of countries by many authors, the approaches used to perform the exergy analyses of countries may be grouped into three types, first two approaches; namely Reistad's approach and Wall's approach, as denoted by Ertesvag [1] and the last one Scuiba's approach [2]. The authors reviewed in detail analyzing and evaluating the energy and exergy utilization of countries [3] .

The concepts of exergy, available energy, and availability are essentially similar. The concepts of exergy destruction, exergy consumption, irreversibility, and lost work are also essentially similar. Exergy is also a measure of the maximum useful work that can be done by a system interacting with an environment which is at a constant pressure P_0 and a temperature T_0 [4,5].

Dincer et al. [6] reported that, to provide an efficient and effective use of fuels, it is essential to consider the quality and quantity of the energy used to achieve a given objective. In this regard, the first law of thermodynamics deals with the quantity of energy and asserts that energy cannot be created or destroyed, whereas the second law of thermodynamics deals with the quality of energy, i.e., it is concerned with the quality of energy to cause change, degradation of energy during a process, entropy generation and the lost opportunities to do work. More specifically, the first law of thermodynamics is concerned only with the magnitude of energy with no regard to its quality; on the other hand, the second law of thermodynamics asserts that energy has quality as well as quantity. By quality, it means the ability or work potential of a certain energy source having certain amount of energy to cause change, i.e., the amount of energy which can be extracted as useful work which is termed as exergy. First and second law efficiencies are often called energy and exergy efficiencies, respectively. It is expected that exergy efficiencies are usually lower than the energy efficiencies, because the irreversibilities of the process destroy some of the input exergy.

Exergy is the expression for loss of available energy due to the creation of entropy in irreversible systems or processes [6]. The exergy loss in a system or component is determined by multiplying the absolute temperature of the surroundings by the entropy increase. Entropy is the ratio of the heat absorbed by a substance to the absolute temperature at which it was added. While energy is conserved, exergy is accumulated

Exergy analysis provides a method to evaluate the maximum work extractable from a substance relative to a reference state (i.e., dead state). This reference state is arbitrary, but for terrestrial energy conversion the concept of exergy is most effective if it is chosen to reflect the environment on the surface of the Earth [8].

The main objective of the present study is to investigate the effect of thermodynamic parameters on the energy utilization efficiencies of the RCS by giving an application of Turkey. In this regard, thermodynamic relations used to perform energy and exergy analyses under varying reference (dead) state temperatures are given first. The relations for the RCS and its subsectors, such as water heating (WH), spaces heating (SH), cooking and electrical appliances (EA), are then presented. Finally, these relations are applied to the TRCS, while the results obtained are discussed.

METHODS

Thermodynamic parameters

A key discussion of the relevant theory of thermodynamic parameters for energy and exergy analyses is stated in this section. At the restricted dead state, the fixed quantity of matter under consideration is imagined to be sealed in an envelope impervious to mass flow, at zero velocity and elevation relative to coordinates in the environment, and at the temperature T_0 and pressure P_0 taken often as 25°C and 1 atm, respectively [5]. Some of the key aspects of thermodynamics in terms of energy and exergy used in the modeling are taken in Table 1 [9,10].

Energy and exergy efficiency calculations in residential-commercial sector

Residential-commercial sector includes space heating (SH), water heating (WH), cooking and electrical appliances (EA). In all activities in this sector, based on electricity, heat is produced. Quality of heat is Carnot factor that is strongly depend on temperature. Quality factors for some energy carriers and forms are 1.00, 0.60, 0.2-0.3,0-0.2, 0 for mechanical energy, steam (600°C),district heating (90°C), space heating (20°C), and earth respectively [11,12]. Energy efficiency is simple comparison of energy content of input and output energy carrier or flow. However, energy efficiency is defined as a function of requirement temperatures in system. Energy and exergy efficiencies values of these categories are determined separately as follows:

Space Heating: Heating options specified for heating systems are district heating, central heating, individual heating and stove. Firstly energy and exergy efficiencies of each other

energy carriers considered for all systems efficiencies are determined than heating system and fuel preference of dwelling units are determined according to their utilization ratios.
43-52% of all direct fuel use was for space heating, which is done entirely by home heaters having the same first law efficiencies of home stoves. Energy and exergy efficiency values of these categories are determined separately as presented above. Energy and exergy efficiencies of each other energy carriers considered for all systems efficiencies are determined and heating system and fuel preference of dwelling units are determined according to their utilization ratios. Quality factors of energy carriers are obtained from ref [13]. Reference state temperatures are from 0°C (273K) to 25°C (298K), SH here needs a temperature of 50°C (323K) Achieved energy and exergy efficiency values are illustrated in Table 2.

Table 1. Some of the key aspects of thermodynamics in terms of energy and exergy used in the modeling [9,10].

Process	Energy efficiency	Exergy efficiency
System Balance	$\dot{Q} + \sum \dot{m}_{in} h_{in} = \dot{W} + \sum \dot{m}_{out} h_{out}$	$\sum_{in} m_{in} ex_{in} - \sum_{out} m_{out} ex_{out} + \sum_{r} Ex^{Q} - Ex^{W} - I = 0$
Specific exergy		$ex^{PH} = (h - h_0) - T_0 (s - s_0)$
General Efficiency	*ε_1=(Energy in products / Total energy input) 100*	*ε_2=(Exergy in products/ Total exergy input) 100*
Electrical heating	$\varepsilon_{1e,h} = Q_p / W_e$	$\varepsilon_{2e,h} = Ex^{Qp} / Ex^{We}$ $\varepsilon_{2e,h} = [\,1 - (T_0 / T_p)]\, Q_p / W_e$ $\varepsilon_{2e,h} = [(\,1 - (T_0 / T_p)]\, \varepsilon_{1e,h}$
Fuel heating	$\varepsilon_{1f,h} = Q_p / m_f H_f$	$\varepsilon_{2f,h} = Ex^{Qp} / m_f \varepsilon_f$ $\varepsilon_{2f,h} = [(\,1 - (T_0/T_p)]\, Q_p / (m_f \gamma_f H_f)$ $\varepsilon_{2f,h} = [\,1 - (T_0/T_p)]\, \varepsilon_{1f,h}$
Electrical cooling	$\varepsilon_{1c,e} = Q_p / W_e$	$\varepsilon_{2c,eh} = Ex^{Qp} / Ex^{We}$ $\varepsilon_{2c,eh} = [(\,1 - (T_0 / T_p)] Q_p / W_e$ $\varepsilon_{2c,eh} = [\,1 - (T_0 / T_p)]\, \varepsilon_{1c,eh}$
Shaft work production via electricity	$\varepsilon_{1e,w} = W / W_e$	$\varepsilon_{2e,w} = Ex^{W} / Ex^{We} = W / W_e = \varepsilon_{1e,w}$
Shaft work production via fuel	$\varepsilon_{1f,w} = W / m_f H_f$	$\varepsilon_{2f,w} = Ex^{W} / m_f H_f = W / (m_f \gamma_f H_f) = \varepsilon_{1f,w} / \gamma_f$
Fuel driven kinetic energy production	$\varepsilon_{1f,ke} = m_s \Delta ke_s / m_f H_f$	$\varepsilon_{2f,ke} = m_s \Delta ke_s / m_f \varepsilon_f = m_s \Delta ke_s / (m_f \gamma_f H_f) = \varepsilon_{1f,ke} / \gamma_{f,ke}$
Improvement potential	$IP = (1 - \varepsilon_2)(Ex_{in} - Ex_{out})$	
Carnot factor	$Q_{carnot} = 1 - (\,T_0 / \,Tp\,)$	
Space/Water heating	$\varepsilon_2 = \left(\frac{\varepsilon_1}{q_{fuel}}\right)\left\{1 - \left[\frac{T_o}{T_2 - T_0}\right] \ln\left(\frac{T_2}{T_0}\right)\right\}$	
Overall SH,WH,EA,	$\varepsilon_{1osh} = [(a_1 * \varepsilon_{1,1c}) + (a_2 * \varepsilon_{1,2c}) + (a_3 * \varepsilon_{1,3c}) + \ldots\ldots.. + (\,a_9 * \varepsilon_{1,9c})]/100$	
Overall SH,WH,EA,	$\varepsilon_{2osh} = [(a_1 * \varepsilon_{2,1c}) + (a_2 * \varepsilon_{2,2c}) + a_3 * \varepsilon_{2,3c}) + \ldots.. + (\,a_9 * \varepsilon_{2,9c})]/100$	
Overall fuel	$\varepsilon_{1of} = [(f_{sh} * \varepsilon_{1osh}) + (f_{wh} * \varepsilon_{1owh}) + (f_c * \varepsilon_{1oc}]/100$	$\varepsilon_{2of} = [(f_{sh} * \varepsilon_{2osh}) + (f_{wh} * \varepsilon_{2owh}) + (f_c * \varepsilon_{2oc})]/\,100$
Cooking/ Cooling	$\varepsilon_2 = \varepsilon_1 \left[1 - \left(\frac{T_0}{T_2}\right)\right]$	$\varepsilon_2 = \varepsilon_1 \left[\left(\frac{T_o}{T_3}\right) - 1\right]$
All sector	$\varepsilon_{1,orc} = \frac{(\varepsilon_{1e} * e_{rc} + \varepsilon_{1of} * f_{erc})}{(e_{rc} + f_{erc})}$	$\varepsilon_{2,orc} = \frac{(\varepsilon_{2e} * e_{rc} + \varepsilon_{2of} * f_{exrc})}{(e_{rc} + f_{exrc})}$

Water Heating: In WH activities, various energy carriers are used that are natural gas, LPG, wood, dried dung, solar and electricity. First law efficiencies of energy carriers in water heating are determined by producer using temperatures 25^{o}C (298) and 60^{o}C (333K) for instance electric water resistant energy efficiencies is 98%, home gas water heater 60% Energy efficiencies of direct fuel use for water heating are assumed to be 27-80% [13,14]**.** We obtained the figures ranging from 3.10% to 10.80% for all energy carriers, as indicated in Table 2.

Cooking: In cooking activities, various energy carriers are used that are natural gas, city gas, LPG, electricity, wood and dried dung. Energy efficiencies used in the previous study, dead state (ambient) and process temperatures used in calculations are for cooking applications 20^{0}C and 120^{0}C respectively cooking efficiencies are assumed to be 50% for gas cooking stove, LPG, natural gas, 80% for electric cooking stove, 22% for wood, 20% for dried dung. These assumptions yield second law efficiencies ranging from 4.1% to17.2% for fuel use over the years studied, as indicated in Table 2.

Table 2. Energy and exergy efficiencies of residential-commercial sector at varying reference state temperatures [13]

		Temperatures (^{o}C)						Temperatures (^{o}C)					
	Energy carriers	0	5	10	15	20	25	0	5	10	15	20	25

Electrical Appliances: Electrical appliances includes, lighting, refrigerator, air condition, dish washer, washing machine, iron, television, computer and others appliances, as hair dryer, mechanical drive. In RCS, electricity is primarily consumed for refrigeration, lighting, air conditioning and other activities. For electrical appliances, input exergy is equal to input energy. However, in refrigeration and air conditioning applications, purpose is extracting heat instead of producing heat. It is assumed that the temperatures inside freezers and refrigerators are approximately –8^{o}C, the room temperature near the refrigerator coil is 20^{o} C and the coefficient of performance (COP) is calculated. It is assumed that the temperatures for air conditioning 33^{o}C and13^{o}C the COP is 2.0. Approximately 35-38% of all electrical use was for lighting. Lighting is assumed to be 80% incandescent and 20% fluorescent with first and second law efficiencies of about 5% and 4.5%, and 20% and 18.5%, respectively [13]. Combining the relevant first and second law efficiencies for lighting, we calculated ε_1 =9.5-15.5% and ε_2 = 8.70-14.3% for the years considered. 6-7% of all electrical use was for television and computer. First and second law efficiencies are assumed to be 80%. Dish washer and iron are heat-producing appliances that are evaluated using the relations given in Table 1. Mechanical drive requirements in the RCS are covered by small electric motors, while both energy and exergy efficiencies are about 70%. Electricity consumption values of other electrical appliances, for instance, computer and hair drying are estimated as given in Table 3, while the first and second law efficiencies of these appliances are listed in Table 2. In this sector, overall first and second law efficiencies for the entire RCS are calculated by aggregating both purchased electrical energy and direct fuel use. Using the numerical values obtained using in these models, the weighted mean overall energy and exergy efficiencies for the entire RCS were found.

RESULTS AND DISCUSSION

An application of the Turkish residential and commercial sector

The present application analyzes of the energy and exergy uses of the TRCS are based on thermodynamic parameters of process. This analysis is also based on the actual data for 2004, and it is used in the calculations. Total energy and exergy inputs for the same period according to energy carriers are obtained from Ref [14]. By 2004, Turkey's population and dwelling unit are determined to be 71332000 and 16487640, respectively. Total energy and exergy inputs to the Turkish sector were 3758.23 and 3710.24 PJ in 2004, respectively. In addition per/capita for total energy consumption and for RCS were determined to be 48.08 GJ/capita and 10.78 GJ/capita in studied year. In 2004, of Turkey's total end-use energy, 42% was used by the industrial sector, followed by the residential-commercial sector at 30%, the transportation sector at 20%, the agricultural sector at 5%, and the non energy (out of energy) use at 3% [15].

Energy and exergy utilization in the Turkish residential-commercial sector

The highest contributions came from fuel with 38.45 %, renewable resources (includes wood) with 38.20% and electric with 23.31% in 2004. In 2004, the highest contributions came from wood with 192.20 PJ [16]. However, natural gas usage has continuously increased in the TRCS for space heating, water heating and cooking purposes in several cities. Share of the energy utilization in the residential-commercial modes is as follows: space heating with 41%, water heating with 25%, cooking with 11% and electrical appliances with 23% in the year studied. These values are determined for 2004 obtained from Refs. [16,17].

Estimation of component and overall efficiencies for SH ,WH and cooking

Various fuels given in Table 3 are used for the purposes of WH, SH and cooking activities in this sector. Energy utilization values for the TRCS are also indicated in Table 3. SH requires the largest fraction of fuel with about 44%, while WH and cooking are responsible for 35%, and 21% of the total fuel inputs in this year, respectively. Based on the values obtained from Turkey's population census, the fuel preferences of dwelling units in the year of 1998 in Turkey [14]. The first and second law efficiencies of space heating were calculated as given below: 44% of all direct fuel use was for space heating, The needed temperature for the SH equipment is 50^{o}C and the ambient temperature is from 25^{o}C to 0^{o}C. Heating system and fuel preferences must be considered for calculating. Those preferences are given in Table 3 for the year of 2004. Overall energy and exergy efficiencies of SH were calculated as follows: Substituting the relevant numerical values into equations at state temperatures from 25^{o}C to 0^{o}C, we obtained ε_{1sh}= 48.74% to 90.02%, $\varepsilon_2$sh= 2.25 % to 7.18% in 2004 for SH.

Table 3. Distribution of residences according to fuel types and components of fuel uses and values for energy and exergy utilization of electric and saturation values of EA in 2004 (%).

Space heating					Water heating	Cookin g	Electrical appliances		
	Ratio of residence				Ratio of residenc	Ratio of residenc		Ratio of saturatio	Utilization of electric
Energy carriers	District	Central	Individua	Stove			Component	(%)	(%)
Coal (stove)				72.5			Lighting	100	36
Coal	58	39					*(Incandescent)*	*75*	*75*
Fuel-oil	21	24	6	0.8	2.04		*(Fluorescent)*	*25*	*25*

Total	**100**	**100**	**100**	**100**	**100**	**100**	Clothes drying	82	1
Ratio of	**4**	**6**	**6**	**84**	**100**	**100**	Other	3.2	3
							Overall electrical utilization		100

[a]The values for 2004 are obtained from Ref.[13].

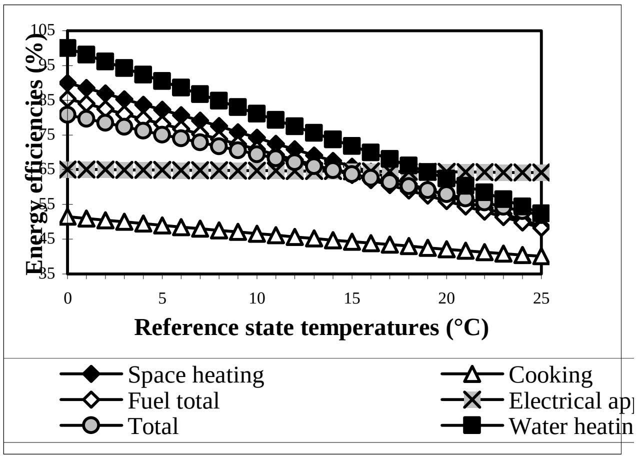
Based on the values achieved from Turkey's population census, the fuel preferences of dwelling units for wafer heating were determined for each province in 2004, 35% of all energy carrier use was for WH. The efficiencies of WH is calculated below. Fuel preferences must be considered for calculating that are given in Table 3 for the year of 2004. Overall first and second law efficiencies of WH are calculated; Using Eqs. and the numerical values assumed, we found $\varepsilon_{1wh,f}$= 52.43% and 100%,and $\varepsilon_{2wh,f}$=3.22% and10.10% in 2004 for WH. Overall first and second law efficiencies are found from 9.85% to16.05% and from 40.06% to 51.51% at reference state temperature changes for cooking in 2004, respectively.

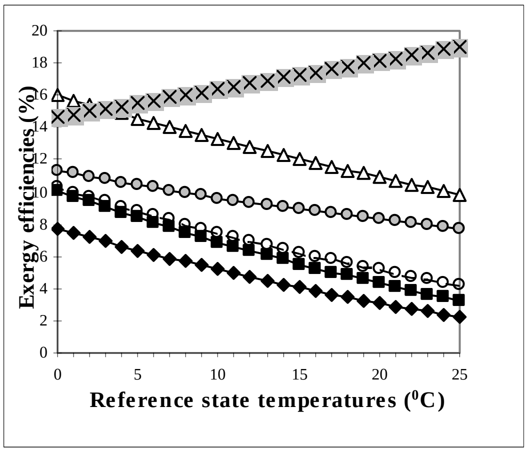
Estimation of overall efficiency and effectiveness values for electric utilization

Energy utilization values and the saturation values of EA for the TRCS are indicated in Table 3. Refrigeration requires the largest fraction of electricity with 42% in the year studied, followed by lighting with 36%. The overall efficiency and effectiveness values for electric utilization are estimated as follows: Lighting is assumed to be 75% incandescent and 25% fluorescent with first and second law efficiencies of about 5% and 4.5%, and 20% and 18.5%, in 2004, respectively [12,13]. Combining the relevant first and second law efficiencies for lighting, we calculated $\varepsilon_{1,l}$ =8.75-15.5% and $\varepsilon_{2,l}$ = 8.0-14.3% for the year considered. Refrigerators are consumed huge share of electricity. 40% of all electrical use was for refrigeration [13]. It is assumed that the temperatures inside freezers and refrigerators are approximately –8^o C, the coefficient of performance (COP) is 1.0 and the room temperature near the refrigerator coil is from 25 to 0^{o}C. Using equations, these assumptions yield second law efficiencies from 3.44 to 12.44% in 2004. Assuming that the COP value of the electric air conditioning unit is 2, this unit extracts heat from air at 14^{o}C and the outside temperature is from 33^{o}C to 8^{o}C, we found $\varepsilon_{2,a}$=14.46 and -3.46% in the year studied. 8% of all electrical use was for television and computer. Annual electricity consumption of television and computer has increased compared to previous years due to an increase in the number of TV channels, and usage of computer spread in daily life as at school and work in Turkey. Energy and exergy efficiencies are assumed to be 75%. Dish washer, iron, are heat-producing appliances that Using Eqs. and the numerical values assumed, we found first and second law efficiencies ε_{1dw}= 50% and 83%, and ε_{2dw}= 7.35% and 28.95% for 25^0C,and ε_{1i}= 100% and 100%, and ε_{2i}= 14.70% and 34.75% for 0^0C in the year studied for dishes washing and iron, respectively. Mechanical drive requirements in RCS meet to by small electric motors and both energy and exergy efficiencies of about 70%. We found energy efficiencies from 64.19 to 65.09% and exergy efficiencies from 14.65% and 19.02% for electrical use in 2004. This changes of efficiencies are illustrated in Figures1 a and b.

Energy and exergy utilization efficiencies in the entire Turkish RCS

Overall, first and second law efficiencies for the entire Turkish RCS were calculated by aggregating both purchased electrical energy and direct fuel use using equations. The weighted mean overall energy utilization efficiencies for the entire residential-commercial sector were found to vary from 51.89% to 80.75% in 2004 for reference state temperatures changes. There is major differently energy efficiencies for reference state temperatures changes in TRCS as shown in Figures 1a and 1b. In terms of energy loses this sector rank rather differently for about 19-38%. Overall exergy efficiencies in the year studied for the entire RCS were found to range from 7.74% to 11.16% in 2004 for reference state temperatures changes. This sector shows considerably important and comparable losses of energy and exergy. In the regard of exergy loses, this sector grades very differently, accounting for about 88-92% of all exergy loses.





a) Energy b) Exergy

Figure 1. Energy (a) and exergy (b) efficiencies of residential-commercial sector in Turkey at varying reference state temperatures for the year of 2004

CONCLUSIONS

In this study, we investigated the thermodynamic parameters of energy and exergy utilization in the RCS. The main results derived from the present study may be summarized as follows:

a) The determination of energy utilization efficiencies is needed for identifying energy efficiency and/or energy conservation opportunities, as well as for dictating the right energy and exergy management strategies of a country.
b) Changes in the reference state temperatures do not have an important impact on exergy efficiencies. Besides, these changes are displayed considerably effect on energy

efficiencies because of energy efficiencies are defined as a function of requirement temperatures in system.

c) A case study included the analysis of the energy and exergy utilization of the TRCS in the year of 2004. This analysis is done based on the actual data for the year of 2004. The energy efficiency value for the TRCS is found to be from 51.89% to 80.75% and the exergy efficiency value for that is obtained to be 7.74% to 11.16% for reference state temperature changes in 2004.

d) This study indicated that exergy utilization in Turkey was even worse than energy utilization. Turkey represents a big potential for increasing the exergy efficiency. It is clear that a conscious and planned effort is needed to improve exergy utilization in Turkey.

As a conclusion, the authors expect that the analyses reported here will provide the investigators with knowledge about how effective and efficient a country uses its energy resources.

Energy consumption vs. Energy performance?

Jorma Railio
FAMBSI, Finland

SUMMARY

The discussions around the implementation of the Energy Performance of Buildings Directive (EPBD) [1] – not only in national legislation but also in real practice – have revealed open questions and caused different interpretations. This paper deals with one question, and is based mainly on discussions and experiences in Finland.

Studies to prepare background material for energy calculation guidelines have been done, and several proposals for national legislation on energy performance certificates have been prepared. Proposals have been on review, with different levels of ambition, and with split views expressed in replies. The approach described here is completely independent of this legal process. It could, however, contribute as a complementary tool beyond the regulatory level.

The core of our approach is: make a clear difference between "energy performance" and "energy consumption". If this difference is vague, then a common misunderstanding of "lower energy consumption automatically means better energy performance" will stay and make an obstacle in all efforts for improved indoor environment and for more effective use of the building. The latter is valid for some building types, especially in public buildings like schools and sports facilities. Complementary tools are still to be developed to describe all elements of energy performance in parallel – suggestions for these will be discussed in the paper.

INTRODUCTION

The aim of this paper is to contribute in the "EPBD discussion" from the "Well Being Indoors" point of view: how to achieve good indoor environment with low energy consumption? This point of view is necessary, because otherwise "energy performance" is understood as "minimum energy consumption", ignoring the demand for good indoor environment. In the near future, more and more efforts in Europe and probably also globally will be put on reducing emissions and energy use, and this may become a real threat to our buildings and their indoor environment.

However, there are means already available to put together the "contradictory" demands for good indoor environment and low energy consumption. In other words, we should really aim at ENERGY PERFORMANCE, which takes into account the indoor environment and the actual usage profile of the building.

In 2003 the European Commission issued a new directive on Energy Performance of Buildings, the **EPBD**, 2002/91/EC [1]. This directive required that all member countries by January 2006 should have implement the directive in national building legislation. By today, delays have been occurred in a number of member countries because of several reasons.

If we go back a little bit, concern has been expressed in several countries about the costs of the obligatory measures (certificates and inspections) and about lack of competent persons to perform these measures. The progress in Finland has brought up also a tendency towards simplified certificates especially for existing buildings, based on the measured consumption only. This actually does not give an "energy performance certificate". For new buildings, the certificate will be based on calculations and is much up to the reliability of the calculation method and the assumptions made in the input data.

There are two major disadvantages in the "energy consumption certificate":

-It does not properly take into account the indoor environment. Closing off the ventilation system is rewarded; aims for high-level indoor environment are punished

-it does not properly take into account the real usage profile of the building. Really efficient use of the building (e.g. using a school building for various activities during evenings and weekends) is punished, keeping the building unoccupied for exceptionally long periods are easily rewarded

Energy performance is a very complicated issue, and therefore it would take probably many years before the methods and practices are established in Member States, and even more time before they become harmonised throughout Europe. On the other hand, there is a need to start the implementation process step by step, to keep the first steps rather simple in order that the process towards a more comprehensive implementation (also in practice) goes towards the right direction from the very beginning. In this way, the "simple" obligatory measures can also provide a good basis – and also encouragement - for complementary voluntary measures.

One of the practically open questions is: how to estimate the cooling load and energy? This may sound a minor issue regarding the overall energy performance. If the cooling loads and summertime temperatures are calculated by a simple monthly basis, this may result in serious underestimation of the loads. As a consequence, the client makes a decision to skip air-conditioning, or to have big windows, and when the building is completed and during the first warm summer days the indoor temperature goes up far over 30 ºC. Then it is too late to keep the temperatures in control by any reasonable combination of architectural means and air-conditioning. This has happened in reality, and this problem is increasing also in (well-insulated) residential buildings! And either the occupants will suffer and lose their productivity further, or the new building will be subject to early and expensive renovation.

To overcome contradictions in efforts for good energy performance and for good indoor environment (IEQ), a methodology is being developed on voluntary basis for guidance on technologies and design for simultaneous optimisation of energy performance and IEQ. If, like is in the case of many household appliances, everyone wants the highest energy performance, this is of course a good objective but what will happen if other key elements of a good building – architecture, and especially **indoor environment** - have to be sacrificed in the name of energy performance. **Figure 1** gives one possible approach [2] to have these aspects in parallel in design, and this methodology can be extended further to include also the regular inspections – using the same system and product data as the basic reference.

The EPBD gives a clear justification to consider IEQ in parallel with energy performance. However, no further guidance is given how to do this in real practice.

THE METHODOLOGY

Main principles and contents

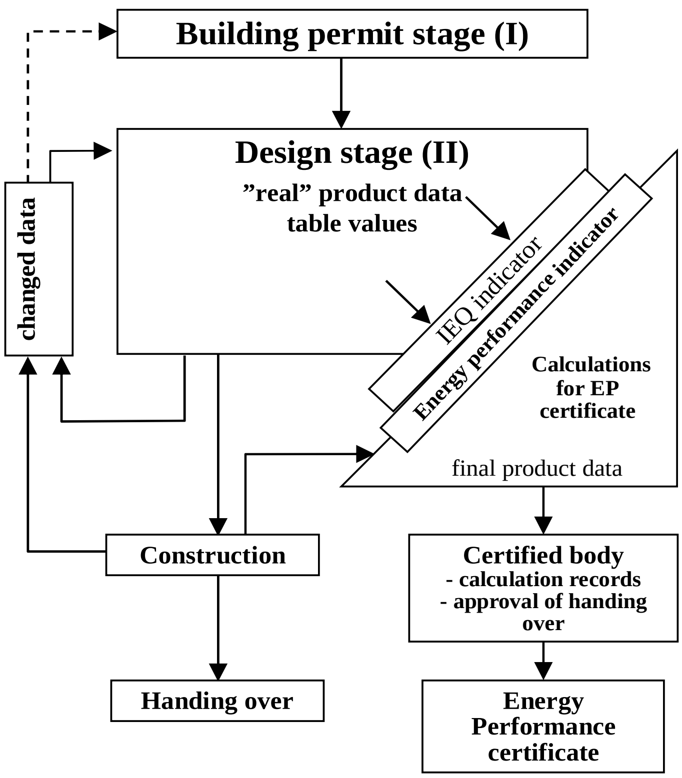
The main principles of the methodology are:
-the energy performance shall be calculated using the data that is available for the building and its building services systems and equipment.
-if, at the early design stage, there is not sufficient data available, default values shall be used for calculations.
-the calculations are revised as soon as exact data is available

Because this methodology was originally developed for other applications, the first stage to develop the procedures was to adjust the principles to fit in the EPBD implementation purposes. Testing of the methodology will take place in real practice.

The key issue is that the TARGET LEVELS for the indoor environment, as well as for energy performance, is defined in the very beginning of the design process. These target levels have to be defined in measurable quantities (indoor temperature summer – winter, energy consumption per surface area, etc.). Because in early design stages (building permit stage) the construction details and HVAC systems are not usually decided, the calculations have to be made first using default values and later on checked with real system and product data. This data should be also used as the basic data for energy performance certificate and for inspection of heating and air conditioning system. One main objective for further development of the methodology is to link together these three main elements of the EPBD.

Figure 1 presents the main flowchart of the methodology. The details will of course be different in different countries depending on how the design process proceeds, and also on the type of building. For example in residential buildings the design flow can be simplified a lot, and data from other similar building projects can be more used as a basis. In complex buildings, the process may become more complicated and contain more backcouplings.

The target level for energy performance could be specified as one figure like "xyz kWh/m^{2}a" or as an energy performance class e.g. according to prEN 15217 [3].



STAGE I

-"Basic" architectural and structural design

-Define TARGET LEVELS for

--Energy Performance (e.g. "A")

--Indoor Environment (e.g. "S1")

-verify by calculation that the legal requirements are fulfilled at standardised loads and operation

STAGE II

Design/Energy performance certificate

- the energy performance, based on standard usage – shall be calculated for the real building and its selected building services systems, and for defined Indoor Environment class

-the Energy Performance class shall be at least as good as targeted and calculated at stage I. If not, then backcoupling to STAGE I

-**Energy performance certificate - calculate** using the final product data (use of certified products should be encouraged and rewarded)

-the real energy consumption, based on the actual use of the building, can be calculated separately, and it may deviate from the consumption estimated for the certificate ("standard consumption")

Figure 1. Principles of design methodology for good energy performance and good indoor environment.

The same system and product data can provide the basis of inspections (obligatory based on Articles 8 and 9 of the EPBD, or voluntary), too. It shall be also pointed out that Figure 1 really concentrates on the elements of design process, just giving a general connection to energy performance certificate. It should be completed with blocks for inspections.

The methodology applies also for existing buildings, but in a different way. In existing building, subject to major renovation, sale or rent, an energy performance certificate is needed. In most existing buildings the data needed for the certificate is far from sufficient. Maybe even the original documentation is incomplete, or changes in the building envelope or building services systems are not completely available. For existing buildings it is very important to encourage the owner/ end user to improve the energy performance. For example it could be stated that in order to be certified to one of the highest categories, certain elements for the indoor environment have to be validated in one way or another (e.g. measured total ventilation air flow rate, recent balancing of ventilation, plus proper documentation). If the owner/ end user has already taken care of these issues by himself, then no more validation is needed. Of course, simple measures are often not sufficient (especially in complex buildings), but in many cases these are the necessary start – and a good wake-up and helping the user to pay attention to both IEQ and energy issues in a proper and balanced way.

Key elements

The stages of the methodology consist of the following calculations. This list does not describe the construction and handing over (commissioning) stages, or how to use the final data as basic information for energy performance certificate or inspections. This list is applicable mainly for newbuildings. In buildings subject to renovation a careful study of the systems and their documentation is necessary in the very beginning. In other existing buildings a case-by-case approach is needed and the list is only partly applicable.

Stage I *(building permit stage)*
-basic data for calculations
--targets for energy performance and indoor environment
--weather data
--indoor environment parameters
--building envelope
--hours of operation and occupancy
--lighting and other internal loads
--ventilation and infiltration

-energy demand calculations to verify that the legal requirements are fulfilled
--heating energy demand
--indoor temperature summertime -> need for cooling
--cooling energy demand
--system energy
--building net energy

Stage II *(design stage – detailed calculation)*
-detailed system calculations using real system and product data as soon as available
--ventilation system
--domestic hot water
--heating system
--lighting system
--cooling system

-delivered energy: heat, electricity etc.

As an example (still just a proposal), we may apply a "star classification" – the example in Table 1 is prepared for multi-storey buildings, both new and existing ones.

Table 1. Example of data sheets for indoor environment and energy performance design

OPEN QUESTIONS

The energy performance certificate has been discussed much more than the methods and inspections. But whatever the principles, final schedules and limitations are on national level in different Member States, it is of extreme importance that the certificate in new buildings is linked to the design process in one way or another, and that it based on what the building and systems really are – not only a "calculation just to satisfy the authorities". Figure 1 gives one approach to link the calculations and certificate together. In existing buildings, perhaps the most important issue is to find out the real performance of the building, in order not to sacrifice the indoor environment.

One big question is that lots of independent experts have to be trained in a relatively short time. Another question is: if, like is in the case of many household appliances, everyone wants the highest energy performance, this is of course a good objective but what will happen if other key elements of a good building – architecture, and especially indoor environment - have to be sacrificed in the name of energy performance. Figure 1 gives one possible approach to have these aspects in parallel in design, and this methodology can be extended further to include also the regular inspections – using the same system and product data as the basic reference.

DISCUSSION

In the implementation of the EPBD we should make a clear difference between **implementation in legislation** (the official implementation) and **adopting of the principles in real practice.** The latter is based on the official implementation, which should be completed by year 2009, and will probably take much more time, and require a high number of voluntary efforts in addition to the legal measures to ensure the fulfilment of the minimum requirements of the Directive.

The methodology presented in this paper is still under development, but based on elements already included in the good design and building practice. More detailed guidance and testing the methodology in real practice is needed, as well as tools to encourage the designers and clients to fix the data needed as early as possible. Testing the methodology in different types of buildings is also important to make the tools really practicable for different purposes, to fit also for use in existing buildings, and to avoid unnecessary complexity and unnecessary repetition of routine calculations in the design and construction process.

Tools for manufacturers – partly extending or revision some existing standards and product certification schemes are also needed so that certification of products will become really rewarding. The classification already applied in mandatory labelling schemes can be useful also in voluntary schemes.

It is too early to give estimates of the schedule of the "**adopting of the principles in real practice".** If we take the experiences from energy-labelling of household products, the future looks very promising: everybody wants to buy "Class A". For washing machines, people want the highest class also for other important characteristics: the washing and drying performance. So, why not to aim at the best energy performance and indoor environment simultaneously?

However, the complexity of decision-making in construction may slow down the development. Where indoor environment is clearly recognised as a key element for productivity, it is surely considered properly (or at least should be). In housing, the main target is still too often "to fulfil the minimum legal requirements with minimum investment".

The EPBD gives many opportunities. The main challenge is, however, to increase the common knowledge among our profession and among our customers, about the benefits of good energy performance and good indoor environment. The presented methodology provides one platform in this mission.

SUMMARY

This paper deals with the use of passive solutions to reach thermal comfort conditions in an educational building under specific tropical climatic conditions. A case study of a green high school building located in the French tropical island of "La Reunion" at an altitude of 600m was used. The building designers initially planned for mechanical air conditioning in the classrooms and in the administrative section however dynamic simulations pointed out that with an optimisation of passive solutions such as solar protection, insulation, natural and mechanical ventilation; active air conditioning systems could be avoided. Condensation risks during the winter season were analysed also. The high school has been in service since September 2003. This research was the first scientific study conducted in the highlands of a tropical island. This paper presents the methodology used and describes the results and passive solutions recommended which are now widely used by building owners to design new building projects located in the same range of altitude.

INTRODUCTION

The methodology and results presented in this paper were developed within the framework of a research project funded by the Regional council of La Reunion and SEMADER, which is the company responsible for the construction of the high school. The island of La Reunion is a small French tropical island located in the Indian Ocean (21° of latitude south and 55,5° of longitude east). The island is only 70km long and 50 km wide (see Fig.1) and has a growing population. It is estimated that in the next 15 years, the population will have reached the billion marks with 25% of them being less than 20 years old. Ten more high schools are needed to account for this growing population, highlighting the importance of influencing green construction for new educational buildings in every sector –elementary schools, primary schools, colleges, high schools and university buildings. The urban areas mainly affected have so far been located along the coastline (see figure 1), but the recent regional urban planning act focuses now on developing the mid-highlands of the island rather than extending new urban areas along the coastline. This is mainly because most of the land is dedicated for the sugar cane industry. Electricity output in these highland areas is restricted and the area is mainly oil-powered (60%) and it is predicted that the energy supply will encounter difficulties with the 7% per year growing energy demand. The Regional Council is aware of the energy problem that is facing the island of La Reunion and has decided to launch a wide program of demand side management and development of the use of renewable energy [1]. The final aim of this programme is to have the island energy autonomous by 2025. A part of this program is dedicated to the construction of green buildings, which is the subject of this paper.

METHODOLOGY

The project consisted of the following steps:

1. Elaboration of typical hourly climatic data representative of the summer season and of the winter season;
2. Choice and Modeling of the typical buildings (that is, classroom, office and computing room);
3. Determination of the outputs and the simulations tools;
4. Simulation and analysis of the results;
5. Synthesis of the results and conclusions.

Climate in La Reunion and typical hourly data.

As shown in Figure 1, the climate in the island of La Reunion can be divided into four main zones [2]. The first two zones correspond to standard coastal tropical climates. They are both located below 400 metres and differ mainly by the average wind speed. The downwind coast, named zone 1, is the driest, the sunniest and the warmest. This part of the island is protected from trade winds by the mountains. The upwind coast (that is, zone 2) is wet because of its wind exposure. The mean global solar radiation is the same as in zone 1 (5000 kWh/m²/year). The highlands, named zone 4, are situated above 800 metres. The temperature is cool in summer and cold in winter with a minimum that can go down to minus 1°C. The period of sunshine remains good and the humidity is very high.

	Inhabitants	
Zone 1	245 000	31%
Zone 2	385 000	48%
Zone 3	132 000	17%
Zone 4	38 000	5%
Total	**800 000**	

Figure 1 : Urban areas and climatic zoning of the island of La Reunion

The high school is located in zone 3 in the suburbs of a town called Le Tampon. For this reason, we will focus on this specific zone. The main climatic features are given in Table 1. Zone 3 is a mid-highlands zone located between 400 and 800 metres above sea level. The average yearly temperature is 18.2°C. The mean solar radiation and the humidity are high all year round. The climate in this zone does not correspond to an existing classification mainly because of the altitude. Comparison with a “standard tropical climate” highlights the main differences to be summer conditions which can be hot and humid with temperature and humidity values that can go up to 30°C/78% and winters that can be cold for a tropical climate with temperature and humidity values that can go below 12°C/70%. Due to this, the existing references on recommendations for building in tropical climates can not be applied to this zone [3]. The recent publications concerning the thermal comfort in classrooms deal with the thermal conception of buildings in tropical climates in Singapore or Hawaii [4] [5] and mainly focus on the comparison between the thermal sensation of the occupants and the ASHRAE Standard 55-92 [6]. Even the recent work of Kwok in Japanese schools deals with a field survey and a comparison of the occupants preferred thermal state to the ASHRAE comfort standard [7]. While the climate there is close to zone 3, with hot and humid summers and mild winters, wider discrepancies exist between the mean temperatures in summer and winter. These are 27°C and 4°C respectively instead of 22.8°C and 17°C for zone 3. Other research concerning the energy performance of school buildings has been conducted in Israel by Becker [8] for hot and dry conditions in summer and moderate conditions in winter. The climate which seems to be the closest to that of zone 3 can be found in the work of Lam where passive design principles have been defined for different climatic zones in China by using a bioclimatic approach. In the southern part of China, the average annual temperature is around 21°C with hot and humid summers and mild winters. Lam recommends using natural ventilation for passive cooling in summer and assesses that passive solar design is sufficient enough to ensure the comfort is maintained during winter.

Table 1: Main features for Zone 3 (mid-highlands) –annual, summer season, winter season

	Air temperature (°C) and associated Relative humidity (%)						Diurnal temperature range ΔT T_{max} - T_{min}	Mean global solar radiation (kWh/m²/day)	Mean wind speed (m/s)
Typical day	T_{mean}	RH	T_{max}	RH	T_{min}	RH			
Annual	**18,2**	**76%**	**25,1**	**64%**	**16**	**73%**	**9,1°C**	**4916**	**1,5**
Mean summer	22,8	79%	28,3	68%	18,9	80%	9,4°C	5812	1,4
Extreme summer	23,5	75%	30,1	62%	19	78%	11,1°C	7008	2,5
Mean Winter	17	73%	21,9	62%	13,2	74%	8,7°C	4855	1,7
Extreme winter	14,8	75%	18	67%	12	70%	6°C	2846	3,5

With reference to school building design, it can be seen that the existing material for school design recommendations is not suitable for the climate in question. That is, in zone 3, the building design has to provide for both tropical climates in summer (use of cross ventilation and solar shadings) and temperate climates in winter (passive solar heating and condensation risk). A main charactistic of the mid-highlands climate of La Reunion is that neither air-conditioning nor heating are necessary if some basic passive design principles are applied. This was the purpose of this study to demonstrate this assessment through the use typical meteorological data file and dynamic thermal simulations. The recommandations through this research could then be applied to new building projects in the area and on a wider scale through setting local thermal standards [2].

The generation of hourly typical meteorological days for zone 3 has been performed by calculation methods developed by David [10], [11]. These methods are based on algorithms of classifications applied to several years of data. An eleven year period from 1993 to 2004 has been considered to generate the typical sequences which can be read as a TMY format file by our simulation code. The climatic data include outdoor air temperature, relative humidity, global and diffuse radiation, wind speed and wind direction.

Main features of the high school

The high school consists of a three storey building with a capacity of 720 college students (which can be expanded to 900). The total floor space is 8352 m². Typical to most schools, it is composed of different sections comprising the administration part and different use classrooms (for tutorials, practical work and computer activities). A specific building on the east side is dedicated to sport activities. All the walls are 16 cm thick concrete walls with no insulation. The roofs are double skin consisting of a terrace concrete roof with 6 cm of external insulation and a 10% slope corrugated iron roof above this. At the design stage of the project, all the buildings were already cross ventilated with sun shading devices, louvres and overhangs. Most windows are louvres but some windows have slide-windows with an additional louvre on the side. Heating and cooling air conditioning systems were supposed to be installed in the administrative building, staff room, and in the on-site row houses of the administrative staff. Computer rooms and classroom are naturally cross-ventilated. No mechanical ventilation or air conditioning was planned for these rooms.
The high school has a rain water storage tank that collects water for the toilet and watering use only. 391m² of PV panels are installed on the northern roof, which represents an installed power of 51 kWp. The annual production is estimated to be 66,300 kWh.

Figure 2 : The three storeys main building with sun shading devices, external corridors facing north and louver windows (right). All the classrooms are cross ventilated with sliding windows, louvers and air fans (left).

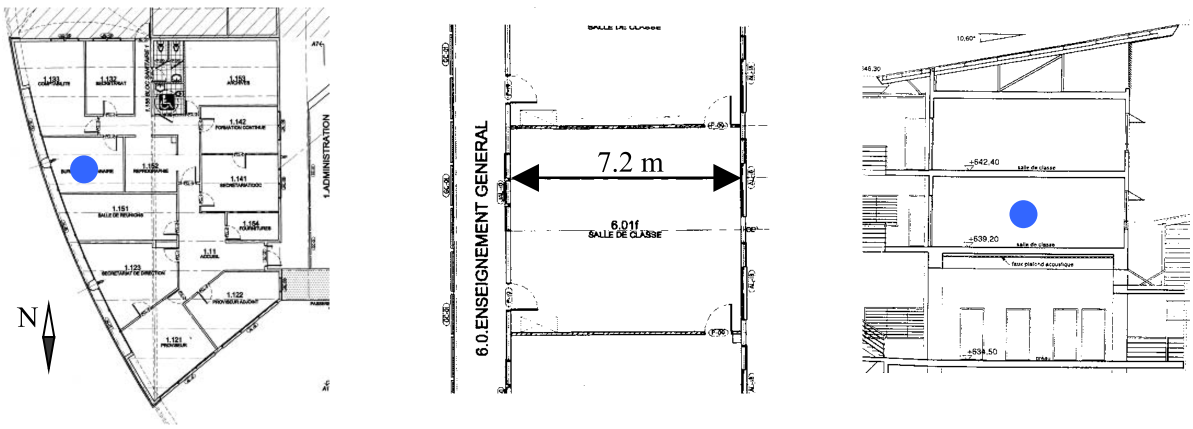

Figure 3 : Plan view of the administrative offices (left), of a typical classroom (middle) and cross section of a typical building with the double skin roof (right). The typical rooms used for the simulations are spot marked.

This study mainly focused on three typical rooms as they represented 80% of the floor space. These were one administrative office, one classroom, and one computing room. The size of the two classrooms is the same. Only the internal loads due to the computers differ.
For each typical room, different scenarios of building components (insulation) and air renewal have been tested. As previously stated, the main problem of thermal design in this area comes from the humidity during winter time [11]. The lack of insulation coupled with no mechanical ventilation is the main cause of such problems. At the same time however, the summers can be hot and uncomfortable. Due to low temperature at night during summer, night cooling is a possible solution to consider. This passive cooling technique (used mostly in European countries) has not been tested as yet in La Reunion [12].

Outputs and simulation tools

A thermal and air flow simulation program was used, which in conjunction with a model of large openings under pressure, showed the impact of natural ventilation on thermal comfort. (See reference [13] for a detailed description of Roldan's mass transfer model. The model takes into account one air volume per room neglecting stratification. The comfort indices chosen for summer time were Givoni's comfort diagram [14] and the resultant temperature T_{res}. The comfort zones allow us to find the percentage of points within each comfort zone (0 $m.s^{-1}$, 0.5 $m.s^{-1}$ and 1 $m.s^{-1}$) as well as the number of hours of discomfort. T_{res} is a weight equation between the air temperature T_a and the average wall temperature T_{rm} for a naturally ventilated room In summer $T_{res} = 2/3.T_a + 1/3\ T_{rm}$. During winter time, the Predicted Mean Vote (PMV) [15], the resultant temperature and the condensation risk were used as outputs. In winter $T_{res} = 0{,}45.Ta + 0{,}55.T_{rm}$ which is the usual equation used for low-level indoor air velocities.

RESULTS AND DISCUSSION

As a large number of simulations and data have been carried out and analysed, the results presented in this section will focus on a typical office only. The most important conclusions for the other rooms studied will be presented however. The whole research report is available by request to the corresponding author or by downloading it at http://lpbs.univ-reunion.fr.
The office room has 13m² floor space with a window facing west which has a solar factor of 0.3 (one meter deep solar shading device with clear glass). The internal loads consist of one person (occupancy from 0800 to 1700hrs), artificial lighting from 1400h to 1700h (13 W/m²) and one computer from 0800h to 1700h. The main objectives are to check the possibility of removing air-conditioning devices while ensuring a good level of comfort is maintained all year round and avoiding problems due to condensation.

Comfort conditions during summer – typical office room

Different scenarios of mechanical air renewal listed in Table 2 have been considered.

- Case 1 : one ACH (ie18 m^3/h) 24 hours a day;
- Case 2 : one ACH from 8h to 19h then 20 ACH from 20h to 7h, window remains closed ;
- Case 3 : one ACH from 8h to 19h then 20 ACH from 20h to 7h, windows is opened from 14h to 17h.

One can notice that the mechanical night cooling lower the morning resultant temperature by 4°C. It remains below 26°C until 13h. With opened window, the mean maximum temperature never goes above 27°C during the whole summer. The effect of opening the window during the afternoon (case 3) lowers the temperature by 1°C compared to case 2.

Figure 4 shows the impact of mechanical night cooling in terms of thermal comfort. Case 3, which is definitely the best scenario, (grey tint in Table 2) allows to have 100% of the time inside the 0,5 m/s comfort zone (see Table3). That means that air-conditioning is not necessary. The speed of 0,5 m/s can be obtained by using cross ventilation and/or coupled with the use of one air fan. Even if for acoustic reasons the window remain closed (case 2), the use of air-fan is sufficient enough to ensure the comfort conditions 100% of the time.

Table 2 : Impact of the different scenarii of mechanical air renewal on the resultant temperature

	T_{res} 8h-12h	**T_{res} noon**	**T_{res} 13h-17h**	**Mean $T_{res,max}$**	**Abs $T_{res, max}$**
Case 1 : 1 ACH 24h/day	27.5	28.5	30.4	30.7	32.2
Case 2 : 1 ACH /20 ACH (20h-7h)	23.6	25.2	27.4	27.8	29.1
Case 3 :1 ACH 20 ACH (20h-7h) windows opened in the afternoon	23.5	25.1	26.1	26.8	28.4
Outdoor temp	25.6	26.2	25.1	27.3	30.1

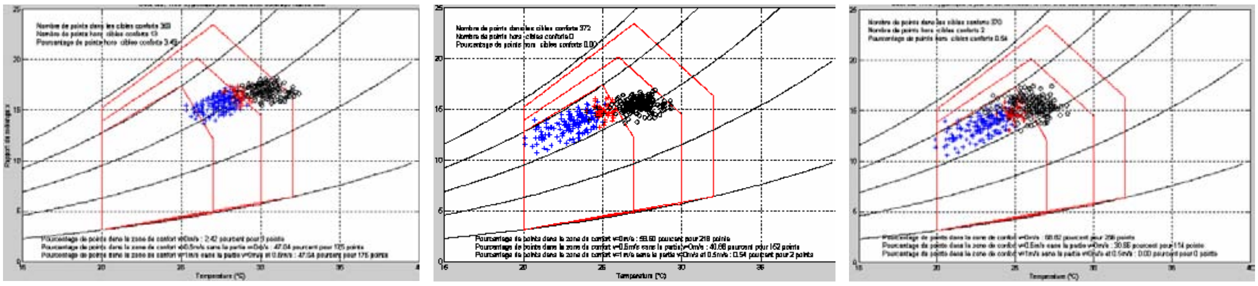

Figure 4 : Impact of the air change rate and mechanical night cooling on thermal comfort : case 1 (left), case 2 (middle), case 3 (right).

Table 3 : Percentage of dots within the comfort zones and number of hours of discomfort

	Office Case 3	Classroom Cross ventilated	Computing room Cross ventilated	Computing room Single side windows
Comfort zone - 0 $m.s^{-1}$	69%	32%	22%	14%
Comfort zone - 0.5 $m.s^{-1}$	31%	60%	60%	30%
Comfort zone - 1 $m.s^{-1}$	0%	4%	13%	49%
% outside the comfort zones	**0%**	**4%**	**5%**	**7%**
Hours of discomfort	***none***	***36 h***	***54 h***	***70 h***

Table 3 synthesises the results in terms of thermal comfort for the all the typical rooms. It is shown that thermal comfort conditions are reached most of the time. The worst configuration is for single sided computing rooms where 70 hours of discomfort were calculated.

As for the impact of the different cooling solutions on the installed power and on energy consumption, several simulations have been carried out with different scenarios that are listed in Table 4. A Coefficient of Performance (COP) of 2 has been considered to determine the electric power of HVAC systems. Case 1 and case 2 represent the initial project with and without artificial lighting. Case 3 and 4 are an intermediate solution where air conditioning is only used in the afternoon thanks to the effect of night cooling. Case 5 and 6 only use mechanical night cooling and ceiling fans. It is noticeable when comparing case 1 with case 2, that the use of artificial lighting increases both the power and the energy use by 30%. The use of night cooling allows a reduction in electric power by 10% and the energy consumption by 40% (see case 3 and case 4). The best solution was found to be the use of air fans that reduce both the power and the energy consumption by a factor of 12 and achieving good levels of thermal comfort.

Table 4 : Impact of the different cooling solutions on the installed power and on the daily electric comsumption

	$P_{max\ el}$ (kW)	*Installed power* *(W_e/m^2)*	Cooling load kWh_{cool}	Electric consum. *kWh_e/day*	Energy Index *($kWh_e/day/m^2$)*
1. Air cond. all day /natural lighting/1 ACH	0.67	*42*	77.5	25.83	*1.61*
2. Air cond. all day/artificial lighting/1 ACH	0.85	*53*	100.73	33.58	*2.1*
3. Afternoon air cond. / natural lighting 20 ACH at night/1 ACH during daytime	0.58	*36*	36.41	12.14	*0.76*
4. Afternoon air cond. / artificial lighting 20 ACH at night/1 ACH during daytime	0.76	*48*	56.03	18.68	*1.17*
5. 1 hour use of ceiling fan /natural lighting 20 ACH at night/1 ACH during daytime	0.05	*3*		2.2	*0.14*
6. 3 hours use of ceiling fan /artificial lighting 20 ACH at night/1 ACH during daytime	0.05	*3*		3.3	*0.21*

Comfort conditions during winter – typical office room

As for the study of comfort during winter, two solutions have been evaluated: case 1, one ACH 24 hours a day, and case 2, one ACH only during the day (8h-19h). Preliminary simulations conducted without mechanical equipment have pointed out that condensation occurred most of the time on the internal surface of windows and even on the walls if they are not insulated. Table 5 shows that when the mechanical air renewal is off at night, the temperature is slightly better (0.7°C) but condensation occurs almost every time on the window. On the contrary, if it is used for 24 hours, the condensation risk is totally avoided. The comfort conditions remains good with only a few hours outside the comfort zone for 0 m/s (see Figure 5). The low-level risk of condensation is confirmed. Most of the humidity/temperature pairs are far away from the saturation curve. The simulated PMV is only 12h below -0,5 throughout the entire winter period.

Table 5 : Impact of the mechanical air renewal on the resultant temperature in winter

	T_{res} 8h-12h	**T_{res} noon**	**T_{res} 13h-17h**	**Mean $T_{res,min}$**	**Abs. $T_{res,min}$**	**Condensation risk**
1 ACH 24h/day	21.5	22.7	24.8	20.3	19.1	none
1 ACH 12h/day	22.2	23.3	25.3	21.1	19.8	Yes. 90% of the time on the indoor window surface.
Outdoor temp.	18.2	19	18.2	13	11.6	

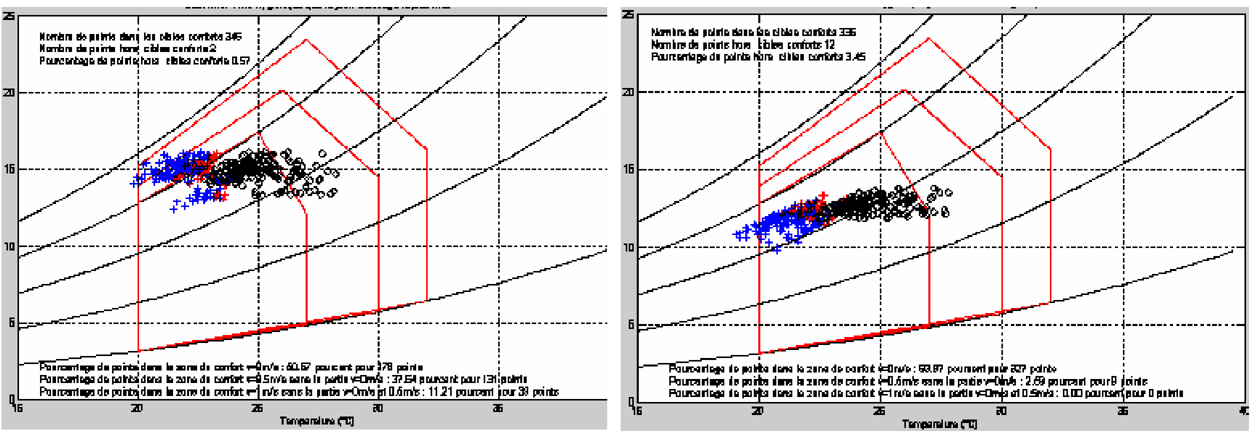

Figure 5 : Impact of the mechanical air renewal on thermal comfort and on condensation risk 1 ACH 12h during daytime (left), 1 ACH 24 hours a day (right).

SYNTHESIS AND CONCLUSION

The keys findings of this study are as follows. The mid-highlands climate in tropical islands must be considered apart because one must cope with the duality of the design principles for tropical climates in summer (use of cross ventilation and solar shadings) and temperate climates in winter (passive solar heating and risk of condensation). Nevertheless, this study has demonstrated that neither air-conditioning nor heating are necessary if some basic passive design principles are applied. With respect to the building envelope, a minimum of 10% of openings for cross ventilation and a minimum solar factor for windows is required. The values of solar factor function of the window orientation are given in [2]. Air treatment in the administrative offices is needed with a 20 ACH of mechanical night cooling coupled with ceiling fans proving to be an interesting alternative to air conditioning during summer time. During winter time, one ACH of mechanical air renewal is mandatory to avoid condensation problems. The comfort conditions are almost reached all year round with only 12 hours of PMV <-0,5. This proposed solution is the first of its kind in La Reunion. It has since been applied to other building projects, either office or educational buildings. In the others typical rooms studied (that is, classroom and computing rooms), natural ventilation and use of air-fans is sufficient enough in summer to ensure good comfort conditions. During winter, louvers must remain slighlty open to avoid condensation. The PMV for this scenario is below -1 only one hour per day.

An adaptable urban house designed for the southern Brazilian climate – emphasis on summer and winter thermal comfort

Marianne Costella

Architectural Association School of Architecture, London, United Kingdom

Corresponding email: marianne@nostracasa.com.br

SUMMARY

The climate in southern Brazil is characterised by mild winters and hot-humid summers which requires the design to be adaptable to the often conflicting summer and winter requirements. In the residential sector, air conditioning consumption is still low, but it has been growing significantly along with an increase in people's purchasing power which emphasizes the importance of encouraging a change in construction practices [1]. The aim of the research is to design a residence that combines traditional and contemporary techniques and technologies, along with a smart design, providing acceptable summer and winter thermal comfort. This was pursued by considering the advantages found in some precedents, such as, passive heating and cooling strategies that respond to the climate; and by controlling the relationships between buildings and outdoor spaces to ensure a response to the different seasons. Environmental design approach is found to go far beyond the quantification of energy consumption through the use of different materials or strategies.

INTRODUCTION

To reduce energy consumption, the adequacy of the architectural standard is the item that requires the lowest investment and provides one of the highest energy savings.

Finding successful means of energy reduction and a solution to the environmental effects of air conditioning is a strong requirement for the future. Possible solutions include the adaptation of buildings to the specific environmental condition of cities in order to incorporate renewable energy technologies efficiently to address the radical changes and transformations of the radiative, thermal, moisture and aerodynamic characteristics of the urban environment. This involves the use of passive and hybrid cooling and heating techniques to decrease cooling and heating energy consumption and improve thermal comfort.

OBJECTIVES OF THE BUILDING

2.1 Project Brief

It is a house designed for a family of 4 to 5 people that enjoy being outdoors and having freedom in the house. The average size required is around 200 m². The programme is composed by Living Room, Barbecue Room, Kitchen and Study Room - mostly occupied during the whole day; 3 Bedrooms - occupied during the night; Laundry, Bathrooms and Garage - occasionally; and Swimming Pool - summer.

2.2 Conceptualization

According to the study of the built examples some conclusions were drawn, such as the importance of the engagement of the architecture with the environment, about rethinking the way that people live and how the design should respond to the climate [2].

The house should be adaptable, able to be changed according to the seasons, responding at the same time to the climate and to the occupants' attitudes and expectations of comfort. In winter it should be more compact and well insulated to keep the internal and solar gains inside the house and save energy when mechanical heating is needed, but at the same time it should be able to be more permeable in the summer and be fully integrated with the outside.

DESIGN GUIDELINES

3.1 Chapecó's Climate

The context of this work is the city of Chapecó, which is located in Southern Brazil, in the west of Santa Catarina State at Latitude 27°14' S, Longitude 52°37' W and Altitude 668 m.

The following description of the climate of Chapecó is based on 10 years of hourly meteorological data recorded in Chapecó's airport processed through the Software Meteonorm [3].

3.1.1 Dry bulb temperature

The annual mean temperature is 19.2°C. The hottest month is January, presenting a mean temperature of 22.8°C and the coldest is June, with a mean temperature of 13.5°C. The annual mean daily range of temperature is 9.3°C. In January, the mean maximum temperature is about 28°C and the mean minimum is 16.9°C, producing a daily range of temperature of about 11.1°C. In June, the daily swing of temperature is also about 11.1°C, ranging from a minimum mean of 7.9°C to a maximum mean temperature of 19°C.

It was observed that during the winter, or even in the summer, there are periods of heat and cold, respectively.

3.1.2 Relative air humidity

The annual mean relative humidity is 73%. The months with the highest average relative humidity are May and June (around 78%) and November is the month with lowest average (around 68.6%).

3.1.3 Wind speed and direction

The annual mean wind speed is 2.5 m/s. March is the month with the weakest winds and September has the highest speeds, both average and maximum.

Wind frequency, relative to its direction, shows the north-eastwards and northwards directions as predominant throughout the year. The north-eastwards direction is predominant during summer and the northwards direction in August. The second highest frequency occurs south-eastwards in most part of the year, mainly in winter and in the months of June and September.

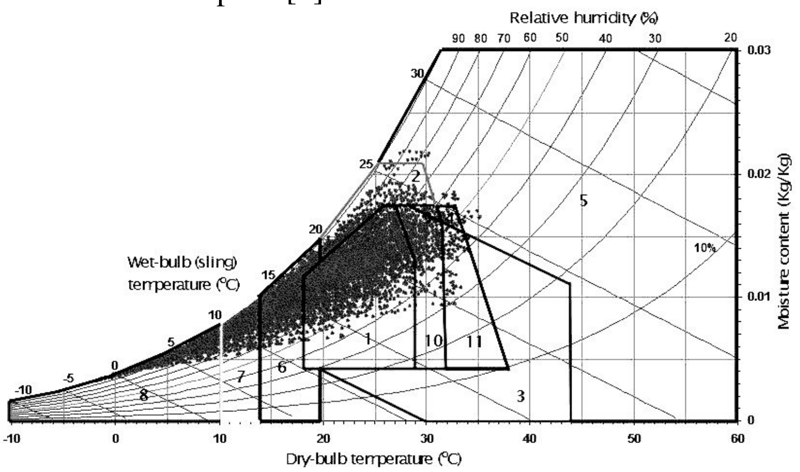
3.1.4 Cloudiness and Insolation

In Chapecó's climate, winter months feature lower cloudiness rates than during summer months.

Annual average cloudiness is 5.4 (part of the sky covered by clouds: from a 1 to 10 scale, that is, greater than 50%); also, cloudiness tends to increase from September to February, reaching 59% in January and February. May is the month with the lowest cloudiness rate and is the only one to fare below 50%.

3.2 Passive Strategies Investigation

To obtain some building design guidelines the result obtained was analyzed by applying the program developed at LABEEE (Laboratory of Energetic Efficiency in Buildings – Federal University of Santa Catarina – Brazil), based on Watson's and LAB's method (1983), thus allowing the crosschecking of all hourly climate data on the Bioclimatic Building Plan tailored to Chapecó [4].



1. Comfort zone
2. Ventilation
3. Evaporative cooling
4. Thermal mass for cooling
5. Air-conditioning
6. Thermal mass/Solar heating
7. Solar heating
8. Mechanical heating
9. Ventilation/Thermal mass
10. Vent./Mass/Evap. cooling
11. Mass/Evap. cooling

Figure 1: Chapecó's climatic year

DESIGN DEVELOPMENT

According to the local climate analysis the primary need is to increase winter heat gains and reduce summer heat gains during the day. This was attempted through a comprehensive set of actions that start on a large scale by controlling the relations between buildings and outdoor spaces.

In the design stage the advantages which were found in the three different houses' approach of designing and passive strategies that would respond to the climate were taken into consideration [2], as a result an adaptable house responding to the local climate is proposed.

4.1 Site layout and Building Form

As a starting point for the design, it was decided to separate the living area (daytime) from the sleeping area (night-time), thus more rooms could get the winter sun and have cross ventilation also allowing the buildings to be connected in winter and disconnected in summer which could lead to a more interesting site layout.

The sleeping area was located at the back of the site, consequently further away from the street and noise. It would comprehend the whole site's width (17 m) to ensure that all the bedrooms would face north. The living area would be more compact allowing 4 m setbacks at the sides to decrease the overshadow created by the neighbouring houses and walls and also for the creation of side gardens and courtyards that would allow the extension of the inside space when the outdoor temperature is comfortable.

The average distance found to ensure that the sleeping area would not be overshadowed by the living area was around 8 m (Fig. 2 and 3). It was considered that the first volume had an average height of 4.5 m, which is going to be used at the final project.

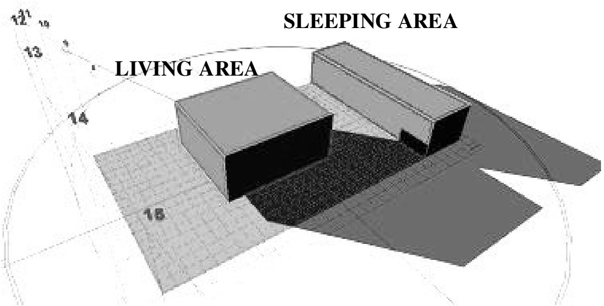


Figure 2: Shading study on June 21st at 9am

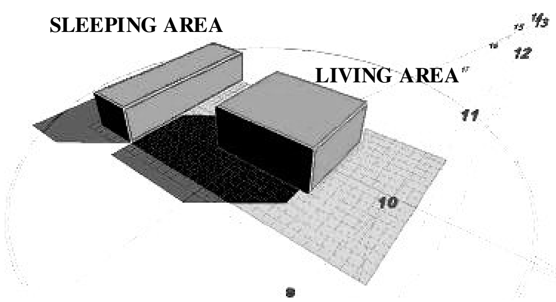

Figure 3: Shading study on June 21st at 3pm

4.2. Internal Layout

The house was designed with an internal layout where the main rooms such as barbecue room, living room and bedrooms are facing north as they are the rooms that will be most occupied at daytime and evening in winter. The study room, the second most used space, is facing east, and kitchen and laundry facing west as they also can be shaded in summer. Openings are not placed on the south façade as it does not have any solar gain in winter and in the summer it gets some sun, and the south façade might require extra insulation to avoid loss of heat gains.

The leisure area of the house would be on the roof of the ground floor as the swimming pool requires maximum solar radiation to heat the water (Fig. 5). The swimming pool also works as heat storage through its thermal capacity. The ceiling, which is cooled by heat conduction through the water, acts as a radiant/convective cooling panel for the space under it. Thus, the indoor air and radiant temperatures can be lowered without elevating the indoor humidity level.

4.3 Design Project - *Summer and Winter House*

The house proposed is adaptable through moveable devices. It can change its configuration through the occupant's interaction responding to the local climate and to the seasons change.

It was focused to design the versions of the house in summer and in winter as they are the most extreme seasons. Thus, in winter the house is more compact and well insulated to keep the internal and solar gains inside the rooms and save energy when mechanical heating is needed (Fig. 4). In summer it is more permeable and the relationship with the outside is stronger (Fig. 5).

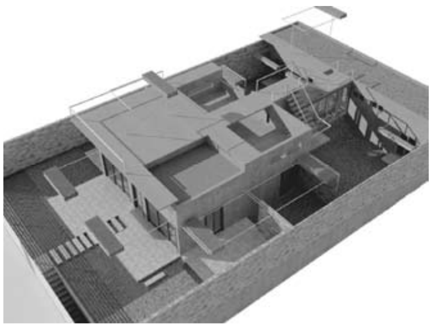

Figure 4: Winter House

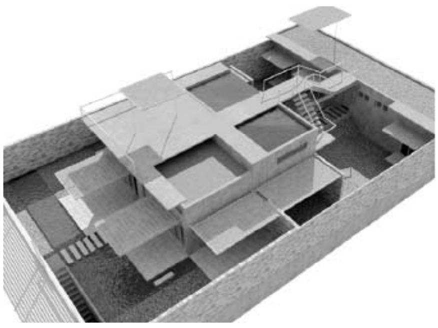

Figure 5: Summer House

The floor plans of the house are presented below with the strategies and the design elements pointed at the floor plans are explained (Fig. 6, 7, 8 and 9).

1. Thermal storage - water
2. Reflection - gardens
3. Thermal mass – stone (walls and floor)
4. Thermal mass – brick (walls)
5. Cross ventilation - sliding doors fully opened

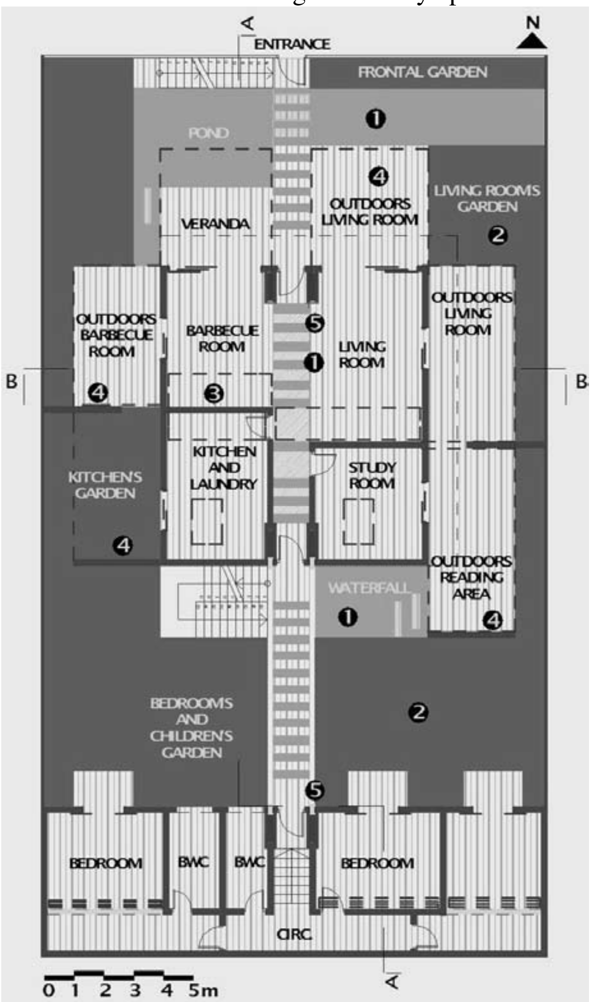

Figure 6: Ground Floor Plan – *Summer House*

1. Thermal mass and wind protection - concrete
2. Compactness - sliding doors fully closed

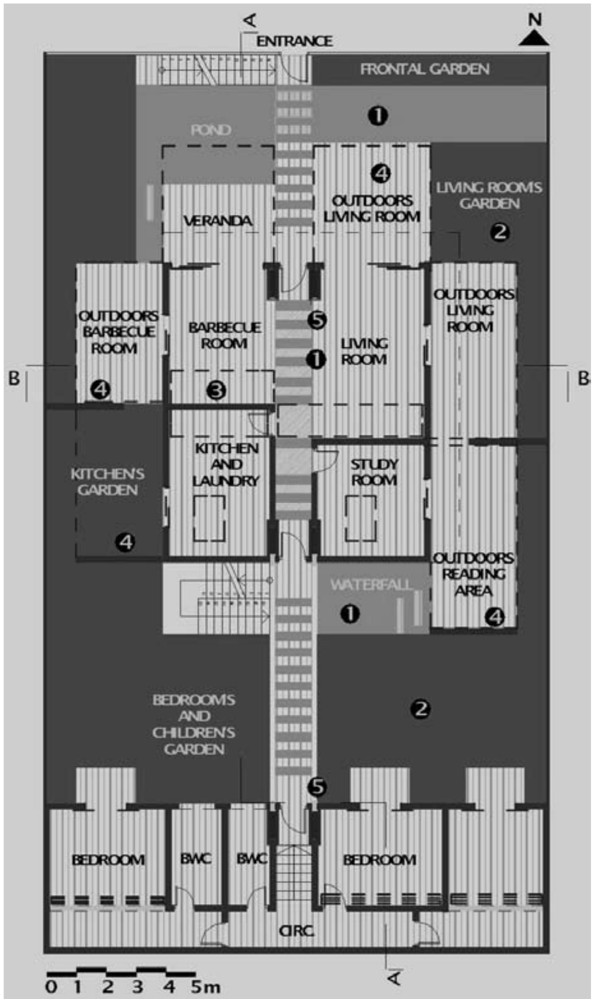

Figure 7: Ground Floor Plan – *Winter House*

2. Moveable shading device/night shutters - position: horizontal fully closed
3. Moveable shading device/night shutters - position: horizontal almost fully closed
4. Moveable shading device/night shutters - position: horizontal semi-opened
5. Reflection – green roof
6. Thermal storage - swimming pool
7. Fixed shading device

1. Solar heating - roof light
2. Thermal insulation – green roof

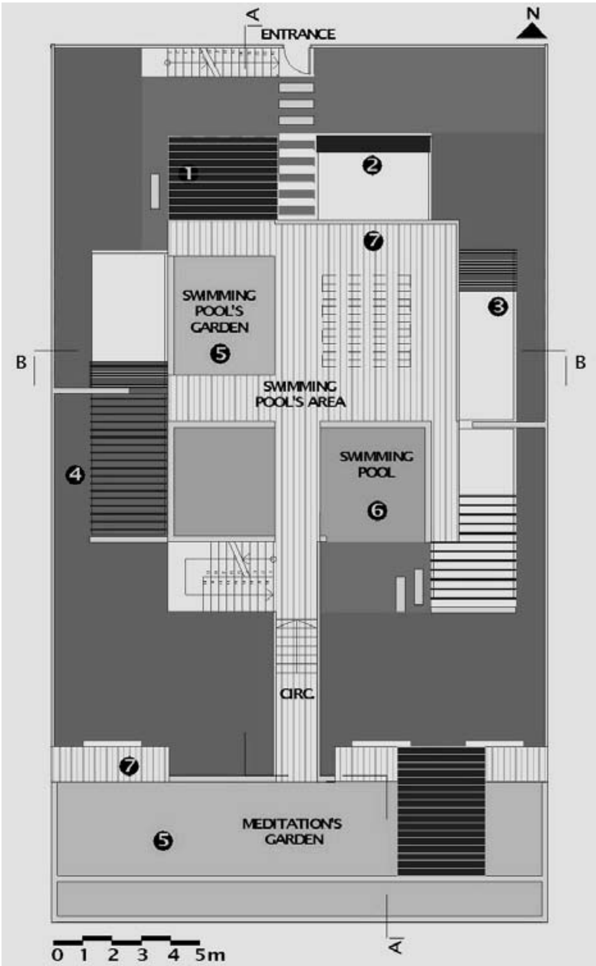

Figure 8: Roof Plan – *Summer House*

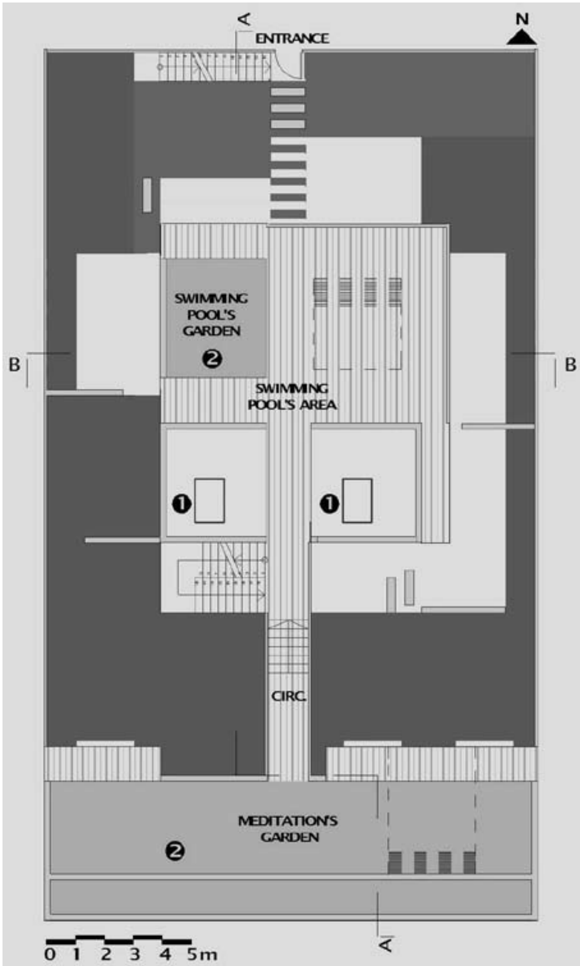

Figure 9: Roof Plan – Winter House

4.3.1. Thermal Mass

Thermal mass was applied through the brick and stone walls, concrete ceilings and floors (Fig. 6). It is a strategy suitable for summer, decreasing the peak of cooling loads and releasing, with a delay, the heat to indoors. In winter, the solar diurnal gain can be stored in the thermal mass and transferred into the building at night, when heating is required.

According to Balcomb [5], thermal mass is best increased by maximizing surface area rather than increasing thickness. Thus, thermal mass was also applied on the walls surrounding the building creating courtyards (Fig. 10 and 11). These walls can store some heat during the day and release it at night creating warmer and more comfortable outdoor spaces.

Figure 10: Barbecue Room's Courtyard – *Summer House*

Figure 11: Living Room's Courtyard –*Summer House*

4.3.2. Ventilation

Ventilation happens through the openings located at the occupant's level, providing comfort ventilation and located at a higher level in the bedrooms, barbecue room and living room (Fig. 12). However, as in these spaces there is a moveable insulated ceiling which can be closed decreasing the height of the room in winter, thus in winter the higher windows stay above the insulated wood ceiling and closed (Fig. 19). All the openings, with the exception of the kitchen and study rooms, are facing northwards which is the main wind direction.

Figure 12: Barbecue Room's openings and shading devices – *Summer House*

4.3.3. Shading Devices/Night Shutters

The shading devices applied in the design are mostly moveable allowing the occupant to control the penetration of direct solar radiation and also daylighting levels, to control direct gain passive heating, maximising useful gains while avoiding overheating. They are more used in summer, however, it was observed that during the winter, or even in the summer, there are periods of heat and cold, respectively. Therefore, within the same season, days may occur with characteristics of the opposite season consequently if the devices are moveable they can also provide shade for the lower winter sun.

As the configuration of operable shading devices can be changed, their performance can be much better than that of fixed devices. They are composed of fins that can be rotated in both directions and if they are not in use they can be folded to one side (Fig. 13). The horizontal and vertical shading devices also work as night shutters and as insulators for the walls covering its whole extension (Fig. 14).

Figure 13: Different configuration of shading devices

Figure 14: Different configuration of shading devices

The higher windows of the living room, barbecue room and bedrooms are also shaded to avoid unwanted heat gains in summer. The shading devices are fixed, and are the floor of the Swimming Pool's Area and the sits of the Meditation's Garden.

According to insolation studies on the 21st December, the sun just heats the northern surfaces between 10.30 am and 2.30 pm, before and after that it is towards the South, so the shading devices needed are quite small (Fig. 15).

According to Shaviv and Capeluto studies [6], the winter performance of the thermal mass is very sensitive to the roof's insulation and the better it is the less energy is required for heating. On the other hand, this is not the case in summer, when the better the roof's insulation, the more energy is required for cooling. This is because the poorly insulated roof allows night cooling by heat conduction and by long wave radiation. Consequently, higher transmittance in the roof is recommended.

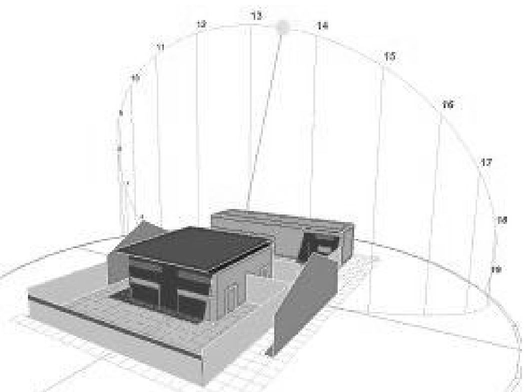

Figure 15: Fixed shading devices for higher windows

Thus, besides the function of shading the higher windows the floor of the Swimming Pool's Area is partially suspended shading the roof below from the Living and Barbecue Rooms. It also allows some cross ventilation as it is open on both sides (Fig. 16). In winter it is closed to avoid the contact of the roof with the outside temperatures (Fig. 17).

Figure 16: Suspended roof – *Summer House*

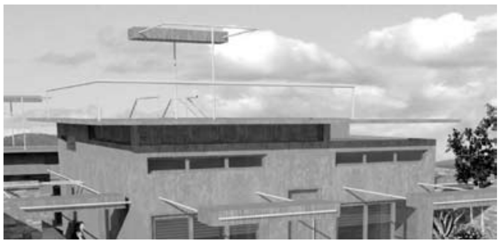

Figure 17: Suspended roof closed–*Winter House*

4.3.4. Swimming Pool and Ponds

Water is used on surfaces outside and inside the building as it has a very high thermal capacity, about twice that of common masonry materials and also has the advantage that convection currents distribute heat more evenly throughout the medium also providing some evaporative cooling. The water way inside of the house in summer is partially open and with moveable glass sheets, so it is possible to see the water through it (Fig. 20). In winter this floor is replaced by insulated wood panels, becoming fully closed. The same happens at the water way that connects the living area to the sleeping area.

The water that circulates around the house and from the waterfall is not the same as that from the swimming pool as one of the requirements for the swimming pool is to have its water heated, so it should be fully under the sun and not in movement.

The swimming pool was located above the kitchen and the study room, thus their roof can be cooled by evaporation and the ceiling then acts as a passive cooling element for the space below. The ceiling, which is cooled by heat conduction through the water, acts as a radiant/convective cooling panel for the space under it. Thus, the indoor air and radiant temperatures can be lowered without elevating the indoor humidity level.

In the winter the swimming pool is empty allowing the entrance of light through the roof lights to heat the study room and the kitchen. The dimension and the location of it were done by shading studies (Fig. 18). According to the shading mask the roof light would get full sun between 10 am and 2 pm, before and after that it could be closed and very well insulated avoiding loss of heat to the outside.

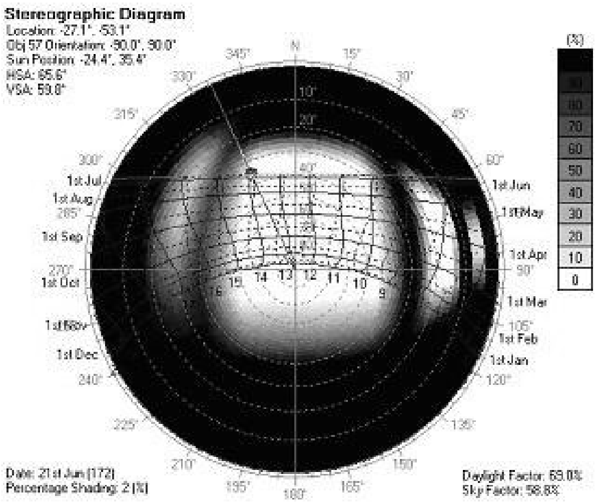

Figure 18: Shading mask of roof light in the kitchen – *Winter House*

4.3.5. Gardens
The roof is the building element which receives the most amount of sun, especially in summer, and that is more exposed to nocturnal cooling by radiation. Vegetation protects the roof from direct solar radiation and enhances its thermal behaviour providing a cooling effect in summer as green surfaces reflect sun radiation and storage heat causing a cooling effect. In winter it can be used for its thermal insulation effect though the air cushion within the vegetation and the fact that the cold wind does not hit the earth surface consequently protecting the surface below. Thus, grass was used on the Bedrooms' and on the Barbecue Room's roof (Fig. 8).

4.3.6. Solar Heating and Architectural Features
Solar Heating was applied at the design stage as storage element exposed to the indoor and outdoor spaces to store excess solar energy during the sunny hours and release it back during the night. This strategy was applied through the mass of the building fabric itself, floor, in the internal layers of external walls, internal partitions, on the roof and in the furniture surface area.

To improve the solar heat and internal gains of the building, a moveable ceiling and sliding doors were applied in the Bedrooms, Barbecue and Living Rooms. The moveable ceiling is composed of wood filled with insulation. There are 4 or 5 sheets of 1 m each that can be fully closed in winter leaving the room with a height of 2.6 m (Fig. 19) and in the summer they can be folded (Fig. 20), leaving the room with a height of 3.5 m. In the summer the height improves ventilation through the high windows (just visible in summer); in winter, the floor-to-ceiling lower height helps to keep the internal gains and solar gains in the room. They also have wood sliding doors that make it possible to isolate the rooms in winter (Fig. 19) and leave them open in summer increasing ventilation (Fig. 20).

The circulation from the living area to the sleeping area is also created by sliding doors that can be fully opened in summer and fully closed in winter, keeping the access between the two zones less exposed to the weather (Fig. 4 and 5).

Figure 19: Moveable insulated ceiling and sliding doors – *Winter House*

Figure 20: Moveable insulated ceiling and sling doors – *Summer House*

CONCLUSION

The design of more enjoyable spaces and their interrelation in a more interesting way was pursued at the same level as the outside penetration/interference at the inside spaces, and, on its occupants interaction with the building's envelope and features.
In response to this, the design started by challenging attitudes in house designing, pointing out that the occupant should be in control of the house in such a way that he feels that he is interacting with the design, having the possibilities of achieving what he wants from the space, mostly by moving architectural features instead of switching on equipments. Its occupants can deliberately see very visible differences between "summer" and "winter" houses through a clear reading of the different devices.

It was found that environmental design combining passive strategies and the intention of achieving a quality design might be more efficient in the overall environmental design picture. The occupant's thermal and psychological comforts were placed as the main issues to be addressed and not energy savings, as the latter is a consequence of the two former considerations.

SUMMARY

The paper presents a comparative study among six different solutions regarding the energy supply of a high-tech building. All the solutions take into account the coupling of the sources of energy and the energy storage, considering equipments like: boilers, compression and absorption refrigeration machines, thermal motors, fuel cells, storage tanks and the use of the underground water and an artificial lake. The functioning of the different solutions was simulated using Simulink - Matlab. The second part of the paper presents technical and economical considerations of the proposed solutions, permitting the choice of an optimal one.

INTRODUCTION

This work presents some results of a technical and economical study concerning different energy supply systems (including heating, cooling, and electrical energy consumption) for a complex (industrial and office) building. The complex building represents a research and development (R&D) centre, having a 35000 m^3 volume, situated in London, England.
The energy supply solutions were designed taking into consideration the modern solutions (cogeneration using internal combustion engines, fuel cells), and analysing the size and costs for each type energy supplied (thermal energy for heating/cooling, electrical energy).
The essential objective of the study is the comparison among different solutions, in order to provide a recommendation by considering their reliability, technical feasibility and their environmental impact.
The specific demands of the client are illustrated by the phrase «the whole building must rise at standards which may not yet have been reached in the UK». This conception leads to the following characteristics: all the services are placed on a common architectural support; the whole building, including installations and the energy units is part of a public space, so a special attention is giving for the integration within the environment; all the services must be flexible, in order to provide a future modification.
The general design data for this building are presented in Table 1.
Because of the great interdependency and the numerous functioning conditions, the design and the estimation of gas and electricity loads are very difficult. In order to facilitate the dynamic analysis of the installations, we simulated the functioning of each solution by using specific modules in Simulink.
The dimensioning of each equipment for energy supply was done for each solution. After dimensioning, the economic calculation was done, including investments costs, maintenance costs and annuities.
The dimensioning of the energy supply equipment and of the storage vessels was based on the variations in heating, cooling and electricity loads of the complex building for two different design days, considered as the most disadvantaged cases:

- the summer normal working day;
- the winter week-end day (because in this particular day we can not use the important heat released by the technological processes inside the building, in the production zone).

All the data regarding the variations in heating, cooling and electricity loads are presented in figure 1 (for a summer normal working day) and in figure 2 (for a winter week-end day).
The heating/cooling are generally (90%) made by using warm/cool air. Air conditioning with humidification for VIP zone, computer rooms, industrial zones and dehumidification for some industrial zones was also provided.
The main technical-economical results for six solutions for energy supply, obtained by using a numerical modelling in Simulink are presented in Table 2.

Table 1. General design data

Industrial and administrative area	40000 m^2
Museum area	4000 m^2
Number of employees	1000-2000 persons
Number of visitors	300-350 persons
Kitchen / Restaurant	600 persons/day
Exterior temperature	summer: 30°C dry bulb, 20°C wet bulb winter: – 4°C (saturated air)
Consumption hot water temperature	minimum: 55°C, maximum: 60°C
Heat transfer coefficients	walls: 0.45 W/(m^2·K), frontal face glazing: 1.80 W/(m^2·K)
Interior temperature (offices)	winter: minimum 20°C
Interior temperature (comfort zone)	22°…26°C
Cooling system for offices	radiant ceiling

ANALYSIS OF THE ENERGY SUPPLY SOLUTIONS FOR THE COMPLEX BUIDING

An energy supply system must produce each moment all the energy needed by the consumer, without overproduction (that is lost when the thermal storage is not used). The system must have the capacity of self regulation, in order to follow the variations in the energy loads.
The primary energy in use is the electrical energy – 2 high-voltage lines of 8 MWe each, and the natural gas, at a flow rate capacity of 2100 Nm^3/h.
The boilers are modern ones, for the production of heating water at 65/45°C temperature. The boilers were equipped with modular combustors.
The cogeneration was considered by using internal combustion engines (as a “classical” solution) and fuel cells (as a future alternative, approved by the European Union).
The phreatic water is available at a level of 6°C, and can be used for cooling.
The cooling is designed for producing cold water at 8/14°C temperature, by using vapour compression refrigeration machines and an absorption refrigeration machine.
The low level heat recovery is taken into account for the air conditioning design cooling load.
The medium level heat recovery is considered from the technological processes inside the building: the compressed air, the vacuum units, the autoclaves, the motor benchmarks units.
An artificial lake was located inside the building complex, as an innovative design solution, leading to energy sparing, a beneficial impact on the environment by means of a non-polluting effect and an ambient harmonisation, with remarkable aesthetic results. The thermal modelling using Simulink shows the feasibility of using the lake as a cooling source for the refrigeration system.
The solutions 1, 2, 4, 5 are presented below, in the figures 3 to 6. The solutions 3 and 6 are schematically the same with solutions 2 and 5, the difference consisting in replacing the fuel cells with internal combustion engines.

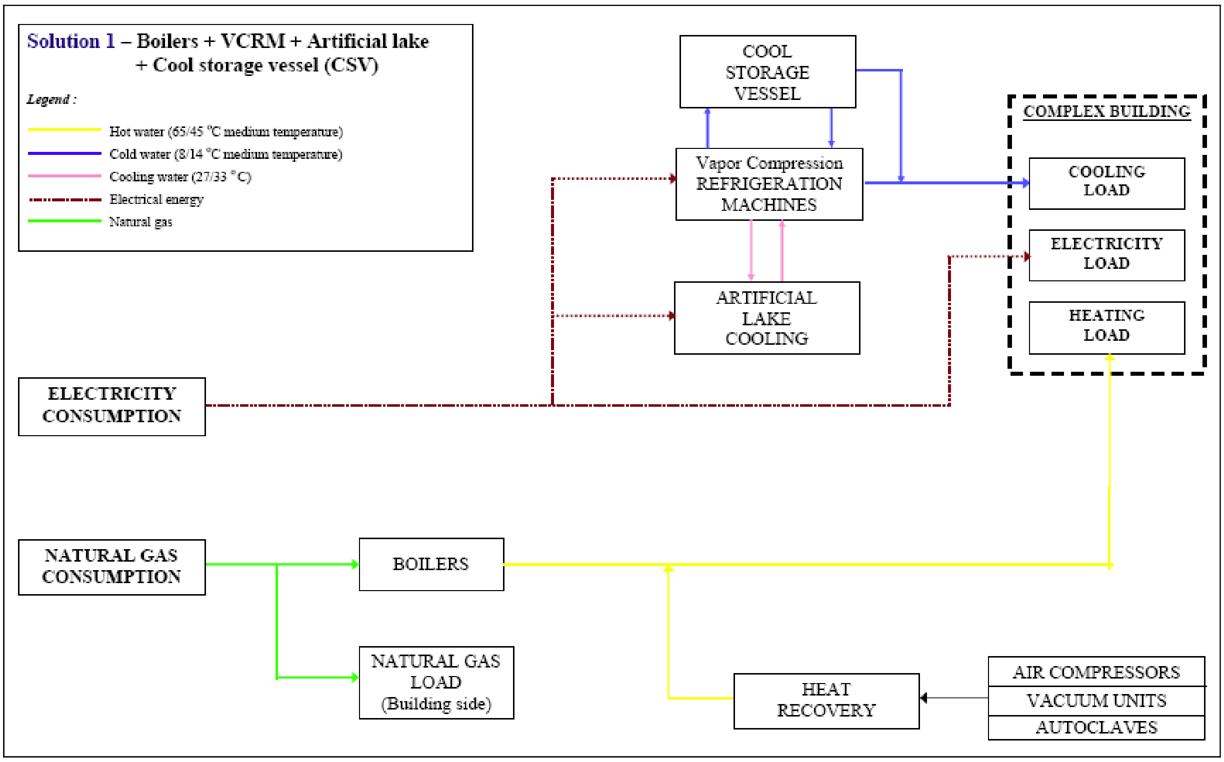

Figure 3. Solution 1 (Boilers + Vapour compression refrigeration machines + Artificial lake + Cool storage vessel).

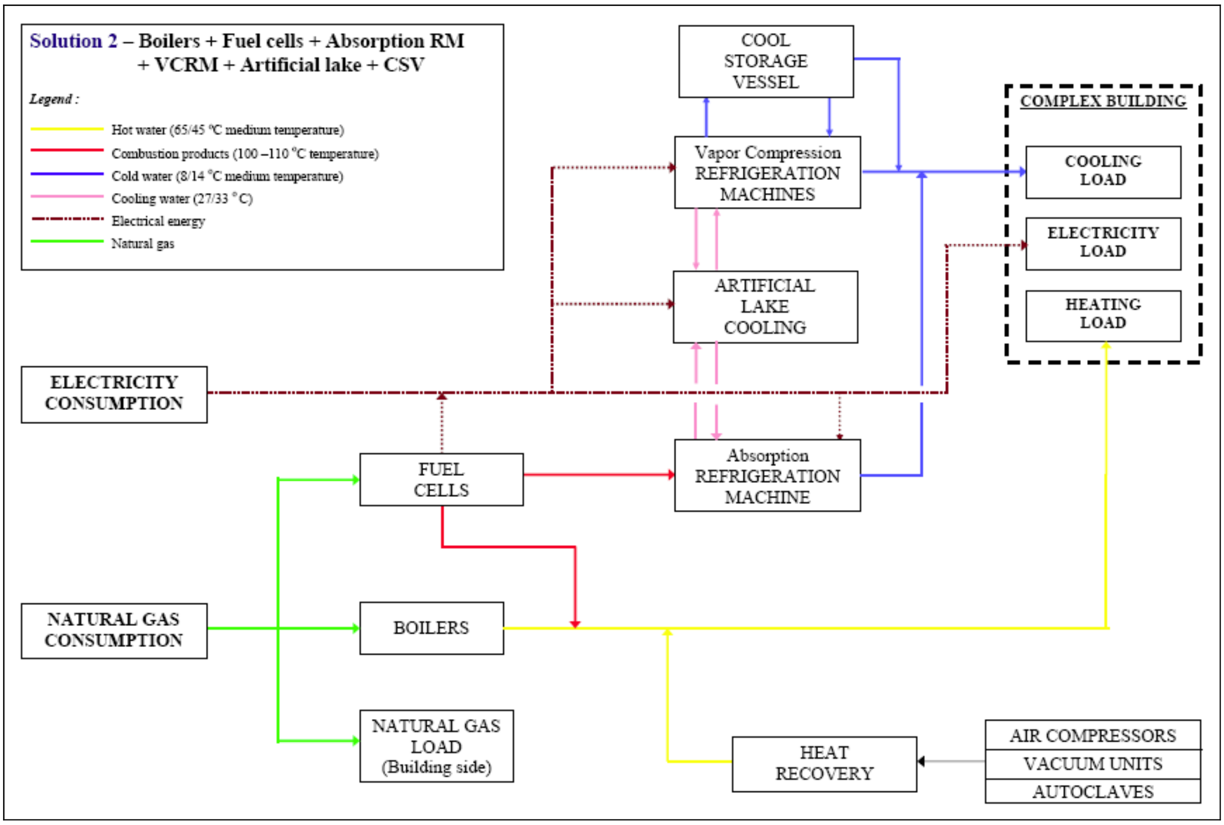

Figure 4. Solution 2 (Boilers + Fuel cells + Absorption refrigeration machine + Vapour compression refrigeration machines + Artificial lake + Cool storage vessel).

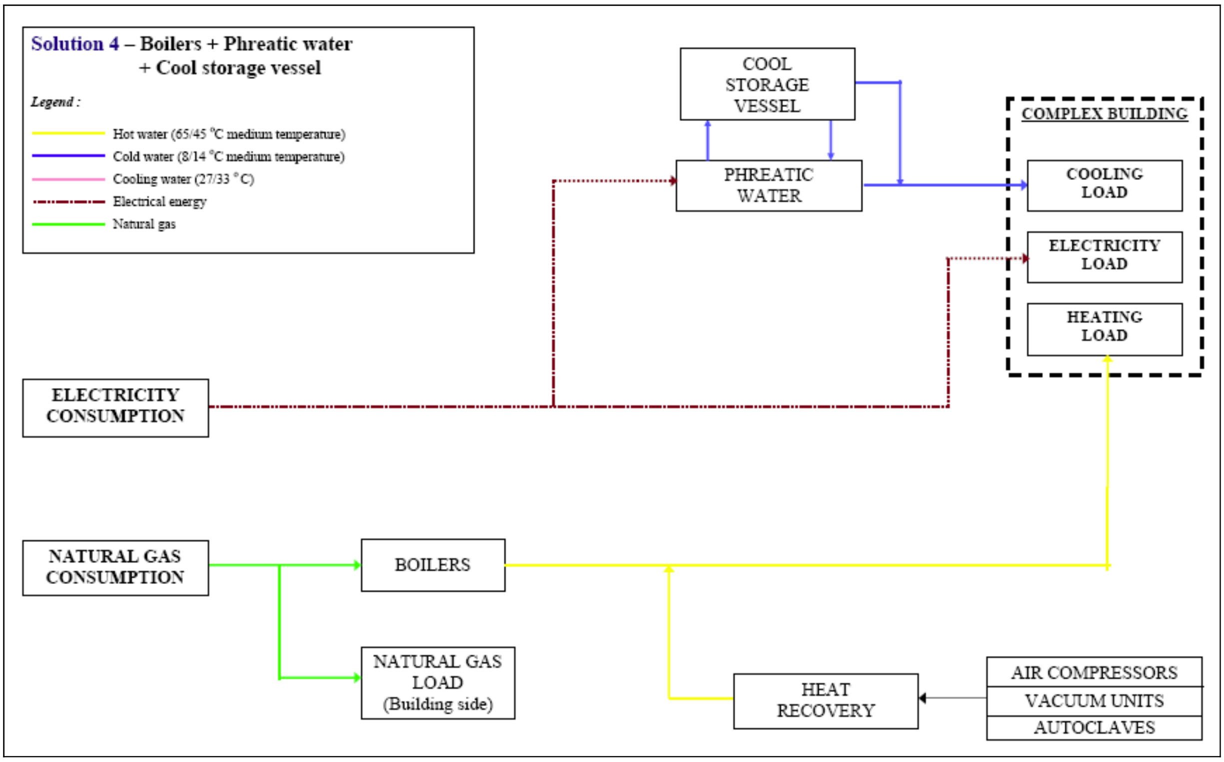

Figure 5. Solution 4 (Boilers + Phreatic (underground) water + Cool storage Vessel).

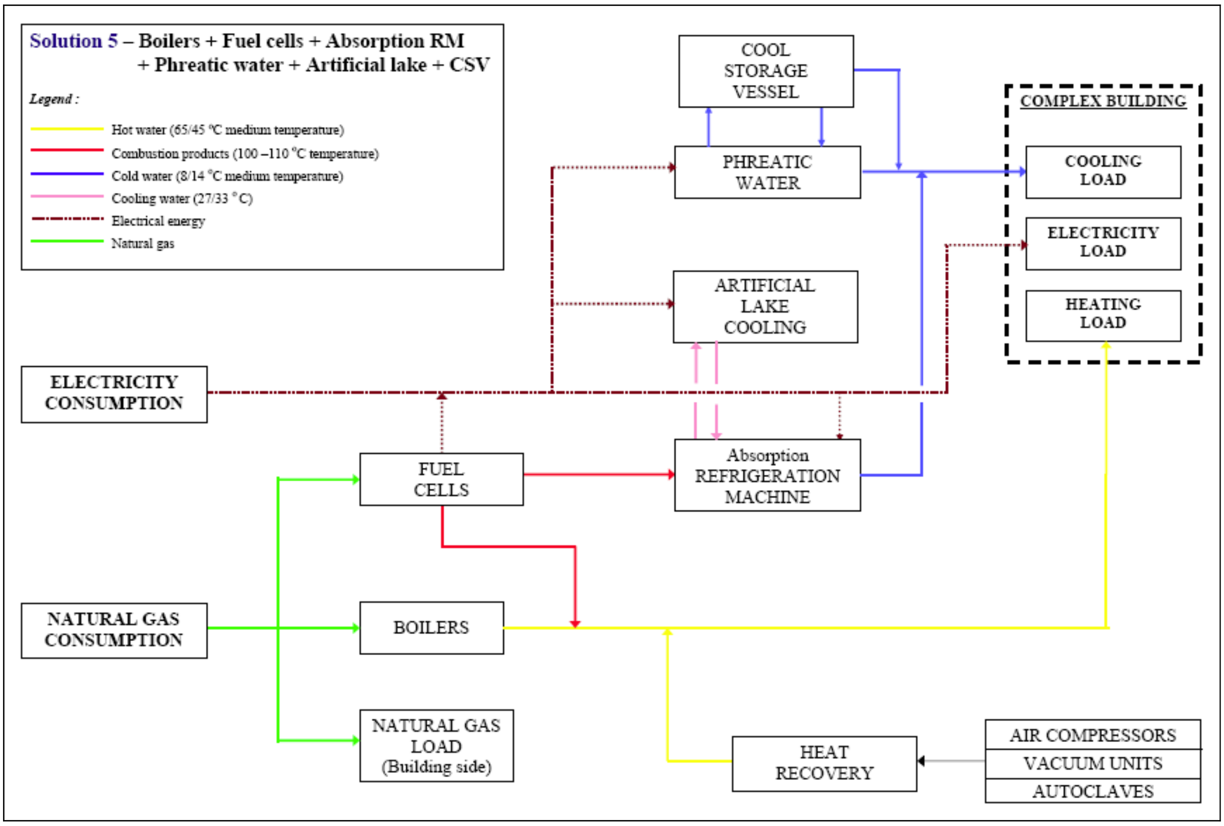

Figure 6. Solution 5 (Boilers + Fuel cells + Absorption refrigeration machine + Phreatic water + Artificial lake + Cool storage vessel).

ECONOMIC EVALUATION OF THE PROPOSED SOLUTIONS

The economic evaluation plays an important role in choosing the right solution, especially if balancing the present and the future needs and costs. Therefore, the economic evaluation was made taking into account the investments costs and the maintenance and operation costs for a long period.
In this study the economic evaluation was done concerning the building investment, the total investment for equipments, the total investment, the total annuity, the fixed costs, the maintenance costs, the total costs of primary energy.

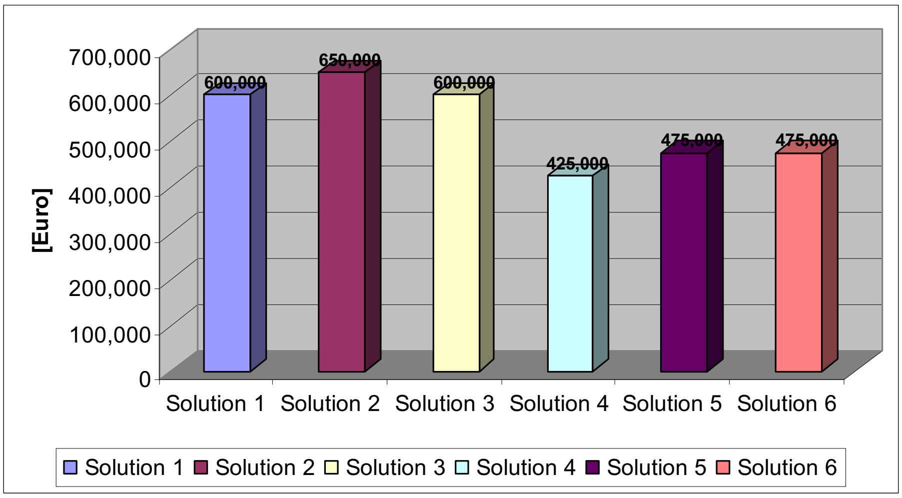

Figure 7. Building investment.

Because the equipments used for different solutions have different life-times, the comparative economic analysis regarding the investments costs is done by considering a mean life-time. In this respect, we calculated a total annuity for each solution. This value is the sum of the mean annuity of the installations (calculated with a 15 years life-time) and the building annuity (calculated for a 50 years life-time).
We can observe in figure 7 that the solutions utilising phreatic water (4, 5 and 6) implies the lower building investment. The solutions 1, 2 and 3 need bigger constructions because of the dimensions of supplementary equipment.
Concerning the cost of the equipments (figure 8), the solution 2 and 5 are clearly more expensive than the others, because of the high price of the fuel cells used. The most inexpensive solutions are the classical ones (1 and 4, with boilers).

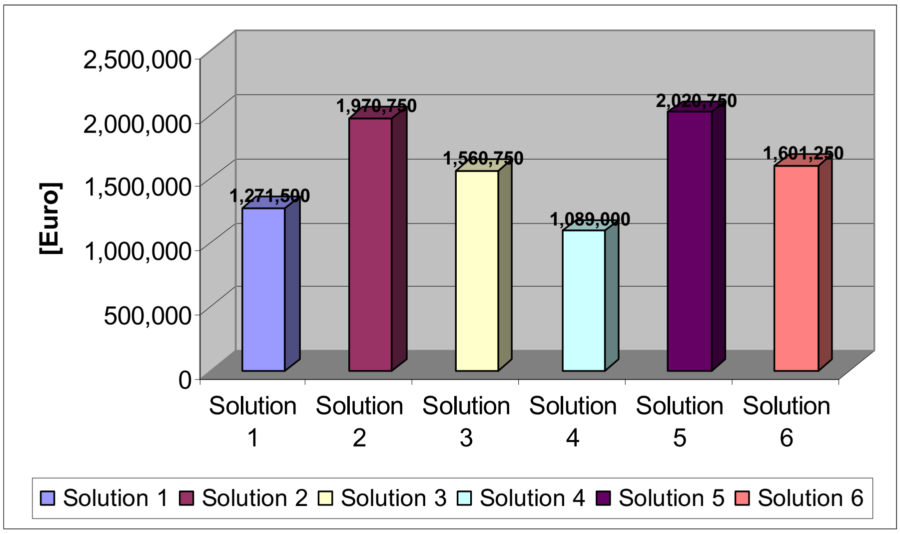

Figure 8. Total investment for equipments.

Finally, the total investments costs (figure 9) reveals three different categories: the expensive solutions 2 and 5 (with fuel cells), the medium-price solutions 3 and 6 (with internal combustion engines) and the cheap solutions 1 and 4 (with boilers).

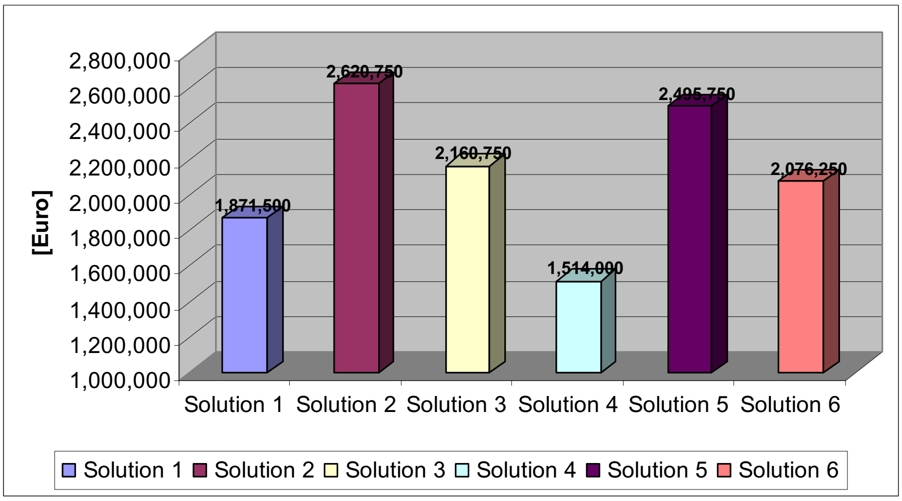

Figure 9. Total investment.

It must be noticed that the calculation of the total costs of primary energy was done for two different hypotheses: without and with selling of electrical energy.

A first observation is that the solutions using phreatic water need less primary energy than the other solutions. Another observation is that the solutions using cogeneration (with fuel cells / internal combustion engines) are more economical than the classical solutions (with boilers). The cogeneration with fuel cells needs less primary energy. As an example, the solution 2 (with fuel cells) has a total annual primary energy cost of 754500 Euro, and the solution 1 (classical solution with boilers) has a corresponding cost of 913200 Euro; it results an economy of primary energy costs of 158700 Euro, that is 18% !

CONCLUSIONS

In order to choose an optimal solution, one must consider different weighting concerning the essential criteria. In our case, we considered the following criteria:

a) economic criterion (investment costs and total costs);
b) legal criterion (financial support for fuel cells);
c) environmental criterion (environmental impact);
d) marketing criterion (commercial impact).

We consider the marketing and the environmental criteria as the most important ones (for the case of a client with a high financial power).
The solutions 1 and 4 raise no interest for a client interested in a commercial impact; these solutions are also expensive in time.
The solutions 2, 3, 5, 6 remain as the basis for choosing the optimal decision.
The solutions with fuel cells (2 and 5) have higher total annuities, and the lower costs of primary energy. The solution 5 has a negative commercial impact, so the final recommended solution for this application and for this particular client was the solution 2.

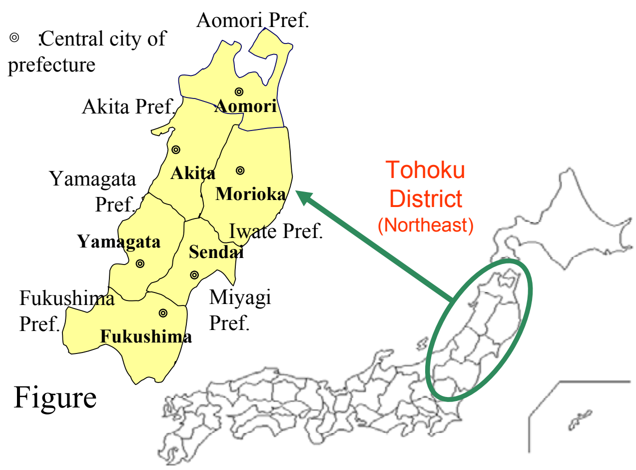
SUMMARY

The energy consumption and indoor temperature of 9 housing units sited in the northern region of Honshu Island, Japan were investigated for a full two years from Dec. 2002 to Nov. 2004. Three of the houses were installed with all-electric equipment. The annual and daily energy consumption profiles of two typical houses were analyzed, and the annual energy consumption per house was found to range from 40GJ/year to 120GJ/year. In some houses, energy consumption during the second year decreased due to a rise in energy saving awareness. The results indicated that the characteristics of energy consumption were not only greatly influenced by regional climate but also by the use of household equipment and lifestyle.

INTRODUCTION

In line with the recognition that a sustainable global environment is the most important environmental issue, global warming must also be handled urgently. As a result of improved living standards throughout the world, energy consumption by households is also growing. In Japan, the average annual growth rate of residential energy consumption was 4.2% from 1965 to 2004 (Handbook 2006). For this reason, it is important to take immediate action to minimize energy consumption by the housing sector.
The objective of this study is to understand the current condition of energy consumption and thermal environment in the daily life of households located in the northern region of Honshu Island, Japan. Detailed measurements of energy consumption for each end use as well as indoor temperature and humidity were carried out over a period of two years.



Figure

MEASUREMENTS

Outline of the houses

In this study, 9 houses located in the northern region of Honshu Island, Japan were investigated (Fig. 1). The outline of these houses is shown in Table 1. Seven detached houses and two apartments in Miyagi, Iwate, Akita and Fukushima prefectures were involved in this investigation. All the detached-type houses are made of wood and the two apartments are built by SRC or RC. The floor areas of the detached houses and apartments are 110~ 180m^2 and 70~ 80m^2, respectively. When these houses were newly constructed, they were well insulated and airtight. The value of heating transmission rate was calculated based on the design plans and components. The value of equipment leakage areas per floor area was measured by the fan pressurization method. In addition, the main energy sources were kerosene, electricity and gas. The three houses investigates used only electricity. In these houses, electric thermal storage heating equipment was installed.

Items of measurement

The major items investigated in the measurement are given in Table 2. These include energy consumption, thermal environment, capacity of electrical appliances and the occupants' lifestyle, etc. The measurement intervals for electricity consumption, gas consumption, kerosene consumption, and temperature were 1 minute, 5 minutes, and 15 minutes.

Categories of energy consumption

End use of energy consumption was classified into six categories, i.e. space heating/cooling, hot water supply, kitchen, audio visual & information, healthcare, lighting & others. The category of "lighting & others" means the energy consumed for lighting and unidentified usage. Receipts for electricity, gas, and kerosene consumption were used to compensate for missing data in situations where the measuring instruments were not functioning.

Table 1. Description of houses investigated (Survey period: from Nov. 2002 to Nov. 2004)

No.		Location	Number of occupants	Floor area [m^2]	Heat loss coefficient [W/m^{2}K]	Equivalent leakeage area [cm^2/m^2]	Construction	Energy sources by usage

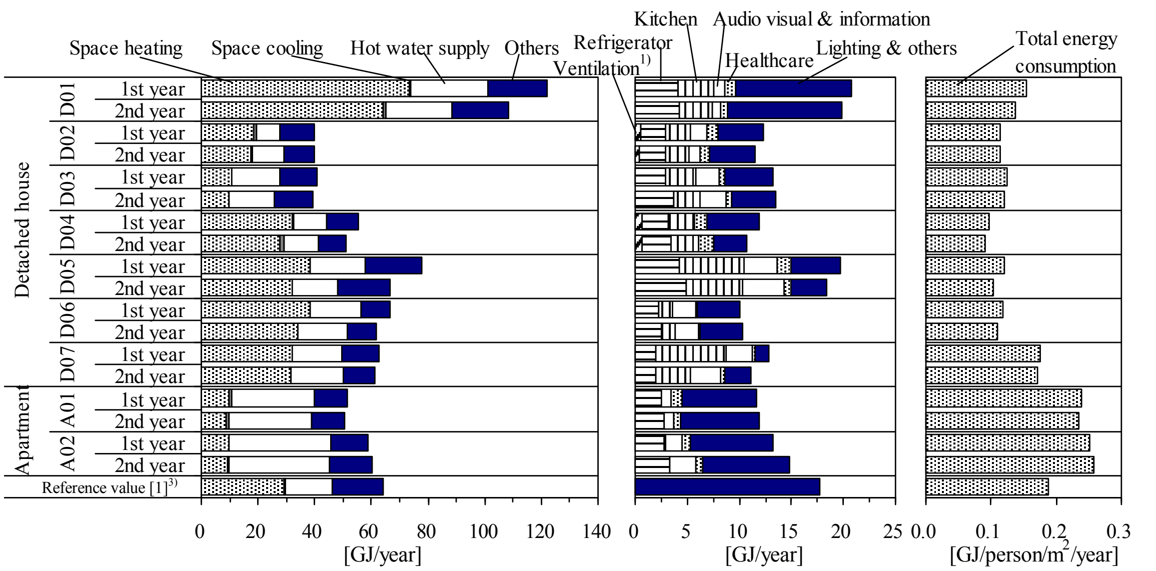
ENERGY CONSUMPTION AND TEMPRATURE OF ALL INVESTIGATED HOUSES

The annual energy consumptions of nine houses are shown in Fig. 2, with the statistical reference values from literature (Handbook 2003) for the Tohoku District in Japan. The periods of the first and second years were from Dec. 2002 to Nov. 2003 and from Dec. 2003 to Nov. 2004, respectively. The statistical reference value is the average of 2002. Energy consumption by end use is classified into four categories; space heating, space cooling, hot water supply and others (Fig. 2.-a). It is noted that the hot water supply includes gas consumption for cooking in the case of apartments. The category of "others" divided as ventilation, healthcare, lighting & others is shown in Fig. 2.-b. Energy consumption for audio visual & information includes consumption for lighting & others in house D04. The statistical reference value is not divided. The total energy consumption per person square meter is shown in Fig. 2.-c.

Difference between houses As shown in Fig. 2.-a, the annual total energy consumption per house varied between 40−120GJ/year. The major energy consuming activities for detached houses and apartments were space heating and hot water supply respectively. The energy consumption in D01 was the largest, which was nearly twice that of the reference value. This house consumed energy largely for space heating because they used it all day. In addition, the floor area was large and required more energy to keep the rooms warm. In contrast, the energy consumption of D02 and D03 was about two thirds of the reference value. In these two houses, occupants practiced energy saving awareness as revealed by a questionnaire. Fig. 2.-b shows the energy consumption of "others", which was used by refrigerator, kitchen & others. The characteristics of end use were different between houses.

Difference between detached houses and apartments Fig. 2.-a shows the trends of energy consumption according to end use for detached houses and apartments. The percentage of space heating and hot water supply in the case of detached houses were approximately 50% and 20% respectively, and 20% and 50% in the case of apartments. In both cases the energy



(a) Total energy consumption (b) Energy consumption of "others" (c) Total energy consumption per person per square meter

1) Ventilation: Electricity consumption for ventilation was measured only in D02 and D04
2) D04: Audio visual & information is included in lighting & others
3) Reference value [1]: Average value of the Tohoku district in Japan

Figure 2. Energy consumption by end use consumed for space heating and hot water supply was above 70% of the total energy consumption.

Comparison between the first and second year The results show that energy consumption in the second year decreased compared to the first year for most houses, especially in house D01, D04, D05 and D06. The rate of decrease in these four houses was 11%, 8%, 14% and 8% respectively. In these houses, energy consumption for heating decreased largely and it affected the decrease of total energy consumption. Based on the questionnaire survey, it was found that the energy saving awareness of the occupants in these houses became higher in the second year. One example of concrete action for saving energy was in house D01 where the warm water heating system was turned off when the house was unoccupied. In the case of D04, they turned the heating preset temperature down in the second year. In house D05, number of occupants changed from 4 to 3 because of husband-alone transfer since May 2004. It is considered as a key factor in decrease of energy consumption. In addition, space heating was used for the entrance, lavatory and toilet in the first year, but was not used for these spaces in the second year. In the case of house D06, electric thermal storage heating equipment was installed for the living room, dining room, bed room and Japanese-style room, and energized shorter hours in bed room and Japanese-style room in the second year.

Energy consumption per person per square meter Fig. 2.-c shows the energy consumption per person per square meter. The values for detached houses were less than those of apartments; approximately 0.12 and 0.23 GJ, respectively.

COMPARISON OF THE ENERGY CONSUMPTION OF TWO TYPICAL HOUSES

Outline of the two houses under investigation

The energy consumption of house D01 (Fig. 3) that used electricity and kerosene as sources of energy, is compared with house D06 (Fig. 3) that used only electricity. The energy consumption of houses D01 and D06 were the largest among the all-electrified houses and non-electrified houses. These two houses were located in Sendai and Morioka cities. The number of occupants in D01 and D06 were 5 and 4, respectively.

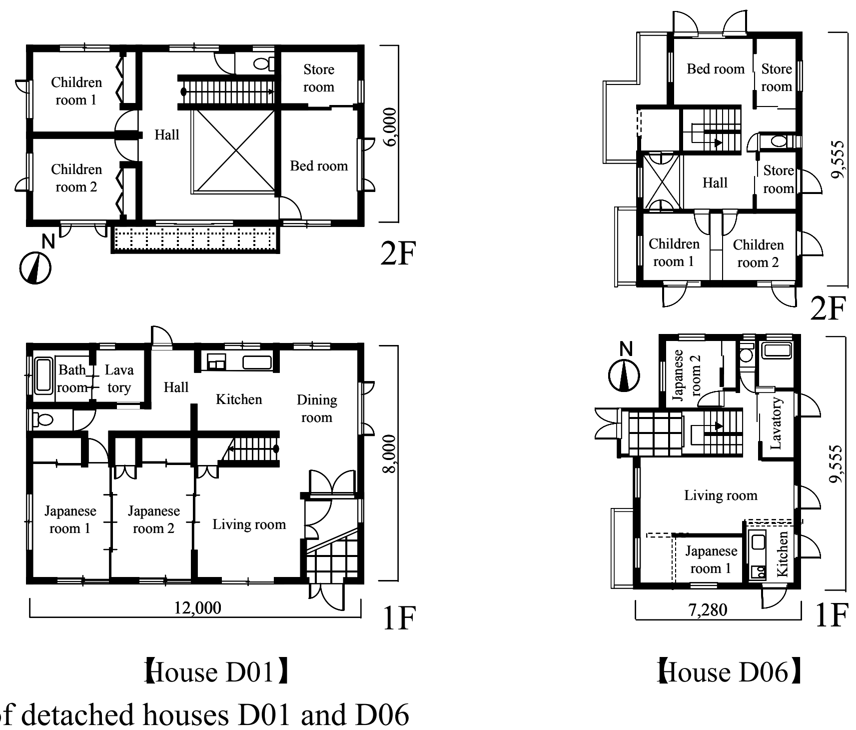


Figure 3. Plan of detached houses D01 and D06

Two-year profile of daily energy consumption

Profiles of daily amount of energy consumption and daily mean temperature of these two houses over a two-year period, from Dec. 2002 to Nov. 2004, are shown in Fig. 4. In house D01, the living room temperature changes in a range of 21˚C to 29˚C during the measured period, while that of house D06 is between 18˚C to 29˚C. Energy consumption in both houses increased in the winter due to space heating, but it is noted that the energy consumption of house D01 is about double that of house D06. The difference is because space hating was used entirely for house D01 but only partially for house D06. Another reason is that the value of heat loss coefficient of house D01 was 1.88 [W/m^{2}K] while house D06 was only 1.01 [W/m^{2}K]. The energy consumption of kitchen, audio visual & information, and healthcare, lighting & others are almost constant. However, the energy consumption of lighting & others changes with different season during the period of the investigation. The total energy consumption is very different due to the different lifestyles in both houses. In winter, the maximum difference of energy consumption between D01 and D06 is about 400MJ/day. On the other hand, in summer, the energy consumption of each house is about 100MJ/day.

Energy consumption profile on typical days

The profiles of energy consumption and temperature during three days in winter/summer are shown in Fig. 5. The middle day among three days was the coldest/hottest day with the lowest/highest outdoor air temperature during the investigation period. Each diagram of Fig. 5 is divided into three sections: the higher section shows the outdoor air and living room temperature, the middle section gives the energy consumption oh three uses (space heating/cooling, hot water supply, and others), and the lower section illustrates the energy consumption of the other items (kitchen, audio visual & information, healthcare, and lighting & others). The energy consumption is shown at intervals of 15 minutes.

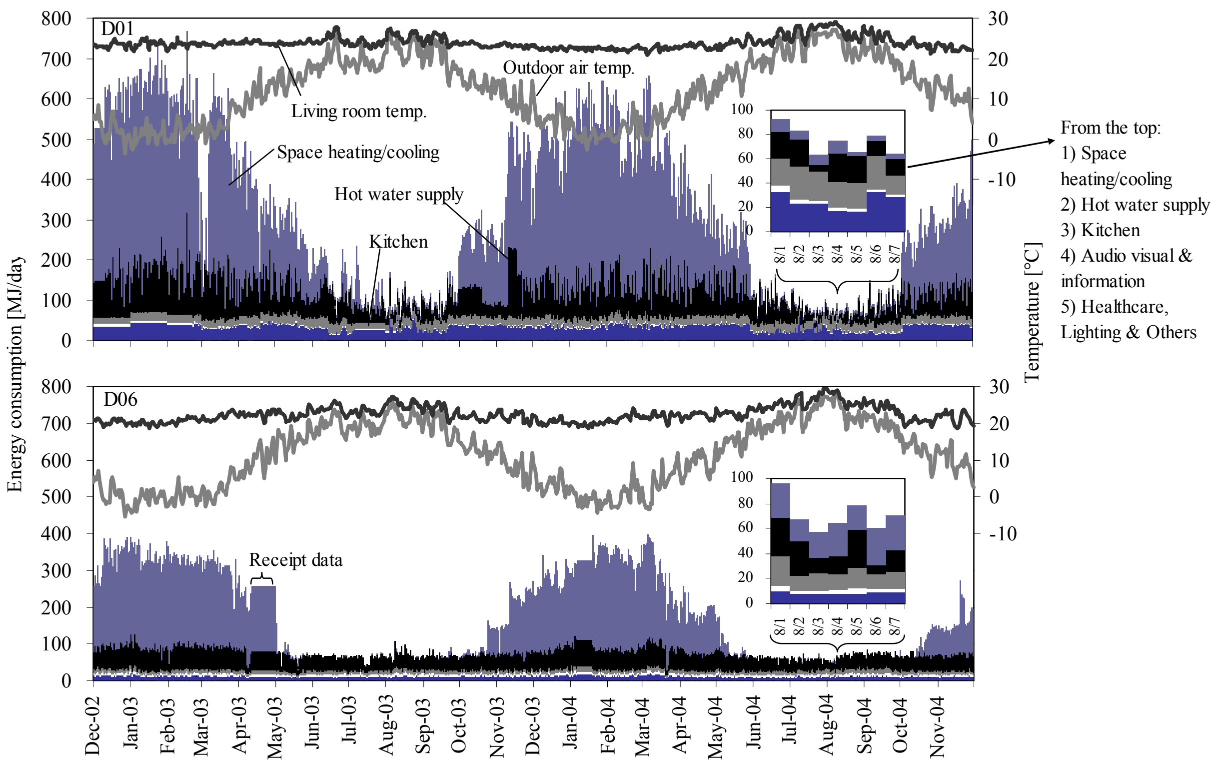

Figure 4. Two-year profile of daily energy consumption and temperature

The coldest day The temperature of the living room in D01 and D06 is almost constant during the coldest period, at 23˚C and 20˚C, respectively. This is due to the fact that the space heating is used all day in both houses. However, the energy consumption profiles are significantly different between the two houses. As the hot water heating panel was operated for the whole day in house D01, there was no peak energy consumption (except for hot water supply). In house D06, the energy was mainly consumed from 11 pm to 7 am by the thermal storage heating equipment using nighttime electric power. As shown in the lower section of diagram in Fig. 5, there are several peaks of energy consumption due to cooking activities.

The hottest day The temperature change in the living room ranged from 27˚C to 30˚C for house D01 and 25˚C to 30˚C for house D06. There was no obvious difference in the energy consumption trends of house D01 and D06, except energy consumption for hot water.

Ratio of energy consumption end use The ratio of energy consumption by end use during three day is shown in Fig. 5. In the coldest day, the percentage of energy consumption for space heating and hot water supply are 70% and 15% approximately in both houses. On the other hand, in the hottest day, the energy consumption for space cooling is small. In house D01, the energy consumption for space cooling and hot water supply share the same percentage of 15%. In house D06, those values are 10% and 50%, respectively.

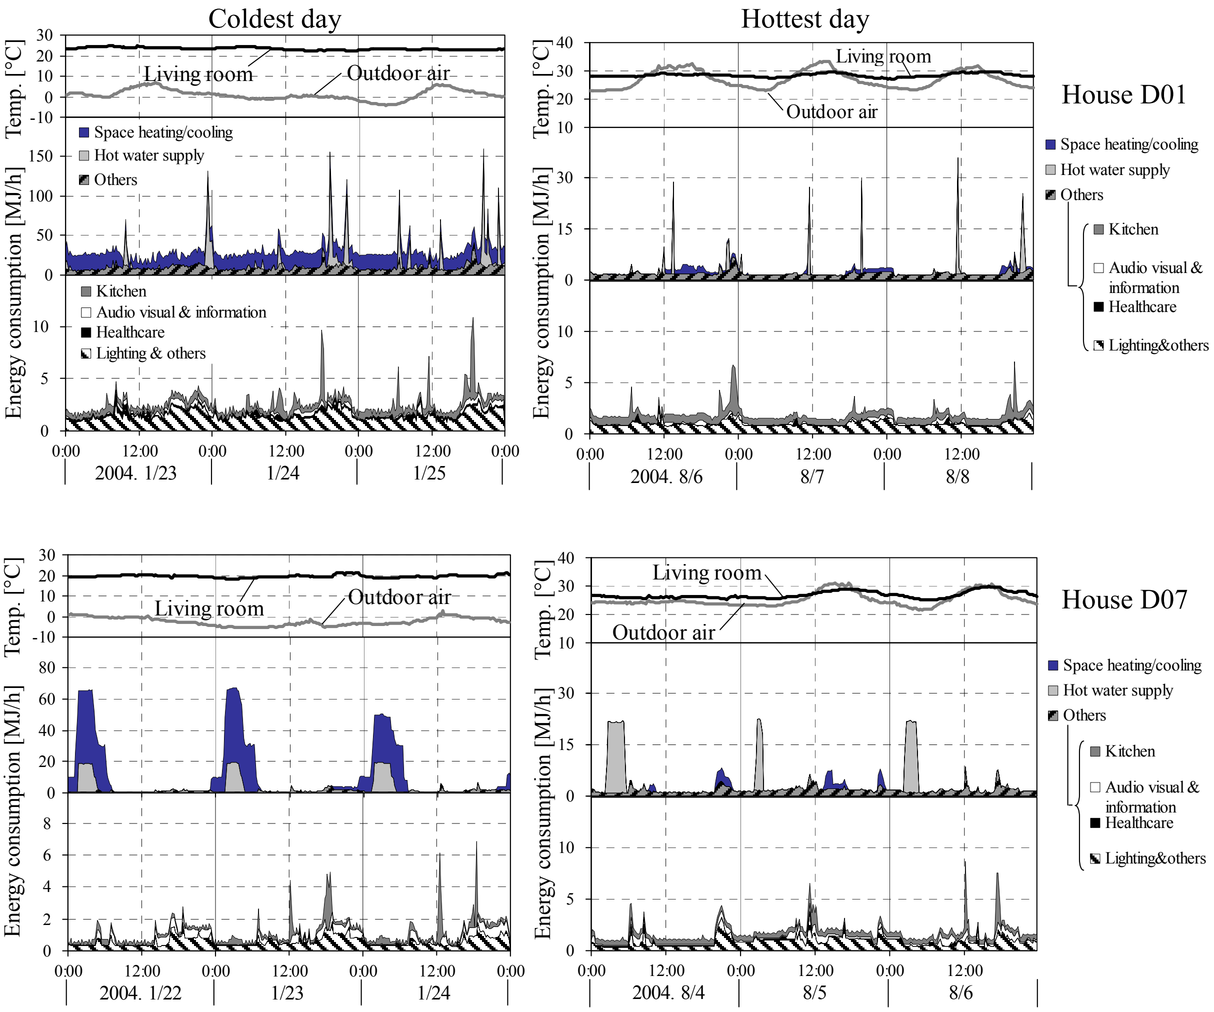

Figure 5. The change of temperature and energy consumption for three days, when the middle of three days is the coldest or hottest

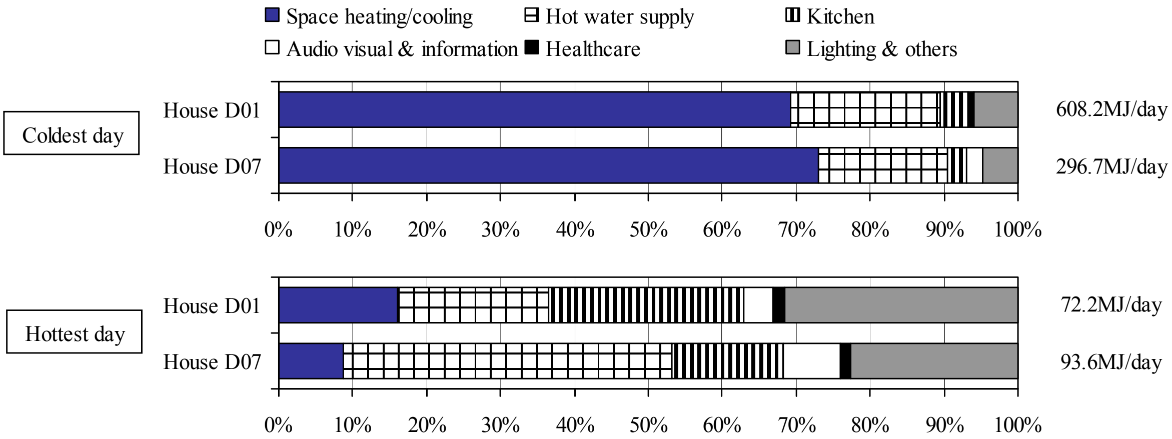

Figure 6. Ratio of end use energy consumption during three days including the coldest/hottest day

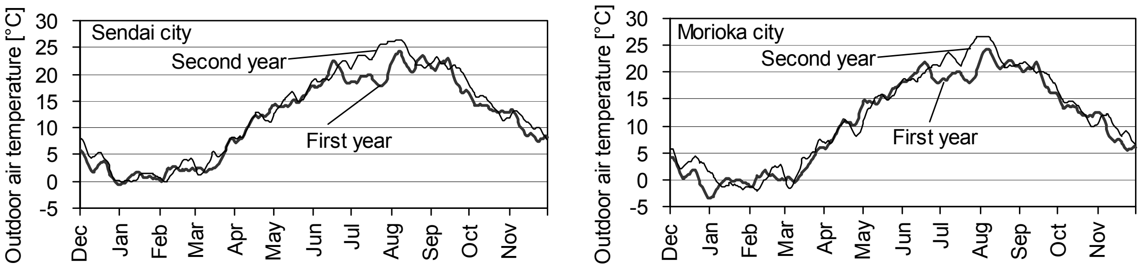

Figure 7. Comparison of outdoor air temperature between two years in two cities

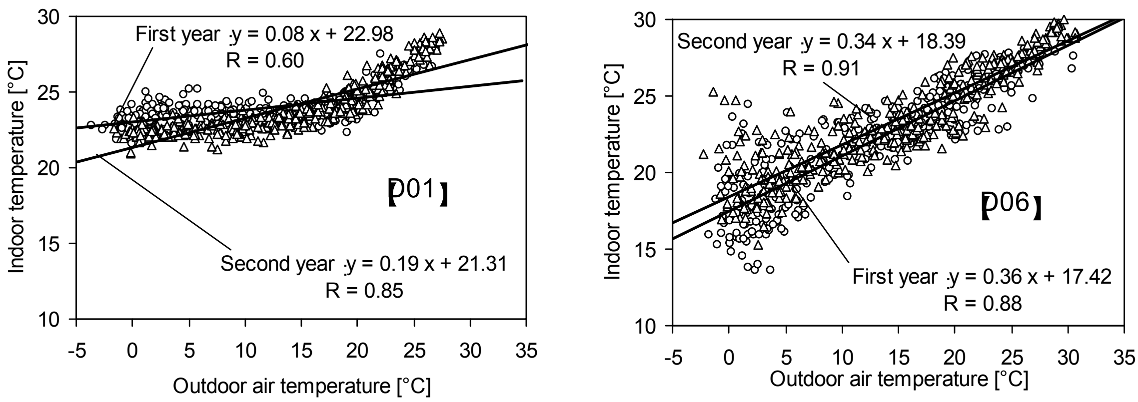

Figure 8. Relationship between daily average temperatures of indoor and outdoor air

Indoor and outdoor air temperatures

(1) Comparison of outdoor air temperatures between two years

Fig. 7 shows comparison of outdoor air temperatures between two years in two cities where the houses located. Temperatures in winter stayed about same in both cities. On the other hand, in summer, there were big differences. It was cold in first year and extremely hot in second year.

(2) Relationship between indoor and outdoor air temperature

The relationships between daily living room and outdoor air temperature in two houses are shown in Fig. 8. As to house D01, the living room temperature in the first year is commonly stable although the outdoor air temperature is remarkably varied. But in the second year, indoor temperature changed under the influence of outdoor air temperature. Based on the questionnaire survey, preset temperature of heating/cooling turned down/up in the second year. In the case of house D06, the relationship in the first year was almost the same as the second year.

CONCLUSIONS

Energy consumption and temperature for 9 houses

(1) Annual energy consumption per house varied from 40 to 120 GJ/year. The major energy consuming activities for detached houses and apartments were space heating and hot water supply respectively.
(2) Energy consumption in the second year decreased compared to the first year for most houses. The energy-saving consciousness of the occupants became stronger in the second year than that in the first year.
(3) Energy consumption per person per square meter for detached houses was less than those of apartments; approximately 0.12 and 0.23 GJ, respectively.

Energy consumption of two typical houses

(1) Energy consumption increases significantly in winter in both houses due mainly to space heating. The energy consumption of kitchen, audio visual & information, healthcare, lighting & others are almost constant. The annual profile was similar between the two years.
(2) In house D01, the living room temperature in the first year is commonly stable although the outdoor air temperature is remarkably varied. But in the second year, indoor temperature changed under the influence of outdoor air temperature. Based on the questionnaire survey, preset temperature of heating/cooling turned down/up in the second year.

This study found that energy consumption patterns of different houses varied significantly. It indicated that there is high energy saving potential by the change of lifestyle. The second year's energy consumptions of some of the investigated houses were lower than that of the first year. It was mainly due to the increased awareness of the inhabitant on the importance of energy saving and improved knowledge on energy saving lifestyles. The findings of this study serve as the basic data for further investigations in energy consumption saving strategies in Japan.

ACKNOWLEDGEMENT

This study was a part of the project entitled "Investigation on Energy Consumption of Residents all over Japan" of the Architecture Institute of Japan. It was supported by Tokyo, Kansai, Chubu, Kyushu Electric Power Co. The Chairman of the project was Prof. Shuzo Murakami of Faculty of Science and Technology, Keio University. This project was carried out in cooperation with Prof. Takashi Sasaki and Assoc. Prof. Masako Sugawara of Iwate Prefectural University. The authors express their appreciation to those who cooperated in, and the occupants who were involved in this survey.

SUMMARY

HVAC load weighs a large portion of overall building energy consumption. A low storey building of 20,000m2 floor area adopted a task ambient conditioning system (TAC) to reduce HVAC load while maintaining work environment. Other design techniques such as double-skin facade and structural thermal storage system, were also applied and the TAC system achieved comfortable personal work-environment with reduced demand.

INTRODUCTION

Generally, HVAC system load is one of the major energy consumption sources of a building. Reduction of such load shall play a significant role on the environment effect of the building but often in return of degraded work environment. This paper introduces a case of a low storey building with floor area of 20,000 m2 for its environmentally conscious design.

Project Outline

The building is a headquarter office in the suburbs of Tokyo.
The building is a four storey building with typical floor plan consisting of two wing zone with an atrium in between. Each wing is pillar-less and 33.6 m x 38.4 m / approximately 1500 m2. South Façade, typical floor plan, and outline of the building are shown in Figures 1, 2, and Table 1.
This building is built on a quake-absorbing structure. The main air conditioning method is under floor air distibution.

Figure 1. Facade of building

Table 1. Outline of building

Building data	Building type	Office
	Site area	4,782 m^2
	Gross area	19,169 m^2
	Floors grade	B1F-4F
	Max height	25.81m
	structure	SRC
M/E data	Heat source system	Ice storage system with Gas fired absorption chilled and hot water unit
	Air conditioner system	Under floor air-conditioning system only in interior zone
	Power supply	High voltage electric supply (main and sub)
	Supply of water system	Public water supply and the utilization of rain water and the well water

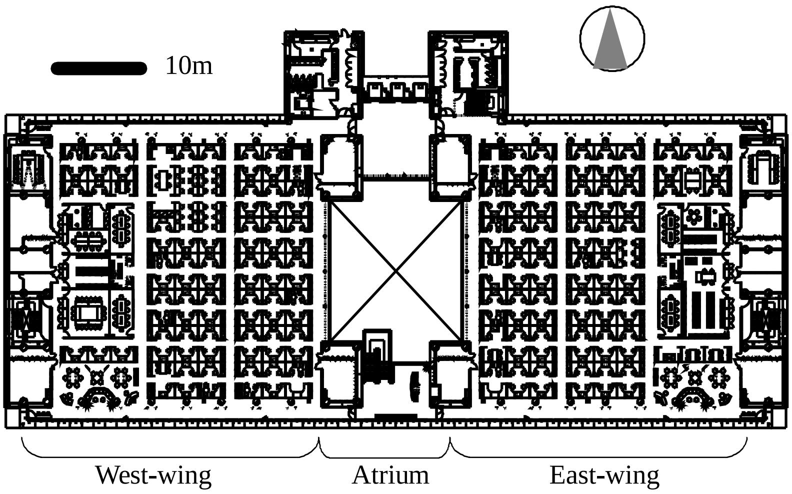

Figure 2 Typical floor plan

System Outline of Double-skin Facade

Double-skin façade (DS) consists of whole surface glasses of full storey height. Its advantages are to make the occupant unaware of the confinement and maximum utilization of natural lighting. In Japanese climate, the double-skin glass is required to satisfy various functions such as the discharging the heated air between the glasses in the summer, the thermal insulation in the winter and the natural ventilation in spring and autumn. These functions are realized by the automatic control ventilation dampers on Double-skin facade. DS has various ventilation dampers such as the top ventilation dampers, the bottom ventilation dampers, the top ventilation dampers of atrium, and each floor ventilation dampers.

During the summer, the top and bottom dampers are opened, to exhaust heat in DS by the natural ventilation and the thermal load to the building is decreased. The dampers are closed during the winter for better insulation.

In intermediate seasons such as spring and autumn, the building can be naturally ventilated by opening the bottom ventilation dampers, floor ventilation dampers, and top ventilation dampers on the atrium.

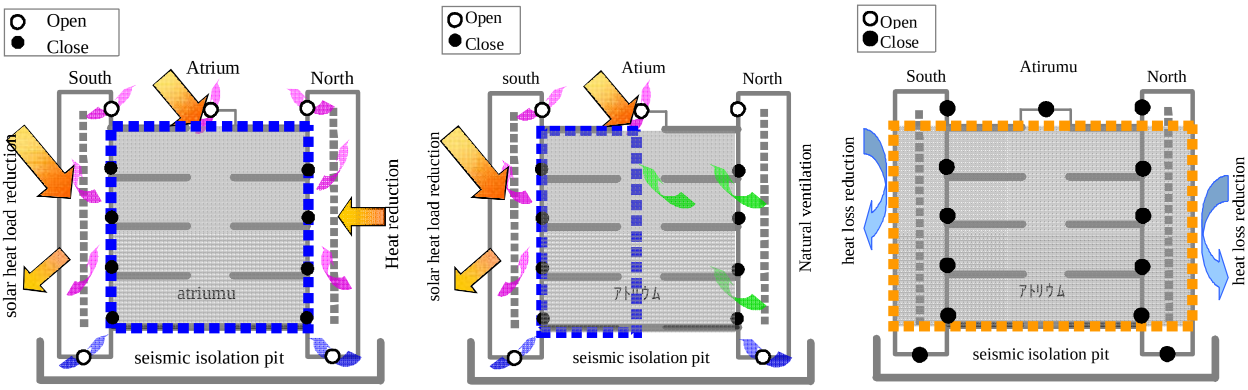

Figure 3. System outline of DS

Design Concept of Air-conditioning System

The air flow from floor distribution system reaches the occupied zone (FL+1,700) to form the temperature stratification between the occupied and unoccupied zone. (Fig.4)
Task air conditioning was introduced to the cubicles parted by partitions equipped with air outlets.
Moreover, by setting the main aisle in the DS, the main aisle serves as a perimeter buffer-zone. As a result, the building does not require dedicated air-conditioning system for perimeter.
In this building, the air-conditioning that suits with the special characteristic of a high ceiling and a wide space was designed by combining a vertical zoning and horizontal zoning.

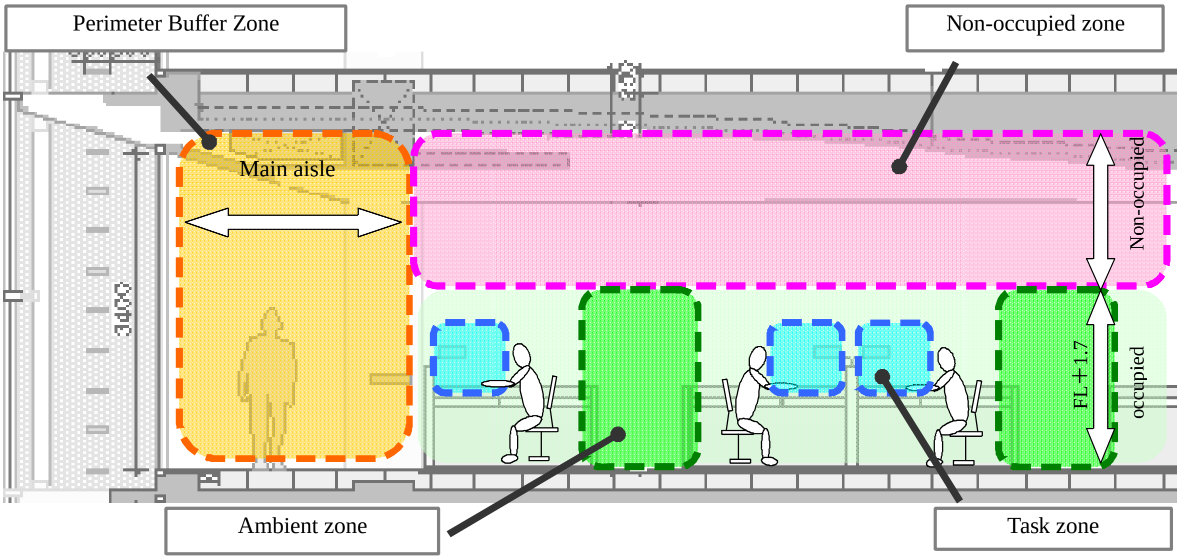

Figure 4. Outline of air-conditioning system

Environmental Assessment (CASBEE)

CASBEE (Comprehensive Assessment System for Building Environmental Efficiency) in Japan is a tool intended to implement the environmental assessments based on new concepts including BEE (Building Environmental Efficiency).[1]
The concept of this project is also “Improvement of environmental quality and performance” and “Reduction of environmental load”.
At the design stage, it was evaluated as S-rank (BEE=3.7) (=”Excellent”) with CASBEE.

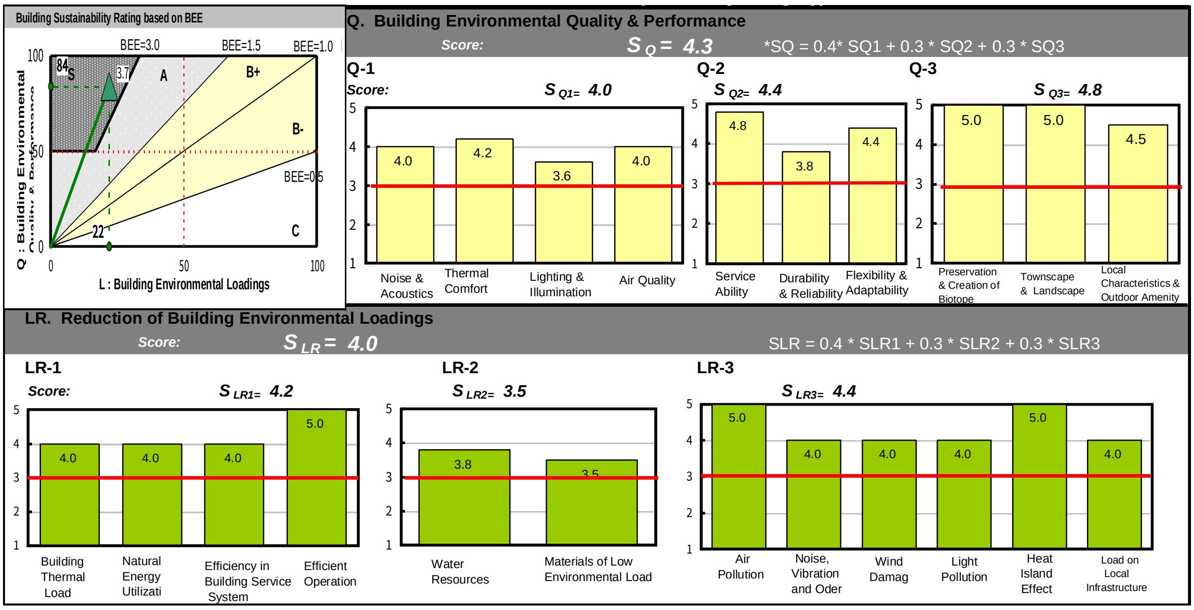

Figure 5. Environmental assessment in Japan

METHODS

Field Measurement Outline of DS

We predicted the performance of DS by the simulation that used the heat ventilation network [2] at the design stage. In 2005, we measured temperatures, the glass surface temperatures a velocity in DS, and a solar radiation in the room etc to confirm the DS performance in operation at each season of summer, autumn, and winter. Table 2 shows the outline of the measurement

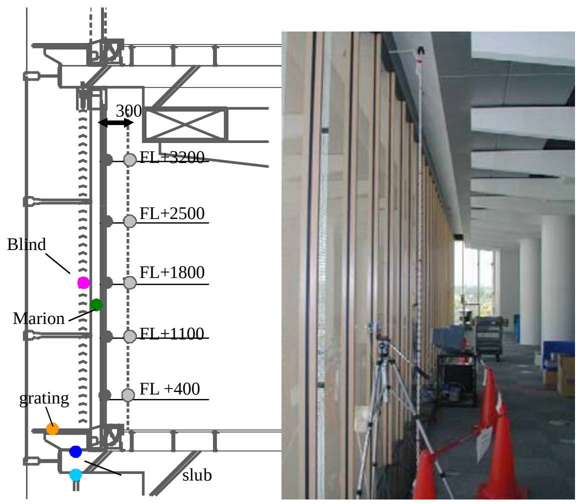

Figure 6. Outline of fielded measurement

Table 2. Outline of fielded measurement

Measurement item	Measurement point
Indoor glass surface temp.	5 p／F×4 place
Indoor air temp. by DS	5 p／F×4 place
Outdoor solar radiation	1 p（Outdoor）
Indoor solar radiation	1 p（3F/south）
Outdoor air temp.	1 p（Roof）
Outdoor velocity	1 p（Roof）
Thermal Graphic	1 place（3F/south）
Velocity in DS	Each Floor x 2 zone/F x 2p
Air Temp. in DS	Each Floor x 2 zone/F x 2p
Object temp. in DS	Grating, slab, blind

RESULTS

Thermal Performance of DS

In summer, the inside temperature of DS on the fourth floor was 35.4 degrees C on the south side, and 36.5 degrees C on the north side. The north and the south sides recorded similar temperatures despite the radiation of sun light.

The surface temperature of inner glass on the 3rd floor was approximately 32 degrees C for both north and south sides and this was almost equal to the outside air temperature. This shows that DS effectively blocks the radiation load by sunlight screening and heat exhaust.

The room temperature around the inner glass (300mm from glass surface) was equal to the AC room temperature setting (27.5 degrees), and the thermal environment in the perimeter section was maintained.

As for the DS in autumn, difference of temperature of the fourth and the first floor was larger with ⊿ T = 9.6 deg than it was in summer. On the north side, natural ventilation leveled the temperature in DS from the fourth floor from the first floor. The indoor glass surface temperature was 30 degrees C and north side 24 degrees C on the north side. The air temperature around DS was 24-25 degrees C, and good thermal environment was maintained.

All ventilation dampers are closed in winter(a day with a little sunlight). During the night, the temperature in DS was around 7 degrees C when the outdoor air temperature was 0 degrees C. The indoor glass surface temperature then was 15 degrees C. In addition, air temperature around DS was 22 degrees C in the daytime, and it was 20 degrees C at night. From these measurements, the heat loss by DS, was shown to be fewer.

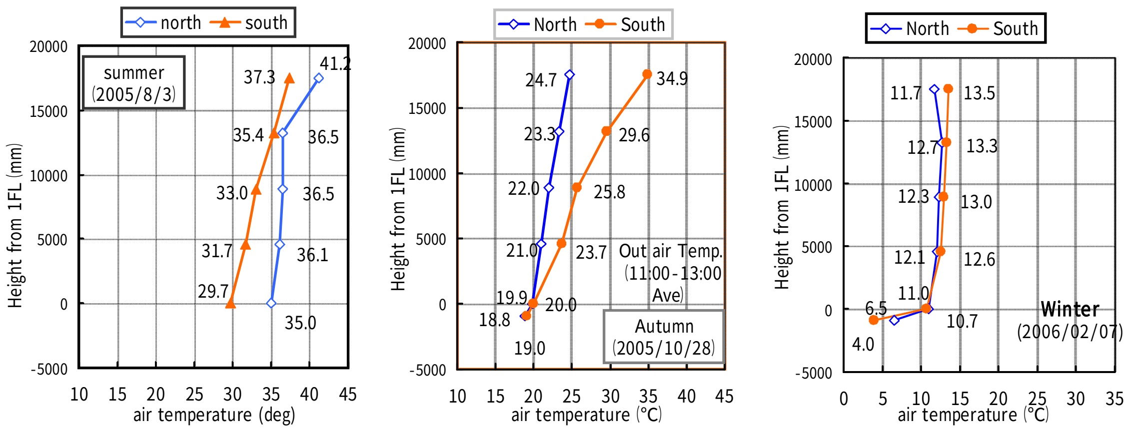

Figure 7. Profile of temperature (DS)

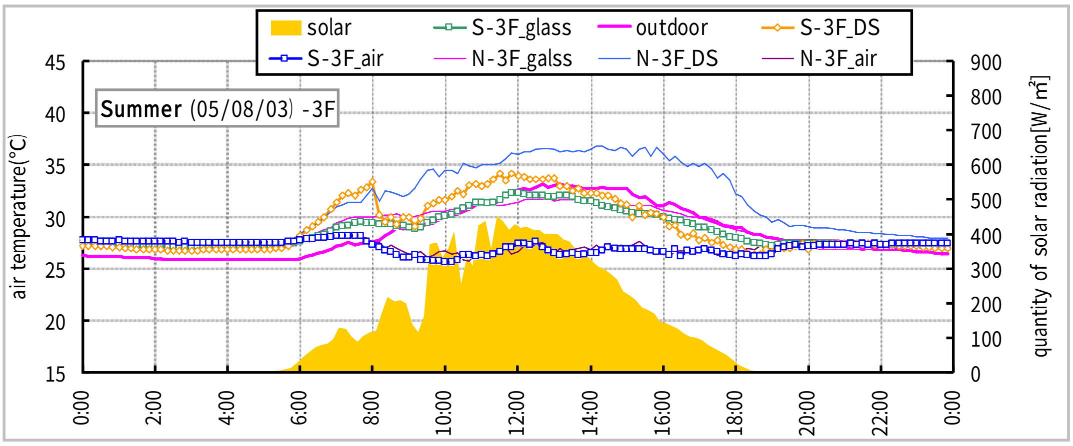

Figure 8. Result of Field measurement on 3F in summer

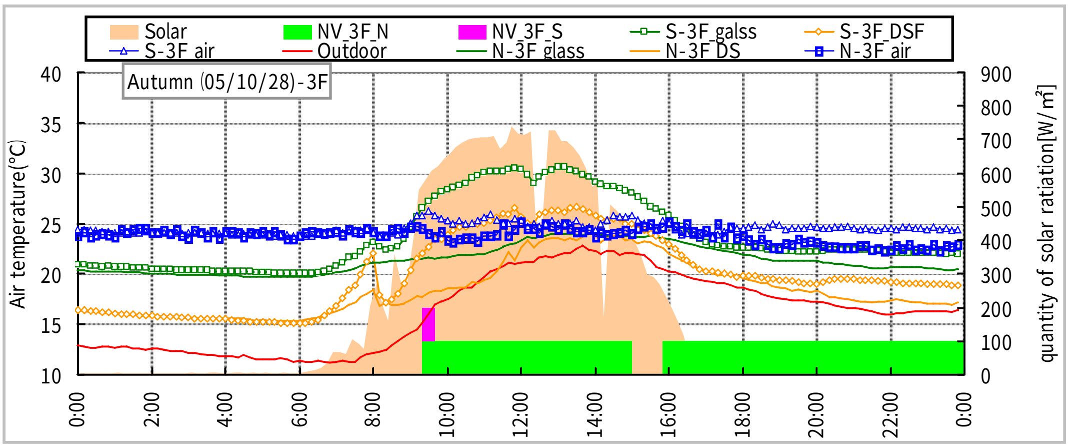

Figure 9. Result of Field measurement on 3F in autumn

Figure 10 shows the measurement result concerning the solar heat gain ratio of DS. The solar heat gain ratio was approximately 23%, showed high solar screening.

The measurement result concerning the thermal insulation efficiency in winter is shown in Figure 11. The over-all heat transfer coefficient of DS was about 2.7W/m2･K.

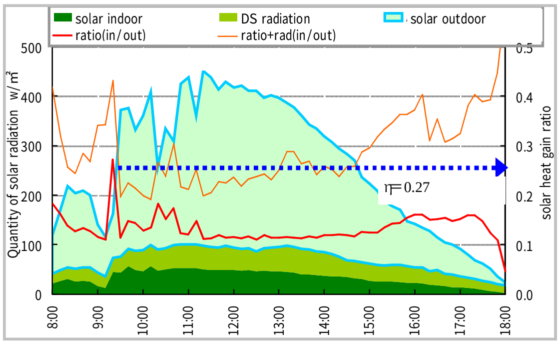

Figure 10. Solar heat gain ratio of DS

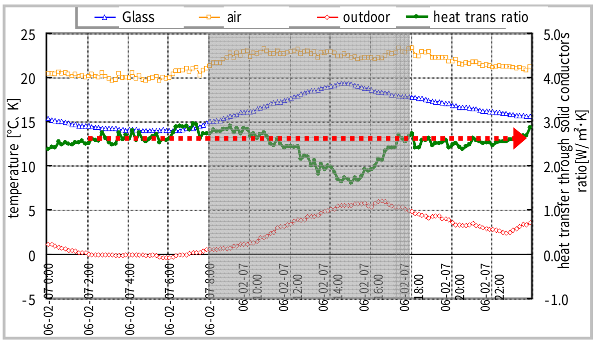

Figure 11. Over-all heat transfer coefficient of DS

Survey of "Cool-Biz"

In this building, a trial operation of "Cool Biz" was carried out together in 2005, 2006. TAC is assumed to maintain a thermal comfort even when the room temperature is setting high (28 degree C in summer).

We executed the survey on "Cool-Biz" to workers.

90 % agreed with the execution of "Cool Biz". A number of people reasoned as "Cooperation to energy conservation" .

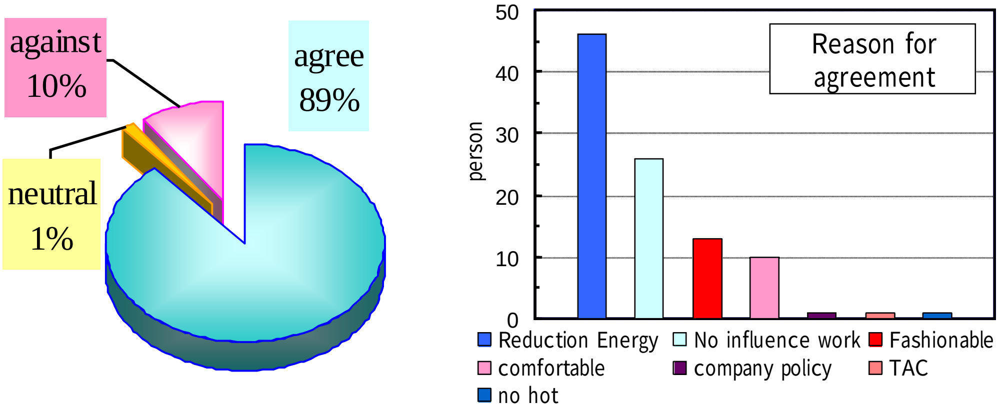

Figure 12. Survey about "Cool-Biz"

Filed Measurement of Energy Demand Profile

Figure 13 shows the annual Primary equipment load. Because of the reduction of thermal load by environmental technologies (DS, natural ventilation, etc), hot water demand in winter, and cold and hot water demand in intermediate season.

Fig.14 show the annual primary energy consumption of this building from July, 2005 to June, 2006. The primary energy consumed value was 1,657 MJ/m2/ year,
It was estimated that 21.9% (comparison object value : 2,121MJ/m2/year) reduction in the primary consumed value was attained by the DS, TAC, and various technologies (e.g. : natural ventilation, cool and heat tubes, using sunlight, etc). And, it was 16.3% less in the primary consumption compared to the standard office building in Japan (1,980MJ/m2/year).Table X. shows primary energy equivalent value when calculated.

Table 3. Primary energy equivalent value

	Electirc power	Natural gas
Value	9,760 MJ/kWh	46,100 kJ/Nm3

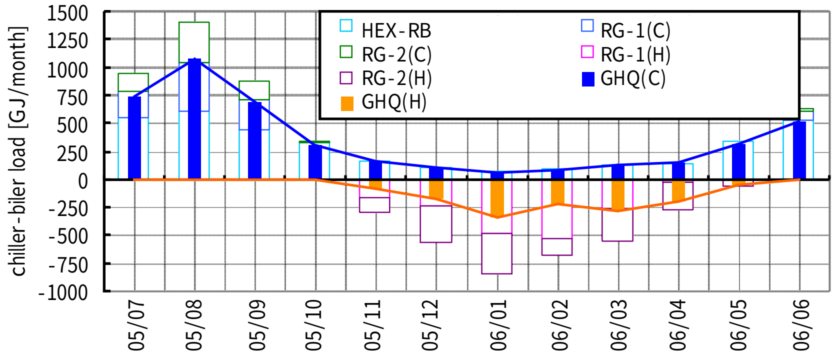

Figure 13. Annual primary equipment load

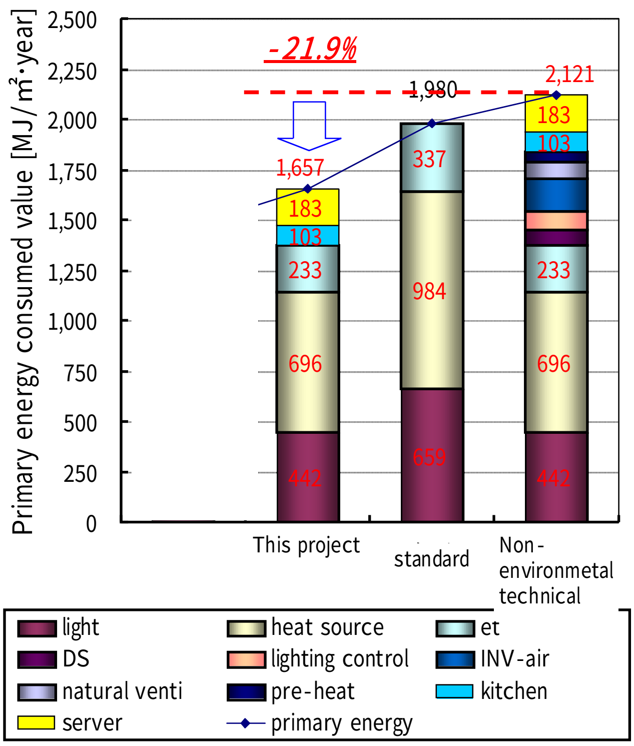

Figure 14. Primary energy consumed value

DISCUSSION

The concept of this project is "Improvement of environmental quality and performance" and "Reduction of environmental load" . So, this building integrated various environmental technologies. Field measurement verified that the building, estimated that 21.9% reduction in the primary consumed value could be attained by the DS, TAC, and various technologies, was sustainable.

SUMMARY

The ICEO Project quantifies the thermal and electrical energy consumption in hospitals of an Italian region (Lazio Region). 26 out of the 57 (45,6%) hospitals of the region were selected for a questionnaire in order to acquire information about activities, structural characteristics, technologies and the energetic consumption during the years 2001-2003. Only 61,5% of the selected hospitals supplied the required information. The consumption data show a great variability between hospitals, not always explained by their technological level or by their complexity. In Italy the energy consumption for housing and other civilian uses is increasing and today it represents the third part of the total energetic consumption. To reduce consumption, economic solutions should be adopted such as effective maintenance programs. It could be also useful to increase the adoption of renewable energetic sources and of a strong training program for the hospital staff.

INTRODUCTION

A hospital represents a classic example of a complex system where every structure is different each other and its characteristics are determined by the variety of supplied facilities, the size and the geographic location, sometimes with sophisticated solutions, but where every plant and technical equipment requires attention, in order to supply the service 365 days a year.

Besides, if the leading mission of a hospital is to supply high-grade medical treatments, in a short lapse of time, in optimal general conditions and at the lowest cost, it's also true that the various equipments employed to achieve that goal, and the whole operation, imply a relevant use of both thermal and electric energy.

The major amount of thermal energy consumption in hospitals is generally absorbed by heating and ventilation systems, covering the 50-60% of total consumption [1], whereas the remaining percentage is employed by the so-called "technical service equipments", such as: hot water production, cookery, laundry, sterilization.

The electric energy, instead, covers an average of the 20% of the entire energy consumption, but it could consist up to an average of 30-35% of the total cost [1].

The increase of electric consumption in the last few years is certainly due not only to the operation of a variety of new diagnostic and therapeutic equipments, but, mainly, to the increasing use of television sets in every rooms and in-patient areas, and to a more generalized use of HVAC systems [1].

The study performed by the ENEA (*Ente Nazionale Energia e Ambiente*) in the '90s (1), estimating a thermal energy consumption equal to the 80%, and the remaining 20% of electric energy consumption, already recorded a valuable waste of energy certainly due to a general obsolescence of plants and buildings, but also to an inadequate management. On the whole, the pure cost of energy constituted just a portion of the total consumption.

Referring to the same study in the '90s, it turned out that in Italy the cost of the National Health Service (NHS) amounted to approximately 70,000 billions of Lire in 1991, about the 50% of which was attributable to hospital service. The incidence of energy was estimated, even in other European countries, around the 4-5% of the entire cost of the hospital services and this entails that the energy bill of the Italian hospitals, at that time, was up to 1,500 billions of Lire [1], around 775 millions of Euro, namely 17,445,000 MWh (1.5 Mtep) yearly.

The average energetic cost, for a hospital bed, is 1,700 Euro/year, whereof 1,300 Euro are due to heating cost.

A remarkable amount of energy could be saved reducing the service cost by 10%, improving the energy efficiency, thanks to a better management and rationalization [1]. Therefore, it is important to make aware the hospitals and their staff about the need of a rational use of energy.

OBJECTIVES

Aim of the ICEO Project (translation: investigation on hospital energy consumption) was to quantify the thermal and electrical energy consumption by the hospitals of an Italian Region (Lazio Region), in order to identify the factors associated with the consumption and to define possible strategies of control.

METHODS

The study covered the 45.6% (26 out of 57) of the regional hospitals. By mean of a questionnaire, each hospital has been asked to supply information about activities, structural characteristics, technologies and energetic consumption (thermal and electric) during the years 2001-2003.

Data sheets on energy accounting by ENEL (*Ente Nazionale Energia Elettrica*), data of ENEA researches [1, 2] on the rational use of energy in hospitals, and data used in a previous pilot study [3] were taken into consideration to draw up the questionnaire.

The questionnaire was sent by fax to 26 hospitals selected from the list published in the Ministry of Health website. The acquired data were treated to find out useful energy indicators to compare energy situations in hospitals. Only 2003 energy data, being the others non exhaustive, have been analysed.

RESULTS

16 (61.5%) out of the 26 selected hospitals submitted the questionnaire and just 14 of them provided all the necessary information. It turned out that the majority of them had given the operation of plants in outsourcing.

Table 1 shows hospitals that answered the questionnaire by typology, structure and service.

Considering the relationship with the National and Regional Health services, the complexity level and the financing, the hospitals were divided in four groups: University hospitals, Major General Hospitals, Research Hospitals and Local General Hospitals.

Table. 1 Characteristics of the hospitals involved in the study

	Name	n° of buildings	Volum m^3	n° beds	n° of patients	Average stay (days)
University Hospitals	UH 1	44	1,287,675	154,0	43,985	11.1
	UH 2	1	180,000	450	639	5
	UH 3	1	--	179,0	63,141	8.8
Major General Hospitals (*)	MGH 1	5	415,889.1	105,5	26,972	9
	MGH 2	3	201,387	783	22,428	9
Research hospitals (**)	RH 1	6	66,577	455	24,545	6.8
Local General Hospitals (***)	LGH 1	1	--	99	4,170	6.4
	LGH 2	1	164,500	420	17,102	7.11
	LGH 3	2	31,500	75	3,129	6.73
	LGH 4	1	12,500	41	1,481	4.08
	LGH 5	3	141,703	434	28,000	6.2

	LGH 7	1	117,000	369	9,069	9.35
	LGH 8	1	28,000	71	1,839	7.2
	LGH 9	1	57,000	122	3,602	9.5
	LGH 10	1	104,803	324	14,620	6.3

(*) Self administered within the Regional Health Service
(**) Self administered within the National Health Service and financed by the State for research purposes
(***) Administered by the Local Health Units within the Regional Health Service

Figure 1 shows the percentage distribution of Regional and selected hospitals depending on their typology. In the investigated sample the percentage of Research Hospital was lower if compared with the Region, but this defect was acceptable because of the higher percentage of University Hospital.

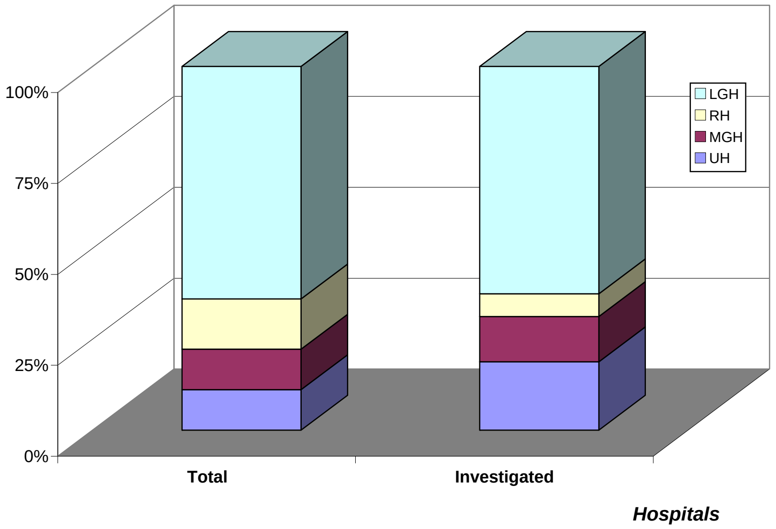

Fig . 1 – Distribution of hospitals by typology: total and investigated hospitals

The largest amount of the hospitals of the Region (73%) use methane as heating fuel (fig. 2), followed by oil (13%), eco-diesel (7%) and Low Sulphur Content (7%).

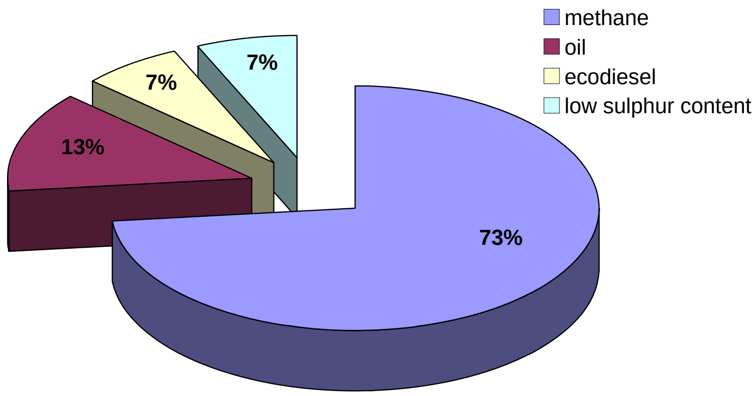

Fig . 2 - Combustible used by hospitals

In regard of electric energy consumption, the yearly average is around 13,500 kWh/bed (min 2,100 kWh/bed - max 23,700 kWh/bed) and the thermal consumption average is around 22,000 kWh (min 9,600 kWh/bed - max 36800 kWh/bed).

Figure 3 illustrates a wide variability among the hospitals, not always explained by their technological level and the level of service supplied. For two hospitals (LGH 6 and LGH 8) data about electric consumptions were not available.

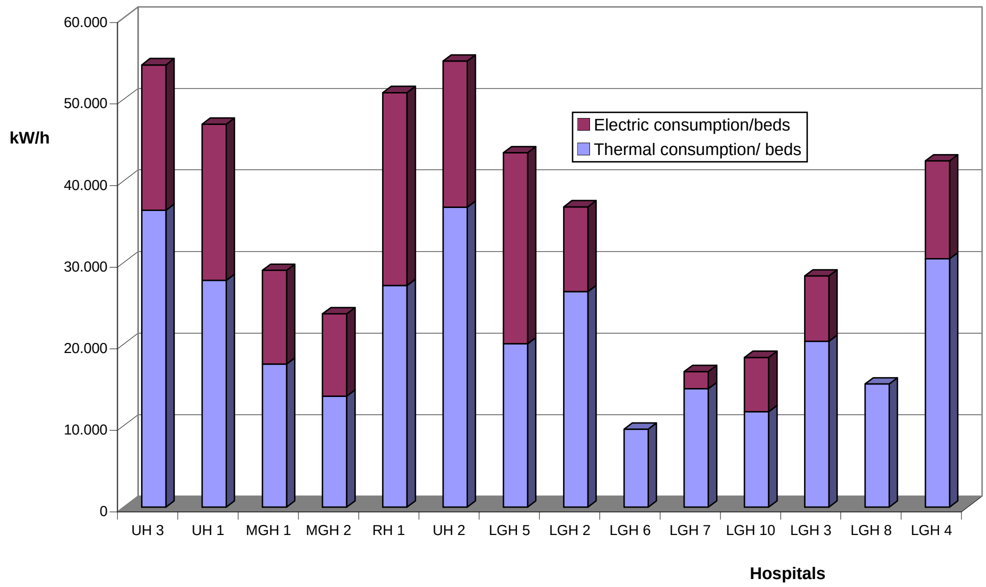

Fig . 3 - Energy consumption (thermal and electric) by hospital

Comparing the average results observed in the study with those obtained by other national and international studies (table 2), we found out that similar proportions of thermal/electric energy requirement are supplied in Italy and in foreign countries.

Table. 2 - Average results observed in the ICEOs study with those obtained in other studies

DISCUSSION

The energy consumption for housing and other civilian uses represents the third part of the total energetic consumption in Italy. Besides, the introduction of new technologies implies a strong and continuous increase of consumption. In various hospitals the Energy Manager, although required by Italian low in all structures consuming a quantity of energy >1,000 OET/year, isn’t in charge or hasn’t a specific competence or is absorbed by other tasks, thus lacking in his reference role for the energetic consumption control program.

The reduction of consumption could be achieved by means of economic solutions such as a greater care by the staff, the use of high-efficiency lamps and heat-saving heating plants, the adoption of renewable energetic sources and the implementation of strong programs of maintenance.

CONCLUSIONS

Hospitals are supposed to be significantly interested in the adoption of new technologies employing “renewable” natural energetic and, above all, non-pollutant sources.

In accordance with the Italian CIPE directive 57/2002 [6], a solution could be the promotion of the efficiency in the production of energy by means of high-productive technologies to generate electric energy, the spread of plants of co-generation electricity-heat, the use of the energy produced by the plants of thermo-destruction of sewage and the saving of dispersed heat, but also sustaining the use of renewable energetic sources and the promotion of studies and development in the area of less impacting energies.

In this field it’s of value the possible planning of a hospital according to the principles of a sustainable development, mainly using sun power by means of systems of active and passive utilization, dampening environmental and economic expenses [7].

The energy consumption in hospital, nowadays, is 3 times greater than the energy consumption for housing, because the whole plant is supposed to assure an extended seasonal heating supply, higher temperatures, more air exchange and particular microclimatic characteristics during the year [7].

As suggested in the literature [1, 7, 8], useful actions to reduce energetic consumption in hospitals could be:
improving the thermal isolation of both the vertical and horizontal envelope;
realizing a computerized control of the illumination, HVCA, doors control systems;
using renewable energetic sources (active and passive sun power systems);
adopting co generative plants and heat pumps;
reducing thermal dispersion.

Sustainable energy systems

Advanced sustainable energy technologies for cooling and heating applications

Bernard Thonon

Greth, France

Corresponding email: Bernard.thonon@greth.fr

SUMMARY

Multi-energy sources, for heating and cooling purposes, are considered to have a large potential in contributing to the penetration of renewable energy sources for domestic, building and industrial applications. But it requires that conventional heating and cooling systems have to be adapted or changed for incorporating renewable energy sources. Nowadays, the heating, ventilating and air-conditioning industries are the actors which have access to the market, and they provide services using mainly fossil fuels or electricity as energy sources. The objective is to have them using renewable energy, combining conventional and renewable sources and proposing environmental cost-effective products.

The technical goal of this project is to set-up technology resource centres in Europe, with the aim of building bridges between the technology providers (research centres, universities and industry) and the technology users (manufacturers, engineering companies…). The project outputs are:

- Creation of the clubs/grouping
- Collection of RTD results
- Development of design tools for evaluating and sizing the new technologies
- Best practice and training programme
- Creation of a knowledge resource centre relying on multi language search engines based on craft ontologies and terminologies
- International collaboration with China

For this 13 partners are collaborating to this project. The consortium is composed of centres of excellence in the area of renewable energies, energy agencies and professional associations representing industry.

INTRODUCTION

The growing demand for energy despite limited fossil fuel reserves and growing environmental concerns is probably the major challenge of the 21st century. To achieve a sustainable development, the origin and the usage of energy have to be addressed, and advanced renewable energy technologies and energy carriers have to be developed, requiring significant progress in research and technology.

The objective of this project is to support industrial manufacturers and engineering companies of heating and cooling systems (including energy storage) in their development, by introducing more renewable energy sources in their technology. For European countries, according to the IEA, thermal use of energy represents more than 25% of the gross energy consumption. Multi-energy sources, for heating and cooling purposes, are considered to have a large potential in contributing to the penetration of renewable energy sources for domestic, building and industrial applications. But it requires that conventional heating and cooling systems have to be adapted or changed for incorporating renewable energy sources. Nowadays, the heating, ventilating and air-conditioning industries (HVAC) are the actors which have access to the market, and they provide services using mainly fossil fuels or electricity as energy sources. The objective is to have them using renewable energy, combining conventional and renewable sources and proposing environmental cost-effective products.

The technical goal of this project is to set-up technology resource centres in Europe, with the aim of building bridges (figure 1) between the technology providers (research centres, universities or industry) and the technology users (manufacturers, engineering companies, architects, local actors…). The technology user is a company or a professional organisation which is going to incorporate in its system/service renewable energy technologies.

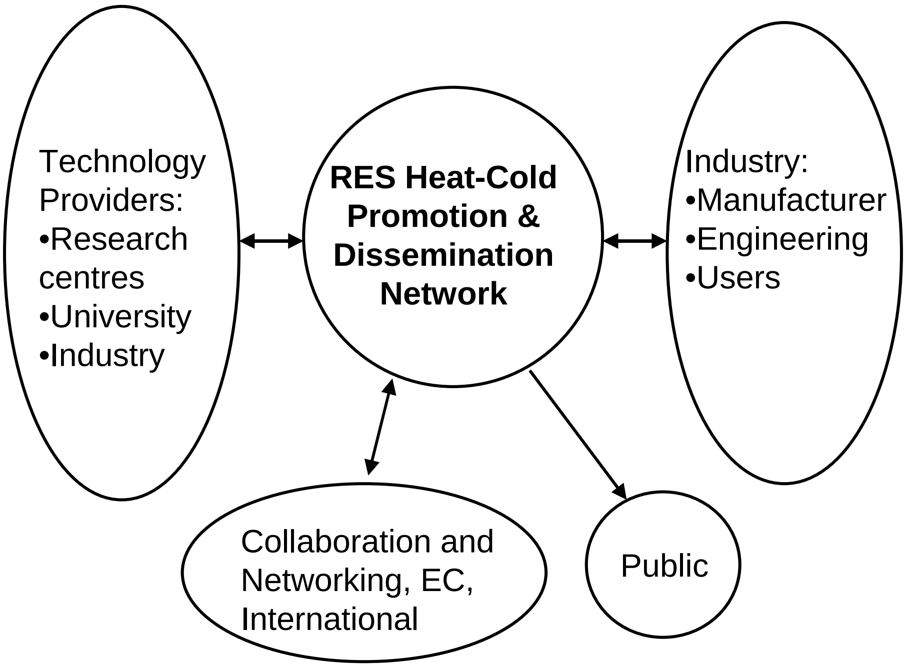

Figure 1 : Overview of the project methodology

A technology resource centre is where industry can found resources for developing and improving their technology. A resource centre might have its own research capacity or collaborates with technology providers such a research centre (private or public) or universities. A resource centre is the focus point of industrial actors in a same area, it associates manufacturers (components and systems), engineering companies, end-users, and energy providers.

Technology resource centres have five main goals:

- To bring new technologies from research to the market
- To promote trans-national collaboration
- To support companies in problem solving
- To be identified as a partner to manage industrial RTD projects
- To access and to share data and expert knowledge base

RENEWABLE ENERGY SOURCES FOR HEATING AND COOLING

To be effective and to take into account the specificity of the market, this project focuses on renewable heating and cooling technologies: **RES-HC**. It concerns **solar heating and cooling, biomass (heat), heat pumps, geothermal heat and energy storage**. The objective is to facilitate the introduction of RTD results into the market by establishing technology resource centres. These centres will operate on a common basis, sharing tools, date-base and exchanging information.

Within this project, 7 technology resource centres will be established and linked by the end of the project. The effective technology transfer will be insured by associating industrial partners to the project. The objective is to get at least 500 industrial partners connected to the network and beneficiating from its output.

A virtual knowledge base resource centre relying on a dedicated multi-language search engine will be created. 6 centres of excellence in the area of RES-HC will contribute by linking their data and project results references. This platform will be open to other centre of excellence wishing to share informations.

This project is technology oriented, and aims in structuring the scientific and technical background for developing and optimising RES-HC systems. It contributes to the technology and industrial development phase of the product life cycle development, as the marketing phase is essentially controlled by non technical issues such as policy measures and financing options.

For RES-HC technologies, it is believed that the market penetration will be insured by associating the traditional actors of the sectors to manufacturers focusing and single RES-HC technology. The growing interest of manufacturers of gas–fired boilers for space heating and hot water to renewable energy sources confirms the strategy proposed in this project.

The traditional actors in the heating and ventilation industry are mainly composed of small and medium enterprises, which have low research and technology development activities. On the contrary, the companies involved in RES-HC are more innovative. Therefore, there is a clear need in supporting the traditional industry in incorporating renewable energy sources in their systems and to associate technology providers of RES-HC for developing and marketing new products.

Individual renewable energy sources have advantages but also drawbacks, such as intermittency of the source or difficulty of supply. To cope with these drawbacks, and to provide an efficient service to the final user, it is necessary to associate various energy sources and energy storage. Solutions have been proposed developed and tested within several research projects and need now to be appropriated by the actual industrial actors. For this they need to get the information, to identify the right partners and to set-up a collaborative agreement for optimising and marketing new products, and these are the role of technology resource centres.

THE POTENTIAL OF RES-HC TECHNOLOGIES

Market Potential

This project focus on renewable heating and cooling technologies for domestic, building and industrial applications. The renewable heating and cooling energy sources are biomass, solar thermal and geothermal (including heat pumps). In 2000, the energy consumption for thermal power generation (including district heating) is 410 Mtoe/year, which represents 25% of the gross EU-25 energy consumption [1]. At this value must be added 16 MWh/year of electricity consumption for building and residential air-conditioning (recent surveys have estimated an electricity consumption of 29 MWh/year in 2010[2]).

For RES-HC [3], the EU 1997 white paper on energy gives a target for 2010, of a market share of 80 Mtoe, 20% of the thermal power generation [1]. In 2001, the market share is 48.7 Mtoe, 12% of the thermal power generation [4]. This requests an average growing rate of 5 to 6% until 2010. Even if the situation has progressed since 1997 (see figure 2), the 20% average market share will probably not be reached in 2010, and an extra 2% must be achieved. In order to reach this objective both market pull and technology push measures have to be adopted. This project will concentrate on developing and promoting cost-effective technologies and systems. The Bielefeld Declaration (14 May 2004), has emphasised that specific measures have to be taken in favour of RES-HC if a 20% market share of the thermal power generation must be reached in 2020.

Even if the overall RTD expenditure on renewable energy sources is slowly increasing in Europe [5], the effort related to RES-HC is decreasing each year since 1980, representing nowadays less than 10% of the total effort on RES. This lower support is in contradiction with the high potential of RES-HC, and a more vigorous support policy must be implemented at the European level [6].

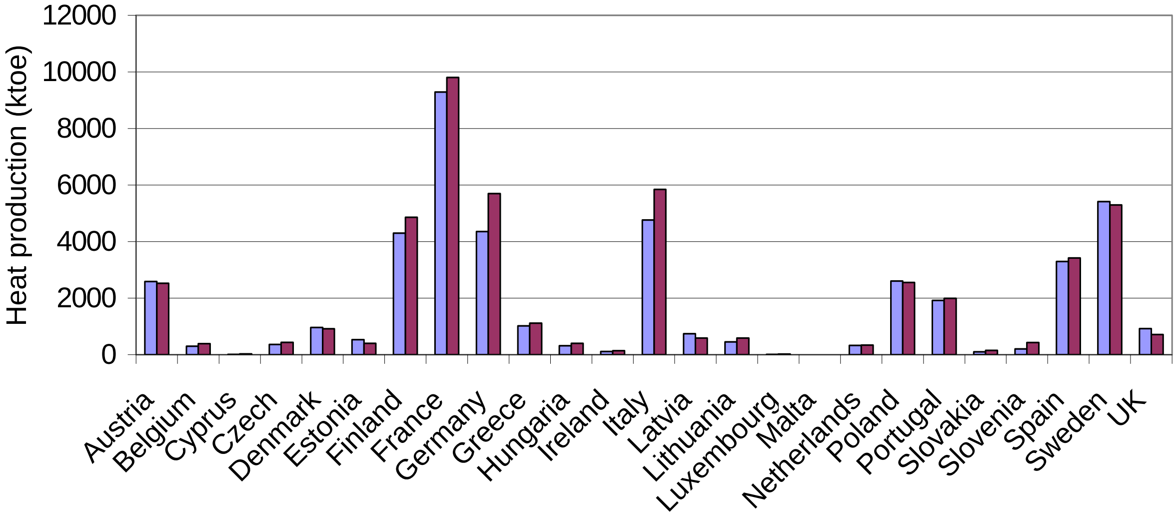

Figure 2: RES-Heat production for the EU-25 for 1997 and 2001

The potential of RES-Heat has been recently evaluated for the European Union [7] and is summarised in the table 1. As it can be seen, depending on the source and the country, there are very significant market penetrations of the renewable energy sources for heating and cooling (RES-HC). Biomass has from far the largest market penetration, having reached almost 50% of its long term potential. For EU-25; biomass and geothermal energies are mature technologies that contribute about 3% to primary energy supply. Solar, heat pumps other new renewables have experienced rapid technology development, but as yet they represent only a small share.

The main figure is that biomass is nowadays the major provider of renewable thermal energy, but it will reach 75% of its potential in 2010. The contribution of the other sources (heat pumps, solar and geothermal) could potentially contribute to the same amount but is nowadays much less important. Heat pumps and solar renewable sources needs another source of energy to provide the total thermal needs, therefore it is only by associating various energy source that these technologies could reach their full potential. This project will concentrate on multi renewable energy sources technologies.

Table 1: Market penetration of RES-HC systems in EU-25 [7-8-9-10]

	Penetration (year 2002)			**Energy (Mtoe)**		
Source	**Minimal**	**Maximal**	**Average**	**2001**	**2010 target**	**Potential**
Biomass	10%	70%	47%	46.90	75.0	100.0
Solar thermal	0%	30%	<2%	0.57	4.0	36.0
Heat pumps	0%	30%	<2%	0.40		32.0
Geothermal (grid)	0%	40%	<2%		1.0	3.0
Geothermal (total)*				0.83		
Total				48.7	80.0	171.0

* The total geothermal heat production is complex to analyse due to various applications and the calculations methods varies from one country to another (contribution of hot springs).

It has been recognised [5] that hybriding fossil fuel and renewable energies will accelerate market penetration of RES. The technical and financial risks can be minimised, therefore being more attractive for investors. Hybrid and multi-sources systems are particularly applicable to renewable heating and cooling.

Social and environmental impacts

Renewable energies and in particular heating and cooling technologies are decentralised markets and create employment essentially at a local stage. The manufacturers involved in such activity are often small and medium enterprises ranging from few employees to several hundreds. Furthermore, the installation and maintenance of these equipments will require specialised workers [5].

The replacement of fossil fuel heating systems by renewables will induce a modification of the individual behaviour and will have impact on employment [11]. Fossil fuel heating systems implies generally relatively low investment and after 10 years of operation, the cost for the fuel is largely the first expense. On the contrary, renewables have high capital cost and low operating cost. Therefore, the financial amount which is spent for buying fossil fuels (mainly imported) is mainly replaced by an equivalent amount in hardware which are mainly produced in Europe. An energy consumption of 80 Mtoe of fossil fuels (gas and oil), correspond roughly to an expense of 40,000 M€ (30 €/MW.h and average energy efficiency of 70%). If this expense is partly replaced by capital costs for investment in renewable technologies, it is expected to induce the employment of 400,000 persons.

This project will contribute in creating employment in small and medium enterprise of the heating, ventilation and air-conditioning industries, by introducing more renewable energy technologies in the systems they are developing and installing. The activity of manufacturers of RES-HC systems (solar panels, biomass heaters, heat-pumps…) will also be strengthened.

From an economic point of view as RES-HC technologies are capital intensive energies, the present period is particularly interesting for the development of RES technologies. This is due to a relatively low cost of money (yearly interest below 4%) and high cost of energy. If the different incitation measures in favour of RES are promoted and increased it will guarantee the development of RES-HC in Europe.

The adoption of the Kyoto protocol implies that Europe has to reduce its CO2 by 5% in respect to its level in 1990, and heating and cooling are particularly concerned by CO2 emissions. Renewable energy sources are by definition environmental clean energies and contribute to preserving natural resources and prevent global warming. The CO2 emissions of such system are significantly reduced compared to fossil fuel system, and this even taking into account the energy required for manufacturing the system (life cycle impact assessment). The use of renewable energies for heating and cooling purpose has indirect environmental impacts. If 80 Mtoe of fossil fuels are replaced by renewable energy it will affect the distribution schemes of energy: (1) less transport of liquid fuels by sea, river, train and road which reduces the harmful effects (pollution risks, number of trucks on the roads…); (2) reduced peak effects for the electric demand in winter time for heating and summer time for cooling and induces a better management of the electric network.

Towards sustainable energy systems – role and achievements of heat integration

Jiří Klemeš, Simon John Perry and Igor Bulatov

Centre for Process Integration, School of Chemical Engineering and Analytical Science
The University of Manchester, UK

Corresponding email: j.klemes@manchester.ac.uk

SUMMARY

This paper presents an established sustainable and integrated design methodology for the efficient heating and cooling of individual buildings and complexes. The methodology includes the design basis for combined heat and power systems, refrigeration, air conditioning and heating with pump systems. It is equally applicable for single family houses as well as large building complexes and meets a major challenge in the design of heating and cooling systems, namely, the complexity of energy and power integration. The efficient use of available heating and cooling resources for serving buildings of various sizes and designations can significantly reduce energy consumption and emissions. Although heat integration (or Pinch Technology) has been around for several decades and has been very successfully applied in large industrial applications, it has only recently been applied for improving the energy efficiency of buildings and building complexes. There is significant scope for application, as energy prices rise and energy related emissions are required to be reduced. This methodology can also be used to integrate renewable energy sources such as biomass, solar PV and solar heating into the combined heating and cooling cycles. Case studies are used to illustrate the methodology. The paper makes suggestions how the methodology can be applied for energy and emissions reduction in single buildings and complexes.

INTRODUCTION

Since 1995 the energy consumption of the EC member countries rose by 11 %, to the value of 1637Mt of oil equivalent [1]. The population of the EC member states however is growing at a much slower rate, approximately at 0.4 %/y [1]. In the UK domestic energy consumption has risen from 35.6 Mt of oil equivalent to 48.5Mt in the period 1971 to 2001, an increase of 36%, despite energy efficiency increases [2]. The increase in energy consumption per household was less, at 5 %, over the same period, better reflecting the increase in energy efficiency in individual dwellings. However in the UK it is proposed that the number of houses built over the next 10 years should increase by 200,000/y, to account for the smaller number of people per household, and the demand for housing [3]. This will have serious implications for energy consumption and greenhouse gas emissions. To date the increase in energy consumption from individuals [2], dwellings, and buildings generally has been met by the burning of carbon based fuels, or in some cases, by the increase in nuclear power. Although renewable energy has seen a large increase, the contribution towards total domestic energy use is still small (in the UK 1.0 Mt of oil equivalent compared to a total use of 47.0 Mt of oil equivalent).

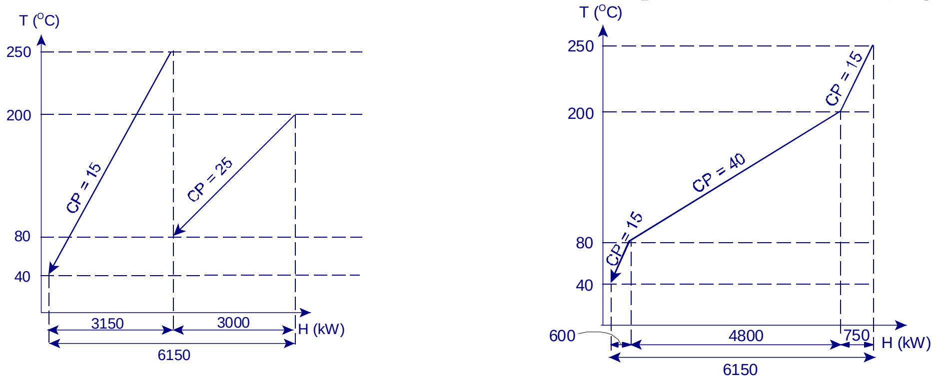
SUSTAINABLE ENERGY AND HEAT INTEGRATION

Heat Integration (or Pinch Technology/Process Integration) is an energy saving methodology that has been extensively used in the processing and power generating industry over the last 30 years. This method examines the potential of exchanging heat between heat sources and heat sinks via the use of heat exchangers and reducing the amount of external heating and cooling required. A systematic design procedure has been developed to provide the final energy reduction design of the system. The method has further been developed to specify the source of heating and cooling required (e.g. steam, hot water, cooling water) and also the potential of power production in the form of shaftwork or electrical production. More details are available elsewhere [4-9]. This methodology is based on the analysis and understanding of heat exchange between process streams through the use of a temperature-enthalpy diagram. The specific steps for drawing the curves in this diagram are presented in Figs. 1 - 3. The methodology first identifies sources of heat (termed hot streams) and sinks of heat (termed cold streams) in the process flowsheet. Tab. 1 presents a simple example.

Table 1 Sources (Hot) and Sink (Cold) streams

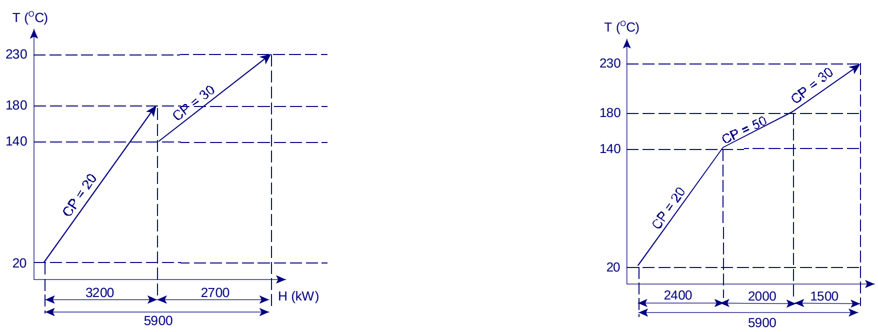
Stream	**Type**	**Supply Temp.** T_S (°C)	**Target Temp.** T_T (°C)	**ΔH** (kW)	**Heat Capacity Flowrate** **CP** (kW/°C)
Fresh Water	Cold	20	180	3200	20
Hot Product 1	Hot	250	40	-3150	15
Juice Circulation	Cold	140	230	2700	30
Hot Product 2	Hot	200	80	-3000	25

Sources of heat can be combined to construct the composite hot stream (Fig.1) and sinks of heat can likewise be combined to construct the composite cold stream (Fig. 2).



(a) The hot streams plotted (b) The composite hot stream

Figure 1. Composing hot streams to create a hot composite curve



(a) The cold streams plotted (b) The composite cold stream

Figure 2. Composing cold streams to create a cold composite curve

The relative location of these curves on the temperature-enthalpy diagram is dependent on the allowable temperature difference for heat exchange. The next step is to select a minimum permissible temperature approach between the hot and cold streams, ΔT_{min}. The selection of the optimum ΔT_{min} is a result of an economical assessment and trade-off between the capital and operating costs (mainly for energy usage) of the process. A large ΔT_{min} implies higher energy use and costs and lower capital costs. For increasing energy cost the optimum ΔT_{min} is reduced, meaning the heat exchanger system is allowed to recover more energy, but at the expense of more capital to pay for the greater heat transfer area. This issue has been discussed in greater detail elsewhere – [10], [8], [11]. In this example a ΔT_{min} of 10 °C was selected for simplicity. Plotting the composite curves (CC) in the same graphical space (Fig.3) allows values to be derived for maximum heat recovery and minimum hot and cold utilities. These are known as targets. In this particular case of ΔT_{min} = 10 °C, the minimum hot utility requirement is 750 kW and minimum cold utility requirement is 1,000 kW.

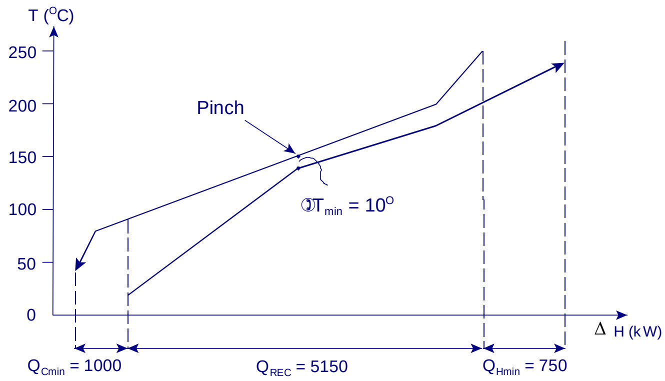


Figure 3. Plotting the hot and cold Composite Curves

In Fig.3 we can also determine the position of the Pinch. The Pinch represents the position where the hot composite and cold composite curves are at their closest (for a ΔT_{min} >0). The Pinch has provided the name for the Heat integration / Pinch Technology and has important features which make a substantial contribution to the design of maximum energy recovery systems and the design of economically efficient heat exchanger networks.

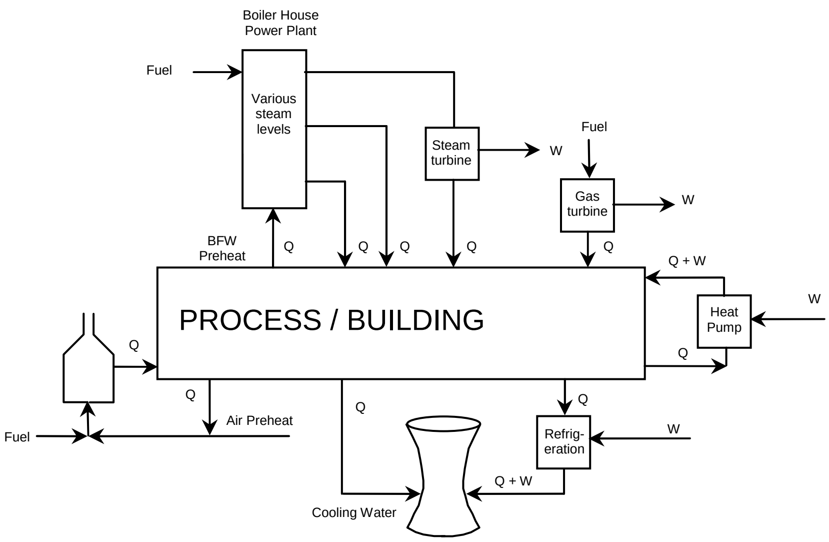

Figure 4. Potential for the choice of hot and cold utilities

Various design methods have been developed which allow these targets to be achieved in practice for both grass roots designs [4], and more importantly, for the retrofit of existing plants [12-14]. These methodologies are supported by process integration software which provides both design and retrofit support and automated design [15, 16]. In most cases there are more than one hot and one cold utility potentially providing heating and cooling requirements after energy recovery. In these situations we have to find and evaluate the cheapest and most desirable combination of the potential utilities that are available (Fig.4). To assist with this choice and to further enhance the information derived from the hot and cold CC, an additional graphical construction has been developed. This is known as the Grand Composite Curve (CC) and provides clear guidelines for the optimum placement and scaling of hot and cold utilities. The GCC together with the Balanced Composite Curves (the CC with the utilities selected added) provides a convenient tool for the optimum placement and selection of hot and cold utilities. An example of selection of utilities and its placement is shown in Fig. 5.

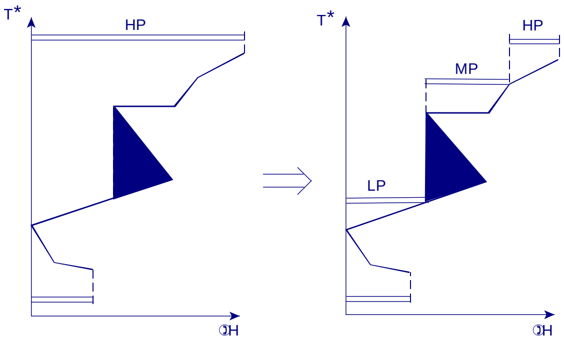

Figure 5. Placement of utilities with the help of GCC

The GCC is also a useful tool for targeting the cooling requirements in sub-ambient processes (such as air conditioning) which require some form of chilling or compression refrigeration. The GCC provides a target for the heat that has to be removed by a refrigeration process, and the temperature at which the refrigeration is needed. However, the overall process/utility system can be improved by using the heat rejected by the refrigeration system to provide low level heating to the process above ambient, thereby saving heat supplied by another utility source (such as hot water). The more detailed description has been provided elsewhere [17].

Traditional Heat Integration assesses the minimum practical energy needs for a process through a systematic design procedure involving five steps: (i) collection of plant data; (ii) setting targets for minimum practical energy requirements; (iii) examination of process changes that contribute to meeting the target; (iv) obtaining the minimum energy design that achieves the target and (v) optimisation which allows a trade-off between energy costs and capital costs.

EXAMPLES – CASE STUDIES

Hospitals are an example of building complexes which are important energy users, especially that of thermal energy. Although considerable research effort has been done to minimise the energy consumption in this sector, there are relatively few studies which apply Heat Integration (Pinch Technology) as a tool to evaluate potential energy savings and thereby reduce emissions.

Herrera et al [18] presented a study of a hospital complex which included an institute, a general hospital, a regional laundry centre, a sports centre, and some other public buildings. The use of diesel as a fuel represented 75% of its total energy consumption and 68% of its total energy cost which was 396,131 US$ in 1999. The hospital complex process diagram is shown in the Fig. 6. In the hospital complex, the heat demand is met by producing steam in boilers fuelled by a high price diesel fuel. There is no heat recovery between the existing heat sources and heat sinks. The hot streams were identified as the soiled soapy water from the laundry and the flow of condensed steam not recovered in the condensation network. The stream data are presented in Tab. 2.

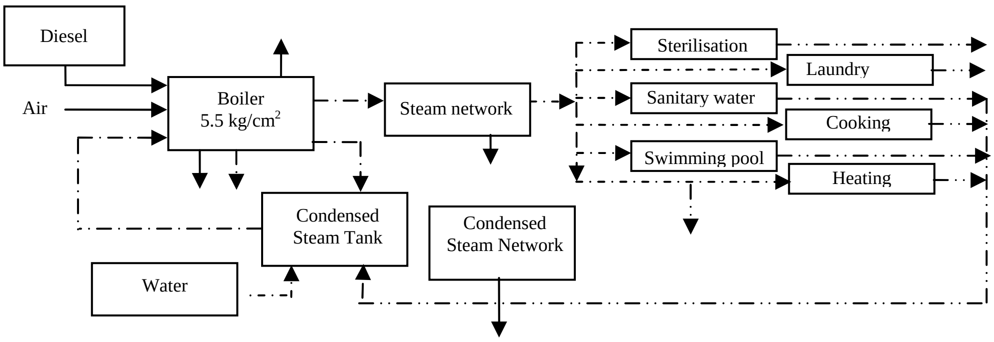

Figure 6. Hospital heat flow block diagram [15]

Table 2 presents the input data extracted from Fig 6.

Streams	**ΔH [kW]**	**CP [kw/°C]**	**Tin [°C]**	**Tout [°C]**
Hot Streams				
Soapy water (1)	23.7	0.53	85	40
Condensed steam (2)	96.32	2.41	80	40
Cold streams				
Laundry sanitary water (LS)	17.60	0.59	25	55
Laundry (L)	77.12	2.20	25	60
Boiler feed water (BF)	7.13	0.24	30	60
Sanitary water (SW)	77.12	2.20	25	60
Sterilisation (S)	12.50	0.14	30	121
Swimming pool water (SP)	151.67	50.56	25	28
Cooking (CO)	59.63	0.85	30	100
Heating (H)	100.82	14.40	18	25
Bedpan washers (B)	4.94	0.05	21	121

It needs to be noted that the CP represents mass flow m multiplied by the specific heat capacity Cp and in this case are considered constants. As can be seen from the CC (Fig. 7) the amount of external heating required, or the hot utility target, of this hospital complex is 388.64 kW. The GCC has been employed to determine the temperature levels of the utilities necessary to satisfy this requirement. This graphical method allows a more precise analysis to be undertaken in order to integrate the thermal utilities considered for the process heating and cooling requirements (Fig.8). This GCC indicates that the required heating of complex should be 388.64 kW. This means a yearly energy requirement of 12.26 TJ. The actual amount of heating provided is in fact 625.28 kW which represents the heat services that are currently transferred to the complex. This results in a potential energy savings of 38 % equivalent to saving 246,000 L of diesel/y (100,000 US$). To reduce energy demands in the form of heating to the value targeted by the analysis, the Heat Integration based analysis suggests that four extra heat exchangers should be added to the network. Two in the laundry to cover part of the heat demand, a third in the machinery rooms which help to heat boiler feed water, and the final one in the condensation tank area that heats the sanitary water. Several other issues could also have been considered to further refine the analysis, such as fouling, pressure drop and non constant heat demand.

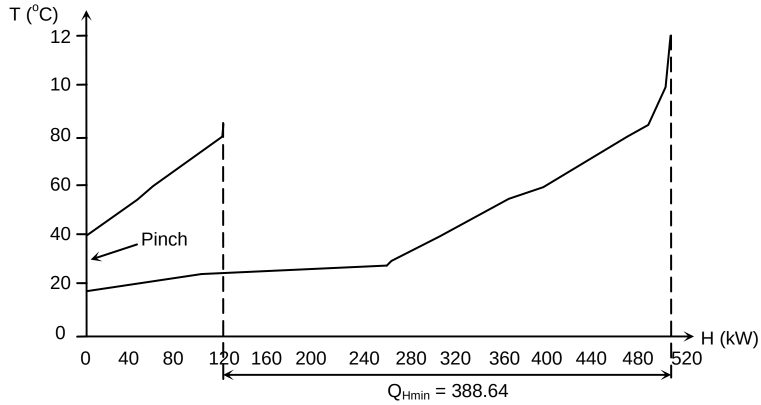

Figure7. CC for the hospital complex process streams

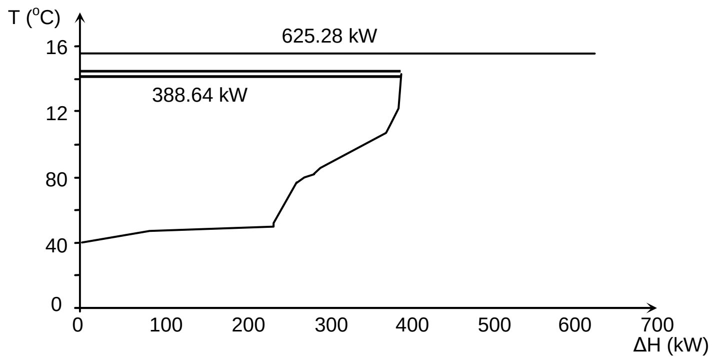

Figure 8. GCC of the hospital [15]

Kemp [9] presented a further more detailed case study of a hospital complex. The main energy demands were found to be space heating, air systems, general hot water supplies and other uses in the laundry and the incinerator. The main part of the complex was fully air conditioned. Central heating water was supplied at 80 ^{o}C, and returned at 71 ^{o}C and then reheated in a gas-fired calorifier. Tap hot water was also provided.

Table 3 Heat requirements and time distribution required during winter

Stream details and locations	No of streams	Hot streams total		Cold streams total		Times of operation
		Temp (^{o}C)	Heat load (kW)	Temp (^{o}C)	Heat load (kW)	
Main air supply	35	20-15	43	5-37	780	24 h: Day
	33	20-15	27	2-37	681	24 h: Night
Space heating	2			71-80	709	24 h: Day
	2			71-80	665	24 h: Night
Domestic hot water	1			5-60	244	24 h: Day
	1			5-60	48.5	24 h: Night
Autocalves	1			162	13	24 h
Kitchen	1			5-30	101	0530-0200
Laundry	3	37-30	67	18-26, 162	797	0700-1630
Incinerator	1	600-217	650			0900-1630
Boilers	1	235-60				24 h
Summary						
Maximum load			760		2,644	0900-1630
Minimum load			27		1407	0200-0530

In some areas (e.g. kitchens) the heat use varied considerably between day and night time. The identified streams are shown in Table 3. Energy use in winter for day time conditions was found to be 2534 kW (all hot utility) whereas in summer this value dropped to 1030 kW (hot utility) and 207 kW (cold utility) as space heating was replaced by air conditioning and the use of some refrigeration. Kemp [9] presented the GCC for the peak demand during winter (7− 9am period). Heat integration analysis of these different time periods provided various schemes for improvement. The first involved rescheduling. This took into consideration the possibility of changing the periods of high utility demand. Suggestions were (i) Moving a cold stream active in 7-9am period to a different time; (ii) Moving a hot stream not operating in 7-9am period to operate during this period. As it was not possible to shut down the central heating or air conditioning systems for this high demand 2 h period, an alternative was that laundry operations could be rescheduled to start 2 h later but finish at the usual time. This would result in the installation of new machines at a high capital cost. For the second suggestion is would be possible to start the incinerator at 7am and run it for a further 2 hours. Retaining the current waste disposal value would result in a reduced exhaust flow rate and heat recovery rate. The daytime total heat recovery would be the same, but one less boiler would be required. It was also found that additional municipal waste could be delivered and that the incinerator could be run at full power over 24 hours. The Heat Integration methodology also investigated the benefits of introducing CHP. The GCC shows that the hospital is represented by four different temperature ranges which were the laundry and autoclaves (160-170 ^oC), space heating (80-85 ^oC), domestic hot water (up to 70 ^oC), and air heating (10-40 ^oC). The heat from the jacket cooling water and exhaust gases could be recovered and be suitable for the space heating system. Standby diesel generators already installed to supply emergency power would be a cheaper option to convert than to provide heat and power from a new diesel generator. These would then provide about 50 % of the peak heat demand. Further options would be to install a micro gas turbine of around 1.5 MW. This would provide all power requirements and the majority of the peak demands. Maintenance for a single source heat and power supplier would leave the hospital complex in a vulnerable state.

Several other case studies have been reported by Linnhoff March Ltd. [19]:
a) A study with the code name BRECSU/BDP was an attempt to define the energy-efficient hospital of the future. LM Ltd looked at all aspects of hospital heating including space heating, ventilation air heating, hot water heating and sterilisation. For hot streams available for heat recovery LM looked at ventilation extraction air, drainage and incinerator flue gas. The major opportunities on an existing building were be in the utility area. There was much detail in the study, including heat generated by the patients in the day (active) and night (sleeping). The work demonstrated that, for a complex new building like a hospital, potential existed for heat recovery between extract and inlet air systems and for heat pumping from the drainage system. The most economic form of heat recovery was from the incinerator exhaust and they also concluded that the optimum utility system would be CHP.
b) Eastbourne Hospital. The largest saving found was in the laundry where dryer exhaust could heat water and fresh air for the dryers and hot dirty wash water could heat fresh water (with storage). A heat engine-based CHP scheme was recommended but this would affect the laundry recommendations because it would provide the necessary hot water.

CONCLUSIONS

Heat Integration (or Pinch Technology) has been used for 20 years in industry throughout the world to increase energy efficiency of any processing plants that have heating or cooling requirements, and also have needs for power to provide electricity or directly drive machinery. Energy savings of over 30% have been recorded, and the methodologies developed have been incorporated into the design offices of all major producing companies. The same methodologies and design rules can also be applied in buildings or their complexes. Examples of two complexes have been given. It is clear that as energy efficiency in buildings and the reduction of emissions becomes a standard issue in existing and new complexes, further examples of heat integration application will be carried out.

ACKNOWLEDGEMENT

The support from EC TREN/05/FP6EN/S07.54455/020114 Project "Network for promotion of Eco-building technologies, small Polygeneration, and renewable heating and cooling technologies for buildings – ProEcoPolyNet" (PEPNet) has been gratefully acknowledged.

SUMMARY

Fuel cells offer an environmentally sound, distributed energy source for individual buildings. Many governments believe that security and sustainability of energy supply can be improved with this technology. Therefore large public support programmes are under way to facilitate the commercialization of residential fuel cell systems. VTT is actively participating in this development work in a number of projects.

Modelling and simulation tools have been developed to provide the means for studying the interaction between fuel cell system and a building.
VTT initiated in 2004 development of a PEM fuel cell based power stack and developed its control system and operating strategies.
VTT supports local industry in developing technologies for SOFC systems, e.g. fuel processing for natural gas and diesel. The most important accomplishment has been the development of a 5 kW SOFC CHP laboratory demonstration plant fuelled by natural gas. The plant was grid connected and successfully operated for 6500 hours.

INTRODUCTION

In most buildings energy in different forms is used: lighting, cooking, heating, cooling, washing and entertainment all need their share of energy. The most convenient way of using energy is trough electricity. The share of electricity in energy consumption is continuously increasing. However, natural gas and oil are used for heating in many areas. In some countries, like Finland, district heating is widely used. In some areas gas is also used for cooking. The situation can be simplified in dividing the use of energy in a building into electricity and heating/cooling.

Until now electricity has practically always been fed to the building from a centralised electricity grid. Recently a growing interest in distributed energy systems has been seen. It can be realised in many ways. The electricity and heat can be produced within the building using fuel cells, Stirling engines, IC- engines or micro turbines.

In this paper we are dealing with different aspects introducing fuel cells as power and heat sources in individual buildings. First the basic idea and some of the international programmes in the field is described. Secondly some related development work performed at VTT is described, starting from the modelling of distributed energy systems in buildings and continuing with the research and development of polymer electrolyte fuel cells (PEFC) and solid oxide fuel cells (SOFC).

The present market situation

Residential and industrial fuel cell systems for power or combined heat and power production (CHP) in single buildings are developed by a number of companies in several European countries as well as Japan and the USA. The residential units are 1-10 kW electric, usually 1-5 kW. The heat produced is everything from 1 to 4 kW for a 1 kW unit. The industrial systems can be everything between 10 kW and 2 MW. The most common sizes are 250 kW, but 1 MW units are built. The residential systems are installed in one, or a few families buildings, while the larger ones are installed in hotels, hospitals, computer centres and other industrial sites. The cumulative number of small systems built until now is some 5000 units [1]. Of the large stationary some 800 units have been built [2]. Naturally only a fraction of these are in use anymore, because the life time of a fuel cell system is still 30000 h, or less.

The technology can be divided into PEFC and SOFC for residential systems and SOFC, molten carbonate fuel cells (MCFC) and phosphoric acid fuel cells (PAFC) for industrial systems. At present most of the installed residential systems are based on PEFC technology, while most of the installed industrial systems being MCFC with PAFC as a good second. Most of these use natural gas as fuel, while some of the industrial systems use different biogases. The low temperature PEFC requires pure hydrogen, which is produced by reforming natural gas. The electrical efficiency is only 30 % or less. The warm water produced has a temperature of 60 ºC, which means that it has to be used locally. The high temperature fuel cells, MCFC and SOFC have electrical efficiencies of 50 % with 60 % to be expected in the future. They produce water at temperatures of several hundred degrees Celsius. This can be used for producing industrial heat as well as cold, using chillers. Hybrid plants, producing only power, might reach 70% electrical efficiency in the future.

The power sources are used for different purposes. Both in Germany and Japan the residential units are usually operating according to heat need, the electricity produced being an added value. When heat is not needed, the electricity is taken from the grid. Thus they are mainly replacing natural gas boilers, and the additional value compensating for higher investment cost comes from the produced electricity. Taking into account the low electrical efficiency, this is an approach which can be doubted in countries were electricity is produced using high efficiency technologies.

The industrial units are often producing electricity and heat to the grid. In many early applications they are used as back up power for instance in hospitals or computer centers. Because high temperature fuel cells are slow to start, they are often used as main sources, the grid acting as back up.

In Europe, especially in Germany more than one hundred FC units have been installed for demonstration purposes. However, Japan has at the moment the most ambitious program in which 1257 units were installed during 2005 and 2006. These are based on PEM technology with an electrical efficiency of 1 kW. The program continues with an escalating number of units to be installed.

In most areas large government programmes are supporting research and development. In Japan NEDO, in USA USDOE and in Europe EU, in addition to several governments have massive support programmes. It can be estimated that more than 1000 M€ public funding is annually used for research and development. The European program has a goal to reach 1 GW installed capacity in 2015 and annual sales of more than a 100,000 units per annum for a system cost of 1000-2000 €/kW in 2020.

The Finnish funding agency for research and innovation (Tekes) has now started a technology program to support fuel cell commercialisation, including hydrogen technologies.

In Finland one major company is developing 20-50 and later 250 kW SOFC units intended for industrial buildings and APU use in ships.

VTT is doing research and development work both for the development of PEM based power units and SOFC based power units. VTT also looks at the use of residential fuel cells as power sources for power systems of buildings. Several universities are also doing research on fuel cell related technologies.

SIMULATION OF RESIDENTIAL SYSTEMS BASED ON FUEL CELLS

Due to constantly increasing electricity consumption, networks are becoming overloaded and unstable. Decentralization of power generation using small-scale local cogeneration plants becomes an interesting option to improve economy and energy reliability of buildings, in terms of both electricity and heat. It is expected that stationary applications in buildings will be one of the most important fields for fuel cell systems. In northern countries, like Finland, efficient utilization of heat from fuel cells is feasible.

Even though development of some fuel cell systems has already progressed to a field trial stage, relatively little is known yet about the interaction of fuel cells with building energy systems during dynamic operation. This issue could be addressed using simulation techniques but there has been a lack of adequate simulation models. International cooperation under IEA/ECBCS/Annex 42 (http://cogen-sim.net/), aims at filling this gap. Our objective was to provide the means for studying the interaction between a building and fuel cell system by incorporating a realistic fuel cell model into a building energy simulation. A new model for a solid-oxide fuel cell system has been developed using a purpose-justified simplified approach. In this approach a system level model was created, in which a control volume boundary is assumed around a fuel cell power module and the interior of it is regarded as a 'black box', Figure 1.

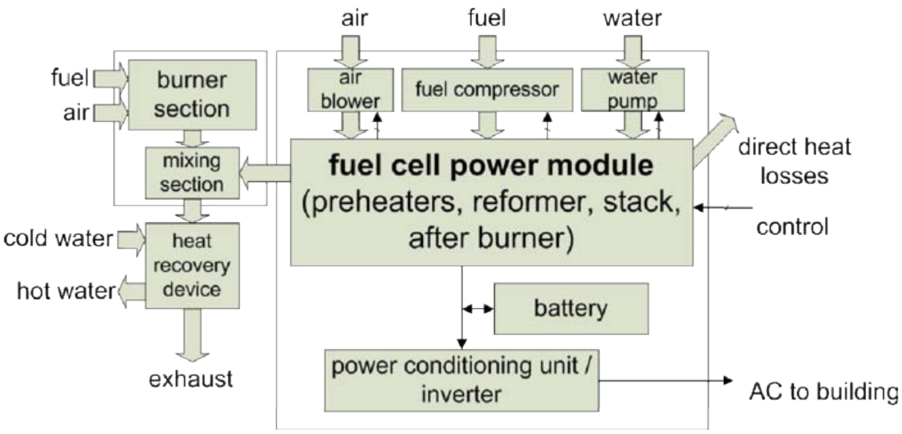

Figure 1. System model diagram according to Annex 42 specification [3].

Inputs to the system are given by flow rates of fuel, water and air. Outputs are electricity, exhaust gas and heat losses from the surfaces.
Subsequently, the system level model has been incorporated into the building simulation tool IDA-ICE (Indoor Climate and Energy) using Neutral Model Format (NMF) language [4]. The first phase of model implementation has been completed and inter-program validation performed within Annex 42 co-operation [5]. In the next phase, model validation and calibration will continue using empirical data. The final goal is to create a comprehensive but flexible model, which could serve as a reliable tool to simulate an annual operation of different fuel cell systems in different buildings, e.g. as in Figure 2.

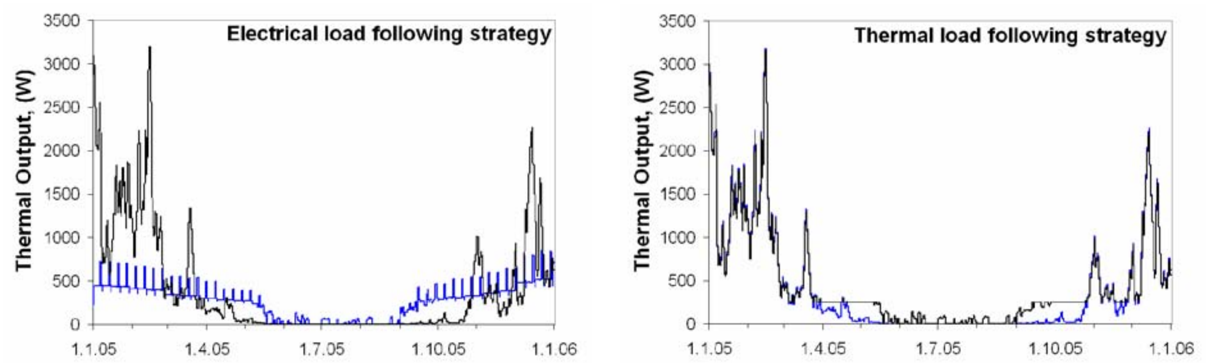

Figure 2. Tentative annual simulation results of heat demand (black curve) and SOFC fuel cell thermal output (blue curve) operated with two different strategies in a single family house. [4]

Another extended application is described in a separate CLIMA2007 paper, in which a community level simulation has been attempted for the first time, covering a group of houses connected by a district heating network. [6]

VTT DEVELOPMENT OF PEFC POWER SOURCE FOR RESIDENTIAL USE

The development of a PEM fuel cell based power pack was started in 2004. The work is co-operation with VTT and Helsinki University of Technology (TKK). Initially the project was restricting to the power level 1 – 2 kW, but at the later phase upgrading to the level of 10 kW has been taken in the program. The construction of the power pack is designed with series production in mind. This project supports the application phase of fuel cell power by deepening the expertise in the essential areas of fuel cell operation. The participating companies include those, which are interested in different phases in the value chain.

The systems are mainly intended to be assembled using commercially available 1-10 kW stacks. Fuel cell stacks are developed in the project mainly in order to understand the technology but also keeping the possibility of own production in mind. The system components are gathered from different manufactures based on performance and cost. System control and control strategies are developed in the project.

Cells and stacks
The initial design of the cell was done in co-operation between TKK Laboratory of Advanced Energy Systems and VTT. Different MEA/GDL constructions were going to be tested in the project in order to know which combination is most suitable for the aimed stack. Because of

limited availability, the tests were performed with two combinations. MEA was PRIMEA Series 56 from W.L. Gore and GDLs were SGK 10-BB from SGL Carbon Group and Carbel from W.L. Gore. Based on the results, the recommended GDL is SGL 10-BB if the cell temperature is relatively low (60 °C), because it was not affected by possible too low or high humidification at that temperature. This also requires that the stack cooling system is efficient enough in order not to increase temperature of some parts of the cell too high. If the cell temperature is higher, the recommended GDL is Carbel.

The effect of impurities [7]

Air contaminants may affect fuel cell performance by many different mechanisms. The effect of NaCl on PEM fuel cell performance was studied. The amount of NaCl used in the experiments presented here was very large. While the exposure time was relatively short, the total salt exposure would be more than most fuel cells could expect to see even under the harshest conditions (marine applications or stationary devices in coastal regions).

Sodium is known to replace protons in Nafion® polymer, thus increasing cell resistance, and chlorine ions adsorb to the catalyst surface, decreasing the number of available reaction sites. In this study NaCl was injected in an operating single cell and degradation of performance observed.

The results showed that the performance loss could be attributed to changes in proton conductivity due to the displacement of protons from the membrane by sodium ions. The effects of chloride ion on catalysis were not evident, although they could be important under longer and higher potential operation. The change in proton conductivity was not accurately reflected by HFR as sodium ion conductivity and ionic conductivity in the electrodes could not be separated.

Optimization based on modeling

Flow field distribution and end plate structure have been modeled and a 2-D fuel cell model that takes into account the inhomogeneous compression of GDL in order to optimize the rib/channel –structure of the flow field plate have been made.

The flow field properties of the cell developed in the project were studied with a finite element method based model that was implemented with commercial finite element software Femlab 3.2. The results showed that for a parallel flow field design, which typically has an uneven flow distribution in the channels, the channel configuration was relatively good. In order to make the flow velocity distribution more even, the distributor channel geometry was modified. The flow velocity distributions in the original and modified distributor channel geometries were also studied experimentally and the results were in agreement with the modelling data.

The main function of the end plates is to offer mechanical support for the stack. The pressure distribution in the stack resulting from the end plates was studied with finite element modelling. The original stack end plates of the POWERPEFC-project cell were two centimetres thick steel plates with a combined weight of approximately 14.2 kg. The results show clearly that despite its bulkiness, the current end plate structure could not provide sufficiently even pressure distributions on the gas diffusion layers of the cell. Different rib structures were tested to improve the gas diffusion layer compression and simultaneously decrease the end plate mass. When aluminium was used as the end plate material, significant improvements on both accounts were reached. [8]

In order to be able to optimize the rib/channel –structure of the flow field plate, the effects caused by the inhomogeneous compression of GDL must be known. The GDL intrusion into the channel was measured with several channel widths and compression values. The evaluation of parameters was done with SGL 10-BA. The gas permeability as a function of thickness was measured with a purpose-build measurement apparatus. The actual model that will be used in the rib/channel –structure optimization has been constructed.

<u>Segmented cell</u>
Anode flow field was divided into 60 segments to study current distribution in the flow field area. The measurement technique used in this work to sense the current from each segment is based on the Hall Effect. The most important result of the measurements has been validation of the calculated result of the shape of the distributor channel.

<u>Design and characterisation of stacks</u>
The stack development has been directed towards cost effective manufacturing and assembling. Due to requirement of low pressure drop on the cathode straight channels were chosen. On the anode and cooling side conventional serpentine channels will be used. Moreover stacks from commercial suppliers have been characterized and also assembled from components.

<u>Bipolar plate development and characterization</u>
VTT Advanced materials has produced composite material with competitive properties for PEM fuel cell bipolar plates. Currently, also steel materials are under study in realistic fuel cell environment.

<u>Development of Instrumentation and BoP for the Power Pack</u>
Currently a prototype version of the balance of plant and control system of a pre-commercial power pack is being tested during operation. The control strategy is towards long life time of the stack, which is achieved by profound understanding of the operation of the fuel cell.

VTT DEVELOPMENT OF SOFC SYSTEMS FOR BUILDINGS

The SOFC systems work aims mainly for larger systems. Here the whole system is dealt with taking into account that mostly hydrocarbon fuels are used. These are natural gas, biodiesel, and gaseous bio fuels. Therefore pre-reformers are developed for all these fuels. The system development includes both the construction and operation of demonstration units and corresponding dynamic system modelling. A 5 kW SOFC demonstration unit fuelled by natural gas and producing electricity to the grid was operated during 6500 hours during 2006 and 2007. The 5 kW SOFC stack was obtained from Forschungszentrum -Jülich in Germany.

<u>SOFC Power station demonstration</u>
The purpose of work is to demonstrate a small-scale combined heat and power plant (CHP) that includes all main BOP components needed in real power plant operation (Figure 3). The system operates at atmospheric pressure using autothermally reformed natural gas as fuel. Alternatively, hydrogen can be use as fuel as well during operation or in system stand-by situations. The system is designed for a planar anode-supported stack. The first 5 kWe stack was delivered by Research Centre Jülich.

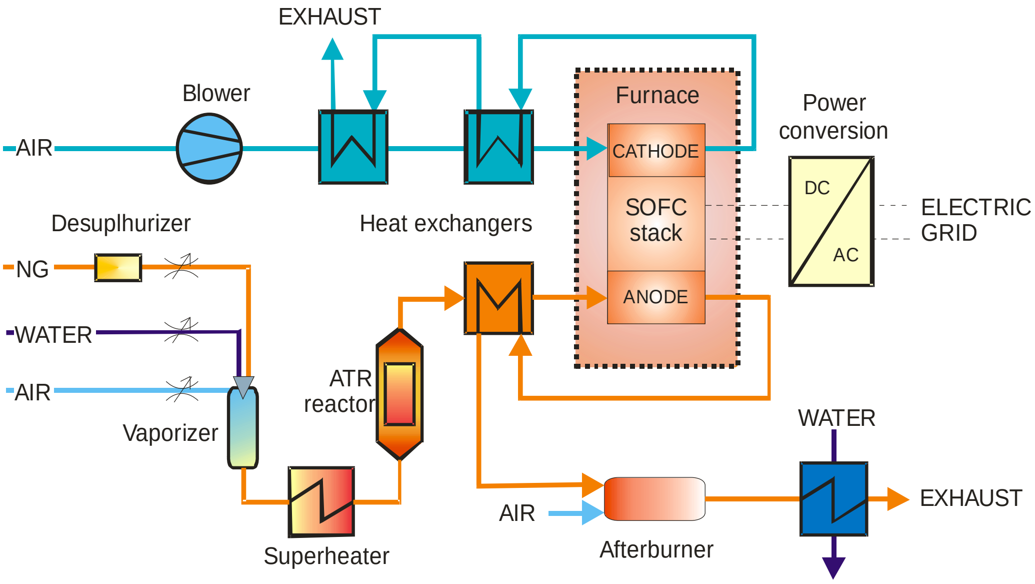

Figure 3. System lay-out of the grid connected natural gas fuelled SOFC based 5 kWe power plant demonstration. The system consist of planar 5 kWe stack, ATR, Hex for fuel, air and exhaust gas, catalytic afterburner, power conversion, grid interconnection, automation, measurement, control and safety system..

The power plant demonstration has been started in May 2006 and currently long period experiments have been stopped after 6500 hours (February 2007). The power plant demonstration produces electricity to the laboratory grid in the power range of 3-5 kWe depending on the operating parameters (Figure 4).

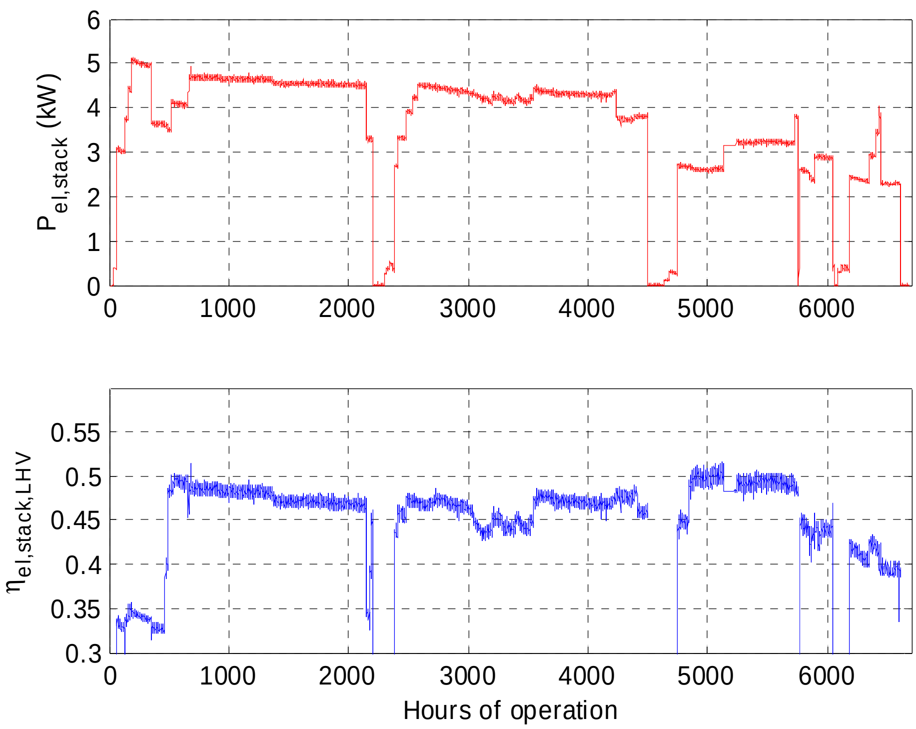

Figure 4. Long period experiments of the power plant demonstration. Degradation is about 1%/1000 hours at 0.35 A/cm2 when fuel utilisation is 70%.

DISCUSSION

Energy production and use is of main concern today in many countries. The main problems dealt with are environmental impacts and reliability of supply. Therefore new solutions are sought for. Fuel cells enable new distributed conversion technology offering high electrical and total efficiency and multi fuel capability. The later makes them especially suitable for high efficiency power production from new types of bio based fuels. Those are renewable hydrogen, biogas, biodiesel, ethanol, gasification gases and other synthetic liquid fuels.

For this reason there is a growing effort to develop fuel cell technology as distributed power sources for buildings. Large international programmes involving private public partnerships have generated and are generating funding for the research and development work.

In Finland VTT is participating in this international effort by supporting the local industry in its work. This work is done in close cooperation with European partners trough EU- funded projects and with international partners trough the International Energy Agency Implementation Agreements. In this work The Finnish Funding Agency for Research and Innovation (Tekes) and its new Fuel Cell Technology Program plays a central role.

ACKNOWLEDGEMENT

The projects, on which this presentation is based, have been funded by The Finnish Funding Agency for Research and Innovation (Tekes), EU, VTT and several industrial companies, which is acknowledged with gratitude.

Prospective and adaptive management of small Combined Heat and Power systems in buildings

Jens Matics and Gerhard Krost

University of Duisburg-Essen, Germany

Corresponding email: Jens.Matics@uni-due.de or Gerhard.Krost@uni-due.de

SUMMARY

In the context of current promotion of Distributed Generation (DG), micro Combined Heat and Power (CHP) systems for single or small ensembles of (residential) buildings are seen advantageous to combine both decentralized generation and rather high overall efficiency. The latter presupposes intelligent management strategies which have to mediate between energy cost minimization and user comfort aspects. A flexible and auto-adaptive approach of such kind of energy and load management was developed and first results are shown with several operational examples gained from simulation based verification.

INTRODUCTION

Micro Combined Heat and Power (CHP) systems powering up to approximately 10 kW_{el} are considered as a future key technology for energy supply of buildings and settlements from the viewpoints of both heating systems manufacturers and energy suppliers; such CHP plants can be based on conventional Diesel, gas or biomass motors, gas or steam turbines, as well as Stirling engines or fuel cells [1]. In combination with existing public gas and electricity supply these technologies are well suited for cardinal provision of electric and thermal energy in single or multi-family residences and buildings with mixed occupancy of habitation and business establishments. It is evident that reasonable economic operation of CHP systems can only be achieved if power peaks are being moderated; for electrical peaks the public grid connection provides a sound basis, whereas thermal peaks can be smoothed out by both thermal storage and an auxiliary boiler. Efficient operation of such plants pivotally depends on their sound layout for the particular building under regard as well as powerful strategies for energy and load management. Energy management in this context means cost-efficient supply of all (electrical and thermal) loads by intelligent operation of all interacting system components, in particular the CHP unit. Load management means the controlled arresting and releasing of the operation of certain devices, especially larger electro-thermal loads with a significant power demand – for instance a washing machine.

So far, commercial CHP plants do not include sophisticated control structures for flexible and automatic adaptation of their operation to the individual customer behavior, given tariffs and local infrastructure. The existing conventional energy management systems usually control the power of the CHP unit with respect to the actual electricity and heat consumption, but do not apply past or forecasted quantities; user specific consumption behavior as well as dynamic weather influences (such as outside temperature, wind, insolation) are not adequately considered. The potential of installed CHP plants therefore cannot completely be exploited.

In the frame of a current research project – accompanied by manufacturers of CHP plants, network operators and natural gas service providers – efficient strategies for a powerful energy and load management of a micro CHP based energy supply for buildings are being developed and verified on a sound simulation of the complete CHP system. Besides regarding the operational demands and boundaries of the plant components involved, the energy management is designed to fulfill comfort demands by flexible adaptation to user habits (evaluation of past and consequential prognosis of future consumption) as well as local tariffs and infrastructure, and therefore provides economic generation of electricity and heat under inclusion of environmental compatibility. The load management controls the operation time of certain (mainly larger electro-thermal) devices based on evaluation of past user behavior – considering both comfort demands and economic aspects. The management functionalities are elaborated and verified on a detailed operational simulation of the complete CHP system under regard; first results are presented in the following.

METHODS

Simulation model

A versatile Matlab/Simulink® based simulation tool containing a library of Distributed Generation (DG) component models was developed, allowing to arbitrarily compose typical residential micro CHP systems and to investigate the characteristics of the components as well as their operational interdependence within the complete supply system under high temporal resolution and simulation fidelity [2]. The minimum simulation step size is 1 s, while 60 s has proven as a good compromise between accuracy and computation time. This simulation tool was used for test and verification of the CHP energy management focused on here.

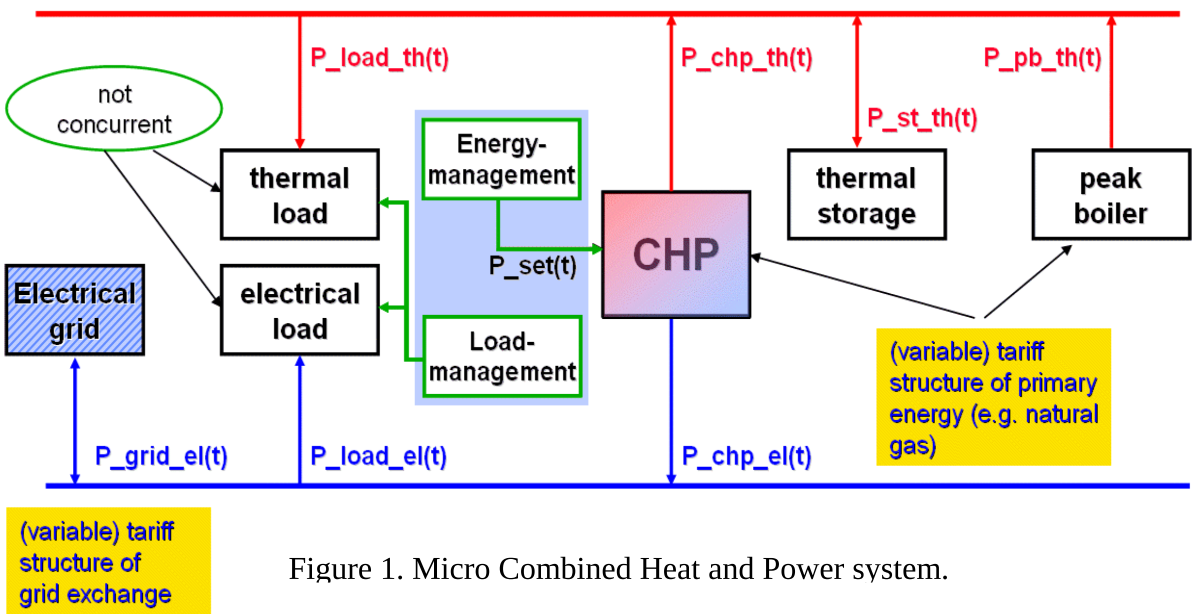

Figure 1. Micro Combined Heat and Power system.

A typical residential CHP system is shown in Figure 1. The system consists of the following main components which were modeled by use of the simulation tool for validating the management functionalities focused on here under largely realistic operational conditions:

Electrical and *thermal loads* are considered as a time series of power samples; these can either be taken from measurements or they can be synthesized by superposition of individual load curves – if required. Innovative energy supply systems are usually installed in connection with modernization of old or construction of new buildings. Therefore, modern building standards and corresponding demand curves were used to develop and verify the CHP plant management. In particular, for the investigations made here, load curves of 140 m^2 low-energy single occupancy houses (4 person's households) over one year in 15 minutes temporal resolution had been available from a German measurement program [3]. As an example, a detailed electrical and thermal (both heating and warm water) demand curve for a cold week in January is shown in Fig.2.

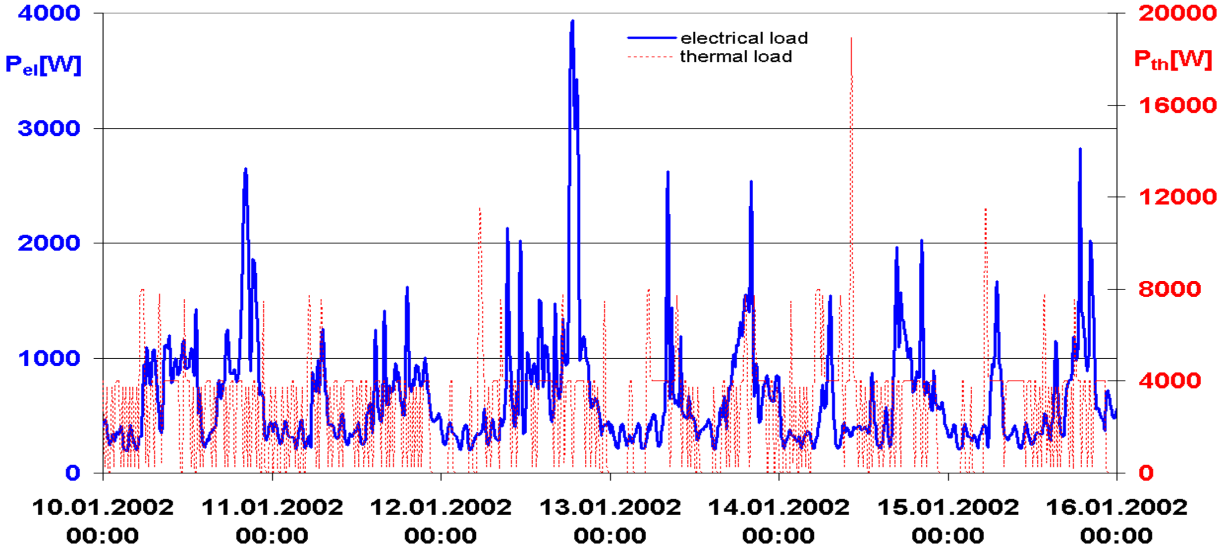

Figure 2. Electrical and thermal load curves in 15 minute resolution (excerpt).

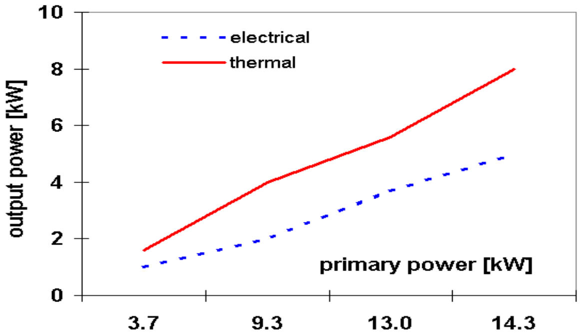
The *CHP unit* is characterized by its stationary power curve including upper and lower operating limits, maximal thermal and electrical power gradients $\delta P/\delta t$, minimal operating and down times, maximal numbers of start-ups and set-point changes per day, performance during the start-up procedure – including auxiliary power demand – and the associated start-up costs. In principle, the simulation system can be set up for various kinds of CHP units as enumerated in the introduction. The examples given in the following are specifically related to a *gas engine based generator set* because such units are presently the most common (and economic) ones used for micro CHP generation. The reference unit has 5 kW_{el}/8 kW_{therm} nominal power and 1 kW_{el}/1.6 kW_{therm} minimal power respectively; the electro-thermal generation interdependency, steady state operating points as well as the start up performance are shown in Figure 3a/b.



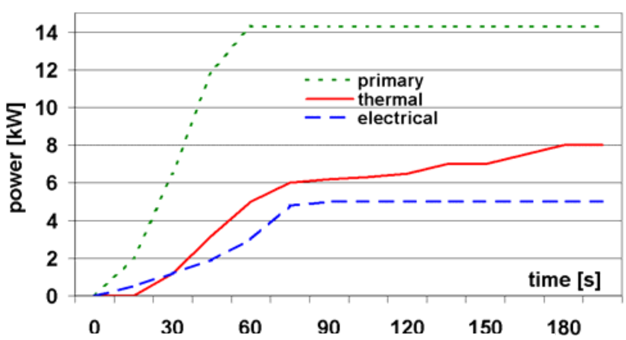


Figure 3. a) Stationary CHP operation points. b) Start-up behaviour of CHP

The *thermal storage* as a crucial component to moderate the thermal power peaks is modeled considering the capacity, maximum charging and discharging powers, maximal power gradients, efficiency of charging and discharging processes, and a fill level dependent loss factor. The storage actually considered here has a capacity of 600 l (≡ 35 kWh at operating temperature); the efficiency of a charge/discharge cycle was set to 95% and a discharging loss factor of 0.1 kWh/h was assumed. The maximal charge and discharge power is 22.9 kW. A dead band control keeps the thermal storage filling level within adjustable threshold values. In case the maximal admissible storage filling level is exceeded the CHP plant is shut down immediately.

The *peak boiler* is operated at nominal power if the thermal storage filling level falls below 20%. Boiler operation is stopped if the storage fill level exceeds 25 %. The simulation model accounts for a characteristic stationary power curve including upper and lower operating limits, and has no gradient limitations.

Coupling to the *electrical grid* – which is considered as unlimited but expensive electricity storage – is constricted by the connection power contracted with the provider.

The *tariff structures* of grid exchange power (feed-in and delivery) as well as primary power (natural gas) consist of both monthly connection rates and time variable kilowatt-hour rates. Even if nowadays electricity and gas rates for private customers are mostly constant (sometimes electricity rates may include special night tariffs for fixed time intervals) new electricity meter information technologies already do exist [4], allowing highly flexible and dynamic tariffs for future Distributed Generation applications; for instance, selective regional price signals can give the system operator an indirect control of a huge number of DG units. In order to prove the flexibility of the system, a tariff structure as shown in Fig. 4 was applied for the examples described in the following. Furthermore, a monthly connection rate of 7.50 € for electricity (each delivery and feed in) and 4.20 € for gas supply were assumed, reflecting actual tariffs in Germany.

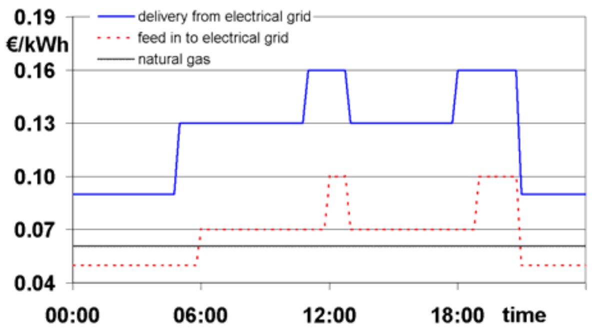

Figure 4. Electricity and gas tariffs applied.

CHP system management

Under regard of the current system states, the operating point dependent component characteristics, their dependencies, varying tariffs, forecasted electrical and thermal loads and potential commercial contracts, ad hoc online cost optimal CHP set-point setting is not a trivial task. The management structure was therefore designed to consist of the three modules *load management*, *load forecast*, and *energy management* (Figure 5), which provide decisions during online operation. The adaptation of the modules to user habits, local tariffs and infrastructure is regularly improved by off-line pre-processing of the archived measurement data, see

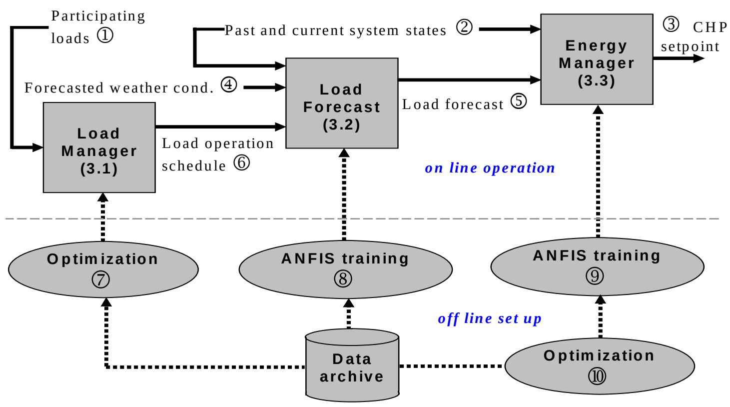

Figure 5. Structure of CHP set point decision making.

Figure 5, lower part. For the very first operation initial default values are implemented. In the following considerations, a weekly pre-processing cycle is applied.

The *load management* module provides a schedule (⑥ in Figure 5) of privileged operation times for each participating load ① one week in advance. These schedules are the result of a cost optimization process ⑦ and are based on the load specific maximal shifting intervals as well as on the measurement data recorded during the previous week. By overruling the proposed schedule, the user still can give emphasis on his comfort demands in which case higher associated costs have to be accepted. Even if controlling particular devices is not yet state of the art, there is current work in progress to establish such techniques, using for instance powerline or wireless communication [5,6]. In the scenarios presented in the forthcoming results section the total electrical load is composed from few controllable devices (e.g., washing machine) and the (uncontrollable) given rest.

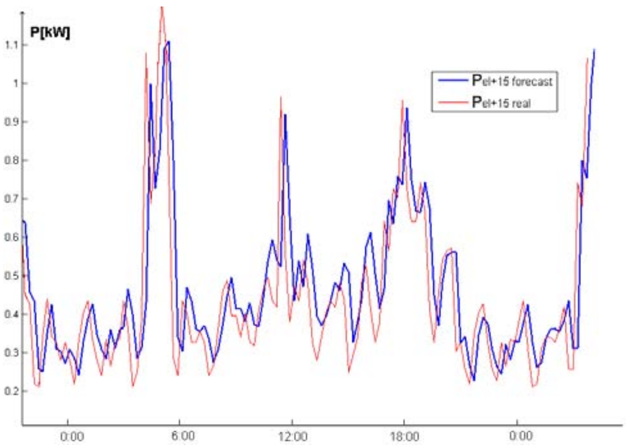

Figure 6. Example of 15 min. el. load forecast.

The *load forecast* module pre-estimates the electrical load at specific, discrete times in the future (15, 30, 60, 120 minutes ahead). Instead of the usually considered influence factors such as temporal and meteorological information the metaheuristic approach applied here (ANFIS, [7]) is based on recognition of characteristic sequences from the data archive. As an example of the forecast quality Figure 6 shows both the 15 minutes forecast and the actual load measured. Owing to the chaotic and hardly predictable instantaneous values of the warm water demand, the expected thermal *energy demand* (warm water and heating) within the next 2 hours is forecasted. The instantaneous difference is balanced by the thermal storage.

The *energy management* finally generates the next power setpoint ③ ensuring cost optimal operation of the micro Combined Heat and Power system. This is achieved based on past, current and forecasted loads ⑤ and tariff information as well as on current and past operating states ②. The appropriate CHP-setpoints are determined by the objective function described below: archived electrical and thermal load curves of the previous week as well as tariff information are applied to the CHP model, and optimal CHP-setpoints are identified with hindsight minimizing the associated costs. The interdependencies between the corresponding inputs and the determined CHP-setpoint values (see above) are periodically identified by means of the metaheuristic approach (ANFIS ⑨) – thereby extending the internal fuzzy knowledge base.

The cost optimal CHP-setpoints and load schedules are regularly determined based on the last week's measurement data, and used to continuously improve the quality of the management system. Owing to the high number of system variables (168 hourly setpoints for one week operation plus additional schedule parameters for all participating loads), the optimization has to be applied *offline* by means of an efficient technique. Taking into account all relevant operating conditions and restrictions, the energy and load management can be formulated as a mixed integer optimization problem:

$$cost_{tot} = cost_{prim\text{-}en} + cost_{grid} - pay_{grid} + cost_{util} \qquad (1)$$

$$\underset{P_{CHP,set},\ load_{lm}}{\mathbf{min}}\ cost_{tot} = f(P_{CHP,set}, tariff_{el,prim}, load_{lm}) \qquad (2)$$

subject to:

<u>energy management:</u>

- 1.6 kW $\leq P_{CHP,th} \leq$ 8 kW
- maximal gradients $\Delta P_{CHP,th}$: +50 / -60 W/s
- start-up cost of CHP : 0.10 €
- maximal number of CHP starts per day: 10
- average time between CHP set point changes: 60 minutes
- minimal CHP run time: 4 minutes,
- minimal CHP stop time: 1 minute
- start-up cost of peak boiler: 0.00 €
- maximal number of peak boiler startups: no restrictions
- maximal no-supply time of loads: 0 s

<u>load management:</u>

- $load_{shift\text{-}min,i} \leq load_{lm,i} \leq load_{shift\text{-}max,i}$

with:

$cost_{tot}$: total costs for supplying all electrical and thermal loads
$cost_{prim\text{-}en}$: costs for primary energy, e.g. natural gas
$cost_{grid}$: costs for connection to and delivery from el. grid
pay_{grid}: refund for feed-in to el. grid
$cost_{util}$: costs for utilities (e.g. start-up, maintenance)
$P_{CHP,set}$: thermal CHP setpoint
$load_{lm,i}$: loads taking part in load management
$load_{shift\text{-}min\text{-}max,i}$: maximal shifting interval in load management

The optimization mode (pure energy- or combined energy/load management) is selected by incorporating one or both of the variables P_{CHPset}, $load_{lm}$ into the optimization process, see Eq. (2). Additional contracts such as minimal CHP overall efficiency for subsidies, or stipulated feed in power can be added if necessary.

In conclusion, the three modules load management, load forecast, and energy management are regularly adapted to user habits, local tariffs and infrastructure by incorporating means of *Computational Intelligence* into the developed control system. The identification of existing correlations between the last week's recorded measurement data (input) and corresponding output data – being results of the optimization or the prognosis – is extended weekly. This process of accumulation and generalisation results in a continuously improving online operation of the CHP system.

RESULTS

In the following first results of the application of the three management modules on a simulated CHP system are presented. The results are based on the load shapes of the January week from Figure 2.

Figure 7 shows the cost optimal plant operation (CHP set points) as determined by the energy management module (load management still disabled). From a broad view it is visible that the energy management in compliance with all active constraints results in

- a shut down of the CHP unit during night hours
- and an individual operation during daytimes.

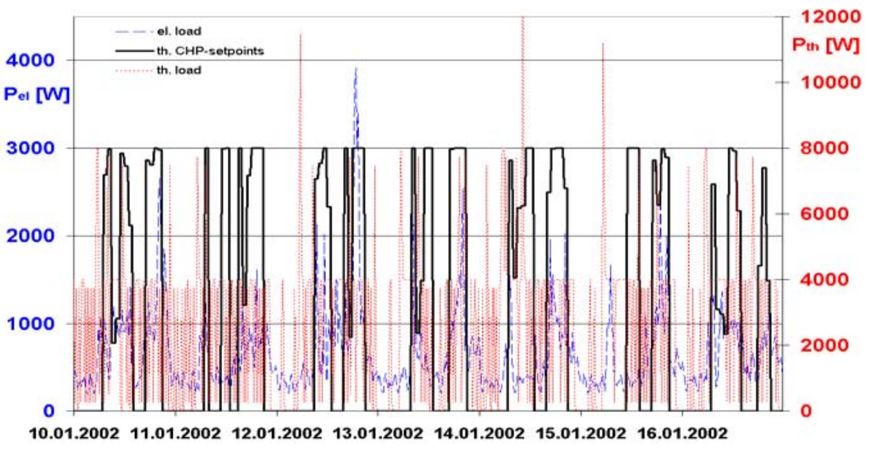

Figure 7. Results of energy management for a cold week in January.

From a more detailed view of the CHP set points, as exemplarily shown in Figure 8 for the Saturday, it can be realized that

- the mutual dependency of the system components,
- the varying electricity and gas tariffs during the course of the day (Figure 4),
- and the constraints as outlined above

do not allow for direct and easy derivation of the optimal system operation from the given electrical and thermal load shapes, thus demanding for intelligent techniques like the approach presented here.

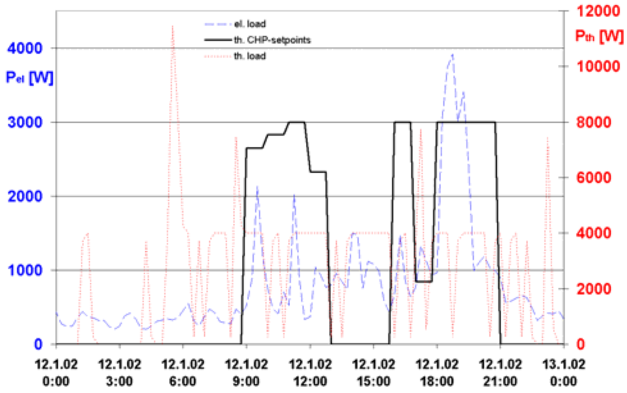

Figure 8. Setpoints determined for Saturday.

As an example of the *modeling detail grade*, the electrical grid exchange power resulting from the CHP operation and the filling level of the thermal storage are shown in Figure 9. It is obvious that the storage is generally charged at daytimes and discharged during the nights, but this is gradually influenced by the electrical grid exchange and the load profiles (Figure 2), thus leading to a rather individual daily operation of the plant.

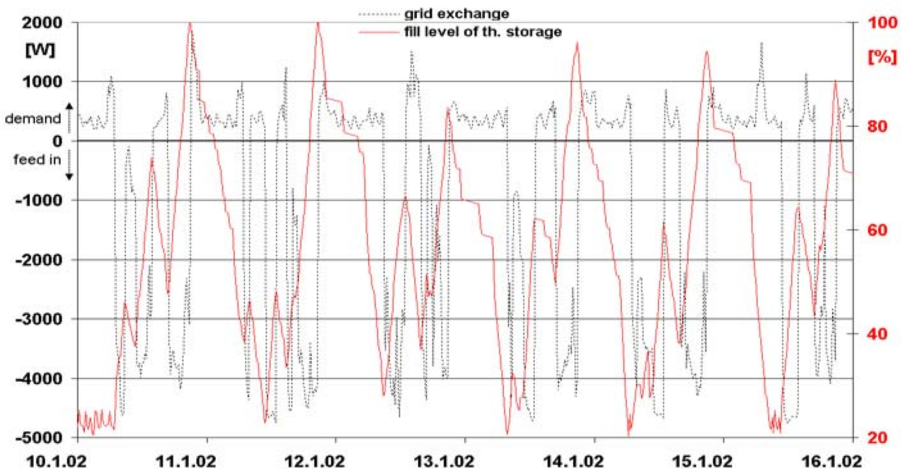

Figure 9. Filling level of thermal storage and el. grid exchange power.

A result of the additional application of the *load management* is shown in Figure 10: for one particular day (January 12th) shifting of certain electrical loads within a 24 hour period has been released. Comparison of the original load curve with the one resulting from load management generally proves that power peaks are defused and high-load periods are shifted to low-tariff regions (according to tariffs from Figure 4).

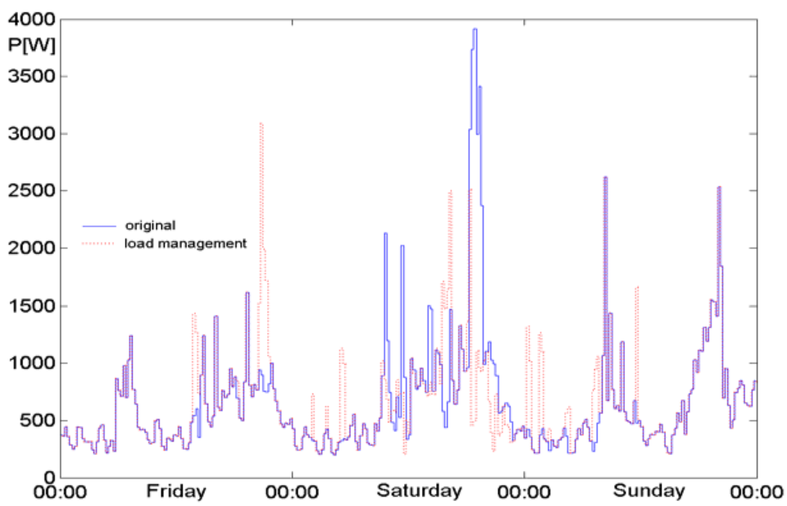

Figure 10. Effect of load management for certain el. devices.

A monetary comparison of different CHP operation modes is finally shown in Table 1 for the winter week under regard.

It is apparent that CHP operation with the energy management enabled (4) is saving approximately 17% of cost compared to no CHP operation - that is, complete electricity demand covered by external grid and thermal demand covered by peak boiler, (3). Having additionally the load management released for one day (see above) saves another 6%, (5). In contrast, blindfold CHP operation at either nominal (1) or minimal (2) constant power is even more expensive than no CHP operation at all.

Table 1: Comparison of energy costs.

CHP operation mode	Weekly cost [€]
1 Constant nominal power	139,16
2 Constant minimal power	54,14
3 No CHP operation	53,22
4 CHP with energy management only 1)	44,00
5 CHP with energy and load management 2)	41,07

1) see Fig. 7-9 2) see Fig. 10

DISCUSSION

Combined Heat and Power (CHP) systems for individual domestic appliances are a promising approach in the context of the recent developments in decentralized energy supply: they are based on an existing infrastructure (gas and electricity systems as well as house installation) and provide good efficiency. Owing to the extreme variation and non-simultaneity of electrical and thermal loads in single households, a flexible and adaptive system management is required. The proposed approach proved in first investigations performed on a detailed plant simulation that

- reasonable set points for the CHP unit are provided by having the energy management rely on historic (archive), actual and forecast data;
- the results are qualified by application of an adaptive load forecast module;
- power peaks are smoothed and heavy-load periods are shifted to opportune times by enabling the load management of certain (electro-thermal) devices;
- the overall energy cost can significantly be reduced.

Thus, by use of intelligent management functionality the benefits of decentralized Combined Heat and Power systems for buildings can fully be exploited.

SUMMARY

We investigate optimal supervisory control of a building energy system with cogeneration of heat and power (CHP). The system consists of a Stirling engine and a supplementary burner, space heating and a domestic hot water (DHW) storage tank. Cost and primary energy (PE)-optimal operation are considered.
The best theoretically possible operating strategy is found using the following assumptions:

- An ideal dynamic model of the system and an ideal prediction of all future disturbance variables (weather, hot-water draws, etc.) are available to the controller ("ideal" here means that model and predictions used by the controller perfectly match "reality", which is used for simulation after applying the control signals)
- The room temperature is allowed to vary within a time-dependent tolerance band (e.g. 21...24°C during the day and 19...24°C at night). Progression of the room temperature is then an output of optimization. A dynamic building model is used, rather than heat demand profiles. A similar tolerance band is used for the DHW storage tank

This strategy defines the so-called *performance bound*, since no real controller can yield a better performance. It is found using model-predictive control (MPC) with moving horizon.
In this general setting, the following results are discussed:

- *Control strategy:* How does the system have to be operated to cover thermal and electrical energy demand with minimal costs, or with minimal PE?
- *Performance assessment:* What annual amount of primary energy and money can be saved by a CHP unit compared to conventional heating?
- *Influence of specific parameters (sizing of Stirling engine)*

The results, although obtained with a Stirling engine, can be used for other CHP units as well.

KEYWORDS: Model-based predictive control, CHP, Stirling engine, performance assessment

INTRODUCTION

Residential cogeneration is an emerging technology with a high potential to deliver energy efficiency and environmental benefits [1]. The concurrent production of electrical and thermal energy can reduce PE consumption and associated greenhouse gas emissions. The distributed generation nature of the technology also has the potential to reduce electrical transmission and distribution inefficiencies and alleviate utility peak demand problems. Leading contenders for residential building cogeneration include fuel cells, Stirling cycles and internal combustion engines.
However, the effective exploitation of the thermal output for space and DHW heating is critical to realizing high levels of overall energy efficiency and the associated environmental (CO_2 and other) benefits. It is believed that building-integrated cogeneration will not deliver the potential benefits outlined above without appropriate control strategies.
This research work has partially been carried out in the framework of the IEA ECBCS Annex42 project called "The Simulation of Building-Integrated Fuel Cell and other

Cogeneration Systems", where also CHP units based on Stirling engines are studied. This paper is based on [2]. Other research projects from Siemens in the field of building automation using the same optimal control approach involve heating applications [3] and integrated room automation [4]. A similar approach has been used in [5].

DESCRIPTION OF THE SYSTEM

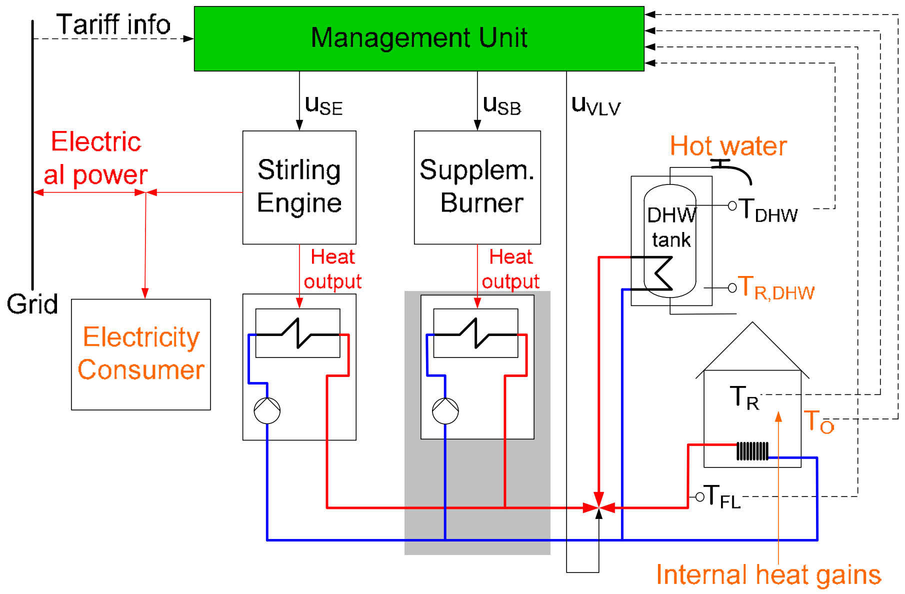

Figure 1: Overview of the system.

An overview on the system is given in Figure 1: A CHP unit heats the building by means of an underfloor heating system, supplies the domestic hot water and may partly or wholly satisfy the electrical demand. The CHP unit is made up of a Stirling engine and a supplementary burner that covers the thermal peak loads. Control signals u_{SE} and u_{SB} represent the gas input of Stirling engine and supplementary burner, and u_{VLV} is the fraction of heat that flows into the heating circuit.

ASSESSED OPTIMAL CONTROL STRATEGIES

Both optimal control strategies must satisfy the following constraints:

Room temperature	$T_R(t) \in [T_{R,min}(t),\ T_{R,max}]$
DHW storage tank temperature requirements	$T_{DHW}(t) \in [T_{DHW,min},\ T_{DHW,max}]$
Maximal flow temperature limitation	$T_{FL}(t) \le T_{FL,max}$
No discharging of DHW tank for heating	$\dot{Q}_{th,DHW}(t) \ge 0$
Minimal and maximal limitation of the control signals (normalized)	$u_{SE}(t), u_{SE}(t), u_{VLV}(t) \in [0,1]$

(1)

Cost optimization

Cost-optimal control minimizes the sum of gas and electricity costs. The cost function is:

$$J_C = \min \sum_{\text{time } t} \left[C_{\text{PE,SE}}(t) + C_{\text{PE,SB}}(t) + C_{\text{el}}(t) \right] \tag{2}$$

where $C_{PE,SE}(t)$ and $C_{PE,SB}(t)$ is the cost of PE, i.e. the gas for the Stirling engine and supplementary burner, and $C_{el}(t)$ is the cost of electricity bought (from the grid) minus the gain from electricity sold (to the grid).

Primary energy (PE) optimization: Electricity credit method

For both PE optimization and performance assessment we compare the CHP system with a system with conventional generation (heat generated in a gas boiler; electricity generated in a gas-driven electrical power plant without exploitation of waste heat). In Figure 2 we first consider the situation *without supplementary burner* (same efficiencies used as later on).

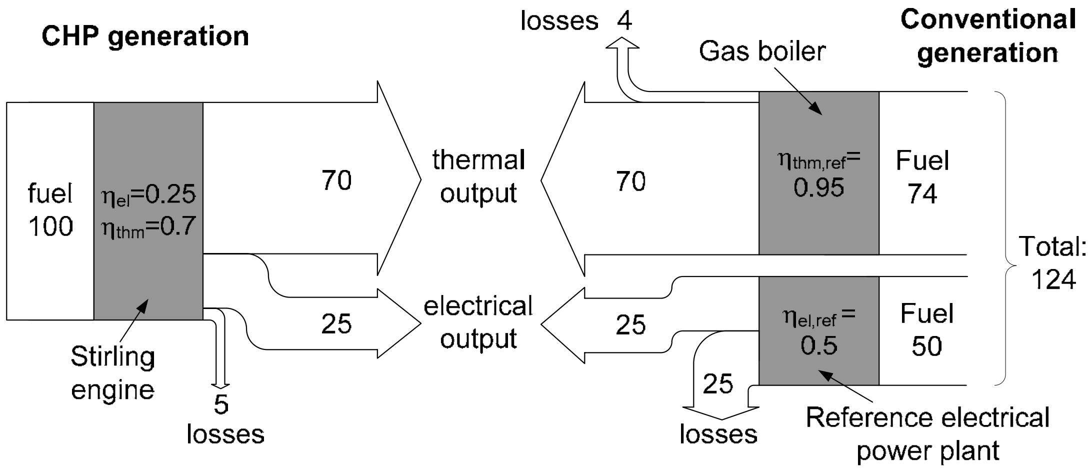

Figure 2: Comparison of energy flows of Stirling engine and conventional generation (situation without supplementary burner).

With 100 kWh of PE (gas), the example CHP unit produces 70kWh of thermal output and 25kWh of electrical output. To produce the same thermal and electrical output with conventional generation (i.e., a conventional gas boiler for heating and a conventional power plant for electricity production), 124kWh of PE would be needed, 50kWh of which for electricity production. For computing the relative savings, we can relate the difference of the PE used to the PE used for heating only with a conventional system, i.e.:

$$relative\,PE\,savings = (124-100)/74 \;=\; 32.4\%. \tag{3}$$

This definition of relative savings is the same as for measures to reduce heating energy consumption, for example improving the building isolation.

There are different possible criteria for PE optimization [9]. Our approach is to minimize overall PE consumption (for heat and electricity, including the grid). Basic idea: The electricity produced by the CHP need not to be produced somewhere else in a conventional power plant (the reference electrical power plant), thus reducing the PE consumption of this reference power plant. These savings (50kWh in Figure 2) are accounted for with a corresponding "credit" in the optimization criterion for PE-optimal control, J_{PE}. We call this method "electricity credit method" [6]. For the system with Stirling engine *and supplementary burner*, J_{PE} is thus:

$$J_{\mathrm{PE}} = \min \sum_{\mathrm{time}\; t} \left[E_{\mathrm{PE,SE}}(t) + E_{\mathrm{PE,SB}}(t) - E_{\mathrm{el,ref}}(t) \right] \tag{4}$$

where $E_{PE,SE}(t)$ and $E_{PE,SB}(t)$ is the PE (gas) consumption of Stirling engine and supplementary burner, and $E_{el,ref}(t)$ is the credit for produced electricity.

Note that without the credit for electricity the Stirling engine is not used at all. PE optimization only favors the Stirling engine if it receives a payback from electricity production. Furthermore, the criterion for optimization should comply with the criterion for performance assessment (assessment of PE used, and of PE savings compared to a conventional system).

Optimization method

We use linear programming (LP) as optimization method. The optimization horizon is chosen to be 24h, with 15-min time steps. A moving horizon technique is then applied to run through the whole period under consideration (e.g. one year).
The optimization problem is formulated in terms of a cost function; see for example eq. (2), that has to be minimized under a set of inequality constraints given by eq. (1). The linearized plant model (in our studies, the plant model was of order 24) is used to express the temperatures $T_R(t)$, $T_{DHW}(t)$ and $T_{FL}(t)$ as a function of the control sequences $u_{SE}(t)$, $u_{SB}(t)$ and $u_{VLV}(t)$ for each time step within the time horizon. The cost function is then minimized by manipulating the optimization variables (i.e., the control sequences).

NUMERICAL VALUES AND PARAMETERS

Building types

We studied three types of buildings with four apartments inhabited by three occupants each: An old one with thin walls and poorly insulated windows, an averagely insulated one corresponding to the German WSV95 building regulation and a well insulated one corresponding to the German EnEV2000 building regulation. More details on these building types can be found in [7]. The apartments all have a floor space of 150 m^2.
The nominal gas input of the Stirling engine has been chosen in such a way as to ensure the basic load, i.e. the engine should supply the average thermal energy needed during a whole year. On the other hand, the supplementary burner is sized so that the peak loads during winter (design temperature of -13.5°C) can be covered by both the engine and the supplementary burner.

Nominal values		Old	WSV95	EnEV2000
Stirling Engine heat output	[kW]	19.9	9.4	5
Stirling Engine electrical power	[kW]	7.1	3.35	1.8
Supp burner heat output	[kW]	41.2	18	8.2
Building heat losses	[W/K]	445.7	194.3	88.4
Building cooldown time constant	[h]	94	162	396

Table 1: Numerical values of the parameters for three building types

Loads and climate

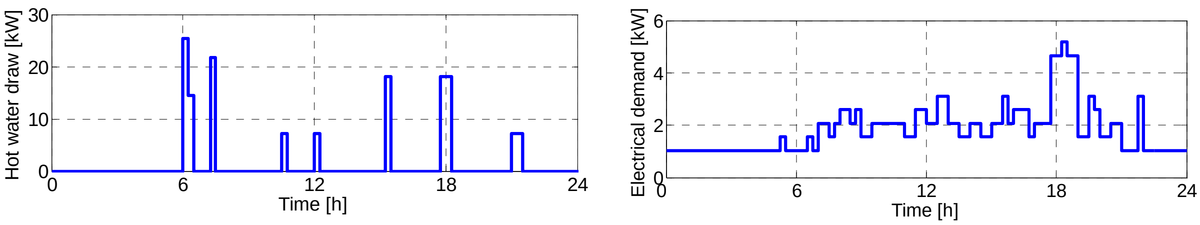

Figure 3: Profiles of hot water draws (left) and electricity demand (right), both in kW. Demand peaks are mapped to 15min-intervals (= sampling time of the control algorithm).

Five disturbance variables are included in our model and are shown in Figure 1 in orange.

- **Hot water**: An overview on typical electric and DHW load profiles is given in [8]. We assume an average daily hot-water consumption of 52 liter/person at a rise of 50K, which corresponds to 36.3kWh for a building with 12 inhabitants. We assume strong peaks in the morning and the evening (see Figure 3).
- **Electricity**: The daily electricity consumption is set to be 43.8kWh with a minimum

consumption of 1 kW and with peaks depending on the time of day (see Figure 3).
- **Outdoor temperature (T_O)**: For whole-year simulations, we use the temperatures measured at Zurich Airport during the year 2000
- **Internal heat gains (persons, electrical equipment etc.)**: Set constant to 0.6kW.
- **External heat gains**: Neglected. Reason: Incorporating solar gains correctly would involve the modeling of sunblinds, including an appropriate sunblind operation.
- **DHW tank**: The air temperature around the DHW tank ($T_{R,DHW}$) is set to be 10°C. The cooldown time constant of the DHW tank is set to be 2 days.

Prices

We use gas and electricity prices of Zurich, Switzerland (all in CHF-cents).
- **Natural gas**:
  - CHP devices: 5.1 cents/kWh
  - Conventional burners: 6.1 .. 7.1 cents / kWh (*lower* for large consumers)
- **Electricity**: Table 2 shows the electricity rates of Zurich.

period	Purchase from grid	Feed-in
Winter day-time	17 .. 19.5 cents / kWh (*higher* for large consumers)	15 cents / kWh
Winter night-time		11 cents / kWh
Summer day-time		7 cents / kWh
Summer night-time	5.0 cents / kWh	4 cents / kWh

Table 2: Electricity pricing, Zurich. Winter: 01.10 – 31.03. Day-time: 6am – 10pm.

Reference electrical efficiency

We adopt a marginal approach with a state-of-the-art gas reference power plant: From the viewpoint of achieving additional electricity capacity with a Stirling engine, the efficiency of an equivalent new central power generation installation should be considered, i.e. 56% for a combined cycle system at the power station, i.e. around 50% with losses resulting from electricity transport from the power plant to the apartment building. (Note that this is an ambitious benchmark. In many publications, the current electricity mix with η_{el} around 35% is used instead.) For more information see [9].
We assume that exported electric energy is consumed in-house or in the vicinity of the Stirling engine. Then the electricity produced by the Stirling engine is not subject to grid losses, in contrast to the electricity from the power plant. The grid losses are therefore included in $\eta_{el,ref}$ for both import and export.

Efficiencies and setpoints

- Efficiencies of the Stirling engine: $\eta_{\mathrm{SE}} = 0.95, \quad \eta_{\mathrm{SE,\,th}} = 0.7, \quad \eta_{\mathrm{SE,\,el}} = 0.25$
- Efficiency of the supplementary burner: $\eta_{\mathrm{SB}} = 0.95$
- Reference electrical efficiency: $\eta_{\mathrm{el,\,ref}} = 0.5$ (after subtraction of grid losses)
- Reference thermal efficiency: $\eta_{\mathrm{th,\,ref}} = 0.95$
- Room temperature: $T_{R,\min} = 19°\mathrm{C}$ between 22:00 and 06:00, $T_{R,\min} = 21°\mathrm{C}$ between 06:00 and 22:00, $T_{R,\max} = 24°\mathrm{C}$
- Flow temperature: $T_{FL} \le 50°\mathrm{C}$
- DHW storage water temperature: $T_{\mathrm{DHW,\,min}} = 20°\mathrm{C}$ and $T_{\mathrm{DHW,\,max}} = 80°\mathrm{C}$.
  ⇨ Note that T_{DHW} is the *average* water temperature of the DHW storage tank, not the measured (sensor) temperature. For the minimal state of charge we assume that 20% of the water in the tank has a temperature of 60°C and 80% has a temperature of 10°C

so that the average temperature is 20°C.

SIMULATION RESULTS

Diurnal progression of the temperatures and control signals (base case)

Figure 4 shows progressions with PE-optimal control over 2 days for a sinusoidal outdoor temperature with a mean value of 7°C, an amplitude of 6°C, and a minimum temperature reached at 3am. The building type is chosen to be an older one for better contrast. Note that the Stirling engine works with full heat output throughout the night. The peaks of the supplementary burner are caused by hot water consumption. The progressions are quite the same for cost optimization with winter tariff as well, but not for cost optimization with summer tariff.

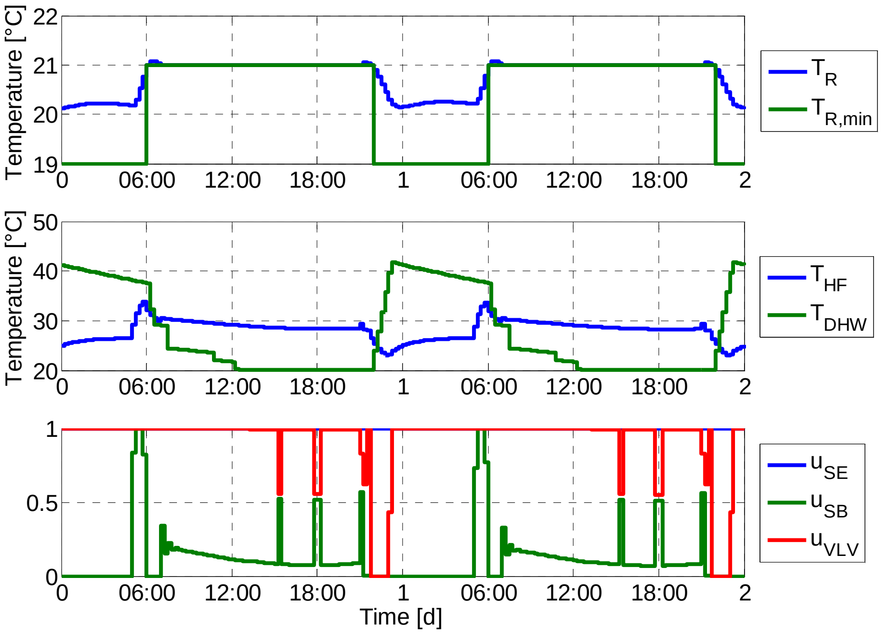

Figure 4: Results of PE-optimal control for an older building with a mean outdoor temperature of 7°C. Middle panel: Flow temperature TFL (blue) and hot water temperature (average over the whole tank, green).

Differences between cost-optimal and PE-optimal control

The characteristics of the control behavior depend in a complex way on many factors. We restrict ourselves to pointing out a few major differences between cost- and PE-optimal control:

- Generally, PE optimization (as well as cost optimization with winter tariff) tries to use the Stirling engine as much as possible and to use the supplementary burner as little as possible.
- As a consequence, the Stirling engine runs throughout the night unless the outdoor temperature is too high. This results in a moderate night setback. The DHW storage may preferably be charged at the beginning of the night.
- Cost optimization with summer tariff tends to shut down the engine, thus producing a more pronounced night setback and postponing the DHW charge to the early morning. As a consequence, more support from the supplementary burner is needed in the morning.

Performance assessment (PA) for whole-year simulations (base case)

The operation cost and PE consumption of the investigated system has been compared to the figures from a conventional generation (reference) system. In the reference system, there is no Stirling engine; however the supplementary burner (conventional gas boiler) is more powerful, such that the total rated thermal output is the same. All electricity is produced by the electrical reference plant ($\eta_{el} = 56\%$). For the computation of the relative PE savings, the PE consumption for heating only with the conventional system is taken as a reference (example without supplementary burner see equation (3)). Table 3 shows the main results:

			Building type		
			Old	WSV95	EnEV2000
Conventional heating (=gas burner alone)		Cost PE consumption for heating	CHF 15,169.-- 196.5 MWh	CHF 8,512.-- 87.4 MWh	CHF 5,650.-- 40.5 MWh
CHP system	Cost-optimal control	Cost saving PE saving	28.5% 20.6%	28.1% 21.9%	23.3% 23.7%
	PE-optimal control	Cost saving PE saving	27.5% 21.4%	25.5% 22.9%	20.6% 24.9%

Table 3: Main PA results for the base case. Reading example for old building: With conventional heating (a conventional gas burner alone), the yearly energy cost is CHF 15,169.- and the PE consumption for heating is 196.5MWh. With cost-optimal control, the one-year energy cost for the reference system with Stirling engine is 28.5% lower than with a gas burner alone, and saves 20.6% of PE. PE-optimal control saves 27.5% energy cost and 21.4% PE.

The differences in cost and PE consumption between both types of optimization (cost/PE) are only a few percent. This means the tariffs in Zurich reward a PE-optimal operation quite well. The equivalent full-load operating time of the Stirling engine is between 260 and 280 days, or about three quarters of the year for all cases. This indicates correct sizing of the SE.
The whole-system PE savings of 21 .. 25% can be related to the PE savings of the Stirling engine alone, which are 32.4% (equation (3)). The latter figure is the limitation for achievable PE-savings with a much more powerful SE. In other words, the base case design (SE for peak load only) achieves 65 .. 75% of the possible savings. This result is backed in the following section.

Variation of the sizing of the Stirling engine

Starting from the base case, the variation of many parameters has been investigated, including time shift of room temperature setpoint profile and electricity tariff profiles; electricity and gas prices; reference electrical efficiency; Stirling and supplementary burner efficiencies; and DHW tank size. In this section, we vary the nominal gas input of the Stirling engine and assess the effect on operation cost and PE consumption. The size of the supplementary burner is varied accordingly, such that the total nominal heat output remains constant. (Note that SE power multiplier = 0 results in the conventional reference system used for the performance assessment, see above).

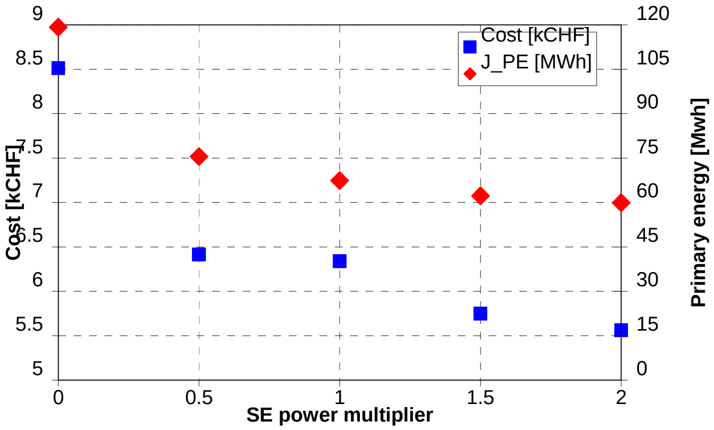

Figure 5: Cost and PE consumption as a function of the SE sizing (power multiplier)

Figure 5 shows the result of PE-optimal simulation over one year with temperatures measured in 2000 for the WSV95 building. We can see that the curves become rather flat when increasing the size of the Stirling engine above the reference case (i.e. SE power multiplier > 1): Doubling the size of the Stirling engine reduces operating cost of only by about 12%. Since on the other hand, investment and maintenance costs increase with the size of the Stirling engine, an SE seems to be correctly sized in the base case.

DISCUSSION

The method described in this paper allows determining the cost- or PE-optimal CHP operation for a given system, with known loads and climate. This optimal solution is the performance bound and can be used for a comparison with real or simpler (suboptimal) control strategies. It also gives us useful hints for developing such simpler strategies.
Numerical values for building model, load profiles etc. used in this paper may be debatable. Nevertheless we are convinced the general quantitative results are usable:

- We investigated a combination of a Stirling engine for the base load and a supplementary burner for the peak load. Using the assumptions on parameters, loads, and climate outlined in this paper, such a set-up can yield a whole-year PE and CO_2 savings are in the range of 20..25% comparing to conventional generation (modern reference electrical power plant with an ambitious $\eta_{\mathrm{el}} = 56\%$).
- Increasing the SE size at the expense of the supplementary burner increases the PE savings only moderately may increase investment costs significantly.

The use of CHP is encouraged by many governments in order to meet the goals of the Kyoto protocol. However in practice, CHP owners and operator will only operate their CHP device in a PE-optimal way if this is financially rewarded. Governments should therefore convince energy suppliers to offer attractive prices for feed-in electricity. (Technically this means that the two cost functions (2) and (4) should be similar, see [2].)

ACKNOWLEDGEMENT

The partial funding of this research by the Swiss Federal Office of Energy (SFOE) in the context of the IEA ECBCS Annex42 project is gratefully acknowledged.

SUMMARY

In this paper, we present the economic analysis of a solid-oxide fuel-cell (SOFC) micro-cogeneration plant in a single-family low-energy house in Finland. Here, we implement a new solid-oxide fuel-cell (SOFC) model in the dynamic building simulation software "IDA – Indoor Climate and Energy" to obtain a match between energy demand and supply. In our computational study, we first estimate the break-even values for both the buyback price of electricity and plant investment that make an SOFC plant financially viable in a comparison with a water-based gas boiler heating system without cogeneration. Second, we determine the sensitivity of break-even prices in terms of the electrical power, overall efficiency and two operational strategies. Our results suggest that the optimal operation would encompass a constant run with electrical power no more than 1 kW_e. In the above case, the break-even buyback price would remain less than 0.04 EUR kWh^{-1}, provided that the overall efficiency exceeds 80 %.

INTRODUCTION

Buildings account for 40% of final energy use, providing a major challenge to the whole energy system. Several studies suggest that the introduction of distributed energy generation would promote the transition to a sustainable energy system (e.g. [1-2]). A solid-oxide fuel cell (SOFC) can be considered a promising alternative to the traditional energy supply for residential buildings due to its general advantages, such as noiselessness and low emissions [3].

The success of new technology in the market presumes, however, that the technology is financially viable with respect to conventional technologies. The key economic drivers are capital costs, energy import and export prices, and plant lifetime [4]. Earlier studies imply that savings in a comparison with traditional residential energy supply solutions may be difficult to obtain by employing solid-oxide fuel cells, partly because of their high capital costs and also due to the high amount of non-utilizable thermal energy (e.g. [5]). The economic key factors that apply to fuel cells, however, strongly depend on the local operational environment and several issues between climatic conditions and taxation policy. A good example is the buyback price of electricity (i.e. the monetary compensation a producer receives for the electricity fed into the grid), which is largely not yet established.

The objective of this study is to evaluate the financial viability of SOFC cogeneration in a low-energy single-family house in Finland. First, we estimate the break-even values for both the buyback price of electricity and plant investment that make an SOFC plant financially viable in a comparison with a water-based gas boiler heating system without cogeneration. Second, we determine the sensitivity of break-even prices in terms of electrical power, overall efficiency and two operational strategies.

METHODS

The applied methodological framework consists of i) creating the hourly electrical and thermal demand profiles of a case building using the advanced building simulation software IDA – Indoor Climate and Energy (IDA-ICE), ii) estimating the hourly electrical and thermal supply profiles of an SOFC plant using the new mathematical model of SOFC implemented in the IDA–ICE and iii) post-processing of the simulation results and conducting an economic analysis in MicroSoft Excel.

IDA-ICE provides an advanced tool for the dynamic simulation of heat transfer and airflows in buildings, allowing the modelling of multi-zone buildings, internal and solar gains and outdoor climate. The software is widely used in Scandinavia both in commercial and research use. It has been developed by the Royal Institute of Technology and the Swedish Institute of Applied Mathematics, reported in detail by Björsell et al. [6] and Shalin [7] and well tested in several studies, e.g. Achermann et al. [8] and Travesi et al. [9].

The SOFC model is based on the principles in Beausoleil-Morrison et al. [10] and is implemented in the IDA–ICE using the modelling language "Neutral Model Format (NMF)", reported by Sahlin et al. [11,12]. Here, the "dynamics" of a 3 kW_e SOFC system is modelled as a modified PI-controller, which drives the fuel-cell system at a limited power change rate. The user provides parameter values manually. Inputs to the system are given by flow rates of fuel, water and air. Outputs are electricity, exhaust gas and heat losses from the surfaces. The model structure with relevant parameters is presented in Figure 1.

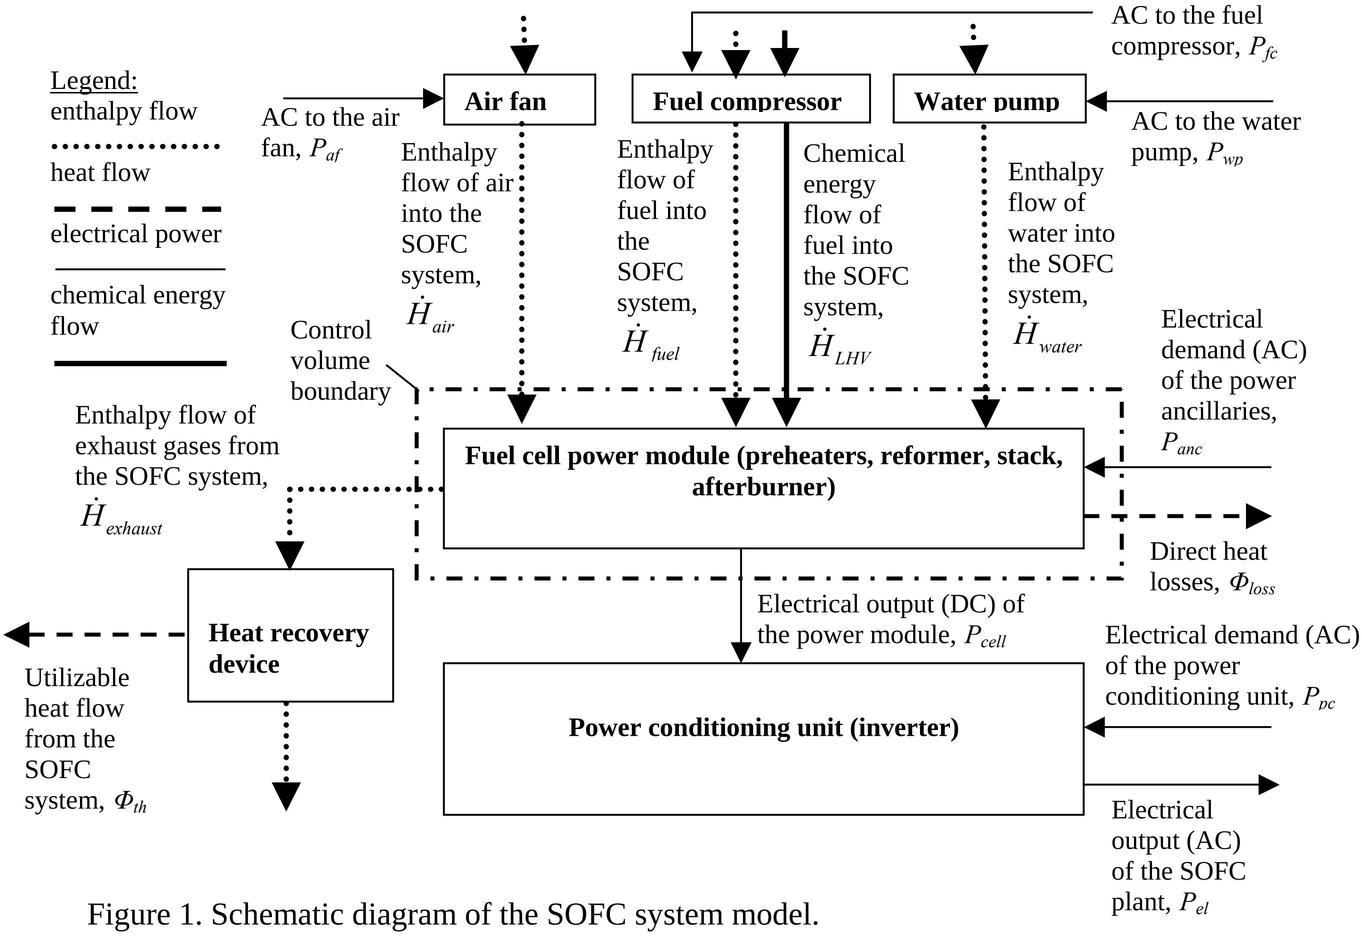

Figure 1. Schematic diagram of the SOFC system model.

The electrical output (DC) of the power module P_{cell} is given by Eq. (1)

$$P_{cell} = \eta_{e,stack} \dot{n}_{fuel} LHV = \eta_{e,stack} \dot{H}_{LHV} \qquad (1)$$

where $\eta_{e,stack}$ is the electrical efficiency, $\dot{n}_{fuel}$ is the molar flow of fuel [mol/s] and LHV is the lower heating value of the fuel. In the present model, the electrical efficiency of the power module $\eta_{e,stack}$ as the function of expected electrical output power is expressed as a polynomial

$$\eta_{e,stack} = (e_{2,\eta} P_{cell}^2 + e_{1,\eta} P_{cell} + e_{0,\eta})(1 - d_{stops} n_{stops}) \cdot \left(1 - MAX\left[\int_0 dt - t_{threshold}, 0\right] \cdot L\right) \qquad (2)$$

where $e_{2,\eta}$, $e_{1,\eta}$ and $e_{0,\eta}$ are polynomial coefficients obtained by experiments. The term "1-$d_{stops}n_{stops}$" is an expression for the degradation of the fuel cell power module's electrical efficiency as a result of stop-start cycling, n_{stops} is the number of stops and parameter d_{stops} is a user-input that represents the fractional performance degradation. The "L-term" represents the degradation of electrical efficiency as a consequence of operation. The time integral indicates the current time of operation, i.e. the accumulated time from the initial system start. L is a fixed, user-defined value that represents the fractional degradation related to operation time and $t_{threshold}$ is a given time when the operational degradation is expected to start.

The energy balance of the power module is

$$\dot{H}_{fuel} + \dot{H}_{air} + \dot{H}_{water} + \dot{H}_{LHV} + P_{anc} = P_{cell} + \dot{H}_{exhaust} + \Phi_{loss} \qquad (3)$$

where H_{fuel}, H_{air}, and H_{water} are the enthalpy flows into the power module by the fuel, air and water, respectively, H_{LHV} is the chemical energy flow into the system by the fuel, $H_{exhaust}$ is the heat flow out of the system by the exhaust gases, P_{anc} and P_{cell} are the electrical draw of ancillaries and the electrical output of the power module, respectively, and Φ_{loss} is the loss heat flow out of the power module.

The enthalpy flows in Eq.(3) are defined as

$$\dot{H}_i = \dot{n}_i h_i \qquad (4)$$

where n_i is the i-th molar flow [mol s^{-1}] and h_i is the corresponding specific enthalpy [kJ/mol]. The relation between temperature T and specific enthalpies is given by the Shomate equation

$$h_i = \frac{AT}{1000} + \frac{B}{2}\left(\frac{T}{1000}\right)^2 + \frac{C}{3}\left(\frac{T}{1000}\right)^3 + \frac{D}{4}\left(\frac{T}{1000}\right)^4 - \frac{1000E}{T} + F - H \qquad (5)$$

where $A,B,\ldots,H$ are polynomial coefficients. Since air, fuel and exhaust gas are mixtures of various gases, the above coefficients are calculated for the gas mixture using molar fraction weighted averages ε_i. The composition of the exhaust is considered stoichiometric. Assuming that the fuel fully reacts, i.e. there is no hydrogen or carbohydrates left in the exhaust gas, the expression for molar fraction weighted averages can be given as

$$\varepsilon_{avg} = \sum_i (\dot{n}_i \varepsilon_i) / \sum_i \dot{n}_i \qquad (6)$$

where ε = {A, B, C, D, E, F, H}.

The electrical demand of ancillaries is defined with separate polynomial equations. The net electrical output power of the SOFC plant can be defined as

$$P_{el} = P_{cell} - P_{af} - P_{fc} - P_{wp} - P_{anc} - P_{pc} \qquad (7)$$

where P_{cell}, P_{af}, P_{fc}, P_{wp}, P_{anc}, and P_{pc} are the electrical powers of the SOFC power module, air blower, fuel compressor, water pump, ancillaries, and power conditioner, respectively. The utilizable heat flow Φ_{th} now depends on the capability of the heat recovery device to transfer heat from the exhaust gases to water circulation. In the present approach, the overall efficiency of the SOFC plant is

$$\eta_{tot} = \frac{P_{el} + \Phi_{th}}{\dot{H}_{LHV}} \qquad (8)$$

In the economic evaluation, savings are assumed to occur during operation, compared to gas heating without a fuel cell (reference). The condition of the financial viability presumes that the discounted savings are equal to the capital costs during a given period of time. This condition is satisfied when

$$C_{I,SOFC} - \frac{(1+r_e)^n - 1}{r_e(1+r_e)^n} \cdot \left[c_{e,p} W_{e,ref} + c_{pr} Q_{pr,ref} - \left(c_{e,p} W_{e,p} - c_{e,s} W_{e,s} + c_{pr} Q_{pr,SOFC} \right) \right] = 0 \qquad (9)$$

where $C_{I,SOFC}$ is the capital (investment) cost of an SOFC plant, r_e is the discount rate for energy costs, n is the number of years on the time period, $W_{e,ref}$ and $Q_{pr,ref}$ are the annual electricity and input energy consumptions in the reference case, respectively, $c_{e,p}$ and c_{pr} are the purchasing prices for electricity and input energy, respectively, $c_{e,s}$ is the buyback price of electricity, $W_{e,p}$ is the annual amount of electricity to be purchased in the case of SOFC operation, $W_{e,s}$ is the annual amount of electricity fed into the grid, and $Q_{pr,SOFC}$ is the input energy consumption of the SOFC plant (directly proportional to H_{LHV}).

RESULTS

The computational study concerns a low-energy single-family house located in the Helsinki area. The habitable area is 131 m^2 and the U-values for envelope, roof, floor, windows and doors are 0.14 W m^{-2}K^{-1}, 0.1 W m^{-2}K^{-1}, 0.15 W m^{-2}K^{-1}, 1.0 W m^{-2}K^{-1} and 0.5 W m^{-2}K^{-1}, respectively. The house is inhabited by four persons; the daily profiles for heat gains and domestic hot water (DHW) demand is illustrated in Figure 2.

The calculations were conducted for the reference case (water-based gas boiler heating) and the SOFC plant with two operational strategies: i) the SOFC plant was operated at a constant power throughout the year and ii) the operation was controlled by the electrical demand of the building. The energy prices were based on the rate schedules of local utilities in December 2006 for both natural gas and electricity. The efficiency of the gas boiler was assumed to be 0.93 [13]. The annual consumption of electricity and natural gas in the reference case were 6089 and 11186 kWh a^{-1}, and the corresponding annual costs were 583 and 771 EUR a^{-1}, respectively. The discount rate of 5 % was used. The annual energy profile of an SOFC system with an overall efficiency of 80 % is presented in Table 1.

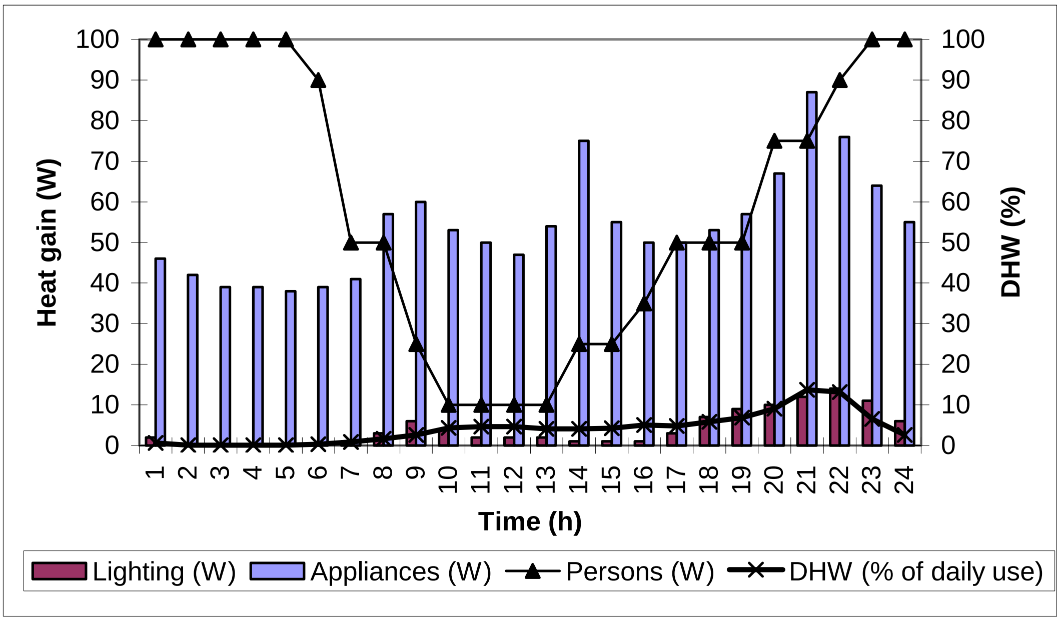

Figure 2. Daily profiles for heat gains and hot water usage [14].

Table 1. Annual energy profile for the SOFC heating system.

Constant operation					
eta = 80 %	Purchased electricity ($kWh\ a^{-1}$)	Delivered electricity ($kWh\ a^{-1}$)	Fuel to SOFC ($kWh\ a^{-1}$)	Fuel to boiler ($kWh\ a^{-1}$)	Fuel total ($kWh\ a^{-1}$)
1 kWe	47	2719	22464	4394	26858
2 kWe	0	11382	39723	2274	41997
3 kWe	0	20108	58204	861	59064
Adapted operation (electricity)					
eta = 80 %	Purchased electricity ($kWh\ a^{-1}$)	Delivered electricity ($kWh\ a^{-1}$)	Fuel to SOFC ($kWh\ a^{-1}$)	Fuel to boiler ($kWh\ a^{-1}$)	Fuel total ($kWh\ a^{-1}$)
1 kWe	87	41	16418	5398	21816
2 kWe	34	55	16565	5351	21916
3 kWe	34	55	16565	5351	21916

As can be seen in Table 1, there is only a minor need to purchase electricity from the grid either when the SOFC plant is operated at constant power or following the electrical demand (adapted operation). The fuel consumption remains quite large in both cases. Instead, in constant operation, the amount of electricity fed to the grid is large. The match between the supply and demand of power in the case of adapted operation (SOFC plant follows the electricity demand) is illustrated in Figure 3.

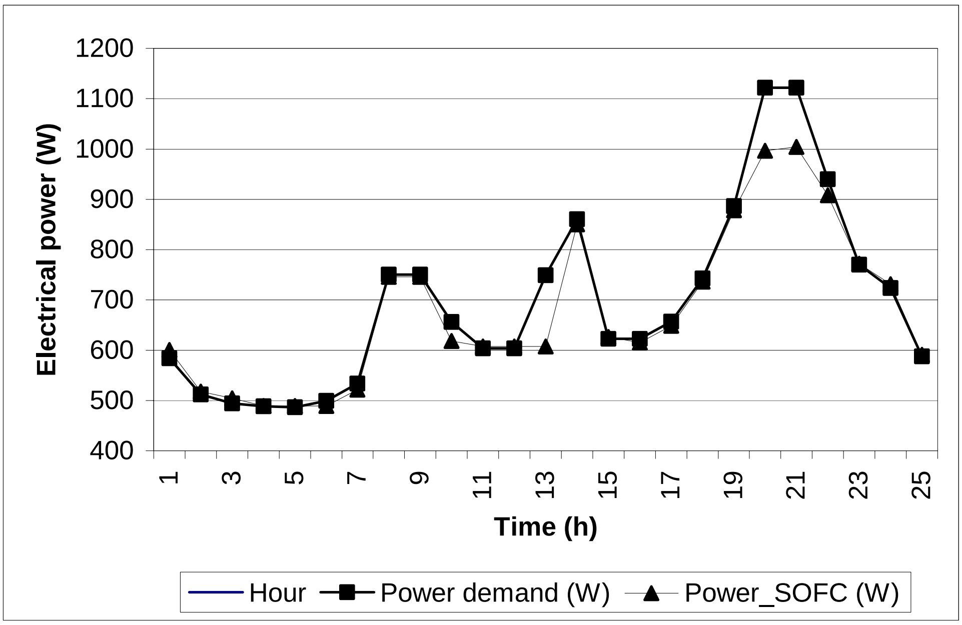

Figure 3. The match between power supply and demand.

The first condition enabling financial viability is that annual savings occur, which presumes here that a break-even buyback price must be first found for electricity (zero savings). Figure 4 illustrates the break-even buyback price of electricity when the SOFC plant is operated at constant power from 1 to 3 kW_e and the overall efficiency, i.e. the ratio of heat that can be transferred from the exhaust gases to the water circulation, varies from 0.5 to 1.0. The result suggests that a significantly low buyback price of electricity is not achievable when the operating power is more than 1 kW_e. Based on the overall efficiency, an obvious reason for this is large, but unavoidable, heat loss in the constant operation, which cannot compensate the incomes from buyback electricity. Figure 4 shows also that annual savings are not possible if there is no compensation for the electricity fed into the grid. The lower the buyback price, however, the more eagerly it will probably be offered by the energy utilities to a private producer. For the above reasons, the further considerations focus on 1 kW_e operation.

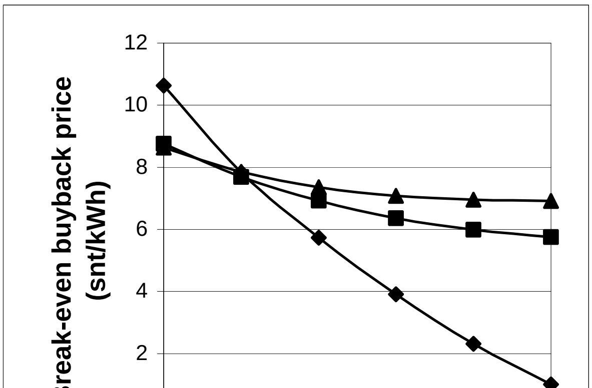

Figure 4. Break-even buyback price of electricity.

In Figure 4, the curve of break-even buyback prices represents zero savings. Considering a 1 kW_e SOFC plant with an overall efficiency of 80 %, the buyback price should be more than 4 snt kWh^{-1} to create annual savings. The relation between the overall efficiency, buyback price, payback period and the maximum allowable capital costs invested in an SOFC plant are presented in Figure 5.

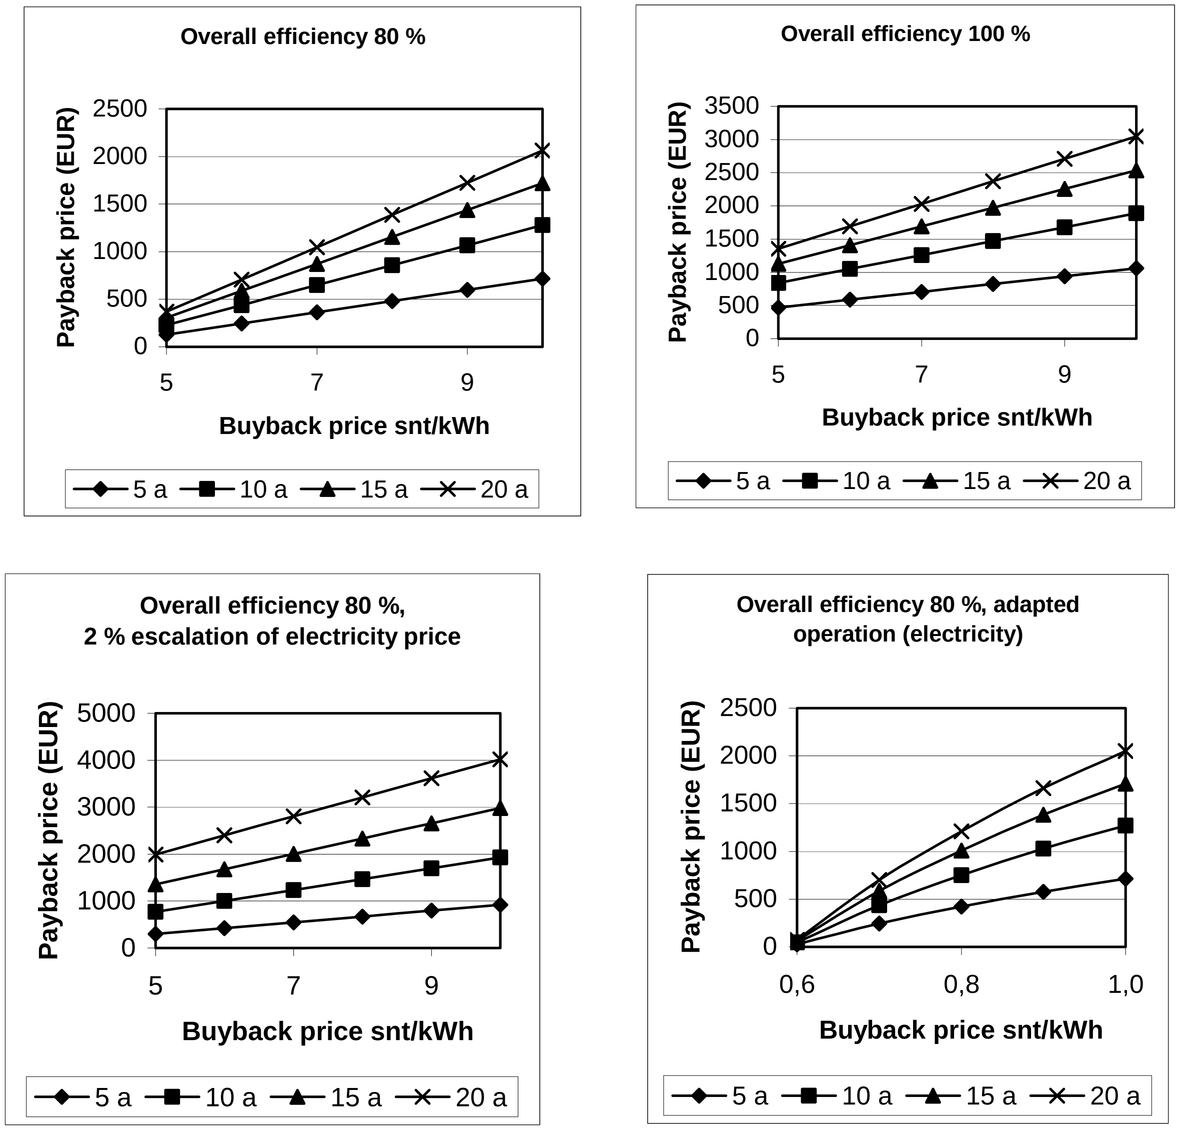

Figure 5. Payback price of SOFC technology.

Figure 5 implies that, in the ideal case (overall efficiency 100 % and payback period 20 years), the maximum allowable technology price would be 3000 EUR. In the sense of earlier studies (e.g. [3]), the life span of an SOFC stack may be less than 10 years, which suggests that an allowable payback period might be rather 5 than 10 years. In this case, the allowable capital costs would remain less than 1000 EUR. The situation from the viewpoint of short payback periods will not improve, even when one assumes that the escalation of electricity price with respect to that of natural gas is 2 % (see Figure 5). Without significant investment support, the investment in SOFC technology does not seem feasible in the case considered here.

DISCUSSION

In this paper, we present the economic analysis of a solid-oxide fuel cell (SOFC) micro-cogeneration plant in a characteristic single-family low-energy house in Finland. Our results suggest that the optimal operation of an SOFC plant would encompass a constant run with electrical power no more than 1 kW_e. Here, the break-even buyback price would remain less than 0.04 EUR kWh^{-1}, provided that the overall efficiency exceeds 80 %. However, taking into account the requirements concerning the payback period and the price of technology, it seems that, without significant investment support, the investment would not be feasible in the case considered here. One should note, however, that this result is only valid for the present case building. Furthermore, our approach did not employ an actual demand profile of a building and the study was unable to analyze the real impact of peak demands. Therefore, more studies are needed to draw further general conclusions about the viability of SOFC cogeneration in Finnish households.

SUMMARY

This paper presents the basic parameters and energy flows of an aquifer thermal energy storage (ATES) system combined with reversible water/water heat pumps used for heating and cooling the new hospital Klina (Antwerp – Belgium). The installation system is one of the first ATES projects in Belgium, and its operation is monitored with the aid of a DAQ system. The energy flows, primary energy consumption, CO_2 emission reduction, … were calculated based on DAQ loggings of the first 3 years of system's operation. It is proved that the ATES system is a highly energy efficient system delivering 74% of the total cooling demand. The $COP_{cooling}$ of the ATES system was 45. A primary energy saving of 69% on cooling energy was achieved. These figures prove that in heating and cooling mode, the ATES system is significantly less demanding in terms of primary energy.

INTRODUCTION

The energy use in the Belgian health sector amounts to 8% of service sector electricity consumption and 10% of service sector fuel consumption. To reduce greenhouse gases emitted by heating and cooling plants the health sector needs to shift away from the use of conventional techniques towards renewable energy sources such as the use of underground thermal energy storage [1, 2].

Aquifer Thermal Energy Storage (ATES) was introduced on the Belgian market since 1995 [3]. Since 1998, many companies showed interest in the technology, but this isn't translated into a steady increase of realized projects. This is mainly caused by the hydro geological circumstances. In Belgium, the Northeastern part of the country has very good technical and economical potential for ATES applications. However, the most interesting economical and industrial areas are located outside this region. A thick clay layer covers the Western part of Belgium; the southern part mainly exists of Silurian schist and Devonian rock. At this time, 15 large ATES-systems (> 300 kW) are operational and most installations are monitored.

A number of ATES projects are monitored within the framework of a subsidy program for the stimulation of innovative energy technologies, called "Energy Demonstration Program" (initiative of VEA – Flemish Energy agency - of the Flemish government). For ATES system the monitoring is 3 years in order to have representative results for steady-state performance. Enterprises can get financial support (35% of the extra investment of the innovative investment in comparison to a traditional installation).

In this paper, the monitoring results of an ATES system coupled to reversible heat pumps for heating and cooling a new hospital in northern part of Antwerp is presented with energy and temperature data recordings over 3 years of operation [4].

METHODS

Description of the building

The ATES system and reversible heat pumps (195 kW heating power) was installed at the new hospital "Klina" of Brasschaat, in northern Antwerp (Belgium). It is located at a distance of 12 km from Antwerp center.

The building is located at 4 floors, covering 440 beds, surgery, technical and consultation rooms and a large atrium is implemented between these zones. This imposes simultaneous heating and cooling of different thermal zones, especially during intermediate seasons (autumn and spring). The KLINA hospital was one of the first in Belgium to incorporate comfort cooling in the patient rooms. In order to avoid expensive cooling with traditional refrigeration a system with long term storage of cold and heat in the groundwater was installed. On average, the hospital is in operation 365 days per year and 24 hours per day. The building was designed in the early 90's and the construction works were completed in 1999. The ATES system went in operation in august 2000.

The heat in the patient rooms, kitchen, etc. is distributed by radiators which are designed to operate at temperatures between 80/50°C. The heat pump cannot be used for such a high temperature regime. Gas-fired boilers will cover this demand. The low temperature heat is used in the ventilation installations (air handling units, AHU) and is typically suitable for use with the heat pump and the ATES system.

The predicted cooling power of the building was calculated at 1.6 MW. The top cooling is used in patient rooms, kitchen, consultation rooms, etc at a temperature regime of 11/21°C. The deep cooling demand is especially needed in surgery rooms at a temperature regime of 6/12°C. The central air handling units with water coils (in total 40) provide make up air to the building and the fan-coils are selected for low temperature heating (34/45°C) and high temperature cooling purposes (11/21°C).

Geohydrology

For the application of an ATES system aquifers (or water-saturated sand layers) are necessary. At the site of the hospital a test drilling was made to explore different sediments or formations in the ground. The drilling reports indicates that the ground, up to a depth of 100 m, consists mainly of sand layers separated by a clay layer at the depth of around 80 m. This geology makes the application of ATES preferable. Groundwater can be extracted out of (and injected in) the formations of Diest, Antwerp and Kiel (all water saturated sand layers). The maximum possible groundwater extraction per well is estimated at 100 m^3/h, given 1.2 MW of cooling power.

Description of HVAC and ATES system

The ATES system provides cooling by means of extracting groundwater from the cold well (see also figure 1). This groundwater cools down the building and ventilation air and incorporates the building heat and is afterwards injected in the warm well. At inadequate cooling power or if an insufficiently low temperature is reached by the system, the heat pumps are operated in summer mode (heat pump is working as cooling machine). The condenser heat is also removed by means of the ATES system to the warm well. In the winter groundwater is extracted from the warm well with as aim preheating the ventilation air. This way the winter-cold is taken from the building and injected in the cold well. The heat pump in this mode is used for heating. One of the main advantages of this installation is that the condenser heat is stored in the warm well for use in winter period when the heat pump is operated in summer mode. An overview of the system (operation in summer period) is shown in Figure 1. Table 1 gives the specifications of the ATES system.

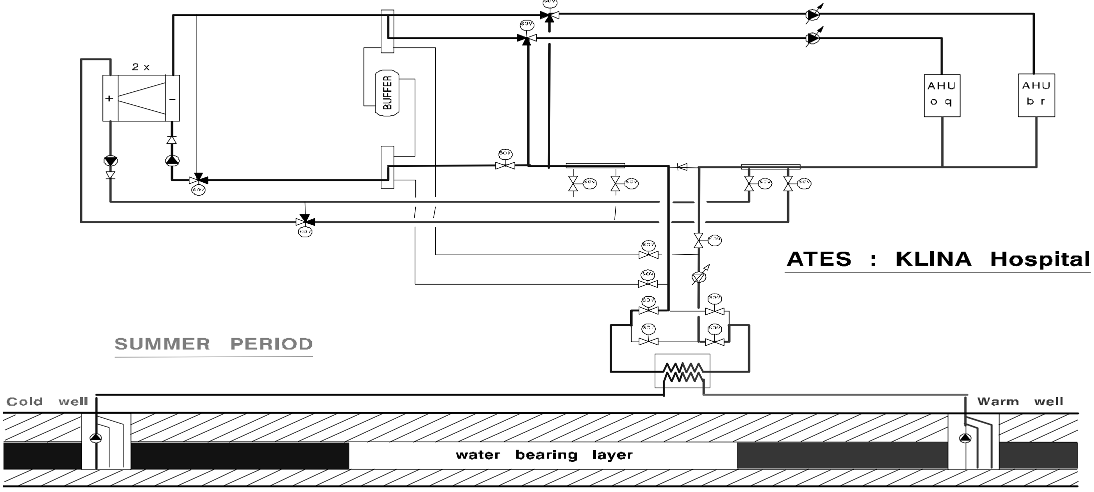

Figure 1. KLINA - ATES operation during summer period.

Table 1. Specifications of the ATES system

Parameter	**Value**
Maximum flow per well	100 m³/h
Maximum cooling power	1.2 MW
Diameter drilling	0.8 m
Depth wells	65 m
Length filters	36 – 40 m
Thickness aquifer	30 – 40 m
Number of cold wells	1
Number of warm wells	1
Distance cold – warm well	100 m
Undisturbed groundwater temperature	11.7°C
Injection temperature warm well	18°C
Injection temperature cold well	8°C

The data logging system

A central BMS is installed, to fully control the operation of all devices of the system and also to provide system monitoring. A full analysis of the ATES system is made by retrieving data on all energy flows (and temperatures), electricity consumption for all auxiliary equipment (boilers, refrigerators, pumps,…), etc. All measurements are stored on a half hourly basis on a computer. For temperature measurements immediate values were stored. Due to some technical problems and data logging incomparability the logging is started at 01/12/2002 (2 years after commissioning). The results presented in this paper cover the period 01/12/2002 - 30/11/2005. The installation and integration of such a groundwater system in combination with a traditional HVAC system isn't self-evident. This was proved with the installation of the first ATES systems where some problems occurred on the integration aspects. A good cooperation between drillers, building/HVAC designers and contractors is absolutely necessary with a clear demarcation of the responsibilities.

RESULTS

Ground water flow and temperatures

During the monitoring period more than 534,000 m^3 groundwater was moved from cold to the warm well and 515,000 m^3 groundwater in the opposite direction. Figure 2 shows the outside air temperature compared to the groundwater flow of the ATES system in the year 2005.

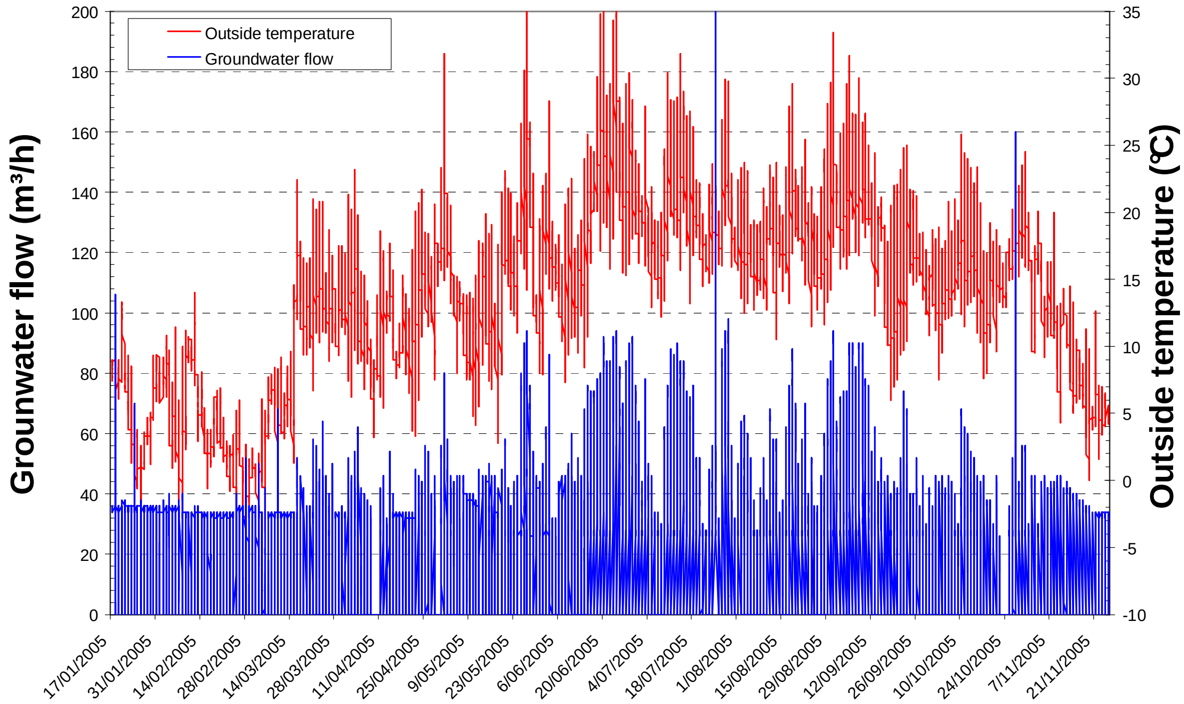

Figure 2. Groundwater flow versus outside temperature (year 2005)

It is observed that the groundwater flow from the ATES system follows the outside air temperature quite well. Due to the large amount of working hours during winter mode the flow is relatively low (35 m³/h) and constant ensuring that enough cold can be stored in the cold well for use in summer period. In the summer period the flow is increased towards the projected value of 100 m³/h. Fluctuations in flow are more likely in the summer period.

Figure 3 shows the groundwater temperature of the warm and cold well. As it can be seen, there is an increase in cold well temperature during summer period (7°C in June 2005 up to 10°C in September 2005). The ground water temperature at the end of the cooling season is still high enough and lower then the natural groundwater temperature (~12°C). This means that there is still some potential for cooling the building and that the ATES system is working properly. Somewhat same conclusions can be drawn for the winter period. Groundwater is extracted from the warm well at temperatures of 16°C and injected in the cold well at temperatures of 7°C. Figure 4 shows the heating and cooling power of the ATES system.

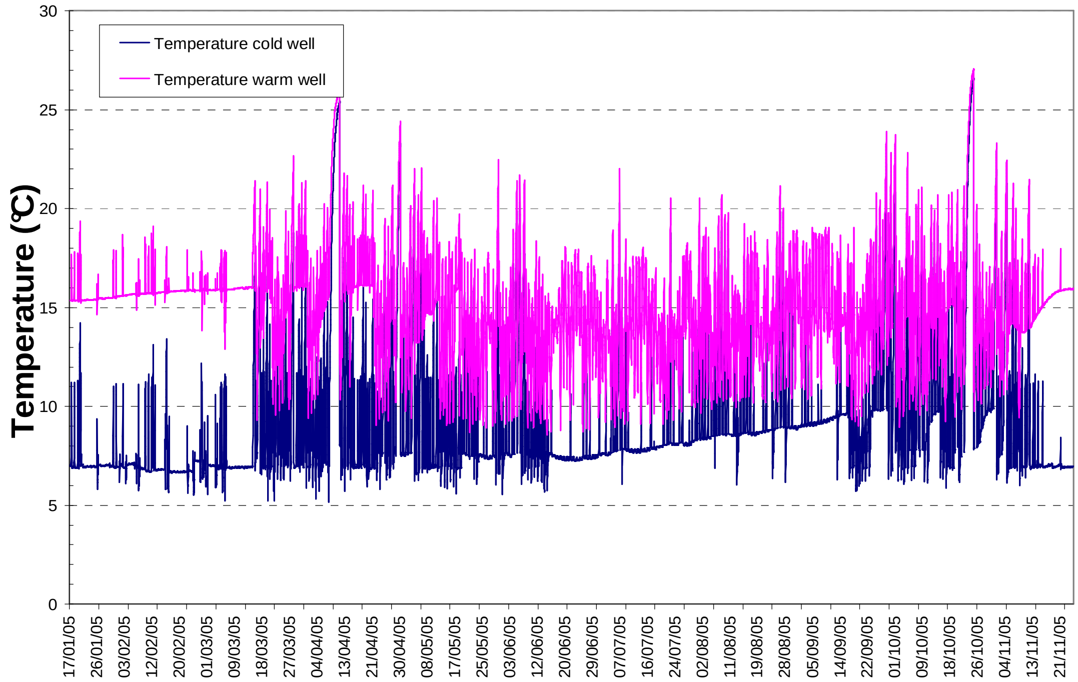

Figure 3. Temperatures groundwater in warm and cold well (year 2005)

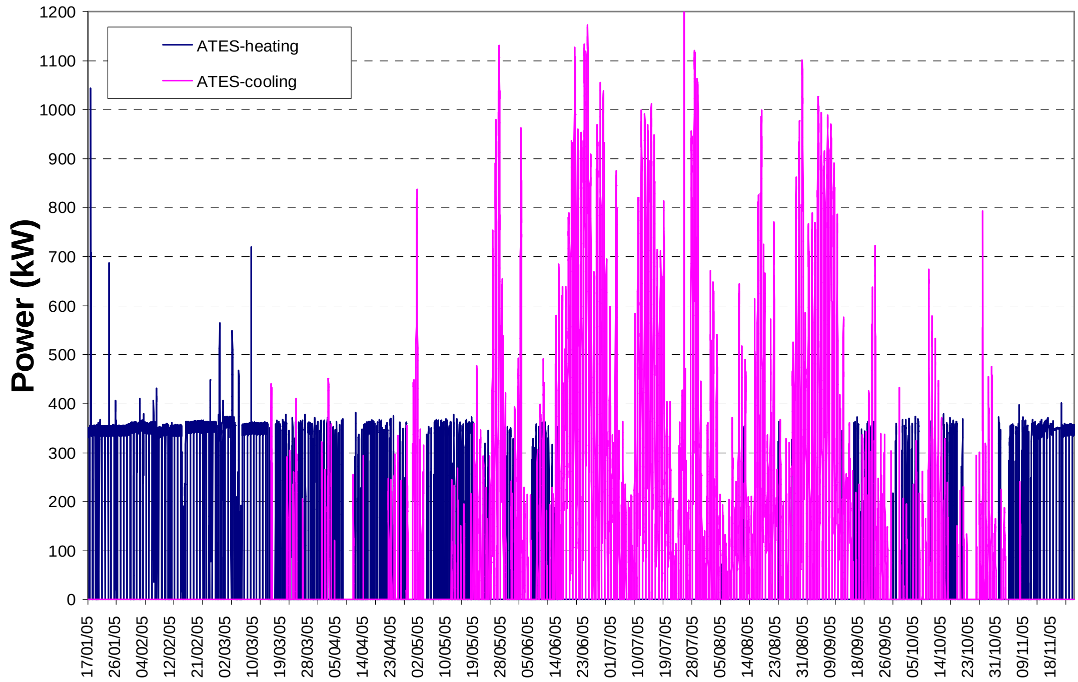

Figure 4. Heating and cooling supply by the ATES system (year 2005)

The ATES system provides a capacity between 100 kW and 1.2 MW. In the winter period there is a more constant but lower capacity supply with an average of 350 kW (provide heat to building or cold charge of cold well). The presence of a heat pump significantly helps in the cold charging process. The number of charging hours increases and is independent of the outside air temperature. Furthermore, the injection temperature is more constant and at an interesting low value. In the summer period the provided capacity varies much more and fluctuates in function of the intensity of overheating of the building.

Energy balance over 3 years of operation

Figure 5 gives a picture of the energy supply of the ATES system and the heat pump covering the entire monitoring period (three years). The largest part (74%) of the ATES cooling is applied directly for comfort cooling of the building (incl. surgery, pharmacy,…). The remaining 26% is used for refrigeration of the condenser of the heat pump during summer situation (operating as a cooling machine). This operation is necessary for supplying cold on low temperature (for dehumidification purposes).
Analogously the groundwater system provides heat, the proportion of direct heat supply to the building is rather limited (17%). Generally, the warm well will provide heat to the evaporator of the heat pump at heat demand. In this way, efficient heat supply is provided to the building and the cold well is charged.

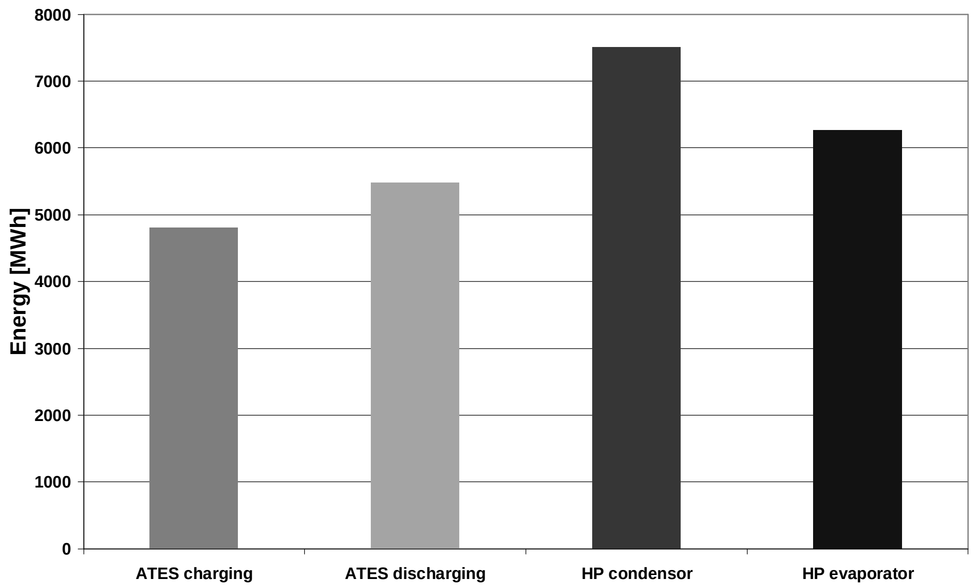

Figure 5. ATES energy amounts (2002 - 2005).

During winter period the heat pump is delivering heat at a $COP_{heating}$ of 6.1 for the first and 5.5 for the second heat pump. During summer period the heat pumps are operating as cooling machine at $COP_{cooling}$ of 5.4 and 4.9. These high figures indicate that the working conditions (temperature levels of condenser and evaporator) are most favorable mainly because the ATES system is designed at relatively high temperatures and the secondary system (the AHUs) at low temperature. The electricity consumption of the ATES system over the monitored period was 229 MWhe given a $COP_{cooling}$ of 45.

It's important to point out that the total heating demand of the building also involves a static heating system with classic radiators and a boiler as heat supplier. It's typical that the ratio static / ventilation heating is about one.

Primary energy savings and CO_2 reduction

In order to determine the primary energy savings, the ATES system is compared with a reference installation based on a water-cooled cooling machine and a gas-fired boiler for heating. Furthermore, the impact of the innovative installation on the CO_2 emissions over the monitoring period of 3 years is calculated and presented in Table 2.

For the primary energy savings and CO_2 emission reduction the following numerical assumptions were made:

- compression chiller efficiency $COP_{cooling}$ = 3.5;
- gas-fired seasonal thermal efficiency η_B = 85%;
- average electrical efficiency Belgian power plant = 44%;
- CO_2-emission factor electricity = 624 g/kWhe,
- CO_2-emission factor natural gas = 181 g/kWht.

Table 2. Primary energy savings and CO_2 emission reduction (2002 – 2005)

	ATES system + heat pumps (installation Klina)	**Gas-fired boilers + cooling machines (reference-installation)**
Electricity consumption	1,474 MWh_e	1,603 MWh_e
Gas consumption	0 MWh_t	9,235 MWh_t
Primary energy consumption	12,060 GJ	39,017 GJ
Reduction primary energy	**- 26,957 GJ**	**-**
CO_2-emissions	**920 ton**	**2,829 ton**
CO_2-reduction	**- 1,909 ton**	**-**
	- 67 %	**-**

The application of ATES reduced the CO_2-production with more than 1,909 ton over the past 3 years. The gas consumption for conditioning of the ventilation air is omitted entirely and is replaced by electricity consumption of the source and heat pumps. Because the heat pumps operate at a very high efficiency, the total electricity consumption remains under this of the reference installation. There is a total primary energy saving of 69% on the climatisation of the ventilation air with a CO_2-reduction of 67 % compared to the reference installation.

Economic analysis

Finally, the feasibility of each option has been assessed and presented in Table 3. Both the investment, maintenance and energy costs (electricity and natural gas) were calculated according to information obtained from the manufacturers and the owner of the hospital. The annual costs are the sum of total energy and maintenance costs. The maintenance costs are assumed to be a percentage of the investments costs.

Table 3. Economic analysis of the ATES system compared to the reference installation (2002 – 2005)

	ATES system + heat pumps (installation Klina)	**Gas-fired boilers + cooling machines (reference-installation)**
Annual costs per year	65 kEuro	100 kEuro
Investments costs	750 kEuro	300 kEuro
SPB ATES system (excluding subsidies)	8.5	-
SPB ATES system (including subsidies)	2	-

DISCUSSION

The HVAC-installation in the new Klina hospital in Brasschaat (Belgium) consists of 2 heat pumps combined with an ATES system (two wells). The system has accumulated 3 years of trouble free operation except the start up period after the commissioning of the installation.

Different parameters such as temperatures, energy flows, … are constantly monitored over this period and the results show that the ATES and heat pump system reaches equilibrium in terms of energy demands. This is also shown in the high COPs of the different components. The primary energy saving reaches 69% (1,900 ton CO_2 is saved) as compared with a reference installation composed of gas-fired boilers and cooling machines.

It's clear that well designed and installed ATES system provides heating and cooling with spectacular efficiency. As a general conclusion it can be stated that of all renewable energy systems (and ATES can be considered as one of them) this technology can present, under good applications, one of the best economical figures and can contributed to the well being indoor quality of hospitals.

ACKNOWLEDGEMENT

The authors are grateful to VEA for supporting this renewable technology and having the opportunity to monitor this ATES system and to gain experience from it. The introduction of ATES in Belgium has been made possible through the exchange of knowledge and experience with other countries through Belgium's participation in the IEA Implementing agreement ECES.

SUMMARY

A more efficient use of energy in the built environment is absolutely necessary. Using the exergy concept delivers more complete information on the use of the energy flows within buildings and opens up room for further improvements within the field. The aim of this study is to gain deeper insight into how the energy is being used in two already efficient building systems, namely a balanced ventilation system with heat recovery and a solar thermal system for space heating supply. Furthermore, desirable optimization chances for them will be pinpointed. The results of energy and exergy analyses of a first study on a typical building with both systems are compared. Annual dynamic simulations were carried out for the space heating case. Another major aim of the present study is to show the key differences between energy and exergy analyses of energy systems in buildings.

INTRODUCTION

Analyses of the exergy flows have been common for the optimization of many thermodynamic systems since the first half of the last century [1]. However, current analyses of the energy consumption in buildings are only based on the study of the energy balance, i.e. on the first law of thermodynamics. To date, the whole energy chain for the supply process is considered by the primary energy factors. Yet, neither the primary energy factors nor the study of the energy balances provide complete information on the use of the potential of the energy, i.e. on the energy quality (exergy) losses during the process [2].

From a thermodynamic point of view, exergy is the maximum theoretical work obtainable from the interaction of a system with its environment, until a state of equilibrium is reached between them [3]. The merit of exergy calculation is that we can explicitly and thoroughly show how different types of energy are used by calculating the flow of exergy and its consumption at different parts of a system [4].

Most of the energy consumed by the building sector is used to maintain constant room temperatures of around 20°C. Because of the low temperature level, the actual demand for exergy in space heating and cooling applications is low. In most cases, however, this demand is filled by high grade energy sources, such as fossil fuels or electricity [5]. Following big mismatching arises between the exergy levels of demand and supply and exergy that shall be used mainly for the production of high quality products is being used instead to meet low exergy demanding applications. Both solar thermal and ventilation systems with heat recovery are able to cover a part of the space heating demands of a building by making use of heat in the environment, i.e. with low exergy content. Thus, they both contribute to matching the exergy content in the demand and supply sides, allowing for a more efficient energy supply for heating in the building sector.

The aim of this study is to get a clearer picture on how energy is used in both systems, and to demonstrate which system leads to a more efficient use of energy within the built environment. Therefore, a first study for a typical building under heating conditions with each system has been carried out and the resulting energy and exergy flows are shown and compared. It is important to underline that the focus of this study is on the whole building facilities system and not on just the individual system components.

SYSTEM DESCRIPTION

The building model consists of a unique square zone (reference zone) whose thermal behaviour will be considered as representative of the whole energy performance of the building. The reference zone has been defined as a corner room with a south/west orientation of the external walls, located within the building at such a height that no influence from the ground and roof exists [6]. In each of the exterior walls, one window of $4.5m^2$ is taken into consideration. The internal heat loads have been set to a constant value year round of $5W/m^2$ [7]. Figure 1 shows a schematic drawing of the particular zone and in Table 1, the main constructive details for the base case are described. Table 2 provides a description of the cases under study.

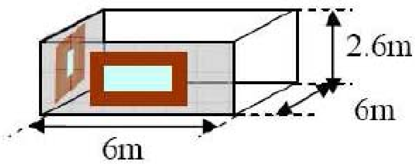

Figure 1. Reference zone for the building under study.

Table 1. Main characteristics of the base case.

Walls	External walls: U_{ew}=0.55 W/m^2K; Internal walls (adiabatic): light gypsum-air construction; Floor and ceiling: U_f= 0.41 W/m^2K
Windows	U_g= 2 W/m^2K; U_f= 1.5 W/m^2K (20% frame surface)
Infiltration rate	$n=0.6h^{-1}$
Heating system	LNG condensing boiler, η=0.95; Floor heating system (30/35)

METHODS

Energy and exergy flows were calculated for the space heating process in the cases stated. The energy/exergy analysis of the processes within the building and its installations for space heating was carried out according to the model developed by Schmidt [8]. This model divides all processes, from the primary energy conversion to the final heat transfer through the building envelope, into several blocks or subsystems. This modular approach aids in developing a better understanding of the processes involved in each subsystem and makes it easier to compare the results obtained for the building installations under analysis. For clearness, the energy required to meet the energy demand of the building is divided into thermal energy/exergy and auxiliary energy/exergy required to operate the different subsystems.

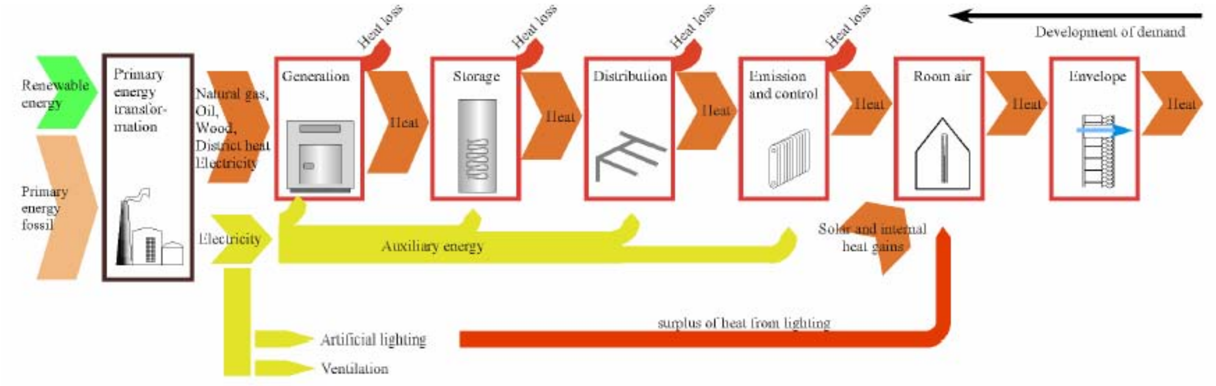

Figure 2. Subsystems and energy flows considered in the model for the energy and exergy analysis in the building. Source: [8]

Energy and Exergy Analysis

The annual energy flows for the heating cases investigated were simulated dynamically with variable time-steps. Primary energy factors for Liquefied Natural Gas (LNG) and electricity are *1.1* and *3.0* respectively, whereas their quality factors are *0.9* and *1.0* [8].

Exergy depends on both the states of the system and its environment, and thus changes on the state of the environment should also be accounted for in the calculation of the exergy flows. Investigations in non-steady state thermodynamics have shown that exergy values calculated with different reference temperatures can be added and compared [9]. The outside air can be regarded as a constant pressure system. Thus, only changes in the temperature of the environment must be taken into consideration. Outside ambient air temperature for the dynamic simulation of the energy flows was subsequently considered as the reference temperature. It is assumed that during each of the variable time steps defined for the energy analysis, no major changes occur in the main variables associated with the process (temperature, energy and entropy). In this way, the exergy associated to the processes can be calculated by applying the quasi-steady-state equations developed by Schmidt [8] to the results of each finite time step of the dynamic simulation of the energy flows and temperatures. In the equations developed in [8], the energy demand and losses of each subsystem were calculated through constant efficiency factors. Here, the energy demands of each subsystem are directly obtained from their dynamic analysis.

The building and the ventilation system were simulated in the same dynamic simulation environment. For the solar thermal system, a different simulation tool was used and the results delivered were introduced into the building model. No real coupling with actual feedback from one simulation tool into the other was done. The output of the solar thermal system is 15% lower when integrated in the building model and simulated in the building dynamic simulation tool. The difference in the solar heat output amounts to 3% of the overall space heating load of the building.

Efficiency Values

To enhance the understanding of the systems analyzed, efficiency values describing their performance were calculated in addition to the absolute energy and exergy flows throughout the subsystems. In many of the involved processes, not all the energy flowing out of the subsystem corresponds to a desired output of it (for instance the return from the floor heating system). Therefore, the rational efficiency as suggested by Cornelissen [10] is the parameter that best describes the actual efficiency of the systems studied here [10]. Rational efficiency is defined as the ratio of the desired output of a process to the useful input required. Equations

(1) and (2) represent the overall energy efficiencies for the generation and primary subsystems.

$$\eta_{overall,prim} = \frac{En_{envelope}}{En_{prim}} = \frac{\Phi_h \cdot}{\left(\Phi_{gen} + p_{aux}\right)}, \qquad (1)$$

$$\eta_{overall,gen} = \frac{En_{envelope}}{En_{gen}} = \frac{\Phi_h}{\left(\Phi_{gen} \cdot F_{p,f} + p_{aux} \cdot F_{p,f}\right)}, \qquad (2)$$

The definition of the overall exergy efficiencies for the generation and primary subsystems is:

$$\psi_{overall,prim} = \frac{Ex_{envelope}}{Ex_{prim}} = \frac{\Phi_h \cdot \left(1 - \frac{T_0}{T_i}\right)}{\left(\Phi_{gen} \cdot F_{q,f} \cdot F_{p,f} + p_{aux} \cdot F_{q,f} \cdot F_{p,f}\right)}, \qquad (3)$$

$$\psi_{overall,gen} = \frac{Ex_{envelope}}{Ex_{gen}} = \frac{\Phi_h \cdot \left(1 - \frac{T_0}{T_i}\right)}{\left(\Phi_{gen} \cdot F_{q,f} + p_{aux} \cdot F_{q,f}\right)}, \qquad (4)$$

The same notation as in [8] has been followed: Φ_{gen} is the energy demand of the generation subsystem, Φ_h stands for the energy demanded by the envelope to the active heating systems, T_i represents the indoor temperature, p_{aux} is the overall auxiliary energy required for the operation of the systems and $F_{q,f}$, $F_{p,f}$, $F_{q,e}$ and $F_{p,e}$ are the primary and quality factors for the fuel (LNG) and electricity respectively.

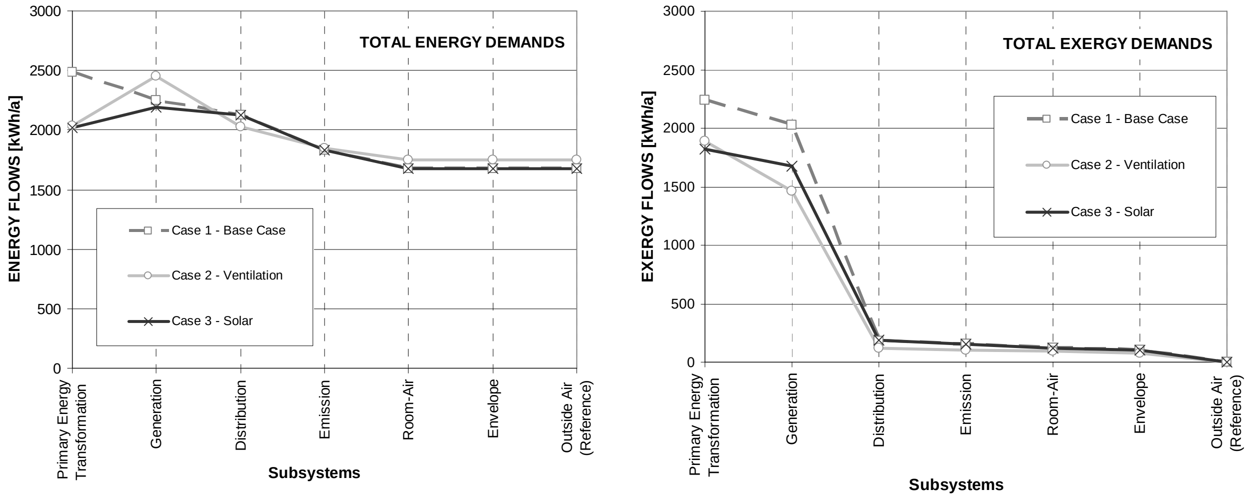
These overall efficiencies represent the degree of matching between the energy and exergy levels of the supply and demand sides.

RESULTS

Figure 3 shows the annual energy (left) and exergy flows (right) through the subsystems for the three cases described under heating conditions. From left to right, energy/exergy is fed into each subsystem, exits it and enters the following one. Because of losses and system immanent irreversibilities and inefficiencies in the heat and mass transfer processes in the components, energy, as well as exergy, dissipates into the environment in each of the subsystems [9].

The energy demand considered in the envelope subsystem does not represent the total losses through the building envelope, but just the part of those losses that has to be provided by the active heating system. The rest of the total losses are covered by solar and internal heat gains in the building. In the primary energy transformation subsystem only fossil fuels are accounted for, i.e. the electricity required for the operation of the ventilation and solar thermal systems as well as fuel and auxiliary energy input required by the boiler. In turn, in the generation system, the energy from the exhaust air which is used by the ventilation system to pre-heat the supply air, and the energy being effectively transferred by the solar buffer tank to the boiler are respectively taken into consideration. This is the reason for the greater energy outputs than inputs that can be seen in the primary energy subsystem in cases 2 and 3.

Despite the relatively high energy demands of the building envelope (around *1700 kWh/a* for all cases), its exergy demands are very low (around *90kWh/a* for all cases) due to the low temperature level required for space heating (*20°C*). When the energy provided by the active heating systems to the indoor air reaches the outdoor ambient its exergy content equals zero since its temperature equals that of the reference state, and the energy flow, no matter how big, has no further potential of performing work.



a) b)

Figure 3. Energy (a) and exergy (b) flows through the subsystems in all cases studied (see Table 2).

The rather horizontal shape of the energy flows in Figure 3 indicates that from an energy point of view, i.e. first law analysis, the systems already seem to be quite efficient. Both the balanced ventilation system with heat recovery and the solar thermal system allow a quite similar reduction of the primary energy that has to be fed into the building for the regarded cases. Overall primary energy efficiency of the building, according to equation (1), subsequently increases: from *67.40%* in case 1 to *85.82%* and *83.05%* in cases 2 and 3 respectively.

The shape of the exergy flows shows quite a different picture: high exergy losses occur in the generation and primary energy subsystems. The overall primary exergy efficiencies amount to only *4.48%, 4.23%* and *5.53%* compared to energy efficiencies of about *80%,* clearly showing that great room for further improvements in the systems still exists. This optimization requirement can be best recognized on the basis of exergy analysis.

The slightly lower efficiency for case 2 as compared to case 1 is due to the high input of electricity (and thus of exergy) required for the operation of the ventilation system and the high primary energy factor associated to electricity. Yet, the efficiency should not be the only parameter for estimating the desirability of one system against another but the absolute values of exergy demand and losses are also to be taken into account.

Both cases 2 and 3 show a reduction in the energy and exergy that has to be fed into the systems and thus represent desirable options compared to case 1. Since both cases 2 and 3 show a similar energy and exergy behaviour, it is worthwhile to take a closer look at them to show differences and optimization possibilities for both systems.

To get a deeper insight into the energy and exergy performance of both systems, their energy and exergy flows are first analyzed without regarding their influence on the overall performance of the building. Table 3 shows the exergy and energy inputs for the ventilation and solar thermal systems. It is to be noted that for the solar thermal system only the energy flowing out of the buffer tank, i.e. being finally transmitted to the boiler, is considered. No energy input or losses within the solar thermal system itself are regarded here. In turn, all existing energy inputs and outputs of the ventilation system have been considered.

The ventilation unit recovers a great amount of energy from the exhaust airflow. However, exhaust air has a temperature level of around *20°C*, and thus the exergy content of this energy flow is very low (see Table 3). To provide this low-quality energy to the building, a high input of electricity is required. In turn, the solar thermal system produces roughly half the thermal energy that the ventilation system makes available, but its exergy content is higher since the temperature of the water coming out of the buffer tank is between *76°C* and *20°C*.

Table 3. Energy and exergy flows through the solar thermal and balanced ventilation systems. "*Th*" stands for thermal energy from the gas boiler and solar system; "*El*" stands for electricity.

Subsystems	Solar thermal system				Ventilation system			
	Energy [kWh/a]		Exergy [kWh/a]		Energy [kWh/a]		Exergy [kWh/a]	
	Elec.	Th.	El.	Th	El	Th	El	Th
Prim. En. Transform.	11.53	-	11.53	-	489.13	-	489.13	-
Generation	3.84	375.43	3.84	39.04	163.04	885.11	163.04	30.84
Distribution	-	375.43	-	39.04	-	708.08	-	16.18
Envelope	-	-	-	-	-	708.08	-	16.18

Efficiencies calculated from the values in the grey cells on the table for each system show how efficient the conversion of fossil fuel input into thermal output coming from the environment is (be it exhaust air or solar radiation). For the ventilation system, these values are *4.34* and *0.099* for the energy and exergy efficiencies respectively, whereas for the solar thermal system they amount *97.76* and *10.16* respectively. These values are not influenced by the primary energy factors but just by the conversion processes taking place in each system. From these values, it can be concluded that for the case under investigation, a solar thermal system is advantageous compared to a ventilation system. The ventilation system could only be competitive if its electrical consumption would first be dramatically decreased.

In the following, the energy and exergy performance of the systems within the building, i.e. of cases 2 and 3, are analyzed and compared in detail. Figure 4 shows energy and exergy flows and losses through the subsystems in the building for cases 2 and 3.

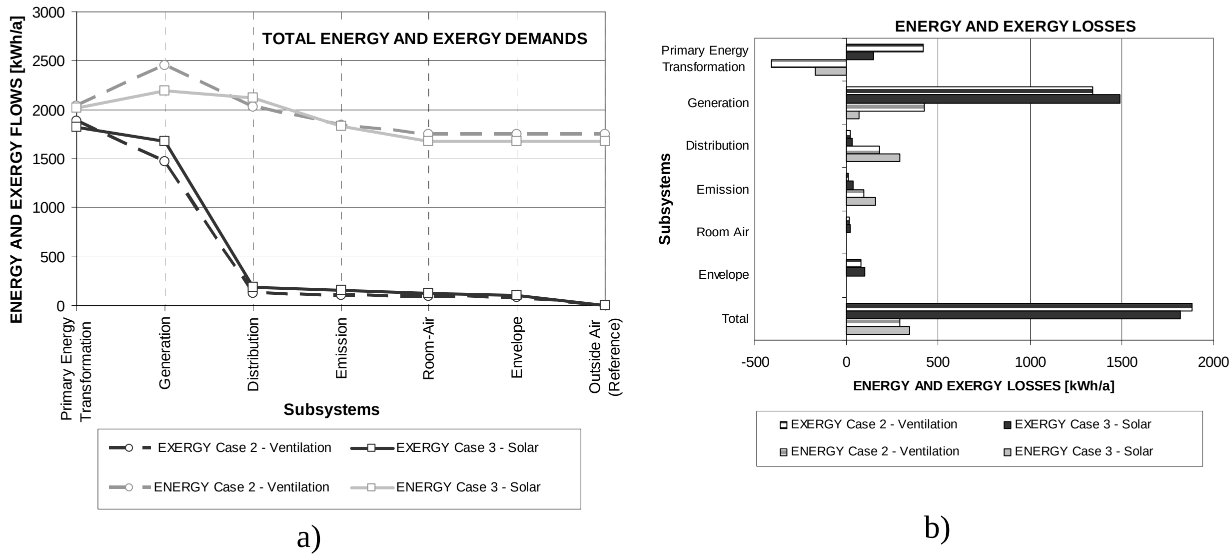


Figure 4. Comparison of the results for cases 2 and 3: a) Energy and exergy flows, b) Energy and exergy losses through each individual subsystem as well as total values.

As it can be seen from the values in Table 3 and in Figure 4, the ventilation system is responsible for reducing the exergy demand of the building envelope. This is due to the low exergy content of the energy it provides to the room-air subsystem, thus saving high quality exergy from LNG to meet that part of the demand. The solar thermal system feeds its output into the generation system, and from there on, its exergy level equals that provided to the distribution system by the boiler, thus making no further reduction of the exergy demand in the envelope possible.

The exergy demand of the generation subsystem is *12.9%* higher in case 3 than in case 2. This is due to the lower amount of energy that the solar thermal system provides (*375.43kWh/a*), as compared to that supplied by the ventilation system (*708.08kWh/a*). This energy is the output from the buffer tank of a solar thermal system whose collector field provides *1062.401kWh/a*. The exergy performance of the solar thermal system could thus be greatly improved if the final heat output for the solar thermal system was higher, i.e. if the energy losses were reduced in the different components within the solar thermal system.

Both systems take more energy from the environment than the primary energy they require, therefore energy losses in the primary system are negative (gains). Despite having smaller gains, exergy losses in that system are lower for case 3 than for case 2 due to the much lower input of electricity it requires (*2.3%* of that of case 2, considering primary energy input of electricity). Energy losses in the generation system are higher for case 2 due to the lower efficiency of the heat exchanger as compared to the boiler. However, exergy losses for case 2 are *l1.5%* lower since energy with very low exergy content gets lost. On the overall balance, exergy losses are *4.2%* lower for case 3, despite the energy balance being favourable for case 2. In Table 4, the overall efficiencies for the primary and generation subsystems, according to equations (1), (2), (3) and (4) are shown. The ventilation system with heat recovery improves both the energy and exergy performance of the building. However, the solar thermal system allows better matching of the exergy levels between the energy supplied and demanded both from a primary and end-exergy perspective.

Table 4. Overall energy and exergy efficiencies for the primary and generation subsystems.

	Case 1- Base Case		Case 2 - Ventilation		Case 3 - Solar	
	$\eta_{overall}$ [-]	$\Psi_{overall}$ [-]	$\eta_{overall}$ [-]	$\Psi_{overall}$ [-]	$\eta_{overall}$ [-]	$\Psi_{overall}$ [-]
Prim. En. Transform.	0.674	0.045	0.830	0.042	0.858	0.055
Generation	0.746	0.049	0.765	0.055	0.714	0.060

DISCUSSION

The ventilation system is very efficient from an energy point of view (*67%*), considering the output it provides to the distribution subsystem compared to the input required for its generation. In addition, it enables to make high amounts of energy with very low exergy content for space heating available, thus contributing to matching the exergy level of supply and demand. However, its high electricity requirements make the overall exergy performance of the system look unfavourable.

On the contrary, the solar thermal system shows a worse energy performance as compared to the ventilation system (*35%*), considering the energy from the collector field as input and the energy delivered by the buffer tank to the boiler as output. In spite of this, the electrical input required by the solar thermal system is 42 times lower, making the overall exergy balance favourable for the building with the solar thermal system.

The electrical demand required for the operation of the fans in the ventilation system has to be lowered. Further research in the development of low consumption fans, which could be called

"LowEx" fans, is absolutely necessary. On the other hand, further reductions in the currently high energy losses through the components of the solar thermal system are also a must to increase its exergy performance. Detailed exergy analysis of the processes in the solar thermal system would be greatly advantageous.

Due to the different nature of the energy inputs and outputs of the systems analyzed, the main differences among energy and exergy analysis have also been shown. Furthermore, exergy analysis has proven to be advantageous in recognizing sources of losses and optimization chances for increasing the performance and reducing the environmental impact of the systems.

FUTURE WORK

The results of a first study for comparing the two systems has been shown here. Further cases where the energy provided by the ventilation and solar thermal systems are equal or equivalent shall be studied, i.e. with bigger solar thermal systems. Furthermore, economic analysis and cost-effectiveness of both systems is to be carried out.

ACKNOWLEDGEMENT

The authors warmly thank the German Federal Ministry of Economy and Technology for their financial support and the ECBCS Annex 49 working group for the encouraging and motivating discussions on the topic.

SUMMARY

Object of the R&D activities of the last 2 years was the development of the new generation of a stationary low temperature PEM fuel cell system (operating temperature max. 80°C) with the following features

- 5 kW electrical power
- 10 T€ / kW electrical power
- robust continuous operation
- lifetime greater than 10.000 h
- system volume less than 1.000 dm³.

This new system is a pre-stage for a market suitable system. With some modifications it also allows an upgrade to a middle temperature system (operating temperature max. 120°C). The accomplished R&D activities are essentially based upon simulations, the development of several versions, experimental analysis in several test systems and a two years lasting field test. The system was integrated into the supply system (heat and electrical power) of a botanical garden. In summary of these activities we could build up a new prototype system which accomplishes all requirements mentioned above. We achieved research results, which allow us the development of a market-driven system suitable for low and middle temperature applications within the next 2 -3 years.

INTRODUCTION

Important international companies, which are developing and producing PEM fuel cell systems, changed their development focus from low temperature PEM fuel cells to high temperature fuel cells (operating temperature up to 200°C, e.g. Plug Power/ Vaillant).This new membrane technology is very CO tolerant and needs no water during operation. Due to these advantages it seems that a high temperature system will be much smaller and cheaper than a low or middle temperature system. But in the present project we demonstrate that proceedings in the R&D of low and middle temperature fuel cell systems have enough innovation potential to be competitive in certain applications. Main reasons therefore are small reformers with carbon monoxide content less than 10 ppm and the high power density of low temperature PEM fuel cells. An increasing of the lifetime and a significant cost reduction for low temperature membranes, the ongoing material and procedural change-over from low temperature membranes to middle temperature membranes are other reasons for it. At least new developments in the nano-technology create new chances for low and middle temperature membranes.

METHODS

We tried to combine theoretical methods and practical tests to get significant results within an acceptable time. One of the central issues is the degradation of the cell. It can be divided into a reversible and an irreversible degradation. Reversible degradation means a degradation of the cell voltage resulting of bad operating conditions (temperature, humidity, mass flow of reactants, pressure), inefficient or inhomogeneous fluid allocation and others. Irreversible degradation means a degradation of the cell voltage resulting of an alteration of the fuel cell components. This includes an alteration and loss of catalysts, carbon corrosion and a disintegration of the membrane caused by radicals. Together with a partner from the german university Hochschule Anhalt we developed a simulation system for low temperature PEM fuel cells. This is an universal mathematical 3 D model and allows the evaluation of physical conditions in a single cell.

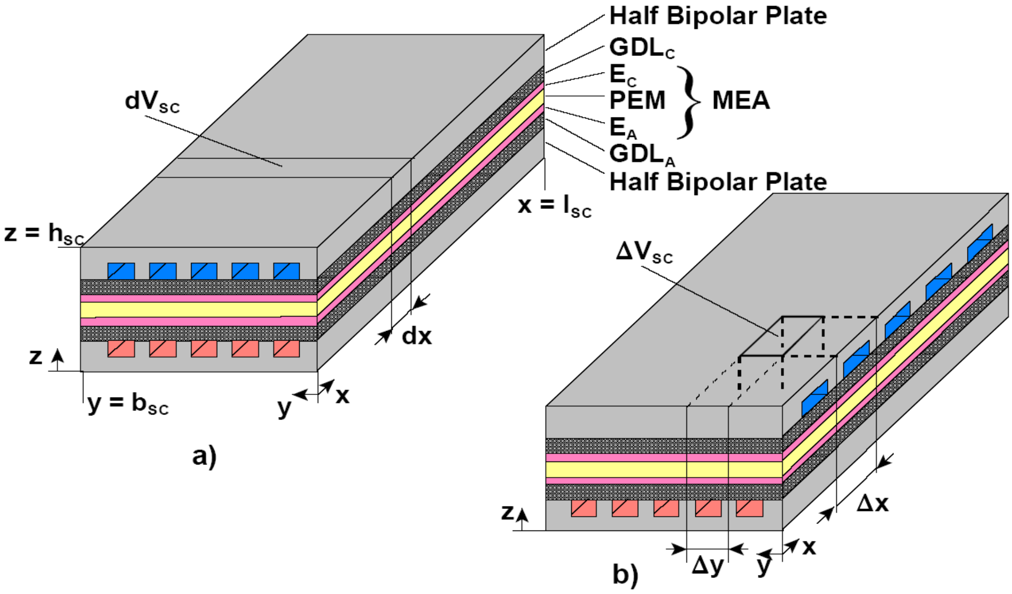

fig.1 illustration of the simulation elements in a cell [1]

The design of the cell and the bipolar plates will be deposited in the simulation. The deposited bipolar plate design will be divided into several simulation elements. One element includes one channel and a half land on each side of the channel. One simulation element includes all layers beginning with the cathode bipolar plate through the gas diffusion layer and the MEA to the anode bipolar plate. The number of modelling elements is selectable. The maximal solution for a single cell is 93 x 93 modelling elements. Each modelling element delivers 50 parameters, which can be analyzed to evaluate the cell.
Most important aim of the simulation was to create a very homogeneous allocation of the fluids, the temperature and the current density. To reach this we diversified the operating conditions (temperature, humidity, pressure, mass flow of reactants) and the structure of the bipolar plates. Another aim was to reach parameters which allow a reduction of costs.

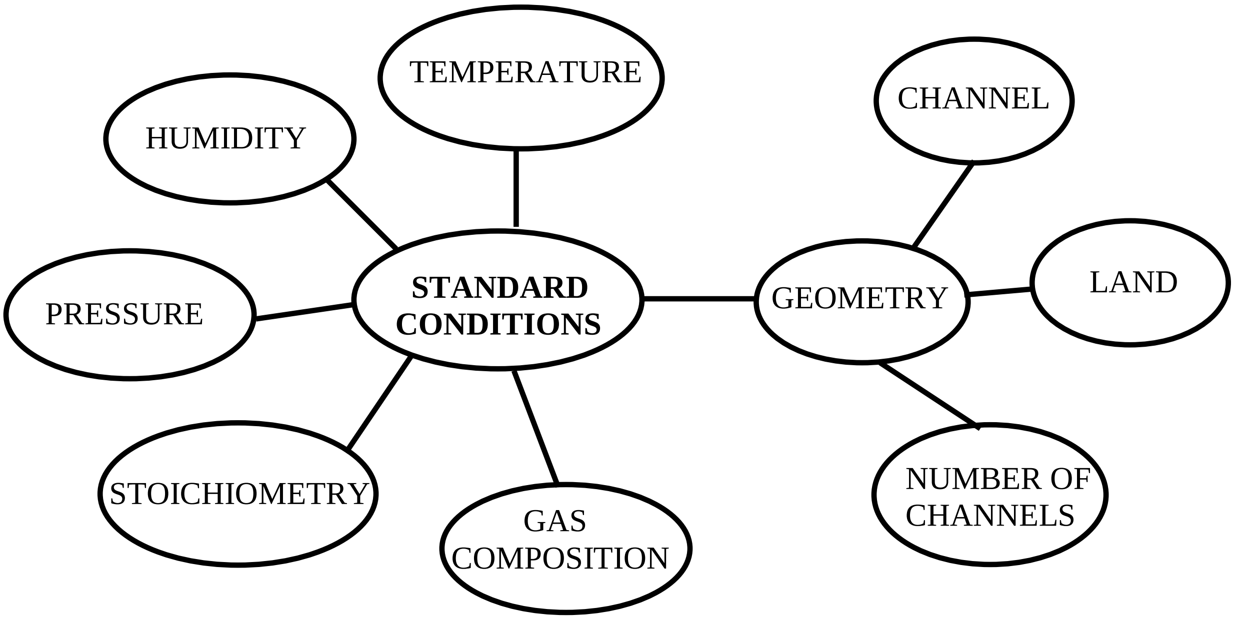

fig.2 variation of parameters for simulation

Another important parameter was the flow direction. All simulations were made with co flow of the fluids and counter flow of the fluids. After the simulation we obtained statements concerning the optimal operating conditions in connexion with the best bipolar plate structure. We could see as shown in fig. 3 the homogeneity of the current density and its changes by differing the operation conditions or flow direction of the fluids.

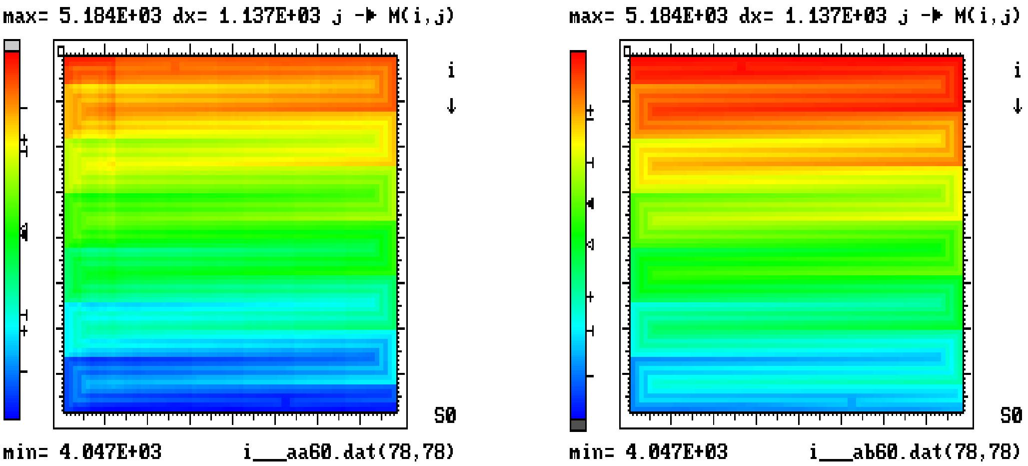

fig. 3 simulation result of one bipolar plate design with different operating conditions [2]

Due to the simulation conclusions we developed several designs for bipolar plates. At first we made some pre-tests. That means we evaluated physical parameters like contact pressures, materials and tolerances. But we also evaluated economical parameters like production costs now and later (mass production). Passing these tests the bipolar plates were integrated into short stacks (300 – 500 W). These stacks were operated several hundred hours. These test results where compared to the simulation results. We obtained a very good consistence between test and simulation. The best short stack/ bipolar plate design was chosen and operated for several thousand hours. The tests with the other designs were terminated.
We had to iterate this process to find the best operating conditions and the best bipolar plate design. After all these tests we adjusted the design of our existing stacks for field test systems. The test of larger stacks (4 kW) with this new design and operation conditions is still running in our field test systems inhouse4000.

fig.4 inhouse4000 system at the botanical garden of the city Chemnitz

Based on these new stacks and our experiences with our field tests systems we also had new conditions for the peripheral devices which required a modification or adjustment of the devices and the process. The air supply system has been reduced about 50% in size and power consumption. The humidification system was radically modified and does not need any auxiliary power. The new air supply system and the humidification system have been running since 10.000 hours in one of our field test systems. The reformat conditioning follows a complete new concept. It is a self regulating system without auxiliary power consumption. The fuel cell operating has been stabilized and its sensitivity against outside influences has been strongly reduced.
The reformer of the inhouse4000 system was revised last year, concerning efficiency, achievable gas quality and dimensions. Size and thermal mass of a reformer can be reduced by improved catalysts. Hence first of all a catalysts screening was carried out to take into account the advances of catalyst manufacturers.

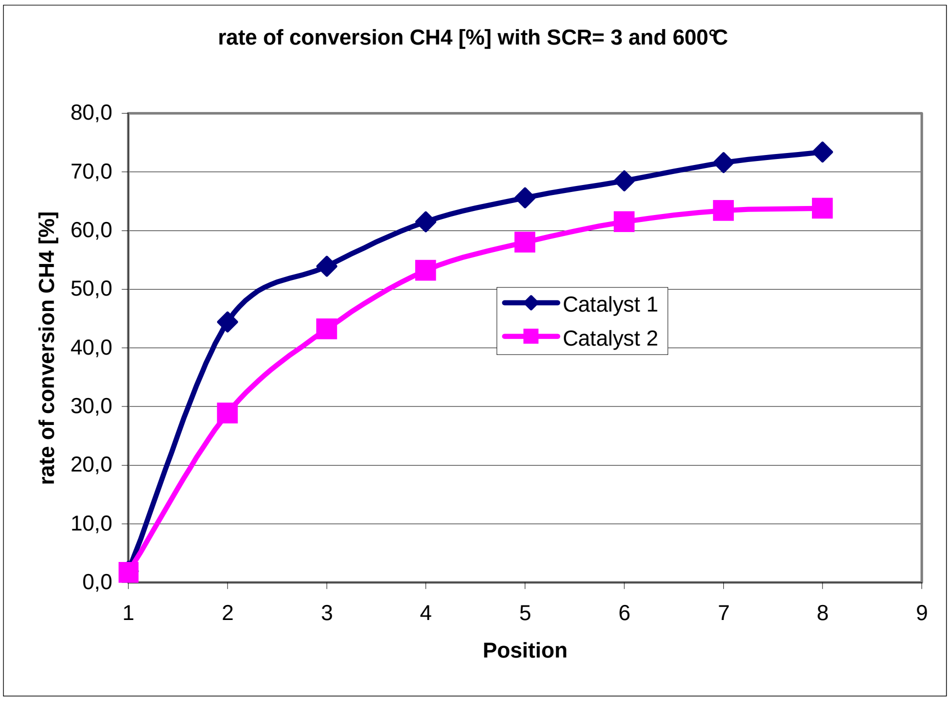

fig.5 results of catalyst screening/ CH_4 [4]

For the steam reforming process two catalysts could be identified, which enabled us to reduce the reforming temperature by 50 K. Furthermore catalyst mass and heat exchange surface could be reduced by 20%. For the new inhouse system this leads to a reformer with a performance enhanced by 25% and a simultaneous reduction in size by 20%. A similar result could be achieved within the gas-cleaning stages. The CO concentration of the reformat gas after the reformer could be reduced by 20%. The achievable gas quality is shown in fig.6

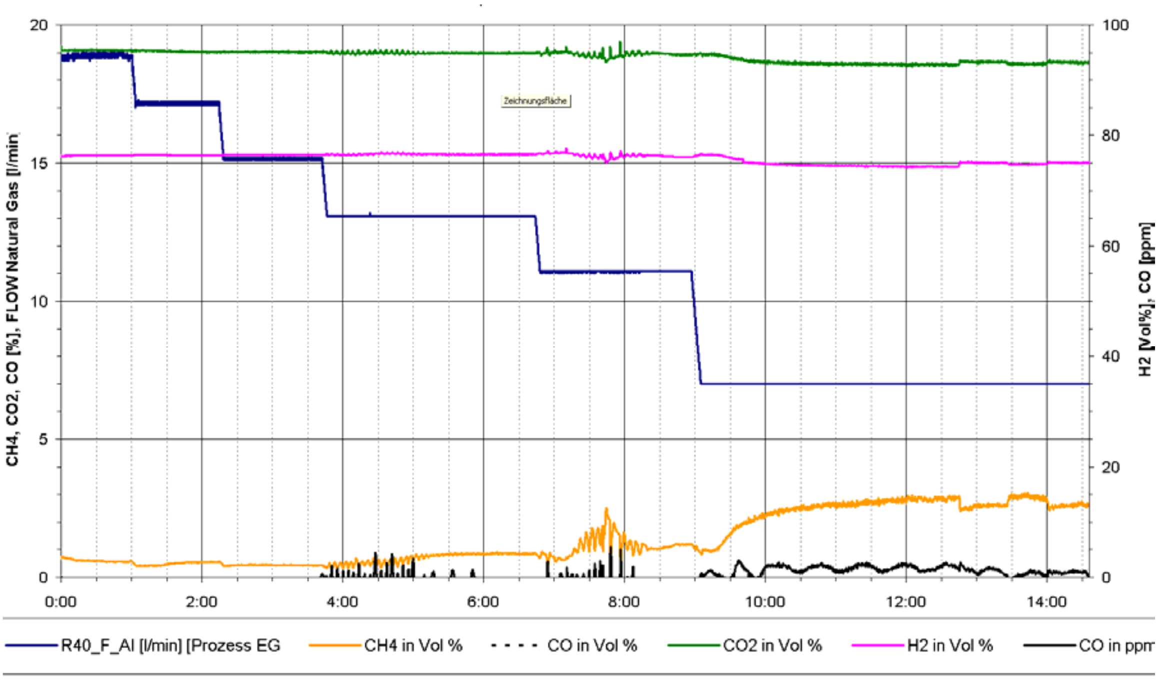

fig.6 gas quality steam reforming [4]

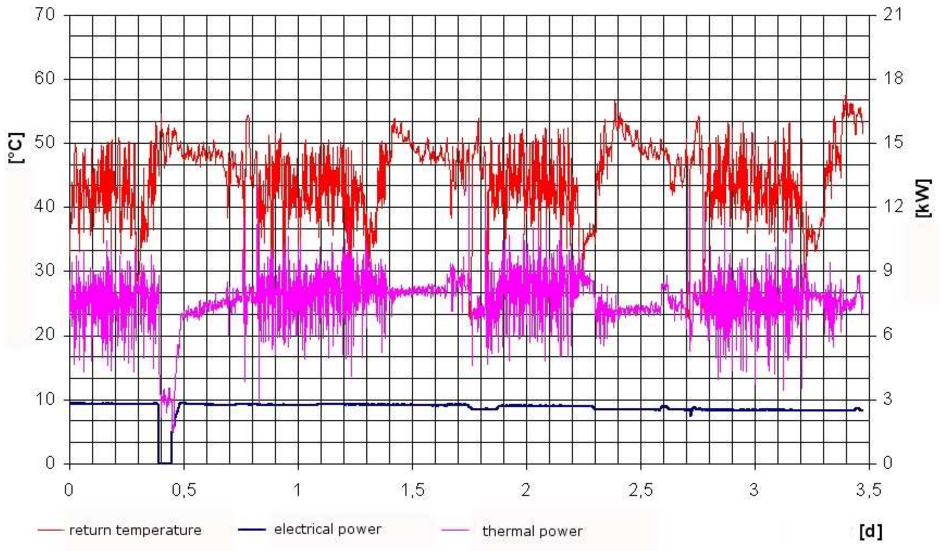
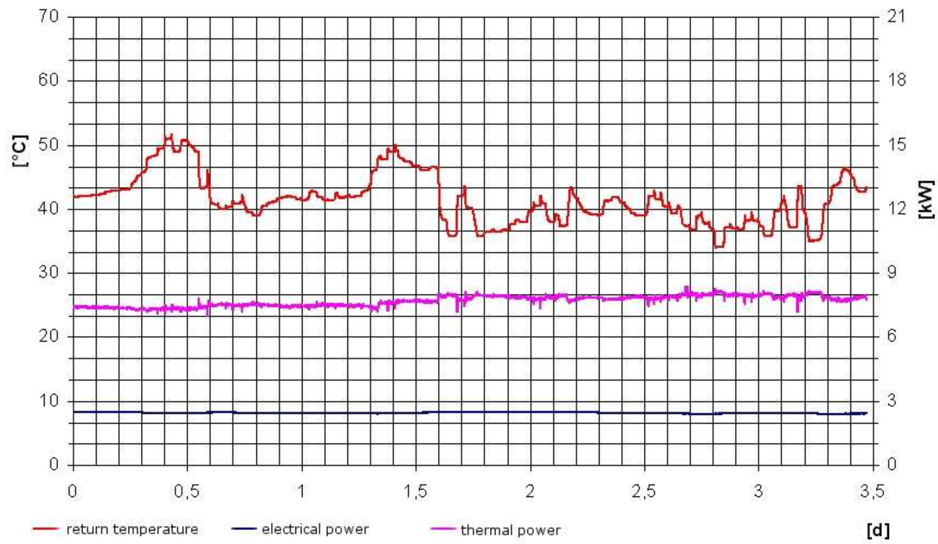
It can be shown that the gas quality and especially the CO concentration are stable during load changes. Another advantage could be gained by using catalytic active heat exchangers. An important aspect to improve the energy efficiency of the entire system was to reduce the heat losses to a minimum. Compared to the new, the old design showed a number of heat bridges, which were eliminated completely. Furthermore a new isolation, which features a heat transfer coefficient that is only 25% of the original value. Therefore the heat losses of the reformer and temperature inside the housing of the system could be reduced essentially. For example the temperature of the external wall of the reformer could be reduced from 90°C to 45°C. Durability and stability of the reformer through 10.000 h of operation under difficult conditions were already shown by the old design. Because of the modified catalyst the new reformer can also reform biogas. A first prototype is already built and is tested extensively at the moment. The first test shows that the reformer is applicable with biogas with CO_2 content from 25% to 55%.

A network of field test systems (inhouse4000 and older types) installed in our labs and at cooperation partners secures a lot of experiences and measure data. Due to the fact that these systems are operated under real application conditions we could eliminate a lot of construction failures and we learnt a lot about failures occurring under real applications. It is really necessary to adjust/ modify the existing conventional system. Mostly it is not possible to completely replace the existing system. It is economical useful to secure the minimum and middle load of the object. Both systems, fuel cell and normal heating system have to work together and should not influence each other. Fig. 7 shows some problems with an inhouse4000 system integrated in a conventional heating circuit. The heat production of the inhouse4000 system is very small comparing to the existing condensing boiler (2x250 kW).



a)



b)

fig. 7 problems heating circuit in inhouse4000 system [3]

Due to switching on and off of the condensing boilers, we had great temperature variations (fig. 7 a), which influenced several systems in the inhouse4000 system. The operation of the fuel cell was badly influenced. A small water storage tank helped to solve this problem (fig. 7 b). The temperatures did not change rapidly anymore.

Taking all experiences from field tests and our new developments we created a new generation of the inhouse system – the inhouse5000. This system is suitable for the energy production in

- multi family residences
- hotels
- wellness centres
- public buildings
- small and medium sized enterprises

The inhouse5000 system produces electrical and thermal power to deliver the minimum and medium load of the mentioned objects. The system is designed for a grid connected operation. It has a modular design and can be adjusted to the customer needs. Ongoing tests with biogas extend the range of applications. Cluster of inhouse systems can be installed on farms to use biogas and produce electrical power and heat for the farm.

RESULTS

With the new system inhouse5000 we solved a lot of problems. The reformer size was reduced by 20 % by increasing the reformer performance by 25 %. The energy consumption (natural gas) of the system was reduced by optimising the isolation of the reformer and reducing the anode stoichiometry. New catalyst screening helped us to reduce the carbon monoxide. The carbon monoxide part is less than 10 ppm. According to the new operating conditions of the stack and the reformer we optimised and adjusted our peripheral devices. The electrical energy consumption for peripheral devices was reduced by nearly 50 %. New materials and the optimised construction of reformer and fuel cell stack led to a significant increasing of the lifetime of stack, reformer and system. As already mentioned one inhouse4000 system is running for 10.000 hours and the test is going on. Surely we can not operate a fuel cell for such a long time. But currently we can operate a stack 4.000 – 5.000 hours in our inhouse4000 system. Saving of primary energy (natural gas) resulted in a reduction of carbon dioxide production. Comparing to conventional systems we produce with our fuel cell system approximately 75% of carbon dioxide. If we are using biogas we have a closed carbon dioxide cycle.

INTERPRETATION OF RESULTS

Sufficient innovation potentials have been revealed with the mentioned methods. Through intensive R&D it is possible to develop competitive products within the next 3 – 4 years. Inhouse5000 is the next step to a competitive product for the market. Already today we can demonstrate the potential of fuel cell systems.

basic principle	
fuel generation	natural gas steam reforming
fuel cell type	PEM fuel cell
nominal power	
electric	1 - 5 kW
thermal	2 - 10 kW
natural gas consumption	0,5 – 1,5 m³/h
temperature of heating circuit	50/ 70°C
cold start time	1 h
load change (30-100%)	15 min
current efficiency	25 – 30 %
total efficiency	60 – 90 %
dimensions(WxHxD)	700x1400x1000 mm³

SUMMARY

This paper gives an overview of selected Micro CHP technologies and products with the focus on Stirling and steam machines. First results of field tests in Germany, the United Kingdom and some other EC countries are presented and commented in the paper. The first field test results available to the date show that along with the overall positive performance there are some differences in sector performance (domestic vs small business). Some negative experiences have been gained, especially regarding the results of field tests with the Stirling engines and the free-piston steam machines and there are still obstacles for market implementation. Further projects and field tests with several kinds of micro-CHP are starting in different countries. If the positive experiences will prevail and deficiencies of the technologies or the operation can be eliminated, a comprehensive serial production and full market implementation can be started in the near future

INTRODUCTION

Decentralized power generation combined with heat supply is an important technology for improving energy efficiency, security of energy supply and reduction of CO_2 emissions. Micro-CHPs are especially interesting for such market sectors as single family houses, smaller multifamily houses and business enterprises due to their technical and performance features:

- A high overall energy conversion efficiency (e.g. in excess of 90 % for Stirling engines)
- Low maintenance requirements equivalent to a domestic gas boiler.
- Very low noise and vibration levels for installation in the home.
- Very low emissions of NOx, COx, SOx and particulates.

According to latest predictions, early adoption of domestic combined heat and power (CHP) by utilities and manufacturers could easily lead to sales and service contracts worth over £1.5bn per annum (aprox. €2.2bn) across Europe by 2010.

The objective of the study is an overview of selected micro-CHP technologies and products with the focus on Stirling and steam machines, an estimation of market potential and an overview and short assessment of first results of field tests in Germany, the United Kingdom and some other EC countries.

METHODS

The paper benefits in particular from the German experience in Stirling machines and field tests of a special Stirling engine (power range 2 – 9.5 kWel) of a German manufacturer, field tests of a Stirling engine (about 1 kWel) of a manufacturer from New Zealand in France and the Netherlands and UK field tests of a number of CHPs. Market studies [1] and the description of experiences with field tests in Germany [2] and UK [3] were evaluated to get comprehensive information for this study.

The market study focused on producers and conversion techniques with a high development status. These products are close to market introduction and either undergo CE-certification procedures (currently) or are already mature products. Background of this classification is the precondition of a timely entrance to the market with the analysed products.

Another determination of conversion techniques was made out of this classification: Stirling engine, hot air engine and combustion engine. The present study excluded fuel cells and micro-gas-turbines because of their low development status and their unfavourable and inefficient application in the small-scale housing and the trading sector.

RESULTS

Applications of micro-CHPs in Germany, the UK, France and the Netherlands have shown different results.

German market study

In the framework of the market study [1], 15 relevant products concerning micro-cogeneration were identified and analyzed. For further research on feasibility and application of micro-cogeneration the following objects were chosen:

1. Lion Powerblock (free-piston steam engine)
2. WhisperGen MicroCHP (Stirling engine),
3. Microgen M-CHP (Stirling engine)
4. Ecowill (combustion engine),
5. Dachs (combustion engine),
6. Ecopower Mini-CHP (combustion engine)

The profitability of the chosen products was analysed considering a cost benefit calculation of the product application in single consumption states and different buildings in Germany.

The results of evaluation of the products application were in most of the examples negative, a larger number of the case studies were analysed as economically inefficient. The energy costs of the different products varied in a range from 38.0 to 9.8 ct/kWh.

In the case of the Stirling-engines WhisperGen micro-CHP and Microgen micro-CHP savings of 10 % of the energy costs can be generated by using it in existing one-family-houses. Because of the less heat consumption (50 %) in new build one-family-houses the feasibility of micro-cogeneration is much lower than in older buildings. Concerning new-build one-family-houses the Stirling is therefore at its feasibility limit. The free-piston-steam-engine (e.g. Lion Powerblock) is the least cost efficient with an energy price of 0.38 €/kWh, which derogates the yearly energy costs.

As the different examples indicate a general statement on the feasibility cannot be given. It can be noticed that the feasibility is dependent on the operational mode and engine application according to the demand structure. Single task oriented products have a better feasibility, as modules designed with an additional “back-up” like a boiler or a gas-fired thermae.

German field tests with Stirling engines

A manufacturing company in Sindelfingen has already started its series-production of a gas-fired Sterling engine (Stirling 161) in 2004. In the meantime over 120 production-models of the Stirling 161 were sold.

Berlin

One of the Stirling 161 engines was made available for a test-run by the Berlin gas utility. In a state public institution building, the Kreuzberg fire station in the district Friedrichshain-Kreuzberg of Berlin, it is used to power the first Stirling CHP unit of this utility.

In association with a large owner of gas distribution systems (VNG) the company is going to check road capability and client acceptance in a three years test-run (since November 2005). According to the utility company, the first engines from the series-production run well – however not without smaller problems.

The VNG evaluated that the electrical power is underachieved, as well as a frequent fault liability which leads to higher costs in maintenance. Nevertheless the VNG gives a positive feed-back, as the Stirling is a very energy- and resource efficient way to convert energy. The future potential of the Stirling lies also in the advanced R&E, in comparison to fuel cells.

In the case of the fire station in Berlin Kreuzberg, the Stirling 161 (2 to 9 kWel; 8 to 26 kWth) was integrated in the existing building-service-engineering. The Stirling engine is parallel spliced with the central heating boiler, in such a way as to take the boiler offline in case of a non heat-requirement. The whole Stirling cogeneration unit can be taken offline with the help of an automatic balanced disc stopped valve. Because of the constant demand of energy and power (heat) this fire station is perfectly suitable for the test run.

According to performance data, the Stirling 161 can be operated full-load about 5,800 hours and part-load about 7,800 hours. The feed temperature (68 °C) in the heating circulation can be judged as less efficient which derogates the electric power. According to the producer a maximum feed temperature of 65 °C should not be exceeded.

Only after the transition to series-production in 2004 several problems with material occurred. After the appraisal of the company Solo this could be the reason for the defect of the connection rod of the aggregate at the Kreuzberg fire station. In the meantime a new method was developed for precise measurement and documentation of tolerances. There was also a change in the subcontractor/deliverance so that the piston rod is available with the requested quality and will be refitted.

Fürth

Another test run of Solo series-production Stirling 161 engines has been proceeding in Fürth. As in Berlin the test run is integrated in a measurement engineering process. In cooperation with the energy agency EAM and a district heating company in Fürth a district heating station was chosen, which is supplying heating power for a residential area (79 buildings).

Because of the combination of the district-heating-station (max. 4.5 MWh) and the Stirling-cogeneration-unit, different operations and charge states can be measured in various test-series, without having an impact on the supply of the client, as explains the EAM. Solo Stirling is said to achieve a degree of efficiency of over 90 % and its optimum in part-load.

Because of the high feed temperature from the district heating station the pre-conditions can be considered as suboptimal. Nevertheless the forecasted degree of efficiency could have been complied since the beginning of the test run. EAMs appraisal is positive saying that fundamental problems do not exist but the testing of a larger number of Stirling engines is regarded to be useful.

Otherwise an EAM project manager has some doubts regarding Stirling 161, questioning if the malfunctions like the defect of the connection rod were system immanent or only an outlier. However Solo maintains that the major part of the 120 Stirling hot-air-engines runs without any problems.

Ditzingen-Hirschlanden

An ESCO (part of a large French utility company) reports only sufficient results using the Stirling 161. In the Swabian town of Hirschlanden a Stirling CHP unit integrated in a district-heating-station is supplying 100 one-family-houses, a home for old people and a nursing home with energy (heat). The Stirling-cogeneration-unit is predominantly used to satisfy the demand of the boiler house.

The correlation between the high feed temperature and the derogation of electric efficiency has occurred also in this test-run. At a feed temperature of 60°C an electric power of 6.5 kWel is measured in Ditzingen-Hirschlanden. The absolute degree of efficiency amounts up to 79%. Because of the external combustion the interior of the Stirling engine remains free of residues. The pollutant emissions are much lower than the emission of other engine-concepts.

The ESCO specified the following disadvantages: the little operation experiences, the lack of a mass production and the still relatively high specific investment costs. The technical potentials are still not taped fully. The service and support could be optimized. But if the positive experiences will proceed, further projects with the Stirling unit will start.

Others

In June 2006, the Berlin gas utility started the second two year test-run in a one-family-house, where a gas-operated Stirling-cogeneration-unit WhisperGen micro-CHP of a New Zealand manufacturer (1 kWel; 7.5 kWth) was installed.

The same cogeneration-unit was chosen by another German utility company in Mannheim, in October 2006 over 20 households started with voluntarily participation in a test-run.

UK market study

The UK market for micro-CHP is assessed to be about 400,000 households [3] within ca 1 million households and SMEs which displace boilers per annum [5].

Unlike mini-CHP (which is regarded as a mature technology and have been applied for quite a long time), micro-CHP technology is not yet available commercially and there are rather few data about its performance in the UK.

Mini systems used in industrial and commercial applications show advantages of their performance for quite a long time. On the other hand, the direct projection of mini-CHP experience to micro-CHP level turns counterproductive due to extra complexity at the micro level and lesser tried technologies (for example fuel cell technology) which still needs to get mature.

Overall CHP are intrinsically more efficient in comparison with other generating facilities and the grid with its 30-40% efficiency [6]. Potentially micro-CHP can have the competitive edge over condensing boilers, but still considerable work has to be done to implement this into real economic and environmental benefits.

The latest research shows that micro-CHP have to improve their performance to become widely accepted in the market. Since the potential market is quite large in terms of units, there are good incentives for improvements.

By 2006, not much progress was made in micro-CHP penetration into the market. There are still very few micro-systems available, the public, architects and civil engineering community en mass are not much familiar with the technology.

Another factor of a rather poor micro-CHP market penetration was a successful campaign to promote energy-saving condensing boilers.

This said, the British government announced in 2001 that CHP was one of important ways to implement the Kyoto commitments. The UK target for installations set for the end of the year 2000 was 5,000 MWe. For year 2010 the target is rather vague, further of 12,000 to 19,000 MWe [5].

UK Carbon Trust field tests

Carbon Trust launched a trial in 2003 aimed to carry out a comprehensive analysis of the current situation and development of recommendations to overcome the barriers that impede the implementation of this energy saving technology. The trial is expected to finish by mid or late 2007 when full results will have been published. Until now only preliminary data are available.

The technologies included in the assessment were Stirling Engines, Organic Rankin Cycle Machines, Fuel Cells and Internal Combustion (IC) Engines. In total about 40 units (of those 31 micro-CHP, mostly in homes) have been assessed.

The performance indicators recorded were: overall thermodynamic efficiency, the amount of electricity generated the carbon intensity of the electricity displaced from the grid.

One very prominent result of this trial is that the first two performance indicators differ very significantly for micro- and small CHPs.

The micro-CHP units assessed show very different performance characteristics in different environments. The carbon footprint and savings being important characteristics, the capital costs needed to be evaluated as well. However, at this stage, the units are not manufactured at the scale sufficient enough to a give a final conclusion on the units capital costs.

The preliminary results of the Carbon Trust trial indicate that the performance of micro-CHPs was not that impressive as expected. Some of the reasons are:

- The units were actual efficiencies is lower than assumed by existing models.
- The amount of electricity generated is much lower than the forecast.

The reasons for the poorer than expected efficiency appear to be related to the design and operation of the units at their current stage of development. The thermal inertia of the micro-CHP units seems to be still too high compared with the conventional boilers when the units are exposed to real-life intermittent demand for heat in buildings.

In many houses the demand is to a large degree intermittent and the heat is required only for short periods but many times a day. In such circumstances the repeated warm-ups cause waste of energy which is not re-released in a useful way, hence reduced efficiency. This conclusion opens up a vast scope for improvements focused on reduction of thermal inertia and/or number of cycles.

Another factor contributing to over-estimation of micro-CHP performance is the assumption of constant average electricity demand. However the trial has proved that for the most of the time demand is much lower than average and also lower than typical micro-CHP output.

This is also combined with short periods of very high demand (when some appliances are running, e.g. kettles, electric showers, etc). So far significance of peaks and troughs has been neglected by the designers. Along with new design of low voltage networks which could cope with high levels of export, in addition to full load import when the units are not running, the micro-CHP industry needs to design units with the ability to modulate electrical output much more widely than currently.

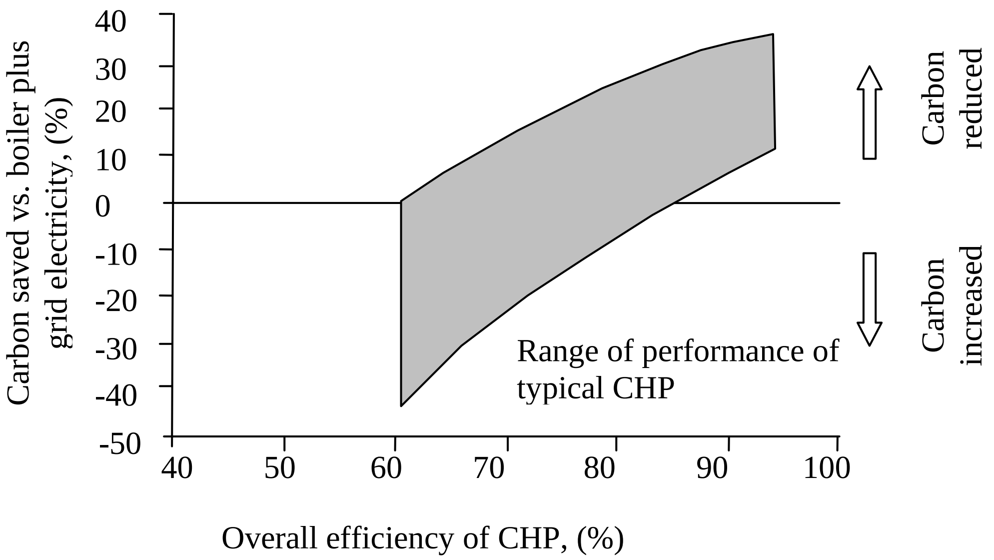

Figure 1. Performance envelope of real CHP [3]

Summarising the preliminary test evaluation of micro-CHP performance (Fig.1), the Carbon Trust [3] indicates that at the current stage of technology, these units will have limited contribution to CO_2 reductions and considerable improvements in technology are required.

Field tests with Stirling engines in France and the Netherlands

Funded by DG TREN the project DEO [4] was launched to compile a comparative study on innovative technologies of power generation in buildings, analysing pilot projects in the years 2001-2003. Partners of the DEO project were several European gas supply companies. The study was focused on the application of innovative gas technologies such as micro-CHP, gas heat pumps, gas fired household appliances and combination systems e.g. with solar heat.

One-family houses or apartments were taken as demonstration objects in the DEO-project. In those houses/apartments the operation was measured and controlled during the period of a year. For the later comparison and calculation of the energy saving potentials, other objects without the installation of the innovative technology were taken into consideration. In the frame of this study micro-CHP units were installed by leading gas supply companies in France and in the Netherlands.

A Whisper-Gen module powered a test run apartment in France and a one-family-house in the Netherlands. In the Dutch test run, the micro-cogeneration unit was supported by actions and applications of other innovative (energy saving) technology, as gas-heat-pumps, gas fired household appliance and electronic thermostatic-valves etc.

The French demonstration-run of micro-cogeneration achieved good, satisfying results. During the test-run there appeared no operational malfunctions. The specific performance of the heat supply was achieved as announced by the producer. The electricity performance was close to the predictions.

A degree 82 % of the efficiency of the installation unit (75% thermal and 7 % electric) was achieved during operation. During the monitored and controlled test-run 55 % of the power demand was satisfied by the micro-cogeneration generation. The average annual electrical power was 0.2 kW. At the test-run-object savings of 13 % of primary energy and 7 % of end use energy were achieved in comparison to a reference building.

The performance of the micro-cogeneration unit of the Dutch test run example was in contrast disappointing. Several problems in the line-operation as well as problems with the start/stop mode operation and noise emissions were observed. During the test-run period the total operation time was limited.

Overall only 278 kWh were generated by the micro-CHP unit which equals only 6 % of the energy demand. Only because of the combination of actions and applications, as per statement above, savings of 13 % primary energy and 12 % end use energy were achieved.

DISCUSION

For certain consumers, micro-cogeneration is already a comprehensive solution for energy supply, according to the present market study [1]. For broad market introduction further research and technology innovation is still necessary. It includes stimulation on the part of energy supply companies as well. As shown for Berlin test study, the potential of demand side (potential customer) for a market introduction of micro-cogeneration units exists and the customers attitude is in principle positive. Nevertheless the further establishment in terms of a market introduction of micro-CHP has to be supported actively e.g. with the help of energy supply companies research institutes, producers, networks and producers cooperation. This need of further stimulation is one of the results of field-tests [2] and [3].

The authors of the paper came to the following conclusions.

A comprehensive serial production and full market implementation can only start in the near future if more comprehensive and long time tests proceed and more positive experiences of micro-CHP are reached. The deficiencies in the technologies and operation found have to be overwhelmingly eliminated before wide implementation could be approached.

ACKNOWLEDGEMENT

The support from an EC DG TREN project “Network for promotion of Eco-building technologies, small Polygeneration, and renewable heating and cooling technologies for buildings- ProEcoPolyNet”, (PEP-Net) Contract No. TREN/05/FP6EN/S07.54455/020114 has been gratefully acknowledged.

Corresponding email: j.klemes@manchester.ac.uk

SUMMARY

This paper presents an established sustainable and integrated design methodology for the efficient heating and cooling of individual buildings and complexes. The methodology includes the design basis for combined heat and power systems, refrigeration, air conditioning and heating with pump systems. It is equally applicable for single family houses as well as large building complexes and meets a major challenge in the design of heating and cooling systems, namely, the complexity of energy and power integration. The efficient use of available heating and cooling resources for serving buildings of various sizes and designations can significantly reduce energy consumption and emissions. Although heat integration (or Pinch Technology) has been around for several decades and has been very successfully applied in large industrial applications, it has only recently been applied for improving the energy efficiency of buildings and building complexes. There is significant scope for application, as energy prices rise and energy related emissions are required to be reduced. This methodology can also be used to integrate renewable energy sources such as biomass, solar PV and solar heating into the combined heating and cooling cycles. Case studies are used to illustrate the methodology. The paper makes suggestions how the methodology can be applied for energy and emissions reduction in single buildings and complexes.

INTRODUCTION

Since 1995 the energy consumption of the EC member countries rose by 11 %, to the value of 1637Mt of oil equivalent [1]. The population of the EC member states however is growing at a much slower rate, approximately at 0.4 %/y [1]. In the UK domestic energy consumption has risen from 35.6 Mt of oil equivalent to 48.5Mt in the period 1971 to 2001, an increase of 36%, despite energy efficiency increases [2]. The increase in energy consumption per household was less, at 5 %, over the same period, better reflecting the increase in energy efficiency in individual dwellings. However in the UK it is proposed that the number of houses built over the next 10 years should increase by 200,000/y, to account for the smaller number of people per household, and the demand for housing [3]. This will have serious implications for energy consumption and greenhouse gas emissions. To date the increase in energy consumption from individuals [2], dwellings, and buildings generally has been met by the burning of carbon based fuels, or in some cases, by the increase in nuclear power. Although renewable energy has seen a large increase, the contribution towards total domestic energy use is still small (in the UK 1.0 Mt of oil equivalent compared to a total use of 47.0 Mt of oil equivalent).

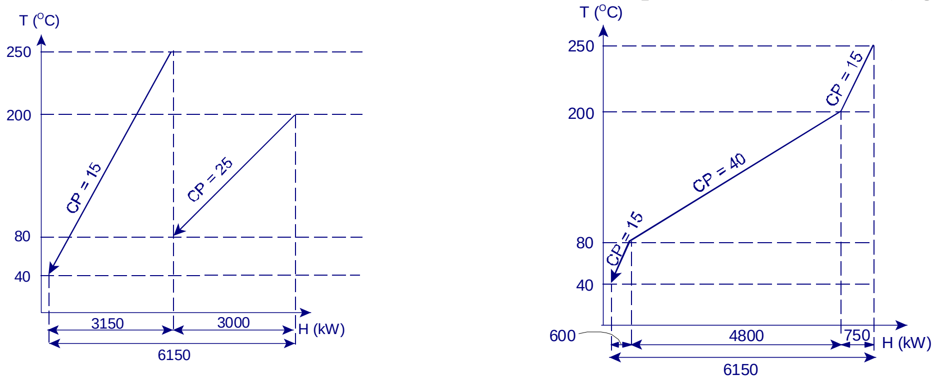
SUSTAINABLE ENERGY AND HEAT INTEGRATION

Heat Integration (or Pinch Technology/Process Integration) is an energy saving methodology that has been extensively used in the processing and power generating industry over the last 30 years. This method examines the potential of exchanging heat between heat sources and heat sinks via the use of heat exchangers and reducing the amount of external heating and cooling required. A systematic design procedure has been developed to provide the final energy reduction design of the system. The method has further been developed to specify the source of heating and cooling required (e.g. steam, hot water, cooling water) and also the potential of power production in the form of shaftwork or electrical production. More details are available elsewhere [4-9]. This methodology is based on the analysis and understanding of heat exchange between process streams through the use of a temperature-enthalpy diagram. The specific steps for drawing the curves in this diagram are presented in Figs. 1 - 3. The methodology first identifies sources of heat (termed hot streams) and sinks of heat (termed cold streams) in the process flowsheet. Tab. 1 presents a simple example.

Table 1 Sources (Hot) and Sink (Cold) streams

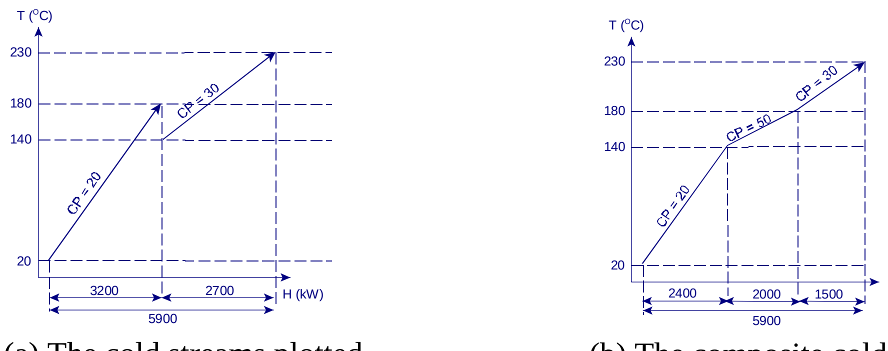
Stream	**Type**	**Supply Temp.** T_S (°C)	**Target Temp.** T_T (°C)	**ΔH** (kW)	**Heat Capacity Flowrate CP** (kW/°C)
Fresh Water	Cold	20	180	3200	20
Hot Product 1	Hot	250	40	-3150	15
Juice Circulation	Cold	140	230	2700	30
Hot Product 2	Hot	200	80	-3000	25

Sources of heat can be combined to construct the composite hot stream (Fig.1) and sinks of heat can likewise be combined to construct the composite cold stream (Fig. 2).



(a) The hot streams plotted (b) The composite hot stream

Figure 1. Composing hot streams to create a hot composite curve



(a) The cold streams plotted (b) The composite cold stream

Figure 2. Composing cold streams to create a cold composite curve

The relative location of these curves on the temperature-enthalpy diagram is dependent on the allowable temperature difference for heat exchange. The next step is to select a minimum permissible temperature approach between the hot and cold streams, ΔT_{min}. The selection of the optimum ΔT_{min} is a result of an economical assessment and trade-off between the capital and operating costs (mainly for energy usage) of the process. A large ΔT_{min} implies higher energy use and costs and lower capital costs. For increasing energy cost the optimum ΔT_{min} is reduced, meaning the heat exchanger system is allowed to recover more energy, but at the expense of more capital to pay for the greater heat transfer area. This issue has been discussed in greater detail elsewhere – [10], [8], [11]. In this example a ΔT_{min} of 10 °C was selected for simplicity. Plotting the composite curves (CC) in the same graphical space (Fig.3) allows values to be derived for maximum heat recovery and minimum hot and cold utilities. These are known as targets. In this particular case of ΔT_{min} = 10 °C, the minimum hot utility requirement is 750 kW and minimum cold utility requirement is 1,000 kW.

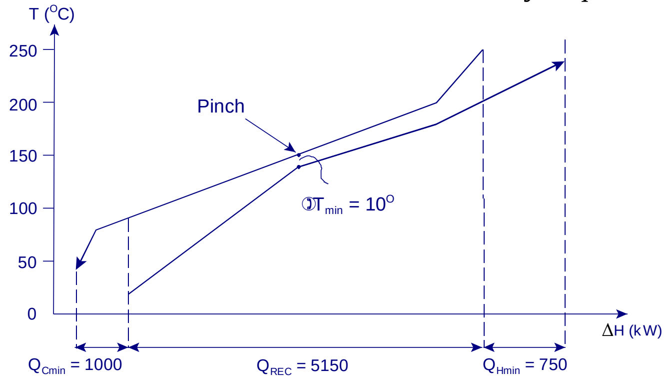


Figure 3. Plotting the hot and cold Composite Curves

In Fig.3 we can also determine the position of the Pinch. The Pinch represents the position where the hot composite and cold composite curves are at their closest (for a $\Delta T_{min} > 0$). The Pinch has provided the name for the Heat integration / Pinch Technology and has important features which make a substantial contribution to the design of maximum energy recovery systems and the design of economically efficient heat exchanger networks.

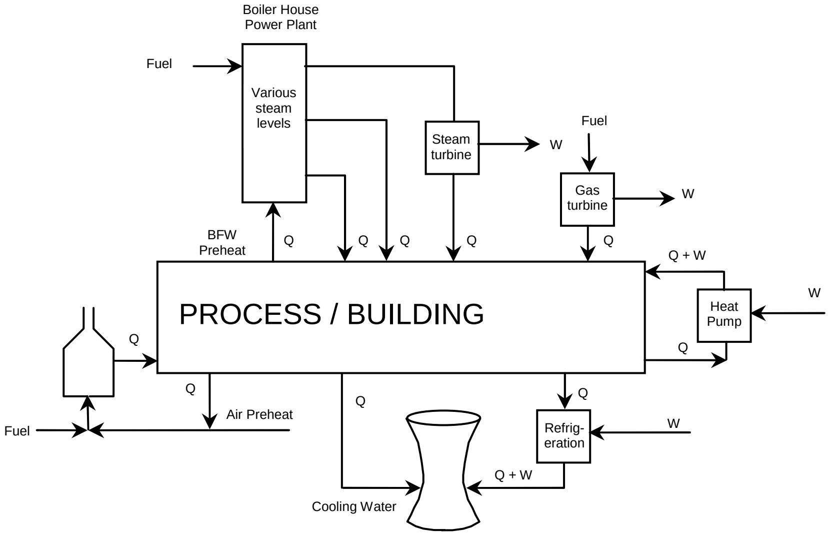

Figure 4. Potential for the choice of hot and cold utilities

Various design methods have been developed which allow these targets to be achieved in practice for both grass roots designs [4], and more importantly, for the retrofit of existing plants [12-14]. These methodologies are supported by process integration software which provides both design and retrofit support and automated design [15, 16]. In most cases there are more than one hot and one cold utility potentially providing heating and cooling requirements after energy recovery. In these situations we have to find and evaluate the cheapest and most desirable combination of the potential utilities that are available (Fig.4). To assist with this choice and to further enhance the information derived from the hot and cold CC, an additional graphical construction has been developed. This is known as the Grand Composite Curve (CC) and provides clear guidelines for the optimum placement and scaling of hot and cold utilities. The GCC together with the Balanced Composite Curves (the CC with the utilities selected added) provides a convenient tool for the optimum placement and selection of hot and cold utilities. An example of selection of utilities and its placement is shown in Fig. 5.

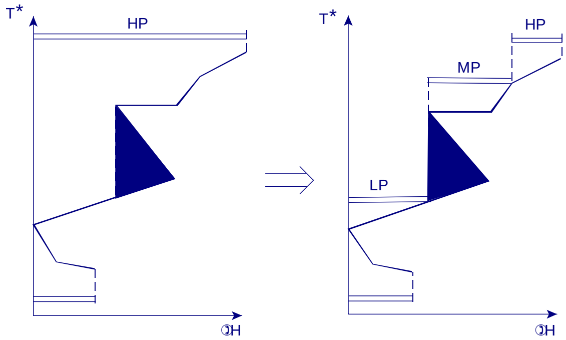

Figure 5. Placement of utilities with the help of GCC

The GCC is also a useful tool for targeting the cooling requirements in sub-ambient processes (such as air conditioning) which require some form of chilling or compression refrigeration. The GCC provides a target for the heat that has to be removed by a refrigeration process, and the temperature at which the refrigeration is needed. However, the overall process/utility system can be improved by using the heat rejected by the refrigeration system to provide low level heating to the process above ambient, thereby saving heat supplied by another utility source (such as hot water). The more detailed description has been provided elsewhere [17].

Traditional Heat Integration assesses the minimum practical energy needs for a process through a systematic design procedure involving five steps: (i) collection of plant data; (ii) setting targets for minimum practical energy requirements; (iii) examination of process changes that contribute to meeting the target; (iv) obtaining the minimum energy design that achieves the target and (v) optimisation which allows a trade-off between energy costs and capital costs.

EXAMPLES – CASE STUDIES

Hospitals are an example of building complexes which are important energy users, especially that of thermal energy. Although considerable research effort has been done to minimise the energy consumption in this sector, there are relatively few studies which apply Heat Integration (Pinch Technology) as a tool to evaluate potential energy savings and thereby reduce emissions.

Herrera et al [18] presented a study of a hospital complex which included an institute, a general hospital, a regional laundry centre, a sports centre, and some other public buildings. The use of diesel as a fuel represented 75% of its total energy consumption and 68% of its total energy cost which was 396,131 US$ in 1999. The hospital complex process diagram is shown in the Fig. 6. In the hospital complex, the heat demand is met by producing steam in boilers fuelled by a high price diesel fuel. There is no heat recovery between the existing heat sources and heat sinks. The hot streams were identified as the soiled soapy water from the laundry and the flow of condensed steam not recovered in the condensation network. The stream data are presented in Tab. 2.

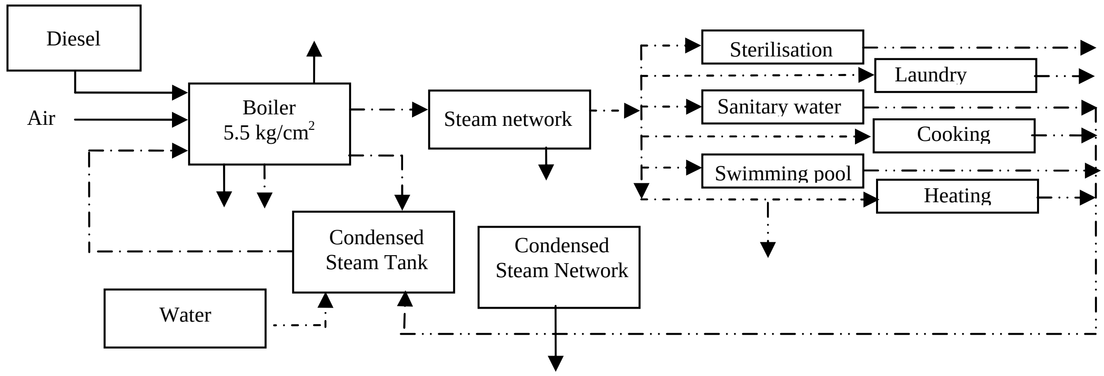

Figure 6. Hospital heat flow block diagram [15]

Table 2 presents the input data extracted from Fig 6.

Streams	ΔH [kW]	CP [kw/°C]	Tin [°C]	Tout [°C]
Hot Streams				
Soapy water (1)	23.7	0.53	85	40
Condensed steam (2)	96.32	2.41	80	40
Cold streams				
Laundry sanitary water (LS)	17.60	0.59	25	55
Laundry (L)	77.12	2.20	25	60
Boiler feed water (BF)	7.13	0.24	30	60
Sanitary water (SW)	77.12	2.20	25	60
Sterilisation (S)	12.50	0.14	30	121
Swimming pool water (SP)	151.67	50.56	25	28
Cooking (CO)	59.63	0.85	30	100
Heating (H)	100.82	14.40	18	25
Bedpan washers (B)	4.94	0.05	21	121

It needs to be noted that the CP represents mass flow m multiplied by the specific heat capacity Cp and in this case are considered constants. As can be seen from the CC (Fig. 7) the amount of external heating required, or the hot utility target, of this hospital complex is 388.64 kW. The GCC has been employed to determine the temperature levels of the utilities necessary to satisfy this requirement. This graphical method allows a more precise analysis to be undertaken in order to integrate the thermal utilities considered for the process heating and cooling requirements (Fig.8). This GCC indicates that the required heating of complex should be 388.64 kW. This means a yearly energy requirement of 12.26 TJ. The actual amount of heating provided is in fact 625.28 kW which represents the heat services that are currently transferred to the complex. This results in a potential energy savings of 38 % equivalent to saving 246,000 L of diesel/y (100,000 US$). To reduce energy demands in the form of heating to the value targeted by the analysis, the Heat Integration based analysis suggests that four extra heat exchangers should be added to the network. Two in the laundry to cover part of the heat demand, a third in the machinery rooms which help to heat boiler feed water, and the final one in the condensation tank area that heats the sanitary water. Several other issues could also have been considered to further refine the analysis, such as fouling, pressure drop and non constant heat demand.

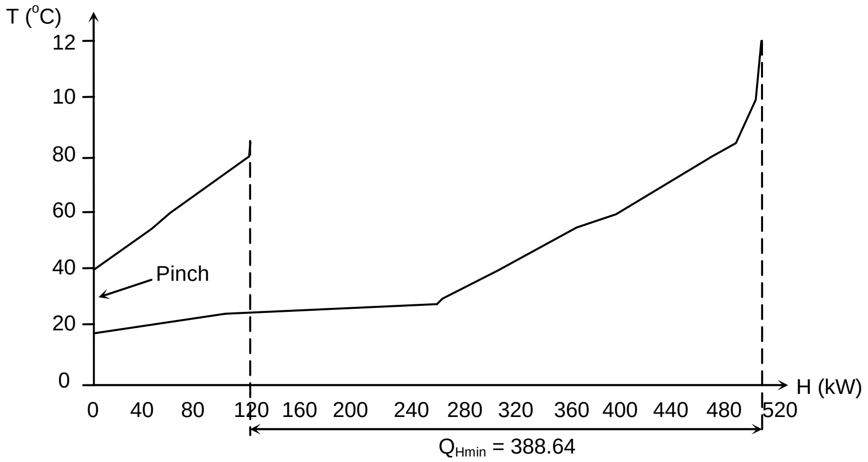

Figure7. CC for the hospital complex process streams

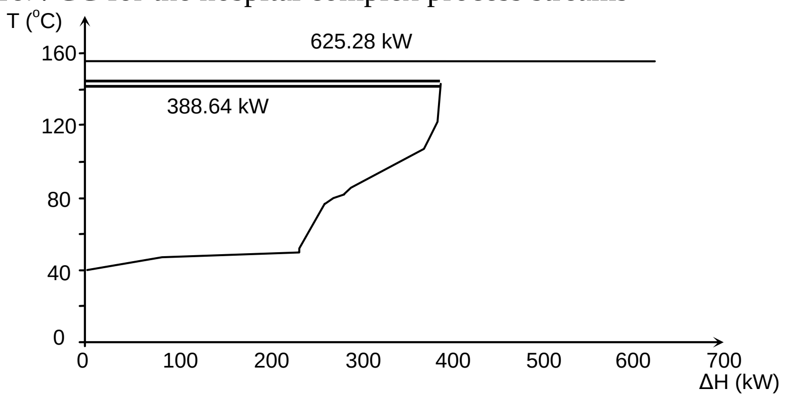

Figure 8. GCC of the hospital [15]

Kemp [9] presented a further more detailed case study of a hospital complex. The main energy demands were found to be space heating, air systems, general hot water supplies and other uses in the laundry and the incinerator. The main part of the complex was fully air conditioned. Central heating water was supplied at 80 °C, and returned at 71 °C and then reheated in a gas-fired calorifier. Tap hot water was also provided.

Table 3 Heat requirements and time distribution required during winter

Stream details and locations	No of streams	Hot streams total		Cold streams total		Times of operation
		Temp (°C)	Heat load (kW)	Temp (°C)	Heat load (kW)	
Main air supply	35	20-15	43	5-37	780	24 h: Day
	33	20-15	27	2-37	681	24 h: Night
Space heating	2			71-80	709	24 h: Day
	2			71-80	665	24 h: Night
Domestic hot water	1			5-60	244	24 h: Day
	1			5-60	48.5	24 h: Night
Autocalves	1			162	13	24 h
Kitchen	1			5-30	101	0530-0200
Laundry	3	37-30	67	18-26, 162	797	0700-1630
Incinerator	1	600-217	650			0900-1630
Boilers	1	235-60				24 h
Summary						
Maximum load			760		2,644	0900-1630
Minimum load			27		1407	0200-0530

In some areas (e.g. kitchens) the heat use varied considerably between day and night time. The identified streams are shown in Table 3. Energy use in winter for day time conditions was found to be 2534 kW (all hot utility) whereas in summer this value dropped to 1030 kW (hot utility) and 207 kW (cold utility) as space heating was replaced by air conditioning and the use of some refrigeration. Kemp [9] presented the GCC for the peak demand during winter (7-9am period). Heat integration analysis of these different time periods provided various schemes for improvement. The first involved rescheduling. This took into consideration the possibility of changing the periods of high utility demand. Suggestions were (i) Moving a cold stream active in 7-9am period to a different time; (ii) Moving a hot stream not operating in 7-9am period to operate during this period. As it was not possible to shut down the central heating or air conditioning systems for this high demand 2 h period, an alternative was that laundry operations could be rescheduled to start 2 h later but finish at the usual time. This would result in the installation of new machines at a high capital cost. For the second suggestion is would be possible to start the incinerator at 7am and run it for a further 2 hours. Retaining the current waste disposal value would result in a reduced exhaust flow rate and heat recovery rate. The daytime total heat recovery would be the same, but one less boiler would be required. It was also found that additional municipal waste could be delivered and that the incinerator could be run at full power over 24 hours. The Heat Integration methodology also investigated the benefits of introducing CHP. The GCC shows that the hospital is represented by four different temperature ranges which were the laundry and autoclaves (160-170 ^{o}C), space heating (80-85 ^{o}C), domestic hot water (up to 70 ^{o}C), and air heating (10-40 ^{o}C). The heat from the jacket cooling water and exhaust gases could be recovered and be suitable for the space heating system. Standby diesel generators already installed to supply emergency power would be a cheaper option to convert than to provide heat and power from a new diesel generator. These would then provide about 50 % of the peak heat demand. Further options would be to install a micro gas turbine of around 1.5 MW. This would provide all power requirements and the majority of the peak demands. Maintenance for a single source heat and power supplier would leave the hospital complex in a vulnerable state.

Several other case studies have been reported by Linnhoff March Ltd. [19]:

a) A study with the code name BRECSU/BDP was an attempt to define the energy-efficient hospital of the future. LM Ltd looked at all aspects of hospital heating including space heating, ventilation air heating, hot water heating and sterilisation. For hot streams available for heat recovery LM looked at ventilation extraction air, drainage and incinerator flue gas. The major opportunities on an existing building were be in the utility area. There was much detail in the study, including heat generated by the patients in the day (active) and night (sleeping). The work demonstrated that, for a complex new building like a hospital, potential existed for heat recovery between extract and inlet air systems and for heat pumping from the drainage system. The most economic form of heat recovery was from the incinerator exhaust and they also concluded that the optimum utility system would be CHP.

b) Eastbourne Hospital. The largest saving found was in the laundry where dryer exhaust could heat water and fresh air for the dryers and hot dirty wash water could heat fresh water (with storage). A heat engine-based CHP scheme was recommended but this would affect the laundry recommendations because it would provide the necessary hot water.

CONCLUSIONS

Heat Integration (or Pinch Technology) has been used for 20 years in industry throughout the world to increase energy efficiency of any processing plants that have heating or cooling requirements, and also have needs for power to provide electricity or directly drive machinery. Energy savings of over 30% have been recorded, and the methodologies developed have been incorporated into the design offices of all major producing companies. The same methodologies and design rules can also be applied in buildings or their complexes. Examples of two complexes have been given. It is clear that as energy efficiency in buildings and the reduction of emissions becomes a standard issue in existing and new complexes, further examples of heat integration application will be carried out.

ACKNOWLEDGEMENT

The support from EC TREN/05/FP6EN/S07.54455/020114 Project “Network for promotion of Eco-building technologies, small Polygeneration, and renewable heating and cooling technologies for buildings – ProEcoPolyNet” (PEPNet) has been gratefully acknowledged.

Low Exergy Systems for High-Performance Buildings and Communities

Dietrich Schmidt

Fraunhofer-Institut für Bauphysik, Project Group Kassel, Germany

Corresponding email: dietrich.schmidt@ibp.fraunhofer.de

SUMMARY

There is an obvious and indisputable need for an increase in the efficiency of energy utilisation in buildings. Heating, cooling and lighting appliances in buildings account for more than one third of the world's primary energy demand. In turn, building stock is a major contributor to energy-related environmental problems. There are great potentials, which can be obtained through a more efficient use of energy in buildings.

An optimisation of the exergy flows in buildings and the related supply structures, similar to other thermodynamic systems such as power stations, can help in identifying the potential of increased efficiency in energy utilisation. Through analyses, it can be shown that calculations based on the energy conservation and primary energy concept alone are inadequate for gaining a full understanding of all important aspects of energy utilisation processes. The high potential for a further increase in the efficiency of; for example, boilers, can not be quantified by energy analysis - the energy efficiency is close to 100%; however, this potential can be showed by using exergy analysis [1], the exergy efficiency of a common gas boiler is about 8%.

This paper outlines the international co-operative work in the general framework of the International Energy Agency (IEA), the ECBCS Annex 49 "Low Exergy Systems for High Performance Buildings and Communities" [2].

INTRODUCTION

As a consequence of the latest reports on climate change and the needed reduction in CO_2 emissions, huge efforts must be made in the future to conserve high quality, or primary energy, resources. A new dimension will be added to this problem if countries with fast growing economies continue to increase their consumption of fossil energy sources in the same manner as they do now. Even though there is still considerable energy saving potential in the building stock, the results of the recently finished IEA ECBCS Annex 37, Low Exergy Systems for Heating and Cooling of Buildings [3], show that there is an equal or greater potential in exergy management [4]. This implies working with the whole energy chain, taking into consideration the different quality levels involved, from generation to final use, in order to significantly reduce the fraction of primary or high-grade energy used and thereby minimise exergy consumption [5]. New advanced forms of technology have to be implemented. At the same time, as the use of high quality energy for heating and cooling is reduced, there is more reason to apply an integral approach, which includes all other processes where energy/exergy is used in buildings. In recent years, we have made substantial progress in the development of new and integrated techniques for improving energy use, such as heat pumps, co-generation, thermally activated building components, and methods for harvesting renewable energy directly from solar radiation, from the ground and various other waste heat sources [6].

The results obtained in research projects on optimised exergy use in buildings are promising and elucidate a huge potential for introducing new components, techniques and system solutions to create low exergy built environments. The exergy conversion, e.g. heat or electricity production, plays a crucial part in possible future activities in the overall system optimisation of the entire energy system within a building.

THE EXERGY CONCEPT AND THE LOWEX APPROACH

Exergy is a concept which helps us distinguish between two parts of an energy flow: exergy and anergy. Only the exergy part of any energy flow can be converted into some kind of high-grade energy such as mechanical work or electricity. Anergy, on the other hand, refers to the part of the energy flow which cannot be converted into high-grade energy, e.g. low-grade waste heat from a power plant. Exergy can be regarded as the valuable part of energy, while anergy designates the low-value portion.

Unless a suitable use for exergy is found, e.g. waste-heat utilisation in buildings, the low-value part of the original energy flow will eventually dissipate into the environment and be irreversibly lost. Such unalterable dissipation is designated as irreversibility. The exergy content of a given flow of energy depends on the attributes, e.g. the temperature, pressure, and chemical composition, of both the substance carrying the energy (energy carrier), and the surrounding environment. The more different the attributes of the energy carrier and the environment are, the higher the exergy content of the energy carrier is. For example, high-pressure steam required for electrical power generation has a higher exergy content than warm water needed by a dishwasher [7].

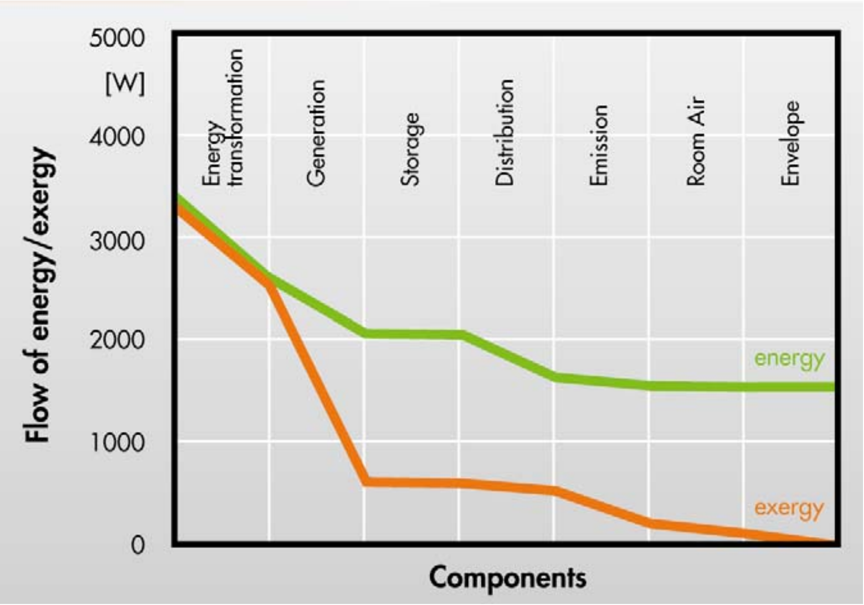

Figure 1. Results of an analysis of energy and exergy flows through a building

The Low Exergy (LowEx) approach entails matching the quality levels of exergy supply and demand, in order to streamline the utilisation of high-value energy resources and minimise the irreversible dissipation of low-value energy into the environment [5],[8]. This approach is the key concept for the work of Annex 49 on energy use and supply structures in the built environment.

SCOPE AND OBJECTIVES OF THE ECBCS ANNEX 49

The scope of this activity is to improve, on a community and building level, the design of energy use strategies which account for the different qualities of energy sources, from generation and distribution, to consumption within in the built environment. In particular, this method of exergy analysis has been found to provide the most correct and insightful assessment of the thermodynamic features of any process and offers a clear, quantitative indication of both the irreversibility and the degree of matching between the resources used and the end-use energy flows [9]. To satisfy the demands for the heating and cooling of buildings, the exergy content required is very low, since a room temperature level of about 20°C is very close to the ambient conditions. Nevertheless, high quality energy sources, like fossil fuels, are commonly used to satisfy these small demands for exergy [5]. From an economical point of view, exergy should mainly be used in industry to allow for the production of high quality products.

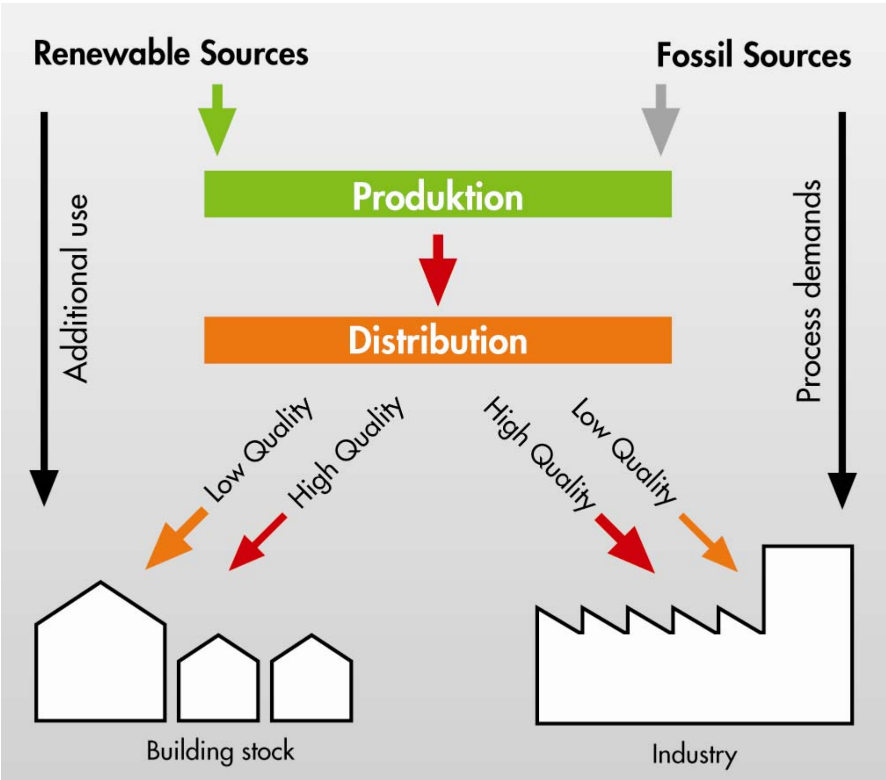

Figure 2. Desirable energy/exergy flow to the building stock and industry. In the building stock, there should be a larger share of low valued energy, whereas high quality energy should be left for other purposes, e.g. industrial processes.

It is known that the total energy use caused by buildings accounts for more than one third of the world's primary energy demand [10]. There is however substantial saving potential in the building stock. The implementation of exergy analyses paves the way for new possibilities of increasing the overall efficiency of the energy chain. Exergy analysis can support the development and selection of new types of technology and concepts with the potential of lowering exergy consumption for built environments and the related supplies. It can also quantify this potential. Up to now, considerable effort has been made to reduce the energy demand of the building stock and to increase the energy conversion factors in power stations. The new approach is not necessarily focussed on a further reduction of the energy flow through a building's envelope. When the demands for heating and cooling have already been minimised, the low-exergy approach aims at satisfying the remaining thermal energy demand using only low quality energy. This creates the potential for reducing the total amount of exergy needed by the energy supply-demand chain, and for providing a more customised distribution of exergy to consumers with different exergy requirements.

The main objective of the annex is to use exergy analysis as a basis for providing tools, guidelines, recommendations, best-practice examples and background material to designers and decision makers in building, energy production and political fields. Another important objective is to promote possible energy/exergy and cost-efficient measures for retrofit and new buildings, such as dwellings and commercial/public buildings, and their related performance analyses viewed from a community level, including the energy supplies.

The major benefit of following low exergy design principles is the resulting decrease in the exergy demand in the built environment. By following the exergy concept, the total CO_2 emissions for the building stock will be substantially reduced as a result of the use of more efficient energy conversion processes. This new concept supports structures for setting up sustainable and secure energy systems for future building stock.

The strategies developed for a better and exergy optimised building design, aimed at a future of clean, clever and competitive energy use, will help in pinpointing specific actions to reach this goal. Additionally, the exergy demand of buildings will be reduced due to new, enhanced heating and cooling systems.

IDENTIFIED RESEARCH ISSUES

The exergy concept applied to buildings and the related supply structures leads to new research topics for building stock. The ECBCS Annex 49 is addressing the following research items [2]:

- Combined exergy/energy analyses for community supply structures and buildings, especially those with changing ambient and boundary conditions. This will lead to the implementation of dynamic analyses for complex systems.
- Optimisation strategies for low exergy distribution and building technology system configurations.
- A mandatory holistic system approach to investigate the dependencies between energy production and the use of energy in buildings. This implies the feedback and the response of the building to the grid and energy production strategies.
- Integrated use of local renewable energy sources. Known and new, innovative techniques will be evaluated using new analysis tools. The results will indicate directions for new developments.
- Better control strategies for building service systems to reduce the overall exergy demand.
- Exergy as an indicator for sustainability and for long term, cost efficient solutions.
- Indoor comfort provided by placing the minimum possible exergy demand on building service systems.

STRUCTURE OF THE NEW ACTIVITY

To accomplish these objectives, participants will carry out research and work on developments within the general framework of the following four subtasks: The first subtask, "Exergy Analysis Methodologies", is aimed at development, assessment and analysis methodologies, including a tool development for design and performance analysis of the regarded systems. The second subtask, "Exergy efficient community supply systems", focuses on the development of exergy distribution, and generation and storage system concepts at a community level. A third subtask, "Exergy efficient building technologies", is based on the reduction of exergy demand for the heating, cooling and ventilating of buildings. The last subtask, "Knowledge transfer, dissemination", concentrates on the collection and spreading of information on ongoing and finished work.

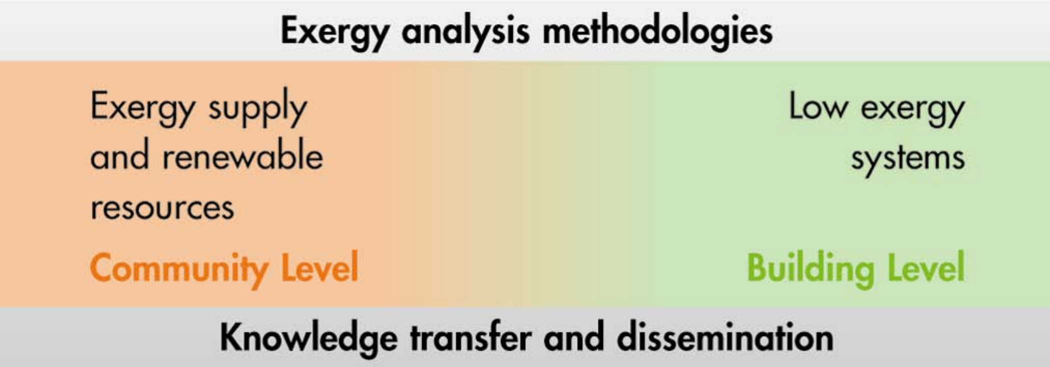

Figure 3. Subtask structure of the ECBCS Annex 49

The community and the building level are directly connected by the final energy conversion process. Nonetheless, the distribution concept for exergy has to be fixed at the community level.

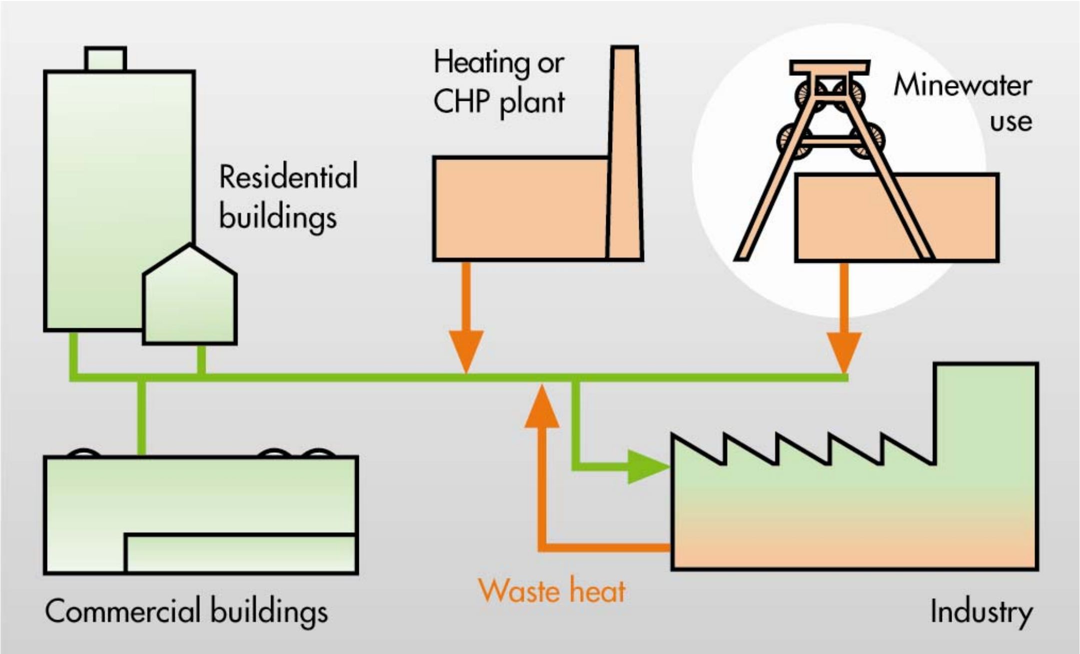

Figure 4. The integration of energy sources from our environment, e.g. the use of water from abandoned mines for heating and cooling buildings., requires exergy efficient supply systems at the community level and adapted building service systems.

EXPECTED RESULTS

The primary presentation of the annex is expected to be an IT based guidebook on how to implement advanced LowEx technology at a community level in the built environment and how to optimise supply structures to ensure low exergy demand of the system solution, while providing good comfort to the occupants and users of the buildings. Furthermore, the work will focus on analysis concepts and design guidelines with regard to exergy metrics for performance and sustainability. A collection of best-practice examples for new and retrofit buildings and techniques will show the potentials of the new approach. With this basis, recommendations for policy measures will be suggested and the aim is to conduct pre-normative work [2].

The focus of the dissemination of documents and other information is to transfer the research results to be used by practitioners. Methods of information dissemination are to include conventional methods such as newsletters and articles, as well as new media, and the Internet is to be used intensively to spread information. Workshops will be organised in different countries to show the latest project results and to provide an exchange platform for the target audience (notably, energy managers, designers, and energy service companies).

OTHER RELATED ACTIVITIES

The International Society of Low Exergy Systems in Buildings (LowExNet) was founded by participants of the completed ECBCS Annex 37. LowExNet members are working with exergy issues, supporting the work n the framework of Annex 49 and have been presenting their results and findings in a number of workshops and seminars, mainly in the framework of international conferences within the field of building technology, building physics and building services. The LowExNet group offers a platform for discussion and information dissemination on the proposed activities. To strengthen and expand the scientific collaboration in the LowEx field, a number of national (e.g. German and Dutch) and European projects have been started [11]. Furthermore, a close collaboration to the ASHRAE Technical Group 1 (TG1) on “Exergy Analyses for Sustainable Buildings” has been established.

CONCLUSIONS

The major benefit of following low exergy design principles is the resulting decrease in the exergy demand in the built environment and related energy supplies. By following the exergy concept, the total CO_2 emissions for the building stock will also be substantially reduced as a result of the use of more efficient energy conversion processes. This new concept supports structures for setting up sustainable and secure energy systems for future building stock. The strategies developed for a better and exergy optimised building design, aimed at a future of clean, clever and competitive energy use, will help to pinpoint specific actions required to reach this goal. Additionally, the exergy demand of buildings will be reduced due to enhanced new heating and cooling systems. The target is to establish a holistic approach for an affordable, comfortable and healthy built environment, while obtaining a minimum input of exergy, and implementing a substantial amount of renewable energy sources into the energy supply of buildings.

Additional and more extensive information can be found on the homepages [2] and [11].

ACKNOWLEDGEMENT

The author would like to acknowledge the financial support of the German Federal Ministry of Economy and Technology for the project and to thank the ECBCS Annex 49 working group for the encouraging discussions during the course of the work within the project.

SUMMARY

The issue of sustainability has been prevailed not only in building industry but also all other industries. It has been raised that the concept of green building system should be taken into account for the design of buildings. This study is to understand characteristics of the green building system and find the solution of urban problems. Now, over 60% people all over the world live in urban areas, and their communities continue to expand. Pollution and other hazards also tend to accumulate in urban areas. Accordingly, the problems of urban environment are true microcosms of environmental afflictions happening on a global scale. Most of urban problems are caused by human and their buildings. This study was conducted by two ways. One is assessment of energy, and the other is water cycle. Energy and water is also typical factors of urban problems. To solve the urban problems, we must change or shift the wrong circulating systems on (buildings) micro scale. The object building is a recently designed as an environmental-friendly building in Korea that has eco-systems. (as earth-berm, thermal labyrinth, concrete core cooling, soil energy, water-recycle, etc.) Furthermore, comparing eco-system to normal system, difference of energy saving between eco-system and normal system were analyzed by calculation of exergy-entropy of the energy and water cycling system. Consequently, control of micro-environment (the consumption-discharge balance of the energy and the water) in buildings is a key of urban problem solution

INTRODUCTION

A city has been rapidly developed due to progress of Industrialization, so population in it is has been increased. We call it urbanization, and it has been making environmental problems more and more serious. More than 60% of people all over the world are living in urban areas, and all of them try to keep expanding their own area, so a lot of buildings are concentrated in it. Moreover, the people and buildings keep spending water and energy, and it makes excessive shifting or problems of circulating system. Accordingly, the roles of it for sustainable development became new and important issues and. Energy and water circulating systems are causes or effects from urban problems, so the aim of this study is to reduce unstable circulating system and to control the factors that cause urban problems as green building system is applied in a building unit. In brief, the purpose of study is to solve environmental problems of urban area indirectly through buildings.

METHODS

A circulating system in terms of urban area was estimated through technologies of green building, and plans for improving it were made indirectly for the purpose of this study. First of all, problems of urban ecology and environment were organized, and the problems about water circulating system were found. Second, the energy and water shifting/circulation in a building were analyzed according to green building technologies. For this, a building that green building method had been applied was chosen, and the building was analyzed through the applied systems previously. Third, the energy/water circulating system that the green building system was applied was compared and analyzed with the energy/water circulating system that it wasn't applied. Finally, improving effects of energy and water shifting systems were proven through third step for the unstable building.

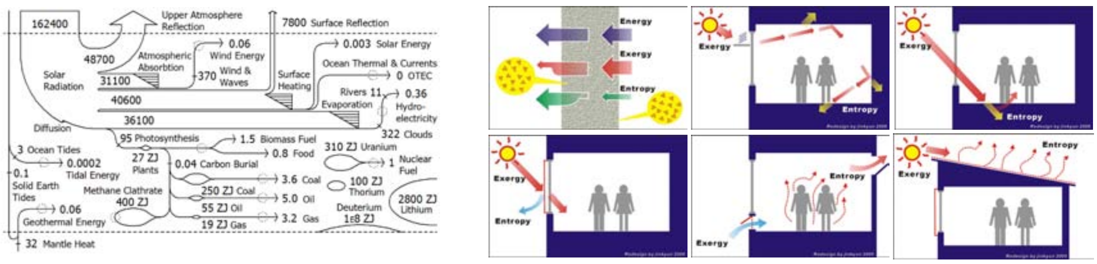
THEORIES

(1) Energy Circulating System

Exergy is originated from energy with the process of material dissolution as all materials in universe are controlled by the second law of thermodynamic. It is also existed in kinetic energy and any other dynamics because most of it is a kind of kinetic energy or dislocating energy that is related with restoration. Exergy is one of energy resources, and an element made by energy production is entropy. Equation (1) is the relationship between exergy and entropy.

$$\text{Consuming Exergy} = \text{Producing Entropy (Inflowing Energy} = \text{Exhausting Energy)} \qquad (1)$$

If the equation (1) doesn't work, the amount of error should be made up from other energy, so the energy shifting can be sequentially unstable.



a) b)

Figure 1. Exergy-Entropy Circulation a) Shifting on The Earth, b) Shifting in A Building

Entropy is made by consumption of exergy in buildings, and energy moves to outside through the envelope of the buildings to be stable state. Generally, the shifting from exergy to entropy can be explained by four processes: ① Supply of exergy ② Consumption of exergy ③ Production of entropy, and finally ④Giving entropy off. Buildings consume exergy like electricity and fossil fuel and give off entropy. It affects on the surrounding of the buildings. For example, if it increases, the temperature around the buildings will increase, and many kinds of environmental problems will be caused like green house effect in terms of global environmental system. Accordingly, exergy has to be consumed as less as possible to minimize the environmental effects.

(2) Water Circulating System

Inconsiderable development and excessive paving destroy the water circulating system which is the basis of ecological function. The paving, that water doesn't permeate, has covered more than 70% of an urban area, and 73% of urban area is changing to desert. They are the main reason that functions of eco-system and amenity are lost. In 2002, surface water was increased as much as 483 mm/year (that was 5.3 times of 1962's one) on the other hand the groundwater was decreased as much as 107 mm/year (that is 60% of 1962's one). Moreover, flow of groundwater that goes to watercourses or rivers and shows reversing acting, so urban areas often have overflow and heat island and are accelerated to desert fast. This situation can be resolved through the recovering water circulating system before spaces of urban areas are considered. Accordingly, the alternatives that can recover the water circulating system are necessary with controlling water circulation about water consumption and release and spontaneous generation.

CASE STUDY : THE APPLIED SYSTEM OF THE OBJECT BUILDING

(1) Analysis of The Object Building

A campus center in E university which is still constructing now was selected for this study to analyze energy and water circulation in it according to the application of green building system. It was planned as a building in earth berm with 6 stories’ basement. The building will be better than any buildings on the ground if it can take enough daylight and ventilation in terms of energy saving, thermal comfort, and residential space. HVAC(or machine and equipment) of the building is based on the energy saving, operating cost, and environmental load as reduction of primary fuel consumption such as enough utilization of regenerative performance and various using of water resources like groundwater and dewatering.

Table 1. Summary of The Object Building And Its Building Service System

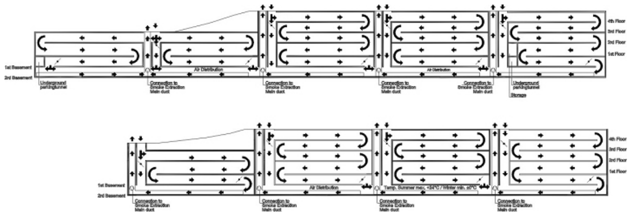
Project	E University Campus Center	Site Location	Seoul, Korea
Structure	RC + SS	Total Floor Area	About 70,000 ㎡ / Basement with 6 Stories
Services	A. Academic : small class room, auditorium, computer lab, seminar room, 24hr reading room, student gallery, theater, recreation, offices. B. Commercial: fitness, academic shop, cafeteria, restaurant, etc. C. Parking Lots		
Cooling	Hot Water Absorption Chillers + Heatpump Type Chillers		
Heating	Co-generation System + Heatpump Type Chillers + Hot Water Boiler		
Ventilation & Air Conditioning	Vairable Air Volume + CCC(Concrete Core Cooling) + CHR(Cooling Heating Radiator)		
Green Building System	Thermal Labyrinth, Geothermal Energy, Water Recyle System (groundwater, dewarering and rain water)		

(2) Applied Green Building System (Eco-system)

• Thermal Labyrinth (Air Soil Duct)

Inside soil of earth berm keeps the temperature constant during a whole year. It is one of the ground characteristics, and it can be used for the energy saving systems through preheating and precooling of outside air to Air handling unit. A double layer wall is used as an air soil duct for the building in earth berm due to the characteristic and architectural necessity, and it plays a role of cool (or hot) tube system. It decreases load of outside air by Δ11℃ (-11℃→0℃) during winter and by Δ7℃ (31℃→24℃) during summer, so operating cost and the size of machine can be possibly decreased.

a)



b)

Figure 3. a) A Building View, b) Thermal Labyrinth in The Object Building

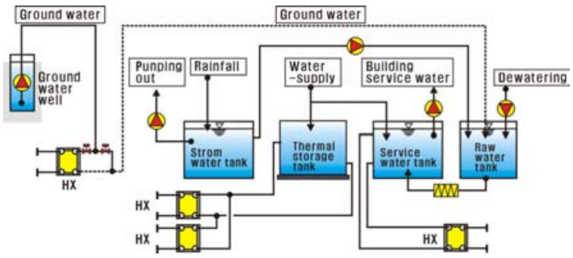
• Geothermal Energy

Pipes are installed on slab of floor to use geothermal energy, and air cooling source is made through the heat exchange with geothermal heat source. The air cooling source is supplied to CCC (Concrete Core Cooling) for 24 hours. After thermal solution (water) is passed by the pipes, the temperature of it is estimated to be around 12℃, and it has heat exchange again until it has 17℃ before it is supplied to CCC.

• CCC(Concrete Core Cooling)

It is a system that controls surface temperature of ceiling, wall or floorboard for residents to be comfortable more than they are with all-air system by cooling radiation even though indoor temperature is over comfort zone. Moreover, water is used as a thermal mass, so the amount of air volume (of AHU) is decreased. Accordingly, duct size can be reduced, delivering (fan) energy can be saved, cooling or heating peak time can be moved during a week, and thermal storage system of concrete (mass) can be combined.

a)



b)

Figure 4. a) CCC (Concrete Core Cooling), b) Recycling of Water Resource

• Recycling of Water Resource

Groundwater with around 15℃ is supplied with 80 ton (8.5 ton/h) per day not only as service water for a building but also as a cooling resource by constant water temperature during a year. The idea about it is to apply heating and cooling system to CCC that cooling source is necessary for 24 hours and to use chilled water, water source, and service water (for washing and gardening). In other words, Groundwater, dewatering, and rainwater are collected in raw water tank, and they get water treatment. After that, the water is used to Re-Cooling. Rainwater is collected in storm water tank during a long spell of rainy weather, and it is usually used for chilled water source, city water for building and landscaping. Dewatering of 150 ton is estimated to be produced.

ENERGY CIRCULATION IN THE OBJECT BUILDING

(1) Comparison with Scheme of Cooling/Heating Plants
A campus center in E university has experimental green building systems, and they are organically interconnected each other. Also, most of the exterior walls are faced on earth berm, so envelop and solar loads can be reduced. The peak load of cooling is about 4,200 kW(1,200 usRT), and the peak load of heating is about 4,000 kW in case of the building, so more than 20% reduction of loads is estimated compare to above ground buildings, and the capacity(size) of cooling/heating plant is decreased. Energy circulating system in the building was compared and analyzed with the case that eco-systems were not applied. Exergy consumption and entropy release were converted into the amount of TOE and CO_2 as a concept of energy input and output.

Table 2. Heating/Cooling System (of Eco-system and Normal System)

Sources		Eco-system		Normal System	
Cooling		App.	Capacity kW(usRT)	App.	Capacity kW(usRT)
1	Geothermal Energy	Y	120(34)	N	-
2	Groundwater & Dewatering	Y	30(9)	N	-
3	Thermal Labyrinth	Y	325(92)	N	-
4	Hot Water Absorption Chillers	Y	950(270)	Y	950(270) x 3ea
5	Electric Chiller	Y	745(212)	Y	745(212) x 3ea
6	(Water) Thermal Storage Tank	Y	2,010(527)	N	-
Total Cooling Capacity		4,180(1,144)		5,085(1,446)	
7	Cooling Tower	Y	3,628	Y	3,628 x 3ea
8	Dry-cooler	Y	500	Y	500 x 3ea
Heating		App.	Capacity kW(kcal/h)	App.	Capacity kW(kcal/h)
1	Geothermal Energy	Y	300(258,000)	N	-
2	Thermal Labyrinth	Y	412(354,300)	N	-
3	Co-generation(Waste Heat)	Y	500(430,000)	Y	500(430,000)
4	Heatpump Type Chiller	Y	960(825,600)	Y	960(825,600) x 2ea
5	Hot Water Boiler	Y	872(750,000) x 2ea	Y	872(750,000) x 3ea
Total Heating Capacity		3,916(3,367,900)		5,036(4,331,200)	

Notes) The difference of heating(cooling) capacity is the difference of load saving between a building on the ground and a building under the earth.

(2) Calculation of Energy Consumption and Release in Building
The full load equivalent hour was use for the calculation of energy consumption for heating and cooling in the building.

Table 3. Boundary Condition for Exergy-Entropy Calculation (in The Object Building)

Full Load Equivalent Hour (hour/year)			
Cooling	273	Cooling Period (90 days : June 15 – September 15)	
Heating	294	Heating Period (150days: November 1 – March 30)	
Carbon Exhausting Coefficient of Energy Sources			
Sources	Calorific value	Carbon Exhausting Coefficient (TC/TOE)	Combustion
Gas	11,000 kcal/N m^3	0.637	0.995
Electricity	860 kcal/kWh	0.787	-

Notes) Operating: 10 hours for every weekday, 6 hours for every Saturday, and no operation on every Sunday
a) TC: Ton Carbon(10^3 Carbon) b) TOE(Ton of Oil Equipvalent) 10^7 kcal

For the energy circulation in the building, exergy and entropy was calculated as the amount of TOE and CO_2 release. The consumption of exergy was 561.75 TOE for the case that the eco-system had been applied and 653.95 TOE for the case that normal system had been applied. Also, release of entropy was 974.51 Ton-CO_2 in former case and 1,202.10 Ton-CO_2 in the latter case. As a result, when the green building systems was applied, exergy was reduced by 14% and entropy was reduced by 19% in terms of energy flow and shifting.

Table 4. The Amount of Exergy-Entropy Release (Between Eco-system and Normal System)

Notes) a) ( ): No energy shifting due to spending of natural/surplus energy
b) Waste heat from cogeneration is calculated as a surplus in terms of heat resources.
c) Electric chiller is operated for 624 hours for cool water thermal storage system during nighttime. (8 hours/day x 6 days/week x 13 weeks)
d) Co-generation is operated for 365 days/year

WATER CIRCULATION IN THE OBJECT BUILDING

(1) Comparison with Schemes of Water Recycling

The object building combines all water sources and redistributes them to maximize water utilization. It is to minimize water source waste and unnecessary sewage exhaust. Water circulating system in the building were analyzed through same ways of the comparison with schemes of energy system of cooling/heating, and the annual consumption of city water and sewage were calculated with the concept of water sources consumption and release.

Table 5. Schemes for Water Recycling (of Eco-system And Normal System)

Sources			Requirement	Production	Eco-system	Normal System
1	Service Water	Potable/Washing Water	220 ton/day	-	City Water + Grey Water Use	City Water Use
		Lavatory Water(Toilet)	330 ton/day	-		
2	Supply Water for Cooling Tower		6.8 ton/h	Scatteration		
3	Water for Gardening		100 ton/day	-		
4	Water for Firefighting		100 ton	-		
5	Groundwater		-	80 ton/day	Reusing for Grey Water	Undeveloping
6	Pumping Dewatering		-	150 ton/day		Out-flow
7	Rain Water		-	22,700 ton/yr		

notes) 1. Service water(ton/day) = 110ℓ/day-person x 0.1 person/㎡ x Occupancy area

2. Cooling tower supply water(absorption chiller) = 567.3 ㎥/h(water for cooling tower) x 0.012(rate of scatteration)

5,6. They get treatment before they move to city water tank, and after they move to city water tank, they are supplied to building.

7. Rain water is calculated as monthly rainfall is multiplied by water catchment area (16,865 ㎡).

In terms of the water circulating, consumption and discharge were calculated to the amount of water supply (grey water) and sewage. Water supply was 98,328 ton/yr in case that a green building system had been applied and 187,341 ton/yr in case that the normal system had been applied. Also, the amount of sewage was estimated by 189,251 ton/yr in former case and 249,251 ton/yr in latter case. As a result, water circulating consumption was reduced by 48% and release of it was reduced by 24% when the green building system was applied.

Table 6. The Amount of Water Service Release (between Eco-system And Normal System)

Sources	Eco-system Calculation	Supply		Release	Normal System Calculation	Supply		Release
		City Water (ton/yr)	Grey Water (ton/yr)	Sewage (ton/yr)		City Water (ton/yr)	Grey Water (ton/yr)	Sewage (ton/yr)
City Water	550 ton/day x 6/7[a] x 365day = 172,071 ton/yr	98,328	-73,743	172,071	550 ton/day x 6/7a) x 365 day = 172,071 ton/yr	172,071	-	172,071
Water for Cooling Tower	6.8 ton/h x 273[b] h/yr = 1,856 ton/yr	-	-1,856	(1,856)	6.8 ton/h x 273[b] h/yr x 3ea = 1,856 ton/yr	5,570	-	(5,570)
Water for Gardening	100 ton/day x 12 day x 8 month = 9,600 ton/yr	-	-9,600	(9,600)	100 ton/day x 12 day x 8 month = 9,600 ton/yr	9,600	-	(9,600)
Water for Firefighting	100 ton (Store)	-	-100	-	100 ton (Store)	100	-	-
Ground water	80 ton/day x 6/7[a] x 365 day = 25,029 ton/yr	-	+25,029	-	Non	-	-	-
Dewatering	150 ton/day x 365 day = 54,750 ton/yr	-	+43,800	10,950	150 ton/day x 365 day = 54,750 ton/yr	-	-	54,750
Rain-fall [c]	22,700 ton/yr	-	+16,470	6,230	22,700 ton/yr	-	-	22,700
Total Supply-Release		98,328		189,251		187,341		249,251

notes) a) Building use : 6-days of One week(7-days) b) Cooling full load equivalent hour: 273 h

c) 20% of it is discharged before they are supplied to stormwater tank / Collectable period (from march to october)

( ) : Cooling tower supply water: scatterate in the air / Gardening water: ground inflow

RESULTS

First of all, energy and water source can be saved a lot when the green building system was applied. However, more important factor is to restrict excessive consumption and release of energy and water circulation in the building. In case of consumption in the building, and exergy was reduced by 14%, and the amount of city water was reduced by 48%. Furthermore, in case of release, entropy was reduced by 19%, and sewage was reduced by 24%. If exergy consumption and entropy release are reduced, bad influence around building area can be minimized, and further, the causes of environmental problems in an urban area can be reduced.

Table 7. The Result of Energy and Water Circulating System

Sources		Eco-system	Normal system	Reduction
Energy	Supplied Exergy (TOE)	561	653	(-)14%
	Released Entropy (Ton-CO_2)	974.50	1202.10	(-)19%
Water	Supplied Water (Ton/yr)	98,328	187,341	(-)48%
	Released Water (Ton/yr)	189,251	249,251	(-)24%

CONCULUSIONS

The data in this study can be little different from the real data after the campus center in E university is constructed completely because the consumption-release calculation of energy and water circulation in this research is based on the (SD)plan of the building. However, to solve the problems of urban environment and eco-system, research of energy and water circulation in building with green building method and minimizing causes of problems is very important. There are four categories of the process about it.

(1) As a human uses a building, circulation of energy and water is caused, and it has an effect on problems of urban environment.

(2) All circulation systems have the process that is from consumption to release. It is from exergy to entropy in energy, and it is from water supply to sewage in water.

(3) Entropy and sewage can be controlled as green building system is applied and as the exergy and water supply are controlled in a building which is micro aspect. This method saves energy and minimized the environmental pollutants with improving circulating system that have excessive consumption and release.
(4) Primarily, matters' release from a building which can be environmental problems for urban area in terms of micro aspect can be reduced by controlling them in the building. In other words, the urban area and the eco-system can be recovered to stable circulating system is as macro environmental(urban) problems are solved with the removal of micro environmental problems in a building. Consequently, when a green building system is planned, the not only energy saving factors but also environmental factors have to be examined practically.

How can we improve the efficiency of exploitation of geothermal energy

Veronika Tóthová and Ján Takács

SUMMARY

Nowadays no energy source should exist without regulation to ensure its efficient use. The regulation can be quantitative, qualitative or combined. This article compares the utilization of geothermal well in two situations. The first situation is when no regulation is used on the geothermal well head. The second situation is when the exploitation of geothermal water is regulated on the geothermal well head, i.e. quantitative regulation is considered. The regulation on the geothermal well head grants savings on the geothermal well because only as much geothermal water is consumed as needed. Therefore the lifetime of the geothermal well is elongated. In this case of regulation, the efficiency of geothermal water utilization is increased and it is nearly constant for all winter months.

INTRODUCTION

Slovak Republic is a small country, but with lots of geothermal wells. On the area of 49 035,81 km^2 there are 117 geothermal wells with the temperature of the geothermal water ranging from 18 °C to 129 °C. The geothermal energy in Slovak Republic is used for recreational purposes (thermal swimming pools), balneology, preparation of hot water, heating of buildings or greenhouses. Although we have a high energy potential of renewable energy – geothermal energy, the effectiveness of using this energy is very low. This article will show the approach of relation between the geothermal energy and its use, especially how to deal with the regulation of geothermal well head.

The main reason for the low effectiveness of geothermal energy utilization in Slovak Republic is that it is used only for one purpose or so called “at one level”, i.e. the cascaded use is not applicated. However, we can achieve increased effectiveness if we harmonize the relation between the heat demand and energy supply.

The heat demand depends on one crucial factor and this is the weather or season. The energy supply of geothermal energy is practically constant because the temperature of the geothermal water on the well head is the same for the whole year. The production of well depends on whether there is or is not a pump. Majority of the geothermal wells in Slovak Republic do not have pump and if they do, the pump is with constant speed, therefore no quantitative regulation exists.

METHODS

A more respectable approach to the use of geothermal energy is shown in this article. The main emphasis is given to the relation between the heat demand an energy supply. The relation is demonstrated at a particular geothermal well FGT-1, which is situated in a small village – Topoľniky. The characteristic values of the geothermal well FGT-1 are: the temperature of the geothermal water $\theta_o = 74$ °C and the production of the well $m_0 = 23{,}0$ l/s.

Characteristic parameters for the geothermal well are: available energy potential Q´ (kW), available energy quantum Q (MWh) and available volume of geothermal water M (m^3).

$$Q' = m_0.c_v.\rho.(\theta_0-\theta_r) \qquad (1)$$

$$Q = 24.Q'.n.10^{-3} \qquad (2)$$

$$M = m_0.n.24.3600.10^{-3} \qquad (3)$$

where m_0 is the production of the geothermal well (l/s), c_v is the specific heat of water (J/kg.K), ρ is the specific gravity of water (kg/m^3),θ_0 is the temperature of water at the geothermal well head (°C), θ_r is the reference temperature of down cooling (°C), n is the number of days (day).

The characteristic parameters of the well FGT-1 used as input data to the calculations are presented in the table 1.

Table 1 Characteristic parameters of the geothermal well FGT-1

Period	**n (day)**	**Q´(kW)**	**Q (MWh)**	**Q (GJ)**	**M (m^3)**
Day	1	5 682	136	489	1 987
Week	7	5 682	955	3 438	13 910
Month	30	5 682	4 091	14 728	59 616
Summer season	62	5 682	8 455	30 438	123 206
Winter season	**202**	**5 682**	**27 546**	**99 166**	**401 414**
Transition period	101	5 682	13 773	49 583	200 707

The reference temperature in Slovakia is $\theta_r = +15$ °C, which is the average statistical temperature and it is calculated as an annual average based on the average month temperature of the discharging waste geothermal water. In the summer the reference temperature is in the range from + 22 °C to + 26 °C and in the winter the reference temperature is in the range from + 4 °C to +8 °C. The energy quantum of geothermal well FGT-1 for winter is calculated for the reference temperature $\theta_r = +20$ °C. This temperature is much more satisfactory and available than the reference temperature $\theta_r = +15$ °C. From the table 1 it is evident, that in the winter season we have 401 414 m^3 of geothermal water and 27 546 MWh of energy quantum at disposal from the geothermal well.

The geothermal water from the geothermal well FGT-1 supplies 7 equal greenhouses. Each greenhouse is 93,12 m long and 24,77 m wide. The height to the side board of the greenhouse is 2,4 m and to the top of the greenhouse is 4,03 m. The heat requirement of one greenhouse is approximately 550 kW, so the total heat requirement from the extraction site is
7 x 550 = 3 850 kW.

RESULTS

The table 2 presents the heat requirements of the greenhouses depending on the year season without the regulation on the geothermal well head. The map curve of the heat demand of the greenhouses without the regulation on geothermal well head in shown on the Figure 1.

Table 2 Heat requirements of the greenhouses – without regulation

Parameter	Month						
	10	**11**	**12**	**1**	**2**	**3**	**4**
Average outside air temperature (°C)	11,0	5,1	1,1	-1,0	0,9	6,0	11,1

DISCUSSION

The utilization of geothermal energy is considered efficient when 90% is used and 10% held as a reserve. The table 2 in the results section shows that the geothermal well FGT-1 is not utilized to this extent even in the coldest moths of the year as December, January and February. However the utilization in the coldest moths of the year is 77%, which is considered satisfactory. The utilization in the months March and November is very low but in October and April it is insufficient. To increase the exploitation in more effective way, the regulation of the production on the geothermal well head according to the heat demand of the greenhouses in each month should be employed. The benefits of the regulation are clearly visible from the results presented in the table 3 and figure 2. It shows that the utilization of the geothermal well FGT-1 is approximately 91% and the rest of the geothermal energy serves as the reserve. In the coldest months the production of the geothermal well is reduced to the value m_1 = 19,5 l/s; in March and November it is reduced to the value m_2 = 14,6 l/s and in October and April to the value m_3 = 6,4 l/s. This approach to the utilization of geothermal energy ensures a reserve of approximately 10 % of the energy in each month.

In the stated example in the coldest months the production of the well with the regulation on the geothermal well head reaches only 85% in comparison to the measured value on the well head. This shows that in the area of the village Topoľniky more than seven greenhouses could be supplied by this well. If the production would be the full 23,0 l/s, ten equal greenhouses could be heated. The regulation of production on the well head ensures preferable map of curve for the greenhouses and the reserve of energy in each month is constant.

Another approach suggests that in the coldest months more geothermal water would be pumped out of the well than it is calculated for these months, but the overall quantity of geothermal water needed for winter season should not be exceeded. Therefore the use of this kind of regulation on the well head would provide supply of geothermal water for more than seven or ten greenhouses. In the coldest months of the year (December, January and February) the production would be increased and would be higher than it is measured on the well head. But in other months the production would be reduced according to the needs of the season.

These two examples show us that the regulation on the well head brings these advantages:

- elongation the lifetime of geothermal well in general,
- constant percentage utilization of geothermal energy during winter season,
- increase of amount of point of supply (e. g. more greenhouses heated with geothermal water).

SUMMARY

New distributed simulation environment has been used to simulate the energy flows in a simple case community consisting of four buildings, power plant and a district heating network. Distributing computing task on different computers accelerates the simulation, but simultaneously some time is spent on communication. The tests indicated that a one year energy simulation of a community could be performed within 3.5-10 days of calendar time depending on the time step used. It was also found that the Internet-communication of data takes approximately 20-25 % of the total simulation time. This share may be even higher if simulated case covers frequent energy consumption peaks and simultaneously high degree of accuracy for the results is required. For optimal performance in the future, the models should be able to recognize steep gradients and adjust the time step accordingly.

INTRODUCTION

This paper presents first results of the simulations covering the whole energy chain extending from the generation site (power plant) through district heating network to the consumption site (buildings). To perform this task, a new distributed computing environment was developed. The basic idea of a distributed simulation environment has been presented in our earlier publication [1] and elaborated in new context, in which building simulators and district heating network simulator are linked. The necessary ICT-architecture was defined to handle the environment stability under consideration of different requirements (convergence, data exchange, security). Considerable effort was spent to sustain a generic approach when defining the requirements.

There is a possibility to have a benefit of using distributed simulation environment, which enables time-consuming simulations to be faster. In addition, the distributed computing with certain rules enables totally new dynamic simulations for the energy system, for example: buildings, district heating networks and power plants simulated synchronized as a whole. Furthermore, anticipating that generic service rules and connection methodology existed, it would be considerably easier in the future to expand an open architecture by linking new models. Our approach utilizes generic ICT-components and interfaces used in distributed solution environment to handle coupling challenge between different simulation platforms. The distributed solution environment can be run over the internet or LAN-networks.

SIMULATION ENVIRONMENT

The distributed generation needs new type of analysis tools to design and to optimize the energy chains from the power plants (both large and small scale) to the consumption points.

Traditional large scale production-consuming environment is less complicated than distributed and can be handled with separate modeling and simulation tools with sufficient accuracy. The suggested distributed generation environment needs new tools to handle the challenging multi-production and multi-consuming phenomena in the transmission networks to enhance the quality of the design and optimize the use of the energy system.

In this context, our simulation environment consists of building simulators and their connections to the district heating network simulator,
Figure 1. The interaction between programs and the synchronization of the simulation is performed by the Master-program. The Master is responsible for handling the data exchange, the project data and the other simulation specific features between the simulator services.

There can be several simulator-instances running on their own hardware, but for simplicity reasons there is only one of each presented in
Figure 1. The connections between different actors (marked as two-headed arrows) are implemented on the WebService technology. By definition, all actors have a WebService-interface. The approach is generic and allows new simulators to be added later on (e.g. marked shadowed in
Figure 1).

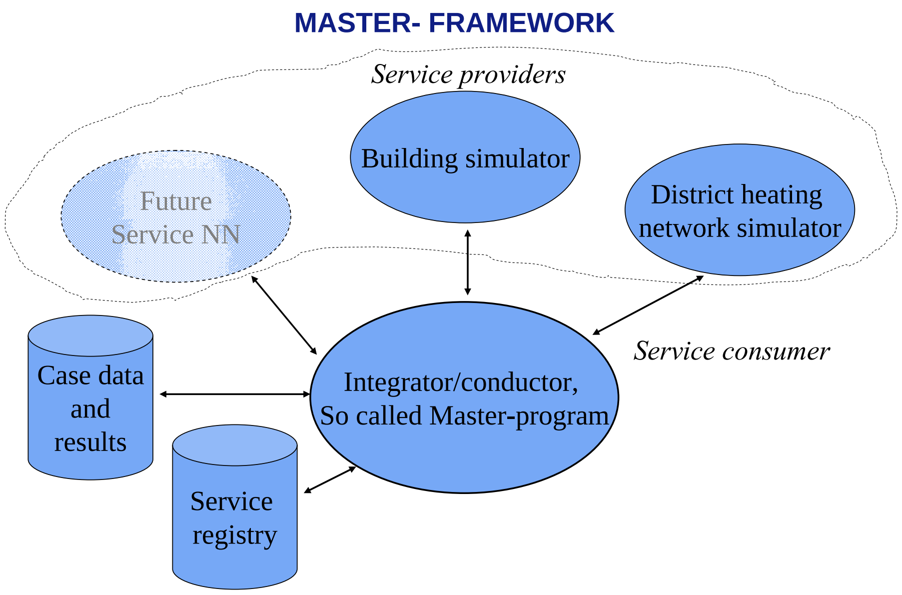

Figure 1. The framework of connections between the building simulator and the district heating network simulator.

Substation model (pT-adapter)

The building heating system as well as the eventual local heat generation system is connected to the district heating network by means of a substation. The main components in a substation are the heat exchangers but also pumps, pipes, valves and controllers are needed. From the modeling point of view, the temperatures and pressures at the coupling points are the parameters that ultimately determine the heat and mass flow and therefore the substation model is called a pT-adapter.
A dynamic simulation model for a counter flow heat exchanger is easily implemented by connecting thermally the two heat exchanging flow channels and dividing them into a number

of successive elements, in order to take into account the variable temperature difference between the two streams in different parts of the heat exchanger. But it was found that a large number of elements are needed if good predicting accuracy is required: about 40 elements are necessary to compute the heat power within 2 % accuracy.

A more accurate modeling option is to use conventional equations for thermal efficiency of a counter flow heat exchanger but then we lose the transient behavior inside the heat exchanger. This is unlikely to be a major restriction because normally plate heat exchangers are used, which have a low mass and a small water volume and therefore this kind of modeling is preferred.

To accurately simulate the behavior of commercial counter-flow plate heat exchangers, we need to know the product data, namely the heat transfer correlations and pressure loss correlations of the flow channels. A new method was developed to extract this data from the results of the manufacturer's simulation program, or from measured results. Then it is possible to size the heat exchanger for the simulations based on the design heat power and pressure losses, the result being the size and number of the heat transfer plates, as shown in Figure 2. All this information is subsequently needed when the heat exchanger is used in the actual simulations.

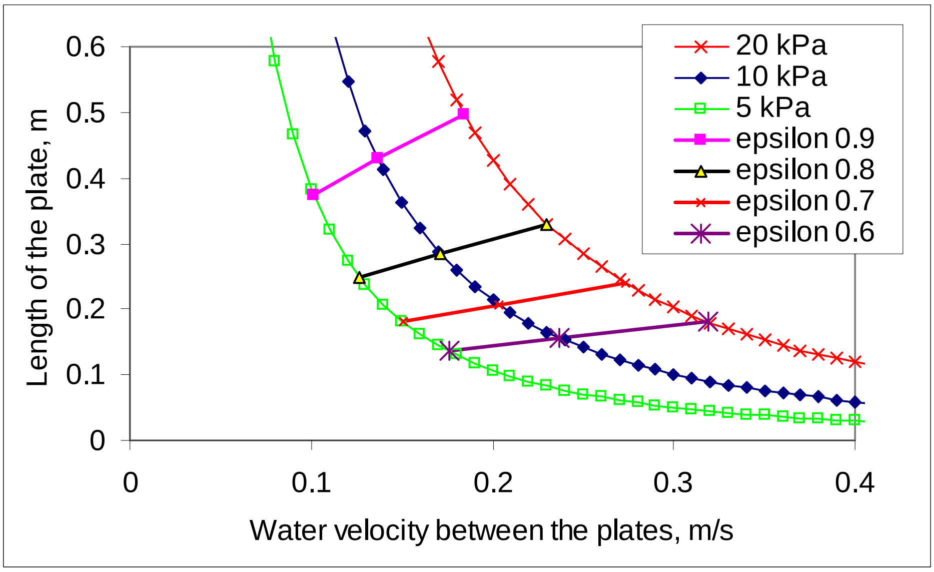

Figure 2. An example of sizing of a plate heat exchanger for district heating.

The intersections of the efficiency and pressure loss lines determine the plate dimensions and the water velocity in Figure 2. The number of plates depends on the required design heat output. The heat transfer and pressure loss properties have been extracted from the manufacturer data.

SIMULATION CASE AND RESULTS

The simulated test case is a simple district heating network consisting of four consumers with varying heat loads and a heating plant supplying the needed energy, Figure 3. Energy consumption in each building was calculated using building energy simulation software. The district heating network along with the heating plant was modelled by a network model. The building and network models communicate through a Master-application. The test application was a totally new whole simulation of a community in Nordic climate (a district heating network together with buildings). The application covered both the hydraulic and the thermal flows in the networks as well as the indoor climate conditions in the buildings.

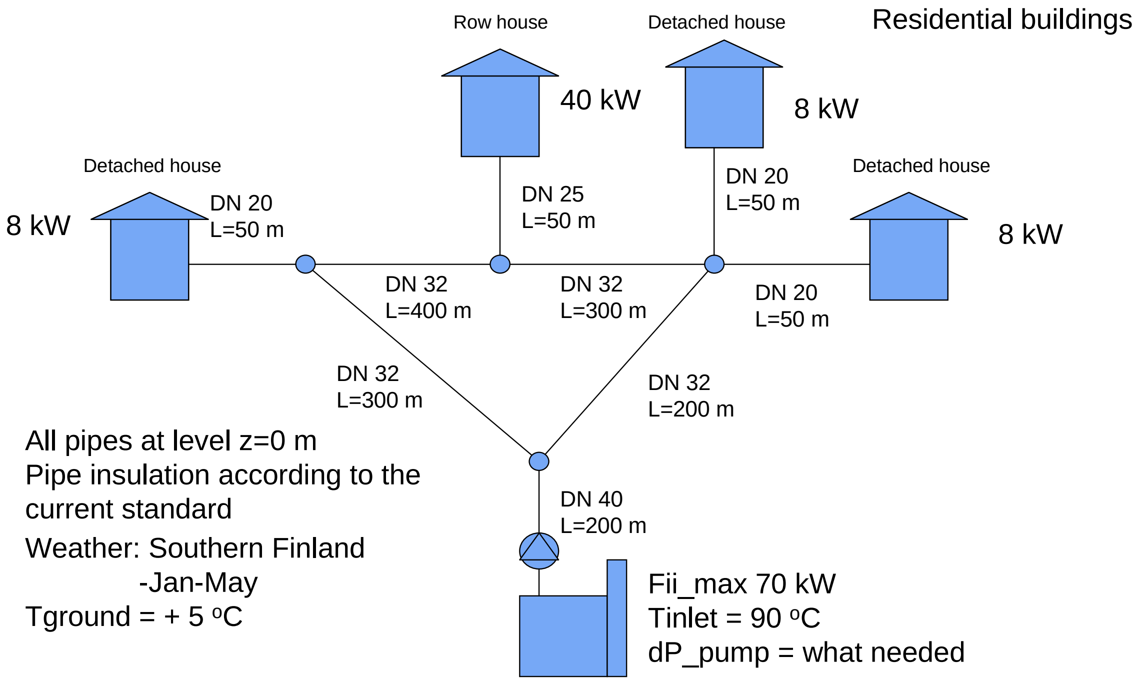

Figure 3. Schematic representation of the simulated case.

All the data produced by the models is made available for the Master-application. In this examination, only the variables needed to construct energy balances were recorded in an output file. These variables were the supply and return temperatures in the consumer and heating plant nodes, mass flows and heat losses in the network. Additionally, the total heat power demand and the variables concerning the tapping hot water, temperatures and mass flow, were recorded for every building.

The heating demand of the buildings and the heat losses in the network were compared to the heating power produced by the heating plant. Also, the consumption of an individual building was compared to the heating power received from the district heating network. The longer term results for the entire network are summarised in Table 1.

Table 1. Energy consumption for long simulation (19 weeks) and relative differences between energy balances calculated by the building energy simulation tool and district heating network simulation tool.

(kWh) -->	13 400	32 400	14 100	15 800	165 200
external time step	Building 1	Building 2	Building 3	Building 4	Power Plant
900 s	1.5 %	0.4 %	1.1 %	1.5 %	-6.6 %
600 s	1.9 %	-0.1 %	1.4 %	1.9 %	-4.9 %
480 s	1.8 %	0.1 %	1.2 %	1.8 %	-3.9 %
300 s	1.0 %	0.1 %	0.8 %	1.0 %	-2.3 %
120 s	0.7 %	0.2 %	0.6 %	0.7 %	-0.1 %
20 s	0.6 %	0.2 %	0.5 %	0.6 %	1.3 %

The results imply that reducing the time step improves the match of energy balances. Closer examination of the dynamic variation of the heating power demand for a single building showed that the load due to basic heating of a building can be calculated with longer time step, because the changes are slow. However, any hot water tapping in the buildings cause rapid changes in the consumption and should be calculated using a shorter time step to improve accuracy, see Figure 4. In the future, the models should be able to recognize steep gradients and adjust the time step automatically.

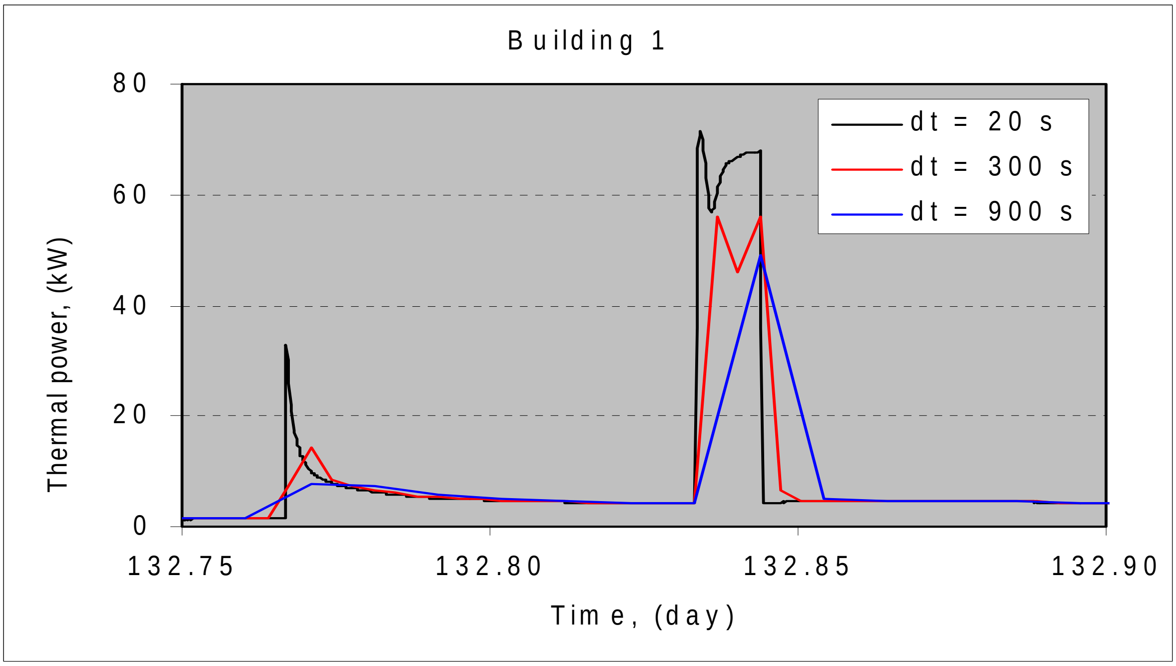

Figure 4. Example of simulated thermal load peak due to hot water consumption in Building 1 (time step is a parameter).

The performance of the distributed simulation environment

Several simulations with various external time-steps were carried out to investigate the general performance of the distributed simulation environment. The hardware set of the distributed simulation environment consists of 4 different desktop-PC:s. Table 2 shows the hardware and software configuration used to simulate the test case. The configuration was first fine-tuned and tested to have balanced load for all hardware components. It was found out that the most computing intensive part of the test case was the building simulator. The district heating network required less computational effort and the Master was easiest to compute.

Table 2. The hardware and software configuration of the distributed simulation environment.

Softaware type	Hardware configuration	Software configuration
Building simulator	Intel 2 CPU 6600	2 x VTT House
Building simulator	Intel 2 CPU 6600	2 x VTT House
District heating network simulator	PC Pentium III	1 x Matlab network simulator
Integrator	PC Pentium IV	1 x Master-program

Test simulations covered the 19 weeks period from Jan 1st to May 15th with external time-steps 20 s, 120 s, 300 s, 480 s 600 s and 900 s. The external time step refers to the data update interval in the Master-program. Both the building simulator and the network simulator may internally use shorter time step when needed. The simulation speed-factor, which means how much faster the simulation is when compared to the real time clock, varied from the 37 to 100. This means that depending on the time step, the full yearly simulation of a test community would last from 3.5 days (dt = 900 s) to 10 days (dt = 20 s).

Using distributed simulation reduces the computing time, but on the other hand some time is spent on communication between the simulators and the integrator program. This latter effect was studied by comparing the shares of the Internet communication time in the external time step. The test simulation with various external time-steps showed that the average network interaction time between the Master and the simulators was 0.361 seconds during one external time-step. This value remained nearly constant in different simulations. Figure 5 shows the average relative share of the Internet communication traffic time plotted against various external time-steps. It can be seen that relative duration of the network traffic drops quickly as the external time-step of the Master-program increases.

For example, during the hot water tapping in the building – when shorter external time steps are necessary – the Internet network traffic of the distributed simulation environment can represent more than half of the total simulation time. When these results are generalized to the community level, it means that mornings (from 7 to 10 am) and evenings (from 8 to 10 pm) are the slowest to simulate. Assuming 5 h of shorter external time step (20 s) and 19 h of longer external time-step (300 s) per one simulated day, the communication would take from 20 % to 25 % of the total simulation time.

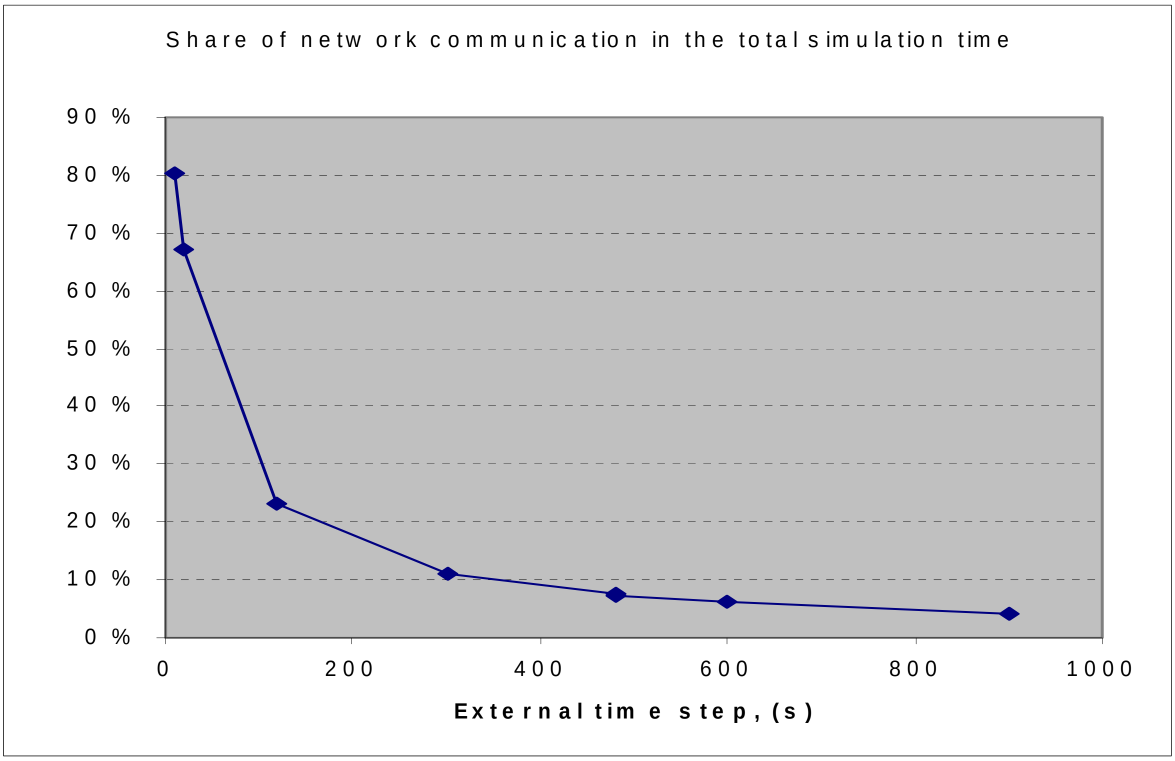

Figure 5. Share of the Internet-network communication time in the total simulation time.

CONCLUSIONS

In reality buildings connect to the district heating network in substations. There are two options to model the heat exchangers in the substation: the dynamic model is computationally heavy whereas the static one may lose some very fast transients. A method was developed for extracting the necessary heat exchanger information from the manufacturer provided data.

New distributed simulation environment has been created and used to simulate the energy flows in a simple case community consisting of four buildings, power plant and a district heating network. To carry out this task, building simulations and district heating network simulation were all performed in different computers linked through the Internet to a Master-program.

Using distributed simulation considerably accelerates computation, but simultaneously some time is spent on communication between the simulators and the integrator program.

It was found that for a typical community level energy simulation the Internet-communication of data may take approximately 20 - 25 % of the total simulation time. This is based on an assumption that more intensive computing is required during the hot water tapping peaks in the mornings and in the evenings. The time share of Internet communication may be even higher if simulated case covers numerous energy consumption peaks and simultaneously high degree of accuracy for the results is required. For optimal performance in the future, the models should be able to recognize steep gradients and adjust the time step accordingly.

SUMMARY

This paper is devoted to the development of a decision support system that could assist district heating authorities in strategic management of their asset. Such a tool is designed in order to answer a variety of questions asked by concerned stakeholders regarding the future of a district heating (DH) system about optimal plant and fuel choice, possible network extension, valorisation of heat surplus, etc.
The kernel of this system is a simulation model which determines the energy balance of a given DH network, over any type period. The time period is cut into different time steps, assuming steady state on each time step.
At each time step, a linear programming LP based approach is used in order to compute the optimal combination of heat power at the plants to meet the demand. The modelling problem is formulated on a graph and LP as the search for minimum energy production cost rooted at the sources.

INTRODUCTION

District heating (DH) is presently considered in Europe as a challenging technology, both as a great step toward sustainability of energy systems and as a powerful instrument for local energy policy managed by communities. The bases for establishing a DH supply is the possibility of obtaining higher efficiency and thereby lower heating costs when producing the heat in few large plants than when using small private boiler units. DH supply gives also the opportunity to utilise waste heat, that otherwise could not be used, especially from incineration plants. DH is also a good way to make efficient use of other local and renewable energy resources such as biomass, biogas, geothermy and to develop cogeneration. Moreover, environmental issues have lead to an even greater interest in DH supply, due to the possibility of cost-effective flue gas treatment in centralised plants, in order to limit local atmospheric pollution, or in the near future, CO_2 emissions.

The need for tools for decision making and strategic management is therefore obvious. The control and strategic management of a DH network is a complex process in which different factors like costs, availability, heat losses and environmental impacts must be taken into account. For this reason, mathematical aided models are being increasingly in use in order to identify the best decision factors in different operating situations and scenarios.
Examples of scenarios to be evaluated are : i) Refurbishment and extension of the DH system ; ii) Changing energy sources or plants ; iii) Variation of the heat demand ;
iv) Changes in control and operational management of the DH ; v) Defining new policies in heat pricing and connections. An important feature is also *ex-post* evaluation of network

operating, in particular when DH is operated by a private company, under authority of the community.

These models require appropriate mathematical description of the different subsystems which form the DH. Typical methods account for simulation by minimizing operational DH costs. A literature study has shown that several methods have been proposed for minimisation of the operational cost of DH systems, but only very few references include case studies where the suggested methods are general and could be applied to any network. Due to the great complexity of the problem, most of the references suggest methods which only regard some parts of the total problem, while other parts are not considered or treated separately. The proposed methods can, thus, be divided into two categories:

(1) Strategic and mid/long term models which includes two subgroups:

- Determination of the optimum load distribution between different heat producing units, in a well specified DH system: network topology, energy supply and heat plants are known. DH supply temperature is considered constant or predetermined and DH networks dynamics is disregarded. Approaches in this area include markedly the linear programming and mixed integer programming techniques as solving algorithms, at each time step [5] [6] [7]. This type of modelling cannot be actually considered as an optimisation approach (although an optimisation algorithm is performed), but rather a time-dependent simulation of a given DH system under specified conditions.

- Optimisation of the network structure by looking for the best construction and operational cost. These methods discuss namely the geometric optimization of the DH distribution system and the choice of the most cost-effective heat plants (to be build) and energy sources, accounting for investment and operation costs [9] [12]. Linear programming and mixed integer programming techniques are generally used as solving algorithms as well, but they incorporate a global cost optimisation over a long-time horizon.

(2) Fully dynamic optimization determining the optimum supply temperatures and system control, often related to operational studies. Some dynamic approaches, based on an aggregation of the DH network, are discussed by a number of authors [3] [4] [8], but a general method for solving the problem does not exist today.

The model proposed in this paper is aimed to emulate the DH running on a given period, either from the past, on the basis of historical data, or for scenarios of the future. The simulation model investigates the energy balance in each time step. The environmental and economic balances could be recognised. The model is a masterpiece of a strategic management tool that includes as well detailed data bases on the DH network e.g. outside temperature records, heat load, maximum heating power, heat losses, etc.

The model could assist decision makers in evaluating the impact of several strategic choices, by simulating the effect of different scenarios related to the introduction of new heating plants, new consumers, etc. Nevertheless, in a perspective of decision support, when the number of potential scenarios to be tested is high or a very large panel of actions is possible, the simulation model is not always sufficient. So it could be complemented and coupled with an optimization module in order to identify the optimal choice of plants, energy sources and

sizing of components. Anyway, the simulation model remains the kernel of the decision support tool.
For the real time control and operating, other tools based on thermo-hydraulic modelling or optimal dynamic control optimisation could be more reliable.

METHODS

The proposed model concerns a completely defined DH system, with given set of power plants and heating demand, and looks for determining the overall DH thermal balance and power flows in the DH network at each time step, under external conditions. As we will see, the model is based on a linear programming formulation. The decision variables are the heat flows in DH pipes. The constraints are of two kinds. First, thermal properties of heat plants and DH pipes will restrict the range of heat flows and second, distributed energy should satisfy consumer (substation) heating demand at any time period.

Analytical formulation

A suitable method to describe a district heating pipe system is to use concepts from network theory. We define a district heating graph G as a set of branches and nodes. A branch is assumed to be a pipe; a node could be a substation or a heating plant. Heat flow is assumed to be directed *a priori* from one node to another and the graph is oriented.

Notations

The following notations are used as subscripts

i, i'	for substations	$1 \le i \le n$
k	for heat plants	$1 \le k \le p$
j	for network branches (lines)	$1 \le j \le m$

A branch j connects two nodes, either a substation i to another substation i' or a heating plant k to a substation i. The corresponding information is provided through connectivity matrices, defined below. *Su(i)* is the set of outlet branches (successor) of node i (substation), *Pr(i)* is the set of inlet branches (predecessor) of node i ; *Su(k)* is the set of outlet branches of node k (heat plant). Heat plant nodes are assumed to be without inlet branches.

At a given time step, the following parameters are assumed to be input data

Δt	the time step length.
P_i^{apl}	heat demand in substation i.
P_k^{max}	maximum heat power of plant k.
c_k	cost of fuel used in plant k.
η_k	efficiency of plant k.
p_j^{max}	maximal heat power transferred through pipe j.
L_j	heat loss in branch j.

Unknown variables, to be determined for each time step, are the heat flows in the network

p_j heat flow entering branch j.

Heat flow leaving a branch corresponds to (p_j - L_j), accounting for heat losses from pipes. Moreover, for each substation, two heat flows may be defined

P_i^- total heat flow leaving node i $$P_i^- = \sum_{j \in Su(i)} p_j \,, \qquad (1)$$

P_i^+ total heat flow entering node i $$P_i^+ = \sum_{j\in \Pr(i)} p_j - \sum_{j\in \Pr(i)} L_j \,, \qquad (2)$$

For each substation, the heat demand from consumers must be met, so the thermal balance leads to

$$P_i^+ = P_i^- + P_i^{apl} \,, \qquad (3)$$

Principle

The proposed model to determine the state variables p_j is based on the minimization of the heat production cost of the whole district system over each time step of a work period, with respect to energy balance (both at substation and heat plants) and thermal pipe capacity constraints. While expressing the objective function and the constraints as function of heat flows, it can be seen that all equations are linear.

The problem is stated to be at each time step as follows:

$$Minimize \;\; f(p_j) = \sum_{k\in Sources} \sum_{j\in su(k)} \frac{c_k}{\eta_k} \times p_j \times \Delta t \,, \qquad (4)$$

With constraints

$$\sum_{j\in \Pr(i)} p_j - \sum_{j\in \Pr(i)} L_j = \sum_{j\in Su(i)} p_j + P_i^{apl} \,, \qquad (5)$$

$$\sum_{j\in Su(k)} p_j \le P_k^{\max} \,, \qquad (6)$$

$$0 \le p_j \le p_j^{\max} \,, \qquad (7)$$

Matrix formulation

Preliminary implementation of the model was done under MATLAB. A graph structure was designed under Matlab as a schematic network layout of the DH system topology and the LINPROG function was used for optimisation. Like many linear programming routines, LINPROG uses the standard simplex algorithm to solve LP problems and it requires data in an LP standard format which is the following:

To find out the vector X minimizing $f = {}^t c \,.\, X$ subject to $$A \,.\, X = b$$ $$A' \,.\, X \le b'$$ $$u \le X \le v$$

Thus the inputs for this function (objective function, equalities and inequalities constraints) should be presented in a matrix format. Let's remind that we consider a DH system with n consumers (substations), m pipes and p heat plants.

The cost function f is written at each time step as a scalar product of two vectors c and P, where c contains the heat production costs (cost of fuel, divided by efficiency, + other possible proportional costs) and P is the unknown vector composed from the heat flows in the DH system pipes, p_j.

$$f = {}^t c \cdot P \,, \qquad (8)$$

Calculation of energy balance at each consumer (substation) is based on the first law of Kirchoff [11]. In order to express these equations in a matrix format we may define the connectivity matrix A of the DH representative graph as follows:

$$a(i,j)=\begin{cases}1, & \text{if the pipe } j \text{ is an incoming pipe for consumer } i.\\ -1, & \text{if the pipe } j \text{ is an outgoing pipe for consumer } i.\\ 0, & \text{if it's not connected.}\end{cases}, \qquad (9)$$

The connectivity matrix is an *n by m* matrix [1]: it has one column for each branch in the system and one row for each consumer. Each column can have two non zeros entries. The connectivity matrix expresses the inflows/outflows relationship in the district heating system.

Considering the energy balances equation at each substation (eqn. 3), the equality constraints of the DH model can be easily expressed as function of heat flows as:

$$A\,.\,P = b, \qquad (10)$$

Where b is the constant term, which contains the heating demand for each node, including heat losses from inlet branches.

$$b_i = P_i^{apl} + \sum_{j\in \Pr(i)} L_j\ , \qquad (11)$$

Inequality constraints express the inability of power plants to exceed a specific heating power value. We define as well a specific matrix denoted A' to present the inequality constraints in a linear format.

$$a'(k,j)=\begin{cases}1, & \text{if pipe } j \text{ is connected to source } k.\\ 0, & \text{otherwise.}\end{cases}, \qquad (12)$$

Hence, the inequality constraints could be expressed as function of the heat flows.

$$A'\,.\,X \le b'\ , \qquad (13)$$

Where b' contains the maximal heating power of each power plant.

The LP optimization routine LINPROG is called at each time step. The function inputs can be classified into two categories, variables and static parameters according to their values over each time step (see Fig. 1). Static inputs includes A and A' and they didn't depend on time since they are related to the network configuration. Variables parameters include the cost function f as well as second term parameters b and b'.

Typical simulation can be done with an hourly time step and a running period of one year, enabling to account for combined time variations of all input data (demand, energy price, heat plant characteristics). With additional assumptions on input data (constant demand, prices, availability, efficiencies), much longer time steps can be adopted, leading to faster simulation.

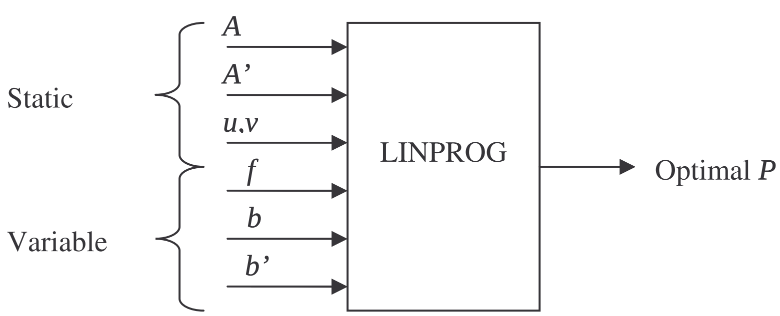

Figure 1. The optimisation routine, called at each time step

RESULTS

The aim of this section is to apply the proposed model in its hourly form to the district heating of Beaulieu Malakoff in Nantes. This district heating counts 20 km in length and 96 substations. The network provides approximately 115 GWh of energy to 16000 consumers. Incineration plants of municipal solid waste built in 1987 provides most of the heat for the network. The waste incinerator is modelled as an ordinary plant with variable maximum power and zero cost. The heat provided by an MSW incinerator is supposed to be totally free; the costs related to plant maintenance and waste transport are disregarded.
The maximum heating power of an MSW plant calculation is based on the lower heating value *LHV*(GJ/tons), the waste fuel rate *r* (tons/hour) and the boiler efficiency η thanks to this formula:

$$P_{\max} = LHV \times r \times \eta \,, \qquad (14)$$

The monthly values of LHV and waste fuel rate are used as inputs. Efficiencies are supposed to be constant and the availability of the plants is set to 100%.

The duration curve shows what proportion of heat production is attributed to each plant to satisfy the demand at any time. It may also give the start and stop moments in the heating plants.

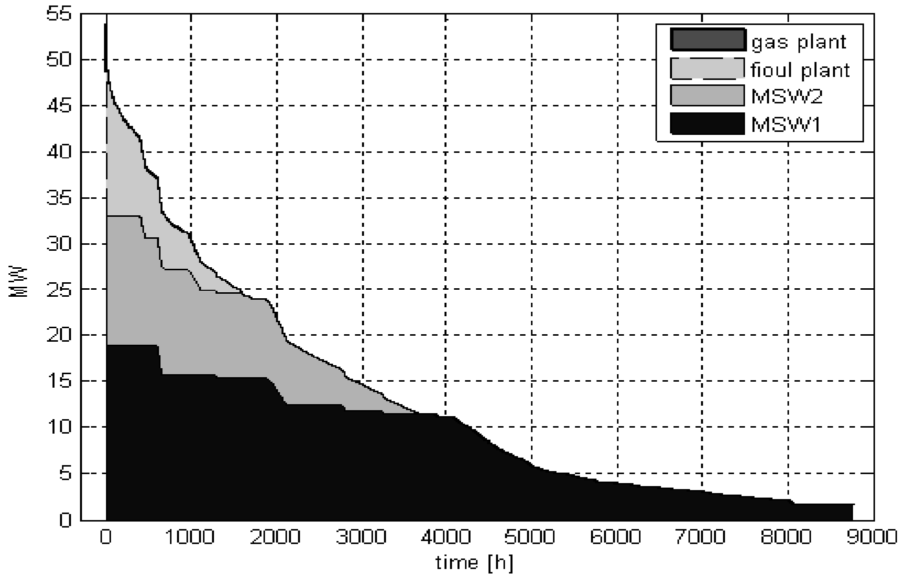

Figure 2. Load duration curve indicating the proportion of the heating plants

The duration curve as presented above shows in reality the production scheduling of the DH plants and their start and stop moments as function of heat load levels.

Table 1. Optimal heat production dispatching

Heat load range	Starting heating plant	Covering ratio
<12 MW	MSW1	67.8%
12-24 MW	MSW2	24%
24-49 MW	Fioul plant	7.9%
>49 MW	Gas plant	0.3%

Fossil basic plants are operational in peak loads; they cover the rest of the heat demand served basically by incinerators. The swap between the fossil heating plants depends obviously on the fuel cost. The model gives a priority to a boiler at a given moment if its fuel is the cheapest at that moment.

Table 2. Yearly balances (energy in GWh, costs in k€)

	Feed in primary side	Valorised heat	Heat surplus	tCO2 realised to the air	Running cost
Incinerators	235.9	105.3	95.2	60872	
Fuel boiler	10.6	9	0	2774	229.35
Gas boiler	0.02	0.015	0	4.19	

From a strategic point of view, the stakeholder could take decisions concerning heat production in the DH system in the future. For instance, assuming the same heat load for next years or using heat load forecasting techniques, the decision maker, by the aid of this model, will have an idea about the amount of energy in primary side required to cover the demand.

DISCUSSION

The mathematical model and algorithm presented in this work contributes as a first step toward the development of a fast, robust and accurate DH strategic planning tool. It can be considered as a general and flexible tool. In order to illustrate this flexibility, some examples are analysed below, considering the main features of district heating.

In term of **network characteristics**, the model is suitable whatever the topology of the network, hierarchical or looped network structure. Although the temperature of the network is not taken explicitly, DH systems with variable temperatures may be tackled. In most cases, flow and return temperatures depend on the total heat demand addressed to the network and can be computed at each time step, as an exogenous parameter (enabling to adjust input data varying with temperatures such as heat losses or heat plant characteristics). So, common network control strategies, either through fixed supply and return temperatures (and adjusted flow rate) or fixed flow rate (and adjusted supply temperature), can be considered by the model. Temporary problems taking place in the network, such as interruption or limitation of supply in a given branch, may be simulated by modifying the maximal heat power transferred through this pipe. Interconnection of a DH with other DH system(s) may also be considered easily. Pumping cost, which represents a non negligible fraction of operation costs (a few percents), can be modelled by giving a cost to heat transferred into branches where pumps are located.

Regarding the **energy demand** addressed to the network, the model may consider simplified demand profiles from consumer or very precise profiles from quite different types of consumers, depending only of the quality of available data and required accuracy. An interesting feature regarding demand is the possibility to simulate temporary and partial disconnection of some customers, using "virtual" heat plants associated to a cost of non-supply: interruption of demand is a service which can be provided by some customers to the network at a given contractual price.

Finally, the flexibility of the model concerns also **heat production plants**. A large variety of heat plant technologies are directly tackled, provided their maximal capacity and efficiency are known at each time step. This includes usual types of boilers, using fossil or renewable energy sources, whatever their cost. Waste heat, such as heat produced from domestic waste incineration plants, can be simulated, being considered as free energy source.

Availability of heat plants vs time (due to maintenance, e.g.) and time varying characteristics of the energy sources (price, lower heating value, maximum capacity) are considered through input parameters. For some heat plants, such as cogeneration, heat pumps or geothermal energy, their characteristics depend on network temperature. They may be simulated as well, as soon as this temperature is pre-determined at each time step.
The main limitation of the model is probably linked to the assumption of constant efficiency for each heat plant (considered as an input data for each time step, possibly varying with time). Efficiency depending on the load (with lower efficiency at partial load, e.g.) cannot be tackled by linear programming algorithm.

Thus, the model incorporates a lot of features, relevant for most of current district heating systems. It is being implemented as a master piece of a strategic management tool of district heating systems. In the same time, additional components are being considered for introduction in model equations, namely heat storage and complex cogeneration (including connection with electric grid).

INTRODUCTION

The district heating system should be accepted as a technical system, functionally and workable to provide heat for thermo technical needs of a higher number of different and connected us ers being located on a wider area usually in urban environment. The thermo technical needs of users mean the needs for heating, ventilation, air conditioning, and preparation of consume sanitary hot water and/or for special purposes. The district heating system on defined quality level provides heating and its delivery to users. The district heating systems are complex in their contents, conditioned in structure and non-alternative in processes and they may be active during heating season or during the entire calendar year.

The DHS is projected on the bases of established and emphasized requirements in written project task, on the level of consciences and expertise of engaged designers, of material, equipment and components being present on open market; after that it is realized by contractors having references and routines and after tests, regulations, technical checks and acceptances they are given to an investor for use in accordance with culture of users. The district heating system is projected and dimensioned for needs of defined environment but also for a longer period of its development; therefore it is constantly developed, reconstructed, revitalized and maintained up to limits of technical, ecological and economic justification in lifetime.

General model of structural arrangement of the DHS, on the level of a subsystem is timely defined [8].The structure is composed of seven constitutive subsystems from No 1 to No 7, where No 4 subsystem is recognized between them, being defined for direct exchange of heat in the sense of delivery of heat to users connected actively to the DHS. Practically, the No 4 subsystem integrates all substations in the one DHS and regularly with not a low number; for example in the town of Pozarevac there are cca 300 active substations in one DHS, and in the city of Kragujevac there are cca 1500 active substations in three DHS. Indisputably there are no DHS without the No 4 subsystem but the No 4 subsystem considerably effects representative quality of the DHS as a whole [10].

SUBSTATION AT DHS

The substation is an universal time determinant that in thermo-technical has single sense and meaning. The substation in thermo-technical is understood as a space, equipment and process for exchange of heat among tube exchanger (primary carrier of heat) and collector (secondary carrier of heat) within technical and technological control. The substation is real, physical and direct limited connection of the DHS and user.

The substation space belongs to the No 7 subsystem, the primary carrier of heat to the No 2, subsystem and the primary equipment to the No 4 subsystem. The secondary equipment in substations belongs to users connected to the DHS [8].

Algorithm composition is characterized for a thermo-technical substation regardless it is about single, group or zone substation [1]. Besides others, any substation equipment is adopted to type of heat, way of heat exchange, needs of users and the DHS concept in composition, contents and capacity.

Any substation consists of a defined group entity, namely of a constitutive group to provide certain process activities [6,7,8,9,10].

Any substation has to have its own particular functional and particular work capacity, and all together makes partial functional and partial work capacity of the No 4 subsystem [10]. Indicators and parameters being featured to the k substation are presented in the figure 1.

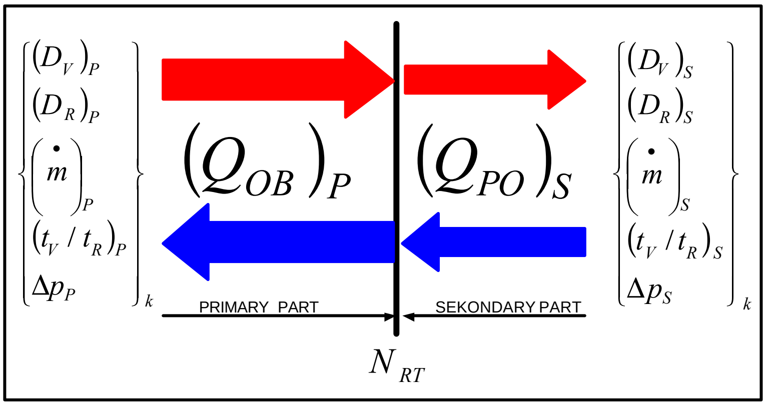

Figure 1. Indicators and parameters of autonomous substation of the DHS.

The process of heat exchanger, between the primary and the secondary heat carrier may substation, and then number, type and operating conditions of users are unchanged input parameters and quantity of heat required by users is changed input value. At any moment of exploitation period the users be recuperative done by surface heat exchanger and mixing, i.e. by elevators. In practice the first principle of heat exchange is more used.

The substation does not produce any heat but it may save some . Such saved heat has higher value than the newly produced one. The basic starting criteria for identification of substations are as follows: location of an object where the substation is located relating to the source (No 1 subsystem); disposition of the substation in the object relating to the magistrate primary pipeline; number, type, operating conditions and quantity of required heat from the subject substation; type and parameters of primary and secondary carrier of heat and way of heat exchange; presence of content components in the substation; structural component arrangement of substation; level of regularity and level of process control on activities in substation.

Users of substation of k subsystem may have status of active, passive and potentional user.

Nominal required heat power of substation has to meet the needs for heat of all users connected to that substation.

SUBSTATION AND THERMO-TECHNICAL DOUBTS

Substation is projected based on the group of reliable starting data such as data on number, type, operating conditions and required heat quantity of every user connected to the substation and for projected conditions, for example outside project heat temperature. It is tacitly considered that in that way quantitative and qualitative needs of users are provided at any moment of exploitation period. Based on final project the substation is constructed and its structural and content complete works are done. Conditionally may be accepted that structural and content composition of substation, and then number, type and operating conditions of users are unchanged input parameters and quantity of heat required by users is changed input value. At any moment of exploitation period the users of k substation require certain quantity of heat from the syste m that is provided directly through the substation. Such required quantity of heat goes from 0 to maximum, i.e. higher limited value. It is undisputedly that the heat exchanger has to provide, on the secondary side, every required heat quantity, even the maximal one. It is also undisputedly that necessary conditions for fulfill of primary task have to be realized by structural and content composition of substation. When the parity of required and provided quantity of heat is realized during the exploitation period, it is said that such substation owns particular functional capacity [10]. A serious question is made: Is it possible, on reliable and energetically effective way, to provide parity of required and delivered quantity of heat at any moment of the exploitation period by conventional, structural and content substation composition? Since it is very complex and important question, and having in mind there is no much room in this paper but to give answer to this question we further analyze the heat exchanger in the k substation only. In this analyze we start with the following assumptions: users use heat during the heating season; projected heat conditions are known for zone of users; heat exchanger is recuperative, in standard; on projected conditions the users require defined heat quantity; selection on producer, type and size of heat exchanger for projected conditions are selected; the heat exchanger has appropriate heat power; regulation of heat efficiency for heat exchanger is made on qualitative principe which means that mass flow rate of heat carriers from primary and secondary heat exchanger sides are stable.

Heat exchanger and thermotechnical doubts

In selected prospect for producer of heat exchanger it is usually mentioned data «heat power of exchanger» is presented as entire number in tens but it is not mentioned if the heat power is on primary or secondary side. Due to unavoidable disipational processes during exchange of heat in the exchanger, the unparity (NRT)P > (NRT)S is uncontested. At calculation and selection of heat exchanger it is usual to reach needed heat power which number value is not the whole number and not in tens. A projector always takes higher value, i.e. higher tens value while selecting heat exchanger. Calculation of heat exchanger is made for outside project temperature, even it is rare during the heating season, for which average outside temperature is prevailingly. Practically, heat exchanger is used during the heating season, under optimal performances. Inertia of primary side, static construction of heat exchanger and dynamism of secondary side based on required heat quantity cause absence of acceptable correlation between the required and delivered heat quantity. Practically, oscillatory unsynchronized exchange of heat is present within limited surplus and deficit state.

Changing of temperature of primary and secondary heat carriers during heating season stipulates variability of coefficient of heat flow and heat flux in the heat exchanger.

Process of exchange of heat in the heat exchanger is done through firm surfaces which they are disturbed with two heat carriers of various temperature initiating formation of deposit on such surfaces and in that way resistance to heat conduct is increased with obligatory reduce of exchange efficiency.

The primary heat carrier circulates through the whole DHS, taking in and out firm, fluid and gas contents.

A part of that content comes also to the heat exchanger, surely to the primary side, going through it or stopping there. These unwanted contents disturb circulation of the heat carrier and in that way they reduce efficiency of the exchange. Similar happens to the secondary side of the heat exchanger. The heat exchanger owns a conceived sensibility to any degradation and/or loss of system functional and/or work capacity that may directly affect the exchange efficiency [2,3].

Outside conditions may inflict needs to users for quantity of heat with even higher values than being calculated for the projected conditions, which objectively exceed real possibilities of the heat exchanger and it becomes insufficiently strong. Circumstances, conditions and function of the heat exchanger in substation point out undoubtfully that we cannot speak on acceptable and reliable energetic determinism.

SUBSTATIONS AND ENERGETIC EFFICIENCY

Heat quantity, requested by users during exploitation period, is surely indeterminist value.

Nominal heat power of the substation is a fix value during exploitation period.

Heat driving power of the substation is understood as substation heat power being equal to real exchanged heat quantity under real conditions, between the primary and secondary heat carriers, at defined time, during substation active function. We differ the driving heat power on projected work regime and on current work regime. Nominal heat power of the substation is understood as substation heat power at ideal heat exchange and it does not depend on real exchanged heat quantity between the primary and secondary heat carriers. Energetic efficiency of the substation goes from 0 to 1 and it means the relationship between the driving and regular substation heat power. During the exploitation period the energetic efficiency of the substation vary within possible values, it represents an indicator for defined k substation and it differs in values for every substation of the same district heating system. The intention is to overcome discrepancy between the requested and delivered heat quantity by constitutive group No 4.8, but it still does not mean that the substation energetic efficiency is improved. The provided heat quantity is possible to vary on three characteristic ways such as: using temperature of the primary heat carrier; changing the flow of the primary heat carrier; and changing simultaneously the temperature and flow of the primary heat carrier; but under condition that involved heat quantity is higher than the provided one, namely the requested one, since there is no sense for inverted combination. Practically, the requested heat quantity is formed from the provided one and the provided heat quantity is formed from the involved one as being presented in the figure 2.

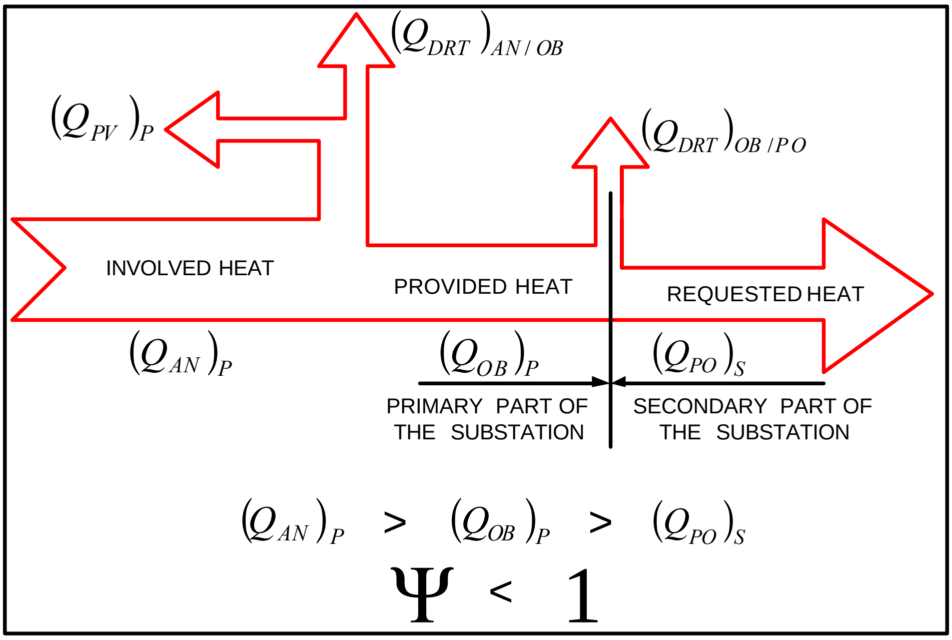

Figure 2. Diagram of heat flows in substation.

By technical-technological improvement of the structure and content composition of the substation and by improvement of the process activity it is possible to reduce the difference between the involved, provided and requested heat quantity.

SUBSTATIONS AT DHS IN THE TOWN OF POZAREVAC

The district heating system of the town of Pozarevac is unique in Serbia or wider in many specific features. The source of heat is located in thermal plant „KOSTOLAC“, where appropriate exchanging substation is constructed that practically makes the subsystem No 1, in the subject district heating system [11].

For needs in heat of places such as Kostolac, Klenovnik, Cirikovac and the town of Pozarevac, regular heat power of 315 MW is reserved. The magistrate conduit of cca 10 kilometers is made of seam steel tubes of Ø 660,4 x 7,1 mm diameter and it connects the No 1ubsystem with users from the town of Pozarevac. The primary heat carrier on the projected regime (-18 °C), is hot water of 130/75 °C temperature and with pressure of NP 16 bars. The secondary heat carrier is hot water of 90/70 °C temperature on the projected conditions. Until now for users in the town of Pozarevac, cca 150 MW of heat power has been involved, which is less than 50% of reserved regular available heat power.

The users are connected to the system through individual, group and zone substations. For now there are cca 170 of individual substations with regular heat power of 10 to 100 KW, and cca 100 of group and zone substations with regular heat power of 80 to 5300 KW. Drum or plate recuperative heat exchangers are installed into substations. The difference between regular heat power and driving heat power on projected conditions is evident of cca 30%. If it is known that average temperature for the town of Pozarevac is + 4,5 0C, than we reach a serious data that the process activity in the substations of this district heating system is performed under unfavorable energetic efficiency.

CONCLUSION

Nominal heat power of the substation is mostly increased by 30% regarding driving heat power on projected conditions, namely, increased by 60% regarding driving heat power at average heating temperature. Heat is no effectively used and the thermotechnical complex is seriously jeopardized. We cannot be satisfied with the existing condition and processes in substations of the district heating systems from the aspects of energetic efficiency. Practically, all advantages and opportunities offered by the district heating systems are not used, namely they are disgraced, according to traditional structural and content composition and process activities in existing substations. Samples of such conditions are numerous, and known, thus the following should be done to improve the conditions and eliminate the sequent: work on and application of standards and regulations in the field of district heating systems; improvement of existing and development of new components, apparatus and equipment used for substations and district heating systems; wean of projectors out of dangerous habits and procedures, based on their inertial brains; training of construction workers in the sense of development of new capabilities; development of culture of users; care of „heating“ cult, as a precondition to keep the development of thermo-technical complex and urgently, with results and global reconstructive improvement of the existing district heating system.

Special attention should be paid to innovation of the heat exchanger in the sense of its „revival“.

Energetic efficiency as a criterion parameter is very grateful in analyses as also being confirmed in this occasion.

ABBREVIATIONS, DESIGNATIONS, SYMBOLS AND INDEXES

DHS	district heating system
N (KW)	heat power
Ψ (-)	energetic efficiency of substation
No ...	numbering of subsystem or constitutive group
Q (W)	heat quantity
q (W/m²)	heat flux
R (m²K/W)	eat resistance in heat duct
A (m²)	Surface of heat exchange
k (W/m²K)	Coefficient of heat duct
c (KJ/kgK)	Specific heat capacity
t (°C)	Temperature
ΔT (K)	Temperature difference
t(s)	time
$\dot{m}$ (kg/s)	Mass flow of heat carrier
D (mm)	Tube diameter
Δ p (bar)	Dissipation pressure outlay

SUMMARY

PREA is a joint project between four European Universities and three African Universities as well as the International Solar Energy Society (ISES), an international NGO, that promotes renewable energy. The aim of PREA is to reduce poverty by influencing energy policy and regulations in Africa, through training and capacity-building of energy professionals, regulators, academics as well as policy- and decision-makers to enhance their skills in implementing Renewable Energy Technologies (RETs) and Energy Efficiency (EE) in buildings in Africa starting with three countries, namely South Africa, Tanzania and Uganda. Training will be offered through Workshops and a Masters Degree Course in Integration of Renewable Energy in Buildings (IREB), both made to suit local requirements in climate, economic and cultural conditions and allowing for exchange and further training opportunities.

INTRODUCTION

Africa is the only continent on this planet that sits squarely on the equator and where both the tropics of Cancer and Capricorn pass through its land mass. Thus Africa is mostly tropical but local microclimate in various parts it are modified by other factors such as relief and proximity to natural features such as mountain ranges and big water masses. Africa boasts of different forms of natural vegetation raging from dense tropical rain forests through grasslands to scrubland and deserts. The biggest desert in Africa is the Sahara. All these features give Africa a unique position in potential on the world renewable energy map.
It has 95% of the world's best sunshine and a huge potential of hydro, wind, bio and geothermal energies.

However, despite the fact that on one hand the African continent is endowed with vast resources of renewable energies (RE), but on the other hand, the energy situation in most African countries is desperate.

For example in Uganda and Tanzania only 10% of the total population has access to electricity at all, the main energy source is biomass, usually in the form of firewood, or charcoal. For the few urban and very few rural areas that are connected to electricity grid, supply failure resulting in blackouts and brownouts is a frequent and increasingly regular phenomenon.

There is, therefore, an urgent need to address RE and energy efficiency (EE) in order to improve the energy situation in an environmentally friendly and sustainable way.

One starting point to implementing RE and EE strategies in Africa is to focus on energy use in buildings, as the built environment contributes significantly to energy waste and pollution.

AFRICAN - EUROPEAN PARTNERSHIP

PREA is a joint project between four European Universities (London Metropolitan University, UK; University of La Rochelle, France; National and Kapodestrian University of Athens, Greece; University of Dortmund) and three African Universities (University of Dar es Salaam in Tanzania, Uganda Martyrs University in Uganda, Witwatersrand University in South Africa), as well as the International Solar Energy Society (ISES), an international NGO, that promotes renewable energy. It aims at a joint development and implementation of coordinated Masters' degree courses in this field that initializes the formation of a network of Southern African Higher Learning Institutions and links them with an already existing European network (TAREB) in which Dortmund University already participates together with six other European Higher Learning Institutions, three of which are also named above as participating in the PREA project. The Masters' courses are to be preceded by, and later to run parallel with a series of Workshops, in order to sensitize African government policy makers, decision makers and implementers, regulatory agencies and senior members of academic institutions about energy efficiency (EE) and application of renewable energy technologies (RETs) in buildings, as a way of fighting poverty and saving the environment at the same time.

This project is intended to run for three years during which time it is expected to have established permanent structures in form of Masters' courses at the three African universities, which are intended to continue even after expiry of the project period.

WORKSHOPS

Together with establishment of Masters' courses at each of the three African universities, organization of sensitization Workshops is one of the major activities in the PREA project. Three Workshops have so far already been conducted in the three African countries, namely South Africa, Tanzania and Uganda. They were all conducted in October 2006 with short intervals in between. All workshops had a common title, **"Sustainable and Energy efficient Building in Africa"** but were further differently subtitled to reflect areas of local focus which are slightly different from country to country among the three participating African countries.

The Workshop in South Africa took place at the Midrand near Johannesburg on 3-4 October 2006. Its subtitle was **"DMEs Energy Efficiency and Renewable Energy Targets: Addressing South Africa's Energy Crisis through Built Environment Interventions",** where DME stands for Department of Minerals and Energy. The particular local situation in South Africa addressed at this Workshop was the fact that the country did not produce enough electricity to meet the growing demand, giving rise to what is locally termed as an "energy crisis". That is why this phrase was used in the Workshop subtitle. The workshop which was supported by the Development Bank of South Africa (DBSA) was attended by 150 participants.

The Workshop in Tanzania, subtitled **"Addressing Tanzania's Energy Crisis through Design and Settlement Development"** was organized at the Landmark Hotel in Dar es

Salaam on 10-11 October 2006. It was attended by 32 official participants from various government offices and professional organizations and individual professionals. In addition 10 students also attended the Workshop where 16 papers were presented 6 of which were from project partners and 10 from other attendees.

In Uganda, the workshop was subtitled **"Promoting Sustainable & Energy Efficient Urban & Building Design practices in Uganda"**. It was organized on 13-14 October 2006 at the Hotel Africana in Kampala and was attended by 35 participants who included government officials mostly policy and decision makers, professionals including Engineers and Architects, university academic staff members and some students. Eleven papers were presented, of which six came from project partners and five were presented by government officials and professionals. The Ugandan Ministry of Energy and Uganda society of Architects were also represented and their papers were presented.

The critical situation of electricity supply and the need for new and sustainable energy resources has been underlined by the long almost daily power cuts, especially in Tanzania and Uganda in the last few years. Coincidentally, as if to underline the fact for the Workshoppers, long duration power failures occurred during the course of the events in both Tanzania and Uganda. Water shortages in Dar es Salaam were also indicative of this power problem.

As a form of side activities, some exhibitions served at these workshops made by manufacturers of sustainable energy and building products as well as service providers in the sustainable buildings industry, such as sales representatives and installers of renewable energy products, e.g. PV modules, Solar water heaters etc. One of the other highlights of the Workshops is that they served to bring together all parties involved and interested in renewable energy activities such as businesses and respective departments and individuals in local academic institutions. Certificates were issued to Workshop participants. These certificates had some extra value because in some cases such as Uganda and South Africa they could be used to gain some professional development points which is a requirement of some professional bodies from their members in those countries.

Another series of workshops is scheduled for later this year (September/October 2007), after which a project meeting will be organized in Uganda to evaluate the milestones reached in the implementation of the project and to asses its impact(s).

MASTERS DEGREE COURSES

Masters courses are to be introduced at the three African Universities in the PREA project for capacity building in education and training and to promote sustainability concepts in the design, construction and occupancy of buildings. The long term target is to train academicians for more research and further propagation of these ideas and concepts in subsequent courses even after the end of the project's scheduled time of three years. The aim is to eventually spread these ideas and concepts throughout the entire continent, by cooperation of the three African Universities and by networking with other African institutions engaged in this area.

The masters courses are supposed to use the expertise gained on a similar project in Europe called TAREB (Teaching about Renewable Energy in Buildings) but will be tailored to suit the local environment and to reflect specific demands of the country in which they are offered and taught as well as the technologies that can be easily made available there. The Masters programs will generally have some compulsory core modules and optional specialist modules some of which will be tailored to reflect local demands.

At Uganda Martyrs University, the Masters' course is planned to be introduced in phases step by step. According to Mark Olweny, the assistant Dean of Faculty of Building and Technology, who is also the local PREA project coordinator there, the project would be phased in, in two steps starting with a Graduate Diploma in Environmental Design to run either as a one year full-time course or as a two year part-time course. The part-time program, 50% of which can be taken in form of off-campus modules, is to be aimed at applicants possessing the equivalent of the basic three-year undergraduate program currently run by the same University as Bachelor of Science in Building Design and Technology (B.Sc. BDT). The second phase will be the actual Masters program will be called Master of Environmental Design (M.Sc. ED). It will consist of specialist modules and will be aimed at professionals who have either completed the full five years Bachelor of Architecture course or have upgraded their basic three year course with the Graduate Diploma. Some people with other professional qualifications e.g. in Engineering, Urban Design or Quantity Surveying will also be eligible to apply directly for the one year full-time Masters. Basic concepts in environmental design, will already have been introduced at undergraduate level, will develop students' interest in this area and serve as a "catchment area" for students and professionals.

The new Masters course at Witwatersrand University (WITS) will aim at both students and professionals. According to plans already under way at WITS, the Masters course will be associated with four separate postgraduate activities namely organization of short open certificate courses and modules in collaboration with other institutions such as Stellenbosch University, establishing new "Continuing Professional Development" (CPD) courses for established professionals, incorporation of Energy Efficiency and Renewable Energy research into existing Masters and PhD work by research and thesis, as well as introduction of taught modules into Bachelor of Architectural Sciences (BAS(HONS)). There will be two masters versions namely the Professional Masters of Architecture (M.ARCH(PROF)) and the Master of Architecture specializing in Housing (M.ARCH(HOUS)). As an unexpected opportunity the PREA project coordinator at WITS, Daniel Irurah, was requested to develop a teaching module on Renewable Energy, in the process of establishing of a new Master of Philosophy (M.Phil) on Renewable Energy due to start at Stellenbosch University later this year (July 2007). PREA has been identified as one of the key strengths of WITS in its collaboration efforts with other institutions in South Africa.

Dar es Salaam University is also quite ready to establish the new Master course. It has all the necessary manpower and teaching facilities for the course to be able to take off this year. Existing departments which are ready to collaborate in establishing the new Masters course include the Department of Architecture in the Faculty of Architecture and Planning (FAP), the Faculty of Civil Engineering and the Built Environment, the Department of Energy in the Faculty of Mechanical Engineering and Chemical Engineering and the Department of Electrical Power in the Faculty of Electrical Engineering and Information Technology.

RESULTS / DISCUSSION

Although only one year of the three-year-project has passed there could be improved already a few things in Africa that would not have happened without PREA:

- Three universities in sub-Saharan Africa have decided to implement masters courses in the area of renewable energies energy and efficient building during the project duration.
- Three workshops about sustainable energy supply and about low cost and high comfort buildings have been carried out with active participation of key actors from the three African countries.
- The network of African institutions working in the areas of energy and building could be improved , last not least by the website www.ises.org/PREA.

Thus the PREA Project has already proved to be an important event in the development of energy consciousness in Africa. Both the Workshops and master courses are developing satisfactorily. Inference from the so far already conducted Workshops is very good. From responses to questionnaires given to both participants and organizers it is indicated that people concerned are very satisfied with the stages and milestones that have been reached so far. Project websites (shown hereunder) have been established, Workshop handbooks with all the papers presented at Workshops have been published and distributed to workshop participants and other interested parties, a CD summarizing all activities has been developed and as requested by the European Commission, a PowerPoint presentation containing "publishable summary slides" has been produced and updated. The most important fact however is that through this PREA project, the issue of energy efficiency and renewable energy in buildings in Africa has obtained a forum through which it will be more specifically and efficiently addressed within an integrated building design and construction approach. Moreover, African universities have had a unique opportunity at South–South collaboration among each other and South-North collaboration with their European counterparts.

CONCLUSIONS

The PREA project, although scheduled to run for three years, is meant to have a long lasting impact in the development of a new energy consciousness in Africa. It has started with the Workshops that are aimed at sensitizing African governments' officials, policy makers, decision makers and implementers as well as regulatory agencies about the importance of energy efficiency and application of renewable energy technologies in buildings as a way of fighting poverty and at the same time preserving the environment for posterity. In short the PREA project is a catalyst for sustainable development and poverty eradication in Africa. It will help Africa achieve some of the millennium development goals sooner rather than later. In the first project year it has become evident that there is interest in capacity building in postgraduate university education and a strong demand for it. The implementation of the masters courses at the three African universities has started a sustainable development.

ACKNOWLEDGEMENT

The European Union's the Intelligent Energy Europe (IEE) program supported 50% of the PREA budget through their COOPENER subprogram, and the German International Academic Exchange Service (DAAD) financially supported Dortmund University by matching funds. The other European partner universities and ISES, are meeting their share of the budget from their own resources. The contributions of the African University partners, are in form of local organization of the seminars and arrangements for accommodating the Masters' programs. The Development Bank of South Africa (DBSA) kindly made their premises at Midrand, Johannesburg, available for the South African Workshop.

ABSTRACT

Customer-focused life cycle building service technologies are changing the operations and networks of companies. New requirements and value-creating mechanisms fall extensively in the various fields of business and in different stages of projects. Effective utilization of life cycle models requires new know-how and the ability to verify the added value from both the client and provider alike. Output-based procurement methods affect the risk transfer and the combination of tasks in a new way. Competitive procurement procedures and output-based long-term contracts bring about new options. Additionally, international consideration has broadened the views on development. The five life cycle service models developed within the *Life Cycle Models in Indoor Environment and Building Services* project (CUBENet) are based on an options selection framework, which also provides a platform for further development of these models. Tools supporting the implementation of the models promote their usage.

INTRODUCTION

In the modern world of fast communications, ideas travel rapidly around the world, and so do the concepts influencing the development of life cycle models in building service technology. For the present, the implementation of life cycle models is new everywhere and projects implemented are numbered. Consequently, the wider introduction of life cycle models depends on local conditions, such as how the usually traditional construction business is locally in favour of employing life cycle analyses, the demand for renovation and repairs of the building stock and, if in connection with this reproduction, the requirement of durability and sustainability may be highlighted. Furthermore, the high energy consumption of buildings or uncertainty as to their energy supply, as well as governmental regulations, might promote the use of life cycle models. For various reasons, in some countries, most of the buildings need repairs, for example, in areas rebuilt after World War II. Apart from China and some similar exceptions, deceleration in the volume of new construction and expansion in the building renovation sectors is a global phenomenon.

The idea of using life cycle models has been adopted into building construction from infraconstruction. Large-scale infraprojects demand large investments. Organizing such investment has induced the transfer into life cycle models. The leading idea is to outsource the implementation of municipal or national projects and the related operational services, i.e., to transfer the total responsibility for providing them to private actors. The conventions have spread from North America throughout the British Commonwealth of Nations and further on to other countries, to Europe in particular. Outsourcing the needs of municipal technical services renders the life cycle model of thinking more common. Life cycle models have been utilized in developing new more efficient contract forms to tighten the project schedules in order to shorten the lead-time and to accelerate the cycle of tied capital, not least in project development in Finnish construction [1] and [2].

Until now, the service tasks related to building services and energy technology maintenance have formed a part of the property and facilities management operations that have quickly been embedded as part of the building management and maintenance business and been adopted by the business widely. These concepts have spread from North America to the English-speaking world and to Europe starting from Great Britain through the Netherlands [3]. The requirements set by sustainable development have turned the attention of the actors in the construction business to the operating costs of the building and the ecological standards of the whole life cycle of buildings. Internationally, building maintenance is seen as the most important factor in the economy of a building. Therefore, energy and building services businesses have woken up to the need of independent life cycle models in building service technology and to the need of offering for sale new progressive services together with hardware supply. Finland, together with Sweden and Great Britain is one of the foremost countries in developing these new service models in Europe.

Above all, common rules and feasible functional technical solutions improving the business prerequisites are sought for the life cycle models. However, appropriate national incentives for energy efficiency have taken an interest in developing support forms or favourable financial arrangements for the life cycle service projects. Frequently, life cycle repairs can start with energy audits that are a well-established practice throughout the developed world. National support obtainable for them can vary between 20, 50, and even 100 percent [4]. Life cycle models can yield significant benefit in the operation costs of building services depending on the standard of energy-efficient or sustainable technology employed during the design and implementation phases or during repairs to achieve an efficient building performance life cycle. The total economical savings yielded can be used either in funding the construction or, as is usual, in funding the repairs and improvements of the building. However, this is still quite rare internationally as the projects implemented have external investment funding.

METHODS

The Tekes (the National Technology and Innovation Agency) CUBE technology programme project CUBENet (the *Life Cycle Models in Indoor Environment and Building Services* project*)* comprised several work packages: procurement, measurement and verification (M&V), risk management, contract documents, business models.

Each of the work packages has used scientific methods suitable for the demand of the tasks. Typically, several case studies have been carried out, particularly in testing the M&V methods in existing building stock, in the development of the risk assessment tool and the CUBENet life cycle cost calculation method, as well as in the generation of the contract model templates. Most of the work has been planned and verified during the sessions of two working groups: the first one for the building service management and the second focusing on the public works and the energy performance contract (ESPC, energy saving partnership ESP) performed by the energy services companies (ESCO).

Various building service technology models developed within the CUBENet project are, and will be, discussed and referred to in scientific literature; the implementation tool box for this theory of models is described in other papers [5].

LIFE CYCLE BUSINESS MODELS

In several industrial fields, product-related life cycle services are becoming increasingly common. The main idea in the development of the life cycle services is that the product manufacturers take further responsibility of the functionality of their product during its life cycle in their client's use. Respectively, the client uses life cycle services in pursuing cost-effectiveness, easier maintenance or better functional quality of their own processes. Life-cycle services may be aimed at the entire product life cycle or at a specific stage according to the situation and as agreed. Indeed, business-to-business (B2B) service business aims at long-term partnership with the client.

Implementing life cycle service models changes the interfaces and processes between companies, sometimes significantly. Services offered by providers replace some of the client's processes or support processes. Cooperation between organizations is facing new challenges and requires new kinds of methods and supportive tools to deal with them. The objective is to build a network-wide value creation process in which the provider not only knows the client's processes but, by using their own expertise, are also able to make them more productive in a cost-effective way. This may indeed be described as life cycle wide management of products and services all the way from product development to after-sales services and discarding of the product.

Similar change is apparent in the real estate business. In the past few years, the implemented projects have also included supporting operational services, such as maintenance, cleaning, and ensuring the energy savings in the building and in the systems. The services take shape case-specifically on the basis of the client's needs, while the contents of the contracts are tailored to the project in question. Insight concerning what should and can be included in the services is developing. Thus, it is now possible to more efficiently develop both the life cycle service user's ability to take advantage of the services, and the service provider's processes and networks to provide cost-efficient services. This way, verifiable added value can be created for the both parties, which is a prerequisite for more extensive implementation of life cycle services in the field of building service technology also.

BASICS OF LIFE CYCLE MODEL

Life cycle models of building service technology refer the procurement method, in which the chosen service provider is responsible for planning, building and maintenance of a building service system for an agreed period of time. A wider scope of obligations compared to traditional form for procurement, and the responsibility of the functionality of the systems, require that the service provider takes into account the life cycle economy and indoor air conditions of the building services.

A very wide variety of method types fall under the concept of life cycle models, depending on the service entity offered and the way the provision of a service is organized. Procurement of building services with life cycle models differs from traditional procurement methods in various aspects [6]. To begin with, including the responsibility for planning, building, and building services in one contract offers better possibilities when striving towards cost-effective solutions and services [7]. These effective mechanisms can be described as the common effect of the following basic solutions [8,9]:

- **Combining tasks.** In traditional methods, the client uses various contracts in obtaining the building services during the building's lifespan. Then, it is difficult to make the objectives of all parties meet, and often the aims of an individual party override the potential overall best for the project and the customer. By combining these tasks, service providers have a chance to remove operational borders between different actors and to develop the service entity in several different ways in the long term.
- **Goal-oriented thinking**. By defining the client's requirements and focusing on the functionality of the building services, the service providers obtain greater possibilities in choosing solutions and preparing service concepts than with traditional methods in which the client defines the technical requirements and solutions. This approach enables and encourages the service provider to provide the services in an economical way for the life cycle and to develop service-related innovations. The output specification gives the service providers increased flexibility to innovate in developing their service provision solutions for the project. This way, the client's goals become the leading idea driving the implementation of the entire project
- **Procurement method**. Procurement methods are used to ensure a good price-quality ratio for the building service acquired as the client may choose from various offers and select the best one. By using competition, it is possible to utilize a significant amount of the potential that is based on combining the building services in planning, construction and use of the building and that has been made possible by, for example, concentrating on determining the requirements at the service level.
- **Risk transfer**. In the life cycle model, the client transfers several risks to the chosen service provider. Some of the risks are shared between the client and the service provider [10]. In principle, the risk lies with the party with the best prerequisites to handle it. With appropriate risk transfer, the client creates incentives for the service provider in developing technical solutions and services.
- **Quality- and output-based service charges**. In life cycle models, the service provider's payment bases are usually not totally fixed, as the sum depends in part on the operational service level. The use of output-based specifications ensures that the client pays only for the provision of a pre-defined service. In addition, these mechanisms create incentives for the service provider to minimize the life cycle costs.
- **Long-term contract**. Mainly, the contractual relationships in life cycle models last for several years. A long-term contract enables the risk transfer and the functionality of the service charges. Moreover, long-term contractual relationships are used to seek a service provider that provides service and maintenance of building systems and is offered a chance to develop building services and integrate the data yielded in planning and building the systems into the operations in the operational stage.

Life cycle services broaden and lengthen the responsibility of the service provider as regards the functionality and maintenance of the target. For planning business also, this offers a new perspective. Life cycle services influence the business relationships between companies. The responsibility for the operational functionality of building technical systems and services forces each party to assess also from the economical viewpoint those factors and risks that are related in depth in the tendering stage when pricing the life cycle service.

DEVELOPED BUILDING SERVICE LIFE CYCLE MODELS

Various life cycle models for building service technology have been developed in the *Life Cycle Models in Indoor Environment and Building Services* project (CUBENet). The models were selected using a so-called option selection framework of thinking in which the construction project is divided into three subsets based on the size and scope of the project, the service provider's project tasks, and the payment base. These subsets are independent of each other, but by combining them, other models can be formed alongside the main models defined. Figure 1 displays the parts of the option selection framework.

The service provider can assume responsibility for planning and implementing the entire construction project or for a defined part only, such as building service planning and building service works. Further, operations within the scope of the project can be targeted to only one building or to several. The service provider's obligation may involve performing one or several tasks needed in implementing the construction project (for more details, see Figure 1). Different tasks may be assigned to the service provider with a different payments base. The payment base may be so-called common grounds, which include fixed price, unit price, invoicing, or target price. In addition to these, the service provider may be paid a service charge. In this case, the reimbursement paid to the service provider is paid partially or entirely during the use of the building. The payment base may also be combined so that, for some of the tasks, the grounds that apply are different from those that apply to others; for instance, design costs are paid according to a fixed price but building technical work is paid on the basis of an invoice, while building technical work is paid for on the basis of service charges.

On the basis of the option selection framework, five different life cycle models for building service were developed.

1. Full responsibility building life cycle service
2. Full responsibility supply of building service technology
3. Life cycle service of building service technology renovation
4. Building service technology renovation with competitive dialogue
5. Savings-funded building service technology renovation

In the *Full responsibility building life cycle service* model, the task of the service provider is to design the entire construction target and to take care of the construction and building technical works. Additionally, the service provider assumes responsibility for building technical and real estate services for an agreed period of time. The client will reimburse the service provider for the design and construction costs according to the general payment base of contract performance, whereas for the services, the client pays monthly service charges during the contract period.

In the *Full responsibility supply of building service technology* model, the task of the service provider is to design and construct the building service technology system and to provide service and maintenance for the system for an agreed period of time. The client sets requirements for the system that may concern a system feature (e.g. efficiency) or the service level (indoor air or energy service). Furthermore, the service provider assumes responsibility for providing the service agreed upon. For the entire project, the payment base may be a service charge that is paid during the contract period. In this case, the service provider assumes responsibility for the investment costs required by the project. The payment base of the investment costs may also be the so-called common base for contract work. Additionally, costs for services provided are covered by service charges.

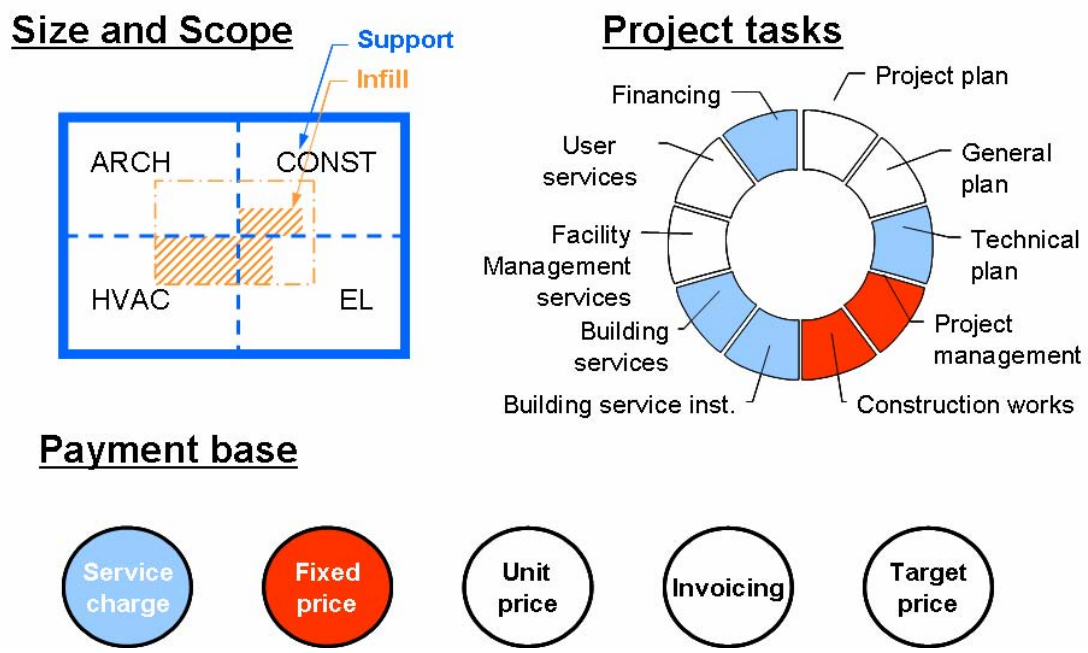

Figure 1 Option selection framework with the choices of model 5.

In the *Life cycle service of building service technology renovation* model, the objective of the project is to renovate old building and construction technology, and, at the same time, to improve the indoor air quality and conditions, and efficiency of energy use. In this model, the client submits a tender with preliminary sketches and system requirements and the service providers offer a target price. The client and the service provider guide the end design and choose the systems in cooperation. The service provider is responsible for some of the building services, and the client is responsible for the rest. The building technical services the service provider caters for are related to the end product, such as indoor air quality. The service provider may also provide some of the real estate services. For the services, the service provider is reimbursed on the basis of service charges.

In the *Building service technology renovation with competitive dialogue* model, the client builds an ensemble of several buildings, for which the conditions or energy efficiency is improved. Since the ensemble may contain buildings of varying conditions, tasks and jobs may vary with the building. In addition to the aforementioned works and services, the measures may be targeted to real estate and user services. Feasibility studies and preliminary engineering is implemented in cooperation with the client and the chosen service providers using competitive dialogue.

In the *Savings-funded building service technology renovation* model, the project is started when the client verifies or assesses the energy savings potential of the building service system. With their own measures, e.g. inspections, the client determines the savings potential and building technical systems to be renewed. In addition to those, the client can define other, non-saving, measures for the same project. The costs caused by those are reimbursed to the service provider in the normal manner during the contract performance. The service levels or periods of utilization are not changed essentially, but are maintained throughout the contract period. The costs incurred by the project may be covered in total or mainly by the savings from energy costs accumulated by the service during the contract period, verified in a manner agreed upon. The service provider takes care of the funding needed for the implementation, while the client pays the implementer a service charge based on the energy savings.

TOOLS OF LIFE CYCLE MODELS

Various tools, as well as contract and project models, are needed to implement the life cycle models in order to set and reach goals, compare life cycle economy, and identify and manage risks. Tools of life cycle models are presented in the article called *Tools for life cycle models in building service technology*.

DISCUSSION

The CUBENet project has acted as an ice breaker in the field of building services. It has introduced the life cycle paradigm to the experts in the field in a very serviceable manner. Strong co-work between the scientists and representatives of Finnish companies and municipalities has taken place. It has not only taken into consideration the needs of experts in building service technology, but also communicated the needs of co-operation to building managers, both in the private sector and in the municipalities. Furthermore, considering the whole life cycle of the building, co-operation between other sectors in construction, from the design team to the property and facilities management operators, is essential.

The option selection framework, used to create five life cycle models for building services, was created. The framework can be used to create appropriate combinations, depending on the size and scope of the project, the service provider’s tasks and responsibilities in a project, and the payment base. Supporting tools to help implementation of these models are presented in the *Tools For Life Cycle Models In Building Services Technology* paper [5].

ABSTRACT

In construction and building services technology, life cycle models are perceived as an increasingly important way of implementing projects, and are gaining in popularity. Implementing and applying life cycle models requires supportive methods, measures, and tools. Above all, tools as well as contract and project models are needed to implement life cycle models in order to set and reach contract targets, to compare life cycle economy, and to identify and manage risks. The Finnish *Life Cycle Models in Indoor Environment and Building Services* project (CUBENet) defined the service level descriptions for setting targeted contract measurements and generated new verification methods, such as an operational verification method to be used by a building automation system. Risk assessment tables for life cycle building service schemes have been drawn up to avoid problems and conflicts; the prepared model document templates are to serve in planning the project content and form, as well as in the agreement of the contract stipulation.

INTRODUCTION

Products and systems delivery-related life cycle services are becoming increasingly common in various fields of business. In other words, in various fields, the new business concept of life cycle services are gaining in popularity as a means of establishing new business models for the concepts that are of concern. The prime idea in the development of life cycle service models is the fact that the responsibility of product providers for the functionality and performance of their products during its life cycle is increasing. The service provider guarantees the operation of the product beyond the traditional guarantee period and takes care of the product during the performance period on behalf of the client in the client's premises. Accordingly, the client uses life cycle services in striving for cost-effectiveness in their inter-company processes and management, as well as in striving to achieve lower maintenance resource allocations and better quality in their operative systems.

The trend described above can also be seen in real estate business and building services technology. In the past few years, projects implemented have also included operational services, mostly in maintenance and cleaning, but also in ensuring energy savings in the building and systems. Often, these services take shape based on the client's needs, while the contents of the contracts are tailored to the set targets of the project in hand. Currently, ideas are developing as to what should and can be included in the services. In order to expand the implementation of life cycle models and procedures, uniform principles, methods, measures, and supportive tools need to be created in the field. In this way, it is possible to develop more efficiently the life cycle service user's ability to effectively use the services, as well as to develop the provider's processes and networks in order to be able to provide services cost-effectively. The CUBENet project has included the processes of developing methods and tools to support the practical implementation of life cycle models.

LIFE CYCLE MODELS

Life cycle models of building service technology refer to procedures for obtaining systems of, and services related to, building service technology, in which the service provider chosen is responsible for planning, building, servicing and maintaining the building service technology systems for an agreed contract period. The wider scope of these tasks compared to traditional contracts, and the responsibility of the functionality of the systems, require that the service provider take into account the life cycle economy and indoor environmental conditions of the building service technical systems. The challenging purchase method, output-based incentives, and charges based on the service level, are the most essential methods for the implementation of the models.
Various tools, as well as contract and project models, are needed to implement the life cycle models in order to set and reach goals, compare life cycle economy, and identify and manage risks.

METHODS

The Tekes (the National Technology and Innovation Agency) CUBE technology programme project CUBENet (the *Life Cycle Models in Indoor Environment and Building Services* project*)* comprised several work packages: procurement, measurement and verification (M&V), risk management, contract documents and business models.

Each of the work packages has used scientific methods suitable for the demand of the tasks. Typically, several case studies have been carried out, particularly in testing the M&V methods in existing building stock, in the development of the risk assessment tool and the CUBENet life cycle cost calculation method, as well as in the generation of the contract model templates. Most of the work has been planned and verified during the sessions of the two working groups: the first one for the building service management and the second focusing on the public works and the energy performance contract (ESPC, energy saving partnership ESP) performed by the energy services companies (ESCO). Various building service technology models developed within the CUBENet project are, and will be, discussed and referred to in the scientific literature; this work on the tool box for the implementation of the models draws much from the work described in other papers [1].

SERVICE LEVEL DESCRIPTIONS

In order to set targets, service level descriptions have been created for building services technology services that are also presented as an independent part of facility services. Traditionally, maintenance tasks, which comprise technical maintenance and repairs, in building service technology have been perceived as part of property management. In future, new kinds of tasks will be numbered among the building service technology services that meet the life cycle demands.

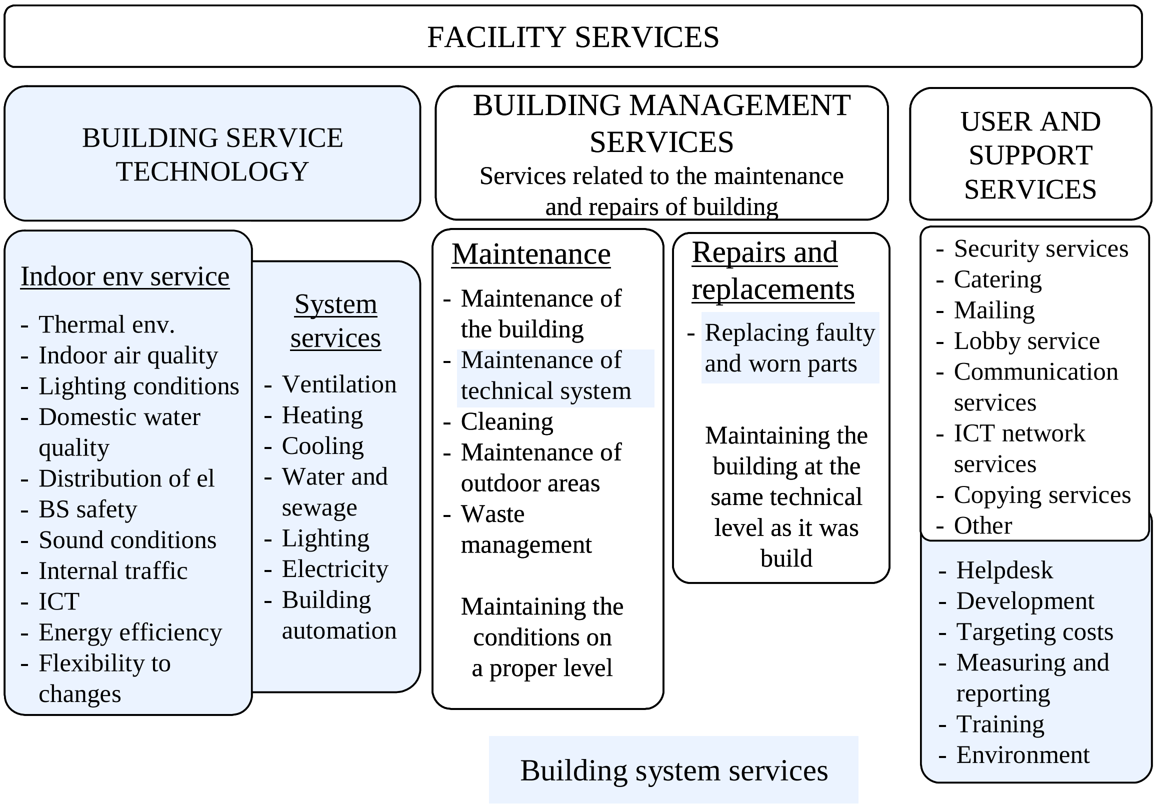

Figure 1 Building system services as a part of facility services.

In life cycle contracts, services should be presented as measurable quantities in order to be able to clearly log the tasks and obligations of, as well as the benefits yielded by, the tasks of the cooperation partners. These service level definitions can also be documented in room and system cards.

The services have been defined either on the basis of the quality of the end result or on the basis of the task by describing the operations or task to be performed. The quality of the end result can refer to, for instance, summertime room temperature with a defined acceptable range and routine to measure it. A task-based service level description is an alternative to the end result description, as it refers to, for example, the cooling power provided in the room by air conditioning. However, in this case, the service provider assumes no responsibility for room temperature.

RISK MANAGEMENT

Methods in risk sharing and assessment have been developed for risk recognition and management. To assess the success factors of projects, corresponding assessment tables have been drawn up to help recognize the special features of successful projects [2].

Systematic risk recognition and assessment is the method for managing risks and pinpointing the responsible party. The stages of risk analysis are defining the target, recognizing hazards, assessing consequences, calculating probabilities, assessing the total risk, and finally, removing, reducing, and preventing the risk. The parties involved in the implementation of the project are assessed for their ability to take responsibility for the risk; usually, the responsibility is given to the party that can handle it and to whom it naturally belongs.

Drafting a contract is a concrete tool for pinpointing the party responsible for risks. Through risk assessment, crucial matters to be included in the contracts are observed, along with the necessary insurances and potential securities.

Risk assessment in planning stage

One practical method for systematic risk assessment is a risk sharing table (or checklist, or matrix). Potential (along with apparently impossible) risks are listed and shown to the project parties. Reference [3] presents the categorisation or risks in macro, meso and micro levels (‘meta-classification approach’), [4] shows the practical risk evaluation and allocation table for a school project in Finland. With the risk-sharing table, the parties share the responsibilities for the risks each party will assume. The responsibility for an individual risk is left to either party, or to both parties, according to principle agreed by the respective parties. The client assesses the risks of the project and assumes responsibility for some of the parties involved in the project. In the call for bids, the bidder is asked to pay attention to the risks transferred to the provider and to describe how they will assume responsibility for the risks or how they will take these into account in the bid. In practice, the provider may not necessarily take the responsibility of all risks offered but will transfer the risk back to the client in the bid. The responsibility for a risk will naturally have an influence in pricing – the party taking the responsibility of the risk will set the price for the risk.

The risk assessment table helps the bidders in evaluating how they accept the risks the client is transferring to the provider. The table forms a foundation for the proposition of the bidders in order to show how well they understand the nature of the risk, how effectively they forward or share the risks in the subcontractor chain, and how they minimize the unfavourable effects caused by risks in relation to the client and the end users.

Risk management during use

After the construction phase in the project has been completed, risks are also managed with the help of components of the information system, such as the building management and monitoring system (BMS). The functionality of the technical system is monitored and measured, paying particular attention to the factors sanctioned in the contracts. The monitoring system can contain risk assessment tools, which focus the monitoring and service to the risk points of the process. Disadvantageous factors of the various parts of the system are assessed on the basis of three factors [5]. The probability of occurrence (showing how probable the occurrence of a factor is) and the probability of discovery or detection (showing how easy it is to discover or detect a factor), as well as the severity (showing how harmful this factor is) of the disadvantageous factors, are assessed separately on a scale of one to ten (or some other selected scale). The product of these three factors is the total risk number. The higher the risk number, the higher the risk caused by the disadvantageous factor. When the risk points have been recognized, the measures can be focused. The risk points of the AC system can be handled with the monitoring system (critical monitoring points), while service can be targeted to the system risk points. Additionally, measurements can be utilized in defining the numerical values. Moreover, applications can be developed to assess risks in energy consumption, which is crucial in some contract models, e.g. in energy service contracts.

PROCUREMENT AND CONTRACT MODELS

All life cycle models in building services technology accentuate cooperation between contractual parties. This cooperation starts in the bidding phase and continues throughout the service stage to the termination of the contract. In life cycle models in building services, the contract acts as the basis for cooperation. The objective of the contractual parties is not only to enter into a contract but, with the help of the contract, to accomplish successful cooperation. In addition to mutual trust, one basic prerequisite for successful cooperation is compatibility of the objectives and endeavours of contractual parties. Building and maintaining strong trust between the client and the service provider should be one of the most important objectives for both parties, even with regard to the preparation stage of the project and, naturally, to the contractual period, all the way to the termination of the contract. Trust makes cooperation possible by supporting the parties' mutual commitment and their ability to take risks [6].

The first stage of entering into a contract is an invitation for bids. In this stage, the service provider obtains the information needed to make a bid. In this stage, clients must recognize and concretize their objectives and requirements concerning the service level and quality of building service [7]. It is essential to concretize the objectives and requirements so that the objectives set for procurement can be turned into functional and technical features, requirements, and contractual obligations that are understood in the intended and in a uniform way. The parties have to identify the party responsible for the risk of functionality, and indicate whether the service provider is committing to an output or operational obligation. Moreover, when the client in a life cycle project is a public authority, purchasing must comply with the regulations and legislation pertaining to public purchases. In the case of public purchases, the public contracting authority is obliged to organize a competition for each purchase and regulate the principals and methods to be complied with in competitions [8].

Depending on the project, the contractual period in life cycle contracts usually spans several years. Due to the long-term nature, the life cycle contracts highlight the role of the contract as a tool of risk management, as well as the preconditions of changing the terms of the contract [9]. In life cycle contracts, risk management is divided into two parts: reactive and proactive [10]. In reactive risk management, the terms of the contract are resorted to due to a failure or triggering of risk. Based on the conditions, the disadvantageous economic consequences are divided between the contractual parties. In proactive risk management, contracts are used in anticipatory preparation, which decreases the probability of risks, diminishes the effects, and speeds up the recovery. At its best, the formulation of the conditions of the contract and the entire contract is really proactive risk management in which legal, technical, and economic expertise is utilized.

Also, due to the long-term nature of a life cycle contract, the implementation of the contract and cooperation are affected by conditions that can vary in a way that could not be foreseen or in a way for which the contractual parties had not agreed in a clear risk-sharing model [11]. The longer the time span, the less foreseeable the problems. The most difficult issues are unforeseeable, essential, permanent, or long-term changes in the conditions. These issues influence either the original cost structure or income formation significantly. However, the parties must prepare themselves for the changes by creating contract mechanisms to remove excessive imbalance. Nevertheless, the main starting point is that the changes do not justify changing the contract if responsibility for the risk of these changes, or for the risks themselves, has been assumed by a contractual party. Some sort of a change in the situation is an overwhelming obstacle for which contract law offers several established solutions. Generally, an overwhelming obstacle involves unforeseeable, overpowering, external obstacles rendering performance impossible. Nonetheless, most changes do not lead to impossible, but rather to essentially altered, implementation costs.

Each life cycle model in building services involves document templates and instructions pertaining to procurement and contracts. The document templates and instructions developed within the CUBENet are intended as guidelines for dealing with the matters to be covered in the procurement documents and contracts. On the other hand, models yield examples of ways of defining and agreeing upon matters. With the help of the models developed, actors can, in practice, define the methods and conditions of the contract suitable for their own needs and projects.

VERIFICATION AND MEASUREMENT

Life cycle project contracts are entered into before the building design phase has been finished, as design is a part of the life cycle delivery. This emphasizes the importance of the agreement on the feasible design criteria, the service level of the life cycle contract and the definition of methods for the measurement and verification for the final outcome of the life cycle project. The CUBENet project provides instructions on agreeing on the M&V tasks and methods, and taking implementation into account as demands of the building automation system. Further, methods and tools have been developed for a partly automatic and, if necessary, manually operated, M&V tool to be used during the performance phase of the contract. The methods developed are designed for M&V of room temperature, air quality, and energy consumption.

COMPARISON OF LIFE CYCLE ECONOMY

The importance of inspecting the economy from the life cycle viewpoint is gaining in importance as service providers provide clients with service solutions covering the entire life cycle of building services. In such projects, the service provider is responsible both building and maintaining the system. As the same body is responsible for the entire life cycle of a building service system, it is sensible to pay attention not only to the investment costs but to the operating costs as well. By developing life cycle cost management, the total costs of building service systems can be cut [12]. By paying attention to life cycle costs in planning and implementation, it is possible to decrease operating costs in the future.

When the client ponders the procurement method with which he will realize the construction project, a calculating tool is needed to help to perform a rough comparison of purchases produced with life cycle services with that implemented with a traditional method. Selection of the procurement method should be based on the selection of a consortium that is best able to provide the desired service [13]. In comparing procurement methods, it is especially important that the tasks and responsibilities of the procurement methods, as well as the risks inherent in these methods, are made comparable. What is crucial in comparing different procurement methods is an assessment of whether life cycle services create added value in the investment process and service provision [14]. A particular significant benefit of comparing procurement methods is the fact that it “forces” recognition and emphasis of the matters influencing the total economy and risks of the project. In this way, decision-making is supported by information that is as extensive and high quality as possible.

In the planning stage, life cycle costs are used in choosing various alternative engineering solutions and as a tool for guiding the plans. The reason for a life cycle cost estimate may be:

- There is a plan to install machines, equipment, or systems in a building in order to conserve energy. In this case, a life cycle cost estimate is used to see if building such systems is feasible, i.e., if the obtainable savings are larger than the investments needed.
- There are several alternatives to choose from, each acceptable for the operations of the building, but with different construction and maintenance costs. In this case, a life cycle cost estimate is used to see which alternative is the best one economically.

In comparing bids, the contents of bids obtained using life cycle costs are compared to the call for bids and conditions set therein, as well as to other bids. With life cycle calculation, bids, and operational and maintenance costs are made comparable. With the calculation, the contents of bids can be opened up and assessed as regards the reasons for potential price differences and if the contents of the bids are uniform with the content of the call for bids and with each other. In life cycle costs, all potential factors affecting the total economy of the project are taken into account, whether quantitative or qualitative.

The calculation tool for life cycle economy (CUBECost) developed within the CUBENet can be used as a tool when deciding on a project form, selecting planning solutions, and comparing bids.

DISCUSSION

The CUBENet project has acted as an ice breaker in the field of building services. It has introduced the life cycle paradigm to the experts in the field in a very serviceable manner. Strong co-work between scientists and representatives of Finnish companies and municipalities has taken place. It has not only taken into consideration the needs of experts in building service technology, but has also communicated the needs of co-operation to building managers both in the private sector and in the municipalities. Furthermore, considering the whole life cycle of the building, co-operation with other sectors in construction, from the design team to the property and facilities management operators, is essential. This has been recognized during the modelling of the building service life cycle and generating the contract tool box, as well as in the establishment of the methods for the M&V. The CUBENet project has kicked-started the development of the building service life cycle approach, in accordance with the EU energy policy that targets ever better energy efficiency and the new directives for the contracting of public works.

Integration of HVAC Value Chains across Eight Competitive Arenas for Better Wellbeing Indoors

Pekka Huovinen[1] and Juhani Kiiras[2]

[1]TKK Helsinki University of Technology, Finland
[2]TKK Helsinki University of Technology, Finland

Corresponding email: pekka.huovinen@tkk.fi

SUMMARY

The aim is to advance HVAC businesses, procurement, and marketing. The Porterian concept is applied to integrating HVAC value chains. The logic of HVAC focused, 8-arena competition is as follows. Arena 1 (of wellbeing indoors): occupants exploit HVAC systems. Arena 2: owners compete with buildings. Arena 3: providers offer services for managing high HVAC system life-cycle performance. Arena 4: investors compete by realizing (renewing) new (old) buildings. Arena 5: wholes contractors and CM consultants compete in realizing buildings as wholes. Arena 6: HVAC engineers compete with solutions and HVAC contractors with systems. Arenas 7/8: HVAC products/materials suppliers and traders compete with (in)direct deliveries. The integration of HVAC value chains is in its infancy in most countries. HVAC inputs procurers (and outputs marketers) are encouraged to set challenging procurement (marketing) objectives and to attain them by adopting the three logics. Cross-national research is called for to conceptualize and to test the espoused logics further.

INTRODUCTION

Two interrelated questions are herein addressed as follows: “How to replace the current ineffective rules of separated or multi-phased competition in building markets? and “How to pioneer some new more effective ways of integrating all HVAC knowledge and value chains for producing better innovative solutions for the wellbeing of occupants indoors?” It is posited that these questions and the related replies are highly relevant as part of advancing HVAC solutions and practices as well as the life-cycle management of new buildings and building stocks as a whole in various (inter)national contexts at least at three levels as follows. **At the broadest level of (inter)national practices**, building markets are facing with constant challenges, that being the separation of designs and construction works culturally, contractually, and technically. Emerging integration efforts are influenced by political, economic, social, and cultural concerns. These efforts become highly significant when supported by governmental stakeholders [1].

At the level of buildings, many new concepts of sustainable and green buildings, spaces, or workplaces are being co-planned and adopted. In the exemplary context of Canada, there is a growing momentum in both the public and private sectors for **more sustainable approaches to buildings**. This momentum arises from the need to reduce raw materials, water, and energy use as well as waste and greenhouse gas output. However, even more important than mitigating these negative impacts is the potential of amplifying the positive impacts of occupant satisfaction and performance. The life-cycle benefits of sustainable construction appear to considerably outweigh their 2-7 % higher first costs. However, there are several impediments to implementation that are slowing the adoption rates. These impediments include (i) changing the ways of implementing buildings, (ii) adopting sustainability and still meeting each owner's needs and cost requirements, (iii) removing the resistance of stakeholders to change, (iv) eliciting action, support, and involvement by all participants in supply chains, and (v) reducing the lack of relevant skills and knowledge. In order to meet these impediments, one of the essential principles is the use of fully integrated teams who consider all aspects of buildings from cradle to grave [2]. In the context of the USA, more and more **workplaces** that are distributed, connected, adaptable, flexible, serviced, enabled, and move seamlessly between space and cyberspace are not only the source of future competitive advantage; such workplaces may now be a matter of company, business, and organizational survival [3].

At the level of HVAC solutions and systems, the first integrated HVAC value chains are readily playing decisive roles in meeting energy efficiency and first cost objectives on high performance green building projects across national building markets. The well thought-out networks of interrelated processes are being designed to satisfy the needs of building owners and users. However, there are still many disabling structural features that must be overcome such as extreme specialization within functionally stove-piped organizations and industry fragmentation, optimized to meet each individual participant's performance objectives but far from optimal from the perspective of integrated HVAC value chains, not to talk about building value chains as a whole (applying [4]).

Herein, **the aim** is to advance core strategic thinking in HVAC business management as well as in related competition, procurement, and marketing by re-defining the three existing logics and applying them to integrating HVAC value chains across many competitive arenas. For advancing the wellbeing of occupants indoors, the sub-aims are as follows: (1) To introduce the logic of HVAC related competition as eight arenas, (2) to introduce the two logics of HVAC related procurement and marketing in terms of principal routes connecting the eight arenas, and (3) to suggest a set of principles for integrating HVAC value chains and solutions across arenas, and (4) to discuss some key implications of such integration for both practitioners and scholars.

METHOD

The nature of this paper is that of **applying one of the authors' recent Porterian concepts** [5], [6] on competition in construction to defining and explaining some new ways of integrating HVAC value chains as part of building markets. Briefly, the original rationale involved the (self-)critical evaluation of the related literature as follows. Within the strategic management literature, **Porter's [7] five forces framework** offers a generic frame of reference for any firm who aims at attaining repeatedly its marketing goals. This framework applies to all high-tech, low-tech, and service businesses, including global and local building and HVAC related businesses. Indeed, Ofori [8] recalls several construction-related applications such as Yates et al.'s [9] analysis of the US construction industry and Betts and Ofori's [10] framework for strategic planning in construction enterprises. Over time, the structures, advancement, and applicability of Porter's frameworks have been criticized in both generic (e.g. [11]) and construction-related (e.g. [12]) terms.

Since the year 1994, Kiiras and Huovinen have applied the same Porter's framework to the various contexts such as a spearhead strategy for entering a new construction market in Europe [13]. Nevertheless, it was concluded that the six aforementioned references had produced only the fairly applicable concepts for practitioners by the mid-2000s. Thus, these two authors engaged themselves in designing three recent concepts or logics [5], [6].

RESULTS

The three logics of arena-based competition, procurement, and marketing are re-defined in the context of HVAC markets. This is followed by the new applications for integrating HVAC value chains when such integrators inside the upstream Arenas 1-5 involve users, owners, investors, wholes contractors, and wholes CM consultants, respectively, and when **pioneering integrators** inside the downstream Arenas 6-7 involve the focal HVAC systems engineers and contractors as well as products and materials suppliers and traders.

Three logics of 8-arena competition, procurement, and marketing in HVAC markets

The logic of HVAC focused competition as part of any building market is herein defined in a form of eight interrelated Porterian arenas. In Arena 1 of wellbeing indoors, users occupy the stocks of buildings and exploit the HVAC systems that enable to perform their purposes in business, public, and private life. In Arena 2, owners compete with their building stocks including HVAC systems on a long-term basis. In Arena 3, providers offer their services for managing the high HVAC system performance over the life-cycles (L-Cs) as part of building stocks. In Arena 4, capital investors compete through investing in the realization of new buildings and the renewal of the existing ones including HVAC systems. In Arena 5, wholes contractors and CM consultants compete through the realizations of new and to-be-renovated buildings as wholes including HVAC systems. In Arena 6, HVAC engineers compete with their solutions and HVAC contractors with their (sub)systems when buildings are realized as parts. In Arena 7, HVAC products suppliers and traders compete with their (in)direct deliveries. In Arena 8, HVAC materials suppliers and traders compete with their deliveries as well.

Table 1. Logic of 8-arena competition in HVAC markets (applying [5], [6], and [7]).

No	Competitive arena	Incumbents and entrants
1	Wellbeing of occupants using HVAC systems	Owner users and tenants
2	Ownership and trading of buildings incl. HVAC systems	Owners + traders
3	Life-cycle services for HVAC systems in buildings	L-C services providers
4	Investing in and trading of buildings incl. HVAC systems	Investors and traders
5	Realization of buildings as wholes incl. HVAC systems	Contractors+ CM consultants
6	Realization of buildings as parts such as HVAC systems	Engineers + contractors
7	Supply and trading of HVAC products	Suppliers + traders
8	Supply and trading of HVAC materials	Suppliers + traders

The logic of the route-based procurement of HVAC inputs from downstream arenas is defined in terms of those procurement routes that couple the eight competitive arenas and the ones that enable sub-procurement inside any given arena. Focal procurers have one or more routes to pull together more or less integrated HVAC value chains across markets, businesses, downstream arenas, and projects. It is axiomatic that each particular procurement route, which any procurer chooses, determines the nature and rules of competition in the next downstream arena(s).

The logic of the route-based marketing of HVAC outputs to upstream arenas is defined in terms of those marketing routes that couple the eight arenas and the ones that enable a marketer to win deals also inside its base arena. Each route is coupled with a particular kind of buying behavior of clients or procurers. It is axiomatic that each marketing route, which any client/procurer in the chain prefers or accepts, determines the rules of competition in the next downstream arena(s). Focal marketers have one or more routes for connecting their base arena to one or more targeted upstream arenas or for enabling their marketing inside the base arena. Each HVAC related firm occupies **the two principal roles** of a marketer and a procurer in its primary competitive arena (or its base arena). As a marketer it interacts via various routes with targeted clients in upstream arena(s). As a procurer it acquires specified inputs via various routes from inside the same arena and from one or more downstream arenas.

Integration of HVAC value chains as part of buildings in base Arenas 1-2 and 4-5

The integration of HVAC value chains as part of value adding building related processes in the base Arenas 1-2 and 4-5 is illustrated in Figure 1. **In Arena 1 of building uses and wellbeing occupation**, many advanced owner users and most attractive tenants aim readily at being extremely well indoors inside pioneering high-performing green buildings, workplaces, and spaces across the globe. On the one hand, they desire to manage well the environmental impacts in terms of reducing energy consumption, emissions, electricity use, water use, solid waste, wood and materials use, and land exploitation (e.g. [14]). On the other hand, future workplaces are ecosystems comprising a careful balance of people, processes, and places. The focus is shifting from places to people: supporting their performance, satisfaction, and wellbeing in indoor climates. By analyzing work people do and then creating the right combinations of spaces, processes, and tools to support it, workplace management enables to increase both effectiveness and efficiency as well as to accelerate cultural/organizational change (applying [15]).

In Arena 2 of building stock ownership and trading, many advanced long-term owners and traders aim readily at cultivating their building stocks toward high-performing green buildings. In the OECD countries, people spend the bulk of their time indoors. Indoor climate has a direct impact on their health and productivity at work. Typically, personnel's salaries form the dominant shares of the life-cycle costs of office buildings (e.g. [16]). By improving indoor climate conditions, the wellbeing and productivity of personnel can be enhanced markedly. Therein, the energy efficiency of HVAC systems and the limited need for maintenance add to the profitability of indoor climate investments. In addition, the Internet convergence requires a new approach to designing the spaces in which principal processes are conducted, from stores to offices to factories to classrooms. This requires a new kind of **convergent architecture** including HVAC systems (e.g. [17]).

In Arena 4 of capital investing, many advanced short-term investors (along long-term owner investors) aim readily at enabling their pioneering clients to stay on the cutting edge in their core businesses or public services by **maximizing the total productivity** of their buildings, workplaces, spaces, and special rooms. Handing-risk-out investors rely on wholes contractors with their integrated value chains or nets. Instead, carrying-risk-themselves investors rely on wholes CM consultants with their core competences in integrating even unique, complex building systems and system-specific value chains. For example, integrating energy efficiency throughout building design processes will yield significant first cost savings. Capital and operating cost impacts are considered in tandem in order to realize maximum value from

HVAC based facility improvements. Efficiency is also associated with healthier and higher quality work environments, especially regarding the use of outside make-up air. In addition, the pre-diagnosis of HVAC solutions as part of the life-cycle engineering of buildings enables the early identification of maintenance problems, safety issues, and premature equipment failures (aligning with [18]).

In Arena 5 of realizing buildings as wholes, many contractors and CM consultants aim at enhancing their core competences to higher levels where they can assume those integrative roles of pulling together value chains or nets. At the same time, many of them may become the providers of life-cycle services vis-à-vis targeted owners and their building stocks. In Finland, special system contracting is being developed to advance the adoption of extended building contracts with the detailed design and engineering, manufacturing, delivery, and installation of various building systems (e.g. HVAC systems), modules (e.g. clean rooms), and functional elements (e.g. wellbeing in a high-level indoor climate) [19].

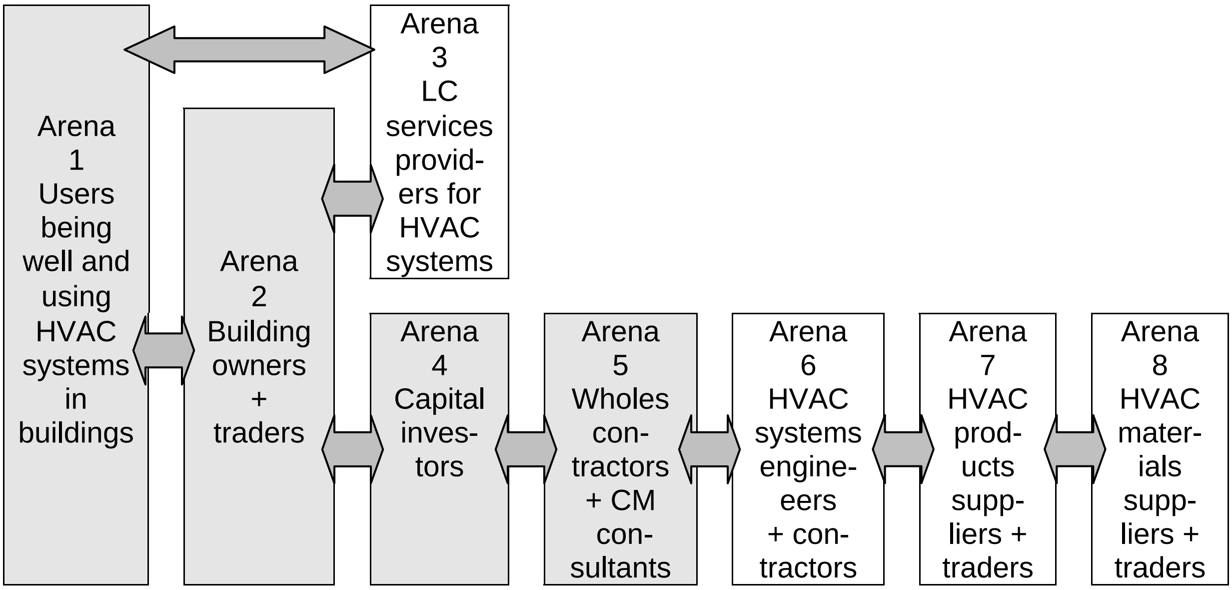

Figure 1. Eight basic routes for (a) procuring HVAC inputs from downstream arenas and (b) marketing HVAC outputs to upstream arenas within any given building market.

Integration of HVAC value chains by systems engineers across Arenas 3 and 6-8

In Arena 6 of HVAC systems realized as parts in buildings, pioneering independent HVAC systems engineers can aim at (i) integrating their engineering-based HVAC value chains in terms of the most advanced and evolving HVAC solutions, expertise, and core E&D competences, (ii) developing such chains internally and acquiring them externally in a form of (inter)national mergers, acquisitions, licensing, and collaboration, (iii) enlarging the scopes of their services to include also an array of HVAC systems life-cycle services, and/or (iv) becoming the HVAC knowledge-based members of the most competitive building-level value chains led by some of globally, internationally, regionally, or nationally leading wholes contractors. Engineering-based HVAC value chains can market their integrated solutions and competences via **four connecting marketing routes** to (a) wholes contractors and CM consultants in the upstream Arena 5 and/or (b) capital investors in the Arena 4. In addition, such integrated engineers can market their HVAC systems life-cycle services to building owners in Arena 2 and/or responsible users in Arena 1. These four marketing routes are shaded in Figure 2.

In particular, it seems that integrated HVAC engineers can attack many pervasive problems such as **the systematic over-sizing of utility systems** and the resulting oversized cooling equipment caused by overestimating first electrical demands thereby creating the fictitious sources of heat within a facility. This is compounded by the aggregate impact of multiple disciplines (owners, process engineers, electrical engineers, HVAC engineers, etc.) each adding “safety factors” to their calculations. The result is also higher operating cost due to excessive and inefficient on-off cycling and/or part-load operation. For example, **a combination** of high-performance glazing, low-pressure-drop HVAC design, and efficient right-sized lighting systems results in major reductions of the mechanical and cooling system sizes. Smaller duct sizes even allow to lower overall building heights for significant construction cost savings. This reduces the sizing of generators, resulting in additional first-costs savings. Ideally, above-standards performing buildings enable substantial savings in annual operating HVAC cost (applying [18]).

In part, engineering-based HVAC value chains can be **virtualized**, i.e. they may establish collaborative one-stop virtual engineering services such as the COVES project in Singapore. With the help of collaborative platforms and virtual communities, collaborative HVAC engineers might target to offer and to integrate services for heat ventilation and air-conditioning, fire and smoke, pollutant dispersion, and indoor air quality. Virtuality is being enhanced via e-modeling, e-analyses, e-simulations, and e-visualizations [20].

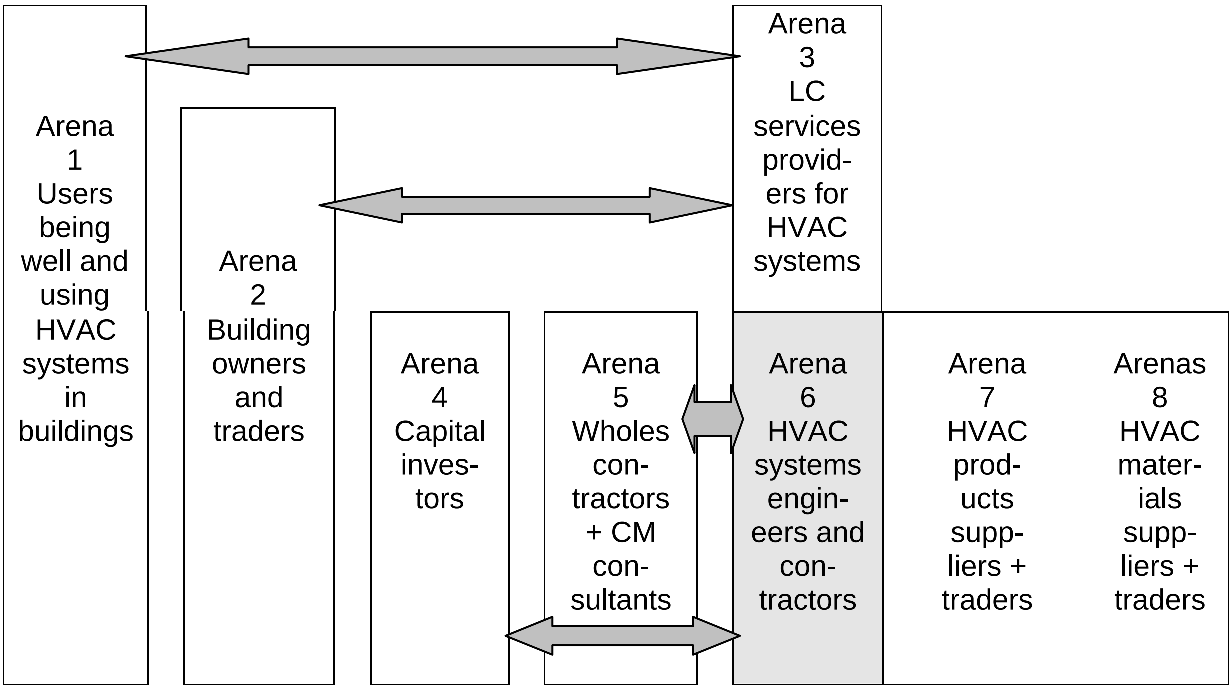

Figure 2. Systems engineers and contractors integrating HVAC value chains across Arena 3 and Arenas 6-8.

Integration of HVAC value chains by systems contractors across Arenas 3 and 6-8

In Arena 6 of HVAC systems realized as parts in buildings, pioneering HVAC systems contractors can aim at (i) integrating their contracting-based HVAC value chains in terms of the most advanced HVAC technologies, systems, products, and materials as well as core system management competences, (ii) developing such chains internally as well as acquiring and procuring them externally in a form of (inter)national mergers, acquisitions, licensing, partnering, networking, and/or competitive bidding (vis-à-vis key contractors, suppliers, and traders), (iii) enlarging the scopes of their services to include also an array of HVAC systems life-cycle services, and/or (iv) becoming the HVAC system-based members of the most competitive building-level value chain led by some of globally, internationally, regionally, or nationally leading wholes contractors. Contracting-based HVAC value chains can market their integrated solutions and competences via **four connecting marketing routes** to (a) wholes contractors and CM consultants in the upstream Arena 5 and/or (b) capital investors in the Arena 4. In addition, such integrated contractors can market their HVAC systems life-cycle services to building owners in Arena 2 and/or responsible users in Arena 1 (Figure 2).

The integration of HVAC systems targets opportunities in terms of integrating better the pieces of equipment, systems, or facilities. High variations in the equipment efficiency (e.g. cleanroom fan-filter units) can be minimized. Challenges and opportunities extend beyond swapping in and out HVAC products/components. It is not enough for pumps to be efficient. Indeed, even small improvements that enable and enhance high system integration can yield large benefits. In turn, **building automation and control systems** enable system-level energy savings opportunities. For example, variable-speed fans need to run at full speed less than 10 hours per month. Buildings with more advanced ventilation control systems are more resistant to chemical and biological attacks. The use of outside air improves the overall air quality [18].

DISCUSSION

This is a theoretical paper where the application of three logics of 8-arena competition, procurement, and marketing to the context of HVAC markets is initially supported with the selected exemplary references on the empirical status in some national contexts. Nevertheless, it is herein posited that **the integration management of HVAC value chains** is still in its infancy. Across most national practices, stakeholders are still focused on achieving partial, in-house process performance improvements. Overall, many pioneering owners, investors, wholes contractors and CM consultants as well as HVAC systems engineers and contractors have shifted to a view outside in their value chains including both first-tier and higher-tier stakeholders along upstream and downstream arenas. However, only a few efforts are spanning the entire length of any one value chain, not to talk about the life-cycles of HVAC systems embedded in building stocks and those of inherent HVAC systems (aligning with [4]). Readily, many existing barriers have been identified and the first progressive paths toward best practices are being outlined (e.g. [18]).

In turn, **pioneering HVAC inputs procurers (outputs marketers)** are hereby encouraged to set more advanced procurement (marketing) objectives and also attain them by (i) adopting the three logics, (ii) identifying the incumbents and their procurement (marketing) routes connecting the base arena with the targeted downstream (upstream) ones, (iii) anticipating changes in the focal arenas, entrants, and routes, (iv) deducing non-existing procurement (marketing) routes and/or inventing the new ones, and (v) (re)designing their procurement (marketing) strategies accordingly. Admittedly, the real usefulness of the espoused applications of three logics to integrating HVAC value chains needs to be tested, for example, in the context of building and HVAC markets in Finland and some other EU countries in the near future. Thus, collaborative cross-national research is called for in order to reveal the most advanced benchmarks for advancing best integrative practices internationally. In addition, the three HVAC focused logics may be conceptualized in more detail, arena by arena, by rolling the focus over upon each of stakeholders forming the targeted HVAC value chains.

Identifying Suitable Procurement and Briefing Processes for Schools

Paula Cardellino[1] and Derek Clements-Croome[1]

University of Reading, UK

ABSTRACT

The UK government are increasingly emphasising the importance of improving the school built environment. Recent studies have demonstrated the influence school architectural design factors have on pupils' achievement. Yet, the procuring mentality continues to be influenced by the legacy of short term decisions based on cost. The long term implications of the designed solutions are not fully appreciated. Procurement strategies exclude the real experiences and needs of the users of the buildings. The briefing process is failing to capitalise on the wealth of design talent that unarguably exists. New procurement methods are presented as means of coming to terms with some of these problems. Yet, these procurement routes have generated a great deal of debate and have received mixed responses. Initial evaluations have been less than conclusive as to their potential benefits. This working paper reports on the preliminary findings from a research project exploring the potential for changed practices in the design stage in these new procurement methods. Particular interest is given to the correlation between the design intent and the design outcome. Including how the chosen briefing and delivery methods allows for sufficient exchange of skills and expertise to produce designs in line with client needs.

INTRODUCTION

This paper addresses the pressing concerns of educationalists and the construction industry about the future approach to school design and procurement and how will this variety of approaches impact on the building design.

The overall aim is to assess whether links exist between new, well designed buildings and the procurement and briefing process utilised. In addressing the aim of the study, a number of key research questions were posed, namely:

- Are users satisfied with the quality and functionality of their buildings and associated facilities, and do they equate good quality with better performance?
- Are designers achieving good school design?

The study ultimate aim is to answer the following question: *Is there an ideal procurement route when designing a school*?

PROBLEM BACKGROUND

The last decade has seen one of the largest school building programmes in UK history However, many reports (Audit Commission 2003) have shown that apart from some notable exceptions, far too many schools now operational are considered to be mediocre or worse. These schools are not providing pupils with an adequate place where to learn. Nor are they providing teachers with an adequate place where to teach.

One of the reasons behind this problem is that the briefs tend to be based on traditional models of teaching and learning. In this way, issues like ICT and personalised learning are not being taken into consideration when designing schools. Added to this, a variety of functional problems are frequently deficient in many of the new schools such as: inadequate entrances and circulation spaces; limited social areas such as dining halls; a lack of future adaptability and; a lack of design of external areas. Environmentally poor many schools have lack of day lighting in classrooms with inadequate ventilation and poor acoustics making it very difficult for teachers and pupils to interact.

The fact that all these schools are a lost opportunity to create interesting and exciting buildings that would make teacher and pupils proud is a very real concern. These schools are inadequate to the shifting pedagogy, curriculum and learning expectations of the present and the future are lacking the agility to cope with anticipated changes(Building Futures 2004). Although there is only sparse evidence that education standards can be better achieved with 'great' buildings, it can still be argued that stimulating environments can be a great motivator for teachers and students.

THE NEED

At present there is a growing recognition that the public sector must be provided with environments that provide children with good places to learn, designed to the highest quality. Schools that are sustainable. Projects that involve users, stakeholders and local communities in their design and implementation. The government is giving the issue considerable attention and several separate but interconnected initiatives have been initiated.

PRIVATE FINANCE INITIATIVE

The Private Finance Initiative (PFI) provides approximately 15 per cent of the public sector's total capital investment and is currently limited to use on projects with a capital value in excess of £20 million. Between 2000 and 2005 PFI has been the main source of funding from the Department for Education and Skills (DfES) for new or replacement schools. One of the reasons behind the use of PFI for provision of new buildings for the public sector is that the finance available for the private sector may be the only way of filling the shortfall resulting form previous decades of underinvestment in infrastructure, in particular in schools.

PFI is a particularly complex and lengthy procurement process and it has frequently been considered to get in the way of creating design quality. In practice it is a commercial arrangement and driven in no small way by commercial interests. As such those involved in PFI, including public sector parties, are predominantly concerned with risk transfer, public sector comparators, 'value for money', output specifications and affordability. Therefore, the importance of 'design quality' has at times been suppressed.

Initially the government's belief was that the involvement of the private sector in the provision and management of the project would provide greater and continuing efficiencies in the construction and operational management of the projects. Also, the private sector would bring commercial and technical expertise and innovation to the project. Overall, the involvement of the private sector would generate cost efficiency and value for money.

However, the introduction of PFI projects into schools in the UK has generated a great deal of debate and has received mixed responses. In terms of the resulting buildings, the PFI in Schools study commissioned by the Audit Commission (Audit Commission 2003) found not only that few schools came out well in terms of the buildings cost of ownership but that the PFI sample scored, were significantly worse than the traditionally funded sample.

In the PFI procurement route, clients produce their requirements in highly structured documents setting out performance standards for bidders to meet. Few, if any, drawings are produced by the client, who takes no direct responsibility for the design. Bidders have to assemble a team that includes designers, contractors and facilities managers. The need to focus on the whole life cycle of a building making sure that standards will be maintained throughout 25 years of the contract is considered to be the great strength of PFI.

The RIBA has identified several problems with PFI including the excessive cost and time necessary to bid for PFI; inadequate resourcing of the public sector client at the early stages of procurement; lack of experience by public sector client who were first time commissioners of school buildings; work project briefs; insufficient direct contact between the client and the design team during the bidding stages. The result is a reduced value for money, excessive costs, barriers to complete competition, delays to delivery with an overall lowering of design quality.

BSF

The Building Schools for the Future (BSF) programme started in 2003/2004 (Building Futures 2004). It is a coordinated national strategy driven by the DfES that over the next 15 years will result in the rebuilding or refurbishing of every secondary school. BSF is not merely a building or procurement programme. The intention is to drive reform in the organisation of schooling, teaching and learning, ensuring transformational educational change.The BSF has now entered into the delivery phase that will see all secondary schools across England rebuilt or refurbished by 2020. 38 local authorities are engaged on BSF in the first three waves of the programme, and a further 33 have been invited to prepare for waves 4−6.

In 2005/06 the government’s investment in school buildings reached £5.5 billion. This included £2.1 billion for the Building Schools for the Future programme becoming a key part of the current strategic and targeted capital programme.

The audit commission report PFI in schools (Audit Commission 2003) which assessed quality and cost in early PFI projects (up to 2002) showed that PFI schemes did not deliver high quality buildings. In this way, BSF attempts to respond to that criticisms, with a programme of improvements. However, a recent study carried out by CABE (CABE 2006) shows that, though still in the early stages, many of the BSF schools on the drawing board are facing the same problems as previous programmes.

WHAT IS GOOD SCHOOL DESIGN?

For a long time reports have been written by different sources pointing out the need for good design in public buildings (RIBA 2001; CABE 2002; CABE 2004). Some of these reports are specifically targeting the PFI procurement route arguing that this approach is not addressing the concern of the government and stakeholders of achieving good design(CABE 2002; Audit Commission 2003; RIBA 2003; UNISON 2003; CABE 2005; CABE 2006). Some reports are aiming to draw lessons from what has been delivered to date that could help improve future PFI schemes (McCabe *et al.* 2001). In a document entitled *'PFI? A question of quality'* the Royal Institute of British Architects (2003) makes key recommendations on how to improve

PFI procurement, lending its support to the scheme as long as architects are involved earlier in the process.

But what does good school design really mean? There will probably be different points of view depending on the different stakeholders. The best people to judge this are the people that have to use the building because if the end users of the school are happy it indicates success.

The Commission for Architecture and the Built Environment (CABE), is charged with promoting good design in public sector building projects. In their report (CABE 2006) that assessed the design of a representative sample of 52 secondary schools completed between 2000 and 2005 using a variation of the design quality indicator for schools (DQI) clients argued that a good school is one that has a *'sense of place'*. This can be interpreted as a building that is inspiring and welcoming, but at the same time has to be functional in a way that encourages good behaviour and is easily managed. Furthermore, one that enables ease of movement with use of wide corridors facilitating easy and logical movement without congestion. Added to this, the outside is as important as the inside, therefore there needs to be good link between the two. Flexibility is another important aspect of the building where the different spaces can be used for different purposes. Last but not least, the school has to be green and sustainable considering alternative forms of energy and be built using robust materials from sustainable resources.

People have different opinions regarding quality, but good design of buildings, specially the public buildings, should respect and enhance the environment, add value and reduce whole-life costs. Buildings should also be created as flexible, durable, sustainable developments that will benefit the user and the community as well as providing functional, efficient and adaptable spaces.

Good design is not just a question of style and taste. It involves adhering to a set of objective principles that determine whether or not a building works well for all users and the community. Good design needs to address the following issues: how a building functions, quality indicators of the building, its environmental effectiveness, its contribution to the surrounding context and its attractiveness.

INFLUENCE OF GOOD DESIGN ON LEARING OUTCOMES

Globally new pedagogies are emerging such as increasing use of ICT and virtual classrooms, tailoring of the education towards the individual child's needs, different means of grouping within schools, opening up schools to wider community and a greater integration of special needs within mainstream schools. In the face of such change in environments there will potentially be a significant impact upon teaching and learning.

However, the question is, *is there is an actual link between the environment and the potential to learn*? Whilst it is easy to calculate and minimise heat loss from a building, the target of minimising a loss of potential learning through good design is considerably more intangible. Different schools, children, cultures and context at different times will create a variety of conditions for potential learning and these needs to be given voice, challenged and defended.

There have been a number of studies (Tanner 2000; Department of Education 2002; Green *et al.* 2004; Design Council 2005) undertaken trying to establish a link between the nature and quality of the physical environment in which students learn, and the learning outcomes associated with this environments. Whilst it is difficult to achieve explicit links, some convincing evidence linking the physical school environment with teaching and learning has emerged from these studies. Similarly in offices there is much evidence concluding that the environments designers create, affect work performance (Clements-Croome, 2005)

In a research study done in America looking at how school architectural factors influenced student achievement scores in elementary schools(Tanner 2000), several design factors were found to correlate with student learning outcomes. Computers where found to be an integral part of the building design where students earned high scores. Freedom of movement within the school and among learning environments was another of the significant design patterns discovered in the study. Furthermore, a lack of expansive pathways implies higher density, which has been proven to affect learning (Bechtel 1997). Crowding and high occupancy density have been associated with decreased attention, lower task performance, behavioural problems, and social withdrawal (Wohlwill *et al.* 1985).

Students with an overall good impression of the learning environment tended to score higher in average than those expressing negative feelings. However, the overall positive impression of a school implies the presence of friendly students and teachers. Students attending schools with poorly designed and maintained outdoor spaces had lower scores. It is clear that positive outdoor spaces invite nature to blend with the school's function and form. It is important for children to have a sense of being in a natural setting (Lawson 2001). A positive outdoor area gives a feeling that the school's learning environments are "in harmony with nature".

A research study done on school building investment and its impact on pupil performance in one area of England (Green *et al.* 2004) provides evidence of a perceived positive relationship between government investment and students achievement from the view point of the building users. The findings showed that the built environment was certainly perceived as having an effect on the well being of the teachers and students.

Perhaps one of the most surprising positive illustrations of the effects of building quality on performance is in the results of a case study carried out by a UK local authority (Williams 2006), which looked at the relationship between building quality and education achievement. Twelve primary school buildings were analysed and given a quality score and the educational achievements were taken from the OFSTED results. It is quite amazing to find that there is almost a straight line correlation between higher quality and better educational achievement.

The discovery of relationships between design characteristics and academic achievement should help in future school planning by pointing to design patterns that complement learning. In any case people experience the environment through their available senses at the same time, and it is this accumulation of experience that produce a physiological and psychological effect that ultimately will provide the stimuli to children and teachers.

PRELIMINARY OBSERVATIONS

Based on the theory stated above and on the questions that have been asked several preliminary observations can be mentioned. They are the result of an empirically based study of 2 architectural studios involved in the design of schools using PFI and BSF procurement methods. The interviews aimed to get a better understanding of the realities behind the design of schools under different procurement routes. In detail, the interviews were looking at the way in which innovation, flexibility and user's participation was handled in the context of different procurement methods.

The interviews captured the concern of the architect involved in the design process. In the future, exploratory semi-structured interviews will be carried out with other professionals with experience in different procurement routes such as contractors, facilities managers and investors and a selection of clients such as principals, teachers, and DfES. Thus, information will be gathered from numerous open interviews with practitioners and public sector representatives having experience of completed schools in the UK and abroad. This will help to determine current practice and increase the understanding of the actors' participation in the design process and their expectations. Most importantly, it will help structure the study through the identification of core areas of interest.

The first stage of the interview asked what separates a good school from a bad school, followed by what are the features of a good school building. Building on these issues, these questions were followed by their own experience regarding design of schools.

From the interviews it is clear that the architects' point of view is closely linked to the building features of a good school. Interviewee 1 argued that the architecture of communal spaces, such as dinning room, and the circulation within the building are the main places that can make the difference between a good and a bad school. In this case, the following question regarding the features of a good school building was almost seen as the same question. He notes that once the basic classroom has been reasonably designed, the architect can contribute to a successful school design by providing the spaces such as the street, the entrance and the dinning hall with a unique identity. This provide each school with a unique signature and a place in the local community. Once the building has achieved a degree of design were things are working accordingly, the really exciting thing about designing a school is the potential the building has to achieve something special and unique that makes it different from any other school. The ability to include the ethos of the school into the building will positively help the school achieve its potential. He argues that this is very difficult to achieve in some of the procurement methods such as PFI. The reasons behind this are that the briefs tend to be very similar, leaving little room for new ideas in school design.

On the other hand, interviewee 2 had a more managerial view of schools where, for him, the difference is done by the teachers and the management together with the head teacher and the leadership. Therefore, buildings have a limited role to play in whether a school is a good or bad. The school is the people in it, the pupils and the teachers, where the building is a component of the school, but it is not the school. Drawing from his experience, a very low achieving school was turned around into a highly performing school with no need for a new building, but with the introduction of a new whole learning program focused on motivation and achievement. Looking at another example where a new school was finished in 2005, the 2002 OFSTED reports and exam results showed 66% A to C and in 2006 the school scored 89% A to C. But was this improvement achieved only because of the new building or was it because, when they where moving themselves from the old site to the new site, the school took the opportunity to completely change the management structure, the way they delivered education. Following the idea the interviewee puts forward an analogy by saying "… *I wonder whether it has to do with the fact that it(the building) doesn't directly influence but it makes the journey better. I think the analogy is that you can get on an old train and you still hopefully will get from A to B, but if you get in a new train you still get from A to B but it just makes it more pleasant. It makes actually the experience a better one*".

He concludes this first stage by arguing that the school is a complete fusion of management, the staff, the pupils and the learning program and the school. Therefore, a good school is one where the design of the building supports the learning and integrates the ICT technologies, as well as a healthy naturally ventilated, well lighted, acoustically responsive and accessible building.

But, can all of these be achieved using the existent procurement routes?

In the second part of the interview, architects were asked what they would consider to be an ideal procurement route for schools. In this part architects complaint about the lack of contact with the end users of the school in some procurement routes such as PFI. In this approach the contact with the end users is controlled. It is quite exhausting for the end users and unsatisfactory for the designers.

One of the interviewees argued that one of the problems with the PFI process is to be cost led and lacking continuity so there is no incentive to produce a better product, the only incentive is to maximise profits. The PFI did not generally include education in the agenda, the PFI was about buildings.

Compared to other procurement methods, the BSF programme was considered to be a good route in the way that brings the constructor, the educationist, the ICT provider and the architect together at the very outset of the project, enabling a proper learning integration into the school. This is the reason why hat is BSF programme was considered to be a good system because it incentivises the market to improve on quality because of the long term relationships. Within the BSF programme the PFI is the funding stream that enables the new school.

In the PFI context there was no incentive for the consortium to improve learning outcome. It was all about the building. In the BSF program is not about buildings, is about the integration of learning into the school.

Other advantage in using the BSF Programme is having the constructor at the beginning of the process. This enables the architect to focus on quality, aligning the cost, the design to the most efficient method of delivery. In this way better quality buildings can be achieved.

The third part of the interview looked at the different issues concerning design quality, such as innovation, flexibility and user participation. In both interviews architects agreed that PFI is not delivering innovation, in fact compared to other procurement methods, PFI is considered to be less innovative.

The reason behind this lack of innovation is because the brief is too rigid. The only way to innovate is overlapping some of the activities to get better spaces. However, as the judgement of everybody involved in the tender process is done under the same criteria designers straggle to prove within a square meter that they meet the brief. There is a temptation that you make sure to tick all the boxes that everything is per square metre. And it turns out to be a matter of ticking out the box. Though, innovation has been achieved in some PFI projects this has been despite of it not because of the fact that it is a PFI.

Risk has been considered to be one of the reasons behind the difficulty to innovate. The contracts are loaded to penalties if failing to deliver. So everything is about managing the risk, certainty of delivering within the cost and on time.

However, BSF has the potential to innovate because of that long term continuity. It really does have a potential.

CONCLUSIONS

The slightly discouraging emerging picture that is appearing is that regardless of the programme/initiative it appears as the public sector continues to be driven by short term calculations of cost. The failure to compute the emotional, social and therefore economic benefits that accrue from good design has led to procurement processes which exclude the real experiences and needs of the people who will use the buildings, objects and experiences that are designed. Briefs are issued which ask the wrong questions and thereby fail to capitalise on the wealth of design talent within the UK.

RIBA in 2005 introduced a paper entitled *Smart PFI* which emphasizes the need for longer preparation of the procurement process so more time is spent between the client and the design team besides giving the opportunity to ensure that innovations and best practice are all deployed on the project. An example of good practice is the Jo Richardson School in London.

Systematic process for commissioning building energy performance and indoor conditions

Veijo Nykänen, Satu Paiho, Jorma Pietiläinen, Janne Peltonen, Keijo Kovanen, Timo Kauppinen and Hannu Pihala

VTT Technical Research Centre of Finland, Finland

Corresponding email: veijo.nykanen@vtt.fi

SUMMARY

In Finland, buildings are commissioned mostly in the end of the construction phase. However, the commissioning of building performance is a systematic process which should kick off already at the pre-design phase and it should be continued through design, construction and acception to occupancy, use, operation and maintenance. During the Cx process, it should be checked that owner's and users' needs and requirements are clearly defined and documented, and indoor and energy performance requirements are included to owner's program. In addition, it should be audited that the design solutions and installation outputs meet given requirements, and verified that the building satisfies given indoor and energy requirements in use. Commissioning should also be included as an essential part of a systematic facility management process over the building life cycle.

This paper describes a systematic process for commissioning building energy performance and indoor conditions. The Cx process is developed to be applied in Finland. In addition, checklists for each commissioning phase for a commissioning manager were developed. Also preparation of a Cx plan, and options for a Cx team and examples of task responsibilities are briefly discussed.

INTRODUCTION

Nowadays in Finland, building commissioning is not a standard procedure during the building life-cycle. Most often it is only used during building hand-over in new buildings, and sometimes as a separate measure in existing buildings.

Commissioning (Cx) process should be launched as early as in the programming phase to check that owner's and users' needs and requirements are clearly defined and documented, and that indoor and energy performance requirements are included to owner's program. In addition, it should be audited that design solutions and installation outputs meet given requirements, and verified that the building satisfy given indoor and energy requirements in use. Cx should also be included as a part of routine facility management process over the building life cycle.

Cx activities include the following goals:

- To provide safety, healthy and comfortable spaces for living and business
- To improve design quality by more effective feedback
- To assure that all building services systems are compatible with each other
- To improve energy efficiency of buildings and building systems

- To decrease operation costs
- To improve operation and maintenance personnel introductory briefing and training
- To improve documentation during the building life-cycle
- To meet customer needs and expectations and satisfy customer requirements

CX PROCESS

In Figure 1, there is the outline chart of the Cx process [1]. The Cx processes presented in [2] and [3] were the starting points for the development of this Finnish Cx process. The attached checkpoints “diamonds” link the Cx activities to the building process phases in general. At the beginning of a construction project, goals are established and the owner’s and users’ needs are determined. Then, the system requirements are set with the help of design procedures. Thirdly, the goals are implemented and performance is verified in the elaboration and construction phases. Finally, indoor climate and energy consumption is managed with new building automation and online reporting systems.

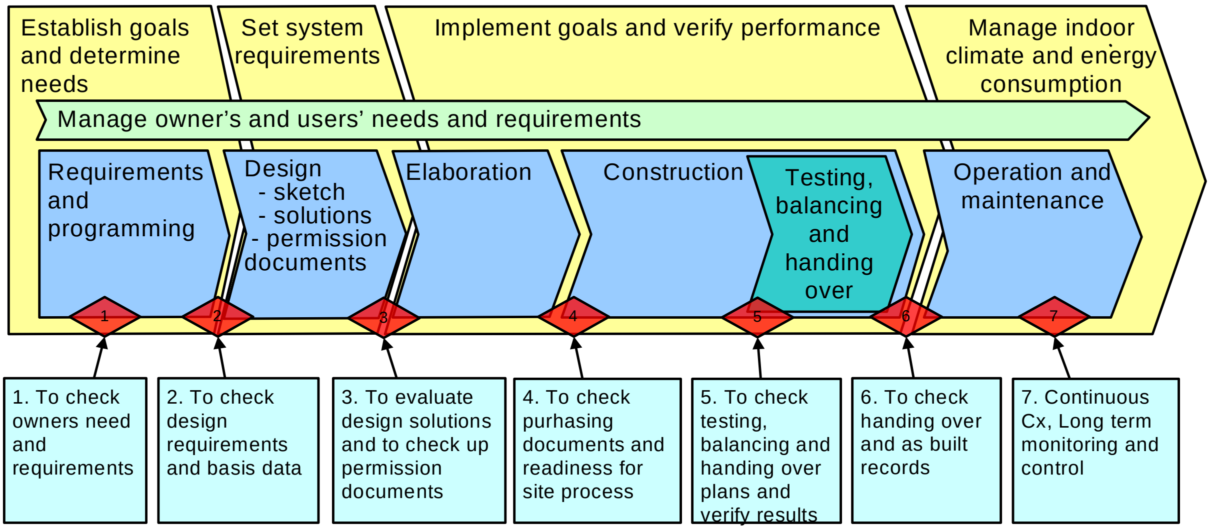

Figure 1. The Cx process.

Requirements and programming review

The objective of the phase (diamond 1) is to ensure that the owner’s and users’ needs and requirements are defined and documented. During the project planning different options to fulfill the owner’s needs are clarified, plans for the project budget are made and the goals for the next phase (diamond 2) are defined.

Key activities are to:

- Check the owner’s future strategies and action plans
- Check the owner’s and users’ needs and requirements
- Check the construction site and detailed town plan
- Check different goals and requirements and identify the possible risks

Design requirements review

The objective of this phase (diamond 2) is to ensure that the design requirements and basic data are relevant for setting up the system requirements. This information is also used to draw up contracts.

Key activities are to:

- Check design goals and requirements
- Check design contract documents
- Check that maintenance and monitoring requirements are sufficiently included

Design solutions and permission documents review

The objective of the phase (diamond 3) is to ensure that the design concepts and permission documents are correct. Indoor climate and energy consumption are based on the design concepts, proper results can be obtained only if the design concepts are relevant.

Key activities are to:

- Check design concepts
- Check building permits
- Take into account the system integration point of view

Purchase and contract documents and construction site reviews

The objective of the phase (diamond 4) is to ensure that the purchasing documents are relevant and the construction site is ready for implementation. In this connection, it is important to accept all system specific objectives with all the contracting parties. Especially, the integration perspective of different subsystems and procurements must be taken into account.

Key activities are to:

- Select and accept the systems to be implemented
- Calculate the design and construction cost levels for every system
- Agree the functional requirements for all systems
- Check that the tender documents meet bidding requirements

Functional testing and balancing review

The objective of the phase (diamond 5) is to ensure that the testing, balancing and hand-over plans are relevant. The main focus is on final tests and preparation for hand-over.

Key activities are to:

- Make sure that the systems and subsystems are functioning as agreed
- Make sure that the agreed level of indoor climate can be achieved
- Make sure that the assignment and maintenance manuals are relevant

Hand over review

The objective of the phase (diamond 6) is to ensure the hand over, also the as built records play an important role. At this phase the interoperation of all systems is crucial.

Key activities are to:

- Review all possible defects in the hand-over process and assess the repair work to be done

- Make sure that the building is faultless
- Make sure that all subsystems are tuned and operating as planned

Long term review of operation and maintenance

The objective of the phase (diamond 7) is to ensure that the indoor climate and energy consumption are managed and monitored for the optimal performance of the building during its whole life cycle. At this phase the continuous commissioning tools play an important role.

Central activities are to:

- Monitor the indoor climate, energy consumption and water consumption
- Measurements, audits and functional tests can be used when needed

CX MANAGEMENT

Before any Cx activities can be realized, a project specific Cx plan must be prepared and a qualified Cx team gathered. In the following, these issues are shortly discussed.

Cx plan

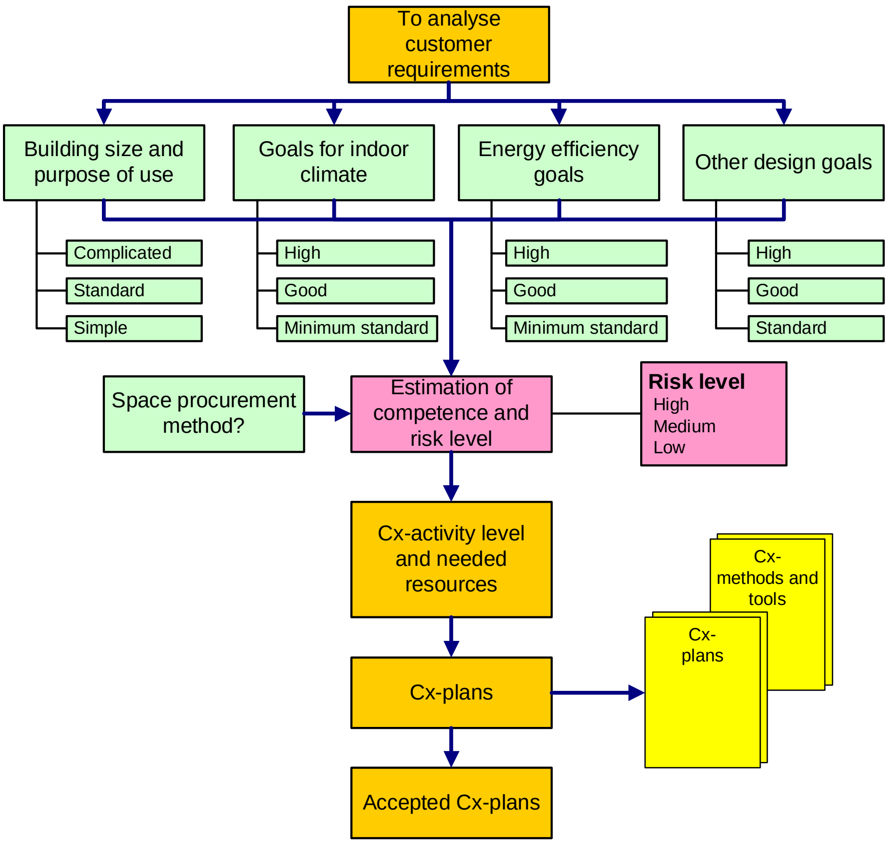

Figure 2. Preparing a Cx plan, applied from [2].

It is necessary to prepare a Cx plan according to the project phases. If on hand, general commissioning planning procedures support the Cx manager’s work. However, different building projects have different features like size, complexity, procurement method or risk profile. Altogether, the Cx manager should prepare a project specific overall plan and detailed phase plans in cooperation with the owner and the design professionals. In Figure 2, there is shown a procedure for preparing a Cx plan. There several important aspects should be taken into account.

In the implementation of the Cx activities a number of checklists and verification documents are also needed.

Cx team

Different procurement and delivery methods establish different starting points and terms to organize Cx activities. In the traditional design-bid-build projects the owner must hire also a Cx manager. In the design Build contracts the owner has only one contracting party and it is possible to transfer at least some of the Cx responsibilities to the general contractor. It's the question of the owner's strategy and decision, how detailed commissioning process he wants to implement. Table 1 gives examples for selecting the Cx manager in different projects.

According to Finnish Land use and Building code every building project must have the principal designer. Tasks and responsibilities of the principal designer are partly similar with Cx responsibilities. It is necessary to adjust the role of a Cx person with principal designer tasks. In many cases the principal designer and the Cx manager could be the same person. It's also related to the project size and complexity as well as the professional background of the principal designer.

Table 1. Options to select a Cx team manager.

Cx manager ¿ Strong role l Participation ¢	Small DBB project	DBB project	DBB project	Design & Build project	Design & Build project	DBOM project
Principal designer	l	¿	l	l	l	l
Independent Cx consult (ToVa)				¿	¢	¢
Owner s agent	l	¢	¿	¢	¢	¢
General contractor s agent	¢	¢	¢	¢	¿	l
HVAC designer	¿	l	l	l	l	l
Electrical designer	¢	¢	¢	¢	¢	¢
Construction designer	¢	¢	¢	¢	¢	¢
Automation designer	l	l	l	l	l	l
FM service engineer		l	l			¿
Supervisor	¢	¢	¢	¢	¢	¢
HEPAC contractor	¢	¢	¢	¢	¢	¢

The most building projects are rather small or medium sized. The Cx team manager may be an external consultant. On the other hand, the Cx manager can be seen as a role and he or she could also be a design professional, a FM service engineer or an owner's supervisor. In design build projects and DBOM projects the Cx manager may be a service provider's agent.

In very large and complex projects, it's a better possibility to engage the whole external commissioning team.

DISCUSSION

In the construction market some big trends point to the need of a systematic Cx process. Especially upward energy prices and increasing requirement for a good and healthy indoor air are the drivers.

The commissioning concepts and processes are not yet widely accepted and in use. The Cx concepts and procedures need to match with the actual project and quality management practices. In addition, the Cx team should match with the normal project organization. So, the key question is the role of the traditional supervisor and the building services supervisor. We cannot only add an extra Cx organization to the traditional construction project practices. The whole project management needs to be reformulated somehow.

The Cx concept has challenging goals: to achieve good indoor conditions, energy efficiency and the other owner's goals at the same time. It's necessary to implement a growing amount of pilot projects in order to prove benefit potential in practice,

Building Performance Optimization Services for the city Boras, Sweden

Johny Hjerpe

Siemens Building Technologies

Corresponding email: Johny.hjerpe@siemens.com

SUMMARY

In 2002 the Siemens branch office of Gothenburg and the representative of Boras started a pilot project to address how Building Performance Optimization (BPO) Services could support the city of Boras to increase energy efficiency in existing school buildings. The subject of the project was a school campus called Erikslund.

Siemens was able, in close cooperation with the management and operational staff of the school campus, to reduce energy consumption by more than 30%. These savings where achieved without major investments in equipment or changes to the building itself.

The key to success was BPO Services and making maximal use of the installed Building Automation Management System.

As a result of the pilot project the comfort and energy efficiency of a total of 12 buildings in Boras has been addressed and improved.

INTRODUCTION

A new Service was introduced in 2002 that reflected the increased interest of the market in energy efficiency, environmental responsibility and increasing energy prices: Building Performance Optimization Services. The aim of the offering was to develop a tailored service agreement together with the customer to optimize the building's performance. The offering, which is part of the Advantage Services, includes Energy Optimization, Operational and Alarm Management Services. Cost effective implementation of these services is made possible by connecting to Siemens' Advantage Operational Centre (AOC).

To give an example of how BPO Services provides value to customers, the school campus Erikslund in Boras was selected as a pilot project. In order to provide a proactive service, the branch office of Boras scanned in the 2002/2003 consumption figures of all customers with existing Siemens Service Agreements, and by benchmarking these figures, identified customer sites with high consumption. In the case of the school campus, Erikslund, the deviation between the benchmark for schools and the actual energy consumption of the campus indicated a need for more in-depth investigation into how the energy in the buildings were being utilized.

THE PROJECT

The school campus is made up of three buildings: The oldest building on the campus is Komvux, built around 1945 and dedicated to adult education. In the early 1970's the school was extended by the Erikslund building, a high school, and a gymnasium. Approximately 1'100 students are on the campus with a total heated area of ca. 12'600 m^2.

Figure 1: Class Room

Figure 2, Komvux Building

All three buildings are supplied by one central district heat substation. The majority of the heat demand of the building is covered by a radiator system; additionally most of the space is mechanically ventilated. The whole campus is controlled by a VISONK- System which is connected to a DESIGO-Insight management station. This allows Siemens to monitor and control the whole facility remotely.

Looking at the specific consumption (kWh/m^2) figures of 2002 and comparing it with benchmark figures, it indicated that how the energy was used on the campus could be improved.

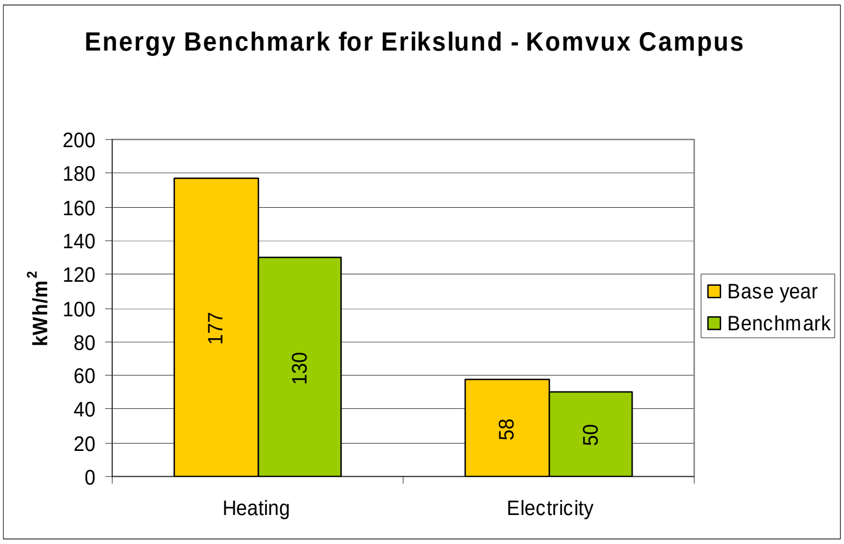

Figure 3

Based on this assessment, the available data and Siemens competence in optimizing HVAC-Systems, the responsible officials of the Boras Community were invited by Siemens to discuss the findings and to introduce the details of BPO Services. A proposal was presented how Siemens could support the owner to increase energy efficiency of the campus with the result of lower energy costs and less CO_2 emission but without effecting comfort levels. The

representative of Boras decided to commission Siemens to implement BPO Services at the school campus.
To understand BPO Services it is important to understand the concept behind it. It's based on two phases:

Phase 1: A tailor made Solution

Build a tailor made solution for the specific needs of the facility and its occupants. As described below, Siemens followed a clear roadmap together with the customer, to gather all necessary information, data and requirements.

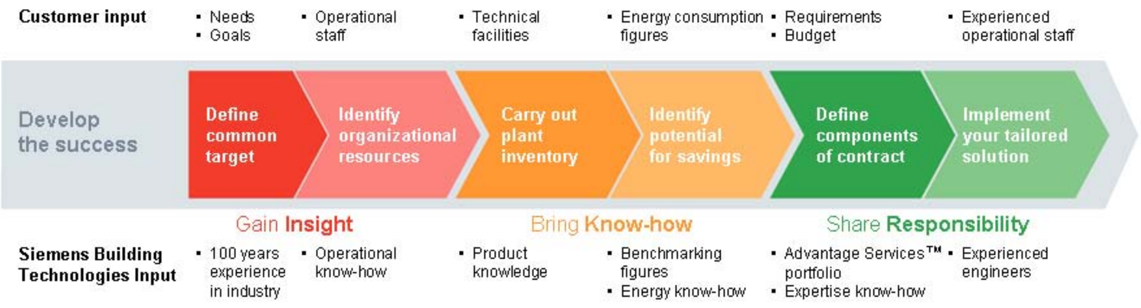

Figure 4

Meetings with the headmaster and operational staff gave Siemens insight in the operational sequences of the campus and its special needs. On the other hand these meetings were a good opportunity for the school personnel to ask questions and understand what was going to happen. At the end of this first phase both sides had a common goal and understanding.

Phase 2: Implementation

In this phase Siemens implements the solution in close cooperation with site personnel by following the process below:

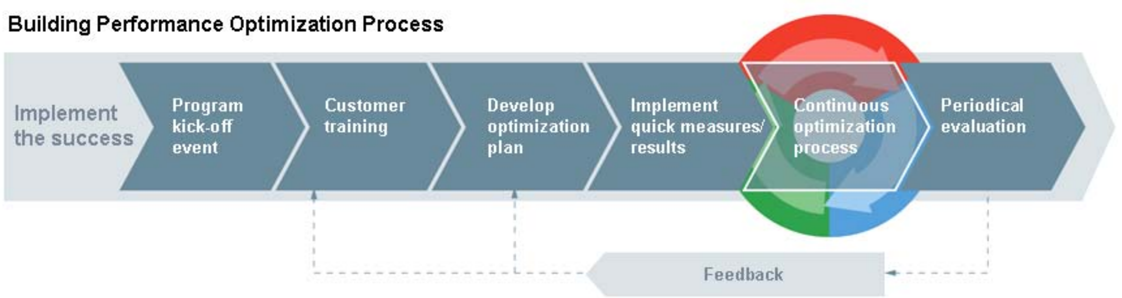

Figure 5

Before the implementation was actively rolled out, the school campus's Building Management System (BMS) was connect to the Advantage Operational Center (AOC). This is an important precondition and gives Siemens operational staff remote access to the site 24/7 to monitor and control building operation as well as helping school staff to identify and fix HVAC related problems.

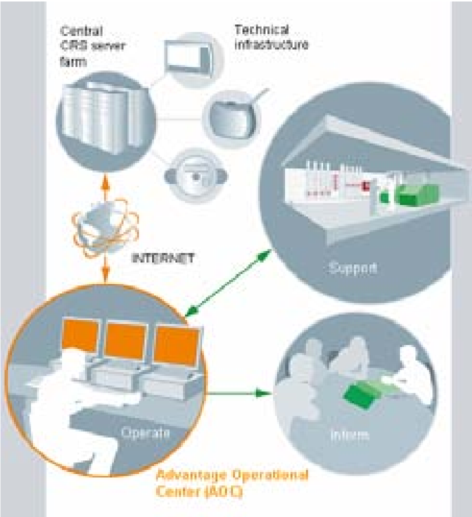

Figure 6: The AOC

After the successful connection to the site, Siemens established a metering concept with all available meters in order to monitor consumption figures. This allows monitoring of the effects that optimization measures have on the consumption and gives indices for changes of operation.
Using the AOC, Siemens staff were able to set up diagnostic reports and analyze plant operation.

In the case of the school campus room temperatures, running hours of pumps and air handling units, flow and return temperatures and the actual district heat demand was trended. An Energy Engineer together with the AOC- Operator assessed and analyzed the gathered data. With this information an on-site meeting was scheduled with the involved operational personal to share the findings and develop an optimization plan for the campus.
In a first step the Energy Engineer, accompanied by a Service Technician and the customer's operational staff viewed al the different plant rooms within the campus to have a full picture of the installation and its condition.

By sharing know-how, the findings from the analyzed data and input from the occupants, Siemens and the operational staff agreed on optimization measures written down in an Optimization Plan.

The measures which were taken can be split up in three categories:

- BMS related measures (Software)
- Organizational measures and
- Structural measures

Measures based on the BMS were to adjust control parameters, optimize set points and change time schedules to actual needed values. The basic requirement to be able to do such changes is a detailed understanding of the requirements of the specific space during a specific time. To always be up to date on these requirements, regular meetings with the headmaster were taking place to discuss needed adjustments of the control strategy.
Additionally, Siemens Engineers applied the latest control strategies to heating circuits and air handling units, e.g. the so called HEAT ECO function, Optimum Start Stop Control or the ECONOMIZER function based on the outside air enthalpy.

As examples for organizational measures, the following two are mentioned:

1. The gymnastic building was supplied by a district heating connection of some one hundred meters from the main substation of the campus to cover the energy demand for heating and domestic hot water of the showers throughout the entire year. By using the existing electric heater in the DHW tanks it was possible to switch of the district

heat connection during the summer period. This resulted in saved pumping energy and heat losses of the pipes.

2. As usual for district heat supplied sites, the customer of the utility provider has to pay a demand charge additional to the consumed kWh. This demand charge is depending on the highest value of heat that the site consumed during a certain period of time (e.g. 1h). Siemens optimized the programming of each heat consumer on site in a way that the maximum demand of heat decreased significantly and the customer now pays less demand charges to the utility provider.

Measures where smaller structural actions were needed were done as well.

BPO Services is not only taking care of optimizing BMS related equipment; a major contribution to the success of this project was the ability to look at the whole picture. Most of the class rooms in the newer building of the campus were heated by single independent ventilation units which were installed beneath the windows. A room temperature sensor controls the heating coil inside the unit and a damper the amount of outside air. During the night the damper to the outside is closed and the room set points are set back. By trending the consumption figures and after questioning the operational staff, Siemens started to check the function of the dampers. It turned out that a high percentage of the dampers were not working well, with the result that too much outside air infiltrated the space and this caused high energy consumption.

The air handling unit in the gymnastic building for example was controlled by a room temperature sensor and schedule. As is the nature of these kind of buildings where the occupancy rate varies heavily during the day, with the effect that more outside air is provided to the space than it is needed to keep the comfort level. Even in cases of very short term changes of the planed building schedule the air handling unit was not able to react to the changed conditions.

Siemens applied CO_2 and occupation sensors in order to control the air handling units based on demand rather than on a fixed set point or schedule. A close monitoring of the plant operation after adding the sensors and changing the control strategy by the AOC ensured the high performance of this measure.

After implementing the measures of the Optimization Plan the necessary data points get trended in the AOC. Each deviation form the pre-calculated budget generates alarms, which are carefully handled by the AOC Operator. Consumption reports generated on a regular basis and discussed with site personnel and the headmaster of the campus ensures long term success and gives the opportunity to extend the savings year by year. The following chart shows the development of the yearly heat consumption figures.

Discussion of the consumption figures

The monthly consumption figures for heat for 2002 (Base year) and 2006 show the savings achieved for Erikslund school campus. The weather adjusted heat consumption for 2006 was reduced by 707’000 kWh or 32% compared to 2002.

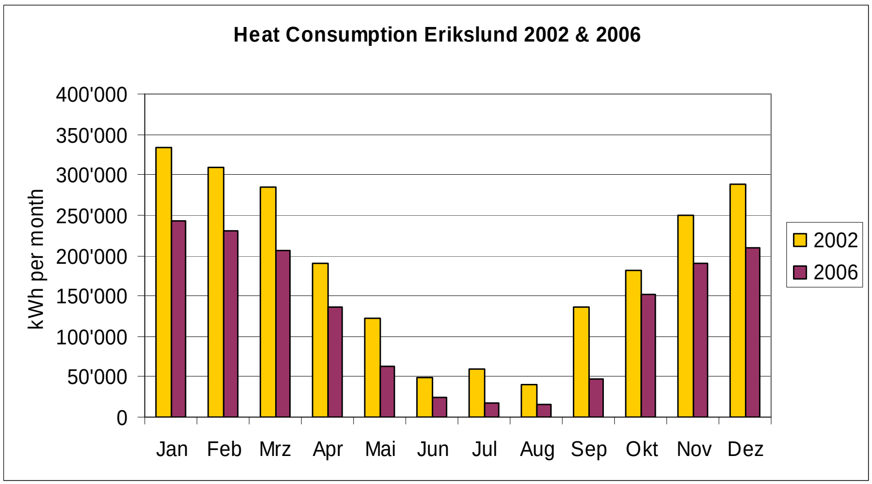

Figure 6

The chart below shows the heat consumption on a yearly base split up in a weather independent (domestic hot water) portion and in one for space heating.

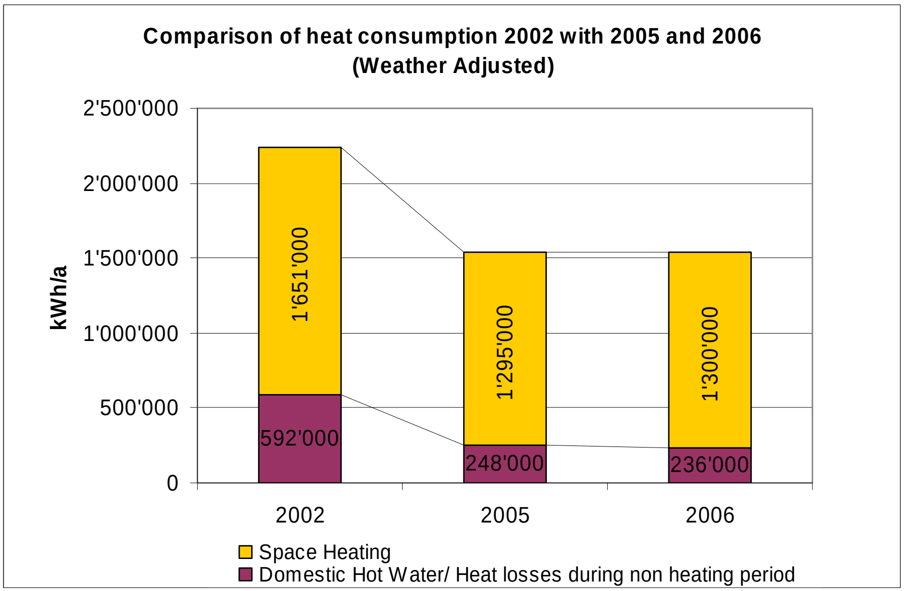

Figure 7

The figures show an interesting detail: The weather independent consumption is reduced by 60%. This is the result of changed heat supply of the gym during summer (less heat losses for district heat piping), the HEAT ECO control function that reduces heat consumption especially in between seasons, the ECOMOMIZER function of the air handling units and the adjustments of heating set points.
(The additional electricity consumption for preparing DHW in the gym is not taken into account for that graph)

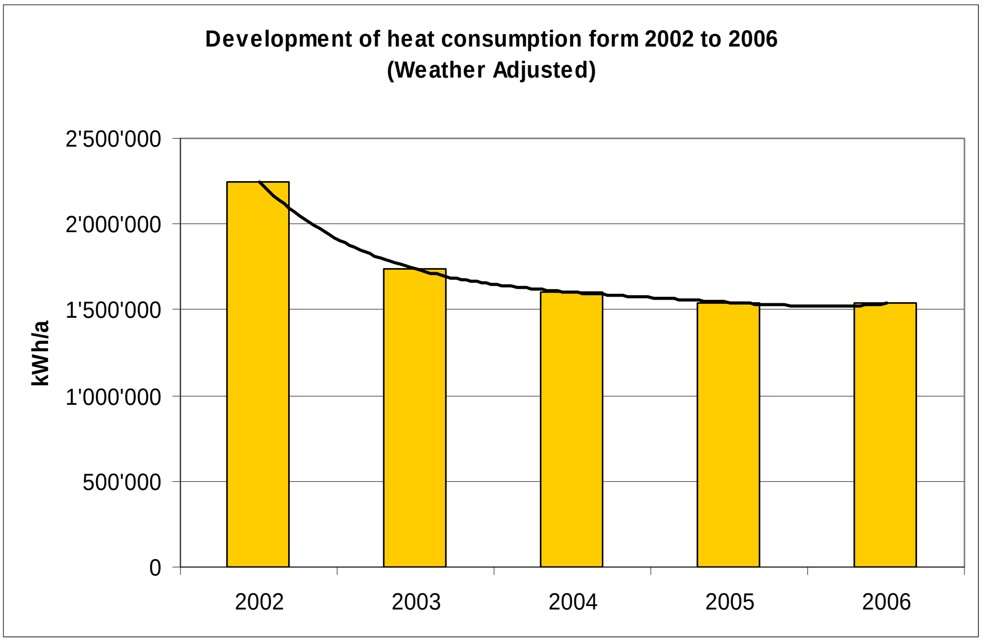

Figure 8

The chart of the heat consumption development is showing the continuing approach of BPO Services. 2002 compared to 2003 shows a big reduction in heat consumption and during the following years it was possible to prevent an increase. Due to proactive optimizing of the plant operation it was even possible to increase the savings.

It can be assumed that if the close monitoring and controlling of the site is stopped, the consumption tends to increase again. Like every process it is necessary to invest some amount of effort to keep it alive.

The development of electricity shows a similar impressive picture to the heating. The consumption is even more dependant on the actual amount of students. Komvux student figures are quite varying, whereas the high school student figures are nearly constant throughout the year.

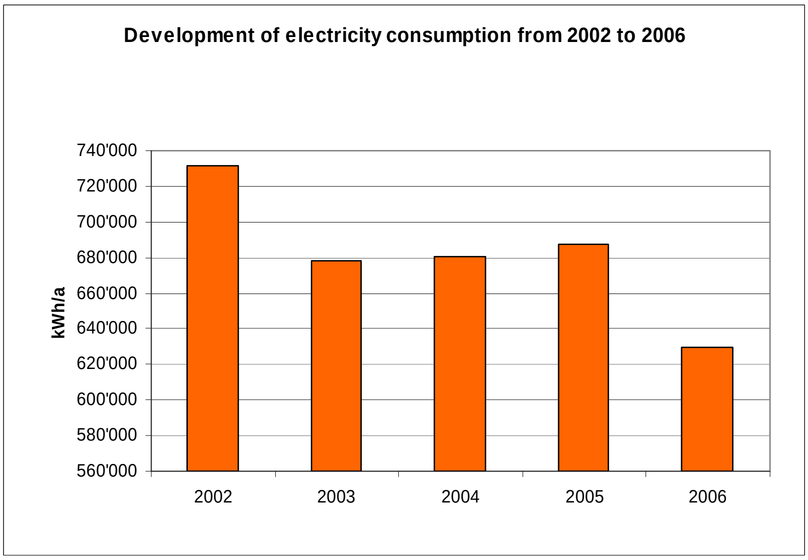

Figure 8

The savings are based on adjusted time schedules and reduced run hours of secondary equipment like pumps and fans because of a more on demand based control strategy. Important to mention is that Siemens and the headmaster of the campus meet at the beginning of each semester to adjust the time schedules to the new class schedules. The daily tracking of the schedules through the AOC is another important factor to keep the run hours at a minimum.

SUMMARY

The design, use and maintenance of buildings and building service systems have become more and more complex, in the sense of management of information and knowledge. The systematical risk management methods and applications are sophisticated ways to evaluate and manage the risks. This paper presents three case studies for risk management. The first case describes the management of risks and success factors in building service life-cycle project, and this is application for design phase. The second case describes the systematic approach for risk management of indoor air quality of ventilation system during the use of system. The method points out the biggest risks inside the system, which may cause problems in indoor air quality, and will help to find out the most important points in the technical system, to be checked and controlled. The third case is evaluating the risks when taking the responsibility of energy consumption of the building service system.

INTRODUCTION

The design, use and maintenance of buildings and building service systems have become more and more complex, in the sense of management of information and knowledge. The systematical risk management methods and applications are sophisticated ways to evaluate and manage the risks.

When planning a new building or renovation of the existing buildings, the best possibilities to effect on the costs, performance and conditions of the building is the pre-design and design phase (figure 1). If the requirements for the building are properly set and also the possible evident risks have been evaluated, the implementation of the conditions and their matching to needs and requirements can be checked following a commissioning procedure (or, in general, mutually accepted quality control procedure) [1] (figure 2). The main reasons, why the building does not fulfil the prerequisites can be divided roughly into three parts: 1) faults in pre-design and design stage, 2) defects in implementation stages and 3) malfunctions in TAB (testing-adjusting-balancing) and in use stage. The energy performance, energy efficiency and indoor conditions, as thermal comfort and indoor air quality, depend on the proper integration of building envelope, functioning of the ventilation system, heating systems, cooling systems, BAS (building automation system) and internal and external loads (weather conditions, use, etc). The crucial matter is how the operations of these factors are integrated together, and how these factors will cohere. In the pre-design phase, the building owner should set his requirements and demands as well as possible matching the needs. The problem has been earlier, that these requirements have not been properly set. In some cases, for instance, when planning a shopping mall or commercial building, the owner probably does not know the final users, or not all of them. The needs of individual end users may vary, which would cause e.g. the use of distributed ventilation system.

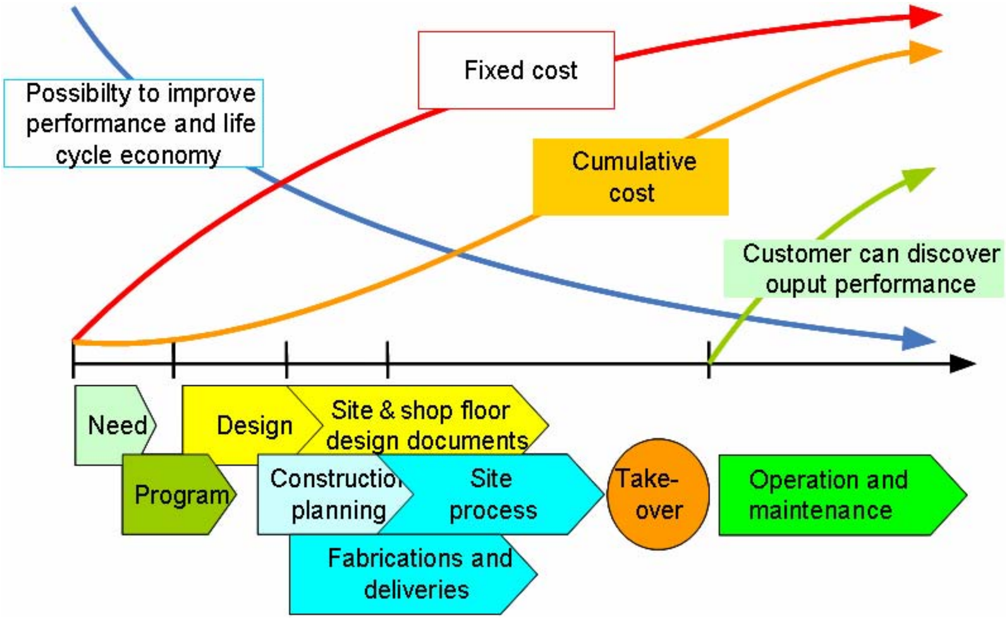

Figure 1. Building process [2] .

Different type of risks exists in the building process from design phase to operation phase. The quality and commissioning procedures are needed to support the building processes. The procedure includes the different stages of the building process. Figure 2 shows how the requirements and goals will be checked between each stages of the project [1]. Each 'diamond' contains check-lists of tasks and operations.

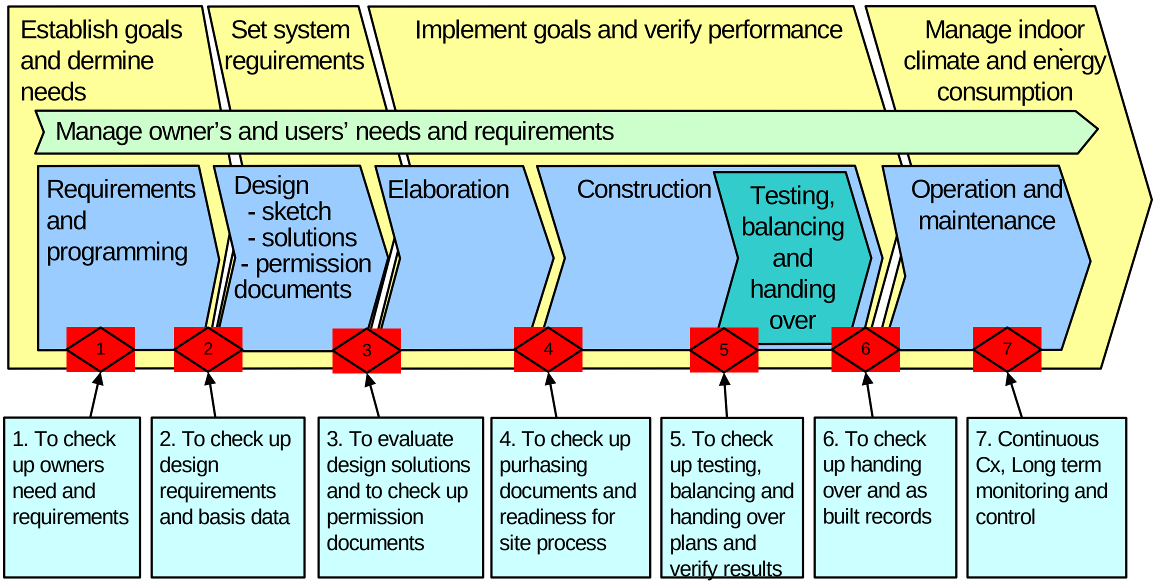

Figure 2. The phases of commissioning [1].

The objective of the paper is to present the methods and three case studies of systematical risk analysis and management, supporting the quality of the overall building process. The general systematic for identification, evaluation and sharing of risks are presented. Classification of risks, model for risk evaluation table (matrix) and risk number method are presented.

METHODS

Risk assessment

Methods in risk sharing and assessment have been developed for risk recognition and management. To assess the success factors of projects, corresponding assessment tables have been drawn up to help recognize the special features of successful projects [3].

Systematic risk recognition and assessment is the method for managing risks and pinpointing the responsible party. The stages of risk analysis are defining the target, recognizing hazards, assessing consequences, calculating probabilities, assessing the total risk, and finally, removing, reducing, and preventing the risk. The parties involved in the implementation of the project are assessed for their ability to take responsibility for the risk, and usually, the responsibility is given to the party that could handle it and to that it naturally belongs. Drafting a contract is a concrete tool for pinpointing the party responsible for risks. Through risk assessment, crucial matters to be included in the contracts are observed along with the necessary insurances and potential securities.

Classification of risks

One example of classification of risks is presented in [5]. Country related risks depend on the situation in the county, including economic risks, political risks and risk related to natural conditions. Implementation risks are risk caused by the realisation of the case, including technical, financial, contractual (caused by the juridical content), personnel risk (caused by actions of employees) and risks caused by methods of implementation. Force Majeure risks are unforeseen risks, which are not possible to remove.

In the project CUBENet [11], the risks were classified for practical building project. Implementation risks include source information, and quality of this information (e.g. conditions of structures in renovation project), technical risks in construction work, investment costs, timetable of construction work and quality of technical plans. Risks related of way of action during contract period include quality source information (e.g. energy consumption of previous years), availability and cost of finance (including interest rate), guaranteed savings and commissioning, maintenance costs (including changes in energy price and cost of maintenance investments). The risks related to partners of the project include economic status of parties and organisational issues (e.g. changes in personnel).

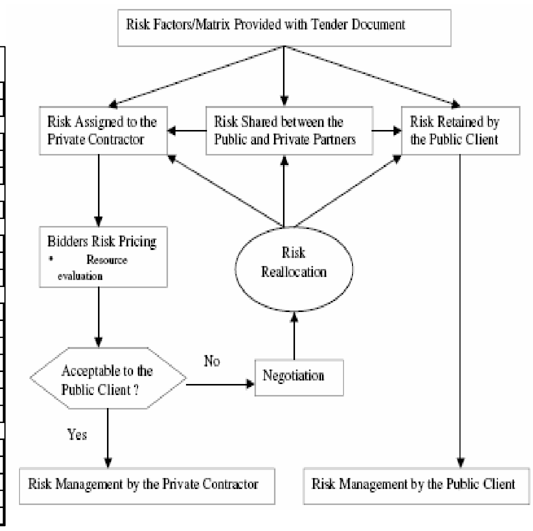
Risk assessment in planning phase – risk matrix and success factor methods

One practical method for systematical risk assessment is a risk sharing table (or check-list, or matrix), figure 3. The potential (along with apparently impossible) risks are listed and shown to the project parties. Reference [4] presents the categorisation or risks in macro, meso and micro levels (‘meta-classification apprach’). Reference [5] shows the practical risk evaluation and allocation table for PPP (Public-Private-Partnership) project in Finland. With the risk sharing table, the parties share the responsibilities for the risks each party will assume. The responsibility for an individual risk is left to either party or to both parties according to principle agreed by parties. The client assesses the risks of the project and assumes responsibility for some of the parties involved in the project. In the invitation for bids, the bidder is asked to pay attention to the risks transferred to the provider and to describe how they will assume responsibility for the risks or will take these into account in the bid. In practise, the provider may not necessarily take the responsibility of all risks offered but will transfer the risk back to the client in the bid. The responsibility for a risk will naturally have influence in pricing – the party taking the responsibility of the risk is setting price for the risk.

The risk assessment table helps the bidders in evaluating how they accept the risks the client is transferring to the provider. The table forms a foundation for the bidders' proposition in order to show how well the bidders understand the nature of the risk, how effectively the bidders forward or share the risks in the subcontractor chain, and how the bidders minimize the unfavourable effects caused by risks in relation to the client and the end users.

. Macro level risks	Risk allocation		
	Client	Bidder	Shared
Political and government policy			
_ Unstable government			
_ Expropriation or nationalisation of assets			

B. Meso level risks	Risk allocation		
	Client	Bidder	Shared
Project selection			
_ Land acquisition (site availability)			
_ Level of demand for project			
Project finance			
_ Availability of finance			
_ Financial attraction of project to investors			
_ High finance costs			
Residual risk			
_ Residual risks			
Design			
_ Delay in project approvals and permits			
_ Design deficiency			
_ Unproven engineering techniques			
Construction			
_ Construction cost overrun			
_ Construction time delay			
_ Material/labour availability			
_ Late design changes			
_ Poor quality workmanship			
_ Excessive contract variation			
_ Insolvency/default of sub-contractors or suppliers			
Operation			
_ Operation cost overrun			
_ Operational revenues below expectation			
_ Low operating productivity			
_ Maintenance costs higher than expected			
_ Maintenance more frequent than expected			



a) b)

Figure 3. a) An example of risk allocation table [3] and b) Flow-chart of negotiations [4].

Critical success factors and sub-factors have been analysed based on method in reference [7].

Risk management during use – risk number method

After the construction phase in the project has been completed, risks are also managed with the help of the information system, such as building management and monitoring system (BMS). The functionality of the technical system is monitored and measured, paying particular attention to the factors sanctioned in the contracts. The monitoring system can contain risk assessment tools which focus the monitoring and service to the risk points of the process. Disadvantageous factors of the various parts of the system are assessed based on three factors [6]. The probability of occurrence (showing how probable is the occurrence of factor) and probability of discovery or detection (showing how easy to discover or detect the factor is) as well as the severity (showing how harmful this factor is) of the disadvantageous factor are assessed separately on a scale of one to ten (or some other selected scale). The product of these three factors is the total risk number (example in table 1). The higher the risk number, the higher the risk caused by the disadvantageous factor. When the risk points have been recognized, the measures can be focused: the risk points of the AC system can be handled with the monitoring system (critical monitoring points), and service can be targeted to the system risk points. Additionally, measurements can be utilized in defining the numerical values (severity based on measured value). Moreover, applications can be developed to assess risks in energy consumption, which is crucial in some contract models, e.g. in energy service contracts.

Table 1. Criteria of the drawbacks.

Severity, S	Numerical value	Probability of detection, Pd	Numerical value	Probability of occurrence, Po	Numerical value
No influence (Category 1)	1	Drawback always detected	1	Occurrence of drawback improbable	1
Category 2	2 ,3	Category 2	2 ,3	Category 2	2 ,3
Category 3	4,5,6	Category 3	4,5,6	Category 3	4,5,6
Category 4	7,8,9	Category 4	7,8,9	Category 4	7,8,9
Health risk	10	No detection of drawback	10	Very probable	10
Severity S Describes the seriousness of the examined drawback factor significance from the point of view of the observed feature		Probability of detection, Pd presents how probable it is to detect the drawbacks by other means than by measuring		Probability of occurrence, Po describes how probable the occurrence of the examined factor is in the system	
The result of these three factors is total risk number: $RPN = S \times Pd \times Po$					

RESULTS

Case study 1 - risks and success factors of ESCO contracting models

New procurement models and service concepts, e.g. energy service concepts, have been developed actively. PPP (Public-Private-Partnership) and PFI (Private-Finance-Initiative) models have become more common in areas of transportation, health-care, power and energy and buildings [8]. The experiences of these projects and possibilities for Finnish applications in construction sector have been reported ([9], [10]). The concepts for building services, e.g ESCO/EPC-services, have been presented in [11]. The first case study describes the management of risks and success factors in building service life-cycle project, e.g. ESCO. The main focus is in the planning phase. These concepts need risk management and risk sharing between client and energy service companies. The sharing of risks will be agreed in practice with contract documents. The risk and success factors have been evaluated based on risk allocation matrix (example in figure 3), success factor tables and interviews. The interviews were done separately for clients and service providers.

The following factors were evaluated the most important risks for the client in ESCO services: 1) control of timetables, 2) success in demolition work, 3) discovery of additional savings and 4) re-utilisation of old devices with new ones. The main risks for the service providers are: 1) initial information (given by the client), 2) trust and familiarity with the client, 3) success and correctness in planning, 4) success and fluency in construction works, 5) identification of ‘grey areas’, which are not easy to control based on the available information, and 6) knowledge of contractual issues.

The main success factors for client using ESCO model are: 1) the traditional ESCO is possible without investment, 2) in case investment is needed for construction work, the investment cost is smaller than in case of traditional, 3) service contracts guarantee extra savings and higher quality of buildings, 4) after 1st contract period, competition between service providers is possible, 5) in case savings are not realised, this is decreasing the fee for service provider. The main success factors for service providers are: 1) fluency in cash flow due to long contract period, 2) investigation of correct basic information, 3) success in evaluation of risks and forwarding the risk aspects in contracts.

In the analysed ESCO projects, there were no big conflicts between the opinions in sharing the risks between the client and service provider, therefore possibilities for successful sharing of risks exists. The concept of risk sharing table will help the discussions about existing risks and will speed up the contract negotiations. The concept of success factors was seen as a tool for strategic planning and selection of successful models for delivery, not as a tool for single building project.

Case study 2 - risk management of indoor air quality of ventilation system during the use of system

The second case describes the systematic approach for risk management of indoor air quality of ventilation system during the use of system. The effects of the component level performance on the system overall performance and existing risks were evaluated using risk number approach. The method points out the biggest risks inside the system, which may cause problems in indoor air quality. This approach will help to find out the most important points in the technical system, to be checked and controlled during the use and maintenance. Figure 4 presents the ventilation system, table 2 evaluation criteria and table 3 risk numbers of the drawbacks [12]. The number values are based on expert opinions, and should be updated by experiences. In this case, the control and service should be focused especially on pre-filter and supply air duct, to guarantee the high quality of the ventilation air.

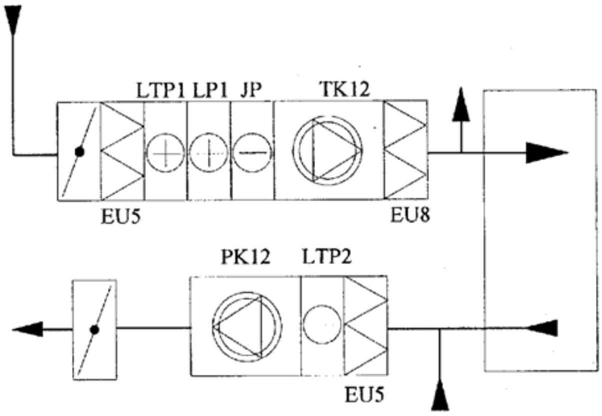


Figure 4. Ventilation system in case study.

Table 2. Evaluation criteria for risk analysis in case study.

Severity, S	Numerical value	Probability of detection, P_d	Numerical value	Probability of occurrence, P_o	Numerical value
No influence on quality of supply air	1	Always detected/noticed	1	Improbable	1
Small decrease in quality of supply air	2 ,3	In most cases detected	2 ,3	Small	2 ,3
Decrease in quality of supply air	4,5,6	Sometimes detected	4,5,6	Possible	4,5,6
Bad quality of supply air	7,8,9	Seldom detected	7,8,9	Probable	7,8,9
Bad quality of supply air has influence on health	10	No detection of drawback	10	Very probable	10
Severity S describes the seriousness of the examined drawback factor significance from the point of view of the observed feature		Probability of detection, Pd, presents how probable it is to detect the drawbacks by other means than by measuring		Probability of occurrence, Po, describes how probable the occurrence of the examined factor is in the system	
The result of these three factors is total risk number: $RPN = S \times P_d \times P_o$					

Table 3. Risk numbers for drawbacks in ventilation system case study.

Part of system	Drawback	Severity S	Probability of detection Pd	Probability of occurrence Po	Risk number RPN
inlet grid (at roof)	smell	5	6	4	120
inlet chamber	microbes	4	8	8	256
prefilter (EU5)	microbes	4	8	7	224
	VOCs	5	8	6	240
	fibres	2	9	4	72
	particles	7	9	8	**504**
	leakage	4	4	4	64
heat recovery device	not evaluated				
heating coil	VOCs	5	8	3	120
cooling coil	microbes	5	8	2	80
supply air fan	VOCs	5	8	3	120
fine filter (EU8)	microbes	8	8	5	320
	VOCs	5	8	5	200
	fibres	4	9	2	72
	particles	7	8	4	224
	leakage	8	4	2	64
supply air duct	microbes	8	8	7	**448**
	VOCs	5	8	5	200
	particles	7	8	6	336
control dampers	not evaluated				
material of sound damper	microbes	8	8	5	320
	fibres	4	8	8	256
Air inlet valves	particles	8	4	8	256

Case study 3 - evaluation of the effects of the quality of building on energy consumption

The third case deals with evaluation of the effects of the quality of building on energy consumption. The quality of structures and HVAC is evaluated from point of view of effects on energy consumption. Case simulations and sensitivity analysis can be added to risk evaluation procedure. The energy performance of the building is depending strongly on the efficiency of the ventilation systems. The example shows the influencing factors and ways to reduce heating energy consumption. Three factors are considered: 1) air flow rates and running times of ventilation, 2) heat recovery of ventilation and 3) air tightness of the building envelope. This case is evaluating the risks when taking the responsibility of energy consumption of the building service system.

Figure 5 shows an energy balance of a building in cold climate conditions. In this example the biggest losses are caused by ventilation. If building owner or facility manager has set targets for energy consumption, they must have possibility to monitor the distribution of energy. By generating energy balance chart (e.g. Sankey-diagram) it is possible to observe, which are the main factors influencing on heat and electricity usage.

Even in well-performing buildings the energy consumption may vary within relatively wide range. The estimated consumption of district heating (DH) of a new school in Southern Finland was 26,3 kWh/m^3/year (real building, calculations based on Finnish Building Code, part D5). The biggest component of heat losses is ventilation 25,7 kWh/m^3. Changing the operation time from daily 12 hours to 10 hours decreases the heating energy consumption to 23,1 kWh/m^3. Increasing the efficiency of heat recovery device from 50 % to 60 % decreases the heating energy consumption to 20,1 kWh/m^3, and finally improving the air tightness of the building from 0,1 change/hour to 0,05 change/hour decreases the heating energy consumption to estimation 18,1 kWh/m^3. This decrease of 32 % in heating energy consumption (DH) is realised by optimising operation hours, selecting more energy efficient heat recovery device and realising the air-tight building. This case simulation is showing the influence and risks of these factors on heating energy consumption ('severity' is presented as energy consumption). The most important influencing factors should be analysed in a systematic way showing the influence of the factor on consumption. This analysis could be presented in form of table or Sankey-diagram including basic value and sensitivity to influencing factors (e.g. heat recovery device has influence 0,3 kWh/m^3/1 % change in efficiency).

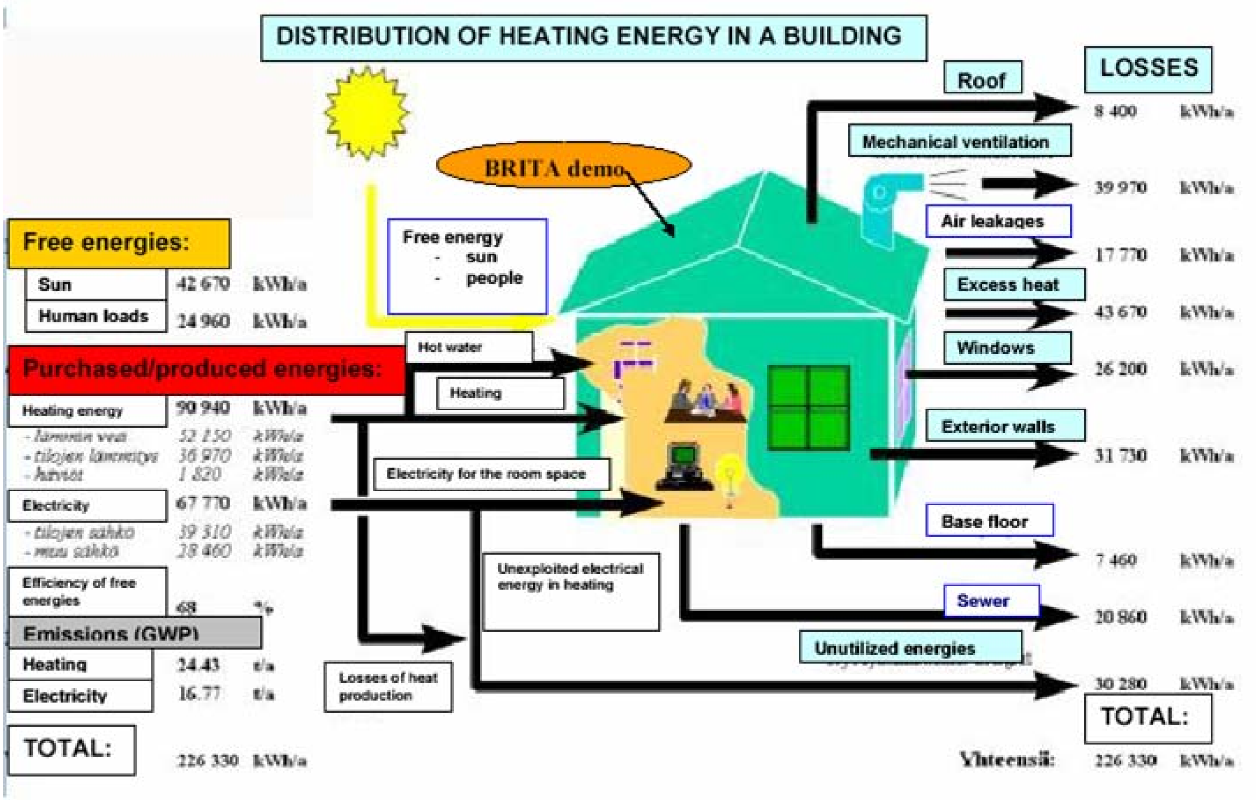

Figure 5. An example of the energy balance of the building.

DISCUSSION

The systematical risk management methods and applications are sophisticated ways to evaluate and manage the risks during the life-cycle of the building and the associated technical systems. Three presented cases show possibilities to utilize methods in pre-design, design and operation phases. The risk table approach is a checking-list type of method, which is a good tool for assessment of all the possible risks existing in the building project. The risk table can be used as part of invitation for bids, annex of contract documents or check-list during the negotiations. The risk number approach is a simple tool for pointing the drawbacks or risk components of the complicated systems. The strength of the risk number approach is evaluation of drawbacks based on three sub-factors (severity, probability of detection and probability of occurrence), which all are evaluated separately, based on experts opinion or measured values. This is giving more confidence on evaluation. The simulation tools can be used as part of risk assessment, when evaluating the effects of the quality of the building structures and HVAC components on the energy consumption and costs.

ACKNOWLEDGEMENT

Financial support from TEKES buildings service program CUBE and participating companies is gratefully acknowledged. Results of projects CUBENet, Cx/Commisioning and EU/Brita in Pubs are included.

SUMMARY

According to several studies there is a remarkable potential for decreasing energy consumption of buildings by optimization the use of the building services and systems.

The energy consumption, indoor climate and life-cycle costs of the buildings are dependent on the performance of the building services and systems. Development of information and communication technology, building automation and simulation tools have created good opportunities to improve control and monitoring techniques of buildings.

INTRODUCTION

Simulation models are often used in designing building services. Advantage is not usually taken of existing simulation models in the operation and maintenance phase of the building. Model has to be revised due the changes during construction phase. The calibration is needed to update the information to the simulation model concerning actual usage of the building. Calibration has to be cost effective before it can be widely used. The building automation system should be used as much as possible to aid the calibration process.

The aim of the study is to develop the methods to calibrate and to use the simulation model in the operation and maintenance phase of the building. This research will focus on studying newly constructed buildings, where information and simulation models have been utilized in the designing process.

The methods to be developed will be tested in 4 pilot buildings in the near future. In this paper the state-of-art situation of the project is presented.

METHODS

Building Functionality Indicators and Measurements

Building functionality metrics is a problematic area of study but often a manageable one with right tools and sufficient amount of expertise.

The functionality of a building and building services can be described with a set of verified indicators by which for example energy consumption, indoor air quality, reliability of operation and life cycle costs can be inspected. The need to inspect building functionality can be justified with the difficulty of determining the state of operation or possibly trying to improve the performance of a building without first inspecting the current and time dependent performance of the building [1].

There are a number of different facility services such as cleaning services, catering services etc. This study focuses mainly on building services and HVAC-systems.

Means by which the state of operation can be monitored are for example tracking energy consumption time wise, benchmarking (referring to similar buildings) or defining and using target levels. Often it is wise to combine these aspects to obtain better results. The importance of tracked history data on building functionality cannot be emphasized enough.

Indicator levels can be divided into sub-groups [2]. The most important of which are
- Building-scale inspection level (e.g. building energy consumption)
- System-scale inspection level(e.g. specific fan power for the air handling units)
- Component-scale inspection level (e.g. COP for the water chillers)
- Independent variables (e.g. building usage, the weather)

Indicator types on the other hand can be divided into
- Energy-indicators
- Indoor air indicators (e.g. PPD and PMV of a building space)
- Money indicators (e.g. net present value of an air handling unit (AHU) with initial investment and operation costs taken into account)
- Environmental indicators (e.g. environmental impact of oil-heating compared to district heating
- Overall efficiency (e.g. overall amount of energy to maintain a certain level of indoor environment, can be used as benchmarking tool)

Building functionality indicators can be applied in numerous ways. Two dependent variables can be compared in order to define saving potential in operating costs. E.g. building energy consumption can be plotted as a function of building specific energy consumption.
From Figure 1 it can be seen that the buildings in the upper right side of the diagram have large energy consumptions and large specific energy consumptions. Therefore these building have large saving potentials and it is cost-efficient to focus on the energy economical improvement of these buildings. This so called functionality fourfold table is an illustrative representation by which also state of operation in general can be monitored.

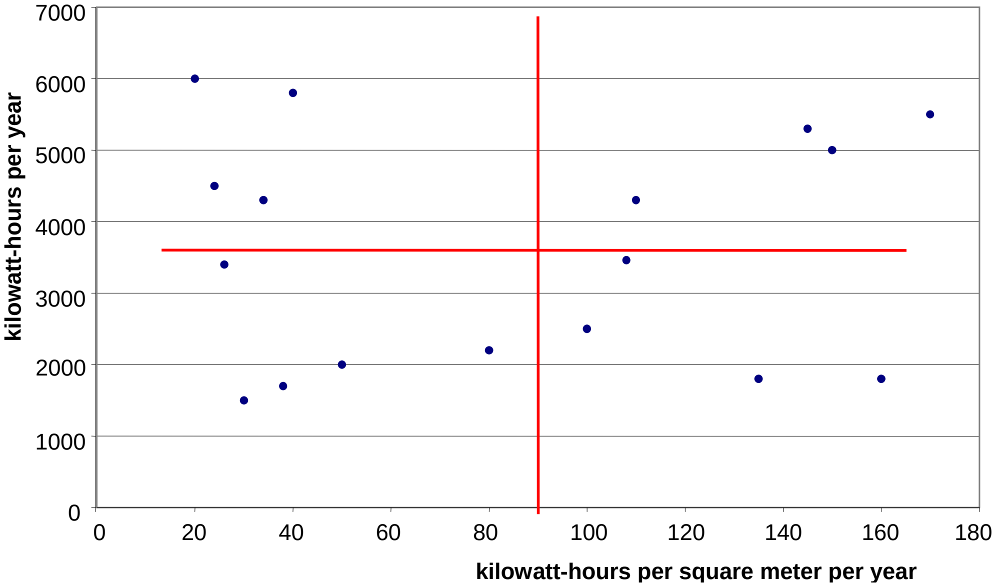

Figure 1 Heating energy consumption vs. specific heating energy consumption

Dynamic target levels with real-time measurement data from the building automation system (BAS) can be utilized, since e.g. the target level of indoor air temperature is not the same throughout the year. User queries integrated into the occupant's intranet can be a powerful tool in trying to restrict the indoor air quality problem zones in the building.

It is often possible to use the BAS in order to obtain functionality data and indicators. However the BAS being insufficient can independent measurements be used.

Whole Building Simulations

Office buildings are usually modeled with simulation programs. Interoperability with Information Foundation Classes (IFC) makes building of the model easier and faster than earlier, especially to create building geometry, when the model was composed using inadequately developed user interfaces. The simulation model is seldom used in evaluation the performance of building in maintenance phase. Simulation model should be calibrated to use it in the performance evaluations.

The simulation model can be composed with several ways; the building can be modeled using single calculation zone or the rooms can be modeled separately. Zones can also consist of several rooms. Less important rooms like corridors and entrance halls can be combined into one space. Windows, electric devices etc. can also be combined in construction of the simulation model, to shorten the execution times. Influence of coarseness of model will be studied in the project.

Nowadays, only the building geometry can be taken from IFC-model. In the future, also the HVAC-components will be included in IFC-model. The work to implement the HVAC-components in IFC is under development in IAI and in LBNL [3].

Calibration of the Simulation Model

Calibration of the simulation model is explained in ASHRAE Guideline 14 [4]. Calibration should include the following actions

1. Produce a Calibrated Simulation Plan
2. Collect Data
   - Obtain Building Plans
   - Collect and Review Utility Data
   - Prepare for Data Collection as Defined in the Simulation Plan
   - Conduct On-Site Surveys
   - Interview Operators and Occupants
   - Conduct Spot and Short-Term Measurements
   - Collect Weather Data
3. Input Data into Simulation Software and Run Model
4. Calibration of Simulation Model Outputs to Measured Data

As shown above, the calibration procedure seems time-consuming and difficult. Collecting the needed information takes most of the time used in calibration. A way to shorten the calibration process could be replacing a part of the calculation parameters with default parameters.

Collecting data is the most time-consuming work in the calibration. Design data has to be gathered from several documents in normal case. Information of the building core is in construction plans, pipes and ducts are in HVAC-plans, performance values are in maintenance manuals, and weather data have to be requested from meteorological stations, many parameters need in-situ surveys and occupant interviews. Internet based maintenance manual would help the information gather, if all the information was transferred there.

When all the information is gathered, construction of the model can be started. There are many ways to make the input work. For example volume flows of air handling units may be given in average values, or in scheduling values of them to the model. Even measured volume flows can be fed to the model. The internal gains can be given in average values per floor-area or by modeling lighting and other electric equipments with certain input power combined with the time tables. The utilization factor of the building has found out to be one on the most difficult indicator to specify. It could be defined by measuring CO_2 or moisture emissions balance on the supply and exhaust air. This will be tested in out project.

The measured output values can be verified with the calculation values. Two most important values to compare are specific heat losses of building envelope and ventilation and heat loss of air infiltration.

Specific heat losses can be calculated from measurements from the BAS. Also the air infiltration has to be taken into account. The measurement can be conducted, when supply or exhaust fan is off, measuring pressure difference between outdoor and indoor air simultaneously. The measurement can be done e.g. in one ventilation zone of the building.

Building Information Models

The use of Building Information Models (BIM) is rapidly increasing. Building service companies see the potential in information technology because it reduces re-work and makes the building models more reliable, and reduces building and maintenance costs [5]. When the shell and the zones of the building are once planned by an architect, it is sensible to utilize the model in planning later. It shortens the modeling time and makes the models more reliable and easier to maintain.

Another way to use building information models is to use it as a information databank. The monitored performance assessment results of the building can be saved to the information model where it can be accessed whenever it is needed. Unreliable paper documentation is not needed and the information is up-to-date more likely than with the paper copies.

The performance of the building services should be evaluated regularly during the life cycle of a building. The first evaluations are done in design phase when the HVAC-components are selected and the use of the building and indoor climate of the zones are planned. The next evaluation is done during the building is taken into use. This is usually called commissioning, but in broader sense the term can mean all the performance assessments done during the life span of the building.

The use of the information models is tested in several projects in evaluations of the building performance in National University of Ireland and Lawrence Berkeley National Laboratory in USA [6-12]. The core of the information model is IFC, but the evaluation results can be saved in broader information model, which consists of measured and calculated performance data. These “additional parts” can be tied to the IFC-model using programs, which have an access to IFC-model and which can reprocess it. The time-series are normally saved in XML-format or other data format. IFC-compatible C++/Java/etc. programs can be used to reprocess the data and to visualization of it. The middleware programs were used because all the simulation programs used in USA are not interoperable with IFC.

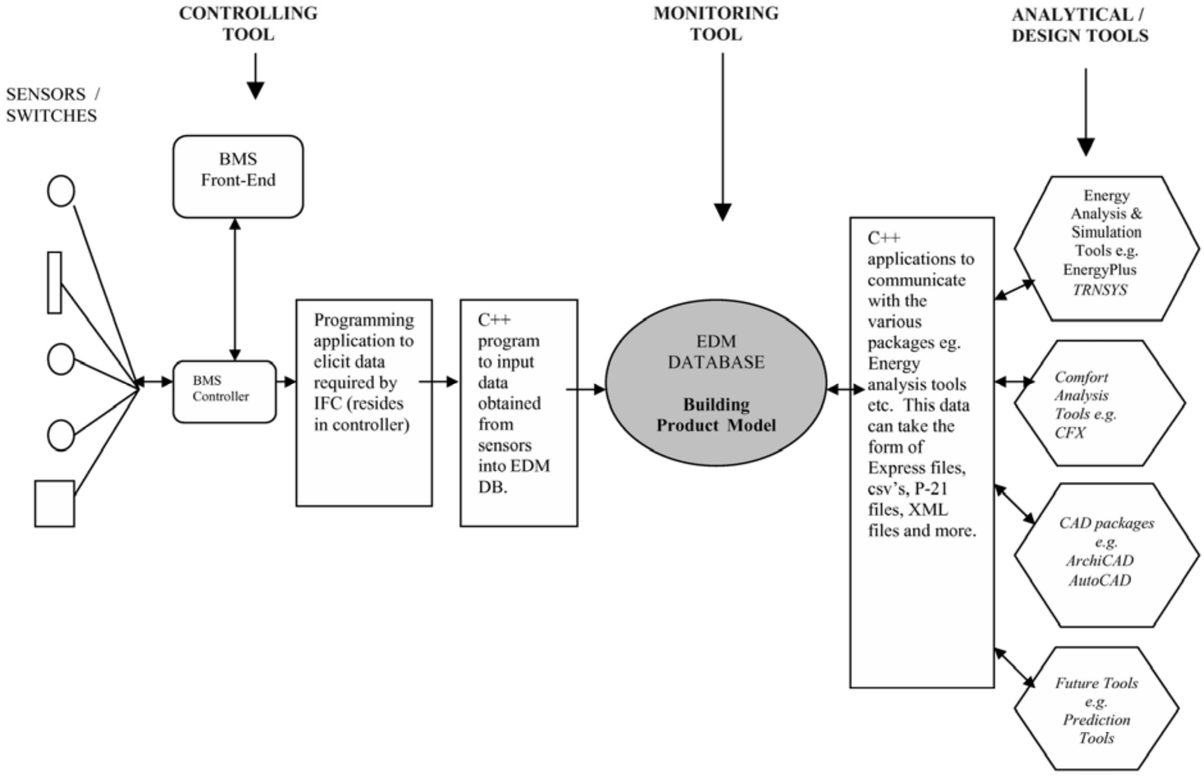

Figure 2 Use of building information model in evaluation of the real and simulated building performance [10]

Figure 2 presents, how building information models can be used in evaluation of the building energy performance using building information models and simulation programs [10]. Express Data Manager 4.5TM (EDM) is a program, which is used to save output values from the building automation and simulation program and to verify measured and calculated performance metrics e.g. the total energy consumption of the building.

Utilizing Building Automation System

BAS is seldom utilized as effectively as possible in maintenance of the building HVAC-systems. That is partly because of great amount of information in the database of BAS, which is not usually post-processed for advanced use. The building automation systems usually save the information in frequency of couple of minutes, which is too short a time concerning energy and environmental analysis. Hourly average values would be more usable in simulations and verifications of the measured and calculated values.

Many metrics can be calculated from information of the BAS. An efficiency of the heat recovery system, the COP of cooling system, the specific fan powers of fans can be calculated easily − if the measurements are designed well. The planning of the in-situ measurements should be done carefully. For example the efficiency of a heat recovery unit needs measurements of the air-side volume flow as well as temperatures before and after the recovery system. The COP of a cooling system needs measurements of the electricity use for cooling and measurements for cooling energy of the rooms and the ventilation system. The specific fan powers can be calculated if the volume flows and electrical power consumption of the AHU is measured.

Figure 3 presents the measured, simulated and benchmarks metrics. They are not identical because they are based on different parameters, simple and advanced models and the actual use of the building is seldom identical to the design parameters. Comparison of the simulated and measured values should provide a way to evaluate total performance of the building or any part of HVAC-system.

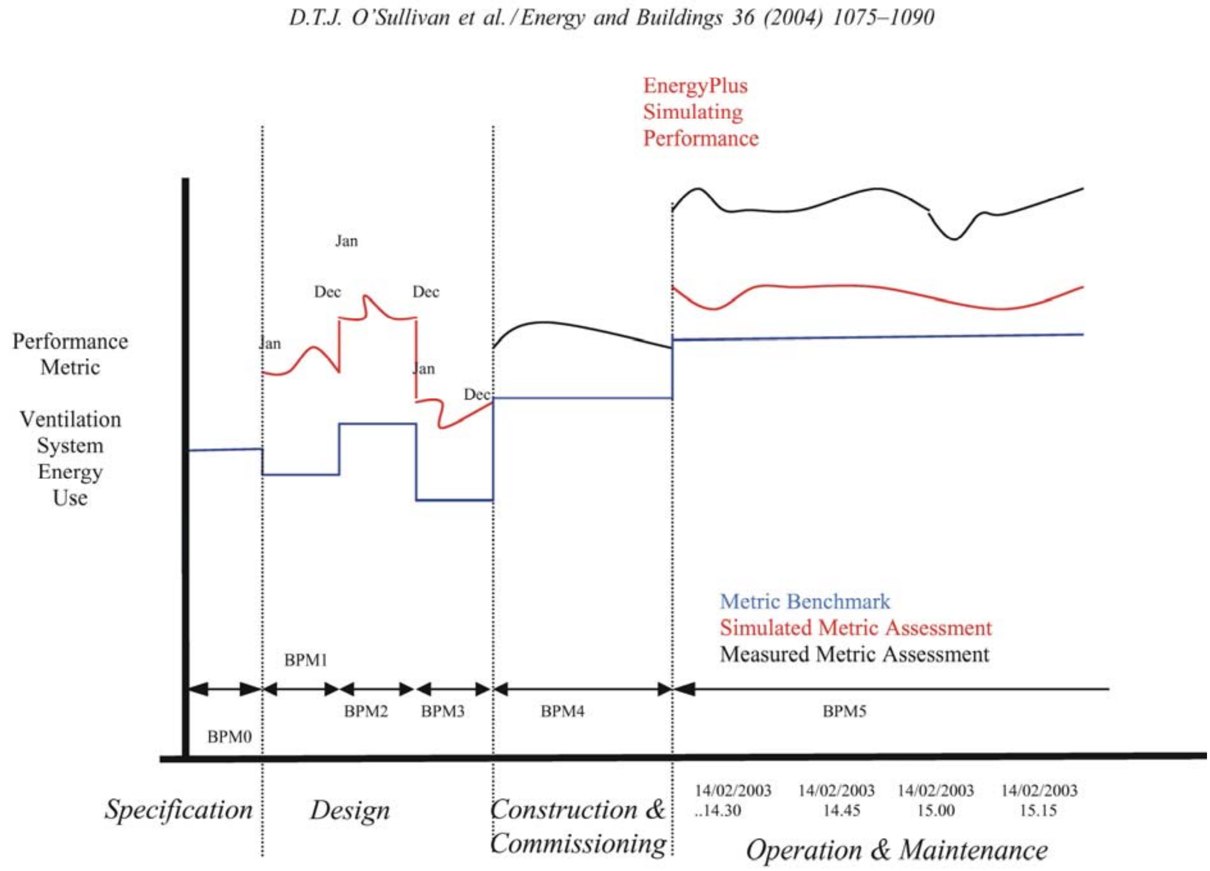

Figure 3 The evaluation of the performance during the life span building of building [10].

RESULTS

A school building was studied concerning indoor climate and energy use. Some of the measurements were done concerning calibration of a simulation model. The results of the building automation are also available.

A specific heat loss of the envelope and of the ventilation of the building was measured using manometer and temperature measurement of the heat transfer liquid. The manometer was installed on to the control valve of the network. The temperature of the entering and the returning liquids were monitored at the same time. Also the outdoor temperature and relative humidity were measured using a self-functioning combined temperature and RH logger.

The ventilation volume flows were also measured using pitot-static measurements and pressure drop measurements of the control units. The volume flows of the supply air were measured in all the five main air handling units of the building.

The tightness of the building envelope was also evaluated using supply fans. The pressure difference between the indoor and the outdoor air was measured and the volume flows of the supply air and the leakage through the return ducts were measured at the same time.

The indoor climate was measured concerning indoor temperature, operative temperature, and draft in two class rooms.

The CO_2-concentration of supply and return air was measured in one of the AHUs. That is because the method will be tested to determine the utilization degree of the building. There is not any easy way to measure the heat gains from people in the school building.

All the measurements are useful, when the simulation model will be calibrated. Especially volume flows and tightness of the building influence a great deal on the heat use of the building. The calculated and measured specific heat uses can also be verified to be sure that the calculation model is correct concerning the heat losses.

The measurement and the simulation results will be available later.

DISCUSSION

The functionality of a building and building services can be described with a set of verified indicators such as energy consumption, indoor air quality, reliability of operation and life cycle costs. The need to inspect building functionality is apparent due to well-known difficulties in determining the state of operation or improving the performance of a building. Building functionality indicators can be applied in numerous illustrative ways. Often it is possible to take advantage of the BAS in order to obtain functionality data and indicators.

The evaluation of the building performance for the maintenance purposes needs systematic methods to make it cost effective. The building information models and simulation programs are used increasingly in design of the building. They could also be used in the maintenance of the building for database to save of simulations and measurement results. They can also be used to visualize results and to make verification of simulated and real performance and indoor climate more effective.

Use of the building information model (BIM) makes modeling easier and faster. Construction of the whole building simulation model does not need so much manual feeds, so there is more time to check, that calculation parameters of HVAC-system are correct. In the future, the control parameters of HVAC-system can be transferred directly to the simulation model using HVAC-IFC, which is under development.

Calibration of the simulation model is needed, if it is used as reference value to measured performance energy and quality indoor climate. Design information, weather data, building automation and is-situ measurements are needed in calibration of the simulation model. If calibration is systematically done, it should be done in some weeks, and the model can be used in the energy performance analysis for decades. The calibration can be done more automatic, if some of the building automation results can be used directly as input of simulation.

SUMMARY

This work is taken part of REVIVAL (Retrofitting for Environmental Viability Improvement of Valued Architectural Landmarks), an energy project supported by European Commission, under THERMIE program, started officially in April 2003 and it will be finished in 2008. REVIVAL is a demonstration on refurbishment of non-domestic buildings, post-war architecturally values, to improve their energy efficient performance and well internal comfort conditions for occupants, especially in summer, with low energy consumption and using innovative measures and best practice. A life cycle CO_2 assessment procedure has been applied and concerned to the emissions due to embodied energy in building materials and transportation. There are six refurbishment demonstration sites, which are included in REVIVAL project in five EU countries. Our paper aims to present a study focusing on CO_2 stock analysis and taking in account GHG emissions on a building site – a secondary school complex, located in France. The REVIVAL target "*WP 10: CO_2 building stock budgeting*" is run under the coordination of Mr. G. Gaudin (engineer, CEO of Gaudin Ingénierie office and technical coordination of REVIVAL), Mrs. T. de Queiroz Gaudin (architect, D. Sc., professor of Federal University of Rio de Janeiro and researcher in REVIVAL project) and, the technical concepts have been realized by Mr. L. Key, engineer from Central University of Nantes and M. Sc., from Munich Technical University.

INTRODUCTION

In most European cities, there is a vast stock of existing buildings, some them of important architectural values. Considering that the refurbishment of existing buildings, it is a viable option for achieving comfortable and energy efficient buildings, REVIVAL (Retrofitting for Environmental Viability Improvement of Valued Architectural Landmarks) is an energy demonstration project supported by the European Commission, under THERMIE program, that includes the energy efficient refurbishment and monitoring of six existing non-domestic buildings in five European countries [1]. This project contributes to both the general objectives of the thematic area "Energy, Environment and Sustainable Development" and the specifics of the "Eco-buildings" Target. The main global objective of REVIVAL is to demonstrate that refurbishment applied to this particular subject buildings type, tertiary buildings from post-war and pre-energy conscious, can show lower life-cycle CO2 emissions, improvements in energy performance and better cost-effectiveness than the original building or an equivalent new building or demolition [2].

REVIVAL project includes upon refurbishment works of six tertiary buildings, architectural values, in five EU countries: one educational building, in France; two hospitals in Italy and in Greece and three office buildings in Netherlands, in United Kingdom and, in Greece. All sites have common characteristics as: poor insulation, over-provision of glazing in large façades, inefficient plants and degraded materials and fabric. Aiming to provide good indoor comfort conditions and low energy consumption, the projects incorporate both passive strategies (daylight, natural ventilation and solar) and renewable components such solar water heating, solar absorption cooling and photovoltaic panels. In order to achieve this project, there are specific technical and scientific objectives to demonstrate that the measures can improve the quality of indoor environment.

Regarding the CO_2 emissions, an assessment procedure of life-cycle CO_2 has been studied to be applied in each site, considering the GHG emissions due to embodied energy in building materials and due to material transportation to site, personal and vehicles for companies and building site machinery. The aim is to apply a life-cycle CO_2 assessment procedure in the refurbishment site, to make comparisons concerning CO_2 emissions during the refurbishment, the demolition and with the new refurbished building. Due to achieve this focus, in the REVIVAL project there are specific technical and scientific objectives, taking part of targets, named works packages.

In this way, this work focuses the work package concerning to life-cycle CO_2 analysis, titled "*WP 10: CO_2 building stock budgeting*", taking in account the analysis of GHG emissions due to embodied energy in building materials, transportation and vehicles on a site. This paper presents one part of an application in a large secondary school complex, located in France [3]. The results demonstrate a comparison of GHG emissions (ton equivalent CO_2) from the beginning of the works and during the building refurbishment, now in its fourth year.

GREEN HOUSE'S GAS (GHG) EMISSIONS AND LIFE-CYCLE CO_2

A control of Green House's Gas emissions can not be reached without a strong act in the building sector. In a global way the aspects from material's extraction and demolition are considered in the building area. Considering that the CO_2 emissions mechanisms are complex, the work about GHG emissions can not be realized against other priority of a building such as: materials extraction, manufacture of components, transportation of materials, transport of persons, architectural quality, functionality, health, comfort, construction, waste and demolition.

Nowadays the industrial buildings are the most energy-lover sector [4]. Rather acrimonious discussions its real impact on the emissions. The discussions are not ended. Regarding gases emissions, carbon dioxide equivalent (CO_2-equivalent) for a greenhouse gas, measure used to compare the emissions from various greenhouse gases based on their global warming potentials (GWPs), it is derived by multiplying the mass of the gas by its associated GWP. For example, the GWP for methane is 21. This means that the emissions of one million tone of methane; it is equivalent to emission of 21 million tones of carbon dioxide. CO_2 is considered the gas which has the shorter life-time and it is the easiest to eliminate. On the other hand, industrial gases are much more harmful (important life-time) and there is difficulty to eliminate them. See table 1.

Table 1. Impact of different gases: global warming potential [5].

GWP	CO_2	CH_4	N_2O	HFC	PFC	SF_6
Life length (years)	50 to 200	12	114	HFC23:257		
Global warming potential (at 20 years)	1	56	280	460 to 9100	4400 to 6200	16300
Global warming potential (at 100 years)	1	21	310	140 to 11700	6500 to 9200	23900

OBJECTIVES OF THE CO_2 BUILDING STOCK BUDGETING TARGET

The objective of the *CO_2 Building Stock Budgeting* target is to determine a life-cycle CO_2 analysis for a period (for example, on a 20 years), associated with building materials, transportation of materials and personal, which can be applied to these cases: (a) partially deconstructed and totally refurbished building; (b) total pull down and erection of a new building; (c) building maintained in state.

In the first case (a), CO_2 emissions are due to: deconstruction a part of the existing building, erection of the new parts of the building, transportation of wastes and building materials. Running of the new building on 20 years it is considered: energy and lighting. In the second case (b), CO_2 emissions are due to: complete pull down of the existing building, erection of the whole new building, transportation of wastes and building materials. Running of the new building on 20 years it is considered: energy and lighting. Finally, in the third case (c), CO_2 emissions are due to: energetic consumption on a period (for example, 20 years), such as: heating, ventilation, auxiliaries, air conditioning (possible), lighting, upkeep and maintenance, demolition for a period. The real stake of the *CO_2 Building Stock Budgeting* target concept is to determine which case produces less CO_2 emissions. As refurbishment is most of the time necessary, we can asses the total life-cycle CO_2 emissions of a procedure and try to demonstrate its environmental added value.

Analysis of a demolition building

In case of a demolition of an existing building and its substitution by a new one, it is not enough the new building be less energy lover/m² to observe reduction of CO_2 emissions. It is necessary to add the supplementary consumptions as: demolition of the existing building, transport of wastes and materials, erection of buildings and manufacturing of the components.

CASE STUDY – SECONDARY HIGH SCHOOL

The case is an educational buildings complex – Chevrollier High School, located in Angers city, in France. Since the 60's, none refurbishment has ever been done to the buildings of Chevrollier school. On the other hand, none ventilation system has ever been installed in the high school. Some areas, such as the workshops, were built with asbestos. Windows and steel frame were degraded. There was the same problem concerning to the stability of the concrete. Table 2 shows the surfaces before and after refurbishment. Figure 1 presents the general plan of Chevrollier site and Table 3 presents the works progress [3] and [6].

Table 2. Surfaces of Chevrollier refurbishment: before and after works.

Work phases	Surfaces (m²)
Before refurbishment	37.000
Refurbishment	33.000
Demolition (workshops)	4.000
New buildings	9.000
Total surface	42.000

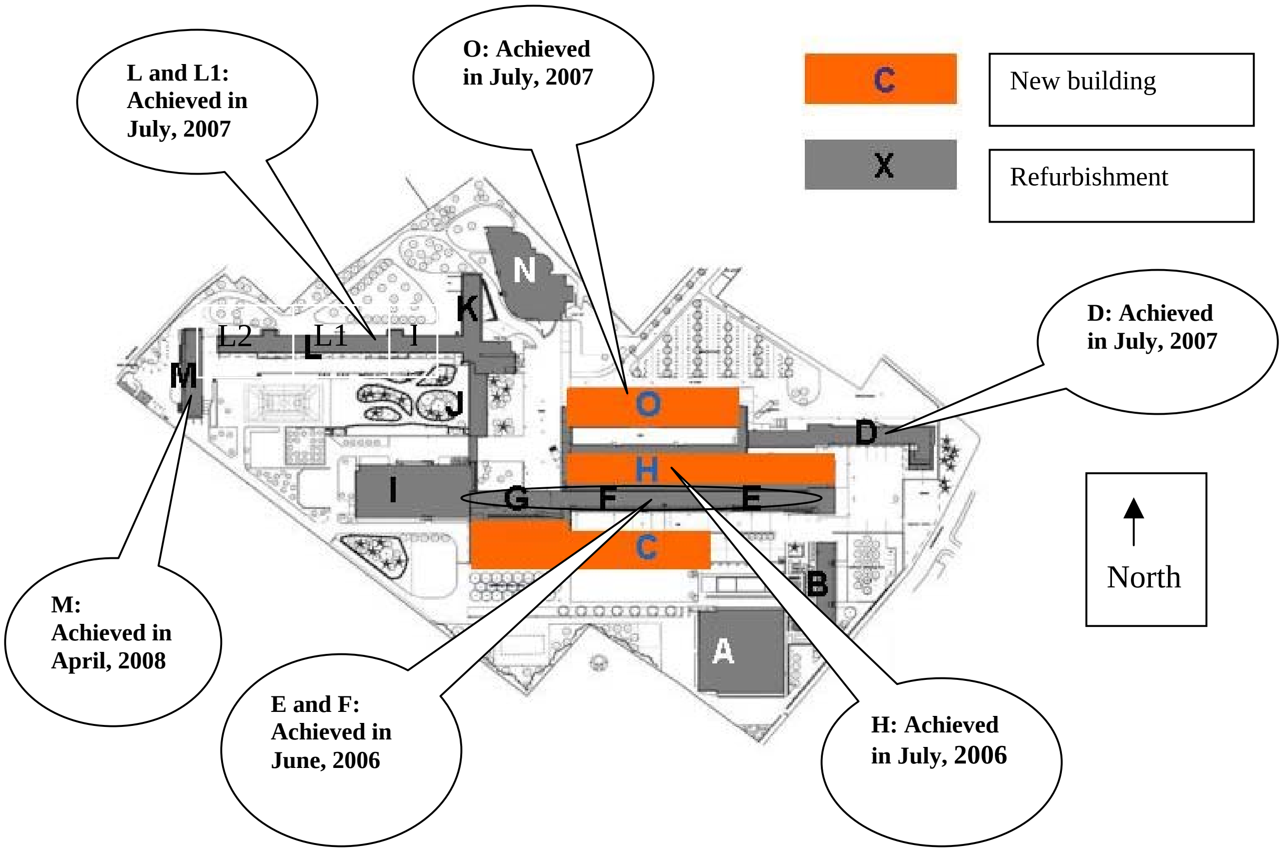

Table 3. Works progress.

Buildings	A	B	C	D	E	F	G	H	I	J	K	L	L 1	L 2	M	N	O
Advance (%)	/	100	100	40	100	100	100	100	100	100	100	0	0	0	0	/	20

Figure 1. Plan of Chevrollier site.

The buildings C, E, F, G and J are used as classrooms. The building H and O are used as workshops and the buildings K and L are the residential buildings for students and teachers. The buildings A (gymnasium) and N (cooking/catering) are not concerned to revival projects. The refurbishment works are completed without stopping the scholarship of the pupils.

METHOD – GHG ACCOUNTING AND CALCULATION PROCESS

In the case of Chevrollier site, studied in this paper, applying the sustainable refurbishment was obviously a necessity because: the school must be kept in state of use during five years of refurbishment and the existing site location is a social stake. Indeed, Chevrollier School is located between the town centre, quite classy, and popular suburb. It is essential to preserve this social coeducational system.

After a short description of the technical design of the solution for GHG accounting, the global results are presented by graphical form. For the first time since the beginning of the

CO_2 building stock budgeting target, GHG emissions figure are able to be exploited, interpreted and extrapolated.

Before refurbishment

Before the refurbishment, the causes of CO_2 emissions were electricity and gas consumption. Concerning to gas consumption, it has realized an average of data for four previously years. In order to obtain the annual emission, it has applied the technical documentation about CO_2 emissions from boilers. Due to electricity consumption, it was used the quantities gave by ADEME [5].

Based on electricity and gas consumptions for year 2003 (the start of works), the following table (4) analyses the amount of GHG emissions before refurbishment.

Table 4. GHG emissions before refurbishment [6].

2003	Consumption (KWh)	GHG emissions (Kg eq. CO_2/KWh)	Source	Total GHG emissions (ton eq. CO_2)
Electricity	880.000,00	0,053	EDF	46,64
Gas	4.200.000,00	0,19	ADEME	798,00
Total				844,64

For future calculations, the figure 850 ton eq. CO_2 /year before refurbishment is retained.

GHG emissions due to transportation on the building site

The method to calculation is based on the methodology realized by Jancovici [7] in ADEME [5], to audit the GHG emissions per Km in Kg eq. CO_2. There are communications between: (a) monthly collected data; (B) GHG emissions data base; (c) GHG emissions calculation results. The audited amounts of kilometers are multiplied by given GHG emissions values (in Kg eq. CO_2/Km), depending on transportation type and brand.

In this study, GHG emissions due to transportation concern the following vehicles categories: personal vehicles, companies vehicles, building site machinery and material transportaion. GHG due to waste transportaion have yet been neglected in the present study, but it will be considered in the progress of the works. For database requirements, the way is filled for each type of vehicles from the main source based in ADEME [5].

GHG emissions due to embodied energy in building materials

The design of an acceptable calculation process to evaluate GHG emissions coming from embodied energy in building materials has been the main research task for this work. The calculations provide different results since 2003, when the refurbishment has started.

Calculation process

No standard data collection is available in order to audit the consumption of building materials. There is technical documentation received per month of all materials used for the building site, from the enterprises involved in the refurbishment works, as manufacturers, constructers. Much computer programming has been realized in order to ease the transcription of paper bills into standard excel worksheet linked to a well informed database of all kinds of materials bought for the building site. Therefore, calculation process is in this case much more complex.

Database requirements

The French institutions as ADEME [5] and AIMCC [8] provide data documentations about life-cycle of materials. According to norm XP-P-01-010 of AIMCC [8], the materials have an analysis of their life cycle about their environmental impact [9]. When a product is not referenced by AIMCC, the impact of its realization on climate change is calculated with the amount of raw material in it and its technical documentation. GHG emissions pro ton of raw material are provided by ADEME. This way of calculation provides the minimum embodied energy for the realization of the product.

RESULTS

Global audit

The following graphic (figure 2) gives overall results of the audit campaign, concerning GHG emissions and realized in Chevrollier refurbishment since the start of works. The total value of mean 3850 ton eq. CO_2 since the beginning of the refurbishment may seem too high, but it is exactly the contrary. Due to a few lack of environmental data, this value is underestimated. However, this graphic is relevant, especially when it is damped and added to prediction on GHG emissions for the life time of the building.

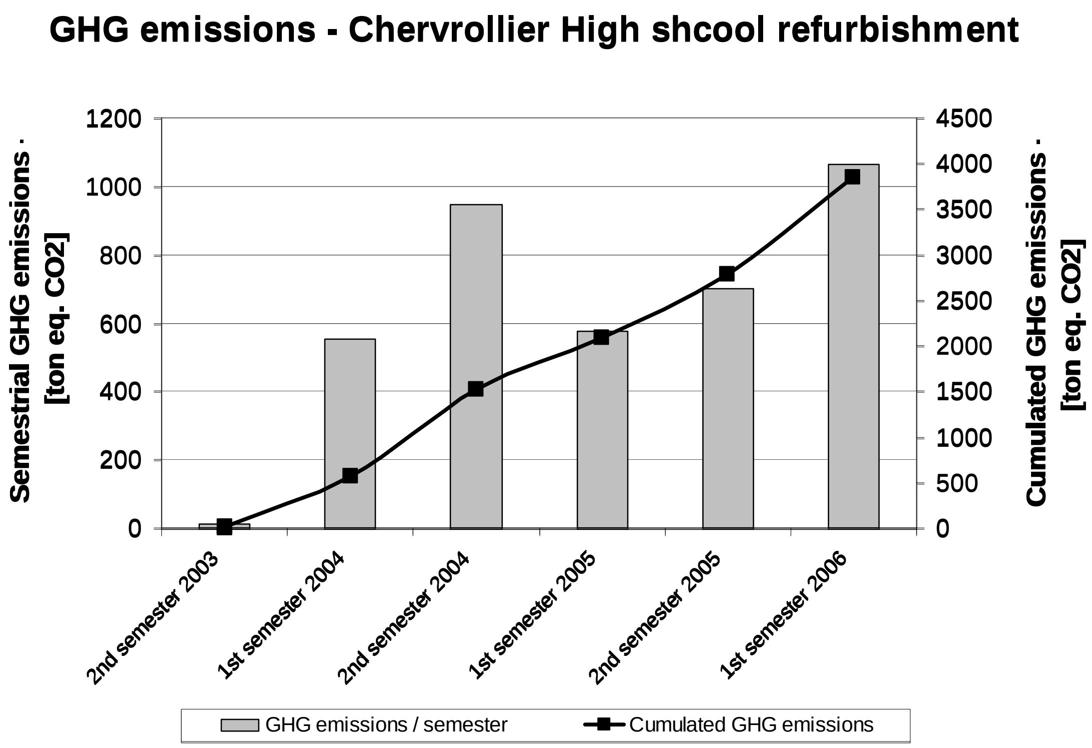

Figure 2. Global results of GHG emissions audit in Chevrollier site.

Source of GHG emissions

Besides the consideration on emissions due to transport and embodied energy, it is relevant to estimate the amount of GHG emissions of each of the four main building tasks achieved on Chevrollier refurbishment site such as: (a) lot 1: road network; (b) lot 2: electricity; (c) lot 3: heating; (d) lot 4: structural work and building shell.

Prediction

A simple regression has been run on the results in figure 2. The upper bound of the prediction gives a global GHG emissions figure of 5438 ton eq. CO_2 for the building site until the end of first semester 2007. See figure 3.

On one hand, in this graphic of Figure 3, the value of 5438 ton eq. CO_2 must be compared to former GHG emissions for Chevrollier high school. On the other hand, we must evaluate the importance of this amount of GHG emissions in the life time of the new high school.

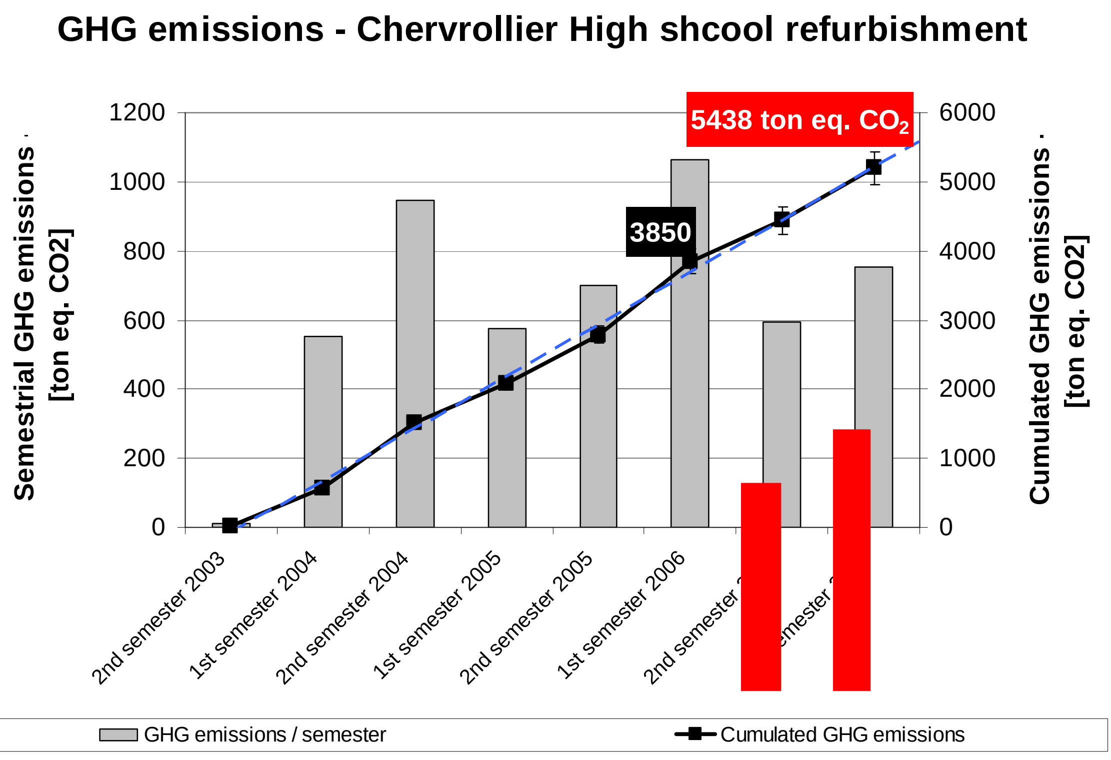

Figure 3. Predicted results of GHG emissions audit in Chevrollier site until first semester 2007.

DISCUSSIONS OVER RESULTS

We can notice that in order to match with a return on GHG investment smaller than 20 years (theoretical life time of the refurbishment building), the improvement of Chevrollier high school meet a GHG reduction goal per year of about 35%. We can observe that without improvement in GHG emissions, refurbishment still represents 32% of annual emissions on the 20 years life time building. However, 5438 ton eq. CO_2 is a very high value and in this case, the amount of GHG emissions due to refurbishment would count for more than 50% of the annual emissions for the building life time.

These results are impressing, but more study will be realized to give a good and scientific interpretation. Actually, the prediction of 5438 ton eq. CO_2 concerns both old building refurbishment and new building construction. The next step of the study is to evaluate the amount of GHG emissions specifically due to refurbishment by studying the time scale of the project.

CONCLUSION

CO_2 Building Stock Budgeting is related to the owners who have management of a large building park. The finale objective of CO_2 Building Stock Budgeting target is to define a budgetary policy, which enables the owners to really reduce CO_2 emissions.

If governments' targets for reduction in CO_2 emissions are to be achieved, refurbishment and renewable technologies should be considered for the existing large stock of typical tertiary buildings in most European cities.

SUMMARY

Presumably, the means of saving energy are not the very same while the climate and culture in Finland compared to those in the ASEAN region are very different. The expert interviews in Finland, in Singapore and in Malaysia proved rather similarities than differences in the energy saving partnerships. Starting the processes with the energy audit, a need of transparent contract models, surprisingly common energy saving measures, difficulties in development and implementation of measuring and verification methods and relaying so far on a handful of active operators are shared. Practise of energy labelling, efforts for defining the national baseline and the accreditation of the ESCOs are strong in Singapore. The Finnish ESCOs apply the latest EU legislation into the ESPCs and seek how to solve the use of multiple ESPCs in the ageing building stock in municipalities all over the country. Ageing buildings form an energy saving potential in both countries.

INTRODUCTION

An energy performance contract (ESPC) project (energy saving partnership ESP) is a partnership between the customer and an energy services company (ESCO). The ESCO conducts a comprehensive energy audit and identifies improvements that will save energy at the facility. In consultation with the customer, the ESCO designs a project that meets the customer's needs. The call for bids precedes the contract. The customer evaluates the competing ESPCs based on demonstrated capabilities to manage the general scope of work, terms, and conditions for firm-fixed-price task orders for performance-based energy savings. Theoretically, the ESPC can be classified as a form of the Life-Cycle Procurement Contracting such as the EPC (also called Third Party Financing), the PFI (Private Finance Initiative), the PPP (Public Private Partnership), the BOT (Build–Operate–Transfer), etc. The key elements of them are the financing, the service level agreement, the financial and energy technological risk assessment and the measurement and verification. The bankers, the ESCOs and the building owners seek for a beneficial win-win-win business concept.

ESPCs allow the customers to accomplish energy retrofit projects in their facilities without up-front capital costs and without special appropriations to pay for the improvements. After the contract period ends, all additional savings benefit the customer. The primary factor motivating the use of ESPC by governments or municipalities has often been the difficulty of obtaining funding for required energy upgrades and infrastructure renovation through the normal budgeting process. These improvements may be needed to replace outdated or poorly performing equipment and to meet externally imposed energy conservation goals. In general, if a project is economically and technologically feasible and is large enough to interest an ESCO, it can be implemented through the funding of an ESPC. To customize the scope of contract to suit local markets, the development and implementation of multiple ESPC projects over a large geographic area, or the call for bids covering techno-economical approach for one or more defined site-specific projects can be used.

Worldwide, including Finland and Singapore, the energy performance related business has been no mainstream field in construction. A handful of new ESPC projects have been started per year nationally. It is a so called radical product without established markets. Nevertheless, the ESPCs match certain customer needs better than any other contract forms. Energy contracting is based on both legislation and energy policies which especially calls upon the public sector to take a leading role in the sphere of energy efficiency. The US and European administrations as well as those within the Commonwealth of Nations have enacted some type of enabling legislation permitting hospitals, day-care centres, schools, universities, etc. to use the ESPC. The ESPC constitutes a successful contracting model in reducing carbon dioxide emission and its negative impact on the climate, as well as in lowering of energy costs. It is therefore not surprising that the model is increasingly finding many imitators.

Not only insufficient funds but also the shortage of specialised labour or the lack of resources in the municipal management might lead to exploit the ESPC, especially in the small communities. The time it takes to implement an ESPC project can be much shorter than the time consumed waiting for directly funded projects. In some cases, the democratic municipal decision making might cause troubles, if the local councillors do not understand the benefits gained by the ESPC. In contrary, quite often, the short term monetary values alone count most when comparing the bids, especially if no emphasis has been put on sustainable values.

The ESPCs can yield significant benefits in the operation costs of building services depending on the standard of energy efficient or sustainable technology employed during the design and implementation phases or during repairs, to achieve an energy efficient building performance life-cycle. Although the total savings yielded can pay the repairs and improvements, still, these so called guaranteed ESPCs are no norm as the feasible projects tend to have external investment funding (the shared ESPCs). Using financing secured by the ESCO, by the customer or by a third party or even, by a combination of them, the ESCO installs the improvements and guarantees that they will result in a specific level of annual cost savings, sufficient to pay for the project or the debt over the term of the contract, often including performance-period services such as maintenance of the equipment. The ESCO must remedy any performance problems and reimburse the owner for any savings shortfalls.

The ESPC can be understood as a tool box for implementing energy efficient and sustainable technology and related services. It has launched a new approach to building services as a turn-key delivery − with the added value of performance guarantees, lasting longer than what the guarantee requires; from a couple of years up to 25 years, instead of the one year guarantee period for the performance of the equipment within a traditional construction contract. The ESCO guarantees that the equipment will perform as specified and that the specified standards of service (temperature, humidity, etc.) will be maintained for the life of the contract. An important difference from the traditional design–bid–build process is that in an ESPC, the ESCO provides a single point of accountability, from energy audit through design, construction, and commissioning. This eliminates any uncertainty about who is responsible if design or construction issues arise.

The loan is often translated into low-risk financing of quite low interest rates, in the case of a governmental or municipal lender. The ESCO’s credit is seldom as good and thus the ESPC programs might be structured so that the customer obtains the financing, not the ESCO. In summary, shared ESPCs lowers the risk to the lender and allows lower financing costs, and sometimes simplifies the process. Guaranteed or shared ESPCs benefit the building owners or occupant companies which is the target of the ESCOs, who in addition, seek for profitable business concepts for themselves. Interest rates can be fairly lower if the risks perceived by the lender are mitigated. Recently the interest rates in financial markets in general have been low enough to offer various business opportunities, influencing also on the demand for the ECPSs. It is of interest to note that sometimes the ECPS could be left without financing because the bankers are not convinced of the feasibility of the project due to lacking knowledge of the concept of ESPC because of the very technical nature of it.

Periodic measurement and verification of savings (M&V) provides the facility owner with assurance that the specified performance and guaranteed savings will be realized. An M&V report describes in detail the results of a program of measurements, inspections, engineering calculations, and comparisons with energy baselines, carried out to estimate the level of savings being delivered by the installed equipment. Standardised M&V methods have been introduced. They can base on calculations and measurements. Common energy conservation measures comprise lighting retrofits, high-efficiency heating and air conditioning equipment, insulation upgrades or replacement of windows with energy efficient window types, sophisticated energy management and intelligent control systems, boiler and chiller replacements, installation of heat recovery and improvements in steam and hot water distribution systems. In addition to the hardware related measures, systems design and end-user empowerment tools have been used such as peak load management, optimisation of HVAC operations and shifts, adaption of systems to demand or user training from briefing the caretakers to the guiding courses for the end users (e.g. nurses in hospitals), and not to mention the instructions for the end users how to operate the building energy efficiently, e.g. opening the windows when too warm or switching off the lights when the room is not occupied [*]. Few ESPCs promote specific advanced technologies such as air or ground source heat pumps, photovoltaics, and biomass or alternative methane fuels as well as solar thermal concentrating systems and new energy storage methods.

The building project or the renovation of a building can be accessed via many modern concepts necessary in the operations of the construction sector: commissioning procedures, total building performance considerations, creation of life-cycle services, new construction contract models and integrated facilities management as well as financing instruments to come. General trends of construction business affecting energy performance contracting can be summarised as: the capital and "renovation" intensity[1] and spend is going up, the knowledge intensity[2] why design should be given to agile designers, the labour intensity[3] and the globalisation of labour market, the win-win-win procurement[4] challenging how to measure and the need or the fairness of incentivisation, the consolidation of companies[5] by developing new contract models, a growing awareness[6] of usability and empowerment of occupants, an ever more sophisticated business concepts[7] creating markets for radical products and services, immaterial finance[8] instruments and unawareness of their risks and a risk management of end-user behaviour[9].

METHODS

Via expert interviews were gathered current knowledge of the ESPCs in Finland, Malaysia and Singapore. The methods for the personal interviews varied: in Finland a theme interview addressed to the 21 experts who had worked on the six recent major ESCO projects [1], a structured questionnaire addressed to the 30 experts within the 12 ESCOs and an energy audit consultant in Singapore, and the 12 experts in Malaysia. However, the last mentioned set of questions worked rather as a source of inspiration than as a strict guideline for the discussions. Realization of these interviews resembled theme interviews. In Finland and in Singapore each ESCO was interviewed separately while in Malaysia group interview method was employed. The key characteristics out of the ESP best practises are summarised in this context.

Both in Finland and in Singapore, the interviews got a freely flowing and open form while the interviewees were keen on the subject and on telling of their aims and efforts. As known the group interview was not the best pick for the method, because during the discussions one interviewee might take the lead and dominate the answering. This could not be prevented totally in this case either.

Locations of Studies

The land area of Finland, in the Temperate Zone, is relatively large and Singapore, again, is a relatively small island in the Tropics, in front of the Malaysian peninsula occupied by Malaysia[1]. In those democracies, the consensus on national interests matter together with the transparency in government's activities and in national financing. The importance of energy and its role under careful administration in all three countries did not live up to expectations of cultural differences − Finland, a homogeneous Christian society; Singapore, a multinational society with several regions; Malaysia, a Muslim society[2].

Finland and Singapore depend mainly on energy imports while Malaysia has own oil resources. Finland has hydro and nuclear power and fairly good chances to benefit from such renewable energy sources as wood, air and earth grounded heat pumps, wind and waste. In contrary to the Finnish multiple set of energy sources, Singapore roughly said is solely oil dependent. In Singapore the chances to use renewables, solar energy in particular have been found limited excluding the potential of waste. In Finland as in Europe in general quite often energy supply and distribution systems are competitive. Building owners have to choose between competing technical systems of oil, electricity or renewables while in Singapore and in Malaysia electrical cooling dominates.

BUSINESS LANDSCAPE

Both in Finland and in Singapore, efforts for energy performance and co-operations between government bodies, scientific institutions and private energy sector are active and versatile encouraging ESPCs. The Malaysian experts are keen on following the same progress. The practice of energy audits has been established by many governments [1] encouraging the national operators to carry out energy audits; in Finland 40 per cent of the costs are granted, in Singapore 50 and in Malaysia 100 per cent. In all studied countries, the energy audit procedure comes first and then the energy performance project follows. The minimum project comprises the management of system and equipment choices with the life-cycle costs calculations, while the maximum concept covers design, contracting, evolution and integrated facilities management of the whole building and the outdoor area. In Singapore, the internationally operating ESCOs could use several financing instruments: self finance, good credit from banks or financing from clients while some ESCOs found financing risky and told that they might face difficulties in covering the financing of the guaranteed ESPC. However,

---

[1] The land area of Finland is 360000 km^2 and population of 5.3 million; the land area of Singapore is 647.5 km^2 and population of 4.4 million; the land area of Malaysia 329 750 km^2 and population 25.8 million.

[2] Religious minorities exists

not only the major Singaporean ESCOs but others as well, operating also in the neighbouring countries: Philippines, Thailand, Vietnam, etc. had committed guaranteed ESPCs. That was neither the case in Finland nor in Malaysia. In Finland, the shared ESPCs dominated the markets where also the municipal financing instruments were used. In Finland, the ESCOs can be granted a public investment aid of 20-25 per cent. In Malaysia, the financing of ESCOs could benefit from the United Nations aid for developing countries and get five year loans for a zero interest rate. An interesting practise obtained by some ESCOs in Singapore proposed an MOU of the upcoming ESP (memorandum of understanding) to the clients based on a preliminary energy audit to make sure of their motivations. After the MOU has been signed the energy audit was finalised.

The trust between the ESCO and the client was found important in Finland as well as in Singapore and in Malaysia. The contracts drawn up without a national contract model were not necessarily very detailed. The contracting was rather based on mutual trust between the client and the ESCO than on written paragraphs of the contract. Thus, the need for contract models was obvious in all countries. Court cases have not been avoidable in total. In addition, contract models establish a certain commonly acceptable commercial usage based on correct business ethics and on fair play. All interviewed shared the difficulty of no common language between the ESCO and the client concerning the service descriptions and the service level requirements (fees, complains and sanctions). In Finland, no one mentioned of the problematic changes due to the end user actions during the ESPCs whereas in Singapore end-user behaviour was quite often considered as a risk. A cultural difference can cause this difference. In Finland, according to common practise, the business partners negotiate the contract and that after it is realised very firmly as written, sometimes even without any flexibility in changed situations. The newly developed template for the stipulation of the ESPC contract in Finland includes the clause of the necessary changes in contract after changed situation. Still, it is recommended to keep the contract in the first place. The Singaporean business culture is evidently one of the most Western economies in Asia if not the most Western. However, the Asian business is more than the Western, and definitely more than the Finnish one based on negotiated terms during the contract. No wonder that the clients of the ESCOs find it correct to negotiate even the baseline of the ESPC during the contract.

Both in Singapore and in Finland the ESPCs were structured on project by project basis after the outcome of the energy audits or according to the targeted savings or energy efficiency defined in the tender documentation. The scientists work for the nationally universal procedures and especially in Singapore on the definition of the national baseline together with the development of energy benchmarking which were not emphasised in Finland, at least by the interviewees. The M&V of the ESPC was also under development in both countries because of improving the problematic quality control of the ESPC. However, to find the best calculation or measurement methods is not easy. The best pick of selected parameters caused troubles as much as the surprises found in lacking HVAC systems and their functionality when measuring the performances. The lively international co-operation can be used in defining the measurements needed for contract stipulation and the M&V.

Legislation and governmental policies, efforts for transparency of business activities, accreditation of ESCOs, as well as energy labelling assist in promotion of energy efficiency and sustainability. In Finland, when implementing the latest European directives, described later within this context, the transparent procurements on public works was considered as a two-edged sword opening the tenders better than earlier to competition while on the other hand, a challenge to the authority of the new directive emerged by some well established effective consortiums of ESCOs and their clients. Also a topical subject was how to organise the neutrality of the consultants working under the contract of an ESCO. Lack of competitive providers for larger ESCO projects was a problem in Finland. The market was not mature enough for numerous large players and smaller providers have not enough assortment to offer for large tenders.

An increasing number of Finnish municipalities have considered outsourcing of their municipal technical services as a good solution for their problems to make those services available. No particular interest in involving the ESPCs in these life-cycle procurement contracts was noticed. However, as the ESPCs theoretically can be classified as a form of life-cycle procurement contracts, the more common any of these contracts become the better the idea of the ESPC will be embedded. This thinking can be considered parallel to the more general thinking in Europe of intentions to extend the classic approach of an ESP focussing on energy efficient equipment and control engineering to the development of life-cycle building services contracting models. In fact, the latest progress of the ESPCs enforced this thinking in Finland, within the CUBENet project[3] [6]. It has been asked if a life-cycle ESPC could be possible in the future. Developing such an innovative model would be a cornerstone in increasing energy efficiency and in offering an attractive financial alternative for the public purse. In addition this offers an opportunity to attract new customers in industry and trade, in office buildings and in the housing industry.

The Finnish municipalities seek also means how to develop and implement multiple ESPC projects covering several small buildings, for example day-care centres or village primary schools. Models of life-cycle contracting of that kind have been found from Sweden [7] and from Great Britain [8].

In Singapore, the American companies established there work together with the Singaporean operator for the interests of both parties. To put it very simple, in addition to their high class scientific work, the Singaporeans have interpreted also the American models of energy performance concepts and modified them suitable for their effective way of operation and economy. Likely, the natural progress of the ESPCs or other forms of life-cycle procurement contracts will continue to follow this feasible line of development. Like in Finland also in Singapore the aging building stock, particularly housing, needs renovation and holds a large energy saving potential. However, so far the efforts to encourage the ESPCs have been on public or commercial buildings, hotels and industry.

In Malaysia, the industrial buildings were in focus in this first wave of implementing ESP. The organisations encouraging the ESPC [11] provide material and courses of the technology, methods and economy of energy performance for local ESCOs and building owners. The interviewed in all countries considered the co-operation with facilities management (FM) organisations and the ESCOs essential. However, the mixing roles of building services and FM services were found confusing. Even, some Asian FM operators thought of their position threatened due to the ESPC.

Motivation of Energy Savings

Since the energy crisis in the 1970's, energy savings and energy efficiency have been continuously the top topics in the research and development of technology (RTD) in the Western economies, in Europe including Finland, while a similar progress has started in

[3] Future Life-cycle Building Services, 2003-2007 (www.sisailmatieto.com/cubenet/) within Tekes (the National Technology and Innovation Agency) technology programme CUBE

ASEAN quite recently. Europe is dependent on imported energy and energy efficiency is an important part of the European energy policy. As recently the prevention of creation of carbon oxide is common around the globe, among other things, the increasing use of renewables has become more important than ever within the European energy policy. In Finland, the ESCOs are in the line of these persistent efforts to save energy. In Singapore, in the democracy of progressive policies, the government is behind all efforts to promote energy efficiency and has launched own programmes to encourage the implementation of ESCO projects. Lack of motivation of clients in energy performance contracting is one major problem in the Malaysian business environment. In all studied countries the private sector favoured the ESCOs while they allow also other additional financial benefits.

The vitality of the energy performance business bases on a win-win-win situation within an ESP. The service provider wins when the customer and its customer, the end-user wins. This is not a traditional business arrangement while earlier businessmen have tried their best to maximise their own profit. Obstacles can be found in any business, why not in this new business. In the first place, due to the modern technical nature of the ESPC third parties such as financiers do not trust on or fully understand this type of profit making. In order to create a positive business climate for energy performance business new thinking or attitudes are needed. Common efforts give right to shared profit. Motivation counts. The ESPCs face hard competition from alternative investments. The Singaporean clients originated from sophisticated financial markets could be characterised as having quite high expectation on the ROI (return of investment). Not the plain saved kilowatts out of energy effective performance motivate the Finnish clients to conclude the ESPCs either.

The European directive of building performance might improve the motivation of energy savings further. The energy certificate to be issued will give a base to argue about energy monitoring and energy management based on the activities of ESCOs. A problem faced in the context of any radical product or service and also in the introduction of the ESCO services, is how to prevent the bad reputation of some false operators to destroy the honest businesses. In Malaysia, in particular, the interviewees mentioned of this problem. The UN money was not found only a blessing while it could draw ESCOs and industrial partners who are more after easy money than energy performance. Accreditation is an asset for preventing problems. In Singapore, an Accreditation Programme for ESCOs was launched in 1995 and it is actively continued since then (www.esu.com.sg). In Europe, Austria has developed the Austrian Logo for Certificated Energy Contracting. Still, in the first place it promotes the effective image of the ESCOs.

The idea of green building comprising the energy efficient technologies has reached wide audience in the Western world (cf. e.g. www.greenbuilding.org). Despite the interest in the sustainable development or in the life-cycle cost analysis, the realisation of the green technology in Finland does not necessarily correspond to the interest in the subject. In the first place, the building providers and developers have aimed energy efficiency simply because of the prevention of high heating costs [12]. Consequently, the green values did not come up during the Finnish interviews either. However, some strong groups exist, who stand behind the sustainable measures to all intents and purposes working on tools for profitable green development [12] and green building labeling [14]. The green city is targeted also with the activities for energy efficiency in Singapore (cf. Energy Smart Building Label, www.esu.com.sg). In Singapore a couple of the ESCOs highlighted the meaning of the green technology and the responsibilities towards the future generations of the condition of the global nature. Thus, they pushed forward the use of renewables and green technology within a long time frame of the ESPC meanwhile they believed the business potential of this thinking. Giving all operators their due, the result of the interviews showed that the Finnish clients of the ESCOs were quite motivated in energy savings while the ESCOs in the ASEAN countries were more cautious of the motivation of their clients.

The empowerment of individual occupants and why not also the occupant companies, in energy saving is challenging in general, and the cultural differences might make it difficult to apply knowledge of it internationally. In either of the countries, the ESCOs have not taken the end user involvement in their set of services if some very end-user oriented energy audits are excluded. It was not directly asked, but the interviewer could not help taking the view of lacking knowledge of the means to empower the end-user for the advantage of the ESPCs and unawareness of the meaning of the end user behaviour for the fact in all countries.

Building Trust by Related Activities
In Europe, municipalities and government organisations are bid to the European energy directives and the legislation on public works contracts. Private sector can operate within the framework of financial interests. However, good public practices might move in on the private business venture. In the European context two recent EU (European Union) directives important to the ESPCs have been launched: The European Legislation on Public Works contracts, public supply contracts and public service contracts[4] [3] and The European Legislation on Energy Performance of Buildings [4]. Most recently the European Commission made a Proposal for a directive on energy end-use efficiency and energy services, which also introduces various modifications of ESP.

As mentioned, in Finland, these directives have been already taken into the consideration in the contract modeling of the ESPCs and other life-cycle contract models for the building service sector [4], [6] and [9]. In Singapore, the development of establishing a transparent contract process is strong because the business operators hunger for it, and the government requires it. In Malaysia, the market should be developed further to find consensus of the ESPC contract models in other sectors than in the industry [10].

The directive of the energy performance of buildings concerns setting of energy performance requirements, making available energy performance certificate on built, sold and rented buildings, inspection of boilers, inspection of air-conditioning systems and independent experts. The only one of the recommendations not adaptable for national purposes is the availability of energy performance certificate. European Commission wants to awaken

[4] Certain rules applicable to all European public works contracts comprise first of all the contract award criteria based either on the lowest price only or, where the contract is awarded to the most economically advantageous tender, on various criteria linked to the subject-matter of the contract in question, such as: quality, price, technical merit, aesthetic and functional characteristics, environmental characteristics, running costs, cost-effectiveness, after-sales service and technical assistance, delivery date, and completion date. The contracting authority should specify the relative weighting it gives to each of the criteria. The legislation highlights combating fraud and corruption, electronic auction, rules on publication and transparency and to put traditional and electronic means of communication on equal footing.
Four alternatives of procedures were included. In an open procedure1, any interested economic operator may submit a tender. In the case of restricted procedures2, any economic operator may request to participate and only candidates invited to do so may submit a tender. In a negotiated procedure3, the contracting authority consults the economic operators of its choice and negotiates the terms of the contract with them. Within the competitive dialogue4 a contracting authority may make use of it for complex contracts if it is not able to define by itself the technical solutions to satisfy its needs or is not able to specify the legal and/or financial make-up of a project. Large infrastructure projects would seem to lend themselves to this type of dialogue.

awareness among Europeans of the possibilities to save energy and to reduce emissions from green house gases, thus, it is not only the matter of energy efficiency but use of domestic energy sources and cultivate sustainability.

The costs for the provision of the Energy Performance Certificate in Finland are estimated to be relatively high[5] [10]. When implementing of the directive the Finnish government looks after means for a lean production of the certificates for example by preventing unnecessary authorisation and the establishment of extra organisation for it which does not advance energy efficiency. This differs from the ASEAN efforts as well as the North American and the British where authorisation in general is more common than in Finland − in a country without a system of post graduate registration and qualification of the practicing architects and engineers. However, it is worth of mentioning that the authorisation of the energy audit experts exists also in Finland. Further on, universities and polytechnics as well as private educative organisations will be obliged to take care of the training of the providers.

The Ministry of Environment and the Ministry of Trade and Industry estimates that the influence of the energy performance certificate directive will be large on the renovation activities the level of which already is high. Further on, after the directive has been implemented as a whole the new born activities will yield savings depending on the realisation of implementations. Energy savings are estimated not to cover the renovation costs or have a remarkable influence on the reduction of green house gases.

Energy Saving Measures in Different Climates

Both in the Northern Europe and the tropical ASEAN difficult climatic conditions are faced. In Finland, some periods in winter are very gold, causing high rated temperatures for HVAC technology, and in Singapore the air humidity and temperature are high all year round. The energy saving measures were expected to be different while carrying out the interviews on the ESPs in two different climates causing contradictory aims for the performance of technology: in one case, extra heat has to be removed by cooling the space, and in the other, heat has to be gained by heating the space. In the first place, the ESPCs in Finland comprise often the adding of heat recovery and in Singapore a removal of extra chillers.

Nevertheless, in the both climates the balance between effective energy use and good indoor air quality is targeted without forgetting the aims of sustainable development and taking into account the worries of global warming. Means for building service technology are many and in addition, interestingly enough the very similar technology available globally can be applied differently. The building automation, often implemented by the ESCOs is self evidently the very same all over despite the climate. Insulation is applied either against cold or heat as well as air-conditioning for high indoor air quality follow universal design criteria. All are concerned of the energy spending in lighting of empty spaces and the optimisation of the interplay between artificial illumination and natural lighting. Meanwhile, it is not clear enough to say how the sustainable or green technology can solve the indoor environment in different outdoor conditions. However, the same technology is considered and tested internationally.

Energy Optimization Services in a Belgian Hospital; Facts & Results

Frederiek Demeyer

University college of West Flanders, technical department PIH, Kortrijk (BE)

Corresponding email: frederiek.demeyer@howest.be

SUMMARY

The presented paper will describe the outcome of a service agreement to optimize the performance of an installed Building Management System (BMS).

In an existing building (a polyclinic) with a BMS, many common control and comfort settings have been questioned and adapted resulting in astonishing energy savings. A thermal reduction of 35,7% and an electrical reduction of 15,7% are achieved after a two year optimization period. These figures resulted in a very fast pay back time of 11 months for the common cost of the audit and service agreement.

The impact of the figures is even more impressive when one looks at the initial benchmark results. On a heat consumption base the hospital under investigation wasn't performing bad, the fact we could even improve this figure really creates opportunities for efficiency optimization services at customers with a BMS. Towards the electrical consumption one can clearly see the impact of uncontrolled computerization and fully air conditioned buildings.

We hope that this paper will help the technical manager of a facility to experience the optimization potential of a well maintained and controlled BMS.

INTRODUCTION

In the beginning of 2005 we introduced the Building Performance Optimization Services on the Belgian market.

As an environmental concerned organization we want to investigate the impact of the energy optimization services potential for a customer whose building is equipped with a BMS. The outcome of this study is important to quantify possible energy- and emission savings in other buildings who are or could be equipped with a BMS.

The customer who participated in this study is a community hospital of the city of Aalst namely the 'ASZ-Aalst'.

The ASZ-Aalst represents a group of three hospitals:

ASZ - Aalst Hospital group			
ASZ - Aalst		m²	# beds
	Hospital	34264	368
	Polyclinic	5025	0
ASZ-Geraardsbergen			
	Hospital	13125	160
	Eldery people clinic	2872	60
ASZ-Wetteren			
	Hospital	7377	101
	Polyclinic	2084	0

Table 1: Overview of the ASZ-Aalst hospital group.

Figure 1: The polyclinic in front of the main hospital

From these three hospitals, only the newly build polyclinic, located on the ASZ-Aalst territory is having a modern BMS. For this reason, all BMS related improvement measures are implemented at the polyclinic.

PAPER

In 2004 the technical director of the ASZ-Aalst hospital group wants to know the potential impact of energy optimization measures related to the ASZ-Aalst hospital. A basic audit shows the major discovered energy opportunities.

Table 2: Energy audit results

	Savings		
Calculated Measures - Main hospital	Energy (kWh)	€	CO2 (ton)
Advanced cooling & compressor control	300000	27000	225,0
Standardisation and optimal control of comfort level & BMS	850000	46580	419,9
Replacement of the existing window panes (bad shape)	1330000	46550	465,5
Total main hospital	2480000	120130	1110,4
Calculated measures - Polyclinic	Energy (kWh)	€	CO2 (ton)
Advanced cooling & compressor control	50000	4500	37,5
Standardisation and optimal control of comfort level & BMS	125000	6850	61,75
Total polyclinic	175000	11350	99,25

Besides a major architectural optimization, the replacement of the current window panes, huge opportunities are waiting in regards to the BMS.

As the polyclinic is entirely equipped with a BMS, we suggest to primarily optimize the small day clinic and to use the optimization results to plan further investments in the other hospitals of the ASZ-Aalst group where no accurate BMS is currently available.

Investments in a BMS are financially important decisions, so the ability of a technical director to prove the financial (environmental) benefits towards upper management is a very important aspect to defend the associated investments.

A first important step in the workout of the paper is the explanation of the task flows and the basic philosophy behind the BPO service model.

Figure 2: Integrated approach of the BPO model[1]

As the graphical representation of the BPO model shows, we want to help the customer improving the all round performance of his BMS. This results in the short quote: 'Helping your building work for you'.

As this paper is focusing on the energy performance optimization of the model a correct alarm handling and online follow up of the installation is very important.

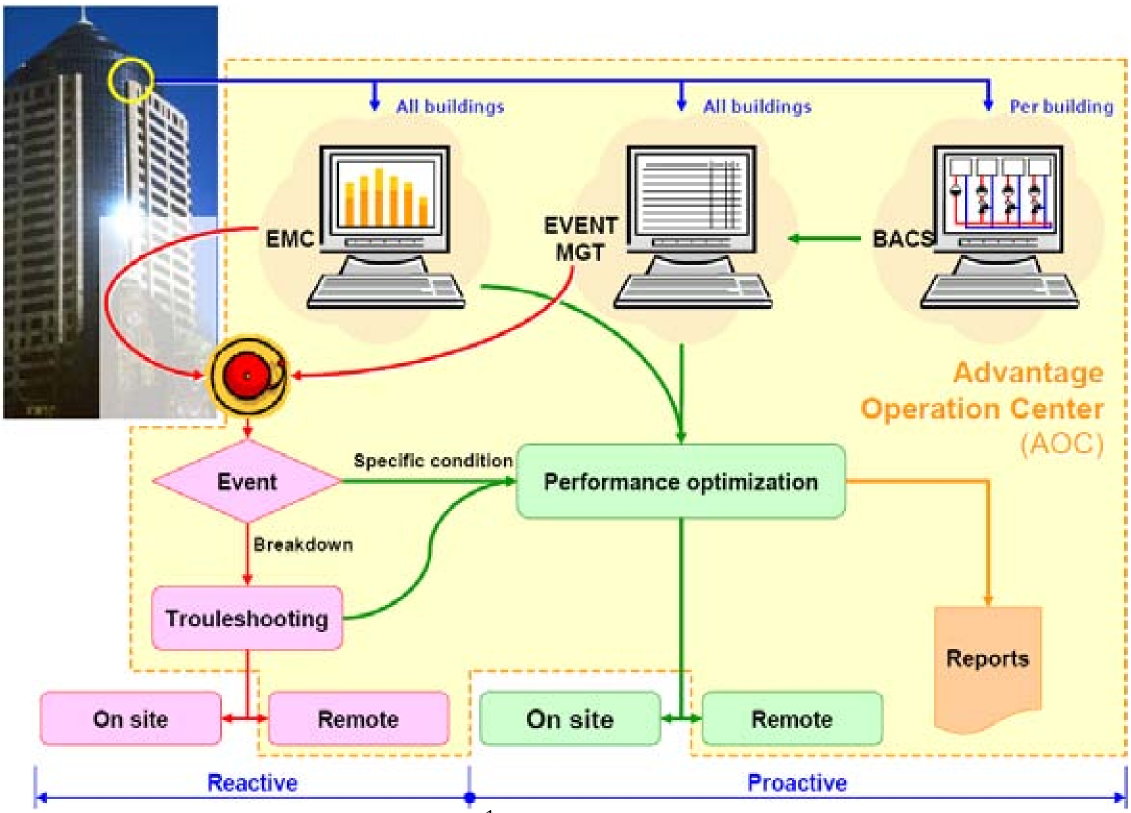

Figure 3: Task flows behind the AOC[1]

In an Advantage Operation Center (AOC) we have a complete online view of the customer. Any process or consumption abnormality is triggered immediately to the responsible. As most of the programming measures are implemented on site, the follow up and proactive tuning can take place from any location which is a major managerial & environmental advantage.

Figure 4: The EMC software label

Part of the AOC is the EMC (Energy Monitoring & Controlling) tool which gives us the opportunity to check & follow up online the current consumption (= achieved optimization results).

A second important step in the optimization process is the implementation of a basic metering structure. A general electricity-, heat- and water meter are installed on site although no separate domestic heat - and electricity for cooling meter are available. As we have an idea on the domestic heat consumption (basic thermal consumption during hot summer periods), we can use the standard HDD (Heating Degree Day) correction functionality of the EMC software tool on the data. Unfortunately towards cooling we can’t use the CDD (Cooling Degree Day) correction as there are no reliable means to quantify this consumption, in the near future a separate electricity consumption meter for the cooling machines will be installed.

Once the metering structure is up and running we started the implementation of the different FIM’s (Facility Improvement Measures).

All the measures can be addressed in one of the following main classes:

- Comfort
- Heat distribution
- Cooling production & distribution
- Lighting

Comfort

The first thing we analyze in the optimization process is the current comfort level of the building. As all rooms own their personal comfort adjustment (PCA) panel, extreme temperature settings can be encountered. Another important setting is the difference between the SPV (set point value) for heating and cooling. In the polyclinic both settings were extremely mixed up. Comfort temperatures were varying between 19°C and 26°C, a majority of the room settings had a gap of 1°C between the heating and the cooling set point.

This resulted in a first implemented measure: the standardization of the comfort temperatures. In the current situation all the rooms have a SPV for heating of 21°C and a SPV for cooling of 24°C. The personal comfort adjustments are reduced from +/- 3°C towards +/- 2°C. Another change towards the PCA panel is the reset of the adjustment at the end of each comfort state. In the past, once you increased the temperature these settings remained the same until someone changed them again. Now, after each working day when the controller changes from comfort to standby mode, the deviation is resetted to 0°C.

Besides these programmable changes, the customer invested in IR protection glass foils. These foils diminish the solar influence on room temperature and increase the thermal resistance of the windows.

Although the first measure obviously limits the personal comfort influence of the individuals in the room, both measures resulted in a dramatic fall of comfort complaints.

Heat distribution

The flow temperature of the different heating circuits is automatically adapted towards the outside temperature, reducing the average temperature of these circuits. Each pump is activated by an underlying demand to reduce the overall amount of running hours and heat input into the building.

A further step is the implementation of an OSTP (Optimum Start Stop) algorithm. This algorithm is self learning and adapts automatically the start up - and stop time of the heating/cooling installation as a function of outside temperature, - humidity, inside - and comfort temperature by interpolating the current situation to past situations.

Cooling production & distribution

The cooling compressors in the past were released based on outside temperature and extreme comfort settings. Now the machine will only be released when one of the rooms achieves an inside temperature of 24°C. By running trends throughout the different rooms in the polyclinic we could shift the air conditioning release temperature from 5°C to 15°C outside temperature. Furthermore the flow temperature of the cold water is adapted as a function of outside temperature.

While in the past the machine was working on a fixed 7°C, now we work between 8°C and 12°C.

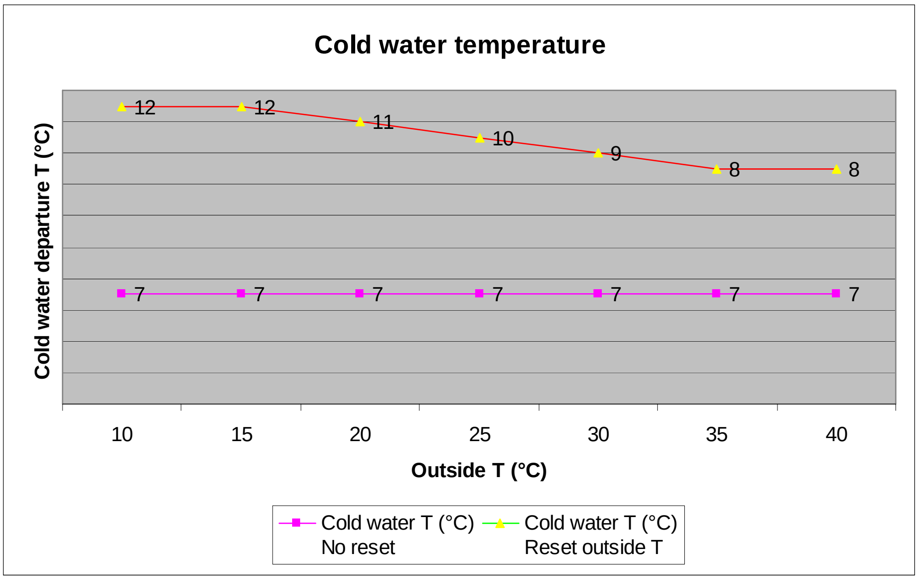

Figure 5: Cold water temperature reset.

As for the heating distribution circuits the same strict pump release conditions and OSTP settings are applying.

Lighting

The light circuits of the hospital are further separated into outside (window) and inside circuits. By means of an outside light intensity measurement we are able to switch of certain circuits. Also during the night there is a control on the minimum amount of lights to guide the employees through the building. For each room an overwork timer function is integrated to allow a general switch off of the lights at 7:00pm. In case someone is still working, by pushing the light button once he is able to work for another hour before the lights will be switched off again.

RESULTS

We will spread this section of the paper over three topics

- Presentation of the impact of the measures on the energy consumption (heat, electricity)
- Presentation of environmental impact & performance of the polyclinic in Aalst, in comparison with other hospitals
- Presentation of the financial return on investment

Impact of the optimization measure on the heat consumption

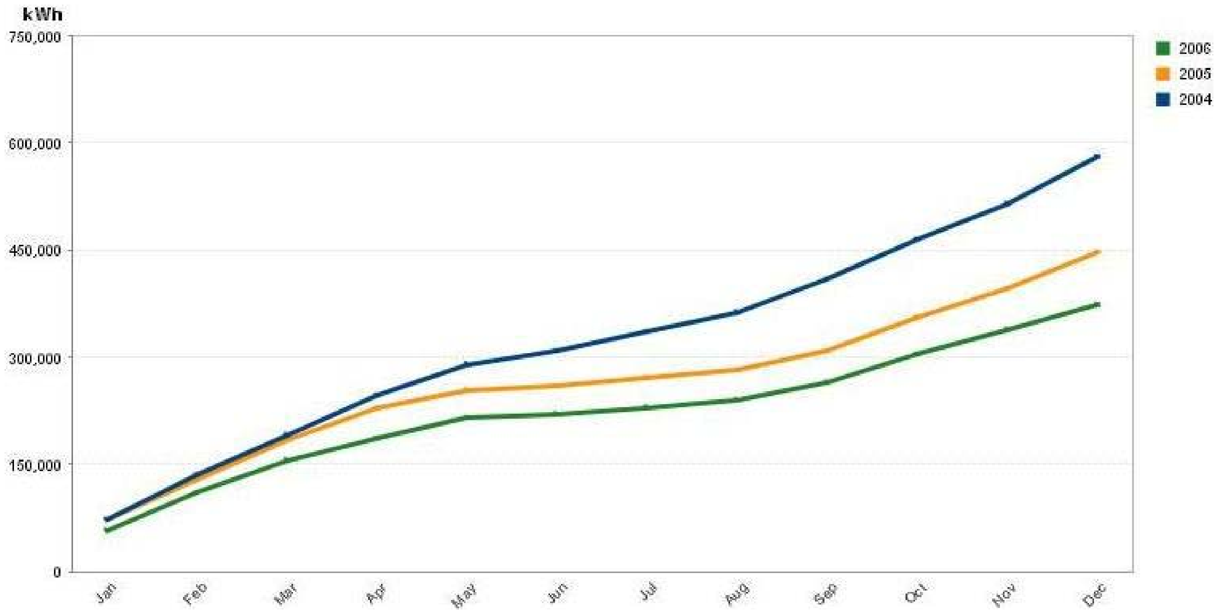

Figure 6: Evolution of the thermal consumption (HDD corrected)

The first graph shows a clear diminution of the thermal consumption throughout 3 consecutive years. A thermal HDD corrected profit of 35,7% is reached over a two year period.

Table 3: Evolution of the thermal consumption (HDD corrected)

Fuel report - HDD corrected			
Year	2004	2005	2006
	kWh	kWh	kWh
Consumption	580074,5	446126,0	372925,3
cumulative saving		133948,5	341097,7
%profit comp. To 2004		23,1%	35,7%

Impact of the optimization measures on the energy signature

The energy signature is showing the thermal consumption as a function of outside temperature.

Three aspects are important when we analyze the energy signature:

- The signature itself should be as low as possible
- The correlation coefficient of the temperature depending points (for the polyclinic this was the interval between 18°C and -10°C) should be as close as possible to 1.
- The rest heat above 18°C (domestic heat) should be as low as possible.

While analyzing the graph we can immediately see that the curve has lowered entirely by more than 10000 kWh (01.2004; 3.68°C → 69824 kWh – 12.2005; 3.91°C → 52096kWh). Also the correlation coefficient (calculated in excel) between consumption and temperature for temperatures below 18°C has increased (2004: 0,95 → 2006: 0,99). On a monthly basis we see an almost linear controlling algorithm.

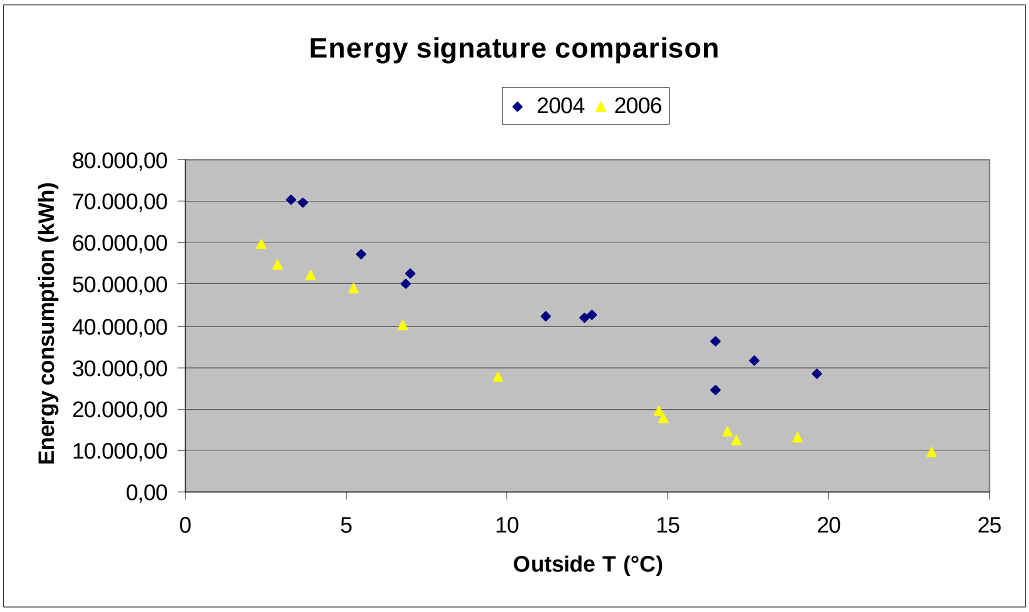

Figure 7: Energy signatures (Before - After optimizations)

Towards the rest consumption for temperatures higher than 18°C, we can also see a dramatic diminution by more than 15000 kWh (08.2004; 19,63°C → 28480 kWh – 09.2006; 19,05 → 13190 kWh). A lower heat consumption during summer and mid season will automatically affect the cooling load on the building.

Impact of the optimization measures on the electrical consumption

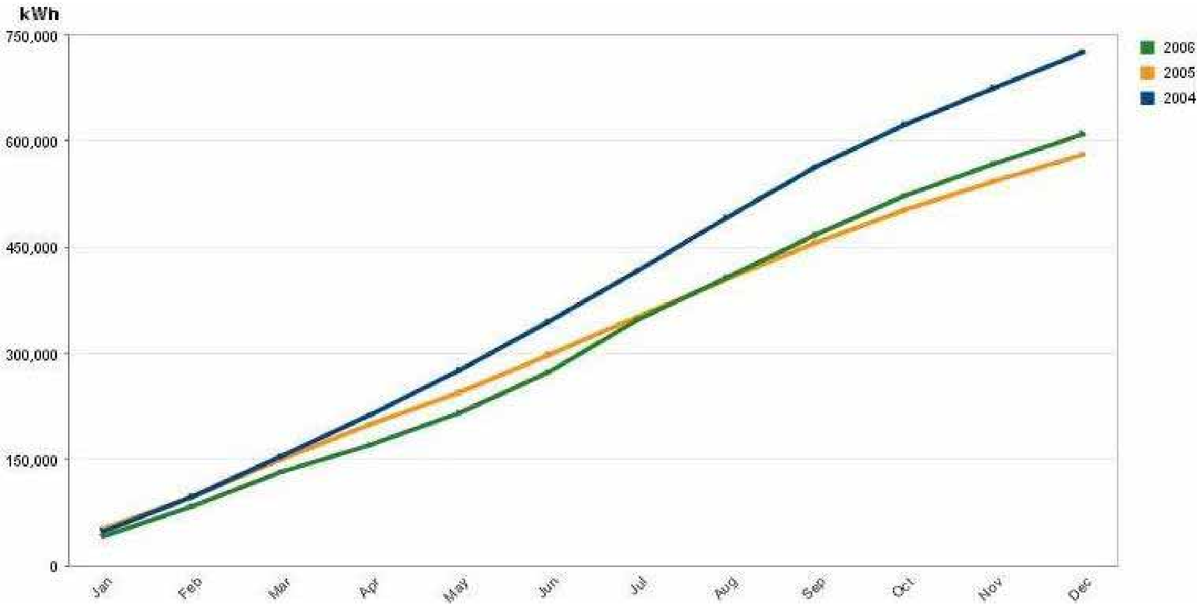

Figure 8: Evolution of the electrical consumption

Table 3: Evolution of the electrical consumption

Electricity report			
Year	2004	2005	2006
	kWh	kWh	kWh
Consumption	725440,0	580928,0	610576,0
cumulative saving		144512,0	259376,0
%profit comp. To 2004		19,9%	15,8%

On the graph and table we can see the impact of the optimization measures on the electrical consumption. In contradiction with the heat consumption we don't see a three year consecutive diminution of the consumption. The answer to this statement can be found in the temperature shift of 2005 in comparison with 2006. The temperature during the typical cooling months (May – October) raised on average with 1,14°C (or 6.8%) . As we have no separate meter registering the electricity consumption for cooling so we can't present a CDD corrected electrical consumption. In the final year comparison we can see a yearly electrical consumption increment of 5.1% for 2006 in comparison with 2005. On average we have lowered the electricity consumption by 18% in comparison to 2004.

After analyzing the thermal and electrical consumption one can see that the audit savings were underestimated.

Impact of the optimization measures on the CO_2 emission

Table 4: Evolution of the CO2 emission

CO2 report			
Year	2004	2005	2006
	kg	kg	kg
Consumption	736070,0	578025,6	573970,0
cumulative saving		158044,4	320144,5
%profit comp. To 2004		21,5%	22,0%

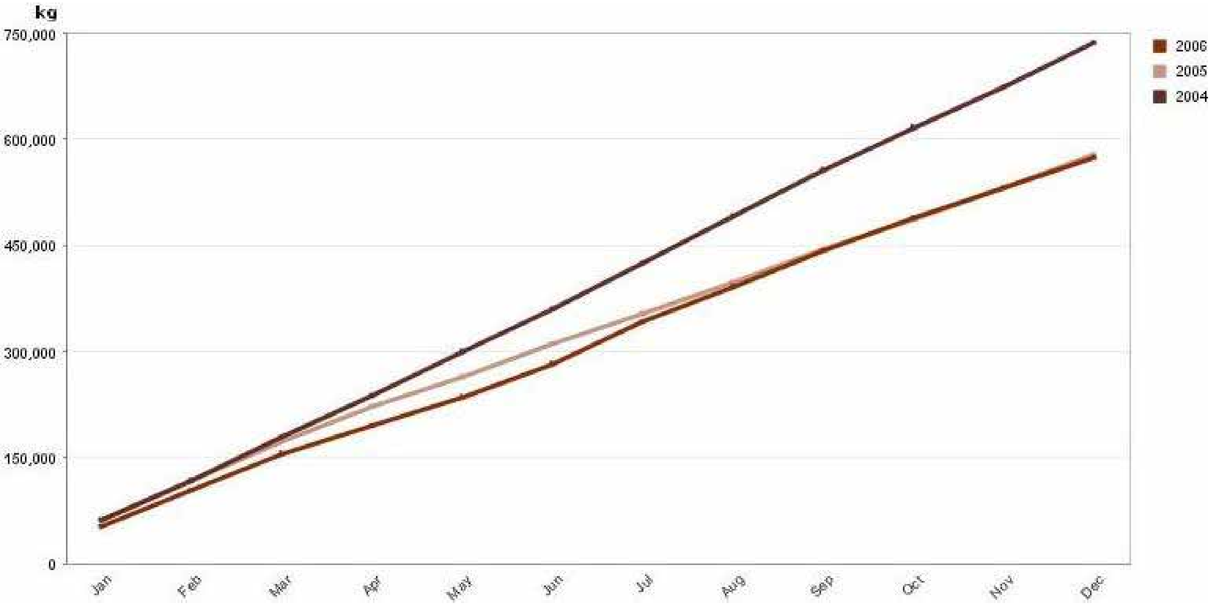

Figure 9: Evolution of the CO2 emission

An immediate effect of an overall diminution of the energy consumption is a reduction in CO_2 emissions. Over a two year period we reached a CO_2 emission drop of 22% representing 320,15 tons of CO_2.

Presentation of the environmental performance of the ASZ-Aalst in comparison to other hospitals

Table 5: Senter Novem benchmark figures[2]

Senter Novem consumption limits					
Specific fuel consumption (m³gas/m²)			Specific electricity consumption (kWh/m²)		
20%	50%	80%	20%	50%	80%
16	50	85	26	95	164

Table 6: Specific consumption figures Polyclinic related to Senter Novem benchmark figures

Specific fuel report - HDD-corrected			Specific electricity report		
2004	2005	2006	2004	2005	2006
m³gas/m²	m³gas/m²	m³gas/m²	kwh/m²	kwh/m²	kwh/m²
11,5	8,9	7,4	144,4	115,6	121,5

Conclusions

In Belgium no official benchmark figures for hospitals are available. So we worked with the official Dutch figures supplied by Senter Novem.

Looking at the thermal consumption figures one can clearly see that the polyclinic was and is still performing well as we have a lower consumption than 20% of all interrogated hospitals. Towards the electrical consumption we get another picture. The consumption is going towards the 80% limit of all interrogated hospitals. A possible explanation of these figures can be found in the fact that there are no residing patients in the polyclinic. No patients mean less thermal consumption for domestic purposes. On the other hand the polyclinic has a denser electrical load because of all the electronic equipment installed for clinical research purposes (scanners, PC etc…), in comparison with an average hospital. Also the fact that the hospital is fully air conditioned is affecting the electrical performance.

Financial returns on investment

Table 7: Financial analysis of the BPO project

Polyclinic ASZ-Aalst	Thermal profit (€)	Electrical profit (€)		Investments (€)	Pay back time (years)
2005	4688,2	13006,1	Audit	10000	
2006	7250,2	10337,8	Services	21000	0,9

Conclusion

We have calculated the savings towards the base year 2004. The BPO services were ended last December and the customer now only pays a fixed cost to supervise his installation from the AOC. The overall payback time for this 2 year optimization project is refunded in less than one year. Besides the on site optimizations the AOC proved it's value in maintaining and optimizing the BMS by means of a web application (see the results of 2006).

Equations

Equation 1: HDD corrected year comparison formula used by EMC software[3]

January: $kWh_{\text{HDD corrected Jan}} = kWh_{\text{actual Jan}} * (HGT_{\text{Ref Jan}} / HGT_{\text{Actual Jan}})\ldots$

October: $kWh_{\text{HDD corrected Oct}} = ((\sum kWh_{\text{Actual Jan + … + Oct}}) * (A/B)) - \sum kWh_{\text{bHDD corrected Jan + … +Nov.}}$

$A/B = (\sum HGT_{\text{Ref Jan + … + Dec}} / \sum HGT_{\text{Actual Jan + … + Dec}})$

The formula above is used by the EMC software to calculate the HDD corrected heat consumption.

The reference year we use is the average Belgian climate at Ukkel over a 30 year period (1970 – 2000).

Advancing The Management of Firms And Their HVAC Related Businesses for Better Wellbeing Indoors

Pekka Huovinen

TKK Helsinki University of Technology, Finland

Corresponding email: pekka.huovinen@tkk.fi

SUMMARY

The aim is to advance HVAC related business management by introducing a platform of 52 construction-related business-management concepts published between the years 1990-2005 (based on the pioneering review) and exploring their applicability to managing HVAC related businesses. 30 (58 %) concepts belong to research in construction management and economics, 9 (17 %) project management, 8 (15 %) real estate development, and 5 (10 %) industrial management. Among the eight schools of thought on business management, the combined share of 13 organization-based, 11 Porterian, 10 dynamism-based, and 10 knowledge-based concepts is 84 %. Concept applicability is explored by coupling each concept with the HVAC related context of application, i.e. all HVAC related firms, engineers, contractors, product suppliers, or life-cycle services providers. No applied research tradition in business management exists as part of construction-related management research. Nevertheless, it is posited that this platform enables business managers and researchers to advance their ways of managing a HVAC related business. Many dynamism-based concepts will be among the ones that will turn out to be most profitable by the year 2010.

INTRODUCTION

The background involves the conduct of **the first-ever review of a population** of 52 construction-related business-management concepts published in English between the years 1990-2005 [1]. The sub-results have been introduced as part of the CIB W55 and W65's symposiums in Singapore [2], Toronto [3], Helsinki [4], and Rome [5], and as part of the 1st and 2nd ASCE Specialty Conferences on Leadership and Management [6], [7] during the years 2003-2006. **Construction** involves design, implementation, servicing, and life-cycle aspects of (capital) investments in natural resources usage, energy supply, telecommunications, transportation, infrastructure, manufacturing, and general building concerns. A firm population belongs to seven business-scope groups: (i) technology-intensive contracting, (ii) construction-related contracting, (iii) process engineering, design, and consulting, (iv) construction-related design and consulting, (v) building products and construction materials supply, (vi) real estate ownership, development, and management, and (vii) life-cycle (incl. FM) services.

HVAC related firms and their businesses belong mainly to construction-related contracting, design and consulting, building products supply, and life-cycle services. Today, the advancement of HVAC firm and business management is triggered by owner and user-based driving forces across building markets. Pioneering investments in **green buildings** target reduced energy consumption and their associated costs, increased occupant productivity and worker retention, increased market values, and reduced health liability risks due to better indoor air quality. Green buildings can save more than 250 % of their up-front costs over the course of their 40-year useable life cycles [8]. In turn, **workplace management** is enabling increased effectiveness and accelerated cultural/organizational change [9].

Thus, the following research problem is herein addressed: "What business-management concepts (to be found in the literature) can readily enable managers to advance the ways of managing of their firms and HVAC related businesses for better wellbeing indoors in building markets?" **The aim** is to advance core thinking in HVAC related business management by introducing a platform of 52 construction-related business-management concepts published in English between the years 1990-2005 and exploring the applicability of this platform to actually managing HVAC related businesses. The sub-aims are as follows: (1) To introduce the eight schools of thought on generic business management, (2) to introduce the 52-concept platform and its relatedness to each of eight schools of thought, (3) to explore initially the applicability of 52 concepts to managing a HVAC related business and readily to point out to some concepts that seem to be the most useful ones, and (4) to discuss some promising implications for HVAC related business managers and scholars.

METHOD

Herein, the outcomes of the pioneering review, i.e. a population of 52 construction-related business-management concepts published between the years 1990-2005 is introduced and **the scope of the applicability of these concepts** is initially explored by coupling each potential concept with the perceived primary HVAC related context of application, i.e. all HVAC related firms, engineers, contractors, product suppliers, or life-cycle services providers. In addition, the applicability areas in HVAC related business management of 52 concepts are roughly presented in the text as the concepts' units of analysis.

The two sub-reviews were conducted in the years 1999-2005 by applying **Hart's [10] literature-review guidelines**. The qualitative literature-review method, i.e. the replicable ways of searching, browsing, in-/excluding, retrieving, inferring, moderate coding, describing, and analyzing the construction-related conceptual data have been specified, used, and documented in detail in Huovinen 2003 [1]. **The coherent nature** of managing a business was maintained by focusing on the research on firms and business units that are based in one of the OECD countries. The exception was to allow the references originating from Singapore and Hong Kong to be included due to these authors' British Commonwealth heritage. Over the 16-year review period, three publication channels have been relied upon, i.e. a population of 25 journals, a population of nine publishers, and 22 conference proceedings. Notably, any new concepts that the nine book publishers may have published during the years 2003-2005 are not yet included in the results. The author will submit the three lists of the publication channels on request.

RESULTS

Eight school of thought on generic business management

Business management (BM) concepts are herein seen as abstractions representing objects or phenomena such as managing a HVAC related business [11]. In BM literature, many distinguished authors have replied to the question "What is the primary way (element) of managing a firm's business that will enable managers to set challenging goals and also to attain them?" Based on the fairly comprehensive literature review [1], this author has regrouped the research traditions into **the eight schools of thought on generic BM** as follows: (i) Porterian, (ii) resource-based, (iii) competence-based, (iv) knowledge-based, (v) organization-based, (vi) process-based, (vii) dynamism-based, and (viii) evolutionary BM. It is the core ideas of the founding scholars that make each of eight schools of thought distinct. By the year 2007, it is assumed that the number of business managers **applying Porter's frameworks** is still exceeding the combined number of practitioners relying on the seven other schools in the OECD countries. However, not even the Porterian school can show the empirical evidence of sustained good performance [12].

Platform of 52 construction-related business-management concepts

Overall, **no applied research tradition in BM** exists as part of construction-related management research in the OECD countries. The authors of 52 concepts have added neither very high theoretical contributions, nor deep practical values onto the original generic BM concepts. A real 16-year platform may consist of 65-70 concepts. In this paper, the identified platform is promoted toward HVAC related business managers and interested scholars alike as follows. **The identified theoretical platform** consists of 52 construction-related BM concepts published within 48 references between the years 1990-2005. The authorship consists of 42 (individual, pairs or teams of) authors. There are 72 individual authors. **Within construction-related management research**, 30 (58 %) concepts are primarily related to construction management and economics, 9 (17 %) to project management, 8 (15 %) to real estate development, and 5 (10 %) to industrial management. **Among eight schools of thought on BM**, the combined share of 13 organization-based, 11 Porterian, 10 dynamism-based, and 10 knowledge-based concepts is 84 %. The temporal pattern is still emerging (Table 1).

Table 1. Relatedness of 52 construction-related business-management concepts, published between the years 1990-2005, to the eight schools of thought on business management.

School of thought	Concepts published btw. 1990-2002 (1st review)		Concepts published btw. 2003-2005 (2nd review)		All concepts	
	No.	(%)	No.	(%)	No.	(%)
Organization-based school	9	(24 %)	4	(29 %)	13	(25 %)
Porterian school	11	(29 %)	0	(0 %)	11	(21 %)
Dynamism-based school	7	(18 %)	3	(21 %)	10	(19 %)
Knowledge-based school	7	(18 %)	3	(21 %)	10	(19 %)
Process-based school	0	(0 %)	4	(29 %)	4	(8 %)
Competence-based school	3	(8 %)	0	(0 %)	3	(6 %)
Resource-based school	1	(3 %)	0	(0 %)	1	(2 %)
Evolutionary school	0	(0 %)	0	(0 %)	0	(0 %)
Sum	38	(100 %)	14	(100 %)	52	(100 %)

A range of 54 home-base contexts includes 19 (35 %) worldwide or global, 12 (22 %) UK, 10 (19 %) US, 4 (7 %) Finnish, 3 (6 %) generic, 3 (6 %) Swedish, 1 (2 %) Australian, 1 (2 %) German, and 1 (2 %) Swiss context. **Among business-scope groups**, 19 (37 %) concepts address construction or building, 15 (29 %) project or contracting business, complex product systems, or combined engineering, purchasing, and construction (EPC) projects, 8 (15 %) real estate development and FM services, and 5 (10 %) capital investments-based businesses, 4 (8 %) design and consulting services, and 1 (2 %) building products supply. So far, no applied concepts have been designed for managing a HVAC focused business.

13 concepts for managing a HVAC business in organization-based ways

Generic organization-based BM school proposes that managers can achieve high long-term business performance through organizational solutions in various business contexts such as those of globalization, multi-markets, and multi-stakeholders (e.g. Hedlund 1994 [13]).

13 (25 %) construction-related organization-based BM concepts are coupled with the HVAC contexts of application in Table 2. Originally, capability building is enabled by Davies and Brady, a project-based organization is matched with products by Hobday, PM-centred organizations are advocated by Sauer et al., PM offices are supported by Kendall, one-size-fits-all approach is opposed by Turner and Keegan, a business system is designed by Huovinen, and an organizational model is offered by Artto for project-oriented firms. A systems-change strategy is designed by Leinberger for real estate firms. Partnering pillars are designed by Bennett and partnering is customized by Cheng and Li. Virtual CM firms are designed by Kiiras and Huovinen. Successful contractors are envisioned by Flanagan. A collaborative model is made by Huovinen and Hawk for building products suppliers. The theoretical advancement of 13 concepts seems to be fairly modest. Instead, the practical relevance is fairly high. It seems that Hobday's [14] principles of project-based organizations (PBO) are truly applicable to managing complex HVAC value chains and integrating their high value HVAC systems. A pure PBO consists only of strategic management and HVAC projects. It is probably best applicable among innovative firms.

Table 2. Potential organization-based concepts for managing HVAC related business (n = 13).

Author	Year	Business management concept	Context of application
Davies and Brady	2000	Capability building and interaction	HVAC related firms
Hobday	2000	Project-based organization	HVAC related firms
Sauer et al.	2001	PM-centered organization	HVAC related firms
Kendall	2003	Support to PM office management	HVAC related firms
Huovinen	2004	Organization-based management	HVAC related firms
Leinberger	1993	Systems-change strategy	HVAC related firms
Bennett	2000	Seven pillars of partnering	HVAC related firms
Cheng and Li	2002	Customized model of partnering	HVAC related firms
Artto	1999	Organizational model for PM	HVAC contractors
Turner and Keegan	2000	Project-based organization	HVAC contractors
Kiiras and Huovinen	2004	Virtual CM company management	HVAC contractors
Flanagan	1994	Successful company (in year 2000)	HVAC contractors
Huovinen and Hawk	2003	Client-supplier relationship model	HVAC product suppliers

11 concepts for managing a HVAC business in Porterian ways

Generic Porterian BM school, i.e. a chain of Porter's frameworks, proposes that superior business performance can be achieved by managing a chain of causalities. Managers can ex ante formulate and then implement a longitudinal strategy for their dynamic businesses, (a) by enhancing their understanding of a firm's initial internal and external conditions as well as their ability to make true choices, (b) by formulating and implementing a set of cross-sectional strategies in innovative and integrative ways, and (c) by learning to identify chances (or ”luck”) and to evaluate their roles in inputs, processes, causal relations, and outcomes [15].

11 (21 %) construction-related Porterian BM concepts are coupled with the HVAC contexts of application in Table 3. Originally, planning concepts are recommended by Betts and Ofori. Product differentiation is addressed by Langford and Male. Low cost, differentiation, and speedy response is linked by Rapp. All Porterian modes are recommended by Kale and Arditi. A model for architectural practices is designed by Winch and Schneider. Strategies for A/E firms are applied by Veshosky. Strategies for quantity-surveying practices are redefined by Jennings and Betts. A customer-based project-success metrics is designed by Pinto et al. Five competitive arenas are chained by Huovinen. Value chains for real estate services are applied by Roulac. The applicability of these 11 concepts varies a lot. Typically, Pinto et al. [16] have adapted **Porter's value-chain model** to establishing a project supplier's success metrics. Besides time, budget and performance, a client-driven model enables to make better project decisions. Superior HVAC systems go hand-in-hand with superior services.

Table 3. Potential Porterian concepts for managing HVAC related business (n = 11).

Author	Year	Business management concept	Context of application
Betts and Ofori	1992	Applying Porter's frameworks	HVAC related firms
Langford and Male	2001	Applying Porter's 5F framework	HVAC related firms
Rapp	2001	Adapting Porter's 5F, value chain	HVAC related firms
Kale and Arditi	2002	Mode and scope of competition	HVAC related firms
Winch and Schneider	1993	Four generic strategies (matrix)	HVAC engineers
Veshosky	1994	Applying Porter's 4 strategies	HVAC engineers
Jennings and Betts	1996	Strategy model with IT support	HVAC engineers
Pinto et al.	2000	Value chain of a project supplier	HVAC contractors
Huovinen	2001	International competitive strategy	HVAC contractors
Roulac	1999	Real estate value chain	L-C services providers
Roulac	2001	Strategy for competitive advantage	L-C services providers

10 concepts for managing a HVAC business in dynamism-based ways

Generic dynamism-based BM school proposes that managers can manage successfully their businesses even in highly unstable, even chaotic markets (e.g. Hamel and Prahalad [17]). **10 (19 %) construction-related dynamism-based BM concepts** are coupled with the HVAC contexts of application in Table 4. Originally, dynamic construction BM is enhanced by Chinowsky (with Meredith), de Haan et al., Huovinen, and Langford and Male. Project BM is advanced by Meklin et al. Real estate focused concepts are offered by Barrett, Mitchell-Ketzes, and Osgood. Some concepts are more theoretically advanced while the others are more pragmatic. It seems that Lampel's [18] extension of the core competency theory [17] is highly applicable to managing HVAC related businesses. Core competencies support core HVAC project processes (instead of core products in the original concept).

Table 4. Potential dynamism-based concepts for managing HVAC related business (n = 10).

Author	Year	Business management concept	Context of application
Chinowsky	2000	7 areas of strategic management	HVAC related firms
Lampel	2001	Core competency-based model	HVAC related firms
De Haan et al.	2002	Market-strategy-capabilities fit	HVAC related firms
Huovinen	2005	Recursive global business system	HVAC related firms
Meklin et al.	1999	Project business management	HVAC contractors
Langford and Male	2001	Model of strategic management	HVAC contractors
Huovinen	2002	Global competitiveness of a firm	HVAC contractors
Barrett	2000	Linking a firm's business and FM	L-C services providers
Mitchell-Ketzes	2003	Linking workplaces to business	L-C services providers
Osgood	2004	Strategy alignment model and map	L-C services providers

10 concepts for managing a HVAC business in knowledge-based ways

Generic knowledge-based BM school proposes that managers can nurture their intellectual capital and manage learning processes for the creation of advantages and the transfer processes for the leveraging of them (e.g. Nonaka and Takeuchi [19]). **10 (19 %) construction-related knowledge-based BM concepts** are coupled with the HVAC contexts of application in Table 5. Originally, learning organizations are advocated by Hawk, Davies and Brady, and Love et al. Knowledge concepts are offered by Langford and Male, Robinson et al., Huovinen, Borner, and Walker. Alliances are enhanced by Love et al. Project-portfolio management is enabled by Anell. The theoretical advancement and the applicability vary.

Table 5. Potential knowledge-based concepts for managing HVAC related business (n = 10).

Author	Year	Business management concept	Context of application
Hawk	1992	Continual learning system	HVAC related firms
Davies and Brady	2000	Organizational learning cycle	HVAC related firms
Love et al.	2000	Learning organization model	HVAC related firms
Langford and Male	2001	4 ways of knowledge management	HVAC related firms
Robinson et al.	2002	Knowledge management model	HVAC related firms
Huovinen	2003	Knowledge-based management	HVAC related firms
Borner	2004	Project and success-oriented KM	HVAC contractors
Walker	2005	Knowledge competitive advantage	HVAC related firms
Love et al.	2002	Construction alliance model	HVAC related firms
Anell	2000	Project portfolio management	HVAC related firms

Four concepts for managing a HVAC business in process-based ways

Generic process-based BM school proposes that managers can manage their businesses as sequenced, deliberate and/or emergent processes over time in various contexts such as internationalization, organizational change, and renewal and, thus, achieve high long-term business performance (e.g Beer and Nohria [20]). **4 (8 %) construction-related process-based BM concepts** are coupled with the HVAC contexts of application in Table 6. Originally, project-based approaches are linked with businesses by Anderson and Merna as well as Morris and Jamieson. World-class FM services processes are designed by Kaya et al. and Rogers. The concepts diverge a lot in terms of theoretical advancement and applicability.

Table 6. Potential process-based concepts for managing HVAC related business (n = 4).

Author	Year	Business management concept	Context of application
Anderson and Merna	2005	Business development process	HVAC related firms
Morris and Jamieson	2005	Linked corporate/project strategies	HVAC related firms
Kaya et al.	2004	World-class FM framework	L-C services providers
Rogers	2004	High performance business unit	L-C services providers

Three concepts for managing a HVAC business in competence-based ways

Generic competence-based BM school proposes that managers can manage organizational competences in ways that enable to attain their business goals and sustain above-normal rents (Sanchez and Heene [21]). Only **3 (6 %) construction-related competence-based BM concepts** are coupled with the HVAC contexts of application in Table 7. Originally, competences are addressed by Huovinen and Langford and Male. Capability assessment is enabled by Trejo et al. The theoretical advancement and the applicability are diverging a lot.

Table 7. Potential competence-based concepts for managing HVAC related business (n = 3).

Author	Year	Business management concept	Context of application
Huovinen	1999	Recursive competence-based firm	HVAC related firms
Trejo et al.	2002	Capability assessment framework	HVAC related firms
Langford and Male	2001	International(ization) strategy	HVAC contractors

One concept for managing a HVAC business in resource-based ways

Generic resource-based BM school proposes that managers can achieve high long-term performance in fairly low-dynamism businesses. In Barney's [22] words, above-normal profits can be sustained based on managing a firm's recourses. **1 (2 %) construction-related resource-based BM concept** is coupled with the HVAC context of application in Table 8. Originally, four resource categories are differentiated by Lowendahl. The categories seem to be highly applicable to managing HVAC engineering and design businesses.

Table 8. Potential resource-based concept for managing HVAC related business (n = 1).

Author	Year	Business management concept	Context of application
Lowendahl	1997	Management of 4 resource types	HVAC engineers

No applied concepts for managing a HVAC business in evolutionary ways

Generic evolutionary BM school proposes that managers can act upon the internal and external forces that affect their destiny over time, i.e. to manage intraorganizational variation, selection, retention, and competition processes in ways that enable to achieve high business performance. Strategy shapes destiny and strategy is shaped by destiny (Burgelman [23]). No applied construction-related concepts exist readily for managing a HVAC related business.

DISCUSSION

It is posited that **this theoretical 52-concept platform enables** both business managers and management researchers to choose and advance their ways of managing a HVAC related business as part of building markets. It is envisioned that many dynamism-based concepts will be among the ones that will turn out to be **most profitable** by the year 2010. Thus, it is suggested that HVAC focused business managers (i) dynamize their BM concepts to exploit flexibility among members belonging to their HVAC value chains and (ii) add many new value-based ways of integrating such value chains, offerings, systems, and services.

Further, it is posited that **each of eight schools of thought on generic BM** deserves to be considered each time a HVAC related researcher will stand at the 8-school crossroad and make a choice about the future direction. For example, CLIMA 2007 related researchers could co-set the research goals jointly with involved HVAC focused business managers to craft the first concepts for managing integrated HVAC systems contracting, HVAC systems life-cycle services, HVAC technology-intensive engineering and design services as well as prefabricated HVAC products and materials supply businesses.

SUMMARY

This paper deals with the current results in the survey for collecting data for building commissioning. The first aim of the survey was to make an overview of the most typical buildings, HVAC equipments and their related problems. The second aim was to establish the criteria for both choosing the buildings in the further research and establishing the existing building commissioning tools. The survey is carried out by developing the questionnaire for the building caretakers. The current results could give some of the criteria for commissioning of the existing buildings. The paper gives the list of the buildings, equipments, and problems, for which the commissioning tools should be developed.

INTRODUCTION

Commissioning tools for existing buildings should be developed to be useable in the most common cases of buildings. Actually, commissioning tools should give the solution for the most typical problems in the most common buildings. Therefore it is important to make an overview of the most common buildings in Norwegian building facilities. A questionnaire is developed as the preliminary step in an overview of the building facilities. The idea of the questionnaire is to give as much as possible straightforward answers. In addition, the idea of the questionnaire is to check which and how much of the building data can be obtained for our further studies.

METODS

The questionnaire is developed as a tool for the survey, and consists of eight groups of the questions. Since the questions are defined to be as straightforward as possible, the answers should be either “yes”, “no”, or some numbers. Together with the questionnaire a short guide is attached, too. The questionnaire has to be filled out by the person who is in charge of the building administration, e.g. it could be the caretaker.

The first round of the survey was to send the questionnaire to the caretakers. After getting the answers, a second round was performed based on the unanswered questions. The second round was performed by sending the e-mails to the persons, which filled out the questionnaire.

The survey is still in progress, because it is necessary to have as good as possible overview of building facilities in Norway.

The content of the questionnaire

Building information
These questions have the aim to get general data about the buildings. The most important questions from this group are about: net total area, year of construction, year of the last renovation and if a renovation is planed in the next two years [1].

Building equipment
This group of the questions should show the most used equipment and type of HVAC system in the buildings. Most of the questions in this group should be answered by ticking off. The questionnaire gives the possibility to tick off the most common HVAC equipments, but there is also possibility for additional equipment. Besides the information about equipment, this group of questions asks for: the number of substations, the number of the particular type of HVAC system, and the age of the oldest HVAC equipment in the building. The guide for fill out the questionnaire gives the explanation of HVAC system based on the following definition: "An HVAC system is functional assembly of equipment for air treatment. The assembly of equipment is connected by a net-work that is determined by the system nature (for example radiators are connected by pipes, air-distribution units by ducts, etc.). An HVAC system is one in which energy is transformed from a source of energy through a distribution net-work to spaces to be conditioned [2]."

Indoor environment
These questions deal with the most common problems in the buildings. The most typical problems concerning the indoor environment are suggested in the questionnaire, but also there is a possibility for additional problems. The suggested problems are noted generally, as the following: too warm or cold, unstable temperature, draft and noise. There is no emphasis on when problems occur. These questions should be answered by ticking off, too.

Documentation
The questions treat the building documentation. All the terms in this group of questions were defined based on the Norwegian translation of the commissioning terms [3]. The aim of this part of the questionnaire is to show how much of building documentation are available. The questionnaire asks for the following documentation: design intention, ordinary operation step, as-built records, and (TAB) testing, adjusting and balancing documentation.

Energy use
These questions aim at energy use and the attitude of the building owners in practicing energy efficiency. A question from this group asks about using *Enova* energy efficiency tools. Enova SF is a governmental agency established to deal with the implementation of energy efficiency and renewable energy policy in Norway. This is a pro-active agency that has the capacity to stimulate energy efficiency by motivating cost-effective and environmentally sound investment decisions. Enova SF advises the Ministry in questions relating to energy efficiency and new renewable energy [4]. The questions about energy efficiency attitude among building owners are important for an overview if the buildings need some additional tools for energy efficiency. There are four questions in this group, and they ask about the following: energy bills during the last two years, practicing the energy efficiency measures in the building, practicing some of the authority measures in the energy efficiency, and using the Enova tools.

Measuring
Since access to a building is necessary to measure, these questions ask about it.

Maintenance
These group of the questions aims at maintenance in the buildings. The aim of this part is to connect the problems and maintenance service. There are questions either the building owners have in company an employed maintenance service or a hired company for maintenance service. There is a question if the caretakers attend training for HVAC equipments. In addition, there is a question about the responsibility of a hired company for the maintenance.

Commissioning
The last question is if they would use some of commissioning tools. A short explanation about commissioning is given additionally to this question. Commissioning is a systematic process of ensuring that all building facility systems perform interactively in accordance with the design documentation and intent. It implies accepting the different methods, guidance and procedures. Process eliminating the need for costly capital improvements, and can give short payback time [5].

RESULTS

The following building owners took part in the survey: Forsvarsbygg (the Norwegian Defense Estates Agency), Telenor (Governmental telecommunication company), and NTNU (Norwegian University of Science and Technology) campus. The questionnaire was completely answered by *32* building caretakers from *15* towns in two months through two rounds. Some of the caretakers sent photos, which are given in Table 1.

Table 1. Photos of some of the buildings participating in the survey.

NTNU-Main building (96 years old)

NTNU-Realfabygget(137 HVAC system)

NTNU-Materialteknisk

Military office building - Rena

Telenor Kolstad - Bergen

Military office building - Bodø

Based on the answers, some of the starting criteria for future research can be established. The age of buildings that participated in the survey is from *1* to *96* years. The answer to this question should be straightforward, but in some cases there are few years of construction. The reason for this is because the buildings have been extended through the entire life time, and there is no any regularity how it happens. The question about the year of the last renovation was not answered in *21* cases. The reason is that the caretakers do not know the exact date.

Using the available data about year of the last renovation, the rate of renovation during the building life time can be explained. The relation is shown in Figure 1.

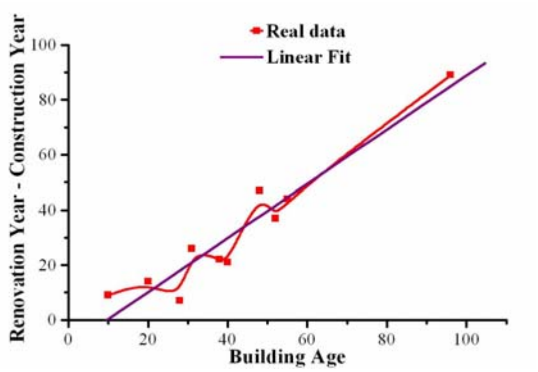

Figure 1. The rate of building renovation during the life time

Figure 1 shows that the buildings had the first renovation approximately *10 years* after the construction. The equation of the fitted line in Figure 1 is:

$$Last\ renovation\ Year - Construction\ Year = -9.52 + 0.98\ Building\ \ Age\,. \qquad (1)$$

The multiplier of the building age is *0.98*. This implies that the building owners invest in the buildings throughout the entire life time. Therefore the building commissioning would be necessary on a continuous basis.

The age of HVAC system is important information for the building commissioning. According to the answers, the relation between the age of building and the age of the HVAC system can be established as in Figure 2.

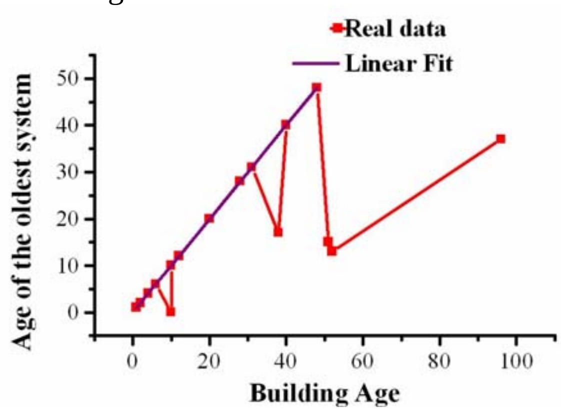

Figure 2. Building Age vs. Age of the oldest system

For *41%* of all buildings there is a linear relation between the age of building and the age of the oldest system. Figure 2 shows that the buildings, which age is less than *50 years*, have at least one of the HVAC equipment of the same age as the building age. The complete data about the year of the construction, year of the last renovation and the age of the oldest system were obtained for *18* buildings. Using this data, the relation between the system age and year of renovation can be established as in Figure 3.

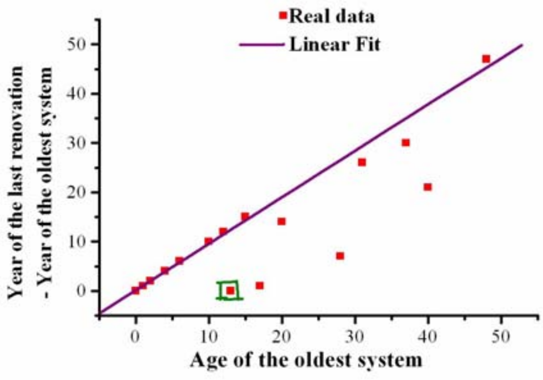

Figure 3. System age vs. Renovation

Figure 3 shows that for 11 buildings there exists a relation between the difference of the year of the last renovation and the year of the oldest system, and the age of the oldest system. Figure 3 shows that the HVAC systems are not replaced after each renovation. This shows that the HVAC systems might be renovated, but not changed completely, because some of the components are still kept. Only in the case of one building, with the green square, (Kaserne Setermoen) the HVAC equipment has been changed completely when the renovation was undertaken. Since most of the buildings are renovated partly, the estimation of the retrofit benefit would be necessary. Therefore the commissioning protocol of a suggested improved measure is necessary.

The answers about the HVAC systems are important for defining the conditions for which the commissioning tools will be developed. *84 %* of all the buildings have a central heating source. 59% of the buildings have both the central heating system and the district heating. Since there is BAS (Building Automation System) in *91 %* of the participated buildings in the survey, the further study will treat buildings with BAS. The obtained results can be used to establish the relation between the number of controllers and the number of HVAC systems as it is shown in Figure 4.

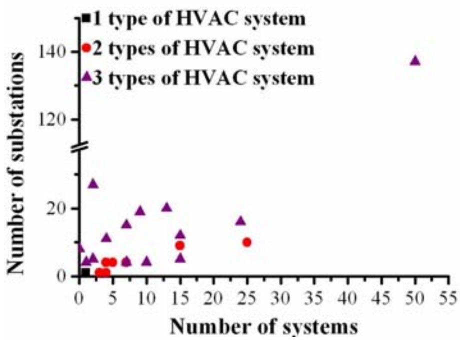

Figure 4. Number of substations vs. Number of systems

Still it is not possible to give the strict criteria for the number of the systems and the number of the substations, but there is a trend that several different types of HVAC systems imply higher number of the substations. The buildings with all three types of HVAC systems (ventilation, heating and cooling) have a higher number of substations than the other, as Figure 4 shows. BAS gives a possibility for the indirect measurements. Therefore a possibility of use the BAS data is valuable for the commissioning procedures.

The question about number of systems was not answered in *22 %*. Some of the answers were obtained through the second round. However, some of the participants in this survey have in the building data base the exact data about the number of the systems (a good example is NTNU Gløshaugen campus). The operation management at NTNU campus uses the data base program LYDIA [6]. Also, they have their own data base in Excel format, which has been developed over seven years.

The results concerning the number of HVAC systems and net total area are shown in Figure 5 and 6.

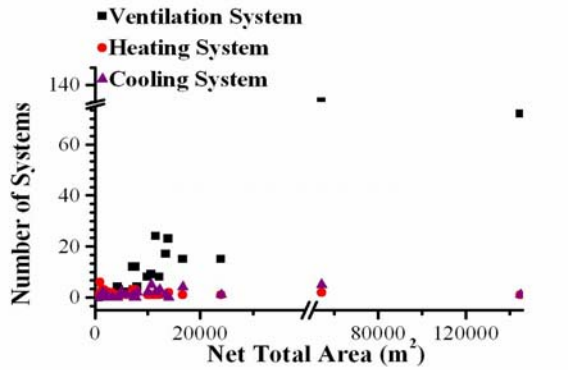

Figure 5. Number of Systems vs. Net Total

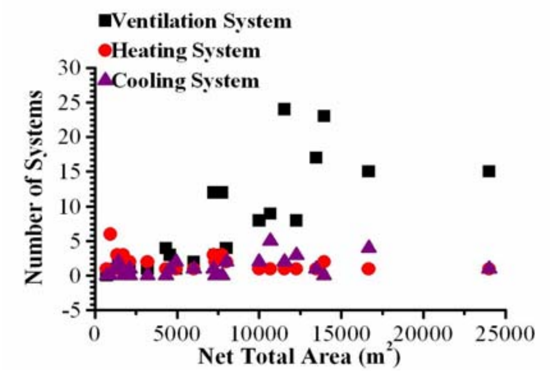

Figure 6. The Subplot of Figure 5

Figure 5 shows a certain relation between the number of the particular type of the system and net total area, but still it is not possible to establish any criteria. In addition, it is obvious that a larger net total area of the building implies a higher number of the ventilation systems. Figure 6 is subplot of Figure 5, so it gives an enlarged view of the narrow area in Figure 5. In Figure 6 is easier to note that the number of the heating and the cooling systems are mostly the same regardless of net total area. Information about building area and the position of HVAC system are important for developing the building models. In addition, the knowledge of the BAS measurements gives a possibility for better understanding of a building performance. Therefore the relation among both the building net total area, number of systems and the number of the substations if beneficial for establishing the commissioning protocols for the building estimation.

The fourth group of the questions should show which building documentation can be obtained. Most of the caretakers have never heard of the term "design intention". This is the reason why only in *19 %* of the answers were "yes". As-built records and TAB documentation can be obtained from *78 %* of the buildings participated. The ordinary operation step documentation exists in *91 %* of buildings. The above information about documentation implies the commissioning criteria that the future studied buildings should have as-built records and TAB documentation and ordinary operation step available.
Energy bills for the last two years are available in *81 %* of the buildings. In most of the buildings, the owners practice some measure for energy efficiency, either on their own way or following the authority measures aimed to the energy efficiency. Enova tools are used in *41 %* of the buildings. These results show that the owners of the buildings practice the energy efficiency measurement in some way, but they also need several tools for that purpose.

Each building in the survey has their own maintenance service employed in the company and all of them attend some courses about the equipment in the building. *69 %* of buildings hire outside company for maintenance. The hired companies have the responsibilities for all HVAC equipments only in *19 %* of the cases, because they are hired only for the particular equipments. This implies the conclusion that for some issues in the building only the employed staffs are in charge. Since there are a few levels of the maintenance services, a discrepancy between their strategies can appear. Consequently, some faults or issues can appear in a building, and therefore a commissioning protocol for the maintenance service can be useful.

For developing and application of the commissioning tools in their buildings, all the participants except one are interested. This is also proven by the fact that in all the buildings we can do research and measuring.

DISCUSSION

For the future study and for developing the commissioning tools, it is necessary that the specific type of equipment exist in at least *50 %* of the buildings. The overview of the most used equipment is given in Table 1.

Table 1. Summarization of the most typical building, HVAC equipment and problems

Type of building	**Num.of Buildings**	**Type of HVAC**	**Equipment**	**Problem**
Office building	13	Ventilation	Water heating coil	Draft
			Cooling coil	
		Heating	Radiator	
		Cooling	Air cooling	Too warm
				Too cold
				Unstable temperature
Hospital	1	Ventilation	Water heating coil	Noise
			Cooling coil	
		Heating	Radiator	
			Floor Heating	
		Cooling	Air cooling	
Barrack	3	Ventilation	Water heating coil	
		Heating	Radiator	Too cold
			Floor Heating	
Multipurpose	12	Ventilation	Water heating coil	Draft
				Noise
			Cooling coil	Bad air
				High air temperature
		Heating	Radiator	Too warm
				Too cold
				Unstable temperature
		Cooling	Air cooling	Too warm
				Unstable temperature
Mess hall	1	Ventilation	Water heating coil	
		Heating	Radiator	
Repair shop	1	Ventilation	Water heating coil	
		Heating	Radiator	
			Floor heating	
			Ceiling Heating	
		Cooling	Air cooling	
Training center	1	Ventilation	Water heating coil	
		Heating	Radiator	

The future study in developing the existing building commissioning tools will deal with the occurred problems for the particular type of building and the appropriate HVAC equipments. Based on the answers, for the most used equipments in the particular type of buildings, the occurred problems are found. For each of these problems in the particular type of building and for the particular type of HVAC equipment, commissioning tools should be developed. The summarization of the most typical problem and equipment in the particular type of building is given in Table 1. The questionnaire is still in progress, and list below will be extended.

CONCLUSION

The survey is a useful tool to start research for the building commissioning. The presented results give a few criteria for the commissioning of the existing buildings. In the future study, the building documentation will be required. The age of both building and equipment will not be strict criteria, but persistence in building renovation would be a required criteria. Therefore, the commissioning protocols should estimate the retrofits benefits. Since BAS give a possibility for the indirect measurements, the future studies will consider buildings, which have HVAC systems with BAS. Even though the relation among both the number of the systems, net total area and the number substations is not established, the further work should find such a relation, since it is important to utilize BAS data for a good understanding of the building performance. The actual summarization the most typical building, HVAC equipment and problems should be spread in the future.

ACKNOWLAGEMENT

The authors are thankful to Gunnar Solbjørg, senior engineer in Forsvarsbygg, Geir Skaaren, project leader in NTNU campus, Nils Bakke, operating manager in Telenor, and Svein Berget from Telenor, for help in our survey.
