In weekdays, students spent 8.68% of their time outdoors while 91.32% of a day indoors including 42.66% in dorms, 48.66% in the classrooms and reading rooms. In weekends, the time students stayed indoor (88.8%) was less than it spent in weekdays, but significantly longer than the time spent outdoor (11.23%). Longer time was also spent in dorms (72.8%). When studying by themselves in scheduled time, 74.4% students selected classrooms, 14.7% students in library (mainly in the reading room), and 7.8% students in dorms. Obviously, undergraduate students surveyed spent over 90% of their time indoors.

Indoor CO_2 concentration, temperature, and relative humidity

Table 1 presents descriptive statistics for indoor carbon dioxide concentration levels, temperature, and relative humidity in different indoor environments.

Table 1 Indoor and outdoor CO_2 concentration, temperature and relative humidity

	CO_2 concentration (ppm)		Temperature (°C)		Relative humidity	
	Average	Range	Average	Range	Average	Range
Dorms	1278±702	612-2466	26.8±5.4	20.1-38.3	68.1±17.8%	37.5-90.0%
Classroom	2580±1854	812-5346	24.0±3.1	20.1-30.4	65.1±15.5%	38.6-76.5%
Reading rooms	767±164	629-994	22.1±3.9	18.9-28.2	60.2±19.4%	30.0-90.0%
Meeting rooms	2394±1106	762-3946	23.5±2.7	19.2-29.4	60.4±14.3%	38.5-75.6%
Outdoor	501±21	478-534	25.2±5.7	18.0-39.0	60.0±21.0%	35.0-90.0%

In this study, almost half of the CO_2 concentrations were above 1000 ppm. In classroom and meeting rooms, over 80% were above 2000 ppm. If the measured CO_2 concentrations had been maximum or steady-state values, a substantially larger proportion would be expected to exceed 1000 ppm. Thus, it is likely more than half of the classrooms in this study had ventilation rates less than specified in current minimum ventilation standards.

Air exchange rates

Based on the measured CO_2 data, we computed the air exchange rates using a decay model. Dormitories and reading rooms monitored were ceiling fans ventilated with opened windows/doors. Meeting rooms were without any ventilation appliance but air-conditioning. Because the CO_2 measurements in this study were short-term (at most 2 days), and AER calculation was made on weekdays at variable times of occupied period, they should be considered only rough surrogates for the long-term average indoor ventilation rates, and may be much lower in some spaces.

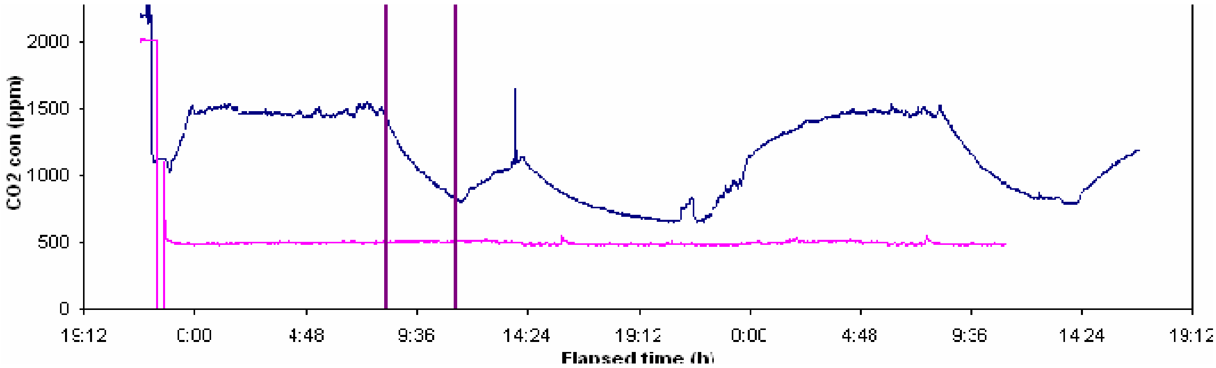

Figure 1a CO_2 concentration monitored in a room where two students lived in.

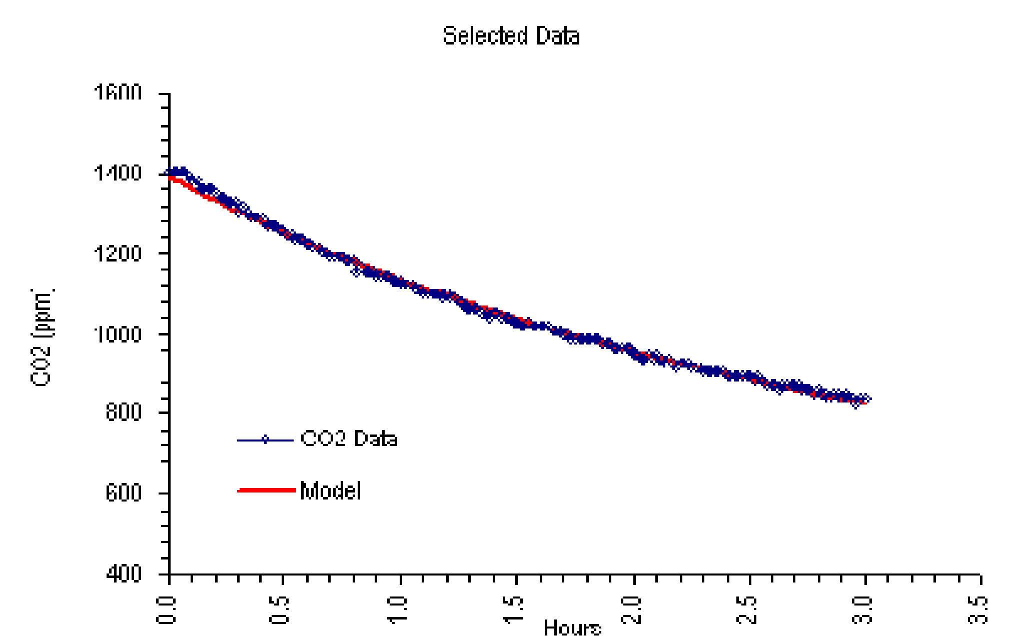

Figure 1b Air exchange rate calculation for selected duration. 1.2, 2.9, 1.6, 1.1 and 0.7 hr^{-1} in dormitories, reading rooms, old classrooms, new classrooms and conference rooms

Table 2 Air exchange rates in different indoor environments on campus

	Air exchange rates (h^{-1})		
	n	Average	Range
Dorms	20	1.22±0.67	0.30 - 2.84
Classroom I	10	1.37±0.68	0.68 - 2.30
Classroom II	10	1.10±0.55	0.15 - 2.16
Reading rooms	5	1.91±0.87	1.10 - 3.11
Meeting rooms	5	0.73±0.48	0.15 - 1.35

Classroom I: air-conditioned classrooms in an old building
Classroom II: classrooms with an air circulation cooling system in a new building

In dormitories, factors such as outdoor climate conditions, deficiency of building design, room usage and living habits of students, were considered to be essential on ventilation and indoor CO_2 concentration. Under same indoor conditions (windows and doors were fully or partially opened, no occupants), the higher the floors were (less than 6 floors), the lower the ventilation achieved in the dorms ($P<0.01$). It illustrated the negative relationship between increase of floor height and outdoor climate conditions, mainly because the climate conditions were uneven and variational vertically.

In classrooms I, ventilations were always low for windows and doors were closed, especially for air-conditionings began to work from the end of June. While weather was cool and ceiling fans were turned on, ventilation conditions became much better. Although there wasn't significant difference between two types of classroom with different ventilation devices, the air circulation cooling system newly employed was not of great help for improving ventilation in classrooms. Available data always indicated many classrooms with ventilation rates below the code minimum or with CO_2 concentrations above 1000 ppm [9, 10].

All the meeting rooms investigated were located in new buildings. Due to the deficiency in design, most meeting rooms had few windows and ventilators for ventilation. Together with occupants' activities, such as keeping the doors closed, indoor CO_2 accumulated quickly under bad ventilation contions.

Judgments of indoor environment quality and performance

Analysis results indicated that the best ventilation was achieved in reading rooms (AERs>1.0 hr^{-1} and [CO_2]<1000ppm), and the worst situation (AERs<1.0hr^{-1} and [CO_2]>1600ppm) was found in dormitories, classrooms and meeting rooms, which was accordant with occupants' more complaint.

Although the indoor RH and temperature were comfortable (40~70%, 22~28°C), students in classrooms easily felt absent of mind, out of breath, smelly, even fidget and headache, especially for the female students. CO_2 concentration is regarded as one key factor. In former researches, higher CO_2 concentrations have been associated with increased frequency of health symptoms and increased absence in studies of office workers [11, 12]. This phenomenon was not obvious in dormitory. A significant impact of temperature and humidity on the perception of air quality was also found. The air was perceived as less acceptable with increasing temperature and humidity, in particular in dormitories.

For all the indoor environments, ventilation conditions had negative relationship with unpleasant smell ($P<0.05$). Female students' judgment on indoor environment quality showed positive relationship with air exchange rates ($P<0.01$) while those of male students didn't. Female students were also more sensitive to bad ventilation conditions and showed aggravating symptoms.

CONCLUSIONS

This study disclosed that high CO_2 concentrations in indoor environments on campus, which indicated that classroom ventilation rates were often below the minimum rates specified in codes. CO_2 concentration is regarded as one key factor for students' judgments on IEQ. In case of a constant pollution level indoors, the perceived indoor environment quality decreases with increasing indoor temperature and humidity. Temperature and humidity also have a strong and significant impact on the perception of indoor environment quality in dormitories.

SUMMARY

Measuring AERs in an effective, real-time, easy and low-cost way is still a challenge, especially in China where rooms were usually naturally ventilated but not with the Heating, Ventilating and Air Conditioning (HVAC) system. A new AER monitoring method using continuous CO_2 sensor was validated through both laboratory experiments and field studies. Controlled laboratory simulation tests were conducted in a 1 m^3 environmental chamber at different AERs (0.1~10.0 hr^{-1}). AERs were determined using steady-state method and decay method based on box model assumptions. Field tests were conducted in apartments, offices, classrooms, dormitories and meeting rooms in during 3-5 weekdays with four sets of sensors coupled with data loggers. Statistic results indicated that good laboratory performance was achieved. In spite of limitations, this new method, along with mini-sized and easily operational instrumentations which provide sufficient continuous data, demonstrated an effective way to measure AERs in various indoor environments.

INTRODUCTION

Ventilation (Air exchange rates, AERs) is a critical ventilation parameter that affects thermal comfort and air contaminant exposure in civil buildings and other indoor environments. The concentrations of indoor pollutants mainly depend on the ventilation rates, source strength, and the emission rates. For many indoor-generated air pollutants, ventilation with outside air is usually the dominant removal process.

Many methods have been established to measure air exchange rates. Some studies reported AERs using perfluorocarbon tracer (PFT) compounds [1-4]. The most commonly used method is sulfur hexafluoride (SF6) decay tests which has been reported in many studies [5, 6] when commercial availability of instruments for SF6 tests has also made possible AER measurements. However, the instrumentation for these methods are usually big sized and expensive.

Although the Chinese national Indoor Air Quality Standard (GB18883 - 2002) regulates that the new air quantity for occupants is 30 m^3 per hour per person, the requirement of new air is not strictly meet based on experiences. The ventilation rate or the air exchange rate was not measured at all when indoor air quality was investigated because of limits of measurement equipment available and convenient for tracer gas such as CO_2, CO, CH4, SF6 and so on. Because the cost of conventional PFT technique in China is high (at least $1,500 only for a bottle of SF6 gas), and its analysis equipment, the GC-ECD is not so popular in China, a convenient, accurate, and low-cost measurement method for ventilation or AERs needs to be set up and employed.

Carbon dioxide (CO_2), although a ubiquitous compound in air, is one of the bioeffluents. Occupants are usually the main indoor source of CO_2, resulting in an increase of indoor CO_2 concentrations compared with outdoor levels. In this study, CO_2 was employed as a tracer gas for determining AERs under certain circumstances satisfied for a box model (described in details in the method part). Commercially available CO_2 sensor have the ability to measure real-time CO_2 concentrations, and therefore semi real-time AERs can be determined using both steady-state and decay methods. The instruments are usually small sized, quiet, easy to use and relatively cheap.

The objective of this study is to validate a method for measuring AERs using continuous CO_2 sensor in both controlled environmental chamber and real settings.

METHOD

Box model for determining AERs

A compartment can be simplified as a box with a specified volume V (m³) and a box model can be established assuming that the inside air is fully mixed (Figure 1). The carbon dioxide in a compartment results from outdoor concentration and exhaled carbon dioxide.

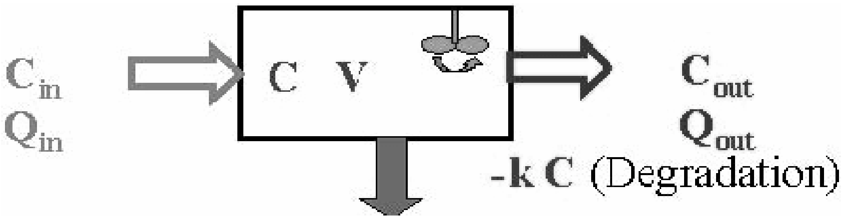

Figure 1. Schematic diagram of a fully mixed box model

The rate of change in concentration of the monitored gas depends on the concentration of the in-flowing air, the concentration of the out-flowing air and the internal generation rate of the gas in question. The time derivative of the monitored concentration is given by:

For a contaminant of interest, the governing equation for this model is:

$$V\, dC/dt = Q_{in}C_{in} - Q_{out}C_{out} + S - kC \qquad (1)$$

i.e. dC/dt = inflows -outflows + sources - degradation where C_{in}, C and C_{out} are concentrations of the contaminant in the inflow, indoor air and outflow (mg/m³), $Q_{in} = Q_{out} = Q$ are air flows into/out of the building (m³/h), S is the indoor emission source of the contaminant (mg/h) and k is the first-order degradation constant (m³/h). Solving (1) by integration yields the final equation, which describes the generation and decay of CO_2 as a function of time:

$$C(t) = W/(ß\, V)[1 - \exp(-ß\, t)] + C0\exp(-ß\, t) \qquad (2)$$

Where:
C_o = concentration at t = 0, $W = Q_{in}C_{in} + S$ and ß = AER + k.
C(t) = internal concentration of carbon dioxide at time t (ppm)
For a conservative contaminant, i.e. k = 0, AER can be determined in two ways:

(1) Steady-state method
When t -> infinity:

$$AER = W/(CV) \qquad (3)$$

(2) Decay method
When there is no source, i.e. S = 0, AER can be resolved from the equation:

$$C = QCin/(ß\ V)[1\text{-}exp\ (\text{-}ß\ t)] + C0exp\ (\text{-}ß\ t) \qquad (4)$$

Environmental chamber simulation

The laboratory simulation is evaluated in a simplified model chamber using a tracer gas technique of CO_2 gas injected into a supply duct. Ventilation systems, which consist of a air supply pump, a CO_2 gas generator, a CO_2 gas analyzer and a small stainless steel environmental simulating chamber (1m×1m×1m, 1.5 mm thick), are set up to evaluate the performance of this box model for determining AER using CO_2 concentrations at steady-state and decay processes. A fan is installed inside the chamber to provide the fully mixing condition. The CO_2 level in the environmental chamber was measured at a height of 3 ft above the floor level using a Vaisala GMW20 series CO_2 sensor (Vaisala Oyj, Helsinki, Finland). This sensor has an accuracy better than ±1% full scale ±1.5% of the reading with a repeatability better than ±1% of full scale and temperature dependence of , 0.1% full scale/°C. An air pump (Yinhu Company, China) is installed inside the chamber and emits CO_2 at a constant rate. One-channel data loggers equipped with temperature and relative humidity sensors Hobo sensors (Hobo H08004-02, Onset Computer Corporation, USA) are used in conjunction with the CO_2 sensor to capture the CO_2 concentration every 10 seconds. Three are placed inside and one outside of the chamber to record ambient temperature and relative humidity simultaneously. Data from the data acquisition system were periodically downloaded via a cable to a PC for processing.

An air pump ((Xinma Electronic Enterprise Co., Ltd., China)) is installed at the downstream of the chamber to control the AER. Dupliate simulations are performed at 10 AERs, i.e. 0.1, 0.6, 1.0, 2.0, 3.2, 4.0, 5.2, 6.0, 7.2 and 10.0 hr^{-1}, respectively. In each test, the chamber temperature and relative humidity are equilibrated with the room temperature at 20 0C and 50%, respectively. The CO_2 pump is running for few minutes. Then the CO_2 pump is shut down but the AER is kept unchanged for about 10 hr.

Calibration of the carbon dioxide sensors was weekly accomplished using zero gas (N2, purity=99.999%) and a series of carbon dioxide standard gas (297, 632, 914, 1212, and 1501 ppm CO_2). Instruments were also cross-compared during short-term (about 15 min) outdoor air CO_2 measurements at each outdoor location distant from potential CO_2 sources. Calibration of the temperature and humidity sensors had been performed by the manufacturer immediately prior to this research.

Field study

The field study will be conducted in 2 residential apartments, 1 office building, and 1 school. In each apartment, CO_2 sensors are placed in each room for 3-5 weekdays. In the office building and school building, CO_2 sensors are placed in selected offices or classrooms. There sets of equipment were placed in different indoor environments for at least 12 hours, approximately 1.5 m high from the floor and away from windows, doors and fans, and at least 1 m from occupants. One set of equipment was also placed out of the windows about 1.5 m high from the indoor floor. A questionnaire and walkthrough survey is completed for each location examining basic building characteristics, occupancy and other information potentially related to AERs.

A daily journal was kept to record activities that might affect the air change rate, for example, when windows were open or closed, and how much the actual width/area of each opening was. The normal practice of the occupants for indoor ventilation was to open windows/doors and fans.

DISCUSSION

Advantages and applications

CO_2 can act as an indicator of ventilation efficiency, showing whether the supply of outside air is sufficient to dilute air contaminants. As examples, to maintain odor-free environments acceptable contaminant levels, China ventilation standards specify a CO_2 ceiling of 800 ppm higher than outdoor levels. Besides bioeffluents, CO_2 has been used or suggested as a surrogate for carbon monoxide (CO) and other combustion products, and radon.

In former researches, it was always found that obtaining the required mixing of CO_2 and air is often difficult. Multipoint injection of tracer gas into the airstream is frequently necessary and multipoint measurements from different locations within the airstream are essential to confirm mixing7. In our study, because of high occupancy, indoor activities/movement of occupants, as well as the full application of ceiling fans, adequate full-mixing was obtained. The AER in each was constant during the sampling period in the light of small variation (COVs < 20%). CO_2 levels were similar within the same building (COVs < 20%), indicating good mixing conditions.

Statistic results indicated that good laboratory performance was achieved: duplicate precision was within 10%, differences between the two methods were within 10%, and the measured AERs were 90 -120% of the real AERs. Fully mixing conditions were observed in most indoor environments with fan operation.

The AERs measured in selected indoor environments were comparable to those reported in literature. Average AERs were 1.4, 1.7, 1.1, 1.0 and 0.6 hr^{-1} in apartments, offices, classrooms, dormitories and meeting rooms, respectively. Two day-long experiments, although air exchange rates higher than 2 h^{-1} were achieved for a brief time, the average over 12 h was never more than $1h^{-1}$

Figure 3 shows that the CO_2 level returned to about 800 ppm in about 3 hours from the time the occupants left the house while the initial indoor level was 1, 400 ppm. This defines the complete air change cycle of the apartment. Thus, a building that takes a longer time for the CO_2 to decay is tighter than that which takes a shorter time.

Limitations

Although CO_2 emission rates have been very well characterized and average 18 L/hr-person or 35.3 g/hr-person for people engaged in typical office work, the main problem with the method is that it can not be well employed when the spaces were occupied or it requires accurate information about the rate of CO_2 production within the space. This is not a problem during the unoccupied period, when the production rate will be zero.

SUMMARY

In this study, energy consumptions associated with the change in outdoor air flow rate are analyzed based on numerical methods. By employing the concept of ventilation effectiveness, possible reductions in the outdoor air load through reductions in the amount of outdoor air flow rate has been estimated. In addition, the effects of optimizing the capacity of HVAC equipment on annual energy consumption and annual CO_2 emissions have been analyzed.

INTRODUCTION

Against the background of a growing concern about global environmental problems, reductions in building energy consumption are required. Reducing heat load, which account for a majority of energy consumption in the operation of a building, is particularly important. One of the measures designed to conserve energy in buildings and facilities is the lowering of outdoor air flow rate (Here after O.A.) to reduce energy consumption.

In this study, energy consumptions associated with the change in O.A. are analyzed based on numerical methods. By employing the concept of ventilation effectiveness, possible reductions in the outdoor air load through reductions in the amount of O.A. has been estimated. In addition, the effects of optimizing the capacity of HVAC equipment on annual energy consumption and annual CO_2 emissions have been analyzed.

VENTILATION EFFECTIVENESS

As shown in Fig. 1, this analysis defines the space up to 1.8 m from the floor as the occupied zone. In this study, the normalized concentration in an occupied zone (C_n) is adopted as the index for ventilation effectiveness.[1],[2] The C_n is an index that represents the extent of incomplete mixing within the room and is defined as the ratio of the average concentration in an occupied zone (C_a) to the perfect mixing concentration (C_p) under conditions in which pollutants are uniformly generated in a room, as shown in equation (1) in Fig.2, where C_o denotes the pollutant concentration in outdoor air.

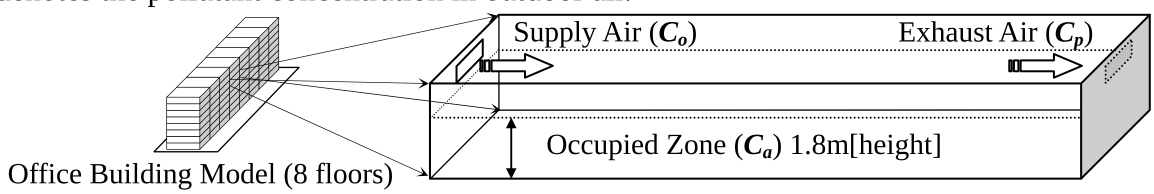

Figure 1 Definition of Occupied Zone in a Room

The equation to estimate the amount of O.A. flow rate using the C_n index is shown as equation (2) in Fig.2.

(1) Investigation of Ventilation Effectiveness into HVAC design
The index for evaluating the ventilation effectiveness

$$C_n = \frac{C_a - C_o}{C_p - C_o} \qquad (1)$$

C_n : Normalized Concentration in an Occupied zone
C_a : Average pollutant concentration in the occupied zone
C_o : Outdoor Air concentration
C_p : Completely-mixed concentration

$$Q = Q_p \times C_n \qquad (2)$$

Q_p : O.A. which defines the perfect mixing concentration
Q : Final O.A.

Q_p = 30 m^3/h/person × 16 persons in the room = 480 m^3/h (in case of this study)
C_n = 0.9 ($C_a < C_p$) Q = 432m^3/h (in case of decreased O.A. by good Ventilation Effectiveness)
C_n = 1.0 ($C_a = C_p$) Q = 480m^3/h
C_n = 1.1 ($C_a > C_p$) Q = 528m^3/h (in case of increased O.A. by bad Ventilation Effectiveness)
Q = Optimization of Outdoor Air Flow Rate by C_n index

(2) Set up Conditions for office Building Model (See Fig. 1)

(3) Set up conditions for outdoor climate
3-1 Sapporo (Cold Climate Area : Temp. - 9.4 - + 29.0˚C , R.H. 66 – 70 %)
3-2 Tokyo (Standard Area : Temp. + 0.6 - + 32.6˚C , R.H. 36 – 64 %)
3-3 Fukuoka (Warm Climate Area : Temp. + 1.5 - + 33.3˚C , R.H. 56 – 63 %)

(4) Optimization of HVAC System in Target Building

(5) Analysis of Energy Consumption, CO_2 Emission

Figure 2 Flowchart of analysis of energy consumption

Here, Q_p is the amount of O.A. when perfectly mixed conditions are assumed. The amount of O.A. when ventilation effectiveness is taken into consideration in the equation represents the amount of O.A. needed to maintain the average concentration in an occupied zone (C_a) below the reference concentration. The value of C_n varies with the placement of outlets and inlets in a room, conditions of supplied air flow, and other factors. The European Standards put C_n value within the range from 0.7 to 5.0 [1], and the authors' previous studies based on CFD an alysis report that the value comes within the range from 0.9 to 1.2 [2].
This paper sets the value of C_n at 0.9, 1.0, and 1.1, and looks into the effects of changes in the outdoor air load on the optimization of the capacity of air-conditioning heat-source equipment as well as on annual energy consumption.

ANALYSIS OF ANNUAL ENERGY CONSUMPTION

Fig. 2 shows the flowchart of annual energy consumption analysis. In general, the outdoor air load accounts for a substantial portion (30% to 40%) of the loads associated with HVAC equipment in office buildings. Accordingly, optimizing the amount of O.A. is an effective energy-saving measure. In the present analysis, an office space with personnel density of 0.2 people / m^2 as shown in Fig.1 is assumed and the amount of outdoor air required per person is set at 30 m^3 /h /person. As a result, the amount of O.A. in the standard office space when perfectly mixed conditions are assumed works out to 480 m^3/h (with 16 persons present in a room).

Table 1 Conditions for the air-conditioning system

Supplied Air Condition (Difference Of temp.)	Target Temp. [˚C]	Heat Load [W/m^2]	Air Change Rate [times / h]	Supply Air Temp. [˚C]	Supply Air Flow Rate [m^3/h]
Cooling (–10˚C)	26	+114	3.65	16	2786
Heating (+10˚C)	22	–108	3.65	32	2639

Table 1 shows conditions of supply inlet. The supplied air flow rate is determined by the heat balance based on the target air temperature and is set at 2,786 m^3/h during cooling and 2,639 m^3/h during heating (with air change rate of 3.65 times/h). When ventilation effectiveness is applied, the amount of O.A. is increased or decreased according to equation (2) and if C_n = 0.9, the amount of O.A. comes to 432 m^3/h and if C_n = 1.1, it works out to 528 m^3/h. With respect to climate conditions, Sapporo area representing cold regions and Fukuoka area representing warm regions were covered in addition to Tokyo area. Fig. 3 shows data on the daily average temperature and humidity on a monthly basis in the areas covered in the analysis. Table 2 shows the cases analyzed. A total of 18 cases are established as different combinations of the climate conditions, types of HVAC equipment, and C_n values.

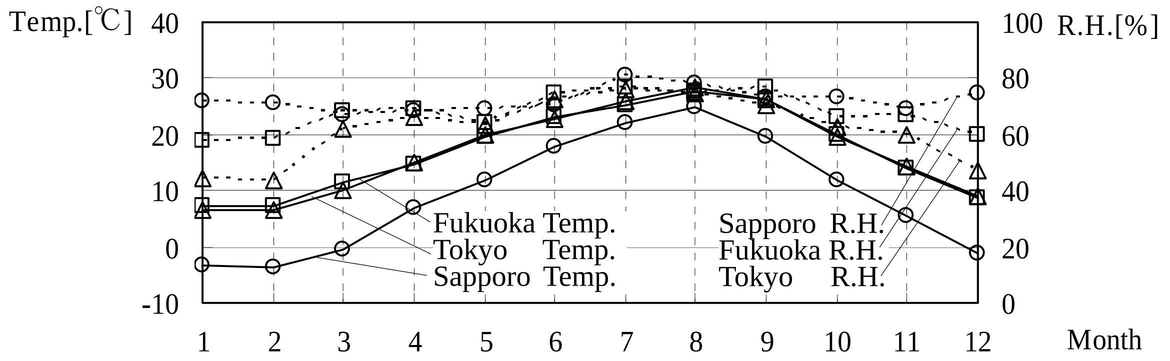

Figure 3 Weather Data of analysis target area

Table 2 Analysis Cases (H.E.=HVAC equipment)

Climate Area	HVAC equipment	C_n
Sapporo (Cold area)	Direct fired double effect absorption water chiller boiler (= H.E.(A))	0.9 [432 m^3/h] 1.0 [480 m^3/h] 1.1 [528 m^3/h]
Tokyo(standard area)		
Fukuoka(Warm area)		
Sapporo (Cold area)	Engine driven heat pump(=H.E.(B))	
Tokyo(standard area)	Air cooled packaged air conditioner(= H.E.(C))	
Fukuoka(Warm area)		

C_n=Ventilation Effectiveness, [ ] = outdoor air supply rate(=O.A.)

Table 3 shows specification of the HVAC equipment. As for HVAC equipment, HVAC equipment (A) (an absorption water heater/cooler unit is adopted (Here after H.E.(A))) is used as a base, and HVAC equipment (B) (an engine heat pump (Here after H.E.(B))) and HVAC equipment (C) (an air-cooled, packaged air conditioner (Here after H.E.(C))) are chosen depending on regional characteristics when analyzing data.

Table 3 HVAC equipment specifications

Type of H.E.	The ratio of Heating capacity to Cooling capacity[-]	The Ratio of Rated Output[-]	
		(supply child water)	(supply hot water)
H.E. (A)	0.84	1.0(=standard)	1.0(=standard)
H.E. (B)	1.2	1.05	1.44
H.E. (C)	1.12	0.26	0.34

Table 4 HVAC equipment Adopted Rate

Area	Adopted Rate [%]	
	1st	2nd
Sapporo (Cold Area)	H.E.(B) 57.1	H.E.(A) 14.3
Tokyo (Standard Area)	H.E.(C) 31.9	H.E.(A) 28.6
Fukuoka (Warm Area)	H.E.(A) 38.0	H.E.(C) 32.0

Table 4 shows adopted rate of each HVAC equipment in each area in Japan.

Building Model and its Conditions for Analysis of Annul Energy Consumption

Table 5 gives basic data on the building that is covered in the analysis. Based on the previously published paper [2], the covered building is assumed to be a central HVAC system-installed eight-storied, 4,000 m^2 office building that has 48 office modules each with space volume of 6.4 × 12.8 × 2.7 m. It is a typical medium-sized building found in Japan. Table 6 shows numerical conditions for annual heat loads analysis. Heat load varies from region to region and from season to season, and it impacts the energy consumption of HVAC equipment. In this analysis, heat loads for 12 months and for every 24 hours have been calculated using commercial software (MICRO-PEAK). Based on the results of heat loads calculated and calculation conditions given in Table 7, annual energy consumption and CO_2 emissions have been determined using commercial software for calculation of the energy consumption of heat sources in buildings (E-pass plan).

RESULTS AND DISCUSSION

Results of Peak Load

Fig. 4-1 and 4-2 shows reductions in maximum cooling and heating loads by regions and by amounts of O.A..

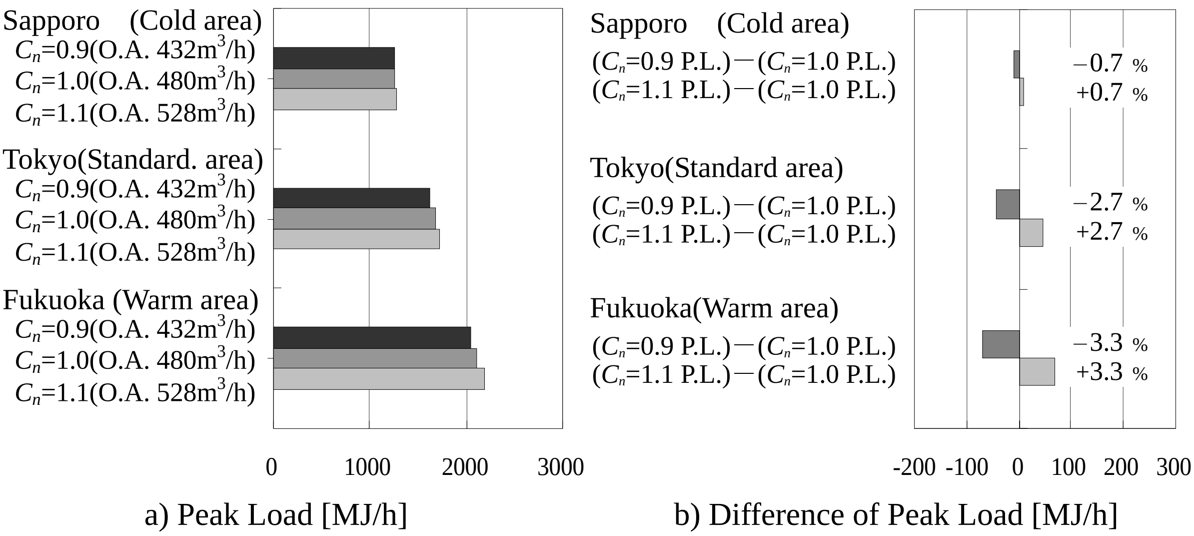

Figure 4 - 1 Cooling Load

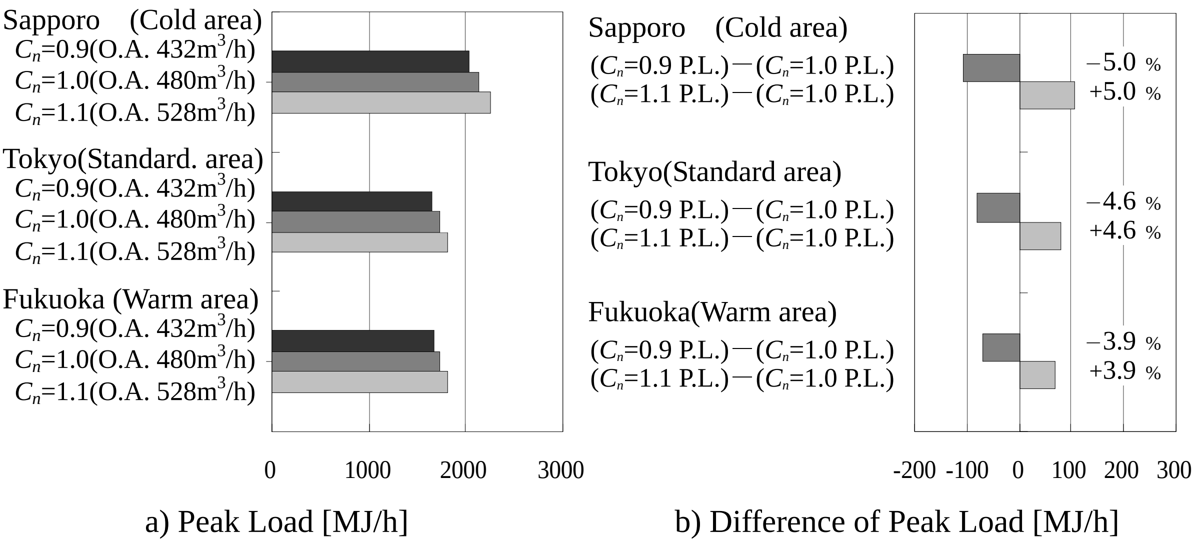

Figure 4 - 2 Heating Load

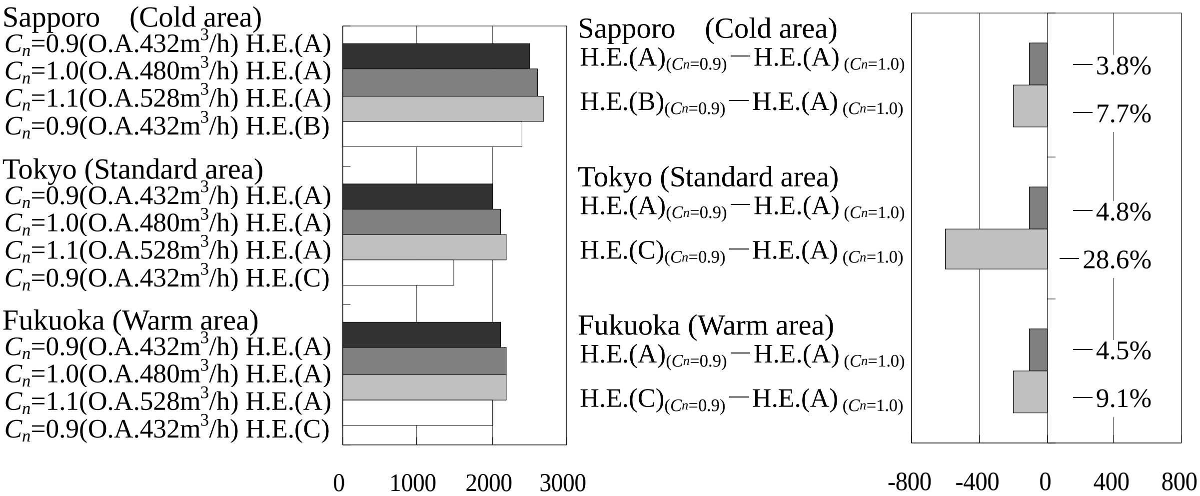
In the Tokyo area, an improvement of 0.1 in ventilation effectiveness C_n (= 0.9) leads to reductions in maximum heating and cooling loads of 45 MJ/h (a 2.7% reduction if the standard is C_n = 1.0) during cooling and 80 MJ/h (a 4.6% reduction when C_n = 1.0) during heating. By the same improvement, in the Sapporo area, it resulted in reductions of 9 MJ/h (0.7%) in the cooling load and 108 MJ/h (5.0%) in the heating load, and in the Fukuoka area, it resulted in reductions of 69 MJ/h (3.3%) in the cooling load and 68 MJ/h (3.9%) in the heating load.Taken together, a reduction in the O.A. has brought about the largest reduction in the heating load in Sapporo, followed by Tokyo. Presumably there is a large difference between room and the outdoor air temperature during heating in Sapporo, a cold area. Likewise, this is similar reason why a difference between room and outdoor air temperature in Tokyo.

Results of Equipment Capacity

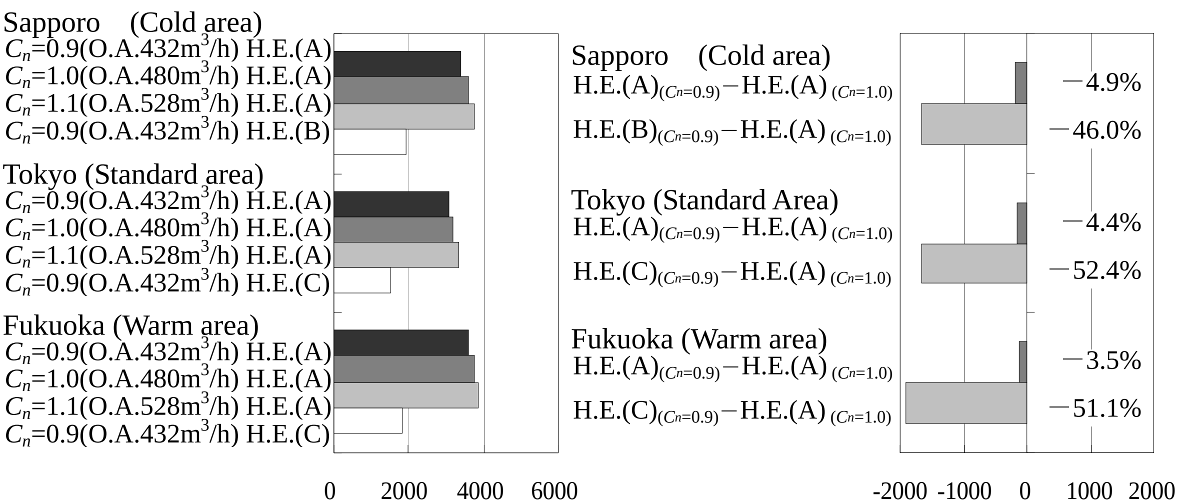


a) Equipment Capacity [MJ/h] b) Difference of Equipment Capacity [MJ/h]

Figure 5 Prediction Results of Equipment Capacity

Fig. 5 shows changes in the capacity of HVAC equipment. Assuming that the same H.E.(A) is adopted in all the areas covered, an improvement of 0.1 in the ventilation effectiveness C_n (=0.9) led to a reduction of 100 MJ/h of equipment capacity in all climate areas. Also shown in Fig. 5 is the effect of the selecting HVAC equipment that is commonly used in each area, in terms of changes from the basic case (C_n =1.0), which adopts H.E.(A). An improvement of 0.1 in C_n (=0.9) reduced 200MJ/h of equipment capacity (a 7.7% reduction when C_n = 1.0) in Sapporo area with H.E.(C), and reduced 600MJ/h of equipment capacity (a 28.6% reduction when C_n = 1.0) in Tokyo area with H.E.(C),and reduced 200MJ/h of equipment capacity (a 9.1% reduction when C_n = 1.0) in Fukuoka area with H.E.(C). H.E.(C) has hardly difference between heating capacity and cooling capacity, and the rated output is 1/4 times smaller than the H.E.(A). Therefore, in Tokyo area with 2% larger heating load than cooling load, equipment capacity became large reduction. Also in Fukuoka area with cooling load 20% larger than heating load, equipment capacity of H.E.(C) by small rated output became smaller than H.E.(A).

Results of Annual Energy Consumption

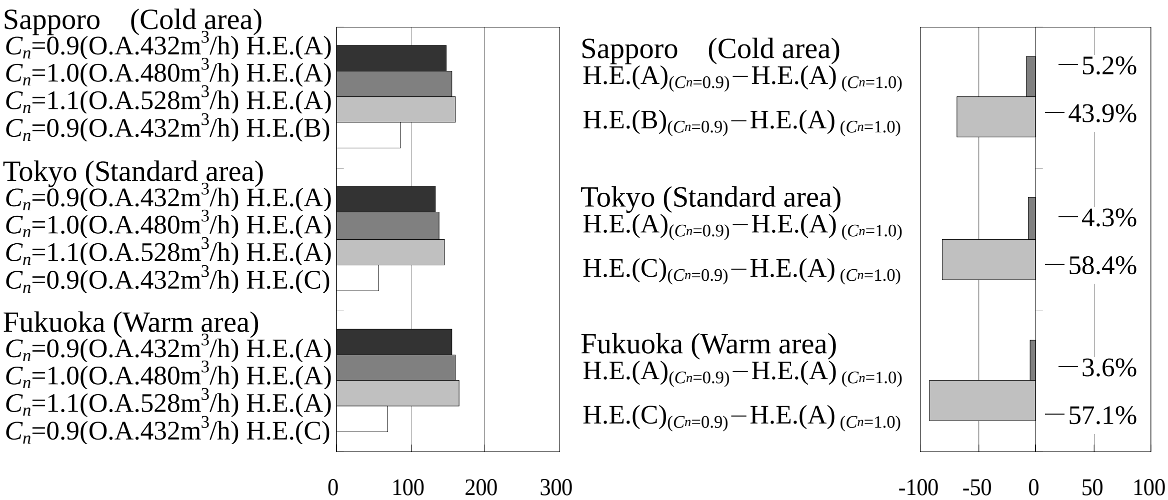


a) Equipment Capacity [MJ/h] b) Difference of Equipment Capacity [MJ/h]

Figure 6 Prediction Results of Energy Consumption

Fig. 6 shows the analysis results of the Prediction results of annual energy consumption. The adoption of the same H.E.(A) in all three climate areas resulted in a reduction of 176 GJ/year (4.9%) in annual energy consumption in Sapporo area, a reduction of 140 GJ/year (4.4%) in Tokyo, and a reduction of 130 GJ/year (3.5%) in Fukuoka. Sapporo achieved the largest reduction in energy consumption, followed by Tokyo, then Fukuoka. This result suggests that the considerable difference between outside air temperature and room temperature during the heating season causes large amounts of energy to be consumed to raise the temperature of outside air, indicating that a reduction in the O.A. helps to greatly reduce energy consumption in cold areas.
Adoption of the H.E.(B) in Sapporo area was reduction of the energy consumption of 1,408 GJ/Year (a 46.0% reduction when C_n = 1.0). This is because gas volume hardly changes between each HVAC equipment, and H.E.(B) in using electric energy reduce to 0.5 times under heating period, and reduce to 0.15 times under cooling period than H.E.(A). Adoption of the H.E.(C), in Tokyo reduced 1,676 GJ/Year (a 52.4% reduction when C_n = 1.0), and in Fukuoka reduced 1,917 GJ/Year (a 51.1% reduction when C_n = 1.0). This is because the H.E.(C) which works only with electric power without using gas.

Results of Annual CO_2 Emissions



a) Carbon Dioxide Emission [t- CO_2/Year] b) Difference of Carbon Dioxide Emission [t- CO_2/Year]

Figure 7 Prediction Results of Carbon Dioxide Emission

Fig. 7 shows reductions in annual CO_2 emissions. The adoption of the same H.E.(A) in all the three climate areas resulted in the largest CO_2 emissions reduction of 8 t- CO_2/Year (5.2%) in Sapporo area. The annual CO_2 emission reduction is 6 t- CO_2/Year (4.3%) in Tokyo and 5 t- CO_2/Year (3.6%) in Fukuoka. This result corresponds to the result obtained in regard to energy consumption. [3],[4]

Also shown in Fig. 7 are the effects of selecting HVAC equipment that is commonly used in each area, in terms of changes from the basic case (C_n = 1.0), which adopts H.E.(A). In this case, the reduction of CO_2 emissions is the largest in Fukuoka at 92 t- CO_2/Year (57.1%), followed by Tokyo at 81 t- CO_2/Year (58.4%) and Sapporo at 55 t- CO_2/Year (43.9%). This result corresponds to the results of analysis of energy consumption.

CONCLUDING REMARKS

The reduction effects on equipment capacity and annual energy consumption of introducing the index for ventilation effectiveness in the design of air-conditioning systems and optimizing outdoor air flow rate as a means to conserve energy in buildings and HVAC equipment have been estimated.

(1) Based on the adoption of the same HVAC equipment for all three climate areas covered, when O.A. is reduced by 10% using the index for ventilation effectiveness, annual energy consumption declined by 4.9% in the cold Sapporo area, 4.4% in the Tokyo standard area, and 3.5% in the warm Fukuoka area. Likewise, annual CO_2 emissions declined by 5.2% in Sapporo, 4.3% in Tokyo, and 3.6% in Fukuoka.

(2) Furthermore, when HVAC equipment that is extensively used in each specific area was adopted and O.A. was reduced by 10%, annual energy consumption declined by 46.0% in cold Sapporo area, 52.4% in Tokyo standard area, and 51.1% in warm Fukuoka area compared to the case in which the same HVAC equipment was adopted but no reduction in O.A. was made. Likewise, annual CO_2 emissions declined by 43.3% in Sapporo, 61.4% in Tokyo, and 60.1% in Fukuoka.

SUMMARY

The focus on implementing cost efficiency energy efficiency measures will in all probability increase in the future, but it has been shown that trustworthy, site specific information are key features is increasing the adoption of such measures.

This study shows that Building Energy Simulation (BES) software gives trustworthy predictions of energy use and average temperature in the studied case, making it possible to study different HVAC control strategies. When coupled with CFD, it is also possible to study thermal comfort, ventilation efficiency, ventilation effectiveness and draught, giving an even wider range of decision support.

This study also shows that a VAV system is an interesting HVAC control technique for the studied foundry. In this case, the technical potential for reducing energy use in terms of both heat and electricity is predicted to be 30.3% and 28.9% respectively.

INTRODUCTION

An increasing focus on environmental issues, energy prices and competition will in all probability make the implementation of cost efficient energy efficiency measures within the energy intensive foundry industry even more necessary, especially for a country like Sweden, where industry has historically enjoyed one of the lowest energy prices in Europe [1]. The Swedish foundry industry accounts for about 2% (300,000 tons) of the entire European casting production. This makes it a relative large casting producing country per capita, with some 7,000 people employed in the industry.[2] Total energy use by Swedish foundries is about 1 TWh. [2] Support processes such as heating, ventilation and air conditioning (HVAC) within industrial premises are an important issue, as they are related to both energy cost and indoor climate management as well as to the health of the occupants. HVAC in industrial premises account for nearly 30% of the total industrial energy use in Sweden. Furthermore, it has been shown that energy efficiency measures are more easily adopted if they are related to support processes, i.e. HVAC, lighting and compressed air, and not to the production process, as the largest technical barriers to energy efficiency are often related to the production process. This has been studied by Rohdin et al in [3-4]. This stresses the need for accurate and trustworthy information as they are key features in increasing the adoption of energy efficiency measures. One way to obtain this type of information is to use validated simulation methods.

The aim of this paper is to study energy use and thermal climate in a large Swedish light alloy foundry by means of energy simulation, CFD and measurements. The technical potential for using Variable Air Volume (VAV) systems is investigated using these methods.

The energy simulation software IDA ICE [5, 6] was used to perform the numerical energy simulation and the CFD software Fluent 6.2 [8] to perform the numerical flow simulations.

OBJECT DESCRIPTION

Energy use at a light allow casting facility

The relative proportions in the different processes are in line with the ”average” non-iron or steel foundry where melting and holding is estimated to be 40%, molding about 20% and support processes about 40%. [2] The light alloy casting facility presented in this paper has 44% melting/holding, 19% molding and about 37% support processes, see Table 1.

Table 1. Presentation of energy use, energy split on different processes and basic data for the foundry.

Description	Data	Process	Energy use [MWh]	%
Total floor Area	2 744 m2	Melting, holding	7 700	44

Energy use/m^2	3 865 kWh/m^2			
Production	~2 100 000 kg/year			

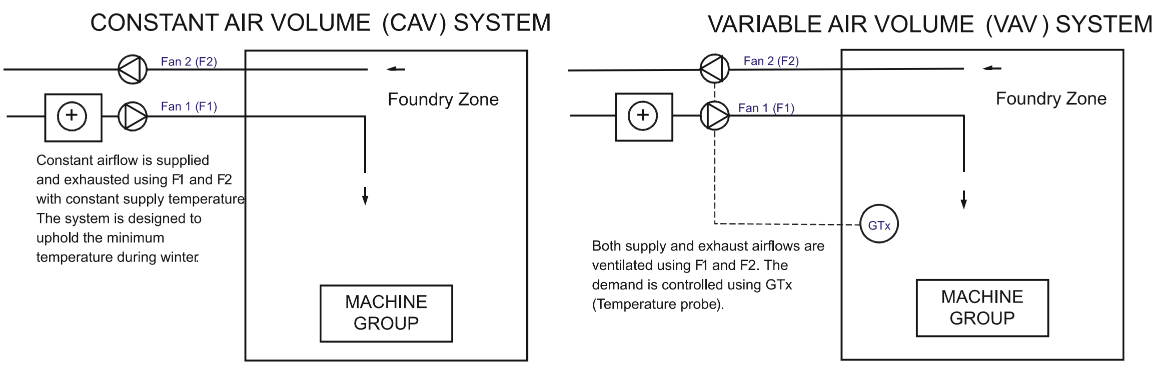

Figure 1. Schematic description of the CAV used today and the purposed VAV system.

THE MODELS

Geometry

The casting facility is 28 m wide and 98 m long, giving an area of 2 744 m^2, see Figure 2. The ceiling height is 12 m. In the facility, there are 16 machine groups (M in the figure) with their associated furnaces (F), and two melting furnaces (MF). Two types of metal are processed in the facility: aluminum and magnesium. Machine groups M1, M2, M4, M12, and M14 process aluminum and the rest magnesium. Air is supplied through 20 displacement supply devices (SD) along the long walls. The exhaust air is evacuated by local exhaust systems located over the machine groups and melting furnaces. All walls are interior walls as the foundry is surrounded by assembly, storage, and other facilities.

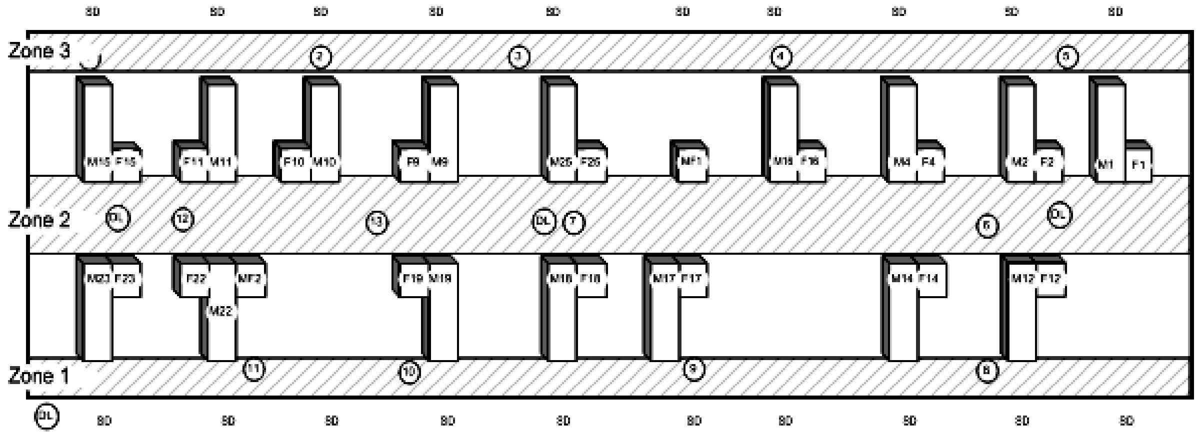

Figure 2. Machine plan of the casting facility.

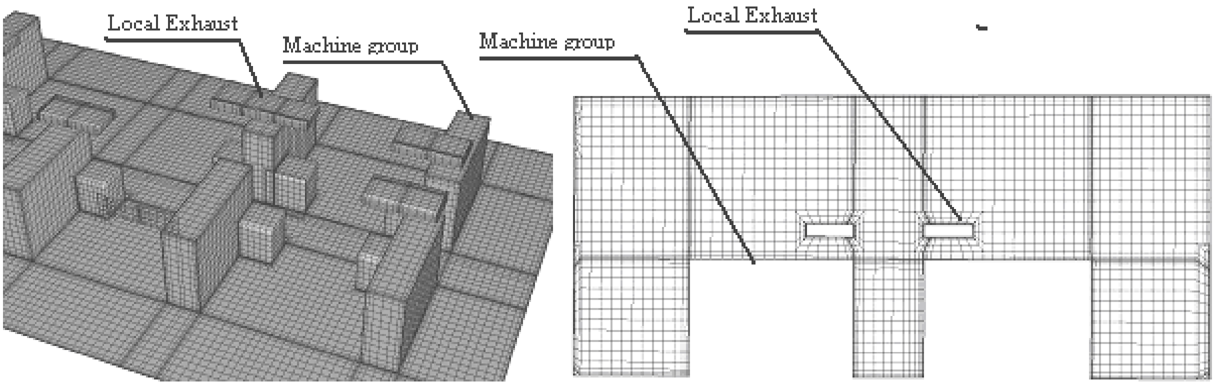

Figure 3. Part of the mesh shown for part of the facility and in section.

CFD Model

Icepack [7] was used to generate the 3-D structured grid shown in Figure 3. The mesh is non-conformal at the interface between wall and coarse region of the model. Fluent 6.2 [8] was used to numerically simulate the thermal climate in the casting facility. The governing equations were solved with a segregated scheme and discretized spatially with a second order upwind scheme. The near-wall treatment used in this model was the standard wall function. The first numerical point was always located at y+>8. The wall boundaries were modeled using the no-slip condition with constant wall temperature. The supply air was modeled as a mass flow inlet with a constant flow rate, and the outlets were modeled using mass flow and pressure outlets. For a more extensive description of the CFD model, where turbulence models and meshing are explained in detail and the model is compared with measurements, see [8]. The Predicted Mean Vote (PMV) and Predicted Percentage Dissatisfied (PPD) are found in ISO 7730 [9], and were implemented in FLUENT by means of a user defined interface (UDF). The calculation of mean age of air was also implemented using a UDF. The Draught Rating (DR) and ventilation efficiency and ventilation effectiveness has been implemented using custom field functions.

Building Energy Simulation Model

IDA ICE 3.0 was used to numerically simulate the energy use aspects of the foundry's construction and HVAC systems. Measured power for the different machine groups and other gains was used as input. The CAV HVAC system, illustrated in Figure 4, was modeled using measured values for supply air temperature, air flows and outdoor temperature. The model was then compared with measured values of the indoor air temperature measurements. The comparison is seen in Figure. 4. A study of time-step independence was made and a maximum of 5 minutes was chosen.

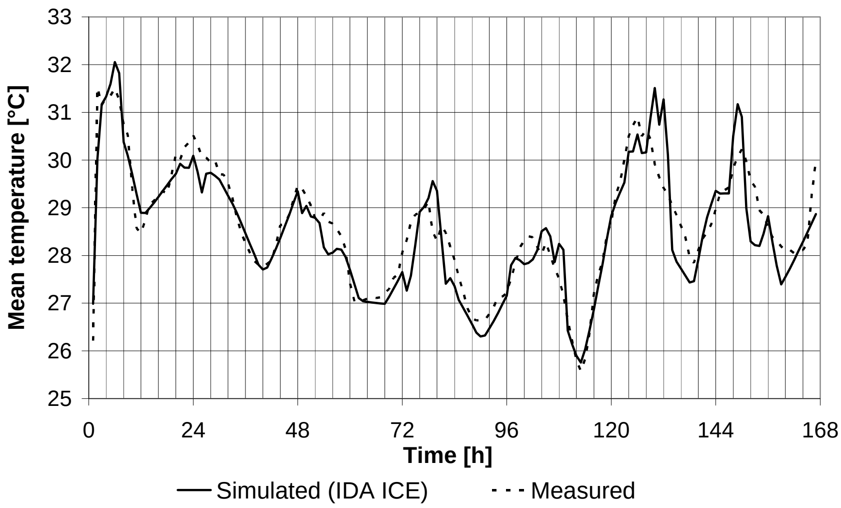

Figure 4. Simulated and measured average temperatures for the entire volume in the facility.

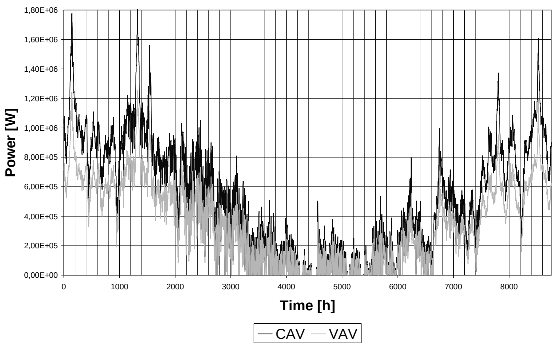
It's important to note that the mean temperature in the occupied zone is lower than the mean temperature as the temperature stratification in this facility is rather high.

VAV VS. CAV IN A FOUNDRY

Two different HVAC control strategies are compared, a CAV system and a VAV system, described in Figure 1. To compare these, both the energy use of the different strategies and their impact on comfort and ventilation effectiveness are studied. Two different methods are used: BES to study energy and power use and a CFD model to study indoor air related parameters.

Energy use aspects



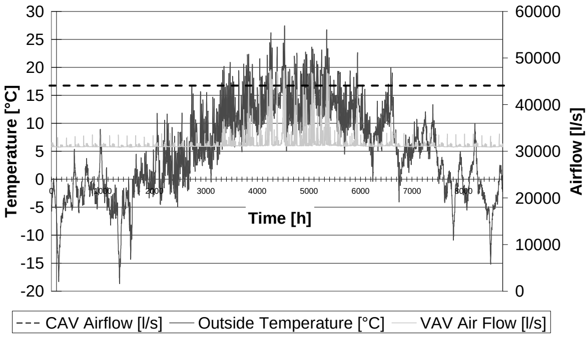


Figure 5. Power used by the heater for the CAV and VAV case (left). Airflows CAV and VAV case.

The mean power for the CAV case is 507 kW and for the VAV case 354 kW. The maximum power for the CAV case is 1.8 MW and 1.25 MW for the VAV case, indicating a decrease in maximum power of 31% from the present case. The energy used for heating the supply air decreases from 4.45 GWh (CAV) to 3.10 GWh (VAV). In addition, the power used by fans is predicted to decrease from 874 MWh to 621 MWh.

Ventilation and thermal comfort aspects

Two different cases have been identified from the energy simulations for further study:
Outside temperature below 14°C, when the supply temperature is 16°C. The VAV system delivers 31 m^3/s.
Outside temperature is 21°C, and the supply temperature 23°C. The VAV system delivers up to full flow of 45.5 m^3/s

To predict changes in comfort for the different cases, both PPD, PMV, and DR [9], were calculated and are shown in Figures 6-9. To predict changes in the function of the ventilation, both ventilation efficiency and ventilation effectiveness were calculated. The Air Exchange efficiency is defined as:

$$\eta_a = \frac{\tau_n}{2 \cdot \tau_i}, \qquad (1)$$

where t_n is the nominal time constant and t_i the average time a particle resides in the facility. The ventilation's effectiveness for heat distribution or heat removal (ε_t) is a measure of how effective the ventilation system is in removing the heat produced internally in the occupied zone and is defined as:

$$\varepsilon_t = \frac{T_o - T_i}{T_{local} - T_i}, \qquad (2)$$

where T_i and T_o are the supply and exhaust air temperatures respectively and, T_{local}, represents the local temperature in the occupied zone. The ventilation effectiveness is presented in Figures 10-12.

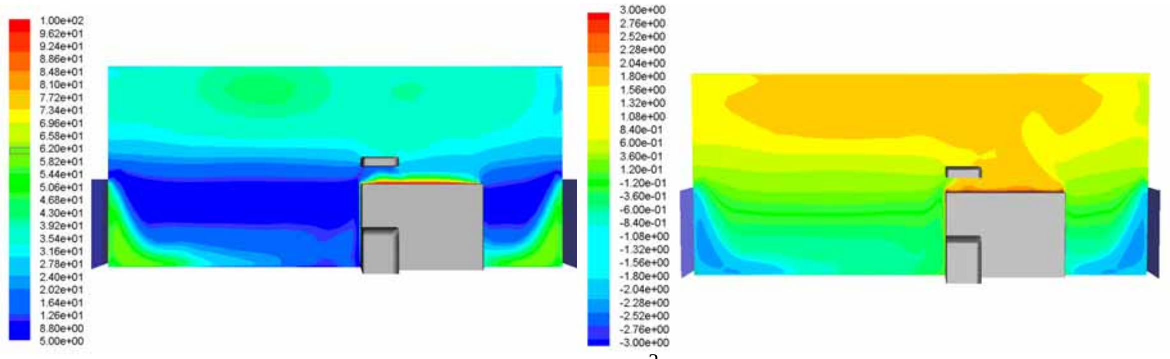

Figure 6. PPD and PMV 16 °C CAV with 45.5 m^3/s airflow.

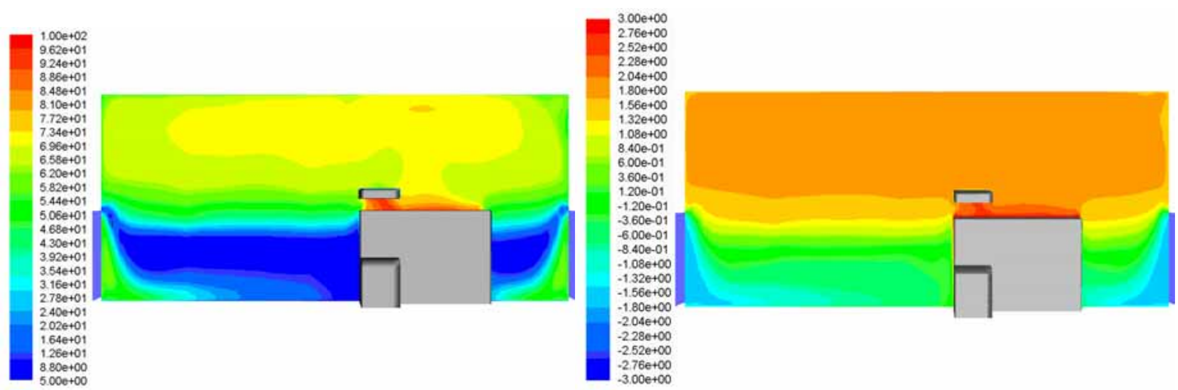

Figure 7. PPD and PMV 16 °C VAV with 31,0 m^3/s airflow.

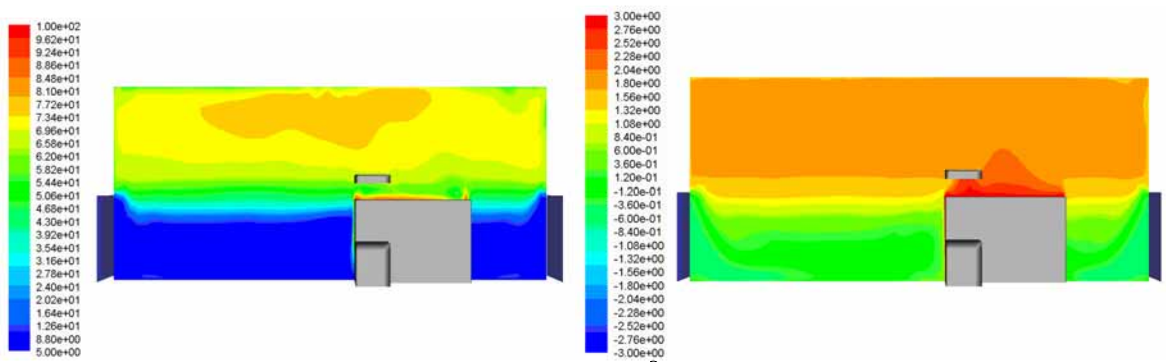

Figure 8. PPD and PMV 23 °C CAV with 45.5 m^3/s airflow.

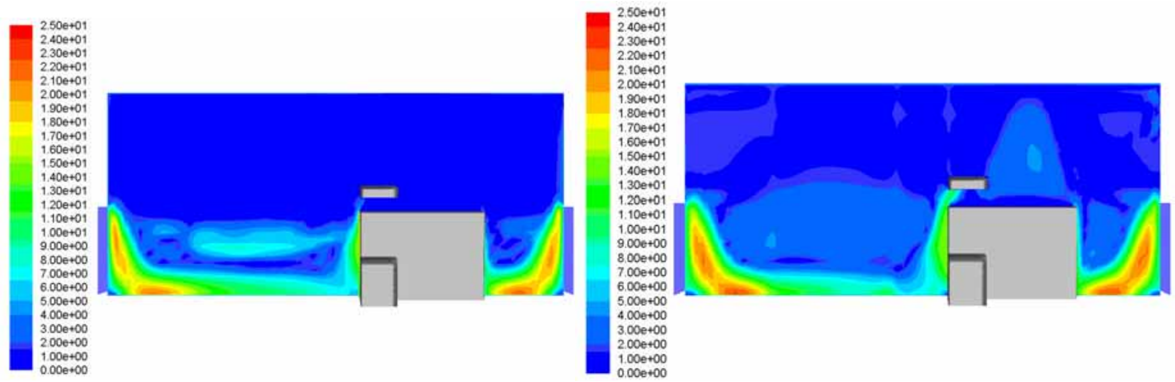

Figure 9. DR (Left) 16°C CAV, (Right) 16°C VAV. The draught decreases slightly when decreasing the flows.

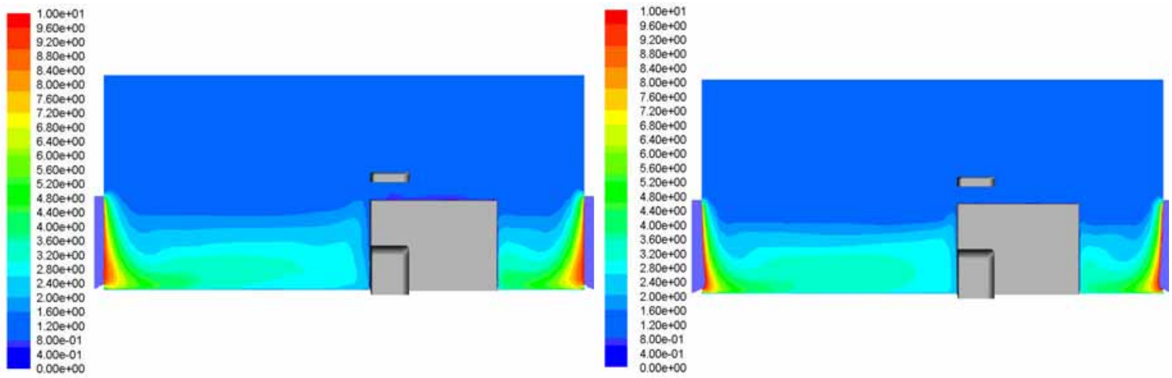

Figure 10-12. ε_t (left) CAV 16 °C (right) VAV 16°C.

For the full flow winter case the air exchange efficiency is 70%, for the 31 m^3/s winter case 76%, and for the full flow summer case 60%. The lower efficiency for the summer case reflects the lower stratification, as the difference between supply air temperature and ambient air temperature is smaller.

The PPD index decreases slightly in the occupied zone when the air flows are lowered when the supply temperature is 16°C. The PMV index indicates that the air is too cold and the air velocity too high. For the summer case when the supply temperature is 23°C the PPD index decreases drastically, indicating a positive thermal sensation. The DR-index indicates that the draught in the supply region in the occupied zone decreases slightly when flows are decreased.

The ventilation’s effectiveness for heat distribution or heat removal decreases slightly, see Figures 10 and 11, when the airflow is reduced. The ventilation effectiveness for the summer case is substantially lower due to a smaller difference between mean air temperature and supply temperature, indicating better functioning ventilation in terms of ventilation effectiveness during winter.

CONCLUDING DISCUSSION

The management of an industrial company requires decisions related to the management of production, maintenance, facilities, energy and labor issues, etc. This management is strongly related to the investment decision the organization has to make in order to achieve and maintain profitability, which is the overall goal of any company. The ability to make the ‘correct’ decision in relation to the overall goal is what separates a successful business from a failure.

This study shows that Building Energy Simulation software such as IDA ICE gives trustworthy predictions of energy use and average temperature in the studied foundry, making it possible to study different HVAC control strategies. When coupled with CFD, it is also possible to study thermal comfort, ventilation efficiency, ventilation effectiveness, and draught, providing an even wider range of decision support. The use of these simulation methods thus gives trustworthy and site specific information which can be used as effective decision support. The importance of site specific and trustworthy information is stressed by, for example, Stern and Aronsson (1984). [11]

This study also shows that a VAV system is an interesting HVAC control technique for the foundry industry. In this case the technical potential for reducing energy use in terms of both heat and electricity is predicted to be about 30% (heat 30.3% and electricity 28.9%). It is also shown that neither the thermal comfort nor the ventilation efficiency is predicted to be negatively affected. The thermal comfort is even predicted to increase. An additional positive effect of the VAV system is the reduced power usage during the cold season, when the demand for district heating and electricity is highest, which in some cases can reduce power related costs even further, since the maximum power demand is reduced.

ACKNOWLEDGEMENT

The work has been carried out under the auspices of The Energy Systems Programme, which is financed by the Swedish Foundation for Strategic Research, the Swedish Energy Agency and Swedish industry.

SUMMARY

When room ventilation is based on the stratification or zoning strategy, the ventilation air flow rate is determined on the grounds of the convection flows of the heat sources. Thus, in the design phase of office ventilation, the convection flows of common office devices should be known. Especially, to correctly dimension the ventilation air flow, it is important to know the volume flow rates. However, even if the convective power of an office appliance is known, the cooling fan makes the prediction of the characteristics of the convection flow very difficult. Therefore, direct measurement data is needed. In this study, the convection flows of an overhead projector and a data projector were examined. Cross sections of the velocity and temperature fields were measured and analyzed to obtain the volume and momentum flow rates.

INTRODUCTION

In the stratification and zoning strategies of ventilation, the ventilation air flow has to overrun the combined convective flows everywhere in the occupied zone to prevent them from returning. Then, when dimensioning the ventilation in a space with numerous (human or non-human) heat sources, the designer must know the characteristics of the flow generated by each source. Mere knowledge of, *e.g.*, the power consumption of a source is not sufficient. The relative proportions of convective and radiative heat transfers have to be known. (Heat conduction is not significant.) In addition, a warm electric device usually has a fan, generating forced convection with properties completely different from those of natural convection. Therefore, experimental information of the convection flows of typical heat sources in ventilated rooms is needed. This paper reports the results obtained from two common office appliances; an overhead projector and its modern counterpart, a data projector. Both devices have a fan, making the prediction of their convection flows very challenging. Velocity and temperature distributions on different cross sections of the flows were measured, and the results were used to compute the air flow rates, momentum flow rates, and convective powers. The results were compared to a basic heat source, which was a heated, black metal cylinder with 40 % convection.

METHODS

The electric power consumed by an electric device dissipates by two basic mechanisms; convection and radiation. Since the devices usually have a fan, convection is further subdivided in two separate portions. In forced convection heat is carried away by a jet generated by the fan, and in natural convection warm surfaces generate a rising plume, also carrying heat with it. This division is illustrated in Fig. 1. The blow from the fan is most often directed horizontally, whereupon the forced and natural convection flows remain separate.

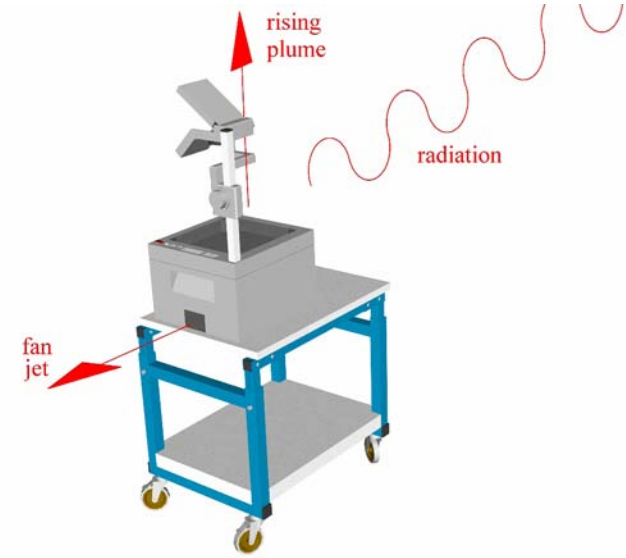

Figure 1. Mechanisms of heat loss from an office device.

The device under examination was placed in a test room shown in Fig. 2. The supply air was delivered through six perforated pipes on the floor to minimize the disturbances inflicted to the plumes, and the exhaust was dispersed at the ceiling. Moreover, the ventilation air current was set as low as possible (~245 l/s) without causing return flow of the plume air. The flow field was measured by two directional sensitive ultrasonic anemometers, attached in a traversing robot, also displayed in Fig. 2. The robot was able to move in all three directions and was programmable, so that measurements could be performed without human presence. In each point of measurement, the anemometers stayed one minute gathering data.

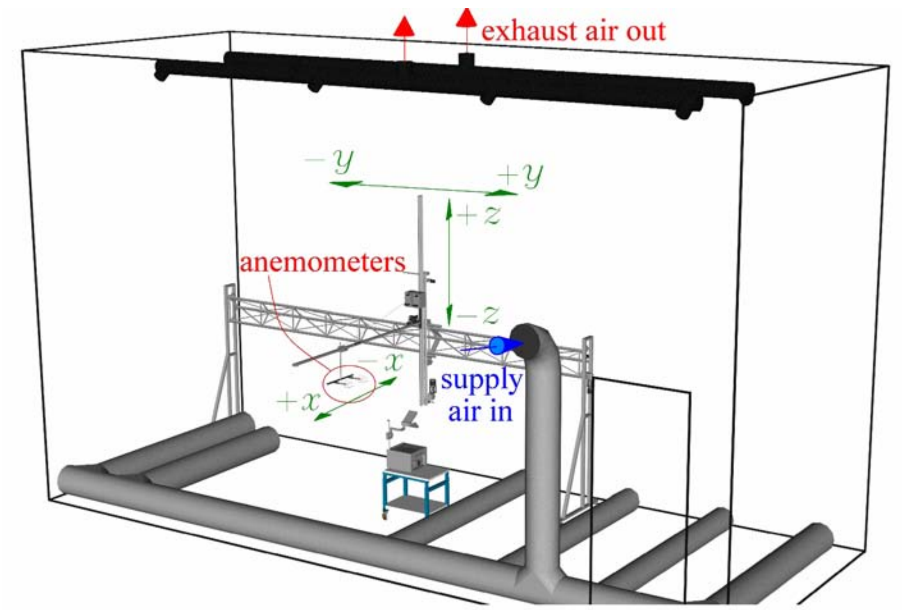

Figure 2. Test room and the measurement robot, carrying the anemometers.

The anemometers were used to measure horizontal and vertical cross sections of the flow fields of the plumes (jets). Figure 3 illustrates one such cross section (the near field in front of the exit opening of the data projector). These cross sections were used to integrate the volume, thermal energy (*i.e.* heat), and momentum flow rates through them. This was possible, since there was a thermistor attached to both anemometers, giving the temperature distributions also.

Figure 3. Measurement grid for the near field in front of the exit opening of the data projector fan. Points of measurement are marked by blue balls. An illustration of the outcome of this measurement is displayed in Fig. 6 (bottom row).

When integrating the air volume flow rate through a plane of measurement, the background velocity has to be subtracted from the velocity measurements. Let $\boldsymbol{v}$ be the velocity vector, and $\boldsymbol{w}$ its background component. Further, let subindex $\perp$ denote the direction perpendicular to the plane of measurement. (This plane can be either horizontal or vertical.) Then the volume flow rate through the plane is

$$q_{\mathrm{pl}} = \int_{\substack{\text{plane of}\\ \text{measurement}}} \left(v_{\perp} - w_{\perp}\right) \mathrm{d}A \ . \qquad (1)$$

The background component $w_{\perp}$ was deduced from the fringe area of the measurement plane.

The heat power P_{c}, conveyed away from the device by the convection flow (plume or fan jet), can be calculated, if at every point we know the flow velocity and temperature rise ΔT of the air. Here ΔT is the increase in temperature, experienced by the air after entering the plume (*i.e.*, the part of the temperature originating from the device). The heat power conveyed through an area element dA is then $\mathrm{d}P_{\mathrm{c}} = c_{\mathrm{p}}\,\rho\,\Delta T\,v_{\perp}\mathrm{d}A$, and the entire power conveyed through the plane of measurement is

$$P_c = \int_{\substack{\text{interior of}\\ \text{conv. flow}}} c_p \, \rho \, \Delta T \, v_\perp \mathrm{d}A \; . \qquad (2)$$

Note that the background velocity $\boldsymbol{w}$ is not subtracted now, since it is the total air flow flushing the device surfaces that is conveying the heat. Also note that the area of integration covers merely the interior of the flow region. This may be difficult to delimit in practice, and if the integration is extended over the entire plane of measurement, it may be necessary to replace $v_\perp$ by $v_\perp - w_\perp$ to reduce the errors accruing from integration outside of the convection flow. Therefore, and for the results to be of general use, the background component of the flow velocity should be insignificant. As for ΔT, its calculation is complicated by temperature stratification. New air is entrained into the flow from all heights, and ΔT should be the present temperature minus the average original temperature of all the air in the flow, which we denote by T_0. When the flow is an upward travelling, natural plume, the effect of stratification can be approximated in a simple way. If at height z above the virtual origin of the plume the ambient temperature is $T_{\mathrm{amb}}(z)$ and plume volume flow rate is $q_{\mathrm{pl}}(z)$, then at an arbitrary height h (above the virtual origin)

$$T_0(h) = \frac{1}{q_{\mathrm{pl}}(h)} \int_0^h T_{\mathrm{amb}} \frac{\mathrm{d}}{\mathrm{d}\,z} q_{\mathrm{pl}} \mathrm{d}\,z$$

and $\Delta T = T - T_0(h)$. If we insert the point source formula $q_{pl}(z) = AP_c^{1/3} z^{5/3}$ and assume linear temperature gradient, *i.e.* $T_{\mathrm{amb}}(z) = T_{\mathrm{amb}}(0) + \beta\, z$, we obtain
$T_0(h) = T_{\mathrm{amb}}(0) + \frac{5}{8}\beta\, h = T_{\mathrm{amb}}(h) - \frac{3}{8}\beta\, h$ and

$$\Delta T = T - T_{\mathrm{amb}}(h) + \frac{3}{8}\beta\, h \, . \qquad (3)$$

Stratification correction (3) was not used when integrating over a vertical cross section of an exhaust jet (*i.e.*, β was set to 0). It was applied after the jet had veered almost vertical and a horizontal cross section was measured. This procedure somewhat underestimates the convection power far from the device, since it underestimates the proportion of cool air entrained into the flow from low heights. However, P_c was only used to judge whether the convection flow has been captured well enough by the measurement. If far away from the source the measured values of P_c have diminished too much, then the flow has probably become too wide or ragged to be analyzed, and the other results are not reliable either.

In addition to volume and energy flow rates, momentum flow rate through each plane of measurement was also calculated. Momentum flow rate $\boldsymbol{M}$ tells the total momentum vector $\boldsymbol{p}$ conveyed per unit time across the piece of plane measured, *i.e.*

$$\boldsymbol{M} = \dot{\boldsymbol{p}} = \mathrm{d}\,\boldsymbol{p} / \mathrm{d}\,t = \int_{\substack{\text{plane of}\\ \text{measurement}}} \boldsymbol{v}\,\mathrm{d}\dot{m} = \int_{\substack{\text{plane of}\\ \text{measurement}}} \rho\,\boldsymbol{v}\,v_\perp \mathrm{d}A \; .$$

This quantity is useful in CFD modelling. The near field momentum flux is a necessary boundary value, and momentum flow rate elsewhere in the flow is useful in validating CFD solutions. The most interesting component of ***M*** is usually that perpendicular to the plane. It gives the perpendicular force that would be impinged by the flow on the plane in case the plane absorbed the flow. It is given by

$$M_z = \int_{\substack{\text{plane of}\\ \text{measurement}}} \rho v_\perp^2 \,\mathrm{d}A \,.$$

The measurement robot only provided one minute time averages $\langle v_\perp \rangle$ and the corresponding standard deviations $s_\perp$. These were then used to calculate the squared average of $v_\perp$ as $\langle v_\perp^2 \rangle = \langle v_\perp \rangle^2 + s_\perp^2$. The deviation originates from the turbulence and fluctuations of the flow. The background flow, which was assumed constant and laminar, was subtracted, so that the final formula for the flow of $p_\perp$ was

$$\langle M_\perp \rangle = \int_{\substack{\text{plane of}\\ \text{measurement}}} \rho \left[\left(\langle v_\perp \rangle - w_\perp \right)^2 + s_\perp^2 \right] \mathrm{d}A \,, \qquad (4)$$

where angle brackets stand for (one minute) time averaging. When computing the above integral, however, the term $s_\perp^2$ was added only in points where $s_\perp < \left(\langle v_\perp \rangle - w_\perp \right)$ to avoid inclusion of mere turbulence in quiescent air.

Finally, the radiative powers of the overhead projector and the data projector were estimated. This was done by measuring the surface temperatures in several points, taking the means of their fourth powers, and applying the formula

$$P = \varepsilon \sigma A \left(\overline{T_\mathrm{d}^4} - \overline{T_\mathrm{r}^4} \right) , \qquad (5)$$

where subindices d and r stand for device surfaces and room surfaces, respectively, overline means spatial average, and emissivity of the device surfaces $\varepsilon = 0.95$. The radiative power of the black cylinder, used as a reference heat load, was calculated more accurately by dividing surfaces into smaller sections and calculating the view factors.

Above formulas (1) – (5) were used to analyze the raw data measured along the flow cross sections. In eqs. (2) and (4), air density ρ is left inside the integrations, since it varies locally along with temperature.

RESULTS

The basic characteristics of the convection flows can be seen from the smoke visualizations in Figs. 4 and 5. It is evident that the convection flow from the data projector is purely forced, but the overhead projector also has a weak plume of natural convection. The jets of forced convection turn more and more vertical on their way, beginning to behave more and more like natural plumes. The jet of the data projector is hotter and slower, whereby it turns faster. The figures also show, how its jet is pasted on the table top (Coanda effect). Therefore, when performing the robot measurements, both the devices were set at the edge of the table. Since the forced convection flow of the overhead projector is slow, cool and wide when it finally rises up, measuring its volume, energy, and momentum flow rates is very inaccurate at high altitudes. The near fields of $v_\perp$ and T of both devices are seen in Fig. 6. They are vertical cross sections in front of the exhaust opening, either 0.2 m or 1.3 m apart from it. They show the fields when looking against the flow, towards the device.

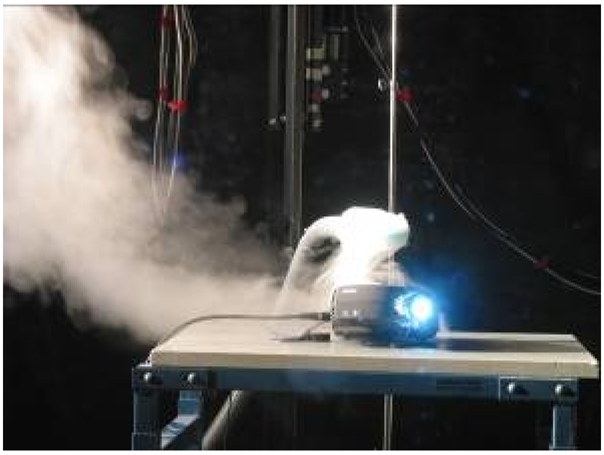

Figure 4. Smoke tests reveal how the convection of the overhead projector (on the left) is divided between forced and natural convection, whereas all convection flow from the data projector (on the right) is forced convection.

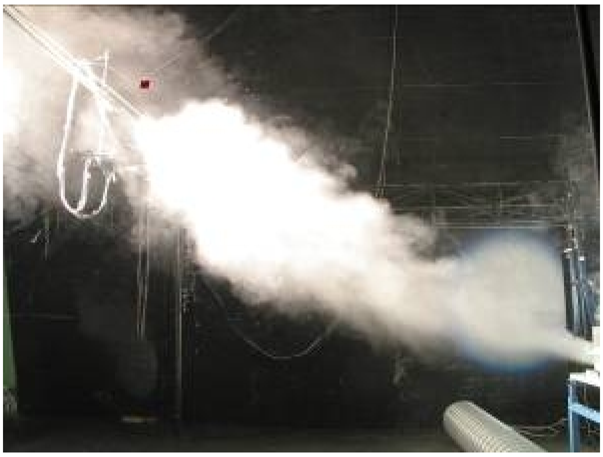

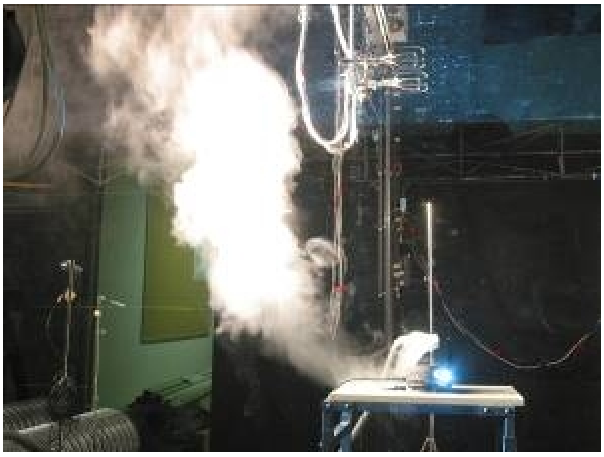

Figure 5. The fan jet from the overhead projector (on the left) is faster and cooler than that from the data projector (on the right), therefore rising up farther away from the device.

The results of the analyses are gathered in Figs 7 – 9. The office devices examined are always compared with a reference plume source, which was a black metal cylinder, heated through its full length. Its properties were known from our earlier measurements, and a measurement with the heating power as close as possible to that of the office appliance was chosen. The height of the cylinder was 1.2 m, and it was standing on a 50 cm high piece of insulator. The height of the table, carrying the projectors, was 0.7 m. The first of the figures, Fig. 7, displays the convection powers (*i.e.*, the heat flow rates) flowing through the cross sections. They should be considered as a test of reliability. For the measurements to be reliable, the sum of the (forced and natural) convection and radiation powers (kinetic energy flow rate is not significant) should be near the heating power used, written in black. Thereby, a reduction in the measured convection power during the rise of the flow tells that the precision is deteriorating.

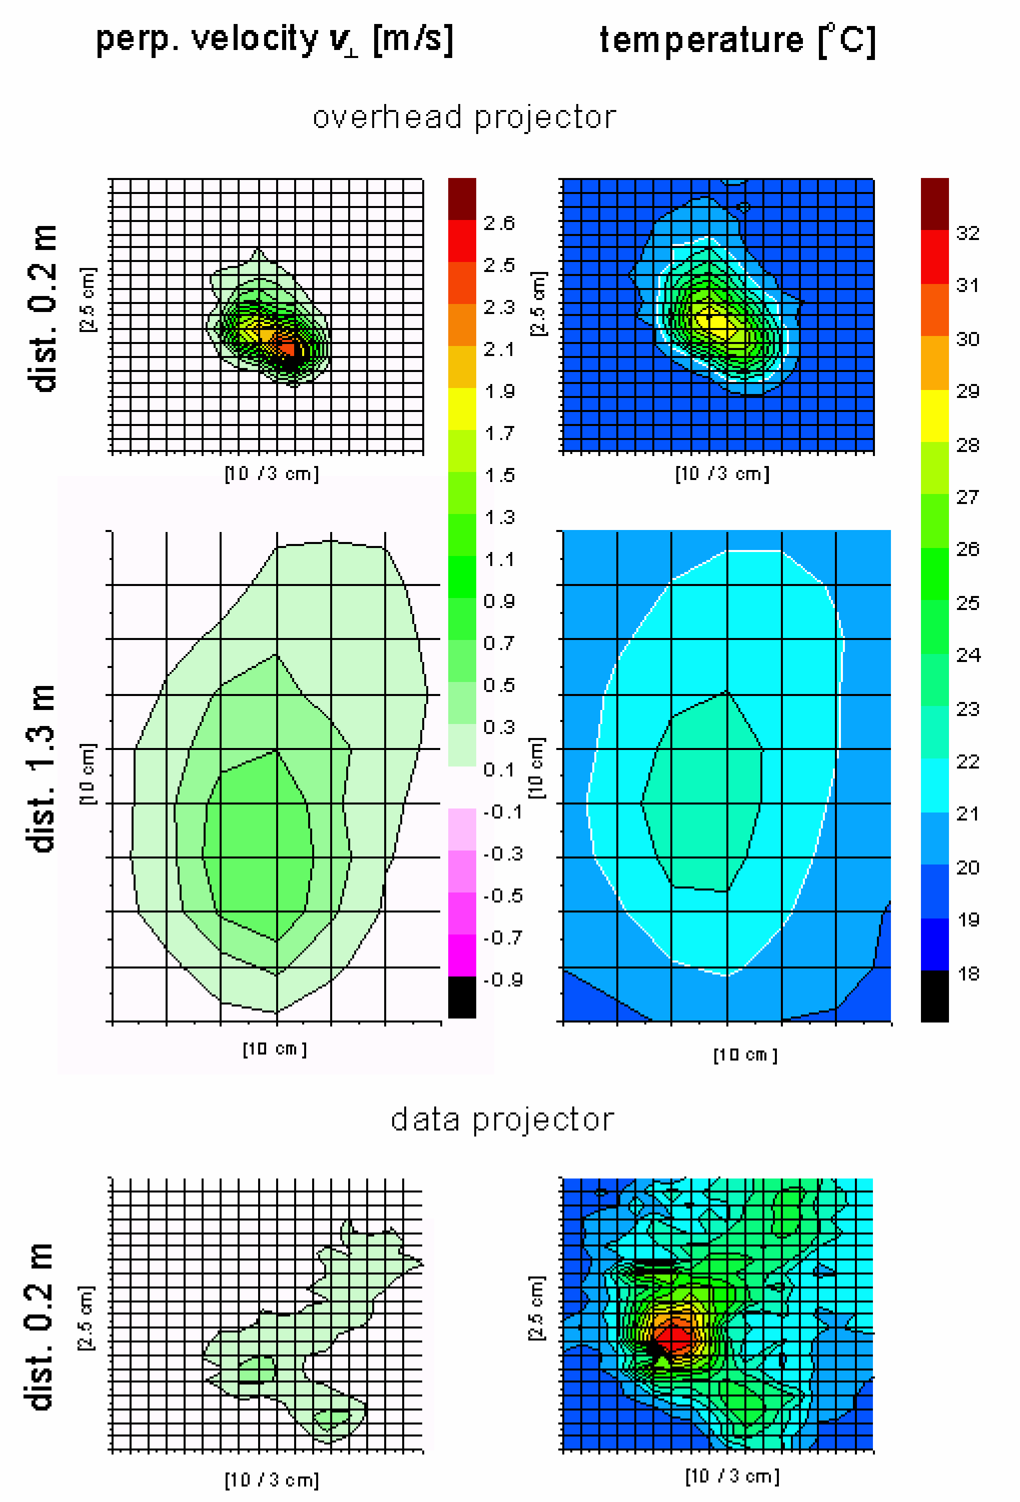

Figure 6. Vertical cross sections of the jets of forced convection. The velocity maps display the component $v_\perp$, parallel with the original direction of the blow and perpendicular to the plane of measurement. All the maps are drawn in the same scale, the grid of measurement points is shown, and the grid size is given in centimeters.

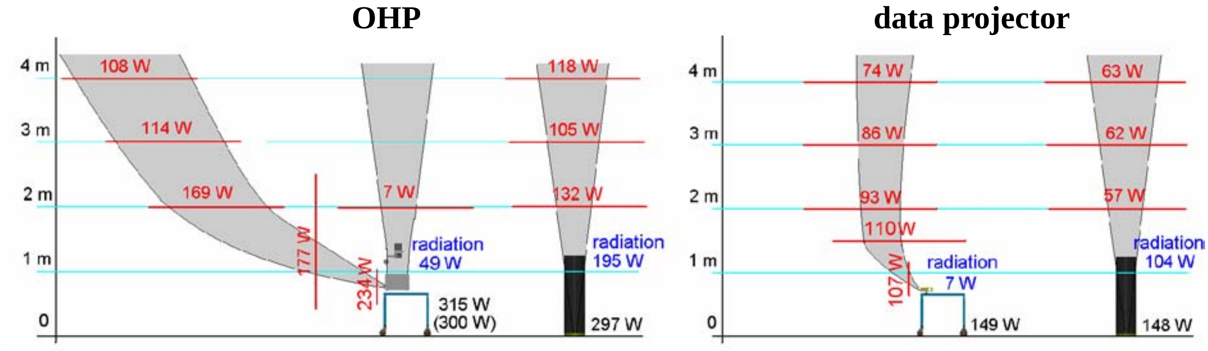

Figure 7. Measured convective and radiative powers of the office devices as compared with those of a black metal cylinder. The power consumption of the overhead projector was normally 315 W, but when measuring the near field 0.2 m apart, a reserve lamp had to be changed, after which the power consumed was 300 W. OHP = overhead projector.

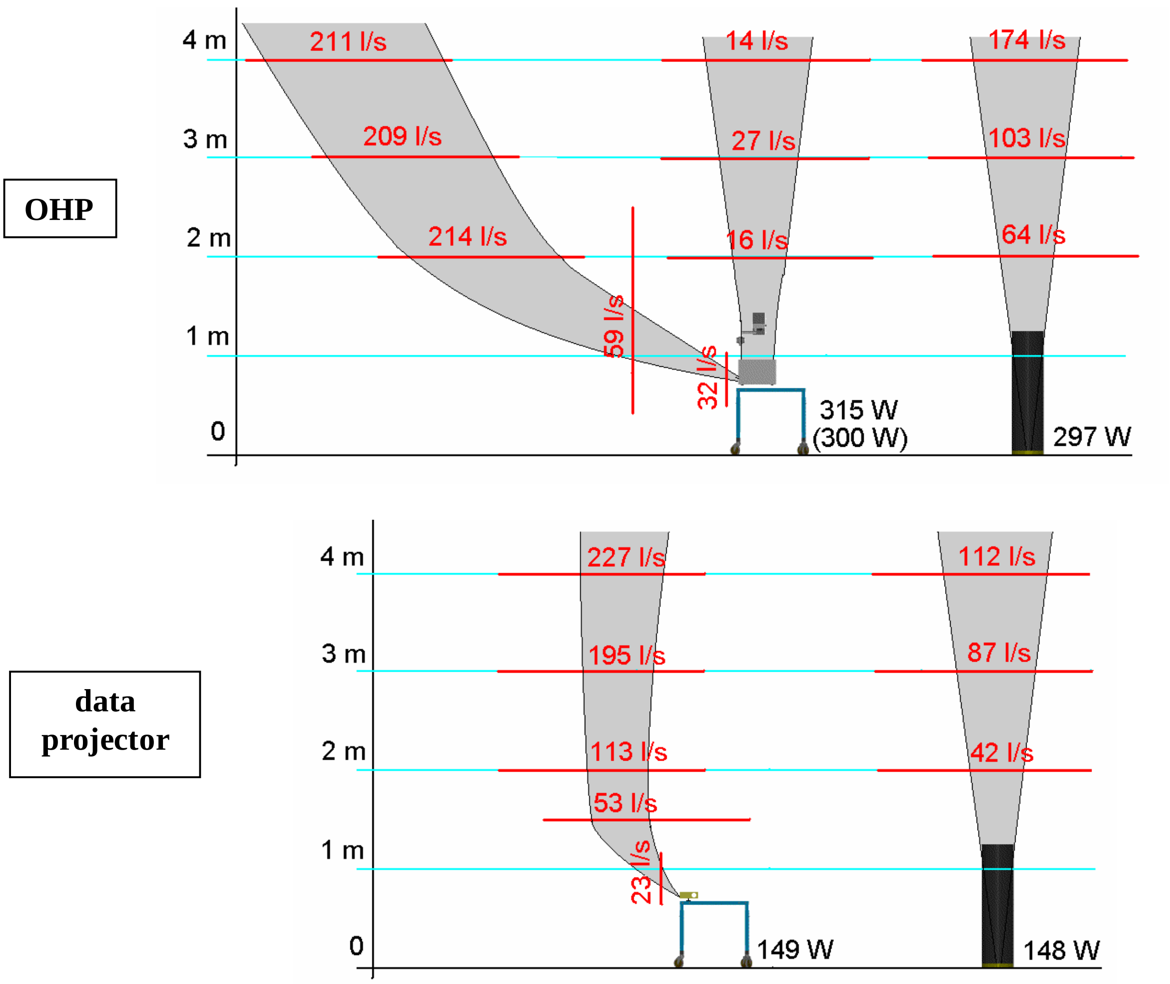

Figure 8. Measured convective volume flow rates of the projectors as compared with those of the black cylinder.

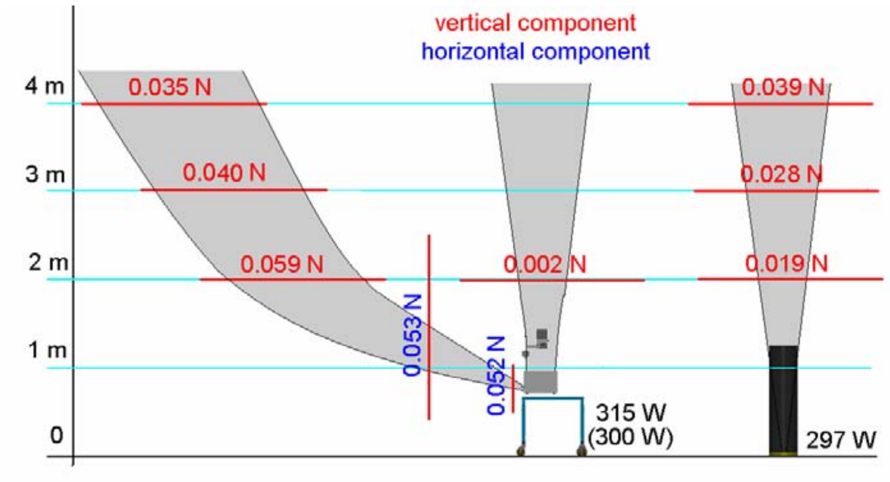
OHP



data projector

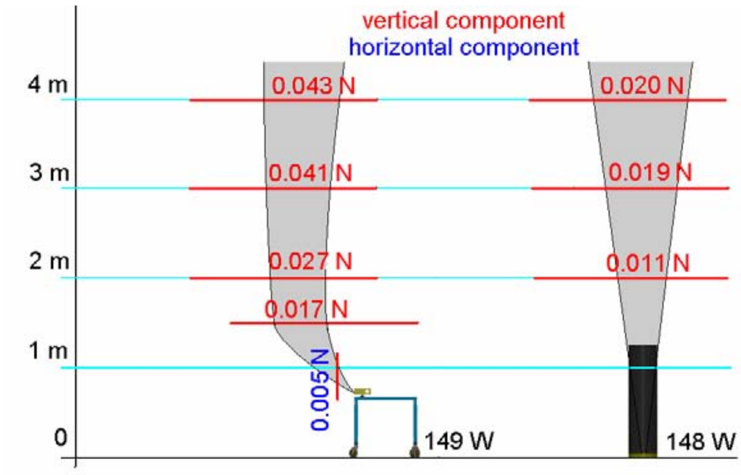


Figure 9. Measured convective momentum flow rates of the projectors v. the black cylinder.

According to the results, the most important of which are shown above, we can say the following:

- In the presence of device fan, a great majority of thermal losses takes place through convection.
- The fan and the increased buoyancy due to increased convection power multiply the convection flow (volume flow rate) by a factor between 2 and 4 as compared with a black cylinder with the same heating power. Therefore, it is a wise idea to attach a data projector to the ceiling.
- The vertical momentum flow rate is increased by a factor between 2 and 3. This can partly be explained by the increased buoyancy, but the most important reason to this are probably the pressure forces at the top surface of the reference cylinder, hindering the growth of the momentum flow rate. These kinds of forces do not confine the exhaust jets of the projectors. A totally new feature is the horizontal momentum flow rate due to the horizontal fan jet (blue numbers in Fig. 9).
- The temperatures of the plume air are not much different between the projectors and the cylinder with the same heating power. At the height of 2 m the maximal temperature in the plume of the overhead projector is 23.9 ºC, when for the cylinder heated by the power of 297 W it is 23.5 ºC. For the data projector and the cylinder heated by 148 W the corresponding values are 21.3 ºC and 22.2 ºC.

DISCUSSION

Common electric office appliances generally have a cooling fan producing a powerful flow of forced convection, which easily absorbs the natural convection flow along. This flow is a horizontal buoyant jet, which first behaves like a jet, and gradually changes to a buoyancy-driven plume. Prediction of the volume and momentum flow rates of such a flow is problematic, and in any case the near field has to be measured to obtain the initial values. In this study the behaviour of the (forced) convection flow in the jet, transition, and plume regions has been measured for two common office devices. The results were compared to results measured for a black cylinder, generating only a natural, buoyant plume.

The farther away the flow has traveled from its origin, the more challenging is its measurement. The reason to this is that the flow becomes cooler, slower, wider, and more disassembled on its way, making it more difficult to distinguish from the background. To provide a criterion to decide, how reliable the results are, the (thermal) energy flow rate (or the convection power) was always calculated together with the volume and momentum flow rates, see Fig. 7. Comparison of the electric power with the sum of the measured radiation and near field convection powers tells us, how the measurement of the initial values has succeeded. After this, the conservation of the measured convection power during the course of the flow gives a conception of how fast the measuring accuracy is deteriorating. Note, however, that when calculating the convection power, the convective temperature rise ΔT is also needed. It is obtained in poorer accuracy than velocity, and therefore the accuracy of momentum flow rate and, especially, volume flow rate is higher than that of the convection power.

As Fig. 8 shows, at the height of 2 m the volume flow rate of the overhead projector is 230 l/s. This is more than ten times the air flow above the head of a person (20 l/s, see [1]). The data projector, despite its relatively small power, also produces a convection flow rate corresponding to several persons. In addition, each person usually has a computer, producing a larger convection flow than the person himself [1]. Therefore, when dimensioning the ventilation air flow rate in stratification or zoning air distribution strategy, the office appliances should definitely be taken into account. Nonetheless, the ventilation air flow rate required can be reduced by attaching the data projector to the ceiling, above the occupied zone.

Filters and air cleaning

The Engineering of Practical Gas Phase Air Cleaning

Paul Spry

Spry Associates, Australian Capital Territory

Corresponding email: paul@spry.com.au

SUMMARY

This is one of two CLIMA 2007 papers on gas phase air cleaning by this author. The Science of Gas Phase Air Cleaning' covers aspects of air quality, gas phase air cleaning (particularly adsorption) limitations and opportunities, capital and energy saving impacts, and the role of Standards.

This paper discusses application parameters, deals with testing of gas phase air cleaners and presents odour removal efficiency test results for a product. Economics of use are discussed.

ACKNOWLEDGEMENT

This author gratefully acknowledges the financial assistance of the Australian Capital Territory Government in developing gas phase air cleaning apparatus and testing facilities.

This author gratefully acknowledges the assistance and cooperation of the Australian National University – particularly in allowing use of its facilities.

INTRODUCTION

The use of gas phase air cleaning (GPAC) in heating ventilation and air-conditioning (HVAC) applications - to remove building/occupant generated pollutants - is rare.

This contrasts with the use of particulate air filters which is near universal.

As indoor air pollutants are either particles or gases this contrast of technology use is stark.

The main barriers to GPAC use in HVAC are:
- Understanding of GPAC
- Product availability
- Testing
- Application approach.

OPPORTUNITY

Presently the HVAC contribution to good indoor air quality (IAQ) is by particulate filtration and use of ventilation to dilute odours (always, for practical purposes, in the gas phase) and other gas phase contaminants like volatile organics.

GPAC use presents the opportunity to reduce ventilation without reducing IAQ.

If ventilation is reduced energy use is reduced, HVAC plant size is reduced, kVA charges are reduced, plant efficiency may be improved, energy infrastructure needs are reduced and greenhouse gas production is reduced – refer to the other paper for more detail.

GAS PHASE AIR CLEANING

Only adsorptive (physisorptive and chemosorptive) air cleaners are dealt with here, as this author sees them as having most potential. Absorptive and (photo)catalytic approaches are not addressed.

Absorptive processes are usually water based, with the obvious problems – humidity control, legionella, chemical contamination of air etc.

(Photo)catalytic media is a possible solution but has the problem that it can sometimes adsorb reasonably harmless chemicals and catalyse them into more harmful species and release these into the airstream (perhaps this problem will be solved by developers).

This author favours adsorption – the pollutant is trapped and held in the media.

Typical adsorptive GPAC ‘media’ are activated carbon, activated alumina, zeolites, silica gel etc. These media may be ‘pure’ or they may be impregnated with chemically active ingredients to allow chemisorption.

A GPAC is usually a bed, of chosen thicknesss, of adsorbent material granules contained between metal mesh or like ‘porous to airflow’ material.

UNDERSTANDING GAS PHASE AIR CLEANING

Adsorption is qualitatively addressed in more depth in the other paper.

Quantitative (mathematical) treatment of adsorption is extremely difficult and the outcomes are exceptionally complex. Also sorbent material performance information is scant.

With application of considerable resources, the matter can be resolved but developed methodologies are largely kept confidential. This author has developed a predictive model. Useful published design recipes are rare, perhaps nonexistent. Industrial adsorption process design seems to be based on considerable experience.

A good (but not simple) overview and basic design data source is Perry’s Chemical Engineers Handbook 7th Edition Section 16 ‘Adsorption and Ion Exchange’.

GPAC BEHAVIOUR

Numerical examination of behaviour of possible and existing adsorptive GPAC’s reveals useful things. Descriptive material addressing adsorption is available – but, without numbers, few useful design conclusions can be drawn.

The efficiency (percentage removal of contaminant from air) of a specific adsorptive bed at a specific time depends on many factors - including contaminant concentration, contaminant nature, adsorbent nature, face velocity, temperature, effect of other contaminants, bed depth.

The actual proclivity of a sorbent to sorb a contaminant is paramount but after this the prime characteristic of interest, when considering performance of practical GPAC units, is depth of the media bed (dimension in the direction of airflow). This can be qualitatively referred to by calling these beds 'thick' or 'thin'.

Media bed depth is not to be confused with the overall size of a commercial GPAC. Such units are often composed of thin sub units arranged in 'v', 'w', etc formation so that much media face area is presented to the airflow. These composite units thus have a large dimension in the direction of gross airflow but the individual sub units have a smaller dimension in the direction of local airflow.

Variation, over time, of efficiency is particularly dependent on bed depth. This is now addressed, but in a simplified manner.

When presented with a substantially constant pollutant removal challenge a thick bed GPAC operates thus:

- At air inlet side of the bed there is part of the bed thickness (say ¼ of the thickness – as an aid to thinking) referred to as the mass transfer zone
- As air moves through the zone the pollutant concentration decreases until it becomes the practical minimum at the end of the zone (i.e. practically, as clean as it is likely to get – often close to 100% pollutant removal)
- As time passes, and more air is cleaned, the upstream part of the zone becomes increasingly saturated with pollutant and the downstream edge of the zone moves further downstream
- As more time passes the bed divides into three zones – an increasingly wide saturated zone, followed, by a largely constant width mass transfer zone and a increasingly smaller 'clean' zone
- The mass transfer zone may widen or narrow as it moves, depending on the adsorption relationship, A narrowing zone will asymptotically approach a constant width.

The practical outcome of the above is that a thick bed GPAC will have a substantially <u>constant pollutant removal efficiency</u> for a period of time and then this efficiency will decrease. Finally, when the bed is saturated the efficiency will be zero.

If a thin bed GPAC is used (i.e. the thickness is less than that of the mass transfer zone - the 'critical thickness') then the initial <u>efficiency</u> will be a chosen value and it <u>will decline from the time of first use</u>. This is usually an undesirable characteristic.

REQUIRED GAS PHASE AIR FILTER PERFORMANCE FOR HVAC

Example (typical in many places) HVAC conditioned airflow into an occupied space is about 50 litres per second per person (l/s/pp) – this is determined by thermodynamic needs i.e. it is the airflow required to deliver the required heat (or "coolth").

Typical "fresh air" flow into a space is about 10 l/s/pp – this is what is needed to maintain odour at acceptable levels – given conventional design practice.

Say 7.5 l/s/pp of this fresh air is replaced by recirculation air that has been 100% cleaned in a GPAC. And, also, that 2.5 l/s/pp of "fresh" air is delivered to dilute CO_2 and other pollutants etc to acceptable levels. In this scenario the 10l/s/pp of ventilation air is replaced by 2.5 l/s/pp of ventilation air plus 7.5 l/s/pp of cleaned air with the cleaned air being, in the case of many pollutants, cleaner than the ventilation (outside) air that otherwise would have been used.

Now, consider that the same outcome is to be achieved by use of a GPAC treating all conditioned air flow (i.e. 50 l/s/pp). The question arises "what is the required efficiency of this GPAC".

The answer: 7.5/50 or 15%. i.e. the required gas phase air cleaner odour removal efficiency is 15%. The required efficiency would be 10% if 5 l/s/pp was cleaned.

So, the required efficiency of a GPAC used for odour control in reasonably normal HVAC systems will be in the order of 10% to 20%.

AVAILABLE GAS PHASE AIR FILTER PRODUCT

Presently GPAC product is available for HVAC application. Mostly this product contains activated carbon or potassium/sodium permanganate impregnated activated alumina. A wide range of other impregnations (for carbon and alumina), including some with catalytic activity, are also available.

Generally, the % efficiency of this product (at any stage of its operational lifecycle) for removal of odours, or many other pollutants, will not be stated by the manufacturer.

Designers must rely on their experience etc and, perhaps, their 'blind faith'.

Most of this presently available commercial product is, in the context of claimed HVAC use for the removal of body odours etc and trace organics, thin bed. There is a small amount of thick bed product available but it seems to be aimed at industrial use.

This product will thus, generally, offer pollutant removal performance that will decline (from what value?) immediately and continuously, or soon and then continuously, after installation.

The presumed reason for one aspect of this undesirable situation is that a GPAC user must limit the air pressure drop to that he/she finds acceptable and GPAC manufacturers provide product to match this presumed requirement.

At the heart of this issue is the balance that must be made between the advantages to be obtained by GPAC use in HVAC (lowered ventilation, plant size, energy use etc) and the costs – particularly fan energy use. In some cases the problem is illusory, in most it deserves attention.

An optimal approach to many, if not most, practical situations is to be found in a recent Patent application[1]**.**

GPAC TESTING

A user of GPAC properly requires adequate performance data – though, to date, much use has been with rule-of-thumb design methods or pure faith.

GPAC may be used to remove pollutants that are undesirable from a health or like perspective. They may also be used to remove odours from air.

As many ventilation standards/requirements are based on odour control (with a smaller ventilation rate set for health reasons) e.g. Australian Standard AS1668.2: 2002[2], the major opportunity for economic application to HVAC use is in odour control – though VOC etc control is of importance.

A number of organisations (ASHRAE, ASTM, CETIAT etc) and some companies have done thorough and advanced work in the development of standards and apparatus for testing the removal efficiency of GPAC or GPAC media for specific chemicals – e.g. toluene.

If theory and data collection were sufficiently advanced then information from such testing may be applicable to calculation of odour removal by GPAC. However, it seems that we are presently a very long way away from this goal.

Accordingly, it is desirable that GPAC be directly tested for odour removal efficiency.

GPAC ODOUR REMOVAL EFFICIENCY TESTING

This author has developed GPAC odour removal efficiency test apparatus (a test rig) at the Australian National University. This apparatus is suited to the testing of full scale GPAC product. The apparatus is designed to test GPAC so that they may be used to gain 'outdoor air' concessions in accordance with the requirements of AS1668.2[2] (1991 and 2002 editions). Product has been successfully tested.

The mentioned test rig is believed to be the only one in operation or under consideration – anywhere. The test approach is now described.

Odour removal efficiency removal testing requires the use of human noses. Current sensor technology is not up to the task. The described methodology uses human odour assessors.

Traditionally, in respect of olfactory assessment of indoor air, there has been debate about whether assessors are to be (a) selected for olfactory capability or selected as being representative of the general population and/or (b) trained or untrained. Assessors selected for testing of devices in accordance with the methodology <u>are selected</u> for adequate olfactory capability and <u>may or may not</u> be trained for the specific or general task at hand. Assessors are selected in accordance with AS2542.1.3[3].

The method is conceptually straightforward:

- A panel of assessors samples two air streams and declares which is the most odorous
- In olfactory science terms this is a bilateral paired comparison test in accordance with AS2542.2.1[4] (tests other than the bilateral type may be chosen)

- Contaminated air is drawn from an enclosure reasonably representative of one for which the GPAC may be used (eg a nominated type of air-conditioned room with people in it)
- "Fresh' air is drawn from outside. Source/treatment conditions are specified
- Cleaned air is drawn from downstream of the GPAC
- A minimum GPAC odour removal efficiency is postulated
- A mixture of contaminated and fresh air (chosen to mimic air that has been cleaned by a GPAC of the postulated efficiency) is delivered to assessors
- Cleaned air is delivered to assessors
- The two airstreams are assessed and the most odorous is declared
- If the cleaned air is less odorous than the mixed airstream then the minimum efficiency of the GPAC (in the tested application) is as postulated
- The test is repeated, at a different postulated minimum efficiency, if required.

In operation the test rig has proved to be robust, efficient and effective.

The rig has few limitations, and these will be soon remedied. Presently the rig will only test a postulated efficiency up to a level just above 90%. At higher efficiencies one airflow falls outside the parameters of the airflow test measurement standard used (AS 2360.1.1: 1993[5]).

TEST RESULTS

A GPAC device for the removal of body odour and other building occupancy odours (established building) has been developed. The composition of the media bed is proprietary (a trade secret).

The GPAC has been tested. It has a minimum tested body odour etc removal efficiency of 90.4% with $P<=0.05$ error probability (criteria that is customary in sensory science, and other scientific and engineering applications). The calculated actual efficiency is in excess of 98%.

ECONOMICS

The economics of GPAC use to reduce ventilation costs is illustrated in the following table. Here the savings to be made by GPAC use for 14 Australian cities are tabulated. The calculations have used precise hourly outdoor dry/wet bulb frequency data. The cities represent most climate types but no really cold climate is represented so conclusions cannot be drawn for many north American and north European places. Note that the estimated savings in the table below are based on energy use at Australian prices. European prices are considerably higher.

Next table below assumes:

Ventilation rate reduction: 1000 litres/second (perhaps a 200 person building)
Cost of electricity for cooling: A$0.138/kWH, Cooling coefficient of performance: 3.0
Heating gas energy cost: A$0.0372/kWH, Heating system efficiency: 76%
Marginal capital cost of cooling effect: A$800/kW
A$=Australian dollar (in early 2007, A$1.0~0.6 Euro~USA$0.8)
6am to 6pm, 6pm to 6am or 24hr operation: 24C summer inside, 21C winter inside.
Economy cycle not used, no humidification, dehumidification only to 60% RH.

Australian City	*Climate*	*Marginal cooling plant cost (A$)*	*Annual cool+heat cost, day (A$)*	*Annual cool+heat cost, night (A$)*	*Annual cool+heat 24 hr (A$)*
Adelaide	Mediterranean	12,480	887	1290	2077
Alice Springs	Hot arid	15,440	1644	1461	3104
Brisbane	Sub tropical	18,240	1417	847	2264
Canberra	Temperate	4,880	1565	2406	3970
Cloncurry	Semi arid tropical	16,080	2622	1751	4373
Darwin	Monsoon	21,280	5011	4350	9361
Hobart	Cool temperate	3,040	1274	1913	3187
Melbourne	Temperate	10,160	1020	1511	2531
Mildura	Semi arid	14,880	1171	1531	2710
Perth	Mediterranean	12,096	893	978	1870
Port Hedland	Semi arid	15,360	3609	2603	6212
Sydney	Temperate oceanic	6,800	1018	1973	2991
Townsville	Wet tropical	25,680	3603	2405	6008
Wagga Wagga	Temperate	12,560	2224	1706	3930

The operation cost (media+energy) of the mentioned 1000 l/s unit, used as shown in reference 1, is likely to be in the region of $A1000 per annum for a typical office space (2500 hrs/year) use. The capital cost is not given here.

Clearly, GPAC use is cost effective in many climates. In many places it is cost effective in capital cost terms regardless of energy savings. It may be used only or principally to reduce capital and kVA etc. charges - thus reducing GPAC fan energy to negligible levels and extending media life to, perhaps, decades.

CONCLUSION

Now is an opportune time for the widespread introduction of gas phase air cleaners into HVAC applications. Various monetary savings and environmental benefits can be had worldwide. There is present ample opportunity for interested commercial entities to leverage recent developments into benefiting the greater good through improving indoor air quality and reducing greenhouse gas emissions.

ABSTRACT

While being used for years in industrial applications, gaseous contaminant sorption units such as activated-carbon filters remain marginal in office and residential buildings. This study deals with models that could help building designers and administrators to design and maintain activated-carbon filters depending on the environmental conditions (pollution load, airflow rate, temperature, humidity) they operate. More precisely, as a necessary first step of the development, the emphasis is put here on demonstrating the relevance of the models by comparing the predicted and measured breakthrough curves of various contaminants (isolated or as a mixture in the air) in dry and isothermal conditions. The results globally show a good agreement between predicted and measured data, while highlighting some interesting trends for future model developments. Beyond the question of model validation, the results also underline great discrepancies in the breakthrough time of the filter from one contaminant to another: the filter breaks within few tens of hours for some species when it breaks after several months for others. Considering the number of contaminant found in indoor settings, this shows that the question of the efficiency of the filter cannot be answered globally, and that the question of how often the filtering medium must be changed is not as simple as one can think.

INTRODUCTION

In the context of climate change, reducing drastically the energy consumption and related CO_2 emission of buildings has become a really challenging problem for most countries. For instance, the European directive on Energy Performance in Buildings (EPBD) estimates that the energy consumption of buildings should be reduced by 22% by the year 2010. Since ventilation can represent from 30 to 40% of the energy loss in new buildings, reducing the air change rate by using air cleaning systems may be an interesting solution to save energy while maintaining an acceptable indoor air quality. Two broad air cleaning technologies exist: oxidation techniques such as photocatalysis or cold plasmas have the advantage of decomposing organic compounds but face the problems of possible deactivation of the catalyst as well as possible yield of harmful secondary chemicals. On the other hand, adsorption systems such as activated carbon filters only trap gaseous species which means that the adsorption medium must be changed periodically to keep the filter efficiency. Then the question becomes to know how often the medium must be changed depending on the conditions the filter operates. Most existing methods are intended for industrial applications and cannot correctly account for the conditions encountered in buildings, especially time-varying mixtures of contaminants at low concentrations in the air, and in most cases fluctuating temperature and humidity at the filter inlet. The present paper addresses this problem. More precisely, the results presented here are part of a larger study aimed at developing physically-based models capable of predicting the dynamic change in the efficiency of a packed-bed activated carbon filter operating in such conditions. As a necessary first step of the development, the emphasis is put on demonstrating the ability of the models to accurately fit the breakthrough curves of any gas. After describing the models for isolated contaminants as well as for mixtures of contaminants in the supply air-flow, the paper presents a comparison between the predicted and measured breakthrough profiles of six contaminants pertaining to different chemical classes.

MODELS DESCRIPTION

The adsorption filter models used for the study have been developed based on contributions from Axley [1] and Yu and Neretnieks [2] in the early nineties, as well as theories and equations proposed for the dynamic modeling of filters used in industrial applications (see for instance Do [3] or Tien [4]). All these studies consider that the sorption dynamics in the filtering medium are governed by four elemental transport phenomena, namely advective transports (contaminants are carried by the airflow passing through the filter), diffusion through the boundary layer separating the bulk air-phase from the adsorbent surface, porous diffusion in the adsorbent, and adsorption/desorption processes at the pore surfaces. The existing models have first been extended for a better representation of the sorption equilibrium of individual species in the field of low concentrations. Then, a multi-component adsorption isotherm model was implemented to account for the interactions between species at the pore surfaces.

Filter model for single contaminants

Under isothermal conditions, the sorption dynamics of a single contaminant in a packed-bed of spherical activated-carbon pellets is described by two equations, one representing the mass balance of the contaminant in the inter-pellet air-phase, and the other representing the mass balance within the pellet:

$$\frac{dC}{dt} = D_x \frac{d^2C}{dx^2} - \frac{d(uC)}{dx} - \frac{1}{\rho_{air}} h_m A_s \left(C - C^*\right) \qquad (1)$$

$$\rho_{air} D_e \left(\frac{d^2 C_p}{dr^2} + \frac{2}{r}\frac{dC_p}{dr} \right) = \rho_s \frac{dC_s}{dt} + \rho_{air} \varepsilon \frac{dC_p}{dt} \qquad (2)$$

In equation (1), the first term of the right-hand side represents the contribution of turbulent axial dispersion. D_x ($m^2.s^{-1}$) is the axial dispersion coefficient, x (m) the axial dimension and C (kg/kg_{air}) the inter-pellet concentration. The second term, where u ($m.s^{-1}$) stands for the interstitial (inter-pellet) air velocity, represents the contribution of advective transports. Finally, the last term represents the contribution of boundary layer diffusion; ρ_{air} ($kg.m^{-3}$) is the air density ($kg.m^{-3}$), h_m ($m.s^{-1}$) the convective mass-transfer coefficient of the contaminant, A_s (m^2) the surface area of the pellets exposed to the bulk air, and C^* (kg/kg_{air}) the contaminant concentration at the pellet surface.

In equation (2), the left-hand side represents the radial diffusion within the adsorbent pellet. The terms on the right-hand side represent the contaminant accumulation in the air-phase of the pores, and the contaminant accumulation at the pore surface due to adsorption/desorption. C_p (kg/kg_{air}) is the pore air-phase concentration at radius r (m), D_p ($m^2.s^{-1}$) the diffusion coefficient in the pores, C_s ($kg.kg^{-1}$) the sorbed-phase concentration, and ρ_s ($kg.m^{-3}$) the activated-carbon density.

The continuity between the two equations is given by $C_p(r=R) = C^*$, where R (m) is the pellet radius. Moreover, since the adsorption/desorption transports at the pore surfaces are much faster than the diffusion transports, C_s and C_p can be considered to be always in equilibrium and related by the adsorption isotherm of the contaminant and adsorbent system:

$$C_s = f(C_p) \text{ or } C_p = f^{-1}(C_s) \qquad (3)$$

The Dubinin/Radushkevic equation is usually taken as the adsorption isotherm model for its predictive characteristics (*i.e.* the model parameters for any gas can be assessed from its physical properties, and the temperature dependence of the sorption equilibrium is included in the model). However, this model is not suitable for many indoor air applications since it isn't defined at $C_p = 0$. It will therefore fail in representing the behavior of filters at the first times and/or when the contaminant air-phase concentrations approach zero. To get round this problem, as well as probably better fit reality, the simulations presented hereafter were carried out considering a linear adsorption isotherm model, $C_s=K_pC_p$, where K_p (kg_{air}/kg) is the so-called partition coefficient of the contaminant / adsorbent system.

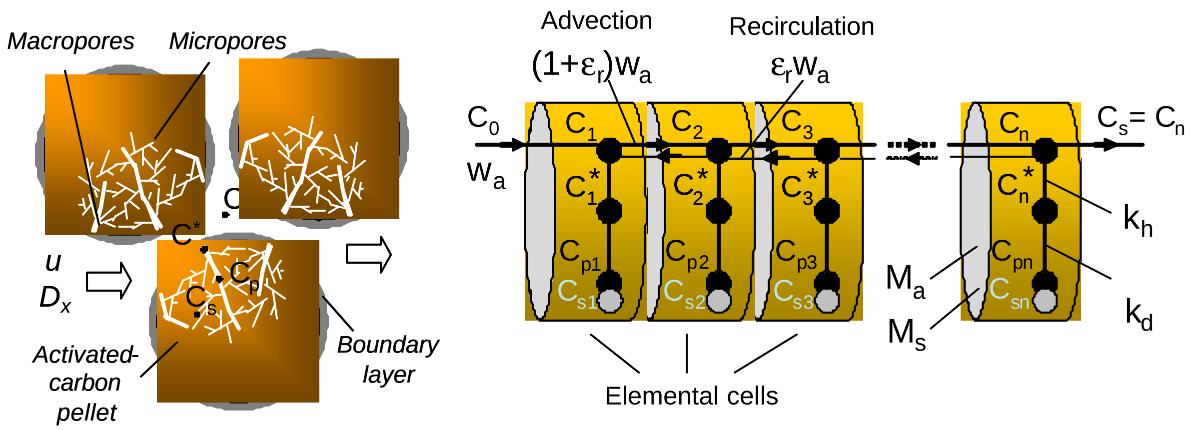

Figure 1: Schematic representation of the discrete filtering medium

To correctly account for the concentration gradients in the direction of the airflow on the one hand, and within the spherical pellets on the other hand, equations (1) and (2) are first discretized by decomposing the filter into n elemental cells connected in series (Figure 1); the concentrations C, C^*, C_p and C_s are assumed to be uniform within a same cell, but are of course different. Then, by using the linear driving force (LDF) assumption to describe the contaminant diffusion in the pores, equations (1) and (2) transform to the following equations where the only unknowns are the inter-pellet air-phase concentrations and the sorbed-phase concentrations in each cell, C_i and C_{si}, respectively:

$$\left|\begin{array}{ll} M_{a1}\dfrac{dC_1}{dt} = w_a C_0 - w_a(1+e_r)C_1 + w_a e_r C_2 - \dfrac{K_d K_h}{K_d + K_h}\left[C_1 - f^{-1}(C_{s1})\right] & \\ M_{ai}\dfrac{dC_i}{dt} = w_a(1+e_r)C_{i-1} - w_a(1+2e_r)C_i + w_a e_r C_{i+1} - \dfrac{K_d K_h}{K_d + K_h}\left[C_i - f^{-1}(C_{si})\right] & \text{for } i=2,n-1 \\ M_{an}\dfrac{dC_n}{dt} = w_a(1+e_r)C_{n-1} - w_a(1+e_r)C_n - \dfrac{K_d K_h}{K_d + K_h}\left[C_n - f^{-1}(C_{sn})\right] & \end{array}\right.$$

$$M_{si}\frac{dC_{si}}{dt} = \frac{K_d K_h}{K_d + K_h}\left[C_i - f^{-1}(C_{si})\right], \qquad (4)$$

M_{si} (kg) and M_{ai} (kg) are the mass of adsorbent and the inter-pellet mass of air in cell i, respectively; w_a (kg_{air}/s) is the airflow rate passing through the filter, and C_0 (kg/kg_{air}) the contaminant concentration at the filter inlet. Given that concentrations are thought to be very low compared to industrial applications, only the possible air recirculations between adjacent cells are considered for axial turbulent diffusion. The latter are characterised through e_r, a user-defined parameter ranging from 0 to infinity. $K_h = r_{air}A_s h_m$ and $K_d = 15 M_s D_p s/R^2$, with s being the slope of the adsorption isotherm at concentration C_p, ($s = K_p$ for a linear isotherm), represent the boundary layer diffusion rate and the diffusion rate in the pores of the pellets, respectively [1]. Each of the filter cells described by equations (4) was implemented as a mass transport component using the dynamic system simulation program Matlab/Simulink.

Filter model for contaminant mixtures

Except in the case of water vapour, contaminant concentrations in the outdoor as well as the indoor air seldom exceed few tens of $\mu g/m^3$. Consequently, it can reasonably be assumed that species do not interact when diffusing, but only compete for sorption at the pore surfaces of the adsorbent. In the frame of a study dealing with the ability of activated-carbon filters to clean the fresh air in heavily-polluted environments, Blondeau et al [5] used the volume exclusion theory as multi-component adsorption isotherm model. This model is more or less an extension of the Dubinin/Radushkevic isotherm for single gases and thus also fails numerically when the concentrations approach zero. Here, multi-component facilities were added in the model described above by implementing the extended Langmuir equation in equations (4). This equation expresses that the sorbed-phase concentration of a given species j, depends on the air-phase concentrations of all components k of the contaminant mixture through the relation:

$$C_{sj} = f\left(C_{pk,k=1,n_p}\right) = \frac{C^0_{sj} K_{Lj} C_{pj}}{1 + \sum_{k=1}^{n_p} K_{Lk} C_{pk}}, \qquad (5)$$

where C^0_s (kg.kg^{-1}) and K_L (kg_{air}.kg^{-1}) are the Langmuir equation parameters for the individual species. The slope of the adsorption isotherm for a contaminant j is then given by:

$$s_j = \left(\frac{\partial C_{sj}}{\partial C_{pj}}\right)_{C_{pk,k\neq j}} = C^0_{sj} K_{Lj} \left(\frac{1}{1 + \sum_{k=1}^{n_p} K_{Lk} C_{pk}} - \frac{K_{Lj} C_{pj}}{\left(1 + \sum_{k=1}^{n_p} K_{Lk} C_{pk}\right)^2} \right) \qquad (6)$$

Practically, implementing the extended Langmuir equation thus contribute to couple the mass transport equations: for n elemental cells and n_p contaminants in the air, the problem to solve is a set of 2 x n x n_p coupled differential equations.

Model parameters

As described by equations (4) to (6), the parameters of the models are the boundary layer mass transfer coefficients, h_m, the diffusion coefficients, D_p, and the sorption coefficients, K_p (single contaminant model) or K_L and C^0_s (multi-contaminant model).

Various correlations between dimensionless numbers can be found in the literature to determine the boundary layer diffusion coefficients in packed-beds of adsorbents. Two were considered here, the Ranz-Marshall (RM) and the Wakao & Smith (WS) correlations [4]:

$$\text{Ranz-Marshall}: Sh = 2.0 + 0.6Sc^{1/3}Re^{1/2} \qquad \text{Wakao \& Smith}: Sh = 2.0 + 1.1Sc^{1/3}Re^{0.6} \quad (7)$$

In these expressions, the Sherwood (Sh), Schmidt (Sc) and Reynolds (Re) numbers are defined by:

$$Sh = \frac{2Rh_m}{D_m},\ Sc = \frac{\mu_{air}}{\rho_{air}D_m} \text{ and } Re = \frac{2RG}{\mu_{air}}, \qquad (8)$$

where D_m ($m^2.s^{-1}$) is the molecular diffusivity of the contaminant in the air, μ_{air} ($Pa.s^{-1}$) the air viscosity, and G ($kg.m^{-2}.s^{-1}$) the mass flux per unit cross-sectional area of empty bed.

If neglecting both solid and surface diffusion transports, diffusion in the adsorbent pellets reduces to air-phase diffusion in the porous interstices. The latter is characterized by the effective diffusion coefficient of the contaminant/adsorbent systems, D_e ($m^2.s^{-1}$), which can be assessed from the relations [3]:

$$D_p = D_e = \frac{1}{\tau}\left(\frac{1}{D_m} + \frac{1}{D_k}\right)^{-1} \text{ and } D_k = 97r_p\sqrt{\frac{T}{M}}, \qquad (9)$$

where D_m and D_k ($m^2.s^{-1}$) are the molecular and Knudsen diffusivities of the contaminant, respectively; T(K) stands for temperature, M ($kg.mol^{-1}$) for the molecular weight of the contaminant, r_p (m) for the macropore mean radius, and τ for the tortuosity factor of the pores.

COMPARISON BETWEEN EXPERIMENTAL AND NUMERICAL RESULTS

As a way to assess the reliability of the models, and to identify the needs for future developments, experiments carried out on a packed-bed of commercial activated-carbon pellets (mean radius R = 1.1 mm) were simulated under Matlab/Simulink. These experiments were small-scale laboratory experiments aimed to determine the breakthrough curves of six contaminants pertaining to different chemical classes. The tests were first carried out with each gas isolated in the air, and then with all the gases in mixture. In all cases the airflow rate was 0.610 kg/h and the temperature was set to 20°C±2°C. In the absence of reliable sorption data for the activated-carbon tested, the partition coefficients K_p were determined from the sorption equilibrium obtained experimentally: after the filter breaks, the air-phase concentration is the same throughout the filter and equal to the concentration at the filter inlet, C_0. The corresponding equilibrium sorbed-phase concentration, and subsequently the partition coefficients, can be assessed from the total mass of gas adsorbed by integrating over time the contaminant masses entering and leaving the filter, that is:

$$K_p = \frac{C_s}{C_0} = \frac{m_s / M_s}{C_0} = \frac{1}{C_0 M_s}\left(\frac{w_a}{\rho_{air}}C_0 t_p - \frac{w_a}{\rho_{air}}\int_0^{t_p} C(t)dt\right) \qquad (10)$$

Equivalent K_L and C_s^0 values were also determined from the computed K_p to feed the multicomponent models. Table 1 summarizes all the model parameters corresponding to the single contaminant and multi-contaminant tests. To simulate the sorption dynamics of a new filtering media for each test, the concentrations in all cells were set to zero at time t=0 (initial conditions of the models). In all cases, the filtering medium was divided into 50 elemental cells of same length in the direction of flow. The re-circulation factor was set to 0 (ideal piston flow). Given the strong uncertainty on 1) the convective mass transfer coefficients (the coefficients obtained from the RM correlation are about three-fold the ones returned by the WF correlation, see Table 1), 2) the actual convective surface area (A_s is lower than the surface area of a pellet times the number of pellets due to contacts between pellets), and 3) the sorption coefficients, five simulations were carried out for each isolated contaminant: first, the uncertainty on K_h was accounted for by considering the reference values of K_p (and resulting K_d, see Table 1), and repeating the simulations for $K_{h,\max} = K_{h,ref} = \rho_{air} A_{s,\max} h_m^{WF}$ and $K_{h,\min} = \rho_{air} \frac{A_{s,\max}}{2} h_m^{RM}$. Then, three other sets of simulations were carried out considering $K_h = K_{h,ref}$ and $K_p = K_{p,ref} \pm 25\%$ to account for the presumed uncertainty on the latter parameter. The predicted breakthrough curves as well as the experimental data for the six contaminants are depicted on Figure 2. For the multicomponent case, the simulations were carried out considering the K_h values computed from the RM correlation and the Langmuir coefficients presented in Table 1 (Figure 3).

Table 1 : Model parameters corresponding to the tests

	R134a	Acetaldehyde	Ethanol	Acetone	Cyclohexane	Toluene

If focusing first on the only numerical results, Figure 1 shows that decreasing K_h tends to level the predicted breakthrough curves. Increasing K_p also contribute to level the profiles but overall to delay the predicted breakthrough time of the filter. Then, it can be noted that the predicted concentrations at the filter outlet correctly fit the experimental data: the predicted breakthrough time agree with the measured ones, and the predicted concentrations are within the combined uncertainty range of K_h and K_p. It is important to emphasize here that only the sorption equilibrium state obtained experimentally were used to draw the K_p coefficients, and therefore the breakthrough profiles are not mathematical fits of the experimental data. The only contaminant for which the results aren't fully satisfactory is R134a: the breakthrough time is correct but the predicted concentration profile clearly do not resemble the measured one. Of all the possible explanations, the most likely is that the linear adsorption model fails for R134a due to its very high vapor pressure. Despite the strong uncertainty on the parameters of the Langmuir adsorption isotherms, the predicted profiles also correctly fit the experimental data for the contaminants in mixture. Exceptions are acetone (breakthrough time overestimated of about 200 h) and acetaldehyde. In the latter case, it is interesting to note that the predicted breakthrough time seems to be correct but the filter surprisingly breaks at a concentration which is about half the inlet concentration. There are few doubts that this phenomenon originates from a binary surface reaction which contribute to consume acetaldehyde (and which is of course not accounted for in the model!). Unfortunately the tests were stopped two early to determine if toluene could be the other reactant involved in the reaction.

Beyond the problems of model validation and future numerical developments, all the results presented here underline the strong discrepancies in the breakthrough time of the filter from one contaminant to another. These breakthrough times vary from few hours for R134a and ethanol to several thousands of hours for toluene, which inevitably poses the question to know which contaminant to consider for maintenance issues. Should the life of the filtering media be based on high affinity contaminants such as toluene, with the consequence that the filter will be ineffectual in removing many other species contained in the air, or should it be based on lower affinity contaminants, with the consequence of much higher operating cost?

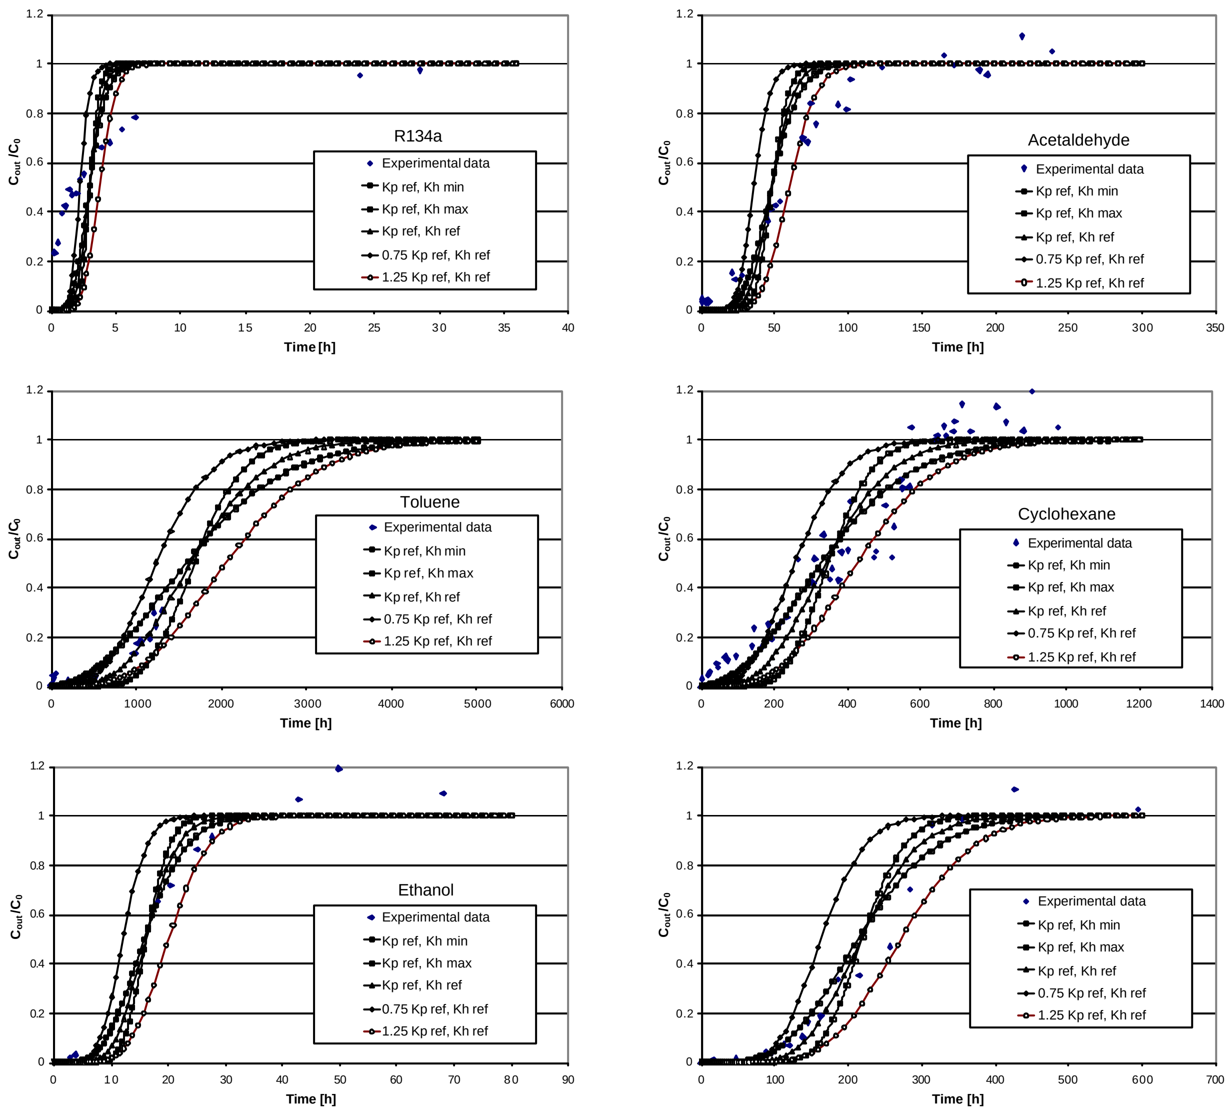

Figure 2: Breakthrough profiles of the contaminants isolated in the air

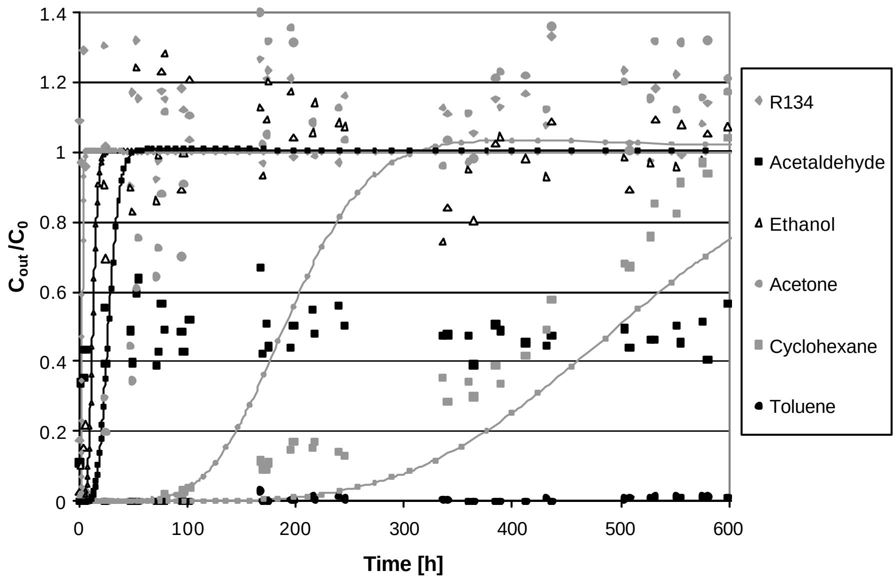

Figure 3: Breakthrough profiles of the contaminants as a mixture in the air

CONCLUSION

The results presented in this paper are a first step in developing dynamic adsorption filter models capable of accounting for all the elemental phenomena involved in the sorption process on the one hand, and the operating conditions characterizing building applications on the other hand. The predicted breakthrough profiles under dry and isothermal conditions globally fit the experimental data, which is a necessary condition for further developments of the models. Priority studies will now be directed toward coupling the mass –transfer equations with equations representing the thermal transfer in the filtering media, implementing functionalities to represent the influence of air humidity (absorption/desorption models, humidity-dependent diffusivities, …), and adding surface chemistry models. It is important to note that progressing toward reliable design tools also needs more experimental data on surface reactions (models exist but very few is known about the species involved and the reaction kinetics) as well adsorption isotherms of contaminants in the range of (very) low concentrations.

SUMMARY

We have performed studies onboard cruise ship to study the particle number concentrations, the commonly used filters and the utilization of novel filtration technologies. We observed that the majority of particles in the indoor air of a ship - and this applies when the ship was sailing in clean or polluted outdoor air - are smaller than 1 micron, and mostly of the of the sizes of combustion particles (ultrafine particles). We also observed that the commonly used filters mainly filtered particles larger than 1 micron. Thus we were able to improve the indoor air quality dramatically by introducing a new filtration technology that filters efficiently not only particles but also gas/vapour phase impurities. The same technology was further applied in an urban office to generate a clean breathing zone, and the results were promising: The breathing zone air was cleaned with up to an efficiency of 73,6%. Also subjective results from the people involved in the test were positive

INTRODUCTION

Indoor particulate and gaseous pollutants cause health problems and make living or working uncomfortable. Recently researchers have shown that there is a direct relationship between the productivity of employees and the indoor climate. Even though studies of outdoor pollutant concentrations and their drifting to indoor environment are abundant, and the awareness of the adverse health effects increase, the utilization of efficient filtration does not.

Ambient particle concentrations and their health effects

Studies of aerosol number size distributions show that the majority of the particles are in the so-called ultrafine mode, i.e. their diameter is less than, or of the order of, 100 nm [1,2]. E.g. Car engines and burning processes emit small particles. Especially the diesel exhaust particles have been shown to cause health problems: the ultrafine diesel particles increase response to allergens and have been proven to be carcinogenic [3,4]. Filtration classes better than EU 7, rather even HEPA class, should be used to efficiently remove the ultrafine particles.

Gaseous phase pollutants

Gas and vapor pollutants are in most buildings not filtrated at all, and thus compounds originating outdoors or emitted indoors are carried around the premises through the HVAC system. Compounds that have recently been studied are e.g. ozone and volatile organic compounds (VOC). Ozone episodes are regular in European cities and VOCs are emitted when e.g. fossil fuels are burned. There are also several indoor sources of VOCs. Much studied VOCs are the benzenes, which are known carcinogens – exposure to benzene is e.g. related to the development of leukaemia and lymphoma.

Re-circulation

In many locations circulation of air is considered the most energy efficient method. Re-circulation, however, also circulates the impurities emitted indoors. By filtering air at the return air units or in a Fan Coil Unit (FCU) it possible to increase the level of comfort and to protect the HVAC system. We have studied different levels of return air filtration and the consequent effect on particle concentration and e.g. sensed odours.

Studies in real environment

Researchers have reported high particle numbers (Aitken and Accumulation mode) measured indoors in urban environment. Several studies also report that these are the most abundant modes in marine air. Thus we saw a need to study indoor air of a cruiser ship. In a cruiser ship the ratio of re-circulated air is usually high – the objective of our study was to determine whether there are significant indoor sources and to what extent are the ambient particles transported indoors. And further to study the effect of different filters in reducing the particle concentrations.

The marine studies also offered us a kind of a micro-environment whose results can directly be applied to land applications and especially to cases where re-circulation of air is used: In some buildings it is not possible to increase the power of the HVAC system to meet the clean air requirements of e.g. people with allergies. For example in a premise with a suspected mould problem, where the actual source of the spores has not been located, clean air should be supplied to the person's breathing zone without a need to increase general air supply. Such an approach has also been studied in an office with good results. We wanted to study the actual particle concentrations, but also the sensed effect of the improved indoor air: does the decrease in indoor pollutants affect the subjective results i.e. make the test persons feel well in their current workplace/station.

METHODS

Ship measurements

The ship study was conducted on a large cruiser ship operating on the Caribbean seas. The trial project phases:
1.) Pre-study and installation of the filters and sampling lines: a) the pre-existing situation was studied through measuring the particle concentrations in airflows of four fan coil units. For this sampling lines were installed into the fan coil units; b) improved particle and gas filters were installed into two of the selected fan coil units; c) the aerosol particle measurements were repeated for each of the four fan coil units to define the short-term effect of the filters.
2.) The concentration of aerosol particles was measured every 1-3 weeks by the ship personnel for a period of six months.

Four sampling lines were installed into each fan coil unit: 1) air that was returned from the cabin to the fan coil unit, 2) return air after the filter in the fan coil unit; 3) the air coming from the main air handling unit (AHU); 4) air mixed of the filtered return air and the air from the air handling unit (supply air to the cabin).

The advanced filter technology was a filter bag that consisted of filter media for both particles and gases. The particle filter media is pre-charged, and thus capable of collecting also submicron particles. The gas (and vapour) media is based on activated carbon. Both filter medias are manufactured in a way that enables a very low pressure drop (filtration efficiency EU7). In one of the cabins also a particle charger was used to gain an even higher filtration efficiency; a particle charger in front of the filter bag results in a HEPA-class efficiency.

Aerosol particle number concentrations were measured with an optical particle counter. The device calculates the number of 0.3, 0.5, 0.7, 1.0, 2.0 and 5.0 mm particles per a litre of sample air, it also measures the relative humidity and temperature. The main focus of the trial was, on sub-micron particles that penetrate traditional filters. Such particles are most abundant in all environments and have been proven to cause adverse health effects.

Measurements in an office

Measurements of the effect of a local clean air breathing zone were conducted in an office in Helsinki, Finland. The office is going to be renovated in the near future, due to suspected mould problems. The office room is used by 4-5 people, out of whom two have asthma and one allergies.

A office desk, with an integrated air filter system, was installed into the office room for the duration of the tests (5 weeks). The filtration system re-circulated air, ths acting as a local air cleaner. The desk had two clean air nozzles leading air from the filter unit to the breathing zone of the worker using the desk. The distance between the nozzles was 120 cm, and they were situated at even distances on both sides of the computer keyboard (which was considered the centre point of the desk).

The effect of using the filter unit was measured using an optical aerosol particle counter, with main focus on 0,3 μm particles. Measurements were performed above the keyboard at the height of the face of the person using the desk. Effect of different flow velocities through the filter system were studied.

During the study the users of the desk was interviewed weekly to find out the subjective response to the filtering of air.

RESULTS

Ship measurements

The installation took place during a dry dock of the cruise ship. The shipyard is located in the vicinity of a European city. During dry dock the measurements the median ratio of the concentration of 0.3 micrometer particles of the supply air to the cabin ("to the cabin" = filtered + air from AHU) compared to the concentration of the particles in the air from the AHU was 0.90 for cabin A (min 0.81, max 4.14), 0.41 for cabin D after installation of the filter (min 0.21, max 0.51), 0.71 for cabin B (min 0.50, max 0.88), and 0.46 for cabin C after the deployment of the filter (min 0.36, max 0.58). This shows that at the dry dock the air from the AHU was usually the biggest source of small aerosol particles. It also shows that even though the filtration efficiency of the advanced filters was on the average 95% for the filter bag, and 97% for the filter bag & charger, the air entering the cabin can only be filtered up to

the ratio defined by the air flows: the amount of air from the AHU with respect to the amount of circulated air from the cabin.
Already during the pre-measurement phase few occasions with very high emissions of particles within the cabins were observed. They were related to people getting ready to go ashore: Perfumes, hairspray, fixing of clothes and similar sources are the likely causes of the detected high particle numbers. Similar events occurred occasionally through out the study period, but mostly the particles of the air from AHU outnumbered the indoor emissions.

We observed that at all times the number of the particles increases dramatically with decreasing particle size. This is true for all measured samples: air that enters the FCU from the cabin, air that has been filtered in the FCU, the so called fresh air that comes from the main AHU and the air supplied to the cabin (mixed of filtered air and fresh air). Fluctuations in the particle numbers are due to the different environments the ship has sailed at: the number of 0.3 micron particles in the fresh air (i.e. the air that came from the AHU) ranged from 2 000 particles per litre up to more than 250 000 particles per litre. During the trial the AHU contained filters that are comparable to the standard filters used in the fan coil units. Examples of the measured particle number concentrations are shown in Figures 1 and 2.

Filtration efficiencies for the studied filters are shown in Table 1. The median is used due to the few occasion when the filters seemed to emit particles – such data points would affect the calculation of averages to an unrealistic level: e.g. for the standard filters in cabin A, the median filtration efficiency for 5 um particles was 67%, but the average only 42%. For the advanced filters the average and the median did not differ remarkably.
Please note that the calculated filtration efficiencies for the largest particle sizes (1, 2 and 5 micrometers) were not representative at all times: occasionally the sample air only contained very few of these particles and thus the statistics during such times is very poor. The largest particles might also in some cases deposit on the surfaces of the FCU and then the observed particles are rather due to re-suspension than penetration through the filter at the measurement time.

Table 1. Median filtration efficiencies for the filters in the fan coil units

Cabin & filter	0.3 μm	0.5 μm	0.7 μm	1.0 μm	2.0 μm	5.0 μm
A, Standard	2%	2%	5%	12%	20%	67%
B, Standard	1%	2%	5%	9%	17%	50%
C, Advanced filter bag	91%	95%	96%	97%	98%	100%
D, Advanced filter bag &Charger	97%	97%	98%	98%	99%	100%

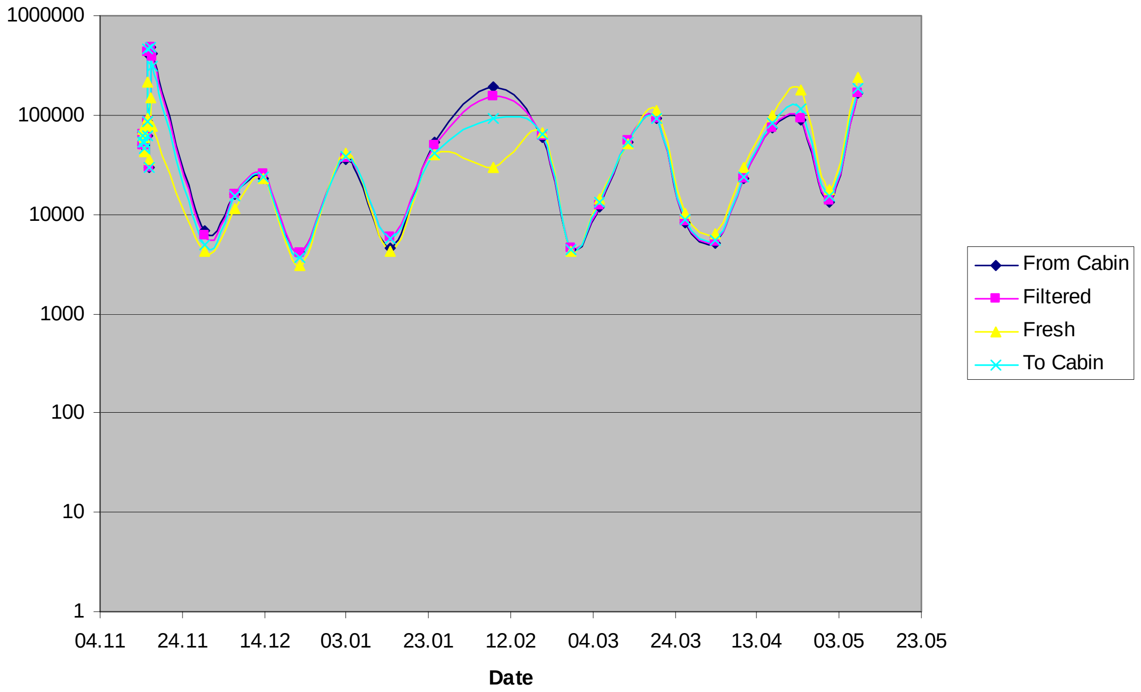

Figure 1. Measured concentrations of cabin A (with standard filter): on vertical axis the number concentration of 0,3 µm particles in a litre of air, on the vertical axis the measurement time.

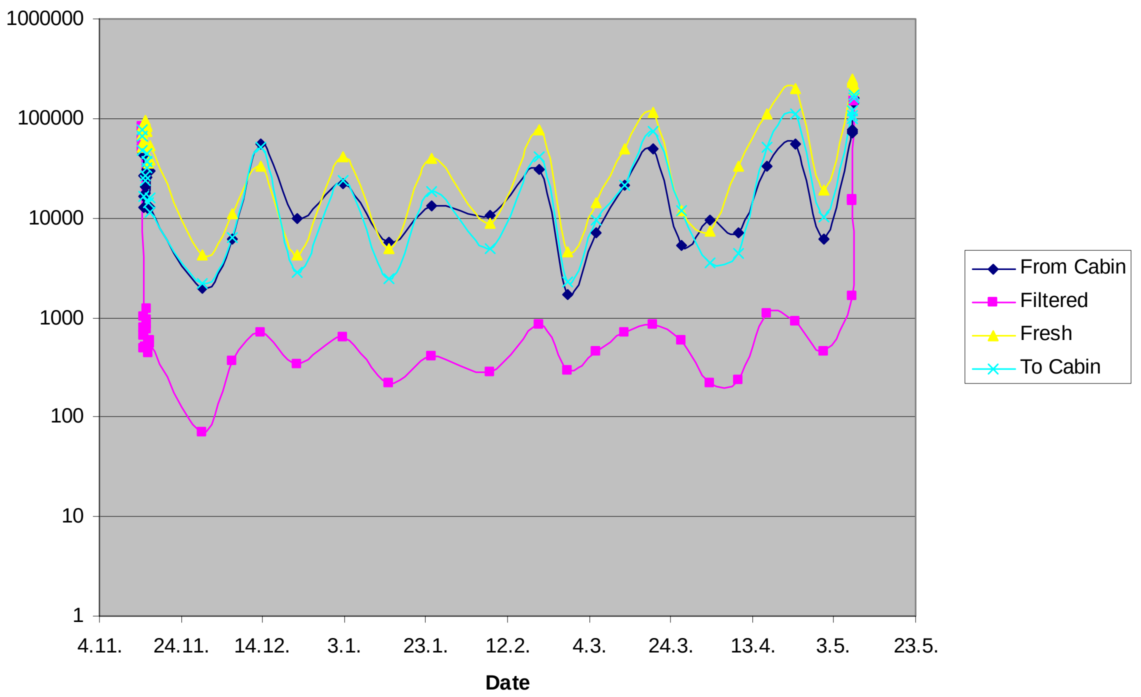

Figure 2. Measured concentrations of cabin D (with advanced filter and the particle charger): on vertical axis the number concentration of 0,3 µm particles in a litre of air, on the vertical axis the measurement time.

Measurements in an office

The effect of the air filtering desk was remarkable. The highest cleaning efficiency (for 0,3 μm particles) within the breathing zone was 73.6% when the system was running on maximum air volume. The cleaning efficiency is defined as the ratio of particles in the breathing zone when the filter system is running compared to the number concentration of particles in the breathing zone when the system is switched of.

Table 2. Average cleaning efficiency of the filter unit integrated to the office desk.

	Cleaning efficiency	Filtration efficiency of the filter unit
Lowest volume flow through the filter	52.1 %	99.55%
Highest volume flow through the filter	73.6%	99.45%

The interviews revealed that during the trial period while working by the desk the symptoms the worker suffered from occurred less frequently or vanished completely.

DISCUSSION AND CONCLUSION

All the studies showed that the effect of using good air filters is dramatic. In the ship, especially when the ship visited urban harbours, ambient pollution is remarkable and thus good filtration should be placed on both the main air handling unit and in to e.g. fan coil units. Filters in the fan coil units reduce the negative effects of recycled air (i.e. removes the indoor emissions)

The office study showed that air in challenging indoor air environments (with respect to particle sources that can not be located & removed) a local clean air zone drastically improves the air quality. The breathing zone air was cleaned with up to an efficiency of 73,6%. Also subjective results from the people involved in the test were positive: they had less symptoms and hence less sick-leaves even though they continued to work in an environment that earlier caused the symptoms to occur. Whether the positive subjective results are due to the reduced air impurities or the psychological effect of the efforts to improve the situation, can not be determined based on the short study. However, if the intention is to minimize the amount of particles in the breathing zone of the work place and hence improve the well being of an employee, then the results are conclusive both based on measurement data and subjectively.

SUMMARY

A satisfactory indoor air quality (IAQ) relies, amongst other things, on the availability of clean ventilation air. The outdoor air cleanliness in many urban environments is far from optimum. Fine particles (FPs ≤ 2.5 μm) and certainly ultra-fine particles (UFPs ≤ 0.3 μm) feature prominently as hazardous constituents of common urban air pollution. Installed filters in ventilation units of buildings and cars can clean mechanically supplied ventilation air. However, because affordable particle sensors of sufficient reliability and robustness are not commercially available, the degree to which the applied ventilation and filtration strategy is able to control the absolute indoor pollution level at any time remains usually unknown. This paper introduces a UFP sensor capable of recording the ambient UFP pollution level, yielding a sensor signal that relates to the relative inhalation-induced health hazard of airborne UFPs. The monitoring functionality of this sensor can be used for creating awareness with regard to the ambient UFP pollution level. For control purposes, UFP sensors can be used in addition to common T, RH and CO_2 sensors. Furthermore, a new type of electrostatically-enhanced particle filter is presented that accomplishes its air cleaning functionality in a more energy-efficient way than a comparable mechanical filter. Providing air handling units with particle filters as well as with UFP sensors downstream of these filters and/or in indoor spaces allows for a versatile control of air handling units that explicitly takes the indoor UFP pollution level into account as a decision factor for the ventilation strategy. This enables an enhanced sensor-controlled fine-tuning of the IAQ with anticipated savings in power consumption.

INTRODUCTION

In the Western World, most people spend over 90% of their time in indoor environments such as homes, offices and cars. The indoor air quality is therefore very relevant for human health and comfort. Important indoor air quality parameters comprise the temperature (T), the relative humidity (RH), the CO_2 level and the air pollution level [1]. In recent years human productivity has also been found to depend on the indoor air quality [2 - 3], thereby further emphasizing the economic significance of optimized air quality parameters. Several air treatment/handling devices (fans, heaters, coolers, (de) humidifiers, ventilation systems, cleaning systems) are often present to help maintaining an acceptable indoor air quality. However, the energy-hungriness of these devices and rising energy prices have since long promoted energy saving measures such as better home/building insulation and partial air re-circulation by air handling units. An accompanying aspect of the latter measures is a generally decreased ventilation rate. Ample evidence has come forth [4] that the decreased ventilation rates are frequently insufficient for maintaining an acceptable if not optimum indoor air quality, and are at least partly responsible for an overall increasing indoor air pollution level.

Indoor air pollution is directly related to various diseases, feelings of discomfort, reduced work performance and a diminished learning capability at school [4]. Part of the indoor pollution comes from indoor sources such as outgassing building materials and equipment, human bio-effluents, and activities like cooking and smoking. Supplied ventilation air and/or exhaust indeed diminish the pollutant concentration derived from indoor sources through dilution, however ventilation also introduces pollutants from outdoors. Hazardous outdoor pollutant species comprise allergenic particles (e.g. pollen), bioaerosols, and particles/gases originating from automobiles and industrial activities. Especially the fine particles (FP ≤ 2.5 μm) and even more so the ultra fine particles (UFPs ≤ 0.3 μm) derived from combustion processes (e.g. soot particles) are currently receiving much attention from various legislative authorities because of their demonstrated long-term impact on human health [5]. Outdoor particle concentrations vary considerably in time and place but are relatively highest in urban areas and/or close to motorways. As of today, the use of air filters in air handling units possessing a substantial filtration efficiency towards all particle sizes down to 100 nm diameter and below is still the exception rather than the rule. Any existing passive ventilation is anyway accompanied by an unhindered intrusion of pollutants from outdoors.

A rigorous filtration of sufficient amounts of ventilation air is the most direct way of dealing with polluted indoor air, however it is not the most economical approach. An introduction of (localized) ventilation on demand and air cleaning on demand offers better prospects in this regard but depends on the availability of practical and reliable air pollution sensors. Only CO_2 sensors and motion sensors detecting human presence are currently used for enabling ventilation on demand in spaces like meeting rooms and school classes wherein many people reside. Reliable and robust particle sensors or gas (VOC, NO_x) sensors capable of measuring the (relatively very low) absolute gas concentration levels in polluted indoor air have up till now not become available in the market place at an acceptable price level.

The present paper discusses a UFP sensor that can be installed in air handling units and/or in separate indoor rooms. Its output signal can be used to adjust the ventilation and air cleaning strategy to existing needs in a more sophisticated and economical way than what has been possible up till now. Ideally, the UFP sensor is used to complement the information obtained from T, RH and CO_2 sensors and can be integrated in a building automation system.

Whenever the outdoor air has an unacceptable cleanliness level, it is desirable to avoid any natural ventilation and pass all mechanically supplied ventilation air through one or more filters to accomplish a sufficient degree of air cleaning prior to its release indoors. The novel embodiment of the electrostatically-enhanced particle filter presented in this paper can be of help to also accomplish the particle filtration step in a more energy-efficient way than what is achievable when conventional mechanical filters of similar size and performance are used.

EQUIPMENT

UFP sensor

All common particle sensors are currently optical sensors capable of detecting particles down to 300 nm diameter, the most expensive ones down to 100 nm. Because of their price (at least a few thousand Euro’s) and maintenance requirements, their use is limited to monitoring clean

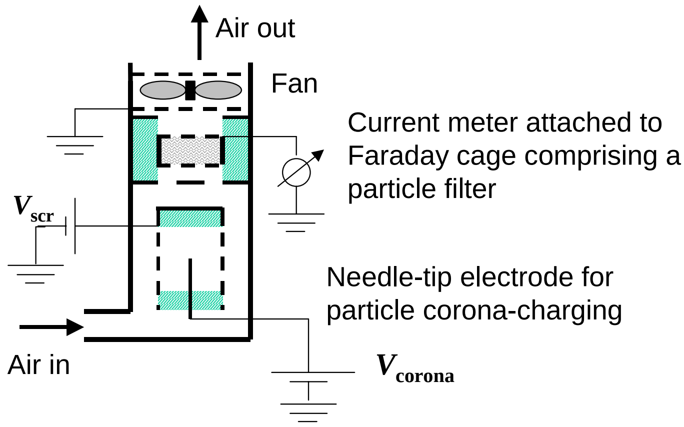

Figure 1:- Schematic design of the UFP sensor

room environments and professional air pollution measurements. Optical sensors are incapable of detecting particles smaller than 100 - 300 nm, even though most combustion-related ultra fine particles, and also cigarette smoke particles, are smaller than 100 nm.

To fill this technology gap, we realized an electrical UFP sensor that is particularly sensitive for detecting hazardous ultra fine particles down to sizes as small as 10 nm. A schematic design of the home-built UFP sensor is depicted in Figure 1. A small airflow ϕ is drawn through the sensor by means of a mini-fan situated atop the sensor. Airborne particles entering the UFP sensor are first charged via diffusion charging [6] with a corona discharge from a needle-tip electrode (set at V_{corona}) that is surrounded by a separate screen electrode whereupon a screen voltage $V_{scr} << V_{corona}$ is imposed. Subsequently, the charged particles are captured within a filter situated inside a conducting Faraday cage. A current meter attached to this cage records the amount of particle-bound charge that deposits inside the filter per unit time as a current I_{sensor}. I_{sensor} constitutes the sensor signal.

Because particles are charged via diffusion charging, one has for the average number of elementary charges "$p(d_p)$" that attach to a particle of diameter d_p the proportionality

$$p(d_p) \propto d_p \tag{1}$$

[6]. In practice, a particle size distribution $\frac{dN(d_p)}{d\ln d_p}$ is encountered in the ambient air wherein $dN(d_p)$ denotes the particle concentration for particles of diameter d_p. An integration of the particle size distribution over all particle diameters d_p yields the total airborne particle number concentration N_{total} (particles/cm^3) according to

$$N_{total} = \int_{d_p=0}^{\infty} \frac{dN(d_p)}{d\ln d_p} d\ln d_p \tag{2}$$

The sensor signal I_{sensor} relates to the ambient particle size distribution and the airflow ϕ (m^3/s) through the sensor according to

$$I_{sensor} = \int_{d_p=0}^{\infty} \phi p(d_p) e \frac{dN(d_p)}{d\ln d_p} d\ln d_p \propto \int_{d_p=0}^{\infty} d_p \frac{dN(d_p)}{d\ln d_p} d\ln d_p \tag{3}$$

$$\propto L_{total}$$

L_{total} (in units m/m^3) denotes the total particle length concentration, i.e. the total length of the string of particles that is created when all airborne particles within a unit volume would be lined up side by side. It is well known that in ambient air, the overwhelming contribution to both N_{total} and L_{total} comes from particles sized between 10 nm and about 200 - 300 nm, i.e. the combustion-derived UFPs. Larger particles ($\geq$ 1 μm) hardly contribute to both N_{total} and L_{total} but are almost exclusively responsible for all airborne particles mass M_{total} (μg/m^3).

The question is now what is learned from knowing L_{total}. It is generally believed that in as far as solid UFPs like soot particles are concerned, the relative health hazard H_{ufp} of inhaled UFPs relates primarily to the deposited UFP surface area $S \sim d_p^2$ in the deep alveolar region of the lung where gas exchange with blood occurs. In contrast with the upper head airways and the intermediate tracheo-bronchial part of the lungs, the alveolar region has significant difficulty cleaning itself from particulate deposits. The UFP surface carries carcinogenic substances like poly-cyclic aromatic hydrocarbons (PAH) and a long residence time of deposited UFPs in the alveolar region adds to their hazardousness. Other than the surface area d_p^2 of a lung-deposited UFP particle, an assessment of H_{ufp} must also take into account the alveolar deposition efficiency of inhaled UFPs as a function of d_p. Figure 2 shows the respiratory deposition efficiency of inhaled particles as a function of d_p in different parts of the airways (see e.g. ref. [6], Chapter 11). Concerning the alveolar region, it can be inferred from Fig. 2 that the alveolar UFP deposition efficiency is approximately proportional to $d_p^{-0.5}$ within the 10 – 300 nm particle size range. The relative health impact H_{ufp} then follows from

$$H_{ufp} \propto \int_{d_p=0}^{\infty} d_p^2 d_p^{0.5} \frac{dN(d_p)}{d \ln d_p} d \ln d_p = \int_{d_p=0}^{\infty} d^{1.5} \frac{dN(d_p)}{d \ln d_p} d \ln d_p \qquad (4)$$

which is more closely related to L_{total} than to N_{total} or M_{total}. Thus, to a first approximation, a measurement of $I_{sensor} \propto L_{total}$ with the UFP sensor can be used to approximately infer the health-hazardousness of the ambient UFP pollution level.

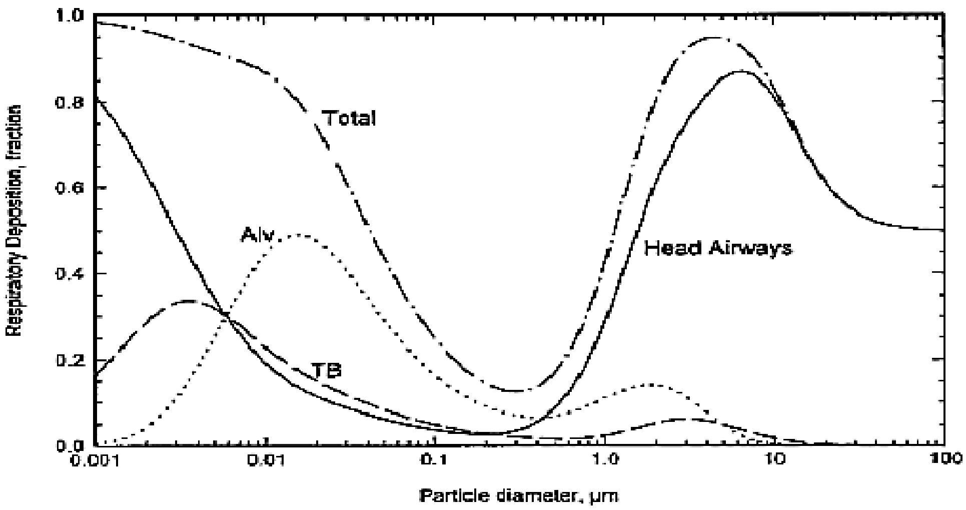

Figure 2:- Predicted total and regional deposition fraction of airborne particles in the human airways during nose-breathing with light exercise according to the International Commission on Radiological Protection (ICRP) deposition model (see e.g. ref. [6] Chapter 11). TB = tracheo-bronchial region; Alv = alveolar region. The total deposition fraction is the sum of the regional deposition fractions in the head airways, the TB region and the alveolar region.

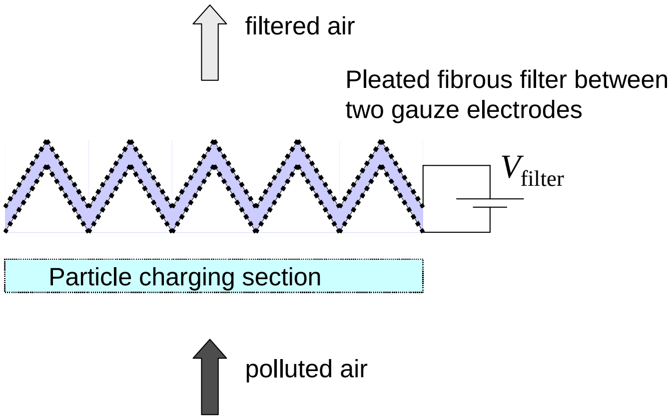

Figure 3:- Schematic design of the electrostatically-enhanced particle filter featuring an upstream particle charging section and a downstream particle filtration section.

Electrostatically-enhanced particle filter
To improve the ventilation air cleanliness, mechanical particle filters can be installed to try removing a substantial portion of airborne particles from air. The incurred pressure drop ΔP across these filters is directly proportional to the HVAC power required for air filtration. It is desirable to have filters of a given size that enable a desired air cleaning efficiency at a minimized power consumption. Figure 3 shows the schematics of a home-designed electrostatically-enhanced fibrous filter. A corona-charging unit is located upstream from the pleated fibrous filter and serves to provide all airborne particles with an electrostatic charge through local air ionization. Importantly, the pleated filter features a filter cloth that is sandwiched between two gauze electrodes possessing a carefully chosen conductivity. By imposing a voltage difference between the gauze electrodes, an electric field is set up across the filter cloth, which was experienced to markedly improve the efficiency with which charged particles can be filtered from air.

RESULTS

UFP sensor
Some typical UFP sensor recordings in indoor air as a function of time are shown in Figure 4 for the extremes of (pre-filtered) laboratory air and of cabin air (pre-filtered by an ordinary cabin filter) in a driving automobile. In all cases, the UFP sensor signal and thus the indoor UFP concentration varies significantly in the course of time, presumably in parallel with the outdoor UFP concentration variation. However the rate of change of the UFP sensor signal in laboratory air is relatively limited whereas fast variations are encountered inside a car cabin due to the rapidly changing proximity of (the exhausts) of other cars. It is evident from Figure 4 that the measured I_{sensor} inside a car and thus the cabin UFP pollution level can be up to 100 times higher than in the “clean” laboratory environment. This is evidence of the relative seriousness of the cabin air pollution level, a situation that most people are not aware off.

The air sampling rate of our UFP sensor ϕ = 0.5 liter/min while the sensor signal I_{sensor} is measurable down to a sensitivity of about 1 – 2 fA within a measuring range 0 – 10 pA. This approximately conforms to a measuring sensitivity of the UFP number concentration of 1000 /cm^3 for UFPs sized in the d_p = 10 - 300 nm diameter range. The average UFP diameter in ambient air is usually between 30 and 70 nm. A UFP concentration as low as 10^3 /cm^3 is encountered only in very clean air (e.g. high in the Swiss Alps). In ordinary sub-urban air,

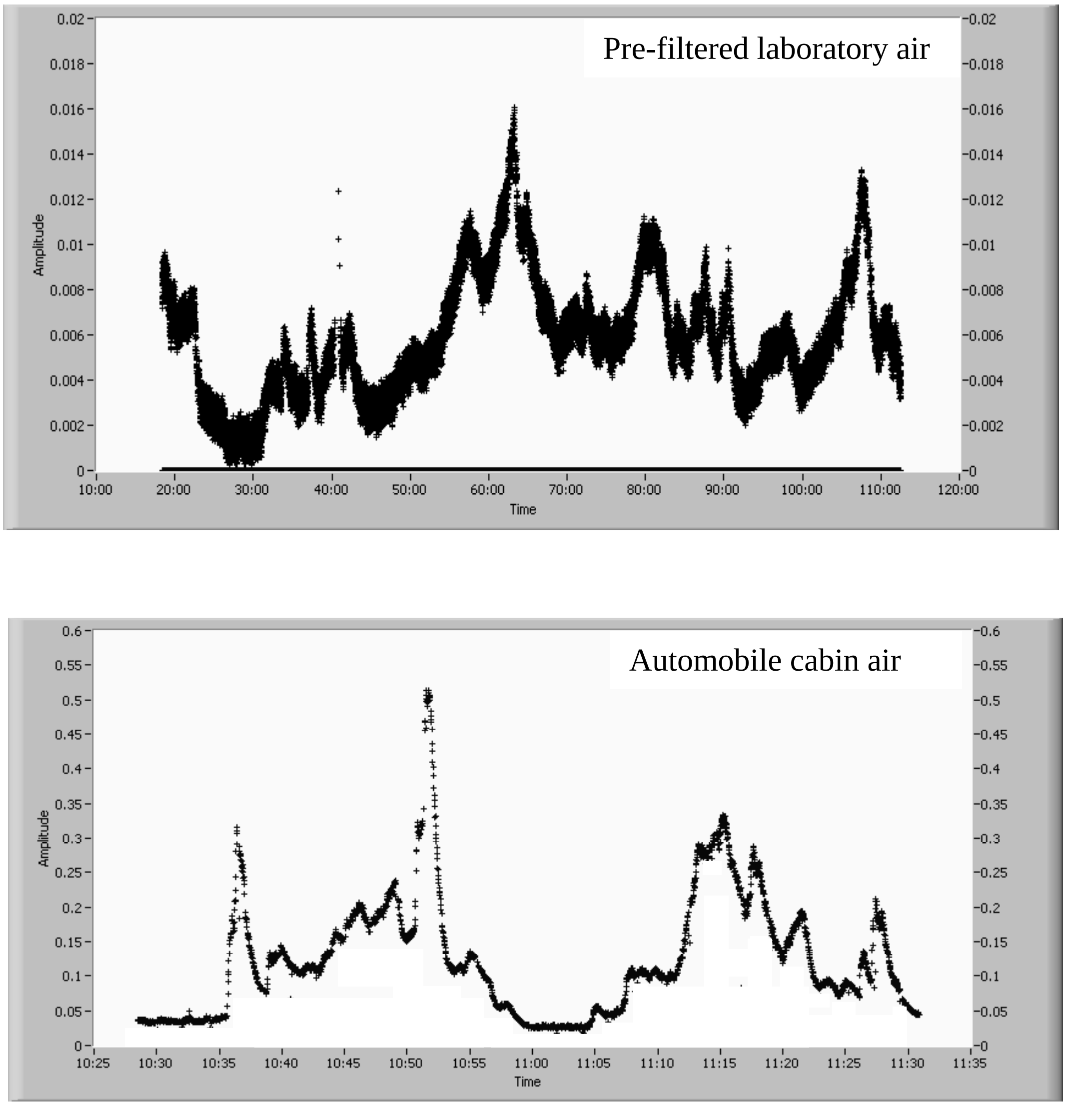

Figure 4:- Measured amplitude of the UFP sensor signal (in units pA) as a function of time (in hours) in a laboratory environment and in the cabin of a driving car.

UFP concentrations are typically close to 10^4 particles/cm^3 (leading to $I_{sensor} \approx 0.03$ pA). Near busy roads, this can rise up to $5*10^4$ particles/cm^3 and up to $5*10^5$ inside the cabin of a car stuck in a traffic queue. The UFP sensor is therefore able to readily discriminate between clean air, moderately polluted air and seriously polluted air.

Electrostatically-enhanced particle filter

An electrostatically-enhanced fibrous filter designed according to the schematics shown in Fig. 4 was realized and subjected to several filtration efficiency tests both in the absence and presence of electrostatic enhancement. For this purpose, the particle size distribution for particle diameters from 10 – 300 nm was measured with a Scanning Mobility Particle Sizing system (Type 5403, Grimm GmbH, Germany) upstream and downstream of the filter at various air flows through the filter. The results are shown in Figure 5.

In the absence of electrostatic enhancement, the filter behaves as an ordinary mechanical filter with a filtration performance that approximately conforms to that of a EU 6 filter, characterized by a poor filtration performance with respect to UFPs larger than 50 nm.

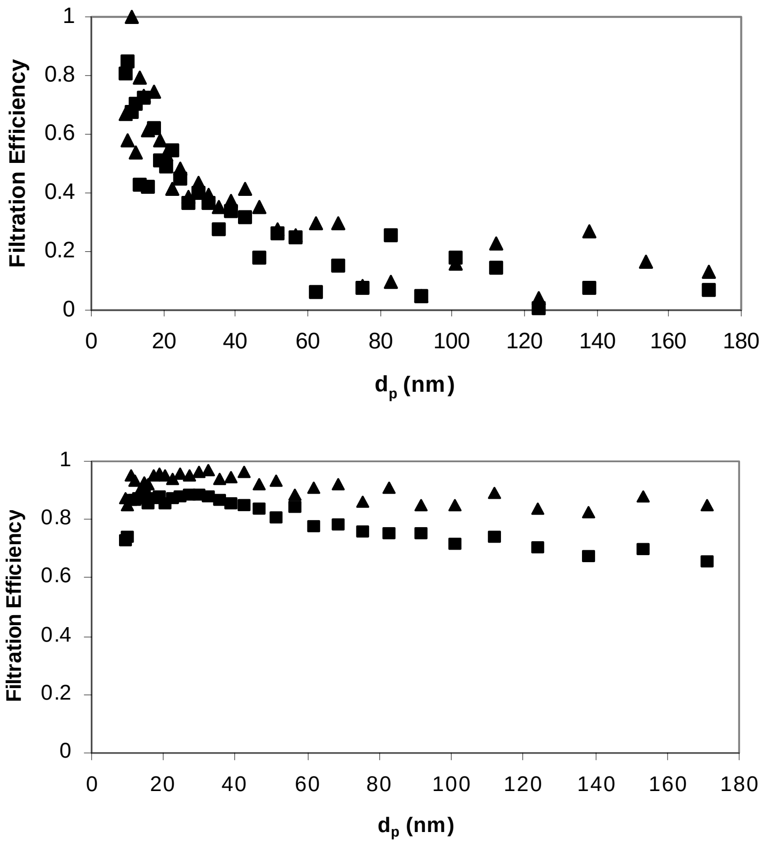

Figure 5:- Measured filtration efficiency of a particle filter before electrostatic enhancement (top) and after electrostatic enhancement (bottom) as a function of the UFP diameter d_p. The superficial airflow speed was set at either 1 m/s (▲) or 2 m/s (■) while the electrostatic enhancement involved both particle charging and the set-up of an electrostatic field E_{filter} = 1 kV/mm across the depth of a fibrous filter cloth.

For particles sized between 100 nm and 200 nm, the filtration efficiency does not exceed 20% at an apparent airflow speed of 1 – 2 m/s through the filter cassette. In the presence of electrostatic enhancement wherein the particles are electrostatically charged and subsequently passed through a fibrous filter across which a field strength $E_{filter} \approx 1$ kV/mm is applied, the filtration efficiency significantly increases up to 70 – 80% for 100 – 200 nm sized particles. Note that this efficiency increase is accomplished at a constant power consumption, airflow speed, and size of the filter cassette. The specific power consumption required for airborne particle charging and filter polarization only amounts to a few W for an air flow of several hundred m^3/hr and is therefore negligible with respect to the total HVAC power consumption.

DISCUSSION

The described UFP sensor yields a real-time output signal proportional to the ambient UFP pollution level according to a metric that approximately corresponds with the relative health-hazardousness of the UFP pollution level. At any locality where the dose of air pollution is received from a more-or-less constant set of pollution sources (e.g. automobile traffic) in the course of time, the UFP pollution level may be expected to at least roughly reflect the total airborne gaseous/particulate pollution level. The UFP sensor readily distinguishes clean air from moderately or seriously polluted air and can be used for assessing pollution levels in outdoor and indoor air. Because the local outdoor and indoor air pollution vary strongly in time and place, it is convenient to continuously monitor these pollution levels with UFP sensors in order to acquire pollution-related decision factors for optimizing the ventilation strategy.

In case all ventilation air is received from a mechanical air handling unit that is supplied with an air filter, it is recommended to position UFP sensors directly downstream of the filter and/or in the indoor enclosure itself away from the supplied ventilation air flow. This allows for a monitoring of the residual UFP pollution level in the supplied ventilation air and/or in the indoor air itself, respectively. Electronic feedback from the UFP sensor, preferably in combination with feedback from other sensors (T, RH, CO_2, human presence), can then be used to enable ventilation on demand, to adjust the total ventilation air flow and/or the ratio between supply air and return air such as to minimize the absolute indoor pollution level while retaining comfortable and productive indoor conditions in an energy-efficient way. The application of an electrostatically-enhanced particle filter in the air handling unit instead of a conventional mechanical filter will help to further minimize the required power consumption necessary for creating a healthy and comfortable indoor air quality.

In case the ventilation air is a mixture of naturally supplied ventilation air and mechanically supplied filtered ventilation air, it is recommended to continuously monitor the UFP pollution both outdoors and indoors. Received sensor signals can then be used to adjust the ratio between natural ventilation and mechanical ventilation either automatically or manually, aiming to minimize the indoor pollution level in an energy-efficient way under all environmental circumstances. It is obvious that the recommended ventilation strategy will usually be the outcome of a judiciously chosen compromise.

Various additional application modes of UFP sensors can be readily construed and applied in homes, offices and cars. A common aspect is always that the very presence of UFP sensors allows for a direct visualization of the UFP pollution level. Except through the application of professional expensive instrumentation, UFP pollution visualization has up till now not been possible and can therefore be of much help in both raising human awareness with respect to the pollution level in inhaled air and in reducing human exposure to indoor air pollution.

SUMMARY

The aim of this study was the experimental determination of particle deposition for both different particle size fractions and different indoor surface materials. The selected surface materials were glass, gypsum plate, carpet, and curtain. These materials were tested vertically in a full-scale test chamber. Experiments took place in a 32 m^3 chamber with walls and ceiling made of glass. Prior to each experiment the chamber was flushed with outdoor air to reach an initial particle concentration typical of indoor air in buildings with natural ventilation. The decay of particle concentrations was monitored. Seven particle size fractions were studied. These comprised ultrafine and fine particles. Deposition was higher on carpet and curtain than on glass and gypsum plate. Particles in the range from 0.3 to 0.5 µm had the lowest deposition. This fraction also has the highest penetration and its indoor concentration is expected to be closest to outdoor concentrations.

INTRODUCTION

In recent years, exposure to fine and ultrafine airborne particles has been identified as an important risk factor for human health [1]. Deposition of particles onto indoor surfaces such as floors, walls, ceilings, and furniture may be thought of as a phenomenon protecting humans from some of the dangers caused by exposure to particles [2, 3].

Measures to reduce exposure to these particles generally fall into three main categories: source control, ventilation control, and removal control. Source control should always be the first strategy examined. When source control is not feasible or practical, ventilation control should be the next option. But in many of our urban environments today, the outside air itself is one of the main sources of indoor particle pollution. Therefore, when it is clear that neither of the first two control strategies mentioned above would reduce the level of contaminants in the affected space, removal of particles should be applied.

One approach to improve indoor air quality is to select such surface materials as are able to remove indoor particles through increased particle deposition. Understanding particle deposition phenomena provides useful information on human exposure indoors. Particle deposition onto indoor surfaces are complex phenomena and varies with particle size and surface roughness. The deposition rate for each particle size can vary over a few orders of magnitudes [5]. For particle sizes larger than 1 µm, gravitation is dominant, while diffusion is dominant for particles of sizes smaller than 0.1 µm. For particle sizes between 0.1 and 1 µm, a mixture of both mechanisms may be assumed [4].

Experimental and simulation studies reported that several other parameters can influence indoor particle deposition. These parameters are chamber size, airflow rates, ventilation strategies, air velocity and degree of turbulence, furniture, roughness of surfaces, orientation and electrostatic forces [6, 7]. Most of the previous experimental studies were carried out in real buildings. Consequently, it is difficult to control the many factors that influence particle deposition rates simultaneously. Therefore, as a complement to field studies, it is necessary to carry out experimental studies in the chamber under controlled experimental conditions to understand the mechanisms behind deposition phenomena.

These previous studies have gathered information about deposition of generated fine particles onto rough and smooth vertical surfaces in small and full-scale chambers. However, few studies have examined deposition of ultrafine particles from ambient air onto the surfaces of building materials under controlled experimental conditions. The aim of the present study is quantification of deposition rates of fine and ultrafine particles onto three building materials often found indoors.

METHODS

The experiments were carried out in the air quality laboratory of the Danish Building Research Institute (SBi). A full-scale chamber with a volume of 32 m^3 was used. The walls and the ceilings of the chamber consist of panes of glass mounted in aluminium frames and the floor is made of high-pressure laminated fibreboard. Low concentration of polluting gases and particles in the supply air was ensured by the use of a fine filter of class F7, a charcoal filter followed by another fine filter of class F7 and finally a HEPA filter. The full-scale chamber was located in an 1800 m^3 hall that was ventilated with an outdoor air change rate of approximately 4 h^{-1}.

The air change rate in the chamber was 0.66±0.1 h^{-1}. Three table-fans were in operation during all experiments in order to ensure complete mixing of the chamber air. The table fans were located at the same places during all measurements ensuring an average air velocity in the chamber around 0.15-0.5 m/s. A tracer gas decay method was used to determine the air change rate and for verification of the air mixing conditions in the chamber. The tracer gas decay concentration was measured continuously over four hours with a photo-acoustic spectroscopy (PAS) instrument from Innova, type 1302. The temperature and relative humidity were recorded during the experiments. The temperature ranged from 22 to 25 ^{0}C, and the relative humidity ranged from 37 to 53 % RH, see Table 1. An over-pressure of 10 Pa was maintained in the test chamber relative to the surrounding hall throughout the experiments. The air velocity was measured to be 0.37 m/s at the centre of the sample, 5 mm above the material surfaces. The air velocity in the chamber was measured to be 0.16 m/s at 1.30 above floor level.

The selected surface materials for the present study were window glass, gypsum plates, wall-to-wall carpet and cotton curtain. The area of each tested material was 10.4 m^2. It should be noted that the walls of the chamber consisting of glass panes were treated as a surface material, i.e. the window glass. It means that a new window glass was not tested in the chamber. The other surface materials were tested vertically on eight places of the walls of the chamber. Test materials were placed directly on the glass panes of the chamber, thus replacing glass pane with test material. The other tested materials were placed at the same locations on the wall of the chamber.

Supply air was particle free, and an initial high concentration was obtained by flushing the chamber with unfiltered heated outdoor air. Prior to each experiment, the chamber was flushed with unfiltered outdoor air to reach an initial particle concentration typical of buildings with natural ventilation. The door of the chamber was open until the concentration of ultrafine particles in the chamber reached approximately 5000 particles/cm^3. During the experiments the decay of particle concentrations caused by ventilation and deposition was monitored.
The outdoor climate conditions were rather similar in all measurements. The air temperature ranged from 11 to 14 ^{0}C, and relative humidity ranged from 60 to 70% RH.

After flushing, the decay of the particle concentrations were monitored using both a condensation particle counter for ultrafine particles (UFP) counter (TSI model CPC 3007) and an optical particle counter for fine particles (PMS model Laser II-310B). The deposition rates were obtained by linear regression of the measured particle concentration for different size fractions while compensating for particle removal by ventilation. Seven particle size fractions were studied. These comprised ultrafine (particles larger than 0.01 µm) and fine particles in the fractions 0.3-0.5, 0.5-1, 1-3, 3-5, 5-10 and particles larger than 10 µm. Particle concentrations were monitored every minute.

The concentration measurements of UFP were made in the centre of the test chamber, 1.30 m above floor level. The CPC 3007 instrument enables real-time measurement of particle number concentrations and data collection. The size range for particle detection of the instrument is between 0.01 and about 1.0 µm. Software is available for later retrieval of measured data. According to the manufacturer the concentration accuracy of up to 100,000 particles per cm^{-3} is ± 20% of the reading. In this concentration range coincidence is low and no correction is required. At concentrations of up to 4 x 10^5 particles per cm^3, the data could be corrected for coincidence loss, e.g. according to Hämeri et al., (2002).

The concentration measurements of fine particles were also placed at the same location as the UFP. The Laser II-310B is an optical particle counter capable of measuring different particle fractions ranging from 0.3 to larger than 10µm in size. Six size fractions were chosen according to the above-mentioned sizes. According to the manufacturer the concentration, accuracy is approximately ± 20% of the reading.

Table 1. Air change rate, relative humidity and temperature in the chamber during the experiments.

Material	Air change rate h^{-1}	Relative humidity % RH	Temperature (^{0}C)
Empty chamber, glass	0.65	53	24.6
Wall-to-wall carpet, polyamid	0.65	42	24.9
Gypsum plate	0.67	37	22.8
Cotton curtain, recently washed	0.67	42	22.8

Calculation of deposition rate

Analyses of the particle concentration during the step-change of the surface materials with different properties provide information both on the particle concentration and the quantity of deposition effects. The particle decay, observed after the concentration of fine and ultrafine particles reached predetermined levels, was used to assess the time constant for the particle decay, T_P. The time constant was obtained through regression of the measured particle concentration decay. The ventilation time constant, T_v , was obtained by tracer gas measurements. The difference between the inverse values of the ventilation time constant and the particle decay time constant represents the particle deposition rate constant, r, which is given in the figures using the unit h^{-1}.

$$C_{(t)} = C_{(0)} \times e^{-\left(r+\frac{1}{T_V}\right)\times t} = C_{(0)} \times e^{-\frac{t}{T_P}} , \qquad (1)$$

where *C(t)* is concentration at time t (particles/m^3 or particles/cm^3), and *C(0)* is concentration at time zero (particles/m^3 or particles/cm^3). This method has been used earlier in another study (Abt et al., 2000).

The particle deposition rate for each material ($r_{Material}$) was calculated according to the following:

$$r_{Material} = r_{Material+chamber} - r_{Chamber} , \qquad (2)$$

where $r_{Material+Chamber}$ is the sum of the deposition rate for material and chamber, and $r_{Chamber}$ is the deposition rate for chamber surfaces.

Where material samples replaced chamber glass, the test procedure did not change the main geometrical properties of chamber and flow patterns. But as a consequence, it should be noted that the deposition rate for materials ($r_{Material}$) actually represents the material deposition minus the previous deposition on the glass replaced by test specimens. It was decided that the other way of conducting the experiments with freely hanging specimens not replacing chamber glass, would be impossible to analyse since the impact of modifications to flow patterns could impact deposition rates.

RESULTS

The deposition rates for materials ($r_{Material}$), chamber ($r_{Chamber}$) and ventilation rates are shown in Figures 1a, 1b and 1c. The deposition rates for all three materials together are shown in Figure 1d. Figure 2 shows the deposition rates for sum of material and chamber, i.e $r_{Material+Chamber}$. Figure 2 also shows the deposition rates of the chamber when it was empty.

Figures 1a-1d illustrates the deposition rates for the seven particle fractions onto the chamber surfaces when it was empty and onto the tested materials when the materials were placed in the chamber.

Figure 1a shows that the particle deposition onto the chamber surfaces and the fixed carpet on the walls follow a similar pattern and also that the deposition rate varies with the particle size. The deposition rate increased both for larger particles and for smaller particles. The measurements for particles with diameters of 0.3 and 0.5 µm give a smaller loss rate than for the other particle sizes.

Figures 1b and 1c illustrate the deposition rates for the seven particle fractions onto the curtain and the gypsum fixed on the walls, respectively. The results show that the particle deposition onto the curtain and the gypsum do not follow the similar pattern as the deposition rates of the chamber and the carpet. The deposition rates for curtain increased for particles larger than 10 µm and UFP. Particles with diameter 3-5 µm and 5- 10 µm give a smaller deposition rate than for the other particle sizes. The deposition rate for gypsum varies from particle size to particle size. The deposition rates of particle sizes 3-5 µm and 5-10 µm is marked with a circle. Their deposition rates are negative after calculation. It may depend on the fact that gypsum and the glass the samples are replacing have very similar deposition properties. The negative numbers may simply be caused by uncertainties.

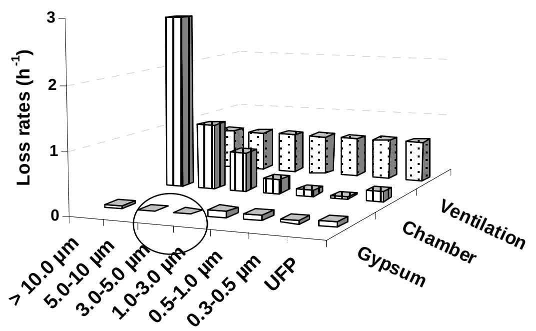
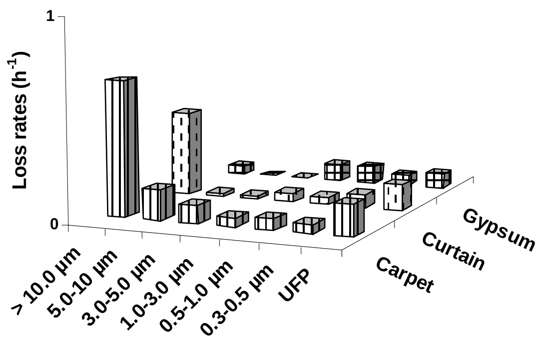
b)



c)



d)

Figure 1. Particle deposition rates onto the surfaces of the chamber and three materials. a) wall-to-wall carpet, b) cotton curtain, c) gypsum plate, d) all three materials

DISCUSSION

The experimental data reveal three different patterns for the tested materials. For the carpet, the deposition rates decrease as particle size increases from the UFP to 0.3 µm, and then begin to increase again. For the curtain, the deposition rates decreases as particle size increases from UFP to 10 µm, then begins to increase. For the gypsum, the deposition rates are very similar to the glass the samples are replacing and no clear trend is observed. The experimental data reveal also that both the surface properties of the materials and the particle sizes have an effect on the deposition rates. The effect of particle size is much stronger than the effect of surface properties. The effect of surface properties is stronger for the UFP and for the particles with diameters larger than 10 µm.

The rather high air velocity in the chamber may have caused an elevated deposition of the larger particles. This may be caused by impaction on surfaces when these particles with some mass inertia have difficulties to follow the flow patterns of the air near the surfaces. At the other end of the particle size range the ultrafine and fine particles have a higher air velocity rate partly caused by collisions with molecules. These Brownian movements cause higher diffusion of the smallest particles and this also causes higher deposition. These two different mechanisms of increasing deposition affecting either the very small or the largest of the particles are causing deposition of the particles in the median range of 0.1-1 µm to be the lowest.

Based on the experimental data illustrated in Figure 2, the deposition rates vary with particle sizes. Figure 2 shows that the measurements for particles with a diameter of 0.3 µm give smaller deposition rates than the other particle sizes. It may depend on particle diffusivity that is dominant for ultrafine particles and sedimentation that is dominant for particles larger than 1 µm. This is in agreement with results from other studies that were carried out in real buildings [9, 10]. A similar pattern found for wall-to-wall carpet, despite that the deposition rates for carpet was over-represented. However, the pattern was not similar for gypsum board and cotton curtain when the deposition rate for carpet was over-represented.

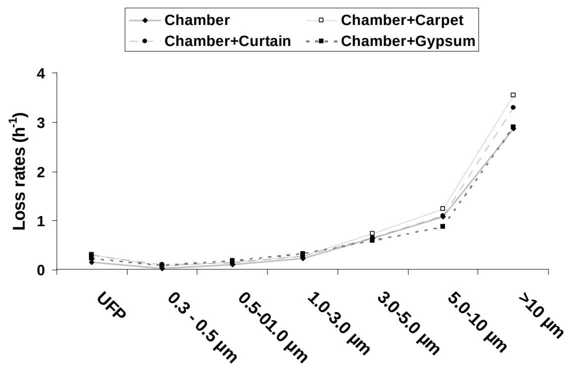


Figure 2. Particle deposition rates onto the surface of chamber and three materials.

The relative importance of particle losses due to ventilation, chamber properties and test specimens follow a typical pattern. For the larger particles down to 5 µm, gravitational settling and other deposition are more important than ventilation and deposition on specimens. For the smaller particles, ventilation losses are more important than deposition on chamber and test specimens.

CONCLUSION

The experimental data reveal that both the surface properties of the materials and the particle sizes have an effect on the deposition rates. The effect of particle size is much larger than the effect of surface properties.

The effect of surface properties is larger for the UFP and for the particles with diameters larger than 10 µm. The measurements for particles with diameters of 0.3 and 0.5 µm give less deposition than for both bigger and smaller particle sizes.

There is a need for further research aiming at the development of an improved method for assessment of deposition of indoor particles on different surface materials.

The Science of Gas Phase Air Cleaning

Paul Spry

Spry Associates, Australian Capital Territory

Corresponding email: paul@spry.com.au

SUMMARY

This paper reviews indoor air quality needs; then it addresses gas phase air cleaning (a little understood, little used in HVAC, high opportunity technology) - particularly by adsorption. Opportunities and limitations are discussed and the capital and energy cost impacts of use are detailed. The role of ventilation/IAQ standards is addressed.

INTRODUCTION - THE NEED FOR AIR CLEANING

It is desirable that people breathe clean air. It is desirable that the air does not have things in it which are harmful if inhaled and it is desirable that the air that is breathed in is not unpleasant i.e. that it does not contain smelly things and irritating things. Air is made up of gases and particulates so control of air quality requires control of both.

Health

Gases *and* Particulates affect health. In extreme cases gaseous components (sulphur oxides, phosgene, cyanides, chlorine etc) can be deadly. In other cases particulates can be deadly (arsenical smoke, plutonium dust, infectious agents etc). In ordinary circumstances (when considering fairly average indoor and outdoor conditions) the most health influencing substances are probably particulates.

Amenity

Particulates can be irritating, they can obscure vision they can make surfaces dirty and they can otherwise be a nuisance (eg. pollens irritate many hay fever sufferers). Particulates, also, can affect systems that keep people comfortable – dirty cooling coils etc. However, virtually all odours are gases and probably a gross majority of oronasal irritants (irritating in the sense of affecting the trigeminal nerve system) are gases. When considering amenity in buildings (those where ambient pollution is not excessive) the main technical opportunity for improving amenity is in control of gaseous pollutants by ventilation or gas phase air cleaning.

BASICS OF GAS PHASE AIR CLEANING

Gaseous pollutants are removed from air by ‘gas phase filters’ or ‘gas phase air cleaners (GPAC)’. ‘Filter’ is a word without universally agreed meaning so ‘GPAC’ is used here.

GPAC’s come in wet and dry types. A wet GPAC is usually an air washer. A dry GPAC is usually a sorptive device (physisorptive, chemisorptive, catylitic or photocatylitic).

An air washer (wet type GPAC) is an Absorptive air cleaner. As the polluted air contacts the water spray some gaseous pollutants will absorb into liquid water and then be sent to disposal or recovery. If a pollutant is water soluble an air washer may use ordinary water but treated waters are sometimes used eg. use of acidic water to remove alkaline pollutants from air. In non air-conditioning applications air washers may be very useful but 'the devil is in the details' e. g. when treating gaseous pollutants in road tunnel exhausts (a thing not often done) it is not particularly difficult to wash sulphur oxides out of the air but it is difficult to wash nitrogen oxides out- the solution and chemical kinetics are inherently unfavourable.

In air-conditioning applications air washers have disadvantages. They, generally, will humidify the air (they may dehumidify), and this may not be desired. If the water is treated with chemicals then these may get into air and be breathed in. Where there is water there is the possibility of Legionella etc. hazard.

Wet GPAC's are a niche product in HVAC so, here, they are not considered further. Dry GPAC's have more potential. For convenience they are hereafter referred to as GPAC's.

Gas Phase Air Cleaners

Presently, GPAC are rarely used in the air-conditioning industry and useful information about their design and use is rare. Such poor commercial information is available that reasonable HVAC engineers may suspect that there is no basis to claims about GPAC efficacy. Consequently there is a need for material that will assist HVAC practitioners.

GPAC Types

There are four principal types of Gas Phase Air Cleaners – Chemisorptive, Physisorptive, Catalytic and Photocatalytic. In each cases the primary mechanism is adsorption i.e. the capture of gaseous pollutant molecules by (onto) GPAC material.

In physisorptive GPAC's the capture of the pollutants is by weak electrical forces and the process is reversible (by change of temperature or pressure). In chemisorptive GPAC's pollutant is attracted to the adsorptive by physisorptive forces and then it chemically reacts with the adsorptive so that it is permanently and irreversibly (for practical purposes) attached. In a sense, chemisorptive GPAC's are a subclass of physisorptive GPAC's.

A well known Chemisorptive GPAC is 'Purafil'. In 'Purafil' the physisorptive is activated alumina but the alumina pellets are impregnated with potassium or sodium permanganate etc (the amount is judged – too little and service life is reduced, too much and the holes in the pellet become clogged and efficiency is reduced). The permanganate will trap some chemicals and not others: so, care in application is needed. Activated carbons may also be impregnated.

In catalytic adsorption, chemical reactions are encouraged by the nature of the surface on which they are adsorbed thus pollutants may be removed from an airstream (a catalyst increases the rate of the reaction influenced but it does not affect the end point). In air conditioning applications catalytic air cleaners are uncommon. One product uses gold/iron oxide on zeolite substrate to deodorise toilet exhaust. Photocatalytic adsorption is essentially the same as catalytic adsorption but with light energy added to accelerate the reaction, probably photons assist dissociative adsorption prior to recombination into the final species.

When air is passed through a photo-catalytic converter many objectionable pollutants are turned into harmless substances and the air is thus ‘cleaned’; unfortunately these devices can also cause the formation of troublesome pollutants from otherwise less objectionable air pollutants. These devices are presently in ‘demonstration’ stage and, basically, the jury is still out where their utility is concerned.

The archetypal physisorption GPAC is the “activated carbon” filter so this filter type is examined here. Many things to be said about activated carbon are also applicable (to varying degrees) to other adsorbents – activated alumina, silica gel, zeolites, organic synthetics etc.

Activated Carbon – its Properties

The most special feature of activated carbon (& other adsorbents) is that it has a very large surface area though the size distribution of the ‘pores’ in it can be of great relevance. Chemically, ‘activated carbon’ is close enough to being ‘pure’ carbon.

A piece of activated carbon may be thought of as a pure carbon object with holes in it and the walls of these holes having smaller holes in them and the walls of these holes having holes that are even smaller etc. This geometry allows a very large accessible surface area.

The specific surface area of a commercial activated carbon will typically be in the region of *1100 square meters per gram of carbon***.** This is extremely large and this can be well appreciated by observing that if *one gram of carbon* is formed into a sheet that is one atom thick then *the combined area of both sides of the sheet will be about 2630 square metres*.

It is possible to debate these observations (how was the surface area measured or calculated? etc) but it remains that in surface area terms ‘activated carbon’ is quite remarkable.

An activated carbon filter is usually a mass (‘pad’, ‘bed’ etc – the descriptor varies to suit the circumstances) of activated carbon fragments that are often granular, cylindrical or flat particles about 4 mm across and these particles are usually enclosed in a metal screen casing so that air can easily be directed through the ‘bed’ so formed. Some other quite clever types of carbon filters are available.

The large surface area of Activated carbon allows it to remove pollutants by *Adsorption*. *Physisorption* is now further described but, for simplicity, being called *adsorption.*

As this carbon may have a surface area of about 1100 $m^{2/}$g there is an opportunity for contaminants to adhere to the surfaces and thus be ‘filtered out’ of the airstream.

Adsorption

Lightly polluted air consists of numerous separate molecules of various gases (oxygen, nitrogen, carbon dioxide, water, trace organics etc).

These molecules are vibrating *and* rotating (on all axes) *and* travelling in straight lines. They ‘hit’ each other quite often and when they hit a surface (eg. the walls of a gas storage cylinder) the aggregate effect of their impacts is called ‘pressure’.

Some rough data about the movement of molecules in air (at normal atmospheric pressure) is

Speed of H_2 molecules: about 1800 metres/sec
Speed of molecules like N_2, O_2, H_20: about 500 metres/sec
Average distance travelled before colliding with another molecule: about 10^{-5} cm
Average number of collisions per molecule per second: about $5*10^9$
Number of molecules per cubic centimetre: about $25*10^{18}$
Number of molecules striking a surface per second: about $3*10^{23.}$

Many people will have been told, in their high school (or university) physics classes, that when molecules strike a surface they usually 'bounce off' the surface in a symmetrical way and this can be true but the more usual case is different. Usually, when a molecule hits a surface it attaches to the surface for, on average, an infinitesimally small time and then it is emitted back into the space. This time of attachment is important, as is the 'sticking probability'. If this time is small (as it normally is) then for practical purposes the behaviour of the gas is much the same as if the molecules always bounced symmetrically off the wall (as, in reality, they sometimes do).

If, in the case of a particular molecule, this time is large (say months, years, centuries etc, on average) then that molecule is removed from the gas for a useful time (if not forever) and we may have the phenomenon of useful *Adsorption.*

Why do molecules adhere to surfaces

At base this is a quantum electrodynamic process but the analysis of the process is usually done at a simplified level.

Molecules adhere to surfaces by electrical forces. These are varied, have various names and there are inconsistencies in how the names are used. The expression 'Van de Waals force(s)' is often used for the various forces, sometimes it is used more specifically.

A useful way of classifying the forces is:
Coulomb force: where a charged molecule (an ion) is attracted to an oppositely charged surface
Ion - Induced Polarisation force: Where an ion induces an opposite charge near a surface so it is attracted
Dipole - Dipole force: Where a polarised molecule is attracted to a polarised surface of opposite polarity

- Some molecules while electrically neutral have an unsymmetrical distribution of electrons so, statistically and rather roughly speaking, one end of the molecule is constantly negatively charged and the other end is positively charged
- Surface molecules, whilst electrically neutral, may have an unsymmetrical charge distribution
- These considerations vary with the type of surface molecule and the surface bonding – metals are quite different.

Dipole-Induced Dipole force: Where a permanent dipole molecule induces a dipole at a surface and is attracted
Induced Dipole - Induced Dipole force, and the forces between various induced dipoles, quadrapoles, hexapoles, octapoles etc: Of these various forces the Induced Dipole - Induced Dipole force and the Dipole - Induced Dipole forces seem to be the ones more commonly emphasised in academic discussion of adsorption.

The Induced Dipole- Induced Dipole force occurs when the fluctuating electron distribution around one (otherwise nonpolar) molecule produces a temporary dipole and that dipole induces a dipole in a neighbouring (otherwise nonpolar) molecule – then the molecules are attracted to each other.

A significant complication is that the various induced forces are subject to ‘retardation’ effects. When a molecule induces a dipole in another molecule the ‘message’ between the molecules moves at the speed of light so if the time of travel of light between the molecules (ie the distance) is significant (when compared to the time taken for valency electrons to move around the molecule) synchronisation is reduced and the attracting forces are attenuated.

Why do Some Gases Adsorb Better than Others

Gas molecules have inherent physical and electrical properties – shape, size, permanent dipole moment and polarisability are quite important.

Gases with particular physical/electrical properties tend to be preferentially adsorbed so a study of these properties may indicate adsorption proclivities.

Larger molecules (molecules with higher molecular weights) may be preferentially adsorbed.

Again ‘the devil is in the detail’ and, though larger/heavier molecules tend to be better adsorbed exceptions abound, e.g. carbon dioxide is much less adsorbed on activated carbon than is acetaldehyde – yet these two chemicals have essentially identical molecular weights.

Practical Outcome

Usefully, the broad trend is for larger molecules to be more readily adsorbed. Also ‘normal air’ molecules are small and many air pollutant molecules (particularly the ones that are smelly) are larger thus as a general rule odorous gaseous air pollutants are attracted to and trapped by activated carbon etc. filters. Many dangerous pollutants are so adsorbed.

OPPORTUNITIES AND LIMITATIONS

Opportunities

Indoor air quality (IAQ) targets are presently achieved by ventilation and particulate filtration and designers can choose commercial particulate filtration product to deal with almost any situation thus the modern IAQ problem can be reduced to the provision of a good mixture of ventilation and gas phase air cleaning – and the problem is usually addressed without reference to gas phase air cleaning.

If, in practice, gas phase air cleaning can be employed to remove odorous and other air contaminants (eg volatile organics) then ventilation may be reduced.

If ventilation is reduced savings may result:
- Ventilation energy cost is reduced (less air is heated and cooled, and there may be a minor air transport cost saving)
- Peak energy charges (eg kVA charges) are reduced
- Plant capital cost is reduced (peak cooling/heating loads are reduced) and there may be some plant efficiency and infrastructure gains from making the cooling/heating loads less ‘peaky’.

Also, gas phase air cleaning (GPAC) use reduces greenhouse gas generation.

Limitations

The following factors limit the application of adsorptive GPAC in HVAC application:
- Misunderstanding about acceptable maximum Carbon Dioxide levels indoors abounds - confusion between health based limits and odour indication levels: also, much quoted odour indication values seem to have a very poor research base
- Little useful information, about the use of adsorption filters, seems to be available – commercially or in design literature (except in the case of a few isolated industrial applications).
- Commercial HVAC application data tends, even in the case of product from well established companies, to be a list of various chemicals that may be adsorbed by the product with the performance in adsorbing each chemical described as “excellent”, “good” etc but few useful numbers being evident: performance curves tend to have meaningless axes.
- The common adsorptive (activated carbon) is a heterogeneous thing manufactured in various ways from various precursors thus the product varies greatly
- Product data is usually basic – at best a notional ‘specific surface area’ or an equilibrium uptake of one particular chemical (eg. ‘65% by weight of CCl_4’) whereas, ideally, ‘uptake Vs. challenge concentration’ data is needed
- Notwithstanding that little data available there is no agreed theory for creating isotherms (uptake Vs. challenge concentration curves) from equilibrium single chemical values or for predicting the performance of an adsorbent with a particular chemical from its performance with a different chemical (there are many isotherm theories and some are more popular than others: in fact, particular theories suit particular chemical species). The fairly popular BET theory (circa 1938) is useful, but, its parameters may be varied to, to some extent, get the desired result!
- Available theories may suit particular (single) chemical species but their application to mixtures (body odour being an obvious example) is not clear.
- Actual GPAC design or application methodology/data is scanty and either crude or hideously complicated (mathematically) and essentially unproven: the better information appears to come from the chemical process industry where
    - most parameters are very different from those in the air-conditioning industry (species, concentration, cycle times, cost structures etc)
    - the available literature suggests that there is a fair bit of ‘suck it and see’ to the design of adsorptive processes (though, presumably, there will be useful tightly held information in some places)

- There is a need to balance the economic advantage to be gained by GPAC use against the cost of fan horsepower energy used to drive air through a GPAC.

A good (but not simple) overview and design data source is Perry's Chemical Engineers Handbook 7th Edition Section 16 'Adsorption and Ion Exchange".

Overcoming the Limitations

The limitations are primarily intellectual (understanding the physics/engineering) – rather than based on fundamental barriers. However the matter of balancing GPAC fan energy cost against overall energy/capital cost savings can be real problem in many normal situations. This matter is addressed in a recent Patent application[1]**.**

ECONOMICS OF APPLICATION

Given the paucity of *current* satisfactory GPAC product (this should soon change) the economics of providing GPAC apparatus is not dealt with here. However the advantages to be gained by ventilation reduction are presented below for a number of Australian cities. The calculations have used precise hourly outdoor dry/wet bulb frequency data. These cities are in different climates (though a truly cold climate is not to be found in Australia) so they may be indicative of the situation in some other places.

The table below assumes:

Ventilation rate reduction: 1000 litres/second (perhaps, a 200 person building)
Cost of electricity for cooling: A$0.138/kWH, Cooling coefficient of performance: 3.0
Heating gas energy cost: A$.0372/kWH, Heating system efficiency: 76%
Marginal capital cost of cooling effect: A$800/kW
A$=Australian dollar (in early 2007, A$1.0~0.6 Euro~USA$0.8)
6am to 6pm, 6pm to 6am or 24hr operation: 24C summer inside, 21C winter inside.
Economy cycle not used, no humidification, dehumidification only to 60% RH.

Australian City	*Climate*	*Marginal cooling plant cost (A$)*	*Annual cool+heat cost, day (A$)*	*Annual cool+heat cost, night (A$)*	*Annual cool+heat 24 hr (A$)*
Adelaide	Mediterranean	12,480	887	1290	2077
Alice Springs	Hot arid	15,440	1644	1461	3104
Brisbane	Sub tropical	18,240	1417	847	2264
Canberra	Temperate	4,880	1565	2406	3970
Cloncurry	Semi arid tropical	16,080	2622	1751	4373
Darwin	Monsoon	21,280	5011	4350	9361
Hobart	Cool temperate	3,040	1274	1913	3187
Melbourne	Temperate	10,160	1020	1511	2531
Mildura	Semi arid	14,880	1171	1531	2710
Perth	Mediterranean	12,096	893	978	1870
Port Hedland	Semi arid	15,360	3609	2603	6212
Sydney	Temperate oceanic	6,800	1018	1973	2991
Townsville	Wet tropical	25,680	3603	2405	6008
Wagga Wagga	Temperate	12,560	2224	1706	3930

The operation cost of the mentioned 1000 l/s unit, used as shown in reference 1, is likely to be in the region of $A1000 per annum for a typical office space (2500 hrs/year). The capital cost is not given here.

Much can be concluded from examining this table (but, bear in mind that no really cold climate is represented so conclusions cannot be drawn for many North American and European places):

- Installing GPAC will be wise in many climates
- Very often the motivation for installing GPAC will be capital plant cost saving (new and retrofit installations)
- Energy savings are a strong motivation in consistently hot/humid climates & this may be so in cold climates
- Some places offer large capital savings but small energy savings ('peaky' climates).

GPAC may be used only or principally to reduce capital and kVA etc. charges - thus reducing GPAC fan energy to negligible levels and extending media life to, perhaps, decades.

Note that the above refers to energy use at Australian prices. European prices are considerably higher

VENTILATION STANDARDS ETC.

Often, national ventilation/IAQ requirements are prescribed in ventilation standards. The Australian ventilation standard (AS1668.2[2], 1991 and 2002 editions) sets ventilation rates based on odour and health criteria. Odour is the controlling variable so the standard allows significant reduction of required ventilation rate so long as enough for health is provided.

The Australia Ventilation (IAQ) standard contains specific and detailed provisions for the use of GPAC and particulate air cleaners (filters). These provisions include full calculation procedures for situations in which a 'body odour' GPAC of a known efficiency is used.

Practical odour removal devices will tend, also, to remove a large range of health related contaminants – though not, normally, the smaller molecular species such as carbon monoxide and carbon dioxide - so the gaining of economies by using GPAC odour control is likely to be accompanied by much increased healthiness of breathing air.

The USA standard ASHRAE 62 also appears to offer scope for GPAC use.

Some other national standards may need improvement if the economic and environmental (indoor and global) benefits of GPAC are to be gained.

CONCLUSION

Gas phase air filters are seldom well understood and seldom used. There is much economic and environmental advantage to be gained by their use. Proper attention to this potentially most beneficial technology is overdue.

Accumulation Behavior of Intermediate Products on The Surface of TiO_2/ACF Catalysts during The Photocatalytic Oxidation of Toluene: Study of The Influence of Environmental Relative Humidity

Ting Guo, Zhipeng Bai*, Can Wu, Tan Zhu

State Environmental Protection Key Laboratory of Urban Ambient Air Particulate Matter Pollution Prevention and Control, College of Environmental Science and Engineering, Nankai University, Tianjin 300071, P. R. China

Corresponding email: zbai@nankai.edu.cn

SUMMARY

Photocatalytic oxidation (PCO) tests have been carried out for toluene adsorbed on the activated carbon fibers (ACFs) supported TiO_2 photocatalyst in an environmental condition controlled chamber. Through exploring the remnant of toluene and the accumulation of intermediates on the TiO_2/ACF catalyst including species, amount and their change processes under different relative humidity (RH), this study aimed to explore the influence of RH on the PCO of toluene and the role of water vapor in the PCO process: PCO reaction paths and the accumulation of intermediates on the TiO_2/ACF catalyst. Results showed that: (1) with the increase of RH in the chamber (15%, 30%, 45% and 60%) the PCO conversion rate of toluene was positive correlated and no catalyst deactivation was observed under all RH; (2) beside the intermediates of side chain oxidation including benzyl alcohol, benzaldehyde and benzoic acid, which had been reported, byproducts of aromatic ring oxidation including p-toluquinone and o (m, p)-cresol were also observed on the TiO_2/ACF catalyst during the gas-solid PCO process of toluene; (3) although benzaldehyde was the primary intermediate under all RH level, amounts of the byproducts of aromatic ring oxidation were increased with the increase of RH; (4) elevated RH increased the accumulation of benzyl alcohol but assuredly decreased the accumulation of benzaldehyde. These results suggested that: (1) RH affects both the PCO rate and the PCO reaction path of toluene; (2) although methyl group oxidation is the major path, aromatic ring oxidation, which is not the expected path for the PCO of toluene, is enhanced when the RH increases; (3) apart from the role of hydroxyl radical (·OH) arose from water by TiO_2, water molecular also directly takes part in the PCO process. A hypothesis has been proposed: transition species comprised of benzaldehyde, hydroxyl and water molecular exists in the PCO conversion process from benzaldehyde to benzoic acid, though the hypothesis has not been confirmed.

INTRODUCTION

Volatile organic compounds (VOCs) are one group of the main pollutants in indoor air released from many kinds of sources and contribute negatively to human health. Despite the success of adsorption as a means to remove VOCs in indoor air, it does not actually destroy the pollutants but merely remove them for recycling elsewhere in the biosphere; moreover, saturation adsorption is another troublesome problem existing in the adsorption technique. Heterogeneous photocatalytic oxidation (PCO) [1, 2] has been proposed as an advanced oxidation technique for mineralization of various environmental organic pollutants, especially for air decontamination. However, there are still issues unanswered in the application of the

PCO technique. Some of these issues are: (1) lower PCO rate than expected; (2) intermediates environmental toxics and behavior; and (3) catalyst deactivation. Environmental relative humidity (RH) plays an important role influencing on the gas-solid PCO process of VOCs. A large number of studies [3-21] related to RH have been devoted to this field in the last two decades to address three issues mentioned above. The work presented here also addresses this topic.

Toluene is a major indoor air pollutant and various studies have tested the potentiality in the use of gas-phase PCO of toluene for air decontamination [6-12]. In this paper, the PCO of toluene has been researched using nano-TiO_2 immobilized on activated carbon fibers (ACFs). ACFs, a new formulation of activated carbon with high BET surface area and uniform micropore structure, were used to support nano-TiO_2, adsorb toluene and catch hold of all intermediates during the PCO process. Toluene was adsorbed on the TiO_2/ACF catalyst in sample vial firstly, and then adsorbed toluene was photocatalytic degraded in an environmental condition controlled chamber. Elimination of toluene and accumulation of the intermediates under different RH were studied in order to explore the influence of RH on the PCO of toluene and the role of water vapor in the PCO process.

METHODS

Reagents

The grade of all reagents was chromatogram purity grade (Guangfu Reagent Corporation, China). Water used for solution and experimental preparations was ultra-pure water (18.2 Megohm.cm resistivity; <10 ppb TOC) from Milli-Q plus (Millipore, USA).

TiO_2/ACF catalyst preparation

Nano-TiO_2 (Degussa P-25: surface area 50 m^2/g, non porous, about 80% anatase) was used as a photocatalyst without any pretreatment. ACFs (Nantong Senyou Carbon Fibers Corporation, China), in the form of felt, were produced from rayon precursor. ACFs were washed with ultrapure water and dried at 105 ºC before use.

Pieces of ACFs (10 mm×12 mm×1 mm) were put into nano-TiO_2 water suspension (2% wt), under ultrasonic treatment for 60 min. Then the pieces (TiO_2/ACF catalysts) were dried at 105 ºC for 2 h. In all experiments, the amount of TiO_2 of 5.2 mg ± 5% loaded on one piece of ACFs was determined by the difference of weight before and after the coating procedure.

Experimental setup

Adsorption was conducted in the EPA-sample vials with PP Screw Seals (20 ml, ND 24, La-Pha-Pack, Ger.). A stainless steel environmental condition controlled chamber (1 m × 1 m × 1 m, 1.5 mm thick, 1Ni18Cr9Ti) was employed for PCO degradation studies. Illumination was provided by a 15 W UV mercury lamp (Nanjing Jinling Lamp Corporation, China) which emits ultraviolet radiation with a primary wavelength at 254 nm. The UV lamp tube (length 50 cm) on a holder was vertically placed on the bottom of the chamber. A stainless steel circle plate (diameter 10 cm) with eight equiangular and spokewise stainless steel thread rods (diameter 2 mm, length 8 cm) was horizontally fixed in the middle of the lamp tube. Eight metal clamps were fixed on each rod by two hexagon thin nuts respectively with a horizontal distance of 5 cm from the lamp tube surface. Surface of clamps was coated with Teflon film.

Constant temperatures (T, 25 ± 0.5 ºC) and 4 RH levels (15%, 30%, 45% and 60%) in the chamber were achieved by a thermostatic and humidifier controller.

Absorption-degradation experiments

Absorption procedure: 9 TiO_2/ACF samples were put into 9 sample vials respectively, and then vials were sealed. Each vial was injected 2.0 ul toluene carefully by a syringe (10UL, Agilent Corp., USA), and then kept in darkness.

Degradation procedure: After 12 h, 8 TiO_2/ACF samples were taken out from the vials, and fixed on the clamps respectively. Lamp was turned on when the T and RH in the chamber reached the set condition. 6 TiO_2/ACF samples were collected respectively at 30 min, 60 min, 90 min, 120 min, 150 min and 180 min as the experimental samples. 2 TiO_2/ACF samples were collected at 90 min and 180 min respectively as the parallel samples. The 9th TiO_2/ACF sample, as the control sample, was analyzed directly without exposure to UV light.

GC-MS and GC-FID analysis

Accumulated intermediate organic products were extracted from the TiO_2/ACF sample by carbon disulfide (CS_2) and ultrasonication. Qualitative analysis of the filtrate was carried out by the use of an Agilent 6890 Gas Chromatograph equipped with a HP-5MS capillary column and a HP 5975 mass analyzer detector.

Accumulated intermediate organic products and remained reactant were extracted from each TiO_2/ACF sample by 2 ml carbon disulfide with 10 min ultrasonication. Quantitative analysis of the extraction was done by GC (Agilent 6890, Agilent Corp., USA) equipped with a HP-5MS capillary column and a FID detector.

RESULTS

Toluene removal

The conversion of toluene in 180 min under different RH was shown in Fig. 1. It showed that the oxidation conversion of toluene increased from 9.5% to 14.2% when the RH in the chamber increased from 15% to 60%. In the control experiments no peak other than toluene was found through GC-FID analysis and no loss of toluene was found. These results indicated that elevated RH increased the PCO conversion rate of toluene. The conversion rate of toluene was not significantly diminished in 180 min, which indicated that no deactivation of catalyst occurred during the gas-solid PCO process in this study.

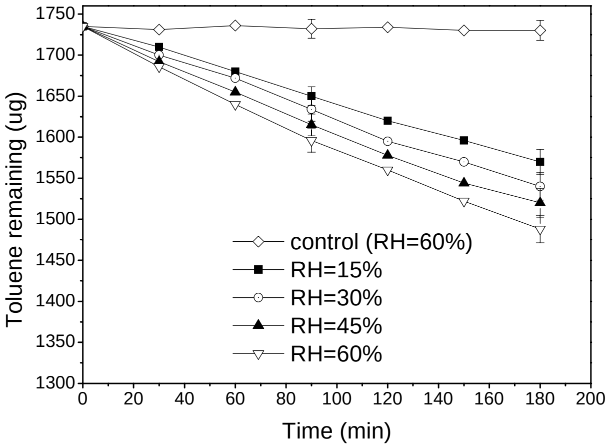

Figure 1. Photocatalytic degradation behavior of toluene adsorbed on TiO_2/ACF catalyst

Intermediate organic products

Intermediate products accumulated on the TiO_2/ACF catalysts during the PCO of toluene were analyzed. Five intermediate products were detected as benzyl alcohol, benzaldehyde, benzoic acid, p-toluquinone and cresol by GC-MS. The accumulation of the intermediate products varied with the increase of RH. Firstly, different levels of intermediate products were found accumulated on the TiO_2/ACF catalysts. Under all RH levels, benzaldehyde was the most abundant intermediate (about 74~89% by mass) and benzyl alcohol was the secondary (about 9~19%). Benzoic acid (about 1%), p-toluquinone (about 1~3%) and cresol (about 1~2%) were trace intermediates. Secondly, the changing trends of the accumulation amount of these intermediates were different. With the increase of the RH in the chamber, the accumulation amount trends of five intermediates: benzaldehyde decreased a lot; benzoic acid increased a little; benzyl alcohol, p-toluquinone and cresol increased a lot.

To explore the detailed reason for the influence of the RH in the chamber, the accumulation process of benzaldehyde and benzyl alcohol were studied and the results were shown in Fig. 2. It can easily be found that the accumulation behaviors of benzaldehyde and benzyl alcohol were opposite. The accumulation rate of benzaldehyde on the catalyst decreased significantly with the increase of RH, however, the accumulation rate of benzyl alcohol increased a lot.

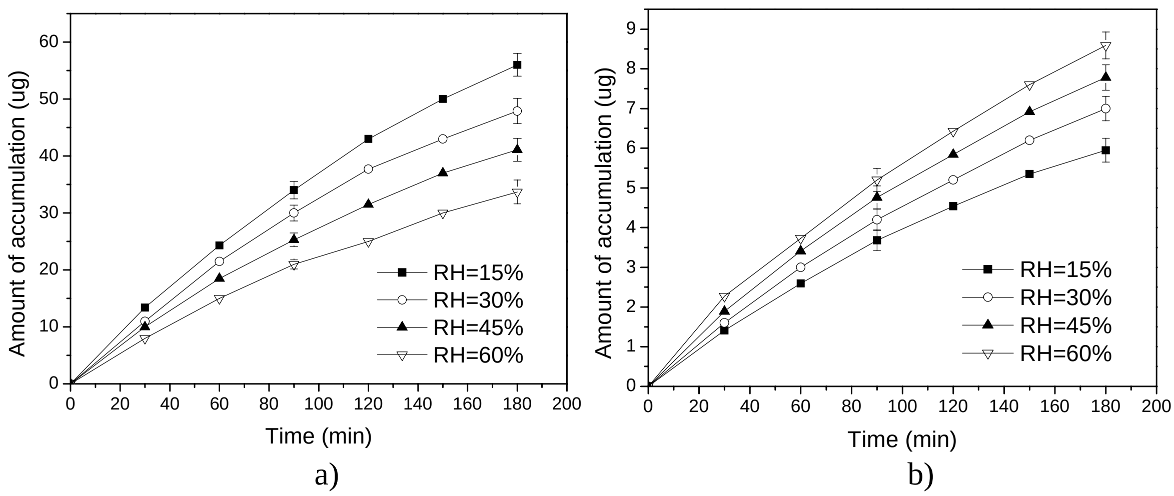

Figure 2. Amounts of intermediate accumulated on TiO_2/ACF catalyst. a) Benzaldehyde, b) Benzyl alcohol

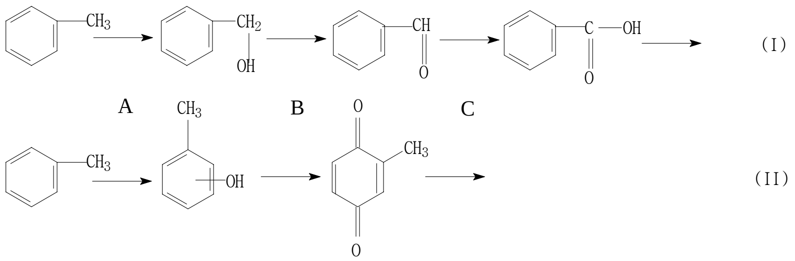
DISCUSSION

Reaction path

There are two kinds of hydrogen atom in a toluene molecule: one is in the methyl group, the other is in the aromatic ring. It is accepted that the oxidation of toluene takes place on the methyl group and proceeds in the following reaction chain: toluene→ benzyl alcohol→ benzaldehyde→ benzoic acid → … → carbon dioxide [16, 17]. At the same time the oxidation of toluene taking place on the aromatic ring as a minor path has been proposed in aqueous solution [20] without much certainty during the gas-solid PCO process [17]. A schematic of the possible degradation paths of toluene is shown:
Path I: Side chain (methyl group) oxidation
Path II: Aromatic ring oxidation



In this study, the formation of benzyl alcohol, benzaldehyde and benzoic acid that have been reported by other researchers [3, 5, 13, 16-17] confirmed the occurrence of path I. At the same time, some intermediate products of the aromatic ring oxidation including p-toluquinone and cresol were also observed in the extraction of the TiO_2/ACF samples, which confirmed the occurrence of path II. However, the intermediate products of the aromatic ring oxidation are usually more poisonous and difficultly oxidized than those of the side chain oxidation. Larson and Falconer [17] reported that the adsorbed m-cresol was photocatalytically oxidized difficulty by TiO_2 catalyst and the catalyst also turned black due to the polymerization of m-cresol to polyphenolic compounds. So, path II is an unexpected path for the PCO of toluene.

Benzyl alcohol, benzaldehyde and benzoic acid were found in all experiments and benzaldehyde also was the most abundant intermediate under all RH. These results indicated that the methyl group oxidation is the main PCO reaction path of toluene. The aromatic ring oxidation is a minor PCO reaction path of toluene because only trace byproducts of this reaction path were observed. However, a fact must be noticed that the accumulation amount of the intermediates of the aromatic ring oxidation increased with the increase of the RH. The distribution sketch map about the intermediate products of side chain oxidation and aromatic ring oxidation after 180 min reaction at 15%, 30%, 45% and 60% RH levels was shown in Fig. 3. It indicated that the condition of RH assuredly changed the PCO reaction process of toluene. The aromatic ring oxidation was enhanced when the RH increased. In view of the environmental toxicity and PCO behavior of their intermediates, it deserves more attention to the PCO of aromatic compounds under high water vapor level.

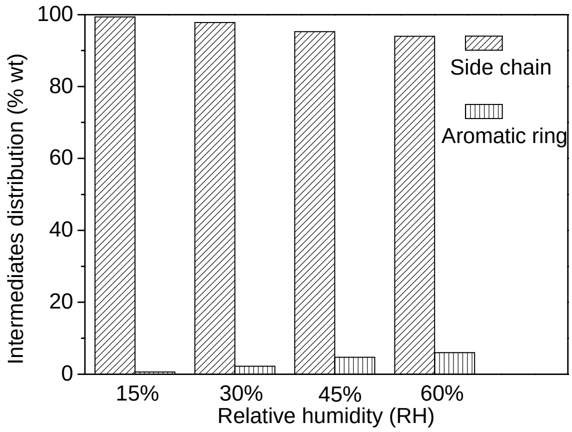


Figure 3. A distribution sketch map about intermediate products after 180min reaction

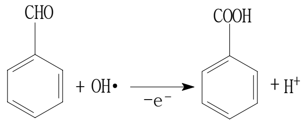
Roles of water vapor

With the increase of RH, the intermediates of side chain oxidation displayed quite different accumulation behaviors on the TiO_2/ACF samples (Fig. 2). Elevation of RH in the chamber increased the accumulation of benzyl alcohol but significantly decreased the accumulation of benzaldehyde.

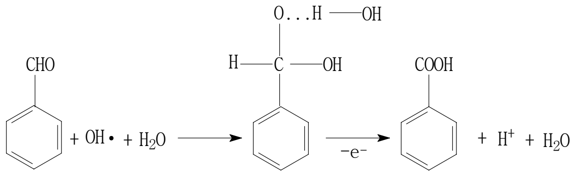
A competitive adsorption between water and organic compounds on catalyst surface had been proposed as a cause of the decrease of adsorption or the increase of desorption of organic compounds under high RH condition [9]. However, two experimental phenomena in our study indicated that it was not the competitive adsorption between water and benzaldehyde that caused the reduction of benzaldehyde accumulation on the TiO_2/ACF photocatalyst when environmental RH was high. Firstly, in the control experiment (using TiO_2/ACF without illumination at 60% RH level), no elimination of toluene by desorption was found within the range of the experimental error (Fig. 1). Secondly, no elimination of the accumulation amount of benzyl alcohol was observed in the experiments though it would be more easily desorbed than benzaldehyde.

In our experimental system, the rate of the conversion of toluene displayed as a quasi-first-order reaction and the increase of RH in the environmental chamber enhanced the PCO conversion rate of toluene, which indicated the apparent reaction rate constant (k) of the conversion of toluene increased (Fig. 1). Hydroxyl radical arose from water by TiO_2 is often assumed to be the major active species to oxidize pollutants without selectivity for aqueous PCO process, however their role in gas-phase PCO is debated [13]. Under fixed illumination intensity, increase of RH in the environmental chamber caused an enhancement of the concentration of OH radical, which should be responsible for the increase of the apparent k. Meanwhile, the increase of the apparent k also suggested that OH radical is the active species in gas-solid PCO system. According to the reaction dynamic principle, the increase of the apparent k of reactant should enhance the accumulation rate of the intermediates. In our experimental system, the accumulation rate of the intermediates increased with the increase of the RH except that of benzaldehyde. So, beside the role of the OH radical, there must exist another role arose from water vapor that significantly affect the dynamic behavior of benzaldehyde.

The photocatalytic oxidation from benzaldehyde to benzoic acid can be simply shown as reaction C1.



(C1)



(C2)

Based on following two facts that: (1) the radical of $C_6H_5CO\cdot$ is unstable and (2) free radical substitution reaction is more difficult than free radical addition reaction for the oxidation of aromatic aldehyde to aromatic acid, we propose a possible PCO mechanism from benzaldehyde to benzoic acid shown in reaction C2. Although no water exists in reaction C1, reaction C2 is consistent with our experimental data. Here, we propose that a transition species comprised of benzaldehyde, hydroxyl, and water may exist in the reaction process though it has not been confirmed yet. We believe that although OH radical is the real active species to oxidize benzaldehyde, water molecular also directly takes part in the PCO process from benzaldehyde to benzoic. The increase of the RH benefits the formation of the hydrated transition species, which enhances the conversion of benzaldehyde and causes the visible elimination of this intermediate compound. In conclusion, water vapor plays two kinds of roles during the PCO of toluene: one arises from the hydroxyl radical which acts as the active species to oxidize pollutants; the other arises from water molecular which improves in eliminating accumulated benzaldehyde.

Species for deactivation

Some researches suggested that it is the nonvolatile carboxylic acid or carboxylate that leads to the deactivation of catalyst [22]. These authors thought that carboxylic acids, usually nonvolatile and with strong bond with catalyst, would accumulate on the surface of photocatalysts and block the active sites on the photocatalysts. However, data from our experiments are inconsistent with this conclusion. If benzoic acid blocks the active sites on the photocatalysts and causes the decline of catalyst activity, a significant accumulation of benzoic acid in the experiment should be observed. However, only trace benzoic acid was observed during the PCO process. Meanwhile, benzaldehyde was the most abundant compound among all intermediate products accumulated on the photocatalyst under all RH. It indicated that benzaldehyde is more difficult to be oxidized than benzoic acid and the step from benzaldehyde to benzyl acid should be the slowest step during the PCO process of toluene. Although there was no deactivation in our experiments, we believe it is the benzaldehyde that should be responsible for the deactivation of photocatalyst in gas-solid system. Besides, due to their quite inert PCO behavior, the accumulated intermediates of aromatic ring oxidation also will be the species for the photocatalyst deactivation especially when the environmental RH is very high.

Merit of TiO_2/ACF

Deactivation of the photocatalyst has been regarded as a fatal disadvantage of the PCO technique in practice and it has involved the attention of any researches aimed at the development of this new technique. When using the bare nano-TiO_2 as the photocatalyst, catalyst deactivation concomitantly exists in the gas-solid PCO process of aromatics especially under low RH condition [3, 6-7]. However, in our study, no catalyst deactivation was observed under any RH conditions. Nano-TiO_2 particles agglomerated only on the outside surface of ACFs, while the inside surface of ACFs was still exposed to the air. The exposed ACFs served as the adsorption centers of pollutants, water and intermediates by physical or chemical process, allowing intermediate accumulated on the catalyst surface without hampering the interaction between pollutant and TiO_2, and reducing the competitive adsorption between pollutants and water [23-27]. So, we believe that lacking active sites is the reason for the deactivation of catalysts and negative effect of water under high RH. TiO_2/ACF composite material, with large surface, is a good photocatalyst suitable for the abatement of catalyst deactivation problem.

Effects of Ionisation Air Purifiers on Indoor Air Quality

Olaf Zeidler, Arne Dahms and Dirk Müller

Hermann-Rietschel-Institut, Technische Universität Berlin, Germany

Corresponding email: olaf.zeidler@tu-berlin.de

SUMMARY

Three different air purifying devices are compared in terms of their influence on indoor air quality. Two systems use ozonisation and ionisation. One system uses ionisation and special filter devices (manufacturer's specifications). In the case of ozone production the perceived intensity and the PD value will increase to inacceptable values. The chemical analyses shows that the increase aldehyde concentration is probably caused by surface reactions between material and ozone.
Purifying devices running with ionisation only have slightly no effect on the perceived air quality. Only one test case, when emissions of human beings are an additionally pollution source in the test room, a small increase in air quality can be recognised.

INTRODUCTION

A common method to achieve good indoor air quality is to reduce concentrations of odorous substances by ventilation. Presently an increasing number of air cleaning devices are offered on the market. The manufactures promise a reduction of odour-active substances in the room air.
Up to now, only very few data is available [1, 2] on the odour removal efficiency. Most of the time the efficiency of these devices refers only to manufacturer's specifications. Therefore systematic tests are made in a new experimental set up.

EXPERIMENTAL SET-UP

With two identical, ventilated test rooms the efficiency of different air cleaning devices are examined. Figure 1 shows the location of the two test rooms (room 1 and room 2) in the air quality lab. The dimensions are 2.5 m x 2.5 m x 2.5 m. Both rooms are supplied with outdoor air by the same supply air duct and two fan coil units.

The rooms are built from the same building materials and have the same furnishing, similar to common office rooms. A controllable air flow of the polluted indoor air of the test rooms is extracted by a potential free tubing of stainless steal. It is presented with diffusers to a panel of subjects to assess the air quality. In addition, the air contaminants are analysed chemically by using GC/MS technology via TENAX probes.

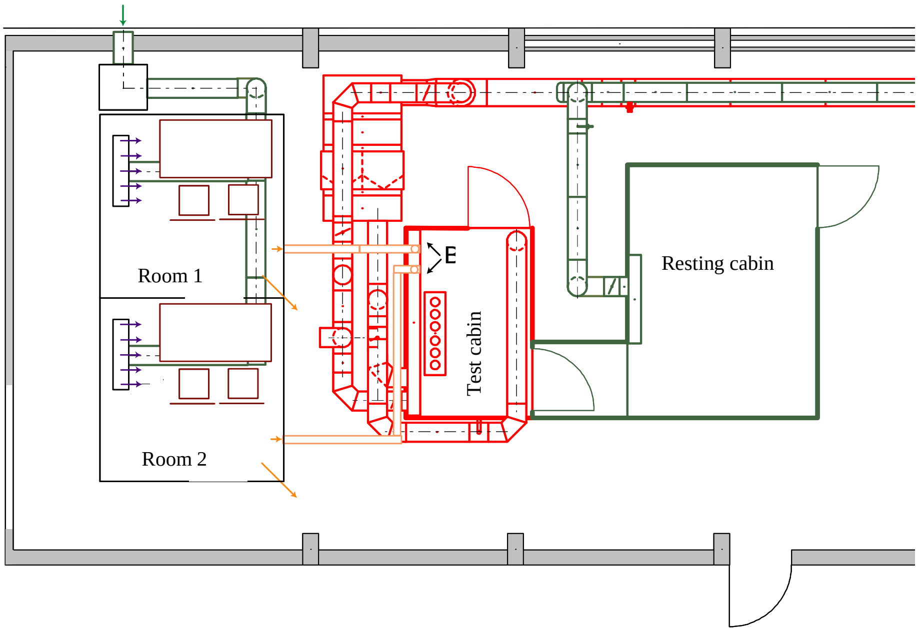

Figure 1: Sketch of Test Setup in the Air Quality Lab with two test rooms and the cabins for the panel [4]

METHOD

The air in the two test rooms is polluted by the equipment (standard building materials like carpet, furniture and wallpapers). In the first step of the experiment the perceived odour intensity, the acceptability and the hedonic impression of both rooms is evaluated.

The perceived intensity is measured with a selected panel of 10 persons [3, 4]. When assessing perceived intensity of unknown samples, panel members can rely on a comparative scale of acetone/air mixtures, the so-called markers, which help to determine the intensity. The perceived intensity Π can only be determined with trained panels using a comparative scale.

Unlike the acceptability method with untrained panels, the intensity of odorous substances in the air is determined by a comparison with different specified intensities of the reference material acetone. The smelling capability varies from human to human. Training and use of comparative sources ensure that the influence of subjective perception of the test result is reduced since all panel members evaluate air quality based on the same scale.

A naive panel of 40 persons is asked about the acceptance of the air quality. Therefore a continuous scale is used for the acceptability. It is converted into values of +10 (clearly acceptable) to –10 (clearly not acceptable). An average value is calculated from all answers to calculate the acceptability [5]. In addition a question to the hedonic impression is answered by both panels.

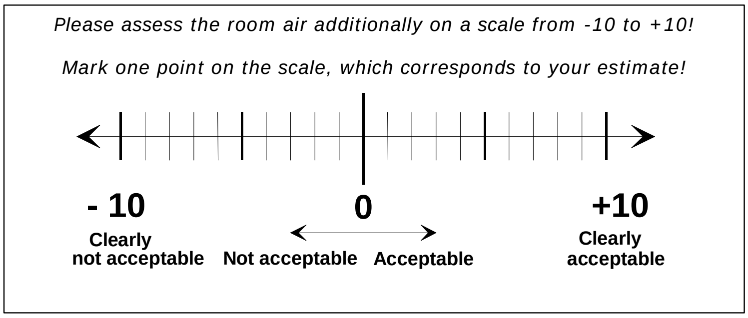

Figure 2: Question to determine acceptability

Three different purifying devices are tested separately. In one of the test rooms the device is installed, the other room is running without any purifying for comparison. For each device a test series over several days is done. In intervals the perceived intensity Π, acceptability and the hedonic impression is assessed for both rooms at the same time in a blind test.

PURIFYING DEVICES

In Table 1 the technical specifications are listed. Type 1 and type 2 have a built in purifying device, which produces ozone and ions. For type 1 there is only the option to run both modes n the same time. Type 2 can produce ozone and ions separately. The stand alone device type 3 has four options for different modes. The manual shows the “turbo” mode as the mode for fast air cleaning. Therefore this mode is tested, additionally all other options are switched on.

Tabele 1: Technical specifications of the tested air purifying devices (manufacturer's specifications)

Type	**1**	**2**	**3**
	Decentralized fan coil	**Decentralized fan coil**	**Stand alone in room**
Purifying Method	Ionization and ozonisation	Ionization and ozonisation	Pre filter Plasma ioniser Bio antibody filter Ionising frame Ionised wire Streamer discharger Opposing pole plates Plated filter (electrostatic) Photo catalyser
Tested working modes	Combination of ionisation and ozonisation runs in out door air modus	Combination of ionisation and ozonisation runs in air recirculation modus	**Auto** (automatically adjusted air volume flow) **Turbo** (fast air cleaning), **Anti Pollen** (removing pollen) **Relax** (negative ions)
	---	ionisation without ozonisation runs in air recirculation modus	---

RESULTS

In the first step a comparison of the two test rooms was done. Figure 3 shows a good analogy in the air quality of both rooms.

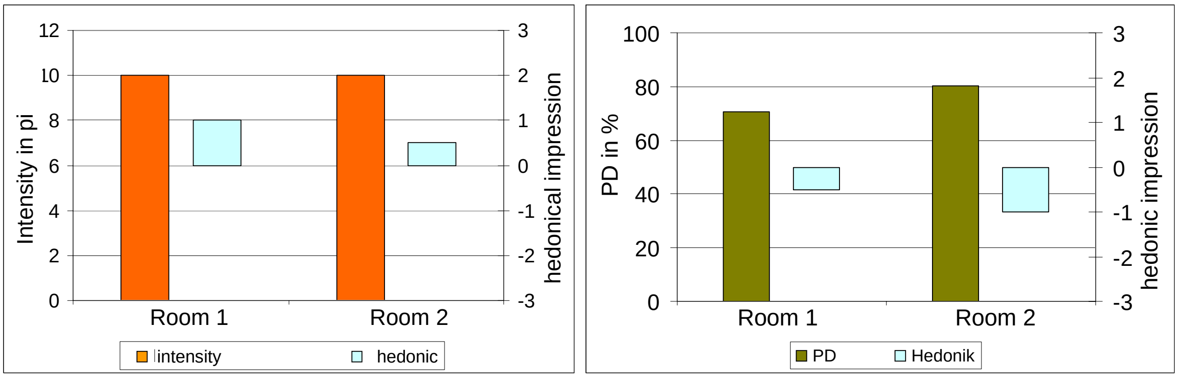

Figure 3: Perceived intensity and hedonic impression, PD and hedonic impression

The perceived intensity is similar for both rooms. The value of 10 pi characterises a strong odour impression. The hedonic impression of the rooms is also quite similar. The acceptability measurements show as well very comparable results for both rooms. During the time the PD-value and the intensity decreases equally in both rooms because of normal emission of the materials and the ventilation.

This similar air quality state in both rooms is the starting point of all investigations of the three different purifying devices.

Device 1

This device runs with a combination of ozone production and ionisation. The ozone concentration in the room is in the range of 50-70 ppb (alternating because of internal control loop).

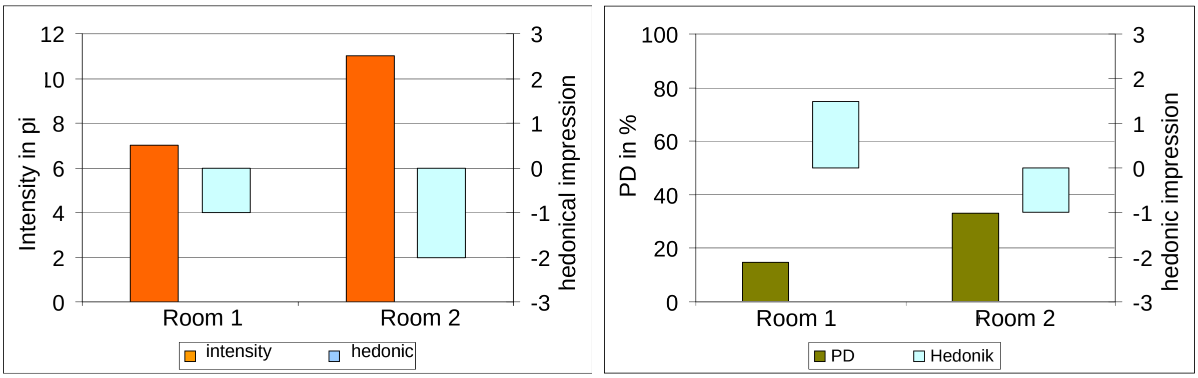

Figure 4: Perceived air quality, hedonic impression and PD for device 1

Figure 4 shows that the purifying device increases the perceived intensity about 4 pi in comparison to the room without purifying device. The hedonic impression becomes negative when the device is switched on. Measurements with the naive panel show similar results. The question of the acceptability gives a PD level of about 15 % for the room without purifying device and about 35 % with purifying device.

Device 2

First device 2 runs in the ionisation mode only with recirculating air. Figure 5 shows that there is slightly no effect on the perceived intensity Π and the acceptance values. Only a positive tendency in the hedonic impression of the panel that perceives the intensity can be recognised.

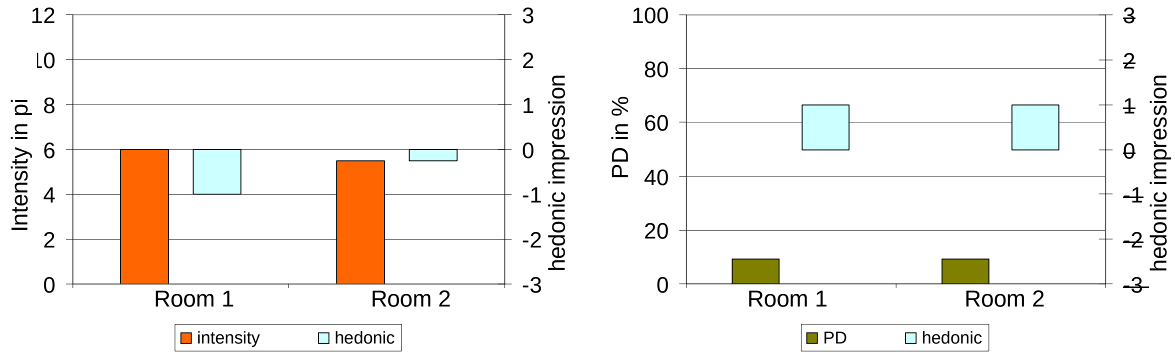

Figure 5: Perceived air quality, hedonic impression and PD for device 2 in ionisation mode (test 1)

Second, device 2 runs in a mode that combines ionisation and ozone production. In Figure 6 the influence of the ozone production (20 ppb) on the perceived intensity is shown. The intensity increases from 6 pi to 9.5 pi.

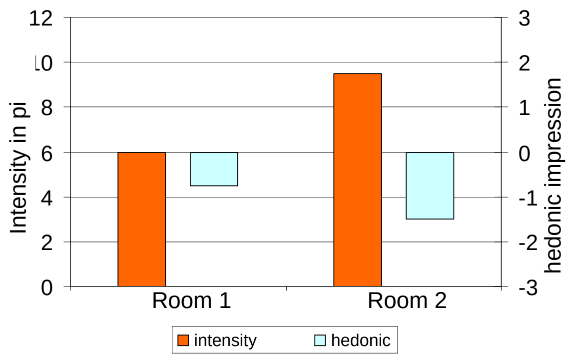

Figure 6: Perceived air quality and hedonic impression for device 2 in ionisation and ozone mode (test 2)

A third test run was made with persons as additional pollution source in the test room. The results are given in Figure 7, where a little increase can be recognised in the hedonic impression. The perceived intensity is nearly the same for both rooms.

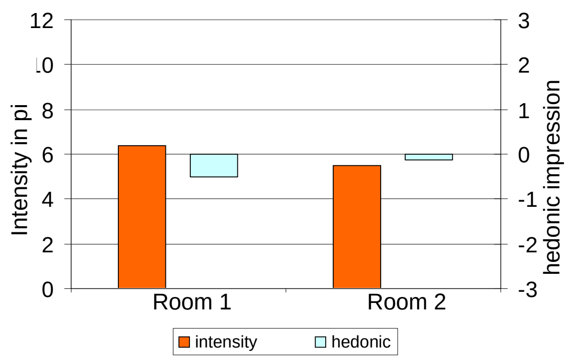

Figure 7: Perceived air quality, hedonic impression for device 2 in ionisation mode, person as pollution source in the test room (test 3)

Device 3

For this stand alone device the internal functions are not documented properly, it runs in the "turbo" mode with all options switched on.

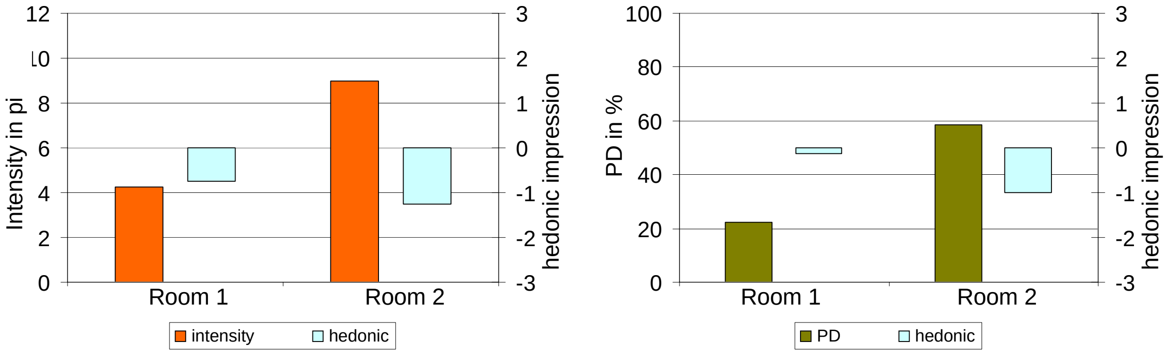

Figure 8: Perceived air quality, hedonic impression and PD for device 3 in automatic mode

Figure 8 shows that perceived intensity and hedonic impression is worse in the case with purifying device also the PD value raises from about 25 % up to nearly 60 %.

Chemical analyses

As an example for all of the chemical measurement the data of device 1 are discussed. The results from chemical analyses using GC/MS technology show the influence of ozone concentration in the room. Figure 9 indicates an increase of the concentration of aldehydes. The dark part of the bar shows the concentration in the test room without air purifier, the whole bar stands for the concentration in the room with running device. One reason of the rising concentrations are chemical reactions of ozone on the surfaces in the room [6]. Products of these reactions are aldehydes. Aldehydes as nonanal and hexanal have a strong odour impression and this might be a reason for the worse perceived air quality. Other concentrations of chemicals are low, but in most cases there is an increasing of concentration according to the ozone concentration. The addition of several chemicals in low concentration can cause odorous irritations.

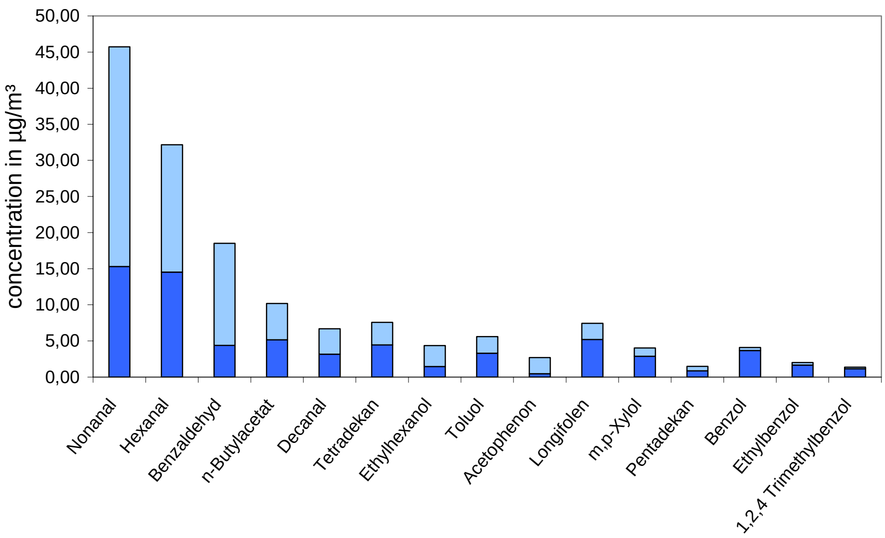

Figure 9: Increasing concentration of aldehydes caused by ozone

SUMMARY

AIRSECURE project develops a protective solution against airborne threats for airport environment. The development efforts are based on risk analysis, and the developed technologies include high efficiency particle filtration, chemical filtration, detection of aerosol particles and hazardous chemicals

INTRODUCTION

The AIRSECURE project is a European Research (CRAFT) project, where the Commission supports the work by providing participating small companies the possibility to utilize the work of large research institutes. The AIRSECURE project will develop a system that consists of filtration and detection solutions against airborne threats at airports. The design and operation of the system is based on Risk analysis and Risk management. Thus the complete AIRSECURE system can be divided into three main component groups: risk management, filtration solutions, and detection solutions.

The fear of terrorist attacks against civil targets has increased recently. One of the most frightful scenarios is the use of airborne chemical, biological or radiological (CBR) weapons against unprotected civilians. Of particular concern are airports where such an attack may cause extensive injury and severe impact on the aviation industry and the whole economy of the European Union.

In a possible attack with CBR agents it is credible that the mechanical ventilation system will be used for agent delivery since any release into the ventilation system would be rapidly spread throughout the ventilated spaces. High efficiency filtration and real-time detection of hazardous agents are among the potential measures that can be implemented in advance to reduce the consequences of intentional CBR agent release. However, while it is possible to rapidly detect chemical compounds, it is a very challenging task to develop fast and sensitive sensors for biological agents.

In principle, high efficiency filtration can be used to reduce the risk of airborne threats delivered through mechanical ventilation systems. However, because of the high pressure drop, large space requirements and the high initial and operating costs the present high efficiency filters are not practical solutions for existing buildings. Moreover, their installation would need costly and time-consuming renovation of the whole ventilation system. The AIRSECURE system will improve the security of passengers and workers at airports by a comprehensive approach including risk analysis for identifying the high-risk areas, novel protective filtration systems, proper air distribution, and detectors for early warnings of threat.

The main idea of the AIRSECURE solution is to combine promising new filtration technologies for removal of both biological and chemical agents with a protective filtration unit. These distributed units can be flexibly and quickly installed in the supply or exhaust air ducts of the high-risk areas. The very low flow resistance of the filter allows its installation without extensive modifications to the ventilation systems. New particle detectors will be developed to monitor the performance of the filtration system for maximum security. The optimum number and location of both particle and gas detectors and protective filtration systems are based on risk analysis. The secure air-filtration and advanced warning systems can deter the attacks, and reduce the effects of a CBR agent release by removing the toxic agents from supply air of the building.

MAIN INNOVATIONS OF AIRSECURE

The main challenges of a protective system and the ways AIRSECURE tackles these challenges are presented in Figure 1. In order to overcome preceding technological barriers, the AIRSECURE system consists of

1) Chemical detectors with centralized monitoring
- Fast evacuation
- Real-time information of the dispersion of toxic chemicals (impurities)
- Protecting large spaces (halls)

2) High efficiency filtration combined with particle detectors
- Continuous protection against bio- and other aerosols in selected premises
- Particle detectors ensure safe operation of the filters at all times and give information about abnormal particle concentration levels
- Particle detectors are monitored through the same centralized system as the chemical detectors
- Versatile chemical filters applied in areas of sensitive operations

The principle of the AIRSECURE system with the possible locations of detectors is shown in Figure 2. Among crowded populations, airborne transmission predominates the spread of several diseases in enclosed spaces. Thanks to the improved filtration, the AIRSECURE system also provides the added benefit of minimizing the transmission of natural diseases through the ventilation system.

In the presentation results of the laboratory tests of the developed components and preliminary field tests will be presented.

SUMMARY

This study is in the frame of indoor air quality from the particle pollution point of view and its goal is to determine the particle penetration factor for different common types of leaks which deteriorate the filter capacity of building envelope. The most important parameters for the particle penetration are: the crack geometry, the pressure difference and the particles' diameter. CFD numerical simulations have been done for rectangular cracks with 0.2mm and 1mm height for 40mm and 94mm length, also changing the pressure difference between 4Pa and 10Pa. The penetration coefficient showed to be bigger than 90% for particle diameters less than 3µm for cracks with 1mm height regardless their length or pressure difference. For the diameter span from 3µm to 8µm the penetration factor varies from 90% to 15% depending on the pressure difference and only the particles bigger than 8µm are completely filtrated by the studied cracks. We have found good agreement between the numerical simulations and bibliography.

INTRODUCTION

People spend most of their time indoors being exposed to the pollution level determined by the inside sources as well as by the change realized between the inside and outside environment through the building envelope. Outside air enters generally by three means: mechanical ventilation, natural ventilation and infiltration. If the first two mechanisms can be almost controlled, the last one refers to the undesired air flows through the cracks of the building envelope. The infiltrated outside air is charged with particles characterized by diameters in the most dangerous domain for human health. The leaks are present in the building envelope, even if they are undesired, around the windows, doors and at the connections between the walls and ceiling. Common cracks are characterized by changing properties in time and space being so very difficult to establish a relation between them and the ones that can be reproduced in laboratory tests or in numerical simulations.
In order to determine the characteristics of infiltration it is necessary to establish the summa of the parameters that influence it and the correlations between them. An overall characteristic number for the process of infiltration it is called the "coefficient of penetration" and states the degree of outside pollution level which is encountered in the indoor climate. The parameter is defined as the ratio between the number of particles encountered at the inside end of the crack and the number of particles assumed to be entered in the outside end of the crack for a certain particle diameter or a granulation range. The shell filtration efficiency can be then easily determined as the difference to unit of the coefficient of penetration.
In residential environments without the operation of mechanical ventilation, infiltration becomes the dominant ventilation mode, while penetration determines how much of ambient

particle can be brought from outside into the indoor environment [1]. The effect of particles size from 0.02µm to 10µm on penetration coefficient was evaluated [1] by Chao et al. and they established a peak of 0.79 at the size range of 0.853-1.382µm. For the domain of 4.698-9.647µm the penetration coefficient showed the minimum value of 0.48.
Liu and Nazaroff proposed a physical model for the evaluation of the penetration factor [2]. Its main components were defined as partial factors and were due to gravitational settling, surface adherence by means of van der Waals forces and Brownian diffusion and impact settling induced by crack bends. They also estimated the air flow characteristics in cracks by respect to the crack geometry and the pressure difference between the crack's ends. The penetration coefficient was calculated for a range of particle diameters from 0.001µm to 100µm, for a pressure difference domain between 4Pa and 10Pa and they concluded that the domain where the penetration factor is different of 0 or 1 is for the particle diameter between 0.5µm and 10µm for simple rectangular cracks.
Liu and Nazaroff later presented the results of laboratory experiments [3] meant to confirm the accuracy of the physical model and to determine its applicability range. In their paper [3] they experimentally studied the same simple rectangular cracks in order to determine the correlation between the physical theoretical model and experiment. Generally speaking the correlation was in good terms especially for the most sensible domain of particle diameters ranging from 0.5-7µm but some discrepancies were found. They explained their origins in the influence of crack material roughness versus boundary layer thickness and boundary layer distribution functions. One of the conclusions was linked to the recommended mesh dimension that must be of the same order of magnitude with the boundary layer determined as a value of 100-400µm for particles averaging 0.3µm in a crack of 0.25mm height at a pressure difference of 4Pa. They also stated that for particles larger than 0.4µm, where gravity became to control deposition, roughness appears to be relatively unimportant, and the smooth surface model generally confirms well to the experimental data.
Regarding the influence of the pressure difference applied on the crack upon the coefficient of penetration, Mosley et al. [4] showed out for the particles of 2µm an increase of the percent value of the penetration factor from 2% at 2Pa to 40% at 5Pa reaching 85% at 10Pa. They linked those results to the variations of the speed distribution in the crack, as the increased value of the aerosol speed determines the advection of the deposed particles to the indoor climate. So, the flow characteristics in the crack as flow and speed distribution are critical in the pressure difference domain of 1-10Pa for cracks averaging 0.5mm in height.
Liu and Nazaroff applied a general model based on mass conservation law to particle transfer from one chamber to another through real windows (both domestic and industrial types)[5]. The measurements were used to quantify general factors introduced in the equations with the purpose of easily evaluating other functioning circumstances and determining a quality factor for the window by respect to the penetration coefficient. They stated that the distribution of window leakage dimensions determines the overall performance of particle filtration rather than the leakage area itself as a global value. The results indicated that airborne particles of 0.2-3µm have greater penetration factors than particles of less or bigger diameters.
Nowadays, as the requests for indoor comfort became more and more demanding, a good approximation of the pollutant transport through the building shell is needed. Those models should be able to describe the complex geometry of the real joints for construction elements, windows and doors. Most of the data found in the literature come from experimental works or general physical models computation, but those means can be applied only on simple geometry cracks which do not characterize the real life case. The idea of applying numerical simulations for the evaluation of penetration factor of the pollutants for the real cracks offers the advantage of rapidity and low costs modeling, especially when a group of different geometries of the cracks is studied in the same project. The present paper aims to determine

the most appropriate input conditions for the numerical simulations as the air flow parameters, the turbulence model, the pollutant injection model, the boundary conditions, the mesh geometry requirements and other specific conditions in order to obtain the pollutant penetration factor. In order to evaluate the accuracy of the numerical simulations, existent experimental data were considered as a reference and compared with the numerical simulation results.

METHODS

A Computational Fluid Dynamics (CFD) program was used for the numerical simulations. The program is able to determine the trajectories and speed distribution fields and the heat and mass transfer for certain imposed boundary conditions, for a linear or non linear mesh distribution. The numerical solution techniques employed in solving the equations of mathematical models use the finite volume method.
The accuracy of the results depends on the conditions imposed in the input section of the program. So, for the general geometry of the model we chose two identical volumes of air linked by a wall provided with a single crack. The volumes were dimensioned as to be large enough in order to be considered an infinite space by respect to the flow disturbances generated by the crack in the flow. The flow engine through the crack is the pressure difference established between the two volumes separated by the solid wall. The pressure difference between the two volumes is obtained with constant pressure boundary conditions imposed on the volume fluid limits. The presence of the solid wall generates wall boundaries conditions specific for fluid flow. A non linear mesh distribution was chosen in a way to allow sufficient precision for the calculus in the zones of interest like boundaries or, more important, close to the crack, but also to diminish the total number of cells having a low refined mesh in the zone were the effects of the crack are not important. In the figure 1 with red color (darker) is represented the fluid zone and with the green color (lighter) the solid wall. It can be noticed the different zonal mesh refinement.

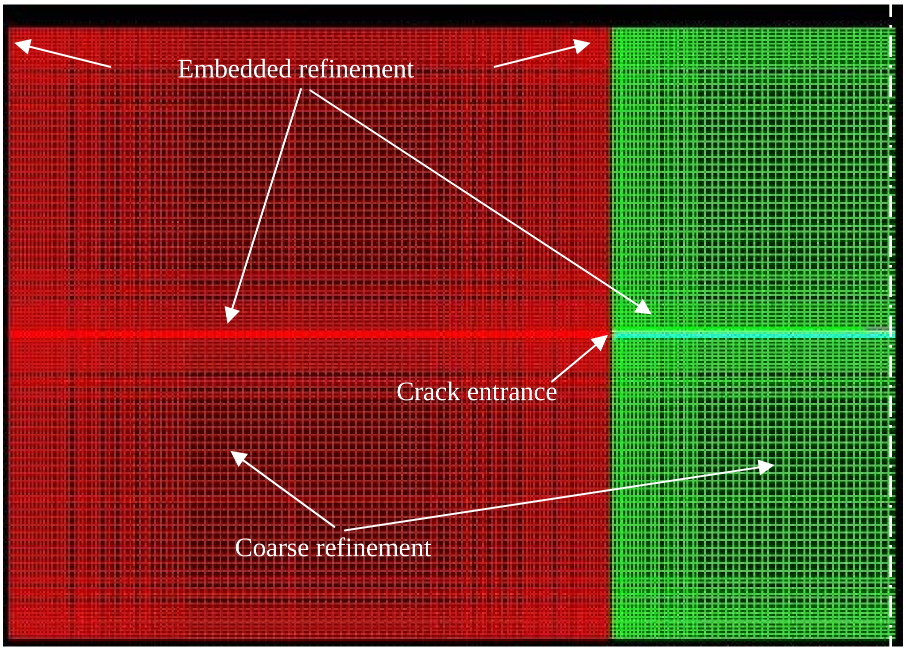

Figure1 – Zonal mesh refinement of the model

For the first step of the study we chose to simplify the model by considering a bi-dimensional case partly because the simulations are to be obtained faster and also because the data used as reference are from bi-dimensional type cracks.

The studied cracks had a simple rectangular geometry. The chosen cracks' height was 1mm for two different lengths of 94mm and 40mm. The solid wall material was defined as well finished concrete with normal roughness. According to the reference data three levels of pressure difference were studied: 4Pa representative for weather induced pressure, a value also considered as reference for the definition of Effective Leakage Area by ASTM (E779-99) and by ASHRAE Standards, 10Pa as the most common wind driven difference pressure and 7Pa as an intermediate value necessary to determine the curve evolution between the two marginal points.

The most dangerous particles' diameters span for the human health reaches from 0.5 to 10μm, so than we have chosen for our case this particles' dimensions domain. Although for this range the penetration factor for the studied cracks' conditions covers almost the entire span. For the numerical simulations the values of 0 and 1 for the penetration factor are not considered representative in the validation of the model. The injected particles were made of a solid with the density of 1000kg/m^3 and had the spherical shape.

Three different types of particles injection were studied and compared among: a punctual injection in the entrance of the crack, some punctual injection points disposed on the height of the crack and the third one, considered being the closest to real case, some points of injection situated on the isodynamic lines at the entrance of the crack. The initial speed of each particle was equal in direction and value to the air speed in the injection point (isocinetical injection).

The Lagrange model was considered for the dispersed phase flow as being the most suitable because of its characteristic of explicitly describing the interactions between particles and fluid. The complexity of the equations and the high number of unknown parameters involved is a disadvantage but did not influence the stability of the numerical solution. In this model the trajectory of the particle is given by the vector equation of the resulting force which drives the particle. The resulting force (R) generally represented by equation 1 has the components expplained in equation 2: the drag force (F_f), the fluid displacement force $(\vec{F}_{dizl.fluid.})$ and the small particle specific forces (F_{sp} - gravity force and diffusion force).

$$\vec{R} = \vec{F}_f + \vec{F}_{dizl.fluid.} + \vec{F}_{sp} \ , \qquad (1)$$

$$\frac{\pi}{6} d_p^3 \rho_p \frac{dU_p}{dt} = C_d \frac{\pi d_p^2}{4} \rho \frac{\left|U - U_p\right|\left(U - U_p\right)}{2} + \rho \frac{\pi d_p^3}{6} \frac{dU}{dt} + F_{sp}, \qquad (2)$$

Where d_p is the particle diameter, ρ_p is the particle density, C_d is the discharged coefficient of the particle, U is the mean air speed, t is the time and U_p is the relative speed of the particle by respects to the carrier fluid.

Three turbulence models were available for the present case: low Reynolds number model, high Reynolds number model and a relaxation model known as V2F. For the high Reynolds number turbulence model the wall function representation of the near-wall turbulent behavior can be not accurate, depending on the degree to which the assumptions and the approximations embodied in the distribution functions correspond with the reality of the application. Due to the lack of information regarding the distribution functions for the present case and also because the number of iterations needed to accomplish the required precision (see figure2) is higher than using other models, the high Reynolds number model was not chosen. The V2F model is a relaxation model based on the equations for the kinetic energy and its dissipation rate. The model is claimed to be valid throughout the flow domain while automatically modeling the region close to solid surface. It was designed to handle wall effects in turbulent boundary layers and to accommodate non-local effects. It has been improved to give a more accurate prediction of near wall flows including separation, heat transfer and wall friction. This model would fit very well the present application, but as it is shown in figure 2 its convergence is slower than in the case of using the low Reynolds number turbulence model. The low Reynolds model also treats the near wall region, in most respects, the same way as the interior flow, with no slip conditions imposed at the boundary surfaces. Therefore, in this model, the law of the wall is not required. In addition to these advantages the smaller number of iterations is accomplished also for low Reynolds number turbulence model and that’s why this model was chosen for the numerical simulations.

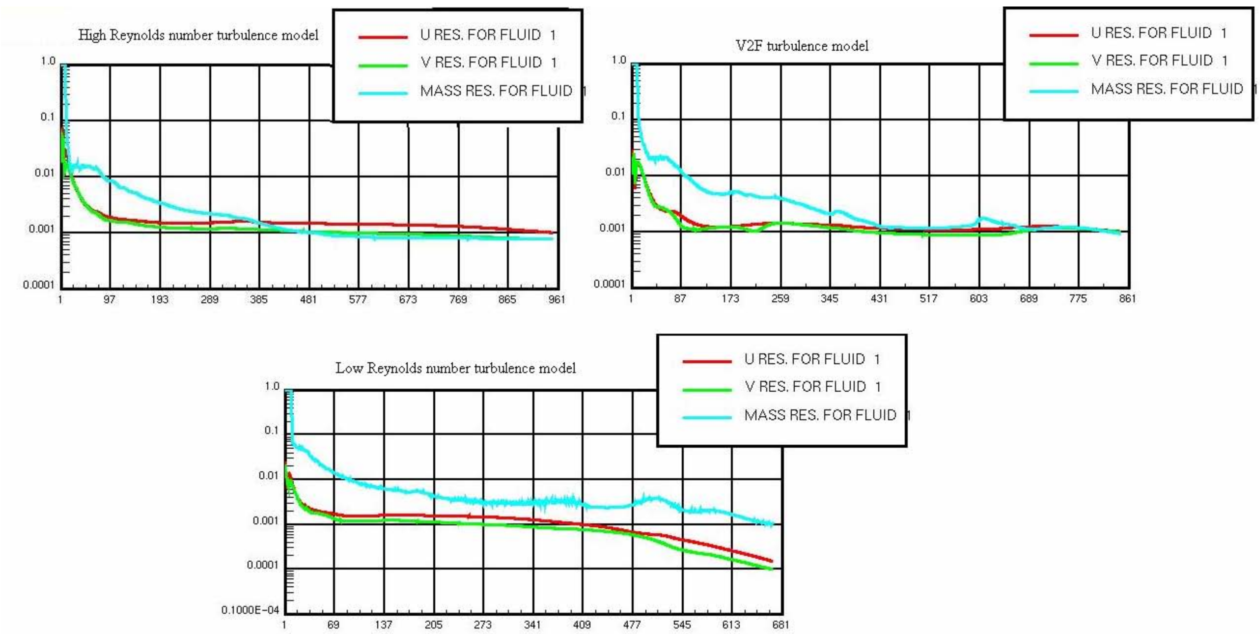

Figure 2 – Convergence residuals as functions of iteration steps for the equations matrices for the three turbulence models considered for the application: high Reynolds number, V2F and low Reynolds number

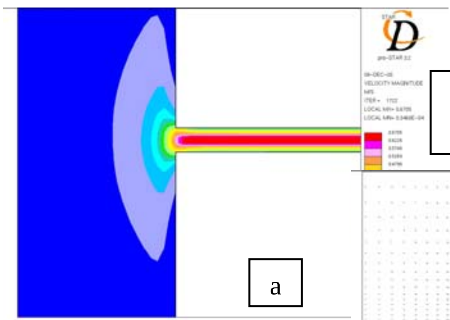
RESULTS

In order to establish the penetration coefficient for a large number of real situations the main parameters were varied and their influence quantified comparatively for sets of simulations. The parameters varied are: the crack length (the dimension of the crack along the main flow direction) 94mm or 40mm, the crack height – 1mm or 0.2mm, the particle diameter – from 1 µm to 15µm and the pressure difference 4Pa, 7Pa or 10Pa.

In figure 3 is presented an example of the calculated flow at the entrance of the crack.



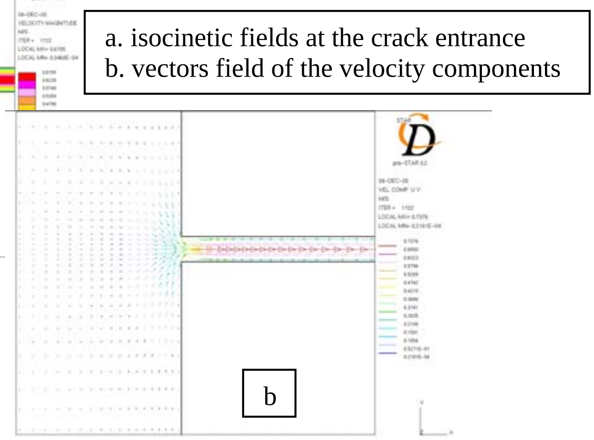


Figure 3 – Example of velocity fields at the entrance of the crack

It is important to mention both the coherence of the velocity fields and the fact that the influence of the crack in the flow is local and does not reach the boundaries where initial conditions were imposed suggesting that the overall dimensions of the chambers are correctly designed.
At first we aimed to verify the validity of the numerical model by comparing the results obtained for a crack of 94mm length, 1mm height and a pressure difference of 10Pa with the data from other authors' calculations [2] and experimental investigations [3]. In figure 4, four sets of values are represented: two of them from literature, one from the bi-dimensional CFD model and one from a simplified 3D CFD model (a small number of cells for the third dimension).

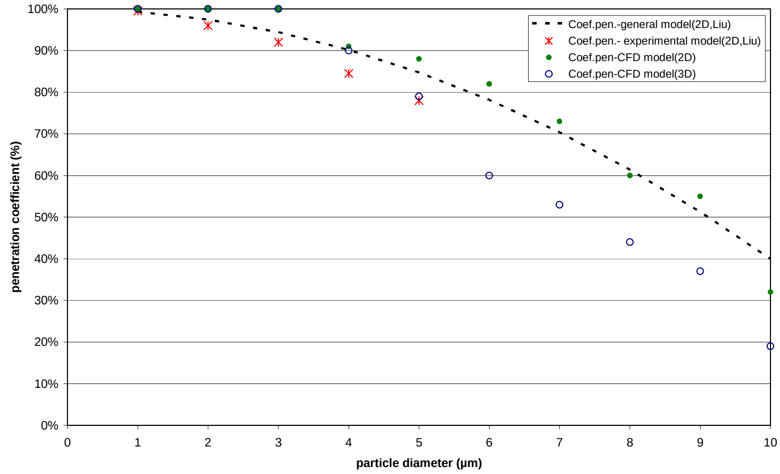

Figure 4 – Compared values for the penetration coefficient for a crack of 1mm x 94mm, 10Pa

For the CFD 2D-model the values are in accordance with those calculated or experimentally determined by other authors. That leads to the conclusion that the flow results and particles' trajectories are correct meaning that the model geometry, mesh definition, boundaries conditions and flow model were correctly set. For the CFD 3D-model the obtained results are in a logic range of values by respect to 2D case but there are no referential data to be compared with.
In figure 5 are compared the results for the penetration factor for a crack of 1mm x 94mm when the pressure parameter is varied among three referential values: 4Pa, 7Pa and 10Pa.

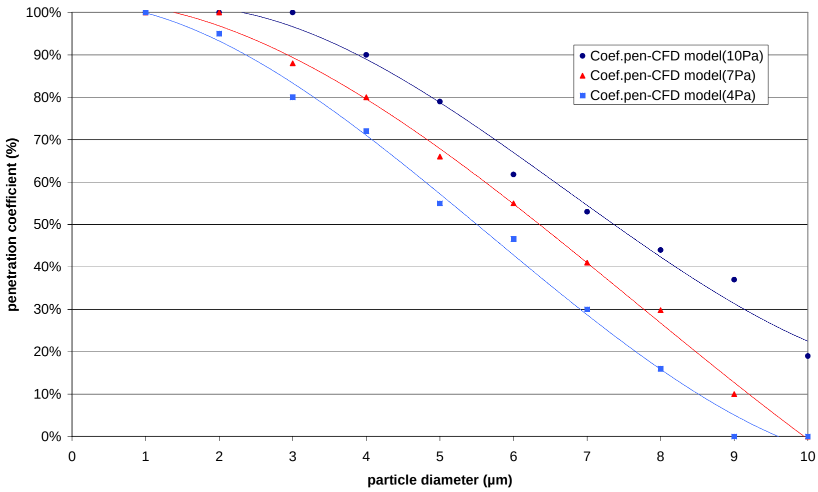

Figure 5 – Compared values for the penetration coefficient for a crack of 1mm x 94mm, at 4Pa, 7Pa and 10Pa

The values obtained clearly reflect the influence of the pressure on the process. For the particles' diameter less than 2µm the penetration coefficient is 100% regardless of the pressure difference. For the particles' diameter in the range 3µm - 8µm a decrease of the penetration coefficient with 10-60% is observed suggesting that this is the domain the most sensible to the variation of the pressure difference. For the bigger particles the penetration coefficient has low values or even reaches 0%.

The next influential parameter that was varied is the crack's length from 94mm to 40mm. The results presented in figure 6 show out the major influence of this parameter for this domain of pressure difference and crack heights. So, the ratio between the crack length and the crack height is one of the most important parameters for the filtration capacity of a construction element as confirmed by the results presented in figure 7 which represents the variation of the penetration coefficient at a fixed crack length for two different crack heights at the same pressure difference.

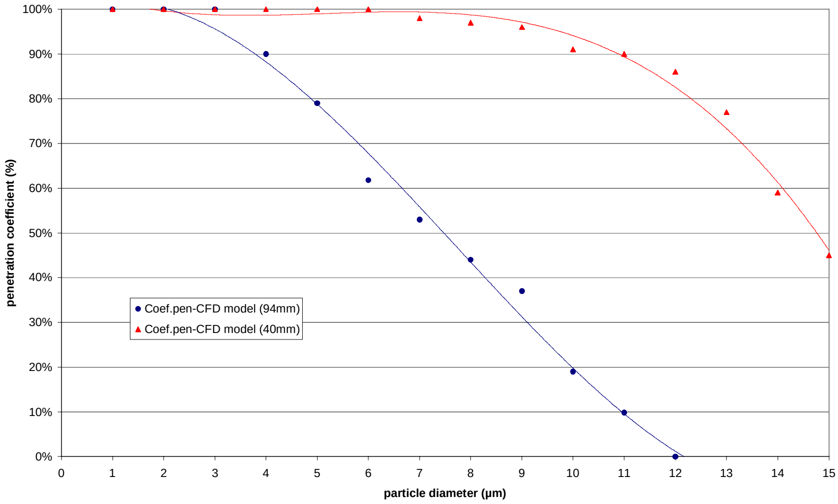

Figure 6 – Compared values for the penetration coefficient for a crack of 1mm height and 94mm or 40mm length at 10Pa

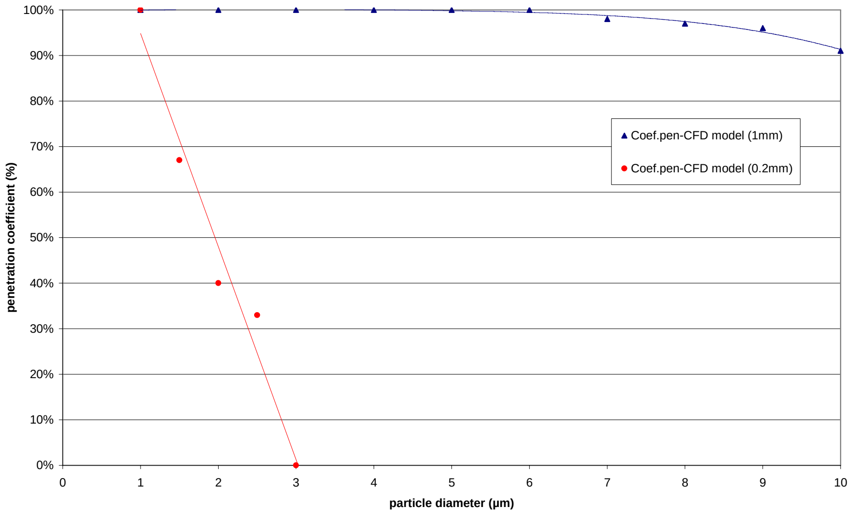

Figure 7 – Compared values for the penetration coefficient for a crack of 40mm length and 0.2mm or 1mm height at 10Pa

DISCUSSIONS

The numerical simulations showed to be in good agreement with the data from literature meaning that an extent of the application can be obtained for more complicated, close to real geometries, for a wider span of particle diameters and pressure differences. The biggest advantage is the quick and costless change of input data by respect to experimental works, but of course we intend to experimentally validate a few future more complex cases of numerical simulations.

The penetration coefficient showed to be higher than 90% for particle diameters less than 3µm for cracks with 1mm height regardless their length or pressure difference for the studied domains. For the diameter span from 3µm to 8µm the penetration factor varies from 90% to 15% depending on the pressure difference, only the particles bigger than 8µm are completely filtrated by the studied cracks.

The data obtained indicated the major importance of geometrical and physical parameters prior considered as important and permitted a global evaluation of their influence upon the infiltration phenomenon. So, for the same pressure difference, the dimensionless parameter (narrowness number) defined by the report between the crack's height and the crack's length has a major influence on the filtration efficiency of the crack. For a particle of 2µm the filtration effect decreases from 60% to 0% for an increase of the narrowness number from 1/200 to 1/100. Increasing the particle diameter to 4µm the effect becomes more evident the filtration effect decreasing from 100% to 10%. These observations determine us to further study the influence of the narrowness number on the filtration efficiency for a wider span of building cracks.

Ozone Removal, ultra fine particles, and VOC levels on sooty supply air filters in the presence of alpha-pinene

Marko Hyttinen, Tuomo Laitinen, Pertti Pasanen, and Pentti Kalliokoski

University of Kuopio, Finland

Corresponding email: Marko.Hyttinen@uku.fi

SUMMARY

Ozone removal, concentration of ultra-fine particles (2 to 64 nm), and VOCs were measured on sooty ventilation filters. A F8 class filter loaded by diesel soot particles in a motor laboratory and a heavily loaded F5 class filter used for 8 months in a bus service terminal were used in the tests. In addition, both filters were saturated with alpha-pinene vapor to examine possible formation of secondary aerosols by heterogeneous reactions. Both filters removed ozone effectively in the beginning. Then, the removal efficiency declined until it reached a steady state level in three hours.
Some particle formation was observed on both filters in the beginning of the test. Alpha-pinene disappeared from the air after F5 filter within three hours, whereas, its concentration remained almost on a constant level after the sooty F8 fine filter during the whole four hour test period.

INTRODUCTION

Ozone (O_3) is a strong oxidation agent in ambient air and it can cause adverse health effects in sensitive people already at low concentrations [1]. Concentration of ambient ozone exceeds health based limit values in several days annually even in Finland where concentrations are lower than in more densely populated southern areas. Ozone reacts on dusty ventilation filters and small fraction of formaldehyde is produced in these reactions [2,3]. Diesel soot increases the removal of ozone. This is beneficial because of toxic effects of ozone. However, more irritating reactive species may form in these reactions.

Ultra fine particles (i.e. secondary organic aerosols, SOA) are formed when VOCs are partially oxidized in air [4]. The reaction products are partially condensed onto existing aerosols and partially form new particles. Ultra fine particles are especially formed in homogeneous reactions between terpenes and ozone in indoor air [5, 6]. These reactions and their health significance are under intensive study.

The aim of the present study is to investigate whether ozone and terpenes can react on sooty supply air filters. Ozone removal and possible formation of secondary aerosols are investigated.

METHODS

A F8 class fine filter loaded by diesel soot particles and a heavily loaded F5 class filter used 8 months in a bus service terminal in Kuopio were used in the tests. Fine (F8) filter materials were made sooty by a vertical 3-cylinder four-stroke turbo-charged 1123 cm^3 (28.5 kW) industrial diesel-engine (Kubota V1105-TE) in laboratory at constant conditions. The engine were fuelled with regular low sulfur diesel oil (sulfur content ≤ 8 mg/kg) (Fortum DIKC 0/-10) and lubricated with fully synthetic lubrication oil of quality SAE Diesel turbo 5W-40 (Valvoline). Particle size distributions and mass concentrations of diesel soot in the dilution tunnel were analyzed by L-SMPS (Long - Scanning Mobility Particle Sizer) system consisting of a DMA3071 differential mobility analyzer (size range 15-740 nm) and CPC 3022A condensation particle counter (Thermo Systems Inc.). The sampling time was one hour. The dilution tunnel was designed according to the ISO-8178 standard [7]. Surface areas of the soot/dust samples were analyzed by BET-method (Micromeritec, model 2200) [8].

Filters were exposed in 48 L volume chamber (steel and glass) which contained 3 ml of alpha-pinene (6 petri dishes at the bottom of chamber 0.5 ml of alpha-pinene/dish). Filters were kept in the chamber for a three days to assure their saturation to the model compound.

Sooty filters were installed into a small scale ventilation system using compressed air. Compressed air was first cleaned from VOCs and NOx by activated carbon and Purafil filtration. The face velocity of air was 0.07 m/s on the filter and it was controlled by mass flow meters. Ozone was produced by a UV lamp (5W) and its concentration was adjusted to 100-250 ppb. Ozone was measured continuously (Dasibi 1008-RS) 0.5 m before and after the filters. The accuracy of the O_3 analyzer was reported to be ±0.5 ppb by the manufacturer. The device was calibrated by the Calibration Laboratory of the Finnish Meteorological Institute and its functionality was checked with an in-built calibration system. Data logger (Grant) was used to collect the measured data (Ozone, temperature, and RH).

Particle size distributions were analyzed by TSI (Thermo Systems Inc.) N-SMPS (Nano - Scanning Mobility Particle Sizer) system consisting of a DMA3085 differential mobility analyzer (size range 2-64 nm) and CPC 3025A condensation particle counter. Particle concentrations were measured in the middle of a duct about 0.5 m upstream and downstream of the filters. Sampling location was changed by using a 3-way ball valve. A half minute stabilization and three minute analyzing periods were used for a typical data collection cycle. Transport efficiency of particles undergoing diffusional deposition flowing through a sampling tube was estimated to be over 90% for the particles greater than 10 nm [9].

VOCs (Tenax GR) (sampling time 10-30 minutes) were collected simultaneously 0.5 m upstream and downstream of the filters. Samples were analyzed with an automated thermal desorption coldtrap injector (Perkin Elmer ATD 400) connected to a gas chromatograph (HP 6980) equipped with a mass selective detector (MSD 5973). The ozonolytic decomposition of the sampling cartridges was prevented by potassium iodide coated copper tubes. The analysis method has been described previously [3].

RESULTS

Ozone was removed more effectively on the sooty F8 filter than on the sooty F5 filter. Mean removal of ozone was 44% on the F8 filter and 22% on the F5 filter. Also, unused F8 filter (saturated with alpha-pinene) removed ozone effectively in the beginning of the ozone exposure, but the removal decreased to 12% within two hours and was less than 10 % after four hours. Typical ozone removal curves on sooty F8 and F5 filter are presented in figure 1.

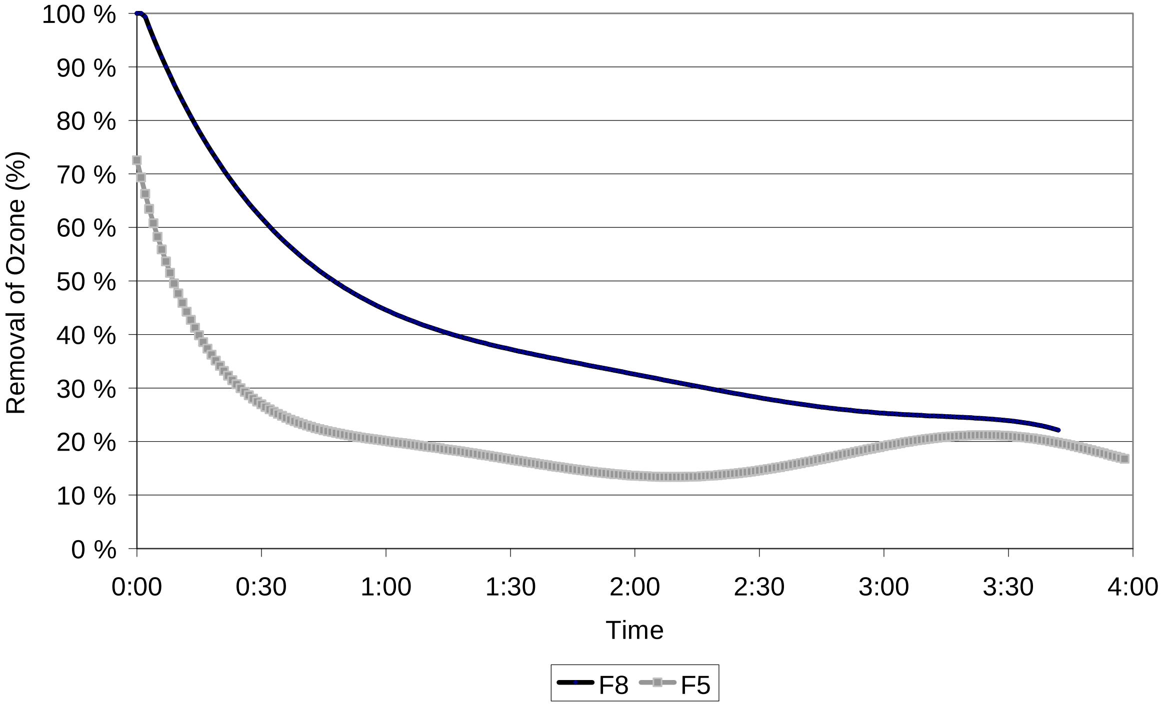

Figure 1. Removal of ozone (%) on sooty F8 and F5 filters saturated with alpha-pinene, face velocity during the test was 0.07 m/s. Conditions in F8 test: O_3 upstream 182±7 ppb, downstream 103±36 ppb, mean removal of ozone (3 hours) 44±19%, RH 10±1%, temp. 23.5±0.3°C; in F5 test: O_3 upstream 198±5 ppb, downstream 156±25 ppb, mean removal of ozone (3 hours) 22±11%, RH 16±4%, temp. 24.0±0.2°C.

Effective surface area of the dust taken from the filters in bus terminal was ca. 4 m^2/g of dust whereas soot made in motor laboratory had as large effective area as 100-103 m^2/g. Properties of soot also affected to the adsorption of the alpha-pinene onto the surfaces of the sooty filter material. Concentration of alpha-pinene decreased from 12 µg/m^3 to undetectable approximately in three hours after the sooty F5 whereas it remained at a relatively constant level of 41±4 µg/m^3 after the sooty F8 filter during the whole test period of four hours.

Particle concentrations were slightly higher downstream of the alpha-pinene saturated F5 filter (figure 2). However, there were no clear particle formation peaks during the test period of four hours.

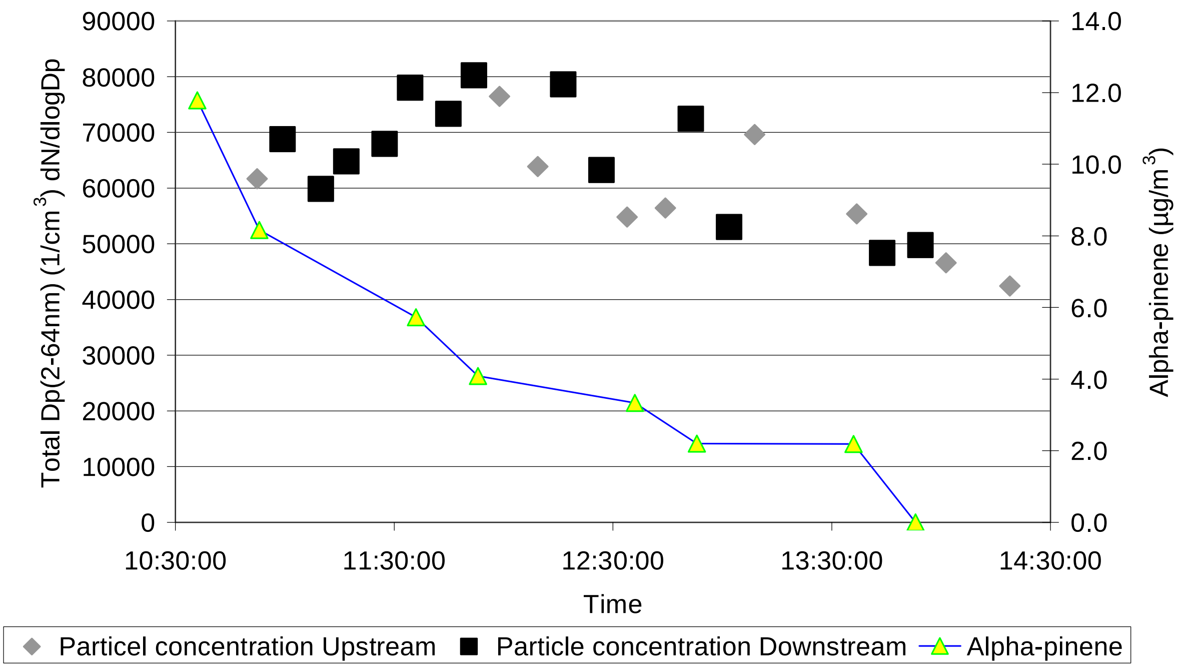

Figure 2. Particle concentrations upstream and downstream of a F5 filter (loaded for 8 months in a bus service terminal) and alpha-pinene concentration downstream of the filter. O_3 concentration 198±5 ppb upstream, 156±25 ppb downstream. Face velocity on the filter was 0.07 m/s.

Particle concentrations behaved similarly upstream and downstream of the sooty F8 filter (saturated with alpha-pinene). Slightly higher concentrations were occasionally observed downstream of the filter. The unused F8 (saturated with alpha-pinene) filter also gave similar results. When there was no ozone present, the particle concentration was negligible, only single particles were detected downstream of the filter and no typical size distribution curves were found. Overall, no clear formation of the ultra-fine particles was detected. However, temporary formation of ultra-fine particles was observed in the beginning of a few tests. An example of such phenomenon is given in figure 3. The duration of the peak was less than 3-4 minutes.

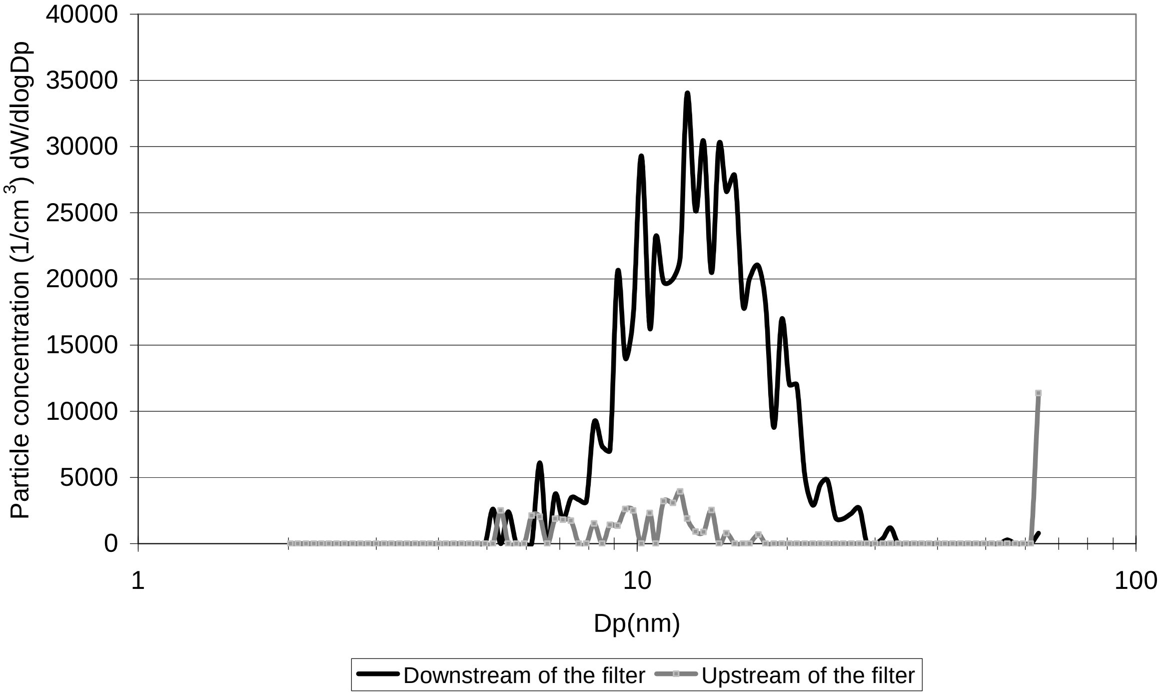

Figure 3. An example of temporary particle formation after sooty F8 filter in the beginning of ozone feeding (saturated with alpha-pinene) (2-64 nm). O_3 concentrations: 115±10 ppb upstream and 103±10 ppb downstream. Temperature 21.6±0.3°C, RH 1.4%.

DISCUSSION

Ozone was removed on sooty filters. In agreement with previous studies [10, 3], the reaction was strong in the beginning and decreased then rapidly during the first few hours. Removal of ozone was also observed on unused F8 filter.

Soot obtained from the bus service terminal had much smaller effective surface area than soot collected in the motor laboratory. This also affected the adsorption and desorption of alpha-pinene and removal of ozone on filters. This is consistent with the fact that effective area is of crucial importance in surface reactions. In addition, bus terminal filters were accumulated 8 months; and ageing of the particles may have changed their reactivity.

Sudden peak emissions of particles were occasionally observed at the start of ozone feeding when filters were still almost saturated with alpha-pinene. The results suggest that formation of secondary aerosols is not practically important on supply air filters. Pinto et al. [11] did not observe any secondary aerosol formation when terpenes were emitted into a test chamber from the plants and ozone concentration was 100 ppb, whereas clear particle formation was observed at higher ozone concentrations (200 and 400 ppb). Concentrations of the six terpenes were 2-15 µg/m^3 (alpha-pinene and limonene were the most abundant compounds). It should be noted that average residence time of air in the chamber was about 17 minutes which is much higher than in the present study where possible particle formation time was only a few seconds.

ACKNOWLEDGEMENT

This study has been financed by the Academy of Finland (project 110087).

Comparison Of HEPA/ULPA Filter Test Standards Between America And Europe

Bin Zhou, Jinming Shen

Heating, Ventilation, Air-conditioning and Gas Institute, Tongji University, Shanghai, China

Corresponding email: zhoubinwx@126.com

SUMMARY

This paper compares the difference of HEPA/ULPA filter test standards between America and Europe from test procedures, aerosol types and its size, to air filter classification. Both of them adopt MPPS method as their trend. According to EN1822, it is recommended to combine the test rigs for efficiency test and leakage test in practice. Influence of different scanning velocity on sampling accuracy, leakage and efficiency test accuracy need further studied and reasonable scanning velocity should be fixed. According to Rongyi Zhao's theoretical analysis, dilution method to test high test aerosol concentration may not be correct, and reasonable test methods instead of dilution need to be further studied.

INTRODUCTION

High efficiency particulate air filters (HEPA) and ultro-low penetrating particulate air filter (ULPA) are widely used in pharmacy, hospital, food processing and microelectronics, they are one of the most important terminals in clean space. In order to guarantee product quality and environmental control, every country makes its strict test standards.

During the late 1950s, China adopted oil mist method from USSR. At the early 1960s, oil mist method was improved to meet requirement of collective safeguard equipment and the development of atomic energy engineering. In 1963 and 1965, sodium flame test rig was successfully developed respectively to test filter media and HEPA. In 1970s, especially after the economic reform and opening-up policy, oil mist method and sodium flame method were used widely, therefore in 1980s national standard GB6165 was made using both methods.

As the development of microelectronics, the orginal standards using sodium salt and oil mist are old-fashioned. Before standard revising, review of test standards is very needed. This paper compares HEPA and ULPA filters between America and Europe from test procedures. Some problems and future development are proposed here for benefit of new standards.

DEVELOPMENT OF HEPA/ULPA FILTER TEST STANDRDS

America

In 1956, MIL-STD-282<Filter Unit, Protective Clothing, Gas-mask Components and Related Products: Performance-Testing Methods> using DOP method was published. DOP liquid is heated and vaporized, then condensate to become DOP particle with mean diameter 0.3μm, which is called thermal generation. It is used to test HEPA filters on Q-127, Q-76 and Q-107 test rigs. Till now it has been revised for 4 times and the latest one is MIL-STD-282:1995.

In 1959, Underwriters Laboratories Inc. published ANSI/UL 586:1959<Air Filter Units>. It is mainly used to test penetration under ambient environment and after hot air, wet air and low temperature treatment. After 8 times revision, the latest version is ANSI/UL 586:2004.
In 1975 and 1976, ANSI N45.8 committee published ASME N509 and ASME/ANSI N510 respectively, and revised them in 1980 and 1981. In 1976, this committee was recognized as “American Society of Mechanical Engineers Committee on Nuclear Air and Gas Treatment”. In 1986, ASME AG-1-1986<Code on Nuclear Air and Gas Treatment> was issued. After several revisions, the latest version is ASME AG-1-2003.

In 1980s, Los Alamos National Laboratory (LNAL) reviewed various HEPA filter testing practices, and pointed out the pro and con of MIL-STD-282 method. LNAL proposed alternative method “High Flow Alternative Test System”, which uses standardized Laskin nozzles and impactors instead of DOP generator to produce aerosols, and uses laser aerosol spectrometer instead of aerosol measuring instrument on Q-107. The test result is equivalent with that of MIL-STD-282 method, and notably efficiency corresponding to certain particle size is determined. However, because the long test time and increased data error caused by particle sizing instrument, it wasn’t popular[1].

During 1992 and 1993, Institute of Environment Sciences and Technology (IEST) issues a series of HEPA/ULPA filter test standards for different requirements and applications, such as IEST-RP-CC007.1:1992<Testing ULPA Filters>, IEST-RP-CC001.3:1993<HEPA and ULPA Filters> and IEST-RP-CC-006.2:1993< Testing Cleanrooms>.

In 2005, IEST issued IEST-RP-CC001.4 <HEPA and ULPA Filters> and IEST-RP-CC034.2<HEPA and ULPA Filter Leak Tests>

Europe

In 1984, EUROVENT issued EUROVENT 4/4 < Sodium Chloride Aerosol Test for Filters Using photometers>. This standard tests efficiency and pressure drop of HEPA filters using sodium flame methods, and then filters are classified. The method was originated from BS3928-1969, which uses mass mean diameter 0.6μm NaCl aerosols. Different concentration of salt mist will cause different color from hydrogen gas flame, so according to the sodium flame color from upstream and downstream samplings, efficiency is determined.

However, since sodium flame methods are not suitable for testing filters with large air flow rate and high-tech requirement, working group 2 of the Technical Committee 195 from CEN began to draft a new standard from 1990. At first many people inclined to accept BS 3928 for its wide use, but at last a completely new test method was preferred. The reasons are[2]:

(1) A consistent and logical classification system covering HEPA/ULPA filters is needed;
(2) The method can satisfy the need of clean room users, where room classes always differ by a factor of 10;
(3) The relationship between leak sizes and efficiency of a specified class is required;
(4) The correlation between different test rigs and fewer errors should be met.

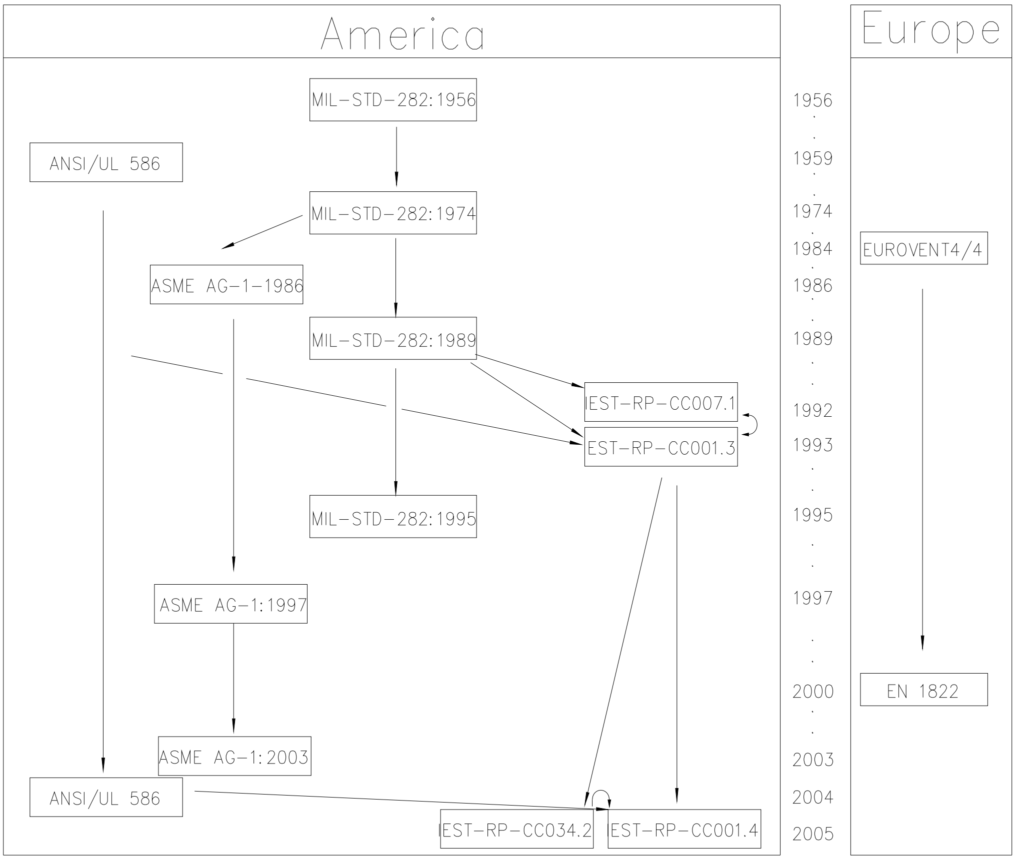

Figure 1. Development of standards for HEPA/ULPA filters.

Through about 10 years' endeavor, during 1998 and 2000, CEN issued EN 1822 in succession. Since EN 1822 is issued, disorder situations have been change in Europe. Compared with former standards, the biggest feature is that Most Penetrating Particle Size[3] (MPPS) efficiency is measured for filter medium and filters.

COMPARISON AND DEVELOPMENT TENDENCY

At present, main HEPA/ULPA filter test standards among Europe and America are MIL-STD-282:1995, IEST-RP-CC001.3:1993, IEST-RP-CC007.1:1992, ANSI/UL 586:2004, IEST-RP-CC001.4:2005, IEST-RP-CC034.2:2005, EN 1822. In the following standards from IEST and CEN will be compared.

Table 1. Comparison of main HEPA/ULPA filter test standards.

	IEST-RP-CC001.3	IEST-RP-CC007.1	IEST-RP-CC001.4	IEST-RP-CC034.2	EN 1822
Test Aerosol	Thermal DOP (HEPA filters) or any aerosol of IEST-RP-CC007(F type filters)	Mineral oil, corn oil, olive oil, oleic acid, DOP, DOS or PSL	Thermal DOP (HEPA filters) or any aerosol of IEST-RP-CC007 (F~K type filters)	DOP, DOS, mineral oil, oleic acid, PAO or PSL	DOS, DOP or paraffin oil
Aerosol size	0.3μm (HEPA filters), 0.1~0.2μm (F type filters)	Polydisperse or 90% in 0.1~0.2μm	0.3μm (A~E filters), MPPS (G type filters), others 0.1~0.2μm and 0.2~0.3μm	n/a	MPPS
Sampling Instrument	Photometers (HEPA filters), particle counter(F type filters)	Optical counter, electrical mobility particle sizer, diffusion separation instrument	n/a	n/a	Optical counter or condensation nucleus counter
Temperature and relative humidity	n/a	10～37.8°, 30～70%	n/a	n/a	23±5°, ＜75%
Pressure	n/a	Positive pressure	n/a	n/a	n/a
Qualification Requirement	(1)air velocity uniformity across duct cross*; (2)aerosol uniformity across duct cross**; (3)pressure drop under rated air flow; (4)test duct leakage test; (5)inlet HEPA filters; (6) velocity uniformity measures; (7)cleanliness of test air; (8)aerosol concentration of upstream; (9)scanning velocity; (10)sampling rate; (11)particle loss; (12)system response time; (13)correlation ratio; (14)aerosol neutralizer;				
	(1)(2)(3)(4)(8)(9)(10)	(1)(2)(4)(5)(6)(7)(11)(12)(13)(14)	(1)(3)	(1)(2)(9)(10)	(2)(7)(10)(11)

* air velocity uniformity of IEST-RP-CC001.3 and IEST-RP-CC001.4 is ±20%, while that of IEST-RP-CC007.1 is ±10%;
** aerosol uniformity of IEST-RP-CC007.1 and IEST-RP-CC034.2 is ±20%, while that of EN1822 is ±10%.

Test Procedure Comparison

IEST-RP-CC001.3 uses thermal DOP method for A~E type filters and “laser test” for F type filter. DOP method uses photometers while the latter uses particle counters. IEST-RP-CC001.4 determines penetration in the same way and are both suitable for testing submicron particle efficiency≥99.97%. By comparison, the main difference includes:

(1) IEST-RP-CC001.3 includes scanning leakage test, while IEST-RP-CC001.4 doesn’t and IEST-RP-CC034.2 is made for the leakage test only;

(2) The leakage test of IEST-RP-CC001.3 is used to test HEPA/ULPA filters in the lab, while IEST-RP-CC034.2 requires testing HEPA/ULPA filters during factory

manufacture, field installation, and after installed in the clean room and unidirectional air cleaners. The methods in IEST-RP-CC001.3 includes: photometer scanning method (for filters with penetration lager than 0.001%) and particle counter scanning method (for filters with penetration smaller than 0.001%), but the method is limited if the background counts are less than 10% of the maximum acceptable leakage count. IEST-RP-CC034 not only introduces the two different scanning methods, another special leakage test method is introduced for filters difficult to access: Aerosol photometer total leakage test method. By introducing aerosol into the test duct, concentrations of upstream and downstream and total leakage are determined.

(3) Compared with IEST-RP-CC001.3, A~F type filters classification are mainly the same. The differences are:
1. the test aerosol for C and D type filter can be PAO or DOP, because the traditionally used DOP poses potentially treat to health, and both the Food and Drug Administration and US Surgeon General have accepted PAO to replace DOP as a test aerosol.
2. Filters with 99.999% minimum efficiency related to 0.1~0.2μm particles are F type filters in IEST-RP-CC001.3, while the same minimum efficiency related to 0.1~0.2μm and 0.2~0.3μm particles are F type filters in IEST-RP-CC001.4.
3. Except for the particle counter, IEST-RP-CC001.4 allows photometers for F type filters.

(4) Compared with IEST-RP-CC001.3, super ULPA (G type)~ ULPA (A type) are added. In Europe, EN 1822 is used to test HEPA/ULPA filters upon MPPS efficiency. The procedures in the standard include 3 sections: filter medium test, filter leakage test and filter overall efficiency test. Firstly, the relationship curve between filter medium efficiency and particle size is established under rated air flow, then MPPS value is fixed; Secondly, under corresponding air velocity, monodisperse or multidisperse aerosols are used to test filters' local penetration, so as to determine whether the filter has leakage, but the precondition is that the particle size of monodisperse aerosols and the number mean size of multidisperse aerosols are MPPS; At last, static measuring method or scan method are used to test the overall efficiency, of which the static measuring method use stationary sampling probes to test the concentration of upstream and downstream, and the scan method uses a scanning probe on the downstream side together with a stationary sampling probe set upstream to get the local MPPS efficiency and then the overall efficiency.

Difference[1] between EN 1822 and IEST-RP-CC001.4 includes the following:

(1) Filters with efficiency≥99.95% in EN 1822 are tested for MPPS efficiency and leakage, while in IEST-RP-CC001.4 most filters should be tested using number mean diameter (NMD) 0.3μm thermal DOP which is approximately near MPPS.

(2) Filters with MPPS efficiency≥85% in EN 1822 are called HEPA filters (in total 7 types), while Filters with NMD 0.3μm thermal DOP efficiency≥99.97% in IEST-RP-CC001.4 are called HEPA filters (in total 14 types);

(3)IEST allows photometer and particle counters (both OPC and CNC), while EN1822 only accept particle counters (both OPC and CNC) and Different Mobility Analyzers (DMA).

(4) The test range for OPC in EN 1822 is 0.1~2μm, which is divided into 6 groups; and for CNC is 0.05~0.8μm; and for DMA is 0.01~0.8μm. In IEST-RP-CC001.4, the test range for OPC is 0.1~0.3μm, while for CNC is also 0.1~0.3μm.

(5) In EN 1822, the efficiency can be tested using scanning method of leakage test, so the efficiency test and leakage test can be one test, while in IEST they are two independent tests.
(6) In EN 1822, filters with MPPS efficiency≥99.95% must be tested through scanning method, while in IEST, whether to scan the filters depends on the performance: A and H type filter only need efficiency test, while B, E and I filters need be tested through dual flow rate leakage test, and the remaining are required to be tested both.
(7) In EN 1822, percentage is usually used to reflect penetration of filters, while in IEST introduces new Par Per Million (PPM).
(8) In EN 1822 MPPS efficiency is used, while in IEST only G type filter uses, and for A~E type filters, mass mean diameter 0.3μm aerosol is used, whose NMD is close to MPPS.

Type selection of test aerosol

Since DOP was first applied by MIL-STD-282, it has been popular and most standards recently use DOP, furthermore, definition of HEPA filter is based on the DOP efficiency.

However, the vapor of transparent liquid DOP is irritative for eyes and respiration channel. When high concentration of DOP vapor is inhaled, people may become uncomfortable, such as headache, nausea, and hypoesthesia. When exposed to DOP for a long time, people tend to be poisoned, or it may even be carcinogenic. Therefore people are concerned about DOP.

America and Europe are both active in seeking new substitute, for example, in IEST-RP-CC001.4 PAO will replace DOP. As for the toxicity and safety, PAO is affirmed to be noncorrosive, stable and cheap. Now it has been used in field filter test and present instrument can produce and deal with it. However, the remaining liquid on the filters will be released gradually after test like DOP and poses pollution. In some HEPA filter test standards of America, PSL is recommended to avoid the above situation. PSL is usually used for calibrating OPC, so it can satisfy the test requirement, but it’s expensive compared with PAO.

The most important properties of a possible aerosol substance are index of refraction, vapor pressure and density, so during the seeking process, the values of the substitute should not differ too much from Table 1 of EN 1822-2.

Filter classification

In IEST-RP-CC001.4, A~E type filters are classified using DOP method of MIL-STD282; F, H~K type filters are based on the method of IEST-RP-CC007.1; G type filter is classified according to the method of IEST-RP-CC021. In EN 1822 H10~U17 type filters are all based on MPPS efficiency. Different test methods, test aerosols and test conditions will bring about different performances for the same filter, which makes the comparison between different standards difficult. IEST-RP-CC001.4:2005 lists the comparative performance.

From comparison, performances of various types of filters in IEST-RP-CC001.4 are closer to each other. The overall efficiency of A type filter is 99.97%, the same as that of B, E, H, and I type filters, while that of C and J type filters is 99.99%, and that of D and F filters is 99.999%, but test aerosols and leakage test requirements are different. In EN 1822, except that the ratio of total penetration of H10 to that of H11 is 3, others between the neighboring type are 10. In

EN 1822, except that the ratio of local penetration to total penetration, of U17 is 20, others are 5. In IEST-RP-CC001.4, the local penetration ratios are different, because errors during scanning leakage test are very big, and the permitted leakage penetration during leakage test should be equal or larger than that of efficiency test.

Existing problems and development tendency

(1) Former HEPA filter test standards were used to test 0.3μm particle efficiency, because it is believed that with the combined effect of diffusion and interception, 0.3μm particle is the most difficult one to collect, so it became the base size of DOP method. However, later research denied this conclusion, which shows that the MPPS range is 0.1~0.25μm and MPPS is different for different types of filters and air velocity [3]. From above comparison between EN1822 and IEST-RP-CC001.4, as test condition changes, MPPS efficiency and filter classification change according to EN1822, but not in IEST-RP-CC001.4. EN1822 has the characteristic of high sensitivity and accuracy, but the test procedure is complicated and test time is long, so a more efficient, simple and reliable test method should be exploited.

(2) In EN1822, both the stationary sampling probe or movable probe can be installed to test the overall efficiency, and for H13~H17 filters scanning probe is needed to test the local penetration, because the test rig and instruments between efficiency test and leakage test are alike, it is recommended to combine the two test rigs in practice for high resource utilization efficiency. C~K type filters in IEST-RP-CC001.4:2005 are the same.

(3) Rrequirements in EN1822 and IEST-RP-CC034.2 are different. In EN1822, the probe inlet air speed should less than 25% of filter face velocity, and be placed 10~50mm from the filter surface, while in IEST-RP-CC034.2, the corresponding values are±10% and 25mm. In EN 1822, the upper limit for scanning velocity is 10cm/s, while in IEST-RP-CC034.2, the value is 5cm/s for photometer scanning and 2.5cm/s for particle counter scanning. As different scanning velocity will influence sampling accuracy and then leakage and efficiency test accuracy, hence further study on reasonable scanning velocity is needed.

(4) EN1822 allows to use two counters simultaneously at upstream and downstream, or one counter with sequential sampling between upstream and downstream[4]. As for the former, the same types should be used and calibrated, and as for the latter, aerosol concentration, size distribution and uniformity in the test duct should be kept constant.

(5) Because particle counters have test range, aerosol concentration in the upstream should be controlled so as to avoid aerosol coagulation and overlap loss in particle counters. Both standards allow the use of dilution system. However, in order to verify the accuracy of tested concentration after dilution, theoretical analysis is made by Rongyi Zhao, showing that the result after dilution is incredible[5].Until now there’s no other methods to deal with high concentration test except, reasonable test methods need to be further studied.

(6) In order to control the sampling error of particle counter, non-isokinetic sampling error and particle loss due to diffusion, sediment, coagulation and impaction in the sampling tube, together with overlap loss should be reduced. Special probe should be designed to keep isokinetic, and the length of sampling tube should be shortened, and the electric performance of sampling tube should be improved, and no other parts are installed in the tube, and the sampling tube should be kept away from noise source[6].

(7) As for field leakage test for HEPA/ULPA filters, EUROVENT issued EUROVENT 4/8:1985 "In Situ Leak Test of High Efficiency Filters In Clean Spaces" using DOP method in early 1985. Because the process from manufacture, transportation and field installation is a system, each part will influence the cleanliness of clean room. Because field test is especially important for CMOS chip workshop and biosafety, IEST makes IEST-RP-CC034 specially, which covers the leakage test of each part, and it's the complete leakage test standard now.

CONCLUSIONS

In America, DOP method has a profound influence, but now particle sizing method is the trend. In Europe, test method changes from Sodium Flame method to MPPS method. It is recommended to combine the test rigs for efficiency test and leakage test in practice.

Different scanning velocity between EN1822 and IEST-RP-CC034.2:2005 will influence sampling accuracy, leakage and efficiency test accuracy, hence, further study on reasonable scanning velocity is needed.

According to Rongyi Zhao's theoretical analysis, reasonable test methods instead of dilution need to be further studied.

Experimental Study on the Effect of Foliage Plants on Removing Indoor Air Contaminants

Hiroshi Matsumoto and Masashi Yamaguchi

Toyohashi University of Technology, Japan

Corresponding email: matsu@tutrp.tut.ac.jp

SUMMARY

The objective of this paper is to demonstrate an ability of foliage plants quantitatively to remove chemical contaminants by experiments using a small desiccator for the different kinds of plant under the different luminescence and light sources, fluorescent, incandescent and light-emitting-diode (LED) lamps. The foliage plants, *Benjamin, Spathiphyllum, Areca palm* and *Concinna*, cultivated in hydroponics were used. As a result of the experiments, the effective performance of contaminant removal was obtained under lighting conditions with the different intensity distribution by wavelength for the case of pulse injection of toluene into the chamber without ventilation. The removal efficiency of toluene under an incandescent light was larger than that under a fluorescent lamp. The different removal efficiency was obtained according to the kind of LED with different intensity distribution and foliage plants. The blue LED lamp showed the highest removal efficiency among the LED lamps evaluated in this study.

INTRODUCTION

An ability of foliage plants to absorb chemical compounds from the indoor air has been demonstrated in many studies. In the report of the National Aeronautics and Space Administration (NASA) Wolverton et al. [1] showed that low-light-requiring houseplants such as *Bamboo palm, English ivy* and so on have demonstrated the potential for improving indoor air quality by removing trace organic pollutants from the air in energy-efficient buildings. In this study they revealed that the root-soil zone appeared to be the most effective area for removing volatile organic chemicals, and proposed an indoor air purification system combining houseplants with an activated carbon filter.

Wood et al. [2] carried out an investigation of the biological decontamination capabilities of indoor plants. The work showed that *Kentia palms* (*Howea forsteriana Becc.*) had capacity to remove several times the maximum occupational levels of n-hexane and benzene in indoor air, and their capacity to do so was increased by exposure. Also they suggested that the intimate association between VOC metabolizing bacteria and the roots system was highlighted by hydroponic conditions.

The removal of airborne toluene by means of the phyllosphere of *Azalea indica* augmented with a toluene-degrading enrichment culture of *Pseudomonas putida* TVA8 was studied by Kempeneer et al [3]. The results presented were promising and could be practical importance in the field of indoor air pollution control.

Sawada et al. [4] measured TVOC and odors to examine purification effect of plants by using *Golden pothos* and *Peace lily*. The results showed that the removal rate for TVOC was 74% and the one for odor was 68%. It was confirmed that plants had high purification capability in the real environment.

Wood et al. [5] obtained the results by the office field-study that the presence of potted-plants brought about highly significant reduction in TVOC levels, of up to 75% when indoor average concentrations rose above 100ppb. The findings also indicated that the potted-plant microcosm represented an adaptive, self-regulating, low-cost, sustainable system for bioremediation of VOC pollution in indoor air.

The authors has been investigated the VOC removal performance of foliage plants under the different lighting conditions, kinds of plant and light, and the illuminance [6]. It was found that the VOC removal efficiency was strongly affected by the illuminance and the intensity distribution by wavelength of light.

The processes of diffusive exchange between air and leaves through stomata and cuticle, metabolism and dilution by growth may be involved with the effect. Nevertheless the valid mechanism of biological decontamination and the quantitative performance to remove indoor air contaminants have not been established. Therefore further studies concerning the effect need to be done; especially the effects of light source on the removal efficiency of indoor plants should be investigated.

The objective of this paper is to investigate an ability of foliage plants quantitatively to remove chemical contaminants by the experiments using a desiccator for the different kinds of foliage plant under the different luminescence and light sources, fluorescent, incandescent and LED.

METHODS

An overview of the measurement system used here is shown in Figure 1. The experiments were carried out for each plant put in a transparent desiccator made of acrylic resin with dimension L560× W 483×H986 mm. Toluene gas was used as a chemical contaminant to be removed from the test chamber. The concentrations of toluene and carbon dioxide were analyzed by B&K Multi Gas Monitor. Sampling points were fixed in the lower part of the desiccator and the outside air. Artificial light was set at the above the desiccator. The illuminance was measured by the illumination photometer (Tokyo Koden). Spectrometer (SOLAR Laser Systems) with the operational spectral range, 190 to 1,100 nm, was used to investigate the intensity distribution by wavelength of lightings used here.

The test plants were set in the desiccator after exposing fresh air for 24 hours and more, and then a small quantity of VOC gas adjusted the initial concentration was injected by a syringe three hours after the measurement start. The measurement data of the VOC and carbon dioxide was obtained every 75 seconds for 24 hours. To avoid the air exchange between the desiccator and the outside, the exhaust air from the desiccator used for detecting the concentration of sampling air was returned to the desiccator. Air temperature and relative humidity in the desiccator and the outside air were also measured every 10 minutes during the experiment.

Experimental items evaluated are shown in Table 1. Toluene, one of VOCs, was used as a chemical contaminant evaluated. Fluorescent light, incandescence light and LED lights such as blue, red and blue mixed with red LED were evaluated. Each LED light was composed of 1,200 LEDs with the maximum rating 100mA per a LED set on a flat board of dimension L50 ×W45 cm. The desiccator was set in a laboratory where the room air temperature was controlled at 20-30 degree C. The illuminance of lighting was set at 350, 700, and 1,050 lx. The foliage plants, *Benjamin* (scientific name: *Ficus benjamina L.*), *Spathiphyllum* (*Spathiphyllum clevelandii*), *Areca palm* (*Chrysalidocarpus lutescens*) and *Concinna* (*Dracaena concinna*), which are considered to remove VOC effectively, cultivated in hydroponics were used.

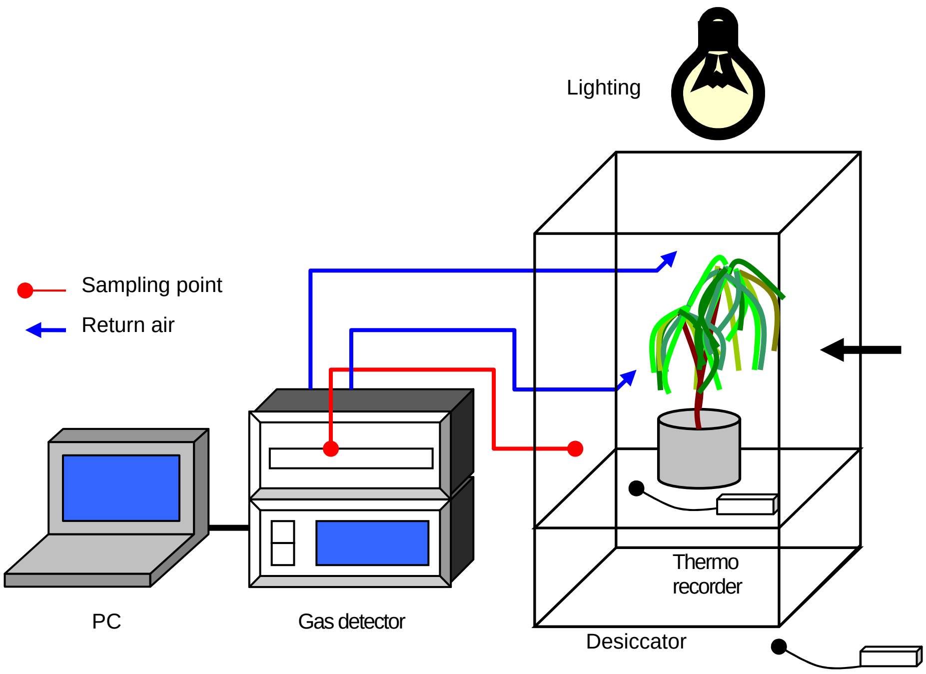

Figure1. Measurement system.

Items	Contents
Chemical contaminant	Toluene
Light sources	Fluorescent light
	Incandescence light
	Light-emitting diode (LED)
Foliage plants	Benjamin
	Spathiphyllum
	Areca palm
	Concinna
Illuminance	350 lx
	700 lx
	1050 lx
Wavelengths of the light	Red LED
	Blue LED
	Red and blue (B/R ratio 0.25)

RESULTS

Effect of light sources

To investigate the effect of light sources on VOC removal of foliage plants, fluorescent and incandescent lights with the relative intensity distribution by wavelength as shown in Figure 2 were used. The incandescent light has relatively continuous intensity distribution through the wide range of wavelength, but the fluorescent light has discrete intensity distribution and some peaks for the specific wavelength.

Figure 3 shows the cumulative removal of toluene for a pot of *Concinna* at 10 and 20 hours after a small amount of toluene injection using a syringe under the different lights, incandescent and fluorescent lights, in comparison with no lighting. The illuminance on the middle plane of the desiccator was controlled at 356 lx. The removal of toluene was strongly affected by the lighting. In this experiment the removal efficiency of toluene under an incandescent light was larger than that under a fluorescent lamp.

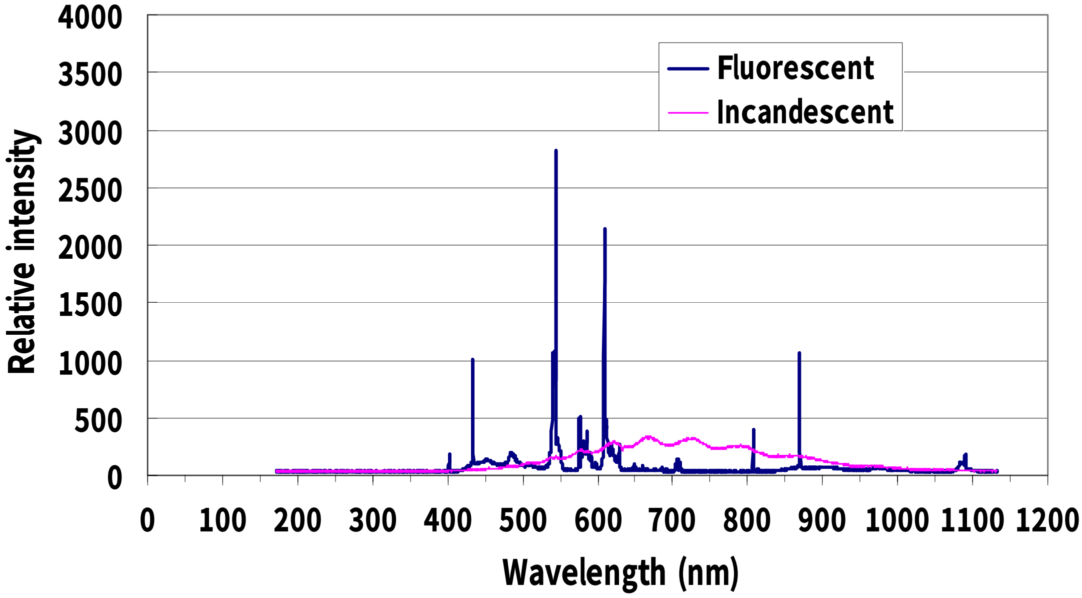

Figure 2. Spectrum distributions of the fluorescent and incandescent lights.

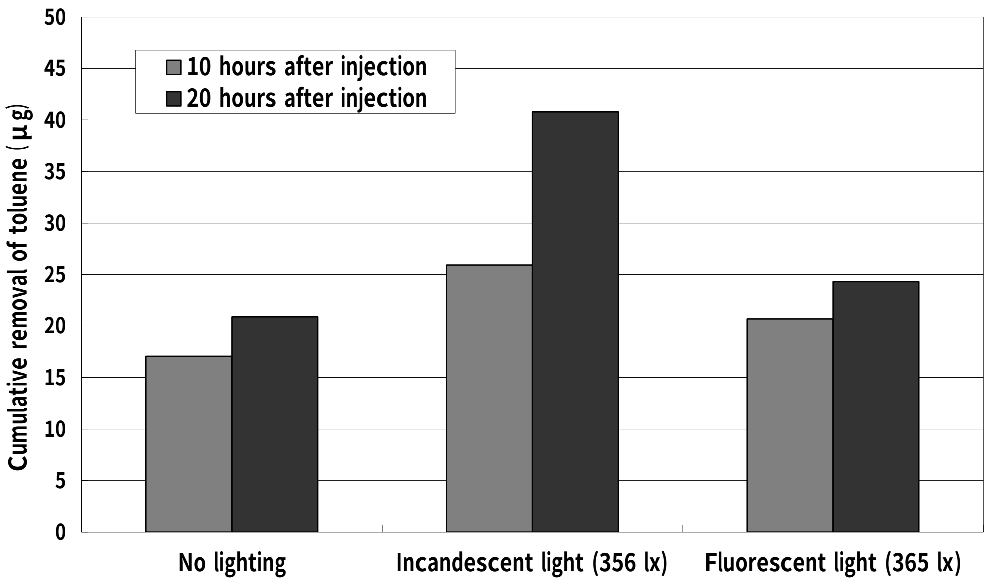

Figure 3. Cumulative removal of toluene under the different lights.

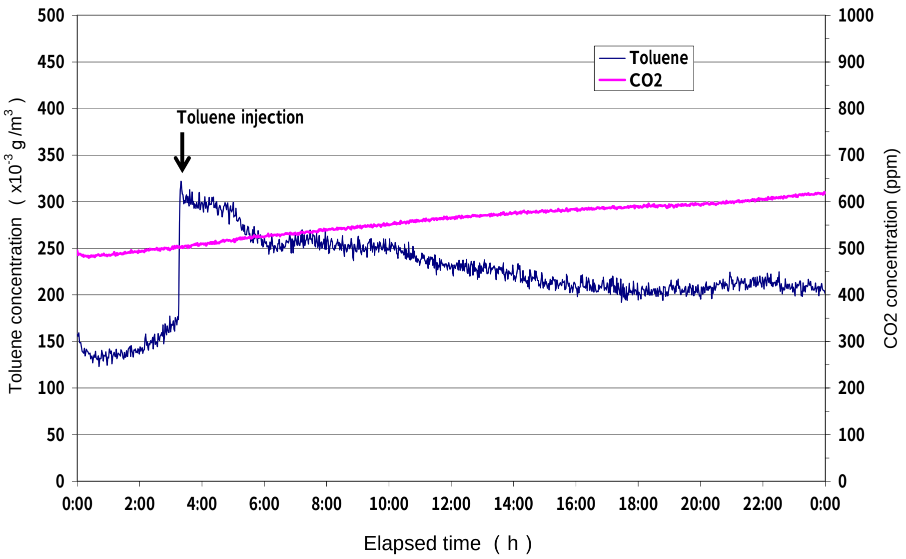
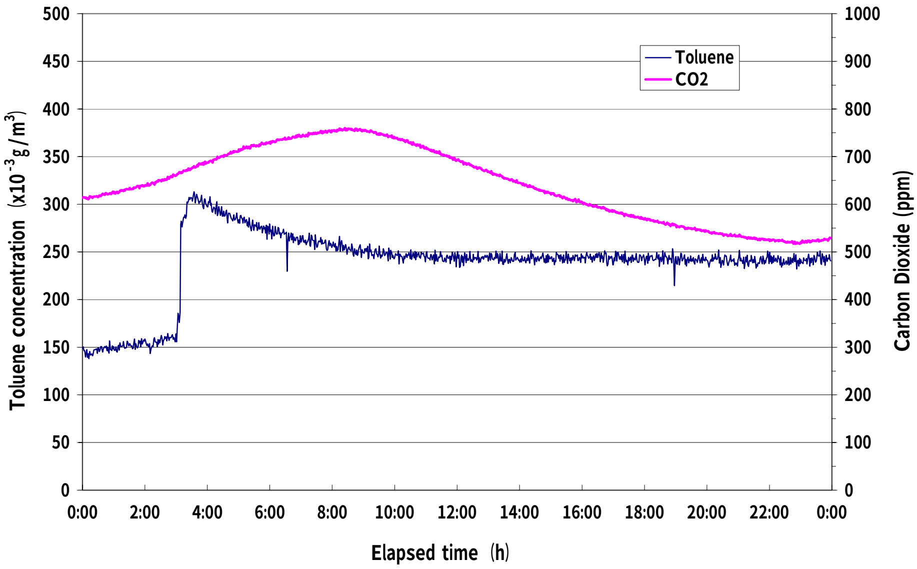
Kinds of plant and illuminance of lights

The foliage plants, *Benjamin*, *Spathiphyllum*, *Areca palm* and *Concinna*, which are considered to have high removal performance of VOC, cultivated in hydroponics were used. Figure 4 shows an example of the measurement results of toluene and CO_2 concentrations for *Concinna* under the fluorescent illuminance 700 and 1,050 lx, to identify the removal of VOC under the different illuminance. In this case the air temperature inside the desiccator was about 23 degree C and the relative humidity was changed from 30 to 80 %. Under the illuminance 700 lx, toluene concentration was decreased from 0.32 to 0.2 mg/m^3 at 15 hours after toluene injection. CO_2 concentration was slightly increased as the elapsed time. For the illuminance 1,050 lx, toluene concentration was decreased from 0.31 to 0.25 mg/m^3 at 15 hours after toluene injection. CO_2 concentration was decreased after 9 hours from the measurement start. This data shows that the photosynthesis of the plant was not active in spite of remarkable VOC removal under the illuminance 700 lx, while photosynthesis was active under the illuminance 1,050 lx.



(a) Fluorescent illuminance 700 lx



(b) Fluorescent illuminance 1,050 lx

Figure 4. Toluene and CO_2 concentrations vs. elapsed time.

Figure 5 shows the VOC removal efficiency, defined by the ratio of the concentration difference between the initial concentration and the concentration at the evaluated time to the initial value, for the different foliage plant under the different fluorescent illuminance. For *Spathiphyllum* and *Concinna*, the removal efficiency under low illuminance was over 80% and larger than that under high illuminance. *Benjamin* and *Areca palm* showed the highest efficiency above 80% for the illuminance 700 and 1,050 lx, respectively. On the other hand the efficiency for *Spathiphyllum* under the illuminance 1,050 lx was very low. These results can be considered that each plant has the particular illuminance to remove VOC efficiently.

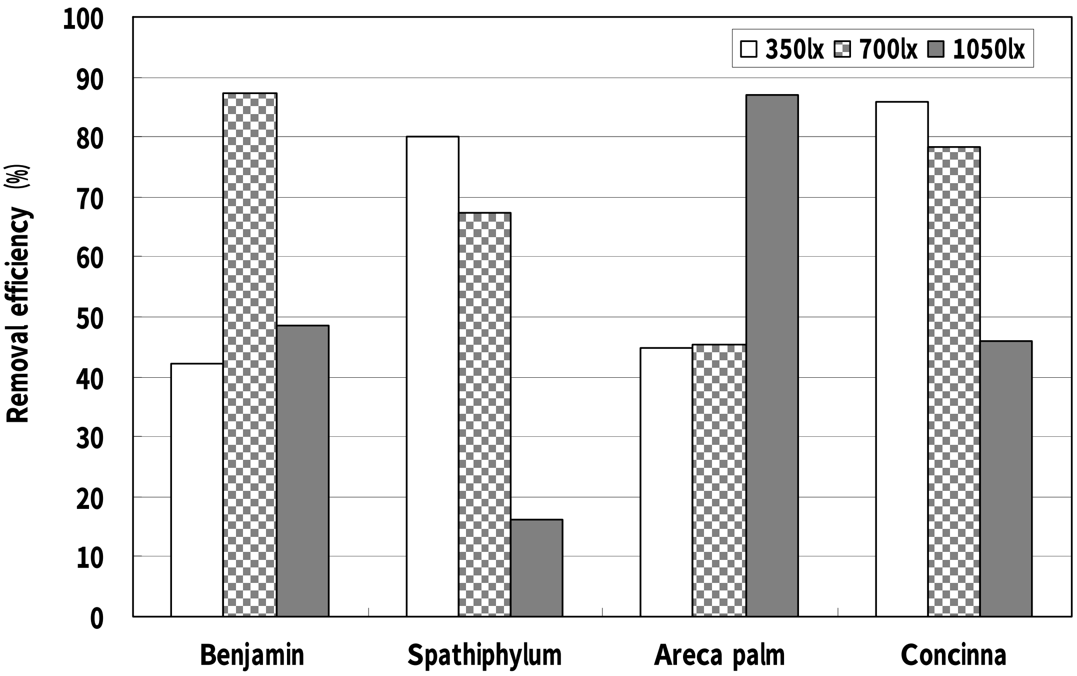


Figure 5. Removal efficiency of toluene under different illuminance.

Wavelength of the lights

Relative intensity distribution by wavelength of LED lights, blue, red and the mixed light (B/R ratio 0.25), used here is shown in Figure 6. The most part of intensity including the peak of the blue LED was covered within the wavelength range 420 to 470 nm, which range is considered to be wavelength range required for normal growth of plants [7, 8]. On the other hand, the most part of intensity distribution of the red LED is close to the wavelength range 640 to 690 nm, which is considered to be wavelength range for effective photosynthesis.

Figure 7 shows the removal efficiency of toluene under the different LED light. The illuminance of the lights on the middle of the plane in the desiccator was controlled at 350 lx. All the cases showed the removal efficiency of 60% and more. Especially the highest removal efficiency was the case under the blue LED, and the efficiency over 100 % means that the plant reduced VOC concentration in the desiccator less than the initial value before setting the plant. For the red LED and the mixing of red with blue, both of the cases were almost similar.

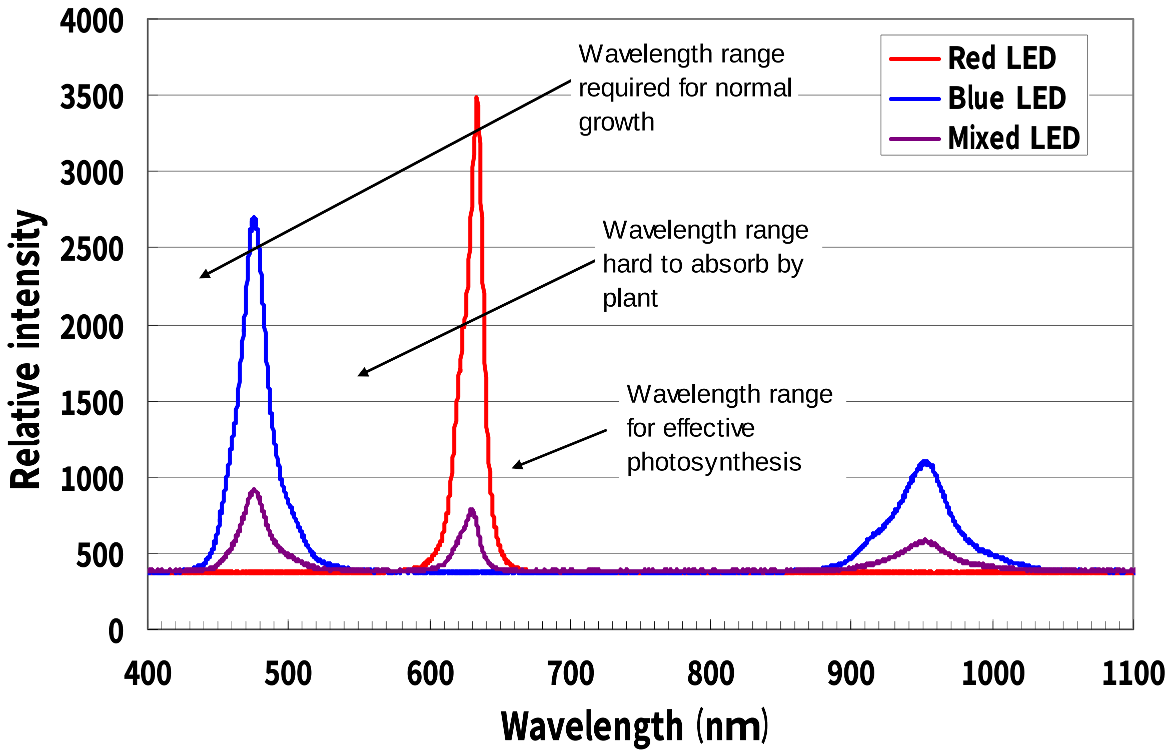

Figure 6. Relative intensity distributions by wavelength of the LED lights.

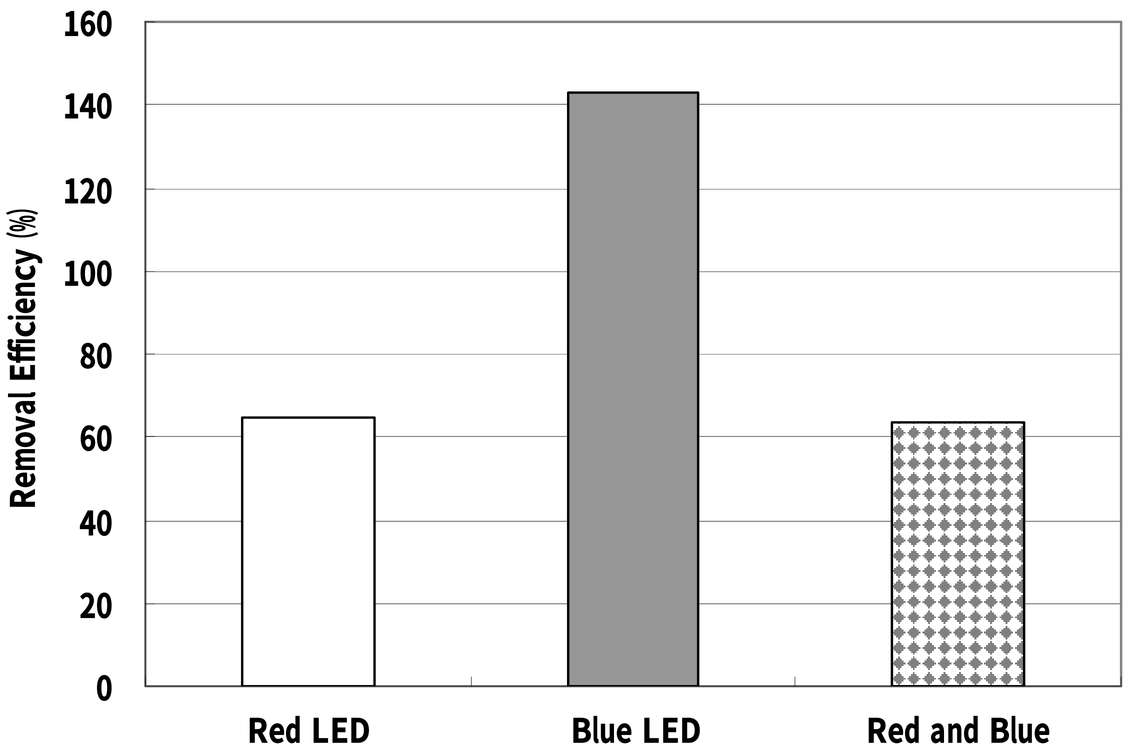

Figure 7. Removal efficiency under the different LED lights (350lx).

CONCLUSIONS

As a result of the experiments, the effective performance of contaminant removal was obtained under lighting conditions with the different intensity distribution by wavelength for the case of pulse injection of toluene into the chamber without ventilation. The removal efficiency of toluene under a fluorescent light, illuminance 356 lx on the upper part of the desiccator, was larger than that under incandescent lamps.

For *Spathiphyllum* and *Concinna*, the removal efficiency under low illuminance was over 80% and larger than that under high illuminance. *Benjamin* and *Areca palm* showed the highest efficiency above 80% for the illuminance 700 and 1,050 lx, respectively. This result suggests that each plant has the particular illuminance to remove VOC efficiently. Also it was found that the highest removal efficiency was obtained under the lighting condition with the blue LED out of the LEDs evaluated in this study.

In the next stage, experiments using a full scale room model to investigate VOC removal performance of foliage plants and further experiments using a desiccator to identify the fundamental characteristic of plants for removing VOC as well are required.

SUMMARY

This study conducted the experiment of concentration reduction effect if indoor air pollutants to Korean native plants, Fatsia japonica Decne. et Planch. and Ardisia pusilla DC. The two plants are advantageous in that they are highly available as they grow wild, and being easy to get. Fatsia japonica Decne. et Planch. is a plant of its wide and large leaf diverged 7 or 8 parts, which is thought to have a high effect of air purification. Ardisia pusilla DC. has a smaller leaf than Fatsia japonica Decne. et Planch., which is characterized by more leaves and beautiful. Field measurements were performed in models where the plants were placed and were not. The dimensions of the two models were equal. The concentration of Benzene, Toluene, Ethlybezene, Xylene, Formaldehyde were monitored, since they were known as most toxic materials. The concentration of VOCs was monitored three hours after the plants were placed and three days after the plants were placed. As a result, they had all an effect of reducing pollution. Especially, Fatsia japonica Decne. et Planch. was more excellent in reducing Toluene and Formaldehyde with a lot of pollutants.

INTRODUCTION

The experiment purifying air using plants was conducted by NASA since 1980s. Of late in Korea, as concern about well-being has risen, there has appeared a movement to make clean air, and improve residential environment using already purified air. This study attempts to the most Korean and effective plant by which we feel beauty growing and maintain pleasant indoor air. For this, the study grasped VOCs reduction effect produced indoors to Ardisia pusilla DC, and Ardisia pusilla DC, Korean native plants. The grasp the effect, the study compared the room with and that without plants, and measured VOCs concentration. Also to compare the effect of the two plants, the study alternated the plating and growing volume and placement, and experimented it.

METHODS

This experiment measured the concentration change of VOCs in the room with plants, and that without them in order to seize the VOCs reduction effect by plants. The kinds of measured VOCs were Benzene, Toluene, Ethylbenzene, Xylene, Formaldehyde on the measured results of which for three days reduction effect was grasped. The experiment room measures 3.5m wide, 5m long, and 2.4m long in a form of reduced apartment, which had a living room and a veranda, with the plants arranged based on the veranda part.

In the experiment regarding planting and growing amount, the plants were divided by 10% and 5% of the experiment space, and that to the placement of planting and growing, sunny spot placement close to the veranda part, and scattered placement were measured respectively. The measurement was made on the apartment measuring method(process testing method) at three in the afternoon for three days in a row after 5 hour closed state for 5 hours after ventilation for 30 minutes in the morning. The experiment room was not operative with an air-conditioner, with the condition of both rooms in all the same. BTEX was sampled with a Charcoal tube, and analyzed using GC-FIID, and HCHO was sampled with a DNPH-cartridge, and analyzed using HPLC.

Figure 1 shows the ground plan of the laboratory, and Figure 2 shows the planting amount and placement.

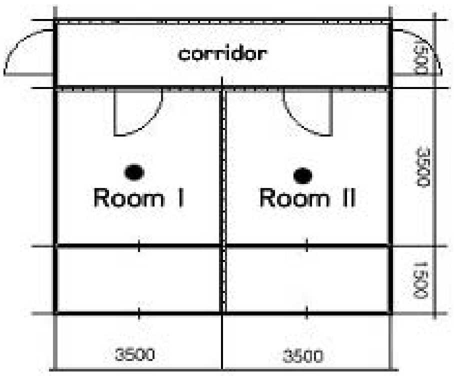

Figure 1. Plan of the space

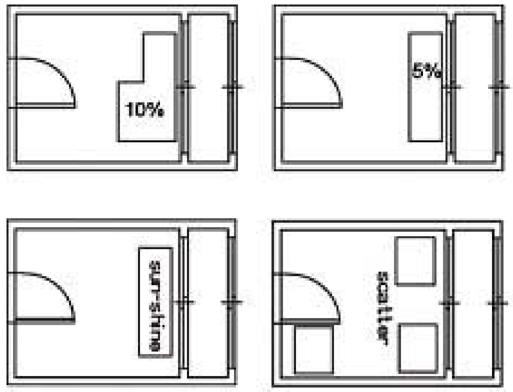

Figure 2. Layout of plant

RESULTS

3.1 Assessment to Planting and Growing Amount

1) Fatsia japonica Decne. et Planch

In case of Fatsia japonica Decne. et Planch, the reduction capability of Formaldehyde was excellent. The more plating and growing volume there was, the more reduced volume there was and as a result of plating Fatsia japonica Decne. et Planch by 10%, Formaldehyde was reduced to 212.33 μg/m³ in total from 251.00 μg/m³.

In planting Fatsia japonica Decne. et Planch by 10% in Toluene, Toluene was reduced by 12.90 μg/m³, which was less than that of Ardisia pusilla DC, showing a reduction effect.

In addition, Benzene was reduced by 6.20~11.60 μg/m³, Ethylbenzene was by 3.40~5.10 μg/m³, Xylene was by 10.40~11.80 μg/m³, Stylene was by 7.80~9.30 μg/m³. In case of setting up all plants, which was effective, where more plants, more effective.

2) Ardisia pusilla DC

Ardisia pusilla DC was excellent in reduction capability in Toluene. In Ardisia pusilla DC planted by 10%, Toluene was most reduced by 15.10 μg/m³, which was more effective than

Fatsia japonica Decne. et Planch. In Ardisia pusilla DC planted, Benzene was reduced by 9.00~12.80 μg/m³, Ethylbenzene by 5.60~7.00 μg/m³, Xylene by 7.90~10.00 μg/m³, Stylene by 4.90~5.80 μg/m³.

Also for Formaldehyde, it was less reduced than for Fatsia japonica Decne. et Planch, but in case of 5%, the reduced volume was great as 96.25 μg/m³, in case of 10%, as 149.58 μg/m³.

Figure 3 indicates the concentration change of Benzene in case of Fatsia japonica Decne. et Planch and Ardisia pusilla DC planted, Figure 4 does the concentration change of Toluene, Figure 5 does the concentration change of Ethylene Benzene, Figure 6 does the concentration change of Xylene, Figure 7 does the concentration change of Stylene, and Figure 8 does the concentration change of Formaldehyde, which is the comparative graph of the set-up case and not set-up case of all plants.

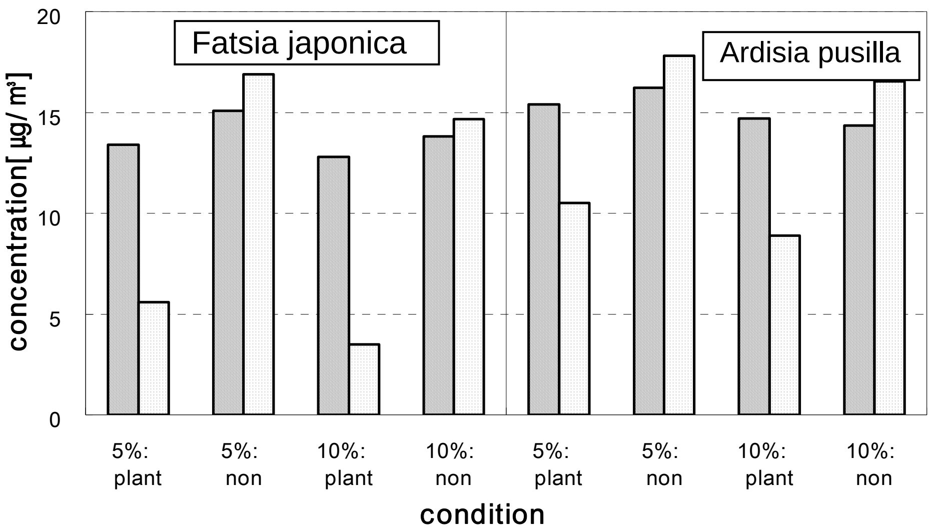

Figure 7. Variation of Stylene concentration according to the amount of plant

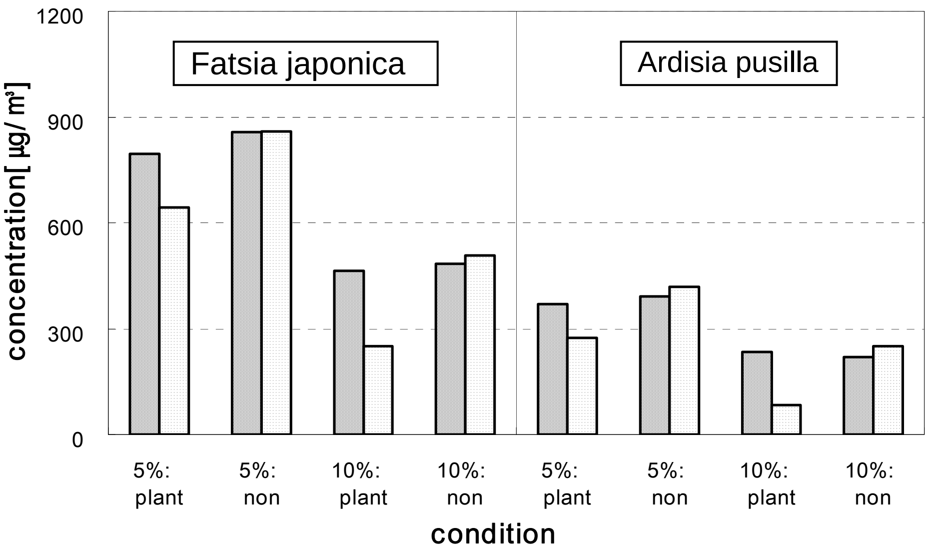

Figure 8. Variation of Formaldehyde concentration according to the amount of plant

3.2 Assessment to Planting and Growing Placement

1) Fatsia japonica Decne. et Planch

In case of planting Fatsia japonica Decne. et Planch, placing it at sunny spot was more effective than that at scattered planting. Benzene was reduced by 6.20 μg/m³ in case of placing at sunny spot, Toluene was reduced by 12.90 μg/m³, which was a bit less than Ardisia pusilla DC. Ethylbenzene was reduced to 1.80~3.40 μg/m³, and Xylene was reduced by 10.40 μg/m³, and Stylene was reduced by 6.00~7.80 μg/m³. Formaldehyde was more effectively reduced in Ardisia pusilla DC and 150.83 μg/m³ was largely reduced in sunny spot placement, and 107.92 μg/m³ was reduced in scattered placement.

2) Ardisia pusilla DC

In planting Ardisia pusilla DC, placing it at sunny spot was more excellent. Benzene was indicated by 9.00 μg/m³ at sunny spot placement, by 5.60 μg/m³ at scattered place, Toluene was indicated by 15.00 μg/m³ at sunny spot placement, by 5.40 μg/m³ at scattered place. Ethylbenzene was indicated by 5.60 μg/m³ at sunny spot place, by 3.90 μg/m³ at scattered placement, and Xylene was indicated by 7.90 μg/m³ at sunny spot, by 4.50 μg/m³ at scattered placement. Ardisia pusilla DC was more excellent than Fatsia japonica Decne. et Planch in Benzene, Toluene, Ethylbenzene. Formaldehyde was more effective in sunny spot placement than scattered placement, where the former was indicated to be 96.25 μg/m³, and the latter was 86.25 μg/m³.

Figure 9 indicates the concentration change of Benzene in case of Fatsia japonica Decne. et Planch and Ardisia pusilla DC planted, Figure 10 does the concentration change of Toluene, Figure 11 does the concentration change of Ethylene Benzene, Figure 12 does the concentration change of Xylene, Figure 13 does the concentration change of Stylene, and Figure 14 does the concentration change of Formaldehyde, which is the comparative graph of the set-up case and not set-up case of all plants.

DISCUSSION

This explored the effect of planting and growing volume and placement of Korean native plants, Fatsia japonica Decne. et Planch and Ardisia pusilla DC. whose findings are as follows.

(1) In all experiments, the room with plants indicated higher reduction effect of VOCs compared to that without plants.
(2) In all cases of experiment of planting and growing volume, the more planting volume, the more excellent the effect.
Toluene was more effective in Ardisia pusilla DC planted, Formaldehyde was more effective in Fatsia japonica Decne. et Planch planted respectively.
(3) In planting and growing and placing experiment, the placement at sunny spot was more effective than that at scattered growing.
When Fatsia japonica Decne. et Planch was placed at sunny spot, the reduction effect of Formaldehyde was the most excellent, and when Ardisia pusilla DC was placed at sunny spot, the reduction effect of Toluene was the most effective.
(4) In all experiments, Toluene was effective in Ardisia pusilla DC, and Formaldehyde was effective in Fatsia japonica Decne. et Planch.

Residential ventilation

Energy Impact of Residential Ventilation Norms in the United States

Max Sherman and Iain Walker

Lawrence Berkeley National Laboratory, Berkeley, CA, USA

Corresponding email: iswalker@lbl.gov

SUMMARY

The first and only national norm for residential ventilation in the United States is Standard 62.2-2004 published by the American Society of Heating, Refrigerating and Air-conditioning Engineers (ASHRAE). This standard does not by itself have the force of regulation, but is being considered for adoption by various jurisdictions within the U.S. as well as by various voluntary programs. The adoption of 62.2 would require mechanical ventilation systems to be installed in virtually all new homes, but allows for a wide variety of design solutions. These solutions, however, may have a different energy costs and non-energy benefits. This report uses a detailed simulation model to evaluate the energy impacts of currently popular and proposed mechanical ventilation approaches that are 62.2 compliant for a variety of climates. These results separate the energy needed to ventilate from the energy needed to condition the ventilation air, from the energy needed to distribute and/or temper the ventilation air. The results show that exhaust systems are generally the most energy efficient method of meeting the proposed requirements. Balanced and supply systems have more ventilation resulting in greater energy and their associated distribution energy use can be significant.

INTRODUCTION

In the United States (U.S.) residential ventilation was not traditionally a major concern because policy makers believed that between operable windows and envelope leakage, people were getting enough outdoor air. Over the past three decades, houses have become much more energy efficient and a key contributor was from reductions in envelope leakage. At the same time, the types of materials used in furniture, appliances, and building materials in houses have changed resulting in more indoor pollutants. People have also become more environmentally conscious not only about the resources they were consuming but about the environment in which they lived.

Historically, people have ventilated buildings to provide source control for both combustion products and objectionable odors [1]. Currently, a wide range of ventilation technologies is available to provide ventilation in dwellings including both mechanical systems and sustainable technologies. Recent residential construction has created tighter, energy-saving building envelopes that create a potential for under-ventilation [2,3]. As a result, new homes often need mechanical ventilation systems to meet current ventilation standards. These standards and related factors have been reviewed in previous studies [4].

ASHRAE Standard 62.2-2004 [5] is the U.S. standard for ventilation for acceptable indoor air quality in low rise residential buildings that (together with its companion Standard 62.1 for all other buildings) represents the current standard for setting ventilation rates. It is the objective of this study to evaluate the energy impacts of meeting this standard in U.S. houses.

ASHRAE Standard 62.2 has requirements for whole-house ventilation, local exhaust ventilation, source control and system requirements. The whole-house mechanical ventilation requirement of 62.2 is given by Equation 1:

$$Q\left(L/s\right) = 0.05 A_{floor}\left(m^2\right) + 3.5\left(N+1\right), \qquad \textbf{(1)}$$

It is assumed that an additional 0.1 L/s/m^2 is supplied through infiltration. Standard 62.2 also requires local mechanical exhaust in kitchens and bathrooms. Kitchens must have the capacity to exhaust at least 50 L/s through a range hood or provide 5 kitchen air changes per hour. Bathrooms must have the capacity to exhaust 25 L/s intermittently or have 10 L/s of exhaust continuously.

METHOD

In order to evaluate the energy impacts of the ASHRAE 62.2 requirements, we used a simulation tool to perform minute-by-minute ventilation, heat and moisture calculations that allowed for the dynamic performance of buildings and Heating, Ventilating and Air Conditioning (HVAC) components. Details of the simulation tool can be found in [6] and a summary of model validation can be found in [7].

Climates Evaluated

Six locations were used that cover the major climate zones:

- **Hot humid**: This zone represents many tropical and semi-tropical areas and is represented by weather data for the U.S. city of Houston,
- **Arid**: This zone represents hot, dry (desert) conditions and is represented by weather data for the U.S. city of Phoenix,
- **Warm humid**: This zone may be typical of some warm temperate zones such as in southern Europe and is represented by weather data for the U.S. city of Charlotte,
- **Continental**: This zone is unmoderated by large bodies of water and has both heating and cooling loads; it is represented by weather data for the U.S. city of Kansas City,
- **Marine**: This zone is typically a cool zone with long, but mild winters; it is represented by weather data for the U.S. city of Seattle,
- **Cold**: This zone had severe winters and short or mild summers typical of Nordic climates; it is represented by weather data for the U.S. city of Minneapolis.

Houses Evaluated

The houses were chosen to be typical of new US homes and complaint with all relevant norms. Different sizes (from 93 m^2 2-bedroom to 372 m^2 5-bedroom) and air tightness levels were used, leading to mechanical ventilation rates from 15 to 40 L/s. Further details of the houses can be found in [8]. For brevity only results for a medium sized house of 186 m^2.

Heating and Cooling Equipment

Equipment sizing was based on ACCA Manuals J and S [10, 11]. Equipment sizing was important in this study because several ventilation systems used the furnace blower to distribute ventilation air. Further details of the equipment can be found in [7 and 8].

Systems Evaluated

We considered nine different ventilation systems derived from previous reviews [11] and rated performance. Fan energy use and HRV/ERV efficiencies were taken from the Home Ventilating Institute directory [12]. The following ventilation systems were simulated:

Standard House (no whole-house mechanical ventilation)

This was the base case for comparison to the other ventilation methods and was simulated for all six climates and three house sizes. This was the same house as the mechanically ventilated cases, except it had no whole-house mechanical ventilation, only bathroom and kitchen source control exhaust. This house was ***not*** 62.2 compliant.

Leaky Envelope that meets 62.2 (no whole-house mechanical ventilation)

This represented existing homes and was simulated for all six climates and three house sizes. This house was 62.2 compliant because of its leaky envelope.

Continuous exhaust

Continuous exhaust was simulated using a bathroom exhaust fan.

Intermittent Exhaust

Intermittent exhaust was simulated using bathroom fans that were on for 20 hours and off for 4 hours during peak space conditioning load. The fan flow was increased from the continuous exhaust case to account for the intermittent operation using algorithms from 62.2.

Heat Recovery Ventilator (HRV) & Energy recovery Ventilator (ERV)

An HRV was used in the cold, marine, continental and arid climates. The hot humid and warm humid climates used ERVs. The HRV and ERVs were connected to the forced air duct system and the air handler fan operated at the same time to distribute the air. Listed recovery efficiencies were applied to the air flow through the unites when calculating the energy use.

Continuous Exhaust plus Air Distribution

The continuous exhaust system was augmented with a central fan integrated (CFI) supply that used the furnace blower to intentionally draw outdoor air through a duct into the return and distribute it throughout the house using the heating/cooling supply ducts. The outdoor air duct was only open to outdoors during heating and cooling blower operation and had a damper that closed when the blower was off. The flow through the outdoor air duct into the return was the same as the continuous exhaust fan flow.

Continuous Supply

The continuous supply system used a fan to supply filtered air from outside to the duct system that then distributed the air throughout the house without using the furnace blower. The supply fan was sized to be four times the ASHRAE Standard 62.2 outdoor air requirements to allow for a 3:1 mixing ratio of indoor air to outdoor air for tempering.

RESULTS

In order to focus on the impacts of the ventilation system and not the details of the house, we have elected to show the results relative to a base case. This approach subtracts out common factors, allowing the results to reflect the difference due to the ventilation treatment chosen. We have elected to use the *unvented house* as the base case, but it is important to remember that that case is a non-compliant one.

The figures are stacked bar charts where we have broken up the total energy use into a piece that represents the energy to induce the desired ventilation (Ventilation), the energy to distribute air (Distribution) and the energy to condition the air (Space Conditioning that combines heating and cooling). The energy use data was converted to dollars ($) using current local energy prices for the US cities chosen.

Figure 1 shows the results for the Hot humid climate where the total energy use for the standard house was 16,500 kWh (cost was $1125). The exhaust systems had the least energy increase of about 800 to 1000 kWh (5% of the total space conditioning) and the intermittent system saved 200 kWh ($18) relative to the continuous system. Both the ERV and Continuous Supply systems used significant distribution energy that made them the least energy efficient. The higher ventilation rates of the continuous supply and continuous exhaust plus intermittent supply lead to greater space conditioning energy use.

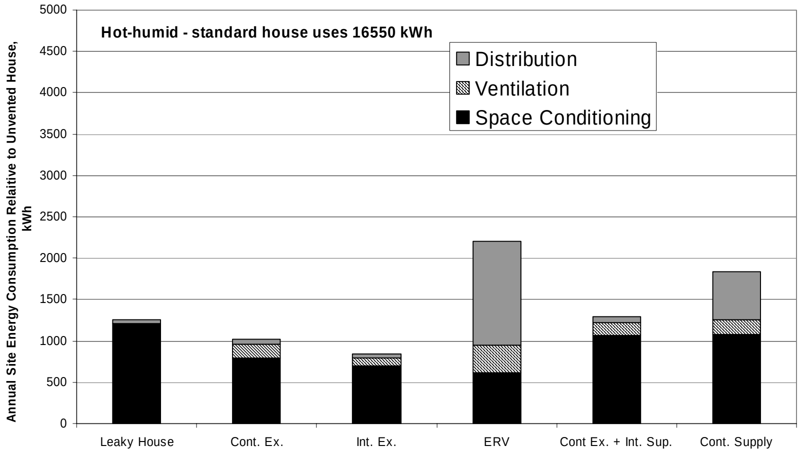

Figure 1: *Energy use of ASHRAE 62.2 compliant ventilation systems relative to standard unventilated house in Hot humid climate.*

Although the ERV had the greatest air change rates, the recovery of energy was shown by the having the least space conditioning energy use. However the distribution energy requirements and ventilation fan power made the ERV the greatest energy user (costing an additional $240 compared to the standard house). If the ERV had not used the central fan for distribution the energy use would be between the continuous and intermittent exhaust cases. In comparison to the leaky house, both the exhaust only systems actually used less energy despite providing greater effective ventilation. The leaky house suffers from having higher ventilation rates when indoor outdoor temperatures are greatest leading to excess energy use.

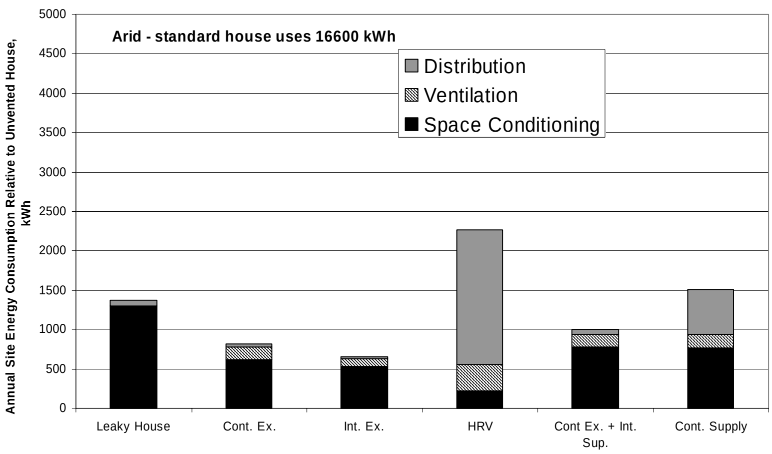

Figure 2: *Energy use of ASHRAE 62.2 compliant ventilation systems relative to standard unventilated house in an Arid climate.*

Figure 2 shows the results for the Arid climate where the total energy use for the standard house was 16,600 kWh (cost was $1170). Although this is considered a cooling dominated climate (with almost four times as much cooling operating time than heating), the energy used for heating (9600 kWh) is still greater than that used for cooling (5500 kWh). The Arid climate results had the same general trends as the Hot humid climate, but the milder climate meant that the space conditioning energy use related to ventilation is lowered. The exhaust system used 800 kWh ($60). The intermittent exhaust saved 160 kWh ($14) relative to the continuous system. With less space conditioning energy, the distribution energy use was even more dominant for the HRV and continuous supply than in the Hot humid climate and made them the least energy efficient. The higher ventilation rates of the continuous supply and continuous exhaust plus intermittent supply lead to greater space conditioning energy use.

Although the HRV has the greatest air change rates the recovery of energy is shown by the having the least space conditioning energy use. However the distribution energy requirements and ventilation fan power make the HRV the greatest energy user: requiring an additional 2250 kWh compared to the standard unvented house (costing an additional $240 compared to the standard house). If the HRV did not use the central fan for distribution the energy use would be between the continuous and intermittent exhaust cases. As with the Hot humid climate, the leaky house used more energy than either of the exhaust systems.

Figure 3 shows the results for the Warm humid climate where the total energy use for the standard house was 24,750 kWh (cost was $1410). For the Warm humid climate, the less benign climate led to the energy for space conditioning increasing significantly - in particular for the higher ventilation rate systems and the leaky house.

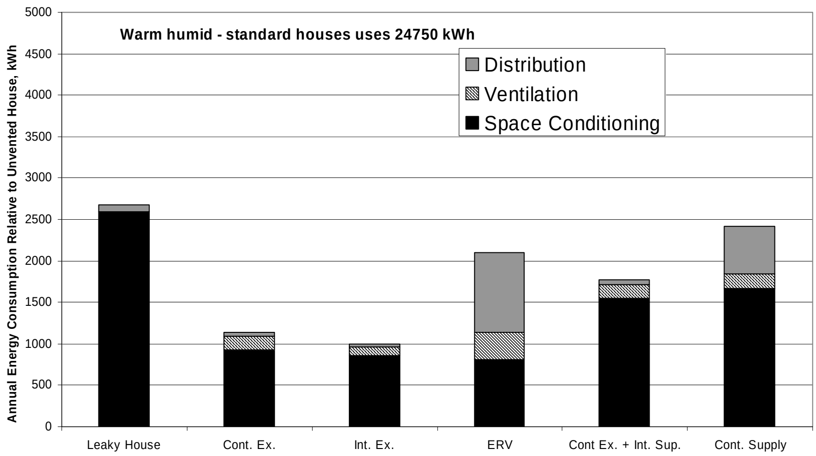

Figure 3: *Energy use of ASHRAE 62.2 compliant ventilation systems relative to standard unventilated house in a Warm humid climate.*

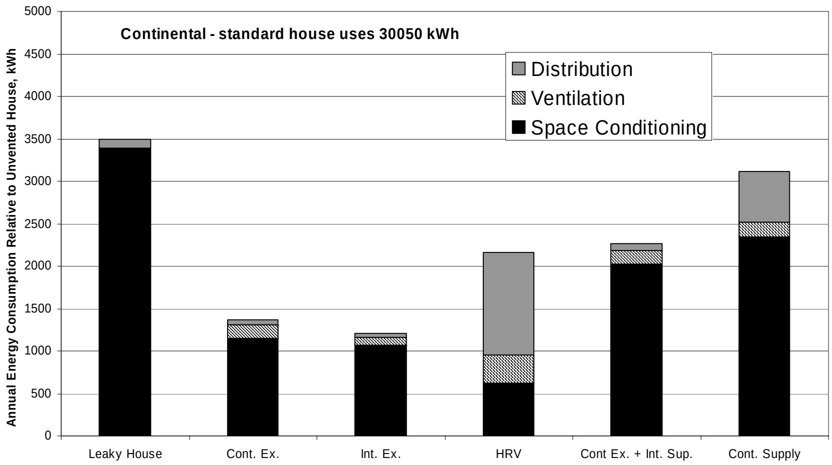

Figure 4: *Energy use of ASHRAE 62.2 compliant ventilation systems relative to standard unventilated house in a Continental climate.*

The exhaust system used 1150 kWh ($75) more than the unvented house. The intermittent exhaust saved only 45 kWh (less than $10) relative to the continuous system. The leaky house was the greatest energy user, followed by the continuous supply. The ERV had the lowest space conditioning energy use that made it more energy and cost competitive with the other systems.

The Continental climate is more heating dominated and cooling energy use is reduced to about 5% of the total. The colder climate is reflected in the space conditioning energy use that in increased relative to the distribution and ventilation fan components. The same trends are seen as for the Warm humid climate, with the leaky house requiring the most additional energy (3500 kWh ($190)) and the continuous exhaust system the least (1365 kWh ($85)).

The marine climate has very little air conditioning - compressor energy was less than 1% of the gas energy used. However, the milder winter climate compared to the Continental climate led to less total energy use and less difference between the unvented standard house and the ventilation systems.

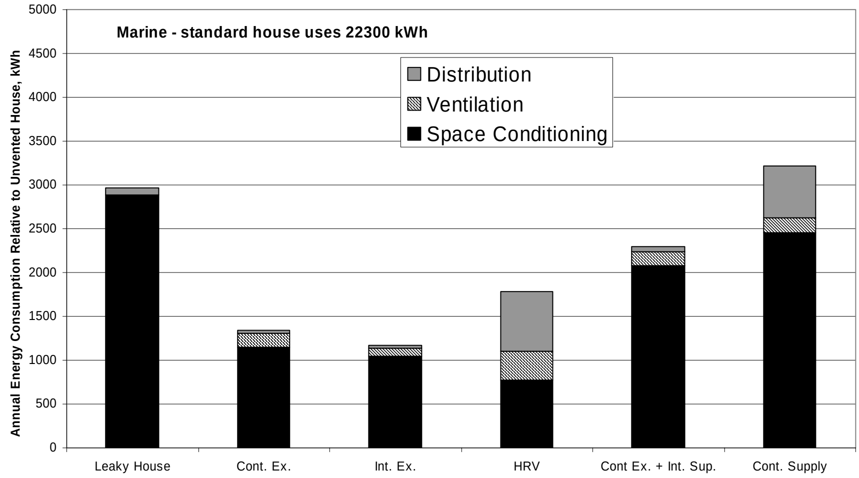

Figure 5: *Energy use of ASHRAE 62.2 compliant ventilation systems relative to standard unventilated house in a Marine climate.*

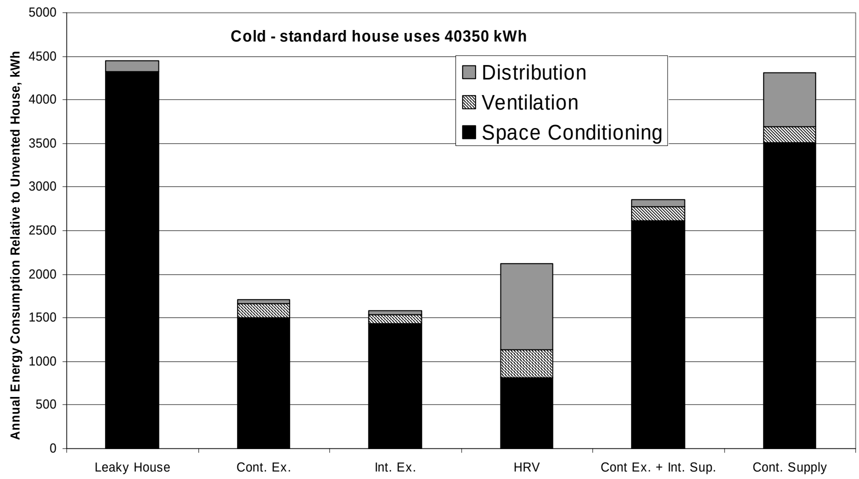

Figure 6: *Energy use of ASHRAE 62.2 compliant ventilation systems relative to standard unventilated house in a Cold climate*.

The distribution energy for the HRV and Continuous exhaust with intermittent supply were reduced due to the small capacity furnace and air conditioner required in the Marine climate with their smaller blower.

The Cold climate was the harshest climate investigated in this study and used the most energy. The low outdoor temperatures in winter make the leaky house a big energy user - requiring 4400 kWh ($240) more than the standard house. Although the space conditioning energy use for the HRV is about half that for the exhaust systems, the blower energy used to distribute the air is such that it requires 400 kWh ($60) more energy. As stated previously this could be reduced if the central furnace blower was not used to distribute the air, in which case the HRV would use the least energy. The higher air change rates of the continuous exhaust plus intermittent supply and the continuous supply lead to much more energy use than the exhaust only cases in this extreme climate.

Exhaust systems were found to be more energy efficient for several reasons: they had the lowest ventilation rates, they used the least ventilation fan power and they did not use fans to mix or distribute air. The most important reason was that requirements of 62.2 do not account for the differences in combining of infiltration with balanced and unbalanced mechanical ventilation.

Air distribution systems are used to distribute heating and cooling, to distribute fresh air, and to filter, clean and recirculate indoor air. As such they can be seen as a separate building function from the rest of the ventilation system and could be treated separately both in regulation and design. One advantage of treating distribution as a separate function is that it will allow efficiency advances in distribution to be made independently from, for example, cooling systems. Other studies [13, 14] have shown that using more efficient variable speed motors at low speed to circulate and mix air in a house results in significant energy savings relative to the blowers in most systems like the ones used in this study. Other options include using the HRV/ERV fans to also distribute the air in the house either through a dedicated duct systems or using the existing forced air system ducts.

CONCLUSION AND RECOMMENDATIONS

In this study we used a simulation approach to determine the likely energy impacts of residential ventilation requirements associated with ASHRAE Standard 62.2 and ventilation strategies for six different climates. The energy to provide such minimally acceptable ventilation was in the range of 800 to 1700 kWh per year ($50 to $100) for the most efficient options, which typically represented about 5% of the heating and cooling energy. The space conditioning energy associated with the extra ventilation provided by the ASHRAE 62.2 ventilation systems was much larger than the fan energy needed to supply or exhaust the air. In every climate the intermittent exhaust system proved to be the most energy efficient system for meeting the proposed requirements—followed by the continuous exhaust system.

Homes with leaky envelopes paid a significant energy penalty without necessarily providing more ventilation then a house with a better envelope and mechanical ventilation. Exhaust systems were found to be more energy efficient than the alternatives because the requirements of 62.2 do not correctly account for the addition of infiltration and mechanical ventilation. Since the exhaust system had a lower impact on the total air exchange, its space conditioning impact was smaller and it was the more energy-effective approach by virtue of producing fewer air changes.

Although the ventilation related energy requires changed by about a factor of three between mild and harsh climates, the general trends for relative energy use between systems was consistent.

Finally, systems that used the furnace or air conditioner blower to distribute air used substantially more energy than other systems. In particular for HRVs and ERVs, the use of the central blower counteracted the space conditioning energy savings of these devices such that they used more energy than a simple exhaust system. This energy penalty may be acceptable if mixing of air is considered desirable for thermal or health concerns.

SUMMARY

Airflow rates were measured in one hundred and two newly built single-family houses during 2002-2004. Of the measured houses, 10 % used natural ventilation, 28 % used mechanical exhaust and 61 % used mechanical supply and exhaust. Exhaust airflow rates were measured during the summer period from terminals. Supply airflow rates and sound pressure levels were measured in master bedrooms. During a 2-3 week period in winter, air change rates were measured with a passive tracer gas technique to determine the overall air change rate.

An average actual air change rate in the summer period was 0,40 1/h in houses with mechanical supply and exhaust ventilation and 0,37 1/h in houses with mechanical exhaust ventilation. Winter period values were respectively 0,41 1/h, 0,34 1/h and 0,3 1/h in naturally ventilated houses. All these values are below the code value of 0,5 1/h. Similarly, the average supply airflow rates in bedrooms were lower than the recommended value in the building code. Both exhaust and supply airflow rates will be reported.

Actual air change rates, room airflow rates together with sound pressure levels compared to airflow rates at the design speed of the ventilation units show possible improvements needed in the ventilation of houses.

INTRODUCTION

In Finnish houses, mechanical supply and exhaust ventilation with heat recovery has been the most common solution during the last 20 years. In apartment buildings, the centralized mechanical exhaust system has been the prevailing system since the 1970s [1]. The situation changed in 2003, when the national building code began to require at least 30 % heat recovery from the exhaust air (D2 2003). Due to this requirement, practically all new residential buildings are today equipped with mechanical supply and exhaust ventilation.

The building code requirement for the ventilation is 0.5 ach in general; the code also gives guideline values for outdoor and exhaust airflow rates for common rooms. These Finnish values follow quite well the second category specified in prEN 15251 [2]. The guideline value for an outdoor airflow rate is 6 l/s per person (4 l/s, per person before 2003) or 0.5 l/s,m^2 (0.35 l/s,m^2 before 2003) for the bedrooms and living rooms. Occupancy by two persons is a common design assumption for bedrooms, giving a 12 l/s design supply airflow rate.

In this study, airflow rates were measured in 102 single-family houses in Helsinki and Tampere area. Most of the measured houses were equipped with mechanical supply (28%) or mechanical supply and exhaust (61%) ventilation. Of the measured houses, 10 % were built with natural ventilation. Only a few houses were older than 5 years in this study. In this article, we concentrate on room airflow rates.

METHODS

The sample of 102 houses was selected according to ventilation system, so that natural ventilation and mechanical ventilation were represented in the study. As mechanical supply and exhaust ventilation has been a standard solution in Finland during last few decades, the sample included more natural and mechanical exhaust ventilation than there is in newly built houses (natural ventilation means here passive stack ventilation). As it was impossible to find newly built houses with natural ventilation, older houses (up to 24 years) were included in the study. Other houses were less than five years old. Half of the houses were located in Tampere and the other half in the Helsinki metropolitan area with a maximum distance of about 200 km between houses and a similar cold climate for all houses.

The houses were selected from databases of companies that manufacture and build houses. In the areas close to the universities in Helsinki and Tampere, announcements were published in local newspapers to get homeowners involved in the study. Also, newsletters were delivered to areas with newly build houses.

In the subgroups according to ventilation system the selection was random. The sample of 102 houses (from which 74 houses in PFT measurement) was according to ventilation system:

- 10% (11%) natural ventilation (passive stack ventilation)
- 29% (28%) mechanical exhaust
- 61% (61%) mechanical supply and exhaust.

The average size of the houses was 156 m^2 of heated area and 386 m^3 volume (medians) and the average age was 3 years (except those with natural ventilation). The average number of occupants were 3.6 and average building leakage value 3.9 ach at 50 Pa (the range was between 0.5 to 8.9 ach at 50 Pa). All the houses were one- or two-storey houses with wooden frame construction.

Dust from outside air can rise filters pressure drop and significalntly reduce airflows of the ventilation unit within a few months. To try to avoid that, tenants were asked to change filters before measurements were taken. In a few cases, measurements had to be repeated because the filters were not changed and there was no airflow to measure.

Exhaust airflow rates were measured in kitchens, bathrooms and saunas during the summer period from terminals. Exhaust airflow rates were measured in the minimum, maximum and normally used fan speed position. The sums of the exhaust airflows were used to calculate the air change rate of the houses. Supply airflow rates to bedrooms were measured with pressure difference from terminals. These air exchange rates were close to the air change rates that were measured in wintertime with tracer gas [3].

Occupants were asked to fill a questionnaire about their perception of indoor climate and the use of ventilation units. Actual use of ventilation units is analyzed based on air change rate and bedroom sound level measurements, as well as occupant complaints and comparison of actual ventilation unit fan speed, in order to design one.

RESULTS

Air exchange rates of the houses were measured from terminals at different fan speeds of the ventilation units. In Figure 1, the air change rates of mechanically ventilated houses can be seen. In the building code, the air change rate is 0,5 change per hour is recommended [4]. The measurements (Figure 1 b) shows that this recommended value can be attained in 90 % of the houses.

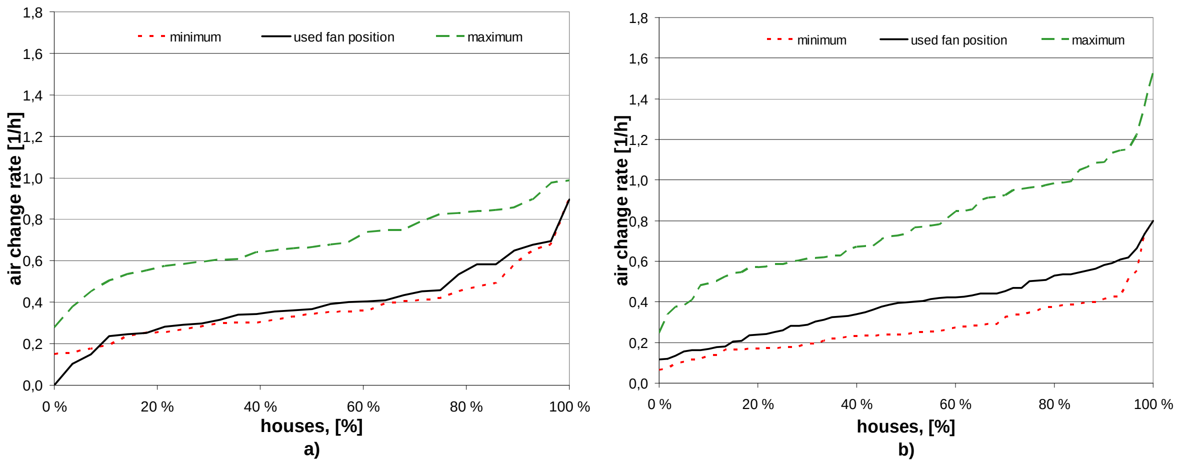

Figure 1 Air change rates in mechanically ventilated houses: a) mechanical exhaust (29) and b) mechanical supply and exhaust (61).

In reality, only 20 % of mechanically ventilated houses exceed the building code value in the normally used fan speed position. With the mechanical exhaust and supply ventilation unit, about 25 % of the measured houses had an air change rate of over 0,5 change per hour.

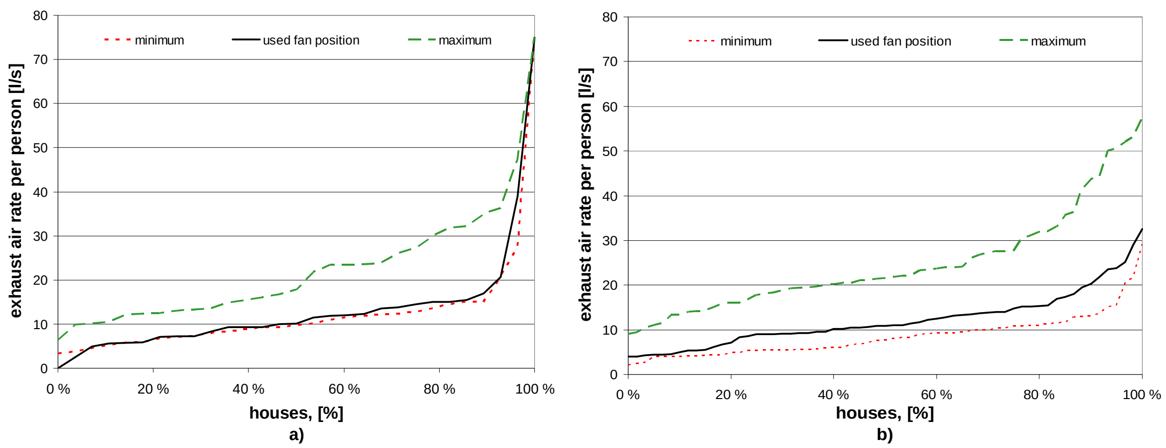

Figure 2 Exhaust air flow rates in litres per person. Overall exhaust air in mechanically ventilated houses a) mechanical exhaust, b) mechanical supply and exhaust.

In Figure 2, we have a graph of the exhaust air rate per occupant. We can see that the average in both systems was near 12 l/s.

Exhaust air rate in kitchens

Finnish building code (D2) recommends a range-hood exhaust air rate of 8 l/s, with a 25 l/s boost if fan speed can be controlled. Without the fan speed control, the airflow rate should be 20 l/s, with 25 l/s boost [4].

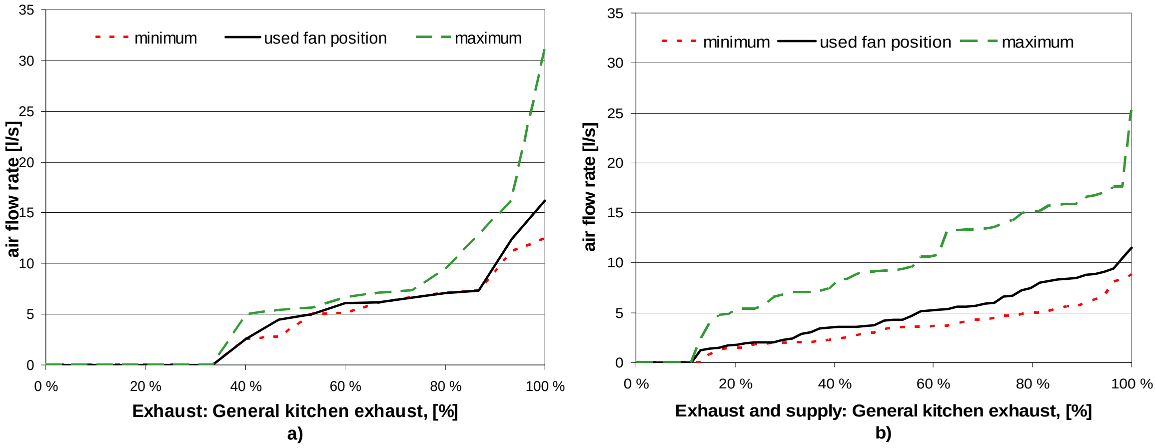

Figure 3 Exhaust airflow rate in kitchens (general ventilation). A) mechanical exhaust (29 kitchens) and b) mechanical supply and exhaust (61 kitchens). Airflow rates in minimum, maximum and normally used fan speed position.

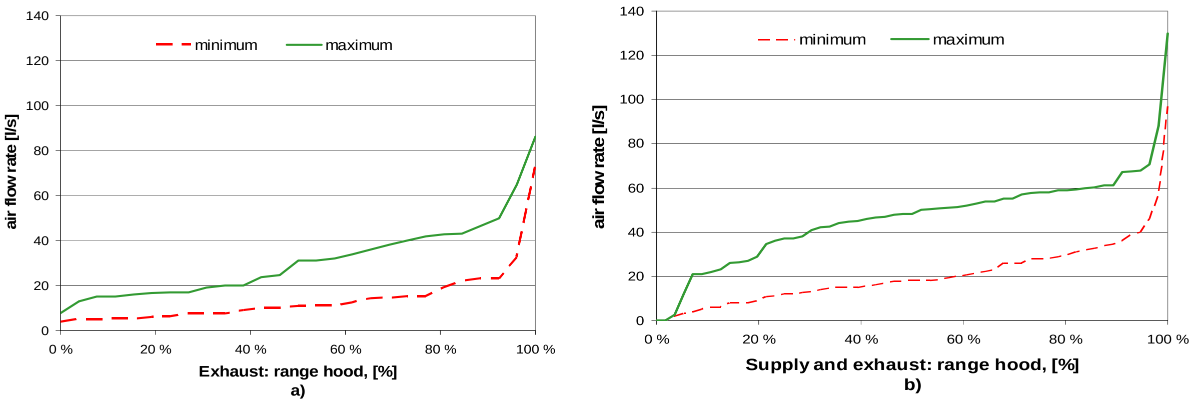

Figure 4 Exhaust airflow in kitchen range hood. A) Mechanical exhaust (27 hoods) and b) mechanical supply and exhaust (57 hoods).

Table 1 General kitchen exhaust and kitchen range hood airflow rates average, median and standard deviation. Mechanical exhaust, and mechanical supply and exhaust.

Mechanical exhaust 29 houses	min	Used fan position	max	Mechanical supply and exhaust 61 houses	min	Used fan position	max
General exhaust 16 kitchens				General exhaust 55 kitchens			
average [l/s] median standard deviation	4 4 4,1	5 5 4,8	7 6 8,2	average [l/s] median standard deviation	3 3 2,2	4 4 3,1	10 9 5,8
27 range hoods				57 range hoods			
average [l/s] median standard deviation	14 11 13,6		31 31 17,6	average [l/s] median standard deviation	21 18 15,7		47 48 21,0

In many houses, the measured airflow was under the 1 l/s (Fig. 3). In mechanical exhaust houses, the 50 l/s was possible to achieve in 10 % of kitchen-range hoods with boost, and in mechanical supply and exhaust houses, in 50 %.

Bathroom and sauna

The Finnish building code recommendation for bathroom exhaust is 10 l/s and for boosted exhaust 15 l/s. In mechanical exhaust ventilated houses, 65 % and in mechanical supply and exhaust ventilated houses, 70 % could have achieved the recommended value of 10 l/s at fan speed normally used.

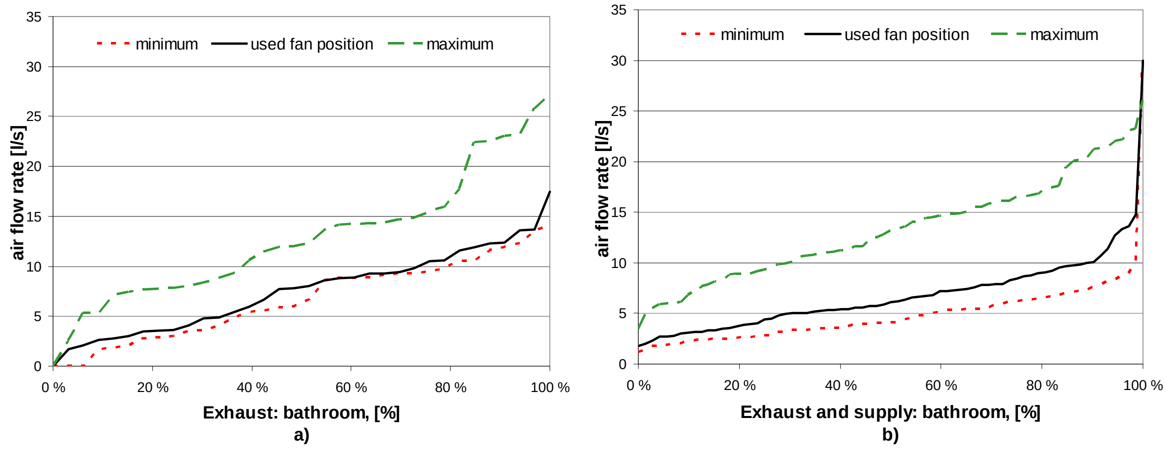

Figure 5 Bathroom exhaust airflow rate. A) mechanical exhaust (34 bathrooms), b) mechanical supply and exhaust (73 bathrooms).

In the sauna, the exhaust should be at least 6 l/s. That was achieved in 70 % of the measured houses using the normally used fan speed position.

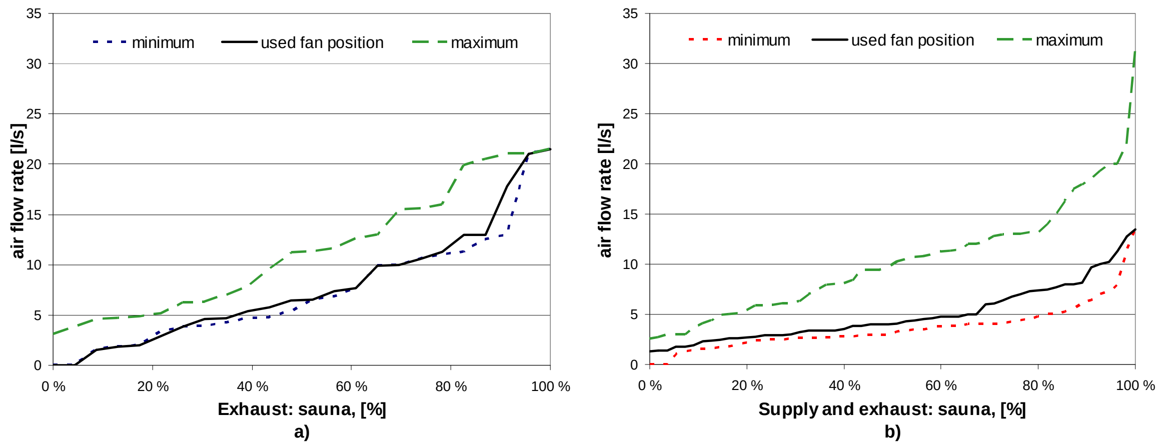

Figure 6 Exhaust air rates in sauna: a) mechanical exhaust (21 saunas), b) mechanical supply and exhaust (56 saunas).

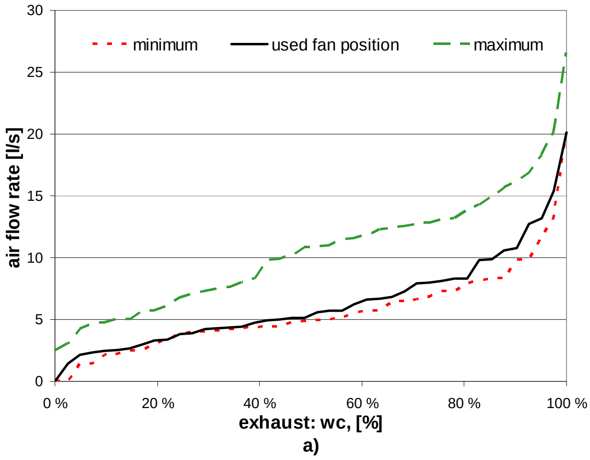
Table 2 Characteristics of mechanical exhaust and mechanical supply and exhaust: bathroom, average, median, standard deviation.

Mechanical exhaust 29 houses	min	Used fan position	max	Mechanical supply and exhaust 61 houses	min	Used fan position	max
34 bathroom				73 bathroom			
average [l/s]	7	8	13	average [l/s]	5	7	13
median	6	8	12	median	4	6	13
standard deviation	4,1	4,1	6,6	standard deviation	3,6	4,0	5,1

Table 3 Characteristics of mechanical exhaust and mechanical supply and exhaust: sauna average, median, standard deviation.

Mechanical exhaust 29 houses	min	Used fan position	max	Mechanical supply and exhaust 61 houses	min	Used fan position	max
24 saunas				56 saunas			
average [l/s]	7	8	11	average [l/s]	4	5	10
median	6	6	11	median	3	4	10
standard deviation	5,8	6,1	6,2	standard deviation	2,4	2,9	5,8

Exhaust airflow rates in toilets



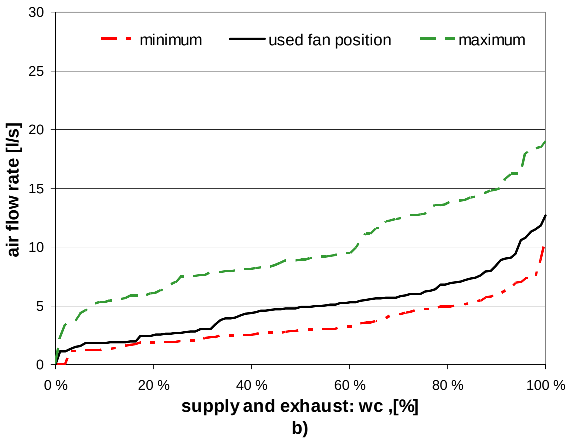


Figure 7 Exhaust airflow rates in toilets. A) Mechanical exhaust 42, normal use position average 6 l/s, median 5 l/s and standard deviation 4,0 at normally used fan speed position. B) Mechanical supply and exhaust 99, normal use position average 5 l/s, median 5 l/s and standard deviation 2,7 at normally used fan speed position.

The Finnish building code recommendation for a toilets exhaust air rate is 10 l/s. In mechanically ventilated houses, this is reached in 15 % of mechanical exhaust and in 5 % of houses with mechanical supply and exhaust ventilation at normally used fan speed position.

Bedrooms

In two-person bedrooms, both supply and exhaust were measured. Normally there is only supply airflow to bedrooms, but, in some cases, there were also exhaust terminal. There were nine houses (3 with mechanical exhaust and 6 with mechanical supply and exhaust) with an exhaust airflow rate of between 2 to 10 l/s.

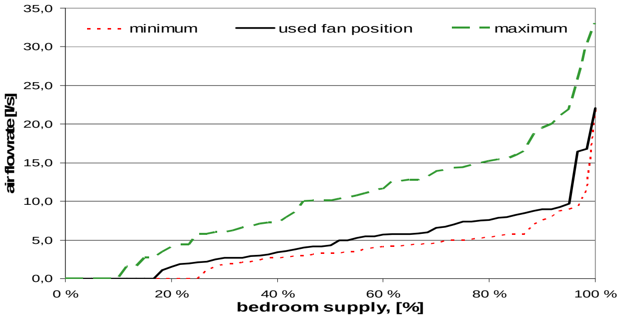

Figure 8 Supply airflow rates in bedrooms (61). Average 5 l/s, median 4 l/s and standard deviation 4,3 at normally used fan speed position.

The recommendation for minimum supply air rate in the Finnish building code is 6 l/s per person. The measured bedrooms were two-person bedrooms, so the minimum recommended supply air rate was 12 l/s.

Figure 8 (right) shows that, in 60 % of the houses, the recommended supply airflow rate could be achieved at some fan speed. It is possible to have a better air change rate for bedrooms with wardrobes (exhaust included). The measured exhaust air rates in wardrobes in Figure 9 shows that 27 % of the measured terminals have over 12 l/s exhaust in the operating range.

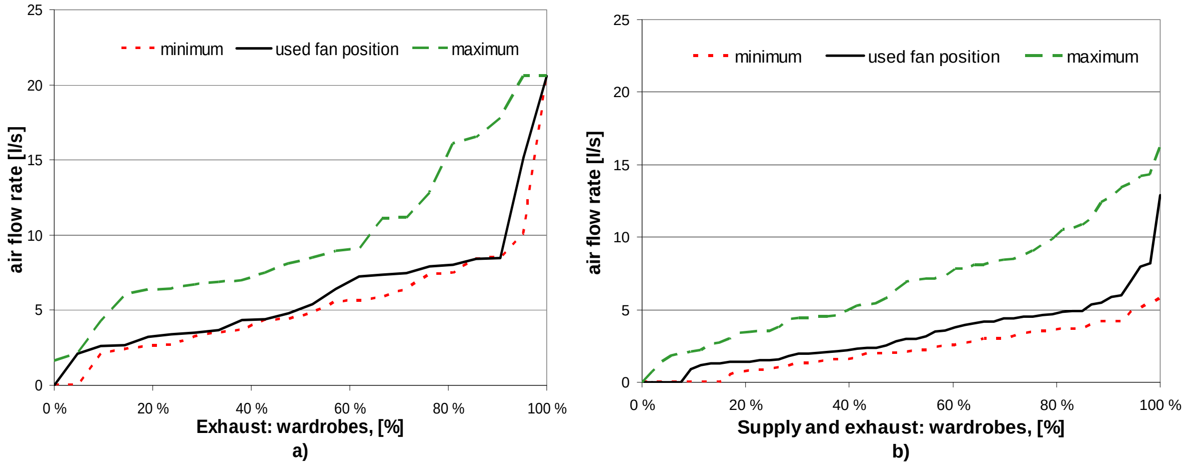

Figure 9 Wardrobe exhaust air rates. A) mechanical exhaust n= 22, normal use position average 6 l/s, median 6 l/s and standard deviation 4,5 at normally used fan speed position. B) mechanical supply and exhaust 54, normal use position average 3 l/s, median 3 l/s and standard deviation 2,4 at normally used fan speed position.

The building code recommended exhaust air rate is only 3 l/s. In mechanically ventilated houses, this value was achieved in exhaust in 77 % of the houses and in supply and exhaust in 48 %.

Sound levels in bedrooms

The sound level of the ventilation unit was also measured in the bedroom and living room. When interviewing the occupants during measurements, only a few of them mentioned the problems with noise from ventilation units.

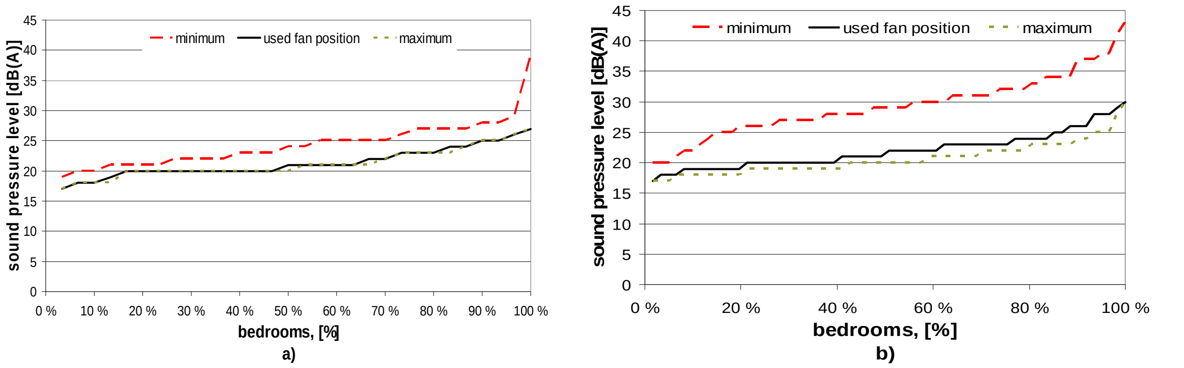

Figure 10 Bedroom sound pressure levels. A) mechanical exhaust, B) mechanical supply and exhaust.

From Figure 10, however, it can be seen that sound pressure levels were low compared to building code value 28 dB(A) [4]. This indicates that the sound pressure levels should be near 20 to 22 dB(A), which is acceptable at night.

DISCUSSION

At normally used fan speed position, room airflow rates were only half of the recommended values of the Finnish building code. Only in a few houses the airflow rate values were higher than 0.5 ach at normally used fan speed position. The recommended value was possible to reach in 90 % of the houses at some fan speed.

Measured exhaust air rates were slightly higher than 10 l/s per person in almost every house at normally used fan speed. In interviews, tenants did not complain about any odour problems, even if the airflow change rate was low.

In many cases, tenants did not have any knowledge about their ventilation system and its operation range. They did not know the best possible way to use it efficiently or how to maintain it properly.

It can be recommended that the design fan speed should be written on the ventilation unit and there should also be instructions how to change the filters and how often that should be done. It would also be useful to provide a guideline with ventilation unit given information about the general principle of the ventilation system, its operation and maintenance.

ACKNOWLEDGEMENT

Measured data analyzed in this study is from the national research project “Moisture-proof healthy detached house”.

SUMMARY

The study aims at quantifying the impact of the retrofit of ventilation systems from the energy, IAQ (Indoor Air Quality) and health perspective
In a first part, the French market has been defined (number of each ventilation system installed in existing building). Both qualitative and quantitative studies of malfunctions noticed on ventilation systems have been made.
In a second hand, the influence of ventilation retrofitting on the building energy performance has been evaluated. The impact of implementing innovative techniques (i.e. decreasing the fan absorbed power…) has also been studied.
Although the study has been held on the French market, it gives an idea of the main trends and results that regulators may expect when acting on ventilation systems in retrofitting strategies.

INTRODUCTION

The aim of the study is first to quantify the impacts of the retrofit of ventilation systems from the energy, IAQ and health perspective then to propose systems upgrades in order to improve the installations.

METHODS

Experienced people from the field (building owners, designers…) analyzed the main causes for poor installation and function of ventilation systems. This has been compared and applied on the building stock in order to determine possible actions, constraints and potential savings when improving the current systems.

RESULTS FOR RESIDENTIAL BUILDINGS

Ventilation systems have been mainly modified in France by different regulations (i.e: whole-house ventilation with shunt in 1969, mechanical exhaust in 1982). There are therefore few retrofits of these systems. Needs for retrofitting ventilation systems while thermal retrofit is being done is a recent trends. It has started recently (after 1985) mainly in public housing because of the condensation problems.

Table 1 : Residential ventilation systems in France

Ventilation systems	**Multi-family house**	**Single-family house**
None	9%	14%
Local grills in wet rooms	34%	36%
Natural and Hybrid ventilation with ducts (whole-house)	17%	22%
Pressure controlled mechanical exhaust	35%	24%
Humidity controlled mechanical exhaust	5%	5%
Supply and exhaust	0%	1%
Type of ventilation		
None	9%	14%
Wet rooms only	34%	36%
Natural & Hybrid with ducts (whole-house)	18%	22%
Mechanical ventilation (whole-house)	40%	28%
All whole-house ventilation systems	57%	50%
Number of dwellings (existing stock)	13 066 266	17 333 069

The survey has investigated the main disorders encountered for each type of ventilation systems. Figure 1 shows overall results, given in frequency of cases encountered; the scale is not mentioned because the survey was only qualitative.

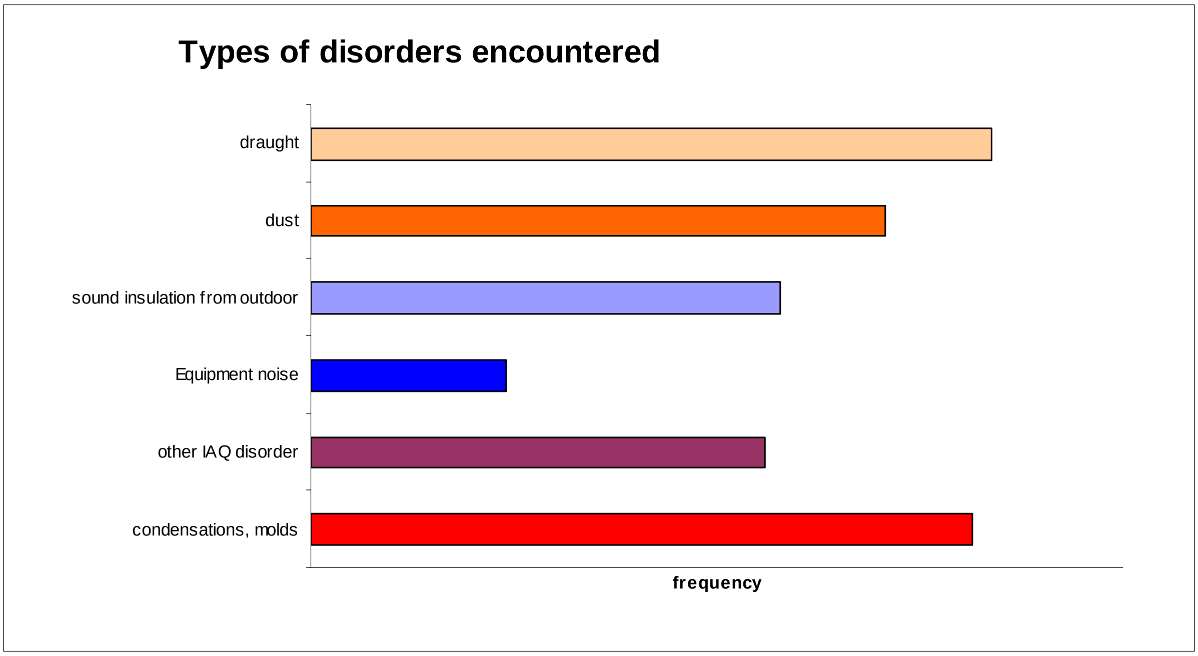

Figure 1 : Type of disorders encountered

More generally, we can note from the survey that:

- 47% of dwellings, mainly built before 1974, are not ventilated or just with some airing of the wet rooms. They are the first target of energy retrofits. Any reinforcement of the building airtightness (windows replacement…) without ventilation system retrofit leads to various disorders: humidity, condensation, moulds…
- 53% of dwellings, mainly from 1969 to the present day, have a whole-house ventilation either natural (20%) or mechanical (33%). Whole-house ventilation has

been mandatory in new buildings since 1969 in order to avoid condensations in bedrooms. The survey showed that these buildings have less air change disorders and better performance than the previous category. Nevertheless, their design and dimensioning as well as their installation are too often poor (duct tightness, fan power, acoustics…).

All disorders have an impact on :

- Durability of the building envelope (insurance companies report that condensation represents 50% of the causes of disorders and repairs cost in average 3300 € per dwelling),
- Occupants' health (as bibliography shows impact on symptoms of asthma, rhinitis…),
- Energy consumption. Uncontrolled air flows in dwellings are the first cause to waste energy, either by leaks, airing or windows opening. Adequate ventilation should provide a controlled ventilation air flow in order to avoid over-ventilation and supply only what is needed where it's needed. The study quantified the potential savings on houses without ventilation system.. .

  On existing stock, some choices of improvements of the ventilation systems have been made and estimation of the savings that would be obtained are shown in tables 2 and 3. Calculations take into account standard dimensioning as applied in France and emissions of CO_2 are calculated with 220 g/KWh as an average. The hypothesis is that all the existing stock would be improved (potential). The scenarios studied were:
  - when no ventilation system is available : switch to whole-house ventilation;
  - when a ventilation strategy is present : improvement of the control of the ventilation strategy (either by Demand Controlled Ventilation (DCV), heat recovery and/or low fan absorbed power).

Table 2 : Energy impact of ventilation improvement in single-family houses in France

	Existing system	**Number of dwellings (millions)**	**Improvement**	**Average savings on the total energy consumption KWh Primary Energy/ house/ year**	**Potential of savings kt eq CO_2**
Old house	none	2.40	whole-house ventilation	4968	2628
	wet rooms only	6.31	whole-house ventilation	4968	***6895***
	natural ventilation with ducts	3.76	mechanical ventilation	4968	**4110**
New house	mechanical ventilation	2.43	single exhaust, low fan consumption	324	173
		2.43	humidity controlled (DCV) balanced system with high recovery efficiency	972	519
	overall	**17.33**			**14326**

Table 3 : Energy impact of ventilation improvement in multi-family houses in France

	Existing system	**Number of dwellings (millions)**	**Improvement**	**Average saving on the total energy consumption KWh Primary Energy/ house/year**	**Potential of savings kt eq CO2**
Old multi-family houses	none	1.16	whole-house ventilation	2340	595
	wet rooms only	4.45	whole-house ventilation	2340	2291
	natural ventilation with ducts	5.23	humidity controlled natural ventilation or mechanical exhaust	2340	2690
Recent multi-family houses	mechanical ventilation	2.22	humidity controlled mechanical ventilation or balanced system	1885	921
		13.07			**6498**

In addition, the study has quantified the savings that could be obtained by a control and audit of installed mechanical ventilation systems (30% are claimed to be not conform to French regulation today). The savings are lower because they apply to a smaller building stock but show that a correct diagnostic of the ventilation systems could lead on the French market to:

- 0,225 Mt CO_2 on single-family houses stock,
- 0,2 Mt CO_2 on multi-family houses.

CEN TC 156 has prepared standards for the diagnostic of ventilation and air conditioning systems (EN 15239 and EN 15240) in the framework of the EPBD directive.

RESULTS FOR NON-RESIDENTIAL (COMMERCIAL) BUILDINGS

Table 4 : Types of ventilation systems in non residential buildings in France

	Offices	Commercial	Schools	Health	Leisure	Hotels	Overall
None or airing (windows)	50%	40%	60%		10%	5%	34%
Natural ventilation with ducts						9%	1%
Local (room) fans	10%	10%		15%	20%		10%
Mechanical exhaust	9%		20%	25%		75%	13%
Mechanical Exhaust with DCV	1%						0.2%
Supply & Exhaust	10%		19%	25%		10%	9%
AHU inc. ventilation	20%	50%	1%	35%	70%	1%	34%
OVERALL	100%	100%	100%	100%	100%	100%	100%
Built 1000 x m^2/year	3026	3732	1747	1700	1666	821	12692
Existing stock 1000 x m^2	176244	193030	167852	100711	67141	58748	763726

Two main conclusions have appeared :

1. A lot of buildings do not have ventilation systems except local exhaust from toilets and bathrooms. Airing by window opening is common although it is not always allowed by French hygiene regulation..

2. In most cases, ventilation air flow rates are not high enough in rooms with high density of occupation (meeting and conference rooms, spectacles…) due to poor dimensioning and sizing and/or change of occupation in time. This leads to IAQ problems although there is less humidity trouble in this kind of buildings than in dwellings. Too high equipment noise is also common and attributed to poor commissioning of the installations.

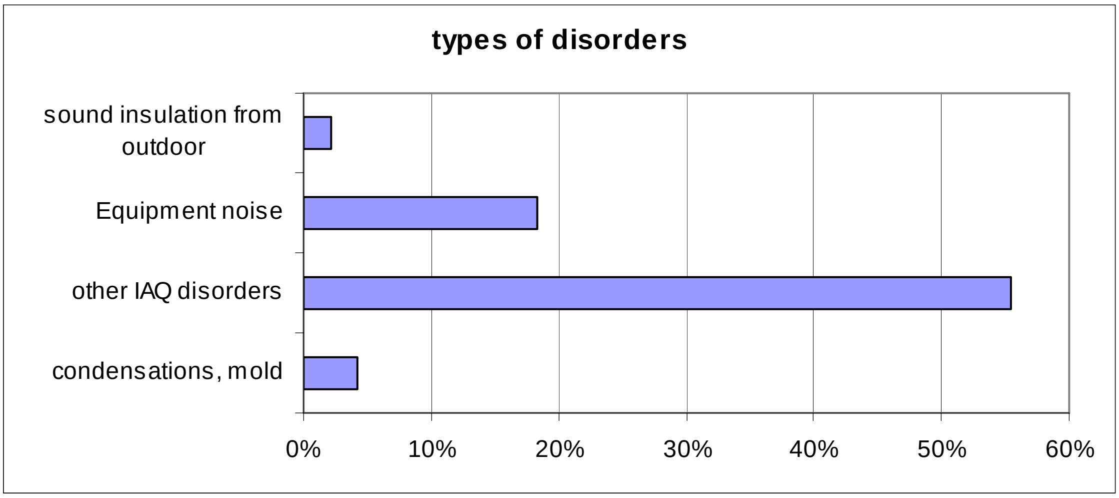

Figure 2 : Main disorders encountered for all types of non residential buildings.

The study has also quantified the potential of energy savings that could be gained from improving the ventilation systems. Where no ventilation was available, the scenario was to install one. When a ventilation system was present, the scenario was to improve the ventilation strategy (timer, heat recovery unit (HRU), DCV...). Results are shown for office buildings stock in table 5.

Table 5 : Energy impacts of improvements in non residential buildings in France

	Existing system	**Number of buildings (millions)**	**Improvement**	**Average saving on the total energy consumption KWh Primary Energy/ m²/year**	**Potential of savings kt eq CO2**
All periods	None	106.2	Mechanical exhaust with timer	32	748
	Mechanical exhaust, no timer	8.0	Mechanical exhaust with timer	32	56
	Mechanical exhaust, with timer	8.0	DCV	7	12

	Balanced AHU with HRU	8.9	Balanced systemwith HRU and DCV	7	14
		177			**1131**

GUIDE FOR IMPROVEMENTS

As quantification of potential savings has shown a real impact, it is necessary to give to professionals some guidance and information about improving ventilation systems when retrofitting.
In order to help diagnostic and improvements, the study listed for main ventilation systems and main buildings the different options and proposed some charts to help decision. As an example, figure 3 shows a decision process for offices.

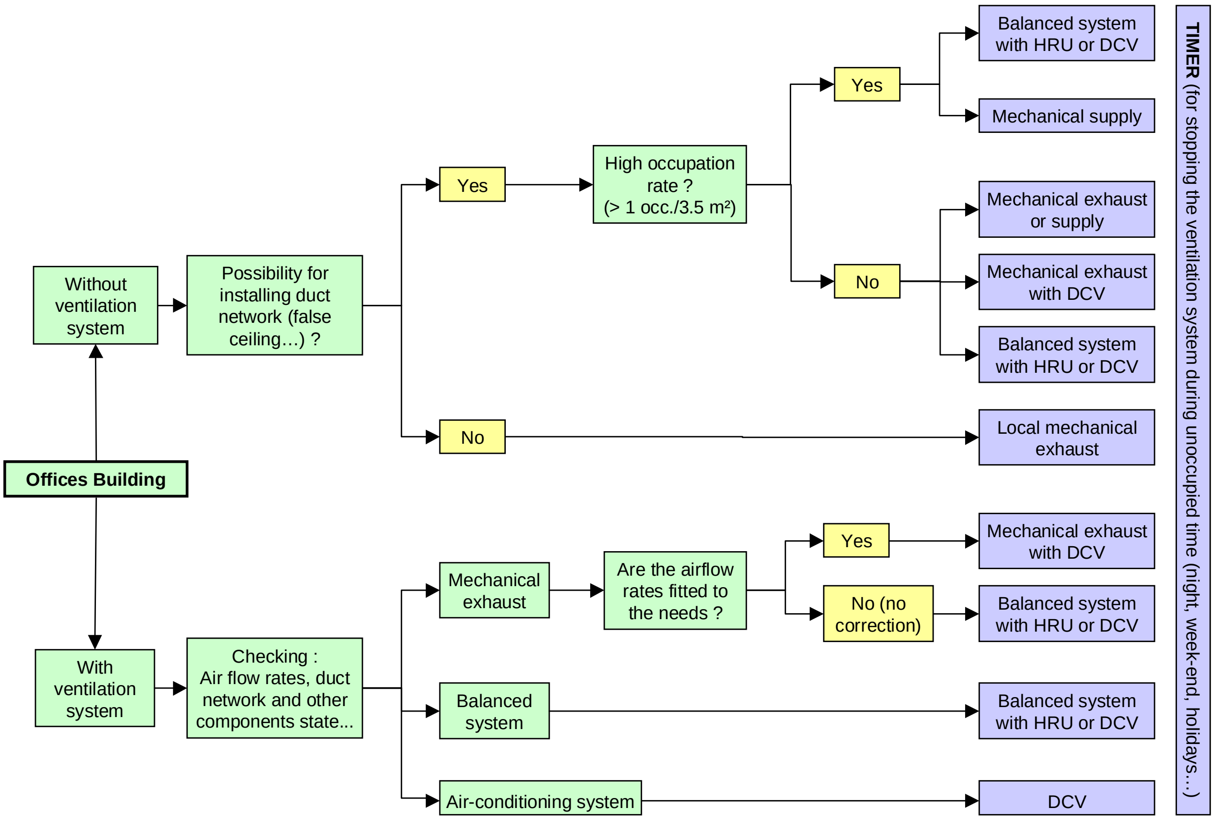

Figure 3 : Decision process for improving ventilation systems in offices

DISCUSSION

All European countries, due to the implementation of the EPBD directive, are studying how to reduce energy consumption on the existing building stock. Ventilation systems are essential when retrofitting:

- To avoid condensations, molds or IAQ disorders too common when the building tightness is reinforced. These disorders have impacts on health, comfort and performance.
- To save energy by the control of air flows in the building. Uncontrolled flows, leakages and airing are too expensive from the point of view of energy. A first step when retrofitting should be to install a ventilation system when none exists. A second step is to check regularly if the performance of the system is correct in order to maintain in time the energy performance. A third one is to improve the ventilation by heat recovery, DCV and/or low fan absorbed power.

The impact of ventilation on the building energy consumption is high enough to be dealt correctly. Poor installations and designs are a cost from the energy point of view.

SUMMARY

This study focuses on the correlation between the airtightness of a building envelope and the average infiltration and energy consumption of a typical modern Finnish detached house. The correlation between tightness and infiltration was determined using an empirically validated dynamic IDA-ICE simulation model of a two-storey detached house. The effect of wind conditions, Finnish climate conditions, balance of ventilation system and leakage distribution on infiltration were studied with the simulation model. According to the results, the average infiltration rate and heat energy consumption increase almost linearly with the building leakage rate n_{50} of the building envelope. Resulting from the linear dependence, the annual average infiltration rate of the detached house in a sheltered suburban area can be approximated with the simple equation $n_{50}/31$. If the average infiltration rate is applied to heat energy calculations, the simple equation is $n_{50}/25$.

INTRODUCTION

This study is part of the cooperation project *Tightness, indoor air and energy efficiency of residential buildings* (AISE), that is being carried out by two cooperating Finnish universities: Tampere University of Technology and Helsinki University of Technology during the period 2005 – 2007. The objective of this study is to find a correlation between the tightness of a building envelope and the average infiltration and energy consumption of a typical modern Finnish detached house in the cold climate of Finland, and to study the effect of other important factors, such as leakage distribution, wind and climate conditions, on infiltration, using an empirically validated simulation model.

Since the late seventies, studies have been conducted on the correlation between airtightness of a building envelope measured with a single pressurization test and annual infiltration rate. In 1982, Kronvall and Persily compared pressurization test results to infiltration rates measured with tracer-gas in detached and terraced houses in Sweden and USA (New Jersey). From their comparison, they obtained the widely used “rule of thumb” for annual infiltration rate: $n_{50}/20$ [1,2], where n_{50} is leakage air change rate per hour at 50 Pa of pressure difference. In 1988, Dubrul found that the infiltration rate can be estimated with n_{50}/K. According to the study of Dubrul, the value of the coefficient K ranges from 10 to 30, depending on, for example, the type of building, wind conditions and leakage distribution. However, the mean value 20 can be regarded as typical [3].

METHODS

Building description

This study was carried out as a sensitivity analysis simulating a single building model in various conditions. The building model describes an existing detached house comprising two floors (Figure 1). The building is situated in the metropolitan area of Helsinki; it was built in 2000. The net floor area of the building is 172 m² and the building structures are of wood-frame construction; the base floor of the house is a concrete slab on the ground. The level of thermal insulation of the house fulfils the requirements of the Finnish building code [4]; the house is equipped with a mechanical supply and exhaust ventilation system with heat recovery. The building corresponds to the typical timber-framed detached house defined by the national project "Moisture-proof healthy detached house" [5].

Figure 1 The object of the study is a detached house.

The building was studied with extensive field measurements, including, for example, a pressurization test of the building envelope and an analysis of the leakage distribution, using infrared photography. The measured leakage air change rate at 50 Pa pressure difference over the envelope (n_{50}) was 3.9 ach. The building was simulated with the measured leakage distribution and two approximated distributions shown in Table 1 [6]. In the "draughty roof" case, most of the leakage openings were at the junction of the roof and external wall, while in the "draughty base floor" case, most of the leakage openings were at the junction of the base floor.

Table 1 The vertical leakage distributions of the building. The measured distribution is based on the infrared photography of the building; the two other distributions are approximated cases.

Place of the leakage routes		Vertical leakage distribution, %		
		Measured	Draughty roof	Draughty base floor
2nd floor	Junction of roof	36	75	12.5
	Upper edge of window frame	4	0	0
	Lower edge of window frame	4	0	0
	Junction of intermediate floor	2	0	0
1st floor	Junction of intermediate floor	21	12.5	12.5
	Upper edge of window	0	0	0
	Lower edge of window frame	24	0	0
	Junction of base floor	10	12.5	75

The dynamic simulation model

This sensitivity analysis was carried out using a simulation model of the preceding detached house. The pressure conditions of this building model were compared against measurement results and the model was found to be suitable for infiltration and energy analyses [6]. The building model was done using IDA indoor Climate and Energy 3.0 (IDA-ICE) building simulation software. This software allows the modelling of a multi-zone building, HVAC-systems, internal and solar loads, outdoor climate, etc. and provides simultaneous dynamic simulation of heat transfer and air flows. It is a suitable tool for the simulation of thermal comfort, infiltration, and energy consumption in complex buildings. A modular simulation application, IDA simulation environment and IDA-ICE, has originally been developed by the Division of Building Services Engineering, KTH, and the Swedish Institute of Applied Mathematics, ITM [7,8]. IDA-ICE has been tested against measurements [9,10] and several independent inter-model comparisons have been made [11]. In the comparisons, the performance of radiant heating and cooling systems using five simulation programs (CLIM2000, DOE, ESP-r, IDA-ICE and TRNSYS) were compared; IDA-ICE showed a good agreement with the other programs.

RESULTS

The effect various factors on infiltration and heat energy consumption of Finnish detached house were simulated. Most of the simulations were carried out with the hourly weather data of Helsinki (1979), which is commonly used as test-reference data for energy calculations in Finland [12]. The temperature dependence of infiltration was studied in two separate cases using the weather data of 1979 from Jyväskylä and Sodankylä. The Finnish climate is cold and the annual average outdoor temperatures of 1979 was 4.3°C in Helsinki, 2.8°C in Jyväskylä and -0.8°C in Sodankylä. The measured annual average wind velocity of these places was between 3 and 4m/s, so the wind conditions were very similar.

Studied cases

The studied factors of the sensitivity analysis and the description of the simulated cases are listed in Table 2. All the cases, except the simulations of different Finnish climate conditions, were simulated with three levels of airtightness. Almost completely airtight detached houses were described with a building leakage rate of n_{50} = 0.15 ach, while the airtightness of typical timber-framed detached houses was simulated using n_{50} = 3.9 ach [5]; the leakage air change rate n_{50} = 10 ach describes leaky detached houses. The effect of wind pressure on infiltration was studied with three levels of wind shielding: an exposed area, a sheltered suburban area and a theoretical case without wind at all. Exposed wind conditions are quite rare in Finland because the country is mostly forested and suburban areas are typically closely built. The sheltered wind conditions describe the typical wind conditions of Finnish suburban areas; the effect of stack-induced infiltration alone is studied in the theoretical case of no wind effect. The effect of the distribution of leakage openings were simulated using the measured and the two estimated distributions shown in Table 1. The effect of the balance of the mechanical ventilation system was studied with equal supply and return air flow rates or with supply air flow rates 15% greater or less than the return air flow rates. The air change rate of the building was 0.56 ach in all the simulation cases fulfilling the minimum requirement (0.5 ach) of the Finnish building code [13].

Table 2 The description of the simulated cases.

Focus of the simulation	Studied factors				
	Wind conditions	Leakage distribution	Supply/ return	Climate	Airtightness n_{50}, ach
Wind conditions	Exposed	Measured	1	Helsinki	0.15-3.9-10
	Suburban	— ‖ —	— ‖ —	— ‖ —	0.15-3.9-10
	No wind	— ‖ —	— ‖ —	— ‖ —	0.15-3.9-10
Leakage distribution	Suburban	Draughty roof	— ‖ —	— ‖ —	0.15-3.9-10
	— ‖ —	Measured	— ‖ —	— ‖ —	0.15-3.9-10
	— ‖ —	Draughty base floor	— ‖ —	— ‖ —	0.15-3.9-10

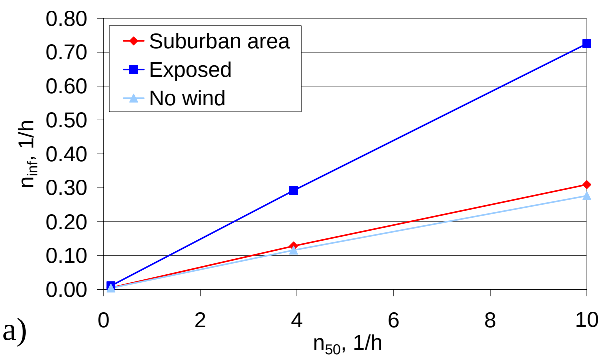
Finnish Climate conditions	— ‖ —	— ‖ —	1	Helsinki	3.9
	— ‖ —	— ‖ —	— ‖ —	Jyväskylä	3.9
	— ‖ —	— ‖ —	— ‖ —	Sodankylä	3.9

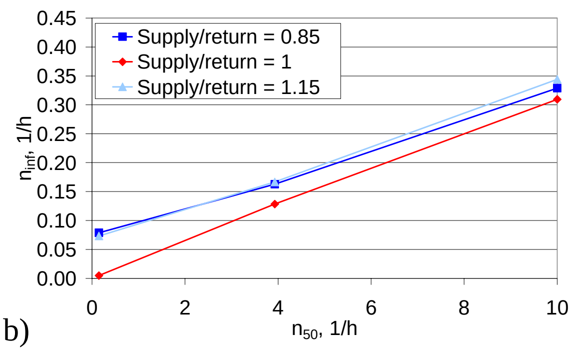
Infiltration

The effect of wind on the average infiltration air change rate is about 10% in the sheltered suburban area (see Figure 2a) of Helsinki. Wind-induced infiltration is more significant than stack-induced infiltration only in the exposed wind conditions, where wind effect is about 60% of the average infiltration air change rate. The effect of the balance of the ventilation system on pressure conditions of the building and infiltration is emphasized in the airtight building (see Figure 2b). If the airtightness of the building is poor, the balance of the ventilation system is not important.

The difference in infiltration between the different leakage distributions is shown in Figure 2c. The average infiltration air change rate is about 10-25% higher in the building with the measured leakage distribution than in the building with the estimated distributions. The effect of the Finnish climate conditions on infiltration is shown for the detached house with a typical level of building leakage rate of n_{50} = 3.9 ach (see Figure 2d). Those cases were simulated with the wind conditions of the suburban area. The average infiltration air change rate slightly increases with decreasing annual average outdoor temperature, but the difference is insignificant (2%) between Helsinki and Jyväskylä. The difference in infiltration between the climate conditions of Helsinki and Sodankylä is 16% according to the simulation results.



a)



b)

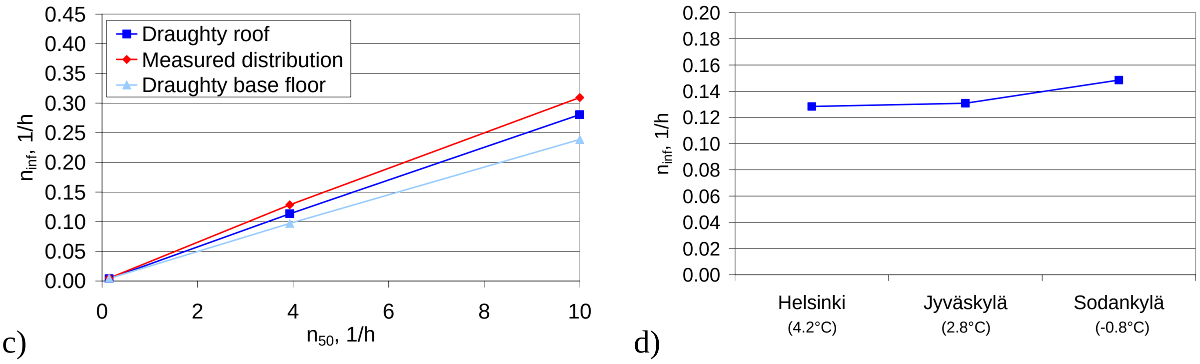


Figure 2 The effect of several factors on the annual infiltration air change rate. Figures show the effect of wind conditions of the building site (a), the balance of the ventilation system (b), the leakage distribution (c), and the Finnish climate conditions (d). (The annual average temperatures are shown in the brackets.)

The results show that the correlation between airtightness and average infiltration air change rate is almost linear when the ventilation supply and return air flow rates are in balance. Then, the annual average infiltration rate n_{inf} can be approximated by dividing the building leakage rate n_{50} by a constant parameter x

$$n_{inf} = \frac{n_{50}}{x}. \qquad (1)$$

If the average annual infiltration air change rate is used in the heat energy calculation, the dependence of infiltration air flows on the temperature-driven pressure difference between indoor and outdoor air should be taken into account in the cold climate. During the heating season in Finland, the infiltration air flow increases with the increasing temperature difference between indoor and outdoor air (see Figure 3).

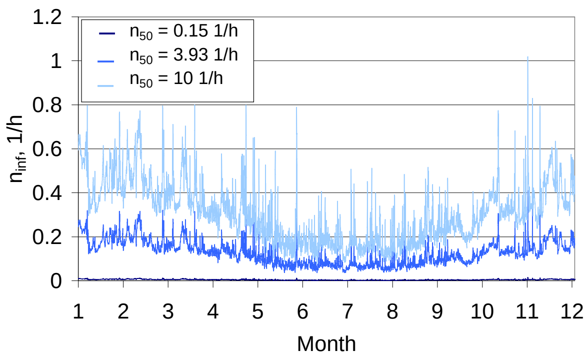

Figure 3 Infiltration air change of the detached house with three different building leakage rates in Helsinki.

The fluctuation of the infiltration air change between the heating season and summer season can be taken into account by, for example, calculating the annual infiltration air change weighted by the temperature difference of the indoor and outdoor air

$$n^{e}_{inf} = \sum_{i=1}^{8760} \frac{(T_{in} - T^{i}_{out})_i \cdot n^{i}_{inf}}{(T_{in} - T^{i}_{out})_i}, \qquad (2)$$

where n^e_{inf} is the average annual infiltration air change rate suitable for heat energy calculation and n^i_{inf} is a normal hourly infiltration air change and T_{in} is a set point temperature of heating, T^i_{out} is hourly outdoor air temperature. If the weighted infiltration air change rate is calculated using the form of Equation (1), the temperature correction could be performed using a correction factor k as follows

$$n^e_{inf} = \frac{n_{50}}{k \cdot x}. \qquad (3)$$

The resultant parameters of the most important simulation cases for the simple calculation methods of Equations (1) and (3) are shown in Table 3. A suitable value of parameter x for the detached house is about 31 in suburban areas in Helsinki. Then, the average infiltration air change can be approximated by dividing the building leakage rate n_{50} by 31. In that case, the correction factor k for the heat energy calculation is about 0.8 and the weighted infiltration air change rate is 20% higher than the mean value of the infiltration air change rate. Substituting the preceding values of parameter x and the correction coefficient k into Equation (3), the simple calculation method for the weighted infiltration air change rate reduces into the form $n_{50}/25$. The determined values of parameters x and k are accurate enough for the climate conditions of Jyväskylä also. In the exposed wind conditions, the average infiltration air change is about two times bigger than in the shielded suburban area and the mean value of parameter x is about 14. If the supply and return air flow rates of the mechanical supply and exhaust ventilation system are unbalanced, the average infiltration rate cannot be approximated using the simple linear calculation method of Equations (1) and (3), especially when the envelope is extremely airtight, because the infiltration air flow rate depends on the difference between supply and return air flow rates.

Table 3 Parameters of the most important simulation cases for the simple calculation methods shown by Equations (1) and (3).

Building leakage rate n_{50}, ach	$x = n_{50}/n_{inf}$	Correction factor for heat energy calculation k
Suburban area, measured leakage distribution, supply/return air flow rate = 1		
0.15	31	0.8
3.9	31	0.8
10	32	0.8
Exposed area, measured leakage distribution, supply/return air flow rate = 1		
0.15	14	0.9
3.9	13	0.9
10	14	0.9
Suburban area, measured leakage distribution, supply/return air flow rate = 0.85		
0.15	2	1
3.9	24	0.9
10	30	0.9

Energy consumption

The effect of wind conditions and the balance of the ventilation system on heat energy consumption are shown in Figure 4. The resultant energy consumption covers the heat energy consumption of the building zones and the ventilation system. The correlation between the tightness of the building envelope and the heat energy consumption is almost linear in simulated wind conditions (see Figure 4a). Because of that, the preceding correlation reduces into a simple rule of thumb: The increase of one unit of the building leakage rate n_{50} gives rise to an increase of about 6% in the heat energy consumption of the zones and the ventilation system. At the same time, the increase in total heat energy consumption is about 4% consisting heat demand of domestic hot water and household electricity. The preceding simple rule is valid for the studied detached house in a sheltered suburban area in the climate conditions of Helsinki. The effect of the balance of the ventilation system on the heat energy consumption of the building is slightly greater in the airtight building (see Figure 4b).

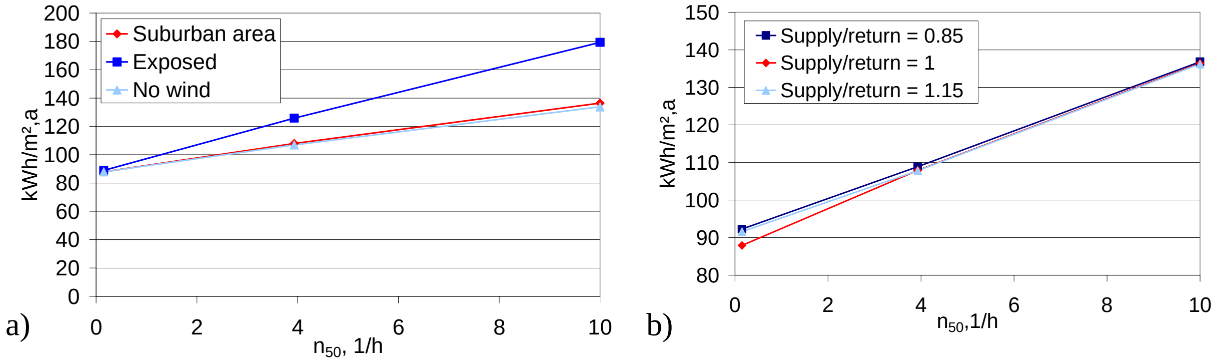

Figure 4 The effect of wind conditions (a) and the balance of the ventilation system (b) on heat energy consumption of the zones and the ventilation system.

DISCUSSION

According to the simulation results, wind has a minor effect on the average infiltration in typical suburban areas of Helsinki and the stack-induced infiltration is dominant in the Finnish cold climate. A correlation between the airtightness of the building envelope and the annual infiltration air change rate is almost linear. In this case, the annual infiltration air change rate can be approximated with the simple equation $n_{50}/31$. The average infiltration air change rate for the heat energy calculations can be calculated by weighting the average infiltration air change rate with the heat demand of a building. The correction for the heat energy calculation can be performed by multiplying the denominator of the preceding equation by the correction factor, which is 0.8 in a typical suburban area. Then the weighted annual average infiltration air change rate can be approximated with the simple equation $n_{50}/25$. These simple approximations are valid in the climate conditions of Helsinki and Jyväskylä, respectively located in Southern and Central Finland. The resultant increase in heat energy consumption regarding zones and the air handling unit is 6% on average, when the value of the building leakage rate n_{50} increases by one unit. Respectively, the increase in total heat energy consumption is about 4%.

Influence of occupants on the energy use of balanced ventilation

Karin Soldaat and Laure Itard

SUMMARY

In this paper we give an overview of the ways occupants use ventilation systems and describe the results of interviews conducted in households equipped with balanced ventilation. An attempt is made to quantify the effects of occupant behaviour on the final energy use of the household for heating. This energy use is studied for several behaviour scenarios, leading to the conclusion that occupant behaviour may easily reduce the predicted savings to zero, or even may increase the energy use when compared to natural ventilation.

INTRODUCTION

In the Netherlands the energy use of new buildings is subject to legislation and should not exceed a certain value, calculated by using the Energy Performance Coefficient (EPC, [17]). The lower the EPC, the more energy efficient the building. Ever since its introduction in 1996, the EPC-value has become stricter. This has led to an increase in the implementation of heat-recovery balanced ventilation systems in newly built dwellings. In 1996-1997, when the EPC-value was 1.4, almost all ventilation systems applied used a natural air inlet and a mechanical air outlet. In 2000-2001, when the EPC-value was 1.0, 40 percent of all new residential buildings were equipped with heat recovery balanced ventilation systems [1]. The recent lowering of the EPC to 0,8 will probably enhance this percentage even further, because balanced ventilation is one of the most cost-effective ways to achieve the prescribed EPC-value. However, occupant behaviour may have a considerable influence on the yearly energy efficiency of the balanced ventilation systems in dwellings. This energy efficiency depends among others on the flow-rate settings chosen by the occupants and on the way they use natural ventilation openings. This paper aims at a first evaluation of the energy efficiency of heat-recovery balanced ventilation systems when actual use is taken into account.

METHODS

Occupant behaviour

First, a literature study was conducted. There are indications that occupant behaviour often plays a considerable role [2,3,4] in the effectiveness of sustainable building options that have a user component. When occupants use certain techniques in a way that differs from the intentions of the designer, the minimisation of environmental impacts might be counteracted. A post-occupancy evaluation (PoE) of mechanically ventilated heat recovery systems showed that the real CO_2-production was higher than the calculated optimum and also higher than the base case with only natural ventilation [4]. Jeeninga found in [3] that the actual energy use of households living in dwellings with the same EPC-value can vary up to a factor two. Four main factors play a role on ventilation behaviour [5, 6]. These factors are occupant characteristics, characteristics of the dwellings and of its environment and finally the characteristics of the ventilation system itself.

Occupant's characteristics: the size and the composition of the households has an influence on the ventilation behaviour [5,7,8], an particularly the presence of children and the age of occupants. The older the occupants, the less ventilation. The presence of occupants is related to the duration of window-opening [9] as well as household activities like cooking, tumble drying, washing clothes or dishes, showering and smoking [5]. Thermal comfort preferences of occupants play also a role. People who have a preference for high temperature open the windows less [5]. The preferred temperature in the bedrooms is lower than in the living room [5,10], which is one of the reasons why windows are opened more often in bedrooms than in living rooms. Ventilation behaviour is strongly correlated to perceived fresh/stuffy air, dry/humid air, cooking odours and other strong odours ([6], [11]). Knowledge about the ventilation system is another important actor. Occupants may not use the system on the right way, because of inadequate operation instructions [8]. From [8] it appears that there is no difference in the frequency and duration of opening of the windows between occupants using different mechanical and natural ventilation systems. However, a difference is noticed in [10] where it appeared that occupants with mechanical ventilations systems tend to use the windows less. The differences between both studies may arise from differences in knowledge or in poorly working systems. Pulmonary diseases may also play a role in the ventilation behaviour. Occupants with lung diseases ventilate longer and more often [12]. Finally some studies show that less conscious occupants and occupants paying a collective energy bill may open the windows longer ([5],[10]). *Characteristics of the dwelling:* The type and design of dwellings influences the opening of windows [9]. In ground-bounded dwellings windows are less often open in the living room and the kitchen than in apartments. For bedrooms, the inverse is observed. In apartments, the windows are more often ajar and in ground-bounded dwellings wide open. Thermal insulation, air tightness and noise insulation of the dwelling may also influence the use of the windows and of the mechanical ventilation. Occupants tend to ventilate less through mechanical system or windows when the air tightness of the dwelling is low (high infiltration rates) or when the rooms are small ([5],[6]). South orientated rooms tend to be more ventilated than other rooms when the sun shines [5]. The use of the rooms itself may influence the ventilation behaviour. Also the location of furniture or the use of decoration stuffs or plants on the windowsill are of importance [13]. Finally, the type of heating system plays a role. In dwellings with central heating windows are less often open than in other dwellings [9]. *Characteristics of the environment:* The weather plays a main role in opening or not the window. The use of windows is linearly correlated with the outside temperature for temperatures between -10 $^{\circ}$C and 25 $^{\circ}$C and inversed correlated with wind velocities.

When it is raining or snowing, windows are less often used. Next to weather, noise nuisance is an important factor ([9], [13]). In about 30 % of Dutch dwellings, occupants close the windows to avoid noise from outside. Odours from industry, traffic or agriculture produce the same effect [10]. Finally, occupants close their windows when they leave the house or at night as protection against burglary [5]. *Characteristics of the ventilation system:* The ventilation system consists in infiltration trough cracks, ventilation through windows and ventilation through a mechanical system if present. The way the window hangs up in the window frame is important as well as the direction of opening. Windows that are fixed on the bottom of the frame and that open inwards are more often open than other types of windows [9]. Upper windows are open twice more often than windows opening outwards. If the window in open stand cannot be fixed at several positions through a grip, it is possible that the window will never be used [10]. If a mechanical ventilation system is used, the location of the switches may be of importance. If the system is not cleaned regularly, which is the case in half of the households with balanced ventilation in the Netherlands [6], the capacity of the system may be reduced strongly. Occupants of dwellings with balanced ventilation report fewer burdens from draught from windows and grilles, but report draught from supply air inlets [12]. If the air inlets don't fit with the esthetical preferences of occupants they may remove them [10]. Finally, noise produced by the mechanical ventilation system plays a main role ([10], [14]). In 28 % of dwellings equipped with balanced ventilation occupants are "always" or "often" annoyed by noise and 37 % of the occupants "sometimes". Because of this noise nuisance, 17 % of the occupants ventilate less with the mechanical system than they would like [6].

Based on this literature study and on 18 qualitative interviews with occupants in their houses, combined with an inspection, different user scenarios are established. All occupants rent their houses from a housing association. The aim of the in-depth interviews is to get insights into the relationship between the technical characteristics of the balanced ventilation system and its use by occupants. In a following phase of this research, these interviews will be used as basis for a large survey in order to gather statistical data. The results of these interviews are summarized hereafter. Most of the occupants are not aware of the energy saving aims of balanced ventilation. They do not know that they can save energy by closing the windows in the winter. They do know that the system is needed to supply continuous ventilation. To control the system they use the switch, in all cases placed in the kitchen, but are not aware of other possibilities like the use of the bypass in summer situation. This is because of the poor quality of the use instructions from the producer (no difference in instructions for servicemen and for occupants) and of the housing associations. The design of the switches plays an important role in the use of the system. Balanced ventilation systems run almost always in the lowest stand. When the system is equipped with a two-stand switch the lowest stand has a capacity about 50 %. Systems with a three-stand switch have a capacity of only 30 % in the lowest stand. The location of the switch is important too. 22 % of the interviewees are lacking a switch in the bathroom. Because of this the bathroom is less ventilated than needed. The design of the control display on the system itself is not adapted to occupants. Most of them do not understand the function of the comfort temperature and of the bypass. Most of the interviewees are aware of the necessity of cleaning the inlets and the filters and also clean them regularly. Occupants have relatively often the impression that the system does not supply fresh air, whereas the window does. They have doubts whether the system provides enough fresh air and open therefore the windows. Some odours from outside, like barbecue odours are smelled inside. When this is the case, some occupants shut the ventilation system down by disconnecting the plug. The air exhaust in the kitchen is perceived as insufficient. As a reaction some occupants placed a supplementary cooker hood on the existing system. As a result the whole system is disturbed. The supply air is often perceived as being too dry. In this case, they would open the window or use humidifiers on the radiators. Some of the occupants close the air inlet when they feel draught. Mostly the air inlets then remain closed. Avoiding noise from the ventilators is a reason why the system works in a lower stand than the maximal one. For the same reason some occupants shut the supply ventilator down. The use of the switch is linked to specific activities like cooking, showering, using the toilet, using a tumble dryer en receiving visit, but in most cases, the switch remains continuously in the same low stand.

Characteristics of the studied dwelling and ventilation scenarios

For the calculations we used a typical Dutch terraced house with three bedrooms and an attic. It is a three storey house with a gross floor area of 124 m² and a gross storey height of 2.8 m. The use area as defined in the building decree is 63 m². Facades, roof and ground floor have a Rc value of 2.5 m²K/W. The south and north façades have an area of 46 m², with a window percentage of 30%. Roof and ground floor have an area of 52 m². The west and south facades are outer separation walls with other dwellings. High efficiency glazing is used (U-value= 2.1 W/m²K). The dwelling is heated by a high efficiency boiler (efficiency of 0.83 on yearly basis).

The Dutch Building Decree prescribes the minimum flow rates given in table 1 [15]. The floor areas and the minimum ventilation flow rates for this dwelling calculated according to the Dutch building decree are summarized in table 2. At the level of the dwelling the minimum required air flow rate is therefore 259 m³/h.

Table 1: Minimum flow rates.

	Living area (bedrooms and living room)	Kitchen	toilet	Bathroom
Flow rate (m^3s^{-1})	$0,9x10^{-3}$ per square meter with a minimum of 7×10^{-3} total	$21x10^{-3}$ total	7×10^{-3} total	14×10^{-3} total

Table 2: Areas and minimum flow rates for a typical Dutch house.

	Living room + kitchen	Bedroom 1	Bedroom 2	Bedroom 3	Bathroom
Area (m²)	37,1	9,9	9,7	6,0	6,6
Flow rate (m^3h^{-1})	120.2	32.0	31.3	25.2	50.4

To limit costs, balanced ventilation systems in the Netherlands are mostly designed to meet the requirements on the minimum ventilation rates, but not more. Furthermore, the legislation prescribes that these minimum ventilation flow rates must be achieved when the system runs at its highest level (level 3). The systems installed in the inspected dwellings were designed this way. Balanced ventilation systems in dwellings are mostly

equipped with switches that can be put in levels 1, 2 or 3. The interviews showed that the systems are running most of the time in level 2 in which only 50 % of the capacity is available. At night time, the system mostly runs in level 1 due to noise pollution from the ventilator, with only 30 % of the capacity. Furthermore, studies have shown [16] a reduction of the capacity of 10% a year, due to a too low level of maintenance (cleaning). After 5 years, the maximum capacity is reduced to 65 % of the original capacity. The total amount of fresh air supplied to the dwelling is also dependent on the air-tightness of the construction. The air-tightness of Dutch new dwellings should not exceed 200 dm³/s per 500 m³ building volume. For the reference dwelling studied, the air flow rate should be lower than 200 dm³/s. In the calculations we used this value as the upper limit of the infiltration flow rate.This is to take into account the possible opening of windows to ventilate. In the Dutch mandatory energy performance norm [17], it is assumed that an air infiltration flow rate lower than 0.4 dm³/sm² cannot be achieved. We used this value as the lower limit for the infiltration rate.

Five ventilation scenarios, depending on occupant behaviour are. For each scenario, a variant is calculated with low infiltration rate (variant a), high infiltration rate (variant b) and with low infiltration rate and supply ventilator shut down (variant c). In this case, the heat recovery doesn't work. In variant a) en c) the infiltration flow rates are 91 m³/h and in variant b) 720 m³/h. The five scenarios' are:

1 Use of a 5 years-old system with a 3-stands switch. The filters have never been cleaned or not often enough, thus the maximum capacity of the ventilation system is 65 % of the mandatory capacity as given in table 1. The system runs continuously in stand 1, thus 30 % of the maximum capacity is available. The mechanical ventilation flow rate is therefore 50.4 m³/h, which is far below the mandatory value.
2 Use of a 5 years-old regularly cleaned system with a 3-stands switch. The system runs continuously in stand 2, thus 50 % of the mandatory ventilation capacity is available, which is 129 m³/h.
3 Optimal use of the system: 100% of the mandatory capacity is available, that is 258 m³/h.
4 The occupants shut the whole system down and only use natural ventilation. The ventilation flow rate is 258+91=349 m³/h.
5 The occupants shut the whole system down and only use natural ventilation. There is a high infiltration flow rate of 720 m³/h.

Calculation model

The calculations are conducted using the software h.e.n.k. [18]. The energy demand for heating is calculated using a heat balance within the dwelling envelope, based on hourly calculations taking into account transmission losses, infiltration and ventilation losses and heat load through sun entering the building and electrical appliances. We assumed that the heat load from lighting was maximum 4 W/m² and for appliances 3 W/m². Maximum 4 people are present in the dwellings. We developed and used occupancy and heat load profiles as shown in figure 1.These profiles give the fraction of maximum occupancy and heat load for each hour of the year. The profiles are identical for all ventilation scenarios.

The ventilation flow rate was kept on the same level all over the day, which is plausible from the interviews. We also assumed that an average temperature of 18 °C was maintained all over the day. The heat exchanger recovers heat from the exhaust air as long as the temperature difference between outdoor and indoor air is 2 K. Below this limit there is no heat recovery. Hourly calculations are made, using the Dutch average climate year TRYdeBilt.

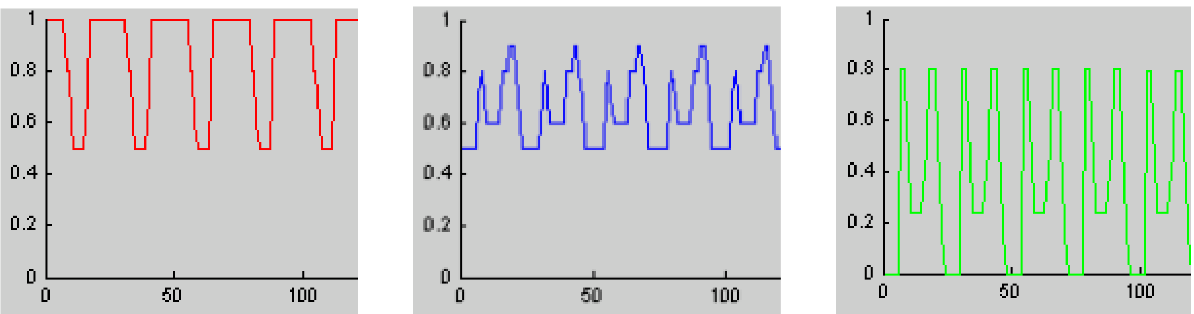

Figure 1: 1) occupancy profile, 2) appliances profile, 3) lighting profile x-as: hours (0 is midnight); y-as: fraction of the maximum occupancy, heat load from appliances and heat load from lighting respectively.

The energy consumption at the meter box, which is the energy delivered to the heating and ventilation system (gas and electricity), is calculated from the energy demand. For room heating a high efficiency boiler is used (η=0.83 on year basis). The electricity needed for the ventilation systems is calculated assuming a pressure drop of 150 Pa in the supply and exhaust ducts. The efficiency of the ventilators is 0.85 and the efficiency of the motor is 0.7. The primary energy use is calculated from the energy consumption. It includes the energy needed to generate electricity. We used an average power plant generation with an efficiency of 0.4.

RESULTS AND DISCUSSION

The results of the calculation are shown in table 3. The total primary energy use of all options is plotted in figure 3. The electricity consumption of the ventilators appears to be minimal in comparison with the gas consumption for heating. If the occupants shut down the supply ventilator, there is no heat recovery (variant c). Compared to the case with heat recovery (variant a), an increase of primary energy use from 11 % (, variant 1) up to 36 % (variant 3) is observed. In variant 3, the system works optimally and the air flow rate is much higher than in variant 1, where the system is sub-optimal. Heat recovery plays a more important role at larger flow rates. That is why the effects of not using heat recovery are stronger in variant 3 than in variant 1. Comparing variant 1, 2 and 3 it appears that the energy use of the sub-optimal systems is lower than the energy use of the optimal system (variant 3). This is logical because of the decrease in ventilation losses arising from the reduced air flow rates. However, the flow rates in variants 1 and 2 are far below the minimum acceptable ventilation flow rate, resulting in a poor indoor air quality and possibly in health problems. It is plausible (see first section of this paper) that the occupants would compensate these too low air flow rates by opening windows more often, resulting in variant 1b, 2b, 4 or 5 depending on the air tightness of the house and on the way occupants use natural ventilation openings. It is therefore possible that no energy savings are achieved by a balanced ventilation systems when compared to natural ventilation. It appears from figure 3 that air tightness of the house and use of the natural ventilation openings will play a major role in achieving or not the aimed savings. The comparison of a well working balanced ventilation system (option 3a) with natural ventilation option 4, shows that the maximum savings could amount 24 %, but could also be reduced to zero or even be negative.

CONCLUSIONS

In this paper we gave an overview of the ways occupants use ventilation systems and made a first attempt to quantify the effects of their behaviour on the final energy use for heating. This energy use was studied for several behaviour scenarios, leading to the conclusion that occupant behaviour may easily reduce the predicted savings to zero, or even may increase the energy use when compared to natural ventilation. From the data we gather it appears that most of occupants use the system in sub-optimal settings, in which energy savings may be high because of the low ventilation flow rates. However this would cause a poor indoor air quality, which may be compensated by a more wide use of natural openings, resulting in an energy performance identical to that of a natural system. More research is needed to obtain statistical data and to validate the calculation model, in order to be able to make more accurate prediction of the possible savings by balanced ventilation systems.

ACKNOWLEDGEMENT

The calculations were made possible by Deerns Consulting Engineers, who put the h.e.n.k software at the disposal of Research Institute OTB for this research. This research was partly financed by Corpovenista, an expert centre of housings associations and universities.

SUMMARY

Air pressure conditions in typical Finnish residences are analyzed using data from field measurements and computer simulations. Field measurements were conducted in a two-storey detached house and in a five-storey apartment building. The effects of airtightness, ventilation rate, air leakage distributions, and outdoor environmental conditions on air pressure conditions in a detached house were simulated on a multi-zone simulation model using the IDA ICE simulation program. There is almost always a positive and negative air pressure difference across the building envelope in detached houses and in apartment buildings. During winter, in detached houses there is continuous positive air pressure at ceiling level on the top floor and negative pressure at floor level on the bottom floor. For detached houses, the design value of air pressure difference across the building envelope for the moisture convection analysis is close to ±10 Pa. The control of air pressure difference in normal and leaky houses is difficult: ± 15 differences in ventilation airflows have only a minor influence on the air pressure difference. To control air pressure differences, the balancing of ventilation systems in airtight houses is very important.

INTRODUCTION

The uncontrolled air movement through a building envelope leads to problems related to hygrothermal performance, health, energy consumption, performance of the ventilation systems, thermal comfort, noise, and fire resistance. Air leakage through a building envelope depends on the result of air pressure differences across the envelope and on the airtightness of the building envelope.

Air and moisture convection through the building envelope may cause severe moisture loads to be imposed on the structure. Indoor air exfiltration in cold climates may cause moisture accumulation or condensation, leading to microbial growth on materials, change of the properties of the material or even to structural deterioration. The relative humidity (RH) at the connection of floors and external walls in multi-storey platform timber-frame houses can be rather high, causing the risk of mould growth and rot fungi when there is positive air pressure inside the building [1]. The simulation results of Janssens and Hens [2] have shown that, even when a roof design complies with condensation control standards, a lightweight system remains sensitive to condensation problems because of air leakage through the discontinuities, joints and perforations, common to most existing construction methods.

Air leakage through a building envelope could introduce outdoor or crawl-space airborne pollutants to the indoor air. Field measurements [3, 4] have shown evidence of fungal spores being transported indoors from a crawl space. Although radon can enter buildings by several mechanisms, the dominant radon entry mechanism is air leakage through the basement floor [5, 6, 7].

Hygrothermal design is one way to assess and predict the long-term hygrothermal performance of the building envelope to prevent moisture damages and to guarantee a healthy indoor climate and longer service life for buildings. Air pressure difference is one load component in the hygrothermal design of building envelopes. Wind, stack effects, mechanical ventilation and distribution of leakage sites in the building envelope influence air pressure difference. Each one of these effects influences the air pressure difference independently and in a specific way.

As many factors affect air pressure conditions, one of the most reliable ways to determine the relevant design values is to perform long-term field measurements in typical residences. To understand how different factors influence the air pressure conditions, the use of simulation is a valuable tool that makes it possible to show the importance of wind, stack effects, mechanical ventilation and distribution of air leakage places. In this study, air pressure conditions in typical Finnish residences are analyzed using data from field measurements and computer simulations.

METHODS

Field measurements

Field measurements were conducted in a two-storey detached house and in a five-storey apartment building, Figure 1. Residences were selected to represent typical Finnish residences. A detached house was selected as having average properties according to a previous field study of timber-fame detached houses [8]. There was mechanical supply and exhaust ventilation and an electrical floor and ceiling heating system in the studied detached house. The apartment building had a centralized supply and exhaust ventilation system that was demand controlled to keep RH and CO_2 below the target values of 50% and 600 or 1000 ppm.

Figure 1 Studied detached house (left) and apartment building (right)

Air change rate, indoor and outdoor temperature and humidity, as well the air pressure difference over the building envelope were monitored during a three-week period in winter. The ventilation airflows were measured from ventilation ducts at different ventilation fan speeds. During the measurement period, the ventilation fan speed was monitored continuously. Whole air change rates of residences were measured with active and passive (only in detached house) tracer gas air infiltration measurement techniques also. The airtightness of the building envelope was measured using the fan pressurisation method [9]. The values of air pressure differences over the building envelope (ΔP), temperature (T), and RH from inside and outside the building were monitored at 15 min. intervals. Table 1 shows the main characteristic of the studied dwellings.

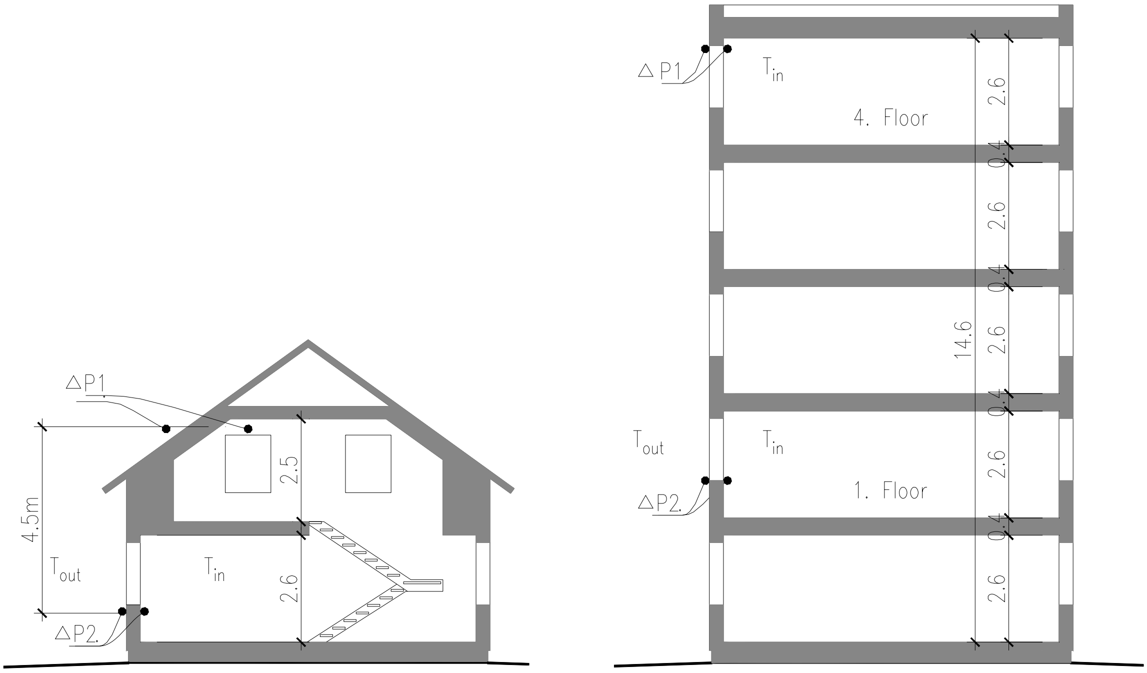

Figure 2 Measurement points in detached house (left) and in apartment building (right)

Table 1 Main characteristic data of the measured dwellings

	Detached house	Apartment on the first floor	Apartment on the fourth floor
Measurement period	4.3…24.3.2005	16.3…06.4.2005	16.3…06.4.2005
Floor area	183 m^2	70 m^2	70 m^2
Volume	452 m^3	183 m^3	183 m^3
Envelope air leakage rate at 50 Pa	3.9 1/h	1.0 1/h	1.9 1/h
Average ventilation rate	0.41 ach 13 l/(s·pers.), 0.29 l/(s·m^2)	0.68 ach 9 l/(s·pers.), 0.49 l/(s·m^2)	0.60 ach 15 l/(s·pers.), 0.44 l/(s·m^2)

Computer simulations

To analyse the effects of airtightness, ventilation rate, air leakage distributions, and outdoor environmental conditions on air pressure conditions, the measured detached house (Figure 1, left) was simulated on a multi-zone simulation model using the IDA-ICE [10, 11] simulation program. The software is an advanced tool for simulation of thermal comfort, indoor air quality and energy consumption in buildings. The simulation model was validated on the basis of field measurements [12]. The effect of the airtightness of the building envelope, distribution of the air leakage places, performance of ventilation, and surrounding conditions (suburban, open country, no wind cases) on air pressure differences were analysed in twenty-one different simulation cases, Table 2.

An air leakage rate per hour at 50 Pa of pressure difference (n_{50}) is changed between n_{50}=0.15…10 ach. In the case of n_{50} = 0.15 ach, a building is almost completely airtight without air leaks. The airtightness value n_{50} = 3.9 ach was the airtightness of the simulated detached house and can be considered typical of Finnish timber-frame detached houses [8]. The airtightness value n_{50} = 10 ach was selected to represent a very leaky house. The effect of the air leakage distribution is simulated with three different cases: 75 % of the leakages at the top of the house and 12.5 % of the leakages at the middle and bottom of the house; equal distribution; and 75 % of the leakages at the bottom of the house and 12.5 % of the leakages at the middle and top of the house. The effect of the performance of ventilation is simulated with three different cases: balanced system (supply airflow = exhaust airflow), 15 % decreased supply airflow, and 15 % increased supply airflow. For the reference case, the "CASE-1 n4" (n_{50} = 3.93 ach, suburban surrounding, normal air leakage distribution and balanced ventilation system) was selected.

Table 2 Simulation cases

Description:		Simulated cases n_{50} = 0.15 ach	 n_{50} =3.9 ach	 n_{50} = 10 ach
Surroundings	Suburban	CASE-1 n0.15	CASE-1 n4	CASE-1 n10
	Open country	CASE-2 n0.15	CASE-2 n4	CASE-2 n10
	No wind cases	CASE-3 n0.15	CASE-3 n4	CASE-3 n10
Air leakage distribution	Most leakages at the top of the house (75/12.5/12.5%)	CASE-4 n0.15	CASE-4 n4	CASE-4 n10
	Normal	CASE-1 n0.15	CASE-1 n4	CASE-1 n10
	Most leakages at the bottom of the house (12.5/12.5/75%)	CASE-5 n0.15	CASE-5 n4	CASE-5 n10
Ventilation performance	15 % decreased supply airflow	CASE-6 n0.15	CASE-6 n4	CASE-6 n10
	Balanced system	CASE-1 n0.15	CASE-1 n4	CASE-1 n10
	15 % increased supply airflow	CASE-7 n0.15	CASE-7 n4	CASE-7 n10

Air pressure differences were calculated from three rooms: from the sauna and living room on the ground floor and the bedroom on the top floor. Air pressure differences were calculated from each room at ceiling and floor levels. The simulations are carried out with hourly Helsinki weather data (1979), which is commonly used as test data for energy calculation in Finland [13].

RESULTS

Field measurements

Field measurements in the detached house showed +3 Pa air pressure at the ceiling level of the top floor and -4 Pa air pressure at the floor level of the ground floor on average, Figure 2, left. The dependency between air pressure difference and temperature difference in the detached house is shown in Figure 3, right. The trend of the measurement results shows good agreement with the theoretical air pressure (red curve) due to stack effect (Eq. 1). The deviation from the theoretical air pressure (red curve) is mainly due to wind effect. The standard deviation from the theoretical curve is 0.4 Pa.

$$\Delta_{ps} = \rho_{in} \cdot g \cdot H \cdot (T_{in} - T_{out}) / T_{out}, \qquad (1)$$

where Δ_{ps} is air pressure due to stack effect, Pa; ρ_{in} is density of the indoor air, g/m^3; g is gravitational constant, 9.8 m/s^2; H is height between measurement points, m; T_{in} is indoor temperature, C; T_{out} is outdoor temperature, C.

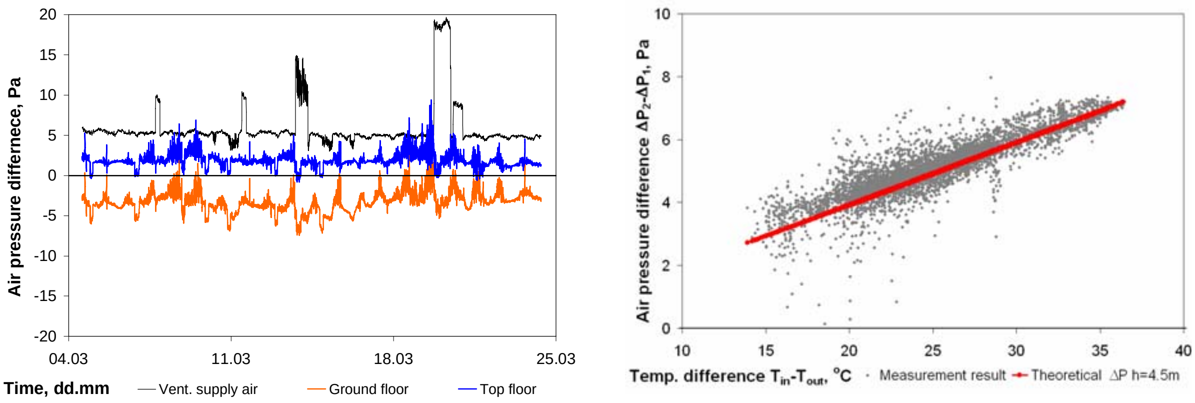

Figure 3 Air pressure difference over the building envelope during the measurement period (left) and dependency between air pressure difference and temperature difference (right) in the detached house

In the apartment building, on the first floor, the daily average air pressure difference over the building envelope was -11 Pa on average, while, on the fourth floor, it was -2 Pa, Figure 4, left. In Figure 4, left, the performance of ventilation on the apartment's second floor is also shown. The black curve is the air pressure measurement from the supply air duct. Ventilation airflows were 20% of the design value when the CO_2 level inside the flat was less than 600 ppm; the design values were switched when the CO_2 level inside the flat was higher than 1000 ppm or when the relative humidity in the bathroom exceeded 50%. This ventilation performance made a 3-Pa air pressure difference across the building envelope (Figure 4,right).

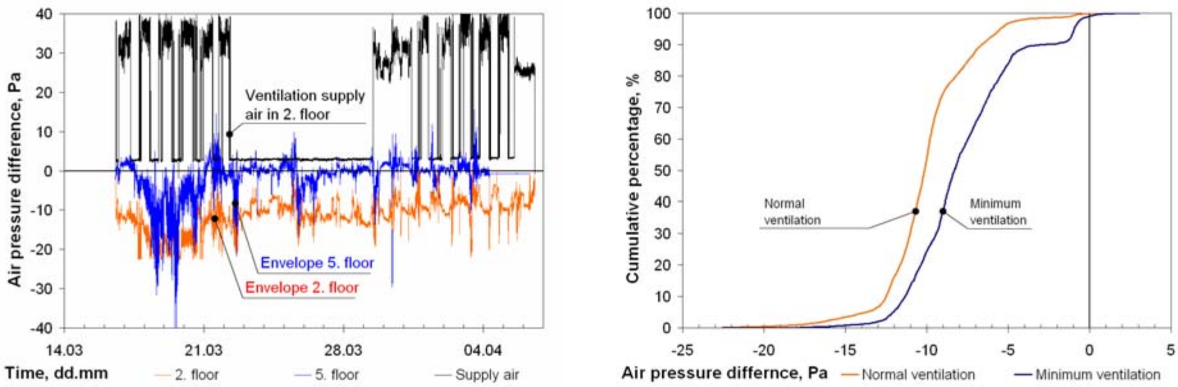

Figure 4 Air pressure difference over the building envelope during the measurement period (left) and dependency of ventilation performance on the air pressure difference (right) in the apartment building

Computer simulations

The annual air pressure difference across the envelope at ceiling level on the top floor and at floor level on the ground floor of the reference case, CASE-1 n4, is shown in Figure 5, left. Distribution of the air pressure difference during the winter season on all six simulation points is shown in Figure 5, right. Figure 6 compares the distribution of the air pressure difference in the average case with 10 % and 90 % percentile cases. There is almost always positive pressure at ceiling level on the top floor and negative pressure at floor level on the ground floor during winter. The intermediate floor can be under either positive or negative pressure.

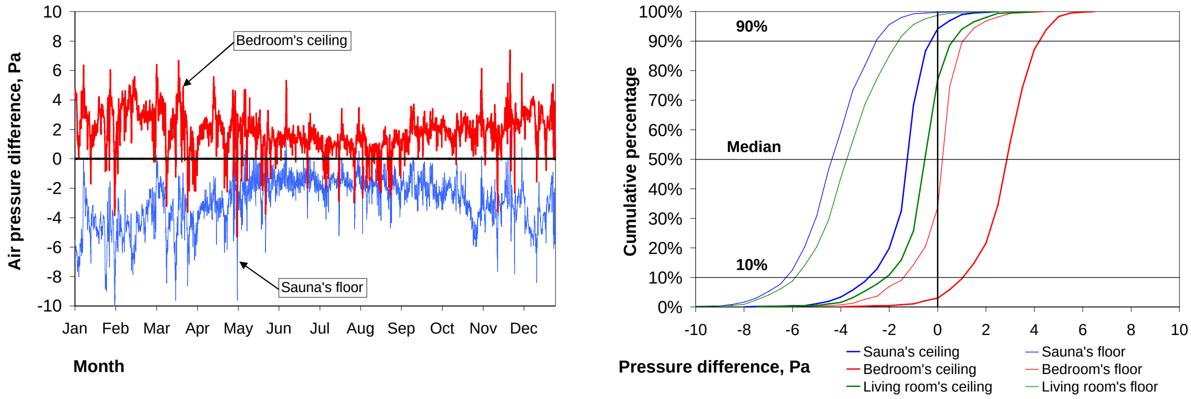

Figure 5 Air pressure difference during whole year (left) and during winter months (right)

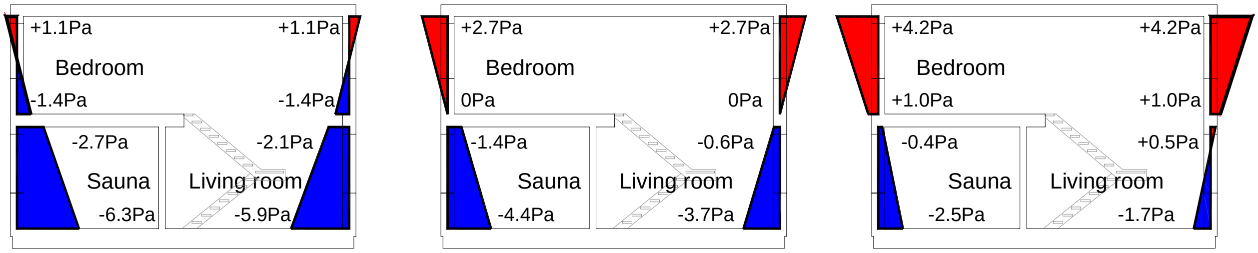

Figure 6 Average (middle), the lowest and highest 10 % percentile (left and right) air pressure difference during winter period

Table 3 shows the simulation results from two points: 10 % percentile value from the sauna at floor level and 90 % percentile value from the bedroom at ceiling level. These two points represent minimum and maximum air pressure differences at the 10 % critical level. The overall consensus [14] is that 10 % is the appropriate level to determine loads for hygrothermal calculations.

Table 3. Simulation results

Description:		Air pressure difference, Pa					
		n_{50} = 0.15 ach		n_{50} = 3.93 ach		n_{50} = 10 ach	
		10%	90%	10%	90%	10%	90%
Surroundings	Suburban	-7	+4	-6	+4	-6	+4
	Open country	-11	+8	-10	+8	-8	+7
	No wind cases	-6	+4	-5	+4	-5	
Air leakage distribution	Most leakages at the top of the house	-10	+2	-9	+2	-8	+2
	Normal	-7	+4	-6	+4	-6	+4
	Most leakages at the bottom of the house	-4	+8	-3	+8	-3	+8
Ventilation performance	15 % less supply airflow	-33	-22	-7	+4	-6	+4
	Balanced system	-7	+4	-6	+4	-6	+4
	15 % more supply airflow	+15	+26	-6	+5	-5	+4

Simulations show that in critical cases value of the air pressure difference across the building envelope at the 10 % percentile level is on the level +8 Pa and -11 Pa. In the most critical cases (airtight envelope with unbalanced supply and exhaust ventilation), the design value of air pressure difference across the building envelope could be up to +26 Pa and -33 Pa.

DISCUSSION

The air pressure difference across the building envelope at the 10 % percentile level in the typical detached house was +8 Pa and -11 Pa. Apartment buildings are much higher, and measurements show that the building envelope of such buildings is more airtight. Both these factors influence the air pressure difference across the building envelope and should be analyzed in addition to the others.

Air pressure simulations in the detached house were carried out during the energy test year in Finland [13]. The annual average temperature is +4.3°C, the average temperature of the coldest month, February, is −9.8°C, and that of the warmest month, August, +16.1 °C. For the period 1971-2000 in Helsinki, the mean annual temperature was +5.6 °C. Since 1900, the warmest annual average temperature in Helsinki has been +7.2 °C (1934) and the coldest +2.7 °C (1902). The annual average temperature in Finland changes from +6 °C in the southern coastal area to -2 °C in the north of Lapland [15]. The influence of different years and different locations, including apartment buildings, on air pressure difference should be studied in future studies.

CONCLUSIONS

There is almost always a positive and negative air pressure difference across the building envelope in detached houses and in apartment buildings. During winter, there is continuous positive air pressure in the detached house at ceiling level on the top floor and negative pressure at floor level on the bottom floor.

Wind influences, first of all, air pressure peak values. Comparing average values, the influence of wind is less.

For detached houses, the design value of air pressure difference across the building envelope for the moisture convection analysis is close to ±10 Pa. In the most critical cases (airtight envelope with unbalanced ventilation), the design value of air pressure difference across the building envelope could be up to +26 Pa and -33 Pa.

The control of air pressure difference in normal and leaky houses is difficult: ±15 differences in ventilation airflows have only a minor influence on the air pressure difference. To control extremely high air pressure differences, the balancing ventilation systems in airtight houses are very important.

ACKNOWLEDGEMENT

This study was supported with a grant from the Finnish Academy (grant 210683). It utilizes the measuring data of national research project “Airtightness, indoor climate and energy efficiency of residential buildings”, which was carried out by the Laboratory of Structural Engineering at Tampere University of Technology and HVAC Laboratory at Helsinki University of Technology. The financial support of the National Technology Agency of Finland TEKES, and Finnish companies and associations participating in the project, is gratefully acknowledged.

SUMMARY

Food odor dispersion from residential unit to core is one of problems in high-rise residential building. In this study, it was analyzed in terms of stack effect, and the method how optimal air inflow of core was estimated and how the location of air in/outlet were decided were suggested to solve it. A combined CFD(Computational Fluid Dynamics) and CONTAMW analysis was used for stack effect of building, dispersion of food odor, optimal air inflow of core, and the location of air in/outlet in the method.

INTRODUCTION

Recently, the number of high-rise residential building is increasing in Korea. In the building, the opening/closing function of window for natural ventilation is not flexible because the upper part of the building has to be safe from strong wind and energy has to be conserved by strong insulation and airtightness. Moreover, curtain wall systems which usually have small area of openable window are used for it. Accordingly, the mechanical ventilation system is used more than natural one in it [1]. The factors that affect on ventilation performance are indoor air flow by envelop airtightness, backward flow of exhaust due to less of ventilation for upper stories, and stack effect by pressure difference between spaces [2-5]. If the amount of ventilation and the location of air in/outlet are decided to exhaust pollutants without considering the factors, the pollutants can be rather dispersed to non-polluted area. Especially, food odor is used for this study. Residents have direct sense of it, so it can be a good sample among pollutants. Korean food usually generates a lot of odors during cooking, so the odors are dispersed to dining room and core area. Ultimately, the residential unit which generates the odors gives discomfort to neighbors which are another residential unit [6].
The purpose of this study is to control the food odor that is dispersed from a residential unit to core and to show a method how the optimal amount of ventilation and optimal position of air in/outlet are decided. For this study, ventilation performance according to stack effect in high-rise residential building is analyzed by CFD and CONTAMW.

METHODS

In this study, the combined CFD and CONTAMW analysis were suggested to decide the optimal amount of ventilation and optimal position of air in/outlet. There are 5 steps for it, and Figure 1 is a summary (diagram) about it.
First of all, Step 1 is about building descriptions. A boundary condition is explained in the step for combined analysis such as building data, operating schedule of air in/outlet in a residential unit, type and density of a food odor, air leakage data, and weather data etc.

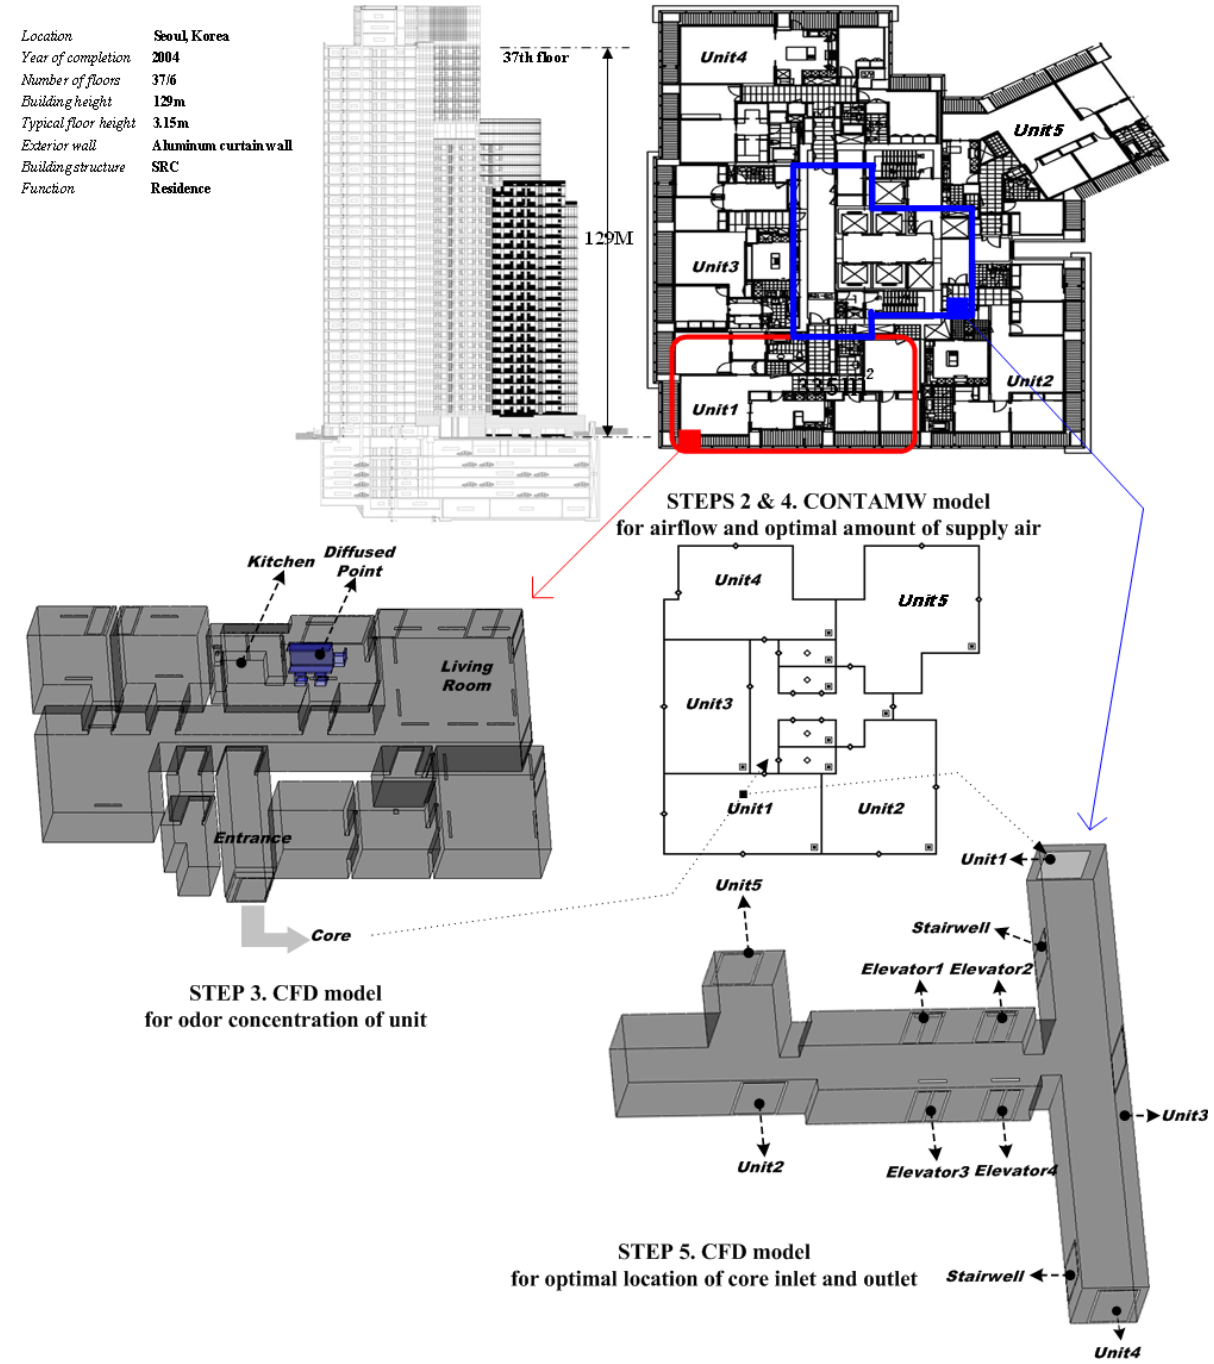

Figure 1. Summary diagram of combined CFD and CONTAMW analysis

Second, Step 2 is to calculate pressure difference of stack effect by CONTAMW and the amount of airflow shifting between spaces. Third, Step 3 is to analyze density distribution of food odor that is dispersed from the residential unit by CFD with the boundary conditions that are result of Step 2 and generated intensity of food odor. Forth, Step 4 is to calculate the optimal amount of ventilation to dilute inflow food odor from the residential unit when air in/outlets are applied in core. For this step, CONTAMW is used, and the result of food odor density that is the result of Step 3 around front door area is used as a boundary condition. Finally, Step 5 is to evaluate the location scheme of air in/outlet that can restrict and isolate the dispersion of food odor by CFD with the boundary condition that is from result of Step 4.

Table 1. Odor elements and intensity

	Food type[a]					Smell	Intensity scale (unit: ppm)[b]				
	Live stock	Fish	Kim-Chi	Starchy	flavors		1	2	3	4	5
Hydrogen sulfide	◐	●	◐	●		rotten egg	0.0005	0.0056	0.063	0.72	8.1
Methyl merchaptan	○	○	○	○		onion	0.0001	0.00065	0.0041	0.026	0.16
Ammonia	○	○			○	urine	0.15	0.59	2.3	9.2	37
Tri-methyl amine		●	◐			fishy	0.00011	0.0014	0.019	0.24	3.0

Table 2. Air leakage data

Building components		Air leakage data
Exterior wall	At lobby	$EqLA_{75}$ 2.1 ㎠/㎡ [a]
	At typical floors	$EqLA_{10}$ 1.51 ㎠/㎡
Door	Residential entrance door	$EqLA_{10}$ 70 ㎠/item
	Elevator door	$EqLA_{10}$ 325 ㎠/item
	Stairwell door	$EqLA_{10}$ 120 ㎠/item
	Door for condensing room	$EqLA_{10}$ 23 ㎠/item
	Swing door located on lobby and basement floor	430 CMH at 50 Pa
	Revolving door located on lobby floor	73 CMH at 50 Pa
Etc.	Top of elevator shaft	Equivalent orifice area of 1.0 ㎡

[a]$EqLA_{75}$: Equivalent leakage area at 75 Pa, $EqLA_{10}$: Equivalent leakage area at 10 Pa

Step 1. building description

In this study, a building is selected for combined CFD and CONTAMW analysis. It has thirty-seven stories above and six under the ground with a core system. Figure 1 shows summary, cross-sectional view, and standard floor plan of it. During cooking, generated food odor is collected by force of kitchen hood and outlet, and line inlet supplies air to prevent dispersion of food odor. However, during meal time, residents are usually turn kitchen hood and outlet off for comfortable meal time even though food odor keeps generating. In brief, food odor during meal time is going to be dispersed a lot more than during cooking because food odor can't be collected by kitchen hood or outlet. There is unusual case in Korea when dispersion of food odor is worst; residents set up table in dining room and have meal rather than they have meal time in kitchen that have good air outlet system. In this study, meal time was set as a boundary condition for CFD analysis for food odor dispersion of a unit, and food odor generating point during meal time was set as dining room which was the worst case.

The type of odor and density. Table 1 is about stench intensity according to type and density odor during food production [7]. It is from measurement method of chemical analysis. There are three main causes of food odor that are meat odor, Kim-Chi odor, and fish odor in Korean household. The factors of meat odor are Hydrogen sulfide(H_2S) and Ammonia(NH_3), the factors of Kim-Chi are Hydrogen sulfide(H_2S) and Methyl Merchaptan(CH_3SH), and the factors of fish odor are Hydrogen sulfide(H_2S) and Tri-methyl amine ($(CH_3)_3N$) etc.

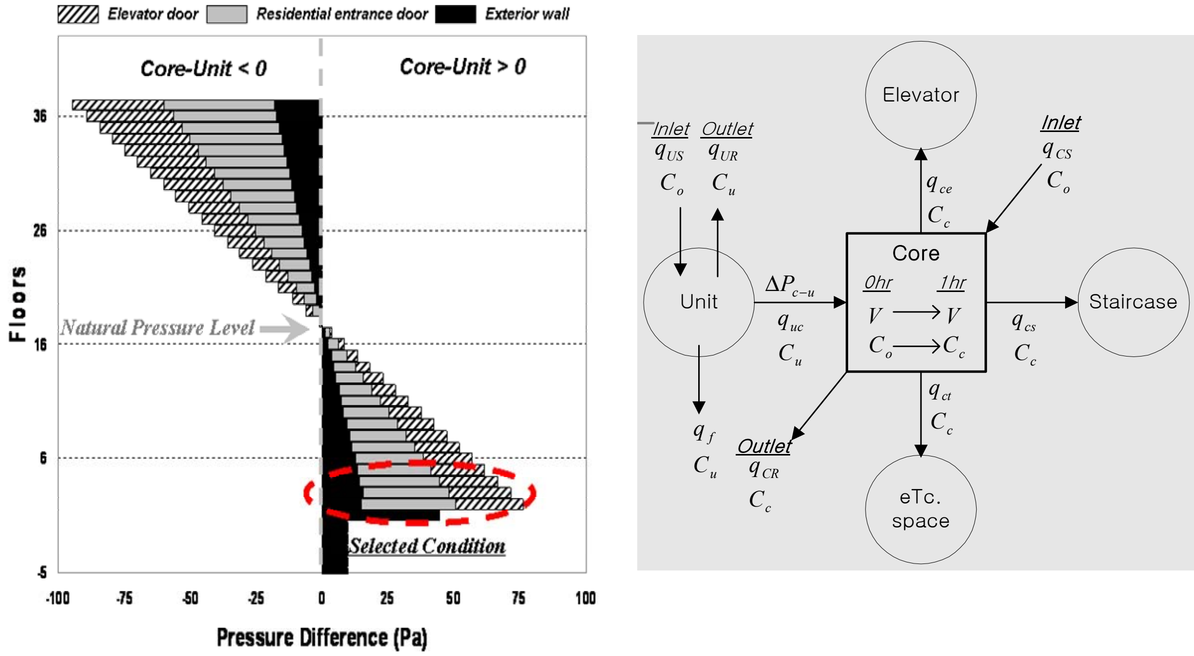

Figure 2. Pressure difference and airflow direction

In this study, fish odor was selected for dispersion of food odor and dilution of it in core was analyzed. In case of fish odor, the main causes of odor are Hydrogen sulfide (H_2S) and Tri-methyl amine($(CH_3)_3N$). Accordingly, the hypothesis was set; Tri-methyl amine($(CH_3)_3N$) of 3ppm which is 5 of stench intensity is generating on diffused point in residential unit in terms of STEP 3. Also, 0.00011ppm of it was set as sensible stench intensity of STEP 4 to decide the optimal amount of air supply that satisfies under sensible stench density.

Air leakage data and weather data. Table 2 is about the air leakage data of exterior wall, the front door, elevator door, a stair hall door, and lobby door etc from the study of Jo et al [5] which analyzed stack effect of high-rise residential building. Stack effect is proportional to difference between indoor temperature and outdoor temperature, so stack effect is going to be bigger as outdoor temperature is decreased. Accordingly, 22℃ and -11.9℃ of TAC2.5 which are standard temperature of heating design in Seoul area were set as indoor and outdoor temperatures, respectively [8]. Also, it is assumed that there was no wind for this study.

Step 2: airflow q

The amount of air in/outflow of residential unit and core, elevator shaft, a stair hall in entire of building that has a standard floor plan as shown in Figure 1, was calculated by CONTAMW. According to Figure 2, the air pressure of core which is above floor from middle floors (17th and 18th floor) is higher than other area, so the air flows from core to residential unit. Also, in case of the floors which are under middle floors, the air flows from residential unit to core because the pressure in residential unit is higher than core. In brief, the dispersion of food odor is happened in the floors that are under the middle floors. In this study, 3 floors which have big difference of the air pressure were selected, and the amount of air in/outflow of residential unit, core, elevator shaft, and a stair hall were calculated. Under the condition that air inflow(q_{US}) is 1369 m^2/h and air outflow(q_{UR}) is 1269 m^2/h, 1761 m^2/h of air flows from residential unit to exterior wall(q_f), 654 m^2/h of air flows from residential unit to core(q_{uc}), 1535 m^2/h of air flows from core to elevator shaft(q_{ce}), 105 m^2/h of air flows from core to a stair hall, and 120 m^2/h of air flows to other places(q_{ct}). There is no information of density of food odor (C_u) which is included in airflows from residential unit to core (q_{uc}) yet.

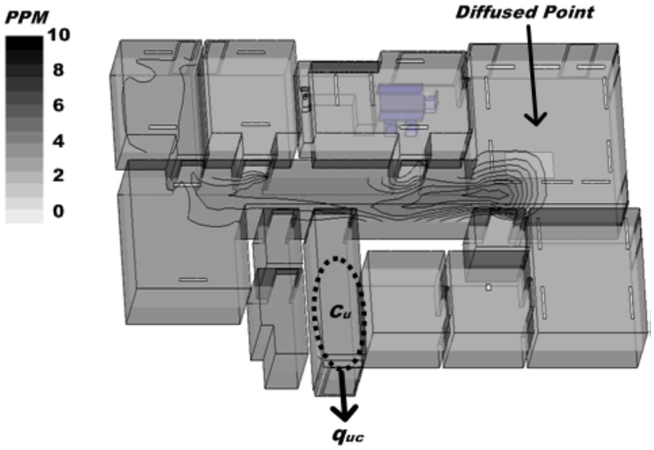

Figure 3. Concentration distribution of the unit

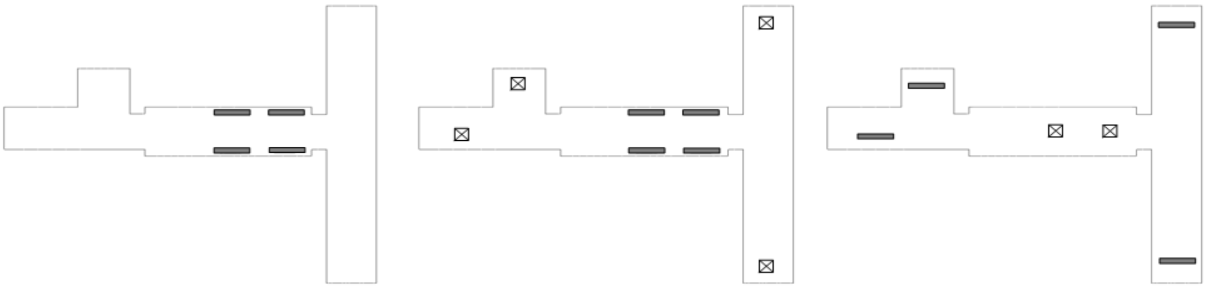
Table 3. Calculation condition of Steps 3 and 5

	STEP 3	STEP 5
Model	Standard k-ε High Reynolds	Standard k-ε High Reynolds
Mesh	700,000	300,000
Wall	Wall function	Wall function



Cases 1 and 2 *Case 3* *Case 4*

Figure 4. Cases according to the location of air in/outlet

Step 3: odor concentration C_u

Dispersion of food odor was analyzed by CFD simulation with residential unit model of Step 3 in Figure 1. In this case, the odor density of the front door area according to dispersion of food odor can be set as C_u. The air inflow of 1369 m^2/h and the air outflow of 1269 m^2/h in residential unit were used as boundary conditions. Also, another boundary condition which were result of Step 2 were used; the amount of airflow of 1761 m^2/h from residential unit to exterior wall and the amount of airflow of 654 m^2/h from residential unit to core. Table 3 is calculating condition. Figure 3 is the result of density dispersion of food odor, and Cu around the front door is 0.495ppm in case of regular ventilation. Accordingly, 89 m^2/h air that has 0.495ppm density flows from residential unit to core. Even though the amount of air and density is small, the stench intensity is very high, so residents can be uncomfortable when they get in or out of the building.

Step 4: Optimal amount of ventilation q_{cs}

Minimum inflow(q_{CS}) that dilutes stench intensity from 1 to 0.00011ppm for each floor can be calculated by CONTAMW with maximum density C_u of a front door area which is the result of Step 3 when Tri-methyl amine($(CH_3)_3N$) is dispersed from residential unit to core. For example, in case of third floor of which pressure difference between residential unit and core were the biggest, the density of Tri-methyl amine ($(CH_3)_3N$) could be kept under the 0.00011ppm when 1000CMH air inflow (q_{CS}) and outflow (q_{CR}) were applied.
However, density of Tri-methyl amine ($(CH_3)_3N$) can be kept under the 0.00011with less than 1000CMH because the pressure difference is decreased as floor get higher until middle floor and the amount of airflow from residential unit to core is getting small.

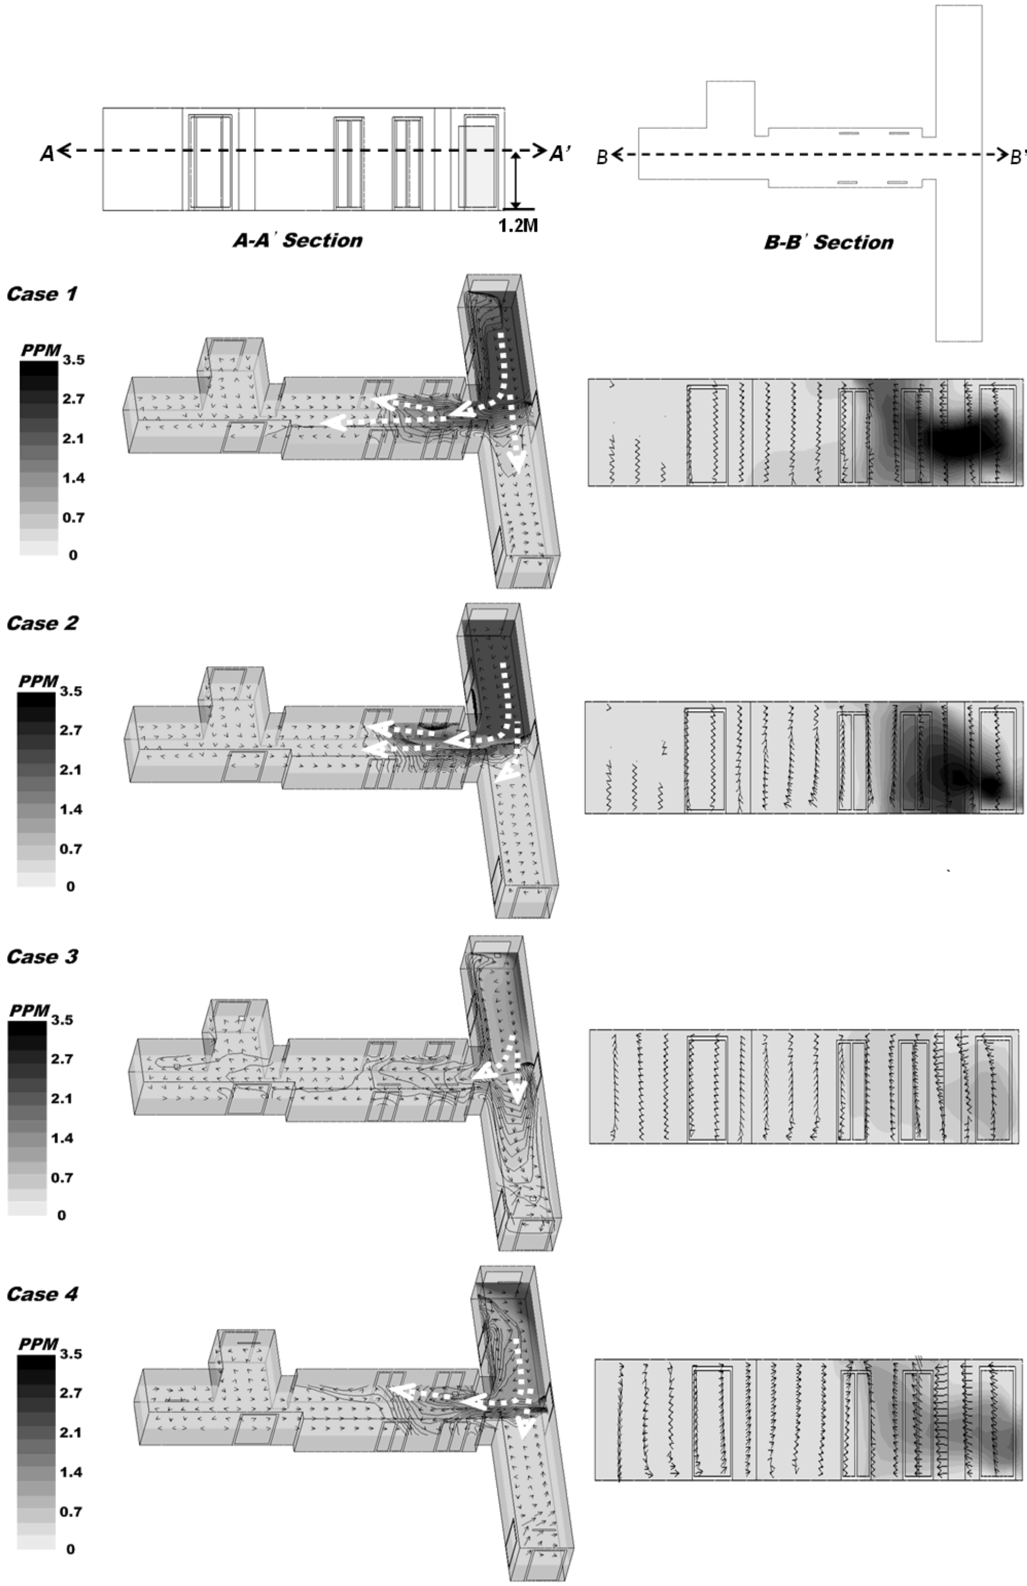


Figure 5. Concentration distribution of each case

With the same way, analyzing air inflows (0, 200, 400, 600, 800CMH) were applied for each floor. After all, to keep the density of Tri-methyl amine($(CH_3)_3N$) under 0.00011ppm, the minimum air inflow were analyzed as 800CMH from 3th floor to 17th floor, 300CMH from 19th floor to 20th floor, 500CMH from 21th floor to 27th floor, and 800CMH from 28th to 37th .

Step 5: location of inlet and outlet
To maximize the efficiency with calculated air inflow (q_{CS}) and air outflow (q_{CR}), the location of in/outlet has to be decided. First of all, Figure 4 is the schemes of ventilating system according to the location of air in/outlet. Four kinds of cases were analyzed: Case1 was about existing scheme, Case 2 was about Case1 with optimal amount of ventilation, Case 3 was about Case1 with air inflow in front of elevator, and Case 4 was about Case1 with air outflow in front of elevator. Figure 5 is about the result of CFD simulation. Case1 shows that the food odor from residential unit was dispersed not only to elevator area but also to stairwell area. Case2 shows that the pollutants were not diluted and dispersed to central core area even though an optimal amount of ventilation was applied. However, Case3 shows the pollutants were diluted by air outlet that is in front of residential, and then the food odor was blocked by airflow which was generated by line air inlet in front of elevator. Finally, Case4 shows that the rest of food odor was dispersed to the core area due to airflow that was made by the air inflow even though the pollutants were diluted by air inflow in front of the residential unit. As a result, the optimal ventilating system was that ventilating system that had air inflow in front of elevator and air outflow in front of residential unit.

RESULTS

This study was about dispersion analysis of food odor which was a serious problem in high-rise residential building in terms of stack effect. Moreover, it was showed the method how to calculate the optimal amount of air inflow and to decide the location of air in/outlet.
As a result of object building, the pressure difference between residential unit and core was big during winter. In case of the floors which were under middle floors, the air flew from residential unit to core because the pressure in residential unit is higher than core. Even though the density of food odor that goes to core area is very small, other residents can be uncomfortable because the stench intensity is very high. Furthermore, the food odor can be dispersed according to the location of air in/outlet even though the amount of ventilation is enough to dilute the food odor.

DISCUSSION

This study brings the stack effect during winter into focus because the winter has the great difference between indoor and outdoor temperatures in South Korea. This difference increases the influence of the stack effect on the airflow between spaces. Also, a phase of stack effect during summer appears in different way from that of the stack effect during winter. In case of summer, the influence decrease because of the small difference between indoor and outdoor temperatures. The air pressure of core, which is above floor from middle floors-neutral pressure level, is lower than residential unit, so the air flows from residential unit to core. Also, in the floors under middle floors, the air flows from core to residential unit because the pressure in residential unit is lower than core. Unlike winter, the dispersion of food odor is happened in the floors that are above the middle floors. Therefore, in hot climate region, this odor problem is less likely to occur because of the small stack effect. Also, intensity of food odor is carefully studied with relation to the human behavior in the residential buildings.

SUMMARY

Improving ventilation performance both for energy and IAQ creates a trend of installing more heat recovery supply and exhaust systems in new buildings and controlling better the airflows. Many studies have shown the impact of improved ventilation system on achieved performance but information about the market status and the difficulties in installing for instance supply ducts in collective dwellings are still lacking.

This studies gives the results of a survey in 6 European countries on ventilation systems installed in new and old building and gives an overview of the market of the different technologies, different of practice in different countries and how the problem of collective ducts, both for ventilation and combustion appliances, have been dealt in these countries.

INTRODUCTION

The study is to determine a state of the art of ventilation in Europe in order to know which systems are installed, in detail, and understand better the constraint and barreer to the implementation of supply and exhaust systems (i.e. installing supply ducts…).

METHODS

The study has been made through a survey. The questionnaire was asked to several European experts in ventilation who answered on the subject for their own country. These experts were from Finland, UK, Netherlands, Denmark, Italy, Poland and France. The survey was conducted in 2006.

RESULTS

The first part aimed at determining the ventilation systems installed in houses and collective dwellings in each country interviewed. Table 1 shows results for new buildings and Table 2 for the existing stock. This panorama has shown that :

- Scandinavian countries are for a long time using whole-house mechanical ventilation systems but in the existing stock, there are still buildings without ventilation or local ventilation (wet rooms)
- Netherlands used to have a lot of natural ventilation but since the energy regulation of 1998 are developing mechanical supply and exhaust systems
- UK used a lot of trickle fans ventilation but has recently renovated its regulation on ventilation showing some trend to both improve performance of trickle fans and start to implement whole-house ventilation

- Italy uses a lot of local ventilation by fans and airing
- Poland has a lot of natural ventilation with collective ducts (90%)
- France is using mechanical exhaust ventilation systems in new buildings and whole-house ventilation is mandatory since 1969.

Table 1 : ventilation systems in new buildings

	Finland	UK	NL	Denmark	Italy	Poland	France
supply and exhaust	90% (house), 30% (coll)	<1%	60%		Yes	5%	5%
exhaust only mechanical ventilation	10% (house), 70% (coll)	<1%	40%	flats	Yes, env 5%(5)	7%	95%
Natural ventilation	0	40%		houses	No	87%	0%
Local ventilation	0	20% (1)			Yes	1%	0%
Airing (window)	0	100% (3)			most common	-	0%

Table 2 : ventilation systems in existing building

	Finland	UK	NL	Denmark	Italy	Poland	France
supply and exhaust	30% (house), 5% (coll)	<1%	10%		Few	1%	1%
exhaust only mechanical ventilation	30% (house), 75% (coll)	around 10%	50%	flats <15 year (4)	Yes	5%	40%
Natural ventilation	<40% (house (1)), 20 (coll)	2%	30%	houses	No	93%	19%
Local ventilation	<10% (house (2)), 0% (coll)	20% (1)	10%		Yes	1%	30%
Airing (window)	0	100% (3)		flats >15 year (4)	most common	-	10%

(1) generally, kitchen hood and fan
(2) generally fan in bathroom, hood+fan in kitchen
(3) airing through window is always used for boost ventilation
(4) over 15 years, no ventilation in dwellings
(5) generally airing through window but more texts show the need of mechanical ventilation

Table 3 : main characteristics of mechanical systems installed

	Finland	UK	NL	Denmark	Italy	Poland	France
average airflow in dwelling	216 m3/h	50-100 m3/h	around 1 ach	Min 0,5 ach	generally 0,5 ach, in some areas 0,35	100-150 m3/h depending on energy and baths	50-140 m3/h average (depends on rooms)
Supply & exhaust HRU / temperature ratio	50% (crossplates, some wheels)		90% counterflow		50% Aluminium	crossflow	90% for new systems (counterflow) , 65% (crossflow) for old
Duct	rigid (flexible max 0,5m with kitchen hood)	flexible	rigid	rigid	rigid	flexible or rigid	flexible (house) or rigid (coll)
Fan specific Power exhaustP W/(m3/h)	0,3 exhaust only, 0,7 supply & exhaust	standard	60-80 W both with ECM, 60-120W old supply & exhaust; 60W exhaust	0,55, soon 0,28 *	0,86	200-400 W supply & exhaust, 300-500 W exhaust for houses, 1,5 to 2,5 kW in collective exhaust	120 W old, 70 W new
control		with light and tempo in toilets, manual for hoods	3 speed	variable speed (humidity) with pressure control or constant	variable speed (humidity) with pressure control or constant	constant	2 speed

From the point of view of the systems performance, we can note that:

- High efficiency heat recovery is used in some countries for new buildings but cross-plates exchangers are still very common
- Fan specific power varies a lot from one country to another ECM motors tends to be used in Scandinavia and Netherlands, more recently in France. Fan control (number of speed..) varies a lot depending of regulations and common practice
- There is no specific constraint on ventilation systems in these countries. In Netherlands though, in collective dwellings, taking care of maintenance (easy to use, friendly…) is required when retrofitting. There is nothing specific about the constraints of installing supply duct when retrofitting ventilation systems transforming them in supply and exhaust systems with HRU.

Table 4 : maintenance and cleaning

	Finland	UK	NL	Danemark	Italy	Poland	France
is it done ?	No, around 5 to 10%	No	No	No	No	No	No
is it mandatory ?	Yes, since 2000	recommended	recommended, but rare	rare	recommended/ mandatory	recommended	recommended
Price is	moderate	low	high (because conception has not dealt with an easy maintenance)	low because little is done, 1000 DKK/flat/year (150 €/flat/year)	high	low	moderate
Cleaning is	recommended (visual inspection	recommended (but not done)	rare	rare	rare/mandatory	recommended	recommended
Price is			high (access difficulties)		high	low	moderate
How is it done	by professionnals (ducts and terminals)		robots and sweeping	fan is disconnected and very high depression applied		natural ventilation – sweeping ; mechanical ventilation – sweeping and chemical	sweeping, robots, chemical...
control procedure	possible voluntarily	No	only for filter replacement + recommandations on hoods not connected to ventilation	cameras	No/Yes	No	No, use of cam voluntarily

Finally, the survey studied the maintenance and cleaning. Answers showed uniformly that maintenance and cleaning are not done or very seldom, although it is highly recommended (and mandatory in Finland). We can mention all the actions in Finland about visual inspection and inspections [1].

DISCUSSION

Recent reinforcement of energy regulations in buildings are inducing two trends :

- An increase of supply and exhaust systems with HRU in Scandinavia and Netherlands to reduce heat losses due to ventilation,
- Retrofits of airing and local ventilation systems in wet rooms in whole-house ventilation for all rooms in dwellings. The object of these retrofits is both to avoid condensations when building tightness is improved and to control air flows.

Yet the survey has shown that high efficiency systems are still used mainly in new buildings and the trends of retrofitting are not very large. Existing stock is still linked to older and lower performance systems. Maintenance and cleaning are judged insufficient and rarely done in all countries interviewed.

ACKNOWLEDGEMENT

We are grateful to all experts who answered the survey

The performance of ventilation systems in apartment buildings

Jari Palonen, Jarek Kurnitski and Olli Seppänen

Helsinki University of Technology

Corresponding email: jari.palonen@tkk.fi

SUMMARY

In Finland 12 apartment buildings were investigated as a part of European project HOPE.. There were one building with passive stack ventilation with fan assisted exhaust air ventilation, four buildings with mechanical exhaust ventilation only and seven buildings with mechanical supply and exhaust air ventilation system. Altogether 600 questionnaires were returned. Modern passive stack ventilation system with separate exhaust fans in kitchen and bathroom did not assure sufficient ventilation even in March when ventilation rates and CO_2-levels were measured. Thermal comfort problems (too cold and draught) were common with passive stack ventilation and mechanical exhaust ventilation without any heating of outdoor air. The fresh air radiators gave the best satisfaction. Thermal comfort problems were common also during summertime due to overheating of apartments. The spread of environmental tobacco smoke was the most common indoor air related problem in apartments together with kitchen hoods performing not satisfactory.

INTRODUCTION

Ventilation systems in apartment buildings

Passive stack ventilation was used in Finland until mid 1960's when centralized and time controlled mechanical exhaust ventilation replaced it. Since that mechanical exhaust ventilation system was major solution until 2003 in the Finnish new production of apartment building. Since 1987 kitchen hoods and outdoor air vents in bedrooms and living rooms has been required. Time controlled centralized exhaust ventilation was replace since mid 1990's by constant exhaust from bathroom and WC with user controlled kitchen hood. From the beginning of 1990's centralized and decentralized mechanical supply and exhaust ventilation system penetrated in the Finnish market of the new production of apartment buildings.

Design air flow rates

Design exhaust airflow rates were almost unchanged between 1940 and 2003. The design exhaust airflow rates were; kitchen 20 l/s, bathroom 16 l/s, WC 8 l/s and cloth room 2 l/s. During the wintertime and nighttime those values could be reduced to 50-67 % of the design value. The total exhaust airflow rate was the same in a small apartment flat (30 m^2) as in a medium size apartment flat (70 m^2). Practically exhaust airflow rates were lower because no outdoor air vents were used until in the end of 1980's. After 1987 a minimum outdoor airflow (4 l/s per person) rate of outdoor or supply air via vents has been required in living and bedrooms. That was increased to 6 l/s per person in 2003 [1].

HOPE-project

The final goal of the project HOPE [2] was to provide the means to enhance the construction of energy-efficient buildings that are at the same time healthy, thus decreasing the energy use in buildings and consequently resulting in a reduction of CO_2 emissions from primary energy used for ventilation, heating and humidity control. Within the European research project HOPE, 71 office buildings and 97 residential buildings were investigated and using checklists addressing the building characteristics and questionnaires to occupants asking their perceived comfort (thermal, IAQ, visual and acoustical), health (SBS) and self estimated productivity. In Finland 8 office buildings and 12 residential buildings were investigated.

METHODS

Buildings were selected with the aim that at least fifty occupant questionnaires would be returned per building. In addition, energy consumption and building description information should be available. The buildings should have been in their current state of operation and occupancy for at least one year, there should be energy saving measures present in most of the building.

The evaluation of ventilation systems was made in 21 apartment buildings in southern Finland. 15 out of 21 buildings were new, 5 out 21 buildings had recently modernized ventilation system and one building in an originally conditions. Ventilation systems were; modern passive stack ventilation with user controlled exhaust fans, mechanical exhaust air systems (time controlled or user controlled) (with of without fresh air vents) (fresh air radiators or no heating of outdoor supply air), mechanical supply and exhaust ventilation (centralized or user separate ventilation units in each apartment).

Design outdoor ventilation rates were quite same in all buildings. All buildings were connected to district heating system and had hot water radiators below window. There were no gas stoves in kitchen. 80 % of apartments had kitchen hood with time or user control.

Buildings are described in Tables 1,2 and 3.

N. of floors	7	7	5	8
Main orientation	S and W	S and N	E and S	Several

Questionnaires

A questionnaire was distributed to each occupant (one version for adults, one version for children) and covered the following factors [3].

- Years in apartment, hours per day in apartment.
- Environmental comfort in summer and winter. (Temperature, air movement, air quality, light, noise)
- Opinions un heating and ventilation in the apartment.
- Effect of environment Heath, and on ability to curry out necessary work.

A household questionnaire was also distributed, one per apartment..

- Ages of household, length and status of tenancy.
- Window orientation.
- Window opening behaviour.
- Condensation and mold.

Performance of ventilation system was checked with checklist developed during the HOPE-project and with some airflow rate measurements and monitoring of CO_2-levels and air temperatures in bedrooms.

RESULTS

A questionnaire was distributed to all apartments in 21 buildings. The first sets of questionnaires were distribution in March 2003. Questionnaires were distributed to habitants by post. They were asked to fill questionnaires and returned in to post box in their building. Another set of questionnaires were distributed in May into apartments who did not returned the questionnaire in April. The last ones were returned after semester season in August 2003. Altogether 600 questionnaires were returned. The mean response rate was 52 %. The highest response rate 69 % was in building Helsinki6 and the lowest 26% in building Helsinki3. The median age of respondents was 49 years. The median age of habitants living in newest buildings was almost 20 years lower than in buildings built in 1960's and 70's. The proportion of answers by female habitant was 62 %.

Comfort evaluations

Results from the questionnaire are shown in table 4 as mean value of all buildings. The value 1 is most preferable value (comfortable or satisfactory) and 7 means very bad conditions (uncomfortable/unsatisfactory) except for air movement and thermal sensation for which the optimum value is 4, 1= too less air movement 7= too much draught.

Table 4. Comfort assessments in apartment buildings (N=600).

Parameter	Mean value	Standard deviation
Thermal comfort (winter)	3.08	1.70
Thermal sensation (winter)	4.15	1.35
Thermal comfort (summer)	3.43	1.16
Thermal sensation (summer)	2.86	1.70
Air movement (winter)	4.14	1.46
Air movement (summer)	2.99	1.11
Air dryness dry – humid (winter)	2.64	1.15
Air dryness (summer)	3.44	1.13
Air quality fresh – stale (winter)	3.39	1.44
Air quality fresh -- stale (summer)	3.43	1.41
Air quality comfort (winter)	3.08	1.45
Air quality comfort (summer)	3.15	1.50
Comfort overall (w)	2.68	1.50
Comfort overall (s)	2.44	1.36
Affects on health 1=very good impact 7=very bad impact on health	3.65	1.33
Ability to carry out work 1=helps a lot 7=hinders a lot	3.53	1.23

Thermal comfort and thermal sensation was less acceptable during summertime than during wintertime. Air dryness during the wintertime was the most uncomfortable indoor air factor. Air quality sensation and comfort did not differ between winter and summertime. Air quality was judged more fresh than stale. In general indoor climate affected more positively than negatively on health and ability to carry out home work.

Thermal sensation

In figure 1 are shown the distribution of thermal sensation during winter and summer (1= too cold, 4 = neutral, 7 = too warm).

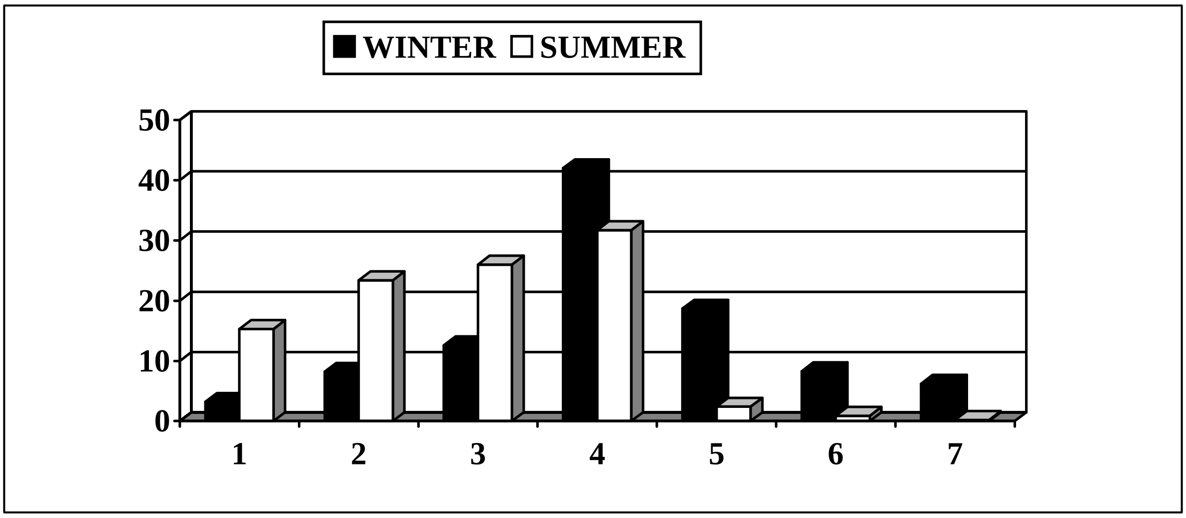

Figure 1.Thermal sensation among habitants during winter and summer (N=600).

Thermal sensations 3, 4 and 5 in the 7-point scale can be asses as acceptable. In that case 73 % of habitants evaluated their apartments as acceptable during winter and 60 % during summer. Even during winter 11.4 % of habitants evaluate room temperatures during winter as too high. During the summertime almost 40 % of habitants evaluate the room temperature too high. There were clear differences between buildings depending on orientation and use of balcony glasses. The worst case was in Helsinki6 were 55 % of habitants evaluated their apartment too hot during summertime.

Thermal comfort and type of ventilation system

Use of preheated (fresh air radiator or mechanical supply with heat recovery and pre heating) supply air improved thermal comfort during the wintertime compared with apartments with supply of unheated outdoor air. In Table 5 are shown statistically significant differences.

Table 5 Ratings of thermal environment and air movement in winter in apartment buildings with and without supply air heating.

Temperature (winter)	Unheated	Pre-heated
Comfort (1=best, 7=worst)	3.35	2.65
Thermal sensation 4=optimum	4.18	3.96
Temperature stability (1=stable, 7=unstable)	3.46	3.10
Air movement (winter)		
1= too less air movement 7= too much draught	4.28	3.72

Odors

As much as 67 % of the habitants did mention at least one source of odors in their apartment. Outdoor air and other apartments were the main source of odors. Other important sources of odors were WC or sewage system inside apartment, stairwell and kitchen. The main odor causing annoyance was tobacco smoke from balconies of neighborhoods. The next common odor source was food preparing but the prevalence was only half of the tobacco smoke.

Performance of ventilation systems

Most of buildings had well adjusted exhaust (supply) air flow rates. Only in building Espoo no adjustment of ventilation rates has been done. In building Helsinki3 with small ventilations inside apartments was a risk for too low air change rates if ventilation units are used with minimum speed.

Modern passive stack ventilation system with separate exhaust fans in kitchen and bathroom in building Helsinki6 did not assure sufficient ventilation even in March when ventilation rates and CO_2-levels were measured. In some bathrooms no ventilation was recorded and in some bedrooms CO_2-levels exceed 2000 ppm. Thermal comfort problems (too cold and draught) were common with passive stack ventilation and mechanical exhaust ventilation without any heating of outdoor air. The exhaust air flow rates were strongly affected by wind speed. Kitchen fans were insufficient to produce exhaust air flow rates required by the building code.

DISCUSSION

Thermal comfort problems were common also during summertime due to overheating of apartments. In several apartment buildings 50 % or more of habitants evaluated their apartment too hot during the summertime.

The fresh air radiators and mechanical supply and exhaust ventilation system with heat recovery gave the best satisfaction against draught. The spread of environmental tobacco smoke was the most common indoor air related problem in apartments together with kitchen hoods performing not satisfactory (too low exhaust air flow or low capture efficiency).

Buildings having hybrid ventilation system should have some kind alarming system showing if CO_2-levels in bedrooms of relative humidity in bathroom are too high.

ACKNOWLEDGEMENT

SUMMARY

Ventilation system is being recommended as an effective tool to improve indoor air quality (IAQ) in apartment houses. Recently, in Korea, apartment house suppliers are required by law to establish ventilation systems in apartment houses. In this study, improvement of IAQ by establishing mechanical ventilation system in apartment houses was investigated through mock-up tests. Seven apartment houses were arranged for the test and concentrations of VOCs and Formaldehyde were examined under various conditions of ventilation rates and duct works. The results of this study show that IAQ of the test houses with mechanical ventilation system was improved from about 30% to 40% compared with IAQ in the apartment houses without ventilation system. However, there were no apparent concentration differences between the cases of changing ventilation rates and ductworks.

INTRODUCTION

Indoor air quality has been deteriorating from bad to worse with a trend towards tighter building triggered by the improvement of technology, and also by increasing use of finished materials containing chemical substances. In Korea, formaldehyde and VOCs are being recognized as very harmful materials to our health, and the law that apartment house suppliers must establish ventilation systems in their apartment houses was enforced on February 13, 2006. However, since there have not been enough studies on improvement of indoor air quality, the reality is that reference data to construct an effective ventilation system is still very insufficient.

In this study, Full scale mock up tests were carried out in order to get a full grasp of improvements of IAQ by establishing mechanical ventilations systems in apartment houses. IAQ was investigated from the point of concentrations of formaldehyde and VOCs. Mock-up tests consist of the improvement of IAQ with changing ventilation rates and ductwork types.

ORGANIZATION OF MOCK-UP HOUSES

Descriptions of examined houses are given in Table 1. Seven apartment houses arranged for the test were constructed with the same interior materials within the same period. One of the seven houses, named ‘NH’, remains blank without a ventilation system, so as to provide comparative criterion for result analysis.

Table 1.Briefs of test houses

Contents	Conditions	Contents	conditions
Site Floor area/height Temperature	Gyeonggi-do, South Korea $85m^2$, 2.3m 20℃ (Ondol system)	Floor Humidity	2nd ~ 5th floor A home humidifier (no adjusting humidity)
Contents	Type	ACH	Ductwork
Ventilator type	No heat exchanger (NH) Total heat exchanger (TH :0.3) Total heat exchanger (TH :0.5) Total heat exchanger (TH :0.8) Total heat exchanger (THIR :0.5)	- 0.3 0.5 0.8 0.5	- Standard* Standard* Standard* Individual room SA &RA

* Ductwork of the standard type is the same as the standard type in Table 2

To examine improvements in IAQ by changing the ventilation rates, total exchanger-type ventilators were installed in 3 houses with respective air change rates of 0.3, 0.5 and 0.8 ACH. To compare and analyze improvements of IAQ caused by different types of ventilators, each total heat exchanger, sensible heat exchanger and alternating current exchanger was installed in each house with the air change rate fixed at 0.5 ACH.
As shown in Table 2, in one of the houses, the supply diffusers and exhaust diffusers were installed in each room, whereas in another house the air supply diffusers were installed in each room while the air exhaust diffusers were installed in the kitchen and near the entrance to examine the improvement of IAQ resulting from different ductworks. Ventilation systems installed in these houses have a total heat exchanger of 0.5 ACH.
Once installations of ventilation systems in each house were done, infiltration rates in two houses were measured to examine the difference in infiltration rates which could affect IAQ. For the test of infiltration rates, constant concentration method was used with SF_6 tracer gas. The result of this test shows a difference of 0.1ACH, as 'NH' house and 'TH : 0.5' house had respective results of 0.75 ACH and 0.65ACH. Although the number should not be ignored, no measure was taken to correct the difference, as it was accepted as a cause of possible error in analyzing IAQ thereafter. The next step was executing TAB(Test, Adjustment and Balancing) which is to control air supply and exhaust rates so that they correspond accurately to determined conditions in each residence.
Indoor temperature was controlled within a range of 20±2℃ by the Ondol system which is Korean traditional floor heating system. When running a ventilation system, it is difficult to

Table 2. Ventilator and Ductwork established in test houses

<table>

(standard)</th><th>Total heat exchanger
(Individual room SA & RA)</th></tr>
<tr><td>Ventilator and ductwork</td><td></td><td></td></tr>
</table>

reach a relative humidity of 50% in indoors, but since the general condition is that a regular house only runs one humidifier, only one humidifier was installed but was run at maximum capacity.

METHODS

Concentrations of formaldehyde and VOCs were measured after operating the ventilation systems. General information and schedule regarding the measurement of the indoor air quality are given in Table 3. Formaldehyde was sampled by using DNPH cartridge for 30 minutes at sampling speed of 500ml/min and VOCs was done by using Tenax tube for 30 minutes at 100ml/min. The measurement started about 2 weeks after the interior construction was completed.

The status 'Ventilator OFF' is the case where the ventilator was always operating except for the day of indoor air sampling, whereas 'Ventilator ON' is the case where the ventilator was operating everyday including the day of sampling.

Table 3. Measurement conditions and schedule

Contents	Conditions
Duration	Dec. 15. 2005 ~ Feb. 28. 2006
Measurement conditions	'Ventilator OFF' : ventilation system was turned on everyday besides the day of sampling the indoor air (date : 12/15/2005, 12/19, 12/23, 12/29, 1/12/2006, 2/2, 2/16) 'Ventilator ON' : ventilation system was turned on everyday inclusive of the day of sampling the indoor air (date : 12/26/2005, 1/2/2006, 1/20, 2/10, 2/24, 2/28)

RESULTS AND DISCUSSION

During the period of measurement, the indoor temperature was under control within a range of 20±2℃ while humidity was maintained differently due to difference in ventilation rates. Change of formaldehyde concentration in both cases (ventilator On/Off) during the measuring period is shown in Figure 1. In both cases, Korean guideline of concentration of formaldehyde (210 $\mu g/m^3$) was mostly satisfied. However, the concentration did not diminish as time went by, but it rather increased gradually. We believe this is due to the gradual increase of emissions coming from the inside of finished materials to the outside, which were constructed in compound.

In case of individual VOC, toluene concentration was the highest, and while reduction tendency of other VOC materials were similar to that of toluene, this paper will only cover the analysis on the change of toluene.

The concentration changes of toluene in both cases of 'ventilator OFF/ON' are shown in Figure 2. In case of 'ventilator OFF', the toluene concentration increased largely on Dec. 29; on Jan. 12, which is 1 month after the measurement initiation, it shows a dramatic decrease below the Korean guideline value of 1000 $\mu g/m^3$. From then on, the reduction becomes more gradual. In case of 'ventilator ON', the concentration reaches its peak on Dec. 26 and shows the distribution that satisfies the Korean guideline value from Jan. 20, which is a month after the initiation.

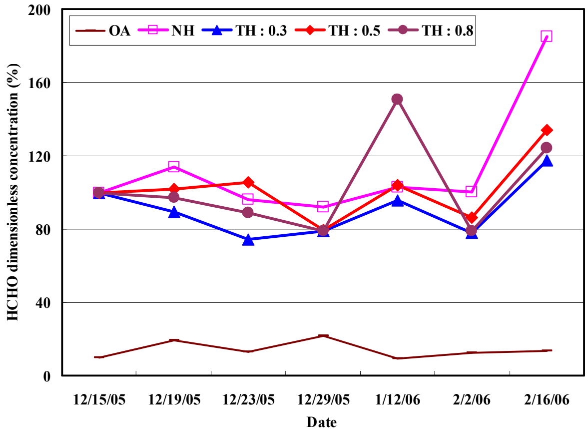
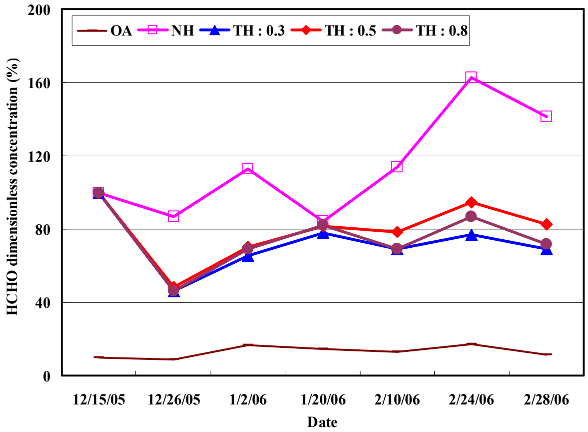
Figure 2. Time series Toluene concentration.

The improvement effect of indoor air quality caused by varied ventilation rates

To compare and analyze the improving effects of indoor air quality among houses, we need to correct the conditions of different temperature and humidity at the time of measurement. We made the corrections according to the formula of INOUE. Also, as initial concentrations differ in houses, as shown in Figure 1, it is difficult to simply compare the diminishing effect of concentration within the time period or the improvement effect of indoor air quality among houses. Therefore, to eliminate the differences in the initial concentration, concentration values earned with INOUE's formula were made dimensionless by the concentration of Dec. 15, and these numbers were multiplied by 100 to get percentage values for comparison and review.
Dimensionless formaldehyde concentration in ventilation rates of 0.3, 0.5 and 0.8ACH is shown in Figure 3. a) of Figure 3 shows the case of 'ventilator OFF', where in the beginning of measurement the house without the ventilator does not show apparent difference in formaldehyde concentration, compared with the case where the ventilator is installed. However, on Feb. 2, 1 1/2 months after initiation, the indoor air quality improved by about 20% and on Feb. 16, 2 months from then, the result went on to improve by about 30%. This

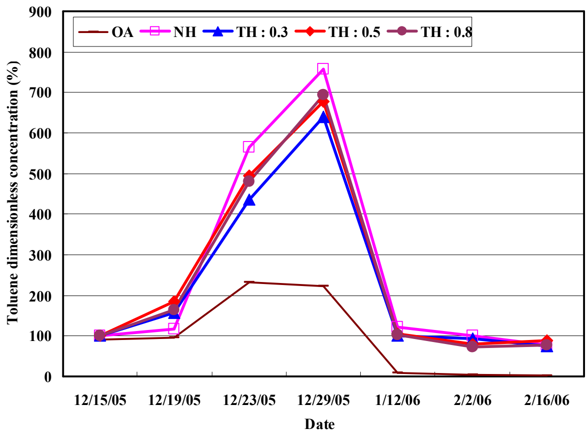


a) Ventilator OFF

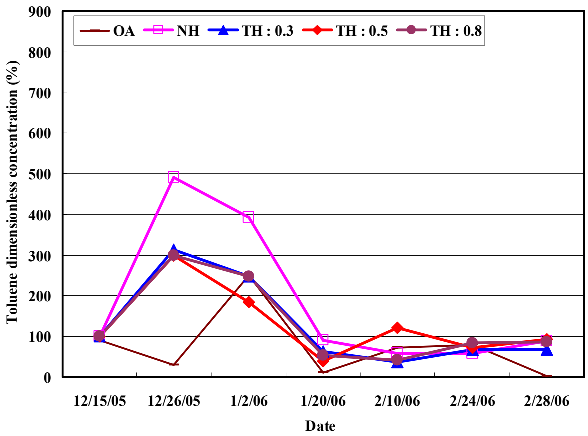


b) Ventilator ON

Figure 3. Comparison of HCHO dimensionless concentration with varied ventilation rates.



a) Ventilator OFF



b) Ventilator ON

Figure 4. Comparison of Toluene dimensionless concentration with varied ventilation rates.

improvement is assumed to have been gained by the all-time operation of the ventilators. In terms of the indoor air quality improvement earned by the change of ventilation rates, the case of 0.3ACH shows a rather lower result in formaldehyde concentration than those of 0.5and 0.8ACH. However, the difference shown (5%) is thought to be in the range of measurement error, therefore, the improving effect of indoor air quality caused by ventilation rates does not show any significant difference.

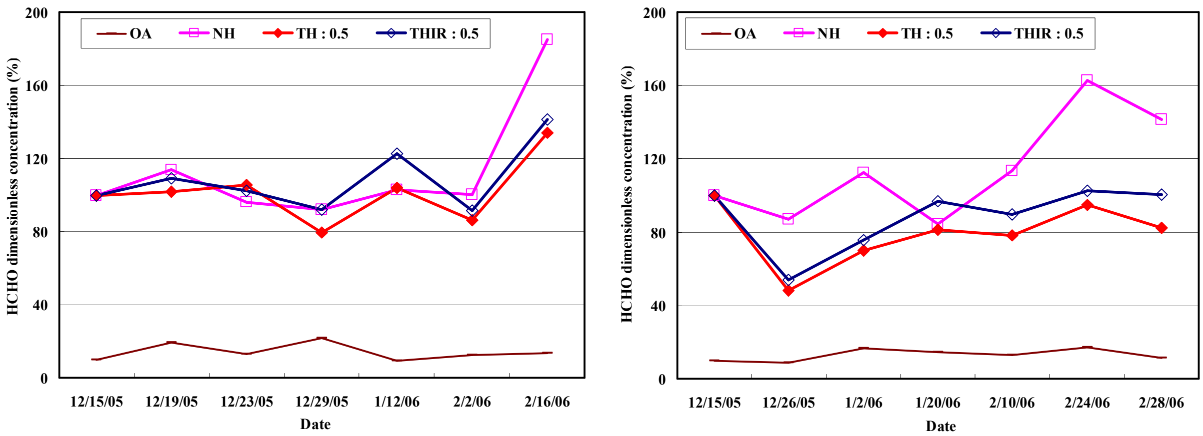
In the case of ‘ventilator ON’, an average of 40% improvement is shown with the exclusion of Jan. 20. However, the difference (5%) caused by ventilation rates is thought to be within the range of measurement error. The following is the presumed cause: since the infiltration rate during the time period (winter time) is about 0.7 ACH, which is relatively high, ventilation rates of 0.3 ~ 0.8ACH became relatively low. Moreover, construction error could have played a role.

In the case of toluene concentration, corrections were not made to the temperature and humidity, but toluene concentration was made dimensionless by the concentration of the first day. Figure 4 shows the dimensionless toluene concentration in both cases of 'ventilator OFF/ON'. From the starting date throughout Dec. 29, which is after half a month, toluene concentration shows relatively high numbers, and the ‘ventilator OFF’ case shows a 15% improved indoor air quality compared with houses without installation. This is considered to be caused by the all-time operation of the ventilator. However, on Jan. 12, which is a month after initiation, the reduction slowed down and improvement caused by the all-time operation

is no longer much effective. Comparing the difference caused by ventilation rates, the case of 0.3 ACH shows numbers that are about 5% lower than the others, but the difference is thought to be insignificant and caused by measurement error.
In case of 'ventilator ON', we will only take into account measured results from Dec. 26, Jan. 20 and Feb. 2, while excluding the remaining dates when pavement construction of the peripheral roads took place and caused high outdoor air concentration.
When concentration was highest on Dec. 26, toluene concentration in houses without installations surged by 500% compared with the initial numbers, whereas in the houses installed with ventilation systems, 300% increase was measured regardless of ventilation rates, thus showing a 40% indoor air improvement. However, from Jan. 20, a month after initiation, the improvement of IAQ caused by operation of the ventilator gradually decreased.

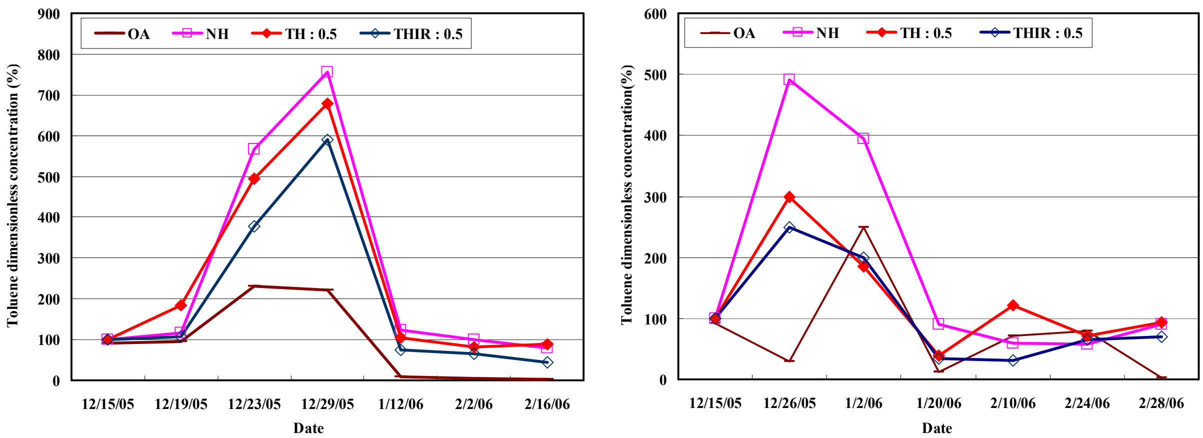
Indoor air quality improvement caused by varied systems of air supply/exhaust duct

Ductwork of ventilation system are classified by 1) whether the air is supplied to each room and exhausted from the kitchen and near the entrance, and by 2) whether the air is supplied to each room and exhausted from each room, and the following shows the indoor air quality improvement caused by varied types of ducts. The dimensionless concentration of formaldehyde is shown in Figure 5.



a) Ventilator OFF b) Ventilator ON

Figure 5. Comparison of HCHO dimensionless concentration by the ductworks



a) Ventilator OFF b) Ventilator ON

Figure 6. Comparison of Toluene dimensionless concentration by the ductworks

In case of 'ventilator OFF', the reduction of formaldehyde concentration is not very apparent until Feb. 2, which is 1 1/2 months after measurement initiation, but afterwards, a slightly diminished concentration is noticeable. On Feb. 16, 2 months after initiation, houses with air supply and exhaust ducts show a 25% improvement compared with houses without ventilator installations. The difference caused by different types of air supply/exhaust is within 5% and is insignificant.
In case of 'ventilator ON', the houses where the air is supplied to each room and exhausted from the kitchen and near the entrance showed a 40% improvement, while houses where the air is supplied to each room and exhausted from each room showed a 30% improvement, showing a 10% difference. However, this is within the range of error, and it is speculated that there is no apparent difference in the diminishing effect of formaldehyde concentration caused by varied duct systems of air supply/exhaust.
Dimensionless concentration of toluene is shown in Figure 6. In case of 'ventilator OFF', houses where the air is supplied to each room and exhausted from each room shows a 25% improvement compared with houses without ventilator installation until Dec. 29, 1/2 month after initiation, while houses where air is supplied to each room and exhausted from the kitchen and near the entrance shows a 10 % improvement.
In case of ventilator ON, checking mainly the results from Dec. 26 when outdoor air concentration was relatively low, improvement of indoor air quality is 50% and 40% respectively for houses where air is supplied to each room and exhausted from each room, and houses where air is supplied to each room and exhausted from the kitchen and near the entrance. However, the 10% difference in improvement effect of indoor air quality caused by varied duct systems of air supply/exhaust is thought to be insignificant.

CONCLUSION

This research aimed to run mock-up tests in order to examine the indoor air quality improvement effect of mechanical ventilation systems in apartment houses. The result only reflects characteristics and field conditions that were applied in the mock-up test, and does not show general characteristics of every ventilation system.
The result of this research data can be summarized as followings:
1) When a ventilation system with 0.3~ 0.8ACH is operated in an apartment house, formaldehyde and VOCs concentrations are reduced by 30~50% compared with those without ventilation systems.
2) When ventilation rates are in the range of 0.3~ 0.8ACH, the difference of indoor air quality improvement effect caused by ventilation rates is insignificant.
3) In terms of indoor air quality improvement caused by different types of supply and exhaust duct systems, there was no significant differences between them.

SUMMARY

This paper describes steady-state energy and exergy analyses on an instantaneous and on a daily basis for dwelling ventilation systems and domestic hot water DHW production systems. The ventilation uses mechanical exhaust with environmental air supply without heat recovery or balanced ventilation with heat recovery. The exhaust ventilation air is used to preheat DHW, using a heat exchanger or a heat pump. Energy and exergy demands in winter days for De bilt, the Netherlands, are presented at the component level, in terms of heat and electricity, for the systems. The results indicates that for these winter days the total energy demands, but not the total exergy demands, of balanced ventilation and DHW production with preheat by the exhaust ventilation air using a heat pump are lowest. The total exergy demands are dominated by exergy of electricity input to heat recovery unit and the heat pump.

INTRODUCTION

Exhaust ventilation air has been used to preheat inlet ventilation air in balanced ventilation systems and as a heat source in other heating systems. In order to recover heat from the exhaust ventilation air, electric power is required. Since electricity input is small relative to the amounts of thermal energy recovered, such systems are efficient from an energy viewpoint. One important yet often overlooked aspect, however, is the difference in ‘quality’ between the high-grade electricity input and the lower grade thermal energy recovered.

Exergy analysis provides a common basis for evaluating forms of energy (e.g. thermal and electric), considering their abilities to produce work in relation to a given environment [1-3]. Exergy recognizes that energy carried by substances can only be used ‘down’ to the level given by the environment. Unlike energy, exergy is not subject to a conservation law.

This paper presents steady-state energy and exergy analyses on an instantaneous and on a daily basis for dwelling ventilation systems and DHW production systems. The exhaust ventilation air is used to preheat DHW. Analysis results, for De Bilt, the Netherlands, are used for discussion of design options for systems.

SYSTEM DESCRIPTION

The systems to be studied are divided into 2 parts: dwelling ventilation systems and domestic hot water production systems.

Dwelling ventilation systems

Energy and exergy analysis is performed for dwelling ventilation systems, using mechanical exhaust ventilation with environmental air supply without heat recovery (Figure 1a) and balanced ventilation with heat recovery (Figure 1b). The mechanical exhaust ventilation system uses a DC fan, Model: CVE ECO-fan 2 of Itho bv. [4]. The balanced ventilation system uses a DC Heat Recovery Unit, Model: HRU ECO-fan 3 S B of Itho bv. [5], containing two DC fans and a heat exchanger with high thermal effectiveness ε. Thermal effectiveness of the heat exchanger is calculated by interpolating from manufacturer's data [5] in relation to ventilation airflow rates (see Table 1). Figure 1 presents airflow rates and temperatures of ventilation and infiltration airflows of the systems. Air infiltration is also accounted for the analysis.

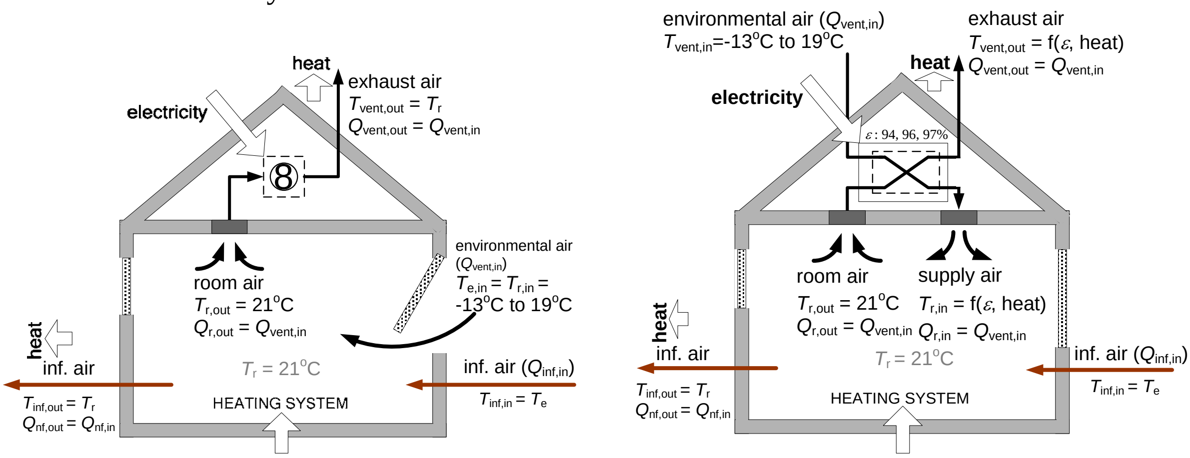

Figure 1. Dwelling ventilation systems. a) Mechanical exhaust ventilation with environmental air supply (left), b) Balanced ventilation with heat recovery (right).

The energy and exergy analysis of the ventilation systems assumes steady state operation and considers only dry air. Pressure difference between air entering and leaving the dwelling is also ignored. General calculation values are given in Table 2.

Table 1. Thermal effectiveness ε versus ventilation airflow rates Q_{vent}, for the DC HRU (left). Table 2. General calculation values (right). [6], [7]

Q_{vent} [m^3/s]	ε [–]
0.063	0.94
0.042	0.96
0.028	0.97

Parameters	Values
Air density (ρ_{air})	1.23 kg m^{-3}
Spec. heat capacity of air ($C_{p,air}$)	1.008 kJ kg^{-1}K^{-1}
Environmental air temperature (T_e)	from -13°C to 19°C
Room air temperature (T_r)	21°C
Ventilation airflow rates (Q)	0.028, 0.042, 0.063 m^3/s

Domestic hot water production systems

The DHW production systems use ground water at a constant temperature (assumed 13°C). The DHW enters the dwelling with/without preheat by the exhaust air from the dwelling ventilation using a heat exchanger or a heat pump. Electricity is needed for DHW preheat if using the heat pump. The thermal effectiveness ε of the heat exchanger and the coefficient of performance COP of the heat pump are assumed 0.90 and 3.7 respectively. The energy efficiencies of the DHW preheat devices are assumed 1.0. The DHW devices operate when temperature of the exhaust ventilation air is higher than the maximum temperature between the inlet water and environment (if using the heat exchanger) and environment (if using the heat pump). The exhaust ventilation air is cooled until a temperature corresponding to the thermal effectiveness ε (if using the heat exchanger) and until environment T_e (if using the heat pump). Air flow and water flow rates are assumed constant at the inlet and the outlet. Flow effects in the systems are also ignored in this study.

Daily operation profiles of winter days in De Bilt, the Netherlands

Figure 2 shows three hourly environmental air temperature profiles, for winter days of maximum, minimum and intermediate mean daily environmental air temperatures. Climate data for De Bilt, the Netherlands are taken from the TMY2 weather data [8].

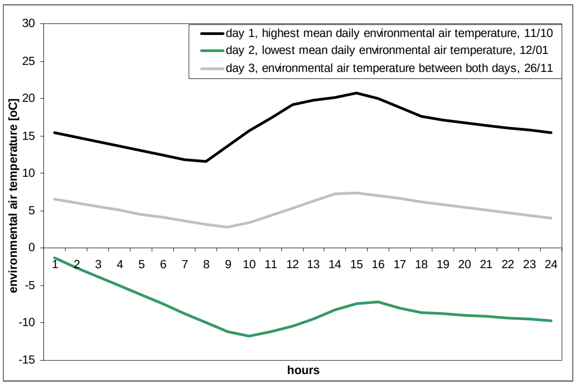

Figure 2. Hourly environmental air temperature profiles in 3 winter days in De Bilt.

The dwelling ventilation and the DHW use in the dwelling for the three days are hourly scheduled, given in Tables 3.

Table 3. Hourly operation plan: the dwelling ventilations (left); and the DHW use (right).

ENERGY AND EXERGY ANALYSIS

The comparison of design options for combination between dwelling ventilation and domestic hot water production is based on calculation of thermal energy and thermal exergy demands by ventilation and infiltration airflows in relation to environmental air temperature, and electricity input to ventilation unit and to DHW preheating device. The energy and exergy analysis is carried out on an instantaneous basis where T_e is between -13^{o}C and 19^{o}C and on a daily basis for the representative winter days (Figure 2).

Energy and exergy demands by infiltration airflows

Infiltration airflow rate Q_{inf} is calculated based on NEN 2867 [9]. The infiltration airflow rate relies on types of ventilation systems: mechanical exhaust ventilation $Q_{inf,mv}$ (equation 1) and balanced ventilation $Q_{inf,bv}$ (equation 2).

$$Q_{inf,me} = \left(\frac{q_{v10}}{500}\right)\left((A + BCv + D\Delta T)q_{v10}\right) \qquad (1)$$

$$Q_{inf,bv} = 0.8\left((A + BCv + D\Delta T)q_{v10}\right) \qquad (2)$$

where q_{v10} [dm^3/s] is the infiltration airflow rate expressed in a volume airflow rate q_v with pressure difference of 10 Pa, ν [m/s] is the wind speed at 10 m above the ground level and ΔT [K] is the temperature difference between the room air T_r and the environmental air T_e. *A*, *B*, *C* and *D* are the coefficients of the effect from turbulent airflow, shielding, partitioning of the air infiltration concerning the dwelling coating, and temperature difference respectively.

The following values are applied for the study. q_{v10} is 150 dm^3/s for the dwelling with the mechanical exhaust ventilation and 80 dm^3/s for the dwelling with the balanced ventilation. *A*, *B*, *C* and *D* are 0.02, 0.25, 0.20 and 0.004 respectively. These coefficient values are according to NEN 2867 [9] and for dwelling whose volume and height are 250 m^3 and 5.4 m, and having a normal shielding. ν, T_i and T_e are taken from the TMY2 weather data [8].

The infiltration airflow rate Q_{inf} is used for calculation of thermal energy $En_{th,inf}$ and thermal exergy $Ex_{th,inf}$ demands by infiltration airflows, using equations 3 and 4.

$$En_{\text{th,inf}} = \rho_{\text{air}} Q_{\text{inf}} C_{\text{p,air}} (T_{\text{out}} - T_{\text{in}}) \tag{3}$$

$$Ex_{\text{inf,th}} = \rho_{\text{air}} Q_{\text{inf}} C_{\text{p,air}} (T_{\text{out}} - T_{\text{in}} - T_{\text{e}} \ln(\frac{T_{\text{out}}}{T_{\text{in}}})) \tag{4}$$

where T_{out} and T_{in} are temperatures of the infiltration air leaving and entering the dwelling respectively. All the air temperatures are in Kelvin.

Since energy demand by the infiltration airflows accounts only the $En_{th,inf}$, therefore the total demands by the infiltration airflows are equal to the thermal demands for energy and exergy.

Energy and exergy demands by ventilation airflows

Energy and exergy demands by ventilation airflows are obtained from thermal demand by ventilation airflows and electricity input to ventilation unit.

Thermal energy and exergy demands by ventilation airflows are calculated by applying equations 3 and 4. The supply air temperatures to the dwelling $T_{r,in}$ for the balanced ventilation system is calculated by using the exchanger heat transfer effectiveness equation [10] and heat balance equation, assuming the same airflow rates though the HRU for the supply air and the exhaust air.

$$T_{\text{r,in}} = T_{\text{e}} + \varepsilon (T_{\text{r}} - T_{\text{e}}) \tag{5}$$

The inputs of exergy and energy for electricity are identical [11]. The electricity *Pe* is calculated by using the fan manufacturer data and the fan law [10] in equation 6.

$$Pe_1 = Pe_2 (\frac{\phi_2}{\phi_1})^4 (\frac{Q_1}{Q_2})^3 (\frac{\rho_1}{\rho_2}) \tag{6}$$

where ϕ is the fan impeller diameter. The fan law is used to predict performance of the fan when test data (data with subscript 2 in equation 6) are available. The test data are used from the fan producer: Itho bv. [4], [5].

Energy and exergy demands by domestic hot water

Thermal energy and exergy demands by DHW flow are functions of the DHW temperature required to supply to the dwelling T_{DHW} (assumed 65^{o}C) and the preheated DHW temperature $T_{preheat}$. The demands are calculated by applying equations 3 and 4 and using inlet water temperature T_w as reference environment. $T_{preheat}$ depends on types of the DHW preheat devices and is calculated by using equation 7 (if using a heat exchanger, $T_{\text{preheat,ex}}$) and equation 8 (if using a heat pump, $T_{\text{preheat,hp}}$).

$$T_{\text{preheat,ex}} = \varepsilon \frac{C_{\min}}{C_{\text{w}}} \left(T_{\text{vent,out}} - T_{\max} \right) + T_{\text{w}} \tag{7}$$

$$T_{\text{preheat,hp}} = \left(\frac{\rho_{\text{air}} Q_{\text{air}} C_{\text{p,air}} (T_{\text{e}} - T_{\text{e,out}})}{\rho_{\text{w}} Q_{\text{w}} C_{\text{p,w}} (1 - \dfrac{1}{\text{COP}})} \right) + T_{\text{w}} \tag{8}$$

where $C_{\min}$ is the minimum value of the thermal capacities between the exhaust air from the dwelling ventilation and the inlet water, C_{w} is the thermal capacity of the inlet water and $C_{\text{p,w}}$ is the specific heat capacity of the inlet water (4.19 $\text{kJkg}^{-1}\text{K}^{-1}$). $T_{\max}$ is the maximum temperature between inlet water and environment. T_{w} is the inlet water temperature and $T_{\text{e,out}}$ is the air temperature of the exhaust ventilation air.

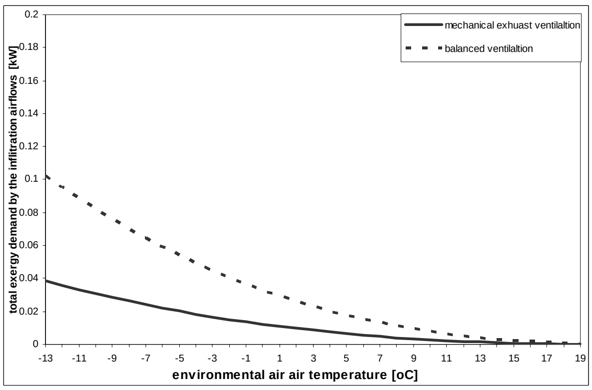
Electricity input to the heat pump is calculated as a different value between thermal energy supplied to heat pump by the exhaust ventilation air and thermal energy released by the heat pump to inlet water, because energy efficiency of the heat pumping process is assumed 1.0.

RESULTS

This chapter presents energy and exergy analysis results for the dwelling ventilation and the DHW production systems on an instantaneous basis and on a daily basis.

Total exergy demands by infiltration and ventilation airflows

Figures 3 and 4 show total exergy demands by the infiltration airflows Ex_{inf} and by the ventilation airflows Ex_{vent}, as a function of environmental air temperature T_{e}. In Figure 4, the mechanical exhaust ventilation with natural air supply and the balanced ventilation with heat recovery are called system A and system B respectively.



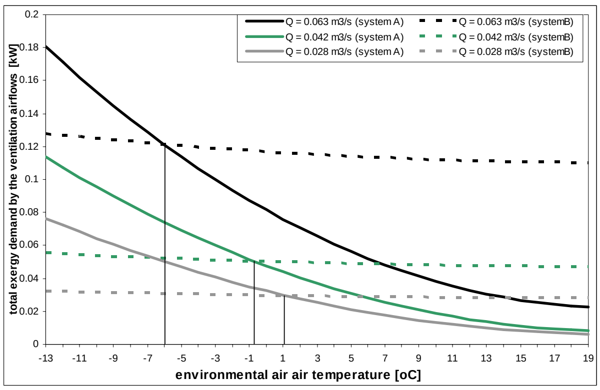


Figure 3. Total exergy demand by the infiltration airflow Ex_{inf} versus T_{e} (left).
Figure 4. Total exergy demand by the ventilation airflows Ex_{vent} versus T_{e} (right).

In Figure 3, the Ex_{inf} lines for the ventilation systems vary nonlinearly with T_{e}. They rely on logarithmic term of ratio between inlet and outlet infiltration air temperatures (see equation 4), since Ex_{inf} is assumed equal to $Ex_{\text{th,inf}}$. In addition, the Ex_{inf} lines for the balanced ventilation with heat recovery is higher than the $Ex_{\text{th,inf}}$ for the mechanical exhaust ventilation due to higher infiltration airflow rate in the entire range of T_{e}.

In Figure 4, the Ex_{vent} decreases for a given Q_{vent}, as T_{e} increases from -13°C to 19°C. The Ex_{vent} lines (smooth ones) for the mechanical exhaust ventilation using the DC fan (called DC fan line) are sharper than the Ex_{vent} lines (dashed ones) for the balanced ventilation with heat recovery using the DC HRU (called DC HRU line). The DC HRU lines are less sensitive in the range of T_e because the DC HRU requires mainly electricity, while the DC fan requires relatively more heat. The DC fan requires more exergy at lower T_e, and relatively less exergy as T_e increases towards the room air temperature T_r. electricity inputs to the DC fan and the DC HRU are given Table 4

Table 4. Electricity inputs to the DC fan and the HRU *Pe* versus ventilation airflow rates Q_{vent}

hour	ventilation airflow rate Q_{vent} [m^3/s]	electricity inputs ***Pe*** **[W]**
DC fan	0.028	6
	0.042	8
	0.063	22
DC HRU	0.028	28
	0.042	47
	0.063	110

The DC fan lines and the DC HRU lines intersect at a given environmental air temperature $T_{e,intersect}$ for a given Q_{vent}. At $T_e > T_{e,intersect}$, using the mechanical exhaust ventilation with the DC fan results in less total exergy demand than using the balanced ventilation with the DC HRU at the same airflow rate. $T_{e,intersect}$ increases when operating the ventilations at lower Q_{vent} since electricity input to the DC HRU is less.

Total exergy demands by domestic hot water flow

Figures 5 shows the total exergy demand by DHW flow with preheat by exhaust ventilation air using the heat exchanger $Ex_{DHW,ex}$ (Figures 5a) and the heat pump $Ex_{DHW,hp}$ (Figures 5b) in relation to T_e, respectively. The mechanical exhaust ventilation with natural air supply and the balanced ventilation with heat recovery are called system A and system B respectively. The thin lines show the total exergy demand by DHW flow without preheat, as a reference for comparison to the $Ex_{DHW,ex}$ and $Ex_{DHW,hp}$.

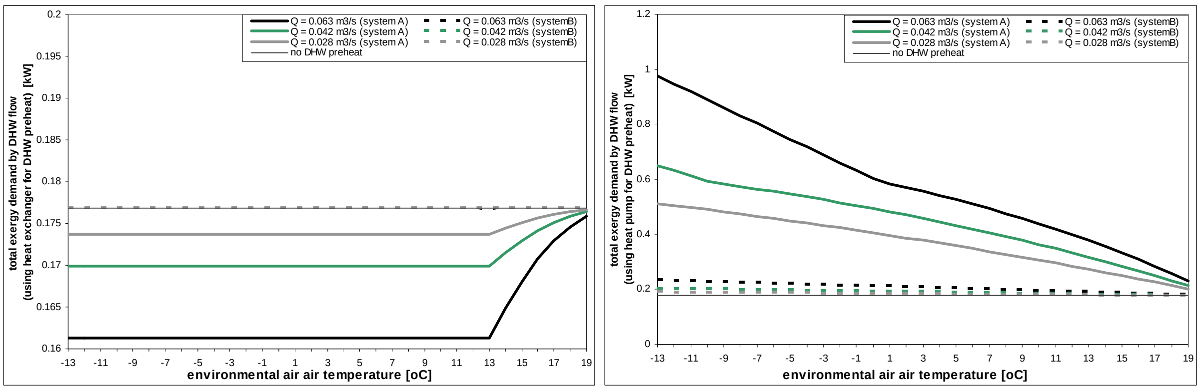

Figure 5. Total exergy demand by DHW flow with preheat by exhaust ventilation air via the heat exchanger $Ex_{DHW,ex}$ (a, left) and via the heat pump $Ex_{DHW,hp}$ versus T_e (b, right).

In Figure 5a, the $Ex_{DHW,ex}$ lines for system B (dashed ones) are almost congruent to the reference line (no DHW preheat), because the En_{th} and Ex_{th} of the exhaust ventilation air are very small. Most of them are recovered in the HRU. The $Ex_{DHW,ex}$ lines for system A (smooth ones) are constant when $T_e < T_w$ according to the assumption that the DHW is preheated until $T_{vent,out} = T_w$. In addition, the $Ex_{DHW,ex}$ depends on the Q_{vent}. For system A operating at Q_{vent}=0.063, 0.042 and 0.028 m^3/s, $Ex_{DHW,ex}$ are 91.24%, 96.06% and 98.24% of the Ex_{DHW} (no DHW preheat) respectively, when $T_e < T_w$. When $T_e > T_w$, $Ex_{DHW,ex}$ increases because the energy and exergy of the exhaust ventilation air decrease.

In Figure 5b, the $Ex_{DHW,hp}$ decreases, as T_e increases from -13°C to 19°C or Q_{vent} decreases. In addition, the $Ex_{DHW,hp}$ lines for system A (smooth ones) are sharper than the $Ex_{DHW,hp}$ lines for system B (dashed ones), because more heat from system A are used in DHW preheat. This costs more electricity, which is high-graded energy, by the heat pump.

The $Ex_{DHW,hp}$ lines for system A (smooth ones) have more than one slope in the range of T_e. At the lower slope (in this case T_e>0°C for Q_{vent}=0.063 m^3/s), the heat pump heats DHW until a temperature less than T_{DHW} and additional heat is then required. On the other hand, at the sharper slope, the heat pump could heat DHW to T_{DHW} only by using electricity. The $Ex_{DHW,hp}$ lines for system B (dashed ones) have only one slope in the range of T_e, since the heat pump could heat DHW until a temperature less than T_{DHW}.

The total energy and total exergy demands by the dwelling ventilation and the domestic hot water production systems in winter days

This item presents examples of cumulative energy and exergy demands for De Bilt (NL) for three representative winter days (Figure 2). Figure 6 shows the energy *En* and exergy *Ex* demands of each design option, in terms of heat and electricity, at the component level (noted that scales of the Figures 6a and 6b are different). The names of the design options consists of an alphabet (A: the mechanical exhaust ventilation with natural air supply; B: the balanced ventilation with heat recovery) and a number (1: no DHW preheat; 2: DHW preheat using the heat exchanger; 3: preheat using the heat pump).

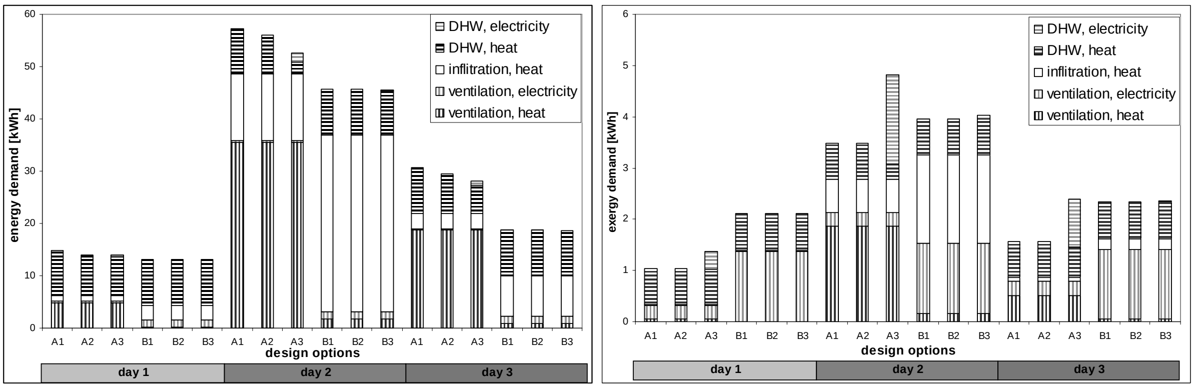

Figure 6. Energy demands (a, left) and exergy demands (a, left) of the design options.

In Figure 6a, option B3 is the most energy efficient one to use in the winter days because it requires the least energy *En* among the other options studied. The *En* of option B3 in the part of ventilation and infiltration depends on environment. The demand is highest on day 2 and lowest on day 1. Option B3 saves 0.45% of the *En* in the DHW production of option B1 (no DHW preheat) because of small heat of the exhaust ventilation air used in the DHW preheat.

In Figure 6b, option A2 is the most exergy efficient one because it requires the least exergy *Ex* among the other options studied, for the winter days. In the part of mechanical ventilation, options A1-A3 require higher thermal exergy than options B1-B3 but much lower electric exergy. In the part of infiltration, options A1-A3 require lower thermal exergy than options B1-B3. In total, options A1-A3 require lower total exergy than options B1-B3 in the parts of mechanical ventilation and infiltration. In the part of the DHW production, the *Ex* of option A2 are smaller than the demand of option A1 (without the DHW preheat), but for option B2 the *Ex* is quite similar to the *Ex* of option A1. However, in the same part the *Ex* of options A3 and B3 (with DHW preheat using the heat pump) are higher than the demand of option A1 (without DHW preheat), due to electricity input to the heat pump. This is because the heat pump uses electricity to pump low-graded heat. Nevertheless, options A3 saves more thermal exergy than options A2. Electric exergy input to the heat pump should be reduced. Besides, options B2 and B3 save very small amounts of the thermal exergy in the DHW production.

CONCLUSION

This paper presents steady-state energy and exergy analyses on an instantaneous and on a daily basis for dwelling ventilation systems and DHW production systems. Analysis results, for De Bilt, the Netherlands, are used for discussion of design options for systems.

On an instantaneous basis, the exergy demands by infiltration airflows for the balanced ventilation with heat recovery are higher than the exergy demands for the mechanical exhaust ventilation in the entire range of environmental air temperature. But this is not for the exergy demands by ventilation airflows because substantial shares of electric exergy input to ventilation unit are big and dominate the total exergy demands. The exergy demands by ventilation airflows for the balanced ventilation with heat recovery are lower than the exergy demands for the mechanical exhaust ventilation, when environmental air temperature close to room air temperature. In the DHW production part, using the heat exchanger for the DHW preheat with the exhaust air from the balanced ventilation with heat recovery saves a small amount of the exergy demands of DHW production, due to a small amount of heat from the air. Preheating the DHW with the exhaust air from the mechanical exhaust ventilation is better according to a bigger amount of the heat. DHW production with DHW preheat using the heat pump requires more exergy than DHW production without the DHW preheat, because the heat pump uses electricity to pump low-graded heat. The exergy of electricity input to the heat pump is larger than the exergy of heat recovered in the DHW preheat.

On a daily basis, for the winter days the total energy demands, but not the total exergy demands, of balanced ventilation and DHW production with preheat by the exhaust ventilation air using a heat pump are lowest. The total exergy demands are dominated by exergy of electricity input to heat recovery unit and the heat pump.

ACKNOWLEDGEMENT

Financial support for this research was provided by the Faculty of Architecture at the Delft University of Technology, and gratefully acknowledged. Dr. E.C. Boelman gave comments on the draft of this paper, and provided academic supervision to the author during the years 2004 and 2005.

Residential HVAC System Sizing

William P. Goss

University of Massachusetts, Amherst, Massachusetts, USA

Corresponding email: goss@acad.umass.edu

SUMMARY

Heating, ventilating and air-conditioning (HVAC) system sizing for existing single family residents in hot and humid and temperate climates present different problems. In hot and humid climates, the proper sizing of residential air-conditioning systems is an important issue, since if the system is over-sized the resulting mold problems can cause significant problems with occupants who are susceptible to airborne spores like mold that can severely affect their asthmatic illnesses.

In more temperate climates, HVAC system sizing for existing single family residential unit is primarily concerned with heating systems. However, there is often a need to retrofit the residential unit with an air-conditioning system.

The technique for properly sizing residential air-conditioning and heating systems is based on methods described in the ASHRAE Handbook of Fundamentals. Heating and cooling spreadsheet programs that duplicate the methodologies were developed and have been used to evaluate the design cooling load for a number of single family residential units (condominium and homes) in Florida and in New York and Massachusetts. Two examples, a condominium in subtropical Tampa, Florida and a condominium in temperate Albany, New York are presented and discussed. Conclusions and recommendations are made on the sizing criteria for residences in these two diverse climates.

INTRODUCTION

In hot and humid climates, the proper sizing of residential air-conditioning systems is an important issue, since if this is not done correctly the resulting mold problems can cause significant problems with occupants who are susceptible to airborne spores like mold that can severely affect their asthmatic illnesses. The author has examined several hundred residences (single family homes and condominiums) that were constructed in the last 10 to 30 years in the State of Florida where both new and replacement air-conditioning systems were significantly oversized. In a recent seminar presentation by Cochell [1] indicated that a study of 1600 homes in Florida by the University of Florida showed that 78% of the homes had oversized air-conditioning systems by more than ½ Ton (6,000 Btu/hr or 1759 W). As a result, the occupants were exposed to a cooled, damp indoor climate where the oversized air-conditioning system runs for short periods of time to bring the indoor air temperature down to the set-point temperature but does not run long enough time to significantly reduce the humidity levels in the air. The mold accumulates in the air-conditioning ducts that were installed at the time of the original air-conditioning system. In several of the worse over-sized air-conditioning systems that the author has seen, the occupants became quite ill from the resulting mold growth and their entire living quarters had to be completely renovated.

In more temperate climates, many middle-aged (30 to 60 years old) and older (greater that 60 years old) residences have old inefficient heating systems where approximately 50% of the heating fuel is wasted. In most situations, the heating and cooling system sizing exercise is more complex since design drawings are usually not available and many residences have undergone a number of renovations. This makes it necessary to spend a lot of time in developing the building envelope plans and ascertaining the construction materials. In addition, most of these residences did not have air-conditioning systems installed at the time of construction. One recent development in air-conditioning duct systems is the use of properly designed smaller diameter higher velocity air ducts that can be installed in a manner similar to the way smaller diameter electrical wiring can be snaked into the walls, ceilings and floors without disturbing the inside and outside surfaces. Here, in addition to the more difficult air-conditioning sizing exercise, the design of the high velocity air duct retrofit also has to be carried out.

The technique for properly sizing a residential air-conditioning and heating system is based on methods described in Chapter 28 of ASHRAE [2]. Spreadsheet programs that duplicate these heating and cooling load methodology have been developed and used to evaluate the design heating and cooling loads for the residences in both hot and humid and more temperate climates using the specified outside design temperatures given in Chapter 27 of ASHRAE [2]. For cooling load calculations, the estimate of the latent cooling load is the most critical element in the selection of the size and type of retrofit air-conditioning system. For heating load calculations, the estimate of the air infiltration/ventilation rate contribution is the most critical element in the selection of the size and type of heating systems. The sizing results for two residences, one for cooling in a sub-tropical climate and one for heating in a temperate climate are presented in the next section of the paper. Conclusions and recommendations are made on the sizing criteria for residences in these two diverse climates.

CLIMATIC DATA TABLES

Two single family residences in a temperate location in Albany, New York (a second floor condominium) and a subtropical location in Tampa, Florida (a first floor condominium Unit) were studied. Tables [1] and [2] present a small portion of the data available for these two locations from Chapter 27-Climatic Design Information in ASHRAE [2] which presents selected climatic data for the United States, Canada and World locations. More detailed climatic data can be found in ASHRAE [3].

In Table [1], for winter design conditions, the second column gives the latitude, longitude and elevation for the two locations given in the first column. The third column gives the design (99.6% and 99% percentile) winter heating dry bulb temperatures that represent temperatures that are expected to only be exceeded 0.4% and 1.0% of the winter heating season. The fourth column represents design (5%, 2.5%, and 1% percentile) extreme wind speeds that are expected to only be exceeded 5%. 2.5% and 1% of the winter heating season.

In Table [2], for summer design conditions, the second column gives the latitude, longitude and elevation for the two locations given in the first column. The third column gives the design (0.4%, 1% and 2% percentile) summer cooling dry bulb and mean coincident wet bulb temperatures that represent temperatures that are expected to only be exceeded 0.4%, 1% and 2% of the summer cooling season. The forth column gives the mean daily range (difference between the daily maximum and minimum temperatures during the hottest month) of the dry bulb temperature.

The data in Tables [1] and [2] can be used in the determination of the design heating and cooling loads that are presented in the next section. It should be stressed here that the emphasis is on equipment sizing, not annual energy use.

Table 1 Winter Heating Design Conditions

LOCATION	Latitude Longitude Elevation (m)	Design Heating Dry Bulb ºC	Extreme Wind Speed km/h
Albany, New York	42.75º 70.38º 89	-21.7 (99.6%) -16.7 (99%)	30.6 (5%) 35.4 (2.5%) 38.6 (1%)
Tampa, Florida	30.38º 84.37º 21	2.2 (99.6%) 4.4 (99%)	24.9 (5%) 27.4 (2.5%) 30.6 (1%)

Table 2 Summer Cooling Design Conditions

LOCATION	Latitude Longitude Elevation (m)	Cooling Dry Bulb/Mean Coincident Wet-Bulb ºC	Range of Dry Bulb ºC
Albany, New York	42.75º 70.38º 89	32.2/21.7 (0.4%) 30/21.1 (1%) 28.9/20.6 (2%)	13.2
Tampa, Florida	30.38º 84.37º 21	33.3/25 (0.4%) 32.8/25 (1%) 32.2/25 (2%)	8.3

RESULTS

The following Chapters in the ASHRAE Handbook [2] were used in the calculation of the heating and cooling loads presented in the load calculation results tables:

Chapter 25: Thermal and Water Vapor Transmission Data
Chapter 26: Ventilation and Infiltration
Chapter 27: Climatic Design Information
Chapter 28: Residential Cooling and Heating Load
Chapter 30: Fenestration

Heating Load Calculation Results

Table [3] presents a summary table that summarizes the detailed room-by-room spreadsheet results for determining the heating load of a second floor condominium unit located in an approximately 100 year old three story building that was being converted to a two unit condominium association. The second floor unit also includes an unheated attic above it and a first floor unit below it. The ground floor is a partially above ground basement that contains the individual heating systems for the two condominium units. The second floor unit heating system uses oil as the heating fuel and the first floor unit uses natural gas as the heating fuel.

The two Unit Owners own the interiors of their individual units and share ownership of the exterior surfaces of the building and the surrounding land.

Table [3] gives results that follow the procedures presented in Table 12 (Summary of Loads, Equations, and References for Calculating Design Heating Loads) of Chapter 28: in ASHRAE [2]. The wall and floor areas and the ceiling height were obtained using a laser measuring device. The various U-values were obtained from the data and calculation methods presented in Chapters 25 and 30 in ASHRAE [2] for the specified building components. The determination of the construction of the wall, floor and ceiling required the temporary removal of a number of electrical fixtures (wall outlets and switches, ceiling lights) to determine the type and thickness of the various building materials used in the original construction. The data for the Albany, New York location from the Climatic Design Information given in Table 1B of Chapter 27 in ASHRAE [2] is listed in the top portion of Table [3]. The inside to outside temperature difference of 42.7ºC comes from the indoor design temperature of 21.1ºC and the 99.6% winter design dry bulb temperature of -21.6ºC. The temperature differences for the unheated attic were calculated from methods given in Chapter 25 in ASHRAE [2].

The critical heating load element, air infiltration, requires the use of Chapter 26 in ASHRAE [2] to estimate the sensible heating load due to air infiltration for the second floor condominium unit. The 5% design exterior wind speed of 30.6 km/h (19 miles/h) was used in applying two calculation models to obtain estimates of the infiltration flow rates. The “basic model” in Chapter 26 in ASHRAE [2] gave an infiltration rate of 0.62 air changes per hour (ACH) and the “enhanced model” gave an infiltration rate of 0.80 ACH. To be conservative in sizing the heating equipment for the not very well sealed 100 year old building, a value of 1.0 ACH was used. Multiplying the floor (or ceiling in this case) area of 118 m^2 by the ceiling height of 2.6 m gives a volume of 307 m^3. With one ACH, the air infiltration volume flow rate is 307 m^3/h as shown in Table 3.

Cooling Load Calculation Results

Table [4] presents a table that summarizes the detailed room-by-room spreadsheet results for determining the cooling load of a first floor condominium unit located in an approximately 30 year old four story building that contains 22 condominium units. The ground floor is a parking garage. The Table [4] results are obtained from the procedures presented in Table 9 (Summary of Procedures for Residential Cooling Load Calculations) of Chapter 28 in ASHRAE [2]. In addition, a number of related tables and figures, their footnotes and detailed example calculations in Chapter 28 in ASHRAE [2] are used in the spreadsheet calculations for determining the various elements of the total sensible load. The areas, material properties are determined in the same manner as in the heating load calculations. Glass (windows and doors) are treated differently. A glass factor replaces the U-value and temperature difference to account for the peak solar and sensible heat load. This factor is a function of the type of glass; the orientation, inside and outside shading; the design outdoor temperature (the 0.4% value of 33.3°C given at the top portion of Figure [4] was used in the calculations) and the indoor design temperature (23.9°C was used). For exterior walls and floors, a cooling load temperature difference (CLTD) is determined by orientation; outside shading; the design outdoor temperature and the indoor design temperature. The air infiltration is not as important a factor as it is for heating situations. In Table [4], an ACH of 0.72 was used. It should be noted that the various temperatures have been rounded off to the nearest °C, however the resulting energy values include the non-rounded off values in the detailed spreadsheet calculations.

The critical cooling load element, the latent load, is estimated from the outdoor design humidity ratio and the type of construction (loose, medium, tight) in Figure 1 of Chapter 28 in ASHRAE [2] to determine a load factor (1.16 was used) which is multiplied by the total sensible load to arrive at the latent load as given near the bottom of Table [4]. A properly sized air-conditioning system has to be able to remove a significant amount of moisture from the air in sub-tropical climates.

DISCUSSION

The total heating energy required in the condominium in Albany, New York is 14363 W (in I-P units 48982 Btu/h). The oil-fired heating system has low pressure steam delivered to radiators in each of the heated rooms. This system also supplies some water vapor to the rooms to allow a comfortable winter relative humidity level to the occupants. Preliminary spreadsheet calculations indicated that insulating the ceiling/attic floor would reduce the energy to the unheated attic space enough to economically warrant the expense of having fiberglass blown into the cavity between the attic floor and 2nd floor ceiling. The original heating system (boiler) was rated at 75000 Btu/h and the new higher efficiency boiler system was rated at 50000 Btu/h. Both ratings account for the heating system piping losses to the basement. The first season of oil consumption with the new heating system was 40% less than the prior years. However the cost savings was much smaller due to the increase in heating fuel prices.

In addition to the new heating systems for both of the Albany, New York condominium units, new 16 SEER (seasonal energy efficiency ratio), two-stage air-conditioning systems were also added to both units. See Dulley [4] for details of this type of modern high-efficiency, split system air-conditioning systems. Detailed cooling load calculations similar to that for the condominium in Tampa, Florida were performed. For the second floor unit studied here, the evaporator coil/air handler unit was located in the basement near the outdoor compressor/condenser unit. New high velocity smaller diameter duct work (supply and return) was snaked through the first floor unit walls to the second floor unit walls. See Dulley [5] for details of these types of mini-duct, pressurized central air-conditioning systems.

The total cooling energy required in the condominium in Tampa, Florida is 11939 W (in I-P units 40745 Btu/h or 3.4 Tons). The original over-sized air conditioning system was rated at 4 tons or 48000 Btu/h. The new replacement high 16 SEER high-efficiency, heat pump air-conditioning system was rated at 3 tons or 36000 Btu/h. The reason for selecting a lower rating than the calculated load was due to the fact the Unit Owner was away during the summer season and had recently installed hurricane shutters which significantly reduce the sensible cooling load and forced most of the replacement air to come from the air-conditioned hallway at a humidity ratio much lower than that of the outside air that normally came in through the west facing outside windows. In addition, a humidistat was added in parallel to the thermostat to insure that high relative humidity ratios did not occur while the Unit Owner was away. After two summers with the new air-conditioner reduced the Unit Owners electric bill by over 30% and the occurrence of mold growth was reduced significantly. During the short winter heating season, the electric costs were also reduced by using the new air-conditioning system in the heat pump mode which is more efficient that the electric heating in the original system.

In summary, it can be seen that significant energy savings can be achieved by properly sizing heating and cooling system without any reduction in user comfort.

Moisture convection performance on the joint of external wall and attic floor - laboratory tests and two-dimensional simulation model validation

Targo Kalamees, Jarek Kurnitski

HVAC-Laboratory, Helsinki University of Technology

Corresponding email: targo.kalamees@ttu.ee

SUMMARY

Full-scale laboratory measurements were conducted to determine moisture convection performance on the joint of external wall and attic floor. According to field measurements in previous studies this joint is one of the most typical air leakage paths. On this joint also the highest air pressure difference forms in winter. Two commonly used external walls: timber-frame and autoclaved aerated concrete walls were measured. The attic floor was in both cases a timber-frame structure. Results from the first laboratory measurement series showed that in leaky joint the moisture convection due to positive air pressure remarkable raised moisture accumulation rate on the inner surface of sheathing. A two-dimensional heat, air, and moisture transport computer model was validated for future analysis. The simulation results showed that CHAMPS-BES program is useful tool in assessing the moisture behaviour of building components including moisture convection.

INTRODUCTION

Accurate assessment of hygrothermal performance of building envelope is important to prevent moisture damages and to guarantee longer service life as well better indoor air quality for buildings. Usually, in consulting companies, the hygrothermal dimensioning of building envelope is limited to the moisture accumulation in structures based on the Glaser-method that is a simple method for determining the risk of moisture condensation. Unfortunately, this method has many limitations: the method is the steady state, it does not consider hygroscopic materials, vapour diffusion is the only transport mechanism, condensation is only performance criterion, there are no coupling between the heat and moisture transport, and material properties are constant.

Ventilated facade claddings are commonly used in timber-frame walls that should protected it from driving rain. If timber-frame wall haves a vapour barrier that controls the vapour diffusion, the major humidity load is usually the outgoing airflows due to air leakage. The role of air exfiltration for the hygrothermal performance of the building envelope is analysed in many studies [1, 2, 3, 4]. The uncontrolled air movement through a building envelope is not only hygrothermal problem, but may lead also to problems related to the health, energy consumption, performance of the ventilation systems, thermal comfort, noise, and fire resistance.

Air leakage through a building envelope depends on the result of air-pressure differences over the envelope and air tightness of the building envelope. The positive air pressure difference over the building envelope can be utilised in the control of radon, particulate matter, fungal spore or other contaminant transport to the indoor air. At the same time high indoor humidity load and positive air pressure conditions may cause intensive moisture accumulation in building envelope. As air pressure difference over the building envelope cannot be avoided even in typical residences [5] and buildings with timber-frame envelope are not totally airtight [6, 7], convection should be take into account in the process of hygrothermal design. As air leakages are concentrated to the joints of different envelope parts (wall, roof, floor, window), the air leakage is multidimensional and two-dimensional measurements and simulation should be done.

In this study typical air leakages and their locations were determined from the field measurement data reported in [8]. A full-scale laboratory measurements were carried out to determine moisture convection performance on the joint of external wall and attic floor. A two-dimensional heat, air, and moisture transport computer model is validated for future simulations.

METHODS

Laboratory measurements

Two commonly used external wall (timber-frame wall (Figure 2) and autoclaved aerated concrete (AAC) wall (Figure 3)) joints with timber-frame attic floor is measured in laboratory conditions between climatic chambers. The warm climatic chamber is equipped with heating and humidification units and it simulates the indoor climate. The cold climatic chamber is equipped with refrigeration, heating and humidification units simulating the outdoor climate. The climatic chambers are automatically controlled and continually maintain equilibrium of various climatic parameters, such as air temperature, relative humidity (RH), air pressure difference over the examined structure.

Studied two-dimensional joint details consist of 1.2 by 0.7 m (width by height) external wall part and 1.2 by 0.9 m attic floor part. Studied setup was built as much as possible airtight and special well-defined air leakages were constructed for the joint. In timber-frame wall/attic floor joint the 10 cm wide air leakage was let between two air/vapour barrier foils. In AAC wall/attic floor joint a ~1…2 mm thick and 10 cm wide air gap was let between wall plate and AAC block. The real air inflow through the air leakage part and overall air tightness of the joint with closed air leakage part were measured with an electronic soap film calibrator (bubble flow meter), Figure 1.

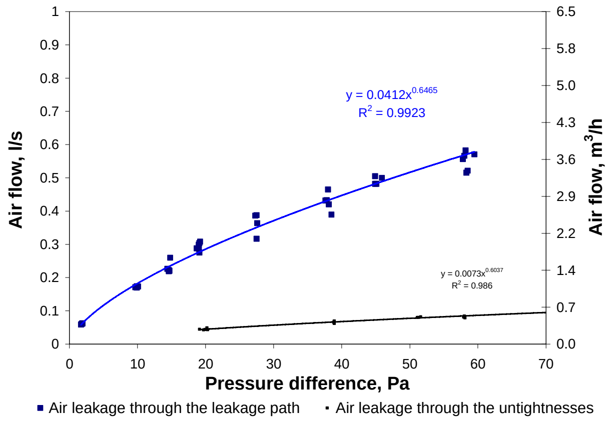

Figure 1 Measured air leakage thought the airgap between two air/vapour barrier foils (timber-frame wall/attic floor).

The laboratory measurements were done at -6 °C and -11 °C outdoor temperature conditions. The moisture excess (Δv, the difference between indoor and outdoor air's humidity by volume) was 4 g/m^3 in both tests. According to measurements in detached houses, this is the design value of moisture excess for dwellings low occupancy [9, 10]. The air pressure difference (ΔP) was +10…+11 Pa. According to measurements and simulations in detached houses the design value of air pressure difference over the building envelope should be at least ±10Pa [5].

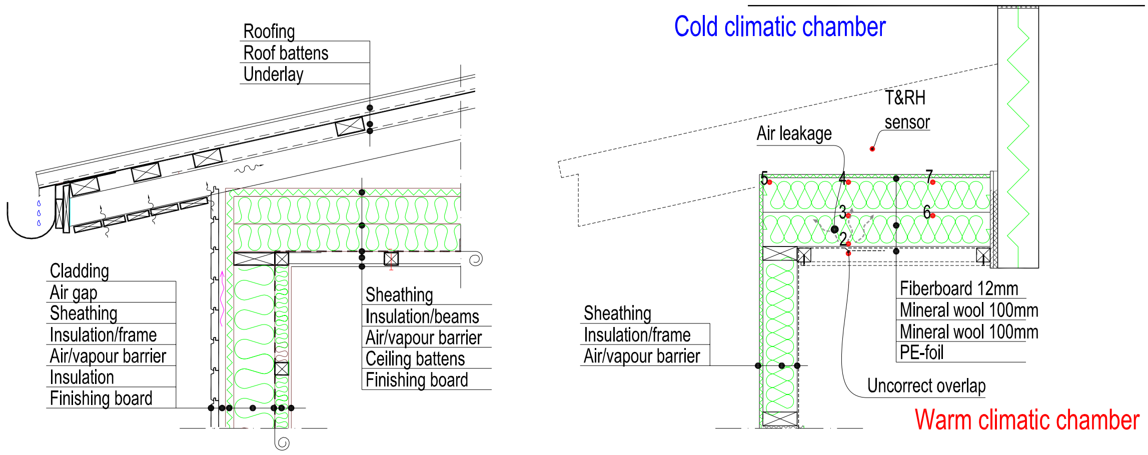

Figure 2 Studied timber-frame wall joints with timber-frame attic floor (left) and the studied joint in laboratory conditions between climatic chambers (right). Temperature and RH measurement points are shown by red dots.

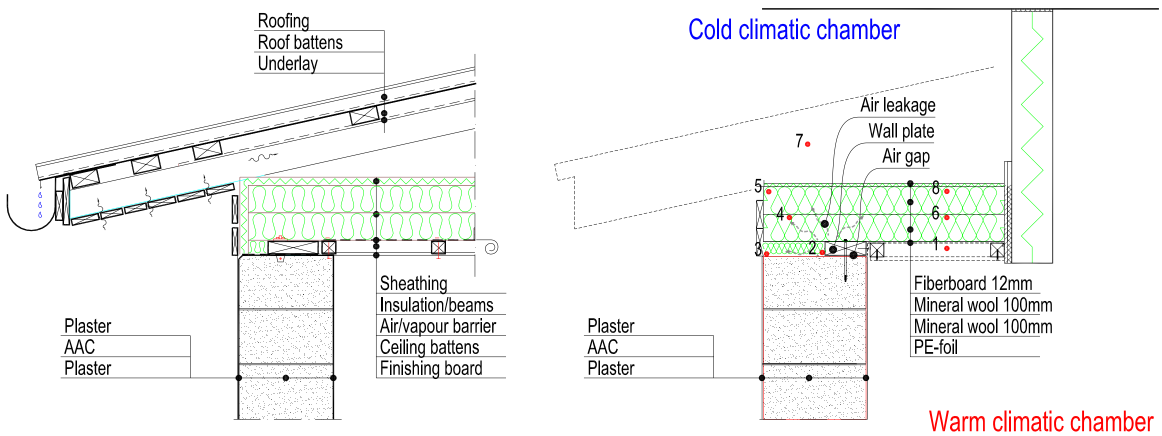

Figure 3 Studied autoclaved aerated concrete wall connection with attic floor (left) and the structure in laboratory conditions between climatic chambers (right).Temperature and RH measurement points are shown by red dots.

Simulation mode

Based on laboratory measurements the simulation model built with CHAMPS-BES program (Coupled Heat, Air, Moisture and Pollutant Simulation in Building Envelope Systems) (version 1.4.1) was validated for future analysis. This program is an outcome of a joint effort between Building Energy and Environmental Systems Laboratory at Syracuse University, U.S.A. and Institute for Building Climatology at University of Technology Dresden, Germany.

CHAMPS-BES modelling comprises the description of fluxes in the calculation domain or in the field (between volume elements including material interfaces) and at the boundary (between volume elements and exterior or interior rooms) by physical models. Also included are models for storage processes like adsorption, desorption and release. The numerical solution is done by semi-discretization in space (using a finite/control volume method) and subsequent integration in time [11].

The governing equation for the moisture balance is:

$$\frac{\partial}{\partial t}\rho_{REV}^{m_{w+v}} = -\frac{\partial}{\partial x}\left[j_{conv}^{m_w} + j_{conv}^{m_v} + j_{diff}^{m_v}\right] \quad (1)$$

where:

$\rho_{REV}^{m_{w+v}}$	Moisture (liquid+vapour) density in reference volume, kg/m^3
$j_{conv}^{m_w}$	Convective liquid (capillary) water flux, kg/m^{2}s
$j_{conv}^{m_v}$	Convective water vapour flux, kg/m^{2}s
$j_{diff}^{m_v}$	Diffusive water vapour flux, kg/m^{2}s

The governing equation for the air mass balance is:

$$\frac{\partial}{\partial t}\rho_{REV}^{m_a} = -\frac{\partial}{\partial x}\left[j_{conv}^{m_a}\right] \quad (2)$$

where:

$\rho_{REV}^{m_a}$	Air mass density in reference volume, kg/m^3
$j_{conv}^{m_a}$	Convective air mass flux, kg/m^{2}s

The governing equation for the energy balance is:

$$\frac{\partial}{\partial t}\rho_{REV}^{U} = -\frac{\partial}{\partial x}\left[j_{diff}^{Q} + u_l\, j_{conv}^{m_l} + u_g\, j_{diff}^{m_g} + h_v\, j_{diff}^{m_v}\right] \quad (3)$$

where:

ρ_{REV}^{U}	Internal energy density in reference volume, J/m^3
j_{diff}^{Q}	Heat conduction, W/m^2
u_l	Specific internal energy of liquid phase, J/kg
u_g	Specific internal energy of gas phase, J/kg
$h_v\, j_{diff}^{m_v}$	Specific enthalpy of water vapour, J/kg

In the simulation for the material properties such as density, thermal conductivity, moisture permeability, and moisture storage function the measured material properties from Tampere University of Technology [12] were used. The example of the construction view of the simulated timber-frame walls connection with attic floor is shown in Figure 4.

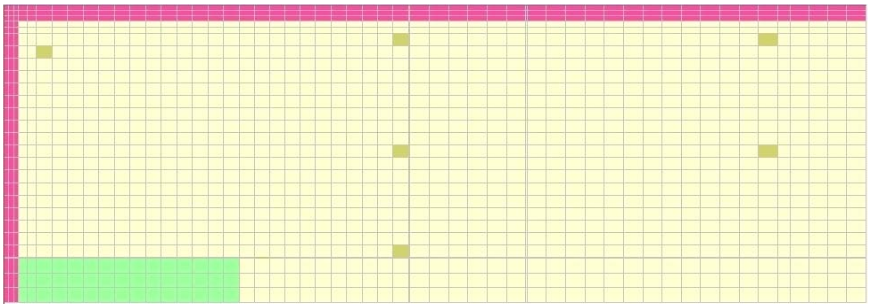

Figure 4 The grid of simulated timber-frame walls connection with attic floor. Temperature and RH measurement points are shown by shaded points. (green, yellow and red colours mark sheathing, mineral wool, and wood materials respectively).

RESULTS

Laboratory measurements

Full-scale laboratory measurements were performed to analyse moisture convection performance of the joint of external wall and attic floor and to get reference data to compare simulation results. Boundary conditions for the first two measurement series are shown in Table 1. Laboratory tests were made in two cycles: first, to stabilise the joint of external wall and attic floor, the test was done with closed (taped) air leakage path. This cycle continued 1…2 weeks. After that, the 10 cm long air leakage was let between air/vapour barrier foils (timber-frame wall/attic floor joint) and between wall plate and AAC block (AAC wall/attic floor joint). The measurements are continued with other indoor humidity loads, air pressure differences, air leakage conditions, and other sheathing materials.

Table 1 Boundary conditions for the first two measurement series

Test	T_{in}, °C	RH_{in}, %	T_{out}, °C	RH_{out}, %	ΔP, Pa	$\Delta \nu$, g/m^3
1	21	32	-11	77	+11	4
2	20	37	-6	75	+10	4

There was condensation and frost formation on the inner surface of the sheathing of the attic floor in the end of the tests 1 and 2, Figure 5. During 30-day measurement period in Test 1 the increase in the mass-related moisture content of the wood fibreboard sheathing of the attic floor on the test 1 was 10 % and the final moisture content was 22 %.

Figure 5 Condensation and frost with mineral wool pieces on the inner surface of the sheathing of the attic floor on the timber-frame wall (left) and the AAC wall (right) cases.

Comparison of laboratory tests and results of simulations

To develop the model for the future analysis, the simulation program CHAMPS-BES was validated based on full-scale laboratory measurements of Test 2.

Comparison of measured (Test 2, Table 1) and simulated temperature, RH, and the humidity by volume on the outer surface of insulation (behind the sheathing of the attic floor: T&RH sensors 4, 5, 7 in Figure 2) are shown in Figures 6-8.

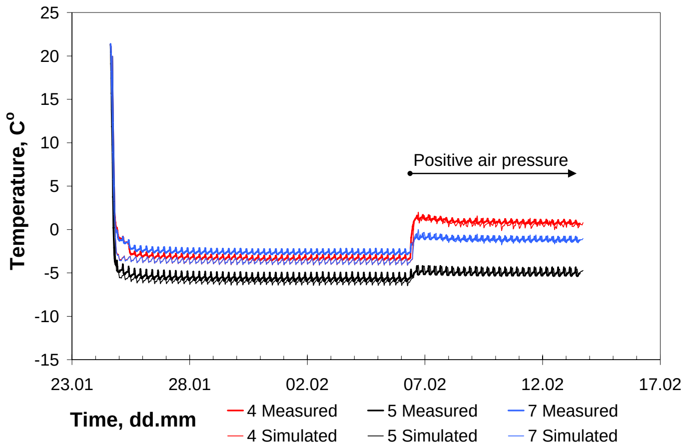

Figure 6 Simulated and measured temperatures behind the sheathing of the attic floor in the case of timber-frame walls connection with attic floor.

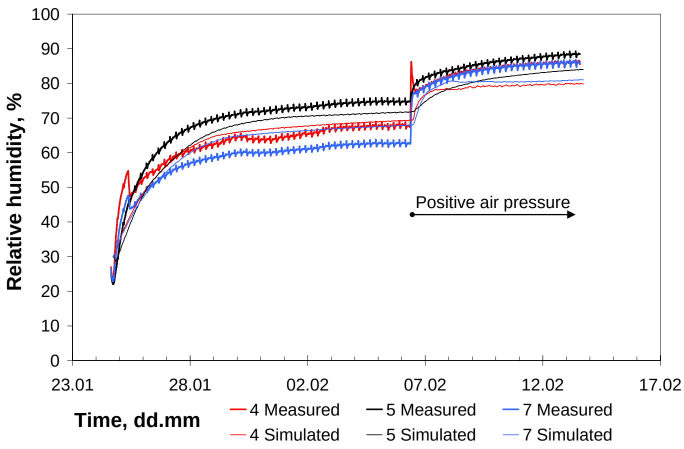

Figure 7 Simulated and measured RH behind the sheathing of the attic floor in the case of timber-frame walls connection with attic floor.

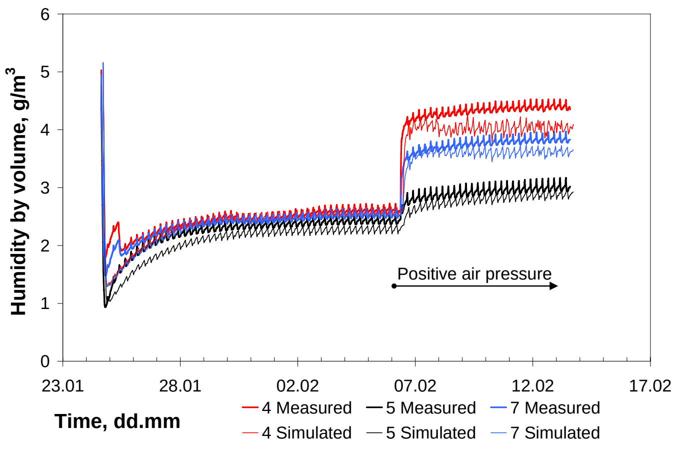

Figure 8 Simulated and measured humidity by volume behind the sheathing of the attic floor in the case of timber-frame walls connection with attic floor.

DISCUSSION

There was condensate and frost formation on the inner surface of the sheathing of the attic floor in case of positive air pressure difference +10…11 Pa and moisture excess +4 g/m^3. Moisture convection remarkable raised moisture accumulation rate: during the Test 1 (T_{out} -11°C) the increase in the moisture content of the wood fibreboard sheathing of the attic floor after 30 day period was 10 % and the final moisture content was 22 %. During the Test 2 (T_{out} -6°C) the frost formation took just longer time. The high moisture content can offer suitable conditions for mould, wood decay fungi, reduce the thermal resistance of building materials and change building physical properties of materials and deform materials.

Field measurements in Finnish detached houses [8] showed that one typical air leakage place was in the joint of attic floor with the external wall. Measurements in Estonian detached houses [7] showed, that more typical air leakage place was in the joint of interstitial floor with the external wall. The RH at the connection of intermediate floor and external wall can be rather high causing the risk of the growth of mould and rot fungi when there is positive air pressure inside the building [13]. As the air pressure difference over the building envelope on the joint of attic floor with the external wall is higher than in the joint of intermediate floor with the external wall, this joint was analysed in current study.

It is not possible to take into account the geometrical change of materials in simulation programs. Nevertheless during measurements the fiberboard sheathing swelled due to moisture accumulation. The joints of timber-frame and AAC walls with the timber-frame attic floor were simulated as two-dimensional joint. In reality, the convection in joint was surely three-dimensional (look condensation areas in Figure 5). These two facts as well as the fact that studied joints consist small imperfections that cannot be modelled may be the main reasons for the difference in comparison of simulation and measurement results. The main difference between measurements and simulations was that the moisture accumulation continued in measurements, while in the simulations the moisture content remained to the fixed level, Figure 8.

CONCLUSIONS

The moisture convection performance on the joint of external wall and attic floor was studied by full-scale laboratory measurements. A two-dimensional heat, air and moisture transport computer model was validated for future analysis.

Results from the first laboratory measurement series showed that in leaky joint the moisture convection due to positive air pressure remarkable raised moisture accumulation rate on the inner surface of sheathing.

Despite of some discrepancies between the results of laboratory measurements and computer simulations, the simulation program CHAMPS-BES showed good performance and is useful tool in assessing the moisture behaviour of building components including moisture convection.

The results will be utilized in further analyses aiming to specify air leakage properties allowing to expose studied structures to defined positive pressure and indoor humidity load. If necessary, the studied structures will be further developed so that the moisture convection problem can be controlled in the construction.

ACKNOWLEDGEMENT

This study was supported with a grant from the Finnish Academy (grant 210683). The authors are grateful to prof. John Grünewald from Dresden University of Technology, one author of the CHAMPS-BES program that was used in this study.

Different strategies to control humidity in Swiss low energy buildings

Beat Frei, Larissa Wenger and Sven Moosberger-Kropf

Lucerne University of Applied Sciences, Switzerland

Corresponding email: bhfrei@hta.fhz.ch

SUMMARY

For the approximation of the internal loads of humidity, too high values are often chosen in Swiss low energy houses. Later on in reality, the occupation and the presence in the dwellings are significantly lower. These leads to high specific air volume rates and consequently to low humidity levels. Humidification by vapour generators, humidity recovery and optimized air volume rates are currently applied. Engineers can now calculate the internal humidity loads without humidity storage in walls etc. They can chose of humidity recovery and/or a vapour generator and set minimal and maximum values for relative humidity. The calculation of the resulting relative humidity and the consumption of electricity and water for the vapour generation are presented in figures. Simulations with IDA ICE have shown that the control strategy with humidity recovery had higher resulting relative humidity than the control strategy with the reduced and optimised air volume rates.

INTRODUCTION

A comparative study on Swiss low energy buildings indicated three important results: Heating energy consumption was reduced by a factor of five compared to conventional buildings, electricity consumption surprisingly remained at the average of Swiss households, and the humidity was below 30 % R.H. for thousands of annual hours. To enhance humidity level manufacturers have now started to promote centralized vapour generators even in low energy buildings. First calculations in the comparative study showed that vapour generators require more specific energy for humidifying than for heating a low energy building. At this point the project “Humidity in Swiss low energy buildings”, funded by the Swiss federal office of energy, has been started. Furthermore six partners from industry are involved in the project. The purpose of the project is to determine how the energy consumption for humidifying in low energy buildings can be reduced or even avoided. Further important parameters are thermal comfort and hygiene. The project was started in June 2006 and will be finished in June 2007.

METHODS

Equipment testing

The first part of the project focuses on the equipment. Rotary and plate heat exchangers in compact ventilation units are now capable of moisture transfer and are tested at the testing facility at the HTA Lucerne. A description of the testing facility with its entire possibilities can be found in the test guideline [2]. The testing facility was designed and built to satisfy present and future requirements as completely as possible, especially key data regarding air conditions. With this testing facility all important operating conditions for comfort ventilation systems can be replicated. The following types of appliances (and combinations thereof) can be tested within a volume flow range from 50 m^3/h up to 1200 m^3/h:

- Units with supply and return air and heat/moisture recovery (recuperative and regenerative)
- Units with supply and return air, heat recovery and exhaust-air heat pump to heat the supply air
- Units with return air, exhaust-air heat pump to heat domestic hot water
- Units with return air, exhaust-air heat pump which heats domestic hot water and/or transfers heat to another water-bearing system

a)

b)

Figure 1. Test center for compact ventilation units a) Outside view b) Internal view

As the test facility is especially designed to accommodate acoustic measurements, the acoustic characteristics of compact units can be tested during thermal performance. Thanks to the two testing chambers with double walls, the base sound level can be minimised, allowing measurements of the sound power level radiated by the casing into the testing chamber as well as the sound power level emitted through the air connections into the ducts. The air can be conditioned to the following specifications for testing purposes:

Table 1. Range of air conditions

Quantity	Outside air	Return air	Testing chamber
Temperature [°C]	-12 to +21	21 to 26	10 to 26
Humidity [% R.H.]	70 to 80	30 to 60	-
Air volume flow [m^3/h]	50 to 1200	50 to 1200	-

For the different strategies to control humidity in Swiss low energy buildings the existing test guideline to test compact ventilation units [2] had to be enhanced. Up to now compact ventilation units were not able to recover humidity. Therefore suitable test conditions in winter and summer had to be determined.

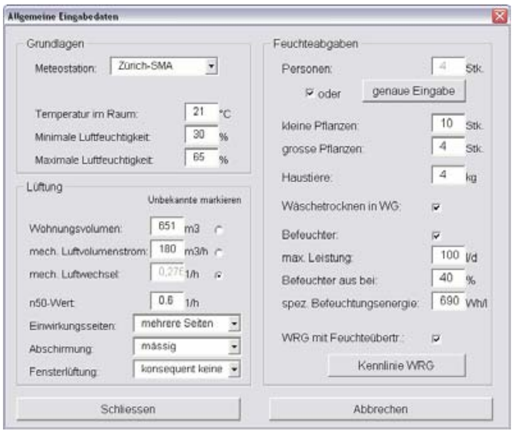
Table 2. Test conditions for humidity recovery

	1	2	3	4	5	6	7	8	9
$\vartheta_{Return.}$ [°C]	21	21	21	21	21	21	21	25	25
Φ_{Return} [%]	25	30	37	45	50	50	50	50	50
$\vartheta_{Outside}$ [°C]	-7	-3	+2	+7	-3	+2	+10	35	35
$\Phi_{Outside}$ [%]	80	80	80	80	80	80	80	50	35
Δx [kg/kg]	0.0022	0.0023	0.0023	0.0021	0.0054	0.0044	0.0017	0.0082	0.0074

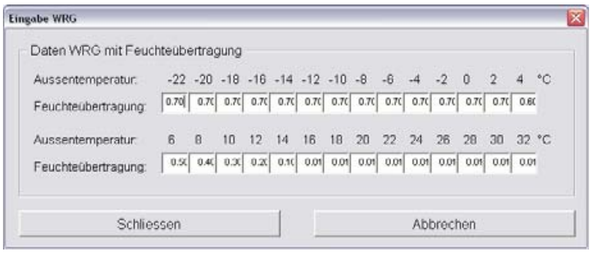
For the second part of the equipment testing the performance of a special type of vapour generator currently used in low energy buildings is determined in laboratory tests. Especially the control characteristics and the use of electricity are of interest.
Furthermore another vapour generator is under investigation by field measurements. In a location in Central Switzerland the behaviour of a commercially available vapour generator designed for low energy buildings is measured. Parameters are temperature, relative humidity, and electrical energy consumption. The same type of vapour generator is also under investigation in the laboratory tests.

Calculation tool

The second part of the project is the development of a calculation tool for engineers to estimate internal humidity loads, performance of humidity recovery, energy consumption of vapour generation and the resulting annual hours of relative humidity during the Swiss heating season from October to March. Actually eleven metrological stations located in Switzerland can be chosen by the user. Earlier studies [1] revealed that the internal moisture loads by plants, animals, and human is overestimated in some cases by a factor of two in calculation standards. Later on low relative humidity values are often measured. By the way it has to be mentioned that high specific air exchange rates – as a result of low occupancy – are frequent in Swiss low energy buildings. More appropriate values for internal moisture loads were once again reviewed in literature and are now fully implemented in the calculation tool. With this development state of the calculation tool the engineer is able to predict the moisture behaviour of the future dwelling. There is only one limitation in this calculation tool: Internal moisture storage capacity of e.g. walls is not implemented. In that case, the use of a simulation tool is recommended. The application of this software package is described in the next part of this paper.



a)



b)

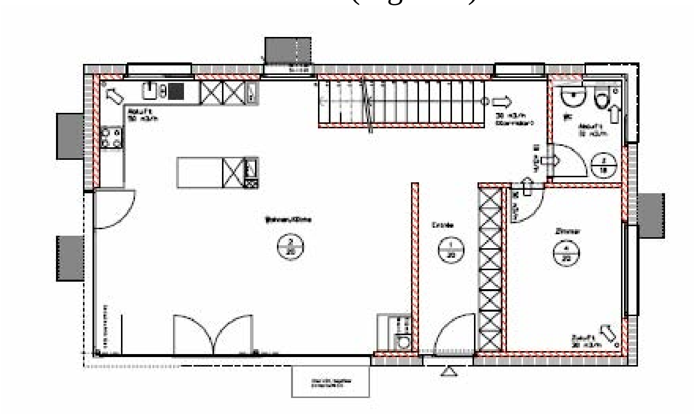
c)

Figure 2. Input data. a) Basic data, b) user-defined values for humidity recovery functions, c) values for occupancy

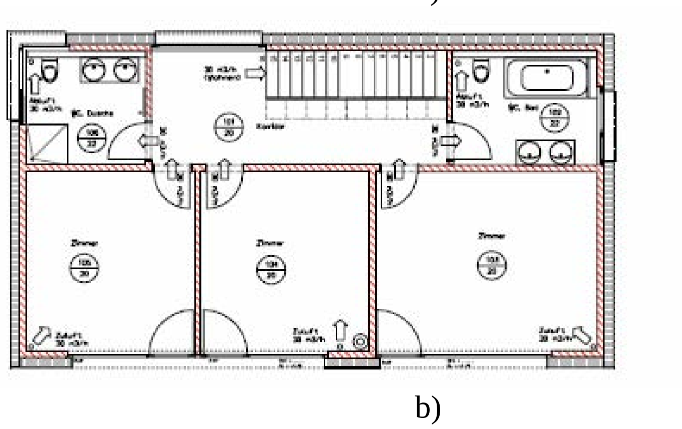
As shown in Figure 2a the user has to select the appropriate metrological station, to determine values for parameters like temperature, minimal relative humidity, maximal relative humidity, room volume, air volume rate, air exchange rate, air tightness of building envelope, number of plants, number of animals, and finally the specific data for the vapour generator. Figure 2b shows the possibility of user-defined values for the humidity recovery functions.

Simulations with IDA ICE

The third part of the project deals with the control of air flow rates to enhance humidity levels. Too high specific air exchange rates – as a result of low occupancy – are frequent in Swiss low energy buildings. The heating load in low energy buildings can be covered by preheating the supply air. A reduction of the air flow rate is therefore limited by the capability to fulfil the heating load requirement by the ventilation system. The control of air flow rate strategy is evaluated by the building simulation tool IDA ICE.
The fundamental input data was taken from the reference dwelling of the Swiss standard SIA 384.201. It is a three floor building located in Central Switzerland. The energy reference area is totally 160 m^2 respectively 80 m^2 for the cases with low occupancy. The floors were divided into thermal zones (Figure 3).



a)



b)

Figure 3. Input data. a) Ground floor with thermal zones, b) 1st floor with thermal zones, c) Ground floor with one respectively two occupants

By definition the following parameters where changed for each calculation:
- Number of occupants (1, 2 or 4)
- Capacity of moisture storage (low, medium, high)
- Control strategy (CO_2, combination of CO_2 and humidity)

Simulations for six cases of parameter combinations were done:

Table 3. Definitions for ten cases of IDA ICE simulations.

Case	**Number of occupants**	**Moisture storage capacity**	**Control strategy**	**Moisture recovery by wheel/plate- HEX**
1	4	low	CO_2	no
2 (Ref.)	4	medium	CO_2	no
3	4	high	CO_2	no
4	2	medium	CO_2	no
5	1	medium	CO_2	no
6	4	medium	CO_2 and humidity	no
7	4	medium	Constant air volume rate	yes
8	4	medium	Constant air volume rate	yes
9	4	low	Constant air volume rate	no
10	4	low	Constant air volume rate	yes

The following border conditions were used in the simulations:
Energy reference area: 80 respectively 160 m^2
• U-value roof: 0.13 W/m^2K
• U-value exterior wall: 0.15 W/m^2K
• U-value ground: 0.21 W/m^2K
• U-value window: 0.91 W/m^2K

Operation data for the simulations (adjusted):
• Air temperature living/kitchen, entrance, corridor, sleeping rooms: 20 °C
• Air temperature WC: 18 °C
• Air temperature bath: 22 °C
• Basic air volume rate depending on occupancy: 130, 80, 60 m^3/h
• Outdoor- / exhaust-air was divided and adjusted to the occupancy

Comparative study

The final part of the project is a comparative study on different ways to control humidity in low energy buildings: Energy, thermal comfort and hygiene are parameters.

RESULTS

Equipment testing

Four different compact ventilation units are currently being tested for this project. The measurements are not yet finished. In Figure 4 some recovered moisture coefficients in function of the condensation potential are shown as an example. The condensation potential is the difference between the absolute humidity of outside and exhaust air.

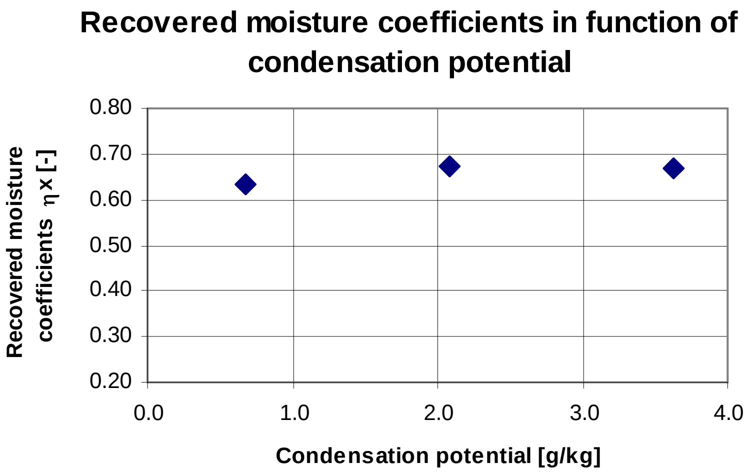


Figure 4. Recovered moisture coefficients in function of condensation potential.

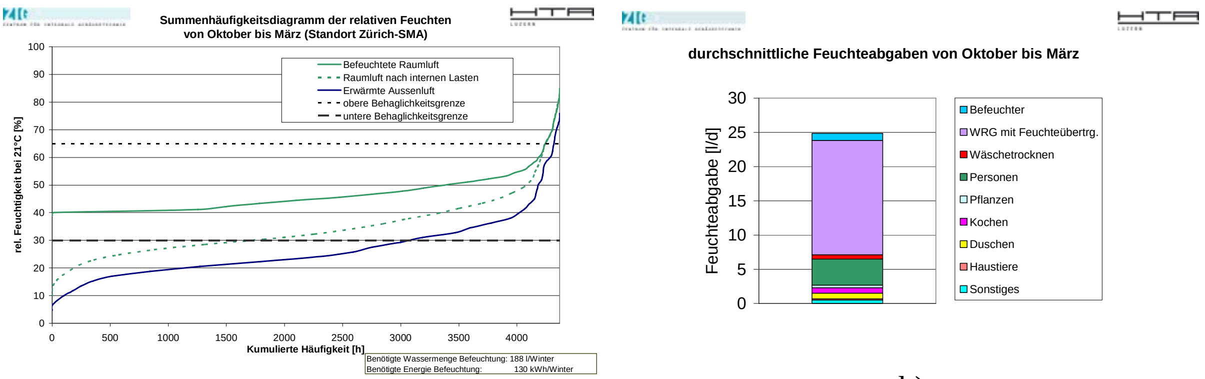
Calculation tool

HVAC Engineers can now calculate the internal humidity loads without humidity storage in walls etc. They can apply the use of humidity recovery and a vapor generator and set minimal and maximum values for relative humidity. The calculation of the resulting relative humidity and the consumption of electricity and water for the vapour generator are presented in Figure 5. The results obtained by the calculation tool will be compared later on to those obtained by simulation in a validation procedure.



a) b)

Figure 5. Output data. a) Annual hours for relative humidity, b) internal moisture loads

Simulations

Simulations have shown that the control strategy with humidity recovery and constant air volume rates had a higher resulting relative humidity than the control strategy with the reduced and optimised air volume rates (CO_2). Obviously the constant air volume rate strategy without recovery or vapour generation leads to the lowest humidity level in January.

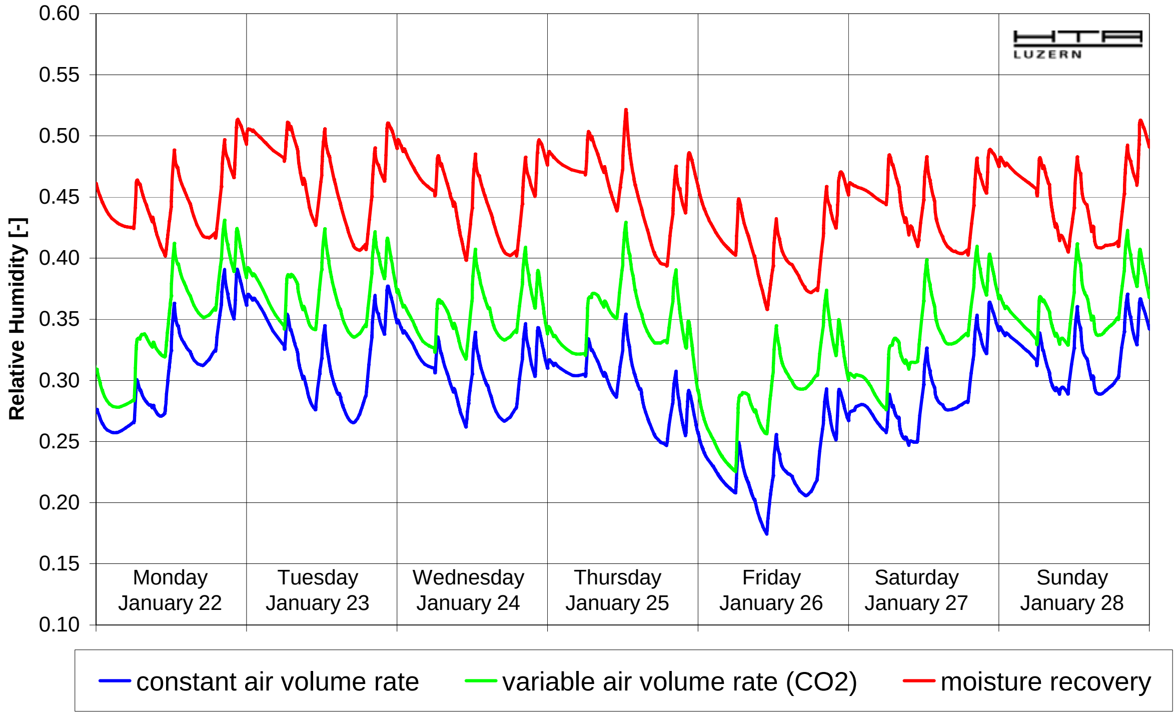


Figure 6. Simulations of three different control strategies for the living room.

Comparative study

From a general point of view, it is clear that every system has its own advantages and disadvantages. The use of vapour generators is certainly not the optimal solutions for low energy buildings. It is demanding that the additional use of electricity has to be minimized. Unfortunately, up to now it was not possible to significantly reduce the consumption of electricity in Swiss energy houses. Often the owners of these houses are not aware of the relatively high electricity consumption compared to the low energy consumption for heating. In newer publications, it was stated that the use of rotary heat exchanger has influences on the hygiene. Obviously, the best solution is the reduction of air volume rates. Surprisingly not in the resulting relative humidity, but it is still the best solution for the low occupancy and presence of people experienced during daytime.

DISCUSSION

Due to technical problems, there is a delay in the project especially in equipment testing. The lack of appropriate standards and definitions for the testing of humidity recovery in compact ventilation units has made the test procedure more time consuming than expected. Currently ISO 13417 is under revision to fit the new developments in compact ventilation units.

Simulations revealed that there is a potential in the application of humidity storage materials in walls to enhance the humidity levels in a longer range in low energy houses.

ACKNOWLEDGEMENT

The Swiss federal office of energy under Contract Nr. 152268 and seven partners of industry funded the research. Their continuous support was valuable and appreciated by the authors.

SUMMARY

The present communication forms part of the conclusions to emerge from the research project "Development of a methodology for the estimation of ventilation efficiency in residential houses" financed jointly by the Spanish Ministry of Education and Science and by ERDF, and carried out from 2003 to early 2006.
The aim is to present the results obtained for ventilation efficiency in systems of hybrid ventilation for houses, which is about to be implemented in Spanish legislation. We will provide a summary of studies conducted on air extraction rooms, such as bathrooms or kitchens, and transit or air circulation areas such as corridors, halls, or distributors.
For this purpose, representative typologies have been chosen, and a twin study has been performed using an experimental model in a laboratory with photoacoustic techniques of tracer gases, and a numerical model with CFD (Computational Fluid Dynamics) software techniques.
Numerical procedure validation has enabled us to emulate a variety of common situations different to the tested model and obtain conclusions on the architectural design of houses, thus allowing us to improve indoor air quality (IAQ).

INTRODUCTION

At the Higher Technical School of Architecture in the University of Valladolid we have been researching into the study of ventilation in houses for several years. This study has emerged to a large extent due to the new legislation on Indoor Air Quality (IAQ) introduced by Spain's "Technical Building Code" in which we have been involved.

The last research project has served as the basis to study efficiency in areas where air extraction in houses is common, such as bathrooms and toilets. This work has also served to define the performance protocols for the remaining rooms in houses.

The ultimate goal of the study is to increase ventilation efficiency in order to seek a reduction in volumetric flow rates with the desired energy savings. The immediate objective for toilets and bathrooms would be to specify design criteria to obtain ideal ventilation for these areas.

METHODS

The experimental model was performed inside a 4.80 x 6.00 x 3.60 m (width, length, height), test chamber designed expressly for this project and fitted with the following equipment and instrumentation:

- to obtain the appropriate volumetric flow rate of the air, centrifugal fans UPE 145/200 cm of 37 W and CAB-125 were used. To provide a homogeneous mixing of the gas tracer inside the enclosure, another independent fan BSH-PAE C_VT01 of 30 W was used.
- to regulate the volumetric flow rate of the air, a frequency inverter was used, and to control it two digital anemometers RS 180-7111 and a nozzle TG-40 of calibration were used.
- to control the airtightness of the room the fans were in use with the same frequency inverter and a manometer for measuring the pressure of the interior of the chamber.
- to monitor air movement, we used a smoke machine, model Fz-1200 of 1.2 kW and 500W halogen cycle projectors, together with a video camera for recording.
- to measure air age, we used equipment with a gas analyzer model 1302, a sampler-doser model 1303 and sulphur hexafluoride as tracer gas, managed by 7620 software on a PC computer.

Figures 1, 2 and 3 respectively show a general outside view of the test chamber, the subchamber that represents the bath, and the most important instrumentation, comprising the multi-gas monitor with the multipoint sampler and doser.

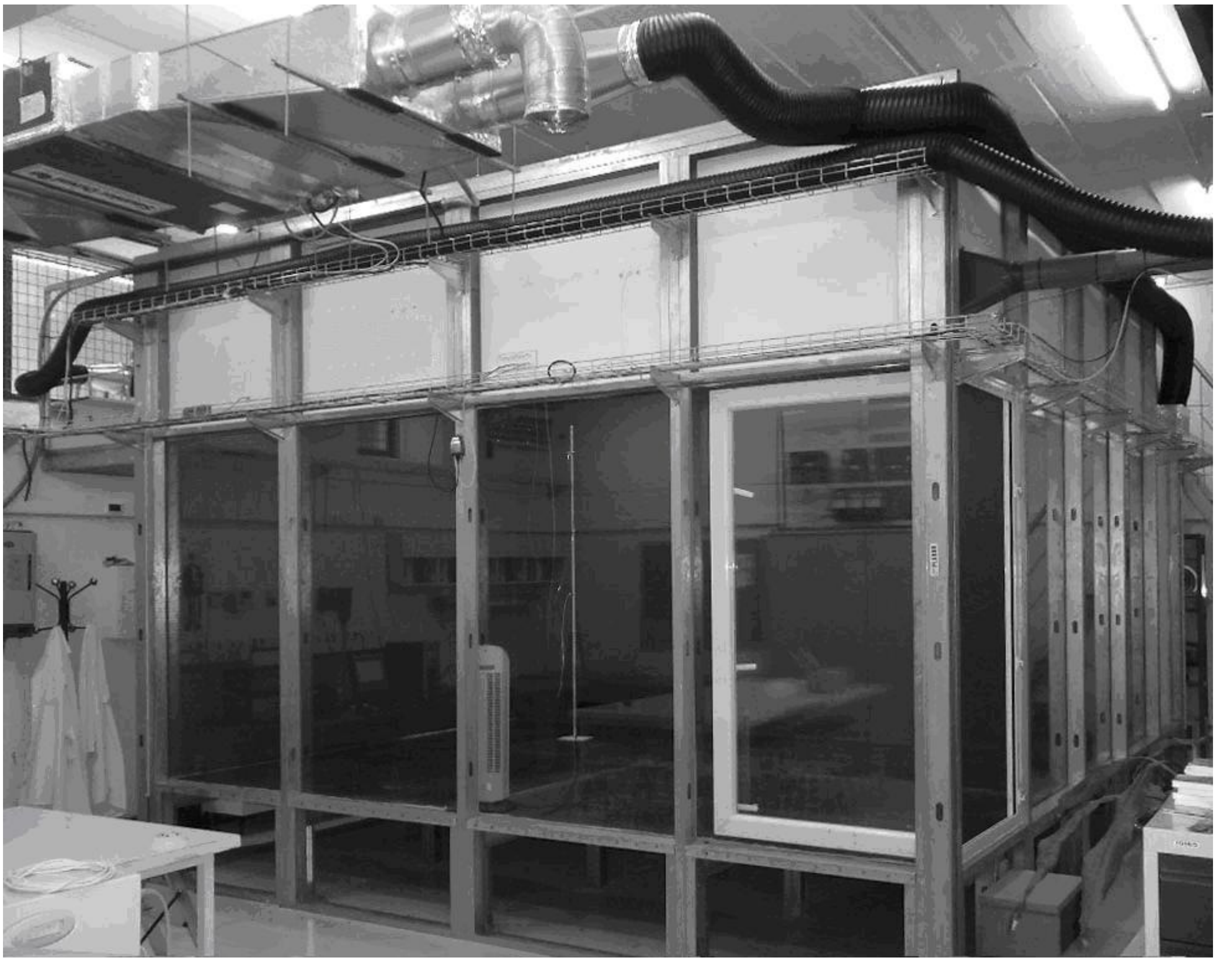

Figure 1. Test Chamber. Exterior view from the air conditioning laboratory.

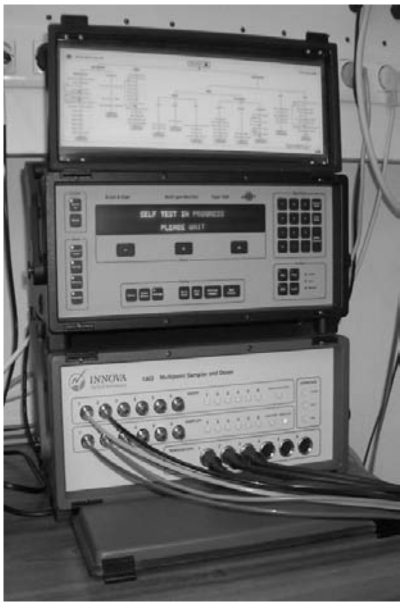

Figure 2. Subchamber reproducing a bathroom. View from the interior of the chamber.
Figure 3. Equipment with multipoint sampler and doser and multi-gas monitor.

The numerical model was carried out using Fluent CFD software with help of the Gambit program for the introduction of the geometry and the meshing of the bath. The process for each test after CFD software adjustment was the following:

• introduction of the geometry, meshing and contour constraints, and the turbulence model.
• validation of the numerical model for comparison with the results of the experimental model, through non-dimensional values.
• numerical study of variants on the same volume and the obtained results.
• graphical results.

PROCESS

We study a prototype model bathroom with a maximum number of alternatives for the distribution of the supply and exhaust openings for the air. The inlet was located in the lower part of the access door and the outlet at the top of the walls. The different distributions were accompanied by the corresponding variations in the locations of the sanitary systems.

Two procedures were employed: the numerical procedure with CFD software (Computational Fluid Dynamics) and the experimental procedure with the mentioned chamber where the size of the bathroom with a specific distribution was reproduced on a real scale. The former allows greater versatility when performing a virtual study of multiple cases, while the second, which is more complex, provides the essential validation of the study in CFD. In both cases the procedure used to calculate ventilation efficiency is based on the expression relating room air age, represented in Equation (1):

$$\varepsilon = \frac{\tau_{exhaust}}{2.\bar{\tau}}, \qquad (1)$$

where ε is the efficiency of the ventilation in the studied room, $\bar{\tau}$ is the room-average age and $\tau_{exhaust}$ is the local mean air age of the outlet.

Since air was entering from other rooms in the house, we were dealing with a common isothermal process, both for the experimental and numerical models. The experimental model applied the concentration decay method using a gas tracer (SF_6) and the averaged data of concentrations obtained were treated in detail by the appropriate spreadsheets.

Figure 4 represents a typical graph showing the evolution of the concentration decay of a gas tracer obtained in one of the numerous tests performed. Conversion from concentrations of gas tracer to mean air ages was carried out by equations (2) and (3).

The experimental results allowed us to validate the results obtained with the numerical model, built with a turbulence model k - ε. The left side of Figure 5 shows a perspective of the model bathroom. The right shows two sections with the mean air ages represented by different colour plots to indicate different ages in seconds.

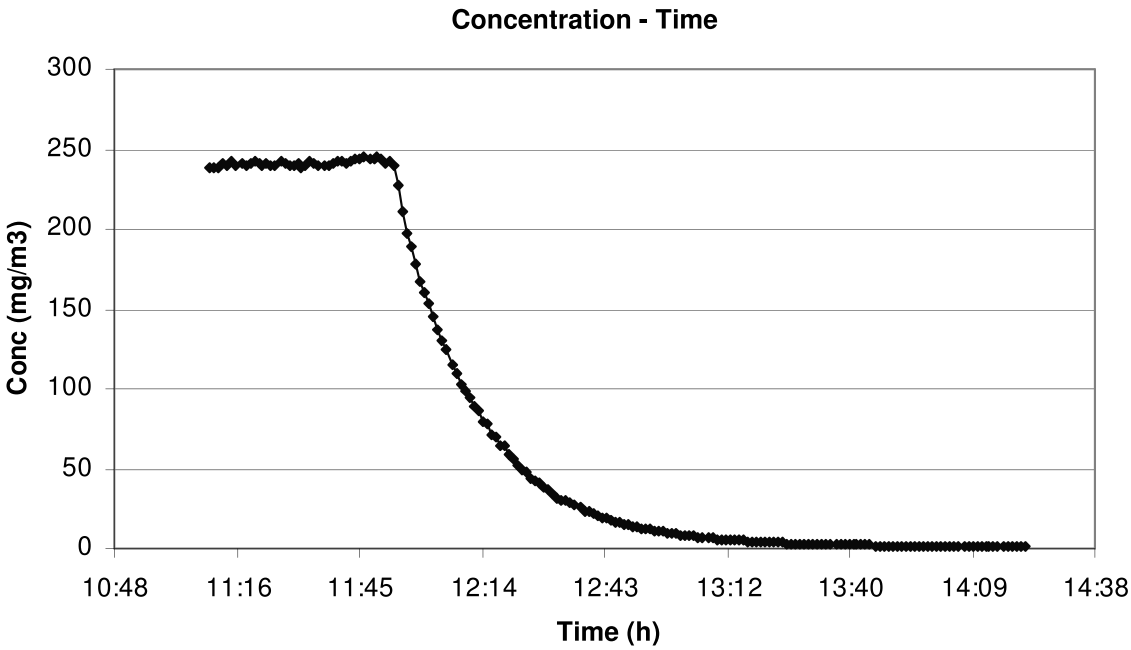

Figure 4. Example of obtained concentration history with SF_6 as tracer gas

Local mean age of air $$\bar{\tau}_p = \int_0^\infty \frac{C_p(r_o,t)}{C(0)} d\tau , \qquad (2)$$

Room average age of air $$\tau = \frac{\int_0^\infty t \cdot C_e(t)dt}{\int_0^\infty C_e(t)dt} , \qquad (3)$$

where:
$C_p(r_o,t)$ tracer gas concentration at point r_o and time = *t*.

$C(0)$ tracer gas concentration at time = 0, where we begin to measure concentration decay

$C_e(t)$ tracer gas concentration at outlet

τ_p local mean age of air (at a random measurement point)

$\bar{\tau}$ room average age of air

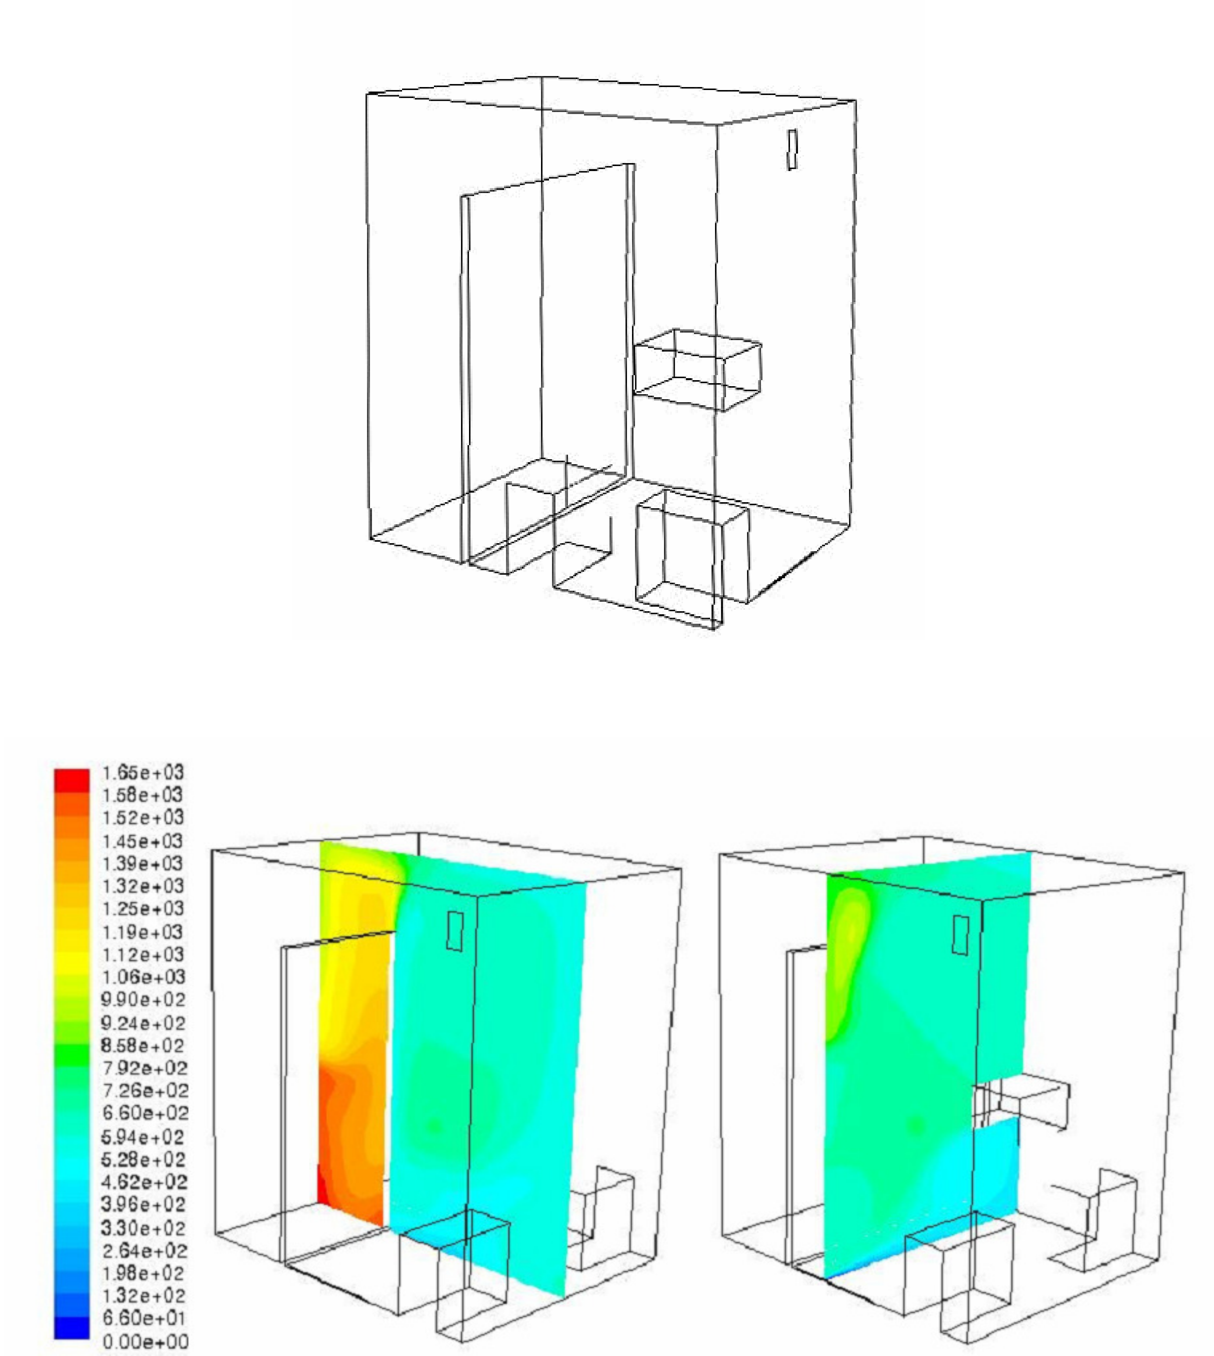

Figure 5. Graphics of the bathroom with graphic results of air ages in certain sections of the room (air age in seconds)

With the obtained results and thinking fundamentally about the possible practical repercussions, efficiencies were sorted into three groups. The first contained values equal to or below 0.45, indicating lower efficiency (near to the theoretical short circuit model), the second group for values above 0.45 and below 0.50, indicating intermediate efficiency (close to the model of perfect mixing) and the third group equal to or higher than values of 0.50, the most efficient (tending to the theoretical model of displacement).

(good) $\varepsilon \geq 0.50$ (average) $0.45 < \varepsilon < 0.50$ (bad) $\varepsilon \leq 0.45$

RESULTS

By way of a summary we now transfer the numerical results to practical concepts that can be applied directly to architectural design. The following symbols represent three valuations of extraction in terms of the above mentioned efficiencies, their location in the perimeter of the bathroom indicating their position near the vertical and corresponding wall.

good location ☐ average location ◧ poor location ■

Figure 6, below, shows the most representative distributions together with the numerical and experimental results obtained corresponding to the first bathroom prototype 2.40 x 1.80 x 2.50m.

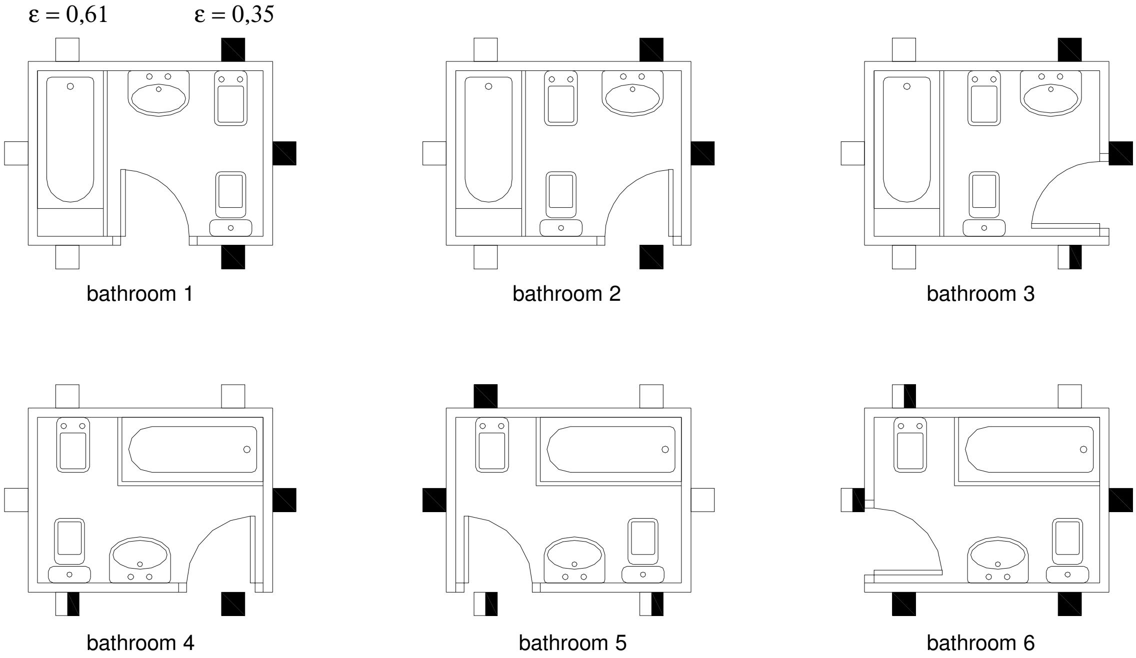

Figure 6. Bathrooms with the same surface and different locations for access doors, sanitary devices and ducts, and the corresponding efficiency for each solution

In two of the variants for the ducts in "*bathroom 1*" (Figure 6), values for efficiencies of 0.61 and 0.35 respectively are shown, coinciding with the maximum and minimum values of all the studied cases.

We also worked numerically with an alternative size of 2.00 x 2.00 x 2.50 m., obtaining a series of results, the most significant of which are shown in Figure 7.

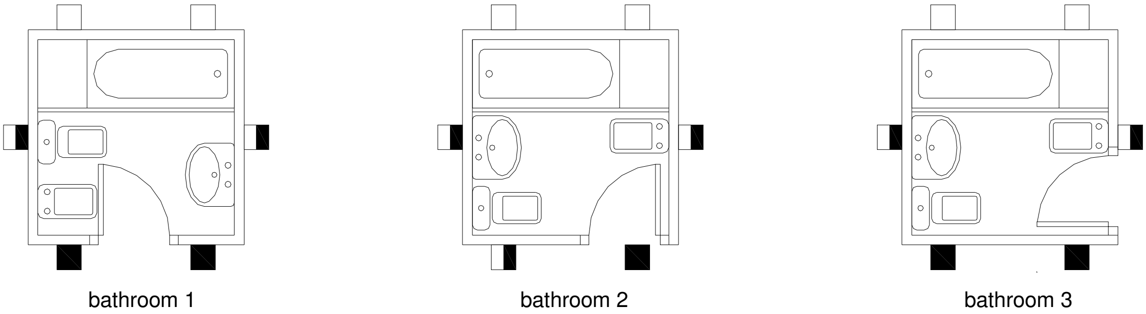

Figure 7. Results of another model of bathroom with other proportions

We even managed to study a conventional 2.00 x 1.50 x 2.50m model of toilet with multiple inlet and outlet variants. One significant example of this study is Figure 8, which offers a perspective of the room with the sanitary devices and a plan with the effects of the distribution.

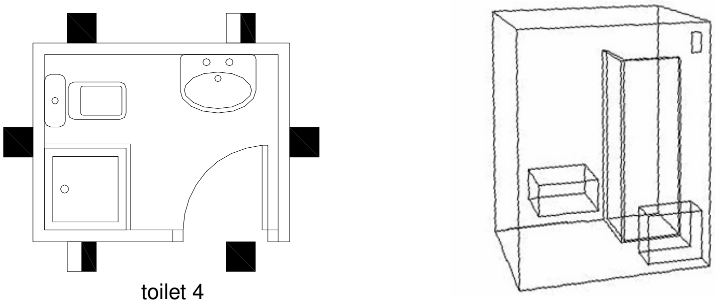

Figure 8. Sample of the results of the toilet

DISCUSSION

The following conclusions concerning architectural design may be drawn from the studies carried out and the results obtained:

- Closing shower spaces and bathtubs with screens, even if they do not reach the ceiling, seriously obstructs ventilation and significantly impacts ventilation efficiency in the toilet or bathroom.
- In general, locating the air outlet close to an entrance door which holds the inlet significantly reduces ventilation efficiency.
- In general, distancing both ducts (inlet and outlet) enhances efficiency, although the key factor is that the outlet should be located on the walls that delimit the shower or bathtub space if these have closed screens.

As pointers for further future research, other conclusions which may also be drawn are:

- The obtained efficiencies in general yielded low values (between 0.35 and 0.61). The induced flow was supposedly nearer to that of displacement, as a result of which theoretically these should have reached efficiency values above 0.7. This encourages further work aimed at improving them.

• In smaller rooms, we seem to have obtained consistently lower efficiencies, between 0.42 and 0.4. It appears that in these cases the location of the inlet and outlet had less impact.

SUMMARY

This study discusses the empirical validation of a multi-zone infiltration model of an existing two-storey detached house in the cold Finnish climate. Empirical validation was performed by comparing simulated and measured pressure conditions of the building during a three-week test period in the heating season. The simulations were carried out using a dynamic simulation tool, IDA-ICE, which combines whole-building energy simulation and infiltration modelling. The initial data of the building model were obtained with extensive field measurements including the measurements of airtightness and leakage distribution of the envelope and performance of a ventilation system. According to the results, pressure conditions are slightly negative on the first floor and positive on the second due to the stack effect in the heating season. The empirical validation shows that the correspondence between the simulated and measured pressure conditions is good and the studied building model can be used for the infiltration and energy analyses.

INTRODUCTION

This study is part of the cooperation project between two Finnish universities; Tampere University of Technology and Helsinki University of Technology. In this project, called *Tightness, indoor air and energy efficiency of residential buildings* (AISE), extensive field measurements are being carried out in 159 dwellings with massive and lightweight structures consisting of flats and detached houses during the period 2005 – 2007. This study is concentrated on the infiltration modelling of one measured detached house. Infiltration, defined as uncontrolled air flows through a building envelope, depends on the air permeability of the structures and the pressure difference between indoor and outdoor air. The pressure difference is caused by wind, temperature difference over an envelope, and balance of the ventilation system. Wind conditions are strongly dependent on the building site and temperature-driven pressure difference is significant in a cold climate during the heating season. The objective of the study is to perform an empirical validation of the detailed multi-zone simulation model, including leakage distribution and other important parameters, with the intention of using the validated model for infiltration and energy analyses.

METHODS

Building description

The object of the study is a detached house comprising two floors (Figure 1). The house is situated in the metropolitan area of Helsinki and was built in 2000. The net floor area of the building is 172 m². The structures of the house are wood-frame construction provided with a plastic vapour barrier and the base floor of the house is a concrete slab on the ground. The level of thermal insulation of the house fulfils the requirements of the Finnish building code [1] and the house is equipped with a mechanical supply and exhaust ventilation system with heat recovery.

Figure 1 The object of the study is a typical Finnish detached house.

The method of construction, the ventilation system and the tightness of the modelling object corresponds to the typical detached house defined by the national project “Moisture-proof healthy detached house” [2], where 102 newly built timber-framed detached houses were measured in Finland during 2002-2004. Airtightness of the building envelope equals the mean level of the measured 102 detached houses.

Measurements

Initial data of the simulation model were collected by means of field measurements of the building. The following factors were measured:

- Ventilation
- Tightness of the envelope
- Leakage distribution
- Pressure and thermal conditions.

The measurements of the ventilation air flow rates, tightness and leakage distribution of the building were carried out using a single-shot measurement. Supply and return air flow rates were measured at the low (3/8) speed of the air-handling unit, which is the normal use of ventilation in the studied building during wintertime. The measured air change rate of the building was 0.3 ach and the ratio of the supply and return air flow rates was 0.93, affecting a slight negative pressure in the building. The measured air change rate is lower than the minimum requirement of the Finnish building code (0.5 ach) [3] and also slightly lower than the typical mean air change rate of the detached houses (0.41 ach) in wintertime when equipped with mechanical supply and exhaust ventilation system [4].

The tightness of the building was measured using a fan pressurization method. To measure the air leakage of the envelope, all the exterior openings – windows and doors – were closed and ventilation ducts and chimney were sealed; a leakage air change rate per hour at 50 Pa of pressure difference was measured. The leakage air flow rate was divided by the internal volume of the building to get the building leakage rate n_{50}; the resultant was 3.9 ach. The distribution of the leakage openings was studied using two-phase infrared-camera imaging of the envelope of the building [5]. The imaging was performed inside the building in a normal and 50 Pa under pressure conditions. The study was carried out during the heating season when the indoor and outdoor temperature difference was 25°C. According to an estimated vertical leakage distribution shown in Table 1, most of the leakage routes are at a junction of the roof and an intermediate floor; the routes are quite evenly distributed between the first and second floor.

Table 1 Vertical leakage distribution of the building based on the infrared camera imaging

Place of the leakage routes		Leakage distribution, %
2nd floor	Junction of roof	36
	Upper edge of window frame	4
	Lower edge of window frame	4
	Junction of intermediate floor	2
1st floor	Junction of intermediate floor	21
	Upper edge of window	0
	Lower edge of window frame	24
	Junction of base floor	10

Pressure and thermal conditions of the building were measured during a three-week period in the heating season. Occupants were living normally in the building during the follow-up measurements, which were carried out between 4th and 24th of March 2005. Pressure and temperature data were collected with loggers using a 5-minute time-step. The pressure difference over the envelope was measured on the first and second floor of the building. The measuring points were at one façade of the detached house; the principle of the measurement is shown in Figure 2.

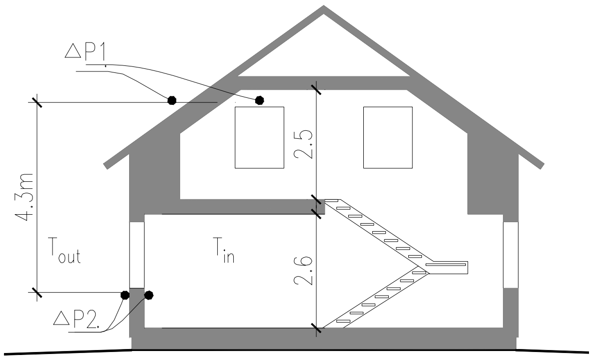

Figure 2 Measurement of the pressure conditions of the building.

Indoor air temperatures of the building were measured in a living room on the first floor and in a bedroom on the second floor. The outdoor air temperature was also measured next to the detached house during the follow-up measurements. The measured outdoor air temperature is shown in Figure 3; it is -7.1°C on average. The three-week period was very cold for Southern Finland, emphasizing the temperature-driven pressure difference over the building envelope.

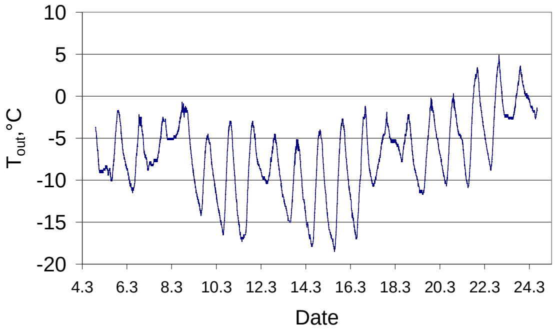

Figure 3 Measured outdoor temperature next to the detached house during follow-up measurements.

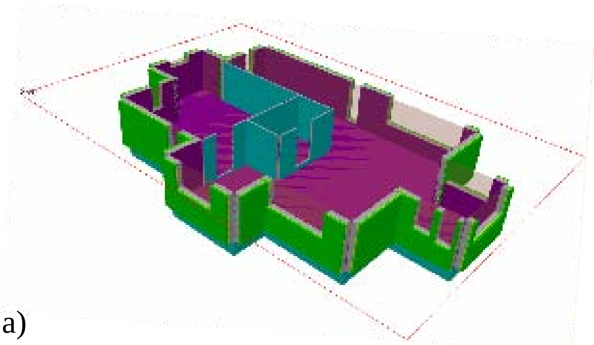
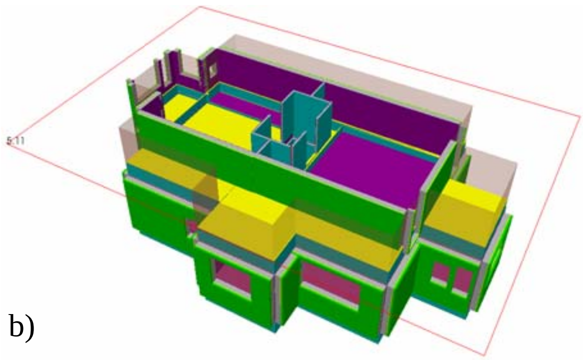
The dynamic simulation model

The building model was done using IDA indoor Climate and Energy 3.0 (IDA-ICE) building simulation software. This software allows the modelling of a multi-zone building, HVAC-systems, internal and solar loads, outdoor climate, etc. and provides simultaneous dynamic simulation of heat transfer and air flows. It is a suitable tool for the simulation of thermal comfort, indoor air quality, infiltration and energy consumption in complex buildings. A modular simulation application, IDA simulation environment and IDA-ICE, has originally been developed by the Division of Building Services Engineering, KTH, and the Swedish Institute of Applied Mathematics, ITM [6,7]. Today the application is commercial tool owned by EQUA AB. IDA ICE has reached high levels of penetration among practitioners and researchers in Sweden and Finland

The building model of the measured detached house comprises three different zones on the first and second floor (see Figure 4); the floors are connected by means of a staircase. Air flow between the zones, two floors and outdoors caused by the pressure differences is simulated by means of the principle of nodal network (see Figure 5.), where flow paths, cracks or openings between the zones or outdoors are described as flow resistances.



a)



b)

Figure 4 Profile of the 3-D plot showing the first floor (a) and the second (b) of the IDA-ICE building model. The figures are generated with the IDA-ICE 4.0 alpha version.

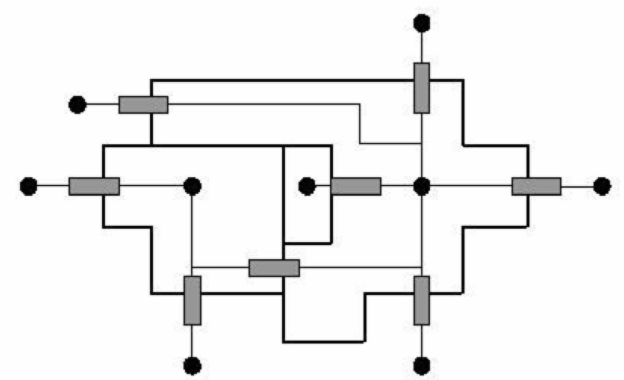


Figure 5 A simplification of the nodal network model of the first floor. Grey boxes describe the flow resistances of the flow paths; the pressures are calculated at the black nodes.

The building model was simulated using the hourly weather data of the three-week measurement period. The measured outdoor temperature data was used and the other required data, for example, wind velocity and direction and solar radiation properties, were taken from the weather station of Helsinki-Vantaa airport. Wind conditions of the environment were simulated using the wind-profile equation [8]

$$U(h) = U_m \cdot k \cdot \left(\frac{h}{h_m}\right)^a, \qquad (1)$$

where U(h) is wind speed at height h and U_m is wind speed measured in open country at the weather station, h is height from the surface of the ground, h_m is height of the measurement equipment and parameters k and a are terrain-dependent constants. The simulated building is in a typical Finnish suburban area with closely built houses where the height of adjacent buildings is approximately the same as the simulated one. The wind-profile equation was simulated with the values of the parameters (k =0.67 and a = 0.25). Wind-induced pressure conditions were simulated using constant wind-pressure coefficients defined at 45° intervals of a wind direction. The values of the wind-pressure coefficients used in the simulation were approximate values for typical detached houses with a height of up to three storeys [9]. Wind pressure outside the building façades was determined with the equation

$$P_w = \frac{1}{2}\rho \cdot c_w \cdot U^2, \qquad (2)$$

where ρ is outdoor air density and c_w is the wind pressure coefficient and U is the local wind velocity defined by Equation (1). The air infiltration is calculated for every façade; the connection between the indoor and the outdoor climate, as well as the connection between the zones, is simulated using bi-directional leakage openings, which are so-called flow resistances of the kind shown in Figure 5. The leakage openings were distributed over the building model according to the measured leakage distribution shown in Table 1. Air flow through the leakage opening is simulated in the building model with the widely used empirical power law equation [10]

$$Q = C \cdot \Delta P^n, \qquad (3)$$

where C is a flow coefficient that is related to the size of the opening and ΔP is the pressure difference across the opening, n is a flow exponent characterizing the flow regime. The flow exponent varies in value from 0.5 for fully turbulent flow to 1.0 for completely laminar flow. The total value of the flow coefficient and the mean value of the exponent for the whole building envelope were determined by the pressurization test.

RESULTS

The results of the three-week empirical validation period are discussed below. The simulated pressure conditions of the first and second floor of the detached house are compared against the measurement results. The simulated pressure differences over the envelope were logged from the building model at the same façade and the same height from the ground as in the measurements; the thermal conditions inside the building model correspond to the measured conditions.

According to the measurements and the simulation, the pressure difference is slightly negative on average on the first floor and positive on the second floor, see Figure 6 (a and b). The model gives some intermittent peaks of the negative pressure that clearly deviate from the measured pressure, but the correspondence is good on average. The pressure difference as a function of temperature difference between indoor and outdoor air is shown in Figure 6 (c and d). Almost completely parallel linear fits of the measured and simulated points show that the pressure difference decreases with an increasing temperature difference on the first floor and that the pressure difference is almost constant on the second floor. The different correlation between the pressure and the temperature differences on the first and second floor is a result of many factors, such as the stack effect, the ratio of the ventilation air flows, and the performance of air handling unit at the low outdoor air temperatures.

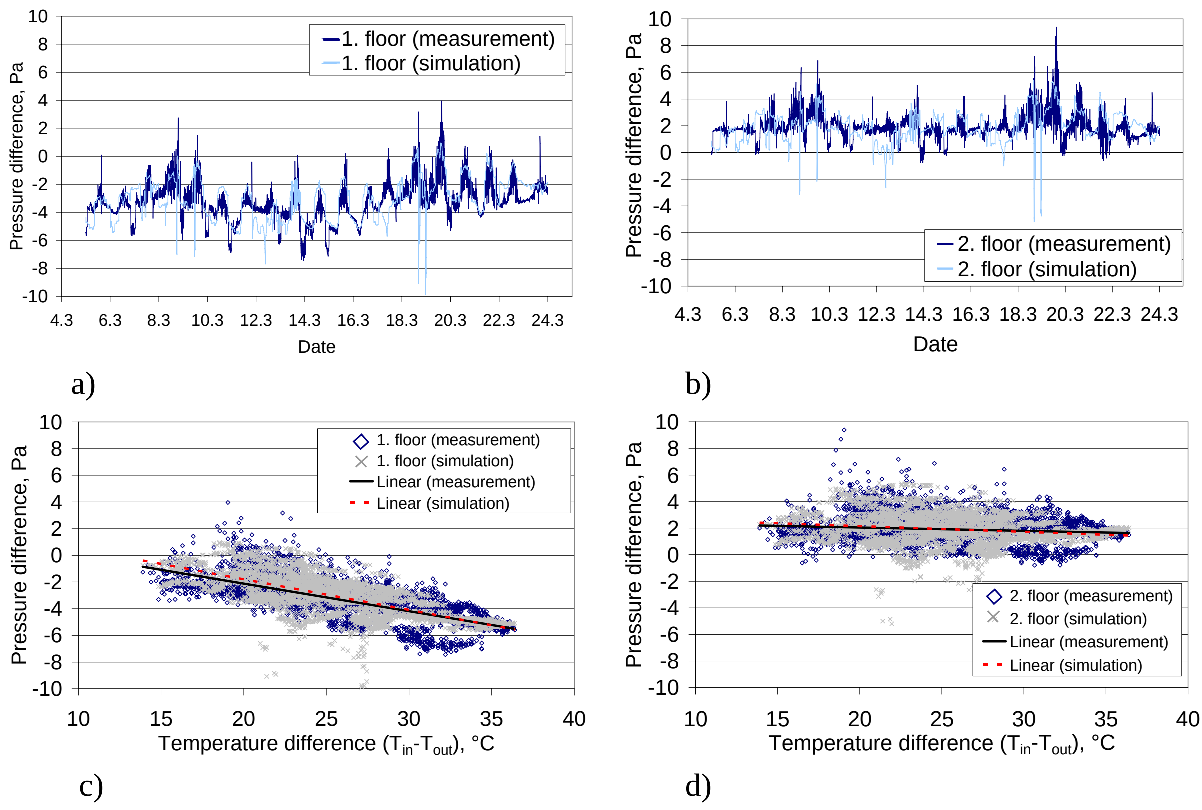

Figure 6 Measured and simulated pressure conditions of the detached house during the three-week measurement period from 4th to 24th of March 2005. The pressure difference over the envelope on the first and second floor are shown as a function of time (a and b) and as a function of temperature difference between indoors and outdoors (c and d).

The measured and simulated average indoor air temperatures and pressure differences of the validation period are almost equal (see Table 2). The set point of heating in the building model is chosen so that the average indoor air temperatures are as close to the measurement result as possible. Indoor air temperatures of the building are rather low, especially on the second floor, due to the occupant's way of life.

Table 2 Measured and simulated average indoor air temperatures and pressure differences across the envelope during the validation period.

Method	Indoor air temperature, °C		Pressure difference, Pa	
	1st floor	2nd floor	1st floor	2nd floor
Measurement	19.7	17.0	-3.3	1.9
Simulation	19.8	17.0	-3.1	1.9

DISCUSSION

The empirical validation of the studied building model shows that the simulated pressure conditions are in good agreement with the measurements. Because of this agreement, the multi-zone model can be used for the infiltration and energy analyses in the cold Finnish climate. Simulated pressure conditions of the building model seem to be realistic, even if the calculation of the wind-induced pressure conditions was simplified. The wind data used in the simulation was taken from the airport's weather station; the wind-pressure coefficients were approximate values for typical low-rise buildings in the sheltered environment and the values were not based on the measurements or CFD-calculations of the studied building. The empirical validation of the model was carried out for the cold period of the winter season when the buoyancy-driven pressure difference was emphasized and the studied building was situated in the sheltered suburban area where wind conditions were not strong. It is obvious that an accurate modelling of the leakage distribution is important, especially when buoyancy-driven pressure is significant.

SUMMARY

Regular air tightness and infiltration measurements were performed in forty houses, in the area of Attica, Greece. Two measurement methods were used, the tracer gas decay method and the Blower Door tests method. Blower Door measurements were done in accordance with EN ISO 13829 [1]. Ambient conditions and temperature fluctuations inside the houses were measured as well.

A classification of houses examined, based on experiments' results was acted out in accordance with EN ISO 13790 [2]. The houses were classified into three air tightness categories, in regard to their air tightness in natural conditions and at a pressure difference of 50 Pa.

Furthermore, the total frame length was estimated for the whole housing stock, and a correlation between the air tightness measurements at a pressure difference of 50Pa and the total frame length was examined, for the sample of buildings and for each air tightness category.

A correlation between the airflow values, as they resulted from the fan pressurization method and the average infiltration rates, calculated by the tracer gas experiment results, has been extracted. Moreover, the effect of climate data including temperature and windiness and construction quality on the houses' infiltration characteristics has been investigated.

INTRODUCTION

Infiltration rates and therefore buildings' air tightness are important because they affect the energy use of the building and they impact the transport of pollutants so as the indoor air quality. From an energy standpoint alone it is almost always desirable to increase air tightness but indoor air quality may suffer [3].

Single-family dwellings in Greece are usually not equipped with mechanical ventilation system. When doors and windows are closed, air exchange occurs only by uncontrolled air leakage across the building envelope. The movement of air through leaks, cracks or other openings of the building envelope is known as air infiltration. High infiltration rates can cause excessive energy demand because of the need to condition the infiltrating air. At the other hand, insufficient air exchange can lead to high exposure to pollutants such as emissions from building materials, cooking, smoking or cleaning activities [4]. It is very important to estimate leakage characteristics in the housing stock in terms of construction's type and quality, buildings' age and climatic conditions, in order to control the energy demand and the pollutants' concentration.

Tens of thousands of fan pressurization measurements have been made in USA buildings. These data were collected and were analyzed in order to determine relevant leakage characteristics in the US housing stock in terms of construction type and quality, region and age [4], [5].
Very few information is available regarding infiltration of buildings in the Mediterranean area. In Italy, the issue building air tightness is still not widespread and ACH limits at 50 Pa pressure difference have not been introduced yet. However, many air tightness measurements were performed in residential buildings, last decade [6]. In France, air tightness measurement studies were performed too, in order to identify the major factors that affect the buildings' leakage area and improve the energy performance of buildings [7].
Tracer gas measurements were performed in order to evaluate the infiltration rates for each building. Blower door measurements were also performed but the data of this method could not be generally used to estimate airflows at natural conditions. The name comes from the fact that in the common utilization of the technology there is a fan mounted in a door [3]. Blower door data estimates airflows at a variety of pressures and mostly at a 50 Pa pressure difference. The advantage of this method is that their results are less affected by climatic conditions.

2. METHODS

2.1 Description of the residences

Regular infiltration and air-tightness measurements were performed in forty residences in the area of Attica, Greece. All forty residences are single-family buildings or double-family buildings and their entrance door is totally exposed to the exterior environment. Table 1 contains information about all the tested houses.

2.2 Measurements of ambient conditions and indoor temperature fluctuation

Ambient conditions were measured using the mobile meteorological station of Group of Environmental Studies of University of Athens. During experiments, ambient temperature, wind speed and wind direction were being traced, at 10m height and at building's average height above the ground. Outdoor dry bulb temperature at the level of the main entrance and indoor temperature in three different building zones were being traced.
Table 1 contains the average values of all parameters that were being traced over the time period of each experiment.

Table 1. Building characteristics ambient conditions and internal temperature fluctuation.

2.3 Infiltration measurements using the tracer gas "decay" method

Infiltration rate was determined by using the "concentration – decay" method. The tracer gas equipment consists of a central unit that controls the gas injection and sampling, an infrared radiation detector and a gas bottle. Mixing was ensured by the use of fans. The (inert) gas indicator that was used was N_2O.
Tracer gas was injected into each of the four building zones through four separate tubes - channels, while all house openings remained closed. As soon as the inert gas – indoor air mixing was complete and N_2O concentration target value was reached, the evolution of the gas concentration in each zone was measured.
The infiltration rate, in air changes per hour (ACH), for each of the four building zones that were tested as well as for the entire building (ACH_{tg}), was calculated by using the traced concentration values.
Table 2 contains the average infiltration rate of the whole building, for all studied houses.

2.4 Air tightness measurements using the fan pressurization method

Each building's air tightness was measured using a Blower Door in accordance with EN ISO 13829.
Blower door has a variable speed fan so that the pressure difference can be adjusted and an aluminum frame in order to seal the fan tightly into the doorjamb. The system is mounted in each house entrance door to measure the leakiness of the house. In order to measure the leakiness of the house, the blower door measures both the airflow through the fan and the pressure difference between the house inside and outside. Measurements are taken by increasing the speed of the fan until the pressure difference between the house and outside is at the desired level. Typically, testing is done between 20 and 70 Pascals (Pa). The airflow out of the house at that pressure is then recorded.
Measurements were carried out following method A – common building use – of EN ISO 13829 while also applying a pressure difference of 50Pa in order to fulfill the requirements of EN ISO 13790 [2] (former EN ISO 832).
All experiments' results are acceptable as they fulfill EN ISO 13829 criteria which require that the wind speed is lower than 6m/sec, the product of maximum building height (m) and temperature difference between outdoor and indoor dry bulb temperature is lower than 500m°K and the building's volume is lower than $4000m^3$.
Table 2 contains the calculated air changes per hour values for a 50Pa pressure differential (ACH50) and the criteria parameters values.

Table 2. Average values of infiltration rate (ACH_{tg}) and air tightness (ACH_{50}) of the buildings.

House	ACHav	ACH50	House	ACHav	ACH50

3. RESULTS

3.1 Classification of houses examined based on experiments' results

Tracer gas decay and pressurization test method were used in order to estimate the infiltration rate under natural conditions and the air tightness of the building respectively. According to EN ISO 13790 (former 832), house buildings can be classified into three categories in regard to their air tightness under natural conditions (infiltration) or at a pressure difference of 50Pa (ACH50) between indoor and outdoor air.
Table 3 shows the limit values (ACH_{tg}) of three air tightness levels for non shielded, naturally ventilated single family buildings with more than one exposed façade and their corresponding values when a 50 Pa pressure difference is applied between indoor and outdoor environment (ACH_{50}).

Table 3. Tightness levels for natural ventilated, non shielded single-family buildings

Air change rate (h^{-1}) at 50Pa	Ventilation rate ((h^{-1}) for naturally ventilated single family houses	Envelope tightness level
10	1.5	Low
4 – 10	0.8	Medium
4	0.5	High

Figure 1 and 2 contain the rating of each tested building, resulting from tracer gas decay and fan pressurization measurements.

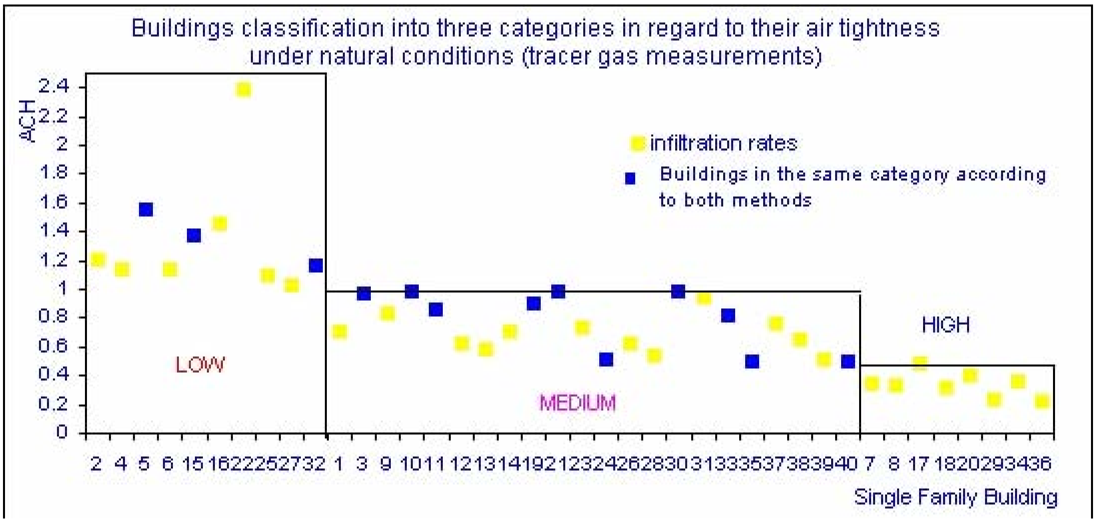

Figure 1. Building classification into three categories in regard to their infiltration under natural conditions (measurements with tracer gas “decay” method)

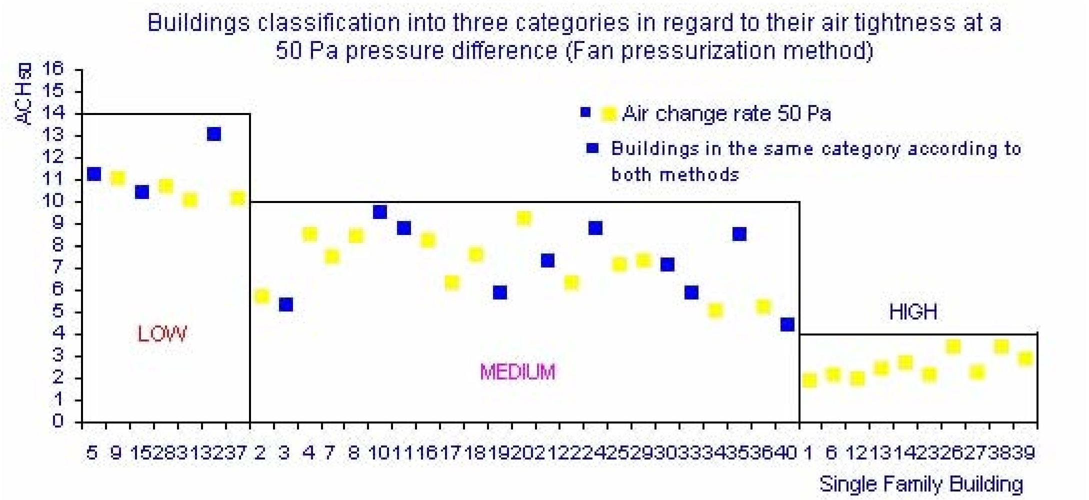

Figure 2. Building classification into three categories in regard to their air tightness at a 50 Pa pressure difference (Fan pressurization method)

3.2 Correlation between air tightness measurements and total frame length

One important factor associated with air tightness of a building is the total window frame length divided by the building’s net volume. The total window frame length was estimated for each building, it divided by the net volume and the “frame length factor (FLF)” was defined.

$$FLF = (TFL) / (NV), \qquad (1)$$

where *FLF* is the frame length factor, *TFL* is the total window frame length and *NV* is the net volume of the building.
Linear correlation between the air tightness measurements at a pressure difference of 50 Pa and the frame length factor FLF was performed for each one of three air tightness levels (high, medium, low).

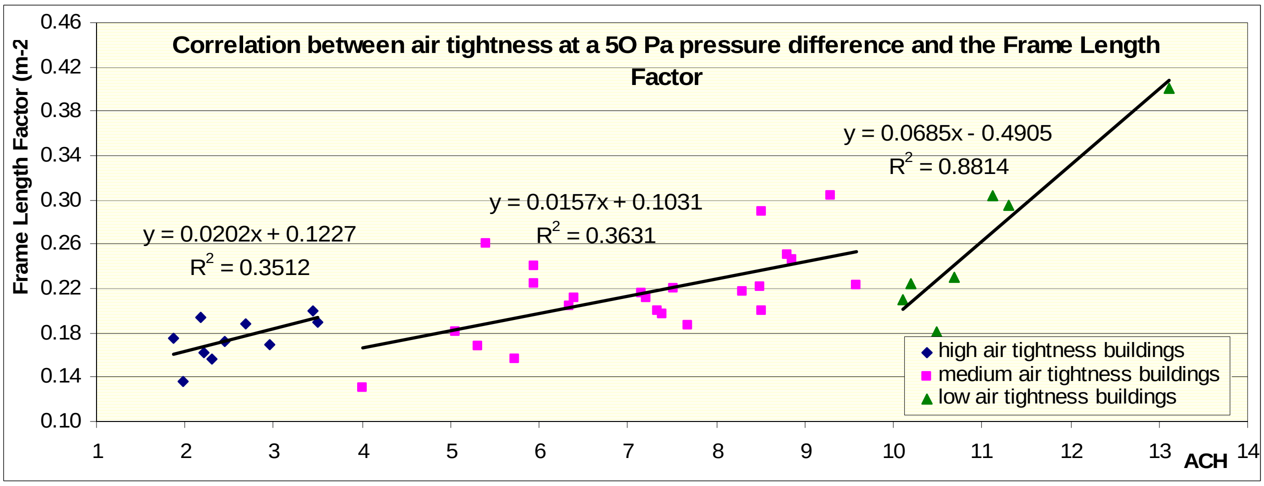

Figure 3. Linear correlation between air tightness at 50 Pa pressure difference and the total frame length factor for three air tightness categories

As it can be seen at Figure 3, the linear correlation for the “high” and the “medium” air tightness levels give lower R^2 values compared with high value of $R^2 = 0.88$ of “low” air tightness buildings. In case of “low air tightness” houses, the most important linear correlation between FLF and air tightness measurements is noticed, while this category is mostly affected by the total window frame length.

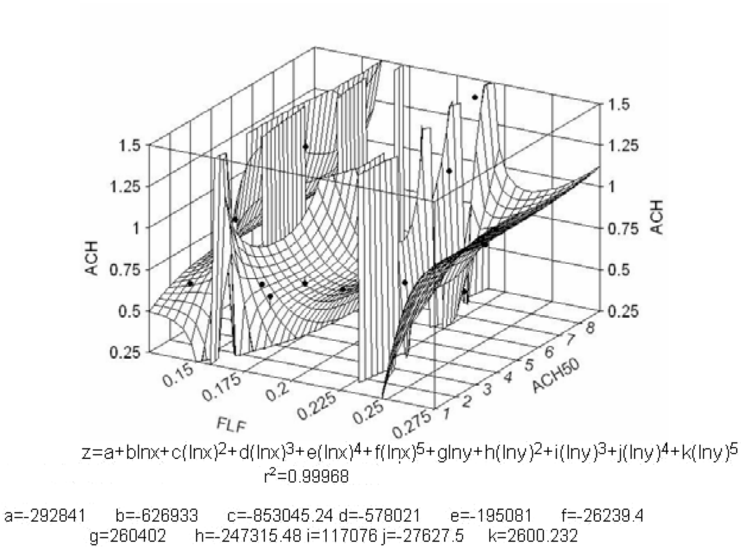
However, the sample of buildings is small and the correlation should be further checked in many cases.

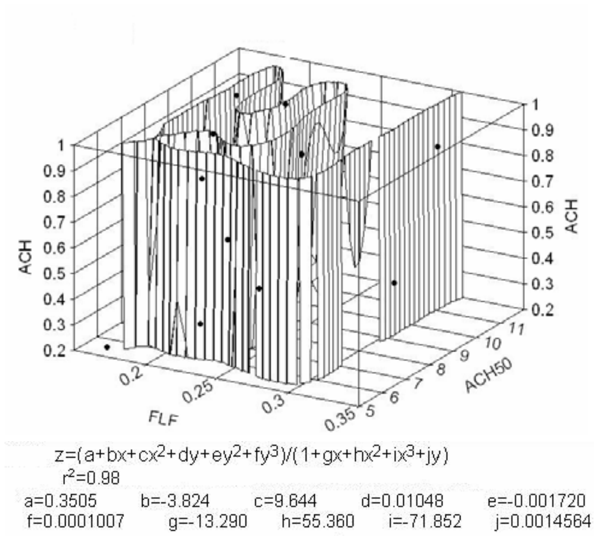
3.3 Correlation between the average infiltration rates, the “fan pressurization method” results and the Frame Length factor

A correlation between the airflow values, as they resulted from the fan pressurization method, the average infiltration rates, calculated by the tracer gas experiment results and the Frame Length Factor has been extracted.

All tested houses were classified in regard to their frame type. The most common frame types of the examined houses are those with wooden frame and those with aluminium sliding frames.

A correlation between the two method’s results was investigated for each “frame type” category. The correlation between three parameters gives the best results in case of buildings with wooden frame ($R^2 = 0.99$), and with aluminum frame ($R^2 = 0.98$) (Figure 4).





Buildings with wooden window frame Buildings with aluminum window frame

Figure 4. Correlation between infiltration rates (ACH), air tightness at 50 Pa pressure difference (ACH_{50}) and the total frame length factor (FLF) for each frame type category.

The effect of climatic data in air infiltration was investigated for each “window frame type” category. For the case of the wooden window frames (R^2=0.80) the effect of temperature difference and wind speed in air infiltration is bigger than in the case of sliding aluminium frames (R^2=0.75). However, the forty buildings have significant differences in their construction’s quality as well as in their age, so the climatic conditions’ effect is not clear. It would be desirable to measure the air infiltration for one specific building in different climatic conditions, so that we can have the appropriate results.

DISCUSSION

Air tightness of forty single-family buildings was calculated under natural conditions and under a 50 Pa pressure difference between indoor / outdoor environment. The buildings were rated according to their measured air tightness.

There is no correlation between infiltration measurements at natural conditions and the total window frame length. It is necessary to study the effect of climatic conditions on these infiltration measurements. A correlation between air tightness measurements at a 50 Pa pressure difference and the total window frame length was noticed, mainly at the “low air tightness” buildings. The total frame length affects the air leakage of each house and its air tightness. Also a classification of buildings according to their window frame type was realized, and a correlation between the airflow values, as they resulted from the fan pressurization method and the average infiltration rates, calculated by the tracer gas experiment results, has been extracted for each frame type category. However, the sample of buildings is very small and a large number of experiments are required.

Indoor environment in schools

Indoor environmental quality in schools and academic performance of students: studies from 2004 to present

Richard Shaughnessy [1], Ulla Haverinen-Shaughnessy [2], Demetrios Moschandreas [3] and Aino Nevalainen [4]

[1]The University of Tulsa, United States

A pilot study investigating classroom ventilation rates, and their association with reduced student performance was conducted within a school district in the USA in the spring term 2004. Data on classroom CO_2 concentrations (over a 4-5 hr time span within a typical school day) were recorded in 5th grade classrooms in fifty four elementary schools. In addition, investigators were able to work with the district to obtain standardized test scores (math and reading), and background data related to the students in the specific classroom studied in each school. Results of the pilot study have been presented by Shaughnessy et al. 2005, and Shaughnessy et al. 2006, demonstrating a modest association between class room ventilation rates and student performance in math standardized test scores, and also a need for further studies with larger sample size and more comprehensive assessment of indoor environmental quality (IEQ). A new school district in the USA with approximately 50 schools is currently undergoing a through assessment protocol and the preliminary results will be available by the end of 2006. In addition there is a new study in Finland starting in spring 2007 that will provide further knowledge on how and to what extend IEQ in schools affect academic performance of students.

Ventilation Rates in Schools and Learning Performance

Zs. Bakó-Biró[1], N. Kochhar[1], D.J. Clements-Croome[1], H.B. Awbi[1] and M. Williams[2]

[1] School of Construction Management.& Engineering, The University of Reading, UK
[2] School of Psychology and Clinical Language Sciences, The University of Reading, UK

Corresponding email: z.bakobiro@reading.ac.uk

Introduction

Previous studies underline the often inadequate ventilation rates in classrooms causing increased health risks among school children. Current UK ventilation guidelines specify a minimum of 3 L/s per person and recommend 8 L/s per person ventilation rate achievable in all teaching and learning spaces. Measured ventilation rates in UK primary schools are often below the minimum requirement. There is growing evidence of impairment of learning performance and increased absenteeism due to inadequate ventilation.

The purpose of the present research was to investigate the relationship between pupils' health, well-being and performance, and the indoor air quality in several primary schools in Southern England and to examine the suitability of current air quality guidelines.

Methods

Field surveys were carried out at eight different primary school buildings located in the proximity of Reading, UK. At each school two classrooms were selected for monitoring for three consecutive weeks. The first week was reserved to follow the classroom conditions without any intervention. During the second and third weeks a mobile ventilation system was installed in each classroom that could be set either to provide outdoor air or to re-circulate the classroom air. Carbon dioxide (CO_2) concentration, thermal conditions and other parameters were monitored in both classrooms and outdoors.

Computerised assessment tests and traditional paper-based tasks (addition/subtraction of numbers and reading comprehension) were used to evaluate pupils' performance on both the intervention weeks at low and improved ventilation conditions. Pupils' perceptions of the classroom environment, comfort, general mood and hunger were assessed on subjective scales following the performance tests.

Results

The current project is still in the phase of data collection hence preliminary results of the physical environment and performance tests conducted on paper from only one school are presented.

The fresh air supply in both classrooms was increased from 0.3-0.5 to 13-16 L/s per person due to the interventions. Average CO_2 levels in the classrooms during testing period were reduced from 1600-4000 ppm to 600-800 ppm as a result of increased ventilation conditions.

The performance of all pupils' increased by 5-6% in both the addition ($p<0.036$) and subtraction ($p<0.052$) tasks under improved ventilation compared to low ventilation conditions. These effects were even more significant for the pupils with higher math skills. They increased the number of error-free units by ~7% in both addition ($p<0.02$) and subtraction ($p<0.007$) tasks when working under the improved ventilation conditions.

Conclusions

- The present results strengthen the evidence of earlier findings that improved ventilation has beneficial effects on pupils' learning performance.
- Without intervention the existing ventilation rates in naturally ventilated school buildings remain below the minimum recommended levels unless thermal conditions make people open windows.
- Measures that allow a minimum supply of fresh air to the classrooms of naturally ventilated buildings are needed particularly if windows are not operated adequately by staff to control ventilation.

Study on Productivity in the Classroom (Part3)
Nationwide Questionnaire Survey on the Effects of IEQ on Learning Performance

Ken-ichi Kameda[1], Shuzo Murakami[1], Kazuhide Ito[2] and Takamasa Kaneko[3]

[1]Keio University, Japan
[2]Kyushu University, Japan

1 Introduction

This series of studies evaluate the effects of changes in the air quality and thermal environments on student performance in the classroom. This paper (Part 3) reports the result of nationwide field measurement based on subjective questionnaire surveys and objective test scores in a unified way. In this research, the relationship between the quality of the indoor environmental and student performance in college are linked quantitatively through this nationwide questionnaire survey and previous laboratory experiments. In addition, human psychology regarded to effect it most when learning performance is measured was evaluated "motivation for learning" using a questionnaire as self-assessment form.

2 Outline of questionnaire survey

It investigated 83 branches of a college, which are located in regions spread throughout Japan. The total number of subjects was about 4000. Objective learning performance was evaluated according to scores in standardized quizzes to measure the level of understanding of lectures. In addition to the objective evaluation using quiz scores, a subjective evaluation of learning performance was carried out using a questionnaire as a self-assessment form.

3 Results

Percentage dissatisfied with air environment did not have the correlation with quiz scores but had a significant correlation with a subjective evaluation of learning performance by a linear approximation ($p<0.006$) (Table 1).

Table 1 Objective & Subjective evaluation vs. Percentage Dissatisfied with the air environment

	Objective	Subjective	
	Quiz Score	Time Lost	Predicted rate of Improvement in Performance
Correlation Coefficient	0.23	0.87	0.82
Significance Level	0.50	0.003	0.006

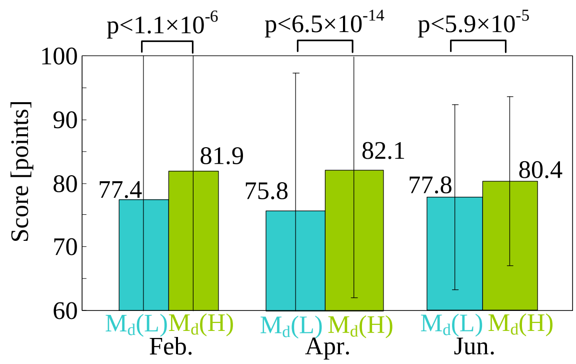

Figure 1 Result for the objective evaluation by motivation group

Figure 1 shows the results for objective learning performance by the motivation group. The quiz scores brought a significant high of 4.5 points ($p<1.1\times10^{-6}$) in February, 6.3 points ($p<6.5\times10^{-14}$) in April, and 2.6 points ($p<5.9\times10^{-5}$) in June by the M_d(H) (= Motivation during lecture is High) group. It became clear that the motivation to learn during the lectures significantly influencing the quiz scores, and the importance of evaluating the motivation to learn was shown. To measure the learning performance more exactly, it is thought necessary to incorporate motivation to learn as an evaluation axis.

4 Conclusions

(1) Objective and subjective learning performance improved with a decrease in the percentage dissatisfied with the air environment.

(2) Objective learning performance in the high motivation group was significantly better. To measure the learning performance more exactly, it is thought necessary to incorporate motivation to learn as an evaluation axis.

Indoor climate and improvement possibilities in educational premises

Teet-Andrus Koiv, Merje Rebane, Peeter Parre

Tallinn University of Technology

teet.koiv@ttu.ee

1 Introduction

The purpose of the study was to investigate the indoor climate, mainly the carbon dioxide concentration and air change in gymnasiums of Tallinn.

There is evidence that many countries have significant and serious indoor environmental problems in schools.

From the educational standpoint, the indoor air quality and ventilation in school buildings may affect the health of the children and indirectly also learning performance.

In Estonia the indoor air quality has not been investigated sufficiently. In 2005 and 2006 a pilot research was done in a cold season. The main aim of investigation was the carbon dioxide concentration and the air change level determination in classrooms.

According to the regulations of the Estonian Ministry of Social Affairs the permitted maximum carbon dioxide level in classrooms is 1000 ppm, relative humidity 30...70%, indoor temperature 19...25°C.

In most school buildings in Tallinn ventilation systems have not been renovated, but windows have as rule been changed and external walls in single cases renovated.

Only natural ventilation and window airing of classrooms is used in these school buildings.

2 Methods

The research included 10 classrooms in 7 schools of Tallinn. The average area of classrooms is 59 m^2. Density in classrooms ranged from 1.6 to 3.3 m^2 per person. The students who studied in schools investigated were 8th to 12th grade students.

The occupation rate of classrooms was 44…92 %, the doors and windows were closed during the class. As rule the duration of the measuring of parameters in classrooms was 40-45 minutes. The instruments used for measurements were Testo series 400 and 435.

3 Results

The rise of CO_2 concentration in classrooms is quite different; it depends mostly on the occupation rate of the classroom, air change per student and the level of CO_2 at the beginning of the class. Air change is very modest: 0.3-3.9 l/s per student. With low air change and normal occupation rate the rise of CO_2 is remarkable– 900-1600 ppm. The level of CO_2 at the beginning of the class differs greatly: ranging from 590 to 2160 ppm.

The range of relative humidity in classrooms is from 24% to 54% and the indoor temperature is between 18 to 25.5 ^{o}C.

4 Discussions

With natural ventilation in classrooms and airing only during breaks it is practically impossible to keep the CO_2 concentration under the permitted limit, 1000 ppm [12], at the end of a class with full occupation rate. Calculations show that in classrooms with average occupation rate, with an approximate air change of 1 l/s per m^2 and with good airing during breaks it is possible to hold the maximum CO_2 concentration on a level up to1500 ppm. To keep the CO_2 concentration under the permitted limits in fully occupied classrooms mechanical ventilation is needed.

5 Conclusions

With high occupation rate in gymnasiums of Tallinn good indoor climate and permitted CO_2 concentration at the end of the class can achieved only with the use of balanced ventilation.

It is advisable to use in a classroom displacement or wall confluent ventilation, the latter increasing the efficiency of air change.

The necessary air change should be 7-10 l/s per student, depending on the method used for air change.

Air distribution and temperature control in classrooms

Jarek Kurnitski[1] and Minna Aalto[2]

[1]Helsinki University of Technology

Corresponding email: jarek.kurnitski@tkk.fi

1 Introduction
Experimental interventions have shown that increasing the outdoor air supply rate and reducing moderately elevated classroom temperatures significantly improved the classroom performance of many tasks. The results suggest that higher ventilation rates up to 10 L/s per person as well as more strict temperature control than commonly used can be recommended for classrooms.

In this study, air distribution solutions for classrooms aiming to lower air velocities and good room temperature control are studied by measurements in 6 schools and by temperature simulations.

2 Methods
Air velocity, room temperature and CO_2 measurements were done in 6 schools. All schools were either relatively new buildings or renovated buildings, all having modern mechanical supply and exhaust ventilation systems. Air velocity measurement points were selected with smoke test, so that the highest velocities could be measured.

Both constant air volume (CAV) or demand controlled (DCV) ventilation systems with constant or controlled supply air temperature were used in schools. Differences between DCV and CAV systems and supply air temperature control options were studied with temperature and ventilation simulations for typical classrooms with a varying heat load.

3 Results
The performance of wall, ceiling, duct and displacement diffusers was compared. The highest measured ventilation rate was 340 L/s in the classroom with two duct diffusers, Figure 1. The maximum air velocity in the occupied zone with supply air temperature by 6°C lower than room temperature was 0.19 m/s. Another duct diffuser with small nozzles showed similar performance. The third duct diffuser without nozzles (just a perforated duct) showed the maximum velocity of 0.29 m/s.

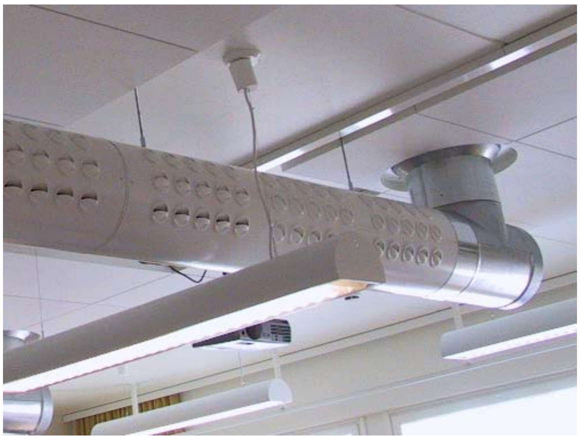

Figure 1. Duct diffuser with highest airflow rate

The wall diffusers were clearly not suitable for classrooms due to high velocities up to 0.43 m/s. Displacement ventilation diffusers were very sensitive to supply air temperature, as with a temperature difference of 3 °C velocities up to 0.28 m/s were measured.

4 Conclusions
Air velocity measurements showed good performance of duct and ceiling diffusers which provided maximum velocities less than 0.2 m/s and can be highly recommended for classrooms. The wall diffusers were clearly not suitable for classrooms due to high velocities which were also the problem of displacement ventilation diffusers at lower supply air temperatures.

Room temperature measurements showed a typical problem with temperature control as at the end of the heating season the temperatures up to 25 °C were measured. Parametric simulations showed that high supply air flow rates up to 10 L/s per person and cool supply air down to 14–15 °C were needed for room temperature control. This can be achieved with duct and ceiling diffusers measured.

Typologies of Hybrid Ventilation in Schools

Peter van den Engel[1]

[1]Deerns Consulting Engineers, Rijswijk / Delft Technological University, faculty of Architecture, Urbanism and Building Sciences, Delft

Corresponding email: p.vd.engel@deerns.nl

1 Introduction

In The Netherlands and other European countries the air change rate in schools increases in order to prevent health problems of students. The minimum air supply in The Netherlands is 7 l/s per student. Due to the high occupancy (generally 1 person at 2 m^2) prevention of draught needs much attention. Architects need ready-to-use ventilation design concepts for schools because of:

- A lack of knowledge of draught prevention,
- Individual architectural opinions,
- A low budget.

A research project is starting in The Netherlands to design options of natural, mechanical or hybrid ventilation. These systems for new or refurbished schools will be presented in a comprehensive way in a Dutch design guide and can be integrated in a REHVA-guide dealing with healthy schools in the near future.

2 Methods

The methods used and subjects discussed are:

a. Architectural research

- Systems of natural air supply, mechanical exhaust and several combinations with ceilings for three different façade typologies (positions of windows).
- A system of natural air exhaust via a double window and mechanical air supply for existing monuments.

b. Research of physical principles of air flows and heat transfer

- The mixing process of cold air with the surrounding warm air in order to prevent draught, with or without a false ceiling.
- An air outlet in a double window, the air resistance and dependency of wind pressures.
- The effects of different heating systems.

c. Airflow measurements and CFD-simulations

- The presented natural air supply and natural exhaust systems have been measured or simulated.

3 Results

Results are design options of:

- Self regulating natural air supply or exhaust systems.
- False ceilings, related to thermal and acoustic parameters.
- Different heating systems.

4 Conclusions

1. An integral approach of all the important “indoor” physical parameters is necessary even for common design problems.
2. For architects and other designers it is very important to have a compact database of images and knowledge to show comfort-problems and optional solutions.

Comparison between thermal comfort predictive models and subjective responses in Italian university classrooms

Roberta Ansaldi [1], Stefano Paolo Corgnati [1] and Marco Filippi [1]

[1]Department of Energy (DENER), Politecnico di Torino, Torino, Italy

Corresponding email: roberta.ansaldi@polito.it

1 Introduction

The Indoor Environmental Quality affects not only health and comfort, but also the occupants' productivity, so it strongly influences the general quality of working and educational environments. This study is focused on thermal comfort and aims at achieving a better knowledge about the subjective perception in naturally ventilated environments, in which the occupants have only some opportunities of behavioural adjustment. A particular, but significant, case is here analysed: naturally ventilated university classrooms. This study is part of a wider research started by the Building Physics and Indoor Environment Engineering Research Group (see http://www.polito.it/ftarch) of the Department of Energy (DENER) of the Politecnico di Torino, focused on environmental comfort in Italian school buildings. This paper focuses on the results from the thermal comfort field investigations in university classrooms.

2 Methods

The field study was conducted through physical observations and questionnaires, performed at the same time during the regular lesson time, in a period just before the start of the heating season. The approach consisted of administrating a questionnaire to a group of occupants while the investigator records certain microclimatic parameters. The object of this study, an extension of the previous study, was a university classroom of the Politecnico di Torino. The classroom was examined during the lesson time, in two periods outside the heating season, the first in September, with 103 students and the second in October, with 108 students. Heating through radiators and mechanical ventilation were off during the field campaigns. Two different comfort criteria, Fanger's PMV and an adaptive thermal comfort diagram, deriving from recent field studies, were applied, for the elaboration of the measured and observed data. The results were compared with the subjective votes of the students. Furthermore the votes of thermal preference were compared to the votes of thermal sensation.

3 Results

The two "objective" approaches lead approximately to the same results, in predicting the percentage of dissatisfied. The expected percentage of dissatisfied (< 10%) was compared to the percentage of dissatisfied from the questionnaires. It was found out a good agreement between the calculated PPD and the percentage of dissatisfied from the questionnaires when people voting (+2) on the seven points thermal sensation scale were considered satisfied. The judgments on the seven points thermal sensation scale were then correlated to acceptability and preference. The cumulate frequency distributions of ''wanting warmer'' and ''wanting colder'' versus the subjective judgment on thermal environment were plotted. The point corresponding to the minimum number of dissatisfied did not coincide with the thermal neutral condition (0 in the subjective vote) but was slightly shifted toward the positive values of the vote scale.

4 Conclusions

This study allowed a comparison between different predictive approaches for thermal comfort and a comparison between the predictions and the observed subjective responses. Furthermore it added new findings to previous researches conducted in Italian university and high school classrooms, during the heating season. The results of this study confirmed the trend outlined by the previous study, but with a minor intensity, suggesting a correlation between the thermal acceptability and preference and the outdoor temperature.

A comparative analysis of the indoor air quality and thermal comfort in schools with natural, hybrid and mechanical ventilation strategies

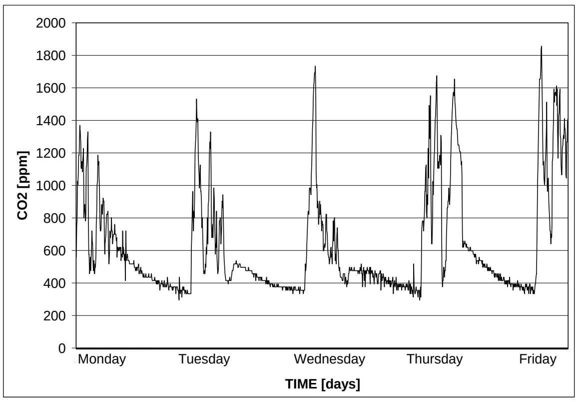
1 Introduction
The UK Government has committed to a massive programme of rebuilding and refurbishing schools in England and Wales in the next 10 to 15 years. To underpin this plan, the Department for Education and Skills has published design guidance - Building Bulletin 101 'Ventilation in School Buildings'. This performance standard document is cited as a means of compliance with the new Building Regulations Part F (Ventilation) in England and Wales. In this document CO_2 concentration has been chosen as the key performance indicator for the assessment of indoor air quality and ventilation performance in schools.

The work presented here forms part of a larger study investigating the ventilation performance of schools. That study, in addition to the requirements stated in Building Bulletin 101, is also investigating whether the comfort of occupants is compromised by the ventilation strategy in a particular classroom. This paper then focuses on a comparative analysis of indoor air quality and thermal comfort in three recently built schools with different ventilation strategies: natural, hybrid and mechanical.

2 Methods
Measurements were carried out in three schools in England during the heating season 2005-2006. All schools were built in compliance with Building Bulletin 93, which defines noise and acoustic criteria in relation to school design. The monitoring was carried out in two selected classrooms in each school over a period of five working days. Levels of CO_2 were monitored at five-minute intervals throughout the occupied day close to the occupied zone at seated head height to indicate the overall indoor air quality and provide a means of inferring the ventilation rate based on the number of occupants. In addition to CO_2 levels, thermal comfort parameters were also measured during the occupied periods in each of the selected classrooms.

3 Results
All the schools satisfied the recommended ventilation performance standards during the week that the measurements were undertaken – a record of CO_2 concentrations for one of the classrooms is given in figure 1.

Figure 1. CO_2 levels in a naturally ventilated classroom



With regards to comfort, not all of the classrooms met the relevant recommended levels.

4 Conclusions
The ventilation measurement results are apparently reassuring. However, this conclusion can be misleading unless one takes into account both the original design assumptions and then the actual occupancy of the classrooms and occupant behaviour in general. The work has raised concerns relating to the comfort provided in some of the classrooms.

Schools: All Problem Buildings?

Hens Hugo S.L.C., De Meulenaer V.

K.U.Leuven, Department of Civil Engineering, Laboratory of Building Physics

Corresponding email: hugo.hens@bwk.kuleuven.be

Seven schools underwent an energy audit, evaluating the existing situation through measurement and simulation and looking to possible retrofit measures and their economic feasibility with the energy performance tool (EPB) as an instrument. The results are troubling. The seven schools audited are all problem buildings: hardly any insulation, windows quite air leaky, central heating systems poorly designed and no usage of an on purpose installed ventilation system. As a consequence, IAQ is poor, with CO_2-levels passing 3000 ppm and a high percentage of dissatisfied with air freshness during teaching hours. Annual end energy use, however, is remarkably low compared to the EPB-prediction, showing that a potentially high energy demand evokes effective rebound behavior. The negative side of that is that hardly any energy conserving measure has enough impact to show a positive NPV at the end of the return period, let it be that the annuity on investment is lower than the annually avoided energy cost.

Ventilation of Dutch schools; an integral approach to improve design

Wim Zeiler[1], Gert Boxem[1]

[1]University of Technology Eindhoven (TU/e)

Corresponding email; w.zeiler@bwk.tue.nl

1 Introduction

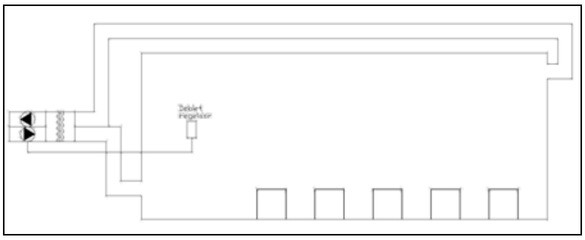
Indoor Air Quality and thermal climate in schools is very important as it has a direct relation to the health and performance of the pupils. The status quo in the Netherlands is presented (e.g. average CO2 levels in schools, quality of ventilation). The goal of a first study was to evaluate the performance of exhaust-only ventilation systems. The performance was rather disappointed there were a lot of problems and insufficient situations found.

Average and range of CO_2-concentrations for Dutch schools:

Study	**number of schools**	**CO_2, ppm** Average	Range
Joosten, 2004	5	1220	480-2400
van Dijken, 2004	11	1580	450-4700
van Bruchem, 2005	6	1355	550-3000

2 Contribution to the conference

During the next years different master students together with the staff of Technische Universiteit Eindhoven were researching different aspects of the problem and trying to find solutions. A new integrated approach to design adequate solutions for ventilation of school buildings was developed. First design results are described in the paper.



Schematic of displacement classroom ventilation

3 Conclusions

Many ongoing research efforts aim at introducing the used methodical design process into building design and architecture, and so linking architectural design with HVAC-design. In the Netherlands this has resulted in a stark interest in what is commonly named ‘integral design’.

Integral design is meant to overcome the difficulties of design team cooperation, by providing methods that make it possible to communicate the consequences of design moves on areas such as construction, costs, life cycle and indoor climate at early design stages, between the different disciplines.

Corresponding email: ikhan@itn.pt

Abstract
This study deals with Particle Matter (PM) levels below 2.5 µm ($PM_{2.5}$) in Portugal and shows that US EPA (United States Environmental Protection Agency) directive is exceeded in a few places. $PM_{2.5}$ total mass concentration measured in several places located in Portugal mainland and islands and the outskirts are quite well correlated for a few sites. Results show that it is important to determine the elemental composition of $PM_{2.5}$, and to develop an epidemiological study in Portugal to find a possible association between $PM_{2.5}$ levels, sources and morbidity/mortality. However, the results imply that a source-oriented evaluation of PM health effects needs to take into account the uncertainty associated with the spatial representativity of the species measured at a few sampling stations. For that purpose the survey using biomonitors may contribute positively.

Indoor Thermal Environment in a Classroom Equipped with Air Forced System

Eusébio Conceição[1], Vitor Vicente[1] and Mª. Manuela Lúcio[2]

Corresponding email: econcei@ualg.pt

Summary
In this work the evaluation of the indoor thermal environment in a classroom equipped with air forced system will be made. In the classrooms' indoor thermal environment, with the air forced inlet in the door and the outlet located above the windows, two situations are analyzed: the inlet forced airflow made in the doors' lower and upper area.
This experimental study, made in a school building located in the South of Portugal (see figure 1), in Mediterranean climate, evaluates the thermal comfort (using the PMV index), local thermal discomfort (using the draught risk and uncomfortable air velocity fluctuations) and air quality levels (using the air renovation rate) that occupants are subjected.
The experimental test was made in Summer conditions in a warm September day using the inlet air flow coming from the corridor compartment. The corridor inlet air temperature, lower than the outdoor environment, is insufficient to guarantee comfortable conditions. Nevertheless, in general in this kind of warm days the students are in holidays.
The draught risk is highest in the occupied area near the door, mainly when the ventilator is placed in the door's upper area.
The equivalent air velocity fluctuations frequencies values are inside the uncomfortable interval, nevertheless the more uncomfortable air velocity fluctuations are verified near the lower members level in the desks placed in front to the window near the blackboard, when the ventilator is placed in the door's lower area, and near the head level in the desks placed in front to the door near the blackboard, when the ventilator is placed in the door's upper area.
The local airflow rate is lightly lower when the ventilator is placed in the door's lower area than when the ventilator is placed in the door's upper area. Nevertheless, in all situations the air renovation flow rate is insufficient.
In order to increase the air renovation rate, in future works, to use more than one extractor fan and to put them in the window upper area instead of the door area are recommended. This fact reduces substantially the influence of external wind direction, which was verified in the present work. Nevertheless the increase of the airflow rate, mainly for lowest air temperature levels, can promote local thermal discomforts levels, associated to the draught risk, mainly in desks located near the blackboard.

A study on the effect of the airflow rate of the ceiling type air-conditioner on the ventilation performance

Kwang-Chul Noh [1], Chang-Woo Han[2] and Myung-Do Oh[2]

[1]Institute of Industrial Technology, University of Seoul, Seoul 130-743, Korea
[2]Department of Mechanical and Information Engineering, University of Seoul, Seoul 130-743, Korea

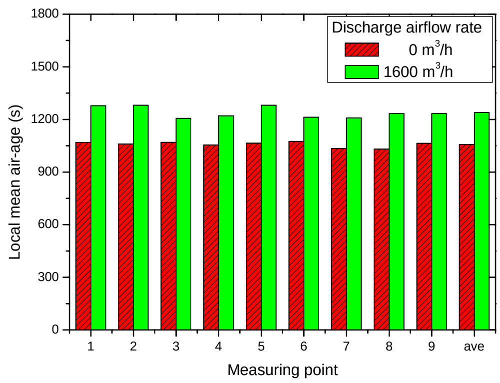
Corresponding email: mdoh@uos.ac.kr

1 Introduction

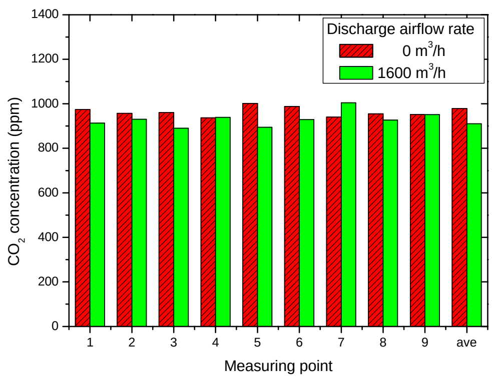
We performed the experiments and numerical simulations in a lecture room with a ceiling type air-conditioner and a ventilation system. With variations of the air discharge rate of the ceiling type air-conditioner and occupancy, CO_2 concentrations and local mean air-ages during class hours were investigated and the effect of the air discharge intensity of a ceiling type air-conditioner on ventilation effectiveness was analyzed.

2 Results

When the discharge airflow rate of the ceiling type air-conditioner, which is one of the indoor momentum sources, is increased, mean air age can be also increased. The reason is that the operation of the ceiling type air conditioner intervene the air current and makes the outdoor fresh air move a longer way. Therefore the indoor air quality may be deteriorated as the discharge airflow is increased. Unlike mean air age distributions, CO_2 concentration get to be somewhat decreased as the discharge airflow rate is increased. This reason is that the operation of the ceiling type air conditioner can make the mixing effect of indoor contaminants increased and the residual life time of indoor contaminants decreased.



(a) mean air age



(b) CO_2 concentration

Fig. 1 Experimental results for mean air age and CO_2 concentration at the measuring points with the different discharge airflow of 4-way cassette air-conditioner

3 Conclusions

The effect of the discharge airflow rate of the ceiling type air-conditioner on ventilation performance was studied. From the results, both of mean air age and residual life time must be considered for evaluating ventilation performance when the contaminants are generated indoors. And the increment of discharge airflow of the ceiling type air-conditioner can induce the piston effect and push the contaminants out of the occupied zone.

This shows that the ventilation performance can be increased when the momentum source like an air-conditioner, air cleaner, and fan is used in the room with mixing ventilation.

The Influence Of Mass Advance For Altitude Tropical Climate: Establishment Of Limit Conditions For Thermal Confort In Classrooms

Clélia Moraes, Architect

University of São Paulo, Brazil

Corresponding email: clelia.moraes@yahoo.com.br

Summary
This article is part of a research in progress about comparative study methods for the Brazilian reality using among many other authors, Givoni (1969), Voght and Miller-Chagas (1970), Fanger-ISO(1970), ASHRAE (55-1992), Mahoney (1971), Humphreys (1978) and Olgyay (1962) methods. This research presents the principal concept to be evaluated by the Universal Fuzzy Controlled aiming to establish a reference to determine a possible interference of the acclimatization factor to determine thermal comfort. An experimental evaluation method was elaborated through a questionnaire applied to the population of students in classroom, monitoring the environmental variables inside and outside the classroom during the years 2004 and 2005. It shows their particularities for the altitude tropical climate of the city of São Paulo -Brazil. This article describes interference of mass advance at the responses of students in classroom comparing to internal and external environment variables. The data was gotten in parallel with classroom in full activity.

Abstract
In this work, 36 basic schools of Lisbon city, Portugal followed a questionnaire of the ISAAC -International Study of Asthma and Allergies in Childhood Program. The questionnaire contains questions to identify children with respiratory diseases (wheeze, asthma and rhinitis) as well as their nutrition habits, ingested medication, environmental aspects, among others. The questioned children are 5 to 10 years old, and the answers are from June to December 2006. The results are from 995 children inquired who have shown 26.7% with wheezing symptoms, 9.2% with asthma, and 26.2% with rhinitis. The results obtained are compared with the results, interpretations and correlations obtained in the ISAAC 2002 program, which questioned 2484 6 to 7 years old children from the basic schools of Lisbon-city from November 2002 till March 2003.

Enhancing visual comfort in classrooms through daylight utilization

Kleo Axarli[1] and Katerina Tsikaloudaki[1]

[1]Laboratory of Building Construction & Physics, Aristotle University of Thessaloniki, Greece

Corresponding email: axarli@civil.auth.gr

1 Introduction

The present study is focused on the analysis and the evaluation of several daylight strategies aiming at the enhancement of visual comfort in classrooms.

2 Methodology

The study was conducted as a parametric analysis. On the basis of a typical classroom, the reference model (C_0) was created. A typical classroom is of rectangular shape, usually side lit with unilateral windows that account for 20% of floor area. The reference model is south orientated, side lit, with an unobstructed view to the sky vault. By changing the geometry, the position and the function of the transparent elements, 5 more models were created:

- Model C_1: glazed area: 20% of floor area. A light shelf is added, projecting towards both the interior and the exterior of the façade.
- Model C_2: glazed area: 25% of floor area. Daylighting is provided by lateral windows with light shelves (as in model C_1) and vertical south-orientated skylights, which are positioned on the roof at a distance of 3.5m parallel to the window wall.
- Model C_3: glazed area: 25% of floor area. Daylighting is provided by lateral windows with light shelves (as in model C_1) and vertical, south-orientated skylights, which are positioned on the roof at a distance of 4.6m parallel to the window wall.
- Model C_4: glazed area: 25% of floor area. Daylighting is provided by lateral windows with light shelves (as in model C_1) and vertical, north-orientated clerestories positioned on the opposite wall.
- Model C_5: glazed area: 25% of floor area. Daylighting is provided by lateral windows with light shelves (as in model C_1) and tilted, north-orientated skylights, positioned in two rows on the saw-tooth roof.

The visual environment prevailing in each case was estimated with the help of the simulation program ADELINE.

3 Results

In reference model C_0, the average levels of daylight are satisfactory, but the uniformity of daylight is not achieved. In order to moderate illuminance in areas near the windows and promote daylight penetration deep in the room, light shelves were incorporated. Simulations showed that the light shelves reduced the amount of light received in the interior of model C_1 relative to the conventional windows of model C_0, while the luminance distribution is better and the contrast between minimum and maximum values is limited. With the south skylights of models C_2 and C_3, daylight levels were increased without decreasing the uniformity of illuminance. In fact, it was found that the performance as regards daylighting is better when the skylights are located across the middle of the model's width. Bilateral daylighting with north orientated clerestories (model C_4) results to high levels of illumination, but the zone formed by low daylight factors is relatively wider, indicating a probable discomfortable visual environment. North orientated skylights (model C_5) have the best performance, since not only there is an overall increase of daylight factor on the working plane, but also the uniformity of its distribution is considerably intensified.

4 Conclusions

The above analysis showed that many alternatives regarding the location of openings exist for the enhancement of daylighting in classrooms. It is found that a combination of façade and roof apertures performs better than advanced façade systems (e.g.light shelves). From the examined models the north orientated skylights arranged in a saw-tooth roof combined with south windows appear to have the best performance. They bring more daylight in the rear areas, where illumination levels are low, daylight distribution becomes balanced and glare is avoided to a great extent as well.

Characterization of Indoor Air Quality (IAQ) in School using Biological Approach: A Case Study

Vinita Katiyar & MK Aggarwal

Department of Respiratory Allergy & Applied Immunology, VP Chest Institute, University of Delhi, INDIA-110007

Corresponding Author Email: vinita.katiyar@gmail.com

Abstract
Microorganisms play an important role in the development of the diseases associated with respiratory/lung function disorder in occupational environment. Biocontaminants forms a considerable part of the organic dust. It is a significant approach to characterize indoor air quality (IAQ) by measuring biological markers. IAQ of a school environment has been characterized by measurements of airborne biocontaminants (Bacteria and Fungi) of indoor dust. An innovative sampling strategy was designed and used to measure the concentration of airborne bacteria and fungi of viable or migrated, to be settled and settled dust. Three types of sampling techniques viz. Volumetric, Gravimetric and Swab sampling techniques were employed. Five sampling stations were installed to cover up maximum area of building. Sampling was carried twice in a month for eight months.

The results show that the airborne concentration of biocontaminants (Bacteria and Fungi) were varied from 10 to ≥3600 colony forming unit cfu). (Fungal concentration was ranged 10 to ≥1500 cfu, while bacterial concentration was ranged between ≥20 to ≤4000 cfu. Concentration of Gram Negative Bacteria (GNB) was found 25 to 30% higher than Gram Positive Bacteria (GPB). In conclusion, children and staff members working in such environment can be exposed to large concentrations of airborne biocontamints, which may increase a risk of work-related diseases. Study shows an impression of poor IAQ.

Study gives an idea about the use of array of sampling techniques concurrently. A combined use of such sampling techniques is simple, inexpensive approach in addition to no time consuming. It makes easy to sampling a large area as well as a large number of predictable samples can be collected at a time and sampling error can be avoid.

SUMMARY

Results of a pilot study published by Shaughnessy et al. 2006, demonstrated a modest association between class room ventilation rates and student performance in math standardized test scores, and also a need for further studies with larger sample size and more comprehensive assessment of indoor environmental quality (IEQ). A new school district in the USA with approximately 50 schools has undergone a thorough assessment protocol and the data is currently being analyzed. This paper focuses on these data, specifically on observations of potential contributors to poor IEQ. In addition there is a new on-going study in Finland that will provide further knowledge on how and to what extent IEQ in schools affect academic performance of students.

INTRODUCTION

It is assumed that poor indoor environmental conditions result in reduced learning potential and subsequent poor student academic performance (AP). However, there is limited data linking poor IEQ in the classrooms directly to student academic performance (Mendell and Heath 2005). Documentation of adverse effects of poor IEQ on AP is critical to motivate protective environmental guidelines in schools. One of the primary IEQ problems identified in earlier studies has been inadequate ventilation with outdoor air. For example, a recent study by Wargocki and Lyon (2006) found an association between improved performance (speed of tasks) and increased outdoor air supply rates.

A pilot study investigating classroom ventilation rates, and their association with reduced student performance was conducted within a school district in the USA in the spring term 2004. Data on classroom CO2 concentrations were recorded in 5th grade classrooms in fifty four elementary schools. In addition, investigators were able to work with the district to obtain standardized test scores (math and reading), and background data related to the students in the specific classroom studied in each school. Results of the pilot study demonstrated a modest association between class room ventilation rates and student performance in math, and also a need for further studies with larger sample size and more comprehensive assessment of IEQ (Shaughnessy et al. 2006).

A new school district in the USA with approximately 50 schools has undergone a thorough assessment protocol and the data is currently being analyzed. This paper will focus on these data, specifically on observations of potential contributors to poor IEQ. In addition there is a new study on-going in Finland (majority of the field work will be done in spring 2007) that will provide further knowledge on how and to what extent IEQ in schools affect academic performance of students. Specifically, the Finland study will explore the possible links between IEQ, AP, and students' health status, as it is assumed that poor IEQ can cause illness that require absence from school, and can cause health symptoms, hence decreasing performance (Daisey and Angell 1998).

This study program, as a whole, is specifically designed for a school setting and looks directly into the relationship between student AP and IEQ. The primary aim of the program is to study if student AP is significantly (in the statistical sense) related to IEQ in classrooms. The study also aims to further characterize the relationships, and identify critical determinants and links.

METHODS

Preliminary data is being acquired on a new school district in the USA with 50 elementary schools. The schools selected are representative of a consistent cross section of elementary schools. Specific emphasis was given to the classroom under investigation related to the students in the 5th grade study room. Schools in the district normally had more than one section of 5th grade students (multiple classrooms). The study room was selected (only 1 from each school) randomly, except for the provision that the HVAC system serving the classroom was restricted, when possible, to that classroom alone.

The new data focused again on the use of CO2 concentrations as a surrogate for ventilation rates. CO2 concentrations were logged over a two day period within typical school day occupancies under closed classroom conditions (i.e. windows and doors closed), and translated into ventilation rates per child, which were then adjusted based on the typical occupancy in the room throughout the school year.

Other indicators of the indoor environment related to the investigated classrooms were recorded by checklists incorporating a thorough assessment protocol. The visual observation data, based on current conditions and building characteristics included observations such as: general building and HVAC characteristics, evaluation of condition and performance of structural assemblies, use of materials, degree of clutter, general cleanliness of environment, sources of chemical and biological pollutants (animals, dampness/mold, VOCs, particles), and cleaning regimen. This paper focuses on building and HVAC characteristics in relation to ventilation rates. Thermal comfort parameters and airborne particle concentrations were also measured, but will be reported elsewhere.

In addition to the measurements and investigations, investigators were able to work with the district to obtain results from results of statewide-standardized test scores (math and reading), and background data related to the students in the specific classroom studied in each school. For the year of classroom IAQ sampling the percent of students scoring satisfactory or above in math and reading tests in each studied classroom was chosen as the primary metric of AP used in the study.

The data presented in this paper was input into a database and analyzed using SPSS statistical package version 14.0. In the initial screening, Pearson's correlation coefficient was used as a measure of linear association between ventilation rate and general building characteristics. Cross tabulation and chi-square test (categorical variables) or independent samples t-test (continuous variables) were used to study univariate associations between ventilation and building –related variables. Multivariate analysis was performed using logistic regression and step-wise method in selecting the independent variables.

RESULTS AND DISCUSSION

General information about the schools is shown in Table 1. Mean age of the buildings was approximately 50 years, and mean size was approximately 5450m2, leading to occupant density of approximately 0.086 occupants/m2.

Table 1. General information of the school buildings.

	mean (min-max)
Year when built	1958 (1907-2005)
Size of the building m^2	5450(3500-11950)
Number of occupants	
teachers	30(13-75)
other personnel	29(9-80)
students	381(162-1000)

Most of the school buildings were one story structures with slab-on-ground, with concrete frame and brick veneer exterior and flat roof (Table 2). All but three out of fifty schools relied on gas as the heating source.

Table 2. Predominant building characteristics.

	n(%)
One story construction	40(80)
Ground slab	45(88)
No basement	46(98)
Main frame structure material concrete/ concrete block	41(82)
External wall covering brick veneer	38(76)
Flat roof	36(72)
Bitumen roof membrane	37(74)
Type of heating source gas	47(94)

Predominant HVAC systems were roof top units and AHU’s (Table 3). Outdoor air was mechanically provided in 32(64%) schools and 17(34%) had mechanical exhaust. A total of 35(70%) class rooms could be ventilated by opening windows and in 13(26%) of the class rooms ventilation could be controlled mechanically. However, ventilation was perceived insufficient in most of the schools.

Table 3. HVAC characteristics

	n(%)
Predominant HVAC systems	
roof top units	15(30)
AHU’s	13(26)
heat only / window AC	10(20)
Predominant exhaust system	
natural (no mechanical exhaust)	33(66)
mechanical exhaust	17(34)

HVAC system provides outdoor air	32(64)
Ventilation be controlled in each class room by opening windows mechanically	 35(70) 13(26)
MERV rating of the filter 0-4 4-8	 14(28) 28(56)
Ventilation not perceived sufficient	30(60)

Ventilation rates ranged from 1.7 to 19.0 l/s per person. The highest ventilation rate observation appeared to be an outlier, and when excluded, mean ventilation rate was 4.6(1.7-11.4) l/s per person.

Ventilation rate did not correlate significantly with building age, size, occupancy, or with occupant density (data not shown). We then roughly divided classrooms into two groups based on whether class room had estimated ventilation rates 1) below or 2) above 4 l/s per person (close to 50th percentile), and cross tabulated the two-category variable with building and HVAC characteristics, as in Tables 2 and 3, which could be potentially associated with ventilation rate.

From building characteristics, a flat roof was significantly ($p \leq 0.05$) more common in the group of higher ventilation rates (above 4 l/s per person). All the class rooms above ground level fell into the group of higher ventilation rates. No significant differences were observed with respect to the other building characteristics (Table 2).

From HVAC characteristics, AHU's and roof top units were significantly more common in the group of higher ventilation rate, whereas five out of six schools with fan coil units fell into the lower ventilation rate category. Other characteristics that associated with higher ventilation rate were mechanical exhaust system, mechanical supply of outdoor air, and higher MERV rating of filter employed by the HVAC unit. Ventilation was perceived sufficient significantly more often in the higher ventilation rate category.

In multivariate analysis, two-category ventilation rate as the dependent variable, independent variables included in the model first round were roof type and HVAC system capacity in providing outdoor air. However, it was noticed that roof type associated with all HVAC characteristics (as in Table 3) in univariate level. It is not plausible that roof type as such would truly effect on the ventilation rate, thus the association seen is more likely to be caused by multicollinearity with other variables. Therefore, a second round was performed without roof type and the resulting two independent variables associated with ventilation rate variable were HVAC system capacity in providing outdoor air, and mechanically controllable ventilation.

Mean math and reading test scores in different ventilation rate categories are shown in Table 4. Although the mean math score was approximately 8% higher, and reading score was approximately 11% higher in the higher ventilation rate category (>4 l/s per person) than in the lower ventilation rate category (<4 l/s per person), this difference was not statistically significant. Further analysis will be made using more specific data on the ventilation rate and related variables, and also taking the confounding factors into account (in the earlier study, the effect of confounding factors was significant).

Table 4. Mean math and reading scores in class rooms with ventilation rates under or above 4 l/s per person.

	Ventilation rate	N	Mean	Std. Deviation
Math	< 4 l/s per person	21	69.7	14.7
	> 4 l/s per person	28	75.0	18.0
Reading	< 4 l/s per person	21	61.1	16.0
	> 4 l/s per person	28	68.4	20.4

ACKNOWLEDGEMENTS

This project has been supported by the National Energy Management Institute, the Indoor Air Quality Association, and Trane Corporation. In addition, Gray Wolf Sensors has contributed to the monitoring equipment for the project. The authors also wish to acknowledge the field work data collection by Mr. Bryan Jewett.

SUMMARY

Associations between classroom ventilation and pupils' performance were investigated in primary schools in the United Kingdom. The concentration of carbon dioxide and other parameters were monitored for three weeks in two selected classrooms in each school. A direct air supply system through the windows was used to alter the ventilation rates in the classrooms. The system was set either to provide outdoor air or to re-circulate the classroom air while all other physical parameters were left unchanged. Computerised Assessment Tests and Paper-based Tasks were used to evaluate pupils' performance. Pupils' perceptions about the classroom environment, comfort, general mood and hunger were assessed on subjective scales. The present paper shows preliminary results obtained for one primary school out of eight being studied. Due to the intervention the fresh air supply increased from 0.3-05 to 13-16 L/s per person that increased pupils' work rate by ~7% in addition ($p<0.036$) and subtraction ($p<0.052$).

INTRODUCTION

Former reviews on the subject of school environments emphasised that ventilation is often inadequate in classrooms causing increased risk for asthma and other health-related symptoms among school children [1], [2]. Mendell & Heath [2] proposed that throughout the life of each existing and future school building immediate measures should be taken for the provision of adequate outdoor ventilation, control of moisture, and avoidance of indoor exposures to microbiologic and chemical substances considered likely to have adverse effects. The current ventilation standards and guidelines [3], [4] recommend a minimum fresh air supply rate of 8 litres/s per person for occupants in all teaching facilities. The recently published Building Bulletin 101 refers to proposed performance based standards limiting the level of carbon dioxide (CO_2) concentration to 1500 ppm over a full school day from 9:00 to 15:30 and specifies a minimum supply of external air at least 3 L/s per person in all teaching and learning spaces when they are occupied. Furthermore, a ventilation rate of 8 L/s per person for the normal number of occupants should be achievable under the control of occupants, although it may not be required at all times if occupancy level decreases. However, according to recent studies the average CO_2 levels in classrooms often exceed the above limit and ventilation rates are often below the minimum requirement of 3 L/s per person [5], [6].
The negative effects of poor ventilation rates on work performance in office buildings have been widely investigated [7]. Knowing the outcome of poor ventilation rates for the adult population it could be expected that not only the comfort and health, but also the learning performance of school children are affected by the poor environmental conditions in classrooms [2]. Following the earlier studies suggesting correlation between pupils' health

and work performance, [8], [9] there is growing evidence showing impairment of learning performance and increased absenteeism due to inadequate ventilation and unsuitable thermal conditions in classrooms [10], [11], [12], [13]. The main purpose of the present research was to investigate the relationship between pupils' health, well-being and performance, and the indoor air quality in several primary schools in Southern England. Another aim was to examine the suitability of the air quality guidelines in preventing the reported negative effects even when the recommended levels of fresh air to the occupants are met.

METHODS

Field surveys were carried out at primary school buildings located in the proximity of Reading during years 2006-2007. Up till now measurements have been done in eight different schools. The sample included schools that were built in the last 20-40 years. Except for one school, none of them had mechanical ventilation system and in most schools no control over the temperature was available to the staff. At each selected school investigations were carried out in two classrooms for at least three consecutive weeks. The first week was reserved to monitor the classroom conditions without modifying any of the indoor climatic parameters and to familiarise the children with the performance tests. During the second and third week a mobile ventilation system was installed in each classroom to control the ventilation rate and maintain the temperature within certain limits. The system was set either to provide outdoor air or to re-circulate the classroom air. Although the ventilation system was visible, the staff and the children were not informed of the ventilation conditions, i.e. whether it was providing fresh air or re-circulated air. The order of presentation of the fresh air/re-circulated conditions were made in a cross over repeated design for the two classrooms.

The ventilation system consisted of an exterior fan placed outdoors and simple ducting of diameter 200 mm led the air into the building through window openings, which were closed with Perspex plates (Figure 1, a). In the classrooms the air was distributed using Softflo air terminal units, which consist of a perforated duct with small nozzles creating confluent jets flow into the room [14]. The temperature of the supplied air was controlled by means of a duct heater (3kW) and a mobile air conditioning unit of 2.7kW built into the ventilation system. The capacity of the supply fan was selected to provide 200 L/s, matching the prescribed level of 8L/s per person in a classroom having on average 25 children. Silencers were also built into the system upstream and downstream of the fan to reduce the noise level propagating through the duct work into the classroom.

a)

b)

Figure 1. a) Exterior fan of the mobile ventilation system, b) Testing area with laptops and measuring trolley with the air terminal device in the background; the trolley was placed close to the testing area during performance tests.

Physical measurements: CO_2 concentration (0-5000 ppm), air temperature, globe temperature, relative humidity (RH), air velocity and light level were continuously monitored in each classroom and recorded with 3 minutes interval on a central logger using a wireless data transmission technique. These sensors were fixed on a trolley (Figure 1. b) and placed close to the testing area in the classrooms. In addition three thermistor type temperature probes were distributed on a vertical pole fixed to the trolley to record the temperature differences between pupils' head and feet levels. Separate units were placed outdoors and in the corridors to measure CO_2 concentration, temperature and RH. Mass concentration of airborne particles (PM2.5) and noise level were measured during the performance tests on pupils over a few hours. The amount of supplied air to the classrooms was measured with Venturi flow meters built into the duct system downstream of the fan.

Subjective evaluations: Simultaneous to the physical monitoring, measures of self-assessed environmental perception, comfort and health were obtained immediately after the performance tests were carried out. With some exceptions all pupils participated in the testing. The targeted age group of the children was between 9-10 years attending Year 5. This age group of pupils was selected because they remain in their classrooms most of the day and are therefore in the same environment throughout a school day. The pupils were asked to complete a simple questionnaire about the classroom environment, thermal sensation, mood, Sick Building Syndrome (SBS) symptoms and life style, such as hunger and quality of sleep over the previous night believed to affect their performance. The questionnaire about the classroom environment included questions about air stuffiness, dryness, perception of light and noise. The SBS questionnaire focused on symptoms of the mucous membrane and in upper respiratory tract, such as nose congestion, nose, mouth, throat and eye dryness, and neurobehavioral symptoms including headache, attention, dizziness, tiredness, sleepiness. Pupils were asked to rate the intensity of each symptom on Visual Analogue (VA) scales [15]. Thermal sensation was recorded using a 7-point PMV scale [16]. Furthermore, pupils were asked to rate the air movement around their body and inform whether it was acceptable or not.

Pupil's Performance Tests: Two different performance tests were administered to the pupils in each school. Traditional tests were carried out on paper for 40 minutes, including simple addition and subtraction of numbers (15 minutes each) and reading comprehension [17] (10 minutes) similar to that performed in a normal school day. New software (VISCOPE – Ventilation in Schools and Cognitive Performance) was developed that uses algorithms based on the work of Iregren *et al.* [18] to study changes of pupils' cognitive performance under different air quality conditions in classrooms. These tests were conducted on laptop computers set up in the classroom, similar to the method used by Coley and Beisteiner [19]. Both the traditional tests and the computer tests were given to pupils during their lessons preferably before the lunch break when the CO_2 concentrations had reached the maximum level of the morning's teaching session. The computer tests lasted for 20 minutes and were conducted in 3-4 consecutive groups, each group including 7-8 children. The tests, whether they were conducted on paper or computers, were carried out on each testing week on the same weekday and time period for each group of children.

Data analysis: Outdoor air supply rate was calculated based on the mass balance model of CO_2 on each testing day. The subjective and performance data were analysed using Wilcoxon matched-pairs test, using each subject as their own control. All p-values are 1-tailed of an effect in the expected direction.

RESULTS

The current project is still in the phase of data collection hence preliminary results of the physical environment and performance tests conducted on paper from only one school are presented. Detailed analysis of the performance results including those conducted on the computers will be published on the completion of the current investigations.

Figure 2 shows a typical CO_2 pattern in one of the classrooms during a weekday when performance tests were completed. The classroom of 156 m^3 was occupied by 23 children and a teacher at normal activity levels. The teaching schedule including lessons and break time can be clearly followed by looking at the changes in the CO_2 concentrations. The uncontrolled condition on Figure 2 shows the CO_2 level prior to any intervention in the classrooms. The CO_2 concentrations obtained during the week with the re-circulation ventilation are matching closely the uncontrolled levels seen during a normal school day. When the ventilation system was switched on to provide outdoor air the CO_2 concentrations were dramatically reduced and remained below 1000 ppm throughout the school day.

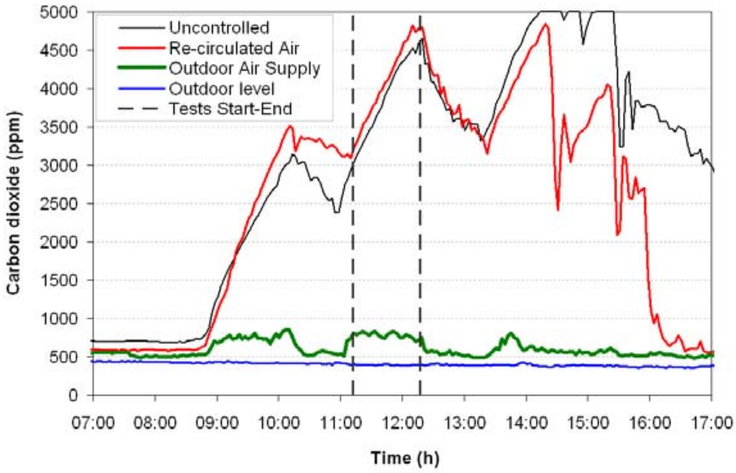

Figure 2. Typical pattern of the CO_2 level inside a classroom at different ventilation conditions on a testing day. The uncontrolled condition reflects CO_2 concentration during a normal school day without any intervention measures.

The average levels of the main physical parameters in the classrooms during the performance tests are presented in Table 1. At low ventilation rates the CO_2 concentrations during the performance tasks at a given day and classroom varied from 1600 ppm up to 4000 ppm depending on the occupancy level prior to testing. Temperature deviations between low and high ventilation rate conditions were within 1.7°C with one exception in classroom B where the difference in the operative temperature reached 2.7°C due to exceptional hot outdoor conditions during the tests conducted on paper. Relative humidity was generally higher at low ventilation rates due to moisture generation from people that is also reflected in the enthalpy of the classroom air. The air exchange rates in the re-circulation mode were not higher than 0.3 h^{-1} in both classrooms, showing an effective building tightness with closed windows that is responsible for the high levels of CO_2 and the extremely low outdoor air infiltration of not more than 0.55 L/s per person. The measured amount of fresh air supplied during improved ventilation was at180 - 190 L/s corresponding to 4.2 - 4.4 h^{-1} air exchange rates. The calculated air exchange based on the CO_2 mass balance model showed higher rates of up to 8 h^{-1} (12 - 16 L/h per person) which is most likely due to some windows being opened that enhanced cross ventilation. The average particle (PM 2.5) concentration during testing was in the range of 0.05 - 0.1 mg/m^3 and did not show major changes due to ventilation improvement. Classroom noise levels during testing were typically between 50 - 70 db(A) depending on the classroom activities. The background noise level originating from the ventilation system installed was less than 48 - 49 db(A).

Table 1. Average levels (± standard deviation) of main environmental parameters inside the classrooms and outdoors during performance testing; the ventilation rate calculation is based on the CO_2 mass balance model for each classroom; outdoor CO_2 level was at 380-420 ppm.

	class room	Testing on Computer		Pen & Paper testing	
		Re-circulated Air	Oudoor Air Supply	Re-circulated Air	Oudoor Air Supply

	B	80	83	n.s.	78	81	n.s.

Selected results of subjective responses to the classroom environment immediately after testing are included in Table 2. The pupils in classroom A perceived the air as being fresher, the classroom less noisy and their general feeling about the classroom environment was significantly better in the condition with increased ventilation compared to that with re-circulation. There was a trend approaching significance towards higher alertness, better work mood and tendency for less tiredness and increased attention following the performance tests conducted on paper at the higher ventilation rates. The pupils' thermal sensation was in accordance with the existing temperature differences shown between the conditions. They were closer to neutral at operative temperatures between 18.8 and 20.2 °C and felt slightly warm at 20.5-21.6 °C.

Evaluation of the reading comprehension task was made according to the marking sheet provided with the tasks. Compared to a maximum mark of 16, the children in classroom A obtained an average mark of 9.4 in the condition with improved ventilation that showed a tendency of a higher rating ($p<0.09$) than 8.1 achieved in the other condition with low outdoor air supply rate. No significant change was found in the reading comprehension marks of children from classroom B between the two experimental conditions. Details of the maths based performance measures for all (40) children who completed the performance tasks in both experimental condition are shown in Table 3.

Table 3. Average speed, accuracy and overall performance (i.e. number of error-free units) of subjects achieved in the addition and subtraction tasks.

Class-room	Condition	Addition task			Subtraction task		
		Speed (units/h)	Error Rate (%)	Performance (units/h)	Speed (units/h)	Error Rate (%)	Performance (units/h)
A	Re-circulated Air	142.3	23%	111.2	149.1	43%	90.1
	Outdoor Air Supply	143.0	19%	118.7	142.7	37%	90.9
B	Re-circulated Air	139.2	15%	121.3	144.4	28%	103.4
	Outdoor Air Supply	144.4	13%	125.5	143.4	21%	114.3
A + B	Re-circulated Air	140.8	19%	116.0	146.9	36%	96.4
	Outdoor Air Supply	143.7	16%	121.9	143.0	30%	102.0

The children in classroom A tended to work more accurately in both addition ($p<0.07$) and subtraction ($p<0.07$) tasks and slight improvement in the overall performance of addition ($p<0.068$) was noticed at the higher ventilation rate compared to low ventilation. Similarly, the pupils in classroom B made significantly less errors ($p<0.01$) and achieved better performance ($p<0.029$) during subtraction at the higher ventilation rate. For classroom B the changes in the performance measures of addition did not reach significance levels. However, when the data for classroom A and B were pooled under the common hypothesis that the children work better under improved ventilation, significant or close to significant improvement was obtained in the overall performance of both addition ($p<0.036$) and subtraction ($p<0.052$). Separate analysis was carried out for children with higher math skills (25 pupils for both classrooms), i.e. excluding those who had a higher than 50% error rate in these tasks. This analysis resulted in similar but more significant effects than those for individual classrooms above. The children with higher math skills increased the number of error-free units in both addition ($p<0.02$) and subtraction ($p<0.007$) tasks when working under the improved ventilation conditions.

DISCUSSION

The CO_2 patterns over a school day are closely linked to the daily activities performed within or away from the classrooms and whether windows and doors are left open or not. The levels presented in Figure 2 reflect a situation when the classroom was occupied throughout a full school day and no windows were opened due to cool outdoor conditions without sunshine. Double glazed windows, installed at the majority of the schools studied, allow very little air infiltration. If windows are left closed in the absence of other means of providing a minimum amount of outdoor air CO_2 levels rise quickly (typically within 15-20 minutes) to 3000-4000 ppm under normal occupancy. Similar high levels in naturally ventilated classrooms have often been reported in UK schools [6], [10]. Adverse health effects associated with CO_2

exposure below 5000 ppm are difficult to evaluate since there are a number of other factors such as high pollution level from off gassing of building materials and elevated allergen concentration, appearing at low ventilation rates that also affect human wellbeing [20]. However, possible alteration in breathing and heart rate as well as loss of concentration and wellbeing due to CO_2 exposures in the range between 3000-5000 ppm may be expected [21]. Other adverse health effects due to CO_2 exposure such as dyspnea, headache, dizziness and lethargy were found mainly in medical investigations and short term exposures to CO_2 concentrations above 1% (10000 ppm) [22].
The thermal conditions during the first testing week were generally cooler both indoors and outdoors compared to the second week of testing. Therefore the average temperatures were somewhat higher under the re-circulated condition in classroom A and under improved ventilation in classroom B. Considering that the thermal environment may also affect work performance [11] the thermal conditions in classroom A would be in favour, and in classroom B would counteract the expected changes in performance due to improved ventilation. However, the alterations in temperature between the present experimental conditions were relatively small compared to those in which such effect were shown [11] and therefore these may be considered not to affect the present performance results. On the other hand the thermal conditions in classroom B have to some extent affected the pupils' perception in air freshness. Although the air quality conditions were improved the pupils did not perceive significant improvement in air freshness mostly due to the increased enthalpy of inhaled air at high ventilation [23]. The children in classroom A who effectively perceived a change in air freshness under improved ventilation also reported more positive effects in neurobehavioral symptoms (alertness, attention, tiredness) and work mood in contrast with children in classroom B.
A significant impact of the ventilation rate on the school work performance of pupils was observed in both classrooms. Summarizing the effects the overall performance of all children increased under improved ventilation by 5.1% and 5.8% for both addition and subtraction respectively. These effects were even stronger for the pupils with higher math skills. They increased their math performance by ~7% when working under the improved ventilation conditions. The magnitude of such effect is in the expected range that was seen in earlier studies investigating work performance due to improved ventilation rates [7], [11].

The present results strengthen the evidence of earlier findings that improved ventilation has beneficial effect on pupils' learning performance. Without intervention the existing ventilation rates in naturally ventilated school buildings remain below the minimum recommended levels if thermal conditions do not influence people to open windows. Measures that allow a minimum supply of fresh air to the classrooms of naturally ventilated buildings are needed particularly if windows are not operated adequately to control ventilation.

ACKNOWLEDGEMENT

The present research project is supported by The Engineering and Physical Sciences Research Council (EPSRC) and carried out in collaboration with the Department for Education and Skills (DfES). Special thanks to Professors Anders Iregren (Nat. Inst. for Working Life, Sweden) and David M. Warburton (Sch. of Psychology, The University of Reading) for providing the free use of their test systems for further development; Lindab Ltd for the free provision of the ventilation components and ducting; Heads of schools and Year 5 teachers from the participating schools for their collaborative work in developing the pupil's performance tests.

SUMMARY

Many research papers have been published on the potential effects of the quality of the indoor environment on productivity in classrooms and offices. This paper (Part 3) reports the result of nationwide field measurements based on subjective questionnaire surveys and objective test scores in a unified way.

It investigated 83 branches of a college, which are located in regions spread throughout Japan. The total number of subjects was about 4000. Objective learning performance was evaluated according to scores in standardized quizzes to measure the level of understanding of lectures. In addition to the objective evaluation using quiz scores, a subjective evaluation of learning performance was carried out using a questionnaire as a self-assessment form.

Percentage of dissatisfied of each schoolhouse did not have the correlation with quiz scores but had a significant correlation with a subjective evaluation of learning performance by a linear approximation ($p<0.006$).

INTRODUCTION

This series of studies evaluate the effects of changes in the air quality and thermal environments on student performance in the classroom. We have already reported the effect of indoor environmental quality on student performance based on field intervention surveys and laboratory experiments.

This paper (Part 3) reports the result of nationwide field measurements based on subjective questionnaire surveys and objective test scores in a unified way. In this research, the relationship between the quality of the indoor environment and student performance in college are linked quantitatively through this nationwide questionnaire survey and previous laboratory experiments. In addition, human psychology regarded to effect it most when learning performance is measured was evaluated “motivation for learning” using a questionnaire as self-assessment form.

NATIONWIDE QUESTIONNAIRE SURVEY METHODS

Questionnaire surveys were conducted to evaluate the relationship between satisfaction level and learning performance at branches of Nikken Gakuin College – i.e. the college used for the intervention surveys in the previous paper (Part 1) [Murakami, et.al, 2006].

Questionnaire surveys were carried out three times in total: in February 19, 2006 (winter) April 2, 2006 (spring), and June 11, 2006 (summer) at branches of the 83 Nikken Gakuin

College scattered over all regions of Japan. Two evaluations methods – an objective evaluation based on quiz score and a subjective evaluation based on a questionnaire on psychological factors – were used, and consistency was evaluated as well. In addition, human psychology regarded to effect it most when learning performance is measured was evaluated "motivation for learning" using a questionnaire as self-assessment form.

The lecture started at 9:00am. After the 180-minutes lecture ended (12 noon), the subjects took a 30-minute quiz, and then filled out the self-assessment form (questionnaire). Three five-minute breaks were provided during the 180-minute lecture.

The trial subjects were students taking a course for the qualifying examination for first-class architects. Those students were all highly motivated because nearly all of them were to take a qualifying examination scheduled for July. The total number of subjects was about 4000, most of whom were employed and in their twenties to forties. Since the students need to attend all of the lectures based on the curriculum provided by the college, the subject groups in individual measurement cases were almost the same.

Evaluation of learning performance

1) Evaluation of Objective Learning Performance

Objective learning performance was evaluated according to scores in standardizes quizzes to measure the level of understanding of the lectures. The purpose of the lectures was to prepare students to take the qualifying examination for first-class certified architects. Each standardized quiz consisted of 20 questions, each of which was answered by choosing one out of five options. Table 1 shows questions in a typical standardized quiz. To compare scores in quizzes for different lecture content, an adjestment was made to the scores based on data on the average scores in the examinations conducted by Nikken Gakuin College in fiscal 2006, and the difficulty levels of all examinations were standardized.

Table 1. Questions in Standardized Quizzes for the Objective Evaluation (in the field of architectural planning)

Question 10; Which of the following descriptions of different wiring methods used in office construction is the **most incorrect**?	
(1)	In the free-access floor wiring method a double floor is constructed, and the method uses the space between floors as the wiring space; this has the effect of reducing the design load on the floor.
(2)	The floor on the standard floor was made to the free-access floor of 6cm in height, and to correspond to the change in the layout of the office, considered in the office building.
(3)	In the under-the-carpet wiring method a thin cable is laid directly on the floor level, and a special floor finish is needed. However, it is possible to correspond to the change easily.
(4)	It wires a necessary place, and the bus baton wiring method is large the maximum, permissible current, and in the method to accommodate and to protect the conductor in this, is suitable for a mass power supply.
(5)	In general, the conductors used in the bus baton wiring method are made of copper or aluminum.

2) Evaluation of Subjective Learning Performance

In addition to the objective evaluation using quiz scores, a subjective evaluation of learning performance was carried out using a questionnaire as a self-assessment form. Table 2 shows the self-assessment form. Subjective learning performance is evaluated with Questions 4-(1) and 4-(2) shown in Table 2. The filing return made it answer by the answer sheet exam. Since a choice prepared only to ten pieces, the choice was set up based on the reply obtained by the previous paper (Part 1).

Table 2. Self-Assessment Form for the Subjective Evaluation

Question 1; **Yourself**
(1) Gender? 1.) Male 2.) Female
(2) Age? 1.) 10's 2.) 20's 3.) 30's 4.) 40's 5.) 50's 6.) 60's
Question 2; **Thermal Environment** (Heat and Cold)
(1) How does the temperature feel?
1.) Cold 2.) Slightly Cold 3.) Cool 4.) Moderate 5.) Warm 6.) Slightly Hot 7.) Hot
(2) Are you satisfied with the current thermal environment?
1.) Dissatisfied 2.) Slightly Dissatisfied 3.) Neutral 4.) Slightly Satisfied 5.) Satisfied
Question 3; **Air Environment** (Contamination and odor)
(1) Are you satisfied with the current air environment?
1.) Dissatisfied 2.) Slightly Dissatisfied 3.) Neutral 4.) Slightly Satisfied 5.) Satisfied
Question 4; **Understanding level** of lecture contents
(1) Please convert the effect and/or the frequency of effect of the indoor environment in the classroom on your understanding of today's lecture contents into lost time.
1.) 0 min 2.) 3 min 3.) 5 min 4.) 10 min 5.) 15 min
6.) 20 min 7.) 25 min 8.) 30 min 9.) 40 min 10.) More than 50 min
(2) How is the understanding level of the content of the lecture thought to improve if the factor of the indoor environment improves the understanding level of today's content of the lecture as 100%?
1.) 0% 2.) 5% 3.) 10% 4.) 15% 5.) 20%
6.) 25% 7.) 30% 8.) 40% 9.) 50% 10.) Over 60%
Question 5; **Motivation for Learning** (Motivation to absorb content of lecture)
(1) After entering your classroom, how high was your motivation for learning (Motivation to absorb content of lecture)?
1.) 0 -10 2.) 10-20 3.) 20-30 4.) 30-40 5.) 40-50
6.) 50-60 7.) 60-70 8.) 70-80 9.) 80-90 10.) 90-100

Evaluation of motivation for learning

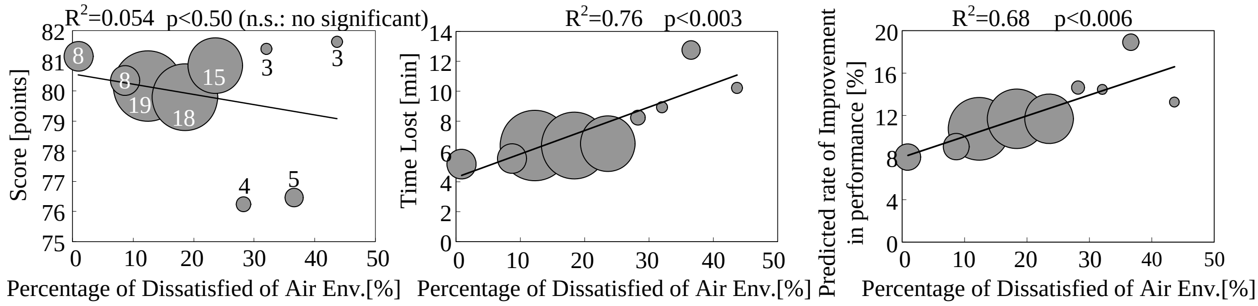
In this research, motivation for learning is defined as "motivation to absorb the content of the lecture." The investigation about motivation for learning tries evaluation of the motivation by which evaluation quantitative until now was not made almost, though it is a very important parameter in productivity research. Motivation to learn during the lecture was assessed using a questionnaire as a self-assessment form, too. Motivation for learning during lecture is evaluated Question 5 shown in Table 2.

The significance level was set at 5% and a corresponding t-test was used to compare the quiz results with varying environmental conditions. The Wilcoxon matched-pairs signed rank test was used as a corresponding rank scale in comparing the results of the self-assessment with varying environmental conditions.

RESULTS / LEARNING PERFORMANCE

Between learning performance and the percentage dissatisfied with the air environment

Figure 1 shows the relationship between the learning performance and the percentage dissatisfied with the air environment. It classified according to the unit 5% after calculating the rate of dissatisfied of air environment for every school building. Furthermore, the average value was calculated. The size of the plot in a figure expresses the number of school buildings in the point. The number of school buildings is shown during the plot. That is, the average value of the learning performance of the school building shown in the number under plot is expressed.



a) (Left) Quiz score vs. Dissatisfaction
b) (Center) Time lost vs. Dissatisfaction
c) (Right) Predicted rate of improvement in performance vs. Dissatisfaction

Figure 1 Learning Performance vs. Percentage Dissatisfied with the Air Environment

Figure 1a) shows the relationship between the results of the object evaluation (quiz score) and percentage dissatisfied with the air environment. Although there was a tendency for the quiz scores to improve as the percentage dissatisfaction decreased, there was no significant correlation between the two.

Figure 1b) shows the relationship between the results of the self-assessment of time lost due to the indoor environment and the percentage dissatisfied with the air environment. Time lost due to the indoor environment is based on the response to Question 4-(1). A linear relationship was observed between the subjective evaluation of time lost and the percentage dissatisfied with the air environment (R^2=0.76, $p<0.003$). In addition, the notation is omitting because the items of the number of school buildings are the same as that of the result with objective evaluation in figure 1a).

Figure 1c) shows the relationship between the results of the self-assessment "predicted rate of improvement in learning performance with an improvement in the environment" and the percentage dissatisfied with the air environment. The subjects were requested to report the learning performance improvement rates that they expected if the indoor environment was improved. Predicted rate of improvement in performance is based on the response to Question 4-(2). A linear relationship was observed between the subjective evaluation of the predicted rate of improvement in performance and the percentage dissatisfied with the air environment (R^2=0.68, $p<0.006$).
In addition, it got the same result the relationship between the results of thermal environment and learning performance.

Between objective evaluation and age

Figure 2 shows the relationship between the quiz scores and age. A linear relationship was observed between quiz scores and age (R^2 = 0.89, $p<0.06$ (n.s.: no significant)). It is thought that it was generated by accumulating experience, whenever it passes through age for preparation of the qualifying examination carried out every year. It was a result with the same said of April and June. In productivity research, in case working and study performance are measured, there is the necessity that experience must be taken into consideration.

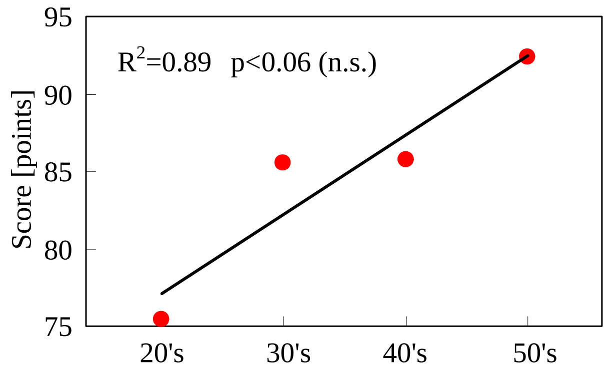


Figure 2 Object Evaluation vs. Age (February)

RESULTS / MOTIVATION TO LEARN

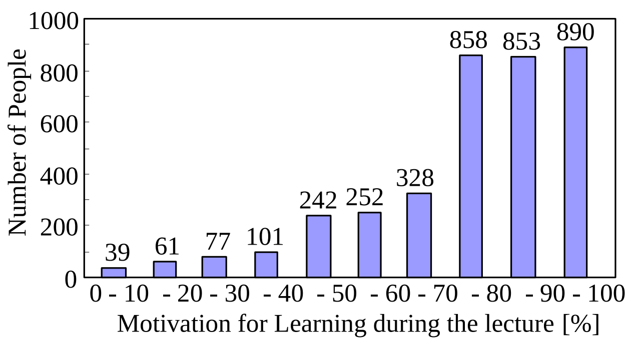
Distribution and classification of motivation to learn

Figure 3 shows the distribution of the motivation to learn during lectures in February. 70.3% of 2601 subjects among 3701 subjects reported themselves with 70% or more. It turns out that motivation for learning is kept high towards a qualifying examination. It was a result with the same said of April and June.

Then, the subjects were put into two groups: a higher motivation group (=M_d(H)) and a lower motivation group (=M_d(L)) to analyze the motivation during lectures on learning performance. Subjects in the higher motivation group were defined as those with 70% or more in the self-assessment.

Evaluation of learning performance by motivation group

Figure 4 shows the results for objective learning performance by the motivation group. The quiz scores brought a significant high of 4.5 points ($p<1.1\times10^{-6}$) in February, 6.3 points ($p<6.5\times10^{-14}$) in April, and 2.6 points ($p<5.9\times10^{-5}$) in June by the M_d(H) group. It became clear that the motivation to learn during the lectures significantly influencing the quiz scores, and the importance of evaluating the motivation to learn was shown. To measure the learning performance more exactly, it is thought necessary to incorporate motivation to learn as an evaluation axis.



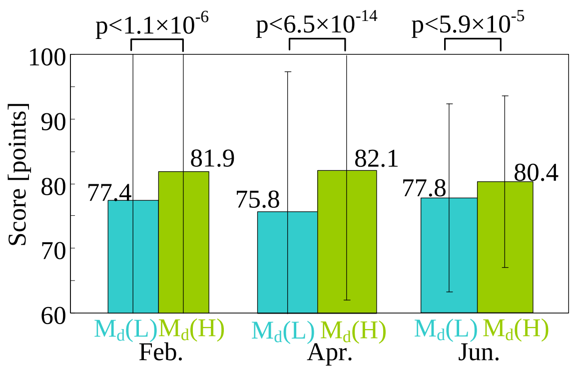


Figure 3 (Left) Distribution of the motivation to learn during lectures (February)

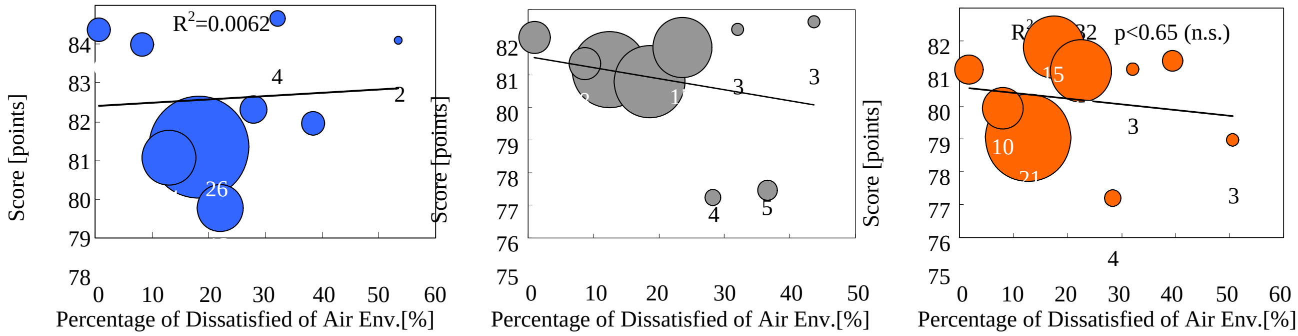
Figure 4 (Right) Results of the objective learning performance by the motivation group

DISCUSSION / DETAILED EXAMINATION OF THE LEARNING PERFORMANCE

Season

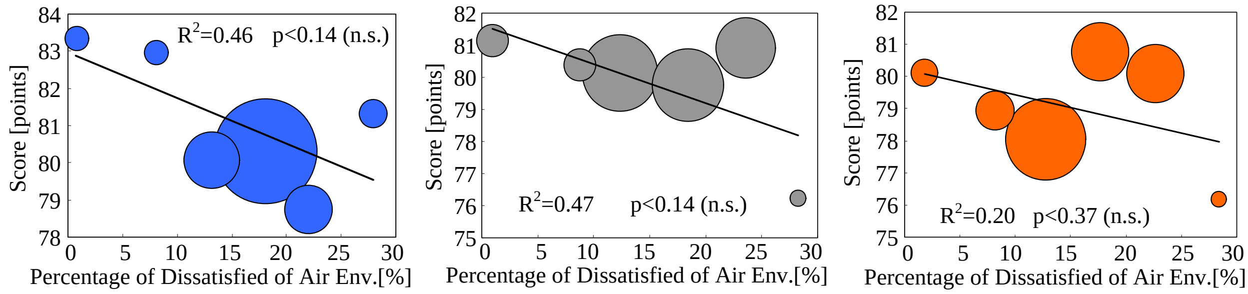
Figure 5 shows the relationship between the quiz scores and the percentage dissatisfied for air environments in every season. There was no significant correlation between the two in which season.



a) February b) April c) June

Figure 5 Object Evaluation vs. Percentage Dissatisfied with the Air Environment by Season

Next, Figure 6 shows the result of having excepted the school building whose rate of a dissatisfied of air environment was 30% or more. A fairly strong linear relationship was observed between the quiz scores and the percentage dissatisfied with the air environment, with R^2=0.46 in February, 0.47 in April, and 0.20 in June. In June, although the percentage dissatisfied with the air environment is high, a tendency with the sufficient quiz score can be observed. It is possible that students are carrying out the report by the side of nearby dissatisfaction more till because they become sensitive to environment then when the qualifying examination has approached. Moreover, even if dissatisfied, a possibility of doing themselves best can be considered.

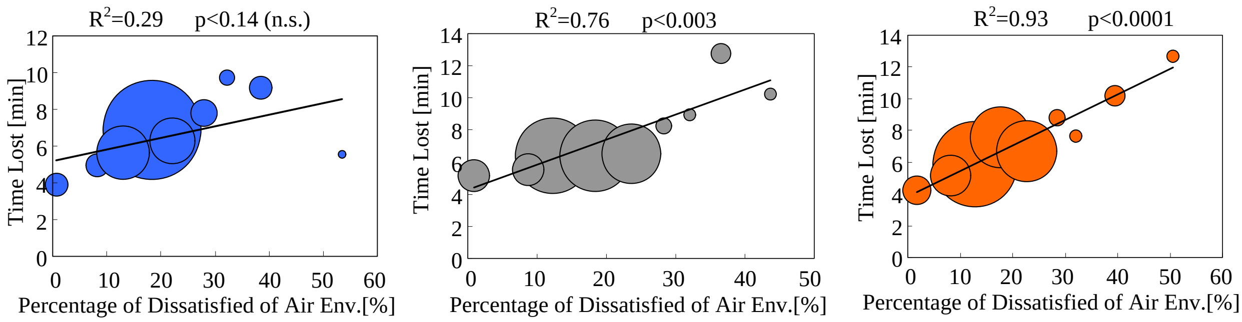


a) February b) April c) June

Figure 6 Quiz score vs. Dissatisfied (Excepted dissatisfied was 30% or more)

Figure 7 shows the relationship between the time lost due to the indoor environment and the percentage dissatisfied with the air environment in every season. A linear relationship was observed between time lost and percentage dissatisfied with the air environment, with R^2=0.29 in February, 0.76 ($p<0.003$) in April, and 0.93 ($p<0.0001$) in June. The correlation becomes stronger as the qualifying examination approaches. It was a result with the same said of predicted rate of improvement in learning performance with an improvement in the environment.

From the above result, it is possible that relation is the period to a target, and the objective and subjective evaluation.

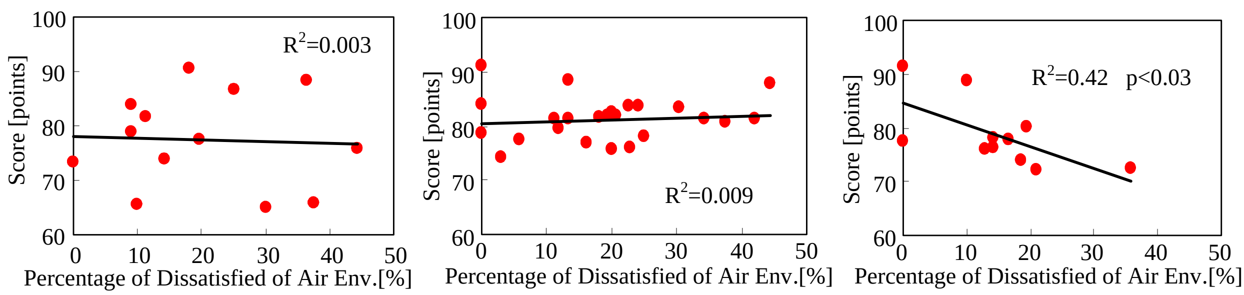


a) February b) April c) June

Figure 7 Subject Evaluation vs. Percentage Dissatisfied with the Air Environment by Season

Area

Figure 8 shows the relationship between the quiz scores and percentage dissatisfied with the air environment in every area for April. As candidates for the survey, Hokkaido and Tohoku were chosen as cold climates with 13 branches, Kanto as a moderate climate with 25 branches, and Kyushu as a hot climate with 11 branches. No relationship was observed between quiz scores and percentage dissatisfied with the air environment in cold and moderate climates. A linear relationship was observed with a significant correlation between the quiz scores and dissatisfaction in the hot climate (R^2=0.42, p<0.03). It was a result with the same said of February and June.



a) Hokkaido, Tohoku (Cold climate) b) Kanto (Moderate climate) c) Kyushu (Hot climate)

Figure 8 Object Evaluation vs. Percentage Dissatisfied with Air Environment by Area (April)

In addition, it got the same result the relationship between the results of thermal environment and learning performance.

CONCLUSIONS

(1) Objective learning performance improved with a decrease in the percentage dissatisfied with the air environment.
(2) Subjective learning performance improved significantly with a decrease in the percentage dissatisfied with the air environment.
(3) Objective learning performance improved with age.
(4) Objective learning performance in the high motivation group was significantly better. To measure the learning performance more exactly, it is thought necessary to incorporate motivation to learn as an evaluation axis.
(5) It is possible that relation is the period to a target, and the objective and subjective evaluation.

Indoor climate and improvement possibilities in educational premises

Teet-Andrus Koiv, Merje Rebane, Peeter Parre

SUMMARY

The results of indoor climate investigation in 7 schools of Tallinn are analyzed in the paper. In classrooms with natural air change carbon dioxide concentration at the end of the class is very high, up to 1.5….3.5 times more than permitted level. With high occupation rate in gymnasiums of Tallinn the good indoor climate and permitted CO_2 concentration at the end of the class can be provided only with the use of balanced ventilation.

INTRODUCTION

Over the last few decades, considerable attention has been directed toward the problems of indoor air quality in schools. It has become increasingly clear that exposure to contaminated indoor air may not only be unpleasant, but can have serious adverse health effects.
Children of today spend increasingly more of their time in school environment.
Because children breathe a greater volume of air relative to their body weight compared to adults, they may be more sensitive to indoor air pollution [1, 2].
Indoor air quality in schools is influenced by many factors, like air temperature, relative humidity, air velocity, radiant temperature, textured surfaces, activities of the occupants in the building, the season, etc [3].
The available floor area per person in classrooms, around 1.5-2.0 m^2, is much less than that in office rooms, where 8-10 m^2 per person is normal. This implies a much larger ventilation demand in schools to remove contaminated indoor air.
Indoor climate in school buildings has been researched in many countries. One of the interesting questions is the carbon dioxide level in classrooms at the end of the class.
There are approximately 6000 school buildings in Finland, in which more than 700,000 people spend several hours of their time every day. Ventilation and indoor air quality of elementary and secondary schools were studied and in general the complaints about poor indoor air quality were more common in the schools with natural ventilation system than with mechanical ventilation systems, being least frequent with mechanical supply and exhaust air ventilation. Before the renovation process, the contents of carbon dioxide in the school buildings ranged between 1200...2400 ppm [4].
In 1996 and 1997 research was done about CO_2 concentrations for 96 classrooms in 38 Swedish randomly selected schools, 61% of them had mechanical supply and exhaust air systems while the reminder had natural ventilation. Concentrations average was 900 ppm CO_2 and the maximum was 2800 ppm [5].
The outcome of a field study in 11 primary schools in Eindhoven, the Netherlands in 2005 shows that average CO_2 concentration in half of schools is near to 2000 ppm and maximum CO_2 levels of 3000 or 4000 ppm in schools are no exception [6].
Indoor air quality testing in 28 classrooms in Warsaw (Poland) in 2000 shows that in most observations the maximum CO_2 level was from 2000 to 4000 ppm [7].

In 1991 CO_2 measurements in a non-random study of 9 U.S. non-complaint schools showed that concentrations ranged from about 400 to 5000 ppm (mean = 1480 ppm). CO_2 concentrations exceeded the 1000 ppm ASHRAE ventilation standard [8] in 74% of the rooms [5]. In Michigan schools CO_2 peak levels reached 2700 and 3300 ppm in a non-portable and portable classrooms [9].
There is evidence that many countries have significant and serious indoor environmental problems in schools. From the educational standpoint, the indoor air quality and ventilation in school buildings may affect the health of the children and indirectly affect learning performance.
In Estonia the indoor air quality in schools has not been investigated sufficiently. In 2005 a pilot research was done in a cold season. The main reason of investigation was carbon dioxide concentration and air change level determination in classrooms with natural ventilation [10]. In most school buildings in Tallinn (about 90%) ventilation systems are not renovated, but windows have as a rule been changed and external walls in single cases renovated. Only natural ventilation and window airing of classrooms is used in unrenovated school buildings. The results of measuring carbon dioxide concentration have shown that in classrooms with non-renovated ventilation, indoor air quality is very bad. At the end of the lesson the CO_2 concentrations reach the level of about 2000...3500 ppm, in single cases even up to 4400 ppm [10]. The cause of that is very low air change; 4–5 times lower than needed and insufficient airing during breaks or the lack of it.
Estonian Standard EVS839:2003 „Indoor climate"[11] permits carbon dioxide concentration 1000 ppm for category A, 1250 ppm for category B, 1500 ppm for category C and indoor temperature in classrooms 21…23°C for category A, 20…24°C for category B, 19…25°C for category C, relative humidity 25…45% and air velocity up to 0.2 m/s for cold season.
According to the regulation of the Estonian Ministry of Social Affairs [12] the permitted maximum carbon dioxide level in classrooms is 1000 ppm, relative humidity 30...70%, indoor temperature 19...25°C.
By prEN15251 recommended maximum values of carbon dioxide concentration in CO_2-controlled ventilation systems can be up to 800 ppm above the external air concentration for category C, 500 ppm for category B and 350 ppm for category A [13].

METHODS

Indoor air quality measurements were carried out in 10 classrooms of 7 typical gymnasiums in districts of Mustamae, Oismae and Center of Tallinn. The area of classrooms varied from 53 to72 m^2 and volume from 153 to 213 m^3, the age of students from 13 to 18 years, Table 1. Density in classrooms ranged from 1.6 to 3.3 m^2 per person.
The occupation rate in classrooms was from 44 to 92%, windows and doors were closed during the class. Information about the investigated classrooms and external air temperature and relative humidity are presented in Table 1. External air CO_2 level during the measurements was 410±30 ppm.
The duration of the measuring of parameters in classrooms was 40-45 minutes, except in the gymnasium of Sytiste, in which one class lasted 35 minutes. In same cases the change of indoor air parameters during breaks was measured. Dynamical registration of CO_2 concentrations make it possible to use CO_2 as tracer gas for air change measuring. Indoor air parameters were assessed at the breathing zone height of seated students, but about 1m away from the students. All classrooms were empty before the beginning of measurements. Initial indoor parameters are shown in Figures 1, 2 and 3.
Instruments used for measurements were Testo series 400 and 435 with probes for measuring

CO_2 concentration, relative humidity, indoor temperature and air velocity.
Natural ventilation and airing during breaks were used in the investigated schools, all of the windows in classrooms had been changed, in the gymnasium of Sytiste, in addition the envelope elements had been insulated.

*The classroom in school investigated first
**The classroom in school investigated secondly

RESULTS

Main attention was paid to measuring carbon dioxide concentration and air change determination in a cold period: from November 2006 to January 2007. At the same time indoor temperature, relative humidity and air velocity were registered.

The dynamic change of CO_2 concentration during the class is presented in Figure 1. The rise of CO_2 concentration in different classrooms is from 550 to1600 ppm. Only in two classrooms the CO_2 level at the end of the class was less than 1500 ppm or near to it, but exceeded the permitted 1000 ppm [8, 12]. In different classes the rise of CO_2 concentration varies, depending mostly on the occupation rate of the classroom and the air change per student. The CO_2 concentration at the end of the class depends greatly on its initial level at the beginning of the class, the latter depending on how intensively the airing during the breaks took place.
Figure 2 shows the variable relative humidity level during the classes, ranging from 24% to 54%. As can be seen the relative humidity rises moderately and mainly stays within the permitted limits 30…70% [12]. Only in the Gymnasium of Arte (in the classroom investigated first) the relative humidity decreased, being caused by the low humidity content in external air at -18 °C, the low occupation rate of classroom and relatively high air change in classroom (when compared with other classrooms investigated). Permitted relative humidity in classrooms is achieved thanks to low air change.
Figure 3 shows the variation of indoor air temperature during the class. As can be seen the indoor air temperature ranges between 18 and 25.5 °C, which to some extent exceeds the permitted limits [12]. Only in the Gymnasium of Liivalaia the indoor temperature was too low 18-19°C.

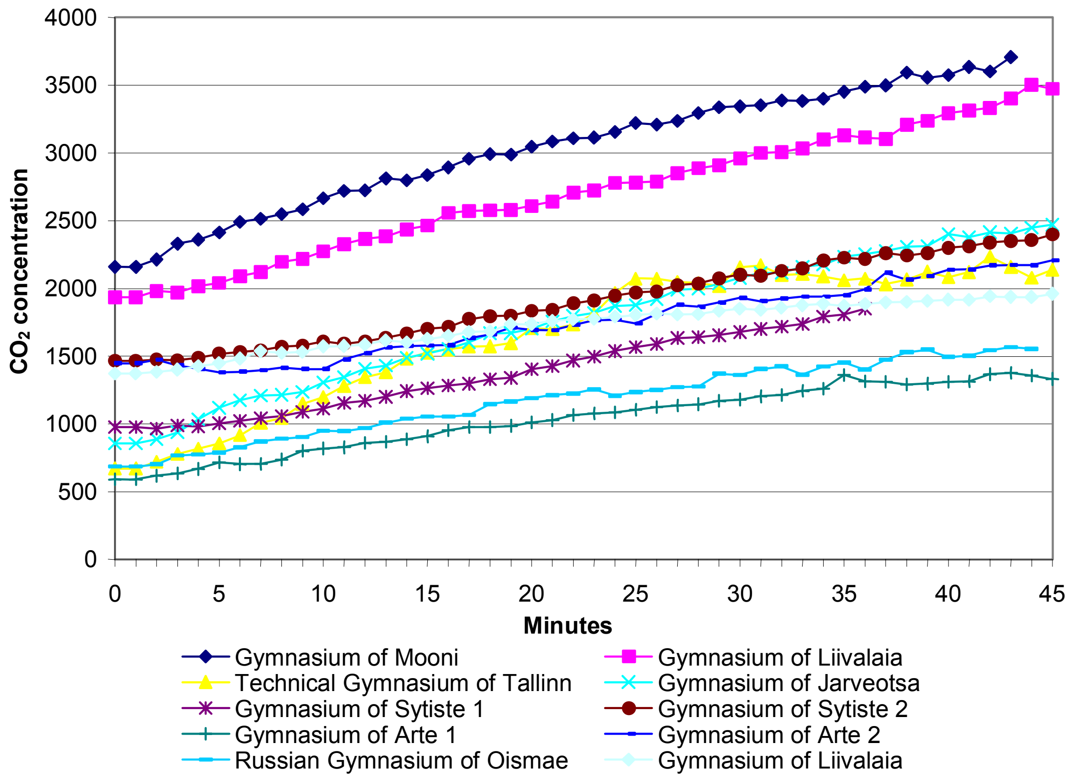

Fig.1. Variation of carbon dioxide in classrooms

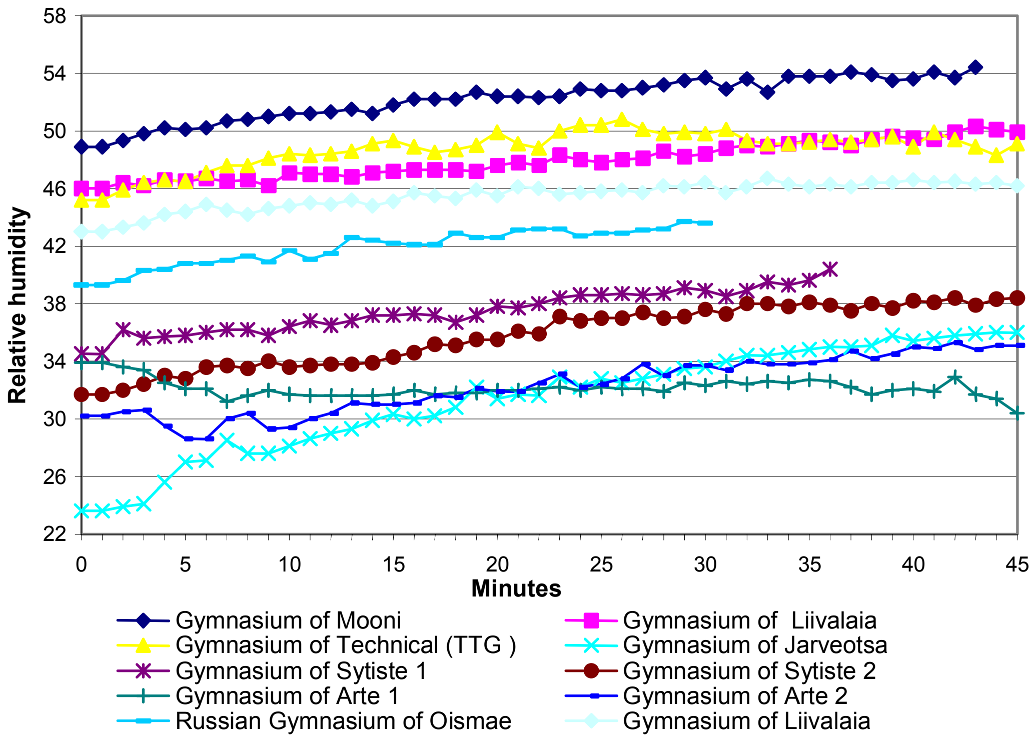

Fig.2. Variation of relative humidity in classrooms

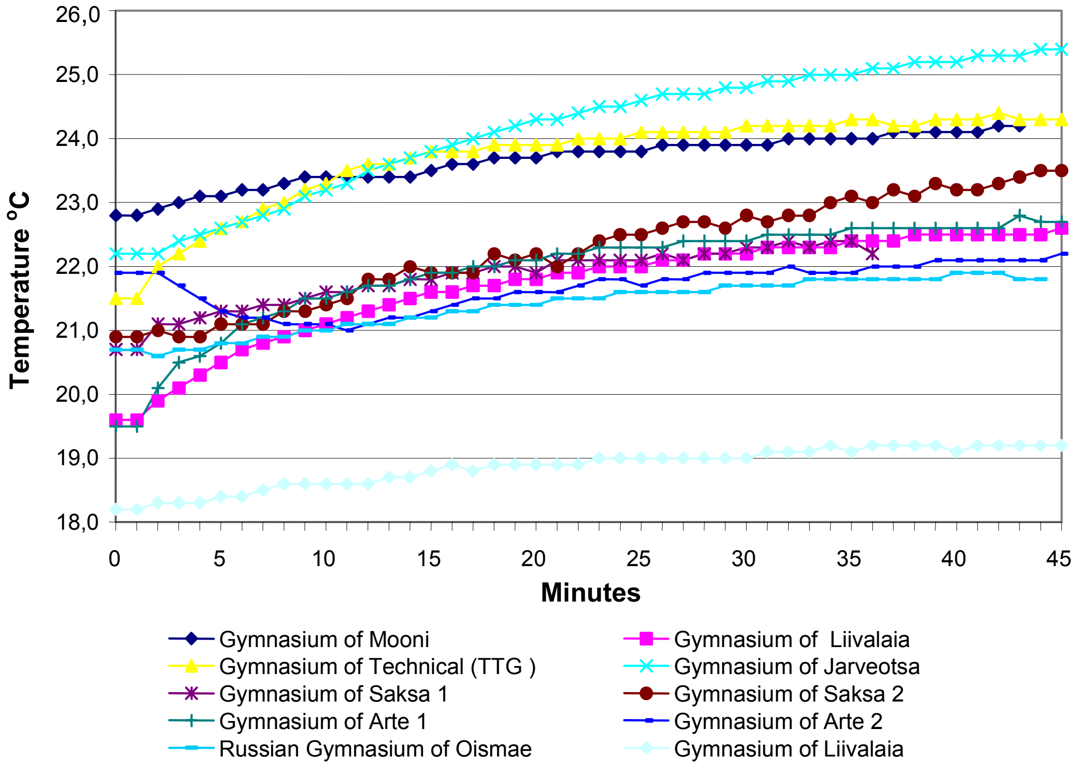

Fig.3. Variation of temperature in classrooms

Due to natural ventilation the air velocity in classrooms investigated was low: less than 0.1 m/s.

Dynamic registering of the carbon dioxide level enables us to determine air change in classrooms. To calculate the air change the following formula was used [10]:

$$\frac{L}{V}\cdot\tau = -\ln\frac{\frac{m}{L}+C_v-C}{\frac{m}{L}+C_v-C_o} \qquad (1)$$

where *m* is carbon dioxide generation in classroom, *L* is air change in classroom, *V* is volume of room, C_v is carbon dioxide concentration in external air (in supply air), *C* is carbon dioxide concentration in classroom air (in exhaust air), C_o is carbon dioxide concentration in the air of the classroom at the beginning of the class, τ is time.

The basic equation for carbon dioxide concentration C at time moment τ [10]:

$$C = C_v + \frac{m}{L} - \left(C_v + \frac{m}{L} - C_o\right)\cdot\left(e^{-\frac{L}{V}\cdot\tau}\right) \qquad (2)$$

The determined air change and other characteristic parameters of classrooms investigated are brought in Table 2. It shows that the air change is very modest: 0.3-3.9 l/s per student. With low air change and normal occupation rate the rise of CO_2 concentration is remarkable – 900-1600 ppm. Only in two classrooms the CO_2 concentration at the end of the class was up to 1500 ppm or near to it.

Table 2. Characteristic parameters of classrooms investigated

Name of school	Air change L/s	Air change L/s per pupil	Occupa-tion rate	CO_2 level at the beginning of class, ppm	Rise of CO_2 level, ppm

Gymnasium of Liivalaia (1)	*30*	1,7	0,44	1373	587

DISCUSSION

With natural ventilation in classrooms and airing only during breaks it is practically impossible to keep the CO_2 concentration under the permitted limit, 1000 ppm [12], at the end of a class with full occupation rate.

With natural ventilation, the airing of classrooms during breaks is very important, without it the CO_2 level is usually over the permitted limit already at the beginning of the second class. In the classroom investigated the CO_2 concentration was 1.5 – 2 times over permitted value.

Calculations show (formula (2)) that in classrooms with average occupation rate, with an approximate air change of 1 l/s per m^2 and with good airing during breaks it is possible to hold the maximum CO_2 concentration on a level up to1500 ppm. This meets the carbon dioxide C class requirements by Standard of Indoor Climate [11], but does not correspond to the regulation of the Estonian Ministry of Social Affairs [12].

In practice, to gain the acceptable indoor climate, especially as regards CO_2, windows are kept opened also during classes.

To keep the CO_2 concentration under the permitted limits in fully occupied classrooms mechanical ventilation is needed. In our practice sometimes mechanical exhaust ventilation is used with fresh air supply through the fresh air valves, but the contemporary solution is balanced ventilation.

The investment of the first solution is quite low, but maintenance costs are high and sometimes it is difficult to assure the convenient indoor climate (the danger of draught). This kind of solution requires warming up the supply air and usually needs to renovate the heating system.

With high occupation rate in gymnasiums of Tallinn good indoor climate and permitted CO_2 concentration at the end of the class can be gained only with the use of balanced ventilation [10].

It is advisable to use in a classroom displacement or wall confluent [14] ventilation, the latter increasing the efficiency of air change and reducing energy consumption.

The necessary air change should be 7-10 l/s per student [10], depending on the method used for air change.

To achieve good indoor climate and energy savings it is necessary in addition to renovating ventilation also to renovate heating systems – automatic control of heat output of heating coils is necessary.

ACKNOLEDGEMENT

The authors are grateful to the schools where different field measurements were carried out.

Air distribution and temperature control in classrooms

Jarek Kurnitski and Minna Aalto

Helsinki University of Technology, Finland

Corresponding email: jarek.kurnitski@tkk.fi

SUMMARY

Air distribution solutions for classrooms aiming to lower air velocities and good temperature control are studied by measurements in 6 schools and temperature simulations. Air velocity measurements showed good performance of duct and ceiling diffusers which provided maximum velocities less than 0.2 m/s and can be highly recommended for classrooms. The wall diffusers were clearly not suitable for classrooms due to high velocities up to 0.43 m/s. Displacement ventilation diffusers were very sensitive to supply air temperature, as with the temperature difference of 3 °C velocities up to 0.28 m/s were measured. Room temperature measurement results showed a typical problem with temperature control as at the end of the heating season the temperatures up to 25 °C were measured. The parametric simulations showed that high supply air flow rates up to 10 L/s per person and cool supply air down to 14–15 °C were needed for room temperature control.

INTRODUCTION

Many studies have shown that poor indoor environmental quality (IEQ) in office buildings can reduce the performance of office work by adults [1,2]. While it is well documented that IEQ in schools is both inadequate and frequently much worse than in office buildings [3], there is little direct evidence that classroom performance is being negatively affected [4].

Experimental interventions [5,6] show that increasing the outdoor air supply rate and reducing moderately elevated classroom temperatures significantly improved the classroom performance of many tasks, mainly in terms of how quickly each pupil worked (speed). In these experiments the room temperature was reduced from 25°C to 20°C and the outdoor air supply rate was increased from 5.2 to 9.6 L/s per person. Thus the results suggest that higher ventilation rates up to 10 L/s per person as well as more strict temperature control than commonly used can be recommended for classrooms. This means new challenges in the design of classroom ventilation and temperature control. High airflow rates and low supply air temperatures, which are needed for temperature control, may easily cause draft. This may be avoided by careful selection of air distribution solutions and terminal devices.

In this study, air distribution solutions for classrooms aiming to lower air velocities and good room temperature control are studied by measurements in classrooms and temperature simulations. Performance of wall, ceiling, duct and displacement diffusers is compared at ventilation rates up to 340 L/s per classroom and supply air temperatures up to 6°C lower than room temperature. Based on the results, design guidelines of air distribution and temperature control solutions leading to healthy and productive indoor environment in classrooms can be given.

METHODS

Air velocity, room temperature and CO_2 measurements were done in 6 schools. All schools were either relatively new buildings or renovated buildings, all having modern mechanical supply and exhaust ventilation systems with ventilation rates, corresponding at least to Finnish minimum code requirements for ventilation of new buildings.

Figure 3. School E with duct diffusers, a) and F with displacement diffusers, b).

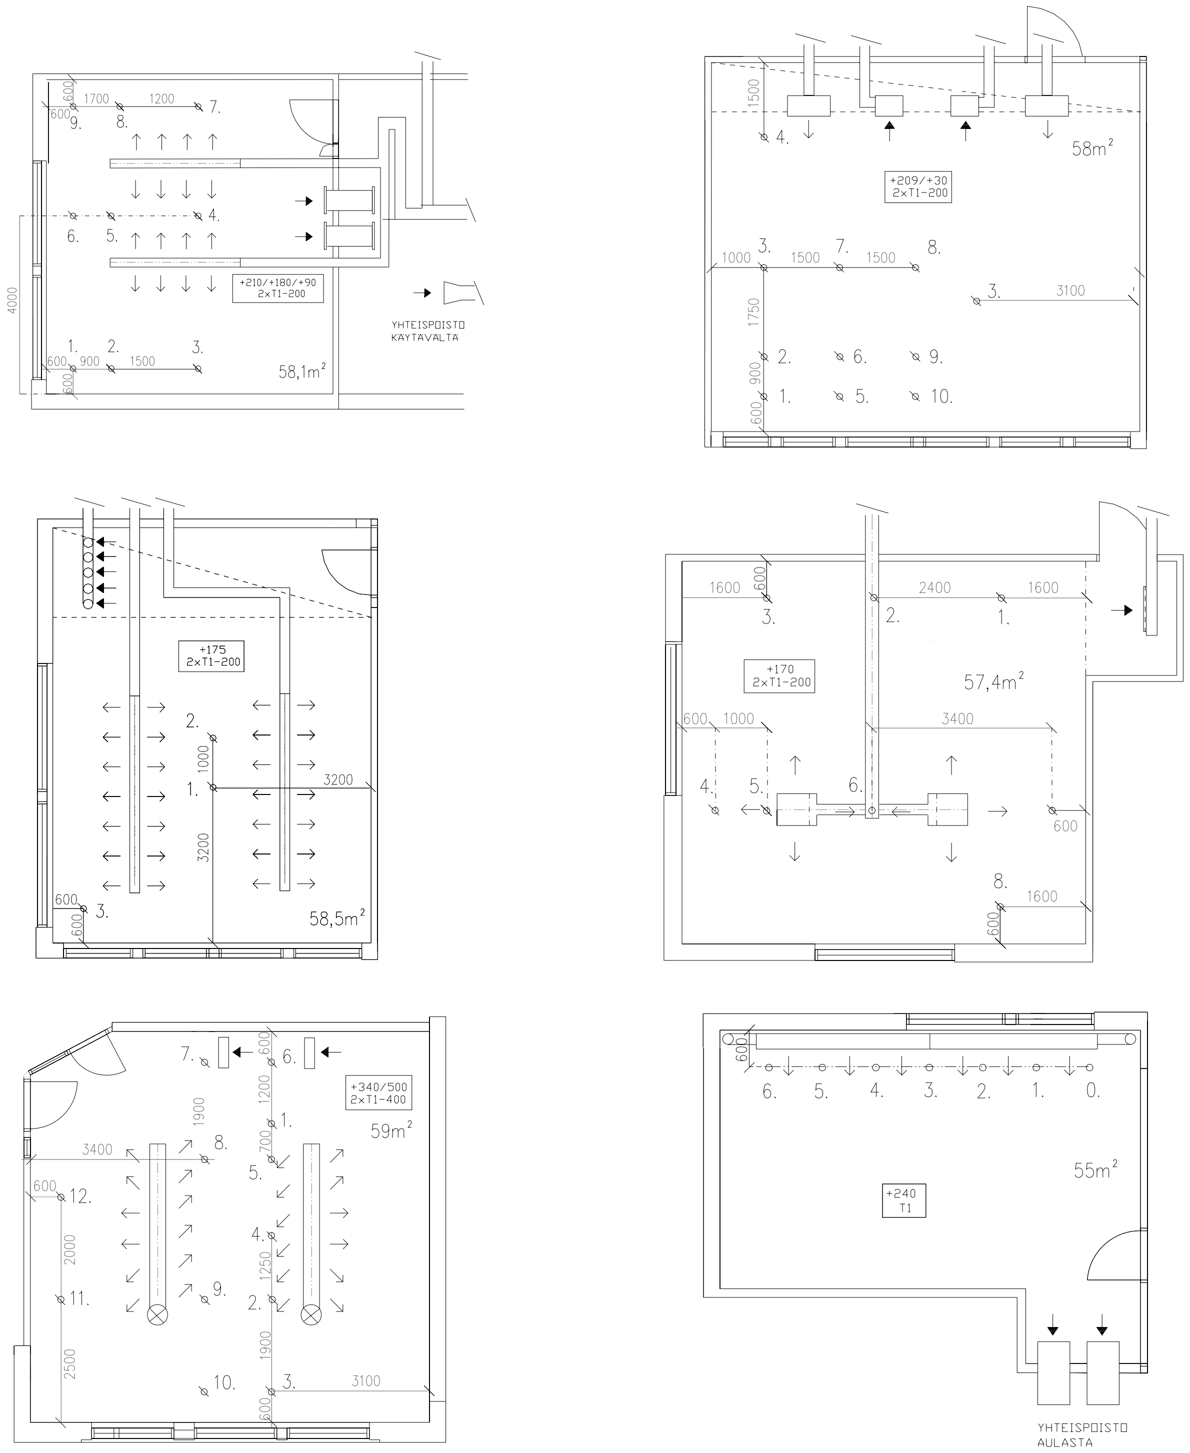

Figure 4. Air velocity measurement points in the classrooms (the classrooms are in the same order as in Figures 1–3).

School *A* had air distribution by ceiling diffusers (two diffusers per classroom) and school *B* by wall diffusers (two diffusers per classroom), which represents a low cost solution most commonly used, Figure 1. In three schools (*C*, *D*, *E*) duct diffusers (two ducts per classroom) and in school *F* displacement ventilation diffusers were used, Figures 2 and 3.

In schools from *A* to *D*, temperature and CO_2 concentrations were measured during a one week period in May 2006 from three classrooms in each school. Air velocity measurements were done in one classroom. In *E* velocity was measured in two classrooms and supply air temperature was set by 4 to 6 °C below the room temperature. In *F* data from previous measurements [7] was used to compare the performance of displacement ventilation to mixing ventilation. Air velocity measurement points were selected with smoke tests, so that the highest velocities could be measured. The measurement points are shown in Figure 4.

Both constant air volume (CAV) and demand controlled (DCV) ventilation systems with constant or controlled supply air temperature were used in schools. Differences between DCV and CAV systems and supply air temperature control options were studied with temperature and ventilation simulations for typical classrooms with a varying heat load.

RESULTS

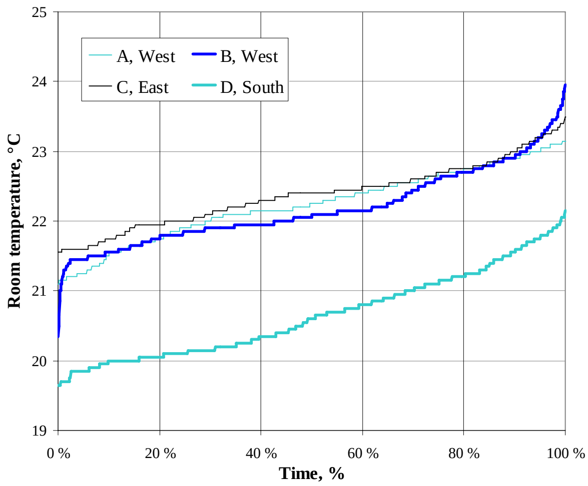
Measurement results in the schools

Supply air flow rates measured from terminal devices and typical occupancy in the classrooms is shown in Table 1. *E* was a new school having almost doubled supply airflow rate (design value of 12 l/s per person, 340 l/s in total) and also other target values of the highest indoor climate class. Schools *A* and *B* had CO_2- and CO_2&temperature controlled ventilation with 3 and 2 airflow steps respectively. In other schools constant air volume systems were used. *A* to *D* had a constant supply air temperature and in *E* and *F* supply air temperature was controlled according to exhaust air temperature.

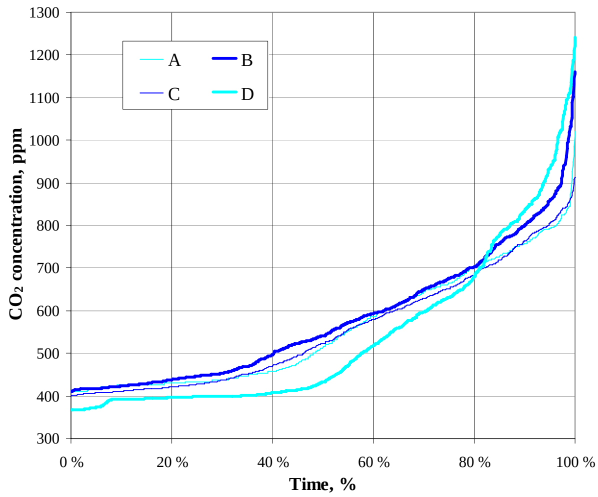
Table 1. Measured supply air flow rates and typical occupancy in the classrooms

School	Occupancy, pers.	Supply air flow rate, L/s per pers.	Supply air flow rate, L/s	Design supply air flow rate, L/s
A	20	7	138	210/150/90
B	27	7	186	210/30
C	22	6	136	175
D	20-25	6.8-8.2	168	170
E			348	340
F			180	180

Outdoor temperature during the measurement week was typical spring weather, between 9…12 °C. This represents the end of heating season and the results are compared to heating season target values. Room temperature and CO_2 results from classrooms where air velocity measurements were done are shown in Figure 5. Results are given only from the school time period which is from 8.00 to 15.00 on week-days. Temperatures measured from other classrooms in schools *A* to *D* (measured with loggers with a lower resolution compared to Figure 5) and previously measured temperatures from *G* are shown in Figure 6.

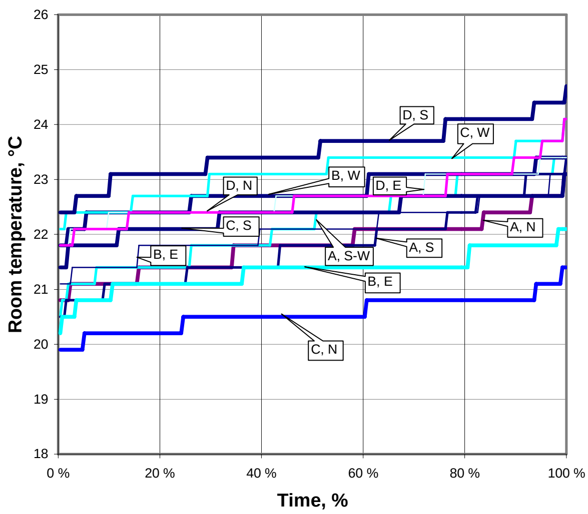


a)

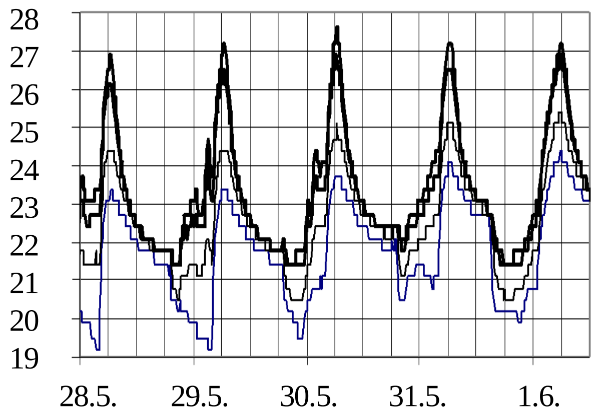


b)

Figure 5. Duration curves of room temperature, a) and CO_2, b); data from 8.00 to 15.00 on week-days



a)



b)

Figure 6. Duration curves of temperatures in other classrooms in *A* to *D* from 8.00 to 15.00 on week-days, a) and temperatures from *E* during 28.5-1.6.2003, b)

Air velocity measurement results from the occupied zone are shown in Table 2. In *A* to *D* supply air temperature was not adjusted, but just measured. In *E* and *F* the effect of supply air temperature on draft was studied by changing the temperature of supply air and repeating the velocity measurements.

In *F* with displacement diffusers the results were very sensitive to the temperature difference. Air velocities at 0.1 m height, 0.6 m from diffusers, were 0.14…0.18 m/s when supply air temperature was equal to room temperature. Measurements with the temperature difference of 3 °C gave higher velocities, as shown in Table 2.

Table 2. Air velocity measurement results. Measurement locations are shown in Figure 4.

Room temperature simulations

Temperature control and ventilation rate options were simulated with IDA-ICE software for CAV and DCV systems without mechanical cooling in order to find good solutions for classroom ventilation and temperature control. The time period was chosen according to the typical use of schools: heating season from Jan 2 to May 14 and Oct 1 to Dec 23, and summer season from May 15 to May 31 and Aug 15 to Sept 30. Two classrooms were simulated as this configuration gave the same results as the configuration with six classrooms, Figure 7. A classroom with 30 students faced south and another with 20 students north. The occupancy profile used and the control curve of supply air temperature determined in the simulations are shown in Figure 8. For the south classroom, solar protection glasses were used.

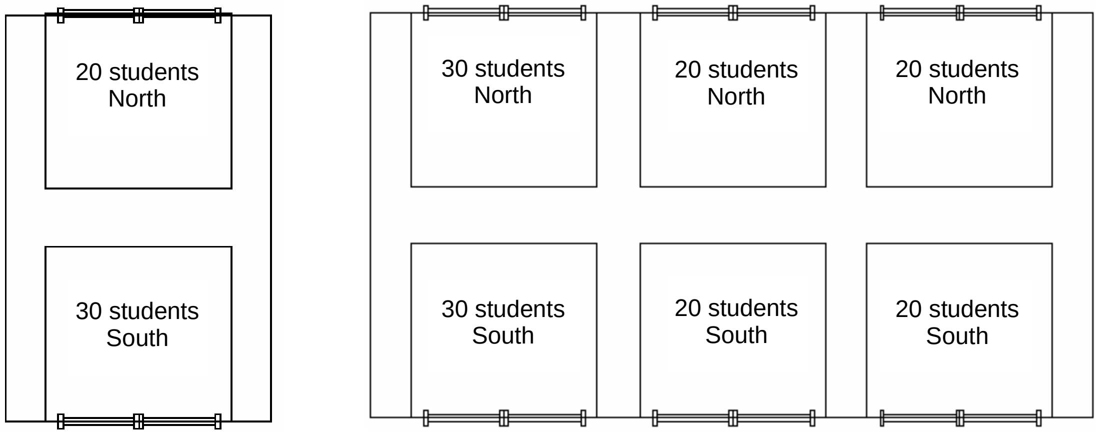

Figure 7. The configuration of 2-classrooms used in the simulations, a) The configuration of 6-classrooms used for the testing of 2-classroom configuration, b)

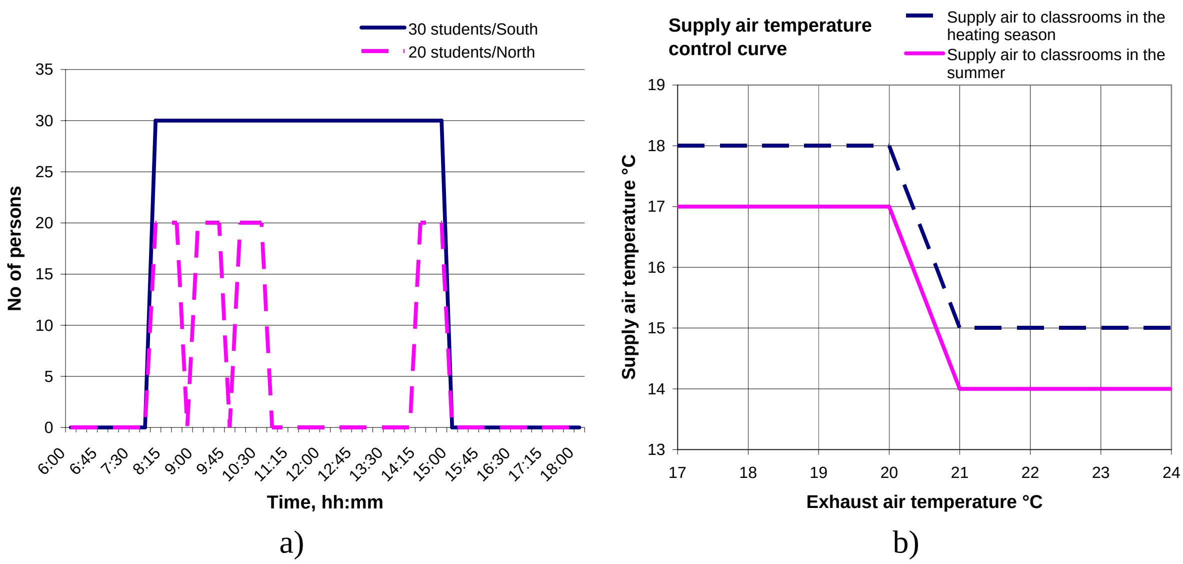

Figure 8. The occupancy profile of students, a) and determined supply air temperature control curve, b) (supply air temperature values can only be achieved if outdoor temperature is lower than supply air temperature, as there is no mechanical cooling in the system)

Two ventilation rates, 6 L/s per person, 180 L/s per classroom in total, and 10 L/s per person, 300 L/s per classroom in total, were simulated. For both rates CAV system and DCV system with CO_2 and temperature control was simulated. DCV system had two air flow steps, 100 %

and 40% of total airflow. The results are shown in Figure 9 for the summer period and in Figure 10 for the heating season. With night time ventilative cooling the summer period temperatures were possible to lower by about 1 °C from values shown in Figure 9.

DISCUSSION

Measured supply air flow rates were significantly lower than design values in three schools out of six. Due to relatively low occupancy the airflows per person were still sufficient, 6 L/s per person or more in all schools and CO_2 concentrations were less than 1200 ppm. Room temperature measurement results show a typical problem with temperature control as at the end of the heating season the temperatures up to 25 °C were measured. Simulated results show that this problem can be avoided without mechanical cooling if high enough ventilation rates and cool supply air is used. In the majority of the schools measured, ventilation rates were too low and supply air too warm for effective control of the room temperature.

Air velocity measurements showed remarkable differences between air distribution schemes. Duct and ceiling diffusers showed good performance with a maximum velocity less than 0.2 m/s and can be highly recommended for classrooms. The duct diffuser in *A* without nozzles (just a perforated duct) showed worse performance with a maximum velocity of 0.29 m/s. The wall diffusers were clearly not suitable for classrooms due to high velocities up to 0.43 m/s. Displacement ventilation diffusers were very sensitive to supply air temperature, as a temperature difference of 3 °C caused velocities up to 0.28 m/s.

The parametric simulations showed the effect of high internal gains: high supply air flow rates up to 10 L/s per person and cool supply air down to 14–15 °C was needed for room temperature control. However, mechanical cooling was not needed in the classrooms as schools are normally not used during summer holidays. DCV ventilation showed better performance in terms of thermal comfort when higher simulated airflow rate of 300 L/s per classroom was used. At lower airflow rate of 180 L/s the classrooms were less overheated with CAV ventilation. It was shown that a DCV system supplying 10 l/s per student and 300 L/s per classroom combined with night-time ventilative cooling ensured good temperature control in fully occupied as well as partly occupied classrooms. A similarly sized CAV system cooled down classrooms with low occupancy, thus, demanded additional heating of the supply air in classrooms. Air flow rate of the lower indoor climate category, 6 l/s per student and 180 L/s per classroom, resulted still tolerable but significantly higher temperatures, often above 23 °C in the heating season.

Typologies of Hybrid Ventilation in Schools

Peter van den Engel

Delft Technological University, the Netherlands

Corresponding email: p.vd.engel@deerns.nl

SUMMARY

This article is the result of a study on how to close the “gap” between architects and a building service consultant. Closing is necessary in order to be able to create both a better indoor climate and an interesting architectural environment. Especially for schools with natural air supply some basic physical principles of draught prevention should be checked in an early stage of the design or commissioning process. Air supply designs for the most common architectural problems should be easily available. Most of the presented design options have been evaluated with measurements and CFD-simulations. For schools with natural air exhaust (overpressure system) the results of an on-site test are presented. This system can be applied even in existing schools with single glass windows and a monumental façade.

INTRODUCTION

In The Netherlands and other European countries the air change rate in schools increases in order to prevent health problems of students. The minimum air supply in The Netherlands is 7 l/s (= ca. 25 m^3/h) per student. Due to the high occupancy (generally 1 person at 2 m^2 = 3.5 l/sm^2) prevention of draught needs much attention. Architects need ready-to-use ventilation design concepts for schools because of:

- A lack of knowledge of draught prevention,
- Individual architectural opinions,
- A low budget.

A research project is starting in The Netherlands to design options of natural, mechanical or hybrid ventilation. These systems for new or refurbished schools will be presented in a comprehensive way in a Dutch design guide and can be integrated in a REHVA-guide dealing with healthy schools in the near future. In this guide higher air change rates will be discussed as well: 35 m^3/h and 45 m^3/h per student = 4.9 - 6.3 l/sm^2.
Hybrid ventilation may have different meanings. Generally it comprises a low pressure natural ventilation system which can be supported by fans when necessary. However, a combination of natural air supply with mechanical exhaust or natural air exhaust with mechanical supply can be considered as hybrid as well.
Sometimes the building service consultant has to make design proposals for the architect. On the other hand architects can stimulate the creativity of a building service consultant to find a specific solution for a specific problem..

METHODS

The methods used during my study and subjects discussed with architects are:

a. Research of physical principles
b. Architectural research
c. Airflow measurements

a. Research of physical principles

The research provides a variety of options to deal with air flows and heat transfer:

- Mixing of cold air

Mixing of cold air with the surrounding warm air in order to prevent draught, without or with a false ceiling.

Research at the Delft Technological University [1] shows that it is possible to prevent draught (3.5 ls/m^2) by means of natural air supply without a ceiling. When the air is supplied just beneath the ceiling with an Archimedes-number of 0,001 (figure 1, II) the DR-value will be maximal 20%. However, it is possible to have an acceptable thermal comfort as well with other Archimedes numbers when the air will be supplied with a wide air inlet with the same size as the width of the room. When the velocity is low (figure 1, I) or very high (figure 1, III) the air velocity above the floor will increase. Concrete core and (floor) heating can - to a certain extend - compensate draught-risks by higher local operative temperatures near the floor.

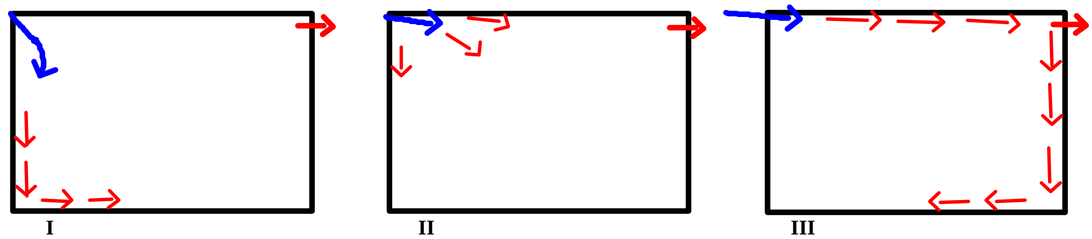

Figure 1: Air supply options without a false ceiling.

The integration of the air inlet at the ceiling needs much attention [2, 4], because of the fact that the narrow inlet-slit should be close under the ceiling.

In case of a false ceiling there are more possibilities of draught prevention and integration of an air inlet into the façade is more easy [4].

- An outlet via a double window

There is no information of the combined performance of an air outlet and a double window. The thermal qualities of the window and air flows are analyzed with CFD-simulations. The outlet system is tested in a police academy in Apeldoorn by measuring the air flow and pressure differences during the heating season.

- Heating systems

The most common heating systems are a radiator under windows, floor or concrete core heating and preheating of air of an air inlet. It is very important to understand the difference of the convection flow characteristic of radiator heating and floor heating. This has been evaluated with CFD-simulations (Phoenics, Flair).

b. Architectural research

Two systems are discussed:

1. Systems of natural air supply, mechanical exhaust and several combinations with ceilings for three different façade typologies (positions of windows).

After analysing the most general typologies of façades, design principles for architects are developed to support their design processes.

2. A system of natural air exhaust via a double window and mechanical air supply for existing monuments.

A design option has been developed for an existing building in which physical, aesthetic, practical and economic requirements are combined.

c. Airflow measurements and CFD-simulations

The presented natural air supply and natural exhaust systems have been measured or simulated.

The performance of the outlet system has been evaluated with the following equations:

The maximum air velocity through a vent with a very low air resistance is [1]:

$$U_{\max} = \sqrt{\frac{2 \cdot \Delta P}{\rho}} \quad (1)$$

Where U_{max} = the maximum air velocity (m/s), ΔP = the pressure difference in (Pa) and ρ is the volumetric mass of air (kg/m^3).

For instance, the maximum air velocity at 4 Pa and 20^{o}C will be 2.6 m/s. The measured air velocity of the system can be divided by the maximum air velocity. This is the airflow-efficiency, $\varepsilon_{airflow}$ (-):

$$\varepsilon_{airflow} = \frac{U_{measured}}{U_{\max}} \quad (2)$$

The air velocity is measured with a hot wire anemometer (Envic AFT-1D, 0-10 m/s, 3% tolerance) in the opening of the air exhaust system. The pressure difference is measured at both sides of the window (SETRA 267, +50 - -50 Pa, 1% tolerance). The measurements have a sample time of 1 minute.

RESULTS

a. Physical principles

In case of a false ceiling there are other options to prevent draught (figure 2). In this situation the warm air from the room en heath from the concrete ceiling is used to warm up the supplied cold air. The false ceiling has a large surface so there is more time for the cold air to mix with the warm air.

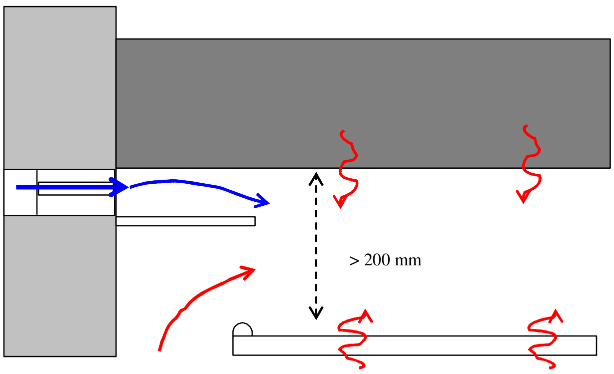

Figure 2. Presentation of some physical principles of draught prevention and promotion of mixing of cold and warm air flows, making use of a “common”-air inlet.

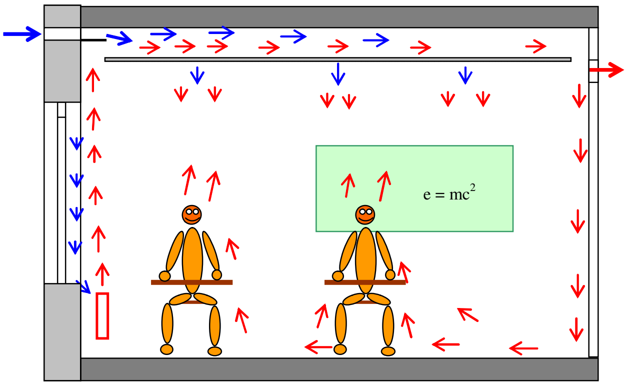

Figure 3. Presentation of the physical principles and comfort qualities of the system of figure 2. Draught is prevented by the false ceiling. Cold downward air flows from the air inlet are prevented by a “spoiler” connected to the air inlet.

Experience shows that a lot of discussions with architects are necessary to integrate this option in their specific design. Generally it is necessary to make draught problems visible for architects underline the draught-problem (figure 4).

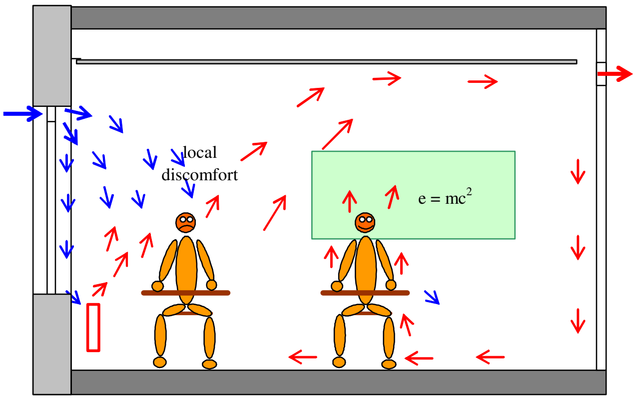

Figure 4. Presentation of local thermal discomfort of the system of figure 7b.

b. Architectural research

Some of the most common systems of natural air supply used by architects in The Netherlands are presented with the following figures:

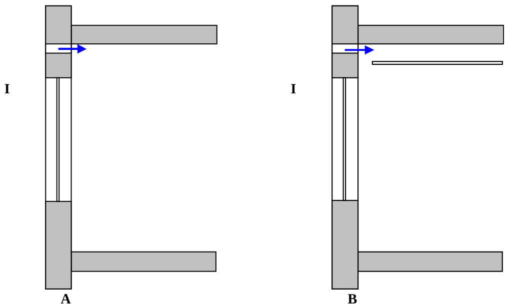

Figure 5. a) Air supply close to the ceiling, b) Air supply in combination with a false ceiling

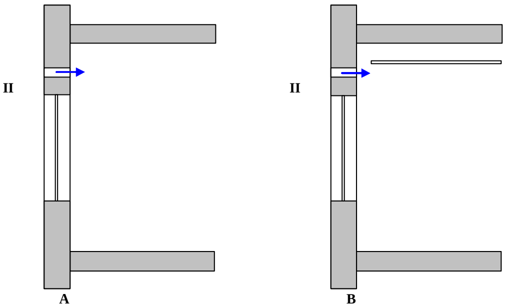

Figure 6. a) Air supply between the window and the ceiling, b) Combination with a false ceiling

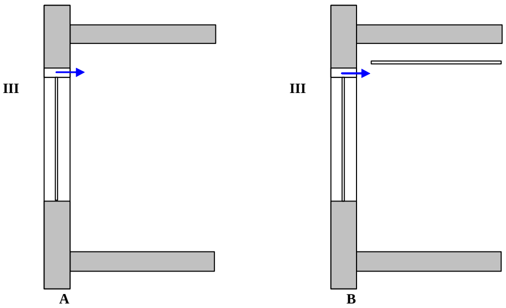

Figure 7. a) Air supply above a window, b) Combination with a false ceiling

An example of how architects try to integrate this knowledge in their design details is presented in figure 8:

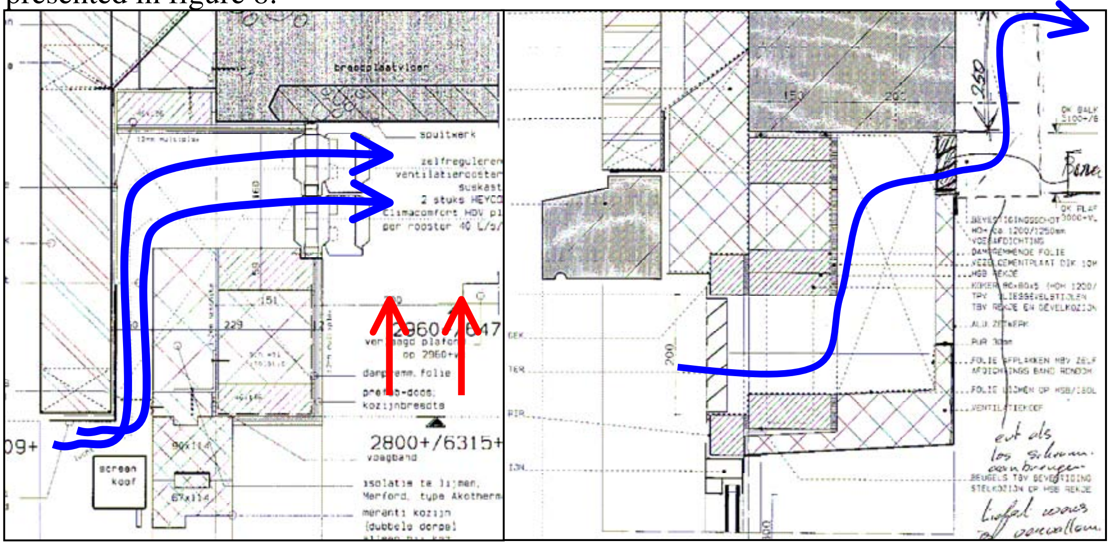

Figure 8: Two examples of air inlets details from different Dutch architects. The supplied air can be transported via the zone above a false ceiling (system III B, figure 7).

c. Airflow measurements and CFD-simulations

Results are design options of:

- A self regulating natural air exhausts system.
- False ceilings, related to thermal and acoustic parameters.
- Different heating systems: Concrete core or radiator heating and options of preheating supplied air.

An example of a self regulating natural air exhausts system is given below:

For a monumental building - the police academy in Apeldoorn - an air outlet system has been tested. In this case the air outlet of a self regulating vent is combined with a double window system (figure 9). Some advantages are:

- reduction of the amount of ducts in the building
- reduction of fan energy
- prevention of downdraught by increasing the temperature of the glass at the inner side
- reduction of infiltration of cold outdoor air

CFD-simulations show that a high position of the outlet is most favourable to prevent downdraught: the temperature of the window at the room side rises and the cold air between the windows cannot flow back into the room.

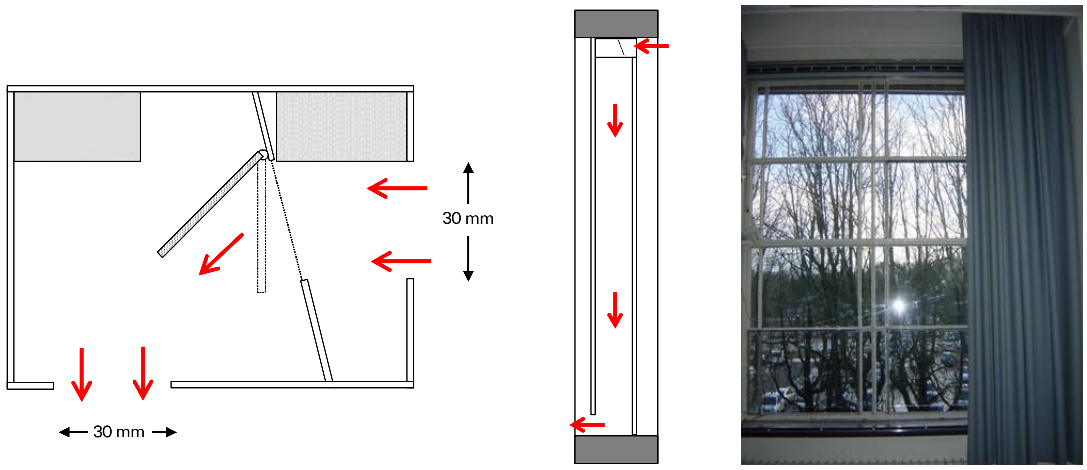

Figure 9: Presentation of the principle of a self-regulating air outlet (system 1, table 1) and a picture with the outlet at the upper side of the window.

The self regulating system prevents the wind to influence the airflow too much. Moreover, when the air supply fan is shut off, the heat loss due to ventilation is small (figure 10 and table 1).

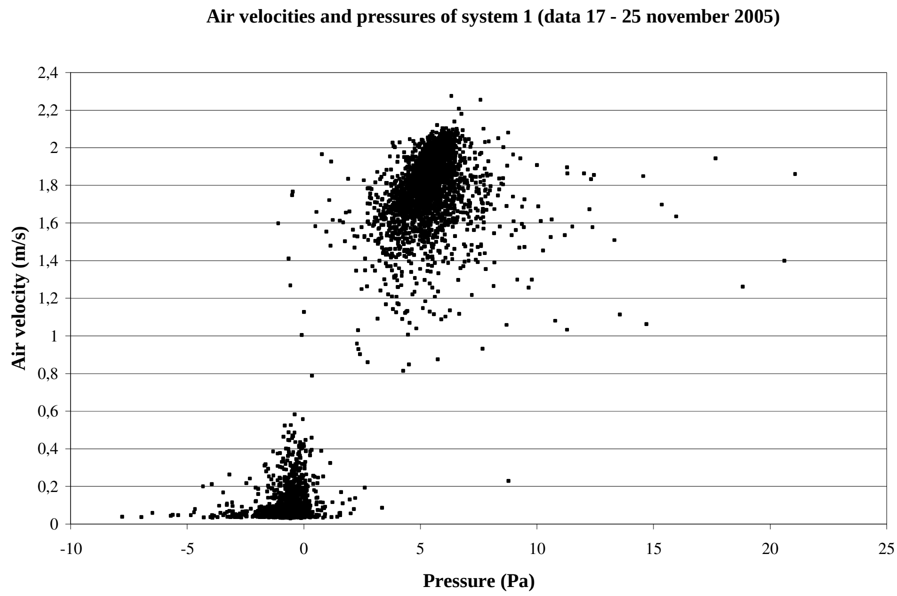

Figure 10: Measurement results of air outlet system 1

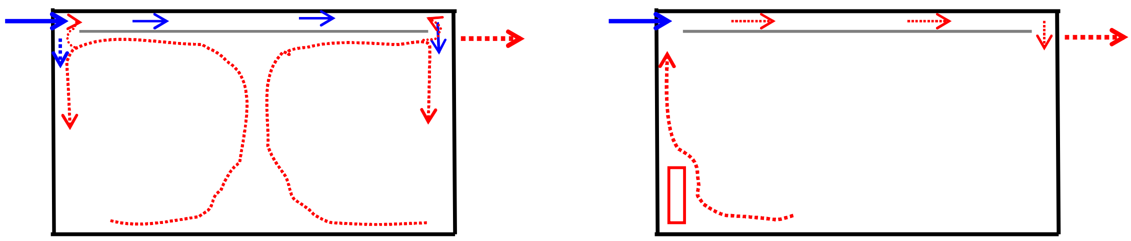
Table 1. Comparison of two natural air outlet-systems (1.72 m long, opening ca. 1.38 m long) with a repulse valve combined with a double window system. The measurements of system 1 and 2 are executed at the same time in a different window in the same classroom (Apeldoorn, 17-25 November 2005)

	System 1				System 2			
	Air velocity (m/s)	Pressure difference (Pa)	Flow (m^3/h)	Air flow efficiency (-) System	Air velocity (m/s)	Pressure difference (Pa)	Flow (m^3/h)	Air flow efficiency (-)
average	1,89	5,49	282	62 %	1,50	6,20	207	47 %
standard deviation	0,13	0,73	19		0,11	0,72	15	
maximum	2,28	21,07	340		1,86	27,91	256	
minimum	0,06	2,01	9		0,05	2,10	7	

Tab1e 1 shows a better efficiency of system 1 compared to system 2. The main reason is that the area of the smallest opening in system 1 is larger than of system 2 and the aerodynamic properties of system 1 are better than system 2. However, even the efficiency of system 1 can be improved avoiding sharp edges of the inlet, outlet and bends and creating a smooth channel without disturbances that can create eddies. In that case an air flow efficiency of more than 83% can be reached [5].

False ceilings, related to thermal and acoustic parameters:
To have the right reverberation time and good speech intelligibility it is necessary to create 25% absorption on the whole inner surface of a class room. For reasons of air quality the floors need a smooth surface and a large part of the walls and the ceiling should be available for acoustic materials. Acoustic elements can diffuse fresh air. They should not hinder the heat transfer and cleaning of these elements should be possible. At his moment there is a database of design options and a calculation model is developed to predict the acoustical properties of a classroom [6].

Floor or radiator heating and CFD-simulations:



Floor heating Radiator heating

Figure 11: Comparison of convection flows of natural air supply, combined with a false ceiling and different heating systems (derived from CFD-simulations).

Figure 11 shows that it is much easier for radiator heating than for floor heating to prevent downdraught from natural air supply and to promote the mixing of cold and warm air above a false ceiling. In case no radiator is available, heating of the ceiling - like concrete core heating - is necessary as well. However, at the opposite side of the façade there is always the risk of downdraught. This can be reduced by creating - for instance- a air permeable ceiling at the opposite side of the façade.

DISCUSSION

When natural air supply and natural exhaust-systems are compared both systems have different opportunities and can be energy effective. In table 2 some of the characteristics of both systems are compared:

Table 2: Comparison natural air supply and natural exhaust

	Air flow	Heat recovery	Heating and cooling	Fan energy
Natural air supply	Max. 3.5 l/sm^2	Heat pump on air exhaust	Heating and cooling with water	Very low
Natural exhaust	3.5 - 6.3 l/sm^2	Aquifer preheats and cools the supplied air	Heating with water and air, cooling with air	Low

This table shows that larger air flows can be supplied with a system of natural exhaust than with a system of natural air supply without creating a draught risk. This is possible by using the right air inlet-systems and using the corridor as an outlet as well.
By preheating natural supplied air, larger air flows might be possible, but this has not been tested up to now.

1. For architects and other designers it is very important to have a compact database of images and knowledge to show comfort-problems and optional solutions.
2. An integral approach of all the important "indoor" physical parameters is necessary even for common design problems.

ACKNOWLEDGEMENT

The author wishes to thank Theo Peters and Linda van Helvoort-Mascini for their assistance with measurements and data-processing and the companies Trox and Buva for developing natural outlet-prototypes.

SUMMARY

This work is focused on the evaluation of indoor thermal quality and shows some results of a wider field study in university classrooms. The field study was conducted through physical observations and questionnaires, performed at the same time during the regular lesson time, in a period just before the start of the heating season. The predictions of dissatisfied occupants, based both on Fanger's heat balance model and on an adaptive approach, were compared to each other. The subjective survey investigated the thermal acceptability, the thermal preference and the thermal sensation, asking students to assess their comfort on subjective scales. The calculated predicted votes were compared to the observed subjective responses. Moreover, the subjective mean votes were compared to the thermal environment perceptions in terms of acceptability and preference. The obtained results give a contribution to the enrichment of knowledge about thermal subjective responses in classrooms.

INTRODUCTION

Recently, CEN is working at the assessment of indoor environmental quality criteria, with the formulation of the prEN15251 European Standard Project [1]. The prEN15251 is strictly related to the European Directive 2002/91/EC [2], about energy efficiency of buildings, and deals with energy consumption problems; it proposes a method for the classification and certification of indoor environmental quality (IEQ), under the point of view of thermal comfort, visual comfort, acoustic comfort, indoor air quality and global comfort [3].
The IEQ affects not only health and comfort, but also the occupants' productivity, so it strongly influences the general quality of working and educational environments, having repercussions on production costs and social costs. In particular, schools are a category of buildings in which a high level of environmental quality may considerably improve occupants' attention, concentration, learning, hearing and performances [4].
This study is focused on thermal comfort and aims at achieving a better knowledge about the subjective perception in naturally ventilated environments, in which the occupants have only some opportunities of behavioural adjustment. A particular, but significant, case is here analysed: naturally ventilated university classrooms. The comparison between the subjective votes and the predicted votes, deriving from the objective monitoring of thermal parameters, allows the test in field of different existing criteria, based both on a deterministic approach and on an adaptive approach.
This study is part of a wider research started by the Building Physics and Indoor Environment Engineering Research Group (see http://www.polito.it/ftarch) of the Department of Energy (DENER) of the Politecnico di Torino, which was focused on environmental comfort in Italian school buildings [5,6]. This paper focuses on the results from the thermal comfort field

investigations in university classrooms. The field campaigns were performed during the lesson periods.
At present, two different approaches to the definition of thermal comfort coexist, each one with its potentialities and limits: the former is deterministic, the latter is adaptive.
Fanger's model [7] based on steady state heat transfer theory, has a deterministic approach and provides the basis of the main thermal comfort standards [8,9], for mechanically controlled environments.
Adaptive comfort models derive from field studies, having the purpose of analysing the real acceptability of thermal environment, which strongly depends on the context, on the behaviour of occupants and on their expectations. The analysis of "real-world" settings reveals that thermal preferences depend on the way people interact with their environment, modifying their own behaviour and adapting their expectations, to match the thermal environment [10].
Moreover, the recent studies on adaptive comfort approach qualify the thermal comfort not only by asking a judgment about the thermal sensation, but also by investigating the acceptability and preference of the indoor thermal condition with respect to conditions corresponding to thermal neutrality [11,12]. This tendency of preferring certain thermal environments was already argued by McIntryre [13]. In his studies, he found out that people of warm climates may prefer what they call a ''slightly cool'' environment and, on the contrary, people of cold climates may prefer what they call a ''slightly warm'' environment.
Furthermore recent field studies in classrooms confirm that people in naturally ventilated indoor environment are comfortable within a range of microclimate values that is larger than in a fully conditioned indoor environment [14].
Among the adaptive comfort diagrams, this study referred to the one developed in a recent EU-funded research project coordinated by the Oxford Brookes University (figure 1) [15]. This diagram is adopted into Standard prEN15251/2006 [1].

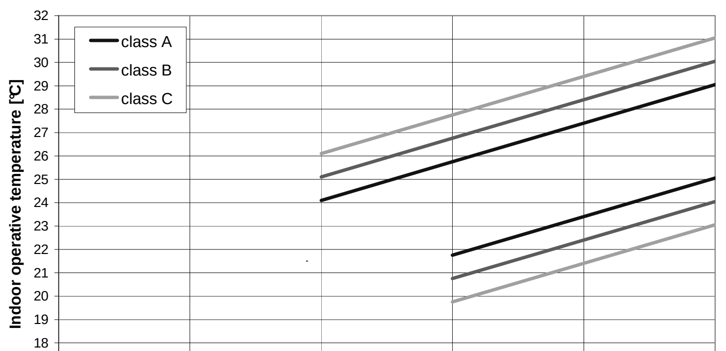

Figure 1. Adaptive thermal comfort diagram for the design of naturally ventilated environments, adopted into Standard prEN15251/2006

METHODS

Object of the study

In this study, a methodology based on both objective and subjective surveys for in field evaluation of thermal comfort was applied. The approach consists of administrating a

questionnaire to a group of occupants while the investigator records certain microclimatic parameters [6,11,14].
Such an investigation methodology is very important in classrooms, that are an example of indoor environment in which the adaptive opportunities are quite limited during the lessons period, but they are free during the hourly lesson breaks. In fact, students have to spend lots of time in listening and understanding lessons, remaining sitting at their desk. Moreover, the freedom of students in modifying and adjusting their activity level according to the thermal environment is, to a certain extent, limited during the lesson time, as well as the possibility to change the functioning parameters of the HVAC systems or to open/close the windows. But the same actions are free during the lessons breaks. The adaptive actions of the students to modify the microclimate parameters may include adding or removing layer of clothing, opening or closing windows, moving sun shading devices, etc. [10].
A previous study examined a representative sample of typical high school and university Italian classrooms; the study was performed during the heating period, that in Turin ranges from 15th October to 15th April; in particular, the investigations were carried out from the end of January to April 2002. The results are shown in [6].
The object of this study, an extension of the previous study, is a university classroom of the Politecnico di Torino, medium-sized and parallelepiped-shaped. The classroom is located at ‘‘Via Boggio’’ campus, a new building in a residential area at the border of Turin downtown, next to the headquarter of the Politecnico di Torino. The classroom has a floor area of 142 m^2, a height of 3,4 m and a volume of 483 m^3; the ratio of glassed area/floor area is W/F = 0,15; the exposition is E–SE. The classroom was examined during the lesson time, in two periods, the first in September and the second in October 2006, outside the heating season, with outdoor warm or mild climate conditions; the direct solar radiation into the classroom was important during the first survey, while the sky was cloudy during the second. Heating through radiators and mechanical ventilation were off during the field campaigns. The classroom contained 103 students at the time of the first survey and 108 in the second.
Two different comfort criteria, Fanger’s PMV [7], and the adaptive thermal comfort diagram (figure 1) [15], were applied to a naturally ventilated university classroom and the results were compared with the subjective votes of the students. Furthermore the votes of thermal preference were compared to the votes of thermal sensation.

Subjective approach

The subjective approach was basically aimed at finding out the judgement about the perception of the thermal environment in terms of acceptability and preference of colder or warmer environments. Moreover, a vote on the Fanger’s 7-points thermal sensation scale was asked to students.
Questionnaires were used to investigate the thermal perception. They were delivered and filled by the students while the measurements (see Section 3.3) were going on. The answers to the questions concerned the instantaneous assessment of microclimatic conditions. Students were uniformly distributed in their own classroom during their regular lecture hours.
The questionnaire was specifically set-up for the assessment of thermal quality in classrooms. It is a section of a more complete questionnaire, concerning the general environmental quality in classrooms, developed by an équipe of indoor environment engineers, mathematicians and physiologists. Its final shape belongs to the results of a number of tests aimed at verifying the reliability of the way in which the questions are proposed and the answers are done.
With regard to thermal comfort, among the general information, it was asked to the students to mark what they were wearing by means of a clothing check-list, in order to find out the actual clothing level (calculated using ISO 7730 [16]). This information was used in the evaluation of the PMV comfort index.

The questions in the section of thermal comfort concerned how the thermal environment was felt. In particular, students gave a judgement about its acceptability and preference, answering the following questions [6,11,14]:

- at this moment, do you consider the thermal environment acceptable or not?
- at this moment, would you prefer to feel warmer, cooler or no change?

Moreover, a judgement on the typical seven points thermal sensation scale (Fanger 7-points scale, ranging from -3 to +3, corresponding to very cold and very hot and 0 being the thermal neutral condition) was asked [7].

Objective approach

The indoor thermal environment was analysed by means of field measurement campaigns. The measured thermal parameters were:

- air temperature,
- plan radiant temperatures,
- air relative humidity,
- mean air velocity and standard deviation of air velocity.

The Indoor Climatic Analyser, type 1213 by Brüel&Kjær was used to perform the measurements of all the thermal parameters and 6 microdataloggers type 175-T1 by Testo, to measure air temperature. The measurements took at least 2 hours and were done only during the lesson time.

The parameters were measured in continuous at a height of 1.1m above the floor, according to the standard ISO 7726:1998 [16] for seated persons, for the whole classroom.

On the basis of ISO 7730 [9], two forms of local thermal discomfort were verified: from the mean air velocity and standard deviation of air velocity, the draft risk was evaluated and the local discomfort from radiant asymmetry was evaluated.

As far as the personal parameters are concerned, the metabolic rate was fixed at 1.2 met (sedentary activity) and the actual people clothing were obtained from the questionnaires.

The recorded data were elaborated in order to evaluate the thermal comfort Fanger's indices, PMV and PPD, according to ISO 7730 [9]; the clothing levels and the values of the thermal parameters were quite homogeneous, so the PMV was calculated from the medium values of the parameters.

In order to apply the adaptive diagram of figure 1, the "outdoor running mean temperature" was calculated from the outdoor daily mean temperatures of the days preceding the examined one (day n), with this formula [1,15]:

$$t_{ORM\,(n)} = (1-\alpha)\,(\,t_{OMD\,(n-1)} + \alpha\, t_{OMD\,(n-2)} + \alpha^2\, t_{OMD\,(n-3)} + \ldots), \qquad (1)$$

where $t_{ORM\,(n)}$ is the running mean temperature in the day n, $t_{ODM\,(n)}$ is the outdoor daily mean temperature in the day n and α is a constant between 0 and 1, defining the speed at which the running mean temperature responds to the outdoor temperature (a value of 0.8 implies that the characteristic time subjects take to fully adjust to a change in the outdoor temperature is around 5 days and corresponds to the highest correlation with comfort sensation).

The outdoor daily mean temperatures of the days preceding the examined one were obtained from hourly data, measured by the Meteorological Station of the Politecnico di Torino; the resulting values of the "outdoor running mean temperature" for the two examined days were respectively 19,8 °C and 20,1°C.

So the indoor operative temperature ranges were obtained from the adaptive thermal comfort diagram of figure 1, in function of the values of outdoor running mean temperatures previously found. The diagram of figure 1 shows three tolerance ranges for the indoor operative temperature, corresponding to three different expected percentages of satisfied people (90%, 80% and 65%).

RESULTS

As explained in the previous paragraph, the whole classroom was qualified "objectively", that is on the basis of measurements, observations and calculations, both through a deterministic and an adaptive approach, obtaining the following results for the global thermal comfort:

- a value of PMV and PPD for the whole classroom, according to the deterministic approach;
- an expected value of dissatisfied occupants, deriving from the comparison between the range of values assumed by the indoor operative temperature and the tolerance ranges obtained from the adaptive diagram for the examined day.

First of all, these two results were compared to each other, then these results were compared to the subjective votes deriving from the questionnaires.
As far as local thermal discomfort is concerned, two forms of local thermal discomfort (draft risk and radiant asymmetry) were evaluated, as explained in the previous paragraph. Both these evaluations didn't show any critical situation under the point of view of local discomfort, in both the surveys.
For both the examined days, the obtained value of PPD was < 10% (9% and 8% respectively). Considering that no particular forms of local thermal discomfort existed, in both the examined days, the expected percentage of dissatisfied was less than 10%.
Comparing the indoor operative temperatures to the tolerance ranges, with the adaptive approach, the expected percentage of satisfied people was at least 90% (indicated as PPD_adapt < 10%); in this case the use of the diagram would predict the effect of both global and local thermal comfort.
So the two "objective" approaches lead approximately to the same results, in predicting the percentage of dissatisfied. The coincidence of the two approaches might depend on the fact that, in the examined period, the outdoor climate is not extreme.
The expected percentage of dissatisfied (< 10%) was compared to the percentage of dissatisfied from the questionnaires, calculated as follows.
The dissatisfied people were first evaluated through the direct votes "non acceptable" expressed by the students for the thermal environment: this percentage is indicated as PD_direct in table 1.
A second way of evaluating the dissatisfied people was considering the ones voting (-3;-2) and (+2;+3) on the seven points thermal sensation scale, following the same approach used by Fanger in its experiments; this percentage was slightly corrected adding to it the percentage of students voting (-1,0,+1) but expressing discomfort for draft (indicated as PD in table 1).
Then, with a third approach, the dissatisfied people were considered the ones voting (-3;-2) and (+3) on the seven points thermal sensation scale; also in this case, this percentage was slightly corrected adding to it the percentage of students voting (-1,0,+1,+2) but expressing discomfort for draft (indicated as PD* in table 1).

Table 1. Results of the two field surveys performed in the same classroom

Survey	PPD	PPD_adapt	PD_direct	PD	PD*
September	9%	< 10%	24%	20%	6%
October	8%	< 10%	29%	24%	9%

The results presented in Table 1 show that both PD_direct and PD, resulting from questionnaires are always sensibly higher than the calculated PPD and PPD_dapt.
In particular, vote +2 (hot) is considered unacceptable by the Fanger approach. On the contrary, in the preformed study, environments voted as +2 seem to be partially accepted, as it is pointed out through the analysis of the subjective judges about ‘‘acceptability’’ and ‘‘preference’’ of a thermal environment. In fact, considering as dissatisfied people voting (-3;-2) and (+3) and as satisfied people voting (+2), the PD* agrees well with the measured PPD. This issue was also argued by Mayer [12]. A similar result emerged from the previous study [6], which was conducted only during the heating season, but it is important to note that in that period this trend was more evident, in fact environments voted as +2 seemed to be more accepted and also preferred.
The judgments on the seven points thermal sensation scale were then correlated to acceptability and preference, as shown in Figs. 2, 3 and 4.

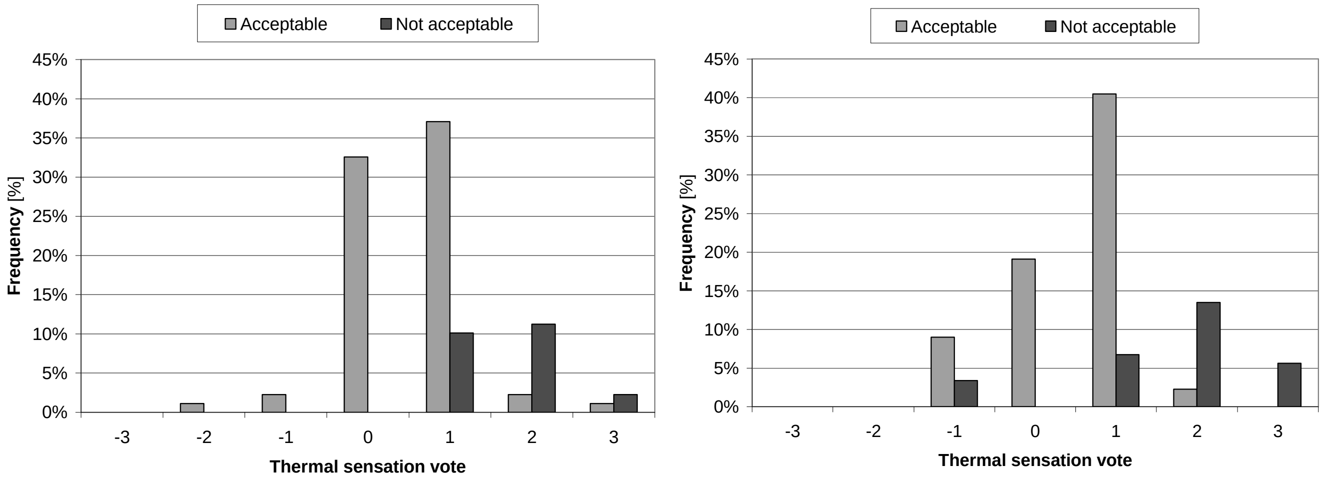

Figure 2. Frequency distribution of thermal acceptability votes versus thermal sensation votes

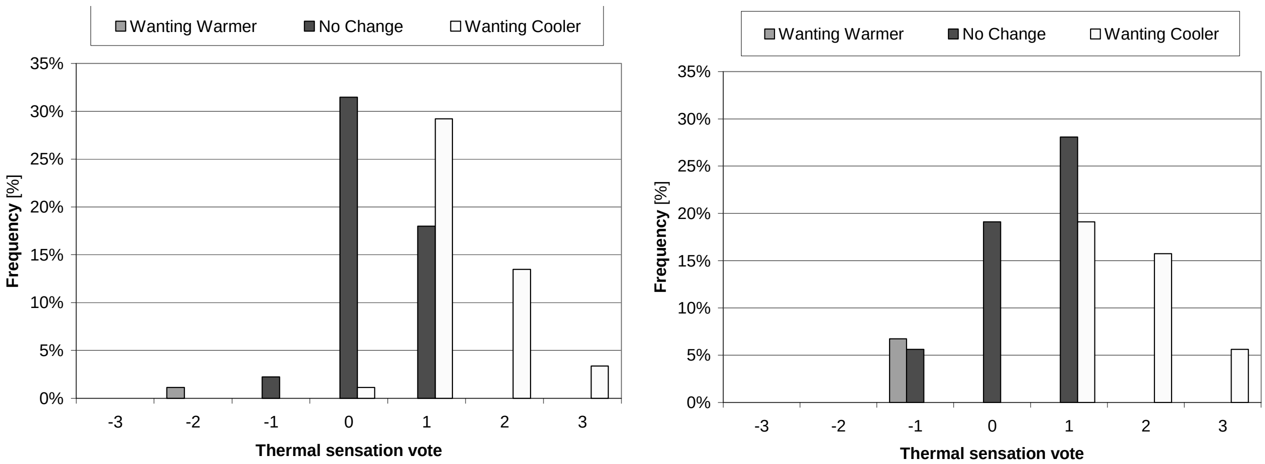

Figure 3. Frequency distribution of thermal preference votes versus thermal sensation votes

In particular, in Fig. 2 the frequency distribution of the acceptability is presented versus the subjective vote about the thermal environment.
Both the results of the surveys show that the distribution of ‘‘acceptable’’ is shifted toward the positive side of the vote scale; in particular, most of the people voting +1 considered ‘‘acceptable’’ the thermal environment. It is important to note that in the previous winter

study a similar trend was found for the examined classrooms, but with a more accentuated acceptability of warmer environments.
These statements are also verified by the diagrams in Fig. 3, plotting the frequency distribution of the preference versus the subjective vote about the thermal environment.
A very high percentage of votes ‘‘no change’’ corresponds to the vote +1, in particular for the second survey. The same phenomenon was very remarkable in the previous winter surveys.
Plotting the cumulate frequency distribution of ‘‘wanting warmer’’ and ‘‘wanting colder’’ versus the subjective judgment on thermal environment (Fig. 4), show the location of the point corresponding to the minimum number of dissatisfied. This point is at the intersection between the two cumulate curves. The figures show that such minimum does not coincide with the thermal neutral condition (0 in the subjective vote) but is slightly shifted toward the positive values of the vote scale.

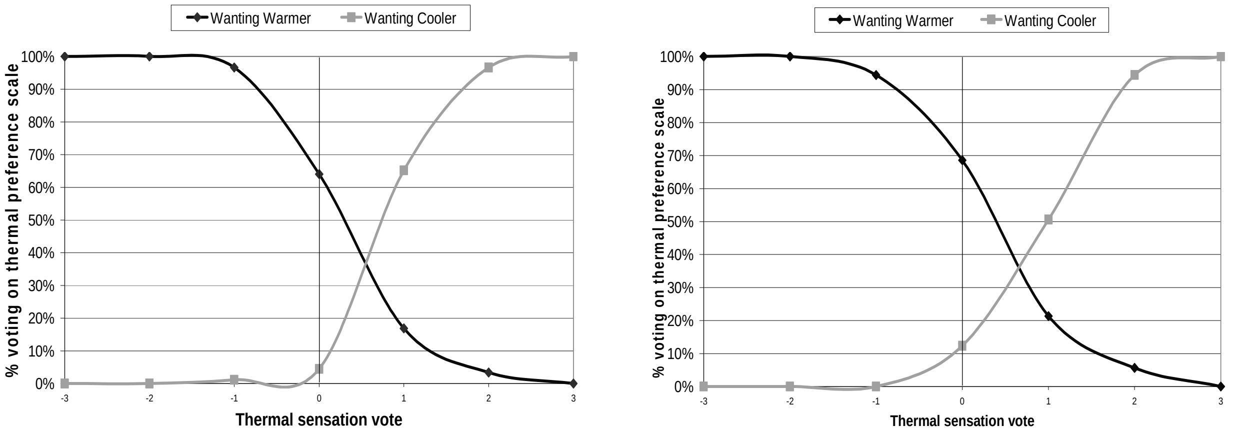

Figure 4.

DISCUSSION

In this work, a in field investigation methodology on thermal comfort was applied. The environmental parameters influencing thermal comfort were measured while, at the same time, the subjective judgements of the people about the thermal environment were expressed. Significant tendency and correlation were found out. The investigations were performed in the same university classroom in two different days, in September and October, before the beginning of the heating period.
This study allowed a comparison between different predictive approaches for thermal comfort and a comparison between the predictions and the observed subjective responses. Furthermore it added new findings to previous researches conducted in Italian university and high school classrooms, during the heating season. The results of this study confirmed the trend outlined by the previous study, but with a minor intensity, suggesting a correlation between the thermal acceptability and preference and the outdoor temperature.
The following results were found:

- it was found out a bad agreement between the calculated PPD and the percentage of dissatisfied from the questionnaires when people voting (-3;-2) and (+2;+3) on the seven points thermal sensation scale are considered all dissatisfied;
- it was found out a good agreement between the calculated PPD and the percentage of dissatisfied from the questionnaires when people voting (+2) on the seven points thermal sensation scale are considered satisfied.
- thermal environments which are judged neutral or slightly warm are accepted;
- thermal environments which are judged slightly warm might be preferred;

- in thermal environments which are judged as slightly cold, ‘‘wanting warmer’’ people are a high percentage and might prevail;
- in thermal environments which are judged as neutral, ‘‘no change’’ people prevail and there are no votes of ‘‘wanting warmer’’;
- in thermal environments which are judged as slightly warm, ‘‘no change’’ people are a high percentage and might prevail.

A comparative analysis of the indoor air quality and thermal comfort in schools with natural, hybrid and mechanical ventilation strategies

Dejan Mumovic[1], Mike Davies [1], Colin Pearson[2], Gareth Pilmoor[2], Ian Ridley[1], Hector Altamirano-Medina[1] & Tadj Oreszczyn[1]

SUMMARY

Within the UK, the importance of providing adequate ventilation in schools has been recognised in a recently adopted document (Building Bulletin 101), which defines the set of performance criteria in relation to ventilation rates and indoor air quality in new school buildings. This paper describes a series of field measurements that investigated the ventilation rates and indoor air quality in three new secondary schools in England with respect to these new criteria. The study also analysed the overall performance of the integrated heating and ventilation systems with regards to comfort. All the schools satisfied the recommended ventilation performance standards during the week that the measurements were undertaken. However, this apparently reassuring message can be misleading unless one takes into account both the original design assumptions and then the actual occupancy of the classrooms and occupant behaviour in general. With regards to comfort, for many rooms the schools did not meet the relevant recommended levels.

INTRODUCTION

The UK Government has committed to a massive programme of rebuilding and refurbishing schools in England and Wales in the next 10 to 15 years [1]. To underpin this programme, entitled ‘Building Schools for the Future’, the Department for Education and Skills has published design guidance - Building Bulletin 101 ‘Ventilation in School Buildings’ [2]. This performance standard document is cited as a means of compliance with the new Building Regulations Part F (Ventilation) in England and Wales [3]. In this document CO_2 concentration has been chosen as the key performance indicator for the assessment of indoor air quality and ventilation performance in schools. The recommended ventilation performance standard can be summarised as follows:

1. the average concentration of CO_2 should not exceed 1500 ppm
2. the maximum concentration of CO_2 should not exceed 5000 ppm during the teaching day
3. at any occupied time the occupants should be able to lower the concentration of CO_2 to 1000 ppm
4. purpose provided ventilation in naturally ventilated buildings should provide external air supply to all teaching and learning spaces with (a) a minimum of 3 l/s per person, (b) a minimum daily average of 5 l/s per person and (c) a capability of achieving a minimum of 8 l/s per person at any time

5. purpose provided ventilation in mechanically ventilated buildings should provide external air supply to all teaching and learning spaces with a minimum of 5 l/s per person at all time, and (b) a capability of achieving a minimum of 8 l/s per person at any time

In addition to the requirements stated in Building Bulletin 101, the authors have investigated if the comfort of occupants was compromised by the ventilation strategy. A previous study has highlighted thermal comfort as an important aspect of providing winter time ventilation [4]. Taking these requirements into account, this paper focuses on a comparative analysis of indoor air quality and thermal comfort in three recently built schools in England with different ventilation strategies: natural, hybrid and mechanical.

METHODS

Measurements were carried out in three schools in England during the heating season 2005-2006. All schools were built in compliance with Building Bulletin 93 [5], which defines noise and acoustic criteria in relation to school design. The monitoring was carried out in two selected classrooms in each school over a period of five working days. Levels of CO_2 were monitored at five-minute intervals throughout the occupied day close to the occupied zone at seated head height to indicate the overall indoor air quality and provide a means of inferring the ventilation rate based on the number of occupants. Two Gascard II infra-red gas monitors ($MYCO_2$) (accuracy: 2% of the range - 0-5000 ppm) coupled with HOBO dataloggers were used for the indoor measurements. In addition, outdoor CO_2 was measured using a Telaire 7001 infra-red gas monitor (accuracy: 50 ppm or 5% of the reading, whichever is greater). Ventilation rates were also estimated over suitable intervals using Equation 1, a form of 'continuity equation' [6] [7] [8]:

$$C_{(t)} = C_{ex} + \frac{G}{Q} + \left(C_{in} - C_{ex} - \frac{G}{Q} \right) e^{-\frac{Q}{V}t} , \qquad (1)$$

where: $C_{(t)}$ - internal concentration of carbon dioxide at time t (ppm), C_{ex} - external concentration of carbon dioxide (ppm), G - generation rate of carbon dioxide in the space (cm^3/s), Q - internal-external exchange rate (m^3/s), C_{in} - initial concentration of carbon dioxide (ppm), V - room volume (m^3), and t - time (s).

In addition to CO_2 levels, the following thermal comfort parameters were measured during the occupied periods in each of the selected classrooms:

1. dry bulb temperature, measured via: a screened platinum resistance sensor to eliminate any thermal radiation effects, an air velocity compensation sensor and a relative humidity compensation sensor.
2. relative humidity was measured with a VAISALA capacitive sensor
3. globe temperature was measured with a platinum resistance sensor within a 30mm black sphere
4. air velocity was measured with a DANTEC heated thermocouple sensors

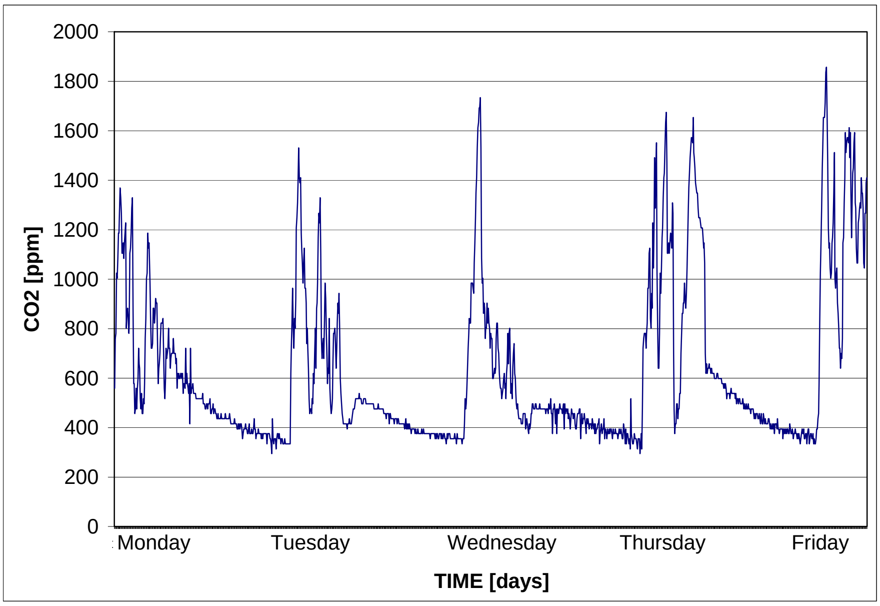
Measurements made every second were averaged over 2 minute intervals. The thermal comfort parameters were measured at two locations simultaneously, one being fixed at the normal work position of a pupil close to an openable window, while the second thermal comfort analyser was moved at different locations across the rooms. The procedure laid out in ISO Standard 7730-1995 was used to determine the PPD (percentage of people dissatisfied) and the DDR (draught dissatisfied rating) indices and specifications of the conditions for thermal comfort. A brief description of the ventilation strategy and findings for each school is given below.

RESULTS

School 1 - Natural Ventilation strategy: This school is located at an exposed rural site and represents a basic single sided naturally ventilated design with openable windows into deep classrooms. Each room had three top hung windows but each had a maximum opening angle of 30°. Some thought had been given to providing cross ventilation by providing a small grill into the suspended ceiling and a duct that led to the atrium space from which the classrooms were entered. No fan was found. A smoke test carried out suggested that the ducted extract contributed insignificantly to the ventilation strategy in the room. Heating was provided by low temperature hot water radiators located under the openable windows. Both classrooms (NV1 and NV2) have an identical ventilation strategy, but different use. Whilst room NV1 was used as a seminar room, room NV2 was used as a 'typical' whiteboard classroom. A number of small intervention studies were carried out in each classroom (windows opened/closed, etc.) to test the capabilities of the design to adequately ventilate the room. Note that the number of students during the 'observed' occupancy in the rooms was very low - usually 50% of the 'as designed' number of occupants. Therefore, two ventilation rates were calculated and reported. For example: in the case of the naturally ventilated room NV1 with three top hung windows opened the calculated ventilation rate for the 'observed' occupancy of 10 occupants was 11.7 l/sp. However, the ventilation rate in the case of the 'as designed' occupancy of 30 reduces to 3.9 l/sp.

Table 1: School 1 – summary of IAQ measurements

A typical CO_2 levels in a room with natural ventilation strategy (NV1)



CO_2 levels [ppm]*		
Classroom	NV1	NV2
average	960	1054
STD	331	397
maximum	1857	1725

Comments:
*note that the occupants kept the door to the atrium open most of the time
** calculated for 10 occupants (calculated for 30 occupants)
*** calculated for 30 occupants

Intervention	All windows opened (l/sp)	2/3 of all windows opened (l/sp)	1/3 of all windows opened (l/sp)	All windows closed (l/sp)	Cross ventilation (l/sp)
NV1**	11.7 (3.9)	n/a	6.0 (2.0)	2.8 (0.9)	20 (6.5)
NV2***	3.9	3.4	1.7	n/a	n/a

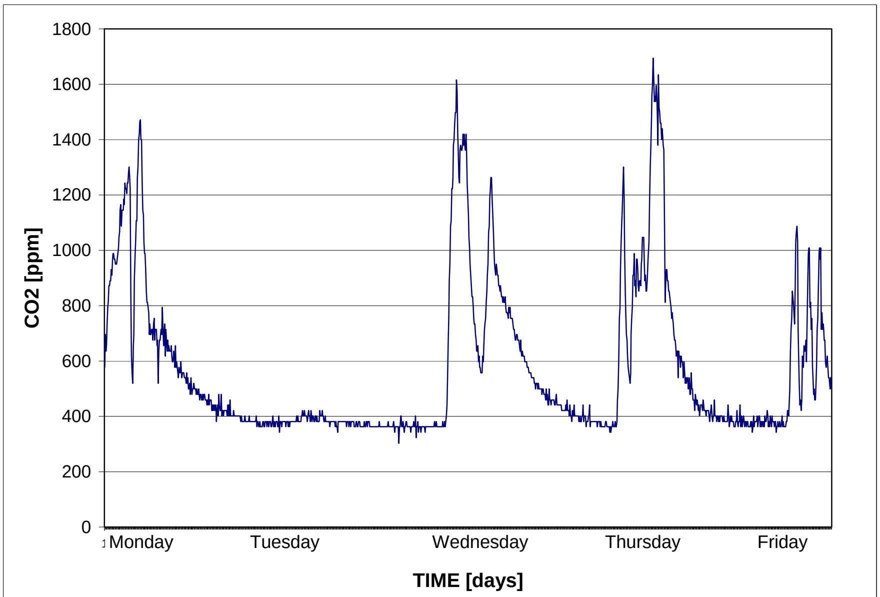
NV1	moving	11.4	15.8	22.4
NV1	stationary	16.9	30.4	25.8
NV2	stationary	12.6	13.4	21.5
NV2	moving	5.5	3	21.4

School 2 - Mixed Mode and Mechanical Ventilation strategy: This school has a combination of mixed mode ventilation and full mechanical ventilation systems. General ventilation is provided to the classrooms mostly by means of a packaged air handling unit (AHU) system. 100% fresh air is fed into the air handling unit where it is conditioned (tempered) - the system being controlled by a BMS. The tempered air from the AHU is conveyed to each classroom through externally buried concrete pipes (any mould growth in the pipes was not an issue that was investigated). Heating is by a combination of underfloor and trench heating. Suspended ceilings were not generally fitted so that the exposed thermal mass could provide some passive cooling. In the mixed mode classroom (HMV1) the designed ventilation strategy relies on both mechanical (variable speed fan) and natural ventilation (automatic windows). In the mechanically ventilated room the designed ventilation strategy relies on variable speed fan only.

Table 3. School 2 – summary of IAQ measurements

A typical CO_2 levels in a room with a mixed mode vent. strategy (HMV1)



CO_2 levels [ppm]*,**

Classroom	HMV1	HMV2

HMV1	stationary	5.5	3	21.4
HMV2	moving	17.4	9.8	20.3
HMV2	stationary	9.1	4.5	20.0

School 3 - Mechanical Ventilation strategy: The school is serviced by mechanical ventilation with under floor heating and manual windows. The teaching rooms (MV1 and MV2 are considered here) have full mechanical ventilation from a ceiling based supply and extract. The fresh air is tempered and conveyed to the room via a simple duct system mounted in a void above the suspended ceiling. There are two air inlets and only one extract within the classroom. The extract, which leads to the large void space above the suspended ceiling is not separately ducted but a small transfer hole connects this plenum void to the corridor. The corridors have additional extract fans located on the roof. This would suggest that mechanical ventilation provides positive pressure within the room. In addition to the mechanical ventilation system, the ventilation strategy in the room is underpinned by two smaller manually operated windows.

Table 5. School 3 – summary of IAQ measurements

A typical CO_2 levels in a room with a mechanical vent. strategy (MV1)

DISCUSSION

A. CO_2 levels

School 1: A typical diagram of CO_2 levels based on the recorded five minutes values is shown in Table 1 for the naturally ventilated room NV1. Generally, on each day, the levels of CO_2 increased from the start of the day reaching a peak at the end of the morning session and decreasing during the lunch time when the classrooms are generally unoccupied. The CO_2 levels start increasing again after the lunch break reaching the afternoon peak at the end of the last period. This is due to the following: a) the breaks between two classes are short (usually 5 minutes) not allowing the CO_2 concentration to equilibrate to the external level, b) in some cases pupils are allowed to stay in classrooms during the breaks contributing to an even more rapid build up of CO_2 levels, c) the lack of an effective ventilation strategy. Note that the standard deviations of CO_2 levels (STD) for the natural ventilation strategy applied here are very high (Table 1). In the case of these naturally ventilated rooms, the average CO_2 levels exceeded 1,000 ppm in room NV2 only. The lower values in room NV1 were partially due to low occupancy levels in the room. Despite low occupancy, the maximum levels recorded were still high.

School 2: A typical diagram of CO_2 levels for the mechanically ventilated rooms is shown in Table 5. The value of 1000 ppm was exceeded only once for a very short period of time. Note that during that short period, the number of the occupants in the room exceeded the designed number of occupants by 2. As expected, fluctuations of CO_2 levels are less significant than for School 1. The fluctuations in these rooms with constant flow rate fans were related either to occasional use of manual windows or to change in number of pupils in attendance. It should be noted that the use of fans with constant flow rate may result in over-ventilation and unnecessary energy consumption in schools with low attendance.

School 3: In the mixed mode classroom HMV1 the designed ventilation strategy relies on both mechanical and natural ventilation (automatic windows). During programmed occupancy periods the windows are set to remain open until the measured room space temperature falls below the set point by more than 2°C. However, due to security reasons (the classroom was located on the ground floor in a less secure area of city) the automatic control was overridden and the windows were kept shut. As a consequence, the role of the mechanical ventilation supply has shifted from a supplementary one to being the main ventilation provider. In order to test the ventilation strategy as it was supposed to be operated, the research team also opened the automatic windows manually (Table 3). Note that the standard deviation in this case of the room HMV1 was lower than in the case of naturally ventilated room. In this room the number of students during the ‘observed’ occupancy was very low, usually 50% of the ‘as designed’ number of occupants. Prior to this study, the volume of the flow entering the room HMV2 (fully mechanically ventilated) through the heater battery was too high causing discomfort to the students sitting near the trench. By reducing the air flow through the battery the problem of discomfort was addressed, but as a consequence of the reduced air flow the operational performance of the mechanical ventilation system was degraded. In this case it was not possible to change the furniture layout without incurring excessive costs (i.e. the furniture was fixed).

B. Estimated ventilation rates

The estimated ventilation rates have shown that the naturally ventilated classrooms were the least well ventilated in the normal style of usage but did not exceed any threshold values because of low occupancy levels under those conditions (Table 1, 3 and 5). The mechanical and mixed mode schools could exceed 8l/s per person but the greatest ventilation rate observed was in the naturally ventilated classroom when the door was opened to provide cross ventilation to the atrium. This mode was frequently used by the school when there were higher levels of occupancy in the classrooms.

C. Temperatures and comfort

With regard to the internal temperatures, CIBSE Guide A1 [9] suggests design criteria for educational buildings. For teaching spaces the specified winter temperature is 19-21°C. The average temperatures found in the schools varied depending on the school and room with NV1 and NV2 being the warmest between 24°C and 26°C and the rooms HMV1 and HMV2 being the coolest between 20°C and 22°C. For many rooms the schools did not meet CIBSE recommended levels for winter conditions and sometimes barely falling within the summer upper limit, indicating that there could be some discomfort among students due to the thermal environment. Note that the average external temperatures were app. 5°C with maximum temperatures exceeding 10°C for a few hours only.

Dissatisfaction due to air movement does not have a simple relationship with air speed; the draught index takes into account fluctuations in local air speeds and local temperatures in order to determine the percentage of people dissatisfied due to draughts. Note that the draught risk exceeded the generally accepted level of 15% a number of times. It should be noted that in mechanically ventilated rooms (Table 4) problems were experienced with draughts from the ventilation systems. In the rooms MV1 and MV2 the incoming ventilation air was 'dumped' from the air inlets causing discomfort to occupants. However, the highest DDR was related to a naturally ventilated room NV1 when all three top hung windows were fully opened (Table 1).

D. General

In this study all the schools satisfied the recommended performance ventilation standards leading to the conclusion that the implemented ventilation strategy was providing adequate ventilation. However, this is misleading unless one takes into account three important factors: a) the occupancy schedule for classrooms (i.e. the classrooms were not fully utilised during the 'normal' occupied hours, preventing CO_2 building up during the day), b) the occupancy level during classes (i.e. number of students attending classes) and c) occupant behaviour. As shown previously, these factors have had a significant effect on the performance of some classrooms.

The mechanical and mixed mode systems generally performed adequately but it was clear that these systems can provide a different set of difficulties for the occupants and operators. They tended to lack the flexibility of operation (for example: zonal control of underfloor heating system) offered by the natural ventilation system and also the reliance on control by a BMS required the school facilities staff to be familiar with the system and its use. The automatic windows used as part of the hybrid ventilation strategy had to be locked shut because of security concerns and this compromised the hybrid mode of operation.

ABSTRACT

Seven schools underwent an energy audit, evaluating the existing situation through measurement and simulation and looking to possible retrofit measures and their economic feasibility with the energy performance tool (EPB) as an instrument. The results are troubling. The seven schools audited are all problem buildings: hardly any insulation, windows quite air leaky, central heating systems poorly designed and no usage of an on purpose installed ventilation system. As a consequence, IAQ is poor, with CO_2-levels passing 3000 ppm and a high percentage of dissatisfied with air freshness during teaching hours. Annual end energy use, however, is remarkably low compared to the EPB-prediction, showing that a potentially high energy demand evokes effective rebound behavior. The negative side of that is that hardly any energy conserving measure has enough impact to show a positive NPV at the end of the return period, let it be that the annuity on investment is lower than the annually avoided energy cost.

Keywords: Schools, energy audit, energy consumption, building performance, indoor environment.

INTRODUCTION

As figure 1 shows, most school buildings in Flanders are quite aged. During the last decennia, retrofit and new construction lagged behind the needs. For that reason, the Flemish government agreed on a major program of retrofit, substitution and new construction, in collaboration with private investors. Investment projected over the years to come totals more than one billion euro. Among the requirements imposed figure energy efficiency and indoor environmental quality.

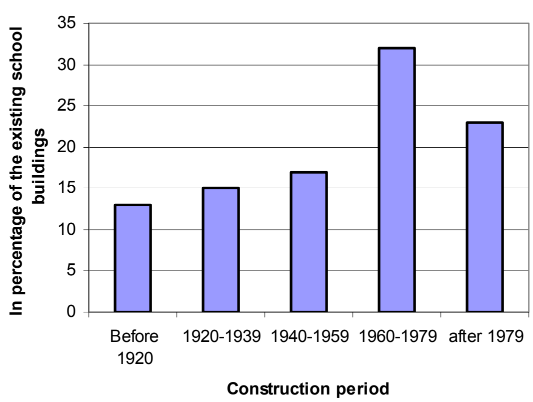

Figure 1 Age structure of school buildings in Flanders

It is thus of interest to find out how inefficient schools are and how successful energy retrofits, taking into account indoor environmental quality, could be. Such objective of course is not new. Some years ago, the IEA, Exco on Energy Conservation in Buildings and Community Systems, initiated an annex on Retrofitting of Educational Buildings (Anon, 2004). Gaitani et al, 2006, undertook a large scale energy analysis in Greek schools. They came up with five energy classes with the normalised annual consumption per square meter of floor area as indicator. Vermeir et al. 2003, reported on school acoustics, based on measurements in 47 classrooms. They found that 40% had a too high reverberation time for good speech transmission. Astolfi et al, 2003, analysed the overall environmental quality in four university classrooms. They saw discrepancies between the comfort indicators, based on measurements, and comfort satisfaction as expressed by the students. Wouters, 1989 and Hens et all, 2004, measured CO_2-concentrations in existing class rooms without on purpose installed ventilation system. The highest value noted was 5000 ppm at the end of a lesson. No class was at IDA3-level, the indoor air quality imposed by the actual Flemish energy performance decree (EPB).

SCHOOLS AUDITED

Seven schools have been audited in detail. Nine others are underway. However these audits are not finished yet. Table 1 lists the seven schools with their main characteristics.

Table 1 The seven schools

School	Type	Floor area m²	Volume m^3	Characteristics
1	Primary education (Machiels et al, 2006)	1083	4614	Oldest buildings from the fifties. Not insulated. First extension in the sixties. No insulation. Last extension in the nineties, insulated. No ventilation system. Hydronic central heating on gas
2	Special primary + secondary education, (Broers et al, 2005)	6738	23975	Built in the sixties. Not insulated. No ventilation system. Hydronic central heating on fuel
3	Special education (Defraeye et al, 2006)	3742	16935	Oldest building from the seventeen century. Gradually extended. No insulation. No ventilation system. Hydronic central heating on gas
4	Primary education (Coppens et al., 2006)	1553	5001	Built in the nineteen twenties. Part of the building retrofitted. Container class added. No to hardly any insulation. No ventilation system. Hydronic central heating on fuel
5	Primary and secondary education (part of a larger school) (Roelens et al, 2005)	7002	19070	Main building from the seventeen century. Reconstructed after world war 2. New part built in the eighties. Hardly ant insulation. No ventilation system. Hydronic central heating on gas
6	Secondary and technical education (part of a larger school) (Campforts et al, 2006)	12651	48453	School built in the nineteen eighties Roof insulated, walls not, mixture of single and double glazing. Ventilation system provided but not used. Hydronic central heating on gas
7	Primary education (Sanders et al, 2005)	2347	14496	School built between 1909 and 1911 Part of the building retrofitted. No insulation. No ventilation system. Hydronic central heating on gas renewed in 2002

BUILDING RELATED THERMAL PERFORMANCE

In Belgium, the thermal performance is expressed in terms of a level of thermal insulation:

$$\begin{array}{ll} C < 1 & K = 100U_m \\ 1 \leq C < 4 & K = 100U_m \Big/ \left(\frac{C}{3} + \frac{2}{3}\right) \\ C \geq 4 & K = 50U_m \end{array} \quad [1]$$

with U_m in W/(m².K) the thermal transmittance of the envelope and C in m the ratio between heated volume and enclosing surface, called compactness of the building. To calculate, the surfaces and layer sequence of all envelope elements plus their thicknesses have to be known. When the design documents fail, gathering those data demands time. It also introduces uncertainty, as even experienced auditors must guess the exact composition and layer thicknesses in roofs, floors and walls. As a consequence, calculated data are approximate, with an error bar of some 10%.
As table 2 shows, the seven schools audited perform poorly. To compare with, the EPB demands K45. The seven existing schools remain far above.

Table 2 Compactness, mean U-value and level of thermal insulation

School	What volume?	Compactness m	Average U-value W/(m².K)	Level of thermal insulation -
1	Whole	1.50	1.53 ±0.08	133 ±6.5
2	Part	1.58	1.98 ±0.10	167 ±8.5
3	Whole	2.33	1.24±0.06	86±4.3
4	Main building Second building 3 (container)	1.78 1.32 0.69	1.83 ±0.09 1.88 ±0.09 0.98 ±0.05	145 ±7 170 ±8.5 98 ±5
5	Old building (O) New building (N)	3.90 3.10	2.20 ±0.11 1.60 ±0.08	116 ±6 96 ±5
6	Whole	3.72	1.78 ±0.08	83 ±4
7	Whole	2.73	1.59 ±0.08	104 ±5

AIR TIGHTNESS

Per school, the air tightness of one to three classrooms was measured, using a Minneapolis blower door. The results are summarized in table 3 (V inside volume in m^3, n_{50} ventilation rate at 50 Pa, b air permeance exponent). The table reveals a large spread, from n_{50}=4 h^{-1} to n_{50}=12 h^{-1}. The real infiltration rate will be much lower, as it depends on the orientation of the exterior wall, the actual pressure difference between that wall and the corridor doors, the leakages in the separation wall with the corridor and the way the corridor acts as discharge. Hence, in none of the cases, infiltration may suffice to maintain correct ventilation during classes. The negative exponents also learn that in some classes important leaks close as the air pressure difference increases!

INDOOR ENVIRONMENTAL QUALITY DURING CLASSES

Indoor environmental quality was monitored by logging temperature, relative humidity and CO_2 in some of the schools during several class days in winter. An excerpt of the results is listed in table 4 and shown in figure 2. PD for air freshness should stay below 10%, while, as asked by the

EPD, in IDA 3 CO_2 should not pass 1350 ppm. Clearly, none of that is realized, making indoor environmental quality unacceptable.

Table 3 Air-tightness of separate classes (exterior walls only)

MEASURED AND PREDICTED ENERGY CONSUMPTION

For each school, energy consumption data were gathered by analysing the bills and measuring usage on a weekly basis. The results, transposed to the standard year of the EPB, together with the EPB-results, are listed in table 5. They show that, with the exception of school 5, the EPB overestimates energy consumption considerably. Several reasons explain that fact:

- The EPB assumes that ventilation guarantees an indoor environmental quality IDA3 during classes. To achieve that, the average on purpose ventilation flow should attain 29 m^3 per hour per pupil. In reality, during class hours, infiltration only does the job. In school 4 for example, CO_2 data gave an infiltration flow totalling 8.3 m^3/(h.pers). Happily, the hours, that on purpose ventilation is needed, are exaggerated in the EPB for schools. Not 2628, but 1332 hours is a better number. That moderates the extra energy needed for correct ventilation
- The EPB supposes that the whole school is continuously heated at 19°C. This is not the case. Corridors for example are not, while 17.5°C for the average temperature in the heated parts is a better guess.
- Internal gains are underestimated. The EPB takes 1 pupil per 4 m² of floor surface. A class of 20 should thus have a surface of 80 m². Classes are typically smaller, with surfaces closer to 55 m² for 20 to 30 pupils.

Table 5 End energy consumption, measured (reference year) versus calculated (EPU-tool)

School	Calculated according to the EPB MJ/a		Measured MJ/a		Boilers		Ratio calc./meas. Heating
	Heating ±10%	Electricity (light, auxill.)	Heating	Electricity (all)	Number	Mean $\eta_{p,flue}$

7	2950700	No data	1215600	No data	1	95.6	2.4

CONSEQUENCES FOR RETROFITTING

Judging retrofitting measures on cost effectiveness may be done by comparing the annuity on investment with the avoided annual energy cost or by evaluating the net present value over a stated period of time. The first possibility is very attractive. In fact, if the avoided energy cost passes the annuity then the measure effectively lowers the annual costs.

The problem yet is that, due to the overestimation of energy consumed, the EPB cannot be used as a basis for evaluation. One should use the measured data instead and multiply avoided energy, calculated by the EPB, with the ratio between measured and calculated energy use. Hence, when schools are retrofitted with inclusion of a correct IDA 3 ventilation system (which must be done), upgrading the insulation, increasing heating system efficiency and relighting may not compensate for the extra energy needed for ventilation. Take for example school 4. In the case being, infiltration and some adventitious ventilation increased energy demand for the main building with some 41000 MJ/a. A forced IDA3 ventilation system without heat recovery lifts that number with some 77000 to 191000 MJ/a. Compensating for that could be done by diminishing the demand with the same amount, for example by insulating the pitched roof, now with a U-value between 2.7 and 3.1 W/(m².K). Yet, even a U-value 0.2 W/(m².K) does not succeed in doing that. Following the EPB, it should as the demand may diminish with some 236000 MJ/a. In reality, decrease will be restricted to some 67000 MJ/a. Even less is possible, as part of that avoided demand is lost by an increase in inside temperature.

Or, the need for a better inside environmental quality, which means more ventilation, and the rebound observed in heating habits to compensate for bad thermal quality of the buildings, makes it extremely hard to realize economy when retrofitting schools with an eye on diminishing energy consumption and CO_2-emissions.

CONCLUSIONS

School buildings in Flanders are quite old, while investment in retrofit and new construction lagged behind. Energy audits in seven schools revealed that on the average the thermal quality of the older and even newer buildings is bad. Also, six out of the seven had no ventilation system and, in the one who had it, it was not in use anymore. Hence, ventilation is mainly infiltration linked, with some adventitious airing by opening a window between class hours. The consequence is bad indoor air quality, a fact which was already stated in previous studies and got confirmation by measurements in four of the schools.

Any school management tries to neutralize deficient thermal quality by persistent rebound behaviour. As a consequence, energy consumption, calculated with the official EPB-tool, typically overestimates energy use. That, and the requirement to guarantee an IDA 3 indoor environment during classes, jeopardizes most attempts to ameliorate energy efficiency during retrofit in an economic affordable way.

Ventilation of Dutch schools; an integral approach to improve design

Wim Zeiler and Gert Boxem

University of Technology Eindhoven (TU/e), The Netherlands

Corresponding email; w.zeiler@bwk.tue.nl

SUMMARY

Indoor Air Quality and thermal climate in schools is very important as it has a direct relation to the health and performance of the pupils. The status quo in the Netherlands is presented (e.g. average CO_2 levels in schools, quality of ventilation). The goal of a first study was to evaluate the performance of exhaust-only ventilation systems. The performance was rather disappointed there were a lot of problems and insufficient situations found. During the next years different master students [1,2,3,4] together with the staff of Technische Universiteit Eindhoven were researching different aspects of the problem and trying to find solutions. In a following study, 6 schools with different ventilation systems were studied. Main conclusions from these studies were: IAQ in the evaluated schools did not meet the requirements and more ventilation was essential for better IAQ. A new integrated approach to design adequate solutions for ventilation of school buildings was developed. First design results are described in the paper.

INTRODUCTION

Indoor air quality has caught attention of the Netherlands Ministry of Housing, Spatial Planning and the Environment and a large campaign was started in 2005 to make the public aware of the dangers to health as result of poor ventilation in housing. Indoor pollutant levels are often greater than the outdoors, and since Dutch people spend nearly 90% time indoors, good indoor air quality is very important. Indoor Air Quality (IAQ) at schools is of special concern since children are extremely sensitive to results of poor air quality. IAQ in schools must reach the basic requirements and should be considered as a high priority because (Landrigan 1997): (1) Children more sensitive as they still developing physically and more likely to suffer from indoor pollutants, these growth processes are delicate and vulnerable to disruption, (2) Children are less well able than adults to metabolise and excrete most environmental toxins, (3) Children are relatively more heavily exposed to environmental toxins as they breathe higher volumes of air relative to their body weights. Good air quality in classrooms supports children’s learning ability. Poor IAQ in schools influences the performance and attendance of students, primarily through health effects from indoor pollutants (Mendell and Heath, 2005).

VENTILATION STANDARDS

There are numerous standards and guidelines covering indoor air quality (IAQ), recommended by international health associations, industry organizations and governments. Ventilation standards state either outdoor air supply requirements (volume per time per person), or outdoor air change-rate (h^{-1}), or both. Dutch schools have to meet the Dutch Building Code (Bouwbesluit), which requires a classroom ventilation rate of 2.8 $l/s{\cdot}m^2$ at an occupancy rate with 1.3 to 3.3 m^2 floor area per person. For a standard classroom of 50 m^2 and a maximum occupation of 32 students, this results in a ventilation rate of 4.2 l/s per person. Dutch Building Code refers also to guideline NEN 1089, which requires a ventilation rate of 5.5 l/s per person based on a level of 1000 ppm CO_2-concentration with a maximum of 1200 ppm. So depending on the situation the highest ventilation rate should be used.

The European legislature (CR1752) uses Fanger's model for dissatisfaction and specifies 3 categories of % occupants satisfied with perceived indoor air quality: high quality (at least 85%), medium quality (at least 80%), and moderate quality (at least 70%).

The guidelines for ventilation in North America, provided by ASHRAE (American Society of Heating, Refrigerating and Air-conditioning Engineers), Standard 62-1999, recommends a minimum ventilation rate of 8 l/s-person for classrooms. They pose an acceptable indoor air quality when the air is free of pollution in damaging concentrations and when a majority of satisfaction (80% or more) is found. Indoor air quality here is a combination of air contaminants and the response of occupants exposed to indoor air.

Carbon dioxide concentrations are often used as a substitute of the rate of outside supply air per occupant (Seppänen et.al 1999). IAQ in schools is primarily evaluated by CO_2-concentrations. ASHRAE Standard 62-1999 recommends an indoor CO_2-concentration of less than 700 ppm above the outdoor concentration (~1200 ppm) to satisfy comfort criteria with respect to human bio effluents. The Dutch standard NEN 1089 asks for a maximum CO_2-concentration of 1200 ppm in classrooms (van Dijken, 2004).

Literature on relationships (Shendell et.al 2004) between indoor air and environmental quality (IEQ) in class rooms and students health and academic performance has been reviewed by Heath and Mendell (2005) and Daisey et.al (2003). Relatively not many field studies were conducted on the performance of ventilation systems in schools. For European schools some results are shown in figure 2 (Daisey et.al 2003).

Smedje,1997	96	990	425-2800

Figure 2. Average and range of CO_2-concentrations reported in the scientific literature for European schools (Daisey et.al. 2003)

In the Netherlands different investigations on indoor air quality were conducted and CO_2 levels measured. In 1987 the Agriculture University of Wageningen conducted research to indoor air quality. Measurements of CO_2 concentrations were done and in 8 out of 12 schools, CO_2 levels rose above the marginal value of 1200 ppm in more than 50% during school hours. (Sandt et al, 1987). In 1992 the local health department (GGD) in West-Brabant researched indoor air quality in secondary education buildings. Measurements of CO_2 levels were done and levels up to 4800 ppm were detected. (Leentvaart et al, 1992). In 1993 in Groningen different primary schools were inspected. In 3 out of 4 classrooms, CO_2 levels reached the marginal value of 1200 ppm. Maximums of 2400 ppm were detected (Meijer, 1993). In 1997 IAQ measurements were done at 4 primary schools in the region of East Noord-Brabant. Peak levels of 3500 ppm were detected. (Boske, 1997). Municipality Groningen did measurements in 16 classrooms and they found median levels of 919 to 1940 ppm (Wassing, 2003).

EXPERIMENTS

The goal of a first study was to evaluate the performance of exhaust-only ventilation systems. In 5 Dutch schools measurements were conducted in the heating season for a period of around 7 days. These measurements included: IAQ (CO_2), thermal comfort, airflow and outdoor conditions. A logbook and questionnaires obtained information about use of ventilation facilities and satisfaction of users. Results of the measurements showed that in 4 out of 5 evaluated classrooms the indoor air quality did not meet the requirements for good indoor air quality. CO_2-concentrations are too high indicating that ventilation is not adequate. Therefore, a first conclusion was that natural air supply in classrooms without any draught prevention is an unacceptable solution. Parallel to the research another study was done by Froukje van Dijken, she studied IAQ of 11 schools. Both results were used by the REHVA Taskforce 4 "Indoor Climate and Energy of School Buildings" in their primarily report.

In a following study, 6 schools with different ventilation systems were studied, to search for concepts, which had fewer problems. Main conclusions from this study were also: IAQ in the evaluated schools does not meet the requirements and more ventilation is essential for better IAQ. The capacity of ventilation systems has to be increased. However air supply by natural ventilation is limited to vents in the façade. In well insulated buildings the required heat supply is not sufficient to prevent draught due to the supply of cold outdoor air. Therefore, a more distributed way of supplying air is needed in these systems.

METHODOLOGY

The results of the measurements indicated that, based on the current ventilation standards, many classrooms are not adequately ventilated. As an object for further research is an improvement of the design process. (Mendell and Heath, 2005). A first line of defense against poor IAQ in classrooms is adequate ventilation and this should be a major focus of design efforts (Daisey et.al 2003).

The current design process for schools normally begins with selection of an architect. It then proceeds with programming and schematic design. Next the design engineer comes in and finally the BS (Building Services)-engineer completes the design team. But already many decisions were made in the early conceptual design that influences the development, contract documents, construction, commissioning and occupancy. Clear goals were not part of the often general programming and the design brief. The sooner goals, to ensure IAQ are brought into the design process, the easier and less costly they are to incorporate.

Integrated design promises major advantages. It draws from all disciplines involved in designing a building and reviews their recommendations as a whole from the early start of a project. Project team collaboration and integration of design choices should begin at the programming phase. Indoor air quality encompasses such factors as maintenance of acceptable temperature and relative humidity, control of airborne contaminants, and distribution of adequate ventilation air. It requires deliberate care and cooperation on the part of the entire project team. BS-engineers must design ventilation systems that dilute the by-products of occupant activities and, to the greatest extent possible, supply fresh air on demand in the right quantities, in the right locations.

Up to now the building design process is more or less sequential; first the building is designed and subsequently the heating/ cooling/ ventilating system. Communication between architect and building services consultants is based on abstraction, i.e., the exchange of abstract descriptions of a design. During design support, it's important to transfer the essentials of the applied structures and mechanisms without overloading the other party with unwanted details.

Design has normally a very dynamic nature, with a tendency to ad hoc actions, which should be supported by design aid systems. To develop the required model of design support an existing model has been extended: Methodical Design (van den Kroonenberg 1978). The methodical design process can be described on the conceptual level as a chain of activities which starts with an abstract problem and which results in a solution.

In order to survey solutions, engineers classify solutions based on various features. This classification provides means for decomposing complex design tasks into manageable size problems. An important decomposition is based on building component functions. The functional decomposition is carried out hierarchically so that the structure is partitioned into sets of functional subsystems. The decompositions are carried out till arrived at simple building functional components whose design is a relatively easy task, see figure 4.

The decomposed functions were put into an array. Left column were the functions listed, which were combined with a row of solutions for each function, see figure 5. The matrix of functions and their solutions are called a Morphological chart and were developed by Zwicky(Zwicky, 1969). Each combination of possible solutions for the functions was combined to overall solution for the design task. Selecting the most likely solution could be done with help of the Kesselring-diagram Kroonenberg, 1978). All the solutions were marked based on the criteria of the design brief. The design criteria were divided into criteria concerning functioning and realization. The relative score was presented in de S-diagram, see figure 6. By using Morphological charts communication between design team members becomes easier and there was a clear overview of all the possibilities discussed. The Kesselring method (Kesselring, 1954) made the decision process clear and understandable for the design team and all so for all people outside the team. The proposed method is used to design a ventilation system for a typical classroom. The solution that resulted is a balanced displacement ventilation system with heat recovery, as shown in figure 7.

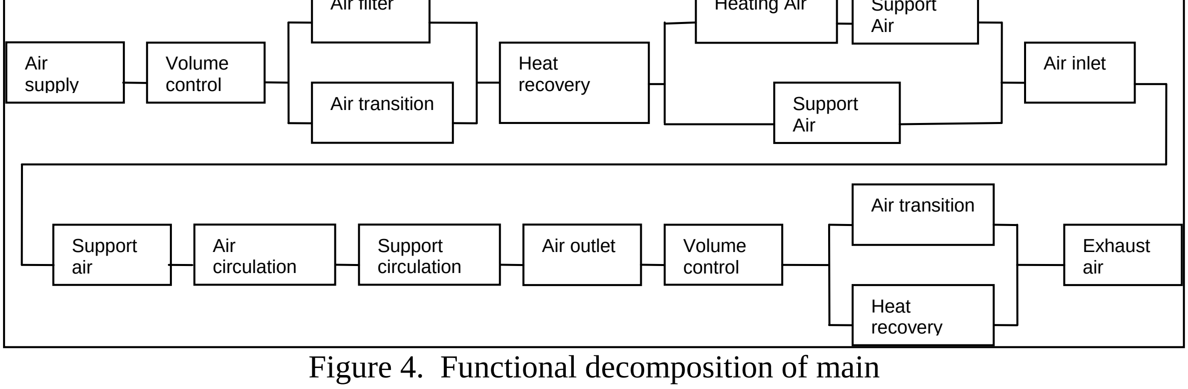

Figure 4. Functional decomposition of main

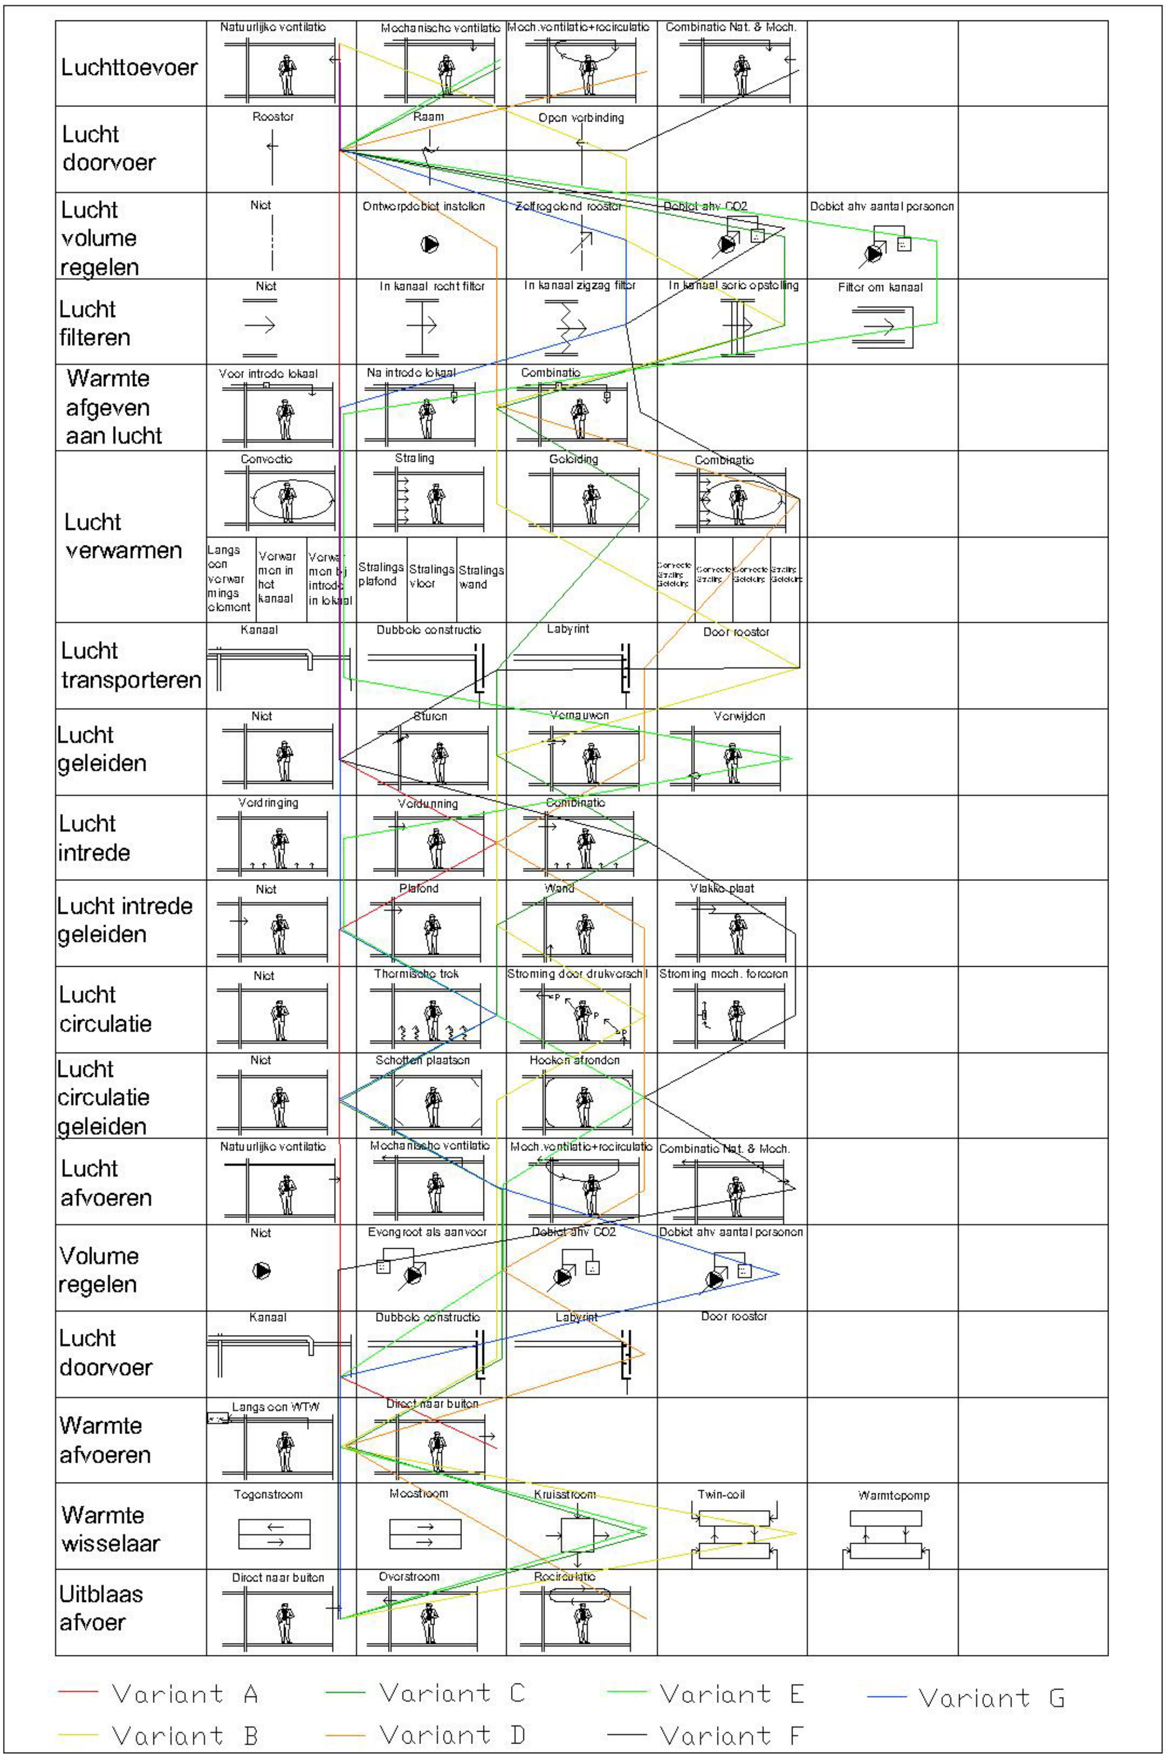

Figure 5. Morphological chart, 18 subfunctions with different solutions.

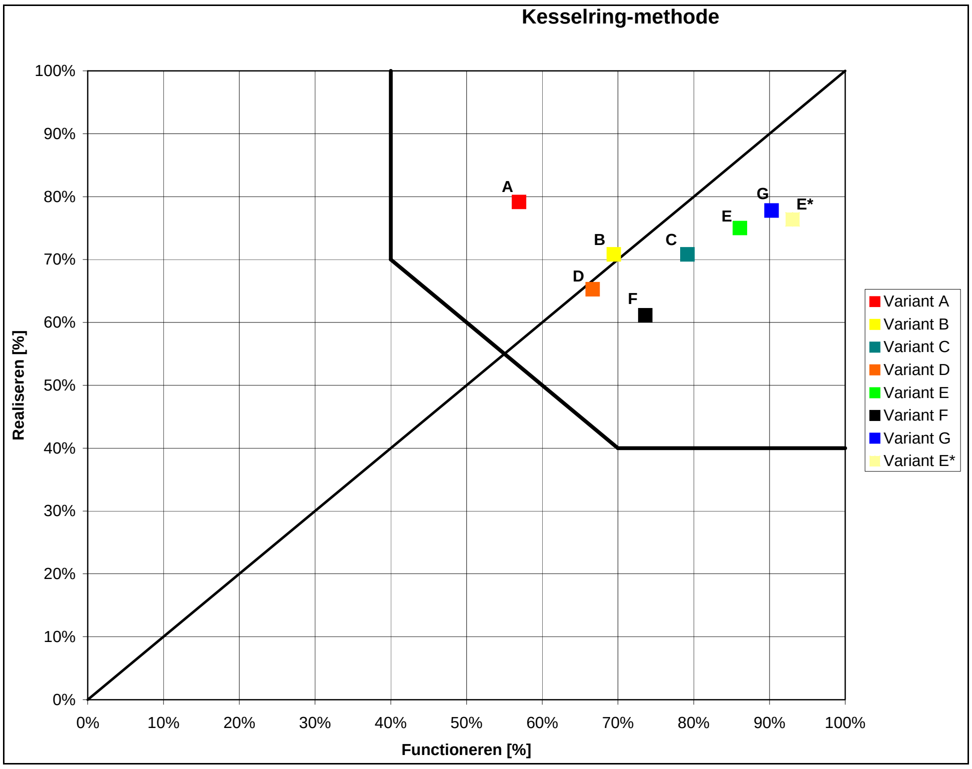

Figure 6. S-diagram Kesselring method

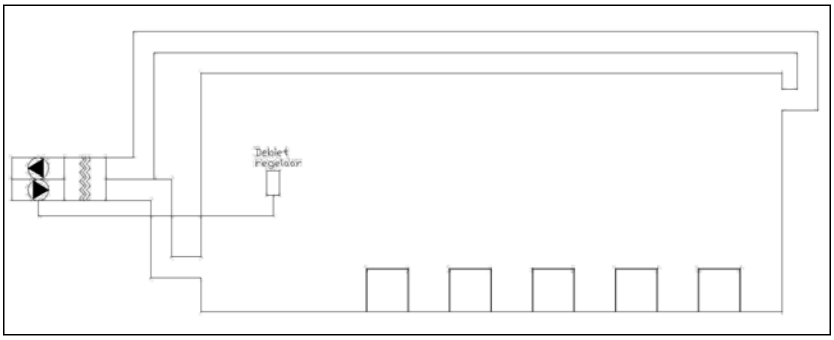

Figure 7. Schematic of displacement classroom ventilation

Instead of normal metal ductwork, textile air ducts are proposed; these can be removed easily and washed in a washing machine.

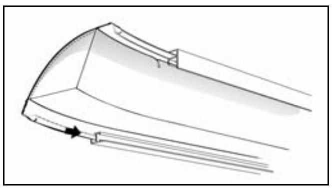

Figure 8. Textile air duct (Euro-Air, 2005)

Normally the flow pattern of heated air is problematic when displacement ventilation is used. In classrooms this is only the situation during start-up, as the pupils generate more than enough heat themselves once they are in the classroom. During the start-up the air distribution is like shown in figure 9. The walls and windows are primarily heated up and there is no good air distribution. But as there are still no pupils this is not a problem. When the room is used there is too much heat and the air through the displacement ventilation system has to be brought in with a slight under temperature. The expected flow pattern will become as shown in figure 9. By putting the textile air ducts nearly all around the floor of the classroom, a good distribution with a low air speed will be generated. In follow-up research, the solution will be simulated and a laboratory test will be done to verify the design.

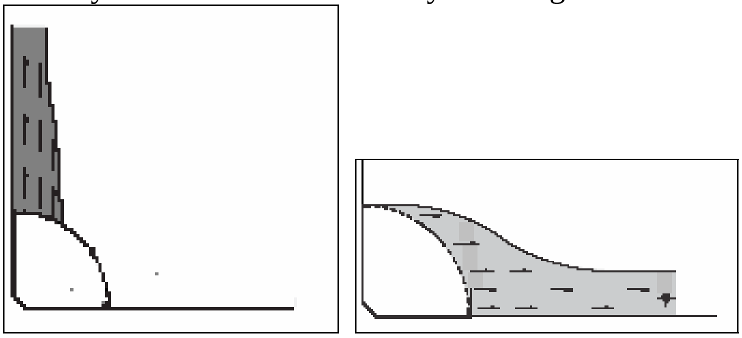

Figure 9. Flow pattern during start-up situation and during normal use

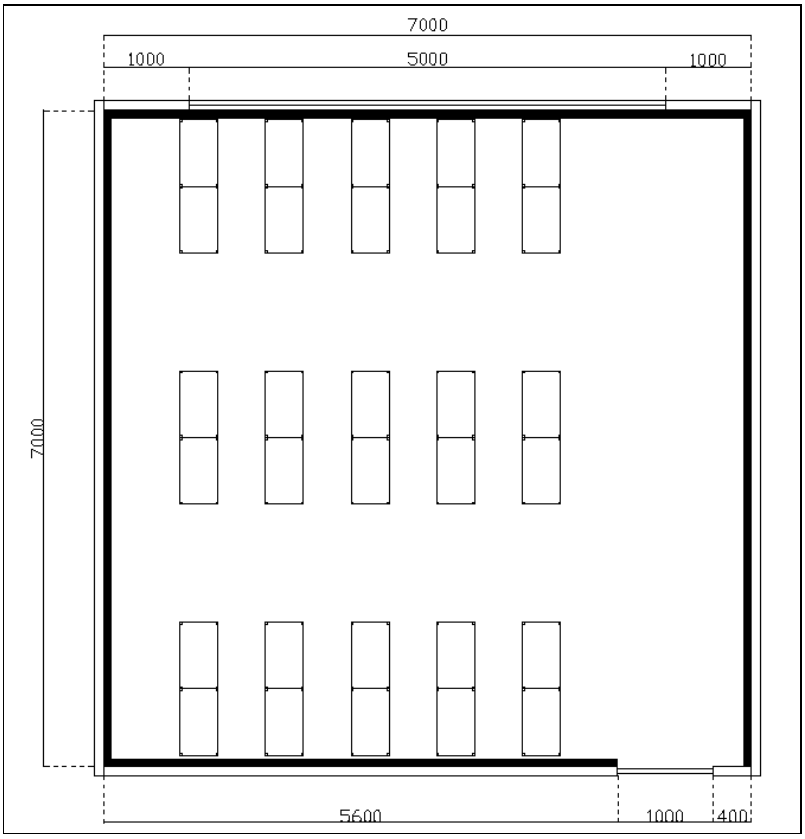

Figure 10. Lay-out displacement air-duct

Many ongoing research efforts aim at introducing the used methodical design process into building design and architecture, and so linking architectural design with HVAC-design. In the Netherlands this has resulted in a stark interest in what is commonly named 'integral design'.

Integral design is meant to overcome the difficulties of design team cooperation, by providing methods that make it possible to communicate the consequences of design moves on areas such as construction, costs, life cycle and indoor climate at early design stages, between the different disciplines.

SUMMARY

This study deals with Particle Matter (PM) levels below 2.5 µm ($PM_{2.5}$) in Portugal and shows that US EPA (United States Environmental Protection Agency) directive is exceeded in a few places. $PM_{2.5}$ total mass concentration measured in several places located in Portugal mainland and islands and the outskirts are quite well correlated for a few sites. Results show that it is important to determine the elemental composition of $PM_{2.5}$, and to develop an epidemiological study in Portugal to find a possible association between $PM_{2.5}$ levels, sources and morbidity/mortality. However, the results imply that a source-oriented evaluation of PM health effects needs to take into account the uncertainty associated with the spatial representativity of the species measured at a few sampling stations. For that purpose the survey using biomonitors may contribute positively.

INTRODUCTION

Several reports revealed significant correlations between PM levels and increased respiratory and cardiovascular diseases, and mortality [1]. Understanding and controlling air pollution becomes then important but difficult, because the emission inventories and transport models are problematic in the evaluation of particulate atmospheric pollution.

In South European regions, such as Portugal, in addition to anthropogenic sources, the ambient aerosol has an important contribution from natural dust, due to local emissions from bare soil, and an influence of episodic African dust transport outbreaks [2]. Moreover, the Portuguese coastal areas have an important input of marine aerosol [3]. This is due to the geographic position of Portugal (on the extreme southwest of Europe) and the dominant western wind regime, influenced by the presence of the semi-permanent Azores high-pressure and the Icelandic low-pressure systems over the North Atlantic Ocean. These air currents bring anthropogenic influences from the three continents: America, Africa and Europe, having a large influence in the measured fine particles.

The present study uses the measurements of particulate air of aerodynamic diameter below 2.5 µm ($PM_{2.5}$) through the country, measured by the Portuguese Environment Institute (IA). The aim is to get a good knowledge of the $PM_{2.5}$ levels and their provenance, to help in interpreting the $PM_{2.5}$ values and their contents obtained by ITN at one site of Lisbon, under a project aiming to study the impact of the atmospheric aerosol in human health (POCI/AMB/55878/2004, financed by the Portuguese Foundation for Science and Technology[4,5].

METHODS

Air pollution data were obtained from the Portuguese Environment Institute (IA) Air Quality Monitoring Network. The latter consists on several stations distributed in Portugal providing hourly data of the main atmospheric pollutants such particulate matter, SO_2, NO, NO_2, CO, and O_3. In this work, data of particulate matter of aerodynamic diameter below 2.5 µm, designated by $PM_{2.5}$, registered every hour and averaged for 24 h, were selected for discussion.

Figure 1 presents the location of the sites where the data were registered: 1) Madeira archipelago: one site in Porto Santo island and three sites in Madeira island (Qta Magnólia, S. Gonçalo, S. João); 2) Portugal mainland – a) two sites in Faro (Afonso III and Joaquim Magalhães), two sites in Lisbon (Entrecampos and Olivais); b) one site in Alcoutim (Cerro), Santiago do Cacém (Monte Velho), Alandroal (Terena), Chamusca, Leiria (Ervedeira), Fundão (Salgueiro), Estarreja (Salgueiro), Viana do Castelo (Sra do Minho), Vila Real (Lamas de Olo), and Vermoim. They cover quite well the whole country and the archipelagoes, with exception of Azores archipelago.

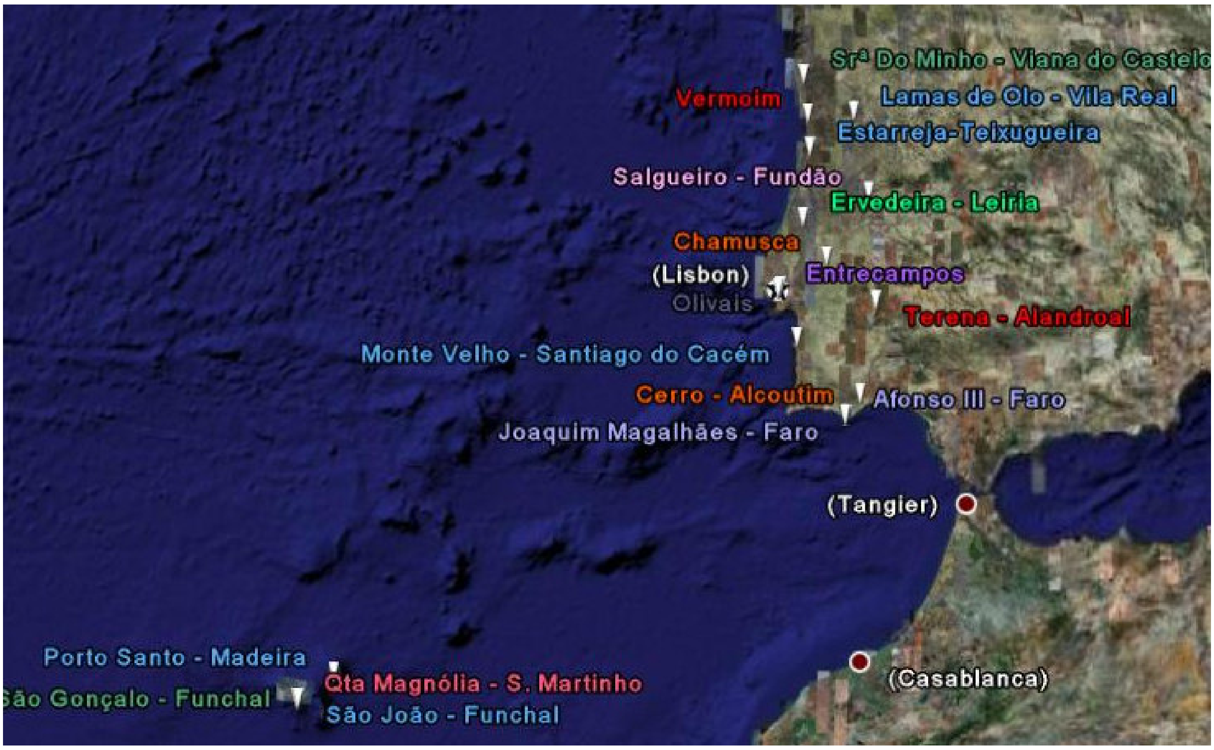

Figure 1. Sites where PM2.5 is being collected by the Portuguese Environment Institute network.

RESULTS

Table 1 presents, for the sites displayed in Fig. 1, the number of days with availability of $PM_{2.5}$ registrations, and some simple statistical data on the sets: mean, median, maximum, and minimum.

A few sites – Porto Santo, S. Gonçalo, Santiago do Cacém, Alandroal, Viana do Castelo, and Vila Real – have less than 75% of the expected annual results, and therefore should be restrictively interpreted. In the calculation of the mean and median, missing data were not filled up and were not considered as zero.

Table 1. Statistical data of $PM_{2.5}$ results.

$\mu g\ m^{-3}$	Porto Santo	Qta Magnólia Funchal	S. Gonçalo Funchal	S. João Funchal	Afonso III	Joaquim Magalhães

	Ervedeira	Salgueiro	Texugueira	Sra do Minho	Lamas de Olo	Vermoim
$\mu g\ m^{-3}$	Leiria	Fundão	Estarreja	Viana do Castelo	Vila Real	
Nr. days	360	360	365	150	251	352
Mean	33.79	9.90	26.32	14.52	13.91	27.33
Median	29.17	7.92	22.71	10.73	9.96	20.31
Maximum	323.79	61.13	129.33	133.17	97.21	121.83
Minimum	5.96	1.13	3.17	3.21	3.92	0.04

Mean and median values are very similar indicating normal distribution of the data. As of today the EU (European Union) has not put forward any $PM_{2.5}$ limit values, and taking this value as a reference one, the $PM_{2.5}$ annual average mass concentrations at S. João (Madeira), Entrecampos (Lisbon), Leiria, Estarreja, and Vermoim exceed it. As a result of a preliminary study carried out in the metropolitan area of Lisbon it was concluded that the EU directive is exceeded in a systematic way in the centre of Lisbon due to the traffic inside the city [6]. Maximum values are a few times too high to be believed, as it is the case for Chamusca, Leiria and Viana do Castelo. Figs. 2 and 3 represent the mean and maximum values of the sites, for a better visualization.

Pearson correlations were established between the sites and the results are shown in Table 2. The latter only shows the correlations for which the correlation coefficients are higher than 0.5. There are five correlations with correlation coefficients higher than 0.7, and they are displayed in bold.

The two sites of Faro are very well correlated, indicating the same emission source. The Faro's source is also influencing Alcoutim, situated at close distance at Faro's northeastern direction (see also Fig. 4). The source is most probably the international airport.

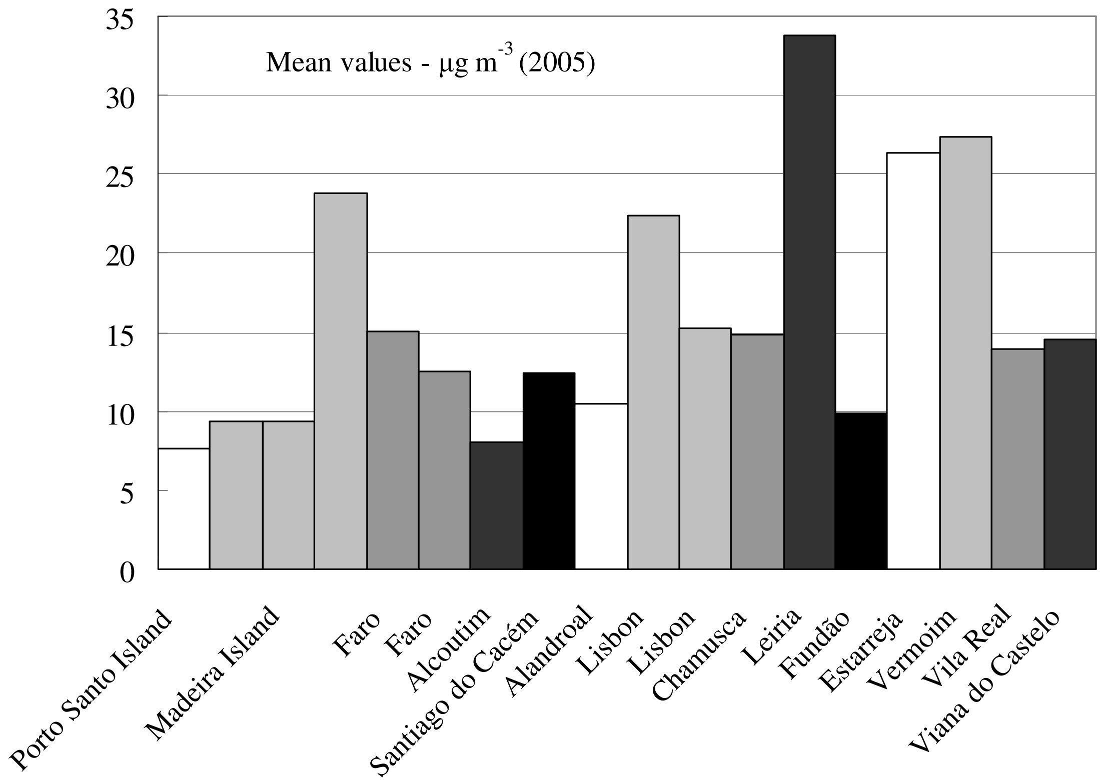

Figure 2. Mean values of PM2.5 registered at the sites monitored by the Portuguese Environmental Institute.

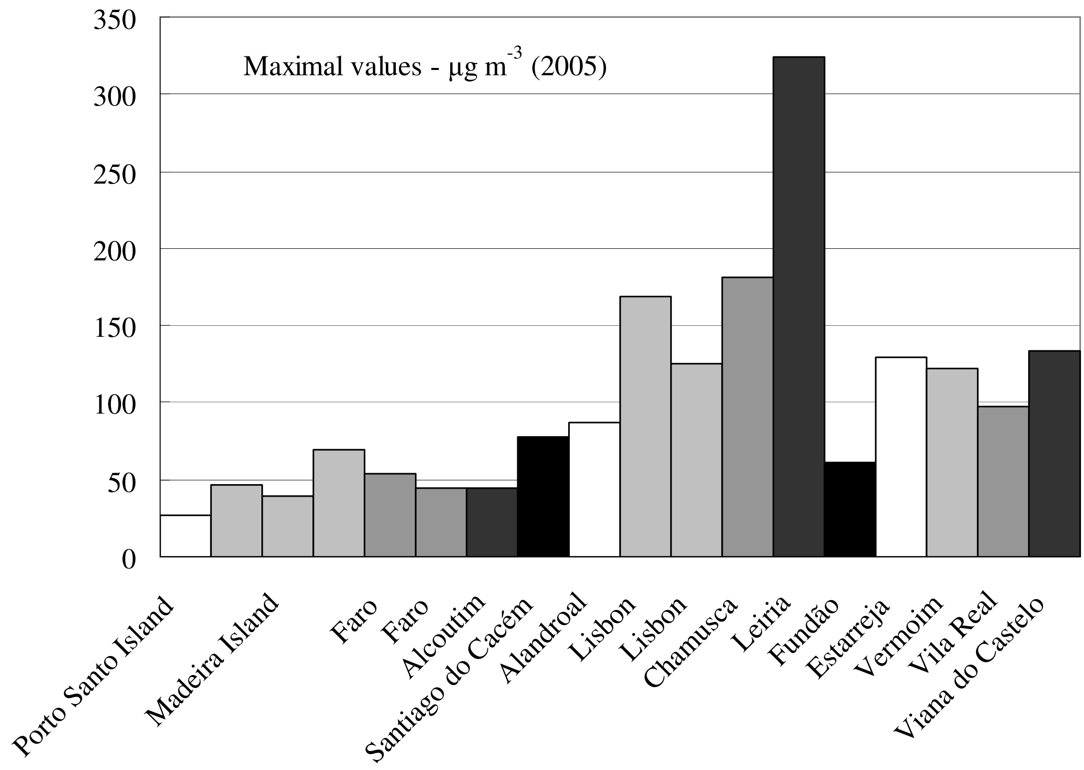

Figure 3. Maximum values of PM2.5 registered at the sites monitored by the Portuguese Environmental Institute.

Table 2. Correlation coefficients between pairs of sites. It is shown the cases with correlation coefficients larger than 0.50 only. Coefficients larger than 0.70 are in bold.

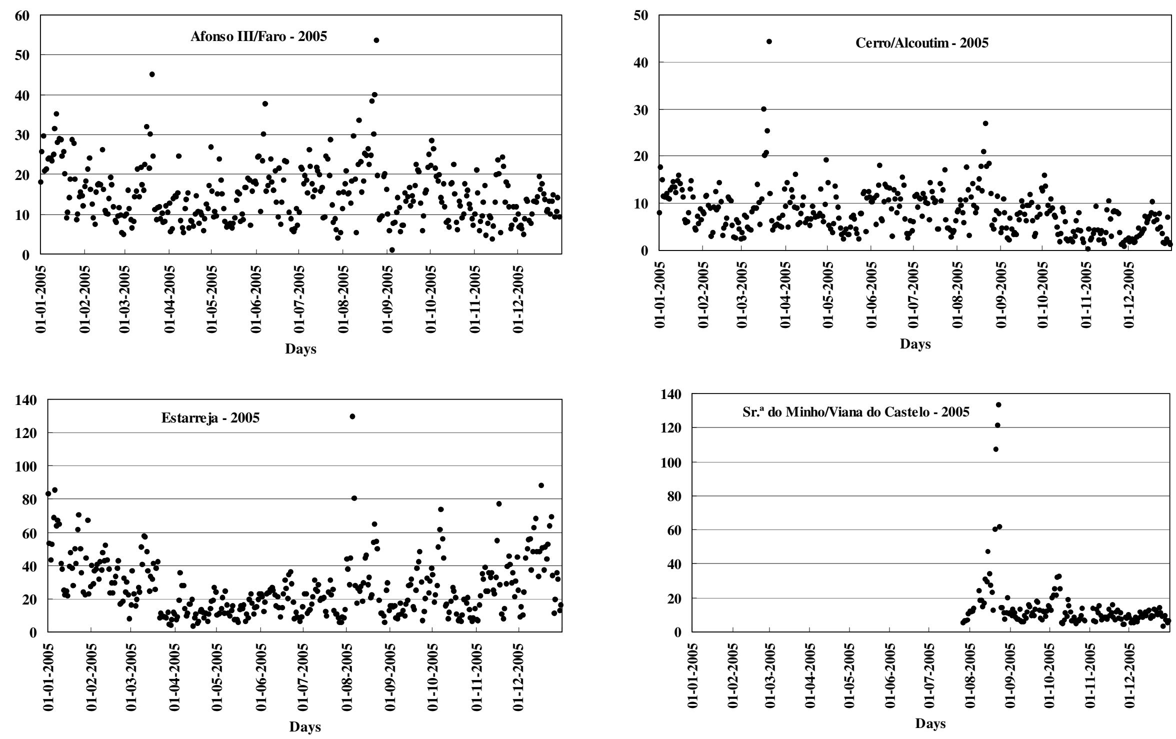

Figure 4. PM2.5 concentrations in μg m^{-3} for highly correlated sites.

Other high correlation concerns Viana do Castelo and Estarreja, the first with paper industry and the second with chemical industry, however Viana do Castelo has just half of the year registered (see also Fig. 4).

Vermoim, Chamusca and Santiago do Cacém, the three sites from north to south over the same direction line, are well correlated, appearing to indicate remote anthropogenic sources (see Fig. 5), originated from the predominant northern winds.

The two sites of Lisbon also correlate well as it has already being mentioned in [6].

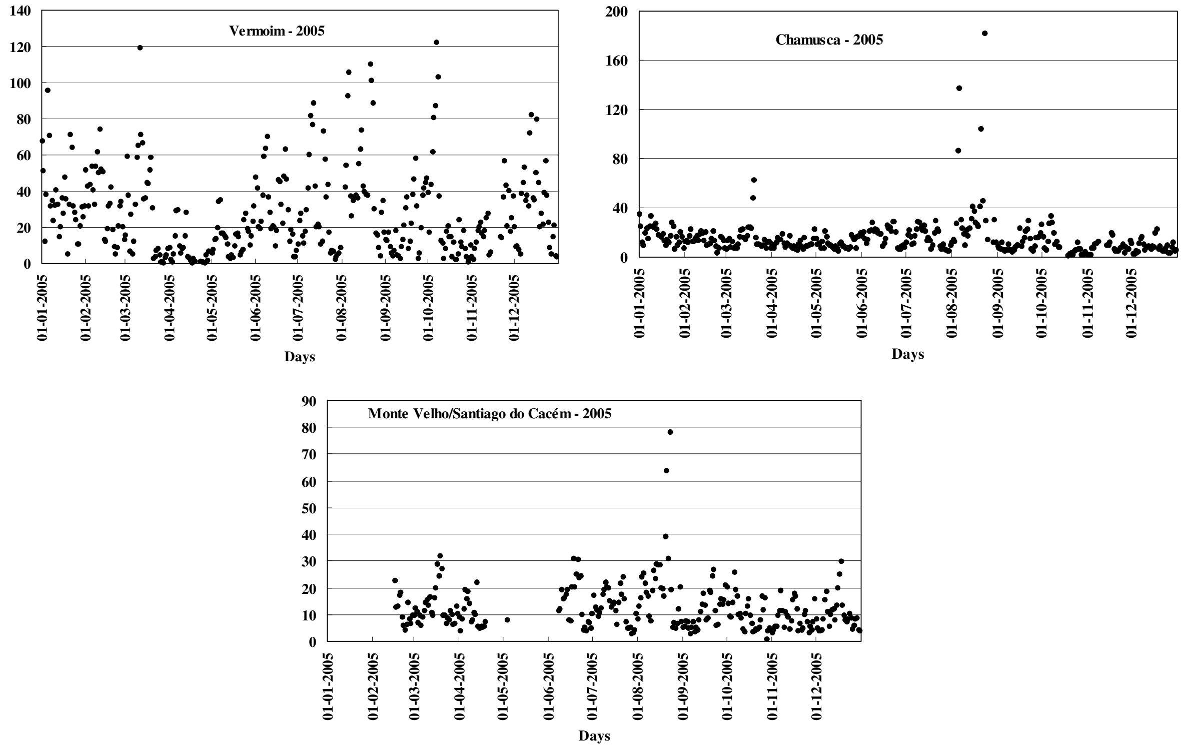

Figure 5. PM2.5 concentrations in μg m^{-3} for highly correlated sites.

At each site, the average per hour was calculated. Three main patterns were found: 1) two peaks of high concentrations, one around 9 h and other during the night (between 22 h and 24 h); 2) one peak during the night (21 h – 8 h); 3) constant emission without visible peaks. Situation 1) occurred for the cities localized sources as Faro and Lisbon, being concluded that it may be related to differentiation in intensity of traffic, either airplanes or cars; situation 3) occurred for the islands and Viana do Castelo, which may be related to sites more influenced by long-distance air mass transportation; situation 2) may be due to local industry . An example of each is shown in Fig. 6.

DISCUSSION

PM2.5 concentrations in Portugal are preoccupant; their values exceed very often the existing US EPA regulated values. There is not yet an EU and Portuguese legislation, however in a near future such regulations are expected. There is need to investigate from where these high values originate, this is, the emission sources. Some, out of the Portuguese borders, are helpless concerning the suggestion of reduction of emissions; others, emitted by Portuguese sources, may be reduced if the composition of PM2.5 is known to identify the sources. It is then suggested that the Portuguese Environmental Institute analyses or requests for analysis their PM2.5 filters, in order to get their composition, on basis of which anthropogenic sources may be recognized.

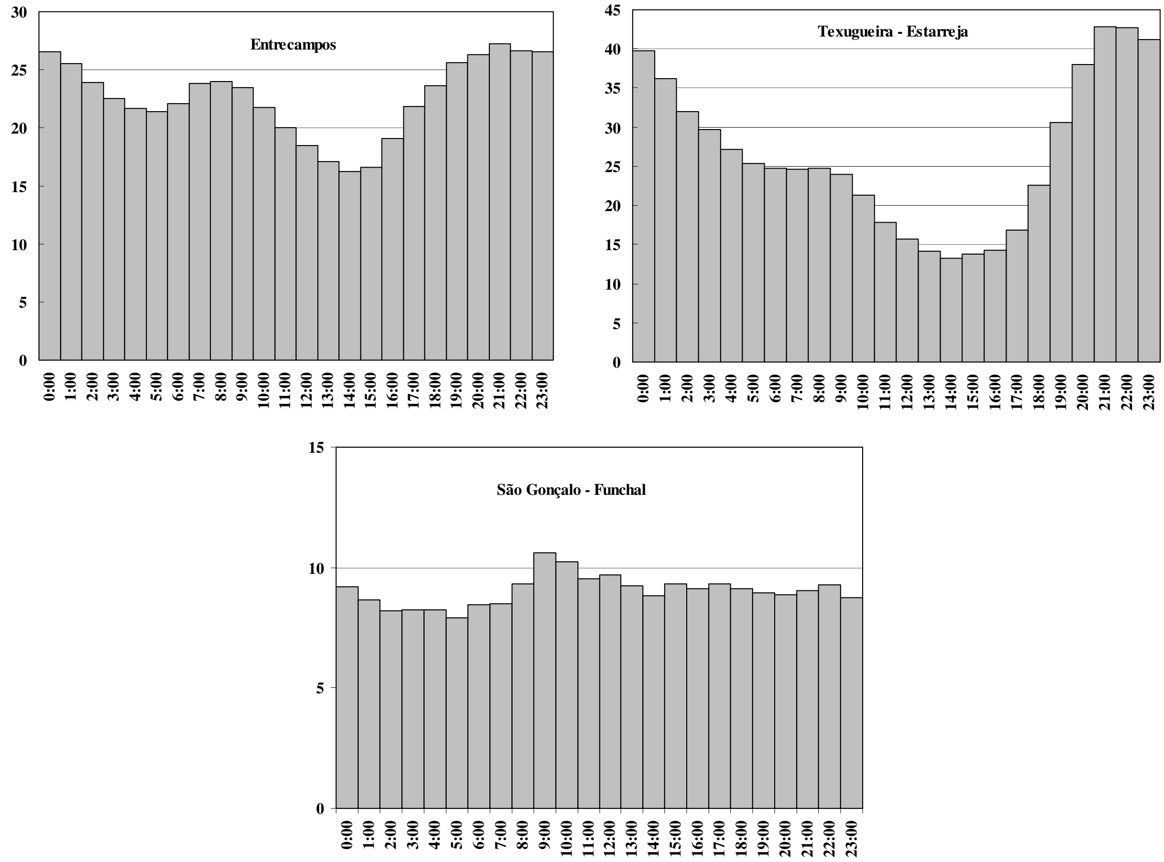

Figure 6. $PM_{2.5}$ concentrations in $\mu g\ m^{-3}$ for the hour average during 2005.

This study will be shortly followed by the recognition of the air mass trajectories which led to the high episodes observed, in order to understand the origin of such high masses.

In a recent crossing between lichen survey data held in 1993 in Portugal [7] with mortality data [8], nickel showed a statistically significant association with mortality from cancer in a simple linear regression without accounting for confounders. Bromine, iodine, lead, sulphur, antimony, and vanadium, were also associated with cancer mortality in this study.

I recent study [9], composition of PM2.5 was investigated in order to identify the main sources affecting an industrial/urban area with a special geographical position— 20km northeast of the southwest European coast, 10 km north of Lisbon, Portugal. Source apportionment results show that the major PM2.5 aerosol mass contributors include secondary aerosol (25%) and vehicle exhaust (22%). Anthropogenic sources affect mainly the fine fraction.

Measurement of PM2.5 is a better methodology to access the impact of anthropogenic activities on air quality. PM2.5 still contains important contributions from sea spray and dust natural emissions (of the order of 25%) but its main source contributions are from anthropogenic activities associated with thermal energy production and road traffic.

Similar speciation studies should be done in the samples of PM2.5 dealt with in this work.

SUMMARY

In this work the evaluation of the indoor thermal environment in a classroom equipped with air forced system will be made. In the classrooms' indoor thermal environment, with the air forced inlet in the door and the outlet located above the windows, two situations are analyzed: the inlet forced airflow made in the doors' lower and upper area.
This experimental study, made in a school building located in the South of Portugal, in Mediterranean climate, evaluates the thermal comfort (using the PMV index), local thermal discomfort (using the draught risk and uncomfortable air velocity fluctuations) and air quality levels (using the air renovation rate) that occupants are subjected.
In the thermal comfort level the air temperature, velocity and relative humidity and the radiative temperature, in the local thermal discomfort the air temperature and velocity fluctuations in different classroom interior points, while in the air quality level, using the decay tracer gases concentration, the carbon dioxide carbon concentration, are measured.

INTRODUCTION

The present philosophy of ventilation in the school building classrooms in the Algarve Region, in the South of Portugal, is the natural and/or crossed. The general idea is associated to the air inlet above the windows area, from the external environment, and the outlet above the door area, to the corridor, nevertheless, depending on the wind direction the airflow can also inlet above the door area, from the corridor, and the outlet above the windows area, to the external environment. In the absence of wind the occupants in the classroom frequently use the door and the windows open to increase the air quality level.
In order to obtain good thermal and air quality in indoor environments, used as educational spaces for young people, the inlet and outlet of clean air with acceptable temperature levels, through strategically placed points are necessary. The clean air when entering spaces should proportionate a pleasant micro-climate around the occupants, assure good air quality in the breathing area and extract the contaminants released by the occupants. Nevertheless, this ventilation system can proportionate local thermal discomforts.
In order to evaluate the thermal comfort level, in moderate environments equipped with air-conditioning systems, the PMV (Predicted Mean Vote) and the PPD (Predicted Percentage of Dissatisfied) indexes, developed in [1] are used. The PMV index is given as a value on the seven-point comfort scale and is based in four environmental parameters (air mean temperature, velocity and relative humidity and radiant mean temperature) and two personal factors (clothing and metabolic activity level). In accord to the main stream of the PMV and PPD indexes, the thermal neutrality of an individual is obtained when the body heat loss is equal to the body metabolic heat (PMV=0).

The extension of the PMV model was developed in [2] to be used in non-air-conditioned buildings in warm climates. This extension, used in warm environments, combines the “static” PMV model and the adaptive model. The idea is to use the traditional PMV model, that considers the human body thermal balance, and the expectations verified in the adaptive model. The extension of the PMV model, to be used in people non-subjected to air-conditioned environment, is based in an expectancy factor that will be multiplied by the “static” PMV value (mean thermal sensation vote). The idea is that people in non-air-conditioning environments in warm climates perceived the environment in a less severe way than the “static” PMV people.
Local thermal discomfort sensations in localized regions of the body may occur by incident airflows from ventilators, due to their intrinsic characteristics such as exit air velocity, airflow symmetry and their location in relation to the occupants. In accord to [3] the local thermal discomfort depends on the local air temperature, velocity and turbulence intensity.
According to [4] the local discomfort sensations, associated to the air velocity frequency fluctuations, are verified in frequencies between 0.3 and 0.5 Hz and according to [5] and [6], are verified to equivalent frequencies between 0.2 and 0.6 Hz.
The airflow rate inside an occupied compartment can be calculated using different recommendations and methodologies presented in national and international standards (also see [7]). Actually, for example, the ANSI/ASHRAE Standard [8] and the Portuguese standard [9] presented some airflow rates recommended values per person, while in [10] are presented some airflow rates based in the occupants comfort levels. In the last normalization is also necessary to consider the pollution load caused by the building itself (including furnishing, carpets and ventilation systems).
The ventilation topology used in the last works (see [11]), that will be used in the school buildings in this region, considers the air entering through the doors (in the first floor), passing through the corridors and atria (in the first and second floors), entering through the doors grids and leaving through the windows extraction fans to the external environment. In this ventilation philosophy the extraction fans in spaces with a long occupation period (classrooms, offices, library, auditorium, students’ and teachers’ rooms) are installed and in spaces with a short occupation period (corridors and atria), where the air is passing to the firsts spaces, will not be installed.
In the present study, using experimental means in real classrooms, in Summer conditions, some experimental tests using extractors, located in the door as well in the windows upper area, in order to increase the air quality level, reduce the local discomfort and increase the thermal comfort levels, will be made. In the present work some experimental results obtained in a classroom, equipped with extractors located in the lower and upper door area, will be presented. The idea is to guarantee a continuum airflow from the corridor to the classroom and after to the external environment, to make easier the indoors pollutants dispersal of the school building, instead of the present systems depending on the wind.

EXPERIMENTAL SETUP

The experimental tests were made in a real classroom with a floor area of 10.8×4.8 m^2 and with a height of 3.5 m (see figure 1). This classroom, inside a school building located in the South of Portugal, had three windows equipped with above dump trucks and one door equipped with air extractors placed in the door’s lower and upper area. The airflow comes into the corridor area, enters in the classroom through the extractors, upper or lower, and comes out to the external environment through the dump trucks located above the window

(also see figure 1). In each one of the experimental tests are calculated, sequentially and respectively, the global thermal comfort, local thermal discomfort and air quality levels.
In these experimental tests, being the objective to evaluate the indoor thermal environment in a classroom equipped with an air forced system, two situations are analyzed: the inlet forced airflow is made in the doors' lower area, while the second one is made in the doors' upper area. This experimental study evaluates the thermal comfort (using the PMV index), local thermal discomfort (using the draught risk and uncomfortable air velocity fluctuations) and air quality levels (using the air renovation rate) that occupants are subjected.
The air velocity and temperature fields are experimentally measured, in the occupied area, in 3 levels (0.5 m, 1.5 m and 2.5 m above the floor level) in a grid of 3×5 points (see figure 1). The other variables, like carbon dioxide concentration and air relative humidity, are measured in the classroom's central area 1.2 m above the floor level. The experimental tests were made in Summer conditions. In these measurements the following orthogonal axis directions were defined:

- The X direction, defined in the transversal classroom direction, with the origin in the door side;
- The Y direction, defined in the longitudinal classroom direction, with the origin in the blackboard side;
- The Z direction, defined in the height classroom direction, with the origin in the floor level.

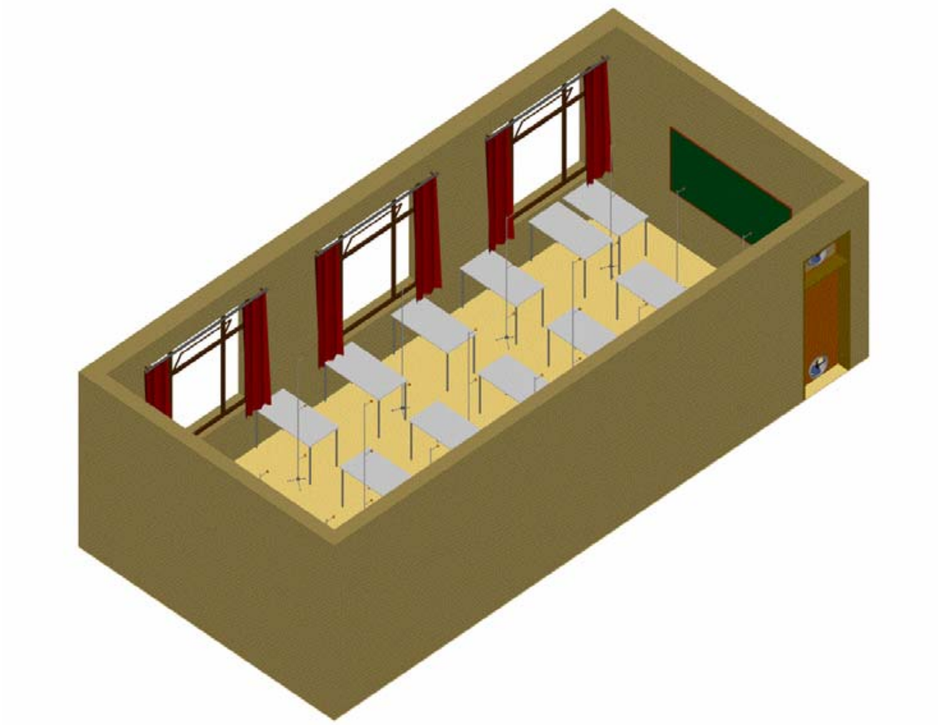

Figure 1. Scheme of the classroom used in the experimental setup. Location of the door, windows, dump trucks, extractors, desks and measuring points.

The air temperatures and velocities evolution are measured with three omni-directional probes, from Sensor, during 5 minutes at a rate of 6 samples per second, while the mean values of other environmental variables and the carbon dioxide concentration, during all test at a rate of 2 samples per minute, are measured by using Babuc-A, of a LSI.
The mean air temperature, velocity, relative humidity and the radiative temperature, with a pre-defined clothing and activity levels, are used to calculate the local thermal comfort level.

The measured air velocity and temperature fluctuations values are used in the calculation of the air velocity root mean square, the air turbulence intensity, the draught risk, the air velocity fluctuations frequencies and the air velocity fluctuations equivalent frequencies.
The carbon concentration decay, using the decay tracer gases method, is used to calculate the local air exchange rates.

RESULTS AND DISCUSSION

In this work, the evaluation of the indoor thermal environment in a classroom equipped with air forced system was made. This experimental study, made in a warm September day, evaluates the thermal comfort, local thermal discomfort and air quality levels that occupants are subjected.

Global thermal comfort level

In order to evaluate the global thermal comfort level, using the PMV index, in the environmental parameters are considered the air temperature (mean value of all measured data in the occupied area), the mean radiant temperature (equal to the air temperature), the air relative humidity and the air velocity value (mean value of all measured data in the occupied area), while in the personal parameters the clothing level (0.5 Clo as Summer clothing) and the activity level (1.2 Met) are considered. In the first tests, when the ventilator is placed in the door's lower area, the air mean temperature, mean radiant temperature, air mean relative humidity and air mean velocity are, respectively, 32,55 ºC, 32,55 ºC, 28 % and 0,21 m/s, while in the second test, when the ventilator is placed in the door's upper area, these values are 31.83 ºC, 31.83 ºC, 39 % and 0.25 m/s. The Predicted Percentage of Dissatisfied people (PPD), using the Fanger model (see [1]) with the correction presented for warm environments (see [2]), are in the first situation 28.98 % (PMV=1.07) and in the second situation 25.99 % (PMV=0.99). In accord to [10], the internal conditions are thermally uncomfortable.

Local thermal discomfort level

In order to evaluate the local thermal discomfort level the draught risk and uncomfortable air velocity fluctuations, that occupants are subjected, are considered. In the first one the percentage of dissatisfied people by draught risk is considered, while in the second one the air velocity fluctuation frequencies and the air velocity fluctuations equivalent frequencies are considered.
The measured air velocity fluctuations are used to calculate the air mean velocity, root mean square values and, consequently, turbulence intensity. This information, in combination with the local air temperature value, is used to calculate the draught risk (see [3]).
In tables 1 and 2 are presented, for the different locations, the air mean velocity (V_{air}), air mean temperature (T_{air}), air turbulent intensity (TI), draught risk (DR) and equivalent frequency (E_f) measured values. The results presented in the first table are associated to the air forced system localized in the door's lower area, while in the second table are associated to the air forced system localized in the door's upper area. The values presented in bold in these tables are associated to the uncomfortable situation, in accord to the present standards.
The air velocity fluctuation frequency, that can cause local discomfort sensation associated to the air velocity fluctuations in the occupants, in the occupied area, are presented in figures 2a and 2b. The results presented in the first figure are associated to the air forced system

localized in the door's lower area, while in the second figure are associated to the air forced system localized in the door's upper area.

a) b)

Figure 2. Air velocity fluctuation frequencies, obtained in the experimental test with inlet forced air located in the door's lower a) and upper b) area and with the outlet air located above the window area.

In accord to the previous results is possible to conclude:

- The draught risk, in general in the two studied situations, is higher in the low body sections than the other bodies sections. Nevertheless, in general, all points are in accord to the Category A of [10];
- The highest draught risks are verified mainly in the desks located near the door, being inclusively in the second situation in the head level verified uncomfortable draught risks;

- The draught risk, in general, when the ventilator is placed in the door’s upper area are higher than when the ventilator is placed in the door’s lower area;
- The values verified in the air velocity equivalent frequencies are inside the uncomfortable interval;
- When the ventilator is placed in the door’s lower area the highest uncomfortable air velocity fluctuations are located near the lower members level, in the desks placed in front to the window and near the blackboard;
- When the ventilator is placed in the door’s upper area the highest uncomfortable air velocity fluctuations are located near the head level, in the desks placed in front to the door and near to the blackboard. Nevertheless, the air velocity fluctuations frequencies verified in this second test are more energetic than the verified in the first test.

Table 2. Measured and calculated values, obtained in the experimental test with inlet forced air located in the door’s upper area and with the outlet air located above the windows’ area.

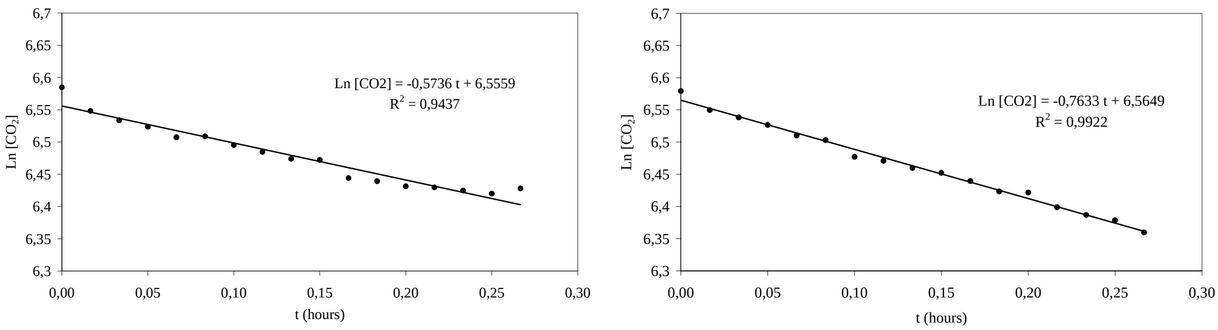
Air quality level

The air quality level, evaluated by local classroom air renovation rate, are obtained in the central room area, 1.2 m above the floor level, in the respiration area, using the decay tracer gases method. In these experimental tests, before the beginning of the test, the carbon dioxide and the air were mixed using two mixing ventilators. In the experimental test, without mixing ventilators on, the local tracer gas is measured around 0.3 hours. In figure 3a) and 3b) are presented the carbon dioxide concentration logarithm decay in function to the time, in the central room point, respectively, when the ventilator is placed in the door’s lower and upper area.

In general the classroom, with a volume of 181.4 m^3, is frequently used by 24 students and one teacher, which are 25 occupants. For a classroom the ASHRAE Standard [8] recommend an air flow rate per person of 5 l/s (using outdoor air rate) and 6.7 l/s (using combined outdoor air rate), while the Portuguese Standard [9] recommend 30 m^3/h. Thus, the air renovation flow rate for the ASHRAE Standard [8] changes between 450 and 603 m^3/h, while for the Portuguese Standard [9] is 750 m^3/h.



a) b)

Figure 3. Evolution of carbon dioxide concentration decay, obtained in the experimental test with inlet forced air located in the door's lower a) and upper b) area and with the outlet air located above the window area.

In accord to the previous results is possible to conclude:

- The carbon dioxide concentration logarithm evolution, in accord to figures 3a) and 3b), shows as example a perfect logarithm decreasing. The experimental air renovation rates change between 0.57 h^{-1} when the ventilator is placed in the door's lower area and 0.76 h^{-1} when the ventilator is placed in the door's upper area;
- The local air renovation flow rate in the central respiration area changes between 103.4 m^3/h when the ventilator is placed in the door's lower area and 137.8 m^3/h when the ventilator is placed in the door's upper area;
- The recommendations defined by the ASHRAE Standard [8] and by the Portuguese Standard [9] are not guaranteed using this kind of ventilation system in this space.

CONCLUSIONS

In this work the evaluation of the indoor thermal environment in a classroom equipped with air forced system was made. This experimental study, made in a warm September day, evaluates the thermal comfort, local thermal discomfort and air quality levels that occupants are subjected, with an air forced system placed in the door's upper or lower area.

The experimental test was made in Summer conditions in a warm day using the inlet air flow coming from the corridor compartment. The corridor inlet air temperature, lower than the outdoor environment, is insufficient to guarantee comfortable conditions. Nevertheless, in general in this kind of warm days the students are in holidays.

The draught risk is highest in the occupied area near the door, mainly when the ventilator is placed in the door's upper area. The equivalent air velocity fluctuation frequencies values are inside the uncomfortable interval, nevertheless the more uncomfortable air velocity fluctuations are verified near the lower members level in the desks placed in front to the window near the blackboard, when the ventilator is placed in the door's lower area, and near the head level in the desks placed in front to the door near the blackboard, when the ventilator is placed in the door's upper area.

The local airflow rate is lightly lower when the ventilator is placed in the door's lower area than when the ventilator is placed in the door's upper area. Nevertheless, in all situations the air renovation flow rate is insufficient.

In order to increase the air renovation rate, in future works, to use more than one extractor fan and to put them in the windows upper area instead of the door area are recommended. This fact reduces substantially the influence of external wind direction, which was verified in the present work. Nevertheless the increase of the airflow rate, mainly for lowest air temperature levels, can promote local thermal discomforts levels, associated to the draught risk, mainly in desks located near the blackboard.

ACKNOWLEDGEMENT

This research activity is being developed inside a project approved and financed by the Portuguese Foundation for Science and Technology and POCI 2010, sponsored by the European Comunitary Fund FEDER.

The authors are grateful to the School E. B. 2,3 Poeta Emiliano da Costa (Estói, Faro), where the experimental tests were made.

SUMMARY

We performed a study on the effect of the discharge airflow rate of the ceiling type air-conditioner on ventilation performance in the lecture room with the mixing ventilation. The experiments and CFD were conducted for analyzing ventilation performance. The concept of mean air age and indoor CO_2 concentration were used for evaluating ventilation performance. We made the CO_2 generation model in the simulation and calculated a lot of cases with respect to the airflow rate of air conditioner and the ventilation flow rate. And the selected experimental measurements were performed in the lecture room of the same layout as the numerical one for verifying simulation results. Mean air age is gradually increased, but CO_2 concentration is oppositely decreased in the occupied zone with the increment of the discharge airflow rate of the ceiling type air-conditioner. This result shows that both of mean air age and residual life time must be considered for evaluating ventilation performance when the contaminants are generated indoors. And the increment of discharge airflow of the ceiling type air-conditioner can induce the piston effect and push the contaminants out of the occupied zone. From this result, it is found out that that ventilation performance can be increased when the momentum source like an air-conditioner is used in the room with the mixing ventilation.

INTRODUCTION

Recent studies [1-4] showed that many buildings have poor indoor air quality, and especially CO_2 concentrations measured in the room exceeded the present guideline [5]. In this case, the role of ventilation is very important as the strategy for more comfortably indoor environment because CO_2 cannot be removed by present air cleaning systems. Accordingly, various researches on the improvement of ventilation performance as well as ventilation itself have been carried out. In the view of IAQ, Lee and Chang [2] investigated the indoor and outdoor air quality of the five classrooms at five different schools in Hong Kong and pointed that PM_{10} and CO_2 concentration exceeded the HKIAQ limits due to the high outdoor PM_{10} concentration and inadequate ventilation respectively. Daisey et al. [3] reviewed the literature on IAQ, ventilation and health symptoms in schools and showed that ventilation was inadequate in many classrooms, possibly leading to health problems. Noh and Oh [4] performed the numerical study on the comparison of ventilation performance with variations of indoor momentum source such as air-conditioners, air cleaners and ceiling fan for displacement and mixing ventilations. They found out that ventilation performance is getting better or worse with variations of the intensity and the location of momentum source due to that the intensity and the location of momentum source affect the residence time of air in the room.

However, there are hardly ever studies on effect of the air discharge intensity of the personal air-conditioning systems such as indoor air-conditioners, air cleaners, and fans in school buildings on the ventilation effectiveness until now. Therefore we performed the experiments and numerical simulations in a lecture room with a ceiling type air-conditioner and a ventilation system. With variations of the air discharge rate of the ceiling type air-conditioner and occupancy, CO_2 concentrations and local mean air-ages during class hours were investigated and the effect of the air discharge intensity of a ceiling type air-conditioner on ventilation effectiveness was analyzed.

RESEARCH METHODS

Model descriptions

Fig. 1 shows the schematic design of a real lecture room which is presently used in one of universities in Korea. The dimensions of this room are 11.2m (L) x 6.65m (D) x 2.4m (H). This lecture room has 3 windows and 2 doors. The lecture room was generally occupied by 20 to 30 people including a lecturer and students when the experiments were carried out. In order to control the thermal loads in the lecture room, the ceiling type 4-way cassette air-conditioner. It is located at the center of this room. The discharge airflow of this air-conditioner is discretely varied from 0m^3/hour to 1600 m^3/hour, while the discharge angle is fixed to 30 degrees when the experiments were conducted. The ventilation system is composed of 4 supply diffusers, 4 exhaust ones, and a heat exchanger. Locations of supply and exhaust diffusers are determined to optimize the ventilation effectiveness.

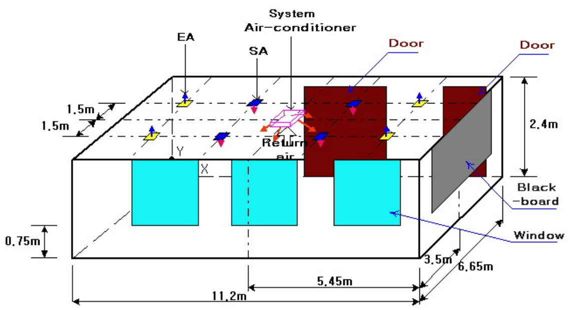

Fig. 1 Layout of the lecture room

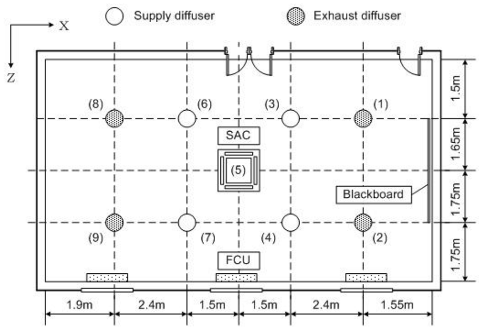

Fig. 2 Measuring points of the lecture room

Experiments

We measured CO_2 concentration and mean air age in the lecture room with respect to the discharge airflow rate of the ceiling type 4-way cassette air-conditioner. The discharge airflow rate was varied from 0 to 1600m^3/hour and ventilation rate was fixed to be 800m^3/hour when experiments were carried out. Based on the previous study [1], the discharge angle of the ceiling type 4-way cassette air-conditioner is fixed to be 30 degrees. As shown in Fig. 2, 9 measuring points were selected to analyze the local or the room-averaged performance for ventilation effectiveness. Sampling probes were placed at 1.1m high from the bottom. The experiments for each case were repeated over three times in the same case. All the measured values of indoor CO_2 were compensated according to the outdoor CO_2 variation. In the case of CO_2 concentrations, all experiments were conducted during the class hours and 20 people were asked not to move around. To examine the mean air age, all experiments were conducted after the class hours. SF_6 gases were released in the supply duct and were sampled at the same points like the case of CO_2 measurement. IAQ monitor (Graywolf, model IAQ-410; USA), Thermal comfort data logger (Innova, model 1221; Denmark), The multi gas monitor (Innova, model 1314; Denmark) were respectively used for CO_2 measurement, velocity and air temperature, and SF_6 measurement

CFD simulations

We adopted this numerical model with appropriate boundary conditions as a prediction tool for a couple of operating conditions. We considered the discharge airflow rate of 4-way cassette air-conditioner and the number of people as the control variables. All the occupants with hexagonal shapes sitting on were modelled as the rectangular objects with 1.2m height and the volume of $1.62m^3$. The CO_2 concentration emitted from occupants' mouth was selected to be $0.014m^3$/hour [5].

The flow in the lecture room was assumed to be 3D steady and incompressible [4]. The standard k-ε turbulence model was applied and the airflow transport can be described by the following time-averaged Navier-Stokes equation:

$$div(\rho \mathbf{V}\Phi - \Gamma_{\Phi,eff}\, grad\ \Phi) = S_\Phi \tag{1}$$

Where ρ is the air density (kg/m³), $\Gamma_{\Phi,eff}$ is the effective diffusion coefficient (kg/m·s), V is the air velocity vectors (m/s), S is the source term of the general flow property, and Φ is any one of the components shown in Table 1. When Φ=1, the general equation becomes the continuity equation. The effective diffusion coefficients and the source terms for different Φ are listed in Table 1. Also, Wall boundary conditions were treated as shown in Table 2.

Table 1 Terms, coefficients and constants in Eq. (1)

Equations	Φ	$\Gamma_{\varphi,eff}$	S_φ
Continuity	*1*	*0*	*0*
Momentum	U_i	μ_{eff}	$-\partial P/\partial x_i + g_i(\rho-\rho_0)$
Turbulence kinetic energy	k	μ_{eff}/σ_k	$P_k - \rho\varepsilon + G_k$
Turbulence kinetic energy dissipation rate	ε	$\mu_{eff}/\sigma_\varepsilon$	$\varepsilon(C_1P_k - C_2\varepsilon)/k + C_3G_k\varepsilon/k$
Concentration	C	μ_{eff}/σ_C	S_C

$P_k=\mu_t(U_{i,j} + U_{j,i})U_{i,j}$, $\mu_{eff} =\mu_t +\mu$, $\mu_t = C_\mu\rho k^2/\varepsilon$,
$(\sigma_k, \sigma_\varepsilon, \sigma_C, C_1, C_2, C_3) = (1.0, 1.314, 1.0, 1.44, 1.92, 1.0, 0.09)$

Table 2 Boundary Conditions for the numerical calculation

Inlet: $k_{in} = \frac{3}{2}(u_{in}\cdot I)^2,\ \varepsilon_{in} = C_\mu^{3/4}k^{3/2}l,\ I = 0.1,\ l = 0.5\times D_h,\ C_{in} = 500\,ppm$

Outlet: $\frac{\partial u}{\partial x} = 0,\ \frac{\partial k}{\partial x} = 0,\ \frac{\partial \varepsilon}{\partial x} = 0,\ \frac{\partial T}{\partial x} = 0,\ \frac{\partial C}{\partial x} = 0$

Wall: $u = v = w = 0,\ \frac{\partial k}{\partial x} = \frac{\partial k}{\partial y} = \frac{\partial k}{\partial z} = 0,\ \frac{\partial C}{\partial x} = \frac{\partial C}{\partial y} = \frac{\partial C}{\partial z} = 0$

Where, D_h is the width of inlet

The mean air age and boundary conditions were calculated by the following equation induced from equation (2) and (3) [6]:

$$div(\rho \mathbf{V} \tau - \Gamma_\tau \ grad \ \tau) = 1 \tag{2}$$

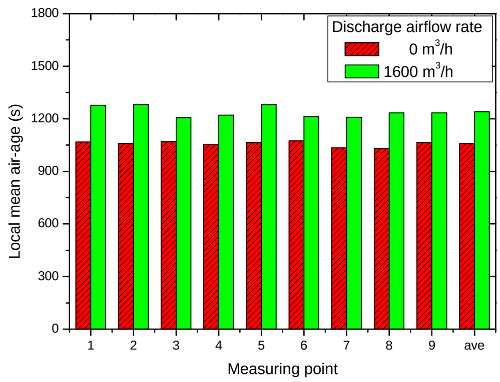
$$inlet: \tau = 0, \ \ outlet: \frac{\partial \tau}{\partial x_i} = 0 \tag{3}$$

Where, τ is the mean air age (s). x_i represent the 3D coordinates. The governing equations were solved by SIMPLE algorithm and 2nd order upwind scheme was used to discretize the convection term in equation (1). STAR-CD was employed to compute the airflow, temperature, and concentration distributions. The number of cells for numerical calculation is about 750,000 and the standard log-wall functions of Launder and Spalding were adopted for the next grid points to the surface.

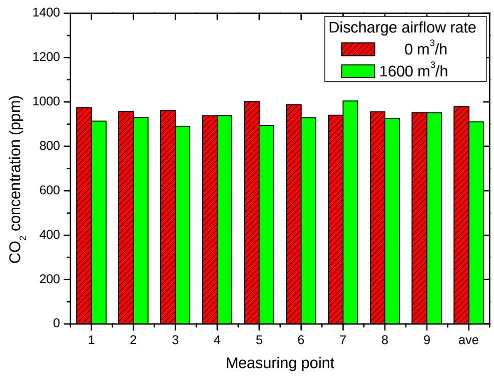
RESULTS

Experiments

Fig. 3(a) shows mean air age distribution for two different discharge airflows of 4-way cassette air-conditioner. When the 4-way cassette air-conditioner was not in operation, mean air age was measured in the range of 1030~1075 seconds. When the 4-way cassette air-conditioner was operated at the discharge airflow rate of 1600m^3/hour, the mean air ages were in the range of 1200~1280 seconds. These results shows that when the discharge airflow rate of the ceiling type air-conditioner, which is one of the indoor momentum sources, is increased, mean air age can be also increased. The reason is that the operation of the ceiling type air conditioner intervene the air current and makes the outdoor fresh air move a longer way. Therefore this indicates that the indoor air quality may be deteriorated as the discharge airflow is increased.



(a) mean air age



(b) CO_2 concentration

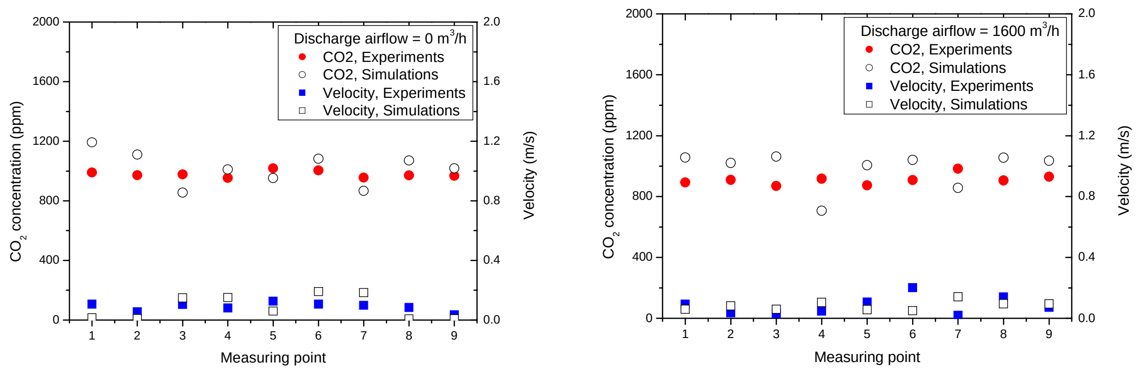
Fig. 3 Experimental results for mean air age and CO_2 concentration at the measuring points with the different discharge airflow of 4-way cassette air-conditioner

Fig. 3(b) shows the locally-averaged CO_2 distributions, which were measured at y=1.1m, with two different discharge airflow rates. When the 4-way cassette air-conditioner was not in operation, CO_2 concentrations were measured in the range of 950~1020ppm. When the 4-way cassette air-conditioner was operated at the discharge airflow rate of 1600m^3/hour, CO_2 concentrations were measured in the range of 870~980ppm. Unlike mean air age distributions as shown in Fig. 3(a), CO_2 concentration get to be somewhat decreased as the discharge airflow rate of the ceiling type air-conditioner is increased. This phenomenon had been

reported by the previous numerical and experimental studies [4]. This reason is that the operation of the ceiling type air conditioner can make the mixing effect of indoor contaminants increased and the residual life time of indoor contaminants decreased.
From these results it was revealed that both of the mean air age and the residual life time must be considered to evaluate the ventilation performance when the contaminants are generated from the indoor.

Validation of CFD model

A part of results from measurements were used for validating the following numerical calculations. Numerical simulations were designed to sufficiently meet the experimental work. Numerical simulations of flow patterns and CO_2 concentrations were compared with measurements at the section of 1.1m high above the bottom in a full-scale room.



(a) discharge airflow is $0m^3/h$ (b) discharge airflow is $1600m^3/h$

Fig. 4 Comparison of experimental results and numerical ones for CO_2 and velocity at the measuring points

Fig. 4 shows the comparison of experimental results and numerical ones for velocities and CO_2 concentrations at the measuring points when the discharge airflow rate is $0m^3/h$ and $1600m^3/h$. There were slight differences between experiments and simulations. In the case of CO_2 concentration, the locally-averaged concentrations were measured nearly the same as the room-averaged value in the experiments regardless of the discharge airflow rate. Their maximum differences of them were under 17% and the agreement was acceptable. In the case of velocity, all values were under 0.25m/s and satisfied an acceptable condition in the occupied zone. From these results we could make sure that the numerical model is sufficient to carry out the applications for evaluating the ventilation effectiveness with variations of the discharge airflow rate of the ceiling type air-conditioner.

Assessment of ventilation effectiveness

Fig. 5 shows the variation of indoor CO_2 concentration in the occupied zone with respect to the discharge airflow rate of the ceiling type air-conditioner, the occupancy and the ventilation rate. Regardless of the occupancy and ventilation rate, CO_2 concentrations is gradually decreased as the discharge airflow rate is increased from 0 to $800m^3/h$, while their values are rarely changed in the case that the discharge airflow rate is over $800m^3/h$. This result demonstrates that a minimum value exists with the increment of the discharge airflow rate. Fig. 6 shows CO_2 distributions at the plane of z=3.2m with respect to the discharge airflow rate of the ceiling type 4-way cassette air-conditioner. As the discharge airflow rate is larger, this deviation of indoor CO_2 concentration becomes smaller in the occupied zone. It is due to that increment of the discharge airflow rate will lead the indoor air to be more mixed as

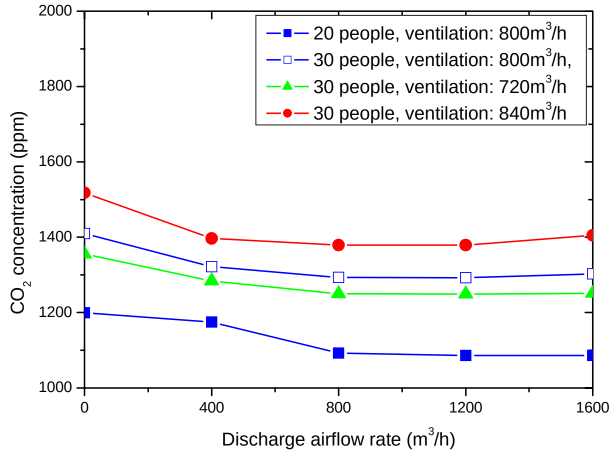


Fig. 5 The variation of indoor CO_2 concentration in the occupied zone with respect to the discharge airflow rate of the ceiling type air-conditioner, the occupancy and the ventilation rate

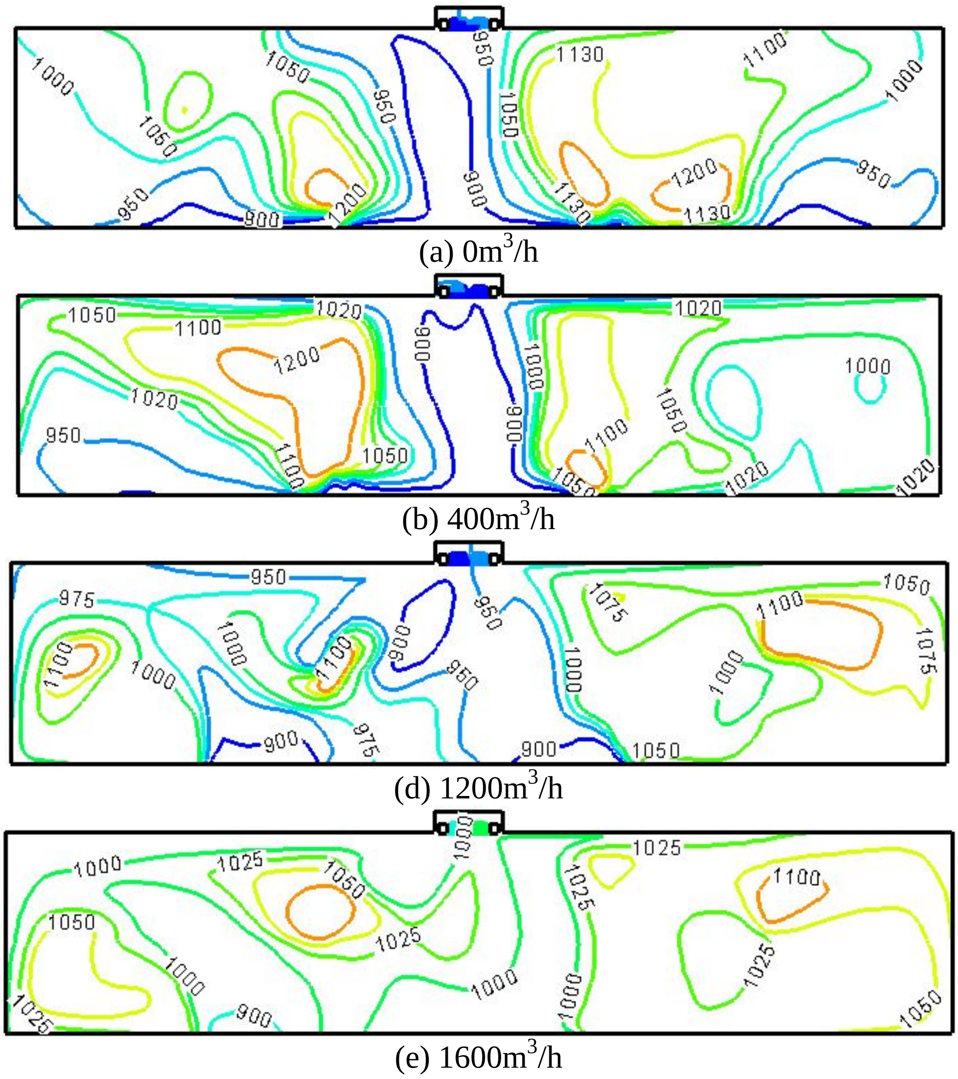

Fig. 6 CO_2 distributions at the plane of z=3.2m with respect to the discharge airflow rate of the ceiling type 4-way cassette air-conditioner mentioned above. Also, it is shown that the maximum area of indoor CO_2 concentration is gradually going up and their value is smaller as the discharge airflow rate is increased. This means that the discharge airflow of the ceiling type air-conditioner can induce the piston effect and push the contaminants out of the occupied zone. But, this effect is gradually diminished with the increment of the discharge airflow intensity as shown in Fig. 6.

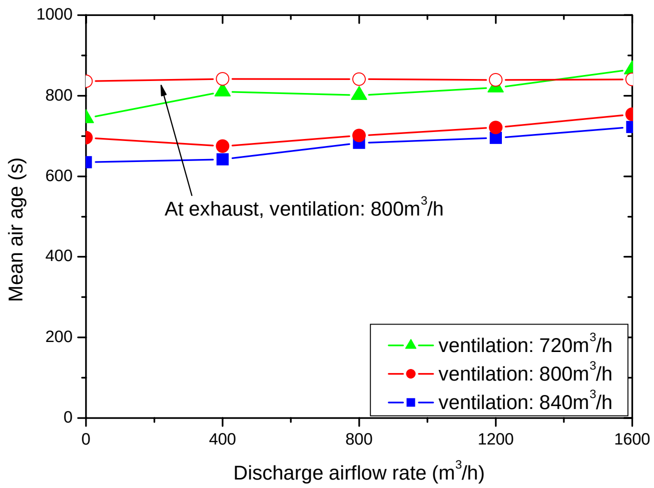

Fig. 7 The variation of mean air age in the occupied zone with respect to the discharge airflow rate of the ceiling type air-conditioner, the occupancy and the ventilation rate

Fig. 7 shows the variation of mean air age in the occupied zone and exhaust with respect to the discharge airflow rate of the ceiling type air-conditioner and the ventilation rate. Regardless of the ventilation rate, mean air age is gradually increased as the discharge airflow rate is increased. This calculation result shows qualitative similarity with the experiment. But, these numerical values of mean air age were not approximated to the experimental ones and there differences were about 200 seconds. It is due to that molecular weight of SF_6 is about 5 times heavier than one of air and the supply airflow rate was smaller than the exhaust one of $800m^3/h$. While, mean air age at exhaust is almost constant even though the discharge airflow rate is increased. This means that the residence time is not changed with the discharge airflow rate of the ceiling type air-conditioner. When the mean air age is increased and the residence time is constant like these cases, the residual life time should be decreased by the definition of air age. Therefore, the contaminant concentration like CO_2 emitted from indoor sources must be decreased with the decrement of the residual life time. These results show that the increment of mean air age does not always make indoor air quality deteriorated. Again, both of mean air age and residual life time are important parameters to be considered for evaluating ventilation performance when the contaminants are generated indoors.

CONCLUSIONS

The effect of the discharge airflow rate of the ceiling type air-conditioner on ventilation performance was studied. Mean air age is gradually increased, but CO_2 concentration is oppositely decreased in the occupied zone with the increment of the discharge airflow rate of the ceiling type air-conditioner. This result shows that both of mean air age and residual life time must be considered for evaluating ventilation performance when the contaminants are generated indoors. And the increment of discharge airflow of the ceiling type air-conditioner can induce the piston effect and push the contaminants out of the occupied zone. This shows that the ventilation performance can be increased when the momentum source like an air-conditioner, air cleaner, and fan is used in the room with mixing ventilation.

SUMMARY

This article is part of a research in progress about comparative study methods for the Brazilian reality using among many other authors, Givoni (1969), Voght and Miller-Chagas (1970), Fanger-ISO(1970), ASHRAE (55-1992), Mahoney (1971), Humphreys (1978) and Olgyay (1962) methods. This research presents the principal concept to be evaluated by the Universal Fuzzy Controlled aiming to establish a reference to determine a possible interference of the acclimatization factor to determine thermal comfort. An experimental evaluation method was elaborated through a questionnaire applied to the population of students in classroom, monitoring the environmental variables inside and outside the classroom during the years 2004 and 2005. It shows their particularities for the altitude tropical climate of the city of São Paulo - Brazil. This article describes interference of mass advance at the responses of students in classroom comparing to internal and external environment variables. The data was gotten in parallel with classroom in full activity.

Key words: thermal performance, building performance, thermal comfort, classroom thermal comfort, simulation, thermal simulation.

INTRODUCTION

This paper presents the experimental results collected in the years 2004 and 2005 about the limit condition of thermal comfort in classroom at altitude tropical climate.

The definition of thermal acceptable limits in edifications can have important implications on the thermal sensation on usuary, on project and on consumption of energy in the edification.

In order to obtain comfort of usuary in edifications there must be attention on limit conditions of thermal comfort – or the adaptation of man to climate. This adaptation is related to heat generated by digestion (produced by metabolism) and the work done by muscles, which must be dissipated in environment to keep the internal body temperature within this limits. Thus, disagreeable sensations as exaggerated heat loss by body, inequality of temperature among different parts of body, difficulty to eliminate excess heat that occur as much in function of environment condition as of acclimatization to this type of environment can be avoided.

It was observed that people living in hot regions and acclimatized to this kind of environment, preferred higher temperatures than those who came from colder climates, which justifies the necessity of different comfort standards for regions with different climatic conditions and economic development stages.

Brazil is a country formed by tropical regions and the occurrence of abrupt climatic alterations caused by air masses is very common – that is, the entrance of frontal systems which alter the perception of thermal comfort by the individual. The climate of the city of São Paulo where the data was collected can be classified as altitude humid tropical, with cold and dry winters, and hot and humid summers, having altitude of 630m, latitude of 21º 57'02"S and longitude of 47 º27' 50"W.

Groups of young attendants with homogeneous characteristics concerning physical vigour (ages), ways of dressing, level of expectations in relation to the termic environment, make up a specific universe of study. We can verify that there's a necessity of establishing specific rules and patterns to this kind of environment which consider its particularities.

The limits of human acclimatization in classrooms are related to their satisfaction with the thermal environment, which involves a certain degree of subjectivity. For that, it is necessary to verify the interference of environmental conditions in classrooms on thermal comfort, identifying the physical variables in the answer of its occupiers through questionnaires.

Afterwards this data is related with the measurements of external climate conditions; analyzing the influence of the advance of air masses in the answer on the comfort of the students in relation to the classroom by monitoring the external environmental conditions, and comparing them to the superior limits of temperature for the environment.

METHODS

The data was collected in classrooms with and without thermal conditioning. We respected the rules present in the ABNT NBR 15220, items 1 to 5 which establish the definitions, symbols and units; procedure for calculation of thermic properties of elements and components of buildings, Brazilian bioclimatic zone; measurement of the resistance and thermic conductivity by the principle of the protected hot plate and by the fluxmetric method related to the thermic performance of buildings.

We consulted the norms ASHRAE 55 -1981/1992/1995/2004, for conditions of thermic comfort to human occupation; ASHRAE 111-1988 to measurements, tests, adjustments, heat balance, ventilation and air conditioning and the norms ISO 7730(1994) to determine PMV and PPD and specification of the thermal comfort; ISO 7243 (1989) to hot environments, estimation of the thermic stress to workers; ISO (7933) 1989 to hot environments, analytical determination and interpretation of thermic stress using calculations of sweat rate. ISO (7726) 1985 to thermic environments, instruments and methods to measure physical values.

Classroom description

Room 2 of Mechanical Engineering building, without thermic conditioning, with capacity for 130 students and area of 200,68m2 composed of the 3 walls of masonry, a glass wall, ceiling with thickness of 10 cms and cold ground. The ceiling presents a lining below in double plates “eucatex” covered with glass wool of 50mm of thickness. Below this lining there are 24 lamps of 2 fluorescent lamps each and four ceiling fans.

Room “Asteróide” of Civil Engineering building with thermal conditioning and capacity for 36 students. Its area is of 60m2, L-shaped, with cold floor and structured by walls of “eucatex” with a wall of tempered glass and a partially open window. Its ceiling is 10 cm thick with a lining below in double plates of “eucatex” covered with glass wool of 50mm of thickness. Below this lining there are 23 luminaries of 2 fluorescent lamps each and an opening for air conditioning.

Classroom A1-02 located in region A of the building “Biênio” with evaporative cooling, with capacity for 100 students, and an area of 60m2 composed by concrete walls with superior openings of “vitraux” open partially, ceilings with thickness of 10 cm, ceiling composed by lining below with double plates of “eucatex” covered by glass wool with thickness of 50mm. Below this lining there are 23 luminaries for 2 fluorescent lamps each and openings for evaporative cooling. The floor presents carpet covering and the room is equipped with fixed and stuffed chairs.

The classroom S23 located in Civil Engineering building has air conditioning controlled by sensors with diffusers installed in the lining below and flagstone under with thickness of 10cm , having 3 walls constituted by dividers of “eucatex” and a glass wall. Its floor is of rubber and it is equipped with 25 working stations and personal computers for 48 students.

Equipments and measurements

Inside environmental conditions

The following instruments were used to measure the internal environmental variables (temperature, pressure and air humidity): - A datalogger, to which thermocouple type “T” and a humid and dry bulb by thermometers, were connected 1) Four thermocouple type “T” which measure the temperature of the air. Four points of the rooms were used, in the levels 0,10; 1,10 and 1,70 which are the recommended measures for evaluation of comfort for seated people. 2) Humid and dry bulb by thermometers measures the temperature of the dry and humid bulb. 3) Hot wire anemometer of manual hot wire (measures the temperature and air velocity of the internal environment, even being a low one). The revolving thermometer was used to check the measures of the anemometer. 4) Globe thermometer, used to measure the radiant average temperature.

External environment condition

The external environment was monitored by meteorological stations. It was obtained data on temperature, velocity, relative humidity and atmospheric air pressure and pollution; verifying the relation of CO_2, O_3, SO_4 between the increase in temperature and atmospheric pollution.

Based on the questionnaires for identification of thermal comfort sensation used in the studies of Fanger (1972), Humphreys (1970, 1972) and Leite (2002), and of post occupation assessment of Orstein (1992) a questionnaire divided in three parts was elaborated: 1) student profile: age, sex, height, weight, origin, nationality, course, ongoing year course, clothes description; 2) thermal conditions: temperature, preferences concerning the period; description of physiological sensations, pathologies; 3) discomfort factors: perception and preference about the movement of the air (air velocity), preference in relation to environment cooling, assessment of thermal comfort and preference concerning the location in the classroom.

The questionnaire was distributed when the classroom was in the maximum, medium and minimum limit of students per group, and they were done in periods, which did not disturb the students who attended classes during the semester. The criterion for the distribution of the questionnaires in the classrooms obeyed the verification of the weather forecast supplied by the Meteorological Station of the INPE which indicated the increase of the atmospheric temperature and its dependence in the advances of air masses or not. Later on, a comparison with data supplied by CPTEC/ DISME (INPE) which presents cross-country meteorological stations versus the time of the frontal systems to verify the periods of air mass arrival in order to observe whether they occurred on the date the questionnaire was filled in.

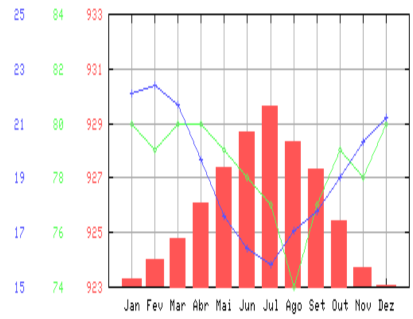
Please note that commercialism (use of company or product names or logos in the text or illustrations) is not allowed.

RESULTS

Climatological of the city of São Paulo

The industrialization of the city of São Paulo brought up alterations in temperature caused by pollution. Another significative factor in the alteration of the microweather of the city is the arrival of sea brise which causes violent summer storms when in contact with the hot air accumulated during the day. Figure a) below illustrates the climatological behaviour of the last 30 years in São Paulo, considering the variables of atmospheric pressure, average temperature and humidity of the air during the winter months (june, july and august). We observe that the highest pressures occur during those months while the temperature and humidity decrease.

Climatologic Graph



Pressure (hPa) São Paulo in the period 1961-1990
Humidity (%) São Paulo - period 1961-1990
Average Medium Temperature (ºC) in São Paulo - period 1961-1990

Climate Analysis of 2004 and 2005

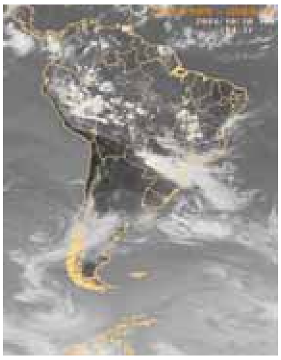
The climate analysis for the Southeast region in the months when the experiments occurred (March, April, May, August and November of 2004 and 2005) were gotten with CPTEC-INPE. (Figure 1).

In March of 2004 nucleus with positive anomalies of rain occurred and in 2005 the rains were associated to the entrance of frontal systems, on day 20 of this month occurred strong rain and hail causing danger to the local population. The occurrence of a greater number of front systems was observed in 2004 than in 2005. This indicates the intense temporal weather variation on the number of frontal systems at the same time of year. (Figure b,c).

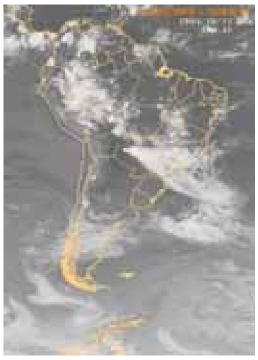
Methods of Thermal Comfort

The importance of application of thermal comfort methods in civil engineering is due to the necessity of revitalizing buildings. We notice that intervening within the possibilities in the climatic elements and in the architecture is important to enable a better adaptation of the human being to his environment in the classroom, work or home.

Figure d) summarizes the aspects of the human being as a homoeothermic organism, who reacts in order to preserve the balance when faced to variations in the temperature. In a short period of time exposed to a thermic differential, his body makes a metabolic effort through the hydrothermal regulation system, like the production of sweat or change in the breathing pace. As for a longer period, we can observe an alteration in the physiological behavior, when, for example, a person who is used to living in mild weather moves to a tropical region. Finally, when it comes to genetic adaptation, we can verify the different human phenotypes which are better acclimatized to determined thermal conditions, as skin color or amount of hair on the body.



b)



c)

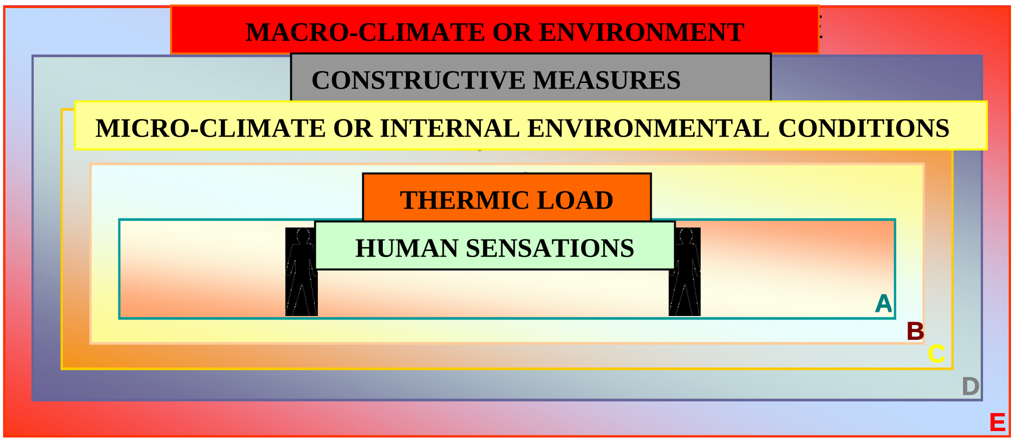
Figure a), b) Frontal System

b) October 10th. Beginning of alterations in weather conditions.

c) October 11th. Beginning of Polar mass domain.

In 1970, Fanger proposed comfort indexes from discomfort sensations.

In this sense, there is an analogy found in the methods proposed for the assessment of thermal comfort so for designed: the presence of two kinds of parameters, the personal and the environmental. Besides that, another observation may be made: all the methods present limitations either connected to the elements considered in the equations that leave aside important aspects, influencing the final result of the assessment or to the level to which a certain method may be used, as the diagram below shows:



d)

Figure d): Levels of reach diagram for the methods - effective levels

Such classification was made having as a rule the possibility of application or the objectivity of the method, that is, which practical application, within the levels above mentioned, of a certain method which determines values (results) for a certain case or construction. For example, there are methods which define values for a comfort zone to determine the best constructive conditions, then identified as “constructive measures”.

Of the mentioned methods, the present analysis takes up only the ones which concern the study of thermal control.
-In the scope of energy, can mention the noteworthy softwares: DOE-2 (1982), ARQUITOP (1990) e Ecotec (2002).
The research lines concerned with thermal comfort, like the works of: Dreyfus (1960); Olgyay & Olgyay (1962); Van Straaten (1967); Givoni (1969); Vogt & Miller-Chagas (1970); Croiset (1970); Mahoney (1973); Koenigsberger (1974); Evans (1980); Rivero (1985), which developed project guidelines, that is, focused on the evaluation of the thermal performance of the edification.

After that thermal comfort for environments was studied, that is, the evaluation of comfort sensation of the occupier, with the creation of methods and norms, that are Fanger (1972); Humphreys (1978) and the norm ASHRAE 55-1995, among other norms.

DISCUSSION

The first analysis allowed identifying and confirming what causes comfort and discomfort when the student is attending a class and it was important to test the proposed methodologies for this research. For all the rooms, the environment was monitored when empty, full or partially occupied. The experiment was valid for all the rooms, since it was possible to find out that all the students prefer cooling rather than heating, for in the winter the thermal balance can be reached by wearing heavier clothes. On the other hand, in summer, despite of wearing lighter clothes and drinking more water to control body temperature, it is hard to keep the concentration due to the heat, which indicates the insufficiency of these procedures. This was reported by the students during the year 2004 and they suggested that questions about concentration should be added to the questionnaire in 2005. Besides that, the majority of undergraduate students told that they organize their schedules in a way to have one or two free afternoons to study at their homes, in order to recover physically, creating conditions to reach their objectives since high temperatures cause a great sensation of tiredness.

Following, data about the population which occupies the monitored rooms is displayed.

The classroom in the Biênio building, with evaporative cooling, is occupied by first, second and third-year students, in the Civil, Mechanical and Environmental Engineering, totalizing 198 students in November, 2004. Their ages varied from 18 to 21 (20 in average), average weight was 60kg, average height 1,70m, 75% males and 25% female. The clothes more commonly used are jeans, shorts, t-shirts and sneakers. This room is not frequently used and its architectonic project is atypical in relation to the classroom pattern of the Polytechnic School of USP.

In the Asteróide room, which has air conditioned and is located in the Civil Engineering building, the attendance is of postgraduate students from the Department of Urban and Civil Construction Engineering, adding up to 20 students in May 2004. Their ages varied from 29 to 35 (28 in average), average weight was 64kg, average height 1,71m, 60% female and 40% male, generally wearing the following: jeans, social pants , shirts, shoes and sandals. This room is occupied in diverse hours, the amount of students varies a lot during a given day and its architectonic project is atypical, characterized by an “L” format.

Room S23 is also located in the Civil Engineering building, with capacity for 48 students. It was built according to a new tendency of architectonical project based on the Fanger’s methods for air-conditioning system installation. It has sensors which obtain the real temperature, which allows regulation for the adaptation to the ideal environment. The room is used by first-year students of the Civil Engineering course, being fully occupied during all the semesters. The questionnaires were answered in August, 2005 by 105 students whose ages varied from 17 to 23 (19 in average). Their average weight was 68,52kg, average height 1,75, 83% were male while 18% were female. They usually wore jeans, shorts, t-shirts and sneakers.

Classroom 2 located in the Mechanical Engineering building has ceiling fans and capacity for 130 students. It’s occupied by first, second and third-year students of the Civil, Mechanical, Naval and Mechatronics (Mechanics/Electronics) Engineering, totalizing 246 questionnaires answered in 2004 and 350 in 2005 by students whose ages varied from 18 to 27 (21 in average). These students had an average weight of 61,28 kgs, average height of 1,64m and 75% were male while 25 were female. Jeans, shorts, t-shirts and sneakers were the clothes usually worn.

The occupant’s characteristics presented similar metabolical rates and the rooms had a regular use. The greatest differences among the classrooms chosen for comparison are related to cooling solutions.

The data about external environment were collected at four Meteorological Stations.

1) Institute of Astronomy, Geophysics, and Atmospheric Sciences (IAG) – USP.
1a) State Park Meteorological Station 1b) University City Meteorological Station 2) Philosophy, Letters and Human Sciences College (FFLCH)– University City of San Paulo-Capital – Department of Geography - Laboratory of Climate and Biogeography 3) Department of Urban and Civil Construction Engineering (Endure Project). The differences

of atmospheric variables on the same day were verified. For instance, the 2nd of March of 2004 can be mentioned, characterized as entrance of pre-frontal, when it was observed the air temperature (°C) at the Meteorological Stations 1 a) 23,4; 1 b) 22,08; 2) 24,6; 3)24,9, the atmospheric pressure (Kpa) 1 a)922,7; 2)924,94; 3) 930, relative humidity (%) 1 a)70,9; 1 b) 84,26; 2)70,9; 3)63,59. This criterion was used for all the days of the field survey which allowed conclusions with the comparison of data from the 4 Meteorological Stations 1 b) and 3), installed on the flagstone of the buildings, coated with asphalt blanket, agree about the edges of atmospheric variables and oppose to the ones of Stations 2) and 1 a), installed in woody places, which explains these contradictions. In 2004 the air temperature for Station 2) agreed with the information from 1a). However, the relative humidity is characterized for the period of events of cold fronts.

Starting from the climatologic data of 2004 and 2005, the entrance of frontal, prefrontal and previous to prefrontal systems data could be verified. It was calculated the difference (ΔT) between the day of entrance of prefrontal temperature (Tp) with the day previous to prefrontal (Tap), relating it to the reply on thermal comfort given by the students. At a second moment it was verified the number of frontal system entrances for the months of the experiment and their passage by San Paulo, also presented in percentages during the years of 2004 and 2005. It could be verified that in 2004 there were more passages of frontal systems than in 2005 which indicates intense temporal variation of frontal systems at the same time of the year. An important datum observed in the student's answers is the ocular irritation reported, which motivated the verification of the conditions of atmospheric pollution. It could be evidenced that this irritation was directly related with the increase of air temperature that causes an increase on pollution. Based on these analyses, a relation was established between the results obtained about external and internal environment and the replies from the questionnaires.

As an example, April 17th 2004 can be mentioned as characterized as entrance of air mass at room 2 in the Mechanic Engineering building, without thermal conditioning. The first case of classroom study without thermal conditioning presents the data as frontal entrance data on April 17th where it was verified the variation of temperature (°C) 1a) 22,9 1b) 22,34 2) 23 and 3) 23,3 and relative humidity of air (%) 1a) 74,2 1b) 88,85 2) 80,8 and 3) 69,59, atmospheric pressure (kpa) 1a) 926,4 1b) 927,49 and 3) 934 from the four meteorological stations.

The day previous to the entrance of prefrontal system, on April 16th the air temperature (°C) variation was identified as 1a) 22,2 1b) 21,92 2) 22,2 and 3) 22,6 and relative humidity of air (%) 1a) 76,1 1b) 88,85 2) 82,9 and 3) 72,74, atmospheric pressure (kpa) 1a) 925,8 1b) 926,76 and 3) 933. With these data the deviation observed on external air temperature from day 17 to day 16 was of 0,6°C. The timetable analysis from the "datalogger" installed in the internal environment on day 17 of April shows that the variation of air temperature (°C) of the was TP1-23,72, TP2-23,78, TP3-22,45 and from the thermocouple that measured the wall temperature was TP4-25,80, relative humidity of air (%)82 and atmospheric pressure (Kpa) 926,40. On the other hand, the analysis from April 16th presents the variables of air temperature (°C) of thermocouple in TP1-23,3, TP2-23,49, TP3-22,08 and the thermocouple that measured the wall temperature TP4-25,63, relative humidity of air (%) 77 and atmospheric pressure (Kpa) 925,80.

The student's replies to the questionnaire about the sensation of comfort was 34% comfortable, 25% slightly cold and 25% cold, and it was observed that although there is a small variation of temperature in relation to the previous day there were no alteration on the questionnaire answers. It was observed that on the 17 of April between 12 and 17 o'clock, the thermocouples TP1, TP2 and TP3 indicated air temperatures very near to the external meteorological stations, that is, from 22 to 23°C. The thermocouple TP4 located near the wall presented an elevated air temperature, measuring 25,80°C, compared with the external temperature due to the influence of the edification envelope.

These analyses were elaborated for the classrooms with and without thermal conditioning and it permits us to conclude that the entrance of air masses significantly interfere on the students' answers

ACKNOWLEDGEMENT

The authors thank deeply UNICAMP – Universidade de Campinas - Faculty Mechanical Engineering, Prefeitura Municipal de Araraquara, CAMPEBELL DO BRASIL, Geographys_USP (USP) and FAU_USP(SP) for providing the equipments used in the experimental research, the Astronomy and Geosciences Institute (IAG) Prof. Amauri P. Oliveira and John, V. M e Sato, Neide M. N. the Polytechnic School - Depto Civil Eng. from USP for the climatological data of the campus and professors, students, workers at the Mechanical Engineering: Polytechnic School at USP. We are most grateful for the financial support of CNPq.

SUMMARY

In this work, 36 basic schools of Lisbon city, Portugal followed a questionnaire of the ISAAC - International Study of Asthma and Allergies in Childhood Program. The questionnaire contains questions to identify children with respiratory diseases (wheeze, asthma and rhinitis) as well as their nutrition habits, ingested medication, environmental aspects, among others. The questioned children are 5 to 10 years old, and the answers are from June to December 2006. The results are from 995 children inquired who have shown 26.7% with wheezing symptoms, 9.2% with asthma, and 26.2% with rhinitis. The results obtained are compared with the results, interpretations and correlations obtained in the ISAAC 2002 program, which questioned 2484 6 to 7 years old children from the basic schools of Lisbon-city from November 2002 till March 2003.

INTRODUCTION

Children's exposure to air pollution is a very important issue mainly because children immune system is not fully developed, as well as their lungs. Consequently their response to pollution from traffic in urban areas, particles and other combustion sources are different to those observed by adults [1]. In addition, children spend more time outside, where the concentrations of our pollution are generally higher. The effects of air pollution in children with respiratory problems might be even higher than recognised.
Overall, evidence for effects of air pollution on children has been growing, and effects are seen at concentrations that are common today. Although many of these associations seem likely to be causal, others require additional investigation [1].

The aim of this work is to identify the children with respiratory problems with ages between 5 to 10 years, studying in the basic schools of the Lisbon city. It will be followed by other studies which will relate air pollution, with acute episodes of respiratory diseases in the same population. The identification was made by simple core questionnaires which followed other identification study – ISAAC - International Study of Asthma and Allergies in Childhood. ISAAC was formed in 1991 to facilitate research into asthma, allergic rhinitis and eczema by promoting a standardised methodology. ISAAC developed from a merging of two multinational collaborative projects each investigating variations in childhood asthma at the population level. It was a unique project which has attracted worldwide interest and unprecedented large scale participation. The aims of ISAAC were to describe the prevalence and severity of asthma, rhinitis and eczema in children living in different centres and to make comparisons within and between countries [2]. The study has included the city of Lisbon, and the results of this work will be compared with the results obtained in this 2002 international study.

The first part of the questionnaire identifies children with wheeze symptoms. Wheeze is a continuous, coarse, whistling sound produced in the respiratory airways during breathing. For wheezes to occur, some part of the respiratory tree must be narrowed or obstructed, or airflow velocity within the respiratory system is higher. Wheezing is commonly experienced by persons with a lung disease.
The aim of the second part of the questionnaire is to identify asthmatic children, a chronic disease of the respiratory system in which the airway occasionally constricts, becomes inflamed, and is lined with excessive amounts of mucus, often in response to one or more triggers. These acute episodes may be triggered by such things as exposure to an environmental stimulant (or allergen), cold air, exercise or exertion, or emotional stress. In children, the most common triggers are viral illnesses such as those that cause the common cold. This airway narrowing causes symptoms such as wheezing, shortness of breath, chest tightness, and coughing. Between episodes, most patients feel fine. The symptoms of asthma, which can range from mild to life threatening can usually be controlled with a combination of drugs and environmental changes.

The third part aims to identify children with rhinitis symptoms and hay fever. Rhinitis is the medical term describing irritation and inflammation of the nose. The primary symptom of rhinitis is a runny nose. It is caused by chronic or acute inflammation of the mucous membrane of the nose due to viruses, bacteria or irritants. The inflammation results in excessive mucous production producing a runny nose, nasal congestion and post-nasal drip. Hay fever is caused by pollens of specific seasonal plants in people who are allergic to these substances. When these symptoms are caused by pollens, the allergic rhinitis is commonly known as "hay fever", after the fact it is most prevalent during haying season. Allergies are caused by an oversensitive immune system, leading to a not direct immune response. Allergy occurs when the immune system reacts to substances (allergens) that are generally harmless and in most people do not cause an immune response. As noted above, hay fever involves an allergic reaction to pollen. A virtually identical reaction occurs with allergy to mould, animal dander, dust, and similar inhaled allergens. Particulate matter in polluted air and chemicals which can normally be tolerated can greatly aggravate the condition.

The ISAAC work concludes that there are several factors which might trigger acute episodes, or on other hand, be protective about respiratory systems diseases.
The last part of the questionnaire, follows this principle as described in the ISAAC studies, and gathers the information about these factors, so that later conclusions can be found.

METHODS

It has been established a contact with the ISAAC coordinator in Portugal – Dr. José Eduardo Rosado Pinto, prior to the study start. This contact lead to the elaboration of the questionnaires based on the ISAAC study.
The next step involved the contact with all the basic schools in the city of Lisbon, to present the project and to get authorization to deliver the questionnaires to the students. The questionnaires were delivered from June 2006 to the participating schools. At the same time oral presentation to the teachers and meetings with the school coordinators took place to explain the main targets to be achieved, and to motivate the filling of the questions and improve the number of students with answers. The distribution of the schools in the Lisbon city is shown in fig. 1

Figure 1 Distribution of the participating schools in the city of Lisbon, and number of answered questionnaires for each.

During this period and till February 2007, the data from the questionnaires were processed to make possible a further statistical treatment. As a first step the data treatment included the validation of the data base by comparing the results processed in two independent databases made by two persons.

RESULTS

Tables 1 to 10 resume the results obtained by processing the questionnaires as well as the results obtained in 2002-2003 on the ISAAC work for comparison. The non valid results were eliminated for each question, and was calculated the total number of answers, the percentages in each question in relation to the total number of answers or in some questions in relation to the number of the positive answers.

Table 1 Resume of schools inquiry

As mentioned before, the ISAAC study found some risk and protective factors for the respiratory diseases studied. These factors are given in the tables 11 and 12, as well as the results obtained with our inquiries:

Table 11 Results relative to wheeze protective and risk factors

WHEEZE				
Eating habits				
Factor	**Protective**	**Risk**	**Results from this work**	**ISAAC RESULTS**
Fish		More than 3 times a week	52.9 %	52.8 %
Margarine	More than 3 times a week		12.5 %	20.0 %
Meat	More than 3 times a week		85.4 %	74.6 %
Milk	More than 3 times a week		94.5 %	86.5 %
Potatoes	More than 3 times a week		50.2 %	63.5 %
Fast Food		More than 3 times a week	4.0 %	4.1 %
Medicines				
Paracetamol		At least once a month (recently)	19.0 %	17.0 %
Antibiotics		In the first year of age	49.5 %	53.6 %
Environment				
Lorries Traffic		All day long	7.4 %	6.4 %
Smoking				
Smoking Mother	Now		35.0 %	26.7 %
Smoking Mother		First year of Age	25.9 %	17.8 %

Table 12 - Results relative to asthma protective and risk factors

DISCUSSION

The results obtained in the questionnaires give a good estimate about the respiratory diseases on the urban area of Lisbon, for the children with 5 to 10 years old. The number of inquiries was lower than the ISAAC study, but pretended to gather information about the population in the same area.

The results given are good information of the respiratory diseases for children in the urban city of Lisbon, for a population with a special concern due to their greater risk for these diseases. Although not exactly the same, the results obtained are comparable to the ISAAC study in 2002, which had a bigger population inquired. For this reason we consider our results acceptable and a good snapshot of the respiratory problems in the area studied.

We found 26.7 % (266) of children with wheezing symptoms from which 42.5 % (113) had the symptoms in the last 12 months and with about 30% (80) having 1 to 3 days of illness in the same period. Again for the children that have recognized having this respiratory disease, 18.4 % (53) have wakened up at night at least once in the last year with wheeze and 6.8% (23) had talking limitation again because of the symptoms. Comparing the results found with the ISAAC study for this respiratory disease, we find a very close percentage, although slightly minor in our Inquiry from 2006.

The results show 9.2 % (92) of asthmatic children with ages from 5 to 10 years in the city of Lisbon. This is a significant result for a chronic disease that might be trigged by an environmental stimulant. This fact reveals the importance of a more detailed study relating asthma (and other respiratory diseases) with atmospheric pollution. In addition the comparison with the ISAAC results from 2002/2003 show a slightly increase of the presence of this disease in 2006.

For rhinitis the results obtained are lower then in the ISAAC study, 26.9 % (268) and 31.2% respectively. The majority of these children had rhinitis in the last year, corresponding to 86.6% (238). According to the results obtained for rhinitis, the months where the disease is more evident are March, April and May, and in lower percentage January. This fact confirms the seasonal prevalence of this respiratory problem, more present in the spring months. In addition 21.6 % (59) of the children inquired with rhinitis had an average affection of the daily activities.

For hay fever, we found in our results the same percentage as in the ISAAC study: 2.6% (26). We recognize this percentage could be slightly higher because part of the population inquired could not identify this disease with the related symptoms and therefore did not answer the question.

The results obtained about the eating habits of the children are similar which is expectable as the eating habits should not change in a 5 year period. This is important when relating the risk and protective factors with the results obtained. Since the similarities of this study with the ISAAC 2002, we can conclude that the factors referred in table 11 and 12 may be applicable to the population studied.
The majority of the children of Lisbon have been breastfeed corresponding to 81.5 % (811). The result was very close to the result of the ISAAC questionnaire in 2002 – 82.2%.
For medicines given to children, our results show a big decrease of Paracetamol administration in the first 12 months of life, and in fewer amounts of antibiotics as well, in comparison with ISAAC results.

The children living with frequent Lorries traffic near home is significant: 23.3 % (232), and similar to what was obtained in 2002 (23.9%)
In terms of the smoking habits, it is important to refer the increase in the number of smoking mothers (26.7 in 2002/2003 to 35.0% in 2006), the increase in the number of smoking mothers in the first year of the children (17.8% in 2002/2003 to 25.9% in 2006) and a slightly decrease on the number of smoking fathers (42.0% in 2002/2003 to 39.4% in 2006).

As referred before, table 11 give the main protective and risk factors found in the ISAAC study for wheeze. For the results found in our work, we can consider important risk factor eating fish more than 3 times per week. This corresponds to 52.9% of children only more 0.1% than in the ISAAC study. We also consider important as a risk factor the ministration of antibiotics in the first year of age. It was found 49.5% of the children which is also close to the 53.6% in the ISAAC study.
In terms of protective factors, we found 85.4% of children eating meat more than 3 times a week (74.6% in the ISAAC study) and 94.5% drinking milk more than 3 times a week (86.5% in the ISAAC results). This can be considered the main protective factors for wheeze because of the higher percentage of answers and because the results are close to the results of the 2002/2003 study.
As we can observe in table 12 for asthma, the same considerations made for wheeze referring antibiotics in the first year of age as a risk factor and eating meat more then 3 times a week as a protective factor can also be taken for asthma.

The results found show the importance and the presence of common respiratory diseases in the city of Lisbon, in the same way ISAAC study in 2002 had shown. The percentages were lower than the ISAAC study in 2002 for wheeze and rhinitis which may show a decrease of these respiratory problems in the city. In opposite, there is an increase of the number of asthmatic children.

The data presented will be used in future studies and the main objective is to monitor episodes respiratory problems with atmospheric pollution.

AKNOWLDGMENTS

The authors wish to thank Susana Sarmento and Rita Veloso for the contribution on the data introduction of the questionnaires. This research was subsidized by European Community Found FEDER trough the project POCI2010/AMB/55878/2004 approved by FCT and POCI 2010.

Enhancing visual comfort in classrooms through daylight utilization

Kleo Axarli and Katerina Tsikaloudaki

Laboratory of Building Construction & Physics, Aristotle University of Thessaloniki, Greece

Corresponding email: axarli@civil.auth.gr

SUMMARY

Research has confirmed that the well-being and the school performance of pupils depend significantly on the quality of the luminous environment, which can be achieved through daylight utilization. This paper focuses on the impact of different fenestration systems on the visual comfort achieved in classrooms. Various window locations, clerestories, roof openings and light shelves were examined with regard to indoor daylight conditions. The study was conducted as a parametric analysis, in which models incorporating the above-mentioned systems were generated on the basis of a typical classroom. The outcomes of the analysis enabled the performance evaluation of the examined apertures. The main objective of this study was not only to derive results regarding the performance of each system separately, but also to highlight specific strategies, which would promote daylight admission without increasing the construction and operation costs in school buildings.

INTRODUCTION

Nowadays the merit of daylight is well acknowledged; research has revealed not only its significant impact on our visual system, but also its supportive role on physical and psychological health, improved productivity and performance of the occupants.

These positive effects are highly appreciated in schools, where daylight levels are directly related to student's performance and enable the creation of a pleasant atmosphere for learning and teaching activities. A research conducted in over 20,000 elementary students and 100 schools in three school districts of USA has provided evidence to this statement. It has been found that students progressed 26% faster in reading and 20% faster in math in classrooms with high levels of daylight. Similar findings were observed in classrooms with well-designed skylights and louvers controlling the illumination level [1]. Among the potential mechanisms that may have been responsible for the positive association between daylight and improved performance of students, improved visibility due to higher illumination levels and better lighting quality, mental stimulation, as well as improved mood and well-being are included.

This link between increased daylight levels and improved student performance has motivated the present study. It is focused on the analysis and the evaluation of several daylight strategies for the enhancement of visual comfort in classrooms.

METHODOLOGY

The study was conducted as a parametric analysis, in which models of classrooms incorporating various window locations, clerestories, roof openings and light shelves were generated on the basis of a typical classroom. The fenestration area in the cases under

consideration was assessed in order to comply with the standards provided by the State Organization responsible for the construction of School Buildings in Greece.
A typical classroom, presented in Figure 1, is of rectangular shape, usually side lit with unilateral windows that account for 20% of floor area. For the sufficient shading of the classroom, overhangs are incorporated in the design. The geometrical and optical properties of the classroom's transparent and opaque elements are displayed in Figure 1 and Table 1.

Sun protection of the openings is a crucial part of the school building design in Greece, where clear skies dominate. It aims not only in the reduction of excessive solar heat gains, but also in the limitation of glare caused by direct solar radiation and extreme differentiation of the luminance between internal surfaces. With respect to the orientation, sun protection is usually offered with overhangs, side fins or semi-transparent curtains and movable internal blinds.

On the basis of the typical classroom, the reference model (C_0) was created. It is assumed that the reference model is south orientated, side lit, with an unobstructed view to the sky vault. By changing the geometry, the position and the function of the transparent elements, 5 more models were created. The aim was to include fenestration arrangements offering a variety of ways to admit daylight, using the standard building design and construction. The transmittance of the glazing and the internal reflectances were kept unaltered. It must be mentioned that the decision concerning models' configuration was based on the initial simulation results and the evaluation of the daylight conditions prevailing in the reference case. A brief description of the models is presented below:

- Model C_1 (Figure 2): the area of the glazed surfaces remains unaltered (20% of floor area); a light shelf is added and divides each window into a view area below and a clerestory above, projecting towards both the interior and the exterior of the window façade. Light shelf plays a dual role; it enhances daylight in the space, while protecting it from direct sun radiation.

- Model C_2 (Figure 3): the glazed area is increased to 25% of the floor area. Daylighting is provided by the lateral windows with light shelves (following the configuration of model C_1) located on the classroom's façade, and the additional vertical south-orientated skylights, which are positioned on the roof at a distance of 3.5m.

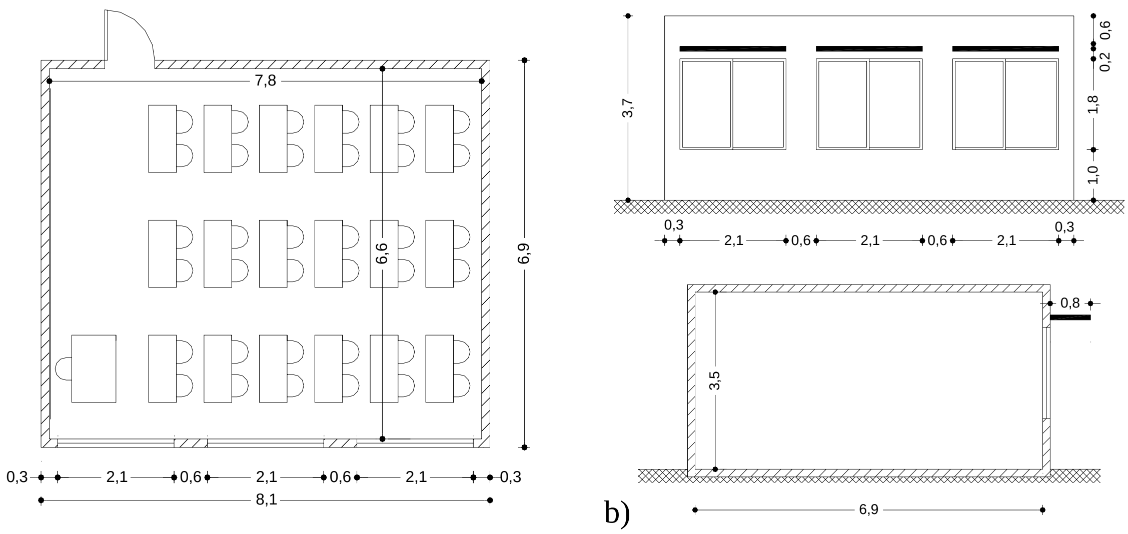

Figure 1. Plan (a), view and section (b) of a typical classroom -model C_0-.

- Model C_3 (Figure 4): the glazed area accounts for 25% of the floor area. Daylighting is provided by the lateral windows with light shelves (following the configuration of model C_1) located on the classroom's façade and vertical, south-orientated skylights, which are positioned on the roof at a distance of 4.6m (accounts for the 2/3 of the classroom's width) parallel to the window wall. In order to improve the daylight distribution, the roof extension beyond the skylight is inclined.

- Model C_4 (Figure 5): the glazed area accounts for 25% of the floor area. Daylighting is provided by the lateral windows with light shelves (following the configuration of model C_1) located on the classroom's façade and additional vertical, north-orientated clerestories positioned on the opposite wall. The roof is inclined across the classroom's width.

- Model C_5 (Figure 6): the glazed area accounts for 25% of the floor area. Daylighting is provided by the lateral windows with light shelves (following the configuration of model C_1) located on the classroom's façade and tilted, north-orientated skylights, which are positioned in two rows on the saw-tooth roof.

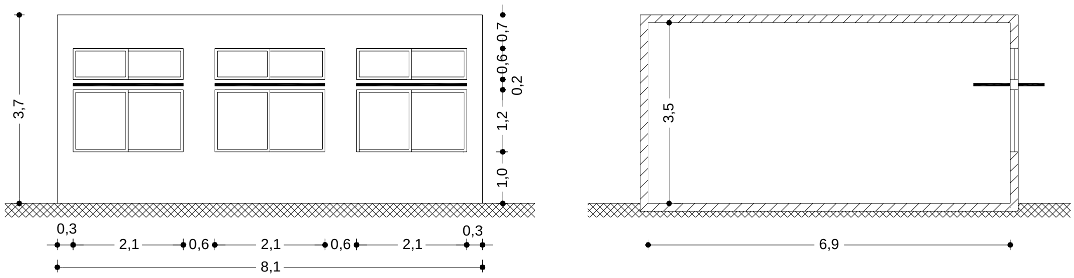

Figure 2. View and section plan of model C_1.

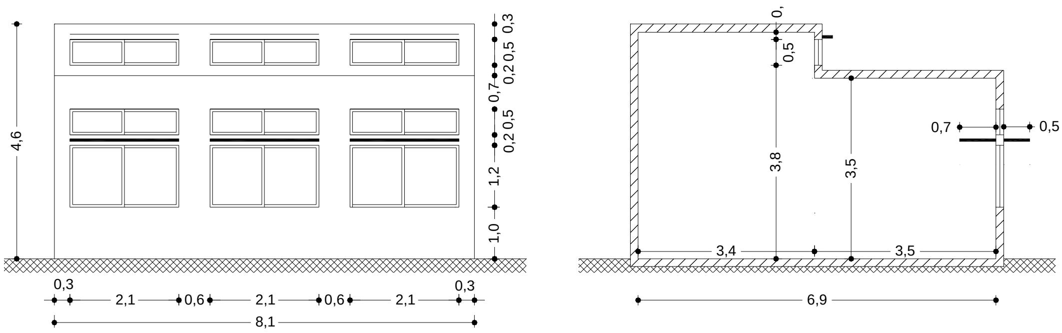

Figure 3. View and section plan of model C_2.

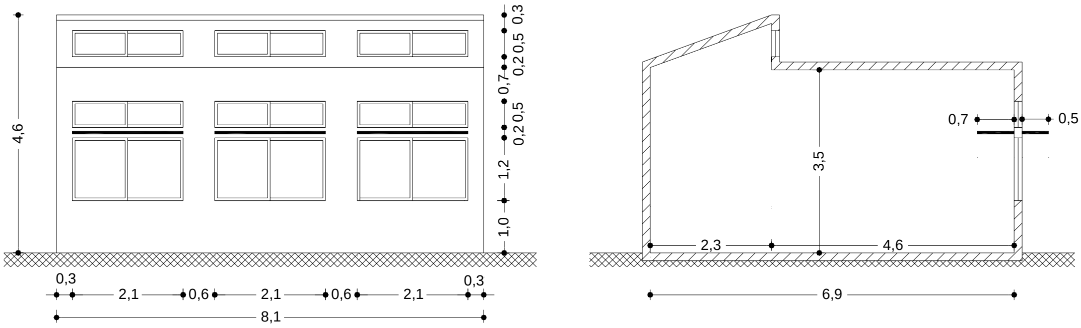

Figure 4. View and section plan of model C_3.

The visual environment prevailing in each case was estimated with the help of the simulation program ADELINE, an integrated lighting analysis tool for building design purposes, developed by the IEA Solar Heating and Cooling Task 12. It uses both radiosity and ray tracing techniques for the estimation and the visualization of daylighting conditions [2]. Details regarding the input data for the geometrical and optical characteristics of the transparent and opaque elements of the reference model C_0 and the models C_1 to C_5 are presented in Table 1. The working plane was regarded at a height of 0.8m above floor level. In order to validate the input data used for the simulations with regard to the local climate, in situ measurements were also conducted. A test cell with southern orientation, located in Thessaloniki, Greece (40^o N), was used for this purpose [3].

For the evaluation of the daylighting conditions prevailing in classrooms, where the adequacy of daylight is the main objective, the daylight factor was considered as the most appropriate parameter for indicating the quantity of admitted daylight and consequently the efficiency of the daylighting design. In bibliography, values of daylight factor ranging from 2% to 5% are reported as satisfactory. Furthermore, the homogeneity of the luminance distribution contributes to the rating of the ability of the daylighting system to attenuate glare. The quality of daylighting can be depicted by the visualization of each classroom’s interior, since the possibility of glare occurrence is associated to the excessive contrast of luminance between the various indoor surfaces. Illuminance ratios, such as minimum-to-maximum can be used in order to quantify lighting uniformity; i.e. ratios between 1:3 and 1:8 are acceptable [4].

RESULTS

The distribution of daylight factor on the working plane of the reference case C_0 and the models of the parametric study C_1 to C_5 are presented in Figures 7(a) to 12(a). The display of daylight factor contours provides a clear interpretation of daylight penetration in the classrooms. The visualization of daylight conditions is shown at figures 7(b) to 12(b). The appearance of excessive difference in luminance distribution is an indication of glare.

In reference model C_0, daylight reaches very high levels in areas near the lateral windows and is reduced across the classroom's length, ranging from 16.8% to 2.8%. The mean daylight factor is equal to 5.4%; however, on approximately 40% of the working surface daylight factor is lower than 3.0%. Moreover, the contrast between daylight levels in the interior of model C_0 often exceeds 1:9. It is therefore indicated that although the average levels of daylight are satisfactory, uniformity of daylight can not be achieved with conventional windows, since adequate daylight can not be admitted deeply in the room.

In order to enhance visual comfort, it is recommended to both moderate illuminance in areas near the windows and promote daylight penetration deep in the room. Towards this direction, light shelves were incorporated in the classroom's openings, in a way that a view window and a clerestory are created, without altering the total area of transparent elements. Their primary function is to redirect daylight to deep areas of the classroom's interior, while providing sunshade. Simulations showed that the light shelves of model C_1 reduced the amount of light received in the interior relative to the conventional windows of model C_0. Daylight factor varies from 15.3% in areas close to the windows to 1.8% in remote zones and is on average equal to 4.3%. Moreover, for almost half of the working surface, the daylight factor is lower than 3.0%. However, the luminance distribution is better and the contrast between minimum and maximum values is limited to 1:8 (fig. 8a & 8b). Such a behavior has also been observed in similar studies for light shelves [5].

With the intention of increasing daylight levels without decreasing uniformity of illuminance distribution, south-orientated vertical skylights were introduced in two models (C_2, C_3). The minimum and maximum values of daylight factor were found to be approximately equal in both models (2.4% and 16.5% respectively), but the average daylight factor was slightly higher in model C_2 (5.1%) than in model C_3 (4.9%). It is therefore obvious that the skylights of model C_2, located across the middle of the model's width, performs better as regards daylighting, when compared with those located at the 2/3 of the classroom width.

Since in Mediterranean climates, such as that of Greece, thermal performance is also very important especially during the hot months, north orientated clerestories placed on the back wall were also examined, given that south orientated apertures are associated with increased solar gains. The illumination in model C_4 ranges in high levels -the average daylight factor reaches 17%-, but the zone formed from values of daylight factor between 2.0% and 3.0%

Daylight factor (it is applied to the diagrams of Figure 7a to Figure 12a):

0,0-1,0 · 1,0-2,0 · 2,0-3,0 · 3,0-4,0 · 4,0-5,0 · 5,0-6,0 · 6,0-7,0 · 7,0-8,0 · 8,0-9,0 · 9,0-10,0 · 10,0-11,0 · 11,0-12,0 · 12,0-13,0 · 13,0-14,0 · 14,0-15,0 · 15,0-16,0 · 16,0-17,0 · 17,0-18,0

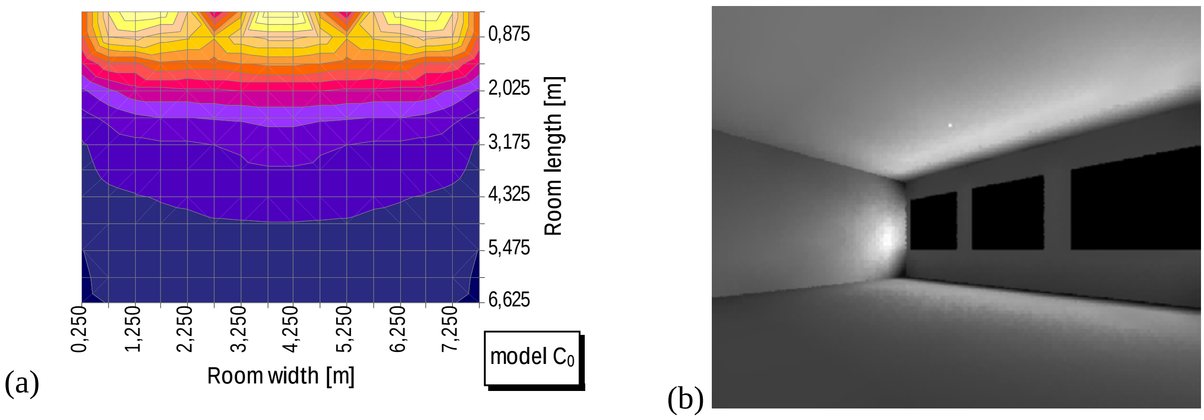

Figure 7. The distribution of daylight factor (a) and the visualization of indoor daylight conditions (b) prevailing in reference model C_0.

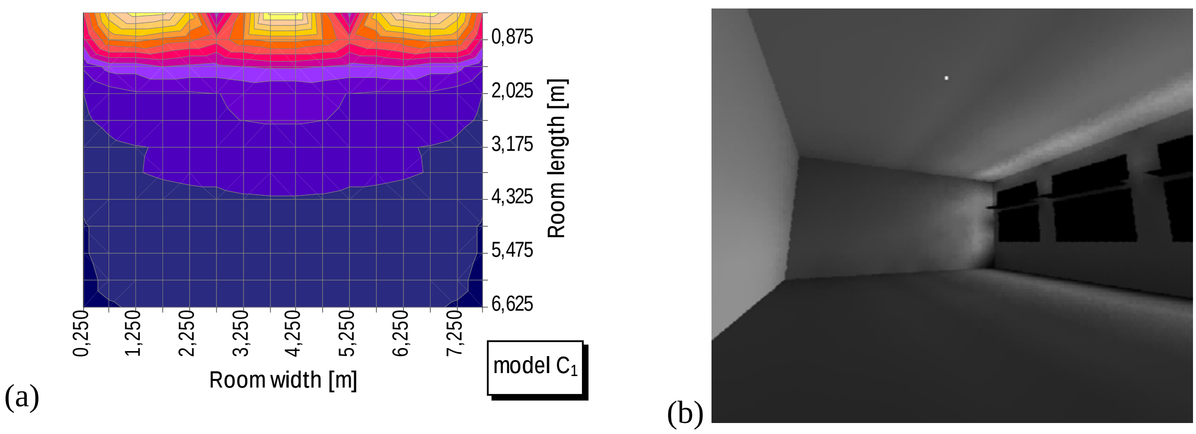

Figure 8. The distribution of daylight factor (a) and the visualization of indoor daylight conditions (b) prevailing in reference model C_1.

appears to be wider than the ones in models with south orientated skylights. The decrease of daylight factor in remote areas and the simultaneous increase of maximum values near the windows indicate a less uniform distribution of daylight on the working plane and consequently a probable discomfortable visual environment (Figures 11a and 11b).

On the other hand, when the north orientated apertures are tilted and arranged as skylights in the form of a saw-tooth roof, daylighting is significantly enhanced, despite of the absence of

the light shelves. Not only there is an overall increase of daylight factor on the working plane, but also the uniformity of its distribution is considerably intensified. The daylight factor ranges from 3.1% to 17.3%, representing a ratio of minimum to maximum equal to 1:6.

CONCLUSIONS

The above analysis has showed that many alternatives regarding the location of openings exist for the enhancement of daylighting in classrooms. It is found that a combination of façade and roof apertures performs better than advanced façade systems (e.g.light shelves). Also, skylights, clerestories and double side openings are better to be used instead of unilateral façade windows.

From the examined models the north orientated skylights arranged in a saw-tooth roof combined with south windows appear to have the best performance. They bring more daylight in the rear areas, where illumination levels are low, daylight distribution becomes balanced and glare is avoided to a great extent as well.

The construction of such a configuration is neither complicated nor expensive; on the contrary its benefits encompass visual comfort, sustainability and quality of life.

Thermal Comfort in a Naturally Ventilated Office Building in Karlsruhe, Germany – Results of a Survey

Andreas Wagner, Cornelia Moosmann, Thomas Gropp, Elke Gossauer

Division of Building Science, University of Karlsruhe, Englerstr. 7, D – 76131 Karlsruhe, Germany

Corresponding email: andreas.wagner@fbta.uni-karlsruhe.de

SUMMARY

In order to compare measurements and subjective votes on thermal comfort in a non-conditioned indoor environment under German climate conditions, a field survey was carried out in an office and laboratory building in Karlsruhe during July 2005. Over a period of 4 weeks 50 subjects filled in questionnaires twice a day every Tuesday and Thursday and accompanying measurements were carried out at the workplaces. 90% of the votes on thermal sensation proofed the room temperatures to be "just right" or "slightly warm"; these votes cover ranges of more than 5 Kelvin of the operative temperature and also include 7.5% temperatures above 27°C. About 75% of all votes rated the indoor climate neutral or better although the room temperatures showed fluctuations in space (rooms of the building) and time (period of the study).

INTRODUCTION

A field study in a German office building was carried out to address the topic of thermal comfort and accepted indoor temperatures during summer, which is of great importance particularly in naturally ventilated and passively cooled buildings. Several studies (e.g. [1], [2], and [3]) showed that the subjective votes of occupants in naturally ventilated or passively cooled buildings correspond with a temperature band dependent on the outdoor temperature under transient summer conditions. With the introduction of the European "Energy Performance of Buildings Directive" an increasing number of commercial buildings without air-conditioning will be realized in the future. Therefore further knowledge is necessary about the perception and acceptance of a varying indoor thermal environment particularly during summer also taking into account future climate changes. Additionally, more experience with field surveys on thermal comfort has to be gained in comparison with climate chamber experiments.

DESCRIPTION OF THE BUILDING AND EXPERIMENTAL SETTINGS

The field study was carried out in an office and laboratory building situated on the campus of the "Forschungszentrum Karlsruhe", Germany. The building has a net area of approximately 5,300 m² and includes an older existing part and a new extension built in 2004, both accommodating (mostly smaller) offices as well as laboratories for chemical experiments. All offices in both building parts are ventilated naturally all year whereas the laboratories are ventilated mechanically due to the special requirements for these workspaces.

The new extension building was built as a low energy building comprising features like high heat insulation standards, a passive cooling concept for the offices as well as high daylight availability. Its thermal mass is discharged by night ventilation due to the stack effect in a central staircase, with cold outside air coming into the building through remote-controlled skylight windows in the offices. The older part of the building has suspended ceilings in the offices and less insulation of the building envelope. No passive cooling is used and it was therefore expected that the occupants' comfort perception would reflect the differences of the thermal behaviour of the two building parts.

During the study, which was carried out in July 2005 over a period of 4 weeks, short questionnaires had to be filled in by the participants twice a day every Tuesday and Thursday, resulting in 16 single surveys during the 4 weeks. In the questionnaire all aspects relevant to comfort, like room temperature, air velocity, humidity, air quality and light were addressed. Two slightly different questionnaires were used for the morning and the afternoon survey to gain some specific information related to the expectations about the indoor climate on entering the building and to changes of the indoor climate during the day. All questions had to be answered within a 5-point-scale by the participants. Sections for free comments were also provided.

A total number of 50 subjects who regularly work in the building participated in the whole study with half of them completing 9 or more single surveys (out of 16 in total). The surveys were accompanied by measurements of the relevant thermal comfort parameters during the time the questionnaires were filled in by the subjects. Additionally, the indoor air temperatures and relative humidity were recorded continuously throughout the 4 weeks in those rooms were the survey was carried out. Outdoor climate data for the site were available for the whole period. Further information on the experimental procedure is given in [4].

RESULTS OF QUESTIONNAIRES AND MEASUREMENTS

The study was carried out in a period which represented a typical but not very hot summer month for Karlsruhe with temperature maxima above 30°C on five days and distinct temperature differences between day and night on most of the days. The variations between single days and between shorter periods of similar climate conditions were strong enough to expect some affect on the subjects' votes. Radiation, temperature and humidity data are given in [4].

The resulting indoor temperatures for this period are given in figure 1. The room temperatures lie in an acceptable range for most of the time; only the temperatures in the rooms on the second floor of the old part of the building exceed 26°C for almost 50% of the whole period. The old part of the building shows a stratification of temperatures between the single floors. In the new part of the building, temperature differences between the floors are much smaller. All floors here show temperatures similar to the first floor of the old part. The effect of night ventilation is very different, both between the two parts of the building and between floors. Temperatures in the new extension did not often decrease below 23°C, even if the outdoor temperature was below 20°C at the same time. The second floor of the old building part without night ventilation hardly showed any cooling effect during the nights whereas the ground floor had the same characteristic as the new extension.

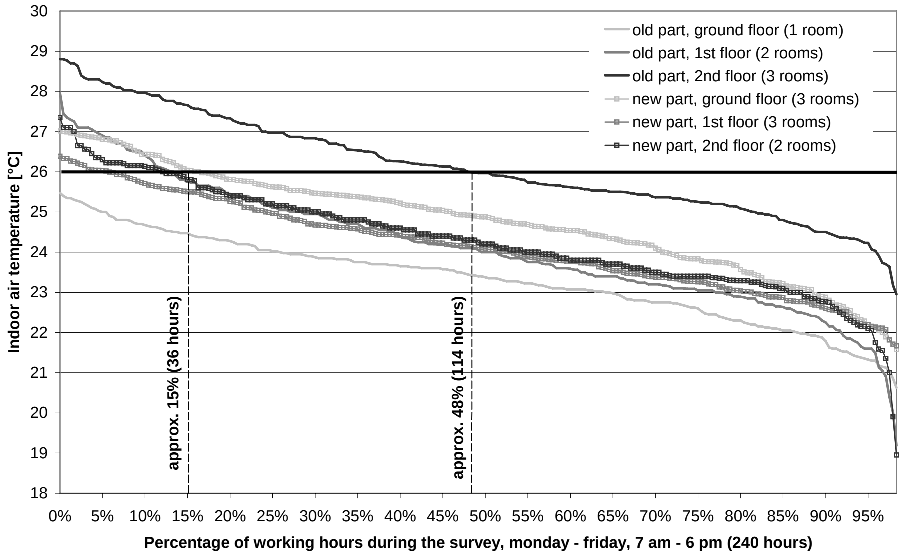

Figure 1. Indoor air temperatures in the rooms where the surveys were carried out. The bold black line at 26°C corresponds to the temperature limit of the German workplace regulations.

In figure 2 the votes for thermal sensation are given subject to the operative indoor temperature. The votes for "just right" and "slightly warm" represent 90% of all votes. They cover ranges in operative temperatures of more than 5 Kelvin and also include temperatures above 27°C. The votes for "very warm" (7% of all votes) cover a range from 25 to 30°C.

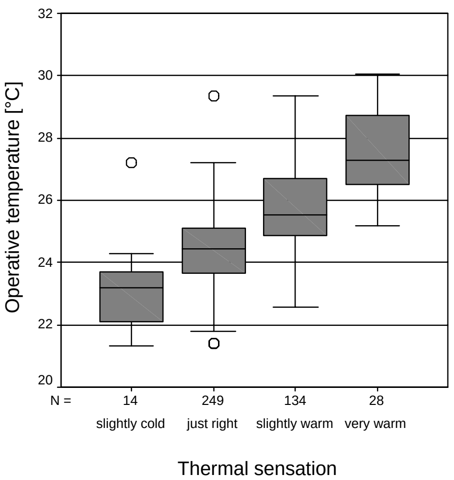

Figure 2. Box plot of votes of thermal sensation against operative temperature in the rooms. The lines in the boxes represent the median values, the grey boxes cover the mean 50% of the values and the thin lines show the whole range of all values. The small circles indicate outlines. The analysis of variance shows a significant correlation between operative temperature and votes of thermal sensation ($\alpha=0.05$, $p<0.001$, $N=425$).

Further analysis shows that the occupants accept higher temperatures in the upper floors – the median of the vote "just right" is at 24°C on the ground floor and 25°C on the second floor (see figure 3). This is also true for differences between the old and the new part of the building where the mean votes of "slightly warm" and "very warm" also differ significantly by up to 1.8 Kelvin ($\alpha=0.05$, $p=0.001$, $N=133$ for "slightly warm" and $N=27$ for "very warm").

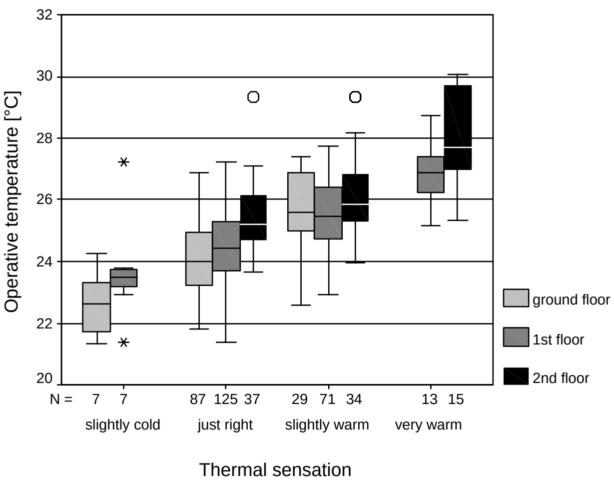

Figure 3. Box plot of votes of thermal sensation against operative temperature for the different floors of the building. The lines in the boxes represent the median values, the grey boxes cover the mean 50% of the values and the thin lines show the whole range of all values. The small circles indicate outlines. The analysis of variance shows a significant difference between the measured temperatures that are voted "just right" for the different floors ($\alpha=0.05$, $p<0.001$, $N=249$).

An increase of the indoor temperature during the day was perceived by approximately 66% of the participants which relates to the character of a free-floating building. Figure 4 shows that temperature ranges for thermal sensation votes are different in the mornings (8 a.m. to 10 p.m.) and in the afternoons (2 p.m. to 4 p.m.). In the afternoons, temperatures are judged "cooler". The median temperature of the vote "slightly warm" is 24.9°C in the mornings. This temperature is below the median value of "just right" in the afternoon (25.2°C). The median temperatures of the same votes are about 1.3°C higher in the afternoon.

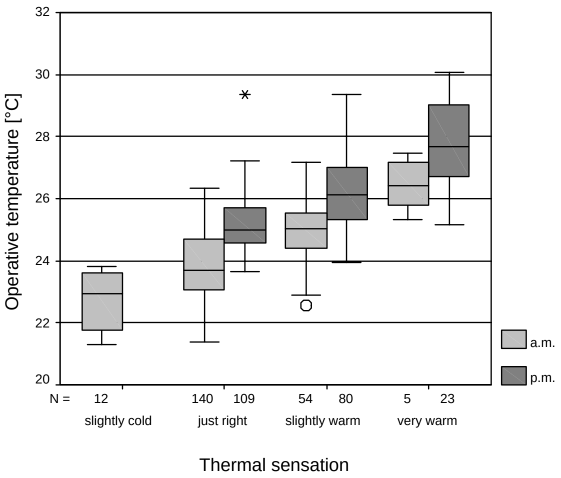

Figure 4. Box plot of votes of thermal sensation against operative temperature in the rooms in the morning and in the afternoon. The light grey boxes cover the mean 50% of the values in the mornings, and the dark grey boxes show the votes in the afternoons. The group "slightly cold" in the afternoon (n=2) has been excluded in the box plot. The analysis of variance shows a significant difference between votes in the mornings and in the afternoons ($\alpha=0.05$, $p<0.001$, $N=425$).

Analysis of the clo-values showed that most persons did not change their clothes on the days the surveys were carried out. The results also showed that the occupants used to open the windows more often in the morning (with cooler outdoor temperatures) compared to the afternoon but there is no indication from the measurements that the indoor temperature was influenced strongly. However, a rather large number of persons did not stay in the room between the two surveys but worked in a laboratory. They re-entered the office approximately 15 to 30 minutes before the afternoon survey.

Regarding the whole survey period the temperature range which is judged as "just right" varies significantly (α=0.05, p<0.001, N=249). Figure 5 shows that the ranges of July 5th, 7th and 21st equal each other, 12th and 19th are similar and July 14th and 28th show the highest temperature ranges voted as "just right". In the mornings, the lowest median temperature voted "just right" is 23.2 °C on July 21st; the highest median temperature is 25.2 °C on July 28th. In the afternoons, the lowest median value is 24.2 °C on July 7th and the highest value is 27.2 on July 28th. The maximum differences in median temperatures for the vote "just right" are 3 K in the mornings and 3 K in the afternoons with 2 K higher median values in the afternoons. It has to be taken into account that the clo-values change significantly throughout the period. People dress themselves according to the outdoor temperature, as can be seen in figure 5.

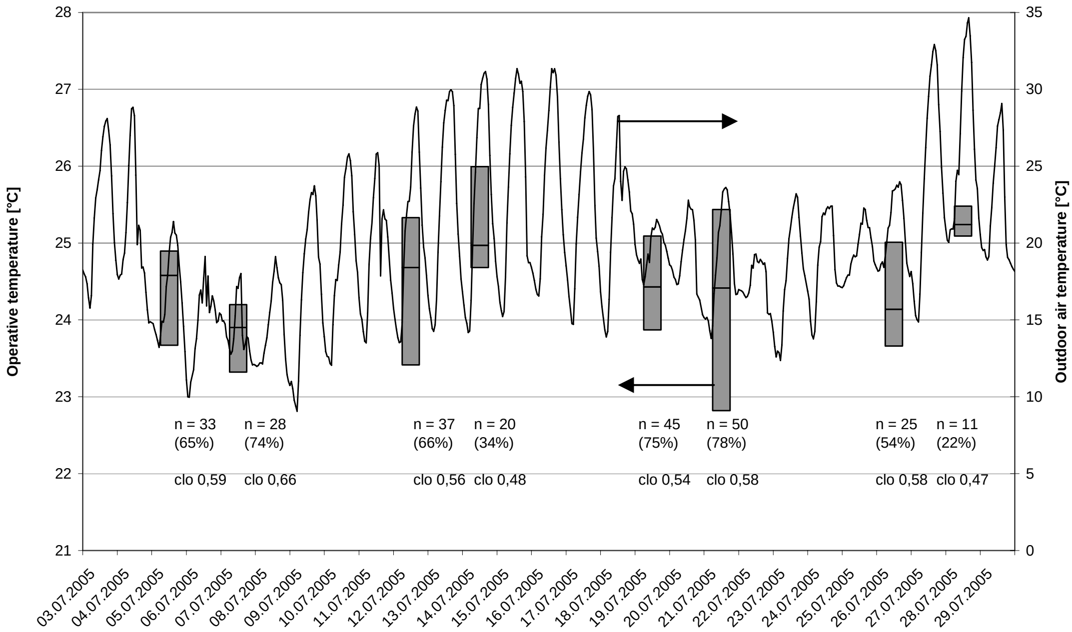

Figure 5. Outdoor air temperature during the whole study and operative indoor temperatures which were judged "just right"; the lines in the boxes represent the median values and the grey boxes cover the mean 50% of the values.

On all eight days most the participants (76%) expected the outdoor temperature to be as it was after they left their homes in the morning. No rules could be found for those votes where expectations were not fulfilled. The results for expectations concerning the indoor temperature before entering the workspace are similar: again, the majority (72%) expected the indoor temperature to be as it was on all days. If the expectations were not met the votes were mainly "slightly warmer" or "much warmer" (84%). Some of these votes can be explained by the cool outdoor temperature on that day or by unexpected changes in temperature. However, the number of votes / subjects is too small to obtain statistically significant correlations.

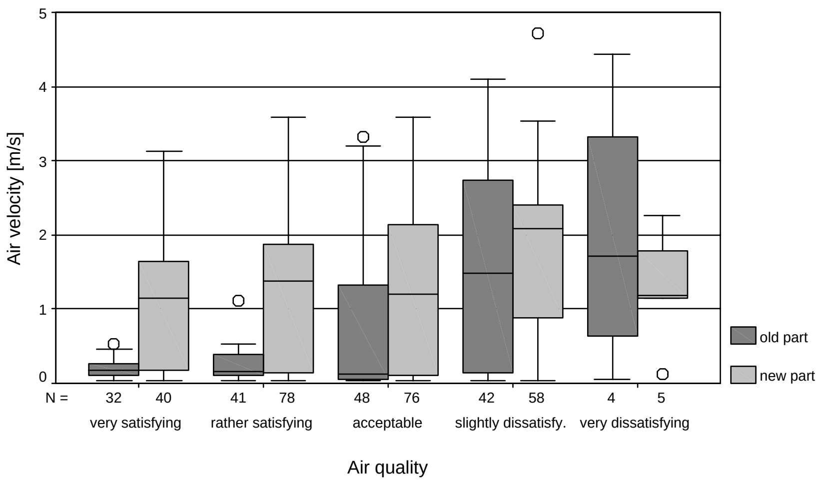

Figure 6. Box plot of votes of the perception of air quality against air velocity in both parts of the building. The dark grey boxes represent the values in the old part of the building, and the light grey boxes show the votes in the new part. The perception of air quality is not significantly different for both parts, air velocity differs significantly ($\alpha=0.05$, $p<0.001$, N=427). The correlation between air quality and air velocity is significant for the old part ($\alpha=0.05$, $p<0.001$, N=167) but not for the new part ($\alpha=0.05$, $p=0.006$, N=257).

With respect to perceived air movement the occupants wished to have higher air velocities with a thermal sensation of "slightly warm" or "warm". Subjects demanding stronger air movements felt no or only a slight movement (chi^2: $\alpha=0.05$, $p<0.001$, N=211). The evaluation of air quality also correlated significantly with the operative temperatures (analysis of variance: $\alpha=0.05$, $p<0.001$, N=424); negative votes were mostly "stuffy" and "sticky" coinciding with higher room temperatures. In figure 6 it can be seen that the air velocities increase with worse votes on air quality in the old part of the building. It seems that the occupants try to compensate the situation – bad air quality mostly as a synonym for high temperatures – by ventilating their offices.

The votes on thermal sensation, indoor air quality and overall indoor climate correlate with each other with a high level of significance. The self-reported productivity also corresponds significantly with these three parameters, and to the reported feeling (bad/well, tired/alert, hard/easy to concentrate on the work, depressed/in a positive mood). Figure 7 shows that only 9 votes out of 425 evaluated the (overall) indoor climate as "very unsatisfying" and 95 votes as "slightly unsatisfying". These votes correspond to a majority of votes of "very warm" and "slightly warm" for the thermal sensation. The neutral and positive votes on indoor climate coincide well with a large acceptance of the indoor temperature.

DISCUSSION OF THE RESULTS AND CONCLUSIONS

The methodology of the survey proofed to be practicable but very intensive for both the subjects and the researchers. After 4 weeks the motivation of the participants seemed to decrease which gives a hint for limiting extensive field studies to similar periods. The acceptance of the surveys was very high, probably because the participants were mostly scientists as well. The study in this particular building had two major shortcomings:

- the participants were not available for all surveys resulting in disparate samples for the single surveys;

- the participants did not work in their offices for the whole day and therefore experienced different room climates (particularly the climate in the mechanically ventilated laboratories).

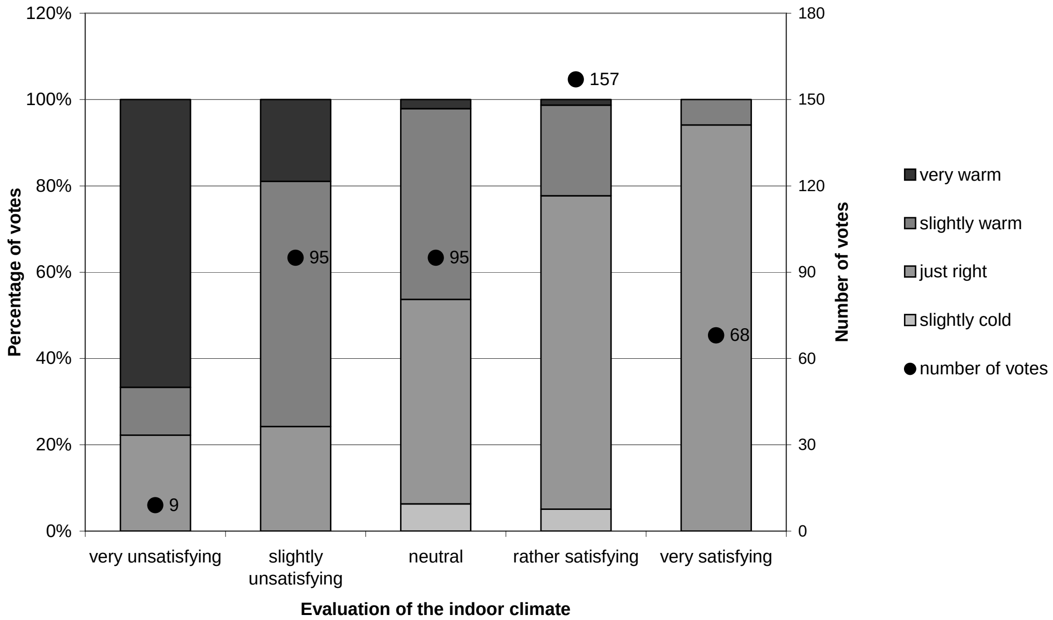

Figure 7. Relationship between votes of thermal sensation and overall satisfaction with the indoor climate

The results of the study show that a positive perception of thermal comfort is not limited by a sharp limit of the indoor temperature. Even the votes "just right" on the thermal sensation include operative temperatures higher than 27°C. About 75% of all votes rated the indoor climate neutral or better although the room temperatures showed fluctuations in space (rooms of the building) and time (period of the study).

On the other hand, the temperature levels in most monitored rooms were rather moderate with only 15% of the working hours of the whole period (240 hours) showing temperatures above 26°C. This proofs the good design of the building, particularly of the new part, in terms of passive cooling. The exception was the second floor of the old part of the building with 114 working hours above 26°C but below 29°C. In this part of the building, 50% of the indoor climate votes are negative, which is significantly above average (25%).

Regarding the fluctuations of temperatures and coinciding thermal sensations in different parts of the building it was found that occupants seem to accept higher temperatures in their offices. Their positive votes correlate to higher temperatures on the upper floors and in the old part of the building compared to other offices in the building. It was also found that the votes of thermal sensation correlate with the outdoor temperatures. The median temperature ranges of positive votes (e.g. "just right") are higher in the afternoon and on days with higher outdoor air temperatures. These findings are in agreement with other results on adaptive thermal comfort (e.g. [1], [2], and [3]).

The study showed that naturally ventilated and passively cooled buildings can be highly appreciated by occupants during summer if they are designed properly in terms of the indoor climate. Positive perceptions of thermal comfort do occur outside the temperature limits set in standards for air conditioned buildings. The study therefore confirms that adaptive comfort models are more suitable to predict the thermal sensation and thermal comfort of occupants, if periods with transient indoor (and outdoor) climate conditions are considered. This is mostly true for summer climate conditions, during which the study had been performed.

SUMMARY

In this article the concept of a new energy-efficient office building and results of a 3-year monitoring are described. The monitoring was performed within the German funding programme EnOB [1]. In this building most of the offices are naturally ventilated and passively cooled. One aspect of the passive cooling is the nocturnal ventilation operated automatically by the building's control system. Another focus of the energy concept is on regenerative heating with wooden pellets.
Monitoring results show that the integrated planning enabled a very low consumption of energy for heating, ventilation, cooling and lighting. The monitoring could help to reveal operating problems and to lower the usage of energy. Though passively cooled, the rooms provided good thermal conditions. The given limits of room temperatures were exceeded only in an acceptable manner. Good air quality could be achieved just by natural ventilation.
In this article first the building and energy concept is described. Then results of the monitoring are shown, with a focus on the passive cooling concept and the achieved user comfort.

INTRODUCTION

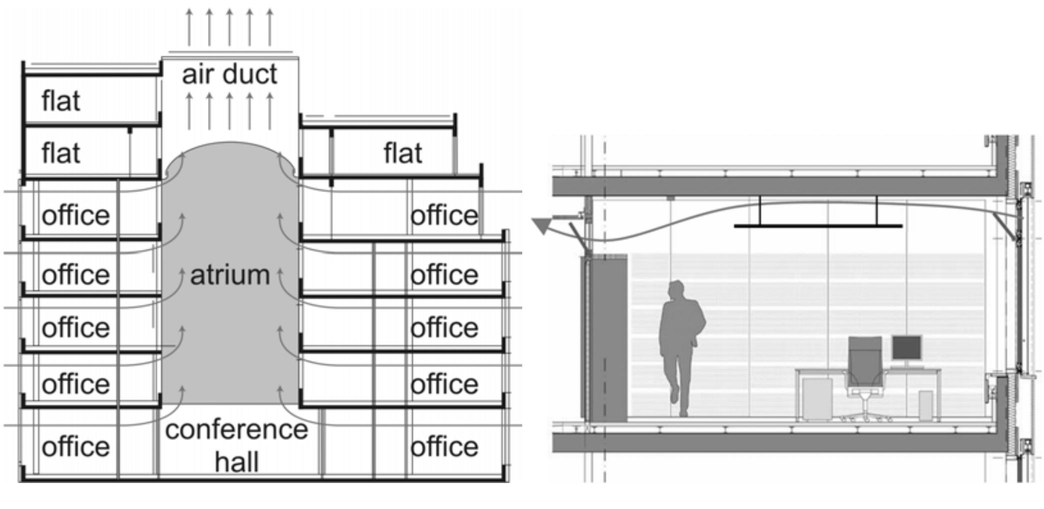
Air-conditioning and active cooling contribute significantly to the energy consumption of a lot of existing office buildings, particularly if primary energy is taken into account. Passive cooling strategies can diminish the energy consumption for cooling.
In new office building "East Arcade" of the KfW bank group (Figure 1) passive cooling and nocturnal ventilation are main aspects of the energy concept. The building is a demonstration project within a German funding programme by the Ministry of Economy and Technology. To apply for the programme the anticipated total annual primary energy use (heating, ventilation, cooling and lighting) had to be below 100 kWh per m² net floor. This was an ambitious aim but it could be achieved, as examination of 25 buildings has shown [2].

Building and Energy Concept

In order to achieve the strict given criteria an integrated architecture and energy concept had been designed. The new building was completed in 2002 and has space for 300 employees. Five of the seven floors are used as offices and the two top floors as apartments. The offices are arranged around an atrium which plays a central role in the passive cooling concept as it is used for night venting the building. It also increases the compactness of the building (area-volume ratio is 0.25 m^{-1}) and - combined with a good insulation - minimizes the heat loss through the façade. The energy for heating is provided by a pellet boiler and a condensation boiler handling peak loads. The pellets cover about 75% of heating energy throughout the year. The offices are heated by radiators mounted on the balustrade.

Figure 1. The south-elevation of the new KfW building

Moderately glazed areas with high selectivity and an efficient automatic external shading system help to reduce the ambient heat loads during warm weather conditions. Only rooms with high heat gains are conditioned by active cooling. For that purpose a heat exchanger derives part of the cooling energy from the fresh water supply.
However the majority of the offices is cooled passively by nocturnal ventilation and activating the building's thermal mass. Thereby the natural ventilation concept utilizes the stack effect in the central atrium (Figure 2a). For this purpose the skylights in the façade and towards the hallways are opened automatically during night. The concrete ceiling is exposed (without suspended ceiling) for optimal heat exchange with the air (Figure 2b).
In addition to the night venting option the rooms offer the opportunity for day-time (single-sided) natural ventilation by manually operable windows and skylights. Here the user can determine the opening times of the skylights himself or choose a short-term ventilation on the control panel, lasting for 3 minutes.



a) b)

Figure 2: a) Cross section of the KfW building with the central atrium, showing air flow pathway during night ventilation. b) Section through an office.

Two main objectives were defined. According to the EnOB-programme the total primary energy use should be lower than 100 kWh/m².
Furthermore the temperatures in the offices should not exceed a defined upper temperature limit during more than 60 hours a year, which is 60 hours with the attendance of the user. According to the decision of a German regional court in 2003 [3] the temperature in offices should not rise over 26 degrees until ambient reaches 32 degrees. Over 32°C outside there should be a minimum difference of 6 Kelvin between ambient and inside temperature.

METHODS

In this project energy consumption, operation of the technical equipment and the occupants' comfort conditions have been monitored since May 2003, using about 300 sensors. One main focus was to check whether the real measured values would match the planned and predicted energy consumption of the building. Therefore the circuits for heat and cold supply were equipped with heat meters. Facilities using much electric energy were stocked with electric meters. For examining the user's comfort room air temperature and CO_2-concentration in some representing offices have been recorded. Additionally the state of the sun blinds, the windows and the window skylights were stored to provide information about the user's behaviour and the function of the automatic building control. Also the efficiency of the passive cooling concept was observed, completed by temperature sensors mounted into the ceiling. Continuous data were recorded in 10-minute-intervals, event data like the opening of a window were recorded in real-time. Every night the data was exported by the control system into different text files on a computer on site and transferred to a database on a server at university.

RESULTS

Energy Consumption

Regarding the final energy usage of the building the energy for heating was detected as the major part. To this point constantly high supply temperatures for the heating circuits of up to 90°C were measured even during summer. The reason was that two supplemented hot water boilers needed permanently high temperatures. The high supply temperatures and active heating circuits lead to heat losses even during summer.
High exhaust temperatures of the pellet boiler revealed a further problem. An expert report indicated that the efficiency of the boiler was too small which led to a higher consumption of the wooden pellets.
Regarding primary energy heating has less influence, as wooden biomass is regarded with a primary energy ratio of only 0.2 whereas electric power is multiplied by 3.0.
The mechanical cooling for the IT and technical service rooms used a big amount of primary energy. The cooling machine runs with electrical power, its COP (coefficient of performance) is only 2.6. In the beginning in a lot of IT rooms set temperatures of 20°C made the cooling run even 24 hours a day. Changing the operation rules and rising the set temperatures to 26°C helped significantly to save both electrical power for ventilators and energy for cooling.
This is just an example of how monitoring can help to reveal problems and reduce and optimise the energy consumption of a building. Thereby the main problem weren't necessarily conceptional flaws but an improper operation of the technical equipment.

Figure 3 shows the total primary energy consumption of the building for 3 measured years and expected values for the 4th year.

During the three years of monitoring not only problems could be found but it also was shown that the building had a very low energy consumption compared to usual office buildings. The performance of ventilation and lighting turned out to be very good and user comfort could be achieved without active cooling.

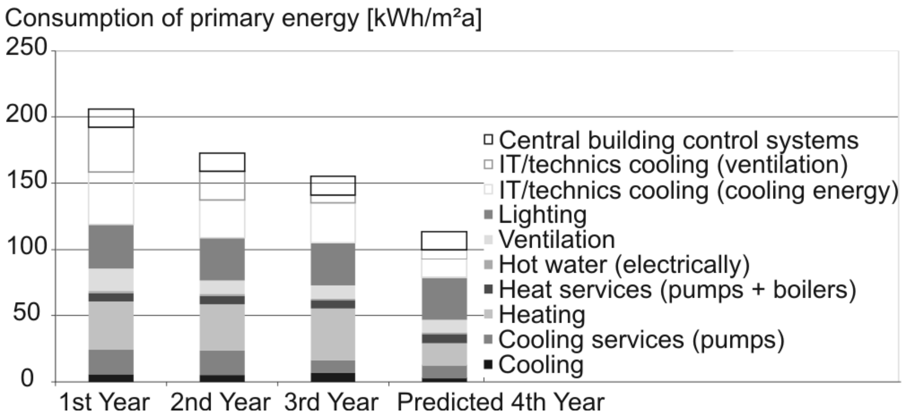


Figure 3: Primary energy consumption during the 3 years of monitoring including a prediction for the fourth year, all according to criteria of the funding programme. Energy for building control and IT-cooling is marked differently as it is not included in each of the compared buildings from the programme.

Passive Cooling

In addition to a glazing of low energy transmission and reduced internal heat loads an automatic shading system supports the passive cooling concept during summer days. For every room an integrated shading calendar of the control system calculates whether the sun hits the façade and whether the blinds have to be closed. The user is able to override the automatic regulation by the control panel in his room.

Within the monitoring project the positions of blinds have been recorded in 30 different rooms on all sides of the building. Looking at the average time that a blind is closed one can see that during summer the rooms are shaded up to 6 hours a day (Figure 4). The blinds are regarded as closed if more than 50% of the window is covered. From November until the end of February the average closing time is less than one hour a day.

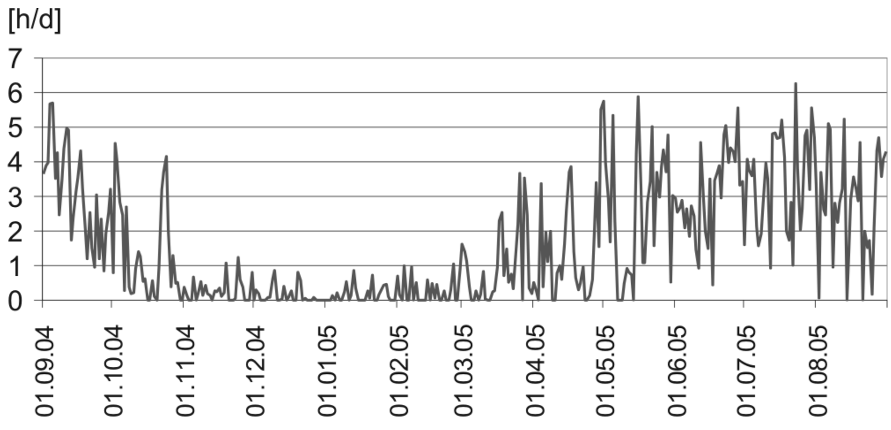

Figure 4: Average closing time of blinds during the day in all 30 measured offices

If you consider the percentage of rooms with closed blinds during a day separated by the orientation you can find out if the shading calendar is working properly. In Figure 5 it is evident that blinds on the eastern façade move down much earlier than the southern or western ones. Shading of each orientation is stopped automatically at a fixed time when the sun cannot hit the façade anymore. Beside a small number of western offices being regulated like southern rooms the function of the shading calendar does not reveal any remarkable failures. During winter it is only the southern façade with blinds being closed.

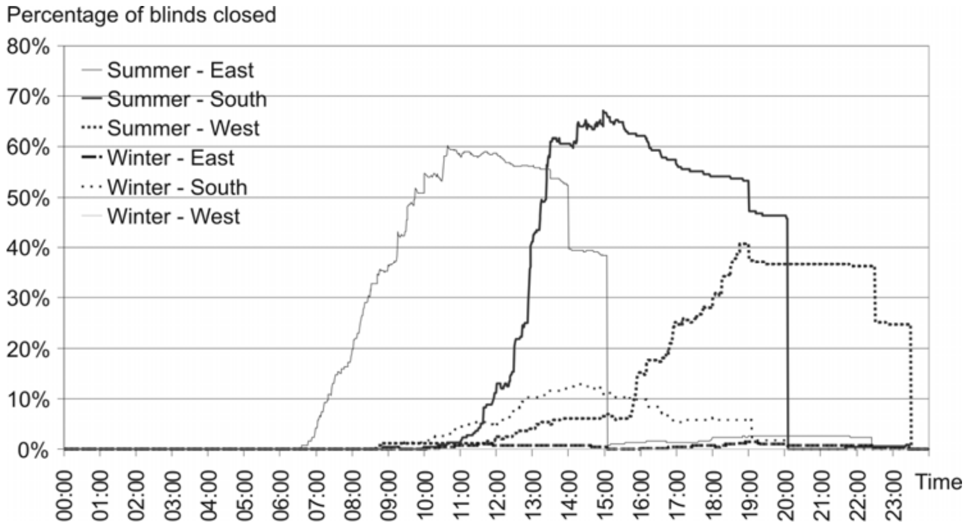

Figure 5: Average percentage of rooms with the blinds closed during a typical day in summer and winter

In order to obtain information on the effect of room air temperatures on the thermal behaviour of the concrete ceilings during night ventilation the temperatures of the ceiling (on the surface and in a depth of 4 cm) were recorded in ten offices.

In rooms featuring exposed concrete ceilings there was a pronounced effect of the room air temperature on the ceiling temperatures. Figure 6 shows how the cooler air temperature reduced the ceiling temperatures. On the other hand, some offices had suspended ceilings in which case there was no correlation between the room air and the ceiling temperatures.

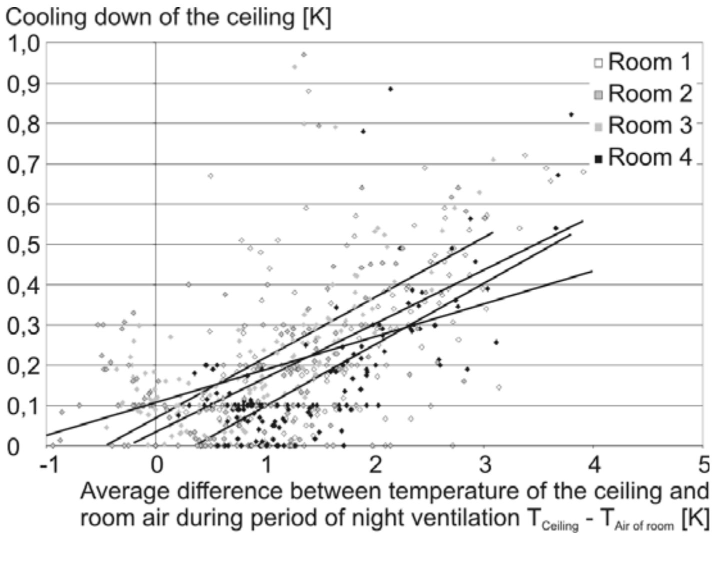

Figure 6: Cooling of the ceiling during the night ventilation from 21 p.m. until 6 a.m. depending on the average difference between the ceiling and the air temperature.

Thermal Comfort

In order to evaluate the thermal comfort conditions in the offices, air temperatures and the attendance were recorded in 10 rooms (out of 200) since 2003 and in 20 further rooms from autumn 2004 on.
The room temperature limit for acceptable conditions had been defined to 26°C for ambient temperatures up to 32°C and with a minimum temperature difference of 6 Kelvin between the indoor and ambient air temperature when the ambient temperature exceeded 32°C (referred to as 32/6-limit). Even during the hot summer of 2003 the room temperatures of frequently used and passively cooled rooms in average surpassed this limit by only 2.1% (32 hours) of the overall attendance time [4]. The maximum temperature in these offices reached 29.6°C with the outdoor air temperatures reaching 40°C (Figure 7).

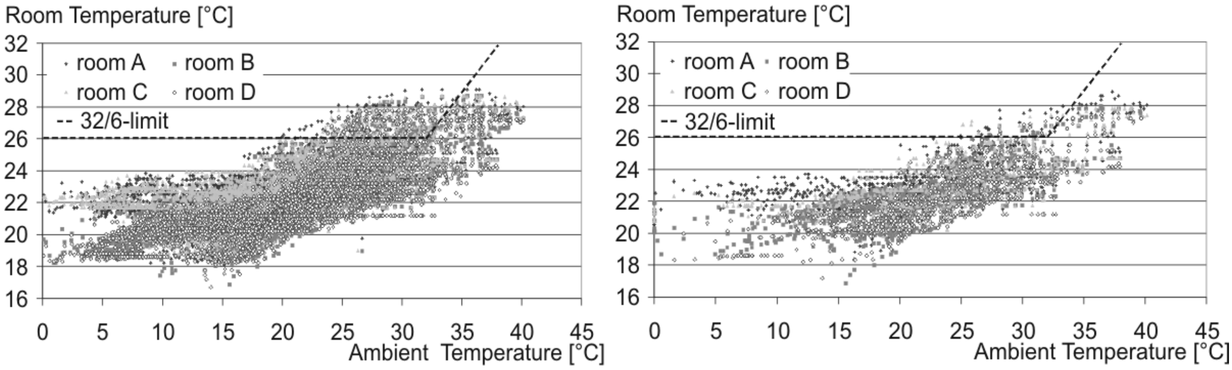

Figure 7: Average hourly air temperature of four passively cooled offices from May 2003 to October 2003 plotted over the actual ambient air temperature. Data including all recorded hours (left) indicate a number of hours when the comfort limit was exceeded. When considering the attendance times (right) there were rarely any temperatures above the limit. The left picture also shows the lower limit of 18°C for the night cooling.

In 2004 the average time above the limit conditions was 0.4% (9 hours), in 2005 2.1% (38 hours) of the total attendance time (Figure 8). The maximum temperature recorded in these offices was 27.2°C during the summer of 2004 and 28.2°C in the summer of 2005.

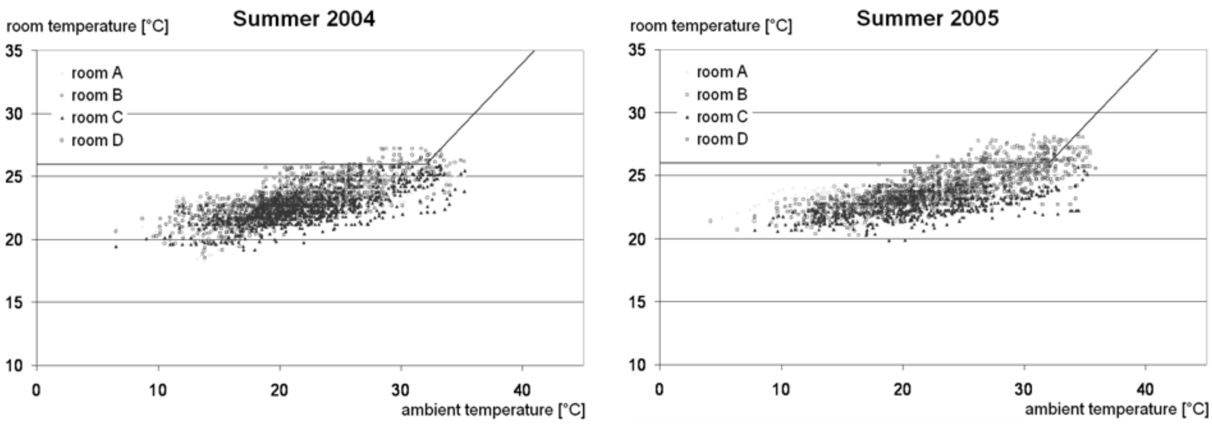

Figure 8: The average exceeding hours for the same four rooms are 9 in summer 2004 and 38 in summer 2005

In summer 2006 however the 60 hour limit was exceeded in different rooms. The reasons were malfunctions of the atrium lid and therefore a failure of the night ventilation. In combination with the very warm nights during June there had been one week with temperatures up to 30°C in the offices. This shows how important the proper operation of the building is if there is no active cooling system for backup.
Though being just a spot sample, the results of the four rooms showed that passive cooling is possible even with extreme weather like in 2003 if the building is operated in the right way.

Air quality

In 5 rooms CO_2-concentrations have been measured additionally for checking if sufficient air quality was achieved just by natural ventilation. Two of these offices were ventilated by air conditioning, the other three by natural ventilation. The results of more than two years monitoring showed that the limit of 2000 ppm was never reached, the limit of 1500 ppm was exceeded just for a few hours - independent of the type of ventilation [5].
On average, the CO_2-concentration was below 1500 ppm for 99.8% and less than 1000 ppm for 98.6% of attendance time. Figure 9 confirms that in every room the concentration was below 800 ppm at least in 90% of the attendance time. There was no significant difference between naturally and mechanically ventilated spaces
The analysis showed that the employees' manual use of the skylights did not depend on the ambient temperature. As an example, on average the skylights were open as often in January 2005 as in June 2005. In contrast, the manual opening of windows was dependent on the outside climate. In June 2005 occupants used the windows more than three times as often for ventilation as in January 2005. With a decreasing frequency of opening the windows in winter, the chance to measure higher CO_2-concentrations rose (Figure 10).

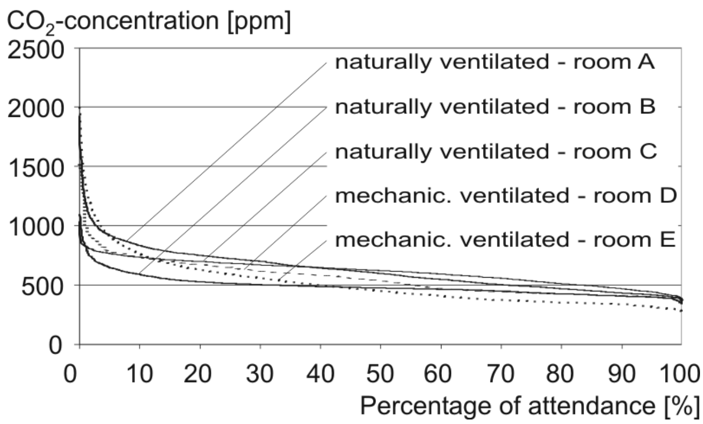

Figure 9: Cumulative frequency distributions for hourly averaged CO_2-concentration of air in 3 naturally and 2 mechanically ventilated offices. Data for one year, only hours with attendance of the occupant

DISCUSSION

The 3-year monitoring of the KfW bank building showed that the ambitious target of a primary energy consumption of 100 kWh m^{-2} a^{-1} was almost reached after the third year with a prediction to fall below this value in the future. Compared to conventional office buildings in Germany this building shows an outstanding energy performance.
Not conceptual errors but failures in operating the building's facilities caused the higher energy consumption in the beginning. This is in accordance to the results of the other

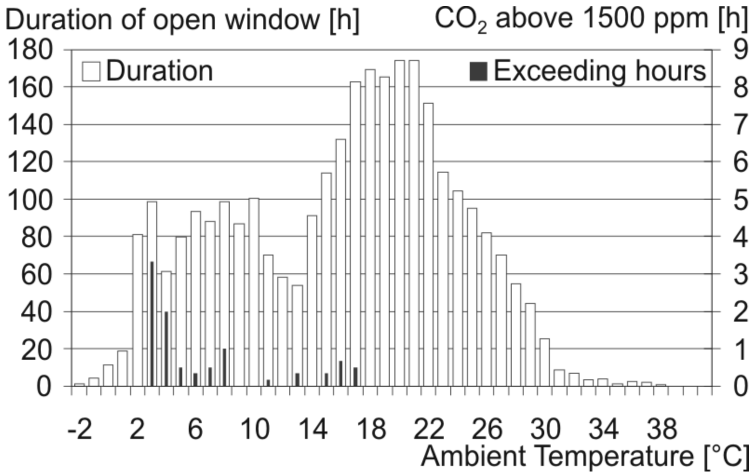

Figure 10: Total time of window opened with CO_2-concentration exceeding 1500 ppm for an office over one year, classified in steps of ambient temperature

demonstration buildings of the programme and underlines the importance of a continuous monitoring of a building. Important preconditions for this are appropriate data management and visualisation as well as experienced facility managers who are familiar with energy performance issues.

It could also be proved that even under extreme climate conditions – like summer 2003 – acceptable thermal conditions in the passively cooled offices could be achieved. The proper operation of the shading system and the night cooling are important to keep the room temperatures within the required limits.

Examinations on the CO_2-concentration in sample rooms have shown that without mechanical ventilation good air quality was obtained.

ACKNOWLEDGEMENT

The work was funded by the German Ministry of Economy and Technology (BMWi) under the reference number of 0335007F. The authors also acknowledge the support from the ministry's project coordinator PTJ in Jülich. Special thanks go to all partners of the project team for providing data and information for this paper.

SUMMARY

Global climatic warming trends are becoming more and more obvious. They are characterized by longer and more intense heat wave periods as witnessed in extreme by the summers 2003 and 2006. This situation asks for mechanical cooling applications in office buildings. Is it possible to reach good indoor environmental conditions using hybrid ventilation strategies only? This question has been investigated by measurements in the *Forum Chriesbach*, a new low energy office building located in Dübendorf, Switzerland. The ventilation concept of this building is based on an earth-to-air heat exchanger system for hygienic air supply during day-time and a passive night cooling strategy by stack ventilation through window openings in the façade and towards a large atrium with roof outlets. Outdoor and indoor climatic conditions as well as internal heat loads have been measured in an office room over the summer heat wave period 2006. The measured data shows, that the hybrid ventilation system is able to hold the operative room temperatures during the heat wave period 2006 in the acceptable comfort range of ±0.5 PMV and to meet the requested indoor air quality limits (CO2 < 1000 ppm). It thus confirms the thermal simulation results made by the project design team.

INTRODUCTION

Hybrid ventilation, the combination of natural and mechanical ventilation, is an encouraging strategy to achieve energy-efficient office buildings with good indoor air quality and thermal comfort. International studies carried out within IEA Annex 35 “Hybrid Ventilation in New and Retrofitted Office Buildings”[1] have shown, that there exist hybrid ventilation solutions which together with other sustainable technologies such as daylighting, passive solar heating and passive cooling strategies may be able to provide good indoor environmental conditions and low energy use in office buildings in moderate climates like those in central Europe. For this kind of buildings an integral approach in the design of the energy, indoor climate, fire safety and security concept is required. Since low-energy buildings interact strongly with solar radiation and indoor load conditions an appropriate overall robust control strategy has to be applied which includes a particularly effective sun protection system. In addition a higher user satisfaction concerning the thermal comfort can be attained when an individual control of the windows is possible.
Air cooling in summer and preheating in winter with buried pipe systems acting as earth-to-air heat exchangers are becoming popular in Switzerland. Studies made at the University of Geneva [2] have shown good energy saving potentials for office buildings at competitive costs. Passive cooling by night ventilation is mainly used to improve the thermal comfort situation in summer and has been applied with success in high mass office buildings. Detailed thermal analysis and simplified design tools have been developed and validated by monitoring the new building of the Fraunhofer Institute for Solar Energy Systems ISE in Freiburg [3]. In a German demonstration and monitoring programme on the energy performance of 22 advanced office buildings without mechanical cooling systems it has been shown, that the yearly primary energy use can be kept within a limit of 100 kWh per m^2 net heated floor area [4] The

Forum Chriesbach is designed to get along with about 14 kWh/(m^2 a) end energy use respectively 36 kWh/(m^2 a) primary energy use for heat, cold and electricity.

METHODS

Building description

Forum Chriesbach, the new main headquarters of the Swiss Federal Institute of Aquatic Science and Technology (Eawag), is an innovative low energy office building [5]. As winner of an architectural competition, the project team has chosen a holistic approach for the design of a sustainable house of the future, which meets the client requirements concerning healthy indoor environmental conditions and substituting primary energy by renewable energy sources and optimizing the careful use of land, materials, water and finances.
The key elements of the 6-story building with a total volume of 38’615 m^3, a ground surface area of 1’886 m^2 and a total floor surface area of 8’533 m^2 are the highly insulated building envelope, the large atrium buffer zone with a glazed double roof, massive concrete floor constructions and fire escape balconies on the façade with moveable blue glass panels for solar control as shown in Figure 1. The smart energy concept consist of 50 m^2 vacuum solar collectors with a heat storage water tank of 12 m^3, 459 m^2 photovoltaic panels on the roof and a mechanical ventilation system using an earth-to-air heat exchanger for preconditioning the air including a heat recovery system (see Figure 2) with a design ventilation rate of 8.3 l/s per person. In summer an additional passive cooling strategy by night stack ventilation through the windows via the large atrium in the centre of the building (see Figure 3) is used.

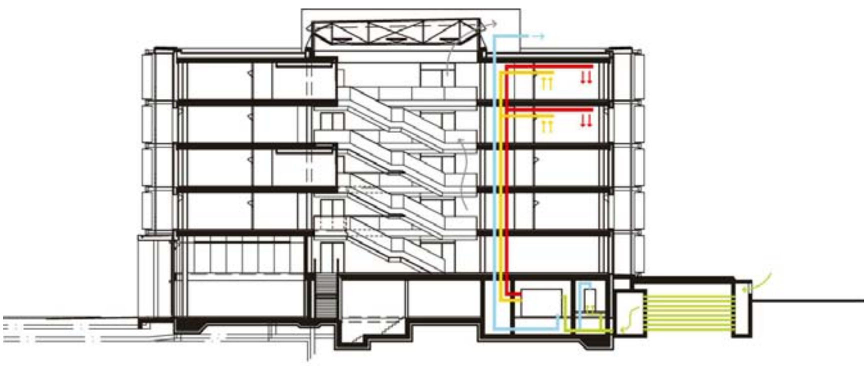

Figure 2. Day time mechanical ventilation via earth-to-air heat exchanger with buried pipes

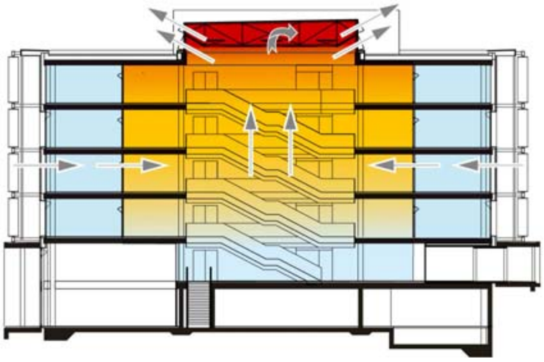

Figure 3. Night time passive cooling by stack ventilation via the atrium to the roof outlets

Measurement layout

The measurement of the indoor environmental conditions has been made in the office room FC-D41 with 30 m^2 floor area in the south-west corner of the 4th level (see Figure 4). The room has 4 working places and was occupied by 1-3 persons (1.2 met, 0.5 clo). The data acquisition system used consists of a comfort analyzer B&K 1213 complying with the requirements given in ISO 7726 [6] and two separate data loggers for the indoor air quality and the electric power measurements. The specifications of the sensors used are given in Table 1. The goal of the measurement was to check if the comfort and indoor air quality criteria given in ISO 7730 [7] and EN 15251 [8] are met during the heat wave period in summer 2006.

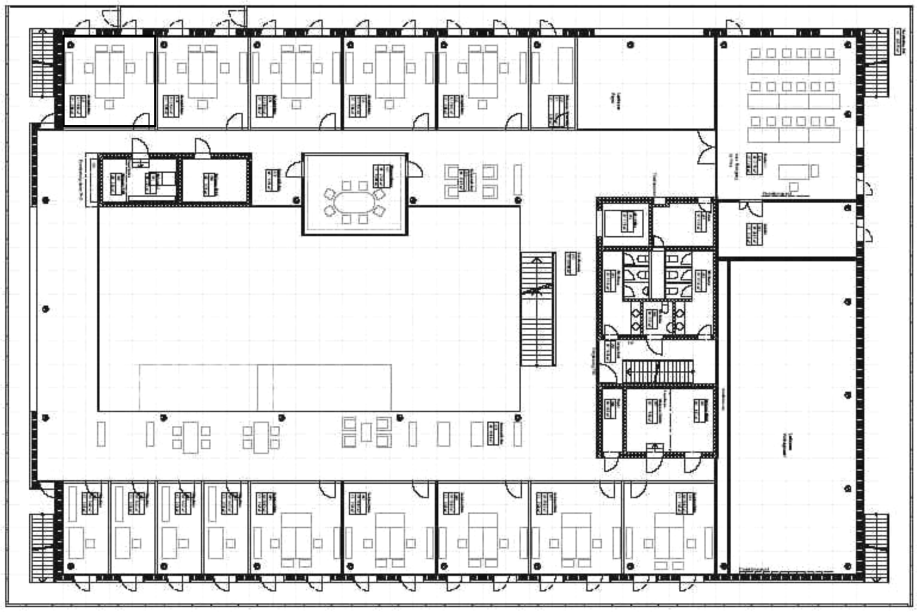

Figure 4. Floor level D with the measured office room D41 in the south-west corner (yellow)

Table 1: Measurement sensors with specifications

Quantity	Sensor	Transducer	Unit	Accuracy
Air temperature	Pt100	MM0034	°C	± 0.3 K
Operative temperature	Pt100	MM0060	°C	± 0.3 K
Air velocity – anemometer	Hot wire	MM0038	m/s	± 0.05 m/s
Supply air temperature	Pt100	Hygroclip	°C	± 0.1 K
Relative humidity	Capacitive	Hygroclip	%	± 3 %
CO2 concentration	Vaisala NDIR	GMW 22D	ppm	± 5 %
Global solar radiation	Kipp & Zonen	CM21	W/m^2	± 2 %

RESULTS

The measurements in room FC-D41 have been started on July 15th and included a heat wave period of 17 sunny days with maximum outside air temperatures up to 35°C, followed by a colder period characterized by a temperature drop of 15 K (see Figure 5 and 6). During this heat wave period, the cooling effect of the earth-to-air heat exchanger is demonstrated in Figure 7: During daytime the supply air temperatures lay 7-10 K lower than the outdoor air temperatures and hardly exceeded the upper comfort limit temperature of 26°C. The operative temperatures are in the requested comfort range and reach at the end of the heat wave period the upper limit of 26 °C (see Figure 8). The relative humidity lies during daytime between 40-60% and during night between 60-80% due to the temperature drops caused by the night cross ventilation (see Figure 9). The same picture can be observed with the air velocity in the office

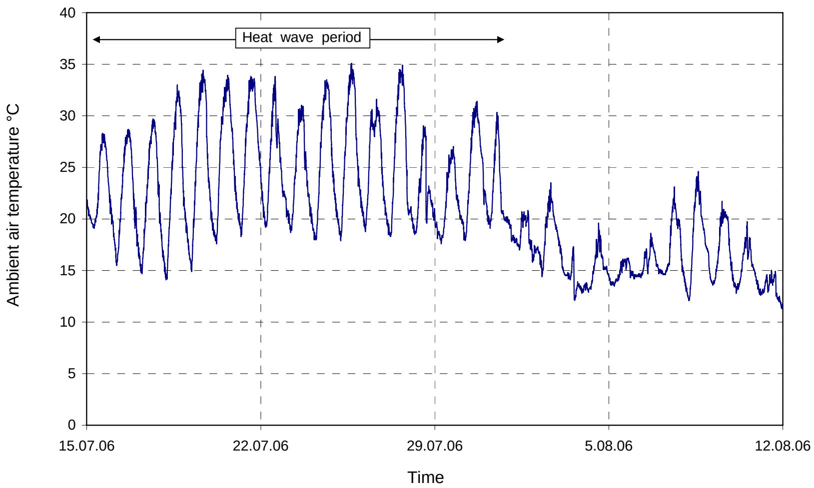

Figure 5: Air temperature in Dübendorf, period 15. July – 12. August 2006 [§]

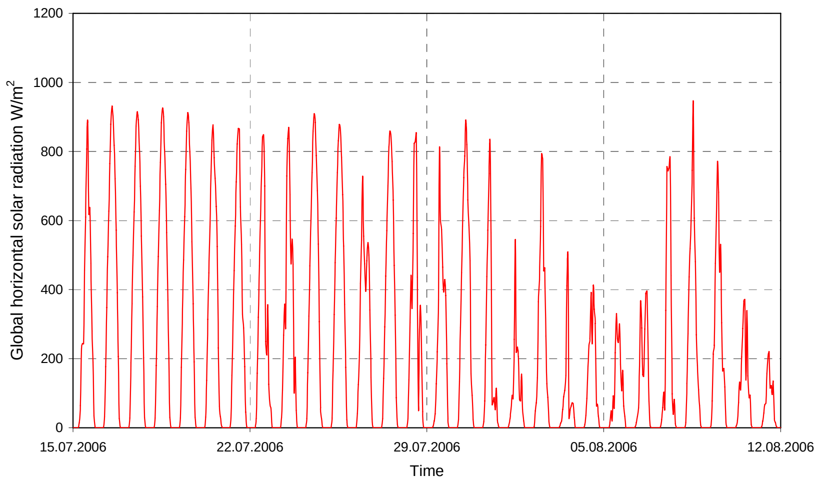

Figure 6: Solar radiation in Dübendorf, period 15. July – 12. August 2006

[§] Measured by the NABEL monitoring network station in Dübendorf (BAFU / Empa) room (Figure 10), which shows some peaks due to controlled window openings during night and some openings in the morning by the occupants.

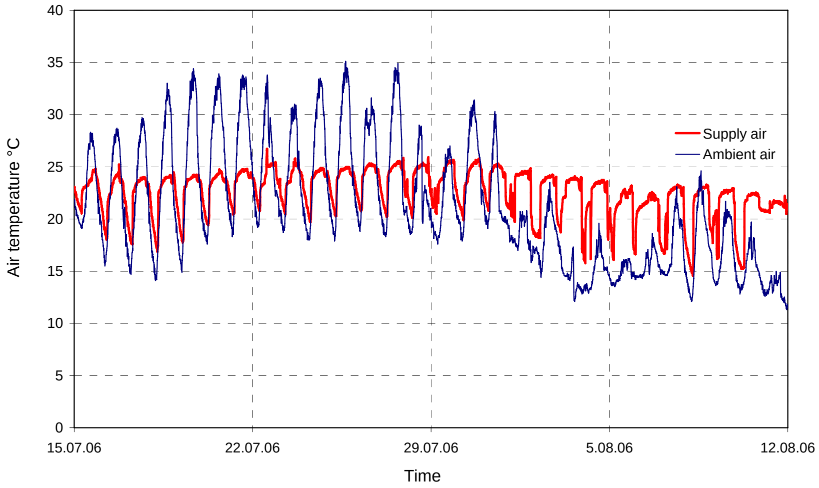

Figure 7: Supply air temperature versus ambient air temperature

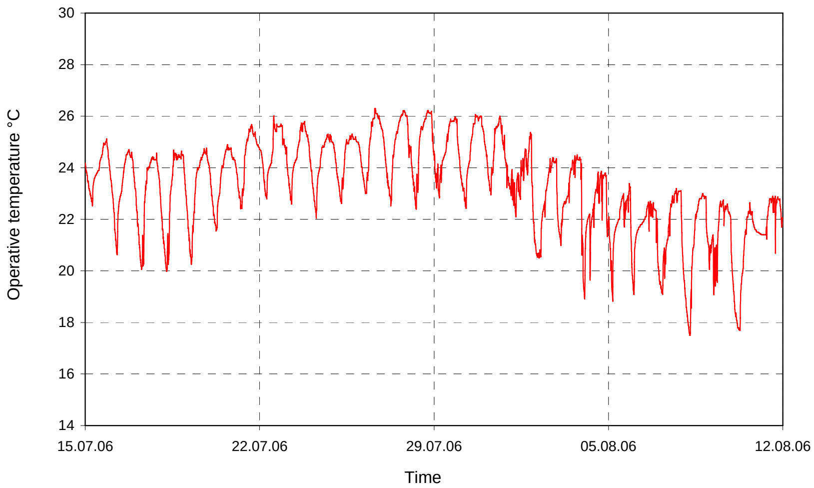

Figure 8: Operative temperature in the office room FC-D41

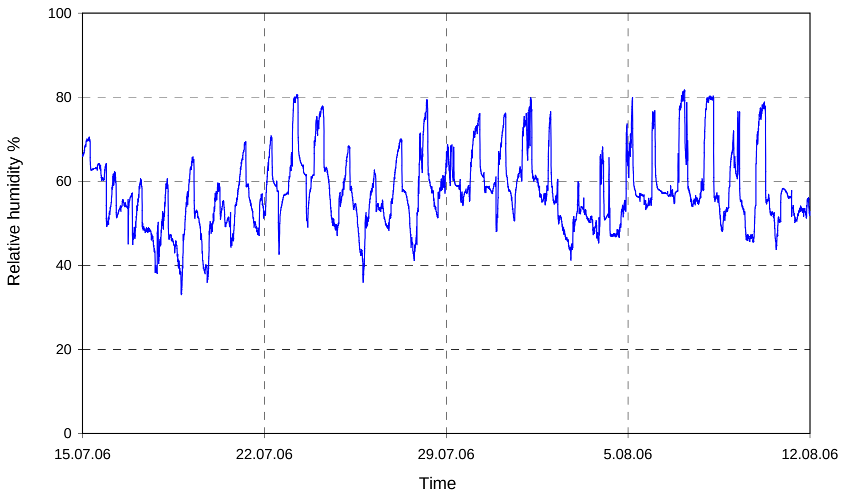

Figure 9: Relative humidity of the supply air in the office room FC-D41

The CO2 concentrations shown in Figure 11 are in an acceptable range, the chosen design supply air flow rate of 17 l/s for the room is obviously sufficient. The total internal heat loads from people, equipment and lightning are given in Figure 12.

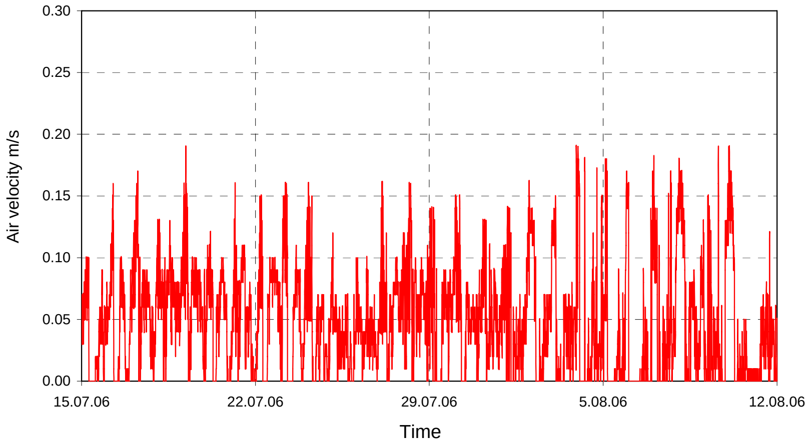

Figure 10: Air velocity in the office room FC-D41

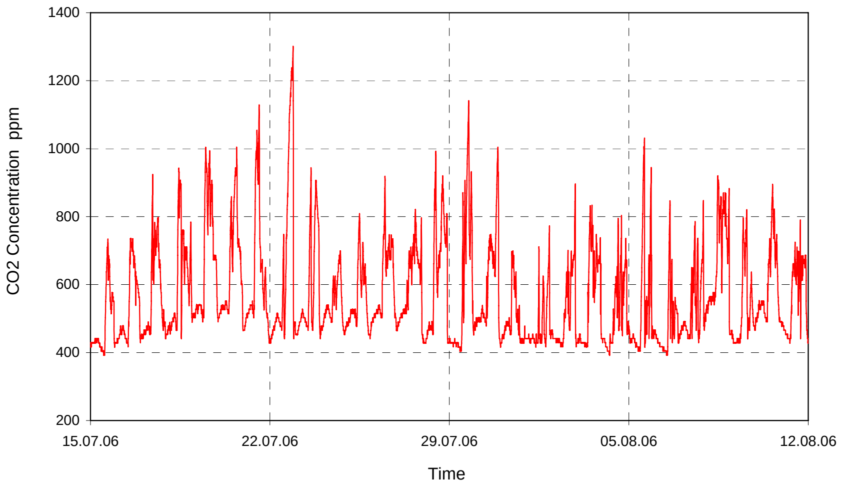

Figure 11: CO2 concentration in the office room FC-D41

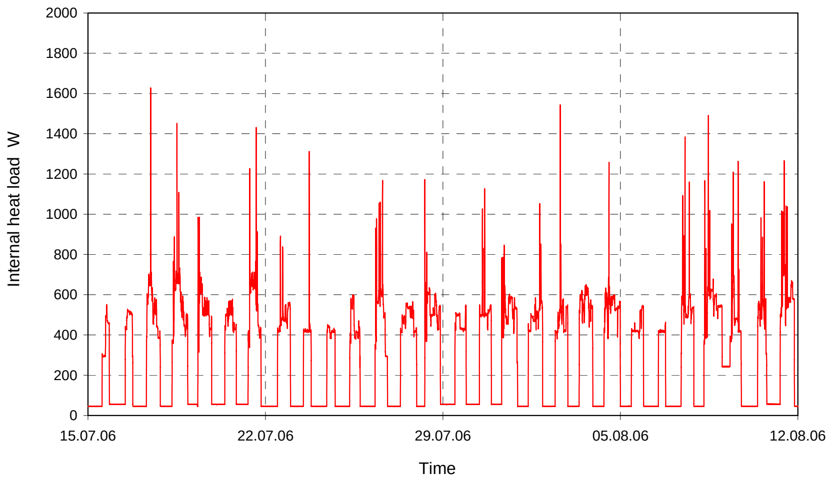

Figure 12: Total internal heat loads in the office room FC-D41

All measurement results are summarized in Table 2. In Figure 13 and 14, the indoor environmental conditions are classified according to EN 15251 for the 17 heat wave days, occupied from 8 am to 9 pm. The operative temperatures lie during 86% of the hours in the category I band (predicted mean vote PMV ± 0.2) and the indoor air quality criteria is met during 91% of the hours in the best category I ($CO2 \leq 750$ ppm).

Table 2: Measured data over the summer heat wave period 15. July – 1. August 2006

Parameter	Mean value	Maximum value
Outdoor environemt		
- Ambient air temperature (10 minutes data)	24,3 °C	35,1 °C
- Relative humidity of the air (10 minutes data)	57,7 %	96,1 %
- Global horizontal solar radiation (hourly data)	271 W/m^2	931 W/m2
Indoor environment		
- Daily internal heat loads (people, equipment, lighting)**	18,4 W/m^2	20,5 W/m^2
- Daily hours of occupancy and operation	11,5 h	15,5 h
- Daily internal heat gains (people, equipment, lighting)	211 Wh/m^2	292 Wh/m^2
- Room air temperature (6-minutes data)	24,1 °C	27,0 °C
- Operative room temperature (6-minutes data)	24,2 °C	26,3 °C
- Rel. humidity of the room air (6-minutes data)	57,1 %	80,6 %
- Air velocity (6-minutes data)	0,053 m/s	0,190 m/s
- CO2 concentration (6-minutes data)	585 ppm	1301 ppm

DISCUSSION

Low energy office buildings like the *Forum Chriesbach* tend to be strongly dominated by internal heat gains from people and electrical equipment. They are very welcome in winter to cover the heating demand, but can be a problem in summer leading to an unwanted cooling demand. The use of a hybrid ventilation concept is one possibility to overcome this summer problem. In the case of the *Forum Chriesbach* building, an earth-to-air heat exchanger system is used to satisfy the hygienic ventilation during occupancy time together with a passive night ventilation to use the high heat storage capacity of the massive concrete building structure. The extensive heat wave period in summer 2006 has been used to check if the *Forum Chriesbach* building is able to achieve the requested indoor climatic conditions. The measurement of the thermal comfort and the indoor air quality parameters has shown that the best comfort category I defined in the new European standard EN 15251 has been met during 86% of the occupied time and that the category II, which complies with the Swiss standard is fulfilled all the time. This result is remarkable since normally one would expect that with passive cooling principles some cut backs in the thermal comfort level have to be accepted. The measurement also demonstrated that the internal heat gain situation was higher than expected due to higher numbers of working hours and that the large ambient temperature drop after the heat wave period was not taken into account by the night ventilation scheme. Demand controlled ventilation becomes therefore a more important topic in order to react to this kind of unforeseen situations.

ACKNOWLEDGEMENT

The authors acknowledge with thanks the technical support given by R. Vonbank for installing the insitu measurements and Th. Seitz for providing the ambient temperature data of Duebendorf, measured at the National Air Pollution Monitoring Network NABEL (BAFU/Empa).

SUMMARY

The specific features of natural ventilation system combined with solar chimney and underground pit installed in a new school building and the measured results for four years are described. In summer and intermediate seasons outside air is introduced into the building of four stories through underground pit from the intake provided in the north end, brought into the different occupied rooms from which the room air is discharged to outside through the solar chimneys of 8 meters high above the roof by chimney action or pulling out action by wind. The measured results for four years after opening the school showed that the energy performance has improved year after year owing to the natural ventilation system. Some consideration on the improvements in the system performance is given for future design of natural ventilation with solar chimney.

1. INTRODUCTION

As can be seen in the minarets of vernacular buildings in hot countries, solar chimney is like the one to give rise to buoyant force by solar energy for natural ventilation. This effect could be enhanced by coupling with the underground pit where outside air is cooled down, thus bringing cool air into the occupied spaces.

The natural ventilation system combined with solar chimney and underground pit was introduced in the buildings of Kitakyushu University in the west island of Japan as shown in Figure 1. The performance of natural ventilation with supply and exhaust air volume and cooling effects, the relationship among the weather factors, indoor/outdoor temperature difference and the exhaust volume out of solar chimney for four years is summarized.

Figure 1. Outside view of main building from southwest

Figure 2. Solar chimney on the roof

2. OUTLINE OF BUILDING AND SYSTEM

The main building consists of two long buildings: north wing with office block attached and south wing as shown in Figure 3. The north wing is subdivided into four blocks of identical size. Field measurement was performed with the Block-1 of the north wing building at 10 minutes interval for a long term.

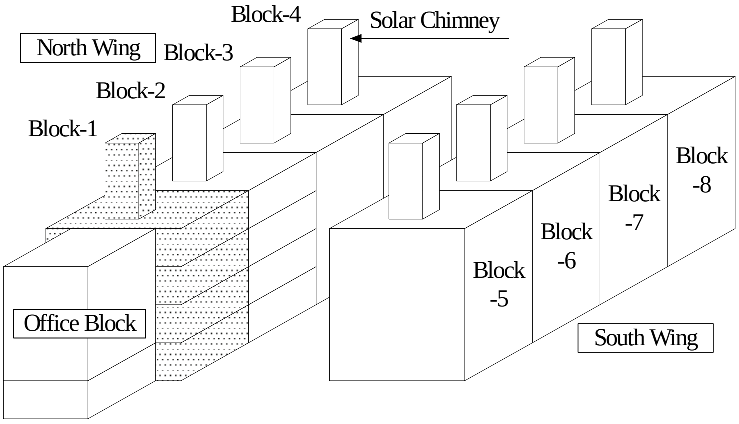

Figure 3. Measured block of north wing

Figure 4 shows the air flow routes during the period of natural ventilation from underground pit to solar chimney on the right side and the air flow routes of auxiliary air conditioning system on the left. Natural ventilation takes place by opening the grilles of outside air intake. During the heating season natural ventilation does not work in order to prevent heat loss, while outside air is introduced through the underground pit warmer than outside. The scheduled operation started since the second year.

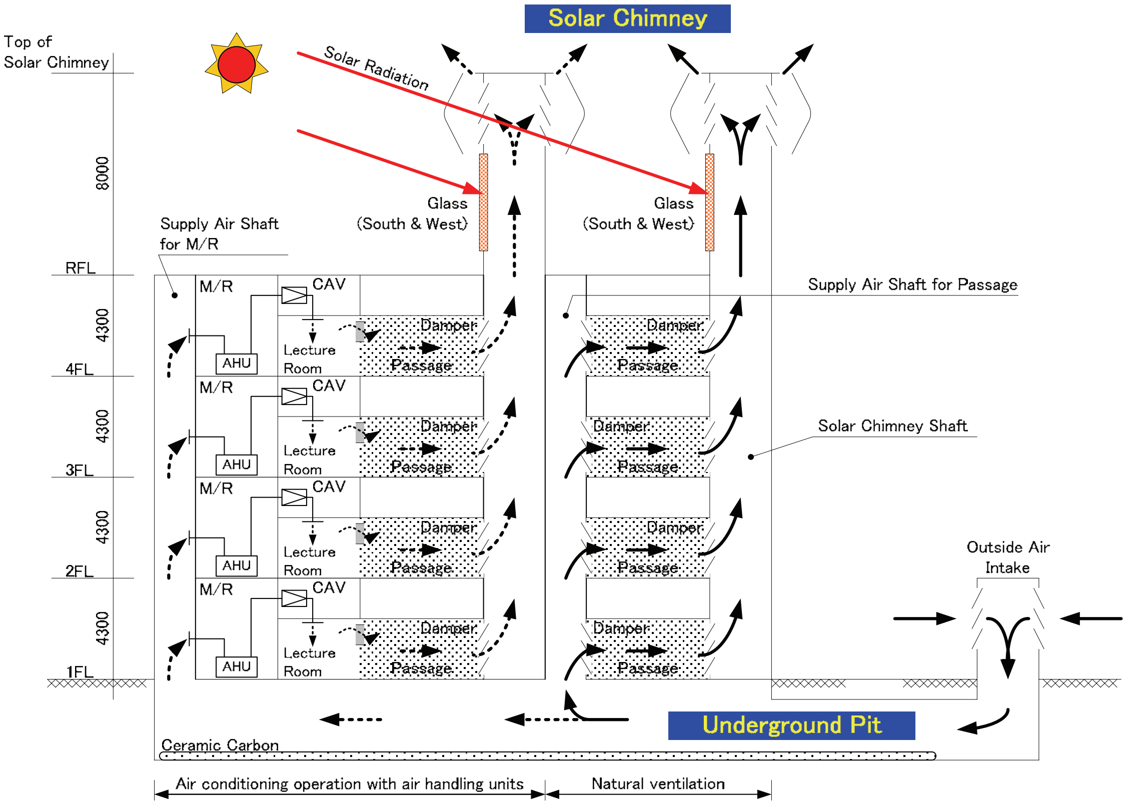

Figure 4. Air flow routes of natural ventilation system (right) and air conditioning system (left)

3. PERFORMANCE OF NATURAL VENTILATION

3.1 Cooling and Heating Periods

Table 1 shows the number of days of natural ventilation during cooling and heating periods. It was found that the cooling period for natural ventilation turned to be greater year after year to occupy 57% of annual total days in the third and fourth years, while in heating period decreased to 43% in the last two years.

Table 1. Number of days of cooling and heating periods

YEAR	1st	2nd	3rd	4th
PERIOD	365	365	366	365
COOLING	185	170	209	211
HEATING	180	195	157	154

3.2 Operation period of Natural Ventilation

Figure 5 shows the monthly number of hours of natural ventilation estimated from the opening hours of the grilles of supply air for the corridor space. The operating hours of natural ventilation in the third year turned out 3,058 hours, while in the fourth year 1,702 hours. This decrease may be attributed to the cool summer in the third year and hot summer in the fourth year. The number of students increased in the fourth year by 25% and this must have affected this difference.

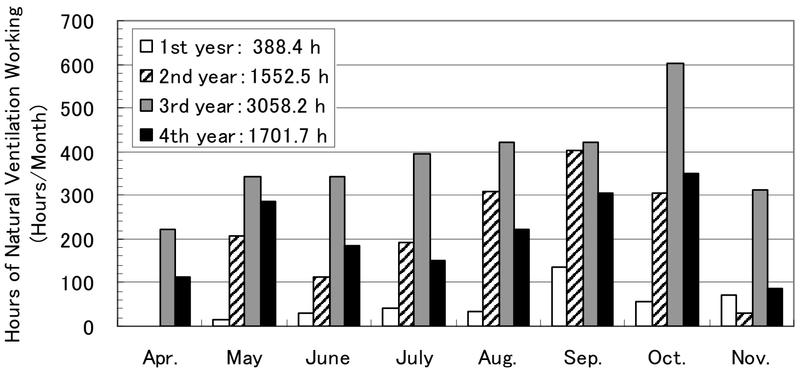

Figure 5. Monthly hours of natural ventilation

Figure 6 shows the percentage of monthly hours of natural ventilation and that of air conditioning operation with air handling units (AHU) in the third year. Except for the month of April and November when switching of heating and cooling operation was made, the percentage of natural ventilation operation during the cooling period was 45-60% in May through September and 80% in October.

Most of the time of natural ventilation took place during the night 18:00 – 8:00, which covered 80% of the total.

3.3 Air flow volume during the period of natural ventilation

In fact quite a large size of exhaust fan is installed on the roof for the toilets of four floors, which affects the performance of natural ventilation. The air flow volume of natural ventilation from the inlet to the underground pit and that from solar chimney to outside are different depending on whether the toilet exhaust fan is operating or not.

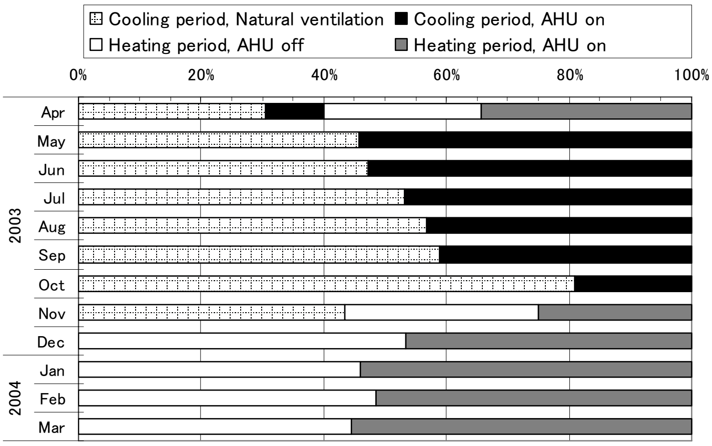

Figure 6. Percentage of hours of natural ventilation and AHU (air handling unit) in cooling and heating periods in the 3rd year

It can be recognized that the supply air volume from the underground pit and the exhaust air volume out of solar chimney tend to increase year after year owing to the improvements of occupants behavior.

The supply air volume from the underground pit of 6,100m^3/h and the exhaust air volume out of solar chimney of 4,100m^3/h are found quite stable for four years.

3.4 Cooling effects under natural ventilation

There are two types of natural ventilation: the first one is the effects of cooling outside air by the underground pit. The second one is the effects of cooling the building skeleton by the outside air after flowing from the underground pit until being exhausted out of the solar chimney.

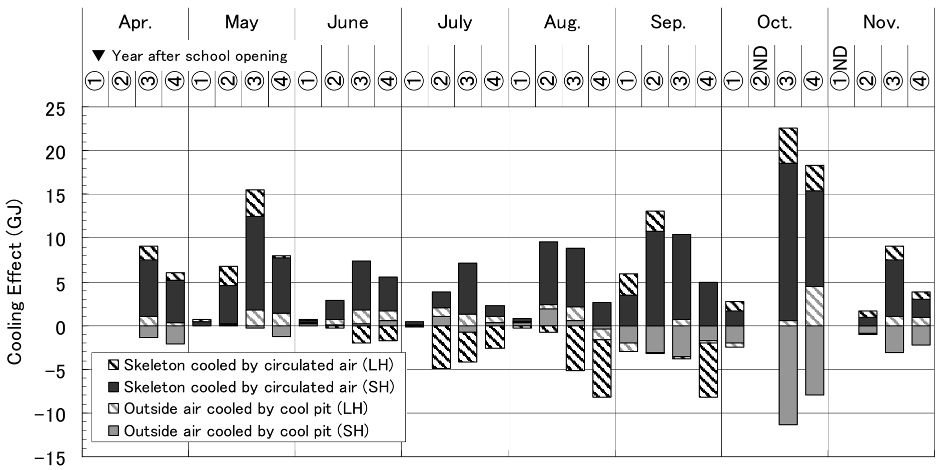

Figure 7. Monthly cooling effects by natural ventilation

Figure 7 and Table 2 show the values of the cooling effect under natural ventilation. It can be found that the sensible cooling effect in the underground pit in spring and summer is negative.

Table 2. Cooling Effects by underground pit

Unit: GJ

Year after school opening	Outside air cooled by underground pit	Skeleton cooled by circulated air	Total
1st	-4.74	10.14	5.40
2nd	1.03	26.59	27.63
3rd	-9.91	68.80	58.89
4th	-7.50	24.80	17.30

This may be attributed to the fact that the underground temperature delays by one month against the outside air temperature in their peak values as shown in Figure 8 and that the cool air introduced from outside during the night is warmed slightly within the underground pit by natural ventilation. However, the slightly warmed outside air is still cool and eventually enters into the building to cool the building structure. When it enters into occupied spaces in winter, the warmed air in the underground pit would bring a natural heating effect.

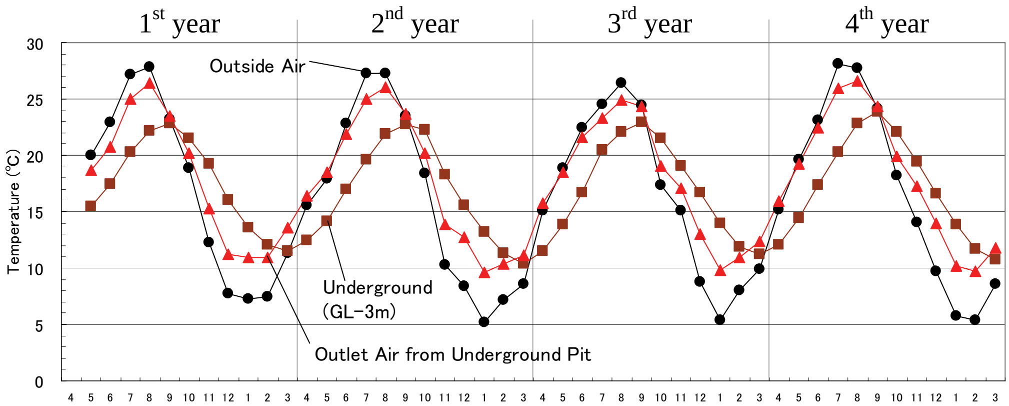

Figure 8. Annual temperature variations of outside air, underground, and outlet air from underground pit

4. AMOUNT OF HEAT EXCHANGE WITHIN THE UNDERGROUND PIT

4.1 Operation hours of AHU

Figure 9 shows the annual variation of air handling unit (AHU) operation hours. It was found that the AHU operation hours in the fourth year during cooling and heating periods increased by 69% and 18% respectively. This was due to the increase in the number of students and hotter summer.

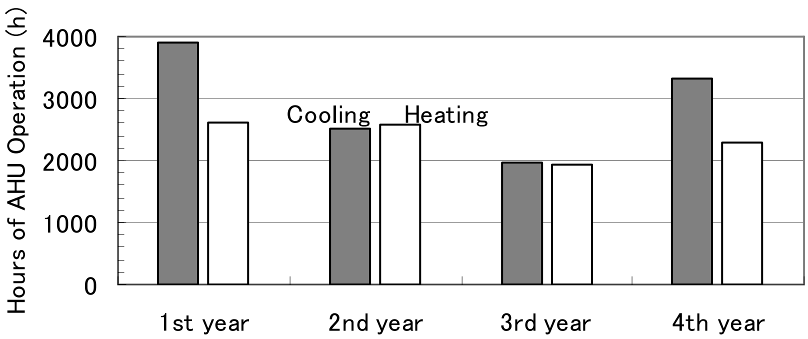

Figure 9. Trend of AHU operation hours

4.2 Amount of heat exchange within the underground pit

The amount of heat exchange within the underground pit in the fourth year was 34.9GJ during cooling period and 20.4GJ during heating period against 39.2GJ and 38.5GJ respectively in the third year.

Table 3 shows the monthly amount of heat exchange within underground pit within the month the amount of heat exchange turned out maximum. The highest value in cooling period of the fourth year may be due to the decrease in air flow speed within the underground pit below 0.5m/s with higher inlet temperature.

Table 3. Monthly maximum amount of heat exchange within underground pit

Period	1st year	2nd year	3rd year	4th year
Cooling	July-01 2.99kJ/m3	July-02 3.00kJ/m3	August-03 4.75kJ/m3	July-04 5.58kJ/m3
Heating	December-01 3.87kJ/m3	January-03 2.98kJ/m3	January-04 4.06kJ/m3	February-05 2.97kJ/m3

The greatest monthly amount of the heat exchange of the cooling period occurred in August with 5.58kJ/m^3 and that of the heating period in January with 2.97kJ/m^3 in terms of total heat exchanged against the air volume through the underground pit in monthly cumulative values.

This suggests that the performance of heat exchange within the underground pit has not been degraded in comparison with that in the past three years.

4.3 Percentage of reduction in energy for air conditioning

Table 4 shows the annual variation of energy for air conditioning recorded in the central monitoring system for the building of north wing and office block. Energy for air conditioning was 2,201GJ in cooling period and 4,077GJ in heating period in the fourth year. The number of students has increased every year after school opening.

Table 4. Trend for energy for air conditioning in north wing and office block

The year after school opening	Period of data	Energy for air conditioning			Number of registered persons			Energy for air conditioning per registered person	Energy for air conditioning per floor area (1～4F) *
		Cooling period (GJ)	Heating period (GJ)	Total (GJ/Year)	Office block (Persons)	North wing (Persons)	Total (Persons)	(GJ／Person·Year)	(GJ／m^2·Year)
1st	May/2001 ～Apr./2002	1,919	3,630	5,549	48	329	377	14.72	0.275
2nd	May/2002 ～Apr./2003	1,734	3,456	5,190	41	598	639	8.12	0.257
3rd	Apr./2003 ～Mar./2004	1,278	3,389	4,667	46	920	966	4.83	0.231
4th	Apr./2004 ～Mar./2005	2,201	4,077	6,278	47	1207	1254	5.01	0.311

*Floor area of measurement : Office block = 2659.75m^2、North wing = 17543.75m^2、Total 20203.50m^2

Energy used for air conditioning in the third and fourth years was 4.83GJ/person/year and 5.01GJ/person/year respectively or 0.231GJ and 0.311GJ/m^2 year, which were found smaller than the preceding two years.

5. DISCUSSION

Some consideration on the improvements in the system performance is given for future design of natural ventilation with solar chimney.

1. In the design of the solar chimney, it is primarily important to reduce friction loss for the sake of obtaining higher driving force of solar chimney. The solar chimney of this building had bent portions in the course of air flow due to some problems against planning scheme.

2. The simple method to find an optimum shape of solar chimney in terms of height and horizontal dimensions should be proposed.

3. The optimum relationship between the size of solar chimney and the length of underground pit should be identified. The section and length of the underground pit of this building could have been a little smaller.

4. Proper combination of natural ventilation system and auxiliary air conditioning system should be investigated. The system in this building seemed a little too complicated.

5. Behaviour of occupants should be taken into account in the system design. For example mosquito screen should have been provided for the windows to be opened.

6. CONCLUSION

1. The hours of natural ventilation have increased year after year. From the third year to the fourth natural ventilation was performed for 61% of the cooling period of 5,016 hours and the cooling effects during the hours of natural ventilation was 58.9GJ. This is regarded as instruction to the occupants to realize not to switch AHU on whenever natural ventilation could be possible.

2. The total amount of heat exchange within the underground pit while AHU operating in the third year after school opening was found 71.7GJ. The monthly cumulative value of the heat exchanged within the underground pit was 4.75kJ/m^3 in cooling period and 4.06kJ/m^3 in heating period.

3. Energy used for air conditioning in the north wing and office block in the third year after school opening was proved to be 4.83GJ/ person/year or 0.231GJ/ m^2/year, which was lower than that of the previous year because of an increase in the number of students.

4. The effect of reducing the fresh air load by the use of underground pit under AHU operation in the third year after school opening could be recognized as 30.7% in cooling period and 11.3% in heating period. Percentage of reduction on the energy used for air conditioning of the north wing and office block turned out 12.3% in cooling period and 3.8% in heating period.

ACKNOWLEDGEMENT

This research was conducted as one of the research project of the Advanced Research Centre for Science and Engineering, Waseda University in Tokyo sponsored by Techno Ryowa, Ltd. The authors would like to express their sincere gratitude to the staffs of Kitakyushu University for their cooperation to conduct the measurements.

Performance Estimation of Window-Mounted Solar Heat Driven Ventilation System by Numerical Analysis

Kae Yoshikawa and Tatsuo Nobe

Kogakuin University, Japan

Corresponding email: dm06073@ns.kogakuin.ac.jp

SUMMARY

This research proposes a simple device added to a window. The device improves indoor ventilation using solar heat. It made from shoji paper, which is the traditional paper of Japan. The structure of the device is five air layers from five partitions of shoji paper. The device provides insulation. In summer, it is used for ventilation. In winter, it is used for insulation at night. Experiments were conducted with the device, and the ventilation performance and thermal insulation were confirmed. This paper reports the results of a numerical analysis of the device installed in a building model. The difference of climate regions and direction of the building were considered in the numerical analysis. The amount of ventilation and the room temperature of the building in six regions were confirmed.

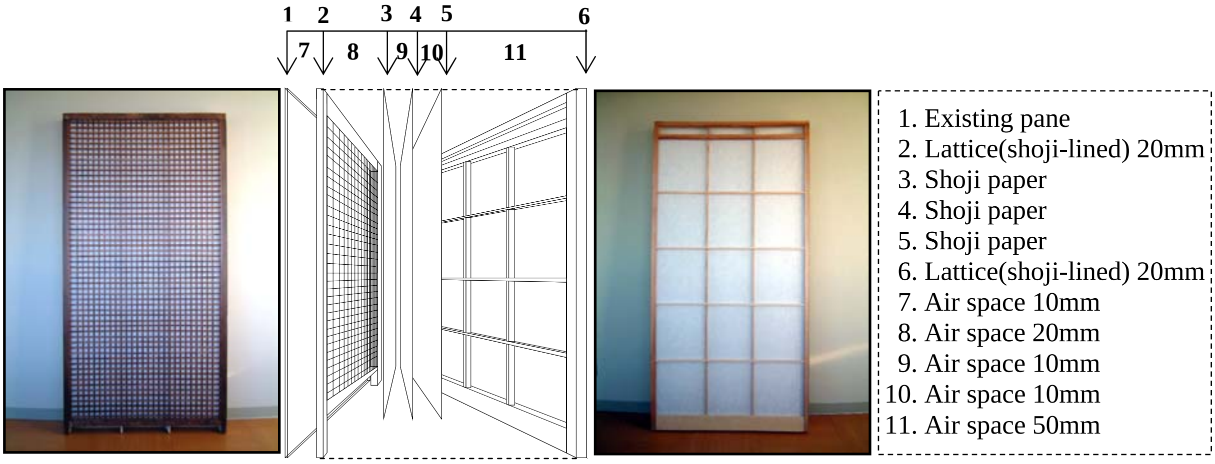
INTRODUCTION

In recent years, various window systems such as Double-Skin and air ventilation windows have been developed with the intent to provide a comfortable indoor environment. These indoor environments have been designed with devices that block the outside environment from entering. As a result, rooms are airtight, highly insulated, and maintain a constant environment. However, one problem is that the devices are complicated. Here, a simple device using solar heat as the driving power of ventilation is proposed. It maintains indoor comfort using changes in the outside environment, as is similar to traditional Japanese construction.

METHODS

Outline of device

Figure 1 shows the designed fitting. It is made from shoji paper, which is the traditional paper of Japan. The structure of the device is five air layers created by the five shoji paper partitions. The multiple air flow of the five air layers due to the shoji paper partitions is installed.
Figure 2 shows the principle of the device. Buoyancy is created by a decrease in the density in the air layers because of the solar heat gain from the outside. This chimney effect is used as the driving power of the ventilation. Indoor air is drawn by the chimney effect, and ventilation is created. The heat generated on the surface of the device is extracted before it reaches indoors. In summer, it is used for ventilation.
Moreover, the device provides insulation when the air layers of the device are sealed up. The midair layers between the shojis do not transmit heat. Therefore, it can be used for insulation at nighttime in winter.



a) b) c)

Figure 1. View of device. a) Outside. b) Detailed cross section. c) Inside.

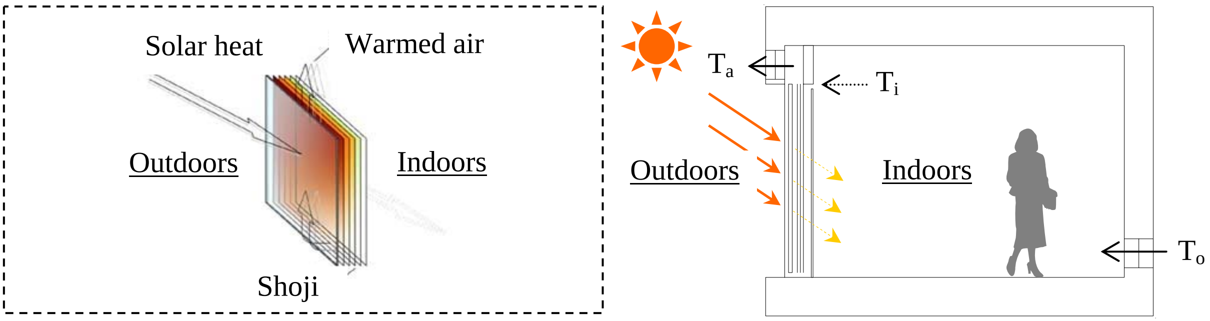


Figure 2. Chimney effect of solar heat.

Performance evaluation experiment of device

The performance of the device was confirmed by experiment. This experiment result was previously reported[1)]. Table 1 a) shows the amount of ventilation to quantity of solar radiation and b) shows various overall heat transfer coefficient. A ventilation experiment was performed to verify the ventilation performance by measuring insolation and circulation. The amount of ventilation obtained by this device was 93 m^3/h. The calculation value was 80 m^3/h. Compared to the calculated value, the experimental value reached a higher value due to the external wind effect. The insulation efficiency of the device was examined to determine whether the performance was adequate for a house. The heat loss experiment was conducted according to the JIS[2)] standard. The overall heat transfer coefficient reached a low value of 1.63 W/m^2K. Moreover, it was a sligthtly smaller value than the value of general fittings. This may indicate that the number of shoji layers should be five in the production fitting to increase the thermal resistance of the air spaces. Therefore, it is thought that this device can be adjusted to most houses because the adiabaticity of the production fitting is more excellent than that of general fittings.

Table 1. a) Amount of ventilation. b) Various overall heat transfer coefficient.

a)

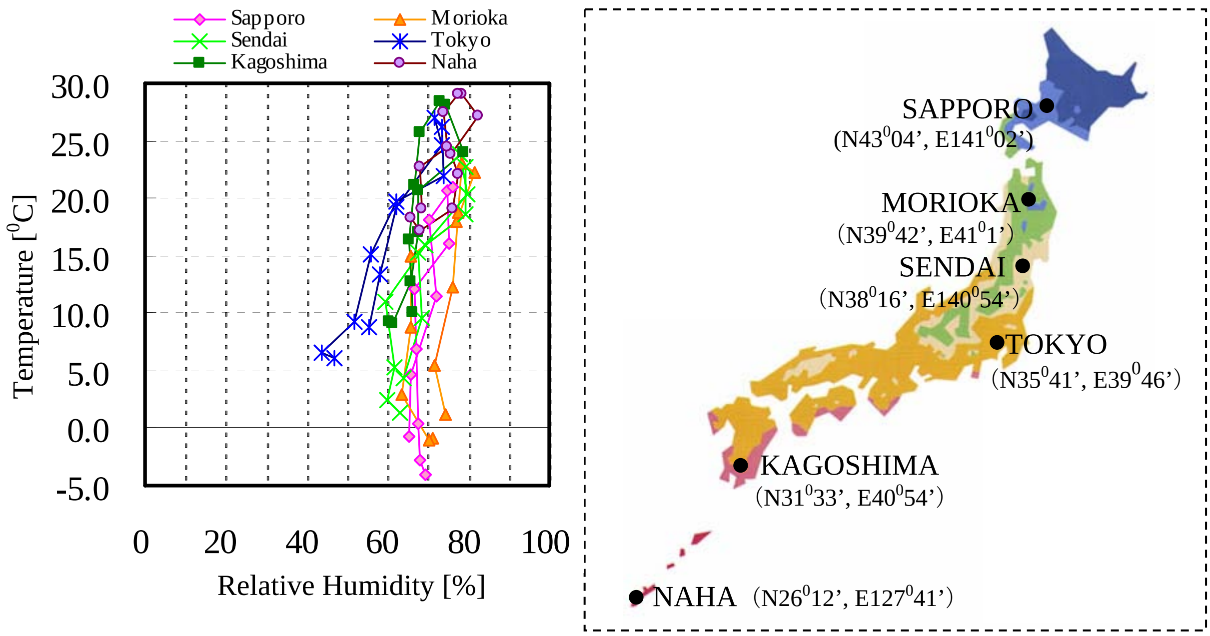
Quantity of solar radiation [W]	Amount of ventilation [m^3/h]	
	Calculated value	Experiment value
733	80	93

b)

Heat street rate [W/m^2K]		
Single window 3mm	Double glass window 12mm	Production fitting
6.00	3.40	1.63

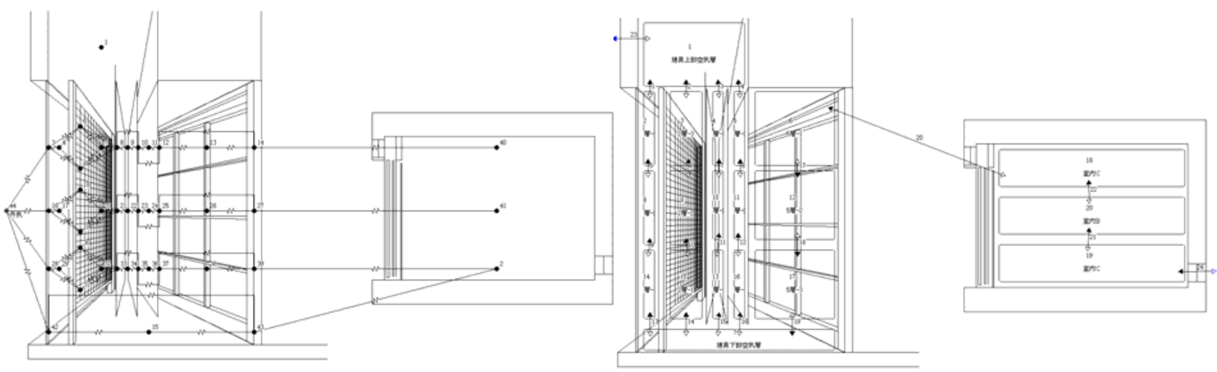
Outline of simulation

The external wind effect was large in the ventilation experiment. The performance of the building model with the installed device was also estimated by a simulation. The performance of the building model was compared for different climate and azimuth conditions. Furthermore, the building models of various conditions were forecasted and the indoor thermal environment of the building models was evaluated.
Figure 2 is a cross section of the building model in the simulation. The floor, wall, and roof are completely insulated. The influence of the insulation heat and the outside temperature is given from the window. Here, the window side of the building model is the azimuth of the building model. The building model was turned to four azimuths facing the south, the north, the west, and the east for the analysis. The building model was analyzed for the weather of six typical areas. Japan is long and has different geographical features in the north and south. Therefore, the climate is greatly different according to the region (Figure 3).
Figure 4 shows the thermal and airflow network model. In the numerical analysis, the thermal and airflow network model simulation program NETS[3)] was used.



a) b)

Figure 3. a) Climograph. b) Analytical regions.



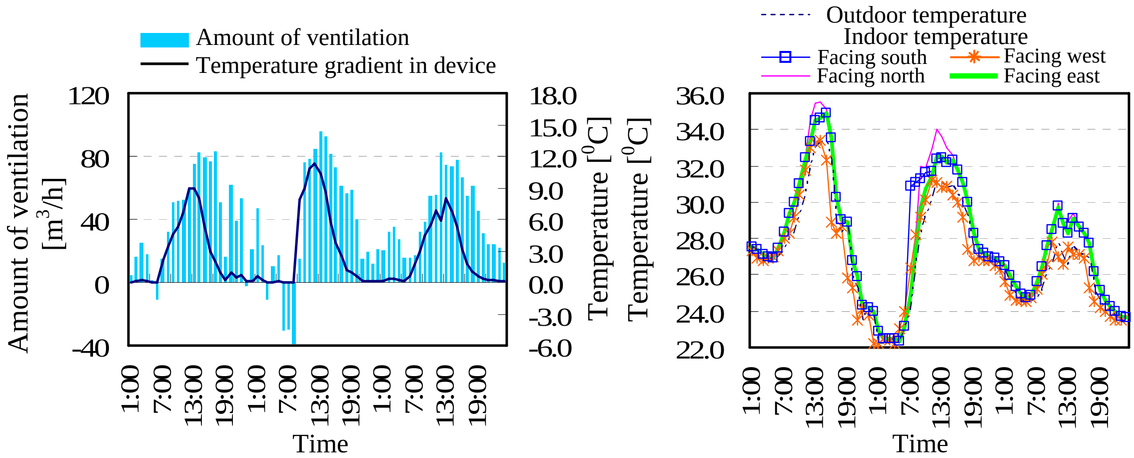
a) b)

Figure 4. a) Thermal network model. b) Airflow network model.

RESULTS

Natural ventilation and thermal environment

Figure 5 a) shows the vertical temperature gradient in device and amount of ventilation. This figure shows the value of the building model facing the south in August in Tokyo. The amount of ventilation follows the temperature gradient. Therefore, ventilation due to the temperature gradient was confirmed. Figure 5 b) shows the outdoor and indoor temperature on the building model for all four azimuths. This figure shows the value of the building model in August in Tokyo. The room temperature of the model facing the east is the lowest, when there is a maximum amount of ventilation.



a) b)

Figure 5. a) Temperature gradient and ventilation performance. b) Outdoor and indoor temperature.

Amount of waste heat

Figure 6 is the scatter chart of the amount of waste heat. This figure shows the value of the building model facing the south and the north in August in Tokyo. There are correlations in the waste calories and the quantity of solar radiation. Ventilation performance is improved when the solar radiation is high, because the amount of ventilation depends on the heat acquisition of the device. However, the amount of waste heat of the building model facing the north was calculated as 50 % of that of the building model facing the south.

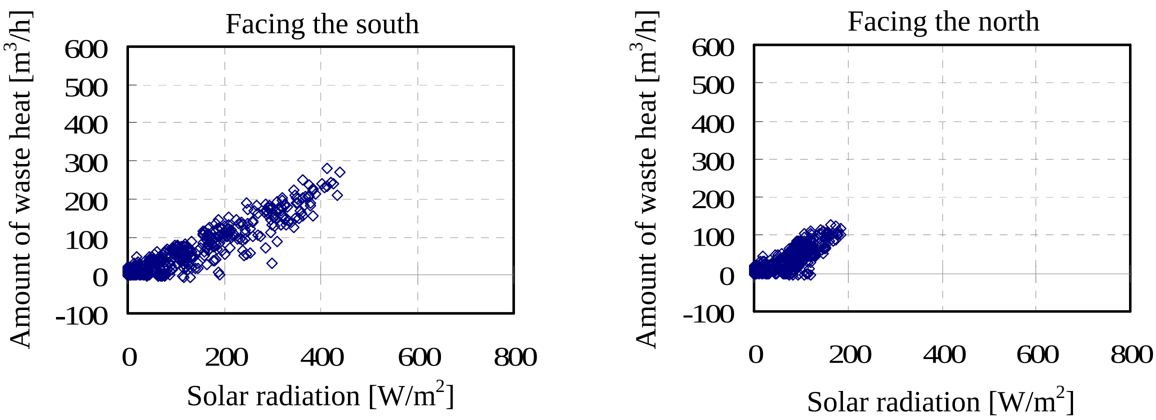


Figure 6. Amount of waste heat to quantity of solar radiation.

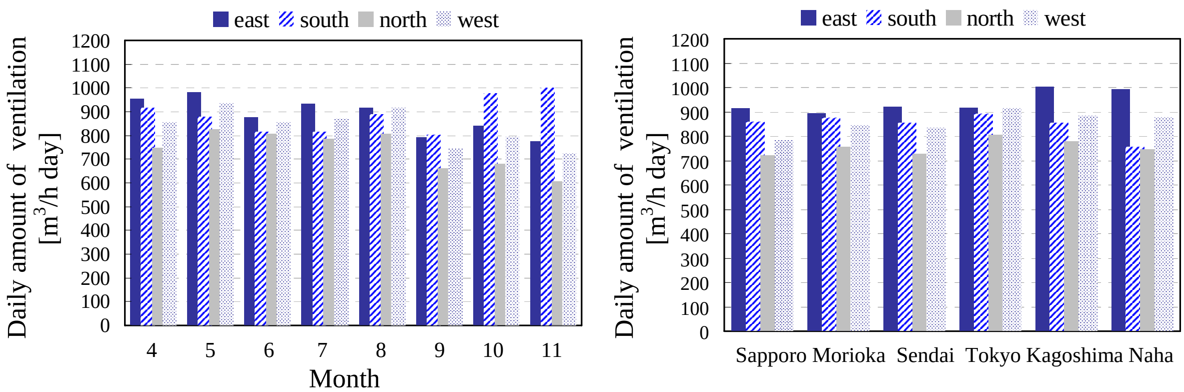
Amount of ventilation

Figure 7 a) shows the daily amount of total ventilation from April to November in Tokyo. The building model facing the north has a calculated amount of ventilation from 60% to 90% of that of the other azimuths models in each period. Figure 7 b) shows the daily amount of total ventilation in the six regions of Japan. The model building facing the north has a calculated amount of ventilation from 84% to 98% of that of the other azimuths models in the various regions. The difference of the amount of ventilation by the region of the building model was slight.

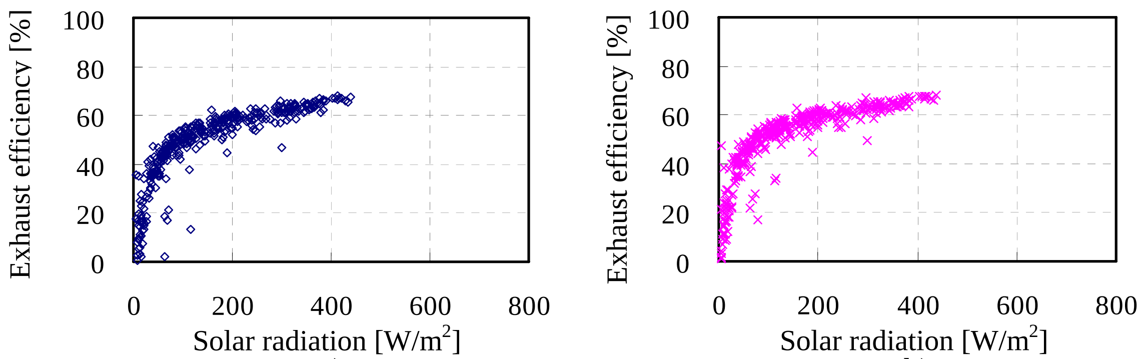


a) b)

Figure 7. Daily amount of ventilation. a) From April to November. b) In six regions in August.

Exhaust efficiency of device

Figure 8 shows the relation of the exhaust efficiency to quantity of solar radiation in Tokyo. It is thought that the width of each air layer in device influenced the amount of ventilation from the result of amount of ventilation. Therefore, performance of the structure which made double of the width of second, third and fourth air layer was confirmed. The exhaust efficiency was calculated from the temperatures fluctuations of T_a and T_i and the temperatures fluctuate of T_a and T_o (Figure 2, (1)). The difference of the exhaust efficiency was slight, when the width of air layers is made wide. When the quantity of solar radiation exceeds 200 W/m^2, the inclination of the scatter chart becomes small. The exhaust efficiency reaches a maximum of 70% as the quantity of solar radiation increases.



a) b)

Figure 8. Relation of exhaust efficiency. a) Before structural modification. b) After structural modification.

$$\text{Exhaust efficiency [\%]} = \left(\frac{T_a - T_i}{T_a - T_o}\right) \times 100\,, \qquad (1)$$

DISCUSSION

This paper next examines the efficiency of the ventilation system on the basis of the simulation results.

Performance of device

There are correlations in the amount of ventilation and the quantity of solar radiation. It was shown that the solar heat helped to drive the power of the ventilation. The amount of ventilation follows the temperature gradient. Therefore, natural ventilation was confirmed. In addition, the heat generated on the surface of the device was extracted by ventilation before it came indoors. Thus, the thermal insulation performance of the device was confirmed. However, the exhaust efficiency by ventilation reaches a maximum when the quantity of solar radiation exceeds 200 W/m^2. Therefore, the difference of the amount of ventilation in the six regions and the four azimuths was slight.

Design of device

The width of each air layer greatly influenced the amount of ventilation. Thermal resistance in the device is large. Therefore, it is necessary to review the design of the device. However, experimental results of the insulation performance may indicate that the number of shoji layers should be five in the production device to increase the thermal resistance of the air spaces. Therefore, the device is thought to have adjustability to various conventional houses.

This research proposes a simple device added to a window with function of ventilation and thermal insulation. The functions demanded from a window are light, view and ventilation. The proposed device must provide a secure, continuous structure from outside to inside. Therefore, the device that provides both ventilation and insulation efficiency was produced. The ventilation performance of the device using a natural resource and the insulation performance of the device using a natural material were confirmed. People will feel the positive effect from connecting to nature by using this device. The technology proposed here can be combined with traditional skills to create a new architectural style for future generations.

ACKNOWLEDGMENT

NETS is thermal and airflow network model simulation program developed by Dr. Okuyama H of Shimizu Corporation Institute of Technology. The author greatly appreciates the offer of NETS.

SUMMARY

Within the Polish - Norwegian project SUREBILD (Sustainable Redevelopment of Buildings) special attention was paid to find the economically feasible technologies that might improve current poor indoor air quality in Polish schools. Detailed analysis has been performed for selected primary school including different scenarios of modernization of ineffective passive stack ventilation system. The results indicated that hybrid ventilation was the most interesting option from energy point of view. The paper describes whole year simulation of natural and hybrid ventilation performance and estimation of indoor air quality. Detailed simulation with 1 min time step was carried out using CONTAMW simulation environment. The comparisons take into account airflows, CO_2 concentrations and perceived air quality expressed in decipol units. Because of huge amount of data the results are partly aggregated by statistical methods.

INTRODUCTION

In order to support theoretical education by practical application, school constructed nowadays usually incorporate elements of sustainable development. However, as 70% of school buildings in Poland are older than 20 years, existing buildings' modernization is the crucial problem. Within the project SUREBILD many potential technologies for sustainable modernization of these schools have been analyzed. Special attention was paid to find the economically feasible technologies that might improve current poor indoor air quality in Polish schools.

Measurements indicate that ventilation rate is typically within the range 2-6 m^3/(h pupil) while required value is 20 m^3/(h pupil) [1]. Inefficient ventilation systems result in high CO_2 concentrations (up to 4200 ppm) in the classrooms [2]. The project team studied number of different ideas that can improve this situation [3]. A general recommendation for modernization of Polish schools is that more attention should be paid to selection of low polluting finishing materials. In addition, natural ventilation should be supported by adapted mechanical systems in order to assure energy efficiency and comfort irrespective of weather conditions and occupants behaviour. Although the installation of fans and pumps will induce an additional electric energy demand, the possibilities for efficient heat recovery in mechanical systems can reduce the need for heat considerably. Demand control of the ventilation can further improve the energy performance without compromising indoor air quality and comfort.

Although relevant measurements were not carried out in schools in Zgierz, the site inspections, discussions with users and indirect indicators like lower than estimated for standardized conditions fuel consumption indicate that similar situation is present in this school.

METHODS

Current ventilation system

At the moment, the school in Zgierz is equipped with ineffective natural ventilation. Fresh air is supplied through leaky windows and then heated within the classrooms by the space heating system. Exhaust air from the classrooms passes into the school hall via transfer grills. Several stacks located in the hall allow the air to leave the building. The cross sections of the transfer grills and the grills mounted in the stacks are strongly reduced by the operating staff partly for energy conservation reasons and partly due to noise transfer.

Indoor air quality is occasionally improved by opening windows in the classrooms (single side ventilation). In winter this procedure is performed during the breaks between lectures. During warm days in spring and autumn windows are also opened during lectures. Because of the climatic conditions in Zgierz (design range of ambient temperature –20 ÷ +30 ºC), a system based purely on natural ventilation without heat recovery has very poor energy performance during the heating season. However, natural ventilation can be a very good passive mean to provide natural cooling and comfort in the cooling season.

Concepts for ventilation system modernization

The initial architectural concept for rehabilitation of the school involves the introduction of a new atrium that would increase the useful floor area in the building [4]. Experiences with energy performance in hybrid ventilated schools in Norway [5] indicate that in order to find the optimal ventilation concept, combined solutions involving both natural and mechanical ventilation should be considered. In the case of Zgierz school, three basic relevant concepts have been analyzed:

- stack based hybrid ventilation with run around heat recovery,
- decentralised mechanical ventilation with high-efficiency heat recovery,
- mixed mode ventilation.

The energy consumption was estimated for these options (taking into consideration additional variants). Basic assumptions for simulations are presented in table 1.

Table 1. Summary of basic assumptions for different ventilation options.

Option	Air volume [m^3/(h pupil)]	Heat recovery efficiency [%]	Specific fan power [kW/(m^3/s)]
Current situation	20	-	-
Hybrid ventilation	30	~ 60	0.5
Decentralized mechanical system	30	>80	2.5
Mixed mode hybrid ventilation and decentralized mechanical system	30	>80	1.5

The results of the simulations presented in table 2 show that the total primary energy demand (560.4 kWh/m^2 in the base case) can be significantly (~63%) reduced by thermo-modernisation (improved thermal characteristics of the building envelope components, replacement of old coal fired boilers - average efficiency ~50% - by new energy efficient gas boilers; average efficiency ~95% and reduction of thermal loses in the heating network) and by improving building air tightness (additional 4%). Implementation of hybrid ventilation or mechanical ventilation can also strongly contribute to energy conservation respectively up to 76% and 73.3% respectively. Primary energy calculation were performed using primary resource energy factors: 0 for renewable energies, 0.5 for biomass, 2.5 for electrical power and 1.0 for all other fuels.

Table 2. Energy consumption simulations extended to whole year [6].

Case	Heating demand [kWh/m^2]	Reduced heating demand relative to base case [%]	Lighting energy demand [kWh/m^2]	Fan energy demand [kWh/m^2]	Total energy demand [kWh/m^2]	Total primary energy demand [kWh/m^2]	Reduced primary demand relative to base case [%]
Base case	209.2	0.0	15	0	224.2	560.4	0.0
Building rehabilitation	152.9	26.9	15	0	167.9	207.4	63.0
Infiltration red. from 0.4 to 0.2 ach	133.1	36.4	15	0	148.1	185.4	66.9
Hybrid not utilizing culvert	81.1	61.2	15	3.1	99.2	135.4	75.8
Hybrid utilizing culvert	80.4	61.6	15	3.1	98.5	134.6	76.0
Mechanical ventilation	65.4	68.7	15	15.7	96.1	149.4	73.3
Mixed mode ventilation (MV/HV)	65.6	68.6	15	9.4	90.0	133.9	76.1
MV/HV with 0.1 ach infiltration	58.3	72.1	15	9.4	82.7	125.8	77.6

As hybrid ventilation turned out to be very interesting solution, this system has been investigated more detailed. The concept of stack based hybrid ventilation with run around heat recovery applies one or a few central air intakes. Outdoor air passes through refurbished, ground coupled culverts in the basement (figure 1). Axial help fans are placed at the culvert entrances to provide the necessary airflow when natural driving forces are insufficient.

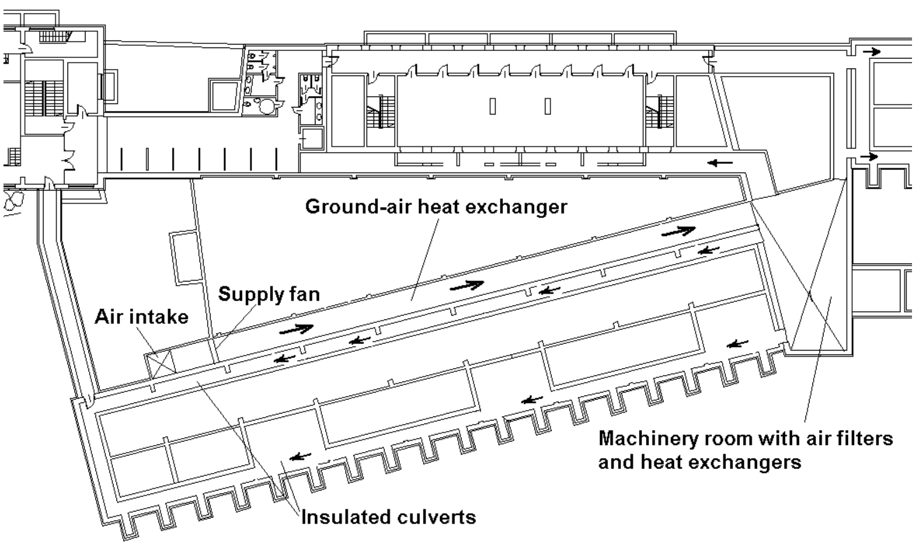

Figure 1. The plan of the basement in primary school in Zgierz after modernization with description of hybrid ventilation – one of the analysed versions [4].

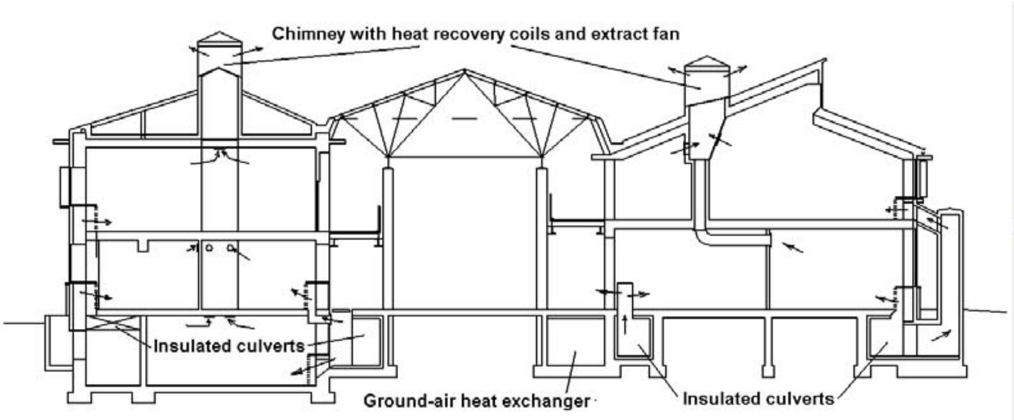

Figure 2. The cross section through two school buildings and the atrium with description of hybrid ventilation – one of the analysed versions [4].

The fans also prevent thermal stratification in the culverts and increase turbulence, resulting in increased convective heat transfer between the supply air and the culvert walls. The air is then filtered before preheating with filters placed at the end of the culverts.

After filtering, the air passes through a first set of heat exchangers connected to similar heat exchangers at roof level via pipes circulating water with some antifreeze solution. The heat exchangers at roof level recover heat from the exhaust ventilation air with an assumed efficiency of 60 %. The supply air then passes through a second set of heat exchangers connected to the central (water) heating system in the building, providing the additional heat needed to reach the desired supply air temperature. The air is distributed to the various rooms in the building via horizontal insulated ducts placed in the intake culverts connected to vertical ducts leading up to the various classrooms. The air is distributed into the classrooms via diffusers for displacement ventilation, and is extracted at ceiling level via bypass openings leading to the corridor.

Central air outlets are connected to the first floor corridors. The ventilation air that enters the ground floor corridors enters the first floor corridors via staircases or other bypass openings (figure 2). In addition to the exchangers for heat recovery, the central air outlets are equipped with demand controlled axial help fans. The control of the supply and extract fans are co-ordinated so that the system operates close to balanced mode.

The design of the exhaust tower/chimney should be given special attention in order to utilize wind as a driving force for ventilation, and prevent cold outdoor air from entering and coming in contact with the recovery heat exchanger, which otherwise would reduce the heat recovery efficiency.

It is also essential that the filter and the heat exchangers have large cross sections to ensure that the required airflow rates can be ensured with minimal pressure drop.
A similar concept has been successfully applied in many Scandinavian school buildings. However, many of these pilot study projects have unnecessary weaknesses that should easily have been avoided. It is therefore important to take advantage from the knowledge gained from these projects if this concept is to be applied at the Zgierz school.

Indoor air quality assessment

As indoor air quality is generally recognized as the key problem in Polish schools, the assessment of contaminant concentration in modernized school was essential for sustainable redevelopment of Zgierz school. As detailed information about properties of finishing materials that could be used during modernization are not available, carbon dioxide generated during room occupation was selected as the characteristic contaminant. The assessment was performed using computer program CONTAMW ver. 2.4 [7]. CONTAMW is a simulation tool designed to determine:

(a) airflows: infiltration, exfiltration, and room-to-room airflows in building systems driven by mechanical means, wind pressures acting on the exterior of the building, and buoyancy effects induced by the indoor and outdoor air temperature difference.

(b) contaminant concentrations: the dispersal of airborne contaminants transported by these airflows; transformed by a variety of processes including chemical and radio-chemical transformation, adsorption and desorption to building materials, filtration, and deposition to building surfaces, etc.; and generated by a variety of source mechanisms, and/or

personal exposure: the predictions of exposure of occupants to airborne contaminants for eventual risk assessment.

Figure 3 presents the sketchpad of CONTAMW program with zonal representation of Zgierz school. Simulations performed with 10 min time step covered all rooms in modernized school [8].

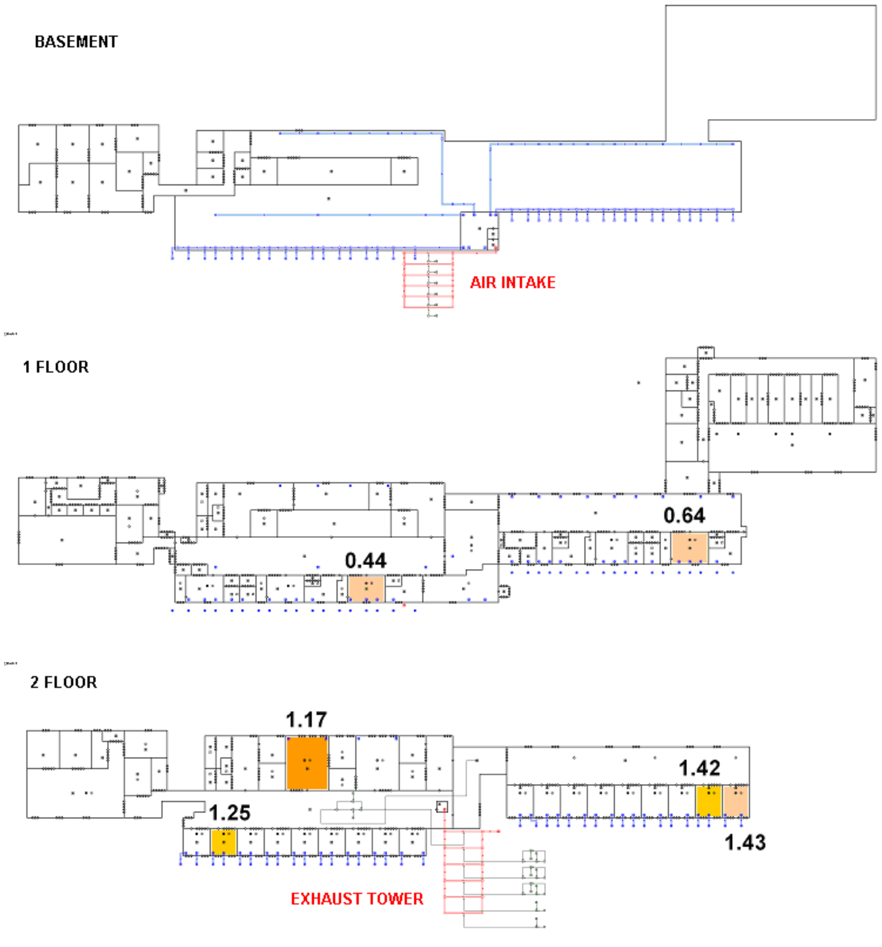

Figure 3. Zonal representation of Zgierz school (centralized hybrid ventilation option and control system connections); sketchpad of CONTAMW program [8].

RESULTS

The results obtained for selected room at 1 floor (room 0.44) are presented at figures 7 while those obtained for room 1.25 (representative of rooms located at 2 floor) are presented at figure 4. Performed estimations indicated that passive stack ventilation should not be recommended any more for modernization of Polish schools. Even though the classrooms was equipped with 12 vents (at 10 Pa) ventilation intensity is too small and resulting levels of CO_2 are high. Such conditions would result in increased concentrations of other pollutants emitted e.g. from finishing materials. Moreover in case of passive stack ventilation indoor air quality is strongly associated with weather conditions. In both presented classrooms concentrations of pollutants are the highest in June (hot period), and the lowest in January (cold period). It is worth to point out that rooms located at 2 floor due to lower stack heights have generally worse level of indoor air quality.

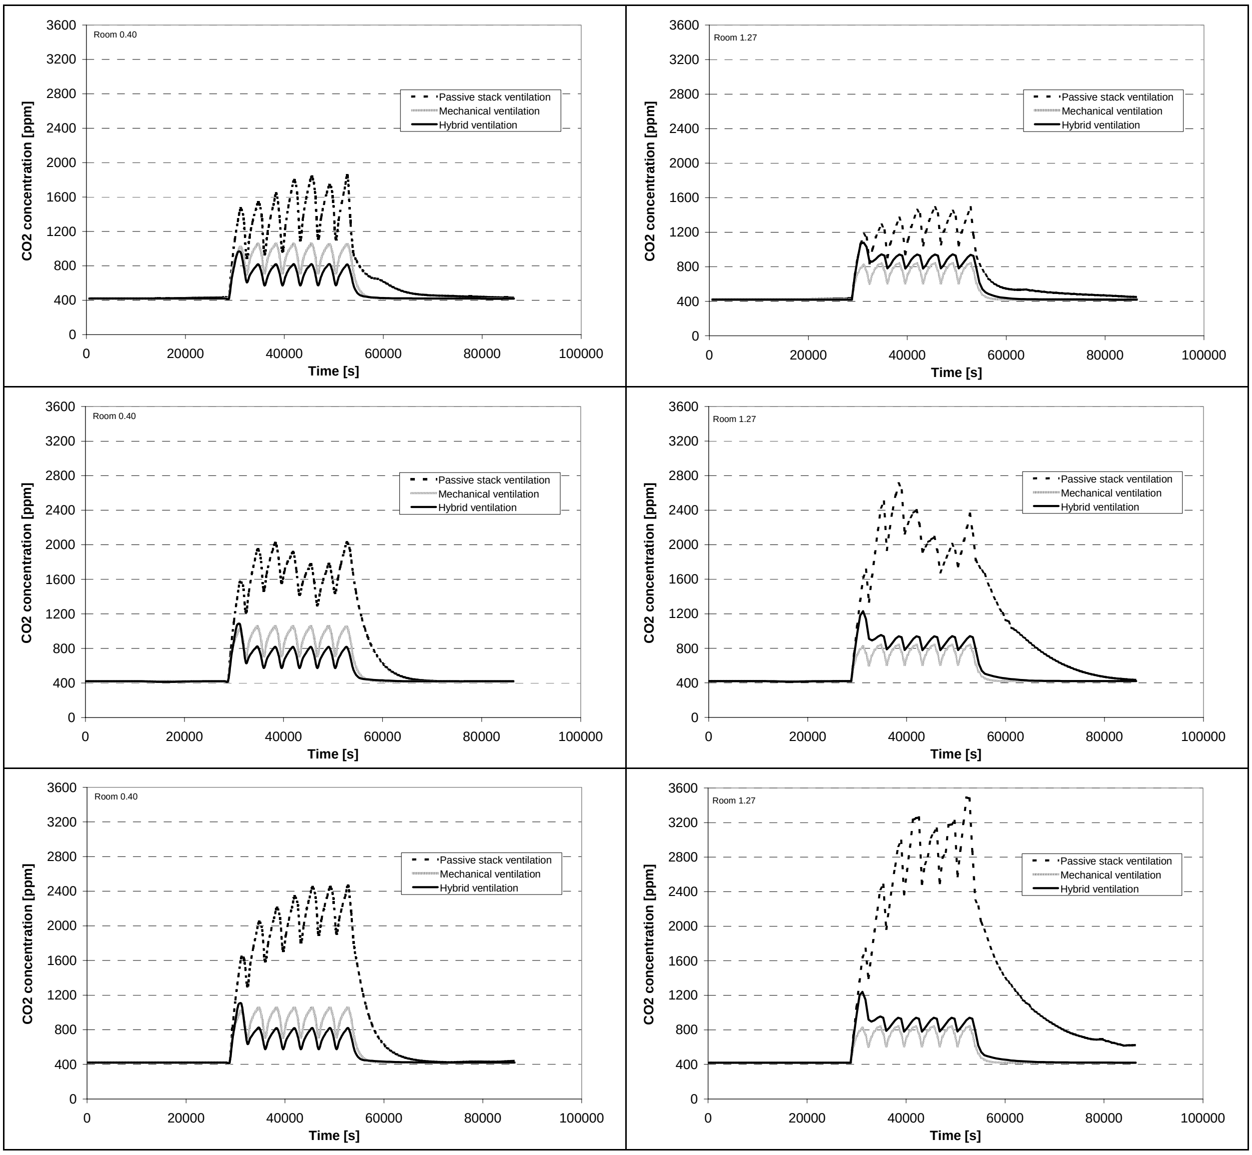

Figure 4. Comparison of CO_2 concentration levels in one of classrooms at 1 floor (room 0.40 - left) and in one of classrooms at 2 floor (room 1.27 right) selected day in January (top); Selected day in April (middle) and selected day in June (bottom) [8].

On the other hand both mechanical and hybrid ventilation are capable to maintain required air quality within classrooms irrespectively of weather conditions.

Mechanical ventilation is based on constant air volume concept (30 m^3/h person) while concept of hybrid ventilation assumes application of control system based on CO_2 concentration. Therefore in some cases the ventilation rates can be lower than minimum 20 m^3/h required for every pupil. However these situations are observed only in the morning after start up of the system when air in classrooms is still clean. The tuning of control algorithm in real building could easily reduce number of hours with ventilation rates below minimum rewired values. On the other hand new proposals of EU standards in case of CO_2 based demand controlled ventilation propose the requirements just fore CO_2 concentration not for ventilation rate.

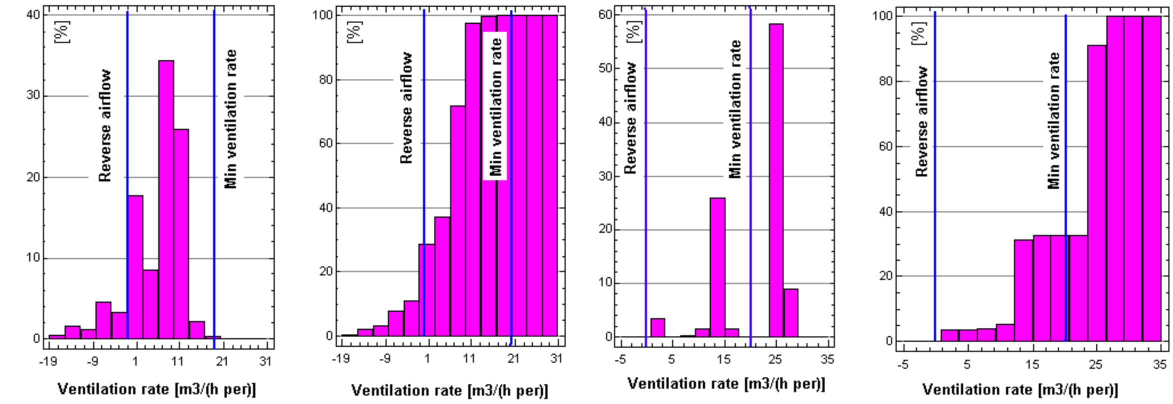

Figure 5. Comparison of frequency and cumulative frequency of ventilation rates in one of classrooms at 2 floor (room 1.43) natural ventilation with air vents (two graphs on left) and demand controlled (CO_2) (two graphs on right) [8].

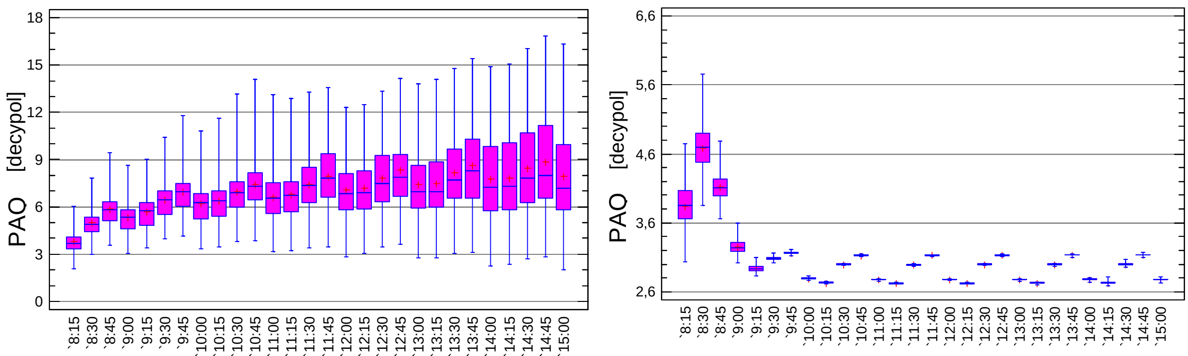

Figure 6. Comparison of average profiles of Perceived Air Quality PAQ in room 1.43 for winter conditions: natural ventilation with air vents (left) and demand controlled (CO_2) (right) [8].

The comparison of distribution of ventilation rates in case of natural ventilation with vents and for hybrid ventilation is presented at figure 5 (for mechanical ventilation air flow rates are constant). These figures represents data obtained for room 1.43 at 2 floor. The graphs once again indicates that natural ventilation does not provide enough fresh air to the classrooms. In analyzed classroom minimum ventilation rates per person are never reached, and moreover during almost 30 % of time air flows has reversed direction (air supply through transfer grills and exhaust through vents in windows. This phenomenon is nor observed in case of hybrid ventilation. It should be pointed out that very low ventilation rates are observed just after pupils enter the classroom. When sensors measure increased concentration of CO_2 ventilation rates are increased.

Figure 6 presents the example of simulations of perceived air quality (assumed emission from finishing materials 0.1 olf/m^2) . It can be observed that PAQ can be lowered from ~8 decipol to 3 decipol that could lead to reduction of percentage of dissatisfied visitors from 57 to 33%.

DISCUSSION

The IAQ analysis indicated that both solutions mechanical ventilation and hybrid ventilation can be regarded as very close to optimal option of ventilation for Zgierz school. Differences between mechanical and hybrid ventilation are the result of applied CO_2 based demand controlled strategy for ventilation intensity and assumed levels switching between speed of fans. The great improvement in IAQ can be obtained together with significant reduction of primary energy use of the school. The results are based on analysis of just one school. However, this object is representative for hundreds of schools erected in sixties in XX century. Similar analysis of these schools would thus probably lead to resembling conclusions.

ACKOWLEGEMENT

The paper describes part of the results from the research project SURE-BUILD, funded by the Royal Norwegian Ministry of Foreign Affairs through the Cooperation Programme with the EU Candidate Countries within Higher Education and Research via the Research Council of Norway and the Norwegian Council for Higher Education.

The importance of accurate wind pressures for natural ventilation design

David Banks and Thomas Scott

Cermak Peterka Petersen, Fort Collins, Colorado, USA

Corresponding email: dbanks@cppwind.com

SUMMARY

Many naturally ventilated building designs rely on buoyancy (or "stack effect") and night cooling of the structure. It is well known that for an exposed building, even mild winds can produce pressures well above those due to stack effect. It is also common for efficient night purging to rely on wind-driven flows. While tools such as CFD can reliably predict airflow rates through the building, without accurate pressure boundary conditions at the openings to the outdoors, these simulations have little value. A common mistake is to underestimate the complexity of the turbulent flow around buildings in the atmospheric boundary layer. Most of the important flow features that control the pressures on the building surface are intermittent and vary significantly with wind direction. In addition, in most locales, pressures for all wind directions need to be considered, since there is no true predominant wind direction. A specific case-study of a natural ventilation design is used to demonstrate these issues.

COMPARING STACK EFFECT TO WIND PRESSURES

It is well known that the forces driving air through a building during natural ventilation are buoyancy (often referred to as "stack effect") and wind pressure. See for example [1], where the possibility of these forces opposing one another is discussed. Stack effect depends upon a temperature difference between the indoor and outdoors, according to the equation

$$\Delta P = \rho_o \cdot g \cdot \Delta h \left(\frac{\Delta T}{T_o + \Delta T} \right) \qquad (1)$$

where ΔP is the pressure difference, ΔT is the Temperature difference between indoors and outdoors, T_o and ρ_o are the air temperature and density outdoors, g is the acceleration of gravity (9.8 m/s^2), and Δh is the height difference between the inlet and outlet.

Wind pressure across a building is often reported as a fraction of the stagnation pressure of the wind,

$$\Delta P = \tfrac{1}{2} \rho_o U^2 \cdot \Delta Cp \qquad (2)$$

where U is the mean wind velocity at some reference height, and ΔCp is the difference in the pressure coefficient between the inlet and outlet locations. The reference height is an important consideration when calculating the wind pressure. Wind data from airports is often recorded at a height of 10 m, yet pressure coefficients are commonly referenced to velocities at or well above building height. All pressure coefficients discussed in this study are referenced to a height of 150 m, where wind speeds will depend upon whether the site in open country (~1.5 times faster than at 10 m) or an urban area (~2.5 times faster).

For a 150m reference height, mean pressure coefficients of between -1.0 and 1.0 are common. If we assume that the windward side of a building has a mean pressure coefficient of +0.6, and that the leeward side is -0.4, the ΔCp = 1.0. By combining Eqs. (1) and (2), we can predict the mean wind speed at which the wind force will exceed the buoyancy force in this case. Results are shown in Figure 1:

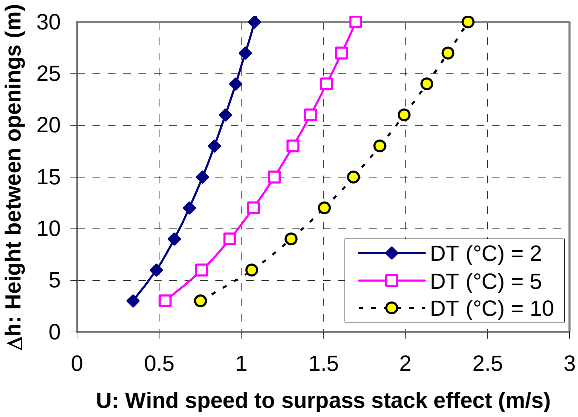

Figure 1. 10 m wind speed above which wind effects surpass buoyancy for ΔCp = 1.0.

It is clear for most buildings that wind pressures will begin to dominate once wind speeds rise above 1.5- 2.0 m/s, which is a majority of the time in most places. For example, wind data for two cities is presented later in this paper. At these locations, winds exceed 2 m/s 84% of the time in Denver, Colorado, USA and 62% (95% in the afternoons) of the time in San Juan, Puerto Rico.

THE IMPORTANCE OF CONSIDERING ALL WIND DIRECTIONS

Many design guides for natural ventilation use the predominant wind direction as a primary consideration in the design [2]. However, many locations do not have a true dominant wind direction. Figure 1 shows wind roses from two cities: Denver, near the center of the USA, and San Juan, Puerto Rico, located in the Caribbean Sea. While south winds are the most common in Denver, the combination of SW-SSE winds accounts for only 38% of the winds. Winds come from other directions nearly twice as often, so a design relying too heavily on these directions may not provide adequate ventilation most of the time. For a design to justifiably focus on only a few wind directions, a truly dominant wind direction is needed, in which case the wind rose should resemble that of San Juan. The tropical trade winds, coming from the NE through ESE, are blowing nearly 60% of the time (and account for 75% of the winds, since it is calm 20% of the time).

It is also important to examine when the winds occur, both seasonally and diurnally. Figure 3 illustrates contours of wind frequency versus direction and time of day for Denver and San Juan in the autumn. Denver's south winds are clearly seen to be a nocturnal phenomenon – useful for night purging, but not for cooling during the heat of the day. Conversely, San Juan's ENE trade winds are absent overnight, but dominate completely in the late afternoon.

A subtle difference in the Denver data between Figure 2 and Figure 3 can be detected. The dominant overnight winds in the contour plot are from SW (225°), rather than south, as in the wind rose. This is because the anemometer was moved roughly 12 miles when a new airport was opened in 1995. The local valleys at the airports are not steep, but they nonetheless

channel the flow differently. It is always worth considering the possibility that winds at the site of a new building will not match those recorded at the airport, particularly where proximity to the ocean or significant topography are involved.

THE IMPORTANCE OF FLUCTUATING PRESSURES

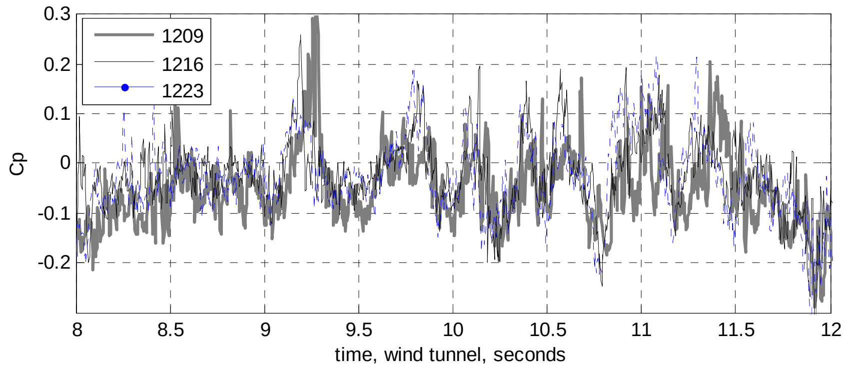
Pressure fluctuations on a building’s envelope are considerable. Peak pressure coefficients most locations on a building vary from -3 to +2, with Cp values below -5 in corner regions if vortices form. These wind pressures will very quickly propagate through the entire internal space. A formula for predicting this response time can be found in [3], but for relatively large indoor spaces such as atria, the time constant is less than one second.

A sample case is examined to demonstrate the importance of pressure fluctuations. Figure 4 is a photo of the pressure model of a 250 m wide, 150 m long 4-level parking garage. Note the absence of any significant nearby structures.

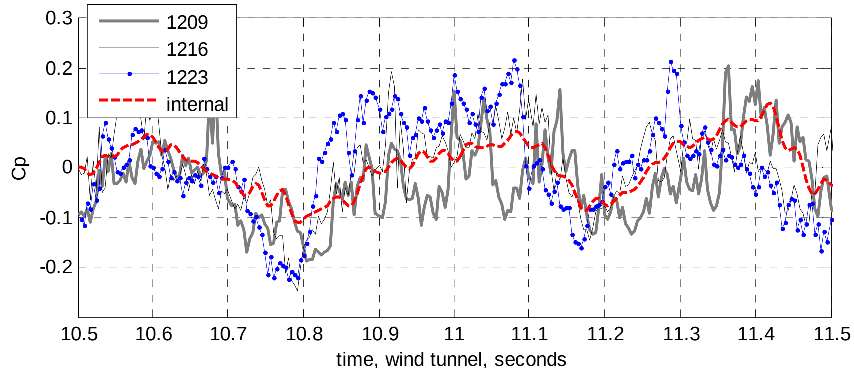
Figure 4. Photo of parking garage pressure model in the boundary layer wind tunnel.

Figure 5 shows a time series of wind pressure coefficients on the northwest face. The pressures shown are all on level 3. The wind is from the southwest in this case. The mean pressure on this face is very close to 0. If the average pressures were used to predict the wind driven flow, there would be none. However, it is clear that air both enters and exits the openings of this face as the pressures rise and fall.

In Figure 5a, the pressures across the entire face appear to follow fairly a common pattern. For example, between 9.0 and 9.5 seconds all three locations experience high positive pressures. Upon closer inspection of the time series in Figure 5b, we see that the pressures do diverge from time to time. This indicates the possibility of air entering at one place on the face, while simultaneously exiting at another.



a)



b)

Figure 5: Pressure Coefficient time series, U_{ref} measured at 150m. a) 4 seconds of data b) 1 second.

The duration of these gusts is an issue – if they are too brief, they will not ventilate as deeply into the garage. The time scale in the wind tunnel can be converted to full scale using Equation (3):

$$t_f = t_{m.} \frac{U_m}{U_f} R \qquad (3)$$

where t is time, the subscripts *m* and *f* indicate model scale and full scale respectively, and R is the model scale length ratio, which is 400 in this case. If wind speeds at full scale match those during the testing (roughly 4-5 m/s at a height of 10 m), then each second in the tunnel is 400 seconds, or nearly 7 minutes at full scale.

Figure 5b also includes a time history of the estimated internal pressure in the garage. (The internal pressure is not measured in the wind tunnel because the time-scaling similarity of Equation (3) does not apply to internal pressures unless the internal volume is modified. [3].) Instead, it is estimated using a flow balancing approach [4]. It is the difference between this internal pressure and the external pressures measured at the openings around the building that will control the ventilation rate. For example, just before the 11 second mark, air would enter at location 1223 (at the west end) and exit at 1209 (at the east end), and shortly after 11 seconds, this pattern reverses itself. In both cases, there is very little flow at location 1216 near the center of the face.

These are the fluctuating pressures that drive single-sided ventilation.

The origin of the pressure fluctuations is twofold – in the approach flow turbulence and local flow structure intability. The approach flow contains turbulence generated by flow over upstream surface roughness. The turbulence includes larger eddies that completely envelope the building, and mid-scale turbulence that produces local high pressures on only one part of the structure. The effects of these scales can be roughly approximated using a quasi-steady approach [5]- for example, the effects of low-frequency lateral turbulence can be approximated by examining the average pressures for a range of wind directions.

The pressures beneath the flow separation at a building's corner is not well predicted by quasi-steady theory, however [6]. This is in part because the separated flow zones are inherently unsteady, with flow structures such as vortices forming, moving, and disintegrating. Pressures in these areas are linked both to wind speed fluctuations and to these flow structures [7]. The behaviour of the flow separation is in turn linked to very small scale turbulence in the incident flow, which is thought to interact with the shear layer and cause earlier reattachment and the ensuing higher suction pressures [8].

Note that while it is not as prevalent in this study as in many urban locations, nearby buildings and terrain present a third source of pressure fluctuations on a building, as they shed vortices, channel flow, and shelter parts of neighbouring buildings with their wakes.

CFD SIMULATIONS

The reality of these pressure fluctuations has considerable implications for CFD modelling of airflow through a building. It is not uncommon for a CFD practitioner to recognize the deficiency of using mean pressure boundary conditions for an isolated square building from a handbook when simulating a building in a more complex environment. Given the flexibility of the tool, it is not uncommon for the CFD practitioner at this stage to simply extend the bounds of his or her simulation a few metres outside of the building.

Unfortunately, there is no way to adequately model the flow around the building without including a good boundary layer approach profile and all significant nearby buildings and terrain features. Essentially, if something was necessary to accurately simulate the external flow in the wind tunnel, then it will be necessary to do so in the CFD simulation as well. The computational requirements for such a simulation are the topic of considerable research, but it is clear that to create a realistic, time dependent, turbulent boundary layer and resolve all of the unsteady shear layers on and near the building would require far more computational resources than the internal flow model.

The pressure data from the wind tunnel tests were used as boundary conditions for an unsteady 3-D CFD simulation of flow through the garage. The simulation used over 4 million cells, with RANS turbulence modelling (realizable k-ε). Simulations were performed both with and without rows of cars in place. In the absence of cars, good agreement was seen when compared to a 2-D simulation. Sample output images from the simulations are shown in Figure 6.

The wind is coming directly from the left of the images in these simulations (from 230°). The top of the image is project north. Around the edge of the domain, staircases are shown in grey, column lines in green, and a floor-to-ceiling walls on the west side is shown in black. The four white blocks in the centre represent floor-to-ceiling obstructions (elevator shafts and service rooms). The two round portions at the bottom of the images are circular access ramps.

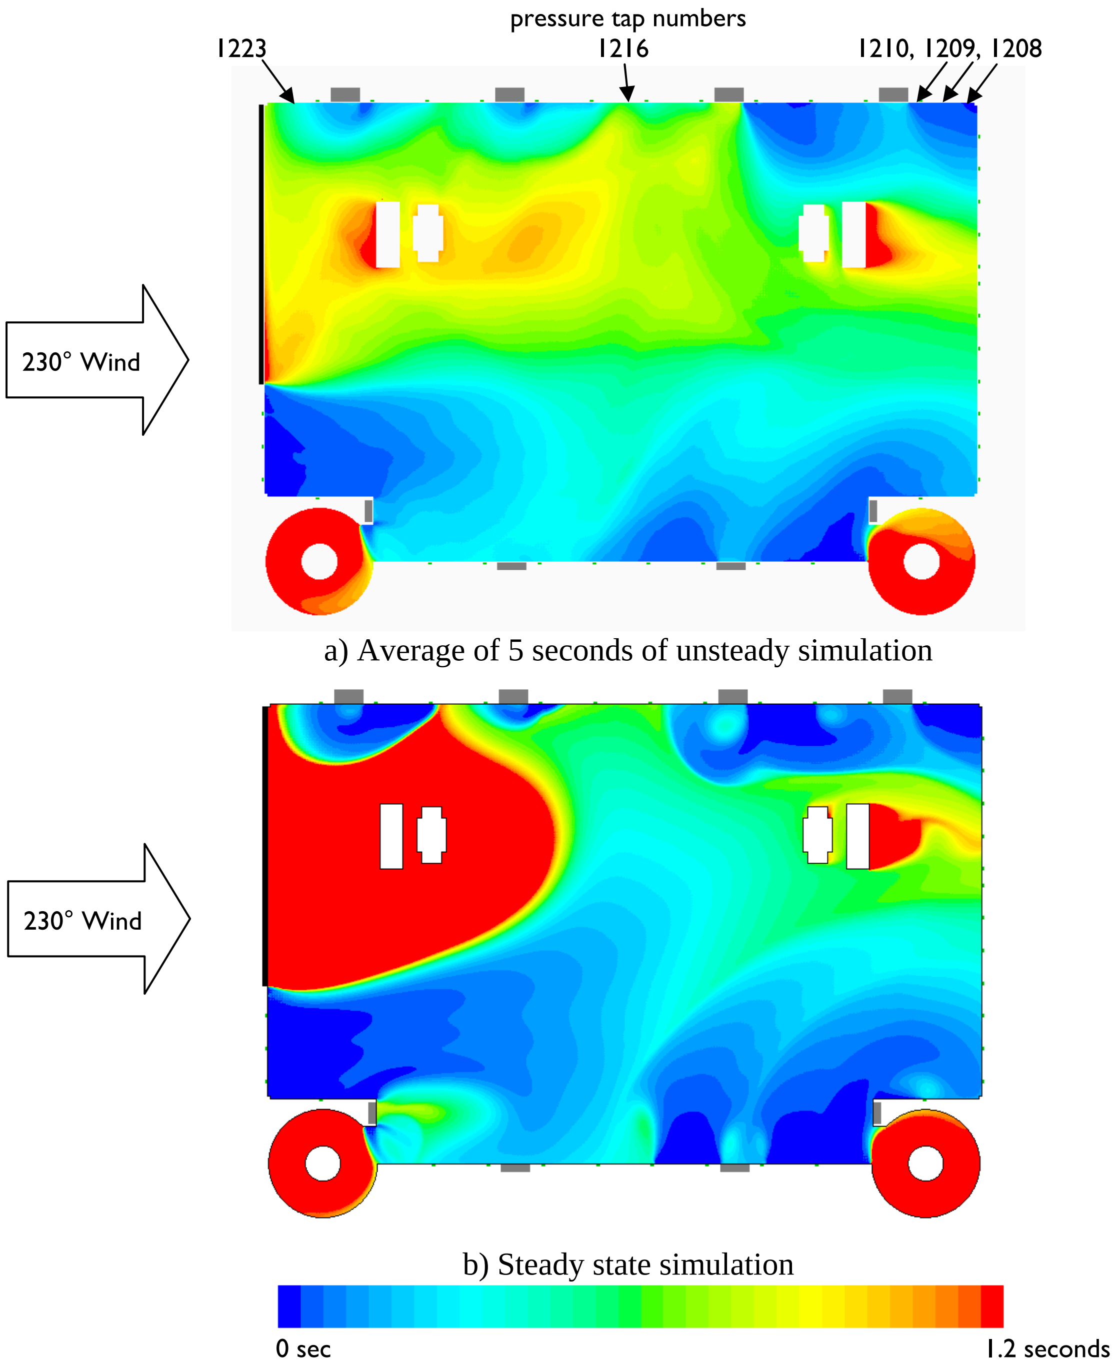


Figure 6. Top view of the garage showing mean age of air (MAA) contours.

In the steady state simulation result of (b), a large, stable recirculation zone forms directly behind the west wall. Some of the air within this zone is over 10 seconds old in the simulation. In the unsteady simulation (a), this area is occasionally flushed clean when tap 1223 sees positive pressures, or exhausted when this location experiences negative pressures. Consequently, the steady state simulation significantly under predicts the natural ventilation.

Note that while this type of flow reversal is beneficial for a parking garage, as it keeps emissions from cars from building up, this is not always the case. For a smoke removal system using natural ventilation, it would be very detrimental to have the exhaust flow reversed by gusts of wind.

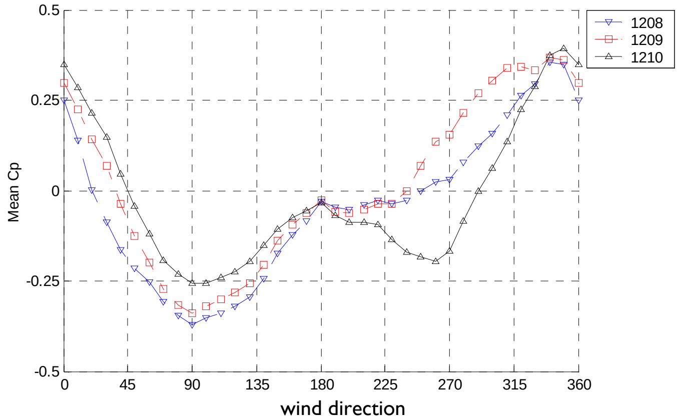

Figure 7. Cp vs. wind direction for taps in NW corner

The flow patterns along the north side of the garage are worth examining more closely. We see that single sided ventilation is enhanced by the two west side stairwells, which create local zones of positive pressure on their upwind sides, and negative pressure downwind, increasing ventilation locally. This pattern is illustrated in Figure 7, showing mean pressure vs. wind direction for three adjacent taps between the northwest stairwell and the corner (see Figure 6). Tap 1210 exhibits negative pressures associated with the separation region behind the stairwell for wind directions between 225° and 290°. It is also important to note how quickly the pressures and the relationship between the pressures changes with wind direction. For this reason, running simulations using only a limited set of wind directions can be misleading. A wind direction shift of only 20° can cause a flow reversal which would not be recognized in CFD simulations run only at every 45 or 90 degrees.

CONCLUSIONS

- Wind pressures will frequently dominate natural ventilation flow rates and paths.
- Winds from all directions should be considered in most designs.
- Pressure fluctuations play a crucial role in ventilation patterns, so steady state simulations are of limited value and should be used with caution.

SUMMARY

The article shows methods for wind influence on building ventilation systems analysis. Solution has been carried out through the experiment in wind tunnel as well as by CFD modelling. Mean pressures and pressure variations have been measured on the model surface with respect of the ventilation intake and exhaust usual situating, with height of the roof parapets modification. The experimental results was presented by pressure coefficients-output is possible convert to different boundary conditions. The wind effect was analysed in different wind direction. The measurement and simulation is focused to the top part of the building façade and to the roof.

INTRODUCTION

Natural ventilation is an air flow inward and outward interior and it is caused by a pressure difference between building interior and exterior. Natural ventilation can create the healthy indoor environment and can save energy but the prediction of ventilation can be difficult. The air is driven in and out due to pressure differences produced by wind or buoyancy forces. Intake air is not usually controlled.

Natural ventilation is typical permanent ventilation, with limited regulation. Energy efficiency depends on the local condition insight and outsight the building. It induces that the same system operates differently from the others in the same conditions. The main influence is caused by the wind.

METHODS

Wind influence on buildings

Wind influence on the building is investigated in the context with static load to the building bearing system. Air flows around the building and the influence on building systems was analysed in the last few years. Wind influence on pedestrians and ventilation systems is significant now.
Natural ventilation systems work with temperature differences or with the wind influence. A typical system works with temperature difference and air intake is realised through the building envelope and air output is situated in the roof. Exterior conditions have influence on an air input (input items) and air flow on the building is fluctuating. There is an impact on the

air output on the roof too. An air output is influenced by positive or negative pressure, which is induced by an aerodynamic effect (a building shape, ventilation systems, a parapet, etc.) Ventilation systems induced by the wind are systems where the wind influence is dominant and the density change by temperature difference is small. A typical system is a one side ventilation or a cross ventilation. But ventilation efficiency is fluctuating.

Exterior and building

There are many ways how to analyse the wind influence on the building. These methods were first of all evaluated for a bearing system design. Maximal pressure influence is needed for this purpose. Maximal wind velocity was statistically analysed in different directions. But ventilation systems work with real wind velocity and wind direction. We need typically average values and local extremes (low and high velocities and pressures). High wind pressure exceeds the ventilation function and regulation is needed, low wind pressure stops ventilation.

Measurement in a real building

Design conditions and the cause of systems failure were already measured in previous studies. Wind velocity measurement was realised in the area where the building was built. Data set was use for a local condition analysis. But data set analysis is really difficult and a correct interpretation is problematic [1].
Real measurement is typically realised with plate or membrane pressure indicators. Plate indicators are put to the building façade and wind pressure pressing the plate. Membrane bending is measured in membrane indicators. These indicators are convenient for extreme pressure measurement in particular.

Figure 1. a) Model scheme of the Faculty and connected buildings, b) Faculty of Civil Engineering model with wind velocity in the roof layer (wind angle 0 - perpendicular to the wind direction)

Computer simulation

Computational fluid dynamics (CFD) provides an alternative approach to calculate ventilation and airflow distributions around buildings. Computer simulation substitute real measurement and save time in this field of study. The most problematic situations can be defined and modelled later in a wind tunnel with better accuracy. CFD models comparison with experimental measurement was compared in previous studies [2]. Experimental 2D model with one side ventilation was compared as the example.
The most common CFD method is Reynolds averaged Navier–Stokes (RANS) method. The method is relatively fast but there can be a problem with a turbulent region around the building especially around the roof. The better method is Large-eddy simulation (LES) which

separates flows into large eddies and small eddies and computes it separately with different methods.

Measurement on building model

Measurement on building model in the wind tunnel is more precise than real measurements. Air flow around the building, pressure on the building façade, flow trajectories can be measured with different wind velocities and azimuth.

The Aeronautical Research and Test Institute (VZLU) boundary layer wind tunnel was used for this measurement. Urban, suburban or plain terrain can be simulated and vertical wind profile can be modified.

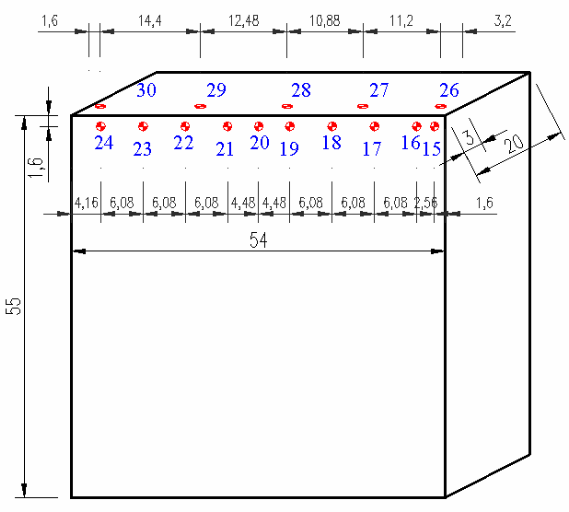

Figure 2. a) Faculty of Civil Engineering, b) The building model with measuring points (dimensions on real building)

A wind effect is determined by a wind velocity and wind direction, time dependence is according to a boundary layer scale. Meteorological effects in large scales are disturbing. That is reason why experimental measurement in the full scale is problematic (dates, intervals). Experimental measurement in the laboratory is time constant and repeatable. Models with complicated geometry and surrounding conditions can be measured too.

RESULTS

Study of the ventilation system performance needs detailed airflow information around and inside the building. The velocity and pressure distributions can be used to determine the ventilation rate.

The measurement was done in boundary layer wind tunnel in Prague. The model was in the scale 1:320 and in different configuration with changeable parapet high on the flat roof. This scale was convenient to model changes (surrounding building), the boundary layer wind tunnel dimension and profile. The real building is a rectangular 15-floor building. Building substructure is connected to surrounding buildings. The wind direction was changed with step 30°.

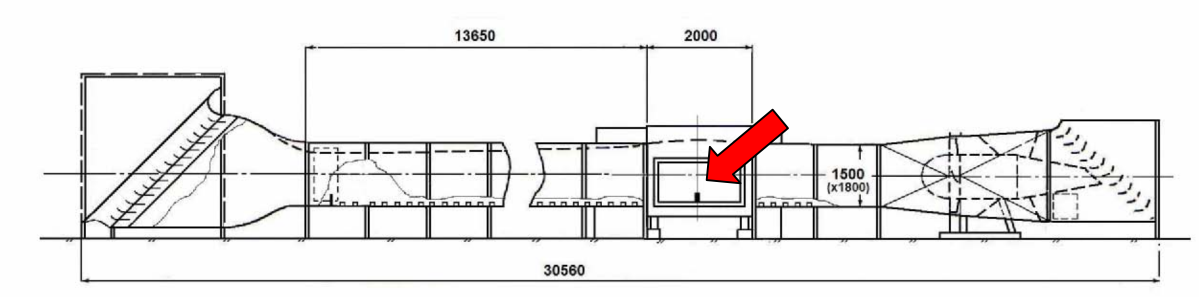

Figure 3. a) The Boundary layer wind tunnel (The Aeronautical Research and Test Institute in Prague) with marked model position

The principle of measurement uses an analogy between a model and a building with given boundary conditions.

Table 1. Measuring points and data set example (angle 0)

Measuring points	15	16	17	18	19	20
Average pressure [Pa]	30,9	42,9	43,4	41,78	41,68	42,27
Standard deviation [Pa]	23,5	22,5	22,3	21,72	19,74	21,75
Pressure coefficient c_{pi}	0,34	0,48	0,48	0,46	0,46	0,47

The measurement was done in the wind tunnel with three different wind velocities in 64 points on the model surface. Wind pressure in the building envelope was measured. The wind vertical profile corresponds to a sub-urban terrain (roughness length is 0,65mm, a suburban roughness). Dynamic pressure is 56,9 Pa in the model roof layer. The pressure was measured by Prandtl probe.
These pressure differences corresponds to the method of unit-less pressure coefficients c_{pi}.

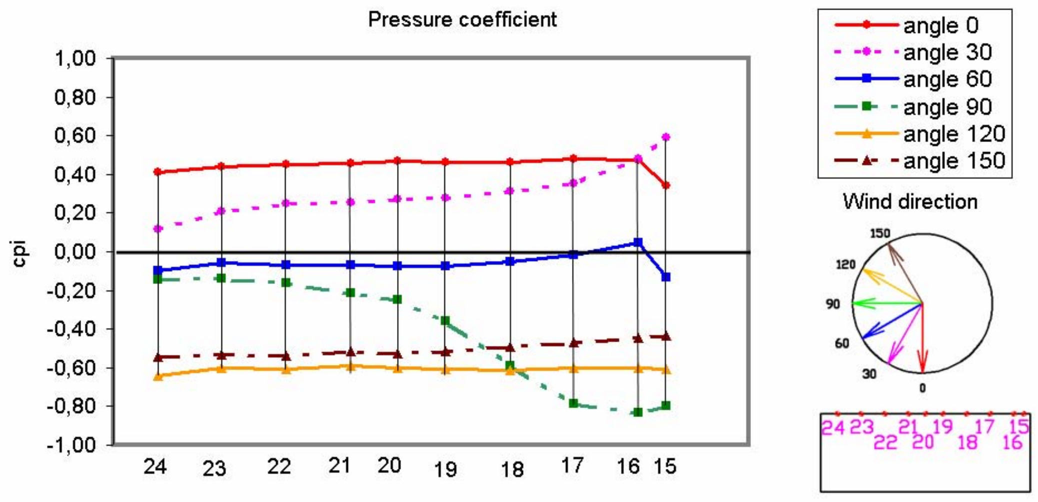

Figure 4. Pressure coefficients (without parapet) 1,6m below the roof layer

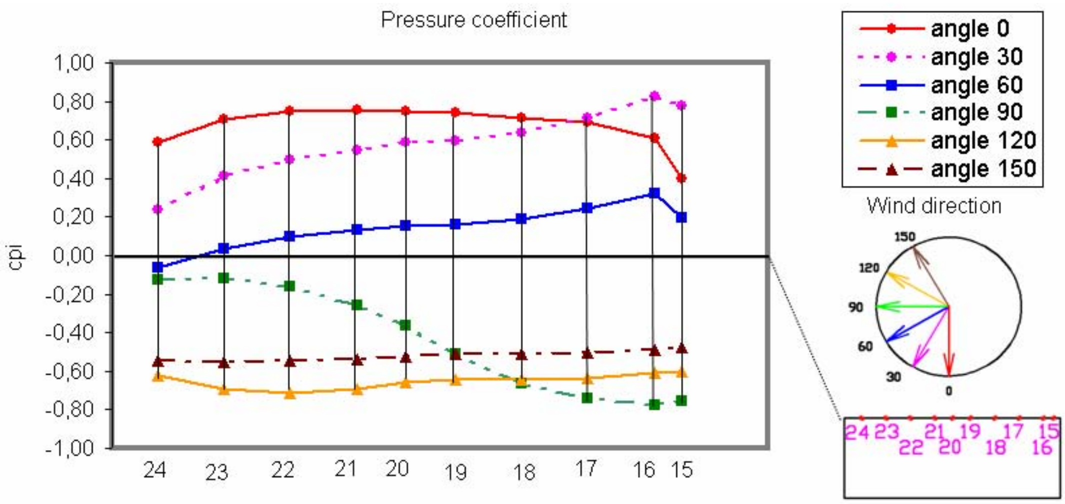

Figure 5. Pressure coefficients (parapet 3,5m) 1,6m below the roof layer

Results from the top part of windward façade (points 15-24) and the roof (points 26-30) are presented.

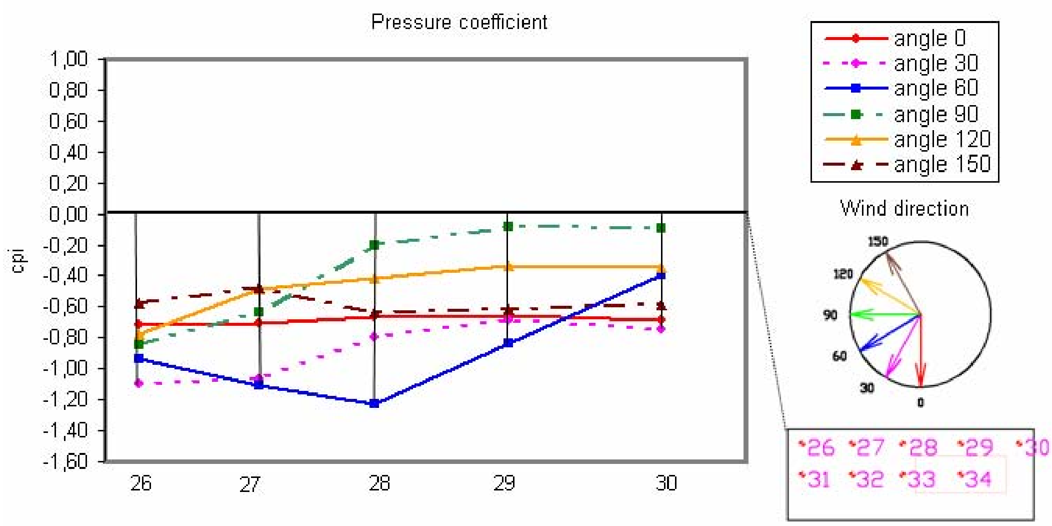

Figure 6. Pressure coefficients (without parapet) on the roof

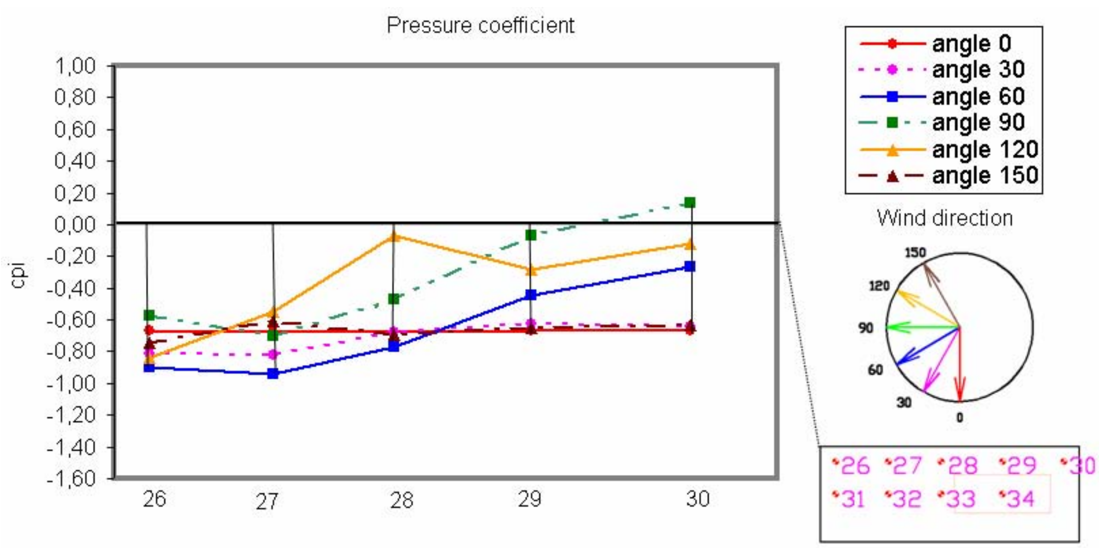

Figure 7. Pressure coefficients (parapet 3,5m) on the roof

The data set was recorded with frequency 10000 s^{-1} and was compared statistically. Average pressures, standard deviations and pressure coefficients cp were recalculated.
The coefficient c_{pi} may be recalculated to different conditions than those used during measurement.

$$c_{pi} = \frac{p_i - p_{ref}}{\frac{1}{2} \cdot r \cdot U_{ref}^2} \qquad (1)$$

Where p_i is pressure [Pa], p_{ref} is reference pressure [Pa] (roof layer), ρ is density [$kg \cdot m^{-3}$] and U_{ref} is reference velocity [$m.s^{-1}$]-air velocity in the roof layer.

CFD simulation

ENVI-MET models

Software ENVI-MET is specialised software for external condition calculations. Surface parameters can be specified, different terrain properties may be applied. Building shapes are limited by rectangles. The exacting character of calculation demands time; the other disadvantage is interface. Boundary conditions are relatively simple.

FLOVENT models

Commercial CFD software is convenient for complicated situations. The wind profile can be specified (or set up) by vertical separation to layers with constant parameters. But the wind profile was not disturbed by a built up area.

DISCUSSION

The air flow around a building surface and the influence on a ventilation system is relatively complicated. Even though simple flow can be determined by CFD simulation, the experimental measurement in the boundary layer wind tunnel must be done in case of detail investigation or complicated situation. The investigation results show that the higher parapet on the model induces higher pressure in the top part of building windward façade (the highest floor level).

The pressure influence on the roof surface with height of the roof parapets modification shows that smaller parapet increases negative pressure on the windward roof area. Higher parapet clams the reverse air flow close the roof surface. The reverse air flow can cause ventilation system failure especially if the input and exhaust is situated on the building roof. The air mixing risk is in this space. Building parapet with lower height (0,5-1,5m) is convenient for natural or hybrid ventilation exhausts – the wind support is the highest in windward part of the roof.

Ventilation Potential: Examining the Effects of Growing Densification in the Tropics

Dr. Zebun Nasreen Ahmed[1] and Gouri Shankar Roy[2]

SUMMARY
The density of Dhaka is increasing exponentially, and with it the demand for residential accommodation. Rapid densification is increasing hard surfaces and changing the urban texture, thereby escalating heat absorption. This intensifies dependency on valuable conventional energy resources, for thermal comfort.
Research shows that regional climatic data differs markedly from localised microclimatic effects within the built environment. In built-up residential areas of the city there is the lack of natural wind flow, one of the most important ingredients for comfort during the warm monsoons. Electricity is growing costlier day by day and its supply is erratic, while load shedding to balance the supply and demand, is very common.
This paper presents the findings of an ongoing research, to investigate the effects of growing densification in the city on the potential for natural ventilation. The work is based on the premise that the effect of variation in density will be reflected in the comparative differences in qualities of the thermal environment (indicated by the temperature and wind speed measurements) in the different residential areas of Dhaka. Higher temperatures in the denser parts of the city may be attributed to larger daytime absorptions and slower night-time cooling, and lack of breeze to distribute the unevenness. In conclusion some passive measures are suggested to rectify the negative aspects of the environment.

Keywords: thermal environment, natural ventilation, urban density

INTRODUCTION
Dhaka is a tropical city lying on the edge of the Tropic of Cancer, with a composite monsoon climate having a rather long warm-humid season [1]. In the past four decades since it became the capital of independent Bangladesh, the city has grown exponentially and is projected to become the second largest city in the World with respect to population growth by the year 2015 [2]. The influx of population increases demand for residential accommodation, which raises the density of the built environment.

Research shows that the main ingredients for comfort [3] during the warm monsoons is the presence of air movement. The built environment modifies values of solar radiation, wind flow and with it, the temperature, humidity, and related climate data [4]. Rapid densification, increases obstacles to wind flow, and also increases hard mass or hard surfaces, affecting the thermal environment by changing the urban texture and escalating heat absorption. There is therefore a wide difference in regional wind availability and microclimate found on urban sites and in the respective temperature data. Previous research also shows that air velocities within building interiors falls dramatically from outdoor regional averages, further lowering the ventilation potential of available wind in typical residential areas of Dhaka [5].

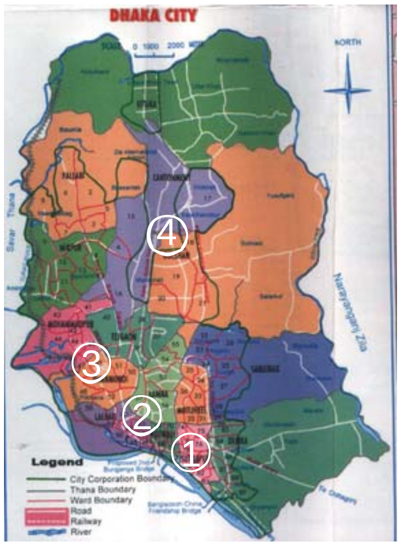

Figure 1: Map of Dhaka with survey Spots indicated by numbers
Source: www.bangladeshdotnet

In the absence of naturally induced air movement within building interiors, residents of Dhaka resort to the use of electricity, to accelerate evaporative cooling, allowing a semblance of thermal comfort, despite the high humidity. But active energy is growing costlier day by day, with the latest price hike scheduled for March 2007 [6], while its supply is very erratic with load shedding a common phenomenon [7]. These black-outs are employed by the authorities, to keep equity between the supply and demand of electricity.

Addressing these issues, this paper presents the findings of an ongoing research [8] conducted by the authors, where the potential for natural ventilation is examined from an investigation into the effects of growing densification in the city.

The basic hypothesis of the work is that the effect of density variation will be reflected in the comparative differences in the temperature and wind speed measurements of the different fabric patterns in the formal and informal residential areas of the city. Higher temperatures found in the denser parts of the city may be directly attributed to larger absorptions during the day and slower night-time cooling due to changed wind speeds and convection patterns.

One of the main objectives of this work was to increase awareness of the wind regime in different residential areas of the city and to suggest passive measures to rectify the negative aspects of the environment.

THE INVESTIGATION

Setting the Context

The study was conducted on the residential areas listed below, representative of differing levels of development and density in Dhaka metropolitan area, including formal and informal sectors (indicated in Map by numbers in Fig.1).

- Informal sector residential development where growth pattern is incremental and dense, and no definitive planning control is followed, e.g. Sutrapur (1) in old part of the city.
- Institutional housing where the development is far more controlled, eg Teachers' Quarters of BUET (2).
- Formal high-density residential area, e.g. Dhanmondi Residential Area (3), where many of the original one-bigha plots (generally in grid-iron layout) have been sub-divided into smaller plots for descendents, and the remaining original one unit houses per plot are now being replaced by six-storied apartment buildings.
- Formal medium-density residential area, e.g. Banani Residential Area (4), with large plot sizes, most still occupied by single families (sometimes joint or extended family) in one unit houses.

Physical survey of these residential districts revealed density of building mass and ratio of open and built areas along with surface characteristics and vegetal cover. These data were then correlated with measured thermal variables of temperature, humidity and airflow using portable instrumentation.

Data collection at survey spots and analysis

Suitable buildings were selected in each of these spots for data collection. For actual data collection, transition points were identified within the buildings, defined as transitional areas either between indoor and outdoor, or the immediate outdoors of dwelling units. These points form the boundary conditions for the building fabric. Recognising that transitional areas form buffers between the external and internal environments, understanding of the thermal environment in these spaces can make passive climatic control easier. Moreover, dependency on active control is largely reduced if the transitional point environment does not get extreme.

Table 1 Comparing the Density and physical qualities of the four residential districts

Location	Sutrapur	Dhanmondi	BUET T. Q.	Banani
Existing avg. Floor Area Ratio (FAR)	4 to 5	3.5 to 4.5	1.1 to 1.3	1.5 to 2.5
Existing avg. land coverage by building structures on plots	85 to 95%	70 to 80%	25 to 30%	55 to 65%
Existing avg. ratio of hard : soft surface (exc. road area approx.)	95 : 05	80 : 20	30 : 70	60 : 40
Population density in persons per acre approx.	357	310	162	180

For Air-flow data, measurements were taken at three different heights at every survey spot using three weather meters[*] simultaneously. Temperature and Relative Humidity data were measured with the help of two additional data loggers[†], while two maxima-minima thermometers were used for simultaneous maximum and minimum temperature data. Prior to the field data collection, necessary field calibration was made by the recommended calibration kit according to the specification supplied with these instruments. The regional averages were also noted from weather stations and published sources for the survey days to note micro-climatic deviation at surveyed spots. For solar radiation data it was assumed that the values would be similar for all sites as they are located within a few kilometres of each other and there is no noticeable difference in air quality/atmospheric condition.

Field data was collected within a limited time, during May, when conditions are representative of high thermal discomfort. April is the hottest month in terms of mean maximum temperature [9] [10], and the effects of its interaction with built form is expected to set in after a few days, i.e. by the middle of May.

A comparative analysis of climatic data collected from the different residential areas was then made to identify variations in thermal environments and to ascertain the extent and causes of variations. This analysis is expected to help formulate correlations between the thermal environment, climate and density of building fabric.

RESULTS AND ANALYSIS

The Context

Physical survey of the four residential districts revealed characteristics given in Table 1. The first row gives the existing *floor area ratio* (FAR) of each of the survey areas, calculated from the volume of built spaces per unit of ground surface area. This ratio is directly proportional to density of development and is found highest in Sutrapur, closely followed by Dhanmondi.

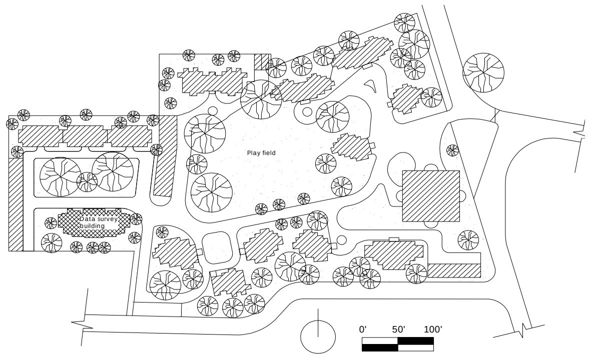

Figure 2a: Low density area at BUET

A new set of construction rules has just been implemented in Dhaka [11], but its effects will not be felt until construction in accordance with it has taken place. Therefore the following discussion is based on the previous Building Construction Act of 1996 [12]. With only 1.25m side setback and 1.5m front setback, residential districts therefore are very compact and dense. Where plots are small, setbacks are further reduced. Owners therefore tend to build upto the limit, leaving almost no open spaces, e.g. in the Sutrapur area. There is also mass scale violation of building construction rules and unauthorized changes in design after formal approval. All this leads to high land coverage and very high density, as seen in the second row of Table 1, resulting in reduced gap between adjacent buildings, poor provision for natural lighting and ventilation.

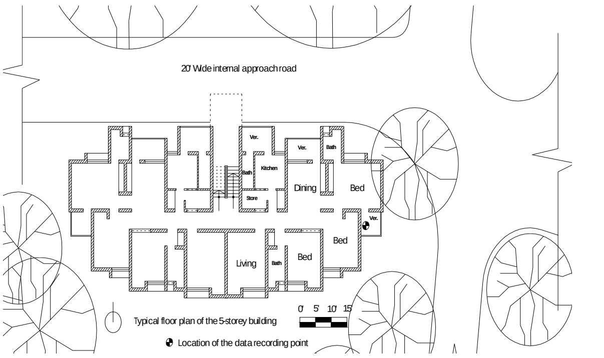

Figure 2b: Plan of Surveyed building at BUET

In the Sutrapur area, a good mixture of buildings of variable heights were found, which created a rough urban texture. In Dhanmondi, most buildings tend to be six storied, and in BUET the norm is five storey walk-ups, with only one eleven storey tower building. The Banani area also has a mix of building heights, many only two storeys high.

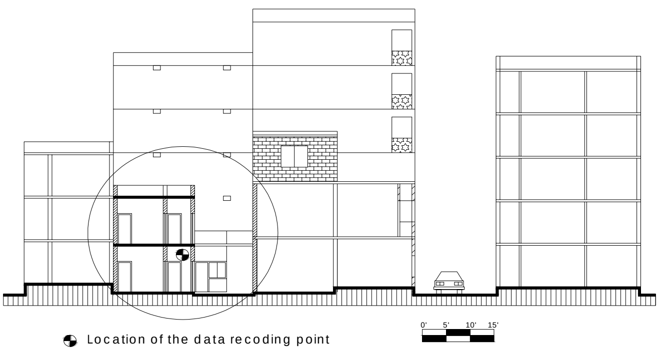

Figure 3a: Lack of setback around buildings, Sutrapur.

Figure 3b: Typical Dense Settlement, Sutrapur

Only in Banani and BUET (Fig. 2a) one-third or more of the plot areas were kept open for vegetation and green development. In areas where the hard to soft ratio is low, evaporation potential increases, while solar absorption is also much reduced.

Population density was found highest in Sutrapur (Figs 3a, 3b), while many professional activities were discovered going on in and around the residences. In Dhanmondi (Figs 4a, 4b) also various commercial activities are encroaching onto the residential environment, which has increased the activity level of this area. Such activities and densities are bound to contribute to higher temperatures.

Figure 4a: Survey Spot: Dhanmondi

Building spacing is seen to vary despite the same setback rules being applicable in all the settings. In Sutrapur, the buildings are constructed very compactly without leaving setback spaces on all four sides. In most cases, buildings in adjacent plots were built without keeping any space in between and no window opening on that side was possible (Fig. 3a). Window openings in the ground floor were only found possible on the road side. Windows on sides are only possible on upper floors, where the adjacent building is lower. These upper storied openings are liable to remain closed permanently, once surrounding adjacent structures are extended vertically. So the provision for natural light and ventilation in the living spaces in this residential area is extremely restricted.

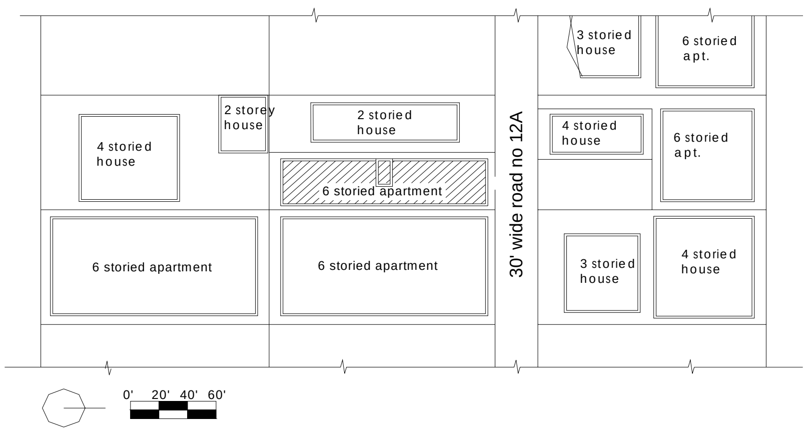

Figure 4b: Plans of surveyed buildings in Dhanmondi

This compact situation acts like a big porous insulating layer between the sky and the earth. The heat that penetrates inside the buildings during day time can not be easily released after sunset. As summer goes on, the cumulative effect could raise the overall indoor temperature posing threat to thermal comfort.

Figure 4c: Section showing transitional space in Survey spot at Dhanmondi.

Because the gap between two buildings was found big enough to facilitate ample light and ventilation through the different vertical layers of the buildings, Banani and BUET area show a different pattern (Fig 2a). During summer, nocturnal cooling can be expedited by this ventilation and by avoiding daytime ventilation, comfortable situations can be retained for a long time.

Temperature and Wind Velocity Data Comparison

Preliminary readings revealed that maximum outdoor air-temperature is found between 1.00 to 3.00 pm. For this reason, temperature at 2.00 pm. taken for fifteen consecutive days at transition points in the four survey spots (Fig 5) shows that generally, Dhanmondi attained highest and Banani the lowest temperatures compared to the other areas.

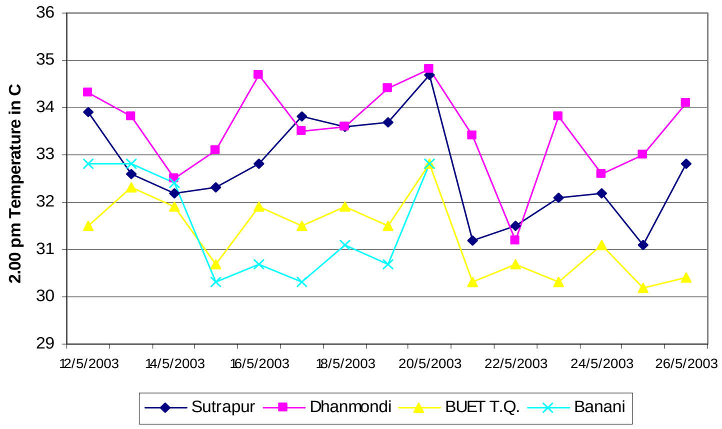

Figure 5:Comparative 2.00pm temperatures in the surveyed spots.

The results also show that the temperature figures are closely related in the Sutrapur and Dhanmondi region (both high density areas) on the one hand, and in the BUET and Banani region (both of lower densities) on the other. Mostly variations between spots were significant, being on an average, about 2°C, reaching a maximum of 4°C. A relationship between the temperature readings and surface quality can also be established from these results. Thus, where the FAR value and proportion of hard surfaces is higher, higher temperature values were obtained.

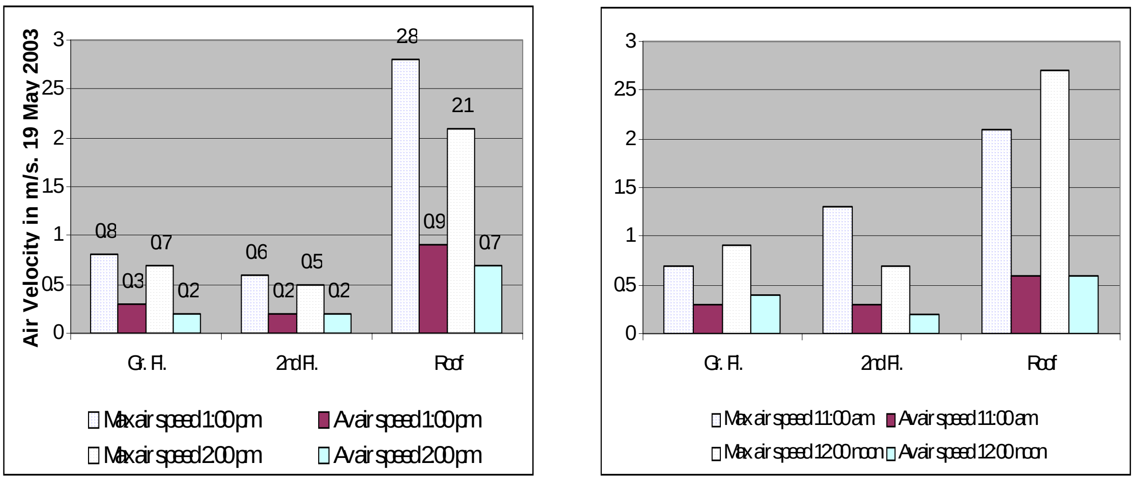

Figure 6: Measured air velocity at different levels of Dhanmondi (left) and BUET (right)

Air velocity readings were also taken at all the survey spots. Fig 6 gives readings for the average and maximum air speeds in high density Dhanmondi and low density BUET. The readings show how the velocity rises with building height for both the low density and high density situations. It is also clear from the readings that there is very little dependence on density when ground level and top level flows are concerned, i.e. almost the same velocity is measured in high and low density areas at these levels. However, at mid-levels, the high density area (Dhanmondi) displays a fall in the wind gradient in comparison with the ground level flow. For the low density area (BUET) on the other hand it is seen that there is a steady increase in wind gradient with height. This is expected because in the former case there is a lot of obstruction at lower levels which results in turbulent and inconsistent wind patterns, while in the case of BUET the wind hits the buildings without its laminar flow being disturbed, as building to building distance is considerable. Therefore there is a steady increase in wind flow with height. This supports research findings that wind velocity reductions at lower levels are more pronounced with increased urban roughness [13] due to turbulence. In the Dhanmondi area, the reason for the air speed at ground level being higher compared to mid levels, could be because the ground floor is kept free for car parking.

DISCUSSION

The following points emerge from an examination of the data:

- Temperature is higher in denser areas. These areas also have a higher percentage of hard surfaces, which may be a contributing factor.
- Wind speed was not found to be directly affected by density of built form, either at ground levels, where there is maximum interruption to airflow, or at roof top levels, where the flow is uninterrupted. But at mid levels, density plays a significant role, possibly due to the higher turbulence in dense spaces, where building heights are also variable.
- It is possible that the higher temperatures measured in denser areas may be caused due to lower wind speeds in these spaces. Therefore the accumulated hot air does not find easy escape and the heat remains trapped.
- As the global horizontal solar radiation data is unlikely to vary in spaces so close to each other, it is possible that the radiation is absorbed by the greater percentage of hard surfaces in the denser setting. This may cause the elevated temperature in the denser regions.

The hypothesis, that a dense area can create a situation similar to a big porous insulating layer between the sky and the earth, trapping heat, seems to be justified from the findings. The effect of density variation is therefore reflected in the comparative differences in the temperature and wind speed measurements.

Recommendations

One of the objectives of the study was to be able to suggest ways in which the situation can be made more comfortable, i.e. where wind speeds can be increased at the lower levels and temperature levels can be kept down. Whereas it is understood that any recommendations should be tested before being considered as having a strong basis, nevertheless, some pointers towards improving the situation, have been tentatively presented below.

1. More openings and height variations at mid levels would undoubtedly increase wind flow at those levels, thus increasing comfort under warm humid conditions. This could be done by introducing terraces interspersed within the built fabric, bringing variation in the building volume.
2. Increasing soft surfaces could bring temperatures down, thus reducing dependency on wind flow to impart thermal comfort. To achieve this, vegetation can be introduced at different levels, cutting down on solar radiation gains.
3. Creating some open areas within an otherwise dense situation would undoubtedly alleviate a lot of the wind and temperature stagnation. Such an open area could draw winds out from the surrounding dense areas, thus improving the overall situation.

Building activity is a continuing activity in Bangladesh, as in much of the developing World. It is imperative to be conscious of the effects of urbanisation and building activity on comfort potential and energy consumption, both of which can be brought to acceptable levels if adequate ventilation can be targeted. This paper is an attempt to make concerned professionals aware of these facets of Architecture and the environment.

Ventilation Design in High-Rise Residential Buildings and Infectious Disease Spread

Jianlei Niu and Thomas Tung

Department of Building Services Engineering, The Hong Kong Polytechnic University, Hunghom, Kowloon, Hong Kong, China

E_mail: Bejlniu@polyu.edu.hk

SUMMARY

In the SARS epidemics in 2003, cluster of cases occurred in high-rise residential(HRR) building blocks, especially in Hong Kong, which gave rise to the concern of the possible roles of air flow. In this paper, the multiple parallel airborne transmission routes are discussed. In particular we closely investigated one of the most likely virus-spread paths, which is related to single-side ventilation air flow through open windows caused by buoyancy effects. Both tracer gas and CFD (computational fluid dynamics) techniques have been employed, and tt was found that the upper floor air can contain up to 7% of exhaust air directly from the lower floor. The results can well explain the RNA fragments of Corono-Virus (CoV) found within the sampled deposits on the window sills of the upper floors of the two index patients' flats during the SARS outbreak. Implication for ventilation design and infection control in HRR will be discussed.

INTRODUCTION

Natural ventilation plays two essential roles traditionally in our buildings. On one hand, ventilation can modulate the indoor temperature for better thermal comfort in summer since outdoor air is usually lower than indoors; on the other hand, it also helps to dilute indoor air pollutants and improve indoor air quality in most cases. The required quantity and quality are actually different for these two purposes. The roles of natural ventilation in modern high rise residential buildings are more complicated. Especially, in the rapid developing Asian regions, a majority of the population live in high-rise, multiple-households apartment buildings. The climatic conditions also render air-conditioning widely applied, with the window-type and split-unit type air-conditioners dominating in the residential buildings. Ventilation is provided via open windows, with exhaust fans provided in the toilets and kitchens. The exhaust air is typically not centrally stacked, but left to drift around the building blocks. This can potentially have many unwanted consequences for multi-households, multi-story high-rise buildings (Niu, 2004). On the ordinary days, it's not uncommon for the residents to detect from the smell in his own unit what the neighbor is cooking – a sign of cross-contamination of the ventilation air. With respect to infectious disease control, this inter-flat or inter-zonal flow becomes a serious issue.

When airborne infectious disease spread is concerned, there are also a number of other parallel transmission routes from person to person. Interior corridors are typically poorly ventilated though the residents tend to spend little time there; lift tend to be crowded, and lift lobbies are usually poorly ventilated as well. Depending on the floor plan, direct, horizontal air flow from one unit to the adjacent unit can occur. In particular, to maximize the land-use efficiency, high plot-ratio, defined as the total floor area over the land area, can reach to 10 in urban development. This tends to result in both horizontally-close units and high-rise designs (Figure 1), which increase the risk of air-borne infection spread (Yu et al 2004). It appears that infection risks associated with these routes have not been well studied, and many infectious diseases like common cold, influenza and tuberculosis may be transmitted through these routes.

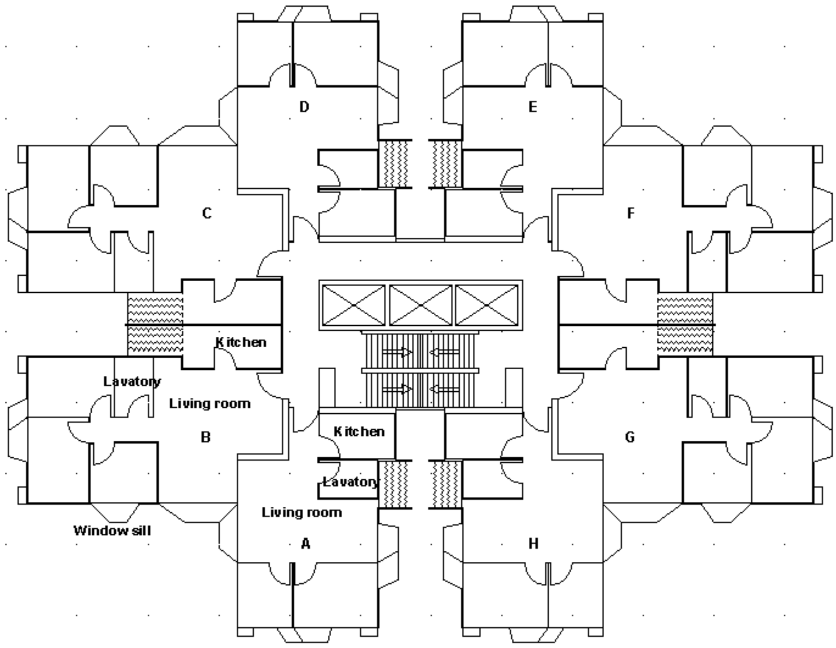

Figure 1. Typical floor plan for high-rise residential apartment buildings, typically around 30 stories high. In this plan, 8 units on each floor share interior corridors and the three lifts.

This investigation is focused on the vertical transmission pattern in high-rise residential buildings observed during the SARS outbreak in the spring of 2003 in Hong Kong. In apartment building A, which is about 30 story high, and where five households were affected with eleven SARS infection cases, RNA fragments of SARS virus were detected within the sampled deposits on the window sills of the upper floors of the two index patients' flats; and in one of these two upper floor households there were no infected SARS cases. In another high-rise building B, all the 6 infection cases in 3 households occurred along one vertical block. In the widely-publicized outbreak in another residential estate, which includes five blocks of 30 story apartment buildings, and where a total number of 321 infections occurred, only one case occurred below the 8th floor. While the transmission paths of such large scale outbreaks remain a myth up to the present moment (Yu et al 2004), it appears that there was a vertical spread pattern.

Our hypothesis is that, on windless days, the outflow from a window on the lower floor will re-enter the adjacent upper floor, and therefore bring the virus-laden droplets generated by an index patient upstairs. For high-rise buildings, there may exist an upward "cascade" air flow, so that the disease can be transmitted from a lower resident all the way to the top floors. The objective of this project is to reveal the mechanisms of this airflow by actually quantifying the fraction of the lower-floor exhaust air within the intake air of the adjacent upper floor. This paper reports the preliminary finding of this study.

SINGLE SIDE VENTILATION

The driving forces of natural ventilation can be classified into two categories: one is the wind pressure, and the other is the buoyancy/stack effect caused by temperature differences. Single ventilation refers to the purposely provision of vent openings on the single side of a room space, so that no cross-ventilation is possible. The original intention is to minimize the effect of wind pressure, and maximize the stack effect due to indoor/outdoor temperature differences. Typically, indoor temperatures are higher than outdoors under natural conditions, outdoor cold air tends to enter the room at the lower apart of an open window and at the same time warm air tends to leave the room at the upper part of the window. In buildings with multiple story and multiple flats on each floor, the overall air flow path through the multiple openings can be highly variable depending on the wind direction and wind speed. With the floor plan as illustrated in Figure 1, residents tend to close their doors when entering their home, so that essentially single side ventilation situation arises. Under high wind conditions, cross ventilations may still be significant via door gaps, but this often causes undesirable horizontal air contaminant transport from one unit to the other. In fact it so happened in an extreme case that VOC(volatile organic compounds) emissions from paint spray during a decoration was suspected to be the cause of an infant death of the neighboring unit. Here it should be emphasized that under low wind conditions, single-side ventilation will be the dominant air flow pattern, as illustrated in Figure 2 and 3. From the point of view of air pollutant accumulation, the worst-case occurs on windless days. In the Hong Kong climate, the windless days can occur in March and April, which happened to be the period during which SARS case clusters. According to our previous survey, residents in Hong Kong may only switch on the exhaust fans in their kitchen or toilets when these two rooms are actually used. In this case, buoyancy due to indoor-outdoor temperature difference will be the only driving force. In multi-story high-rise buildings, it is suspected that this single side air flow may cause vertical transmission of air-borne infectious diseases. In this study, we attempt to quantify the percentage of air from the lower floor present in the upper floor via this route.

INVESTIGATION METHODS AND RESULTS

Onsite tracer gas measurements

This investigation is performed using experimental tracer-gas and flow visualization technique. The building investigated has single-side natural ventilation via open windows. Two rooms located at immediate upper and lower floors, which have windows flush with the façade (Figure 2), were selected for site measurements. The floor to ceiling height is about 2.7 meters, and the room depth is about 5 meters, and the width is about 3.5 meters. This façade feature is similar with buildings A and B as described in the introduction, where clusters of SARS case occurred and vertical transmission patterns were observed. The measurements were continuously conducted form one month in February and March respectively in 2004 and 2005. The experiment was conducted in the spring time because it was the season of SARS outbreak, and is also the high season of common-cold and influenza occurrences in Hong Kong. During the periods of measurement, the outdoor temperatures varied from 10.6 to 24.0^{o}C with the mean of 17.3^{o}C. The indoor temperatures of the two rooms varied 12.8 to 23.3^{o}C (mean = 18.4^{o}C) and 14.1 to 23.1^{o}C (mean = 18.7^{o}C), respectively.

In the on site experimental studies, SF6 was released at a constant release rate in the center of the single room flat in the lower floor, while the SF6 concentration levels at six points were monitored simultaneously using a B&K1302 multi–gas monitor (Figure 3). An example of the monitored concentrations upstairs and downstairs are shown in Figure 4. At the same time, a smoke generating machine released smokes into the lower flat, and air movement of the exhaust air from the lower floor, and possible direct re-entry into the upper floor can be visualized by the smoke movement. Since we cannot control the weather, the flow phenomena we observed would be the combined results of both the wind pressure and buoyancy effects.

Figure 2. Two rooms located in adjacent upper and lower floors in a student dormitory were selected for tracer gas measurements

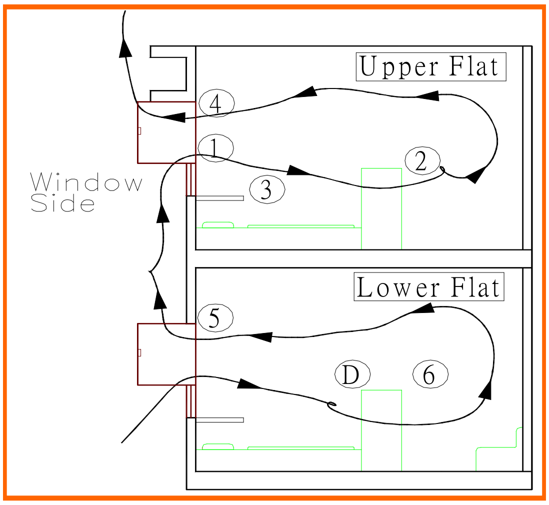

Figure 3. Possible air flow path associated with single side ventilation and locations of the tracer gas dosing point (D), and sampling point (1 to 6)

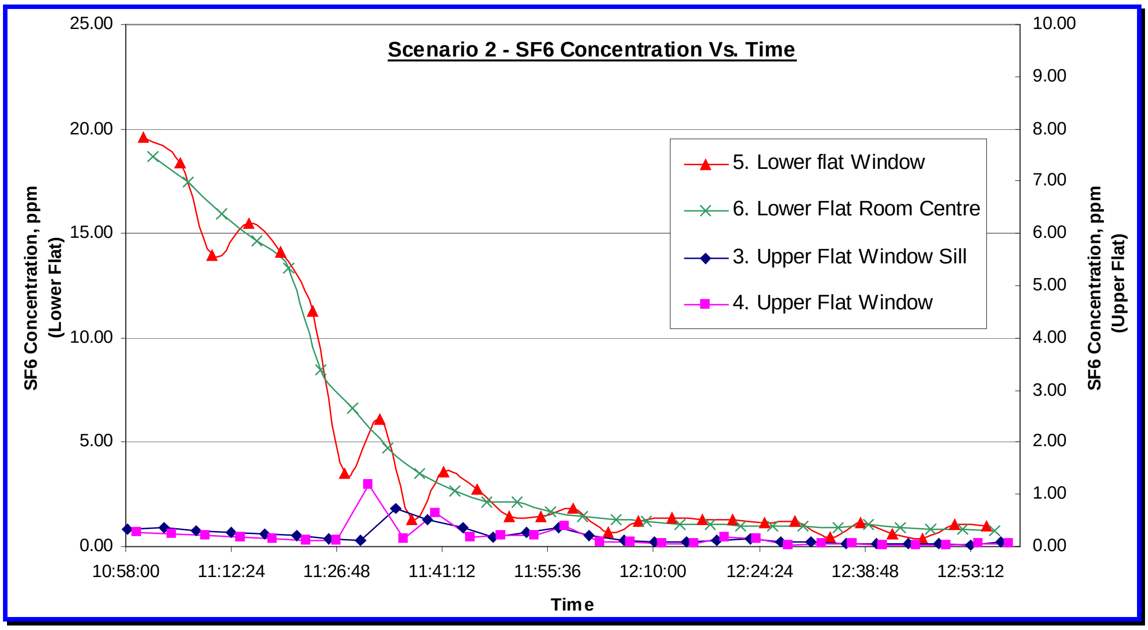

Figure 4. Monitored tracer gas concentrations in the two flats when tracer gas was released in the low floor

Based upon these monitored tracer-gas concentrations, an index, called mass fraction *M*, can be worked out. For instance, M_{6-3} can be calculated based upon the monitored tracer gas concentration at point 3 and 6, which would indicate the fraction of the air originating from point 6 but present at point 3. Using the one month data obtained in 2005, such an index is plotted as Figure 5, it can be seen that the maximum value of the mass fraction is 0.07, which means 7% of the air in the upper floor directly comes from the lower floor. It appears that higher wind decreases the re-entrance slightly.

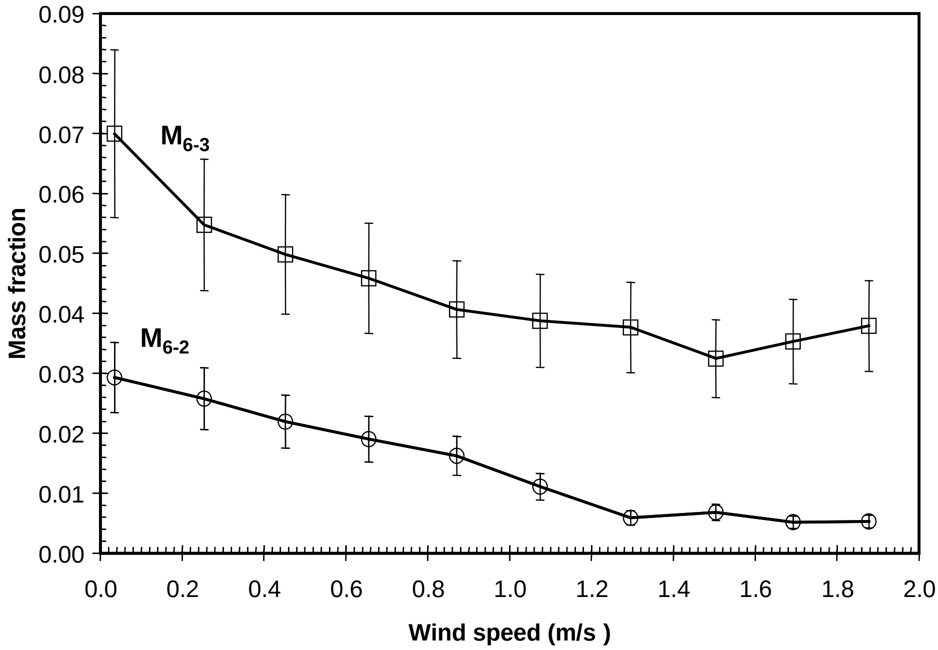

Figure 5 The mass fractions indicating the presence percentages of air coming from the lower floor at two points in the upper floor.

CFD simulation

CFD(computational fluid dynamics) simulation technique (Launder and Spalding 1974; Niu and van der Kooi 1992a, 1992b) was also employed. Both transient and steady-state simulation results have been obtained using the standard k-ε turbulence model. The reliability of the numerical simulation has been first checked with good quality laboratory experimental results obtained from Denmark (Heiselburg 2003). In Heiselburg's laboratory experiments, the transient air exchange via a single-side ventilation window was measured using fast-response anemometry system, and the indoor surface and outdoor air temperature differences were closed monitored.

Presented in Figure 6, is the simulated air flow path-lines and the velocity magnitude through two open windows of two adjacent vertical floors. In general, the velocity caused by buoyancy alone is rather low, with the maximum around 0.5 m/s, as indicated by the colored zones in Figure 6, 7, and 8. On a windless day of outdoor air temperature of 20 ºC and indoor room surface temperature of 28ºC, it can be seen in Figure 8 that the outdoor air enters the lower room through the lower part of the window, and leaves the room at the upper part of the window. At the same time, it can be clearly seen in Figure 7 that a portion of the outflow from the low floor re-enters the upper room through the lower part of the upper window. It looks as if the warm exhaust plume from the lower floor functions as an air curtain, with which ambient air has to mix first to enter the room. Based upon the calculated velocity across the two window openings, air change rates through the two window openings have also been calculated, and tracer gas have also been added into the lower room, and similar results as for the onsite measurements have been obtained.

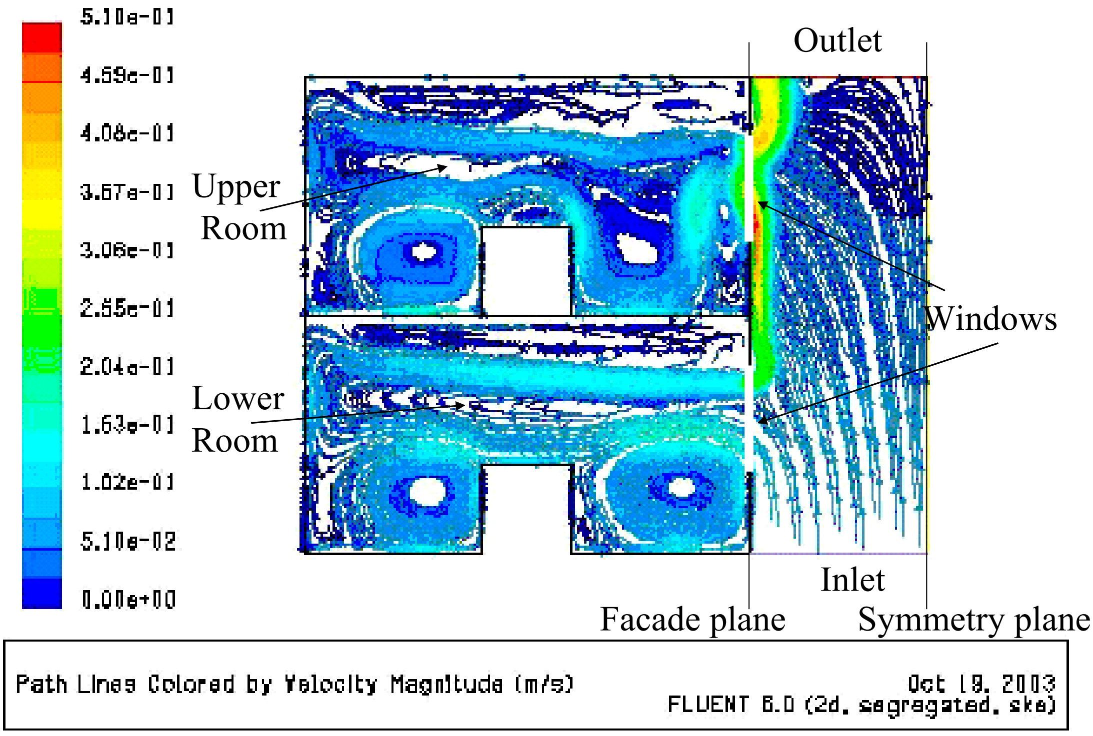

Figure 6. Air flow patterns indicated by flow path lines

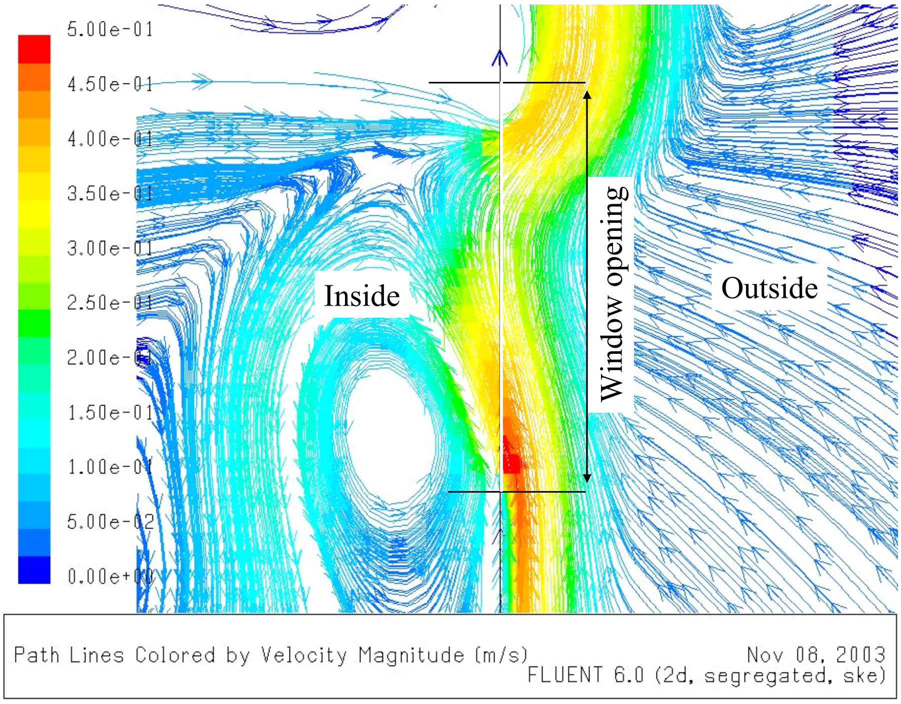

Figure 7. Airflow path lines across the window at the upper floor

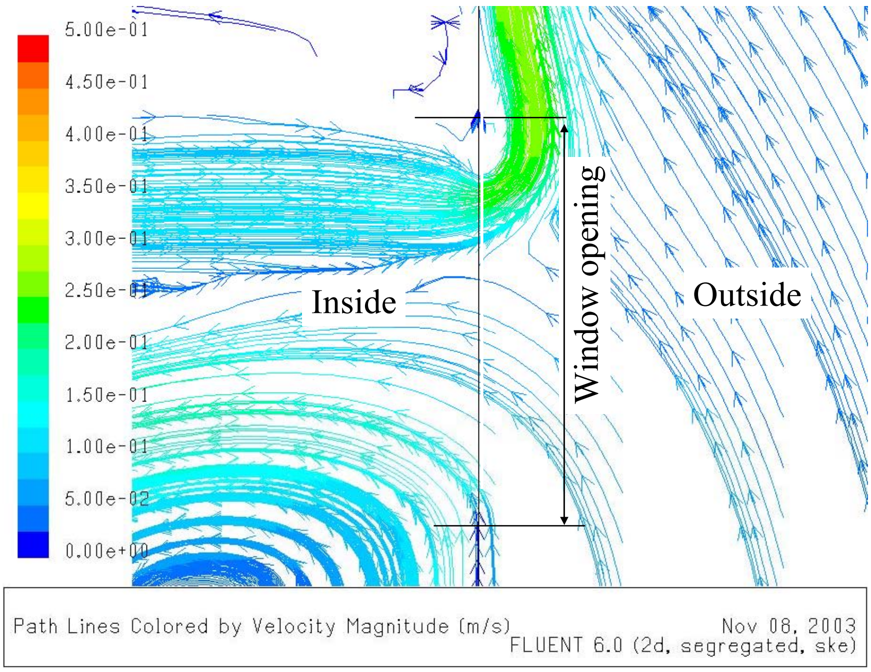

Figure 8. Air flow path lines across the window at the lower floor

CONCLUSION AND IMPLICATIONS

During the SARS outbreak, the presence of SARS virus RNA strings were found in the window deposits, and this study revealed the virus could have been transported up by the single side ventilation air flow. It should be noted that, depending on the window opening habits of the residents, this could be a continuous transmission route. More epidemiological data on other aerosol transmitted diseases would also be helpful to further confirm this significant transmission route. The confirmation of the transmission route can have a number of implications to both building design and infectious disease control. With respect to the former, windows flush with façade should be avoided, and ledges added above the window can reduce the transmission to a certain extent. It appears that complete avoidance of this cross contamination through ventilation control is costly and difficult. With respect to the latter, more targeted and sooner intervention can be implemented in case of any highly-infectious disease outbreaks, which may be more cost-effective.

SUMMARY

This paper presents a new design concept of hybrid air conditioning system by using a portable air conditioner to achieve a better personal control of indoor environment without sacrificing the responsibility to a sustainable environment. The results of the detailed computational flow dynamics (CFD) simulation in this study, through a systematic analysis on the parameters of wall opening, outdoor wind speed and temperature, show that with an appropriate design of wall openings, this hybrid system can sustain a comfortable environment until affected by strong wind blast. At that moment, a suitable control of the sizes of these openings is suggested to extend the proper functioning of this hybrid system to achieve the dual benefits of comfort and energy conservation.

INTRODUCTION

In recent years, personalized cooling systems are under research and development to reduce CO_2 emission and achieve energy conservation. Most of the research focused on commercial HVAC systems to improve the energy performance, air quality and productivity of indoor environment. Akimoto et al. [1] and Sasaki et al. [2] developed a task air conditioning system and conducted a subjective field study on the thermal comfort and productivity. Furthermore, Chiang et al. [3, 4, 5] designed a new partition-type fan-coil unit (PFCU) system to provide the users with greater flexibility and convenience for dedicated local environment control. According to their results, as compared with a conventional air-conditioning system using ceiling diffusers, this personalized cooling system can reduce about 45% of cooling energy consumption.

The same concept can also be applied to the residential dwelling or small office buildings. However, at these places, portable air conditioner is more flexible to be implemented than the task or PFCU air-conditioning systems. Actually it has been used as a spot cooler for a long time to provide occupants cooling without wasting energy to cool the entire room. The cooling capacity can be largely reduced to as little as 500 W in comparison to several kWs for the one using a conventional window or split-type room air conditioner. However, the need of a hose to ventilate the hot air discharged from the condenser to the outdoor often prohibits this appliance from being widely used. In this regard, this paper intends to develop a hybrid air-conditioning system to create an environment with natural but comfortable room air circulation that combines the buoyancy-induced airflow formed by the direct hot air discharged from this machine and the ventilation air flowing through some wall openings.

Aiming at the hybrid air-conditioning system in an office building, Chang et al. [6] studied a natural ventilation system for a model office building where air flows in through the opening on one wall, removes the heat and contaminants generated at the task zone and exhausts to the outdoor through another opening on the opposite wall adjacent to a courtyard. Mechanical cooling system with underfloor air distribution is used as assisted cooling only when the natural ventilation is unachievable to meet the demand. Their work and Axley et al. [7] both indicate that the outdoor conditions and the designs of wall openings are the crucial parameters which affect the performance of the hybrid air-conditioning system. For residential buildings, the circumstances may be different because of the limitations of building structures and the use of a portable air conditioner. Therefore, the objective of this study is to achieve the following conditions so that the hybrid ventilation system can perform its ideal design functions in a residential building as well,

1. The hot air discharged from the condenser must rise as a thermal plume [8] to the upper portion in the room and, in the process, avoid any mixing with room air.
2. Thermal stratification must be established such that hot air can be exhausted from the upper opening on the wall.
3. Sufficient outdoor air must be introduced to make up the air being exhausted.

METHODS

The concept of designing this hybrid system was first proved by conducting a simple experiment. As shown in Figure 1(a), a spot cooler supplied cool air to a test room and a manikin sat inside the room to measure the comfort level. Initially, the temperature of the test room was set at 28^{o}C and the outdoor chamber was controlled at 30^{o}C. After the machine was turned on, the equivalent temperature perceived by the manikin dropped to the lowest values in 10 minutes and then gradually increased because of the accumulation of heat discharged by the condenser in the room. The variations of equivalent temperature were compared for two test conditions: one with a window opened on the wall and the other with the window close. For both cases, the equivalent temperatures eventually rose to an uncomfortable circumstance because heat was not efficiently removed from the space. However, when the window was opened, the indoor temperature increased in a slower rate. But, due to a large amount of hot air continually moved into the room from outdoor without any control mechanism, the perceived temperature of the manikin was finally not in the acceptable range. This experiment implies that we can avoid the accumulation of heat in the room by having an opening but, to achieve this hybrid system correctly functioning, a proper design of the opening is the prerequisite.

(b) Equivalent temperature perceived by a thermal manikin

Figure 1. Experimental set-up for testing a portable air conditioner and its test results

Although it is not difficult to study the proper wall openings in a climatic chamber, simulating the outdoor wind effect is not easy at this moment. Therefore, this paper uses computational flow dynamics (CFD) method to complete a systematic analysis on the influential parameters such as wall opening, outdoor wind speed and temperature. Moreover, the use of CFD method can reveal detailed phenomena of flow fields and temperature distributions in such a closely interacting system.

In this study, a model room, as shown in Figure 2, has the size of 4m x 3m x 5m. The heat gains from the ceiling and through the floor are assumed to be 12 W/m^2 and 18 W/m^2, respectively. The influence of outdoor temperatures is studied by adopting two temperatures of 28^{o}C and 25 ^{o}C, corresponding to a severe and a mild outdoor condition. The impact of outdoor wind blowing toward this building is analyzed under the conditions from the static wind (namely, completely calm) to a maximum wind speed of 0.75 m/s. Inside the model room, a portable air conditioner is placed on a short stool of 0.6m height and about 2m away from the left wall. An occupant in sitting position faces toward the portable air conditioner and is subject to the cool air supplied by this machine. Cool air leaving the evaporator with the air flow volume of 100CFM (air speed 0.84m/s) and temperature of 20^{o}C. The hot air discharged by the condenser has the air volume of 80CFM (air speed 0.63m/s) and temperature of 40^{o}C. It should be noted that we have slightly increased the hot air discharge ports on the machine so that the air speed is reduced so as to be able to form a thermal plume flow rising from the machine. This modification avoids the mixing of the discharged hot air with the room air and ensures an acceptable thermal stratification in the room.

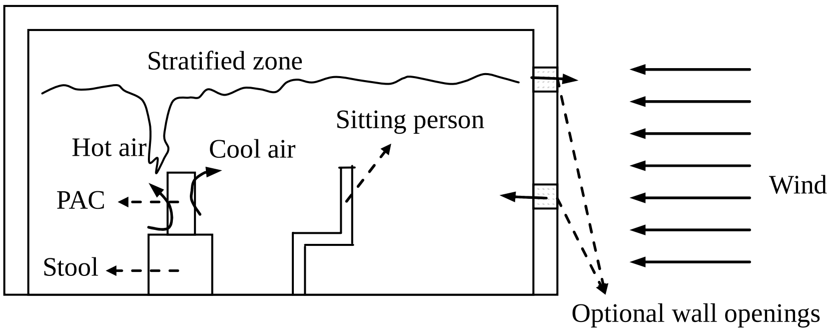

Figure 2. Sketch of the model room for CFD simulation

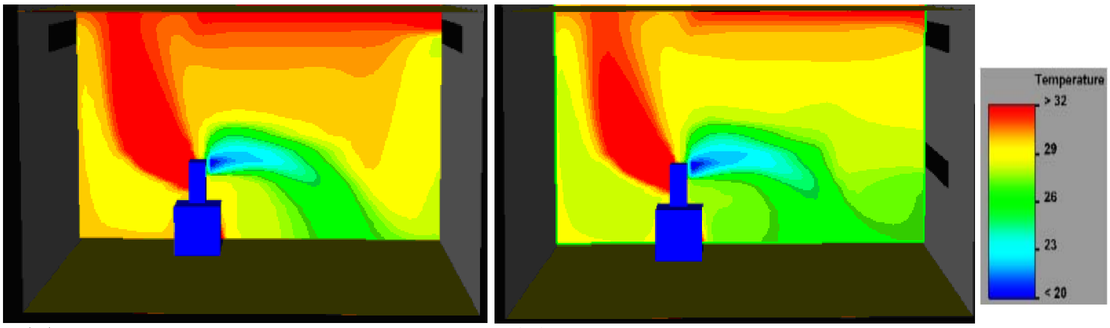
RESULTS

From the preliminary experimental test results, as demonstrated in Figure 1, we have found that although hot air discharged from the portable air conditioner can be exhausted to outdoor through the opened window. However, proper design of the openings is very important to form proper natural ventilation, including the processes of introducing cooler air into the room, removing interior heat loads and exhausting hot air outside. Chang et al. [6] investigated the hybrid ventilation in the intermediate seasons for an office room with large depth. There are openings on the opposite two side-walls in their model room. Low temperature outdoor air flows in through the opening on the exterior wall and rejects from another opening on the wall adjacent to a courtyard. The air flow in their model room is in a unilateral direction. The implementation of the similar design in this study, however, is found inferior to the design with two opening on the same wall. As depicted in Figure 3(a), under the circumstance that the wind speeds is zero, high temperature air tends to accumulate in the upper portion of the room and air movement is almost blocked. In contrast, for the design with two openings on the same wall, as indicated in Figure 3(b), the outdoor air can easily flow through the lower opening to the room and discharge from the upper opening. This hybrid system demonstrates a smooth air circulation and a favored thermal stratification.

Hence, the follow-up discussion of this paper will focus on this kind of openings deign to explore the effect of opening size, outdoor temperature and wind speed.



（a） openings on two opposite walls （b） openings on the same wall

Figure 3. Influence of openings design on the room temperature distribution

After adopting the design of two openings on the same wall, openings with the sizes of 2m x 0.3m and 2m x 0.15m were investigated. Because achieving a comfortable local environment surrounding the occupant is the main goal of this study, a mean perceived temperature is defined to justify the comfort level of the sitting occupant by averaging the air temperatures at the selected positions of 1.1m, 0.6m, 0.1m heights, corresponding to the temperatures experienced by the head, waist and legs of the occupant. The perceived temperature calculated from the CFD simulation results are shown in Figure 4 for different openings and outdoor conditions. It is found that when the outdoor wind speed is below 0.4 m/s, the perceived temperature can be kept at less than 26.5^{o}C, which satisfies the general requirement of a comfortable environment. Also with larger openings, the perceived temperatures are comparatively lower than those of the small openings. It must be due to the fact that the discharged hot air can be more smoothly vented outdoor. However, a reversed situation occurred as the outdoor wind speed is increased to over 0.5 m/s. The occupant might feel a sharp increase of the perceived temperature. To improve this drawback, using a small opening (*eq.* 2m x 0.15m) can completely suppress this problem.

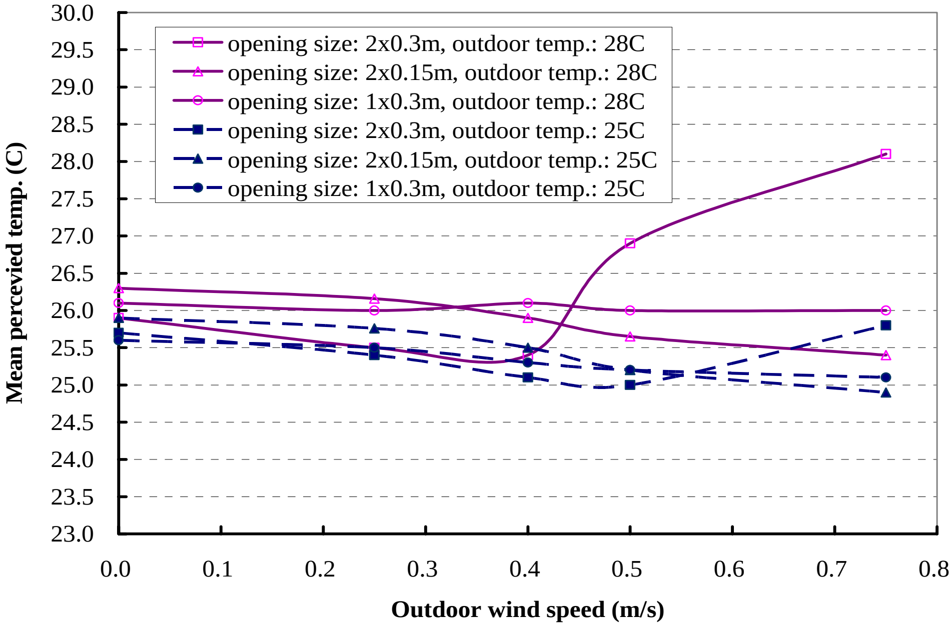


Figure 4. Variations of outdoor conditions vs. mean perceived temperature

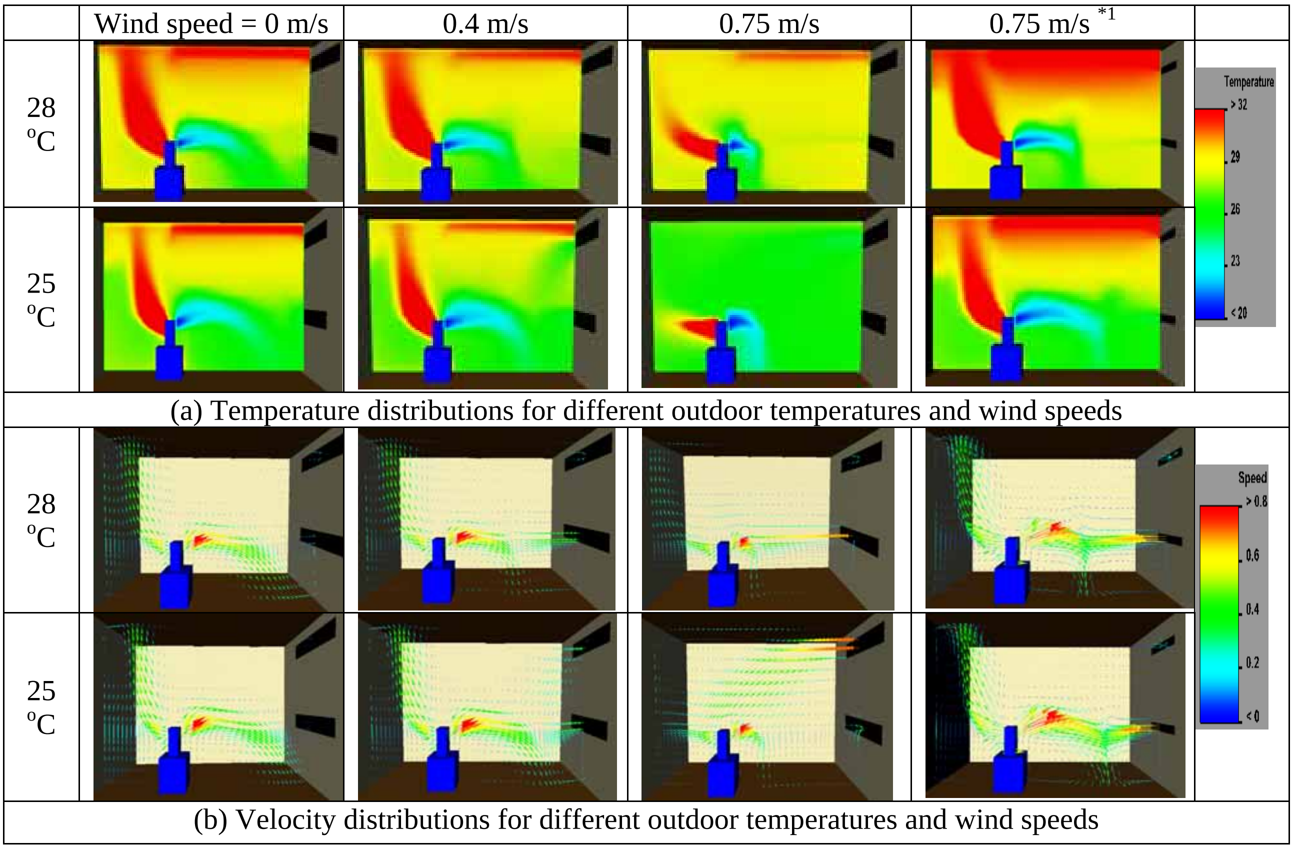
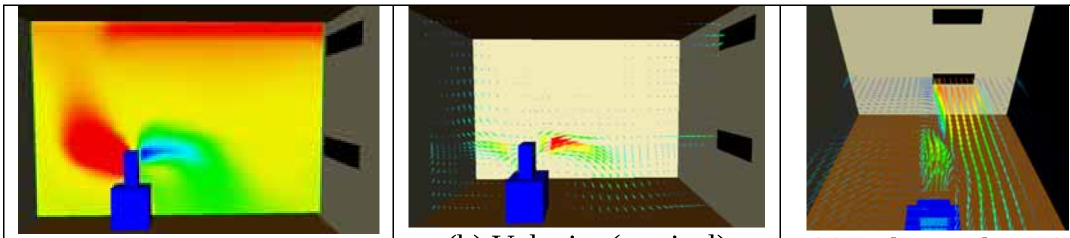
Figure 5 summarizes the detailed air flow patterns created by the interactions of the portable air conditioner and the natural ventilation system. For the high outdoor air temperature (*i.e.* T_o=28°C) cases, the ventilation air always flows in from the lower opening and flows out from the upper opening. As outdoor wind speed is slow, the stratification of temperature distribution is well established in the room. With the movability of this air conditioner, comfortable cooling can be provided to any portion of the space with less energy consumption. The hot air discharged by the machine moves quickly upward without disturbing the occupied zone. Nevertheless, ventilation air flow starts to hold back the cool air supplied from the machine by the increasing outdoor wind speed. The cool air is not able to reach the occupant when the wind speed is higher than 0.75 m/s. In this circumstance, the occupant is subject to complete outdoor conditions. With a reduced opening (*i.e.* 2m x 0.15m), the machine can regain its control of the living environment, but the upper stratification layer dramatically increases. For the low outdoor air temperature (*i.e.* T_o=25°C) cases, the flow patterns present an interesting different feature. Without the assisting of the strong buoyancy force, the cold ventilation air is found to flow in from both openings as the outdoor wind speed increases.



Note:*1 flow fields with reduced openings (*i.e.* 2m x 0.15m)

Figure 5. Air flow distributions of the hybrid system formed by the portable air conditioner and natural ventilation system

Although, reducing the opening sizes from 2m x 0.3m to 2m x 0.15m can mediate the disturbance caused by the high speed air flows through the lower opening, a large stratified zone containing a lot of hot air is formed in the upper portion of the model room. To overcome this deficiency, an improved design by shifting the openings to one corner in the room can successfully avoid the confrontation of two air streams formed by the portable air conditioner and the natural ventilation. As shown in Figure 6, although the inflow through lower opening is of high velocity, the air stream can keeps off the cool air supplied from the machine. Hence, the comfortable level of the occupant can be held in a better condition. This finding implies that if these openings mounted with some adjustable louvers to divert the air flow direction, the portable air conditioner can always perform very well with natural ventilation.



(a)Temperature (b) Velocity (vertical) (c) Velocity (horiz.)

Figure 6. Flow fields for the cases where the openings are shifted to the right corner (opening size: 1m x 0.3m, wind speed: 0.7 m/s, T_o:28^{o}C)

DISCUSSION

A thorough research on a new hybrid air-conditioning system is accomplished. With the room air circulation that combines the buoyancy-induced airflow formed by the direct hot air discharged from a portable air conditioner and the ventilation air flowing through some wall openings, a comfortable environment is achieved while consuming much less cooling energy. The detailed CFD simulation results reveal the detailed flow fields influenced by the major parameters of wall opening, outdoor wind speed and temperature. As manipulating the wall openings design, this hybrid system can sustain a comfortable environment until affected by strong outdoor wind blast. To avoid this circumstance, two additional designs, one with narrow openings and the other with swapped openings, are found to be able to extend the proper functioning of this hybrid system. In practices, mounting these openings with adjustable louvers to divert air flow direction, the portable air conditioner can always perform very well with natural ventilation. Expected flow phenomena at the beginning of this study are all satisfied including the formation of a thermal plume and a thermal stratification in the room and the induced natural ventilation flow through the openings on the walls.

SUMMARY

Recently, the ventilation for the removal of pollutants has received much attention in response to the increased needs for the health and better comforts of the occupants in apartment housing. To provide constant ventilation air flow, constant airflow mechanical ventilation system is predicted to be installed, and the installation of such mechanical system would lead to many problems.

The purpose of this study is to evaluate application of hybrid ventilation system using the balcony space in apartment housing. As a result through research method, this paper begins with a conceptive explanation of the hybrid ventilation system. Also, through the analysis of thermal condition of balcony space and seasonal characteristics of ventilation in Seoul, the design condition of hybrid ventilation system is investigated. The simulation on hybrid ventilation mode showed that natural ventilation is possible 50.96% of time yearly. CFD simulation result for the analysis of visible flow testing showed that the optimal ventilation mode was maintained smoothly during the intermediate period everywhere except in the room next to the kitchen. For the ventilation in summer and winter, mechanical ventilation was determined to be adopted for the more ventilation airflow.

INTRODUCTION

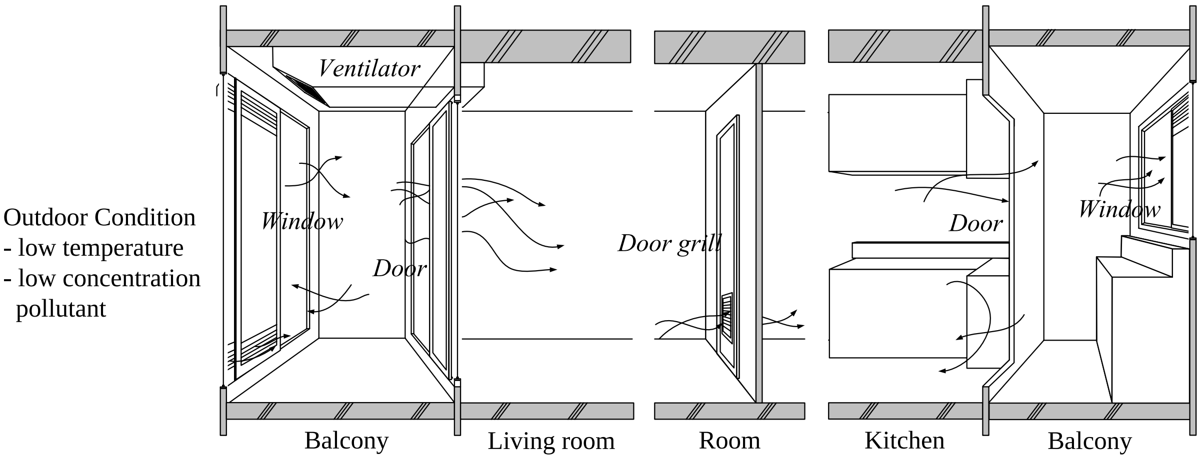
Recently, the quality of indoor air has received much attention as people try to secure a comforting and healthy living environment. Also, the improved construction techniques and energy conservation ideas have made ventilation an essential part of living [1].

Moreover, having to notify the people of indoor air condition of apartments before the moving in under the Code of Indoor Air Quality has raised people's concern about their living environments in apartments [2].

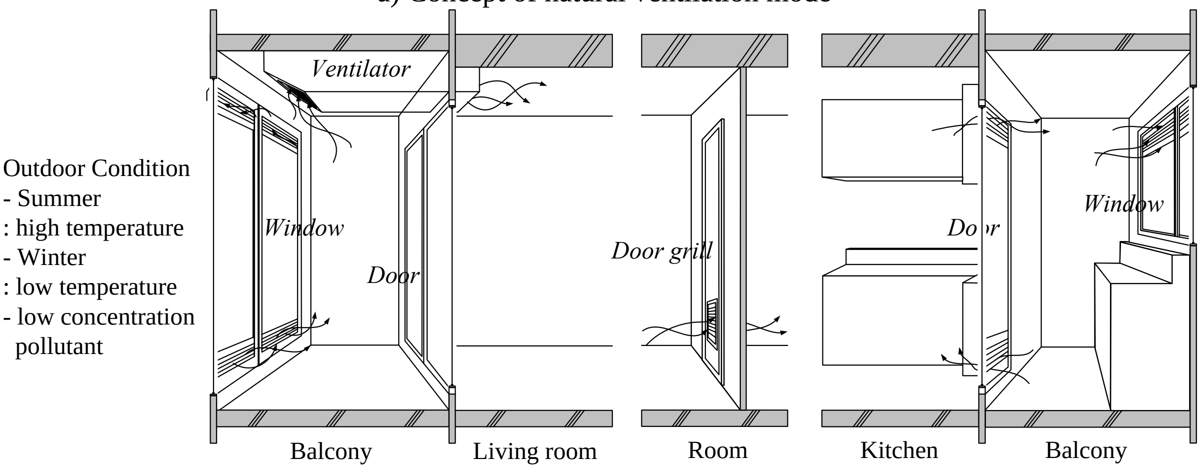
Consequently, the constant airflow mechanical ventilation systems that aim to remove any indoor pollutants are actively being used as the necessity of ventilation in living environments increases. These systems, however, are expected to increase energy consumption because most of them heavily rely on machineries. In addition, Outdoor air induction is expected to influence thermal comfort during the heating and cooling periods

Therefore, the performance of the hybrid ventilation system that jointly uses natural ventilation and mechanical ventilation using the balcony space in apartment housings is evaluated as a proposal in this research.

Apartment housing was selected as the target model of this research. TRNSYS, TRNFLOW and CFD were used to verify the applicability and evaluate the performance of the hybrid ventilation system.



a) Concept of natural ventilation mode



b) Concept of mechanical ventilation mode

Figure 1. Concept of the hybrid ventilation using balcony space proposed in this research

THE CONCEPT OF HYBRID VENTILATION

The hybrid ventilation system uses natural ventilation to maintain the indoor environment status in the spring and fall and the amount of direct solar is reduced by installing sun blinds in the balcony in the summer while providing minimum required ventilation through mechanical ventilation to decrease ventilation load and to remove any indoor pollutants.
The balcony space is minimally ventilated in the winter to use the preheating effect and it is maximally ventilated in the summer in order to maintain a condition similar to outside. Ventilation load is reduced by using a fan coil unit that chills the air coming in from the balcony. Figure 2 illustrates the structure of hybrid ventilation system attached fan coil unit

The concept of the natural ventilation mode

The natural ventilation mode of the hybrid ventilation system can balance and dilute the lower pollutant concentration and the temperature of indoor than outdoor by bringing in outside air. A cross ventilation occurs when opening all the indoor and balcony windows during natural ventilation as shown in Figure 1(a). A pressure difference between inside and outside is induced by operating the ventilation fans in the kitchen and the bathrooms to support the ventilation when there isn't enough natural ventilation taking place.

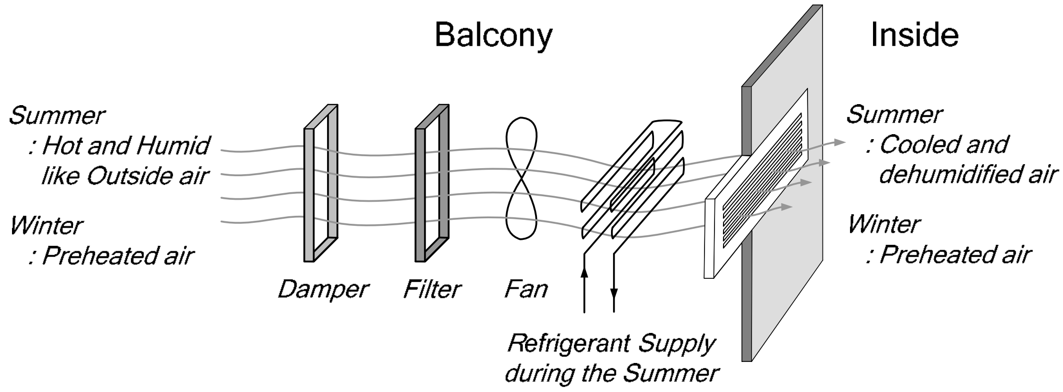


Figure 2. Structure of ventilation system attached fan coil unit

The concept of the mechanical ventilation mode (Figure 1(b))
The mechanical ventilation mode of the hybrid ventilation system secures the required ventilation amount to maintain the indoor air quality. The mechanical ventilation mode is applied when natural ventilation is not applicable due to the season and it chills the air in the balcony before inflow it indoors in the summer. In the winter, it sends in air preheated in the balcony space. The supply air dilutes the indoor pollutant concentration and flows out through the exhaust fan in the kitchen.

SIMULATION

Selecting the target building

The following conditions were considered in selecting the target for evaluating the performance of the hybrid ventilation system in apartment housings.
(1) An RC-structured apartment in Seoul
(2) A new apartment ready for moving-in within the next year
(3) An average sized apartment with high rate of residency for applications in the future
An 85m^2 apartment facing south that was completed in 2005 was selected according to the above conditions. It has been the most common size for the recent 5 years (1998~2002) and its floor plan is shown in Figure 3.

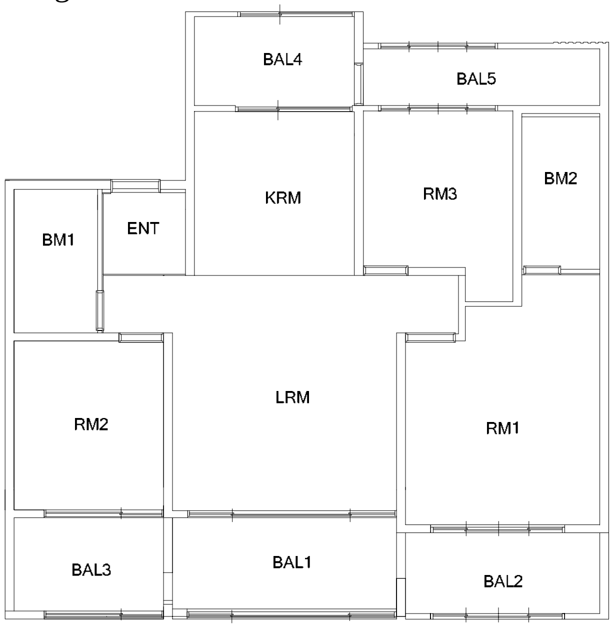

Figure 3. Target evaluation model and zoning

The evaluation model of this research was divided into 8 zones according to their spatial features as shown in Figure 3. Of these zones, heating and cooling are applied to the master bedroom (RM 1), bedroom 1(RM 2), bedroom 2(RM 3), the living room and the kitchen, and the entrance. Natural ventilation window was set up in the window of balcony considering the thermal properties of the balcony.

Simulation Conditions

The 33-P type (surface area 85.8 m^2) evaluation model in Seoul is an apartment housing facing south with RC-structure as shown in Figure 3. The ceiling is 2.3m high with envelope's overall heat transmission rate at 0.483 W/m^2 K. Seoul Standard Weather Data (SAREK, 1995) was applied as the weather data.

The experiment assumed that there were 4 family members with weekdays and weekends strictly distinguished. It was assumed that the parents used the master bedroom (RM 1) and each child used each of the two rooms (RM2, RM3). Regular times were set for going to and returning from school (8AM - 6PM), going to and returning from work (7AM - 8PM), meals (7AM, 1PM, 8PM), and sleeping (11PM - 6AM) and the room activities were scheduled accordingly. The air tightness was set to the average apartment housing at 0.22 ACH [3].

(b) Monthly time ratio of ventilation modes

Figure 4. Configuration settlings of ventilation modes and monthly time ratio

Simulation Results

(1) Ventilation mode settings

The ventilation mode setting is as shown in Figure 4(a) to maintain a comfortable indoor thermal atmosphere. The ventilation method suitable to this country is classified according to

the ranges of the outside temperature and the room temperature and the conditions were configured based on the standard comfortable room temperature (20℃~26℃).
Figure 4(b) shows the monthly ventilation mode usage. Minimal ventilation (MODE 1) is applied in January - May, September - December, when low outside temperatures are brought inside and heating is therefore required to reach a comfortable room temperature. The rate of use of MODE 2 and MODE 3 during these periods was 22.08%. This 22.08% indicates the amount of time required for the outside temperature to be preheated in the balcony before flowing indoors.
MODE 4 is applied from June to August, when the outside temperature is higher and uses the minimal ventilation in order to prevent from any heating overloading. The ratio of the use of MODE2 and MODE 3 was 30.09% during this period.

(2) Optimal operation plans by ventilation modes
The operation condition of the hybrid ventilation system is detailed based on simulation results. It derives the surface area of the opening appropriate for optimal operation through sensitivity analysis.
The operation concept of the hybrid ventilation mode is divided into 4 ventilation modes and the seasonal operation conditions and methods are as shown in Table 1.

EVALUATION

Analysis Plans

In order to evaluate the applicability of the hybrid ventilation system, the airflows of the 4 seasonal modes were examined through the CFD (Computational Fluid Dynamics) simulation analysis and Star-CD was used as the CFD program.
The size of the openings of each ventilation modes were set according to the previous ventilation operation methods, the outside wind speed was set to the average value in Seoul at 2.5m/s, and the wind speed was set to 0.5m/s in the case where exhaust fan has to be operated due to the lack of the natural ventilation.

Analysis Results

(1) Minimum ventilation in the winter
Table 2(a) (1) shows the air flow on the surface of the door louver installed 0.4m above the floor. The outside air in the balcony from the inflow is distributed to room 1, room 2, and the living room through mechanical ventilation (1 ACH) and the air on the inside flows out through the door louvers to the kitchen and the rooms. Most of the air flowing out from the rooms flows into the living room and room 3 and it circulates with the walls of room 3. Therefore the overall air flow seemed moderate except for the bathrooms.
(2) Adequate ventilation in the inter-season
Table 2(b) (1) shows the air flow on the surface at 1.5m above the floor (breathing height). The air velocity when it enters was 2.0 m/s and the overall air velocity was 1.0 m/s. It can be seen that the air is naturally ventilated to the balcony in the kitchen.
(3) When lacking natural ventilation in the inter-season (using ventilation fan)
When lacking natural ventilation in the inter-season, the surface airflow pattern [Table2(c) (1)] is similar to the airflow pattern [Table2 (b) (1)] in adequate natural ventilation but it was 0.5m/s lower overall. It can be seen that air is forcibly ventilated from the kitchen and the bathrooms, airflow is ventilated from the kitchen area to the balcony and through the ventilation fan in the kitchen [Table (2(c) (2) (3)].
(4) Maximum ventilation in the inter-season

An airflow pattern similar to the adequate natural ventilation can be seen on the surface as shown in Table2 (d) (1). Furthermore, the airflow occurs over a wider range than the adequate natural ventilation around spots with faster airflow, and the stagnancy has also decreased.
(5) Minimal ventilation in the summer
Table2 (e) (1) shows the airflow on the surface of a door louver installed 0.4m above the floor. Although it shows airflow similar to that of the winter, the indoor airflow was the lowest in the summer.

CONCLUSION

The hybrid ventilation system was evaluated considering indoor air quality and thermal comfort of a 33-P type (surface area 85.8 ㎡) apartment.
The research can be concluded as following.
(1) A comfortable environment can be maintained with the balcony-using hybrid ventilation system, operating the natural ventilation for 50.96% of the year.
(2) As for the operation strategies of the hybrid ventilation system, the balcony windows were closed, only vent grill (1.9ACH) was used for the ventilation in the winter, the balcony window was opened 1.5 ㎡ for the adequate ventilation in the inter-season (maintain 38 ACH), the inside window was opened 0.5 ㎡ (22 ACH, supply and return air control), the balcony window was opened 3.0 ㎡ during the maximum ventilation in the inter-season (maintain 74 ACH), the inside window was opened 1.0 ㎡ (42 ACH), the balcony window was opened 3.0 ㎡ during the minimum ventilation in the summer (maintain 74 ACH), and the operation strategies by outside temperature is shown in Table 1.
(3) According to the results from CFD simulations of hybrid ventilation modes, the adequate and the maximum ventilation in the inter-season both showed satisfactory air flow. However, room 3 was anticipated to have higher pollutant concentration because it is used as an exhaust air path as well as showing indoor air circulation. The minimum ventilation used the mechanical ventilation system (1 ACH) in the summer and winter showed low airflow as well as frequent stagnations, therefore need for more ventilation and a more fluent airflow.

Hybrid Controlled Trickle Ventilators

Ian Ridley, Mike Davies, Dejan Mumovic and Tadj Oreszczyn

SUMMARY

The performance of "hybrid controlled" trickle ventilators, that is background ventilators whose opening area depends upon both the pressure difference across the vent and the relative humidity of the room air, are investigated by means of computer simulation and compared to that of conventional fixed ventilators for two internal moisture production rates. The results show the hybrid ventilator performs better than the fixed ventilator, resulting in lower ventilation heat loss while maintaining lower relative humidity.

INTRODUCTION

In UK dwellings "controlled" background ventilation is often provide by the installation of trickle ventilators. These units are controllable to the extent that they can be opened or closed by residents. They do not adjust automatically to environmental conditions. The relationship between the opening area of such vents and indoor air quality has recently been investigated [1]. It was noted that the ventilation provided by such ventilators is highly dependent upon weather conditions, leading to the possibility of both under and over ventilation unless appropriately controlled by occupants. Automatic ventilators however have the potential ability to react appropriately to environmental conditions. Two types of automatic ventilator, pressure and relative humidity, RH, controlled, are currently commercially available. Pressure controlled ventilators reduce their opening areas when exposed to higher pressure differences, reopening at lower pressures. Such ventilators could in theory reduce over-ventilation due to gusts of wind, leading to improved comfort and energy efficiency. Relative humidity controlled ventilators open when internal relative humidity is high and partially close when relative humidity is low, potentially leading to improved indoor air quality, energy efficiency and comfort.

The possible benefits of automatic ventilation control of trickle ventilators, in dwellings have been recently investigated [2]. Results confirmed that active vents could be of use in eliminating over ventilation and hence reducing ventilation heat loss whilst at the same time as ensuring adequate air quality. An improved type of automatic ventilator however, would be controlled by *both* RH and pressure, closing in times of high pressure only if internal RH was below a given threshold. This current work then focuses on the potential performance of such a 'hybrid' trickle ventilator i.e. a *combined* RH and pressure device. An extensive series of relevant simulations have been performed and this paper reports on the performance of such a device. The simulations explore the potential benefits of the hybrid ventilator, compared to fixed ventilators, specifically in relation to different internal moisture productions rates. When internal moisture production is low, the hybrid vent should react by reducing the ventilation rate and hence ventilation heat loss, reducing over ventilation. When the moisture production rate is higher, the hybrid ventilator should increase the ventilation rate and hence reduce the occurrence of high internal RH.

Hybrid ventilators in low moisture producing houses should have the potential to reduce ventilation heat loss, but not improve indoor air quality. In dwellings with high moisture production rates hybrid vents will increase ventilation heat loss in order to improve indoor air quality. The relationship between the equivalent opening area of the ventilators, pressure, moisture production rate and internal relative humidity can be represented in a simplified manner mathematically, in the following equations. The internal vapour pressure excess, V_x (Pa), can be expressed in the following form:

$$V_x = G.R_v.(T_i+T_e)/(2n.Vol) \qquad (1)$$

where: G is the rate of moisture production, (kg/hr),$R_{v,}$ water vapour gas constant 462 Pam3/kgK,$T_{i,}$ internal air temperature, (K), $T_{e,}$ external air temperature, (K), n, air change rate, (ach^{-1}), Vol, Volume of dwelling, (m^3).

Note, this equation assumes zero hygroscopicity of the building and furnishings. The air flow through the ventilator is related to the open area of the ventilator A_i:

$$A_i = 1272.5(p)^{-0.5}.q_v \qquad (2)$$

Assuming n, the whole house ventilation rate, is the sum of the ventilation through ventilator n_v, and background ventilation, n_b, through cracks, and if we make the simplifying assumption that air enters through half of the ventilators and exits through the other half, and that the flow through all ventilators is equal in magnitude, then:

$$q_v = n_v Vol/N.1.8 \text{ (l/s)} \qquad (3)$$

$$n = n_v + n_b \qquad (4)$$

If

$$Z = G.R_v.(T_i+T_e)/2.Vol.((SVP_i.RH_i)-V_e) \qquad (5)$$

then

$$Z - n_b = (1.8N.A(p)^{0.5})/1272.5.Vol \qquad (6)$$

given

$$n_b = A_b(p)^{0.5}/1272.5.Vol \qquad (7)$$

then

$$1272.5.Vol\ Z = [1.8NA + A_b].(p)^{0.5} \qquad (8)$$

Given the internal and external temperatures, the external relative humidity, the volume, external façade area and air permeability of the dwelling, and the number of ventilators, then the equivalent opening area of each ventilator needed to maintain a given indoor RH as a function of pressure and moisture production rate can be calculated and graphed, figure 1. In this example the following has been assumed: T_i =293 K, T_e = 278 K, RH_e= 0.80, house volume of 200m^3, an external façade area of 170m^3, with a measured air permeability of 5m^3/hr/m^2, 10 ventilators. When pressure across the ventilator is high and moisture production is low, only a small equivalent opening area is necessary to maintain acceptable room RH. With moisture production rate of 8kg per day and a pressure of 6Pa, an opening area of 1000mm^2 is sufficient to result in RH of less than 65%. At a higher moisture production rate of 12 kg/day and lower pressure differences, of only 1Pa an equivalent opening area of 4000mm^2 is required to maintain RH below 70%.

METHOD

In order to assess the theoretical benefits of automatically controlled trickle ventilators, annual simulations of a test house using EnergyPlus were carried out. Energy Plus [3], was chosen as the computer simulation model as it allows the thermal, energy, ventilation and moisture performance of the house to be modelled simultaneously in one program. In order to simulate automatic control of the ventilators, a visual basic routine was used to set the ventilator opening schedules, based on room RH and pressure across the ventilator, and a series of iterative simulations run. The ventilators are modelled in a standard dwelling previously detailed by the authors [1] used to test the performance of standard trickle ventilators. A schematic layout of the house showing positioning of the trickle ventilators is given in Figure 2. The air infiltration of 5m^3/hr/m^2 at 50Pa is distributed evenly among the three external walls. The external climate used for the modelling was the Kew, (London, UK), TRY.

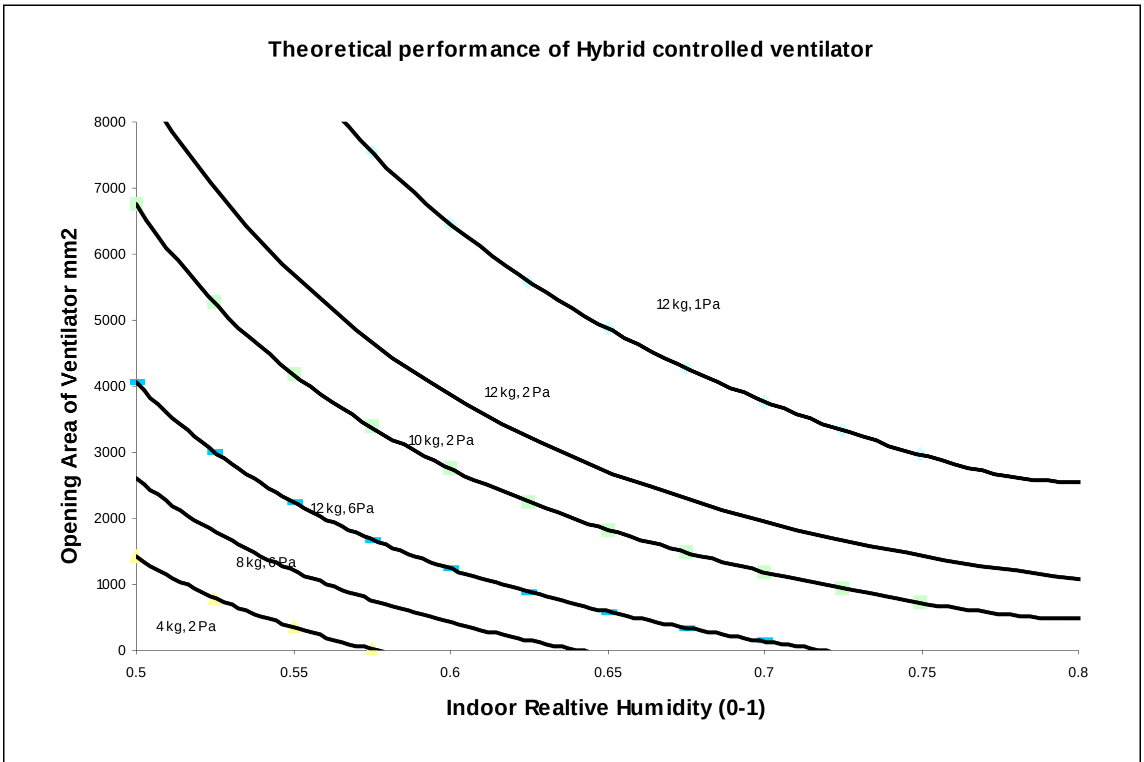

Figure 1. Theoretical performance of a hybrid controlled ventilator

Figure 2. Schematic layout of dwelling. House Volume 200m^3

Two ventilators were modelled were:

1) A standard fixed vent with a fixed open area of 4000mm^2

2) A hybrid (pressure and RH) controlled ventilator with an opening area of 1000 mm^2 if room RH<60% **OR** pressure>6Pa, and 6000mm^2 for room RH> 60% **OR** pressure <6Pa

Two moisture production rates are modelled 6kg/day and 12 kg/day.

RESULTS

The results of annual simulations comparing the performance of the 2 ventilators are summarised in Table 1, for both the low and high moisture production rates. The average heating season ventilation rate, ventilation heat loss and average RH are presented. The heating season was assumed to be October to April inclusive.

Table1. Performance of ventilator during the heating seasons

Ventilator (moisture production)	**Mean background ventilation rate (ach^{-1})**	**Mean Vent Heat Loss (KWh)**	**Mean RH (%)**	**Hours RH >70 (hrs)**
Fixed (lower)	0.51	1760	49.9	20
Fixed (higher)	0.51	1760	58	496
Hybrid(lower)	0.32	1093	50.6	2
Hybrid(higher)	0.43	1425	58.9	394

DISCUSSION AND CONCLUSIONS

The results show the hybrid ventilator performs better than the fixed ventilator, which cannot react to the moisture load. At the lower moisture load the hybrid ventilator reduces ventilation heat loss by 38% compared to the fixed ventilator without incurring an increased number of hours when average internal RH is above 70%. At the higher internal moisture production the hybrid ventilator still reduces the ventilation heat loss by 19% at the same time as reduces the number of hours RH>70% by 21% compared to the fixed ventilator. It is noted that the method of simulating the performance of hybrid trickle ventilator is a simplification, considering only two discrete states, (opening area), and does not model the ventilator continually adjusting to changing conditions. The absolute values of the improvements in ventilation heat loss and relative humidity are of course subject to many uncertainties and assumptions. Further work is underway to develop the model and these results should only be treated as a proof of concept, indicating that hybrid controlled ventilators appear to be of benefit when compared to fixed ventilators. Moisture is considered as the only pollutant, the presence of other indoor contaminants may require greater ventilation rates than those provided by a ventilator designed purely to control on internal relative humidity and pressure differences.

Improved Motor Technology for Small Fans – Impact of Efficiency Gains on System Design

Andreas Karlsson[1] and Caroline Markusson[2]

SUMMARY

Small energy efficient fans have become commercially available for use in HVAC-systems; this open up new possibilities for alternative design of air distribution systems. In this paper the effect of integrating small fans in duct systems is investigated. Modelling and measurements shows that this design has the potential to save energy. When integrating fans in a duct system it is important to consider the system as a whole to find the most energy efficient system solution.

INTRODUCTION

With increased demands for energy efficient and flexible ventilation variable air volume (VAV) systems is an attractive solution. The conventional approach to VAV-systems in Sweden is to use a central fan that pressurise the whole distribution system and use dampers to control and divide the airflows. By replacing control dampers with small, variable speed fans each zone or room of the building can have an individually controlled airflow without any unnecessary fan work. Even for constant air volume (CAV) systems, small integrated fans can have advantages such as reduced fan energy usage and better flexibility.

To reduce the energy consumption, the efficiencies of these fans have to be good. Traditionally small fans have had poor efficiencies compared to larger fans. Now, however, permanent magnet motors (PM-motors) are commercially available for small fans and the efficiencies are much better. Driving the fans with these motors have many advantages such as higher torque or output power per volume, better dynamic performance, low maintenance [1] and built in variable speed drive. Thus the benefit of improved efficiency over a wide working range and reliability is maintained at negligible cost [2].

In conventional distribution systems a centralised fan pressurises the whole duct system and dampers control the airflows. The dampers control the airflow by introducing a flow resistance into the duct system. In VAV systems all branches are equipped with control dampers to adjust the airflows. The requisite pressure for a distribution system is what is needed for the function of the distribution system. Damper authority, diffuser function, stability and flexibility decide how large this requisite pressure is.

There are two main advantages of this new system design compared with conventional distribution systems regarding required fan power: lowered requisite static pressure in the distribution system and less fan work needed to transport the airflow. The latter advantage is present in both CAV and VAV systems whereas the first will only occur for VAV systems.

In conventional systems the fan must provide enough static pressure to overcome the pressure drop in the duct branch with the highest flow resistance. This means that in all other branches there will be a surplus pressure that does not provide any useful work. With the new system design this unnecessary fan work can be avoided since each fan just provides the work needed for that particular branch. Both CAV and VAV have this saving potential. In VAV systems the dampers that control and regulate the airflows requires a certain available static pressure to function properly. The new system design does not include dampers for airflow control so the requisite pressure will be lower than for conventional system and will therefore be a part of the savings potential.

METHODS

This paper is based on a laboratory study of a distribution system and theoretical modelling. The laboratory study includes both measurements and calculations. In the theoretical model a hypothetical distribution system was used for simulations.

Laboratory Study

The measurements were performed on a small-scale distribution system normally used for demonstration purposes, see figure 1. Measurements were performed for two system design cases; 1) on a conventional system set-up, with a VAV-box in each branch, and 2) with the VAV-boxes replaced by variable speed fans. The airflow in each branch and in the main duct was calculated from measurement of the pressure drop across a measuring flange. The static pressure was measured with nipples placed at best possible positions to minimise disturbances of the flow inside the duct.

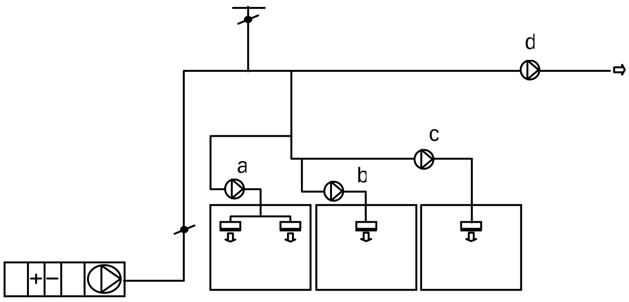

Figure 1. The distribution system for the laboratory study.

The branches are divided into three parts: duct, VAV-box and diffuser. Flow resistance coefficients, k_i, are used to describe these three parts. The relation between pressure drop and flow in each branch is given by:

$$\Delta p = (k_{duct} + k_{VAV-box} + k_{diffuser}) \cdot \dot{V}^2 , \quad (1)$$

where Δp is the pressure drop and $\dot{V}$ is the volume airflow. In case 2, where fans replace the VAV-boxes, the $k_{VAV\text{-}box}$ is set to zero. Power demand for case 2 is calculated according to equation (2).

$$\dot{W} = \frac{\Delta p_{CentralFan} \cdot \dot{V}_{CentralFan}}{\eta_{CentralFan}} + \sum_i \frac{1}{\eta_i} \Delta p_i \dot{V}_i , \quad (2)$$

where $\dot{W}$ is fan power and η is the fan efficiency. For simplification of the modelling and to make it possible to compare results at different operation the efficiencies are assumed to be constant. Due to the non-optimised distribution system design, both the central fan and integrated fans worked at low efficiencies during measurement. The efficiencies used in the calculations and the theoretical model are therefore set to 75% for the central fan and 40% for the small fans, when not stated otherwise.

Measurement Uncertainties – Two types of manometers were used, Furness Control Limited, type FCO332 and Halstrup, type EMA 84. The instrument uncertainties are at worst 0.20% and 1% respectively. Since the objectives are to evaluate potential energy savings and practical limitations the measurements give a satisfactory accuracy.

Theoretical Modelling

A hypothetical model of a medium sized distribution system with seven branches was used to investigate limitations and potentials of the new system design. The pressure gain was divided between the air-handling unit and the distribution system and the total maximum airflow was 1,4 m^3/s. The required fan power was calculated with equation (2).

The flow resistance of the air-handling unit is given as a pressure drop and the pressure drop of the distribution system is a function of the length of the duct branch. There is a requisite pressure necessary for the function of the system, this is divided into two parts: requisite pressure for the diffuser and requisite pressure for the VAV-box. For the new system design the requisite pressure only consists of the diffuser part since there are no VAV-boxes. The requisite pressure is set as constant.

For airflows lower than 1,4 m^3/s the pressure drop for the distribution system and air-handling unit varies with airflow according to equation (3), where index max indicates the highest airflow and pressure drop for the system in the model.

$$\Delta p = k \cdot \dot{V}^2 = \frac{\Delta p_{Max}}{\dot{V}^2_{Max}} \cdot \dot{V}^2 , \qquad (3)$$

RESULTS

Laboratory Study

Measurements were performed for several operating conditions for both the conventional and the new system design. For an example of results for the conventional system see table 1. In this case the static pressure after the air-handling unit was 190 Pa and the total volume airflow roughly 400 l/s. Using data from the measurements the potential reduction of required fan power for the distribution system was calculated and presented in figure 1.

Table 1. Airflows and static pressures, conventional system.

Branch	Static pressure [Pa]		Airflow [l/s]
	Before VAV-box	After VAV-box	
A	116	15	58
B	67	46	61
C	101	53	38
D	-	-	248

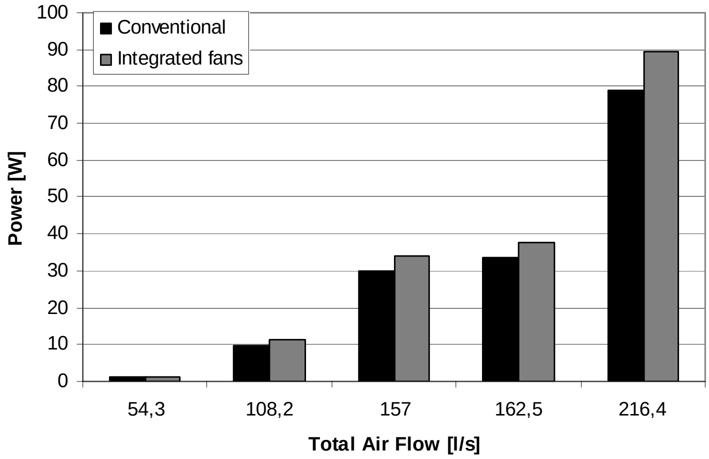

Figure 2. Total fan power demand for the studied distribution system at different air flows, both with conventional design and with integrated fans.

Figure 2 shows that for this distribution system a change from conventional to new system design will lead to increased fan power demand. There are several reasons for this, for example non-optimised duct system design and that the reduced flow resistance by removing the VAV-box is not enough to compensate for fan efficiency decrease when using integrated fans instead of a centralised fan.

Theoretical Modelling

The results from the simulations are presented as the new system designs performance relative to a corresponding conventional system, so the value 1 means equal to the conventional system. Figure 3 shows the effect on the total required fan power of the system as a function of the pressurisation provided by the central fan.

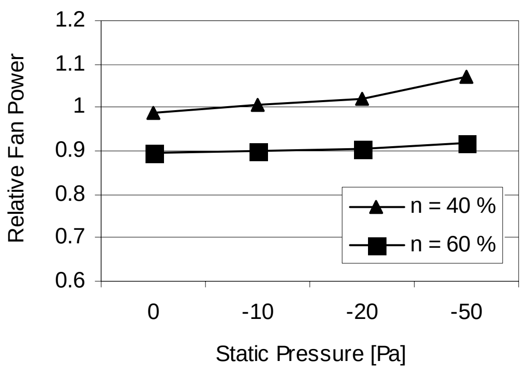

Figure 3. Relative fan power as a function of static pressure before the first fork for two efficiencies for the integrated fans.

As can be seen in figure 3 the system with integrated fans goes from being more energy efficient to less with small decreases in static pressure at the point where all the duct branches join. During measurements the same effect could be observed. Figure 3 also shows that with higher efficiency of the integrated fans this trend is less pronounced but will still be present as long as the efficiency of the integrated fan is lower than that of the central fan. This limits the extent to which the pressure gain from the central fan can be reduced from an energy efficiency point of view.

Pressurisation from the central fan is an important aspect and is closely linked with the duct system design. To show the effect of duct system design several simulations were performed and some results are presented in figure 4. For all cases the total airflow and the necessary pressure difference for transporting the airflow through the longest duct branch is the same. There are three cases presented here: 1) with symmetrical duct system where all the branches are of equal length and have equal airflow, 2) with an asymmetrical duct system (different duct length in the branches) where one branch is dominant and 80 % of the total airflow passes, and 3) with the same asymmetrical duct system but where all branches transport equally large airflows.

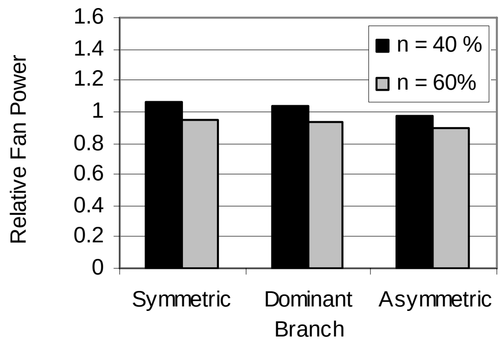

Figure 4. Relative fan power for different duct system designs and efficiencies of the integrated fans.

As can be seen in figure 4 the saving potential with the new system design for CAV systems and today's fan efficiencies is limited and is highly dependant on duct system design and distribution of airflows. But for increased fan efficiency the new system design will require less fan power regardless of duct system design and for the asymmetrical case the potential energy savings will be as large as 10 %.

Simulations showing the improvement of system performance as a function of increased integrated fan efficiency were made for both VAV and CAV, see figure 5. The airflow for the VAV system was equal to half the CAV airflow. For VAV systems the new system design can require less fan power even with a perfectly symmetrical duct system but, as for CAV, some degree of asymmetry leads to an increased savings potential.

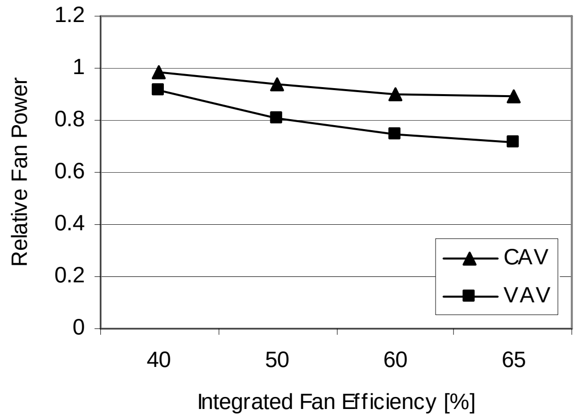

Figure 5. Relative fan power as a function of integrated fan efficiency for different system designs.

To show the potential advantages of the new system design the results for a suitable duct system was simulated. These results show that the potential savings with the new system design is about 10 % with an integrated fan efficiency of 40 %. As figure 5 shows the new system design can have an even bigger saving potential for VAV than for CAV. With increased fan efficiency the energy savings for this system can be up to 25-30 %.

DISCUSSION

Requirements

To make this system design feasible some requirements must be fulfilled. Here only those requirements that separate the new system design from conventional systems are discussed. First and foremost there must be available fans with suitable working range, size and performance. The fans must be able to provide a high enough pressure gain to overcome the flow resistance of the distribution system even at low airflows. The measurements performed showed that the fans used in this study fulfilled these requirements. However, the efficiency of fans and motors of this size is still not very high, around 35 to 40 %.

Savings potential

As mentioned above the savings potential is due to the unnecessary fan work that results from differences in flow resistance between the duct branches. Therefore the design of the duct system and distribution of airflows will determine the potential savings. For a perfectly symmetrical duct system the savings potential will be limited, in fact such a system can be less efficient than a conventional system. There should not be an airflow distribution where one duct branch transports the main part of the total airflow. Such a system can be even less suitable for the new system design than perfect symmetry. Worth mentioning here is that since energy for fans is a big part of total energy usage for buildings even small savings or increases in system efficiency can be profitable. In VAV systems the saving potential also depends on how the airflows vary in different parts of the duct system. The new system design is especially suited for systems where there is a varied demand for airflows.

Limitations

As shown above there is definitely a potential to save energy by replacing conventional systems with this new system design, however there are of course limitations to the applicability of the new system design and its savings. The measurements did not show any saving potential. Figure 2 shows that it is less effective with integrated fans for this system. This is due to limiting factors that will be discussed below.

Control of the Central Fan - Since the central fan has a higher efficiency than the integrated fans it should provide as large part of the work as possible. Ideally that means that the central fan should provide the work necessary to transport the airflow through the air-handling unit and pressurise the distribution system so that no additional fan work is necessary for the branch with the *least* flow resistance. For all other branches the integrated fans will add the extra pressure gain necessary to overcome the pressure drop of that branch. In a CAV system it is straightforward to pick out the branch with least resistance but in a VAV system this can vary. A more simple approach would therefore be to control the work of the central fan so that it keeps a constant static pressure at the first fork in the duct system. Since the integrated fans work parallel to each other a reduction of this static pressure will result in an increase in the necessary pressure gain for *all* the integrated fans and thereby an increased energy usage.

Duct system design - In the section about Requirements and Savings Potential the effect of unsuitable duct system design is shown and as mentioned above this design will also affect the control of the central fan. For a duct system to be suitable for this new system approach it should have the following attributes:

- System size (several duct branches)
- Airflow in each duct branch of the same magnitude (no single dominant branch)
- Preferably varied length of the duct branches
- No small ducts branching off, a collected system

The measurements for this study were performed on a very small duct system with just three branches and small airflows. For this system no energy savings were measured, even if this system was modelled and simulated it was not big enough to give any energy savings, see figure 1. This was due to several factors. Branch *b* has the highest flow resistance and in addition the flow through this branch is high. The pressure gain by removing the VAV-box is not enough to compensate for the decreased efficiency when driving this branch with the smaller fan. As a result of this the power demand increases. However, in branch *a*, the power demand is almost halved whereas in branch *c* a slight increase is seen.

The saving potential with integrated fans is dependent on the surplus pressure and following fan work for all branches except the one with the highest flow resistance, as described above. But by reducing the pressure gain from the central fan the necessary work is instead performed by the smaller integrated fans that have lower efficiency than the central fan. For this new system design to be profitable the savings due to surplus pressure and fan work must outweigh the loss in fan efficiency and this requires a system with several duct branches

The varied duct branch length and similarly sized airflows are necessary to provide the desired difference in surplus pressure and fan work. In conventional systems it is common with small ducts, supplying one single diffuser branching off from the main duct. Since the central fan pressurises the whole duct system this works fine. The same approach will lead to an impossible amount of integrated fans with the new system design.

Practical Aspects

Apart from the above discussion there are also several practical aspects that will affect this new system design. In this section some of these will be discussed.

Placement of Fans - By placing the fans in the duct system, the inhabitants of the building will be affected by maintenance since this will take place right among them. Another effect of fan placement is noise.

Economy - This system approach requires a number of fans, each with sensors for airflow control. This study has not included any economical analyses but the expected high cost of this system must be weighed against the energy savings and other advantages such as flexibility.

Pressurisation of the Duct System - In conventional duct systems there is a positive static pressure compared to the pressure inside the building. That means that any leakage will be directed out from the ducts. With the new system design parts of the duct system will have a negative pressure and leakage airflow could enter the duct system and thereby spread to other parts of the building.

Reversed Airflow - Negative pressure in parts of the duct system require careful design and a control system to prevent reversed airflows. During the measurements in this study one integrated fan was turned off while the two others were turned on to give maximum airflow. This resulted in a reversed airflow through the branch with the turned off fan. A simple solution to prevent this would be to place a static pressure sensor downstream of the fan. The fan would then be programmed to always maintain a certain positive static pressure even if no airflow is necessary.

Conclusions

There is definitely a potential to save energy by changing the design of ventilation systems by replacing the conventional approach with one centralised fan with many decentralised fans integrated in the duct system. The saving potential is not universal for all duct system but depends on several factors such as symmetry, pressure drop and flow for each branch etc. It requires careful design and there are many practical aspects that need to be considered. This approach will also put demands on engineers to think in different ways in planning their duct systems, choosing fans, placement of sensors and so forth.

SUMMARY

The electrical energy needed for ventilation fans and air handling units (AHU) plays an increasing role in the energy demand for buildings. Recent studies show that the electrical energy consumption can rather easily be reduced from the "traditional" level (between 5 and 10 kW/m^{3}s) into a modern level (2 to 2,5 kW/m^{3}s) with proper design and installation. Even lower levels are technically possible, but not yet widely economically feasible.

Several countries have already set, either as requirements or as recommendations, maximum target values for SFP. This has been the first important step towards energy efficient air handling systems. However, in real practice other measures are needed, including simple but reliable tools for designers for SFP calculation, and measuring guidance for installers. To check and assess the SFP should be easy and clear also for the building owner, the end user, the inspectors etc. The need for measurements should be taken into account in the AHU construction to enable easy but reliable measuring, and guidance is needed for system design as well as for those who perform the measurements.

INTRODUCTION

The electrical energy needed for ventilation fans and air handling units (AHU) plays an increasing role in the energy demand for buildings. Recent studies show that the electrical energy consumption can rather easily be reduced from the traditional level with proper design and installation.

The "Specific Fan Power" (SFP) value, expressed in kW/m^{3}s, indicates the demand on power efficiency of all supply air and extract air fans in a building. Several countries have already set, either as requirements or as recommendations, maximum target values for SFP. This has been the first important step towards energy efficient air handling systems. However, in real practice other measures are needed, including simple but reliable tools for designers for SFP calculation, and measuring guidance for installers. To check and assess the SFP should be easy and clear also for the building owner, the end user, the inspectors etc.

The present regulatory values vary typically between 2 and 3 kW/m^{3}s. The newly revised European Standard EN 13779 [1] gives a classification of SFP values, which also takes into account the fact that in some special cases (requiring e.g. HEPA filters, humidification or high-efficiency heat recovery) a higher electrical energy consumption is unavoidable. In the new EN 13779, the whole range is from 1 up to 9 kW/m^{3}s, and the recommended maximum excesses of the classified SFP values (e.g. due to high-efficiency filtration) are also defined.

WHAT IS SPECIFIC FAN POWER?

The new EN 13779 [1] includes an Annex which gives more detailed guidance about how to express, specify and also validate the SFP value in practice.

Target value for the **Specific Fan Power, SFP**, indicates the demand on power efficiency of all supply air and extract air fans in a building. This value should be defined during the early design stage for determining the useful power demand and so the energy consumption required for transporting air throughout an entire building.

A supplementary factor SFP_E makes it possible to assess how efficiently **individual** air handling units or fans utilize electric power. The definition of the SFP_E is different for heat recovery air handling units with supply air and extract air, and for separate supply air or extract air handling units and individual fans.

During the design process the SFP value for the entire building, defined as the weighted average of the SFP_E values of individual units and fans (see item "Example"), shall be compared to the target value and checked in case any changes in the individual SFP_E values appear.

Another useful specific fan power is SFP_V for validation. The intention with this value is to have a factor which is simple to specify and check. The difference between SFP_E and SFP_V is the load condition, **design for SFP_E and validation for SFP_V**. It is recommended that both SFP_E and SFP_V values are calculated (using manufacturer's software, for example).

The SFP value for the whole building is defined as follows: "The combined amount of electric power consumed by all the fans in the air distribution system divided by the total airflow rate through the building under design load conditions:

$$SFP = \frac{P_{sf} + P_{ef}}{q_{max}} \qquad (1)$$

where

SFP is specific fan power demand in kW x m^{-3} x s

P_{sf} is the total fan power of the supply air fans at the design air flow rate in kW

P_{ef} is the total fan power of the extract air fans at the design air flow rate in kW

q_{max} is the design airflow rate through the building, generally the extract air flow in m^3 x s^{-1}

In terms of SFP **for the whole building**, any fan powered terminals shall be included when they are connected to the main air supply system.

For individual air handling units or fans, to enable the designers of building projects to quickly determine whether a given air handling unit will positively or negatively meet the overall demands on power efficiency, a SFP_E for the individual fan or AHU has been defined. In a constant air volume flow system, the demands shall be met at the design air flow and design external pressure drop (pressure drop in the ducting). In a variable air volume flow system, the demands made on the SFP_E shall be met at the partial air flow and the related external pressure drop, specified for each air handling unit specification or at another point in the reference documents of the project. Therefore data at design maximum air flow and design maximum external pressure drop shall be specified, as well as the partial flow and the related external pressure drop. If the data concerning partial air flow and related external pressure drop is not specified, the following figures can be used as default values for determining the SFP_E (background and more details are presented in EUROVENT 6/8 [2]):

Partial air flow (default value): 65 % of the design maximum air flow
Partial external pressure drop (default value): 65 % of the design maximum external pressure drop.

.The **specific fan power** ***SFP*****E – ** for **supply and extract air units** (normally also equipped with heat recovery), is the total amount of electric power, in kW, supplied to the fans in the AHU, divided by the largest of supply air or extract air flow rates (i.e. not the outdoor air or the exhaust air flow rates) expressed in m^3/s under design load conditions.

$$SFP_E = \frac{P_{sfm} + P_{efm}}{q_{\max}} \qquad (2)$$

where
SFP_E is the specific fan power of a heat recovery air handling unit in kW x m^{-3} x s
P_{sfm} is the power supplied to the supply air fan in kW
P_{efm} is the power supplied to the extract air fan in kW
q_{max} is the largest supply air or extract air flow through the air handling unit in m^3 x s^{-1}

Air handling units with liquid-coupled coil heat exchangers and separate supply air and extract air sections also belong to this category of air handling units.

For separate supply air or extract air handling units and individual fans, the **specific fan power,** ***SFP*****E** is the electric power, in kW, supplied to a fan divided by the air flow expressed in m^3/s under design load conditions.

$$SFP_E = \frac{P_{mains}}{q} \qquad (3)$$

where
SFP_E is the specific fan power of the air handling unit/fan in kW x m^{-3} x s
P_{mains} is power supplied to the fans in the air handling unit/fan in kW
q is air flow through the air handling unit/fan in m^3 x s^{-1}

The intention with the SFP_V value is to have a factor which is simple to specify during building design and straightforward to validate when commissioning and controlling the ventilation system. The ***SFP*****v** is the electric power, in kW, supplied to a fan divided by the air flow expressed in m^3/s **under validation load conditions.** When defining a ventilation system specification it is convenient to specify the highest permissible SFP_V as this will help to influence the choice of air handling units or fans towards those of a desired power efficiency.

EXAMPLE

In a typical commercial or public building there are a few air handling units and also some separate supply or extract air fans to serve different purposes. There may also be a wide variety of activities in the building, some of which can be served by a simple fan (e.g. exhaust from toilets) and others requiring high-level air treatment and distribution (auditoria, exhibition facilities etc.). For this reason, the SFP values for individual units and fans can vary within a wide range especially in multi-purpose buildings. The following example presents also how to calculate the SFP for the whole building as a weighted average of all individual SFP's, as the total power consumption of all fans altogether, divided by the total supply **or** extract air flow, whichever the greater. EN 13779 [1] actually defines several ways to determine the SFP values, due to the still remaining national differences in the definitions. It is therefore important also to include in the design and commissioning documentation, which calculation procedure has been applied in each individual case.

AHU equipped with both supply and extract air units

Supply air fan	**Air flow m^3/s**	**Ductwork pressure Pa**	**Power supplied to the fan 1) kW**	**Extract air fan**	**Air flow m^3/s**	**Ductwork pressure Pa**	**Power supplied to the fan 1) kW**	**SFP_E of this AHU $kW/(m^3/s)$**

SFP =	**39,4/15,9**	**2,48 $kW/(m^3/s)$**

1) Power supplied to the fan
This means the power supplied to the fan at design air flow and given pressure loss of the ductwork. This value can be calculated for example using the manufacturer's dimensioning software. This figure is used as input data for calculation of the SFP for the entire system. This figure includes the efficiency of fan, motor, belt drive and frequency converter. This is also the power, which should be verified by measurements in the completed installation after balancing and final adjustment of air flows.
2) Ductwork pressure, in case of separate extract air fan

APPLICATIONS, AND TASKS FOR DIFFERENT TARGET GROUPS

Guidance for design, measuring and documentation has been developed during the recent years in Finland in order to support practical implementation of the relevant clauses of the National Building Code [3], which gives a maximum target value for SFP (**2,5 kW/m^{3}s for ordinary systems;** for special applications a higher value is allowed) and also requires validation by measurements in commissioning.

An unofficial guideline was published in 2004 and revised in 2005, freely available in www. A simple excel calculation tool for designers was included in the second edition. The feedback from designers and inspectors indicated that the information was not very widely known.

In order to have the SFP calculation and validation widely adopted also in practice, a short summary was added in the information package in 2006. It points out the importance of the issue to the "key players" as follows:

-the designer will make the system design, including: specifying the target value for SFP, selecting the AHU's, calculating the exact SFP value (for each unit and fan, and finally the overall SFP as the weighted average as described in the example above), and dimensioning of the air distribution and diffusion system accordingly. The designer also makes the design documentation including the SFP calculation sheet

-the installer will install the system and take care that the system is built according to the designer's specifications – not only physically, but also functionally. The installer takes also responsibility of the SFP measurements at the commissioning stage, including the relevant measurement report

-the building inspector will check the design documentation and the measurement report and confirms their conformity to the building regulations

It has to be pointed out that the use of SFP as guidance for system design and construction is a relatively new issue everywhere. There is no scientific data yet available about the SFP level and how much it has reduced during the recent years. However, the measurements done by some manufacturers and inspectors indicate that the most common regulatory values, between 2 and 2.5 kW/m^{3}s, represent the state-of-art in modern applications. Lower regulatory values do not yet seem to be very realistic, taking also into account the fact that some 15 years ago a much higher power consumption (between 5 and 10 kW/m^{3}s) was the normal practice. Levels down to 1 – 1,5 kW/m^{3}s are technically possible, but not yet widely economically feasible.

DISCUSSION

Recent studies show that the electrical energy consumption can rather easily be reduced from the "traditional" level (between 5 and 10 kW/m^{3}s) into a modern level (2 to 2,5 kW/m^{3}s) with proper design and installation. Even lower levels are technically possible, but not yet widely economically feasible.

In addition to put some target values for the SFP number, it is also important to give tools for practitioners so that the target values can really be achieved and maintained in real practice.

The SFP value can be easily measured in practice, if the measurability is taken into full consideration in design and construction of the AHU. Normally the power consumption can be easily measured in modern AHU's, see the figure on the left.

Also the air flow has to be measured to determine the SFP value. To do this in an easy but reliable way, the AHU or fan should be equipped with a built-in air flow measurement arrangement. One example is presented in the figure below.

SUMMARY

The potential for draught discomfort and high air velocities in the occupied zone are often studied with only cooling design in mind. During the transition season, however, downward flows with high air velocities may occur in the occupied zone due to cold window surfaces. Airflow generated by supply air terminal dervices may further enhence the velocity in the occupied zone. Furthermore, convection flows caused by thermal loads may significantly affect the air flow conditions in the room as a whole and assist the occurance of high velocity near occupants. Analyses of results from full-scale measurements with chilled beams presented in this paper reveal that installations with possibilities of convection flow oposing the supplied flow should be avoided. Generally speaking, convection flows have less impact on air distribution in rooms with chilled beams installed in lengthwise direction than when installed crosswise in rooms.

INTRODUCTION

The local air velocity, temperatures of the room air and air jets, and fluctuations in air velocity are the key factors that determine the risk of a draught. In designing an indoor environment, it is important to evaluate the impact of the various solutions on the air flows in the room. It is particularly important to analyse air velocities in office buildings and on other business premises with relatively high requirements for cooling capacity. The maximum allowed speed in the occupied zone is specified in the present standards for the cooling and the heating seasons. No recommendations have been set for the transition season in the standards, which, in practice, means that designers are free to use the recommendations for either the winter or the summer season.

Convection flows, for example caused by a cold window, may, however, be sufficiently strong during the transition season and may generate high velocity in the occupied zoned and cause draught discomfort. When chilled beams are used the air velocity in the occupied zone is affected by the window's surface temperature, the direction of the supplied air flow relative to the convection flow from the cold window, and the convection flow from operating radiator (if any) below the window.

The effect of the convection flows on the air distribution in rooms is usually ignored and the assessment focuses only on the flow supplied from air terminal devices. This article addresses the effect of convection flows on the room air distribution. In particular the interaction of convection flows from heat sources with different strength and location and from warm window with the airflow supplied by chilled beams is studied and reported.

EFFECT OF CONVECTION FLOW ON JET DETACHMENT

The effect of a convection flow created by a thermal load on the detachment point of the supply air jet as shown in Figure 1 was studied [1]. The measurements aimed at examining the variation occurring in the detachment point of the jet when the thermal load and the chilled beam's supply air flow rate were altered. The test room (4.0 x 2.8 x 2.8 m (H)) had a room-wide unidirectional beam and a 1.2-metre-wide band-shaped reheat coil (Fig. 1). In the measurements, the output capacities of the convector was set to 200 W (71 W/m), 300 W (107 W/m), 400 W (143 W/m), and 500 W (179 W/m), while the primary flow rate supplied from the chilled beam was 6, 8, and 10 l/s per m.

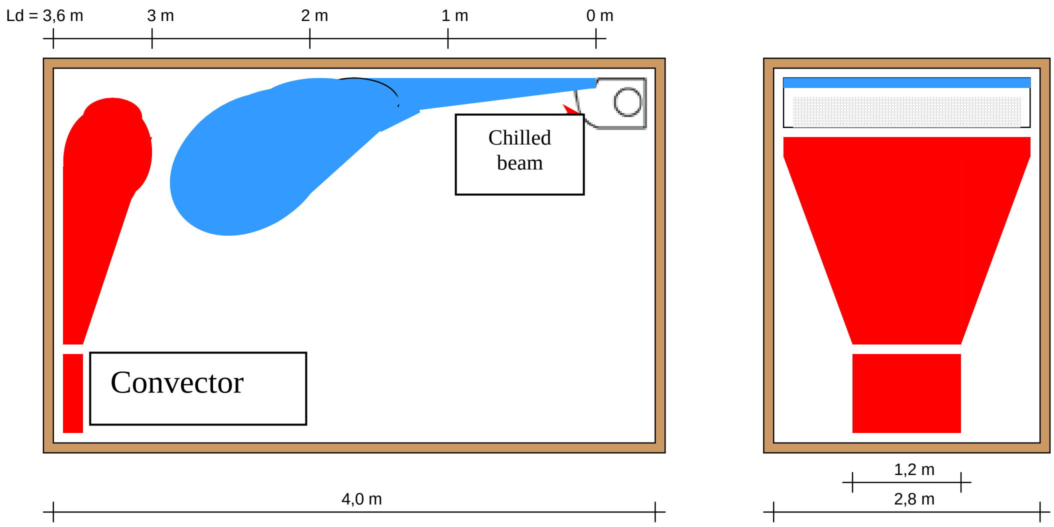

Figure 1. Test arrangement used to study the effect of convection flow on the detachment point of an opposing supply air jet of a room-wide unidirectional chilled beam.

Figure 2 presents the distance of the detachment point of the supplied air jet as a function of the thermal load's capacity is shown. The supply air flow rate from the unidirectional chilled beam is a parameter. The results indicate that the convective flow corresponding to the cooling effect of a 150 W/m room device is sufficiently great to cause the detachment and jet droped in the occupied zone with all air flows studied. With the typical airflow rate of 8 l/s per m (2 l/s per m^2) for a unidirectional beam, the momentum flux caused by a thermal load of 50–75 W/m is sufficient to release the jet before it reaches the opposite wall. In general, instalation of unidirectional chilled beams with supplied jets opposing convection flow from heat sources should be avoided.

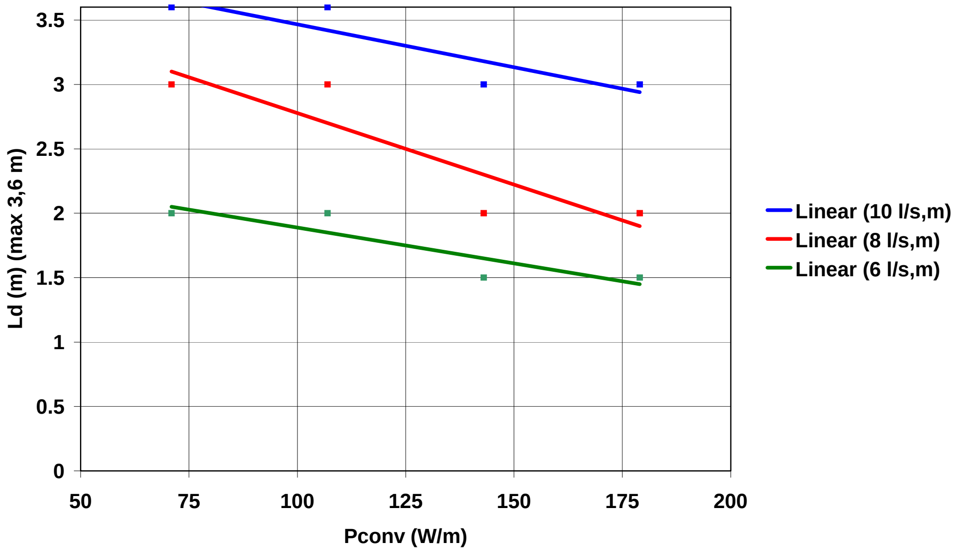

Figure 2. The detachment point of the jet as a function of the convection load of a band-shaped heat source (W/m) and the supplied primary air flow (l/s/m) from a unidirectional chilled beam.

SIGNIFICANCE OF THE POSITIONING OF THE AIR SUPPLY DEVICE

The impact of the positioning of the air supply device on the flow distribution in the room during cooling (summer) and mid-season situations was studied in a test room (2.4 x 4.6 x 2.8 m (H)). A 300 mm wide chilled beam with a total length of 2,100 mm (1,900 mm effective length) was installed in both the longitudinal and latitudinal direction in the room as shown in Fig. 3. The air velocities in different points of the occupied zone were measured and compared. Figure 4 presents the air velocities measured in the cooling season (60 W/m^2), while Figure 5 for the transition season (25 W/m^2). In the case of 60 W/m^2, the heat loads were: a computer (100 W), a dummy (60 W), light fittings (144 W) and warm window (350 W). Heat loads in the transition case as before, except the window was not heated.

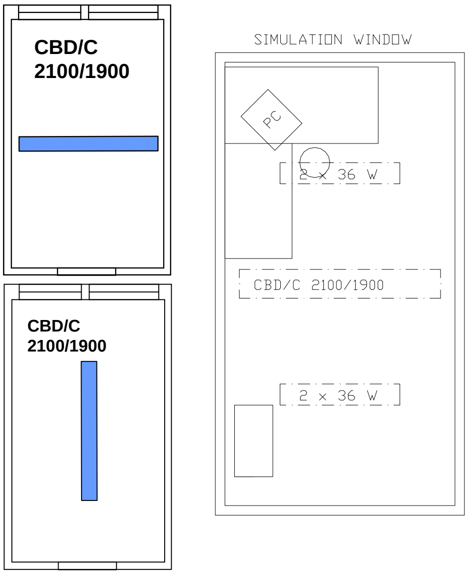

Figure 3. Test room arrangements with a longitudinal and latitudinal active chilled beam.

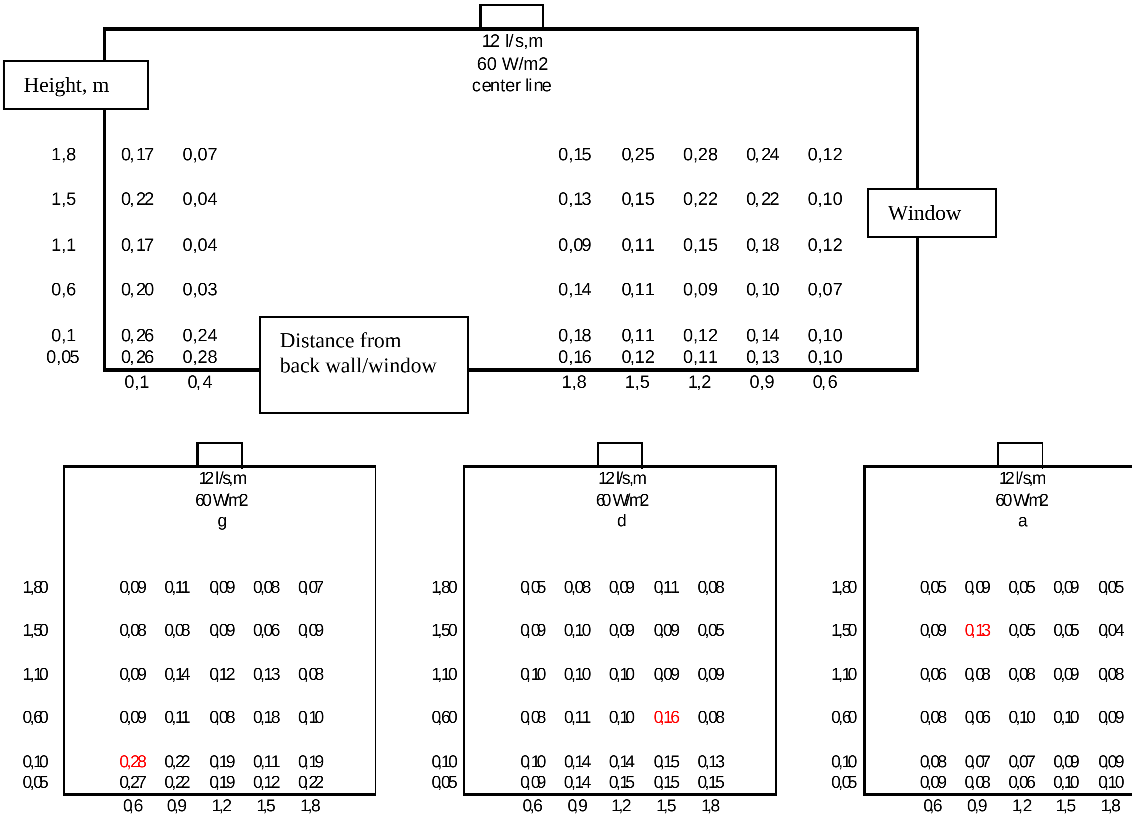

Figure 4. Air velocities (m/s) in the latitudinal (top cross-section) and longitudinal installation (bottom cross-sections: a = 0.6 m, d = 1.5 m, and g = 2.4 m from the window) measured with chilled beam (2100 mm length) at cooling capacity of 60 W/m^2. Cooling case (summer season).

In the cooling situation (Fig. 4), the convection flow from heat sorces concentrated at the window wall (a warm window, human occupant, and computer) reverses the air flow from the latitudinal beam and the maximum velocities occur close to the corridor-side wall. In the longitudinal installation (Fig. 5), the effect of the convection flows is smaller, and the air velocities are lower, than in the longitudinal installation.

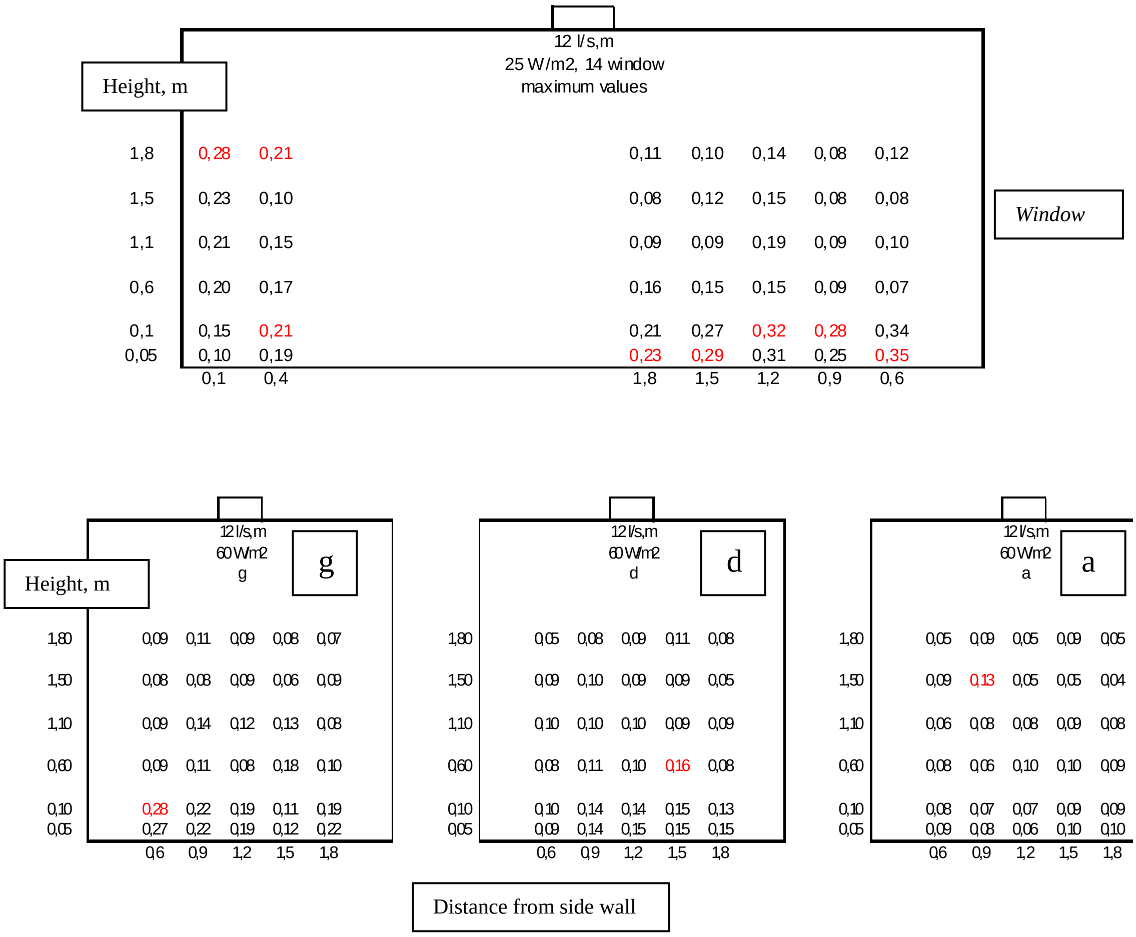

Figure 5. Air velocities (m/s) in the latitudinal (top cross-section) and longitudinal (bottom cross-sections: a = 0.6 m, d = 1.5 m, and g = 2.4 m from the window) installation of a same-size beam with a cooling effect of 25 W/m^2 and a window surface temperature of 14 ^{o}C.

During the transition season (Fig. 5), the supply air jet of a beam installed in the latitudinal direction emphasises the convection flow of a cold window, and high speeds (0.23–0.32 m/s) are found at floor level (5–10 cm from the floor) at a distance of 0.6–1.8 m from the window. The velocities are lower in a longitudinal installation than in a latitudinal one. However, rather high velocities occur at certain points, primarily in the centre of the room. Generally speaking, it should also be noted that a radiator installed below a window can eliminate the convection flow that increases the risk of a draught caused by a cold window. In practice, this means that, to minimise the draught risk, the radiator must be turned on during the transition season – regardless of the cooling requirement.

THE EFFECT OF THE LOCATION OF THE THERMAL LOAD ON ROOM AIR DISTRIBUTION

The effect of the location of the thermal load on air velocities in the occupied zone was studied in a test room (6.5 x 4.0 x 2.8 m (H)) with an exposed active chilled beam. The chilled beam with a total length of 5 m was installed in longitudinal direction in the centre of the room. The beam's distance from the ceiling was 250 mm. The total cooling load was 85 W/m^2 when the primary (outdoor) supplied air flow rate was 2 l/s per m^2. In the measurement, the heat loads were: three computers (3x 123 W),three dummies (3x 120 W), light fittings integrated into the chilled beam (140 W), heat gain from floor panel (300 W) and warm window (350 W). The size of the window was 1.3 (W) x 1.9 (H) m. The area of the heated floor was 5.5 m². The velocity field was measured at three different thermal load distributions: 1) normal office room with thermal load on the window and side walls, 2) 50% on the window wall and 50% on the corridor wall, and 3) all load on the window wall (Fig. 6).

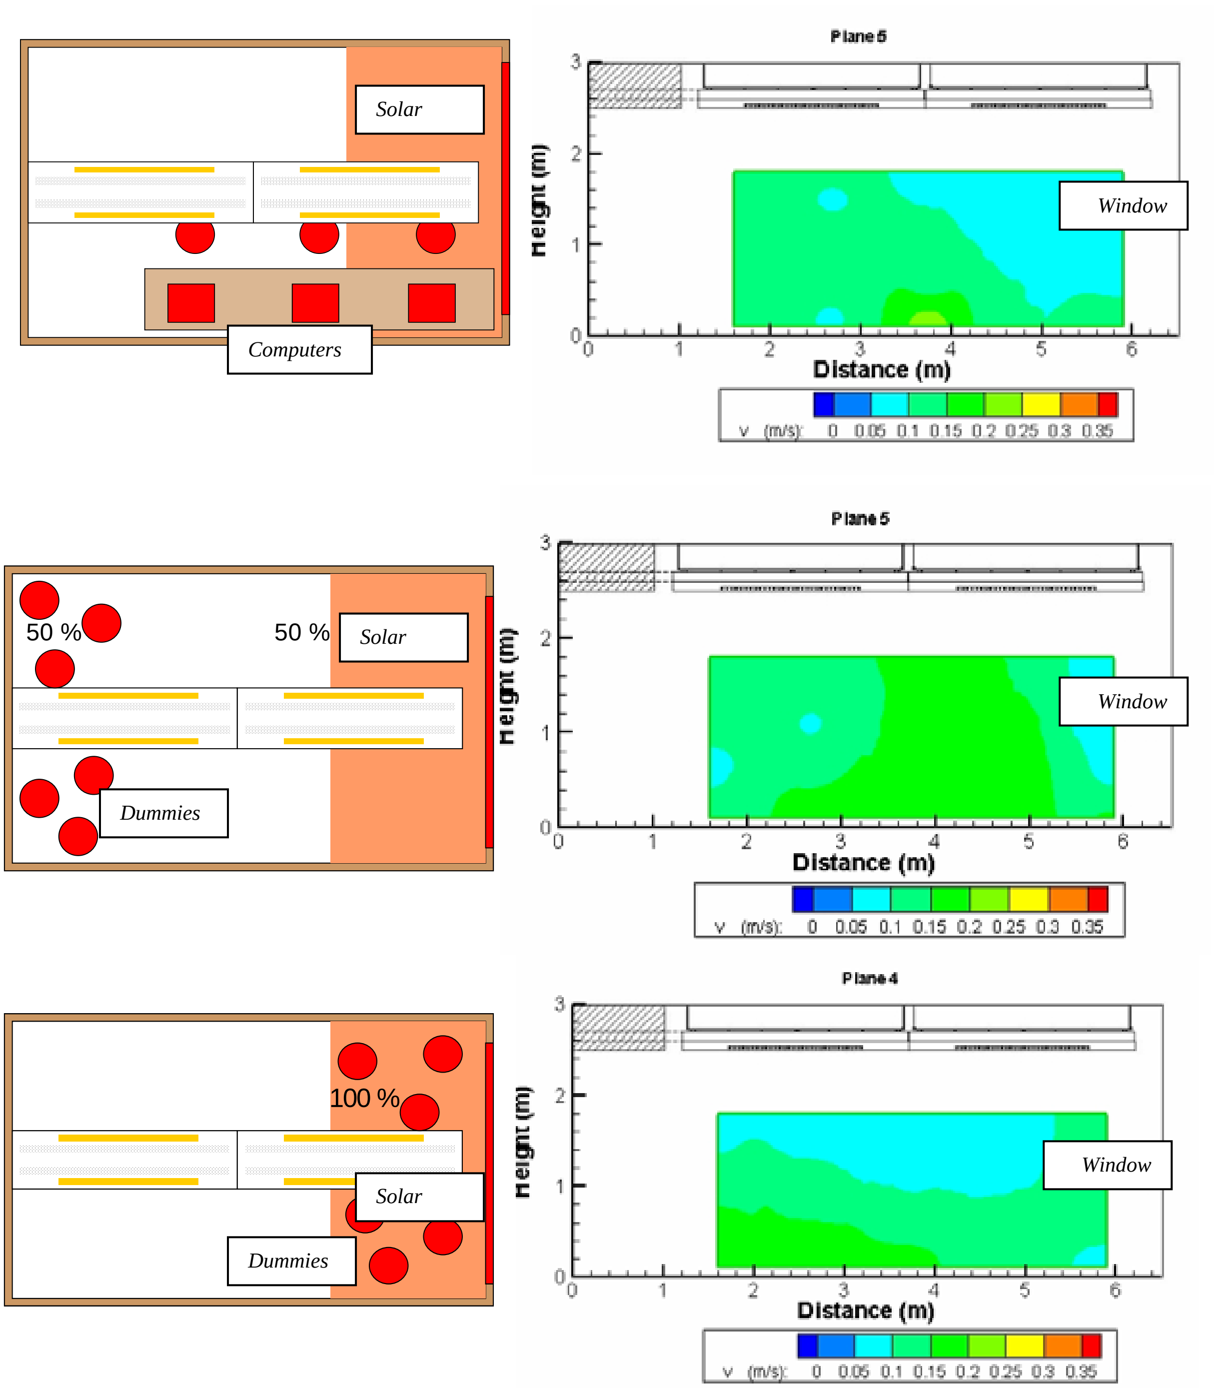

Figure 6. The location of thermal load and its impact on air velocities in the occupied zone. Top: normal office load. Middle: 50% on the window wall and 50% on the corridor wall. Bottom: 100% of the load on the window wall.

In all cases studied, the air velocities were relatively low (less than 0.22 m/s). The highest air velocities occurred in cases where the load had been altered from that of a normal office. The results shown in Fig. 6 by colored field of constant speed reveal that locating all heat sources close to the window wall generates air distribution with a maximum speed in the proximity of the corridor wall, while, when the heat sources were evenly distributed between the window and corridor walls, the maximum speed occurred in the middle of the room. Overall, the location of the thermal load did not significantly affect the operation of the chilled beam for the conditions of the performed measurements.

DISCUSSION AND CONCLUSIONS

Draught discomfort is one of the most often reported compaints in rooms. During design, the draught risk should be considered not only for the conditions which require maximum cooling (summer season) but also for the transition season between summer and winter, e.g. spring and authumn. Depending on the location of the air supply device and the convection flows generated in the room , the transition season may feature air velocities comparable or even greater than those of the maximum cooling sonditions. In general, the air velocities in rooms with latitudinal-installation of chilled beams are greater than than those in rooms with longitudinal-installation of the chilled beams.

The area of occurrence of the maximum speed in the occupied zone depends on the streangth and the location of the heat sources, its momentum flux and on the supplied flow pattern with respect to the convection flow. Generally speaking, convection flows have less impact when the chilled beam is installed in the longitudinal direction than when it is installed in the latitudinal direction.

The results of this study identify a complex interaction of lows which takes in rooms ventilated with chilled beams. Simple analytic modelling of the jets and thermal flows is not sufficent to identify the airflow distribution in rooms. Therefore, it is possible to accurately analyse the various load situations only by full-scale measurements and/or CFD predictions. The design tools currently available enable studying the distribution of air supplied from chilled beams (and in general from other air supply terminal devices) however without taking account of the effect of the convection flows from heat sources. It should be noted that there are no standardised methods for presenting air velocities in rooms, and each manufacturer of air terminal devices has its way of presentation.

ACKNOWLEDGEMENT

The writers should like to thank TEKES (Technology Agency Finland) for funding this project. Special thanks go to Mika Komulainen (Lappeenranta University of Technology) for measuring the thermal sources and supply air jets and to Lyuben Bozhkov and Boryana Yordanova (International Centre for Indoor Environment and Energy, Technical University of Denmark) for the measurements related to the effect of the heat sourse location.

SUMMARY

The purpose of this paper is to investigate the thermal performances and the effect on the thermal comfort of a cooling ceiling installed in an experimental test room called Minibat. With a 9.6m^2 surface and controlling the temperatures on all the exterior walls of the cell, Minibat was the perfect environment for this experimental study. The studied ceiling panels were equipped with capillary mats using polypropylene as material. During the experiment we have analyzed different cases where the ceiling surface temperature varied between 15°C and 19°C. Different parameters like air temperature, humidity or surface temperature were measured during the experiment. To evaluate the thermal comfort we have calculated the PMV value for different chilled ceiling surface temperatures. The results indicate that the cooling ceiling could assure the indoor thermal comfort and with good thermal performances in terms of specific cooling rate or vertical temperature asymmetry.

INTRODUCTION

The majority of air-conditioning devices function on the principle of pulsated air, where the hot air of the room is recycled, cooled and returned into the room. The increase of the thermal loads in the buildings, mainly due on arrival of data processing and of office computers, the installation of air-conditioning systems was necessary to neutralize these loads and to create a good indoor thermal comfort. Air conditioning systems, which consume large quantities of energy, have become a necessity for almost all the buildings [1] to provide a comfortable indoor environment.

Currently the evacuation of these quantities of latent and sensible heats is done mainly with air treated introduced by air diffusers. To maintain comfort under these conditions, a greater volume of cooled air must be provided to the working area. Disadvantages such as noise, cold-drafts, air temperature differences between the human head and foot or energy wasting in certain cases, show that a new cooling system needs to be proposed.

The use of water as a coolant to cool surfaces of buildings (ceilings or walls) is consequently a tempting alternative solution. It is even more appealing as water cooling requires much lower flow rates and thus much smaller areas of piping. The chilled ceiling radiant panels are room cooling systems for placement in the ceiling zone.

Their cooling surfaces are connected with closed circuit heat conducting pipework containing flowing chilled water. With a cooled ceiling, the temperatures of a room's surfaces are lower than with air-conditioning solutions and the same is true when other partition surfaces are cooled. The principles of cooling ceilings are not very different from those of a radiator with tubes or hotplates.

The hot air arriving in contact with the cooled surface is cooled below the average temperature of the room and therefore descends at low speed into the occupation zone [2, 3]. The main difference between cooling ceilings and air-conditioning systems is the mechanism of heat transportation. Air-conditioning using air employs convection only, while cooled ceilings employ a combination of radiation and convection. With cold ceilings, the transfer of radiant heat occurs by a clear emission of electromagnetic waves from the hot occupants and their environments to the radiant ceiling.

The sensation of comfort produced by a cold ceiling can be compared to that felt during a summer night where one feels the freshness of the sky even if the ambient air temperature can be higher than 26°C so when using a chilled ceiling it is possible to get the same conditions of comfort with more elevated air temperatures than a classical air-conditioning system [5]. With a cooling ceiling the temperature of water or its flow rate can be varied so that the surface temperature is adapted to the desired conditions.

However the many advantages on thermal comfort [4] or energy reduction [5], the cooling ceiling has not reached its full potential because of the condensation risk on the chilled surface. To prevent the risk of condensation on the chilled water pipes or radiant surfaces, the water flow temperature should not be below 16°C. The dew point temperature of the indoor air must always be lower than the surface temperature of the cooling ceiling, this being a reliable way to avoid condensation.

For a more precise protection dew point detectors can be installed at the coldest point on the flow pipe of the cooling ceiling installation. They indicate the beginning of condensation at an early stage and trigger an increase in supply water temperature or a chilled water supply shutoff. To reduce the dew point temperature and assure the hygienic quality of the indoor air it is necessary to have a ventilation system to bring fresh air in the occupancy area.

This article purpose is to present an experimental study on a chilled ceiling installed in a test cell called Minibat. The main aims were to analyze the vertical temperature asymmetry and the thermal comfort. By taking measurements of air temperature, relative humidity or surface temperature we have been able to give relevant and realistic conclusions on this subject.

THE EXPERIMENTAL SET-UP

The experimental cell Minibat, presented in Figure 1, is composed of two identical parts which dimensions are 3.10m x 3.10m x 2.50m respectively to (x, y, z). In our study we have used the test cell number 2 where we have installed the radiant cooling ceiling panels. The glazed façade separates Minibat from a climatic chamber whose temperature is controlled and can vary between -10°C and 40°C. A thermal guard allows keeping the five others faces at a constant temperature, which can vary between 5°C and 30°C. During our tests, the thermal guard temperature was kept at 26°C. A battery of 12 spotlights, of 1000W each one, not used in this study, makes it possible to simulate an artificial sunning (gas-discharge lamps with metal halides which spectrum is similar to the sun one). All the faces temperatures are measured using thermocouples of resolution ±0.4°C, and each face with 9 thermocouples. The temperatures of the climatic chamber and the various parts of the thermal guard are measured using Pt100 probes which resolution is of ±0.3°C.

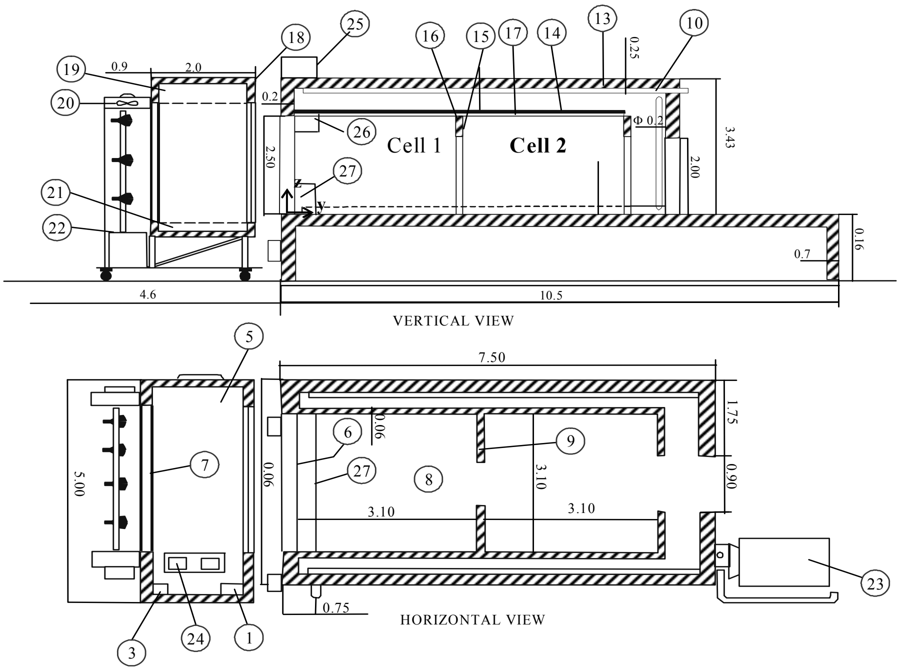

Figure 1. Experimental test cell Minibat

Table 1 presents the structure of the wall, ceiling and floor of the experimental test chamber. The cooling ceiling panels are metallic and are insulated with 8 cm foam to reduce the heat losses. These one have been added on the lower face of the existing ceiling.

Table 1. Composition of the test cell Minibat (before adding the cooling ceiling)

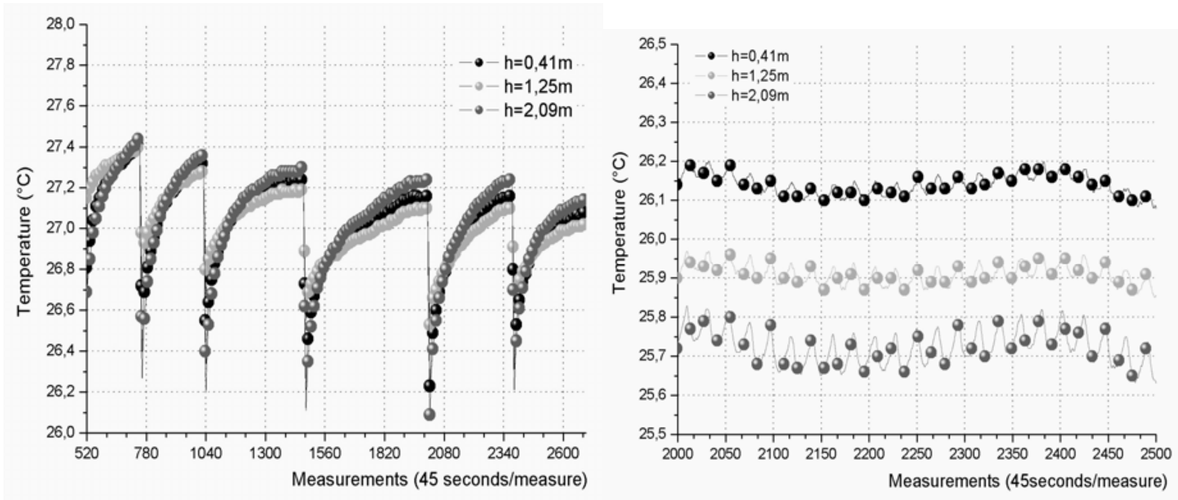
Wall	**Material**	**λ [W/m°C]**	**ρ [kg/m³]**	**Thickness [mm]**
Floor	concrete	0.16	400	200
Wall	plaster plate	0.35	817	10
	insulated material	0.06	200	50
	plaster plate	0.35	817	10
	wood plate	0.136	544	50
Ceiling	plaster plate	0.35	817	10
	wood plate	0.136	544	8
	insulated material	0.06	200	55
	wood	0.136	544	25

For the data acquisition we have used a computer and a multifunction board with more than 100 connections. To measure the indoor humidity we have used a humidity sensor placed at the centre of the room with a precision of ±2.5% for measurement of relative humidity between 10 and 90%. A globe temperature is also measured at the center of the room. Concerning the cooling ceiling, we have used 9 panels equipped with capillary mats and being placed only in cell 2. The exterior diameter of the tubes is 3mm and they are spaced by 1.5cm. An indoor heat gain of 250W was installed in the test cell which has a surface of 9.61m^2. To measure the vertical asymmetry of temperature we have taken measurements for six points of height.

Several tests were done by modifying the surface temperature of the cooling ceiling in order to see the effect on the thermal comfort or the vertical asymmetry.

RESULTS

The temperature of the thermal guard was set to 26°C during the whole experimentation. It was observed that there were variations but with a maximum of 1°C due to the system controller but which we have considered totally acceptable. Figure 2 presents the temperature for different heights on the exterior and interior walls surfaces of the test cell.



Exterior walls (thermal guard) Interior walls (cooling ceiling activated)

Figure 2. Temperature variation against the walls during the experiment

Being surrounded by surfaces that have large temperature differences (cooling ceiling and the walls in our case) may be a cause of discomfort, even when the air temperature is considered in the comfort zone. These conditions of discomfort are frequently caused by cold windows, un-insulated walls or direct sunlight. In general, people are more sensitive to asymmetric radiation caused by a warm ceiling than that caused by warm vertical surfaces [7].

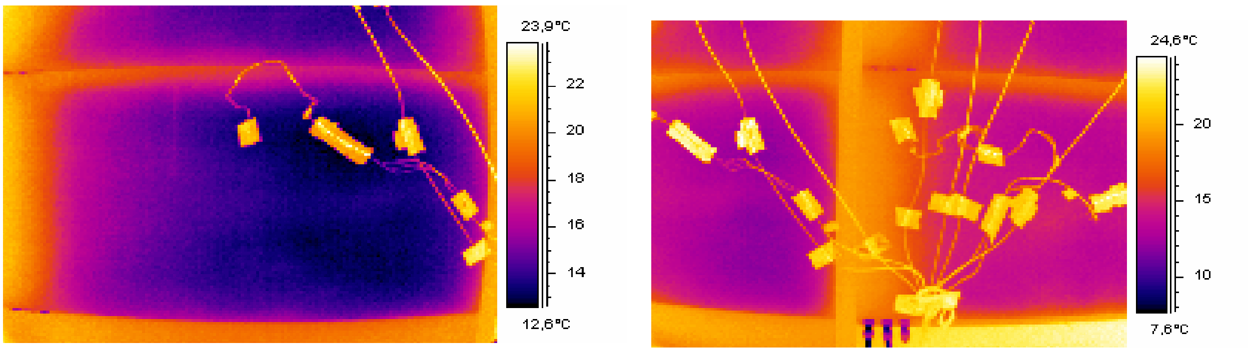


Figure 3. Thermal screenshots of the cooling ceiling during the experiment

The temperature on the surface of the chilled ceiling is relative constant on each panel, except the connection between them (see Figure 3). A reason that temperature on the surface is not perfectly uniform could be that a gap of air was formed between the tubes and the metallic panels and acting like an insulation on some areas.

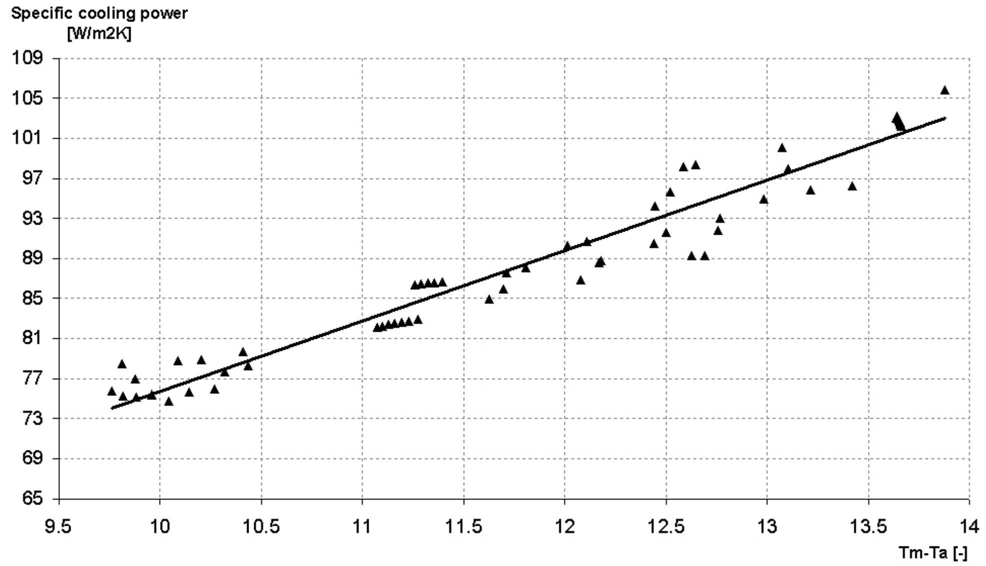

Figure 4. Specific cooling power of the cooling ceiling in function of the difference between the mean water temperature and the air temperature

The cooling power of a radiant ceiling (RC) system is a function of the heat transfer between the room and the cooled ceiling. This heat transfer has two components: radiation and convection which can be calculated. In Figure 4 is presented the specific cooling power of the chilled ceiling depending on the difference of the mean water temperature which was measured during the experiment and the air temperature.

The specific cooling power of a cooled ceiling can be expressed by the following empirical equation:

$$q = 8.92\ (t_{air}-t_{cold\ surface})^{1.1}$$

where q is the sum of the convective and radiant heat transfer [W/m^2]
t_{air} is the air temperature of the room [°C]
$t_{coldsurface}$ is the temperature of the cooling ceiling [°C]

A large vertical air temperature difference between the head and ankles may be also a discomfort cause. Based on criteria of 5% dissatisfied, the allowable temperature difference is 3°C, which applies for situations where the temperature increases with height from the floor (i.e., the head is warmer than the feet). With a cooling ceiling the temperature decreases when we are approaching the chilled ceiling height and when the temperature of the ceiling is low enough we can even sense the refreshment on the body skin.

The results indicate that in the centre of the test cell, the stratification is acceptable and is smaller than the 3°C limit imposed by standards. In Figure 5 it can be observed the vertical temperature asymmetry for three different cooling ceiling temperatures. In all the cases the difference between the ankle and the head is about 1°C. The data presented in Figure 4 was obtained by measuring the temperature in six points of height, from 0.4m to 2.3m. The time step of one measure was of 45 seconds which correspond to the minimum imposed by the acquisition system to pass throw all the measurements including air and surface temperatures, water temperature, relative humidity or globe temperature. We can conclude on this part that the cooling ceiling don’t create discomfort in the working area but the need of taking measurements also near the walls seems necessary to be done. All the temperatures were measured by thermocouples type K with a precision of ±0.3°C.

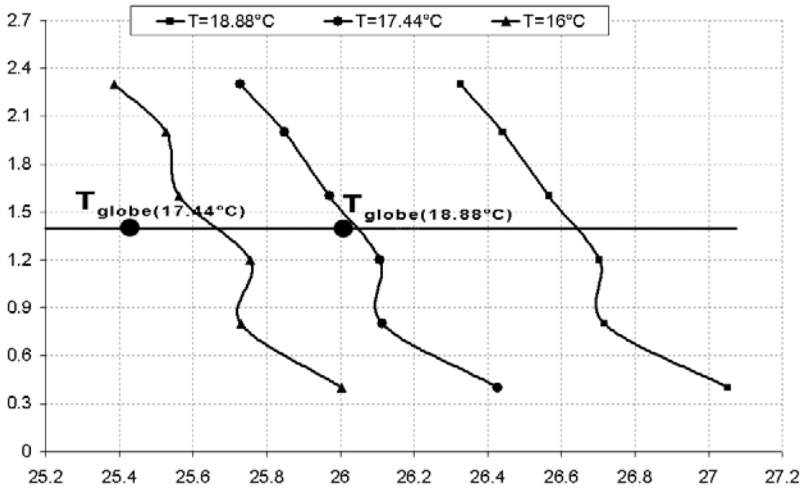

Figure 5. Vertical temperature asymmetry in the centre of the test room for different ceiling temperatures

Thermal comfort is very difficult to define because we need to take into account a range of environmental and personal factors when deciding on the temperatures or the ventilation that will make a comfortable indoor space. The best that we can realistically hope to achieve is a thermal environment which satisfies the majority of people or the so called ”reasonable comfort”. In order to analyze the thermal comfort in a room cooled by a chilled ceiling we have taken measurements of air temperature, globe temperature, relative humidity and surface temperatures (9 thermocouples per internal surface of the room). By simulating the test cell using the computational fluid dynamics (CFD) we have estimated the air velocity inside the room. The PMV (Predicted Mean Vote) [6] was calculated by using the data obtained after the tests. The PMV index establishes a thermal strain based on steady-state heat transfer between the body and the environment and assigns a comfort vote to that amount of strain.

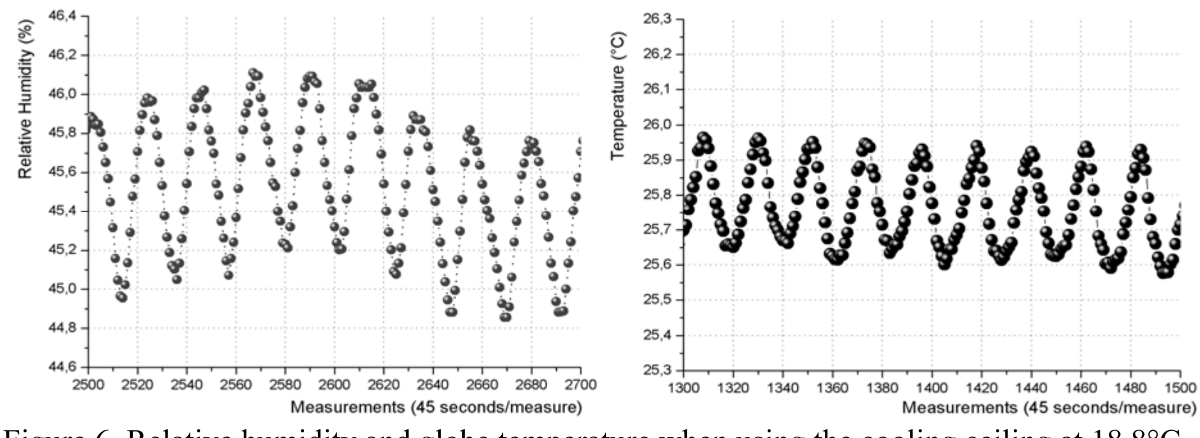

Figure 6. Relative humidity and globe temperature when using the cooling ceiling at 18.8°C

In Figure 6 are presented the evolutions of relative humidity and the globe temperature during more than 12 hours of experimentation. We can observed that the relative humidity was stabilized at a value of 43.5% and the globe temperature at 25°C when using the chilled ceiling at 17.4°C. The PMV equation for thermal comfort is a steady-state model. It is an empirical equation for predicting the mean vote on an ordinal category rating scale of thermal comfort of a population of people. The air velocity was considered after the CFD simulations of 0.15 m/s, the rest of parameters influencing the thermal comfort being measured. In Figure 7 it can be observed that the PMV index for different clothing insulations when using the cooling ceiling surface at different temperatures. We have only presented two cases of ceiling surface temperature which were the more relevant, knowing that in general the cooling ceiling temperature must be kept at higher values than the dew point temperature of the indoor air in order to avoid the condensation risk.

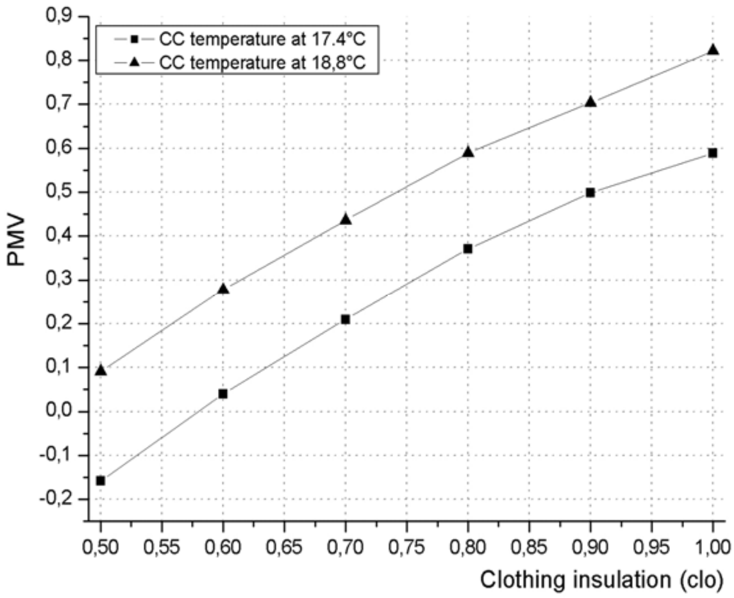

Figure 7. PMV for different clothing insulation when using the cooling ceiling at different temperatures

The values presented in Figure 7 show that the cooling is a very attractive solution for the thermal comfort. It can be observed that when the cooling ceiling temperature is at 17.4°C and when the metabolism is 1.2 met (70W/m^2) and the clothing insulation is 0.9 clo the obtained value of PMV is in the limit proposed by the norms.

DISCUSSION

The results obtained after the experiment showed that with a cooling ceiling the vertical temperature asymmetry is less than 1.1°C, acceptable value which not create a discomfort in the occupancy zone. Another important aspect of the test was the effect of the chilled ceiling on the thermal comfort. The temperature of the ceiling was changed in order to see the effect on the thermal comfort, the results being very satisfying. The PMV was calculated for different clothing insulation, its values fulfilling the limits imposed by the standards. These discussions prove that ceiling radiant cooling systems can be more comfortable than conventional air cooling systems, due to less air movement, minimal vertical air temperature difference and with good results on the thermal comfort even for higher values of the ceiling temperature. However the big amount of data obtained more extensive experimental test research are sorely needed especially on the condensation risk problems or the effect of hygroscopic materials on the thermal performances.

Calculation Method For Summer Cooling With Radiant Panels

Francesco Causone, Stefano Paolo Corgnati and Marco Filippi

SUMMARY

Radiant panels achieved a growing success in the last years as a cooling system, because they guarantee improvement in comfort and energy saving.
The aim of the present work is to propose a method to evaluate the thermal behavior of radiant panels used for summer cooling. Experimental observations lead to notice that part of the radiant load hitting panels surface is directly removed by the refrigerating fluid (Direct Water Load), never becoming a room load. In order to evaluate the role of this fraction of load on thermal balance, it has been developed a specific procedure deriving from the Room transfer functions method.
Through a lighting analysis tool it has been furthermore evaluated the Direct Water Load due to solar radiation, the most important radiative load for typical office rooms, in function of geometrical configuration and surfaces reflection factors (α, ρ). The right understanding of the role played by Direct Water Load on thermal behavior of radiant panels may lead to a better design of this kind of cooling systems.

INTRODUCTION

The use of radiant panels as a cooling system is quite new in a lot of countries, but it is developing extremely fast, conquering each year relevant market slices.
The success of this kind of HVAC system is bound to design, comfort and energetic reasons. The use of radiant panels leads to have more free usable net floor space, to reduce draft risk, typical of cooling air systems, to achieve quite uniform temperatures into the rooms, to obtain significant energy saving.
For comfort reasons, anyway, the surface temperature of panels must not be lower than 19°C and in order to avoid moist condensation it must not be lower than the dew point temperature of the room. Since cooling panels can control only sensible loads and not control air humidity and quality, they are always coupled with primary air, which can provide any air control. Sometimes primary air may even help the radiative system to balance peak loads, if they grow up beyond panels thermal efficiency.
Radiative systems use wide exchange surfaces, and since human body exchanges heat through radiation approximately for the 50% of the whole balance (in cooling period), it is clear that panels temperature can be quite near to project air temperature maintaining optimal comfort condition. At the same time, since the most of heat exchanged between the body and the cooling system is through radiation, air temperature can have little higher values, without creating comfort problems, since operative temperature doesn't change so much, so the thermal sensation of people remain the same. Higher values of air temperature bring anyway to a reduction of the cooling load, for the reduction of heat dispersions through walls and air infiltration.

The most important element which can bring to significant energy saving is anyway the opportunity of using energy transfer mediums, usually water, with moderate temperature (near to 16°C) [1]. This is why these systems are often called as "low exergy", because they can work using energy which has a very limited convertibility potential, such as heat close to room air temperature and this means that radiant panels can be fed by solar collectors (solar cooling) or heat pumps [2, 3].

METHODS

Cooling Load Evaluation

In order to study a cooling system, it is essential to use a multi-step analysis which considers the effect of loads distribution during the whole day. Heat gains and cooling loads to be removed by the cooling system are not the same during different hours, because the thermal mass of the building accumulates heat (especially due to solar radiation) and after a time lag re-emits this into the room. So a specific heat gain at the time T_θ, may have its real effect on the cooling system only at the time $T_{\theta+n}$.
The most common calculation methods, as the Room transfer functions method, use therefore the concepts of Heat Gain and Cooling Load, as explain after:

- The *Heat Gain* is the amount of heat gendered or introduced into the room at a specific time T_θ
- The *Cooling Load* is the amount of heat that must be taken away from the room at the same time T_θ, in order to maintain the project conditions of temperature and humidity
- The *Heat Extraction Rate* is the real heat rate taken away from the room by the plant at the time T_θ (it is linked to the plant inertia)

The thermal inertia of the room hence correlates Heat Gains and Cooling Loads. It is possible to break Heat Gains between convective gains and radiative gains, the fist ones, working directly on air, are not involved in thermal mass absorption phenomena, the radiative gains are, on the contrary, partly absorbed by the elements of the room having relevant thermal mass. After a certain time, only a reduced part of the absorbed radiation is re-emitted into the room through infrared wave and convection. So thermal mass operates on radiative loads delaying and dimming their effect, while convective and latent loads directly become cooling loads (fig.1).
Heat Extraction Rate is mostly important for estimating energy use over time, but it is not relevant to calculate design peak cooling load, for this reason we don't consider it in our analysis.

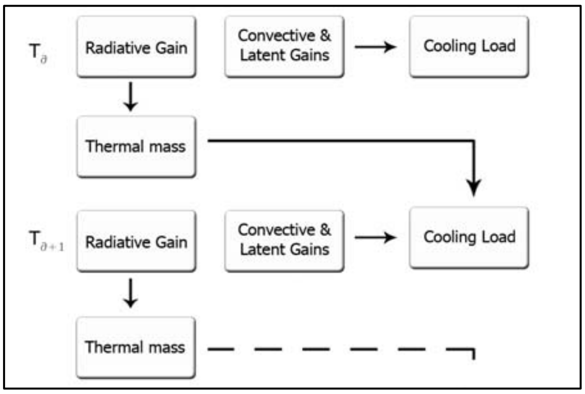

Figure 1. Heat loads scheme inside a room

Cooling Load Evaluation For Radiant Panels

Cooling load evaluation for radiant panels needs a further level of analysis, due to specific characteristics of this kind of cooling systems [4].

Radiant panels are light elements, usually in metallic alloy or plasterboard, without relevant values of thermal mass; they have on their backside a coil system for the refrigerating fluid flow (typically cold water). If a radiative flux (solar radiation, artificial light, far IR radiation…) hits the surface of the panel, the energy transfer medium directly removes it. So that radiative gain will never become a Room Load, because it will never be re-emitted through convection into the room. It is therefore possible to compare the behavior of radiant panels to the one of a well with a radiative power foisted by the temperature of the refrigerating fluid. The scheme about Heat Gain and Cooling Load previously shown (fig.1), must consequently be corrected when radiant panels are used, considering the rate of the radiative gains hitting the panels surface and directly removed by water.

Each Radiative Heat Gain at time θ must be divided in the rate F directly removed by water, called Direct Water Load (DWL) and in the remaining part (1-F) which will be influenced by the room thermal inertia (fig.2). If we consider the Room transfer functions method for predicting cooling loads, the ratio of radiative Heat Gain absorbed by thermal mass at time θ (1-F), will become a Room Load (RL) at time θ+n.

In the most general situation, in which both panels and air are used to removed sensible loads, the RL at time θ will be partly (X) contrasted by the radiative system through the Surface Load (SL), and partly (1-X) by the air, through the Cooling Load air (CLa). The sum of Surface Load at time θ, together with the Direct Water Load at time θ, represent the Cooling Load water (CLw), so the amount of heat removed from the room by the radiative system at time θ (fig.3).

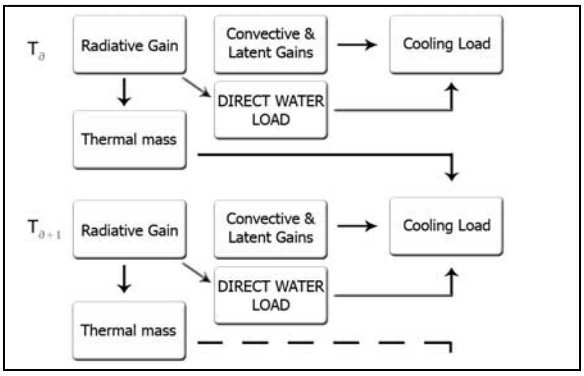

Figure 2. Heat loads scheme inside a room with radiant cooling panels

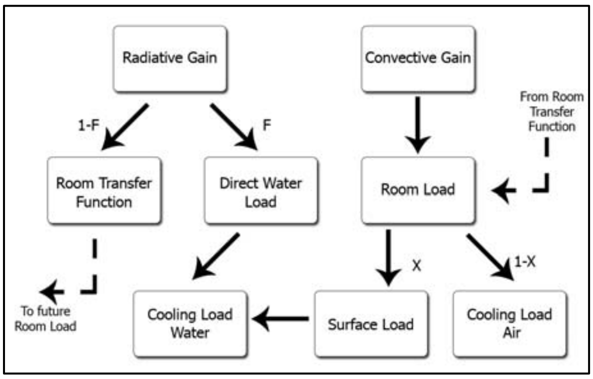

Figure 3. Cooling Load generation with radiant cooling panels

It is very important to underline the different origin of the two component of cooling load burdening at time θ on the radiative panels: the Direct Water Load directly derives from Heat Gains at time θ while the Surface Load derives from Room Loads and so its value is influenced by delay effect due to room thermal inertia and expressed by room transfer functions. This analysis is confirmed by the empirical approach adopted by some constructors, which suggest to subtract a certain ratio of the radiative gains, from the cooling load evaluated with traditional methods, before determining the efficiency of panels.

Distinguish between DWL and SL is not just a theoretical exercise, it has indeed practical design consequences [5, 6]. When it exists a high Direct Water Load, the Room Load is strongly reduced, and so the Surface Load and/or the Cooling Load Air. Since the Surface Load is limited by the panels surface temperature, when the Room Load is little, panels can anyway succeed in removing the whole sensible load or even a lower radiant surface may be

needed in order to contrast the load. It is possible otherwise to reduce the Cooling Load air, if primary air is anyway needed to control indoor climate.
It must be however underlined, that even if Surface Load or Cooling Load air are lowered by using this analytical approach, the whole load burdening on the plant is higher, because the Direct Water Load is an instantaneous load, so it is not dimmed by room thermal mass effect.
Another interesting aspect depends on the different origin of DWL and SL: if the temperature difference between air and panel surface is zero, the Surface Load is zero too, but if there is at the same time a radiative flux hitting the panel, the Cooling Load is not zero because there is a Direct Water Load. The fundamental equation for cooling load evaluation is the following:

$$\dot{Q}_{CLw} = \dot{m}_w \cdot c_p \cdot \Delta T_w, \quad (1)$$

where ΔT_w is the difference between inlet and outlet temperature of the refrigerating fluid.
So the cooling efficiency of the radiative system can be expressed as follow:

$$\dot{q}_{CLw} = \left(\dot{Q}_{CLw} / A\right) = \left(\dot{m}_w \cdot c_p \cdot \Delta T_w / A\right), \quad (2)$$

And the surface cooling efficiency:

$$\dot{q}_{SL} = \left(\dot{Q}_{SL} / A\right), \quad (3)$$

The two characteristic efficiencies are linked together through the following relation, which considers the DWL:

$$\dot{q}_{CLw} = \dot{q}_{SL} + \left(\dot{Q}_{DWL} / A\right) = \dot{q}_{SL} + \dot{q}_{DWL}, \quad (4)$$

In order to evaluate the Cooling load, DWL and SL must therefore be studied separately.

Heat Removed By Panels Surface – Surface Load
Concerning the calculation method shown before, the amount of load removed by the panels surface at each time step, depend on:

- Convective heat exchanges between room air and panels surface
- Radiative heat exchanges among panels surface and walls surfaces

The cooling power of the panels is therefore strictly bound to panels surface temperature, which is however strongly limited by moist condensation problems and comfort needs. The value of this temperature is the most critical point of the whole system thermal behavior.
The heat power removed by the panels surface can be evaluate through the follow equation:

$$\dot{Q}_{SL} = h \cdot A \cdot \left(T_{sp} - T_{op,eq}\right), \quad (5)$$

where h is the surface conductance, A is the panels surface, T_{sp} is the temperature of the panels surface, and $T_{op,eq}$ is the operative equivalent temperature of the room, expressed as follow:

$$T_{op,eq} = \frac{h_r \cdot T_{mr} + h_c \cdot T_{air}}{h_r + h_c}, \quad (6)$$

T_{mr} represents the mean radiant temperature of the room, calculated excluding the panels surface temperature. Since the most common value used in design stage is the air temperature, and since the T_{mr} is a difficult parameter to be obtained, it is commonly used a simplified equation to evaluate the heat power removed by the panels surface:

$$\dot{Q}_{SL} = h \cdot A \cdot (T_{sp} - T_{air}), \quad (7)$$

Direct Water Load Evaluation

The most difficult element to evaluate is the Direct Water Load, because its value depends not only on the characteristics of the radiative source and on the radiative properties of the surfaces of the room, but even on the geometrical shape of the room.
Generally it can be expressed as:

$$\dot{Q}_{DWL} = F \cdot \dot{Q}_{rad}, \quad (8)$$

where F represent the ratio of the radiative flux Q_{rad} which is directly removed by the heat transfer medium.
The F value has been studied with the help of two simulations tools, the first one is a simple calculation sheet, based on the Reflection method, which lets to follow the path of the radiation (solar, human body, appliances) within the room. Through the Angle Factor source-wall, the radiation is spread over the floor, the walls and the ceiling. After this, through the Shape Factor, part of the incident radiation is reflected from the walls surfaces all around again [7]. Following all the reflections it is possible to evaluate the amount of each radiative flux removed by the radiative panels.
The other one is instead a lighting analysis tool, called Lighscape and so it lets to study the F value just for solar radiation and some artificial light source, but not for fully IR radiation sources. Anyway solar radiation is the most relevant radiative flux, especially in highly glassed buildings. This second tool is able to simulate both direct and diffuse radiation, drawing maps of light distribution over the different walls, and this is extremely important to improve the accuracy of the analysis, since the first model simulates just perfectly diffusing sources and materials.
It is interesting to point out that, for solar radiation, even do not considering the UV and IR fractions, lighting tools produce just little errors, whom bring to little underestimations of the Direct Water Load. Solar spectrum is divided in four main parts, which at ground level assume the following values: ultraviolet (6%), visible (55%), near infrared (39%) and far infrared (0%) [8]. Since all kind of glass used in the construction field are opaque to far infrared radiation, it can’t enter into the room, so it is not considered for cooling load evaluation. Anyway it is just a principle statement, since solar far infrared radiation at ground level is practically inexistent, because filtered by atmosphere.
To obtain the most general considerations, in the following analysis we will consider a clear glass with the common thickness of 6 mm, having the following standard characteristics:

Table 1. Solar radiation mean transmission factors, for UV, Visible and IR wavelengths

Global	UV	Visible	near IR	far IR
τ_e	τ_{UV}	τ_v	τ_{IRn}	τ_{IRf}
81%	56%	89%	74%	0%

So the solar radiation entering into the room is composed by:

2. Percentage of UV, Visible and IR entering into the room through a clear 6 mm glass

Φ_{IN}	UV	Visible	near IR	far IR
100%	4%	60%	36%	0%

The elements into the room are anyway generally considered as gray bodies, so with an emissivity and an absorption factor to infrared radiation of the 90% ($\varepsilon=\alpha=0,9$) [9]. It means that just the 10% of the IR radiation entering into the room is involved in DWL generation, the remaining 90% is absorbed by opaque elements, then re-emitted after a time lag into the room and so it is involved in SL generation. The 10% of the 36% represent just the 4% of the whole entering radiation, so using a lighting tool to evaluate the F factor, which doesn't simulate UV and IR radiation, it is committed a global error of the 8%, acceptable for engineering applications.
Furthermore, UV radiation has a little contribution to cooling load generation, its energy is principally involved in surface material aging and degradation, and just a little portion of it generates heat [10].
It is obvious that all F values obtained with the lighting tool must be multiplied for a reduction factor (0,6 for a clear glass with thickness of 6mm), in order to be referred to the global radiation, since solar loads values are expressed for the whole solar radiation.
It is interesting to notice that DWL is practically generated only by visible radiation since IR contribute just for the 4% of the entering radiation, when it is considered a clear glass with thickness of 6mm. With other kind of commercial glass this consideration is anyway correct, since the ratio τ_{IRn}/τ_v usually reduces or, at least stays the same.
Within a room with cooling radiant panels, therefore, light reflection factors of surfaces play a fundamental role in DWL, SL and CL generation. A highly reflective room, for instance, will have high Direct Water Loads, and lower Surface Loads. Furthermore peak values of Cooling Load will occur in correspondence with solar gain peak values.
For this particular condition, it is possible to state that part of the thermal inertia of a room is constantly operating with IR radiation, while another slice of it works, or not, in function of the surfaces light absorption and reflection factors. In a room with cooling radiant panels, the effective activation of the room thermal inertia depends therefore not only on the surface thermal resistance of walls, but even on surfaces light reflection factor.
On the contrary it is possible to observe that if room surfaces had lower emissivity, some more IR radiation would be involve in Direct Water Load generation and less in Surface Load generation.

RESULTS

F Value For Solar Radiation

The two analysis tools described before have been used to evaluate the F value for a radiant ceiling, as a function of different light reflection factors of the room floor, and of different room dimensions. All the other room surfaces has been considered with a constant light reflection factor of 70%, corresponding to light paint colours and a metallic ceiling.
In the following graphs, the ratio *L/h* is used as an adimensional indicator of the room geometry. It grows with the growing of the floor surface, in fact *h* is the height of the room, while *L* is the side of the square floor.
The following simulations consider solar radiation for a latitude of 45° North, a full glassed building, and rooms with only one surface facing outside, therefore completely glassed. This is the condition in which it is possible to reach the highest level of DWL, and furthermore it has become very common in office buildings.
The commercial lighting tool can give different F values as a function of the window orientation, because it considers both direct and diffuse radiation. It could be possible to have a F value for each orientation, each hour and day of the year, but it would require huge amounts of simulation time. The reflections method, instead, considers the window like a diffusing light source, so the relative position of the room respect to the sun is not evaluated.

In order to have a useful design instrument, the values obtained with the commercial lighting tool at different hours, have been used to obtain mean values for summer design day (21 July) and winter design day (21 Janurary). Buildings with fully glassed envelope, usually office buildings, may indeed need cooling even during winter time, because solar heat gains and internal gains can be very high; this is why even the winter design day has been investigated.

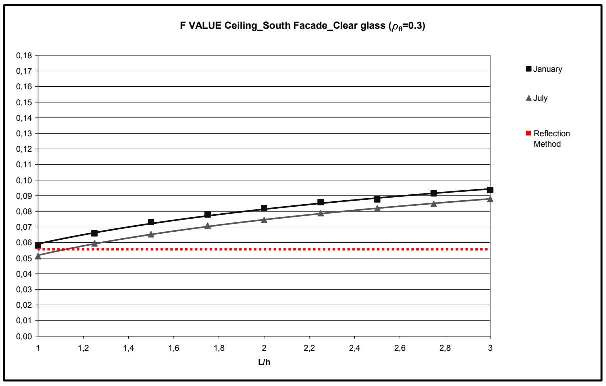

Figure 4. F values for a low reflecting floor

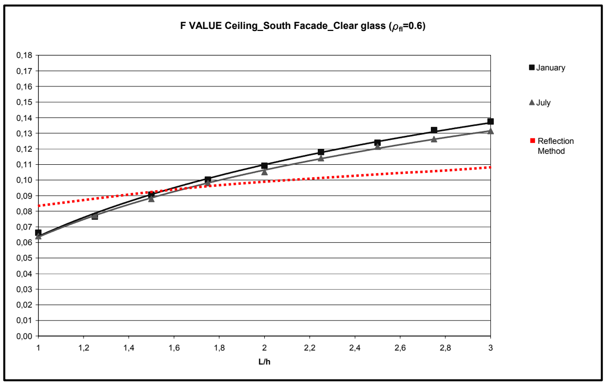

Figure 5. F values for a high reflecting floor

As shown in Figure 4 and 5, curves obtained with the reflection method are generally lower than the ones obtained with the commercial lighting tool, because the first method doesn't consider the real path of light inside the room.

Calculation Example

In order to evaluate the effect on design choices deriving form the use of the different curves proposed, a calculation example has been developed.

It is considered a room with a completely glass façade (L/h=2,5), oriented toward south at latitude 45° North and realize with a single clear glass. Just solar radiation is consider to overheat the building. Internal summer condition of project are established: T_{air} = 26°C and U.R. = 50%.

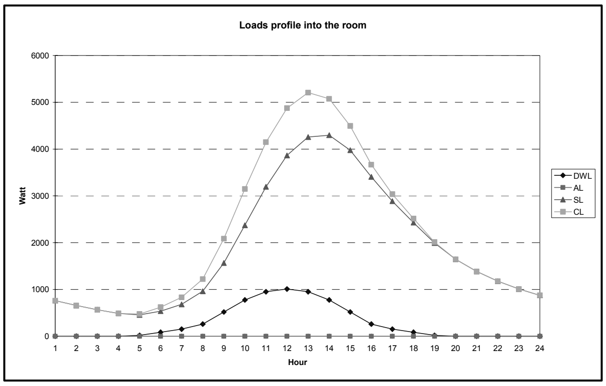

Figure 6. Load profiles with lighting tool

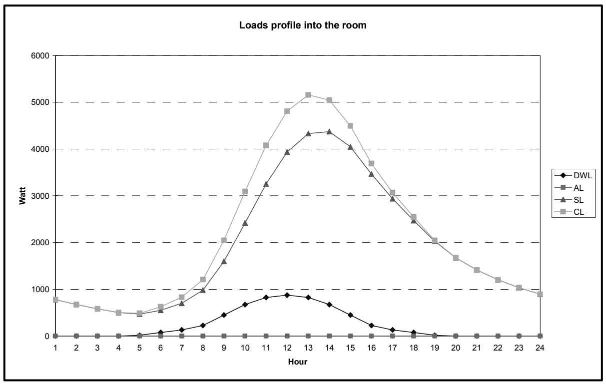

Figure 7. Load profiles with reflection method

Figure 6 shows Direct Water Load, Surface Load and Cooling Load hourly profiles inside the room, obtained using F value calculated with the commercial lighting tool. Figure 7 shows the same Loads evaluated with F value obtained using reflection method.

It is easy to see that in the second graph DWL is lower, while SL increases, furthermore in the second graph the load not carried by the radiant system is higher than in the first evaluation, and this means that primary air must works strongly when DWL is low.

The peak value of Cooling Load is anyway higher when DWL is higher, and this because this is an instantaneous load, that is not dimmed by room thermal mass.

Surface Load peak value, using F values evaluated with the reflection method, is 100 W higher than peak value calculated using the commercial lighting tool as reference. This means that in design phase lower temperatures for the heat transfer medium or wider radiative surfaces, will be considered.

DISCUSSION

The calculation method proposed in this paper may help the designers to better understand thermal behavior of cooling radiant panels. It has been developed using the Room transfer functions method, but it can be easily and worthily adopted even with the Radiant time series method [11].
The effect of Direct Water Load, is extremely important for design aspects, because it strongly influences Cooling Load and Surface Load peak values. As seen before, higher Direct Water Loads means lower Surface Loads but higher Cooling Loads, and even the delay of Cooling Loads may be reduced if Direct Water Loads are sensibly high.
Two different tools have been used in this analysis in order to evaluate DWL. For little rooms, the tools give similar results, while for larger rooms the values tend to be different, anyway values can be considered quite closed. F values obtained with the commercial lighting tool are generally higher, because this instrument considers even the direct solar radiation. The reflection method, instead, considering just diffusing surfaces, tends to underestimate the DWL, producing more cautious solutions in the design phase.
In order to confirm these reflections it would be extremely important to obtain real values, or values deriving from physical tests into a climatic chamber, to deal with the ones obtained with simulation tools.

SUMMARY

The importance of heat load and airflow pattern control for occupants' thermal comfort is studied in a full-scale test room ventilated with chilled beams. The room was furnished with two desks, computers and table lights. Solar irradiation on window and part of the floor was simulated as well. The room temperature was maintained at 24ºC. Thirty subjects (15 female and 15 male subjects) participated in the experiments. The increase of the heat load from 30 W/m^2 to 70W/m^2 increased substantially non-uniformity of the thermal environment in the room. The percent of subjects dissatisfied due to their thermal comfort conditions and due to draught increased with the increase of the heat load. The provided induction control of the chilled beams changed the air flow distribution in the occupied zone and decreased the reported draught discomfort. The induction control is efficient way for improving occupants' thermal comfort but it should be used carefully in practice.

INTRODUCTION

The air-conditioning of office buildings is maintained mainly with systems based on the mixing ventilation principle. During the recent years the use of active chilled beams for ventilation of buildings has increased due to their ability for removing higher heat loads in more energy efficient way than other systems for office ventilation [1]. Furthermore chilled beams, allow for control of the induced amount of room air and thus for change of airflow pattern in rooms when uncomfortably high velocity is reported by occupants.

Air distribution in rooms with active chilled beams is result of complex interaction of ventilation flow from the beams with the convection flow generated by heat sources, occupants, warm/cold window surfaces, office equipment. The airflow distribution depends on several factors, including arrangement of chilled beams, supplied airflow rate and momentum flux, lay out of workplaces, strength and location of heat sources, etc. Only limited studies on the air distribution in rooms with chilled beams is reported in the literature [2, 3, 4]. The impact of the airflow interaction in rooms with active chilled beams on occupants' comfort is needed. The efficiency of the airflow pattern control for achieving comfortable thermal conditions for occupants is not documented.

This paper presents results on human response to thermal environment generated by active chilled beams. The impact of heat load and airflow pattern control on thermal comfort is studied with human subjects under realistically simulated laboratory conditions. Only part of the collected and analyzed results are presented and discussed in this paper.

EXPERIMENTAL DESIGN

Experimental facilities

A full-scale test room (L *x* W *x* H = 5.4m *x* 4.2m *x* 2.5m) was used to simulate a real office room. The room was furnished with two desks each with a real computer to simulate the heat loads from office equipment. Artificial windows with surface temperature control were used to simulate the impact of the outdoor environment during summer season. Several heating panels were placed on the floor and used in some of the experiments to generate heat and simulate solar irradiation (it is difficult to simulate properly the solar radiation). The work place near the window is referred as WP2 and this on the opposite side as WP1 (Figure 1).

Three chilled beams were mounted crosswise installation as shown in Figure 1. Previous physical measurements identified this lay out as most critical in regard to occupants' thermal comfort [3]. The amount of room air inducted into the beams was regulated by shutters placed in the beams. When the shutter is closed (right side of the chilled beam shown in Figure 1) maximum cross section area for the flow is ensured and thus maximum amount of room air is induced through the beam). This setting is referred in this paper as "Induction 1 (I1)". When the shutter is open (left side of the chilled beam in Figure 1) the cross section area decreases and thus the air supplied to the room decreases (the amount of induced room air also decreases). This setting is referred as "Induction 2 (I2)".

The surface temperature of the artificial windows, the air temperature, etc. were measured and controlled.

Experimental conditions

Three experiments referred in Table 1 as Case 1, Case 2 and Case 3 were performed. In cases 1 and 2 the heat load was kept constant but the induction of room air was changed, Induction 1 (I1) and induction 2 (I2). The low induction (Case 2) was activated for the side of the chilled beams facing WP1. The cooling capacity of the chilled beams was maintained the same by lowering of the temperature of the inlet water for the heat exchanger. In Cases 1 and 3 the induction was kept constant (I1) but the heat load was changed.

Table 1. Experimental conditions.

Case number	Induction control	Temperature in the room, °C	Heat loads, W/m²	Surface temperature of windows, °C
Case 1	High induction (induction 1)	24.0± 0.2	70	40.4
Case2	Low induction (induction 2)	24.1 ± 0.1	70	41.5
Case 3	High induction (induction 1)	24.0 ± 0.2	30	36.1

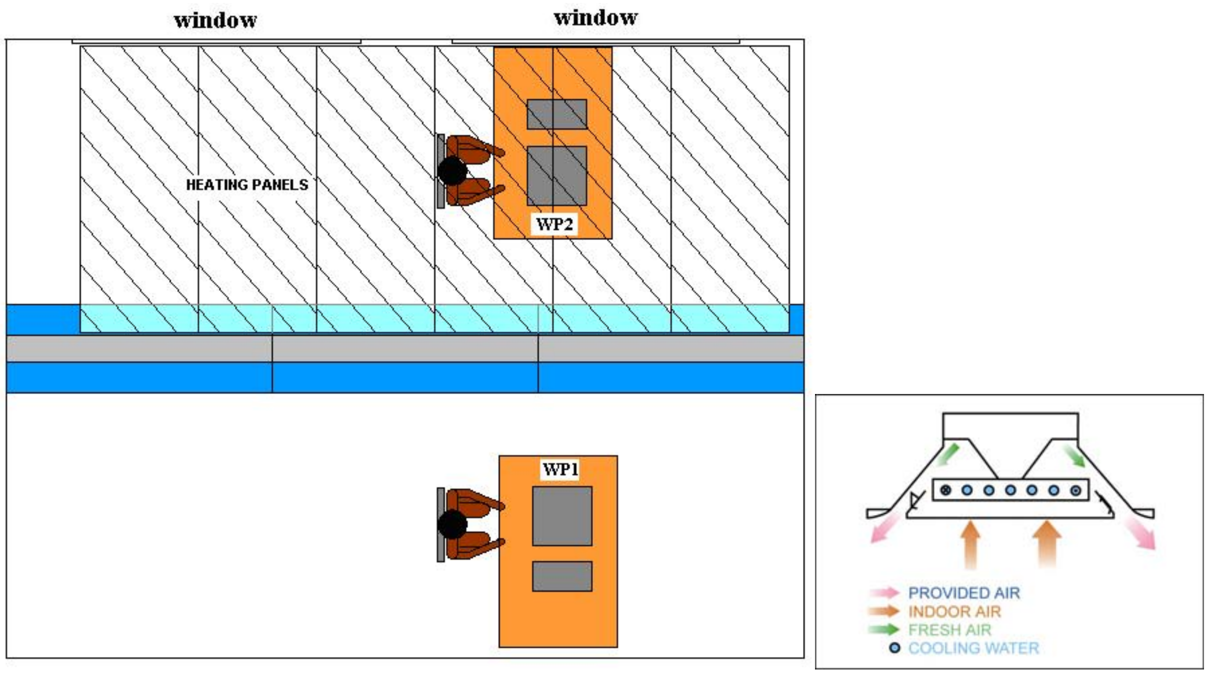

Figure 1. Experimental set-up in the room and sketch of cross section of the chilled beam with right shutter closed and the left shutter open is shown as example.

During the experiments the flow rate of the primary air was 1.5l/s/m². The experiments represented summer conditions and the room temperature was maintained to be 24ºC.

The distribution of the heat loads in the test room for each case is listed in Table 2. The window surface temperature of 40.4 ºC is high but possible in practice.

Table 2. Distribution of the heat loads

Case number	Heat gain from windows, W	Heat gain from PCs, W	Heat gain from people, W	Heat gains from floor panels, W	Heat gain from lightning, W
Case1	2x325	2x80	2x75	520	116
Case2	2x325	2x80	2x75	520	116
Case3	2x220	-	2x75	-	116

Subjects

Thirty subjects, 15 males and 15 females, participated in the experiment. They were at age from 20 to 45 years (average 24.3 ± 5 years).

Experimental procedure

Each subject participated in three experiments (Cases 1, 2 and 3 in Table 1). At their arrival, before entering the experimental office, the subjects relax for 20 minutes from previous activities. During that time they were explained the experimental procedure and how to fill in the questionnaires. They were not informed about the experimental conditions, e.g. the temperature in the room, the ventilation system, the flow rate, etc. After 20 minutes the subjects entered the test room two at a time and sat at the workplaces. They were asked to fill in the questionnaires every 5 minutes staring from the fifth minute. The subjects were allowed to write or read while seated on the desk. The subjects stayed in the office 25 minutes then they went out for 10 minutes break. After the break they returned to the office and stayed there for another 25 min. This time they changed the workplaces. They completed questionnaires as during the first 25 min. During the whole experiment the subjects were encouraged to adjust their clothing according to their preferences. At the end of the experiment for the day they filled in a questionnaire about their clothing. This procedure was identical for the three experiments the subjects participated.

Questionnaires

The subjective response to the thermal environment was collected by means of questionnaires. They were presented to the subjects on a paper. The questions related to whole body and local thermal sensation - 7-point ASHRAE scale [6], acceptability of the thermal environment (ranging from clearly unacceptable to just unacceptable and then from just acceptable to clearly acceptable, air movement sensation, body part where the movement was felt, whether it was acceptable or not, and the last question was on preference for more, less or unchanged air movement.

Data analyses

The data obtained from the questionnaires was analyzed statistically using the program Statistica 5. Each of the samples was tested for normality of the distribution using the Shapiro-Wilk test. Tests for significant differences of the samples were performed with Wilcokson match pair test.

RESULTS AND DISCUSSION

The individual whole-body thermal sensation votes as reported by the subjects were used to define the average thermal sensation vote. Figure 2 compares the obtained results for each of the three experiments. The average thermal sensation of the occupants in all of the cases was within the comfortable range of ±0.5 (from slightly cool to slightly warm) recommended in the present standards [6, 7]. Only at WP2 in Case 2- 70W/m²- I2 the thermal sensation was above slightly warm, 0.7. In this case the thermal sensation of the occupants was influenced by the thermal radiation from the warm windows which were located 0.9 m from WP2. The thermal sensation was just below neutral only at WP1 in the experiment with 30W/m² (Case 3).

The results were statistically checked for significance. Significant differences were found in the average thermal sensation between WP1 and WP2 in Case 2-70W/m²- I2 ($p=0.006$), at WP2 between Case 1- 70W/m²-I1 and Case 2- 70W/m²-I2 ($p=0.0262$) and at WP2 between Case1-70W/m²-I1 and Case3-30W/m² ($p=0.039$). The subjects felt warmer the whole body with the conditions at WP2 in Case 2-70W/m²- I2.

The local thermal sensation for the different body parts as reported by the subjects was analyzed. The local thermal discomfort due to warmth was defined for the body parts with local thermal sensation “slightly warm”, “warm” or “hot” which was felt as uncomfortable. Figure 3 shows the results of these analyses.

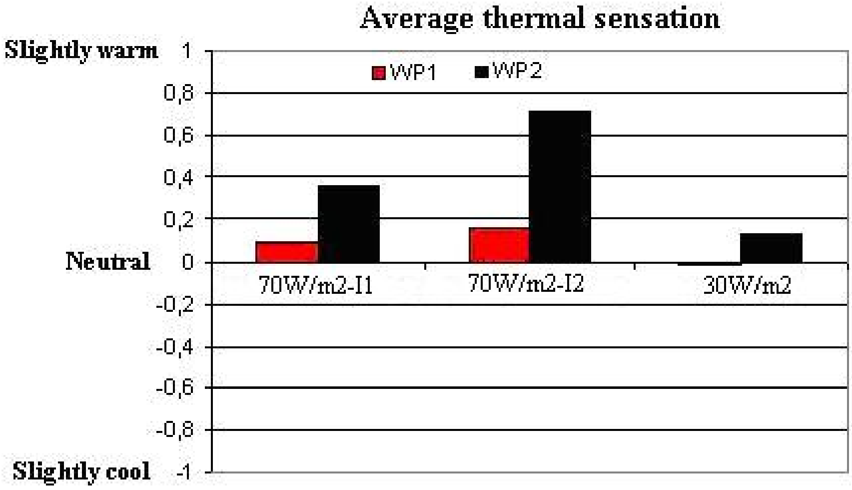

Figure 2. Average thermal sensation of the subjects at workplace 1 (WP1) and workplace 2 (WP2).

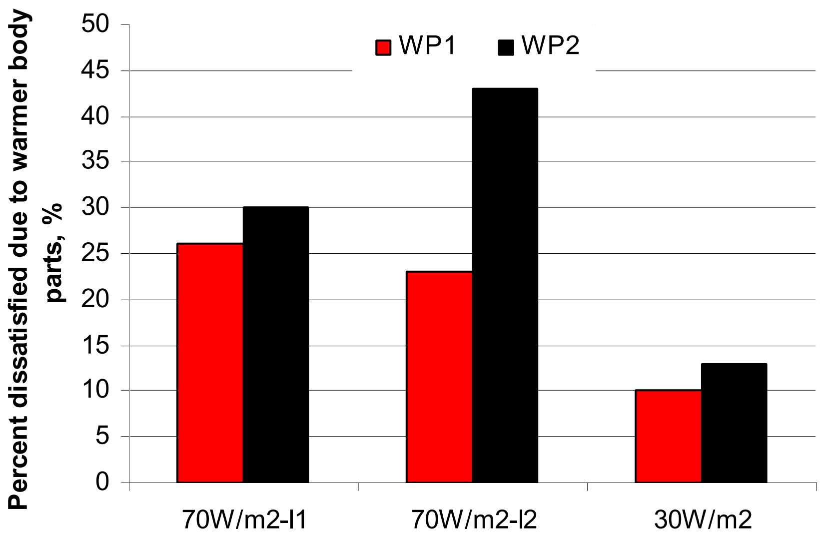

Figure 3. Percent dissatisfied due to warmer body parts

The highest percent of subjects who felt local warm discomfort for one or more body parts was for Case 2 -70W/m²- I2. The conditions at WP2 in Case 2 -70W/m²- I2 were identified as the worst; almost half of the assessment panel (43%) felt discomfort at that workplace located close to the heated window. The local warmth discomfort decreased when the heat load in the room decreased (Case 3- 30W/m²).

During the experiments the subjects were asked to assess whether they felt air movement at any of the specified body parts and if so, if the air movement was comfortable or not. The subjects’ responses were defined as draught discomfort if: 1) the person felt particular body part cooler than neutral and 2) if the person felt the local cooling uncomfortable; and 3) if the person felt air movement and voted that the feeling is uncomfortable and 4) the subject requested for “less air movement”. Figure 4 represents percentage dissatisfied due to draught at any body part.

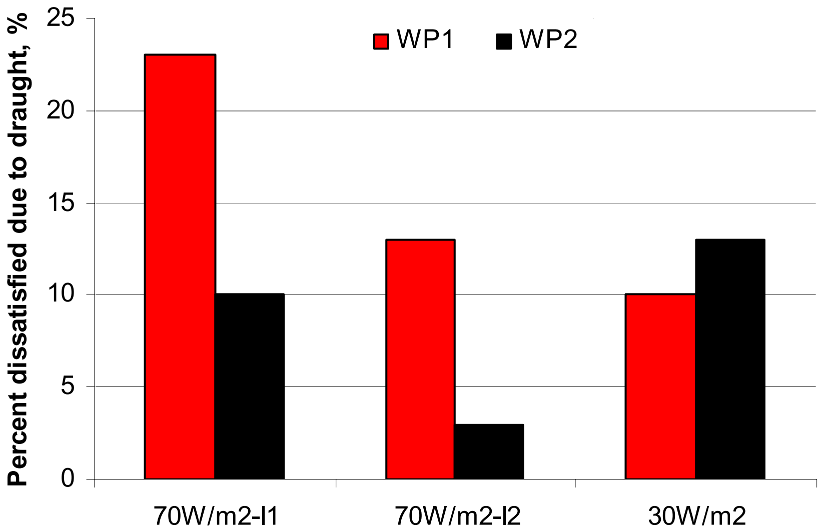

Figure 4. Percent dissatisfied due to draught based on all four criteria

The highest percent of subjects who felt draught was reported in Case 1 - 70W/m²- I1 at WP1. When the induction control was used, Case 2-70W/m²-I2, the percent dissatisfied due to draught subjects at WP1 was lowered substantially; in this case only one person reported on draught. The results show that with the lowering of the strength of the heat sources (Case 3 - 30W/m²) the total percent of draught complaints decreased.

DISCUSSION

Acceptable thermal environment for the whole body was achieved under all the tested conditions. The average thermal sensation of the subjects achieved with the chilled beams at the two workplaces was between neutral and slightly warm. As expected due to the radiant temperature asymmetry generated by the warm window the subjects felt warmer at the WP2 than at WP1. The flow interaction as discussed in the following left the subjects at WP2 with less air movement for cooling their body. However this did not affect subjects’ general thermal sensation.

The general thermal sensation, the local thermal sensation and the draught discomfort reported by the subjects was result of the interaction of the thermal flows generated by heat sources and the ventilation flow supplied from the chilled beams. The convection flows from the window, the solar irradiation simulated on the floor, the person and the PC concentrated on one side of the window (WP2) in Case 1 (70W/m²- I1) were powerful enough to deflect the ventilation flow toward the opposite side of the room as shown schematically on Figure 5. This resulted in large number of draught complains at WP1 (Figure 4). The use the induction control of the chilled beams on the side of the WP1 (Case 2-70W/m²-I2), decreased the velocity which resulted in decreased draught complaints at WP1 as well as at WP2. The local thermal discomfort decreased as well (Figure 3). Thus the efficient use of the induction control for decrease of draught discomfort in rooms with chilled beams was validated.

The activated induction control decreased the draught complaints but the number of subjects reporting warmth discomfort at WP2 increased from 10 to 13, i.e. near the window. Due to the airflow interaction less cooling air reached the subjects at WP2 and this resulted in warmer thermal sensation. Thus the warmth discomfort should be carefully considered together with draught discomfort in practice in rooms with chilled beams when induction control is provided.

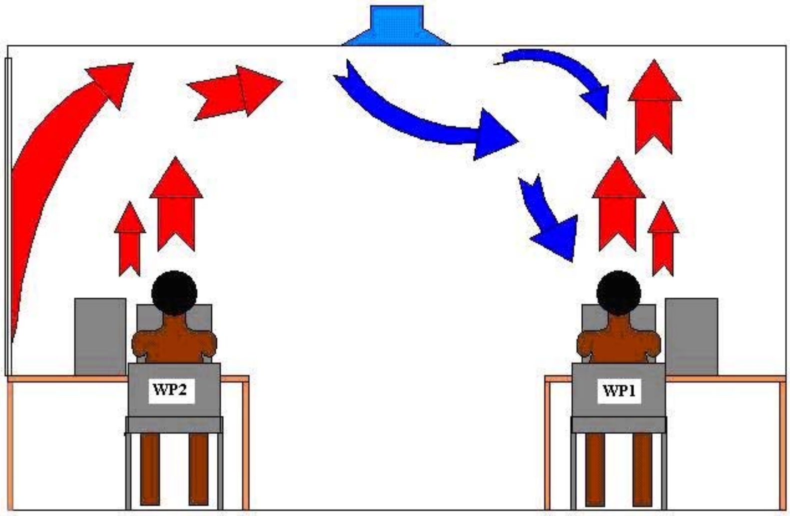

Figure 5. Air distribution in Case 1 (70W/m²- I2)

The importance of the airflow interaction was demonstrated in the experiments with different heat load as well. Non-uniformity of the thermal environment decreased when the heat load was decreased from 70W/m² (Case 1) to 30W/m² (Case 3) and this affected occupants' thermal comfort. Draught discomfort decreased (Figure 4), the whole body thermal sensation improved (Figure 2) and the reports on uncomfortable local warmth discomfort decreased (Figure 3).

The results reported in this paper were supported by results from comprehensive physical measurements on air distribution and thermal environment in rooms with chilled beams [3, 4]. They confirm the importance of careful consideration of flow interaction in rooms in general. In future buildings occupants and solar irradiation will remain the major heat sources. The increase of the outdoor temperature due to global warming and the use of glass facades will affect the airflow interaction in spaces resulting in increased non-uniformity of the thermal environment. At the same time the recognized impact of the indoor environment on occupants' performance [9] will lead to requirements for higher quality of indoor environment in the future standards than the requirements specified in the present indoor climate standards. Therefore the need for of individually controlled environment in buildings which will be able to compensate for the non-uniformity of the indoor environment and for the large individual differences existing between people in regard to the preferred environment will increase.

CONCLUSIONS

For the conditions provided by the chilled beams the average thermal sensation of the subjects was within the requirements of the existing standards and guidelines (ISO 7730, CEN 1752, REHVA Guidebook).

The flow interaction in the room under the studied conditions had major impact of occupants draught sensation. Higher draught discomfort was discovered for the conditions with higher heat load in the room. The induction control proved to be efficient way for diminishing draught discomfort.

SUMMARY

Active chilled beams are an air conditioning solution for ventilation, cooling and heating. By careful design the solution can result in a comfortable indoor environment with a high degree of individual control at a low operational cost. During the design process draught risks should be analyzed since many factors can influence the resulting airflow pattern from chilled beams. The paper focuses on the factors affecting the thermal comfort in a room ventilated by chilled beams. Both experimental results as well as theoretical considerations are included in the analysis. Practical guidelines for minimizing draught risk are given and features of active chilled beams are described in the paper.

INTRODUCTION

Active chilled beams is the complete indoor environmental solution. Maintaining both a comfortable thermal as well as atmospheric indoor climate by handling both ventilation, cooling and heating using only a minimum of energy it is a solution which should be considered for all new or refurbished buildings. The solution offers high temperature cooling and low temperature heating resulting in high energy performance as well as only the amount of fresh needed for maintaining a comfortable atmospheric indoor climate. Additionally the solution offers small space requirements for ducting and good individual control of the indoor environment.
The working principle of an active chilled beam is shown in figure 1.

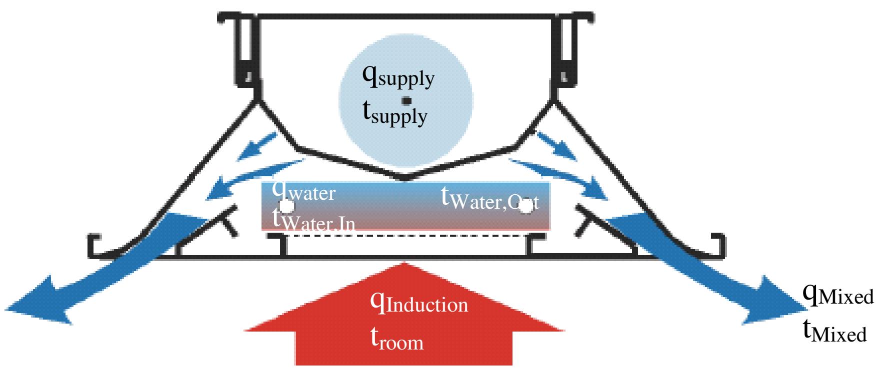

Figure 1 Working principle of active chilled beam.

The supply air is dispersed at a high velocity through a number of nozzles placed inside the chilled beam. The jets from these nozzles creates a withdrawal of the air in the vicinity of these small jets and subsequently creating an airflow through the coil of the chilled beam ($q_{induction}$). This induced air flow is cooled when passing the chilled water coil and supplied to the room mixed together with the primary (outdoor) air. The temperature of the air supplied to the room is dependent on the room air temperature, the primary air temperature and the cooling of the coil. The cooling output is controlled by adjustment of the water flow through the coil. This beam works similarly in heating mode.

A chilled beam system delivers only the necessary amount of primary (outdoor) air in order to obtain a good atmospheric indoor climate. The thermal indoor environment is maintained as described above.

Since the first active chilled beams were introduced in the 1980s the development has been extensive – increasing cooling outputs and higher supply air flow rates, but also additional features such as heating, adjustment of velocity as well as build-in service features have been added subsequently up until today. The increased output of cause increase the risk of draught subsequently increasing the need for good design of systems.

The paper focuses on the factors affecting the thermal comfort in a room ventilated by chilled beams.
As illustrated in the following figure 2 a number of different factors influence the flow pattern as well as the resulting thermal comfort in a room ventilated and cooled or heated using chilled beams. The dimensions of the room, the location of the chilled beams, the number, size and location of heat sources, the primary and secondary airflow rates from the chilled beam, but also possible ceiling mounted obstacles can influence the airflow from the chilled beam.

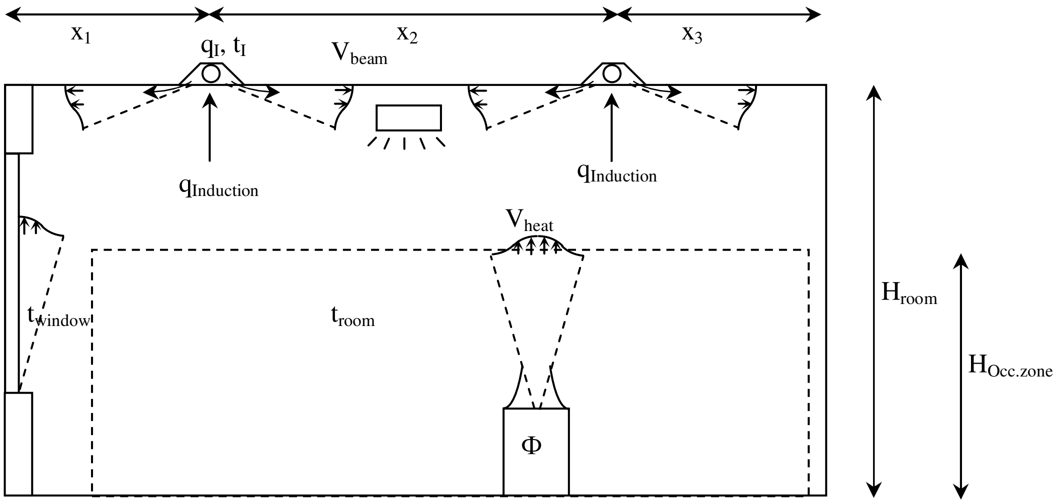

Figure 2 Factors influencing flow pattern and thermal comfort in room ventilated by chilled beams.

The present paper focuses on the practical design of active chilled beam systems and states certain guidelines in connection to the design of chilled beam systems. Experimental data are used for analyzes of theoretical relationships describing the airflow and for outlining practical considerations.

METHODS

All measurements were conducted using active chilled beams integrated in a suspended ceiling placed in a full scale office room. The chilled beams used were 1800 mm long with a coil length of 1500 mm. The measurements were conducted in a room representing an office room. The room had dimensions 5.4 x 4.2 x 2.5 m. The chilled beams were all equipped with a device (*Halton Velocity Control*) which can limit the slot opening of the beams and hereby reduce the induced airflow rate.

Different factors influential for the flow interaction in the room were analyzed through the measurements including placement of chilled beams in rooms (3 or 4 chilled beams), different strengths of heat loads and locations (heated surfaces of window and floor simulating solar radiation, heat generated by occupants (1 or 2 sitting persons in front of computer were simulated), primary air flow rate and induced airflow rate. Both temperatures and velocities were measured in a vast number of points in the room in the experiments. Further information concerning these measurements can be found in [1].

RESULTS

When designing chilled beam systems it is of great importance to optimize the thermal comfort in the room not only by matching the needed cooling capacity, but also to avoid possible draught risks that otherwise could occur due to the airflow from the chilled beams. It is however not easy to predict the complete picture, since the location of heat sources may change many times during the lifetime of the building as well as location and effect of flow diverting obstacles may be difficult to estimate. However there are a number of factors which can be accounted for and which should always be taken into consideration when designing chilled beams systems.

The height of the room will have an effect on the flow pattern in the room since the air from the chilled beam has a lower temperature than the ambient, and the air acceleration due to the temperature difference can cause draught risks. The recommended maximum height of rooms equipped with chilled beams is approximately 3.5 meters, above this value the thermal forces can cause draught risk in the occupied zone if the cooling need is high.

Due to the air flow from active chilled beams being dispersed from slotlike diffusors the velocity decay can be described as a plane wall jet (when attached to ceiling and also when diverted down a wall). The velocity decay for a plane wall jet can be shown theoretically to being inverse proportional to the square root of the distance [2]. This means that the velocity is maintained much better than a normal radial diffuser ($v \sim 1/x$), and that the temperature decay of the jet is small and can cause draught risks when the jet is directed downwards, either due to meeting a jet generated by a neighboring chilled beam or due to a wall or an obstacle.

Despite the fact that the primary supply air flow rate is kept at a minimum the total recirculated airflow in the room may be quite large. This is also an important matter limiting the installation height due to the undercooled air from the chilled beams.

The following figure shows velocity and temperature distribution measured in the test room with chilled beams installed in a lengthwise positioning compared to the window façade. The depictions show a measured example of a bad positioning of the chilled beams which clearly results in some flow interaction between the heat sources and the flow from the chilled beams. The flow from the chilled beam is diverted away from the ceiling immediately after leaving the chilled beam and subsequently dropping straight into the occupied zone. It can be seen from the figure that this also results in a very uneven temperature distribution.

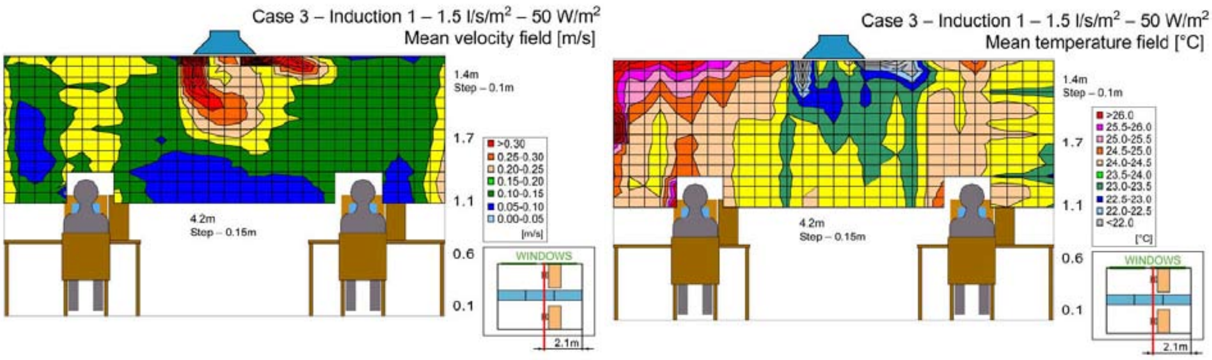

Figure 3 Measured velocity (left) and temperature distribution (right) in an office room with two occupants and a lengthwise chilled beam installation. Heat load strength and distribution and the primary airflow rate are defined. Induction 1 means maximum induced room air. . The measurement plan in shown with red line on the sketch in the figure [1].

Possible flow interaction should be taking into account when designing chilled beam systems (to the extent possible) and the depictions above gives a clear indication that chilled beams installed in a lengthwise position can cause unnecessary draught risks.

As already discussed the distance between chilled beams and the distance to the nearest wall are also matters of great importance for the velocity in the occupied zone, i.e. for the draught discomfort. Opposing beams can have impinging jet flows which have a resultant flow directed downwards and beams close to walls will have a resulting flow downwards. Here the earlier mentioned velocity decay can be used to estimate the necessary distance between the beams and the distance to the nearest wall, it is however necessary to know the constant (K value) describing the velocity decay:

$$\frac{v_x}{v_0} = K_P \sqrt{\frac{h_0}{x}} \qquad (1)$$

The K value is dependent on the specific slot of the beam, and the internal nozzles in the beam.
Assuming that the thermal forces are small compared to the initial forces the equation must then be solved for $v_x = 0.2$ m/s or similar demand and the necessary distance x can then be determined as from half the distance between the beams (or the distance to the wall) plus the vertical distance from the ceiling to the occupied zone. This assumption can be checked if horizontal distance here is larger than the penetration length which can be estimated by the following expression [3]:

$$x_s = 1{,}58 \cdot K_P^2 \cdot \left(\frac{v_0^2}{\Delta T_0}\right)^{2/3} \cdot h_0^{1/3} \qquad (2)$$

The following figure shows the velocity distribution of two opposing beams which clearly shows the two airflows being joined and directed downwards.

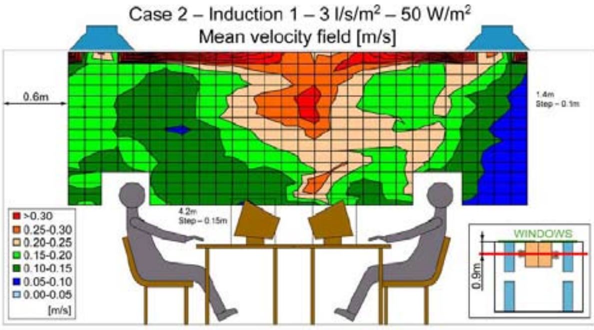

Figure 4 Measured velocity distribution of two opposing beams with joining airflows at 3 l/s/m² (primary air) and 50 W/m². Induction 1 means maximum induced room air. The measurement plan is shown with red line on the sketch in the figure [1].

The importance of the heat load strength for the velocity and temperature distribution in rooms with chilled beams is shown in Figure 5. The depictions show the same general airflow distribution with high velocities near the beams and close to the concentrated heat sources. However the general velocity level around the persons is higher when the cooling is 80 W/m² compared to 50 W/m². The higher velocity level is caused by the larger difference in the temperature level between the airflow from the beams and the ambient as well as the larger heat load from the floor.

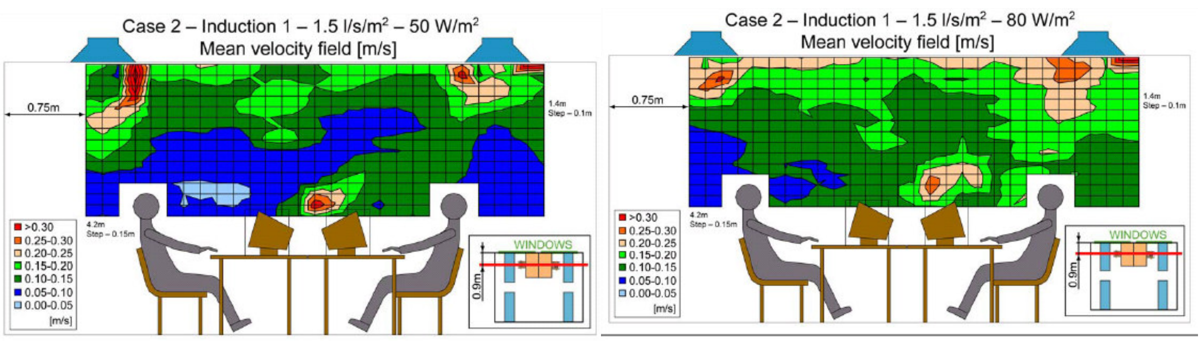

Figure 5 Measured velocity distribution at two different heat loads. Heat load strength and distribution and the primary airflow rate are defined. Induction 1 means maximum induced room air. The measurement plan is shown with red line on the sketch in the figure [1].

Comparing the left depiction in Figure 5 with the measurements shown in Figure 4 it is obvious that a higher air flow rate causes a higher general velocity level and thereby a higher draught risk.

Another way of changing the velocity distribution or limiting the velocity level in the room is using a device that limits the slot opening which in turn limits the induced air flow.
The following Figure 6 shows the measured velocity distribution for two different positions of the velocity control; fully open shown in the left depiction and limited in the right. The figure shows a higher velocity level when the velocity control is fully open, due to the higher total amount of recirculated air. On the other hand the figure also shows that the airflow detach from the ceiling when the slot opening is limited. This device which has 3 positions has

proven very useful in many office buildings since it is possible to change the local velocity level when unforeseen matters such as local heat sources and flow diverting obstacles change the flow from the chilled beams. Designing the chilled beam systems when using the middle position of the velocity control gives the possibility of adjusting the local draught risks.

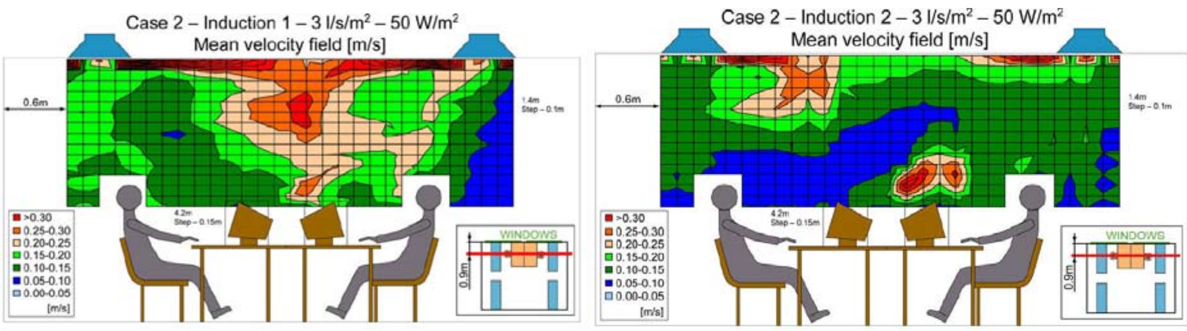

Figure 6 Measured velocity distribution at two different positions of the velocity control (device reducing the slot opening). Induction 1 means maximum induced room air, while Induction 2 means reduced induction of room air. Heat load strength and distribution and the primary airflow rate are defined. The measurement plan is shown with red line on the sketch in the figure [1].

DISCUSSION

Active chilled beams offer good indoor climate conditions and high level of flexibility in the office. It is a solution that can offer a comfortable indoor environment with a high degree of individual control at a low operational cost. However active chilled beam systems requires careful design since many factors influence the airflow in the room and thereby the possible draught risks.

Chilled beams should be installed perpendicular to the window façade thus avoiding flow interaction between the heated surface and the flow from the chilled beams. If other considerable heat sources are known these should also be taken into account.
Chilled beams should not be used in rooms with a room heights above 3.5 m since this will increase the draught risk in the occupied zone significantly.
The higher the necessary cooling capacity or the higher the outdoor airflow rate the higher the general velocity level which may result in unnecessary draught risks.

Further guidelines for design of chilled beam systems can be found in [4] as well as documentation provided by manufacturers.

High Quality Thermal Environment by Chilled Ceiling in Office Building

László Kajtár, Levente Herczeg, Tamás Hrustinszky and Anita Leitner

Budapest University of Technology and Economics, Budapest

Corresponding author email: kajtar@epgep.bme.hu

SUMMARY

An air-condition system shall be designed to provide the required indoor environment under specified condition. According CEN Report 1752 it could be distinguish three categories for indoor environment. Considering higher level of comfort there is a rising cost of HVAC systems. In hereby published research main parameters of thermal comfort and IAQ in offices have been measured such as PMV and PPD indexes, indoor air velocity (w), percentage of turbulence intensity (TU), DR index, and carbon-dioxide concentration.

Results are seem to be proved that in order to provide the highest comfort category there is a need of more expensive HVAC systems.

INTRODUCTION

The examined office building, located in downtown Budapest, is equipped by BARCOL CBA chilled ceiling system (cc. 4000 m^2), supported by radiators to provide the required comfort level in heating season.

During working hours the building was occupied by 687 office workers. A central ventilation systems is cover the required amount of fresh air for them (68,3 m^3/h,person). 75-85% of total area of chilled ceiling is made up suspended ceiling panels in size 600x600 mm. In some area with significant heat loads it is additionally placed further passive cooling coils above the suspended ceiling. Otherwise rooms with slightly significant heat load, 45-55% of the ceiling area is covered by cooling panels. Designed cooling inlet/outlet water temperature level is 15/17°C. However higher water temperature level (17/19^{o}C) have found sufficient to provide proper thermal comfort in summer. In this case condensation could not be an issue.

In the building windows are free to open, although sensors are installed to close the cooled water valves in case of airing.

METHODS

In field studies following parameters have been investigated: air temperature (t_a), wet globe temperature (t_w) mean radiant temperature (t_{mr}), air velocity (w), PMV and PPD indexes, carbon-dioxide concentration (c_{CO2}), cooled water inlet (t_{wi}) and outlet (t_{wo}) temperature. Schematic diagram of chilled ceiling systems, measuring equipment and self –control system can be seen in Figure 1.

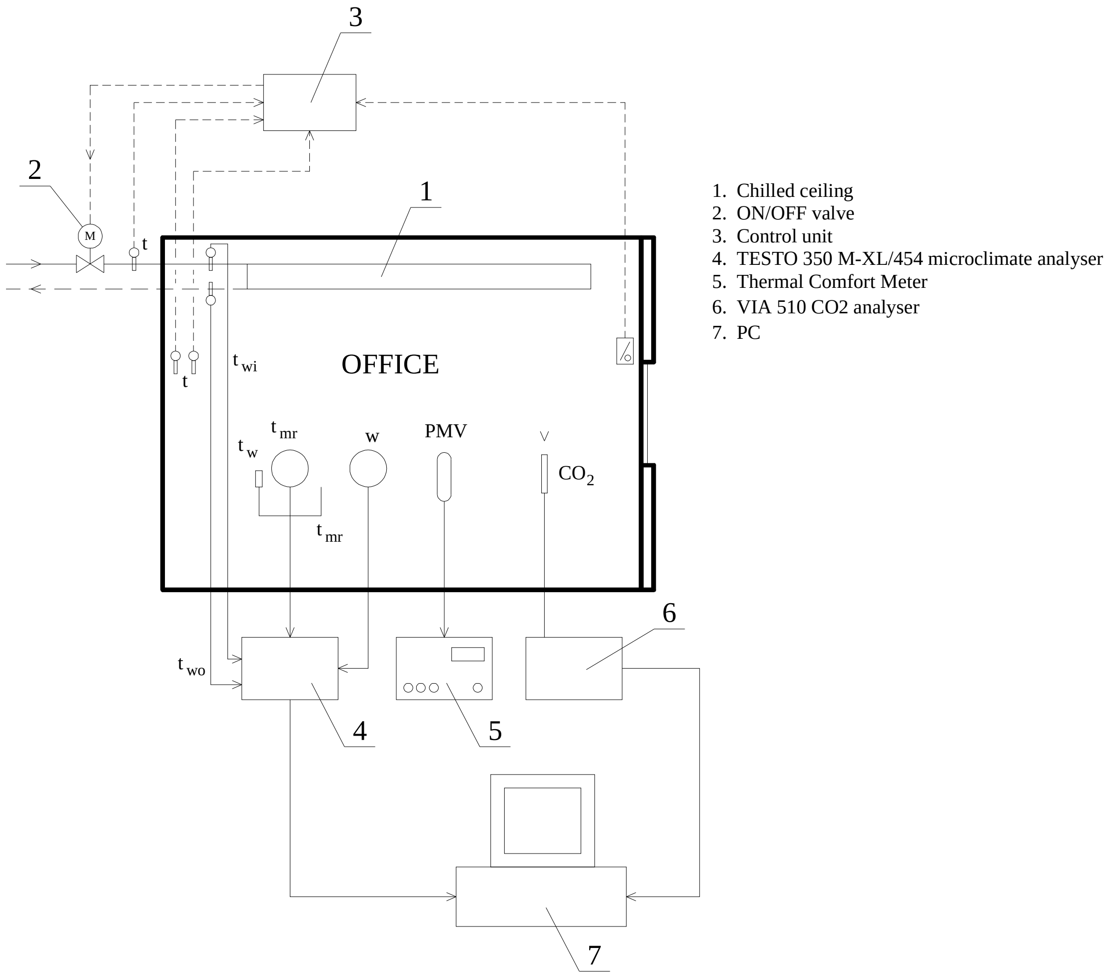

Figure 1. Schematic diagram of chilled ceiling systems, measuring equipment and self – control system

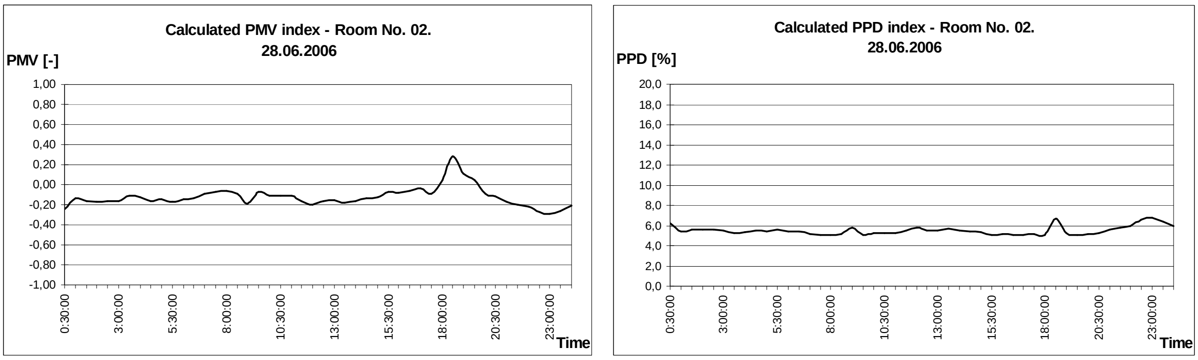
Air velocity values have been collected in every 12 second; other parameters have been measured in 5 minutes. Due to automatic measuring system two week long continuous examination and data collection have been carried out in summer and intermediate season as well.

By evaluating thermal comfort following parameters have been taken into account: activity level 1 met (light sedentary office work); thermal capacity of clothing 1 clo.

RESULTS

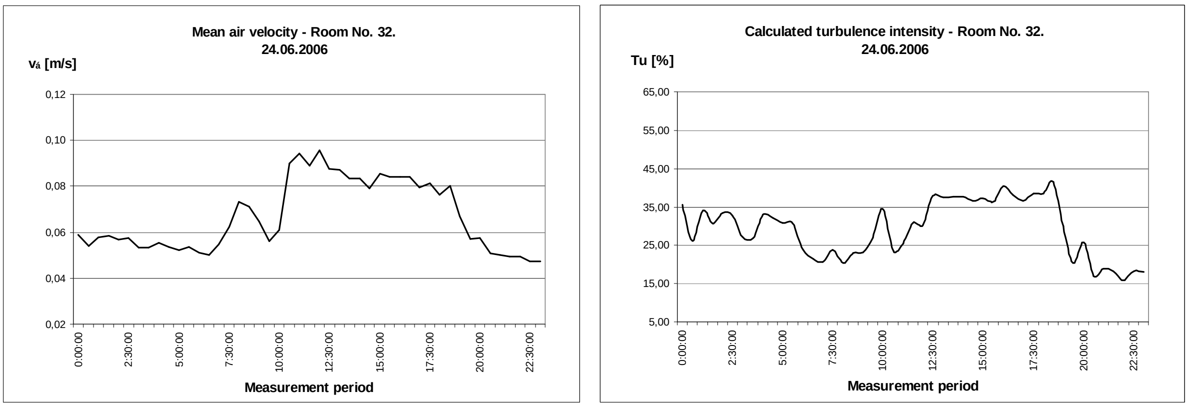
Results have been collected and saved using computer software. PMV index has been measured by Thermal Comfort Meter and also it has been calculated based on additionally measured thermal comfort parameters. Air velocity data has been as a base at the calculation of turbulence intensity and DR index, using computer software, developed by our research team. Considered measuring period to averaging has been 3 minutes.

In Figure 2. show variation of PMV and PPD indexes in an average summer day. Calculated mean air velocity and turbulence intensity can be seen in Figure 3. Percentage of dissatisfaction due to draught can be seen in Figure 4.



a) b)

Figure 2. Variation of a) PMV and b) PPD indexes in an average summer day



a) b)

Figure 3. Calculated a) mean air velocity and b) turbulence intensity

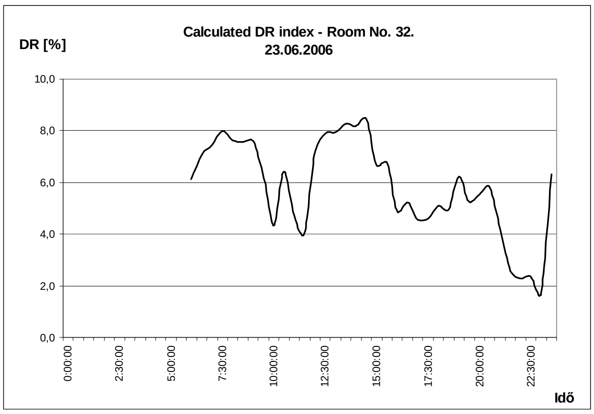


Figure 4. Percentage of dissatisfaction due to draught

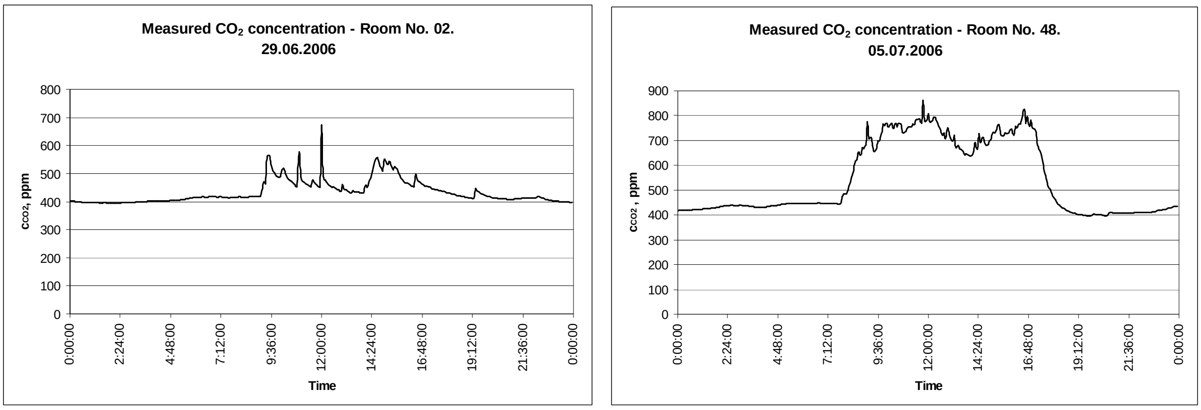
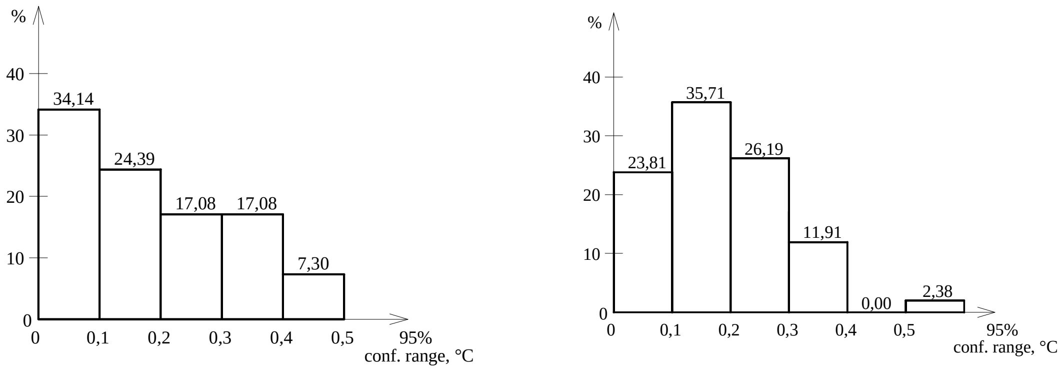
Carbon-dioxide concentration has been also measured in singular and landscape offices too. Results can be seen in Figures 5.



a) b)

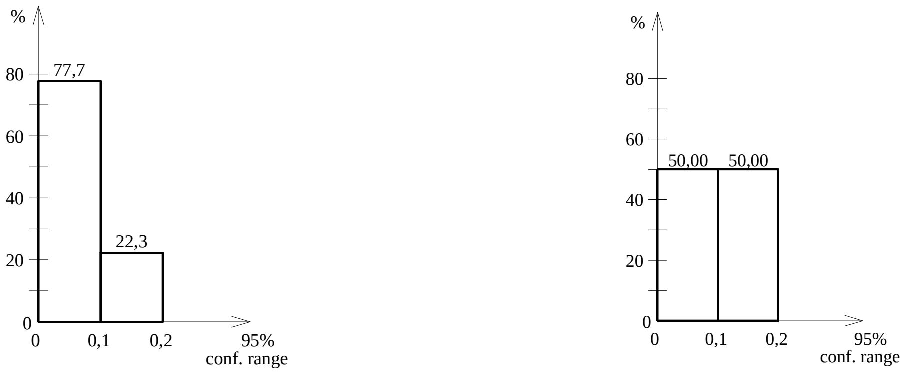
Figure 5. Carbon-dioxide concentration in a) singular and b) landscape office

Mathematical evaluation of results has been carried out according principles of probability theory. Thus distributions of measured and calculated data are presented graphically as well. Histograms are shown in Figure 6. (air temperature) and in Figure 7. (PMV index, for intermediate season and in case of designed outdoor temperature in summer).



a) b)

Figure 6. Histograms of air temperature in a) intermediate season and b) case of designed outdoor temperature in summer



a) b)

Figure 7. Histograms of PMV index in a) intermediate season and b) case of designed outdoor temperature in summer

DISCUSSION

To draw conclusions guideline CR 1752 has been taken into consideration. These are as follows:

- In intermediate season maximum air temperature difference is lower than 0,5 K. (Category “A”: Δt_{max} = 1K)
  Under design condition (summer) maximum air temperature difference is lower than 0,6 K as well. (Category “A”: Δt_{max} = 1K)

- Variation of PMV is lower than 0,3 in intermediate and summer season as well. (Category “A”: ΔPMV_{max} = 0,4)

- Percentage of dissatisfaction caused by draught (DR index) is lower than recommended value according category “A”. Maximum indoor air velocity is 0,12 m/s, maximum DR value is 10,61% (Category “A”: w_{max} < 0,18 m/s, DR < 15%).

- Average outdoor carbon-dioxide concentration is 440 ppm, thus to meet requirements for category “A” concentration should be lower than 900 ppm.

According measuring results indoor comfort level is “A” in the investigated office space.

Indoor comfort guidelines described in CR 1752 gives three different levels (A, B and C) to classify an enclosure. In Hungary it has been an issue the opportunity and way of providing indoor comfort at level “A”. Due to strict requirements, there is a need of design and maintenance at high level of accuracy.

New office buildings are typically designed with significant glassed area and decreasing heat capacity. Fluctuations of indoor / outdoor loads make automatic control system crucial. Further consideration has to be made in accordance of required cooling capacity of chilled ceiling systems. Chilled ceiling is one of the most complicated HVAC system. To avoid harmful condensation on cooling panel proper design is essential. Atypical water temperature ranges (e.g. 15/17 °C) give a further aspect of complicity of system design. Higher water temperature level (17/19^{o}C) have found sufficient to provide proper thermal comfort in summer. In this case condensation could not be an issue.

Based on our research, using chilled ceiling system it is possible to provide indoor comfort at level “A”. Investment cost is higher, although thermal comfort parameters are meet standard. Moreover there is a decreasing level of dissatisfaction. Measured PMV index has been slightly lower than neutral value (Figure 2.). Therefore thermal comfort can be said slightly cool. Given value of PMV can be controlled using automatic control system. In summer there is a common problem with relative high indoor air temperature in office buildings. However it has not to be proved in this case, thanks to proper design, implementation, hydraulic balancing and maintenance of HVAC system.

ACNOWLEDGEMENT

Measurement of Flow Characteristics of a Ceiling Fan with Varying Rotational Speed

Hsu-Cheng Chiang, Chung-shu Pan, Hsi-Sheng Wu, Bing-Chwen Yang

Energy & Environment Laboratories, Industrial Technology Research Institute, Taiwan, ROC

Corresponding email: hchiang@itri.org.tw

SUMMARY

This paper conducts an experimental measuring of the airflow generated by a modern ceiling fan that has an electronic device to vary the instant rotation speed for simulating natural winds. The measuring results are then used to calculate the mean air velocity, standard deviations, turbulence intensity, equivalent frequency, power spectrum, and other comfort evaluation parameters. The results have shown that, by adopting the natural wind mode, even at a lower mean air velocity, a substantial comfort level can be achieved while consumes much less electric energy. In the consideration of achieving a sustainable built environment, this finding is of great importance. This study also completes a so-called *1/f* power spectrum analysis to identify the feature of natural wind generated. It seems that we can achieve environmental sustainability by further exploring the characteristics of natural environment.

INTRODUCTION

Ceiling fans are widespread used in hot or tropical climate zones for providing cooling and comfort. It consumes relatively low amount of energy in comparison to air-conditioning units. Although in these days, air-conditioning is preferable to operating a ceiling fan in modern office or residential buildings. Complementarily using ceiling fans as additional air circulating devices in air-conditioned rooms can often lead to the same comfort level at an elevated temperature setting, which means a potential saving of energy. Whereas, as ceiling fans are such common appliances nowadays, little effort has been paid on the new fan designs and its consequent influence on room airflow. This paper conducts an experimental measuring of the airflow produced by a modern ceiling fan which has an electronic device to vary the instant rotation speed to simulate natural winds.

The interest of this paper is to investigate the draught caused by a rotating ceiling fan because the space leans to have higher mean velocity. Therefore, thermal comfort considering only mean velocity and temperature as was done in a central air-conditioning system is not enough without considering draught. Draught is defined as an unwanted feeling due to locally convective cooling of the human body caused by air movement. In fact, the sensation of draught has direct relation to the airflow fluctuation, for examples, turbulence intensity and frequency of fluctuation. Several studies relevant to draught and airflow have been performed by Fanger and Christensen [1] and Fanger et al. [2]. In these studies, the percentage of people dissatisfied due to draught was defined by the following equation:

$$DR = (3.14 + 0.37\bar{v}Tu)(34 - t)(\bar{v} - 0.05)^{0.62}, \qquad (1)$$

where *DR* is the percentage of people dissatisfied, $\overline{v}$ mean velocity, *t* air temperature and *Tu* turbulence intensity. Recent study [3] shows that the frequency of air velocity has great impact on draught feeling. In that article, an equivalent frequency parameter was defined to describe the frequency characteristics of the airflow. It indicates that most people are sensitive to airflow at an equivalent frequency between 0.2 and 0.6 Hz. For spaces using a central air conditioning system, the air speed is relatively uniform. Draught can be easily inhibited in such a well-designed system. However, it is not a similar case for the space, using a unitary air conditioner, where persisting air speed might exist in occupied zone. Shih et al. [4] studied the draught induced by a split-type air-conditioner. Their results show that, for such a type of air conditioners, the equivalent frequency falls between 0.3Hz and 0.6Hz, which is in the uncomfortable range.

Recent research in personalized air conditioning systems with fluctuating air movement [5] and simulated natural wind [6] brought out a concept which is different from that of common systems with steady-state air distribution. The fluctuation of airflow is one main factor that affects indoor comfort. According to the research results [7, 8, 9], the fluctuating airflow brings more cooling effect to the human bodies, especially the airflow with a frequency similar to that of natural wind. The research result of [6] shows that the distribution of a constant airflow at the outlet of an air moving devise is quite different from that of a simulated natural wind. Only the airflow reaches its full stage of diffusion ($v < 0.25$m/s), does the structure of the airflow approach to that of natural wind. Nevertheless, the velocity of the air current is too low and has little effect to the thermal comfort.

Power spectrum analysis is an essential tool to be used to analyze the patterns of the airflow. It evaluates the relationship between the frequency of occurrence of the velocity and corresponding magnitude (or the energy) of the air current. The criterion to be used to make the judgment is the slope of the spectrum curve (normally in natural log of base 10). The mathematical relationship of power spectrum density to the slope of spectrum curve can be expressed as $E(f) = 1/f$, where f is the frequency of occurrence of the velocity. According to the finding of relevant literatures, the power spectrum distribution of natural wind is in $1/f$ fluctuation and its slope falls in the range of -1.10 to -1.67. As to the airflow produced by the mechanical devises, its slope of power spectrum curve is approach to the range of $1/f^0$ fluctuation (namely, the range of white noise).

A transient thermal environment can be established by changing the air temperature and/or the air velocity. Simulated natural air movement can be used to offset high air temperature and to improve perceived air quality slightly. A new conditioning strategy focuses on the effective use of simulated natural wind, which has special characteristics in turbulence intensity, velocity distribution and power spectrum. A prediction of energy use shows that substantial energy saving can be achieved by effective use of transient air movement.

In this paper, we focus our experiment upon the flow phenomena of a ceiling fan since such an air devise is believed to be able to achieve a certain degree of thermal comfort with energy saving. The results of the experiment are then studied and evaluated respectively for mean air velocity, velocity distribution, turbulence intensity, equivalent frequency and power spectrum etc., of the airflow produced. The corresponding indices reflect some well-known approaches for evaluating the comfort and thermal pleasance in a warmer environment and for preventing cold draught, in particular, in an air-conditioned space.

METHODS

The ceiling fan to be studied was installed in an open space indoor, as shown in Figure 1, providing airflow blowing down to the space below it. A hot wire anemometer made by TSI Co., Model IFA300, displayed in Figure 1(b) was used to measure the airflow characteristics. The instrument has the maximum scanning rate up to 1MHz. But, in this study, the scanning rate of the anemometer was set to be 10Hz. which can best demonstrate the *1/f* features and avoid unwanted noises. So the data of air speed was recorded once every 0.1 seconds. The measuring time lasted approximately for 6.8 minutes and 4096 data sets were recorded for every single measuring point. Longer data logging time was also tried, but the deviations of results analysis are less than 5%.

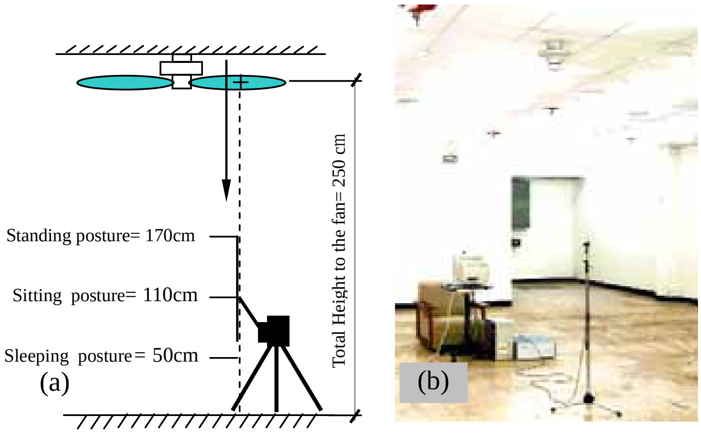

Figure 1. Layout of test site and some representative measurement heights

The speed of the air delivered is measured in a matrix consisted of several measuring points below the fan, as shown in Figure 2. A preliminary study for the fan speed is initiated where a series of measuring points are taken horizontally, 100 cm below the fan. Experimental setup shows that the ceiling fan is equipped with the fan blades in a spindle shape. The air distribution of the fan exhibits a unique pattern that the higher speed occurs somewhere below the center of the fan blade and the velocity declines as the measuring points are gradually away from the center, as Figure 2 shows. The measuring results are then used to calculate the mean air velocity, standard deviations, turbulence intensity, equivalent frequency, power spectrum, and other flow characteristic parameters.

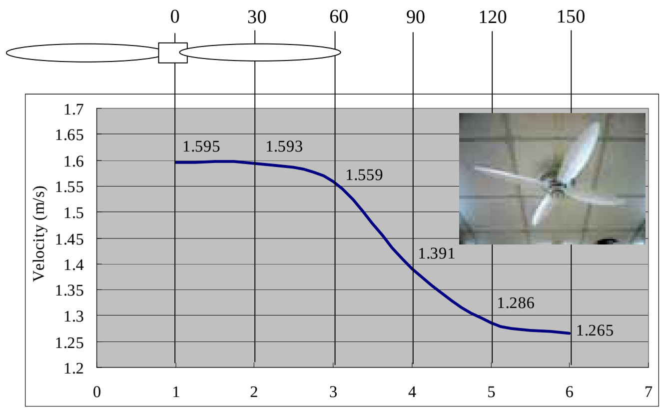

Figure 2. Profile of mean air velocity generated by the studied ceiling fan at height 150cm (fan was set at medium rotation speed)

RESULTS

The ceiling fan studied in this paper, unlike the traditional one only operating at a constant rotation speed, can make fan blade subject to an instant speed change, with the aim to simulate nature breeze. It is claimed that the additional variable speed function can make occupants feel more comfortable in this indoor environment.

In order to find out the difference of air velocity variations for the ceiling fan operating at the constant speed mode and the variable speed mode, a measuring point located at the half of the blade length and 100 cm down from the fan blades was chosen to represent the flow characteristics in the occupied zone subject to direct air moving. The measuring results are shown in Figure 3-5 (a), correspondent to fan rotation in high, medium and low speeds. Basically, in the constant rotation speed mode, air flow measured at this location shows that the mean air velocities are around 1.4~1.7m/s, and the fluctuations are in the scopes of 0.2~0.3m/s.

In contrast, when the fan was operating in the variable speed mode, the air velocities measured, as shown in Figure 3-5(b) for different fan speed settings, all demonstrate the instantaneous velocity varying with time and show erratic change in fluctuation scale significantly larger than that of the constant speed cases. If we observe Figure 5(b) in more detail, the change of air velocity for the low-speed fan rotation condition was found with a specific fluctuation pattern. In some cases, the air speed measured even dropped to a very low speed to the extent about 0.2m/s, the condition lasting for about 20 seconds, and then the fan was quickly increased speed again. However, after observing the air velocity change for a longer time, it was found that the air speed pattern was not very repeated and the fan speed modulation could be explained as a random act.

The air speed variation shown in Figure 3-5, by using some statistical analysis techniques, the data in time-domain can be converted to some flow characteristics in frequency-domain, and the results are shown in Table 1. Obviously, when the fan operating in natural wind mode, the mean air velocities are comparatively lower than those of constant speed mode, but the standard deviations of velocity and acceleration are roughly 2~3 times higher. The combined effect of a lower mean air velocity and a larger flow fluctuations results in a much stronger turbulence intensity for the natural wind cases. As indicated in Equation (1), turbulence intensity is the main cause, beside the temperature and speed differences, to introduce cold draught which has a direct impact on occupant’s feelings of comfort. In order to calculate the percentage of people dissatisfied with the draught. An average indoor temperature of 28^{o}C was chosen for the places using the tested ceiling fan in which the room temperature can be kept at a higher level than the normal setting in a traditional air-conditioned environment. The calculation results are shown in Table 1 in term of parameter *DR*. Surprisedly, though with higher turbulence intensity, the natural wind cases present lower *DR* values, mainly because of smaller mean air velocities. Hence, based on these results, fan operating in the natural wind mode can be inferred to achieve higher comfort levels and energy conservation.

Figure 5. Velocity fluctuations for ceiling fan rotating at the low-speed setting

To further explore the flow characteristics of the main air flow and the induced air motion, six data points were selected to calculate the parameters, as listed in Table 2, to stand for the features in two different flow regions. As the velocity profile shown in Figure 2, measuring points, PT-8,20,32 were positioned at half of the fan blades and 60,120,180 cm under the fan rotation plane. These positions can be interpreted as the heights of the fan discharge, standing and sitting postures of occupant, respectively, in which are under the influence of direct fan blowing. The other three measuring points, PT-10,22,34, were measured at the similar heights of the former group but are about 30 cm away from the tip of fan blade. In this region, the air motion is mainly induced by the main air stream such that the mean velocities are relatively small. Interesting phenomena can be found in Table 2 that, in the natural wind mode, the mean air velocity differences between these two regions are clearly larger than those in the constant speed mode. When the probe was being moved outside of the coverage of the rotating fan blades, the measured wind velocities rapidly decreased to about 0.2m/s, a speed often encountered in a central air conditioning system. In addition, the issue of discomfort caused by draught (*i.e. DR*) becomes almost negligible.

The frequency of flow fluctuations will also affect occupant's perception of comfort. To identify the influence from the frequency aspects, two common statistical analysis methods are used: the first one is the so-called equivalent frequency. It is a function of the instant changes of wind velocity and the corresponding acceleration. According to the quoted literatures, equivalent frequency in the range of 0.2-0.6 Hz, the human body is most likely to suffer from the cold draught. The second one is the so-called *1/f* fluctuation index, which is the slope of linear equations in a logarithm plot of speed vs. frequency obtained from the Fourier transformation of air velocity. Based on the literatures, when this factor is less than 1.0, it represents that the air stream is still in the process of developing; when larger than 1.0, the air movement is caused by induction; when closer to 1.0, the air flow characteristics is more similar to a natural wind spectrum, and the human comfort level will be increased. Table 2 shows the calculation results for the ceiling fan rotating in a constant speed and in variable speed modes. The equivalent frequency (*fe*) are not in the aforementioned frequency range which is most likely to cause uncomfortable draught. In the aspect of *1/f* analysis, the results for most cases are all close to 1.0. The ceiling fan might demonstrate a more uniform air flow in comparison to a conventional jet-flow-typed air distribution device due to the slow rotation speed and large fan blade of a ceiling fan. No matters operating in the constant speed or the natural wind mode, the measured air velocity, after making Fourier transform, are found contribute insignificant differences on the slopes of *1/f* curves for different conditions. It is indeed a surprising finding.

DISCUSSION

In this paper, the measurement of a new ceiling fan, which can vary its instant motor rotation speed to simulate a natural wind pattern, has shown that by adopting the natural wind mode operation, even at a lower mean air velocity, a substantial increase of airflow turbulence intensity can be easily achieved. Hence it, in terms, results in a better comfort level while consumes much less electric energy. In the consideration of achieving a sustainable built environment, this finding is of great importance. But according to the literatures, the so-called natural wind must present itself as a linear equation with the negative slope close to a value of 1.0 in a logarithm plot of velocity vs. frequency. It is surprised that the characteristic values have no significant difference no matter the ceiling fan is operating in a constant speed or natural wind mode. The results might indicate that the judgment of comfort should utilize multiple analysis methods, rather than a single target analysis method. A coherent argument about the description of comfort for the present study seems not fully established yet. However, it is believed that through continuous in-depth studies, we can achieve environmental sustainability by further understanding the characteristics of natural environment.

SUMMARY

In the last decade, quite a few carbon-monoxide intoxications occurred in Hungary due to the inadequate operation of gas appliances with open combustion chamber, connected to chimneys. These cases emphasized the importance of faultless air supply of the appliances and the safe removal of the incipient flue gases. This problem gave reason for the modelling of air supply, temperature and velocity distributions in the space that contains the gas appliance. For the modelling of changes caused by the variations in the inside or outside ambient conditions, numerical modelling can be used. With the help of CFD, the phenomena can be studied in what is virtually a computational environment.
CFD modelling gives results for the changes in the magnitude and direction of air velocity in the room and between the air inlet and the appliance, temperature distribution in the room and from the weather factors, the effect of wind on the operation of the air inlet.

INTRODUCTION

"B" type gas appliances have an open combustion chamber; combustion air comes from the room in which the equipment operates, while flue gases leave through a chimney. The two primary groups of "B" type gas appliances according to the European grouping are [8]:

– Appliances with atmospheric burner and draught hood, connected to a chimney with natural draught (e.g. B_{11}, Figure 1.),
– Appliances, which have burners installed with ventilators, connected directly to the chimney, without draught hood (e.g. B_{23}, B_{33}, B_{53}).

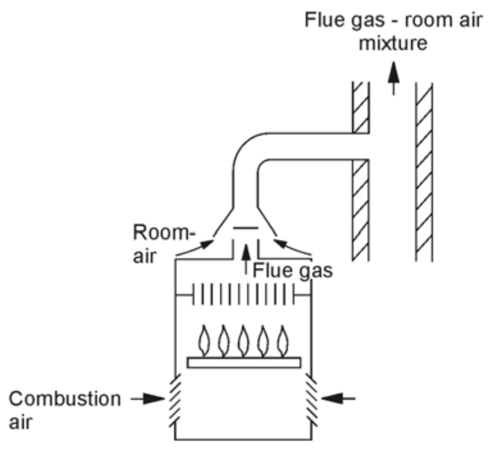

Figure 1. B_{11} type gas appliances, with opened combustion chamber, connected to a chimney

9-10 million gas appliances are estimated to operate in Hungary, most of which connected to a chimney and have open combustion chamber (B_{11} type gas appliances). In the case of these appliances, flue gas has immediate contact with the air of the room in which the machine is installed. Thus, if the air-flow conditions are unfavourable, the flue gas may re-enter the space.
Air flows into the room due to the draught in the chimney. To be able to determine the operating point of the system the mathematical model of the chimney, the gas appliance, the room and the air inlet has to be worked out. However, the simultaneous or variance-based examination of several factors cannot be carried out analytically because of the large number of equations and their complexity (differential and integral equations etc.). For the modelling of changes caused by the variations in the inside or outside ambient conditions, numerical modelling can be used. With the help of CFD, the phenomena can be studied in what is virtually a computational environment.
CFD modelling gives results for the changes in the magnitude and direction of air velocity in the room and between the air inlet and the appliance, temperature distribution in the room and from the weather factors, the effect of wind on the operation of the air inlet.

METHODS

Steps of the CFD modelling:
- creating the geometry of the model,
- stating the differential equations for the numeric model,
- developing the CFD model,
- modelling the air supply and flue gas removal of a gas appliance for different conditions and operation modes, compute the air velocity and temperature distribution in the room.

First step of investigations: creating the geometric model
For the modelling of the B_{11} type gas appliance a conventionally sized room is used, in which the appliance is the only equipment (Figure 2). A volume of the room is 15 m^3, and its size in detail is: 2 m (width), 2,5 m (length), 3 m (height). The windows and doors of the room are air-tight structures made of wood or plastic, sealed with several layers of rubber sealing. Outside air can barely or cannot enter at all in the room through natural (gravitational) means. The air necessary for combustion is provided via air inlets that in the model were inserted in the window frame in different ways, under and above the window.

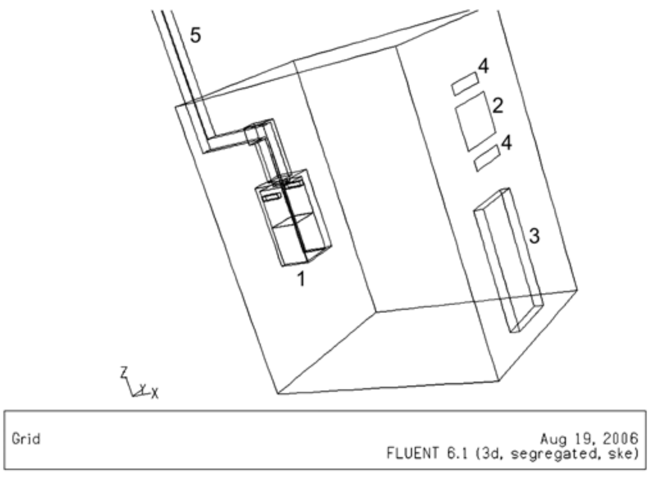

Figure 2. The geometric model used for the examination of B_{11} type gas appliances
1 – wall-mounted gas appliances, 2 – window, 3 – radiator, 4 – air inlet, 5 – chimney

The *U*-value of the external wall is 0.45 W/m²·K, while the window has a *U*-value of 1.4 W/m²·K.
Under the window a radiator is situated that is controlled by a thermostatic radiator valve which adjusts the heat loss so that the desired room temperature is achieved.
Nominal heat output of the gas appliances in the investigation are: 12 kW, 24 kW, 28 kW and 36 kW.
The connecting flue pipe consist of: 0,5 m long vertical section, bend, 1 m long horizontal section. The pipe is made of aluminium and has a maximum absolute roughness of 1 mm.
The chimney is situated partly in the heated space and partly outside.
The outdoor air temperature is -15 °C, which is the best condition regarding the chimney but is the worst from the room's comfort point of view.
Figure 3 shows the main sizes of the geometric model that was shown in Figure 2.

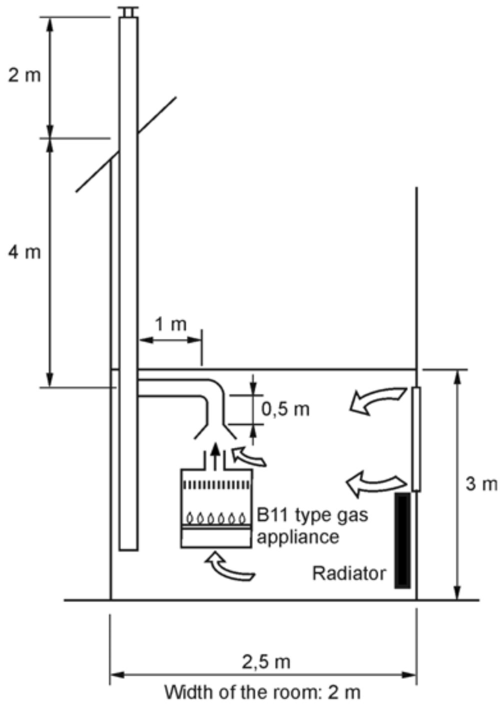

Figure 3. The main sizes of the geometric model

Stating the differential equations for the numeric model
The numeric model, based on the geometric model, was developed by adding principal initial and boundary conditions.
The air movements of closed areas are described by the differential equations of continuity and *Navier-Stokes*. The thermo balance of the areas is expressed by the equation of energy; its distribution of concentration is described by the differential equation of material balance. As we are talking about turbulent air conduction, also the proportion of the kinetic energy and the dissipation (k-ε) of the airflow has to be determined. Resulting from a system of equations, this is the mathematical model of closed spaces.
Assuming an incompressible agent the listed equations are formed as follows:

Continuity:

$$\mathrm{div}\,(\rho \cdot u_\mathrm{i}) = 0\,, \qquad (1)$$

where ρ is the air density and u_i are the air velocity components in *x, y, z* direction.

Equation of movement:

$$\frac{\partial}{\partial x_i}(\rho \cdot u_i \cdot u_j) = \frac{\partial}{\partial x_i}\left((\mu + \mu_t)\left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i}\right)\right) - \\ - \frac{\partial}{\partial x_j}\left(p + \frac{2}{3} \cdot \rho \cdot k \cdot \delta_{ij}\right) + g_i(\rho_x - \rho) , \qquad (2)$$

where μ is the viscosity, and μ_t is the turbulent viscosity, p is the pressure, k is the kinetic energy, and δ_{ij} is the *Kronecker* symbol.

Equation of energy:

$$\frac{\partial}{\partial x_i}(\rho \cdot u_i \cdot h) = \frac{\partial}{\partial x_i}\left\{\left(\frac{\mu}{\sigma} + \frac{\mu_t}{\sigma_t}\right)\frac{\partial h}{\partial x_i}\right\} + Q , \qquad (3)$$

where h is the enthalpy, Q is the quantity of heat per volume, σ_t is a factor, depends on *Prandtl*- and *Schmidt*-numbers.

The turbulent viscosity:

$$\mu_t = K \cdot \rho \cdot \frac{k^2}{\varepsilon} , \qquad (4)$$

where K is a constant, ε is the dissipation of kinetic energy.

Turbulent kinetic energy:

$$\frac{\partial}{\partial x_i}(\rho \cdot u_i \cdot k) = \frac{\partial}{\partial x_i}\left\{\left(\mu + \frac{\mu_t}{\sigma_k}\right)\frac{\partial k}{\partial x_i}\right\} - \\ - K_4 \cdot \rho \cdot \varepsilon + \mu_t \frac{\partial u_i}{\partial x_j}\left\{\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i}\right\} + F , \qquad (5)$$

where σ_k is the kinetic energy factor.

Dissipation of turbulent kinetic energy:

$$\frac{\partial}{\partial x_i}(\rho \cdot u_i \cdot \varepsilon) = \frac{\partial}{\partial x_i}\left\{\left(\mu + \frac{\mu_t}{\sigma_\varepsilon}\right)\frac{\partial \varepsilon}{\partial x_i}\right\} - K_2 \cdot \rho \cdot \frac{\varepsilon^2}{k} + \\ + K_1 \cdot \mu_t \frac{\partial u_i}{\partial x_j}\left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i}\right)\frac{\varepsilon}{k} + K_3 \cdot F \cdot \frac{\varepsilon}{k} , \qquad (6)$$

where

$$F = g_i\left\{\beta \frac{\mu_t}{\sigma_t}\frac{\partial T}{\partial x_i} + \beta_c \frac{\mu_t}{\sigma_{ct}}\frac{\partial C}{\partial x_i}\right\} . \qquad (7)$$

Standard *k-ε* turbulence model

The *k-ε* transport equation is created from *Navier-Stokes*-equation on condition that the turbulence effect dominates over the whole flow field. The *k-ε* turbulence model ensures the option to operate turbulence effects as transport equations.
The continuity equation for incompressible and source-free medium:

$$\frac{\partial u_i}{\partial x_i} = 0 \ , \qquad (8)$$

where u_i are velocity components, x_i are coordinates, $i = 1, 2, 3$.

The conservation of momentum equations use *Newton's* movement laws. The resultant of external forces, affecting the elementary volume, equals to the resultant of total momentum's growth and total outgoing impulse from the elementary cell with reference to same elementary volume. These external forces on one hand are external stresses on the surface of the primary cell, on the other hand split force effects, like the force effect resulting from gravity:

$$\rho \cdot \frac{\partial u_i}{\partial t} + \rho \cdot \frac{\partial}{\partial x_j}(u_i u_j) + \frac{\partial p}{\partial x_i} - \frac{\partial \tau_{ij}}{\partial x_j} - \rho \cdot F_i = 0 \ , \qquad (9)$$

where τ is symmetrical liquid viscosity stress tensor, $\rho \cdot F_i$ is split force effect (e.g. gravity), for our purposes it is considered to be zero.

Liquid viscosity stress tensor in *Newton*'s medium:

$$\tau_{ij} = \mu \left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i} \right) \ , \qquad (10)$$

where μ is the dynamic viscosity, Ns/m^2.

Equations (9), (10), and (11) describe *Newton*'s medium flow in laminar and turbulent case. If the computations were based on these equations, the model would have such a fine resolution for the investigation of smaller and greater fluctuations that in the end the necessary calculation power would be greater what an average computer could handle. Because of this, the *Navier-Stokes* equation's time average modification has to be used. However, it can only be used for the calculation of large-scale fluctuations. Small fluctuations have to be described with the help of imminent or empirical methods. In 1883, *Reynolds* proposed and introduced the *f(x,t)* value, which could manage the fluctuation's size with an average in time.

Reynold's filter can be stated in a more general form, where *f(x,t)*'s first component is the large-scale fluctuation's average in the time, $\bar{f}(x,t)$, while the other component is the small-scale fluctuation's average in time $f'(x,t)$:

$$f(x,t) = \bar{f}(x,t) + f'(x,t) \ . \qquad (11)$$

This average-creating method can be understood as filter permeable at the bottom, which, in function of time, filters small-scale fluctuations.

The modified *Navier-Stokes* equation system and the continuity equation is as follows:

$$\frac{\partial \overline{u}_i}{\partial x_i} = 0 \quad \text{and} \tag{12}$$

$$\frac{\partial \overline{u}_i}{\partial t} + \frac{\partial(\overline{u}_i \overline{u}_j)}{\partial x_j} + \frac{\partial}{\partial x_j}(R_{ij} - \frac{1}{\rho}\overline{\tau}_{ij}) + \frac{1}{\rho}\frac{\partial \overline{p}}{\partial x_i} = 0 \ , \tag{13}$$

where

$$R_{ij} = \left\langle u_i' \ u_j' \right\rangle \ , \ u_i' = u_i - \overline{u}_i \ , \ p' = p - \overline{p} \ , i, j = 1, 2, 3$$

By introducing the concept of turbulent viscosity, which connects *Reynolds* stress and the gradient of the spatial mean velocity, and, following the suggestion of *Boussinesq* from 1887, the following can be stated:

$$-R_{ij} = \nu_t \left(\frac{\partial \overline{u}_i}{\partial x_j} \frac{\partial \overline{u}_j}{\partial x_i} \right) - \frac{2}{3} k \cdot \delta_{ij} \ , \tag{14}$$

where ν_t is the turbulent viscosity in m^2/s.

Turbulent medium kinetic energy:

$$k = \frac{1}{2}\sum R_{ii} = \frac{1}{2}\langle u_1'u_1' + u_2'u_2' + u_3'u_3' \rangle . \tag{15}$$

Using these terms, the definition of the R_{ij} value is simplified to the calculation of the turbulent viscosity. However, turbulent viscosity depends on flow and not on the medium. The turbulent viscosity after the dimension analysis is:

$$\nu_t = \frac{\mu_t}{\rho} = C_\mu \frac{k^2}{\varepsilon} . \tag{16}$$

With the *k-ε turbulence model* it becomes possible to manage turbulent effects as a transport equation. It is an important advantage that numerical methods can handle transport equations and thus, besides the known transport (diffusion) processes, turbulence can be modelled as well.

Yet, the *k-ε turbulence model* does not provide satisfactory accuracy in the case of flows in the wall region. Therefore, the application of wall law cannot be avoided, adding more equations to the equation system.

RESULTS

Figure 4 and 5 show the temperature and velocity distributions and the temperature flow lines in the room.
It can be seen on Figure 4 that the air coming through the air inlet is heated up quickly and the temperature in the occupied zone is between 20 and 22 °C. Figure 5 shows that in the occupied zone velocities are far below 0.1 m/s.

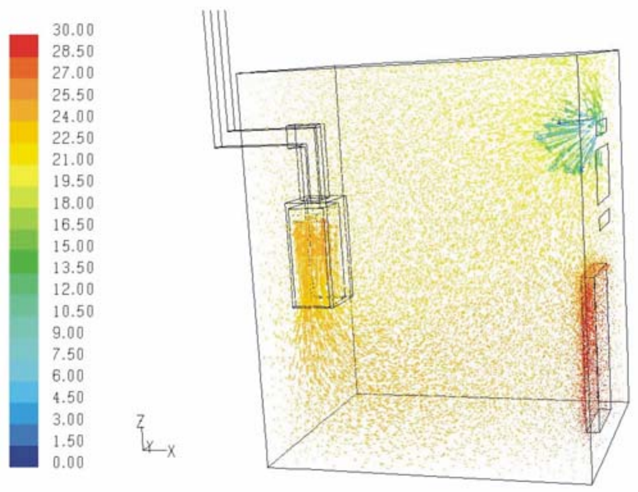

Figure 4. Temperature distribution in the room

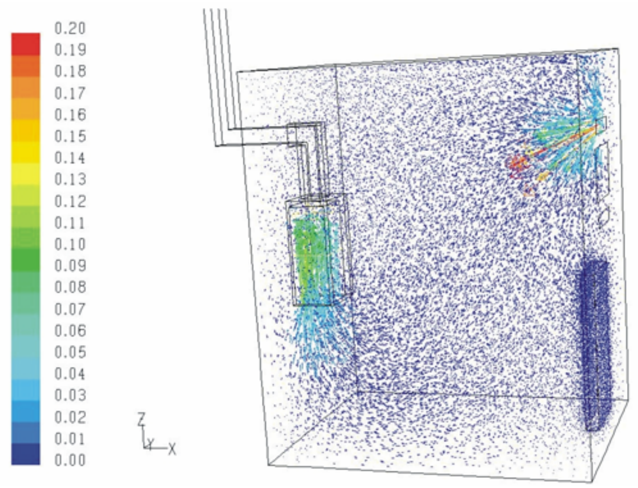

Figure 5. Velocity distribution in the room

The numerical data from the CFD simulation are collected in Table 1.

Table 1. Results of the modelling for winter case

Nominal heat output of the appliance, kW	12	24	28	36
Mass flow of the flue gas, kg/h	22.3	49.3	75.6	108
Temperature of the flue gas leaving the appliance, °C	101	121	122	118
Temperature of the flue gas in the beginning of the chimney's indoor section, °C	88	104	112	108
Temperature of the flue gas in the beginning of the chimney's outdoor section, °C	70	75	89	82
Temperature of the flue gas at the outlet point, °C	60	62	84	71
Air flow rate, m^3/h	23	45	53	73.3
Pressure difference by the air-inlet, Pa	3.9	4.4	4.5	4.5
Average air temperature of the room, °C	24.1	23.6	23.5	23.6
Average air velocity in the room, m/s	<0.1	<0.1	<0.1	<0.1

DISCUSSION

Based on the data introduced in the table and on the distributions indicated in the figures the following can be stated:

- the average air temperature in the occupied zone is adequate (24 °C) and uniform,
- the relative air velocity in the occupied zone is far below 0.1 m/s,
- the air velocity in the occupied zone has a uniform distribution,
- 30 cm from the air-inlet the entering fresh air has a temperature that hardly differs from the average air temperature of the room,
- it is reasonable to place a heat-transfer appliance (accurately sized radiator) under the air-inlet so that the cool zone of the air-inlet can be reduced.

The investigation about appliances' air supply and the publication of the design aiding results is of importance as in Hungary numerous B_{11} type appliances with atmospheric burner and draught hood, connected to a chimney with natural draught operate.

SUMMARY

Field surveys on thermal environment were carried out at Station T which is a large station in Tokyo, mainly in summer 2006. It appeared that the thermal environment in concourse is closely related to passenger's comfort. As the result of surveys, it was clarified that thermal environment in the concourse was not acceptable enough for passengers. At most place and time, thermal environment in concourse was easily over 32°C in SET*, upper limit of acceptable range for passengers. In addition, thermal environment in the concourse was widely distributed. But passengers stayed in relatively uncomfortable place for the reasons of meeting people. For improving thermal environment and comfort in the station, it should be considered that the detail of thermal environment and occupancy characteristic of passengers.

INTRODUCTION

Most of the people in Japan use railway stations everyday to commute to their office or school. Since the stations can be easily crowded especially in a rush-hour, it has been designed for smooth transit. On the other hand, railway stations lately started to draw attentions as commercial opportunities. Not only small shops but also big shopping malls are introduced, which includes café, restaurant, bookstore, boutique, travel agency and so on. Therefore the usage of stations is being changed for the passenger to stay longer.
Therefore the comfort in stations is getting more important. However its thermal environment is not comfortable enough especially in summer. As a result of a previous field survey in several stations in 2004[1], air temperature and radiant temperature of the concourse was generally higher than outdoors and air velocity in concourse was distributed on lower range. From these facts, thermal environment of summer is especially a problem in concourse. In addition, as a result of questionnaire to passengers about thermal sensation and acceptability, the upper limit of acceptable range for passengers was found to be 32°C in SET*. In order to solve this situation, introducing an air-conditioning system for the whole station-building would cause a huge energy loss due to the open structure of stations. Being both comfort and less energy consumption required, more studies for the current environment of the station and its solution are necessary.
In this research we investigated about Station T, which has a plan to introduce a shopping mall inside next year, whereas lots of compliment exists for the hot environment in summer. Field survey on thermal environment and questionnaire survey were conducted mainly in summer, and thermal environment and comfort was quantitatively evaluated.

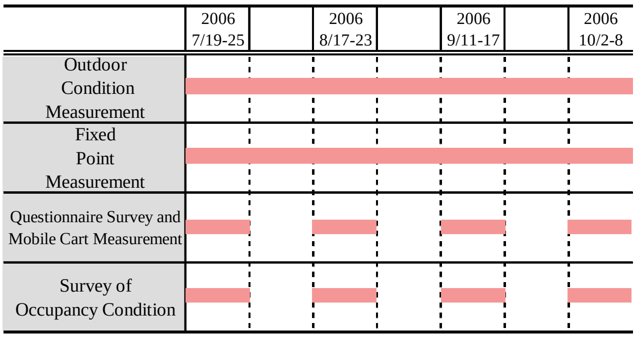
METHODS

Field surveys were carried out during July to October 2006 in Station T. Descriptions of the station are given in Table 1. Station T is located in Tokyo and has a large-scale with 4800m^2 floor area. There are many skylights made of polycarbonate in concourse. Field survey mainly consists of outdoor condition measurement, fixed point measurement, questionnaire survey with mobile cart measurement, and survey of occupancy condition. Mobile cart measurement was conducted for measuring thermal environment around passenger answering questionnaire. Survey periods of each item are given in Table 2 and measuring instruments are shown in Figure 1.

Table 1. Description of the station

Station Name	Tachikawa
Photo	
Daily Passengers	148,000
Concorse Type	Bridge
Number of Platforms	4
Floor Area	4800m^2

Table 2. Survey periods



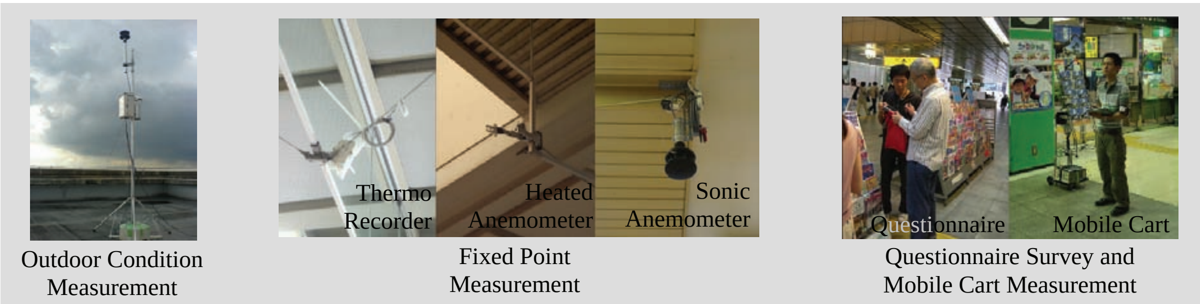


Figure 1. Measurement instruments

Thermal Environment Measurement: Measurement items of outdoor condition measurement, fixed point measurement and mobile cart measurement are given in Table 3. Since Station T have large floor area, it was thought that thermal environment in the concourse have a wide distribution. Therefore many measuring instruments were set up evenly for fixed point measurement. Floor plan of Station T and measurement points is shown in Figure 2.

Table 3. Measurement items

	Measurement Items	Instruments
Outdoor Condition Measurement	Air Temperature	Thermo Recorder
	Humidity	Thermo Recorder
	Air Velocity	Sonic Anemometer
	Air Direction	Sonic Anemometer
	Solar Radiation	Solar meter
Fixed Point Measurement (Height=3m)	Air Temperature	Thermo Recorder
	Humidity	Thermo Recorder
	Air Velocity	Heated Anemometer
	Air Direction	Sonic Anemometer
Mobile Cart Measurement (Height=1.1m)	Air Temperature	C-C Thermocouples
	Humidity	Thermo Recorder
	Air Velocity	Heated Anemometer
	Total Radiation	Directional Radiometer (0.3-40μm)
	Solar Radiation	Silicon Pyranometer (0.4-1.1μm)

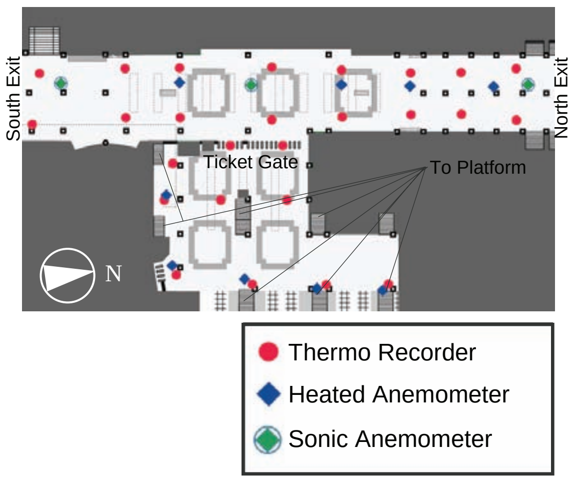

Figure 2. Measurement points

Survey of the Passengers: Questionnaire survey and survey of stay place were carried out in concentrated survey period. Items of questionnaire survey are given in Table 4. 1,960 answers were collected throughout the survey. Survey of stay place was conducted every hour in 10 to 18 o'clock. In this research, occupants plotted on the sheet of floor plan.

Table 4. Items of questionnaire survey

Background	Sex, Age, Occupation, Items of clothing , Stay place , Purpose of stay
Psychological Responses (Scales)	General Comfort (+3 Very comfortable / +2 Comfortable / +1 Slightly comfortable / 0 Neutral / -1 Slightly uncomfortable / -2 Uncomfortable / -3 Very uncomfortable)
	Thermal Sensation (+3 Hot / +2 Warm / +1 Slightly warm / 0 Neutral / -1 Slightly cool /-2 Cool / -3
	Thermal Preference (Cooler - As it is - Warmer)
	Acceptability (Acceptable - Not acceptable)

RESULTS

Weather Condition

Daily mean temperature in measurement period is plotted in Figure 3, together with the average year temperature variation. In 2006, although the end of the rainy season was delayed, outdoor temperature in summer tended to be higher than that of average year. Since outdoor temperature in concentrated survey period of august was especially high, result of field surveys of this period are mainly shown afterwards.

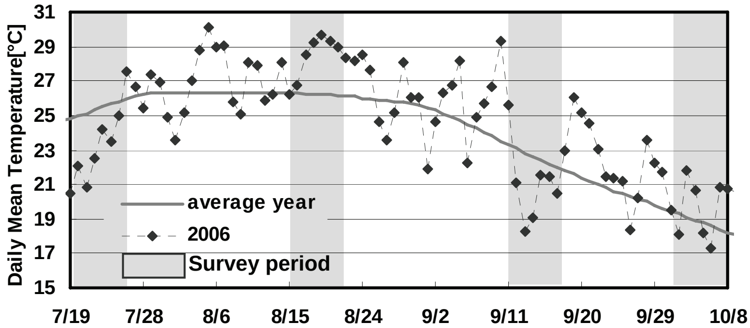

Figure 3. Daily outdoor temperature

Temporal Change of Thermal Environment in Concourse

Temporal change of air temperature and radiant temperature are shown here. It paid attention to the difference between indoor and outdoor environment.

a) Air Temperature: Daily temporal change of air temperature in the concourse is plotted in Figure 4, together with external air temperature and solar radiation. In sunny day of august, average air temperature of concourse was almost equal to that of outdoor at noon. But difference of indoor and outdoor temperature grew bigger in the night to early morning. In cloudy day, air temperature in the concourse was over 2 degrees higher than that of outdoor through almost a day.

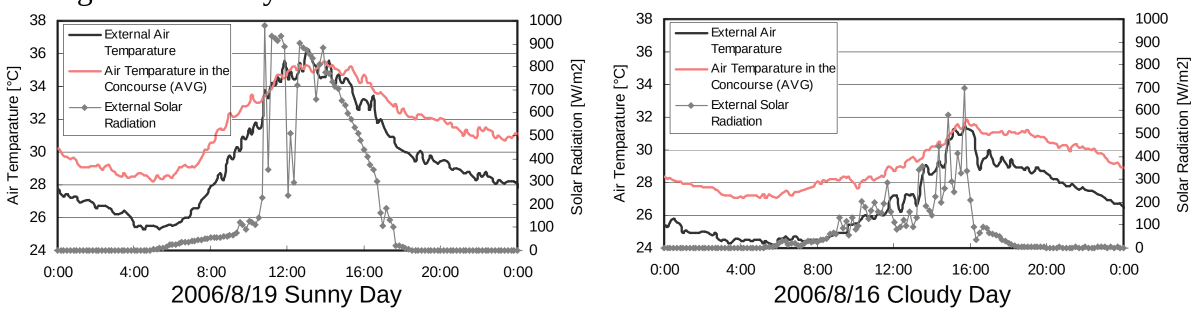

Figure 4. Temporal change of air temperature

b) Radiant Temperature: Mean radiant temperature (MRT) of the concourse and the platform is plotted against air temperature in Figure 5 and thermal images in the concourse are shown Figure 6. In this case, weighted-mean radiation of six directions was used as MRT. MRT was generally 2 degrees higher than air temperature in the concourse. According to thermal image of daytime, the surface temperature in the vicinity of skylights reached 42°C. In the evening, the surface temperature of skylights and ceiling was still higher than air temperature. It is thought that these high surface temperatures related to high MRT in the concourse.

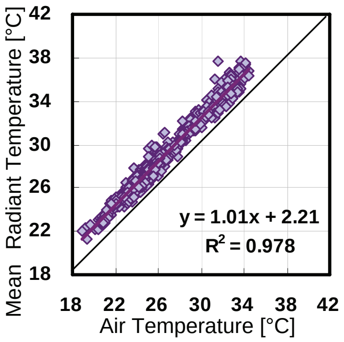

Figure 5. Air temperature and mean radiant temperature

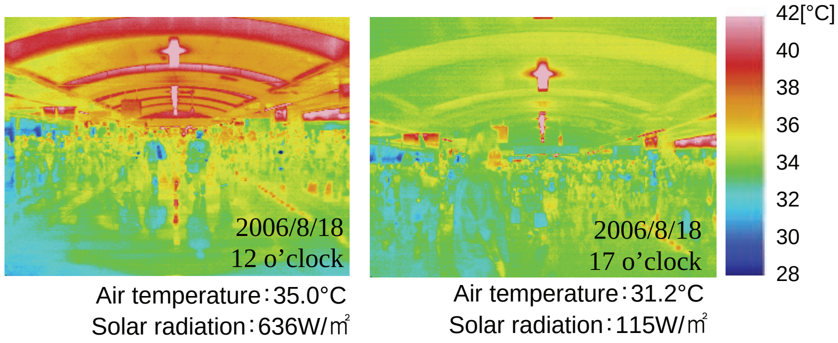

Figure 6. Thermal images

Distribution of Thermal Environment in Concourse

Spatial distribution of thermal environment became clear from the result of thermal environment measurement in each measurement points. Distribution of air temperature, air velocity and SET* shown in this thesis, because tendency of these distribution was especially clear.

a) Air Temperature: Distribution of air temperature in the concourse is shown in Figure 7. At 12 o'clock, air temperature exceeded 33°C in almost all places of the concourse. At 18 o'clock, air temperature in the concourse decreased overall. But it was still higher than that of outdoor and reached 35°C in the hottest place.

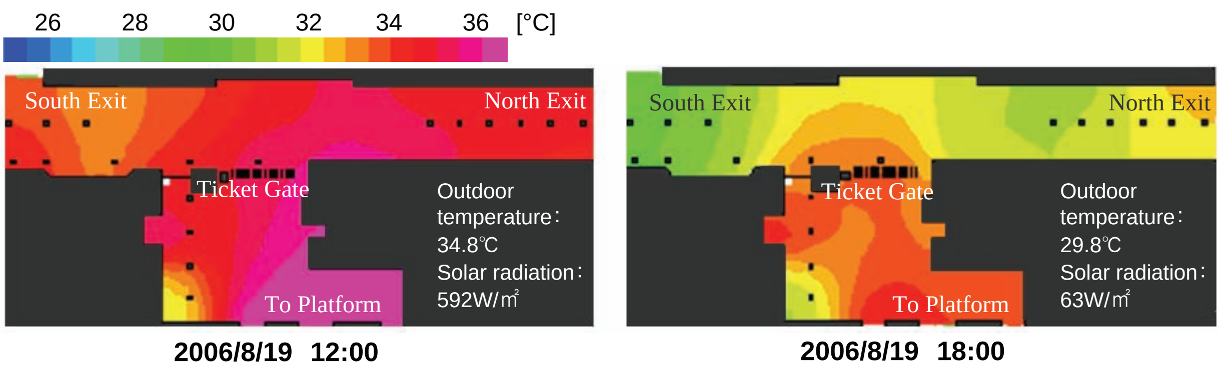

Figure 7. Distribution of air temperature

b) Air Velocity: Air velocity in the concourse was generally distributed in lower level, regardless of external air velocity. Distribution of air velocity in the concourse is shown in Figure 8. Since the external wind blew from the south at either time zone, air velocity in the vicinity of the south exit was comparatively large. But the wind from south didn't reach the center of the concourse. Therefore air velocity around the ticket gate was too small.

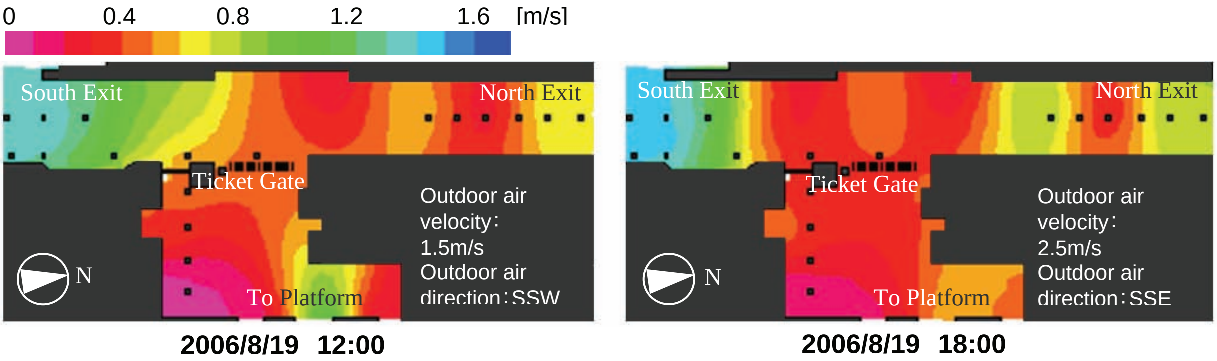

Figure 8. Distribution of air velocity

c) SET*: SET* in the concourse was calculated from measured items (air temperature, humidity, radiant temperature and air velocity) and assumptive clothing insulation (0.5clo) and metabolic rate (1.4met). Distribution of SET* in the concourse is shown in Figure 9. It showed the tendency to look like Distribution of air temperature. SET* in the vicinity of the south exit was low comparatively. It is thought that this is because the influence of the air velocity. According to the past investigation, the acceptability range for passengers was found to be 32°C or less in SET*. But in such a sunny day, it found that SET* in concourse was over 32°C in much place even in the evening.

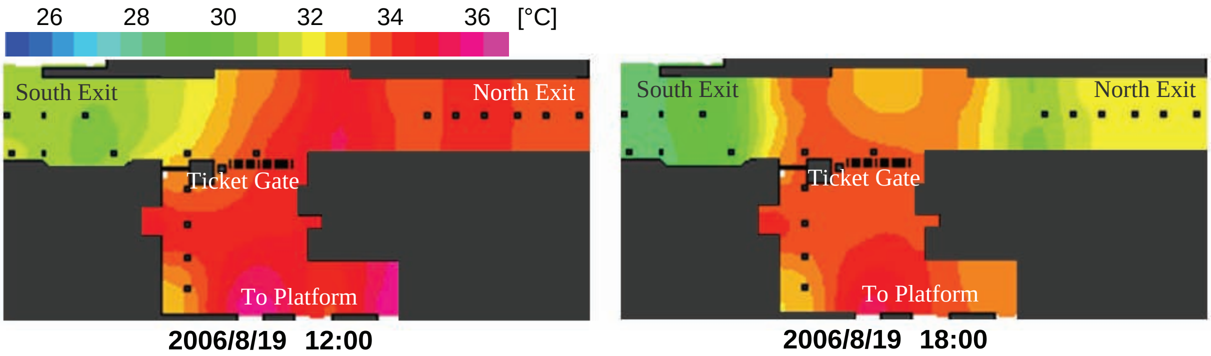

Figure 9. Distribution of SET*

Occupancy Condition

Characteristic of occupants and its occupancy in Station T are shown here.

a) Attribution of Occupants: Attributions of staying passenger are shown in Figure 10. These are from answer of questionnaire to passenger. Total number of answers was 1960, and answers were collected from various people impartially. The ratio of female was a little larger than that of male. Seeing according to the age, the ratio below 20's was large. But a certain amount of answer was collected from each age.

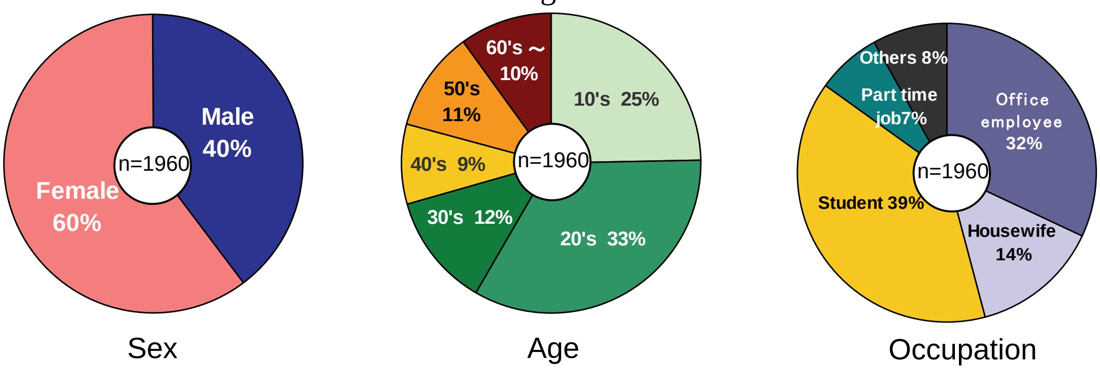

Figure 10. Attribution of occupants

b) Number of Occupants: Number of occupants in concourse is shown in Figure 11. These are from the result of survey of stay place. The transition pattern of number of occupants was almost constant regardless of the month. It appears that numbers of occupants grows most in the evenings, when number of passenger was most.

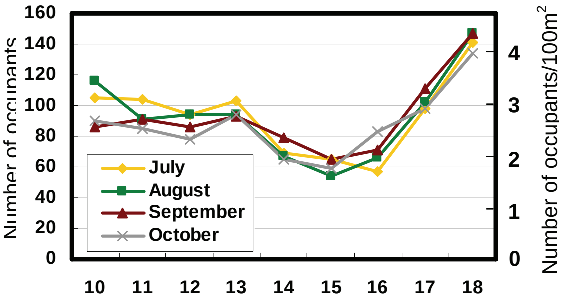

Figure 11. Number of occupants

c) Stay Place and Purpose of Passengers: Results of survey of stay place are shown in Figure 12. The tendency is clearly seen in it. The number of occupants was large at the center of the passage and near the wall. It is thought that passengers willingly stayed there for meeting people. Results of questionnaire about stay are shown in Figure 13. Much of passengers answered yes about question of “Do you wait time?” In addition, the question of “Why are you here?” was set up for the passengers who answered yes about the previous question.

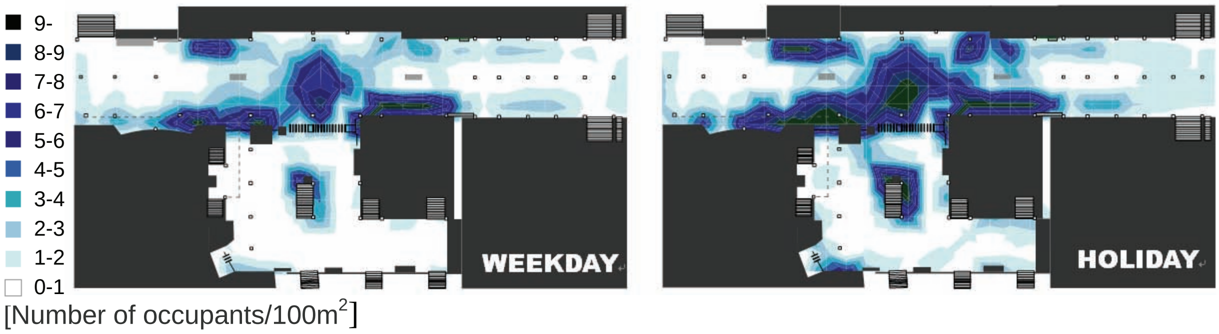

Figure 12. Stay place of occupants

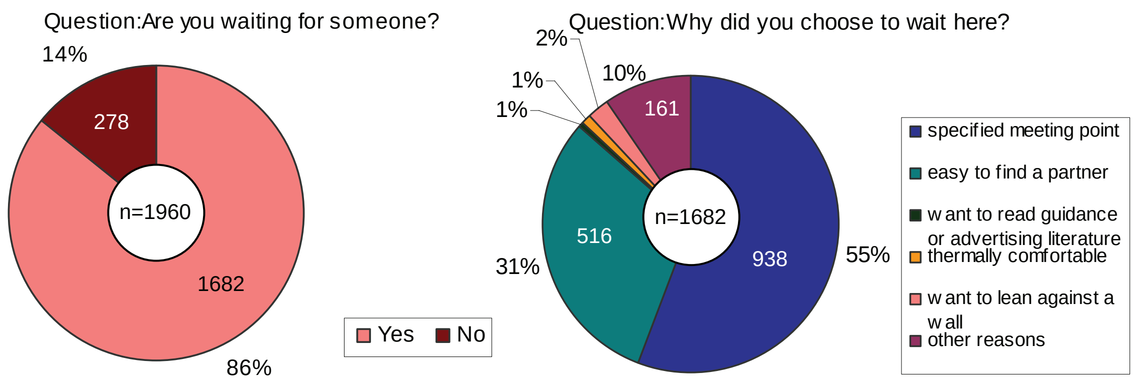

Figure 13. Purpose of occupancy

As a result of that, many of passengers answered “Specified” or “Easy to find partner”. It can be said that these people couldn’t change stay place easily regardless of comfort. On the other hand, a little number of passengers answered “cool, comfortable” or “want to lean over”. In a word, it is found to be that passengers had not decided the stay place for the comfort.

Thermal Comfort Condition and Adaptation

Thermal comfort condition and Adaptation of occupants in Station T are shown here, including comparison with the result of past investigation in 2004.

a) Air Temperature and Clothing Insulation: Clothing insulation of passengers who answered questionnaire is shown in Figure 14. The data set of air temperature in concourse by the interval of 1 was averaged, and corresponding clothing insulation was averaged. Circle shown in Figure 14 describes the number of corresponding subjects. Clothing insulation increased due to the effect of high temperature. When air temperature was over 31°C, average clothing insulation became constant about 0.5clo.

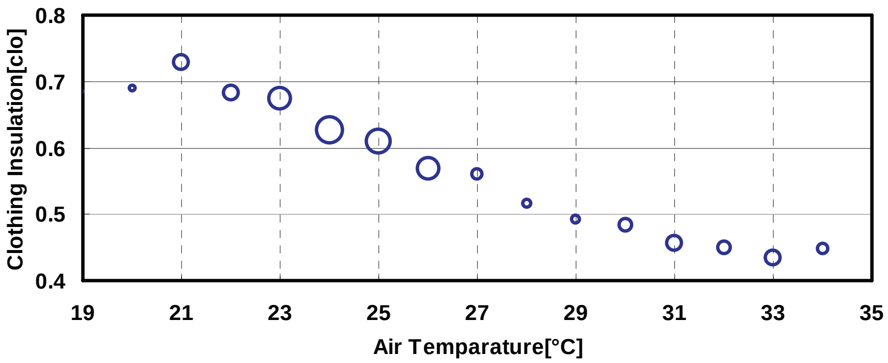

Figure 14. Clothing insulation of passengers

b) Thermal Sensation: The correlation about thermal sensation and percentage of uncomfortable or percentage of "Not acceptable" was shown in Figure 15. The data set of thermal sensation by the interval of 1 is from answer of questionnaire survey. Circle shown in Figure 15 describes the number of corresponding subjects. In figure of thermal sensation and percentage of uncomfortable, uncomfortable means answer of "Slightly uncomfortable", "Uncomfortable" and "Very uncomfortable". The clearest correlation was seen in this figure. Percentage of Uncomfortable increased with the rising of thermal sensation. The correlation appeared in the other figure. When thermal sensation is +3 (Hot), percentages of "Not accepted" was obviously large. In this way, it is thought that the thermal environment in concourse is closely related to passenger's comfort.

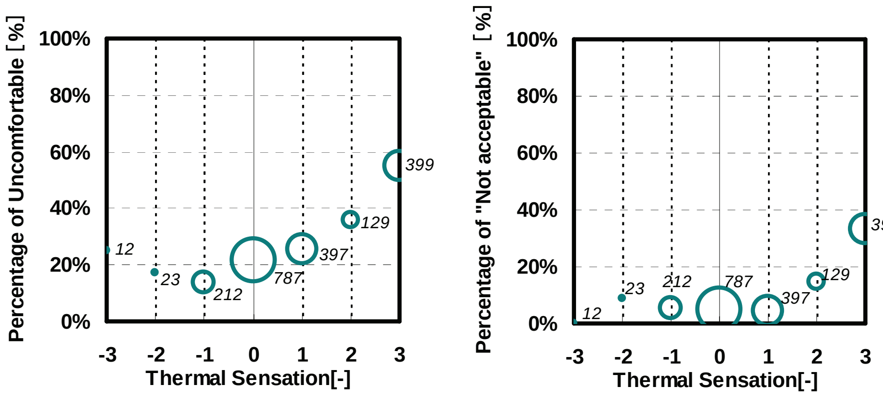

Figure 15. Thermal sensation

c) SET* and Thermal Comfort Condition: The correlation about SET* in concourse and percentage of vote about thermal sensation is shown in Figure 16. SET* was calculated assuming the metabolic rate of 1.4met for all passenger. In this figure, "Thermally Uncomfortable" means voting ±2, ±3 in thermal sensation and voting -1,-2,-3 in general comfort. "Thermally Unacceptable" means voting ±2, ±3 in thermal sensation and answering "Not acceptable" in acceptability. Two lines in Figure 16 drawn by result of past investigation in 2004 and its probit analysis. The data set of SET* in concourse by the interval of 1 was averaged, and corresponding percentage of vote averaged. Circle shown in Figure 5 describes the number of corresponding percentage of vote. The lines and circles showed clear correlation. From these results, there is a possibility of setting a constant standard about thermal environment and comfort in train station. When considering the result in the preceding clause, thermal environment in the concourse was not acceptable enough for passengers.

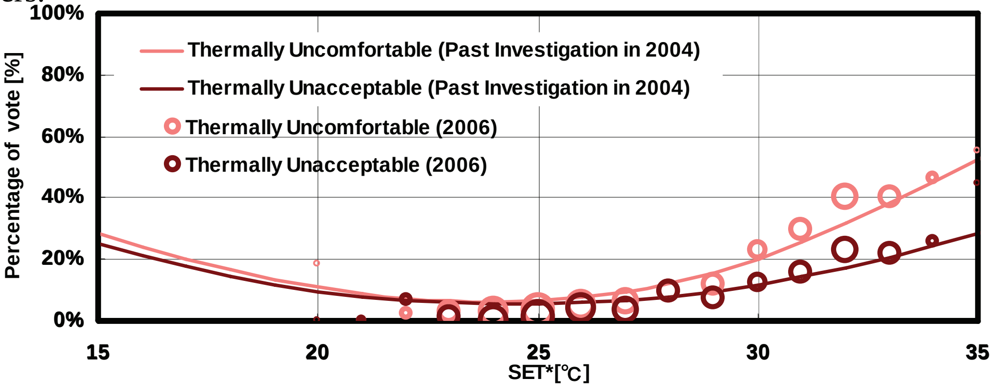

Figure 16. SET* and thermal condition

It is understood that there are the clear correlation with thermal environment and comfort from these results. In addition, contradiction was not seen between result in 2006 and past investigation. So these results can be used as index of thermal comfort in train stations. But temporal change of environment and occupants, together with spatial distribution of thermal environment must be considered when thinking of the improvement of thermal environment.

DISCUSSION

As a result of field survey, thermal environment in the concourse of Station T have many problems. The environment in the Station T was generally worse than outdoors due to the higher air temperature and radiant temperature, and lower air velocity. High sensible temperature over 32 °C in SET* was recorded often in summer, when lots of people voted that they couldn’t tolerate thermal environment. In sunny day of summer, it found that SET* in concourse was over 32°C in much place even in the evening. Moreover, comparing Figure 9 with Figure 12, it was clarified that passengers stayed in the place where the environment is comparatively bad. Considering results of questionnaire about stay, passengers couldn’t change stay place liberally. It is clear showed in Figure 4 that the difference of air temperature inside and outside of the station was depending on time. At time zone when this difference is large, thermal environment in concourse could be made improvement by means of bringing in outdoor air. When the external temperature is also high, it is possible to use spot cooling system in stay place of passengers. It is thought that the thermal environment in concourse is closely related to passenger’s comfort, so it should be considered that the detail of thermal environment and occupancy condition of passengers to improve thermal environment and comfort in railway station.

Smoke removal in uni-storey smoke control system

Bogdan Mizieliński and Jacek Hendiger

Institute of Heating and Ventilation, Warsaw University of Technology, Poland

ABSTRACT

There is pronounced interest of engineers in new systems for storey smoke control system. The operational principle of this system is based on independent smoke removal from each storey. Independent ducts with fans and outlets are built for each floor of the building. For this approach it is important to safety remove smoke from the building. One of the proposed approaches is to use nozzle type outlets characterized with high flow and velocity to evacuate combustion products from the building. At the same time, due to system safety requirements it is crucial to dispose combustion products at a distance from building walls. The research interest in smoke removal systems at the Warsaw University of Technology was recently oriented for testing smoke outlets. The primary focus was on analysis of the performance of these elements taking into account flows, diameters and throws with respects to those typically applied in smoke removal systems. Therefore, in contrary to typical diffusers tests our studies included long-throw jets. The air streams generated by ventilation nozzles working as torch outlets were examined in the spacious (high cubic capacity) hall using specially prepared test site. Obtained results were used as a basis for evaluation of effectiveness of smoke removal for the smoke removal system operation.

INTRODUCTION

Uni-storey smoke control system can operate interdentally from other systems or in connection with building ventilation system. Modern offices spaces are built in the form of open space, that is arranged by user according to their needs. In buildings like this smoke exhaust are located in corridors. Smoke evacuation system is mainly assuring smoke removal towards staircase.

Compensating air, due to overpressure in the staircase, is flowing from the staircase, and then from the smoke removal grilles located beneath the corridor ceilings. The number of smoke removal grilles used is dependent on corridor length and shape; however, it should be sufficient to efficiently remove smoke in the event of fire in any of the rooms accessible from the corridor. Uni-storey smoke control system is especially attractive arrangement for buildings with high storey area.

The major advantages of uni-storey smoke control system are:

- individual smoke removal system for every storey guarantees better tightness of each level,
- there is no connection between ductworks of smoke control system of proximate storeys,
- the system can be limited to selected storeys only (important from the fire protection point of view)

- the system cost can be reduced, because smaller number of fire dampers and other elements are required,
- reduced inertia of system, due to shorter distance between the exhaust element and the smoke control fan,
- system is more flexible and easy to control,
- the exhaust ventilation ducts of air-conditioning system can be used as a part of smoke control system provided that the elements of installation are resistant to high temperature.

The new idea of smoke control system has a lot of advantages, but also disadvantages have to be considered. The major disadvantages are as follows:

- the higher number of smaller smoke control fans are needed,
- if different smoke control systems are used in the same building, the proper connection between them have to be assured,
- the precise assessment of removal conditions is required, followed by careful choice of type and localisation of exhaust outlets,
- the requirements for supply airflow: volume and localization need to be specified.

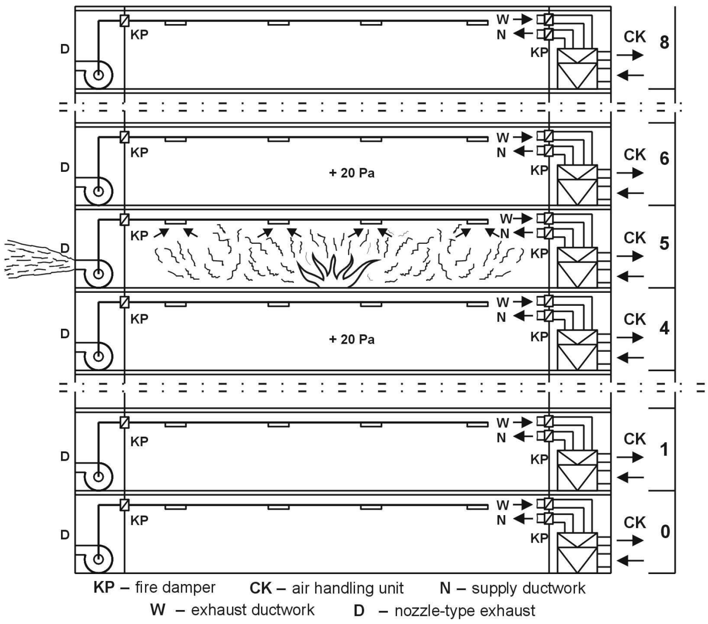

Fig. 1. Uni-storey smoke control system

SMOKE OUTLETS

Smoke control fans can be situated in relatively small room. However, it is required that the minimal distances from the walls are observed as to provide necessary access for assembly and maintenance, it also required that enough room for smoke removal ducts is reserved. Fans serving single storey are relatively small, therefore shock absorption and building protection from vibration transmission is it more easy.

One of the key problems to be solved is safe and effective smoke evacuation from the building. The choice of outlet type used is dependent on architectural building layout, position in surrounding area and general, typical, weather conditions, especially wind direction.

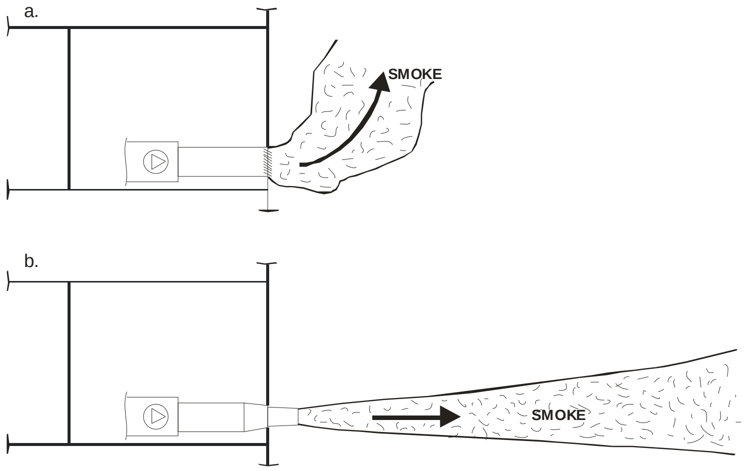

Fig. 2. Smoke outlets. a) shutter type outlet, b) long throw jet type outlet.

Using classical type wall outlet, smoke is discharged at a relatively small distance from the building, with low velocity. The localization of outlet has principal effect on its efficiency and operational safety. Optimal localization of the outlet is at leeward side of the building as well as at the outer wall, where is no window. In practice, fulfilling all above conditions is quite difficult. Therefore, a convenient solution is to locate smoke outlet either at the wall where is no windows or at the wall with windows that cannot be opened, away from other buildings. The influence of wind should be considered taking into account predominant wind direction in the considered area. Inappropriate localization of wall outlet brings a risk of inefficient smoke removal and in consequence can lead to smoke introduction to above storey.

In order to minimize the effect of wind direction and to make the system less sensitive to localization of the outlet, nozzle type outlets are used. The latter assures high rate of smoke removal. The air flow velocity (at outlet plane) achieved during tests conducted at the Institute of Heating and Ventilation, Warsaw University of Technology using outlets of diameter ϕ300 and ϕ400 mm were within the range from 8 to 16 m/s.

TESTS

As mentioned above the typical elements for storey smoke removal system is nozzle type wall outlets, used to evacuate combustion products from the building. The tests conducted were focused on properties these type nozzles in terms of volumes and diameters and on achieving appropriate smoke evacuation ranges for storey smoke removal system. Taking safety of the system into consideration it is important to discharge combustion products at the distance from the building walls. Therefore, in contrary to typical ventilation system elements, these tests were using long throw jets. The air streams extracted trough nozzles, working as torch outlets were examined. The measurements were conducted in a spacious, high cubic capacity, test-room using specially prepared test stand. The test room dimensions a=132m, b=32m, h=7m were appropriate to obtain long throw air jets, air tightness requirements were fulfilled, too. The natural air movement in the room was negligible. Two nozzles of efficiency sufficient for studied smoke extraction system were tested. The aim of the study was to characterize the reduction in axial velocity of air stream as well as to determine the throw of streams, for which the maximal airflow velocity was reduced to about 0.2m/s.

a) b)
Fig. 3. Test room: a) general view, b) measurements setup.

METHODS

The measurement set-up (Fig. 4.) included air supply system consisting of: fan equipped with speed control element, damper, measuring duct with measuring orifice, expanding box as well as multipoint anemometric system for air velocity measurement. Expanding box was raised to obtain air streams not disturbed by the building barriers. Ventilation nozzles used of diameter 300 and 400mm were fulfilling criteria for geometrically similar nozzles. The measuring system was composed of six thermoanemometric probes with transducers mounted on a vertical measuring stand, 5 m high, and data recording system. Probes used allowed us to measure the air streams within the range from 0.05 to 10 m/s and to compensate temperature with in the range from –10 to +50 ^{o}C. The air flow volume was determined using orifice connected to micomanometer. The characteristic of the reduction in axial velocity of air stream, for different air flow volumes of involved elements as well as characteristic of the jet throw was obtained. During tests the airflow velocities at cross-section of the stream were determined for two air flow volumes for each element (3000m^3/h, 4000m^3/h). The measuring stand with probes was located at the geometric axis of the air stream, at defined distance from the outlet. The axis of the air stream was determined by air flow visualization and trial measurements orientated to find the best position of the measuring stand, resulting in maximal air flow velocities at the define cross section.

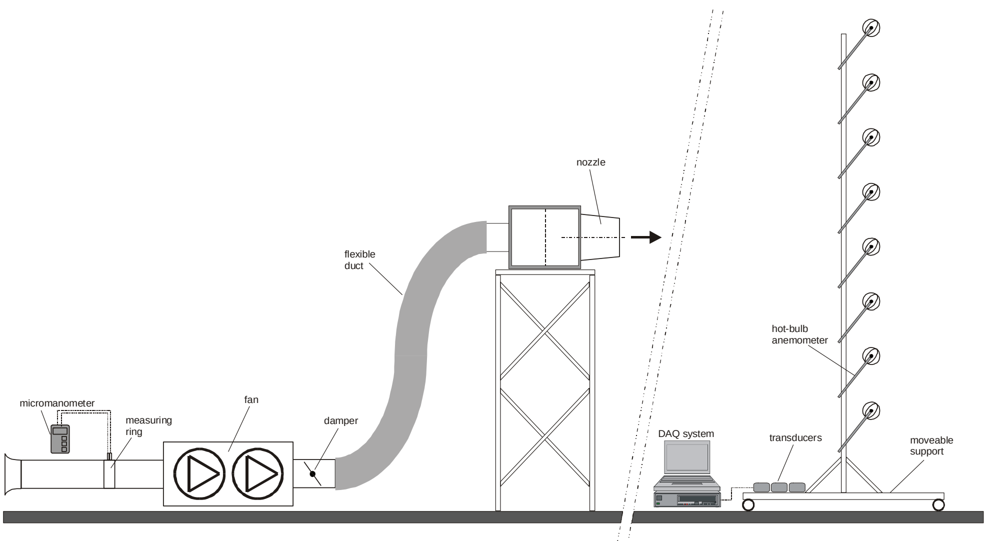

Fig. 4. Measurement set-up

RESULTS

The profiles of air flow velocities and ranges of air streams were determined. The results - profiles of air flow velocities at cross-sections located at certain distance x [m] from tested nozzle are presented. The profiles determined by airflow velocities were approximated, Fig 5 and 6.

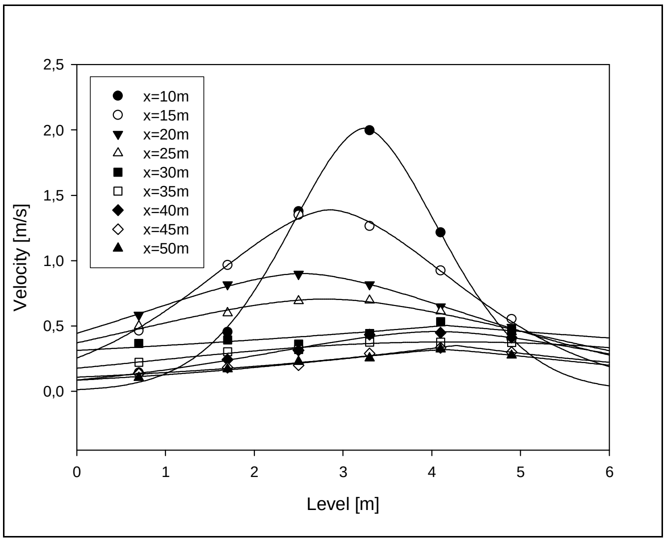

Fig. 5. Air flow velocity profiles, nozzle diameter 300mm, V=3000m^3/h

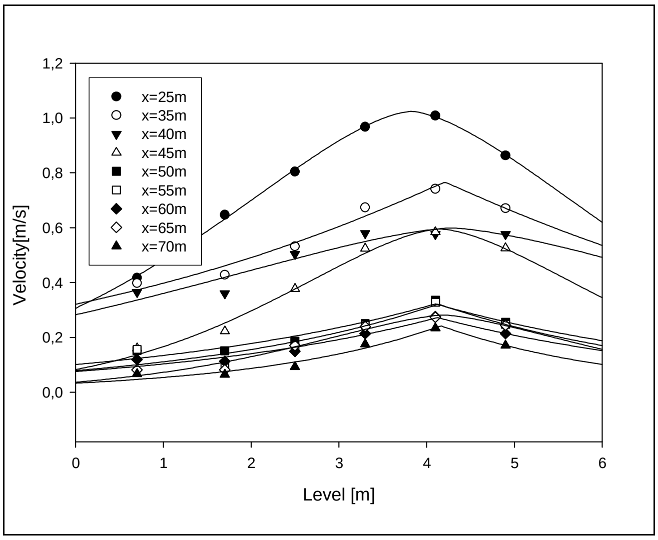

Fig. 6. Air flow velocity profiles, nozzle diameter 300mm, V=4000m^3/h

Fig 7 presents the airflow distribution at the stream axis obtained for the nozzle of diameter ϕ300mm. The initial airflow velocity was equal to 12.2 m/s for a 3000m^3/h stream. Results presented in Fig 7 show that velocity 0.4m/s is reached at the distance close to 40m. At the distance 25m the velocity is equal to 0.8m/s, this value is considered as enough resistant for disturbances caused by average wind speed. The distance from external wall is enough to achieve smoke dispersion. In the same time smoke stream is significantly thinned, due to high level of induction leading to suction of surrounding air and to increase of stream volume.

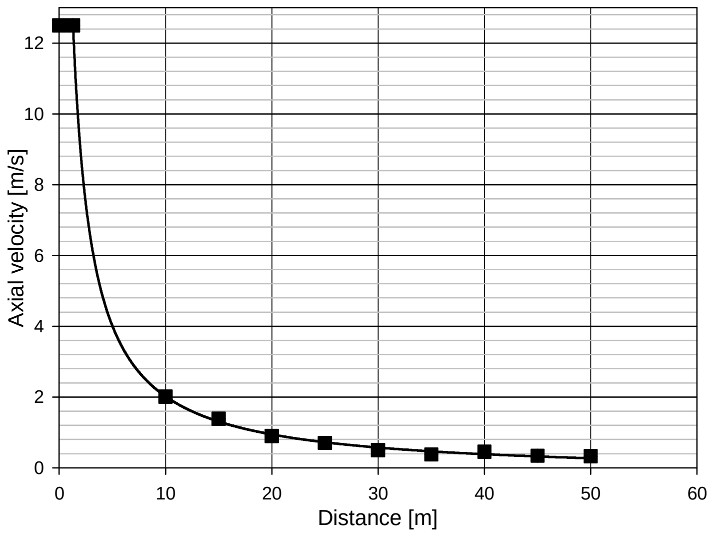

Fig.7. The distribution of axial velocity, nozzle Ø300mm, V=3000m^3/h.

For the stream 4000m^3/h evacuated through the same outlet the air velocity at the nozzle is equal to 16 m/s and the velocity 0.4m/s in stream is reached at the distance close to 50m, Fig 8. Thus the choice of the nozzle diameter need to adjusted according to stream volume of exhausted smoke to keep the appropriate air velocity at the nozzle outlet for the surrounding environment, i.e. construction and decoration type, anticipated influence for surrounding buildings and interferences form wind.

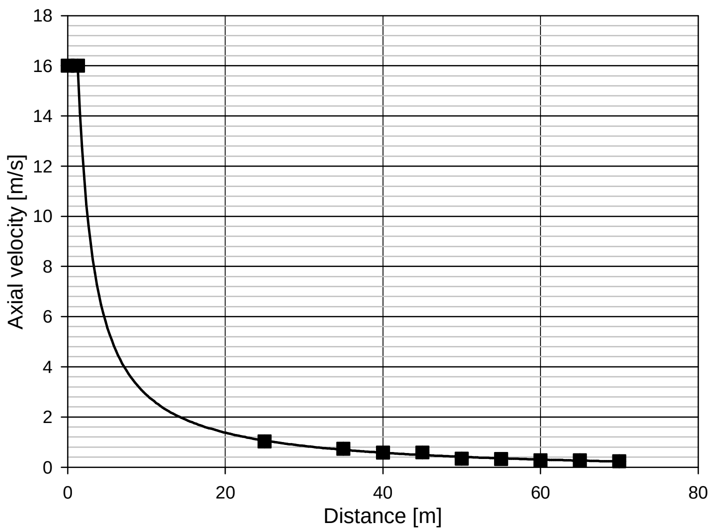

Fig. 8. The distribution of axial velocity, nozzle Ø300mm, V=4000m^3/h.

CONCLUSIONS

1. The analysis of experimental data allowed calculation of jets throws, i.e. the distances from the nozzle outlet at which the maximal air velocity is reduced to assumed limiting value of 0.4m/s. Thus defined throws for tested elements and volumes were close to 50m.

2. In order to prevent the occurrence of wind interferences, which can reduce the smoke discharge distance, the high velocities at the nozzle outlet need to be maintained.
3. Experimental data allowed us to determine the distribution of velocities at certain distance from outlet plane as profiles approximated by Gauss type function. At longer distances from the nozzle the profiles showed only minor fluctuations of air velocities at cross section.

SUMMARY

Uni-storey smoke removal system is an interesting alternative for classical approaches. In some cases this is the only possibility to evacuate smoke, especially when there is no enough room in the building for vertical ducts and central plant room. While setting the smoke removal system layout the special attention should be paid to safe removal of smoke from the building. Above presented results can help to pick up the right diameters and velocities in wall outlets of the system.

The research project concerning uni-storey smoke control systems, financed by State Committee of Science Research (project for years from 2003 to 2005) was realized in the Institute of Heating and Ventilation in Warsaw University of Technology.

ABTRACT

The numerical and experimental analysis was carried out to study the thermal-hydraulic characteristics in elliptical finned-tube heat exchanger under the dry and air/water spray cooled system. Three kinds of major/minor axis ratios (2.5、2.8 and 3) were examined for the elliptic finned-tube heat exchangers and the results were also compared with the corresponding circular finned-tube having the same perimeter. The numerical results for the pressure and heat transfer coefficient at various inlet frontal velocities (1~5 m/s) are shown and compared with the available experimental data. The numerical results indicated that the pressure drop of circular finned-tube heat exchanger is 3 times that of the elliptic finned-tube heat exchanger, while the heat transfer coefficient of the circular finned-tube is 1.51 times that of the elliptic finned-tube. The heat transfer coefficient per unit of pressure drop for elliptic finned-tube is 1.6-2.5 times of circular finned-tube. When the air/water spray system is applied, the heat transfer could increase up to more than 30%

Keywords：elliptic finned-tube heat exchanger, mist flow , thermal-hydraulic characteristics .

INTRODUCTION

Numerous designs for industrial heat exchangers involving a bank of tubes in a fluid crossflow were applied. Among many types of finned-tube heat exchangers, those constructed of circular and elliptic fins have been used in many industries. The advantage to use elliptic finned-tube is that it can provide a lower pressure drop when the fluid flows around the tube banks. But the disadvantage is that elliptic tubes are generally restricted to low-pressure applications on the tube side. There have been a number of studies [1-5] on the characteristics of the flow field and heat transfer adjacent to a bare elliptic tube. The dry coil correlations for a staggered circular tube layout are the Briggs and Young [6] correlation for heat transfer, and the Robinson and Briggs [7] correlation for pressure drop. The convective heat and mass transfer coefficient and friction factor for circular finned-tube heat exchanger under dry and wet conditions were reported by Idem et al. [8, 9].

For the elliptic finned-tube heat exchanger, Brauer [10] was the first author to study the thermal-characteristics with an axis ratio of 1.77 under dry condition. Dunwoody [11] had discussed the variation of local Nusselt number with different axis ratio under laminar flow and constant wall temperature. In order to enhance the heat transfer, the dry/wet schemes were wildly used in many industrial applications. MaClaine-Cross and Bank [12, 13] analyzed the heat and mass transfer characteristics in a wet surface of the heat exchangers. Finlay and McMillan [14] obtained the data with the tube bank, and reported the significant effect of the water spray in heat transfer enhancement. The formula for the design of mist cooled heat exchangers on the assumption that the tubes are fully wet was proposed by Oshima et al. [15].

In this study, the 3-D thermal hydraulic simulation for the elliptic finned-tube heat exchangers was developed. The effect of heat transfer and pressure drop coefficients due to different axis ratio of elliptic fins was also discussed. A water spray system was established for the elliptic finned-tube heat exchanger and the spray effect on the thermal hydraulic characteristics were also discussed.

EXPERIMENTAL SETUP AND DATA REDUCTION

Three types of finned-tube configurations, as shown in Figure 1, were tested in the present study. The physical model and the configuration were shown in Figure2 and Figure 3. Their detail geometric parameters are tabulated in Table 1. The experiments were conducted in an induced open wind tunnel as shown in Figure 4. This setup was based on the ASHRAE 41.2 standard [16]. The air flow was driven by a 3.73-kW (5-hp) centrifugal fan with an inverter to provide various inlet velocities. An air-straightened equalizer and a mixer were provided to minimize the effect of flow maldistribution. The air temperatures at the inlet and the exit zones across the test section were measured by K-type thermocouples the accuracy of which was approximately 0.2 %. The pressure of the test coil was detected by a precision YOKOGAWA differential pressure transducer, reading to 0.1Pa.

The working fluid on the tube side was hot water and the temperature of the water was controlled by a thermostat reservoir. The hot water inlet temperature was controlled at 75℃; for the spray condition, the chilled water was controlled at 20℃. Both the inlet and outlet temperature of the working fluid (water) were measured by two precalibrated RTDs (pt100). Their accuracy was within ±0.05℃. The water volumetric flow rate was measured by a magnetic volume flow meter with 0.002 L/s resolution. A data acquisition system (hybrid recorder) was used to collect and convert the entire data signals and then transmit the converted signals through a GPIB interface to the host computer for further operation. The energy balance between the air and tube side was ±5% for dry condition and ±7% for spray condition.

For spray condition, water was sprayed into the stream of air. The so-called "steady–state method" was employed in determining the heat transfer performance of the core. The water spray water system which includes water pump, air - compressor and 3 spray nozzles was introduced into the air tunnel about 0.5 m upstream of the heat-exchanger. The spray nozzles used were IKEUCHI two-fluid fan-shaped (type BIMV 8002) for small flow rate. The permitted spray rate was 1.0 to 10.2 L/hr depending on the pressure of air and water at the back of the nozzles, as shown in table 1. To obtain the average heat transfer coefficients h from the measured experimental data, the ε -NTU (effectiveness-number of transfer unit) method [17] under the cross overall counterflow with both fluids unmixed was applied.

THREE-DIMENSIONAL MATHEMATICAL ANALYSIS

Figure 3 designates the computational domain, and the coordinate system is also illustrated in the figure. The dimensionless equations for continuity, momentum, and energy may be express in tensor form as

$$\frac{\partial \overline{u_i}}{\partial x_i} = 0 \quad (1)$$

$$\frac{\partial}{\partial x_j}\rho(\overline{u_i}\,\overline{u_j}) = -\frac{\partial \overline{p}}{\partial x_i} + \frac{\partial}{\partial x_j}[\mu_{eff}(\frac{\partial \overline{u_i}}{\partial x_j} + \frac{\partial \overline{u_j}}{\partial x_i}) - \rho\overline{u_i' u_j'}] \quad (2)$$

$$\frac{\partial}{\partial x_j}\rho c_p(\overline{u_j}\,\overline{T}) = \overline{u_j}\frac{\partial \overline{p}}{\partial x_j} + \overline{u_j'}\frac{\partial \overline{p'}}{\partial x_j} + \frac{\partial}{\partial x_j}(k\frac{\partial \overline{T}}{\partial x_j} - \rho c_p\,\overline{u_j' T'}) \quad (3)$$

In this study, the k-ε turbulent model was introduced to simulate the flow field more accurately. The k-ε turbulent is shown as below

$$\frac{\partial}{\partial x_j}\left(\rho\overline{u_j}k\right) = \frac{\partial}{\partial x_j}(\frac{\mu_{eff}}{\sigma_k}\frac{\partial k}{\partial x_j}) + \rho(P_r - \varepsilon) \quad (4)$$

$$\frac{\partial}{\partial x_j}\left(\rho\overline{u_j}\varepsilon\right) = \frac{\partial}{\partial x_j}(\frac{\mu_{eff}}{\sigma_\varepsilon}\frac{\partial \varepsilon}{\partial x_j}) + \rho\frac{\varepsilon}{k}[(c_1 + c_3\frac{P_r}{\varepsilon})P_r - c_2\varepsilon] \quad (5)$$

$$P_r = \frac{\mu_t}{\rho}[2(\frac{\partial u_i}{\partial x_i})^2 + (\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i})^2 - \frac{2}{3}(\nabla u_i)^2] \quad (6)$$

Because the governing equations are elliptic in spatial coordinates, boundary conditions are required for all boundaries of the computation domain. At the up-stream boundary, located the distance as tube outside diameter from the first row tube, uniform flow velocity u_{in} and temperature T_{in} are assumed. At the down-stream end of the computational domain, the Neumann boundary condition was applied.

At the solid surface, no-slip conditions and constant temperature T_{tube} are specified. At the symmetry plane, normal velocity and the temperature variation along the normal direction is set to be zero. The local heat transfer coefficient could be expressed in dimensionless form by the Nusselt number Nu, define as

$$Nu = \frac{h \cdot H}{k} = \frac{q'' \cdot H}{k \cdot (T_w - T_b)} = (\frac{\partial(\frac{\overline{T}}{\overline{T_b}})}{\partial n})_{wall} \quad (9)$$

Where k is the thermal conductivity of the fluid. To represent the pressure drop, the friction factor f was introduced as below

$$f = \frac{p_{in} - p}{\frac{1}{2}\rho u_{in}^2} \times \frac{H}{4L} \quad (10)$$

where p_{in} is the pressure at the inlet plane.

In this study, a body-fitted coordinate system along with a multiblock system was used to generate a general curvilinear coordinates system numerically by solving Laplace equations with proper control of grid densities. A control-volume-based finite-difference formulation was used to solve the governing equations. The system of finite-difference equations were solved iteratively using the SIMPLER algorithm [18]. A gird system, as shown as Figure 5, for the elliptic finned-tube bank was adopted in the computation domain. To ensure the accuracy and validity of the numerical results, three different grid systems, 158×12×8, 190×15×10, and 228×18×12 for the elliptic finned-tube bank were tested. It was found that the relative error for the total amount of heat transfer was less than 1.2%. Iterative computations were performed on a computer with Pentium 4 1.8G CPU. Typical CPU time was 3-4 hours for each case.

RESULT AND DISCUSSION

Experimental and numerical simulations of thermal-hydraulic characteristics of three types of elliptic finned-tube heat exchangers with different fin axis ratio (3.1, 2.8, and 2.5) were presented. The pressure drop and average heat transfer coefficient of circular finned-tube heat exchanger were also being compared with the experimental and numerical results of elliptic finned-tube heat exchangers.

The pressure drops of the three different axis ratios of elliptic finned-tube heat exchangers for different values of inlet frontal velocity are shown in Figure 6. As shown in Figure 6, the value of the pressure drop increased as a parabolic curve with an increase of the frontal velocity. In general, the experimental results are 18-23% higher than the numerical results. The pressure drop of the circular finned-tube heat exchanger is 2.4 times the value of elliptic finned-tube heat exchanger with axis ratio 2.5; 2.9 times the value of elliptic finned-tube heat exchanger with axis ratio 2.8; and 3.2 times the value of elliptic finned-tube heat exchanger with axis ratio 3.1.

Figure 7 presents the variations of the average heat transfer coefficient $\bar{h}$ with the frontal velocity for the three types of finned-tube heat exchangers, respectively. Also shown in the figure for comparison is the circular finned-tube heat exchanger data. It is shown that the numerical results are 32-45% higher than the experimental results. This is probably due to the fact that the actual boundary conditions for the tube surfaces in the experiment do not occur under constant wall temperature. As shown in the figure, the average heat transfer coefficient $\bar{h}$ of the circular finned-tube is about 49% higher than the value of the elliptic finned-tube heat exchanger with axis ratio 2.5; 52% higher than the value of elliptic finned-tube heat exchanger with axis ratio 2.8; and 56% higher than the value of elliptic finned-tube heat exchanger with axis ratio 3.1.

The numerical and experimental results for the heat transfer coefficient per unit pressure drop $h/\Delta P$ versus the inlet frontal velocity are shown in Figure 8. Both the experimental and numerical predictions indicate that the $h/\Delta P$ ratio decreases with the increase of the frontal velocity, and this ratio for elliptic fined tube is about 55-150% higher than for the circular finned tube. Figure 9 shows the heat enhancement while applying the air/water spray system under different air/water ratios. As shown in the figure, when the air/water ratio are 0.15% and 0.3%, the amounts of heat transfer are 16% and 33%, respectively, higher than the dry condition for the elliptic finned tube with axis ratio 2.5; 18% and 34%, respectively, higher than the dry condition for the elliptic finned tube with axis ratio 2.8; 25% and 38%, respectively, higher than the dry condition for the elliptic finned tube with axis ratio 3.1.

CONCLUSION

Experimental and numerical predictions of the thermal-hydraulic characteristics of elliptic finned-tube heat exchangers are presented. For the dry conditions, the pressure drop of circular finned-tube heat exchanger are respectively 2.4, 2.9 and 3.2 times the values of elliptic finned-tube heat exchanger with axis ratio 2.5, 2.8 and 3.1. The average heat transfer coefficient $\bar{h}$ of circular finned-tube are respectively about 49%, 52% and 56% higher than the values of elliptic finned-tube heat exchangers with axis ratios 2.5, 2.8 and 3.1. The heat transfer coefficient per unit pressure drop $h/\Delta P$ for elliptic fined tube is about 55-150% higher than for the circular finned tube. The heat transfer could be enhanced while applying the air/water spray system. When the air/water ratio are

0.15% and 0.3%, the amounts of heat transfer are 16% and 33%, respectively, higher than the dry condition for the elliptic finned tube with axis ratio 2.5; 18% and 34%, respectively, higher than the dry condition for the elliptic finned tube with axis ratio 2.8; 25% and 38%, respectively, higher than the dry condition for the elliptic finned tube with axis ratio 3.1.

SUMMARY

This paper deals with measurements of temperature distribution of rotary heat recovery units. A special grid of thermocouples has been made to measure air temperature in equally distributed sampling points on each side of a heat recovery wheel. Air flow rates and the amount of recirculation air (leakage) were measured using a tracer gas. The results show that the temperature profile is generally dependent on both the rotational speed of the wheel and the flow rate. Measurements also show that the placement of temperature sensors in the duct can be significant, since wrong placements may lead to both faulty or non-optimized control of the units, and wrong readings of the temperature efficiency. Propitious sensor placements have been proposed.

INTRODUCTION

There are many types of air-to-air heat recovery units (HRU) which are in use in ventilation systems (see for instance Schild [1]). Rotary heat recovery exchangers are widely used, and the units are known for their high efficiency and trouble-free operation. Temperature efficiencies above 80% are not uncommon. For balanced ventilation systems, the recovered heat power can be at the same rate. Unfortunately these units are also infamous for transmission of polluted air from exhaust to supply. Due to the rotation of the device, there will always be a direct and indirect connection between exhaust and fresh supply air. Cross-contamination through rotary heat recovery units comes from two mechanisms; (1) Leakage, (2) Carryover. The former is dependent on the differential static pressure across the wheel, and the placement of supply and exhaust fans may affect its value significantly. The latter (carryover) occurs as a result of air being entrained within the wheel volume. Contaminated air is then carried into the other, clean air stream. The degree of carryover air is strongly dependent on whether the unit has a purge section or not. Rotor speed is normally relatively low and in a range of 3-15 rpm. The cross sectional temperature distribution on the supply or discharge side of a rotary HRU is in many cases non-uniform. This means that placement of temperature sensors for control or for calculation of energy transfer and efficiencies is crucial.

SITE DESCRIPTION AND MEASUREMENT SETUP

Flow and temperature measurements where performed in a laboratory test ventilation system (the heat recovery AHU part of the system is shown in figure 1). This is a ABB EC2000 unit with a non-hygroscopic rotary wheel. Flow rates where measured with a tracer gas. A tracer gas (SF_6) was released into the air, and concentrations upstream and downstream of the dosing points determined the flow rate and cross-contamination of the heat recovery unit (according to figure 2).

Figure 1. The AHU subsystem containing the rotary heat recovery unit

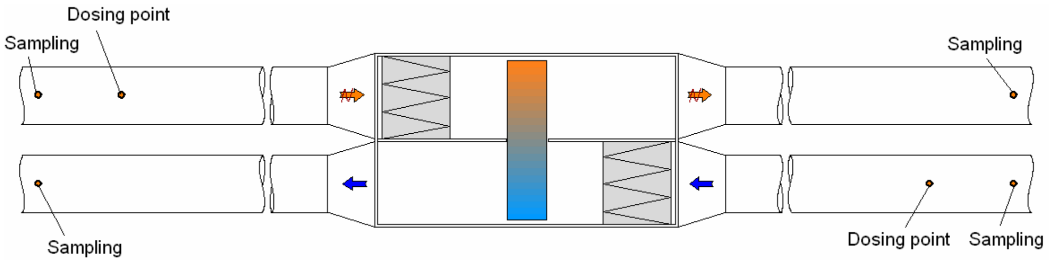

Figure 2. Flow measurement setup and tracer gas sampling points, Eian/Sørensen [2]

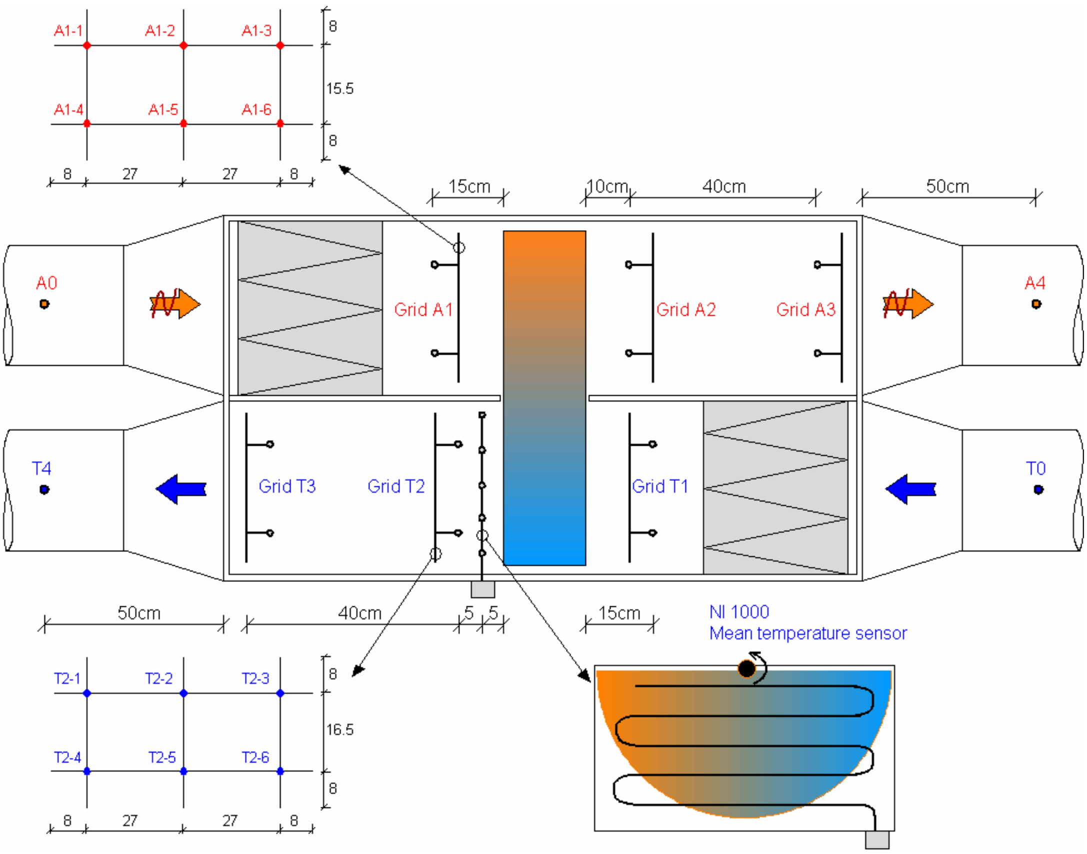

Figure 3. Temperature sampling points

The temperature measurement system (refer to figure 3) consisted of:

- Three grids of thermocouples on the intake and supply side (grid T1, T2 and T3), each containing 6 sample points (figure 3 and 4)
- Three grids of thermocouples on the exhaust and discharge side (grid A1, A2 and A3), each containing 6 sample points
- Temperature in the ducts T0, T4, A0 and A4.
- A NI1000 mean temperature sensor on the exhaust side (this sensor was not used in this study)

Figure 4. Picture of a thermocouple grid in front of the rotary heat recovery unit.

RESULTS AND DISCUSSION

Flow rates

Figure 5 shows the flow rates that were measured for different speeds of the fan and heat recovery unit. Figure 6 shows the percentage return air being recirculated to the supply side.

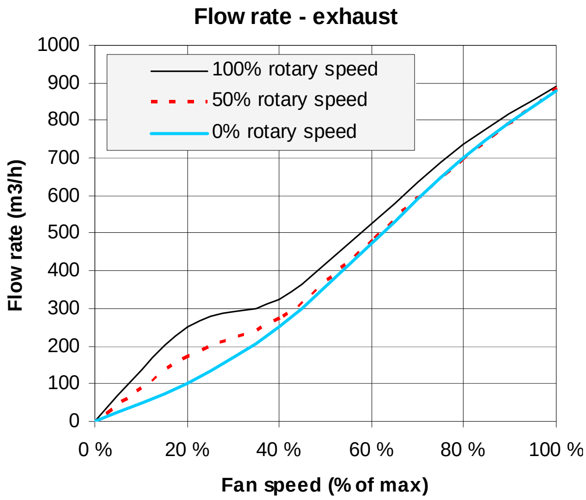

Figure 5. Flow rates measured in the exhaust

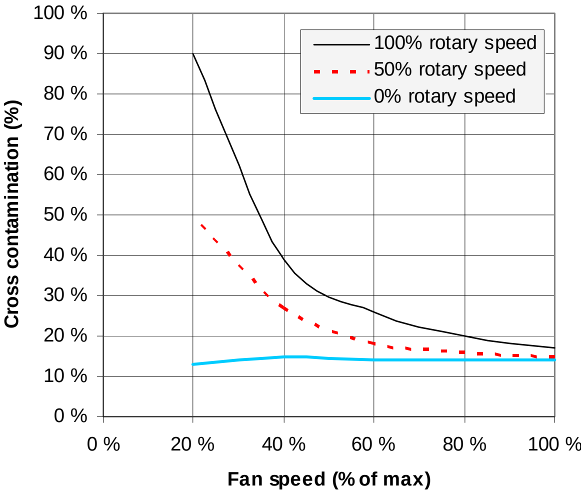

Figure 6. Cross contamination (%)

A large amount of recirculated return air was measured. The large amount of return air was mainly a result of the rotary HRU having no purge sector and an unfavorable placement of the fans in the system. This resulted in a low static pressure on the intake side of the HRU and a relative high pressure on the exhaust side, forcing air to cross to the supply side. The latter caused a 12-15% air recirculation. It was also noticed that the amount of recirculation increased significantly with increased speed of the HRU wheel. This indicates that carryover air stands for a large amount of total recirculation. Furthermore, at low fan speeds, the relative amount of recirculated air increased significantly. While the fans were running at only 20% of maximum speed, and the HRU was at full speed, there were almost no fresh outdoor air on the supply side (90% recirculation). Thus this confirms the importance of obtaining proper pressure conditions around the rotating wheel. The results also suggest that for VAV systems running on low fan speeds, the amount of return air can become very high and thus unacceptable.

Measurements with the HRU not rotating show an almost constant amount of recirculated air (independent of fan speed). Hence, the increase of recirculation was mainly caused by carryover air in the rotating wheel. Furthermore, the amount of carryover air from the supply to the exhaust was quite noticeable, as can be seen in figure 5 (since flow rates on the exhaust side varied with the speed of the rotating wheel).

Similar measurements were performed on the supply side of the HRU, showing that the ventilation system was very good balanced with respect to supply and exhaust flow rates.

Temperature measurements

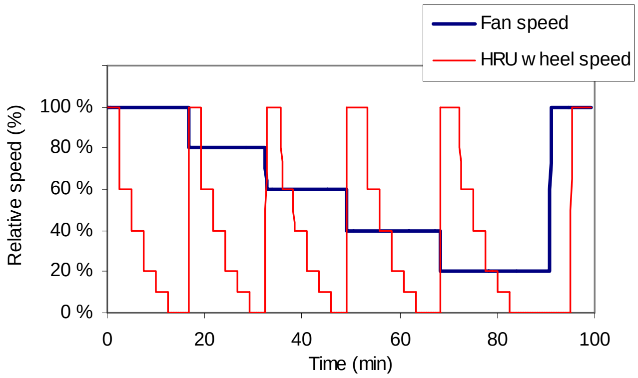

Figure 7: Fan and HRU wheel speeds (% of max) during temperature measurements

Two measurements series were performed, each resulting in responses from altered fan speeds (0-100% of max, 20% step) and HRU wheel speeds (0%, 10%, 20%, 40%, 60% and 100% of max), see figure 7. The outdoor temperature was fairly constant around 0°C. Figure 8 shows the temperature measurements as a function of time from grid T2 (supply side, closest to the wheel) for measurement series 2. At a first glance, it is obvious that the temperature varied quite noticeable across the section/grid for a given fan and HRU wheel speed. If looking closer it is possible to see the variations in temperature due to the alternations of the wheel rotary speed. The most conspicuous temperature drops happened when the rotary HRU was shut down to 0% speed. When this occurred, the temperature on the supply side naturally dropped towards the outdoor temperature.

In figure 9-12, the results have been arranged so that they correspond to the location of the actual sampling point. The two upper rows of graphs correlate to the grids on the supply side of the HRU wheel, grid T2 and T3, while the two lower rows of graphs correlate to the grids on the discharge side, grid A2 and A3. In addition, the duct temperatures (T4 and A4) are plotted on the supply and discharge graphs respectively. Since these sampling points are located away from the wheel (in the ducts), they are used as references to decide whether a temperature value is too low or too high in the grids. Each graph has been numbered in accordance with the setup given by figure 3. The direction of the HRU is also shown. Figure 9 and 10 show steady state temperature levels (according to the variations in fan speed and wheel speed defined by figure 7) for each sampling point at 20% respectively 100% fan speed, as a function of the relative HRU wheel speed. Likewise, figure 11 and 12 show temperature levels for each sampling point at 20% respectively 100% HRU speed, as a function of the relative fan speed.

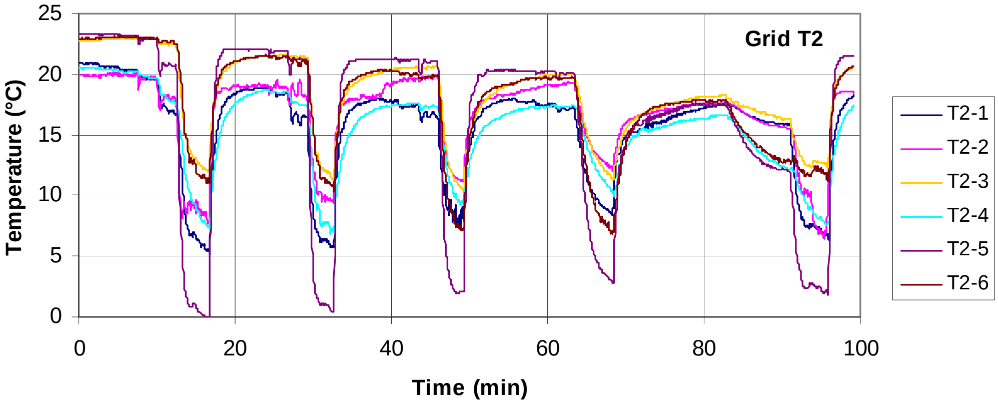

Figure 8. Temperature measurements, grid T2 (supply side, close to wheel).

From figure 9 and 10 it can be seen that the HRU speed is of minor importance as long as it is above 20% (in this case, 20% speed corresponds to an absolute speed of 2.25 rpm). Furthermore, while the fans run on low speed (20% of max) the cross sectional stratification bedding is small on the supply side, and the temperature distribution is fairly uniform. As the HRU speed is increased, temperatures on the supply side decrease slightly. Most likely this is caused by the large increase of recirculation air (refer to the flow measurements discussed earlier). However, in a system with an efficient purge sector this tendency will not show. On the discharge side, the distributions are more scattered, with highest values near the center line of the wheel.

When the fan speed is increased (figure 10), the cross sectional temperatures on both the supply and discharge sides of the wheel become increasingly scattered, and a cross sectional stratification is revealed. In this situation, the air is warmest near the center line of the wheel.

From the next two figures (figure 11 and 12) it can be seen that the fan speed of course affect the temperature levels significantly. While the fans run on low speed (20% of max) the cross sectional stratification bedding is small on the supply side, and the temperature distribution is fairly uniform. There is however a tendency of high temperatures near the center of the unit and low temperature around the edges. On the discharge side, the warmest air is near the edge of the wheel, close to the center line. Table 1 shows a simple summary of the temperature levels from figure 9-12, as a color map of grid T2 and A2. Levels are shown as +/- differences from the duct levels T4 and A4, which are believed to be more representative for the actual air temperature.

Placement of temperature sensors in the duct

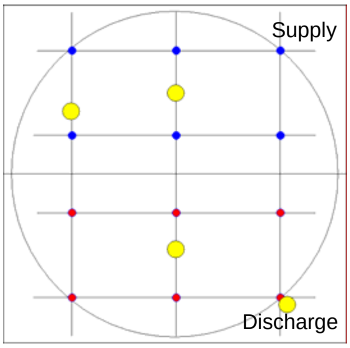

Figure 13. Placement of sensors

The ideal placement of a temperature sensor used for control or efficiency calculations is away from the wheel so it is not affected by stratified air nor by radiation from the wheel media. However, this is rarely convenient or possible, so the compromise must be to find a spot near the wheel (on all sides) that approximately resembles the actual air temperature as if it was measured away and shielded from the device. From table 1, an assessment of sensor placement is possible. For this actual HRU wheel it seems most appropriate to place the supply side and discharge side sensors as shown by the yellow spots in figure 13. It should also be mentioned that the temperatures on the exhaust and intake side of the wheel were fairly uniform, but small variations can be expected due to radiation from the wheel and in cases with leakage. A similar assessment may be required here.

Possible sources of error

Measurements should be carried out on several different heat recovery units. Also, the number of repeated measurements series are low, and it is thus not possible to establish a basis for categorical conclusions. Nevertheless, the results serve to pinpoint typical tendencies.

CONCLUSIONS

The flow rate measurements results suggest that for ventilation systems running on low fan speeds (VAV), the amount of recirculation of air from the exhaust to the supply can, due to *carryover*, become very high and thus unacceptable.

The rotational speed of the heat recovery unit has shown to be of minor importance as long as the wheel is rotating. For this particular case, above 20% of maximum speed.

The ideal placement of a temperature sensor used for control or efficiency calculations is away from the wheel so it is not affected by cross-sectional stratification bedding, nor by radiation from the wheel media. For the particular HRU in question, measurement results suggest that the sensors on the supply and discharge side should be placed approximately in the middle of the AHU duct, or displaced to the sides.

FURTHER WORK

This work represents the first report in a project on air-to-air heat recovery devices carried out at Narvik University College. Future work will address temperature and energy efficiency, transient conditions, control, modelling and simulation.

Using field synergy theory to discuss the performance of mass transfer in dehumidifying air-conditioner

Wei Lifeng

Beijing Institute of Civil Engineering and Architecture, Beijing, China

Corresponding email: cnwlf0501@sohu.com.cn

ABSTRACT

This paper analyses the problem of improving the performance of the mass transfer withthe standpoint of field synergy theory. It mainly studies with the view that adjusting an angle between velocity field and density field could enhance the performance of dehumidifying air-conditioner. At the same time, it cites one kind of the structure of screw type beehive wad dehumidifying airconditioner and screw baffler dehumidifying air-conditioner which is fixed with an angle, validates its performance of intensifying mass transfer and discusses the extensive applications in engineering. The elementary result is that the mass transfer effect will be better when the screw inclination angle is between 25°and 45°.And the total mass transfer coefficient could enhance 20% 30% in most cases.

Key words: dehumidifying air-conditioner ,field synergy theory, convection and mass transfer

INTRODUCTION

Field synergy theory [1] pointed out that the size of the heat transfer intensity was decided not only by the gradient of temperature, the speed and the nature of the fluid but also by the synergic degree of the velocity field and the hot flow field . Namely, The fluid flows may both strengthen the heat transfer coefficient, and weaken the heat transfer coefficient, so changing and controlling the synergy of the speed of flow and the heat flow may control the intensity in the convection of heat transfer. The mass transfer process has also occurred in field synergy theory. Under the same condition, changing the included angle of the velocity field and the concentration gradient field may enhance the mass transfer intensity. This article uses the field synergy theory's viewpoint of mass transfer to re-know and study the performance of dehumidifying airconditioner, and through improving the synergic degree of the fluid velocity field and the concentration gradient field enhance the dehumidifying air-conditioner's performance. It is applied into the practice of projects.

THE BASE OF MASS TRANSFER'S FIELD SYNERGY THEORY

Regarding to the three dimensional and the stable state's convection mass transfer, its differential equation is:

$$u\frac{\partial \rho_A}{\partial x}+v\frac{\partial \rho_A}{\partial y}+w\frac{\partial \rho_A}{\partial z}=D\left[\frac{\partial^2 \rho_A}{\partial x^2}+v\frac{\partial^2 \rho_A}{\partial y^2}+w\frac{\partial^2 \rho_A}{\partial z^2}\right] \tag{1}$$

Among the above formula, u v w = the velocity of x, y, z -dimension's coordinates , m/s, D = the diffusion coefficient of part A m²/s and ρ_A = the diffusion coefficient of part A kg/m³.

According to the boundary layer theory, the density boundary layer's convection and mass transfer quantity is equal to close-wall layer's diffusion mass transfer quantity, formula (1) is integrated from 0 to the boundary layer thickness δ_C in rectangular coordinates y, according to the density boundary layer and write down in the vector description form as follows:

$$\int_0^{\delta_c} U\nabla\rho_A dy = \cos\alpha \int_0^{\delta_c} |U||\nabla\rho_A| dy = -D_{grad}\rho A\big|_0 \qquad (2)$$

In the above formula,

U = the velocity vector of the close-wall layer's mobile fluid m/s
$\nabla\rho_A$ = fluid's concentration gradient kg/m³
α = the included angle of the velocity vector and concentration gradient vector
δ_C = the thickness of boundary layer m
D_{grad} = the diffusion coefficient of concentration boundary layer m²/s

In the above equation ,the vector form of source equivalent interior production rate is:

$$U \bullet \nabla\rho_A = |U| \bullet |\nabla\rho_A| \cos\alpha \qquad (3)$$

From the above equation, we can concluded that the dot metrix size has relation to the module of the two vector and their included angle. Under the condition of invariable mold, the smaller the included angle is, the larger the scalar product is. Namely, with the same energy consumption of mass transfer, we adjusts the included angle α between the velocity field and the density gradient field to achieve the goal of strengthening mass transfer.

THE FIELD SYNERGY THEORY OF DEHUMIDIFYING AIR-CONDITIONER'S MASS TRANSFER

The mass transfer model of two dimensional laminar flow

In the same temperature, stable state, non-internal production rate, humid air will produce the laminar boundary layer when wet air has flowed the absorbent surface in the laminar way, as shown in Figure 1, which belongs to the two-dimensional convection and mass transfer situation. Among them, the air velocity changes only along x direction, the concentration increases along the y direction, integrates the both sides to coordinates y according to its corresponding differential equation:

$$\int^{c} U \bullet \nabla\rho_A dy = D\frac{\partial\rho_A}{\partial y} + C \qquad (4)$$

In the above formula, the character C is constant , the fluid velocity is along horizontal direction, the concentration gradient is vertical upwards, and the included angle between the two vector is 90 degree.

From $U \bullet \nabla\rho_A = |U| \bullet |\nabla\rho_A| \cos 90° = 0$, we can see that the mass transfer quantity that is caused by the equivalent source item is zero. When diffusion coefficient D is invariable, the concentration was taken on linear distribution along the y direction in the boundary layer.

This kind of situation equates the simple diffusing phenomena which proliferates mutually in the quality. Namely, through close-wall layer, the mass transfer quantity was only able to be the pure diffusing phenomena with the correspondence of mass transfer quantity, convection has not any function to strengthening the mass transfer, in other words, fluid flowing in this time was the same as the static situation. As a result, dehumidifying or desiccating equipment can be optimized from this period and it has further instructed significance for energy saving.

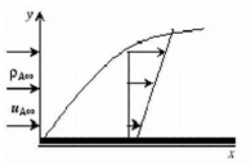

Figure1.

Extremely mass transfer model

When laminar humid air vertically flows from the porous big area plate, as shown in Figure 2, the incident flow passes through in turn from left side and right side. By now, on both sides of the board included: the left side of the boundary layer has hole pumping effect, its thickness attenuates inevitably Right side of the boundary layer has hole injector head effect, thickness will possibly increase a lot. The research indicates [3], on the left side of the plate, the boundary layer's velocity direction is parallel to the concentration gradient direction but their direction is opposite, and the velocity direction was the same as the mass transfer direction (mass transfer), it has prevented the boundary layer from accumulating, but it has the hole pumping effect and causes the boundary layer to become much thin, thus strengthens the mass transfer in the greatest degree, this is one kind of ideal situation on the right side of the plate, the boundary layer's velocity direction is parallel to the concentration gradient direction and their direction is the same , the velocity direction was opposite to the mass transfer direction (mass transfer), but has the hole pumping effect and causes the boundary layer to become much thick, thus weakens the mass transfer in the greatest degree, decreases the mass flow density, makes the mass transfer to be weak, its effect is so far inferior to the static mass transfer effects.

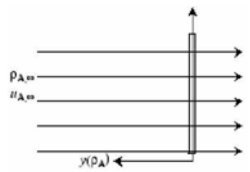

Figure 2.

MODEL DESIGN AND APPLICATION

Discussion

According to the mass transfer field synergy theory, we can conclude that the velocity field and the density field which fixed a suitable included angle will be beneficial to strengthen mass transfer effect. This article is going along with a model design in view of the dehumidifying airconditioner present research situation and proposing the application tentative plan.

4.1 Design the dehumidifying airconditioner's beehive wad as the screw type

The common dehumidifying airconditioner with beehive wad was beehive wad straight channel , speaking to the dehumidifying air-conditioner's beehive wad straight channel, fluid velocity gradient is vertical to the concentration gradient, their vector included angle α is 90 degree, according to the formula $U \bullet \nabla \rho_A = |U| \bullet |\nabla \rho_A| \cos 90° = 0$, the mass transfer quantity is only correspondence to the pure diffusing phenomena mass transfer quantity, convection has not any effect to strengthen mass transfer, just as one kind of static phenomenon Presently we designs it as the screw channel (as shown in Figure 3, the contrasts of the two kind channels as shown in Figure 4). Due to the certain included angle between the dehumidifying air-conditioner screw beehive wad 's velocity gradient field and concentration gradient field, namely, $\cos\alpha \neq 0$ thus we can greatly enhance the dehumidifying airconditioner's mass transfer performance. Literature [4] has given the moisture absorption capacity's research study when the air flow through the straight channel and the screw type channel. And their tentative data curve are shown in figure 5. See from Figure 5, under certain air flow velocity, the moisture absorption capacity of the screw channel is far higher than the straight channel's. Thus it validates that the screw channel's dehumidifying effect is distinctly enhanced.

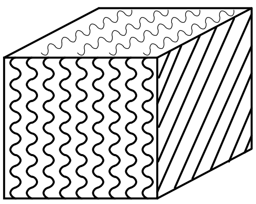

Figure3 the screw beehive wad.

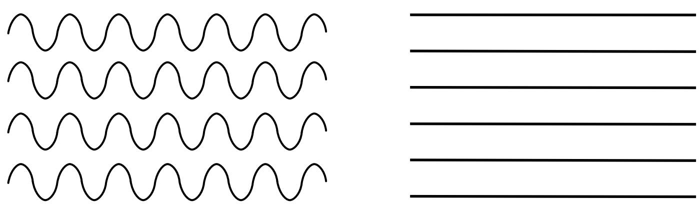

(a) straight channel. (b)screw type channel.

Figure 4 the beehive wad sketch map.

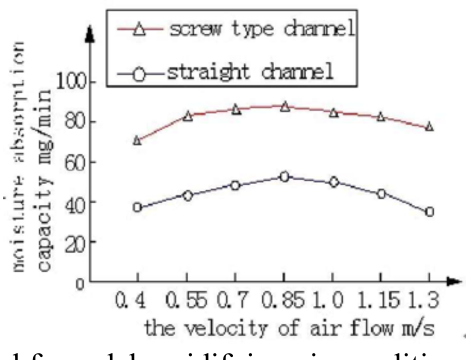

Figure 5 The different channel form dehumidifying air-conditioner's moisture absorption capacity along with the velocity of air flow change curve.

4.2 Design the dehumidifying air-conditioner as the screw type baffle plate fixed with inclination angle *β*

Regarding to the situation mentioned above, it is very difficult to realize in the actual project when the laminar humid air vertically flows through the porous plate of the extremely mass transfer model situation. Because the air vertically flows through the two-sided perforated plate situation, although having holes, it enormously increases the fluid flow's resistance. Considering to designing the form of an inclination angle between the board and the air flow direction in screw type baffle plate, as shown in figure 6, it may cause an included angle β between the velocity gradient and the concentration gradient in the screw type channel's columnar air flow ,thus influences the boundary layer's formation, strengthens dehumidifying air-conditioner's mass transfer performance, and the smaller the included angle is ,the better performance of mass transfer is.

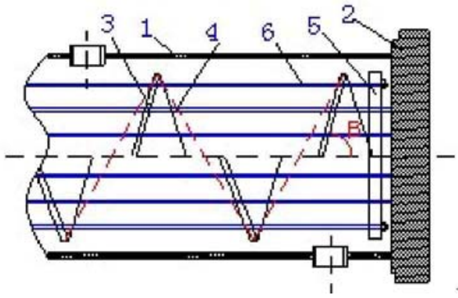

Figure 6 The screw baffle plate sketch map. 1-shell body 2- Tube plate 3-baffle plate 4-spoiler plate 5- Base plate 6-distance tube β-screw angle.

In relative to the traditional vertical arc plate, the screw type baffle plate has completely changed 180°time after time to turn back the transverse mobile way, make the fluid cause an included angle between velocity field and the density field , attenuate the boundary layer, reduce the thermal resistance, thus greatly enhance the mass transfer efficiency. It is suitable to deal with the solid particles, dusts, silts containing in the fluid. According to the related literature reported, the total mass transfer coefficient could enhance 20% -30% in most cases byusing the screw type baffle plate of dehumidifying air-conditioner, especially when the screw inclination angle is 25° - 45° the mass transfer effect is better.

CONCLUSION AND APPLICATION

It is significant to analyze the dehumidifying air-conditioner's mass transfer problem with field synergy theory. Because the convection and mass transfer process of the dehumidifying air-conditioner happens under the velocity field and the density field's together action, when fluid flow through the dehumidifying air-conditioner, we can make use of the included angle between the concentration gradient and the velocity gradient to control the mass transfer intensity. Under certain conditions, we design dehumidifying air-conditioner to adopt to have a certain angle screw beehive wad structure and screw type baffle plate fixed with an inclination angle of the dehumidifying air-conditioner form, the research indicated that it will be actually able to enhance the mass transfer performance. As its design is not very complex, it is suit for large scale production and promotion, it also has a broad prospect in the field of application.

Efficiency Investigation of an Induction Motor drive system with Three Different Types of Frequency Converters with focus on HVAC applications

Johan Åström

University of Chalmers, Sweden

Corresponding email: johan.astrom@chalmers.se

SUMMARY

This paper discusses the efficiency of induction motor drives for HVAC applications, based on measurements made on three 4kW induction motor drives. Both converter efficiency as well as induction motor efficiency is studied and in particular the total system efficiency is determined. Measurements have been performed on a 4kW induction motor fed by three different types of frequency converters. Converters A and B use an open loop, constant flux control, where B has a L-C filter on its output. Converter C uses an open loop, field weakening algorithm but also a special pulse width modulation (PWM) technique in order to reduce the switching losses in the converter. Simulations and measurements have shown that an efficiency improvement of the system can be achieved using a field weakening algorithm which improves the efficiency at light load with 18% at 30Hz which in particular is of importance in HVAC applications. At full load the difference in efficiency is negligible between system A and C but 3% lower using system B due to the sinus filter. Efficiency improvements were also accomplished by using the special PWM technique. It was also found that it is important to make a complete optimization of the energy efficiency. Using system B, with L-C filter, gives higher machine efficiency but a low overall efficiency due to high converter losses. As a general conclusion, it has been shown that system C was the best solution from an efficiency point of view for a typical HVAC application.

INTRODUCTION

Electrical machines for HVAC applications contributes to approximately 40% (320TWh) of the energy consumption of electrical machines in EU(1996) [1]. The flow from pumps and fans are often mechanically controlled by valves, which leads to a reduced efficiency of the system. A better approach is to allow the pump/fan to determine the flow [2]. This is done by using a frequency converter, adjusting the voltage and the frequency of the motor to meet the demand of the load. This type of drive system has become more common throughout the years due to the energy savings that can be made. The energy efficiency of an induction machine (IM) is relatively high at optimal load and speed. However, in many situations, the load is not optimal. A common practice regarding dimensioning of drive systems are to use a 10% marginal and then choose the next available size above this limit [3]. As a result, the drive system can in some cases become highly over dimensioned and will not be operating at its optimum. Furthermore, drive system used in HVAC applications are often season/weather dependent and will be operating at light load during extended time periods [4]. It is therefore of great importance to optimize the energy efficiency over the whole operating range. Hence, it is of interest to investigate efficiency improvements, both in the frequency converter but also in the IM which can be done with design and control of the system. However, this paper will be focused on the issues regarding control. There are several control techniques in order to minimize the losses in the converter. Techniques related to the minimization of the switching losses have been proposed in [5, 6]. However, the described technique in this paper is only mentioned briefly.

Efficiency improvements of the IM can be made using optimal volt/frequency control which is described in detail in [4] and will just be mentioned briefly in this paper.

The purpose of this paper is to investigate the different loss components in a drive system consisting of an IM fed by a frequency converter. Moreover a goal is to use measurements and simulation to determine the difference using three types of converter technologies.

SYSTEM DESCRIPTION

Measurements where made on three different types of frequency converters feeding an IM. The different systems are referred to as A, B and C.

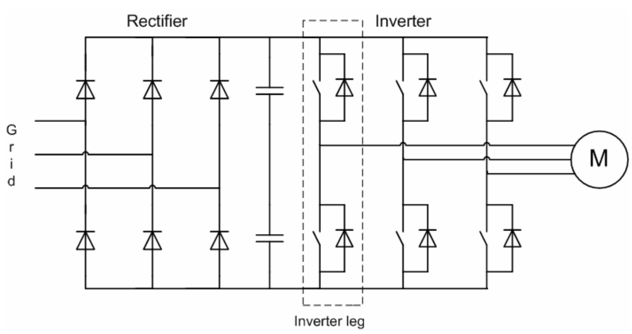
The frequency converter used in system A was a 4kW converter using constant voltage/frequency ratio.

Converter B contained a 4kW frequency converter with same control as system A. The converter was also equipped with an internal L-C filter on its output, which reduced the harmonic content significantly compared to system A and C.

Converter C used a field weakening algorithm but also a special pulse width modulation (PWM) technique in order to reduce the switching losses in the converter. At each half period the switching was stopped for 60° when the phase voltage was around its peak voltage.

LOSS COMPONENTS IN AN INDUCTION MOTOR DRIVE

The drive system of consideration is an IM fed with a frequency converter, shown in figure 1. The different losses that occur in the IM are resistive losses in the stator and rotor, core, mechanical harmonic and stray losses.



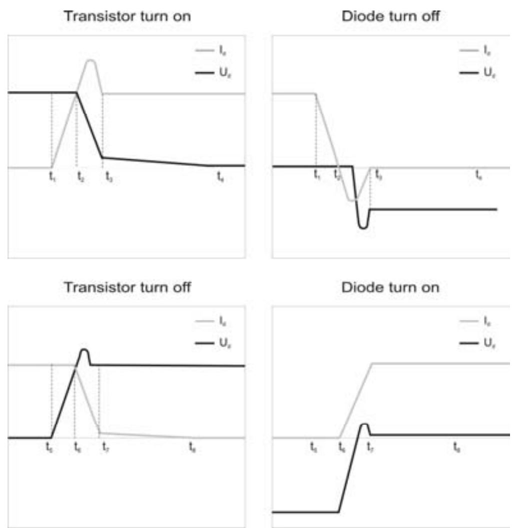


Figure 1a) Schematic figure of a frequency converter feeding an IM.

b) Turn on and turn off voltage and current waveforms

These losses has been measured separately according to the IEEE standard 112-1991 method B [7].

The different loss components in a frequency converter are much more complicated to measure/estimate due to the compact construction of the device. Hence, the measurement in this study did not consider these losses separately. Instead the total loss components of the frequency converters were measured. The loss components are on state losses in the diode rectifier and in the inverter stage and switching losses in the inverter stage.

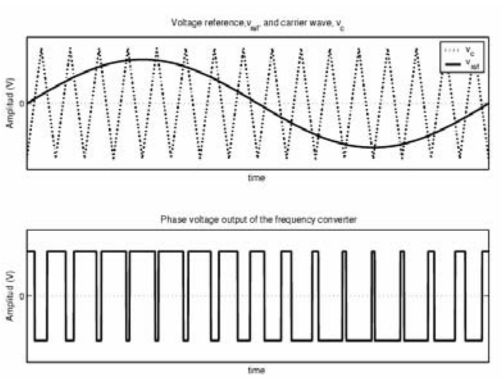
IMPROVEMENTS IN ENERGY EFFICIENCY

The improvement in energy efficiency can be divided into two broad groups, the design of a drive system and the control of the system. This section will describe the factors that improve the energy efficiency related to system C which both falls under the category of control.

PWM switching strategy

The most commonly used control technique in converters is Pulse Width Modulation (PWM). The PWM voltage is a pulse train of fixed magnitude and frequency with variable pulse width. The pattern is created by comparing a modulating carrier wave with a reference wave. If the frequency of the carrier wave is increased the switching frequency of the converter also increases. The choice of switching frequency are balance between switching losses in the converter and harmonic losses as well as torque pulsation in the IM, (of course physical limitations of the device must be taken into account). Furthermore, the switching losses also depend on the load type, which in this case is inductive. Typical voltage and current waveforms for turn on and turn off of an inverter leg feeding an inductive load can be seen in figure 1b.

This paper will investigate a discontinuous PWM technique which stops the switching at different time durations during the peak voltage, figures 2a) and b) shows examples of the continuous and discontinuous PWM scheme respectively. However, during continuous PWM sampling, at the so called over modulation, the switching stops for a certain time interval, ie when the voltage reference amplitude is higher than the carrier wave. This occurs at frequencies of approximately 40Hz for the investigated case when constant voltage/frequency ratio is used.



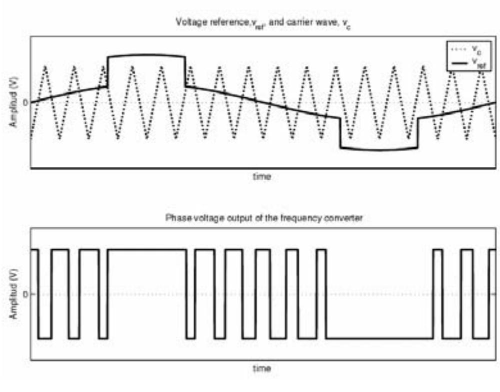


Figure 2a) Continuous PWM b) Discontinuous PWM

Optimal Voltage/frequency control

Improvements in energy efficiency of the IM can be made with different control strategies. A simple control strategy is the constant air-gap flux control which keeps the ratio between voltage and frequency (V/Hz) constant at all loads, (system A and B). However, every loading situation can be achieved with various combinations of voltage amplitude and frequency and it can be shown that there is an optimal frequency and an optimal voltage at each loading point [8,9]. The goal is to control the voltage and the frequency in order to optimize the balance between the copper and iron losses [4]. Different control strategies can be divided into three groups, *Power factor control* [10,11], *model based control* [12-14] and *search method* [15-18]. Evaluation and description of the different methods can be found in [4]. A previous work [4] has shown that the improvements in efficiency has a larger effect at light loads and are therefore suitable for HVAC systems where the power demand varies with the square or the cube of the speed. Furthermore, many HVAC applications, as mentioned in the introduction, can be assumed to operate on reduced load for a long period of time. Furthermore, over dimensioning of HVAC system also contribute to lower efficiency in constant air-gap flux control since the motor now constantly is lightly loaded. Figure 3 shows a simulation of the efficiency using optimal control and constant voltage/frequency control. The applied load is representing a pump/fan.

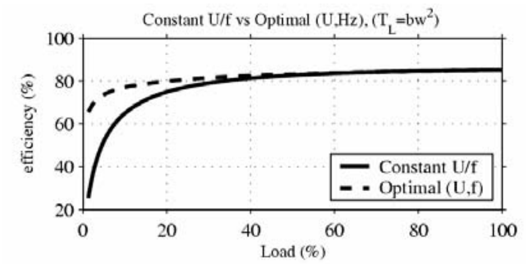

Figure 3 Optimal control and constant voltage/frequency control of an IM. The load is represents a pump/fan

Simulation of inverter switching losses

Calculation of the switching losses were made using Matlab Simulink ®. A state space model of the three phase IM used during the measurement where constructed, fed by a frequency converter using a switching frequency of 18kHz. At each switching instant, current magnitude and the conducting device where detected (i.e. if the current was flowing in a transistor or the freewheeling diode). The losses were then calculated using the voltage and current waveforms shown in Figure 1b using the datasheet of an IGBT type IRGPS40B120UDP.

TESTEQUIPMENT

The measurements were performed on one standard 4kW, 4 pole IM, and three different types of frequency converters A, B and C. The drive system was loaded using a DC machine and the test procedure was equal to all system setups. The various loadings were represented by sweeping the frequency between 10Hz and 60Hz with 5Hz increments. The drive system was operated at the same loads at each frequency, with the exception for the over rated loading points at the lower frequencies.

Table 1 Measurement equipment

Type	**Model**
Torque transducer	Tn 30
Power analyze	Norma 61D2
Power analyze	Yokogawa WT
Digital Oscilloscope	Lecroy 9304 CM
Ohmmeter	CM 1703
Stroboscope	1531 AB
Data aquision card	PC - MIO - 16E -1

MEASUREMENT RESULT AND ANALYSIS

Measurements were performed according to the description found in the previous section. Figure 4 a) and b) shows the different loss components for system C at 50Hz and varying loads. It can be noted that the mechanical and core losses are increasing with increasing load. This is due to the fact that the voltage in converter C is decreased at decreasing load, which differs from system A and B which has a constant core loss component due to the constant V/Hz control (the mechanical losses can be assumed constant in all three systems at a fix frequency). The resistive loss component are naturally increased with increasing load so is the converter loss component due to the increased power transfer.

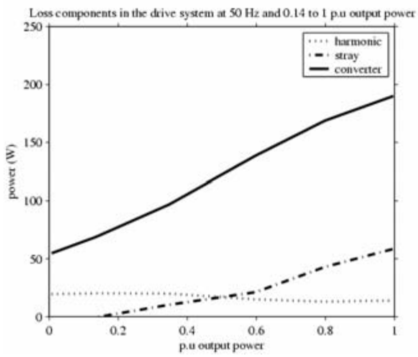

Figure 4a)Measured harmonic, stray and converter losses at 50Hz

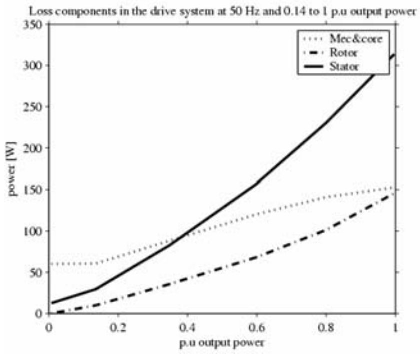


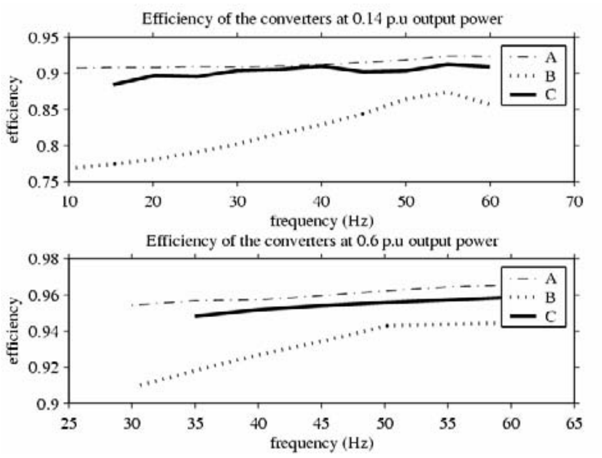
b) Measured mechanical+core, rotor and stator losses

Efficiency of the frequency converters

Figure 5a) shows the efficiency of the three converters at two load situations, 0.14 pu and 0.6 pu output power respectively. It can be seen that the difference in the efficiency decreases as the load increases and that converter B has the lowest efficiency while converter A has the highest.

Efficiency of the IM

Figure 5b) shows the efficiency of the IM in the three cases. It can be noted that system A and B has the lowest and the highest efficiency respectively. It can also be noted that the difference is higher at light load. This is due to the field weakening algorithm used by converter C as was explained in the previous section. The converter lowers the output voltage at lower load. As a result, the iron losses are reduced significantly compared to the other systems.



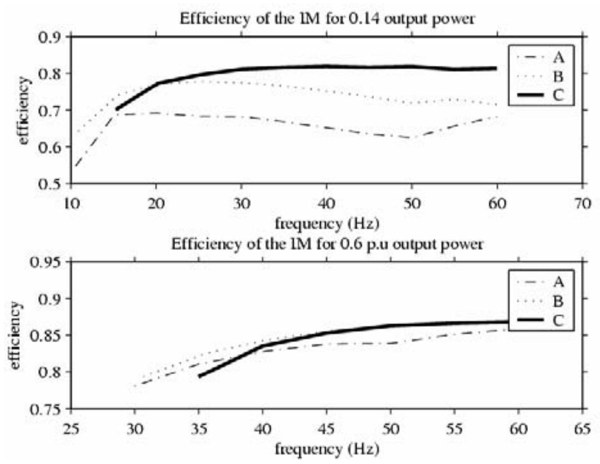


Figure 5a) Calculated efficiency of the converters using measurement data b) Calculated efficiency of the IM

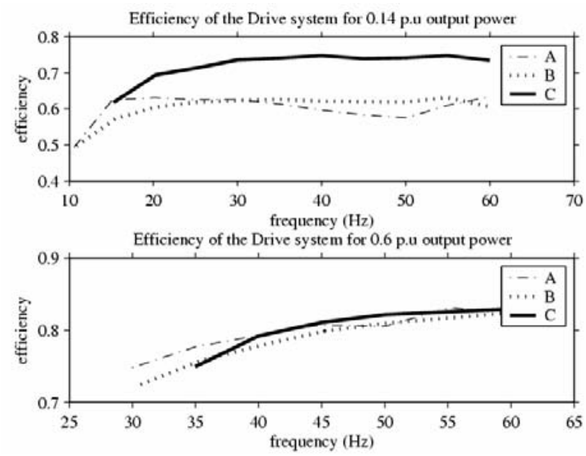

c) Calculated efficiency of the drive system using measurement

Efficiency of the whole drive system

Figure 5c) shows the efficiency of the whole drive system. System C has the highest efficiency due to its field weakening algorithm but also due to its PWM switching scheme.

COMPARIOSON BETWEEN SYSTEM A, B AND C FOR HVAC APPLICATIONS

Figure 6 shows a typical annual load cycle for a variable air volume (VAV) system according to [19]. The operating time is assumed to 8760h (one year). It is further assumed that the system is 25% over dimensioned. The estimated energy consumption using the measurement data is presented in table 2.

Table 2

System	Yearly consumption (kWh)	Difference (kWh)
A	19270	152
B	19368	250
C	19118	0

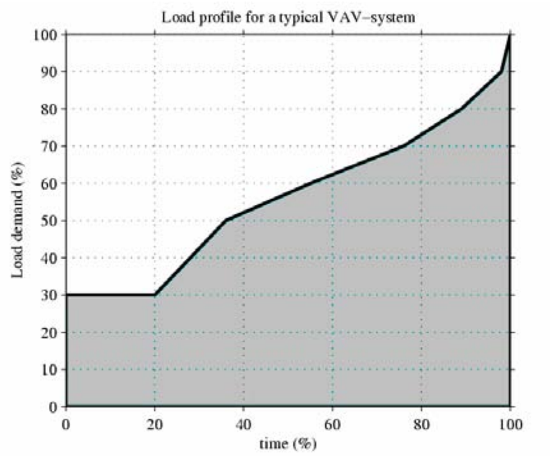

Figure 6 Annual load profile of a VAV-system

Simulation result

The above VAV-system was adopted as the load to the simulation model described in previous section. The switch stop at each half period was set to 0-80 degrees with 20 degrees increments. Figure 7 shows a decrease in the switching losses as the switch stop period increases, as expected. It can also be noted that the losses starts to decrease at certain load points which is due to the natural switch stop at over modulation mentioned earlier.

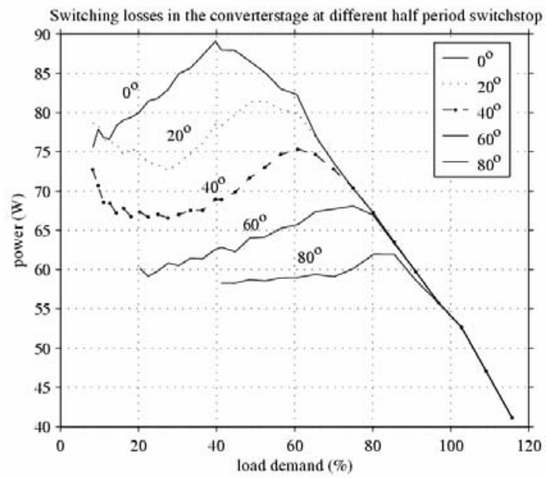

Figure 7 Switching losses in the converter at different half period switch stop. The IM is feeding the fan.

CONCLUTIONS

It was found that it is important to make a complete optimization of the energy efficiency. Using system B, with its special filter, gives higher machine efficiency but a low overall efficiency due to high converter losses. As a general conclusion, it has been shown that system C was the best solution from an efficiency point of view for a typical HVAC application. This is mainly due to the field weakening algorithm. Regarding the switching techniques improvements can be made. However, the relative difference was found small using this type of IGBT and switching frequency, especially at high load due to the over modulation of the converter.

SUMMARY

The purpose of the present paper is to investigate the effect of outdoor weather conditions on the performance of a plate-type heat recovery ventilator. The performance should not be affected in a theoretical point of view. However, the performance varies in real applications, because of air leakage, motor heat generation, and etc. Experiments have been conducted to measure the sensible, latent, and enthalpy efficiencies by varying outdoor temperature and humidity conditions with the indoor conditions fixed at the standard heating or cooling conditions. The coefficient of energy has been introduced to quantify recovered energy in comparison with the electric power consumption.
Results indicate that the temperature exchange efficiency under winter conditions shows larger values than in summer conditions due to the heat generation by an internal fan. With the heat gain eliminated, the modified temperature efficiency remains almost constant regardless of outdoor temperature conditions. The enthalpy efficiency can exhibit very large values or negative values in case outdoor conditions are in the vicinity of the indoor enthalpy line. The direction of heat flow, in such a case, can be opposite to that of moisture flow between two air streams. Discussions are included about various interesting features of the psychrometric processes occurring in a heat recovery ventilator for various outdoor temperature and humidity conditions.

INTRODUCTION

Heat recovery ventilators are basically air-to-air heat exchangers to retrieve energy from building exhaust air. They are used to provide fresh ventilation air while saving heating and cooling energy. Heat recovery ventilators are expected to install commonly in apartment houses as well as in office buildings in Korea. The Act of Indoor Air Quality for Public Buildings [1] has been legislated and the Standards for Building Facilities [2] have been amended recently so as to include proper ventilation systems in public buildings and residential buildings.

The attestations for HRV's have been conducted by the Korea Energy Management Corporation [3] and the Korea Association of Air-conditioning Refrigerating and Sanitary Engineers [4]. However, the test conditions were different from each other and there were resolution problems in reporting test results depending on the temperature and humidity conditions and their uncertainties. A research has been conducted to provide theoretical backgrounds for the revision of the test protocol.

Theoretically speaking, heat recovery efficiency should be unchanged regardless of the indoor and outdoor temperature conditions. There are previous investigations that showed the dependence on the test conditions. Allan et al.[5] performed uncertainty analysis for an air-to-air heat exchanger installed in a commercial building and reported the efficiency can vary depending on outdoor weather conditions. Yoo et al.[6] compared the efficiencies of various paper plate-type heat exchangers for given outdoor conditions. Yee et al.[7] compared KS and JIS attestation standards and conducted sensitivity analysis. They raised a sensitivity issue related to the standard test conditions.

It is the objective of the present paper to investigate the effect of outdoor temperature and humidity conditions and their uncertainties on the performance results and their uncertainties so as to provide background information for revising the test protocol and to understand psychrometric processes occurring inside the heat recovery ventilator further.

METHODS

Experimental Apparatus

The heat recovery ventilator used in the present study is a ceiling-mount permeable fixed-plate heat exchanger. The HRV is one of typical kinds sold for apartment houses in the market. It has an average performance in terms of efficiency, capacity, and noise level. The measured values of the airflow rate and the electric consumption are 307CMH and 205W, respectively.

Experiments are conducted in Korea Test Laboratory. The test facility consists of two constant temperature chambers. The capacity of the calorimeter is 80MW, and the temperature range is -50^{o}C~100 ^{o}C. The HRV is installed between two chambers as shown in Figure 1. Temperature measuring points are located three diameters away from the duct inlet. The accuracy in measuring temperature is within ±0.1^{o}C. Flow rates are measured beforehand according to the test method by KS A 0612 [8]. Return airflow rate is adjusted to match the supply airflow rate within ±5%. The internal leakage rate is measured by a tracer gas method. A non-disperse infra-red detector is used to measure carbon dioxide concentration in each duct. The measurement range of the detector is 0~1000PPM, and the uncertainty is considered to be within ±2%.

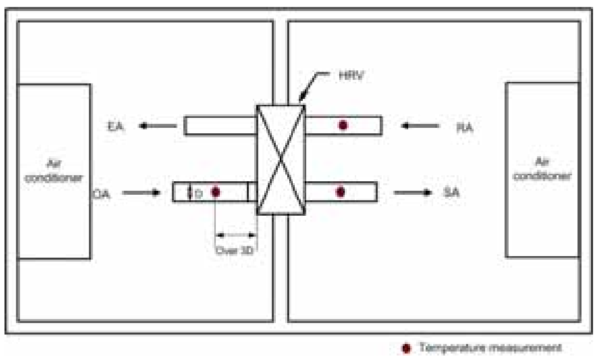

Figure 1. Schematic drawing of the test facility for heat recovery ventilators.

Experimental Conditions and Procedure

Table 1 shows the standard indoor and outdoor conditions by KARSE. The indoor condition is fixed for either heating or cooling condition, and various outdoor conditions are applied. The experimental conditions for indoor and outdoor are shown in Figure 2. The experimental number 'C' represents a cooling condition, and 'H' represents a heating condition. C0 and H0 are the standard test conditions by KARSE for cooling and heating conditions, respectively. C1 and C4 have the same humidity ratios with C0. C2 has the same temperature with C0, and C3 has the same enthalpy with C0. There is no difference between indoor and outdoor humidity ratios at C2, and therefore there is no moisture transfer. For heating conditions, H1 is the case when the relative humidity is the same with H0, and H2 and H3 are the cases when the enthalpy is the same with H0. Finally, H4 is a severe weather condition when condensation is expected to occur inside the heat exchanger module.

Table 1. Test conditions for HRV.

	Indoor condition		Outdoor condition	
	T_{dry}(°C)	T_{wet}(°C)	T_{dry}(°C)	T_{wet}(°C)
Cooling	24±0.3	17±0.2	35±0.3	24±0.2
Heating	22±0.3	13.9±0.2	2±0.3	0.44±0.2

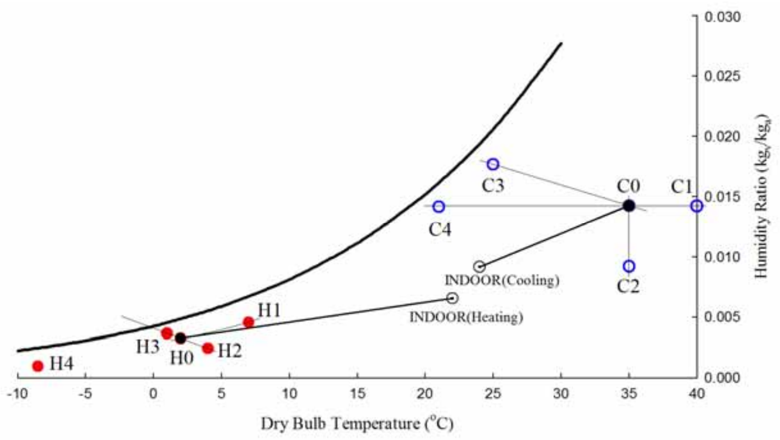

Figure 2. Test conditions shown on a psychrometric chart.

Each experiment is conducted after more than two hours when a steady state is reached for a given test condition. Dry-bulb and wet-bulb temperatures are measured for 30 minutes and averaged. The humidity ratio is obtained from the average dry-bulb and wet-bulb temperatures and the saturated vapor pressure at the temperature [9].

The temperature efficiency is defined as the ratio of the sensible heat recovered to the sensible energy difference between indoor and outdoor air.

$$\eta_T = \frac{T_{OA} - T_{SA}}{T_{OA} - T_{RA}} \times 100 \qquad (1)$$

The humidity efficiency is defined in the same way for the latent heat. The enthalpy efficiency is the efficiency including both sensible and latent heat recovered by the heat exchanger.

$$\eta_h = \frac{h_{OA} - h_{SA}}{h_{OA} - h_{RA}} \times 100 \qquad (2)$$

The effective enthalpy efficiency indicates the performance of energy transfer between supply and exhaust air excluding that by leakage. When the leakage ratio is zero, the effective efficiency is identical with the original enthalpy efficiency. As the leakage ratio increases, the supply air temperature approaches to the indoor air condition. When the leakage ratio is 100%, then the enthalpy efficiency becomes 100% as well. The effective enthalpy efficiency is always lower than the enthalpy efficiency. It is a function of leakage ratio as well as enthalpy efficiency, as is shown in Equation (3).

$$\eta_e = \frac{\eta_h - \eta_q}{100 - \eta_q} \times 100\,, \qquad (3)$$

where η_q is the leakage ratio. Leakage ratio is the volumetric leakage rate divided by the supply airflow rate. It is measured beforehand by the tracer gas method according to the following equation. Carbon dioxide is injected into the return air duct and concentrations are measured in each duct.

$$\eta_q = \frac{C_{SA} - C_{OA}}{C_{RA} - C_{OA}} \times 100\,, \qquad (4)$$

The coefficient of energy (COE) is defined as the recovered energy to the electric energy consumption. It indicates the cost benefits and usability of a heat recovery ventilator. The COE is not a unique property of a HRV but depends on test condition. As the indoor-outdoor enthalpy difference increases, the amount of recovered energy increases, while the denominator remains nearly constant. Therefore, the COE value changes from one test protocol to another.

$$COE = \frac{\rho \eta_e Q_e \left| h_{OA} - h_{RA} \right|}{W} \qquad (5)$$

It should be noted that the airflow rate in the equation is the effective airflow rate, which is the supply airflow rate subtracted by the leakage airflow rate.

Uncertainty Analysis

Uncertainty analysis shows the effect of individual measured quantity on the efficiency results. The measured quantities are indoor and outdoor dry-bulb and wet-bulb temperatures. The enthalpies are calculated from the measured quantities. The uncertainties in temperature efficiency, humidity efficiency, and enthalpy efficiency are analyzed according to the root-mean-square method as followings.

$$\frac{\Delta Y}{Y} = \sqrt{\sum_{i-1}^{n} \left(\frac{\partial Y}{\partial x_i} \frac{x_i}{Y} \frac{\Delta x_i}{x_i} \right)^2} \qquad (6)$$

RESULTS AND DISCUSSION

Table 2 shows the experimental results [10]. Various efficiencies and COE are shown with uncertainties associated. The humidity efficiency for C2 is not shown in the table, since there is no difference between indoor and outdoor humidity levels. Figure 3 shows the temperature and humidity efficiency results with uncertainty ranges. The horizontal axis shows the outdoor-indoor temperature difference, which is negative for heating conditions and positive for cooling conditions. As can be expected the error bar is large when the indoor-outdoor temperature difference is small. For most cases, temperature efficiency is in the range of 50~70%, whereas humidity efficiency is between 20~40%. It can be noticed the uncertainty in humidity efficiency is greater than that in temperature efficiency. This is due to the fact that the uncertainties in measuring humidity ratios are larger than those in measuring temperatures.

Table 2. Experimental results on various efficiencies and COE .

Experimental No	Temperature efficiency (%±%P)	Humidity efficiency (%±%P)	Enthalpy efficiency (%±%P)	Effective enthalpy efficiency (%±%P)	Coefficient of Energy (COE)
C0	58.75±1.09	20.49±3.95	38.72±1.86	32.66±2.05	3.47±0.23%
C1	61.35±0.78	19.17±3.98	42.53±1.57	36.85±1.73	4.70±0.24%
C2	57.68±1.13	-	61.68±3.56	57.89±3.91	2.81±0.23%
C3	-51.71±21.47	27.84±2.24	24.72±2.10	17.28±2.30	1.75±0.24%
C4	97.61±4.59	25.02±3.65	0.53±5.17	-9.31±-5.68	-0.38±0.23%
H0	69.46±0.63	29.27±3.49	57.43±0.98	53.22±1.08	7.02±0.19%
H1	71.69±0.84	30.34±6.65	61.86±1.50	58.09±1.65	5.33±0.19%
H2	69.93±0.70	26.19±2.86	54.03±0.97	49.48±1.06	6.47±0.18%
H3	69.27±0.60	31.32±4.08	59.48±1.00	55.47±1.10	7.27±0.19%
H4	67.32±0.41	34.47±1.94	56.97±0.58	52.72±0.64	10.94±0.21%

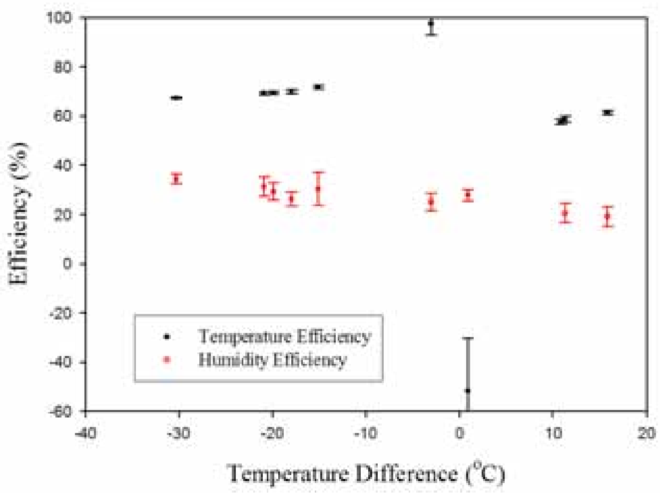

Figure 3. Temperature efficiency and humidity efficiency with respect to the indoor-outdoor temperature difference.

It is interesting to notice the temperature efficiency is negative for C3. This means the supply air has higher temperature than the incoming outdoor air for the heating condition. This is due to the temperature increase by a fan motor when the indoor-outdoor temperature difference is small.

As can be observed in Table 2, the effective enthalpy efficiency is lower than the enthalpy efficiency. Both of them are in the range of 30~60%. The COE is in the range of 2~10. As the power consumption of a fan motor is nearly constant, the COE can be considered to be proportional to the indoor-outdoor enthalpy difference.

Figure 4 shows processes on a psychrometric chart when outdoor air is passing through a HRV. The outdoor air at O reaches S' as it exchanges heat with return air. When temperature efficiency is greater than humidity efficiency, the slope of the line OS' is less steep than the line OR which represents the sensible heat ratio (SHR) of the space heating/cooling load.

The point moves from S' to S, as the heat generated by a motor is supplied to supply air. The temperature efficiency can be represented by the ratio of the length Rc to bc, consequently. In case the temperature rise is large enough so that the point b is beyond the point c, the temperature efficiency becomes negative, as for C3. Similarly, the humidity efficiency is the ratio of Od and Oc.

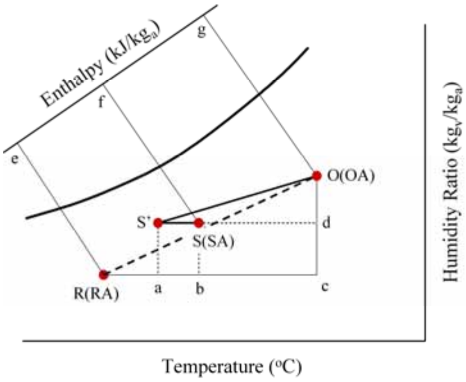

Figure 4. Process lines on a psychrometric chart inside a heat recovery ventilator.

The modified temperature efficiency is defined as the temperature efficiency with the internal heat gain removed, as shown in Equation (7). It is assumed that the heat gain is 50% of the power consumption of a fan motor. Yoo et al. [6] has estimated 40~50% in calculating internal heat gain.

$$\eta = \frac{T_{OA}\left(T_{SA} - \Delta T_m\right)}{T_{OA} - T_{RA}} = \frac{\overline{ac}}{\overline{Rc}} \qquad (7)$$

As can be observed in Figure 5, the modified temperature efficiency is nearly constant, i.e. 64~68%, regardless of the outdoor conditions. It is interesting to notice the effective enthalpy efficiency of the case of C4. The outdoor temperature is lower but the humidity ratio is larger than the indoor condition. The direction of heat transfer is opposite to that of moisture transfer through heat exchange medium. As the enthalpy of C4 is quite close to that of indoor condition, the enthalpy efficiency can have any value with large uncertainty. In case, the enthalpy efficiency is lower than leakage ratio, the effective efficiency becomes negative.

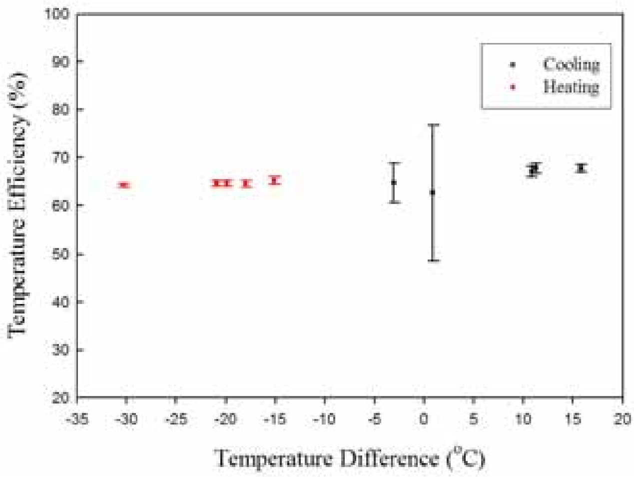

Figure 5. Temperature efficiency modified with the heat gain eliminated.

A psychrometric chart can be subdivided into several regions as shown in Figure 6. D is the region where most weather data fall on. A is the region where the effective enthalpy efficiency exceeds 100%, and B and C are the regions of negative efficiency. The enthalpy efficiency is positive in C but less than leakage ratio, so that the effective value is negative. The lines between these regions have specific slopes. The solid line is an enthalpy line.

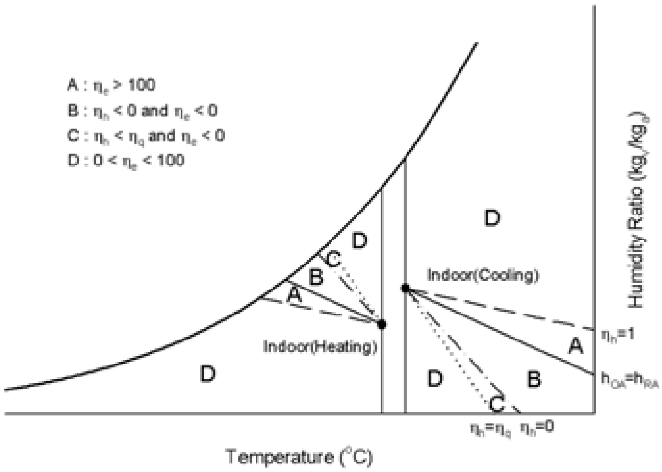

Figure 6. Psychrometric regions categorizing enthalpy efficiency.

CONCLUSIONS

Various outdoor temperature and humidity conditions are applied to a plate-type heat recovery ventilator to investigate the effect of weather conditions on various efficiencies and their uncertainties.

Firstly, the humidity efficiency is lower than the temperature efficiency for all cases regardless of heating or cooling weather conditions. The uncertainty of humidity efficiency is greater than that of temperature efficiency, since the uncertainty in measuring humidity is greater than that in measuring temperature.

One of the reasons that the efficiencies show different values depending on outdoor temperature and humidity is due to the heat gain by the internal heat generation of a fan motor. That is the reason why the temperature efficiency is greater for a winter condition than a summer condition.

When the indoor-outdoor temperature difference is not large, it is possible that the temperature efficiency can show negative values. Results show that the modified temperature efficiency with the internal heat gain eliminated remains nearly constant and within the uncertainty range.

The enthalpy efficiency can be negative or over 100% when the indoor-outdoor enthalpy difference is small. The effective enthalpy efficiency can be negative in case the enthalpy efficiency is less than the leakage ratio.

SUMMARY

Ventilated ceiling system is an energy-saving replacement ventilation system for maintaining comfortable working environment in kitchens. The technology was introduced from Germany, but there have been no clearly determined relationships between their designs in an electric kitchen and the ventilation design standards and no established design methods. This study aims to establish design methods of ventilated ceiling systems appropriate for electric kitchens by assessing the thermal environment created and energy consumed by the systems while changing the amount of ventilation and the temperature of the air supplied. The ventilated ceiling system formed thermal stratification, which improved displacement ventilation, and maintained a good thermal environment in the working area. To meet the standards of the Ministry of Health, Labour and Welfare, the system should be operated at a ventilation rate of 25 times per hour with supply air at 16^{o}C or a ventilation rate of 20 to 40 times per hour with supply air at or below 20^{o}C.

INTRODUCTION

Ventilated ceiling system is an energy-saving replacement ventilation system for maintaining comfortable working environment in kitchens. The technology was introduced from Germany, but there have been no clearly determined relationships between their designs in an electric kitchen and the ventilation design standards and no established design methods. This study aims to establish design methods of ventilated ceiling systems appropriate for electric kitchens by assessing the thermal environment created and energy consumed by the systems while changing the amount of ventilation and the temperature of the air supplied.

METHODS

The study was conducted in the main kitchen on the 19th floor of K Building (Osaka City, Osaka Prefecture) and involved:
1) Monitoring the temperature and humidity of the kitchen and the amount of cooling water supplied to the air conditioner while ordinarily using the kitchen and changing the amount and temperature of air supply,
2) Analyzing the monitored data in terms of both the indoor environment and the amount of cooling water consumed, and

3) Constructing a model for analyzing air flows that almost reproduced the monitored results, and using the model to comparatively analyze and estimate the system performances at different heat emissions, which represented an assumed gas kitchen.
A plan of the kitchen and the positions of kitchen equipment are shown in Figure 1. The kitchens were zoned into the heating zone, dishing zone, and rice-cooking zone from the left to right in Figure 1. The ceiling was the ventilated ceiling system. A list of the kitchen equipment is shown in Table 1. The total electric power capacity of the equipment was 155.1 kW (448A). The amount of ventilation supplied is shown in Table 2 for each zone. The design ventilation was determined by the manufacturer by following the standards for air conditioner and ventilation equipment (VDI) in Germany. An energy-saving method is used to control the amount of ventilation based on the air current used by the kitchen equipment listed in Table 1. Controlling the amount of ventilation so as to be proportional to the electric current consumed in the kitchen may result in rises in the room temperature after the usage of the equipment since the equipment does not quickly cool down. To prevent the problem, ventilation control was tested which involved controlling the ventilation based on electric current consumption at the time point certain period prior to the control as shown in Figure 2. When ventilation was to be increased, the delay control was not used but the ventilation was increased spontaneously to ensure safety. The monitored changes in the automatic control output signals to the supply fans when the electric current consumption sharply dropped from 160A to 6A are shown in Figure 3. Approximately 60 seconds (10 minutes) after the drop in current consumption, the ventilation was reduced to the set value.
A large amount of vapor produced from brazing pans and other equipment was confirmed to have been attracted by the cold air supplied form nearby outlet slits, causing rises in the cold air temperature and dew on the surface of the slit metal plates. To minimize the mixing of the vapor and the cold air, a hanging wall was installed to separate the heat-producing grills from the slit metal down to a height of 150 mm.
The points where temperature and humidity were monitored are shown in Figure 4. The monitoring conditions are shown in Table 3.

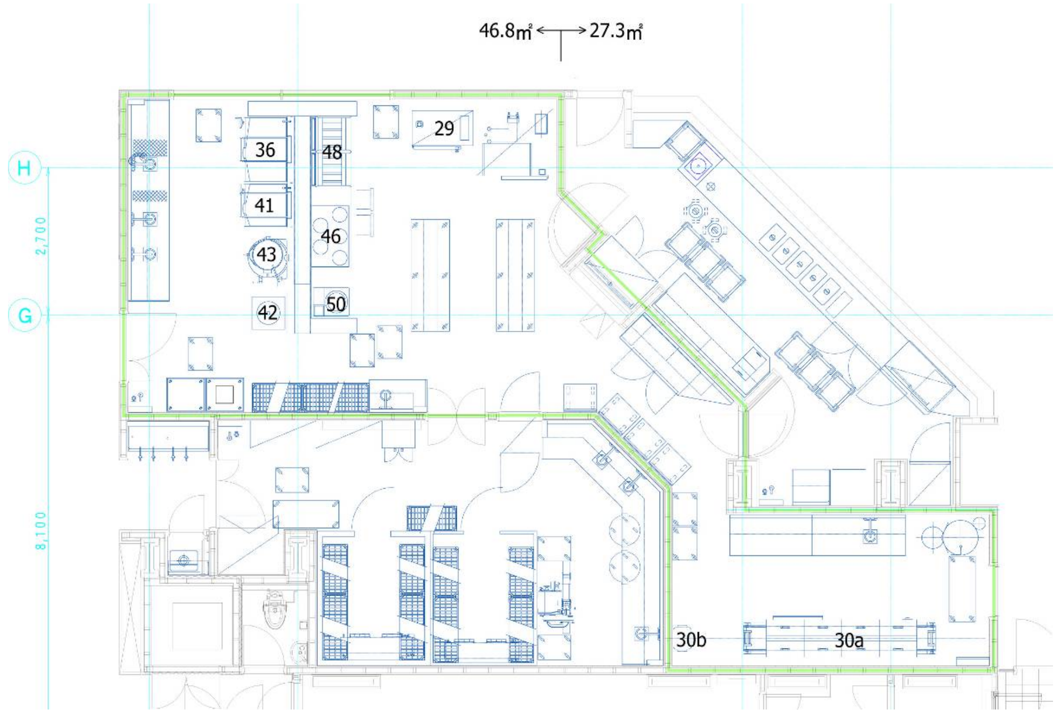

Figure 1. Plan of the kitchen

Table 1. List of principal kitchen equipment

	Article	Electric power capacity
29	Steam convection oven	36.8kW
30a	Multiplex IH rice cooker	31.5kW
30b	IH rice cooker	
36	Blazing pan	18.0kW
41	Blazing pan	12.0kW

Table 3. Monitoring conditions

	Ventilation rate	Supply air temperature	Delay control	Hanging wall	Date of monitoring	Representative day
Case 1	18 to 45 times/h	22℃	w/o delay control	w/o hanging wall	7/10～7/13	7/11
Case 2	25 times/h	18℃	-	w/o hanging wall	7/18～7/21,24	7/19
Case 3	25 times/h	16℃	-	w/o hanging wall	7/25～7/26	7/26
Case 4	25 times/h	14℃	-	w/o hanging wall	7/27～7/28	7/28
Case 5	20 to 40 times/h	18℃	w/ delay control	w/o hanging wall	8/1,3	8/3
Case 6	20 to 40 times/h	16℃	w/ delay control	w/o hanging wall	8/2,4	8/2
Case 7	25 times/h	18℃	-	w/ hanging wall	8/8	8/8
Case 8	25 times/h	16℃	-	w/ hanging wall	8/9	8/9
Case 9	20 to 40 times/h	20℃	w/ delay control	w/ hanging wall	8/10	8/10
Case 10	20 to 40 times/h	18℃	w/ delay control	w/ hanging wall	8/11	8/11

RESULTS

Analysis of measurements

Figure 5 shows the electric current consumption in the kitchen and inverter output. When no delay control was performed, the data aligned on a proportional line. On the other hand, when delay control was used, the data scattered above the proportional line because the ventilation was immediately increased when the electric current consumption increased. Figure 6 shows the ventilation rate for variable air flow and effects of delay control. The mean ventilation rate was 32.1 times per hour when the air flow was allowed to vary within the range of 18 to 45 times per hour and was 33.6 times per hour when the air flow was allowed to vary within the range of 20 to 40 times per hour. The changes in air flow were smooth for the case in which air flow was 20 to 40 times per hour and delay control was used. The electric current consumption in the kitchen and temperature at A2 are shown in Figures 7 and 8. The temperature fluctuated less with variable air flow (Figure 8) than with fixed air flow (Figure 7). This was likely attributable to the effects of replacement ventilation and to changes in ventilation rate according to the heat produced from the kitchen equipment. The electric current consumption in the kitchen and humidity at A2 are shown in Figures 9 and 10. The humidity fluctuated less with variable air flow (Figure 10) than with fixed air flow (Figure 9), but was more stable at temperatures shown in Figure 8.

Comprehensive comparison

The mean heat quantity of the cooling water, electric current consumption in the kitchen, room temperature at A2, etc. are comparatively shown in Figure 11 for Cases 1 to 10 (excluding Case 7 in which some data were missing), for a hood surface speed of 0.3 m/s, and with air for gas combustion. The values for Cases 1 to 6 are the means for six hours between 7:00 to 13:00, when the loads were high, and those for cases 8 to 10 are the means for five hours between 8:00 to 13:00. The heat quantity of the cooling water was set to be the heat necessary for cooling the outdoor air of 30^{o}C, 70% humidity and 78.16 kJ/kg to the temperature of the supply air determined for each case to eliminate effects from the differences in outdoor air temperature. The power for moving the fan was calculated using:

$$kW = Q(T.P.) / 6{,}120\eta_T$$

where, *kW*: the power for moving the fan [kW], *Q*: air flow [m^3/min], *T.P.*: total pressure of the fan (= 120 mmAq, total of the air supplying and exhausting fans), and η_T: the fan total efficiency (= 0.5).

The results showed that: (1) The primary energy consumption was the smallest in Case 9 (ventilation rate of 20 to 40 times, supply air temperature of 20^{o}C). Since the electric current consumption in Case 9 was large, the small energy consumption was not attributable to small internal loads. (2) Even with a ventilation rate of about 25 times per hour, which was determined by multiplying the total electric capacity of the kitchen equipment and 30 m^3/kW, the ventilated ceiling system could satisfy the standards of the Ministry of Health, Labour and Welfare by setting the temperature of the supply air at 16^{o}C. (3) The temperature of the supply air, as well as ventilation rate, largely affected the energy consumption by cooling water. For example, the energy consumption by cooling water differed by 30% and 40% between Case 6, in which the ventilation rate was 20 to 40 times and the temperature of the supply air was 16^{o}C, and the case in which the ventilation rate was the same but the supply air was at 20^{o}C. (4) The power of the fans accounted for a small percentage of only 5 to 10% of the energy consumed by cooling water. (5) Ordinary hoods required much more energy for cooling water since the ventilation rate was larger than the ventilated ceiling system. (6) With Case 9, which consumed the least amount of energy, a gas kitchen, in which a theoretical amount of air was assumed to be burnt, required a double amount of energy for cooling water.

DISCUSSION

The ventilated ceiling system formed thermal stratification, which improved displacement ventilation, and maintained a good thermal environment in the working area. To meet the standards of the Ministry of Health, Labour and Welfare, the system should be operated at a ventilation rate of 25 times per hour with supply air at 16°C or a ventilation rate of 20 to 40 times per hour with supply air at or below 20°C. Of the cases tested, a ventilation rate of 20 to 40 times per hour with supply air at 20°C resulted in the smallest heat quantity in the cooling water. The mean ventilation rate in the variable air flow operation of 10 to 40 times per hour was 33.4 times per hour. Ordinary hoods and gas kitchens required large ventilation and thus resulted in large heat quantities in the cooling water. Variable air flow operation with delay control resulted in small room temperature fluctuations. Since the ventilation rate was kept to be at least 20 times per hour, the room temperature became too low after the termination of kitchen works. Thus the system should be desirably controlled by raising the minimum ventilation rate and/or raising the temperature of the supply air. Since the amount of cooling water used depended largely on the temperature of the supply air, the set temperature should be decided by considering the running costs and comfort of kitchen workers as well as the standards of the Ministry of Health, Labour and Welfare. The kitchen investigated in this study mainly performed secondary processing of precooked foods and cooked no stir-fried foods, which need large fire power. The system met the standards of the Ministry of Health, Labour and Welfare even at a constant ventilation rate of 25 times per hour in the kitchen, but there may be kitchens in which the standards cannot be met depending on the works to be performed. On the other hand, variable air flow operation is widely feasibly since the ventilation can be changed depending on the usage of kitchens via the software program for determining the electric current and ventilation rate.

Ventilation and Industrial Hygienic Measures to Reduce Chemical Exposure in Car Repair Painting Shops

Timo Hautalampi, Maj-Len Henriks-Eckerman, Hannu Koskela and Pekka Saarinen

Finnish Institute of Occupational Health

SUMMARY

The main target of this research project was to find technical and industrial hygienic solutions for small car body repair shops to reduce worker's exposure to chemicals during the painting process. Worker's exposure to isocyanates and solvents was measured during painting with portable instruments in five car body shops of different ventilation and occupational hygiene levels. Ventilation performance was studied as well. Concentrations of isocyanates were high in the painter's breathing zone when solvent-based paints were sprayed. Also, the varnish applied on water-based paints contains isocyanates, and therefore their concentrations in the air were high during spraying. The highest solvent concentrations in the breathing zone were measured during the cleanup of the spray gun. Therefore, it is highly recommended to use a paint spray respirator and proper gloves when cleaning up the spray gun. In addition, use of a fume cupboard in paint mixing and spray gun cleanup is preferable . Primers were commonly applied to car bodies in a poorly ventilated preparation room without the use of a proper breathing respirator. Therefore, personal exposure to solvents was often higher in the preparation room than in the spray booth. It is recommended that all painting should be done in the spray booth.

INTRODUCTION

Workers are still exposed to hazardous isocyanates and solvents in car body repair shops despite the implementation of water based paints. The main target of this research project was to develop technical and industrial hygienic solutions for small car body repair shops to reduce worker's exposure to these chemicals during the painting process. Because the main target was in small companies, it was also important to find economical solutions. It was assumed that the painters' personal exposure to chemicals can be substantially reduced by quite simple adjustments to the working process. For example, previous studies by the research group have shown that it is quite common in Finland to spray primers to car bodies outside the painting booth. It was also assumed that ventilation performance could be improved by some minor development of the system. This presentation is based on the research project called "Preventive ventilation measures to reduce chemical exposure in car painting shops".

METHODS

A preliminary study was done in 22 car painting shops in southwestern part of Finland in order to find out the level of both the ventilation techniques and the occupational hygiene. The pre-study consisted of visual observations, interviews of the painters and observations of their work, examination of the ventilation method, smoke tests (pressure conditions, air flow directions) and observation of the used chemicals (paints, varnish and solvents). A lot of attention was paid on personal working manners, used chemicals and personal protective equipment.

After the preliminary study, five typical car painting shops were selected for more detailed investigations. They all had different types of ventilation systems. Worker's exposure to isocyanates and solvents was measured during the painting process with portable instruments. The same car hood was painted in all five shops. Ventilation performance was studied by measuring the air flow rate and the air velocity. Air flow pattern was visualized with smoke tests.

Table 1. Description of the car paint shops.

Car Painting Shop	1	2	3	4	5
Air change rate (1/h)	0.7	14	123	260	240
Characte-rization	natural ventilation	locally made booth	old factory made booth	good shop	high quality shop
Supply air distribution	leakage air flow rate	ceiling (2x2 m²)	whole ceiling	whole ceiling	whole ceiling
Exhaust location	near ceiling	6 pcs h=1,0 m	on the floor level	on the floor level	on the floor level
Water based paints				x	x
Paint mixing	grinding room, no ventilation	no mixing, use of factory mixed paints	paint mixing room, poor ventilation	paint mixing room, poor ventilation	paint mixing room, good ventilation
Spray gun wash	grinding room	grinding room	grinding room	paint mixing room, poor fume cupboard	paint mixing room, good fume cupboard

Total concentration of solvents was measured with VOC monitor (PID) at painter's breathing zone and the measurement signal was combined to video. This was done in order to find out the most exposive working tasks. Also the effect of different working methods was examined.

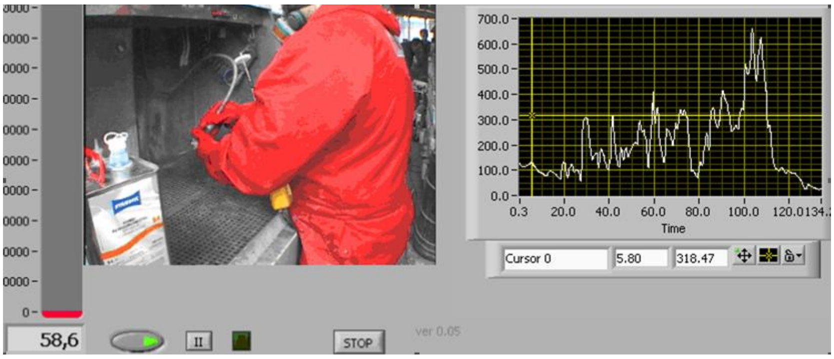

Figure 1. Combined measurement signal and video

Furthermore, computational fluid dynamics (CFD) was used in order to compare the effect of different air distribution methods and exhaust placements to concentration distribution and air flow pattern. Calculations were done in a steady state situation just after the car hood had been painted. Calculations were made with ANSYS CFX 10.0. In the basic situation (case 1), supply air was blown from the whole ceiling area and the exhausts were on the floor level. In case 2, supply air was blown to the room from a smaller area (2x2 m^2) of the roof and exhausts were on the wall at the height of 0.5 m. Booth air concentrations were compared to exhaust air concentration in both cases.

RESULTS

Main results of the pre-study

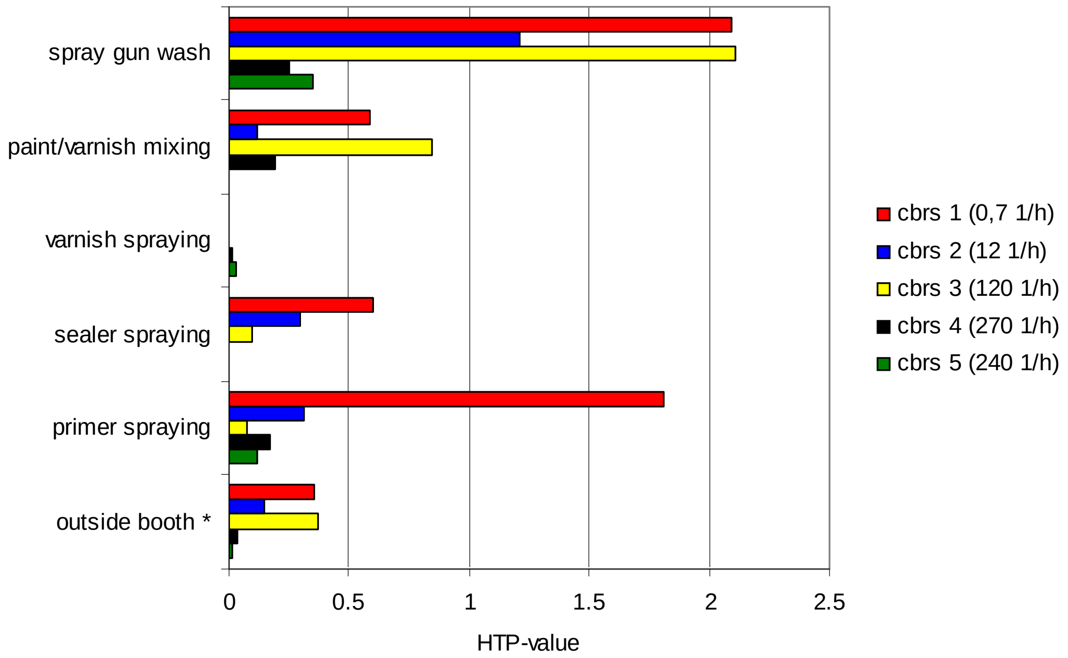
Water based paints were used only in the four biggest of the studied car painting shops. Other shops were still using traditional solvent based paints. Even in cases where water based paints were used, the varnish applied on paints still contained isocyanates. The hardeners of traditional paints also contain isocyanates (HDI). Primers were sprayed commonly outside the spray booth in premises where ventilation was often quite poor.

The use of respirators varied in different car body repair shops. Painters used half mask during painting in most of the cases, but only in some cases in spray gun washing and paint mixing.

Main results of the study

The results of the measured mean solvent concentrations with samplers in different work tasks are presented in Figure 2 and the measured isocyanate concentrations are presented in Table 2.

A typical example of the time variation of measured solvent concentrations is presented in Figure 3.



* Compared to Finnish 8 h OEL, others 15 min OEL

Figure 2. Measured solvent concentrations in different car body repair shops

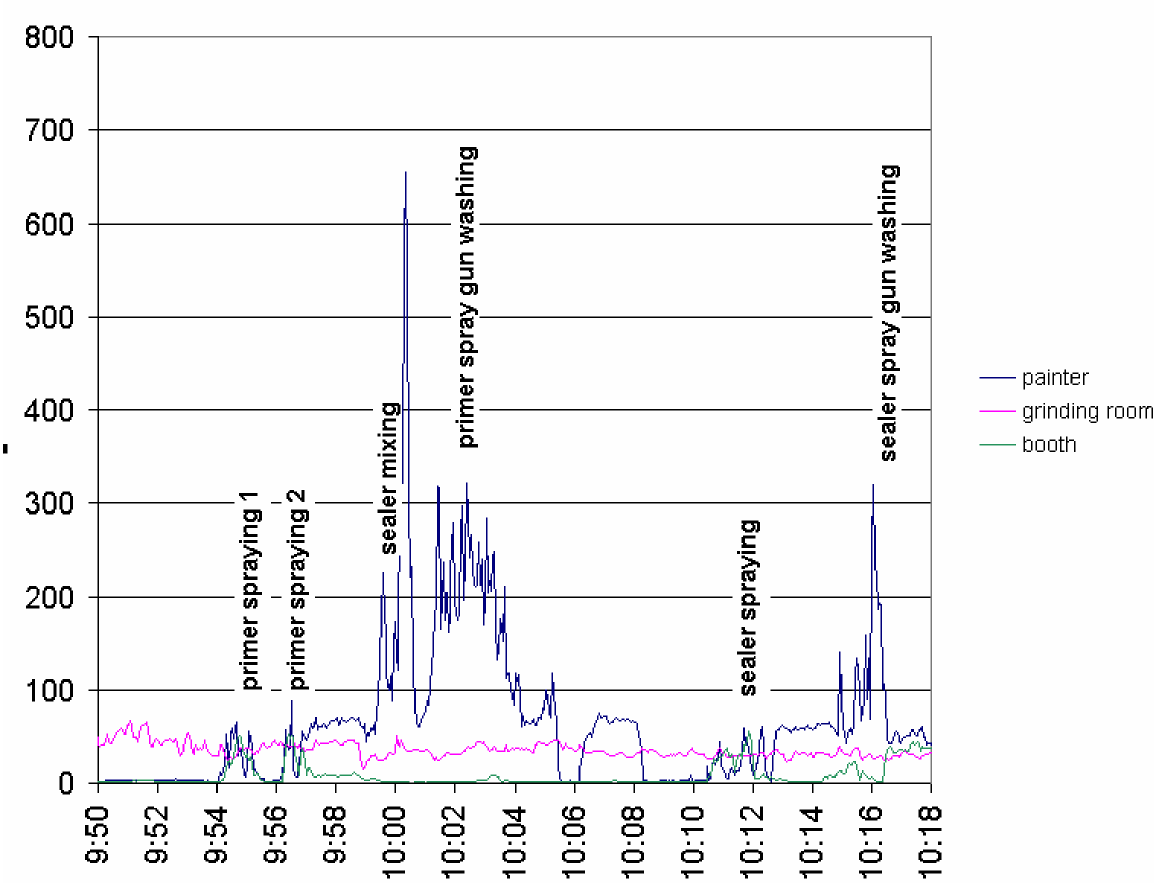


Figure 3. Measured time variation of relative solvent concentrations during different work tasks.

The highest solvent concentrations were measured during spray gun washing. High concentrations were measured also in mixing and liquid pouring. Special attention was paid to spray gun washing. It was examined with combined video and measurement signal. Personal working customs affected significantly painter's exposure to solvents. Worker's exposure to solvents was also remarkable in the grinding room when compared to the 8 hours exposure limit. This finding is important, because painters don't use personal protective equipment. Solvent concentration in the spray booth was below 20 % of TLV (Threshold Limit Value) when air exchange rate exceeded 100 1/h.

Concentrations of isocyanates were high in the painter's breathing zone when solvent-based paints were sprayed. Measured levels exceeded 5 – 170 times the TLV. The varnish applied on water-based paints contains isocyanates and therefore their concentrations were high during spraying (2 times the TLV). Concentrations of isocyanates were very low in sealer/varnish mixing and spray gun washing.

Table 2. Isocyanate concentration in painter's breathing zone
(Finnish $TLV_{15\ min}$ = 0.035 mg NCO / m³)

work phase	n	Isocyanate concentration level (mg NCO / m³)
primer spraying	3	0.003 – 0.42
sealer spraying in the booth	3	0.18 – 6.0
varnish spraying in the booth	2	0.044 – 0.070
sealer/varnish mixing	4	< 0.001
spray gun washing	5	< 0.001

The results of cfd-calculations are shown in Figure 4 and Figure 5.

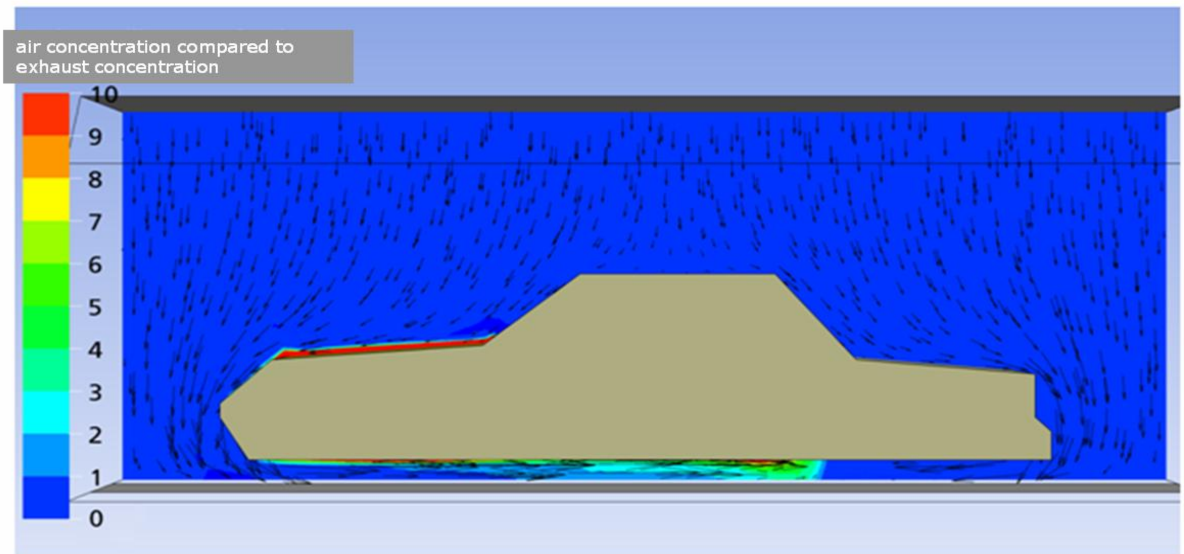

Figure 4. Calculated solvent concentrations in case 1, where supply air was blown from the whole ceiling area and the exhaust was placed on the floor level.

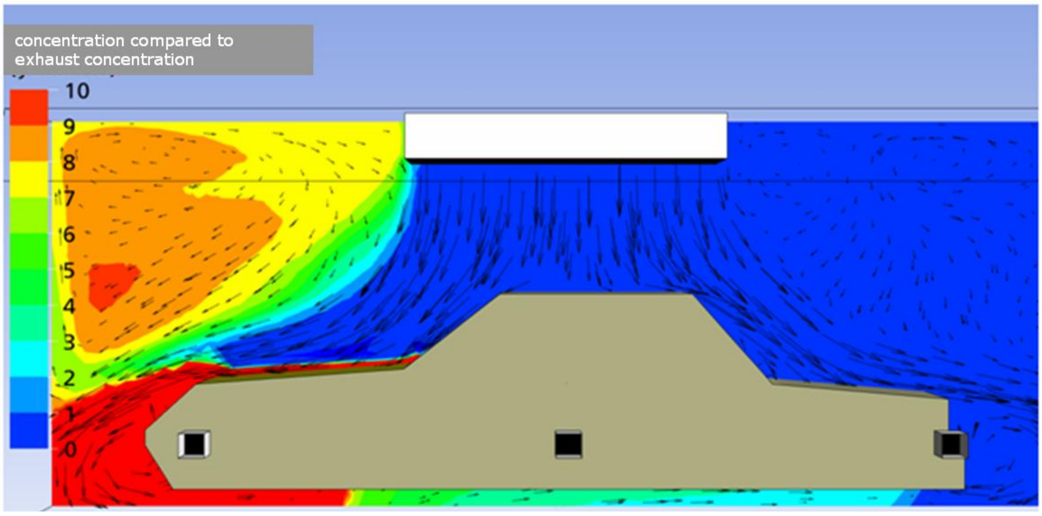

Figure 5. Calculated solvent concentrations in case 2, where supply air was blown from a small ceiling area and the exhaust was placed on the walls at the height of 0.5 m (black squares).

In case 1 the air flow in the booth is directed towards the exhausts, which are placed on the floor level. High solvent concentrations are located just above the painted hood and on the floor level. In case 2, where the supply air was blown from a smaller ceiling area, a large eddy distributes solvents widely to the booth. Smoke tests in real booths gave flow directions similar to the modeling.

DISCUSSION

Highest solvent concentrations were measured during the cleanup of the spray gun. Therefore, use of a proper paint spray respirator and gloves is essential when cleaning the spray gun. Paint mixing and spray gun washing should be done in a fume cupboard or in a separate under pressured room. The effectiveness of fume cupboard is not always adequate. Especially, cleaner solvent spraying from the spray gun often spreads outside the fume cupboard. Therefore, it should be possible to spray the solvent directly to the exhaust. Moreover, open solvent cans should be placed in a fume cupboard or in an under pressured space.

In the spray booth the solvent concentrations were below 20 % of the Finnish TLV when air exchange rate exceeded 100 1/h. Primers were commonly sprayed in a poorly ventilated preparation room without a breathing respirator. Therefore, personal exposure compared to the 8 h exposure limit to solvents was often higher in the preparation room than in the spray booth. All spraying should be done in the booth to minimize unnecessary exposure to solvents.

Concentrations of isocyanates were very high in the painter's breathing zone when solvent-based paints were sprayed. Measured values exceeded 5 – 170 times the Finnish TLV.
The varnish applied on water-based paints contains isocyanates and therefore their concentrations were high during spraying. Measured levels were twice the Finnish TLV for isocyanates.

The most effective way to ventilate the spray booth is the use of downdraft. Supply air should be blown from the entire ceiling and the exhaust should be placed on the floor level. The booth should be slightly under pressured to prevent contaminant leakage from the booth.

The most serious inadequacies of ventilation were found outside the spraying booth. More attention should be paid on the ventilation of paint mixing, spray gun mixing, paint storage and grinding premises.

It is essential to improve the workers' awareness of the health hazards of the chemicals and the importance of using personal protective equipment.

ACKNOWLEDGEMENT

The financial support of The Finnish Work Environment Fund is highly appreciated.

Ventilation Concepts in Operating Rooms An Innovative Research Project

Prof. Kurt Hildebrand and Dominique Helfenfinger

University of applied sciences of Central Switzerland, Switzerland

SUMMARY

The current state of building services engineering in the healthcare sector is characterized by ambiguity and prejudice. There is a conflict, with inadequate knowledge of the necessity and effectiveness of ventilation-based protection concepts on the one hand – with the associated investment and operating costs if an integral view is adopted – and the economics of antibiotic prophylaxis and infection treatment costs on the other.

Keywords: HVAC systems in hospital, engineering in health facilities, operating room
Category: Innovative technologies and solutions / Innovative research project

INTRODUCTION

The "GiG" building services engineering in healthcare project is an interdisciplinary research and development project. The cost transparency and lump compensations per treatment unit required by healthcare policies are giving rise to new strategies and new cost/benefit considerations. Having to treat customers (i.e. patients) for as short a time as possible is becoming an increasingly attractive proposition. In order to achieve this, building services equipment as a whole must comply with requirements on hygiene.

The continuing spread of multi-resistant pathogens and the corresponding rise in the use of increasingly expensive antibiotics in hospitals and other healthcare facilities must be sustainably reduced.

This project will make contributions to building services engineering research and development with the aim of reducing both healthcare and building services costs in Switzerland by CHF 24 MN per annum. It is a project of international consequence in terms of private enterprise, research and health policy.

The major foreign research partners are represented by Prof. Dr. Ing. Rüdiger Külpmann, TFH Berlin and Dr. med. habil. Peter Lüderitz, AYSID Hygiene-Institut, Berlin. The main domestic partner is the Innovation Promotion Agency KTI/CTI of the Swiss Confederation, which is providing half of the project financing.

Surgical procedures make the highest demands on the sterility of the air in operating rooms, but not in the anterooms. Today we concentrate on creating the best possible conditions (asepsis) for the operating team in the vicinity of the operative field and instrument tables.

Heating, ventilation and air-conditioning systems are necessary for reasons of
- physiology / physical comfort (wellbeing)
- hospital-specific indoor air hygiene (infection prophylaxis),
- the technical process (functionality and safety requirements).

The primary purpose of air-conditioning is to ensure optimal conditions in terms of physiology and occupational health. The latter will require increasing attention in future. Bearing in mind all the routes to infection, the current expense in terms of ventilation technology to reduce the germ number of the indoor air outside the operating room appears excessively high, especially with regard to investment costs and ongoing maintenance costs.

New air-conditioning technology concepts can also be put to meaningful use in healthcare facilities. The basis is provided by requirements for hygienic air quality in hospitals as reformulated by hygienists, and the associated simplification for ventilation and air-conditioning technology from the point of view of hospital hygiene. High demands on the sterility and protective action of the air pertain only to the immediate vicinity of invasive procedures, to the care of immunosuppressed patients, to handling of hazardous airborne materials, and to isolation care. Therefore, interest in highly sterile air or directed airflows focuses on precisely defined areas in modern hospital hygiene. Requirements are function-specific, and they differ from room to room.
In the characterization of the necessary air treatment equipment, therefore, it seems useful to make a distinction according to characteristics of physical comfort and infection prophylaxis.

Assuming that, downstream of the upright filters, the supply air entering the conditioned space is sterile, the operating team, the nurses and the patient must be considered to be the primary emitters of microbes. Medical equipment and furnishings mainly represent thermal loads. Air treatment systems must also meet "normal" requirements in addition to hospital-specific requirements.

Evaluations, student dissertations and laboratory tests have revealed that existing concepts have clearly lacked an overall approach. Results and measurements are unsatisfactory in all respects.

Status of our own research

Development activities, and the resultant new Swiss SWKI 99-3 directive, represent the philosophy that air hygiene should concentrate only on areas where there is a risk to patients, instead of operating aseptically in all areas.

This philosophy has two important goals: to provide the best possible patient protection with the least possible energy expenditure and, at the same time, to make an intensive effort to get under control the costs of treating the infections and the problems of antibiotic resistance occurring in hospitals.

The basic idea of OR ventilation promoted by the new Swiss SWKI 99-3 directive stems from the experience that a very wide variety of procedures are performed in many hospitals – from urological procedures, which are of lesser significance in terms of air hygiene, to the highly demanding implantation of prosthetic joints. On the basis of numerous publications, the conviction has become prevalent that only a large LAF (Laminar Air Flow) ceiling panel with very good shielding effect is suitable for demanding procedures. On that basis, there are no resultant special requirements for the other areas of the OR and even in the environment of the LAF field itself in terms of ventilation technology. Consequently, activities with increased hygienic requirements must only be performed in the OR, specifically in the LAF zone only.

Until now, independent technical and/or hygienic investigations have been performed in different ways, with different task definitions and according to different procedures (mainly in specific, already completed and no longer modifiable clinical operating rooms, under time pressure and only if the clinic was kind enough to grant access to the room during off-peak hours). Therefore, the individual investigations are barely comparable with each other. Clinical issues always took precedence, and structural or technical changes were barely possible. The results of investigations performed so far in the development departments of LAF outlet manufacturers, for example, are not generally available for scientific evaluation and use, with the exception that the influence of structural factors or of OR lighting was taken into account in those investigations.

Within the hospitals section of the Swiss administration's Energie 2000 program, memoranda generated during the operational optimization phases of the hospitals clearly reflect the unsatisfactory state of hygiene-relevant spaces.

This means that, although some development has taken place, there has as yet been no systematic and comprehensive, application-oriented research using exact and reproducible scientific methods.

State of the art (national, international)

The national situation is reflected directly at the international level. German, Austrian and Swiss hygienists and engineers have been working together for some time to discuss requirements and technical possibilities, at least in the German-speaking region.

Additionally, the Swiss standardization body for the construction sector, SIA, has expressed willingness to intensively support the standardization efforts of CEN (based on Switzerland and Germany). The German Association of Engineers, VDI, took over the current version of SWKI 99-3 and published it in Germany in 2004 as the applicable directive for hospitals and building services engineering (draft VDI 2167).

Since 2003/04, therefore, there has been a single directive that is able to reflect the present and future state of the art. The blanket deployment of this instrument/knowledge is to be accomplished via the network/center of competence of HTA Lucerne and the Berlin University of Applied Science TFH as well as the project partners from the industry.

An ad hoc CEN meeting took place in March 2004 to discuss the question of research and standardization of building services engineering in hospitals. The European CEN partners that attended were unanimous: today's knowledge is somewhere between imprecise and incorrect, and must be urgently revised. Working Group WG 13 of Technical Committee TC 156 officially began its work in November 2004. The convenor of the WG is the author of this document.

RESEARCH GOALS

The research goal is to analyze the contamination paths of airborne germs (particles) and to eliminate them via new and innovative ventilation concepts. Since ventilation investigations for operating rooms cannot be done in scale model environments, and there are no simulation tools today that deliver sufficiently precise results, it is clear that today's OR ventilation technology must be investigated in the laboratory.

Investigations (among others in 2003/2004 term papers and dissertations of the HVAC/S department of HTA Lucerne) have shown that new systems with laminar flow ceilings do not always function as desired. OR lighting, for example, can cause undesirable mixing. Therefore, research and development work is needed.

Ventilation and measurement methods should be developed further, and not only theoretical but also experimental work is necessary.

There is no laboratory test facility for OR ventilation in Europe today. Professional associations, the industry, hospitals and German institutes are interested in our OR ventilation laboratory test facility.

The hospital hygiene project is of far-reaching international significance, since most hospitals (over 500 in Switzerland alone) are entering the renovation phase of their life cycles, and new, focused standards of hygiene need to be reviewed and developed further. Complementary work is required in the research sector. Airborne contamination paths and the ingress of germs attached to airborne particles must be investigated. Initial investigations have shown that insufficient attention has been paid to particle ingress from the sides and to contamination of the operating table from below, and that such ingress is being found to be considerable.

For this purpose, a test facility for OR ventilation is being set up to facilitate work in the field of OR qualification, hygiene, airflow investigations and metrology.

We have divided the overall project into five sub-projects:

Sub-project 1: heating and ventilation engineering concepts
Sub-project 2: OR lighting (flow optimization, new development)
Sub-project 3: measuring methods (quality controlling, quality assurance)
Sub-project 4: CFD (flow simulations as a supporting resource)
Sub-project 5: knowledge transfer and implementation

In addition to these research and development activities, an accreditation center for measurement of operating rooms or for companies providing such services is to be established at HTA Lucerne in cooperation with TFH Berlin.

NEW PERSPECTIVES

The current state and understanding of building services engineering in the healthcare sector is characterized by ambiguity and prejudice. There is a conflict, with inadequate knowledge of the necessity and effectiveness of ventilation-based protection concepts on the one hand – with the associated investment and operating costs if an integral view is adopted – and the economics of antibiotic prophylaxis and infection treatment costs on the other.
The research project is intended to contribute to the objectification and clarification of the situation.

What is new is above all the possibility to perform systematic investigations in a realistic operating room without the constraints on time and scope that real operating rooms impose. This alone makes it possible for the first time to perform comprehensive scientific investigations. Also new is the aspect that the investigations include the entirety of the OR equipment instead of individual aspects with findings that are not transferable to actual practice.

Therefore, the desire for an overall view of building services engineering and hygiene, and with it the desire for a functioning OR unit, also becomes the assignment. How can a concept be developed that meets both the needs of hygiene and the usual requirements on building services equipment? What will the future protection concept for hygiene and building services be like in order to achieve the defined characteristic values?

The goals have been divided into the five sub-projects described above for better understanding and simpler coordination. They will be accomplished individually and integrated at a higher, interdisciplinary level.

ALL PARTICIPANTS ARE WINNERS

Contribution to healthcare

Cost savings for health insurance providers and premium payers, as well as a reduction in patient suffering due to:

Infections: prevention of hospital acquired infections.
Hospitalization times: patients will spend less time in hospital.
Treatment: patients will not always require additional treatment with expensive antibiotics, and staff can concentrate on treating the basic condition.

Hospital and healthcare cost reduction:

Hygiene: Concentration on (in future, verifiably effective) hygienic protection concepts where there is a real risk. Cost reduction through reduced use of antibiotics, which is also appropriate in the light of the antibiotic resistance problem. (MRSA – multiresistant staphylococcus aureus, which occurs in hospitals in particular, is a serious problem, since these bacteria are resistant to most antibiotics)

Energy: avoiding needless asepsis in all areas means reduced air volume and less expense for hygiene in no-risk areas in the vicinity of invasive procedures (i.e. asepsis in the OR only, and not in the entire green zone).

Investment: The enclosed space (building investment) for central building services and ventilation shafts will be reduced. The outdoor air treatment equipment will be reduced to the dimensions necessary to meet the actual requirements for hygienic ventilation. Relatively little space is required between or above the conditioned spaces for the air circulation equipment and the necessary silencers (but it must be considered by the architects!). The ventilation equipment can be optimized selectively. Less investment expense will be necessary on average. Simplifications in the concepts will be possible.
Operating costs: Energy savings with local air recirculation instead of vast volumes of outdoor air that require constant heating or cooling. Reduced expense of preventive and corrective maintenance.

Medical product liability: Room air treatment systems make an important contribution in the field of medical product liability.
The sterility chain must be assured via organizational measures and improvements in ventilation. Sterile items must be protected against contamination, from unpacking to readying on instruments tables to use.
Lump compensations will necessitate a philosophical change in healthcare that will make investments in correct building services inevitable. If doctors are no longer paid according to hours worked but according to lump sums for each service provided (e.g. hip replacement) it will become economically relevant if a patent acquires an infection or can be discharged a few days earlier.

Goal = benefit for industry partners:

The goal of the industry partners is to optimize or redesign their products according to the redefined building services engineering requirements, i.e. taking the aspects of hygiene-relevance into account.

This will help them to achieve or maintain competitiveness, and create sustainable jobs in the healthcare supply sector while also reducing costs.

Goals from the hospitals' perspective:

Cost reductions are to be achieved in the OR area due to a highly sterile environment (reduced use of antibiotics) as well as energy savings on OR ventilation.

In the coming years, more than 600 operating rooms will be due for renovation in Switzerland alone; over 8'000 in the whole of Europe. The ongoing costs, which have until now been caused by poor hygiene, partially due to building services equipment, could be reduced in this context.

Direct cost reduction:

We have estimated the cost reduction in Switzerland and Germany based on reports from the statistical authorities in both countries as well as on statistics from the Energie 2000 program and dissertations from HTA Lucerne and TFH Berlin. With optimal use of building services equipment, i.e. through optimization and deployment of new products, costs could be reduced by an amount in excess of CHF 12 MN (a factor of 10 more than that in Germany, i.e. CHF 240 MN) per annum.

Benefit from economic recovery:

As a result of the new SWKI 99-3 directive for hospitals, which has been applicable in Switzerland since 11/2003 (VDI draft 2167), products are being withdrawn from the market and replaced with new developments (e.g. OR lamps, LAF outlets, media supply units, etc.).

The inevitable result is better and cheaper medical care for our population. This benefit is naturally also transferable to surgical day hospitals and outpatient surgeries.

Air Distribution Strategy Impact on Operating Room Infection Control

SUMMARY

This paper discusses the impact of different air distribution strategies on infection control in operating rooms. The quality of air in an operating room is primarily assessed with regard to how effective the air distribution strategy is in minimizing the possibility of airborne particles causing infection to the patient. The ASHRAE Research Transaction paper titled, "Comparison of Operating Room Ventilation Systems in the Protection of Surgical Sites" [1], is reviewed as a starting point. A number of air distribution strategies are then reviewed and a qualitative assessment of each strategy will be presented. The design concepts to be reviewed were:

- Type of supply air diffusers
- Exhaust/ Return air locations
- Lighting and medical equipment location effects

Constant air exchange rates and supply air temperatures were assumed in the case studies, which include: 1) The new operating rooms at University of Massachusetts (UMass) Memorial in Worcester, MA, USA in which an air curtain/ laminar flow supply air diffusion concept was implemented: and 2) The new Hospital for Special Surgery in New York City in which laminar flow panels with manually variable airflow direction have been installed to study impacts on patient outcomes and infection control. Computational Fluid Dynamics (CFD) models of each of the case studies are presented with documented findings which support the qualitative assessment.

INTRODUCTION

Infection Control Overview

The assessment of indoor air quality depends on the type of space being assessed. In a healthcare environment, indoor air quality is primarily assessed by minimizing the effects of the rate at which the ventilation distribution system either protects the patient from infection, or conversely, contributes to infection risks. While infection control is clearly the primary focus in air distribution strategies, thermal comfort issues should also play a role in assessing the quality and effectiveness of the air distribution system, even in a healthcare environment. This is especially true in what many consider to be the most critical of spaces in a hospital- the operating room- where the thermal comfort of the patient and medical personnel in the operating room are a very different issue.

Recognizing that patient outcomes may be affected by the thermal comfort of the operating room occupants, infection control is still the main concern. One recent study [2] has shown that 2.54% of patients that have invasive procedures experience complications related to post operative infections. While it is commonly held, and for good reason, that the major concerns are the sterile procedures used by the healthcare practitioners, the air distribution and exchange rate strategy can have a significant effect on the patient outcome as it relates to the likelihood of complications due to infection.

Intuitively, indoor air quality would not appear to be a primary concern in a critical environment like an operating room. Instead, issues such as the quality of the lighting, room layout and how potentially life saving equipment is placed, sterile procedures, and overall cleanliness of the room would seem to be paramount. However, as evidenced by the detailed requirements outlined in the American Institute of Architects (AIA) Guidelines for Healthcare [3], the concepts for how air is distributed, filtered or exhausted, and how often the air is changed in the room are very important.

In an operating room, the AIA Guidelines specify a minimum exchange rate of 15 air changes per hour. It is important to understand that the guidelines only address minimum standards for the air distribution and thermal control systems. Most hospitals have standards that require higher air exchange rates than the minimum AIA standards. The most recent version is the 2006 AIA release of "Guidelines for Design and Construction of Hospital and Health Care Facilities".[3] There are other guidelines, such as Association for Heating Refrigeration and Air Conditioning Engineers (ASHRAE) and the Center for Disease Control (CDC) in the U.S. These guidelines include ASHRAE's new design manual "HVAC Design Manual for Hospitals and Clinics" [4] and CDC's "Guidelines for Environmental Infection Control in Health-Care Facilities". These new standards are being updated due to the Infection Control Risk Assessment (ICRA) [5] which is "conducted by a panel with expertise in infection control, risk management, facility design, construction, ventilation, safety, and epidemiology" as required by AIA Guidelines [3].

In addition to these guidelines, there are studies, both theoretical and evidenced based, that show that increasing the air exchange rate reduces the amount of contaminated air in a space and, therefore, reduces infection risks for the patient. In a study done by The Center for Heath Design, it was found that infections are transmitted through air, surface contact and water [3].

In addition to the evidenced based support for the importance of higher air exchange rates, there have been recent ASHRAE-supported studies which used some of the latest software techniques to attempt to model air distribution concepts in operating rooms to determine theoretical optimization of the air distribution concept, as they relate to infection control. Specifically, one by Memarzadeh and Manning [1] attempted to address this topic from a computer modeling framework utilizing computational fluid dynamics software.

The intent of this paper is to extend concepts presented in this theoretical study to two real-life systems designed and constructed within the past year; the new operating rooms at the University of Massachusetts Memorial Lakeside Addition in Worcester Massachusetts, and the new operating rooms at the Hospital for Special Surgery in New York City.

Summary of the paper "Comparison of Operating Room Ventilation Systems in the Protection of the Surgical Site [1]"

The main focus of this paper was to examine the different outcomes of a common operating room with two variables, first being the diffuser locations and second being the air change rate per hour (ACH). The reader is referred to the study for detailed criteria regarding assumptions for modeling the space and equipment in the room.

This study evaluated eleven systems, each of which consisted of a different diffuser set up, a different ACH, or a combination of the two. During the simulations performed for this study, particle tracking was done from three different sources. These particle origination sources were the surgical staff leaning over the patient, the circulating nurse and the tracked particles known as "main" which represented the particles passed from general surgical activity around the table.

The three different particle start locations were tracked with each of the eleven possible ventilation systems. The outcome of the research was analyzed in two different categories based on whether the particle was removed or if it hit the surgical site or back table. For the first situation of the particle being vented from the room after one hour it was found that the laminar flow diffuser with 150 ACH system was the best for all three particle cases. The most inefficient concept was the U-shaped diffusers.

The second category for evaluating the different system concepts was based on if the particle hit the surgical site or the back table proved that the laminar flow diffuser with mixed (high and low) exhaust / return elevations was the most efficient at keeping the particles from hitting the surgical site, however only had a mediocre performance at keeping particles from hitting the back table. The most inefficient at keeping the particles from the surgical site was the conventional diffusers.

From this research it can be concluded that the best systems were the laminar flow systems. While the outcome varied based on location of the diffusers, it was not significant enough to firmly conclude that the high and low exhausts systems should not be used. However, the updated AIA Guidelines 2006 recommend that the high and low return/exhaust strategy is preferred [3].

RESEARCH

The Memarzadeh and Manning study advanced the understanding of air flow concepts by identifying the thermal plume from the patient, doctor and nurses as a critical factor to be addressed. Assuming these findings to be accurate, it is important to note a couple of other important factors in assessing laminar flow concepts in an operating room that are often assumed to be negligible. These are the effects of the lighting and the obstructions (booms and movement of surgeons) on laminar flow systems. This study attempted to model the effect of these variables in the context of the two case studies. The assessment is done utilizing similar CFD analyses. The IES Macroflow [6] software was used. The particulate count was not addressed, rather, air flow patterns from clean to "less clean" spaces were modeled. Key model parameters and assumptions were:

- 8m x 7.7m x 4m (24 ft x 23 ft x 12 ft)
- One surgical staff members
- One patient
- One surgical stand
- Three surgical lights
- Two monitors (and stands)
- One operating table

The following sections summarize the results of the CFD studies as applied to the two field site case studies.

UMass Memorial Case Study

The UMass Memorial air distribution concept utilizes the standard laminar downdraft flow concept delivering air at a low velocity directly above the patient area, as shown in Figure 1.

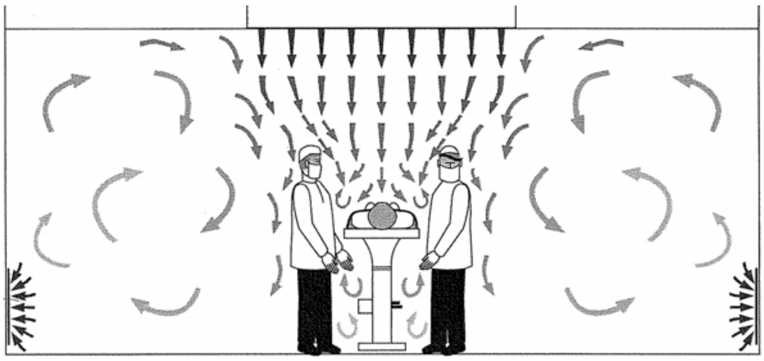

Figure 1. Standard laminar flow system concept without curtain. [2]

In addition, a linear supply air flow can be provided to apply an air curtain at the boundary of the operating area, protecting the clean area of the space from the less clean area of the space. (See Figure 2.)

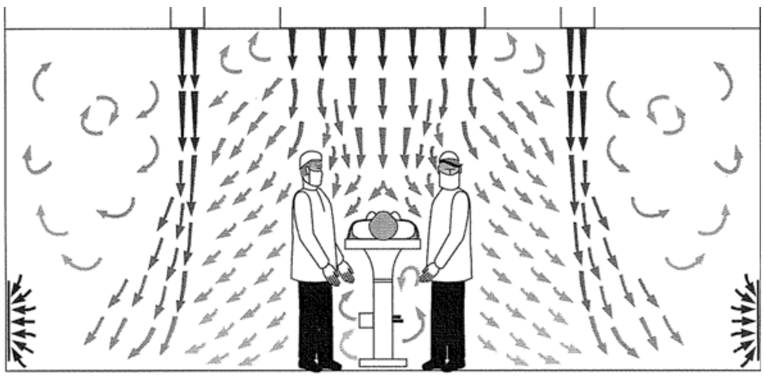

Figure 2. Laminar flow system with air curtain concept. [2]

Return grilles are located low in opposite corners of the space, and the room is under a positive pressure, consistent with the clean to less clean concept. The central air handling system has high efficiency particulate absorbing (HEPA) filters. The air is returned from the space. Of the flow needed to achieve 25 ACH; approximately 33% is brought in from the outside. This exceeds the minimum requirements of 15 ACH and 3 ACH of outside air required by the AIA Guidelines.

There are three medical booms in the laminar flow surgical area. The thermal plume from the patient is assumed to be 0.04 kW (136 Btu/hr), and the heat from the lights (which are located at the ceiling between the laminar flow diffusers and the linear, air curtain diffusers) is assumed to be radiating at 0.32 kW/m^2 (100 Btu/hr-ft^2). The heat from the lighting on each boom is estimated at 0.41 kW/m^2 (130 Btu/hr-ft^2).

The CFD model results (Figure 3) indicates that the particle path does flow from the clean to less clean area. The positive effect of the linear diffuser concept is clearly indicated. The air curtain has effectively isolated the clean zone, and has also provided an increase in air change rate in the patient zone by inducing air flow away from the clean zone. This results in an increase in the effective air exchange rate within the clean zone from 25 ACH to well above 40 to 50 ACH [2]. It is important to have as little space as possible between the linear diffusers as to reduce the induction of less clean air into the airstream and to avoid stagnant or low velocity areas which will trap contaminants [2]. As noted in the reference to the ASHRAE research studies on this topic [1], this results in a reduced likelihood of patient infection.

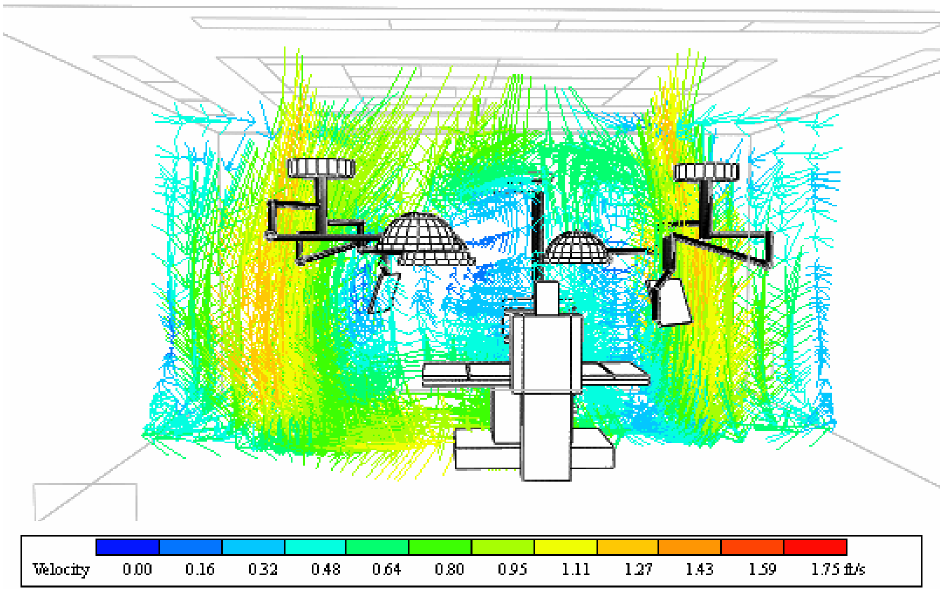

Figure 3. Velocity profile from the UMass study showing the laminar flow air curtain surrounding surgical area.

The next two figures (Figure 4 and 5) represent the particle path from the location directly above the patient to the return/exhaust location. The path shows that the particle disperses from a point directly above the patient and is trapped by the air current, flowing in a relatively linear path to the less clean zone, and then out of the room. The CFD models provide theoretical results that support the air distribution manufacturer’s technical literature [2] with respect to the air curtain concept. The results further validate the ASHRAE study [1] that advocates for more than 20 ACH.

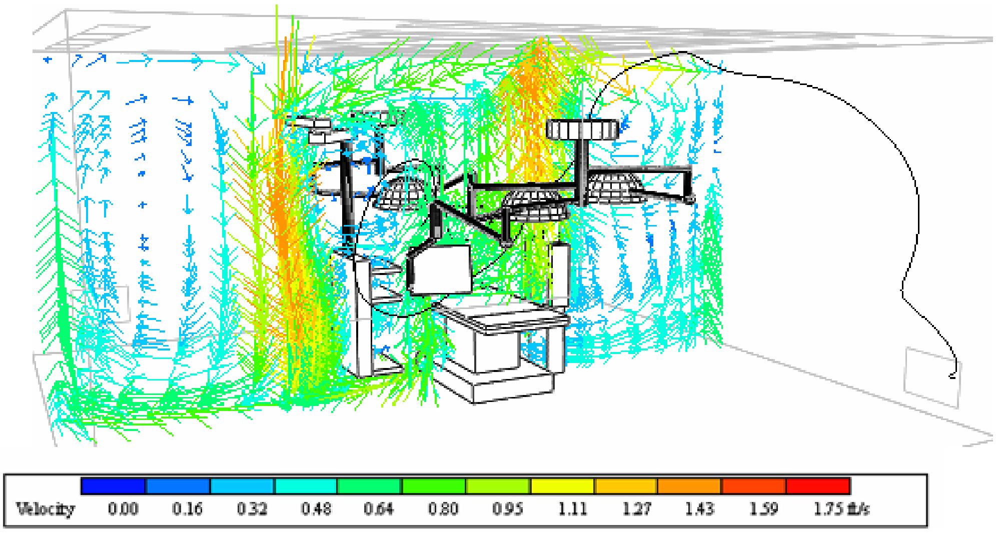

Figure 4. Velocity profile from UMass study showing particle being removed from surgical area.

Hospital for Special Surgery Case Study

The New York City's Hospital for Special Surgery (HSS) air distribution concept is based on the laminar flow concept, but does not utilize the air curtain concept previously described. The variations include diffusers that can be adjusted to direct air flow, and an enclosed plexi-glass curtain that isolates the clean zone. The ceiling layout is altered regarding the diffuser, light and grille locations. The motorized directional vanes on the laminar flow panels are manually adjusted by the surgical team to allow for the air flow to change from the vertical direction to a 45-degree deflection. This feature is utilized when the surgical team is required to work directly above the patient and vertical laminar flow would cause for the air particles to be carried directly into the patient area. The 45 degree adjustment results in the particles to be angled away from the surgical area. The arrangement of the room, as far as equipment and people, was modeled similarly to the UMass Memorial model. However, changes were made to the supply and return diffusers as well as the lighting locations to reflect the actual room layout. The layout of the HSS (Figure 6) consists of eight 0.6m x 1.3m supply diffusers and two 0.6m x 1m supply diffusers located directly above the operation table. Surrounding the diffusers are ten 0.6m x 1.3m fluorescent lights. In addition there are three 0.3m x 0.3m fluorescent lights located in the room. The return grilles are located at opposite corners of the space.

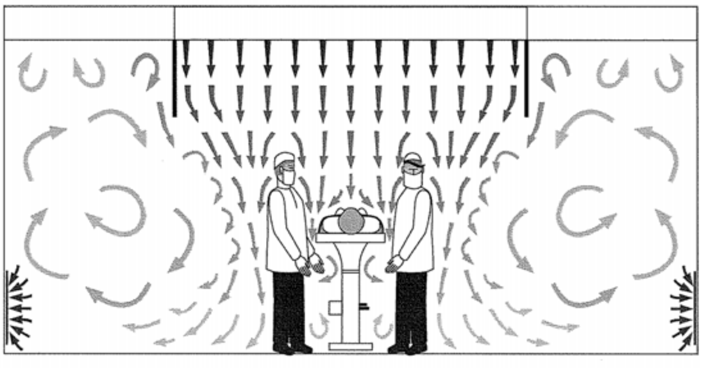

Figure 5. Laminar flow system with physical curtain [4].

The physical curtain provides a barrier between the clean zone and the less clean zone. The curtain seen in Figure 5 is a partial curtain which is used to help direct the laminar flow air towards the surgical area. As an improvement on this method, the design of HSS includes a physical curtain which surrounds the surgical zone on all four sides. Instead of hanging from the ceiling to only a few feet below the ceiling, the design includes the curtain hanging from the ceiling to 8" above finished floor.

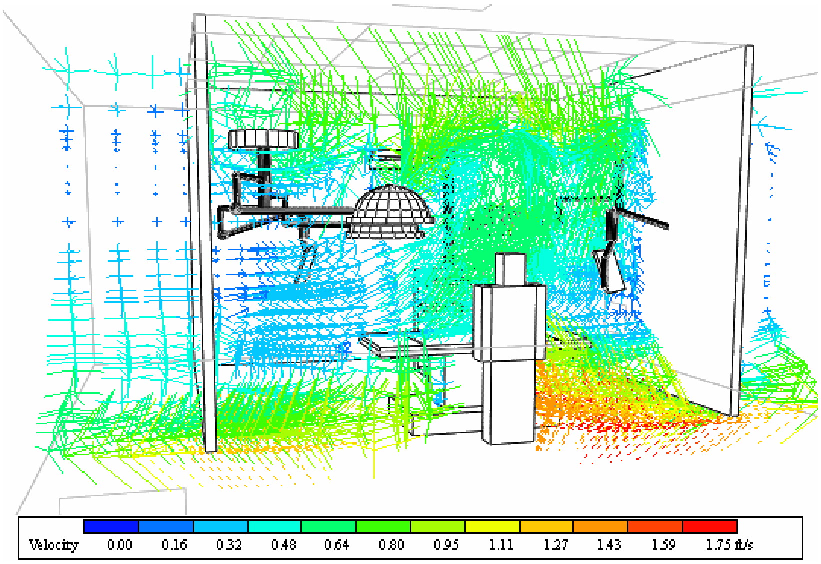

Figure 6. Velocity profile for HSS study showing general air movement coming from ceiling diffusers and under curtain and out of the surgical area.

The CFD models clearly indicate that the directional flow from the laminar diffusers creates a customized air flow dynamic in the room. There is a significant increase in velocity at the floor where the plexi-glass curtain acts in a similar fashion to a slotted return/exhaust opening. It is also evident that the equipment in the room causes turbulence that inhibits the direct removal of particles. The directional diffuser concept could be optimized by the use of similar studies.

SUMMARY

The case studies and analyses developed based on actual operating room installations show that the theoretical air distribution will optimize the concept of maximizing air exchange rates and directing particles in the air from the critical clean area above the patient to the less clean areas at the outer parts of the room. The systems also isolate any particles already located in the less clean areas in such a way that there is a very low probability that they will be re-entrained into the critical clean zone.

SUMMARY

This case study deals with the renovation project of ventilation system in the Natural Science Building of Tallinn University of Technology, covering the established aims and principles of technical solutions, in general, and results of monitoring. The reconstruction project involved the task of creating a new ventilation system for required indoor climate of laboratories, avoiding dissemination of harmful materials to rooms. In addition, it was required to keep the operations costs approximately at an acceptable level.

There are two separate central supply-exhaust air ventilation systems for general air exchange and for local ventilation systems. To assess the operating systems and to achieve the established aims, special testing of joint work between fume cupboards and main ventilation was conducted, using airflow smoke to emphasize the effect.

Results of monitoring demonstrate that investments for these ventilation systems were justified and the installed ventilation systems corresponded to our technical and sanitary-hygienic expectations.

INTRODUCTION

The main target of the ventilation systems for a laboratory is to guarantee a healthy working environment, avoiding dissemination of harmful materials from fume cupboards to rooms and between the rooms.

At the same time, an optimum energy consumption of the ventilation systems is required.

This case study deals with the renovation project of ventilation in the Natural Science Building of Tallinn University of Technology, covering the established aims and principles of technical solutions, in general, and results of monitoring. In this building there are mainly educational and scientific laboratories. Additionally there are some office and maintenance rooms. The present study only deals with subjects pertaining to the laboratories.

The reconstructed building has 4 floors with 7900 m^2 of total area. The laboratories hold 97 fume cupboards, 18 local exhaust - ventilation systems for specific purposes and 45 cupboards for chemical reagents, all situated dispersed in 50 different rooms.

TECHICAL SOLUTION

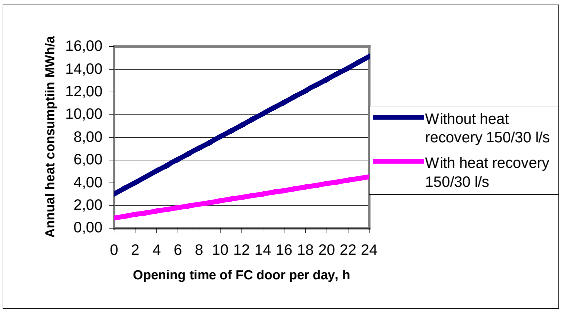
Target Requirements

The following target requirements were adhered to while working out the technical solution:

- The constant air speed 0,5 m/s in fume cupboard holes will be restored after a couple of seconds;
- The air pressure balance in the rooms;
- The maximum inside temperature 25 °C;The maximum CO_2 900 ppm;
- The optimum energy consumption

Energy Consumption and Fume Cupboard's Door Opening Time

Several earlier studies have shown that it´s necessary to guarantee constant air speed 0,5 m/s in fume cupboard holes for the fume cupboards to work effectively. The dimensioning of the fume cupboards in the present study is based on assumption that the design air flow of one equipment is 150 l/s while the door is opened and 30 l/s in stand-by. The longer fume cupboard door is opened, the larger is the consumption of heat and electric energy. The figures below illustrate estimated consumption of heat and electric energy per fume cupboard in a year, depending on the length of time the door is open during astronomical day in Estonian climate conditions.



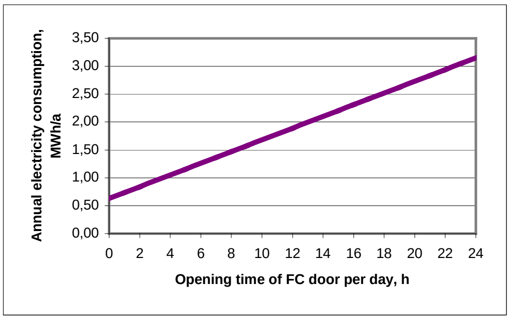


Figure 1 Annual heat (left) and electricity (right) energy consumption per fume cupboards (FC) dependig of FC's door opening time.

The usage of heat recovery allows for significant savings in heat energy. The supply and exhaust air may not mix in the heat recovery system.

Design Solution

Two separate supply-exhaust air ventilation systems are designed for the laboratories: for general air exchange and for local ventilation systems. Both systems have recuperative indirect heat recovery units with a circulating fluid medium. To extract dangerous and abrasive materials, additional separate local exhaust ventilation systems are provided.

Air handling units (AHU) are situated in the maintenance room of the last floor. The AHU-s are equipped with heating and cooling coil and heat recovery. The main ducts of the ventilation are situated in the technical room of the last floor where the vertical risers are going down from. The risers are branching off horisontally on every floor, in the start of branches there are constant pressure dumpers. Generally one horisontal branch services 1 to 4 rooms (laboratories). Figure 2 illustrates the global ventilation solution.

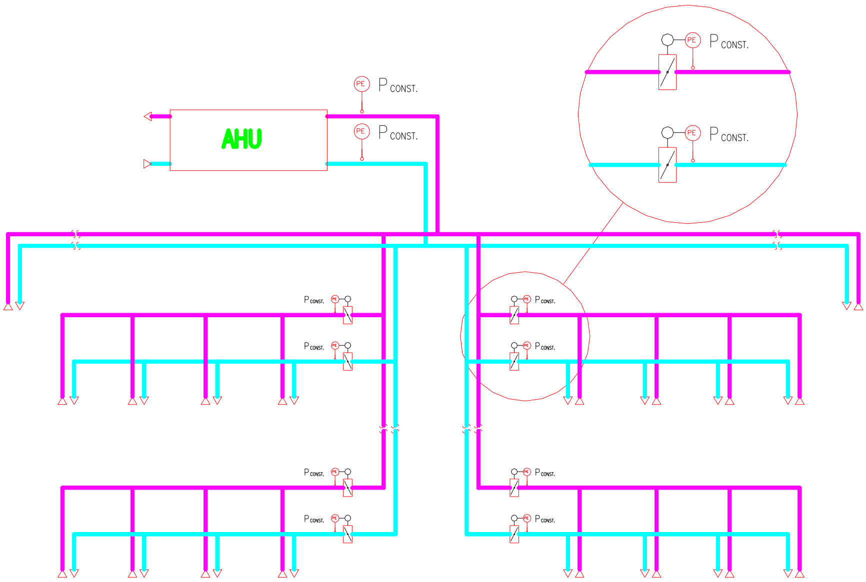

Figure 2. General scheme of ventilation ducts

There is a local automation system in every laboratory room. Automation of ventilation systems is characterized by a short-time response – 1…3 seconds. Indoor conditions of the rooms during some changes (e.g. after regulation of the size of fume hoods opening), the required air pressure balance in the rooms and constant air speed in fume cupboard holes will be restored after some seconds. The system of automation has several additional functions, such as to ensure the minimum main air exchange rate in the rooms (so-called standby conditions), signalisation about system disturbances and non-economical operation in part of the rooms to guarantee the required level of CO_2 concentration or indoor air temperature. Figure 3 illustrates the ventilation control system of a typical laboratory room.

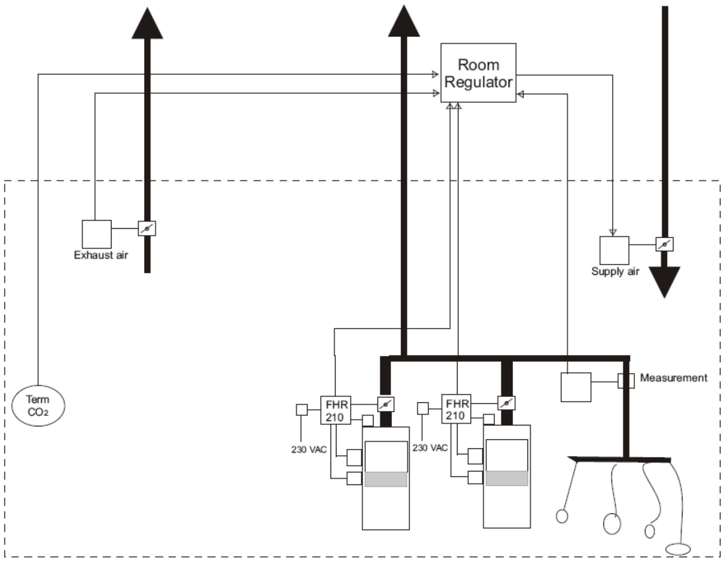

Figure 3. The ventilation control principle of a typical laboratory room

RESULTS

To assess the operating systems and to achieve the established aims, there was conducted a special test of collaboration between fume cupboards and main ventilation, using air flow smoke to emphasize the effect. During this monitoring, CO_2 concentration and air temperature in the rooms and the air speed values in the fume cupboard openings were scrutinised.

In the educational laboratories the concentration of CO_2 stayed below the target value of 900 ppm during mass attendance of students (Fig. 4).

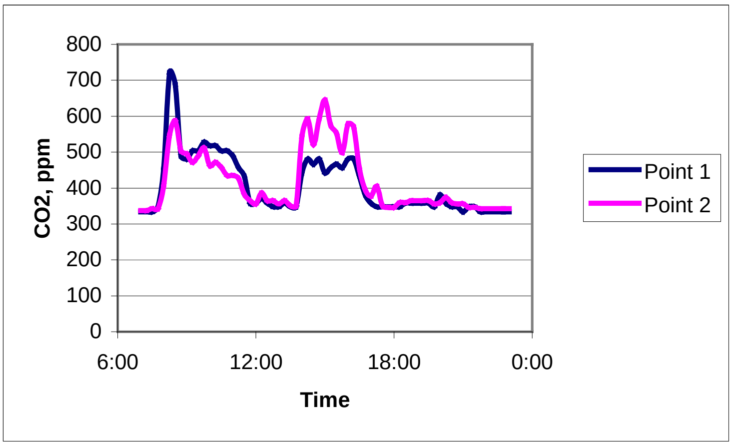

Figure 4. The concentration of CO_2 in the room air of educational laboratories during a typical school day.

The temperatures of indoor air stayed generally in between 21 ... 25 ^oC (Fig. 5).

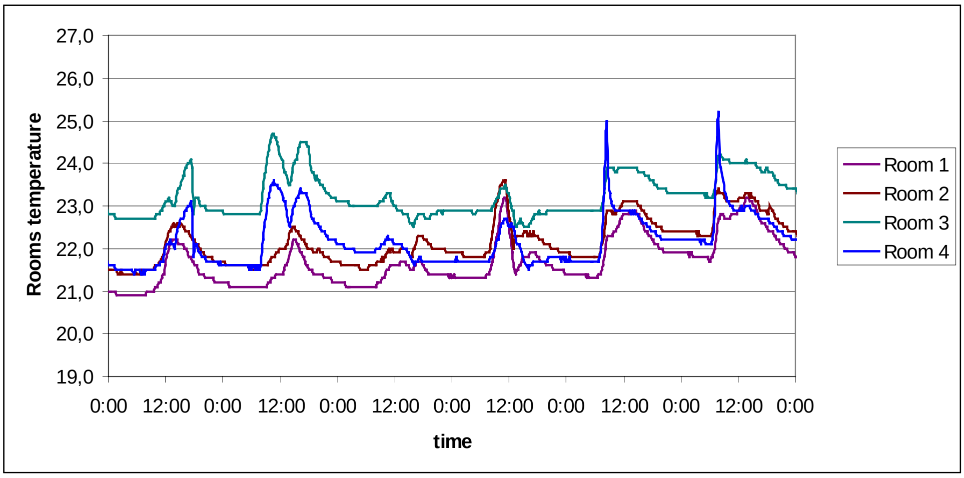

Figure 5. The temperatures of indoor air in different rooms.

Smoke tests proved that necessary over/underpressure in between different rooms was predominantly assured. During significant changes of air amount in the ventilation system (the opening of numerous fume cupboard doors at the same time), necessary pressure balance stabilised after up to 10 seconds.

In the course of monitoring air movement speed in fume cupboard holes was measured during different usage regimens. Necessary speed (0,5 m/s) stabilised in the work holes after 1…5 seconds. Changing the positions of the fume cupboard doors in neighbouring rooms connected to the ventilation system practically did not influence air speed in other fume cupboard holes connected to the same system.

The total heat energy consumption in 2006 of the building was 1 752 MWh and specific consumption was 222 kWh/m^2 (55 kWh/m^3). There is no official statistics in Estonia on energy consumption of laboratory buildings. The specific consumption is in the same order of magnitude as the indices of Estonian dwelling fond. Considering the air exchange in laboratories is significantly larger than in dwellings, the achieved energy expenditure is satisfactory.

Results of monitoring demonstrate that investments into these ventilation systems were justified and the installed ventilation systems corresponds to our technical and sanitary-hygienic expectations.

CONCLUSIONS

From the viewpoint of both investments and operation, it´s expedient to prefer central ventilation systems. A great number of fume cupboards and other local exhaust devices can be connected into a global ventilation system – in case of the case study there were 60-70. Separate local exhaust ventilation systems have to be provided to extract dangerous and abrasive materials. With the help of special short-time response regulation valves and respective room-specific automatics system, necessary indoor air quality requirements can be guaranteed in the laboratories with reasonable investment- and operation costs. While designing such ventilation systems, long ventilation stub networks should be avoided.

Energy Saving Potentials In Laboratory Facilities In The Context Of Safe Environment

Emil Sandru

Research Facilities Design, San Diego, CA, USA

Corresponding email: ers@rfd.com

SUMMARY

Laboratory facilities are known as significant energy consumers. High ventilation rates are required for providing safe and comfortable environment as well as optimum operation of the equipment. Air from laboratories involving chemical activity is exhausted to the outdoors and should be replaced by outside air. Recirculation is not considered a good practice with regard to safety. Protection of the outside surroundings is an additional environmental challenge. The purpose of the study is to reveal various ways of saving energy through minimizing the ventilation rates in laboratory facilities in the contest with providing safety conditions in laboratory space. Two key contributors are analyzed: the air flow requirements from laboratory exhaust equipment and the minimum air change recommended by laboratory design guides or engineering and safety practice.

INTRODUCTION

Providing safe environment, the health and comfort of the occupants is the primary goal of the design of laboratory air conditioning system [1]. Among air exhaust equipment in laboratories the fume hoods (fume cupboards) represent the most important energy consumer. Used to prevent the exposure to hazardous materials, the fume hoods could exhaust to the exterior a considerable amount of conditioned air. Reducing the air flow, while maintaining safe conditions, has been an enduring objective of HVAC industry. Most of the latest innovations in fume hood design aim to reduce the face velocity or to restrict the hood opening area. Their implementation in laboratory practice has been received with mixed reactions revealing psychological and habitual resistance from some the users. The face velocity accepted in practice as satisfying safety conditions may vary from 0.3 to 0.6 m/s. The most common design value is 0.5 m/s. Adopting low velocities of this range is not always received with confidence by the safety managers and the users comfortable with traditional values employed over the years. However, 20% to 40% reduction is generally acknowledged in practice at least for periods when the operators are not present in front of the hood. On the other hand, the measure of minimizing the hood opening area challenges the users on accepting restricted access to the work area. Some tend not to be appreciative, viewing it as work restraint. Limitations of the vertical sash opening or various combinations of vertical and horizontal sashes have been developed. Reducing the energy cost of operating the fume hoods is a multidisciplinary mission involving the designers, the managers and the users.

On the safety side, it is common in the design practice to impose a minimum air change rate (air changes per hour -ACH) as an operating limit of the ventilation system . The recommended values for various types of laboratories fit into a range of 4 to 15 ACH, sometimes higher. No method or procedure, other than practical considerations and observation, is known to be the source of these values. Adjusting this range on more justified basis has been objective of energy saving in laboratory ventilation. The concentration of hazardous substances in a laboratory environment is the major criterion in discussing the minimum ACH. The release of chemicals inside the laboratory environment could only happen by accident. A spill of a chemical could result from defective material, equipment malfunction or negligence. Laboratory protocols do not allow the use of hazardous materials in open laboratory space. Chemicals must always be handled in containment equipment such as fume hoods, biological safety cabinets or glove boxes. Regardless of the limits of the design of laboratory ventilation system, the air dilution or replacement could not protect personnel from exposure to concentrated bursts [2]. If this point of view is acknowledged, the current minimum air change rates in laboratories could be reconsidered based on calculations and measurements of the concentration levels.

METHODS AND RESULTS

Methods of reducing the laboratory fume hood exhaust flow rates are analyzed considering a variety of design solutions and operational measures. The possibility of minimizing the air flow is discussed from the safety view point, by evaluating the concentration of hazardous substances and comparison with the permissible safety limits.

Reducing the air flow of at fume hoods (cupboards)

A comparison of various fume hood design solutions for reducing the access area is presented in Table 1. A 1,800 mm wide fume hood is used for reference. A laboratory of $90\,m^3$ and $3\,m$ ceiling height is considered for evaluating the corresponding number of air changes per hour (ACH). In the concept of modular laboratory design the space is equivalent to a laboratory module.

Table 1. Comparison of design solutions

Design solution	Face velocity	Face opening	Air flow	Air flow reduction	ACH
	m/s	m^2	l/s	%	
Full open sash - 70 cm open	0.5	1.20	600	-	25
Vertical sash - 45 cm open	0.5	0.76	380	36	15
4 horizontal sashes on 2 tracks	0.5	0.57	285	52	12
Vertical sash at 45 cm open low velocity	0.4	0.57	285	52	12
Vertical sash at 45 cm open minimum velocity	0.3	0.57	215	64	9
Combination of vertical and reduced height horizontal sashes on 2 tracks	0.5	0.33	165	72	7

It results that this measure has a potential of reducing the flow rates more than three times of full open sash reference case. It should be noted that the rates of air change remain high. The room yet changes 7 volumes of air even in the most extreme saving solution. Further reductions are possible with the user’s input in employing the features offered by design along with a relentless sash position management.

The variable air flow control solution based on sash position (VAV) is a traditional measure of reducing the energy consumption of exhaust equipment. Employing the benefits of this solution involves a dependable attitude of the user of maintaining low or closed sash position. The technology of automatic sash position control has been developed; the sash moves safely as sensing the presence at the hood. The ideal scenario is that the sash should be actually open only during the loading, unloading or interacting with the process inside.

The current concept of low-velocity hoods is based on constant flow. Optimizing the pattern of the flow inside the hood enclosure is used to enhance the containment at lower face velocities. Such hoods have passed the required safety tests at velocities as low as 0.3 m/s. In the case of constant air flow (CV) hoods, the only means of reducing the energy consumption is using two position control settings for occupied/non-occupied periods. During the non occupied time, the hood face velocity is usually reduced to 60%.

A comparison of various methods under different operating conditions using as reference a conventional hood operating at constant flow (CV), with full open sash is illustrated in Fig. 1 A good management of keeping the sash closed 20 hours a day can potentially reduce the flow to 20%. For the 90 m^3 reference laboratory this represents a drop from 25 to 5 ACH

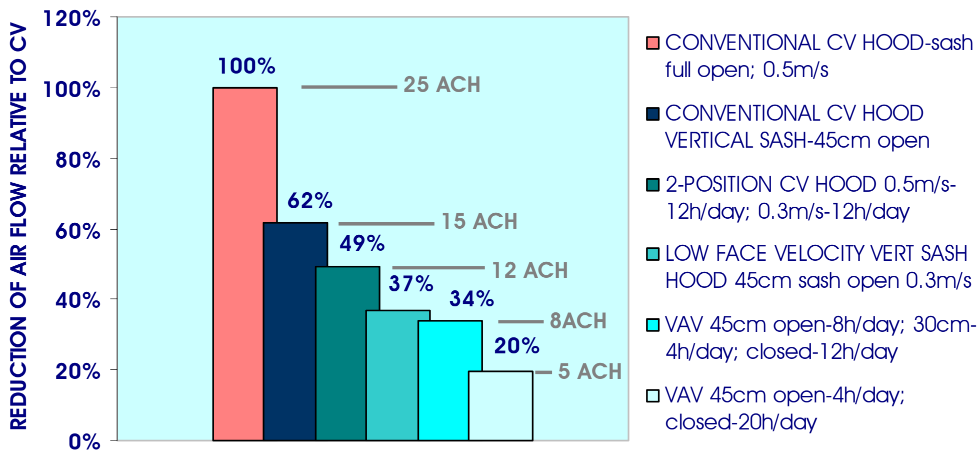

Figure 1. 24 hour potential savings using various fume hood design and operating conditions

Figure 2 shows the average air flow and air changes per hour in a 3-module laboratory (270 m^3) with the same hood in the similar operating configurations.

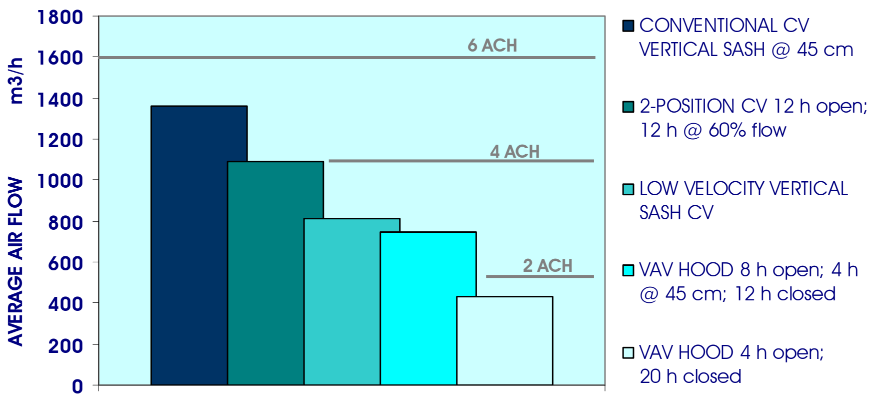

Fig. 2. Average air change rates from one 1,800 mm fume hood in a 3-module laboratory

With the chemical activity safely contained inside the fume hood the volume of air in the laboratory environment could be changed to as low as 2 to 4 times every hour. Reducing the exhaust flow from fume hoods should not be a concern with regard to safety of the outside environment. Along with the substantial dilution in the fume hood, combining the effluents from fume hoods into a single exhaust system provides further dilution and reduces the energy consumption [3] [4].

It could be concluded that various design solutions, along with proper fume hood usage and management, offer great opportunities of reducing the room air changes and consequently the energy consumption in laboratory environment. The remaining question is whether the low level of air change possible to be employed through these measures assures a safe environment in the laboratory, outside the fume hood. The next section intends to offer a response by focusing on the concentration in laboratory environment.

Minimum air change in laboratories

The discussion of minimum air changes per hour (ACH) is primarily related to the level of concentration of hazardous materials in the laboratory environment. An extreme condition of an accidental spill is analyzed.

The concentration of chemicals is neither steady, nor homogeneous because of continuous change of air patterns affected by the air diffusing system, people's movement or doors opening. The development of a generalized model that quantifies the influence of all interfering factors inside the space is not possible. In case of a spill, the maximum concentration at the source is diminished but the distribution in space is not known. Permissible exposure limits imposed by the safety codes must be satisfied regardless the location.

In safety practice, Permissible Exposure Limits (PEL) criterion was introduced, along with other similar criteria, for defining the concentration of chemicals in air under which it is believed that workers could be exposed without adverse effects.

This section evaluates the concentration produced by evaporation of a chemical liquid spill. The results are compared with permissible exposure limits (PEL) and correlated with air changes (ACH) in the laboratory space. The procedure of the analysis is described in Sandru and Xing [5]. The rate of evaporation of $1\,m^2$ of liquid area is calculated and used for calculating the average volumetric concentration in the $90\,m^3$ volume of the reference laboratory. 20 chemicals frequently used in laboratory practice, in the range from low to extreme health hazard are examined. Heat-mass transfer analogy was applied considering steady state conditions of a parallel flow over smooth liquid surface, at uniform liquid and air temperature. The mass flow rate from convective evaporation was determined by equation

$$\dot{m}_v = h_m A_v \left(\rho_{v,s} - \rho_{v,\infty}\right), \qquad (1)$$

where h_m is the average mass transfer coefficient. A_v is the area of mass transfer, $\rho_{v,s}$ is the vapor density at liquid-air interface and $\rho_{v,\infty}$ the vapor density in the free air stream.

The mass transfer coefficient was evaluated from heat and mass transfer analogy [6]

$$h_m = Sh \frac{D_v}{L} \qquad (2)$$

Sherwood number (Sh) was calculated considering parallel flow over a flat plate and D_v, the diffusion coefficient of vapor into air selected from CRC Handbook [7]

Volumetric concentration C_V (ppm) was calculated as

$$C_V = \frac{\dot{m}_v / \rho_{v,s}}{\dot{Q}} \times 10^6, \qquad (3)$$

where $\dot{Q}$ is the air flow rate in the space (m^3 / h).

The results are illustrated in Figure 3. Remarkably low air changes are shown to be sufficient for diluting the moderate and low hazardous substances. However the highly hazardous chemicals could not be safely diluted witin the air change rates currently accepted in laboratory design. It is obvious that increasing the ventilation air flow could not eliminate the hazard generated by an accidental spill.

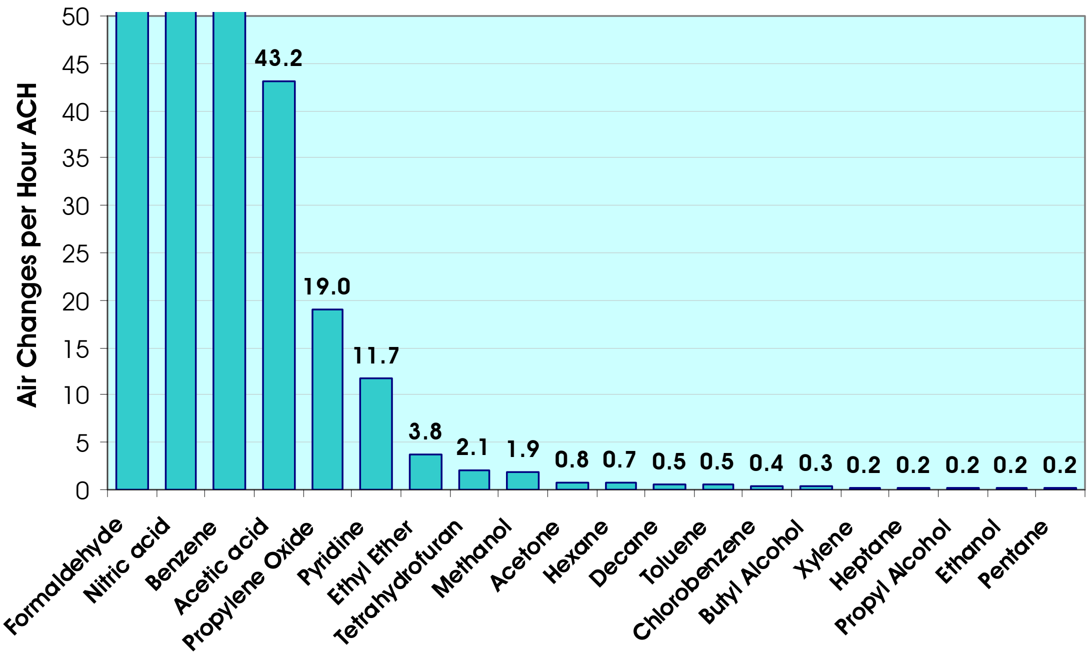

Figure 3. Air changes per hour required to attain permissible exposure limits. Evaporation of 1 m^2 of spill in 90 m^3 laboratory space.

Evaporation from an open tray of 0.04 m^2 in the 90 m^3 reference laboratory space is also evaluated for comparison. As in the case of the large spill the air velocity was selected at 0.2 m/s, simulating possible air drafts from laboratory ventilation. The results displayed in Figure 4 lead to the similar conclusions. With one exception, the low evaporation rate brings the concentration below the PEL at air changes within the current range of 4-15 ACH.

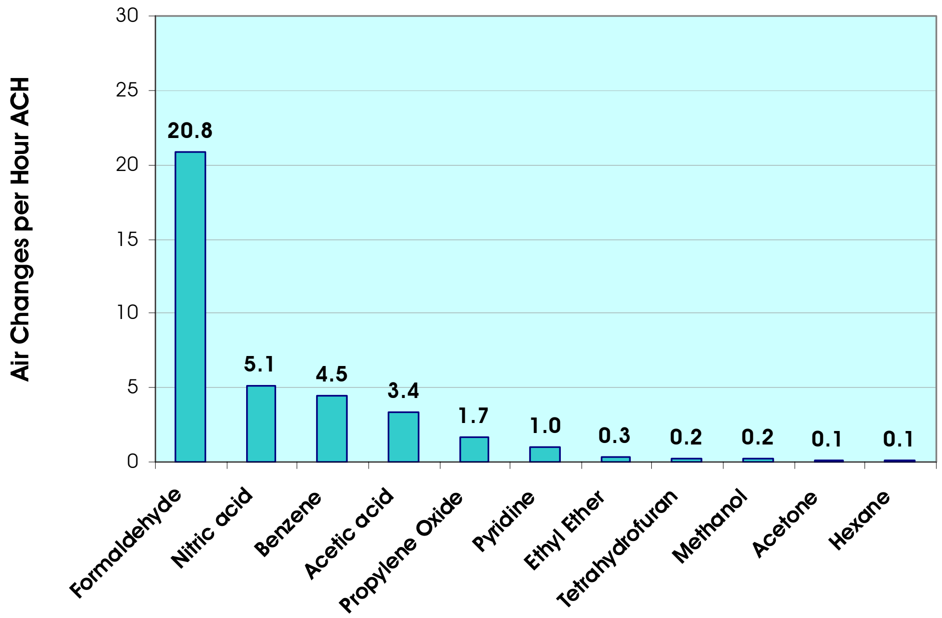

Figure 4. Air changes per hour required to attain permissible exposure limits. Evaporation from 0.04 m^2 open tray in $90\,m^3$ laboratory space.

DISCUSSION

Two ways of reducing the energy consumption related to laboratory ventilation have been analyzed. Various methods of reducing the average air flow exhausted from laboratory fume hoods have been compared. Current design solutions available in industry along with user's discipline in operation the fume hoods offer great potentials for energy saving. The analysis reveals the fact that a fume hood could operate at average flow rates as low as 20% of maximum flow in ideal conditions of operation.

Safety aspects of saving energy by adopting low flow rates in laboratories handling hazardous substances are discussed. The air changes per hour necessary to maintain the laboratory environment below permissible exposure limits are calculated in the case of an accidental chemical spill. The evaluation is theoretical considering the homogeneous distribution of concentration in space. The odor criterion has not been considered. The analysis proves that, regardless the level of the air flow, most hazardous chemicals could not be diluted to safe limits. Maintaining high flow rates could not avoid the hazard. Purging the space with high emergency flow rates could only provide a faster dilution before the space could be reoccupied. The results also show that extremely low air changes are sufficient to dilute the moderate and low hazardous substances. In this context could be observed that:
High flow rates are not justified to ventilate the space where chemicals are not present. Lower than traditional minimum flow rates could be considered in designing the laboratory ventilation system. The observations are based on the fact that the laboratory written code of behaviors does not allow the use of hazardous materials in open laboratory space and always requires immediate evacuation of the space in case of an accidental spill.

SUMMARY

A novel ventilation system which introduces bench exhausts and radiant cooling panels is proposed. The benefits of using bench exhausts and radiant cooling panel system in removing heat from equipment intensive laboratory are quantitatively evaluated using CFD simulations. This study resulted in a recommendation for a ventilation strategy using a combination of ceiling exhausts, bench exhausts and ceiling radiant cooling panels that appears to give the best thermal condition and energy saving in the laboratory. The system offers the potential for application in new and existing research laboratories where a large portion of the space cooling load in a laboratory is a result of the heat produced by the research equipment on the bench.

INTRODUCTION

Laboratories are usually equipment intensive. The ventilation flow rate required to cool these laboratories is higher than in a less equipment intensive zone of the building. A large portion of the space cooling load in a laboratory is a result of the heat produced by the research equipment on the bench. If the heat can be captured at the source, its impact on space cooling load and the resulting HVAC requirements and cooling cost will be reduced.

Traditionally, HVAC systems are designed as All-Air Systems. These systems achieve the tasks of ventilating and cooling a building by convection only, which means that air is used to ventilate the buildings in order to maintain a high level of indoor air quality as well as provide thermal comfort in the buildings. An alternative is to separate the tasks of ventilation and thermal space conditioning through a combination of radiation and convection inside the building by using the forced air to fulfill the ventilation requirements and radiant cooling panels to provide most of the cooling. This is because radiant cooling can be more energy-efficient than air-based systems [1-2]. It requires less parasitic energy (pump and fan energy) to remove heat from a space. Since the walls are radiantly cooled, the air temperature can be warmer to achieve the same level of thermal comfort. The warmer air temperature results in lower energy loss to the outdoors. In addition, the radiant cooling system also reduces noise and drafts of air-based HVAC systems. The preferred installation of the radiant cooling panel is ceiling mounted, as this reduces air stratification and facilitates collection of condensation. To investigate the possibility of further reduction in cooling cost, the combination of benchtop exhaust system and ceiling mounted radiant cooling panels needs to be considered. The purpose of this study is

- to assess the performances of bench exhaust system and ceiling mounted radiant cooling panels in achieving required thermal comfort with reduced ventilation flow rate.
- to evaluate the saving of annual cooling cost by using bench exhausts and cooling panel at reduced ventilation flow rate.

METHODOLOGY

Computational Fluid Dynamics (CFD) uses numerical procedure to solve the conservation equations, Equation (1), that govern the airflow and heat transfer in a space. It is a very powerful and efficient methodology to investigate temperature and flow field in a room where there are many parameters involved [3-4]. Therefore, CFD is employed in this study [5].

$$\frac{\partial}{\partial t}(\rho\varphi) + div\,(\rho\,\vec{V}\,\varphi - \Gamma_{\varphi}\,\mathrm{grad}\,\varphi) = S_{\varphi} \qquad (1)$$

Where :

ρ = density
$\vec{V}$ = velocity vector
φ = dependent variable
Γ_{φ} = exchange coefficient (laminar + turbulent)
S_{φ} = source or sink term

The airflow in a ventilated laboratory is turbulent. In this study, the turbulence is simulated with the k-ε model [6-7] that represents the most appropriate choice because of its extensive use in other research applications, such as predicting mixing rate of a jet flow and modeling airflow in urban open space [8-9].

The Predicted Percentage Dissatisfied (PPD) introduced by Fanger and given in the ASHRAE guide [10] is a widely used index in assessing the thermal comfort [11]. This index can be estimated by equations that are based on an empirical investigation of how people react to environments. As each individual has a different perception of the climate produced in a building, any given climate is unlikely to be considered satisfactory by all. Therefore, 80% occupant satisfaction is considered good, or a PPD of less than 20% is good. The equations implemented in the study shown below are taken from Fanger's equations for Predicted Mean Vote (PMV) and PPD as given in BS EN ISO 7730: 1995.

<u>Definitions</u>

$$PMV = (0.303e^{-0.036M} + 0.028)\{(M - W) - 3.05\times10^{-3}[5733 - 6.99(M - W) - p_a] - 0.42[(M - W) - 58.15]1.7\times10^{-5}M(5867 - p_a) - 0.0014M(34 - t_a) - 3.96\times10^{-8}f_{cl}[(t_{cl} + 273)^4 - (t_r + 273)^4] + f_{cl}h_c(t_{cl} - + t_a)\} \qquad (2)$$

where

$t_{cl} = 35.7 - 0.028(M - W) - I_{cl}\{(3.96\times10^{-8}f_{cl}[(t_{cl} + 273)^4 - (t_r + 273)^4] + f_{cl}h_c(t_{cl} - t_a)\}$

$h_c = 2.38(t_{cl} - t_a)^{0.25}$ or $h_c = 12.1v^{0.5}$ whichever is the greater

$f_{cl} = 1.00 + 1.29I_{cl}$ for $I_{cl} \leq 0.078\ m^2KW^{-1}$ or $f_{cl} = 1.05 + 0.645I_{cl}$ for $I_{cl} > 0.078\ m^2KW^{-1}$

$$PPD = 100 - 95e^{-n} \quad (3)$$
where $n = 0.03353PMV^4 + 0.2179PMV^2$

List of Symbols

PMV = Predicted Mean Vote
PPD = Predicted Percentage Dissatisfied
M = Metabolic rate (W/m^2 of the body area)
W = External work (W/m^2 of the body area (= 0 in most cases))
Icl = thermal resistance of clothing (m^2KW-1)
fcl = Ratio of clothed surface area to nude surface area
ta = Air temperature (°C)
tr = Mean radiant temperature (°C)
v = Air velocity relative to the body (ms-1)
pa = Partial water vapor pressure in Pa
hc = Convective heat transfer coefficient (Wm^2K)
tcl = Clothing surface Temperature (°C)

CASE DESCRIPTION

A generic laboratory with a conventional air distribution system, shown in Figure 1, was developed as the baseline laboratory model. The same laboratory space was then modeled with the bench exhaust ventilation scheme at different exhaust flow rates and cooling panels of different arrangements for more than 30 cases among which 16 cases were presented in this paper as listed in Table 1. The bench exhausts used in this study were continuous slots along the length of the benches, mounted beneath shelves of the bench. The cooling panels were flushed on the ceiling above the bench top and aisle in as shown in Figure 1. One set that was mounted above the bench top, called bench panels (light blue colored in Figure 1), included 3 panels. The central panel was 0.6m wide, and the two against the side walls were 0.3m wide. The other set, called aisle panels, was mounted above the two aisles. These cooling panels were maintained at 13.9°C temperature. The total heat generation from the bench devices was 5808W. The lighting heat sources were 2275W. The sensible heat from each occupant was assumed to be 80W. Solar loading from south-facing windows on the external wall was divided as 1160W transmitted into the room and 1273W absorbed by the glass and the external wall section. The supply temperature was 11.1°C for all cases.

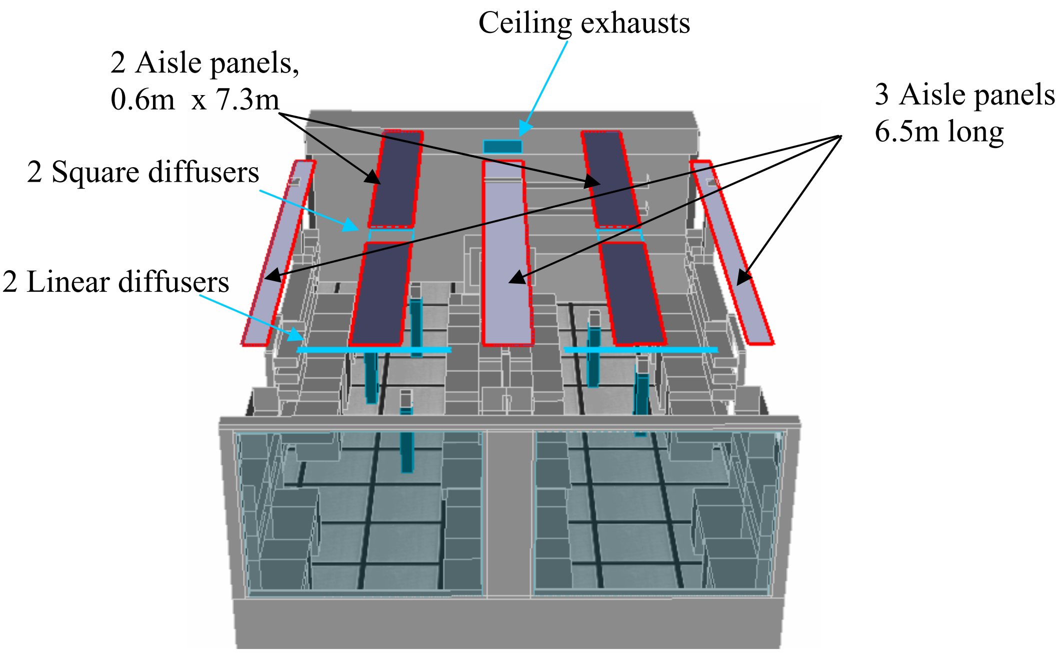

Figure 1. Laboratory layout

Table 1. Case description and results

	Cooling panels	ACH	Bench exh. CFM	Ceiling exh. CFM	Average Air T (°C)		Average PPD (%)	
					Walking zone	Bench zone	Walking zone	Bench zone
Baseline	-	13	0	-1750	21.1	22.2	12.8	12.8

Case14	Bench Panels	4	-600	-86	28.0	29.3	19.5	32.1
Case15	Aisle panels	4	-600	-86	27.9	29.2	18.5	31.2
Case16	Bench & Aisle	4	-600	-86	27.5	28.8	15.0	26.7

RESULTS

In order to evaluate the performance of bench exhausts and cooling panels, the occupied zone is divided into two, the walking zone and the bench zone, as highlighted in a) and b) of Figure 2, respectively. The walking zone covers the regions of aisles and the doorways from the floor to

1.8m above, and the bench zone includes the volumes from the top of the bench to 1.8m from the floor.

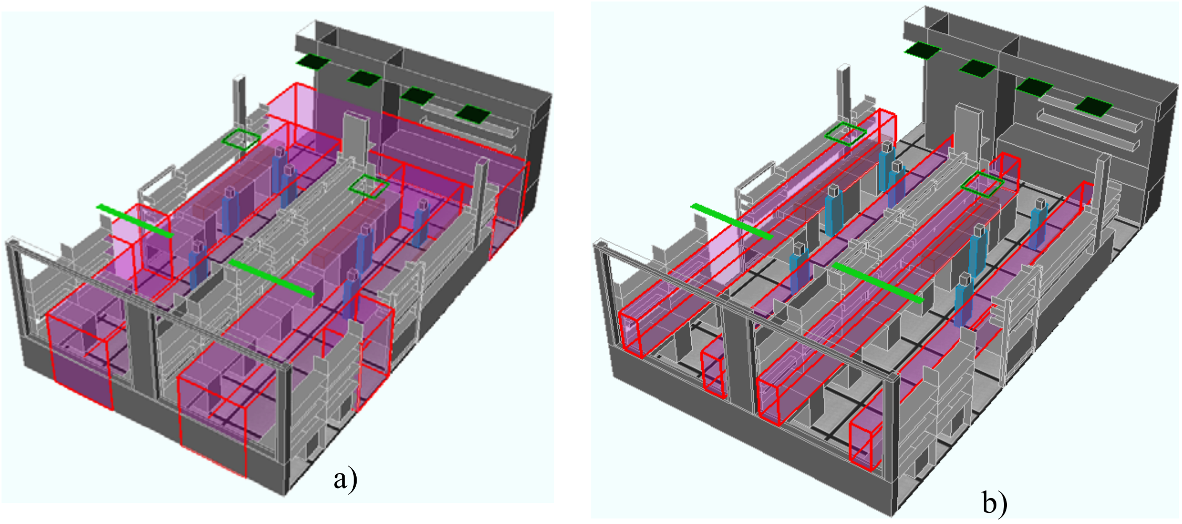

Figure 2. Two sets of occupied zones. a) Walking zone includes the 5 highlighted regions; b) Bench zone is the volume above the bench top in the 4 highlighted areas

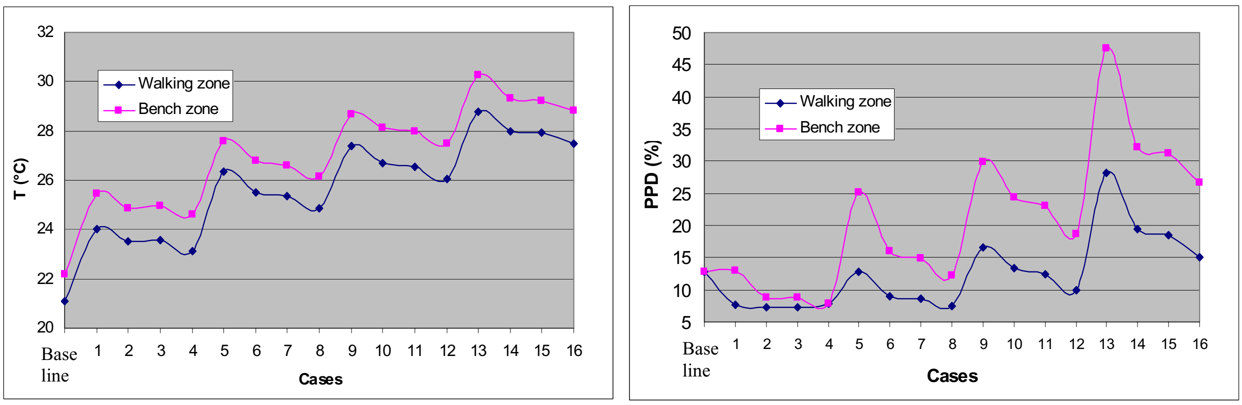
Let's first discuss the effects of bench exhaust on thermal comfort. The average PPD and temperature in the two occupied zones are summarized in Table 1. They are also graphically presented in Figures 3 to demonstrate the trends. Table 1 shows that the PPD in the occupied zone is 12.8% in the baseline case with 13 ACH. When using bench exhausts, the PPD in the walking zone drops to 7.6% in Case 1 even at reduced supply flow rate of 8 ACH. When further reducing the supply flow rate to 6 ACH (see Case 5), the average air temperature in occupied zones increases by 2.3°C, and PPD, especially in bench zone becomes significantly higher. This indicates that, when using bench exhausts, the supply flow rate can be reduced from 13 ACH to 8 ACH to achieve similar level of thermal comfort in the lab.



a) b)

Figure 3. Average a) air temperature and b) PPD in occupied zones

Secondly, we would like to evaluate the performance of cooling panels. Comparing the cases of same flow rate with and without cooling panel, Cases 1 through 5 for example, shows that the cooling panels reduce the average air temperature in the occupied zones by about 0.8°C to 1.4°C. When cooling panels are used, sensible heat is removed from the room by both ventilation and radiation. Through radiative heat transfer, the heat emitted by occupants is absorbed by the cooling panel. Therefore, even the average air temperature in the occupied zone is reduced by only 1°C, the thermal comfort can be improved significantly as seen in Table 1 or Figure 3. It is especially so when the supply flow rate is lower, for example Case 13 and Case 16. Table 1 shows that at 8 ACH, the PPD in the walking zone increases slightly if the two sets of cooling panel are used together. This is because the air temperature is already slightly lower than the desired temperature of 23.5°C (74.3°C), cooler temperature of surrounding surfaces can have negative impact on thermal comfort. With aisle panels, the air temperature is, in general, lower in both walking and bench zones than with bench panels since the total surface area of aisle panels is larger. The average PPD in the two occupied zones at 6 ACH all drop below 20% with any cooling panel arrangements. At 5 ACH, however, it requires both bench and aisle panels working together to bring PPD below 20% in occupied zones. At 4 ACH, even combination of the two sets of cooling panels cannot bring the PPD to lower than 20% unless more cooling panels are installed.

OPERATING COST REDUCTION

The ventilation flow rate required for equipment-intensive laboratories to be thermally comfortable can be as high as 13 ACH, referring to the baseline case. With the proposed bench exhausts, the ventilation rate can be reduced to 8 ACH (Case 1) to achieve similar level of thermal comfort. The combination of bench exhausts and ceiling mounted radiant cooling panels can further bring the ventilation flow rate down to 5 ACH as seen in Case 12. Figure 4 illustrates the annual cooling costs of these three cases estimated for a typical lab located in Washington DC area.

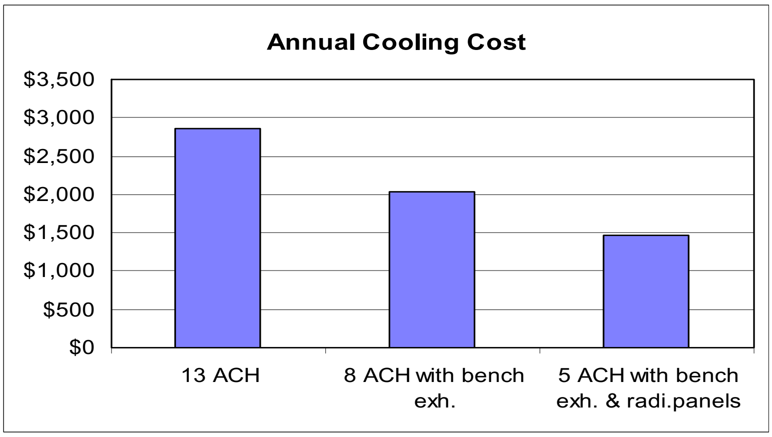


Figure 4 Saving in annual cooling cost of a lab

Comparing 13 ACH and 8 ACH, both without cooling panels, the total saving in annual cooling operating cost by utilizing bench exhausts alone is around 29%. Comparing the cooling costs of 8 ACH without cooling panel and 5 ACH with cooling panels, the saving by using cooling panels alone is about 28%. The total saving for annual cooling season when using bench exhausts together with radiant cooling panels is around 49%. The following conditions/assumptions are used in this cost calculation.

- The outdoor condition is taken from weather data in Washington DC.
- The cooling season is considered to be 4489 hours annually.
- The percentage of outdoor air is 70% for 13 ACH case and 100% for other two cases.
- Supply air temperature is 11.1°C (52°F), and the desired room temperature is 23°C (73.5°F) which is used as return air temperature in the calculation.
- Cooling load per CFM is considered to be the difference in air enthalpy when entering and leaving the HVAC system. Perfect duct insulation is assumed.
- The ventilation flow rate (CFM) in Table 1 is the flow rate required during the peak load of the day. The average cooling load of a day is assumed to be 64.3% of the day's peak load. So is the ventilation flow rate used in the cost calculation.
- The cost of electricity is 0.1$ / KWH, fuel is 8.0$ /100Btu; chilled water generation efficiency is 1.0KW / TON; fan efficiency is 68%.

DISCUSSION

The following conclusions are drawn from this study:

- For laboratories with high bench heat sources, using bench exhausts in conjunction with ceiling exhausts improves the thermal condition in the occupied zone at even relatively low total ventilation flow rates.
- Without cooling panels, the case of 8 ACH with 30% to ceiling exhausts and 70% to bench exhausts (Case 1) appears to give the best thermal condition in the laboratory.
- With bench and aisle radiant cooling panels, the ventilation flow rate can be reduced to 5 ACH while maintaining the PPD in occupied zone below 20%. The cost reduction of annual cooling associated with using bench exhausts and radiant cooling panels is about 49% for a typical lab located in Washington DC, USA.

Performance Based Design for Ventilation Systems of Operating Rooms Supported by Numerical Simulation - Discussing the Methodology

Mônica A. Melhado, Jan L. M. Hensen, Marcel Loomans

Technical University of Eindhoven, Eindhoven, Netherlands.

Corresponding email: m.d.a.melhado@bwk.tue.nl

SUMMARY

This paper discusses a methodology to support the performance assessment of ventilation systems of operating rooms (ORs), with a further focus on the application of numerical simulation tools in this design assessment. The performance based design should provide good information quality that advises the needs and expectation of the stake holders. The methods consist of literature review, the development of an information matrix to assess ventilation systems of ORs, and two case studies that will elucidate the approach and verify its applicability. The methodology chosen combines the performance base approach with the Building Evaluation Domain Model. The results will permit to identify which type of numerical simulation tools is best applicable for the assessment of a specific performance indicator and how the assessment should be performed. The conclusions will indicate directions for future work and which areas need to be focused on.

INTRODUCTION

The ventilation system in an OR is responsible for keeping a good indoor air quality in ORs. Previous research has shown that some types of ventilation systems used in ORs can contribute to the reduction of surgical site infection [1, 2, 3, 4 and 5]. They furthermore establish working conditions for the operating staff.

Several different ventilation systems/strategies are available for application in ORs. However, no general assessment methodology is available to compare different ventilation systems for a given design problem towards identified performance requirements (e.g. indoor air quality). The focus in the research therefore is on the design decision support information that will provide a methodology to support the design assessment for the ventilation system in ORs.

The objective is to discuss a methodology to support designers and decision makers in the objective performance assessment of here applied as an example, the ventilation design for ORs. The performance based should allow for a good information quality, and balances the needs and expectations of the stake holders. It will permit application for different types of ventilation system and surgeries.

This paper discusses the primary results of a PhD study [6]. After a brief introduction, the method will be described which has been used in order to develop the “Performance Based Design for Ventilation Systems of ORs”. The result will be presented in a matrix, and will be used to discuss some points and two case studies. Finally the conclusions and directions for future work.

METHODS

The methods consist of literature review, the development and the discussion of an information matrix of the assessment of design for a ventilation system of ORs supported by numerical simulation, and finally, two case studies will be presented to elucidate the approach and to verify the applicability of the evaluation proposed.

The development of the performance assessment methodology has a basis in the Building Evaluation Domain Model (BEDM) that was developed by Mallory-Hill, 2004 (see Figure 1). This model can be visualized as a three dimensional matrix. The three axes in this case refer to ‘Human Systems’, ‘Building Systems’ and ‘Architectural System’ levels. A subdivision is provided for each axis. The Human System level (HSL) focuses on the stakeholders ranging from the individual occupants to the global community and the performance specifications that are set by them. Naturally, the individual occupant is most interested in the basic performance value (e.g. working conditions). For the global community, e.g., the functional value is more important. The Building System level (BSL) is subdivided in several levels that relate to the number of changes that may occur during the building life time. Finally, the Architectural System level (ASL) has levels that subdivide the level of detail for decision making.

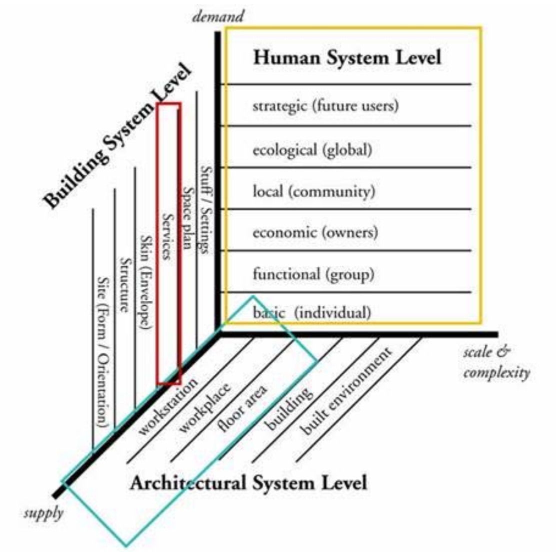

Figure 1. Building Evaluation Domain Model [7]

For example, for the ASL, the operating room is divided in workstations, workplace and floor area. The workstations now are defined as the zones of the patient, surgeon and auxiliary nurse, and supporting staff including the anaesthesiologist. The workplace encompasses the total environment of the operating room, while the floor area includes also the hallways, antechamber, storage and other adjacent areas that are directly connected to the operating room. For the HSL in principle all levels may be included with respect to the operating room. Focus, naturally, is on the individual, group, future users and owner level. The individual refers to the individual persons in the operating room and the group to the surgical team as a whole. The future users, in this case, need to accommodate the needs of many different occupants and, for example, deals with the adaptability for developments in the medical field.

The BEDM encompasses the whole building. For the assessment of the ventilation system in an operating room, only parts of the model are of interest. Figure 1 indicates the parts of the model that at first instance will be taken into account. One can see that the attention is focused to one slice of the matrix.

Next step is to identify for each point in the model the performance requirements that can be set. Figure 2 presents a part of the Performance Assessment Methodology. One can notice the axes of the BEDM. Now for each point Functional requirements have to be identified and performance indicators have to be related to these requirements. For this development literature study, in combination with expert interviews and information from attending surgical operations have been used. The list of requirements and indicators is quite large, nevertheless, several indicators overlap. Furthermore, only those indicators that have an evaluation possibility in the design (simulation) and use (measurement) phase are regarded, in order to adhere to the performance based approach.

The final result will permit to identify which type of numerical simulation tool is best applicable for the assessment of a specific performance indicator and how the assessment should be performed.

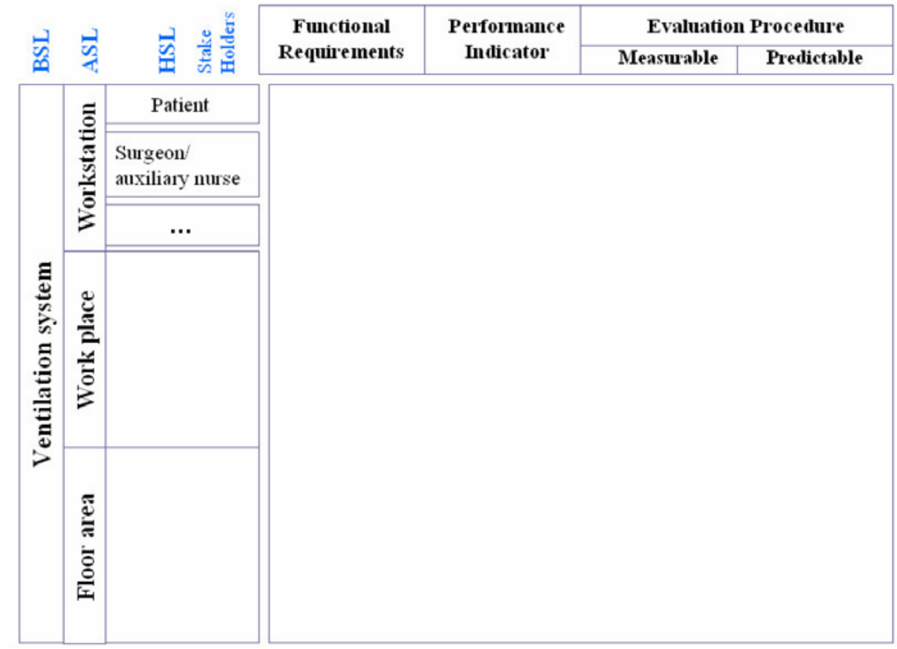

Figure 2. Performance Assessment Methodology [6]

RESULTS AND DISCUSSION

Figure 3 presents a part of the matrix that has been developed. Notice that it specifically addresses the performance assessment of ventilation systems for an OR. Compared to Figure 2, three columns have been included: OR zones, Performance requirements and How. The ‘OR zones’ column was included to define the workstation for each stake holder. The assumption is that in ORs several subzones can be identified which can be given different Functional requirements. This column furthermore is important to identify stake holders that have more than one workstation, e.g. the surgeon. Next, the Performance requirement column indicates the physical parameters that should be assessed in order to determine the performance indicator. The columns ‘How?’ describe the steps that are required to evaluate the performance indicator using experiments and numerical simulation tools. This may be read as recipes for performing the assessment. Although several performance requirements have been evaluated, this paper will focus on the surgeon thermal comfort in the zone 2. The correspondent row is identified in grey in Figure 3. The example will be used to describe the procedure.

		Stake Holders	OR zones (involved)	Functional Requirement	Performance Requirement	Performance Indicators	Evaluation Procedure: Measurable	How?	Predictable	How?
VENTILATION SYSTEMS	WORKSTATION	Patient	Zone 1	Safety (SSI rate)	Airborne Infection	CFU/m^3		M1		P1
					Hypothermia			M2		P2
		Surgeon	Zone 1 and Zone 2	Ergonomic (health, productivity and satisfaction)	Indoor Air Quality			M3		P3
								M4		P4
								M5		P5
					Thermal comfort	PMV index	Yes, but indirectly	M6	Yes	P6
						Local Thermal Comfort	Yes	M7	Yes	P7
					Visual comfort	LUX / CRI		M8		P8
					Acoustic comfort	dBA / PNC / PSIL		M9		P9
		Auxiliary nurse	Zone 1 and Zone 2	Ergonomic (health, productivity and satisfaction)	Indoor Air Quality					
					Thermal comfort	PMV index				
						Local Thermal Comfort				
					Visual comfort	LUX / CRI				
					Acoustic comfort	dBA / PNC / PSIL				
		...								

Figure 3. Performance Based Design for Ventilation Systems of ORs – draft version [6]

In order to better understand the evaluation and discussion of the literature review, two points will be explored: how previous researches assessed surgeon thermal comfort and what parameters were considered in the analysis. After that, the case studies will be discussed.

The thermal comfort in relation to environmental variables depends on metabolic rate, clothing, air temperature, mean radiant temperature, air velocity and air humidity [8]. In ORs these variables can change in accordance with the type of surgery. Managing the thermal discomfort of the surgeon is complex, because it is usually not possible to reduce the amount of clothing, to alter the activity being performed, or to reduce the various heat sources used during the surgery. This problem has been discussed and evaluated by several researchers [4, 9, 10, 11, 12, 13, 14, 15, 16, 17, 18 and 19]. These researchers evaluated the surgeon thermal comfort using Fanger's PMV model [20], with the exception of one study that used a thermal physiological model. Many of these studies were experimental and only few used numerical simulation to predict the thermal comfort. The surgeon thermal comfort reported in the literature review was between slightly warm and very hot - this difference resulted of the type of surgery performed, some times of the ventilation system used, or of the environment variables that were not necessarily the same.

Next, two case studies will be presented to verify if the approach proposed in Figure 3 is applicable, and with them, more details will be discussed. The focus is on the last column "How" for a specific performance indicator - the thermal comfort. This step is divided in three parts: first describing how the performance indicator can be assessed using numerical simulation; second describing the case studies; finally, the application will be discussed.
In accordance with Figure 3, the surgeon thermal comfort can be predicted, e.g., using PMV index and Local Thermal Comfort. The Local Discomfort can result of draught, vertical air

temperature difference, warm and cool floors, and radiant asymmetry. The PMV index can be calculated using Building Energy Simulation models (BES), while the Local Thermal Comfort generally would require the use of the Computational Fluid Dynamic (CFD) technique. These approaches have different resolution level.

When the OR is in the use phase, the variables at the surgeon workstation can be assessed through experiments. In case the OR is in the design phase, it will be possible to predict the variables using numerical tools. If one applies CFD it is possible to zoom in at the surgeon workstation which will permit to look at the problem in detail, identifying the variables and parameters that influence the thermal comfort. From the literature and observations in ORs identified the parameters which need to be taken into account include: characteristics of the OR, medical equipment (type and number), position of the operating table and of the patient; requirements; layout performed in the surgery, people (number and function), types of clothes and ventilation system design. Another important parameter to consider is the surgical lights effects.

In the case studies, two types of surgery are evaluated: a Hip and a Foot, both orthopaedic surgeries. The characteristics of the OR: 36 m^2 and h = 3.50 m. A 'Large downflow Plenum' ventilation system is used and its area is represented thought the dash-line, corresponding to 9 m^2. The layouts performed in each surgery are reported in Figure 4, which were designed through observations in ORs. The numbers correspond to: surgeon (1); others people of the staff (2, 3, 4, 5 and 11); instrument tables (7); back table (8); and equipment – defibrillators and accessories (9), anaesthesia, respiratory ventilator and vital signs monitor (10), and X-ray (12). The surgical lights are also considered above the surgeon focussed at the wound.

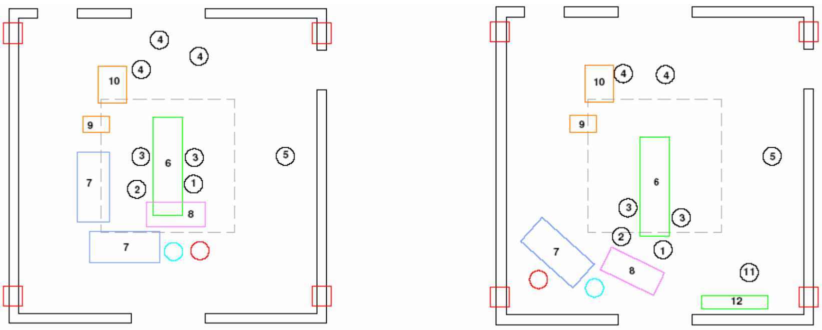

Figure 4. Layout Hip and Foot surgeries, respectively

In both surgeries the surgeon thermal comfort can be calculated using the PMV index. However, a more accurate evaluation, and in order to identify the local thermal discomfort caused by the supply air and the surgical lights will only be possible using CFD. In accordance with the layout performed in the Hip surgery, the draught could have a big influence on the local thermal discomfort, because the surgeon is positioned in the downflow area. Therefore, zooming in at this zone, it will be possible to see if the thermal discomfort is significant. In the Foot surgery the draught probably is not significant as the surgeon is not positioned in the downflow area. Therefore, calculating the PMV index would be enough. However, if we want to assess the local thermal discomfort caused by the temperature gradient, it is important to use the CFD. In the Foot surgery, the surgeon is in a mix zone, the same situation that occurs when there is mixing ventilation system in the OR. Probably, in the mix zone the surgeon will present more thermal discomfort than the surgeon below the supply air, because the air temperature will be higher and the velocity of the air is lower.

CONCLUSION

The purpose of this paper was to discuss the methodology and the approach to support the design assessment for ventilation systems in ORs. The BEDM was taken as the point of departure for the development of the Performance Based Design. The numerical simulation is a useful and important tool in design phase, permitting to observe if the ventilation system adhere to the needs for specifics surgeries. In the evaluation procedure, it was identified the types of numerical tools that could be applicable for the assessment of the surgeon thermal comfort. The case study permitted to identify benefits from the method and to verify the applicability of the evaluation proposed.

In the other hand, for the example discussed, although previous studies evaluated the thermal comfort in ORs, there is yet a strong need for future research to identify performance indicators that permit to assess efficiently the thermal comfort in ORs. Next step will be to complete the matrix presented in Figure 3, to evaluate other stake holders, performance requirements and indicators, and the other architectural system levels.

Validation of a Neutral Pressure Isolation Room

Andrew Fletcher, William Booth and Blanca Beato Arribas

BSRIA Ltd., UK

Corresponding email: Andrew.Fletcher@bsria.co.uk

SUMMARY

The principles behind a new design of isolation room are set out. The process of validating the design is described using a range of physical modelling techniques. A CFD model was also constructed and compared to the basic operational mode. Characterisation of the internal airflow patterns was used to assess the level of mixing under steady state conditions. The techniques were extended to cover the response of the design to various challenges such as door opening. There are two reasons for using an isolation room – the patient is a source of infection and the patient is at risk from infection. The concept of a protection factor is introduced as a measure of the effectiveness in protecting staff or a patient against a source of infection. The PPVL isolation room provides a protection factor of 10^5 between the corridor outside and the isolation room (all doors closed) and a factor of 10^3 within the isolation room.

INTRODUCTION

The UK Department of Health (UKDH) has issued guidance for the design of a neutral pressure isolation room. The design incorporates a positively pressurised ventilated lobby (PPVL). The PPVL provides a barrier to airborne infection originating within the isolation room (i.e. equivalent to the negative type isolation rooms) and a barrier to airborne infection originating in the corridor (i.e. equivalent to the positive type). A static pressure differential between the isolation room and the adjacent corridor of close to zero is intended in the design - hence the term neutral pressure isolation room. [N.B. It is probable that the UKDH will adopt the terminology of PPVL rather neutral to make its purpose clear and unambiguous].

Air is supplied mechanically into the lobby through a central ceiling mounted supply diffuser. The supply flow rate was 220 $l.s^{-1}$. The majority of the air supplied to the lobby passes into the isolation room (160 $l.s^{-1}$) via a pressure stabiliser fitted above the door between the lobby and the isolation room. A proportion of the air leaves the lobby and enters the corridor via gaps around the door. Air also enters the isolation room via gaps around the door below the pressure stabiliser. Air is extracted from a ceiling mounted grille in the ensuite bathroom and so air is drawn from the isolation room via a low-level transfer grille in the ensuite door. The extract flow rate was 160 $l.s^{-1}$. The design intent is for around 10 air changes per hour ($ac.h.^{-1}$) to be delivered to the isolation room with good mixing, which is equivalent to 60 $ac.h^{-1}$ in the lobby.

The mechanical stabiliser is set to maintain a nominal pressure difference of +10 Pa between the lobby and the isolation room when all doors are closed. As the static pressure differential between the isolation room and the corridor is intended to be close to zero, the static pressure in the lobby is also designed to be around +10 Pa above the corridor when all the doors are closed.

In a PPVL isolation room, effectiveness is achieved by means of diluting airborne pathogens in the vicinity of the patient by a well-mixed pattern of room air movement. Therefore, the contaminant is removed from the isolation room by means of the mechanical extract system. Tracer gas (nitrous oxide) was used to simulate airborne infections. It was released into the isolation room and its concentrations were measured around and outside the room using tubes connected to analysers, to investigate the dilution, transport and removal of a contaminant. Further tests were done with the source in the lobby and with doors being opened and closed to simulate personnel movement.

Dilution ventilation is only one of the protective features afforded by the design. Challenges such as high-speed ejection of infectious material (e.g. a cough, sneeze or excretion of bodily fluids) or direct contact routes of infection are handled by use of appropriate PPE and/or barrier nursing procedures. Other factors come into play when considering the situation where the patient is at risk from their surroundings. However, this paper is not concerned with operational and maintenance issues [1] or the rationale for selecting a particular ventilation strategy.

The following schematic is taken from the recommended guidelines [1], upon which the principles of design and operation were based, where the minimum requirements for such a facility are listed.

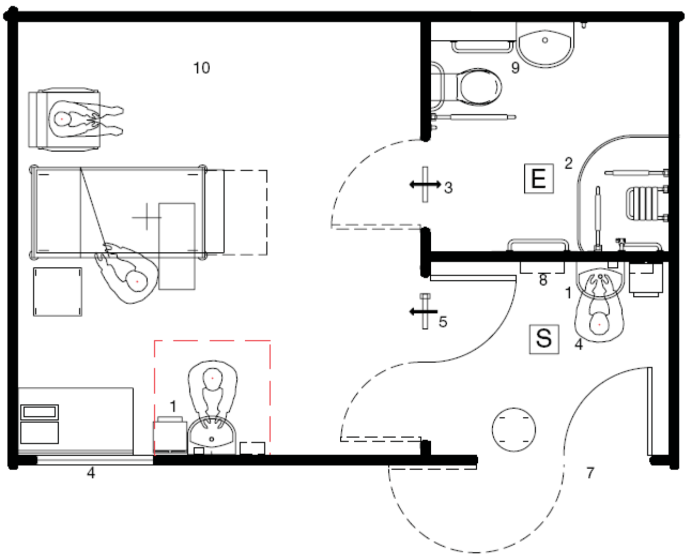

Figure 1. Single Room for Isolation [1]

The independent validation exercise was carried out to build and test a PPVL isolation room in a laboratory. It was decided in the outset of the project to validate the performance of the PPVL design with the following key issues:

1. Can the PPVL concept be built (within the test facility environment)?
2. Is it a robust design (from the point of view of construction, commissioning, maintenance, integration and testing – as far as the laboratory permits?)
3. Are the preferred design flow patterns achieved within the space, and are they stable?
4. Is the performance of the facility compromised with the lobby door left open to the main isolation room?
5. How do the internal conditions withstand challenges from door openings and personnel movement?
6. Is the thermal comfort of the patient and staff acceptable under normal operating conditions?
7. Is the performance acceptable with regards to infection control?
8. How does layout of furniture affect the room performance?

METHOD

Test facility

The design was based upon a specific configuration of PPVL isolation room, adapted for the laboratory environment. The isolation facility was constructed within the boundaries of an existing purpose built chamber, in order to maintain stable conditions and hence repeatable results. As far as practically possible, preferred suppliers and fitters of the Health Service were used to fit out the chamber. This helped to aid the authenticity of the project and to highlight any key issues with building the design. The construction included door fitting and sealing, pressure stabiliser balancing, and the use of hospital furniture and fittings within the isolation room, ensuite and lobby. The adjacent laboratory space still within the outer environmental chamber was used to model the corridor of the hospital.

Figure 2. View of completed PPVL test facility

Measures to provide a stable and quantitative environment for the test facility were employed from the onset to gain repeatable results. Cables and sample tubes were passed into the chamber through sealed glands, data acquisition and power metering of all heat loads (IT, occupancy and lighting) within the facility was used, and volumetric flow rates from the mechanical supply and extract were monitored using Air Movement and Control Association (AMCA) standard nozzle boxes. The dedicated data logging system with custom designed software took regular spot measurements of air temperature, air speed, power consumption, internal and external wall surface temperatures and inter-room static pressure differentials. Further details on the techniques used within the project are presented elsewhere, see [2] and [3].

Test Procedure

The principal aim of the test facility was to establish whether the ventilation patterns inherent in the isolation room were operating as a single, well-mixed zone. Sufficient mixing of fresh air from the lobby with the room air, effective extraction from the ensuite, and maintaining the pressure barrier with the stabilisers, were the key aspects in making the design work.

The design also required a wholly stable environment from which tests could be repeated with confidence in producing repeatable test results. All instrumentation used that is key to understanding the physics of the facility was calibrated at regular intervals to provide confidence in the results.

Multiple routes to validate the design were explored throughout the project, including:

- Air leakage performance through pressurisation to commissioning standard in [1].
- Room Air Movement (RAM) survey to measure temperature and air speed over a regular 11 x 13 grid at 11 heights within the facility. This provides information to calculate the thermal comfort parameters, such as draught risk.
- Flow visualisation using smoke pencils for local effects, and smoke generators for facility air mixing visualisation.
- Gas Tracer Tests (GTT) to study the release of nitrous oxide (N_2O) into the isolation room as the source of contaminant from the patient, analysed at multiple points within the facility through analysers. Protection levels and air change rates were deduced.
- Computational Fluid Dynamics (CFD) to accurately model the facility as built and to compare predictive computed results against the physical results found with the RAM surveys.

RESULTS

Fundamentally, it was found that the chosen configuration could be built, and that the isolation room does operate as a single zone and as a well-mixed space under standard conditions.

The design provides a nominal 10 ac.h^{-1} from the mechanical ventilation supply to the lobby, working with the pressure stabilisers. The test facility exhibited approximately 8 ac.h^{-1} within the isolation room, demonstrating the predominantly well-mixed behaviour that was predicted.

The main findings are reported below as an overview. Figure 3 shows air temperature and air speed results from two RAM surveys within the facility, one under standard operating conditions (Test 5), and the other when the lobby door to the isolation room has been left open (Test 6). It would not be expected that the door would be left open for a prolonged period, however tracer gas tests demonstrated that the isolation room still behaved as a single zone, but with air interchange between the lobby and the isolation room. The mixing in the isolation room (door closed) was characterised by a factor of 0.89; the corresponding factor for door open was 0.53.

The plots in Figure 3 demonstrate the supply air jet from the balancing diffuser entering the isolation room (door closed), and highlight the uniform distribution of air temperature within the entire space. Satisfactory levels of thermal comfort are experienced across the floor space. Opening the lobby door removes the supply jet as expected, and introduces a level of stratification to the facility. Analysis of the results was performed for four tests, with results being averaged for each anemometer height within the zone that were conducted under thermally steady state conditions:

Test 3: All doors closed, no furniture in room, original pressure stabiliser used
Test 4: All doors closed, no furniture in room, alternative pressure stabiliser used
Test 5: All doors closed, furniture introduced, alternative pressure stabiliser used
Test 6: Lobby to isolation room door open, with furniture in room

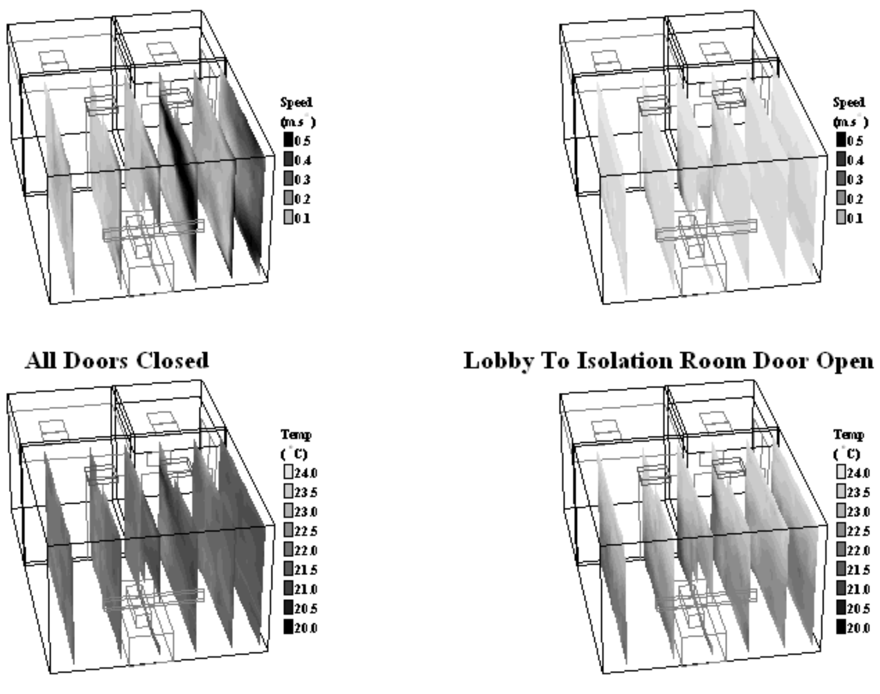

Figure 3. RAM Survey visualisation plots, Tests 5 and 6.

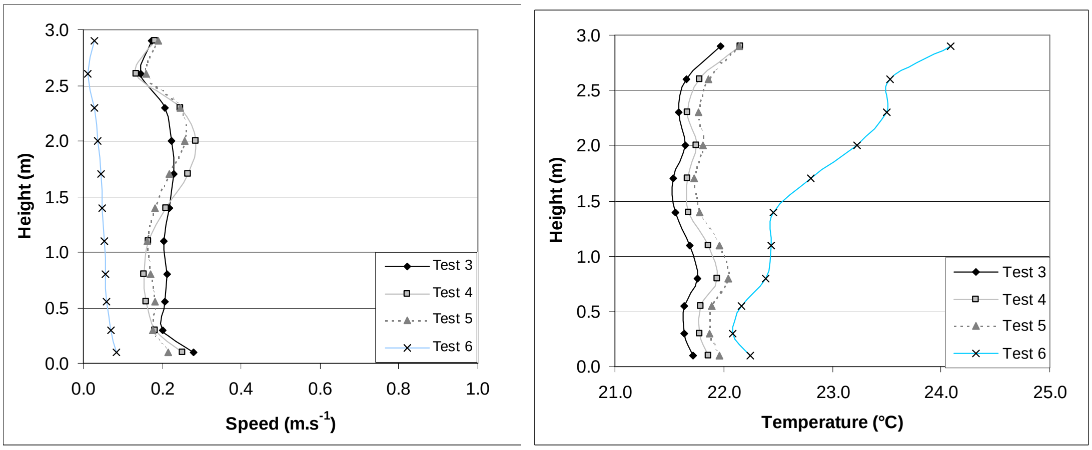
Figure 4 demonstrates the room averaged air temperature and air speed profiles at the anemometer heights within the facility. Good levels of air mixing within the space can clearly be seen in Tests 3, 4 and 5, with the significant temperature stratification present in Test 6 when the lobby to isolation room door is opened.



a) b)

Figure 4. RAM Survey thermal analysis. a) Speed ($m.s^{-1}$), b) Temperature (°C).

The distribution of contaminant (tracer gas) with the patient as a source has been studied and reported. [4]

Single failure modes were explored within this project and included supply and extract fan failures. The simulated supply fan failure indicated no significant leak of tracer gas into the corridor, with the isolation room remaining effectively well mixed and under negative pressure. Extract fan failure lead to increased levels of detection within the room as expected, but the lobby still provided a layer of protection to the corridor. A patient vulnerable to infection would not be at a significantly higher risk as long as the doors remained closed in this particular failure mode. The worst-case failure mode explored within this project is for the lobby door to be left propped open. Tests show that under these conditions the tracer gas can pass into the lobby, with barely detectable levels reaching the corridor.

Determination of the level of protection presented by the isolation facility (from the PPVL) was a major objective in the project. Minimum detection levels of 10ppm (parts per million) of N_2O against 100% (10^6 ppm), implies a dilution ratio of 10^5. This is expressed as the protection factor.

The principal conclusion is that the PPVL design is considered to be validated. The main qualifications to this principal conclusion are set out below:

- Full size room with ensuite successfully constructed following published guidance. Construction follows ethos of guidance with standard lighting and HVAC components. Specific recommendations were followed with regard to key features such as pressure stabilisers.
- Isolation room functioned as expected once commissioned.
- Preferred flow patterns were characterised by smoke, anemometry techniques, CFD prediction (base case) and tracer gas tests. Stability and repeatability were clearly demonstrated.

- Transient issues were addressed mainly through remote door operation to simulate personnel movement. Only scenarios compatible with proper use were considered (e.g. scenario such as both doors open was not relevant).
- Standard thermal comfort indices provide standard basis for assessment and comparison but individuals vary widely in their perception. Medical conditions may have significant impact. Potential mismatch between patient and nurse clothing level and metabolic rate is a consideration applying to all types of isolation room.
- Airborne infection covered for scenarios where tracer gas is a good model for the infection mechanism. A 10^5 protection factor was introduced and established.

DISCUSSION

The test facility demonstrated exhibited well-mixed (turbulent) air distribution, operating as a single zone of movement under standard operating conditions. The introduction of transient situations (opening and closing of doors) proved successful in indicating that the isolation room can return to its initial well-mixed state when disturbed.

The protection factor was introduced as a measured degree of effectiveness in protecting staff and patients against a source of contamination.

There are two reasons for using an isolation room – the patient is a source of infection and the patient is at risk from infection. The PPVL isolation room provides a protection factor of 10^5 between the corridor outside and the isolation room (all doors closed). Conformance with air tightness standards in construction coupled with the operation of the isolation room itself at near neutral pressure differential relative to the corridor is a further safety factor.

There is a further role other than isolation. The patient has to be nursed and medical examinations and minor procedures have to be carried out. Where the patient is a source of infection, potential hazards must be reduced to provide a safe and ideally comfortable environment. The dilution ventilation strategy is based on dilution of airborne pathogens by the incoming fresh air. The validation using tracer gas has shown that normalised concentrations within the isolation room (doors closed) are within a range of 0.5 and 2.0. This expresses the typical variation in concentrations that would be expected in the working zone of nursing staff away from the immediate source of aerosol ejection. The alternative view is to regard the ventilation within the isolation rooms providing a conservative protection factor of 10^3. For the patient at risk from infection, a similar protection factor can be assigned with regard to the dilution ventilation as viewed by the patient.

It has been established that a configuration of the design presented in HBN4 [1] can be built and operated as intended, through the use of multiple established validation techniques. The PPVL concept provides a quantifiable barrier of protection for the patient from the corridor, and for the inhabitants of the corridor from the patient. The design as tested will operate correctly as an isolation room if built as an isolated system. Sanitation, mechanical ventilation and power supplies need to be independently sourced for it to function effectively for extended periods of time.

The PPVL isolation room design offers real potential to control infection in hospitals contributing to a healthy and productive environment.

ABSTRACT

This text contains attainments from indoor climate and air conditioning equipment monitoring in clean rooms in the public health service. The editor is designer of HVAC systems in the modern hospital near Brno in the Czech Republic. The text includes the experiences from the design phase as well as from the function the hospital. Monitoring of the HVAC systems enables during 2 years operation efficiency evaluation of heat recovery system from waste air. We are able to evaluate its economy effect. And benefit of heat recovery system depends of course of outdoor climatic conditions.

INTRODUCTION

The general requirement for energy consumption lowering in buildings includes also the requirement to bring down the energy consumption for heating. Czech technical standard for thermal protection of buildings is permanently innovated and the requirements for thermal-technical properties of buildings are strict. It is necessary to deal with lowering the heat losses by ventilation, especially in buildings where the air change rate is higher. By current standard for the envelope of the building the heat loss by ventilation is higher than the heat loss caused by transmission already for air change equal to one. That is the reason to intensify dealing with systems for energetic demand for ventilation lowering – systems for heat recovery. Other possibilities that follow are related to the operation of the equipment – the choice of the optimal temperature of the inlet air with respect to the required indoor temperature, taking the advantage of the operating hours of the equipment by using damping mode with lowered air supply. If it is not possible to set the equipment away in non-operating hours due to hygienic reasons, it is advisable to lower the air temperature (similarly as when heating) at damping mode.

The eldest and simplest method of heat recovery of air is mixing when a part of the airflow circulates and another part is mixed with the outside air. This is not a fortunate solution, when ventilation is concerned, especially for large systems operating a greater number of rooms. The air circulation spreads the noxious agents from a single room into the other areas of the building via air conditioning. This is evident e.g. while air-borne spread of cold disease. Therefore the mixing of air of ventilation and air conditioning systems should be nowadays replaced by hygienically more favorable methods.

EXPERIMENT AND METHODOLOGY

Most frequently used exchangers for recycling of heat from outlet air are plate heat exchangers in counter-flow or cross-flow connection. These particular heat exchangers in air conditioning units that operate clean spaces were subjected to detailed observation while running in reality. A special attention was devoted to these effects:

- Efficiency of heat recovery from outlet air. Based on measurements of necessary variables by Measurement and Regulation system the efficiency of heat recovery was calculated and heat savings were evaluated.
- Heat loss by transportation of air by piping and in air conditioning unit.

Individual fields were elaborated experimentally based on measured variables provided by Measurement and Regulation system of the object, some variables were derived and calculated. The system measures and saves the values in the interval of 6 minutes.

HEATING OF THE AIR IN THE RECUPERATOR AND HEAT SAVINGS

Air conditioning equipment from two operating rooms was chosen for monitoring. The airflow of the inlet air is 6200 m^3/h; the airflow of the outlet air is 5750 m^3/h.
The building control system permanently measures and saves the temperature of the outer (suction) air, inlet and outlet air and waste air behind recuperator. The humidity of outlet air is measured as well. The variables are indicated on fig. 1. The air temperature behind the heat exchanger on the inlet airside was calculated from equality of heat flows of inlet and outlet air:

$$V_p\left(t_e^{/}-t_e\right)=V_o\left(t_i-t_i^{/}\right) \qquad (1)$$

Airflows are determined from measurement of speed in piping made by testcrosses. Based on this measurement the speed of the fan is adjusted in order to reach constant airflow by means of conversion transducer.
Because of this the airflow in piping is constant without the influence of pressure relations in piping network. The measurement of speed is made on the treated inlet airside and the outlet air leaving the room before the AC unit side. The temperature of inlet and outlet air is similar; the difference is not bigger than 5 K. Hence the influence of different thermal capacities of airflows and their densities can be neglected.

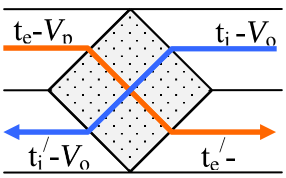

Fig. 1 Observed variables of the plate

An individual problem is the condensation of water vapor on the outlet airside while observing the plate exchangers efficiency. No moistening of inlet air was applied in monitored period; therefore the humidity of outlet air was low (under 30%, commonly about 25%, consequently dew point lower than 5 °C). Because of this low humidity and assumed efficiency of heat recycling up to 60% it was possible to exclude the condensation of water vapor on the exchanger.

The graph representing the temperature relationships while cooling of the waste air on the plate exchanger is shown on fig. 3. We can also see the outlet air temperature variation corresponding to room temperature variation. In operation period the room temperature is 24,5 °C, otherwise 19,5 °C. In regard to high air change rate (23x per hour) the temperature rise and drop is very fast, temperature difference of 6K in operation field is balanced in 15 minutes. Lowering of temperature in non-operating hours is another advisable saving measure. However it is necessary to synchronize the temperature modes of ventilation (air conditioning) system and heating system. From measurement it is obvious that if the heating elements are not adjusted accordingly, the heating system automatically increases its power to compensate the loss by ventilation. Thus the temperature of outlet air remains the same in operating and non-operating hours.
It is possible to calculate the heat savings based on measured and calculated variables in the formula 2:

$$Q = \int_{\tau} V_p \rho c \left(t_e^{/} - t_e\right) d\tau = \int_{\tau} V_o \rho c \left(t_i - t_i^{/}\right) d\tau \qquad (2)$$

At the average outer temperature is 3,0 °C the thermal energy savings of heat recovery system by 50%.
It is necessary to mention another factor. When using the heat recovery system, the Building control system should contain control of the plate exchanger bypass and provision of the antifreeze safety. But if the heat recovery system substitutes air mixing, the mentioned modifications of MaR are equivalent to the control of mixing valve.
Thermal efficiency of the exchanger is defined by the formula [3]:

$$\eta = \frac{V_o \left(h_i - h_i^{/}\right)}{V_o . h_i - V_e . h_e} = \frac{V_e \left(h_e^{/} - h_e^{/}\right)}{V_o . h_i - V_e . h_e} \qquad (3)$$

Above the assumption makes simplified formula:

$$\eta = \frac{t_i - t_i^{/}}{t_i - t_e} \qquad (4)$$

In monitored period the outer temperature varied from -1 °C to +5 °C. The average efficiency of the exchanger was 50%. This low efficiency is given by low humidity of outlet air (to 30%), so that there is no condensation of water vapor by cooling of outlet air. For such conditions the manufacturer states the efficiency to be 52%. It is necessary to respect the real efficiency while thinking about the importance heat recovery equipment saves 1,18 GJ of thermal energy per day. If the thermal energy is acquired from a central heat supply system the savings per day can be enumerated to 13 Euro. We assume this day as a representative day for whole heating period. For a total number of 195 days would the year savings of one heat recovery unit be 2 555 Czk. The length of the heating period is derived from average monthly temperatures according in Czech Republic.
The pressure loss of the chamber of the plate exchanger in optimal operating conditions does not exceed 200 Pa, in monitored case it is 120 Pa. Total pressure of a supply fan is 1 200 Pa, which means at given airflow and efficiency of the fan the power of 2,79 kW. At the decrease of supply pressure by 120 Pa the required power drops to 2,48 kW. The real consumption of energy for the fan driving is determined according to the engine power assigned to the fan. The lowering of total pressure of the fan would mean in this case the lowering of required

engine power from 4,0 to 3,5 kW. The equipment runs 24 hours per day, 10 hours of it to 100% and 14 hours to 50% air power. In this operating mode is the difference of electrical energy consumption 7,8 kWh/day for supply fan and 2,3 kWh/day for outlet fan. The difference of electrical energy consumption makes 2 890 kWh per year. The operation of the fans in the AC unit without the plate exchanger would be cheaper by 286 Euro, considering market price of electrical energy. The increase of supply pressure of fans lowers of heat recovery. In despite of relatively low efficiency the thermal energy savings mentioned above are significant.

HEAT LOSS BY PIPING AND IN AIR CONDITIONING UNIT

If we look at possibilities for savings of thermal energy for air conditioning, it is necessary to be concerned with heat losses in air conditioning distribution system. Average values of heat transmission coefficient shows table 1.

Tab. 1 Heat transmission coefficient of air conditioning units and their insulated piping

Insulation	Heat transmission coefficient (W/m^2K)
AC unit panel cover PUR panel 50 mm	0,57
AC unit panel cover PUR panel 25 mm	0,95
Steel piping with insulation from mineral wool 60 mm	0,67
Steel piping with insulation from mineral wool 40 mm	1,0

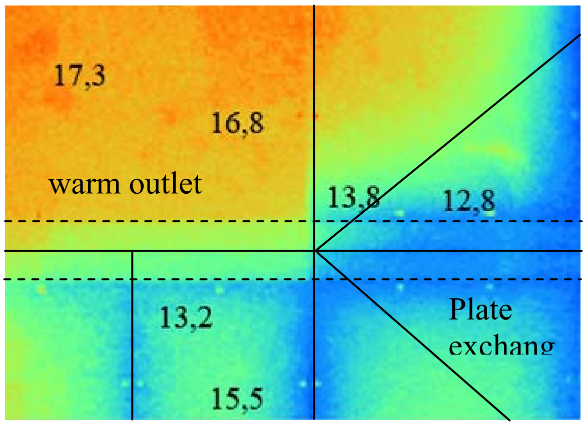

Fig. 2 Thermal field of the cover panel of AC unit with indicated chambers (temperature of sur-roundings 17 °C,

The heat loss through AC unit panel cover is neglected if the AC unit is placed in interior heated environment. The thermally treated air passes only through short part of the unit (exchangers are usually placed at the end of the formation) and the heat loss does not exceed 50 W. Fig. 2 shows thermal image of an AC unit. Even though is the total heat loss not significant, it is obvious that the temperature field of the outer cover of the panel corresponds to the supply air temperature. The AC unit is modular, made of chambers. From the thermal insulation point of view are the critical places connections of the chambers, since there are the stiffening elements. The temperature difference in the middle and in corners is 5 K by temperature difference of 19 K between the warm (waste) air and fresh (outer) air. Condensation of water vapor can occur under unfavorable thermal moisture conditions.
The piping in the machine room has thermal insulation of the thickness of 60 mm. besides heat losses and risk of condensation it is necessary to take into account the noise propagation. At the temperature difference between the air in the machine room and in the piping 10 K is the heat loss for 50 m^2 of the heat transfer surface of the piping 330 W. For average conditions (above mentioned example) this heat loss does not mean a change greater than 0,3 K in the temperature of supply air. Thermal imaging proved a good quality of the insulations, which should be nowadays standard in HVAC field.

Current design standard of thermal resistance of constructions of building envelopes ensures that even in unheated spaces of buildings the temperature approaches the temperature in surrounding rooms. In ordinary circumstances the piping does not pass though different spaces concerning temperature. If the temperature of the supply air does not differ from the temperature of the surroundings by more than 4 °C it is not necessary to insulate the piping. In running of public health services the ventilation systems usually take over the role of air conditioning and therefore the piping is insulated because of the summer temperature conditions. We can summarize that air transportation by piping is no more a source of heat losses.

RESULT

From all of the heat losses in air-conditioning equipment that was analyzed above is the most significant one a heat loss by ventilation, which can be effectively lowered by means of heat recovery system. The values presented in this article were obtained by monitoring of real air conditioning equipment. Air conditioning in health service is specific with regard to operation time and higher air change rates. These are favorable circumstances for usage of plate exchangers that ensure hygienically clean running by separation of the inlet and outlet airflows. In this case study were found annual savings of thermal energy under real climatic conditions in the CR 2 270 Euro. Considering the price of a chamber with a plate exchanger to be 3 100 Euro, the payback of this measure is very short.
Another suitable measure is consequent respecting of working hours in attended spaces. Only then it is possible to use lowered air supply and lowered temperature in damping time. Mutual correspondence between set values of air conditioning and heating is essential.

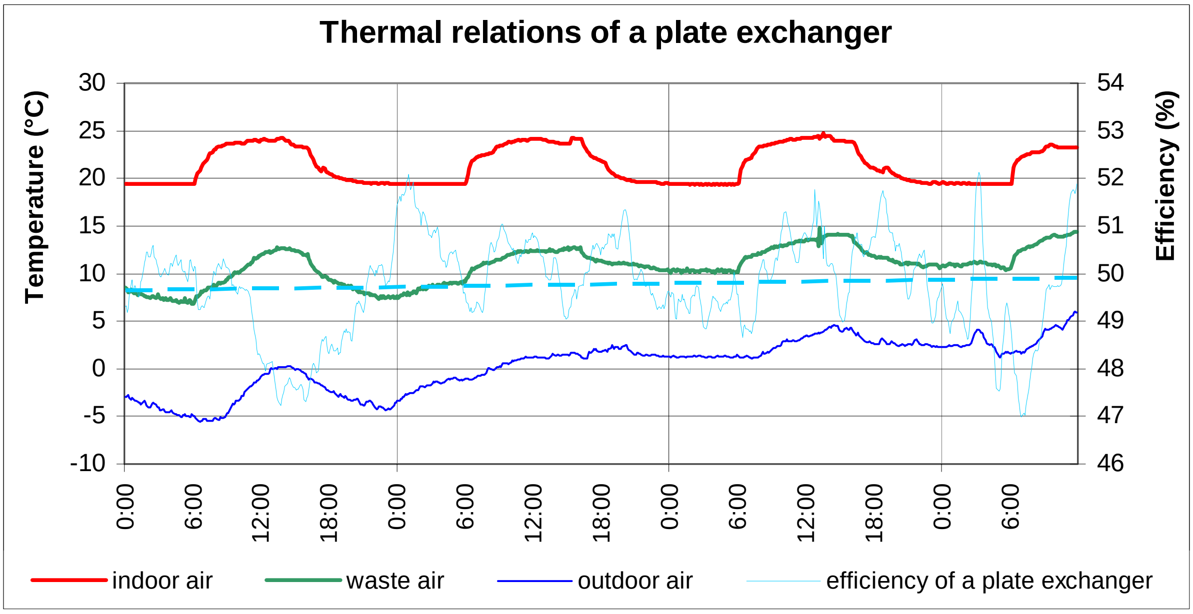

Fig.3 Thermal relations of a heat recovery exchanger in Januar 2006

DISCUSSION

Efficiency off-heat reverse obtaining can markedly be lowered by low outdoor temperature with effect antifreeze exchanger safety. By temperature fall of waste air below 5°C is outdoor air input partly or completely bypass. Surface temperature of exchanger could be in this time lower then 0°C (figure 4). Heat exchanger is for this time off the function. Temperature 5°C waste air can be reach with outdoor temperature about -7°C (figure 3). The real efficiency with low outdoor temperatures is accordance with lower regulating antifreeze safety exchanger.

Ventilation Considerations for Indoor Environmental Quality for a Control Center

Peihong Zhang

Jacobs Engineering, Inc., NYC, NY, USA

Corresponding email: Peihong.Zhang@Jacobs.com

SUMMARY

This paper presents design considerations of ventilation and indoor environmental quality (IEQ) for a control center. Raised access floors are extensively used to provide flexibilities for control cables and wires required by a control center. Underfloor air distribution system (UFAD) is more practice and economical than an overhead mixing system. It improves indoor ventilation effectiveness due to the air stratification of thermal plume, and it provides a better indoor environment for the equipment and occupied people. From the analyses and calculations for a control center, when the load density is less than 40 btuh/s.f., and the throw height of the floor panel diffuser is less than 4', the ventilation effectiveness is up to 1.2, similar to the displacement ventilation. When the load density is between 40 and 60 btuh /s.f, and the throw height of the floor panel diffuser is between 4' and 6', the stratification of thermal plume is still generated, the ventilation effectiveness is approximately 1.1. When the load density is over 60 btuh/s.f., the throw height of the floor panel diffuser is over 6'. Without the air stratified layer, the ventilation effectiveness is 1.0, equal to perfect mixing air distribution. In the high supply airflow rate situation, ventilation airflow for providing an acceptable IAQ around people should be maintained at least 10% of supply air, in order to provide at least 5 cfm fresh air for people who can obtain nearby.

INTRODUCTION

A control center differs from a data processing center because it is continuously occupied by people performing various activities whereas a data processing center is infrequently occupied by one or two persons for brief periods. Its heat load is similar to the data processing center, there are high density heat loads emitted from control devices. Then, it is more complicated than the data processing center because an acceptable indoor air quality is required for the occupants' health and thermal comfort.

High density heat loads from computer workstations and control devices result in high air flow rates in a control center. Outdoor air flow for ventilation is mixed in supply air flow, ventilation air percent of supply airflow is decreased with the increase of supply air when the required outdoor air flow rate 15 cfm per person is used. Ventilation air that people can catch in the breathing is greatly decreased. Hence, the ratio of ventilation to supply air should be hold at some proportion.

Raised access floors are built to accommodate the large number of electrical cables and wires required by the control center. Under floor space is available, it is reasonable and economical to use for an underfloor air distribution system (UFAD) for air conditioning of the control center. UFAD uses raised access floors as a conditioned supply air plenum, the conditioned air is delivered to the occupied space through diffusers installed in the floor, that can be relocated easily.

Compared with displacement ventilation, UFAD uses air buoyancy that helps to drive air up to return openings, and air stratification of thermal plumes to improve indoor air quality. Furthermore, when supply air is mixed with room air in this system, much higher cooling loads can be handled. Hence, an underfloor air distribution system is specially suited for a control center.

Figure 1 shows a sketch for an underfloor air distribution system for a control center. Floor panel diffusers throw conditioned air up to the occupied space. When the throw height is proper, the stratification of thermal plume is formed. The ventilation effectiveness and indoor air quality are improved and outdoor air flow rate may be decreased.

For this project, the area of the control center is approximately 1520 s.f., there are 8 workstations, 5 wall videos and 14 people occupancy. The load densities will be analyzed from 40 btuh/s.f. to 110 btuh/s.f..

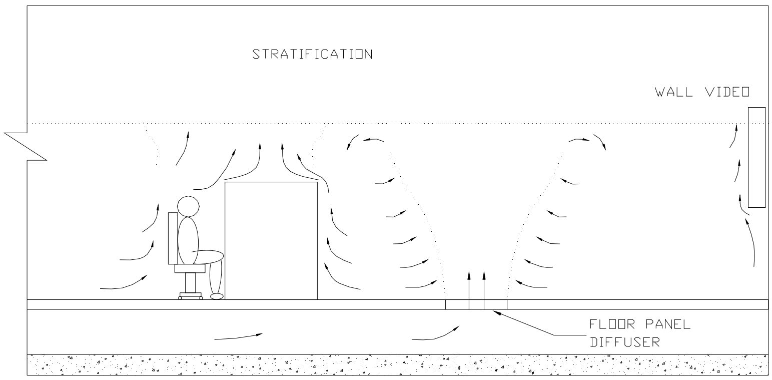

Figure 1 Sketch for Underfloor Air Distribution for a Control Center

VENTILATION CONSIDERATIONS

Outdoor air is brought to an occupied space by an air handling unit, complying with ASHRAE Standard 62. Conditioned air mixed with the acceptable outdoor air in a pressurized underfloor air plenum through floor panel diffusers is delivered to an occupied space, that includes the breathing zone around people under 6’ height and the above area. If the conditioned air with the fresh outdoor air is concentrated to send to the breathing zone, the ventilation improves the indoor air quality around people. The air velocity and temperature distributions directly affect the ventilation for improving an indoor air quality. Furthermore, ratio of ventilation air to total supply air should be kept to provide the minimum fresh air nearby people who can catch in the breathing.

AIR VELOCITY DISTRIBUTIONS

An area of a floor panel diffuser for this control center is 2’x2’ with a 25 % free area. For a load density 55 btuh/s.f., required airflow rate is 300 CFM for a floor panel diffuser at the air temperature difference 15 °F between the supply and return air. There are total 17 floor panel diffusers in this control center. The air velocity through the perforated floor panel is 300 fpm with an effective area 1 square feet. Table 1 presents the air flow rate for a floor panel diffuser and the required total pressure in the pressurized underfloor plenum at different load conditions.

Table 1 Air flow Rate at Perforated Discharge of a Floor Panel Diffuser with a 25 % Free Area at Different Load Densities and Total Pressure Required in the Pressurized Plenum for the Control Center

Load Density btuh/s.f.	40	55	75	90	110
Airflow Rate per Floor Panel Diffuser, cfm	230	300	400	500	600
Velocity at Perforated Discharge, fpm	230	300	400	500	600
Required Total Pressure at the Pressurized Underfloor Plenum, W.G.	0.04	0.07	0.13	0.20	0.29

By calculating the pressure losses through the perforated panels plus velocity pressure, the total pressure 0.072" w.g. in the pressurized underfloor plenum is required to deliver the air flow rate 300 CFM to the occupied space. When the airflow rate increases, the total pressure of the supply air plenum is required to increase according to the power of the flow rate. If the air flow rate is over 600 cfm, the floor panel diffuser with a 25 % free area requires the total pressure over 0.29 W.G. to carry the conditioned air to the space and results in high energy consumption of fan power and noise issues. At the situation, a floor panel diffuser with a higher free area is required to decrease the pressure losses through the diffuser.

When air is discharged from perforated panels, the constant velocity core formed by coalescence of the individual jets extends a distance from the panel face. For the panel diffuser throw the air to the space, the air stream velocity above the floor panels is expressed at the equation (1).

$$V_x = 1.2V_0\sqrt{C_d R_{fa}} \tag{1}$$

where:
V_x is an average initial velocity at the perforated discharge.
C_d is a discharge coefficient.
R_{fa} is a ratio of free area to gross area.

The centerline velocity of a floor panel diffuser in jet expansions zone 2 and zone 3 are expressed in equations (2) and (3) below.

$$Vx=V_0\,(1.13KH_0\,/X)^{1/2} \tag{2}$$

$$Vx=V_0\,(1.13KA_0^{1/2}/X) \tag{3}$$

Where:
A_0 is an effective area of stream, ft^2.
H_0 is an effective width of jet at outlet, ft.
K is a centerline velocity constant.
V_0 is an average initial velocity at the outlet, fpm.
V_x is a centerline velocity at distance X from outlet, fpm.
Figure 2 shows the air velocity distributions at the centerline of jet expansion at the room height when the floor panel diffuser delivers the airflow rates at the range of 230 CFM to 600

CFM, the load densities have a range of the 40 btuh/s.f. to 110 btuh/s.f.. After the air velocity at the centerline reaches 50 fpm, the velocity and temperature are decreased rapidly. The throw height is obtained at the air velocity 50fpm. If the air throw height is under a breathing zone height, the stratification of thermal plume is generated over the breathing zone. Ventilation air originated from the outdoor is concentrated and distributed in the breathing zone of the occupied area, it is not distributed in the un-breathing zone in the stratified area. The ventilation effectiveness in breathing zone is improved.

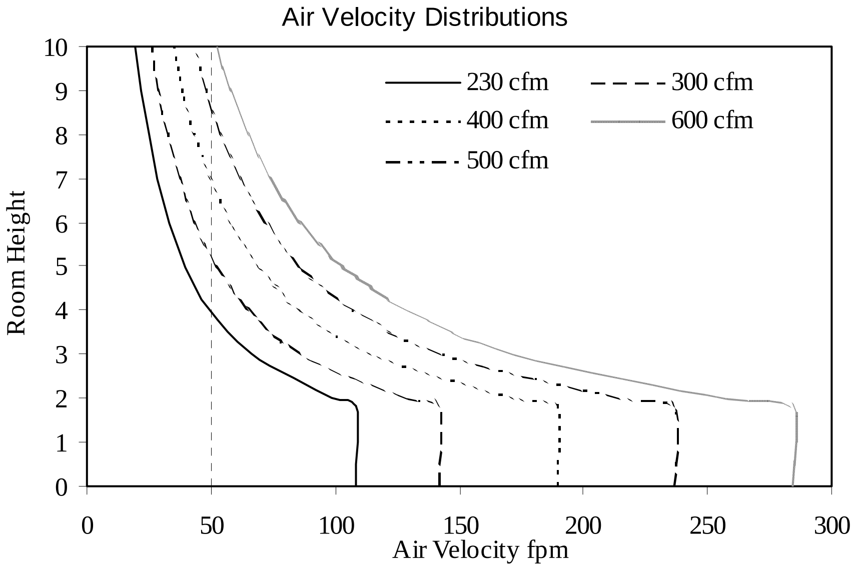

Figure 2 Air Velocity Distributions at the Room Height for a Floor Panel Diffuser.

For the air flow rate 300 CFM and load density 55 btuh/s.f., the throw height is approximately 5 feet, while the throw height is close to 9 feet at the air flow rate 500 CFM and the load density approximately 90 btuh/s.f. When the throw height is 5 feet, the stratification of the thermal plume may be formed above 6 feet. Furthermore, if the load density is under 40 btuh/sf and the air flow rate is under 230 fpm, the throw height is under 4 feet, that is height of main equipment and control devices. When the stratification of thermal plume is generated, the ventilation for this situation is similar to the displacement ventilation. When the load density is over 90 btuh/s.f., the throw height is over 8’, the stratified layer of thermal plume disappears because the air velocity is turbulent in the area. Although the stratification disappears, the room air is fully mixed with the conditioned air from the underfloor plenum. This case is equivalent to an overhead air mixing system, the ventilation air is uniformly distributed to the whole control center space.

In the stratified case, the ventilation air is distributed at the breathing zone under the stratification. It increases the ratio of ventilation air to the room air at the breathing zone, if the stratification of thermal plume is formed at 6 feet height (it is above the breathing zone). When higher the stratification is formed, less the ratio of ventilation air to the room air at the breathing zone. The ventilation air is decreased until reaching the ventilation effectiveness of uniformly mixing ventilation.

AIR TEMPERATURE DISTRIBUTIONS

An air temperature distribution is similar to an air velocity distribution for the underfloor air delivery. The temperature difference at the distance X is presented in equation (4).

$$\Delta Tx=\Delta T_0\,(0.73V_x/V_0) \qquad (4)$$

ΔT_0 presents a temperature difference between an initial temperature and ambient temperature, V_x and V_0 present velocity at an initial and velocity at a distance X, respectively. An air temperature changes with an air throw distance. The air temperature difference with the ambient air at the throw height for the control center is stated in Table 2. When the load density is 55 btuh/s.f. or under, the temperature difference is 3.7 °F or over at the throw height. At that height, the air density is higher than the ambient air density. The air starts to move down, and is drawn by heat source, and makes the space air movement. If the ventilation is brought around people, the ventilation effectiveness is over 1.0. When the air temperature difference is approximately 1.5 F at the throw height 8.5' for the load density 90 btuh/s.f., the air is fully mixed with the room temperature, including the breathing zone and zone over that in the room. The ventilation effectiveness equals to 1.0.

Table 2 Air Temperature Differences at the Throw Heights for the Floor Panel Diffuser.

	Velocity at Perforated Panel Discharge, fpm				
	230	300	400	500	600
Throw Height, ft	4	5	7	8.5	10
Temperature Difference,°F	3.3	2.7	1.9	1.5	1.3

VENTILATION EFFECTIVENESS

Ventilation effectiveness describes the air distribution system's ability to remove internally generated pollutants from an occupied space, it is defined by the fraction of the outdoor air delivered to the space that reaches the occupied zone. When the ventilation air is perfectly mixed with the air in a space, the ventilation effectiveness reaches 1.0. Furthermore, the ventilation effectiveness can be greater than that which would be realized with perfect mixing. For displacement ventilation, the ventilation effectiveness is 1.2. For an UFAD system, the ventilation effectiveness should be over perfectly mixing ventilation and under displacement ventilation.

Table 3 states the ventilation effectiveness for this control center at different load conditions. When the loads density is under 40 btuh/s.f., and the thrown height of design panel diffuser is lower than 4', the ventilation effectiveness is approximately 1.2, similarly displacement ventilation. When the load density is between 40 btuh/s.f. and 60 btuh/s.f., the ventilation effectiveness would be over 1.0 and under 1.2. The stratification of thermal plume may be formed. When the load density is over 60 btuh/s.f. in this case, the ventilation effectiveness is 1.0, that equals to the perfect mixing system.

Table 3 Ventilation Effectiveness at Different Load Conditions for the Control Center.

	Ventilation Effectiveness
Ceiling Supply, Perfect Mixing	1.0
Displacement Ventilation	1.2
Floor Supply, Throw Height < 4.0'. Load Density < 40 btuh/s.f.	1.2
Floor Supply, Throw Height > 4' and < 6.0'. Load Density > 40 btuh/s/f. and <60 btuh/s.f.	1.1
Floor Supply, Throw Height > 6'. Load Density > 60 btuh/s.f.	1.0

THE MINIMUM VENTILATION AIRFLOW RATE

High density loads in a control center result in high density supply airflow rates, and low ventilation air percent of total supply air. If the minimum outdoor airflow per person 5 cfm is required in the breathing area, when heat release of people seating work is sensible 280 btuh and latent 270 btuh, then the approximately air flow rate 50 cfm is required to carry the heat out for a temperature rise 5 F. Its outdoor air percent of supply airflow is approximately 10 %. When airflow rate is increased in HVAC system, the ratio of outdoor air to supply air is decreased if outdoor airflow rate 15 cfm per person is used. For a 55 btuh/s.f. heat load, the percent of supply air is approximately 4% around people. According to air flow rate 50 cfm passing through person for heat release, fresh air that person can catch is 2 cfm. Outdoor air around people breathing area is low to result in IAQ problems. For this case, the minimum outdoor air percent of supply air is maintained at 10%, similar to the above normal situation that 5cfm ventilation airflow rate can be obtained per person, then the air flow for ventilation is greatly increased.

Table 3 shows the outdoor airflow rates in various load conditions. Outdoor airflow rate in a control center should be higher than required 15 cfm per person even the ventilation effectiveness is considered.

Table 3 Outdoor Air Flow Rate for the Control Center when Ventilation Airflow is 10% of Supply Airflow.

Load Density	Required Ventilation Airflow by ASHRAE 62	Supply Airflow Rate	Ventilation Airflow Rate
btuh/s.f.	cfm	cfm	cfm
40	175	3900	325
55	190	5200	475
90	210	8500	850

CONCLUSION

The stratification of thermal plume improves indoor air quality and ventilation effectiveness. The ventilation effectiveness in this project is obtained by analysis and calculations of air velocity and temperature distributions. In conclusion, when the load density is less than 40 btuh/s.f., and the throw height of the floor panel diffuser is less than 4’, that is control equipment and devices’ heights. The ventilation effectiveness is up to 1.2, it is similar to the displacement ventilation. When the load density is between 40 and 60 btuh /s.f, and the throw height of the floor panel diffuser is between 4’ and 6’, the stratification of thermal plume is still generated, the ventilation effectiveness is approximately 1.1. When the load density is over 60 btuh/s.f., the throw height of the floor panel diffuser is over 6’ (breathing zone), the ventilation effectiveness is 1.0, it equals to perfect mixing air distribution. For high supply airflow rates of a control center, the ventilation air should be maintained at least 10% of supply air for providing an acceptable indoor air quality around people who can obtain the minimum 5 cfm fresh air in the breathing.

Improving exhaust rates in machine tools based on flow simulations

Jörg Schmid[1] and Bing Gu[2]

[1]HLK Stuttgart GmbH, Germany
[2]University of Stuttgart, Institute of Building Energetics, Germany

Corresponding email: joerg.schmid@hlk-stuttgart.de

ABSTRACT

Three dimensional simulation of flow and material dispersion processes inside the enclosures of machine tools opens up perspectives of assessment not by far achievable experimentally. Visualisations of these processes in terms of velocity and directions, temperature and pressure allow for an in-depth understanding of the processes and their consequences in view of a reduction of emitted metal-working fluid aerosols. This is demonstrated by one example from the machine tool laboratory (Werkzeugmaschinenlabor, WZL) at the University of Aachen (Rheinisch-Westfälische Technische Hochschule, RWTH).

PROBLEM DESCRIPTION

The cooling lubricants (CL) on machine tools are flowing into the production hall and the workplace in the following ways:

- via residual concentration in the so-called clean air,
- via the heated or hot swarf and work pieces wetted by cooling lubricants (CL),
- via holes and leaks at the spin-off area of rotating pieces by exerting local overpressure,
- when opening the door at the end of a processing cycle.

To avoid the release of the cooling lubricants via holes and leaks it must be guaranteed that a negative pressure exists at all these holes or leaks. This is one of the main function of an exhaust air system which is used for such machine tools (typical air changes are 300 h^{-1} and more).

Additional functions of the exhaust air system consist as well in limiting the cooling lubricants concentration for reason of explosion protection as in removing thermal loads. The latter case is only of importance to the minimal quality of lubricating system and to the dry processing because of the fact that the essential thermal loads are to be absorbed by flooded cooling/lubricating.

One of the difficulty is to respect the dependency of the separators efficiencies on the air flow. With an increased air flow the efficiencies are principally decreasing and that’s why the cooling lubricants components in the clean air are as well increasing.

In the majority of cases, it’s easy to avoid the direct spin of swarf and/or cooling lubricants particles. If the exhaust air openings are not clearly arranged outside of the spin area, they must be equipped with a closing device whose diameter is greater than that of the exhaust air openings.

To obviate the access of cooling lubricants particles to the separator, it's necessary that so-called splash water separators or pre-separators are directly installed at the exhaust air openings at the enclosure.

The releasing of the cooling lubricants particles through the swarf can be evaded by integrating the swarf removal into the exhaust air system. This will be demonstrated later.

ANALYSIS OF FLOW PATTERN

Figure 1 shows one of the engine lathes in the machine tool laboratory at the University of Aachen (RWTH), which were tested exemplarily within the scope of a research project promoted by the association of commercial and industrial workers' compensation insurance carriers (HVBG). Figure 2 pictures a machine for flow simulation with the essential fixtures, holes and leaks.

Fig. 1: Engine lathe at the machine tool laboratory(WLZ) at the University of Aachen (RWTH)

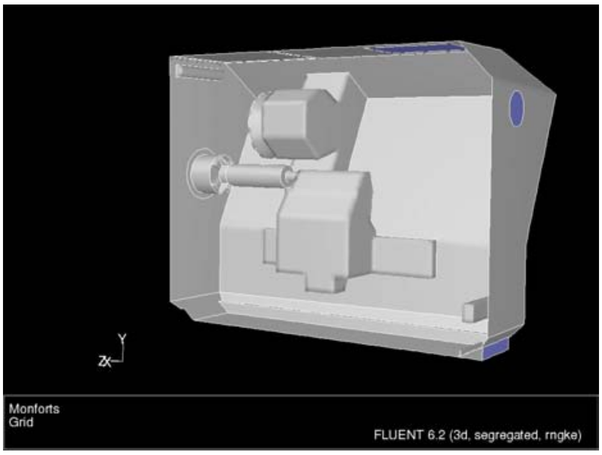

Fig. 2: Engine lathe model for flow simulation.

In the following figures 3 – 8 the conducting path lines and the appropriate pressure ratios inside the enclosure concerning as well the exhaust air flow of 650 m³/h as the maximum spindle speed of the machine of 3,000 rpm are presented.

The ratios for the following cases are shown:

- the exhaust air system is working only (no rotating pieces)
- the spindle etc. is rotating only (without exhaust air flow) and
- the combination of both processes corresponding with the real operation

Fig. 3 shows the conducting path lines which are starting from the opening for the swarf removal. In case that only the exhaust air system is working, half of the after flowing air is going through this hole into the enclosure. The air flow locates itself on the ground and streams to the left by conducting then from the side wall upwards and from the ceiling to the right side of the exhaust air opening.

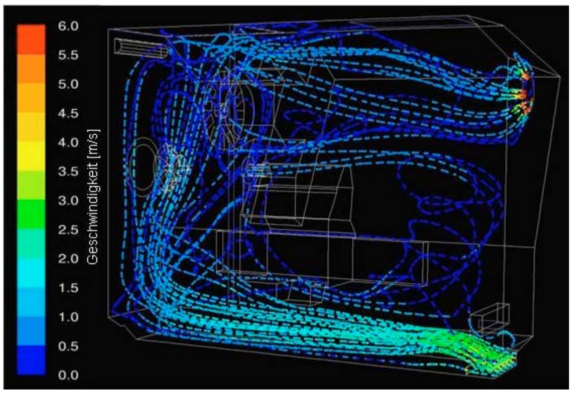

Fig. 3: Conducting path lines intra-machine during on-line operation of the exhaust air system.

The appropriate pressure distribution inside of the exemplified tested engine lathe is shown in fig. 4. On average, a negative pressure of 7 Pa is exerting on the ambience. It can be recognised that the negative pressure at the redirection places in the bottom left corner and top corner is weaker because of the dynamic pressure.

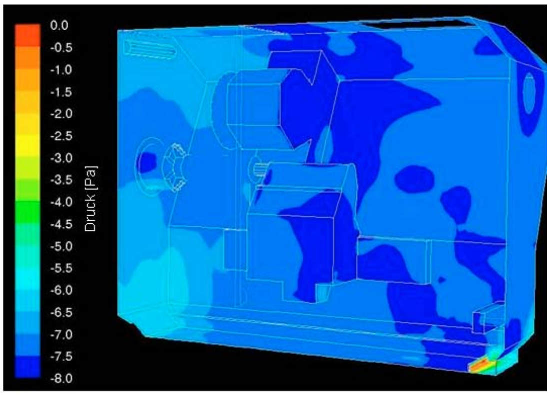

Fig. 4: Pressure distribution intra-machine during on-line operation of the exhaust air system.

During off-line operation of the exhaust air system the gripping jaws are working like a propeller which is radially displacing the air. The after flow happens axially over the fixed work piece. Starting from the jaw chuck two opposed air rolls are developing.

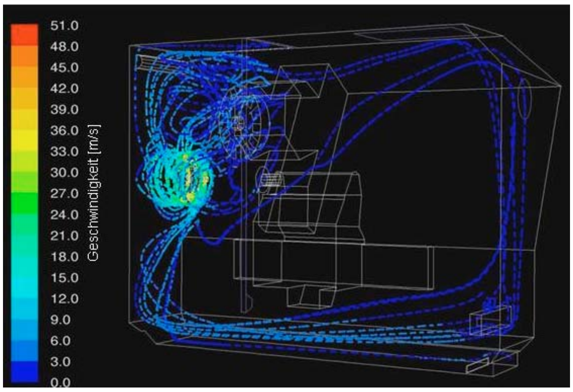

Fig. 5: Conducting path lines intra-machine during off-line operation of the exhaust air system and a spindle speed of 3,000 rpm.

- In the lock joints zone of the slide door, which is lockable from right to left, an over-pressure is occurring (see fig. 6). The air loaded by cooling lubricants (CL) can escape at these places.

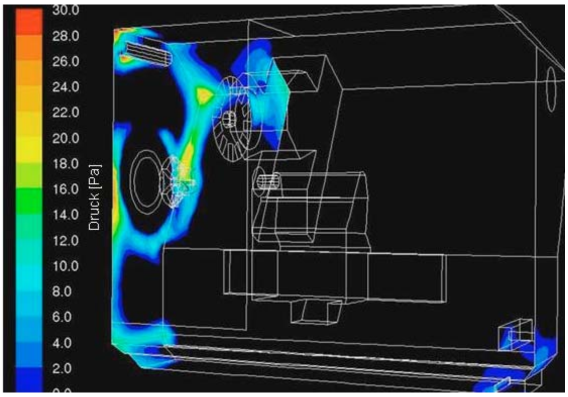

Fig. 6: pressure distribution intra-machine during off-line operation of the exhaust air system and a spindle speed of 3,000 rpm.

By combining both processes which are appropriate to simulate the real operation, clear air rolls can’t be more recognised (see fig. 7). The flow covers in that case the whole enclosure.

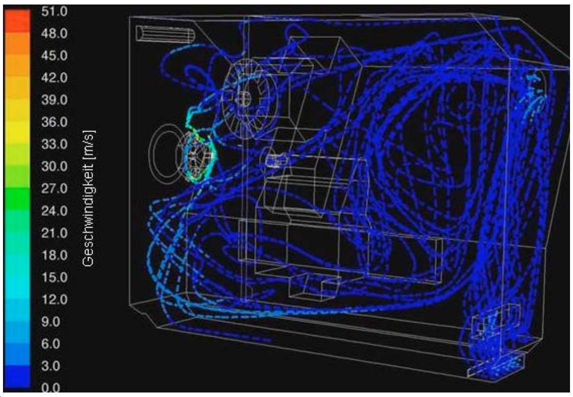

Fig. 7: conducting path lines intra-machine during on-line operation of the exhaust air system and a spindle speed of 3,000 rpm.

The negative pressure generated by the exhaust air ventilator is not enough to avoid the flow of the air loaded by cooling lubricants (CL) at the door joints (see fig. 8).

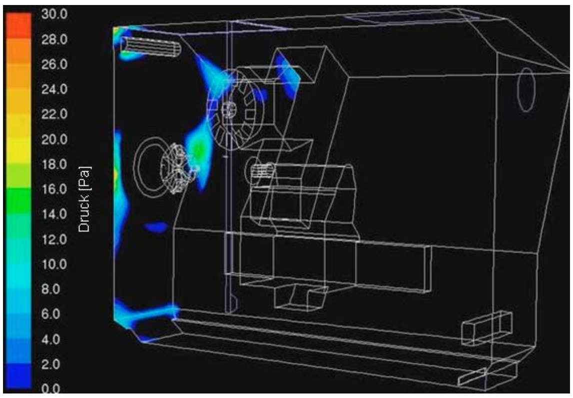

Fig. 8: pressure distribution intra-machine during on-line operation of the exhaust air system and a spindle speed of 3,000 rpm.

METHOD OF CALCULATING THE MINIMUM AIR FLOWS

By comparing the pressure ratios of spindle and work piece rotations without exhaust air applied with the appropriate pressure ratios during the operation of the exhaust air system the correlation between the static pressure at the potential places of leaks inside the enclosure and the air flow can be deduced. The diameter of the exhaust air opening can be practically ignored. Fig. 9 illustrates this correlation.

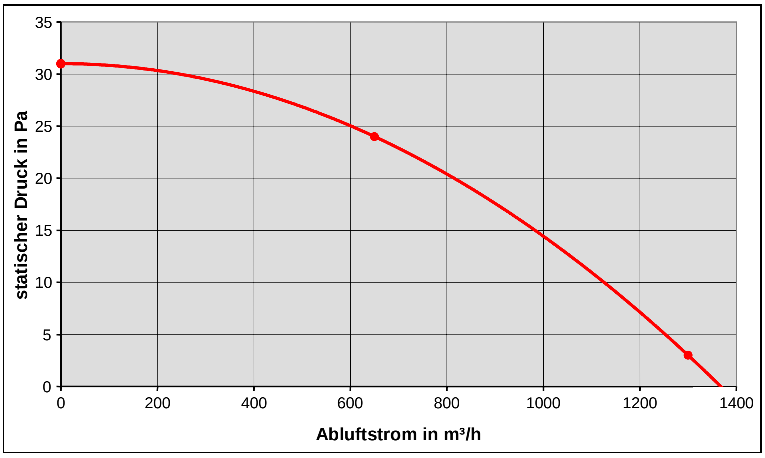

Fig. 9: Graphical determination of the minimum air flow for an engine lathe with a spindle speed of 3,000 rpm.

For determining the behaviour, two points are enough because the dependence between the 2 quantities is quadratic. During the operation with a maximum rotational speed of 3,000 rpm the machine reaches a static pressure of 0 Pascal at the critical points when the air flow comes to 1,350 m³/h.

Fig. 10 illustrates the correlation between minimum air flow and spindle speed. If there exists no or minor thermal energy inside the enclosure and if there are no pieces rotating, an air flow is not necessary, so that the zero point is given. Because of the linear correlation of the both variables another point is sufficient for the determination of a diagram.

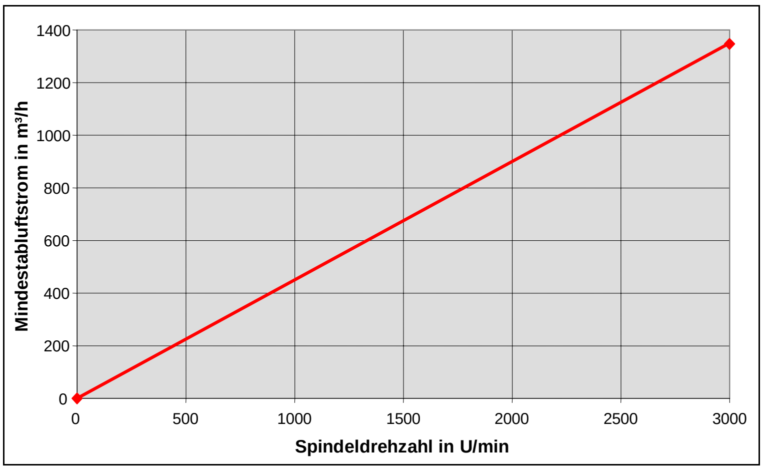

Fig. 10: Dependence of the minimum air flow on the spindle speed.

During the tests on the machine in the laboratory WZL carried out by the Institute for occupational safety and health of the employer's liability insurance association (BGIA) the maximum speed during the smoothing came up to 950 rpm. The consequence arising out of the fig. 10 is the fact that under these conditions a minimum air flow should be necessary.

If the air flow mustn't be hold in a higher position for other reasons (like limiting the cooling lubricants concentration for reason of explosion protection or for reason of the necessary removing of thermal loads), it is possible to connect the air flow to the spindle speed and to influence favourably the separator degree at the separator.

AIR FLOW INFLUENCE ON THE DISTRIBUTION OF THE CL-CONCENTRATION INSIDE THE ENCLOSURE

The following figures 11 - 14 demonstrate the distribution of the cooling lubricants concentration in a longitudinal level of the enclosure for the reference case and 3 versions. The scaling of the cooling lubricants concentrations is standardised on the average concentration in the exhaust air. Therefore, the read zones show which local concentrations are three times higher than that in the exhaust air.

In the reference case (see fig. 11) the smoothing procedure takes places with a speed of 950 rpm. This corresponds to a cutting speed of 400 m/s which is based on the actual workpiece diameter. The exhaust air (650 m³/h) dissipates via the provided exhaust air opening (right on the top). The distribution is uneven and the average concentration inside the enclosure is high. The concentration is at a ratio of 1,4 : 1 of that in the exhaust air.

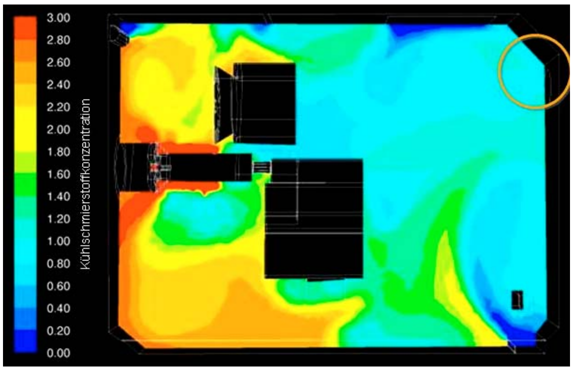

Fig. 11:Distribution of the cooling lubricants concentration in the reference case.

At variance with the given reference case, the exhaust air opening is closed in version I (see fig. 12). The exhaust air system is closed at the opening for the automatic swarf removal. The zones with high concentrations are smaller than in the reference case so that the average concentration inside the enclosure is considerable lower. The concentration is at a ratio of 0,9 : 1 of that in the exhaust air.

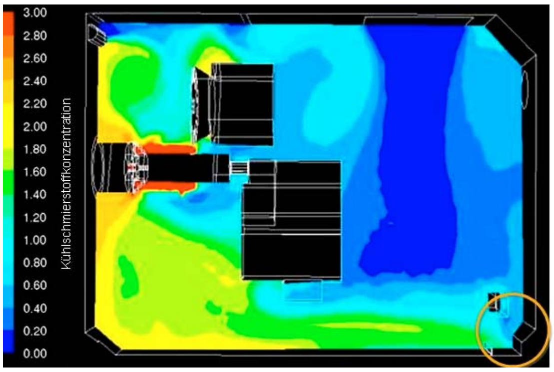

Fig. 12:Distribution of the cooling lubricants concentration for the version I.

In version II the door joints on the top are provided as exhaust air openings (see fig. 13). Compared with the version 1 the ratios are once more ameliorated. The average concentration inside the enclosure is at a ratio of 0,4 : 1 of that in the exhaust air.

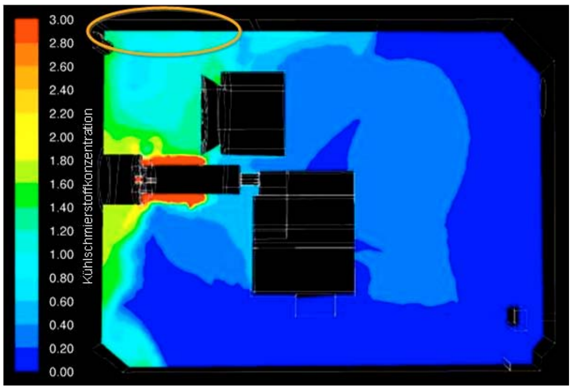

Fig. 13: Distribution of the cooling lubricants concentration for the version II.

In version III the air in the opening zone for the swarf removal is supplied in such a way that a really hydraulic short-circuit occurs up to the exhaust air opening (see fig. 14). According to this the average concentration inside the enclosure is at a ratio of 1,5 : 1 of that in the exhaust air.

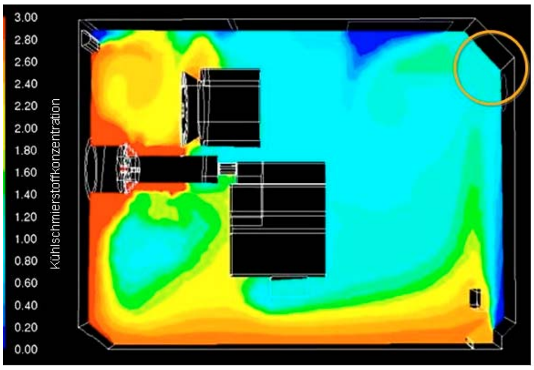

Fig. 14: Distribution of the cooling lubricants concentration for the version III.

The cooling lubricants concentration constitutes no suitable criterion for the arrangement of the exhaust air openings inside of the enclosure. In conjunction with the circulation of the supply air the arrangement has a considerable influence on the distribution and on the average concentration inside of the enclosure. This fact is important with regard to reasons of explosion protection and to the starting conditions at the moment of opening the door.

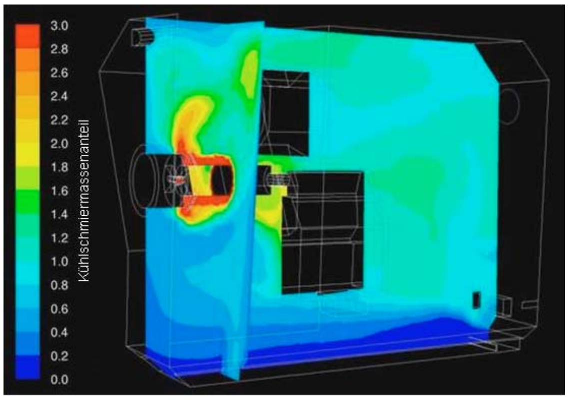
TRANSIENT PROCEDURES DURING THE OPENING OF THE ENCLOSURE'S DOOR AT THE END OF THE MACHINING

The procedures during the opening of the door are individually very differing and depend on the machine's geometry as well as on the following criterions:

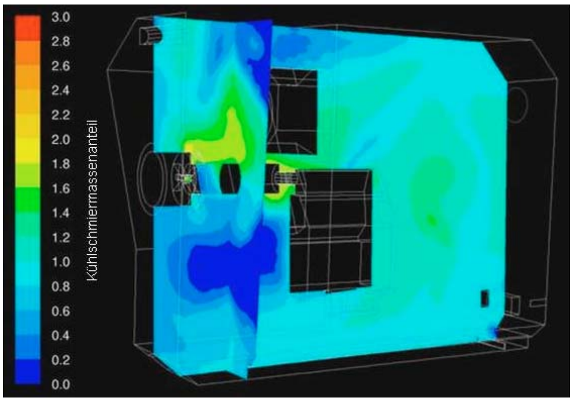
- velocity and direction of air streams just before opening the door; this momentum drop down fast but have an impact on the procedure anyway;
- thermal air streams along more or less hot tools and work pieces;
- air flow and air routing when the door is open; both can be different from the steady state phase of machining.

Fig. 26 demonstrates the time-dependant CL-concentration in the enclosure for two orthogonal section planes for the phase of opened door at the end of the machining. The four figures show the distribution of CL-concentration immediately after the end of the machining and one, four and ten seconds after that moment. The figures give an impression of how the CL loaded air gets exhausted from the enclosure.

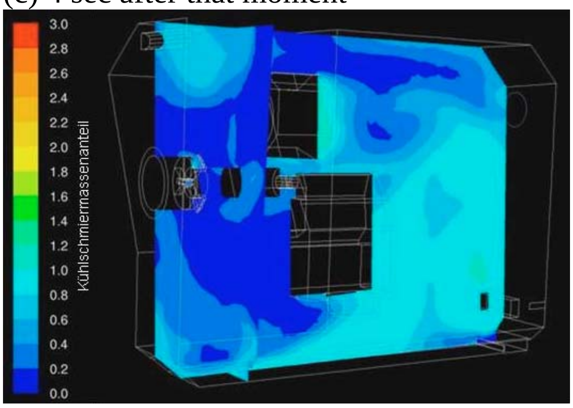
(a) immediately after opening of the door



(b) 1 sec after that moment



(c) 4 sec after that moment



(d) ~10 sec after that moment

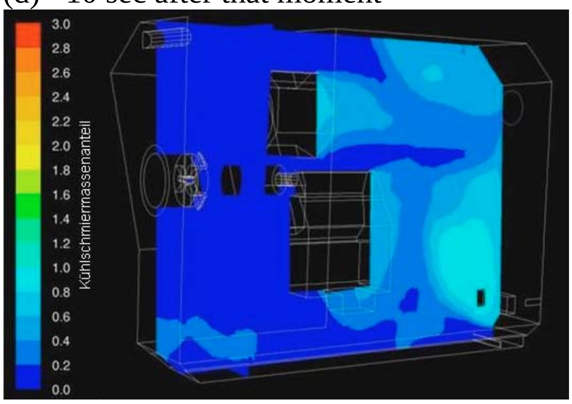


Fig. 26: time-dependant distribution of CL-concentration in the enclosure after opening of the door at the end of the machining.

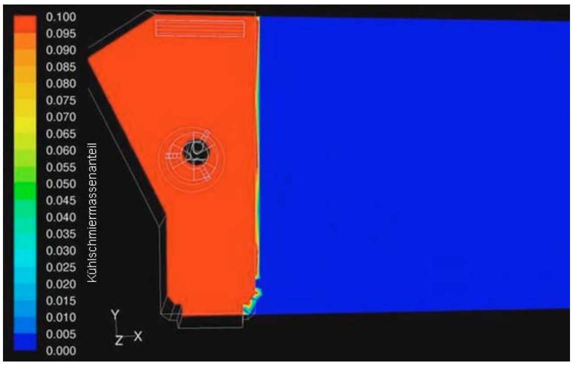
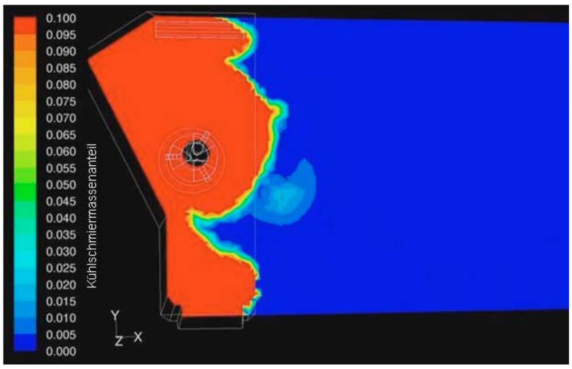
Fig. 27 for the same moments as fig. 26 shows the distribution of CL-concentration in the enclosure and in the worker's area. The section plane is placed in the middle of the doorway. The scaling is different from the one in fig. 26; the maximum value shown is 0.1 of the CL-concentration in the exhaust air. The figure demonstrates clearly how CL loaded air streams into the worker's area.

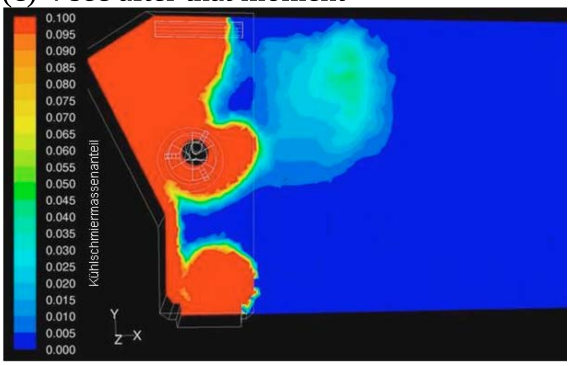
(a) immediately after opening of the door



(b) 1 sec after that moment



(c) 4 sec after that moment



(d) ~ 10 sec after that moment

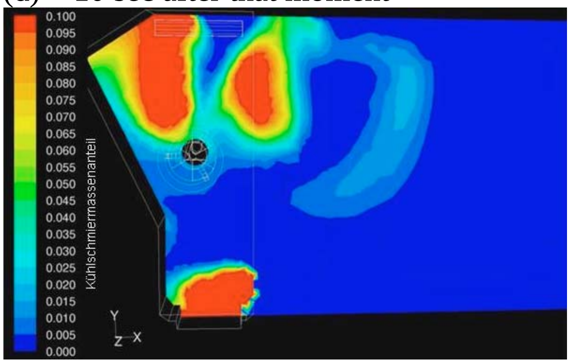


Fig. 27: time-dependant distribution of CL-concentration in the enclosure and in the worker's area after opening of the door at the end of the machining.

SUMMARY

- Rotating parts have an important impact on the pressure distribution. The exhaust air flow can be varied depending on their rotation speed.
- The concentration of CL in the exhaust air is no valid criteria for the layout of the air discharge opening.
- The air routing has a strong impact on level and distribution of CL-concentration inside of the enclosure. Then this concentration is important regarding explosion prevention and concerning the phase of opening the enclosure's door.
- Due to short response time the CL-concentration gets stationary very fast which is important for the weighing of the emissions during machining on the one hand and during opening of the door on the other hand.

Computational Study of Contaminant Control by Multi-slotted Hoods in an Industrial Exhaust System

SUMMARY

The subject of this paper is the numerical simulation of the capture of contaminants with a local exhaust system. The objective is to evaluate the influence of multi-slotted hoods on the capture efficiency and its impact on indoor air quality. The ventilation in the proximity of slots and the contaminant dispersion throughout the room were predicted using the commercial tool "Fluent". Characteristics of the polluted air were examined for different geometrical opening configurations for a two-dimensional model. Two parameters were examined: the number of slots and the slot width. Two-dimensional simulations revealed that, at a constant volumetric exhaust flow rate, a gradual reduction in contaminant concentration is experienced throughout the room as the number of slots increases. It was found that there is an optimal number of slots that reduces this concentration to 12% compared with a non-slotted hood system. The slot width analysis also revealed the existence of an optimum value for which the contaminant reduction is maximal. Following this basic assessment, computations were performed on a more realistic, three-dimensional model. These preliminary calculations indicate that flow computations need to be three-dimensional to address real-life situations more accurately.

INTRODUCTION

Industrial exhaust ventilation systems are used to remove airborne contaminants consisting of particulates, vapor and gases, all of which can create an unsafe, unhealthy or undesirable atmosphere for workers. There are two types of exhaust systems: *general exhaust ventilation* (GEV), in which an entire work space is exhausted without considering any specific operation; and *local exhaust ventilation* (LEV), in which the contaminant is controlled at its source [13]. In the industry, LEV is the preferred method because the flow rates, and therefore the costs, are lower than in GEV. Moreover, with GEV only, it may be difficult to achieve the high level of contaminant control that is needed to reduce the worker's exposure near a contaminant source. The main concept used in an LEV to select the adequate volumetric flow to with draw air through a hood is the capture velocity. This is the velocity of the air at the point of contaminant generation. The contaminant enters the moving air stream at the point of generation and is conducted along with the air into the hood. Traditionally, the design of LEV hoods is based on the empirical velocity formulas [4,13] that give the capture velocity profile at the front of the hood. While useful, this method does not quantitatively take into account the effects on the efficiency of the LEV of the momentum of the contaminant source, disruptive air currents and obstacles in the flow field. For this reason, a better option is to study indoor air quality using computational fluid dynamics (CFD), because CFD is capable of providing information on factors such as the distribution of flow and concentration at all grid points, independently of the complexity of the geometry. The single rectangular slot is highly applied since it is very efficient for capturing large amounts of contaminants. CFD has been used on this type of slot to assess the performance of LEV systems and to define new design guidelines [1,8,10]. Kulmala [2] investigated the accuracy of the numerical simulation of an air flow field generated by a rectangular exhaust opening. The calculations were made using the standard k-ε model, and the results were verified with laser Doppler measurement. Multi-slotted hoods are often used on exhaust systems, and it is widely excepted that the slots only help to distribute air over the hood face and do not influence capture efficiency. In this paper, we use CFD to analyze the influence of slot number and slot width on capture efficiency. We first examine the effectiveness of the multi-slotted hood in a 2-D model, and then we apply similar concepts to the 3-D case of a worker positioned near a contaminant source.

BASIC GEOMETRY

The 2-D room geometry, including a hood configuration with 6 slots, is depicted in Fig. 1 (not to scale). The contaminant source is considered to spread material over a surface 2 m in length. The area to be studied is near the hood, and the dimensions of the room have been increased to impose boundary conditions (BC) that will not affect the region of interest.

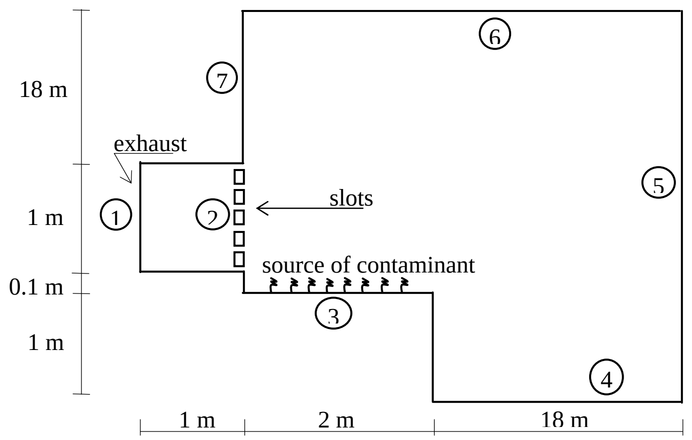

Figure 1: Geometry with slots.

NUMERICAL METHOD

Governing Equations

The aim of the numerical prediction is to solve the governing set of partial differential equations representing an isothermal incompressible flow without buoyancy effects. The equations that describe the flow of a fluid, heat and concentration within an enclosure are based on the conservation of mass, momentum, energy and species concentration. The general form of transport equation for property Φ is:

$$\underbrace{\frac{\partial(\rho\Phi)}{\partial t}}_{Transient} + \underbrace{\frac{\partial}{\partial x_i}(\rho\Phi U_i)}_{Convection} = \underbrace{\frac{\partial}{\partial x_i}\left(\Gamma_\Phi \frac{\partial\Phi}{\partial x_i}\right)}_{Diffusion} + \underbrace{S_\Phi}_{Source} \text{ ; i=1, 2, 3}$$

In this expression, ρ represents the density of the fluid, Γ_Φ the diffusion coefficient, S_Φ the source term and U_i the velocity components along the x_i coordinates. From this general form, the Navier-Stokes, energy and species concentration equations can be obtained. Namely:

Conservation of mass:

$$\frac{\partial \rho}{\partial t} + \frac{\partial \rho U_i}{\partial x_i} = 0$$

Conservation of momentum:

$$\frac{\partial \rho U}{\partial t} + \frac{\partial \left(\rho U_i U_j\right)}{\partial x_j} = -\frac{\partial P}{\partial x_i} + \frac{\partial}{\partial x_j}\left(\mu \frac{\partial U_i}{\partial x_j}\right) + g_i\left(\rho - \rho_0\right)$$

Conservation of energy:

$$\frac{\partial \rho H}{\partial t} + \frac{\partial}{\partial x_i}\left(\rho U_i H\right) = \frac{\partial}{\partial x_i}\left(\lambda \frac{\partial T}{\partial x_i}\right) + \frac{\partial P}{\partial t}$$

Conservation of species:

$$\frac{\partial}{\partial x_i}\left(\rho \overline{U}_i \overline{C}\right) = \frac{\partial}{\partial x_i}\left(D \frac{\partial \overline{C}}{\partial x_i} - \rho \overline{\mu_i c'}\right)$$

where P, H, T, μ, g, λ, C and D denote pressure, enthalpy, temperature, dynamic viscosity, gravity acceleration, thermal diffusivity, concentration and molecular diffusivity respectively. The contaminant used in this study is a gas.

To handle turbulence, the renormalization group (RNG) $k-\varepsilon$ was selected. The SIMPLE algorithm was used for the pressure-velocity coupling. Boundary conditions and meshing aspects are discussed in the next section.

Grid and boundary conditions

In order to obtain a numerical solution of the above equations, a descretization of the room is required, followed by the application of a solver. Because solutions will be sought using the commercial package Fluent, the companion software Gambit was applied to generate the grid. Based on the topology room and of the slotted hood, hybrid grids, both structured and unstructured, were applied. An adaptive mesh refinement algorithm around the slots was employed, which permits a more accurate representation of the boundaries.

In order to compute a solution, boundary conditions need to be applied. In this study, the most relevant parameter is at the exhaust boundary. To enforce an adequate exhaust mass flow rate, an adequate capture velocity must be established. Based on successful experiments, ASHRAE [13] proposes ranges of capture velocities for several industrial operations under specific conditions of contaminant dispersion. In this case, we consider the contaminant source as an evaporation tank, which means that the contaminant is released into still air with essentially no velocity. The proposed capture velocity range is 0.25 – 0.5 m/s [13]. To ensure the corresponding exhaust mass flow rate, the transport equations were solved several times until a velocity of 0.35 m/s was obtained at a reference point. This was located 1 m from the hood face and 0.5 m above the surface of the source of contaminant.

At the outlet (side 1 in Fig 1), a mass flow rate of 0.1 kg/s was imposed. This same rate was also imposed at the inlet (side 5). Solid walls were considered on all the other surfaces. A constant standard temperature of 300^o K was considered at both the inlet and the outlet. All solid walls where considered to be adiabatic. Table 1 summarizes the boundary conditions.

Table 1: Boundary Conditions

1	Exhaust	Mass flow - outlet = 0.1 kg/s
2	Hood slots	Wall - adiabatic
3	Contaminant source	Wall - adiabatic with diffusion flux. Mass fraction = 1
4,6,7	Wall	Wall - adiabatic
5	Inlet	Mass flow - inlet = 0.1 kg/s

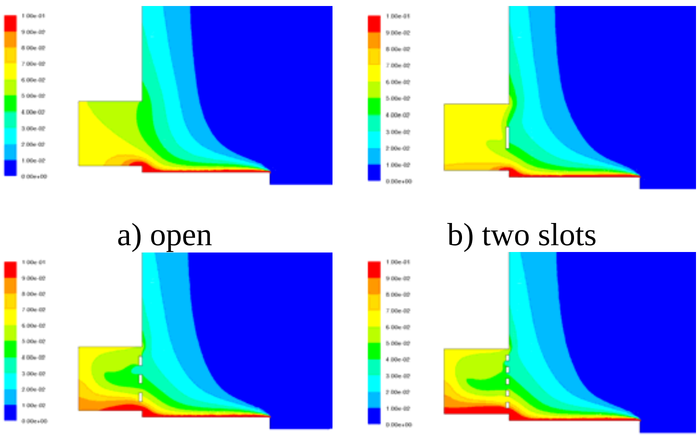
Below, we present the solution of the governing equations for 2-D and 3-D geometries using the commercial package Fluent [11].

2-D CALCULATIONS

These calculations were carried out to assess the impact of the number of slots and the slot width.

Influence of the number of slots

This test is quite simple and involves conducting computations of hood performance by changing the number of openings at the hood inlet. Fig. 2 shows iso-values of species concentration for various numbers of slots for a constant outlet mass flow rate of 0.1 kg/s. Although this qualitative view indicates better suction with the increase in the number of openings, a quantitative analysis is required. This result is illustrated in Fig. 3, where the total mass of the contaminant in the entire room has been plotted against the number of slots. Based on this simple representation, it appears that the optimum outcome corresponds to 6 slots, and that a further increase in their number does not help to reduce the species concentration. On the contrary, it amplifies it.



a) open b) two slots

c) four slots d) six slots

Figure 2: Iso-values of species concentration. The outlet mass flow rate is constant, at 0.1 kg/s.

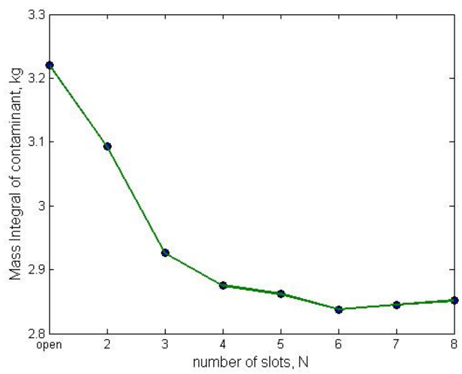


Figure 3: Mass integral of contaminants for various numbers of slots.

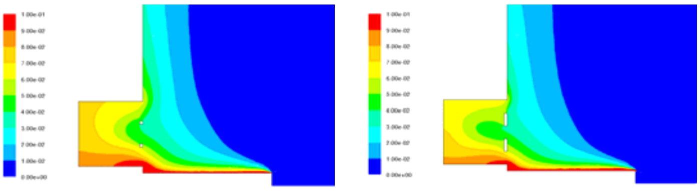
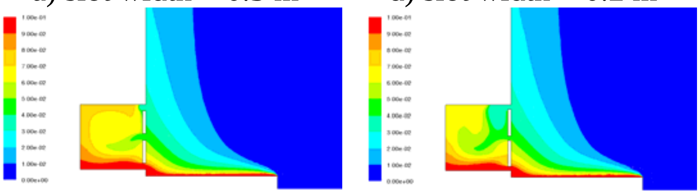
Influence of slot width

A second test was conducted to analyze the impact of slot width on species concentration. Only the case of a hood with two slots was studied.



a) slot width = 0.3 m d) slot width = 0.2 m



g) slot width = 0.1 m h) slot width = 0.07 m

Figure 4. Iso-values of contaminant concentration for slot widths of 0.3, 0.2, 0.1 and 0.07 m.

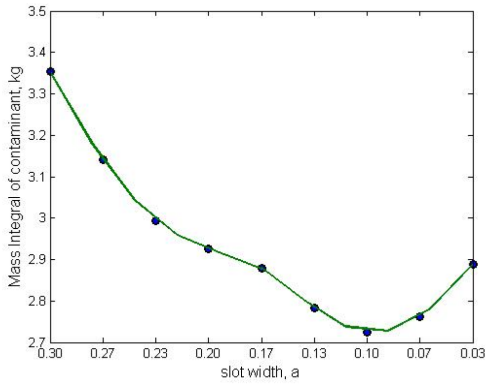


Figure 5: Mass integral of contaminants for the variation in slot width.

Again, this is a naïve test, in which the slot width varied from 0.3 m to 0.03 m. As in the previous test, Fig. 4 shows the simulation results by means of iso-values of concentration. As expected, the differences are noticeable behind the hood inlet. However, what is needed is quantitative information on the room. This is presented in Fig. 5 as the total contaminant in terms of slot width. The curve indicates that the slot width plays an obvious role, and that the optimum width is 0.1 m.

Using these results as a basic platform, we proceeded with 3-D modeling.

3-D MODELING

Because a 2-D world corresponds to “a slice” of a 3-D geometry, a first calculation in three dimensions was carried out by considering a wall-to-wall hood with various numbers of slots. Thus, a vertical plane passing through the middle of the hood corresponds to the 2-D world previously analyzed. An illustration of this idea is shown in Fig. 6, where iso-values of the species concentration obtained when using four slots are shown. As expected, these results coincide with the 2-D calculations.

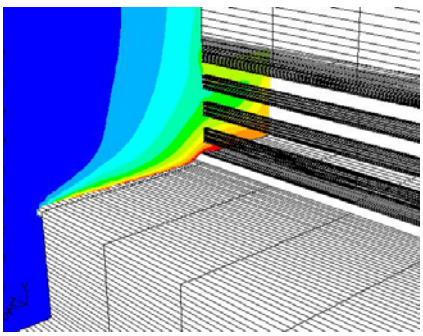

Figure 6: Contours of the mass fraction of the contaminant at mid-plane.

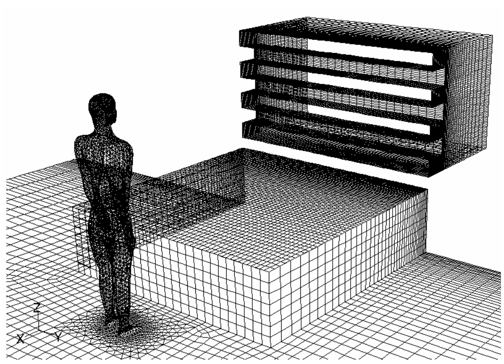

Figure 7: Meshing the worker and the hood.

After completing this basic verification, a more realistic geometry was considered (Fig. 7), which includes a mannequin positioned near contaminants released from the horizontal surface and controlled by a lateral hood. In this type of 3-D modeling, mannequins have been introduced ([5] [6]) to investigate numerically the influence of different body shapes on the exhaust efficiency. In these studies, it was found that the use of such a simplified human body is satisfactory when focusing on the global airflow pattern in a ventilated room. In our study, the model is intended to closely represent an actual worker standing in a particular spot. With this more realistic shape, the airflow pattern around the human body may also be addressed. Because there are many possible locations for the person, a position facing the grid exhaust was chosen for a preliminary test.

Fig. 8 shows qualitative results by means of path lines near the hood colored according to the mass fraction concentration. Details around the body are shown in Fig. 9, where the swirling nature of the flow in front of the face can be appreciated.

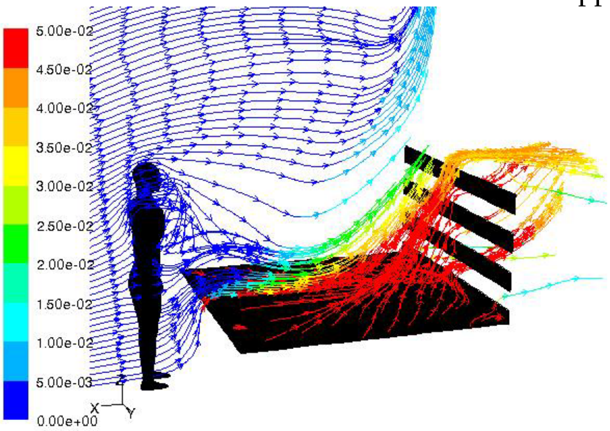

Figure 8: Path lines colored by the mass fraction of the contaminant.

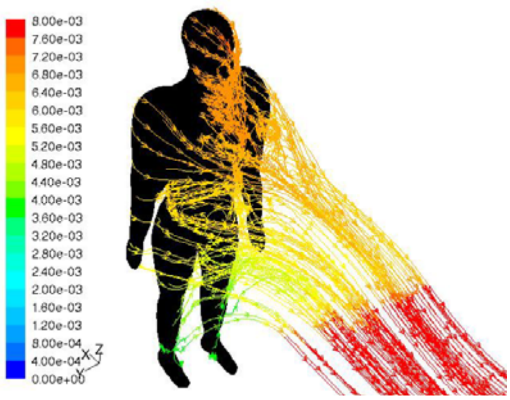

Figure 9: Path lines near the mannequin colored by the mass fraction of the contaminant.

Quantitative results are displayed in Fig. 10, where the total mass integral of the contaminant is shown against the number of slots.

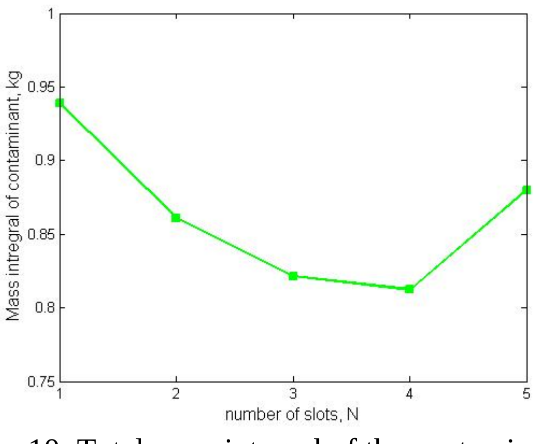

Figure 10: Total mass integral of the contaminants for different numbers of slots.

This particular configuration for a mannequin facing the hood shows a similar behavior to that found for the 2D case; that is, a predicted ideal number of slots to achieve a better configuration of the contaminant’s control system.

Note that the number of slots calculated (4) is not the same as that found in the 2-D analysis (6). This has been attributed to two factors: first, the width of the hood, for which the lateral effects do not exist in 2-D; second, to the presence and position of the worker, which were not considered in the 2-D analysis either. From this particular result, it becomes apparent that more elaborate 3-D investigations need to be carried out.

CONCLUSION

Two- and three-dimensional studies where conducted using CFD to investigate the benefit (12% concentration reduction) of slotted hoods in controlling contaminant levels in working environments. The commercial software Fluent was used to perform the simulations. An optimum number of slots to reduce the contaminant concentration was found in both cases. Differences in the predicted number of slots indicate that hood size and the presence and position of a worker require a variety of 3-D calculations to assess the impact of the number of slots in more realistic situations.

ACKNOWLEDGMENT

The authors are grateful to the Institut de Recherche Robert-Sauvé en Santé et Sécurité du Travail for providing the necessary support to carry out this work.

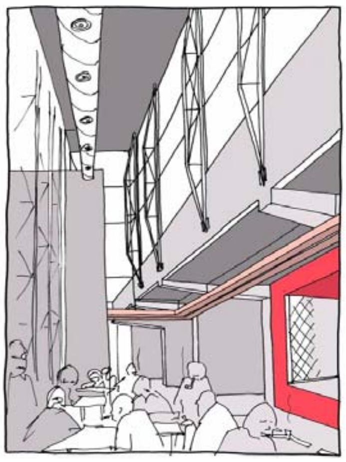
SUMMARY

Cfd-calculations were performed to test whether it is possible to separate a non-smoking zone from a smoking zone using an air curtain. The cfd-calculations resulted in the following conclusions: 1. A larger exhaust flow is best. 2. An air curtain with a low air curtain velocity and an air intake from the smoke zone (as opposed to an air intake from the non-smoking zone) has the lowest smoke concentration in the non-smoking zone. 3. For a maximum of 40 smokers and a ventilation flow compatible with the Dutch building law (1500 m^3/h for this smoke area) an air curtain velocity of 0.75 m/s is the best solution for the smoke zone in the hall of the faculty of Architecture in Delft. 4. With higher air curtain velocities, the air curtain will become a smoke curtain if the exhaust flow is not large enough.

INTRODUCTION

Based on the Tobacco law of 2002, smoking in many buildings is only allowed in separate smoking rooms. However, by physically separating the smokers and the non-smokers, the visual, social and function unity is lost. This problem can be solved by making smoke areas in common rooms where the smoke-free zone is separated by air curtains in stead of walls. In this article computational fluid dynamics (CFD) simulations are presented which show the effectiveness of an air curtain for various air-curtain configurations and various ventilation flows.



All simulations were performed for the hall of the faculty of Architecture of the Delft University of Technology (The Netherlands), see figure 1. The smoke area is situated on the west side of the common hall and has a floor area of 80 m2 with about 40 seats for the smokers. Three sides of the smoke area are outfitted with air curtains, the fourth side of the smoke area consists of a glass facade. A mechanical exhaust is situated on the façade side. A lowered ceiling is applied at a height of 3 meters, compatible with the average room height in the Netherlands.

Figure 1. The smoke room in the hall of the Architecture faculty of the Delft University of Technology

THEORY

The air curtain is not only a separation between the smoking and the non-smoking zone. The air, which is blown downward by the air curtain, mixes with air from both the non-smoking zone and air from the smoking zone, see figure 10. This is not a negligible amount but can amount to 90 % of the air volume flow from a single air curtain [3]. This has the unwanted side-effect that the higher the air curtain velocity, the larger the amount of air that mixes with the air curtain air.

From the schematic drawing in figure 10 it is possible to understand why an air curtain which circulates smoking air (top drawing) has a better performance than an air curtain which circulates non-smoking air (middle drawing). The total amount of air which flows from the bottom of the air curtain to the non-smoking zone due to the air curtain is larger with a recirculating air curtain which draws its air from the non-smoking zone. This airflow from the bottom of the air curtain to the non-smoking zone does have a fair amount of unwanted smoke due to the entrainment (mixing) of air on either side of the air curtain.

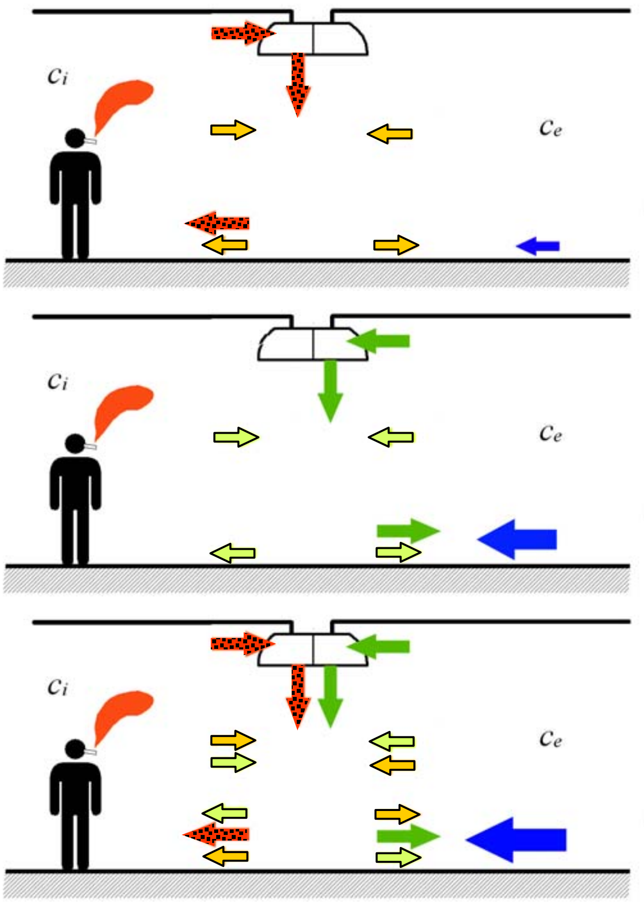


Figure 2. Schematic drawing of the working of the different air curtain configurations. From top to bottom: the smoking side air curtain, the non-smoking side air curtain and the double air curtain. The framed arrows represent the induced air. The dark arrows represent the necessary amount of exhaust air which is necessary to countermand the induction effect.

Having a larger or equal amount of ventilation air flowing in the opposite direction should be present to prevent the smoke-mixed air from reaching the non-smoking zone. A lower exhaust ventilation amount can therefore be enough to prevent the smoke-mixed air from a smoking-side air curtain to reach the non-smoking zone but not enough to prevent the smoke-mixed air from a non-smoking side air curtain to reach the non-smoking zone. Similarly, a higher air curtain velocity requires a larger exhaust ventilation flow to counterbalance the effect of a higher air curtain velocity.

As a criterion for obtaining a low smoke concentration in the non-smoking zone, the parameter G can be defined. This parameter depends on the kind of air curtain, the air curtain velocity and the amount of air curtain ventilation: $G = \frac{FQ_0}{Q_v}$. Q_0 is the air curtain flow. F Q_0 is the amount of air flow from the bottom of the air curtain to the non-smoking zone, Q_v is the amount of exhaust ventilation. The criterion is then G < 1 which indicates that the amount of air flow from the bottom of the air curtain to the non smoking zone is less than the amount of exhaust ventilation. F is the entrainment factor of the air curtain. This factor can be approximated by 0.9 for a smoking side air curtain, by 1.8 for the non-smoking side air curtain and by 2.7/2 for the double air curtain.

METHODS

Simulating cigarette smoke and a smoker

The smoker is simulated by block of 0.2 by 0.2 by 1.7 m^3 with a heat production of 80 W. The smoker is situated at a distance of 1.5 m from the west façade, see figure 3. The smoker exhales 1 m^3/h at a height of 1 m over a surface of 4.0 cm2 in horizontal direction facing the air curtain. The exhaled air has a temperature of 35 °C and a velocity of 0.7 m/s. The exhaled air has a concentration of 1.152 mg nicotine per kg air [2]. Nicotine is assumed to have the same density as the air (1.19 kg/m^3).

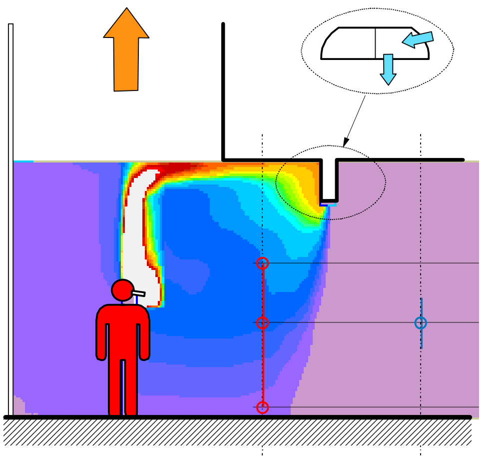

Figure 3. Schematic drawing of the smoker as a source in the cfd-simulations

Modelling the hall

Only a vertical cross section of the hall (from glass plane to glass plane, see figure 4) is modelled. In the middle of the model a smoker is situated. Perpendicular to the cross section two adiabatic boundaries are defined. The outside air is assumed to have a temperature of 20 °C. The simulated model has a length of 13.2 m a width of 10 m and a height of 3.5 m, thus a volume of 462 m^3.

The exhaust is modelled as an exhaust area of 0.3 m. over the entire width of the glass, see the upward arrow in figure 4. The inflow is modelled as an opening of 4.2 by 10 m^2 (again over the entire width of the glass), see the downward arrow in figure 4. For a maximum number of people of 40, the exhaust is simulated with a capacity of 1500, 3000 en 4500 m^3/h. This correspond to approximately to one to three times the Dutch Building Regulations. However, the amount of 4500 m^3/h is height and should preferably not be applied due to corresponding large energy costs and a risk at high air velocities (draught).

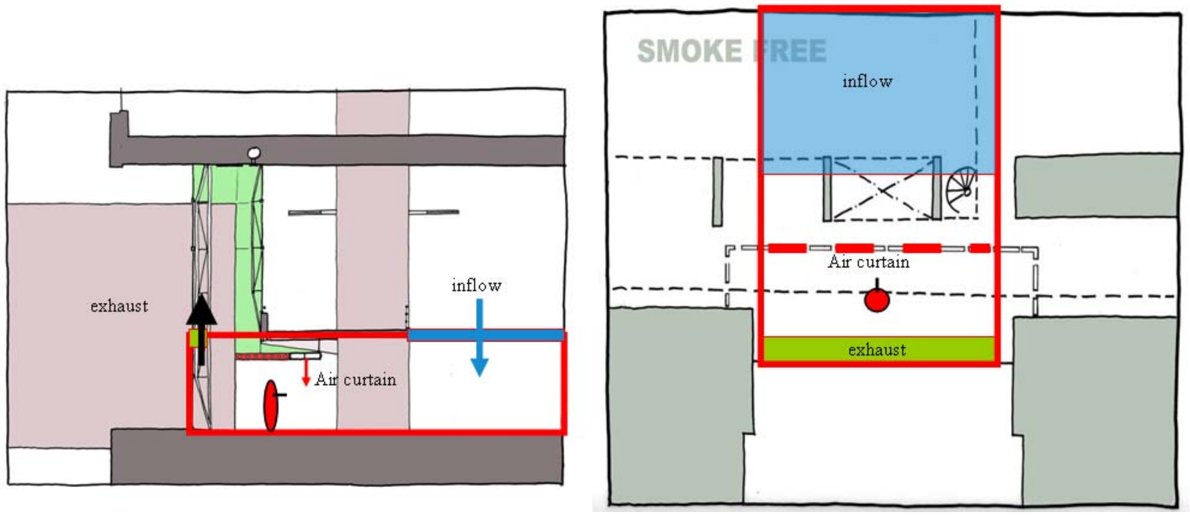

Figure 4. Cross section and floor plan of the hall of the Architecture faculty of the Delft University of Technology.

Modelling the air curtain

Cfd-simulations have been performed for 21 combinations of air curtain configurations (7) and exhaust volume flows (3) in order to calculate the lowest smoke concentration in both the non-smoking zone, and the smoking zone. The simulated air curtain configurations are given in table 1.

Table 1. The simulated variants and their names, totalling 7 air curtain combinations.

Name	**Air curtain**	**Air curtain velocity (m/s)**	**Air curtain volume (m^3/h)**
Er_0.75	Non-smoking side	0.75	2700
D_0.75	Double	0.75	2700
Er_0.5	Non-smoking side	0.5	1800
D_0.5	Double	0.5	1800
El_0.75	Smoking side	0.75	2700
El_0.5	Smoking side	0.5	1800
no	No air curtain	0.0	0

The air curtains are simulated as simple air curtains without any heating or cooling capacity. The simulated downward velocities from the air curtain(s) are: 0.0, 0.5 en 0.75 m/s with corresponding air curtain volume flows of 0 m^3/h, 1800 m^3/h and 2700 m^3/h. The total installed air curtain configuration consists of two air curtains. One inside ring with an inflow from the smoking area, and one outside ring with an inflow from the non-smoking area, see figure 2. The air curtain size is 0.2 by 0.6 m^2 over the entire width of the glass plane at a distance of 4.2 meters from the glass plane. Both the outside and the inside ring are simulated as recirculation elements in the cfd-simulation.

Points

To quantify the results, the smoke concentrations have been calculated at three positions in the smoking area and 1 position in the non-smoking area, see figure 5. The points are taken in the smoking zone at a height of 0.1 m., 1.1 m. (sitting position) and 1.8 meter (standing position). The point in the non-smoking room [ce] is taken at a height of 1.1. m.

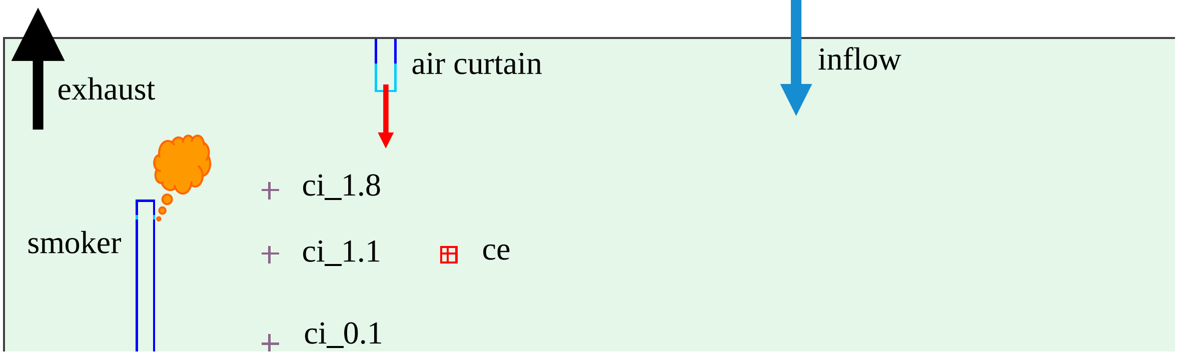

Figure 5. Position of all measured points. At 3 meters from the left glass wall in the smoking zone the point ci_0.1, ci_1.1, ci_1.8 at a height of 0.1, 1.1 en 1.8 meters; at 5 meters form the left glass wall in the non-smoking zone, the point ce at a height of 1.1 meters.

CFD-simulations

The simulations were performed with the commercial computerprogramm Flovent [2], version 5.1. Flovent uses a rectangular grid. A single simulation is performed with around 140.000 grid cells, the k-ε model, and a calculation time of around 2 hours until convergence on a Pentium computer.

RESULTS

In figure 6 the cfd-simulations are shown. In figure 6 both the smoke concentration and the route of certain selected air particles from the inflow of clean air (see the square in figure 7) to the exhaust point is shown for various configurations. The legend of figure 6 ranges from light (purple, 0.0 kg smoke/kg air) to dark (red, 8.4 10^{-6} kg smoke/kg air). A smoke concentration of 8.4 10^{-6} kg/kg air corresponds to a percentage of 8.4 10^{-6} kg / 1.512 mg = 0.5 % of the smoke concentration which is exhaled by the smoker. Areas with a smoke concentration higher than 0.5 % are white.

The lighter (purple) area is larger for a larger exhaust flow; a larger exhaust flow therefore leads to a lower smoke concentration over a larger area. When the flow pattern of the clean air is compared with the smoke concentrations in the non-smoking room, it can be seen that the lowest concentrations are obtained when the clean air passes the air curtain with the smallest distance from the floor. This is exceptionally clear for a smoking side air curtain with a velocity of 0.5 m/s and an exhaust flow of 4500 m^3/h and for the no air curtain configuration with an exhaust flow of 4500 m^3/h.

In figure 7 the smoke concentration in a number of points is shown as a function of the air curtain configuration. As expected from figure 6, the smoke concentrations decrease with increasing exhaust volume flow. Also concluded from figure 6 is the fact that the smoking side air curtain (El) is to be preferred over a non-smoking side air curtain or a double air curtain. A non-smoking side air curtain is simulated to have a higher smoke concentration than a double air curtain for most velocities and exhaust flows.

	Exhaust flow: 4500 m^3/h	Exhaust flow: 1500 m^3/h
no		
Er_0.5		El_0.5		
El_0.75		
Figure 6. Simulated smoke concentrations and simulated airflow patterns for certain inflow air particles for a number of air curtain configurations and two exhaust flows(1500 m^3/h and 4500 m^3/h).

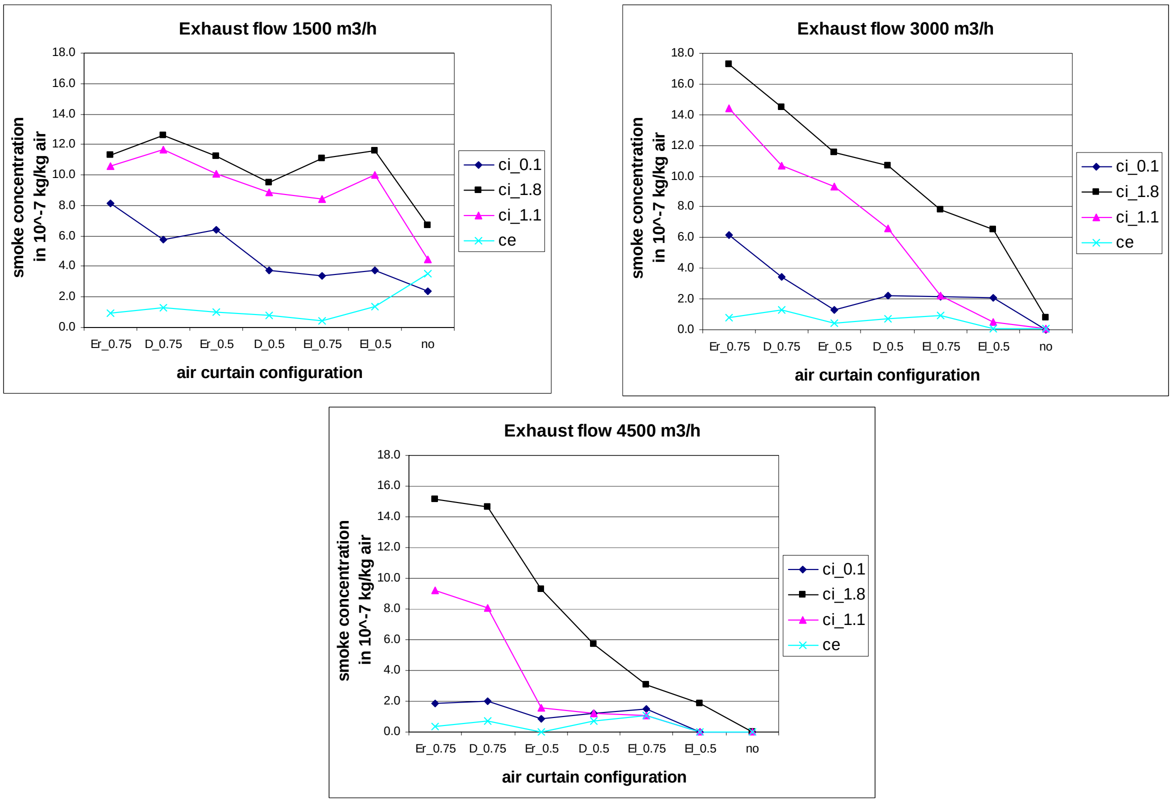

Figure 7. Simulated smoke concentrations ce, ci_0.1, ci_1.1 en ci_1.8 as a function of the air curtain configuration for three exhaust flows (4500, 3000 and 1500 m^3/h).

Contrary to expectations by a general public, the lowest possible air curtain velocity should be applied in order to obtain the lowest smoke concentration in the non-smoking and the smoking room. For high exhaust flows, this velocity is close to 0.0 m/s, for lower exhaust flows this value increases due to the adverse effects of diffusion of smoke to the non-smoking zone.

DISCUSSION

The most important value which determines the smoke nuisance is the smoke concentration in the non-smoking zone: ce. In figure 8, this value is presented as a function of the above defined G (= FQ_0/Q_v). Figure 8 shows that the value of G indeed influences the smoke concentration in the non-smoking zone (ce). However, for one point the cfd-simulated ce concentration is far too high although G is smaller than 1. This is the situation where there is no air curtain (FQ_0 = 0 and thus G = 0) and where the exhaust flow is not high enough to counterbalance the effect of diffusion (1500 m^3/h). For G-values between 0.8 and 1.0, the cfd-simulations show an increase in smoke concentration in the non-smoking zone. In practice a criterion of G < 0.8 seems more appropriate from these cfd calculations.

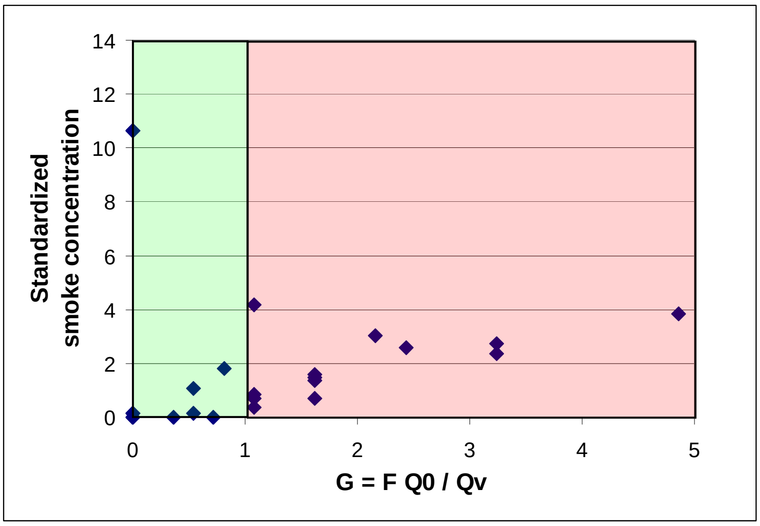

Figure 8. Standardized smoke concentrations in the non-smoking zone as a function of G. The smoke concentration in the non-smoking zone (ce)is standardized with respect to the smoke concentration in the exhaust air at an exhaust flow of 4500 m3/h.

That the G value is an appropriate criterion can also be seen when two simulations with the same G-value are compared. Compare for example the configuration of a double air curtain with an air curtain velocity of 0.5 m/s and an exhaust flow of 3000 m3/h and the double air curtain configuration with an air curtain velocity of 0.75 m/s and an exhaust flow of 4500 m3/h, see figure 8. Both simulations look remarkably alike.

	Exhaust flow: 3000 m^3/h Air curtain velocity: 0.5 m/s	Exhaust flow: 4500 m^3/h Air curtain velocity: 0.75 m/s
Double air curtain		
Figure 9. Comparing two simulations with the same G-value.

CONCLUSIONS

From the cfd-calculations the following conclusions can be deduced:

- A larger ventilation flow is best.
- An air curtain with a low outlet velocity and an air intake from the smoke zone (as opposed to an air intake from the non-smoking zone) has the lowest smoke concentration in the non-smoking zone.
- For the maximum of 40 smokers and a ventilation flow compatible with the Dutch building law (1500 m^3/h for this smoke area) an air curtain velocity of 0.75 m/s is the best solution for the smoke zone in the hall of the faculty of Architecture in Delft, according to the CFD-simulations.
- With higher air curtain velocities, the air curtain will become a smoke curtain if the exhaust flow is not large enough.

SUMMARY

Three experiments were carried out in an underground station of Paris. The aim was to evaluate the influence of three parameters on particle number concentrations: ventilation, passengers and trains. These experiments took place by night when traffic stopped to freely study all the three parameters individually. Different measurements have been performed: particle number concentrations, air velocity, CO_2 concentration and particle mass concentration (PM_{10}).
First results do not show any influence of ventilation when turned off and on during one night. Passengers' activity and especially trains pass-by have an influence on particle concentration. Due to the fact that fine particle concentration levels are not reproducible, results should be interpreted very carefully. But as influences can be observed, this study could be completed by another one that could permit to distinguish emission and transport of particles, especially particles with a diameter less than 1µm that represent the major part of particle number concentrations.

INTRODUCTION

Indoor air quality in offices, schools and houses has been studied for years. It is not the case of the indoor air quality in underground train stations, which is still not well understood. Different studies have been carried out in several underground stations (Stockholm [1], Helsinki [2], London, New York, Rome,..) to evaluate mass concentration level. Measurements performed in Helsinki also mentioned particle number concentrations (10 nm<Diameter<500 nm) in the station. All these studies have been carried out to better investigate personal exposure. But it is also interesting to understand what kind of phenomenon influences particle concentrations in order to better appreciate station particle's sources.
To this end, three experiments have been carried out, in order to find the influence of three different parameters, namely ventilation, passengers and trains on the pollutant concentrations. These experiments took place by night when public access is forbidden in order that these three parameters could be individually investigated.

METHODS

The three measurements were performed in Magenta station (RER line E) at the same place at the end of one platform. The ventilation system of the station is described on Figure 1, arrows schematise the air circulation. This air circulation is the least favourable mode in terms of particles concentration.

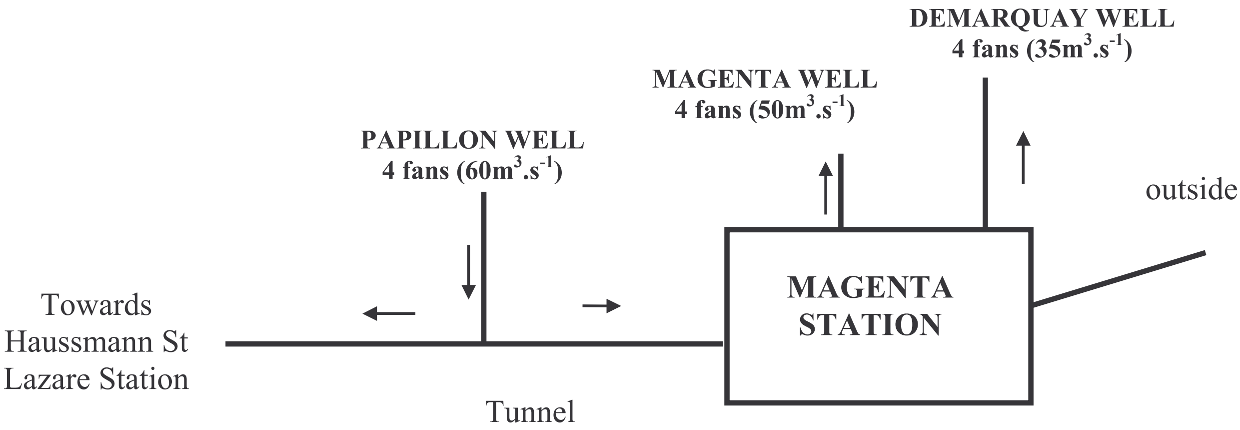

Figure 1: description of the ventilation system.

Three particles counter were arranged at three different heights (0.50, 1.10 and 1.70m) and another one was arranged at 1.70m height 1m further. An anemometer was also placed 1m from the three counters. Measurements of particle mass concentration (PM_{10}) and CO_2 concentration were also performed. Measurement devices were placed as shown on Figure 2.

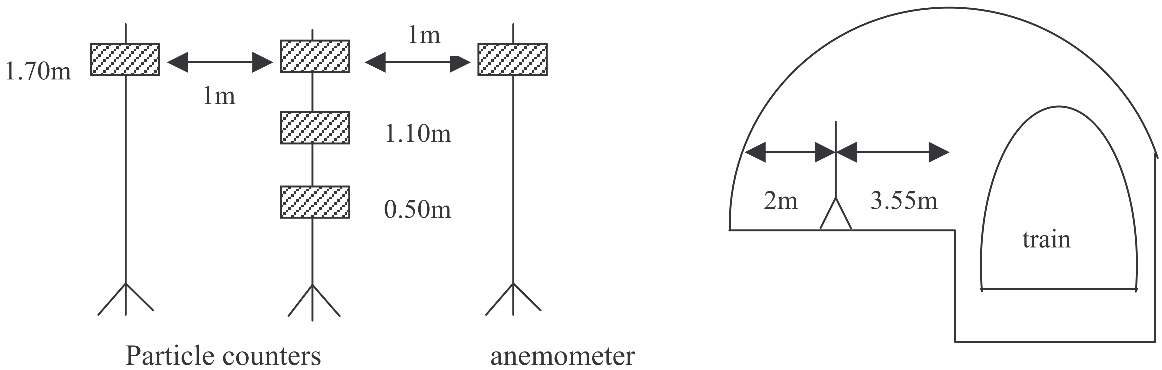

Figure 2: arrangement of the material.

During the first experiment, Demarquay, Papillon and Magenta well fans were turned off between 11:05pm and 11:35pm. Fans were turned on between 2:55am and 4:50am.
During the second experiment, to study the influence of passengers' activity on particle concentrations, forty subjects followed three scenarios. After the traffic stopped and a waiting time of approximately 45' (time for particle concentrations decreasing to urban level), the first one consisted for the forty subjects in staying in front of captors during 15'without moving to assess a possible natural emission. During the second one, named "off-peak period", four groups of ten subjects walked one after the others during 4' each in front of sensors. The last scenario, named "rush hour", consisted in walking all the forty subjects in front of captors during 15'.
During the last experiment, to study the influence of train pass-by on particle concentrations, two scenarios were repeated: pass-by without stopping and pass-by with braking and stopping.
The timetable of the different pass-by is shown in Table 1.

Table 1: Timetable of the different pass-by.

	braking 1	stop 1	braking 2	stop 2
entry	2h18min57s	3h02min40s	3h47min34s	4h32min31s
stop	2h19min24s	/	3h48min03s	/
Setting in motion	2h20min30s	/	3h49min04s	/
departure	2h20min56s	3h03min07s	3h49min33s	4h32min57s

RESULTS

Ventilation

During the measurement period the relative humidity ranged from 47% to 57% and the temperature from 11.4 to 13.4°C.
Firstly, measurements of particle concentrations show higher concentrations for particles ranged between 0,3 and 0,4µm than those for bigger height classes. During the night, fine particle (0,3 to 0,4µm) concentrations part increase whereas the others decrease (Table 5 and Table 3). Globally, air becomes impoverished in particles and PM_{10} concentration in the station reduces to the urban level.

Table 2: Granulometric distribution in Magenta at 00h

Disturbances due to trains pass-by have an important effect on particle concentrations (less than 1µm). As one can see on Figure 3 and Figure 4, between 00:00am and 01:00am and after traffic started, the particle concentrations variations fit with trains pass-by. When considering air velocity (that also fits with trains pass-by), ranged from 1.0 to 2.2m.s^{-1} on nearest track of measurement's one before traffic stopped and up to 4m.s^{-1} after traffic start on measurement's track, it is easier to understand that particles are under high trains' disturbances. When there is no traffic in the station, air velocity ranged from 0.02 to 0.6m.s^{-1}. Then, particle concentrations decrease to lower level on 45', as shown on Figure 3.

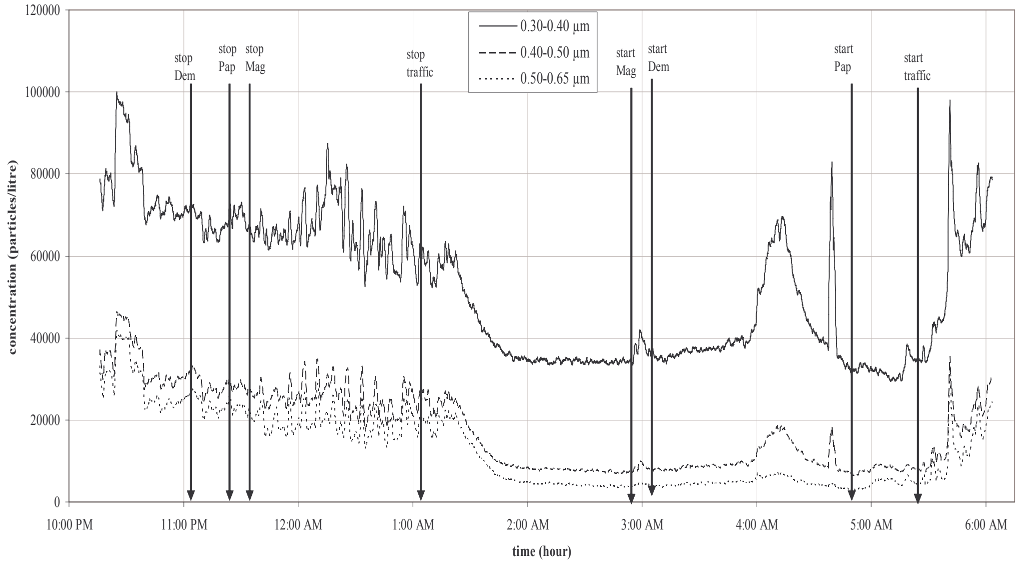

Figure 3: particle concentrations variations at 1.70m.

When looking on a smallest period during the night (on Figure 4), after 11:30 pm, 1' after each train entry on nearest track of measurement's one (when train sets in motion) corresponds to a particle concentrations decrease. This can be explained by the fact that particles move outside the station with train's wake.
As fine particle concentrations are relatively close for each measurement's height, only fine particle concentrations at 1.70m is represented on Figure 4.

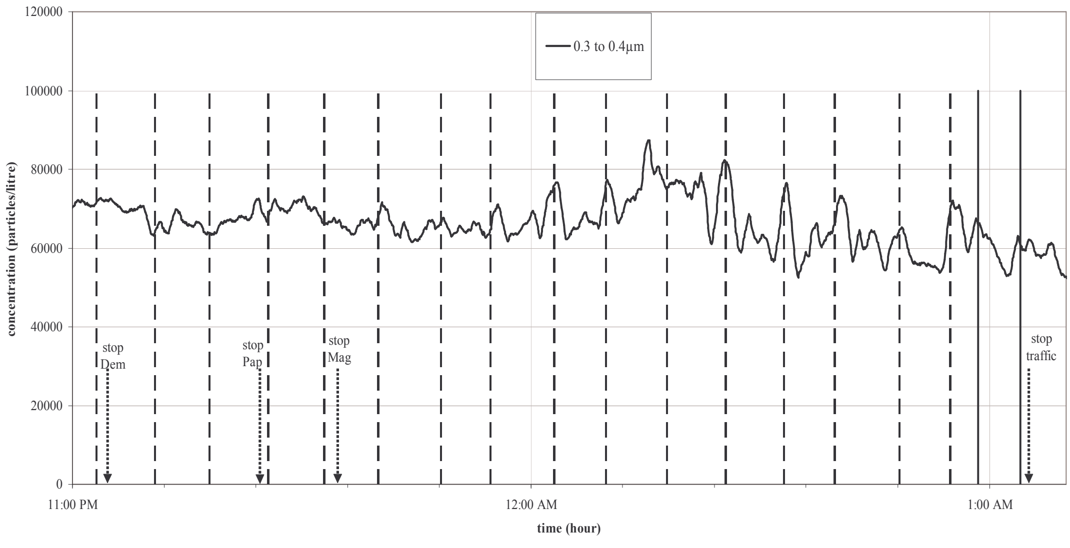

Figure 4: trains entry on nearest track of measurement's one and particle concentration at 1.70m between 11:00pm and 1:15am

: trains entry on the nearest track of measurement's one
: unstopped trains on nearest track of measurement's one
stop Dem/Pap/Mag: stop of Demarquay, Papillon and Magenta well fans
stop traffic: end of traffic
Before traffic stopped, measurements also show that relative humidity increase (approximately 3%) when trains enter in the station. This can be due to passengers when

coming-out from trains or to trains if outside relative humidity is higher than inside one. Because of low variations of CO_2 concentrations, we cannot conclude on the passengers' influence on relative humidity.

Passengers

During the measurement period the relative humidity ranged from 32% to 41% and the temperature from 10 to 12°C.

Concentrations of particles ranged between 0.30 and 0.80µm were very high and others very low during this experiment. As only particles ranged from 1.6 to 4.0µm can be analysed, other particle concentrations variations have not been represented here. Fine particle concentrations were three times higher during this experiment than during the first one. This may be due to "fire tests" that took place the day before. It consisted in smoking out the station and turning on fire ventilation.

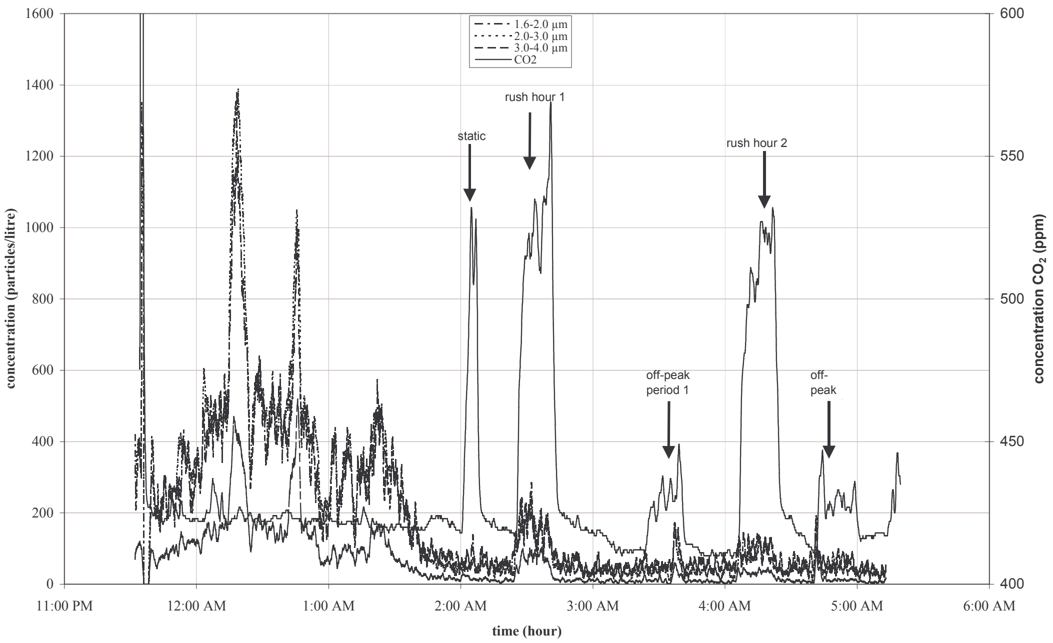

Figure 5 : particle (1,6 to 4,0µm) concentrations variations and CO_2 concentrations variations at 1,70m

Figure 5 shows concentrations of particles ranged from 1.6 to 4.0µm and CO_2 concentration (human presence's indicator).

Five CO_2 concentration peaks can be observed. It corresponds to the different scenarios: static, rush hour and off-peak period.

First rush hour peak (2:30am) is more marked than the second one (4:15am) and off-peak period are spotted with a thin peak at 3:40am and 4:40am.

For the first rush hour scenario, the concentrations variations around the peak are given in Table 4.

According to particle height, concentrations vary from a factor 2 to 10 around the peak.

Although the variations around the second peak of rush hour scenario are less marked, one can observe an influence of subjects' activity on particle concentrations.

Table 4: mean concentrations (part.L^{-1}) during the first rush hour between 2:00am and 3:00am.

time	1.6-2.0 µm	2.0-3.0 µm	3.0-4.0 µm	4.0-5.0 µm	5.0-7.5 µm	7.5-10.0 µm
2:00-2:24am	62	45	14	6	4	1
2:25-2:45am	139	131	57	38	29	11
2:46-3:00am	55	38	11	6	3	1

For the first off-peak period, variations around the peak are given in Table 5.
According to particles' height, concentrations vary from a factor 1.4 to 3 around the peak. Nevertheless, for particle ranged from 5 to 10 µm, concentrations values are in the measurement uncertainty. Concentration variation must be carefully considered.

Table 5: mean concentrations (part.L^{-1}) during the first off-peak period between 3:00am and 4:00am.

heures	1.6-2.0 µm	2.0-3.0 µm	3.0-4.0 µm	4.0-5.0 µm	5.0-7.5 µm	7.5-10.0 µm
3:00-3:23am	50	33	9	5	2	1
3:24-3:39am	68	52	17	10	7	3
3:40-4:00am	55	33	9	4	2	1

For these particles' heights, the influence of subjects' activity is less marked for off-peak period than for rush hour. During the two different scenarios, air velocities are relatively close, ranged from 0.3 to 0.5m.s^{-1} when people walked and close to 0.2m.s^{-1} when there was no activity in the station.
No interpretation can be done on others particles' height because of the unexpected concentrations during this experiment.
As in the first experiment, the same relative humidity variations (approximately 3%) have also been observed during this second campaign.

Trains
During the measurement period the relative humidity ranged from 56% to 64% and the temperature from 16 to 18°C.
Four pass-by were performed during this test: two when breaking and stopping and two other without stopping. Measurements give four different signatures for the four pass-by.
Fine particles are one more time present in majority, even during pass-by trains.

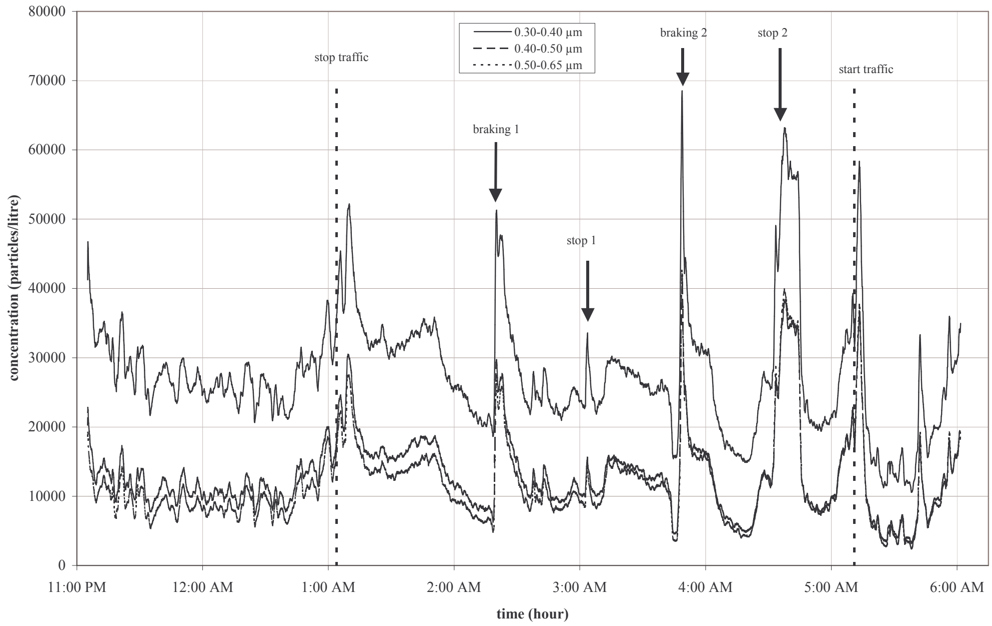

Figure 6 : particle concentrations variations at 0.50m

During this last experiment, the concentrations of particles ranged between 0.3 and 0.65µm are approximately two times lower than during the first one.
Table 6 gives granulometric distribution during this third experimentation. It shows, as during the first one, fines particles represent the major part of particles numbers.

Table 6: Granulometric distribution during the experimentation at 00h

size (µm)	0.30-0.40	0.40-0.50	0.50-0.65	0.65-0.80	0.80-1.0	1.0-1.6	1.6-2.0	2.0-3.0
Concentration (part.L-1)	24984	9632	7940	3350	2120	790	337	362
Repartition (%)	50.33%	19.41%	16.00%	6.75%	4.27%	1.59%	0.68%	0.73%

size(µm)	3.0-4.0	4.0-5.0	5.0-7.5	7.5-10.0	10.0-15.0	15.0-20.0	>20.0	total
Concentration (part.L-1)	78	31	8	4	0	0	0	49636
Repartition (%)	0.16%	0.06%	0.02%	0.01%	0.00%	0.00%	0.00%	100%

As we can see on Figure 6, trains' signatures due to the four pass-by are not reproducible two by two in spite of the same conditions (same operator, same speed…). One pass-by, the first without stopping, does not cause an important signature.
The other three pass-by cause fast increase and decrease particle concentrations. These variations can be observed for the whole particles' height and are probably due to the transport caused by trains' air mixing, as air velocities are up to 4.5m.s^{-1} on measurement's track, as during the first experiment.

The difference which can be observed between the two last pass-by in term of maximum concentrations represents approximately 5400part.L^{-1} for particles ranged between 0.3 and 0.4µm. As trains pass-by are not reproducible, it is difficult to maintain this difference represents the breaking emission's part.

As during the previous experiments, the same relative humidity variations(approximately 3% to 4%) have also been observed during the period of trains pass-by. As there were no passengers in the station during this test, we can conclude that this variation is due to trains pass-by.

DISCUSSION

The first experiment did not show an effect of ventilation on particle concentration. Ventilation may not have an influence on resuspended particles but it may be have an impact on the accumulation of particle concentration. So it could be interesting to turn off the station's ventilation during several days or weeks if it's possible.
The second experiment permitted to evaluate the passengers' influence. As this campaign was polluted by "fire tests", we can only observe trends on a few particle heights. This experiment could be completed by another one that should take place in a more enclosed space with controlled conditions before starting it again in an underground station.
The last experiment gave an idea of trains pass-by influence on particle concentration. This source is probably the most important in the station. But it is also the most complex because it is difficult to estimate the part of emission, transport and resuspension.

Many studies have been carried out to determine PM_{10} and $PM_{2.5}$ levels in underground stations. Particle number concentrations are rarely performed. Such measurements have been done by P.Aarnio [1] to compare it to urban level. In our study, such measurements have been carried out to characterize different particle sources.
To have more information on particle transport, it could be interesting to measure the concentration level in tunnel to compare respective pollution of tunnels and station. But punctual measurements could not be sufficient to understand such difficult phenomenon as particle transport and resuspension.
Nevertheless, these three experiments show particles less than 1µm represent the major part of particle number concentration in the underground station. In order to reduce their concentrations, it is very important to better understand their origins and behaviour.

ACKNOWLEDGEMENT

Personnel of Magenta station, Laboratoire d'Etude des Phénomènes de Transfert Appliqués au Bâtiment and Agence d'Essais Ferroviaires from SNCF are acknowledged for technical help in arranging this campaign.

SUMMARY

The design of buildings for animal keeping and the dimensioning of ventilation equipment for such buildings require knowledge about heat, moisture and CO_2 production of the animals. In addition to these parameters the emission streams of odour and gases are interesting on the part of action on the environment. Therefore basic research was carried out in different cattle barns, different designed buildings and different number of animals under one roof. Special investigations were done in two naturally ventilated livestock buildings for 288 dairy cows and for 251 beef cattle. The paper reported about the measuring methods and the results regarding the microclimate parameters and the ammonia emission streams.

INTRODUCTION

The design of buildings for animal keeping and the dimensioning of ventilation equipment for such buildings require knowledge about heat, moisture and CO_2 production of the animals. In addition to these parameters the emission streams of odour and gases are interesting on the part of action on the environment. Therefore basic research was carried out in different cattle barns, different designed buildings and different number of animals under one roof. Special investigations were done in two naturally ventilated livestock buildings for 288 dairy cows and for 251 beef cattle.
The climatic parameters are measured by data logger. The air flow pattern is made visible by smoke and the air velocity in the animal zone is measured by hot wire anemometer. Inside the building the gas concentrations (NH_3, CO_2, CH_4 and N_2O) will be recorded by a Multi-Gas-Monitor. To determine the air volume stream the air exchange rate is measured by tracer gas technique. The ATB has developed a special method and technology using the radioactive gas Krypton 85. Up to 40 measuring sensors can be used at the same time – with the measuring frequency of 1 second. High air exchange rates can be measured.
The paper will show the correlation between outside wind speed and air exchange rate. The large openings lead to high air volume streams and therefore the temperature difference between inside and outside is small. Also the ammonia concentration inside the building is very low because of the high air exchange rate. But from the high air volume stream results a high ammonia emission stream. In our paper we will show the air flow pattern and the measured air velocity in the animal zone.

BASICS

The necessary ventilation of livestock buildings can be realised by using forced ventilation, natural ventilation or the combination of both kinds of ventilation. In cattle barns the most commonly used ventilation system is the natural ventilation. In some cases an additional forced ventilation system is used – especially during the summer period if the outside temperature is high and the outside air velocity is low. Under such weather conditions the additional ventilation system is used to achieve more air movement in the animal zone to improve the heat dissipation of the animals. During wintertime such system can be used for a better mixing between fresh air and room air for a better using of the heat production of the animals inside the building.

The driving forces of the natural ventilation are the thermal lift and the outside wind. Both forces produce pressure differences at the building and effect the air stream trough the openings in the structure of the building. The thermal lift results from the temperature difference between inside and outside air (see Figure 1).

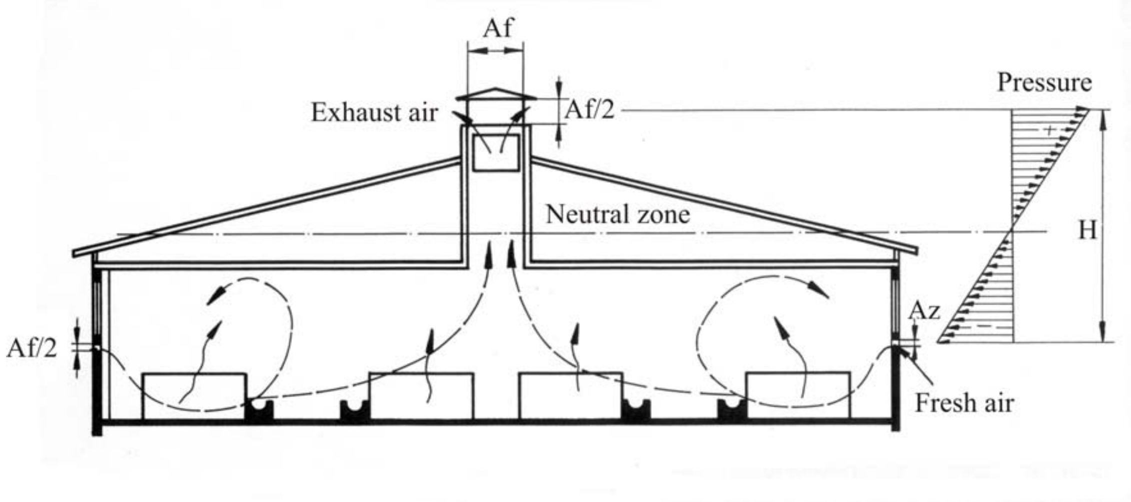

Figure 1. Schematic presentation of thermal lift in an animal house with shaft ventilation.

The pressure difference is proportional to the density difference (a result of the temperature difference between inside and outside air) and the height difference between air outlet and air inlet:

$$\Delta p_{th} = g\ H\ \Delta \rho \qquad (1)$$

Where Δp_{th} is the pressure difference, g is the gravity, H is the height difference between air outlet and air inlet and $\Delta \rho$ is the density difference between inside and outside air.

The air flow around the livestock building because of the outside wind effects pressure differences at the building (Figure 2).

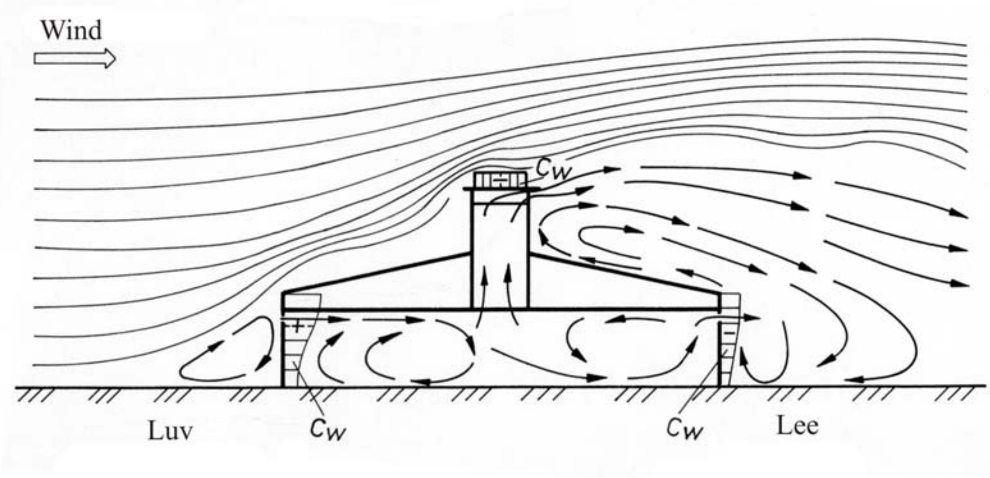

Figure 2. Schematic presentation of the wind effect on air flow trough the building.

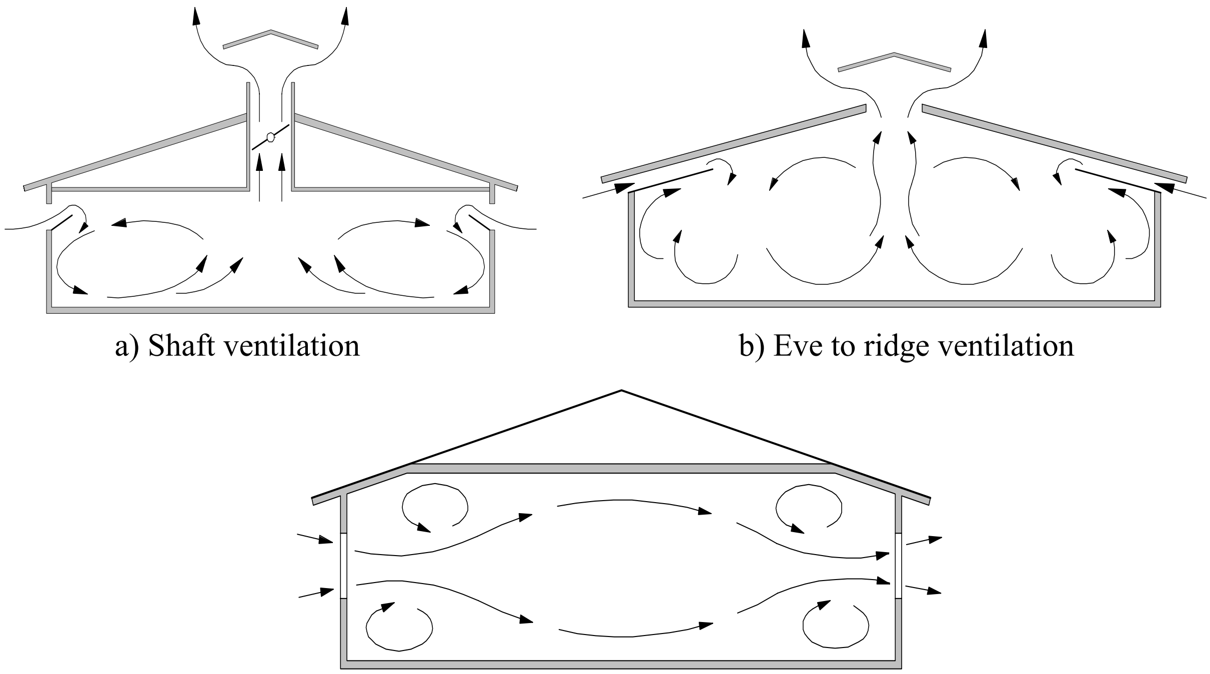
The wind pressure results from the dynamic pressure of the wind can be written in the simplest way as the following:

$$p_W = c_W \frac{\rho}{2} w^2 \qquad (2)$$

Where p_W is the wind pressure, c_W is the coefficient of the wind pressure and w is the wind velocity. It is to consider that the coefficient of the wind pressure c_W depends on different influencing factors such as the wind profile, the location of the opening at the building and the shape of the opening. This coefficient must be determined by empirical methods.

Different types of natural ventilation are applied in farm buildings (Figure 3).



a) Shaft ventilation

b) Eve to ridge ventilation

c) Wind induced cross ventilation

Figure 3. Different types of natural ventilation used in animal houses

INVESTIGATED CATTLE BARNS

Investigated building 1

First measuring period (16 – 24 March, 2004):
Size: 74.4 m long and 34.2 m wide; room volume 19 731 m³
Number of animals: 288 dairy cows
Ventilation: natural ventilation; ridge opening; openings in side walls controlled by curtains; doors with adjustable windbreakers
Second measuring period (24 April – 04 May, 2006):
Size: (extended) 96.15 m long and 34.2 m wide; room volume 25 499 m³

Number of animals: 359 dairy cows (animal mass: 655.5 kg per animal; milk performance: 33.6 l/d per cow)

Ventilation: natural ventilation; ridge opening; openings in side walls controlled by curtains; doors with adjustable windbreakers; 3 additional ceiling fans

Investigated building 2

Size: 86.4 m long and 11.91 m wide; room volume 3 972 m³
Number of animals: 251 beef cattle
Ventilation: natural ventilation; shaft ventilation; openings in side walls (windows, which can be opened by hand); doors, which can be closed or opened by hand

Methods

Climate parameters

Run measurements for air temperature and humidity sensors connected with data logger. Wind outside is measured by ultrasonic anemometer and inside by thermistor sensor.

Air volume stream

- CO_2 – balance method [1]
- Especially during summer, when air change rates are high and cattle barns are ventilated naturally the small number of measuring locations and the small temporal resolution leads to higher measuring uncertainties. Therefore a special measuring system for Krypton 85 as tracer gas has been installed at ATB. With this system it is possible to measure the concentration of Krypton 85 in the barn at 40 locations in parallel. The shortest measuring interval per location is 1 second. The tracer gas is distributed in the building in thinned solution and as fast as possible. This is done manually, that means the dosing device is moved evenly across the entire surface of the livestock building. Then the tracer gas is mixed with the air of the livestock building by waving big cardboard fans. It is recommended during this time to close all openings. After that, the openings of the building must be opened quickly and the decay of the concentration of Krypton 85 is measured. The exponent of the decay function is the air change rate. In connection with the volume of the livestock building, the volume flow can be determined. This method is described in [2]. 18 measuring points (MP) are evenly distributed in 3.5 m height (each 3 MP in line across to the longitudinal axis of the building).

Concentrations

Run measurements for CO_2, NH_3, CH_4 and N_2O are realized by means of a Multigas-Monitor. Using a multiplexer it is possible to connect up to 12 measuring points. The time resolution drops with the increase of the number of measurement points and amount to approx. 12 minutes in case of 12 measurement points.

Emission mass flow

The emission stream from the livestock building is the product of both, the difference in concentration between emitted air and fresh air and the air flow rate.
One needs to take into consideration that both the concentration and the air volume stream vary permanently. That means the emission mass flow is temporal variable. To indicate the temporal run of the emission mass flow rate both parameters have to be measured the air volume stream and the concentration. The product will be calculated from both factors for each time step.

RESULTS

Investigated building 1

Climate parameters

The location of the investigated cow shed is in the north of Germany near the Baltic See. In this region there is more wind than in other parts of Germany. The air volume stream is mostly much higher than the minimum ventilation rate. Figure 4 shows the run of inside and outside temperature.

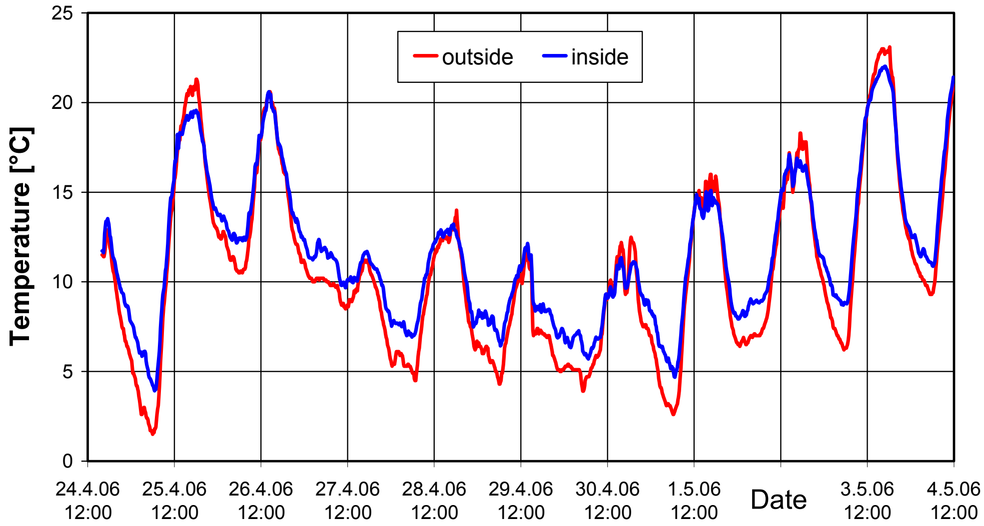


Figure 4: Run of inside and outside temperature during the second measuring period (24 April – 04 May 2006). Inside values are averaged over 4 MP.

The difference between inside and outside temperature is small and the inside temperature follows the variation of the outside temperature. The same pattern can also be seen for outside temperatures lower than 0°C. The air flow pattern and also the air velocity in the animal zone are strongly influenced by the outside wind situation (Figure 5).

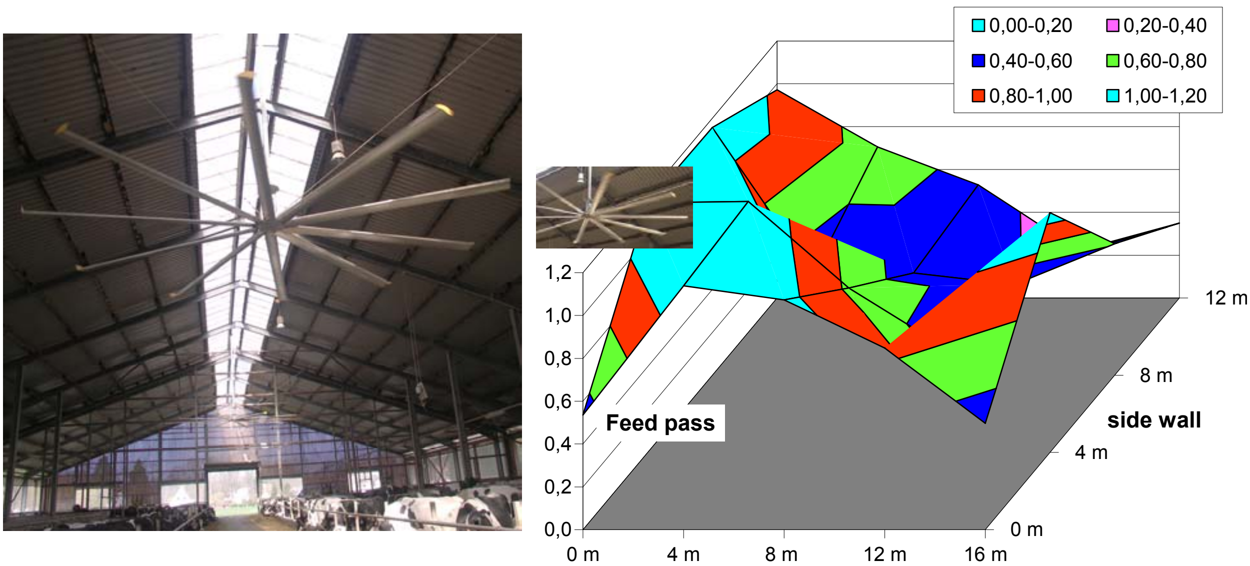

Figure 5: Ceiling fan (left) and air velocity field 1.2 m above the floor (04 May 2006). The velocity values are average values about 2 minutes

On 04 May 2006 the air velocity in the animal zone was measured with three different speed steps of the ceiling fan (speed step 1; 4.5; 9). Figure 5 shows the fan (left) and an example for speed step 4.5 (right).
Directly beneath the fan the air comes up and the velocity is low (0.5 m/s). In a distance to the fan between 3 m and 6 m the air velocity increases up to 1 m/s. In a bigger distance the velocity decreases again and near the side wall there are the highest values caused by the outside wind near the big openings in the side wall. In the German standard DIN 18910-1 an air velocity up to 0.6 m/s is permissible – but this standard regards only to closed livestock buildings.

Air volume stream

The volume stream is measured and calculated by CO_2-balance and the tracer gas method using Krypton 85 as tracer gas. The openings in the side walls and gable walls lead to a very high air exchange rate. In both measuring periods the air exchange rate (measured by Krypton 85) differed between 17.3 h^{-1} (341.346 m³/h => 1 185 m³/h per animal) and 89.2 h^{-1} (2 274 511 m³/h => 6 336 m³/h per animal). These air flow rates per animal are much higher than required in the standard DIN 18910-1 (minimum air flow rate = 84,3 m³/h per cow and maximum air flow rate = 333 m³/h per cow). Figure 6 shows results of air stream measurement by CO_2-balance and by tracer gas method using Krypton 85 as tracer gas. The CO_2 analyser cannot follow the fast fluctuation of air change, but in the most cases exist a good correspondence between both methods. The very high measured value by the Krypton method (11:35 – 11:40) results from a bad mixing between tracer gas and room air. The Krypton gas was dosed with open walls and doors, so that tracer gas already escaped from the room during dosing time.

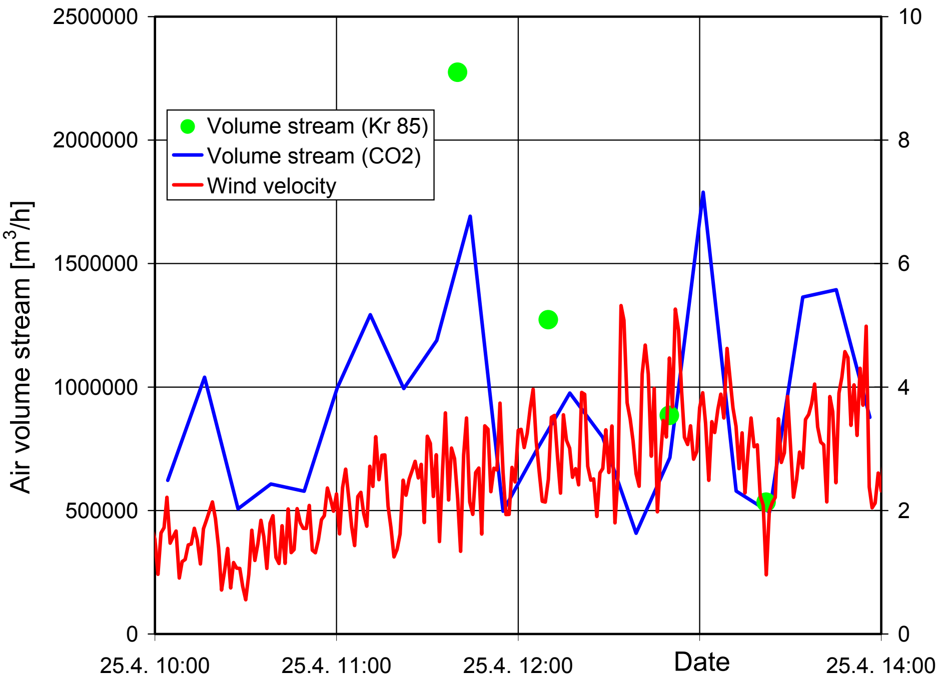

Figure 6: Air volume stream measured by CO_2-balance and air exchange rates determined by the decay method (Krypton 85) in a short time period.

The comparison of both measuring methods shows that the application of CO_2-balance can be used for assessment of air volume stream trough naturally ventilated large animal houses also for long periods of time. The correlation between air volume stream and wind velocity over both measuring periods shows the strong influence of wind velocity on the air change rate.

Concentrations

The high air volume stream through the cow shed leads to low gas concentrations. Sometimes the inside concentration is close to the outside concentration. In both measuring periods the CO_2 concentration is most of the time lower than 1000 mg/m^3 and the average value for NH_3 is 1.10 mg/m^3 in the first period and 1.16 mg/m^3 in the second period. For both gases peaks have been observed. These peaks appear especially during feeding time. Reasons for that are the higher animal activity and also the emission from the fresh feed. Investigations in the "emission laboratory" of the ATB have shown that the fresh feed emits CO_2 and NH_3.

Emission mass flow

The emission mass flow is calculated with the measured NH_3 concentration and by the determined air volume stream (CO_2 balance) during the whole periods. In spite of low NH_3 concentration a relatively high emission stream results – for the first period 2.6 g/(h LU) and for the second period 1.4 g/(h LU).

Investigated building 2

Climate parameters

The measured climate parameters are comparable to building 1. The maximum values inside and outside are nearly the same but during night time the temperature inside the house decreases not so deep than the outside temperature.

Air volume stream

The measured air volume stream is shown in Figure 7.

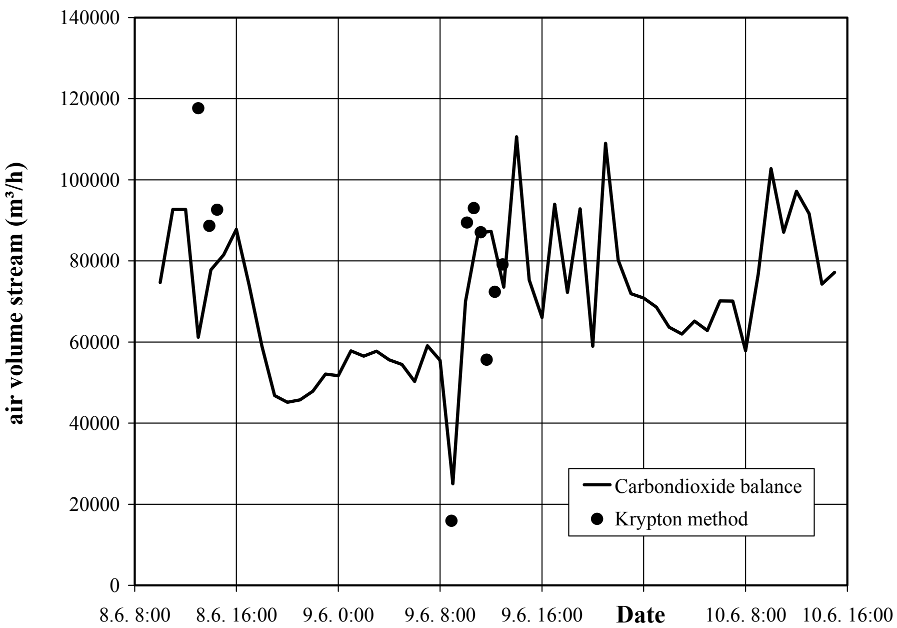

Figure 7: Air volume stream in a beef cattle house – determined by carbon dioxide balance and by Krypton method (June 2004)

Concentrations

During feeding time in the morning the ammonia concentration increases dramatically up to 25 mg/m^3. During the day the concentration decreases to 2 mg/m^3 in the night time.

Emission mass flow

The emission mass flow is calculated with the measured NH_3 concentration and by the determined air volume stream (CO_2 balance) during the measured period. The high NH_3 concentration in the morning lead to a relatively high emission stream of 1.4 g/(h LU).

CONCLUSION

- In naturally ventilated livestock buildings the air volume stream through the building is strongly influenced by the size of the openings in the building and by the outside wind velocity.
- The inside temperature follows the outside temperature, but the oscillation of the inside temperature is a little bit damped.
- By means of ceiling fans the air movement in the animal zone can be increased especially during summer to reduce the heat stress.
- The Krypton method is applicable to determine air exchange rates in naturally ventilated livestock buildings - for short term measurements – high air exchange rates in large buildings are measurable.
- The CO_2-balance method is also applicable for natural ventilation to assess the air volume stream for longer periods of time.
- In naturally ventilated livestock buildings the gas concentrations are low but in spite of high air volume streams the emission streams are relatively high.

Maintenance and improvement of ventilation systems

Modern Concepts for Refurbishment of Ventilation and Air- Conditioning Systems

Harri Ripatti

Climaconsult Finland Oy

Corresponding email: harri.ripatti@climaconsult.fi

SUMMARY

A research project has been carried out to develop new methods and technical solutions to refurbish ventilation and air-conditioning systems of office and commercial buildings built during 1970`and 1980`. More than twenty refurbishment concepts have been developed, which deal with all parts of ventilation and air-conditioning system (air-intake, filtering, cleaning, tightening and balancing of ductwork, noise control, air distribution, demand based ventilation, night cooling, adding mechanical cooling etc) and which can be carried out one by one or all together depending of the actual needs. Special attention has been paid for the installation work on site to minimize the disturbance and nuisance to users of the building. Therefore dustless and noiseless installation methods have been developed. For each concepts design criterias and installation rules are given. Finally the commissioning procedure for each concept has been discribed. This project has been carried out in Finland, where building owners, manfacturers, contractors and designers have been working together with researches to achieve means to refurbish old buildings to meet todays reguirements of modern indoor air climate.

INTRODUCTION

There exist a great number of office, commercial and public buildings, built during 1970` and 1980`, which do not any more meet the users and building owners requirement concerning indoor air quality and climate. Those buildings are not anymore competitive in the market, where modern buildings with latest ventilation and air-conditioning technology are available.

These ventilation and air-conditioning systems shall be refurbished without disturbing the users. This project deals with public and private offices, commercial buildings and schools built during 1970` and 1980` in Finland. In this project refurbishment concepts to improve performance of ventilation systems has been developed. An integral part of the work has been to develop a procedure in which way and means refurbishment of ventilation and air-conditioning systems can be carried out in actual refurbishment projects.

METHODS

Typical ventilation systems and their problems

Analyses of ventilation systems, built during those two decades have shown that they have many common, recognized technical features, which are not any more acceptable by the building users and owners. Additionally one can recognize the same complains, which users raise continuously, when indoor air quality is concern. The main factors in this field are:

- poor indoor air quality

- high noise level
- draft
- too high room temperature
- lack of individual temperature control
- unbalanced ventilation system
- unclean ventilation system
- high energy consumption

Addition to problems with ventilation and air-conditioning these buildings have other features, which were not considered here. They are such as moisture damages, used hazardous materials etc. which problems showed out to be often bigger than inadequate ventilation and temperature control.

All these factors, combined with technical problems in service and maintenance has forced the building owners to reconsider the value of the building and take necessary steps to update the ventilation and air conditioning system to meet their user's needs.

<u>Development of refurbishment concepts and procedure to carry refurbishment project</u>

Refurbishment concepts to improve indoor air conditions were selected based on the analysis of existing buildings. Concept development varied a lot, depending on concept and its features. Anyhow, all concepts were finally tested in actual construction conditions. Procedure to carry out refurbishment project was developed simultaneously with the concepts but concentrating more design, installation and management features.

Research approach to determine the concepts have been:

- design
- studies and models
- laboratory tests
- field studies
- modeling and simulation
- prototypes
- pilot projects

RESULTS

<u>Refurbishment concepts of ventilation and air-conditioning systems</u>

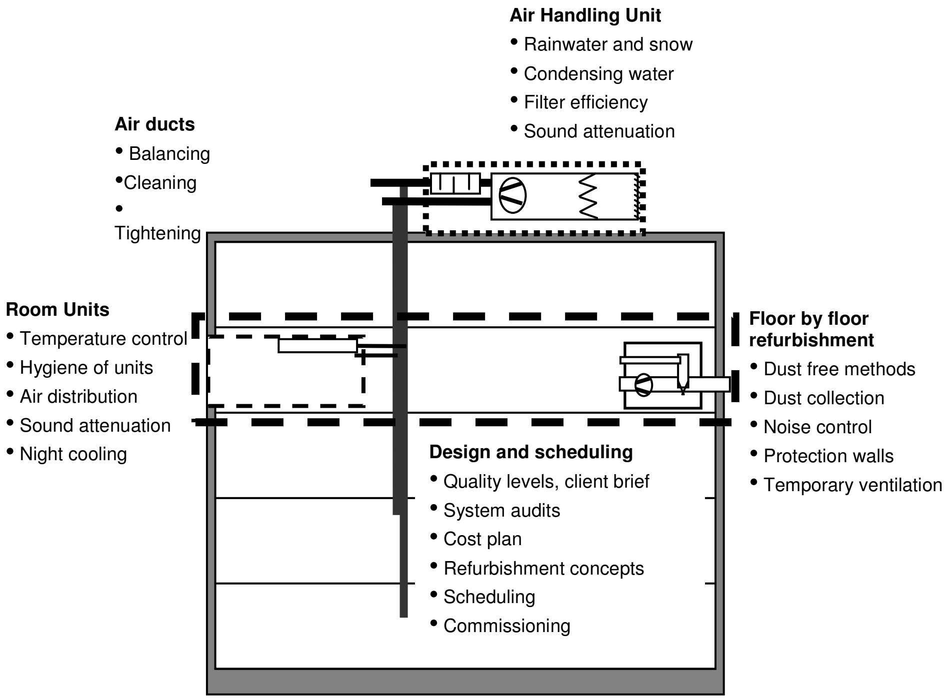

Figure 1. Refurbishment concepts of ventilation and air-conditioning systems.

The developed concepts are:

1. Concepts related to ventilation and air conditioning systems such as:
    - Balancing of air flows
    - Decreasing the noise levels
    - Increasing the air flow rates
    - Demand based ventilation
    - Adding the mechanical cooling
    - Night ventilation and cooling
2. Concepts based on spatial needs in offices and schools such as:
    - Air distribution in an office room
    - Air distribution in open office
    - Air distribution in classroom concepts
    - The hygiene of local cooling units
3. Concepts based on improvements in mechanical rooms such as:
    - Prevention of snow to enter the air handling units to keep the filters dry
    - Improvement of filtering efficiency
    - Cooling coil draining solutions
4. Concepts related to ducting such as:
    - Tightening of sheet medal air ducts
    - Cleaning of sheet metal ducts
    - Cleaning, tightening and layering of hollow core concrete slabs used as air ducts
    - Layering of noise attenuators
5. Concepts related to work on site such as:
    - Minimizing of noise and silent working methods

- Minimizing of dust generation and dustless working methods
- Temporary ventilation systems

Procedure to carry out the refurbishment concepts

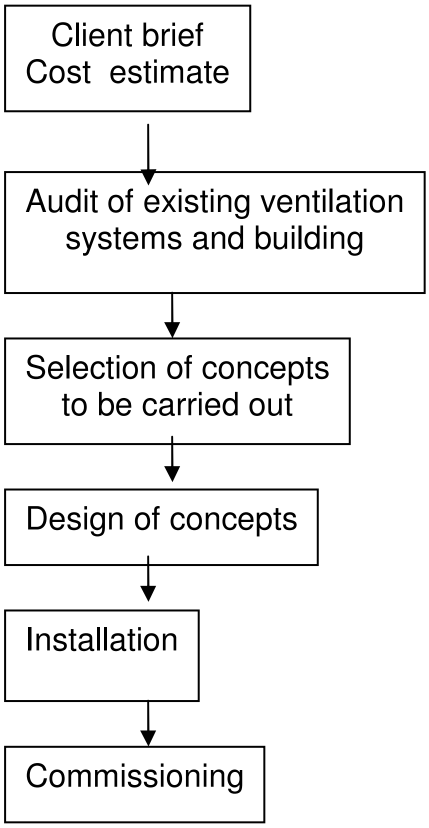

Figure 2. Procedure to carry out the refurbishment concepts of ventilation and air-conditioning systems.

The developed procedure has the following steps:

- client brief and cost estimate
- audit of existing ventilation system
- selection of concepts to be carried out
- design of concepts
- contract to carry out of concepts
- commissioning
- use of the building and systems

Client brief is the phase of the project, where client oriented design analysis is made concerning not only indoor air conditions and other performance of building services systems, but also such features as flexibility, durability, ecology, energy and security of the building. Cost estimate is essential part of client brief.

Audit of existing ventilation system is necessary to determine before starting the refurbishment work:

- to find out the existing condition of ventilation system
- to make sure, that the design targets can be achieved
- to make sure, that the actual work on site can be done

Selection of concept to bee carried out in that specific case is based on feasibility study, client brief and audit of ventilation system. Concepts can be divided into three groups based on the purpose of the refurbishment.

- To remove the nuisance of the user, such as noise, draft, poor air quality, too high temperature etc.
- Increase of indoor air quality, such as from satisfactory level to good level etc.
- Technical improvement, such as changing the old component, improving the energy efficiency etc.

Concepts most often deal with multipurpose targets, so that the concentration is to select a total improvement instead of individual improvement.

Design principles of each concept are given in the design manual. Design manual includes results of the researchers´ work, which have been done in the project. Additionally good design and construction practices related to the concepts have been collected into the manual.

The design manual includes the following items:

- Target values for indoor air climate
- Other targets, such as flexibility levels, environmental requirements, cost targets etc.
- Design principles for each concept (dimensioning, calculation methods, materials, working methods etc.)
- Instructions, how to handle that part of ventilation system, which is not covered by the concept itself
- Construction documents for the bidding (specification, drawings etc.)
- Quality control documents
- Maintenance documents

In construction phase special attention is paid for installation methods, so that minimum disturbance to the users of the building will take place. Particularly dustless and noiseless working methods are used.

Related to each refurbishment concept instructions are given in construction documents, which are the technical requirements and working methods to carry out the concept.

Commissioning and handling over procedure consists of the following actions, which will be carried out by the supervisor with close co-operation with the contractor:

- Approval of materials, products and components provided by the contractor
- Checking of installations
- Functional tests
- Test runs
- Indoor air quality and other technical measurement (temperature, air velocities, noise, air-flows, tightness, cleanliness etc.)

A checklist has been prepared for each refurbishment concept to clarify, which are the essential technical features for the concept. At the end of the refurbishment project both design and commissioning documents will be attached to buildings service and maintenance documentation.

DISCUSSION

As the result of this research and development project, twenty concepts for refurbishment of ventilation systems have been developed. These concepts cover several critical areas of ventilation systems.

Partial refurbishment requires effective use of existing ductwork. The ductwork must meet modern requirements for cleanliness, air tightness and adjustability.

Noise from fans and terminal devices is one of the most common complaints. Therefore several concepts to eliminate this problem were developed.

Improving thermal comfort is one essential step which is needed to take when heading towards updated indoor air quality. This project focused on means to add mechanical cooling to existing building, for nighttime free cooling and air distribution solutions for draughtless indoor conditions.

Refurbishment of ventilation systems while building is in use means that new methods, tools and systems has to be developed to minimize disturbance from noise and dust. Additionally partitioning systems and temporary ventilation is needed guarantee safe and healthy conditions for the users also during the refurbishment work.

Cleanliness of supply air is an essential performance criterion for good ventilation system. In order to get rid of old systems hygiene problems, concepts concerning filtering efficiency, snow and water penetration to air-handling units and local filtering systems were developed.

The results of the project have been collected to design manual, which has three parts:

1. Instructions to carry out the refurbishment project for building owners and end users
2. Design, installation and commissioning rules to carry out of refurbishment project
3. Researchers reports of refurbishment concepts

ACKNOWLEDGEMENT

This development project “Modern Concepts for Refurbishment of Ventilation systems” was financed by Finnish building services industry, contractors and consultants, building owners and Technology Development Centre in Finland (Tekes). Without their financial support the results of this project would not have been realized.

Protecting the HVAC System During Construction: An Industry Standard of Care for Contractors

Vernard D. Holden, CIH, CSP, ARM

Hydro-Environmental Technologies, Inc., Acton, Massachusetts, USA

Corresponding email: vernh@hydroenvironmental.com

SUMMARY

The relationship between construction activities and an increased risk of microbial contamination and degradation of air quality in new building construction and renovation projects was studied. Poorly designed or installed ventilation systems and inferior workmanship during construction were determined to have an adverse impact on the performance of the building ventilation system. This presentation will provide guidelines to protect HVAC system components during building construction and renovation projects and for building commissioning procedures for building ventilation systems. It also underscores the importance of educating the building owner on proper operation and maintenance of building mechanical systems as part of the building commissioning and transfer process.

INTRODUCTION

Heating, ventilation and air conditioning (HVAC) system components often collect significant amounts of debris and particulates during construction activities within a building. A faulty or contaminated HVAC system can lead to poor humidity and temperature control and cause degradation of indoor air in the building. Newly installed HVAC systems or those in buildings undergoing renovation must be protected before the system is permitted to operate and should be verified to be clean [1]. Protecting HVAC system components from water, dust and debris during construction activities is the major control method to prevent degradation of indoor air quality and microbial contamination. Building commissioning procedures should include quality assurance testing of the ventilation system, prior to building transfer to the owner, to ensure that it is properly tested, and balanced and functioning according to building design parameters. A systematic approach is required to address reported ventilation problems during the warranty period. This presentation describes an industrial hygienist's role in building construction and renovation, from project planning through testing, and the contribution an industrial hygienist can make to protect HVAC systems from airborne contaminants during construction.

METHODS

The focus of this presentation is on protecting building HVAC systems. Major considerations to prevent adverse impacts on the performance of the building ventilation system are presented by the author based on microbial investigations and case studies involving construction of commercial and residential buildings located throughout North America and the Pacific Rim.

The HVAC system includes the interior surfaces of a building's air distribution system that services conditioned indoor spaces and/or occupied areas. This includes the entire building ventilation air conveyance system. The return air grilles; return air ducts to the air handler unit (AHU); variable air volume boxes; interior surfaces of the induction, convection, fan-coil units and the AHU; and mixing boxes, heat exchangers, condensate drain pans, humidifiers and dehumidifiers, supply air ducts, fans, fan housings, fan blades, air wash systems, spray drift eliminators, turning vanes, filters, filter housings, reheat coils, ductwork, and supply diffusers are all considered part of the HVAC system. Protecting the integrity of the HVAC system in construction starts with proper building and ventilation system design. Proper building design includes choice of proper building materials; specifications for building construction with detailed attention to critical tasks such as waterproofing, vapor barriers and HVAC systems; procedures for reviewing plans and specifications with explicit consideration of water infiltration and potential mold-related exposure from construction materials, methods, and HVAC system requirements; and procedures for reporting building design weaknesses that can cause water intrusion during construction.

Moisture control in building ventilation design requires diligent engineering. The temperature and relative humidity in climate-controlled areas of the building should be designed within a range considered both comfortable and healthy according to consensus guidelines[2]. Design of the HVAC system, natural airflow, and temperature fluctuations can also help to control moisture condensation and humidity on jobsites. Proper design starts with appropriate material selection. Some materials are more amendable to cleaning during and after construction. For example, unlined galvanized sheet metal and borosilicate glass ducts are corrosion-resistant and cleanable, compared to other duct material, such as fiberglass ductboard and flex duct. Flex duct is extremely difficult to clean because it contains a tremendous amount of surface area inherent in its expandable accordion design. Anti-microbial silver ion-based paints are available to coat sheet metal to minimize mold growth in ductwork[3].

Contractors should provide detailed shop drawings and specifications for the building envelope, including exterior cladding, roofs, windows, walls, doors, and interfaces between the building features and the HVAC system components. For example, Figure 1 shows an exterior wall cavity prior to closing on a multi-story residential construction site. The wall cavity is clean, with no organic debris and minimal dust. This is especially important in places where you have condensation buildup; for example, around the package terminal air conditioning (PTAC) unit housing. PTAC units should be snugly fitted and sealed in the wall with weatherproof silicone sealant, and have flashing and drainage to the exterior for proper condensate pan overflow.

Figure 1. PTAC unit housing in multi-story residential building.

Strategies to protect HVAC systems during construction are broadly categorized into proper ventilation system design, quality construction methods and work practices, and adequate building commissioning procedures. Design should include easy access to HVAC components, which is essential for proper maintenance and inspection of HVAC systems. Access doors or panels must be provided for all components including ductwork, plenum walls, drain pans, upstream and downstream areas of filters and fan coil units, and terminal boxes [4]. Construction work practices must include proper sequencing of work to protect work-in-progress and to ensure that porous materials, such as fiberglass-lined duct, are installed after the roof structures are dried-in and the building envelope is intact. The time between material delivery and installation should be minimal. Contractors should place emphasis on protection of building materials delivered to and stored at the jobsite from water, dust and debris, and mold growth. Figure 2 demonstrates poor work practices as evidenced by water damage to stockpiled fiberglass duct wrap stored outdoors and exposed to ambient conditions and inclement weather.

Figure 2. Water-damaged fiberglass duct wrap stored outdoors.

Pre-construction planning should include implementation of weather protection plans in project schedules. For example, tenting of the building envelopes using polyethylene sheeting in building construction is a control strategy routinely used to protect exterior wall assemblies during damp, rainy seasons in the U.S. Pacific Northwest.

Because water availability is one of the most critical factors controlling microbial amplification in indoor environments, prompt correction and elimination of water intrusion/ moisture sources are imperative. Protecting HVAC system materials and components, and work-in-progress from water, moisture, construction dust and debris is critical to prevent microbial growth and degradation of indoor air. Figure 3 shows proper storage of an AHU in a large commercial building prior to installation, i.e., elevated above the concrete slab floor to protect from water intrusion and covered to shield from construction dust and debris. Figure 4 shows a 30-centimeter diameter branch entry opening to a duct near a supply drop, covered with black plastic, to protect the ductwork interior during construction. Equipment and material movement and a lack of adequate space on construction jobsites can also result in physical damage to HVAC system components. Stored materials and work-in-progress on HVAC systems should be inspected on a daily basis and safeguarded from physical damage.

Figure 3. Proper AHU storage – pre-installation.

Figure 4. Protected branch entry duct opening.

Proper location of outdoor air intakes (OAIs) and cooling towers are of special concern. The location of the OAI can significantly affect the nature of outdoor bioaerosols that enter a building. Rooftop OAIs are especially vulnerable to bioaerosol sources such as cooling towers, sanitary vents, building exhausts, and standing water. Cooling towers located close to or directly upwind of OAIs are potential bioaerosol sources. To minimize entrainment of cooling tower mist, it is recommended that OAIs and other building openings be located at least 7.5 meters and preferably 15 meters upwind of, and horizontally separated from, cooling towers [5]. Even OAI placement at this distance does not ensure that aerosols in the exhaust air / drift will not be entrained. Airflow patterns and prevailing wind direction are important factors affecting drift entrainment. Install drift eliminators on cooling towers to intercept water droplets where air is discharged to limit dissemination of bacteria, such as *Legionella*, from water-cooled heat transfer systems. The cooling tower shown in Figure 5 is constructed of materials that can be readily disinfected and is located in an area that is remote from building air intakes, and easy to inspect and maintain.

Figure 5. Cooling tower installation.

Building renovations performed without proper planning and design can also result in degradation of indoor air caused by moisture problems and subsequent mold growth. An indoor air quality study in the United States in 2001 found that some indoor air quality problems in office buildings are the result of contractor errors and omissions including inappropriate balancing and reassessment of HVAC systems during building renovation or modification [6].

Contractors should reduce exposure to liability by contract review, proactive risk transfer methods, and independent third-party construction oversight. Contracts should be carefully reviewed to verify that they: adequately protect the contractor from construction defects or negligence of subcontractors; specifically address the responsibility for repairs; and contain enforceable language providing for indemnification of damages. Contractors should document activities at certain critical stages of construction to establish proof of proper construction practices. Superintendents should take photographs of work-in-progress to document conditions during construction, for example, prior to closing ceiling plenums and wall cavities and covering work with interior finishes, furnishings and contents. Damaged materials should be properly marked and replaced during construction, as shown in Figure 6. Comprehensive field notes and inspection checklists should be retained on file for the project. Contractors should require subcontractors to provide documentation that materials and HVAC system components are installed per manufacturer's instructions and engineering design drawings. All of this documentation will be valuable in mitigating damages and associated costs. In addition, third-party consultants should be retained to perform independent peer review of the HVAC system design and to make inspections during construction. They should document HVAC system commissioning procedures and inspect the completed project prior to transfer to the owner.

Figure 6. Water-damaged duct riser – marked for removal.

DISCUSSION

Post-construction activities should include final cleaning of all interior finishes and functional testing of building mechanical systems. Protect the HVAC system from dust, dirt and water during construction and make certain it is clean afterwards. Cleaning is the final defense in managing indoor environmental quality and preventing microbial contamination. After the areas of source management and building operations have been addressed, cleaning is still necessary. The importance of this was demonstrated in a year-long study of cleaning effectiveness in a multi-use building without evident infrastructure problems. The routine use of high efficiency vacuum cleaners, damp dusting, and improved cleaning products – particularly in high traffic areas – along with attention to leaks and spills, resulted in meaningful decreases in particulate and microbial contamination [7].

Building commissioning procedures of the completed project should include quality assurance testing of the HVAC system to ensure that it is properly tested and balanced and functioning according to building design parameters. Procedures and methodologies for documenting and verifying the performance of HVAC systems according to design are published by the American Society of Heating, Refrigeration and Air Conditioning Engineers (ASHRAE) [8]. Replace pre-filters and filters on all air moving equipment in the HVAC system after construction is completed. Filters should be of the highest grade compatible with the HVAC system and the air handler fan – with a 50% to 70% dust spot efficiency rating. Ensure that complex computer-controlled systems for building ventilation have been properly programmed. Operate the HVAC system for 7 to 14 days to stabilize its operation prior to building occupancy.

In addition to these guidelines, testing the HVAC system for acceptance by the owner may include a microbial risk assessment performed on various HVAC system components most susceptible to contamination during construction – including supply air ductwork and plenums, heat exchangers, air washers and humidification devices, AHUs, filters, drain pans, and outdoor air intakes. The assessment should always be performed by a qualified environmental health professional, such as a Certified Industrial Hygienist (CIH), with experience in potential health implications of indoor contaminants, including microbial growth and a familiarity with commercial and residential HVAC systems. If needed, based upon the results of the microbial assessment, remedial action should be taken prior to occupancy of the building. The risk assessment should include a visual inspection of HVAC system components to ensure that they are clean and dry – with no signs of water intrusion, physical damage, or mold growth – and microbial sampling of a representative portion of the building and HVAC units. Procedures to verify cleanliness of the HVAC system proposed by the author should include:

- A visual inspection should be conducted to make certain HVAC system components are clean after construction with no residual dust or visible contamination. Test and balance the system per industry standards. Observations of airflow and pressure differentials should be made after system startup.

- Fungal spore samples should be collected pre-HVAC system operation. The system should then be turned on for 60 to 120 minutes to stabilize its operation, followed by the collection of post-HVAC system fungal spore samples from several random areas of the building. Pre-HVAC and post-HVAC samples should also be collected in areas of the building where the highest building occupant load or population density is expected. Air sampling is performed using a calibrated air sampling pump operating at 28.3 LPM. Fungal spore samples should be collected from the ambient indoor air and the outdoor air intake. One sample should be collected from the ambient indoor room air; another at a supply air diffuser; and another near the outdoor air intake. An additional outdoor sample should be taken at ground level outside the building for reference control purposes. Each sample should be collected for two minutes. The microbial samples should be analyzed by an Environmental Microbiology Accredited Laboratory using cultured methods or Quantitative Polymerase Chain Reaction (Q-PCR) analysis. Although more costly, Q-PCR analysis appears to be the most likely technology to be used in the future because it provides very rapid turnaround and greater accuracy, sensitivity, and precision in identifying microbial species present; but conventional techniques are also acceptable. Microbial air samples are interpreted by comparing the types, distribution and levels of fungal spores found in pre-HVAC system operation samples to post-HVAC system operation samples and to outdoor control areas. General guidelines for interpretation of fungal spore data specify that indoor levels of mold spores should be less than outdoors. The biodiversity of fungal spores indoors should also be similar to outdoors. The levels of mold spores and fungal genre in the post-HVAC samples should be less than and similar to those in the pre-HVAC samples.

- Sampling of cooling towers and domestic water supplies for the presence of *L. pneumophila* and other waterborne bacterial pathogens is also recommended. The location of the OAIs and air pathways within the building should be identified and evaluated to prevent aerosolization of *Legionella*-containing water droplets in the building. Water samples should be collected using sterile sampling containers with Sodium Thiosulfate preservative provided by an AIHA-accredited laboratory. Samples should be analyzed for the presence of *Legionella* using a combination of culture analysis and Deoxyribonucleic Acid (DNA) sequencing.

Third-party inspections should be performed by qualified professionals to review shop drawings and to inspect the integrity of the building envelope during and after construction – to identify any defects that could cause potential problems with water intrusion, moisture accumulation, mold growth or structural integrity. A systematic approach for addressing reported problems and customer complaints during the warranty period should be developed to help prevent small problems from becoming big. Educate the building owner on proper operation and maintenance of all building systems. Train the building owner's property management and building engineers/maintenance staff on preventive maintenance of the HVAC system; humidity control; ventilation of moisture producing processes; inspections and maintenance of the building envelope; and operation of the plumbing, heating, fire sprinkler and mechanical systems, including outside irrigation and landscaping. Train building maintenance staff in mold prevention methods for the new building after completion. Prompt attention to water intrusion should be emphasized with the owner and maintenance staff to prevent and minimize costly structural damage and mold growth, and to increase the life span of the building.

Air quality can be enhanced by properly designed, operated and maintained building ventilation systems. Fanger suggested that air quality be defined by the extent to which human requirements are met [9]. Sources of contaminants and the effectiveness of control measures, including HVAC systems, should continue to be evaluated to assess indoor air quality after building occupancy.

ACKNOWLEDGEMENT

The author wishes to express appreciation to Robert Reiser, Robert Gilmore, Bob Kallotte, and Bruce Ludke for their assistance in this presentation.

Cleaning initiation criteria for heating, ventilation and air conditioning (HVAC) systems in non-industrial buildings

Jacques Lavoie, Ali Bahloul, Yves Cloutier and Rodrigue Gravel

IRSST, 505 De Maisonneuve Blvd. West, Montreal, Quebec, Canada H3A 3C2

Corresponding email: Lavoie.Jacques@irsst.qc.ca

SUMMARY

The objectives of this study are to reproduce in the laboratory different levels of cleanliness in non-porous ducts of HVAC systems, to compare a new method for sampling surface dust in ducts with those methods cited in the literature, to compare the numerical evaluation method to the visual method, and to propose objective cleaning initiation criteria. For each of the simulated cleanliness conditions, a committee of specialists did a visual assessment based on a scale of 3, where level 1 meant normal, 2 meant above normal, and 3 meant serious. According to these assessments, the established initiation criteria correspond to 0.2 g/m² for the NADCA method, 0.3 g/m² for the ASPEC method, and 0,6 g/m² for the new method. These criteria are significantly different ($p \leq 0.05$). Any of the surface sampling methods can be used, insofar as the corresponding initiation criterion is used.

INTRODUCTION

Ventilation systems can be potential sources of pollutants due to the accumulation of dust in their air systems. Building managers have to deal with a wide range of proposals from specialized cleaning companies and have difficulty arriving at a decision because there is no recognized or standardized method for assessing a system's dust contamination. Ventilation systems must therefore be maintained under optimal cleanliness conditions. For the optimal maintenance of facilities, it is therefore important to be able to measure the amount of dust that has been deposited in ventilation networks. In all cases, an objective diagnosis avoids unnecessary network cleaning, or if decontamination is required, allows the cleaning methods to be chosen (1).

In the United States and Canada, the initiation of air system cleaning is currently based on visual inspection (2,3). However, these criteria are subjective and rather impractical for major cleaning work. In 2005, the American National Air Duct Cleaner Association (NADCA) published criteria for cleanliness acceptance after cleaning. However, these criteria are inadequate if you want to know when to start cleaning HVAC system networks (4). As well, these criteria can only be applied on rigid and non-porous surfaces, meaning smooth surfaces (e.g., metallic surfaces).

The Association pour la prévention et l'étude de la contamination (ASPEC, association for the prevention and study of contamination) in France, has published a guide on methods for keeping non-porous air systems for clean rooms and related controlled environments clean (1). In this guide, the initiation criteria for tertiary environments (office buildings) and the methods used are reported for different countries. Table 1 presents these criteria.

Table 1. Criteria for initiating cleaning of non-porous ducts (1)

Country	Cleaning initiation criterion based on surface density (g/m^2)	Cleaning initiation criterion based on thickness (µm)	Post-cleaning acceptance criterion (g/m^2)	Sampling method
United States (NADCA 2005)	-	-	0.075	Surface sampling on membrane at 15 L/min (open cassette)
Great Britain (1998)	Blowing : 1 Exhaust: 6	Blowing : 60 Extraction: 180	0.1	Surface sampling on membrane for at 15 L/min
Finland (1995)	Blowing 2 Exhaust: 5	-	-	Surface sampling on membrane at 15 L/min (sampling tube)
France (2004)	Blowing : 0.4 Exhaust: 6	-	0.1	Surface sampling on membrane at 15 L/min (sampling tube)

This table shows that the criteria are accompanied by different dust sampling methods, consequently making comparisons difficult. According to ASPEC, these methods can be applied only to rigid and non-porous ducts of sufficient dimensions, i.e., larger than 30 cm in diameter for round components; in addition, the ducts must be horizontal; and finally, the walls must be dry (1). Sampling must be done on a layer of dust distributed on the bottom surface, and not on an accumulation of dust (1). Furthermore, the sampling methods have some deficiencies, mainly the absorption of moisture from the air by the cellulose ester membranes, and the adhesion of dust on the walls of the cassettes and sampling tubes.

One method that would eliminate these two problems would involve weighing a complete sampling cassette such as the IOM cassette (SKC Inc. Eighty Four, PA, USA) equipped with a cellulose ester membrane. However, this surface sampling method has not yet been evaluated. We will compare this cassette with the sampling systems mentioned in the literature in order to choose the most accurate method.

The objective of this activity is therefore to propose a methodology for measuring the dust contamination of ducts in order to compare the numerical value to the value obtained from the visual evaluation corresponding to the limit value that determines the need for cleaning.

METHODOLOGY

The steps in this project are: to develop a dust contamination chamber and technique, to choose the most appropriate surface sampling method for dust, and to determine a limit concentration for initiating cleaning.

Development of the dust contamination chamber

A preliminary study undertaken during the summer of 2004 at the IRSST led to the development of a chamber for the laboratory simulation of dust contamination of ducts (5). Figure 1 presents a diagram of this chamber.

This chamber was designed with smooth and non-porous surfaces. It is also equipped with a PALAS RBG 1000 dust generator. The standard dust used is the dust recommended by ASHRAE (5). It consists of (6):

- 72% fine test dust (Arizona road dust).
- 23% carbon powder (Molocco black).
- 5% No. 7 cotton linters.

The work undertaken by the IRSST in 2004 has shown that with this chamber, known and uniform concentrations of dusts can be obtained (5).

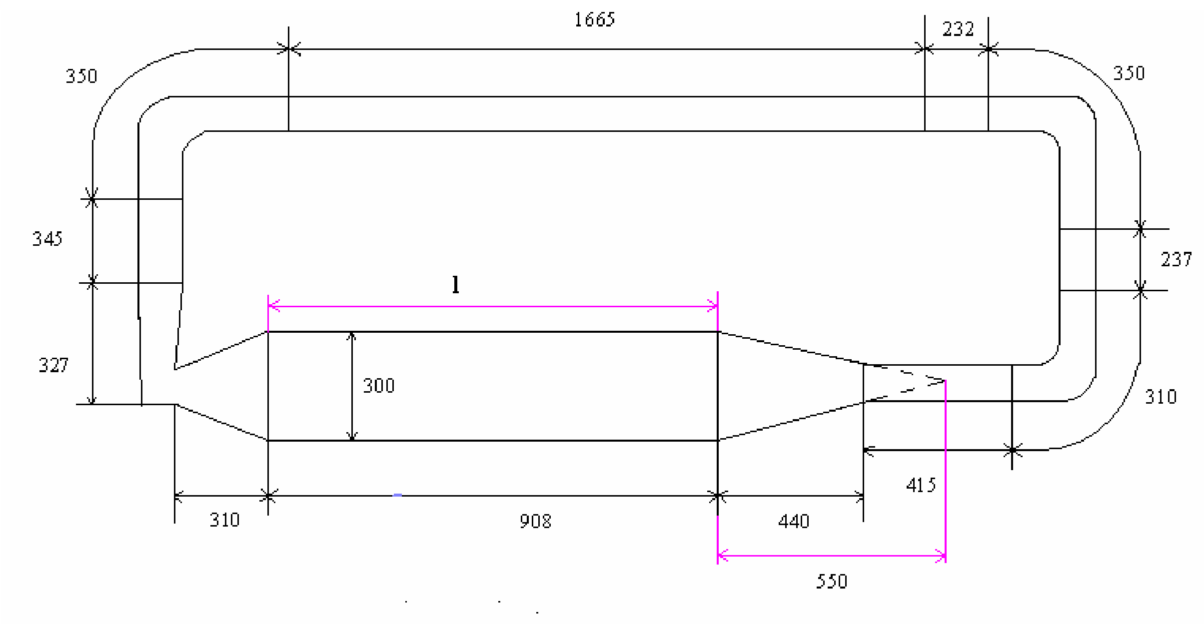

Figure 1. Diagram of the actual dust chamber (in mm)

However, to optimize this system, different improvements will have to be made in order to improve its performance. The following modifications will be made to the system (7,8):

- maximum extension of the sections
- elimination of asperities and interior joints
- replacement of the fan in order to eliminate leaks

Choice of sampling methods

Twelve control substrates (aluminum filters 47 mm in diameter, MSP Corp., Shoreview, MN, USA) uniformly distributed over the entire surface of the base were used for each dust contamination test. Figure 2 presents their location on the plate.

Three sampling methods were chosen for the dust contamination chamber. The first principle was the NADCA principle (4). It involves vaccuming dust over a predefined 100 cm² duct surface from a template 0.381 mm thick and of collecting it on a preweighed 0.8 µm cellulose ester membrane in an open cassette 37 mm in diameter (SKC Inc. Eighty Four, PA, USA), in order to determine the difference in surface density (Figure 3).

Figure 2. Distribution of control substrates

Figure 3. NADCA method

The second sampling method was the ASPEC method (1). It consists of a 0.8-µm pore size cellulose ester membrane in a 37-mm closed cassette (SKC Inc. Eighty Four, PA, USA) connected to a beveled tube. The aspirated duct surface is 50 cm^2. Figure 4 presents this method.

The third method is the method recommended by the IRSST. It uses an IOM cassette (SKC Inc. Eighty Four, PA, USA). In the latter, the entire 25-mm-diameter cassette including a 0.8-µm pore size polyvinyl chloride membrane is weighed (SKC Inc. Eighty Four, PA, USA). This avoids underestimations of weight. To be able to compare this method to the NADCA method, the cassette is slipped onto a template with a distance of 1.5 mm between the sampling cassette and the aspirated surface. Figure 5 presents this latter method. All the sampling flows were 15 L/min.

Figure 4. ASPEC method

Figure 5. IRSST method

Experimental plan

9 samples (3 per method) were collected each time in the dust chamber in order to compare the methods (paired Student's t-tests over a bilateral distribution). In total, 22 different tests were compiled. The tests were carried out on the natural logarithms due to the log-normal distributions of the data. Mulhausen and Damiano (1998) estimated that 6 to 10 measurements are required to suitably estimate a mean and a standard deviation (9). These tests were conducted by varying the fan operating time and the amount of dust in the generator. The average velocity of the air in the dust contamination chamber, measured with a hot-wire anemometer (TSI Inc., model 8384, Shoreview, MN, USA), was 0.59 (±0.15) m/sec (calculated using 50 measurement points). The precision of this instrument is ±3%. Weighing was done using the standard IRSST method (10) whose minimum reported value is 25 µg.

Visual inspection

In parallel with this dust sampling, a committee of experts from different disciplines related to air quality did a subjective evaluation based on visual assessment of the dust contamination. In addition to the four people in charge of this activity, this committee consisted of four other specialists (chemist, certified hygienist, building engineer and microbiologist), all from the IRSST. This assessment was based on direct visualization of the deposits with concentrations unknown to the committee. It involved a 3-level scale, where level 1 or normal, is characterized by clean ducts or ducts with a thin uniform layer of dust; level 2 or above normal, is characterized by a uniform layer and localized accumulations; and level 3 or serious, is characterized by significant accumulations (11,12). Level 2 corresponds to the limit concentration (or concentration range) for initiating cleaning.

RESULTS AND DISCUSSION

Initiation criterion

Table 3 presents the results of the corrected weighings of the control substrates. The minimum value used for concentration calculations is the method's reported minimum value, 25 µg divided by the square root of 2 (13,14).

Table 2. Corrected weighings[1] (mg) for the aluminum control substrates for the 22 tests

1st third of the base	2nd third of the base	3rd third of the base
0.004	0.020	0.111
0.004	0.020	0.111
36.375	34.661	30.895
5.509	5.329	5.883
12.545	11.976	10.053
3.625	3.501	3.218
20.579	19.366	17.902
8.510	8.410	7.342
4.825	4.939	4.857
3.228	3.273	3.289
2.367	2.749	2.775
5.576	5.995	5.703
6.464	6.551	6.307
12.979	12.913	11.773
24.551	23.127	21.096
5.535	5.765	5.024
2.546	2.882	2.780
7.368	7.183	7.235
9.360	9.158	8.072
5.399	5.412	5.150
28.045	25.659	23.138
31.430	27.336	25.362

[1]: Each of these values represents an average of six weighings

The paired Student's "t" comparison tests on the normal logarithms between the first third and second third ($p \leq 0.185$), between the first third and third third ($p \leq 0.279$), and between the second third and third third ($p \leq 0.393$) are all non-significant. The deposits are therefore considered as uniform along the entire base.

Table 3 presents the comparisons of the average votes of the committee of experts in relation to the average weighings for each of the methods evaluated, including the control substrates. Therefore, for an average vote of 1.6/3, or approaching level 2 which is characterized by a uniform layer and localized accumulations, the corresponding values are 0.2 g/m² for the NADCA method, 0.3 g/m² for the ASPEC method, and 0.6 g/m² for the IRSST method. All these methods are significantly different ($p \leq 0.05$) from one another. Despite the fact that there is generally a significant difference between the weighings for the control substrates and the IRSST method, the same value is obtained for these two methods, or 0.6 g/m² for a vote of 1.6.

Table 3. Results of the evaluation of the 3 methods (g/m²) in relation to the vote of the committee of experts

Substrate	IOM (IRSST)	ASPEC	NADCA	Committee's vote (n=6)
0.264	0.402	0.075	0.069	1.0
0.274	0.235	0.086	0.066	1.0
0.326	0.205	0.131	0.031	1.3
0.346	0.110	0.114	0.073	1.1
0.488	0.151	0.244	0.126	1.2
0.538	0.411	0.226	0.146	1.7
0.545	0.517	0.289	0.238	1.4
0.558	0.423	0.187	0.186	1.0
0.575	0.624	0.286	0.200	1.6
0.647	0.414	0.244	0.162	1.8
0.727	0.612	0.343	0.171	2.1
0.811	0.628	0.364	0.234	1.7
0.885	0.569	0.430	0.325	1.9
1.152	1.077	0.786	0.494	1.3
1.257	0.970	0.797	0.490	2.6
1.928	1.479	1.222	1.087	2.3
2.294	1.530	1.292	1.338	2.8
2.557	1.382	1.576	1.550	2.9
2.805	2.407	1.174	1.607	2.6
3.399	3.136	2.470	1.923	2.0

CONCLUSION

We can therefore state that the numerical criteria for initiating cleaning of smooth non-porous ducts were determined from a laboratory study. Clearly, the method recommended by the IRSST requires some adjustments before being used commercially. In addition, the method's conditions of application will have to be determined for existing smooth non-porous ducts from a ventilation system and with the actual dust from occupied buildings.

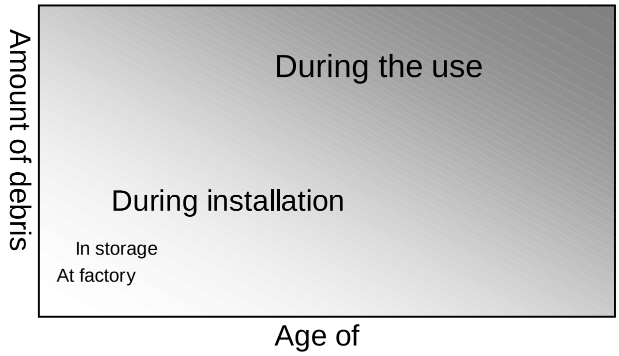
SUMMARY

The published REHVA guidebook provides comprehensive up-to-date information about design features, criteria for cleanliness, inspection and cleaning instructions of ventilation systems. The guidebook is aimed at practitioners, designers and those who are setting criteria for cleanliness of ventilation systems. The design practice includes guides to construct a clean ventilation system and which cleanliness can be maintained during whole lifetime of the building. This provides to take account the cleanliness in building construction and installation processes as well as demands for proper maintenance actions including the functional checks and cleaning. A pathway for verification of the cleanliness and measuring methods are presented. Training practices for inspection and maintenance personnel in different countries are also introduced. The content of the guidebook is a consensus of the state of art information reviewed and discussed with the European specialists representing practice and science.

INTRODUCTION

Dust and other contaminants accumulate on the surfaces of the ventilation system during construction and operation and it is revealed that the ventilation systems itself may be potential sources of pollutants in buildings. Dusty surfaces may increase energy consumption, decrease air flow rate and cause malfunction problems to ventilation system. Additionally, contamination in the supply air duct may cause negative health impacts to occupants. Thus, the ventilation system has to be inspected regularly and cleaned whenever the inspection has revealed that the amount of accumulated dust has exceeded the acceptable limit. Ventilation systems, which convey very dusty and/or fire hazardous contaminants must be cleaned frequently.

During the last few years there has been increasing awareness of the importance of cleanliness in air ducts. Dust accumulation in newly installed air ducts was found to be high when attention had not been paid to the cleanliness of the ducts during construction. Dust and other impurities in new ducts originate particularly from installation work and when the particle concentration is high at the building site. After the construction process, pollutants accumulate on duct surfaces during the operation of the ventilation system. During operation, the main causes of dust accumulation in the supply air duct are polluted out-door air and inadequate maintenance of the filters (Figure 1). Highly efficient filtration protects supply air ducts during operation of the system and thus can increase the length of the intervals between cleaning.



(a)

(b)

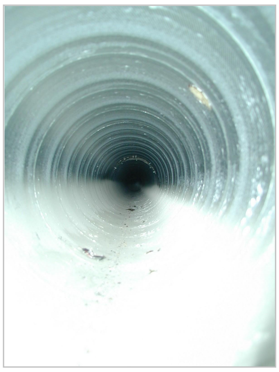


Figure 1. (a) Principle of dust accumulation on ventilation system after the components are manufactured. (b) Typical dust accumulation on round air duct.

The guidebook gathers the scientific and practical information in a way that it is easy to utilize during the many phases of the work towards cleaner ventilation systems. These guidelines will give guidance to practitioners on how to take the cleanliness aspects properly into account in design, construction, commissioning and operation.

CRITERIA FOR CLEANLINESS

In some countries official guidelines are given for cleanliness criteria for ventilation systems. However, most of these guidelines focus on fire safety and seek to minimise the amount of flammable material in ducts, especially in exhaust-air ducts. In only a few countries cleanliness criteria are specified for hygienic reasons. Different are given for new and existing systems. E.g. European standard gives hygiene requirements and recommendations for air-handling units (AHU), different components and sections of AHUs [1].

The guideline for **new systems** focuses on design and installations instructions and the demands for cleanliness of components. It aims that the new ventilation system is clean after installation and building construction as well as the system can be kept clean during the whole lifetime of the building. Limit values for dust accumulation in newly installed air ducts and systems are presented in Table 1. The production and installation of components for new ventilation systems is very important. Manufacture of sheet metal components includes critical phases because lubrication is needed between a tool and the metal sheet. Oil residues may serve as nutrients for micro-organisms which produce odour. During operation a surface with oil residues tends to accumulate dust faster, and the resulting dust layer is sticky and difficult to remove. In a system it is important to use only equipment and components which do not emit harmful substances, fibres or odours.

The following three major contaminants from all components which may reduce IAQ should be kept to minimum:

- residues of lubricants
- dust accumulated during manufacture and installation, or debris from construction
- micro organisms, particularly when toxic species are present and conditions during installation and storage are favourable for their survival and growth.

Table 1. Limit values for dust accumulation in newly installed air ducts and air-handling systems.

Country	Application	Category	Prior to clean ducts	Evaluating method	Reference
Finland	Supply	P1 [a] P2 [a]	1 g/m² 2.5 g/m²	Visual [d] or Vacuum test [e]	[2]
Germany	General	High [b] Middle [b] Basic [b]	Visually unclean Visually unclean Heavy dirt	Visual [f] Visual [f] Visual [f]	[3]
Norway	Supply	Class A [c] Class B [c]	3% 5%	Optical [g] Optical [g]	[4]
Sweden	Supply	–	1 g/m²	Not mentioned [h]	[5]
USA	General	–	Visually unclean	Visual [i]	[6]

Categories:
[a] cleanliness categories, [b] cleanliness levels, [c] cleanliness class levels
Evaluating methods:
[d] Visual inspection with a reference scale as the primary method [7]
[e] Vacuum test (FiSIAQ -test 2) [8]
[f] Requirements for specific categories (A and B) and training to inspectors before they are authorised to inspection work [9]
[g] Optical method with gelatine tapes [10]
[h] Requirements for specific qualification (classes K and N) and experience to inspectors before they are authorised to inspection work
[i] Requirements for qualification and experience of inspectors before they are authorised to inspection work

More detailed requirements for single components and ducts are given in a Finnish guideline [2]. Limit value for oil residues in ducts and the components manufactured by cutting, bending or jointing the limit value is 0.05 g/m^2, for parts that needs deep drawn the limit is 0.3 g/m^2. The amount of surface dust shall not exceed 0.5 g/m^2.

The emissions of new filters are controlled according to odour emissions and it is stated that low polluting new filters shall be used. Naturally, the efficiency of filter is most important feature and it shall be tested according to [11].

Control of cleanliness is a part of maintenance of **existing ventilation systems**. The majority of national maintenance guidelines do not include cleanliness inspections, rather they presents intervals for checking and maintenance. The hygiene of moist surfaces, such as humidifiers and cooling coils, needs to control to avoid or detect microbial contamination of the surfaces or water reservoirs. Criteria for the quality of humidifier water are specified, e. g., in the German guideline [12].

Cleanliness target values for existing air ducts are presented in Table 2. In the guidebook gives more detailed cleanliness control instructions for filters, heating and cooling coils, humidifiers and cooling towers.

RECOMMENDED DESIGN PRACTICES

Ventilation system design should be a "design for lifetime" rather than a "design for construction". This means that the cleanliness criteria should be defined and documented so that the maintenance of the system allows maintaining of cleanliness during the whole lifetime of the building.

Table 2. Current target values on the hygiene of air ducts presented as amount of accumulated dust.

Country	Application	Prior to clean ducts	After cleaning	Evaluation method	Reference
USA	(1)		0.1 g/m²	Filter with vacuum	[13]
Great Britain	Supply Air	1 g/m² 60 µm	0.1 g/m²	Filter with vacuum	[14]
	Recirculation Air	1 g/m² 60 µm		Filter with vacuum	
	Exhaust Air	6 g/m² 180 µm		Filter with vacuum	
Sweden	Supply Air	1 g/m²		not mentioned	[5]
Japan	Supply Air		1 g/m²	Wiping with cloth	[15]
Finland	Supply Air	2g/m² 5 g/m²		Scrape/Filter with vacuum	[2]
Germany	general	20 g/m²	10 g/m²	Scrape/Filter with vacuum	[9]

For new buildings the required standards for the indoor air quality (IAQ) should be high. This means that all designers have to consider the IAQ in their design solutions. In aiming at high IAQ the ventilation system, the designer should plan sufficient air-flow rates, adequate cleaning of the supply air, i.e. filtration, and ensure the system is constructed using clean components and a clean installation technique.

Design should also include sufficient guidance and instructions for

- assessment of cleanliness and need for cleaning
- default cleaning intervals
- cleaning method
- checking after cleaning, both for cleanliness and system functioning.

Guidebook presents design principles for different parts in ventilation systems. For example space for maintenance needs to be taken account in design of lay out in AHU room, Figure 2.

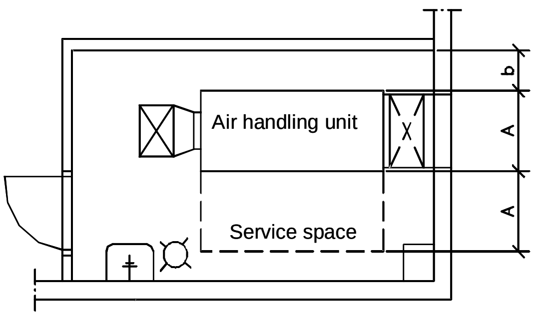

Figure 2. Sufficient space is required for maintenance access

INSTALLING CLEAN VENTILATION SYSTEMS

Ventilation systems are exposed to dust and debris during some phases of the system's history. The building process and installation are the most critical phases when dust from the building construction is likely to contaminate the system. Prevention of dust entering the partially built ventilation system is an effective technique for ensuring a clean system in the new building.

The best results are obtained by implementing the following actions:

- install the system during construction phases when no dust producing work is being carried out
- store uninstalled ducts and components under a cover or in a shed to prevent dust and debris from entering the components (Figure 3a)
- remove the packing materials or coverings just before installation
- check that the environment remains clean during the installation work
- cap or recap the installed openings, duct ends or airways during breaks in the installation
- only use cutting methods that do not produce metal shavings or powder
- where contamination has occurred, clean before closing the system
- check the cleanliness before commissioning of the system.

According to field studies the protection methods to keep the system clean during the installation process are very advantageous. In figure 3(b) the amount of accumulated dust is presented after each construction phase; P1 refer to technique in which attention is paid on the cleanliness during construction process and P2 refers to the method in which the installation is carried out without special care. At its best the amount of accumulated dust found in the duct work has been around the detection limits of the measuring methods.

(a) 

(b) 
Figure 3. (a) An example of protection of air ducts during storage at building site (left).
(b) Effect of different installation processes on dust accumulation on ventilation ducts. Class P1 and P2 are cleanliness classes expressed in [2].

VERIFICATION OF CLEANLINESS

In newly installed ventilation systems, the verification of cleanliness is required during the commissioning process to confirm that the building contractor has built a system that is as clean as the building owner has demanded. In existing buildings, the periodic inspection of cleanliness is most often done to evaluate the need for cleaning. The verification process is shown in the schematic of Figure 4(a).

The evaluation of cleanliness begins with an inspection plan. The content of the plan depends on the size and design features of the system. Firstly the evaluation is done visually, aided by a source of light, possibly also using a mirror and some tools. The level of cleanliness is compared against a cleanliness scale (Figure 4(b)) which contains six illustrations showing different amounts of dust accumulation.

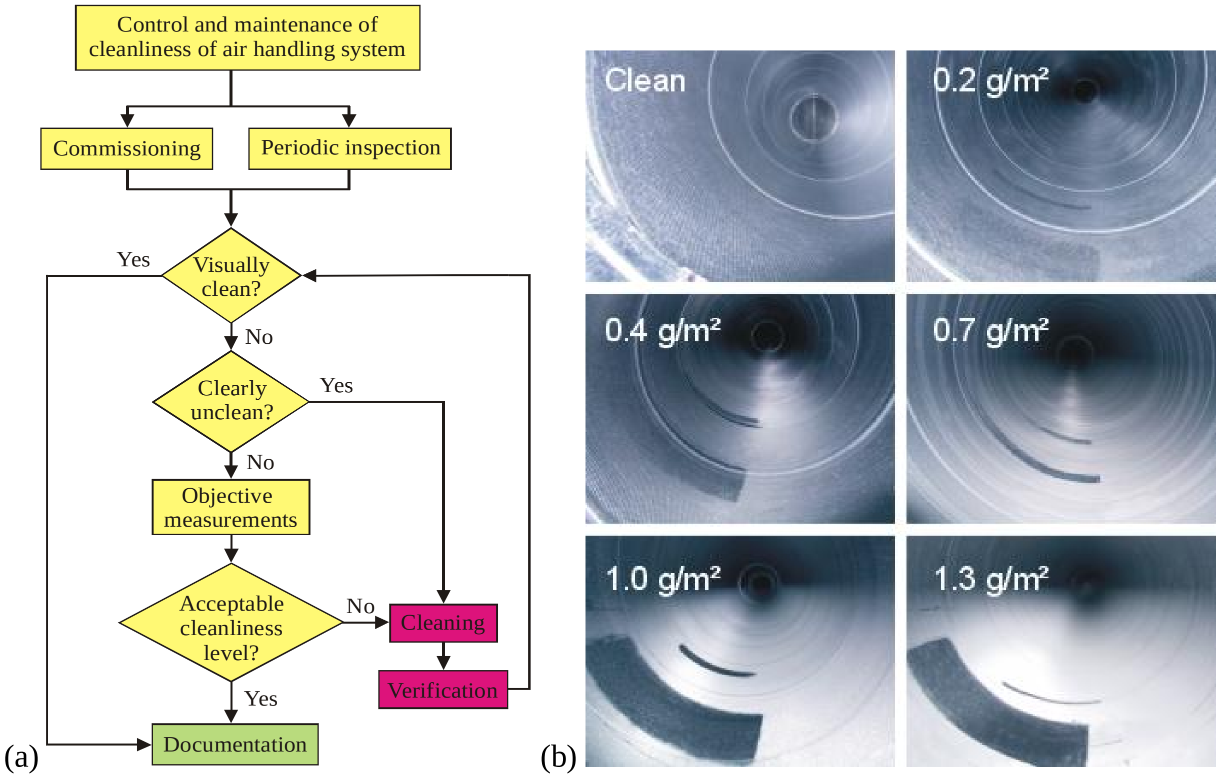

Figure 4 (a) A pathway for verification of cleanliness. (b) A reference scale for visual inspection of new installations [7].

If the contractor, duct cleaner or building owner is not satisfied with the results of the visual inspection, a more objective method of assessment should be used; this is carried out by collecting and weighing the dust deposited on a known area of the duct surface. For round ducts the dust is collected from the lower half or side quarter (as seen in figure 4(b)), and in rectangular air ducts from the bottom of the duct.

During the sampling notes from visual observations shall be done and also photographs e.g. with digital camera will aid the reporting and decision making if the system shall be cleaned or not. Finally, the results of the evaluation should be documented, with photographic evidence.

Different parameters or contaminants need different methods. Several methods for dust deposits are developed; vacuum sampling with loosening the dust by scraping is recommended in the guidebook. Microbial contamination on surfaces is useful to sample by swiping technique followed by cultivation of the sample. The microbial concentration in water samples are analyzed with the cultivation techniques as used in water hygiene control.

CLEANING OF VENTILATION SYSTEMS

The ventilation system should be cleaned according to a cleaning plan. The plan consists of a selection of methods suitable for the different components and surface materials. The methods should be selected so as to avoid damage to surfaces and components being cleaned.

A basic distinction is made between dry and wet cleaning. Compressed air cleaning, mechanical brushing, hand vacuuming are examples of dry cleaning methods. Compressed air is used e.g. for cleaning narrow gaps, e.g. between the fins of heat exchangers, or for irregular surfaces of other parts of ventilation systems. Mechanical brushing with a vacuum technique to remove the loosened dust is the most common cleaning method for spiral seamed ducts. With proper equipment the mechanical dry cleaning method is an effective technique to remove loose dry dust from the surface of air ducts (Figure 6).

Hand vacuuming is suitable for small areas like filter banks or the surfaces of silencers.

(a) 
(b) 

Figure 6. (a) A schematic picture of mechanical brushing with a vacuum collector. (b) Duct cleaning with mechanical brushing.

Wet cleaning methods are used, for example, for cleaning terminal devices after they have been removed from the duct work. Wet cleaning methods can also be used for the cleaning of heat recovery units if they are installed in a location where water can be drained from the air handling unit.

Cleaning robots are also useful in both in round and rectangular air ducts. The robots are usually equipped with a camera which provides an opportunity to see the progress of the cleaning work.

EDUCATION TO MAINTAIN CLEANLINESS

Guidebook gives a brief introduction to the education programs for hygiene inspections and maintenance of ventilation systems. However, as training procedures and legislation vary from country to country it is difficult to harmonize training practices. As training is imperative it is important to focus on local codes and guidelines, although an international training programme would be beneficial.

Another REHVA Guidebook “Hygiene Requirements for air-conditioning systems and units” presents an example of a training system established in Germany, Austria and Switzerland. EVHA guidebook states the training demands from point of view of cleaning professionals.

RELATIONSHIPS TO OTHER GUIDEBOOKS AND STANDARDS

The REHVA guidebook (nr8) is not an official guideline or regulation; but recommends the best proven practices for maintaining hygienic and clean ventilation systems. However, this guidebook does present some recommended minimum or maximum values for different parameters, such as default values. National regulations, which may require more stringent values should always be followed. The guidebook is useful for practitioners who like to follow the recent international practices. It offers a wide approach to the factors affecting indoor air quality and is aiming to conform to the European standards of HVAC maintenance. Standard EN 12097 gives requirements for ductwork design and construction in order to ensure the cleanability of the system, focusing on the size and location of access openings.

The other REHVA guidebook "Hygiene requirements for ventilation and air conditioning systems and units" (nr 9) goes in more detail to hygiene and health issues of the systems and components. The European Ventilation Hygiene Association guidebooks "EVHA Guide to cleaning and hygiene management of ventilation systems" and "EVHA Good practice document for grease extract cleaning" are targeted to cleaners.

SUMMARY

Man made mineral fibers (MMMFs) that can cause irritation in upper respiratory tract, eyes and skin, can be emitted to indoor air from the HVAC system. A Finnish project was set up to measure fiber emissions and to develop design and materials of the HVAC systems to improve indoor air quality. Within the project laboratory tests and field measurements were carried out.

As a result, new methods of testing the emission rates of the MMMFs from HVAC-components have been developed. With these methods HVAC-components can be classified within the Finnish Indoor Air Classification. For instance, in the vibration test the limit value will be 10 fibers/m^3.

Also, there were differences between fiber emissions in the studied buildings. The fiber concentrations (length > 20 µm) in the supply air ranged between 0.01 – 85 fibers/m^3. The building with the highest emissions had also many workers suffering from respiratory and skin symptoms.

INTRODUCTION

Man made mineral fibers (MMMFs) that can cause irritation in upper respiratory tract, eyes and skin, can be emitted to indoor air from the HVAC system. A Finnish project "Particle discharges of air-conditioning systems: health risks, measurement and product development" was set up to measure fiber emissions and to develop design and materials of the HVAC components to improve indoor air quality. This was implemented by measuring fiber emissions and exposures in buildings and by emission tests in laboratory. Also the sampling and analytical methods were developed and the limit values of fiber emissions were specified.

Preliminary results of the projects have been introduced in Clima2005-conference in Lausanne [1], [2]. This paper deals with the final results.

METHODS

Laboratory measurements

In the laboratory tests fiber emissions from HVAC-components (round silencers) were examined by several methods. The components were sent to VTT by the HVAC-companies that participated in the project. In every silencer the fiberglass cloth and perforated sheet metal prevented the emission of fibers (glass or rock wool) from the attenuation material.

Fiber emissions were measured in accordance with the Finnish Classification of Indoor Climate 2000 [3].

The product to be examined was installed as a part of the test-duct (ϕ160 mm). The other parts were the adjustable fan, HEPA-filter, flow measuring device and polypropylene filter cloth, Figure 1. The cloth sampled all the fibers that emitted from the HVAC-component.

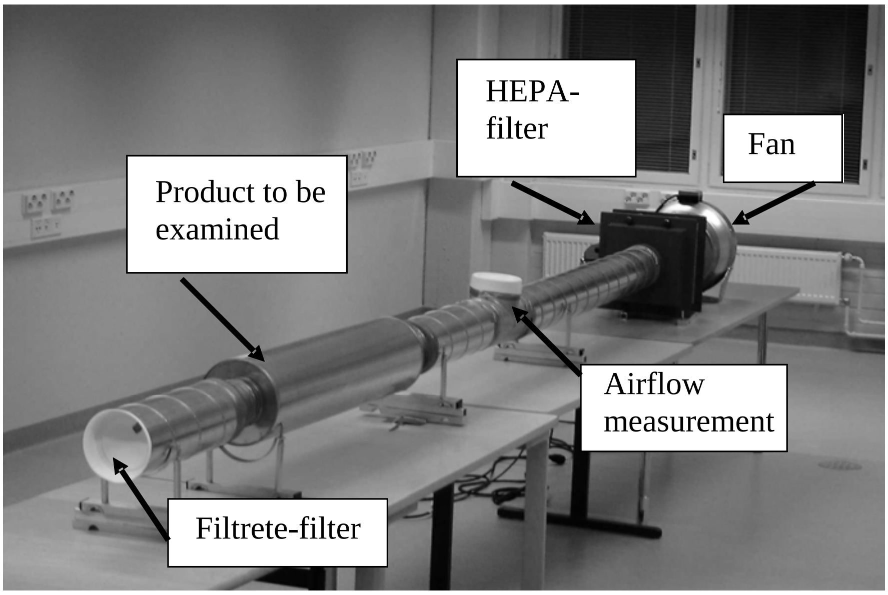

Figure 1. The measuring device for mineral fiber emissions (airflow flushing test).

As the filter cloth had been placed, the first measuring period was the initial flushing of 0.5 h. This was carried out to ensure that eventual fibers from the manufacture, transportation and storage do not have an effect on the actual tests. The airflow rate during the initial flushing was 50 dm^3/s. After this initial flushing the cloth was changed for the actual tests of several methods.

The airflow flushing tests lasted 1 h and 24 h. After each test the filter cloth was changed. The airflow rate during the actual tests was 80 dm^3/s. As the diameter of the test duct was 160 mm, the air velocity in the duct was about 4 m/s.

Besides, the emissions of fibers were measured by pressure shock of about 100 Pa. This was carried out by turning the damper in the test-duct from open to closed position in turn during 5 minutes. Every turn lasted about 5 s. The airflow rate during the tests was 80 dm^3/s.

Other tests were a vibration test of 1 hour and a cleanliness or brushing test of 5 minutes. The airflow rate during both tests was 80 dm^3/s.

In the vibration test the round silencer to be tested was installed on a carrier that caused a frequency of 25 – 35 Hz (amplitude about 5 cm) on the silencer, Figure 2.

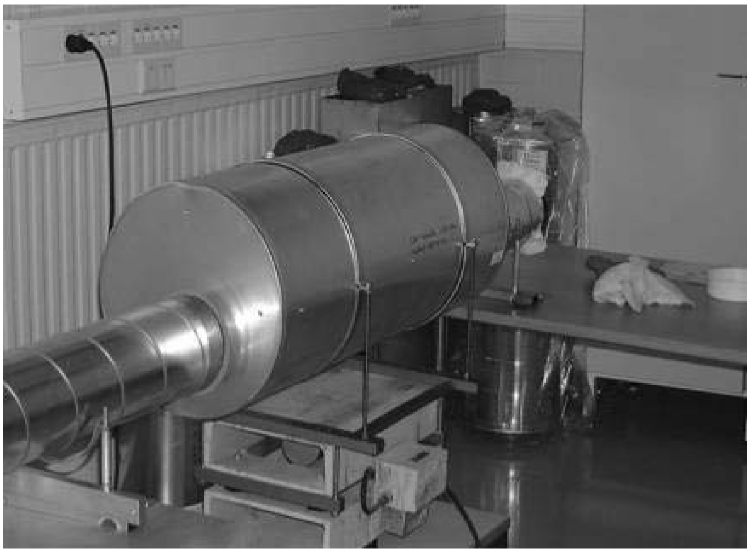

Figure 2. Round silencer on the carrier for the vibration test.

In the cleaning or brushing test the cleaning brush was pushed back and forth 10 times in the test duct and the silencer, Figure 3. A drilling machine was used to rotate the brush. The brushing lasted 5 minutes. After that an airflow flushing test was performed during 24 hours. The airflow rate during these tests was again 80 dm^3/s.

Figure 3. The measuring device for the cleaning or brushing test.

The samples were prepared for fiber (length > 20 μm) counting with polarization light microscope equipped with phase contrast optics (magnification 100X). The analyses were made in the Finnish Institute of Occupational Health. A new analytical method has been developed, where organic polypropylene fibers and inorganic glass or rock wool fibers can be separated. The results were given as fibers/cm^2 on the polypropylene filter.

The concentration of the fibers in the airflow can be calculated by Equation 1.

$$C_V = \frac{C_A \times A}{q_V \times T}, \qquad (1)$$

where C_V is the concentration of fibers in the airflow [fibers/m^3], C_A is the accumulation of fibers on the polypropylene filter [fibers/m^2], A is the cross-sectional area of the polypropylene filter (or the duct) [m^2], q_V is the airflow rate [m^3/s] and T is the measuring time [s].

Field measurements

MMMF emission from the ventilation equipments was surveyed in 10 buildings: one school, one day-care centre, one library, one community centre and six office buildings. Preliminary samples had shown that settled dust in every building contained MMMFs. In some of the buildings people were known to have prolonged sick-building symptoms, the cause of which was suspected to be MMMFs. Some buildings were quite new without excessive irritation symptoms among occupants. In each building, two to four rooms were selected for the fiber measurements in supply air and in settled dust. During preliminary visit selected surfaces were cleaned before the sampling of settled dust. The studied buildings had mechanical supply and exhaust ventilation systems. Ventilation rates were in accordance with The National Building Code of Finland.

Fiber emissions from HVAC-components were surveyed by measuring the MMMF concentration in supply air. As in the laboratory tests, samples were collected on a polypropylene filter cloth (3M Filtrete™). Now the cloth was installed on the supply air terminal device with tape, Figure 4. Air flow rate was measured after the installation. The sampling time was 2 - 4 days.

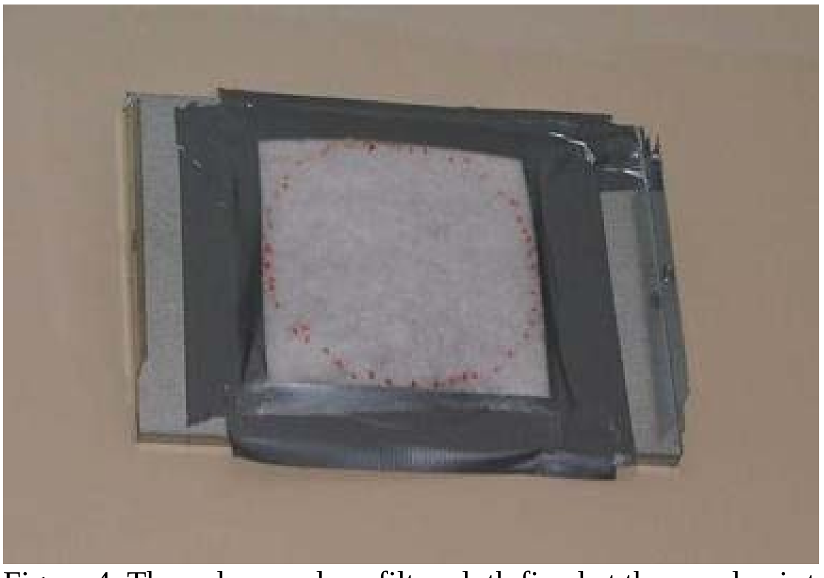

Figure 4. The polypropylene filter cloth fixed at the supply air terminal device.

Settled dust samples were collected with special tape (BM-Dustlifters®, tape area 14 cm^2), which was pressed against the surface (desks, shelves, supply air terminal devices). MMMFs (length >20 μm) were counted with a stereomicroscope (magnification 80-100X). The results were given as MMMF/cm^2.

In addition, the composition and origin of the dust collected from the ducts and indoor air were determined by electron microscope. Also the structure, functioning, materials and cleanliness of the ventilation equipment were examined in each building.

RESULTS

Laboratory measurements

Results of the airflow flushing test of 24 hours in Figure 5 reveals the difference in fiber emissions between various silencer types.

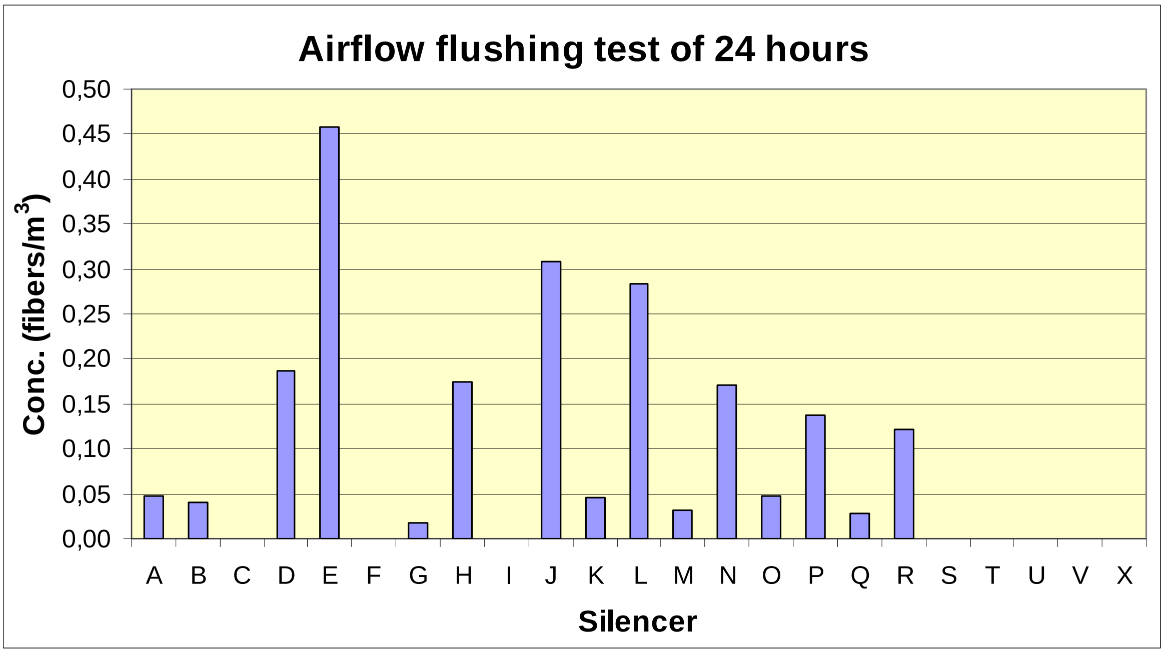

Figure 5. An example of the results that reveals the difference between various silencers.

In Figure 6 all results are collected and average fiber concentration in each tests are highlighted.

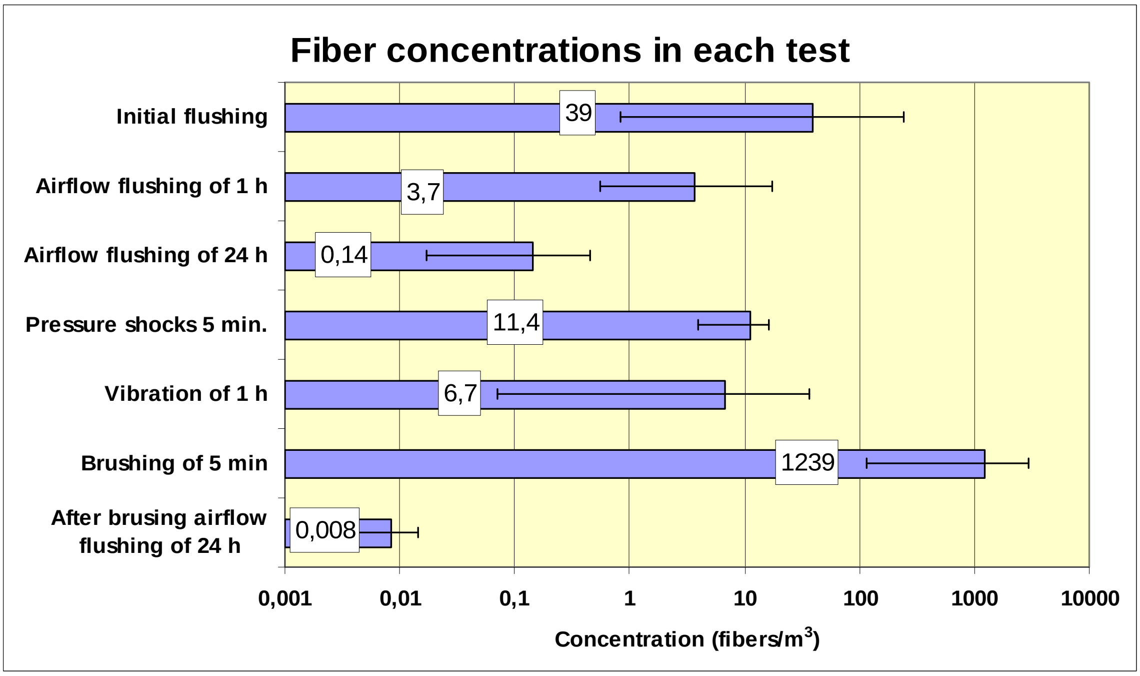

Figure 6. Fiber concentrations of different test methods. The averages and variations of the results are seen in the columns.

According to Figure 6 the highest fiber concentrations during the initial flushing were about 1000 times as much as the lowest value during the airflow flushing of 1 h test. In the airflow flushing of 24 h the range of fiber concentration was between 0.02 – 0.46 fibers/m^3. Highest fiber concentrations were during the brushing tests, over 1000 fibers/m^3. However, during the airflow flushing tests of 24 after the brushing tests, concentrations were again less than 0.01 fibers/m^3.

Field measurements

The concentrations of MMMF in supply air and in settled dust of ten studied buildings are presented in Table 1.

Table 1. MMMF (length > 20 µm) concentrations in the supply air and surface fiber density (during 14 days).

Building	Number of samples (conc. / density)	MMMF concentration (fibers/m^3)	MMMF density (fibers/cm^2)
School	9 / 7	0.3 – 1.8	
Office A	3 / 5	<0.07	<0.1 – 0.2
Office B	5 / 7	<0.06	<0.1 – 0.1
Office C	16 / 3	0.2 – 85	0.1 – 2.6
Office D	2 / 4	0.1 – 0.3	<0.1
Library	2 / 6	0.7 – 1.2	<0.1 – 0.3
Office E	3 / 9	0.03 – 0.12	0.1 – 1.1
Day-care centre	3 / 5	0.1 – 0.4	0.2 – 0.4
Community centre	3 / 3	0.01 – 0.10	0.1 – 0.5
Office F	3 / 4	6.6 – 10.1	0.2 – 0.7

The fiber concentrations (length > 20 µm) ranged between 0.01 – 85 fibers/m^3. Concentrations higher than 1 fiber/m^3 were measured in four buildings.

The surface fiber densities (length > 20 µm) during 14 days ranged between <0.1 – 2.6 fibers/cm^2. In several surface samples, the density exceeded the value of 0.2 fibers/cm^2. The detection limit is 0.1 fibers/cm^2.

The emitted dust composed mainly of various mineral particles, soot and organic material.

DISCUSSION

In laboratory the fiber concentrations in airflow flushing tests of 24 h ranged between 0.02 - 0.46 fibers/m^3. However, one must remember that only fibers that are longer than 20 µm have been taken into account. Therefore these concentration values are not comparable with the present limit value of 0.01 fibers/cm^3 or 10000 fibers/m^3 presented in the Finnish Classification of Indoor Climate 2000 [3]. This limit value originated from the clearance value of asbestos fiber measurement after asbestos removal and it contains all respirable fibers.

In conclusion, a new method of testing and analyzing the concentration of MMMFs from HVAC-components has been developed. With this method HVAC-components can be classified within the Finnish Classification of Indoor Climate. Within this project the limit values of fibers will be updated as

- 10 fibers/m^3 in vibration test
- 0.1 fibers/m^3 in airflow flushing of 24 h test after the brushing.

With these values about 90 % of sound dampers that were examined in the project can be considered as acceptable.

In the studied buildings fiber concentrations of supply air were mainly under 1 fiber/m^3. Surface fiber densities during 14 days were up to 2.6 fibers/cm^2. The sound dampers of ventilation equipment were one reason to elevated fiber emissions in the studied buildings. Workers suffered from airway and skin symptoms in the building where the highest fiber concentrations of supply air were detected. In many rooms the surface fiber density exceeded the recommended value 0.2 fibers/cm^2 [4]. The sound damping sheets on the roofs in some buildings may have increased the surface fiber density.

The new method of sampling and analyzing the concentration of MMMFs that was used in laboratory can be applied in the field measurements. With this method, the limit value of 1 fiber/m^3 in supply air is recommended. The recommended value of surface fiber density during 14 days is 0.2 fibers/cm^2. In buildings, where these limit values are exceeded, finding fiber sources and solving the possibility to reduce them, are strongly recommended.

ACKNOWLEDGEMENT

The study was included in the "Particle discharges of air-conditioning systems: health risks, measurement and product development" project, which was funded by Tekes (Finnish Funding Agency for Technology and Innovation), two mineral fiber producers (Saint-Gobain Isover and Paroc), two HVAC-manufactures (IVK-Tuote and Fläkt Woods) and a representative of end users (City of Helsinki). The project was part of the "FINE Particles"-Technology Program of Tekes.

SUMMARY

The sources of man-made mineral fibres (MMMFs) settled on furniture surfaces and in supply air were determined in an office building. The impact of renovation on indoor air and the perception of air quality by the occupants were studied. Renovation improved the air-tightness of the inner parts of structures. Settled MMMFs were collected with gelatine tape by pressure and deposition techniques. MMMFs in supply air were collected using the filter installed to the supply diffuser. Sources of MMMFs were determined by comparing the found fibres to the fibres of insulation materials in the building using SEM/EDS. Occupants' perceptions of air quality and how it affected their wellbeing were collected using a questionnaire. The results showed that MMMFs originated mainly from fire insulations outside the main air ducts in shaft structures. The renovation improved indoor air quality and reduced the number complaints and symptoms of occupants. This study indicates that it is important to maintain the air-tightness of building preventing air leakage from shaft structures to indoor air.

INTRODUCTION

Man-made mineral fibres (MMMFs), which are also referred to as man-made vitreous fibres (MMVFs), are amorphous silicates manufactured from glass, rock, or other mineral [1, 2]. The concentrations of man-made mineral fibres in indoor air and the sources of mineral fibres have been studied in Europe and in the United States since the 1980´s. Based on current knowledge, the sources of man-made mineral fibres can be thermal, sound, acoustical and fire protection insulations in building structures and ventilation equipments. Although MMMFs are not considered to have a carcinogenic effect [4], high levels have been related to symptoms experienced by occupants in particular irritation of the respiratory tracts, eyes and the skin. Exposure to fibres occurs mainly through surfaces [3].

The purpose of the study was 1) to identify the sources of MMMFs settled on furniture surfaces in the office building and 2) to assess the impact of renovation on the indoor air quality and on the experiences of occupants. This study is the part of comprehensive study that focuses on the condition of indoor air quality and climate of the building.

METHODS

A 8(9)-storey office building in which occupants perceived building-related symptoms was studied. The stone-structured building comprised of three sections connected to each other by an intermediate part. The study building had a mechanical air handling system. The main air ducts of ventilation units were located in vertical shafts located in the centre of the each building sections.

Man-made mineral fibres settled on room surfaces were sampled with gelatine tape (tape size 2 cm x 7 cm) by pressing the tape against surface or by allowing fibres deposit on the tape placed on the surface. The deposition time was one week. MMMFs were calculated with a light microscope. Two replicate samples were taken from each measurement point. The results were expressed as fibres/cm^2.

Man-made mineral fibres in supply air were collected using the polypropylene filter cloth that was attached to the supply diffuser. Mineral fibres were calculated using light microscopy. The samples were taken in different parts of the building complex, in the service areas of different ventilation units. Results were expressed as fibres/m^3.

The sources of MMMFs were determined using scanning electron microscope with X-ray microanalysis (SEM/EDS). The sampled MMMFs were compared to the insulation materials of structures and ventilation equipments.

Complaints and symptoms experienced by occupants were collected using the Indoor Air Questionnaire (modified MM-40 questionnaire). Complaints and symptoms attributed to the building every week were reported from the past three months. The inquiry was conducted twice, before and after renovation in 2004 and in 2006, and in one part of building five times between years 2001 and 2006. The percentage of answered questionnaires ranged from 53 % to 60 % yielding 250 and 310 answers.

After determining the initial quality of the indoor air, the building was renovated. The feedthroughs of the vertical shafts and the manholes were sealed and an under pressure was created in the shafts. Old transfer air vents leading from rooms to the corridors were also sealed. The air-tightness of structures was checked with tracer gas, sulphur hexafluoride gas, and gas analyser after renovation.

In the statistical analysis the results were tested with the testing method of proportional sample (questionnaires) and with the *t*-test (mineral fibre concentrations).

RESULTS

Man-made mineral fibres on surfaces

A significant decrease in settled man-made fibres ($p<0.001$) was observed after renovation of an office building (Table 1). The decrease in concentration levels had taken place in 2006 both as regards the number of samples exceeding the target maximum value of 0.20 fibres/cm^2 and as regards the average concentration level. In 2004 the variation of the MMMF concentrations was high ranging from <0.07 fibres/cm^2 to 100 fibres/cm^2. The high single concentrations may be due to the basic repairs of ventilation equipments in process simultaneously in part of the building and insufficient protection during work. This becomes evident in the check-up measurements carried out after the repairs in 2004 whereby equally high single concentrations were not observed.

Table 1. Concentrations of man-made mineral fibres before (2004) and after (2006) renovation works.

	Pressure samples		**Deposition samples**	
	2004	**2006**	**2004/2 (check-up measurements)**	**2006**
Number of samples	137	80	19	80
Average fibres/cm^2	4.27	0.07	0.18	<0.07
Median, fibres/cm^2	0.29	<0.07	0.07	<0.07
Minimum, fibres/cm^2	<0.07	<0.07	<0.07	<0.07
Maximum, fibres/cm^2	100	0.29	1.43	0.29
Samples exceeding target value of 0.20 fibres/cm^2 , %	58	4	11	1

Man-made mineral fibres in supply air

In general, the mineral fibre concentrations in supply air were low. The MMMF concentrations varied from <1 fibre/m^3 to 21.4 fibres/m^3. It was found that the MMMF concentrations were below the target value of 1.0 fibre/m^3 suggested by Finnish Institute of Occupational Health [5] in 80 % of samples.

Sources of man-made mineral fibres

X-ray microanalysis of settled man-made mineral fibres showed that MMMFs originated mainly from the fire insulations outside the main air ducts of the vertical shafts. Some fibres originated from the insulation materials of partition walls and from old transfer air vents in 2004, but not after renovation in 2006. MMMFs in supply air and on furniture surfaces originated from the same source i.e. the fire insulations outside main air ducts of vertical shafts.

Indoor Air Questionnaire

In general, the amount of building related symptoms and environmental complaints decreased after renovation (Figures 1 and 2). No exceptional amount of building-related symptoms (above 20 %) and environmental complaints (above 40 %) emerged in autumn 2005 or in the spring months of winter 2006. The amount of reported eye irritation symptoms and dry air perception diminished significantly ($p<0.05$) in the winter spring months (in 2006 compared to 2004). Similarly, the dry skin symptoms and dry air perception diminished significantly ($p<0.001$) in autumn (in 2005 compared to 2001). In late winter in 2006 more symptoms were reported than in autumn 2005. In winter time indoor air is dry in Finnish buildings and may increase the perception of dry air.

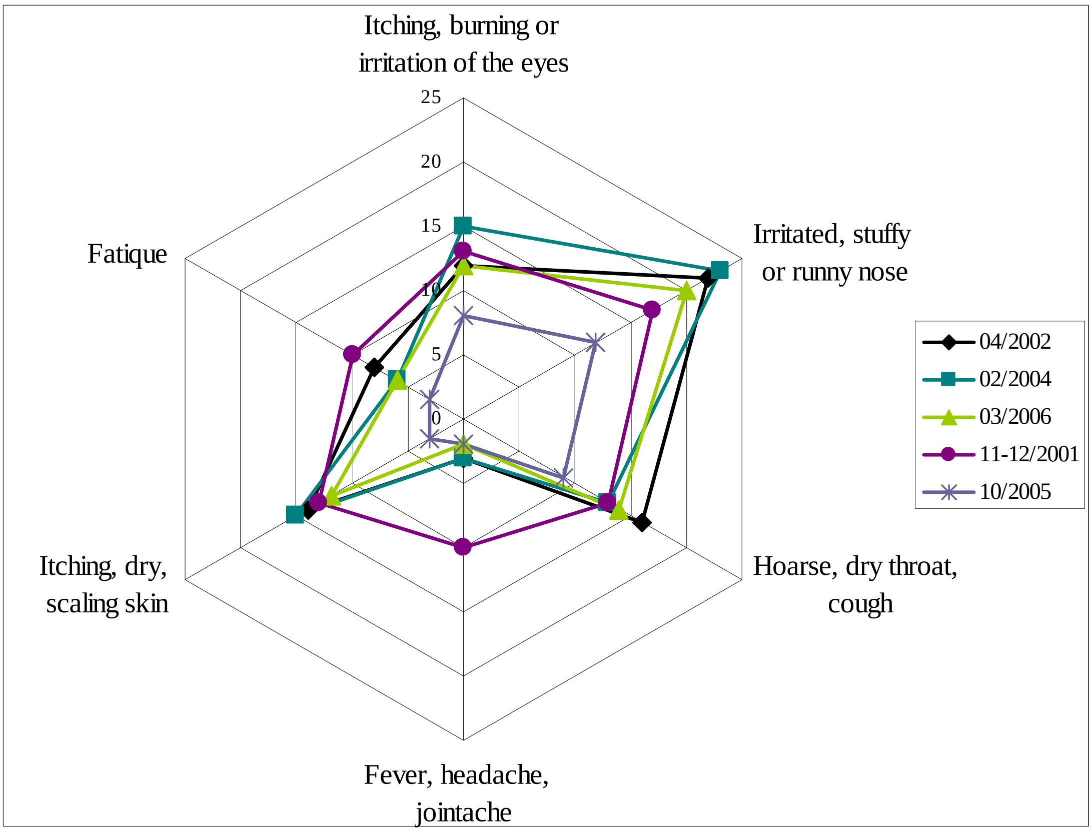

Figure 1. Building related symptoms in the study area of the building. After the inquiry of 02/2004 the comprehensive measures were made in the building.

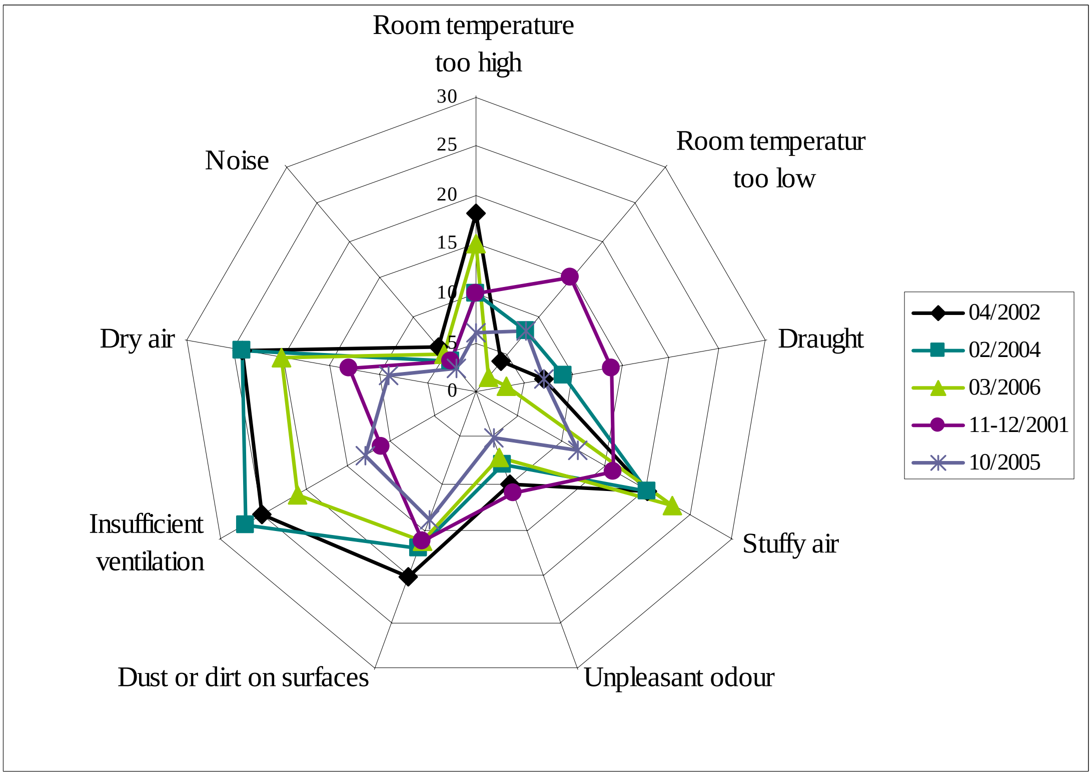

Figure 2. Environmental complaints in study area of the building. After the inquiry of 02/2004 the comprehensive measures were made in the building.

DISCUSSION

These results showed that man-made mineral fibres found in dust settled on furniture surfaces and in supply air originated mainly from the fire insulation materials outside the main air ducts of the vertical shafts and also to a lesser extent from the insulations of the partition walls and from transfer air vents. This study indicated importance of renovation for indoor air quality. The indoor air quality improved, and, complaints and symptoms experienced by occupants decreased as the emissions of MMMFs decreased.

Thus the renovation work of sealing the inner parts of the structures towards the shaft structures, can be considered useful. The present study does not provide adequate evidence to conclude the reasons for symptoms and complaints. The symptoms and complaints may have been caused by mineral fibres, or they may also be related to the migration of the air into indoor air through non-airtight structural components. The air flowing through the structures contains various impurities originating from building materials or for example from microbes attached to the inner walls of shaft structures. The joints between the indoor spaces of the building and the shaft structures were non-tight and air flowed towards indoor spaces from the shaft structures. Buildings with mechanical ventilation system have mainly negative pressure. Based on this research results it is important in buildings with mechanical ventilation system to maintain the air-tightness of the inner parts of structures e.g. towards shaft and air conduit structures.

SUMMARY

Since the study by P.O Fanger (1988) [1] we know that the Heating Ventilating and Air Conditioning (HVAC) system could be responsible for a large amount of indoor air pollution and Sick Build Syndrome (SBS). The pollution could become from filters, cooling coils and dust accumulated on duct surfaces in systems with poor maintenance.
While the importance of maintenance of air handling units and replacement of air filters is well recognized in Portugal, the cleanliness of ducts is sometimes forgotten. Research is needed on standard methods to measure the surface pollution and criteria to appreciate the cleanliness of duct surface, as well as the requirement for duct disinfection after an adequate mechanical cleaning.
In this paper the results of a study undertaken in a 9 year old office building in Lisbon area with a VAV system are presented, including the methods used to measure the air quality and the surface pollution. The results show that mechanical cleaning contributes to a large reduction in dust concentration in surfaces and in the air supplied to spaces. The concentration of bacteria and moulds in surfaces and in the air was quite low and therefore in this building chemical disinfection is not required.
A continuous audit of the system is recommended (with visual inspection for instance and some measurements) to choose between cleaning some components or the complete system and some suggestions about the criteria to be adopted before cleaning ducts are also offered.

INTRODUCTION

To promote good indoor air quality in buildings we need to supply an adequate air flow rate to dilute and remove pollutants and the supplied air should also be fresh and clean.
In the study of Fanger [1] in 1988 it was shown that HVAC systems could be responsible for 42% of the pollution sensed by occupants. The pollution of HVAC systems has many sources, namely air filters, heating and cooling coils, humidifiers, water condensation pans and ventilations ducts.
The contamination of inert HVAC components (ex. components made of steel, copper, aluminum, etc) could be associated with the transport of contaminants germinated in air handling units, high humidity levels on surfaces, oil residues on surfaces, accumulated dust on ducts which in the presence of water allow the germination of microorganisms.
To reduce the risk of HVAC contamination is proposed [2] an annual audit of HVAC system, periodic replacement of air filters, cleaning of humidifiers, heat exchangers, water condensation pan, etc. Regarding duct it is recommended the cleaning when necessary, without defining the criteria to decide when it will be necessary. Duct cleaning was first

introduced to reduce the fire hazard or the blockage of duct by the dust which reduces the air flow. Nowadays, the impact on the air quality supplied to the building, is also a concern (figure 1).
Regarding the impact of duct pollution in Indoor Air Quality (IAQ) currently there isn't information available that could allow the definition of safe limits for dust or microorganism accumulation in duct surfaces indicating good/bad air quality supplied to spaces. Some previous work suggests that duct cleaning has a minor effect in IAQ [3, 4].
In this study we were interested in showing, using quantitative measurements, the impact of HVAC and especially duct cleaning in the air quality supplied to the building and in the pollution of the duct surfaces.

Dirty duct

Clean duct

Figure 1. Ducts

CRITERIA TO EVALUATE DUCT CLEANLINESS

The simplest method to appreciate duct cleaning is the visual inspection, which allows the identification of a large number of anomalies. For instance, dust concentration of 5 to 10 g/m^2 are thick and easily seen [3]. When dust concentration is lower than 0.1 g/m^2, a cleaned duct is observed.
Quantitative methods could be used to appreciate more objectively the dust level inside ducts, namely: the vacuum test method, the gravimetric tape or the optical method [3,4]. To measure microorganism levels contact plates are used [5,6].
To measure dust accumulation, Holopainen [5] showed that the most precise method is the Vacuum test. The tape test method could be used for lower concentrations (lower than 3 g/m^2).
As already referred, a correlation between surface dust concentration and it's impact on indoor air quality, it has not yet been defined. For that reason, quantitative methods have been adopted essentially to determine adequate duct cleaning.
The NADCA association [7] refers that ducts are clean when the measured surface dust concentration (obtained with the vacuum test method with air flow rate of 15 l/min and with the cassette (filter holder) sliding over a structure not touching the surface of the duct) is lower than 0.075 g/m^2.
The APIRAC association [8] considers that acceptable cleanliness of ducts is achieved when the obtained concentration of surface dust is smaller than 1 g/m^2. APIRAC's method uses a collection airflow of 25 l/min and the cassette contact directly with the surface of the duct.
FISIAQ considers two cleanliness classes [9] in new air conditioning ducts: for the P1 class the limit for the concentration of surface dust is 1.0 g/m^2 and for the P2 class the limit is 2.5 g/m^2, if we consider existing ducts limits are 2.0 g/m^2 and 5.0 g/m^2 for the classes P1 and P2 respectively. For P1 category oil residues must be lower than 50 mg/m^2.

In the United Kingdom [9] the maximum limit allowed is de 1.0 g/m^2 in supply ducts and 6 g/m^2 in exhaust ducts, measured according NADCA method.
A technical note from Chow et al [10] recommends cleaning when surface dust measured with the NADCA method detects concentrations higher than 6 g/m^2 in exhaust ducts and higher than 1 g/m^2 for supply air duct or exhaust ducts on a system with air recirculation
There are no reference limits for microbiological contamination. Luoma et al reports [4] presents some results with mean concentrations of fungi ranging from 0.05 to 11 cfu/cm^2 and bacterial concentrations ranging from 0.03 to 13 cfu/cm^2.
A Norwegian expert group [3] presents three risk classes for surface microbiological contamination. For fungi, concentrations lower than 1000 cfu/g of dust presents a low risk, for concentrations smaller than 3000 cfu/g of dust present medium risk and, finally, the risk will be high for concentrations higher than 3000 cfu/g. For bacteria, low risk is defined for a concentration lower than 6000 cfu/g, medium risk for concentrations lower than 10000 cfu/g and high risk will be for concentrations higher than 10000 cfu/g .
Regarding recommendations for surface cleanness, we have rules for surfaces in contact with cold stored foodstuffs [11], which states that the microbiologic contamination should be lower than 1 cfu/cm^2 to be in the excellent class, a microbiological contamination lower than 10 cfu/cm^2 to be in the good class. Clean Rooms for pharmaceutical industry have four classes: A - 0.04 cfu/cm^2, B - 0.2 cfu/cm^2, C - 1.0 cfu/cm^2, D - 2.0 cfu/cm^2 [11].

DESCRIPTION OF THE HVAC SYSTEM

This study was conducted in a 9 years old office building in Lisbon area, with a VAV ventilation system. The study was carried out on the east side of the building with the air handling unit is placed at the roof, figure 2. This system is 100% outdoor air (without recirculation). The air handling unit has a nominal capacity of 45 690 m^3/h and is connected to a duct 1.5 m × 0.9 m. In this air handling unit a two step filtration scheme is applied, with filters of class G3 and F9 [12].
The system is made with galvanized steel ducts. At the exit of air handling unit and in the vertical shaft the duct has rectangular cross section. For air distribution in every floor one main duct spiral oval is used, (figure 3). The connection of VAV box to the oval duct is made with oval or round ducts. The connection of air supply diffusers to the VAV box is made with flexible ducts. Inside the VAV box a sound insulation material is used.

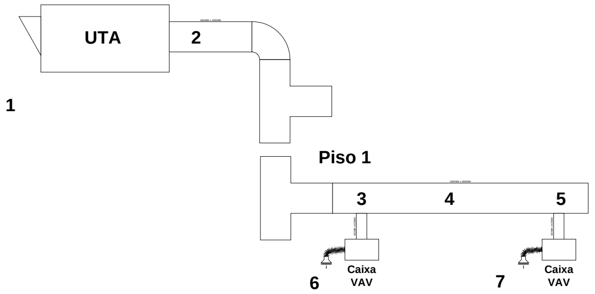

Figure 2. Schema of supply air duct and measurement location

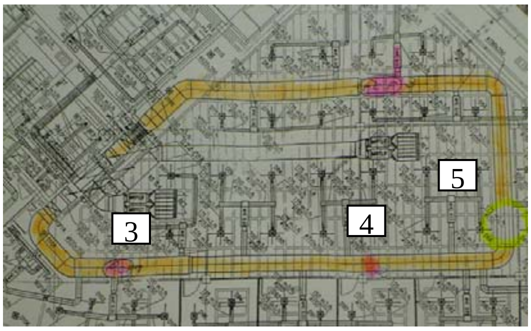

Figure 3. Supply air duct and measurement location

METHODS

To appreciate the effect of 9 years of HVAC system use on the quality of supplied air to the rooms, and to test the effect of HVAC cleaning without disinfection, concentrations of bacteria, fungi and particulate matter (dust) were determined in air and inner surfaces of air ducts, before and after cleaning.

To obtain the worst possible scenario, we studied the first floor of the building, because it's bigger the distance to the air treatment unit and dirtiest ducts are expected.
Figure 2 and 3 represent the measuring points for air determinations (1 to 7) and inner duct surface determinations (2,3,4 and 5). The selection was made in order to obtain information about the effect of HVAC components in the quality of supplied air and also to study correlations between surface and air pollution.
To obtain an estimation of airflow, we measured air velocity profile at the same points where the air contamination was assessed.

Surface Contamination

To collect surface samples for microbiological or dust analysis, the HVAC system was turned off and holes were opened in ducts at selected locations to give assess to inside of ducts. The measurements were done on inner surfaces near the holes.
Sampling of viable microbiological samples on the surfaces was performed using bioMerieux contact plates filled with the appropriate culture media, Count-Tact (ref. 43 501) to collect bacteria and Count-Tact Sobouraud Glucose Chloranfenicol with neutralizer (CTSCD, ref. 43 580) to collect fungi. At least two samples at each measuring point were taken.
The collection of surface particulate matter (accumulated dust) was done according with the APIRAC procedure [8], using the vacuum test method. It was used the ROBImech equipment, with a flow rate of 25 l/min. Filters were weighted before and after collection, at the laboratory.
The amount of dust inside ducts is not homogeneous, presenting higher concentrations near the joints of the steel duct. The methods for measuring the accumulated dust do not specify the sampling places. Therefore, to correct this possible source of error, we performed collections in both "clean" and "dirty" points.

Air Contamination

The collection of total particulate matter in the air was performed using pumps calibrated for a 2 l/min flow rate and membrane filters previously weighted. The collection time was approximately 12 hours.
Sampling of viable microorganisms inside the ducts was performed using impact samplers. Andersen-N6 impactor, calibrated to 25.32 l/min, was used inside the ducts and a MAS 100 impactor (Merck) calibrated to 100 l/min used to collect microorganisms at the terminal devices in unoccupied spaces because human beings are important sources of bacterial contamination.
To culture fungi Malt Extract Agar with chloranfenicol was used and Trypticase Soy Agar was used for bacterial counts. Plates were incubated at 27ºC and 37 ºC for fungi and bacteria respectively.
Inside the ducts the air velocity was measured using an Airflow thermo-anemometer model TA 5.

RESULTS AND DISCUSSION

The measurements before system cleaning were carried out on the 18th and 19th of March 2005 (figure 4 and 5 – Before Clean). The measurements after cleaning were performed on the 5th and 6th of May, 2005 (figure 4 and 5 – After Clean).
In figure 4 the results of measurements in air are presented, namely: bacteria, fungi and total particulate matter. In figure 5 the results of measurements in duct surfaces before and after

cleaning are shown. The results of bacteria and fungi are the average of two measurements, while the particles are the average of 12 h measurement.

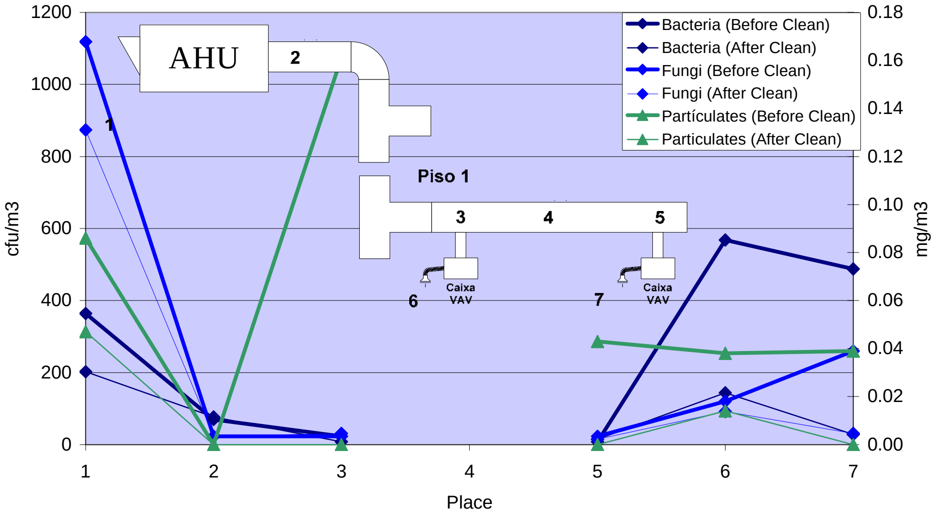

Figure 4. Measurement in air

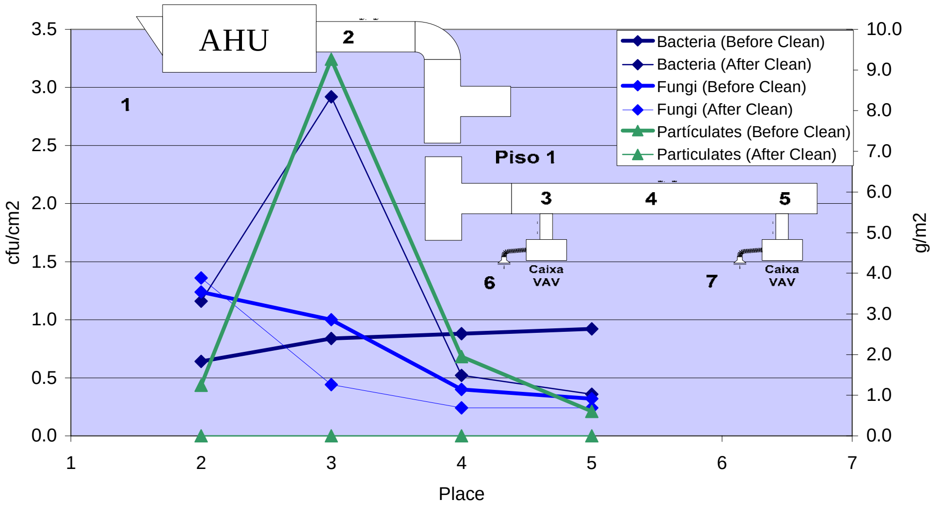

Figure 5. Measurements in duct surface

General appreciation

The duct network of the HVAC system under study was relatively clean, with a surface dust concentration under $2g/m^2$ and a microbial concentration inside the range classified as excellent for surfaces in contact with food, class C for "clean rooms" and close to the lowest levels referred by Luoma et al [4].
In the following paragraphs we present the main conclusions regarding the effect of mechanical duct cleaning in supplied air.

Air handling unit

Comparing the results obtained outdoors (A1 point) with the results obtained beyond the air handling unit (A2 point), it's possible to conclude that filters were effective in the removal of contaminants, as we can see for the reduction of pollutants (microorganisms and particulate matter).

The results obtained before and after cleaning (points A1 and A2) were not significantly different, despite the cleaning.

Ducts

To appreciate the effect of duct network in the contamination of air, we compare the results obtained beyond the air handling unit (point 2) and 1st floor entrance (point 3) and between point 3 and point 5 the remote point of duct system.

There is no difference between the results obtained for microbiological contamination in point 2 (after passing the air handling unit) and 3 (1st floor entrance), although there is an increase on particulate matter concentrations (from not detected to 0.16 mg/m^3). This increase on particulate matter in air may be associated to the displacement of particles settled at the bottom of the vertical shaft

Analyzing the results obtained in surfaces we verify that bacterial and fungal concentrations are almost constant between samples collected after passing the air handling unit and 1st floor entrance point. However there is a larger dust deposition at the entrance of 1st floor (10 g/m^2) than after passing the air handling unit (1.3 g/m^2). The observed difference may be due to the air flow bend near the collection point, which promotes the settlement of particles, and also to the large particle concentration in air in this zone.

Between the entrance in the 1st floor and the remote point (points 3 and 5) a reduction in particle matter concentration in air is registered (0.16 mg/m^3 to 0.04 mg/m^3), with almost the same concentration of micro-organisms. The reduction of particle concentration in air is associated with the reduction of average air velocity along the duct, which promotes the settlement of heavier particles. Regarding surface concentration, we detect the same changes as in air, *ie*, the micro-organism concentrations are almost constant and there is higher concentration of dust at the beginning of duct (10 g/m^2) than in the most remote point (2.0 g/m^2).

Analysing these results we conclude that there isn't a direct correlation between particle and micro-organism concentration in duct surface, because the micro-organisms remain almost constant in several collection points, while the particle concentration presented a large variation. Regarding particle concentration in air and in surface, there is a direct correlation.

With those results we can see that mechanical cleaning of duct surface is effective to remove particles, since we obtain a substantial reduction in surface particle concentration after mechanical cleaning and we also obtain a large reduction of particle concentration in air. After mechanical cleaning, the surface particle concentration complies with APIRAC criteria (≤1 g/m^2) and also with NADCA criteria (0.075 g/m^2), in spite of the large differences in measurement method of APIRAC and NADCA.

The micro-organism concentrations present slight variation (before and after mechanical cleaning). Because of the low micro-organism concentration (surface concentration of 0.2 and 1.4 cfu/cm^2 and concentration in air of 8 and 70 cfu/m^3) it seems that the impact in air quality is low and therefore chemical disinfection can be avoided.

In this study, we find that the collection point in duct surface could have an impact on the results obtained. Points very close to duct irregularities (the bending zone in spiral duct, joints, etc) could have large differences in dust concentration. The changes in dust deposit, however, didn't correspond to a change in micro-organisms concentration. We also notice that the higher micro-organism concentrations were found near the places of lower particle concentration.

VAV box and diffusers

To assess the impact of VAV boxes, flexible duct and diffusers we compared the results of measurement points 3/6 and 5/7.

From the results obtained at these points, we can see a large increase of micro-organisms in air between the main duct of the room and the exit at air diffusers. This indicates that VAV boxes, flexible duct and diffusers have good conditions to the germination of micro-organisms (namely bacteria) that are drawn by air flow. Regarding particle concentration between collection points 3/6 we can see that there is a settlement of particle in these components, which could create media for the development of micro-organisms if the humidity conditions are adequate, because the availability of water is the driving force in the growth of micro-organisms.

In this case study, with mechanical cleaning we detected a large decrease of particles and micro-organisms in the air supplied indoors. If we look at contamination classes of air [13], the air supplied before cleaning would belong to the intermediate contamination class and after cleaning would be classified as very low pollution.

The main focus of contamination of air supplied to the building was the branch VAV box and the flexible ducts, which were very dirty.

CONCLUSION AND RECOMMENDATIONS

In this case study the contamination of one VAV system and its impact on the air quality supplied to the building before and after mechanical cleaning, was analysed.

We found that after 9 years of use the system could be considered clean, even though this was not clean after construction. The concentration of micro-organisms and particles was generally low, and some points presented higher particles concentration but that still didn't compromise the air quality.

The main focus of pollution are the VAV box and/or flexible duct. Before the cleaning an air concentration of bacteria of 500 cfu/m^3 was measured and after cleaning this concentration decreased to 28 and 140 cfu/m^3. In spite of this reduction, after cleaning, these components remained the main source of air pollution.

For the dirt in duct surface we didn't found a correlation between particle concentration and micro-organism, because micro-organisms concentration remains almost constant from dirty collection points to clean collection points. However, we obtained a correlation between particle matter in air and duct surface.

Regarding the criteria for clean ducts, we found that the 1 g/m^2 limit [11] to start cleaning duct system is very stringent, because in this system (which presented higher values in some places) the duct was not source of pollution of air. In absence of other information, we think that it could be reasonable to adopt the class P2 criteria (5 g/m^2) [9] as the limit beyond that which cleaning the ducts is needed. As criteria to asses the cleanliness of the cleaning operation we could use the criteria of 1 g/m^2, or a lower value, for example 0.1 g/m^2, measured with the APIRAC method, because in this building both criteria were satisfied. Regarding the micro-organisms concentration in duct surface, we think that the contamination risk is low for ducts that comply with class D of pharmaceutical industries (2 cfu/cm^2) [11], taking into account the results obtained and the Norwegian recommendations [4]. For concentrations above this limit (2 cfu/cm^2), we think that a study of the impact of surface contamination in the contamination of air supplied to the building should be performed, before cleaning or disinfecting the ducts.

We found that the vacuum test method could be adopted as measurement method for the assessment of duct cleanliness regarding particles and that the mechanical cleaning is effective in the removal of particles and micro-organisms.

With these results we also show that before a complete system cleaning, some measurements should be done to find potential sources of pollution and clean only the contaminated components, cutting maintenance costs.
In the course of this work we also noticed the importance of the dirt left from construction. It is quite important to follow rules to protect HVAC during construction and probably do some cleaning after construction and before turning on the HVAC installation.

Duct Cleaning: The Good, The Bad...and The Need for An International Consensus Standard

Vernard D. Holden, CIH, CSP, ARM

Hydro-Environmental Technologies, Inc., Acton, Massachusetts, United States

vernh@hydroenvironmental.com

SUMMARY

Cleaning ventilation system ductwork has been a topic of controversy for several years. Guidance documents are available for duct cleaning, but uniformity in application of remediation and cleaning methods is inconsistent in many cases. Means and methods for cleaning range from high-volume negative pressure vacuum cleaning of residential ductwork ...to use of sanitizing agents on the interior of galvanized ducts...to ultraviolet germicidal irradiation for treatment of re-circulated air and control of infectious viral aerosols in operating room suites. A comprehensive visual inspection of the components of the building ventilation system and a risk assessment to determine the nature and magnitude of contamination form the basis of effective remedial cleaning. This presentation describes a proposed industry standard of care for duct cleaning and a quantitative method to determine an acceptable level of cleanliness. The information presented underscores the need for an international consensus standard for duct cleaning.

INTRODUCTION

Over the past decade heating, ventilation and air conditioning (HVAC) system cleaning and decontamination to remove dust and biological growth has expanded into a large industry serving both residential and commercial building markets [1]. Guidelines for duct cleaning are available in Japan, Sweden, the United Kingdom and the United States, but are routinely violated by many contractors. Decisions to remediate ductwork are frequently driven by financial motives and are not always based on sound judgment. Improper remediation of HVAC systems can cause degradation of indoor air. Duct cleaning is often performed without a comprehensive visual inspection due to limited accessibility to HVAC system components, resulting in a failure to properly identify sources and implement corrective actions prior to cleaning.

The focus of this presentation is on mold-impacted and/or particle laden ductwork. HVAC systems are especially conducive to mold growth because they draw supply air, which usually contains fungi and moisture, into a building containing numerous organic materials that provide food sources for mold growth. The remediation of HVAC systems is an extremely sensitive undertaking due to the potential of disturbing and distributing spores or dust throughout the ventilation system.

HVAC system ductwork is an air-conveyance system that requires diligent cleaning methods and a quality assurance process to protect the health of building occupants. The purpose of this presentation is to provide guidance in the proper assessment and remediation of contaminated ductwork and to encourage development of international consensus standards.

METHODS
Building Ventilation Ductwork Components and Characteristics

In a typical building HVAC system, the fan pulls air from the occupied space through return air grilles into ductwork...then through the filter, heating and/or cooling coils and supply ductwork...then back into the occupied space. Various types of ducts and ductwork materials are available. Basic types include: straight metal sections; spiral-wound; flexible and expandable; and plastic made of polyvinyl chloride, reinforced fiberglass, or acrylonitrile butadiene styrene. Ductwork materials include: fiberglass, metal with fiberglass interior, metal externally wrapped with fiberglass, and insulated flex duct. The duct type and material will depend on the type and age of building and ventilation system, the nature of occupancy, the cost of materials and ease of installation, corrosion, temperature and other factors. Galvanized steel is probably the most common duct material; circular, rectangular and oval ducts the most common shapes. Some types and shapes of duct are capable of retaining more particulates regardless of their design velocity. For example fiberglass duct will generally accumulate more particles because of its rough, porous interior surface, compared to galvanized steel which has a relatively smooth surface except at section joints and seams. Duct manufacturers publish friction loss data, based on the surface material, which is useful in determining the potential for particulate loading on interior duct surfaces and the corresponding frequency recommended for maintenance and cleaning. The design of the ductwork will also determine the potential for interior particulate loading. Elbows, junctions, branch entries, and expansions and contractions are areas where there is greater potential for excessive surface deposits compared to straight sections.

Measurement of static pressure losses in a duct provides useful data to evaluate if particulates are being trapped in the duct. A pitot tube connected to an inclined manometer is the primary method of measuring duct static pressure. To reduce static pressure losses in ductwork design: (1) Branch entry angles should be designed at 30º – with a 45º maximum. (2) Expansions and contractions should be gradual – for example, one centimeter of duct diameter change for every five centimeters in length. (3) Rectangular duct should be as square as possible. (4) Seams on spiral-wound ductwork should be sealed with high or low pressure seals and pressure (leak) tested.

To evaluate the potential for particulate loading within HVAC ductwork, it is important to understand airflow in ventilation duct and duct velocity profiles. Airflow in ventilation duct is turbulent, not laminar. Turbulent airflow, in comparison to laminar airflow, is a function of the Reynolds Number – a dimensionless parameter represented by:

$$Re = \frac{VD\rho}{\mu}$$

Nomenclature:
V = air velocity (cm/sec)
D = duct diameter (cm)
ρ = air density (g/cm³)
μ = air viscosity (poise)

If $Re < 1200$: Airflow in duct is laminar, free of eddies and swirls, direction is predictable

If Re 1200 – 3000: Transitional airflow depends on acceleration or deceleration

If $Re > 3000$: Airflow is turbulent

Re in ducts is usually 100,000–1,000,000; therefore, it is always turbulent [2].

Dust in ventilation ducts usually has a very minor effect on air flow rates. However, heavy dust accumulations on critical components of the HVAC will limit air flow, for example dust on air supply diffusers, dampers and fan blades. Velocity profiles can help define the potential location of particulate accumulations in ductwork, and are best determined by taking duct velocity Pitot tube traverses. Velocity distributions inside ductwork are not uniform across the area of the duct due to factors such as obstacles in the airflow path and changes in airflow direction. Velocity is always zero at the wall surface of the duct. Velocity in duct must be corrected for the moisture content in the air, temperature and altitude. For air with no industrial particles, duct velocities of 9 to10 mps are considered optimum in main ducts, considering initial and operating costs, noise control, and naturally occurring dust transport. Air velocities in branches near room registers should be lower than in main ducts.

Sources of HVAC System Contamination

The cause(s) of mold growth must be identified and corrective action taken before remediation of either the building or the HVAC system is undertaken. Any identified HVAC deficiencies must be corrected. Sources of water intrusion, moisture accumulation, and/or surface condensation must be resolved prior to remediation. If the HVAC system and building problems are not resolved, recurrence of microbial amplification should be expected. Source identification and control form the basis for an effective and successful remediation.

Over 52% of all indoor air quality problems are caused by inadequate or improper ventilation [3] including poorly designed, installed, operated and maintained building ventilation systems. In some cases there can be widespread mold growth in a building, without a recognizable source of water intrusion, caused by improper moisture control in ventilation design. Proper building pressure management, ventilation system design engineering, and humidity control are critical elements to prevent mold and degradation of indoor air. Whenever the author performs an indoor air quality investigation, he frequently finds the source of the problem in one of “4 Ps” – pollutants, people, pathways or pressure. The latter two areas involve the ventilation system.
Common problems include:

- Poor air filter maintenance and efficiency – causing particulates to build up in ducts and at supply diffusers. Poorly maintained or improperly sized filters allow particulates (including ambient aerosols and those from local sources) to be distributed throughout a building, resulting in an increased risk of microbial contamination. When filters become clogged, the fans use more energy to operate and move less air, causing a detrimental effect on cooling, humidity control and proper air distribution. Filters in HVAC systems should be of the highest grade compatible with the system and the air handler fan – with a filter glass F6 to F7.
- HVAC units that are oversized for an area or a building – resulting in overcooling, system short-circuiting, improper dehumidification, condensation build-up, excess humidity and mold growth.
- Pressure differentials created by ventilation systems – notably if the system operates under negative pressure…as opposed to ideally operating under slightly positive pressure.
- Surface condensation in ductwork immediately downstream of cooling coils caused by moisture wicking off the coils. Condensation also occurs when the temperature of the surface of the ductwork falls below the dew point of the surrounding air. Particles not removed by the filters can collect on surfaces in the HVAC system resulting in microbial growth.
- Surface condensation on the exterior of sheet metal ductwork – caused by water vapor in the air; improper dehumidification; high relative humidity; lack of air circulation; openings in the building envelope; and poor indoor climate control.

- Duct leakage – due to loose-fitting joints and connections; improperly fabricated seams; physical damage to crawl spaces or attics; and leakage of return ducts below floor slabs allowing soil gases and moisture entry into ductwork.
- Use of fiberboard duct in warm, humid climates.
- Ductwork installed in vented attic spaces, especially in warm humid climates.
- Improper location of outdoor air intakes (OAIs) – for example, near exhaust air from kitchens, laundries, bathrooms, parking areas, loading docks, or dumpsters; or unprotected from birds and weather. Rooftop OAIs are especially vulnerable to bioaerosol sources from cooling towers, building exhausts, and standing water.
- Cooling towers providing heat transfer for the building's ventilation system that contain microbial growth on wet surfaces. Regardless of the recommended separation distance between the cooling tower and the OAIs (7.62 m), fastidious maintenance and treatment programs should be implemented to control growth of *Legionella* and other microorganisms in cooling towers [4].

Visual Inspection of HVAC Systems

Inspection of HVAC systems should be an integral part of building preventive maintenance. Inspection procedures and intervals should be based on building use/occupancy, length of heating and cooling season, building age and type of ventilation system, modifications to original building design, preventive maintenance and condition of the building and mechanical systems, and geographic location. In general, the older the ventilation system or building, the more frequent inspections should be conducted. Inspection intervals should not exceed one year. Geographic areas with climates having high humidity require more frequent HVAC system inspections, because of an increased risk of microbial contamination. Building occupancy also determines minimum inspection requirements. For example, a hospital is held to a higher standard of care than a retail outlet. HVAC inspections should include the AHUs, humidifiers and representative areas of the HVAC system components and ductwork [5]. Duct inspections should include a representative portion of supply system and return system ductwork components. Supply diffusers, mixing/control boxes, reheat coils, return air grilles, dampers, return plenums, and make-up air plenums should be inspected. Inspections should be conducted in a manner to prevent disturbance of settled dust and mold amplification. If mold contamination is suspected, then a qualified environmental health professional, such as a Certified Industrial Hygienist (CIH) with experience in performing microbial investigations, should be contacted to conduct an investigation. The cause should be identified and corrective action taken before remediation/cleaning. Safety precautions should be taken during the investigation to prevent aerosolization of fungal growth and microorganisms and cross contamination of other areas. In all cases, a conservative approach should be taken to protect the health and safety of building occupants. A moisture meter and an infrared thermal imaging camera to detect moisture in building materials, and a borescope (an inspection mirror with an illuminating light source to view spaces interstitial spaces, such as wall cavities and ductwork) are useful diagnostic tools. Procedures to identify problems with ductwork include checking supply diffusers for air movement using smoke tubes. If no air movement is detected, then check the fan motors. Improperly wired fan motors or reversed fan blades can cause fans to move air in the wrong direction. Inspect for closed dampers, clogged filters, open service openings, or ductwork leaks. Other specific causes for lack of airflow in ductwork may include air pressure losses from an inadequate fan motor, improper branch entry angles for ductwork, addition of exhaust ventilation hoods, installation of a duct turn or elbow too close to the fan inlet, and duct losses from friction and turbulence. If an inspection indicates that the HVAC system has excessive surface deposits or microbial contamination, then the system should be remediated.

DISCUSSION

Standard of Care for Duct Cleaning

A standard of care for duct cleaning starts with a comprehensive preventive maintenance program to mitigate conditions that created the need for cleaning. Consider installation of monitoring systems for proper climate control and periodic monitoring of air quality parameters – including temperature, relative humidity, air movement, pressure drop across a filter bank, and carbon dioxide – which are all surrogates for problems with degradation of indoor air. The installation of a manometer can provide an immediate indication of filter condition without performing a visual inspection.

The presence of dust in ductwork does not necessarily indicate microbial contamination. A small amount of dust on duct surfaces is normal. Problems with dust and other contamination in ductwork are a function of filtration efficiency, regular HVAC system maintenance, the rate of airflow, and housekeeping practices in the occupied space [6]. Condensation on the interior/exterior of ductwork, however, creates favorable conditions for microbial growth. If particulates accumulate in or on ductwork and the relative humidity reaches the dew point, then condensation occurs and the nutrients in the dust/dirt will cause microbial growth. Mold growth in HVAC systems and buildings requires timely remediation. Because water availability is a critical factor controlling microbial amplification in indoor environments, prompt correction and elimination of water intrusion/moisture sources are imperative.

Water-damaged or mold-impacted ductwork composed of porous or semi-porous materials – including fiberglass duct board, metal duct with fiberglass interior, metal duct externally wrapped with fiberglass insulation and insulated flex duct – should be removed and replaced under controlled conditions. Prior to removal engineering controls should be implemented. Engineering controls refer to equipment and procedures utilized to isolate a work area and to protect the occupants and the remediation workers – for example, temporary containment barriers, negative pressure enclosures, decontamination practices, specialized exhaust fans equipped with high efficiency particulate air (HEPA) filters, dehumidification equipment, and use of respiratory protection. Shut down all mechanical ventilation and HVAC system air handling equipment in the building prior to removal and remediation. All mechanical ventilation in the contaminated area, except that required to maintain the negative pressure, must be sealed off. All HVAC supply and return air vents, floor drains, doors, pipe chases, risers, and other penetrations within the rooms must be sealed with two layers of 6-mil fire retardant polyethylene sheeting to prevent migration of contaminants to other parts of the building. In general, controls are least stringent for building restoration and greatest for protection of sensitive populations [7]. For example, a greater standard of care is required to protect building occupants during remediation in schools and healthcare facilities.

Unlined sheet metal ductwork that is not physically damaged or corroded should be cleaned using mechanical agitation methods to dislodge attached particulate and debris and convey it to a collection device in a controlled manner. Agitation devices include: cable-driven brush, compressed air, and power water wash systems; pneumatic and electric driven brushes; and hand brushing tools. The collection device should be capable of creating a negative pressure differential between the ductwork and the surrounding area. It must maintain a minimum capture velocity to keep loosened particulate entrained during vacuuming, to prevent particle settling on the interior of HVAC system surfaces while being conveyed to the collection device. Minimum capture velocities depend upon the type of particulate and its aerodynamic diameter, particle size and density. Capture velocities required for dust transport range from

0.25 mps for small particulates in quiet air to 10 mps for large particulates released at high initial velocity into an area at very rapid air motion. The American Conference of Governmental Industrial Hygienists (ACGIH) *Industrial Ventilation: A Manual of Recommended Practice*, 26th ed., provides velocity requirements for contaminant removal.

Dry duct cleaning methods are preferred in almost all cases. Cleaning using water wash systems should be performed with extreme caution to prevent microbial growth. This method should be used only in places where porous insulation materials are not present on internal or external duct lining or in close proximity to the ductwork. Clean contaminated surfaces of non-porous ductwork using HEPA vacuums. Surfaces of the ductwork should then be damp-wiped with clean cloths using a water and detergent solution and HEPA vacuumed a second time. Ductwork components and the AHU should also be cleaned of mold-contamination and particulates. Return air grilles, supply diffusers, fan blades, and blower wheels should be cleaned and restored to their original position. Restorative drying equipment, such as portable power fans and dehumidifiers should be used to completely dry the ductwork after cleaning. The ductwork and HVAC system components should be clean and dry prior to re-starting the system. Biocides should not be used for cleaning ductwork. Biocides are not recommended for remediation because they: do not remove allergens and other metabolites from mold, do not kill all mold spores, and may pose health risk to some individuals.

Particle-laden ductwork composed of porous or semi-porous materials has a large surface area which can trap dust/dirt and absorb water compared to sheet metal ductwork. Procedures for cleaning sheet metal ducts should not be used for cleaning particulates from fiberglass-lined ductwork. Cleaning of lined ducts should be performed according to proven industry procedures described in the National Air Duct Cleaners Association (NADCA) *ACR 2006*: *Assessment, Cleaning and Restoration of HVAC Systems.* Lined ducts require a special type of cleaning to maintain their integrity and prevent damage to the lining. Fiberglass ductwork that shows evidence of damage, deterioration, delaminating, friable material, microbial growth, biological material, water damage or moisture accumulation should be replaced. The components being cleaned must be under a consistent negative pressure differential to the surrounding work area. It is extremely important that the cleaning procedure does not create abrasions, breaks, tears or other damage to fiberglass liner or duct board surfaces. Fiberglass materials that become wet during cleaning should be removed and the ductwork replaced.

Duct cleaning should be scheduled during periods when the building is unoccupied. Negative air pressure must be maintained at all times in the duct cleaning area to prevent migration of particulates and contaminants into occupied areas. Large high-volume vacuum equipment should be used with extreme care because negative pressure, together with limited airflow, can collapse ducts. Use existing duct system openings for cleaning unless the ductwork can be safely dismantled and removed under controlled conditions. Duct cleaning should be performed according to project-specific protocols described in a written mold remediation work plan. The plan should be developed by a qualified environmental health professional, such as a CIH, and detail specifications for scope of work, engineering controls, isolation and containment, proper personal protective equipment, and other protective measures necessary during the course of remediation. Specific protocols should be based on consensus guidelines developed by the Institute of Inspection, Cleaning and Restoration Certification (IICRC) S520 *Standard and Reference Guide for Professional Mold Remediation*; the U.S. Environmental Protection Agency (USEPA); NADCA ACR 2006; the New York City Department of Health; and other organizations. Remediation of mold impacted building materials and contents should be included in the work plan [8]. If the building containing the HVAC system has moderate, large or extensive areas of mold contamination, then HVAC remediation should be conducted after remediation of the building and contents is completed to prevent recontamination of the building's ventilation system. HVAC system remediation should be monitored by a qualified environmental health professional during all project phases, to ensure implementation of project-specific engineering controls and cleaning procedures. Maintaining the integrity of containments must be a high priority throughout the project.

Verification of Ductwork Cleanliness

Verification of ductwork cleanliness by means of a visual inspection should be performed by a qualified environmental health professional after cleaning, prior to HVAC system startup, to protect the health of building occupants. Measuring the effectiveness of cleaning may include a quantitative assessment as a secondary method if the results of the visual inspection are inconclusive. Visual inspection of the ductwork should be performed – to ensure that it is visibly clean, dry and free of contamination – while the containment is still intact. Service openings in the ductwork should be accessed to perform a visual inspection and closed afterward. The author typically performs a crude "white glove test" to help make a simple qualitative determination of cleanliness of non-porous surfaces (such as the interior of sheet metal duct immediately upstream of supply diffusers and downstream of the filter bank). The area within the containment should also be inspected to ensure that contaminated materials, visible dust and debris have been removed. There should be no malodors detected in the remediated area. If qualitative judgment in verifying ductwork cleanliness is not sufficient, then a quantitative assessment should be considered. Measuring the effectiveness of cleaning using secondary quantitative methods is best accomplished by a combination of methods: air sampling, surface sampling, laser particle counting, and moisture measurements. Samples and measurements for each method should be obtained before cleaning is performed to establish a baseline for comparison and after cleaning as part of post-remediation verification.

Air sampling is performed using a calibrated air sampling pump operating at a flow rate of 15.0 or 28.3 LPM. Fungal spore samples should be collected from the ambient indoor air and the outdoor air intake. One sample should be collected from the ambient indoor room air; another at a supply air diffuser; and another near the outdoor air intake. An additional outdoor sample should be taken at ground level outside the building for reference control purposes. Each sample should be collected for 2 to 5 minutes. The microbial samples should be analyzed by an Environmental Microbiology Accredited Laboratory using cultured methods, direct microscopy or Quantitative Polymerase Chain Reaction (Q-PCR) analysis. Although more costly, Q-PCR analysis appears to be the most likely technology to be used in the future because it provides very rapid turnaround and greater accuracy, sensitivity, and precision in identifying microbial species present. Microbial air samples are interpreted by comparing the types, distribution and levels of fungal spores found in suspect areas to non-suspect areas or outdoor control areas. General guidelines for interpretation of fungal spore data specify that indoor levels of mold spores should be less than outdoors. The biodiversity of fungal spores indoors should also be similar to outdoors. Surface sampling for fungal growth should be performed using sterile sampling swabs or tape lifts. A one square-centimeter surface should be sampled in each collection area. Samples should be collected on the interior of ductwork: one from the return and one from the supply air ducts. Samples should also be collected in a non-suspect/uncontaminated part of the building. The surface samples should be analyzed by an Environmental Microbiology Accredited Laboratory using cultured methods or direct microscopy. A general guideline for contamination using surface sampling is a comparison of samples collected from suspect and non-suspect areas. The sampling results should also be compared to those collected prior to duct cleaning. A decrease in spore counts should be observed after cleaning.

Particle counting is performed using a calibrated laser particle counter operating at a flow rate of 0.1 CFM. Particle measurements should be taken at approximately 50% of supply air diffusers and at a return air grille. Three samples should be taken at a representative return air grille. A sampling probe should be used for the return air measurements and an isokinetic probe for supply air measurements. Each sample should be collected for one minute. A printout should be generated from each sample enumerating individual particle sizes in the respirable size ranges of 0.3, 0.5, 0.7, 1.0, 2.0, and 5.0 µm. The data collected should be used to calculate the percentage increase or decrease in particulates measured in the air using the following formula:

$$\text{\% Increase or Decrease} = 100\left(\frac{\text{Supply Air}}{\text{Return Air}} - 1\right) \quad [9]$$

The data should be plotted on a modified ASHRAE filter efficiency performance chart. The data should also be compared to pre-cleaning measurements to evaluate the effectiveness of cleaning efforts. The data is also useful to evaluate the performance of the HVAC system filters and could demonstrate the need for upgrades in filter efficiency. Choice of the appropriate filter and proper maintenance are critical to keep ductwork clean.
The remediated ductwork should be both clean and dry after cleaning. Moisture measurements should be taken on the ductwork and components using infrared thermal imaging cameras or non-penetrating moisture meters. Ambient indoor conditions should be monitored during and after cleaning. Relative humidity in occupied spaces should be maintained below 60% and ideally 30 to 50% to increase comfort and minimize the growth of allergenic or pathogenic organisms. After post-remediation verification is completed and deemed to be satisfactory, new HVAC filters should be installed and the system operated to allow at least eight air changes prior to occupancy.

In conclusion, risk assessment, source identification, mechanical and building corrections, HVAC system cleaning, and post-remediation verification is a course of action that should be incorporated into best management practices for building HVAC systems throughout the world. Properly designed, operated and maintained HVAC system ductwork is paramount to achieve healthy indoor air in order to protect human health.

ABSTRACT

The effectiveness of UV radiation lamps in order to reduce fungal contamination of HEPA filters, to extend filter efficacy and to reduce maintenance costs, is experimentally studied by means of a dedicated air conditioning unit. An experimental HVAC system, with HEPA filters and UV-C lamps (λ=254 nm), was built. Two experiments were performed. After disinfection and control of airtightness, the internal surface of the HVAC system was contaminated (1) with *A. niger* spores and (2) with *Actynomices*. Temperature level was 300 K and Relative Humidity (RH) ranged from 30-90%. The results show that the addition of UV-C lamps to HVAC system reduces *A. niger* and *Actynomices* air concentrations; the effectiveness increases with the decrease of RH level in the HVAC system.

INTRODUCTION

The need of reducing the particulate contamination in hospital wards, especially the one biologically active, is of paramount interest for the health of both patients and hospital personnel, in the light of the recent UNI-EN 14644 ([1], [2], [3]) regulations on clean rooms and the associate controlled spaces, and also of regulations UNI EN 14698 [4] and [5] for the control of biocontamination. For the latter purpose several researchers have considered the possibility to adopt UV-C rays (wavelength λ=100÷280 nm) with the germicide lamps located inside the air ducts of the conditioning systems or directly on the roofs, with the purpose to inactivate the microorganisms present in the air flow ([6], [7], [8], [9], [10]).

The germicide capacity of UV-C rays is well known, and is explained by the absorption of such rays into the nucleic acids structure, especially for those with λ=254 nm. Many researchers have studied in detail their mode of action, and the susceptibility of several microorganisms to UV-C ([11], [12] ,[13], [14]).

During the disinfection procedures generally four types of survival curves have been observed for the microorganisms, described by linear-logarithmic graphs, having the log of the surviving microorganisms number plotted as a function of the employed treatment parameter (time of exposure or the doses of UV-C rays).

Such types of graphs are represented through linear curves A, curves with one shoulder B, curves with a tail (two stage survival curves C) or sigmoid curves D ([15], [16], [17], [18], [19]), such as qualitatively reported in Figure 1.

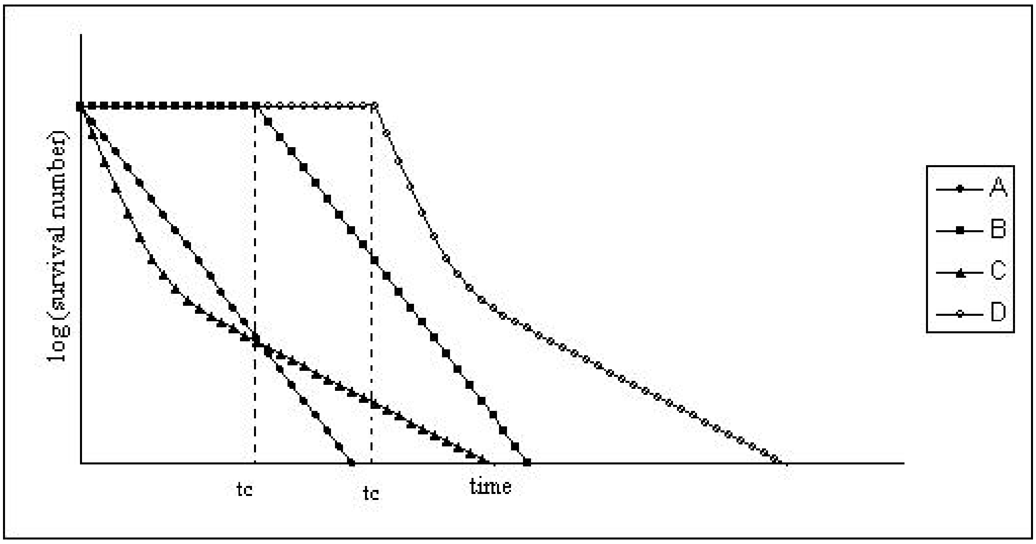

Figure 1- Survival curves (generic for bacteria or fungi):
linear (A), shoulder curve (B), two stage curve (C), sigmoid (D)

The mathematical models which represent such curves A, B, C, D can be expressed respectively as

$$N = N_0 e^{-\alpha t} \tag{1}$$

$$N = N_0 e^{-\alpha(t-t_c)} \quad \text{for } t \geq t_c \tag{2}$$

$$N = N_0\left[(1-F_0)e^{-\alpha_1 t} + F_0 e^{-\alpha_2 t}\right] \tag{3}$$

$$N = N_0\left[(1-F_0)e^{-\alpha_1(t-t_c)} + F_0 e^{-\alpha_2(t-t_c)}\right] \quad \text{for } t \geq t_c \tag{4}$$

where

- N and N_0 represent the microorganisms surviving at time t and those initially present at time t=0 respectively;
- α is a parameter proportional to the applied UV-C intensity and depends on the sensitivity of the microorganism to the UV-C rays exposure;
- F_0 represents the most resistant fraction, characterized by a lower sensitivity to the UV-C rays exposure, in a population of microorganisms, compared to the fraction (1 - F_0) less resistant to such exposure;
- t_c is the time during which microorganisms are substantially not inactivated

Among the different factors influencing the phenomenon of UV-C disinfection there are the air temperature and the air relative humidity ([20], [21], [22]).

The paper showes the results of an investigation on microorganisms *Aspergillus niger* and *Actinomices spp* exposed to UV-C both in the air stream and on the surface of HEPA filter. Inactivation curves at different values of relative humidity (RH) for the air (30%, 60% and 90%) are presented.

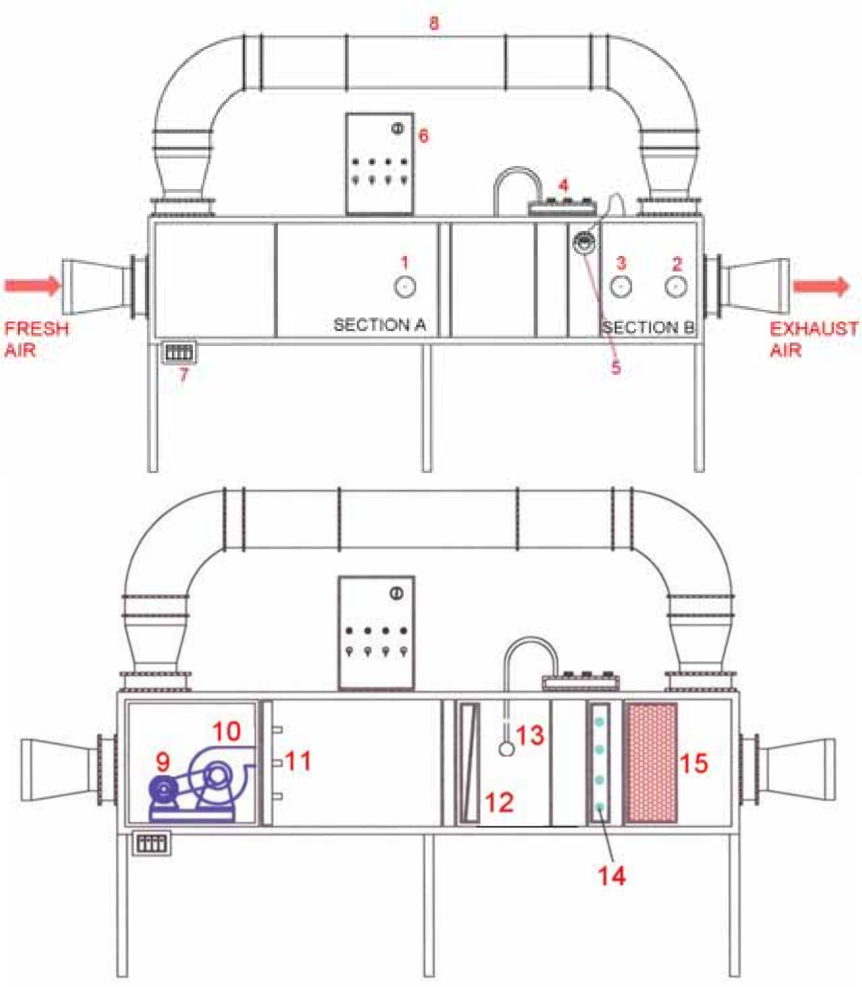
METHODS

Experimental Facility

The experimental apparatus is an air conditioner unit for air treatment (Figure 2), composed by

- A section including the fan together with his electric motor;
- A zone for microbiological charge (Colony Forming Units CFU);
- A section containing the air heating resistor and the steam humidifier with drops separator;
- A section containing the germicide lamps;
- A section containing the filtering media.

For each section there is the possibility of air sampling through an opening equipped with special butterfly valves, in order to avoid losses during the sampling. The box containing the Air Conditioning Unit (ACU) is made by galvanized steel sheets with finished surface; this is to avoid the growth of bio-film on the surfaces and to obtain a good reflection coefficient to increase the germicide action of the UV-C lamps installed.



Figures 2 - Experimental facility schemes. At top lateral view, at bottom lateral section.
1 air sampling intake A, 2 air sampling intake B, 3 inspection intake, 4 humidifier,
5 thermometer, 6 general electric panel, 7 UV-C lamps control, 8 air recirculation duct,
9 electric motor, 10 fan, 11 CFU plates, 12 heaters, 13 humidifier distributor,
14 germicide lamps UV-C, 15 HEPA filter

In the first section of the air conditioner unit ACU, along the air circuit, there is a fan with a static prevalence of 100 Pa and a capacity of 1,500 m^3/h, driven by a monophase electric motor fed at 220V.

In the second section are included

- Three armoured electric resistors, fed at 220 V, as heating device for the temperature control. They are regulated through a temperature probe and can absorb power up to 5000 W.
- The steam distribution for the relative humidity (RH) control of the circulating air into the ACU. It is an inox steel linear distributor which introduces steam obtained by a submersed electrodes humidifier that can reduce the water pollution by 99.8%. The humidifier is controlled by a humidity probe with modulating signal and absorbes a power of 5.8 kW supplied by an electrical transformer providing 8 kg/h of sterile steam. The humidifier with submersed electrodes is fed by the water line of the laboratory. This type of humidifiers operates through the Joule effect using as electrical resistance that of the water which is heated and evaporates. An anti foaming system (AFS) can detect and discard the foam produced in the cylinder. Due to the fact that the steam produced inside the ACU can condensate, the pipe of the distributor is positioned sub-horizontally, with a slope of 2-3% in order to avoid biological growth.

The third section houses the germicidal lamps mounted, with their standard supports for fluorescent lamps, on supports built ad hoc, standing on a squared frame. Four lamps (PHILIPS TUV UV - C G15T8 LONG LIFE, 15 W each) are used. They are tubular quartz lamps, 450 mm long, 26 mm diameter, fed at 220 V, with a specific UV-C emission of 40 μW/cm^2 and they are located on the air flow.

The last ACU section houses the aluminium sledges containing the HEPA filter employed during the experiments, with efficiency DOP of 99.995%**,** mounted at a distance of 150 mm away from the germicidal lamps.

MEASUREMENT PROTOCOLS

The objectives pursued during the experiments with UV-C as air disinfectant are the following:

- To verify the efficacy of the association of mechanical filters and UV-C apparatuses.
- To verify the microbial growth on the mechanical filter surface is avoided.
- To evaluate the opportunity of irradiating a filtering medium at high efficiency.
- To prolong, if possible, the operative life of mechanical filters.

To perform the research phases and obtain correct conclusions, it has been necessary to plan correctly the different steps. Before of each measurement campaign detection of possible air leakages from the plant, clean-up and disinfection of inner surfaces, disinfection of inaccessible parts using “Fumispore” was performed. After the introduction of fungal dose by means of the Colony Forming Units CFU and the start up of plant, three air samples was drawn in order to determine the initial situation. The air sampling was performed by means of a SAS device.

- PRELIMINARY PHASE: empty plant. Determination of the right dose of fungi to introduce into the ACU. Quantification of the natural decay of the microbial concentration due to three simultaneous events: (a) microdispersion outside the ACU, (b) deposit of fungi onto the internal surfaces, (c) lysis of the fungi due to the mechanical collision against the hard surfaces of the plant.
- FIRST EXPERIMENTAL CONDITIONS: plant operated with UV-C only.
- SECOND EXPERIMENTAL CONDITIONS: using Hepa filter inside the plant with UV-C not operating;
- THIRD EXPERIMENTAL CONDITIONS: using Hepa filter and operating UV simultaneously.

During the first, second and third phases, air sampling and sampling from the inner surfaces of ACU have been performed. For air we performed three samples for each sampling interval; the sampling interval was time 0, after 15 min, after 30 min, after 45 min, after 1, 2 4 and 6 hours. For the surfaces, several samples was drawn at the end of the single experiment.

RESULTS AND DISCUSSION

In this paper we report results regarding survival curves into the air samples, whereas those regarding the surface samples will be reported in future work. Also the opportunity of irradiating the filter at medium efficiency will be investigated in future work.

Figures 3, 4 and 5 report the inactivation curves toward time. The curves show the typical two stage shape with tail: it confirms what has been observed by many researchers, in particular Cerf 1977 [23], Smerage and Teixeira 1993 [24], Fujikawa and Itoh 1996 [25] and others ([26]). In general, in every microbial population there exists a small fraction resisting the UV-C radiations or other bactericidal agents. In that case, the mathematical model of inactivation can be represented by the relationship (3).

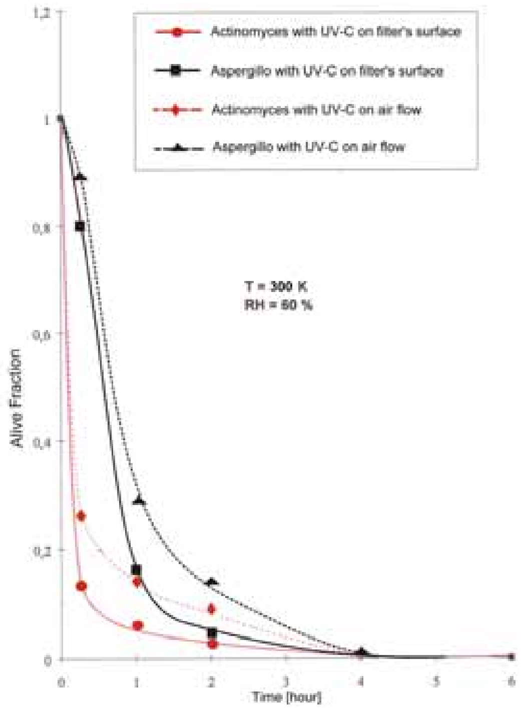


Figure 3 – Comparison of two radiation techniques for *Actinomices* and *Aspergillus niger*

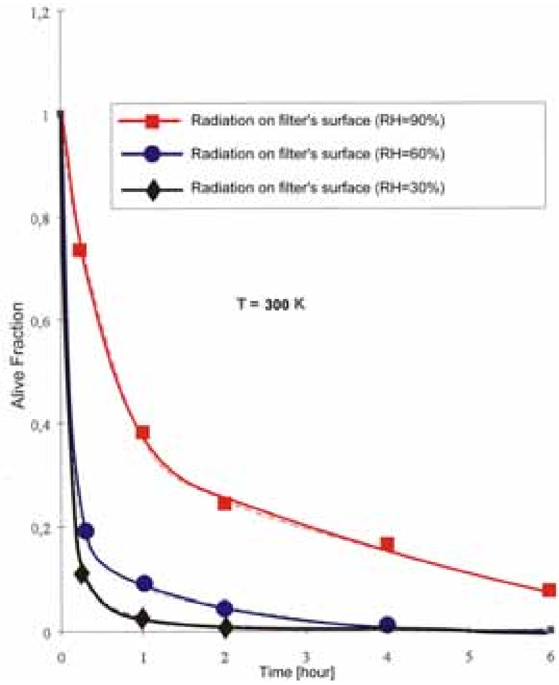

Figure 4 – Inactivation curves of *Actinomices*

Figure 3 shows the inactivation curves at 300 K and 60% RH for *Aspergillus niger* and *Actinomices*. It is clear that *Actinomyces* has a higher sensitivity compared to *Aspergillus niger*. Curves refer to measurements performed when irradiating the air stream and the HEPA filter surfaces respectively. The fraction of *Actinomyces* surviving 15 min later after irradiation of the air stream and of the filter results less than 25% and 15% respectively, whereas the fraction of *Aspergillus niger* it is still 90% and 80%. Irradiation of the filter surface gives better results than irradiating the air stream, as it appears evident from the much faster decay of the surviving population.

Decay curves of *Actinomyces* at 300 K temperature toward variation of RH are reported in Figure 4, while Figure 5 compares the decay curves of both microorganisms toward the variation of the test conditions, RH and modes of irradiation. When increasing irradiation, the fraction of surviving population increases neatly, and becomes much higher when RH is 90%.

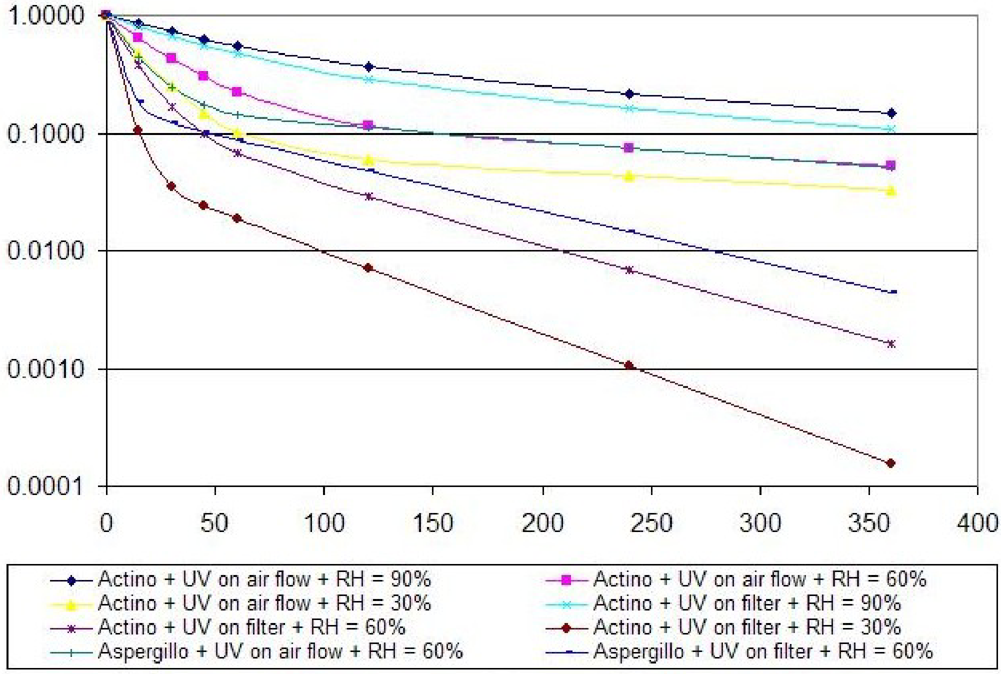

Figure 5 Decay curves of surviving Aspergillus niger and Actinomices fraction for different values of relative humidity and for two irradiation targets (air flow or filter surface)

At this value the differences observed in the decay curves with different irradiation procedures (irradiation of the air stream and irradiation on the filter surface) are quite small. Absorption of UV-C radiation by the steam becomes very high and, therefore, the effect of UV rays is reduced, especially for the more resistant population fraction. The tails do not differ significantly one from the other.

On the contrary, with low RH values (30%), the direct irradiation of the filter surface has amplifying effects on the decay of microrganisms, compared to the other irradiation procedure. Also the resistant population fraction decays faster, as it is demonstrated by the slope of the tail.

The Prevention of the Snow Entrance to the HVAC-systems

Vesa Asikainen and Pertti Pasanen

University of Kuopio, Department of Environmental Science

SUMMARY

Entrance of snow into the HVAC-systems is common problem in the arctic- and sub-arctic climates and may cause moistening or wetting of filters and outdoor air chambers which promotes microbe growth. Blocking the filters also increases pressure drop or even damages the filters. The design features and velocity of air in the outdoor air intake play key role when the problems occurs. To eliminate the snow entrance into the HVAC-systems the face velocity of the outdoor air shall be below 1 m/s at the intake louvre. The pressure caused by wind is one of the external conditions that influence the snow penetration through the intake louvre and some solutions for elimination of this problem are presented. If the snow, however, is entranced to the HVAC-system good design and hygiene control of the intake section of the HVAC-system is important which is discussed more detailed in this paper.

INTRODUCTION

Supply air filters are designed for collection particles such as pollen and other bioaerosols from the outdoor air. The better the filtration is more efficiency the concentration of particles in the supply air decreased. Besides decreased particle concentration in the air, the dust accumulation on the duct surfaces is minimized with proper filtration. Microbes of the outdoor air accumulate to the filters and especially during the warm seasons the concentrations of microbes increased. In normal operation conditions when the HVAC-system is running the filter is dry and air velocity through the filter is high enough that microbes will loose their viability. The life times of the microbes on the filter vary from few hours to few days. Non-viable spores of fungi and bacteria stayed on filter are comparable to the other particles which are not considered to cause adverse health effects. However, spores of the microbes are able to activate when conditions on the filter turns favourable for the microbial growth. These conditions could be possible it the air humidity is high or the filters get wet by the rain water or the melted snow and the supply air fan is shut down. If massive microbial growth occurs on the filters some of the spores will be released to down stream of the filter. The microbial growth is also possible on other parts of the HVAC-system if the moisture is present.

Control of humidity or water entrance to HVAC-system is important because excess moisture will be a risk for microbial contamination of the system [1]. When outdoor air intakes of the HVAC-systems were dry the microbial contamination of the HVAC-systems were not observed. The transportation of microbes via supply air ducts from the outdoor air intake to the supply and indoor air has been reported [2]. Hansen [3] has concluded that dry and clean outdoor air intakes are less likely to be microbiologically contaminated, and thus a good design and maintenance of the air intakes is a key factor for minimizing the risks from potential problems.

When the snow accumulates to the outdoor air chamber of the HVAC-system the surface of the snow can be at the same level than the outdoor air damper, ductwork and filter. In worst case the snow even totally blocks the outdoor air dampers and filters (picture 1). When the filter is blocked the supply air flow will decrease remarkably and the pressure difference in the building may be changed dramatically. This may cause serious indoor air quality problems in buildings like laboratories and hospitals. In some cases the pressure drop over the filter blocked with snow has increased so high that the filter has broken. The broken filter may release dust accumulated to the filter and this dust may spread to the supply and indoor air.

Picture 1. The filter blocked up with snow.

The humidity penetration to the HVAC-system is difficult predict because it is accidental and depends on weather conditions. In Norway 31 HVAC-systems were studied and in 15 of them supply air fans had humidity problems [4]. In our study we revealed a questionaire for the service people of about 270 HVAC-systems in Finland. Serious snow entrance problems existed annually on the average of 10 % (range 7-42%) of the studied HVAC-systems.

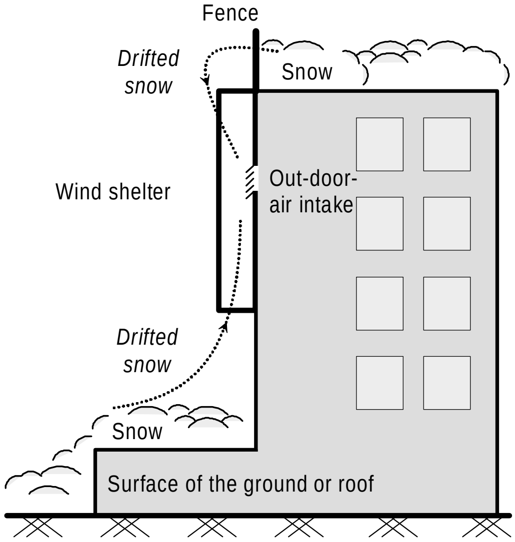
The penetration of the snow or rain water into the HVAC-system's outdoor air chamber is most probable in those where the face velocity of the air is too high and air intake is located incorrectly. The most serious problems in HVAC-systems are focused on the systems where the moisture penetrate through the air intake louvre and due to too high air velocity, too small outdoor air chamber or incorrectly located outdoor air duct the humidity drift to the filter.
The most serious snow entrance problems are detected in the HVAC-systems equipped with an alarm system which alarms when the pressure drop over the filter increases if outdoor air damper or the filter is fully or partial blocked up with the snow. In these cases, the alarms for pressure-drop indicate air flow limitation and malfunction of ventilation system. In the HVAC-systems which had not been equipped with the alarm system the snow entrance was difficult detect. These systems need checks of the outdoor air intake section after every snowfall.

DESIGN OF AIR INTAKE AGAINST THE SNOW ENTRANCE

Outdoor air intakes shall be located so that the outdoor air is as clean as possible. Instructions for location of the intakes have been given for example in Finish building code [5]. Also the maximum face velocity of the outdoor air on the intake shall not exceed 2 m/s.

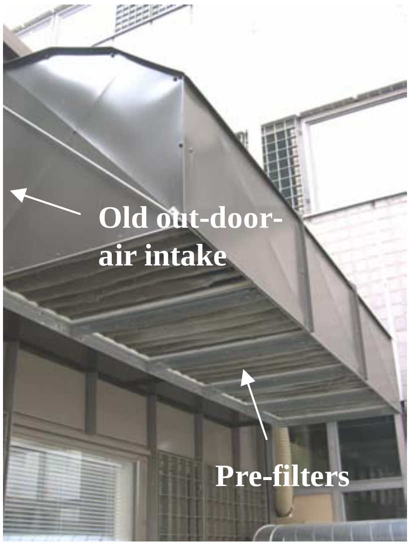
On the snowfall the falling speed of the snow flake is slow 0.2-1.0 m/s [6] and that's why the snow flakes drifts easily to the HVAC-system if the face velocity is too high in the air intake. Because of the slow falling speed the prevention of the snow penetration is more difficult than the rain water penetration and it is recommended that the face velocity of the outdoor air shall be below 1 m/s. If intake is located just above roof or ground, the snow will be driven to the system more easily (Picture 2). A proper location higher from the roof or ground levels prevents snow entrance. Also the wind shelters and fences could be used against the drifted snow (pictures 2 and 3).

The effect of the wind pressure on the penetration of the snow into the HVAC-system has not been studied, but effect might be remarkable because typical annually mean wind speed for example in Finland is 2.0-6.7 m/s and during stormy raining wind speed will be much faster. The pressure caused by wind may at times even exceed the pressure caused the supply air fan and that's why the air intake shall be located so that the wind pressure is low as possible. Good placements for air intakes are in inner yards of the building because the wind speed is typical lower than on outer facades. Also other buildings and plants especially conifers decrease the wind speed. The effect of the wind pressure could be reduced also with the wind shelters (Picture 2 and 3). The wind shelters shall be dimensioned wide enough or they shall be open only from bottom so that wind could not directly blow to the air intake. When the wind shelter is used it's important that the opening of the outdoor air intake is wide enough so that the air velocity and pressure at the opening is not too high.



Pictures 2 and 3. The wind shelters and the fence against the drifted snow and wind pressure.

There are many commercial prevention solutions for the snow and rain water penetration which are based on the mechanical separation or/and melting of the snow. The function of **mechanical louvres** based on the separation of the water and snow particles to the air flow with the labyrinth construction of the louvre. In some mechanical louvres **electric heating devices** are also used which melt the snow and increases louvre's prevention efficiency for snow. The function of the **needle heat exchanger** is also based on the melting of the snow and separation of the snow and melted water to the air flow. On the needle heat exchangers the needed energy is transferred from the exhaust air. **Pre-filters** are also applied for of snow penetration and for example the method in picture 4 is used for prevention of the snow entrance. With this solution one of very difficult snow penetration problem has solved. During the snow fall snow is collected to the pre-filter and after the snow fall snow will drip from the filter.



Picture 4. The pre-filter used for prevention of the snow entrance.

THE MINIMIZING OF THE PROBLEMS CAUSED BY THE MOISTURE AND SNOW PENETRATION

The outdoor air chamber shall be large enough to prevent the snow entrance to the supply air filter and into the HVAC-system which allows to snow settle down to the bottom of the chamber. For dimensions of the outdoor air chamber are not given in any instructions but size of the chamber shall be in relation to the air flow rate. The outdoor airduct and damper shall be located to the upper part of the chamber which increases the efficiency of snow capture in the chamber. The melt water shall be sewed from the chamber and the bottom of the chamber shall slope to the drain. However the enlargement of the outdoor air chamber is often difficult and expensive renovation solution because the chamber shall re-located. The hygiene of the outdoor air chamber shall taken account and all unnecessary material and debris shall be removed from the chamber. The coating material of the chamber's ceiling, walls and especially floor shall be hygiene, easily cleanable and moisture-resistant because on the dirty and moist materials are increases the risk of the microbial growth. For the same reason porous sound attenuation material in the outdoor air chamber is not recommended if there is the risk of the moisture penetration.

The snow entrance to the filters located too near of the outdoor air intake and chamber is more probable because the snow has no time to settle down before the filter. However if there is long outdoor air duct between the outdoor air chamber and filter care shall be taken for drainage of the melted water from duct. To ensure proper drying of the filter it shall install so there is no contact with the bottom of the filter chamber even when supply air fan is turned off. The operation time of the HVAC-system has effect to the moisture and the microbial contamination of the filters and it is concluded that the continuously operated HVAC-system creates less favourable conditions for microbial growth in filters than does the periodically operated system [7].

THE INSTRUCTIONS IF SNOW OR MOISTURE IS PENETRATED TO THE HVAC-SYSTEM

If the snow or moisture entrance to the HVAC-system and filters are filled up with the snow:

1. Supply air fan shall turn off
2. Wet or snowy filters shall remove as soon as possible
3. Filter shall be changed
4. Outdoor air chamber, -damper and other components of the HVAC-system shall check and snow and moisture shall remove
5. Supply air fan shall turn on

ACKNOWLEDGEMENT

SUMMARY

Following the continuous growth of the air conditioning market and the European Directive on the energy performance of buildings (EPBD), many changes are expected on the European air-conditioning market. The article 9 of the EPBD takes care about the Inspection of air-conditioning systems promoting possible improvement or replacement of the air-conditioning system. The AuditAC project reached its conclusion with a set of deliverables showing: the advantages from the new inspection system, how to benefit from the combination of air-conditioning (AC) systems audit and inspection, to promote the best practices and to help harmonising the implementation all over the European countries. The results are delivered in form of tools and guides freely accessible from the AuditAC web site. Ten technical guides and tools for owners, energy managers and auditors have been delivered with the aim to rise the awareness of the users about the energy savings subsequent to a “wise” management of the air-conditioning plant, to discover the energy conservation opportunities of an air conditioned building from a full list of possibilities, guiding auditors in audit procedures and supplying advices to identify the actual system performances and forecast energy savings.

INTRODUCTION

In the coming years the stock of Air Conditioning (AC) equipment in use in Europe will partly become obsolete. Most systems will be renovated for the first time (after 10-15 years of operation) and an opportunity exists to introduce higher efficiency systems. Out of the 2.200 Mm² of air-conditioned building area in use in 2010 in Europe, 800 Mm² will date by more than 15 years and will need urgent renewal (Figure 1). A SAVE Study [1] had the result that there is an energy saving of about 50 %. That means: AC – Systems are able to operate with about 50 % less energy.

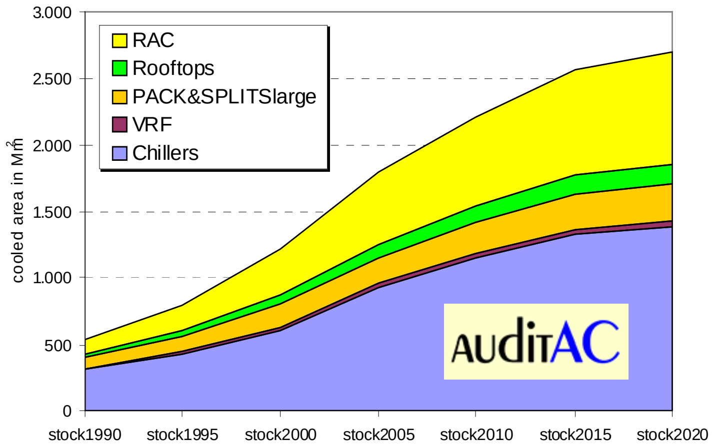

Figure 1 Estimated air-cooled area (Mm²) growth in Europe

This market will be influenced by the Directive 2002/91/EC of the European Parliament and of the Council of 16 December 2002 on the energy performance of buildings (EPBD [2]). According this new directive all over Europe, the building legislation will be changed to create higher energy efficiency within the European buildings.
The Directive takes care about the Inspection of air-conditioning systems:

Article 9- Inspection of air-conditioning systems

With regard to reducing energy consumption and limiting carbon dioxide emissions, Member States shall lay down the necessary measures to establish a regular inspection of air conditioning systems of an effective rated output of more than 12 kW.

This inspection shall include an assessment of the air-conditioning efficiency and the sizing compared to the cooling requirements of the building. Appropriate advice shall be provided to the users on possible improvement or replacement of the air-conditioning system and on alternative solutions.

AuditAC [3] is the short name for the two years project about "Field benchmarking and Market development for Audit methods in Air Conditioning", completed in December 2006. AuditAC was not a project about the implementation of Article 9 of the EPBD. It was much more a project about the questions that comes after the legislation on the national level. Within the focus of AuditAC was to support the European AC market to reach higher efficiency, by taking benefit of good inspections and subsequent audit.
Inspectors or auditors are external or internal engineers (or qualified technicians) in charge of establishing the status and proposing improvements on a plant which is not in failure mode. This is true for Air Conditioning as for any other piece of equipment. In case of failure, a maintainer should be called, not an auditor…Inspection or audit should be the initial stage of any of the following actions: starting or restarting operation of a plant, energy efficiency improvement, study of possible renovation, etc. The owner that decides to go through various stages to reach Energy Efficiency looks for answers to which only the audit procedure can answer: is there an opportunity? How large could be the benefit and the cost of my action? How make the best decision between several possibilities? How check that the measure is effective? AuditAC wants to supply the tools and help to best answer to these questions and make the owner confident facing the investment for energy efficiency.

AIR CONDITIONING ACTORS: HOW TO PROMOTE ENERGY EFFICIENCY

The initial review of existing pre audit and audit methods for air conditioning systems proved they were very scarce. A number of measures in the EPBD do not benefit from experience

feedback, among which the AC plants inspection. Inspection can be considered as a sort of short compulsory audit.
Audit behind inspection has been saw as a sporadically measure, although it should be repeated all along the plant lifetime in a continuous improvement strategy. Nowadays, there is always a factor giving birth to an audit. In the normal life of the plant it can only be a significant failure. For most plants an audit will only take place if the building suffers a deep renovation or ownership change. We see immediately that EU inspection from EPBD aims at introducing more audit opportunities.
If we look at the actors involved in the audit (Figure 2), only the owner or the manager is responsible for the decision but he rarely has the elements for the decision. These elements came from the auditor/inspector after exchanged information with all the other actors. Normally operators and maintainer do not have interest in the energy efficiency (except for specific O&M contracts). Finally best audit is a synergy from the different parts.

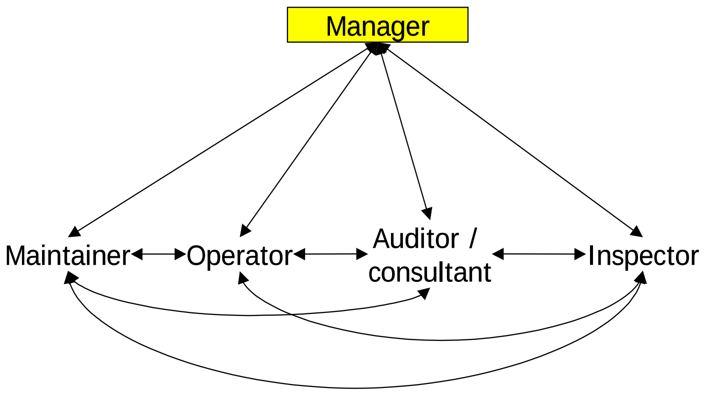

Figure 2 Actors and relationships in a situation of AC audit

So firstly, the AuditAC objectives were to disseminate information about the new measures and to rise the awareness of the AC actors about the benefits of the audit. A set of deliverables in form of technical guides explains which are the key points of energy efficiency in an AC plant (TG 1: Are you sure you are not paying for inefficient cooling?), makes light on the new inspection systems (TG 2: Energy Auditing of Air Conditioning Systems and the Energy Performance in Buildings Directive: what does the new regulation say?) and makes the owners more familiar with the AC aspects: equipments and comfort requirements (TG 3: System recognition guideline for field visit).

A training package (TP) including the information of the project results has been released in order to promote the AC audit. This TP contains 150 slides made in simple and non-technical language, an open version is proposed to users who want to take inspiration and ideas for their presentation and training. A default version is proposed to the large public (Figure 3): it starts from the basic of the air conditioning and the systems summary, then go through the inspection measures and finally through the air conditioning audit and the energy conservation opportunities. The training package has been tested initially internally to the group and published at the end if the project after validation.

Figure 3 Training package: title and index

Furthermore, AUDIBAC interface (Figure 4) allows to retrieve in the AuditAC case studies database the cases that fit more to real problem starting from simple parameters choice (system type, sector building etc.): it is a real shop window for the air conditioning audit! In simple layout the TG 10 documents includes all the AuditAC successful case studies of audited of AC buildings in a simple brochure.

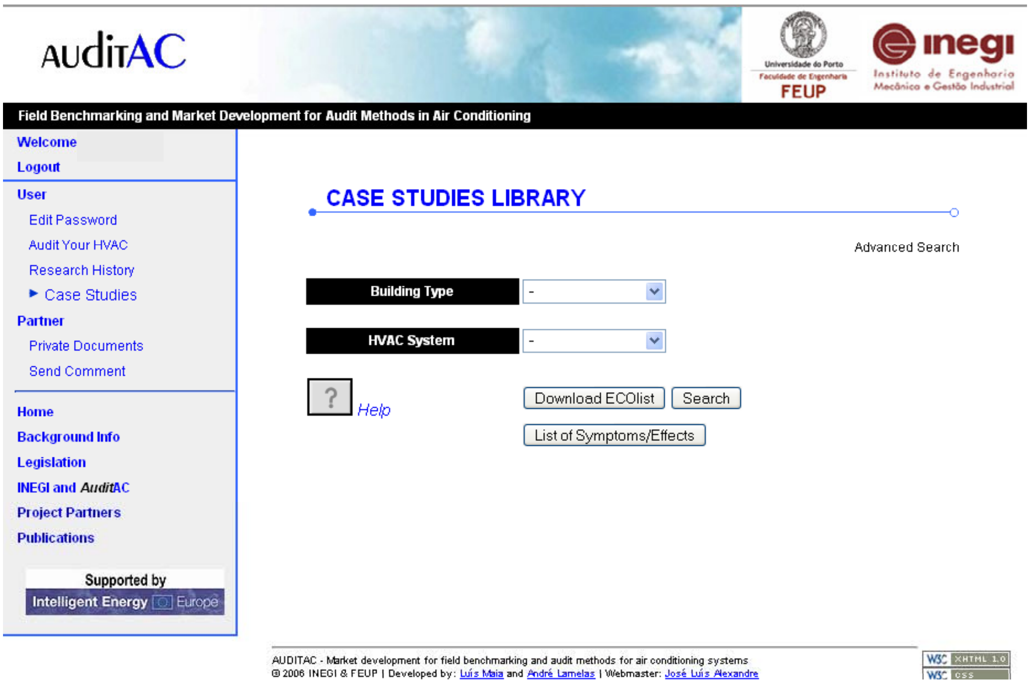

Figure 4 AUDIBAC database screen capture

All these documents are aimed to remove the prejudices of the owners about the air conditioning and rise the awareness of the opportunities to better operation of the systems maintaining or improving the comfort aspects. To improve the knowledge of the air conditioning is a first way to eliminate the barriers to the audit.

THE AUDIT PROCEDURES

In a second phase of the project we focused on the formal presentation of the characteristics of the procedures and the development of the procedures themselves. We made distinction between two levels of audit.

PRE-AUDIT

Pre-audit is a preliminary procedure mainly consisting in: inventory of thermal equipment in place and documentation, treatment of electricity consumption bills, disaggregation of AC data from others. We have found no existing real tool for pre-audit of air conditioning, except some check lists, outdated in some cases or mainly adapted to US practice. That led us to the definition within Auditac of a pre-audit procedure for air-conditioned buildings to support the pre-audit process (TG 4).
The procedure should preliminary investigate the possible of energy conservation opportunities (ECOs): we propose a full list of ECOs including actions at different levels: improvement through actions on Envelope and Loads, improvement through O&M, improvement through Building Energy Management System (BEMS), performance enhancement through adequate improvement works. Energy managers and owners can help the procedure with a continuous follow up of their consumptions and bills. TG 7 propose some simplified methodologies for non professional auditors to observe and track the AC operation and efficiency through the analysis of bills and consumptions: where auditor already find the owner doing a track of its consumption he will not need to do it again.
A simple spreadsheet calculator tool, called AC-cost, allow to have a first savings estimation due to four common actions in term of money savings based on real or estimated running costs. The sheet is easy to use; it helps the user to estimate the requested information when unknown and its results are easy to understand as they are showed in form of cost savings in euros, as gain of annual running cost and payback times in years.
The Customer advising tool (CAT) (Figure 5) allows to rapidly observe the effect of actions on the existing envelope, taking into account the building structure and location, a link allow simply to explore existing audit case in the database AUDIBAC.

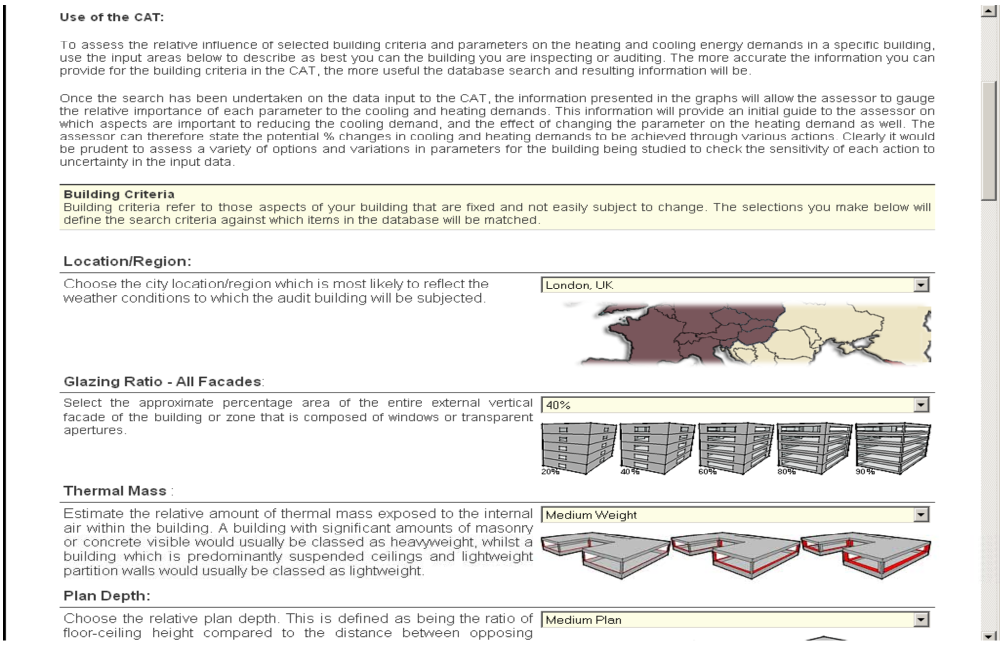

Figure 5 CAT tool screen capture

AUDIT

Thanks to the work on pre*audit, we may enter the audit phase going deeper in the selected ECOs in the previous procedure. There are tools to support the detailed audit of heating plants. We have found no specific tool for auditing air conditioning. Audit duration is a cost issues: more and simpler are the auditor tools, shorter and more efficient would be the audit. In this sense, we proposed several tools to help the auditor in the unfortunate audit work!

The AuditAC-EES model (Simplified load calculation tool defining the consumption of ideal system with the same comfort demands) will lead the auditor to estimate consumptions and the impact of the retained ECOs through the introduction of few parameters from the audited building (Figure 6). The AuditAC-EES model is accompanied by its explaining user's guide.

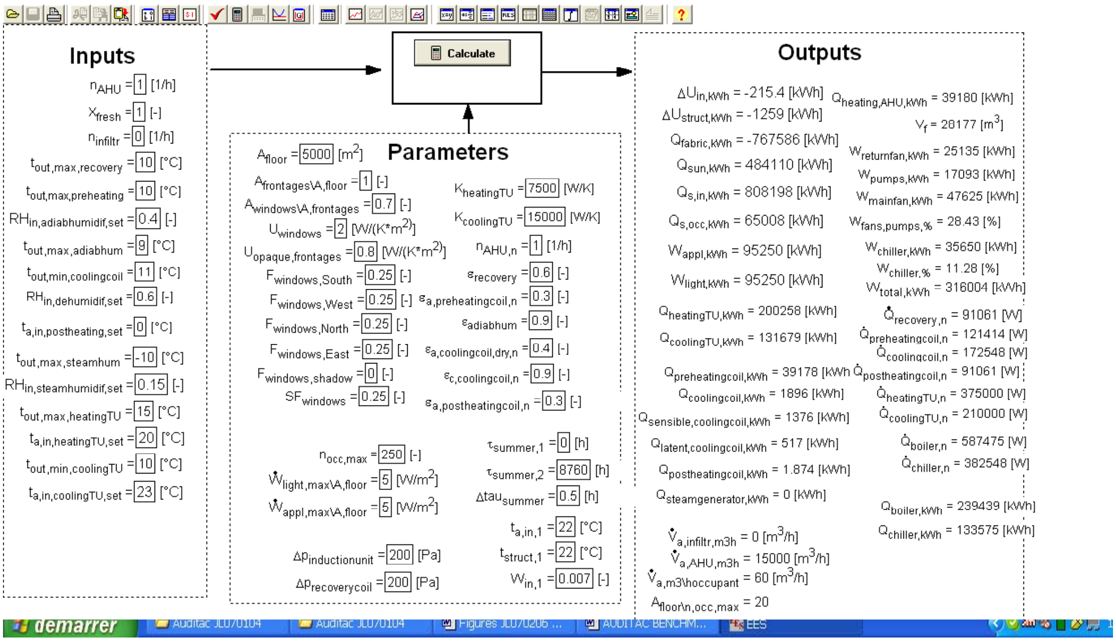

Figure 6 Inputs, parameters and outputs of the EES model

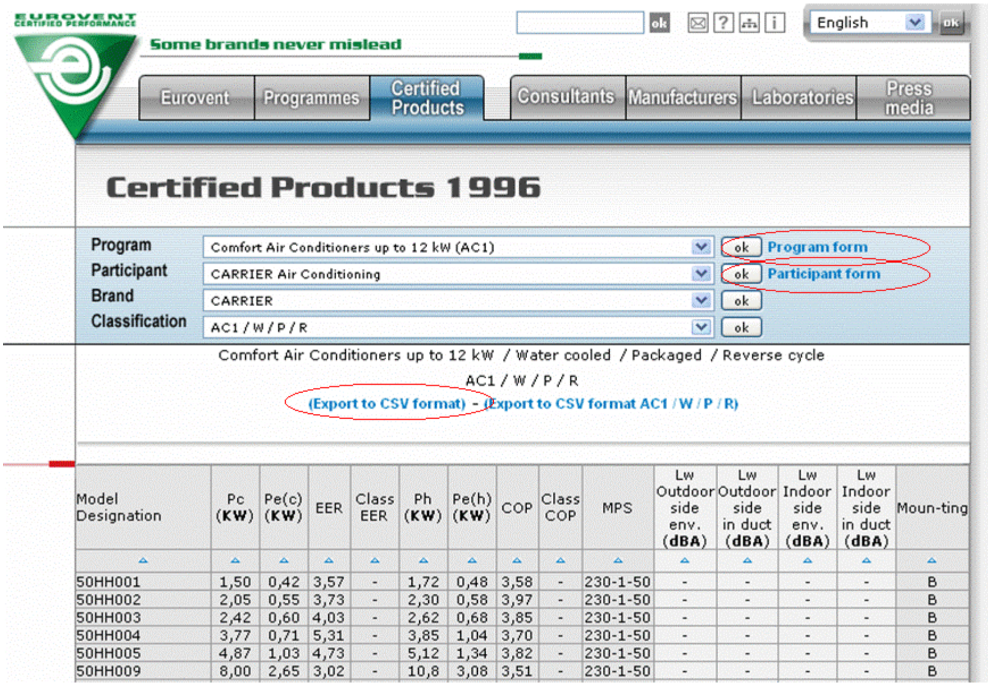
More help can come from the Eurovent-Certification database created in the AuditAC project. This database includes the Eurovent certified directories from 1995 until 2006 (an example in Figure 7). This directories includes certified values of performance for AC conditioners, auditor can retrieve data on the installed equipment when this is unknown, or retrieve data on the equipment of the same period and compare with performances of recent model and technologies looking for a better solution of replacement. How to benefit from this database is illustrated in the TG 6 "How to benefit from the Eurovent-Certification database and to retrieve past equipment data in the audit process".



EUROVENT CERTIFIED PERFORMANCE
