Contents

Key-note lectures

A01 Indoor environment, health and productivity

A02 Performance of ventilation systems

A03 Filters and air cleaning

A04 Criteria for thermal environment

A05 Pollutants in the indoor air

A06 Residential ventilation

A07 Advanced components for ventilation and AC

A08 Indoor environment in schools

A09 Ventilation for special environments

A10 Maintenance and improvement of ventilation systems

A11 Human responses to thermal environment

A12 Sources of indoor air pollution

B01 Evaluation and rating of building performance

B02 Building components and double skin facades

B03 Energy efficient building design

B04 Energy performance of buildings and building stock

B05 Sustainable energy systems

B06 Natural and hybrid ventilation systems

C01 Life cycle services and commissioning

C02 Simulation of building systems

C03 Demand controlled systems

C04 Calculation of energy performance and implementation of EPBD

C05 Building automation and information systems

C06 Computer based design methods

D01 Heat pumps

D02 Air-Conditioning systems

D03 Refrigeration and cooling systems

D04 Energy efficient heating systems

D05 Heating and piping systems

D06 Low energy cooling

FOREWORD

The Clima 2007 congress is an official congress of Federation of European Heating and Air-conditioning societies (REHVA). The Clima Congress series was established to transfer research results into practice in the area energy efficient building services and to increase the exchange of information between countries with different experience in building services engineering. The first Clima congress was held in Milan (1977), then in Copenhagen (1981), Sarajevo (1985), London (1989), Budapest (1993), Brussels (1997), Naples (2001), and Lausanne (2005).

The 9th Congress in Helsinki held in Finland June 2007 focused particularly on how to design, build and maintain healthy and productive indoor environment with low use of energy. The title of the congress “WellBeing indoors” reflects this goal. The Clima 2007 Congress was organised in co-operation of four organisations: Finnish Association of HVAC Societies (FINVAC), the official Finnish member of REHVA, Helsinki University of Technology (TKK), Finnish Association of Mechanical Building Services Industries (FAMBSI), and Finnish Society of Indoor Air and Quality (FiSIAQ).

The invited key-note lectures and the one-page summaries of the over 460 papers presented in the Clima 2007 congress are published in the Abstract book. The full papers are published in the Proceedings CD, organized in 30 sessions under the following themes:

Theme A: Healthy and productive indoor environment
Theme B: Sustainable energy use of buildings
Theme C: Intelligent design and management of buildings
Theme D: Energy efficient heating and cooling systems

The main objective of the congress was to share the knowledge between scientists, practitioners and manufactures. A significant outcome of the congress are the reports from the 20 workshops organised during the congress. The results of the workshops will be available at REHVA website (*www.rehva.eu*). The summaries of the workshops will also be published as a booklet. After one year of the Congress the papers will be also available in a AIRBASE bibliography database at *www.aivc.org*.

Many people have worked hard to make the Clima 2007 congress successful. We wish to thank all of you for the effort. We are also grateful for the congress partners, sponsors and supporters of the congress whose support made the congress possible. We wish to present our thanks also to the scientific committee that reviewed the papers and helped in organising the sessions and proceedings. For technical assistance in compiling the proceedings we thank Mr Jarkko Narvanne.

Providing Better Indoor Environmental Quality Brings Economic Benefits

William Fisk[1], Olli Seppanen[2]

SUMMARY

This paper summarizes the current scientific evidence that improved indoor environmental quality can improve work performance and health. The review indicates that work and school work performance is affected by indoor temperature and ventilation rate. Pollutant source removal can sometimes improve work performance. Based on formal statistical analyses of existing research results, quantitative relationships are provided for the linkages of work performance with indoor temperature and outdoor air ventilation rate. The review also indicates that improved health and related financial savings are obtainable from reduced indoor tobacco smoking, prevention and remediation of building dampness, and increased ventilation. Example cost-benefit analyses indicate that many measures to improve indoor temperature control and increase ventilation rates will be highly cost effective, with benefit-cost ratios as high as 80 and annual economic benefits as high as $700 per person.

INTRODUCTION

Recently completed research, reviewed in this paper, indicates that there is a large untapped opportunity for economic benefits resulting from improvements in indoor environmental quality (IEQ) in non-industrial work places and homes. The most clearly established sources of economic benefits include improved work performance, e.g., work speed or quality, reduced absence, and reduced health care costs. There is also evidence that providing better IEQ can improve student learning which, in turn, should lead to more effective future workforces. At the societal level, economic value can also be assigned to the reduced suffering of ill health and to extended average lifetimes expected when IEQ is improved.

This paper will summarize the current scientific evidence that improved IEQ can improve work performance and health, building upon the conceptual framework of Seppanen et al. [1]. The paper will address only the thermal and air-quality-related aspects of IEQ. When possible, the relationship between IEQ parameters and health or performance outcomes will be expressed in quantitative terms that provide a basis for cost-benefit analyses applicable to building design and operation [2]. Calculations for hypothetical case studies will contrast the expected economic benefits with the required investment costs. The paper will also argue for using the most energy efficient options possible to bring about the improvements in IEQ.

METHODS

This paper is based on a review and analysis of the published scientific literature addressing the linkages of IEQ with health and work performance. The original scientific research employed a variety of study designs. Some of the research employed cross-sectional multi-building surveys of IEQ conditions and health, absence, or work performance outcomes.

These studies used statistical models to analyze the resulting data and quantify the effect of specific factors, such as ventilation rates, on outcomes (e.g., absence rates), controlled for other factors that also influence the outcome (e.g., student age and socioeconomic status). Other research has experimentally modified IEQ factors (e.g., temperature or ventilation rate) in real buildings and measured the resulting health or performance changes. Several of these studies were performed in call centers where workers interact with the public via telephone and use computers to obtain, input, and process information. Speed of work, such as average time to complete a call and associated information processing, was used as an indicator of work performance. Numerous experimental studies have also been performed in laboratories. With few exceptions, the laboratory spaces have been very similar to real workspaces, but the laboratory setting enabled more precise control of experimental variables. Normally the subjects performed simulated work tasks, such as addition, typing, and proof reading, with the speed and accuracy of task performance measured under different IEQ conditions.

In other papers reviewed, various approaches have been used estimate economic costs of health effects, so that the economic value of improved health from better IEQ can be estimated. In one approach, the total national annual cost of a health outcome, e.g., total annual cost of asthma in a country, was multiplied by the estimated fraction of ill health attributable to an IEQ risk factor, e.g., to moldy buildings. In another approach, each health outcome was assigned a unit cost per incident (e.g., cost per hospitalization for asthma) and this unit cost was multiplied by the estimated percentage decrease in the health incidents resulting from improved IEQ. One of two different types of unit costs are utilized. “Cost of illness” (COI) unit costs reflect the cost of health care and often also include the cost of lost work. “Willingness to pay”(WTP) unit costs are estimates of how much individuals are willing to pay to avoid a health effect, often based on surveys and analyses of consumer spending for safer products. WTP values, thus, assign an economic value for avoidance of pain or suffering or premature death from ill health and are often much larger than COI unit costs. COI and WTP values are available from various sources including the U. S. Environmental Protection Agency [3].

IMPACTS OF IEQ ON WORK AND SCHOOL PERFORMANCE

Temperature and office work performance

The influence of indoor air temperatures on objective (measured) work performance relevant to offices has been assessed experimentally, primarily in call centers and laboratory settings representative of real offices. A few additional studies used vigilance tests to measure ability to concentrate. Most of the studies experimentally manipulated temperatures while holding other factors constant to investigate the influence of temperature on performance, although one call center studied relied on natural changes in air temperature. Recently, a formal statistical meta-analysis of 24 of these studies was completed [4] to assess the average relationship between temperature and performance of work. The authors analyzed primarily office studies and laboratory studies that simulated office work, although three of 24 studies were performed in classrooms. Their analyses are the source of Figure 1 illustrating a best estimate of how office work performance varies with temperature. The graph in Figure 1 shows that performance increases with temperature up to 21 to 22 ^{o}C, and that performance decreases with temperature above 22 or 23 ^{o}C. The maximum performance, i.e., relative performance equal to unity, occurs at temperature of 21.8 ^{o}C. The equation for the curve in Figure 1 is

$$RP = 0.1647524 \cdot T_C - 0.0058274 \cdot T_C^{\ 2} + 0.0000623 \cdot T_C^{\ 3} - 0.4685328 \qquad (1)$$

where RP is relative performance, i.e., performance relative to maximum value, and T_C is room temperature, ^oC.

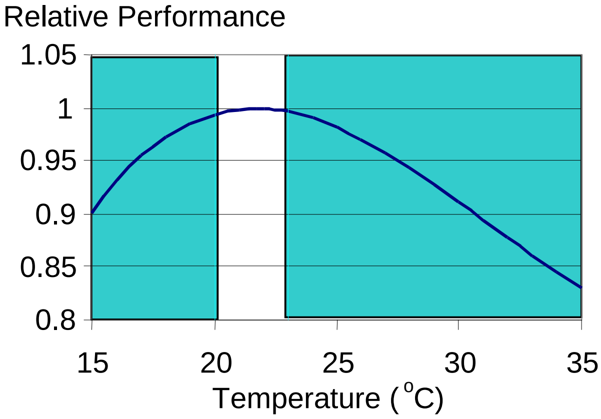

Figure 1. Relationship between office work performance and indoor temperature based on a statistical analysis of reported data. The shaded areas in the figure represents the regions where a statistical analyses indicates that decrements in performance have less than a 10% probability of being the result of chance.

Temperature and school work performance

Several studies conducted in the 1950s and 1960s found that students performed better in thermally conditioned classrooms than in classrooms without heating or cooling [5]. However, there have been few studies of the influence of temperature in thermally-conditioned classrooms on school work performance or learning. In the late 1960s, six groups, each with six students, were brought to a climate-controlled chamber at a U.S. university [5]. Each group of students performed simulated school work with chamber temperatures ranging from 17 to 33 ^oC. Error rates and speed of work were used as performance indicators. Two out of four performance measures, error rates and time required to complete assignments, were affected by temperature. The error rate was highest at 17 ^oC and lowest, about 20% lower, at 27 ^oC; however, students worked most slowly at 27 ^oC and fastest, about 10% faster, at 17 ^oC. Several similar studies were also performed in the 1960s [6]. Some of these studies performed in climate chambers and other studies in actual classrooms found reading speed, reading comprehension, and multiplication performance of school children to be poorer with temperatures of 27 to 30 ^oC, relative to 20 ^oC. In one case, the performance decrement was as large as 30%.

The influence of more moderately elevated temperatures on student performance was investigated recently via field studies conducted in classrooms [7, 8]. Classroom temperatures were manipulated by turning cooling systems on and off, while keeping all other factors constant to the degree possible, although, teachers opened windows "slightly more often when it was warm in the classroom". Performance tasks representing eight aspects of schoolwork, from reading to mathematics, were embedded into the normal school work. The speed and accuracy of task performance was assessed. The average speed of eight simulated school work tasks was increased by approximately 2% per 1 ^oC as temperatures decreased from 25 ^oC to 20 ^oC, although from visual inspection of the data there appeared to be no significant change in performance as temperature decreased from 23 to 20 ^oC. The number of errors in school work was not significantly affected by temperature changes in this temperature range. Figure 2 provides more detailed results from this study.

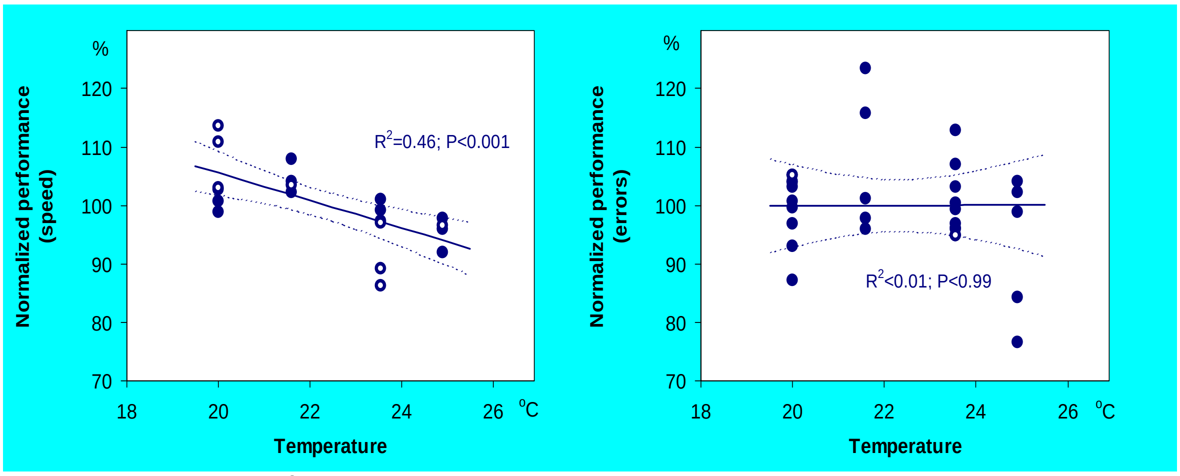

Figure 2. Student performance versus temperature based on study in Denmark [8]. Performance was based on the speed (left figure) and accuracy (right figure) of completing various school work tasks. Open dots represent tasks for which the performance increases with ventilation rate were statistically significant. [Figure 2 reproduced with permission.]

Ventilation rates and office work performance

The influence of ventilation rates (i.e., rates of outdoor air supply) on office work performance has been assessed experimentally in call centers and laboratory settings using the same methods described previously to assess how temperature affects work performance. Seppanen et al.[9] performed a statistical meta-analysis of eight studies of how ventilation rate affects office work, plus one study in schools of how ventilation rate affected concentration and vigilance, to assess the average relationship between ventilation rate and performance of work. Their analyses are the source of Figure 3 illustrating a best estimate of how office work performance varies with ventilation rate.

The curve in figure 4 is well fit by the equation

$$RP = (5.56 \text{ x } 10\text{-}8)\ V^3 - (1.48 \text{ x } 10\text{-}5)\ V^2 + (1.49 \text{ x } 10^{-3})\ V + 0.983 \qquad (2)$$

where *RP* is the relative performance and *V* is the ventilation rate in L/s per person.

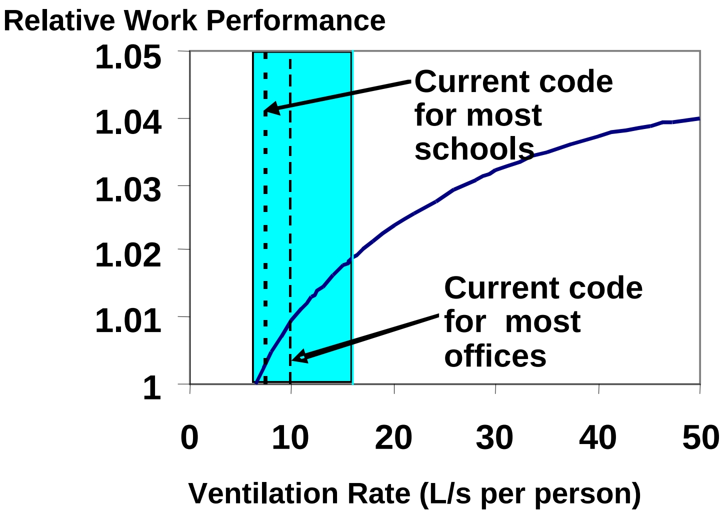

Figure 3. Performance of office work at various ventilation rates relative to performance with a ventilation rate of 6.5 L/s per person based on the meta analysis by Seppanen et al. [9]. In the shaded region, the trend of increased performance with ventilation rate has a 10% or smaller probability of being the result of chance.

Ventilation rates and school work performance

Four studies in schools have investigated the linkage of ventilation rates to objectively measured, as opposed to self-reported, school work performance. A Norwegian study [10] performed in 35 classrooms used reaction times to measure student concentration and vigilance. Reaction times were 5.4% less (i.e., faster) with a ventilation rate of 8.1 ach (12 L/s per person) compared to 2.6 ach (4 L/s per person). A U.S. study [11] in 5th grade classrooms from 54 schools, used student performance in standard academic tests as the measure of performance. Performance in both math and reading tests increased with ventilation rate. Test scores increased about 13% from classrooms with the lowest ventilation rates (less than 2.2 L/s per student) to classrooms with the highest ventilation rates (greater than 4.5 L/s per student); however, statistical analyses indicated greater than a 10% probability that the increases in performance were due to chance. In a Danish study in six classrooms [8], Wargocki and Wyon used performance tasks representing various aspects of schoolwork, from reading to mathematics that were embedded into the normal school work. The speed and accuracy of task performance were assessed. This study reported an 8% increase in speed of school-work tasks with a doubling of ventilation rate. There was no statistically significant influence of ventilation rate on the number of errors made by students. Figure 4 provides more detailed results from this study.

In Japan, college student performance in classroom settings and in a laboratory setting on standardized tests was evaluated at different ventilation rates [12, 13]. In three tests implemented in the field study, one on theory and two involving memorization, performance improved 5.4%, 8.7 %, and 5.8%, respectively, with increases in ventilation rate from 0.4 to 3.5 ach. The laboratory study included only tests of memorization performance, and had results similar to those from the field study. However, in these studies, the ventilation rates

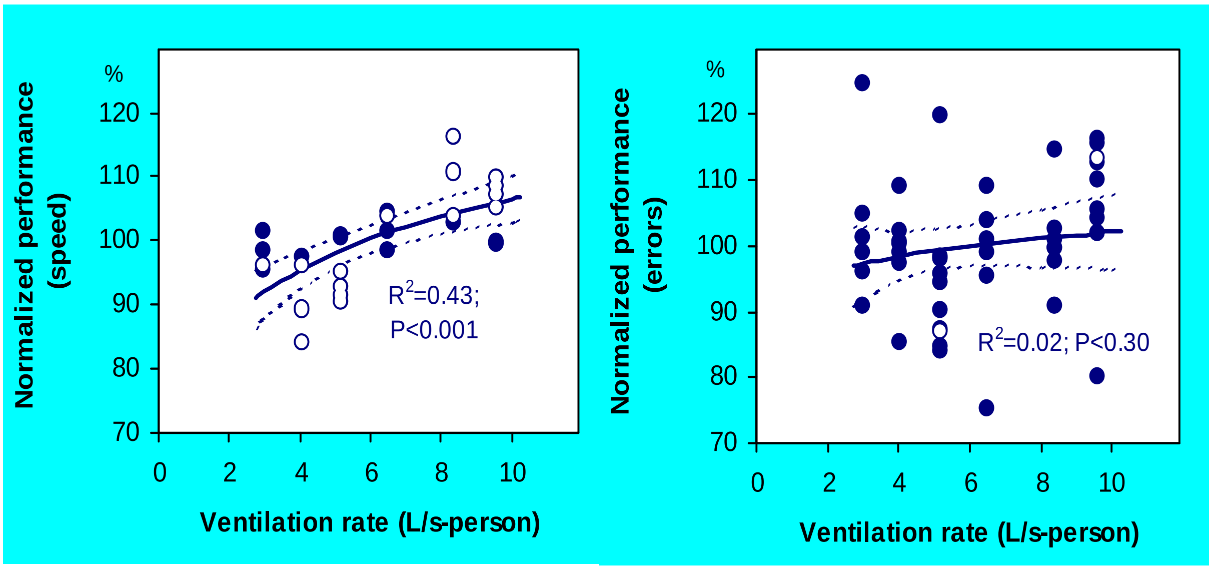

Figure 4. Student performance versus ventilation rate based on study in Denmark [8]. Open dots represent tasks for which the performance increases with ventilation rate were statistically significant. [Figure 4 reproduced with permission.]

per person at the lower air exchange rates were very low even for classrooms, e.g., less than 1 L/s per person. In addition, this study intentionally did not disentangle the effects of ventilation and temperature. Temperatures were higher by approximately 2 °C in the low-ventilation conditions, as they would be in building cooled by the outdoor air supply. Higher temperatures, in the temperature ranges encountered in this study, have been shown to reduce work performance [14]. Thus, these two studies do not provide information about how ventilation rates affect student performance when temperature is maintained constant.

Higher classroom ventilation rates have also been linked to a reduction in student absence [15], which, in turn, may improve student learning.

In summary, while the applicable research is limited, the available scientific literature indicates the potential for 5% to 10% increases in aspects of student performance with increased classroom ventilation rates. Ventilation rates in roughly half of U.S. public elementary school classrooms appear to be less than specified in codes [11, 15, 16]; thus, the opportunities for increasing student performance by increasing ventilation rates, at least in U.S. schools, may be substantial.

Indoor pollutant sources and performance

The improvements in work and school work performance with higher ventilation rates is presumed to be a consequence of the reduction in indoor concentrations of indoor-generated air pollutants with more ventilation. If this explanation is correct, we would expect performance to also increase if indoor pollutant concentrations were reduced by reducing the emissions from indoor pollutant sources, e.g., by removing indoor pollutant sources. We have limited research that directly assesses the effects of source reduction measures on performance, but the results of this research are at least qualitatively consistent with the finding that increased ventilation rates improve work performance. Most of the relevant studies were performed in a laboratory setting representative of real offices [17-19]. In these studies, subjects performed tasks representative of office work, such as proof reading of text, text typing, and simple arithmetic operations and speed and accuracy in these simulated work tasks was measured and used to indicate work performance. In three studies [17, 18], a section of carpet removed from a complaint building was placed in the laboratory, but hidden from the study subjects. Performance, based on typing, addition, and proof reading tests, was improved by approximately 4% by removing the carpet, as depicted in Figure 5.

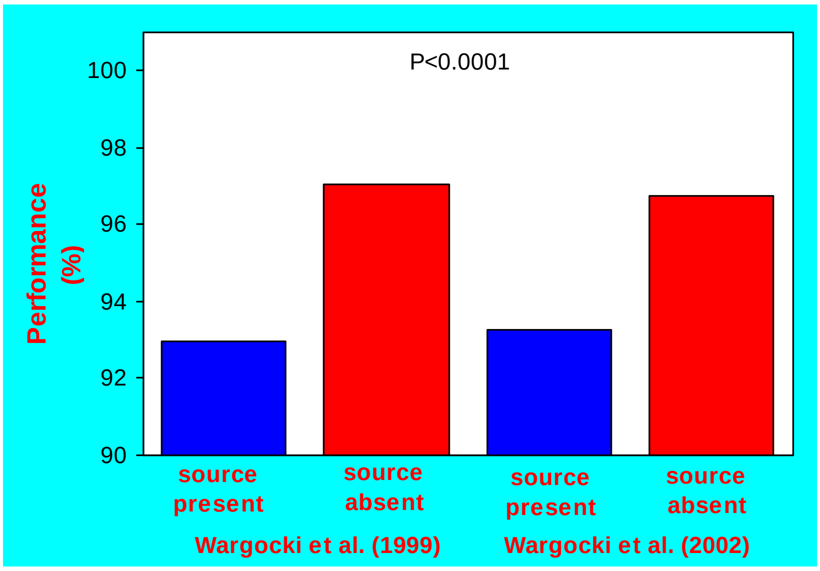

Figure 5. Controlled laboratory studies performed in Denmark show that performance, based on typing, addition, and proof reading tests, improved when a carpet taken from a complaint building was removed. [Figure 5 reproduced with permission.]

Bako-Biro [19] performed similar laboratory studies, but with three-month old personal computers with CRT monitors as the pollutant source. When the computers were removed, performance in proof reading and arithmetic calculations were unaffected; however, text typing errors diminished by 16% and typing speed improved slightly. The improvements in typing performance were statistically significant. Additional research by Bako-Biro [20] employed three-year-old linoleum flooring, shelves with books and paper, and three-month-old caulk sealant as the pollutant sources. Speed and accuracy in arithmetic calculations were used to assess work performance. In this study, few and only small statistically significant impacts of the pollutant sources on performance were identified, although there is some evidence of improved text typing when the pollutant sources were removed.

One additional study of the effects of pollutant source removal on work performance was performed in a call center with the time required to talk with customers used as an measure of work performance [21]. The pollutant source was a 6-month old particle filter in the building's ventilation system. When the used filter was replaced with a new filter, at times unknown to the call center workers, average talk time decreased by approximately 10%.

Perceived Indoor Air Quality and Work Performance

Peoples' perceptions of indoor air quality, as reported on questionnaires, have often been used as subjective indicators of the quality of indoor air. The questionnaires normally ask subjects to rate air quality on a scale ranging from clearly acceptable to clearly unacceptable. Research, performed primarily in the laboratory [18-20, 22-24] , has found that improved perceptions of, or satisfaction with, indoor air quality are associated with improvements in some aspects in work performance. In this research, performance of some tasks has increased by approximately 1% for each 10% reduction in the percentage of the occupants dissatisfied with indoor air quality. However, it is not known if an increased satisfaction with indoor air actually causes people to work better. It could be that the indoor environmental exposures, e.g., pollutants, directly cause both poorer work performance and dissatisfaction with indoor air, leading to a correlation of performance with perceived air quality.

HEALTH-RELATED ECONOMIC BENEFITS OF IMPROVED IEQ

Eliminating Environmental Tobacco Smoke

Environmental tobacco smoke (ETS) is the tobacco smoke to which non-smokers are exposed. Most ETS exposures occur indoors. Based on reviews of a very large body of research, various organizations or panels of experts have concluded that ETS is the cause of an increased number of several health outcomes including premature death from lung cancer and cardiovascular disease, and cases of asthma exacerbation. A critical review by a California health organization provides estimates [25] of annual ETS-caused health effects in the U.S.. Fisk [26] used these data and unit costs for health outcomes to estimate the preventable cost of ETS exposures, assuming that ETS exposures are 100% preventable. The results are shown in Table 1.

Table 1. Estimated annual health effects and preventable costs ($U.S.) in the U.S. of indoor ETS exposures in 2000.

Heath Effect	**Annual U.S. Cases (1000s)**	**Unit Cost ($ U.S.) [cost type^]**	**Total Cost in U.S. (billions of $U.S.)**	**Cost per U.S. smoker# ($U.S.)**
Death	40.5 – 68.8	6300K [WTP] (2100K–10600K)	$260 - $430* $85 - $730+	$4000 - $6600* $1300 - $11000+
Asthma induction	8.1 - 26	$33K [WTP]	$0.27 - $0.86*	$4 - $13
Day of asthma exacerbation	400 – 1000	$42 [WTP]	$0.017 - $0.042*	$ 0.26 - $0.65
Bronchitis or pneumonia hospitalizations	7.6 – 15.2	$11K [COI]	$0.084 - $0.170*	$1.30 -$2.63
Acute Bronchitis or Pneumonia	150 – 300	$59 [WTP]	$0.009 - $0.018*	$0.13 – $0.28
All morbidity			$0.38 – $1.09	$5.87 - $16.80

#based on 64.7 million smokers in the U.S. in 2000 [27] *range in costs reflects only the range in number of health effects +range in costs reflects the range in number of health effects and the range in the estimated unit costs per health effect, when available ^ WTP = willingness to pay, COI = cost of illness

From the numbers in this table, it is evident that the health-related costs of ETS are still very large in the U.S., despite considerable progress in reducing smoking rates. On average, each smoker is responsible for 3100 to 8500 € ($4000 to $11000) of cost per year from premature death in non-smokers and for 5 to 12 € ($6 to $16) in annual health costs for morbidity. The estimated health cost imposed per smoker may be roughly similar in other regions of the world with similar living standards.

Dampness and Mold

Many studies have found that dampness or mold is common in homes and is associated with increases in asthma exacerbation and various respiratory symptoms [28]. To estimate the cost of asthma from indoor dampness and mold (C_{DM}), Fisk [26] used the following equation

$$\boldsymbol{C_{DM}} = \text{(attributable fraction of asthma) X (total cost of asthma)} \qquad (2)$$

The same basic approach was used by Nguyen et al. [29] for the asthma attributable to dampness or mold in Finland. The fraction of asthma symptoms attributable to dampness and mold was estimated using a standard equation for calculating the attributable fraction (AF)

$$AF = [P(RR-1)]/[P(RR-1)+1] \qquad (3)$$

where P is the prevalence of the risk factor (e.g., household mold contamination) and RR is the relative risk, which indicates the increased prevalence of the health effect in the population with the risk factor. Using the results of four large studies, three from North America and one from Europe, approximately 13% of asthma symptoms were attributable to asthma and mold in housing [26]. The total annual cost of asthma in the U.S. in year 2000, was estimated to be between 5.8 to 10.7 billion € ($7.5 to $13.9 billion U.S.) [26]. Thus, the annual cost of asthma in the year 2000 attributable to dampness and mold in housing is 13% of this range or approximately 0.8 to 1.4 billion € ($1 to $1.8 billion U.S.). This equals 19 to 35 € ($25 to $45 U.S.) of annual asthma-related costs for every home with dampness and mold, given that the U.S. had 121 million housing units [27] in 2000 and roughly one third of homes have visible dampness or mold [26]. This 19 to 35 € ($25 to $45 U.S.) estimate may be a reasonable initial estimate of the annual asthma-related costs for damp homes in other countries with similar living standards. Based on the prior analyses of the asthma health cost of dampness and mold in Finland in 1996 [29], one can estimate that the cost was 18 € ($29) per home or apartment in need of repair due to moisture. The costs of other health effects of dampness in mold have not been estimated but may be substantial. In addition, dampness and mold in workplaces and schools is common and is expected to impose additional health costs.

At present, we do not have a defensible estimate the portion of dampness and resultant indoor mold that is preventable. Many dampness problems, possibly a majority, result from water leaks that could be prevented through better building maintenance and improved design and construction. Better ventilation in winter and use of dehumidifiers in summer could reduce dampness problems that result from high indoor humidity. Thus, it is technically feasible to eliminate a large majority of the dampness problems. However, poverty, insufficient training of homebuilders, lack of public awareness, and resistance to behavioral changes remain substantial obstacles.

Communicable Respiratory Illnesses and Sick Leave

The limited data available suggest that occupants of buildings or spaces with higher ventilation rates on average have fewer communicable respiratory illnesses, e.g., common colds and influenza, and less absence from work or school. These data are from buildings in which multiple occupants share the same airspace, i.e., air is transported from person to person. Much of the research has been performed in buildings with a high occupant density such as jails or military barracks. Three studies have investigated linkages between ventilation rates and absentee or sick-leave rates in more typical buildings; two were performed in offices [30, 31] and one in elementary grade classrooms [15]. One office study [31] found no association of sick leave with building carbon dioxide (CO_2) concentrations, as indicators of ventilation rates; however, this study included only two buildings and had experimental periods that did not integrate over the yearly cycle of respiratory disease. The two much larger studies, one of offices [30] and the second of classrooms [15], assessed absence over full-year periods. In the office study, short term sick leave was 25% less in buildings with 24 L/s-person compared to 12 L/s-person of outdoor air. In the classroom study, a CO_2 concentration decrease corresponding to a 10 L/s per person increase in ventilation rate was associated with a 9% to 17% decrease in total student absence.

From the office building study, one can estimate the economic benefit of the 12 L/s-person increase in ventilation rate. In the office workers, the total average sick leave rate was 1.71% or 4.3 days assuming 250 work days per year. The 25% lower sick leave in the buildings with 12 L/s-person more ventilation corresponds to an average annual reduction in absence of 1.1 days per person. If the annual salary plus benefits is 77,000 € ($100,000 U.S.), the reduction in sick leave is worth $338 € ($440 U.S) per worker.

COST EFFECTIVENESS OF IMPROVEMENTS IN IEQ

To inform decisions about investments in building design, retrofit, or operation, it is common to employ cost-benefit analyses that account for initial equipment costs, energy costs, maintenance costs, and taxes. The economic value of changes in work performance, absence, and health are normally neglected. However, using the information provided above, it is now possible to account for some of these changes in human outcomes. Although uncertainty about the magnitudes of changes in performance, absence, and health remain high, application of best available estimates should lead to better decisions than the current practice of neglecting these factors. This section provides some examples.

Night Time Ventilative Cooling

In buildings without mechanical cooling, work-time air temperatures can be diminished by using fans (or by opening windows) to ventilate the building during the cooler night-time periods. The night-time ventilation reduces the temperature of thermal mass in the building and, by absorbing heat during the subsequent workday, this cooled thermal mass reduces workday temperatures. Kolokotroni et al [32] report temperatures in a Finnish office building with and without ventilative cooling. We previously used these temperatures with a very simple temperature-performance relationship [33], to compare the value of predicted work performance increases with the costs of running the fans to ventilate the building at night. We assumed that 2.5 kW of fan power was required per each 1 m^3/s of ventilation, a 4 air change per hour ventilation flow rate, 83 m^3 of indoor air volume per occupant, 8 hours of fan operation, and that salary, benefits, and overhead cost the employer 25 € per hour per worker. We now provide an updated analysis using the temperature-performance relation in equation 1. For each hour of the workday, the percent decrease in work performance and equivalent lost working time were calculated using the indoor temperatures with and without night-time ventilative cooling. Table 2 shows the calculation of lost working time. It was estimated that ventilative cooling reduces the lost work time from 26.1 to 8.8 minutes per day, which has a value of 7.2 € per worker per day. If the electricity to operate fans cost 0.10 € per kWh, the daily energy cost is 0.18 € per person. The benefit-cost ratio is then 7.2/0.18 or 40. With electricity costs of 0.05 and 0.15 € per kWh, the benefit-cost ratios are 80 and 27, respectively.

Table. 2. Example calculation of work performance gains from night time ventilative cooling in an office building without air conditioning.

Hour	No Ventilative Cooling			With Ventilative Cooling		
	T ^oC*	RP	Lost Min	T ^oC*	RP	Lost Min
8 - 9	27.0	0.954	2.73	23.4	0.991	0.55
9 - 10	27.2	0.952	2.90	23.5	0.990	0.58
10 - 11	27.6	0.946	3.24	23.9	0.988	0.74
11 - 12	27.8	0.943	3.42	24.2	0.985	0.88
13 - 14	27.8	0.943	3.42	25.2	0.976	1.42
14 - 15	27.8	0.943	3.42	25.4	0.974	1.55
15 - 16	27.9	0.941	3.51	25.4	0.974	1.55
16 - 17	27.8	0.943	3.42	25.4	0.974	1.55
Total			26.08			8.83

*Estimated operative temperature as average of air and slab temperatures
Lost time each hour = (1 – RP from equation 1 at T*) x 60 minutes

Comparison of Building Cooling Strategies

In another set of example cost-benefit analyses [34], the following options for cooling an office building located in Helsinki were compared: a) base case with no mechanical cooling and a 2 L/s-m^2 supply air flow 10 h per day; b) mechanical cooling with capacity of 20 W/m^2, c) base case but with the ventilation system operation increased from 10 to 24 h per day; d) base case but with the ventilation system operation increased from 10 to 24 h per day and supply flow rate increased to 4 L/s per m^2; e) base case plus all measures in b, c, and d. The assumed value of an hour of work was 32.3 € and the cost of heat and electricity were 0.04 €/kWh and 0.1 €/kWh, respectively. Other assumptions are provided in reference [34]. The key results of this analysis are provided in Table 3.

Table 3. Comparison of life cycles costs of cooling an office building in Helsinki [34]

Factor	Base Case	Mechanical Cooling	Increased Operation Time (No Mech. Cooling)	Increased Outdoor Air Flow (No Mech. Cooling)	All Meas -ures
Increased annual energy cost per person, €	--	1.6	6.3	40.0	39.9
Increased first cost, € per person	--	9.5	0	10.0	19.5
Effective lost work hours per person-year, h	21.2	15.5	12.6	6.5	4.4
Value of lost work hours per person-year, €	686	501	408	211	141
Value of improved work, €	--	184	278	475	545
Total annual savings per person, €	--	131	272	380	398

This example analysis projects annual savings of 131 € to 398 € per worker from implementing the various measures for space cooling. In the Helsinki climate, with relatively few days where cooling is needed, the mechanical cooling option consumes less energy than increasing ventilation time or flow rate.

Addition of an Outdoor Air Economizer

In an air-conditioned building, an economizer system increases the outdoor air supply above the minimum amount required by codes whenever doing so eliminates the need for energy-intensive mechanical cooling. Normally, economizers are used in buildings with air recirculation by reducing the amount of recirculation and increasing the outdoor air supply. Economizer systems save energy. In many climates, economizers also dramatically increase time-average ventilation rates. Economizer systems are common in large U.S. HVAC systems with air conditioning, but are often considered too costly for small HVAC systems.

A prior paper [35] evaluated the energy savings and projected financial benefits from reduced sick leave when an economizer system was used in an office building located in Washington, DC. A building energy simulation model predicted hourly ventilation rates and energy consumption with and without an economizer system. A model of airborne disease transmission calibrated with empirical data on the relationship of ventilation rates with respiratory disease and absence was employed to estimate sick leave rates with and without the economizer. The doubling of the work-time average ventilation rate, from 10 to 20 L/s per person, when an economizer was used saved about 23 € ($30) in energy costs per person per year and reduced annual sick leave by an estimated 0.9 to 1.2 days per person. With each day of sick leave valued at 154 € ($200 U.S), corresponding to an annual cost of salary plus benefits of 38,500 € ($50,000 U.S.), the annual value of the reduced sick leave is approximately 160 € ($210 U.S.) per person.

One can instead easily use the ventilation rates in this paper and estimate the work performance benefits from increased ventilation via Figure 4 or equation 2. The annual value of the projected 1% increase in work performance is $380 € ($500 U.S.)

Table 4 summarizes the results of these two analyses. Decisions about whether or not to use an economizer would normally be based on a comparison of the economizer system costs with the 23 € ($30) per person projected annual energy savings. However, when best estimates of the impacts of ventilation rate on absence and work performance are considered, the economizer saves roughly 570 € ($740 U.S.) per person per year.

Table 4. Example analyses of financial benefits of an economizer system in an office building located in Washington, DC.

Increase in annual average ventilation rate	10 L/s-person
Normally considered benefit Annual Energy cost savings	 $30 U.S. (23 €) per person
Normally neglected benefits Annual value of reduced absence Annual value of productivity increase	 $210 U.S. (160 €) per person $500 U.S. (380 €)

Increased Ventilation Rates in an Office Building

Another example analysis [34] compared the energy and equipment costs of providing a higher ventilation rate in an office building with the value of work performance increases estimated from Figure 4 or Equation 2. The office building had a typical design for a medium-size northern-European, mechanically-cooled building with supply and exhaust air flows, no recirculation, and air-to-air energy recovery with a 75% temperature efficiency. Energy consumption and energy costs were estimated with a simulation program, Helsinki climate data, and energy costs of 0.04 € per kWh for heat and 0.1 € per kWh for electricity. The annual value of work per employee was 30,000 C. Table 5 summarizes the main results from this analysis. Increasing the ventilation rate results in a 4.4 to 22 € increase in annual energy cost per employee, a similar magnitude increase in maintenance costs, a 22 to 63 € annualized increase in first costs, performance increases of 1% to 2.4 % valued at 300 to 690 € per person per year. The estimated benefit-cost ratio ranges from 6.2 to 9.4. The largest benefit-cost ratio was predicted for increasing ventilation rates from 6.5 to 10 L/s per person, but further economic benefits are predicted from increasing the ventilation rate from 10 to 20 L/s per person. This example analysis neglected the value of reduced health effects and absence from increased ventilation.

Table 5. Predicted costs and benefits from increasing ventilation in an office building [34].

Change in Ventilation Rate (L/s-person)	Annual Cost Increase (€ per person)			Increase in Performance		Benefit-Cost Ratio
	Energy Consumption	Maintenance	Equipment (annualized)	%	€ per person	
6.5 to 10	4.4	4.7	22.5	1.0	300	9.4
6.5 to 20	22.5	13.3	63	2.3	690	7.0
10 to 20	18.1	8.5	41	1.4	420	6.2

DISCUSSION

Main findings

Based on the information presented above, we have fairly compelling evidence that indoor environmental factors and related building operating conditions affect health and work performance. Higher ventilation rates are associated with improved health and better work and school performance. Removal of pollutant sources is associated with improved work performance, at least in some cases. Indoor temperatures in the 21 to 22 ^{o}C range are associated with maximum overall work and school performance. We now have estimates of quantitative relationships between some of these indoor environmental factors and health or performance outcomes. These quantitative relationships enable an accounting of some health and productivity benefits in cost-benefit calculations pertaining to building design and operation. Example cost-benefit analyses indicate that many measures to improve indoor temperature control and increase ventilation rates will be highly cost effective, with benefit-cost ratios as high as 80 and annual economic benefits as high as 500€ ($700) per person.

Implications

The research findings and cost-benefit analyses summarized in this paper suggest that more effort and investment be devoted to improvement of IEQ, which will often lead to more productive and healthy workers and financial benefits that greatly exceed costs. Designers and those who construct buildings must be educated about the technologies and practices needed to enable good IEQ. To assure that good IEQ is maintained over the life of buildings, periodic or continuous commissioning and building and HVAC system maintenance will be necessary. It would be helpful to develop and utilize lease and maintenance contracts that incentivize building owners and maintenance providers to maintain good IEQ. In addition, building operators and maintenance staff should be educated about means of maintaining good IEQ.

Limitations

There remain substantial uncertainties in the quantitative relationships between indoor environmental factors and health and work performance outcomes. The limited body of related research is one source of uncertainty. In addition, much of the research completed to date uses the speed and accuracy of simulated work tasks as the work performance outcome. While such outcomes are clearly relevant to real work, the quantitative relationship between average performance of these simulated work tasks and average performance of overall real-world work remains uncertain. In particular, speed and accuracy of simulated work tasks, such as addition, typing, and proof reading, might not be a good predictor of higher-level cognitive functioning such as the decision making of many managers and executives. Another limitation of the currently available quantitative relationships is that they are not tailored for specific building conditions, types of work, or types of workers. Rather, the existing quantitative relations presented in this paper are estimates of the average relationships for the average building, type of work, and worker. In specific situations, larger or smaller improvements in health and performance may be expected. For example, an increase in ventilation rate would seem more likely to substantially improve health or work performance in a building with initially poor IEQ due to the presence of strong indoor pollutant sources. Despite the substantial uncertainties, application of the best information available today should lead to better decisions about building design and operational practices than the current practice of totally neglecting impacts on health and work performance.

Who Benefits and Who Pays?

Users of quantitative relationships between IEQ factors and health and productivity must recognize that costs and benefits may affect different parties. For example, in a leased building, the building owner usually pays for building or HVAC improvements while the employer benefits most directly from improved work performance and reduced absence. However, the owner of a leased building may indirectly benefit the improved worker health and work performance through increased rent, higher property values, and longer tenant retention when IEQ is improved and the building has a more positive reputation. The employee and health care insurer may directly benefit from reduced health care costs, but often the associated financial benefits will not be passed on to the employer. In an owner-occupied building, the incentive for investments to improve IEQ may be greatest because the owner-employer benefits directly from both improved work performance and reduced absence.

Energy use concerns

Because increased ventilation rate is associated with improved work performance and better health, and often increases energy use, there is a conflict between energy efficiency and health/productivity goals. Given the broad concerns about global climate change resulting from use of fossil fuels for energy, there is a strong need for technologies and practices that bring about the productivity benefits without increasing energy use, and ideally with simultaneous energy savings. The economizer system, described above, is an example of such a technology. In the longer term, we should be able to identify and utilize pollutant source control measures and air cleaning technologies to bring about the same health and productivity benefits as increased ventilation, but with no or minimal increases in energy use.

Priority research needs

While there are many research needs related to the subjects discussed in this paper, the following are suggested as high priority research needs:

- the influence of IEQ factors on high-level cognitive performance such as decision making;
- the influence of IEQ factors on quality and speed of real work, as opposed to simulated work tasks;
- the relationship between performance of school work tasks and student learning;
- the relationship between worker health, which has already been shown to be associated with many IEQ factors, and work performance;
- means of obtaining the health and productivity benefits of increased ventilation with minimal increase in energy use, or ideally with energy savings.

ACKNOWLEDGEMENTS

Preparation of this document was supported through interagency agreement DW89922244-01-0 between the Indoor Environments Division, Office of Radiation and Indoor Air, Office of Air and Radiation of the U.S. Environmental Protection Agency and the US Department of Energy, to support EPA's IAQ Scientific Findings Resource Bank. Conclusions in this paper are those of the authors and not necessarily those of the U.S. EPA. Support for Prof. Seppanen was provided by the Rockwool Foundation.

Effect of outdoor generated pollutants on indoor air quality and health

Matti J. Jantunen

KTL (National Public Health Institute), Dept. Environmental Health, Kuopio, Finland
Corresponding email: matti.jantunen@ktl.fi

SUMMARY:
The significant public health effects of ambient air pollution are mostly caused by exposures in indoor environments, where we spend over 90 % of our time. Indoor concentrations of air pollutants are in general higher than and often also independent of the outdoor air concentrations. In average, urban outdoor air contributes significantly to indoor concentrations of carbon monoxide (CO), nitrogen dioxide (NO_2), benzene and some other aromatic VOC:s, ozone (O_3), and fine particulate matter ($PM_{2.5}$), but not to, e.g., most VOCs and carbonyls or to the highest concentrations of CO and PM. Indoor concentrations of pollutants of outdoor or ambient origin, however are at most equal to, (e.g. CO) and for reactive (e.g. O_3 and ultrafine particles) significantly lower than the outdoor air levels. $PM_{2.5}$ is the urban air pollution which causes the biggest mortality, over 300 000 excess deaths annually in Europe. To the vulnerable population groups the current building envelope, ventilation and air conditioning technologies can provide effective and targeted protection against the risks of outdoor air fine PM and O_3.

INTRODUCTION

Air pollution epidemiologists have - with remarkable success - studied the short term associations of daily mortality and morbidity of urban populations with respective daily ambient air (outdoor air) pollution monitoring data [1,2] and the long term mortality of urban cohorts with respective long term urban ambient air pollution monitoring data [3,4]. Epidemiologists talk about the health effects of outdoor air pollution, which has sometimes given rise to a false interpretation, namely that the observed health effects are due to the exposure that the population acquires while outdoors. To avoid confusion, some USEPA documents and articles use the terms 'air pollution of ambient origin' and 'air pollution of indoor origin' [5,6,7]. The current presentation focuses on the former, air pollution of ambient/outdoor origin, acknowledging that – due to our time-microenvironment-activity patterns - most of the exposure to such pollution occurs in indoor environments.

The significance of indoor exposures – even to pollution of ambient origin - arises from the fact that most people in the industrialised societies spend a very high portion of their total time indoors. One of the objectives of the *EXPOLIS* study [8,9], was to determine the time spent - average hours per workday - by active adult European urban populations in different microenvironments and activities. Grand average time spent indoors was 22.3 h/d or 93%, which does not include time spent in transit - also mostly indoors. [10]

Outdoor generated air pollutant is relevant for indoor air quality and health, if it meets three criteria; (i) penetrates effectively indoors, (ii) contributes a significant portion of the level of that pollutant in indoor air and (iii) is harmful for the health of at least some fraction of the population at the observed indoor levels.

Table 1. Time allocations for indoor Environments in seven European cities; Athens, Basle, Grenoble, Helsinki, Oxford and Prague. (h/d)

Indoor	Min (city)	Max (city)
Home	13.5 (Milan)	15.8 (Oxford)
Work	6.1 (Athens)	7.5 (Milan, Prague)
other	1,3 (Oxford)	2.2 (Grenoble)

CONTRIBUTION OF OUTDOOR AIR POLLUTION TO INDOOR AIR QUALITY AND HEALTH EFFECTS

The contribution of outdoor air pollution to indoor air quality and health vary greatly in relation to the pollutant, the climate zone and building stock, and also between the individual buildings. The current presentation, by necessity, focuses on the typical and average conditions and situations in urban areas across Europe, but it is important to realise that individual buildings may behave quite independently of these averages. Still, the variation of outdoor air contribution to indoor air quality is much smaller than the variation induced by the indoor sources.

Carbon monoxide (CO), and nitrogen dioxide (NO_2)

The health impacts of CO are caused by its strong affinity to blood haemoglobin, where it blocks the oxygen carrying capacity of the blood. Acutely dangerous CO concentrations in indoor air are responsible for thousands of lethal and many more non-lethal poisonings annually in Europe. These very high levels, up to hundreds of ppm, however, originate almost exclusively from indoor sources. Also ambient air CO concentrations are associated with daily mortality [11,12], although it is unclear how much of this is due to its strong correlation with other combustion generated pollutants - ultrafine and fine particles, NOx, CO etc. - and how much to the independent effects of CO. CO is a universal marker of incomplete combustion products, which also include gas, vapour and particle phase organics, soot particles and numerous carcinogenic substances.

The health effects of NO_2 at the environmentally relevant levels are not nearly as well understood as those of CO, although a body of epidemiological evidence associates bronchitic symptoms of asthmatic children with NO_2 concentration, and reduced lung function growth in children is linked to elevated NO_2 concentrations within communities already at current North American and European urban ambient air levels. Yet, in the recent risk assessments these effects have been increasingly assigned to other combustion and atmospheric chemistry generated co-pollutants, which are highly correlated with NO_2 [13]

The sources of CO and NO_2 are the same, stationary and mobile combustion devices. CO is generated in incomplete combustion conditions with low quality fuel, poor mixing or insufficient quantity of combustion air and/or low combustion temperature. The opposite conditions, well mixed excess air and high combustion temperature, produce NO, which is in the presence of ozone (O_3) in ambient air rapidly oxidised to NO_2.

Although urban ambient air CO levels have been reduced by an order of magnitude in the past 30 years, CO remains the most abundant urban air pollutant, and its concentrations range from a few hundred up to a few thousand $\mu g/m^3$. In indoor and urban air CO is an inert gas with an atmospheric half life of weeks, and therefore, in the absence of indoor sources, the indoor air CO concentration smoothly follow the 1..3 hour average ambient air concentration.

Unlike CO, NO_2 rapidly reacts with co-pollutants in the air or is absorbed by many indoor materials. When integrated over a full day or longer, indoor concentrations of NO_2 are usually, even in the presence of some indoor sources, like gas stoves or smoking, lower than respective ambient air concentrations, as can be seen from Table 2. In the PRIMEQUAL study on I/O relationships of air pollutants in 8 French Schools, the I/O ratios of NO_2 ranged from 0.87 to 1.17. The variation of I/O ratios for NO was much wider, 0.5 to 2.59 [14].

Table 2. 48 h. average outdoor and indoor NO_2 concentrations ($\mu g/m^3$) in three EXPOLIS cities [15]

City	Outdoor	Indoor	Workplace
Helsinki	24 ± 12	18 ± 11	27 ± 15
Basel	36 ± 13	27 ± 13	36 ± 24
Prague	61 ± 20	43 ± 23	39 ± 18

Short term concentrations of NO_2 in kitchens with gas stoves and (bath)rooms with gas fired unflued hot water heaters, however, may exceed 1000 $\mu g/m^3$, far above the levels ever observed in outdoor air [16].

Volatile organic compounds (VOC)

After CO, VOCs are found in highest indoor air concentrations and are consequently also responsible for the highest long-term population exposures, but high indoor VOC concentrations originate only rarely from outdoor air.

The health effects of concern for VOC:s are as variable as the VOC:s themselves. Benzene is an IARC classified category 1 carcinogen, causing leukaemia. A number of other VOCs and carbonyls (e.g. 1,3 butadiene, formaldehyde, etc) are suspected or known carcinogens, some are neurotoxic, many irritating and odorous. Their combined “cocktail effects” have risen great interest over the years, but are very complicated to study in practice. As for their population level health risks, on the one end the contribution of residential indoor VOC:s to human carcinogenesis is likely to be real but small, on the other end the sensory effects of VOC cocktails are mild but affect millions of individuals.

The simplest and often useful approach for assessing the relative contributions of outdoor and indoor sources to indoor concentrations, is to look at the indoor/outdoor (I/O) concentration ratios, which have been extensively reported since the late '70's. Ratios close to 1.0 indicate outdoor air as the main contributor to indoor exposure. High ratios up to 10 and above indicate that indoor sources dominate. This approach, however, is not reliable for compounds with high reactivity or absorbance to indoor surfaces.

Outdoor sources contribute the most (½ or more) to indoor air concentrations of, e.g., benzene (and often other aromatics), butanal and carbon tetrachloride [17,18,19,20]. Of these benzene warrants a closer look. Combining the result of the *EXPOLIS* [17] and Macbeth [21] studies provides a cross section of the residential indoor, outdoor, workplace (*EXPOLIS* only) and personal exposure levels of benzene in 10 European cities, see Figure 1.

Figure 1 highlights the large regional variations in the average contributions of urban outdoor air benzene to indoor concentrations and personal exposures. Outdoor air contribution to indoor air levels was highest, about 100% in Padua, Athens and Murcia, lowest about ½ in Basle, Rouen and Antwerp. Respectively the outdoor air contribution to personal exposure was highest in Oxford, and lowest $^{1}/_{3}$ – ¼ in Rouen, Antwerp and Basle. For most other VOCs and carbonyls the indoor source contributions to the indoor air concentrations are higher, close to or above 90 % in average for, e.g., acetone, formaldehyde, propionaldehyde, other aldehydes, limonene, isopropanol, α-pinene, camphene, undecane, dodecane and decane [18,19,22,23,24]. For the indoor air concentrations and possible health effects of these compounds, outdoor air contributes, in average, very little.

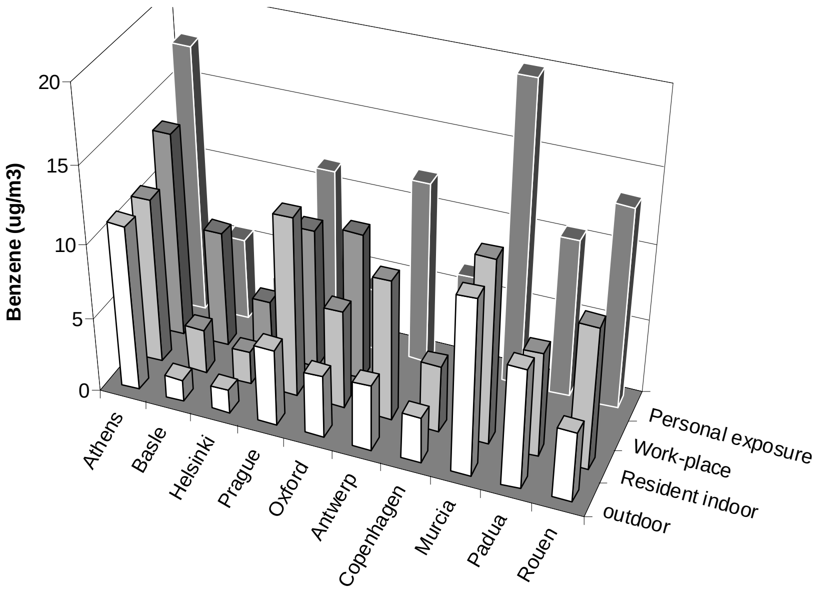

Figure 1. Averages of outdoor, residential and workplace indoor concentrations and personal exposures to benzene in 10 European cities.

Urban - rural: In a German study outdoor and indoor concentration differences for benzene, toluene, ethylbenzene and xylenes (BTEX) were assessed between urban (High traffic area in the city of Hannover) and rural (in Wedemark, no major traffic nearby) areas [25, 26]. Although the average outdoor air concentration were about 10 times higher in the urban vs. rural area, the respective indoor air concentrations of benzene were only about 50% higher in the city. For the other aromatics the average indoor concentrations in the urban and rural areas were even closer. I.e. the indoor sources for BTEX all but eliminated the urban-rural outdoor concentration differences. Because the outdoor source contributions are generally higher for BTEX than for the other VOCs, urban-rural indoor exposure differences for the other VOC:s - terpenes in particular - are likely to be even smaller and only weakly reflect the respective outdoor air concentration differences.

Ozone (O_3)

Ozone levels in ambient air are almost inversely proportional to most other air contaminants. The highest ozone levels are found in rural and seaside areas away from the pollution sources, and in urban areas in sunny afternoons, when the vertical mixing is at its highest. Conversely the levels are very low in the street canyons under high traffic conditions, where traffic emitted NO consumes all O_3 in its oxidation reaction to NO_2. Because of the very different concentration pattern compared to other air pollutants, the health effects of ozone are relatively easy to differentiate from those of the other pollutants.

According to the European CAFÉ report [27] O_3 is the other pollutant, after fine PM, which causes significant excess morbidity in Europe. Ozone is not clearly associated with increased mortality, but it reduces the lung function in children, and induces and aggravates asthma and other inflammatory respiratory conditions [13]. The difficulties in long term ozone epidemiology studies arise from the facts that the highest ozone levels are found in sparsely populated rural areas, and that the indoor levels are generally much lower, and highly variable in relation to the outdoor concentrations. In other words, ambient air ozone monitoring reflects poorly the ozone exposures of the population. On the other hand, indoor ozone sources (large or old photocopiers, ozonizers) are rare and therefore do not disturb the I/O ratios in most indoor environments.

Ozone is clearly more reactive than the other regulated air pollutants, and therefore indoor air ozone levels remain below the ambient air concentrations even under open window ventilation. Ozone levels in sealed and centrally air conditioned buildings are only in the order of 1/10 of the ambient air levels. In the PRIMEQUAL study the indoor air ozone levels in French schools ranged from 0 to 45% of the ambient air levels [14].

Particulate matter (PM)

Particulate air pollution is (in sampling, regulation and research) usually divided according to particle size into coarse (2.5 - 10 µm aerodynamic diameter), fine ($PM_{2.5}$ < 2.5 µm) and ultrafine (< 0.1 µm) fractions. The two first fractions are measured as mass concentrations, the third by counting the particles in a unit air volume.

After years of debate and research, the general understanding has emerged that urban fine PM represents the air pollution that has the biggest health effects [1,2,3,4]. CAFÉ report [27] estimates that in 2000, fine PM with a smaller contribution from O_3 caused 370 000 excess deaths and 3.62 million lost life years in Europe. These numbers exceed by far the mortality or lost life years estimates for any other environmental contaminants in Europe. Most of this excess mortality is due to acute cardiac death, but also respiratory disease and lung cancer contribute significantly.

In the Western urban context, the most important source of indoor air particles - in the absence of smoking - is usually outdoor air. PM2.5 is the particle size fraction that is most evenly distributed over large urban areas. Ultrafine particle numbers (UFP#) are, instead, quite unevenly distributed, and data at two urban monitoring sites correlate poorly with each other [28], let alone with personal and indoor air concentrations. Penetration of particles from outdoor air into indoor spaces is therefore a matter of great interest for indoor air quality and public health.

Of the commonly monitored particle size fractions, $PM_{2.5}$ infiltrates best (30 - 90%) from outdoor to indoor air. Indoor infiltrations of ambient coarse ($PM_{2.5\text{-}10}$) and ultrafine particles are lower. In non-smoking homes in Boston, MA, minimum infiltrations were observed for ultrafine and coarse, maximum for 0.1 - 0.5 µm particles. Infiltration efficiency depends also on the season and home characteristics - high in the summer with no air conditioning (AC) and high air exchange rate (AER), but low with AC and low AER) [29]. In two studies made in very different climate zones and building types, namely residences in Brisbane, Australia

[30], and offices in Helsinki, Finland [31], indoor concentrations followed the outdoor concentration changes in a smoothed and delayed pattern. In the Australian homes, however, the I/O ratios were 0.8 - 1.0 for both particle number and $PM_{2.5}$ mass concentrations, while in the Finnish offices the I/O ratios fell within a much broader range, 0.05 - 0.75. In another Finnish office building with a mechanical ventilation system equipped with EU7 class filters, infiltration of outdoor air particles was highest (0.25 - 0.3) for 0.2 - 0.5 um particles, lower (0.15 - 0.2) for 0.1 um, and lowest (0.02 - 0.06) for 0.01 um particles [32]. In the PRIMEQUAL study on French schools, the I/O ratio increased with increasing particle size (0.3 to 20 µm), and averaged 0.82 (0.41 – 1.18) for $PM_{0.3\text{-}0.4}$, but was 3.7 (0.15 – 9.0) for $PM_{5\text{-}7.5}$. [14]

In an American study of two retirement homes (in Baltimore, DE, and in Fresno, CA), indoor $PM_{2.5}$ concentrations in air conditioned apartments were, in average, only 45% of outdoor concentrations, but reached 80 % when AC was turned off and homes were ventilated through open windows (April - May in Fresno, CA). Personal exposures of the residents followed closely the indoor air concentrations with a mean 3 $\mu g/m^3$ increase from personal cloud [33].

I/O ratios of fine PM and NO_X depend also on outdoor meteorological parameters, which influence both the ventilation methods and air exchange rates. In Hong Kong the impacts were quite similar for both pollutants, namely strongly increased I/O for increased ambient temperature and humidity, weak increase for solar irradiation and no effect for wind speed and atmospheric pressure. [34]

RISK MANAGEMENT OPTIONS FOR AMBIENT AIR POLLUTION INDOORS

Most of the population exposure to and therefore - logically - also mortality and morbidity from ambient air $PM_{2.5}$ is caused by indoor exposure to $PM_{2.5}$ of ambient origin. An interesting epidemiological study [35] pointed out that, indeed, increased fraction of buildings with central air conditioning within the community significantly reduces the community wide association between ambient air PM and serious health effects (CVD, COPD, Pneumonia). This predictable fact opens a significant reduction potential for urban $PM_{2.5}$ mortality risk in buildings.

In more recently built buildings with advanced two way mechanical ventilation with intake and circulation air filters and air conditioning systems, the infiltration of outdoor air $PM_{2.5}$ is significantly lower than in older buildings with natural ventilation via open windows and vents. A probabilistic exposure modelling exercise demonstrated that reducing the $PM_{2.5}$ infiltration into all buildings in the city of Helsinki to the level of the office buildings built after 1990, would reduce the population exposure to $PM_{2.5}$ from ambient origin as well as its adverse health effects by 27%, in fact almost as much as total elimination of all traffic sources from within the metropolitan area limits. [36]

O_3 is another air pollutant with significant public health risks, against which buildings and ventilation & AC systems can provide a significant level of protection. Also *nitrogen dioxide* is sufficiently reactive to be significantly reduced indoors vs. outdoors.

Urban air pollution risk management applying building technologies should not be seen as an alternative, but rather as a complementary strategy for urban air pollution risk reduction. This is highlighted by interesting differences between the two strategies. Reduction of local air pollution sources has no impact on exposure to the air pollution load from extra-urban sources, which are often responsible for 50...66 % of the exposure. Building technologies reduce pollution exposure from intra- and extra-urban sources equally. Reduction of local air pollution sources has only limited and slowly materialising potential to protect vulnerable population groups or individuals, while building, ventilation and filtration technologies can be targeted for efficient and rapid individual or building level protection.

Integrated management and control of building services

Dipl.-Ing. Hans R. Kranz VDI
HAK Consulting (Building Automation), Germany
for Siemens Building Technologies, HQ Switzerland

Hans@Kranz.com

SUMMARY

Professional building owners and facility managers require system solutions featuring integrated building management comprising building automation and control along with fire safety and/or security for the operator and at technical levels. Those solutions require coordinated procedures during the design phase as well as during the execution phase. The integration of different systems is carried out by using standardized communication protocols. One of these protocols to combine different building systems is the globally accepted protocol BACnet according to EN ISO 16484-5. The same standard, Part 3 defines the “BACS functions”. The definitions are valid for the entire branch of the building automation and control (BAC) industry to serve as a common language for all those involved in the design, implementation and operation of such systems.

A functional networking of systems from different disciplines calls for involving complex efforts in terms of design engineering and implementation. The uniform object model of BACnet provides the brand and system neutral application and WEB services for interoperable integration with enterprise systems and other BACS using XML and the internet technology for networking, the transport of data.

The standards for communication protocols in the various fields of building applications are BACnet, LonWorks with LonMark and KNX/EIB as well as more or less “open” methods as OPC, and MODbus. LonWorks is a national American and national European standard under the property rights from Echelon Inc. used mainly for data transportation and complex functionality in the field of room automation and smaller BACS. LonMark is a private “standard” to achieve interoperability using LonWorks products. KNX/EIB is also an American and European standard, but for 100% interoperability of products used in general electrical installation that also includes integrated room automation.

The field of building automation and control and the integration of related building services needed a more comprehensive functionality. So BACnet became the international communication standard for BACS. Both, LonTalk (the transport protocol of LonWorks) and KNX/EIB have become a normative part of BACnet and therefore they are already part of the global EN and ISO standard for building automation and control systems. To use LonMark products within a BACnet environment, a Gateway to match the different semantics is necessary.

BACnet already has defined provisions for the functional integration of integer fire safety and access control systems supporting the BACnet standard; the “life safety” communication objects and services.

The question of responsibility in projects with combination of autonomous systems for safety/security alarming and building automation and control is a serious matter of the various construction contracts – and is not covered by standards yet.

INTRODUCTION

Integrated technical building management

Technical building management probably represents the most important task within the scope of facility management while a building is being used. This is where all technical tasks to manage a building and its equipment come together.

The control of plants for technical building services as well as with building operation monitoring for life safety and security management, energy management and supervisory control for of power distribution installations are the tasks for technical building management.

The operating of modern industrial and commercial buildings requires clearly delineated building management tasks:

- Commercial building management focuses on managing and controlling processes.
- Infrastructural building management for general services rendered during building use.
- Technical Building Management with tools for operation and supervision.

Communications for human interaction and for alarm notifications is using facilities such as telephone, pager, intercom, radio, and staff paging systems. However communication within and between technical plants is carried out via networks using communication protocols.

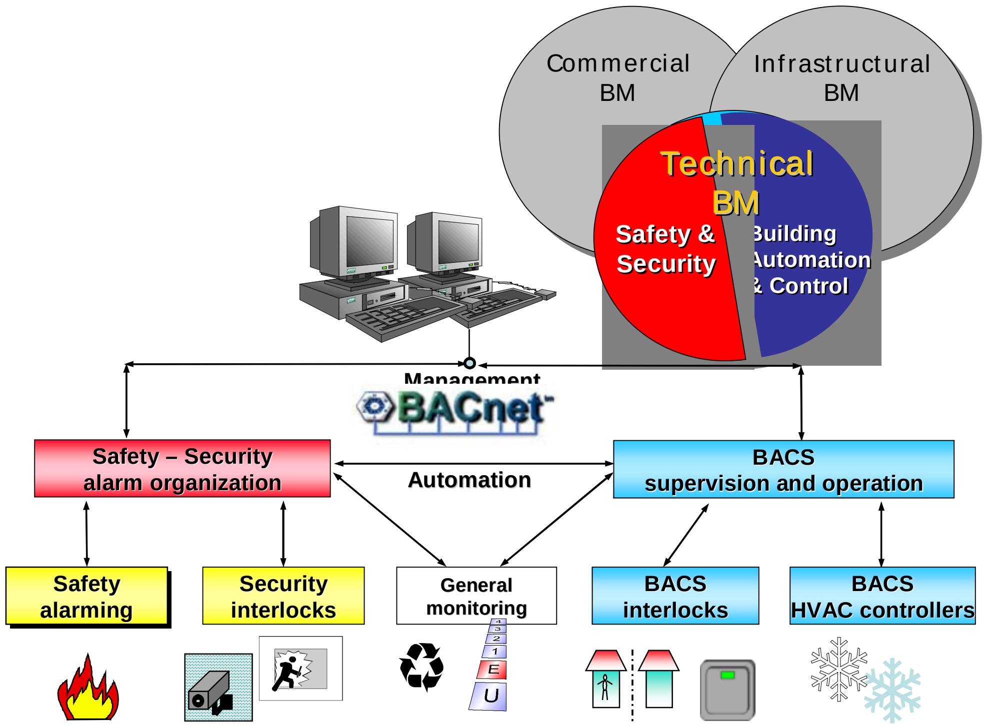

Figure 1. Technical building management and different systems in interaction.

The discussion of system integration has become an increasingly important topic on the agenda of engineers and other experts involved building automation and control systems technology. This discussion is influenced by contributions from the different bus systems or networks available for building applications. The heart of the matter is to solve the problem of exchanging unambiguous “functional” information between different technical systems. Comprehensive, project and estate-specific data management with a building management system will be cheaper from the lifetime point of view because the owner only has one database that needs to be managed and updated. It also eliminates data inconsistencies resulting from a multitude of different local or department-specific databases. The user can then transform the financial advantages into increased competitiveness.

RESULTS

Combined technical building systems

To understand the needs of systems integration, first a definition the different systems installed in a building is essential. The possibilities of an interoperable connection between life safety/security alarm systems and systems for building automation have to be considered.

Figure 2. The different disciplines to be interoperable combined.

The operating of modern industrial and commercial buildings requires clearly delineated building management tasks. The European standardization bodies have subdivided the management tasks as follows:

Commercial building management

Commercial building management focuses on managing and controlling processes. Examples for commercial building management are:

- Contract management,

- Tennant billing,
- Cost planning and controlling,
- Object accounting,
- Procurement,
- Project management.

Infrastructural building management

The infrastructural building management comprises general services rendered during building use such as:
- Security services,
- Guard services,
- Telephone services,
- Cleaning and waste disposal,
- Moving services,
- Campus services,
- Winter/snow removal services,
- Courier services/internal mail services.

Life safety and security systems

We can subdivide these systems into:
- Danger Alarm Systems:
- Fire alarm systems (fire safety),
- Burglar alarm systems (security),
- Raid alarm systems,
- Transmission systems for such alarms.

Often the following installations are combined with the detection and alarming systems:
- fire extinguishing devices,
- fire alarm devices,
- CCTV systems for room monitoring,
- access control systems,
- watchman's reporting systems.

Criteria for life safety and security systems

From the security engineer’s point of view, the terms "integrity" and "integration", on closer consideration, become antonyms. The term "integrity" is an important factor within their security concept. A look in the dictionary might be helpful in casting light into the depths of terminological confusion.
- integer (Latin adj.): untouched, entire, soundness;
- integration: the act of combining or adding parts to make a unified whole.

Asking the users of security systems about their expectations with regard to the performance and usefulness of these systems, their main criteria are as follows:
- fail-safety/availability,
- low incidence of false alarms,
- fastness and reliability of repair service,
- state-of-the-art technology,

- user-friendliness,
- service quality,
- delivery safety,
- confidentiality.

(It is interesting to note that the above criteria frequently even range before the price!)

Building automation and control systems (BACS)

The concepts of "supervisory control systems", "centralized control systems" or "building services management systems", have been supplanted by the term "building automation and control systems" (BACS), as a complete system for digital measuring, control, supervision and management.

Almost invisibly, building automation and control systems and their operators ensure ecological, economical and safe operation of a building.

The past experience made sure that it never would work sufficient to interconnect functions without standardized semantics.

Functions within the building automation and control systems

The BACS industry has learned that automatic functions need to become clearly defined and to be standardized for reducing the risk during tendering and construction (for both sides). This includes the I/O-functions as well as the complex processing and optimization functions such as "start-up control", "sequence control", "frost protection", "night cooling mode", "peak load limitation", "long term history", "dynamic display" etc.

Therefore the industry hardly is promoting standard descriptions of building automation functions and of a communication standard describing semantic communication objects.
The common definition of "BACS functions" is given in the global standard EN ISO 16484-3 to serve as a common language for all those involved in BACS projects. Fifty standardized functions include the I/O-functions as well as the complex processing, optimization and operator functions.

Those fifty standardized functions cover:

1. Hardware-related and communicative (shared) input and output functions for event detection, measuring, counting, switching and actuating – the "basic I/O functions",
2. Functions for monitoring and display of the different processes, as well as alarm functions in case of faults or of limit violations,
3. Processing functions for safe local automation - closed-loop and open-loop and PID-control - of building services and user-specific installations,
4. Processing functions for energy-saving operation of the different processes (local optimization),
5. "Centralized" processing functions for time scheduling and comprehensive optimization strategies covering all areas and components of a building (general optimization and coordination of plant operation),
6. Process control functions for "human system interface", including service operation on the "field level" with local direct process control and indication devices,
7. Management functions for analysis and statistical display of current or historical process values to facilitate decisions,

8. Tools for calculation or estimation of optimized operation parameters, and for combination and programming of new modes of operation,
9. Functions for data exchange and interoperability with other systems (system integration),
10. Remote control or telecontrol functions via the web or public networks,
11. Tools for modifications, expansions, and testing,
12. Data archiving functions for backup and restore.

The complexity of combining systems

Fire detection systems have been integrated with door locks and with HVAC fan and damper controls for smoke management for several years, but these systems have relied on relays controlled by the fire alarm system to override the normal controls. This kind of integration has primarily involved constant-volume HVAC systems and required only on/off control of fans and dampers to be moved to fully open or fully closed positions. Many modern HVAC systems are far more complex. Variable air volume and individual room control systems are used to reduce energy consumption. These systems require sophisticated control algorithms to operate either a continuously variable-speed fan or inlet guide vanes to control the static pressure in the supply air duct. Variable air volume boxes control the airflow from the supply duct into individual rooms by modulating dampers. What is needed is a way for the fire alarm system to command the HVAC control system to enter zone wise a smoke control mode and let the HVAC controllers manage the equipment.

Purchasing of system integration

To purchase (and to offer) system solutions featuring integrated building management
- fire safety and/or security along with building automation and control -
coordinated procedures during the tendering phase, the construction phase as well as during service are required.

Another important aspect is the intentional interdependence of different functions. This means that, for instance, signals from safety and security installations (fire/burglar alarm) should trigger suitable reactions in the lighting, elevator and supply systems. Mutual exchange of electronic information between the different systems, without restricting their individual autonomy, would thus be useful for all systems involved.

Damage to staff and/or buildings can be limited through automatic "secondary" actions in the technical installations initiated by alarms from the safety and security installations, which, in turn, initiate "primary" actions (emergency call, fire extinction etc.). In many cases, these functional chains are stipulated by the laws on the erection of buildings.

Integration is not just a question of supplying equipment, but it is a task in its own right. For this reason, the networking of functions requires that the objects, properties and services used for the interaction of these functions are standardized as well as there is a need to restrict the methods for the data transport (the lower communication protocols in the ISO/OSI reference model), i.e. the interface definitions must describe the data transfer medium, the transport protocol, but above all the "application objects".

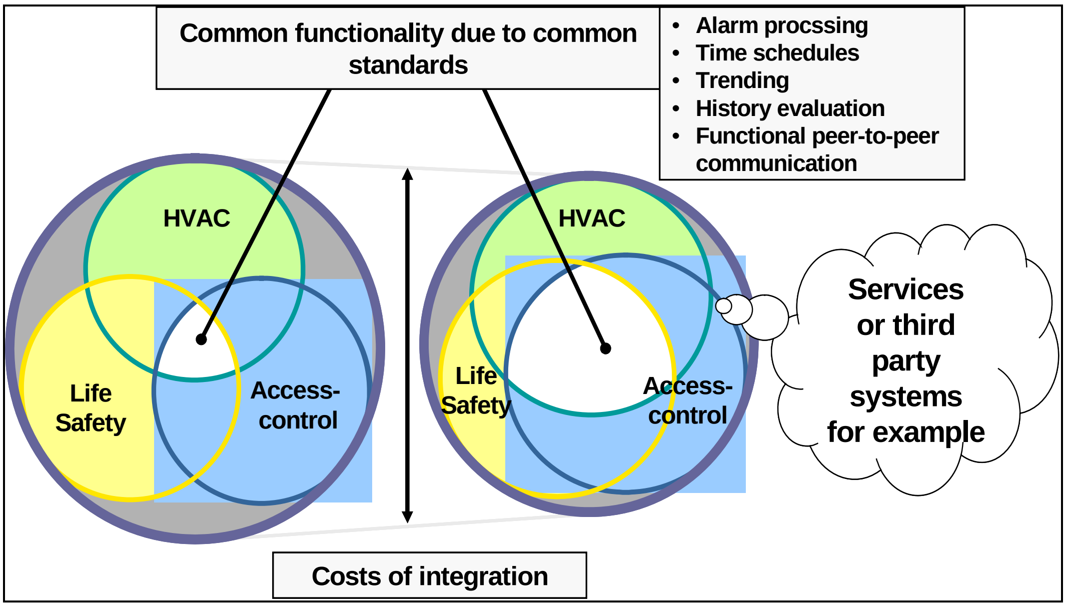

Figure 3. The van diagram of system integration and standardization

Characterization of combined and integrated systems

“Combined systems” fulfill their functions with jointly used system components within the valid standards, making sure that there is no impact of faults on the defined main functions. If faults occur in a specific installation these have no impact on any other system.
“Integrated systems” are characterized by a joint utilization of system components with possible interferences between system components. In this context, new and more detailed regulations and standards are necessary which take into account the need to preserve the integrity of the individual system components.

The discussion of system integration has become an increasingly important topic on the agenda of engineers and other experts involved in alarm systems technology. This discussion is influenced by contributions from the different bus systems or networks available for building applications. The heart of the matter is to solve the problem of exchanging unambiguous “functional” information between different technical systems.
All together is what we call “systems integration”.

Methods for combining different systems

Coupling of different systems can be implemented through direct "parallel" transfer of each information via coupling relays, or by means of "serial communication" in the case of larger building complexes. The different systems must be able to "understand", but not interfere, with each other. It is even more important that the aforementioned actions/measures do not reduce the functionality of the involved systems or installations. Of course, it also is necessary that the performance of different integrated systems can be accounted for individually (acceptance test/warranty). Furthermore, we have to be aware that systems integration or simple coupling of systems is subject to certain restrictions caused by safety and insurance regulations.

We have seen that the principal expectations of the two user groups for automation and safety differ considerably. Nevertheless, it is important to look for common ground because there is undoubtedly a large demand for combined/integrated systems on the market. However, it is important to judge these systems on the basis of safety aspects.

Great diversity and complexity also mean an increased interdependence between the different systems. The different processes required for project planning and design, erection, commissioning, acceptance test, operation and service involves a continually increasing number of people who have to cooperate and communicate by means of various different interfaces.

Is OPC a solution?

Control devices and operator interfaces often are interconnected via an OPC interface. OPC is a general industry standard depending on and restricted to the procedures of the former Microsoft Windows operating system, it does not work under MS Vista. It also is not a standard in the ISO/EN sense. It is used for the connection of PLC’s (controllers) and monitoring stations under Windows.

For professional BACS, OPC has too many functional restrictions and limited reliability with respect to the data transmission within Windows-PC. OPC does not use semantics, data points and application objects. This means that the relationships between the functions of an object, e.g. between a counter input and the associated limit values and other parameters get lost. It requires double and more engineering efforts because all variables of a control data point need to be created within the controllers and to be re-created for the monitoring system.

Uniform Object Model

One can easily imagine that a well-planned data model for building automation and control is a lucrative asset both for owners, for prime contractors and for facility managers particularly if this data model is based on a globally accepted International Standard. A uniform data model, however, is only possible through the creation of a uniform object model which enables access to the internal data of different systems.

Common ground

Fortunately, with “BACnet” we have the global standard that provides such an object model, the required procedures and data access services. And… it supports the appropriate data transport methods by referencing the most common networks used in buildings. In the following we will have a closer look to BACnet.

What is BACnet?

BACnet is originally the ASHRAE data communication protocol for building automation and control networks. The field of application covers the communication needs systems for applications such as heating, ventilating, and air-conditioning control, lighting control, access control, and fire detection systems, and some more are in development [1].
BACnet was not intended for use in the application fields for home automation, medical applications, white and brown goods, and consumer electronics.

After a parallel voting within ISO and CEN, BACnet became an ISO and an European Standard in 2003. It now is: **EN ISO 16484 Part 5 „BACS protocol“** [2] [3]. “EN” shows that this also is a National Standard in 30 European (CEN) countries.

The protocol is describing:
1. Object types for application messages,
2. Services for data-/information access, with messages and their format and syntax,
3. Data transport to convey data by referencing standards. with networking options (LANs, WANs, Dial-up),
4. Joining networks together to form "internetworks".

BACnet is designed specifically for building operation - some functional examples are: Alarm and event processing, scheduling, trending, command prioritization, control logic, life safety and security/access objects. But: The protocol does not specify the system itself, only provisions for interoperability of different systems or products.

BACnet Object Types

The BACnet “objects” represent the behavior of physical inputs, outputs and software processes. Each object is characterized by a set of “properties” that govern its operation. The BACnet Standard in the moment defines a collection of 28 standard object types. For example, an analog input is represented by a BACnet Analog Input object that has a set of properties that include its present value, sensor type, location, alarm limits, and others. Some properties are required and others are optional, depending on the functional use. A device is represented by an appropriate collection of network-visible objects. Once the information and functionality of a device are represented on the network in terms of standard objects and properties, messages can be defined to access and manipulate this information in a standard way.

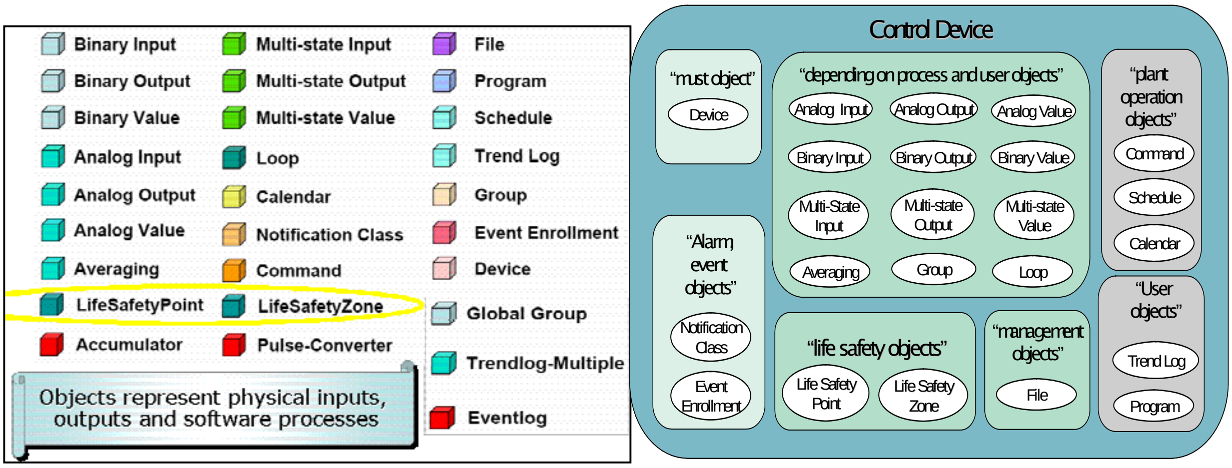

Figure 4. a) The recent BACnet object types, and b) objects in a BACnet device

The object-oriented structure also provides a way to add new application functionality to BACnet by defining new objects and/or new application services. The safety/security additions were developed with assistance from the fire alarm industry and have been approved by the BACnet committee. Other new object types have been developed for video surveillance (CCTV), access control, other security applications, utility and lighting control integration. Hey are being integrated into the global standard soon.

Application services

A communication with BACnet is described by reading and writing of information as contents of the objects' properties. The definitions are unambiguous and complete.

1. Alarm and Event Services,
2. Data reading and writing Services,
3. File Access Services,
4. Object Access Services,
5. Remote Device and Network Management Services,
6. Virtual Terminal Services (for engineering),
7. WEB services for integration with enterprise systems using XML.

XML is a mechanism to describe information in a manner that is flexible and can easily be communicated across IP networks. Web Services can best be described as a mechanism for applications (both system and device-centric) to communicate with each other across the Internet and intranets.

These services include provisions for Scheduling, calendar and time depending actions and for Trending with Logs of analog values and events.

BACnet's data exchange philosophy follows the well known client and server concept, but dedicated to functionality not to certain devices. Additional BACnet is providing procedures for applications and other services. Examples are the prioritizing of event notifications and commands. Other procedures exist for system start up, power recovery, and failures with additional error, reject, and abort codes.

BACnet Networking Options

BACnet provides a wide variety of options for the transport of data. These options comprise:

1. Ethernet, IEC 8802-3,
2. ARCNET, ATA/ANSI 878.1
3. Master-Slave/Token-Passing (MS/TP), ISO 16484-5, EIA RS 485,
4. Point-to-Point (PTP), EIA RS 232-C
5. Echelon's LonTalk, EIA/CEA 709.1-B
6. BACnet/IP, (Internet protocol),
7. BACnet/WS (Web services), ISO 16484-5 Am. 2004-c
8. In recent discussion are wireless networks such as ZigBee or Bluetooth, WLAN already is provided by Ethernet/IP.

The first option is ISO 8802-3, better known as "Ethernet", also together with the Internet Protocol (IP). It is the fastest option and is typically used to connect workstations, controllers and high-end field devices. Further on, in combination with the internet protocol Ethernet develops as the most future proof method. The second option is ARCNET, which comes in slower, lower-cost versions (mainly in US). BACnet defines the MS/TP (master-slave/token-passing) network designed to run over twisted-pair wiring. Echelon's LonTalk network can also be used. The Ethernet/IP, ARCNET, and LonTalk options all support a variety of physical media. BACnet also defines a dial-up or "point-to-point" protocol called PTP for use over phone lines or hardwired EIA-232 connections.

A key point is that BACnet messages are the same no matter which LAN is used. This makes it possible to easily combine LAN technologies into a single system.

BACnet/WS Web Services facilitate integration of BACS and "enterprise" systems for scheduling, energy management, preventive maintenance, and other global applications, using XML, SOAP and other standard Internet Protocol capabilities.

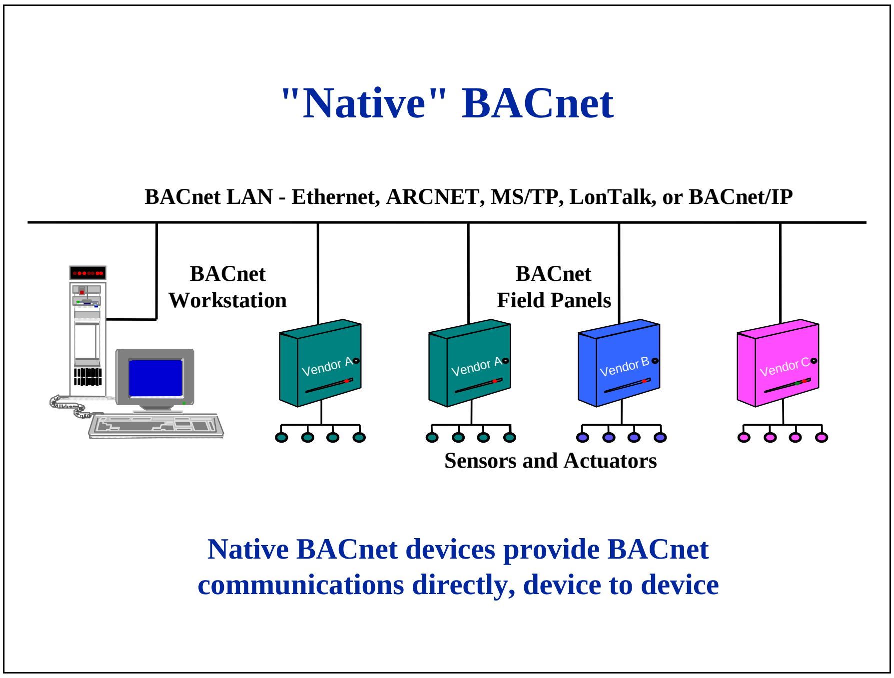

Figure 5. A flat architecture

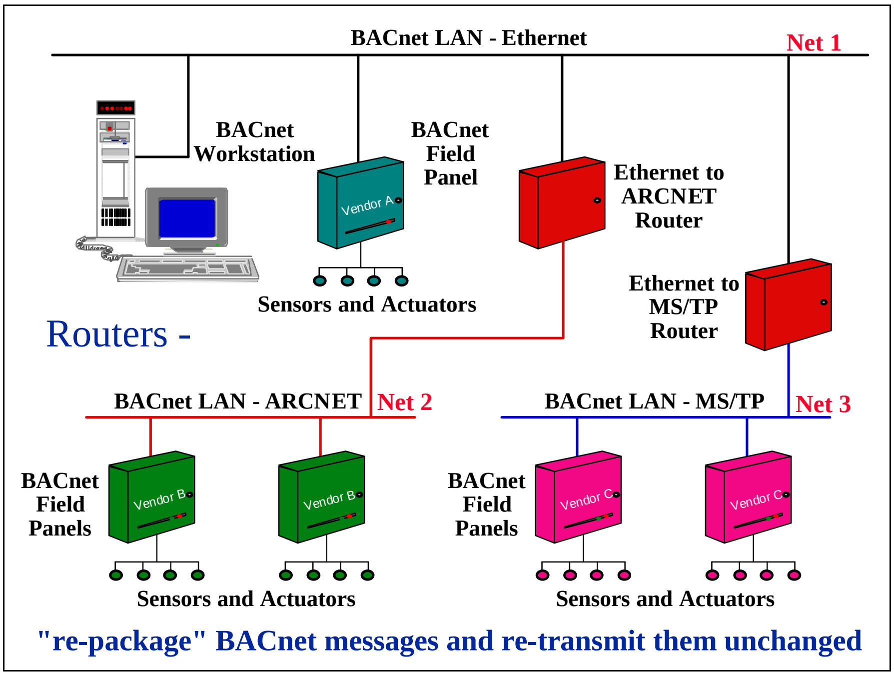

Figure 6. A hierarchical architecture – BACnet allows both

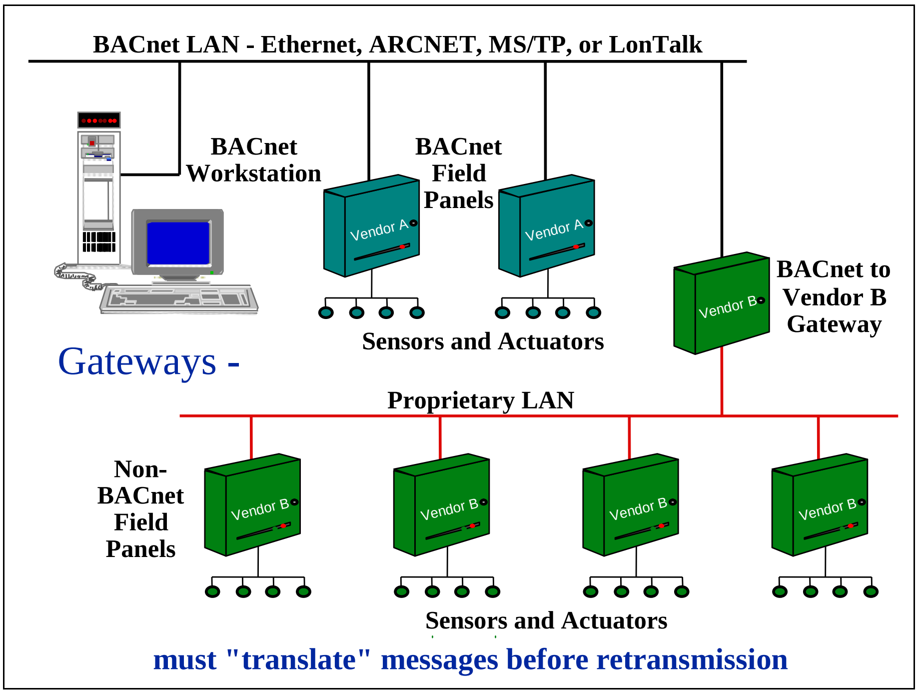

Figure 7. Integration of existing systems by gateway

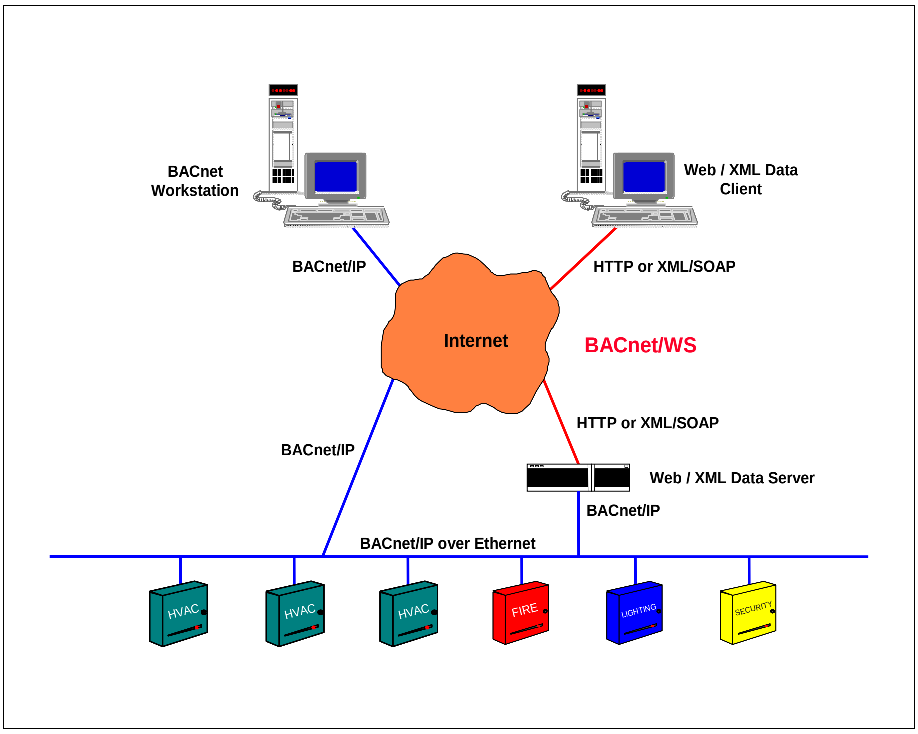

Figure 8. BACnet via internet

BACnet maintenance

BACnet is maintained under ASHRAE “continuous maintenance” procedures by a committee (SSPC 135) representing all sectors of the industry, including liaisons from Europe and Asia. The current ASHRAE SSPC 135 Working Groups:

1. Applications (AP-WG)
2. Internet Protocol Issues (IP-WG)
3. Lighting Applications (LA-WG)
4. Life Safety and Security (LSS-WG)
5. MS/TP LAN Issues (MS/TP-WG)
6. Network Security (NS-WG)
7. Objects and Services (OS-WG)
8. Utility Integration (UI-WG)
9. XML (XML-WG)

Changes can be proposed at any time by the public or a committee member. All changes are subject to public review and comment. There are formal liaisons with:

- ABOK (Russian HVAC society),
- CEN/TC247 (Building Automation and Building Management),
- IEIEJ (Institute of Electrical Installation Engineers of Japan),
- NEMA (National Electrical Manufacturers Association),
- SIA (Security Industries Association),
- SWEDVAC (Swedish HVAC society).

BACnet and Conformity

Open communication is designed to enable the erection of dissimilar systems with common functionality, including systems with products and/or engineering by different suppliers and manufacturers.

During the development of interfaces and other software, faults with the implementation of communication protocols cannot always be avoided. It therefore is necessary to test the devices for conformity with the given specification or standard. The global standard BACnet already has such a test specification as EN ISO 16484-6. The association "BACnet International" has created the "BACnet Testing Laboratories" (see BTL-sign) in USA, Europe and India.

This testing is a type test of whether or not the reaction of the product's software being tested conforms to significant test parameters of the protocol. These tests are carried out by authorized institutes, in accordance with standard testing conditions, so as to ensure that all products are tested under identical conditions. These tests do not provide insights into the dynamic behavior of the test object within an integrated system as a whole.

Only an interoperability test under typical working conditions which includes all the different products involved in one project would bring up the system behavior under different fault conditions. But this can be very expensive indeed – so it is better to leave this task to a trustworthy company.

Figure 7. The BACnet test logo

BACnet testing

The Companion standard ANSI/ASHRAE 135.1, Method of Testing Conformance to BACnet was published in 2003 [4]. The BACnet functionality of listed products is published on a web site, accessible to everyone: www.bacnetassociation.org.

Testing requirements and procedures are made public. Most testing tools are easy to obtain from http://sourceforge.net/projects/vts. Another automated test software was developed in Europe. Information is given by the BIG-EU: - www.big-eu.org [5].

Manufacturers can run tests in their own labs before submitting products. Organizations in North America and Europe worked together to create a unified testing and listing program. For the tests, the functional scope of the BACnet devices is defined by the manufacturers and – if successful tested - listed by BTL.

The BACnet standard defines the PICS (Protocol Implementation Conformance Statement) and the BIBBs (BACnet Interoperability Building Blocks) to allow an accurate assessment of interoperability. A classification of BACnet devices is described with device profiles. Each device profile (operator workstation, building controller, advanced application controller, application-specific controller, smart actuator, and smart sensor) has a minimum of BIBBs expected of it.

BIBBs are definitions of functions which are important to operate and monitor the special objects subdivided into data sharing, alarm and event management,
scheduling, trending, device and network management.
PICS are provided by manufacturers and give information about devices:
1. The implemented object types, (input, output, schedule ….) for the Application,
2. Application services and their role (initiate or execute),
3. Physical media and lower protocol layers,
4. Character sets supported.

BACnet Vendors and Users

There is a steady growing community of BACnet vendors, as of May 2, 2007, 255 Vendor IDs have been issued and are distributed internationally from 29 countries [6].
There are ten-thousands of installed systems ranging in complexity from a single gateway to very large office buildings with top-to-bottom native BACnet systems, to campus or city-wide systems linking multiple buildings in over 82 countries and on all continents of the earth.

The benefits of BACnet

This protocol has been designed specifically for building operation - some functional examples are:

* Alarm and event processing,
* Scheduling,
* Trending,
* Command prioritization,
* Control logic,
* Life safety and security objects.

Remember: BACnet does not specify the system itself, only provisions for interoperability of different systems or products.

1. BACnet doesn't depend on current technology,
   * BACnet is implemented through software, not hardware,
   * BACnet's objects and services are independent of the underlying network technology,
   * BACnet/WS allow communication between BACS and enterprise applications.
2. BACnet has no fixed architecture,
   * BACnet devices can be arranged in flat, bus-like topologies,
   * BACnet devices can be arranged hierarchically.
3. BACnet can be implemented in devices of any size:
   * General purpose, programmable controllers,
   * Configurable, fixed program controllers,
   * Application specific controllers,
   * Workstations and Web servers,
   * Tool devices and protocol analyzers.
4. BACnet can be easily enhanced and improved by extending the object model.
5. There is no charge for the use of BACnet - no fees, licenses, royalties, etc.!

DISCUSSION

A question of responsibility

One important motive for the client to contract only one supplier is to be able to assign responsibility in case of faults. It is therefore obvious that all attempts at integration of different functions or systems have been limited to individual manufacturers or suppliers of systems.

Faults occurring during the integration and operation of systems, including signaling failure, malfunctions, or other faults, inevitably lead to the question as to who is to account for the resulting damage. Another problem is to allocate the proper share of responsibility for faults or damage to every single supplier involved. “External" systems, for instance, can be infinite sources of faults. For this reason, the question of insurance is particularly important, especially where the protection of life and limb is concerned [7].

Combination or integration of security and signaling systems with other systems is only acceptable if the possibility to detect faults, and the possibility to document any external influence on the safety alarm system can be fulfilled. Combination of autonomous systems for safety/security alarm and building automation and control becomes feasible if responsible-minded companies create interfaces ensuring that all external influences on the system can be traced back to their origins.

Anyway - whatever the future may have in store with regard to system integration, we should not let ourselves be guided by wishful thinking and idealized notions about technological feasibility. Instead, we should always be aware of the human weaknesses and their impact on the functioning of combined or integrated systems.

With regard to project integration, we can normally assume that a trustworthy supplier of "combined systems" assumes the role of the general manager and therefore also ensures the necessary degree of integrity.

ACKNOWLEDGEMENT

The BIG-Fi (BACnet Interest Group Finland) made it possible to provide this paper. (ABB, Honeywell, Siemens and VTT). Special thanks to Siemens Building Technologies, Finland, for the great support.

Heating and cooling systems for better energy efficiency

Bjarne W. Olesen, Ph.D.

International Centre for Indoor Environment and Energy, Department of Mechanical Engineering, Technical University of Denmark.

Corresponding email: bwo@mek.dtu.dk

SUMMARY

Heating, ventilation and cooling of buildings is responsible for 30-40 % of the energy consumption in buildings and a corresponding significant amount of CO_2 emission. Since 2006 the European Energy Performance of Buildings Directive (EPBD) is being implemented in building codes on a national level. For new and existing buildings this requires a calculation of the energy performance of the building including heating, ventilation, cooling and lighting systems, based on primary energy. Each building must have an energy certificate and regular inspections of heating, cooling and ventilation systems must be performed. This has increased the focus on energy efficiency of systems and there components. The concept of the European standards developed to support the EPBD is presented in this paper. These standards may include alternative calculation methods and many European countries are using national methods. This means the heating system may be evaluated differently in different countries.

In Northern Europe a heating system is still needed even if the insulation of buildings will increase significantly. However, in middle Europe the increased insulation may result in a very low heat demand and a full heating system may not be needed. Also global warming will in the future impact the need for a heating system in many geographical areas. This may lead to alternative solutions for heating of buildings.

On the other hand peoples wish for more comfort, future higher outside temperatures, heat islands in big cities will increase the use of cooling systems. Further more we must increase the use of renewable energy sources. This requires systems, which can be used for heating at relative low temperature (air-water) and used for cooling at relative high system temperatures. The paper will present studies on the use of water based radiant heating and cooling systems with water temperatures close to room temperatures. The paper also introduces the concept of exergy for evaluation of sustainable heating and cooling systems.

INTRODUCTION

In 2003 the European Commission (EC) issued a directive, 2002/91/EC [1]. The objective of this directive is to promote the improvement of the energy performance of buildings within the community, taking into account outdoor climatic and local conditions, as well as indoor climate requirements and cost-effectiveness. The directive refers to the energy use and dos not take into account the life cycle energy demand (energy used to produce the products used for the building) For new and existing buildings this requires a calculation of the energy performance of the building including heating, ventilation, cooling and lighting systems, based on primary energy. Each building must have an energy certificate and regular inspections of heating, cooling and ventilation systems must be performed. This directive required all member countries by January

2006 to implement the directive in the building codes on a national level. Until now this has only been implemented fully in a couple of countries.

CONCEPT OF THE EPBD-STANDARDS

A mandate to the European Organization for standardization (CEN) from the Commission, M343-EN-2004 [2] was issued. This mandate asks CEN to elaborate and adopt standards for a methodology, calculating the integrated energy performance of buildings and estimating the environmental impact, in accordance with the directive. To coordinate the standardization related to the EPBD, CEN established an EPBD-Project Group including the following Technical Committees (TC's):

TC 89 Thermal performance of buildings and building components;
TC156 Ventilation for buildings;
TC169 Light and Lighting;
TC228 Heating systems in buildings;
TC247 Building automation, controls and building management

The standards under the mandate shall constitute an integrated and interacting methodology for the calculation of the energy uses and losses for heating, cooling, ventilation, domestic hot water and lighting systems, taking into account natural lighting, passive solar systems, passive cooling, position and orientation, automation and controls, and auxiliary installations necessary for maintaining a comfortable indoor environment. The methodology shall integrate, where relevant, the positive influences of active solar systems and heat and electricity from renewable energy sources, as well as quality co-generation heating plants (CHP, including micro-CHP) and district heating and cooling systems. It should also facilitate an estimation of the environmental impact from this energy use and provide data requirements for carrying out standard economic evaluations for the use of different systems.

This series of standards (about 40) have or are being voted for as final standards. The objective is to establish common calculation methods in Europe for energy performance of buildings and HVAC systems. Unfortunately this did not happened because the standardization work started too late and several countries have adopted national calculation methods. Also some of the standards do include alternative methods, which mean the energy performance of the same system may be evaluated differently in different countries.

Energy performance of heating systems

A basic standard for the calculation of the building energy demand (EN ISO 13790 [3]) will form the central point of the calculation procedure. To perform this calculation, input data for indoor climate requirements, internal loads, building properties and climatic conditions are needed. Standards and methods for these input data exist already to a great extent. The calculation of the building energy demand does not take into account the heating-cooling-ventilation system. The calculated building energy demand serves then as an input to the calculation of the system energy requirement.

The boundary between building and system is shown in Figure 1 for a heating system. The additional losses are calculated for heat emission, distribution, storage and generation. The auxiliary electrical energy needed for fans, pumps etc. will also be calculated. The effect of the control system is included in the building energy demand as well as the additional losses from the system due to sub-optimal control. The additional energy savings obtained with a whole building automation system (heating, cooling, ventilation, electrical appliances, light etc.) will be taken into account in a separate standard (EN 15232[4]).

Output from the calculation (Figure 1) will be the net energy (building energy demand) together with the required heating/cooling ventilation energy for the HVAC systems, including the auxiliary energy. Finally, the total delivered energy for the building/system can be calculated by adding the required energy for all the systems, including lighting. This will be converted to Primary Energy, taking into account renewable energy sources and national conversion factors. The calculation process comprises three basic points, which are, calculation of net energy (building energy demand), calculation of delivered energy (system energy demand), and conversion to primary energy. Delivered energy takes into account the losses coming from the heat emission, heat distribution and heat generation system.

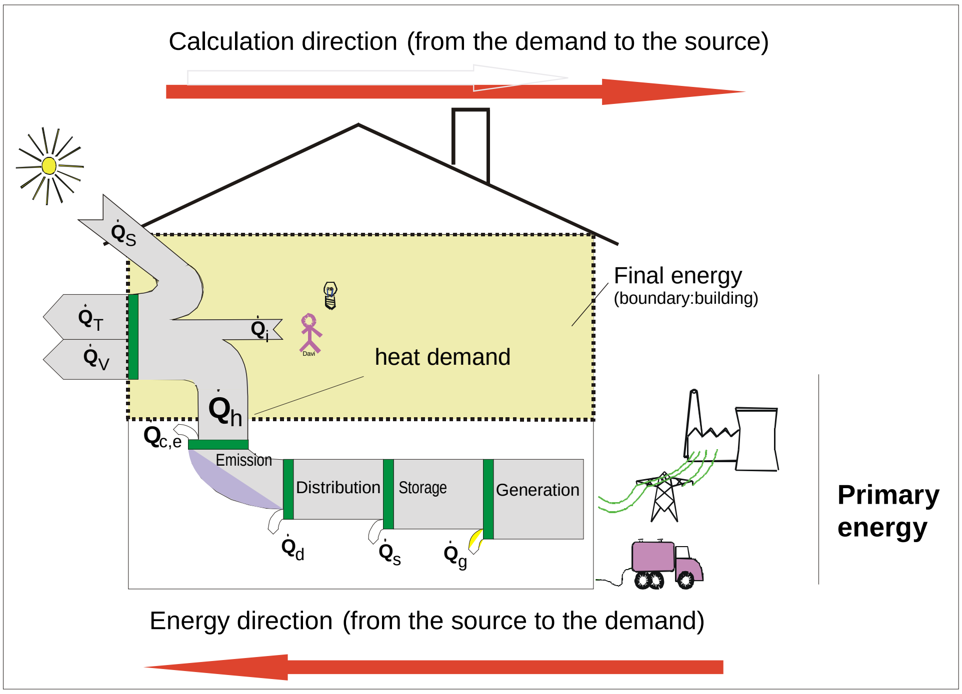

Figure 1. Calculation concept and building-system boundaries for heating (EN15316-1 [5])

Heat losses for the heat emission system (EN15316-2.1)

Emission losses are due to three factors, namely, non-uniform temperature distribution, losses to the outside from embedded heating devices in the structure, and losses due to non-perfect control of the indoor temperature. The heat energy losses of heat emission are calculated as:

$$Q_{em,ls} = Q_{em,str} + Q_{em,emb} + Q_{em,ctr} \qquad [J] \qquad (1)$$

where:

$Q_{em,str}$ heat loss due to non-uniform temperature distribution in Joule (J);
$Q_{em,emb}$ heat loss due to emitter position (e.g. embedded) in Joule (J);
$Q_{em,ctr}$ heat loss due to control of indoor temperature in Joule (J).

Two methods are recommended in the standard. The two methods do not give exactly the same results, but the same trend. The two methods shall not be mixed.

Method using efficiencies of the emission system

The evaluation of $Q_{\mathrm{em,ls}}$ takes place monthly or by another time period in accordance with equation (2).

$$Q_{\mathrm{em,ls}} = \left(\frac{f_{\mathrm{Radiant}} f_{\mathrm{int}} f_{\mathrm{hydr}}}{\eta_{\mathrm{em,ls}}} - 1 \right) Q_{\mathrm{H}} \qquad (2)$$

where

$Q_{\mathrm{em,ls}}$ is the additional loss of the heat emission (time period), in kWh;
Q_{H} is the net heating energy (time period) (EN ISO 13790), in kWh;
f_{hydr} is the factor for the hydraulic equilibrium.
f_{im} is the factor for intermittent operation (as intermittent operation is to be understood the time-dependent option for temperature reduction for each individual room space);
f_{rad} is the factor for the radiation effect (only relevant for radiant heating systems);
η_{em} is the total efficiency level for the heat emission in the room space.

The total efficiency level η_{em} is fundamentally evaluated as

$$\eta_{em} = \frac{1}{(4 - (\eta_{str} + \eta_{ctr} + \eta_{emb}))} \qquad (3)$$

where

η_{str} is the part efficiency level for a vertical air temperature profile;
η_{ctr} is the part efficiency level for room temperature control regulation;
η_{emb} is the part efficiency level for specific losses of the external components (embedded systems).

In individual application cases this breakdown is not required. The annual expenditure for the heat emission in the room space is calculated as

$$Q_{\mathrm{em,ls,a}} = \sum Q_{\mathrm{em,ls}} \qquad (4)$$

where

$Q_{\mathrm{em,ls,a}}$ is the annual loss of the heat emission, in kWh;
$Q_{\mathrm{em,ls}}$ is the loss of the heat emission (in the time period) in accordance with equation (2), in kWh.

Default values fro the different efficiencies and factors can be found in an informative annex to the standard. Some of these values are based on real data from experiments and/or computer simulations, while others are made by agreement. Examples of the values included in the annexes are given in table 1 to 3.

Method using equivalent increase in internal temperature

The internal temperature is increased by:

- The spatial variation due to the stratification, depending on the emitter;
- The control variation depending on the capacity of the control device to assure a homogeneous and constant temperature.

The equivalent internal temperature, $\theta_{\mathrm{int,inc}}$ taking into account the emitter, is calculated by:

$$\theta_{\mathrm{int},inc} = \theta_{\mathrm{int},ini} + \Delta\theta_{str} + \Delta\theta_{ctr} \qquad (°\mathrm{C}) \qquad (5)$$

where:

$\theta_{\mathrm{int,ini}}$ initial internal temperature (°C);

$\Delta\theta_{str}$ spatial variation of temperature;
$\Delta\ \theta_{ctr}$ control variation.

The influence of an equivalent increase in internal temperature. of the heat emission system may be calculated in two different ways:

- by multiplying the calculated building heat demand, Q_H, with a factor based on the ratio between the equivalent increase in internal temperature, $\Delta\theta_{int,inc}$, and the average temperature difference for the heating season between the indoor and outdoor temperature for the space:
  $Q_{em,ls} = Q_H \cdot (1 + \Delta\theta_{int,inc} / (\theta_{int,inc} - \theta_{e,avg}))$ [J] (6)

- by recalculation of the building heat energy requirements, according to EN ISO 13790, using the equivalent increased internal temperature. as the set point temperature of the conditioned zone. This second approach leads to a better accuracy.

For η_{str} an average value is to be formed from the data for the main influence parameters "over-temperature" and "specific heat losses via external components".

$\eta_{str} = (\eta_{str1} + \eta_{str2})/2$

Table 1. Efficiencies for free heating surfaces (radiators); room heights ≤4 m.

Influence parameters		Efficiencies			
		η_{str}		η_{ctr}	η_{emb}
Room space temperature regulation	unregulated, with central supply temperature regulation			0.80	
	Master room space			0.88	
	P-controller (2 K)			0.93	
	P-controller (1 K)			0.95	
	PI-controller			0.97	
	PI-controller (with optimisation function, e.g. presence management, adaptive controller)			0.99	
		η_{str1}	η_{str2}		
Over-temperature (reference Θ_i = 20 °C)	60 K (e.g. 90/70)	0.88			
	42.5 K (e.g. 70/55)	0.93			
	30 K (e.g. 55/45)	0.95			
specific heat losses via external components (GF = glass surface area)	radiator location internal wall		0.87		1
	radiator location external wall				
	- GF without radiation protection		0.83		1
	- GF with radiation protection[a]		0.88		1
	- normal external wall		0.95		1

[a] The radiation protection must prevent 80% of the radiation losses from the heating body to the glass surface area by means of insulation and/or reflection.

EXAMPLE: radiator external wall; over-temperature 42.5 K; P-controller (2 K)

$\eta_{str} = (\eta_{str1} + \eta_{str2})/2 = (0.93 + 0.95)/2 = 0.94$; $\eta_{ctr} = 0.93$; $\eta_{emb} = 1$

$\eta_{em} = 1/(4 - (0.94 + 0.93 + 1)) = 0.88$

Factor for intermittent operation f_{im} = 0.97
Factor for radiation effect: f_{rad} = 1.0

Table 2. Factor for hydraulic balancing: $f_{hydr.}$

	Influencing parameters	Factor for hydraulic balancing, f_{hydr}
Hydraulic balance	non balanced systems	1.03
	Signed balancing report and in compliance with EN 14336 • more than 8 emitters per automatic differential pressure control or only static balanced systems	1.02
	Signed balancing report and in compliance with EN 14336, • Max 8 emitters per automatic differential pressure control	1.00

For η_{emb} an average value is to be formed from the data for the main influence parameters "system" and "specific heat losses via laying surfaces".

$$\eta_{emb} = (\eta_{emb1} + \eta_{emb2})/2 \qquad \text{(A4)}$$

Table 3. Efficiencies for component integrated heating surfaces (panel heaters); room heights ≤4m.

influence parameters		**Part efficiencies**			
		η_{str}	η_{ctr}	η_{emb}	
Room space temperature regulation	Heat carrier medium water				
	- unregulated		0.75		
	- unregulated, with central supply temperature regulation		0.78		
	- unregulated with average value formation ($\vartheta_V - \vartheta_R$)		0.83		
	- Master room space		0.88		
	- two-step controller/P-controller		0.93		
	- PI-controller		0.95		
	Electrical heating				
	-two-step controller		0.91		
	- PI-controller		0.93		
System	Floor heating			η_{emb1}	η_{emb2}
	- wet system	1		0.93	
	- dry system	1		0.96	
	- dry system with low cover	1		0.98	
	Wall heating	0.96		0.93	
	Ceiling heating	0.93		0.93	
Specific heat losses via laying surfaces	Panel heating without minimum insulation in accordance with DIN EN 1264				0.86
	Panel heating with minimum insulation in accordance with DIN EN 1264				0.95
	Panel heating with 100% better insulation than required by DIN EN 1264				0.99

EXAMPLE: Floor heating - wet system (water); two-step controller; floor heating with high level of heat protection

$\eta_{str} = 1.0$; $\eta_{ctr} = 0.93$; $\eta_{emb} = (\eta_{emb1} + \eta_{emb2})/2 = (0.93 + 0.95)/2 = 0.94$

$\eta_{em} = 1/(4 - (1.0 + 0.93 + 0.94)) = 0.88$

Factor for intermittent operation:	f_{im}	= 0.98
Factor for radiation effect:	f_{rad}	= 1.0
Factor for hydraulic balancing:	f_{hydr}	same as for radiators

Heat losses for the heat distribution and generation system

The heat losses of a distribution system depend on the average temperature of the heating medium, the temperature of the surrounding envelope, length and insulation of the pipes. For the heat losses in a time step the following formula applies:

$$Q_D = \sum_i U' \cdot (\vartheta_m - \vartheta_a) \cdot L \cdot t_H \qquad \text{[J]} \qquad (10)$$

where:

U' U-value per length, [W/mK]
ϑ_m average medium temperature, [°C]
ϑ_a surrounding temperature, [°C]
L length of the pipe [m]
t_H heating hours in the time step, [h]

The standard EN15316-2.3 gives both approximated and detailed methods. The most important factors are the temperature level of the heating medium. Low temperature heating will result in decreased losses.

The calculation of losses from heat generation systems like boilers, heat pumps, CHP, district heating, solar heating and biomass combustion systems are considered in other standards. Also here a lower water temperature will result in increased energy efficiency.

Figure 2 show an example of the energy performance calculation for a one-family house for a radiator and a floor heating system. It can be seen that the additional losses from the heating system contributes with about 20% to the total primary energy.

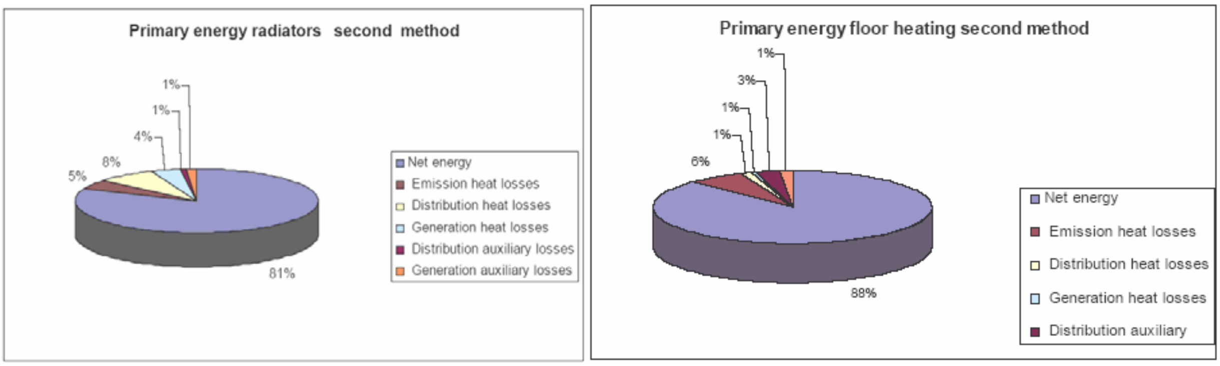

Figure 2. Losses in primary energy for a radiator and a floor heating system.

EMBEDDED WATER BASED SYSTEMS FOR LOW TEMPERATURE HEATING AND HIGH TEMPERATURE COOLING

In Europe it is mainly water-based heating systems that are used. These systems use radiators or floor heating as heat emitters. One advantage compared with air systems is the more efficient means of transporting energy. The demand for comfort, better insulation of buildings, and greater internal loads from people and equipment have increased interest in installing also a cooling system to keep indoor temperatures within the comfort range. This resulted first of all in the introduction of suspended ceiling panels for cooling and in recent years also in the use of floor systems for cooling (Simmonds et al. [8]; Olesen [9]). Typical positioning of pipes for wall, floor and ceiling systems is shown in Figure 3.

A new trend, which started in the early nineties in Switzerland (Meierhans [10]), is to use the thermal storage capacity of the concrete slabs between each storey in multi-storey buildings. Pipes carrying water for heating and cooling are embedded in the centre of the concrete slab (Figure 3).

By activating the building mass, you will not only get a direct heating-cooling effect, but you will also, due to the thermal mass, reduce the peak load and transfer some of the load outside the period of occupancy. Because these systems for cooling operate at a water temperature close to room temperature, they increase the efficiency of heat pumps, ground heat exchangers and other systems using renewable energy sources.

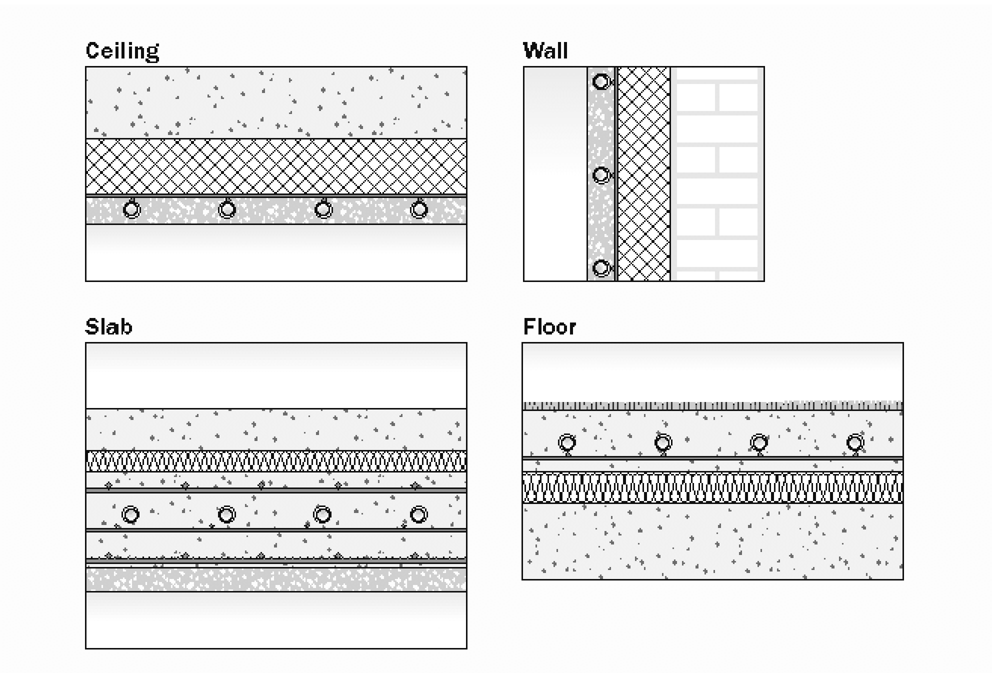

Figure 3. Examples of the positioning of pipes in floor, wall, ceiling and slab.

Even if surface heating and cooling systems often have a higher thermal mass than other heating/cooling systems, they have a high control performance. This is partly due to the small temperature difference between the room and the system (water, surface) and the resulting high degree of self-control. Studies on controllability of floor heating/cooling (Olesen [11]) show that floor heating control the room temperature as good as radiators. To avoid condensation on a cooled surface, there is a need to include a limitation on water temperature, based on the space dew-point temperature.

Design and dimensioning of these systems including calculation of heating and cooling capacity can be done according to the new standards EN15377-1 and 2. [12, 13]

Thermo Active Building Systems (TABS)

A Thermo-Active-Building-System (TABS) is a water based heating and cooling system, where the pipes are embedded in the central concrete core of a building construction. The heat transfer takes place between the water (pipes) and the concrete, between the concrete core and the surfaces to the room (ceiling, floor) and between the surfaces and the room.

The peak-shaving is the possibility to heat and cool the structures of the building during a period in which the occupants may be absent (during night time), reducing also the peak in the required power (Figure 4). In this way energy consumption may be reduced and lower night time electricity rate can be used. At the same time a reduction of the size of cooling system including chillier is possible.

The performance and dimensioning of TABS can be done by full dynamic building simulations with commercial programs including calculation models for embedded pipes. (Olesen and Dossi, [14]). A study was performed with the aid of the dynamic simulation program. The system considered is shown in Figures 5 and 6. The meteorological ambient boundary conditions correspond to those of Würzburg/Germany and Venice/Italy. The external temperature data for winter and summer design days are shown in Table 3. Summer was the period from 1 May to 30 September, and winter was the period from 1 October to 30 April

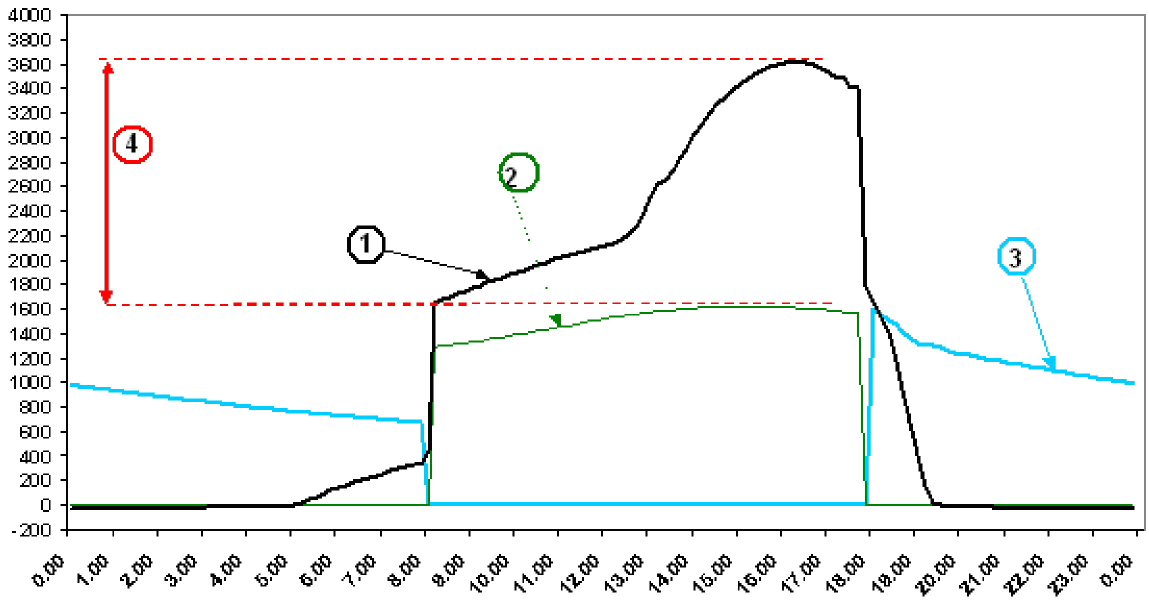

Figure 4. Example of peak-shaving effect (X-axes: time; y-axes: cooling power W)
1) heat gain, 2) power needed for conditioning the ventilation air, 3) power needed on the water side, 4) peak of the required power reduction

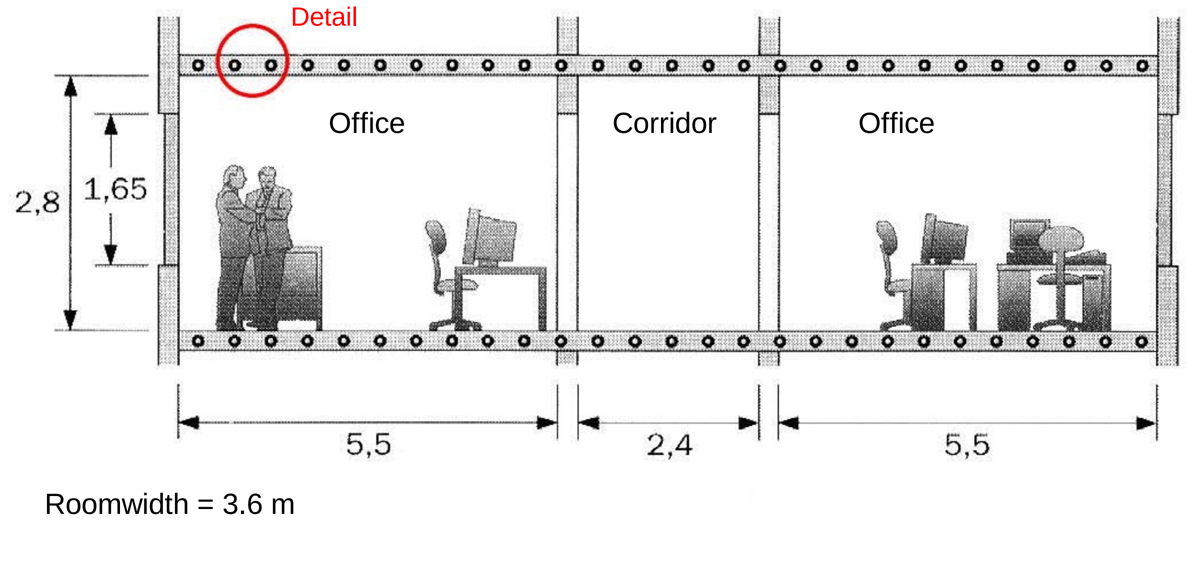

Figure 5. Central room module used for the computer simulation of a building with concrete slab cooling. All dimensions are in metres.

The time of occupancy was Monday to Friday from 8.00 to 17.00, with a lunch break from 12.00 to 13.00. The system was in operation only outside the period of occupancy, from 18:00 to 06:00. *Internal heat sources: d*uring occupied periods corresponding to 27.8 W/m^2. *Ventilation (ach*): outside time of occupation 0.3 h^{-1} (infiltration); during occupation 1.5 h^{-1} (~ 11 l/s per person). *Sun protection*: during occupation, by direct exposure of sunlight and operative temperature above 23°C, reduction factor z = 0.5.

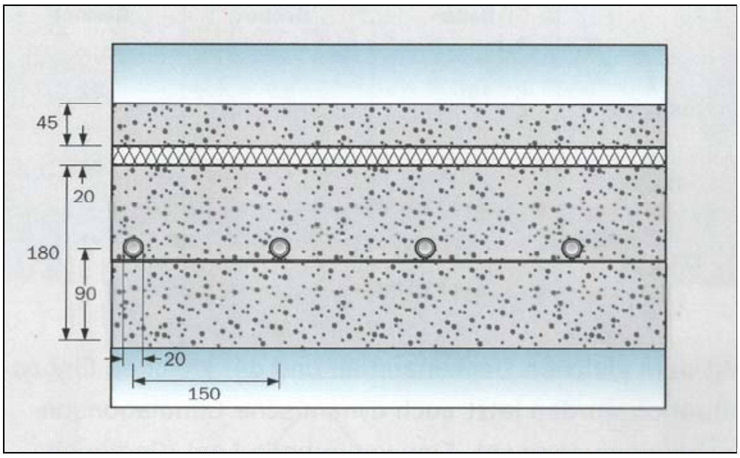

Figure 6. Position of the plastic pipes in the concrete slab between two storeys.

Table 4: Design day outdoor temperatures for Würzburg, Germany and Venice, Italy.

City	Lat. [°]	Long. [°]	Elev. [m]	Heating Dry Bulb [°C]		Cooling Dry Bulb [°C]	
				99,6%	99%	0,4%	2%
Venice	45.30 N	12.20 E	6	-4,9	-3,1	30,8	28,2
Würzburg-Frankfurt	50.05 N	8.60 E	113	-11	-8,2	30,3	26,7

The goal for the system used in the study was to operate water temperatures as close to the room temperature as possible. If very high or very low water temperatures are introduced into the system it may result in over-heating or under-cooling.

In the present study, the supply water temperature was controlled so that it was not lower than the dew point in the space. For this purpose, a humidity balance (latent loads from people, outside humidity gain from ventilation) was also included in the simulation. It was then possible to calculate the dew point in the room for each time step in the simulation.

Instead of controlling the supply water temperature it may be better to control the average water temperature. The return water temperatures are influenced by the room conditions. By maintaining a constant supply water temperature, an increase in internal loads from sun or internal heat sources will increase the return temperature. The average water temperature will then increase and the cooling potential will decrease. If, instead, the average water temperature ($\frac{1}{2}(t_{return} - t_{supply})$) is controlled, an increase in return temperature will automatically be compensated for by a decrease in supply water temperature.

In well designed buildings with low heating and cooling loads it may be possible to operate the system at a constant water temperature. The following concepts for water temperature control were studied:

Supply water temperature is a function of outside temperature according to the equation:

$$t_{supply} = 0{,}52 * (20 - t_{external}) + 20 - 1{,}6 * (t_{operative} - 22) \quad °C \qquad \text{(case 801)}$$

Average water temperature is a function of outside temperature according to:

$$t_{average} = 0{,}52 * (20 - t_{external}) + 20 - 1{,}6 * (t_{operative} - 22) \quad °C \qquad \text{(case 901)}$$

Average water temperature equal to: 22°C in summer and 25°C in winter. (case 1201)

Supply water temperature is a function of outside temperature according to the equation:

$$t_{supply} = 0{,}35 * (18 - t_{external}) + 18 \quad °C \quad \text{summer} \qquad \text{(case 1401)}$$

$$t_{supply} = 0{,}45 * (18 - t_{external}) + 18 \quad °C \quad \text{winter} \qquad \text{(case 1401)}$$

The results of the simulation are shown in Table 5 for summer conditions and in Table *6* for winter conditions. The operative temperature of the cases 0801, 0901 and 1401 (Table 5) is for most of the time (>85%) in a comfort range (22-26°C). In Würzburg, 27°C is never exceeded and 26°C is exceeded less than 5% of the time. In Venice, only 5% of the temperatures are above 27°C. The difference between controlling the supply water temperature (case 0801) or the average water temperature (case 0901) is very small. In the case of 1401, the control does not take into account the internal operative temperature, but the results are almost identical to cases 0801 and 0901. With a constant average water temperature (22°C), the cooling effect is too low and the operative temperature is often too high (60% of the time above 27°C in Venice and 27% in Würzburg). The energy use is the same for the cases 0801, 0901 and 1401 in Venice. For Würzburg, case 1401 is the energy use, but it is about 10% lower than case 801 and 901. Energy use in case 1201 with a constant water temperature is relatively high. The pump running time for case 1401 is equal to or lower than for the other cases. In the summer, case 1401 is overall better than the others. Due to the warmer climate in Venice (Table 5) the room temperatures are higher, and energy use and pump running time are also higher compared to Würzburg.

Table 5: Operative temperatures, temperature drift, pump running time and energy transfer for different water temperature control strategies. Summer conditions. Dead-band 22–23°C. Ventilation rate: 0.3 ach from 17:00 to 8:00, 1.5 ach from 8:00 to 17:00.

Standard EN15377-3 [15] includes more simplified methods to evaluate the dynamic performance of TABS. Besides the standard includes diagrams like the one shown in Figure 7 [16]. This simplified diagram give the relation between internal heat gains, water supply temperature, heat transfer on the room side, hours of operation and heat transfer on the water side. The diagrams correspond to a concrete slab with raised floor (R=0.45 m^2K/W) and a permissible room temperature range of 21 °C to 26 °C. The upper diagram shows on the y-axis the maximum permissible total heat gain in space (internal gains plus solar gains) W/m^2, and on the x-axis the required water supply temperature. The lines in the diagram correspond to different hours of operation (8h, 12h, 16h, and 24h) and different maximum amount of energy supplied per day Wh/m^2 d. The lower diagram shows the cooling power W/m^2 required on the water side (for dimensioning of chiller) for thermally activated slabs as a function of supply water temperature and operation time. Further, the amount of energy rejected per day is indicated $Wh/(m^2$ d). The example shows, that by a maximum internal heat gain of 38 W/m^2 and 8 hour operation, a supply water temperature of 18,2 °C is required. If, instead, the system is in operation for 12 hours, a supply water temperature of 19,3 °C is required. In total, the amount of energy rejected from the room is app. 335 Wh/m^2 per day. The required cooling power on the water side is by 8 hours operation 37 W/m^2 and by 12 hours operation only 25 W/m^2. Thus, by 12 hours operation, the chiller can be much smaller. The total heat rejection on the water side is app. 300 Wh/m^2 per day.

EXERGY ANALYSIS

"Energy saving" and emission reduction are both affected by the energy efficiency of the built environment and the quality of the energy carrier in relation to the required quality of the energy. Taking into account qualitative aspects of energy leads to introduction of the exergy concept in comparison of systems, which is the key idea of IEA-Annex 37. Energy, which is entirely convertible into other types of energy, is exergy (high valued energy such as electricity and mechanical workload). Energy, which has a very limited convertibility potential, such as heat close to room air temperature, is low valued energy. Low exergy heating and cooling systems use low valued energy, which is delivered by sustainable energy sources (e.g. by using heat pumps, solar collectors, either separate or linked to waste heat, energy storage etc.). Common energy carriers like fossil fuels deliver high valued energy. The reason for "energy saving" being in quotation marks in the first sentence, is that we actually are talking about saving exergy, not energy!

Future buildings should be planned to use or to be suited to use sustainable energy sources for heating and cooling. One characteristic of these energy sources is that only a relatively moderate temperature level can be reached, if reasonably efficient systems are desired. The development of low temperature heating and high temperature cooling systems is a necessary prerequisite for the usage of alternative energy sources. The basis for the needed energy supply is to provide occupants with a comfortable, clean and healthy environment.

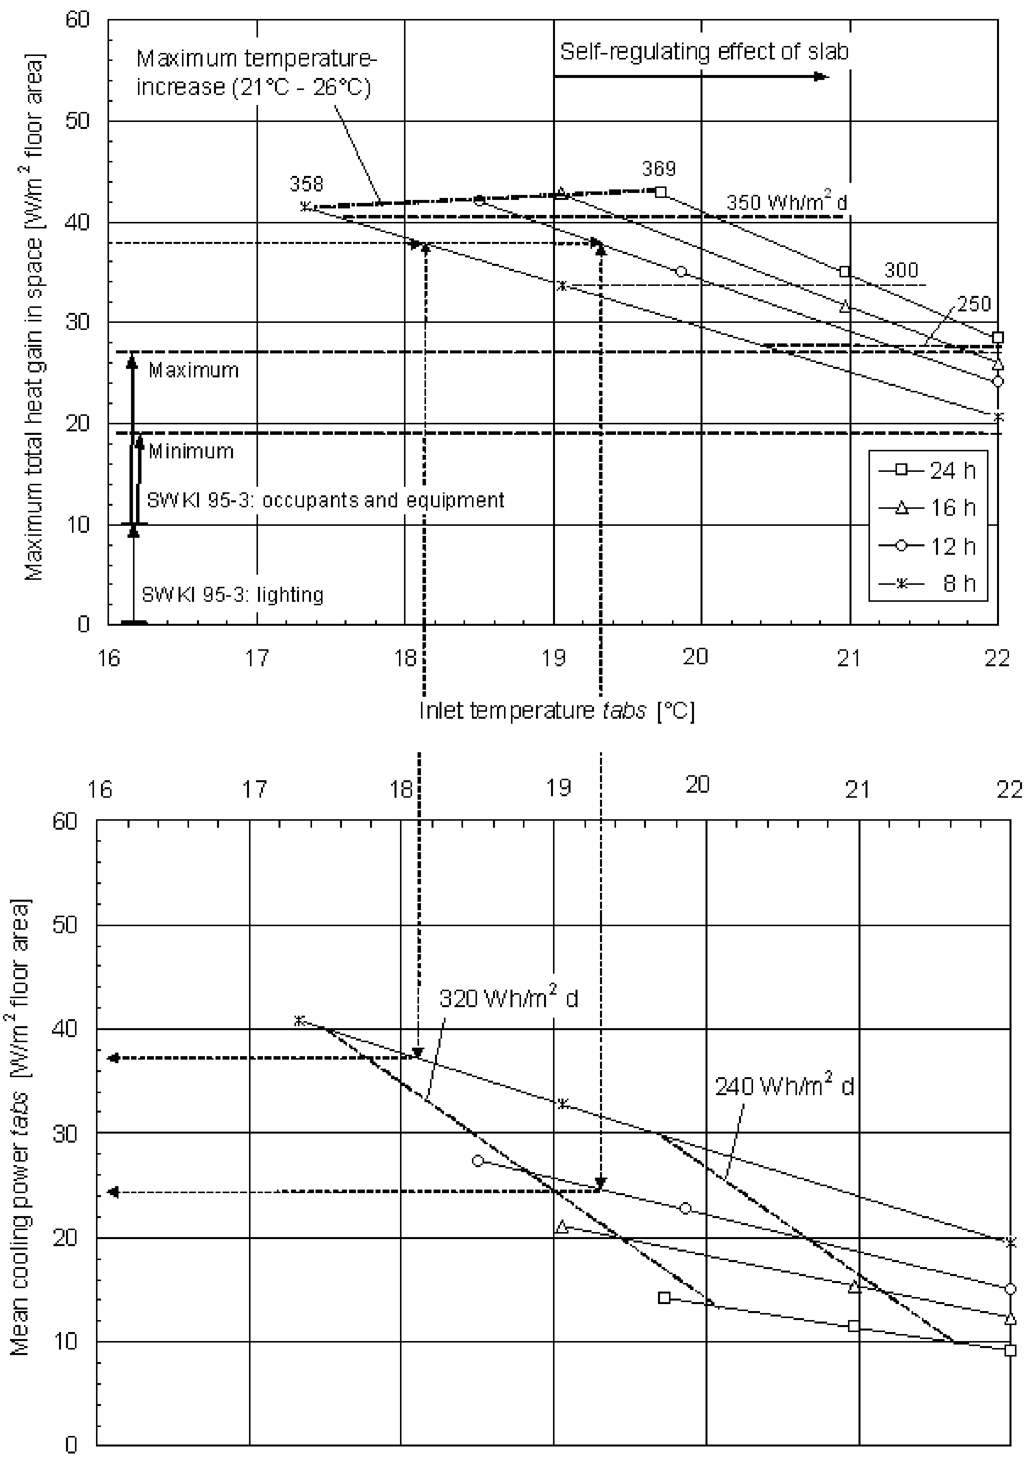

Figure 6 – Working principle of TABS (Koschenz and Lehmann [16].

Figure 7 is showing an example of a calculated energy flow and exergy flow from primary energy, heat generator, emission in room and loss to the outside. The figures show that a low temperature heating system will result in less exergy consumption.

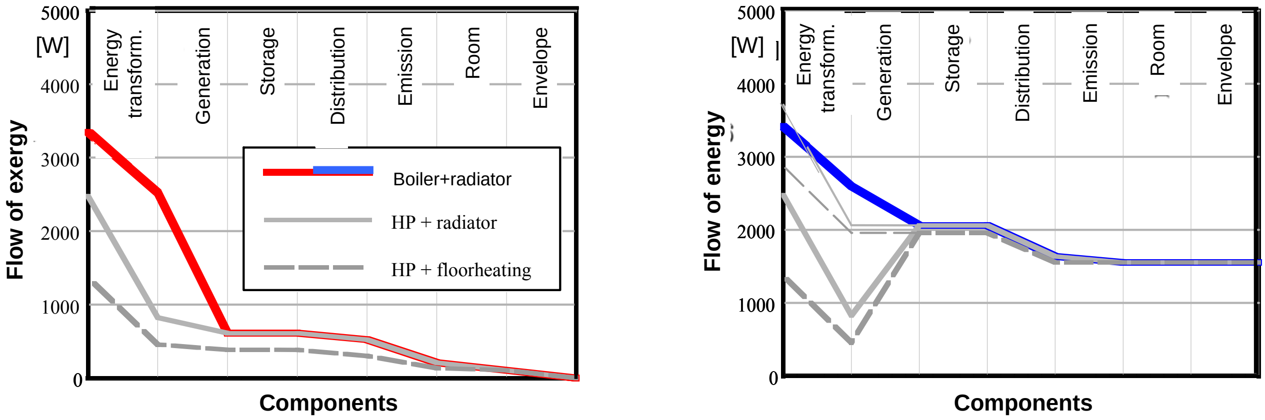

Figure 7. Examples of exergy and energy flow for three type of heating systems. (IEA-Annex 37).

DISCUSSION AND CONCLUSIONS

New demands for lowering the energy consumption of buildings require increased insulation of houses, tight constructions with mechanical ventilation and heat recovery. A trend for residential building is the concept of passive houses, where a “normal” heating system may not be needed. This trend will result in much smaller heating systems and in many cases systems using air as the energy transport medium. Also the global warming will result in less need for heating.
Because of the EPBD all European countries will in a couple of years have implemented a requirement for calculation or estimation (measurements/calculation) of the energy performance of new and existing buildings. With the development of the new CEN standards related to the EPBD it will in the future be possible to use common method and avoid that the same building system will be evaluated differently. While it is relative well established how to calculate the energy performance of the building alone, there is a lack of data on energy performance of HVAC systems. Especially for cooling systems the calculation methods are not well established. Many manufacturers will try to show that their system has a high energy performance and will also aim at developing more efficient systems and controls. But if the energy performance evaluation methods used are not detailed enough, new development may not be reflected in the calculations. On the other hand detailed calculations may make the methods more complicated. Another trend in Europe is the increasing need for cooling. Peoples increased comfort requirements (air conditioning in cars), increasing thermal loads in many office buildings, global warming, heat islands and the aim for optimal productivity of people, are all issues that will result in a higher demand for cooling.

In middle Europe a trend to use water based cooling systems at high water temperature is a way of making the cooling more sustainable with less energy consumption compared to full Air Conditioning. Some of theses systems also use the building mass (TABS) to reduce the peak cooling load and transfer some of the cooling from daytime to night. This trend has resulted in new CEN standards for design and dimensioning of systems and evaluation of the dynamic effect. Also new research studies are looking at the performance and optimal control of such systems.

Procedures for calculating the steady-state heating/cooling capacity are available. By a proper control the risk for condensation on the cooled surfaces can be limited. The results of a dynamic computer simulation of different control concepts for a water-based radiant cooling and heating system with pipes embedded in the concrete slabs have been presented. The system was studied for both the summer period May to September and the winter period October to April in two geographical locations, Venice, Italy and Würzburg, Germany. The best performance regarding comfort and energy is obtained by controlling the water temperature (supply or average) as a function of outdoor temperature. There is no need to take into account the room temperature. The system was able to keep the room temperatures within a comfortable range, in both summer (cooling) and winter (heating), and in both climatic zones.

Due to the use of water temperatures close to room temperatures water based surface heating and cooling systems will increase the possibility to use renewable energy sources like ground source heat pumps, ground heat exchangers, geothermal energy, solar energy, evaporative cooling etc. The level of water temperatures used also increase the efficiency of boilers, chillers and heat pumps.

Contribution of the Eurovent Performance Certification programs into providing incentive to manufacturers to improve the energy efficiency of HVACR products

Dany Chalmet, Chairman and Sulejman Becirspahic, Technical Director

Eurovent Certification Company, Paris, France

Corresponding e-mail: Chalmet.d@skynet.be

SUMMARY

The Eurovent Certification company was established in 1994 and administers industry driven certification programs consisting of verification testing in a network of independent test laboratories of efficiency and capacity ratings of HVACR products against published data in manufacturer's sales catalogues.

A Certified Products Directory is available to consultants, architects and equipment specifiers for evaluation and selection of equipment, providing assurance that the products will perform as indicated in the directory.

Nowadays, nine groups of air-conditioning and refrigeration related products, are verification tested and the latest list of participating manufacturers, has grown impressively to more than 180 manufacturers.

As energy efficiency became one of the most important issues for the HVACR industry, the future trend for the Eurovent Certification Programs is to evolve from the original set-up of providing a fair competition level ground for manufacturers and increasing customer's confidence towards an additional instrument of providing incentive for manufacturers to improve the energy efficiency ratio of HVACR products.

This paper will shed a light on the certification programs and how the future trends in Eurovent Products Certification ,with regard to Energy Efficiency, are dealt with.

INTRODUCTION

Eurovent is the European Committee of Air Handling and Refrigeration Equipment Industries. The Committee was established in 1959 and has amongst its members 15 national associations active in the field of HVACR industry.

List of member associations in Eurovent:

Country	National Association	National Association
Belgium	AGORIA	
Denmark	DANSK Ventilation	
France	UNICLIMA	
Germany	FV Alt im VDMA	
Italy	ANIMA	CO.AER
Finland	FAMBSI	
Netherlands	FKL	
Norway	NVEF	
Slovenia	HVAC Cluster	
Spain	AFEC	ANEFRYC
Sweden	KTG	SWEDVENT
Turkey	ISKID	

The Committee represents more than 800 companies , mainly in the manufacturing industry and producing various products to be applied in Air Conditioning, Refrigeration, Air Handling and Ventilation as well as auxiliary refrigeration and air distribution component manufacturers. The estimated turnover of the companies is in excess of 20 billion €.

The essential activity is organised through working groups where manufacturers of a particular type of products meet together, examine relevant issues and decide actions to undertake. Working groups for fans, liquid chilling packages, air conditioners, fan coil units, air handling units, air filters, refrigerated display cabinets are particularly active having usually several meetings a year. A number of application documents, guides, recommendations and other agreements have been finalised and published.

A very important feature of Eurovent organisation is the existence of the certification programmes. Eurovent Certification Company was established in 1994 on a voluntary basis by the manufacturers of HVACR equipment. The performance characteristics of HVACR products are checked by at random sampling testing of products and equipment in independent laboratories. Eurovent certification covers a large part of relevant products and more than 180 manufacturers participate in one or more programmes. Checking data claimed in catalogues is extremely important as it was shown by testing in independent laboratories that there are always actors on the market not respecting clarity and honesty in data presentation. For instance a decision on minimum efficiency for particular equipment if not supported by certification will not be applied by all manufacturers and distributors. Only regular checking by an organised system will guarantee the performance of the application.

As all products in the scope of Eurovent consume energy – mainly in the form of electricity, the energy efficiency – intrinsic to the products but also related to use and installation – has become one of the most important issues for our industry. The implementation of the Kyoto protocol has now a high priority for the European Union and strong measures shall be applied to achieve its targets fixed for Europe as a reduction of 8 % of equivalent CO_2 emission in period 2008 – 2012.

In almost all Eurovent working groups the issue of energy efficiency has been discussed during the last several years. There is a general agreement that industry must be proactive and propose relevant actions in advance, before some mandatory measures are being decided by the European Commission or National Authorities. That would be the best way to help the industry to meet this important challenge.

EUROVENT CERTIFICATION – INCREASING INTEGRITY [1]

Eurovent Certification administers and promotes the Product performance and energy efficiency certification by means of Certification Programmes.

Existing Certification Programmes:

Air Conditioners up to 12kW cooling capacity
Air Conditioners from 12kW to 45kW cooling capacity
Air Conditioners from 45kW to 100kW cooling capacity
Close control Air Conditioners for computer rooms
Fan Coil units
Liquid Chilling Packages up to 750kW
Air Coolers for Refrigeration
Air Cooled refrigerant Condensers
Dry Coolers
Cooling Towers
Cooling and Heating Coils
Air Handling Units
Refrigerated Display Cabinets
Air to Air Plate and Rotary Heat Exchangers
Filters
Chilled Beams

Eurovent Certification maintains and publishes an updated list of certified Products in the Certified Products Directory and on the Eurovent Certification Website (www.eurovent-certification.com).

The system of Product Certification started in 1994 on a voluntary basis . The performance characteristics of HVACR products is checked by at random sampling testing of products and equipment in independent laboratories.
.
The total number of participating companies today amounts to 185 companies.

Major issues besides the data checks of actual products versus the published data in sales and promotion catalogues are the Energy labelling implementation beyond what is provided for in the existing European directive (for air conditioners with a cooling capacity up to 12kw) and the determination of minimum energy efficiency levels below which certain products are not eligible to carry the logo "Eurovent Certified Performance".

A Certification Manual defines the organisation and general rules of Eurovent Certification and gives principles to follow in each programme. It must be emphasised that the Manual is regularly updated in order to keep the integrity at the highest possible level.

EUROVENT CERTIFICATION

General Principles

The following general principles are used in all certification programmes. The staff of the Certification Company must check their application and inform the Compliance Programme and Policy Committee (CPPC)of any deviation.

- Eurovent Certification Programmes are open to all manufacturers of relevant products – European and non-European - without any discrimination.
- Eurovent Certification is intended for European market and only products that could be sold in Europe* may be certified.
- Products produced by European or non-European manufacturers for other markets and which could not be sold in Europe (for instance 60 Hz units, non-authorised refrigerants etc.) could not be certified.
- Products which could be sold in Europe but are intended for other markets must comply with specific rules applied in Europe (for instance refrigerants, energy labelling for air conditioners and minimum efficiency).
- Conformity with safety directives (LVD, EMC, MD, PED) shall not be part of certification but will be required if applicable. However independent laboratories shall be asked to inform participants and Eurovent on possible irregularity .If non-conformity is confirmed the certification shall not be granted.

  *Europe represents members of European Union, and associated countries.

EUROVENT CERTIFICATION

Certify-All

The scope of each certification programme is clearly defined. Only products that may be tested by an independent laboratory either inside the laboratory or at participants' facilities shall be included. If for some large equipment there is no available laboratory above some defined size, the scope shall be limited to smaller units.
For some products like Air Handling Units the selection software is certified and the smallest size of the range must be such that the testing in an independent laboratory is possible.

All products of the relevant certification programme manufactured or sold by a participant inside the defined scope must be certified. When applicable, "certify-all" procedure means at least "all products inside the defined scope presented on the European market", but each Compliance Committee may implement larger applications.

"Certify-all" brings clarity and transparency and therefore increases the value of the whole system. If for some products due to their nature it is difficult to define a scope satisfying all participants the approval of the CPPC must be asked.

EUROVENT CERTIFICATION

Independent Laboratories

For each certification programme only one independent laboratory shall be preferably selected. The laboratory must be independent with no connection to any participant in the programme. Accreditation in accordance with the EN 45001 shall be requested. If for some certified characteristics this accreditation is missing, Eurovent staff shall organise the verification of technical competence of the concerned laboratory by a competent expert. An audit following the procedures given in ISO 17025 shall be performed.

The independent laboratory shall be regularly inspected by the technical staff of the Certification Company, following a schedule decided by the Compliance Committee.

If more than one laboratory is selected for a same type of products, the regular comparison testing shall be organised in order to assure that all laboratories provide similar results. The Compliance Committee may modify selection of laboratories if necessary.

List of Independent Laboratories involved in the performance testing:

TEST LABORATORY	CITY	COUNTRY
CEIS	Madrid	SPAIN
CETIAT	Lyon	FRANCE
DMT	Essen	GERMANY
HTA	Luzern	SWITZERLAND
IMQ	Amaro/Milano	ITALY
SP	Boras	SWEDEN
TUV	Essen/Munich	GERMANY
VTT	Espoo	FINLAND
WSPLab	Stuttgart	GERMANY

EUROVENT WORKING GROUPS ACTIVITIES ON ENERGY EFFICIENCY

WG 6B "Air Conditioners" [2]

The WG 6B "Air Conditioners" has been directly involved in the SAVE project EERAC concerning energy efficiency of room air conditioners. This project was finalised at the end of 1999. Using the data provided by manufacturers and available from Eurovent Directory of Certified Products, it has been observed that energy efficiency of air conditioners presented on the market varies widely: the best units have sometimes two times higher efficiency than the worst.

Two possible policies have been analysed in detail: energy labelling and minimum efficiency.

Energy Labelling as applied with success to many home appliances like domestic refrigerators was an obvious measure. However the labelling itself means only a clear information to buyers – it is expected that buyers will prefer better equipment and that in this way the global, average efficiency of the products sold on the market will increase. Labelling Directive for small Air Conditioners has been prepared by the European Commission and was published in April 2002. The WG 6B took a very active part examining drafts, proposing modifications and clarifications to the Labelling Directive.

Mandatory minimum efficiency has been introduced in many countries outside of Europe. This is the simplest way to eliminate low efficiency products from the market but it has a very important effect on the industry and must be applied carefully. In order to avoid such regulation the WG 6B has prepared a proposal on voluntary minimum efficiency to be supported by Eurovent certification. After many discussions the proposal received overwhelming approval from individual manufacturers and national associations.

The first practical action was applied on 1 January 2004 when air conditioners under 12 kW cooling capacity having the lowest classification (class G) were eliminated from the certification programme and, as the certify-all procedure must be applied, from the market. The effect of these measures can be seen on following table .Units with lowest efficiency (Class G) were eliminated and the minimum value is now 2.21. Manufacturers are presenting units with higher efficiency and the average energy efficiency of all air conditioners is increasing.

	EER (min)	EER (max)	EER (mean)	N0. of Units
2001	1.64	3.63	2.55	2597
2002	1.76	3.97	2.55	3251
2003	1.75	3.85	2.58	3078
2004	2.20	4.55	2.68	2081
2005	2.21	4.64	2.87	3502
2006	2.21	5.51	2.88	2396

The next step to eliminate classes F and E has been scheduled to be implemented in 2008. A proposal in connection with the Energy using Product Directive has been prepared by the WG6B in June 2005.

WG 6A "Chillers" [3]

The WG 6A "Chillers" has been examining the energy efficiency issues for liquid chilling packages – involved products cover capacity range from few kW to several MW. Several possible actions have been examined. In the certification programme, it was already decided that the energy efficiency (EER and COP) replace the power input as the certified characteristics. A voluntary classification system has been implemented although for such large equipment no physical labels will be fixed. However product classes will increase awareness of users that the energy efficiency is an important issue but also the manufacturers when they design new equipment. With a classification it may be easier to eliminate, like for air conditioners, the low efficiency products. The effect on the market has already been identified as some users simplify their request asking Class A products.

The use of chillers and the real annual energy consumption has been largely discussed. As the part load efficiency has a very strong impact on consumption, in the SAVE study EECCAC – (Energy Efficiency and Certification of Central Air Conditioners) - this issue has been treated exhaustively. This study was initiated by Eurovent/Cecomaf and manufacturers are actively participating. An integrated energy efficiency index called ESEER (European Seasonal Energy Efficiency Ratio) similar to IPLV (Integrated Part Load Value) developed in the USA and used by ARI, was established for the European conditions. The study was finalised in 2004 and experimental application started in 2005. Part load certification was implemented in the Eurovent certification in 2006.

From the certified part load table, Eurovent will compute ESEER allowing the comparison of chillers performances in the cooling mode. This global single figure shall be published in Eurovent directory together with cooling capacity and power input for standard conditions at full load. At present, the Energy Labelling Directive is restricted to household appliances. Indeed, the label is mandatory only for Room Air Conditioners with capacity equal to or lower than 12 kW. However, Eurovent WG6A established classification for full load Energy Efficiency Ratio of each type of chillers. The classification follows the A to G approach used in the European Energy Label for household appliances but the limits between classes have been defined for the existing chillers as listed in Eurovent directory, see Table1 for cooling mode.

EER Class A	Air Cooled EER≥3.1	Water cooled EER≥5.05	Remote condenser >=3,55
B	2,9≤ EER< 3,1	4,65≤ EER<5,05	3,4≤ EER<3,55
C	2,7≤ EER< 2,9	4,25≤ EER<4,65	3,25≤ EER<3,4
D	2,5≤ EER< 2,7	3,85≤ EER<4,25	3,1≤ EER<3,25
E	2,3≤ EER< 2,5	3,45≤ EER<3,85	2,95≤ EER<3,1
F	2,1≤ EER< 2,3	3,05≤ EER<3,45	2,8≤ EER<2,95
G	<2,1	<3,05	<2,8

Next steps will be the elimination of Class G chillers (poorly efficient) from Certification and reviewing the classification of chillers according to ESEER instead of EER.

WG 6C "Air Handling Units" [4]

The WG 6C "Air Handling Units" after finalising the Life Cycle Cost project has realised that the most important part of this cost is the energy consumption. Although other factors, like maintenance, are also very important, the best means to decrease the life cycle cost of an air handling units is to design and operate in the optimum way with respect to energy consumption.

A Eurovent Document 6/8 called "Recommendations for calculations of energy consumption for Air Handling Units" has been prepared. This document provides the detailed analysis of all components: fans, cooling and heating coils, heat recovery units. The document 6/8 was published in May 2005.

WG 4B "Air Filters"

The Eurovent WG 4 B "Air Filters " has found, during the work on Life Cycle Cost project, that energy consumption represents the largest part of the cost. Although the filters are passive elements and do not consume energy directly, the pressure drop they introduce in the flow is related to fan consumption. Selection of filters and their replacement should be made taking into account not only their primary purpose (cleaning the air) but also the possible energy saving. The relevant Eurovent Recommendation concerning calculation of Life cycle Cost of Air Filters was revised in 2004.

WG14 "Refrigerated Display Cabinets"

The WG 14 "Refrigerated Display Cabinets" has been working on annual energy consumption. The Group has been very much involved in the action undertaken by public authorities in the United Kingdom where Market Transformation Programme is aimed to increase the use of more efficient products. In order to implement the Eurovent Certification as the single data base for all Europe it will be necessary to highlight more efficient display cabinets. In addition, the users need to estimate the cost of annual energy. Conventional formulas have been presented, but more study will be necessary to achieve a valid method.

The energy efficiency appears now everywhere, for almost all products and under different aspects. In standardisation, the valid methods of testing have to be established. The certification will be more and more used not only to check the validity of claimed data but also to remove low efficiency products from the market.

The studies of Life Cycle Cost almost always shows that the energy consumption represent the highest part of this cost; even for passive elements like filters, a small decrease of pressure drop represents a huge economy of energy on the life cycle basis.

Eurovent/Cecomaf continues to show its commitment to energy efficiency improvement and tries to propose practical and easily verifiable measures.

Conclusion

Undeniably Eurovent Certification has greatly contributed in providing ground for fair competition and in delivering a framework for assuring to the users of HVACR products the cooling / heating performances to be expected from the products applied.
Equally the energy input at specified conditions could be certified.
Gradually in the last few years, when energy efficiency became a more hot topic in the general media in relation to global warming, the working groups within Eurovent took and still take important steps to distinguish further the more energy efficient products and determining minimum levels of energy efficiency, below which, products cannot be certified and thus cannot be listed in the Directory of Certified performance or the website of Eurovent Certification. Such orientation can only help the markets in applying more energy efficient products to the benefit of society as a whole and it's well being indoors.

Indoor environment, health and productivity

Productivity, Energy, and Economics in Modern Offices

Shin-ichi Tanabe, Masaoki Haneda and Naoe Nishihara

Waseda University, Japan

Corresponding email: tanabe@waseda.jp

SUMMARY

To promote the effort for energy conservation, it is also important to estimate the indoor environmental quality (IEQ) from the aspect of office worker's productivity. A conceptual diagram for the evaluation of the effect of IEQ on productivity was proposed. The results from subjective experiments of short term showed that human responses, such as fatigue, cerebral blood flow, sensation to the environment and SBS symptoms, were important for the evaluation of productivity. The results from a subjective experiment of long term exposure revealed the relationship that performance decreased with the increase in the level of fatigue. The results from another subjective experiment showed that the subjects performed well when they were satisfied with the IEQ. A survey in call-center showed the decline in performance in warmer environment. Economical and global environmental impacts from the modification of cooling temperature settings in office were also discussed.

INTRODUCTION

Productivity in general is defined as the quotient of Output over Input. The economic index for expressing the cost effectiveness of the improvement of IEQ can be proposed by dividing the benefits (Output) obtained through the improvement of IEQ by the cost factors (Input) for the improvement. Input-side cost factors, e.g. expenditure of the facility investment, are rather simple to estimate. Output-side benefits, on the other hand, were calculated by converting the quantified performance changes in terms of salaries [1], [2]. However, the output-side factors, e.g. the performance of the workers, are difficult to quantify in most cases, because the factors include intellectual activities, which can be influenced by psychological factors such as arousal level and motivation, as pointed out by McIntyre [3]. From the results of our laboratory experiments [4], [5], the effects of indoor environment were observed in human responses, such as fatigue, cerebral blood flow, sensation to the environment and SBS symptoms, even when there was no significant change in the performance. The performance would eventually decrease, in hypothesis, when workers were tired or dissatisfied with the environment.

A conceptual diagram for the evaluation of the effect of IEQ on productivity is proposed as shown in Figure 1. As indicated above, human responses are considered to be the intermediate factors affecting the performance of the workers by the indoor environment, and hence included in the conceptual diagram. In this paper, several evidences from subjective experiments and a field survey to explain the diagram. Also, an example of the evaluation of productivity was shown on the modification of cooling temperature settings in a typical office in Japan.

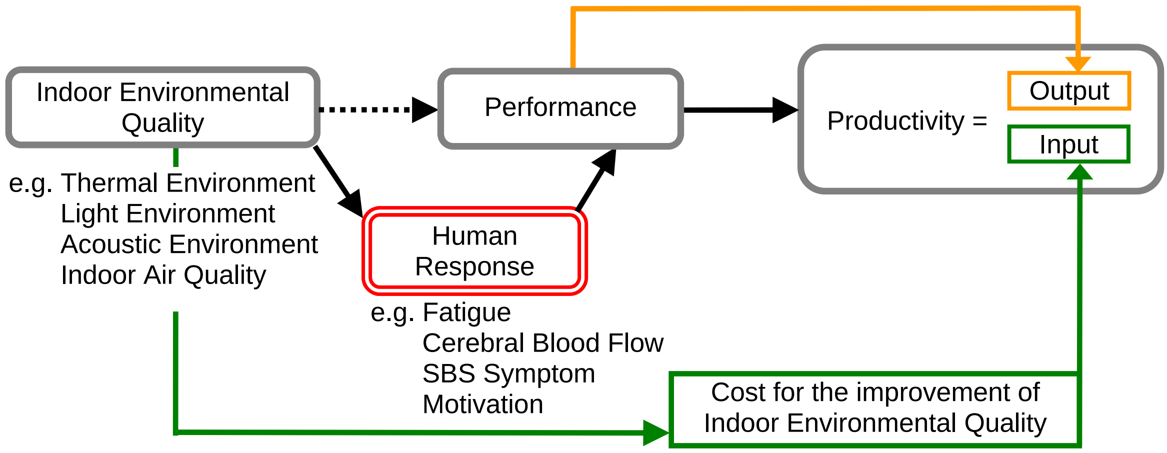

Figure 1. A conceptual diagram for the evaluation of the effect of indoor environmental quality on productivity

EFFECT OF HIGH TEMPERATURE ON TASK PERFORMANCE AND FATIGUE (SHORT EXPOSURE)

Method

To study the effect of moderately high temperature on task performance and fatigue, a subjective experiment was conducted in a climate chamber [6]. College-age subjects, 20 males and 20 females, participated in the experiment. The chamber was conditioned at operative temperatures of 25.5°C, 28.0°C, and 33.0°C with still air. Previous to these three conditions, a practice session at an operative temperature of 25.5°C was conducted. Relative humidity was controlled around 50%. Subjects wore a uniform with an insulation value of 0.76 clo. Task performance tests on computer were conducted for 1.5 hours.

The experimental procedure is shown in Figure 2. After entering the climate chamber, subjects waited in a sedentary position for 30 minutes, and then reported their first thermal sensation in the chamber and their feeling of fatigue. Four tests were carried out: the addition test for 10 minutes, the positioning test for 5 minutes, the text typing test for 5 minutes, and the Walter Reed Performance Assessment Battery test (PAB) [7] for about 15 minutes. After each test, an intermission of 5 minutes was taken and the subjects reported their thermal sensation, their feeling of fatigue, and their evaluation of the task load. Subjects filled in the sheets for evaluation of subjective symptoms of fatigue 30 minutes after entering the climate chamber as "before task" and after all computer tasks were finished, as "after task".

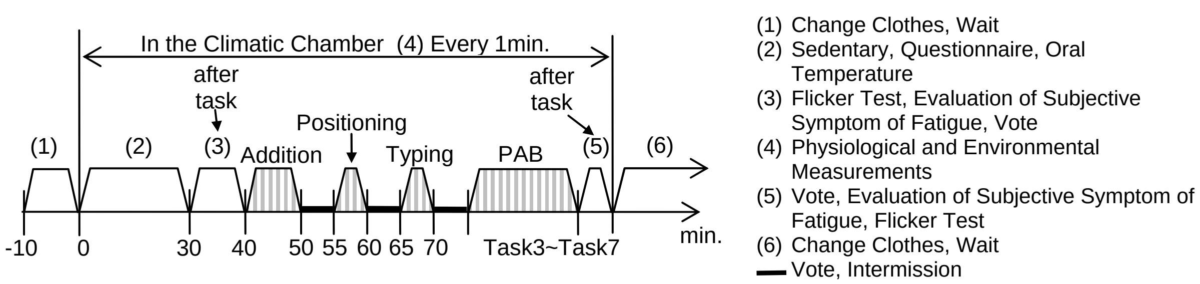

Figure 2. Experimental procedure

Task Performance

For female subjects, there was no significant difference in the performance of all computer tasks under the environmental conditions. For male subjects, there was no significant difference in the performance of the addition test and the positioning test under the environmental conditions. The performance of addition task is shown in Figure 3. In this study, the effects of thermal environment on task performance were contradictory among the task types as in previous findings [8], [9]. It is difficult to evaluate the effect of thermal environment on productivity by measuring only task performance.

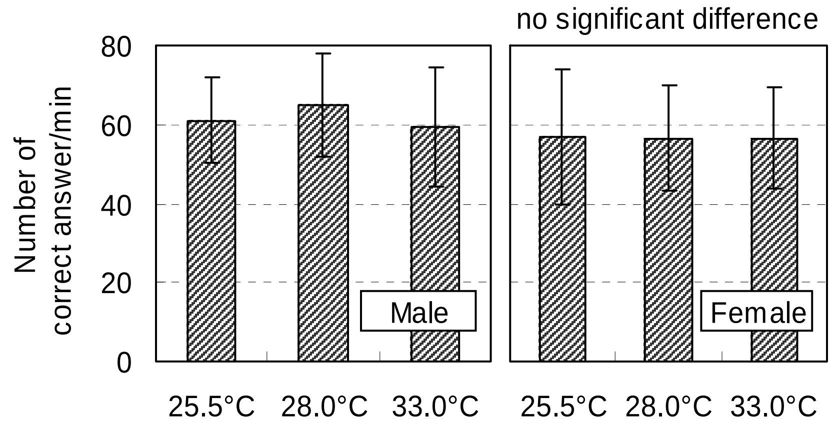

Figure 3. Performance of addition task

Evaluation of Subjective Symptoms of Fatigue and Cerebral Blood Flow

To evaluate the feeling of fatigue, subjects filled in the sheets of "Evaluation of Subjective Symptoms of Fatigue" [10]. It consists of three categories; I-group consists of 10 terms about "drowsiness and dullness", II-group consists of 10 terms about "difficulty in concentration", and III-group consists of 10 terms about "projection of physical disintegration". The subjects complained of a feeling of mental fatigue and complained the most just being in the room with operative temperature of 33.0°C.

Previous studies reported that increase of ΔO_2Hb and Δtotal Hb and decrease of ΔHHb were the typical findings by NIRS during the brain activation and mental work [11], [12]. In another experiment, it was showed that there was no significant difference in task performances between 26.0°C and 33.5°C conditions, but the increase of ΔtotalHb was higher at 33.5°C than that at 26.0°C [13]. Hot environments required more cerebral blood flow to maintain the same level of task performance.

EFFECT OF HIGH TEMPERATURE ON TASK PERFORMANCE AND FATIGUE (LONG EXPOSURE)

Method

To study the relationship between the task performance decrement and the work time, six hours of subjective experiment was conducted in a climatic chamber [14]. Fifteen college-age male subjects participated in this experiment. The conditions were set by the combination of operative temperature in the chamber and the amount of clothing insulations as: 25.0°C with 1.0 clo; 28.0°C with 1.0 clo; 28.0°C with 0.7 clo. Previous to these experimental conditions, a practice at 25.0°C with 1.0 clo condition was conducted.

The experimental procedure is shown in Figure 4. After entering the chamber, the subjects waited for 30 minutes in sedentary position, and then reported their first thermal sensation in the chamber and their feeling of fatigue. Subjects were then assigned nine sessions of addition tasks. In each session, the subjects worked for 30 minutes on the task and they reported thermal sensation, their feeling of fatigue, their evaluation of the task load in 5 minutes.

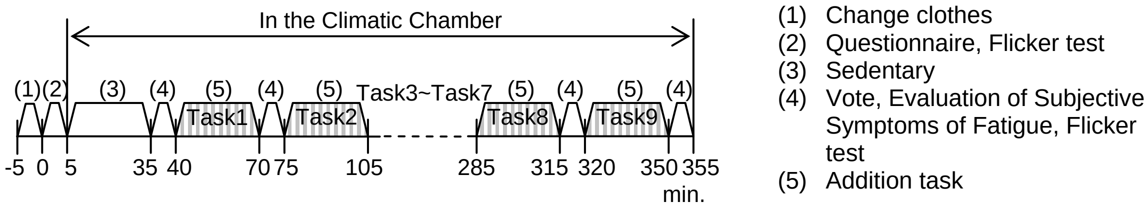

Figure 4. Experimental procedure

Task Performance

Figure 5 shows the result of normalized performance. The normalized performance did not changed significantly at 25.0°C with 1.0 clo condition over the time. However, the performance was significantly lower after sixth session (each $p<0.05$) at 28.0°C with 1.0 clo condition. Also, the performance was significantly lower after the third session (each $p<0.05$) at 28.0°C with 0.7 clo.

Fatigue and Performance

To determine the relationship between the level of fatigue and performance, the results of "Evaluation of Subjective Symptoms of Fatigue" were analyzed. Personal rates of complaints of fatigue, which were the general rates of complaints of fatigue for individual in each environmental condition excluding the results of practice session, were calculated. Figure 6 shows the correlation of personal rate of complaints of fatigue and normalized performance. It showed strong relationship that performance decreased with the increase in the level of fatigue. The correlation coefficient was -0.76. From the regression equation obtained from the results, increase in 10% of fatigue corresponds to the decrement in performance by 1.7%. The result showed the link from the fatigue of the occupants to the performance of them. It implies that evaluating fatigue is useful for estimating the effect of indoor environment on performance in offices and in experiments.

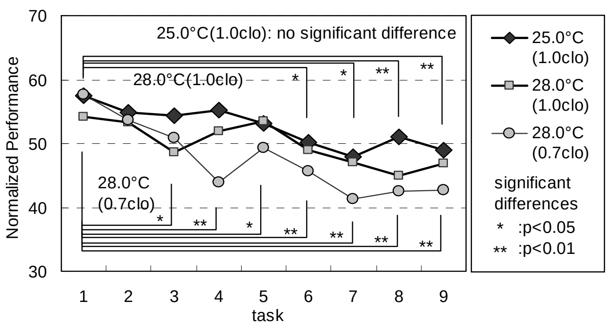

Figure 5. Result of normalized performance

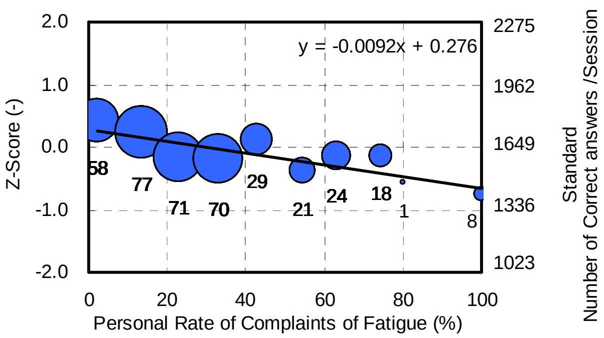

Figure 6. Correlation of the personal rate of complaints of fatigue and normalized performance

EFFECTS OF SATISFACTION WITH IEQ ON PERFORMANCE

Method

A subjective experiment was conducted in a climatic chamber to evaluate the effects of improvement of IEQ on occupant's performance [15]. The chamber was conditioned with the combination of: operative temperatures of 25°C or 28°C, illuminance of 750lx or 400lx and with or without traffic noise. Eight conditions were named as "Control(28°C, 400lx, with traffic noise)", "T(25°C, 400lx, with traffic noise)", "N(28°C, 400lx, without traffic noise)", "L(28°C, 750lx, with traffic noise)", "TN(25°C, 400lx, without traffic noise)", "TL(25°C, 750lx, with traffic noise)", "NL(28°C, 750lx, without traffic noise)" and "TNL(25°C, 750lx, without traffic noise)".

The experimental procedure is shown in Figure 7. Duration of the experiment lasted for 210 minutes. First, subjects entered the climatic chamber, and they voted satisfaction with indoor environment and fatigue on a PC screen. They rested in a sedentary position for 45 minutes to adopt themselves to the environment. Then, they performed thirty-minutes of multiplication task four times, and voted satisfaction with indoor environment and fatigue before and after the tasks. They were asked to answer predicted-performance-vote at the end of the day.

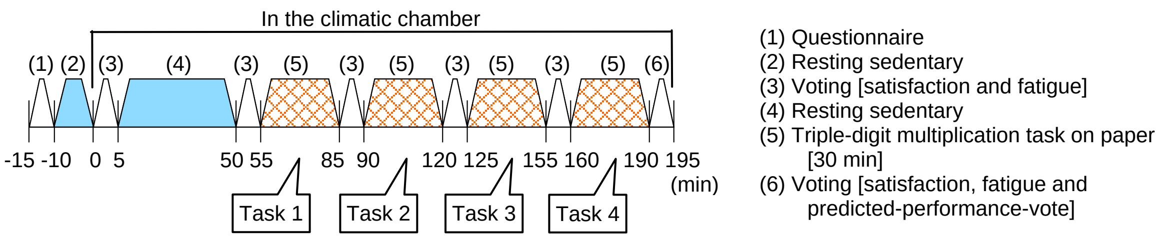

Figure 7. Experimental procedure

Relationship between Satisfaction with Indoor Environment and Performance

Subjects voted their satisfaction with indoor environment six times a day, before and after each session of resting and task. The results of the votes of satisfaction with indoor environment are shown in Figure 8. They were satisfied with environments of TN and TNL, and dissatisfied with those of all other conditions.

To evaluate how much satisfaction with indoor environment affects task performance, the relationship between satisfaction with indoor environment and the Z-score of multiplication task were examined. The data set of satisfaction with indoor environment by the interval of 0.2 was averaged and corresponding Z-score was also averaged. The relationships between satisfaction with indoor environment and the Z-score are shown in Figure 9. The Z-score was related to subjects' satisfaction with indoor environment (r=0.43). The results from the experiment showed that the subjects performed well when they were satisfied with the IEQ. To promote increase of productivity in the office, it is effective to build up the environment providing high occupants' satisfaction.

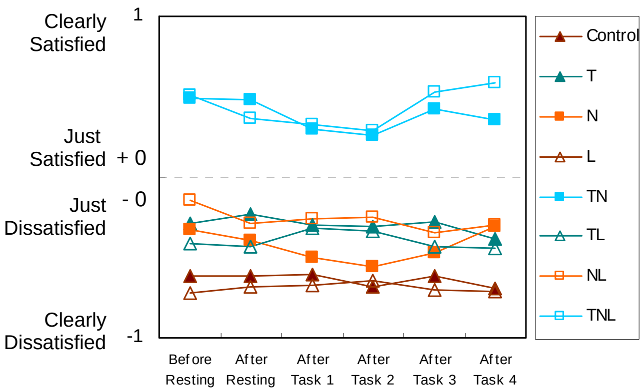

Figure 8. Satisfaction with Indoor Environment

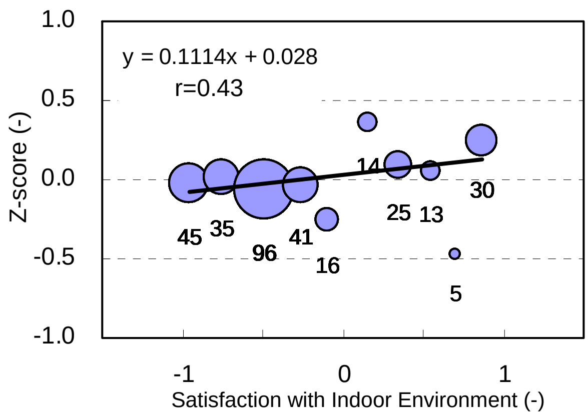

Figure 9. Relationship between Satisfaction with Indoor Environment and Performance

FIELD SURVEY IN CALL CENTER

Method

Data in a call center was collected for one year [16]. Indoor air temperature, humidity, lighting, and CO_2 concentration were monitored. Measurement was conducted from February 18, 2004 to February 1, 2005. Figure 10 shows the interior of call center. Call data of 13,169 were collected in total. This call center is performing guidance and consultation for customers, and technical support. Although the number of communicators changes with a day and time, total number of workers is about 70-120 persons/day in general. Business-hours of a call center are 8:45-19:00 from Monday to Saturday. Air-conditioning is operated from 8:00 to 20:00. Detailed research result is published by Kobayashi et al., see reference [16].

Call Response Rate

The relationship between indoor air temperature and the average call-response rate is shown in Figure 11. A linear regression model weighted by the number of relevant operators was obtained with the correlation coefficient of -0.69. Based on the regression model, the increase in air temperature by 1.0°C is relevant to the decrease in call response rate by 0.15calls/h. In particular, increasing indoor air temperature by 1.0°C from 25.0 to 26.0°C would result the decrement in call response rate from 7.79 to 7.64calls/h, which is 1.9% loss in performance. Seppänen et al. reported that 1.0°C of room air temperature rise is equivalent to decline in 2% of working performance [17]. The result of this research agreed quite well with the model of Seppänen. The average arrival telephone calls time per response number of cases, average receivable time, and the average desk work time were performed stable for whole period. Call-response rate was adopted as an index to evaluate the worker performance. For long period field study indoor air temperature has effects on workers' productivity.

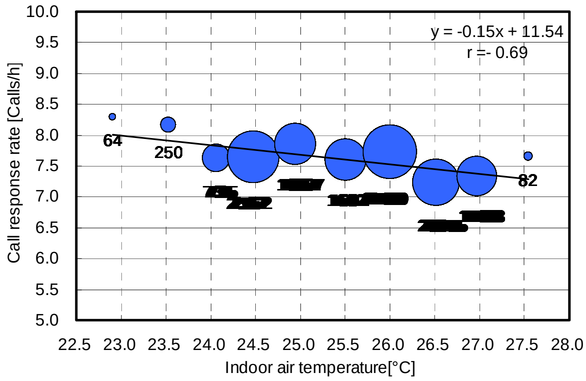

Figure 11. Relationship between indoor air temperature and the average response number of cases

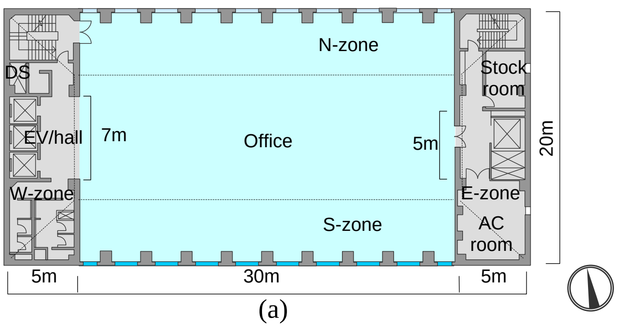
ECONOMICAL AND GLOBAL ENVIRONMENTAL IMPACTS FROM THE MODIFICATION OF COOLING TEMPERATURE SETTINGS IN OFFICE

The effects of the modification of the cooling temperature settings were evaluated and analyzed. The primary energy consumption of the typical office building in Japan, Building K, was calculated by the Building Energy Consumption Simulator (BECS), which is commonly used in Japan for the Energy-Saving Law. The conditions for the simulation are shown in Figure 12. The temperature settings of the air-conditioning system changed by the seasons as: spring and autumn at 24°C (April, May, October, and November); summer at 26°C (June to September); and winter at 22°C (December to March).



(a)

Building K	
Building use	Office
Place	Tokyo, Japan
Floors	BF1 to 11F
Total floor area	10,001.76m^2
Floor area for AC	6082.90m^2
Heat source	2 absorption chillers
Air-conditioning System	Office/Dining hall
	AC for each floor (CAV) and FCU
Office hour	9:00-18:00

(b)

Figure 12. Conditions for the energy consumption simulation. (a) typical floor plan for the Building K, and (b) description of the Building K

The cases studied were: the standard operation of the office buildings as Case-26°C; and the modification of cooling temperature settings during summer for two Centigrade, at 28°C, as Case-28°C. Same air-conditioning systems were assumed to be operated in both cases, and the simulations were conducted over a year. From the results, the primary energy consumption was 1180.5MJ/m^2/year for Case-26°C and was 1161.2MJ/m^2/year for Case-28°C. The difference between the two cases was only 19.3MJ/m^2/year (-1.64%), because chillers were not always operated at the rated point.

The effects of the modification of the cooling temperature settings were evaluated in terms of: (I) the benefit by the reduction in the running cost (yen/m^2/year), (II) the cost by the performance changes (yen/m^2/year), and (III) the reduction in the amount of emission of carbon dioxide (kg-CO_2/m^2/year). They were calculated with the following three equations

$$\text{(I)} = \Delta E_{AC} \times M_E, \quad (1)$$
$$\text{(II)} = k_{summer} \times M_p \div S_p \times \Delta P, \quad (2)$$
$$\text{(III)} = k_{CO2} \times \Delta E_{AC}, \quad (3)$$

where, ΔE_{AC} is the reduction in energy consumption (kWh/m^2/year), M_E is the price of energy (yen/kWh), k_{summer} is the number of months in summer to year (=4/12), M_p is the average salary ($\approx$4 million yen/person/year [18]), S_p is the space per person (=10m^2/person), ΔP is the change in performance (%), and k_{CO2} is the CO_2 emission rate for a thermal power plant (=0.378kg-CO_2/kWh). The building facility was assumed to be operated by electricity from a thermal power plant, whose conversion factors are 9MJ/kWh [19] and 11.08yen/kWh in Tokyo. The change in performance was cited from the result of the survey, 1.9%/°C.

The results of the cost analysis and the reduction in carbon dioxide emission when the cooling temperature settings were modified by 2°C in the Building K are shown in Table 1. The net profit by the modification was -5043 yen/m^2/year, while the reduction in CO_2 emission was 0.81kg-CO_2/m^2/year. It was suggested from the results that (I) the benefit by the reduction in the running cost and (III) the reduction of the CO_2 emission would be minimal compared to the possible cost generated by the performance decrement. The reduction in the emission of greenhouse gases is essential for the world wide concern of the global warming issue; however, it is also important to give considerations on productivity for the measures in offices.

Table 1. The results of the cost analysis and reduction in carbon dioxide emission by modifying the temperature settings by 2°C

(I) Reduction in running cost	(II) Cost by performance change	(III) Reduction in CO_2 emission	(I)-(II) net profit
23.8 yen/m^2/year	5067 yen/m^2/year	0.81kg-CO_2/m^2/year	-5043 yen/m^2/year

CONCLUSION

1) A conceptual diagram for the evaluation of the effect of indoor environmental quality on productivity was proposed.
2) The results from subjective experiments of short term showed that human responses, such as fatigue, cerebral blood flow, sensation to the environment and SBS symptoms, were important for the evaluation of productivity.
3) The results from a subjective experiment of long term exposure revealed the relationship that performance decreased with the increase in the level of fatigue.
4) The results from another subjective experiment showed that the subjects performed well when they were satisfied with the IEQ.
5) A survey in call-center showed the decline in performance in warmer environment.

6) From the simulation on the economical and global environmental impacts for the modification of cooling temperature settings in an office, it was suggested from the results that the benefit by the reduction in the running cost and the reduction of the CO_2 emission would be minimal compared to the possible cost generated by the performance decrement.

ACKNOWLEDGEMENT

This study was partially funded by the Project Research of Advanced Research Institute for Science and Engineering, Waseda University and by the Global Environment Research Fund (H-061) by the Ministry of Environment, Japan.

SUMMARY

The impact of simultaneous short-term exposure to three environmental parameters (temperature, noise and air quality) on human perception and performance was studied in two identical climate chambers. Eight conditions were created exposing the subjects for 20 minutes to combinations of two levels of operative temperature (23,5 ºC and 28,0 ºC), two noise levels (52 dB(A) and 60 dB(A)) and two pollution loads (pollution load absent, pollution load present). 56 participating subjects performed simulated office work (addition) and completed questionnaires concerning their perception of the environment and adverse symptoms in each combination of conditions. The subjects were informed of the conditions so they were able to make a conscious or unconscious choice to work more or less according to their perception of the conditions and their attitude to them. Despite the short time allocated for performance of the addition task a significant decrease in performance in warm noisy, warm polluted and warm noisy polluted conditions could be demonstrated. Subjects reported a highly significant reduction in the acceptability of the indoor environment, in self-reported performance and in their ability to concentrate in all deteriorated conditions, i.e. they tended to overestimate the negative effects of each factor. This was especially the case for noise.

INTRODUCTION

The impact of indoor climate parameters on human comfort, health and performance has been studied for decades. Most of this research has evaluated the influence of one environmental parameter at a time. Very little research has been performed on the effects of exposure to multiple indoor environmental parameters as they occur in real life. In real buildings, interventions to improve one factor may fail to achieve a positive effect when several other factors are causing discomfort or they may not achieve as large a positive effect as if more factors had been altered simultaneously. An intervention that reduces one negative factor may even increase the discomfort caused by other factors. A familiar example of this is when opening windows to refresh the air in the room causes increased discomfort due to the traffic noise that can be heard through the open windows. It is therefore essential to study not only the influence that each individual parameter has but also what interactions exists between them in terms of their effects on occupants, and what influence they have on each other.

Toftum [1] concluded in a literature review that there is only limited evidence for the existence of significant interactions between different aspects of the indoor environment. Only for the effect of air temperature and air humidity on perceived air quality are well-established relationships available. Fang et al. [2,3] showed that the acceptability of inhaled air decreased with both increasing air humidity and air temperature, whereas the odour intensity of the air was independent of its psychrometric properties. Furthermore, Fang et al. [4] showed that a decrease in outdoor air supply rate could be compensated for by decreasing indoor air enthalpy so as to avoid reducing perceived air quality. The effects of other combined factors were described by Clausen et al. [5], who determined the relative importance of sensory air pollution, thermal load and noise. Their study showed that a 1 ºC change in operative temperature had the same effect on comfort as a change of 2,4 decipol in the perceived air quality or a change of 3,9 dB in the noise level. Witterseh [6] investigated the impact of combinations of the same three parameters on environmental perception, SBS symptoms and the performance of office work. The combination of ventilation noise and emissions from carpet was found to cause significantly more self-reported fatigue and there was a tendency for a negative effect on performance. The interaction between noise and temperature was found to have a significant effect on the performance of office tasks and on self-estimated performance, ability to think clearly, ability to concentrate and fatigue. Banhidi at al. [7] studied the effect of combinations of two levels of temperature (20 and 30ºC), noise (60 and 70dB) and lighting (280 and 920lux) on performance and physiological measures. A significant effect was found for elevated noise level negatively affecting the performance of a game (Tetris, a falling blocks puzzle video game requiring high concentration and logical thinking) and interaction between lighting and temperature affecting the number of characters written. The influence of a combination of irrelevant speech and indoor lighting on performance was examined by Knez and Hygge [8]. No interactions between noise and light were shown but there were negative effects of presence of noise and cool-white light on long-term memory recall. Furthermore, unpleasantness increased over time in the silence condition and decreased when the subjects were exposed to irrelevant speech. Clausen and Wyon [9] further investigated the influence of 6 combined factors on the acceptability of the environment and on the performance of office work. One group of subjects performed simulated office work in a set of poor environmental conditions with overhead fluorescent lighting, recorded traffic noise, 27 ºC operative temperature, supply air polluted by emissions from linoleum, recorded open office noise, and almost no daylight. The realistic annual cost of improving each of the six conditions was estimated and expressed as a percentage of the total sum. A second group of subjects briefly experienced all poor and improved conditions and individually selected the improvements they preferred, up to a 50%-budget, while the members of a third group of subjects were randomly paired with each of these subjects. The fourth group was exposed to 100%-budget conditions. Significant improvements in subjective assessments of the environment occurred at high budget levels and when individual choice was provided, and the self-reported performance of office tasks improved, but no effects on performance could be shown.

The studies reviewed above showed that the acceptability of the indoor environment and human performance decreases with deteriorating conditions, although in some of them the decrement in performance was not always significant or as large as could have been expected. This might be due to the motivation of people to counteract the uncomfortable conditions and perform well in the experimental setting. However, in reality, if people are aware that their working conditions vary from day to day or during a day, it is conceivable that they will avoid working hard in poor conditions and choose to work better in more comfortable conditions.

The purpose of the present experiment was to study the impact of exposure to three environmental parameters (temperature, noise and air quality), occurring individually or at the same time, on the overall acceptability of the indoor environment and on office work performance, taking into account subjects' motivation to work. It is presumed that if the subjects are aware of the conditions they are about to encounter, and are aware that conditions will later improve or deteriorate, they will make a choice (consciously or unconsciously) to exert more or less effort in their work according to the conditions prevailing at the time.

METHODS

The experiment was carried out in two identical climatic chambers at the International Centre for Indoor Environment and Energy, DTU in June 2006. Both chambers were equipped with four workstations, each comprising a chair, desk and computer.

56 subjects participated in the experiment. The participants were recruited among students attending DTU. The average age of the group was 24 years and it consisted of 26 females and 30 males. The participants were paid for their participation.

Eight conditions were created and the subjects were exposed in groups of four to all combinations of two levels of operative temperature, two noise levels and two states of indoor air quality (Table 1.).

Table 1. Environmental parameters

Environmental parameter		Reference condition	Deteriorated condition
1	Operative temperature	23,5 ºC (PPD 5 %)	28,0 ºC (PPD 38 %)
2	Traffic noise	52 dB(A)	60 dB(A)
3	Air quality	Pollution load absent	Pollution load present 23 m^2 of old carpet

The eight experimental conditions are shown in the Table 2. The groups of subjects were exposed to these conditions in randomized balanced order.

Table 2. Combinations of exposures

Symbol	Pollution load	Operative temperature	Noise level
C1	Absent	23,5 ºC	52 dB(A)
C2	Absent	23,5 ºC	60 dB(A)
C3	Absent	28,0 ºC	52 dB(A)
C4	Absent	28,0 ºC	60 dB(A)
C5	Present	23,5 ºC	52 dB(A)
C6	Present	23,5 ºC	60 dB(A)
C7	Present	28,0 ºC	52 dB(A)
C8	Present	28,0 ºC	60 dB(A)

A recording of traffic noise was played inside the chambers using a CD player and one speaker in each chamber. In the reference condition of 52 dB(A) the traffic noise was barely audible as through a closed window; in the deteriorated condition of 60 dB(A) the traffic noise was clearly audible as if the window was open. An old carpet taken from an office was used as a source of pollution; 23 m^2 of carpet were used corresponding to the floor area of the chamber. The carpet was placed in a "pollution chamber", through which the supply air to one chamber was passed. The outdoor air supply rate was kept constant at a high level of 26 l/s per person to eliminate the effect of bioeffluents and other pollution sources than the old carpet. Prior to the experiments the subjects participated in a one-hour preliminary session. During the preliminary session 10 minutes were allowed for experiencing the environmental conditions and the subjects performed an olfactory ranking test [10] to ensure they had a normal sense of smell.

During the experiment the subjects were exposed to sequentially changing combinations of conditions while working on a computer. Only minor breaks disturbed the continuity of the subjects' work when they exited one combination of conditions and entered another. The subjects performed simulated office work (addition) for 15 minutes in each combination of conditions. In the last 5 minutes of each exposure they then completed a questionnaire concerning their perception of the environment, thermal comfort and adverse symptoms. The task and questionnaires were administered using the DTU software tool "Remote Performance Measurement" (RPM) [11]. At the end of the exposure period the experimenter signalled the subjects to exit the chamber. In this very short break the subjects were asked to state which of the environmental parameters they considered it would be the most important to improve if they were working in such an environment and which would be the second most important to improve. They then received a notice describing in informal terms the next conditions they were to work in and returned to work in one of the chambers where the respective conditions were set. This break served also as an exercise to keep the activity of subjects at approximately the same level as in a real office. The whole experimental session lasted for 3 hours.

The data obtained in the experiment and their residuals were analysed for normality using the Kolmogorov-Smirnov test. Paired t-tests and the Wilcoxon matched-pairs signed-rank test were then used for analyzing normally and not normally distributed data respectively. The results of a comparison analysis between the reference condition C1 (23,5 ºC; 52 dB(A); pollution load absent) and the seven deteriorated conditions and between the deteriorated conditions themselves are presented.

RESULTS

The results of an addition test, i.e. the number of completed additions per exposure, are presented in Figure 1. The difference from the result obtained in C1 was significant in conditions C4 and C7 at the level of significance $p<0{,}05$ and in the condition C8 at the level of significance $p<0{,}01$. No significant difference was found between conditions in terms of the percentage errors committed. Self-estimated performance showed a significant drop in all deteriorated conditions compared to C1 ($p<0{,}001$) (Figure 2).

Figure 1. Number of completed additions per exposure ± standard deviation

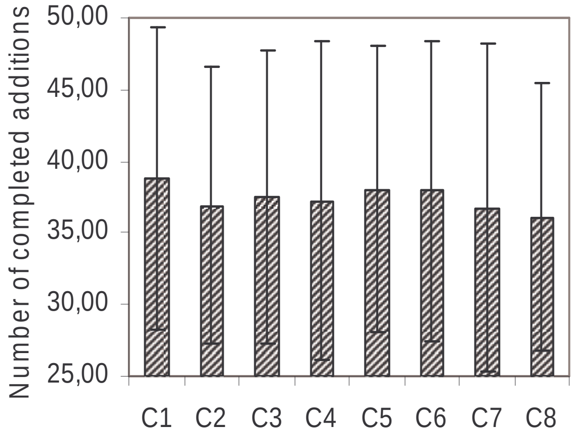

Figure 2. Self-estimated performance (%) ± standard deviation

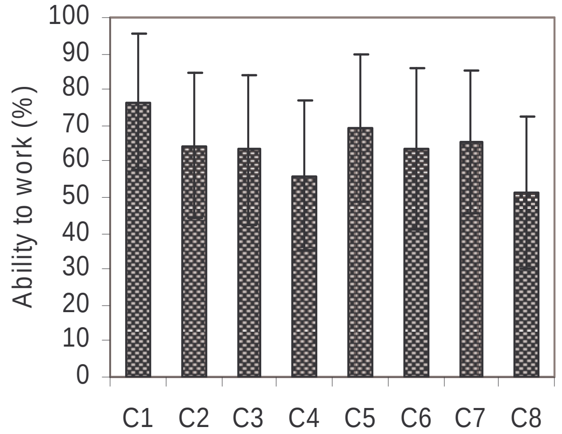
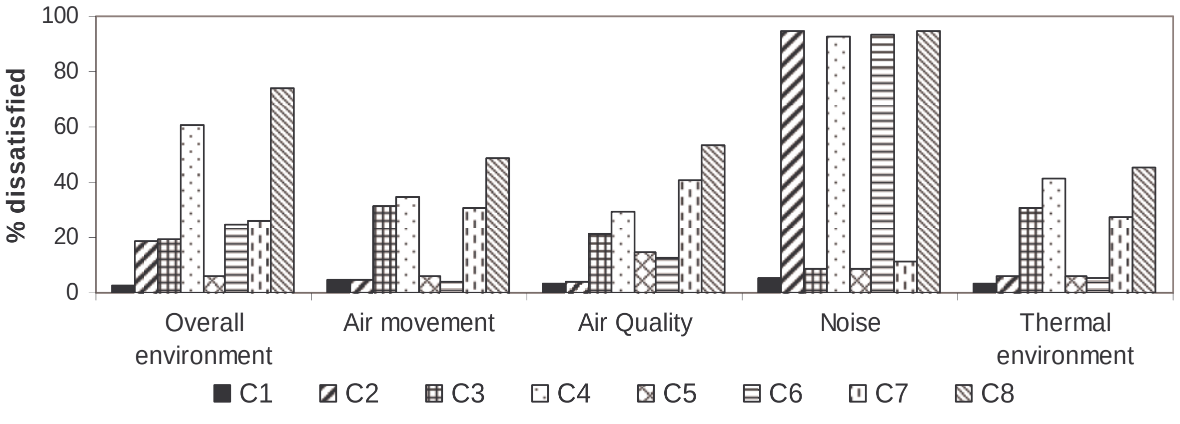


The mean acceptability votes are shown in Table 3 and the percentages dissatisfied with the overall environment, air movement, air quality, noise and thermal environment are presented in Figure 3.

Table 3. Acceptability of the environment and its factors

	Mean acceptability ± standard deviation							
	C1	**C2**	**C3**	**C4**	**C5**	**C6**	**C7**	**C8**
Overall indoor environment	0,64 ±0,30	0,25 ±0,36	0,24 ±0,40	-0,11 ±0,47	0,48 ±0,35	0,18 ±0,45	0,16 ±0,42	-0,24 ±0,50
Air movement	0,55 ±0,32	0,55 ±0,33	0,12 ±0,46	0,09 ±0,47	0,49 ±0,33	0,55 ±0,28	0,12 ±0,43	-0,02 ±0,44
Indoor air quality	0,61 ±0,31	0,56 ±0,33	0,21 ±0,41	0,13 ±0,45	0,30 ±0,43	0,33 ±0,45	0,04 ±0,46	-0,06 ±0,43
Noise	0,51 ±0,38	-0,57 ±0,38	0,41 ±0,42	-0,52 ±0,49	0,41 ±0,33	-0,54 ±0,40	0,36 ±0,43	-0,58 ±0,39
Thermal environment	0,61 ±0,30	0,49 ±0,39	0,12 ±0,42	0,03 ±0,41	0,48 ±0,39	0,51 ±0,34	0,15 ±0,45	0,00 ±0,45

Figure 3. Percentage of dissatisfied with the environment and its factors



The acceptability of the overall environment was significantly lower in all deteriorated conditions compared to the reference condition C1 ($p<0,001$; except C5 where $p<0,01$). However, when the deteriorated conditions that differ only in pollution load were compared between each other (i.e. C2 against C6, C3 against C7, C4 against C8), the analysis did not show a significant difference in acceptability. A major drop in acceptability can be observed in the two conditions exposing subjects to both elevated operative temperature and elevated noise level (i.e. C4 and C8).

The air movement was significantly less acceptable in the conditions with elevated temperature C3, C4, C7 and C8 ($p<0,001$) than in the reference condition C1.

The air quality was significantly less acceptable in all deteriorated conditions compared to C1 ($p<0,001$), except C2. The acceptability of air quality decreased significantly when the pollution load was present in conditions C5, C6, C7 and C8 but also in the conditions where the pollution load was absent but the temperature was elevated (C3 and C4). In the condition with pollution load present and low temperature (C5), 15% occupants were dissatisfied with the air quality. Elevating the temperature only (C3) had an even greater impact on the acceptability of the air quality, with 21% dissatisfied; however the difference between the acceptability of the air quality in C3 and in C5 is not significant. As many as 41% were dissatisfied with the air quality in the combination of elevated temperature and presence of pollution load (C7). The effect of the combination was significant comparing to both the effect of elevated temperature only in C3 ($p<0,05$) and to the effect of pollution load only in C5 ($p<0,01$). The addition of an elevated noise level had a significant effect on the acceptability of air quality only when noise was added to both elevated temperature and pollution load ($p=0,04$) (C7 compared against C8).

The conditions with elevated noise level caused the acceptability of noise in the environment to decrease ($p<0,001$). Similarly, the acceptability of thermal environment was significantly lower in the conditions with elevated temperature ($p<0,001$) than in the reference condition C1.

The ability to concentrate was negatively affected in all deteriorated conditions ($p<0,001$; except C5 where $p=0,01$). The subjects felt worse (subjective feeling marked on a continuous scale from feeling bad to feeling good) in all deteriorated conditions ($p<0,001$; except C5 where $p=0,02$).

The subjective importance of the three deteriorated conditions is summarised in Table 4. The results shown were obtained after the last exposure when the subjects had already experienced all possible combinations of conditions and were making the final decision on the relative importance of the three factors.

Table 4. Ranking of the deteriorated conditions by subjects after the last exposure

Condition	**Chosen by subjects (%) to be**	
	The most important to improve	**The second most important to improve**
Elevated noise level	42	40
High temperature	36	35
Deteriorated air quality	22	25

DISCUSSION

Despite the very short time allocated for performance of the addition test in each condition, it was possible to demonstrate a deterioration in the subjects' performance in conditions C4, C7 and C8 compared to the reference condition C1. It seems likely that in longer exposures the effect on performance would be larger.

The highly significant differences in the acceptability of the indoor environment and its component factors may have been due to the experiment not being blinded. This was the expected bias. The subjective overall ranking of the three deteriorated conditions are supported by the acceptability ratings: the air quality seemed the least important to subjects when they were asked directly and the addition of air pollution did not cause a significant drop in the acceptability of the overall environment. The assignment of lower importance to air quality may also have been due to the subjects completing the questionnaires at the end of each exposure when they were fully adapted to the air quality in the climate chamber.

The air movement was considered significantly less acceptable in the conditions with elevated temperature, compared to the reference condition. The subjects were not asked whether they would prefer more or less air movement but it is likely that they would have preferred more air movement to provide some cooling in the warm conditions.

The results on acceptability of air quality show a decrease in acceptability when the pollution load was present or the temperature was elevated. These results are in agreement with the findings of Fang [2,3] on how perceived air quality is affected by raised temperature. The results indicate that moderately raised air temperature may have even greater influence on acceptability of the air quality than the pollution caused by an old carpet.

The subjects' choice of the noise level being the most important to improve and the air quality the least important accords with the results of the experiment conducted by Clausen and Wyon [9]. However, subjects still differed as to which of the three conditions it was the most essential to improve.

The most important implications of these results for practice are that: 1) Although self-estimated performance predicted environmental effects on actual performance quite well, it exaggerated the magnitude of the effect (33% in the most negative condition instead of 7%); 2) Warm air had almost the same negative effects as polluted air on SBS and on environmental perceptions, providing support for the widespread practice of lowering the temperature in offices to improve perceived air quality; and 3) Although noise had a large and consistent negative effect on the perceived ability to concentrate, clearly more than that of any other factor, it had virtually no other effect of any kind, i.e. subjects tended to over-estimate the importance of noise, so more selected it as the most important to change, even though it was not the most important.

CONCLUSIONS

- The addition test was performed significantly less well in the warm noisy condition, the warm polluted condition and the warm noisy polluted condition.

- Self-estimated performance and the overall acceptability of the environment were both significantly worse than in the reference condition when any negative factor was present.
- Poor air quality had less of an effect than elevated temperature or noise on the overall acceptability of the environment.

ACKNOWLEDGEMENTS

This work has been supported by the Danish Technical Research Council (STVF) as part of the research program of the International Centre for Indoor Environment and Energy established at the Danish Technical University for the period 1998-2007.

SUMMARY

The impact of the work motivation on the occupants' work performance of serial one-figure addition task and proofreading task was studied in two types of experiments, i.e., type A of cool condition (22 deg C) and type B of neutral condition (25 deg C). During the occupancy of 120 minutes under each condition, the subjects performed the above tasks with financially motivated situation and without motivated situation. The subjects also answered the questionnaire, which asked the indoor environmental quality and sick building syndrome symptoms during the conditions. It was found that there was significant difference in the performance of theses two tasks between the motivated situation and no-motivated situation. The shape of the performance curve for type A during no-motivated situation was similar to that during motivated situation. The performance of addition task was well correlated with the thermal acceptability vote during motivated situation. On the other hand, the good correlation was not found between the performance and thermal acceptability during no-motivated situation.

INTRODUCTION

Many researches in various research fields, such as occupational hygiene, ergonomics, psychology, architecture and so forth, have investigated the effects of indoor environmental factors on productivity since Vernon's research. He investigated the monthly output of five plating factories with monthly outside temperature and concluded that an output fallen along with the rise of temperature [1]. In the early stage of the psychological research on workplace, the effect of an environmental stimulus was considered to be uniform to everybody. Sundstrom *et al* mentioned that the relation between people and environment was mechanistic and deterministic [2]. They explain that, in theory, a person's response to the environment may involve several processes, which in turn will affect his/her performance. The main processes are, arousal, stress, distraction, overload, fatigue and adaptation. Sundstrom reports that mental tasks have generally been unaffected by heat whereas motor tasks have suffered in heat. As a result of the experiments the effect of various illuminance levels on the productivity of assembly workers was studied in Hawthorne Works, it was found that even decreasing the illuminance level increased worker productivity. It was thought that increased motivation could lead to increased productivity; this is commonly referred to as the Hawthorne effect [3].

In the work performance studies in Japan, the serial one-figure addition task has been used as an index of the productivity from prewar days. Since this task was developed as "Uchida-Kräpelin mental work test" in psychology, the performance curve of the one-figure addition task could be used to investigate a person's aspect of mental process [4]. Many researches on productivity studies in built environment use total amount of calculation of the addition task

within given time as an index of performance. However we use the performance curve as an index of his/her mental aspect [5].
The purpose of this study was to investigate the impact of the work motivation on the occupants' work performance of serial one-figure addition task and proofreading task in two conditions, i.e., type A under cool condition (22 deg C) and type B under neutral condition (25 deg C). During the occupancy of 120 minutes under each condition, the subjects performed the above tasks with financially motivated situation and without motivated situation. The difference between the performance conducted during motivated situation and that during no-motivated situation could be discussed.

METHODS

Experimental condition

The experiments were conducted in the test room shown in Figure 1. The room with two windows facing south had a floor area of 32m^2 and a volume of 96 m^3 (L×W×H=8×4×3). Two different thermal conditions were set up in the room as listed in Table 1: 1) type A, room temperature 22 deg C, 2) type B, 25 deg C. The air temperature was controlled by the air conditioner equipped in this room.

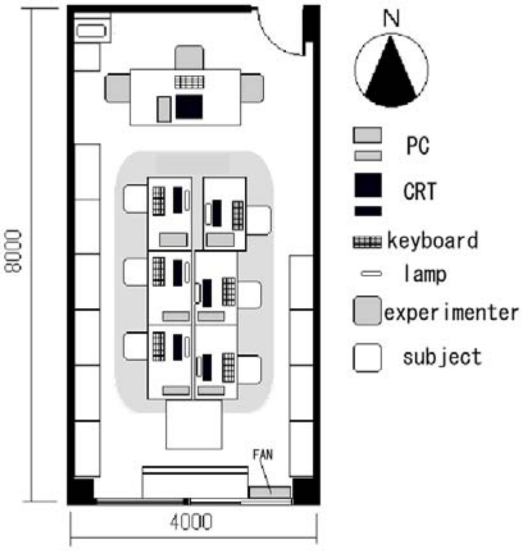

Figure 1 Experimental Room

Table 1 Experimental type

type	Room temperature	Relative humidity
A	22 deg C	40～
B	25 deg C	

Subjects sat at six workstations, each consisting of a table, a chair, a desk lamp and a personal computer (PC). Thirty female subjects participating in the present experiments were all students. The subjects were paid a salary for participating in the experiment at a fixed rate. To increase their motivation during the motivated situation, they were also paid a bonus of up to 15% of the total salary, depending on their performance.

Experimental procedure

The experimental procedure is presented in Figure 2 (upper). The experiment was carried out for 7.5h from 9:00 to 16:30. Figure 2 (lower) shows in detail the schedule. From 9:30 to 11:00 subjects took the training for the tasks, i.e., serial one-figure addition and proof reading, used in the following experiments. After 30 minutes break, subjects participated the experiment of type A or type B (random order) for 120 minutes (11:30 – 13:30). Then subjects participated the experiments of type A or type B for 120minutes (14:20 – 16:20). For each experiment, subjects entered the room and approached their workstations. Once seated, they assessed perceived air quality, general perceptions of the environment, SBS symptoms and thermal comfort. These evaluations were made several more times during exposure in the experiment.
The questionnaire for the indoor air condition is listed in Table 2 and for self-condition and SBS symptoms in Table 3. While exposed to the conditions in the room, subjects performed tasks. In 1st session, they performed serial one-figure addition task for 10 min. and proofreading task for 10 min. under no-motivated situation. After the no-motivated situation, they performed serial one-figure addition task for 10 min. and proofreading task for 10 min. under motivated situation. In 2nd session, the above tasks were repeated.

RESULTS

The measured levels of the general parameters describing the indoor climate inside the room are shown in Table 4. The average air-change rate of the room measured by tracer gas decay method was 0.8 h^{-1}.

Table 4 Measured room temperature and relative humidity

	Type A	Type B	Outdoor
Room temperature (deg C)	22.0±0.9	25.3±0.8	13.8±1.6
Relative humidity (%)	46±5	39±4	58±15

(average±SD)

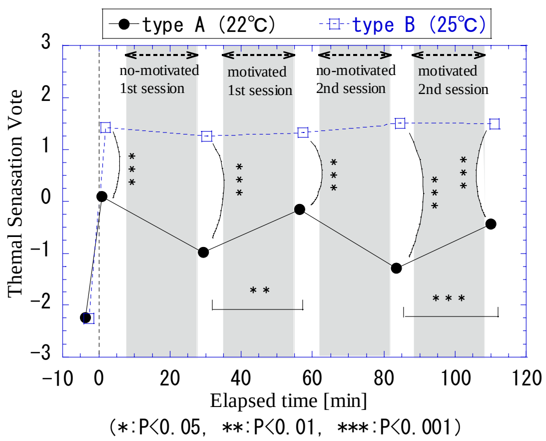

Figure 3 Thermal Sensation Vote as a function of time

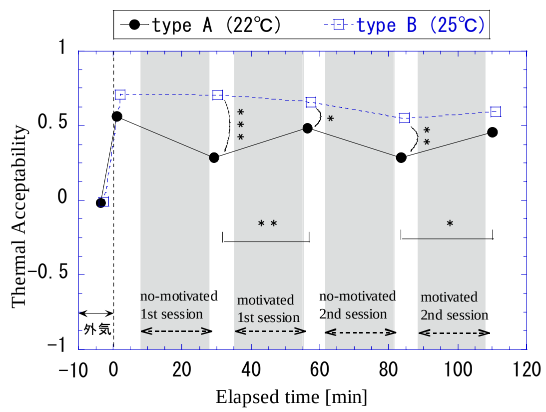

Figure 4 Thermal acceptability as a function of time

The average Thermal Sensation Vote (TSV) voted by subjects during no-motivated situation and motivated situation for type A was –0.7 and that for type B was 1.4. The average TSV value as a function time was presented in Figure 3. For type A, the average TSV values voted just after motivated situation was significantly higher (warmer) than those just after no-motivated situation. However there was no impact of the motivation on the TSV for type B.

Figure 4 shows the average thermal acceptability vote as a function of time. Since the experiments were conducted in autumn, subjects preferred the warmer condition of type B.
The average amount of calculation in one-figure addition task as a function of time is shown in Figure 5. There was no significant difference in the amount of calculation between type A and type B. On the other hand, the amount of calculation during motivated situation was significantly more than that during no-motivated situation both in type A and type B (P<0.01).

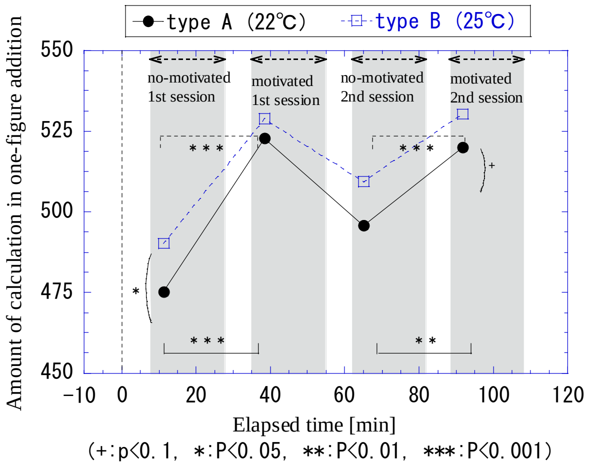

Figure 5 Average amount of calculation in one-figure addition task as a function of time

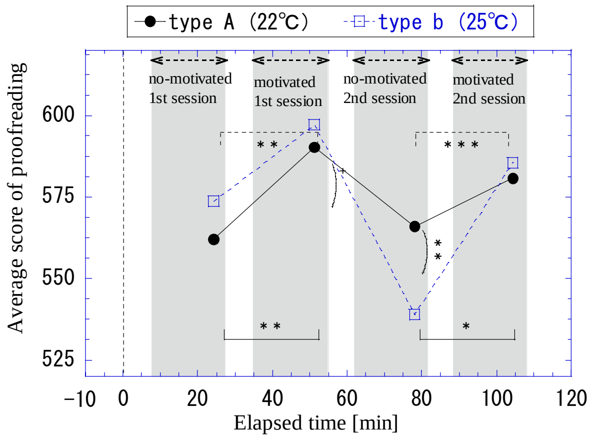

Figure 6 Average score of proofreading task as a function of time

The average score of proofreading task as a function of time is presented in Figure 6. Comparing the score of proofreading in type A with that in type B, the score in type A was significantly less than that in type B only during no-motivated situation in 2nd session. In terms of the motivation, it was found that the score during motivated situation was significantly more than that during no-motivated situation both in type A and type B as same as the result of one-figure addition task.

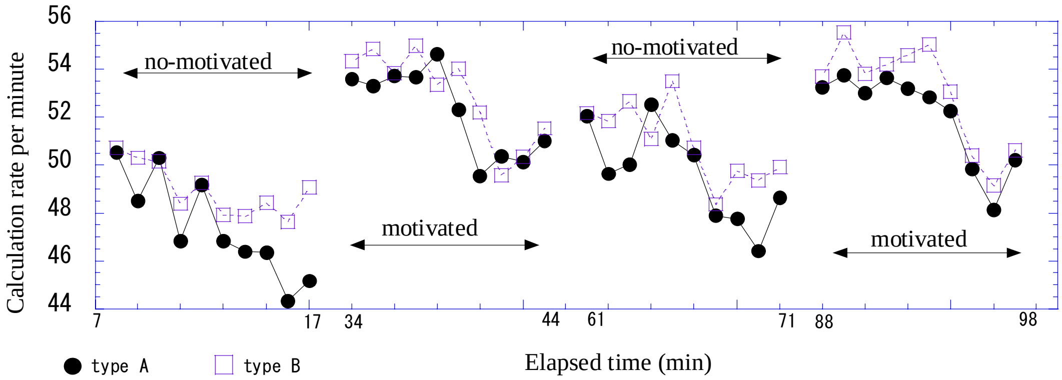

Figure 7 Average calculation rate per one minute as a function of time of one-figure addition task (ten minutes each)

In “Uchida-Kräpelin mental work test”, the performance curve of the one-figure addition task has been used to investigate a person’s aspect of mental process in psychology. Also for productivity study in the built environment, this performance curve was used to guess the mental process of subjects who were conducting tasks [5]. The average calculation rate per one minute as a function of time of one-figure addition task (ten minutes each) is shown in Fig.7. This figure shows that the calculation rate change curve (performance curve) had time decay trend. For each task, the calculation rate in the latter 4 minutes was much lower than

that in the first 6 minutes during no-motivated situation for type A. During motivated situation in 2nd session, the calculation rate in the first 6 minutes for type B was higher than that in the first 6 minutes for type A.
Therefore the calculation rates in the first 6 minutes and that in the latter 4 minutes for each experimental type were determined from the performance curve in Figure 7. The calculation rates during no-motivated situation were drawn in Figure 8 and those during motivated situation in Figure 9. The calculation rate in the latter 4 minutes for type B was significantly more than that for type A during no-motivated situation both in 1st session and 2nd session (Figure 8). On the other hand, the calculation rate in the first 6 minutes for type B was significantly more than that for type A during motivated situation in 2nd session (Figure 9).

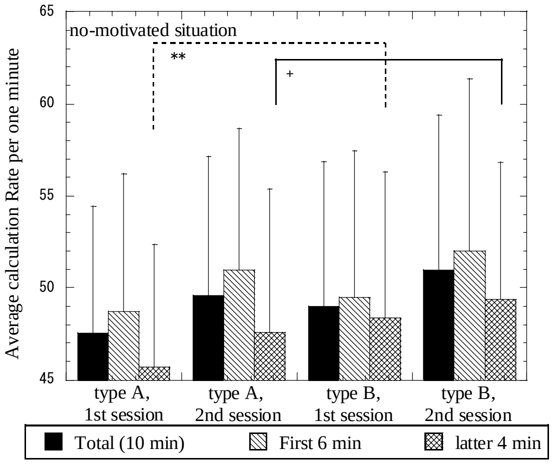

Figure 8 Average calculation rate for each session during no-motivated situation

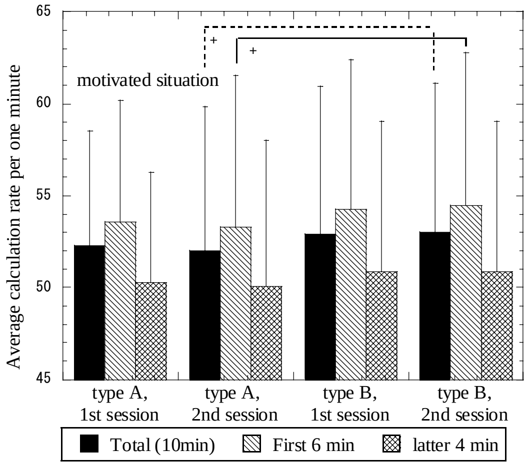

Figure 9 Average calculation rate for each session during motivated situation

DISCUSSION

While there was no large difference in performance curve between type A and type B during motivated situation, large difference was seen in calculation rate in the latter 4 minutes between type A and type B during no-motivated situation (Figure 7). The time decay trend was found in the performance curve for type A more remarkably than type B during no-motivated situation. The above time decay trend might be used for the index of arousal since this trend was seen during motivated situation. Figure 10 shows the relation between the average thermal acceptability and calculation rate in the first 6 minutes and that between the average thermal acceptability and calculation rate in the latter 4 minutes.
It was found that there was higher correlation between the calculation rate and the thermal acceptability during motivated situation than that during no-motivated situation. During motivated situation, arousal level of the subject could have been high because of the chance of bonus. Therefore lower arousal stimulus by indoor environment might have been needed during motivated situation. During no-motivated situation, arousal level of the subjects could have been low because of no chance of bonus. In this case, the subject performed more task in the cooler environment of the higher arousal stimulus even the thermal acceptability was low. In this study the thermal environment had no significant effect on the work performance during motivated situation. However there was effect of thermal environment by arousal on the work performance during no-motivated situation.

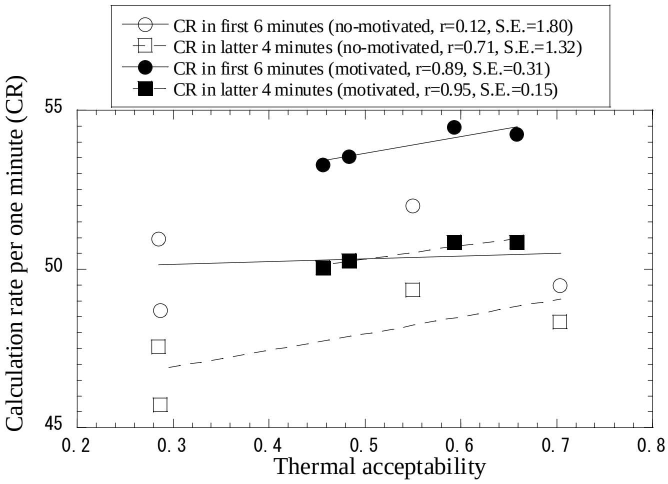

Figure 10 Relation between the average thermal acceptability and calculation rate in the first 6 minutes and that between the average thermal acceptability and calculation rate in the latter 4 minutes.

CONCLUSIONS

1) Thermal acceptability voted by subjects for type B (25 deg C) was significantly higher than that for type A (22 deg C) during no-motivated situation.
2) There was no significant difference in work performance (i.e., amount of calculation in one-figure addition task and average score of proofreading task) between type A and type B. For each experimental type, work performance during motivated situation was significantly better than that during no-motivated situation.
3) Performance curve, which presents the time change of calculation rate in one-figure addition task, showed time decay trend. During motivated situation, the calculation rate in the latter 4 minutes was much lower than that in the first 6 minutes. This time decay might be an index of the arousal. During no-motivated situation, the time decay trend was remarkable for type A.
4) It was found that there was higher correlation between calculation rate and the thermal acceptability during motivated situation than that during no-motivated situation. During motivated situation, arousal level of the subject could have been high because of the chance of bonus. Therefore lower arousal stimulus by indoor environment might have been needed during motivated situation. During no-motivated situation, arousal level of the subjects could have been low because of no chance of bonus. In this case, the subject performed more task in the cooler environment of the higher arousal stimulus even the thermal acceptability was low.
5) In this study the thermal environment had no significant effect on the work performance during motivated situation. However there was effect of thermal environment by arousal on that during no-motivated situation.

SUMMARY

This paper presents the development of distribution models of office employee's thermal sensation and an introduction to a methodology how to integrate the fact that humans perceive temperature differently with the effects of temperature on mental performance. Two different distribution models have been developed; one for occupants in mechanically ventilated buildings and one for occupants in naturally ventilated buildings. The results show that there is a significantly difference ($P<0.05$) in how people assess the indoor thermal environment depending on ventilation principle. Thus when calculating the effects of temperature on occupants' mental performance it is important not only to take the individual differences into consideration between humans, but also building ventilation principle.

INTRODUCTION

Effects on employee performance of different indoor climate parameters have received considerable attention during recent years [1, 2, 3, 4]. Several studies have shown an increase in mental performance from 5-10% (in some cases up to 20%) when improving the indoor climate e.g. by increasing the air change rate, provide better temperature control or use better filtration [1, 5, 6, 7]. Based on substantial numbers of field and laboratory studies, Seppänen et al. [2, 3, 8] have suggested models to describe relationships between performance and different indoor climate parameters. Design tools for evaluating the economical implications of investments in indoor environmental quality, which take into account employee productivity, may provide strong arguments to companies to invest in improved indoor environment. Such tools need appropriate relation between indoor environment factors and performance to be functional and convincing.

Development of relationships between indoor climate parameters and mental performance (e.g. an indoor air temperature of 30 °C reduce performance of office workers with 10%) is the first element of a model that can be used for estimating the potential economical gains of an investment in better indoor environment. Two other elements should be included in order to make the model stronger and more precise:

1. Hourly data of the indoor environment
2. Distribution models of the employees in a given environment

Since the indoor climate is normally dynamic (variation over day and season) calculation on an hourly basis during a year may be used as a more representative input to estimate the effects on mental performance of the indoor climate. These hour by hour values of the indoor climate can typically be obtained using computer simulation. Many different building simulation tools to evaluate the indoor climate exit on the market. Using the output from such tools in a performance calculation program, enables easy comparison of different building designs and their effects on performance.

Even when exposed to a uniform indoor environment (e.g. in well controlled climate chambers) humans perceive the indoor environment differently e.g. [9]. It is thus likely that occupant performance will be affected differently in different individuals, e.g. as a consequence of individuals having a different thermal sensation even though their exposed to only one (uniform) temperature.

Using distribution models of the employees' perception of the indoor environment allows differences between individuals to be taken into account. People do not sense the indoor climate the same way, some find it draughty, too cold, and too stuffy while others find the same conditions comfortable. Knowledge of the distribution of sensation of different indoor climate parameters may be a step to better assess indoor climate effects on performance.

Temperature is one of the most investigated parameters and it is one of the indoor climate parameters that cause most complaints [10]. Figure 1 shows schematically, the different steps of the methodology on how to evaluate effects on mental performance of temperature. Step 1, first the air temperature needs to be calculated on an hourly basis using building simulation tools. Step 2, air temperature is used with other factors (clothing insulation, relative humidity, air velocity, ventilation system etc.) to evaluate mean thermal sensation distribution of the employees. Step 3, the corresponding perceived temperature for each level of thermal sensation in the distribution is calculated. Step 4, mental performance decrement can be calculated on an hourly basis during a year.

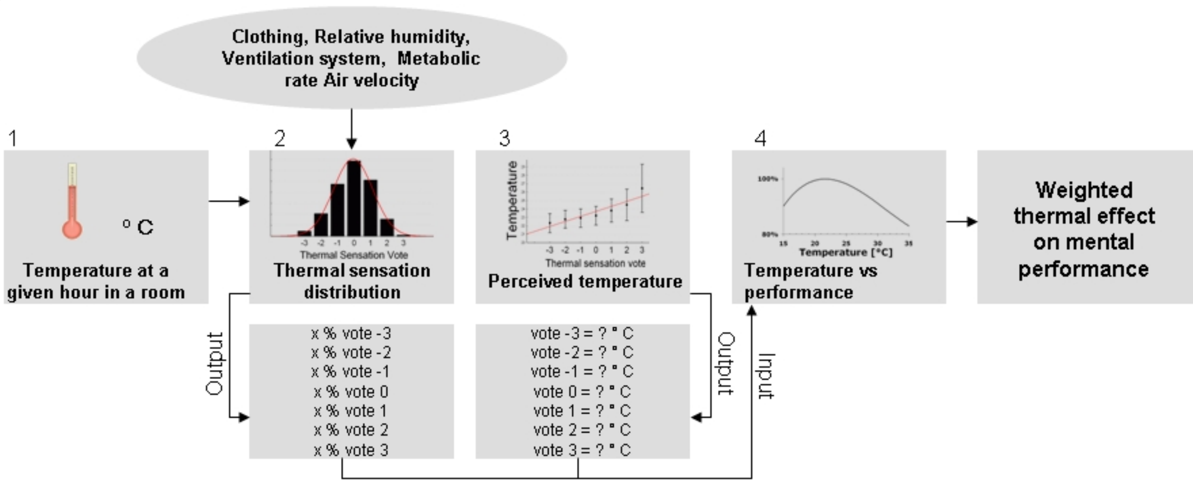

Figure 1. Methodology of calculating mental performance loss due to the effects of air temperature

In this paper distributions of thermal sensation votes will be used to assess the resulting distribution of perceive temperature and the corresponding weighting factors. The distribution will be based on data from ASHRAE RP-884 Adaptive Model Project [11]. The database contains corresponding set of indoor climate measurements and thermal sensation votes from thousands of office employees around the world, occupying hundreds of mechanically and naturally ventilated buildings. The distribution will be based on responses from building occupants, rather than subjects in laboratories, to reflect better the non-uniform condition that occur in buildings in practice. This distribution will be used as input to model effects mental performance effects of the thermal environment during a full year.

METHODS

Taking into consideration that individuals respond differently, even when exposed to the same environment, it is likely that at 22 °C some occupants will feel warm or neutral while others may feel cool or cold. Fanger [9] observed a distribution of thermal responses from sensation votes under different air temperatures. This distribution was based on votes cast by human subjects during exposure to uniform conditions in laboratory environments. During the exposure, subjects were asked to vote on the 7-point ASHRAE scale ranging from Cold to Hot (see Figure 2).

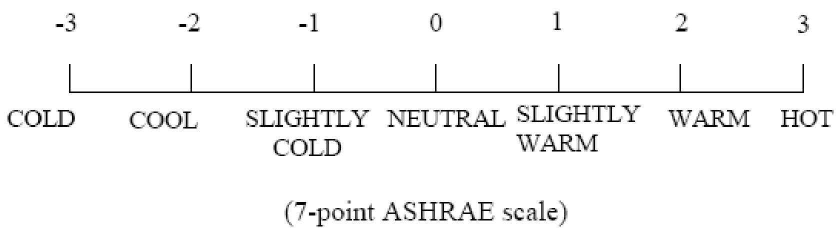

Figure 2. ASHRAE 7-point Thermal Comfort scale

Instead of using climate chamber data we choose to investigate data from field studies. These studies used the scale in Figure 2, but in real office environments. Table 1 shows an overview of the data used in this paper. Data has been divided into two main categories: Mechanically ventilated and naturally ventilated (NV) buildings.

Table 1. Overview of investigated data

Ventilation system	**Number of subjects**	**Buildings**
Mechanical	8119	100
Natural	4679	24
Total	12798	124

The data consists of information from over 12700 occupants in 124 different buildings. Subjective assessments of the thermal conditions and physical indoor climate parameters (e.g. air temperature, air velocity, relative humidity) have been monitored. The buildings were primarily office buildings. Only data with occupant activity levels below 1.3 Met and clothing insulation values below 1.1 clo was included. The data from ASHRAE RP-884 Adaptive Model Project was classified in three broad classes: Class I, Class II and Class III. Class III field studies were based on simple measurements of temperature and simple questionnaires, and these data where excluded from the present investigation. Only data from investigations which were classified as Class I or Class II was included in the present analysis. Class II data includes data where all indoor physical environmental variables necessary for the calculation of PMV/PDD indices were made at the same time and place as the thermal questionnaires were administered. Class I data consists of data of same type as Class II data, but the measurements and procedures were in 100% compliance with ASHRAE Standard 55 (1992) and ISO 7730 (1984) (e.g. measurements in three heights, measurement of turbulence intensity etc.) The statistical program Statistica 7.1 was used for data management and statistical calculations.

For each one-degree interval of indoor air temperature from 20-30°C measured in the mechanically ventilated buildings and from 20-33°C in naturally ventilated buildings, the count of corresponding thermal sensation votes in one scale-unit intervals from -3 to +3 was recorded and used to describe the distribution.

RESULTS

Table 2 and 3 show the distribution of thermal sensation votes for occupants in mechanically and naturally ventilated buildings. The tables show the number of occupants who were exposed to a certain air temperature and the corresponding percent of occupants who voted a certain category on the 7-point ASHRAE thermal comfort scale.

Table 2. Distribution of Thermal Sensation Votes (%) in mechanically ventilated buildings

°C	N	-3	-2	-1	0	1	2	3
20	109	9%	27%	34%	24%	6%	1%	-
21	374	8%	14%	30%	32%	11%	4%	1%
22	1590	7%	16%	32%	30%	12%	3%	-
23	2712	3%	11%	28%	35%	19%	4%	-
24	2093	2%	10%	23%	33%	24%	7%	-
25	752	-	4%	16%	30%	35%	14%	2%
26	234	-	-	5%	24%	44%	22%	5%
27	113	-	2%	5%	8%	39%	31%	15%
28	32	-	-	-	3%	22%	41%	34%
29	15	-	-	-	-	53%	27%	20%
30	43	-	-	-	-	16%	44%	40%

Table 3. Distribution of Thermal Sensation Votes (%) in naturally ventilated buildings

°C	N	-3	-2	-1	0	1	2	3
20	37	3%	27%	32%	11%	19%	8%	-
21	129	7%	16%	23%	20%	17%	15%	2%
22	212	2%	10%	24%	28%	20%	14%	2%
23	308	2%	7%	19%	32%	24%	13%	2%
24	243	2%	3%	15%	36%	26%	14%	4%
25	301	3%	13%	24%	23%	24%	11%	3%
26	531	2%	13%	26%	25%	25%	9%	1%
27	626	1%	7%	24%	30%	25%	12%	1%
28	390	-	3%	16%	28%	30%	19%	4%
29	434	-	-	6%	35%	40%	15%	2%
30	544	-	1%	3%	29%	42%	21%	4%
31	511	-	1%	3%	27%	42%	23%	4%
32	245	-	-	3%	22%	46%	25%	4%
33	88	-	-	1%	17%	61%	18%	2%

Table 2 and 3 show that at e.g. 21 °C, 24 °C and 27 °C there is a difference in the distribution of thermal sensation votes between occupants in naturally and mechanically ventilated buildings. This difference is significantly ($p<0.05$) for all temperatures between 20-30 °C, a finding also described in [11]. It is evident that when temperature increases, the thermal sensation of the occupants also increases in both types of buildings, but at the indoor temperature 21 °C in NV buildings, 40% of the occupants was dissatisfied (voting -3,-2, +2 or +3 on the 7-point scale) compared to only 27% dissatisfied occupants in mechanically ventilated buildings. At 24 °C the number of dissatisfied is similar comparing the two different ventilation principles, 23% and 20% for NV and mechanically ventilated buildings, respectively. In warm indoor environments at 27 °C in mechanically ventilated buildings occupants are more dissatisfied than occupants in NV buildings, 48% dissatisfied compared to 21% dissatisfied, which corresponds with the rationale behind the adaptive model of thermal comfort [11].

Perceived air temperature

This data set allows establishment of a relationship between thermal sensation votes and temperature. This can be used to estimate occupants' perceived air temperature corresponding with a given vote on the thermal sensation scale. Figure 3 shows this relationship in mechanically and naturally ventilated buildings, respectively.

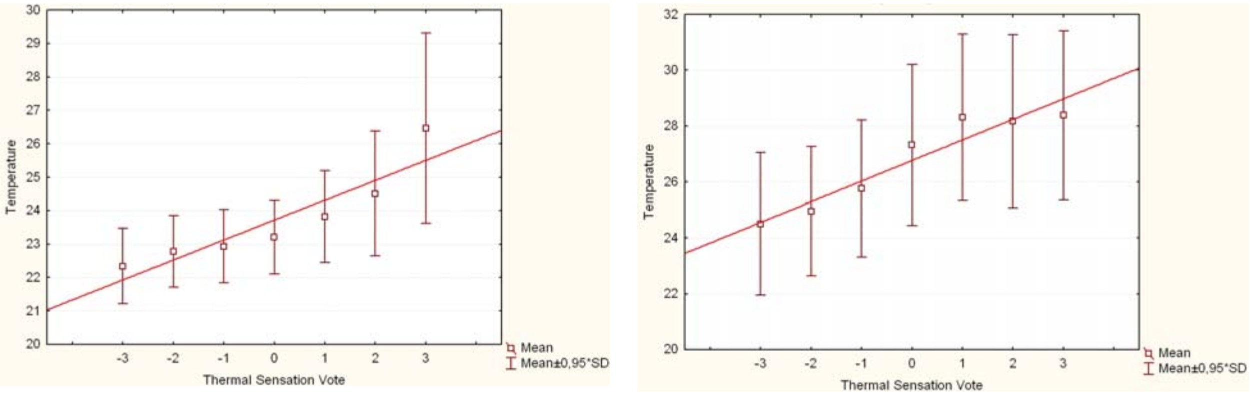

Figure 3. Relationship between office employees' thermal sensation votes and measured temperature in mechanically ventilated building (left figure) and NV buildings (right figure)

Figure 3 shows the mean temperature measured for each thermal sensation vote and the standard deviation. The mean temperature perceived as neutral (the average temperature measured for occupants who voted 0 on the thermal sensation scale) in mechanically ventilated buildings was 23.2 °C and 27.3 °C in naturally ventilated buildings. A linear regression line is used to describe the relationship between thermal sensation and temperature. E.g. for occupants in mechanically ventilated buildings voting 2 (warm) on the sensation scale the corresponding perceived air temperature will be 24.9 °C.

Table 3 shows an example of the combination of the thermal distribution at 24 °C for occupants in mechanically ventilated buildings and the corresponding perceived air temperature (the point on the regression line from Figure 3).

Table 3. Perceived air temperature for occupants exposed to 24 °C indoor environment

Thermal sensation vote	-3	-2	-1	0	1	2	3
Thermal distribution	2%	10%	23%	33%	24%	7%	-
Perceived air temperature	21,9 °C	22,5 °C	23,1 °C	23,7 °C	24,3 °C	24,9 °C	25,5 °C

From table 3 it is seen that 33% of the occupants in mechanical ventilated buildings who voted 0, may perceive the air temperature as being 23.7 °C, but 7% perceive the temperature as 24.9 °C. When calculating the effects of temperature on mental performance, occupants are affected differently even when exposed to the same temperature, due to the differences in thermal sensation between individuals. When the temperature varies the distribution of thermal sensation changes, thus by calculating this weighted effect of temperature on performance hourly over a year, an expression of the total yearly performance can be estimated.

DISCUSSION

In order to estimate the effects of temperature or other indoor climate parameters on mental performance of office work, the distribution of individual perceptions may be used as input to the calculations. With thermal sensation it is well established that not all people feel neutral at 22 °C, but as seen from this study e.g. 14% of occupants in NV buildings sense 22 °C as “warm”. This could be due to behavioral or psychological differences, a variation that normally occurs between occupants in offices around the world. Over an entire population occupants voting “warm” on the thermal sensation scale, would perceived the indoor air temperature to be 28.2 °C. Thus this is the temperature that will affect the mental performance.

By using a relationship between mental performance and air temperature established in e.g. [2], the distribution of thermal sensation votes and their corresponding perceived air temperature, a weighted effect of temperature on mental performance of office workers can be calculated. Since some occupants will perceive temperatures that differ from the optimal performance point of view, it will not be possible to reach 100% performance for a group of occupants even under thermal conditions that are acceptable to a majority of the occupants.

Future challenges are to integrate hourly temperature output from building simulation programs and a relationship between mental performance and temperature with the developed distribution and perceived temperature in a design decision tool. This tool could make it possible to compare different building designs in relation to investments in improvement of the thermal indoor climate and the corresponding effects on occupants’ mental performance.

CONCLUSION

The distributions developed in this paper can be used for future estimation of the effects of temperature on mental performance. Occupants do not perceive the temperature or other indoor parameters uniformly. The approach suggested in this paper allows individual differences to be accounted for when assessing effects on performance of indoor climate, as it varies during the year.

ACKNOWLEDGEMENT

We would like to thank Richard De Dear for providing the data used in this paper. It is now possible to download the datasets from the internet [11]. We would also like to acknowledge Professor P.O Fanger for his pioneering work in the field of thermal comfort.

SUMMARY

A long-term field study was conducted in an office for seven months to clarify the effect of thermal environment on productivity. Seven male software programmers participated as subjects. They answered the questionnaires on their personal computer including thermal sensation votes, complaints about their working environment, fatigue, vitality, mental workload and self estimated productivity every workday. The numbers of keystrokes were automatically recorded during the operation of their computers. Advanced Trail Marking Test (ATMT) was also conducted as the estimation of performance. Under lower temperature, the percentage of dissatisfied about “Low temperature” and “Draft” were higher and the vitality level was lower. The decrement in the total number of keystrokes of one day was 7.8% and that in the numbers of reaction per second of ATMT was 2.6% as temperatures dropped by 1.0°C below thermally neutral temperature. The result showed that overcooling brought the decrement of performance in the office.

INTRODUCTION

The objective of this study was to clarify the effect of thermal environment on productivity in the actual office. Especially, the effect of overcooling on office workers’ productivity was discussed in this study. A field study was conducted in a programmers’ office for seven months. The air temperatures were measured near the subjects’ desks. The relationships of air temperature, subjective vote and their performance were analyzed.

It is not simple to quantify the effects of thermal environment on performance of actual office works objectively. In this study, the numbers of keystrokes of the programmers were automatically recorded during their work time as their performance. Advanced Trail Marking Test (ATMT) [1] which was the standardized performance test that requires searching and clicking on the target character from twenty-five randomly appeared alphabets on their computers’ screen, was also asked to subjects.

METHODS

The field study was conducted from July 2005 to January 2006 in the programmers’ room. During the field study, the office was cooled by air-conditioner. The setting temperature of air-conditioning unit during the survey is shown in Table 1. The scene of the programmer’s room and the floor plan of the programmers’ room are shown in Figure 1.

Air temperature, relative humidity, the concentrations of CO_2 and CO were measured 10-minute intervals by IAQ -Calc Model 8762 (TSI) during the survey. The concentration of CO_2 was 577±135ppm and that of CO was 2.6±0.4ppm. Air temperature and relative humidity near the subjects' seats were measured. At each with measurement point, the environmental factors at the height of desktop and floor were measured 10-minute intervals by thermo recorder TR-72U（T and D）. The measurement points are shown in Figure 1.

(a) (b)

Figure 1. (a) Scene and (b) the floor plan of the programmers' room

In the room, ten to twenty programmers were working depending on the type and scale of their projects. In this study, seven male software programmers, with their age of 28.4±2.9, height of 168.1±3.5cm, and weight of 57.6±6.6kg, participated as the subjects. They were in their suits as usual and they were allowed to adjust their clothing.

They answered the questionnaires on their computer including thermal sensation votes, complaints about office environmental quality, fatigue and vitality at the beginning and the end of their office hours. They also answered mental workload and self estimated productivity at the end of their office hours every workday.

The voting items are shown in Table 3. Thermal sensation was voted on scales. Complaints on other indoor environmental elements were reported by checking the applicable items listed in "Complaints about indoor environment".

As the scale for subjective evaluation on mental workload, National Aeronautics and Space Administration Task Load Index (NASA-TLX) was proposed by Hart and Staveland [2]. The Japanese version of NASA-TLX [3] was used. NASA-TLX consists of six components: 'mental demand', 'physical demand', 'temporal demand', 'performance', 'effort' and 'frustration level'. The subjects indicated these components by a mark on each scale. The leftmost end was 'good (0)', and the rightmost end was 'poor (100)' for 'performance' scale. The leftmost ends were 'low (0)', and the rightmost ends were 'high (100)' for the other scales. For a comprehensive evaluation of the mental workload, Raw TLX (RTLX) proposed by Miyake was used. RTLX were calculated by averaging ratings of six components.

To evaluate the feeling of fatigue, 'Evaluation of Subjective Symptoms of Fatigue' suggested by the working group for occupational fatigue of the Japan Society for Occupational Health [4] was used. 'Evaluation of Subjective Symptoms of Fatigue' has been used in the field of labor science and ergonomics in Japan. It consists of 30 terms of fatigue symptoms. 'General rate of complaints' was defined as the rate of complaints about all 30 symptoms and calculated by equation (1) for each subject.

Rate of complaints (%)

$$= \frac{\text{Total number of a corresponding fatigue symptom of each subject}}{\text{Total number of symptoms on the evaluation sheet}} \times 100 \qquad (1)$$

To evaluate the vitality level, each subject listed up 20 items that they want to do on their free time before the survey, and they filled in whether they want to do them at the time of voting. Along with 'Evaluation of Subjective Symptoms of Fatigue', the vitality level was defined as the rate of applicable items about respective 20 items.

Subjects also reported the self estimated performance by marking a scale. The scale was the estimation on how subjects thought their productivity at work would be enhanced or interfered by the environment near their seat (+100: enhance their productivity, 0: interfere their productivity).

</table>

For the performance of work, their numbers of keystroke were automatically recorded during the operation of their computers, since much of their works involve in typing. For the analysis, the data for ten minutes at the beginning and the end of the operation time of their computers were eliminated to exclude the possible keystrokes for responding questionnaire.

ATMT was also conducted at the beginning and the end of office hours as the estimation of performance. In this test, subjects were asked to search and click on the target character "R" in twenty-five alphabets on their computers' screen. The distributions of the alphabets are presented randomly and repeatedly 70 times on their screen. For the analysis, the numbers of reaction per second at the end of their office hours were calculated.

The air temperature at the height of desktop near each subjects were averaged from ten o'clock to eighteen o'clock. The data sets of air temperature by the interval of 0.5°C were averaged, and corresponding subjective vote and their performance were averaged. The size of the plots shown in figures describes the number of corresponding subjects. For analysis of correlation between the air temperature and corresponding subjective vote and their performance, Pearson's product moment correlation coefficients weighted by the number of subjects were used.

RESULTS

Thermal sensation vote

The relationship of air temperature and thermal sensation vote with the linear regression model obtained from the plots is shown in Figure 2. Thermally neutral temperature was derived from the regression model as the temperature at which the thermal sensations vote becomes zero. The temperature was 28.6°C in this study. The reasons that thermally neutral temperature was relatively high were: air velocity in the room was 0.2-0.4m/s and was relatively high for offices, and subjects were able to adjust their clothes.

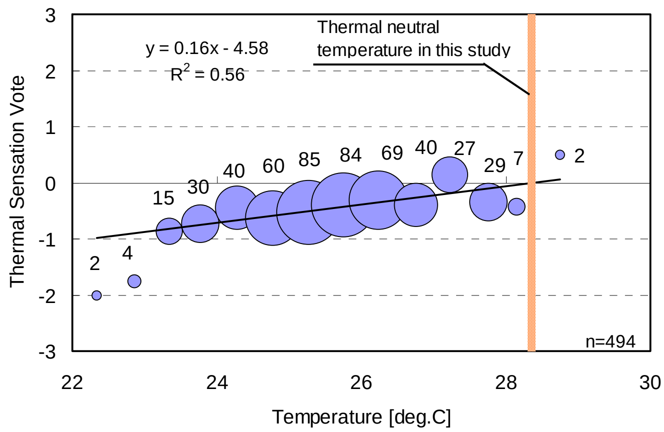

Figure 2. The relationship of air temperature and thermal sensation vote

Complaints about indoor environment

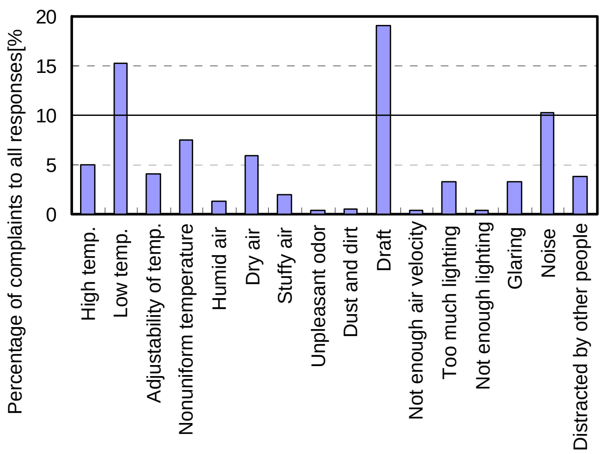
The percentages of complaints to all responses are shown in Figure 3. The percentage exceeded 10% were "Low temperature", "Draft" and "Noise". The equivalent sound level of the office was 60dBA, which it might have lead to the high rate of complaints on "Noise". Figure 4 shows the breakdown of these data for each air temperature range. Complaints about "Low temperature" and "Draft" were high under 23.0°C of air temperature in this room.

Mental workload

The relationship of air temperature and RTLX is shown in Figure 5. There was no significant correlation between air temperature and RTLX.

Fatigue

The relationship of air temperature and general rate of fatigue is shown in Figure 6. There was no significant correlation between air temperature and general rate of fatigue.



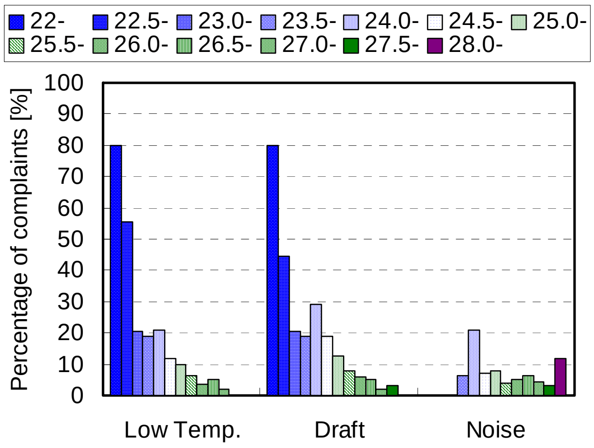


Figure 3. Percentage of complaint to all responses

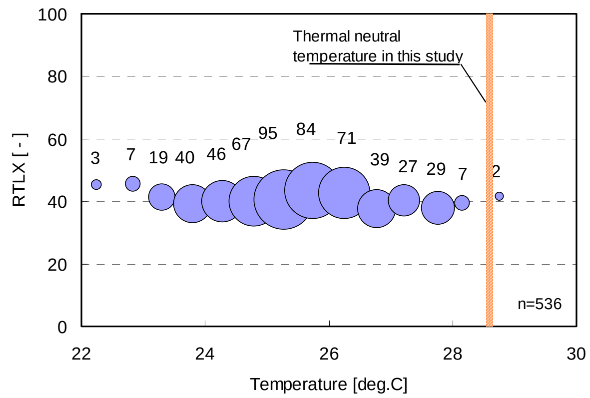
Figure 4. Percentage of complaints for each air temperature range



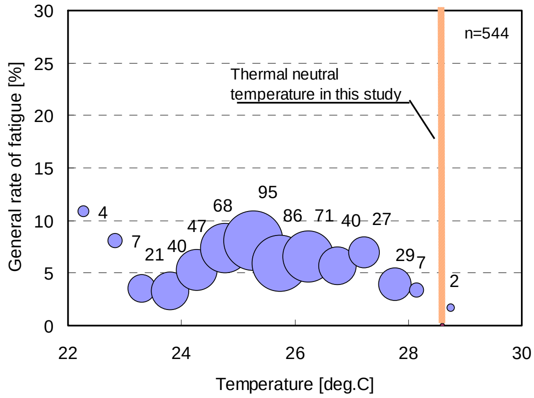


Figure 5. Air temperature and RTLX

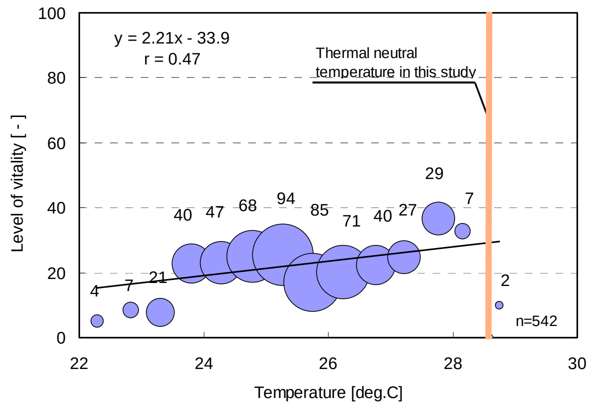
Figure 6. Air temperature and General rate of fatigue

Vitality level

The relationship of air temperature and the level of vitality is shown in Figure 7. The correlation coefficient of air temperature and the level of vitality was 0.47. From the result, the vitality level decreased when the air temperature decreased from the thermally neutral temperature.



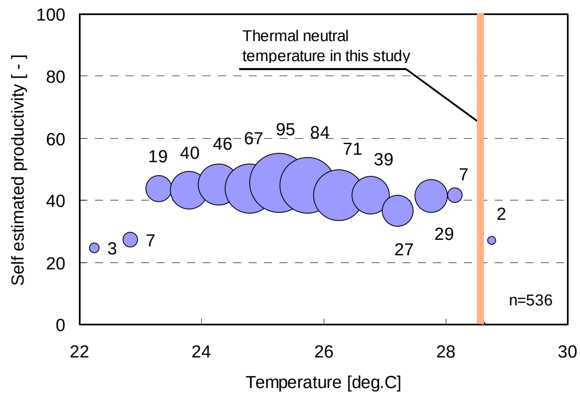


Figure 7. Air temperature and vitality level

Figure 8. Air temperature and self estimated productivity

Self estimated productivity
The relationship of air temperature and self estimated productivity is shown in Figure 8. There was no significant correlation between air temperature and self estimated productivity.

The numbers of their keystrokes per day
The relationship of air temperature and the number of keystrokes per day is shown in Figure 9. The correlation coefficient of this relationship was 0.70. From the linear regression model obtained from the results, decrease in 1.0°C of air temperature from thermally neutral temperature of 28.6°C corresponds to the decrement in the number of keystrokes per day by 7.8%.

The numbers of reaction per second of ATMT
The relationship of air temperature and the number of reactions per second is shown in Figure 10. The correlation coefficient of this relationship was 0.85. From the linear regression model obtained from the results, decrease in 1.0°C of air temperature from thermally neutral temperature of 28.6°C corresponds to the decrement in the number of reactions per second of ATMT by 2.6%.

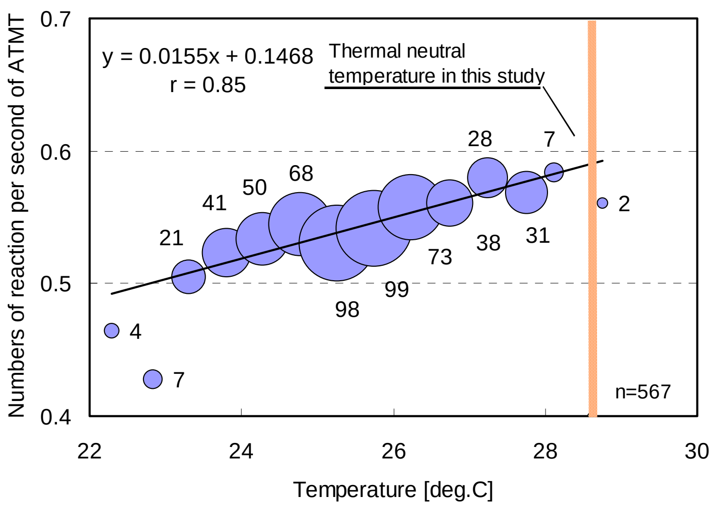

Figure 10. Air temperature and the number of reactions per second of ATMT

DISCUSSION

The results showed that the decrement in the total number of typing of one day was 7.8% and that in the numbers of reaction per second of ATMT was 2.6% as temperatures dropped by 1.0°C below thermally neutral temperature of 28.6°C. This result showed that overcooling brought the decrement of performance in the office. In our previous study of a year-long field survey of a call-center, the regression model of indoor air temperature and call response rate had shown that the rising of indoor air temperature by 1.0°C from 25.0 to 26.0°C would lead to the decrement in performance by 1.9% [5]. These studies showed the tendency that the deviation from the optimal temperature for office work lead to performance decrement. The relation of temperature and performance that had been developed by Seppänen et al [6] also showed this tendency.

It is important to specify the optimal temperature for work for creating the productive work place. However, it is not easy and the optimal temperature differed from one study to another. For example, Seppänen et al. mentioned that performance increases with temperature up to 21-22°C, and decreases at temperature above 23-24°C. On the other hand, in this study, thermally neutral temperature was 28.6°C and relatively high because of high air velocity in the room (0.2-0.4m/s) and the adjustability of clothes. Thermal environmental factors (not only air temperature, but also radiant temperature, air velocity, humidity, clothes and activity level) are needed for consideration. Additionally, the difference of task types may affect the optimal thermal environment for work. In this study, programmers' performances were estimated by the tasks, most of which requires the use of fingers such as keystrokes, and clicking response and they were relatively susceptible to cooler environment.

The results of this study and our previous call center study [5] showed the significant relationship between air temperature and performance at work. Tham et al. [7] and Niemelä et al. [8] also showed the significant relationship between air temperature and performance by the field studies in call centers. On the other hand, our previous laboratory experiment showed that it was difficult to evaluate the effect of thermal environment on productivity by measuring only task performance in the short-term exposure studies (about 2 hours) [9]. It was important to measure the human responses, such as fatigue level, physiological responses, and psychological responses, as the factors to influence workers' performance. For longer exposure, it became clearer that thermal environment affect physiological and psychological process such as fatigue, mental effort and so on, which would consequently affect workers' performance. The result from long-term exposure study (about 6 hours) had revealed that increase of fatigue level causes decrement in performance [10]. In the field study, relatively strong relationship of indoor air temperature and their performance could be obtained compared to laboratory experiments. The reason why the stronger relationship of indoor air temperature and their performance at the actual office work than that at laboratory experiments may be that the motivation level is higher in the short exposure studies and the human responses makes it hard to verify the direct relation between air temperature and performance.

CONCLUSIONS

A long-term field study was conducted in an office for seven months to clarify the effect of thermal environment on productivity. Seven male software programmers participated. The following results were obtained.

1) Complaints about "Low temperature" and "Draft" were high under 23.0°C of air temperature in this programmers' room.
2) The vitality level decrease when the air temperature decreased from thermally neutral temperature of 28.6°C.
3) The decrement in the total number of typing of one day was 7.8% and that in the numbers of reaction per second of ATMT was 2.6% as temperatures dropped by 1°C below thermally neutral temperature of 28.6°C.
4) The result showed that overcooling brought the decrement of performance in the office.

ACKNOWLEDGEMENT

The authors wish to express their appreciation to Dr. O. Kajimoto (Soiken Holdings Inc.) for his advice and cooperation concerning on Advanced Trail Marking Test and Ms. A. Tanaka, Mr. M. Nishikawa, Ms. M. Hayakawa, Mr. S. Hyodo, and Mr. T. Kumata (Waseda University) for their assistance during the field study. This study was partially funded by the Global Environment Research Fund (H-061) by the Ministry of Environment, Japan.

SUMMARY

A computer program for both field survey and laboratory experiment was developed to evaluate performance of office works and to link the findings from experiments to the actual offices. The program has three parts: namely, Voting Tool, Task Tool, and Performance Evaluation Tool. In this study, the Performance Evaluation Tool, which is consisted of twelve standard tests, was examined. The abilities required for the office works in two companies and one branch of the government office were collected to verify the applicability of the Performance Evaluation Tool. Two subjective experiments were conducted to determine the abilities required to work on each of twelve tests and to examine the reliability as a measurement tool for performance. From the results, there were some abilities required in offices but not for the tests, and the need for further modification was addressed. The performances of the tests were positively correlated with that of multiplication task (r=0.86).

INTRODUCTION

Performance is essential for the evaluation of productivity. Unfortunately, the performance of office works is mostly hard to quantify. To evaluate the effect of indoor environmental quality on performance quantitatively, mental tasks, such as three-digit multiplication, text-typing, and memorization of letters, have been assigned in the subjective experiments [1][2][3][4]. However, there is no guarantee that those simulated tasks are good representations of actual office works. Also, the importance of evaluation of human responses, such as fatigue, cerebral blood flow, sensation to the environment, was reported from the results of short-term experiments [5][6]. The survey tools developed in this study were to equip the quantitative measurement method of performance with the appropriate relationship to the performance of office works and the measurement method of human responses as used in the previous studies. The main purposes of this paper were to introduce this survey tools and to examine the characteristics and practicality of the Performance Evaluation Tool, which was developed as a part of the survey tools to measure performance quantitatively in both field surveys and laboratory experiments.

METHODS

First, a summary of the survey tools was briefly described and the tests of the Performance Evaluation Tool were introduced. Then, the questionnaire form was described with the categories of cognitive abilities, which were used to relate the Performance Evaluation Tool to tasks and office works. Also, the methods of this study, which includes questionnaire surveys on two companies and one branch of the government office and two subjective experiments, were explained.

Survey Tools for Indoor Environmental Quality and Productivity

PC-based survey tools were developed to evaluate the effect of indoor environmental quality on productivity. The tools are programmed as computer software with a mouse and a numeric keypad to respond. The tools include three types of evaluation tools, which include Voting Tool (V-Tool), Task Tool (T-Tool) and Performance Evaluation Tool (P-Tool). V-Tool is consisted of questionnaire forms including: votes on environment, Evaluation of Subjective Symptoms of Fatigue [7], and NASA-TLX [8], to evaluate human responses and fatigue. T-Tool is a set of experimental assignments such as multiplication tasks. P-Tool contains twelve standard tests as described in the next section.

Performance Evaluation Tool

P-Tool was developed to evaluate objectively the performance level of the persons in both field survey and laboratory experiment. The P-Tool was also rebuilt as web-based programs for the field surveys, because it has recently been difficult to directly install personally-built programs into the computers in offices for the security reasons. The P-Tool was installed into the PCs of the laboratory and was run without internet access in this study. It is consisted of twelve standard tests programmed with references from the Walter Reed Battery Tests [9] and examples given in the literature [10].The twelve tests are:

(I) Manikin – a manikin surrounded by circle or square carries circle and square on his hand appears on the screen. Subjects are to answer the side of hand that carries same or different shape compared to the shape surrounds manikin;

(II) Coordinate – based on the table of numbers with corresponding alphabets, subjects are to choose the coordinate point that are implied by the randomly selected combination of two alphabets;

(III) Coding - based on the table of numbers with corresponding alphabets, subjects are to input a number that is implied by a randomly selected alphabet letter;

(IV) Four choice – a panel with 1,2,4,5, corresponding to a portion of numeric keypad, is appeared with background color of one number is highlighted. Subjects are to input the highlighted number;

(V) Nine choice – similar to the Four choice but the panel with numbers from 1 to 9;

(VI) Time-lag input – subjects are to input the number that is appeared previously;

(VII) Arithmetic symbol – subjects are to answer the correct arithmetic symbol to complete the equation; appeared on the screen

(VIII) Positioning – subjects are to select the number as instructed from the randomly positioned 25 numbers appear on the screen;

(IX) Pattern memory – subjects are to answer whether randomly positioned dots appear twice are the same or different;

(X) Letter search – from the thirteen alphabet letters, subjects are to answer whether the target two letters are included both, only one, or neither;

(XI) Classification rule – subjects are to answer the rule that classifies the boxes with □■△▲○● as appeared; and

(XII) Pattern search – target pattern of sixteen mosaics with alternatives were shown. Subjects are to select the same pattern from the alternatives.

Cognitive abilities

In this study, the abilities required for the office works and P-Tool were in focus. The ability classification questionnaire was used in the questionnaire surveys and in the Subjective Experiment 1. The abilities and its definitions were cited from the Cognitive Abilities proposed by Fleishman [10]. The abilities include: (1) Oral comprehension; (2) Written comprehension; (3) Oral expression; (4) Written expression; (5) Fluency of ideas; (6) Originality; (7) Memorization; (8) Problem sensitivity; (9) Mathematical reasoning; (10)

Number facility; (11) Deductive reasoning; (12) Inductive reasoning; (13) Information ordering; (14) Category flexibility; (15) Speed of closure; (16) Flexibility of closure; (17) Spatial orientation; (18) Visualization; (19) Perceptual speed; (20) Selective attention; and (21) Time sharing. The abilities required to the subjects or workers for their works were marked with the ability classification questionnaire, which is shown in Figure 1.

Q1. Briefly explain the type of your work ________________________________.

Q2. Mark in the left box of the following abilities that are required for your work.

	Ability to understand spoken (English) words and sentences
	Ability to understand written sentences and paragraphs
	Ability to use (English) words or sentences in speaking so others can understand
	Ability to use (English) words or sentences in writing so others can understand
	Ability to produce a number of ideas about a given topic
	Ability to produce unusual or clever ideas about a given topic or situation
	Ability to remember information, such as words, numbers, pictures, and procedures
	Ability to know when something is wrong or is likely to go wrong
	Ability understand and organize a problem and then to select a mathematical method or formula to solve the problem
	Ability to add, subtract, multiply, divide, and manipulate numbers quickly and accurately
	Ability to apply general rules to specific problems and to come up with logical answers
	Ability to combine separate pieces of information, or specific answers to non-mathematical problems, or to form general rules or conclusions
	Ability to correctly follow a rule or set of rules specifying how to arrange things or actions in a certain order
	Ability to produce many rules in such a way that each rule tells how to group a set of things in a different way
	Ability to quickly make sense of information which initially seems to be without meaning or organization
	Ability to identify or detect a known pattern (e.g., a figure, word, or object) that is hidden in other material
	Ability to know one's location in relation to the environment one is in or to know where an object is in relation to oneself
	Ability to imagine how something will look when it is moved around or when its parts are moved or rearranged
	Ability to compare letters, numbers, objects, pictures, or patterns, quickly and accurately
	Ability to concentrate on a task over a period of time
	Ability to shift back and forth efficiently between two or more activities or sources of information

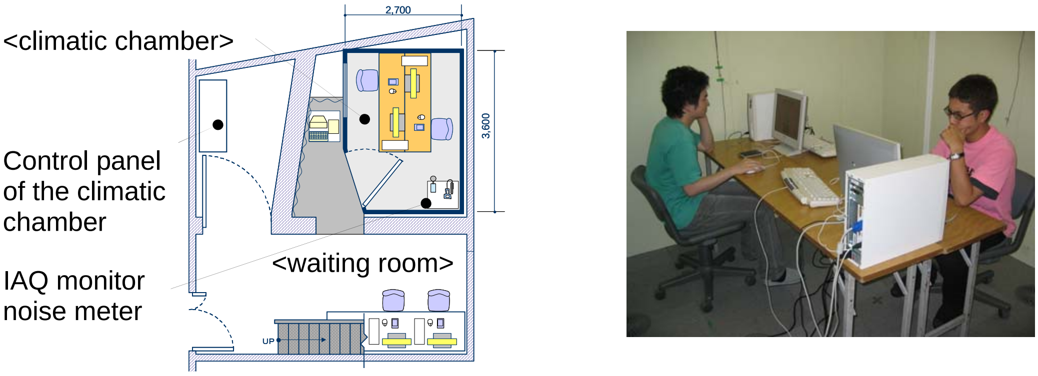
Figure 1. The ability classification questionnaire

Questionnaire surveys

To obtain the balance of abilities of the office works, the ability classification questionnaire had been collected in Company M, Company T and one branch of the government office. In Company M, 75 workers were surveyed; of 69 took over clerical job, of 3 took over technical job and of 3 had no response. In Company T, 50 workers were surveyed; of 46 took over technical job and of 4 took over clerical job. In the government office, 76 workers were surveyed; of 66 took over clerical job and of 10 took over technical job.

Subjective Experiment 1

The purposes of the experiment were to gather information to modify the operationality of P-Tool and to understand the characteristics of P-Tool by obtaining the abilities required for each test. Thirty-one college-aged subjects, eight female and twenty three male, participated in the experiment. Subjects wore their own clothes and were allowed to adjust their clothes during the experiment. The experiment was conducted on July 26-28, 2006 in a climatic chamber and the waiting room. The layout of the chamber with the waiting room and a picture during the experiment were shown in Figure 2. Two subjects were paired and participated only once in this experiment. The physical environment for the climate chamber was measured with IAQ monitor for air temperature, relative humidity, the concentration of CO_2, and noise meter for sound level. The conditions of the climatic chamber were as follows: average air temperature was 25.4°C with standard deviation of 0.1°C; average relative humidity was 50% with standard deviation of 0%; the concentration of CO_2 was 576ppm with standard deviation of 55pppm; and equivalent sound level was 56dBA.



(a) (b)

Figure 2. (a) The layout of the climatic chamber and the waiting room; and (b) a picture during the Subjective Experiment 1 in the climatic chamber.

Procedure of the experiment is shown in Figure 3. In the waiting room, instructions and procedures of the experiment were given to the subjects first, and the subjects worked on each test of P-Tool for 1.5 min and then reported on the evaluation sheets on the test. After all twelve tools were finished; subjects moved into the climatic chamber and reported the Evaluation of Subjective Symptoms of Fatigue. They again worked on each test of P-Tool for 3 min and then reported the ability classification questionnaire on the test. After all twelve tests were finished, subjects reported the Evaluation of Subjective Symptoms of Fatigue.

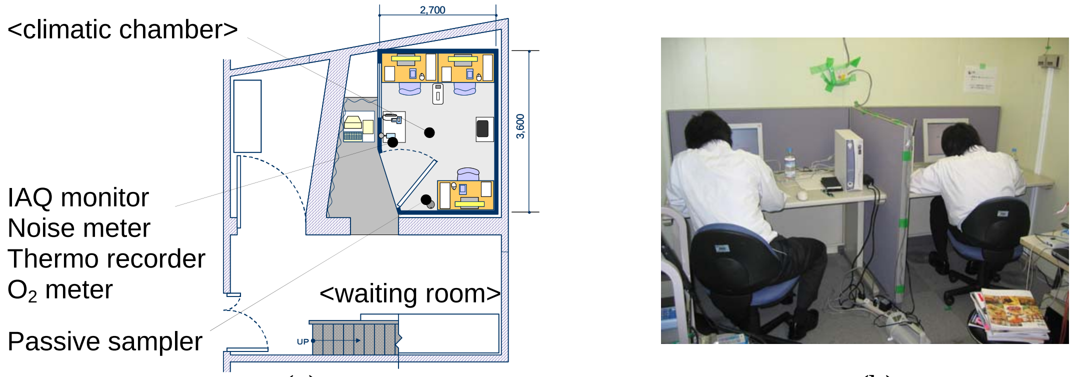
Figure 3. Procedure of Subjective Experiment 1

Subjective Experiment 2

Another subjective experiment was conducted to evaluate the compositive effect of thermal environment and indoor air quality. From the perspective of evaluating the P-Tool, this experiment was conducted to examine the relationship between the performance of the P-Tool and multiplication task. The experiment was conducted in the climatic chamber as shown in Figure 4 with twelve male subjects from September 18 to October 19, 2006. Three subjects were participated together in this experiment. Subjects wore shirt with long sleeves and pants (0.66clo) [11] during the experiment. A practice and four experimental conditions were set: A) Practice with operative temperature of 28.5°C and Low ventilation rate; B) 28.5°C-Low ventilation rate; C) 28.5°C-High; D) 25.5°C-Low; E) 25.5°C-High. Subjects experienced

Practice first and then these four conditions in balanced order. They were exposed on the same time of the day in the successive weeks to avoid the influence of time. The tests of P-Tool used in this experiment were selected based on the results of the Subjective Experiment 1. Because one subject had fever in one of the conditions, his data was excluded for the analysis, i.e. data from eleven subjects were used for analysis in this experiment.



(a) (b)

Figure 4. (a) The layout of the chamber; and (b) a picture during the Subjective Experiment 2

The procedure of the experiment is shown in Figure 5. In the waiting room, subjects changed their clothes, instructions were given, and they rested in sedentary position for ten minutes. Then, the subjects moved into the chamber, reported on the environment and the Evaluation of Subjective Symptoms of Fatigue, and worked on P-Tool. After resting in sedentary position for thirty minutes, subjects voted on the environment, reported the Evaluation of Subjective Symptoms of Fatigue, and worked on P-Tool. Then six sessions of multiplication task with votes and P-Tool between the tasks were assigned to the subjects. After the sessions, they reported the predicted-performance-vote [12] at the end of the experiment.

RESULTS

Questionnaire surveys

The results of ability classification questionnaires were shown in Figure 6. Abilities were evaluated by the fraction of the number of workers who responded the ability to be required to the number of total workers. In these offices, (1) Oral comprehension, (2) Written comprehension, (3) Oral expression, and (4) Written expression were the abilities that were evaluated as "required" by over 85% of workers. The abilities such as (6) Originality, (11) Deductive reasoning, (12) Inductive reasoning, (14) Category flexibility, (16) Flexibility of closure, were required in Company T, in which most of workers took over technical jobs unlike the other two. The ability classification questionnaire can be a useful method for understanding the characteristics of the office.

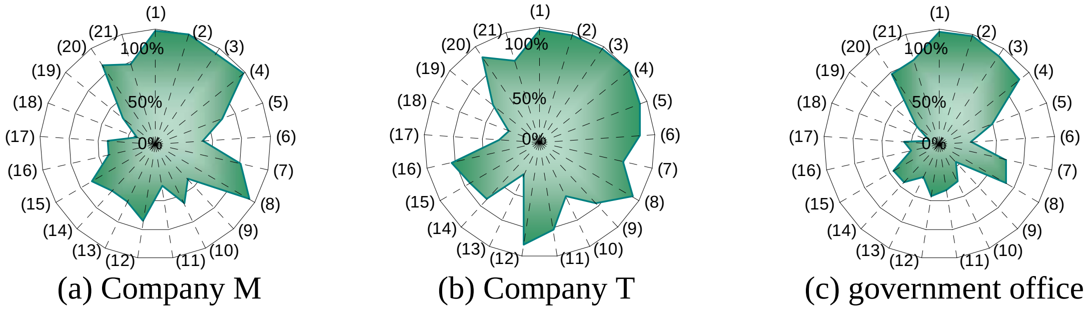

Figure 6. Results of ability classification questionnaire at (a) Company M, n=75; (b) Company T, n=50; and (c) government office, n=76. The numbers in parenthesis in the figures correspond to the abilities described in the section “Cognitive abilities”.

Subjective Experiment 1

The balance of the abilities required to work on each test are shown in Figure 7. (19) Perceptual speed and (20) Selective attention were the abilities that were highly required in all of the tests. Other than the two, the balance of the abilities required differed from test to test. There were some tests, however, that were similar in terms of required abilities. For the practical use in future researches, six tests were selected keeping the new set of tests to have similar balance of required abilities as a total. The selected six tests, together called P-Tool$_6$, were: (I) Manikin; (II) Coordinate; (IV) Four Choice; (VII) Arithmetic symbol; (XI) Classification rule; and (XII) Pattern search.

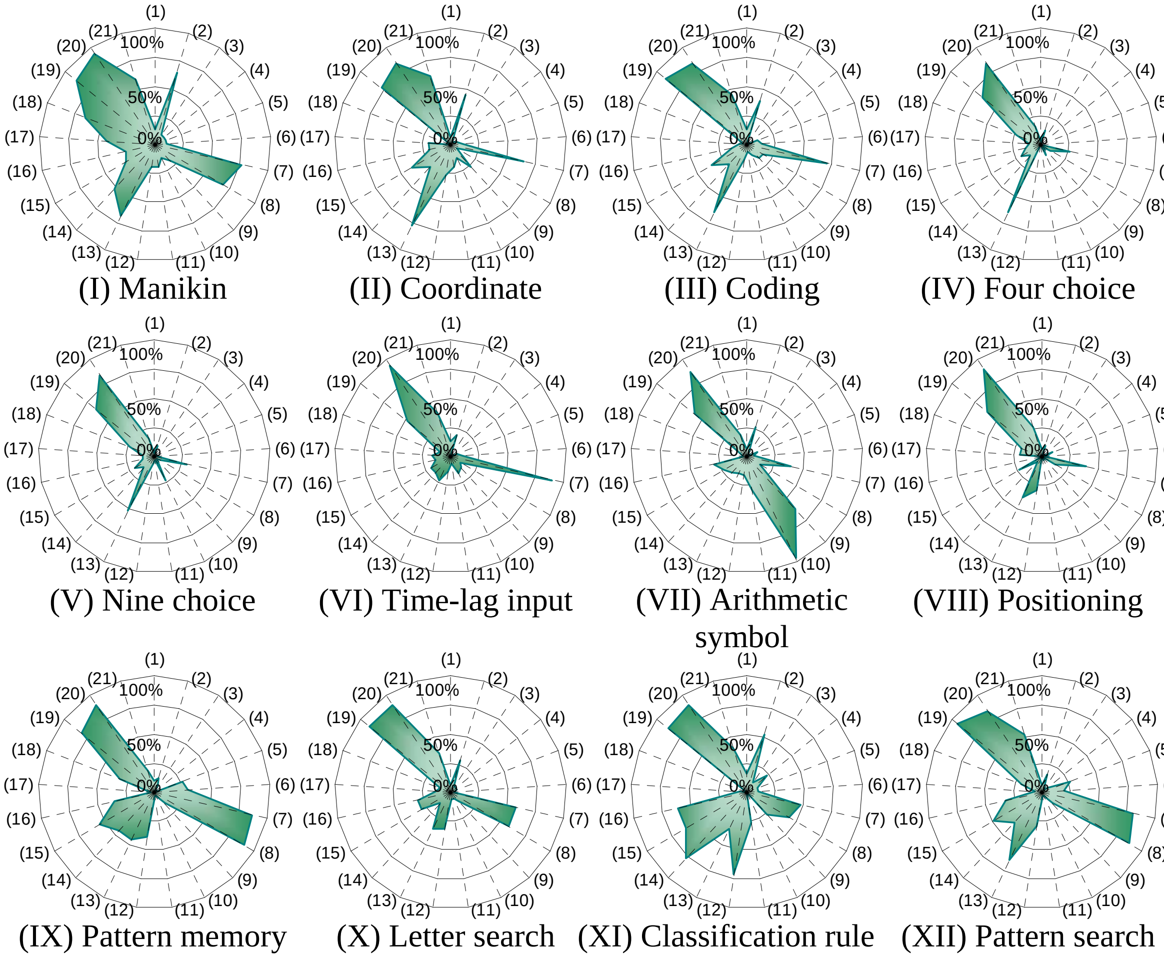

Figure 7. Results of abilities classification questionnaire of each test of the Performance Evaluation Tool. The numbers in parenthesis in the figures correspond to the abilities described in the section “Cognitive abilities”.

Subjective Experiment 2

To examine the reliability of the P-Tool, it was compared with the multiplication task. The results of ability questionnaire survey for the P-Tool$_6$ from the Subjective Experiment 1 and that for the multiplication task are shown in Figure 8. The balance of the abilities required for the P-Tool$_6$ covered that for multiplication task.

(a) P-Tool$_6$ (b) Multiplication task

Figure 8. Results of ability classification questionnaire for (a) P-Tool$_6$ and (b) multiplication task. The numbers in parenthesis in the figures correspond to the abilities described in the section “Cognitive abilities”.

Performances of both the P-Tool$_6$ and multiplication task were normalized to exclude individual variability by obtaining z-scores for each subject. The data set of performance of the P-Tool$_6$ with interval of 0.5 in z-score was averaged and corresponding performance of the multiplication task was averaged. The relationship between the two performances is shown in Figure 9 with a linear regression model weighted by the number of subjects. It was positively correlated with the correlation coefficient of 0.86. The result gave some proof on the adequacy of the P-Tool as a measurement method of the workers’ performance indirectly.

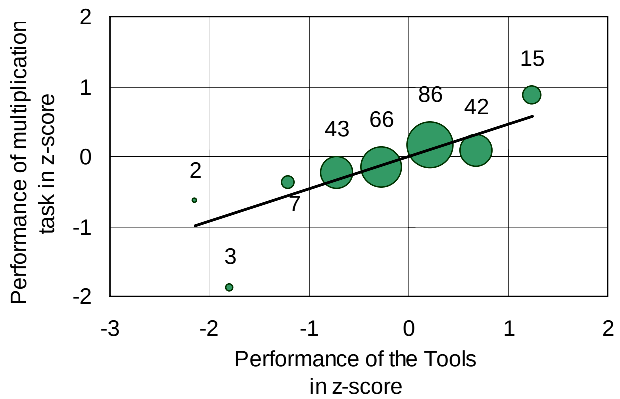

Figure 9. The relationship between normalized performance of the multiplication task and of the P-Tool$_6$, and a linear regression model weighted by the number of subjects.

DISCUSSION

Cognitive abilities required in offices and in the Performance Evaluation Tool

From the results of ability classification questionnaire in offices and Subjective Experiment 1, there are some differences in the abilities required between office works and the P-Tool. For office works, major abilities required were of (1) Oral comprehension, (2) Written comprehension, (3) Oral expression, and (4) Written expression, which were not evaluated as much for the P-Tool. Some of the methods to test these abilities have been introduced in the previous works [10]. However, they are not suitable for repetative use, for scoring objectively and automatically, to avoid uniformality of the difficulty of each question, etc., that are not negligible when the use in offices is assumed. Further modification of the P-Tool for these abilities may be needed.

Performance Evaluation Tool as measurement of performance
From the results of Subjective Experiment 2, the performance of the P-Tool was correlated well with the performance of multiplication task. There would be still some more studies needed on the tasks other than multiplication for conclusive evidences to convince that the P-Tool can be applied in the situation where direct performance is difficult to quantify. Also, the web-based version of the P-Tool needed to be practiced in the field.

CONCLUSION

In this paper, the survey tools for indoor environmental quality and productivity were introduced, and the characteristics and practicality of the Performance Evaluation Tool were examined.

1) The results from survey and experiment, there were some abilities required in offices but not for the tests, and the need for further modification was addressed.
2) The balance of the abilities required for the Performance Evaluation Tool covered that for multiplication task. The performance of the Performance Evaluation Tool was positively correlated with the performance of multiplication task.

ACKNOWLEDGEMENT

The authors express gratitude to the subjects of the experiments and the workers participated for the surveys. The authors also appreciate Miss M. Isemura, Miss K. Nakajima and Mr. S. Nakamura for their contributions to this study. This study was partially funded by the Global Environment Research Fund (H-061) by the Ministry of the Environment, Japan and by the Project Research of Advanced Research Institute for Science and Engineering, Waseda University.

SUMMARY

The life cycle cost (LCC) of the heating and ventilation system was simulated for a typical multi family dwelling and a typical detached house. Different ventilations systems were simulated resulting in different heating system designs. A health related cost dependent on the airflow rate which was based on recent studies was added to the life cycle cost. The health related costs are not analyzed but varied in a parametric study. An optimal airflow rate can be found depending on the assumed size of the health related cost. It is not well known how the airflow rate influences the health and comfort. Furthermore, it is not well known or defined how to valuate that possible influence. Despite this, this study is a demonstration of a method which can be used to optimize airflow rates in buildings if the influence and costs on human health related to the airflow rate is known.

INTRODUCTION

People spend up to 90% of their time indoors [1]. To ensure people's health and comfort when they are indoors, the indoor air quality and thermal comfort must be appropriate. An indoor climate system, consisting of heating, cooling and ventilation, serves this purpose [2]. The aim of the indoor climate system is to provide the building with a good thermal comfort and indoor air quality. An increasing number of studies have indicated a significant relationship between the ventilation airflow rate and health and productivity, in regards to offices, schools and dwellings.

In this study, the life cycle cost (LCC) of the heating and ventilation system was simulated for a typical multi family dwelling and a typical detached house. Different ventilations systems were simulated resulting in different heating system designs with the computer program ProLive [3]. A health related cost dependent on the airflow rate which was based on recent studies was added to the life cycle cost. A higher airflow rate results in a more expensive indoor climate system both regarding the life cycle cost and the initial cost.

No comprehensive literature review was done regarding the cost and health impacts from the ventilation airflow rate. Only theoretical buildings have been simulated, one typical multi family dwelling and one typical detached house. Field measurements were not an alternative, since it would be difficult to measure the life cycle cost, particularly for different airflow rates. Only mechanical ventilation systems were included.

METHODS

One problem with the design of an indoor climate system is that there has been a predominant focus on initial costs. A life cycle approach could improve both the energy and economic performance of the indoor climate system. The life cycle cost of a product is the sum of all costs related to that product over its entire life span. Future costs are discounted to the value of today, the net present value, by the use of a discount rate of interest.

The computer program ProLive was developed to calculate the life cycle costs for indoor climate systems in offices, schools and dwellings [3]. It handles thousands of combinations of heating, cooling and ventilation systems typically used in Sweden, and takes into account the initial costs for buying and mounting components through a power demand calculation, energy costs, maintenance costs, repair costs and costs for space loss due to system components. Costs are based on Swedish prices from Sektionsfakta [4], which is a known cost database for the building sector. Outdoor climate data is obtained from the computer program Meteonorm [5], which simulates outdoor climate data for the entire world. ProLive has features to model productivity and health costs based on indoor temperature and airflow rate even if the user has to provide the correlation data between the parameters and the costs. ProLive uses Swedish costs in SEK excluding VAT (25% value added tax). 1 SEK ≈ 0.14 US$ ≈ 0.11 € as of 2007-02-15.

In this study, the price of heat was set to 0.6 SEK/kWh and the price of electricity was set to 0.8 SEK/kWh excluding VAT. The discount interest rate was assumed to be 1% for electricity, 2% for heat and 3% for other costs representing a real price increase for heat and even more for electricity. An annual value of 800 SEK/m² was assumed for space loss. It was assumed that there is a 20% deduction from the initial costs for both air and hydronic components compared to Wikells [4]. A 40 year calculation period was used. The scrap value was assumed to be zero.

Buildings

None of the buildings were set up with cooling. Hydronic radiators were used for heating. Assumed data for the buildings are given in Table 1. The outdoor climate data are from Stockholm, Sweden. Table 2 gives the apartment areas, the window areas, the heat transmission areas and the number of people per apartment. The rooms with supply devices are the rooms that are not kitchens or bathrooms. Exhaust devices are located in the kitchen and in the bathrooms.

The multifamily dwelling was assumed to have four storeys with two one-room, two two-room, two three-room and two four-room apartments on each storey. It was assumed that there were two exhaust devices for each apartment, except for the four-room apartments where it was assumed that there were three exhaust devices. The building was assumed to be a medium weight construction.

The detached house was set up with two storeys. There were three exhaust devices on the bottom floor and two on the second floor while there were two supply diffusers or air inlets on the bottom floor and three on the second floor. It was assumed that four persons were living in the house.

Table 1. Data for the simulated buildings. Internal load means internal heat gain not from people. Heat transmittance is the average value for the building.

	Detached	Multi family		Detached	Multi family
Storey height	3 m	3 m	Chiller COP	2	2
Building length	12 m	43.3 m	Room temperature	22°C	22°C
Building width	8 m	12 m	Internal load presence	3 W/m²	3 W/m²
Total floor area	192 m²	2080 m²	Internal load abscence	1 W/m²	2 W/m²
Heat transmission area	288 m²	Table 2	Heat recovery eff.	0.8	0.8

Heat transmission area	34.2 m²	57.0 m²	91.2 m²	114 m²

Ventilation systems

Specifications of the indoor climate regarding thermal comfort and air quality are determined by requirements, recommendations, national regulations or by the building's user. This helps to simplify the design process of an indoor climate system. Usually, the minimum and maximum temperatures and the supply airflow rate are set depending on the activity in the building. In Sweden, there is a requirement of 0.35 l/(s·m²) [7].

The included systems in this study were exhaust ventilation system (E) with air inlets at the windows, exhaust ventilation system with a heat pump (EHP) recovering heat from the exhaust air to tap water and heating, and supply and exhaust ventilations system with heat recovery (SEH) with ceiling diffusers for supply air. A constant airflow rate was assumed. For the exhaust system with heat pump, it was assumed that half of the energy use for hot tap water, 30 kWh/(m²·year) [8], was covered, that is 15 kWh/(m²·year), plus half of the heating energy. For the supply and exhaust system, the heat recovery temperature efficiency was set to 70%.

Health costs

It is proposed that a health related cost can be expressed by Equation 1. The benefit from a raised airflow rate goes towards zero at high airflow rates. At zero airflow rate the equation is not valid.

The constants k_1 and k_2 must be determined in relation to the units of the health related cost, C_{health}, and the airflow rate, q. Two examples are given in this paper based on recent studies.

$$C_{health} = k_1 \cdot e^{-k_2 \cdot q}, \qquad (1)$$

Sick leave could reasonably be blamed on poor ventilation at home and not only at work. If it is assumed that the influence is the same, Johansson [3] gives an equation based on a compilation of other studies over the world [9]. If it is assumed that the labour cost is 200

SEK/h, the number of annual working hours is 1700, the calculation period is 40 years, the discount interest rate is 3%, the detached house is taken into account with four people in 192 m², k_1 becomes 774 and k_2 becomes 3.28 with [q] = l/(s·m²) referring to the floor area and [C_{health}] = SEK over the calculation period.

In the other example, Bornehag et al. [10] performed a case-control study on children in 390 Swedish dwellings and found that the prevalence of allergic symptoms decreased significantly with an increased ventilation airflow rate. The dwellings were sorted into four quartiles depending on the airflow rate of 0.44 to 1.43 air changes per hour at a median of 0.62 as reference case. The odds ratio increased constantly to 1.95 for the group with 0.05 to 0.24 air changes per hour with a median at 0.17. The mean air change rate from the study was within the air change rate quartile with an odds ratio of 1.14 compared to the reference case. This quartile had a mean air change rate of 0.38. The reported prevalence of allergic symptoms was 9.7% based on a former cross-sectional study. Allergy and asthma was reported in around half of the cases of allergy [11]. Jansson [12] determined a cost for asthma of 15919 SEK/(person·year) based on the OLIN-studies in Sweden. If it is assumed that the reported prevalence of allergic symptoms and asthma corresponds to the average mean air change rate of 0.38, the prevalence of asthma can be approximated to 5% at 0.38 air changes per hour. If the risk ratio is approximated with the odds ratio, the prevalence becomes 4.4% for an air change rate of 0.17 per hour and 8.6% for an air change rate of 0.62 per hour. If the house has a height of 2.4 m, k_1 becomes 10.9 and k_2 becomes 2.23 if C_{health} represents the expected prevalence of asthma in percent at a certain airflow rate, q, in l/(s·m²) referring to the floor area. 10.9 must be multiplied with 159.19 which is the cost per percent prevalence and 23.115 which sums 40 years with 3% discount interest and 4 due to 4 people per house and must be divided by the floor area of 192 m² to get C_{health} to represent health cost over 40 years per floor area. k_1 becomes 838.

RESULTS

Figure 1 gives the life cycle cost for the multi family dwelling and the detached house respectively split into components and parts as a function of the airflow rate, q, for a simulated exhaust ventilation system. The heating pipes do not change relative to the airflow rate, while the radiators become larger to be able to heat the supply air. Figure 2 gives the same for the supply and exhaust ventilation system with heat recovery. For the detached house, there is a new brand of air handling unit installed at 1.2 l/(s·m²). Figure 3 shows the resulting life cycle cost for the exhaust ventilation system with heat pump. Space loss is the space that is taken up by ducts and air handling unit. At some points the cost increases in large steps due to the available component sizes on the market.

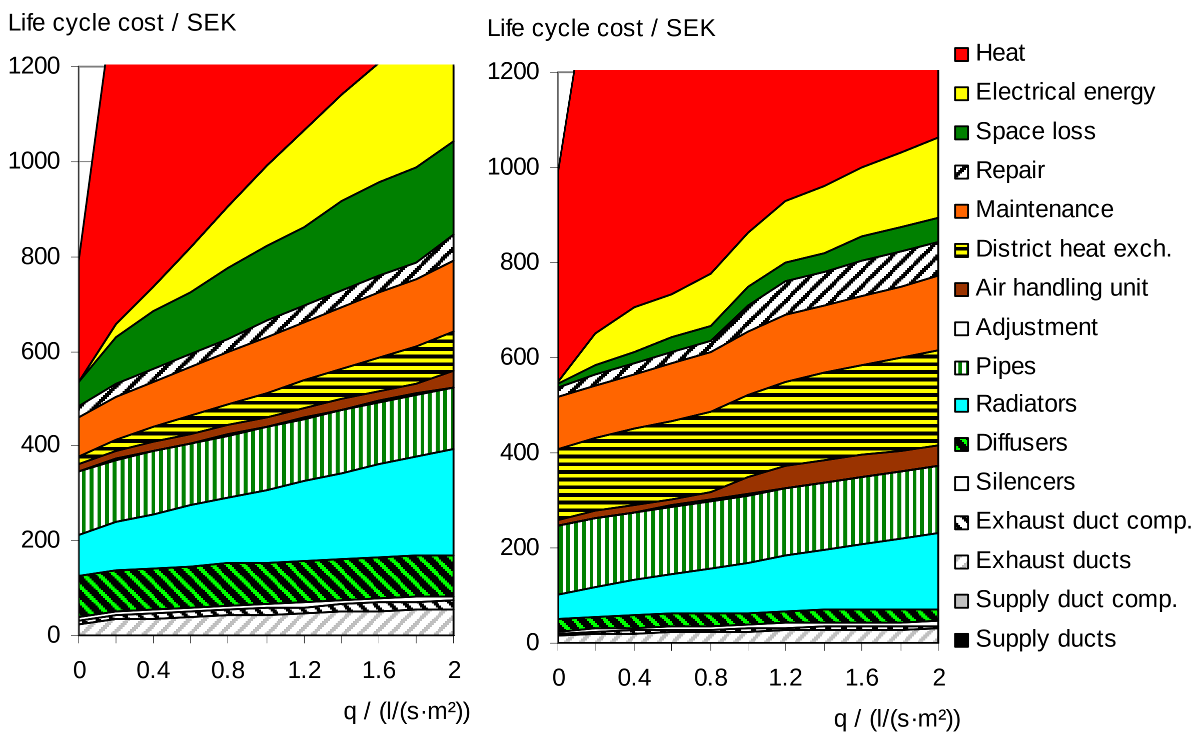

Figure 1. The life cycle cost as a function of the airflow rate for the multi family dwelling, to the left, and for the detached house, to the right, with exhaust ventilation system (E). There are no supply duct components or supply ducts within this system.

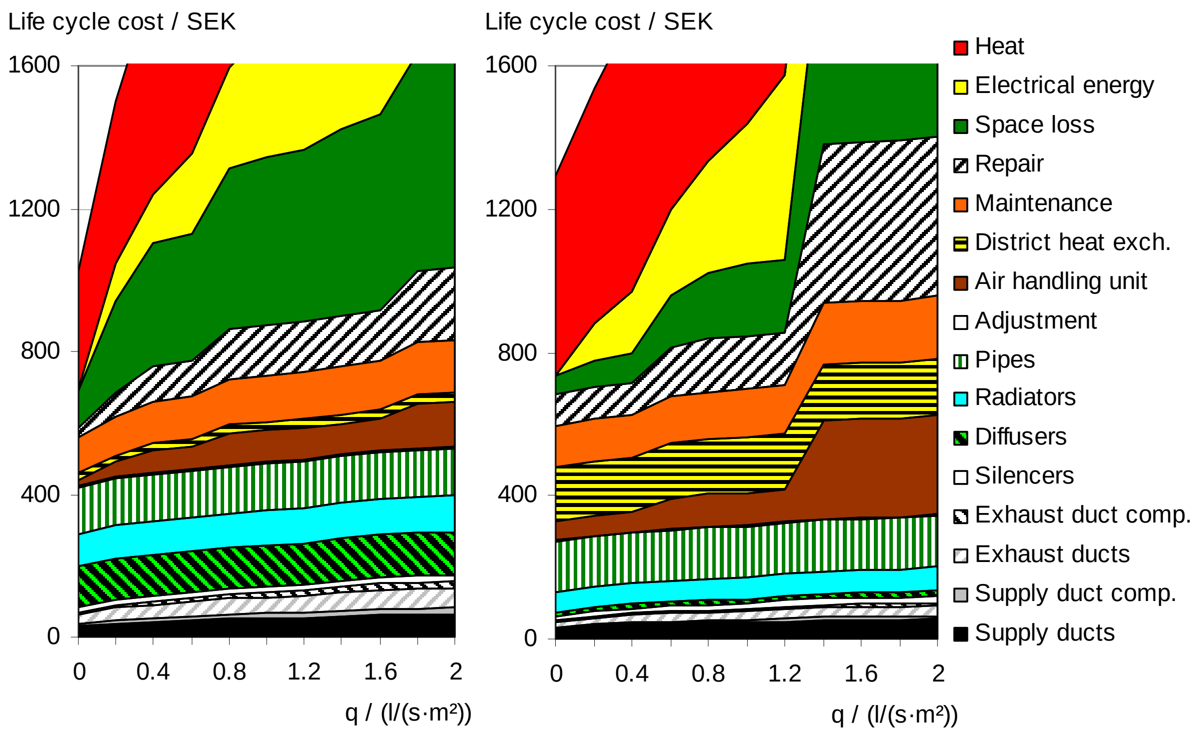

Figure 2. The life cycle cost as a function of the airflow rate for the multi family dwelling, to the left, and for the detached house, to the right, with exhaust ventilation system (E).

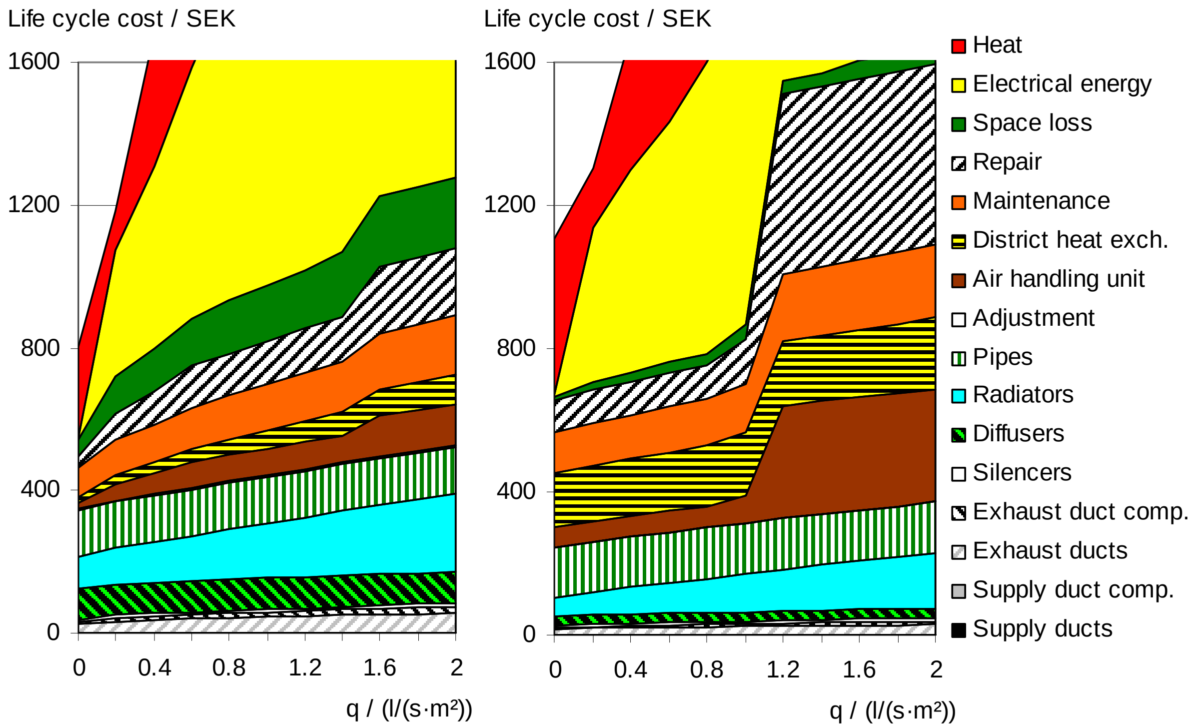

Figure 3. The life cycle cost as a function of the airflow rate for the multi family dwelling, to the left, and for the detached house, to the right, with exhaust ventilation system (E). There are no supply duct components or supply ducts within this system.

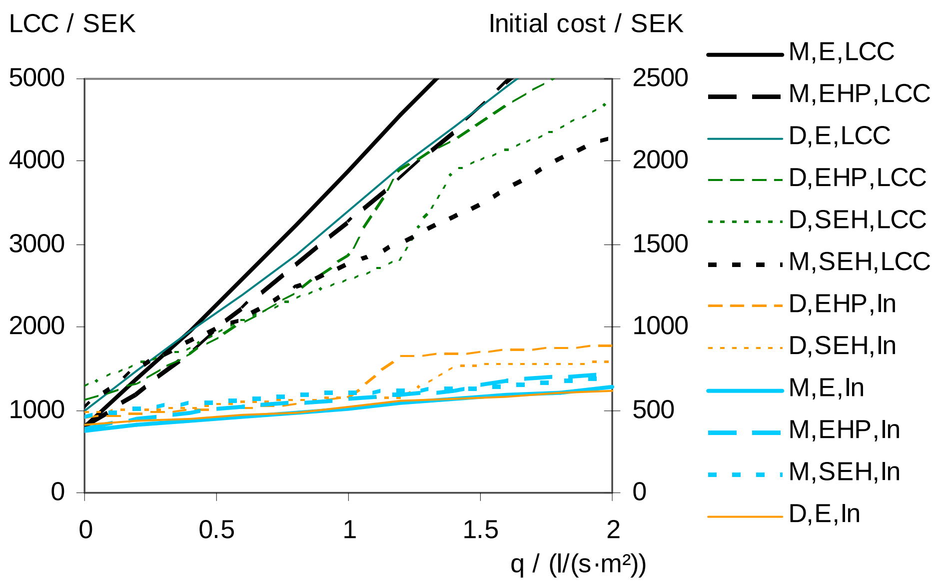

Figure 4. Life cycle cost (LCC) and initial cost (In) per floor area for the simulated buildings. E means exhaust ventilation, SEH means supply and exhaust ventilation, EHP means exhaust ventilation with heat pump.

Figure 4 shows the resulting life cycle cost for both buildings and all three systems together with the initial cost. In Figure 5, the health related cost according to the given examples is added for the detached house with exhaust ventilation and supply and exhaust ventilation. In Figure 6, k_1 is varied with k_2 = 2.23 and the optimal airflow rate is shown for the detached house.

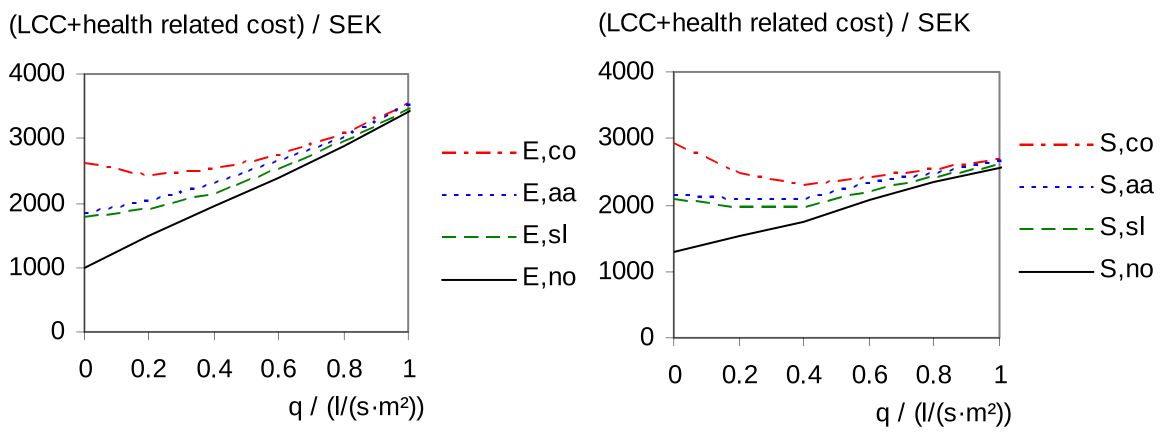

Figure 5. Life cycle cost (LCC) including health related costs for the simulated detached house. E means exhaust ventilation, S means supply and exhaust ventilation. The sick-leave example is denoted sl, the asthma example aa and the combination cost of the sick leave and asthma example co.

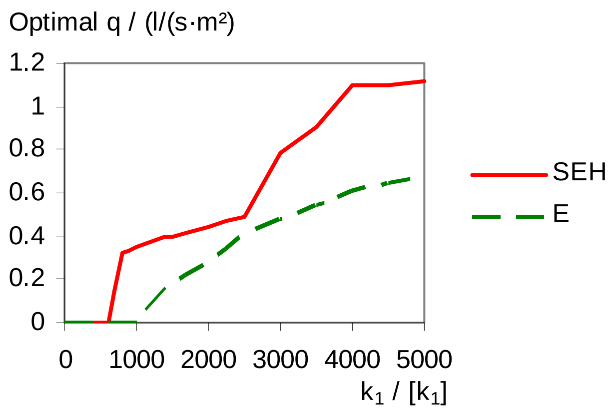

Figure 6. Optimal airflow rate, q, resulting in lowest sum of system life cycle cost and health related cost with k_2 = 2.23 for exhaust ventilation (E) and supply and exhaust ventilation (SHE) for the detached house.

DISCUSSION

The presented life cycle costs for heating and ventilation systems of multi family dwellings and detached houses show that heat is the largest part of the life cycle cost except for the system with heat pump where heat comes from electricity. The initial cost of the systems in dwellings is not negligible. It is also shown that supply and exhaust ventilation has a lower life cycle cost than exhaust ventilation at required airflow rates. The exhaust ventilation with heat pump is even lower even if exhaust systems have problems with controlling the air movements and draughts. There is also a problem with knowing the ratio between electricity and heat price in the future, which can make the heat pump unprofitable.

If the assumed health related costs is added to the costs of the heating and ventilation systems, an optimum is found in some cases. A combination of the two examples of health related costs is realistic and results in a lowest life cycle cost for supply and exhaust ventilation with an airflow rate slightly above the required 0.35 l/(s·m²). In fact, Bornehag [10] indicates that the airflow rate is lower than required, which is no surprise. If so, it means that the airflow rate should be increased in Swedish dwellings. The examples of health related costs does not take into account possible productivity increases and only takes into account the illness asthma. Even if asthma has high prevalence, there could be a number of other illnesses which costs money and are influenced.

With higher airflow rates, the relative humidity indoors would decrease which would decrease the risk of moisture problems, which in turn can be suspected to decrease costs for repair and for illnesses influenced by moisture problems. On the other hand, with higher airflow rate there is a risk of having air that is too dry during cold winter days.

A feature of the ventilation system would be to use a variable airflow rate which is controlled by the occupancy level. That means that the assumed benefit would be the same, the initial cost would be the same since the designed airflow rate is the same, but the energy use would decrease which in term would increase the optimal airflow rate.

Parametric studies of parameters, such as discount interest rates, building data or system data, would give different results, but most likely, the results would be rather close and representative for this kind of building. The health related costs are not analyzed in this study but varied in a parametric study. It must be noted that it is not well known how the airflow rate influences the health and comfort. Further, it is not well known and defined how to valuate that possible influence. Despite this, this study is a demonstration of a method which can be used to optimize airflow rates in buildings if the influence and costs on human health related to the airflow rate is known.

SUMMARY

Due to criteria for building energy efficiency today's buildings are better insulated and the envelope is more air tight. These improvements have led to a more comfortable buildings and lower running costs. However, the new indoor environments are more dependent on controlled ventilation system thus, the role of ventilation is emphasised.

Impurities in indoor air can originate from different sources: e.g. materials, structures, adjacent zones such as crawl spaces or attics or ventilation systems. Ventilation and pressure differences as well as leakage routes are key factors in understanding the concentrations of impurities in indoor air and their penetration to indoor air. This paper reviews the current understanding of the relationship between ventilation and its effect on sick building syndrome.

INTRODUCTION

In epidemiological population studies, moisture damage and microbial growth in buildings have been associated with a number of health effects, including respiratory symptoms and diseases and other symptoms [1-4]. The health effects associated with moisture damage and microbial growth seem to be consistent across different climates and geographical regions [5-8].

Microbiologically clean buildings probably do not exist, as some contamination in the structures begins to build up even during the construction phase. In the case of moisture damage, even after repairs, a significant amount of contaminated materials can remain in structures [9]. Therefore, the potential transport of pollutants from and through structures has great importance in respect of the design and construction of buildings. It is important to know which factors affect the release and penetration of pollutants and possible measures, such as sealing and pressurising, that can be taken to avoid this.

Ventilation does not directly affect on occupant health or perception outcomes, but the rate of ventilation affects indoor environmental conditions including air pollutant concentrations that, in turn, may modify the occupants' health or perceptions. The air pollutant concentrations in a given space depend on several factors other than air flow rate.

In steady state conditions where the ventilation air is well mixed to indoor air the concentration of indoor air can be calculated from simple balance equations. In practice, however the situation is not that simple. Typically pollution source is not uniform and mixing not complete thus, the concentration of pollutants in breathing zone may vary significantly depending on the air distributions pattern and the locations of the pollutant sources. Also the indoor pollutant generation rate (source strength) is usually not constant and has very high variations. Pollutants may be adsorbed by room surfaces during high concentration periods. Therefore non emitting surfaces may be emitting sources. Indoor pollutant source strengths are highly variable among buildings, and considered the biggest cause of the variation in pollutant concentrations among buildings [10].

In many buildings, ventilation rates are not constant. Often old residential buildings are running with a natural ventilation thus, the climatic conditions are strongly affecting on ventilation rates. Typically in office buildings ventilation systems may not operate at night or are operated at reduced level, and the rates of ventilation during operation may change with internal heat loads or with outdoor air temperature. Since the reduced night ventilation is usually created only by using exhaust fans, the pressure difference over the building is also dramatically changing between day and night. Pollutant concentrations may not reach equilibrium or they reach that until several hours after ventilation rates stabilize. Thus, the indoor air quality is also dependant on the operating schedule of the ventilation system.

In addition to above mentioned factors, the concentration of pollutants in indoor air is affected by following other major forces: the level and type of pollutants outdoors, possible recirculation of return air, the location of the outdoor air intake relative to outdoor air pollution sources including exhaust air outlets, pollution sources in the air handling unit, and pollutant removal from supply air filters, sorbents or deposition on duct surfaces. Therefore with a same ventilation rate indoor air quality may vary significantly due to variations in the quality of the supply air [11,12].

VENTILATION, PRESSURE DIFFERENCE AND PENETRATION OF IMPURITIES

Residential buildings often have mechanical exhaust ventilation, where intake air comes through inlets and cracks. In cold climates, inlets will cause a draught in winter and they are often closed, resulting in a high under-pressure indoors and forced airflow through cracks. Typically, mechanical exhaust ventilation creates an under-pressure of 5-10 Pa in the apartment [13] if the inlets are open. A field study [14] showed high air flow rates through leaks in the base floor to the apartment at a pressure difference of around 6 or 15 Pa, depending on the speed of the exhaust fan. Field measurements [15,16] have shown evidence of fungal spores transported indoors from a crawl space. According to a literature review by [4], concentrations of viable fungi in the indoor air of residential buildings vary between 10–100,000 cfu/m^3. Although the range is wide, average levels of 100–10,000 cfu/m^3 are typical. Lower levels have been reported in winter not only in a cold climate [17] but also in a subtropical climate [7].

Concentration of fungal spores and ventilation system

Many studies have proven that the concentration of microbes outdoors is clearly higher in summer than in winter. However, there is only a very limited number of reports on concentrations in the crawl spaces or attics, even though impurities might be transported from there as well. Especially crawl spaces could have favorable conditions for fungal growth especially in the summer, when the outdoor air is usually warmer and has a higher moisture content, which is transported via ventilation to the crawl space. The extra moisture condensates to the surfaces in the crawl space giving better conditions for microbes in the surfaces.

The concentrations of viable fungal spores in the crawl spaces were a few thousand cfu/m^3 [16]. There are no guidelines or sufficient reference data in Finland for the concentration of fungal spores in crawl spaces. The high concentrations of fungal spores in the air under the floor may exposure occupants to fungal spores or fungal metabolites if there are cracks or holes between the spaces.

In subartic climate, in summer the concentration of fungal spores indoors is usually smaller than the concentration outdoors, whereas in winter the indoor/outdoor –ratio often is over 1 in the apartments as well as in the offices [18]. Generally outdoor air is the main source of fungal spores and the seasonal variation is wide; three to four order of magnitude in subartic climate (Finland), [e.g. 19,16] .

Indoor/outdoor –ratio had been higher in buildings with mechanical exhaust ventilation than in buildings with mechanical supply and exhaust ventilation [e.g. 19]. In a study [16] such a relationship couldn't be found. A reason for this might be that in this study all the measured buildings with mechanical supply and exhaust ventilation were primary schools or day-care centres, and the measurements were done during the working day and the influence of outdoor air to indoor air concentrations could not be avoided. Also the clothes of the children might be a potential carrier of spores [20].

Transport of fungal spores indoors

It has been found out in many studies that in indoor air particle concentration is highly influenced by outdoor particle concentration. Also the type of the particles is similar. According to [16] the total concentration of fungal spores did not correlate statistically between indoor and crawl space but higher concentrations in crawl spaces could be seen elevated concentrations indoors as well. Crawl space concentrations of fungal spores were tens or thousands of times higher than indoors.

However, when specific species of fungal spores were examined a relationship was found in Acremonium which is not typical microbe indoors, indicating presence of high counts in crawl spaces reflecting as high counts in indoor air.

The size of a particle has an important role in respect of penetration of a crack in a building envelope, thus, it is important to study the size distribution of fungal spores to estimate their penetration indoors. The size distribution is varying depending on microbial species. According to [16] fungal spores analysed from indoors, outdoors and crawl space were similar in shape when size distributions were compared. The highest counts were impacted (Andersen) in stages whose average aerodynamic diameter was between 1.4-2.6 μm. This size range is interesting as the alveolar deposition of particles above 0.5 μm has a maximum at about 3 μm. Therefore, even small changes in particle size around this maximum value effect on the deposition pattern of particles [21].

There are many factors affecting the size of fungal spores such as age, dehydration, agglomeration and relative humidity of surrounding air. In a study [21] it was found out that the most common fungal spores, such as *Penicillium, Cladosporium, Aspergillus* and yeasts, have their maximum concentrations in the size range 2.1 – 3.3 μm. In this study, the maximum counts were observed in smaller fungal spores, between 1.4 – 2.6 μm, indicating that the fungal spores are mainly detected as single spores and not as aggregates.

Air change rate and air flow patterns

In [22] it was found out that the levels of airborne microbes were higher in naturally ventilated office buildings than in offices with mechanical ventilation. In a wide review by [23] it was found out in that there is a strong evidence between ventilation and the control of air flow directions in buildings and the transmission and spread of infectious diseases such as measles, TB, chickenpox, anthrax, influenza, smallpox, and SARS. However, they didn't found data to support the specification and quantification of the minimum ventilation requirements in schools, offices and other environments in relation to the spread of airborne infectious diseases.

Particles and their penetration indoors

It is not only the moisture and microbes which can cause problems, but also exposure to fine particles. According to recent studies particles smaller than 2.5 μm in diameter can reach the lower respiratory system and cause adverse health effects [24,25]. However, usually the limit value for respirable particles is considered between 2.5-5 μm. Comite European de Normalisation (CEN 1992) and International Organization for Standardization (ISO 1992) both define the limit value for respirable particles 4 μm. It is still unclear what causes the health effects of such particles, but it seems that the type of particle has some role. According to studies [26,27] sand dust is not so harmful as particles of the same size originating from the combustion of fuels. About 70-90% of the viable fungi in indoor air have been estimated to be in the respirable size fraction [7]. The median aerodynamic diameter for fungi in indoor air is typically 2-3 μm [28]; the highest concentrations of airborne viable fungi are also usually in the same size range.

A number of studies have focused on properties of ambient particulate matter in recent years. Elevated concentrations of aerosol particles have been associated with increases in mortality as well as adverse health effects [29] Even though the particulate matter outdoors and its penetration indoors is very important topic, it is typical for all kind of buildings and not specific to buildings with SBS symptoms.

Many studies have been carried out to estimate the penetration of particles through cracks. [30] report penetration factors of 0.5-0.8 for particles in a size range of 0.5-2.5 μm. [31] found that at a pressure of 5 Pa 40% of 2-μm particles and <1% of 5-μm particles penetrate through horizontal slits of a height of 0.5 mm. In a study by [32] particles of 0.1-1.0 μm are predicted to have the highest penetration efficiency, nearly unity for crack heights of 0.25 mm or larger at a pressure difference of ≥4 Pa. These results are important, since the peak of the size distribution of fungal spores is often between 2-3 μm and is very suitable for penetration. [33] reported that Sulfur-containing particles of sizes below 1.5 μm penetrated a office building's filter unit in ventilation channel easily, elemental removal efficiency of the filter being only 7%. Only a limited number of studies have been carried out on those structures commonly used in buildings. [32] predict, by a simulation model, that penetration through mineral wool insulation is negligible. In reality structures mineral wool insulation is seldom perfectly installed, and timber frame structures are, in respect of particle transport, a combination of cracks, surface contacts, and mineral wool.

Ventilation rate of a building affects indoor particle concentrations, and as the fluxes from indoor to outdoor and outdoor to indoor are typically different, indoor air might become contaminated from other sources than outdoors, such as sources from crawl space or from contaminated building materials. Indoor concentrations are reduced by deposition and increased by re-emission of deposited material. The amount of deposited material depends e.g. on deposition rate, re-emission rate and the cleaning frequency.

Recent studies on particle deposition to indoor surfaces make it clear that the deposition rate varies broadly across conditions. Particle size is undoubtedly important. However, other factors can also influence the deposition rate significantly including interior furnishing (quantity and type of the surface) and the indoor air movement. According to [34] the air movement from zero to 0.142 m/s (which is a typical air velocity indoors) increased the deposition rate by 15% for 1 μm particles and by 24% for 1.9 μm particles. Furnishing had a great impact deposition rate; deposition rate increased over 100% for 1 μm particles at air velocity 0.054 m/s and 78% for 2.5 μm if the empty room was furnished [34]. The highest deposition rates had been reported mainly from field settings [e.g. 30], where the control of experimental settings is limited. Even in the best conditions it is difficult to isolate deposition from the many competing factors that can influence airborne particle concentrations.

In studies [30-32], penetration factors of particles within range of 0.5-2.5 μm have been between 0.5 and 1 depending on the dimensions of studied cracks. These results cover the size distribution of fungal spores; and the peak of spores of 1-2 μm seems to be very capable for penetration if the crack height is higher than 0.1 mm [32]. [32] have estimated that the penetration through mineral wool insulation is negligible. In [16] study mineral wool was inside a real base floor structure, and still the results showed penetration occurred, due to the installation of mineral wool which is seldom perfect allowing some routes for particles. The penetration factors determined by [16] were significantly different than in former studies indicating that surface contacts of mineral wool and other building elements are likely to have important effect on the penetration. The importance of surface contacts seems to be confirmed by tests; e.g. for 1.3 μm particles the penetration factor at 20 Pa was 0.19 when the boards didn't have any penetration and 0.15 when the four 10 mm holes on the surfaces were open, when the pressure was decreased to 6 Pa the penetration factors were 0.08 and 0.03 respectively. Thus, the holes on the surface boards did not have any effect on the measured penetration of particles but probably the small leakage routes between surface contacts of mineral wool and other building elements.

[35] measured particle and fungal spore penetration through a wooden structure in laboratory. They found out that the penetration was roughly the same within particle size range of 0.6-2.5 μm. The penetration was highly dependant on the pressure difference on the and not that much on the holes in surface boar of the structure (the structure included mineral wool layer under the structure acting as a filter).

Particle emissions from HVAC components

Fibre emission from HVAC components such as round silencers can be remarkable pollutants in the indoor air. In a field study [36] particle emission from HVAC components and occupational exposure were studied in 10 office, school and day care centres. The surface fibre dust density varied in the range of < 0.1 – 4.9 fibres/cm^2 and the accumulation during two weeks period in the range of < 0.1 – 2.6 fibres/cm^2. Fibre concentration in the supply air varied between 0.01-85 fibres/cm^3(fibre length >20 μm). In the study the silencers were also studied in laboratory but no relationship between silencers surface area to the particle emissions could not be generally be drawn but it was feature of different silencer. Detailed results from that study are presented by Kovanen in this Clima2007 congress.

Ventilation rate and VOCs

There are many studies in which the VOC concentrations are evidently lower in buildings with higher ventilation rates. In United States new buildings were measured, built with low-VOC and conventional building products [37]. In that study the air change rate varied between 0.14 to 0.78 ach, TVOC concentrations varying between 1.5 to 2.7 mg/m^3. In a Finnish study by [38] “Allergy House” building with 1.7 ach had the TVOC concentration 10-fold lower than in reference building with 0.8 ach. However, also the materials in allergy building were low emitting, thus, the low concentrations are not only because of higher ventilation rate.

In a recent study by [39] there was not a clear trend showing the concentrations of VOCs being lower in buildings with higher ventilation rate. In the newly finished buildings, the TVOC concentration was significantly lower ($p<0.01$) in the buildings with mechanically supply and exhaust air than in the buildings with mechanical exhaust air. The TVOC and formaldehyde concentrations were also lower ($p<0.01$) in the 6- and 12-month-old buildings with combined mechanical ventilation.

DISCUSSION

Strikingly, there are only a few studies in which the ventilation system of the measured building was mentioned and even less reports of the ventilation rate. However, the ventilation rate and pressure differences as well as leakage routes of the studied building/zone are key factors in understanding the concentrations of impurities in indoor air and their penetration to indoor air. Impurities can arrive indoor air from materials and their surfaces or adjacent zones such as crawl spaces or attics. Also the filters and their contamination and its influence indoors are not well known.

Effect of household specificity on exposure time to CO_2 when balanced ventilation systems are used

Olivia Guerra Santin, Jan van Ginkel and Laure Itard

Corresponding email: o.guerrasantin@tudelft.nl

SUMMARY

The purpose of this study is to evaluate the relevance of household characteristics on exposure time to CO_2 in houses with balanced ventilation. Statistical tests were conducted to measure the significance of household differences on time indoors. Household scenarios and ventilation scenarios were constructed to determine the level of CO_2 indoors. The production of CO_2 was calculated with the metabolic rate per age of the members of the household. Households are exposed to levels of CO_2 higher than 1000 ppm in houses with low infiltration rate. In practice, the air flow does not comply with the requirements because of the use of the system and for lack of maintenance. High levels of CO_2 (over 5000 ppm) were not shown to be a risk in this study, but exposure to levels of CO_2 between 1000 and 2000 is used as an indicator of other pollutants indoors.

INTRODUCTION

CO_2 emissions in the indoor environment may have negative effects on the occupants. The effects produced by exposure to CO_2 have been studied extensively in the past [1,2]. Under concentrations less than 5000 ppm, CO_2 is not particularly toxic, but is accepted as an indicator for the presence of other contaminants and therefore for indoor air quality. Concentrations above 1000 ppm are related to complaints like fatigue or headache. Some studies tend to show that certain subjects already show these complaints at concentrations as low as 600 ppm [1,2] In the indoor environment of dwellings, CO_2 emissions, as an indicator of air quality, may affect more vulnerable occupants, such as children, the elderly, and people with poor health condition, because they tend to spend more time in the dwelling [3]. In reducing such effects, ventilation has a prominent role. The volume flow rate of ventilation needed to keep the carbon dioxide concentration at the desired level depends on the production rate of CO_2 in the indoor environment. CO_2 levels depend on several factors closely related to household composition, size of household, age and activities of the dwellings occupants. Building regulations set minimal ventilation flow rates per squared meter but recent studies have shown that these minimal ventilation rates may not be sufficient for bedrooms [2]. This research aims to study if differences in households can lead to differences in exposure to CO_2, and therefore, to different requirements of ventilation flow rates.

In order to calculate the indoor exposure to CO_2 in Dutch dwellings, it is necessary to determine the time of exposure, the type of activities realized indoors and the sources of CO_2 found indoors. For this, the Dutch Time Budget Survey (TBO) was used. The exposure time was analyzed by statistical means in order to test the influence of occupants' and households' characteristics on the exposure to CO_2. Scenarios of exposure per household were constructed to test the relevance of differences on exposure time. CO2 production and needed ventilation flow rates for the different household scenarios are then modelled, calculated and compared.

METHODS

Household specificity

The data of the TBO were collected by means of a self-administered diary. Respondents were asked to record their daily activities and place of activities during a period of one regular week. Only groups of subjects with a sample large enough for the statistical analysis were used. Mean times were calculated for the total time indoors, the time spent in spaces of the house and the type of activity realized (table 1).

Table 1. Categories of activities

Category (Place and activity level)	Sub-category (Activities)
Kitchen (medium level)	Cooking
Living room (medium level)	Sporting, household work, caring for pets and plants, playing indoors, childcare
Living room (low level)	Eating, studying and writing, group activities, working at home, hobbies, telephoning, reading, watching TV
Bedroom (very low level)	Sleeping
Bathroom (low level)	Personal care

The survey collected information of 1813 respondents from 12 years and older, therefore, the exposure times of children below 11 years old is not taken into account. It was realized during regular days, so variation in exposure time in other days such as holidays is neglected. In the case of non-response, it can be attributed to lack of time due to a special activity (e.g. birthday), therefore it does not cause bias in the data collected [4]

Statistical Analysis

In the Kolmogorov-Smirnov and Shapiro-Wilk tests of normality, the distributions per place and level of activity were shown to be non-normal with a large percentage of the Sig. values falling below 0.05; though the histograms of some activities showed resemblance with a normal distribution, and the normal probability plots showed a reasonable straight line. Therefore, a non-parametric test was conducted to evaluate the significance of the differences in exposure time within the groups. The Kruskal-Wallis test showed very significant results, therefore adding the fact that the sample is large, parametric tests were conducted to identify the location of the differences in exposure time within the groups, as well as the magnitude of the differences. An independent-samples t-test was conducted for groups of gender, and ANOVAs for groups of age and household size. In order to determine the magnitude of the differences, the eta-squared per variable was obtained, considering an eta-squared of 0.02 as a small effect, 0.06 as moderate effects and 0.12 as large effect [5].

Differences in exposure time attributable to gender

An independent samples t-test (ANOVA) was conducted to analyse the relevance of the differences in exposure time in different places indoors that are attributable to gender. The test showed that there is no significant difference for time spent in the bedroom (p-value=0.379) and the bathroom (p-value=0.745). The differences are significant for the time spent in the living room (p-value=0.013) and the kitchen (p-value=0.00). The differences between time spent in the different spaces were shown to be small for the living room (eta-squared=0.01), bedroom (eta-squared=0.029), and bathroom (eta-squared=0.013). The differences for the time spent in the kitchen do show a large effect (eta-squared=0.16). The results of the t-test showed that there is a significant difference for low level activities (p-value=0.00) and high level activities (p-value=0.00). The differences in the mean of low level activities show a small effect (eta-squared=0.001), while high level activities showed to have large effect (eta-squared=0.18). In other words, gender affects principally the time spend doing high level activities in the kitchen.

Differences in exposure time attributable to household size

A one-way analysis of variance test was conducted for analysing the relevance of the differences in mean times within groups of household size. Subjects were grouped according to the size of the household they belong. The households of 3 persons were not further considered because of the lack of representation within the sample. The results showed that there is a significant difference for the mean scores of the time spent in the living room (p-value=0.00), bedroom (p-value=0.012), and kitchen (p-value=0.005). There is no significant difference for the time spent in the bathroom (p-value=0.72). An eta-squared calculation showed that the differences for time spent in bedroom (eta-squared=0.007), and kitchen (eta-squared=0.008) have a small effect; while the differences for the time spent in the living room (eta-squared=0.059) shows a moderate effect. Post Hoc comparisons showed that 2 person's households spend more time in the living room, followed by 4 person's households. Singles tend to spend less time in the living room. 4 person's households spend more time in the bedroom, while singles and couples spend less time. The time spent in the kitchen is lower for couples than is for singles and 4 person's households. Low and high level activities showed to be significantly different among the groups (p-value=0.00). Nevertheless, the eta-squared calculation showed only a small effect for low level activities (eta-squared= 0.058), and moderate effect for high level activities (eta-squared=0.035). Post Hoc tests showed that singles spend less time in high level activities than 4 person's households and couples. Couples are the households that spend more time involved in high level activities. Households of 4 persons and singles spend less time in low level activities than couples.

Differences in exposure time attributable to age

A one-way analysis of variance test was conducted to estimate the effect of age in variations of mean times in the indoor environment. Six groups were formed according to the age range of the subjects (Group 1: 12-24, Group 2: 25-34, Group 3: 35-44, Group 4: 45-54, Group 5: 55-64, Group 6: 65 and older). The results of the ANOVA for the time spent in different places showed a significant difference for the time spent in the living room (p-value=0.00), kitchen (p-value=0.00), and bedroom (p-value=0.00). The mean differences for the time spent in the bathroom did not show significant difference (p-value=0.095). An eta-squared calculation showed large effects in the differences on the means for time spent in the living room (eta-squared=0.20), and in the kitchen (eta-squared=0.15). The effect is moderate for the time spent in the bedroom (eta-squared=0.06). Post Hoc comparisons showed that the time spent in the living room and in the kitchen increases with age. The time spent in the bedroom also increases with age, except for group 1 (12-24 years), which tend to spend more time in the bedroom. Significant differences were found to have large effects for low level activities (p-value=0.00, eta-squared=0.26), and high level activities (p-value=0.00, eta-squared=0.13). The time spent in high activities increases with age. The time spent in low level activities increases with age, except for group 1 (12-24 years) which tend to spend more time than groups 2, 3 and 4; but not as much as groups 5 and 6.

The trends on time spent indoors are shown in table (2). The exposure time in all cases is higher for women and elderly people. Though there is a relation between household size and mean times, the variations do not show a clear trend. The time spent in the bathroom is considered not to be different for the different groups, and the time spent in the bedroom shows little variation.

Table 2: Trends in time spend in different rooms per occupants' characteristics

Place / activity level	Gender		Household size		Age range	
	Effect	Trend	Effect	Trend	Effect	Trend
Bathroom	-	-	-	-	-	-
Bedroom	-	-	Small	4>2,1	Moderate	Increases with age
Living room	Small	Females > males	Moderate	4,2>1	Large	
Kitchen	Large	Females > males	Small	4,1>2		
Low level activities	Small	Females > time	Small	2>4,1		
High level activities	Large	Females > time	moderate	2>4>1		

Based on these data, four different scenarios are identified that could cover the bandwidth of Dutch households. The household's scenarios are: 1a) single male adult 20-24 years old, 1b) single female elderly, 2a) 4 person's household composed by two adults and two children (12 years), and 2b) 4 person's household composed by two adults and two children (20 years)

Method for the calculation of exposure to CO_2

For this research we assumed that CO_2 is produced only by human beings. Other sources of CO_2 production like cooking hobs, boilers and plants are neglected. The CO_2 volume flow rate in a room qco2(m^3/s) can be described in steady state as:

qco2 = V.(Ci-Co)

Where Co is the CO_2 concentration of the fresh air supplied to the room (usually about 350 ppm) and Ci is the concentration of CO_2 in the air leaving the room. V is the volume flow rate of air. It is assumed that the quantity of air leaving the room is equal to the quantity of air supplied to the room. For Dutch living rooms and bedrooms of average dimensions steady state conditions are assumed to be achieved after 2 hours constant occupancy when the air change rate (ACH) is above 0,8 h-1 [2]. Once qco2 and V are known, it is possible to calculate the concentration of CO_2 in the room (Ci).

Calculation of the CO_2 production rate qco2

In general, energy production in living organisms is obtained from the oxidation of glucose, see equation 1.

$C_6\ H_{12}\ O6 + 6O_2 \rightarrow 6CO_2 + 6H_2O$ - 2843 KJ mol-1 glucose, (1)

Under aerobic conditions the energy consumption by this reaction is 2843 kJ per mol glucose. At the same time, 6 mol of CO_2 are produced. This means that the consumption of 474 kJ by the human body produces 1 mol of CO_2. With the specific volume of CO_2 being 22,4 m3/kmol, an energy consumption rate of 1.0 J/s will result in 4.7×10^{-8} m^3/s of CO_2.

The carbon dioxide production rate follows therefore from the energy consumption rate of the human body. This energy consumption rate is called metabolic rate and is dependent on the activity performed and the surface area of the body. The calculation of the metabolic rate is conducted according to [6]. It is assumed that the metabolic rates at a same level of activity and age are identical for men and women. The surface area of the body Adu (m^2) is calculated using the formula of DuBois [6].

Adu= 0.202.W0,245 .H0.725

where W is the body weight in kg and H the body height in m.

In table 3, calculated metabolic rates and CO_2 production rates are given as a function of age and activity.

Table 3: Metabolic rates and CO_2 production per age

Age	Weight (m)	Height (kg)	CO_2 production [m^3/s] per level of activity			
			Sleeping	Low	Middle	High
12	28	1.54	2.4 $x10^{-6}$	5.4 $x10^{-6}$	8.9 $x10^{-6}$	$12x10^{-6}$
20	74	1.84	4.1 $x10^{-6}$	9.3 $x10^{-6}$	15 $x10^{-6}$	21 $x10^{-6}$
35	70	1.7	3.8 $x10^{-6}$	8.5 $x10^{-6}$	14 $x10^{-6}$	20 $x10^{-6}$

Calculation of the concentration of CO_2 at room and dwelling level

The concentrations are calculated for a typical Dutch terraced house with three bedrooms. The Dutch Building Decree prescribes the following minimum flow rates given in table 4 [11]. The floor areas and the minimum ventilation flow rates for this dwelling calculated according to the Dutch building decree are summarized in table 5.

Table 4: Minimum flow rates

	Living area (bedrooms and living room)	Kitchen	toilet	Bathroom
Flow rate (m^3s^{-1})	$0,9x10^{-3}$ per square meter with a minimum of 7 $x10^{-3}$ total	$21x10^{-3}$ total	7 $x10^{-3}$ total	14 $x10^{-3}$ total

Table 5: Areas and minimum flow rates for typical Dutch house

	Living room + kitchen	Bedroom 1	Bedroom 2	Bedroom 3	Bathroom
Area (m^2)	37,1	9,9	9,7	6,0	6,6
Flow rate (m^3s^{-1})	33,4 $x10^{-3}$	8,9 $x10^{-3}$	8,7 $x10^{-3}$	7 $x10^{-3}$	14 $x10^{-3}$

To limit costs, balanced ventilation systems are mostly designed to meet the requirements on the minimum ventilation rates, but not more. Furthermore, the legislation prescribes that these minimum ventilation flow rates must be achieved by the system when it runs at its highest level (level 3). Balanced ventilation systems in dwellings are mostly equipped with switches that can be put in levels 1, 2 or 3. Studies by Hasselaar [7] and Soldaat [8] show that the systems are running most of the time in level 2 in which only 50 % of the capacity is available. At night time, the system mostly runs in level 1 due to noise pollution from the ventilator, with only 30 % of the capacity. Furthermore, studies have shown [9] a reduction of the capacity of 10% a year, due to a too low level of maintenance (cleaning). After 5 years, the maximum capacity is reduced to 65 % of the original capacity. The total amount of fresh air supplied to the dwelling is also dependent on the air-tightness of the construction. The air-tightness of Dutch new dwellings should not exceed 200 dm^3/s per 500 m^3 building volume. For the reference dwelling studied, the air flow rate should be lower than 200 dm^3/s, which is about 1.5 dm3/sm2. In the calculations shown in this paper, we used this value as the upper limit of the infiltration flow rate, referred as “high infiltration rate” in the graphics. In the Dutch mandatory energy performance norm [10], it is assumed that an air infiltration flow rate lower than 0.4 dm3/sm2 cannot be achieved. We used this value as the lower limit for the infiltration rate (referred as “low infiltration rate” in the graphics).

Four household scenarios and six ventilation scenarios are studied for the reference dwelling. The household scenarios were described earlier in this paper. The six ventilation scenarios are:

1. Non optimal use of a 5 year- old system: 50 % maximum capacity in living room, kitchen and bathroom, 30 % maximum capacity in bedrooms (night). The maximum capacity is 65 % of the mandatory capacity as given in table 4. With 1) low infiltration rate and 2) high infiltration rate

2. Non optimal use of a new system: 50 % mandatory capacity in living room, kitchen and bathroom, 30 % mandatory capacity in bedrooms (night). With 1) low infiltration rate and 2) high infiltration rate
3. Optimal use of a new system: 100% mandatory capacity in living room, kitchen, bathroom and bedrooms. With 1) low infiltration rate and 2) high infiltration rate

Calculation of exposure time

The time spend doing an activity (sleeping, low level or high level) is calculated from the statistical data for each room (living room, three bedrooms, kitchen en bathroom) and each person of each household type (1a, 1b,2a, 2b). The CO2 concentration per room per activity is calculated according to the method described here above, taking into account the number of persons present in the room. The exposure time per person per household is then obtained by adding the times of exposure to a certain level in the different rooms of the house. Four types of exposure levels are distinguished, according to the findings reported in the introduction. These exposure levels are above 2000 ppm, between 1000 and 2000 ppm, between 600 and 1000 ppm and lower than 600 ppm.

RESULTS

For single person households, scenarios 2 and 3 (fig 2 and 3) have a good performance; there is only a slight variation in exposure to CO2 levels between the optimal and non-optimal use of the new system. The exposure to higher levels of CO2 increases in dwellings with low infiltration rate and non-optimal use of 5 years old system (scenario 1.1). Scenario 1.2 (high infiltration rate and non-optimal use of old system) shows also a good performance for single person households (fig 1). For four person households, there is little difference between old and new ventilation systems when these are not optimally used. In dwellings with low infiltration rate, the exposure to levels of 1000 to 2000 ppm is very high. The exposure decreases in dwellings with high infiltration rate, in which the exposure is mainly to levels of 600 to 1000 ppm. The exposure decreases drastically for scenario 3 (fig 3), but the exposure is still high for households of 2 adults and 2 children of 20.

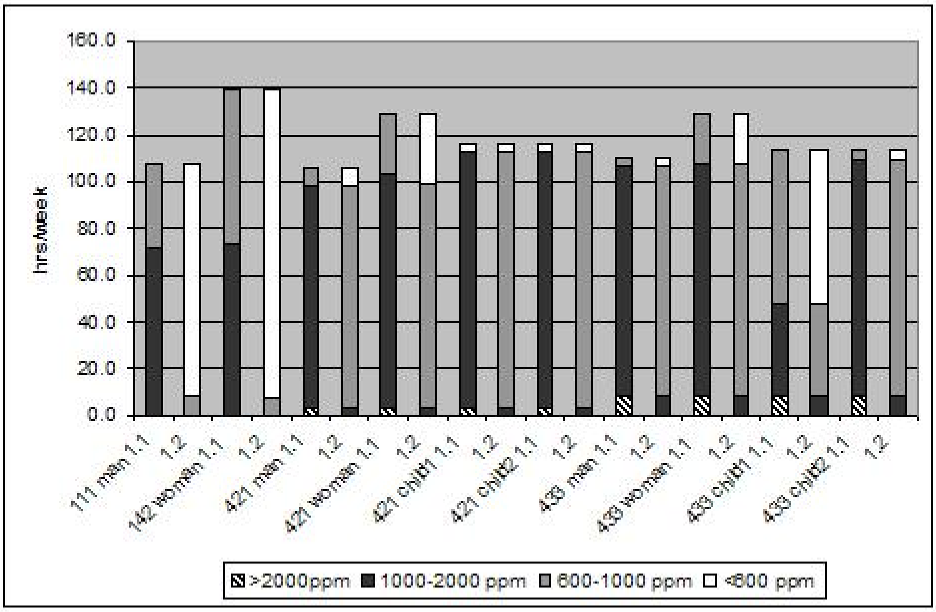

Figure 1: Time of exposure to levels of CO2 per occupant in ventilation scenario 1.1) airtight dwelling, and 1.2) no airtight dwelling, child1= bedroom 2, child2= bedroom 3

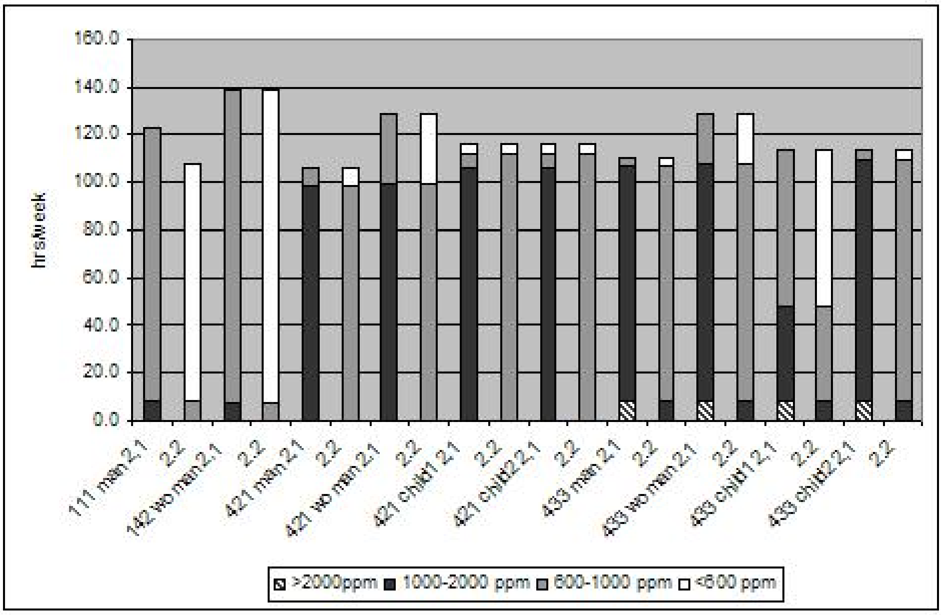

Figure 2: Time of exposure to levels of CO2 per occupant in ventilation scenario 2.1) airtight dwelling, and 2.2) no airtight dwelling, child1= bedroom 2, child2= bedroom 3

In dwellings with low infiltration rates with a ventilation system not used at its optimal capacity, all occupants show a high exposure time to CO2 levels of 1000 to 2000 ppm. In addition, large households may be at risk of exposure to levels of CO2 of more than 2000 ppm for few hours per week. For these dwellings, if the ventilation system is optimally used, the time exposed to high levels of CO2 decreases; though the occupants may be still exposed to CO2 levels of 600 to 1000 ppm. In dwellings with a high infiltration rate, regardless the age or use of the ventilation system, large households are exposed to levels of CO2 of 600 to 1000 ppm, which is under the level recommended by the Ashrae standards; and singles are not exposed to harmful levels. Nevertheless, the exposure of children to possible harmful levels increases when the ventilation system is older than 5 years.

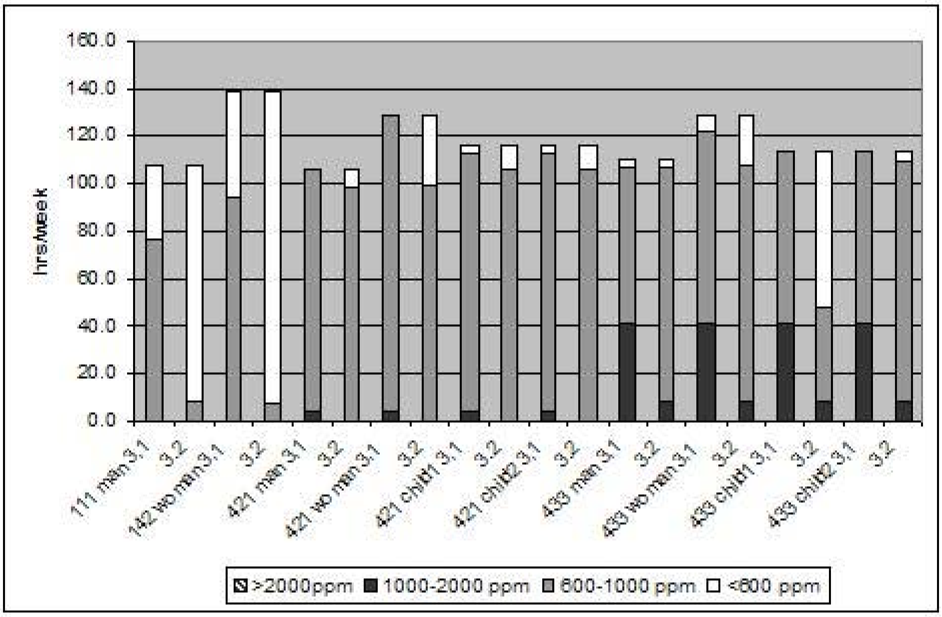

Figure 3: Time of exposure to levels of CO2 per occupant in ventilation scenario 3.1) airtight dwelling, and 3.2) no airtight dwelling, child1= bedroom 2, child2= bedroom 3

CONCLUSION AND DISCUSSION

From this study, we can conclude that the regulation on air flow rates does not comply with the needed ventilation for large households composed by 4 adults. Therefore, large household are at risk, which confirms some results of Hasselaar [7].

Because of the use of the system (users regulate the levels), the ventilation is in practice not enough. This could be solved by having the minimal rates already obtained in the lower levels. In addition, lack of maintenance of the ventilation systems decreases their capacity of satisfying the needed flow.

The statistical analysis of time spent indoors, showed significant differences within different age ranges and gender, nevertheless, differences in exposure between one person household may be neglected under the assumptions we made in this paper.

This research showed that differences in exposure time can be relevant for determining the ventilation required for a good indoor air quality. Though carbon dioxide does not cause health effects at the concentration levels considered for the analysis, it can be used as an indicator of the presence of other harmful substances in the indoor environment. Some groups of people are more exposed to the effects of the indoor environment. The statistical analysis of the time spent indoors showed that the elderly and women tend to spend more time in the indoor environment (table 2). The calculation of exposure time to CO2 showed that large households are more exposed to higher levels. For the statistical analysis, only Dutch people older than 12 years were considered. The exposure time of young children, and households with non-Dutch backgrounds should be considered for further research. Exposure to levels above 2000 ppm exists only for short time. In our calculations, this time is probably overestimated, because we worked with steady state concentrations. In case of short staying times, the steady state conditions would probably not be achieved. In further work, this should be taken into account.

Office noise and work performance

Valtteri Hongisto

SUMMARY

Field studies have shown that speech is the most distracting sound in open-plan offices. On the other hand, laboratory studies have shown that speech impairs the performance of cognitively demanding work tasks, e.g. reading and memory-recall tasks. The sound level of speech does not determine the degree of distraction caused by speech. Instead, Speech Transmission Index, *STI*, which correlates with speech intelligibility can explain the distracting power of speech much better. *STI* can be determined also between workstations in open offices. This study presents a new general model that gives the decrease in work performance as a function of *STI*. Work performance decreases with increasing *STI*. The average performance of cognitively demanding tasks decreases at least by 7 percent when speech is highly intelligible. In practical design, the ability to calculate the payback time of investments leading to proper acoustical environment is important. The new model represents the missing link in such economic estimations. This paper is based on Reference [1].

INTRODUCTION

According to field surveys, noise is often the most detrimental factor of the indoor environment in open-plan offices [2-4]. Speech is usually the most distracting sound source in offices. Sounds of phones ringing and walking on corridors are on the second place. Ventilation noise and traffic noise are very seldom causing distraction.

The effects of continuous steady noise, such as ventilation noise or pink noise, on performance have been studied several decades. Steady noises have not seen to affect work performance directly. Colle and Welsh (1976) were among the first researchers to study the effect of speech on the performance of memory-recall tasks. The effect of speech on task performance was strong [5]. Their study has been repeated by many researchers using different tasks and sound environments. It is a well-known fact that the speech interferes with the performance of cognitively demanding work tasks. However, the distraction mechanism of speech on working memory is still under research and this is beyond the scope of this study.

Colle (1980) found that it is not the level of speech that causes the distraction but speech intelligibility [6]. The decrease in performance was almost independent of speech level within 40 to 80 dBA (Colle 1980). At 20 dBA, performances in silence and speech did not differ from each other. This was obvious because the level of consonants above 500 Hz fell below the auditory threshold level.

The aim of this study is to emphasize the important finding of Colle and to convert the finding into such form that it can be applied in room acoustical design.

Currently, there are no methods for showing that room acoustical improvements enhance work performance. Therefore, the investments on room acoustical conditions are difficult to justify as their positive effects on workers are unknown.

The primary aim of this study is to present a new general model that predicts the decrement in work performance as a function of speech intelligibility.

METHODS

Speech intelligibility is a subjective measure that describes the percent of correctly heard items. Items can be syllables, words or sentences. Speech intelligibility can be determined by using listening tests.

A good estimate of subjective speech intelligibility can be made by measuring the Speech Transmission Index, *STI*, between the speaker and listener. The correlation of *STI* and subjective speech intelligibility is presented in Figure 1.

STI has been used for 20 years to characterize the speech intelligibility in auditoria, class rooms and telephone communication. It has been started to apply in open offices recently [7-9]. The *STI* of an open-plan office is easy to measure and most acoustic consultants own the apparatus to measure *STI*. Therefore, the selection of *STI* as the explaining parameter of the model is meaningful and topical. The measurement arrangement of *STI* between office workstations is presented in Figure 2.

The subjective meaning of *STI* is presented in Table 1. *STI*=1.00 and *STI*=0.00 mean perfect and zero speech intelligibility, respectively. It should be noted that the aim of acoustical design of offices is good speech privacy, i.e. bad speech intelligibility.

Table 1. The subjective meaning of Speech Transmission Index, *STI*. Good speech intelligibility is desired in auditoria. In open offices, the opposite situation is appropriate.

STI	Speech intelligibility	Speech privacy	Examples in offices
0.00 … 0.05	very bad	confidential	Between two single-person office rooms, high sound insulation
0.05 … 0.20	bad	good	Between two single-person office rooms, normal sound insulation
0.20 … 0.40	poor	reasonable	Between workstations in a high-level open-plan office
			Between two single-person office rooms, doors open
0.40 … 0.60	fair	poor	Between desks in a well designed open-plan office
0.60 … 0.75	good	very poor	Between desks in an open-plan office, reasonable acoustical design
0.75 … 0.99	excellent	no	Face-to-face discussion, good meeting rooms
			Between desks in an open-plan office, no acoustical design

More than 30 psychological laboratory studies were reviewed to evaluate the performance decrements caused by speech or office noise. Only statistically significant differences were considered in this review. Most of the studies had been carried out by brain researchers that study the operation of working memory using speech stimulus. Therefore, the experiments had been carried out in two situations, with and without speech. They did not pay attention to the effect of speech intelligibility which would be of main interest if the results were to be applied in acoustic design. However, these studies are valuable since they prove that unwanted speech undoubtedly impairs task performance.

The decrease in performance, *DP*, was defined from the previous studies as the arithmetic difference in error percentage during speech and silence, that is,

$$DP = P_{speech} - P_{silence} \qquad (1)$$

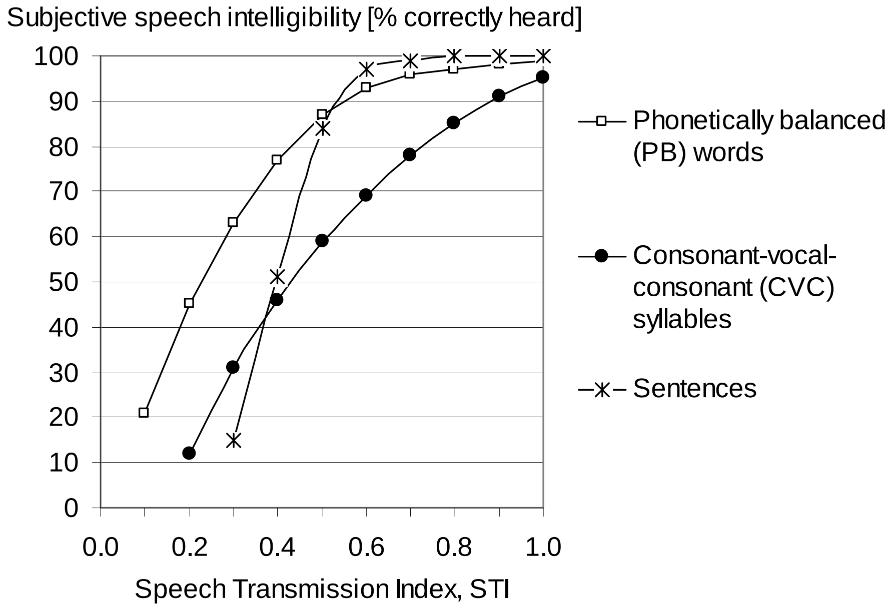

Figure 1. Experimental relations between subjective speech intelligibility and *STI* [10].

Figure 2. Measurement of STI between two neighboring workstations. Speaker is placed on one workstation and the measurement is carried out in the other. Workers are absent during the measurement.

RESULTS

Office noise containing speech deteriorates work performance significantly. The summary of literature review is presented in Table 2. Performance decrements due to speech have been between 4 and 41 % compared to performance in silence. Large variation results from the differences in types of tasks and sound environments.

Table 2. Summary of literature review showing the decrease in performance depending on task type and sound environment. *N* is the number of studies.

		Decrease in performance [%]		
Task type, sound environment	***N***	**AVERAGE**	**Minimum**	**Maximum**
Memory for letters presented visually, speech	4	19	15	29
Memory for 9 digits presented visually, speech	5	11	9	13
Reading comprehension, speech	1	10	10	10
Proof-reading, speech	3	7	4	10
Other tasks, speech	7	16	7	29
Varying tasks, office noise with or w/o speech	5	26	13	41
Short-term memory of digits, music with or without voice	1	10	4	14
	26	14	4	41

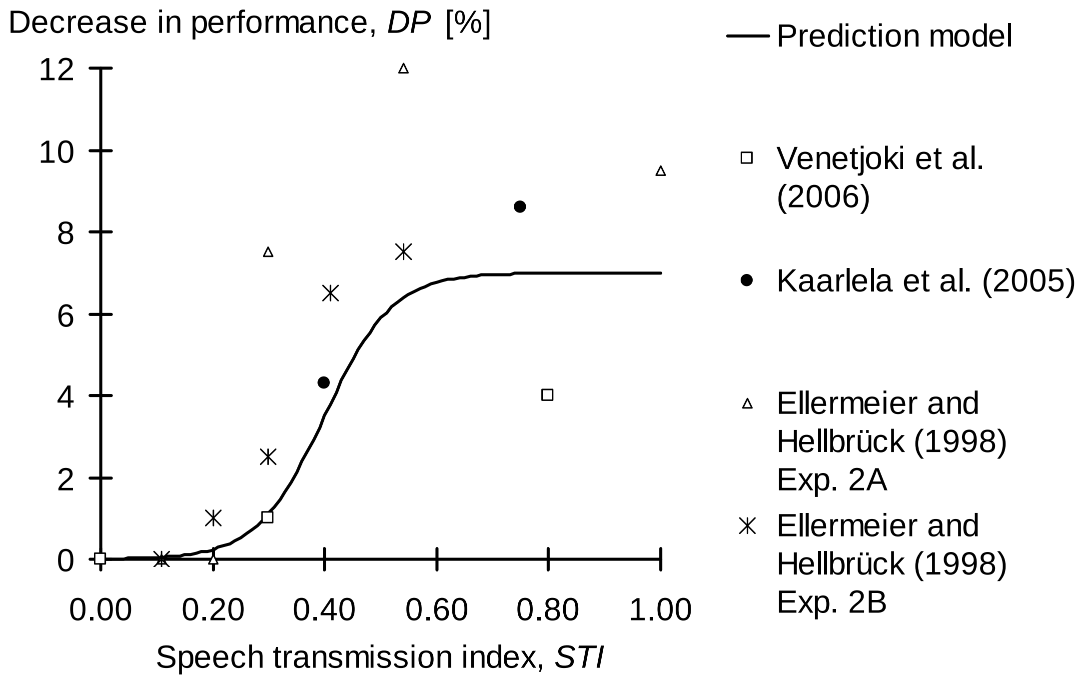

Figure 3. Work performance decreases with increasing speech intelligibility in offices.

There is clear evidence that distraction of speech increases with increasing speech intelligibility. Therefore, it was justified that the *STI*-dependence of work performance can be based on the relation between *STI* and subjective speech intelligibility of sentences, as shown in Figure 1. The mathematical form of the prediction model is

$$DP = \frac{-A}{1+\exp[(STI-0.4)/0.06]} + A \qquad (2)$$

where *DP* is decrease in performance [%] and *STI* is the average Speech Transmission Index at the office workstation. The mathematical model is outlined in Figure 3. [1]

The value of constant A depends on task type and sound environment. For this study, a value A=7 % was used which means that the highest decrease of productivity is assumed to be at least 7 %. It should be noted that this is not a universal value. The choice represents merely a bottom line of previous research. Most studies resulted in larger *DP* values as Table 2 indicated. The maximum decrease in performance depends on the cognitive demands of the office work. Personality factors explain the differences between individuals.

DISCUSSION

The main criticism should concern the existence and the shape of the prediction model of Figure 3 and Equation (2). The model was based on three corner stones:

1. highest performance is obtained when speech is absent, *STI*=0.00,
2. the largest decrease in performance is 7 % and this is reached when speech is perfectly heard, i.e. *STI*=1,00, and
3. the range *STI*=0.00 - 1.00 is based on the *STI* vs. sentence intelligibility curve of Figure 1.

The model should be validated with experimental data where *STI* of speech is varied. This work is mainly the topic of our future work. So far, there are three experimental studies to support the shape of the model. They are indicated as individual points in Figure 3 and discussed below.

Venetjoki et al. (2006) studied the effect of speech of varying speech intelligibility on proof-reading performance [11]. Three *STI* values were used, 0.00, 0.30, and 0.80. Their study clearly showed that performance is not affected when *STI* remains within 0.00 and 0.30. This study will be continued in FIOH. The aim is to find more data to the *STI* range 0.20 - 0.60 where the performance is expected to be decreased very rapidly. This range is of main interest for the motivation of acoustic improvements in offices.

Ellermeier and Hellbrück [12] studied the recall of digits in different signal-to-noise ratios of speech. They carried out two laboratory experiments with speech-to-noise ratios +4, -4, -12 dB in experiment 2A, and speech-to-noise ratios of +4, 0, -4, -8, and -12 dB in experiment 2B. These signal-to-noise ratios were converted by the author into *STI* values using the model of Hongisto et al. (2004) [7]. The results of both experiments followed the formulated prediction model reasonably well in a wider *STI* range.

Kaarlela-Tuomaala et al. (2004) studied the effects of office noise on office workers using questionnaires [13]. The study was carried out in a company which moved from a single-room office to an open office. The self-estimated daily waste of working time due to noise was 4.3 % in a single-room office (*STI*=0.40) and 8.6 % in an open-plan office (*STI*=0.70). The field studies of Helenius et al. confirm this finding. [2]

CONCLUSIONS

Work performance declines with increasing speech intelligibility. The performance decline due to office noise can be predicted when the average Speech Transmission index, *STI*, between office workstations is known. Present acoustical design guidelines already aim at the reduction of *STI* between office workstations [14]. The new model enables the estimation of the payback time of noise control investments that lead to better speech privacy. The model can be utilized in promoting actions that aim at better acoustic environment.

ACKNOWLEDGEMENTS

This study was a part of the national research programmes Productive Office 2005 and MAKSI (Perceived and modelled indoor environment) funded by Tekes, FIOH, and several participating companies during 2001-2004 and 2006-2007, respectively. Thanks are due to my colleagues Niina Venetjoki, Anu Kaarlela-Tuomaala, Petra Virjonen, Riikka Helenius, Jarkko Hakala and Esko Keskinen, who also act as co-authors in our journal papers. Thanks to my colleague Annu Haapakangas for giving valuable comments to this manuscript.

SUMMARY

A subjective experiment was conducted using 15 college-aged subjects of both genders in order to evaluate their physiological and psychological reactions, performance and fatigue under the different combinations of indoor humidity, local air velocity and illuminance.
The five-hour exposure periods were divided into three sections of 1.5 hours by 10-minute breaks. During each section, subjects performed 3 times of 20-minute task. During the exposure time subjects rated their sensations, visual fatigue and general fatigue, and measured their break up time (BUT) and skin moisture after each task.
Higher rate of complaints related to visual fatigue was reported under the condition with local air velocity than without it at the same humidity. High humidity caused subjective low visual fatigue. Subjective BUT was shorter in the environment with local air velocity or at low humidity, where people rated greater eye dryness sensation. High illuminance caused no difference in occupants' physiological and psychological reactions although correct answer rate was higher in environment with high illuminance.

INTRODUCTION

Tsutsumi et al. [1] [2] [3] conducted subjective experiments on the effects of low humidity on occupants' comfort and productivity. As the result, occupants' discomfort caused by dryness was not found in the thermally neutral condition at below 40%RH. On the other hand, visual data acquisition could be interfered at very low humidity. In the daily life, local air velocity and illuminance could cause occupants' general dryness sensation and eye dryness, blink, and visual fatigue as well as indoor humidity. Wyon et al. [4] reported other environmental factor like air velocity and illuminance also cause eye and skin dryness as well as indoor humidity. Present paper reports the subjective experiments carried out to evaluate their physiological and psychological reactions, performance and fatigue under the different combinations of indoor humidity, local air velocity and illuminance.

METHODS

Experimental design

A subjective experiment was conducted in a climate chamber using 15 college aged subjects, 7 males and 8 females, in order to evaluate their physiological and psychological reactions, performance and fatigue under the different combinations of indoor humidity, local air velocity and illuminance.

Experimental conditions:
The experimental conditions are listed in Table 1.

For all conditions, air temperature was kept at 25.0 °C. Two levels of humidity conditions, 30%RH and 70%RH, were set. For each humidity condition, two conditions of local air velocity to subject's face with a small fan on the desk, with and without velocity of 1.0 m/s, were examined. A condition with high illuminance at 30%RH without local air velocity was also studied. Under the condition with high illuminance at 30%RH, vertical illuminance in front of PC screen on the desk of subject was about 1200 lx while under other four conditions it was 400-450 lx. Each subject wore the clothing ensembles that consisted of a long-sleeve shirt, short-sleeve T-shirt, trousers, socks and shoes. All subjects wore their own underwear. Clo value was measured to be 0.85clo by using a thermal manikin.

Table 1. Experimental conditions.

Conditions	Air Temperature (=MRT)	Relative Humidity	Local Air Velocity	Vertical Illuminance
30%RH	25.0°C	30%RH	Without	400-450lx
30%RH +Local Air Velocity (LV)			With	
30%RH +High Illuminance (HI)			Without	1200lx
70%RH		70%RH	Without	400-450lx
70%RH+LV			With	

Experimental procedure:

Figure 1 shows the experimental procedure. People were exposed in a climate chamber for 5 hours. The five-hour exposure periods were divided into three sections of 1.5 hours by 10-minute breaks. During each section, subjects performed 20-minute task three times: 1) Short-term memory task [5], 2) Vigilance task [5], 3) Visual recognition and reaction task. Subjects could only drink a bottle of water provided by the experimenters during the exposure time. During 10-minute break between sections, people were allowed to go out the climate chamber. Air temperature, relative humidity and globe temperature in the chamber were logged every minute. Air velocity before and after the exposure time was also recorded.

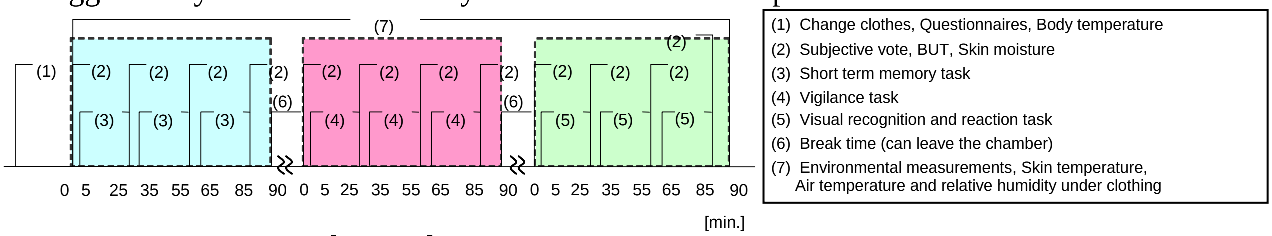

Figure 1. Experimental procedure.

Tasks:

During the exposure, subjects performed 3 types of task: 1) Short-term memory task [5], 2) Vigilance task [5], 3) Visual recognition and reaction task, as presented in Table 2. High visual data acquisition, quick judgments and response are needed for all tasks. Therefore, short Break up time (BUT) or visual fatigue due to the indoor environment could affect their performance. Subjective discomfort to the environment would also cause general fatigue that reduces their performance.

Table 2. Detail of 3 tasks.

Short-term memory task		Vigilance task		Visual recognition and reaction task	
	1. Total of six numbers were displayed every second. 2. One number to be judged were shown. 3. If the number was included in 6 numbers, subjects reacted as soon as possible. If not, they didn't. Time limit was 3 seconds.		1. Total of 3 numbers were displayed every second. 2. When three different odd numbers were shown, subjects reacted as soon as possible. If not, they didn't. Time limit was 3 seconds.		1. For three seconds, ten characters that consist of numbers (1-9) and alphabets (a-z) were shown at random. 2. When an odd number appears, subject reacted as fast as possible. If not, they didn't.

Statistical analysis

Data obtained in the experiments were analyzed with Non-parametric statistical analysis method [6]. The Wilcoxon Matched-Pairs Signed Ranks test was administered between each condition. Indoor humidity effect was discussed in the pair-wise comparison between 30%RH and 70%RH, and between 30%RH+LV and 70%RH+LV. According to the comparison between 30%RH and 30%RH+LV, and between 70%RH and 70%RH+LV, local air velocity effect was reported. Pair wise test between 30%RH and 30%RH+HI reported the effect of indoor illuminance. P-values presented in the figures indicate the level of significance.

RESULTS AND DISCUSSION

Physiological responses

Skin moisture

Skin moisture was measured on a subject's left forearm with "Skicon-200" (IBS Corp.). Skicon-200 adopts the high frequency impedance method [7]. As shown in the Figure 2, skin moisture after all tasks at 30%RH was lower than at 70%RH and at 30%RH+LV than 70%RH+LV ($p<0.01$). Low humidity caused their low skin moisture. No significant difference was observed between 30%RH and 30%RH+LV and between 70%RH and 70%RH+LV. Local air velocity did not have great impact on subjective skin moisture. No significant difference was observed between 30%RH and 30%RH+HI. The effect of illuminance was moderate in this experiment.

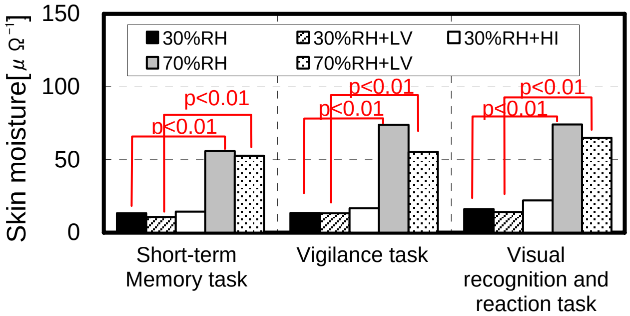

Figure 2. Skin moisture.

Break up time (BUT)

Break up Time (BUT) of precorneal film is one of the physiological reactions that might affect the subjective eye comfort [8].During the exposure time, the subjects measured their interval time between each blink by themselves using a stopwatch as "BUT" after each task for this research.

BUT recorded at the end of exposure was shown in Figure 3. BUT after all task under 30%RH+LV was significantly shorter than under 30%RH ($p<0.02$). Shorter BUT was observed under 70%RH+LV than 70%RH although no statistically significant difference was observed. It is found that BUT became shorter in the environment with local air velocity. There was significant difference in BUT after Visual recognition and reaction task between 30%RH+LV and 70%RH+LV ($p<0.05$). BUT measured after Short-term memory task and Vigilance task at 30%RH and at 30%RH+LV were shorter than 70%RH and 70%RH+LV respectively. Low humidity had the impact that makes subjective BUT gotten shorter.
No statistically significant difference was observed between 30%RH and 30%RH+HI.

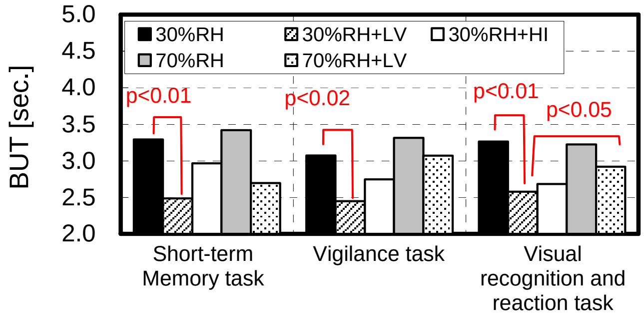

Figure 3. BUT measured at the end of each task.

Psychological reactions

General humidity sensation

Figure 4 presents the general humidity sensation rated by subjects after each task. Subjects tended to feel dryer after Short-term memory task and vigilance task under 30%RH+LV than that under 30%RH ($p<0.1$). While no significant difference was found, general dryness sensation under the condition with local air velocity was higher than under the condition without local air velocity at the same humidity.

General dryness sensation tended to be higher at 30%RH+LV than 70%RH+LV after Vigilance task and the Visual recognition and reaction task ($p<0.1$). Subjects reported significantly higher dryness sensation at 30%RH than at 70%RH after the Visual recognition and reaction task ($p<0.03$). It is found that people perceived air to be dryer under low humidity condition.

No significant difference was observed between 30%RH and 30%RH+HI. Difference of illuminance examined in this experiment did not have great impact on subjective general humidity sensation.

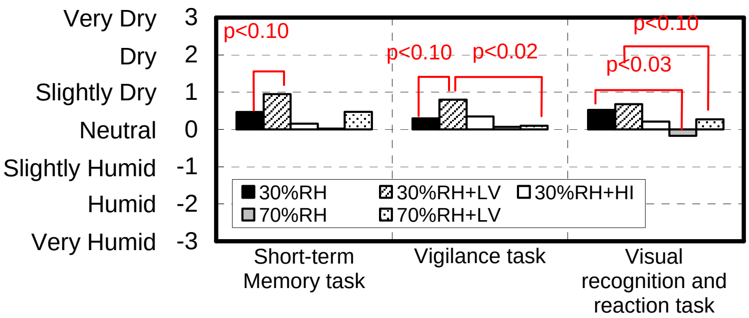

Figure 4. General humidity sensation.

Sensation of eye dryness

Eye dryness sensation vote after each task was shown in Figure 5.

Eye dryness at 30%RH was significantly higher than at 70%RH after all tasks in pair-wise comparison ($p<0.01$). Subjects reported greater eye dryness at 30%RH+LV than 70%RH+LV after all tasks although no significant differences were gotten. It proved that indoor humidity has an impact on subjective eye dryness sensation.

Statistically significant differences occurred between 70%RH and 70%RH+LV after all tasks, and between 30%RH and 30%RH+LV after the Short-term memory task and Vigilance task ($p<0.04$). People reported their eyes were dryer in the environment with local velocity than at the same humidity without velocity.

Since no significant difference was found between 30%RH and 30%RH+HI, it is concluded that the effect of illuminance on subjective sensation of eyes were not found in this experiment

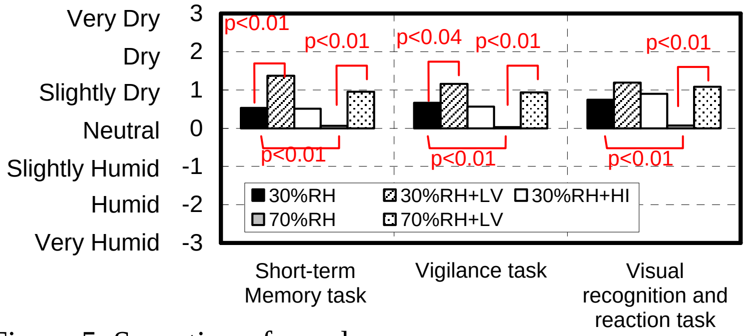

Figure 5. Sensation of eye dryness.

Sensation of eye comfort

As shown in Figure 6, there was no significant difference between 2 humidity levels for both of with and without local velocity. Subjective discomfort was significantly greater at 30%RH+LV than 30%RH after Short-term memory task and Vigilance task and at 70%RH+LV than 70%RH after Short-term memory task and Visual recognition and reaction task ($p<0.04$). People reported greater eye discomfort at 30%RH+LV than at 30%RH after Visual recognition and reaction task, and at 70%RH+LV than 70%RH after Vigilance task but these findings were not significant. This result demonstrated that subjects felt their eyes were more uncomfortable in the air with velocity.
According to no significant difference between 30%RH and 30%RH+HI, illuminance did not affect subjective sensation of eye comfort.

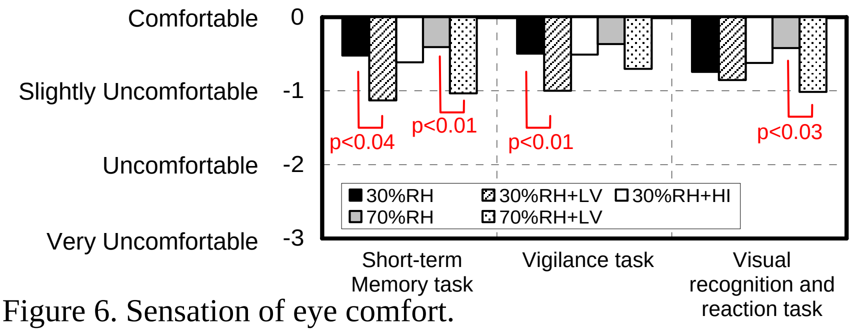

Figure 6. Sensation of eye comfort.

Performance and fatigue

Correct answer rate

Figure 7 shows the correct answer rate of last task for each section. The correct answer rate indicates the ratio of correct answers to all questions during a 20-minute task. Correct answer rate of Vigilance task was above 90% for all conditions, while that of Short-term memory task was between 60 and 85%. It was found that Short-term memory task was the most difficult task and Vigilance the easiest.
Same tendency of the correct answer rate under different conditions were obtained for all tasks. Correct answer rate at 30%RH+HI tended to be higher than at 30%RH for all tasks.($p<0.07$)
No significant difference between 70%RH and 70%RH+LV were found. Correct answer rate of Short-term memory task at 30%RH+LV was significantly higher than at 30%RH ($p<0.05$) and that of Visual recognition and reaction task tended to be higher at 30%RH+LV than at

30%RH ($p<0.06$). This might be caused by the comfortable thermal environment at 30%RH with air velocity, where PMV (Predicted Mean Vote) was +0.72, between "0: neutral" and "+1: slightly warm", at 30%RH and –0.1, near "0: neutral", at 30%RH+LV.
As for the effect of indoor humidity, correct answer rate of Short-term memory task at 30%RH tended to be lower than 70%RH ($p<0.08$). Higher rate of correct answer at 70%RH was found compared with that at 30%RH, nevertheless there was no statistically significant difference.

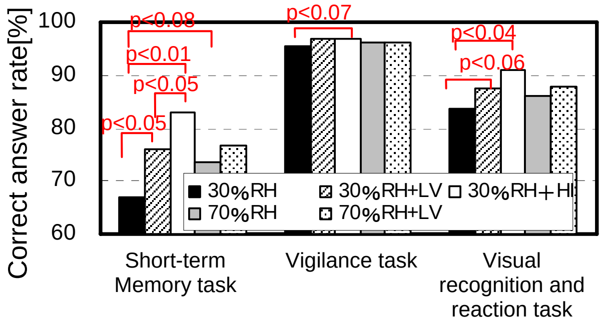

Figure 7. Correct answer rate of each task.

Figure 8 presents the relationship between subjective BUT and correct answer rate of the Short-term memory task and the Visual recognition and reaction task. Both figures demonstrated that longer BUT could cause higher correct answer rate. It is concluded that in case that the subjective BUT gets shorter due to indoor environment, subjective performance would become lower.

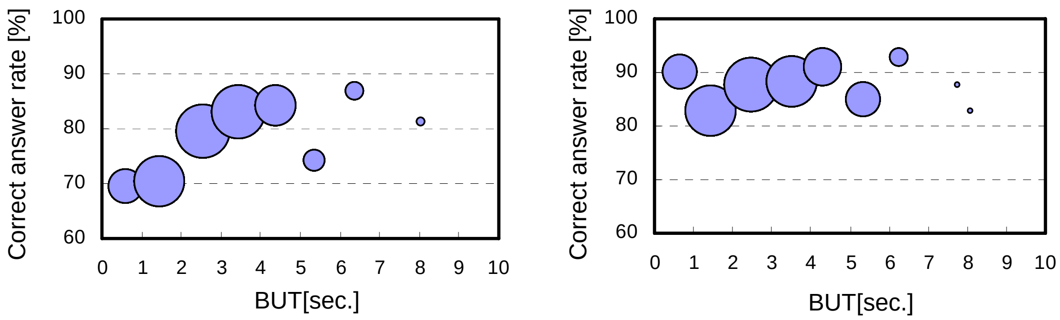

Figure 8. Relationship between BUT and correct answer rate.
(Left: Short-term memory task, Right: Visual recognition and reaction task)

General fatigue

Subjects were asked to assess their general fatigue [9]. The questionnaire is composed of 3 groups. Each category has 10 symptoms related to subjective fatigue. Subjects marked "O" if they had the given symptoms, and marked "X" if they did not. Ratio of complaints was calculated for each category using the equation below:

$$\text{Rate of complaints [\%]} = \frac{\text{Total number of complaints}}{\text{The number of symptoms} \times \text{ The number of subjects who used a questionnaire}}$$

Three patterns were suggested by comparing the rate of complaints for each category: I>III>II: I-dominant, I>II>III: II-dominant, and III>I>II: III-dominant. "I-dominant" indicates a general pattern of fatigue, "II-dominant" a typical pattern of fatigue for mental work or night work and "III-dominant" a typical pattern of fatigue for physical work.

Table 3 listed the rate of complaints. Total rate of complaints was about 10% for all conditions examined in this experiment. On the other hand, type of fatigue reported after Short-term memory task under 30%RH+LV, 30%RH+HI and 70%RH was I>II>III; II-dominant, while I>III>II was rated under any other condition. It is concluded that mental work load was greater during performing the Short-term memory task than any other task.

Table 3. Rate of complaints related to fatigue.

Task	Condition	Category I[%]	Category II[%]	Category III[%]	Type of fatigue		Total rate of Complaints[%]
Short term memory task	30%RH	27.3	0.7	6.0	I>III>II	I-dominant	11.3
	30%RH+LV	14.7	7.3	4.0	I>II>III	II-dominant	8.7
	30%RH+HI	22.8	8.7	6.0	I>II>III	II-dominant	12.5
	70%RH	21.3	7.3	6.0	I>II>III	II-dominant	11.6
	70%RH+LV	15.3	4.7	7.3	I>III>II	I-dominant	9.1
Vigilance task	30%RH	13.3	0.7	8.0	I>III>II	I-dominant	7.3
	30%RH+LV	17.3	3.3	4.0	I>III>II	I-dominant	8.2
	30%RH+HI	25.3	7.3	5.3	I>II>III	II-dominant	12.7
	70%RH	9.3	2.0	4.7	I>III>II	I-dominant	5.3
	70%RH+LV	18.0	6.0	8.0	I>III>II	I-dominant	10.7
Visual recognition and reaction task	30%RH	14.0	3.3	7.3	I>III>II	I-dominant	8.2
	30%RH+LV	16.7	3.3	5.3	I>III>II	I-dominant	8.4
	30%RH+HI	15.3	2.7	5.3	I>III>II	I-dominant	7.8
	70%RH	8.7	1.3	4.7	I>III>II	I-dominant	4.9
	70%RH+LV	23.3	5.3	7.3	I>III>II	I-dominant	12.0

Visual fatigue

Subjects reported their visual fatigue on the questionnaire referred to Takahashi [10]. Twenty symptoms related to visual fatigue were shown on the questionnaire. Subjects marked “O” if they had the given symptoms, and marked “X” if they did not. Total rate of complaint related to visual fatigue was calculated by using the same method as equation mentioned in the session of general fatigue.

Figure 9 presents the visual fatigue rated at the end of each task. People complained more after all tasks in the environment with local air velocity compared with the condition without air velocity at same humidity. More complaints were reported at 30%RH than 70%RH after all tasks.

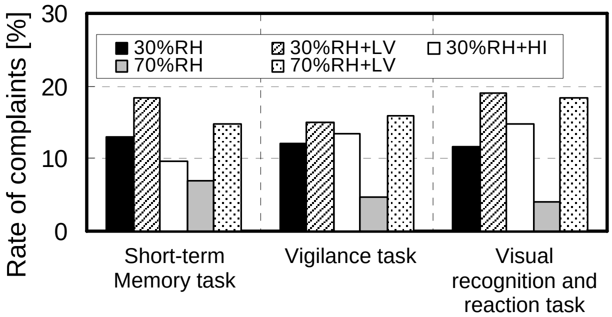

Figure 9. Visual fatigue rated at the end of each task.

CONCLUSION

A subjective experiment was conducted using 15 college-aged subjects of both genders in order to evaluate their physiological and psychological reactions, performance and fatigue under the different combinations of indoor humidity, local air velocity and illuminance.

The five-hour exposure periods were divided into three sections of 1.5 hours by 10-minute breaks. During each section, subjects performed 3 times of 20-minute task.

Low humidity caused subjects’ low skin moisture and general dryness sensation. On the other hand, local air velocity did not have great impact on subjective skin moisture while general

dryness sensation under the condition with local velocity was higher than under the condition without local velocity at the same humidity.
It is found that BUT became shorter and visual fatigue became greater in the environment with local air velocity and at low humidity. It proved that of indoor humidity and local velocity has negative impact on subjective eye dryness sensation and visual fatigue, while only local velocity affects their sensation of eye comfort.
Subjective mental work load was found to be greater during performing short term memory task than other tasks.
According to the results in their performance, it is concluded that if the subjective BUT gets shorter due to indoor environment, subjective performance would become lower.
High illuminance caused no difference in occupants' physiological and psychological reactions although correct answer rate was higher in environment with high illuminance.

ACKNOWLEDGEMENT

SUMMARY

A subjective experiment was conducted in a climatic chamber to evaluate the effects of improvement of indoor environmental quality on occupant's performance. The chamber was conditioned with the combination of: operative temperatures of 25°C or 28°C, illuminance of 750lx or 400lx and with or without traffic noise. The subjects performed triple-digit multiplication and voted satisfaction with indoor environment and the subjective symptoms of fatigue before and after each session of task. "Predicted-performance-vote", which estimates the effects of improvement of thermal, lighting and acoustic environment on productivity, was proposed in this study. In the environmental combinations of this study, subjects gave priority to improve thermal and acoustic environment rather than lighting environment. The self-estimated performance was related to occupants' satisfaction with indoor environment and was inversely related to fatigue. The results from the experiment indicated that subjects evaluated themselves well-performed when satisfaction with indoor environment was higher and fatigue was lower.

INTRODUCTION

In offices, indoor environmental qualities (IEQ) such as thermal environment, lighting environment, acoustic environment and IAQ may affect intricately on occupants' performance and productivity. In previous studies, the effects of environment on human responses and performance have been evaluated, and it was suggested that poor IEQ would increase the occupants' fatigue and decrease the level of satisfaction with indoor environment and performance [1]. In this study, a subjective experiment was conducted to consider the evaluation method for effects of improvement of indoor environmental factors on productivity by using not only performance but also subjective votes.

METHODS

Experimental Conditions

The subjective experiment was conducted in a climatic chamber at Waseda University between October 14th and November 11th in 2005. The chamber was conditioned as the conceivable environments in office with the combination of: operative temperatures of 25°C or 28°C, illuminance of 750lx or 400lx and with or without traffic noise. Eight conditions were named as "Control(28°C, 400lx, with traffic noise)", "T(25°C, 400lx, with traffic noise)", "N(28°C, 400lx, without traffic noise)", "L(28°C, 750lx, with traffic noise)", "TN(25°C, 400lx, without traffic noise)", "TL(25°C, 750lx, with traffic noise)", "NL(28°C, 750lx, without traffic noise)" and "TNL(25°C, 750lx, without traffic noise)". In "with traffic noise" conditions, the traffic noise, which was recorded near the heavy traffic street in Tokyo was played in the chamber from the speakers. The relative humidity was kept at same level in all conditions. The environmental conditions measured during the experiment are shown in Table 1. Subjects experienced these eight conditions in balanced order. Prior to the above-mentioned eight conditions, the subjects underwent a practice session under the same condition as Control.

Table 1. Environmental conditions

	Air temp [°C]	Operative temp [°C]	Relative humidity [%RH]	Equivalent sound level [dBA]	Illuminance [lx]	CO_2 [ppm]
Control	28.3 (0.4)	28.5 (0.4)	44 (3)	63	405 (15)	941 (50)
T	25.2 (0.6)	25.2 (0.6)	44 (1)	64	404 (12)	875 (88)
N	27.4 (1.3)	27.9 (0.8)	43 (2)	51	401 (13)	825 (50)
L	27.9 (0.8)	28.2 (0.4)	41 (1)	64	773 (17)	825 (138)
TN	25.6 (0.8)	25.7 (0.7)	43 (3)	51	401 (16)	792 (93)
TL	25.1 (1.3)	25.1 (1.4)	44 (3)	64	772 (28)	862 (87)
NL	27.7 (2.0)	28.0 (1.2)	42 (3)	51	757 (24)	798 (132)
TNL	26.1 (1.4)	26.4 (1.4)	42 (3)	51	752 (20)	963 (100)

( ) Standard deviation

Subjects

Ten male college-aged subjects participated in the experiment with their age of 22.1±1.3, height of 170.1±3.7cm, and weight of 61.5±5.8kg. Subjects were exposed in the climatic chamber in groups of 3 or 4 on the same time of the day in the successive experimental weeks to avoid any influence of time. All subjects were volunteers and they were paid at a fixed rate for their participation. In order to keep their motivation at the same level, they were informed that higher performers of the task could earn bonus. Subjects wore a uniform business suit with an insulation value of 0.93 clo [2].

Measurements

During the experiment, subjects performed thirty minutes of triple-digit multiplication tasks on paper four times in a day. The task performance for each subject was evaluated by his Z-score as a normalized performance to precisely reflect the performance change of each subject. The Z-score was calculated from the equation (1).

Z-score $$S_{A,i} = \frac{x_{A,i} - \bar{x}_A}{s_A} \qquad (1)$$

where,

$x_{A,i}$: number of correct answers during the session i for subject A [-]

$\bar{x}_A$: average number of correct answers of the subject A among all sessions [-]

s_A : standard deviation for the number of correct answers of the subject A among all sessions [-]

Satisfaction with indoor environment was asked to evaluate the perception of the environment. It was measured using a scale with rating of: -1="clearly unsatisfied", -0="just unsatisfied", +0="just satisfied", +1="clearly satisfied".

To evaluate the feeling of fatigue, subjects filled in the sheets of "Evaluation of Subjective Symptoms of Fatigue", which was suggested by the working group for occupational fatigue of the Japan Society for Occupational Health [3]. This evaluation method is used in the field of science of labor and ergonomics in Japan. It consists of three categories: group I consists of 10 terms on "drowsiness and dullness", group II consists of 10 terms on "difficulty in concentration", and group III consists of 10 terms on "projection of physical disintegration". Based on Yoshitake's method, the rate of complaints was calculated by Equation (2).

$$\textit{Rate of complaints}\ [\%] = \frac{\textit{number of selected symptoms of all subjects}}{\textit{number of terms concerned} \times \textit{number of subjects}} \times 100 \qquad \ldots(2)$$

"Predicted-performance-vote", which estimates effects of improvement of thermal, lighting and acoustic environment on productivity, was introduced in this study. The questionnaire sheet is shown in Figure 1. Subjects predicted and answered in this questionnaire how they thought their performance at task would increase if thermal, lighting and acoustic environment were improved. First, a subject marked on a scale (0: worst performance, 100: best performance under the environment assumed thermal, lighting and acoustic environments were all improved) how he could perform well in the office under same condition with the experiment. This value is named "predicted performance before environmental improvement (PP-0)". Second, he chose one of the environmental factors which they wanted to improve the most, and marked on a scale how they could perform well under the environment assumed to be improved (PP-1). Then, he chose another environmental factor which they wanted to improve the next, and marked on a scale how he could perform well under the environment assumed that two environmental factors of his chose were improved (PP-2). If all the environmental factors were selected to be improved, subject marked his predicted performance on the scale at 100. To estimate the effects of improvement of indoor environmental factors on performance simply, subjects were asked to answer predicted-performance-vote at the end of the day.

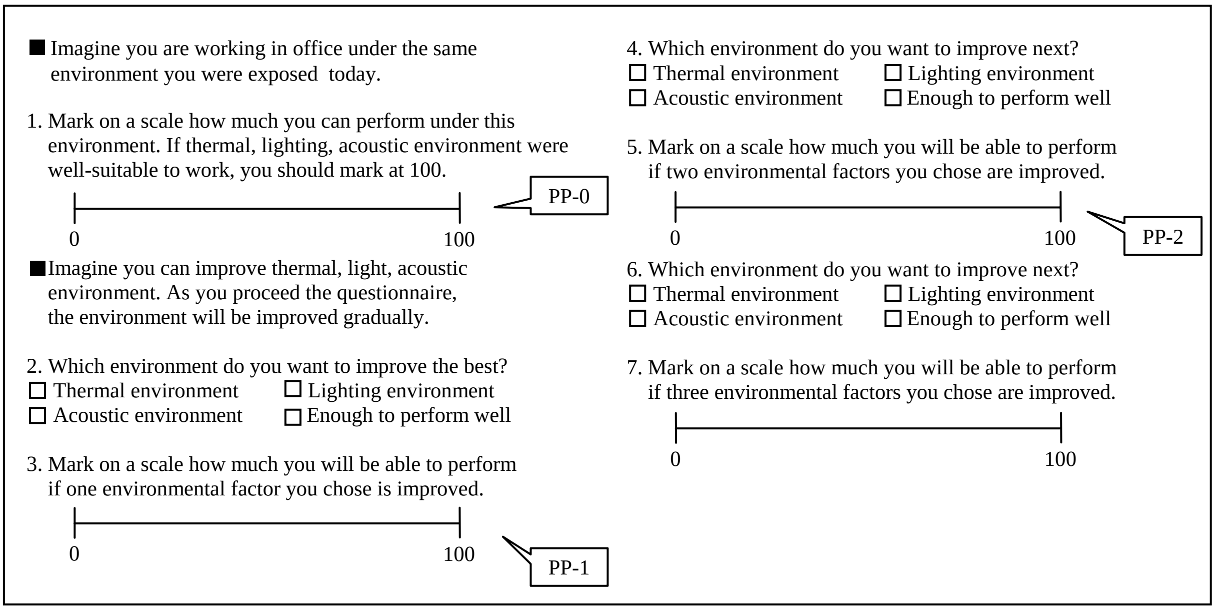

Figure 1. The questionnaire sheet of predicted-performance-vote

Experimental Procedure

Procedure of the experiment is shown in Figure 2. Duration of the experiment lasted for 210 minutes. First, subjects answered questionnaire in an anteroom. After entering the climatic chamber, they seated in the chair and voted satisfaction with indoor environment and fatigue on a PC screen. They rested in a sedentary position for 45 minutes to adopt themselves to the environment. Then, they performed thirty-minutes of multiplication task four times, and voted satisfaction with indoor environment and fatigue before and after the tasks. They were asked to answer predicted-performance-vote at the end of the day.

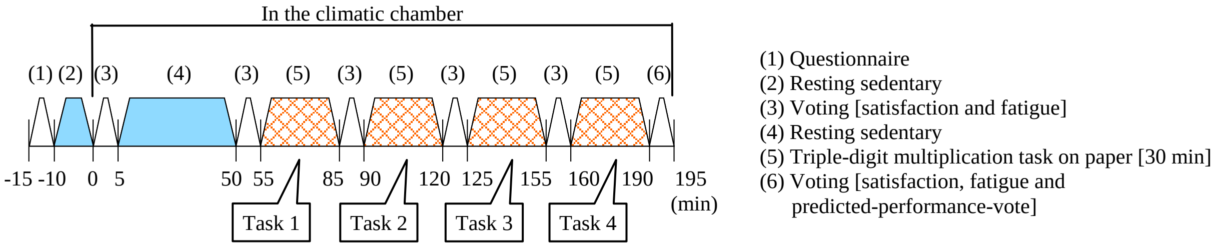

Figure 2. Procedure of subjective experiment

Statistical Analysis

The comparisons between the environmental conditions were analyzed using one-way ANOVA. When a statistically significant result was found, post hoc comparisons were made by using Fisher's protected LSD. The level of significance was set at $p<0.05$. The comparisons between PP-0 in Control and that in the others were analyzed by paired t-test with the level of significance of $p<0.05$. For the analysis of correlation, Pearson's product moment correlation coefficients were calculated.

RESULTS

Performance

The performance of multiplication task was evaluated by Z-score. The results of Z-score are shown in Figure 3. At the 3rd session of multiplication task, the Z-score in Control was significantly lower than that in L, TN, TNL ($p<0.01$), and TL ($p<0.05$).

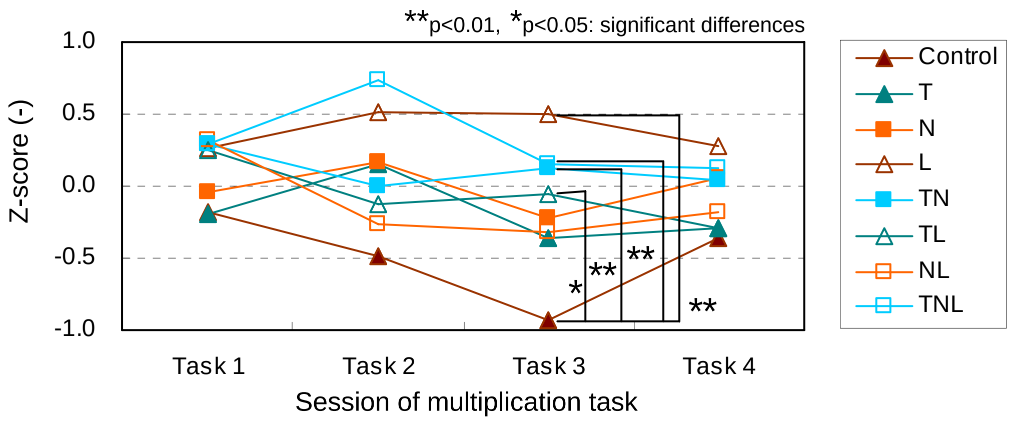

Figure 3. Z-score of multiplication task

Satisfaction with Indoor Environment

Subjects voted their satisfaction with indoor environment six times a day, before and after each session of resting and task. The results of the votes of satisfaction with indoor environment are shown in Figure 4. They were satisfied with environments of TN and TNL, and dissatisfied with those of all other conditions.

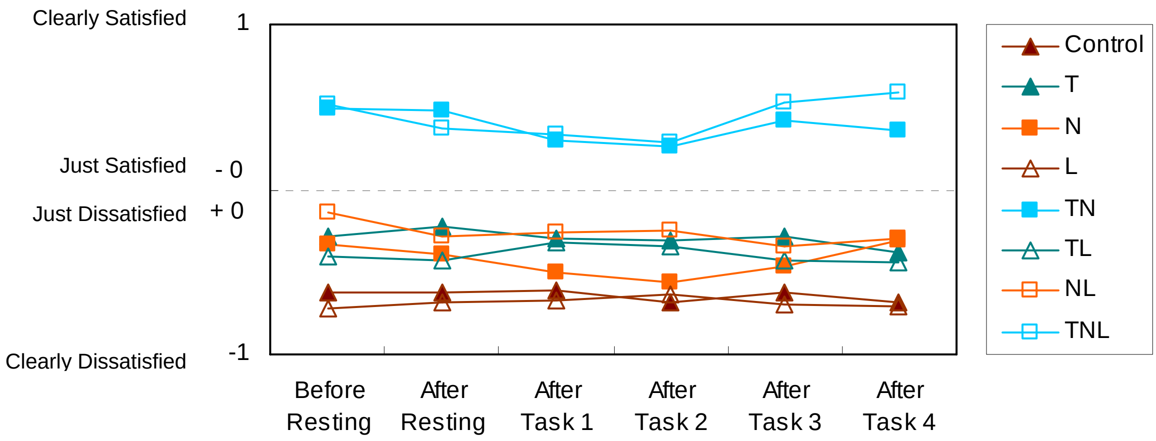

Figure 4. The votes of satisfaction with indoor environment

Fatigue

The results of the general rate of fatigue are shown in Figure 5. The general rate of fatigue was increased as the experiment proceeded. The general rate of fatigue in the “28°C” conditions (Control, N, L, NL) was higher than that in the “25°C” conditions (T, TN, TL, TNL), and that in the conditions “with traffic noise” (Control, T, L, TL) was higher than that in the conditions “without noise” (N, TN, NL, TNL).

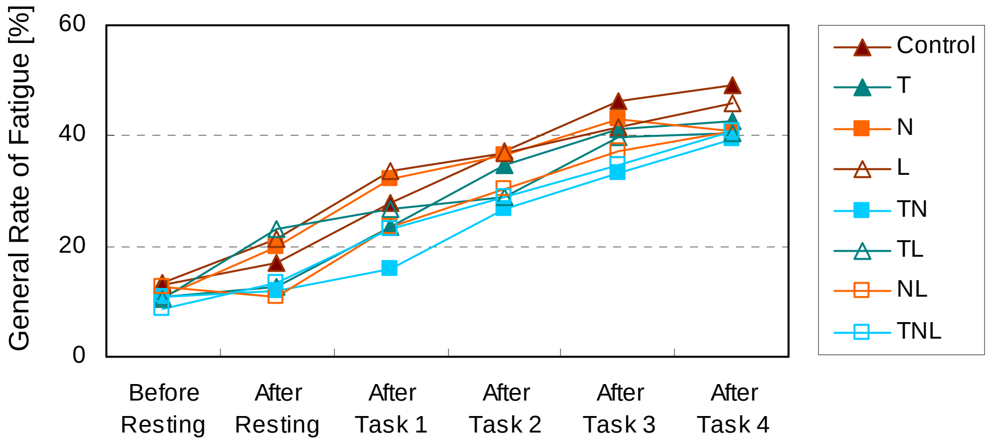

Figure 5. The general rate of fatigue

Predicted-Performance-Vote

The results of a part of the predicted-performance-vote are shown in Table 2. PP-0 is the predicted performance in the office under the same condition with the experiment. PP-1 is the predicted performance after one environmental factor was assumed to be improved. PP-0 in each condition was in the order from TNL, TN, NL, T, TL, N, L and Control. It indicates that the conditions considered to be well-suited to office work in this study were in that order. The subjects gave priority to improve thermal and acoustic environment rather than lighting environment in the environmental combinations of this study. PP-1s in Control and L were lower than those in all other conditions. Control and L were the conditions that combination of poor thermal and acoustic environment, one of the two was left to be improved when PP-1 was voted. The subjects estimated their predicted performance highly under the condition that both of thermal and acoustic environments were assumed to be improved. In the environmental combinations of this study, the supposed improvement of thermal and acoustic environment affected predicted performance more than that of lighting environment.

Table 2. A part of the predicted-performance-vote

		Control	T	N	L	TN	TL	NL	TNL
Predicted Performance before environmental improvement (PP-0)		56.1 (16.0)	66.7 (20.3)	75.7 (9.6)	61.9 (15.4)	81.2 (13.0)	76.5 (9.4)	71.0 (19.6)	86.5 (11.0)
Environmental factor chosen to improve	Thermal	5	0	10	4	5	0	10	7
	Lighting	0	0	0	0	3	0	0	0
	Acoustic	5	10	0	6	1	10	0	1
	Enough to perform well	0	0	0	0	1	0	0	2
Predicted Performance after one environmental factor was assumed to be improved (PP-1)		81.7 (13.0)	93.3 (9.2)	93.4 (7.7)	83.6 (11.4)	92.7 (6.1)	96.6 (3.5)	93.6 (7.5)	97.4 (5.0)

() Standard deviation

To evaluate the effects of improvement of environmental factors on self-estimated performance, PP-0 in Control was compared with PP-0s in all other conditions. The results of the effects of difference of environmental factor on PP-0 are shown in Figure 6. PP-0s in N, TN, TL, NL, TNL were significantly higher than that in Control (p<0.01). When one environmental condition was differed, the environmental factor whose difference affected PP-0 was acoustic, thermal and lighting environment in that order. The combinations of the two environmental factors whose differences affected PP-0 were acoustic and thermal, thermal and lighting, acoustic and lighting in that order.

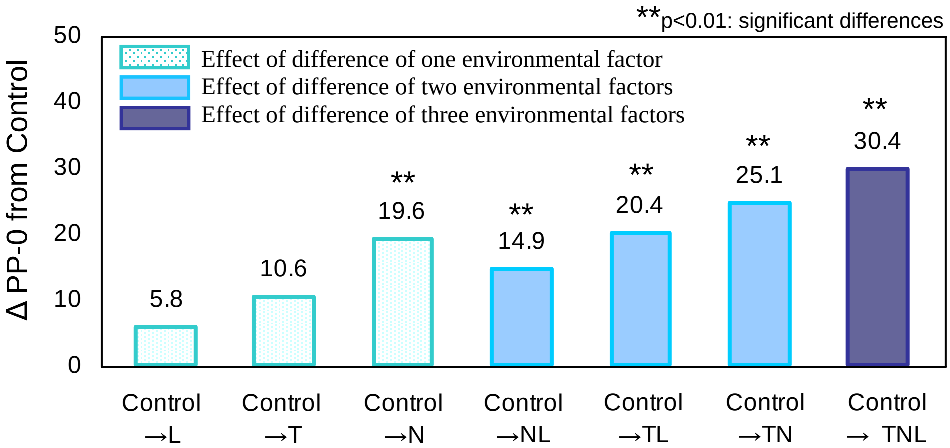

Figure 6. Effects of difference of environmental factors on PP-0

Relationship between Satisfaction with Indoor Environment or Fatigue and Performance

To evaluate how much satisfaction with indoor environment and fatigue levels affect task performance, the relationship between satisfaction with indoor environment or general rate of fatigue and the Z-score of multiplication task were examined. The data set of satisfaction with indoor environment by the interval of 0.2 was averaged, the data set of general rate of fatigue by the interval of 10% was averaged, and corresponding Z-score was also averaged. The relationships between satisfaction with indoor environment or general rate of fatigue and the Z-score are shown in Figure 7. The Z-score was weakly related to subjects' satisfaction with indoor environment (r=0.43) and was inversely weakly related to fatigue(r=-0.42).

Relationship between Satisfaction with Indoor Environment or Fatigue and PP-0

To evaluate how much satisfaction with indoor environment and fatigue levels affect self-estimated performance, the relationship between satisfaction with indoor environment or general rate of fatigue and PP-0 were examined. The data set of satisfaction with indoor environment by the interval of 0.2 was averaged, the data set of general rate of fatigue by the interval of 10% was averaged, and corresponding PP-0 was also averaged. The relationships between satisfaction with indoor environment or general rate of fatigue and PP-0 are shown in Figure 8. PP-0 was related to subjects' satisfaction with indoor environment (r=0.80) and was inversely related to fatigue(r=-0.87).

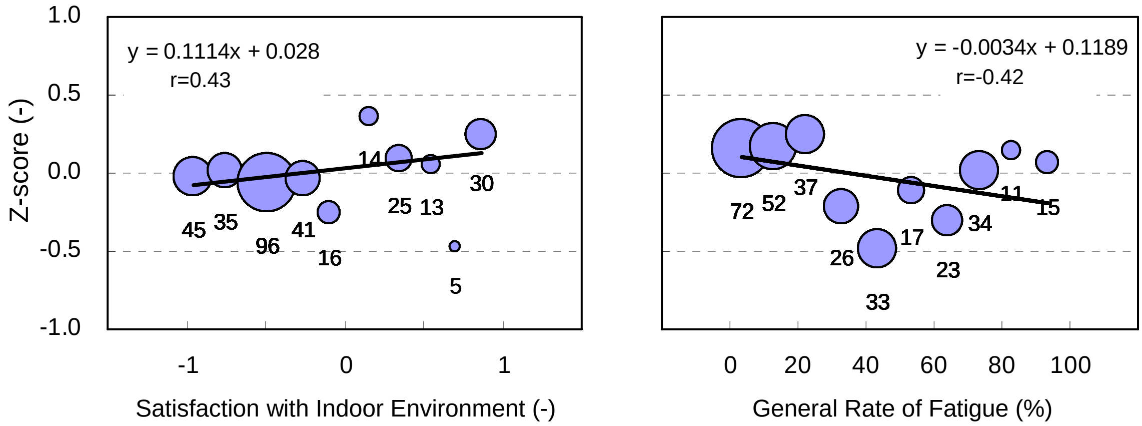

Figure 7. Relationship between satisfaction with indoor environment or fatigue and Z-score

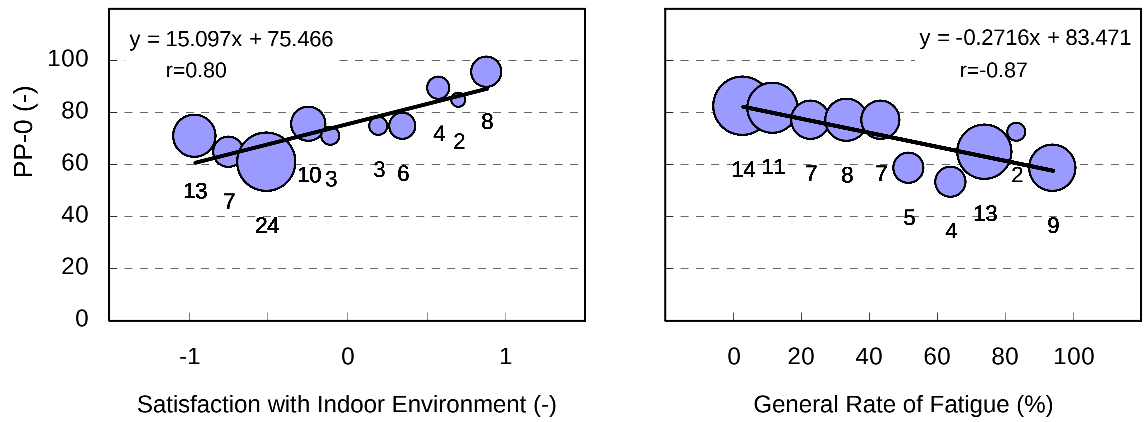

Figure 8. Relationship between satisfaction with indoor environment or fatigue and PP-0

DISCUSSIONS

It was shown that the environments in TN and TNL were evaluated as satisfied, and those in all other conditions were evaluated as dissatisfied by the subjects. The general rate of fatigue in the conditions of "28°C" was higher than that in the conditions "25°C" and that in the conditions "with traffic noise" was higher than that in the conditions "without noise". These results suggested that the effects of improvement of thermal and acoustic environment on subjects' satisfaction with indoor environment and fatigue levels were higher than that of lighting environment in the environmental combinations of this study.

Clausen and Wyon [4] conducted a subjective experiment to investigate people's priorities to IEQ and whether individual choice of working environment affects work performance and individual perceptions of the indoor environment. It was reported that the possibility to individually choose which parameters to improve within a given budget had a positive effect on acceptability with the overall indoor environment [4]. In our experiment, there was not obvious change of task performance between the conditions. On the other hand, the results of predicted-performance-vote showed that subjects gave priority to improve thermal and acoustic environment rather than lighting environment, and effects of improvement of thermal and acoustic environment on predicted performance were higher than that of lighting environment. Predicted performance can be practical as self-estimated performance under a certain environmental condition, and subjects also seemed to evaluate how the environmental condition was well-suited to perform task by predicted performance. It is possible to figure out the environmental factors occupants want to improve, and they can simply estimate the effects of improvement of environmental factors on their performance by using the predicted-performance-vote.

The task performance and PP-0 was related to occupants' satisfaction with indoor environment and was inversely related to fatigue. The relationships with task performance were rather weak in this experiment, however, strong relationship between task performance and fatigue was reported for the long time exposure [5]. Predicted-performance-vote is possible to simply estimate the effects of IEQ on output-side of productivity for short term study.

CONCLUSIONS

A subjective experiment was conducted to evaluate the effects of improvement of indoor environmental quality on occupant's performance. Subjects were exposed eight conditions and performed thirty-minutes multiplication task four times in each condition.

1) The effects of improvement of thermal and acoustic environment on subjects' satisfaction with indoor environment and fatigue levels were higher than that of lighting environment in the environmental combinations of this study.
2) The results of predicted-performance-vote indicated that the conditions considered to be well-suited to office work were in the order from Control, L, N, TL, T, NL, TN and TNL.
3) The Z-score and PP-0 were related to subjects' satisfaction with indoor environment and were inversely related to general rate of fatigue. Subjects evaluated themselves well-performed when satisfaction with indoor environment was higher and fatigue was lower. To promote increase of productivity in the office, it is effective to reduce occupants' dissatisfaction with IEQ and fatigue.
4) It is possible to figure out the environmental factors occupants want to improve, and they can simply estimate the effects of improvement of environmental factors on their performance by using the predicted-performance-vote.

ACKNOWLEDGEMENT

The authors wish to express appreciations to Mr. M Nishikawa, Ms. A Tanaka, Ms. M Hayakawa, Mr. S Hyodo, and Mr. T Kumata for their assistance during the experiment. This study was partially funded by the Project Research of Advanced Research Institute for Science and Engineering, Waseda University, by the Grobal Environment Research Fund (H-061) by the Ministry of Environment, Japan and by the Grant-in-Aid for JSPS Fellows.

The Health Impact Of Space Planning Policies In Relation To Walking And Exercise In The Workplace

Edward Finch

Heriot Watt University, Edinburgh, Scotland

Corresponding email: e.f.finch@hw.ac.uk

SUMMARY

This paper presents an evidential review of current knowledge on the issue of walking versus sedentary behaviour in office environments. It considers the medical evidence in relation to cardio-vascular activity and the long-term effect of sedentary compared to mobile work routines. The paper then goes on to consider the concept of 'embedded health' within buildings, reflected in the way that buildings are designed and managed. It highlights in particular the role of the facilities manager in enabling such embedded health. The argument in the paper is that health activities cannot be assumed to occur simply by the provision of health facilities. Professionals, with busy working lives, working long hours, inevitably neglect health activities. It is therefore incumbent on employers to 'design in' healthy behaviour as part of the daily work routine. The author argues that current space planning practices are intent on achieving quite the reverse outcome.

INTRODUCTION

A mounting body of evidence is highlighting the widespread problem of obesity, particularly in developing countries. According to a recent World Health Organization report [1] "obesity poses one of the greatest public health challenges for the 21st century, with particularly alarming trends in several parts of the world, including the WHO European Region. More than 75% of all deaths in the European Region are caused by non-communicable diseases, the highest proportion in the world. Coronary heart disease (CHD) is the most common cause of premature death, alone accounting for 16% and 12% of all premature deaths in men and women, respectively". This problem is influenced to a significant extent by work routines and behaviours. The office worker population represents a significant proportion of the working population, particularly with the emergence of the knowledge worker and the increased growth of the service sector. In this paper we consider the impact that facilities design and space planning has on the health of individuals. In particular it considers the cardio-vascular health impact, largely arising from walking. The following hypothesis is considered;

'The cardio-vascular health of office workers is significantly affected by the spatial design, adjacencies and routines imposed by facilities management policies'.

One example where office workers may consciously choose to take the 'healthy option' in the working environment is the 'lift or stairs' scenario. Such a decision may impact on travel time to a destination. Furthermore it may not be an individual decision but may be influenced by the consensus of a group. The dilemma then involves a number of competing values, some of which may be in relation to productivity (i.e. the organization); some to the group (i.e. interests of the group) and some to personal wellbeing (or indeed reluctance to exercise).

However, many of the 'embedded' health opportunities of facilities are prevented: no such choice exists (compared to the lift or stairs dilemma). Individuals cannot choose to take the more energetic route to an office coffee area, if the position of such a facility has been positioned in order to minimize travel distance. Indeed, evidence suggests that unless individuals are forced to travel to a more remote facility (through lack of choice) individuals will invariably choose the most proximal facility. The question then arises as to whether the facilities manager should socially engineer behaviours that force individuals to be more mobile. This paper firstly considers current medical evidence in relation to workplace behaviour and health. It then goes on to consider the potential impact that space planning and service delivery can have on human energy expenditure during the course of a working day.

THE MEDICAL EVIDENCE RELATING TO HEART DISEASE AND EXERCISE AMONGST WORKERS

The evidence suggesting an association between vigorous exercise and the apparent protection it affords against heart disease stems back as far as the ancient Greeks two thousand years ago. Both Hippocrates and Gallen argued that a lack of exercise was detrimental to human health. Paffenbarger *et al* [2] document how such evidence continued to develop throughout history culminating in a vast body of evidence in modern day epidemiology. By the *Middle Ages,* the Italian physician Bernardini Ramazzini (1690-1731), founder of modern day epidemiology, studied the health of various tradesmen. He came to the conclusion that messengers and similar 'fleet footed' trades managed to avoid many of the occupational hazards that other trades such as tailors and cobblers experienced. Ramazzini (cited in [2]) stated: 'let tailors be advised to take physical exercise at any rate on holidays. Let them make the best use they can of some one day, and so to counteract the harm done by many days of sedentary life'.

Today a wealth of research has been undertaken to uncover the relationship between physical activity and health, particularly in relation to heart disease. This research has covered many continents, social groups, age bands, ethnic groups and specific genders. Much of this has been informed by the work of the Morris Group who by 1973 were starting to show clear evidence that an association existed between exercise levels and the occurrence of coronary heart disease (CHD). An initial study was undertaken by Morris *et al* [3] involving 9400 men aged 45-64 years. All of the participants were civil servants with no history of CHD. The study showed a reduction by more than a half for CHD incidence, non-fatal and fatal, with moderately vigorous or vigorous exercise. The study focused on leisure based activities since there was considered to be insufficient cardiovascular activity in the workplace to differentiate between the subjects studied. In a later study Morris *et al* [4] followed middle management civial servants for non-fatal and fatal diseases. The subjects were initially required to complete five minute logs over a two day period. This was then followed up some years later by detailed mail-back questionnaires on their health habits and health status. Having traced the subsequent occurrence of heart disease, Morris *et al*[4] identified two categories of worker: that undertook 'vigorous' exercise; those that 'moderately vigorous exercise' for whom there was a demonstrable association between vigorous exercise and coronary heart disease (CHD). Vigorous exercise consisted of sports undertaken twice or more a week, including swimming, fast regular walking (>4 mph) or cycling. The findings suggested that short bouts of regular exercise were most effective in combating heart disease. Intensity, followed by frequency are more important than duration: most exercises being less than 20 minutes in duration.

The early studies by the Morris Group focused primarily on leisure activities of office workers. However more recent work has considered the health effects of activity during the work period as well as activities associated with getting to and from work. For example, a study extending from six to sixteen years in Osaka, Japan (see [5]) involving over sixteen thousand Japanese men between 35 to 60 years considered the effect of walking to work, in relation to the risk of hypertension. The findings suggested that the activity of walking to work was associated with a decreased risk for incident hypertension, even after adjustment for age, body mass index and other factors.

CARDIO-VASCULAR HEALTH IN THE WORKPLACE

For many organizations seeking to promote healthy living, it is not possible to legislate against ‘unhealthy modes’ of transport to and from work: this, despite the increasing efforts to promote ‘green policies’ and discourage driving by car to work. However, many organizations, as well as encouraging gym membership (either on-site or through a gym membership scheme) have also introduced exercise in the workplace. Using such an ‘interventionist’ approach, Chan *et al*[6] recruited participants from five workplaces, where jobs were moderately or highly sedentary. A recognized exercise regime was introduced to the workplaces and it was hypothesized that this exercise regime would increase participants’ daily ambulatory activity. This was determined using pedometers. The pedometers served a three-fold purpose; (1) for feedback on baseline and increasing levels of activity during the programme; (2) as a motivational device and (3) to objectively measure changes in physical activity. Changes in body weight index (BMI); waist girth and heart rate were measured during the study. Participant’s heart rate as well as waist girth and body weight reduced significantly during the intervention period although there were no significant changes in systolic or diastolic blood pressure.

So far, we have considered only the effects of exercise on the effects of cardio-vascular health. However, the psychosocial work environment has also be considered as a possible source of stress and hence hypertension. In a study by Unden *et al* [7] a study group of 148 working men and women from seven occupational groups including teachers, musicians, policemen, engineers and saw mill workers were examined. They underwent 24 hour recordings of electrocardiograms (ECG) to determine cardiovascular health. Psychosocial work characteristics were determined by means of the following parameters: social support at work; work demand; decision latitude; and skill direction. The results suggested that mean heart rates are significantly higher in people reporting low social support at work. This applied to each of the seven occupational study groups considered.

The willingness of employees to participate in workplace exercise was the subject of a study by Waikar and Bradshaw [8]. The attention in this study of sedentary workers was not on cardiovascular health but on musculoskeletal exercise to overcome problems associated with working long hours on VDT display screens. However, many of the findings are pertinent to the present discussion, since they provide insight into the propensity of individuals to engage in exercise during working hours. In attempting to design a suitable exercise regime, workers were asked to comment on:

- The ease of comprehending exercise instructions
- Degree of difficulty of the exercise
- Degree of privacy when exercising
- How exercises are initiated
- Length of exercise breaks

- Level of embarrassment of exercises
- Places where exercises are completed
- Types of exercise

The results indicated that almost two-thirds of respondents do not exercise on their own during work houirs to relieve pain and discomfort. However, two-thirds indicated that they would be willing to participate in formal exercise programmes. Around forty per cent suggested that embarrassment is not an issue when it comes to exercise and one-third of the respondents prefer to exercise in a group. ‘Types of exercise’ and ‘degree of difficulty of exercises’ were the two most important categories for the participants.

FACILITIES MANAGEMENT AND ITS ROLE IN CARDIOVASCULAR HEALTH

In a paper entitled ‘The escalating pandemics of obesity and sedentary lifestyle’, Manson *et al* [9] provide a blueprint for action on the part of health care professionals in curbing the obesity epidemic associated with sedentary work. It suggests that only a few minutes of a clinician’s time will facilitate more effective intervention related to obesity. However, in view of the previous discussion it is clear that intervention in the form of health programmes in organizations are replete with difficulties. Many people are reluctant to participate in exercises as a group, in part due to embarrassment. Moreover, heavy work schedules often deter employees from taking time out.

For these reasons, this paper suggests that exercise be designed into the daily routine of employees. This could in principle be crafted into a worker’s daily activity without any ongoing intervention on the part of the organization or indeed by any planned approach on the part of the employee. In this sense the activities could be seen as being ‘embedded’ into the work, by virtue of the design of the facility. It is worth considering typical design and facilities management planning decisions that will impact on the amount of energy expended by employees in the course of the day. These include:

- Vertical circulation paths between individuals and resources that necessitate walking
- Horizontal circulation paths between individuals and resources that necessitate stair climbing or descent

The type of resources that might be sought and necessitate walking include printing facilities, photocopying facilities, archives, coffee areas, cafeterias and wash rooms. The location of people and resources within a facility as well as the overall size of the facility and layout efficiency will determine the likely amount of expended energy in a given day. Facilities managers, tasked with optimizing the effectiveness of an organization by efficient space planning will typically be concerned with the following:

- Minimizing travel time thus liberating ‘dead’ time to enable effective work to be done
- Minimizing the disruption to ‘neighbours’ when circulating
- Maximizing space use efficiency, thus eliminating the amount of unused space
- Maximizing productive interaction, both formal and informal
- Maximizing convenience, providing resources at hand with minimal interruption
- Maximizing use of costly equipment such as printers through sharing and networking

Many of these objectives are consistent with attempts to reduce the sedentary behaviour of employees. For example, the increased recognition of the role of informal interaction in organizations (with the advent of the flattened organization) provokes a need to ‘mingle’.

Often, this involves moving to informal meeting areas such as coffee bars or kitchens. However, the association of ‘interactions’ with some form of consumption activity may itself undermine any such benefits. Moreover, the increasing practice in facilities management of supplying the catering needs on location (e.g. at a business meeting), whilst stimulating the socialization element, will also obviate the need to walk. Pressures to make more efficient use of expensive office equipment has stimulated more widespread use of shared resources such as printers. This in turn may necessitate that employees get up from their workstations and move around. Furthermore, with the advent of the ‘activity-settings’ workplace solution (a term originally coined by Stone and Luchetti [10]), employees are encouraged to migrate from one work area to another, to attain a work environment suited to the task, whether it be private study, collaborative working or meetings.

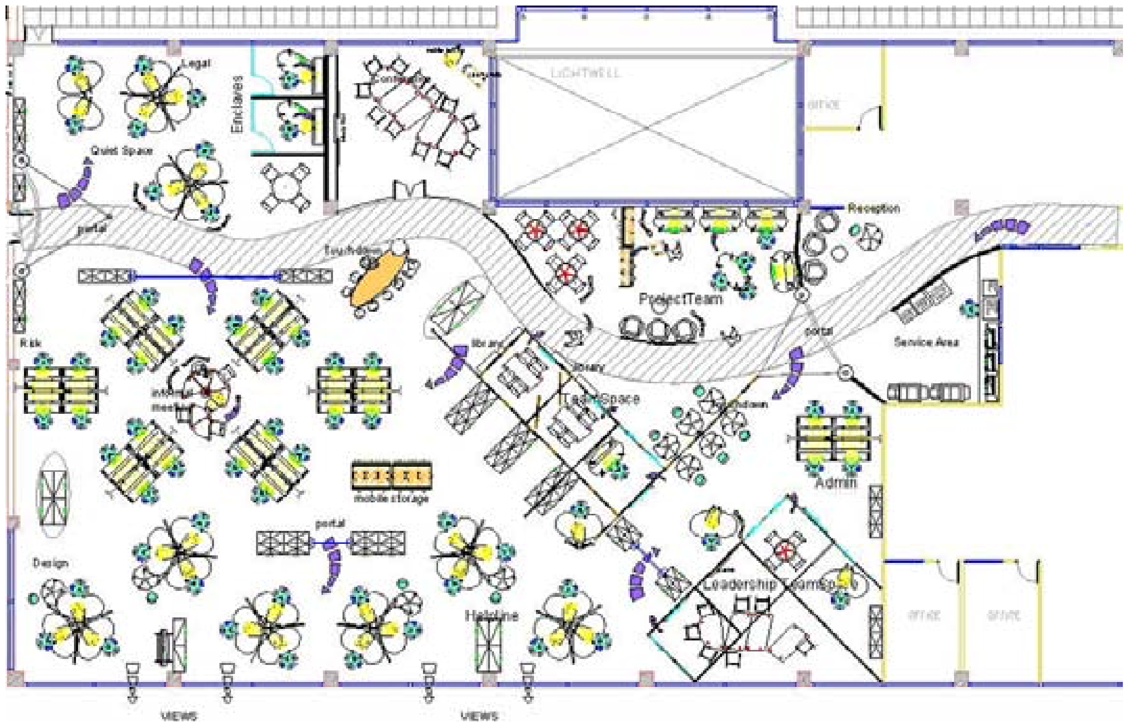

Figure 1. Modern ‘activity-settings’ space plan.

THE FACILITIES MANAGER’S DECISION RULE

Undoubtedly, the overriding rule used by facilities managers, which in turn determines the ‘embedded’ health of a building layout, is the ‘stacking’ and ‘blocking’ plan. Both techniques are routinely used as part of a ‘computer-aided facilities management’ (CAFM) package. They incorporate algorithms that enable the minimization of travel times, based on ‘affinity diagrams’ or ‘interaction matrices’. These matrices indicate the relative strength of relationships that exist or are sought between departments and resources/services within a facility. The optimized stacking plan indicates how departments and individuals are dispersed throughout the building to enable efficient functioning of the organization. Those parts of the organization that require proximity to one another are typically located on the same floor, since a floor separation is detrimental to such intense and regular exchanges.

It is however, the intention in the remainder of this paper to consider the implications of these decision rules used by facilities managers. The assumptions upon which they are based are challenged and the author suggests a more flexible contingency approach to space planning that embraces the concept of 'embedded' health in buildings.

IS TRAVEL TIME 'WASTED TIME'?

Implicit in space planning systems widely used today is the belief that the necessity to travel (walk) is inherently bad. This, despite the growing evidence that the sedentary nature of work brought about by reliance on the car and the computer have 'designed out' exercise from the normal work routine. In particular, the ubiquity of email has circumvented the need to walk to a colleague's workstation, even if only a few metres away. From an organizational perspective, travel time is universally considered to be undesirable. Not only is it perceived as 'lost' time: it also is seen to hamper 'processes', that are seen to be affected by layout. However, some of these assumptions need to be challenged.

- Work involving one-to-one communication can be undertaken whilst walking. Little is known about how the activity of walking affects the richness or productivity of such interactions. Indeed it is possible that an active behaviour may positively affect the interaction.
- Adjacency to support 'process' is significantly less important in modern work environments where most knowledge exchange is played out in a virtual environment (e.g. exchange of documents). Thus the imperative for close proximity to support process is less evident.
- Organisations are seeking to stimulate 'non-routine' rather than 'routine' interactions whereby individuals exchange ideas and approaches with people in different departments or areas. This cross-fertilisation thus challenges 'the way we do it here' mentality and encourages innovation and inter-group collaboration.

Quite at odds with organizational desires to increase efficiency, compact designs may only be producing organizational 'straight jackets' imposed by space plans.

DOES 'EMBEDDED' HEALTH IN BUILDINGS CONFLICT WITH ACCESSIBILITY?

One of the potential conflicts between the development of 'embedded' health in buildings is the need to satisfy accessibility requirements. Travel distance and vertical separation (i.e. stairs) are potential impediments to accessibility. Accessibility (or just access) refers to the ability to reach desired goods, services, activities and destinations (collectively called opportunities). Accessibility can be affected by (modified from [11]):

- *"Mobility*, that is, physical movement. Mobility can be provided by walking, lifts and escalators.
- *Mobility substitutes*, such as telecommunications and delivery services (including delivery of post and catering services)..
- *Transportation system connectivity*, which refers to the directness of links and the density of connections in the path network.
- *Land use (spatial use)*, that is, the geographic distribution of activities and destinations. The dispersion of common destination increases the amount of mobility needed to access goods, services and activities, reducing accessibility."

Accessibility is affected by a number of competing factors including time, money (in the case of transport usage), security, discomfort and risk. Each of these issues needs to be considered in relation to the ‘embedded’ health in terms of the challenging physical requirements of the workplace.

DISCUSSION

This paper has presented an argument for the creation of ‘embedded’ health in buildings. In other words, an environment which coerces occupants into physical activity, as part of their everyday work routine. One such example is stair walking (i.e. not taking the lift). It recognizes the fact that direct intervention involving scheduled workplace exercise activities are often difficult to implement, largely as a result of apathy and embarrassment on the part of employees (particularly in Western societies). Furthermore, provision of specialized gym facilities may fail to attract those employees most in need of exercise and who are unable to commit time to exercise activities, because of their busy working day.

The paper also argues that facilities management decisions in relation to stacking and blocking have a fundamental influence on the ‘embedded’ health of buildings. This profession needs to carefully reexamine their assumptions in relation to space utilization and travel time. Is travel distance something that should always be minimized? Accessibility and the ‘embedded’ health of buildings need not be conflicting objectives. Travel distance is only one of the factors that affect the accessibility of environments. A contingent approach, rather than a ‘one-size fits all’ approach may be most appropriate (for example, the choice of taking the lift or stairs). Undoubtedly we are only just beginning to wake up to the immensity of the obesity challenge in modern workplaces. This paper has attempted to highlight the pervasive effect of facilities management decisions in this context. The questions raised in this paper present the framework for a research project currently being formulated, to understand the impact of space planning on the cardio-vascular activity of office employees.

On the Effect of Thermal Environment on Meat and Carcass Quality in Swine Raised on Privately-Owned Pig Farms

Cornelia Petroman, Ioan Petroman, Horia Sarandan and Letitia Stana

Agricultural and Veterinary University of the Banat, Timisoara, România

Corresponding email: c_petroman@yahoo.com

SUMMARY

Environmental temperature in which perform commercial hybrids on privately-owned family farms in the Banat area (România) has a strong impact on the valorisation of feed and particularly on energy, as there is an optimal temperature at which feed is valorised with maximum efficiency resulting, upon slaughter, in quality carcass ranging at a level of objective graduation depending on lean meat percentage. Fat deposits are thicker in swine bred at low temperatures (35.2%) compared to swine bred during fattening at 16-18^{0}C, the average of lumbar fat being 2.9 cm, of abdominal fat being 1.9 cm, and of dorsal fat being 3.1 cm. The percentage of lean meat in commercial hybrids on family exploitations is 56.06%, and high quality carcass represent 79%, with a meat: fat ratio of 1.8/1, i.e. neatly superior values compared to animals exploited in sheds with non-controlled temperature and having access to the paddock during winter.

INTRODUCTION

During their life, swine are exposed to different variations of temperature as they are exploited in different systems (intensive, semi-intensive, and extensive), and on pig farms thermal conditions are not always constant. Even in the sheds ensuring constant temperature there are temperature variations due either to improper mechanical control or to the variation of external environmental factors.

Research [2, 3, 5] concerning fattening swine physiology in different thermal environments were carried out on animals bred in constant thermal environments or, in some cases, on animals moved from a constant environment to other environments with different temperatures, showed the impact of air temperature on some physiological indices in swine (body surface temperature, body temperature, breathing rate, and pulse rate).

Environmental temperature influences at the same time all fundamental biological processes: global energetic metabolism, growth and development processes, carcass quality, and pork quality [1].

Temperature is the environmental factor that exerts the strongest influence on fundamental biological processes – metabolic processes – and, through them, on all the rest of biological processes and phenomena.

The dependence on temperature of metabolic processes intensity reflects its dependence on chemical reaction speed they rely on. It is known that a raise in temperature determines a raise of kinetic energy of the molecules that react and, therefore, a raise of the chemical reaction rate. In the area of thermal neutrality, energy expense is minimal, which characterises basal metabolism. When the temperature of the environment decreases until it reaches the critical point, there is a quick and intense raise of energetic metabolism, i.e. a defence reaction against cold.

As growth and development are biological processes depending strictly on metabolism and displaying simultaneously, optimal temperature ensuring their maximum rate varies depending on the different stages of swine life. In general, it is admitted that growth rate in commercial hybrids is lower during cold seasons, which means that environmental temperature must be controlled as swine are homoeothermic animals and sweat little.

Experiments carried out by different authors [5, 6] show that commercial swine have, during the growth and fattening periods, an average daily gain 2-4 g higher when shed temperature was 25^0C compared to higher temperatures (>25^0C), when there is a decrease of weight gain; this means that the larger the body weight, the more the animal suffers because of high temperatures.

Though they practice heating sheds for fattening swine, environmental temperature has a strong impact on valorising feed and, particularly, energy. For each category of swine there is an optimal temperature at which feed is valorised with maximum efficiency and, as a result, carcass and meat quality meets EU and objective grading system requirements. Maximum growth rate in swine is reached at temperatures between 15 and 23^0C in an intensive system, and 12 and 17^0C in a family system. Commercial hybrids are strongly affected by temperature changes than fattening swine. At low temperatures, part of the energy is used in thermal regulation through burning intensification and heat release [3].

Most research show that, the more temperature differs from the thermal comfort area, the poorer the valorisation of feed is, sudden changes and particularly the dropping of temperature lead to an increase of feed consumption and to a decrease of swine's performance with all the implications on meat quality, i.e. low-quality carcass upon slaughter (classes O and P).

METHODS

Our experiment lasted for 90 days. We took under study two lots of commercial swine [(Large White x Landrace) x Duroc], as follows:

- the first lot, made up of 100 heads, was raised at an environmental temperature of 8-10^2C, in a shed with paddock, with no heating source, on a straw litter, and was put to fattening when weighing 40.7 kg at the age of 70±2 days;

- the second lot, made up of 100 heads, was raised at an environmental temperature of 16-18^0C, in a shed with paddock, but without any access to it, with temperature regulating facilities, full pavement over 40% of the box area and grill over 60% of it, and was put to fattening when having the same weight and age as the first lot.

During the study period we monitored the average daily gain for the 90 days of fattening and specific consumption at different temperatures, aiming at developing a fattening technology for family-owned farms in the Banat area (Romania) that have such shed with paddocks, analysing carcass and meat quality and classifying carcass and meat depending on the EUROP objective graduation.

We measured fat layer thickness of carcasses in the 100 heads of each lot and measured the percentage of meat per carcass, as well as the meat: fat ratio in order to point out the impact of temperature on the raising-fattening process and on carcass quality to be able to implement the most convenient fattening system for privately-owned family farms in the Banat area, taking into account the fact that these last years these farms have no longer bred swine, preferring to sell the grains to larger pig farms, though they are not always satisfied with the prices they can get. Implementing such fattening technologies could be an alternative source of income for these farms, particularly if we take into account the fact that they own the infrastructure (sheds) and, for the surplus of grains, they can take in commercial hybrids for fattening, thus obtaining profit.

RESULTS

During the 90 days of fattening, the two lots of animals were fed mixed feed specific to the fattening period and having the nutritious value mentioned in Table 1.

Table 1. Nutritious value of feed supplied to commercial swine

Metabolisable energy	Matter	Raw protein	Raw cellulose	Raw fat	Salt
Cal/kg	%	%	%	%	%
3093.02	84.12	16.21	3.67	2.56	0.43

Swine were fed at leisure, feed being prepared with the available grain (maize, barley, and wheat in shares of 36.50%, 10%, and 20%), and purchased protein plants (sunflower 5%, soy 11%, meat flour 6%), microelements, calcium carbonate, salt, and protein-vitamin-mineral mixture (grower).

The average daily gain in the first lot fattened at a temperature of 8-10^{0}C varied between 595 and 709 g with a feed conversion index of 3.65-4.22 kg of feed for 1 kg of gain.

The second lot reached an average daily gain of 631-817 g for the 3 fattening months with a feed conversion index of 2.68-3.10 kg of feed for 1 kg of gain. The temperature of 16-18^{0}C in the shed of the second lot had a positive impact on growth rate and a lower specific consumption of feed per 1 kg of gain. The swine in the lot fed at a temperature of 16-18^{0}C needed a lower amount of energy for thermal regulation, most of the energy being used for growth and development.

In the first lot there were no shivering during the fattening period even at temperatures of 8-10^{0}C, because they were exploited on straw litter which ensured some kind of protection from cold: results were almost as good as in swine exploited in sheds with temperatures of 16-18^{0}C, with expenses somewhat higher because of the energy consumption for maintaining temperature constant (Table 2).

At the age of 160±2 days, the two lots reached an average weight of 100.34 kg (Lot I) and 105.83 kg (Lot II): the 100 heads in Lot I being slaughtered and classified in accordance with the objective graduation of the carcass, they ranged as shown in Tables 3 and 4.

Table 2. Average daily gain and specific consumption depending on temperature

Lot	Fattening period (days)	Average daily gain (g)	Specific consumption (kg of feed/kg of weight)	Shed temperature
I	70-100 101-130 131-160	505 684 709	3.65 3.93 4.22	8-10^{0}C
II	70-100 101-130 131-160	631 723 817	3.10 2.90 2.68	16-18^{0}C

Table 3. Swine carcass classification in Lot I fattened at 8-10^{0}C

Class	Class (lean meat)	Number of carcasses	%	Lean meat (%)
E	= 55%	5	5.0	56.30
U	50-55%	36	36.0	53.80
R	45-50%	32	32.0	49.70
O	40-45%	20	20.0	44.50
P	< 40%	7	7.0	39.60
Total		100	100	50.59

Results of classifying carcasses of commercial swine in the two lots are shown in Figure 1. We can see that swine fattened at low temperatures have a higher percentage of fat per carcass compared to the swine fattened at a temperature of 16-18^{0}C, having 56.06% lean meat compared to 50.59% in Lot I.

Table 4. Swine carcass classification in Lot II fattened at 16-18^{0}C

Class	Class (lean meat)	Number of carcasses	%	Lean meat (%)
E	= 55%	14	14.0	56.80
U	50-55%	65	65.0	54.20
R	45-50%	19	19.0	49.80
O	40-45%	2	2.0	44.80
P	< 40%	-	-	-
Total		100	100.0	56.06

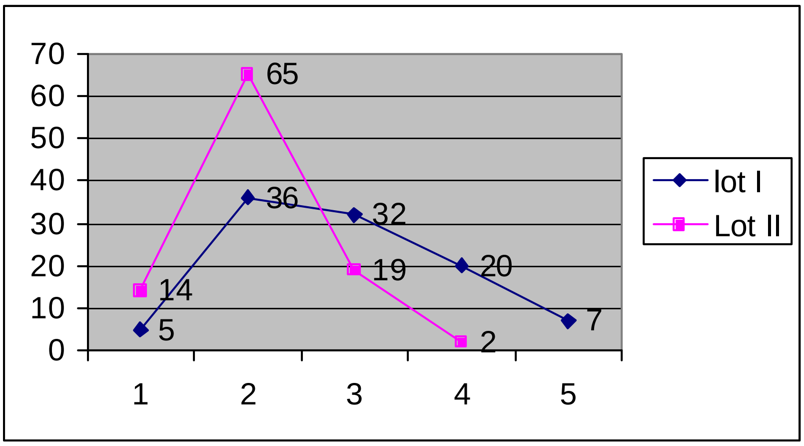

Figure 1. Results of carcass classification in the two lots depending on shed fattening temperature

Measurements made concerning the thickness of the fat layer in the carcasses of the two lots (cervix – between vertebrae 6 and 7, thorax – between vertebrae 19 and 20, lumbar – at the fore extremity of the *gluteus medius*, lumbar – at the middle of the *gluteus medius*, lumbar –

at the hind extremity of the *gluteus medius*, abdominal – at the sternum, abdominal – at the belly button, abdominal – at the side) shows that the average of lumbar measurements in Lot I is 3.7 cm, of abdominal ones is 2.0 cm, and of dorsal ones is 3.1, which shows that low fattening temperatures result in a thickening of the fat layer (Table 5).

Table 5. Thickness of the fat layer in commercial swine carcasses fattened at different temperatures

Lot	Average of lumbar measurements (cm)	Average of abdominal measurements (cm)	Average of dorsal measurements (cm)
I	3.7	2.0	3.8
II	2.9	1.9	3.1
Differences ±	+0.8	+0.1	0.7

Cutting carcasses showed the meat: fat ratio in Lot I (1.43: 1) and in Lot II (1.8: 1) (Table 6).

Table 6. Meat: fat ratio in the two lots

Lot	Lean meat (%)	Fat (%)	Bones (%)	Total (%)
I	50.59	35.20	14.21	100
II	56.06	31.13	12.81	100
Differences ±	+5.47	-4.07	-1.40	

Studies carried out to establish the influence of temperature on commercial swine hybrids raised and fattened show that at low temperatures (8-10^{0}C) the maximum average daily gain was 709 g with a conversion index of 4.22 kg of feed per 1 kg of gain. Animals exploited in environments with controlled temperature (16-18^{0}C) reach a maximum average daily gain of 817 g with a conversion index of 2.68 kg of feed per 1 kg of gain, as they are no longer forced to consume energy for thermal regulation, all of it being converted into weight gain.

CONCLUSIONS

Animals raised at low temperatures produce fatter carcasses than animals raised at higher temperatures (16-18^{0}) and have a close gain rate. The percentage of lean meat per carcass in hybrids raised at high temperatures is 56.06%: thus, 79% of their carcasses range in higher quality classes, compared to only 41% in the carcasses of animals raised at low temperature. The meat: fat ratio also records higher values in commercial hybrids exploited in optimal thermal conditions.

Health and wellbeing in a deep plan air-conditioned commercial property

Graham Capper, John Holmes and Guy Brown

Northumbria University, Newcastle upon Tyne, NE1 8ST, UK.

Corresponding email: graham.capper@northumbria.ac.uk

SUMMARY

The purpose of this paper is to assess the health and wellbeing implications of working in a deep plan office building in a temperate climate and illustrate how office design can add to or detract from productivity.

The authors have carried out post occupancy evaluation surveys on employees before and after the move from a naturally ventilated, shallow plan office to a deep plan, air-conditioned office. The workforce and workload remained constant, which enabled true comparison between building types. The public sector employer specified an environmentally friendly building that incorporates health and wellbeing factors.

It is anticipated that in future, deep plan buildings will become increasing expensive to service and maintain. In this study there was no discernable increase in productivity and a significant number of correspondents preferred the shallow plan old building.

INTRODUCTION

This research tracks public sector employees as they move from an old office building into a purpose-built, environmentally sound, office building. It hypothesises that the attempts to change the image and effectiveness of an organisation by changing workspace layouts has been ineffective and considers the consequent implications for individuals working in that organisation. It looks at the likely relationship between health and wellbeing of individuals and productivity.

BACKGROUND

Productivity and the workplace

The Commission for Architecture and the Built Environment (CABE) in the UK reports [1] that differences in productivity can be as high as 25 per cent between comfortable and uncomfortable staff. Individuals react differently to different stimuli, but the most important factors in achieving health and comfort are air quality, temperature, overall comfort, noise and lighting. Most of these environmental factors can be readily and easily measured in any office, particularly in an era with the widespread use of Building Management Systems (BMS) to control mechanical and electrical building services plant.

Clements-Croome and Baizhan [2] however draw a distinction between 'comfort' and 'wellbeing', inferring that although comfort is an important factor in productivity, wellbeing is a 'prime requisite'. They suggests that productivity depends on:

> *"Good concentration, technical competence, effective organisation and management, a responsive environment and a good sense of well-being."*

Putting personal environmental control into occupants' hands can also be important for both comfort and productivity [3]. CABE suggests that variances in individual preference and the growing importance of staff autonomy both point to the value of introducing a means of personal control to the greatest degree consistent with efficient operation of the air conditioning, lighting and related building systems. Wyon [4] has indicated that a good indoor environment may only satisfy eighty per cent of an occupants' perceived level of comfort, with individual control satisfying the remaining twenty per cent. It has also been suggested in a number of studies that in order to improve productivity, firstly comfortable conditions have to be provided (and conditions should be improved periodically) and, secondly, occupants' requirements have to be met rapidly.

Workspace Development

Historically in the UK, public sector workspace has developed reactively and in an *ad hoc* manner, often inhabiting impressive buildings designed to reflect status and support top-down government structures. As a result of the wide scale expansion in the public sector workforce between 1945 and 1950, purpose-built structures were designed to accommodate whole government organisations under one roof [5]. Internally, these were organised into corridor offices [6] and continued to reflect status according to grade, and the horizontal and vertical boundaries of the hierarchical structure [5]. These slab blocks in the 'modernist' style were identified by Duffy in his seminal work 'The Responsible Workplace' as the most flexible form to accommodate the work styles, hive, club, club and den he classified [6].

More recently there are a range of workplace and cultural changes affecting the way the public services operate; the geography of an organisation; and redesign of workspace has been introduced to reinforce a culture of internal communication and break down traditional hierarchy [1]. The aim of creating a flexible working environment where staff would feel valued and well motivated, whilst improving the efficiency of space usage was a key aspect of the reform and modernisation agenda.

One aspect of modernisation is the use of the workplace to drive business change [5] which may be achieved through: *efficiency* - making economic use of real estate and driving down occupancy costs; *effectiveness* - using space to support the way that people work, improving output and quality; and *expression* - communicating messages both to the inhabitants of the building and to those who visit it, to influence the way they think about the organisation [1].

Sir Anthony Turnbull speaking of the refurbishment of the UK government's Treasury Building summarised these aims as:

> *'It has prompted communication, both formal and informal and has encouraged flexible ways of working. Above all it has fostered a feeling of self-confidence and presented an attractive image to the talent we need to recruit.'* [1]

THE STUDY

The Properties

This study examines the employees of two office developments within a city centre in the North East of England. In 2005 the participants moved from a 1960s office building to a new, adjacent, building that had been completed the previous year.

The 1960s building is of concrete frame and cladding construction and is a shallow floorplate building, 14 storeys in height. The building is single glazed with steel frame windows. Heating is by central gas fired boiler with perimeter radiators. All the radiators are fitted with thermostatic valves, allowing some level of occupant temperature control. Social facilities in the form of 'tea points' are provided on each floor.

No air conditioning system is installed within the building and the working areas are naturally ventilated by way of opening windows. Lighting to all work areas is provided by luminaires recessed into suspended ceilings, with additional task lighting in the form of desk lamps. No specific noise control measures are used within any of the buildings working areas, although meeting and interview rooms are constructed to provide a high level of acoustic performance.

The majority of floors within the building are open plan in nature, although a small number of departments retained cellular offices. Floors within the building each housed approximately fifty staff.

The 2004 building is a deep plan floorplate building constructed with a steel frame and double glazed steel framed windows. It is divided into an east and west wing with seven and four working levels respectively. The majority of floors within the building are open plan with minimal cellular offices constructed for senior staff.

Heating is by gas fired central boiler and radiators, cooling by passive chilled beams. Mechanical ventilation is provided through floor diffusers. A BMS automatically controls the internal environment.

Environmental assessment

The Building Research Establishment's Environmental Assessment Method (BREEAM) is the most widely used environmental assessment tool in the UK and is a voluntary scheme that aims to quantify and reduce the environmental burdens of buildings by rewarding those designs that take positive steps to minimise their environmental impacts. Projects are assessed using a system of credits that are grouped within the following categories: Management, Health and Wellbeing, Energy, Transport, Water, Materials and Waste, Land use and Ecology and Pollution. The assessment process results in a report covering the issues assessed together with a formal certification giving a rating on a scale of 'Pass', through to 'Excellent'. One of the deciding factors for selection of the 2004 building was that it is a BREEAM 'Excellent' building.

Research methods

This research carried out evaluations of comfort and wellbeing (as perceived by occupants) to determine a relationship between these factors and productivity.

Historical methods of productivity research are seen as largely scientific, and conducted in controlled, limited environments [7]. There have been a number of more recent studies considering the interactive and subjective nature of a 'real world' workplace (such as Leaman and Bordass [8]) that utilise occupants' self-assessment of workplace quality and personal productivity levels.

Building performance, and the effect this has on occupant satisfaction and productivity is often measured through the use of post-occupancy evaluation surveys (POE). This form of evaluation came to prominence during the 1980s, with the rise of the facilities management (FM) discipline demanding more information on the buildings they manage, and the development of the Office Environment Survey, conducted to address increasing reports of incidences of sick building syndrome within the UK.

POEs were used in this study and were carried out in 2002 and 2006, before and after the move. The POEs were identical apart from identifying those employees who had moved from the 1960s building. The research has the benefit therefore of drawing upon two identical surveys of the same staff in two offices. In contrast to many research projects trying to relate staff productivity and satisfaction over a number of case studies [9] this has the benefit of having the staff as a 'constant', notwithstanding some turnover between the two surveys.

The questionnaire design allowed respondent staff to indicate their views on a wide variety of issues using 'tick box' responses and the opportunity to provide a written commentary, this data was subsequently analysed to provide quantitative data to compare with the previous office. More interesting in many resects was the qualitative data which was gathered by allowing staff the opportunity to comment on the issues being measured.

Response data from the second survey are reported below with the comparable results from the first survey in brackets.

The second survey was administered to 400 (143) with a response rate of 41% (47). Of the respondents 61% (70) worked in open plan offices occupied by 8 or more persons. 53% (48) of the respondents described themselves as professional or managerial staff, which clearly implies that individual offices are a rare commodity in both buildings. Some 84% of the respondents in the second survey had worked in both offices.

RESULTS

Health and Wellbeing

It is possible to have an environmentally sound building, as defined by a recognised scheme such as BREEAM, but fail to address any health or wellbeing issues for occupants (as BREEAM is not prescriptive, the points may be obtained in other sections, such as Transport). BREEAM attaches considerable weight to health and wellbeing and includes a variety of indicators such as openable windows, proximity to windows to allow a view out and the provision of occupant controlled blinds to control glare. In this instance the building scored very well in the 'Health and Wellbeing' section but lost points on the 'view out' of a window due to the shape of the building. Credit was given for installing openable windows but in practice these are locked shut.

In the previous office, although the building did not have air conditioning and staff described it as *'smelly and stuffy'*, they did have an element of control over their environment to the extent that they had access to opening windows and could open them at will.

In contrast, the staff in the modern, open-plan, building have little or no control over their working conditions. An uncomfortable environment might only be improved by phoning the FM team, requesting more heating or cooling, then waiting for a sensory indication that their request had been dealt with. The situation may be exacerbated by a perception of longer response times that are common due to the practical difficulty in matching the different preferences of groups or individuals.

Layout

People tend to prefer working at low densities rather than at high densities due to them being given more freedom in the workplace. Open-plan layouts typically involve problems of raised noise, visual distraction and reduced privacy as well as an inability to control an individuals' environment referred to above.

There were complaints from staff that they could not concentrate on their work due to noise and distractions from colleagues. For example *'the noise levels make it very difficult to concentrate when people are talking to one another'*. The design of the building has attempted to compensate for this problem by providing 'quiet rooms ' which could be booked for concentrated works, however *'when in quiet rooms you can hear every word from adjoining rooms and the kitchen'*. The 'quiet' rooms have well insulated walls and soundproof doors, however sound is easily transmitted across the suspended ceiling.

Analysis of the questionnaires indicates how important these factors are in practice. The problems do not arise from a switch from cellular to open plan offices as, in the sample 10% fewer staff were working in open plan accommodation. The difficulties arise in the number of people per floor and the configuration of the office. Staff have moved from narrow floor plans with light and ventilation on both sides, to a deep plan building with up to 100 people in a large open space (where it may be 20 metres to the nearest window). In these circumstances staff feel more subjected to control of their environmental conditions via the FM team and the BMS and subject to noise coming from all directions.

There may also be a layout/social aspect to the working conditions revealed by anecdotal evidence from staff. In the previous office each floor had its own social breakout space in the form of a ‘tea-point’. This fostered a sense of community amongst the team working on the floor. In the new building the tea-making / lounge area is equal in area, but is accommodated in two large (anonymous) spaces shared by the whole building, thus losing the team ownership or the social space.

Personal control and response time

Individual occupants need systems to provide comfortable environment and also require systems to respond quickly to avoid their discomfort [10]. It is stated that the occupants become healthier, happier and more productive the more rapid the response times become and that an occupants’ tolerance threshold can be widened by a rapid response.

One of the major findings of the study relates to the control of environment afforded to staff. In the old building the staff were close to windows and although in poor condition were openable to improve ventilation. They had individual control of the ceiling lights and because the standard of lighting was perceived to be poor, had been provided with task lighting on an ad hoc basis. In the new building there was a complete absence of individual control exacerbated by an absence of commissioning of the building services during a rushed occupancy programme.

As a result parts of the building were too cold or too hot, the lighting generally was too bright and the windows, although openable, were locked shut to avoid extraneous natural ventilation compromising the BMS. Staff complained constantly to the FM team with requests to adjust temperatures at the local level (the BMS was addressable down to four workstations). Staff perceptions were of a lack of control over their environmental conditions, an unseen intermediary (the FM team) has to be phoned or e-mailed to request changes, and then there was never any certainty that action had been taken. Understandably, this was a considerable impediment to productivity.

Building commissioning

It is now three years since the building was occupied and the FM team have spent much of that time identifying and correcting defects, for example the location of sensors next to heat sources, which jeopardised the effective running of the BMS. The lighting was found to be well over the 400-lux design level and has been adjusted to a more comfortable specification. Low humidity and the carpet specification had conspired to create a chronic static electricity problem, to such an extent that at one stage the FM team considered issuing gloves to all the staff! (this has now been ‘cured’ by increasing the relative humidity levels).

Any of the problems could have been avoided if the building had undergone a comprehensive commissioning of the building services installation during the hand-over phase. In the event, completing the work was rushed to avoid penalty payments by the developer. It is ironic that the rush to move into the building transferred the commissioning process from the specialist installers to the building occupants.

Discussion

Reviewing the data the most remarkable aspect is the extent to which the new building fails to meet the aspirations of the staff that moved from a building, which by common consent was accepted as providing a poor working environment.

The survey revealed that 35% of respondents felt that their productivity was reduced in the new building whilst only 15% felt that productivity had increased.

Overall, most of the respondents considered that environmental conditions had improved, but in this instance environmental conditions include the ‘newness’ and appearance of the building as well as matters of temperature and humidity.

The most telling statistic is the response to the question ‘In respect to your overall satisfaction with your workspace, given the choice would you prefer to return to your physical conditions at the previous building’. 24% of staff would prefer to return to the conditions of the ‘poor’ building.

CONCLUSIONS

Organisations are aware of their responsibility to provide a healthy productive workplace for their staff. In the move to the new building the employers felt they were moving from a building that was of poor quality to a new building with excellent environmental credentials.

In the short term, benefits were lost due to inadequate commissioning of the building services that made the new building very uncomfortable for a significant number of staff for a considerable time.

In the long term it may be questioned whether the move to the new building was a good idea in principle. The old building could have been refurbished with new windows, solar shading and high efficiency boilers. The building would have had a new lease of life as a light, airy and flexible workspace.

The new building, whilst employing relatively efficient heating and cooling plant, has a considerably larger carbon footprint as well as higher energy costs. The shape of the building means that it is inflexible as regards work styles [6] and cannot be occupied without the extensive mechanical services.

In future energy costs will increase ahead of the rate of inflation and will become more significant in relation to overall office accommodation costs. An environmentally sensitive refurbishment may have not only retained the embedded energy in the 1960s building but also have provided a healthier working environment.

SUMMARY

Field survey in the M-Office which installed Task/ambient conditioning systems (hereinafter referred to as the “TAC”) was conducted in 2005 and 2006. It was intended to investigate the influence of the worker's behavior and task-conditioning to worker’s comfort sensation. In this survey, immediately thermal environment and worker’s behavior were measured, and questionnaire to occupants who worked as usual were conducted. We found that both activity level of occupant and exposed thermal environment is greatly different one by one. It was suggested that an increase in metabolic rate according to worker’s behavior influence on thermal and comfort sensation certainly. It is necessary to recognize the metabolic rate to estimate the occupant’s declaration in a field survey. In an actual office where occupants stay long terms, the tendency that occupant prefer isothermal airflow was seen. It was thought that adjustment performance with wide amount of task air-conditioning airflow and operationality was desirable to cover occupant’s sense integrally or to connect with occupant’s comfort and satisfaction. Based on the knowledge obtained from this investigation, needs for TAC were discussed.

INTRODUCTION

To stop the environmental destruction that progresses globally, the energy reduction is demanded in an architectural industry. In Japan, it is recommended by the Government to set the air temperature in an office building to be 28 °C in summer. TAC is assumed to be one of the solutions to it. By installing TAC, total energy can be lowered by moderating the amount of energy to ambient zone and giving intensive to the task zone. Moreover, the improvement of the comfort and satisfaction is expected by individual adjustment to create the desirable environment and by direct supply of a fresh air to the breath region. In this survey, it was intended to investigate the influence of worker's behavior and task air-conditioning to worker’s comfort sensation. For that purpose, immediately thermal environment and worker’s behavior, like a sit-down state, walking distance, and metabolic rates, were measured, and questionnaire to occupants who worked as usual for thermal sensation, comfort sensation, and so on were conducted.

METHODS

Outline of the M-Office and TAC

Figure 1 shows perspective of the M-Office, both interior view and exterior view [1]. It has a site area of 4,782 m^2 and a gross area of 19,169 m^2, and four floors above ground and one below ground. Structure of the M office is SRC.
Figure 2 shows the outline and layout of TAC in the M-Office. There is a unit of under floor air-conditioning (100 CMH) per two occupants, and a unit of task air-conditioning (25 CMH) per one occupant. The partition connects under floor, so air for floor-supply is used as for it from task unit. All occupants can handle the task unit for adjusting air volume between 0% and 100%, and air direction between 0° and 45° of the task air-conditioning by an individual.

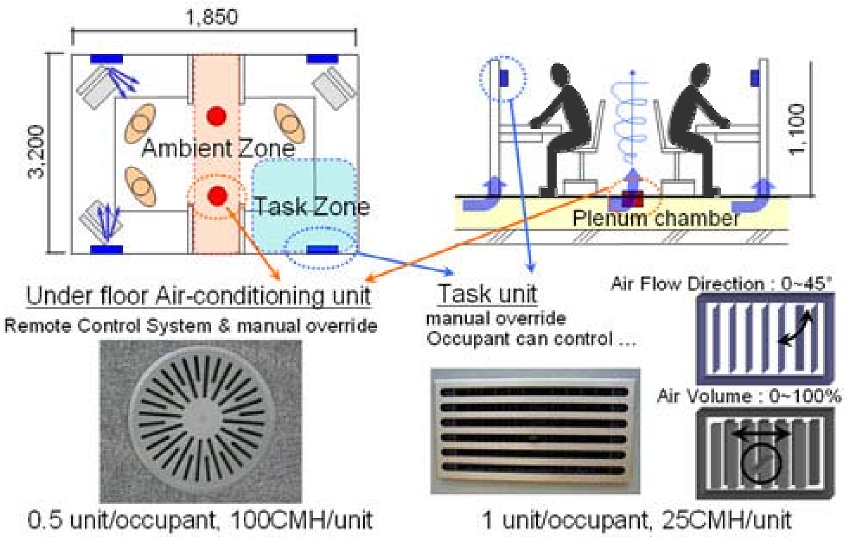

Figure 1. Perspective.

Figure 2. Walking distance and Metabolic rate.

Measuring methods

Field survey was conducted for five days in summer, between period, winter of fiscal year 2005, and summer of 2006. Twenty people who work at the M-Office, namely twelve males and eight females, participated in this survey. It was investigated that the influence of the worker's behavior and task air-conditioning to worker’s comfort sensation. Table 1 shows measuring items in this investigation. In the investigation in 2006, immediately thermal environment, temperature of airflow from task-conditioning, sit-down state, number of steps, and metabolic rate were measured at any time in work hours to understand the worker’s activity state and the thermal environment workers were exposed. Only the investigation of sit-down state was also measured in fiscal year 2005. Questionnaire to occupants who worked as usual for thermal sensation, comfort sensation, and so on were conducted once in the morning and once in the afternoon. At that timing, air temperature, relative humidity, radiant temperature, and airflow velocity at the position of subject were measured. Questionnaire was done only for three days, and it was made conditions in the use of task air-conditioning. Occupants cannot use task air-conditioning in the 1st day (TASK-OFF), must open fully the shutter of task air-conditioning in the 2nd day (TASK-ON), and can use task air-conditioning freely in the 3rd day (TASK-FREE).

Table 1. Measuring items.

Measuring items	Measuring equipment	Subject number	Interval	Timing
Air temperature	C-C Thermocouples	8 people	1 sec	declaring
Relative humidity	RH sensor	8 people	1 sec	declaring
Radiant temperature	Directional Radiometer	8 people	1 sec	declaring
Airflow velocity	Heated Anemometer	8 people	1 sec	declaring
Immediate air temperature	Thermohygrometer	20 people	1 min	any time
Airflow temperature	Thermohygrometer	20 people	1 min	any time
Opening level of task-conditioning shutter	Eye Observation	20 people	1 hour	-
Number of steps	Pedometer	20 people	1 hour	any time
Metabolic rate	Accelerometer	8 people	1 min	any time
State of seating	Thermometer	20 people	1 min	any time
Sensation vote	Questionnaire sheet	20 people	1 min	declaring

RESULTS

Worker's behavior

Working hours in M-Office is 9:00-18:00. The clerical worker was targeted in the measurement of 2006, and worker whose type of job in the measurement of 2005 is coexistence of the business employment, the research employment, and the clerical work. All data that will be shown are the average of five days on the weekday. But, absentee and occupant who sat only by ten minutes or less weren't included in the average.

1) Seating rate, Seat occupancy rate

Whether occupant seated or not was judged by the change of the surface temperature of the seats in one minute [2]. So there is a possibility that too short sitting down is not counted. The definition of seating rate and seat occupancy rate are as follows.

seat occupancy rate = (the number of the occupants seated) ×(total number of the attendance)
seating rate = (hour while the occupants seated) ×(Work hours)

Figure 3 shows temporal change of seat occupancy rate, and Figure 4 shows seating rate that was the average of twenty occupants. The same tendency was seen at three terms of fiscal year 2005. Excluding the break in daytime, seat occupancy rate, that shows the rate of person exposed to the task air-conditioning at given times, in 2005 hover nearly 40%, that in 2006 hover at 60-80%. In other measurement, seat occupancy rate hovers at 30-50% [3]. It becomes 0-20% at lunchtime, but 80% immediately after lunchtime. Seating rate in summer is 37%, that in between period was 35%, that in winter was 39%, that of yearly average is 37%. But that in summer 2006 is high, 63%. It is found that the rate of hours occupants stay in task-zone during work hours baries by occupational category and the content of work.

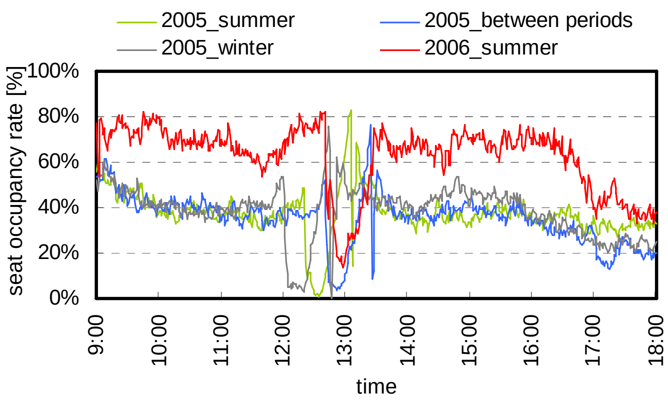

Figure 3. Seat occupancy rate.

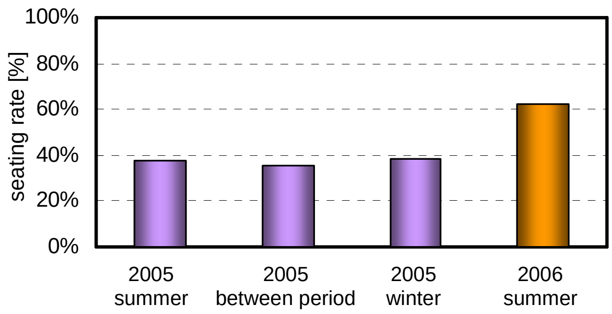

Figure 4. Seating rate.

2) Sitting down, Getting out of the seat

Figure 5 shows the penchant for sit-down. The rate of the number of 1-5 minute sitting down is the highest, nearly 50%. In the mean while, the rate of the number of 1-5 minute getting out of the seat is the highest, nearly 70% in 2005, 86% in 2006. Number of times shows occupant doesn’t leave one's desk easily when occupant sits down once. It is found that workers are not frequently repeating sit-down and leaving-out, so it is thought that metabolic rate while occupants are sitting down is sort of steady.

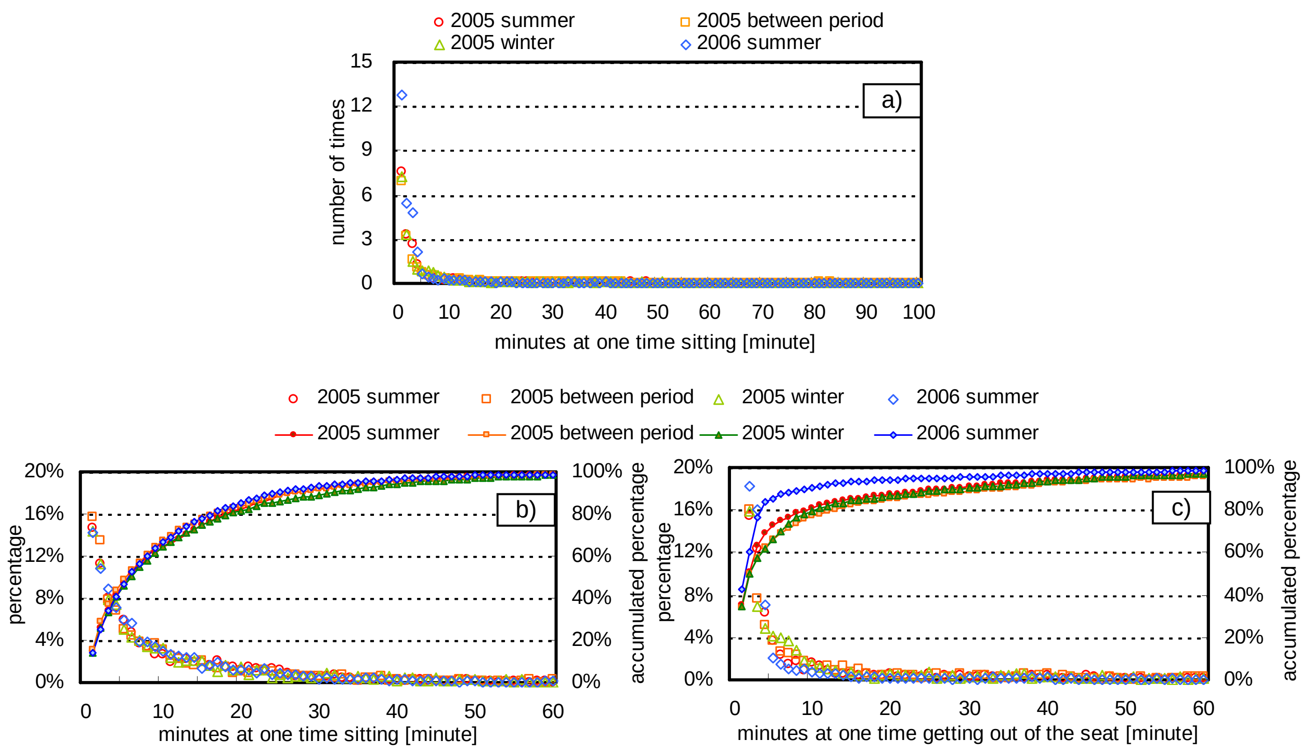

Figure 5. Penchant for sit-down.

3) Worker's behavior and thermal environment

Figure 6 shows worker's behavior and exposed air temperature of M2, one of the male subject, at TASK-OFF condition, that task conditioning system was not allowed to use. It also shows the declared time zone and timing he declared. Metabolic rate in this paper indicates the instant mean value per minute measured by omnidirectional accelerometer, that is a physical activity logging system. When a strong movement is momentarily done, a high value is measured, like 3.0 met or more. Almost activity level of occupant can be recognized. It was found that both activity level of occupant and exposed thermal environment is greatly different one by one.

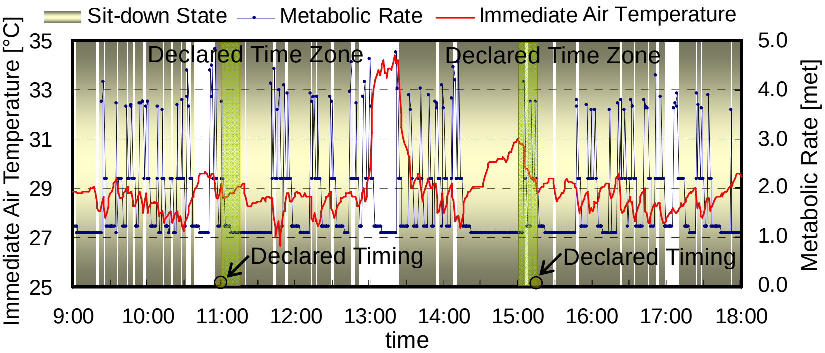

Figure 6. Worker's behavior and Exposed air temperature.

Figure 7 shows number of steps and metabolic rate that is mean value of all occupants. Table 2 shows five days average of metabolic rate while seating and that while leaving from the seat of each occupant. It is found that the number of steps in an hour was about 300 steps or more in work hours. Average of metabolic rate through work hours is 1.4 met, that while seating is 1.3 met, and that while leaving from the seat is 1.7met. Average of metabolic rate, which shows activity level, while seating is to each occupant. Metabolic rate measured in this survey could be one of the useful basic design value.

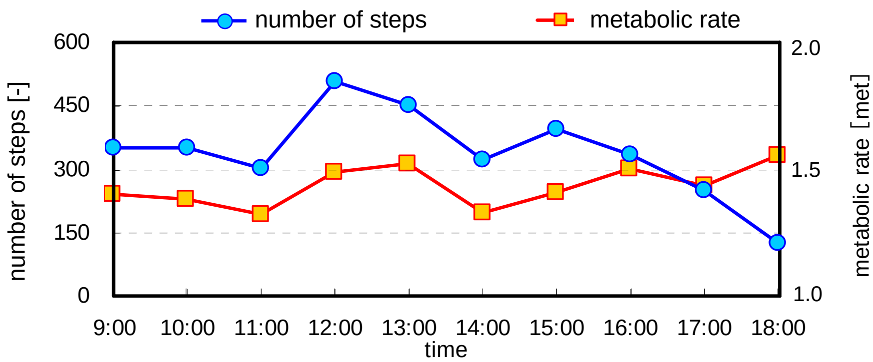

Figure 7. Number of steps and Metabolic rate.

Table 2. Metabolic rate [met] while seating and while leaving from the seat.

	M1	M2	M3	M4	F1	F2	F3	F4	Ave.
Work hours	1.4	1.7	1.3	1.4	1.3	1.4	1.3	1.7	1.4
While seating	1.3	1.5	1.2	1.2	1.2	1.2	1.2	1.4	1.3
While leaving	1.5	2.3	1.5	1.8	1.6	1.5	1.4	2.2	1.7

Occupant's sensation vote and metabolic rate

Figure 8 shows relation between declaration and metabolic rate. Standard new effective temperature (hereinafter referred to as the "SET*") was derived from questionnaire about amount of clothes in the morning and environmental measurement at declaration timing, namely air temperature, relative humidity, radiant temperature, and airflow velocity at the position of subject. But difference was not found by the classification by SET* between conditions. So the declaration was classified from the viewpoint of metabolic rate that was 30 minutes average before occupant declared, metabolic rate is less 1.2 met and is 1.2 met or more, so declarations in this figure are mixed with TASK-OFF, TASK-ON, TASK-FREE condition.
In case metabolic rate is 1.2 met or more, the declaration of thermal sensation votes (TSV) increased that on the hot side, and that of thermal comfort sensation votes (TCSV) increased that on the uncomfortable side. It was suggested that an increase in metabolic rate according to worker's behavior influence on thermal and comfort sensation certainly.

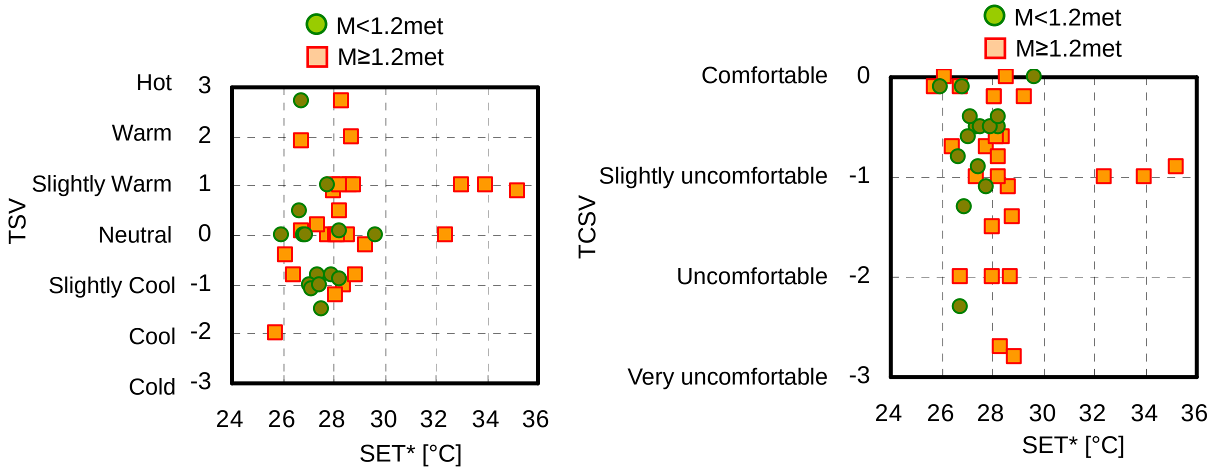

Figure 8. Relation between Metabolic rate and Declaration.

Occupant's sensation vote and temperature of airflow from task air-conditioning

Figure 9 shows relation between Δt and declaration of twenty occupants (Δt-TSV, Δt-TCSV, Δt-ECSV, Δt-EAV). Table 3 shows voting scales. The definition of Δt in this paper is as follows, and Δt as isothermal is between -1 °C to 1 °C, Δt as non-isothermal is more or less than 1°C.

$$\Delta t = \text{(temperature in task-zone)} - \text{(temperature of airflow from task air-conditioning)}$$

Temperature in task-zone and temperature of airflow from task-conditioning was averaged in time zone occupants declared, 11:00-11:30 and 15:00-15:30. The declaration in TASK-FREE condition, that occupants could operate task-conditioning systems freely, targeted only the occupants whose opening rate of the task air-conditioning shutter was 50% or more because of searching the influence that the task air-conditioning gives to sense of occupant. For TASK-ON condition, task-conditioning systems were forced to use without any occupants' control.

When airflow was isothermal, thermal sensation votes (TSV) were almost installed between from -1 to 1. Thermally or environmental comfort sensation votes (TCSV, ECSV) were positioned on the comfort side, and environmentally acceptable votes (EAV) were on the acceptable side. Meanwhile airflow is non-isothermal, both the hot side and the cold side declarations were seen with TSV. The declarations of the uncomfortable side were seen with TCSV, ECSV, and the declarations of the unacceptable side were seen with EAV. In an actual office where occupants stay long terms, the tendency that occupant prefer isothermal airflow was seen.

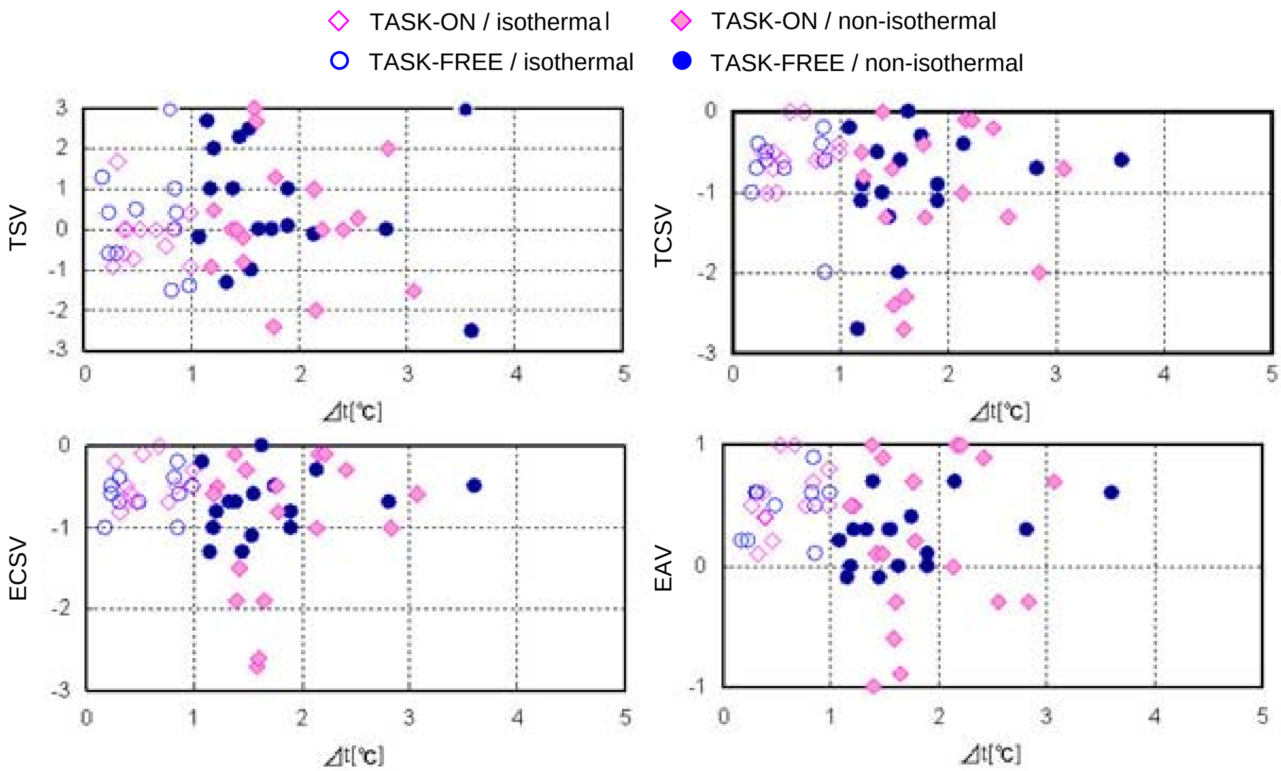

Figure 9. relation between *⊿t* and declaration.

Table 3. Voting scales

Declaration items	3	2	1	0	-1	-2	-3
Thermal sensation	hot	Sl. Warm	Warm	Neutral	Sl. Cool	Cool	Cold
Thermal and Environmental comfort sensation	-	-	-	Comfortable	Sl. Uncomfortable	Uncomfortable	Very Uncomfortable
Environmental acceptable sensation	-	-	Acceptable	-	Unacceptable	-	-

DISCUSSION

We found that the rate of hours occupants stay in task-zone during work hours is few by the type of job, and workers are not frequently repeating sit-down and leaving-out, so it is thought that metabolic rate while occupants are sitting down is sort of steady. But while leaving from the seat, both activity level of occupant and exposed thermal environment is greatly different one by one. It was confirmed that an increase in metabolic rate according to worker's behavior influence on thermal and comfort sensation certainly. It is necessary to recognize the

occupant's situation, especially like metabolic rate and exposed air temperature, to estimate the occupant's declaration in a field survey.
In an actual office where occupants stay long terms, the tendency that occupant prefer isothermal airflow was seen. It was thought that adjustment performance with wide amount of task air-conditioning airflow and operationality was desirable to cover a lot of occupants of sense integrally or to gain occupant's comfort and satisfaction. There is a report which is research of causing the delay in changing the metabolic rate and the skin temperature [4]. It is thought that air-conditioning at space that occupant fit in is very important for gaining occupant's satisfaction. It is possible to decrease dissatisfaction by the task air-conditioning. TAC is an air-conditioning system considering energy balance of task-zone and ambient-zone totally. How to use the building and office changes depending on the occupational category and the content of work, so it is desirable to design HVAC system and to decide operation considering usage. Therefore it is needed to design the HVAC system which can change the operation balance of ambient air-conditioning supply and task air-conditioning supply on some level. Environmental load reduction may be realized without losing occupant's comfort.

Criteria for thermal environment

Revised Swedish Guidelines for the Specification of Indoor Climate Requirements released by SWEDVAC

Lars Ekberg

CIT Energy Management AB, Sweden

Corresponding email: Lars.ekberg@cit.chalmers.se

SUMMARY

The Swedish indoor climate guidelines issued by Swedvac has been thoroughly revised. The new document is adapted to harmonize with related international, European and Swedish standards. The document comprises thermal climate, indoor air quality, sound and light.

The new R1-document is mainly intended to provide guidance for the specification of indoor climate requirements. It is recommended for use as a reference document in the very early phase of planning a new building or the reconstruction of an existing building. The document provides guidance regarding planning of measurements for verification of indoor climate quality, which is an issue to consider already when the indoor climate requirements are being specified.

INTRODUCTION

In the beginning of the nineties the first version of the Swedish indoor climate guideline document "R1" was published by Swedvac. In May 2006 a thoroughly revised version was released [1]. The new document has been updated with respect to knowledge that has evolved over the years and it is adapted to harmonize with related international, European and Swedish standards. The document comprises thermal climate, indoor air quality, sound and light; all indoor climate factors which are influenced by the installation systems in a building, and consequently should influence the design of the building services.

The starting point is that requirements and recommendations from Swedish authorities shall define the basic indoor climate requirements. As in the original R1-guideline, there is an opportunity to select a higher quality level. However, the system for classification of the indoor climate has been radically rearranged in the new version. Thermal climate and indoor air quality are divided into two quality classes each, and sound comprises three quality classes. Only one set of guideline values are specified for light.

The main objective of the new R1-document is to provide guidance for the specification of indoor climate requirements. As illustrated in Figure 1 it is intended as a reference document in the earliest phase of planning a building project. The document does neither provide guidelines for the details in the HVAC-design process, nor for the contracting or administration of buildings in operation. However, it is mandatory that the indoor climate requirements specified using the guidelines should be verified by measurements. The document provides guidance regarding the planning of such measurements, which is an issue to consider already when the indoor climate requirements are being specified.

The objective of the present paper is to provide a summary of the revised Swedish indoor climate guidelines, “R1”.

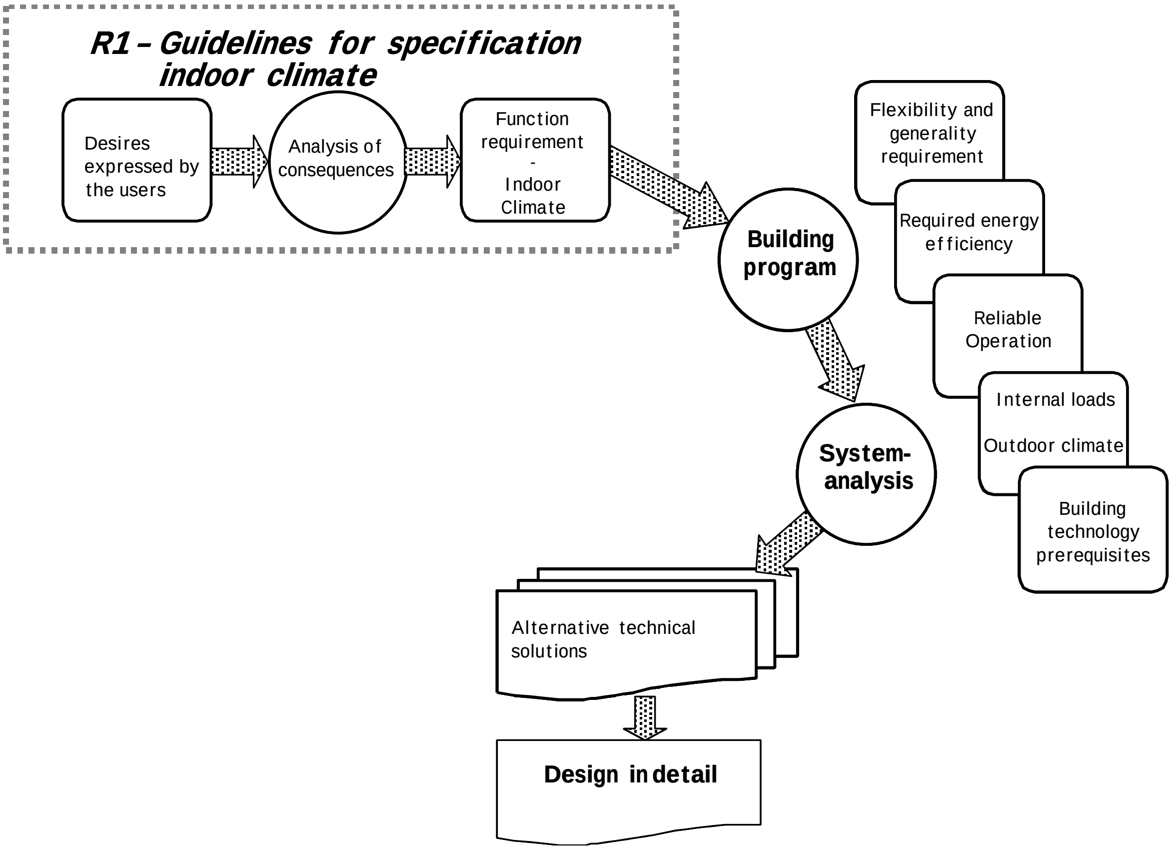

Figure 1. Illustration of the transformation of occupant’s desires to an unambiguous indoor climate requirement specification, and further towards selection and design of feasible technical solutions.

BASIS FOR THE GUIDELINES

Thermal climate

The guidelines regarding thermal climate are based on the ppd/pmv approach specified by the standard SS EN ISO 7730:2006 [2]. The ppd-index, defined in this standard, is used as a parameter to find a suitable target interval for the operative temperature. The starting point is to aim at a climate that is *normally perceived as comfortable*. According to the R1-guideline this corresponds to a ppd-index not exceeding 10%. However, the climate requirement is not explicitly expressed using the value of the ppd-index, since such an approach is deemed dubious and not feasible in practice. The requirement must be specified in a manner that enables a rather straightforward method of verifying compliance by measurements. The operative temperature is judged as a feasible measure, the ppd-index is not.

Some standards and guidelines suggest classification of the thermal climate based on the ppd-index. For example, SS EN ISO 7730 suggests 6%, 10% and 15% as the maximum allowable ppd-index values in three alternative quality classes. A ppd-index of 6% leads to a very narrow temperature range close to the “optimal operative temperature”. For example in an office during summer conditions the temperature range would be about 24.5±1.0°C. The precision of the pmv/ppd approach suffers from uncertainties of the assumed input data, especially regarding the clothing and activity of people, as well as the air velocity. For example, a small change of the met-value from 1.2 to 1.3 may correspond to a change of the preferred operative temperature of more than 0.5°C. Changing the assumed clo value from 0.5 to 0.6 (e.g. by assuming a thin long-sleeved shirt instead of a t-shirt being worn) has a similar effect on the predicted temperature preference. Thus, it can be questioned whether the narrow temperature interval ±1.0°C in practice reflects a higher quality level than the interval 24.5±1.5°C, resulting from calculations using a ppd-index value of 10%. According to the R1-guideline for offices and other premises the higher quality class is obtained by individual temperature control, not by trying to keep the temperature as constant as practically possible.

The R1-guideline does not comprise a third thermal quality class, as e.g. SS EN ISO 7730 does, allowing ppd-index values up to 15%. Such high ppd-values exceeds the recommendation of ppd<10% made by the Swedish Work Environment Authority, and cannot be applied: -A basic principle of the R1-guideline is that not only mandatory requirements, but also the recommendations made by the Swedish authorities shall be met. Thus, the R1-guideline comprises two thermal quality classes, denoted TQ1 and TQ2.

In residential buildings the occupants shall have the possibility to influence the room temperature in both climate classes. The higher quality class is in this case instead obtained by reducing high temperatures during hot summer days. This shall not be interpreted as a recommendation to install mechanical cooling in residential buildings, but rather implies extensive thermal insulation and sun shading.

Values to minimize local thermal discomfort follows the SS EN ISO 7730 closely, but with a few modifications justified by recommendations from Swedish authorities regarding, e.g. floor temperatures. In quality class TQ1 the requirements for reduction of the risk of local discomfort are more sharp than they are in quality class TQ2.

Indoor air quality

According to the R1-guideline, not only the mandatory requirements, but also the recommendations given by the Swedish authorities shall be met (The National Board of Housing, Building and Planning, the National Board of Health and Welfare, the Swedish Work Environment Authority). It is a matter of prescribing minimum outdoor airflow rates, and maximum acceptable concentrations of various pollutants. The R1-guideline does not explicitly prescribe requirements regarding emissions from building products. However, it is mandatory that this issue be addressed by quality assurance in line with some established method. In this respect the R1-guideline refers to, and implies the use of either the Finnish system, administered by The Building Information Foundation [www.rts.fi], or the recommendations made by SP The Swedish Technical Research Institute, in connection to the quality system for “P-marking” of indoor environments [3].

The R1-guideline provides a set of recommendations for target values regarding maximum acceptable pollutant concentrations. The set of target values is a synthesis of previously established guidelines [4, 5, 6], and the implementation in Sweden of the European directive for outdoor air quality (published by the Swedish Environmental Protection Agency) [7]. The recommended target values are the same for both indoor air quality classes, AQ1 and AQ2. The distinction between the quality classes is based on the risk for annoyance due to odors, primarily originating from bio-effluents. In the basic quality class, AQ2, odors must be accepted, at least shortly after entering the building. In the higher of the two classes, AQ1, this risk shall be substantially reduced. The concentration of carbon dioxide (above that outdoors) is used as the quality measure.

Sound and noise
The requirements regarding acoustic quality are based on two Swedish national standards [8, 9]. One of these standards addresses sound in residential buildings and the other addresses premises like offices, schools etc. According to the R1-guideline it is mandatory to consider noise from installations, e.g. the ventilation system. Target values are given both for A-weighted and C-weighted noise levels. However, it is recommended to consider all acoustic quailties comprised in the two standards, e.g. outdoor noise, reverberation, sound insulation etc. The R1-guideline comprises the three sound quality classes NQ1, NQ2 and NQ3.

Light
The R1-guideline prescribes that the lighting system shall be planned and verified according to the standard SS EN 12464-1 [10]. This standard does not comprise a distinction between various light quality classes, and neither does the R1-guideline. Target values are presented for the average illumination, the evenness of the illumination, the unified glare rating index (UGR-index) and the average color rendering index (Ra-index). Furthermore, recommendations regarding the reflectance of various surfaces and the daylight factor are made.

Other factors
In addition to thermal climate, air quality, sound and light, a requirement specification prepared according to the R1-guideline also addresses the risk for legionella growth in water systems, radon in tap water and electromagnetic fields.

TARGET VALUES

This section provides a summary of target values presented in the R1-guideline.

Table 1 concerns thermal climate requirements in offices and similar premises. The guideline prescribes that the ppd/pmv concept shall be used in order to determine a suitable target interval for the operative temperature, considering the clo and met values estimated for the activity the building is planned to house. As can be seen in the table the guideline also comprise recommendations on how to consider deviations from this interval, e.g. during the hottest summer days. According to the R1-guideline the designing engineer shall clarify to the commissioner the consequences of suggested technical solutions, e.g. by an estimation of the percentage of the occupied hours the indoor temperature will rise above the maximum value of the target interval.

Table 2 indicates the corresponding information for residential buildings. Table 3 summarizes target values to minimize the risk of local thermal discomfort. The criterion for reducing the risk of draught is in each quality class given at two alternative temperatures.

Table 1. Example of target values regarding the operative temperature in an office room. The same values are applicable in both quality classes, TQ1 and TQ2. In TQ1 (but not in TQ2) there is an additional requirement of individual temperature control in single rooms and/or smaller zones of large rooms.

Parameter	Target values	Deviations	Note
Operative temperature			
Winter	20.0-24.0ºC	It shall be possible to maintain the indoor temperature below 23ºC	1.0 clo / 1.2 met
Summer	23.0-26.0ºC	At outdoor conditions above 27ºC the indoor temperature should be about 3ºC below the outdoor temperature	0.5 clo / 1.2 met

Table 2. Target values for operative temperature in residential buildings. Note that the difference between quality class TQ1 and TQ2 concerns the prevalence of high temperatures during hot summer days.

Parameter	Target values	Deviations	Note
Operative temperature			
Winter	20.0-24.0ºC	It shall be possible to maintain the indoor temperature below 23ºC	1.0 clo / 1.2 met
Summer	23.0-26.0ºC	TQ1: Indoor temperatures above 26ºC accepted during short periods (hot summer days) TQ2: Indoor temperatures above 28ºC accepted during short periods (hot summer days)	0.5 clo / 1.2 met

Table 3. Target values for minimizing local thermal discomfort.

Parameter	TQ1	TQ2
Floor temperature	22-26ºC	20-26ºC 16-27ºC in rooms not intended for children
Vertical temperature difference	<2ºC	<3ºC
Radiant temperature asymmetry	Warm ceiling <5ºC Cold wall <10ºC	Warm ceiling <5ºC Cold wall <10ºC
Air velocity (draught risk)	<0.10m/s at 20ºC <0.15m/s at 26ºC (Draught rating < 10%)	<0.15m/s at 20ºC <0.25m/s at 26ºC (Draught rating < 20%)

As mentioned above the distinction between the two air quality classes AQ1 and AQ2 is based on the risk of annoyance due to odors caused by bio-effluents. Thus, in quality class AQ1 the concentration of carbon dioxide may not rise above 800 ppm (about 400 ppm above the outdoor concentration) more than temporarily, while in quality class AQ2 the limit is set to 1000 ppm (about 600 ppm above the outdoor concentration). In this respect class AQ2 corresponds to advice given by Swedish authorities.

In both air quality classes AQ1 and AQ2 the aim shall be to maintain the pollutant concentrations below the values given in Table 4.

Table 4. Target values regarding maximum acceptable pollutant concentrations. All values are applicable to both air quality classes, AQ1 and AQ2.

Substance	Designation	Maximum concentration	Reference
Radon	Rn	100 Bq/m^3	FiSIAQ [4]
Carbon monoxide	CO	2 mg/m^3	SP, FiSIAQ [3, 4]
Nitrogen dioxide	NO_2	40 µg/m^3	WHO, ISIAQ-CIB, Swedish EPA [5, 6, 7]
Ozone	O_3	50 µg/m^3	FiSIAQ [4]
Formaldehyde	HCHO	50 µg/m^3	SP, FiSIAQ [3, 4]
Particulate matter <10µm	PM10	40 µg/m^3	FiSIAQ, Swedish EPA [4, 7]
Particulate matter <2.5µm	PM2.5	15 µg/m^3	FiSIAQ, ISIAQ-CIB, Swedish EPA [4, 6, 7]

Furthermore, the R1-guideline prescribes that the outdoor airflow rate shall be selected according to recommendations given by Swedish authorities. In office buildings and other similar work premises this means at least 7 l/s per person plus 0.35 l/s per m^2 floor area. In residential buildings the corresponding values are 0.35 l/s per m^2 floor area or 0.5 air changes per hour, but at least 4 l/s per person. However, the requirement to limit the carbon dioxide concentration is valid also for residential buildings, which typically leads to a higher airflow rate than 4 l/s per person.

The entire occupied zone shall be efficiently ventilated without occurrence of stagnant zones. This shall be verified, e.g. by measurement of the local ventilation index (>90%) or the air change efficiency (>40%). A recommendation is to carry out this verification according to applicable Nordtest medhods [11, 12]

If air filters are needed these should preferably at least be of class F7, and they should be quality assured, e.g by the Swedish “P-mark” system for air filters [13], administered by SP Technical Research Institute of Sweden.

Table 5 gives examples of target values for thee selected indoor environment types regarding noise from installations. As mentioned above the R1-guideline specifies target values regar-ding noise from installations, but recommends that also other acoustic qualities be considered, with reference to two Swedish standards [8, 9].

Table 5. Examples of recommended target values regarding noise from installations.

	Office room			Classroom			Residential room*		
Class	NQ1	NQ2	NQ3	NQ1	NQ2	NQ3	NQ1	NQ2	NQ3
LpA, dB(A)	35	35	35	26	30	30	22	26	30
LpC, dB(C)	55	-	-	45	45	50	42	46	50**
LpAFmax, dB(A)	-	-	-	-	-	-	27	31	35
Note.	-	-	-	-	-	-	No tones	No tones	No tones

* Less stringent values specified for kitchens

** Applies to bedrooms

In addition to the illumination parameters presented in Table 6 the R1-guideline specifies that the illumination in no single point may be lower than 70% of the average illumination over a workplace-surface. The corresponding value for surrounding surfaces and corridors etc is 50%. The daylight factor is recommended to be at least 1%. Furthermore, light sources shall be located with respect to the location of the occupants in order to avoid glare. It is recommended to shade sources of strong luminance, e.g. windows. Guidance regarding the reflectance of various surfaces are given: ceiling: 0,6-0,9; walls 0,3-0,8; floors 0,1-0,5; writing table 0,2-0,6.

Table 6. Examples of recommended target values regarding light.

	Office room	Classroom	Waiting room
Average illumination, lux	500	300*	200
UGR-index	<19	<19	<22
Ra-index	>80	>80	>80

* Classroom for adults, 500 lux

DISCUSSION

The Swedish R1-guideline for specification of indoor climate requirement has been revised. The guideline is adapted to Swedish conditions and regulations, although it has been of priority also to harmonize the document with respect to European standards and guidelines.

The main purpose of the guideline is that it shall be used as a reference document in the earliest planning phase of the building process. The guideline provides a basis for the communication between primarily the commissioner and the HVAC-engineer, but it can also serve as a common basis for the united efforts by all participants in the building process, e.g. also the architect, the tenant and the contractor.

SUMMARY

Field measurements and recording of occupant thermal responses and behavioral actions in 4 buildings clearly demonstrates adaptation: at higher outdoor temperatures, higher indoor operative temperatures are judged as comfortable by the occupants. The comfort votes however didn't relate well with the climate types Alpha and Beta as determined according to the Dutch ATG guideline. But when the climate types were restructured on the basis of the occupants' perceptions the comfort temperatures match very well with the climate types. Furthermore, compared to the former GTO-guideline a higher cooling capacity is needed to keep the indoor temperature strictly below the ATG-limit, but when the temperatures are allowed to exceed this limit for some 5% of the time, both GTO and ATG lead to almost similar capacities.

INTRODUCTION

In 2004 the Dutch ISSO-74 Adaptive Temperature Limits guideline (ATG) was introduced for the design and assessment of thermal comfort in buildings [1,2,3]. To gain experience with the ATG-method a field study in 40 office rooms in 4 buildings during 5 weeks in the summer of 2005 was conducted. The main focus was to assess the performance of the ATG-method in relation to the perceptions of the occupants in real buildings and to the former GTO-method [4] (Weighted Temperature Exceeding Hours).

The ATG-method was developed as an alternative for the former GTO-guideline, which is based on the analytical PMV model. According to the Government Buildings Agency guidelines an adequate thermal indoor climate had to comply with $-0.5<PMV<0.5$ and this limits were allowed to be exceeded for a maximum of 100 hours a year. The time during which the calculated PMV exceeds the limit of +0.5 is then weighted proportionally to the PPD (table 1). It was found that a building with medium thermal mass had a mean PMV of approximately 0.7 at 100 hours exceeding the PMV limit of 0.5 and thus a PPD of 15%. So the weighting factor is 1.5 and the limit of the GTO was determined at 150 (weighted) hours.

Table 1: PMV, PPD and weighting factor

PMV	PPD	weighting factor
0	5	0
0,5	10	1.0
0,7	15	1.5
1,0	26	2.6

Experiences with the GTO-method for a 15 year period have lead to the need for a method that could communicate more clearly than the somewhat abstract "150 weighted exceeding hours". Furthermore consultants started to use the GTO method in a sort of "adaptive" way. Buildings with sealed windows were designed on the basis of 0 (zero) GTO, while in buildings with operable windows more than 150 weighted temperature hours were allowed, although no research evidence was available to support this approach. This changed when [5] was published; the data of this study formed the basis of the ATG (Adaptive Temperature Limits) guidelines. Figure 1 shows the ATG limits for 90, 80 and 65% acceptability of the indoor thermal conditions.

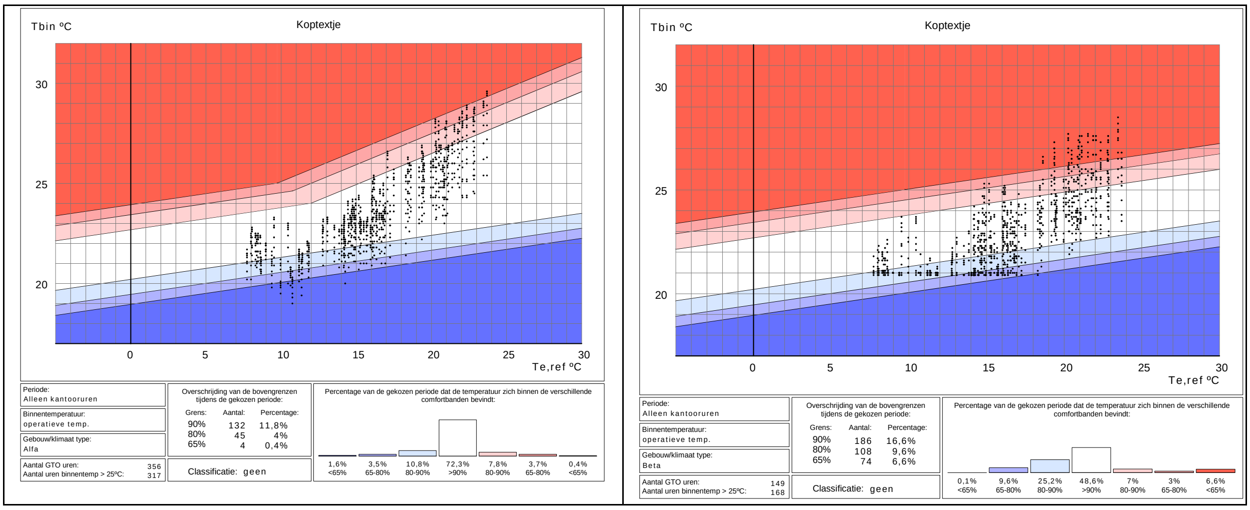

Figure 1: Alpha (left) and Beta (right) type building/climate. Limits of operative indoor temperatures for 90%, 80% and 65% acceptability, as a function of the weighted outdoor temperature Te,ref.

It is assumed that the indoor operative temperature is never allowed to exceed the limits. Whether this is justifiable also is a subject of the current study.

In this study naturally ventilated buildings were defined as “buildings with operable windows and ceiling fans within small single- or dual occupant offices that afford high degrees of adaptive opportunity” and were called Alpha buildings in the ATG guideline. Air conditioned buildings, defined as “sealed centrally air-conditioned buildings with open plan floor layouts” that provide minimal adaptive opportunities and where the occupants are presumed to have no option to open/close windows” were called Beta buildings or climates. The definitions appeared to be unpractical in the Netherlands, because most buildings have operable windows and a variety of room or group sizes (single cellular offices, group offices, landscaped offices) and most buildings combine operable windows with various types of HVAC systems (e.g. all air systems, passive façade ventilation systems, induction units, peak cooling).

As an attempt to overcome the problem to assign the correct comfort limits to a certain building type a flow chart (figure 2) had been developed to distinguish between Alpha and Beta on the basis of the theoretical aspects “sealed façade/operable windows”, clothing adaptation possibilities”, “mechanical cooling/no mechanical cooling” and “temperature control”.

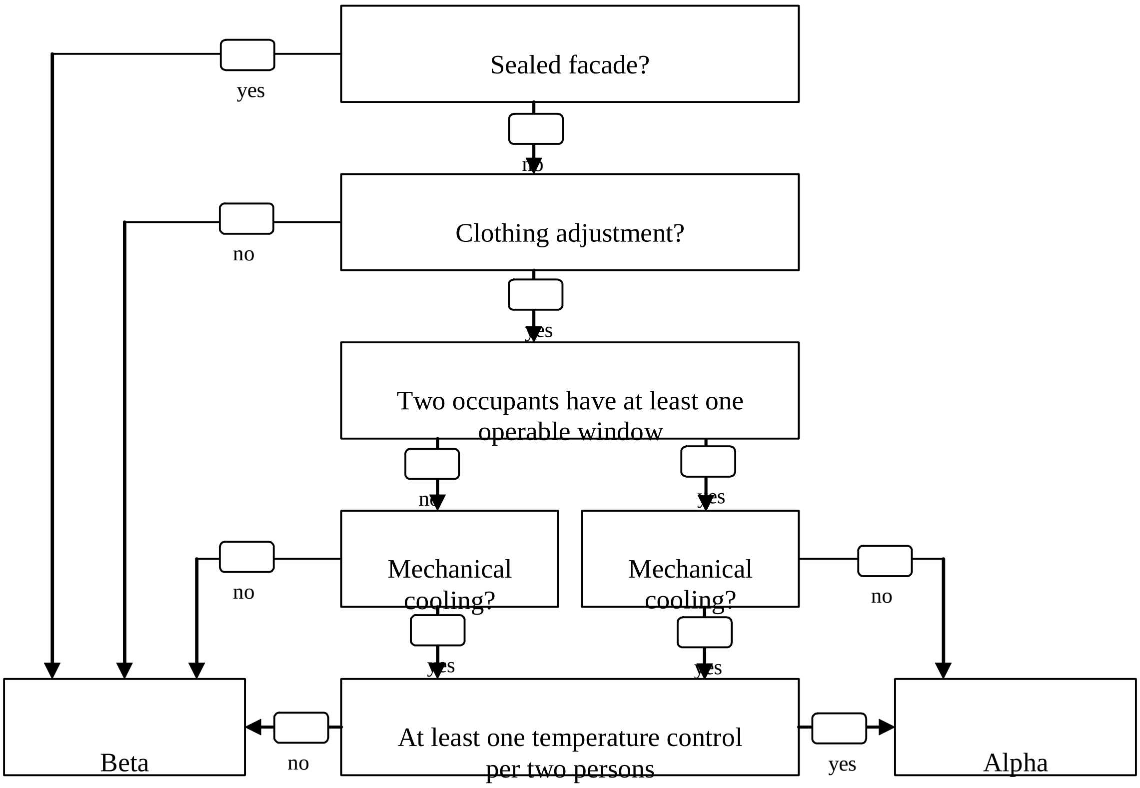

Figure 2: Diagram for determining type of building/climate Alpha or Beta

METHODS

Four office buildings in the Netherlands were monitored in the summer of 2005. See table 2 for details.

Table 2: Details of the four studied buildings

Building	**A**	**B**	**C**	**D**
GFA (m^2)	48400	11800	12550	9000
Number of occupants	1200	280	325	250
Ventilation system	MV No cooling	MV No cooling, cooling	Air-conditioning (induction)	MV Peak cooling
Operable windows	Yes	Yes	Yes	Yes
Room size (p)	1-4	1-10	1-2	1-4
SAM (kg/m^2)	60	62	62	60
IHL (W/m^2)	20	20	20	20
SGF	0,19	0,21	0,22	0,20
Climate type	Alpha	Alpha/Beta	Alpha/Beta	Alpha

GFA=Gross Floor Area, MV= Mechanical Ventilation, SAM= Specific Active Mass, IHL= Internal Heat Load from occupants, office equipment and lighting, SGF= Solar Gain Factor, Climate type according ISSO 74, p 16 and figure 2.

In each building physical measurements were taken in 10 office rooms during a period of at least 5 weeks. Air temperature, globe temperature, relative humidity, air speed and outdoor temperature were measured with a 15 minute interval and operative temperatures and running mean outdoor temperatures were calculated. Twice a day thermal responses of the occupants were monitored by means of a web-based questionnaire, including thermal sensation expressed on the seven-point ASHRAE-scale, thermal preference, acceptability and satisfaction. Also the clo-value, metabolism and adaptive opportunities, including control of operable windows, temperature controls, operation of sun-shading were recorded.

RESULTS

The use of adaptive opportunities show mixed results. The sun shading is open most of the time, despite the fact that the observations were made in mid summer with sunny weather most of the time (Table 3).

Tabel 3: Position of sun shading according to the respondents.

Building	**A**	**B**	**C**	**D**
Open	78%	91%	65%	86%
Half closed	5%	3%	19%	11%
Closed	17%	6%	16%	3%

On the other hand table 4 shows that the operable windows are used on a very regular basis, but there are large differences between the buildings. In building A the occupants were instructed not to open the windows when they felt warm and buildings C and D are mechanically cooled. Further results show that the doors of the office rooms were open most of the time, temperature adjustment knobs of the cooled buildings were seldom used and lighting in the buildings was switched on most of the time in three of the buildings. In building A lighting was off 24% of the time due to an automated, light dependent lighting system.

Table 4: Position of operable windows according to the respondents and measured minimum operative temperature at opening the windows.

Gebouw	**A**	**B**	**C**	**D**
Closed	56%	14%	74%	61%
Just open	10%	43%	10%	38%
Open	34%	43%	16%	2%
$T_{op,\,min}$ (°C)	20,9	21,5	20,6	18,9

The average, self-administered, clo-value was 0,67 ± 0,10 clo and the metabolism was 1,24 ± 0,14 met (72 ± 8 W/m^2).

The thermal comfort votes, represented by the linear regression line through the operative temperatures at which the respondents voted -1, 0 or 1 on the ASHRAE-scale ánd the respondents also voted “no change” on the preference scale, were plotted against the running mean outdoor temperature and compared to the comfort temperatures according to the ATG guideline. When the Alpha and Beta climates were defined according to the scheme of figure 2, no close agreement was found (figure 3).

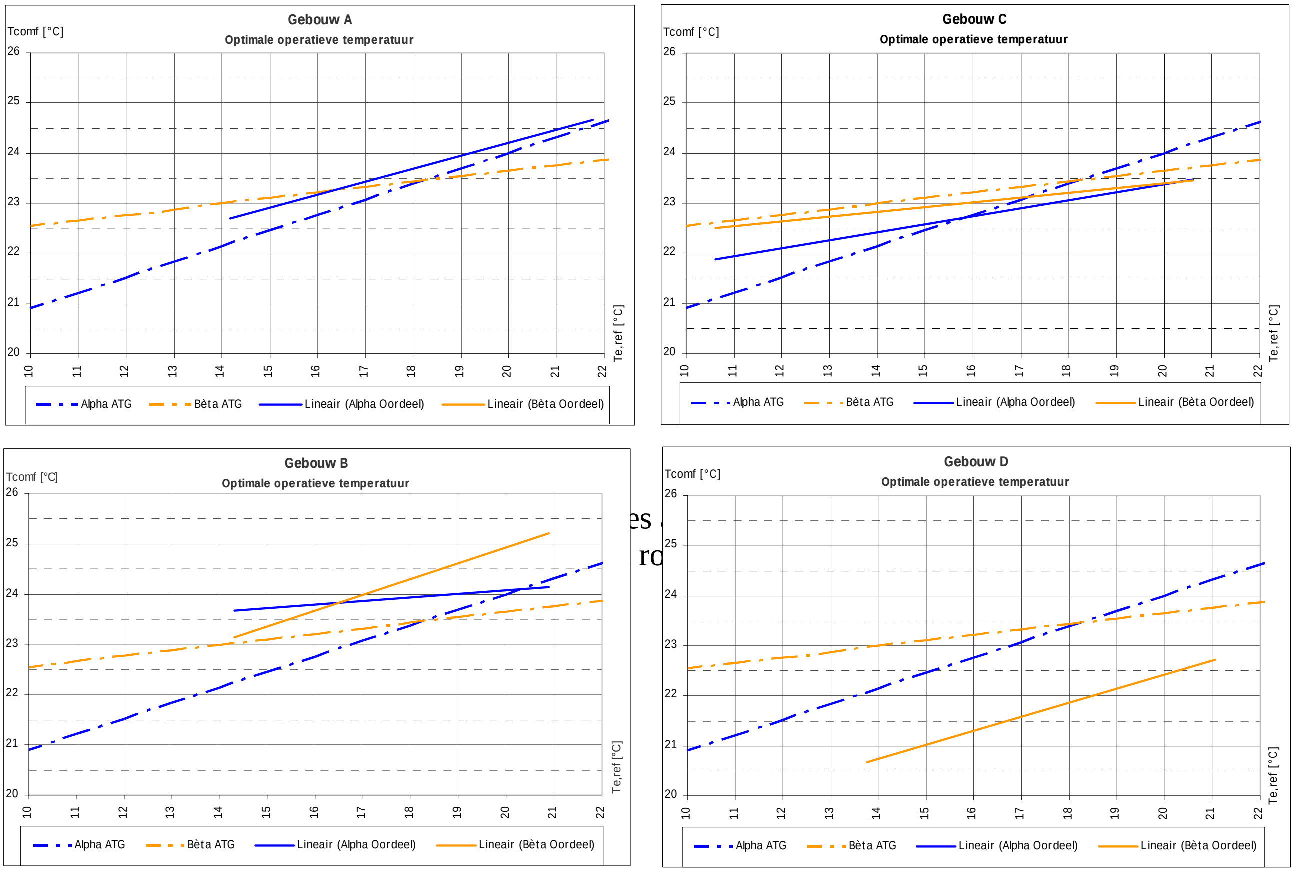

Figure 3: The perception of comfort temperature plotted against the running mean outdoor temperature for Alpha climate (solid blue line) and Beta climate (solid yellow line). The dotted blue and orange lines are the comfort temperature according the ATG-guideline for Alpha and Beta climates respectively, *according to the scheme of figure 2*. The comfort temperatures are represented by the linear regression line through the operative temperatures where the respondents voted -1, 0 or 1 on the ASHRAE-scale ánd were they also voted “no change” on the preference scale.

In figure 4 the same perceptions of thermal comfort are plotted against the running mean outdoor temperature for Alpha and Beta climate types, but now the distinction between Alpha and Beta is defined the perceptions, the slopes of the regression lines through the comfort votes in each room, rather than according to the scheme of figure 1. Again the dotted blue and orange lines are the comfort temperatures for Alpha and Bèta climates.

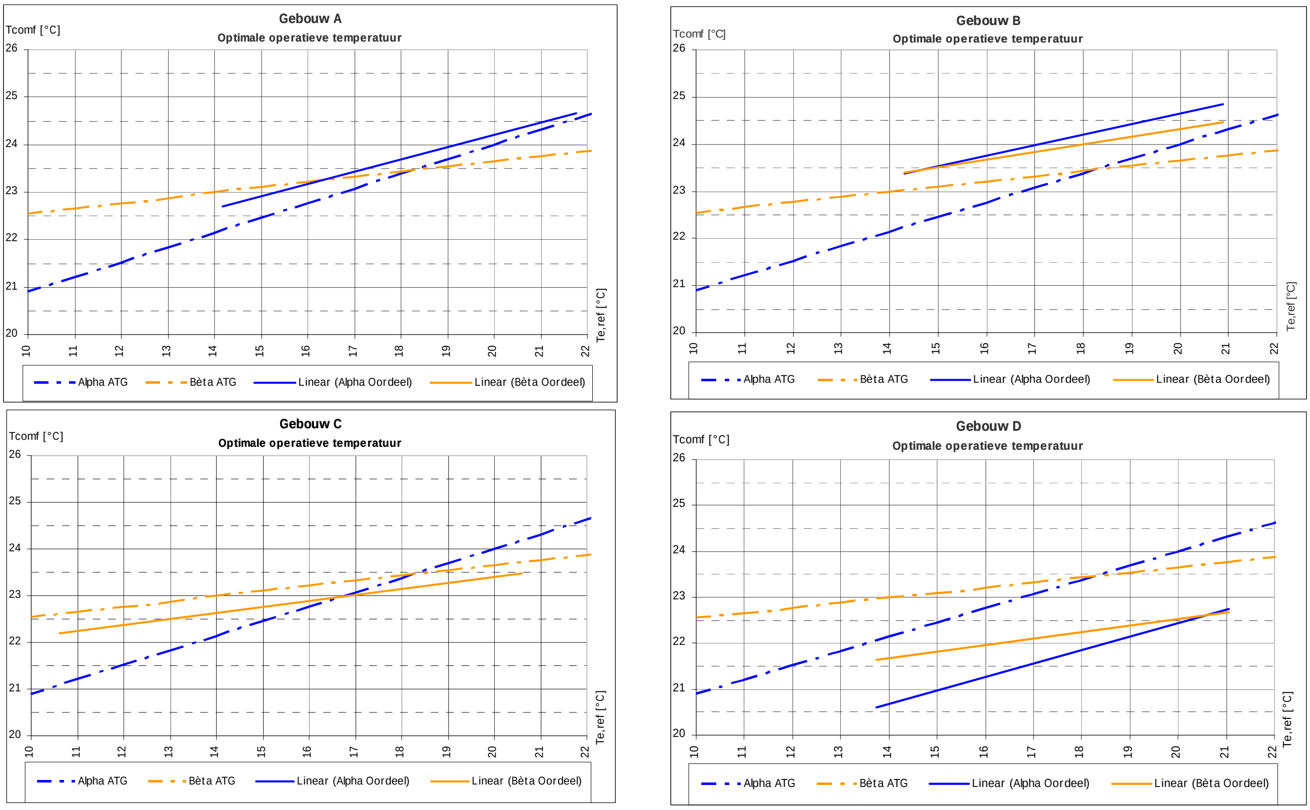

Figure 4: The perception of comfort temperature plotted against the running mean outdoor temperature for Alpha climate (solid blue line) and Beta climate (solid yellow line). The dotted blue and orange lines are the comfort temperature according the ATG-guideline for Alpha and Beta climates respectively, *according to occupants' perceptions*. The comfort temperatures are represented by the linear regression line through the operative temperatures where the respondents voted -1, 0 or 1 on the ASHRAE-scale ánd were they also voted "no change" on the preference scale.

Next, the measurements and occupants' perceptions and actions were used to calibrate temperature simulations to be able to compare the behavior of the GTO en ATG guidelines. The results of new simulation calculations show that to meet the ATG limits strictly, a substantial rise of the cooling capacity is needed, compared to the GTO-criterion, in particular for the Beta climate type (59% more cooling capacity), but also for the Alpha climate type (+14%). One of the goals of the introduction of the ATG-guideline was to allow more room for the design of passive buildings by less stricter temperature limits and these results counteracts with this intension.

DISCUSSION

This field study clearly shows adaptation: at higher outdoor temperatures, higher indoor operative temperatures are judged by the occupants as comfortable. This relation is demonstrated even in the relative small sample of only 10 office rooms in each single office building. But in buildings B, C (Alpha) and D (Alpha) the comfort votes didn't relate well with the climate types of the ATG guideline, when determined on the basis of the scheme in the Dutch guideline (figure 2). This flow chart was developed in an attempt to distinguish between Alpha and Beta climates on theoretical considerations, but not on research data. However when the climate types were restructured on the basis of the occupants' perceptions of thermal comfort (the slopes of the regression lines through the comfort votes in each room) the comfort temperatures according the ATG-guideline for Alpha and Beta climates and those according to occupants' perceptions show a good agreement. This indicates that the distinction between Alpha and Beta climates should be made on the basis of the dependence of the operative indoor temperature on the running mean outdoor temperature or to what extent the indoor climate is "free-running". The dependence of the indoor climate on the outdoor climate is the result of the combined effects of building characteristics (e.g. thermal mass, thermal isolation, external heat load), type of HVAC system (ventilation, mechanical cooling) and usage (internal heat load, operable windows, use of sun shading). Specifically the cooling capacity of the HVAC-system seems to influence the voting behavior and is subject for further research.

Furthermore it should be noticed that the adaptive opportunity of temperature control doesn't seem to have an effect on the dependence of the operative indoor temperature from the running mean outdoor temperature and should not be taken into account in the scheme in figure 2. All this is evidence that the scheme to determine between Alpha and Beta climates should be revised and that topics like group size, clothing adjustment and temperature control should be reconsidered and information concerning the properties of HVAC systems (cooling capacity) should possibly be added.

The higher cooling capacity that is needed to comply to the ATG-limits compared to the GTO-guideline is caused by allowing 150 weighted hours to exceed the PMV=0,5 limit in the GTO-method, whereas the ATG-guideline doesn't allow the limits to be exceeded at all. These arbitrary choices treat the ATG-guideline stricter than the GTO-guideline. However, when the temperature is allowed to exceed the ATG-limit for 2,5% to 7,5% of the time both GTO and ATG show similar results. Further research is needed to asses the acceptability to allow the temperature limits in the ATG-guideline to be exceed to occasionally.

CONCLUSIONS

This study clearly shows the effects of adaptation: at higher outdoor temperatures higher indoor temperatures are judged to be comfortable by the occupants. Furthermore the degree of adaptation according to the occupant's perceptions complies very well with the Dutch ATG guideline (ISSO 74), provided the climate classification is made on the basis of the occupant perceptions, rather than on the basis of the flowchart in ISSO 74. This clearly should be subject of further research. Adaptive opportunities are being used by the occupants, but in some cases differently than foreseen during the design. Sun shading is used sparsely, but opening windows is used regularly, even at relative low indoor temperatures. The ATG-method is judged stricter compared to the GTO-method because 150 weighted exceeding hours are allowed whereas in the ATG-method no exceeding of the limits is allowed. It seems reasonable to allow temperatures to exceed the limits a small percentage of time.

ACKNOWLEDGEMENT

This study was supported by the Dutch Governmental Building Agency.

SUMMARY

The objective of the presented research work was to study the effects of moderate operative temperature drifts on human thermal comfort, perceived air quality, and intensity of SBS symptoms. Experimental subjects (52, 50% female) were seated in a climatic chamber and exposed to operative temperature ramps with different slope, direction and duration during two related experiments (±0.6 K/h, ±1.2 K/h, +2.4 K/h, +4.8 K/h). The studied temperature ranges were 22-26.8ºC (light clothing - 0.5 clo) and 17.8-25ºC (heavier clothing - 0.7 clo). Exposure to steady temperatures (24.4, 21.4ºC) corresponding with a neutral thermal sensation was included in the experimental design. Results of the experiment showed that all tested operative temperature ramps were perceived by sedentary subjects when the exposure time exceeded four hours. No significant effect on SBS symptoms related to local irritation of mucous membranes was found, while the intensity of headache, well feeling and concentration ability was significantly higher at the end of the exposure to the temperature ramps. A linear relation between perceived air quality and temperature (enthalpy) was found.

INTRODUCTION

The fact that about one third of the primary energy production in developed countries is consumed by heating, ventilating and air conditioning of non-industrial and residential buildings initiated extensive development of new HVAC systems that allow indoor climate control with reduced energy demand. Some of these systems are associated with moderate drifts of indoor temperatures, also during the building occupancy period. Allowing indoor temperatures to drift rather than to keep them steady, which is common practice in most air-conditioned buildings, may be a feasible means to reduce the building energy demand. The results of previous research suggest that slow temperature ramps up to ±0.5 K/h (23-27ºC) have no influence on the width of the comfort zone as established under steady-state conditions [1, 2]. Berglund and Gonzalez [1] also concluded that temperature limits for 80% acceptability of the thermal environment, particularly the upper limit, defined by ASHRAE Standard 55 [3] might be conservative in case of drifting temperatures. Knudsen et al. [4] addressed the possibility to use the PMV/PPD model [5] (developed and intended for use mostly under steady-state conditions) to predict thermal sensation during temperature ramps up to ±5 K/h. On the other hand, an increase of indoor temperatures in a building has been shown to increase symptoms of fatigue, headache and difficulty in thinking clearly [6]. A field study by Mendell et al. [7] showed significant effects of temperature on the prevalence

of SBS symptoms, even within the comfort zone. Elevated intensity of SBS symptoms may be expected to negatively affect the performance of occupants' mental work.
In the view of the fact that expenses incurred in employee salaries exceed building energy and maintenance costs by a factor of 80 to 100, it becomes clear that reduced energy consumption should not be achieved at the expense of occupants' comfort, productivity or even health [8]. Although previous studies conducted in the climate chambers examined a large range of temperature ramps, their focus was mostly on establishing temperature limits for acceptable thermal comfort. The objective of this study was to extend the knowledge on the effect of moderate operative temperature drifts to cover not only human thermal comfort, but also the intensity of SBS symptoms and perceived air quality.

METHODS

Fifty-two healthy subjects (mean age: 23.7±4.4 (yrs); mean height: 176.6±9.4 (cm); mean weight: 74.7±11.9 (kg); 50% female), recruited college students, were seated in a climatic chamber and exposed to different conditions during two related experimental series; see Table 1. The climate chamber (5 m wide, 6 m long and 2.5 m high) was developed to control accurately the thermal environment [9]. Ventilation system provided approx. 170 L/s of fresh air (air change rate 9 h^{-1}). That corresponds to about 28 L/s per person when considering 6 persons seated in the chamber at the time. Air and radiant temperatures, which were identical during all exposures, air velocity and air humidity were measured continuously at the center of the chamber at 0.6 m above the floor. The water vapor pressure 1.53 kPa (corresponding to 50% RH at 24ºC) was kept constant during all exposures.

In both experimental series, subjects were divided into groups of six. Each group came to an experimental session on the same week-day. Each group experienced one condition a week and the order of the conditions was randomized (Latin Square Design). Subjects were seated at separate workstations consisting of a desk, a chair and a PC. Each session started with an acclimatization period (30 min.). Two times per hour, subjects filled in a questionnaire that included a 7-point thermal sensation interval scale, scales to assess the acceptability of the thermal environment and perceived air quality, a scale to assess odor intensity (Figure 1a) and Visual Analogue Scales (VAS) to assess the intensity of selected specific and general SBS symptoms [10]. A scale to assess self-estimated performance was also included in the questionnaire. Subjects' performance was measured by simulated office work tasks but these results are not included in this paper. Both questionnaires and office work tasks were presented to subjects in an Internet browser [11]. Subjects wore their own clothing during all experimental sessions. Clothing composition was determined during pre-sessions in which subjects were exposed to constant operative temperature 24.4 and 21.4ºC (50% RH, 2 hours) for experiment 1 and 2 respectively. They were also allowed to move around the chamber casually, so that their metabolic rate was approximately 1.2 met.

A commercially available statistical software package was used to analyze the data. Data with normally distributed residuals were tested with Linear Mixed Effects model. Kolmogorov-Smirnov goodness of fit test was used to test whether residuals were normally distributed. In case of not normally distributed residuals, a non-parametric Friedman Rank Sum test was applied.

The percentage of subjects dissatisfied with their thermal condition was determined by calculating the percentage of votes that were placed in the "negative" part of the thermal acceptability scale (from "just unacceptable" to "clearly unacceptable") for each vote.

RESULTS

Results of physical measurements and mean values of clothing insulation for examined conditions are summarized in Table 1. Measured air velocity was lower than 0.1 m/s during all experimental sessions.

Table 1. Experimental conditions and results of physical measurements (mean±SD)

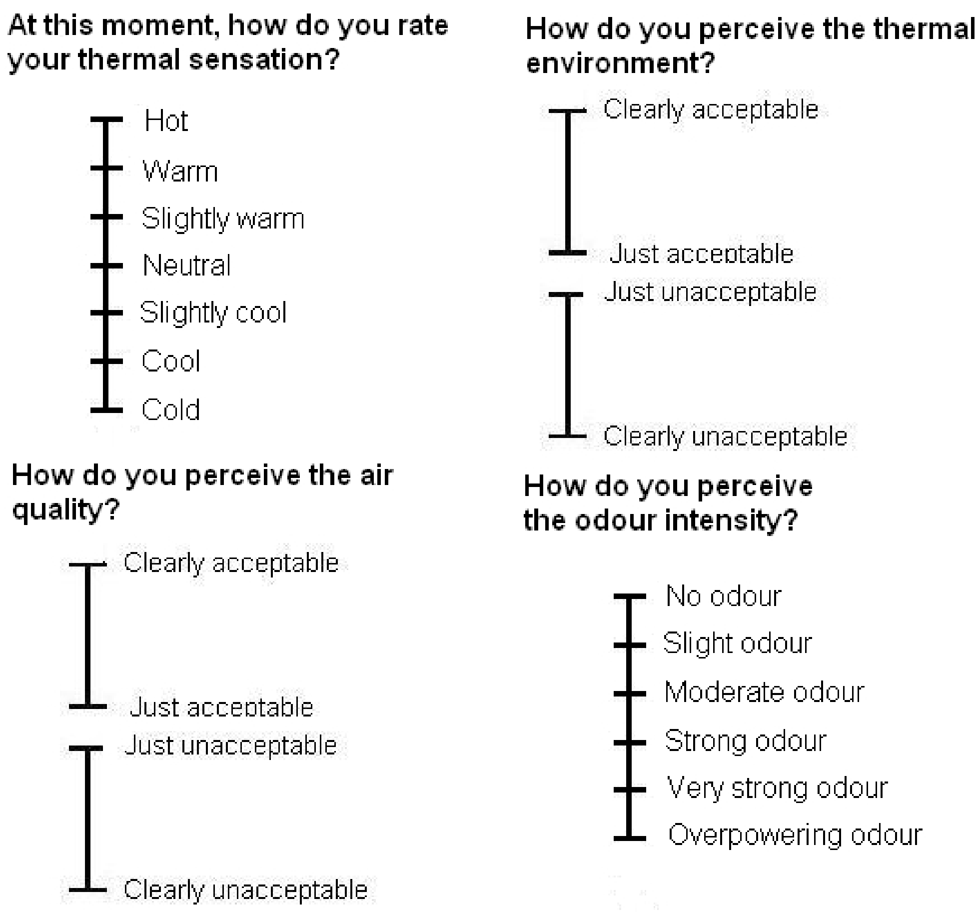
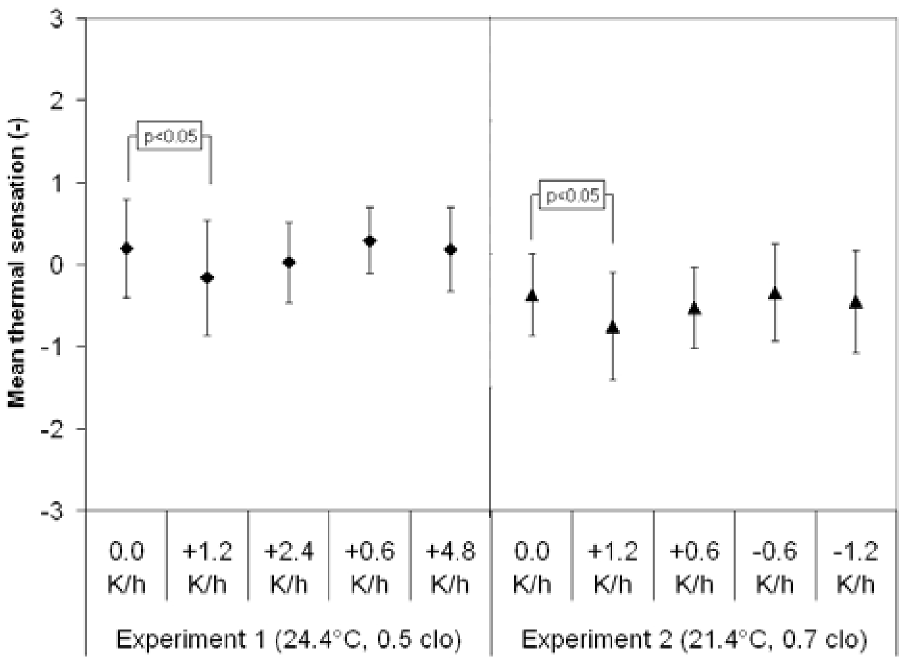
[1]In case of exposure to constant temperature mean value for whole condition is given;

Thermal sensation

Comparison of the mean thermal sensation from conditions with constant temperature (24.4 and 21.4ºC) to data from the same temperature level reached by different ramps is depicted in Figure 1b. The analysis showed, that mean thermal sensations differed significantly only in case of comparison to +1.2 K/h ramp at both temperature levels.



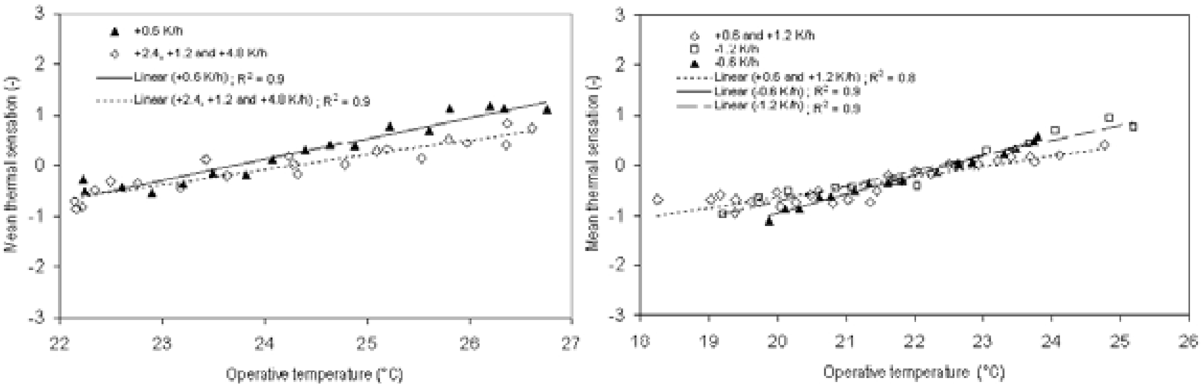
a)



b)

Figure 1. a) Interval and acceptability scales; b) Comparison of mean thermal sensation at the level of thermal neutrality reached by temperature ramps to data from exposure to constant temperature, vertical bars indicate ± SD

A linear relation between thermal sensation and operative temperature was observed in all studied ramps. The data obtained in experiment 1 are depicted in Figure 2a. Analysis with Linear Mixed Effects model showed that an intercept and slope of the linear relation did not differ significantly for +2.4, +1.2 and +4.8 K/h ramps. With these ramps, subjects perceived operative temperature the same way regardless the ramp they were exposed to. Common linear fit for +2.4, +1.2 and +4.8 K/h ramp is indicated by dash line in Figure 2a. The development of thermal sensation was different in +0.6 K/h ramp (Figure 2a – solid line). During this exposure, thermal sensation for the same level of operative temperature was higher. This difference tended to be larger for higher temperatures. Analysis showed significant difference in both slope and intercept ($p<0.001$) when +0.6 K/h ramp was compared to +2.4, +1.2 and +4.8 K/h ramps.



a) b)

Figure 2. Mean thermal sensation votes as a function of operative temperature: a) experiment 1 - 22-26.8ºC, 0.5 clo, b) experiment 2 - 17.8-25ºC, 0.7 clo

Figure 2b presents a linear relation between operative temperature and mean thermal sensation in experiment 2. Analysis of the data showed no significant difference in slope or intercept of the regression line for +0.6 and +1.2 K/h ramp. Common linear fit for +0.6 and +1.2 K/h ramp is indicated by the dashed line. In case of decreasing ramps, the thermal sensation changed with temperature significantly faster than in increasing ramps. The solid line in Figure 2b represents a linear fit for -0.6 K/h ramp data. Its slope is significantly different ($p<0.0001$) from the one of the line representing increasing ramps (+0.6 and +1.2 K/h). The slope of -1.2 K/h ramp differed both from the slope of increasing ramps ($p<0.05$) and the slope -0.6 K/h ramp ($p<0.01$).

Percentage of dissatisfied with thermal environment

Figure 3 shows the percentage of dissatisfied with the thermal environment (calculated from thermal acceptability data) as a function of mean thermal sensation. The curve indicating Predicted Percentage of Dissatisfied (PPD) [5] was included in the figure for comparison. As it can be seen from the figure, observed data follows rather closely the PPD curve.

Acceptability of air quality and intensity of odour

The results from exposures to constant temperature indicated that subjects needed approximately 120-150 minutes to adapt their olfactory senses to the pollution level in the climatic chamber. During exposure to temperature ramps, the acceptability of the air quality depended linearly on the operative temperature. This relationship was statistically significant for +0.6 K/h ramp in experiment 1 and -1.2 K/h ramp in experiment 2 (Figure 4a). The results seem to be in agreement with results obtained by Fang et al. [6]. The effect of adaptation observed under steady-state conditions could not be studied with temperature ramps as the acceptability of the air quality was affected both by changing temperature (enthalpy) and different initial temperature level.

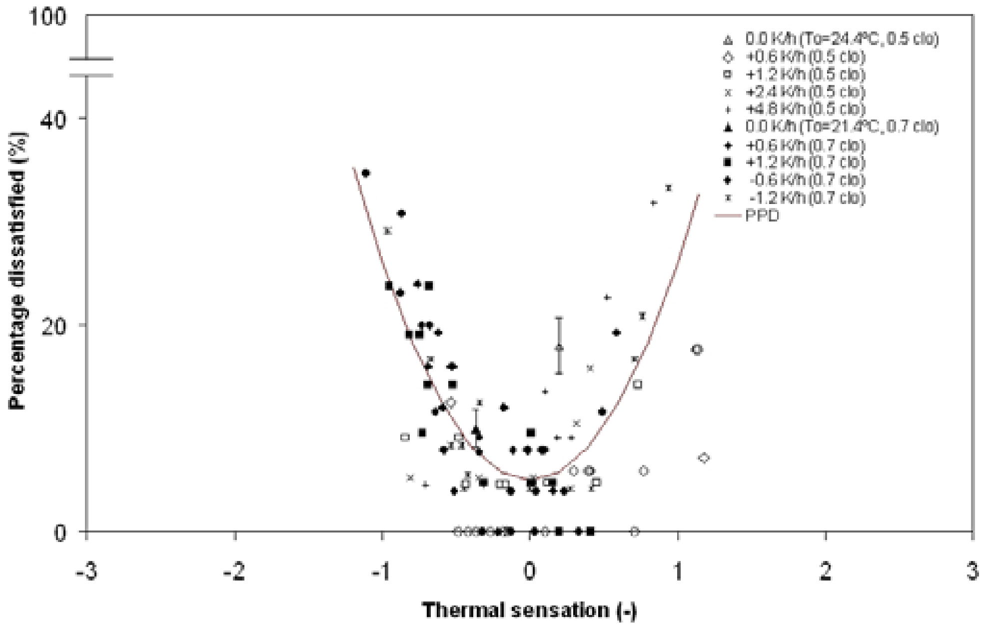


Figure 3. Percentage of subjects dissatisfied with the thermal environment; in case of exposure to constant condition the mean percentage of dissatisfied ± SEM calculated for this condition is given

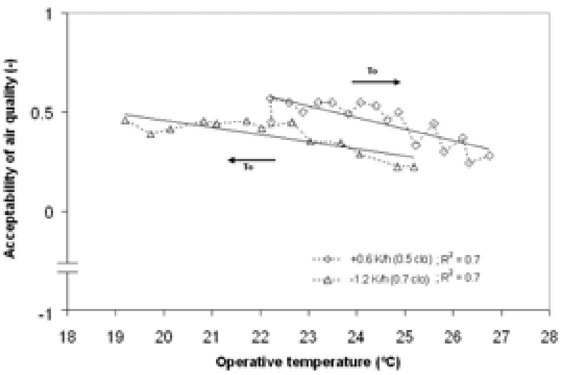
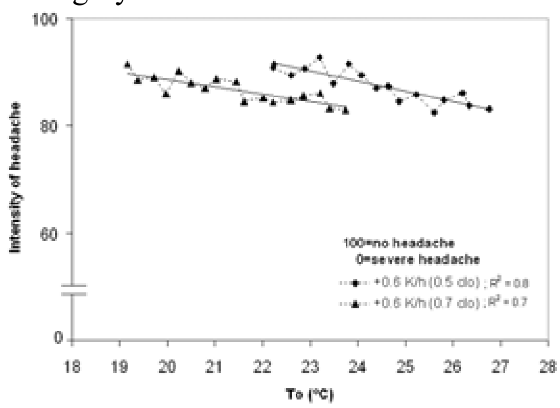
No significant change in the intensity of odour was observed in experiment 1 and 2. Overall means were 0.8 ± 0.6 and 0.7 ± 0.5 for experiment 1 and experiment 2 respectively, which corresponds to a little bit less than "slight odour" category on the scale.





a) b)

Figure 4. a) Acceptability of air quality as function of operative temperature, arrows indicate direction of the temperature ramp; b) Development of intensity of headache for +0.6 K/h temperature ramp in experiment 1 (0.5 clo) and experiment 2 (0.7 clo)

Intensity of SBS symptoms

Increasing temperature ramps increased the intensity of headache, aggravated concentration ability and decreased self-evaluated performance. An example of the development in intensity of headache for the +0.6 K/h ramps is depicted in Figure 4b. On the other hand, -1.2 K/h ramp had a positive effect on the ability to concentrate, self-evaluated performance and decreased fatigue. It also decreased mouth and skin dryness. Table 2 summarizes results of the analysis of data regarding intensity of SBS symptoms for all tested conditions. The results clearly show that general symptoms were more affected than specific symptoms related to local irritation of mucous membranes (nose, eyes, mouth).

Table 2. Development of intensity of SBS symptoms during exposure to operative temperature ramps and constant temperature; see legend below table

Ramp (K/h)	Nose	Mouth Dryness	Skin Dryness	Eye	Smart. eyes	Gritty eyes	Head-ache	Well feeling	Fatigue	Con. ability	Self-eval. perform.
Experiment 1											
0.0	NS	NS	NS	NS	NS	NS	↓	NS	NS	NS	NS
+0.6	NS	NS	NS	NS	NS	NS	↓	↓	↓	↓	↓
+1.2	NS	|	NS	|	↓	NS	↓	↓*	NS	↓	↓
+2.4	NS	NS	NS	NS	NS	NS	NS	NS	NS	NS	NS
+4.8	NS	NS	NS	NS	NS	NS	↓	↓	NS	↓	↓*
Experiment 2											
0.0	|*	NS	NS	NS	NS	|*	NS	|	|*	NS	↓
+0.6	NS	NS	NS	NS	NS	NS	↓	↓	NS	↓	↓
+1.2	↓	NS	NS	NS	NS	NS	|*	NS	|	↓	↓
-0.6	NS	↑	NS	NS	NS	NS	|	↓	|	↓	↓
-1.2	NS	↑	↑*	NS	NS	NS	NS	NS	↑*	↑	↑*

Legend: vertical line (|) indicates that there was a significant change of the symptom along the condition, but no consistent trend of mean values was observed; arrow (↑) indicates that symptom became significantly less severe along the condition; arrow (↓) indicates that symptom became significantly more severe along the condition; NS = no significant change of symptom was observed; asterisk (*) indicates that statistical analysis showed either low level of significance (0.05 > p > 0.01) or result was very close to significance (0.1 > p > 0.05)

DISCUSSION

No significant effect of temperature ramps was observed for SBS symptoms related to local irritation of mucous membranes, while general symptoms like intensity of headache, well feeling and concentration ability were significantly affected in most of the ramps. The results are in agreement with previous research [13]; An increase of the operative temperature increases also the intensity of a particular symptom. However, it should be noted that the slope of the symptom increase is much lower than shown previously; about 2% in intensity per 1ºC increase in temperature in comparison to 12% increase in intensity of SBS symptoms per 1ºC increase temperature above about 22.5ºC as estimated by Seppänen and Fisk [14]. Moreover, the general level of the symptom intensity was rather low in the present study.

The observed relationship between the acceptability of air quality and operative temperature (respective enthalpy of the air) suggests that in case of insufficient ventilation, temperature increase can cause further degradation of perceived air quality. Poor air quality may, in the end, result in increased intensity of SBS symptoms, decrease overall comfort and productivity of the occupants.

Subjects dressed in summer clothing (approx. 0.5 clo) immediately perceived operative temperature ramps +2.4 K/h, +1.2 K/h and +4.8 K/h in the range 22-26.8ºC. The perception of the thermal environment was the same regardless of the ramp they were exposed to. Temperature ramp +0.6 K/h was recognized with about 3 hours delay. Afterwards, the same operative temperature was perceived as warmer than in case of steeper ramps. However, a higher thermal sensation was not accompanied by higher dissatisfaction with the environment.

During exposure to +0.6 K/h ramp at lower temperatures (19-23.8ºC, 0.7 clo) subjects did not perceive given operative temperature differently from +1.2 K/h ramp. This results suggests it may not be the temperature ramp itself, but rather the combination of a temperature level above 24.4ºC and time of the exposure that influenced the thermal sensation of the subjects. Although the design of the experiment did not allow separation of the combined effect of rising temperature and time, the fact that subjects spent 8 hours in the climatic chamber could result in fatigue, which consequently influenced thermal sensation. The results of the present study seem not to be in conflict with findings of previous research [1]. Subjects did not distinguish slow temperature increase +0.6 K/h for the first 3 to 4 hours of the exposure. However, as the exposure continued, a linear relation between thermal sensation and temperature was observed. A higher level of clothing insulation seemed to enlarge the delay period for flat ramps (+0.6 K/h) and even introduce it for steeper ramps (+1.2 K/h).

A comparison of the percentage dissatisfied with thermal environment obtained in the present study with PMV/PPD model did not consistently show that acceptability range specified by current standards could be extended when subjects were exposed to temperature ramps [3, 12]. During exposure to the +4.8K/h ramp, the percentage of dissatisfied increased faster than predicted by the model. On the other hand, subjects accepted the slightly warm environment during the +0.6 K/h ramp more readily than the model would predict. The data from ±1.2, +2.4 and -0.6 K/h ramps followed quite well relationship given by PMV/PPD model. A rather high percentage of dissatisfied during the exposure to constant temperature 24.4ºC can not be fully explained. It is possible that as thermal acceptability data were not adjusted for higher initial metabolic rate, higher dissatisfaction in the beginning of the ramp influenced mean value given in Figure 3.

CONCLUSIONS

- Increasing operative temperature had a slight but significant negative effect on general SBS symptoms, such as intensity of headache, well feeling or fatigue. Similarly for self-evaluated concentration ability and performance.
- No general effect (negative or positive) on specific symptoms related local irritation of mucous membranes (nose, eyes, mouth) was observed.
- Adaptation to indoor air quality occurred after approx. 2 hours during exposure to steady temperature. A linear relationship between acceptability of air quality and temperature (enthalpy) was observed in temperature ramps.
- A linear relationship between mean thermal sensation and operative temperature was observed in all studied ramps. Flat ramps (±0.6 K/h) were realized by sedentary subjects with 3 to 4 hours delay (depending on the level of clothing).
- A relationship between mean thermal sensation and the percentage of thermally dissatisfied subjects was in fairly good agreement with prediction by PMV/PPD model.

Derivation and analysis of the indoor Wet Bulb Globe Temperature index (WBGT) with a human thermal engineering approach — Part 1. Properties of the WBGT formula for indoor conditions with no solar radiation.

SUMMARY

Based on a heat balance equation between humans and the environment, the authors developed a theoretical derivation of the indoor WBGT formula, which was originally established empirically by Yaglou and Minard. We demonstrated that the coefficients of wet bulb temperature T_w and globe temperature T_g (= air temperature T_a), in the indoor WBGT formula contain variables such as the metabolic activity, the clothing insulation and the wind velocity, and that these three coefficients do not remain strictly constant. We also considered the thermophysiological significance of the WBGT based on the derived formula. In addition, we performed a numeric examination and indicated irrational results of the WBGT.
The newly derived formula is WBGT = $0.85T_w + 0.20T_g$ (= T_a) or WBGT = $0.80T_w + 0.20T_g$ (= T_a) which differs from Yaglou et al's original formula WBGT = $0.7T_w + 0.3T_g$ (= T_a) in the coefficients.

INTRODUCTION

In 1957 Yaglou and Minard invented Wet Bulb Globe Temperature (WBGT) [1] as an index to evaluate thermal sensation and heat stress during training. The empirical index, developed for the prevention of heat stroke in U.S. soldiers, is now standardized by National Institute for Occupational Safety and Health (NIOSH) and International Organization for Standardization as ISO-7243. Although its use is recommended in many countries for the evaluation of the thermal environment during labor and outdoor sports, its background has hardly been discussed from the perspective of the heat transfer theory.

The original WBGT formula suggested by Yaglou and Minard has two versions depending on the usage environment [1].
For indoor conditions with no solar radiation;

$$WBGT = 0.7T_w + 0.3T_g \tag{1}$$

For conditions with solar radiation;

$$WBGT = 0.7T_w + 0.2T_g + 0.1T_a \tag{2}$$

where T_w is (natural) wet bulb temperature[°C], T_g is globe temperature[°C] and T_a is air temperature[°C].
Humans produce metabolic heat in the body and release or receive heat in accordance with the physical law of heat transfer. Given that a thermal sensation arises when heat produced in the body is transferred between humans and the environment, evaluation indexes of sensation, including those developed based on empirical rules or experimental data, must be in accordance with the law of heat transfer.

From the above-mentioned perspective, we derive theoretically WBGT, which was originally suggested empirically, employing the heat transfer theory based on the heat balance equation between humans and the environment. Then, based on the derived theoretical formula, we clarified the structures of the three constant coefficients of wet-bulb temperature, globe temperature and air temperature that define the original WBGT formula. Furthermore, we performed an examination using real values to present the characteristics and applicable conditions of the WBGT [2].

METHODS

First, we derive the indoor WBGT formula (1) and its analog by expanding heat balance equations between humans and the environment, and those of the wet bulb and the globe. The heat balance between humans and the environment is expressed as follows:

$$M = C + R + E_{sk} + E_{res} + W + S \qquad (3)$$

Where M is metabolic rate per unit body surface area[W/m^2], C is convective heat loss [W/m^2], R is radiative heat loss[W/m^2], E_{sk} is evaporative heat loss[W/m^2], E_{res} is evaporative heat loss from respiration[W/m^2], W is external mechanical work[W/m^2] and S is rate of heat storage[W/m^2].

The heat losses through convection C, radiation R, evaporation from the skin E_{sk} and respiration E_{res} [3] in Equation (3) are expressed by Equations (4), (5), (6) and (7).

$$C = h_c F_{cl}(T_{sk} - T_a) f_{cl} \qquad (4)$$
$$R = h_r F_{cl}(T_{sk} - T_r) f_{cl}\, f_{ref} \qquad (5)$$
$$E_{sk} = LR h_c F_{pcl}(P_{sk} - P_a) f_{cl} \qquad (6)$$
$$E_{res} = 0.0014M(35 - T_a) + 0.0173M(5.87 - P_a) \qquad (7)$$

where h_c and h_r are human's convective and linear radiative heat transfer coefficients [W/(m^2°C)], F_{cl} is thermal efficient factor[N.D.] [4], F_{pcl} is permeation efficiency factor[N.D.] [5], T_{sk} is mean skin temperature[°C], T_a is air temperature[°C], T_r is mean radiant temperature[°C], f_{cl} is clothing area factor[N.D.] [6], f_{ref} is effective radiation area ratio of human body[N.D.], LR is Lewis relationship (= 16.5) [°C /kPa], P_{sk} is water vapor pressure at skin temperature[kPa] and P_a is water vapor pressure in air[Pa].

Though Yaglou et al's paper supposes the use of the natural wet bulb temperature measured by August psychrometer, the general heat balance equation for the wet bulb is given in the form of Equation (8). Because the sensing part of the wet bulb thermometer is very small, about 6mm in diameter, the convective heat transfer coefficient h_c' is approximately 24.4~31.0W/m^2°C in normally air-conditioned rooms with wind velocities of 30~50cm/s. Meanwhile, the linear radiative heat transfer coefficient hr′ in the normal indoor environment is about 4~5W/m^2°C, an order of magnitude less than h_c', and therefore can be ignored. On the assumption that h_r'/h_c' is nearly equal to zero, Equation (8) leads, through Equation (9), to Equation (10).

$$h_c'(T_w - T_a) + h_r'(T_w - T_r) + LR\, h_c'(P_w^* - P_a) = 0 \qquad (8)$$
$$(T_w - T_a) + \frac{h_r'}{h_c'}(T_w - T_r) + LR(P_w^* - P_a) = 0 \qquad (9)$$
$$(T_w - T_a) + LR(P_w^* - P_a) = 0 \qquad (10)$$

where, h_c' and h_r' are wet bulb's convective and linear radiative heat transfer coefficients [W/(m^2°C)], T_w is (natural) wet bulb temperature[°C], T_r is mean radiant temperature[°C] and P_w* is saturated water vapor pressure on wet bulb[kPa].

As far as the thermal environment surrounding human work is concerned, the relationship of the saturated vapor pressure of water P_w* to the wet bulb temperature T_w on the psychrometric chart is sufficiently linear, as shown in Figure 1, and can be approximated as follows:

$$P_w^* = .T_w + . \qquad (11)$$

where κ and ζ are constants of linear approximation of saturated water vapor pressure to wet bulb temperature[kPa/°C] (See Figure 1).

During work in a hot environment, the mean skin temperature is within a range of 35~40°C. Therefore, by treating the skin temperature in the same way as the wet bulb temperature, the relationship of the saturated vapor pressure of water on the skin P_{sk} to the skin temperature T_{sk} can be linearly approximated by Equation (12).

$$P_{sk} = .^*T_{sk} + .^* \qquad (12)$$

where κ* and ζ* are constants of linear approximation of saturated water vapor pressure to mean skin temperature[kPa/°C].

In the forth coming numerical examination, we will adopt the following values shown in Figure 1: κ = κ*= 0.279kPa/°C and ζ= ζ*= – 4.03kPa. The vapor pressure of water on the skin surface P_{sk} is expressed by Equation (12) ′, accompanied with μ that indicates the degree of saturation on the skin surface. Here we expand equations with μ preserved, but in the later stages, we will suppose μ=1 because WBGT index is designed for use within the thermal limitation where the vapor pressure of water on the skin surface is almost saturated in consequence of promoted sweating[7].

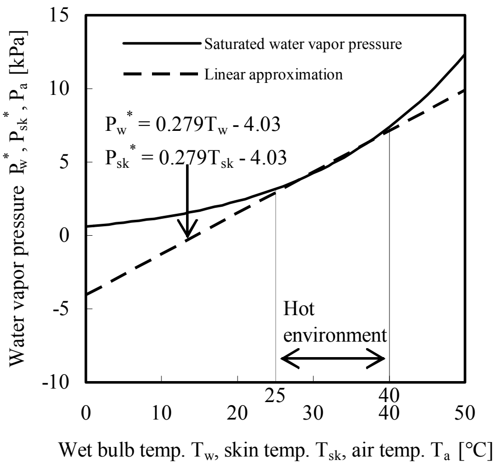

Figure 1 Linear approximation of saturated water vapor pressure to skin and air temps.

$$P_{sk} = \mu(.^*T_{sk} + .^*) \qquad (12)'$$

where μ is saturated ratio of water vapor pressure on skin surface[N.D.].

Meanwhile, the steady-state heat balance after sufficient exposure of the globe thermometer to the indoor environment with little influence of solar radiation for actual measurement is expressed by Equation (13).

$$h_c''(T_g - T_a) + h_r''(T_g - T_r) = 0 \quad (13)$$

where h_c'' and h_r'' are globe's convective and linear radiative heat transfer coefficients [W/(m^2°C)].

RESULTS

Substituting Equations (4)~(7) and Equations (10)~(13) into Equation (3) to eliminate C, R, E_{sk}, E_{res}, P_{sk}, P_a, P_w* and T_r and arranging the yielded equation, we obtain Equation (14).

$$\begin{aligned}
&\left[(h_c + h_r)F_{cl}f_{cl} + \mu\kappa^* \cdot LRh_cF_{pcl}f_{cl}\right]T_{sk} \\
&+\left[(\mu\zeta^* - \zeta)LR \cdot h_cF_{pcl}f_{cl} - M(0.8494 + 0.0173\zeta) + W + S\right] \\
&= \left[h_cF_{pcl}f_{cl}(1 + \kappa \cdot LR) + 0.0173M\left(\kappa + \frac{1}{LR}\right)\right]T_w \qquad (14) \\
&+\left[F_{cl}f_{cl}(h_c'' + h_r)\right]T_g \\
&+\left[F_{cl}f_{cl}(h_c - h_c'') - h_cF_{pcl}f_{cl} + M\left(0.0014 - \frac{0.0173}{LR}\right)\right]T_a
\end{aligned}$$

The convective heat transfer coefficients of the human body [8], the wet bulb [9] and the globe [10] show a significant difference for the same wind velocity according to the difference between their representative parameters, whereas their radiation heat transfer coefficients h_r, h_r' and h_r'' are nearly equal. Furthermore, in the indoor environment, which is free from the influence of solar radiation, T_r and T_a can be regarded as the same, and the relationship $T_r = T_a = T_g$ makes it possible to arrange Equation (14) into Equation (15).

$$\begin{aligned}&\left[(h_c + h_r)F_{cl}f_{cl} + \mu\kappa^* \cdot LRh_cF_{pcl}f_{cl}\right]T_{sk} \\ &+\left[(\mu\zeta^* - \zeta)LR \cdot h_cF_{pcl}f_{cl} - M(0.8494 + 0.0173\zeta) + W + S\right] \\ &= \left[h_cF_{pcl}f_{cl}(1 + \kappa \cdot LR) + 0.0173M\left(\kappa + \frac{1}{LR}\right)\right]T_w \\ &+\left[(h_c + h_r)F_{cl}f_{cl} - h_cF_{pcl}f_{cl} + M\left(0.0014 - \frac{0.0173}{LR}\right)\right]T_g\end{aligned} \tag{15}$$

Writing the coefficient of the skin temperature T_{sk} as ξ, the other terms on the left-hand side as η and the coefficients of T_w and T_g on the right-hand side as α and δ, respectively, in Equation (15), we obtain Equation (20). Dividing the first term on the left-hand side of Equation (20) by ξ, we obtain Equation (21), a form based on the skin temperature T_{sk}.

$$\left[(h_c + h_r)F_{cl}f_{cl} + \mu\kappa^* \cdot LRh_cF_{pcl}f_{cl}\right] = \xi \tag{16}$$

$$\left[(\mu\zeta^* - \zeta)LR \cdot h_cF_{pcl}f_{cl} - M(0.8494 + 0.0173\zeta) + W + S\right] = \eta \tag{17}$$

$$\left[h_cF_{pcl}f_{cl}(1 + \kappa \cdot LR) + 0.0173M\left(\kappa + \frac{1}{LR}\right)\right] = \alpha \tag{18}$$

$$\left[(h_c + h_r)F_{cl}f_{cl} - h_cF_{pcl}f_{cl} + M\left(0.0014 - \frac{0.0173}{LR}\right)\right] = \delta \tag{19}$$

$$\xi T_{sk} + \eta = \alpha T_w + \delta T_g \tag{20}$$

$$T_{sk} + \left(\frac{\eta}{\xi}\right) = \left(\frac{\alpha}{\xi}\right)T_w + \left(\frac{\delta}{\xi}\right)T_g \tag{21}$$

The right-hand sides of Equations (20) and (21) both take the same form as Yaglou et al's WBGT formula (1) does. In particular, Equation (21) expresses the relationship of the skin temperature T_{sk}, the wet-bulb temperature T_w and the globe temperature T_g in a form based on the temperature on the human side.

We show the results of examination using concrete values of the α/ξ and δ/ξ in Figures 2 to 4, changing the combination of parameters.

Figure 2 shows the variation of the α/ξ and δ/ξ values in response to that of metabolic rate with clothing insulation and indoor wind velocity held constant. The vertical axis indicates the α/ξ, δ/ξ and $\alpha/\xi + \delta/\xi$ values, and the horizontal axis indicates metabolic rate. Responding to metabolic rates of 1 to 4met, the α/ξ value ranges from 0.81 to 0.88 and the δ/ξ remains around 0.21. These values are close to 0.8 and 0.2 rather than to 0.7 and 0.3, the coefficient values in the original formula (1). The sum of α/ξ and δ/ξ ranges from 1.02 to 1.09, slightly exceeding 1.0. Since α/ξ and δ/ξ represent a prorated proportion, their sum must remain at 1.0 constantly. However, as seen in Figure 2, both values increase as metabolic rate increases.

Similarly, Figure 3 shows the variation of the α/ξ and δ/ξ values in response to that of wind velocity (horizontal axis) with metabolic rate and clothing insulation held constant. The α/ξ and δ/ξ values are almost constant at 0.85 and 0.21, roughly 0.85 and 0.21 as in Figure 2, respectively. However, in Figure 3, unlike Figure 2, the δ/ξ value decreases and the sum of α/ξ and δ/ξ approaches 1.0 as wind velocity increases.

Figure 4 shows the variation of the α/ξ and δ/ξ values in response to that of clothing insulation (horizontal axis) with metabolic rate and wind velocity held constant. The α/ξ value is 0.86 and the δ/ξ value ranges from 0.18 to 0.23. As clothing insulation increases, the α/ξ value remains almost constant and the δ/ξ value increases, and consequently, the sum of α/ξ and δ/ξ increases.

DISCUSSION

We consider the general properties of Equation (21).
Seeing the structure and constituent elements of the coefficient of air temperature Ta in Equation (14) preceding Equation (21), we understand that the value of the coefficient is either very small or negative depending on the values of the constituent elements. This means that air temperature makes a small contribution to human heat stress during work in a hot environment compared to wet bulb temperature (humidity) and globe temperature (radiant heat), which qualitatively agrees with Yaglou et al's original formula (1) in which the coefficient of Ta is small compared to the other coefficients.
Comparing the coefficients of wet bulb temperature T_w and globe temperature T_g in Equation (14) with each other, assuming the values of their constituent elements, we understand that both of the coefficients are positive and that the coefficient of T_w is much greater than that of T_g. This agrees qualitatively with the original WBGT formula (2) in which the coefficient of T_w is 0.7 and that of T_g is 0.2.
Next, we consider the thermo-physiological implication of the two formulas through Equations (20) and (21), which are derived for indoor use.
In 1923, Houghten and Yaglou developed the Effective Temperature [11]. Afterward, Yaglou focused his attention on the mean skin temperature, speculating about its close connection with thermal sensation and comfort [12]. These facts provoke the supposition that the WBGT value on the left-hand sides of Equations (1) and (2) is meant for the mean skin temperature and that the coefficients of T_w and T_g, 0.7 and 0.3, on the right-hand side merely represent a prorated proportion. More specifically, the left-hand side of Equation (21) can be considered to express human heat stress caused by heat loads from the environment as the degree of increase in the mean skin temperature.
Using Equation (20), we consider the possibility that the left-hand sides of Equations (1) and (2) express the quantity of heat, not the mean skin temperature.
As is clear from Equations (16) and (17), the left-hand side of Equation (20) has the unit of heat quantity W/m^2. This means that α and δ on the right-hand side are not dimensionless but have the unit $W/m^2°C$. Comparing Equation (20) with the definitional equation of the WBGT (1), we understand that α and δ correspond to $0.7W/m^2°C$ and $0.3W/ m^2°C$, respectively. Viewed in this light, Equation (20) possibly expresses something like the body heat content of a person working, under certain conditions of wind velocity and clothing, in an environment characterized by an air temperature of Ta (= a mean radiant temperature of T_r = a globe temperature of T_g) and a wet bulb temperature of T_w. It is unlikely, however, that Equation (20) expresses the heat content of the human body because the coefficient of T_{sk} represents the heat transfer between the skin and the environment. Thus, the physical meaning of $0.7W/m^2°C$ and $0.3W/m^2°C$ remains unclear. The values of α and δ in Equations (18) and (19), corresponding to the coefficients on the right-hand side of the WBGT formula (1), are $9.8\sim28.8W/m^2°C$, or 13~41 times larger than $0.7W/m^2°C$, and $2.7\sim5.0W/m^2°C$, or 9~17 times larger than $0.3W/m^2°C$, respectively, showing an order of magnitude difference. Based on these results, it is reasonable to consider 0.7 and 0.3 in Equation (1) to be dimensionless and to merely represent a prorated proportion.
Furthermore, we will examine the variation range of the second term η/ξ on the left-hand side by substituting different state values on the assumption that external work W=0 and heat storage S=0.
Since WBGT is an index that indicates the thermal limitation, S is unlikely to be strictly equal to 0 at every moment. Our assumption that S=0 is based on the thought that the body temperature is not raised by continuous heat accumulation throughout the working hours but is put into a certain cycle through work and rest. The NIOSH and ISO-7243 have provided

their recommended proportions of work time to all working hours, typically 8 hours, based on WBGT.

We calculated the value of η/ξ, changing metabolic rate from 1 to 4met, clothing insulation from 0.2 to 1.0clo and indoor wind velocity from 0.15 to 0.7m/s. The calculated values were all negative, ranging from –15.6 to –1.4°C, which is in accordance with the recommended WBGT limits for heat stress given at 20~33°C, temperatures lower than the skin temperature. The negative values are also partly attributed to the assumption that external work W and heat storage S are equal to zero. The ratio of the absolute value of η to metabolic rate M, ranging from 1 to 4met, or $|\eta|/M$, is approximately 0.78 and external work is about 0.2M at most[3], so heat storage S needs to be as large as 0.5~0.6M for η/ξ to be positive.

CONCLUSIONS

The most important points for a thermal index is that it be in accordance with thermo-physiological and psychological reactions and that the heat balance be maintained. The index must qualitatively and quantitatively reflect the thermal reactions of humans with high accuracy.

WBGT has been used for almost 50 years. However, despite its frequent use, the index has infrequently been theoretically analyzed. In this study, we derived theoretically the WBGT formula, which was originally developed empirically, based on the heat transfer equation. We clarified the internal structures of the three constant coefficients of wet-bulb temperature, globe temperature and air temperature, and we performed an examination using real values. Based on the derived formulas and the obtained results, we presented the characteristics of WBGT as an index.

Examination by the derived formula confirmed the following points:

1-The coefficients of wet-bulb temperature T_w, globe temperature T_g and air temperature T_a in WBGT formula, considering their elements and structures, are not strictly constant but variable depending on metabolic rate, clothing insulation, wind velocity and other such factors.

2-An examination using real values showed the possibility of the new formula WBGT = $0.85T_w + 0.20T_g$ (= T_a) or WBGT = $0.80T_w + 0.20T_g$ (= T_a), which differs from Yaglou and Minard's original formula WBGT = $0.7T_w + 0.3T_g$ (= T_a) in the coefficients.

3-WBGT can be used more accurately by specifying the values of the coefficients of T_w, T_g and T_a, substituting human and environmental conditions into Equations (14) and (15) derived based on the heat balance equation concerning the human body.

SUMMARY

The existing draft guideline [1] is based on laboratory studies, in which participants were exposed whole-body to each condition for 15 minutes. However, the understanding is limited on acceptable air velocity of locally applied air flow over a longer duration.

This study explores human perception of a group of 24 people in the Tropics with 90-minute (medium-term) facial exposure to local air movement with the aim of examining the local velocity preference and how this preference changes over time. The subjects were exposed to local airflow at six velocity levels, at temperatures between 21.0 to 26.0°C.

The study shows that the subjects preferred a range of local air movement during the 90 minutes of facial exposure, with the optimum velocities identified to be between 0.2 and 0.6 m/s within the experimental conditions. These optimum velocities are relevant to the design of personalized ventilation in practice.

INTRODUCTION

The existing draft guideline [1] is based on laboratory studies [2,3], in which participants were exposed whole-body to each condition for 15 minutes. Numerous studies reported the decrease of thermal sensation or the increase of draft sensitivity either with whole-body or local exposure to air flow [4,5,6]. However, the understanding on acceptable air velocity of locally applied air flow over a longer duration is limited. The understanding of acceptable local air velocity/flow rate is indispensable for the design of personalized ventilation. This is especially so for tropically-acclimatized people who has been shown to demonstrate a preference for some air movement over a short-term (15-minutes) exposure.

This study explores human perception of a group of 24 people in the Tropics with 90-minute (medium-term) facial exposure to local air movement with the aim of examining the local velocity preference and how this preference changes over time.

METHODS

The experiment was conducted in a controlled indoor air quality (IAQ) chamber with dimensions of 6.6m (L) x 3.7m (W) x 2.6m (H) in Singapore. (The detailed description of the experimental chamber can be found in [7]). Interior partitions divided the chamber into six workstations, each being equipped with a personalized air terminal device to supply conditioned outdoor air. Twenty-four tropically acclimatized subjects, 12 males and 12 females, participated in the experiments and responded to questionnaires on their thermal and draft sensations using visual-analogue scales. (The details of personalized air terminal devices, the human subjects, the questionnaires and experiment procedure can be found in [8].

The subjects were exposed to predefined local air movement with velocities ranging from 0.15 to 0.90 m/s, and localized (personalized ventilation) airflow temperatures of 21.0 and 23.5 °C at room temperatures of 23. 5 and 26.0 °C (refer to Table 1). Ambient-local temperature (T_a-T_f) is used to denote each condition. Each combination was maintained for 90 minutes of facial exposure, during which the subjects performed normal office work and responded to the questionnaires at the 5th, 10th, 15th, 30th, 45th, 60th, 75th and 90th minutes during the experiments.

Table 1. Experimental conditions

Room Temperature T_a (ºC)	26.0		23.5
Target Temperature T_f (ºC)	21.0	23.5	21.0
Target Velocity V_f (m/s)	0.15, 0.30, 0.45, 0.60, 0.75, 0.90		

RESULTS

The percentage dissatisfied is plotted against air velocities at different times in Figure 1 through Figure 6 to examine the optimum velocities. Quadratic regression is applied in the figures. The curves have similar shape, in which percentage dissatisfied initially decreases with the increasing air velocity and beyond a certain velocity (optimum velocity) the percentage dissatisfied begins to increase. This scenario illustrates that to a certain extent, air movement may be considered pleasant by the subjects during the 90-minute duration of exposure.

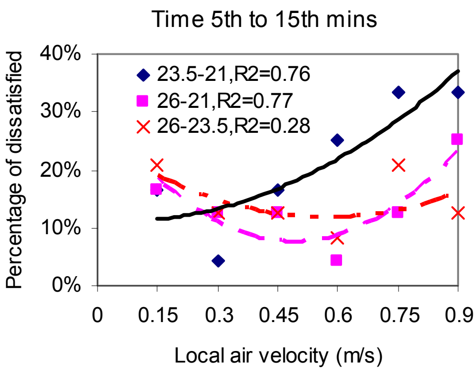

Figure 1 Percentage dissatisfied from exposure time 5th to 15th minutes

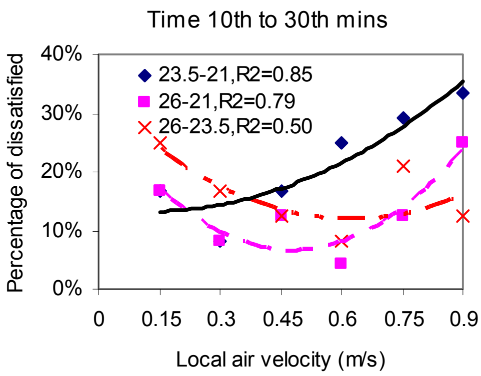

Figure 2 Percentage dissatisfied from exposure time 10th to 30th minutes

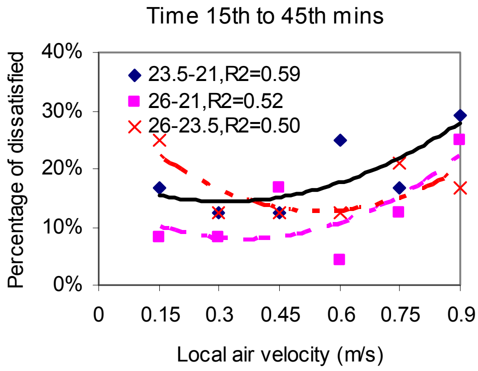

Figure 3 Percentage dissatisfied from exposure time 15th to 45th minutes

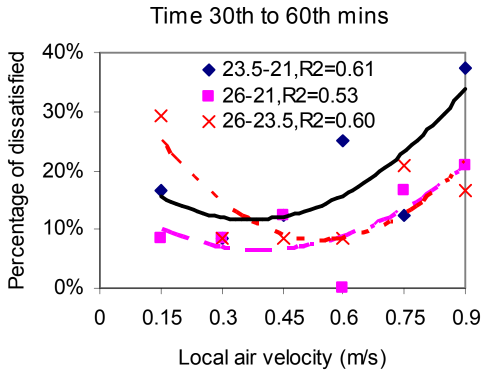

Figure 4 Percentage dissatisfied from exposure time 30th to 60th minutes

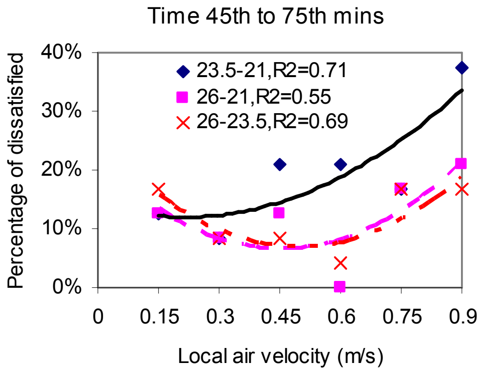

Figure 5 Percentage dissatisfied from exposure time 45th to 75th minutes

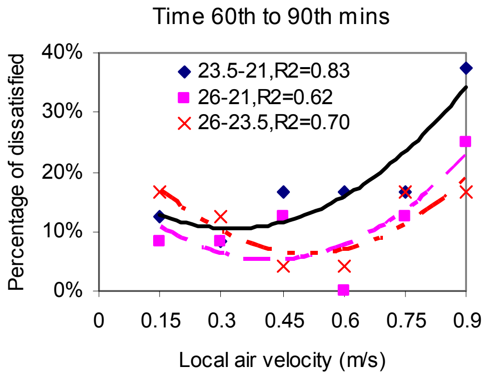

Figure 6 Percentage dissatisfied from exposure time 60th to 90th minutes

The optimum velocity is defined as the velocity value associated with the lowest percentage of dissatisfied. Applying the first derivative on the regression lines for percentage dissatisfied, the velocities with minimum percentage dissatisfied are calculated and depicted in Figure 7. The optimum velocities for the condition 26-23.5 range between 0.5 and 0.6 m/s, and that for condition 26-21 range between 0.35 and 0.5 m/s. The optimum air velocities (not shown) for the 15th and 30th minute for the 23.5-21 condition are unreasonable low compared with the values at the 45th minute and beyond; however, the reason is unknown.

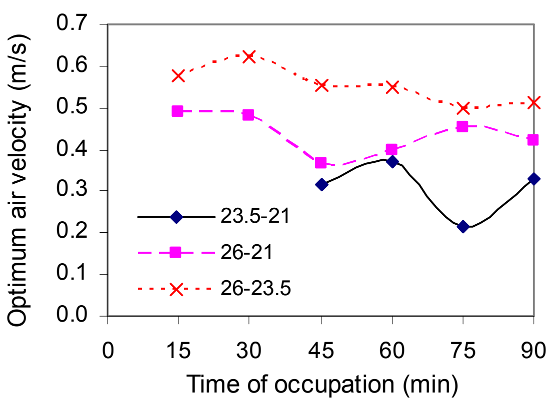

Figure 7 Optimum air velocity during 90 minutes

DISCUSSION

This study has identified the optimum velocities for a 90-minute (medium-term) facial exposure to local air movement and found the optimum velocities to fluctuate within the range between 0.2 and 0.6 m/s. Expectedly higher optimum velocities occur with higher background temperature (26^{o}C) and T_a-T_f conditions.

In a similar but separate study involving short-term exposures of 15 minute duration to localized air movement achieved through personalized ventilation, it had been demonstrated that tropically acclimatized subjects prefer facial air movement within the range 0.3 and 0.6 m/s under the same set of temperature conditions of 23.5-21.0, 26.0-23.5, 26.0-21.0 [9]. The optimum velocity ranges for 90-minute exposure identified in this study and that for 15-minute exposure are comparable.

As the optimum velocity study shows that the subjects preferred air movement to varying magnitudes at different sets of conditions during the 90 minutes' exposure to local air flow, the air movement perception and preference of the subjects were examined. These are depicted in Figure 8 and 9.

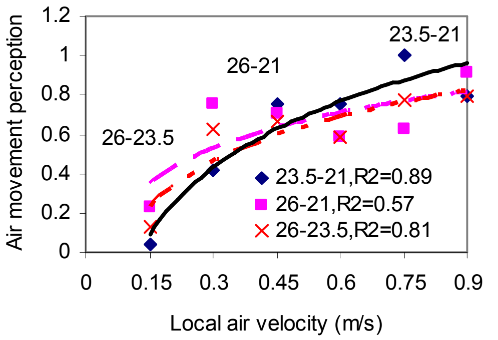

Figure 8. Logarithmic regression of air movement perception at the 90th minute (Y-axis: -3=Much too still; -2=Too still; -1=Slightly still; 0=just right; 1=Slightly breezy; 2=Too breezy; 3=Much too breezy)

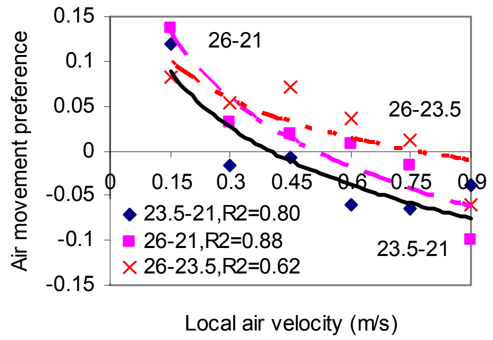

Figure 9. Logarithmic regression of air movement preference at the 90th minute (Y-axis -1=Less air movement; 0=Same air movement; 1=More air movement)

Preference of air movement was neutral around 0.45 m/s, 0.5 m/s, and 0.75 m/s for the 23.5-21, 26-21 and 26-23.5 conditions respectively. Below and above these velocities, subjects preferred more air movement respectively. It was interesting note that subjects perceive low localized air velocities to be "just right", and that at neutral air movement preference, they perceive the conditions to be between "just right" and "slightly breezy". The preference is consistent to the observation of optimum velocities that local air movement is preferred until to a certain limit, which is relevant to the temperature conditions.

CONCLUSION

The key findings of this air movement perception study of medium term exposure to local air movement of tropically acclimatized people are as follows:

1. optimum velocities for 90-minute (medium-term) facial exposure to local air movement were found to be within the range 0.2 and 0.6 m/s over the time
2. optimum velocity ranges for 90-minute exposure identified in this study and that for 15-minute exposure are comparable
3. higher optimum velocities occur with higher background temperature (26^{o}C) and T_a-T_f conditions
4. preference of air movement was neutral around 0.45 m/s, 0.5 m/s, and 0.75 m/s for the 23.5-21, 26-21 and 26-23.5 conditions respectively
5. at neutral air movement preference, the conditions were perceived to be between “just right” and “slightly breezy”.

The Substitution Of Comfort Pmv Values By A New Experimental Operative Temperature

Miloslav Jokl and Karel Kabele

Czech Technical University,Prague, Czech Republic

Corresponding email: miloslav.jokl@fsv.cvut.cz

SUMMARY

Problems following the application of optimal operative temperatures estimated on the basis of PMV and the necessity to apply correct values into the new Czech Government Directive No. 523/2002 Code led to experiments based on the physiological human body response instead of on solely man's feelings in a defined environment. On the basis of experiments on 32 subjects (university students) it has been possible to estimate: a) total balance of hygrothermal flows between the human body and environment, b) the optimal operative temperature as a function of the subject's activity, c) the thermoregulatory range for each optimal operative temperature, i.e. maximal (category C_{max}) limited by the beginnings of sweating, minimal (category C_{min}) limited by the beginnings of shivering (category C can be applied to the natural ventilated buildings), optimal (comfort level – category A) defined by time constant 0.368 (can be applied to air conditioned buildings) and submaximum (decreased comfort level – category B) defined by time constant 0.632 (can be applied to buildings with basic air conditioning systems).

INTRODUCTION

The provision of optimal hygrothermal conditions, i.e. first of all optimal operative temperature (air being calm and air temperature reaching radiant temperature) is the principal condition for healthy living of a man in building interior. Optimal operative temperature so far is to be calculated from PMV (Predicted Mean Value) (see e.g. EN ISO 7730 Moderate Thermal Environment) estimated on the basis of positive feeling of 80% of present persons. The feelings of a man are very subjective values being impacted by many other factors in addition to hygrothermal conditions, e.g. by indoor interior colors, a man's mood etc. Furthermore, as a result of the way of experimental estimation of PMV and proved by other experimental works (see Fishman, Pimbert 1979, Newsham, Tiller 1995), it is valid approximately for the neutral zone only. The more leave the neutral zone the more the real values leave the values calculated from PMV. And more: the higher man's activity the higher the difference. The application of high activity values is then impossible in practice.
This may be due to three main reasons. The first are the assumed steady state laboratory conditions used in the derivation of the PMV equation. The second is the oversimplified approach to the assessment of the metabolic rate of the occupant. The occupants rarely sat in the room for a long period, say one hour, without moving around. The third is the sensitivity of PMV to clo values (Croome et al. 1993). It can be concluded that the PMV equation over predicts the neutral temperature by as much as 2K and under predicts the comfort requirement when air temperature deviates from neutrality.
And maybe the most important: from PMV system no thermoregulatory ranges can be estimated.

These are the reasons we decided to estimate optimal operative temperatures on the basis of the physiological response of human organism.

MATHEMATICAL MODEL OF THE PHYSIOLOGICAL BODY RESPONSE

The total heat rate production and its distribution into individual components during heat exchange between the human body and the environment are shown in *Fig.1*, where q_m=M-W = metabolic heat (see Jokl 1989). q_{res} and $q_{ev,d}$ are the components of the heat rate from the organism by respiration and by skin moistening (evaporation), with the human body being in the thermal neutral zone. The heat flow q_{dry} represents the component transferred from the organism through the clothing layer with a total thermal resistance $R_{t,wa}$(q_{dry}= q_c+q_r). The regulatory process within the neutral zone is achieved mainly by vasodilatation and vasoconstriction changing the body's internal resistance into the thermoregulatory and adaptational heat flux q_{tr} a q_a to the skin surface. q_{tr} a q_a is the heat flux regulating the instantaneous value of the skin temperature during the subject's interaction with environment, q_{tr} is the organism's immediate response to the changes of the microclimate or metabolic heat changes; q_a is the reaction shift due to adaptation to heat in summer and cold in winter. q_{tr} + q_a may be negative (heat loss) or positive (heat gain). It is the transient heat flow – even in the thermal neutral zone – that is called "quasi-stationary", to be differentiated from the hyperthermia and hypothermia zone.
q_{tr} + q_a represents the rates of heat storage or heat debt accumulation. When the body is in a steady-state thermal balance with the environment, these therms are equal to zero. But it is possible to consider the state of the subject in the neutral zone by non-steady-state conditions due to periodical changes of metabolic heat rate, q_m, or short thermal excitations in time followed by changes of internal thermal resistance of body within the neutral zone.
The temporary characteristics of each non-steady process are determined, in addition to the thermal resistances $R_{t,i}$ and $R_{t,wa}$ by the human body heat capacity, C_t. The values characterizing the heat exchange are: T_{sk}, T_{core} and T_g. The internal thermal resistance, $R_{t,i}$ also determines the changes in thermoregulation and the adaptational heat, q_{tr} + q_a, which is necessary for maintaining the skin temperature within physiological values if the core temperature should remain constant (T_{core} = 36.7 ± 0.4 °C).
The heat flow balance, as presented in the model shown in *Fig.1* can be expressed by a thermal flux equation at the boundary: subject-environment. Thus (if heat conduction is neglected):

$$q_{dry} = \frac{1}{R_{t,wa}}(T_g - T_{sk}) = q_m - q_{res} - q_{ev} + q_{tr} + q_a = q_i - q_{sw} \quad [\mathrm{Wm}^{-2}] \qquad (1)$$

where q_{ev}=$q_{ev,ins}$ +$q_{ev,sens}$= $q_{ev,ins}$+q_{sw} [W.m^{-2}]
q_m-q_{res}-$q_{ev,ins}$= q_i [W.m^{-2}]
q_{sw}= 0.6(q_m-58.14) [W.m^{-2}]
= the quantity of excreted sensible but mostly invisible sweat, it was estimated by weighing during experiments as a mean value for the whole range.
Heat flux within the human body can be represented as (see model in *Fig.1*):

$$q_m - q_{res} + q_{tr} + q_a = G_{t,ti}(T_i - T_{sk}) = \frac{1}{R_{t,ti}}(T_i - T_{sk}) \quad [\mathrm{Wm}^{-2}] \qquad (2)$$

where $G_{t,ti}$ is total body thermal conductance, which could be expressed by Equation 3:

$$G_{t,ti} = \frac{(q_m - q_{res})}{(T_i - T_{sk})} + \frac{(q_{tr} + q_a)}{(T_i - T_{sk})} = G_{t,m} + G_{t,i} \quad [\mathrm{W.m^{-2}.K^{-1}}] \qquad (3)$$

where $G_{t,i}$ is the internal thermal conductance and $G_{t,m}$ is the metabolic thermal conductance.

The thermoregulation and adaptational heat flux first affects the skin temperature, T_{sk}. The internal thermal resistance value, $R_{t,i} = 1/ G_{t,i}$, characterizing the vasodilatation and vasoconstriction process, can be calculated from the equation:

$$R_{t,i} = \frac{(T_i - T_{sk})}{(q_{tr} + q_a)} \qquad [W^1 m^2 K] \qquad (4)$$

EXPERIMENTAL ESTIMATION OF MATHEMATICAL MODEL PARAMETERS

An experiment lasting several years was undertaken in the climatic chamber from which the parameters in Equation (1) and (4) could be identified.
The experimental subjects were male university students each of them underwent six experiments lasting about three hours at four levels of activity: (1) sitting in a chair, (2) sitting on a bike-ergometer without pedaling, (3) pedaling on a bike-ergometer with a 40 W load and (4) pedaling on a bike-ergometer with a load of 1 W per kg body mass (as long as he was able to do it). Metabolic heat production during each activity was measured by indirect calorimetric method. Mean skin temperature, heat rate and body water loss were estimated continuously during each experiment.

Two sets of clothing were used by the subjects: lightweight (pajamas) and a heavier one (anti-g suit for fighter pilots). The results of anti-g suit experiments will be presented is a separate report.

There were no differences between air temperature and surface wall temperatures – it could be supposed globe temperature equals operative temperature. Six temperatures were chosen (29±3 °C and 14±3 °C, which determine temperature ranges where some of the subjects started to leave the neutral zone and appeared to begin sweating or shivering). The originally chosen range of temperatures 8, 11, 14, 17, 20, 23, 26, 29, 32°C was found not to be necessary and thus they was reduced.

Within the comfort range the relative humidity was maintained corresponding to a partial water vapour pressure from 700 to 1850 Pa. The beginning of sweating and shivering was always assessed by the same person. Experiments were carried out during all seasons, thus reflecting the seasonal adaptation effect on maximal and minimal thermoregulatory heat, i.e. it was possible to determine adaptational heat. But it was evident that it can be neglected (Jokl, Moos 1992) being lower as 0.2 °C (it is within the range of experimental faults of measuring the temperatures). The same finding has been described by other authors (see Fanger 1970). The results were only accepted from subjects within the thermal neutral zone with the thermoregulatory heat constant.

The graph construction of $T_g = f(q_m)$

The measured values are plotted as $q_{dry} = f(q_i - q_{sw})$ in *Fig.2*, where for optimal valuesthe linear equation - $q_{dry} = q_i - q_{sw}$ [$W.m^{-2}$] representing equilibrium is valid. The application of this graph into the practice is very difficult; useful is the relationship $T_g = f(q_m)$. Therefore the linear relationship from *Fig.2* has been transferred into the graph in *Fig.3* by plotting a regression line through points limited by equation – $q_{dry} - (q_i - q_{sw}) = \pm 4.8$ [$W.m^{-2}$] in *Fig.3*. The value of ±4.8 $W.m^{-2}$ of the regression line is the minimal thermoregulatory heat, i.e. represents maximal vasoconstriction in human body and can be estimated from the minimum value of human body internal thermal conductivity (see Fig.4) which equals 9.07 W/m^2K (for core body temperature T_i= 36.6 °C, skin temperature T_{sk}= 30.5 °C and q_m= 45.7 W/m^2).

$$q_{tr,min} = G_{t,i,min}(T_i - T_{sk}) = 1.57(36.6 - 30.5) = 9.6\ Wm^{-2},\ tj. \pm 4.8$$

$$\text{where}\quad G_{t,i,min} = G_{t,ti,min} - G_{t,m,min} = 9.07 - 7.5 = 1.57\ Wm^{-2}K$$

$$G_{t,m,min} = \frac{q_m}{T_i - T_{sk}} = \frac{45.7}{36.6 - 30.5} = 7.5\ Wm^{-2}K$$

The estimation of thermoregulatory range

The widest thermoregulatory range, i.e. from optimum up to the beginning of visible sweating can be estimated by plotting the regression line into the points of beginning of sweating. But for comfort lower values are necessary, without visible sweating occuring. This area is between the line of optimum and the tangent from origin (being an intersection of the line of optimum and the regression line of beginning of sweating) to the area of beginning of shivering (see *Fig.5*). These tangents are analogous to the thermoregulatory range of C category according to CR 1752-1998.

For A and B categories account must be taken that the human is a thermoregulatory mechanism in the surrounding environment balancing the operative temperature changes by thermoregulatory heat flows in the human body so that an equilibrium can be reached, this at three levels (analogically to technological mechanisms) (see *Fig.6*):

- level A, corresponding to the time constant 0.368 $\Delta T_{o,tr,max}$
- level B, corresponding to the time constant 0.632 $\Delta T_{o,tr,max}$
- level C, corresponding to the time constant 1.000 $\Delta T_{o,tr,max}$

Level A is valid for the building interiors with the highest requirements and can only be attained by air conditioning systems application. The level C is valid for the building interiors with the lowest requirements, usually only naturally ventilated. Level B covers the remaining buildings where air conditioning is necessary only in some cases.
The time constant according to control theory characterizes the system response, (human organism response) to the operative temperature changes and equals to the product of system thermal resistance R and its thermal capacity C:

time constant = R.C
where R= $R_{ti} + R_{twa}$ [$W^{-1}.m^2.K$]

For a complete list of values see *Table 1*.

A COMPARISON OF OPTIMAL VALUES AND THERMOREGUATORY RANGES WITH ACCEPTED VALUES

The proposed optimal temperatures and their thermoregulatory ranges were compared with the values according to ISO 7730 (Moderate thermal environments ISO 7730-1984 (E)), CR (1752) (1998) and ISO/DIS 7730 (2003), ANSI/ASHRAE Standard 55-2004.

The comparison of the above proposed operative temperatures with the values by CR 1752 and ISO/DIS 7730 is presented on *Table 2*. There is agreement of operative temperatures for 50 W/m^2, 70 W/m^2 and 80 W/m^2. For higher activities the values differ: the higher the activity, the higher the operative temperature difference. There is agreement with experiments (sitting persons in the neutral zone) on which PMV value is based.

The comparison of the proposed optimal operative temperatures with the values according to ISO and ANSI/ASHRAE is presented in *Table 3*. There is an evident agreement for low activities (graph is also based on ISO 7730).

RESULTS

From the mathematical model (*Fig.1*) the role of various heat flows produced by the human body as it interacts with the environment is evident. All the heat flows must be in mutual equilibrium the human body to stay homoiotherm. The application of this graph in practice is very difficult and T_g=f(q_m) is a more useful relationship (*Fig.3*). This equilibrium is the basis for optimal operative temperature estimation (*Fig.2*). The experimental data on the beginning of sweating and the beginning of shivering enable the thermoregulatory ranges to be estimated (*Fig.5*). The thermoregulatory area is between the line of optimum and the tangent from pole, defined as the intersection of the line of optimum and the regression line of beginning of sweating, to the field of beginnings of sweating (upper limit, level C_{max}) and to the field of beginning of shivering (lower limit, C_{min}). It is interesting and in agreement with human feelings, that the thermoregulatory field for cold is smaller than the thermoregulatory field of the warm area – human body is more sensitive to temperature decrease in cold area. The question is how to sub-divide the thermoregulatory range into categories (A, B and C). Instead of qualified assumption, it is proposed to base the categories on control theory. The human body does behave as any other system to which control theory can be applied. It is proposed that human body time constant is used to differentiate the categories. These values were used: time constant $0.368\Delta T_{0,tr,max}$ (A), $0.632\ \Delta T_{0,tr,max}$ (B) and $1.0\ \Delta T_{0,tr,max}$, which correspond to categories A, B and C (*Fig.3*). Category A can be applied to air conditioned buildings and category C to natural ventilated buildings. As a result, two previously separate methods of assessment can be merged, those for air conditioned buildings, based on PMV, and for natural ventilated buildings, based on a mean monthly outdoor temperature. The results have been compared with the values according to ISO 7730, CR (1752) (1998), ISO/DIS 7730 (2003) (*Table 2* and *3*) and with ANSI/ASHRAE Standard (*Table 3*). But, most importantly, it was possible to base the new Czech Government Directive No. 523/2002 Code (*Table 3*) on the new findings, which were used to derive the compulsory microclimatic condition for workplaces in the Czech Republic.

DISCUSSION

The optimal operative temperatures derived from PMV values (from the 1970's) are now not fully acceptable. It is more precise to use optimal operative temperatures based on the physiological human body response and not based on the man's feelings only. It has been proved by experimental works (Fishman, Pimbert 1979) and shown when ISO values have been applied in practice. The higher the man's is activity, the higher the discrepancy in the optimal temperature. Because of this discrepancy, the new Czech Government Directive No. 523/2002 Code is based on the presented values and not on ISO/DIS 7730, which is based on PMV. The absence of adaptation to heat and cold, for example resulting from a stay in heated rooms in winter and in air-conditioned cars in summer, in the directive results in the same optimal operative temperatures for winter and for summer; temperatures are differentiated only by various clothing.

Modeling human thermal comfort

Miimu Airaksinen, Pekka Tuomaala and Riikka Holopainen

VTT, Finland

Corresponding email: Miimu.Airaksinen@vtt.fi

SUMMARY

Thermal comfort standards determine indoor conditions in buildings as well as the energy consumption for heating and cooling purposes. Existing thermal comfort standards are based on steady-state thermal conditions, and according to recent research these standards can not describe thermal comfort accurately enough with transient boundary conditions. In this paper, a method based on Hui (2003) is presented to calculate local and overall human body thermal sensations in time dependent and non-uniform. In addition, local and overall thermal comfort predictions can be performed based on these thermal sensation values.

INTRODUCTION

Due to increasing awareness of energy consumption and environmental issues, modern buildings have better thermal insulation and ventilation heat recoveries. This lead also to other kind of demands in design phase, especially when low temperature levels are utilised. So far most human thermal comfort models are based on estimates assuming steady-state conditions. However, this often leads to underestimations of local cold or hot surfaces. In addition, that kind of models do not take into account variable conditions.

It is important for people that they feel comfortable with the environment when they are inside buildings. This is regardless of their role (employer, employee, resident) in a specific environment. Therefore, a large amount of research has been conducted in order to establish how the variables creating the environment in a building should be tuned so that the users feel comfortable.

Two widely used standards - ANSI/ASHRAE Standard 55-1992 (Thermal Environmental Conditions for Human Occupancy) [1] and ISO 7730 (Moderate thermal environments - Determination of the PMV and PPD indices and specification of the conditions for thermal comfort) [2] - present a necessary method (originally presented by Fanger in 1972 [3]) for evaluation of moderate thermal environment. When using this method, human's thermal sensation is related to the thermal balance of a body as a whole. This balance is influenced by occupant's physical activity and clothing, as well as the environmental parameters: air temperature, mean radiant temperature, air velocity, and air humidity (ISO 7730). The method is derived for steady-state conditions and - due to treating a human body as whole - is does not allow estimations in any spatially non-uniform conditions.

The aim of this paper is to present a method how to predict human thermal sensation and comfort under transient and non-uniform boundary conditions.

METHODS

The transient and non-uniform thermal environment as well as our body including our clothing are affecting to our thermal sensation and thus our comfort. Since neither the physiology nor the thermal comfort are not uniform to the whole human body, a detailed model is needed in order to estimate realistic thermal sensation. The model used here for estimating thermal sensation and comfort is based on Hui [4]. Basically, the model calculates local human body part's thermal sensations and local thermal comfort, and based on that information also the overall thermal comfort can be estimated.

Human Body Model

For the estimation of thermal sensation and comfort, a human body model interacting with thermal environment is needed. The body model used here is based on Smith's model [5]. In this model the human body is divided to 15 parts, and each body part has bone, muscle, fat and skin layers as well as blood circulation. The blood circulation and body core temperature is controlled by a human body control model which acts rather close as the real body "control systems". For example, when human body core temperature rises above its neutral value, vasodilation occurs and cardial output increases dramatically. Nearly 100% of this increase goes to the skin tissue. For this development, a state of maximum vasodilation is achieved when core temperature reaches 37.2°C. At this state, the total skin blood flow rate may be as much as seven times its basal value. This increase in cardiac output is distributed to the individual body parts according to surface area.[5] A more detailed description of that model is presented by another paper by Tuomaala et al. in this congress.

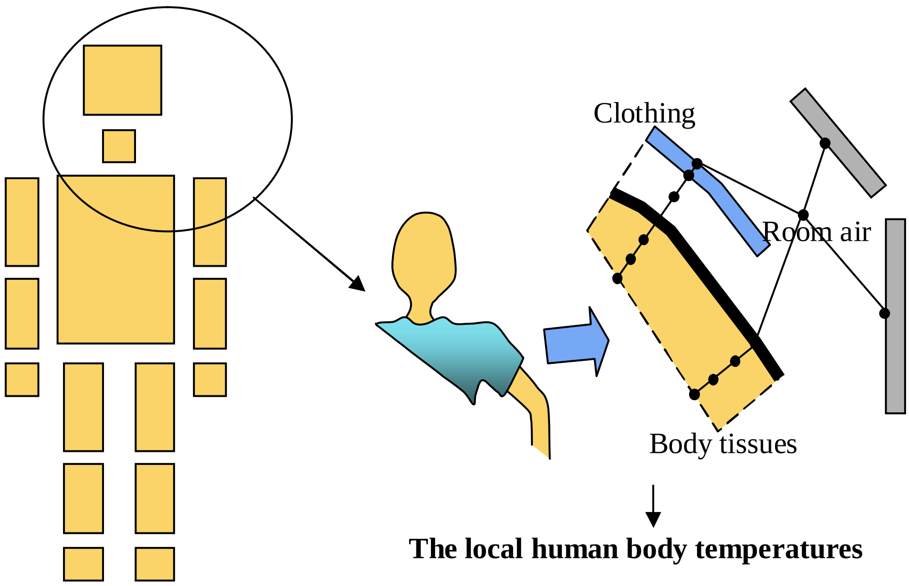

Figure 1. The human model is divided to 15 parts.

Thermal sensation and comfort prediction model

The model used in this study is based on Hui's study [4] which includes results from 109 human subject tests that were performed under non-uniform and transients conditions in the UC Berkeley Controlled Environmental Chamber. In those experiments, local body surfaces of the subjects were independently heated or cooled while the rest of the body was exposed to a warm, neutral or cool environment. Skin temperatures, core temperature, thermal sensation and comfort responses were collected at one- to three-minute intervals. [4] The Figure 1 shows the flow chart how the overall thermal comfort is calculated.

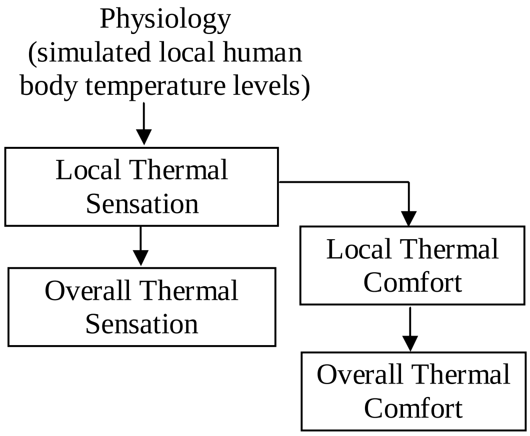

Figure 1. Overall thermal comfort calculation flow chart.

The local sensation model is a function of skin and core temperature and their rates of change (Eq. 1). The model has a sub-model to each body part, and together they capture the asymmetry of thermal conditions.

$$S_l = f\left(T_{skin}, \frac{dT_{skin}}{dt}, T_{core}, \frac{dT_{core}}{dt}\right) \quad (1)$$

Local comfort is predicted from local sensations and average of all body's local sensations, and the overall sensation model integrates the local sensations. The whole body comfort model integrates the local comfort values. Overall thermal sensation is modelled as a weighted average from the local sensations:

$$S_o = \frac{\Sigma weight_i \cdot S_{l,i}}{\Sigma weight_i} \quad (2)$$

where *weight* is a function between the difference of local sensation and geometrical average of all sensations.

weight can be calculated for each body part:

$$weight_i = a \cdot (S_{l,i} - \overline{S_l}) \quad (3)$$

where *a* is a factor depending on local and overall sensation, $\overline{S_l}$ average value from all local thermal sensation factors.

For some body parts (e.g., chest and back) the weight is higher than for other parts. The weight is higher either due to body part size or sensitivity. Some body parts are not behaving similarly if the local sensation is higher or lower compared to average thermal sensation. One body part may be more important to determine cold than warm sensation. As the *weight* is a function between the difference of local and geometrical average of all sensations it assigns larger weights when the local thermal sensation is opposite to rest of the body's thermal sensation.

Sensation can have values from -4 to 4. Value 4 corresponds very hot, 3 hot, 2 warm, 1 slightly warm and 0 neutral.

Local comfort is a function of local sensation and overall sensation:

$$C_{li} = f(S_{l,i}, S_o) \quad (4)$$

and overall thermal sensation is a function of local thermal comfort. Overall thermal comfort is evaluated from two rules:

•Rule 1: Overall comfort is the average of the two minimum local comfort votes unless Rule 2 applies.

•Rule 2: If the following criteria are met the overall thermal comfort is average of the two minimum and the maximum comfort vote.
Criteria are:
•the second lowest local comfort vote is higher than -2.5
•the person has some control over his/her thermal environment or the thermal conditions are transient

If both hands or both feet comprise the two most uncomfortable body parts ignore the second lowest hand or foot comfort value, and use the third lowest comfort vote as the second lowest vote in both Rules 1 and 2.

Comfort can have values from -4 to 4 and value 4 corresponds to very comfortable, 2 comfortable and 0 neutral.

RESULTS

When the body surface temperatures and core temperature are close to neutral conditions, local thermal sensations are close to zero, thus no big thermal sensations. The local and overall comfort values are close to 2, indicating comfortable thermal conditions, Figure 2. It should be noted that according to [4] the very comfortable conditions (value 4) was only recorded in transient conditions when thermal stress is suddenly removed.

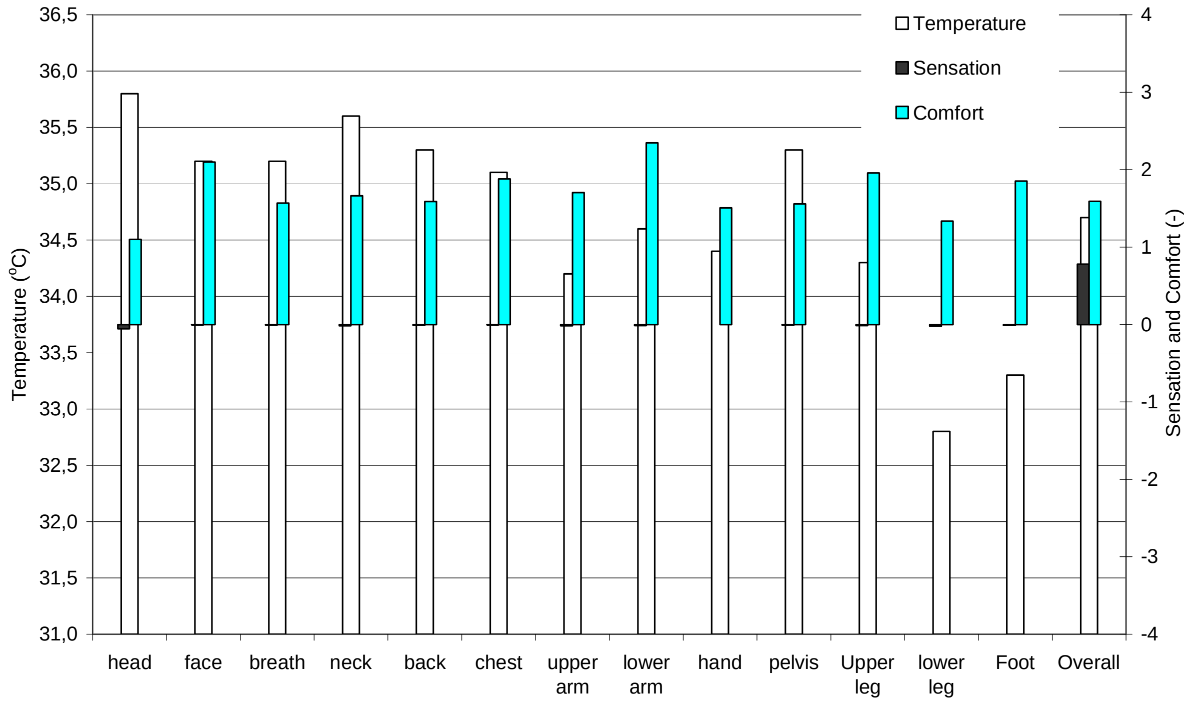

Figure 2 Local sensations and comfort values close to thermal neutral area.

When body temperatures are decreasing in cold environments, the sensation and comfort values are negative. If body part temperatures are decreasing by 4 degree the local thermal comfort is lower than -2 indicating uncomfortable cold, Figure 3. In calculations for Figure 3 it was assumed that the core temperature is not changed.

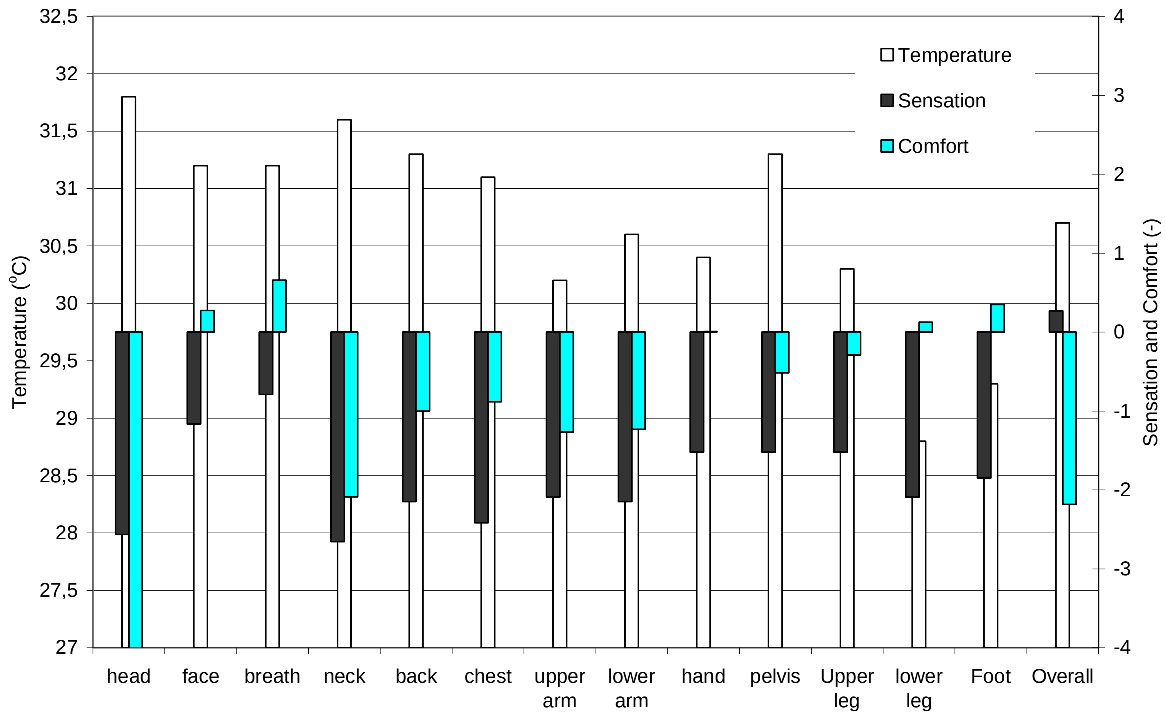

Figure 3 Local sensations and comfort values when body surface temperatures are in average 4 degrees lower than thermal neutral area. Core temperature was not changed.

Head of human body is sensitive to temperature changes. If all other body parts are kept in thermal neutral area, but head, face, breath and neck temperature is decreasing 2^{o}C lower than thermal neutral temperatures it is affecting overall comfort dramatically, Figure 4.

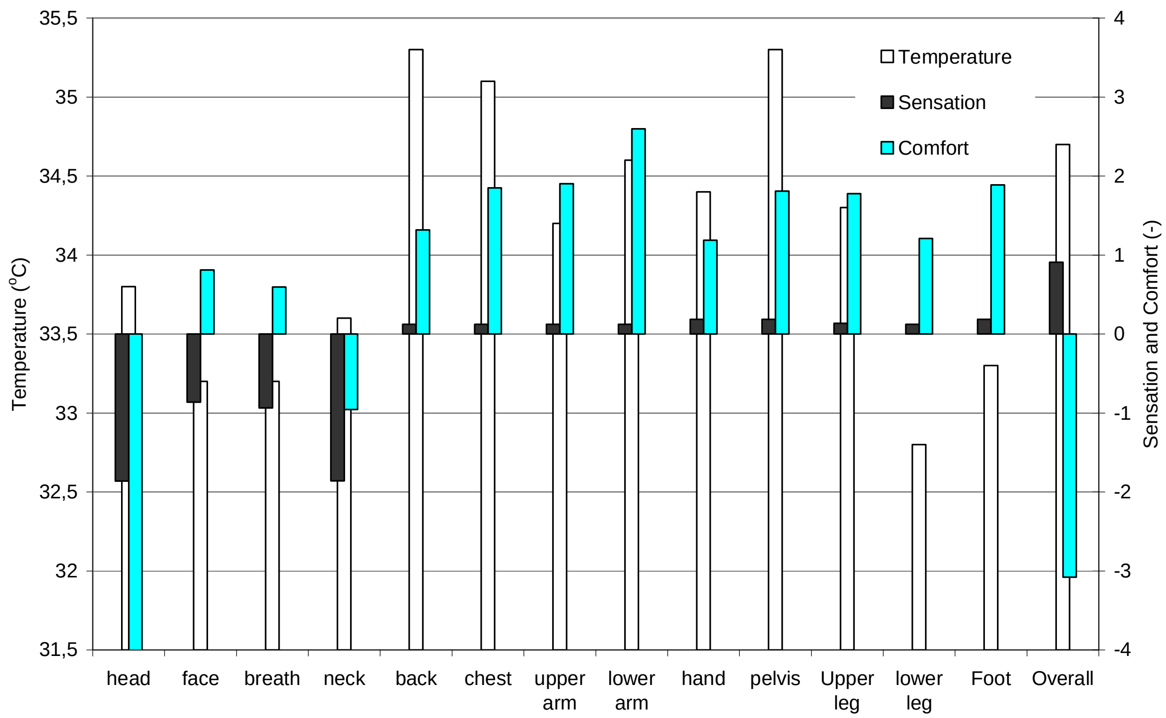

Figure 4 Local sensations and comfort values when head are is 2 degrees Celsius lower than the thermal neutral area, other body parts remained close to thermal neutral conditions. Core temperature was not changed.

DISCUSSION

The model based on Hui's study [4] gives new understanding about the thermal comfort and how changes in thermal environment are effecting on human thermal sensation. The new knowledge is valuable in designing and developing new indoor environments. It would also help us to find out the most suitable renovation alternatives for old buildings in respect to indoor environment comfort.

A concept for utilizing detailed human thermal model for evaluation of thermal comfort

Pekka Tuomaala, Miimu Airaksinen and Riikka Holopainen

VTT, Finland

SUMMARY

This paper presents a concept for more realistic and reliable evaluation of thermal indoor environment. A detailed thermal model of a human body, interacting with building simulation model, makes it possible to predict transient tissue temperatures of a human body as well as local skin temperature levels in realistic working and living conditions. Using these temperature distributions of a human body as input data for a new thermal comfort prediction model (Hui 2003), both local and overall estimations of thermal comfort of a human body can be obtained. In the future, these estimations of thermal comfort can be used when analysing links between alternative technical solutions vs. productivity and health issues.

INTRODUCTION

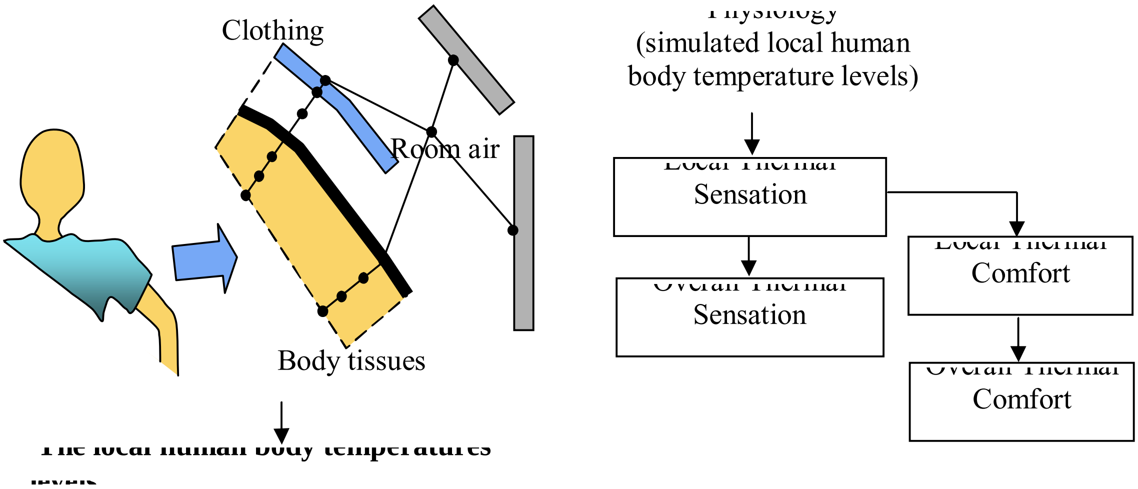
Two widely used standards - ANSI/ASHRAE Standard 55-1992 (Thermal Environmental Conditions for Human Occupancy) [1] and ISO 7730 (Moderate thermal environments - Determination of the PMV and PPD indices and specification of the conditions for thermal comfort) [2] - present a necessary method (originally presented by Fanger in 1972 [3]) for evaluation of moderate thermal environment. When using this method, human's thermal sensation is related to the thermal balance of a body as a whole. This balance is influenced by occupant's physical activity and clothing, as well as the environmental parameters: air temperature, mean radiant temperature, air velocity, and air humidity (ISO 7730). The method is derived for steady-state conditions and - due to treating a human body as whole - is does not allow estimations in any spatially non-uniform conditions.

There is a very old and simple experiment described by English philosopher John Locke in his 1690 *Essay Concerning Human Understanding*. A person places one hand in a basin of warm water and the other in a basin of cool water. After a short time, both hands are placed together in a third basin of water, which is at intermediate temperature. The hand previously in warm water feels cool and the hand previously in cool water feels warm even though they are actually at the same temperature. In a similar way, people are probably more often exposed to spatially non-uniform and transient temperatures than to thermal environments that are uniform and stabile. We experience transient and non-uniform temperature conditions when moving between spaces - e.g., from indoors to outdoors, from shun to shade, and when occupying spaces with widely varying temperatures. [4]

The aim of this paper is to present a concept how to predict and evaluate human thermal sensation and comfort under transient and non-uniform boundary conditions. The concept includes guide-lines for predicting transient thermal behavior of a detailed human body model, and an estimation method for quantifying thermal sensation and comfort of a human body.

METHODS

Since we experience transient and non-uniform temperature conditions in our real living and working environment, both human body and surrounding indoor environment need to be modeled. In addition, both human body and indoor environment models need to be detailed enough for estimating transient thermal behavior of individual body parts and local skin temperature levels. After obtaining estimations of local skin temperature levels, as well as body core and local skin temperature change rates, a detailed prediction of both local (body part) and overall (whole body) thermal sensation and comfort can be conducted.



(i) (ii)

Figure 1. The two main phases when predicting human thermal comfort: (i) simulation of the local human body temperature levels, and (ii) quantifying local and overall thermal sensation and comfort by Hui's method [4].

Human Body Model

In the first phase of this evaluation concept, the human thermal simulation model - having a true physical inter-action with a surrounding space model - estimates human body tissue and skin temperature levels. The human thermoregulatory system senses the thermal state of the body, interprets these thermal signals, and responds accordingly. Because the body's thermoregulatory response is determined using feedback from the thermoreceptors, it is appropriate to model the human thermal system using two interactive systems: (i) the passive or controlled system, which includes the body tissues, internal organs, circulatory and respiratory systems, and (ii) the control system, which initiates and controls the physiological responses of the body. [5]

<u>Human Body Model - Passive system</u>

A model of the human thermal system ought to be sufficiently detailed and flexible enough to be easily modified for different types of applications. For this reason, a finite-difference method with free description of the thermal calculation network generation will be used to develop the new thermal model. When using this technique in the passive system defined above, the human body is discretized into a number of smaller nodes (with thermal mass) and inter-nodal connections (thermal conductance). This network represents tissue sections, blood vessels, segment of the respiratory track, or portion of an internal organ. Energy, momentum, and mass balance equations of the human thermal model calculation network, incorporating the environmental conditions, can then be solved for the unknown variable of interest (e.g., variations of the skin temperatures around the body). The control system uses thermal input in the form of local tissue temperatures to determine the appropriate thermoregulatory responses. Possible responses include sweating, shivering, and the increase or decrease in blood flow rates to the skin. How the thermal state of the passive system changes, and to what degree, depends on the thermoregulatory responses initiated by the control system. A state of thermoneutrality exists when core and mean skin temperatures are 36.8°C and 33.7°C, respectively. [5]

Because of simplicity, the individual 15 human body parts (see Figure 2) are approximated by concentric rectangulars describing the human body tissue type distribution presented in Table 1. The basic idea is to model the body parts mimicking the true anatomy as a single bone core surrounded by muscle, fat, and skin layers. Further divisions are then made in the angular and axial directions until each body part is composed of small tissue elements.

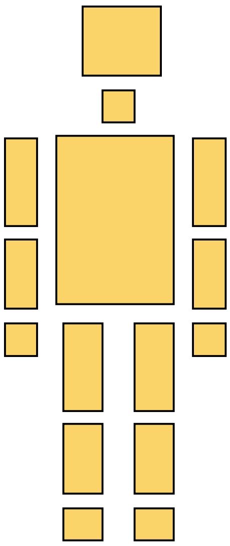


Figure 2. Adopted multi-element thermal model of human body divided into body parts.

Human Body Model - Control System

As core temperature rises above its neutral value, vasodilation occurs and cardial output increases dramatically. Nearly 100% of this increase goes to the skin tissue. For this development, a state of maximum vasodilation is achieved when core temperature reaches 37.2°C. At this state, the total skin blood flow rate may be as much as seven times its basal value. This increase in cardiac output is distributed to the individual body parts according to surface area. [5]

As mean skin temperature falls below its neutral value, vasoconstriction occurs. Skin blood flow, and therefore, cardiac output, decreases. At a state of maximum vasoconstriction, assumed to occur when mean skin temperature falls to 10.7°C, the total skin blood flow rate may be as low as one eight of its basal value. As before, this change in cardiac output is distributed among the body parts according to surface area. [5]

Regional blood flow rates and skin blood vessel radii have been calculated for a hypothetical state of thermoneutrality and for states of maximum vasodilation and maximum vasoconstriction. This establishes the range over which skin blood vessel radii can vary, with respect to the model. Core temperatures above 36.8°C govern the effects of vasodilation while mean skin temperatures below 33.7°C govern those of vasoconstriction.

Control equations for skin blood vessel radii have been developed as functions of core and mean skin temperatures. For core temperatures less than or equal to 36.8°C, skin blood vessel radii experience no dilation and assume their values at thermoneutrality. At a core temperature of 37.2°C, skin blood vessels are maximally dilated. Between these two core temperatures, skin blood vessel radii vary linearly with core temperature.

Thermal sensation and comfort prediction model

Most existing thermal comfort models are applicable only in uniform, steady-state thermal environments. However, Hui (2003) has developed predictive models of local and overall thermal sensation and comfort derived from results from 109 human subject tests that were performed under non-uniform and transients conditions in the UC Berkeley Controlled Environmental Chamber. In these tests, local body surfaces of the subjects were independently heated or cooled while the rest of the body was exposed to a warm, neutral or cool environment. Skin temperatures, core temperature, thermal sensation and comfort responses were collected at one- to three-minute intervals. [4]

The local sensation model is a function of skin and core temperature and their rates of change (see Equation 1). The temperatures of skin and core represent stable conditions and the rate of change transient conditions respectively. The model has a sub-model to each part and together they capture the asymmetry of thermal conditions.

$$S_l = f\left(T_{skin}, \frac{dT_{skin}}{dt}, T_{core}, \frac{dT_{core}}{dt}\right) \quad (1)$$

Local comfort is predicted from local sensations and average of all body's local sensations, the over all sensation model integrates the local sensations. The whole body comfort model integrates the local comfort values. Overall thermal sensation is modelled as a weighted average from the local sensations:

$$S_o = \frac{\Sigma weight_i \cdot S_{l,i}}{\Sigma weight_i} \quad (2)$$

where *weight* is a function between the difference of local sensation and geometrical average of all sensations.

weight can be calculated for each body part:

$$weight_i = a \cdot (S_{l,i} - \overline{S_l}) \qquad (3)$$

where a is a factor, $\overline{S_l}$ average value from all local thermal sensation factors. The values for a are written in Table 2.

Table 2. Coefficient a for calculating overall thermal sensation. [4]

Body Part	S_l-S_o< 0	R^2	S_l-$S_o \geq 0$	R^2
Head	-0.13	0.82	0.21	0.57
Neck	-0.13	0.71	0.23	0.68
Chest	-0.23	0.90	0.23	0.70
Back	-0.23	0.81	0.24	0.80
Pelvis	-0.17	0.85	0.15	0.73
Upper arm	-0.10	0.69	0.14	0.42
Lower arm	-0.10	0.69	0.14	0.42
Hand	-0.04	0.29	0.04	0.23
Thigh	-0.13	0.38	0.26	0.30
Calf	-0.13	0.38	0.26	0.30
Foot	-0.09	0.10	0.14 (1 foot)	0.20
Upper back	-0.16	0.86	0.26	0.88
Lower back	-0.21	0.84	0.35	0.88

For some body parts e.g. chest and back the weight is higher than for other parts. The *weight* is higher either due to body part size or sensitivity. Some body parts are not behaving similarly if the local sensation is higher or lower compared to average thermal sensation. One body part may be more important to determine cold than warm sensation. As the *weight* is a function between the difference of local and geometrical average of all sensations it assigns larger weights when the local thermal sensation is opposite to rest of the body's thermal sensation.

Thus, the local thermal sensation can be presented as:

$$S_{l,i} = 4\left(\frac{2}{1+e^{-C1_i (T_{i,skin,local} - T_{i,skin,local,set}) - K1_i \left[(T_{i,skin,local} - T_{i,skin,local,set}) - (\overline{T}_{skin} - \overline{T}_{skin,set})\right]}} - 1\right)$$
$$+ C2_i \frac{dT_{i,skin,local}}{dt} + C3_i \frac{dT_{core}}{dt} \qquad (4)$$

The coefficients $C2_i$ and $C3_i$ are presented in Table 3.

Table 3. Coefficients $C2_i$ and $C3_i$ for calculating local dynamic thermal sensation. [4]

Body part	$C2_i$ $\left(\frac{dT_{i,skin,local}}{dt} \le 0\right)$	$C2_i$ $\left(\frac{dT_{i,skin,local}}{dt} \ge 0\right)$	$C3_i$	R^2
Back	88	192	-4054	0.73
Chest	39	136	-2135	0.61
Face	37	105	-2289	0.74

Upper arm	156	167	0	0.74
Lower leg	206	212	0	0.85
Upper leg	151	263	0	0.94

RESULTS

Transient tissue and skin temperatures can be simulated. Table 4 presents one distribution of local skin temperatures, and corresponding local thermal sensation values are also presented. Local thermal sensation can have values from -4 to 4, where value 4 corresponds to “very hot”, 3 to “hot”, 2 to “warm”, 1 to “slightly warm”, and 0 to “neutral”.

Table 4. A basic distribution of local skin temperatures with a human body core temperature of 37.4°C, and corresponding predicted local thermal sensations.

Body part	Skin temperature [°C]	Local thermal sensation [-]
Head	35.7	0.76
Neck	35.5	1.58
Torso	35.1	1.34
Right upper arm	34.1	1.64
Left upper arm	34.1	1.64
Right forearm	34.5	2.58
Left forearm	34.5	2.58
Right hand	34.3	0.99
Left hand	34.3	0.99
Pelvis	35.2	1.37
Right thigh	34.2	1.92
Left thigh	34.2	1.92
Right calf	32.7	1.39
Left calf	32.7	1.39
Right foot	33.2	2.23
Left foot	33.2	2.23

DISCUSSION

The presented human thermal model seems very promising when predicting tissue temperatures under transient and non-uniform boundary conditions. However, further development, testing and validation are still needed until this human body model can be utilized for producing reliable thermal data for thermal sensation and comfort prediction model under extreme boundary conditions.

The presented concept (i.e., linking interacting human body and building simulations together with thermal sensation and comfort prediction model) offers a new mechanism for evaluating interactions and connections for example between thermal properties of individual building components, design and dimensioning building service devices and systems, human thermal comfort and sensation, productivity, etc. This way, well being indoor environments can be improved in a controllable way.

THE THERMAL ENVIRONMENT LEVEL ASSESMENT BASED ON HUMAN PERCEPTION

M. V. Jokl

Czech Technical University, Czech Republic

Corresponding email: miloslav.jokl@fsv.cvut.cz

SUMMARY

A new way of the thermal level environment assessment based on "operative temperature thermal level" and new units "decitherm" is introduced, which allow the feelings of man to be followed. Simultaneously the fact that the operative temperature decrease is felt the more unpleasantly the lower are temperatures is also taken into account. The assessment in decitherms also allows the comparison (based on numerical values comparison) with the noise level in decibels and odor level in deciodors and the whole environment level assessment (based on weighted constituent levels adding). Also syndrome SBS can be estimated, the effectiveness of heating and cooling appliances and even the condition of human organism threat by overwarming (hyperthermia) or undercooling (hypothermia).

INTRODUCTION

The paper presents a new way of the thermal environment level assessment being able to give a true picture of the thermal environment level as perceived by man. Thus this way respects also the fact that the operative temperatures decrease is perceived the more uncomfortable the temperatures are lover, e. g. the decrease by 3 °C from 10 °C to 7 °C is always more unpleasant than the decrease from 20 °C to 17 °C. The distribution of 15-day moving means of mortality against temperature is shown in Fig. 1. Simple correlation gave a coefficient of r= -0.64. Mortality expressed as a quadratic function of temperature ($Y= 17.69-1.149T+0.025T^2$) produced a multiple correlation coefficient of 0.72 and *t*-values of -14.0 and 12.2 for temperatures T and T^2, respectively. These appeared to be high enough to justify the preference for the polynomial model over linear. Minimum mortality was predicted by the quadratic equation at 23° C.

From Fig. 1 it appears that mortality is accelerated below a 'critical' mean temperature of about 18° C and especially those below 16° C. On the warm side, temperatures did not reach sufficiently high values to enable identification of particularly critical thresholds (see Auliciems and Skinner 1989). There is also a physiological background of perceiving cold and warm in different way: special sensors for cold and warm in the skin (see Fig. 2) and special evaluation centres in the brain (Fig. 3). New way originates from human body physiology where Weber-Fechner law is valid:

$$R=k.\log S \qquad (1)$$

where R… the human body response
S… the stimulus of the environment causing the response
k… the coefficient

PROPOSAL OF NEW EVALUATION SYSTEM

At the thermal condition of environment this law can be applied as

$$L_{th} = k_{th} \cdot \log\left(\frac{T}{T_{threshold}}\right) \quad [dTh] \qquad (2)$$

where L_{th}…operative temperature thermal level [decitherm], [dTh]
T…operative temperature [°C]
$T_{threshold}$… threshold operative temperature, in this case optimal operative temp. [°C]

Equation (2) corresponds with the formula for noise assessment with the so called acoustic pressure level

$$L_p = 20 \cdot \log\left(\frac{P}{P_0}\right) \quad [dB] \qquad (3)$$

Where the ratio of acoustic pressures forms the stimulus, P is the acoustic pressure within the space investigated, P_0 is the acoustic pressure perceived lower limit 20 μPa. The unit decibel (dB) has been used for acoustic pressure level, the unit decitherm (dTh) for operative thermal level.
The analogical equations also exist for odor constituent of the environment (Jokl 1998, 2000), the so called deciodors, based on carbon dioxid, so called decicarbdiox (dCd) and on total volatile organic compounds (TVOC), so called decitvoc (dTv).

CORRESPOND NEW UNITS TO HUMAN FEELINGS?

The equation (2) for thermal environment assessment seems to be reasonable, both from the human body physiology aspect and from the theory of similarity (Kline 1965, Kožešník 1983), however, its approval by an experiment is necessary, i.e. that decitherms describe the man's perception.
The perception of the thermal environment level can be described by ASHRAE scale (ANSI/ASHRAE 55-1992) (cold, cool, slightly cool, neutral, slightly warm, warm, hot). These should be proportional to thermal level, i.e. it must be proved that

$$L_{th} = k_1 \cdot (AV) \quad [dTh] \quad (4)$$

where AV… the values of ASHRAE scale
k_1… coefficient of proportionality

Of course, Weber-Fechner law (2) is valid simultaneously, so it must be proved that

$$AV = k_2 \cdot \log\left(\frac{T}{T_{opt}}\right) \qquad (5)$$

to be $L_{th} = k_1 AV$.

After substitution

$$L_{th} = k_1 \cdot AV = k_1 \cdot k_2 \cdot \log\left(\frac{T}{T_{opt}}\right) = k_{th} \cdot \log\left(\frac{T}{T_{opt}}\right) \quad [dTh] \qquad (2)$$

See fig. 4 where the results of experiments by Fishman and Pimbert (1979) are presented. There is the relationship between operative temperatures (axis x) and averages votes ASHRAE (axis y). Average values ASHRAE have been estimated in the range ±0.2°C for each temperature, e.g. for 20 °C: 19.8 °C to 20.2 °C. The average activity was 80 W/m^2. The feelings of 26 subjects were registered 8 times per day (between 9.30 and 16.30 hour) for the whole year, i.e. 54080 values were registered altogether. From the graph is evident that the ASHRAE and calculated PMV values differ (the lowest difference is near neutral physiological state for which the PMV was derived). The relationship (6) can be estimated for ASHRAE values from the graph (*Fig. 4*):

$$AV = 14.469 \log T - 19.172 = 14.469 \log T - 14.469 \log 21.14 = 14.469 \cdot \log\left(\frac{T}{21.14}\right) \qquad (6)$$

This can be rewritten in a general form

$$AV = k_2 \cdot \log\left(\frac{T}{T_{opt}}\right) \qquad (5)$$

and therefore it is valid
$L_{th} = k_1 AV$
and it is evident that decitherms correspond to human feelings and that operative temperature do not correspond to human feelings.

THE OPERATIVE TEMPERATURE THERMAL LEVEL ESTIMATION

Now thermal levels can be estimated for operative temperatures optimal and long-term and short-term tolerable.

Optimal operative temperatures

Optimal operative temperatures are determined by the neutral physiological state of man at his activity and clothing. The experimental estimation on this basis being very difficult (however in this case values from Jokl and Kabele 2006 experiments have been available) the optimal values were estimated by the votes of the subjects satisfied with the evaluated environment (or dissatisfied – in the range 10% to 30% related to the requested environment quality) (Fanger 1970, EN ISO 7730).
To optimal operative temperatures (analogically as by noise and odors) correspond dTh=0 because log1=0.

Long-term tolerable operative temperatures

Long-term tolerable operative temperatures have ranges too. Their beginning is identical with optimum upper limit and their end is determined by the operative temperature on an average skin temperature level because by higher operative temperatures: there is the danger of human body hyperthermia with the body temperature increase. Range in dTh: 46-90, see item Scale.
The long-term tolerable operative temperatures can be admitted in warm environment only: the disturbed thermal equilibrium is balanced by sweating. In cold environment sweating corresponds shivering which does not exist within most people (shivering caused by nerves cannot be taken into account). Thus shivering cannot be respected as a protective mechanism of the human body. Therefore only short-term values can be taken into account in cold environment.
The operative temperature can be estimated for the value minus 46 dTh, the beginning of hypothermia of human body.
It is interesting that the area of long-term values is the area of sick building syndrome as well (it is out of optimal values being long-term tolerable at the same time).

Short-term tolerable operative temperatures

Short-term tolerable operative temperatures are also determined by their limits. The beginning they have in warm environment is identical with maximal long-term tolerable values, in cold environment with minimal values of optimum. The end in the warm is before the threshold of pain (cca 42 °C, 135dTh)(pain is the same criterion for noise). Range in dTh: 91-134, see item Scale. In cold environment there is a new limit: if a man is able to work continuously (e.g. during the whole shift) during the chosen operative temperature. The limit in Czechia is 10 °C, in USA 15 °C only.

Intolerable operative temperatures

Intolerable operative temperatures are characterized only by their beginning identical with the end of short-term tolerable values. Range 135dTh and more, see item Scale.

SCALE OF OPERATIVE TEMPERATURE THERMAL LEVELS

It is determined by the basic equation (2) in which

$$k_{th} = \frac{135}{\log\left(\frac{42}{T_{opt}}\right)} \qquad (7)$$

Thermal levels, analogically to operative temperatures, are optimal, tolerable and intolerable (*Table 1*).

Optimal values are very pleasant, pleasant and acceptable (optimal admissible from directives point of view). Tolerable are long-term and short-term tolerable.

APPLICATION

Two examples have been chosen:

- Application to experimental values (Jokl, Kabele 2006)
- Application to optimal operative temperatures in an airliner cabin starting also from experimental values in (Jokl, Kabele 2006) but transformed into Czech Directive.

Application to experimental values based on neutral physiological state of man (*Table 1*)

The following values have been chosen from the experimental results (Jokl, Kabele 2006):

a) For 1.2 Met (70 W/m^2), 0.5 clo (optimal operative temperature 24.5 °C)

$$L_{th} = 576.718 \cdot \log\left(\frac{T}{24.5}\right) \quad [\text{dTh}]$$

The skin temperature determining the upper limit of long-term tolerable values:

T_{sk}= -0.0276q_m+35.7= 34 °C (Fanger 1970)

where q_m= 70W/m^2 (activity).

The scale of operative temperature thermal levels is presented in *Fig. 5*.

b) For 1.72 Met (100 W/m^2), 0.5 clo (optimal operative temperature 21.5 °C)

$$L_{th} = 464.22 \cdot \log\left(\frac{T}{21.5}\right) \quad [\text{dTh}]$$

The skin temperature determining the upper limit of long-term tolerable values: 33 °C

The scale of operative temperature thermal levels is presented in *Fig. 5*.

c) For 2.1 Met (120 W/m^2), 0.5 clo (optimal operative temperature 19.5 °C)

$$L_{th} = 405.144 \cdot \log\left(\frac{T}{19.5}\right) \quad [dTh]$$

The skin temperature determining the upper limit of long-term tolerable values: 32.5 °C
The scale of operative temperature thermal levels is presented in *Fig. 5*.
In all three cases following the corresponding thermal levels it can be assessed which measured operative temperatures in an interior are very pleasant, pleasant, acceptable or only long-term or short-term tolerable or intolerable.

Application to optimal operative temperatures in an airliner cabin
Optimal operative temperature in an airliner cabin is 22 °C (dTh=0). The corresponding scale of operative temperature thermal levels for activity 1.2 Met and clothing 0.75 clo ($L_{th} = 480.724 \cdot \log\left(\frac{T}{22}\right)$) is presented in *Fig. 6*. At the flight beginning operative temperature can be decreased to 21 °C (dTh=-10). After some flight time, when passengers make themselves comfortable by putting off their jackets (decrease to 0.5 clo) and start to walk in the cabin (increase to 1.72 Met) it should be increased to 23 °C (dTh=9). The maximal admissible operative temperature increase can be 25.5 °C (31 dTh). In the case of some failure the long-term tolerable values are closing at 33.76 °C (89.4 dTh).

A NEW PROSPECT: THE ASSESMENT OF THE EFFECT THE THERMAL LEVEL ON THE TOTAL ENVIRONMENT

Perhaps the greatest advantage of the new decitherm unit is possibility of a new type microenvironment evaluation. First each constituent is assessed separately, and then its effect on the whole environment. Decitherms can be also a new basis for a constituent mutual interaction study.
The paper by Rohles et al. (1989) can be used for this purpose. Various constituents have different effects on the resulting environment; e.g. our health is more threatened by cold than by aeroions.
The preliminary results by Rohles are presented in *Table 2*. The operative temperature seems to be very important (16%), the corresponding hygrothermal constituent has the greatest impact (30%), it is followed by illumination (24%), acoustic (22%), toxic (10%), odor (8%) and aerosol (6%) constituents.
The influence of acoustic, odor and hygrothermal constituents on the overall environment can be expressed as follows:

$$L_{acoustic} = AC20\log\left(\frac{P}{20}\right) = \frac{22}{100} 20\log\frac{P}{20} \quad [dB] \qquad (8)$$

$$L_{odor} = OD(50\log\left(\frac{\rho_{TVOC}}{50}\right) + 90\log\left(\frac{\rho_{CO_2}}{480}\right)) = \frac{8}{100}(50\log\left(\frac{\rho_{TVOC}}{50}\right) + 90\log\left(\frac{\rho_{CO_2}}{480}\right)) \quad [dCo] \qquad (9)$$

$$L_{th} = HT(480.7\log\left(\frac{T}{22}\right) = \frac{30}{100}(480.7\log\left(\frac{T}{22}\right) \quad [dTh] \qquad (10)$$

where dCo = deciodors.

CONCLUSION – THE BENEFITS OF DECITHERMAL SCALE

The advantages of new proposed evaluation system can be summed up in the following items:
1. The undoubtable benefit of using the decithermal scale is that it gives a much better approximation to human perception of the thermal environment level compared to the operative temperature in grad Celsius.
2. The new decitherms values also fit in numbers very well with the dB values for sound and odors, i.e. so they can be compared to each other.
3. The new decitherms values allow the estimation of operative temperature impact on the whole environment.
4. The new units, decitherm and deciodor, can be a new basis for a constituent mutual interaction study.
5. Decitherms can be estimated by direct measurement: thermometers can be calibrated directly in new units, i.e. grad Celsius scale can be completed by decitherm scale.
6. Decitherms allow assessing the feasibility of the thermal environment level, i.e. to which extent it is pleasant or unpleasant.
7. Decitherms allow defining newly the ranges of optimal, short-term and long-term tolerable environment condition.
8. Decitherms allow a new definition of Sick Building Syndrome (SBS) caused by thermal environment condition – it equals to long-term tolerable values.
9. Decitherms allow estimating the condition of human organism threat by overwarming (hyperthermia) or by overcooling (hypothermia) as a result of long-term tolerable values overcoming.
10. Decitherms allow assessing the effectiveness of heating and cooling devices by a new way – by estimation to which extent they can satisfy optimal environment level for a user.

CFD validation of the thermal comfort in a room using draft rates

Authors: Mika Ruponen[1] and John A. Tinker[1]

[1]School of Civil Engineering, University of Leeds, UK

Corresponding email: mika.ruponen@halton.com

SUMMARY

Air temperature and velocity are the two main factors affecting the thermal comfort indoors. These two values can be easily obtained using computational fluid dynamic (CFD) simulations together with the turbulence kinetic energy value. This paper evaluates methods of calculating thermal comfort indices using CFD. Simulated results are compared against experimental data measured in a purpose build full-scale model room. The results show that CFD data can reliably predict thermal comfort values.

INTRODUCTION

Computational fluid dynamics (CFD) has become a popular tool for evaluating air distributions in a buildings and it is becoming common practice to simulate different designs alternatives before building a full or reduced-scale physical model. Quite often CFD is used alone to evaluate thermal comfort conditions in a room at design stage and when this is the case, it becomes important that both the user and method are validated against some form of measured data.

The main objective of this work is to validate how closely simulated results represent measured thermal comfort conditions in a room. Experimental data for CFD validation purposes is readily available [1-3]. However, as mentioned earlier, CFD is often used for initial design instead of building a physical model. In many cases the final design of the physical model can be very different from the earlier simulated design.

Air velocities are traditionally measured using omni-directional hot-sphere anemometers which record an average air speed (V). This averaged air speed reading consists of a time averaged unidirectional velocity component as well as an unidirectional turbulent fluctuation. The comparable result from a CFD simulation is a directional velocity vector (Vv) which includes a turbulent kinetic energy component. This has being addressed by Koskela et al [4] and a method has been developed to correct the vector value to a simulated speed value (Vo). The directional results obtained from CFD simulations are being reported to have smaller values than the omni-directional results obtained using a hot-sphere anemometer. Thermal indices such as the Draft Rate (DR) defined in ISO 1994 [5] are based on omni-directional results where the effect of the proposed correction for velocity on DR are evaluated.

METHOD

Test room

The test room had a floor area of 2.83m x 4.725m and a height of 3m and was surrounded by a cavity in which the temperature could be controlled. The room had insulated walls, ceiling and floor to reduce the heat flow through the surfaces. A bulkhead 300mm high and 600mm deep was built inside the room to accommodate the supply and extract ductwork. An air handling unit (AHU) was located adjacent to the test room which provided a temperature and volume controlled supply of air to the room.

Supply and exhaust of air into and from the test room was provided via two 100mm ϕ ducts located in the bulkhead as shown in figure 1. Two dummies [6] also as shown in figure 1, were used to provide a potentiometer controlled heat load into the space. The dummies were absent in case 1.

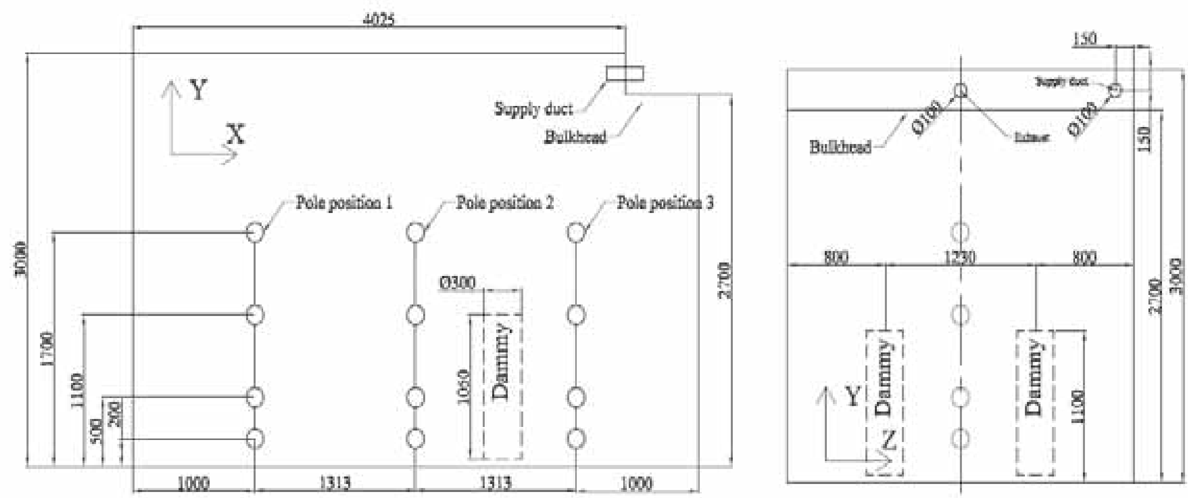

Figure 1. Test room plan and dimensions from Z and X-directions

Measurement equipment

The supply and extract volume flow rate was measured using calibrated MSD flow measurement units whose accuracy was ±5%. Temperatures were measured using PT 100 temperature probes that were calibrated to an accuracy of ±0.3K over the temperature range 15°C to 35°C. Omni-directional hot-sphere anemometers were used at various locations to simultaneously record air velocity to an accuracy of ±0.02m/s. The velocity and temperature sensors were fixed to a pole. Each pole had 4 sensors to measure air velocity and 4 for temperature (figure 2). The sensors were fixed 200mm away from the pole to reduce any effect the pole may have on the flow. Light-weigh paper strips were placed immediately below the sensors to visualise the air flow pattern in the room in addition to using a smoke tracer system. The heat load from the dummies was controlled using potentiometers and the power to them recorded using current meters.

Figure 2. Velocity and temperature measurement equipment

Test Procedure

Two different experimental test cases were used to study the conditions and flow fields in the room as shown in Table 1.

Table 1. Specification of the test cases

Case	Supply air (l/s)	Supply air temperature (°C)	Air extraction rate (l/s)	Dummy heat load (W)
1	50	23	50	0
2	50	19.2	50	240

In both tests the cavity air temperature was controlled at 23°C to minimize the heat exchange between the cavity space and the test room. The supply air temperature and volume were controlled to the specified rates and prior to any temperature and velocity measurements being recorded, the room was allowed to stabilize. A stable condition was assumed when the temperature difference across the room was less than ±0.5°C. In case 2, the desired room temperature under a heat load was controlled by reducing the supply air temperature.

Once the room had stabilised the measurement poles were placed in the room at the predefined locations as shown in figure 1. The test room was allowed to stabilize for a further 3 minutes before measurement was started. Each measurement period lasted for 3 minutes with recordings being taken at 1 second intervals and averaged. Each measurement was repeated 5 times to ensure time independent results.

Computational model

Several commercial CFD codes are available which can be used to simulate room air conditions. In this work ANSYS CFX 10 [7] was used. The continuity, momentum and energy equation were used to calculate the 3-dimentional flow field and heat transfer. The finite control-volume method was implemented for the spatial discretisation of the domain.

The geometry and boundary conditions used in the simulations represented the test room. The vertical surfaces of the dummies were defined as surfaces with a heat flux. The K-ε turbulence model was initially used because it has been regarded as industry standard for many years and its robustness and reliability has being reported in many studies [8-10]. One of its weaknesses is its ability to predict convection flows. In the most types of indoor spaces, convection flows are present and the STT turbulence model has a reputation for predicting these realistically [11] although comparisons are difficult to find. In this work CFD simulations have been made using both the K-ε and STT turbulence models and results reported.

Method used for calculating Draft Rates

The basic equation to calculate the DR is presented in ISO 7730 [5]. Turbulence intensity cannot be obtained directly from CFD results but a method to calculate turbulence intensity is presented by Koskela et al [4].

RESULTS

The velocity and temperature results were shown not to be time dependent. The variation between the results taken over five 3 minute measurement periods was less than the accuracy of the equipment used.

The average velocities recorded at the 12 measurement points are shown in Table 2 and as can be seen, simulated and experimental results show fairly good agreement. The SST simulated values show better agreement in the non-isothermal case 2. The values reported are average values taken over 5 measurements.

Table 2. Average velocity values for experiments and simulated cases

	Experiment	Simulation SST		Simulation K-E	
Case	V	Vv (m/s)	Vo (m/s)	Vv (m/s)	Vo (m/s)
1	0.20	0.16	0.20	0.18	0.23
2	0.21	0.20	0.23	0.18	0.20

The simulated and experimental velocity readings for the isothermal test (case 1) are shown in figure 3. Measurements recorded at different locations show a similar trend with regions of high and low velocities agreeing with simulated results. The biggest difference being equal to, or less than 0.1 m/s.

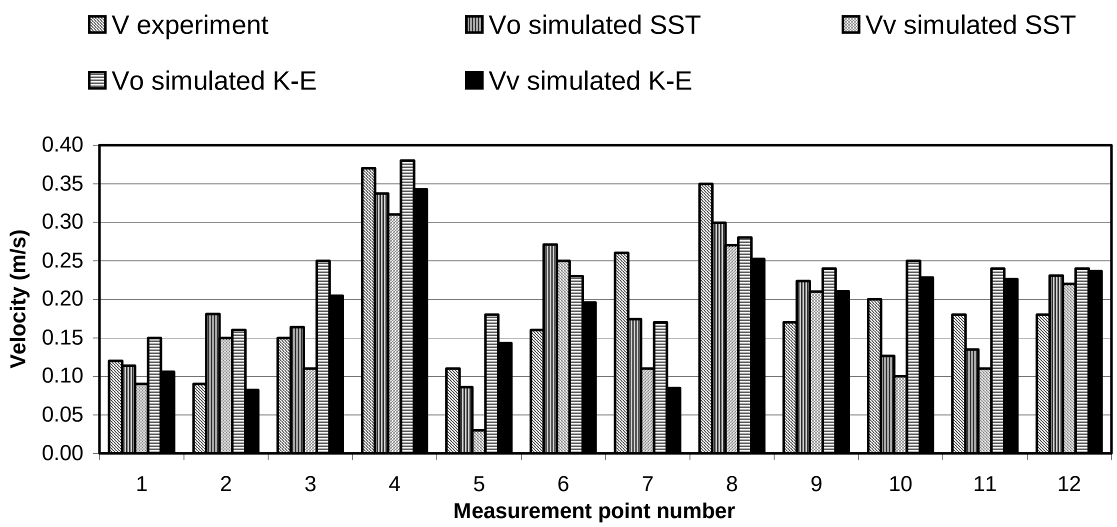

Figure 3. Velocity readings for experimental and simulated data for the isothermal test case 1

The experimental and velocity readings for the non-isothermal test (case 2) are shown in figure 4. Again in this case, experimental and simulated results agree closely but the difference between the results using the two different turbulence models is becoming evident. Both turbulence models seem to have difficulties accurately simulating high and low velocities.

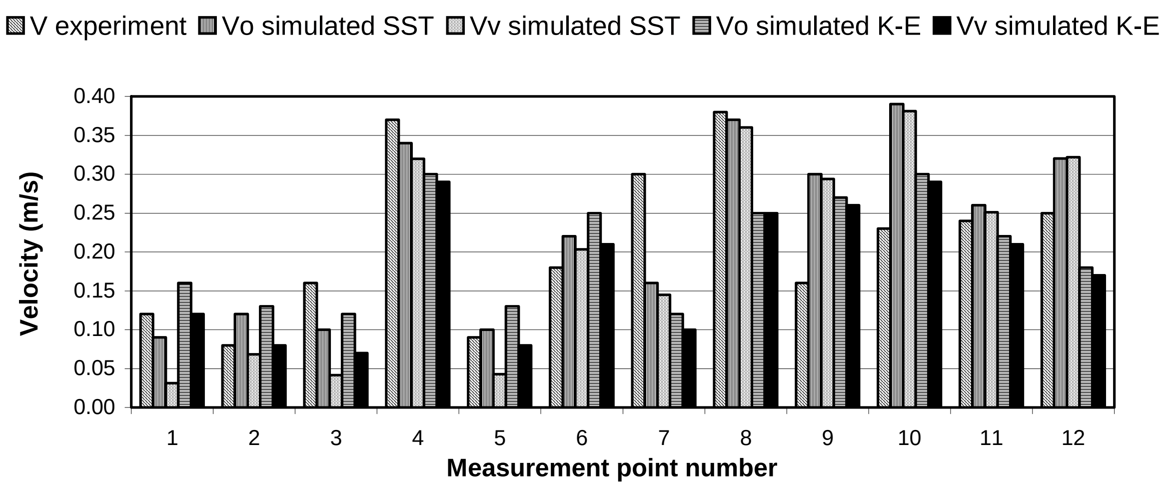

Figure 4. Velocity readings for experimental and simulated data for non-isothermal test case 2

The average draft rate (DR) results shown in Table 3 were obtained using the method reported by Koskela et al [4]. The DR values are important because in most cases, thermal comfort predictions are based on this value.

Table 3. Average Draft Rate percentage values obtained from the measured and simulated values.

Experiment	SST		K-E	
V	DR Vv	DR Vo	DR Vv	DR Vo
18	15	18	15	17

As can be seen from the table, the percentage difference between all the average DR values is small. The omni-directional simulated values agree closely with the measured data. The vector values are lower as would be expected since the correction is only applied to the higher values. Figure 5 shows the measured and simulated draft rates at various locations in the room and as can be seen, the results are in line with earlier results.

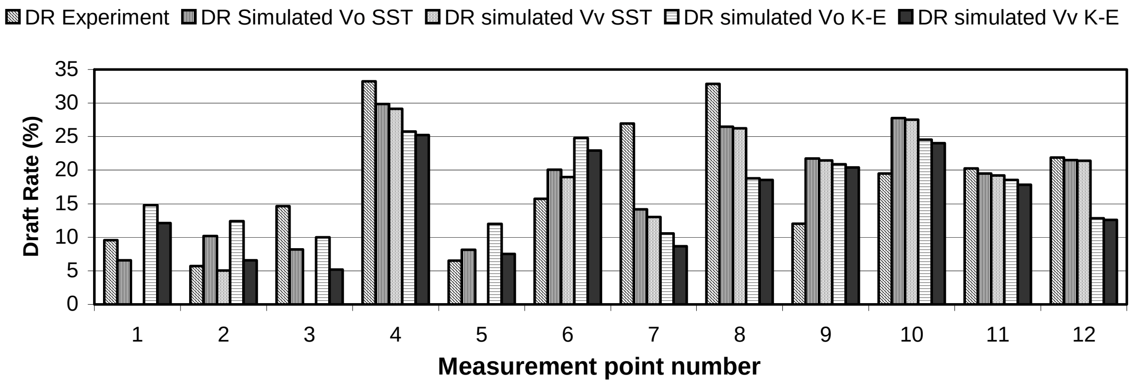

Figure 5. Draft Rate values for the experimental and simulated data

DISCUSSION

The purpose of the work was to study the capability of CFD to predict the comfort conditions in a room under different air flow scenarios. Experimental work was carried out in a full-scale test room and the same geometry and boundary conditions then used in a computational model. The experimental results are in good agreement simulated values although some differences are evident.

The results show that CFD is a useful tool to predict comfort conditions at design stage. In this study a simple room geometry was used which produced a complicated flow scenario. Both turbulence models were able to simulate the flow reliably but the performance of the SST model was better.

All new room designs have to guarantee specified levels of comfort. Common target levels of either DR 15 or 20 are specified for new designs. In addition, a maximum velocity can also be specified. The results of this study were compared with the DR 15 and DR 20 threshold values. Table 4 shows the number of points that are above these defined threshold values. CFD simulations using the SST model seem to agree slightly better with the experimental results although the differences are very small. Omni-directional CFD values seem to have very little effect on the DR.

Table 4. Measurement points above threshold values

Treshold	Experiment	Simulation SST		Simulation K-E	
DR	V	Vv (m/s)	Vo (m/s)	Vv (m/s)	Vo (m/s)
15	7	7	7	6	6
20	5	5	5	4	3

Great care has to be taken when results are presented and comparison made. The methods used to obtain experimental results must clearly stated to clarify whether the results are vector values or omni-directional values. In the present study there was little notable difference on the DR but for validation, velocity and temperature correction is highly recommended.

CONCLUSIONS

- The work showed that CFD can be reliably used to evaluate the thermal comfort provision in a new design.

- CFD simulations using a K-ε turbulence model have slightly better agreement with experimental velocities particularly in isothermal test cases. In non isothermal cases, SST turbulence models perform better.

- Correcting simulated velocity results to an equivalent omni-directional value has negligible effect on any subsequent DR evaluation. Use of a correction is however recommended when experimentally measured omni-directional velocity results are used for validation purposes.

ACKNOWLEDGEMENT

The financial and other support of Halton Oy is acknowledged and this enabled the work to be carried out.

SUMMARY

In this study, a subjective experiment was conducted in a climatic chamber to clarify the effect of moderately hot environment on productivity, especially on the relationship between performance and fatigue. The climatic chamber was conditioned at operative temperature of 25.0°C (insulation value of 0.93 clo), 28.0°C (insulation value of 0.93 clo), and 28.0°C (insulation value of 0.57 clo). Subjects were exposed in the environment for six hours. The performance at 28.0°C condition was lower than at 25.0°C condition. Performance decreased as the sessions proceeded, while the total rate of subjective symptoms of fatigue increased. Correlation between personal rates of complaints of fatigue and performance in Z-score was observed with correlation coefficient of -0.76. From the linear regression model, increase in 10% of fatigue corresponded to the decrement in standard number of correct answers by 1.7%. These results implied that thermal environment effected on performance and fatigue and subjects performed worse when they felt high level of fatigue.

INTRODUCTION

It was reported that subjects exposed to moderately hot environment condition worked as much as exposed to thermally neutral conditions for short time exposure [1], [2]. However, it was shown that the subjects felt more tired in hot environment conditions than in thermally neutral conditions, so it was suggested that the evaluation of fatigue feeling was useful to evaluate productivity in thermal environment from the assumption that performance would eventually decrease when workers were tired. But there was little clear scientific evidence for the relationship between the level of fatigue and performance. The objective of this study is to clarify the effect of moderately hot environment on productivity, especially on the relationship between performance and fatigue. Subjective experiment for six hours exposure was conducted in this study.

METHODS

Experimental Conditions

Subjective experiment was conducted in a climatic chamber to clarify the effect of moderately hot environment on productivity, especially on the relationship between performance and fatigue. This experiment was conducted from July 13 to August 10, 2005. As effort for energy conservation, Japanese government has recommended to modify the cooling temperature setting in offices and to also modify the dress code to keep the workers be comfortable in summer. From this perspective, the conditions were set by the combination of operative temperature in the chamber and the amount of clothing insulations [3] as: 25.0°C with 0.93 clo, 28.0°C with 0.93 clo, and 28.0°C with 0.57 clo. A practice at 25.0°C with 0.93 clo was conducted prior to these experimental conditions, and these conditions were balanced for order. Experimental conditions are shown in Table 1. Air temperature was measured by Type T thermocouples, relative humidity was measured by Thermo Recorder RS-11(ESPEC), desktop illuminance was measured by digital illuminometer T-10 (MINOLTA), equivalent sound level was measured by sound level meter NL-31 (RION), and the concentration of CO_2 was measured by IAQ monitor MODEL2332 (KANOMAX). Air temperature, relative humidity, and the concentration of CO_2 were measured at 1.1 meters from the floor every one minute. Desktop illuminance was measured on each desk prior to the experiment. And sound level was measured at 1.1 meters from the floor every one second.

Table 1 Environmental conditions

Conditions	Operative Temperature [°C]	Relative Humidity [%RH]	CO_2 Concentration [ppm]	Desktop Illuminance [lx]	Equivalent Sound Level [dBA]
Practice	25.0 (0.16)	47 (1.2)	841 (49)	730 (43)	59.5
25°C with 0.93 clo	25.0 (0.30)	48 (0.9)	843 (113)	679 (38)	57.9
28°C with 0.93 clo	28.3 (0.42)	48 (2.9)	880 (117)	710 (43)	57.6
28°C with 0.57 clo	28.1 (0.34)	48 (3.2)	910 (61)	682 (39)	58.0

( ) Standard Deviation

Subject

Fifteen collage-age male subjects participated in this experiment. For the analysis, data of fourteen subjects were available except for the data of one subject whose data was partially missing. The anthropometrical data of the fourteen subjects were age of 20.8 ± 1.6, height of 171.7 ± 7.0cm, and weight of 62.3 ± 10.9kg. To keep the motivation of the subjects at same level, they were informed to be paid a bonus depending on their performance. Every subject participated in this experiment on same day of the week and same time of the day in the successive weeks to avoid the day and/or time influence.

Experimental Procedure

The experimental procedure is shown in Figure 1. First, subjects changed into suit coat, long-sleeved shirt, T-shirt, necktie, socks, suit trousers and leather shoes (without suit coat and necktie at 0.57 clo conditions), and then answered questionnaire on paper in the anteroom. After that, subjects entered the chamber, and then reported first thermal sensation in the chamber and their feeling of fatigue on PC and took flicker test. Subjects rested for 30 minutes in sedentary position to adapt themselves to the environment. Then, subjects were assigned to work on nine sessions of one-digit addition tasks on PC. In each session, the subjects worked for 30 minutes on the task and they reported thermal sensation, their feeling of fatigue and their evaluation of the productivity on PC and took flicker test.

Figure 1 Experimental procedure

Measurement Items

Thermal sensation votes, thermal acceptance, and comfort sensation votes were asked to evaluate the perception of the thermal environment. Subjective votes on thermal environment are shown in Figure 2.

Satisfaction level, suitability for work, and effect of thermal environment on workability when subjects were exposed to the thermal environment were asked in order to evaluate the productivity which was evaluated by the subjects. Subjective votes on productivity are shown in Figure 3.

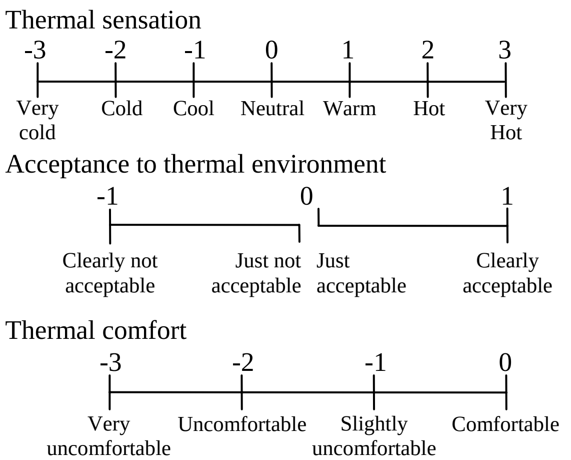

Figure 2 Subjective votes on thermal environment

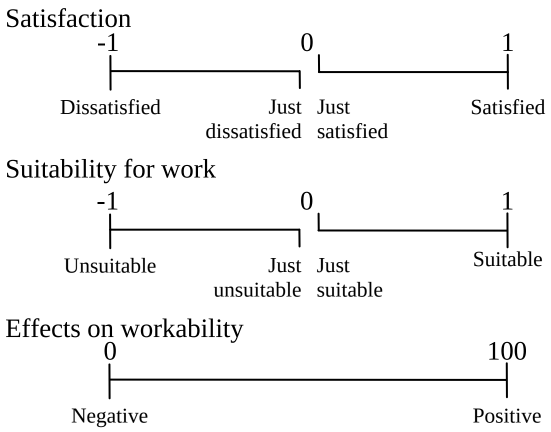

Figure 3 Subjective votes on productivity

To evaluate the feeling of fatigue, subjects filled in the questionnaire of “Evaluation of Subjective Symptoms of Fatigue [4]” on PC. It consists of three categories: group I consists of 10 terms on “drowsiness and dullness”, group II consists of 10 terms on “difficulty on concentration”, and group III consists of 10 terms on “projection of physical disintegration”. Based on Yoshitake’s method, the rate of complaints was calculated by the equation (1). By the order of rate of complaints among three categories, three types of fatigue feeling were suggested: “I>III>II” for general pattern of fatigue, “I>II>III” for typical pattern of mental work and overnight duty, and “III>I>II” for typical pattern of physical work. “General rate of complaints” is defined as the rate of complaints about all thirty symptoms.

$$Rate\ of\ complaints\ [\%] = \frac{number\ of\ selected\ symptoms\ of\ all\ subjects}{number\ of\ terms\ concerned \times number\ of\ subjects} \times 100 \ \ldots(1)$$

Subjects were assigned to work on nine sessions of one-digit addition tasks which were programmed in computers. In each session, subjects worked on the task for 30 minutes. Performance was evaluated by the number of correct answers per session in terms of Z-score (standard score). Z-score was calculated from the equation (2)

$$\text{Z-score } S_{A,i} = \frac{x_{A,i} - \bar{x}_A}{s_A} \qquad \ldots(2)$$

where, $x_{A,i}$ is the number of correct answers during the session *i* for subject *A*, $\bar{x}_A$ is the average number of correct answers of the subject *A* among all sessions, and s_A is the standard deviation for the number of correct answers of the subject *A* among all sessions.

To evaluate fatigue from physiological responses, flicker tests were taken at the first vote, after the rest in sedentary, and after each task session. In each test, flicker values were measured for five times, and the average of three flicker values without the highest and the lowest values was calculated. Then, the flicker value was evaluated by the change rate from a value of flicker value measured after sedentary.

Statistical Analysis

The comparisons between the environmental conditions were analyzed by using one-way ANOVA with the level of significance of $p<0.05$. When a significant difference of $p<0.05$ was found, Fisher's protected LSD was used for further analysis. For analysis of correlation between fatigue level and corresponding Z-score of task performance, Peason's product moment correlation coefficients weighted by number of subjects were calculated.

RESULTS

Perception of thermal environment

The results of thermal sensation, thermal acceptance and thermal comfort votes are shown in Figure 4, 5 and 6. From these results, subjects evaluated the conditions of 28.0°C with 0.93 clo and 28.0°C with 0.57 clo as hotter, less acceptable, and less comfortable than the condition of 25.0°C with 0.93 clo ($p<0.01$, $p<0.05$).

Productivity evaluated by the subjects

Satisfaction level of the thermal environment reported by the subjects is shown in Figure 7. Suitability of the thermal environment of the conditions for work reported by the subjects is shown in Figure 8. Effect of thermal environment of the conditions on workability reported by the subjects is shown in Figure 9. From the results, the environment of 28.0°C was evaluated as dissatisfied, unsuitable for work, and negative on workability, while that of 25.0°C was evaluated as satisfied, suitable for work, and positive on workability. Subjects evaluated the conditions of 28.0°C with 0.93 clo and 28.0°C with 0.53 clo as less satisfied, less suitable for work, and less positive than the condition of 25.0°C with 0.93 clo ($p<0.01$, $p<0.05$).

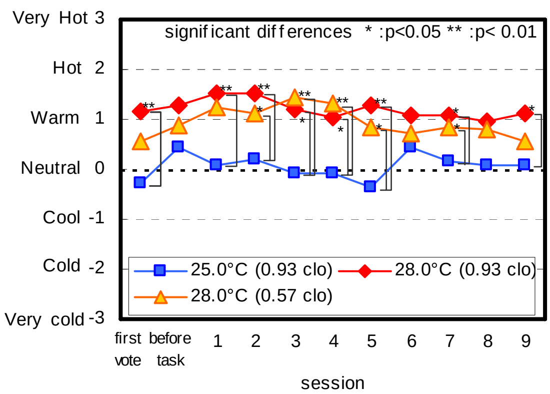

Figure 4 Thermal sensation

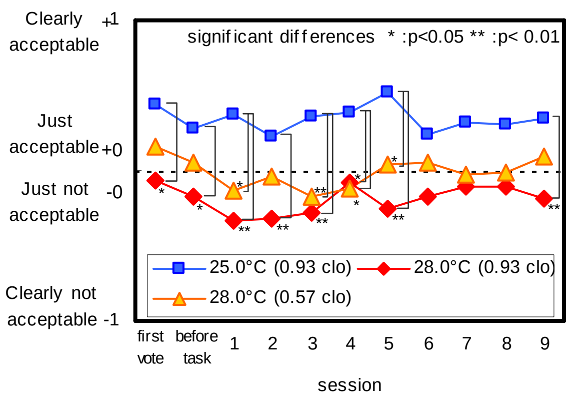

Figure 5 Thermal acceptance

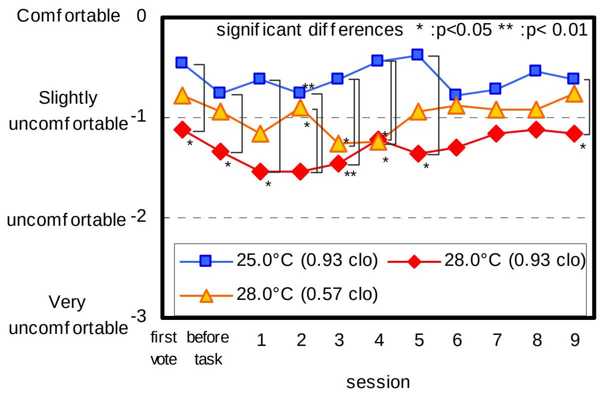

Figure 6 Thermal comfort

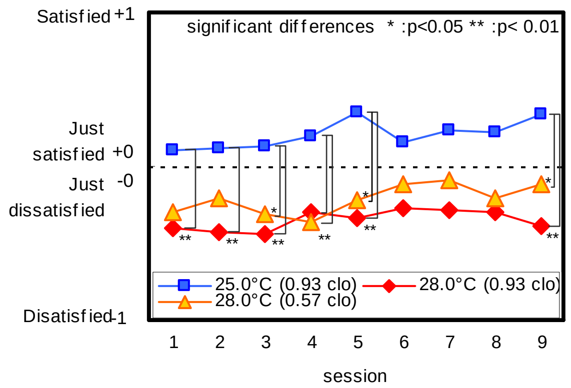

Figure 7 Satisfaction level of the thermal environment

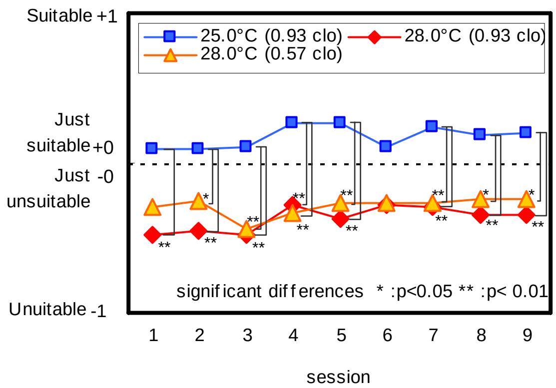

Figure 8 Suitability of the thermal environment

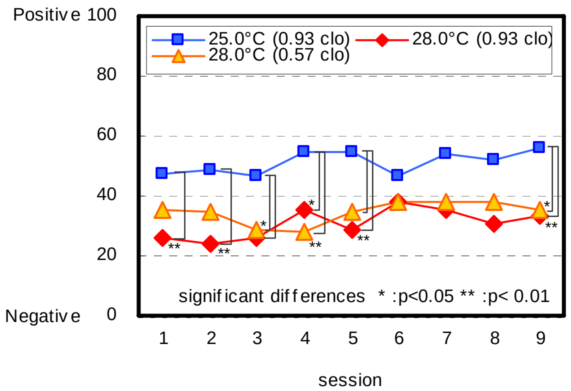

Figure 9 Effect of thermal environment on workability

Fatigue

The results of "Evaluation of Subjective Symptoms of Fatigue" are shown in Figure 10. The general rate of complaints tended to increase over the time in all conditions.

To evaluate fatigue after entire task sessions, the general rate of complaints of before and after tasks, i.e. the rates of complaints after sedentary and that after session 9, were calculated. The results are shown in Table 2. After the tasks, the general rate of complains increased, and the type of the fatigue feeling the subjects felt was the typical pattern of mental work and overnight duty (I>II>III) from the order of the categories in all conditions.

The change rate of flicker value is shown in Figure 11. The change rate of flicker value of after resting in sedentary, i.e. before task, was compared with the sessions after that. The increase rate of flicker value tended to decrease over the time in all conditions.

Table 2 The result of "Evaluation of Subjective Symptoms of Fatigue" before and after tasks

	Conditions	Rate of Complaints[%]				Category
		I	II	III	T	
Before task	25.0°C (0.93 clo)	17	11	9	12	I > II > III
	28.0°C (0.93 clo)	23	21	7	17	I > II > III
	28.0°C (0.57 clo)	20	4	12	12	I > III > II
After task	25.0°C (0.93 clo)	45	29	21	31	I > II > III
	28.0°C (0.93 clo)	45	43	22	37	I > II > III
	28.0°C (0.57 clo)	47	35	23	35	I > II > III

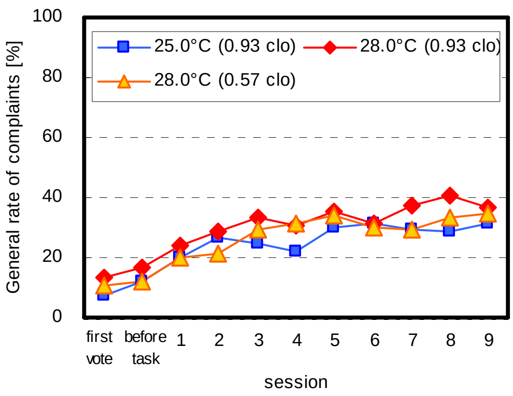

Figure 10 General rate of complaints

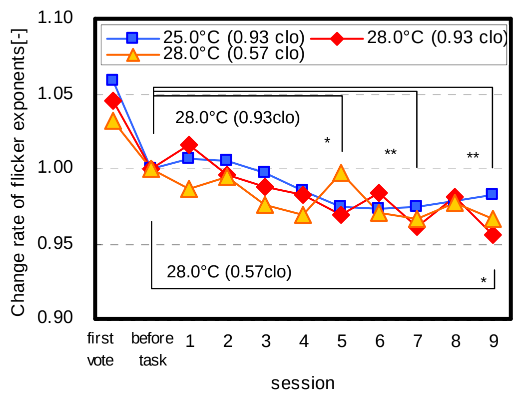

Figure 11 Change rate of flicker exponents

Performance

The result of Z-score is shown in Figure 12. The performance decreased as the sessions proceeded. The performance of the first session was compared with the sessions after that. Z-score did not changed significantly at 25.0°C with 0.93 clo condition over the time. However, the performance was significantly lower after six session ($p<0.01$, $p<0.05$) at 28.0°C with 0.93 clo condition. Also, the performance was significantly lower after the third session ($p<0.01$, $p<0.05$) at 28.0°C with 0.57 clo condition. The performance at 28.0°C condition was not significantly lower than at 25.0°C condition.

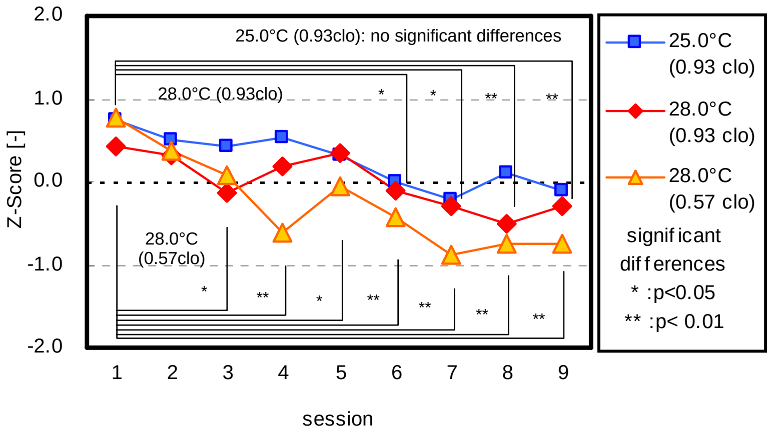

Figure 12 Task performance in Z-score

To determine the effects of thermal environment on fatigue, fatigue were analyzed in terms of the personal rates of complaints of fatigue, which are calculated by equation (1) whose number of subjects is 1. The relationship between the subjective votes on thermal environment and the personal rate of complaints of fatigue are shown in Figure 13. The data set of thermal sensation by the interval of 0.5 was averaged, and corresponding Z-score was averaged. Similarly, thermal acceptance the interval of 0.2 and thermal comfort by the interval of 0.2 were calculated. Circle shown in Figure 13 describes the number of corresponding subjects. The correlation coefficients of fatigue and thermal sensation was 0.44, thermal acceptance was -0.91 and thermal comfort was -0.93. From the result, fatigue increase when the subjects evaluated the thermal environment as hot, unacceptable, and uncomfortable.

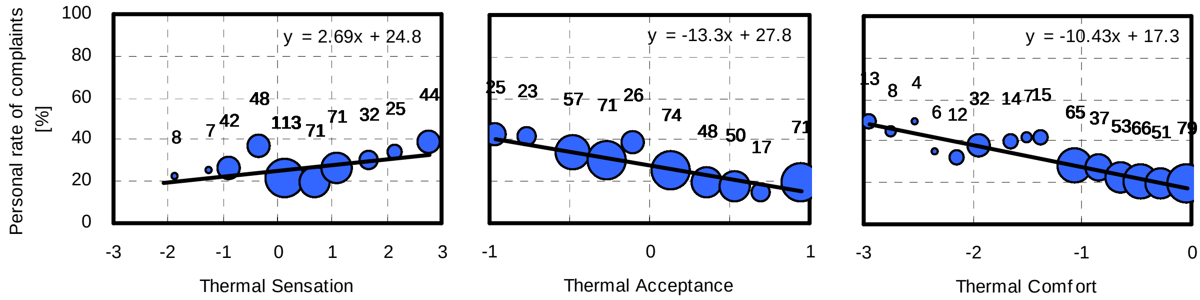

Figure 13 The correlation of the subjective vote on thermal environment and personal rate of complaints of fatigue

To determine the relationship between the level of fatigue and performance, personal rates of complaints of fatigue were analyzed. The relationship between personal rates of complaints of fatigue and task performance is shown in Figure 14. The date set of personal rates of complaints by the interval of 10% was averaged, and corresponding Z-score of task performance was calculated. The correlation between personal rates of complaints of fatigue and performance was observed (r = -0.76). In order to standardize the number of correct answers which included individual differences, standard number of correct answers was calculated by the equation (3).

$$\text{Standard number of correct answers } T = \frac{\sum_{i=1}^{N}\left(\bar{x}_A + S_{A,i} \times s_A\right)}{N} \qquad \ldots(3)$$

where, $\bar{x}_A$ is the average number of correct answers of the subject A among all sessions, $S_{A,i}$ is the number of correct answers in Z-score, s_A is the standard deviation for the number of correct answers of the subject A among all sessions, and N is the total number of data.

From the linear regression model obtained from the results, increase in 10% of fatigue corresponds to the decrement in the standard number of correct answers by 1.7%.

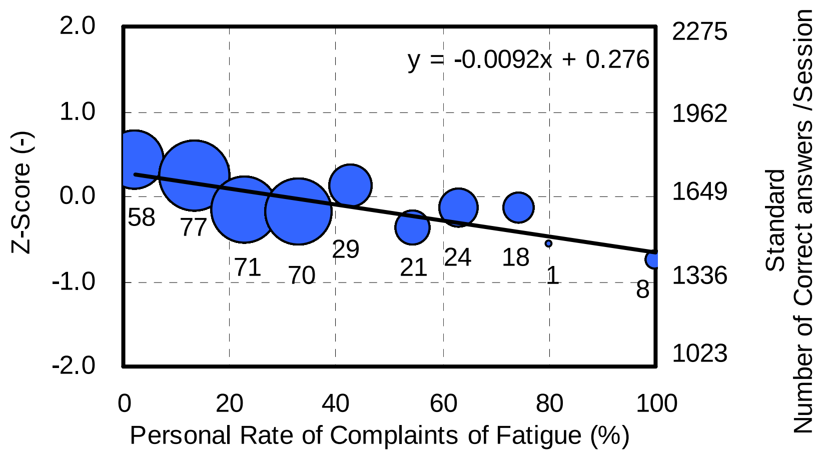

Figure 14 The correlation of the personal rates of complaints of fatigue and performance

DISCUSSION

It was suggested to evaluate productivity not only with task performance but also with human responses such as feeling of fatigue and cerebral blood oxygenation in the short exposure (2-3 hours) studies [1], [2]. There was an assumption that the high level of fatigue would lead the workers to perform worse. In this study, six hours experiment was conducted, and the results showed that there was a relationship between the subjective votes on thermal environment and the level of fatigue. Also, a relationship between the level of fatigue and performance was observed. Increase in 10% of fatigue corresponds to the decrement in standard number of correct answers of one-digit addition by 1.7% in this experiment. The results, higher level of fatigue had negative effect on task performance, supported the earlier assumption and implied the possibility that to measure subjective votes, productivity would be evaluated with higher dimensional accuracy.

CONCLUSION

To examine the effect of thermal environment on performance and fatigue, and the relationship between performance and fatigue, subjective experiments were conducted and the following results were obtained.

1. The general rate of complaints of fatigue tended to increase over the time in all conditions.
2. The performance decreased as the sessions proceeded. The performance at 28.0°C condition was not significantly lower than at 25.0°C condition.
3. The personal rate of complaints of fatigue increased when subjects evaluated the environment as hot, unacceptable, and uncomfortable. From the results, there might be effects of thermal environment on fatigue.
4. The correlation between personal rates of complaints of fatigue and performance was observed ($r = -0.76$). From the linear regression model obtained from the results, increase in 10% of fatigue corresponds to the decrement in the standard number of correct answers by 1.7%

ACKNOWLEDGEMENT

The authors wish to express their appreciation to Ms. A. Tanaka, Ms. M. Hayakawa, Mr. S. Hyodo, and Mr. T. Kumata for their assistance during the experiment. This study was partially funded by the Project Research of Advanced Research Institute for Science and Engineering, Waseda University and by the Global Environment Research Fund (H-061) by the Ministry of Environment, Japan.

Thermal comfort evaluation in workplaces in Brazil: the case of furniture industry

Lucila C. Labaki and Marcia Piovesana Barbosa

University of Campinas, Brazil

Corresponding email: lucila@fec.unicamp.br

SUMMARY

Then main objective of this work is to create subsidies for an analysis of Predicted Mean Vote (PMV) from ISO 7730 (1994) and from the new version of the norm, from 2005, for thermal comfort evaluation in Brazilian workplaces. The furniture industry in the city of Itatiba, São Paulo State, in Brazil, was chosen for the study. A survey among the workers was carried out through questionnaires, collecting data about thermal sensation, clothing and worker's activities. Dry and wet bulb temperatures, as well as globe temperatures were measured, simultaneously to the questionnaires. The Software Conforto 2.03 was used to estimate thermal resistance of the clothes, metabolic rates, mean radiant temperature, relative humidity and the correspondent PMV for the set of environmental and personal variables. The declared votes were compared with those obtained by calculating the PMV. The obtained results were compared to the patterns specified by the standards ISO 7730, 1994 and only 4,3% of the answers are in the limits of PMV recommended for thermal comfort. An analysis is performed about the work conditions in this industry, considering the workplace conditions, especially the poor ventilation.

INTRODUCTION

The growth of industrial processes and the diversification of the economic activities show that most of urban population lives for a great number of hours in the working environments. In hot climates, like in Brazil, there is an increasing interest about the possibility of mechanical air conditioning. But this technique for achieving comfortable thermal environments is very expensive and energy consuming. The artificial climates for human occupation are designed with the objective to provide comfortable environments and also that the thermal ambient can be adapted so that each individual will be in a condition of thermal comfort.

Thermal comfort studies are based in the thermal balance of the body. With the objective of establishing optimum comfort criteria for the greatest of people Ole Fanger [1] performed studies in controlled chambers in Denmark. Fanger's model was adopted as the basis for the international standard ISO 7730 (1984), and updated in 1994 [2]. This standard establishes the determination of the PMV and PPD indices and specification of the conditions for thermal comfort in moderate thermal environments.

With the advancement of thermal comfort evaluation studies, many researches have been accomplished in different regions around the world. Some of these researches question the defined limits established by ISO 7730 in regions with tropical climate. Most of the accomplished studies evaluate ambient where the occupants sedentary activities, like offices and schools.

Thermal discomfort is a common feature in the Brazilian work environments and that certainly affects the efficiency and the workers' productivity. Most of the complaints refer to discomfort due to heat, but there are also complaints due to cold environments. These occur mainly in places where cold or frozen products are kept or manipulated. Designers of buildings and ventilation systems, as well as those responsible for work safety and health can find few practical tools available for thermal comfort evaluation in the built environments.

In Brazil, there are not available standards for thermal comfort evaluation adequate for the work conditions in the country, and especially, for no sedentary activities, as those developed in most industrial workplaces. In the national context, there is only a norm by the Ministry of Labour that regulates the exposition to extreme temperatures.

Due to this lack of information, in the last years some researchers are trying to overcome this problem, and carrying out some field studies about thermal comfort evaluation in the different climate conditions of the country.

With the aim of finding the PPD of students in school rooms, in the process of development of their normal activities, Xavier & Lamberts [3], have measured the environmental variables, simultaneously to the survey among the users with questionnaires about their thermal sensation. The study was carried out in a Technical School in the State of Santa Catarina, south region of the country, from April to July, in the morning and afternoon, with 25 sets of measurements. The authors adopted a constant metabolic rate of 70 W/m2 (1,2 met). It was obtained the following equation relating the percentage of dissatisfied (PI) with the operative temperature (T_o):

$$PI = 1{,}4151.T_o^2 - 65{,}772.T_o + 784{,}22 \qquad (1)$$

The obtained temperature of neutrality was 23,24ºC, corresponding to a minimum percentage of dissatisfied equal to 19,96%.

Gonçalves [4] carried out a study in the city of Belo Horizonte, State of Minas Gerais, in the Southeast Region of the country. His object of study was to find the intervals of comfort temperatures for undergraduate students and compare the results with those of International Standards. In the survey 570 people were interviewed. In his conclusions, the author states that Fanger’s model [1] can be applied to this population, although the obtained PPD for neutrality condition – about 27%, is much higher than Fanger’s result of 5%.

In the same year, Xavier, [5] analysed the variables which could influence thermal comfort of people in school and office buildings in three cities of the country: Florianopolis, at the South, Brasilia, with an extremely dry climate, especially in winter, and Recife, at the northeast of the country, located at seaside, with a hot humid climate. Besides the six influence variables (environmental and personal ones) from the PMV model, the author researched also habits like lifestyle, physical activities, stress, age, sex and body form. Results show that, for sedentary activities, metabolic rate is not only function of activity, but also of age and body mass. The author also found a high Percentage of Dissatisfied for neutrality temperature – 25%.

Gouvea and co-authors [6] accomplished a research with the main objective of creating subsidies for an analysis of PMV for thermal comfort evaluation in Brazilian workplaces. The clothing industry in the city of Amparo, São Paulo State, was chosen for the study. A survey among the workers was performed through questionnaires, collecting data about thermal sensation, clothing and worker's activities. Dry and wet bulb temperatures, globe temperatures and air speed were also measured, simultaneously to the questionnaires. A probit analysis was also performed which allowed to identify the temperature of neutrality. By using the average values of environmental parameters and personal variables of the surveyed population, the neutrality temperature was calculated through the PMV/PPD model. In this case the temperature of neutrality was 22,8 ºC, corresponding to 5% dissatisfied people. The probit analysis showed nearly 22,5 ºC for this temperature, corresponding to 16% dissatisfied.

Then main objective of this work is to create subsidies for an analysis of Predicted Mean Vote (PMV) for thermal comfort evaluation in Brazilian workplaces where moderate activities are performed. In this paper, results of a field research carried out also in the region of Campinas, State of São Paulo, Brazil, are presented. The evaluations followed the ISO Standards – ISO 7730 [2] which establishes the determination of the PMV and PPD indices and specification of the conditions for thermal comfort in moderate thermal environments, the prescriptions of ISO 7726 [7] regarding the instrumentation and methods recommended for the measurement of the environmental variables. Also the standards ISO 8996 [8] and ISO 9920 [9] dealing respectively with Ergonomics-determination of metabolic heat production and Ergonomics-estimation of the thermal insulation and evaporative resistance of a clothing ensemble were adopted.

METHODS

Two furniture industries in the city of Itatiba, State of Sao Paulo, Brazil, were chosen to the study. The city is 23º01'00'' South latitude and 46º50'00'' West longitude, at an altitude of 760 m. Its climate is temperate, with 20,6º C average annual temperature, oscillating between 18 ºC average minimum and 25 ºC average maximum. Average relative humidity is 72,4%. The city has a population of approximately 100.000 inhabitants, and the main economic activity is the furniture industry.

Two companies were chosen for analysis, here called companies A and B, with different sizes and characteristics. Company A is a modern one, but still maintains some old machines together with those with modern technology. Their production is mainly of special furniture, designed for specifically orders. Production sectors are well organized with defined spaces for each one. All the powder generated is collected through an exhaustion system. The polishing and woodworking sectors were analyzed. Company B is smaller, with old equipment. Sectors are separated in two sheds: one for the production and the second for polishing and painting. Some eolic exhausters are installed, but there are no openings for air renovation. The two sheds were analyzed.

Data were collected through visits to the companies for measurement of the environmental parameters. The questionnaires were applied to all the users of the buildings. For each day of measurement three questionnaires were applied throughout day: one in the morning and two in the afternoon. The daily pre-established schedules for fulfilling of the questionnaires were: 9:00 a.m., 2:00 p.m and at the end of the working period. The fulfilling was carried through by the employees without the interference of the researcher.

The measurements had been carried through in 20 days in the months of March, April, July and August 2003. Through the application of the questionnaires 914 valid answers for comparison with ISO 7730 were collected. (1994), 719 sets of answers in the company A and 195for the company B. The analyzed population was composed only of male individuals. Four values of thermal insulation of the clothing had been found: 0,55, 0,56, 0,70 and 0,89 clo. Seven activity levels were obtained, according to the description and the interviews: 1.45, 1.71, 2.05, 2.31, 2.48, 2.65 and 3.34 met as shown in Table 1.

Table 1. Metabolic rate for the different activities in the two companies A and B

Activity	Met
Clerk Production Supervisor	1,45
Electrical fitter Press worker	1,71
Expedition Cutting machine operator Hammer worker Glass worker	2,31
Machine Polisher	2,05
Hand working Polisher	2,48
Machine Woodworker Maintenance Mechanician	2,65
Mounter	3,34

Thermal sensation and preference are presented in Tables 2 and 3. It is observed that for the evaluated interval, 37.96% of the workers consider the environment as thermally neutral (0) and 31.51% consider the environment hot (+2). With regard to the preference, 55.58% consider the environment as thermally neutral (0) and 28.45% manifested the desire that the environment could be little colder. The answers supplied for the workers, with regard to the sensation and preference, do not present a symmetrical distribution. While 529 workers (57.88%) consider the environment between slightly hot (+1) and very hot (+3), 373 workers (40.81%) would only desire that the environment could be between little more cold (+1) and much more cold (+3). It is observed that 288 workers (31.51%) consider the environment hot, approximately the same number - 260 (28.45%) who desired that the environment was little colder (+1) and only 11 workers (1.20%) desired the environment much colder (+3).

Table 2 – Distribution of workers thermal sensation

Scale	Sensation	Total occurrences	Occurrence Frequency (%)
+ 3	Hot	66	7,22
+ 2	Warm	288	31,51
+ 1	Slightly warm	175	19,15
0	Neutral	347	37,96
- 1	Slightly cool	31	3,39
- 2	Cool	5	0,55
- 3	Cold	0	0
No answer		2	0,22
Total		914	100,00

Obtained data were compared with the specifications of ISO 7730 [2] which considers and environment comfortable when the PPD is below 10%, corresponding to the PMV between -0,5 and +0,5. Only 39 results are in accordance to these specifications, as shown in Graph 1. Tables 4 and 5 show the distribution of the workers sensation and preference for the interval of PMV between - 0,50 and +0.50. It is also observed that with regard to the thermal sensation, 21 workers (53.8%) considered the environment as neutral (0), 6 workers (15.4%) considered the environment hot (+2) and 8 workers (20.5%) considered slightly cold (-1). When asked about the preference in relation to the environment, 24 workers (61.5%) did not desire a change (neutral 0) and 11 workers (28.2%) wished that the environment could be a little colder (+1).

Table 3 – Distribution of workers thermal preferences

Scale	Preference	Total occurrences	Occurrence Frequency (%)
- 3	Much hotter	2	0,22
- 2	Hotter	9	0,98
- 1	Warmer	19	2,08
0	Neutral	508	55,58
+ 1	Cooler	260	28,45
+ 2	Colder	102	11,16
+ 3	Much colder	11	1,20
No answer		3	0,33
Total		914	100,00

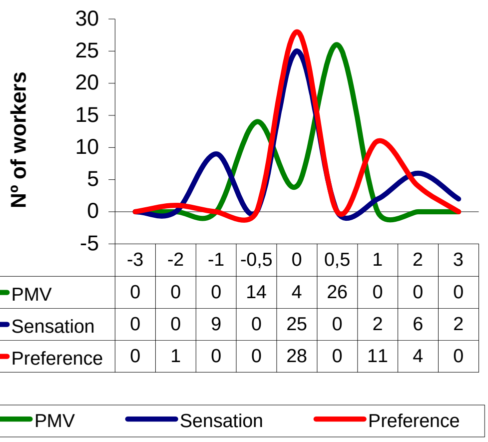

Figure 1. PMV, thermal sensation and preferences for PMV between -0.5 and +0.5

Since the measured valued of air speed were very close to zero in the first stage measurements, this parameter was not measured throughout the whole period, since the powder present in the air could damage the sensor. Most of the tasks were performed in standing position, so it was calculated the relative air speed due to the movement of the body in relation to air. This velocity was calculated as a function of the metabolic rate, in accordance with the equation proposed in the standard ISO 7730 [2].

$$v_{air} = 0,3\ (M-1) \text{ for } M>1 \text{ met.} \qquad (1)$$

By doing so, 44 results for PMV between - 0,5 and + 0,5 were obtained, as it is shown in Graph 2.

Tables 4 and 5show the distribution of the sensation and the preference of the workers for the interval of PMV between - 0,50 and + 0.50, after the correction for air velocity. One observes that with regard to the thermal sensation, 25 workers (56.8%) considered the environment neutral (0), 6 workers (13.7%) considered the environment hot (+2) and 9 workers (20.5%) considered the slightly cold environment as (-1). When asked about the preference in relation to the environment, 28 workers (63.6%) did not wish any change (neutral 0) and 11 workers (25%) desired a little colder (+1) environment.

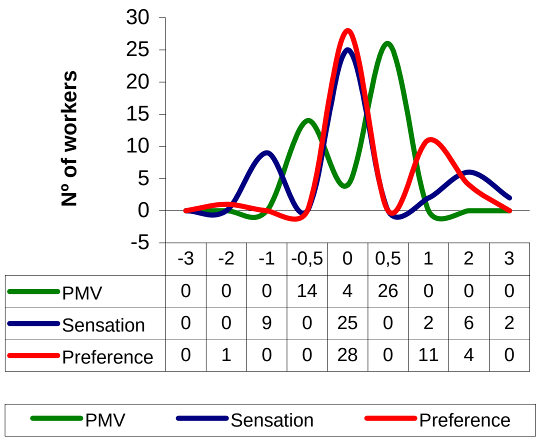

Figure 2: PMV, thermal sensation and preferences for PMV between -0.5 and +0.5.

Table 4. Workers thermal sensation for PMV between –0,50 and +0,50, after air-speed correction

Scale	Sensation	Total occurrences	Occurrence Frequency (%)
+ 3	Hot	2	4,5
+ 2	Warm	6	13,7
+ 1	Slightly warm	2	4,5
0	Neutral	25	56,8
- 1	Slightly cool	9	20,5
- 2	Cool	0	0
- 3	Cold	0	0
Total		44	100

Table 4. Workers thermal preference for PMV between –0,50 and +0,50, after air-speed correction

Scale	Preference	Total occurrences	Occurrence Frequency (%)
-3	Much hotter	0	0
-2	Hotter	1	2,3
-1	Warmer	0	0
0	Neutral	28	63,6
+1	Cooler	11	25,0
+2	Colder	4	9,1
+3	Much colder	0	0
Total		44	100

DISCUSSION

Obtained data in this field research were compared with the standards specified by ISO 7730 [2] and it was verified that, from a total of 914 sets of answers from the survey, only 39 answers (4.3%) are in the limits of PMV recommended for thermal comfort. From the total of 20 days of the survey, only in six days of measurement the recommendations for thermal comfort were reached, in some schedules. Considering the relative air speed caused by the movement of the body, an addition of 0,5% in the amount of answers that in accordance to the recommendations for thermal comfort was observed.

In this research, it was verified that there is little available information for the determination of the metabolism of the Brazilian worker, as well as data on the thermal insulation of the clothing. These values of personal variables are of extreme importance for studies about thermal comfort evaluation; so the estimate of these variables for the attainment of the PMV eventually influenced in the final results. The lack of ventilation and renewal of internal air can be considered as one of the factors that contributed for the discomfort of the users in relation to analyzed environments. Another important factor is that some of the activities performed by the workers were of medium intensity, for which Fanger's method is not the most indicated.

SUMMARY

When dimensioning closed rooms according to the thermal sensation solving the relevant equations is necessary for a prediction of the PMV and for the determination of the surface temperature of clothing without using expensive simulation programmes in many cases, since they are not available for every designer.
Thus we considered the drawing up of thermal comfort ranges as necessary plotting the PMV ranges corresponding to the categories *A*, *B* and *C* of the general thermal comfort according to the standard CR 1752.
We have determined the terminating lines on both sides of the comfort range plotted for this purpose by fixing the values PMV = ±0.2, ±0.5 and ±0.7 using Fanger's equation on the t_{lev}-t_{ks} plane. When drawing up comfort ranges for different applications we have considered the changes in relative humidity and air velocity as well.

INTRODUCTION

During the last decades dimensioning methods have been developed enabling an even more exact calculation and evaluation of the temperature sensation of a person staying in a room. A forecast of thermal comfort is already prescribed by standards as well, however they do not determine any simple calculation method of the parameters PVM and PPD. Comfort ranges given depending on air temperature and on the radiant temperature of the surfaces surrounding the room, which could help the dimensioning do not contain references on PVM values being fixed in CR 1752 as preconditions of thermal comfort. Therefore it necessary to develop a comfort range demonstrating the connection between the expected temperature sensation corresponding to the building quality categories A, B and C, the air temperature and surface temperatures.

METHODS

When evaluating the thermal environment the environmental parameters playing the most important role are the air temperature (t_a), mean radiant temperature of the surrounding surfaces (t_{mrt}), relativeair movement (v_r), partial water vapour tension of air (p_a) as a result of relative moisture content (φ) and personal parameters, i.e. thermal insulation ability of clothing (I_{cl}), ratio of body surfaces being naked and covered with cloth (f_{cl}) and activity level (M/F_{Du}).
Criteria related to the general thermal comfort in CR 1752 are determined by the operative temperature (t_{op}) on one side and by the expected values of the temperature sensation (PVM) on the other side.

Local discomfort factors have an important role as well during evaluating the thermal environment, which are the followings: draft (i.e. medium air speed and turbulence intensity), vertical differences in air temperature, radiant temperature asymmetry and surface temperature of the floor.
Forecast of thermal comfort can be numericated by the parameters of the expected temperature sensation (PVM) and PPD. The parameter PPD gives the ratio of those being unsatisfied with the thermal environment, thus it is a characteristic value of evaluating the thermal environment quality.
Numerication of the expected temperature sensation can be determined with the help of the comfort equation written by Fanger. This thermal equilibrium equation written on the basis of thermal equilibrium of the human body is an equation defining the identity of heat produced by the human body and the heat amount transferred to the environment.
Definition of thermal comfort sensation is based on the assumption that a person feel his/her environment - in which he/she stays - as comfortable, if he/she can give over the heat produced by him/her under such conditions being appropriate to evaluate the environment as pleasant. In this case heat production and heat transfer is in equilibrium and PMV = 0.
Temperature sensation depends on thermal load (L_h) being the difference between the internal heat production and the heat amount transferred to the environment.
In case of comfort sensation the value of heat load $L_h = 0$ and the expected temperature sensation PMV = 0 (neutral). Equation determined by Fanger for the expected temperature sensation:

$$PMV = \left(0{,}352 \cdot e^{-0{,}042\left(\frac{M}{F_{Du}}\right)} + 0{,}032\right)\left\{\frac{M}{F_{Du}}(1-\eta) - 0{,}35\left[43 - 0{,}061\frac{M}{F_{Du}}\cdot(1-\eta) - p_a\right] - 0{,}42\left[\frac{M}{F_{Du}}(1-\eta) - 50\right] - 0{,}0023\frac{M}{F_{Du}}(44 - p_a) - 0{,}0014\frac{M}{F_{Du}}(34 - t_a) - 3{,}4\cdot 10^{-8}\cdot f_{cl}\left[(t_{cl}+273)^4 - (t_{mrt}+273)^4\right] - f_{cl}\cdot\alpha_c\cdot(t_{cl}-t_a)\right\} \quad (1)$$

Value η in the equation is the efficiency of mechanical work and t_{cl} the surface temperature of clothing, for which equation (2) is relevant.

$$t_{cl} = 35{,}7 - 0{,}032\frac{M}{F_{Du}}(1-\eta) - 0{,}181\cdot I_{cl}\cdot\left[3{,}4\cdot 10^{-8}\cdot f_{cl}\cdot\left[(t_{cl}+273)^4 - (t_{mrt}+273)^4\right] + f_{cl}\cdot\alpha_c\cdot(t_{cl}-t_a)\right], \quad (2)$$

Value α_c in the above equation is the heat-transfer coefficient for convection:

$$\alpha_c = \max\left\{2{,}05(t_{cl}-t_a)^{0{,}25};\quad or \quad 12{,}1\sqrt{v_r}\right\}, \quad (3)$$

Air velocity (v_r) is influenced by the activity level and by the air state built up in the room, the relative air speed caused by the ventilation and by the natural air flows arising near to cold or warm surfaces. Equation (1) does not take into consideration the turbulence intensity caused by the air flow, limited by CR 1752 together with air speed depending on the air temperature.
For the forecast of the general temperature sensation equations (1) and (2) related to the calculation of PMV are to be calculated during dimensioning - according to CR 1752 - with the given parameters by the designer for the resting points in the room.
Therefore it is necessary to draw up a thermal comfort range supporting the design demonstrating at the same time the PMV ranges corresponding to the categories A, B and C of the general thermal comfort according to the standard CR 1752.

For the forecast of PMV and for determining the surface temperature of the clothing the solving of the equations (1) and (2) and their calculation is necessary even several times within a room, since PMV values are changing in the room.
Calculations can not be performed by calculators or with EXCEL software with results of satisfying accuracy and within an acceptable period because of the multiple iteration steps.
For performing the calculations we have applied the MAPLE software calculating iteration steps within an acceptable time and gives the results with an adequate accuracy.

RESULTS

When realising the comfort range drawn up with the determination of PMV lines corresponding to the building quality categories A, B and C of the standard the following sequence were followed:

1. The standard MSZ CR 1752 gives increasing PMV ranges (±0.2; ±0.5; ±0.7) to the different thermal environment categories (A, B and C).

2. Writing these extreme PMV values into the PMV equation derived from Fanger's comfort equation the corresponding mean radiant5 temperatures can be determined for the given air temperature. During calculations determination of the t_{cl} value is also necessary depending also on air temperature and on the mean radiant temperature, thus the calculation can be performed with multiple iteration with the help of a computer.

3. As a result of the calculations six PMV = constant lines are given and by drawing them into a diagram the boundaries of the comfort range can be determined from two sides (Fig. 1).

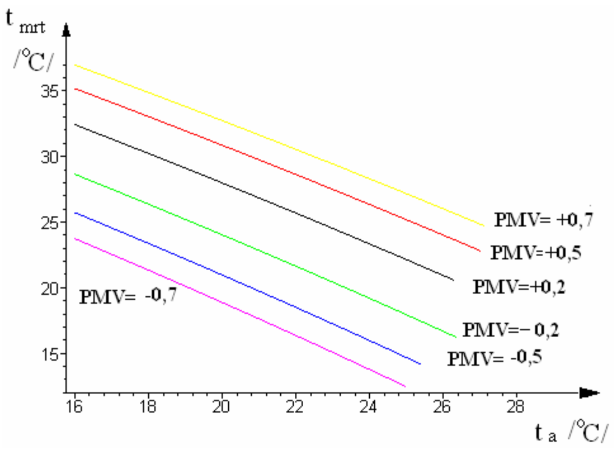

Fig.1. PMV = ±0.2; ±0.5; ±0.7 curves corresponding to the building quality categories A, B and C depending on the air temperature and the mean radiation temperature with p_a = 7.5 Hgmm, v = 0.1 m/s, M/F$_{Du}$ = 58 W/m^2, I_{cl} = 1.0 clo and f_{cl} =1.15

4. Closing the other two sides of the comfort range is possible only when meeting the condition that the ratio of convective heat transfer is fixed for different thermal environment categories, i.e. by fixing the value of "m" within all of the dry heat transfer. Thus based on

data in the literature the value of “m” was taken for 0.6 and 0.4 for the categories B and C and for 0.55 and 0.45 for the category A.

5. With the help of a computer programme developed directly for this purpose we have determined the points on the PMV = constant lines for which the above preconditions are met.

The drawn up comfort range (Fig. 2) is closed on every sides, however it is relevant only for given p_a and v. The diagram can follow the changes in air speed and partial water vapour tension if the ranges corresponding to the possible values of the variables are drawn up together. The solution is given by drawing together the ranges corresponding to v_{min} and v_{max} and $p_{a,min}$ and $p_{a,max}$.

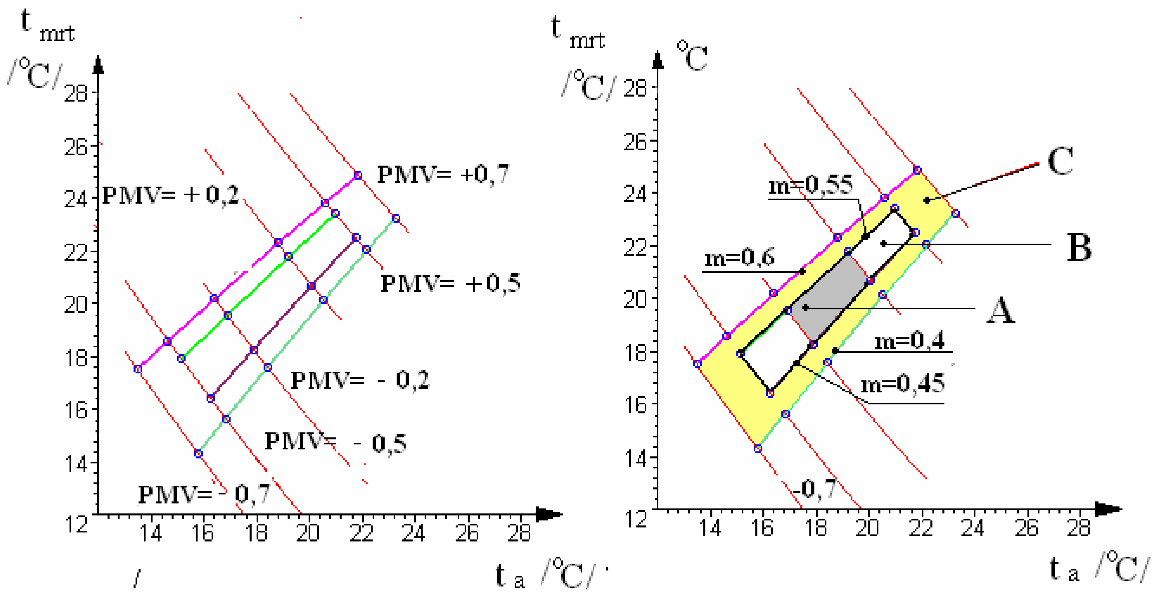

Fig. 2. Drawing up the lines for m = constant and PMV = ±0.2; ±0.5; ±0.7 by marking the ranges A, B and C

Table 1. Air velocity and partial water vapour tension values of the three room groups related to the different categories

Building types :	GROUPS	Cate-gory	Cooling season (summer)				Heating season (winter)			
			p_a (Hgmm)		v (m/s)		p_a (Hgmm)		v (m/s)	
			min.	max.	min.	max.	min.	max.	min.	max.
Offices, auditoriums, conference halls, school, restaurants, coffee-shops	**I.**	**A**	8,7	14,2	0,05	0,18	7,0	12,4	0,05	0,15
		B	5,1	15,6	0,05	0,22	5,1	14,2	0,05	0,18
		C	5,1	15,6	0,05	0,25	5,1	14,2	0,05	0,21
Nurseries	**II.**	**A**	8,7	14,2	0,05	0,16	7,0	12,4	0,05	0,13
		B	5,1	15,6	0,05	0,20	5,1	14,2	0,05	0,16
		C	5,1	15,6	0,05	0,24	5,1	14,2	0,05	0,19
Store-rooms	**III.**	**A**	8,7	14,2	0,05	0,16	7,0	12,4	0,05	0,13
		B	5,1	15,6	0,05	0,20	5,1	14,2	0,05	0,15
		C	5,1	15,6	0,05	0,23	5,1	14,2	0,05	0,18

Together with the operative temperature corresponding to the building quality categories also maximum air speeds are limited. Rooms marked in the standard CR 1752 can be classified into three groups of Table 1 according to the values t_{op}. and v_{max}. Supposed minimum value of air velocity is 0,05 m/sec in every cases taking into accout slow natural air flow and little movements during working activities.

The standard contains no information about the impact of changing φ on the offset of comfort range. Original researches and experiments composing a basis of these requirements correspond to a value of φ = 50%. Other standards are relevant for the drawing up of comfort ranges following the changes in partial water vapour tension. The diagrams of ASHRAE STANDARD 55 (1994) follow the impact of changing relative water vapour tension (φ) well and partial tension of water vapour can be clearly determined for winter and summer periods in cases where comfort sensation is guaranteed. According to our assumptions values given by the diagram correspond to the building quality categories B and C which values are shown in Table 1. Assumed value of the relative humidity in category “A” is φ = 40 ÷ 60%.

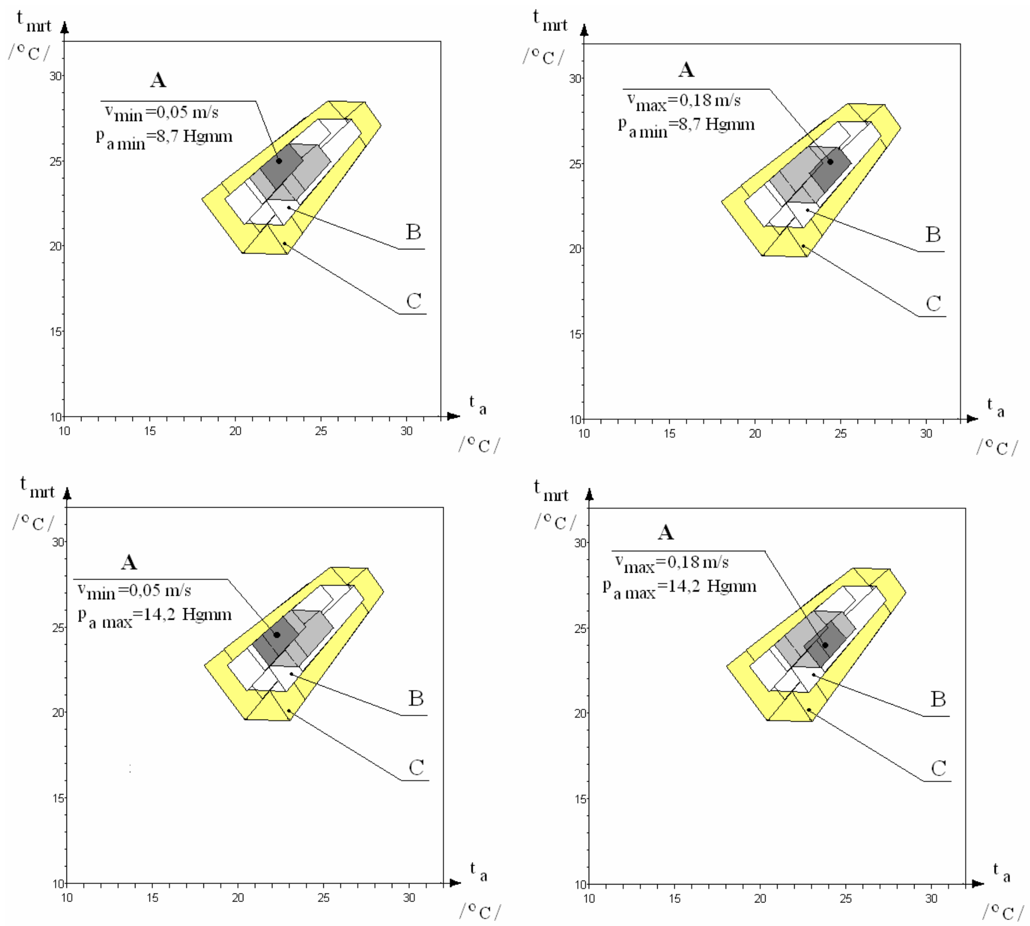

Fig. 3. Building quality categories of group 1 for summer on the plane t_a - t_r with markings for the ranges corresponding to the values of air speed and partial water vapour tension

Parameters classified into three groups depending on the type of the building are shown in Table 1, having limitations related to the clothing according to the standard, for the cooling season: I_{cl} = 0.5 clo, f_{cl} = 1.1; for the heating season: I_{cl} = 1.0 clo, f_{cl} = 1.15. The standard determines also the activity levels of the groups, for the 1st group: M/F_{Du} = 1.2 met, for the second M/F_{Du} = 1.4 met and for the third group M/F_{Du} = 1.6 met. When running the MAPLE software with the variables of Table 1, $p_{a,min}$ and $p_{a,max}$ and v_{min} and v_{max} four figures are the result drawn onto each-other giving so possible comfort areas related to a certain category.

Fig. 3 shows the building quality categories of group 1 for summer season. Rectangles within category A in the figures are relevant to changing humidity and air speed.

CONCLUSIONS

In the course of the investigations of comfort ranges the followings can be stated:

1. Fundamental difference between the groups is the activity level, the increase of which pushes the ranges nearer to the origin.
2. With increasing air velocity the ranges corresponding to the categories move to the direction of increasing t_a.
3. With increasing relative humidity, i.e. increasing partial water vapour tension the ranges move nearer to the origin, i.e. the same comfort sensation can be reached with a lower air temperature (t_a) and lower mean radiation temperature (t_{mrt}).
4. Temperature boundaries of the ranges drawn up for summer season look being appropriate related to the practical experiences in spite of the fact that in the time of the development of Fanger's PMV equation building service engineering was limited mainly to the heating and cooling had a smaller importance.
5. Ranges developed for the winter season - taking into consideration also the values of partial water vapour tension higher than those in our everyday experiences - contain low air and medium radiation temperature value pairs because of the position of the parameter lines PMV = -0.7 and PMV = -0.5. In spite of the correct mathematical processing of the PMV equations it is uncertain, if the low value pairs guarantee the expected comfort sensation in the practice.
6. With drawing up the line $t_{mrt} = t_a$ it is clear that the comfort range moves to the direction of higher wall temperatures, i.e. from the point of view of the comfort it is more desirable to guarantee a radiation temperature slightly higher than the room temperature.

SUMMARY

The attitudes can reveal the hidden reasons behind the customer choices. Referred interview studies identified typical indoor environmental requirements of the residents and made international comparison of the feedback from both young families and senior citizens.

Good housing conditions have positive influence on people's wellbeing and they should be archived without energy usage in vain. Even if most the elderly can manage well in nominal indoor air conditions, some of them might complain of draft or low room temperatures. The aged housing of the studied elderly lacked proper heating and good indoor air. Senior citizens' feedback was quite similar when comparing response from Finland and from Spain.

For the differences in the indoor air quality needs control possibility could be a solution. The acceptance of energy saving technology was low if the basic needs were not satisfied comfortable enough or the control set disturbs the routines of daily life, which in this case concerned the restrictive technology of room temperatures and in comparison that of home appliances in the sake of energy efficiency.

INTRODUCTION

It is a well-known fact that better housing conditions influence people's health. Normally with this is meant such old problems as bad heating, draft due to leaking structures, lack of tap water, shower or toilet, large amounts of hard maintenance work due to materials wearing out easily and being difficult to clean or maintain otherwise, etc. As known, many accidents happen in homes [1]. Even then, the way of building matters.

Even if most the elderly can manage well in nominal indoor air conditions, some of them might complain of draft or low room temperatures easier than people on average, most obviously due to retarded vital functions and motions or immobility. The gender differences in thermal comfort are often underestimated. Latest research carried out by Karjalainen (in press) showed significant gender differences in thermal comfort, temperature preference, and the use of thermostats. Women were less satisfied with room temperatures than men, preferred higher room temperatures than men, and felt both more uncomfortable when cold and uncomfortable when hot than men. Men used thermostats in the households more often than women, although women were more critical of their thermal environments.

Healthy building design and construction has paid special attention to health, safety and security, and functionality. Green building is a building concept promoting sustainable development by energy labelling such as American LEED (www.usgbc.org), British BREEAM (BRE Environmental Assessment Method), (www.bre.co.uk/) or Finnish WWF

Green office (www.wwf.fi/greenoffice/), etc. The prime aim is an ecological building process and buildings, and energy efficiency. However, sustainable solutions can be many.

Many house owners favour ecological and energy efficient technology. Unexpectedly, the professionals – not homebuilders, consumers and housing associations – retard the implementation of new products in housing sector. The traditions of the conservative building sector have several reasons for this [4, pp. 9, 108−109], cf. e.g. [5]. For example, prejudices against new and loyalty to workable professional paradigms play their own roles, short-term financial arguments or existing long-term contracts might prevent the building provider from picking new technology or architects are afraid for their reputation if the new products turn out to perform in an impropriate manner.

The indoor air quality was important for the elderly. The seniors expressed they clear opinion of it by favouring mechanical ventilation during the Elderly housing survey (Table 1). They named also the lack of good indoor air when asked for the three most important matters their current homes were lacking (Table 5). Expectedly, an older person wants to have warm housing without draft more often than a younger person does. Often, the elderly housing is aged too and needs repair and better indoor air, which was obvious from the result of the Elderly housing survey carried out in Western Central Finland. An exception of the need of low indoor air velocity is the summer time in the Mediterranean countries, where people and the elderly particularly suffer from the periods of high temperatures. There can be a need of proper cooling and even the motion of air – unwanted in Northern climates – mitigates the hot feeling and will not necessarily considered that bad in the Southern parts of Europe.

Indoor air quality was also the sixth most important option picked by the respondents of the interview study carried out in the Pirkanmaa region in Finland, when it was studied the residents' opinions of the smart home qualities [6]. Out of 39 smart home facility options, the top of five before the indoor environmental quality were about safety: fire-fighting equipment (55 per cent of the respondents), water leakage detector (55 per cent), automatic on/off system of home appliances (48 per cent), distant alarm receiver (41 per cent) and smart home security system (36 per cent). The respondents belonged to all adult age groups. Interestingly, also office workers valued indoor air quality control highly according to the study of intelligent building technology “What Office Tenants Want” by the BOMA and the ULI in USA. Furthermore, office workers in Finland complained of poor indoor air quality not only in the other high quality offices, but also in the intelligent office buildings according to the Intelligent Buildings Survey [7].

As there were personal differences in the needs concerning indoor air quality, personal control possibility could be a solution. The earlier Elderly housing survey gave evidence that the elderly could not combine together the indoor air quality and its controls [3]. Instead, many of them mentioned only good indoor air quality to be important for them. That was rational thinking. Actually, as mentioned earlier good indoor air was important for women, while men rather than women use the control devices [2]. Latest research by Karjalainen (in press) shows significant gender differences in thermal comfort, temperature preference, and use of thermostats among all aged subjects. Females were less satisfied with room temperatures than males. Females feel both uncomfortable cold and uncomfortable hot. Males use thermostats in households more often than females, if only females were more critical of their thermal environments.

METHODS

Urala (2005) has found that the respondents' attitudes have revealed statistically significant differences in both liking and purchase intentions. The study of attitudes can reveal the hidden reasons behind the customer choices, which often remain unclear even for the individuals themselves. The surveys referred in this paper had almost the same themes and used quite often similar questions [8], [10]. It has been possible to identify typical indoor environmental requirements of the end users, as well as to make comparisons within the international context between various customer groups based on feedback from both young families and senior citizens.

Within the EU 5th FP project Demulog (Living Conditions and Preferences of Families in Housing Need, Table 3) the numerical analysis were carried out (using the SPPS program). The qualitative responses to the open ended questions from the EU 5th FP project Elderathome (The Prerequisites of the Elderly for living at home: Criteria for Dwellings, Surroundings and Facilities, QLK6-CT-200-00405, Table 4) have been grouped, listed and summed up. Results from two corresponding Finnish studies were used as reference values (Table 5). All samples in each country were dominated by residents who dwell in the block s of flats and in most cases in cities as well as their demography represented quite well the national averages cf. [10].

ADJUSTMENT OF INDOOR AIR MEASURES FOR ENERGY SAVING

The Demulog interview studied the user requirements of energy saving options carried out by the smart home technology, such as saving energy by reduced room temperatures or limiting the use of electricity for home appliances to certain periods of the day. The families in Finland (71 per cent of the responses) and in France (55 per cent) responding to the Demulog interview oppose an energy saving system using a restrictive technology [8]. Only in the United Kingdom 58 per cent was in favour of such savings. The preferable room temperatures turn out to be as follows [8]:

- A large majority (> 80 per cent) accepts lower temperatures when nobody was at home or during the night.
- A small majority (from 50 to 57 per cent) accepts lower temperature in the bedrooms but not in other living spaces, and a third (35 to 45 per cent) wants to have the same temperature all over the dwelling.
- A large majority (95 per cent in Finland, 93 per cent in France, 72 per cent in UK) wants as high or higher temperatures in the bathroom and toilet as in the living areas.

Nevertheless, the respondents did not oppose all other means of saving energy as the limitations of room temperatures. The acceptance of low energy consuming home appliances was very good in Finland (in most cases 99 per cent, n=106), good in the United Kingdom (in most cases from 91 to 96 per cent or more, n=90) and rather good in France (in most cases from 64 to 70 per cent, n=101). The acceptance of water saving measures was good (Finland 69 per cent, France 70 per cent, the United Kingdom 87 per cent), but the acceptance of a composting latrine was not that good (Finland 19 per cent, France 18 per cent, the United Kingdom 29 per cent).

The lesson of the result of the Demulog interview teached that if residents seem in practical terms flexible in timing during the daytime, still, when they were without any compulsory ties they do not feel free. The daily routines of the society were still usually followed. Changing the timing of domestic work is not necessarily possible.

The elderly can be considered as citizens without responsibilities and with free time, and thus flexible in the timing of daily activities. However, also they follow the common timing of daily routines. The travel experiments which have offered the elderly the chance to use public transportation with a reduced charge have resulted in a failure because those trips were not made to a great extent beyond the peak hours (Discussions at the NECTAR (Network on European Communications and Transport Activities Research) conference "Transport Innovations, Competitiveness and Sustainability in Information Age". no 4 in Israel). Furthermore, Fox (2004) found that seniors use computers on a typical day similarly to the younger computer users.

IMPORTANCE OF GOOD INDOOR ENVIRONMENT

It was interesting to find out how similar the response from the two geographically and climatically very separated countries, Finland and Spain was when it concerns the lacking qualities of present housing of seniors. Within the EU 5th FP project the Elderathome such lacking qualities mentioned during the Finnish interviews as the lack of elevators or the need for other types of easy access out, needs for kitchen repair, poor soundproofing and indoor air quality, difficulties in using the bathtub or the wish to have a balcony (or two) and more natural light, were common to all studied cases of senior citizens. Similarly to the earlier Finnish studies, the indoor air quality turned out to be important.

The Spanish respondents paid special attention on such shortcomings as (in order of importance) [9]:
Basic contraction issues
- Dwelling was not equipped with central or electric heating. (This was a frequent problem in old quarters.)
- The surface outside the entrance was not horizontal and on a different level with the surface of the entrance.
- No elevator.

The Spanish respondents paid special attention on such best qualities of housing as (in order of importance) [9]:
Positioning of the house in relation to the sun.
- Natural light.
Outside space.
- To have a terrace, a balcony, a little space outside where they can have some plants.
Neighbourhood issues
- Services in the neighbourhood and near to the urban centre. No one was worried about the house technical aspects. They thought that was too expensive and difficult to understand.

In Finland, the respondents to the Elderathome interview reported problems with the HVAC measures and technology in their current homes quite as often as problems with sounds and noises, after the major problems of mobility and spatial needs (Table 6). The result was quite same as gained earlier during the Elderly Housing survey (Table 2). When asked about the ideal future home for old ages the importance of the qualitative HVAC technology guaranteeing the good indoor environment turned out not to be that important by the Finnish respondents (Table 7). Similar result can be found from the summary of the Spanish responses.

The sample in Spain had the male majority or men were over presented compared to the national average in that age group, and the Finnish sample had the female majority or over presentation compared to the national average in that age group. Despite gender differences in the two samples, when comparing them in their entirety this study did not show any differences between genders in the needs and wishes for the indoor environmental requirements. However, during this study too the gender differences were found in the preferences of the choices between different control technologies [12].

DISCUSSION

The concept of sustainability as a whole necessitates both the energy conservation activity and the human acceptance of it, because sustainability equals both the human wellbeing and integrity of the nature. According to the results of the Demulog project, the possibilities to use smart home control for energy saving were dependent on which home electronics and appliances were in concern and which types of means were used for the energy saving. The quality of the technical application counts in the acceptance of using energy saving measures. On one hand, a large majority accepted lower temperatures when nobody was at home or during the night, and on the other hand, a higher temperature in the bathroom and the toilet than in the living areas. A small majority accepted a lower temperature in the bedrooms but not in the other living spaces. The acceptance of energy saving technology was low if the basic needs were not satisfied comfortable enough, which in this case concerned the room temperatures. Using technology which saves energy and is ecological was also in favour. If the control did not disturb every-day life, the daily rhythm or the routines of the activities, the control was acceptable. To prevent electricity consumption peaks by changing the time schedule of the domestic work does not seem to be possible largely.

Table 6. The three worst shortcomings of present dwelling in the studied Finnish elderly homes (the numbers of the respondents).

Problem type	Problem	n
Mobility	Entering the house: no elevator, too many steps or too small elevator cage	22
	Moving indoors: two floors and steps upstairs	5
Need of space	Too big apartment, garage and sauna bath in vain	8
	More space needed, too small rooms	8
	Missing space	22
Sound and noise	Poor soundproofing	7
	Noise from traffic disturbing or metro disturbing	3
HVAC	Bad air-condition or bad indoor air, draft	4
	Cigarette smoke in the balcony, cooker hood	2
	Personal control on air-conditioning needed	1
	Too hot in the summer time	1
Bathroom	Bathtub difficult to use, change of the tub to shower	7
Maintenance	The courtyard in the winter time overwhelming because of snow, caretaker takes care of removing snow and sweeping up and residents not allowed	8
	Too much work, too much to clean	2
	Other	4
Renovation	Old building needs renovation	4
	Planned renovation, future boiler room, bathroom or kitchen renovation, damages due to damp in the basement, bad structures, cold floor	7
	Renovation took too long time/renovation disturbing	2
Costs	Energy consumption	1
	Too high rent, dwelling (housing) is expensive	2
Electricity	Location of lighting switches could be better	2
Interior design	Thresholds, darkness, kitchen cabinets too high	4
Other		15
No complains	Satisfied	6

Both the Finnish and the Spanish elderly respondents kept the indoor environmental qualities as important. Both groups had problems with the HVAC measures and technology in their current homes but other factors than good building service technology counted less when they told about their "dream homes" for old ages. The Elderly housing survey [3] tested the importance of the HVAC measures against a limited number of factors, against those of the building services and then the importance of the HVAC technology emphasized (Table 1). The same was the case with the other Finnish study of the residents' opinions of the smart home qualities which also found the relevance of the indoor air requirements important for the residents [6]. All studies have concluded that the current homes of the elderly tend to be in such a shape that they need renovation, and the residents have problems with the HVAC measures.

This study found no gender differences in relation to the importance of the indoor air quality measures. However, the samples were small − although well representative [10], compared to that of Karjalainen (n=1000) [2], which showed gender differences in relation to the indoor air measures. Most importantly, the studies were not otherwise fully comparative either. The set of the questions were different. Importantly of all, the method of analysis was different. This analysis has reached up to the comparison of two sample as a whole − the one with female majority and the other with female majority, on the basis of the response to the qualitative open ended questions and without any statistical comparison between gender factors. In stead, Karjalainen has accomplished careful scientific analysis on the gender differences [2].

Furthermore, the comparison of this study was made between two nationalities. Then, the cultural differences and climatic factors may influence the result. It can be concluded though that cultural differences often have less influence on the satisfaction of such basic needs as the indoor air quality [10]. However, the cultural influence on the standard of housing might have an effect on the requirements for the indoor air quality as was seen from the results of the Demulog study. The English were more ready to accept the lower temperatures than the Finnish or French respondents. When comparing the Finns and the Spaniards, the comparison was made between two nations where the housing habits were quite similar (most housing in the blocks of flats) despite climatic differences.

Table 7. Important qualities in an ideal home building, especially, if the life as a senior citizen was in concern in Finland (the numbers of the respondents).

Wish type	Wish	n
Services	All services available or near by	34
	Health service near by	6
	Services - cleaning, services – shopping	7
	Other	5
Mobility	Easy entrance (wheel-chair taken into account in design)	34
	Easy access indoors	6
	Good (public) transportation	11
Need of space	Sauna	6
	Balcony, balcony also next to bed room	5
	Enough space, applicable size, own room, missing rooms	10
Interior design	Functional lay-out and for domestic work, materials easy to take care	12
	Peaceful dwelling,	7
	Other	3
Bathroom	Bath easy to use, free access to bath, shower (no bath tub)	3
	Bigger bathroom, spacious enough and of good quality	3
	Floor heating, safety system in bathroom	2
HVAC	Mechanical air conditioning, good indoor air or air conditioning and no draft	3
Electricity	Safety system in electricity	1
Sound and noise	Good sound proofing	1
Maintenance	No winter maintenance – snow	1
Surrounding	Peacefulness, safe, sea near by, etc.	20
Neighbourhood	Friends, communality, help available, safety	17
Not classified	Not many floors	7
	Other	19

SUMMARY

The authors present a theoretical derivation of the WBGT formula for outdoor conditions that was originally developed from the results of experiments on human subjects, based on a heat balance equation between the human body and its outdoor environment. The three coefficients of wet bulb temperature T_w, globe temperature T_g, and air temperature T_a were expressed in almost the same way as in the indoor WBGT formula, but they contain a new element characterizing solar radiation. In addition, we calculated the coefficients in the theoretically derived formula, changing the amounts of metabolic activity, clothing worn, wind velocity, and solar radiation. We obtained the new formula WBGT = $0.84T_w + 0.30T_g - 0.08T_a$, characterized by a negative coefficient of air temperature T_a, as an alternative to the original outdoor formula WBGT = $0.7T_w + 0.2T_g + 0.1T_a$. Finally, we indicated the characteristics of the WBGT as an index as well as instructions for use.

INTRODUCTION

The Wet Bulb Globe Temperature (WBGT [1]) has been developed from experiments by Yaglou and Minard in the U.S. in 1957 for the prevention of heat stroke in soldiers. The index is standardized by the National Institute for Occupational Safety and Health (NIOSH) and the International Organization for Standardization (ISO) as ISO-7243. Therefore the index is now frequently used as an evaluation index for thermal environment during work and outdoor sports, and its use is recommended in many countries including Japan.

The WBGT was developed based on experiments with humans, but its background has not been discussed from the perspective of the heat transfer theory. The physical heat exchange between humans and the environment provides physiological and psychological reactions. Hence the properties of indices, even those based on human experiments, can be examined from the viewpoint of physical heat balance.

In this paper, we carry out theoretical derivation and analysis of the WBGT for outdoor conditions employing the heat transfer theory based on the heat balance equation between human body and an outdoor environment. Then, based on the derived theoretical formula, we clarify the structures of the three constant coefficients of wet-bulb temperature, globe temperature and air temperature that define the original WBGT formula for outdoors. In addition, the derived formula for outdoors is compared with that for indoor conditions derived in another paper [2], and we consider points of difference and similarity between two formulae. Furthermore, we perform an examination using actual values to present the characteristics and applicable conditions of the WBGT.

METHODS

Yaglou and Minard have suggested the original WBGT formula (1) for outdoor conditions.

$$WBGT = 0.7T_w + 0.2T_g + 0.1T_a \qquad (1)$$

where WBGT is wet bulb globe temperature [°C], T_w is (natural) wet bulb temperature [°C], T_g is globe temperature [°C] and T_a is air temperature [°C].

The heat balance equation (2) between the human body and an outdoor environment is expressed as follows:

$$M = (C + R) + E_{sk} + E_{res} + W + S \qquad (2)$$

where M is metabolic rate per unit body surface area [W/m^2], C is convective heat loss [W/m^2], R is radiative heat loss [W/m^2], E_{sk} is evaporative heat loss [W/m^2], E_{res} is convective and evaporative heat loss from respiration [W/m^2], W is external mechanical work [W/m^2] and S is rate of heat storage [W/m^2].

The heat transfer equations by convection C, radiation R [3], evaporation E_{sk} and respiration E_{res} [4] are given as the following equations.

$$C = h_cF_{cl}(T_{sk} - T_a)f_{cl} \qquad (4)$$

$$R = h_rF_{cl}[(T_{sk} + 273) - \lambda(T_{gr} + 273)]f_{cl}f_{ref} - F_{cl}(H_d + H_s + H_r)f_{cl} \qquad (5)$$

$$E_{sk} = LRh_cF_{pcl}(P_{sk} - P_a)f_{cl} \qquad (6)$$

$$E_{res} = 0.0014M(35 - T_a) + 0.0173M(5.87 - P_a) \qquad (7)$$

where h_c and h_r are human's convective and linear radiative heat transfer coefficients [W/(m^2°C)], F_{cl} is thermal efficiency factor [N.D.] [5], T_{sk} is mean skin temperature [°C], T_a is air temperature [°C], f_{cl} is clothing area factor[N.D.] [6], λ is long-wave radiation coefficient [N.D.] [3], T_{gr} is ground temperature [°C], f_{ref} is effective radiant area factor [N.D.], H_d, H_s and H_r are direct, scattered and reflective solar radiation absorbed into body surface [W/m^2], LR is Lewis relationship (= 16.5) [°C/kPa] , F_{pcl} is permeation efficiency factor [N.D.] [7], P_{sk} is water vapor pressure at skin temperature [kPa] and P_a is water vapor pressure in air [Pa].

λ in Equation (4), physical quantities expressing the properties of radiation specific to the region, date and time, are defined by the following equations:

$$\lambda = (1 + \Omega)^{0.25}(1 - U_r)^{0.25} \qquad (7)$$

$$\Omega = (T_{sky} + 273)^4U_r / (T_{gr} + 273)^4(1 - U_r) \qquad (8)$$

where Ω is ratio of atmospheric radiation to long-wave radiation from the ground to the human body [N.D.], T_{sky} is hypothetical sky temperature [°C], U_r is sky view factor for the human body [N.D.].

Also, Ω in Equation (7) expresses a ratio of atmospheric radiation to long-wave radiation from the ground to the human body. U_r in Equations (7) and (8) denote configuration factor between the human body and the sky, and is referred to as sky view factor for the human body [3].In this study, f_{ref} = 1 in equation (4).

Even in the outdoor environment with solar radiation, the wet bulb thermometer is essentially used for measurement in shaded areas, so there is no need to modify the general heat balance equation (9) for the wet bulb [2]. Because the sensing part of the wet bulb thermometer is very small, on the assumption that h_r'/h_c' is nearly equal to zero, Equation (9) leads to Equation (10).

$$h_c'(T_w - T_a) + h_r'(T_w - T_r) + LR\, h_c'(P_w^* - P_a) = 0 \qquad (9)$$

$$(T_w - T_a) + LR(P_w^* - P_a) = 0 \qquad (10)$$

where h_c' and h_r' are convective and linear radiative heat transfer coefficients of wet bulb [W/(m^2°C)] , T_r is mean radiant temperature [°C], P_w* is saturated water vapor pressure on wet bulb [kPa].

As far as a hot environment surrounding human work is concerned, the relationship of the saturated water vapor pressure P_w^* to the wet bulb temperature T_w on the psychrometric chart is sufficiently linear, and can be approximated as follows:

$$P_w^* = \kappa T_w + \zeta \qquad (11)$$

where κ and ζ are constants of linear approximation of saturated water vapor pressure to wet bulb temperature [kPa/°C].
During work in a hot environment, mean skin temperature is within a range of 35-40°C. Therefore, by treating skin temperature in the same way as the wet bulb temperature, the relationship of saturated water vapor pressure on skin P_{sk} to skin temperature T_{sk} can be linearly approximated by Equation (12).

$$P_{sk}^* = \kappa^* T_{sk} + \zeta^* \qquad (12)$$

where κ* and ζ* are constants of linear approximation of saturated water vapor pressure to mean skin temperature [kPa/°C].
In the forth coming numerical examination, we will adopt the following values shown in Reference [2]: $\kappa = \kappa^* = 0.279$ kPa/°C and $\zeta = \zeta^* = -4.03$ kPa.
Water vapor pressure on skin surface P_{sk} is expressed by Equation (12)′, accompanied with μ that indicates the degree of saturation on skin surface. Here we expand equations with μ preserved, but in the later stages, we will suppose μ = 1 because the WBGT index is designed for use within thermal limitation where water vapor pressure on skin surface is almost saturated in consequence of promoted sweating.

$$P_{sk} = \mu (\kappa^* T_{sk} + \zeta^*) \qquad (12)'$$

where μ is saturated ratio of water vapor pressure to skin temperature [N.D.].
The globe thermometer is basically intended for measuring heat radiation, and steady-state heat balance after sufficient exposure of the globe thermometer to an outdoor environment with solar radiation for actual measurement is expressed, with reference to heat transfer equation by radiation for the human body (4), as follows:

$$h_c''(T_g - T_a) + h_r'' F_{cl}'' [(T_g+273) - \lambda''(T_{gr}+273)] f_{cl}'' - F_{cl}'' (H_d''+H_s''+H_r'') f_{cl}'' = 0 \qquad (13)$$

where h_c'' and h_r'' are convective and linear radiative heat transfer coefficient of globe [W/(m^2°C)], λ″ is long-wave radiation coefficient of globe [N.D.], F_{cl}'' is thermal efficiency factor of globe [N.D.], f_{cl} is clothing area factor of globe [N.D.], H_d'', H_s'' and H_r'' are direct, scattered and reflected solar radiation absorbed into globe [W/m^2].
For the globe thermometer, $F_{cl}''=1$ and $f_{cl}''=1$. In this study, $\lambda''=\lambda$.

RESULTS

Substituting the relevant equations including Equations (3) ~ (8) and (10) ~ (13) into heat balance equation of the human body (2) gives the outdoor WBGT formula (14) in conformity with the indoor WBGT formula [2].

$$\begin{aligned}
&\left[(h_c + h_r)F_{cl}f_{cl} + \mu\kappa^* LRh_c F_{pcl} f_{cl}\right]T_{sk} + \left[F_{cl}f_{cl}\left(H_d'' + H_s'' + H_r''\right)\frac{\lambda h_r}{\lambda'' h_r''} - F_{cl}f_{cl}\left(H_d + H_s + H_r\right)\right.\\
&\left. + \left(\mu\zeta^* - \zeta\right)LRh_c F_{pcl} f_{cl} - M(0.8494 + 0.0173\zeta) + W + S\right]\\
&= \left[h_c F_{pcl} f_{cl}(1 + \kappa \cdot LR) + 0.0173M\left(\kappa + \frac{1}{LR}\right)\right]T_w\\
&+ \left[h_r F_{cl} f_{cl}\frac{\lambda}{\lambda''}\left(1 + \frac{h_c''}{h_r''}\right)\right]T_g\\
&+ \left[F_{cl}f_{cl}\left(h_c - h_c''\frac{\lambda h_r}{\lambda'' h_r''}\right) - h_c F_{pcl} f_{cl} + M\left(0.0014 - \frac{0.0173}{LR}\right)\right]T_a
\end{aligned} \qquad (14)$$

Writing the coefficient of T_{sk} and the constant term on the left-hand side of Equation (14) as ξ and η, respectively, and the coefficients of T_w, T_g and T_a as α, β and γ, we obtain equations (15) ~ (20).

$$\left[(h_c + h_r)F_{cl}f_{cl} + \mu\kappa^* LRh_c F_{pcl}f_{cl}\right] \equiv \xi \tag{15}$$

$$\begin{aligned}&\left[F_{cl}f_{cl}\left(H_d'' + H_s'' + H_r''\right)\frac{\lambda h_r}{\lambda'' h_r''} - F_{cl}f_{cl}\left(H_d + H_s + H_r\right)\right.\\ &\left. + \left(\mu\zeta^* - \zeta\right)LRh_c F_{pcl}f_{cl} - M\left(0.8494 + 0.0173\zeta\right) + W + S\right] \equiv \eta\end{aligned} \tag{16}$$

$$\left[h_c F_{pcl}f_{cl}\left(1 + \kappa \cdot LR\right) + 0.0173M\left(\kappa + \frac{1}{LR}\right)\right] \equiv \alpha \tag{17}$$

$$\left[h_r F_{cl}f_{cl}\frac{\lambda}{\lambda''}\left(1 + \frac{h_c''}{h_r''}\right)\right] \equiv \beta \tag{18}$$

$$\left[F_{cl}f_{cl}\left(h_c - h_c''\frac{\lambda h_r}{\lambda'' h_r''}\right) - h_c F_{pcl}f_{cl} + M\left(0.0014 - \frac{0.0173}{LR}\right)\right] \equiv \gamma \tag{19}$$

$$\xi T_{sk} + \eta = \alpha T_w + \beta T_g + \gamma T_a \tag{20}$$

Dividing both sides of Equation (20) by ξ yields Equation (21), a form based on the skin temperature T_{sk}.

$$T_{sk} + \left(\frac{\eta}{\xi}\right) = \left(\frac{\alpha}{\xi}\right)T_w + \left(\frac{\beta}{\xi}\right)T_g + \left(\frac{\gamma}{\xi}\right)T_a \tag{21}$$

Equation (21), on removing the physical quantity related to solar radiation, corresponds to the WBGT formula for indoor use [2].

We examine the varying properties of the variable coefficients in Equation (21) that correspond to the constant coefficients in the original WBGT formula (1) for outdoor conditions with solar radiation, substituting concrete values. We calculated the value of η/ξ, α/ξ, β/ξ and γ/ξ, changing metabolic rate from 1 to 4 met, clo unit from 0.2 to 1.0 clo and outdoor air velocity from 1.0 to 5.0 m/s with global solar radiation set at 600 W/m^2.
The calculated values of η/ξ ranged from –10.0 to 2.3. If air velocity, clo unit and metabolic rate were low, the η/ξ value was positive.
Figures 1 to 3 show the results of calculation of the α/ξ, δ/ξ and γ/ξ values. Figure 1 shows the variation of each coefficient in response to the variation of metabolic rate M with clo unit and air velocity held constant. The horizontal axis indicates metabolic rate, and the vertical axis indicates the α/ξ, β/ξ, γ/ξ and α/ξ + β/ξ + γ/ξ values. Responding to metabolic rates of 1 to 4 met, α/ξ ranges from 0.81 to 0.86, β/ξ is constant at 0.33 and γ/ξ is approximately –0.12. Thus, the values of α/ξ, β/ξ and γ/ξ are roughly 0.84, 0.33 and –0.12 rather than 0.7, 0.2 and 0.1, the coefficients in the original formula (1). The sum of α/ξ, β/ξ and γ/ξ ranges from 1.02 to 1.07, slightly exceeding 1.0. It is remarkable in the numerical examination in Figure 1, also in the following examinations in Figure 2 and 3, that the mean value of the coefficient γ/ξ of T_a is negative. The value shifts to the positive side when air velocity exceeds a certain value.
Figure 2 shows the variation of the coefficients in response to the variation of air velocity (horizontal axis) with metabolic rate and clo unit held constant. The values of α/ξ, β/ξ and γ/ξ are, respectively, 0.84 ~ 0.82, 0.33 ~ 0.24 and –0.12 ~ –0.02, as in Figure 1. In Figure 2, unlike Figure 1, the α/ξ and β/ξ values decrease, when the sum of the three coefficients approaches 1.0.
Similarly, Figure 3 shows the variation of the coefficients in response to the variation of clo unit with metabolic rate and air velocity held constant. The values of α/ξ, β/ξ and γ/ξ are 0.86

~ 0.84, 0.24 ~ 0.29 and –0.08 ~ –0.05, respectively. As clothing insulation increases, the α/ξ values decreases and the β/ξ and γ/ξ values increase. The sum of α/ξ, β/ξ and γ/ξ increases gradually from 1.02 to 1.07.

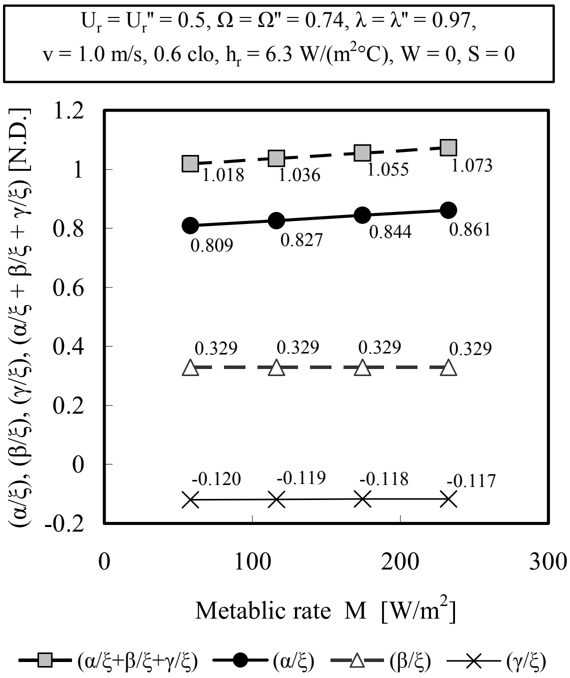

Figure 1 The variation of each coefficient in eq.(21) in case of variable metabolic rate with constant clo unit and air velocity.

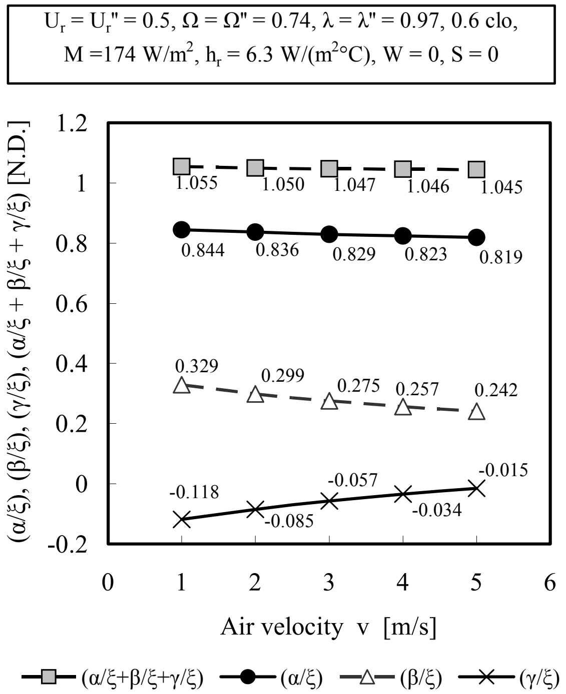

Figure 2 The variation of each coefficient in eq.(21) in case of variable air velocity with constant clo unit and metabolic rate.

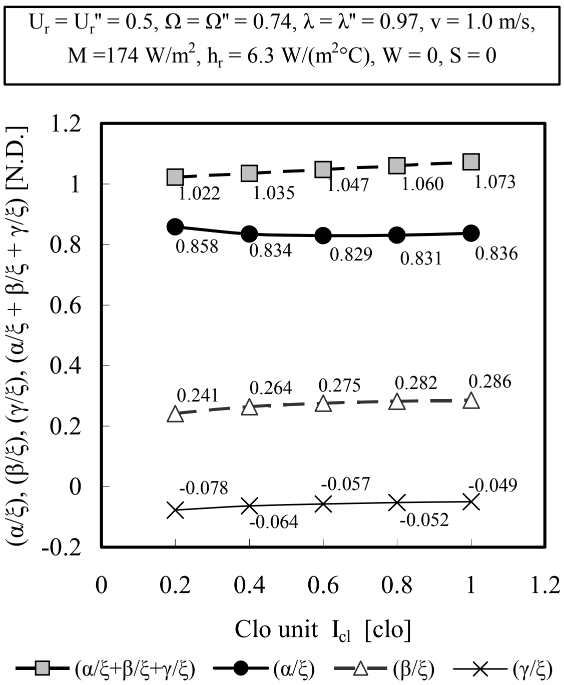

Figure 3 The variation of each coefficient in eq.(21) in case of variable clo unit with constant metabolic rate unit and air velocity.

DISCUSSION

We consider points of difference and similarity between the derived formula for outdoor conditions and that for indoor conditions [2]. The derived formula for indoor conditions in Reference [2] is shown as follows:

$$\begin{aligned}
&\left[(h_c + h_r)F_{cl}f_{cl} + \mu\kappa^* \cdot LRh_cF_{pcl}f_{cl}\right]T_{sk} \\
&+\left[(\mu\zeta^* - \zeta)LR \cdot h_cF_{pcl}f_{cl} - M(0.8494 + 0.0173\zeta) + W + S\right] \\
&= \left[h_cF_{pcl}f_{cl}(1 + \kappa \cdot LR) + 0.0173M\left(\kappa + \frac{1}{LR}\right)\right]T_w \\
&+\left[F_{cl}f_{cl}\left(h_c'' + h_r\right)\right]T_g \\
&+\left[F_{cl}f_{cl}\left(h_c - h_c''\right) - h_cF_{pcl}f_{cl} + M\left(0.0014 - \frac{0.0173}{LR}\right)\right]T_a
\end{aligned} \tag{22}$$

Comparing the coefficients of T_w, T_g and T_a in Equation (14) with those in Equation (22), the coefficient of first term on the left- and right-hand side is the same between two equations. The coefficient of second term on the left-hand side is the same constituent elements between two equations except solar radiation term. Meanwhile, the second term on the right-hand side in equation (14) includes the long-wave radiation coefficient, and third term in equation (14) includes the elements with respect to globe thermometer. Other elements of the coefficients in two equations are equally common. Examination using concrete values in Equation (22) provides that coefficient values in two equations were nearly equal.

Examination of the derived formula confirmed that the coefficients of T_w, T_g and T_a in the derived WBGT formula, considering their structures, are not strictly constant but variable depending on metabolic rate, clothing insulation, air velocity and other such factors.

We calculated the concrete values of each coefficient in Equation (14), changing metabolic rate, clothing insulation and air velocity. The calculated values of η/ξ ranged from –10.0 to 2.3. We consider the effect of solar radiation on the η/ξ qualitatively. Assuming that $\mu = 1$ in Equation (16), the inequality, which turns into $\eta \geq 0$, is expressed as follows:

$$\frac{F_{cl}f_{cl}\left[\left(H_d'' + H_s'' + H_r''\right) - \left(H_d + H_s + H_r\right)\right] + W + S}{M} \geq 0.781 \tag{23}$$

Equation (23) shows that $\eta \geq 0$ is obtained if the sum of the solar radiation H, external work W and heat storage S for the metabolic rate M is greater than 0.781. The difference between the first and second terms in the left-hand side of Equation (23) represents the difference between solar radiation absorbed by the globe thermometer and that absorbed by the human body. This difference, dependent on solar absorptance, projected area factor and configuration factor, is positive because solar absorptance of the human body is generally less than that of the globe thermometer. This indicates that in an outdoor environment with solar radiation, the η/ξ value may be positive even without external work or heat accumulation, and also that in an environment without solar radiation, the η/ξ value cannot be positive without them.

The calculation showed the coefficients α/ξ, β/ξ and γ/ξ of T_w, T_g and T_a to be 0.81 ~ 0.86, 0.25 ~ 0.33 and -0.12 ~ –0.02, respectively, roughly 0.84, 0.30 and –0.08 rather than 0.7, 0.2 and 0.1 the coefficients in the original formula. The coefficient γ/ξ of T_a is negative value for low air velocities and positive for high air velocities, and that lower air velocities resulted in larger negative values. Negative values, seen for low air velocities, mean a relatively small influx of dry heat by convection and radiation from an environment and the cooling of skin due to sweat evaporation, whereas positive values, seen for high air velocities, indicate a relatively large influx of dry heat from the environment which, negating the effect of sweat evaporation, raises the skin temperature T_{sk}.

The meteorological conditions included in the outdoor WBGT formula depend on the region, date and time. In particular, solar radiation and air velocity vary significantly depending on the place and hours of work or exercise. Consequently, it is safer for the use of the WBGT to adopt the coefficients of T_w, T_g and T_a specific to the region, date and time than to adopt the constant coefficients suggested by Yaglou et al.

CONCLUSIONS

We derive theoretically the outdoor WBGT formula, which was originally developed empirically, based on the heat balance equation between the human body and an outdoor environment. We clarify the inner structures of the three constant coefficients of wet-bulb temperature, globe temperature and air temperature, and we perform an examination using real values. Examination of the outdoor WBGT formula using concrete values provides the new formula $WBGT = 0.84T_w + 0.30T_g - 0.08T_a$, compared to the original formula $WBGT = 0.7T_w + 0.2T_g + 0.1T_a$ of Yaglou and Minard. Based on the obtained results, we present the characteristics of the WBGT as an index as well as instructions for use.

Effective Thermal Insulation of Body Segments by Summer Clothing

Tomonori Sakoi and Kazuyo Tsuzuki

National Institute of Advanced Industrial Science and Technology (AIST), Japan

Corresponding email: t-sakoi@aist.go.jp

SUMMARY

The aim of this study is to create a database of the effective thermal insulation provided to the body segments by various types of summer clothing ($R_{cle\mathrm{i}}$). In a climatic chamber with calm air conditions ($v \leq 0.15$ m/s), $R_{cle\mathrm{i}}$ was obtained for 52 garments and 97 ensembles. In the measurements, a female thermal manikin that had twenty segments was arranged in a sitting posture. In the chamber, operative temperature was set to 27.0°C, 25.0°C, and 24.0°C for a nude manikin, a manikin clothed in a garment, and one clothed in an ensemble, respectively. $R_{cle\mathrm{i}}$ were calculated for the nine segments—the chest, back, abdomen, buttock, upper arms, forearms, thighs, legs, and feet. The common regression for all the body segments, $R_{cle\mathrm{i}.en} = 0.784\ \Sigma R_{cle\mathrm{i}.gr}$, was proposed for estimating the $R_{cle\mathrm{i}}$ for the ensembles ($R_{cle\mathrm{i}.en}$) from the sum of the components' $R_{cle\mathrm{i}}$ ($\Sigma R_{cle\mathrm{i}.gr}$).

INTRODUCTION

In order to use human thermal models with multiple segments, it is essential to obtain data on the thermal insulation provided to each body segment by a type of clothing. In previous studies [1, 2, 3, 4], these data were measured for several ensembles. However, the authors were unable to find the sufficient database for estimating the thermal insulation provided by various types of clothing. The aim of this study is to create a database of the effective thermal insulation provided to body segments by various types of summer clothing ($R_{cle\mathrm{i}}$).

METHODS

In order to express the thermal insulation of a clothing, three kinds of insulation—total insulation (I_T), intrinsic insulation (I_{cl}), and effective insulation (I_{cle})—are used [5] [NOTE1]. For expressing the thermal characteristics of a clothing, the usage of I_{cl} is recommended [5, 6] since it is the actual thermal resistance for a temperature difference between the skin and clothing surface. However, it has the following characteristics. (1) I_{cl} for the same clothing changes depending on the airflow around the human body and the body motions. (2) At present, it is difficult to set adequate heat transfer characteristics for the clothing surfaces in each segment. Considering these characteristics and the intended application of the clothing thermal insulation data on the various body segments as an input to the human thermal models with multiple segments, the use of I_{cl} instead of I_{cle} is considered to be less advantageous. Therefore, the present authors have described the clothing thermal insulation in terms of the effective thermal insulation.

In a climatic chamber with calm air conditions ($v \leq 0.15$ m/s), the effective thermal insulation of the body segment i, denoted by ($R_{cle\mathrm{i}}$) [1], was measured for summer clothing garments and ensembles. $R_{cle\mathrm{i}}$ is the hypothetical thermal resistance that expresses the effect of the addition/removal of clothing. It is calculated as follows.

$$\begin{aligned} R_{cle\mathrm{i}} &= R_{dress\mathrm{i}} - R_{nude\mathrm{i}} \\ &= \frac{Q_{dress\mathrm{i}}}{Tsk_{dress\mathrm{i}} - To_{dress\mathrm{i}}} - \frac{Q_{nude\mathrm{i}}}{Tsk_{nude\mathrm{i}} - To_{nude\mathrm{i}}}, \end{aligned} \tag{1}$$

where R is the total thermal resistance [m^{2o}C/W]; Q, sensible heat loss [W/m^2]; Tsk, skin temperature [ºC]; and To, operative temperature [ºC]. The suffixes are as follows: *dress*i is the value for segment i when the body is clothed and *nude*i is the value for segment i when the body is not clothed.

With regard to the thermal insulation for the overall body, all total insulations are calculated by the global method [7] from the data on the segments. Then, the effective thermal insulation I_{cle} is calculated as follows.

$$\begin{aligned} I_{cle} &= I_T - I_a \\ &= \frac{\sum\left(Q_{dress\mathrm{i}} \cdot W_\mathrm{i}\right)}{0.155\sum\left[\left(Tsk_{dress\mathrm{i}} - To_{dress\mathrm{i}}\right)\cdot W_\mathrm{i}\right]} - \frac{\sum\left(Q_{nude\mathrm{i}} \cdot W_\mathrm{i}\right)}{0.155\sum\left[\left(Tsk_{nude\mathrm{i}} - To_{nude\mathrm{i}}\right)\cdot W_\mathrm{i}\right]}, \end{aligned} \tag{2}$$

where I_a is the total thermal insulation when the body is not clothed [clo], and W_i is the weighting coefficient for the data on segment i that is set in accordance with area ratio [N.D.].

Table 1 shows examples of the garments that were studied. Table 2 shows examples of the ensembles that were studied. For the measurements, a female thermal manikin that had twenty segments was arranged in the sitting posture. The manikin had an electrical heating source that was located just below its surface. The *Tsk* of each segment was maintained such that it conformed to the typical skin temperature distribution of human subjects who are in a thermally neutral state in a uniform environment [8]. The average *Tsk* for the overall body was 33.8°C. In the chamber, *To* was set to 27.0°C, 25.0°C, and 24.0°C for a nude manikin, a manikin clothed in a garment, and one clothed in an ensemble, respectively. The relative humidity was within 40 ± 20%. The data in the steady state were used for calculating $R_{cle\mathrm{i}}$ and I_{cle} in Eqs. (1) and (2). In these conditions, the measured Q from the overall body ranged from almost 30 to 70 W/m^2. I_a was 0.81 clo (= 0.13 m^{2o}C/W). $R_{cle\mathrm{i}}$ values were calculated for nine segments—the chest, back, abdomen, buttock, upper arms, forearms, thighs, legs, and feet. Measurements were carried out two or three times for each type of clothing. Two or three data sets were then obtained for each type of clothing. From these data sets, two that satisfied the condition of the difference in their $R_{cle\mathrm{i}}$ values being less than 0.031 m^{2o}C/W (= 0.2 clo) were selected. The average of these two selected data sets was then obtained as the final output of the measurements.

RESULTS AND DISCUSSIONS

Tables 3 and 4 show the examples of the obtained results. The $R_{cle\mathrm{i}}$ values for 52 garments and 97 ensembles were obtained through the selection of the data sets. In this selection, the rejections were mainly attributed to the large difference in $R_{cle\mathrm{i}}$ in the abdomen and thighs. We consider the reasons for the large differences in these segments to be as follows. In the sitting posture, there was a strong curvature along these two segments on the front side of the body. Since the clothing on these segments was located inside this curvature, the thickness of the air layer inside the clothing was largely influenced by the magnitude of the curvature. Therefore, a slight difference in the posture resulted in a large difference in $R_{cle\mathrm{i}}$. In addition, since many garments overlapped on these segments, the errors in the manner of dressing appeared were more apparent in these segments compared with the others. Even in the selected data, with regard to some ensembles in which the legs were covered only by pantyhose, $R_{cle\mathrm{i}}$ in the legs took negative values (≥ –0.005 m^{2o}C/W). We consider that the level of accuracy in the measurements was insufficient for detecting the effect of the addition/removal of the pantyhose.

With regard to the value for the overall body, I_{cle} ranged from 0.02 clo to 0.24 clo for the garments and from 0.13 clo to 0.60 clo for the ensembles. Fig. 1 shows a plot of I_{cle} for ensembles ($I_{cle.en}$) against the sum of the components' I_{cle} ($\Sigma I_{cle.gr}$). The slopes of the regressions of $I_{cle.en}$ by $\Sigma I_{cle.gr}$ (indicated in Fig. 1) are slightly less than those reported by McCullough et al. ($I_{cle.en}$ = 0.76$\Sigma I_{cle.gr}$ + 0.079, $I_{cle.en}$ = 0.84$\Sigma I_{cle.gr}$) [9]. The Difference in the posture (standing in study [9] and sitting in the present study) and difference in the clothing type (only summer clothing is used in our study) are possible explanations for this discrepancy. In order to ascertain the reasons for this discrepancy, it is necessary to measure

I_{cle} of the same clothing as used in our study in the standing posture and also to measure I_{cle} of various types of clothing.

Table 5 shows the ranges of the calculated R_{clei} for the garments and ensembles. R_{clei} was large in the trunk and was relatively small in the periphery of the limbs. Fig. 2 shows a plot of

	A					0.784				
	sd	0.016	0.019	0.041	0.031	0.012	0.008	0.022	0.007	0.004

the R_{clei} values for the ensembles ($R_{clei.en}$) against the sum of the components' R_{clei} ($\Sigma R_{clei.gr}$) for nine segments. In each segment, $R_{clei.en}$ tends to be slightly less than $\Sigma R_{clei.gr}$. The plot exhibits an approximately similar relationship for the all segments. Table 6 shows the slope (A), intercept (B), standard deviation of error (sd) [9] [NOTE2] for the regressions of $R_{clei.en}$ by $\Sigma R_{clei.gr}$ for each segment and the values common to all the segments. In the individual regressions with an intercept, large sd values were observed for the abdomen (0.036 m^2°C/W) and buttock (0.023 m^2°C/W). Many overlaps of the garments explain the larger sd in these segments in comparison to the sd in the other segments. When an sd of 0.041 m^2°C/W (slightly larger sd than that in the abdomen of 0.036 m^2°C/W) is regarded as acceptable, the common regression ($R_{clei.en} = 0.784\Sigma R_{clei.gr}$) can be used for the nine segments.

Fiala et al. [10] developed a clothing insulation model of in which the intrinsic thermal insulation of a body segment provided by the clothing ensemble ($R_{cli.en}$) is expressed by the sum of the components' intrinsic clothing thermal insulation of the body segment ($\Sigma R_{cli.gr}$). However, the definition of clothing insulation in their model is different from that used in our study; the slope of our regression (0.784) is much less than unity (used in their model). The overlap of garments compresses the air layer inside the clothing. This can explain why the slope of our regression becomes less than unity. In the previous study of Sakoi et al. [2], the relations between $R_{cli.en}$ and $\Sigma R_{cli.gr}$ were different among the body segments. However, their definition of clothing insulation was different from that in the present study and their data set was smaller. On the other hand, the variety of clothing types was large as compared with the summer clothing used in the present study. Therefore, the accuracy of our common regression may reduce significantly when the regression is applied for estimating the R_{clei} provided by the types of clothing other than summer clothing.

The slope of the common regression for the nine segments becomes 0.784 and is larger than the slope of regression for the overall body ($I_{cle.en} = 0.725\Sigma I_{cle.gr}$ in Fig. 1). With the insulation for the overall body, it is reported that the effect of addition/removal of clothing garments becomes less when the clothing is worn nonuniformly [9]. The fact that the slope in the common regression for nine segments is larger than that for the overall body is explained by the same reason, i.e., the clothing distribution is more uniform for segments than it is for the overall body.

CONCLUSIONS

In a climatic chamber with calm air conditions ($v \leq 0.15$ m/s), the effective thermal insulation provided to body segments (R_{clei}) by summer clothing was measured. R_{clei} of 52 garments and 97 ensembles was obtained for nine segments—the chest, back, abdomen, buttock, upper arms, forearms, thighs, legs, and feet. In each segment, R_{clei} for the ensembles ($R_{clei.en}$) tends to be slightly less than the sum of the components' R_{clei} ($\Sigma R_{clei.gr}$). Since the plot of $R_{clei.en}$ against $\Sigma R_{clei.gr}$ exhibits an approximately similar relationship for all the segments, the common regression for all the body segments, $R_{clei.en} = 0.784\Sigma R_{clei.gr}$, was proposed for estimating $R_{clei.en}$ from $\Sigma R_{clei.gr}$.

NOTE

[1] The total thermal insulation I_T is defined as the actual thermal resistance for a temperature difference between the skin and the operative temperature of the surrounding environment. It includes the thermal resistance of air (including the effect of radiation) in addition to that of the clothing itself. Therefore, it does not express the heat transfer characteristics of the clothing itself, but that of the clothing and the environmental conditions together [5, 6]. The intrinsic thermal insulation I_{cl} is the actual thermal resistance for a temperature difference between the skin and the clothing surface. It expresses the heat transfer characteristics of the clothing itself. The effective clothing insulation I_{cle} is the hypothetical thermal resistance that expresses the effect of the addition/removal of clothing. It is defined as the difference between the total thermal insulation when the body is clothed (I_T) and the total thermal insulation when the body is not clothed (I_a). Since this hypothetical resistance I_{cle} includes the effect of the environmental conditions as well as the clothing itself, it changes with the environmental conditions [5].

[2] The standard deviation of error (*sd*) [9] is calculated as follows.

$$sd = \sqrt{\frac{\sum(\text{predicted value} - \text{measured value})^2}{\text{number of data}}}$$

SUMMARY

In order to calculate mean radiant temperature in an outdoor environment, we had to calculate a hypothetical sky temperature from directly measurement or an empirical formula of atmospheric radiation expressed as functions of daily mean air temperature, cloud amount, etc. The aim of this research is to propose new expression for simply calculating the radiative heat exchange in an outdoor environment. In this paper, we defined the long-wave radiation coefficient based on the ratio of atmospheric radiation to long-wave radiation from the ground to the human body and derived linearized radiative heat exchange equation in an outdoor environment to be expressed only in the ground temperature and solar radiation. We qualitatively analyzed the long-wave radiation coefficient and the radiative heat transfer coefficient. Finally, based on measured data in an outdoor environment, we proposed the empirical formulae for calculating the long-wave radiation coefficient using solar radiation or the ground temperature.

INTRODUCTION

It is necessary to represent accurately heat exchanges by long-wave and short-wave radiations between the human body and an outdoor environment in order to evaluate thermal and comfort sensations of humans in outdoor environments. The authors have already proposed a series of effective radiant temperatures as mean radiant temperature in an outdoor environment [1] [2]. One is only based on the direct radiation between the human body and the surroundings [1], and the other is based on the multiple radiations between the human body and the surroundings [2]. The effective radiant temperature based on the direct radiation requires determining a hypothetical sky temperature by use of the empirical formula of downward atmospheric radiation defined as functions of daily mean air temperature, cloud amount, etc. Therefore, the calculation of the effective radiant temperature requires not only measured data but the meteorological data. The effective radiant temperature based on the multiple radiations requires calculating incidence factor to describe the influence of multiple radiations by use of linear simultaneous equation. Consequently, it is difficult for evaluation of an outdoor environment to calculate these temperatures on-site.
In this research, to simply calculate a radiative heat exchange in an outdoor environment, we define new long-wave radiation coefficient based on the ratio of atmospheric radiation to long-wave radiation from the ground to the human body, and propose new expression of the heat exchange by radiation between the human body and an outdoor environment considering solar radiation and the ground temperature. We qualitatively analyze the long-wave radiation coefficient, and propose concrete formulae for calculating the long-wave radiation coefficient by use of measured data in an outdoor environment.

METHODS

In an outdoor environment, heat exchange by long-wave radiation occurs between humans and the ground, the sky and body surfaces such as buildings. Besides, the outdoor radiative environment contains short-wave radiation, specifically, direct solar radiation, scattered solar radiation and reflected solar radiation from the ground and buildings.
The heat exchange R between humans and the environment containing short-wave and long-wave radiation is given as Equation (1). We assume the buildings' surface temperature is equal to the ground temperature and only consider reflected solar radiation from the ground.

$$\frac{R}{A_{cl}} = \varepsilon_{cl}\varepsilon_{gr}\sigma\left[(T_{cl}+273)^4-(T_{gr}+273)^4\right](1-U_r)f_{ref} + \varepsilon_{cl}\varepsilon_{sky}\sigma\left[(T_{cl}+273)^4-(T_{sky}+273)^4\right]U_r f_{ref} - (H_d+H_s+H_r) \quad (1)$$

$$H_d+H_s+H_r = a\{f_p I_{DN} + I_{SH}U_r + \rho_{gr}I_{TH}(1-U_r)\}f_{ref} \quad (2)$$

where R is radiative heat exchange [W], A_{cl} is surface area of clothed human [m^2], ε_{cl} is emissivity of clothed human body [N.D.], ε_{gr} is emissivity of ground [N.D.], σ is Stefan-Boltzmann constant (=5.67 * 10^{-8}) [$W/(m^2K^4)$], T_{cl} is mean surface temperature of clothed human [°C], T_{gr} is ground temperature [°C], U_r is sky view factor for the human body [N.D.], f_{ref} is effective radiant area factor [N.D.], ε_{sky} is emissivity of sky [N.D.], T_{sky} is hypothetical sky temperature [°C], H_d, H_s and H_r are direct, scattered and reflected solar radiation absorbed into body surface [W/m^2], a is absorptivity of human surface [N.D.], f_p is projected area factor [N.D.], I_{DN} is direct solar radiation to normal plane [W/m^2], I_{SH} is scattered solar radiation to horizontal plane [W/m^2], ρ_{gr} is reflectivity of ground [N.D.], I_{TH} is global solar radiation to horizontal plane [W/m^2].
Figure 1 shows atmospheric radiation and the long-wave radiation from the ground in an outdoor environment. Atmospheric radiation maintains a stable condition during any season. Long-wave radiation from the ground varies with the climate condition of day. Broken line in Figure 1 demonstrates the ratio of atmospheric radiation to long-wave radiation form the ground. The ratio is distributed between 0.5 and 0.7.

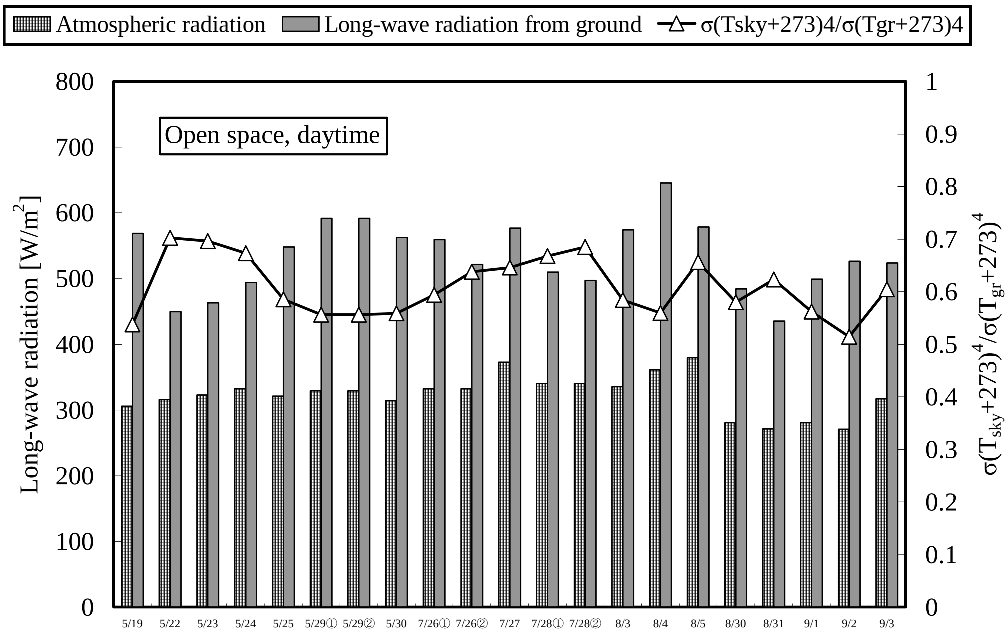

Figure 1. Long-wave radiations in an open space in the daytime of Sapporo city

We define the ratio Ω of atmospheric radiation to long-wave radiation from the ground to the human body as equation (3), and try to simplify the radiative heat exchange equation(1) between the human body and an outdoor environment by use of the ratio Ω.

$$\Omega = \frac{U_r \sigma (T_{sky} + 273)^4}{(1 - U_r)\sigma (T_{gr} + 273)^4} \qquad (3)$$

where Ω is ratio of atmospheric radiation to long-wave radiation from the ground to the human body [N.D.].
U_r in equation (3) denote configuration factor between the human body and the sky, and is referred to as sky view factor for the human body.

RESULTS

Substituting equation (3) into equation (1) to eliminate T_{sky} yields equation (4).

$$\begin{aligned}
\frac{R}{A_{cl}} &= \varepsilon_{cl}\sigma\left[(T_{cl}+273)^4 - \left\{(T_{gr}+273)^4(1-U_r) + (T_{sky}+273)^4 U_r\right\}\right] f_{ref} - (H_d + H_s + H_r) \\
&= \varepsilon_{cl}\sigma\left\{(T_{cl}+273)^4 - (1+\Omega)(T_{gr}+273)^4(1-U_r)\right\} f_{ref} - (H_d + H_s + H_r) \\
&= \varepsilon_{cl}\sigma\left\{(T_{cl}+273)^2 + (1+\Omega)^{\frac{1}{2}}(1-U_r)^{\frac{1}{2}}(T_{gr}+273)^2\right\} \\
&\quad \times\left\{(T_{cl}+273) + (1+\Omega)^{\frac{1}{4}}(1-U_r)^{\frac{1}{4}}(T_{gr}+273)\right\} \\
&\quad \times\left\{(T_{cl}+273) - (1+\Omega)^{\frac{1}{4}}(1-U_r)^{\frac{1}{4}}(T_{gr}+273)\right\} f_{ref} \\
&\quad - (H_d + H_s + H_r)
\end{aligned} \qquad (4)$$

Defining equation (5) makes it possible to define linear radiative heat transfer coefficient h_r in an outdoor environment as equation (6). λ in equation (5) expresses the long-wave radiation properties of the human body specific to the region, date and time, and is referred to as long-wave radiation coefficient.

$$(1+\Omega)^{\frac{1}{4}}(1-U_r)^{\frac{1}{4}} \equiv \lambda \qquad (5)$$

$$h_r \equiv \varepsilon_{cl}\sigma\left\{(T_{cl}+273)^2 + \lambda^2(T_{gr}+273)^2\right\}\left\{(T_{cl}+273) + \lambda(T_{gr}+273)\right\} \qquad (6)$$

where λ is long-wave radiation coefficient [N.D.], h_r is human’s linear radiative heat transfer coefficient [W/(m^2°C)].
The use of the radiative heat transfer coefficient h_r provides the linearized radiative heat exchange between the human body and an outdoor environment as follows:

$$\frac{R}{A_{cl}} = h_r\left\{(T_{cl}+273) - \lambda(T_{gr}+273)\right\} f_{ref} - (H_d + H_s + H_r) \qquad (7)$$

Finally, convective and radiative heat exchange equation considered clothing insulation R_{cl} is shown as follows:

$$\begin{aligned}
\frac{C+R}{A_{sk}} &= h_c(T_{sk} - T_a)F_{cl}f_{cl} \\
&\quad + h_r\left\{(T_{sk}+273) - \lambda(T_{gr}+273)\right\} f_{ref}F_{cl}f_{cl} - (H_d + H_s + H_r)F_{cl}f_{cl}
\end{aligned} \qquad (8)$$

where A_{sk} is skin surface area [m^2], C is convective heat loss [W], h_c are human’s convective heat transfer coefficient [W/(m^2°C)], T_{sk} is mean skin temperature [°C], T_a is air temperature [°C], F_{cl} is thermal efficiency factor [N.D.], f_{cl} is clothing area factor[N.D.].

If the long-wave radiation coefficients λ were preliminarily calculated in each region and time, the radiative heat exchange could be calculated using solar radiation and ground temperature.

DISCUSSION

We qualitatively analyze λ and h_r. λ means a correction factor to calculate the heat exchange by long-wave radiation using ground temperature only. Substituting equation (3) into equation (5) gives equation (5)'.

$$\lambda = \sqrt[4]{1-\left\{1-\frac{\sigma\left(T_{sky}+273\right)^4}{\sigma\left(T_{gr}+273\right)^4}\right\}U_r} \qquad (5)'$$

Because the term in brace on the right-hand side of equation (5)' is positive, the long-wave radiation coefficient λ increases with the decrease of the sky view factor for the human body U_r and is close to 1. Figure 2 shows the variation of λ in response to the variations of U_r and $\sigma(T_{sky} + 273)^4/\sigma(T_{gr} + 273)^4$. The long-wave radiation coefficient λ decreases with close to an open space, which means the increase of the sky view factor for the human body U_r, and the decrease of $\sigma(T_{sky} + 273)^4/\sigma(T_{gr} + 273)^4$.
Figure 3 shows the variation of linear radiative heat transfer coefficient h_r in response to that of the ground temperature T_{gr} and the long-wave radiation coefficient λ. The ground temperature T_{gr} in an outdoor environment ranges approximately from 0 to 50 °C and the radiative heat transfer coefficient h_r varies with the variation of λ. Therefore, it is difficult to regard h_r as a constant value in an outdoor environment unlike an indoor environment. The limitation of a temperature condition could regard h_r as a constant value.

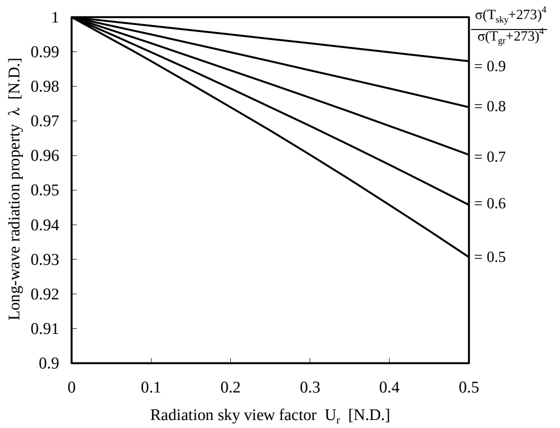

Figure 2. Variations of long-wave radiation coefficient λ

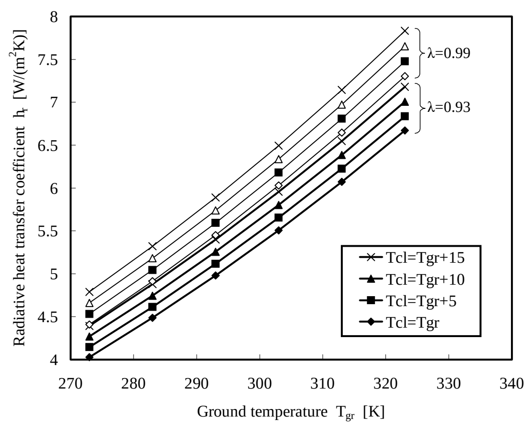

Figure 3. Variations of radiative heat transfer coefficient h_r

We determine concrete formulae for calculating the long-wave radiation coefficient λ using the data of human experiments. Human experiments for evaluating thermal and comfort sensation in an outdoor environment were carried out from 1999 to 2004 in Sapporo and Nagoya city of Japan [3]. The experiments were conducted on the roof of a six-storied building which could be considered an open space, in a courtyard surrounded by four buildings in Sapporo city, and in a street space near a three-storied building in Nagoya city. The sky view factor for the human body U_r of the open, courtyard and street space is, respectively, 0.5, 0.16 and 0.41. Experimental time was 20 or 30 min, and mean value during an experiment was used. We simultaneously measured ground temperature and solar radiation, and used for calculating the long-wave radiation coefficient λ. Atmospheric radiation was calculated from empirical formula of downward atmospheric radiation defined as functions of daily mean air temperature, cloud amount, etc.[4].

Figure 4 shows the variation of the long-wave radiation ratio $\sigma(T_{sky}+273)^4/\sigma(T_{gr}+273)^4$ in equation (5)' in response to that of global solar radiation. Rise in the ground temperature caused by increased solar radiation decreases the long-wave radiation ratio. There is no regional difference between Sapporo and Nagoya city. However, the range of the ratio is approximately 0.1 in response to same solar radiation. Therefore, the long-wave radiation ratio Ω of atmospheric radiation to the long-wave radiation from the ground to the human body depends on the season, solar radiation and sky view factor for the human body.

Figure 5 shows the variation of the long-wave radiation ratio in response to that of the ground temperature after sunset. Because the ground surface is exchanged for only the sky after dark, there is a proportional relation between the two. There is no difference in regions or spaces which has different sky view factor for the human body. Long-wave radiation ratio ranges from 0.64 to 0.9.

The relationship between global solar radiation and long-wave radiation coefficient λ in an open space of Sapporo city is shown in Figure 6. Increased solar radiation decreases the long-wave radiation coefficient λ, as in Figure 4. Therefore, the long-wave radiation ratio defined as a function of solar radiation or ground temperature makes it possible to calculate the long-wave radiation coefficient λ using solar radiation, the ground temperature and sky view factor for the human body U_r.

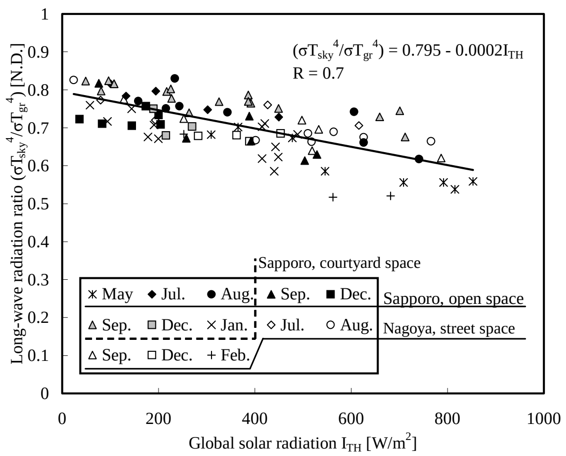

Figure 4. Relationship between global solar radiation and long-wave radiation ratio $\sigma(T_{sky}+273)^4/\sigma(T_{gr}+273)^4$ in daytime

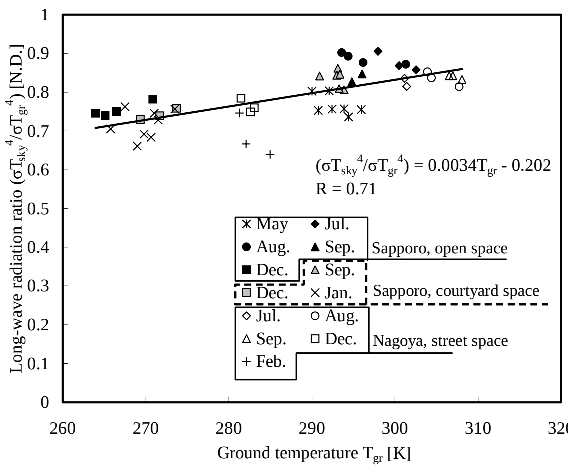

Figure 5. Relationship between ground temperature T_{gr} and long-wave radiation ratio $\sigma(T_{sky}+273)^4/\sigma(T_{gr}+273)^4$ at night

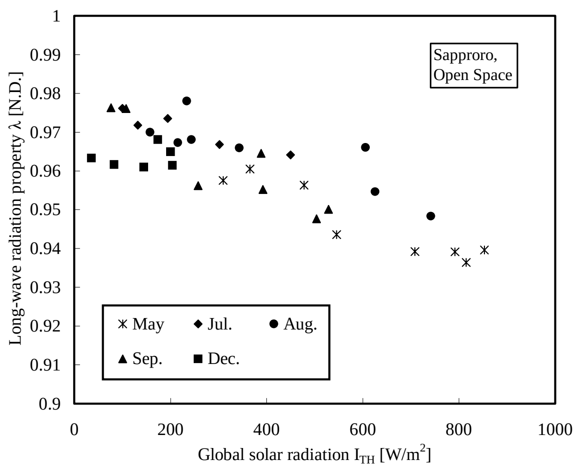

Figure 6. Relationship between global solar radiation and long-wave radiation coefficient λ

Equation (9) shows an empirical formula of the long-wave radiation ratio based on global solar radiation derived from Figure 4. Equation (10) shows an empirical formula of the long-wave radiation ratio based on the ground temperature derived from Figure 5.

$$\text{At daytime: } \frac{\sigma\left(T_{sky}+273\right)^4}{\sigma\left(T_{gr}+273\right)^4} = 0.795 - 0.0002 I_{TH} \qquad (9)$$

$$\text{After sunset: } \frac{\sigma\left(T_{sky}+273\right)^4}{\sigma\left(T_{gr}+273\right)^4} = 0.0035 T_{gr} - 0.202 \qquad (10)$$

Calculating λ using equations (9), (10) and sky view factor for the human body U_r makes it possible to calculate the heat exchange by radiation between the human body and an outdoor environment using λ, the ground temperature and solar radiation. However, these empirical formulae can be applied in moderate season because there are seasonal differences in Figure 4. Empirical formulae considered seasonal differences must be determined with detailed data seasonally.

CONCLUSIONS

In order to simply calculate a heat exchange by radiation between the human body and an outdoor environment, we propose a linear expression formula of radiative heat transfer based on a long-wave radiation coefficient of the human body. We qualitatively analyze the long-wave radiation coefficient and the radiative heat transfer coefficient, and derive concrete formulae for calculating the long-wave radiation coefficient from solar radiation, the ground temperature and the sky view factor for the human body using human experiments' data in an outdoor environment.

The linear expression formula can be applied to the modification of the original WBGT for an outdoor environment [5], based on a heat balance equation between the human body and an outdoor environment [6].

SUMMARY

Half the electricity use in supermarkets derives from the display of refrigerated food. Climate influences the performance of the cabinets and their energy use as well as the thermal comfort of people and the temperature quality of the food. This work is an interdisciplinary study of perceived comfort in relation to measured local climate. The aim is to define an appropriate climate and to improve energy efficiency with maintained or even better climate for goods, staff and customers. Perceived comfort depends on thermal balance of the whole body. ISO7730 is valid only for situations where people spend a longer time. This study involves temporary situation of supermarket shopping. Perception data have been obtained by means of a questionnaire based on ISO10551. The results show that according to ISO7730 people should be dissatisfied with their thermal comfort. The questionnaires (ISO10551), however, indicate that the thermal conditions are acceptable.

INTRODUCTION

In supermarkets there are three different categories that must be considered when a good climate should be established; goods, staff and customers. They are three different categories with incompatible requirements depending on many diverse factors. When installing energy efficient systems or improving existing installations it is important that it will be done without affecting any instance of the categories negatively. Refrigerated food is to be stored according to temperature intervals given by legislation which is harmonized within the EU. Staff in supermarkets is spending longer time in the environment and can adjust their dress-code according to the existing environment and their own activity. Customers on the other hand are and will be dressed in accord to the outdoor conditions which means that during summer while they are light-dressed they can be to cold in the supermarkets. However, the customers are in transit and are spending a shorter periods of time in the supermarkets compared to the goods and staff. The wish from the merchandiser on the other hand is to keep customers, as long as possible, within the sales area in order to sell as much as possible.

Supermarkets are large energy users and energy savings can be done through energy efficient equipment and systems but that is not enough as an argument for the merchandiser. There is a need of further arguments for the merchandisers and people involved when choosing the systems and technical solutions for supermarkets so that the energy use can be lowered with a result of less impact on the environment. An interdisciplinary analysis provides further arguments for the merchandiser to select energy efficient systems in the supermarket. The analysis highlights from an environmental and a financial point of view, advantages of energy efficient systems, improved thermal comfort and improved temperature quality of the food in the supermarkets. As defined by ANSI/ASHRAE Standard 55-2004, Thermal Environmental conditions for Human Occupancy, thermal comfort is “that condition of mind which expresses satisfaction with the thermal environment” [1]. The hypothesis is that energy efficient display cabinets and system solution, as well as increase knowledge, results both in an improved thermal comfort and better temperature quality of the food. The thermal comfort problem in supermarkets especially in front of display cabinets have been studied by several researchers by using CFD-modelling, e.g. Foster [2] and Foster and Quarini [3]. Their results also show that cold air spillage can be a problem. Cold air from the cabinet falls out of the cabinet on to the floor, causing the customer's feet to become cold, commonly known as the 'cold feet' effect. Local discomfort can be caused when one particular part of the body is exposed by unwanted cooling. A high vertical temperature difference between head and ankle is an example of local discomfort. Fang et al [4] studied both in laboratory and in controlled field experiments in an office room the effect of temperature and humidity on the perception of indoor air quality. Conclusions were that air temperature and humidity have a significant impact on both the immediate and the adapted perception of indoor air quality. Decreasing the indoor air temperature and humidity improved the perceived air quality significantly, the acceptability of air increased linearly with decreasing enthalpy of air. The study included different combinations of three levels of temperature (18 °C, 23 °C and 28 °C) and three levels of humidity (30%, 50% and 70%).

This paper presents measured air temperatures along with questionnaires answered by mainly customers in front of vertical cabinets during summer and winter. The objective of this paper is to present results from field measurements and describe how staff and customers are judging the thermal environment (temperature and overall indoor environment) by variations, summer and winter, in front of open vertical display cabinets. The long-term aim of the project is to define the desired indoor climate that would satisfy both people (staff and customers) and the quality requirements of the food. When the desired indoor climate is declared the aim is to improve energy efficiency in supermarkets with a maintained or even better climate for goods, staff and customers.

METHODS

Field measurements have been carried out in three different supermarkets, denoted A, B and C in Sweden. The size of the three supermarkets differs where A is the largest and C the smallest supermarket. In the three different supermarkets questionnaires have been collected in order to find out how the indoor climate was judged by the people in the supermarket. On the same time as people have responded to the questionnaires physical measurements on indoor parameters have been performed continuously. Questionnaires and measurements have been collected during a whole day (opening-hours) for summer (2005) and winter (2006) conditions in front of vertical display cabinets. In supermarket A, 425 people (34 staff) responded in supermarket B, responded 378 people (47 staff) and in supermarket C responded 405 people (49 staff). Totally 532 responded during the summer and 676 during the winter. Answers received were from 48% male and 52% female.

Presented in this paper is from physical measurement air temperatures in front of display cabinets. Together with questionnaires have people answered how they perceive, evaluate and prefers the temperatures. The presentation from the questionnaire also includes answers on how the overall indoor environment is judged.

SUPERMARKETS

Refrigerated food can be displayed in horizontal or vertical display cases/ cabinets with different design. The vertical display cabinets are common but are however more sensitive to infiltration and are also large users of electrical energy. Two common open vertical display cabinets as shown in Figure 1 are included in the study; (a) A Vertical open display cabinets for roll-in and back-loading of goods. It is mainly for storage of refrigerated food, dairy-goods. The cool air is distributed as an air curtain in the front of the cabinet and the rear is closed by curtains. The cold room behind is separated by curtains, the cold room is used for storage of goods. From the back is the cabinet loaded with new goods. (b) A Vertical open display cabinet, front-loaded, for storage of refrigerated food. The cool air is distributed through perforated plates in the rear and as an air curtain in the front of the cabinet. New goods are filled up from the front. One way for the merchandiser to increase the sales area and display refrigerated food in a larger volume for the customers is to use Cold rooms, Fig. 2. The cooled air inside the room is kept separated from the warmer air outside the room. Customers are transported through the room while purchasing the food. Inside the Cold room refrigerated food can not only be stored in vertical display cabinets but also as examples be kept on shelves, boxes and pallets on the floor.

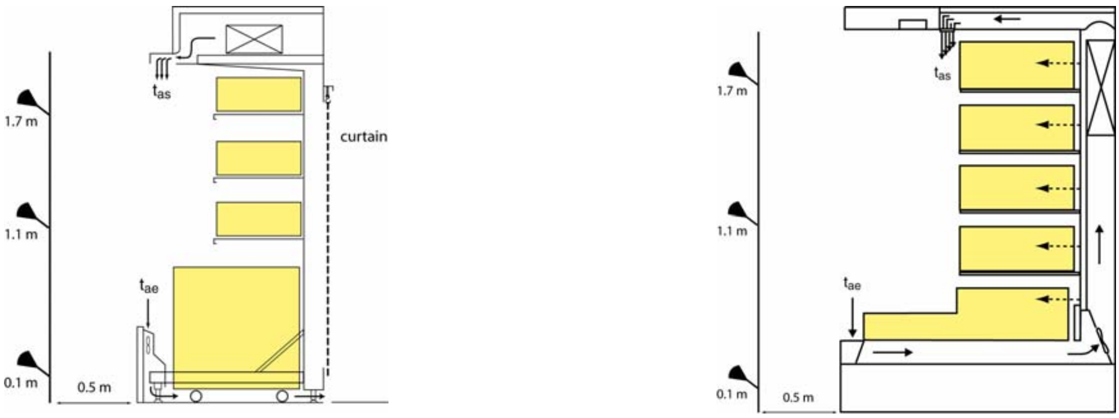

Figure 1: Open vertical display Cabinets and rack positioned 0.5m in front of the cabinet. The sensors are on levels 0.1m (ankle), 1.1m (abdominal) and 1.7m (head) (a) Roll-in and back loaded for Supermarket A, B and C (denoted A1, B1 inside a Cold room and C1) and (b) Front loaded for Supermarket A, B and C (denoted A2, B2 and C2).

OBJECTIVE MEASUREMENTS – PHYSICAL PARAMETERS

During the field measurements environmental parameters were collected from a rack with sensors vertical on three levels above the floor (Figure 1), recommended heights according EN ISO7726 [5]. The sampling intervals were 6 times/ hour and in each supermarket two different vertical display cabinets were measured. The refrigerated foods in the vertical cabinets were keeping temperatures between 0 °C and +8 °C. The Annual mean outdoor temperature for locations of the Supermarkets were 6 °C and during the measurements average temperatures for summer-condition was15 °C and winter-condition around 0 °C. Supermarket B has a Cold room for displaying refrigerated food for customers. In previous work by Axell and Lindberg [6] measurements shows that supermarket B uses the energy most efficient, measures as total energy consumption per square meter total or sales area, A and C have similar energy performance using (energy/sales are).

SUBJECTIVE MEASUREMENTS - QUESTIONNAIRES

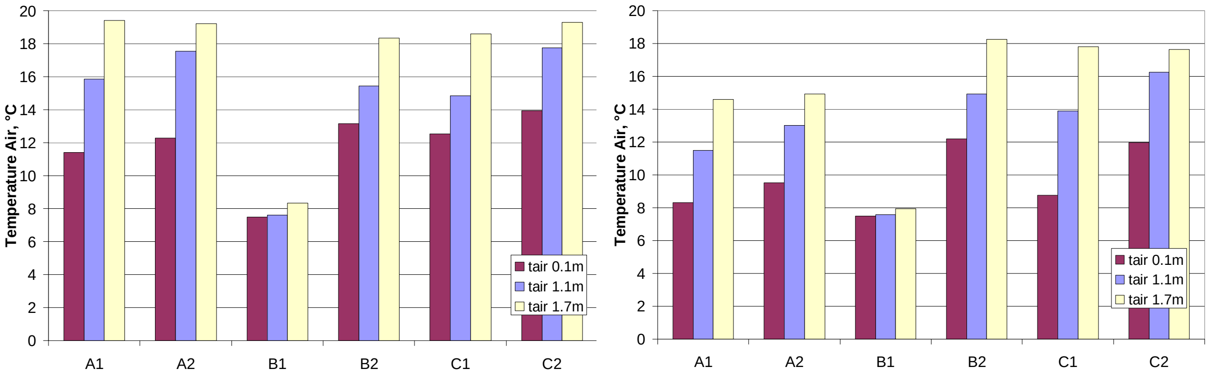
The thermal sensation can be predicted but existing thermal comfort standards, e.g. ISO7730 [7] are based on experiences where people spend longer time. The standard ISO10551 [8] covers the construction and use of judgment scales and proposes a set of specifications on direct experts assessment of thermal comfort/discomfort expressed by persons subjected to various degrees of thermal stress. This approach has been done in order to supplement the objective measurements with the aim of receiving reliable and comparative data on the subjective aspects of thermal comfort/discomfort. Judgment scales as proposed in the standard have used and questioned in following order;

- Perception scale - the scale of Perception is a 7-degree two-pole scale, comprising a central indifference point and two times 3 degrees of increasing intensity. The central point of indifference corresponds to the absence of hot and cold. Neutral = 4, very cold = 1 to very hot = 7.
- Evaluative scale - the Evaluative scale is a 5 degrees scale with a point of origin indicating the absence of the effect, and 4 degrees of increasing intensity of the comfort. Comfortable = 1 and 4 degrees of increasing intensity of the effect, extremely uncomfortable = 5 and
- Scale of preference - the Thermal preference scale is a symmetrical 7-degree scale bipolar comprising a central point of indecision and two times 3 degrees of increasing intensity. Preference scale 1-7, where neutral = 4, much colder = 1 to much warmer = 7.

The questionnaires have been answered by staff and customer standing 0.5 m in front of the vertical cabinet where also the rack has been positioned (Figure 1 and Figure 2). The persons interviewed have been informed briefly about reasons for the questionnaire. Together with backgrounds parameters such as activity, clothes, age etc other physical parameters concerning indoor environment have been collected from the responders. A total of five indoor environment parameters (e.g. air temperature, humidity and air velocity) with above three judgments scales have been questioned. Answers from questionnaire in this paper concerns the temperature and an overall question on how the acceptability is of the indoor environment (local climate) on a personal level.

RESULTS

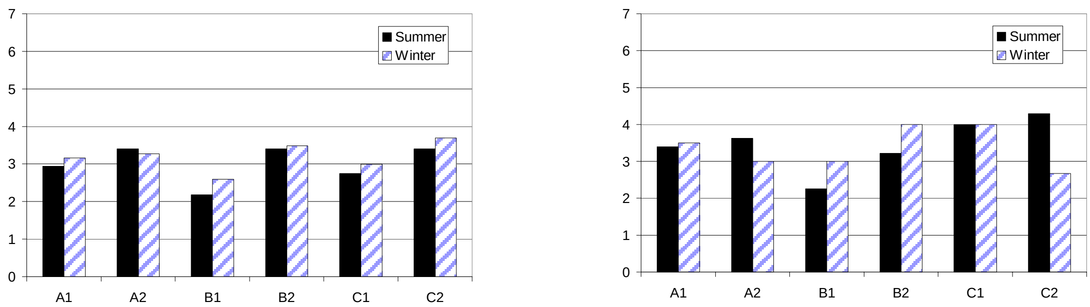
Depending on the outdoor conditions during the year there will also be an influence on the indoor environment. Ambient temperatures are depending on where and when it is measured as shown in Figure 3 with different levels presented during summer and winter conditions. The ambient temperature in front of the vertical cabinets is lower at all levels in all supermarkets during summer compared with winter. For supermarket B, B1, measured in a Cold room the temperature is keeping 8 °C on all three levels during summer and winter. In supermarket A there is a larger difference between summer and winter measurements compared with supermarket B, which also is using the energy more efficient.



a) b)

Figure 3. Average values, air temperatures (tair), during a) Summer and b) Winter. Levels on measurements 0.1, 1.1 and 1.7 m above the floor. For positions, A1-C2, see Figure 1.

The temperature is felt colder for the staff compared with the customers. For example when evaluated in front of A2 the average value for staff was 0.3 colder compared with the customers. Position A2 is measured where two vertical display cabinets are facing each others, during winter the temperature is perceived colder for staff (3.27) compared with customers (3.0). Inside the cold room, B1, lowest temperatures is evaluated from all positions for summer and winter.



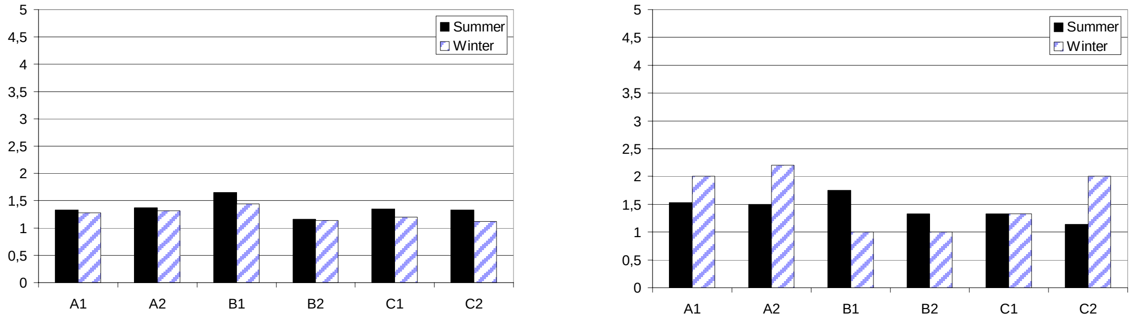
a) b)

Figure 4. Average values during Summer and Winter. For positions, A1-C2, see Figure 1.
a) Customer and b) Staff.
Question answered regarding the Temperature "How do you feel at this precise moment?"
Perceptions scale 1-7 where neutral = 4, very cold = 1 to very hot = 7.

The temperature, see below Table 1 and diagrams in Figure 5, is found to be more uncomfortable for staff than customers (comfortable = 0). During summer and winter more than 60 % of the customer and staff answered comfortable, an exception is B1, inside the cold room where 57 % answered comfortable during summer conditions. During summer 57 % of the customers answered comfortable compared with 70 % during winter conditions.

Table 1. Average values of preference scale for Customer and Staff during Summer and Winter (s/w). For positions, A1-C2, see Figure 1.
Question answered regarding Temperature "Do you find it….?" Scale 1-5, where comfortable = 0 and 4 degrees of increasing intensity of the effect, extremely uncomfortable = 5)

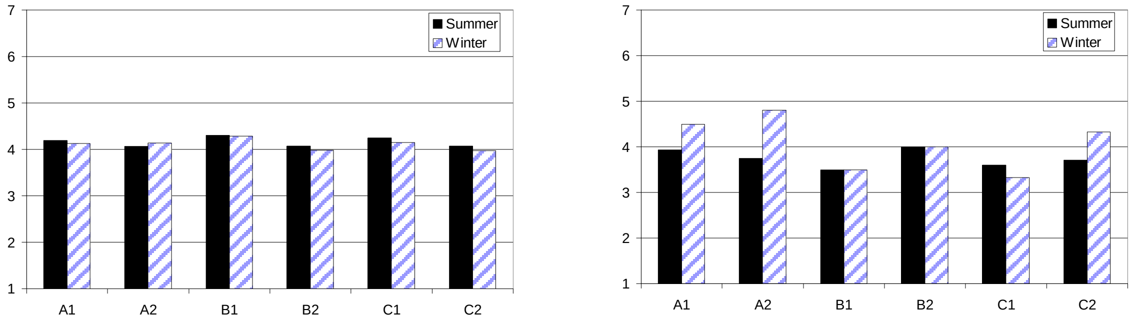
	A1 s/w	**A2 s/w**	**B1 s/w**	**B2 s/w**	**C1 s/w**	**C2 s/w**
Customer	1.33/ 1.28	1.37/ 1.32	1.65/ 1.44	1.16/ 1.14	1.35/ 1.20	1.33/ 1.12
Staff	1.53/ 2.00	1.50/ 2.20	1.75/ 1.80	1.33/ 1.00	1.33/ 1.33	1.14/ 2.00



a) b)

Figure 5. Average value during Summer and Winter. For positions, A1-C2, see Figure 1.
a) Customer and b) Staff.
Question answered regarding the Temperature "Do you find it ....?
Evaluative scale 1-5, where comfortable = 1 and 4 degrees of increasing intensity of the effect, extremely uncomfortable = 5)

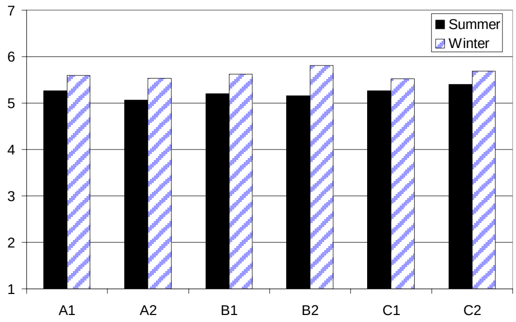
The temperature is preferred to be neither warmer nor colder (4=neutral) for customers. Variation of the preferred temperature is larger for the staff as shown in b) Figure 6 below.

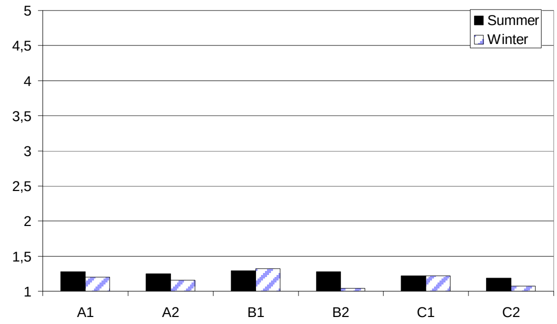


a) b)

Figure 6. Average value during Summer and Winter. For positions, A1-C2, see Figure 1.
a) Customer and b) Staff.
Question answered regarding Temperature "Please state how you would prefer to be now…"
Preference scale 1-7, where neutral = 4, much colder = 1 to much warmer = 7.

When finally judgements about the indoor environment was asked in the questionnaire it was better during winter-conditons for customers as shown in a) Figure 7 below. Followed was the question on how the indoor envrionment was found. Average value was below 1,5 for all cases (1= comfortable, 2= slightly uncomfortable).





a) b)

Figure 7. Average value during Summer and Winter. For positions, A1-C2, see Figure 1.
a) Question answered "How do you judge the indoor environment at this precise moment?" (Scale of 7 degrees from very bad = 1 to very good = 7, 4 = neutral)
b) Question answered "Do you find the indoor environment …..? (Scale 1-5, where comfortable 1 and 4 degrees of increasing intensity of the effect, extremely uncomfortable = 5

DISCUSSION

The cabinets are cooled and kept cold by chilled air. The chilled air is circulating, through the cold cooling-coil and as an air-curtain in the front (sometimes also from the rear) of the cabinet. The air-curtain works as a barrier between the cold air in the cabinet and the warm ambient air outside the cabinet. The variations in the outdoor condition seem to have the strongest influence on the climate condition outside the display cabinet during summer. During summer are ambient temperatures and enthalpy higher and the air-curtain in the cabinet will be weaker. Due to frost growth on the cooling-coil, the air-flow will be lower, the air-curtain weaker and cold air falls easier out from the cabinet. The cold air will lead to colder ambient, higher temperature differences (head-ankles) and warmer temperatures in the cabinets so that the temperature quality of the goods will be influenced. In order to maintain the same temperatures for the cabinets the cooling-demand for the cabinets will be higher and in order to maintain the same ambient temperature outside the cabinets the heating demand will increase for the heating system which often is in combination with the ventilation system. It is of importance how the ventilation system together with the other systems in the supermarket is controlled in order to condition the air where and most needed. There exist a large need of knowledge and further arguments for the merchandiser and people involved with supermarkets in order to choose efficient systems, the systems in the supermarket includes both the system for storage of chilled and frozen goods as well as the heating and ventilation system. A lack of knowledge for people seems to exist since they believe that goods are kept cold when the ambient areas outside the refrigerated cases are cold. The cabinets are not suppose to cool the customers, the are supposed to keep the good cold. The physical measurements and questionnaires presented will be used in order to define a suitable indoor climate for goods, staff and customers in supermarkets. In this paper physical measurements (temperatures) are presented along with answers from questionnaires (regarding temperatures and indoor environment). Further physical parameters along with answers from the questionnaires concerning humidity, illumination, air velocity, background parameters (age, gender etc) are to presented in future publications. The relation between the subjective and objective data will be used to define a desirable indoor climate.

CONCLUSION

The results show that according to ISO7730 people should be dissatisfied with the thermal comfort, especially during summer. Analysis from physical data, Figure 3, indicates that in all supermarkets especially customers during summer are dissatisfied. Temperature differences (between ankle and head) are higher than 5K. According ISO7730, local discomfort caused by vertical air temperature differences, at least 20% are dissatisfied. However customers in front of the cabinets perceive the temperatures to be in average 3.1 (3 = neutral). Inside the cold room, B1, for customers the temperature is perceived lowest (2,18 for summer resp. 2,59 for winter). During summer customers evaluated the temperature as more uncomfortable compared with the winter. Customers are wearing less clothes during summer compared with winter season which most probably is the reason for that answer. However as answer on how the overall indoor environment in the supermarkets during summer and winter was the average value higher than 5 (4 = neutral, 5 = slightly good). During winter the indoor environment was judged as better than summer conditions. However Customers answered 0.78 higher for summer and 0.45 higher for winter compared with staff. The staff answered an average value of 4.85 for summer respectively 5.18 for winter conditions. The questionnaires however, indicate that customers find the indoor environments as comfortable to slightly uncomfortable. When asked how the temperature is preferred an average of 4.1 was given from customers and 3.9 for staff, see Figure 6. Results from previous presentations on field measurement in this study shows that supermarket A, which use the energy less efficient, also have highest difference on the enthalpy measured in front of the display cabinet. With a lower temperature and humidity the energy use can be lowered. For appropriate indoor air climate and environmentally sustainable supermarkets it is of importance that all systems in the supermarket are optimized in order to run efficient.

Pollutants in the indoor air

Health risk based ETS targets for design of room environments

Paul Spry

Spry Associates, Australian Capital Territory

SUMMARY

This paper outlines the Australian Standard 1668.2: 2002 ETSHI risk methodology and extends it to give a means of calculating the numerical death risk from exposure of specific age/gender groups to defined Environmental Tobacco Smoke, (ETS) exposures.

Acceptable risk exposure is discussed (with numbers) and actual mortality statistics are presented for comparison.

A 'smoking permitted office' situation is analysed and some conclusions are drawn.

This paper (and the underlying research) was not funded by 'pro' or 'anti' tobacco interests.

INTRODUCTION

The Environmental Tobacco Smoke Harm Index (ETSHI) was introduced in the 2002 edition of Australian Standard 1668 Part 2. (Appendix 1 of Supplement 1)[1].

This author chaired the Standards Australia committee responsible for AS1668.2: 2002. He also chaired the working group that developed the ETSHI methodology.

The ETSHI is an estimate of a significant part (over 50%) of the mortality risk associated with exposure to environmental tobacco smoke in an environment that is ventilated and that is, or is not, fitted with a device for removal of some components of airborne environmental tobacco smoke (ETS) which contribute to the risk.

The ETSHI is a specific aggregate of the mortality risks associated with lung cancer (LC, more specifically: malignant neoplasm of trachea, bronchus and lung), and ischaemic heart disease (IHD) - and these diseases are said to be the causes of at least one half of ETS related deaths.

In AS1668.2: 2002 the development of the ETSHI equations is presented clearly so that the underlying principles may be applied by ventilation system designers to systems other than those that exactly fit the situations covered by its Appendix.

The ETSHI methodology has been extended by this author to give estimated deaths from lung cancer and ischaemic heart disease that are specific to gender and age groups.

Neither the ETSHI methodology nor the extended version described herein takes into account the morbidity (non-fatal disease) effects of ETS exposure e.g., childhood respiratory disease, asthma exacerbations. Also, the methodology does not deal with adverse effect of ETS exposure on child development.

It appears to be reasonably well accepted that Lung Cancer (LC) and Ischaemic Heart Disease (IHD), together, account for at least half of the deaths caused by ETS thus it may be appropriate to view (x)*(ETSHI) as a reasonable estimate of ETS caused deaths – where x is a number in the 1.0 to 2.0 range.

ETSHI methodologies should be used with caution - appreciating the underlying medical and scientific issues and the limitations of the methodology would seem essential.

VENTILATION SYSTEMS

The ETSHI methodology allows for the influence of ventilation system design on ETS mortality to be estimated though it is probably best used for sensitivity analysis i.e. for determining how variation of ventilation parameters varies outcomes.

In the modelled case of a single 'smoking permitted' enclosure in which non smokers are present the parameters that may be varied are : ETS generation, time of exposure of non-smokers, ventilation rate, air recirculation rate, filtration of particulate and gas phase carcinogens and filtration of particulate and gas phase contributions to IHD.

The ventilation model assumes an occupied enclosure with fully mixed air conditions thus the alleged benefits of 'displacement' systems are not accounted for. Similarly the influence of local concentrations etc. of ETS in the enclosure are not modelled.

Manipulation of the model quickly reveals a limitation of technology i.e. that ETS, in a space, has the capacity to influence health *before* it is taken to an air cleaning system.

THE ENVIRONMENTAL TOBACCO SMOKE HARM INDEX

The development of the equations of the ETSHI is presented fully in AS1668.2 Sup.1: this should be referenced if detail is required.

An example of ETSHI calculation is provided later in this paper.

In developing the index it was asserted that an index of the mortality risk associated with ETS exposure can be represented by an aggregate of the risk of death from ETS induced LC and risk of death from ETS induced IHD by considering the following:

- The mortality risk from ETS induced IHD is correlated with short-term, medium-term and, perhaps, long-term exposures to ETS. This correlation is, likely, linear in the range of exposures up to that represented by typical spousal exposure. At higher exposures, the relationship is better correlated with that of smoking.
- For smoking-induced IHD it is reasonable to assert a dose response relationship corresponding to the expected response of a statistically log-normal (i.e. Gaussian Distribution) population. Accordingly, the dose vs cumulative risk curve, for smoking, is a modified sigmoid (viz. integral of the log-normal distribution) shape with the curve asymptotic to {Relative Risk = 1.0} at the low end and asymptotic to {Relative Risk = a higher value, AS1668.2:2002 estimates 2.0} at the high end

- The IHD effect(s) of ETS exposure is (are), at least partially, correlated with the tendency of exposure to enhance human blood platelet aggregation. An initial estimate is that 50% (likely range 30% to 80%) of the mortality contribution of ETS lies in its enhancement of blood platelet aggregation.
- For ETS induced LC, the nature of the disease and the dose response evidence suggests that it is reasonable to assess mortality risk as proportional to average medium to long-term exposure with no nil-effect dose.
- The LC causing effect of ETS is predominantly related to ETS particulates, though ETS gas phase components may contribute.
- The relative extent to which the particulate component of ETS is responsible for LC deaths can be estimated with reasonable accuracy. An initial estimate is 80% (likely range 70% to 95%) of risk attributable to particulate and the balance attributable to gas phase components.
- Published NHMRC (National Health and Medical Research Council, Australia) estimated ETS induced spousal LC death rates and IHD death rates are appropriate.

For LC and IHD a dose response reference point, consisting of an outcome and its associated dose, was determined. RSP was the chosen indicator of ETS concentration or exposure. A dose response relationship was asserted for LC and IHD.

From this information, a steady state ventilation/air treatment/dose/risk relationship was calculated. The development of the Index was presented in AS1668.2 in an unreduced form so that the constituent logic and variables were not obscured.

A simple model was used with one enclosure containing mixed air, and one air treatment assembly taking air from the enclosure, treating it, and returning it to the enclosure.

Allowance was made, in respect of each challenge, for two-component cleaning action of the air treatment unit.

For LC and IHD deaths the NHMRC has reported data for non-smokers attributable to spousal smoking . This is 'official' health authority data for Australia. This or other data may be used in the ETSHI approach.

In calculation of the Index, it was, recommended that not less than 80% of the LC inducing effect of ETS be attributed to the particulate phase of ETS and that fine particulate air filters rated in accordance with the requirements of AS1668.2 be considered effective in removal of the particulate phase of ETS.

Similarly, it was recommended that approx. 50% of the IHD inducing effect of ETS be attributed to the characteristic of ETS that enhances blood platelet aggregation. Neither demonstrated means of removal of this characteristic nor a test specification for apparatus for removal of this characteristic from air are not known to exist.

The ETSHI estimates apply to where the stated daily ETS exposure has been repeated every day for an indefinite period prior to the time of risk assessment.

The ETSHI is the sum of (a) the population average estimated mortality outcome for LC, and (b) the estimated mortality outcome for IHD is based on data applying to an age sixty-five person.

Given the limited accuracy of the data in the model etc. it was considered appropriate to consider the simple arithmetic sum of the two mortality outcomes to be a useful index.

VALIDITY OF THE ENVIRONMENTAL TOBACCO SMOKE HARM INDICES

The validity of ETSHI, or like approaches to other hazards, is to be assessed by users.

AS 1668.2: 2002 Sup. 1 provides full detail of the ETSHI methodology and all of the underlying assumptions, data and references so this assessment is facilitated.

One opinion of the validity of the approach is known to this author. In a report[2] to the Cancer Council of New South Wales (an Australian State) James Repace, a noted ex-USEPA anti-smoking activist, found that his risk calculation was 'consistent with the Environmental Tobacco Smoke Harm Index published in Australian Standard 1668.2:2002 Supplement 1'.

The ETSHI was developed without reference to James Rapace's work and he refers, in his paper, to calculations of his published in 1998. The Standards Australia and Rapace approaches were developed independently.

The example calculated in AS1668.2:2002, for a smoking permitted office situation, gives an ETSHI of 225 deaths per million persons per year using mean NHMRC ETS death estimates.

James Rapace evaluated an essentially identically situation (assumptions vary in minor respects) and calculates a death rate of 244.

The similarity of these results is remarkable.

ACCEPTABLE RISK

Few reputable persons or government/other agencies have chosen to state acceptable mortality risks for exposure to hazards.

It is more common to depend on less solid criteria such as the Precautionary Principle and the ALARA (As Low As Reasonably Achievable) exposure approach.

There is a quite useful and nuanced discussion of the precautionary principle in the EC document[3] 'Communication from the commission on the precautionary principle'.

In reference 4 Mark Tweeddale refers to UK government HSE (Health and Safety Executive) proposed risk criteria. These, in turn, draw upon RSSG (UK Royal Society Study Group) information.

The HSE/RSSG information, which in this paper ETS hazard is referred to, is interpreted as proposing these risk criteria (with various caveats applicable).

- An 'upper bound' criteria of 10 fatalities per year per million persons for a normal population where a risk above this level would be regarded as 'unacceptable in essentially all circumstances except perhaps for activities entered into voluntarily with full knowledge of the risks'

- A lower bound of 1 fatality per year per million persons where a risk below this level may 'legitimately be regarded as trivial by the decision maker'.

These proposed risk criteria may be viewed against actual mortality rates. Some approximate mortality rates for Australia are shown below. The actual rates have year-to year scatter, longer term time trend and gender dependence.

Homicide: 22 deaths per million persons per year
Suicide: 127, Firearm accident: 2, Machinery accident: 5, Drowning: 18
Fire: 6, Air transport: 4, Motor vehicle: 95, Birth trauma: 2, Intestinal infection: 3
Septicaemia: 22, Viral diseases: 8, Malignant neoplasm of colon: 183
Malignant melanoma of skin: 48, Malignant neoplasm of female breast: 286
Malignant neoplasm of prostate: 245, Alcohol dependence: 12,
Drug dependence: 17, Multiple sclerosis: 4, Epilepsy: 12,
Cerebrovascular disease: 708, Pneumonia: 101, Influenza: 4, Asthma: 49

THE <u>EXTENDED</u> ENVIRONMENTAL TOBACCO SMOKE HARM INDICES

The ETSHI was developed within the Australian Standardisation process. The extended ETSHI indices (e-ETSHI), described here, have been developed outside this framework.

Although the ETSHI is a useful indicator of overall societal mortality risk from ETS exposure it does not allow examination of the effect of gender and age on the risk.

e-ETSHI provides this information. As reasoned above (for ETSHI) it may be appropriate to view (x)*(e-ETSHI) as a reasonable estimate of ETS caused deaths, for specific age/gender groups – where x is a number in the 1.0 to 2.0 range.

Given that 'relative risk' is at the core of the ETSI methodology the extension to calculating e-ETSHI is simple – merely a matter of proportioning in accordance with mortality tables[5] - so it is not treated here in detail. A hypothetical example will suffice:
If,

- the population average death rate for a disease, from all causes, is 100 per million persons per year, and
- the gender/age group subset death rate for a disease from all causes is 70 per million persons per year
- the population average death rate for a disease – from a particular cause - is, 30 per million persons per year.

Then,

- the gender/age group subset death rate for a disease from a particular cause is (70/100) * (30) = 21 per million persons per year.

AN EXAMPLE

The example in AS1668.2:2002 is typical of an office ETS exposure situation with these parameters (an alternative e.g. a bar is equally easily analysed): smoking is permitted, 100 people are present, each person is present for 8 hr per day, 1/3 of those present are active smokers, each smoker consumes 2 cigarettes per hr, outdoor air supply is 10 litres per sec. per person (l/s/pp), recycle (return) airflow is 50 l/s/pp, 35% (hot DOP) return air filter is fitted, 80% of the cancer risk is contained in the particulate phase of the ETS, air treatment for the removal of factors affecting ischaemic heart disease is not installed.

When calculating the ETSHI or e-ETSHI a consideration is the base judgement of severity of mortality risk set by the responsible health authority.

In Australia the peak health body (the NHMRC) has dealt with uncertainty by publishing data corresponding to situations that represent Highest Plausible risk, Estimated risk and Lowest Plausible risk.

For the example the ETSHI corresponding with the estimated risk is 225 deaths per million people per year.

For the example e-ETSHI values corresponding to the mean, lowest plausible and highest plausible risk assessments are stated in the following tables for the various disease, gender and age groups.

Table 1. RISKS: USING NHMRC MEAN ESTIMATES

* odd value due to an aberration in mortality data

COMMENT ON THE EXAMPLE

Viewed in the context of the above discussion of acceptable risk (say, 1 to 10 deaths per million persons per year) The ETSHI index of 225 indicates that the examined situation is probably unsafe.

In the three tables of e-ETSHI (above) the situations wherein the population e-ETSHI is less than 10 deaths per million persons per year (and the population is aged less than about 18 years, and thus respiratory organs are normally well developed) are printed in **BOLD.** In examining these tables it is wise to recollect the above developed likely relationship: death rate = (e-ETSHI) * (x) where 1 <= x <= 2.

Examination of the tables allows a number of conclusions to be drawn

- Exposure to ETS can be quite dangerous
- The main risk from ETS exposure is death from heart disease, lung cancer risk though significant is not as high
- Exposure rapidly becomes more dangerous as one ages - it is wise to be young
- It is wise to be female – you have a lower ETS death risk (though there may be some data aberrations contributing to the lower lung cancer estimate)
- The risk of lung cancer death from ETS exposure increases monotonically with age
- The risk of Ischemic Heart Disease from ETS exposure increases up to age 80 and then decreases. Perhaps the cohort of susceptible people has been largely exhausted by age 80
- There may be an age range (somewhere in the larger 20 to say 45 years range) where the sheer robustness of human construction allows that ETS exposure will present a death risk, in defined circumstances, that is within some definition of acceptability. This age range seems to be greater for females. Perhaps this may tempt the morally challenged to justify the predominance of young female employees in service jobs in smoking permitted bars and the like?

The relative prominence of Ischemic Heart Disease in the ETS exposure risk situation, as seen above, has an interesting prophylactic consequence: it allows something to be done to reduce the risk of ETS exposure.

It is difficult to see how Lung Cancer risk of ETS exposure can be reduced other than by exposure reduction/avoidance.

However, with Ischemic Heart Disease, these measures could be augmented by medicines such as aspirin during periods of ETS exposure - the ‘not young’ may be wise to dose with such anticoagulants before being exposed to ETS. This effect could be easily incorporated in the e-ETSHI model.

SUMMARY

This study presents the first Flemish monitoring campaign on indoor air quality in children's living environment. The main aim of the study was to determine for sensitive groups of children the indoor environment exposure a result of contaminants that occur in the outdoor and indoor air, and to quantify the relative importance of ambient and indoor-source related exposure to total personals exposure of children.
The monitoring campaign was performed in January – February 2006 in 50 dwellings, and 24 other children's micro-environments. Indoor and outdoor concentrations (7-day averages) of 15 pollutants were measured: MTBE, benzene, trichloroethene, tetrachloroethene, ethylbenzene, m+p xylene, styrene, o-xylene, 1,2,4 trimethylbenzene, p-dichlorobenzene, TVOC, NO_2, formaldehyde, acetaldehyde and PM.
Since MTBE has no indoor source (petrol additive), the slope of indoor versus outdoor MTBE (F_{INF} = 0.86; 95 % C.I.: 0.59-1.13) could be used to assess the infiltration of other gases. Using this indirect technique, it was estimated that, on average, the relative importance of indoor sources to total indoor concentrations indoor varied from 85 % for formaldehyde to 34 % for traffic related components such as benzene. The MTBE infiltration technique was not suitable for PM and NO_2.
Typical children's personal exposure was modeled based on typical time patterns and median indoor concentrations of different micro-environments. It revealed that on average, the indoor-source exposure attributed from 32 % (benzene) to 80 % (formaldehyde) to personal exposure, whereas ambient exposure accounted for 66 % (benzene) to personal exposure. Exposure experienced during transport consisted of 2 % (tetrachloroethene) to 15 % (MTBE).
It is concluded that the relative importance of indoor sources or ambient sources is pollutant-dependent and it is advised to take this pollutant-dependent behaviour into account when stipulating policies aiming at reducing exposure to children.

INTRODUCTION

Whereas ambient air quality in Flanders has been monitored for years, indoor air quality in Flanders has not been investigated systematically in a quantitative way in the past. However, people spend up to 90 % of their time indoors, which indicates the relevance of indoor air quality to respiratory health.
Air pollutants present in the indoor environment are the result of (1) product emissions such as furniture, consumer products, cleaning materials,… and (2) infiltration of ambient substances. Knowledge on the relative importance of these two terms is crucial for stipulating a good indoor air quality policy.
The aim of the study was (1) to make an inventory of indoor concentration in Flemish dwellings and other micro-environments in which people spend a large part of their time, (2) to assess if traffic density affected indoor and outdoor concentrations and (3) to determine the

personal exposure of children and, (4) to differentiate the personal exposure in an ambient and non-ambient fraction. It is hypothesized that traffic density affects the concentration of typically traffic-related compounds such as MTBE and benzene and not for other compounds Children were selected as sensitive groups because they experience a higher air pollutant load given their 50 % larger body-weight rescaled or 35 % larger long-surface rescaled exposure than adults.
The selection of the investigated pollutants was based on 3 criteria : 1) only pollutants with possible outdoor sources were selected (biological agents and ozone not retained) and 2) only pollutants for which health effects have been proven in the past (e.g. based on WHO health criteria). Terpenes, pesticides and bromated flame retardants were not measured in the first Flemish Indoor Exposure Survey because of too specific and demanding sampling techniques.

METHODS

Selection of measuring locations

The monitoring campaign was performed in January-February 2006 in the eastern part of Flanders in 50 dwellings of volunteers. The dwellings were selected based the proximity to traffic: 12 houses in rural background (RB) areas (< 50 cars passing/day), 24 houses in urban background (UB) area (< 500 cars/day) and 12 houses in urban hot spot (HS) area (>15000 cars/day). The emphasis on dwellings in UB areas is because of the 75 % of Flemish houses are of this type.
In the houses, 2 indoor locations, namely living room and bedroom, and 2 outdoor locations, namely front door and back door (if applicable) concentrations were sampled. The set of 50 houses existed of a heterogeneous mix of dwelling types: detached dwellings (12), semi-detached dwellings (n =3), connected dwellings (n = 23), flats at ground floor (n = 1) and flats above the ground floor (n = 7). Additionally, indoor and outdoor air was sampled at schools or daycares (n= 10), transport (n= 9; car, public transport, wandering) and sport and leisure infrastructures (n =7). The number of sampled dwellings was smaller for PM (10 living rooms, 34 bedrooms and 19 dwelling outdoor locations) because of logistical reasons.

Questionnaires

Information regarding possible indoor sources (presence of consumers products, cleaning products, furniture, heating devices, …), dwelling characteristics (ventilation types and frequency, isolation, single or double glass windows, presence of an attached garage …) was obtained by means of a detailed questionnaire. The second part of the questionnaire investigated the children's time patterns (7-day diary with 1 hours intervals for each child).

Sampling and analysis techniques

Except for particulate matter, all pollutants were measured by diffusive sampling techniques. For VOC's Radiello samplers were used. After 7-days sampling, the samplers were extracted with carbon disulfide containing an internal standard. Analysis were performed on a HP6890 gas chromatograph hyphenated with a HP5975 mass spectrometer. Total volatile organic compounds (TVOC) was measured in full scan-modus, while the selected individual compounds were measured in selected ion monitoring mode. External standards were used for calibration. Aldehydes were sampled with diffusive dosimeters manufactured by SKC. Mechanism of the dosimeters is chemisorption with dinitrophenylhydrazine. After the sampling period, the aldehydes were desorbed with acetontrile and analyzed by LC-UV. NO_2

was sampled with diffusive monitors IVL (Swedish Environmental Institute) and analysed by IVL. Particulate matter was measured by Grimm dust, Buck or Aeromini monitors. The latter was provided with a weather proof enclosure and was used outdoors. Grimm and Buck monitors were used indoors.

Infiltration of ambient pollutants

The total indoor concentration of a substance can be expressed with equation 1 [1] which included a left term related to outdoor concentration and a right term representing the contribution of indoor sources:

$$C_{indoor} = \frac{Pa}{a+k} C_{outdoor} + C_{indoor\ sources}, \qquad (1)$$

The infiltration factor (F_{INF}) can be derived in the absence of indoor sources, assuming the following relationship between concentrations indoor (C_i) and outdoor (C_o) [2,3]:

$$F_{INF} = \frac{C_i}{C_o} = \frac{Pa}{a+k}, \qquad (2)$$

with P: penetration factor (-); a is the air exchange rate (/h) and k is the deposition, removal or sorption rate (/h). In this study, MTBE was selected as a tracer with only outdoor sources to calculate F_{INF} and thus, in a next step, to discriminate the outdoors generated from indoor generated fractions of other pollutants:

$$C_{ig,x} = C_{i,x} - F_{INF} \times C_{o,x}, \qquad (3)$$

with ig = indoor generated and x = substance x
This method is analogous to the principle used in other studies using other tracers (e.g.SO_4 as tracer for PM2.5) to determine outdoor to indoor infiltration of PM [4,5]

Personal exposure

The typical children's personal exposure was modeled based on time activity patterns obtained through the questionnaires and concentrations of each micro-environment. Total personal exposure can be split up in a 1) ambient exposure (directly and infiltrated), 2) indoor sources and 3) exposure experienced during transport. The latter micro-environment is difficult to separate in a ambient and indoor generated fraction under the current set-up. Thus, personal exposure to substance x was calculated as:

$$T_x = A_x + N_x + TR_x, \qquad (4)$$

Ambient (A_x) and non-ambient (N_x) exposure were respectively calculated as :

$$A_x = \sum_j t_{o,j} \times C_{o,j,x} + \sum_j t_{i,j} \times F_{INF} C_{o,j,x}, \qquad (5)$$

$$N_x = \sum_j t_{i,j} \times C_{i,j,x}, \qquad (6)$$

with $t_{o,j}$ and $t_{i,j}$: time fraction spent respectively outdoor and indoor at µ-environment j.
Exposure experienced during transport (TR_x) (I or O) was calculated as a separate term. Total personal exposure to x is the sum of A_x, N_x and TR_x.
The variability in exposure was assessed based on Monte Carlo simulations (Crystall Ball software) by accounting for variability in dwelling indoor concentrations, which is the micro-

environment with the highest variation in concentrations and the most important compartment with respect to time budget. Variations in other micro-environments were not accounted for because they affected to a much lesser extent the exposure and because a distribution on concentrations could not be established because of the limited dataset for micro-environments other than dwellings.

Statistical analyses

The statistical analyses were performed using the statistical tool package Statistica (version 7). The non-parametric Kruskal-Wallis Anova test and non- parametrical correlation analyses were applied because of not normally distributed datasets.

RESULTS

A summary of indoor and outdoor concentrations in 50 Flemish dwellings is given in Table 1. Concentrations of gases show a very high variability between different houses (n=50), both indoors and outdoors. The most abundant gases in both indoor and outdoor environments were toluene, NO_2, formaldehyde and acetaldehyde.
Indoor concentrations generally exceeded corresponding outdoor concentrations (except for NO_2 and PM10). The target value of the Flemish Indoor Decree of 11/06/2004 [6] of 200 µg/m² is exceeded in 95 % of the investigated indoor environments. The Flemish target values for formaldehyde (10 µg/m³) and for benzene (2 µg/m³) were exceeded in nearly 50 % of the cased. The Flemish intervention limits for benzene and formaldehyde were exceeded in respectively 3 and 1 indoor dwelling locations. The Flemish Indoor Decree does not define intervention limits for TVOC's.

Table 1: Indoor (living room and bedroom) and outdoor (front door and backdoor) concentrations in 50 Flemish dwellings

	Dwelling Indoor (n=100)			Dwelling Outdoor (n=86)		
	median	min	max	median	Min	max

Styrene	0,21	0,01	2,95	0,06	0,01	1,94
o-Xylene	0,86	0,14	6,14	0,41	0,12	3,48
1,2,4-Trimethylbenzene	1,99	0,17	16,94	0,64	0,14	3,32
p-Dichlorobenzene	0,07	0,03	7,11	0,03	0,03	0,09
TVOC	491	138	2793	218	136	396
NO2	21,3	7,1	122,1	40,9	1,9	71,2
Formaldehyde	23,7	1,4	124,1	3,4	2,2	64,9
Acetaldehyde	21,8	1,1	65,2	13,8	0,4	63,2
PM10	11,7	2,3	58,0	33,8	17,8	73,7

Statistics in Table 1 include both living room and bedroom concentrations and front door and backdoor concentrations. On average, the ratio of bedroom to corresponding living room concentration was near 1 (average ratio varied from 0,80 for acetaldehyde to 1,51 for styrene). In general, backdoor concentrations were slightly (± 0,9) fold lower than frontdoor concentrations. This suggests that the dwellings act as a barrier for pollutants that are mainly formed at the street.

For some gases, outdoor concentrations were affected by the traffic density, concentrations for HS locations being highest, followed by urban background, and by rural background (Table 2). As expected, traffic related compounds (MTBE, benzene, toluene and NO_2) are higher in outdoor environment of HS compared to RB. For some traffic pollutants, higher indoor concentrations in HS than in RB and UB (e.g. NO_2) were observed. Compared to the outdoor concentrations traffic-related pollutants like toluene are no longer significantly different in the different locations, indicating an additional contribution from indoor sources. For other, more indoor generated pollutants (xylenes, …) no effect of traffic density indoor concentrations was observed. The distribution of PM sampling sites was not balanced enough over HS, UB and RB classes to allow a statistical comparison (data not shown).

Table 2: Mean outdoor and indoor concentrations for 3 traffic density classes (UB: urban background; HS: hot spot; RB: rural background) Statistical different values between location type classes (Anova, P<0,05) are marked with different letters (for gases without differences between any of the 3 groups are not marked with letters)

The MTBE infiltration method (see above) can only be used under the assumption of absence of indoor sources of the tracer However, exceptionally high indoor/outdoor MTBE ratios were observed for 2 dwellings. In these two dwelling, MTBE indoor concentrations 7,6- 33 µg/m³ were measured, while concentrations were as low as 0,146 - 0,195 - µg/m³. The only potential MTBE indoor source was the presence of gasoline indoors. Indeed, the presence of a garage in the dwelling, or adjacent to the dwelling (with passage between garage and house) in these 2 houses suggests the presence of MTBE indoor source. In 6 other houses, indoor concentrations above 1 µg/m³ were measured; although the MTBE ratio was I/O remarkably lower than of the 2 above mentioned dwellings, I/O of these 6 dwellings was largely above the remainder part, and 5 of 6 of these houses had a garage in the dwelling (directly or adjacent with passage), suggesting MTBE indoor sources. Therefore, these houses were excluded and based on the filtered dataset (n = 42), the average F_{INF} factor was derived from the slope of indoor MTBE versus outdoor MBTE.

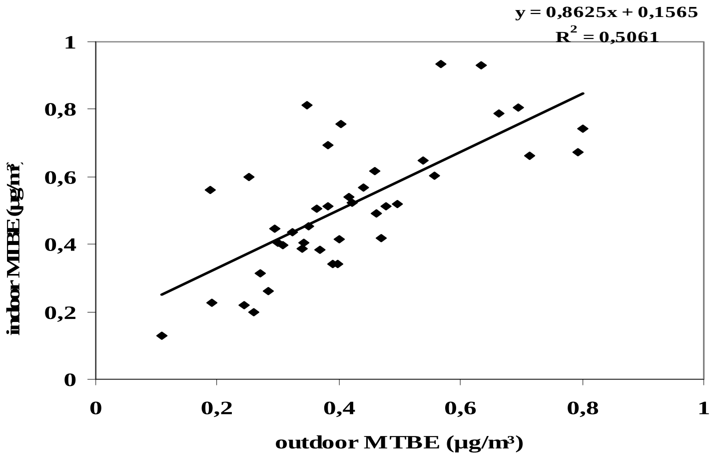

Figure 1: Indoor versus outdoor MTBE concentrations in 42 houses without indoor sources of MTBE. The average infiltration factor FINF is defined as the slope of indoor versus outdoor MTBE.

The indoor generated concentrations of pollutants (C_{ig}) were calculated for each dwelling individually, using an average $F_{INF,\ MTBE}$ factor (0,86; 95% CI: 0,59-1,13). It should be kept in mind that the individual $F_{INF,\ MTBE}$ values may differ between houses. However, dwelling type and ventilation frequencies, building properties (isolation, single versus double glass windows) did not statistically affect I/O MTBE ratio's. It was thus not feasible to stratify $F_{INF,\ MTBE}$ for building type and ventilation classes due to the limited dataset of houses in this study.

The pollutant with the largest median C_{ig}/C_i ratio was formaldehyde ($C_{ig}/C_i = 0.85$) and the pollutant with the lowest C_{ig}/C_i was benzene ($C_{ig}/C_i = 0.34$). For each component, rather large deviations from this median value was observed (e.g. formaldehyde P25 of $C_{ig}/C_i = 0.71$ and P75 of $C_{ig}/C_i = 0.91$; for benzene: P25 of $C_{ig}/C_i = 0.22$ and P75 of $C_{ig}/C_i = 0.55$). This is not surprising given the wide spread in possible indoor sources between individual dwellings. Notwithstanding the dominance of indoor sources to indoor formaldehyde concentrations pointed out by this indirect MBTE infiltration method, the statistical analyses between indoor sources, building and ventilation characteristics and measured concentrations did not reveal significant relationships for formaldehyde. Also for other pollutants, the statistical relations between indoor sources and measured concentrations were generally poor. The most important significant relations were the significant effects of (1) smoking on C_i and C_{ig} of toluene, (2) use of glue and stain removers on C_i and C_{ig} TVOC and (3) use of sealing products on C_i and C_{ig} benzene.
The MTBE infiltration method was not successful to estimate C_{ig} for NO_2 and PM10.

The typical exposure for children is calculated based on median concentration in each micro-environment and average time patterns. Typical children's exposures attributed 0,52 – 0,71 µg MBTE/m³, 1,9-2,7 µg benzene/m³, 0,17-0,23 µg trichloroethene/m³, 6,3-7,5 µg toluene/m³, 0,24-0,48 µg tetrachloroethene/m³, 0,9-1,4 µg ethylbenzene/m³, 2,0 – 2,9 µg m+p xylene/m³, 0,10-0,70 µg styrene/m³, 0,8-1,1 µg o-xylene/m³, 1,6-2,3 µg 1,2,4-trimethylbenzene, 0,1-0,9 µg p-dichlorobenzene, 410-522 µg TVOC/m³, 19-34 µg NO_2/m³, 15-25 µg formaldehyde/m³, 10-27 µg acetaldehyde/m³ and 8-13 µg PM10/m³. These ranges of typical exposure refer to variation in typical exposure for different age classes (0-2,5 years, 2,5-6 years, 6-12 years, 12-18 years) and proximity of the houses to traffic density (UB, RB, HS). The differences in typical exposure between different age classes and traffic density classes were rather small. It was assessed that the highest exposed children (P95) were 2-4 fold higher exposed than the median, typical exposed children for most gases. Exceptions were tetrachloroehtene (x11), and p-dichlorobenzene (x 50). These extremes were related to the extremely large range of indoor concentrations (Table 1).

The distribution of exposure over ambient (A: $A_i + A_{o,;,}$ with A_o, exposure to ambient pollutants directly in outdoor environment and Ai, exposure to ambient pollutants that have infiltrated indoors)), indoor source-related (N) and exposure during transport (TR) is given in Figure 2 for TVOC and for the 2 components with the most extreme A,N, TR distribution profiles (except for MTBE, NO_2 and PM).
For other pollutants, either ambient exposure dominated typical personal exposure (for MTBE, trichloroethene, tetrachloroethene), or indoor sources exposure (toluene, ethylbenzene, m+p xylene, styrene, o-xylene, 1,2,4-trimethylbenzene, p-dichlorobenzene) dominated the personal exposure. Exposure during transport was for most components below 5 % to the total personal exposure and varied from < 2% (tetrachloroethene) to 15 % (MTBE).

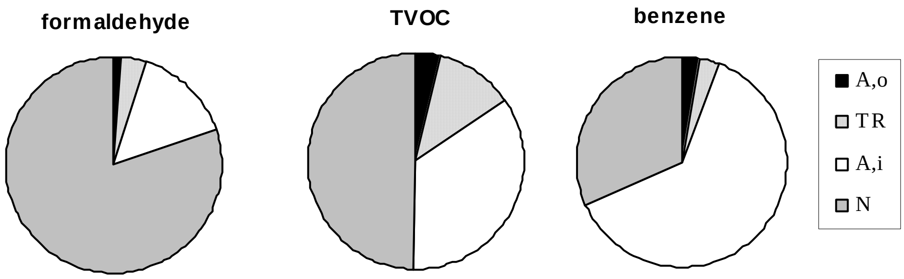

Figure 2: Distribution of typical exposure to formaldehyde, TVOC and benzene over ambient, non-ambient (indoor sources) exposure and exposure during transport.

DISCUSSION

Indoor concentrations of benzene, toluene, o-xylene, ethylbenzene, trimethylbenzene,… in Flemish dwellings were generally within ranges reported previously elsewhere [7,8]. In contrast, the low indoor-outdoor PM ratio of this study (mean I/O ratio: 0.3) are not in line with previous studies [9] and could not be explained.

The use of MTBE as infiltration tracer is relatively new, and this MTBE based infiltration method gives realistic values of F_{inf} for dwellings, in accordance with infiltration factors reported by others using other tracers (e.g. F_{inf} based on sulphate = 0,7 (90 % CI: 0,5-0,9) [5]. The intercept of the MTBE indoor versus outdoor graphs refers to small residual (background) MTBE concentrations in houses. Similar background concentrations were also found for SO_4 [10]. However, the MTBE based infiltration factor was not applicable to discriminate indoor and outdoor generated NO_2 and PM10 concentrations in this study. The inappropriateness of MTBE to estimate the infiltration of PM and NO_2 probably lies in different penetration factors and/or removal/sorption rates or, in the extreme low indoor-outdoor ratio's for PM10. The 95 % CI of F_{INF} (0.59-1.13) indicates that there is a further need to refine F_{INF} for different dwelling types with respect to ventilation. A larger dataset than the one of this study is needed hereto.

Children’s exposure is mainly determined by indoor dwelling exposure given the majority of time spent indoors. Variation in exposure between children is mainly due to variations in indoor dwelling concentrations (up to 100-fold), rather than variations in children’s time budgets, which are limited.

This study shows that the contribution of infiltrated outdoor air pollution to personal exposure is different among investigated pollutants. This is a point of attention in ambient air quality policies, to include the indoor exposures more explicit. Recommendations for precautionary measures to reduce or avoid exposure indoor exposure to certain gases, for example for formaldehyde, are difficult to make based on this study because only few clear source-concentrations-exposure relationships were found. For this, work on short-term and long-term emission sources and their relation to concentrations, using various time average measurements should be performed. This is best placed in the context of product policy.

ACKNOWLEDGEMENT

The authors wish to acknowledge the Flemish Environment, Nature and Energy Department, Environment and Health Unit for financial support to this study.

ABSTRACT

The buildings' environment plays a very important role in health matters and the quality of life.

A series of experimental measurements were carried out in the residential sector of the greater region of Athens. Parameters influencing the indoor air quality such as particles, CO, CO2 and total organic compounds (TOCs) concentrations were monitored. Thermal and acoustic comfort as well as characteristics linked to the type, size and existing thermal insulation materials of the buildings were investigated.

INTRODUCTION

It is well understood that since 70 per cent of a humans' time is spent indoors, indoor air pollution may pose a serious threat to human health. Indoor air pollution can be caused by outdoor and/or indoor sources as well as anthropogenic activities. There are many studies on this topic which refer primarily to the air pollution aspect and secondarily on its impact on health. The evidence of indoor air pollution and its impact on public health is consistent in showing adverse health effects at exposures that are currently experienced by urban populations in both developed and developing countries. The range of health effects is broad, but is predominantly to the respiratory and cardiovascular systems. All population is affected but susceptibility to the pollution may vary depending on the age and health condition of the subjects. The risk has been shown to increase with exposure and there is little evidence to suggest a threshold below which no adverse health effects would be anticipated.

Recently the research interest is focused on the indoor concentration of pollutants such as particulate matter, carbon monoxide, carbon dioxide and total volatile organic compounds. Naturally the evaluation of the indoor environment is also affected by the outdoor regime.

The sources of indoor pollution and its impact has been a research topic in a great number of studies. In particular detailed research on the impact tobacco smoking on human health was discussed by Rushton (2004). Indoor air quality measurements performed in the work environment in Greece (Lagoudi et al, 1996, 1996a, Bernhard et al, 1995), followed by similar studies in schools (Synnefa et al, 2004, Chaloulakou and Mavroidis, 2002), hospitals (Santamouris et al, 1994) and residences (Baya et al, 2004, Alexopoulos et al, 2006, Lai et al 2006) report a number of pollutants including black smoke, nitrogen dioxide, volatile organic compounds, PM10 and PM2.5.
The present work takes into account both outdoor and indoor measurements as well as the type and characteristics of the buildings under investigation. The measurements

presented here extend to over seventeen private residences in a number of different locations in Athens.

EXPERIMENTAL CAMPAIGN

The experimental campaign incorporates automated instrumentation placed for short periods in and around seventeen private buildings. The details of these buildings are shown in table 1.

No	Cite	Location	Area (m2)	Building type	Inhabitants number	Specific remarks
1	Drafi	Rural	240	Detached house	2	Non smokers
2	Ekali	Suburban	100	Apartment	1	Non smokers

16	Nea Ionia	Urban	110	Detached house	2 (+2 children)	Smokers
17	Nea Ionia	Urban	110	Detached house	3	Non smokers

The instrumentation included monitors of the determination of particulate matter with dynamic diameter 10, 2.5 and 1 μm (PM10, PM2.5, PM1), total volatile organic compounds (TVOCs), carbon monoxide (CO) and carbon dioxide (CO2).

The instrument used to collect the particulates is a lightweight personal sampling device consisting of a single-stage impactor and a final filter. Aerosol particles are sampled through the single-stage impactor to remove particles above the cut-point, which is either 2.5 or 10 μm aerodynamic equivalent diameter, depending on which a sampling head is chosen. Particles smaller than the cut-point are collected on a 37mm

diameter filter. The impactor uses the principle of inertial separation of airborne particles.
Measurements of carbon monoxide, carbon dioxide and TVOCs have been performed using a multigas analyser. The gas analyser is a highly accurate, reliable and stable quantitative gas monitoring system. By installing up to five filters in the analyser, it can measure the concentration of up to five component gases and water vapour in any air sample. Although the detection limit is gas-dependent, it is typically in the 10^{-2} ppb region. The analyser has a built-in pump system that allows samples to be drawn from up to fifty metres away.

RESULTS

The results are conveniently divided into two categories: homes without smokers and homes with smokers.

Non smoking residences

A guideline for the carbon dioxide concentration limit has been set by the American Society of Heating, Refrigerating and Air Conditioning Engineers (ASHRAE). This allowance is 1000 ppm for schools, offices, and areas where people spend extended periods of time indoors. The Federal Standard for exposure limits of carbon monoxide in the home is 50 ppm. The Environmental Protection Agency (EPA) standard for ambient air is 9 ppm averaged over an eight-hour period and 35 ppm for one hour.
The mean measured concentrations of the carbon dioxide, carbon monoxide and total volatile organic compounds are shown in Figure 1. The average indoor concentration varied between 350 and 610 ppm for all residences without smokers, however measurements of the maximum indoor CO2 concentration showed that 85% of the buildings were below the 1000 ppm limit.

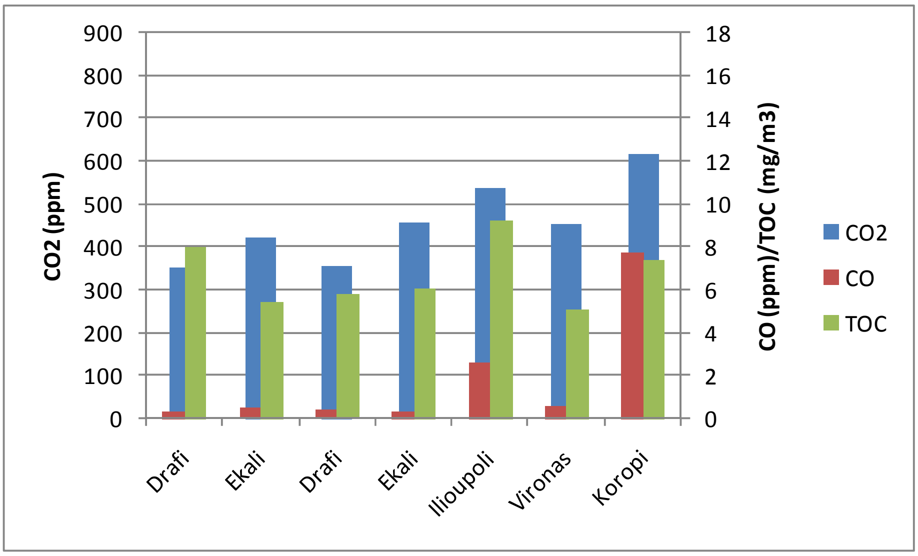

Figure 1. Mean concentration of carbon dioxide, carbon monoxide and total volatile organic compounds for houses without smokers

The mean carbon monoxide concentration did not exceed the 9 ppm limit in any of the residences tested. The maximum carbon monoxide concentration showed that approximately 16% of the buildings were above the limit.
The mean concentration of the total volatile organic compounds (TVOC's) in the non smoking homes was between 5 and 9 mg/m^3, while the absolute maximum measured concentration reached 15 mg/m^3. According to Molhave (1990) the maximum permitted concentration for TVOC's depends on the health consequences. It is considered that indoor concentrations below 0.2 mg/m^3 do not pose any threat for the human health, while concentrations between 0.2 to 3 mg/m^3 may cause discomfort when in combination with other environmental problems. Concentrations higher than 3 mg/m^3 have been shown to cause respiratory problems.
The existing air quality standards for PM_{10} entered into force on 1 January 2005 (Directive 1999/30/EC). The daily limit is 50 microgrammes per cubic metre (averaged over 24 hours) and the annual limit 40 microgrammes per cubic metre. This limit can be exceeded for up to 35 days a year taking account unusual and adverse weather.
The limit on $PM_{2.5}$ concentrations introduced by WHO Air Quality Guidelines is 25 micrograms per cubic metre, 24-hour mean. On the contrary, limits on PM1 concentrations do not exist.

The measured concentrations of PM10, PM2.5 and PM1 in the non-smoking residences are shown in figures 2-4. On average the concentration of PM10 was approximately 42.5 μg/m3 and the mean concentration of PM2.5 and PM1 was 31.8 μg/m3 and 25.2 μg/m3 respectively.

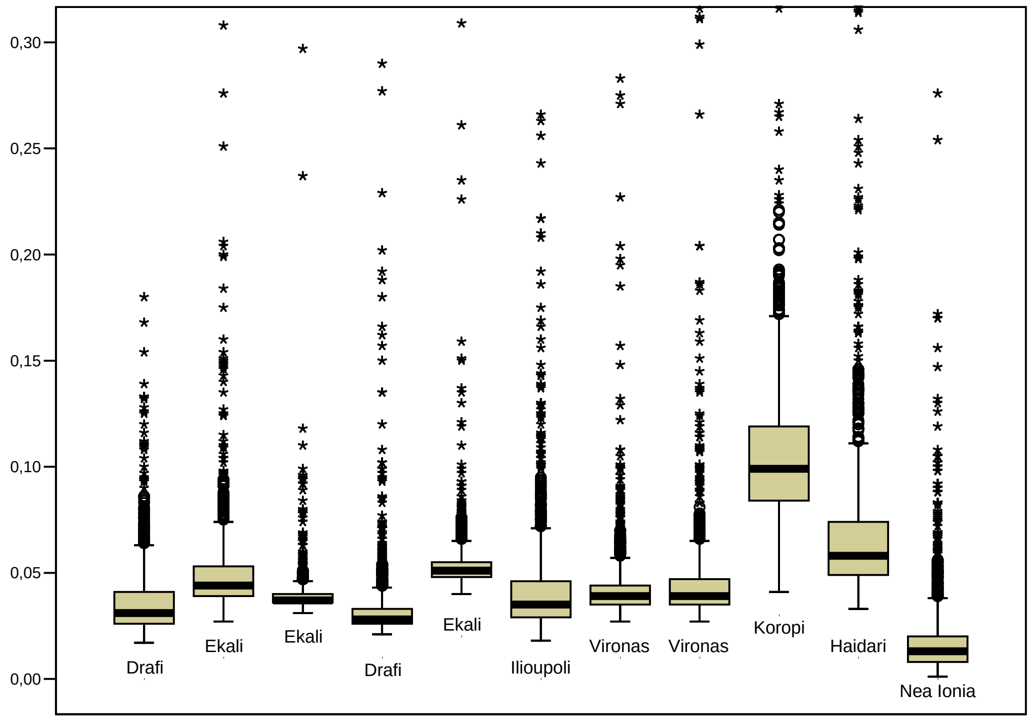

Figure 2. PM10 concentrations in the non-smoking residences (in mg/m^3)

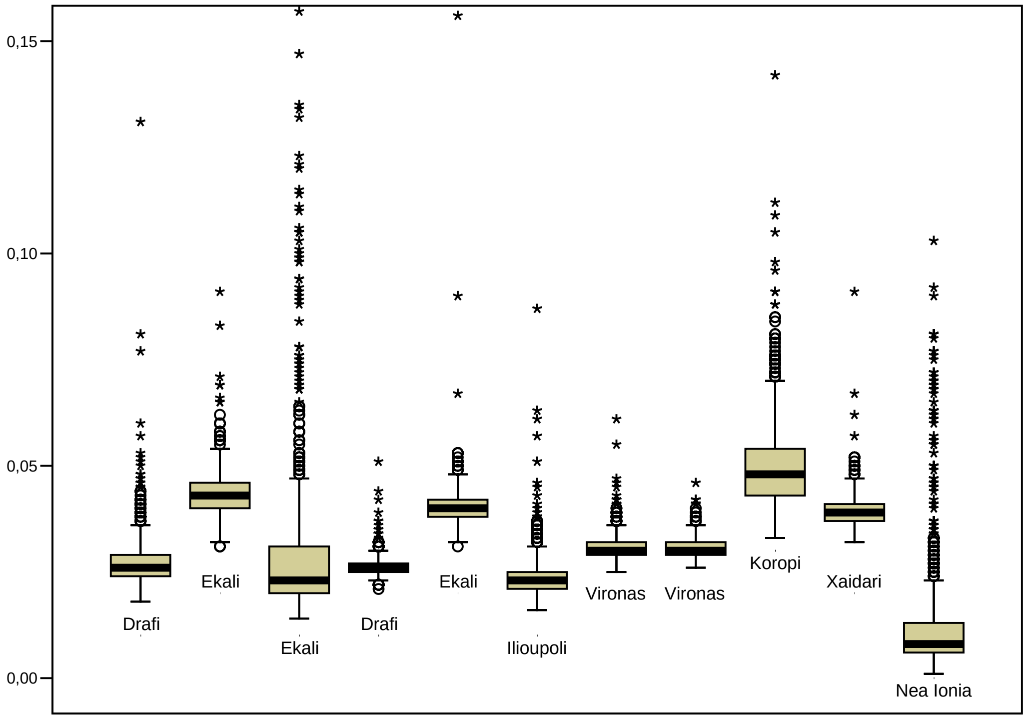

Figure 3. PM2.5 concentrations in the non-smoking residences (in mg/m^3)

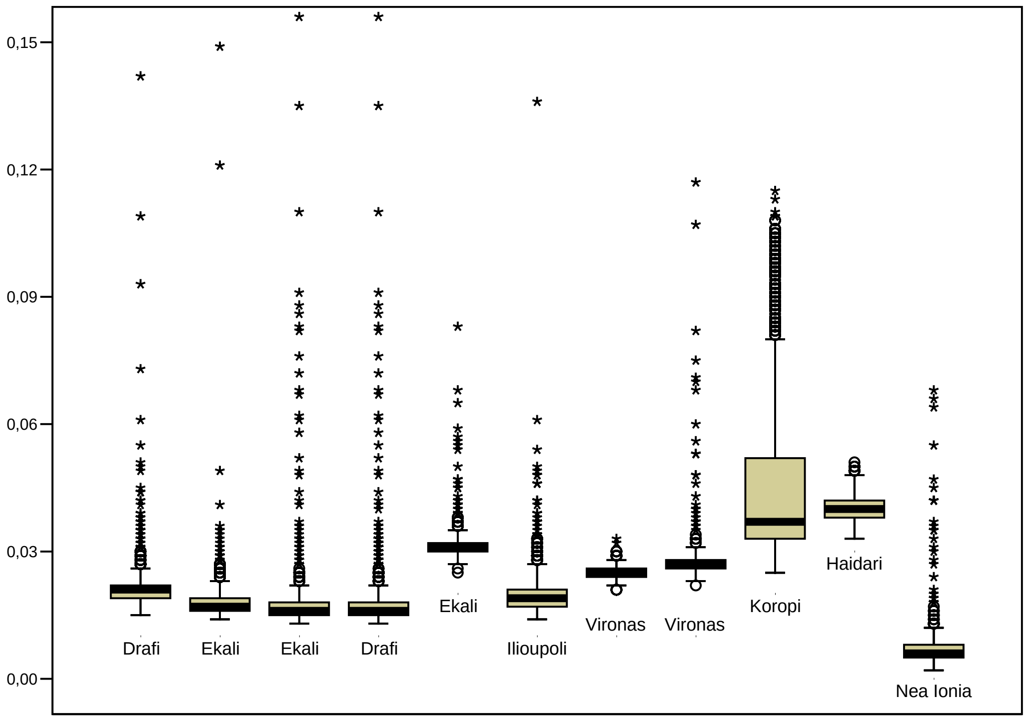

Figure 4. PM1 concentrations in the non-smoking residences (in mg/m^3)

In the majority of the non smoking residences (approximately 72%) the concentrations of PM10 measured were below the 50 µg/m3 limit, while 28% presented PM10 concentrations ranging from 50 to 90 µg/m3. Measurements

performed in dwellings in Beijing found that the mean indoor PM_{10} concentration was 109.9 μg/m3, (Houyin, Z. et al, 2005)
Measurements of the PM2.5 concentrations, however, showed that only 18% of the residences were below the limit of 25 μg/m3, 63% of the buildings ranged from 25 to 50 μg/m3 and 19% of the buildings reached 70 μg/m3. Measurements performed in 20 residences in California found that the median $PM_{2.5}$ concentrations were 32.2 μg/m3, (Sawant et al, 2004).
It is important to mention here that the PM1 concentrations showed that 71% of the residences were below 30 μg/m3, while 29% were between 30 and 70 μg/m3.

Smoking residences
Tobacco smoking is a major source of indoor carbon dioxide and contributes highly to indoor TVOC's concentration (Santamouris et al., 2006).
The mean measured concentrations of the carbon dioxide, carbon monoxide and total volatile organic compounds are shown in Figure 5. The average indoor concentration varied between 450 and 810 ppm for all residences with smokers however, measurements of the maximum indoor CO2 concentration showed that approximately 33% of the buildings were above the 1000 ppm limit.

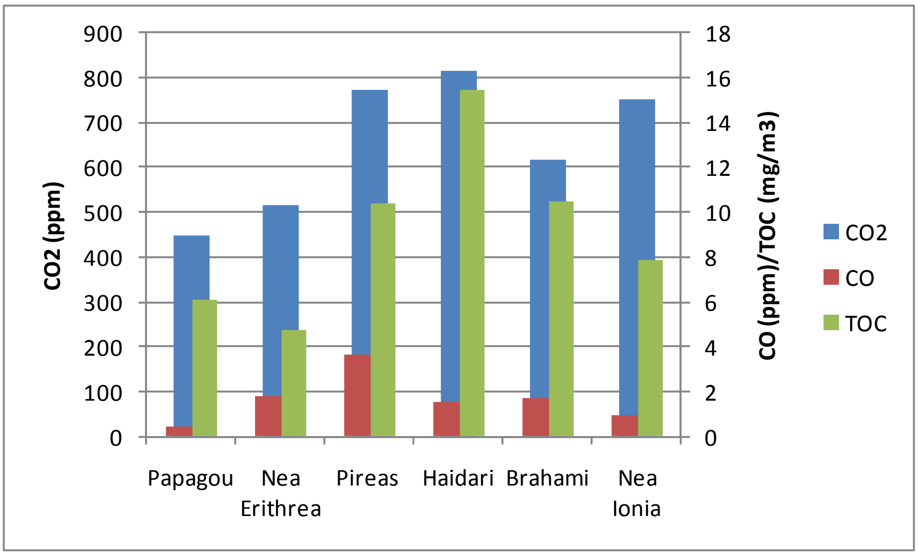

Figure 5. Mean concentration of carbon dioxide, carbon monoxide and total volatile organic compounds for houses with smokers

The mean carbon monoxide concentration did not exceed the 9 ppm limit in any of the residences tested. On the contrary, the maximum carbon monoxide concentration showed that approximately 50% of the buildings were above the limit.
The mean concentration of the total volatile organic compounds (TVOC's) in the smokers' homes was between 5 and 15 mg/m^3, while the absolute maximum measured concentration reached 37 mg/m^3.
The measured concentrations of PM10, PM2.5 and PM1 in the smokers' residences are shown in Figures 6-8. On average the concentration of PM10 was approximately 105 μg/m3 and the mean concentration of PM2.5 and PM1 was 224 μg/m3 and 131 μg/m3 respectively.
In the case of residences with smokers the majority of the buildings present very high PM10 and PM2.5 concentrations. In approximately 67% of the buildings the PM10

and PM2.5 concentrations exceeded 100 µg/m3, while in 33% of the buildings were 50 µg/m3.

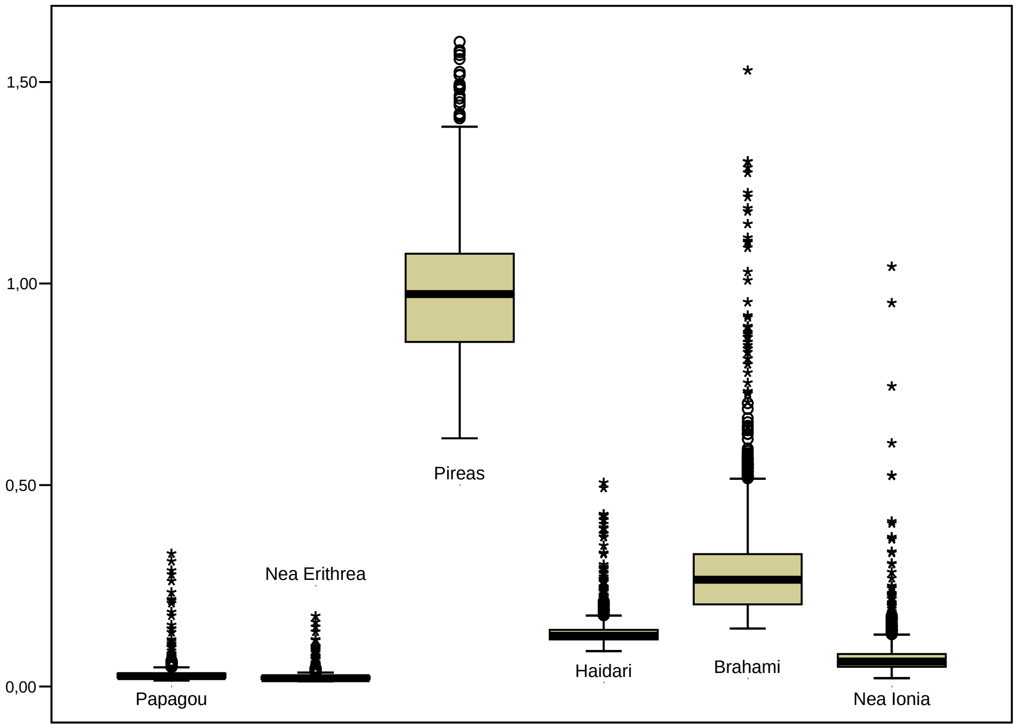

Figure 6. PM10 concentrations in the smoking residences (in mg/m^3)

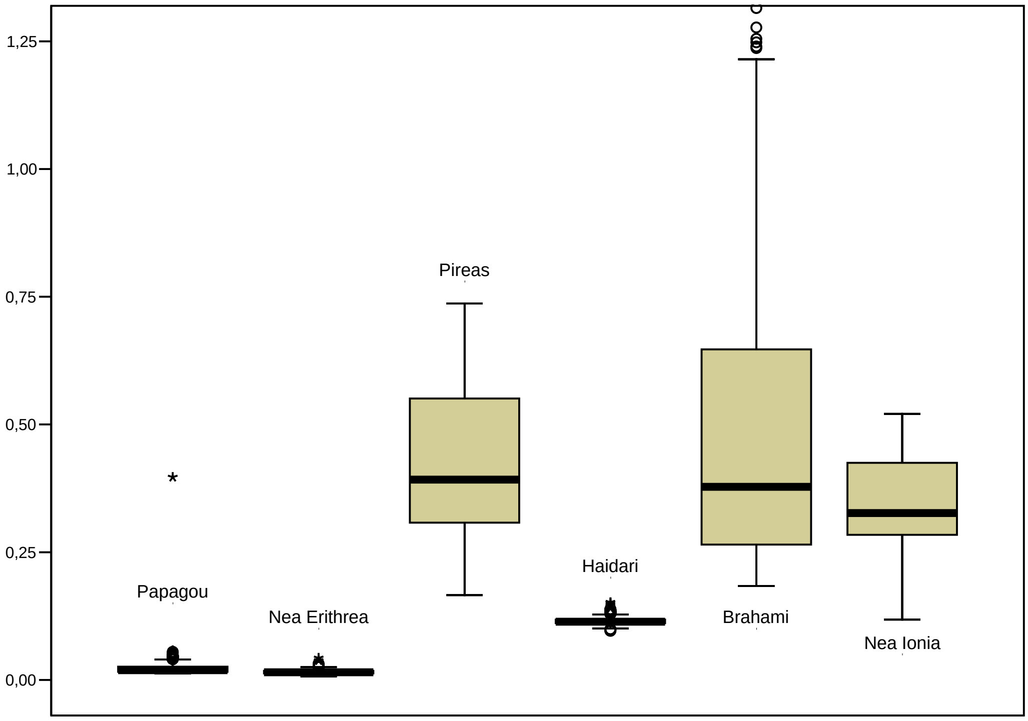

Figure 7. PM2.5 concentrations in the smoking residences (in mg/m^3)

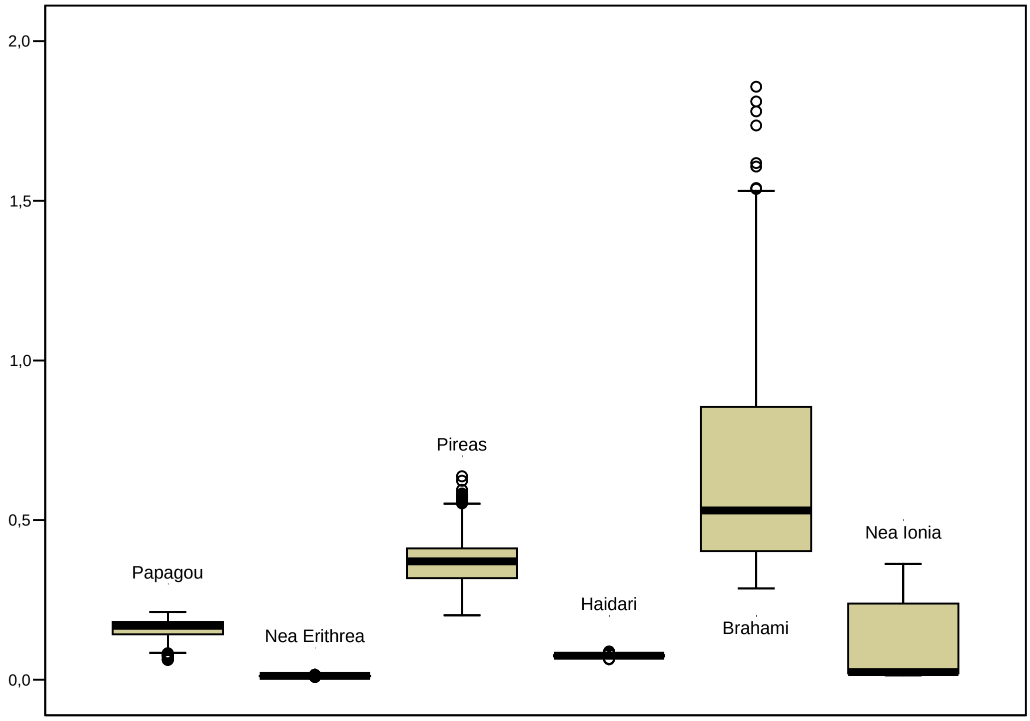

Figure 8. PM1 concentrations in the smoking residences (in mg/m^3)

Measurements of the PM1 concentrations however showed that only 17% of the residences were below 50 µg/m3 and in 83% of the buildings the concentrations measured were higher than 100 µg/m3. The above levels are very high and may pose a serious threat for the health of the residents.
For the PM2.5 almost 24 % of the dwellings present a concentration below 50 µg/m3, while the 64 % are below 100 µg/m3. The ratio between PM2.5/PM10 varies between 0.2 to 0.8. Measurements performed in 20 residences in California found that the median $PM_{2.5}$ concentrations were 32.2 µg/m3, (Sawant et al, 2004).

CONCLUSIONS

Measurements of the indoor concentration of CO2, CO, TVOC's and PM10, PM2.5and PM1 quality in seventeen buildings have been performed in the greater area of Athens, Greece. The main conclusions are :

- CO2 concentration measurements showed that in houses with smokers the 1000 ppm limit was exceeded in more cases than in houses without smokers. On average, buildings without smokers were found to have lower CO2 concentrations than the 600 ppm limit.
- Concerning the average CO levels, the 9 ppm limit is not exceeded in any case. Maximum carbon monoxide concentrations increase highly as a function of smoking levels inside the dwellings.
- The mean total volatile organic compounds (TVOC's) measured in all homes was above 5 mg/m^3. The absolute maximum measured concentration for residences without smokers did not exceed the limit of toxicity of 25 mg/m^3 while this was not the case for the houses with smokers.

- In the majority of the non smoking residences the concentrations of PM10 measured were below the acceptable limit however the PM2.5 concentrations showed that only 18% of the residences were below the acceptable limit. The highest measured PM2.5 concentration did not exceed 70 μg/m3. PM1 concentrations showed that 71% of the residences without smokers were below 30 μg/m3, while 29% were between 30 and 70 μg/m3.
- All the smokers' residences had concentrations of PM10 and PM2.5 exceeding the acceptable limits while in most cases the measurements approached the 100μg/m^3 mark. PM1 concentrations in only 17% of the residences with smokers were below 50 μg/m3 and in 83% of the buildings the concentrations measured were higher than 100 μg/m3.

In conclusion it is obvious that indoor pollution in homes has a major significance in the health and well being of their inhabitants. There is an unmistakable effect of tobacco smoking in the indoor air quality of dwellings and measurement clearly show non-smokers homes to have a cleaner environment with fewer adverse effects due to indoor air pollution.

SUMMARY

Controlled milling of natural source materials has led to establishment of an allergen carrier particle sample bank for common, indoor, allergen proteins. Allergen "reference" powders are obtained from controlled processing of spent dust mite culture, roach colony fras, and cat and dog fur samples from pet grooming establishments. Due to wide variations in parent material particle size, shape, hardness or tensile strength, different milling prescriptions are required to produce appreciable yields of suspendable particles in the 0.5 - 20 µm size range with substantial mass fractions less than 12 µm. Characterization data includes: mass fraction and number particle size distributions determined by optical scattering and inertial impactor methods; particle morphology as determined by scanning electron microscope examination; allergen concentrations determined by immuno-assay enzyme-linked analysis (ELISA); inhalation exposure risk analysis of the powders as reservoir dusts. Certified quartz powders (99% < 10 microns) and Bacillus Thuringiensis spores serve as reference powders.

INTRODUCTION

Epidemiological studies report significant increases in health care and hospitalization of patients for respiratory system related diseases, such as asthma, over the last 35 years [1-3] According to the Center for Disease Control and Prevention, approximately 5 - 6 % of all Americans suffer from asthma and approximately 5000 people die each year of asthma related complications. The economic burden of this illness in the United States is estimated at $12.7 billion dollars per year[1]. The allergic response disease trends appear to be mirrored in urban societies globally[2].

Allergic response and asthmatic disease symptoms may be triggered in genetically predisposed individuals and developed in non-atopic individuals by repeated exposure to allergens. The link between allergic response diseases and common indoor allergens is based on epidemiologic investigations of allergic response related hospital visitations, environmental measurements of protein allergen levels in building reservoir dusts of asthmatic populations, and specific IgE antibody levels in identified allergic and asthmatic populations [4, 5].

Indoor allergens are most often specific protein structures associated with cat and dog fur and saliva, cockroach and dust mite droplets and body parts, mice urine, as well as some fungi. These sources contribute allergens to the reservoir dusts of building surfaces, either in standalone particulates or, upon mechanical and microbial disintegration of parent particles, as adherents to "inert" dust particles. When disturbed and aerosolized by human activity the allergen containing reservoir dusts become available for inhalation exposure with resultant allergic sensitization and bronchial hyperresponsiveness disease development, i.e., asthma, in susceptible individuals. Protein allergens have molecular weights in the tens of thousands of Daltons and sizes in the nanometer range, but are associated with micron sized “carrier” particles in building dusts (See Figure 1).

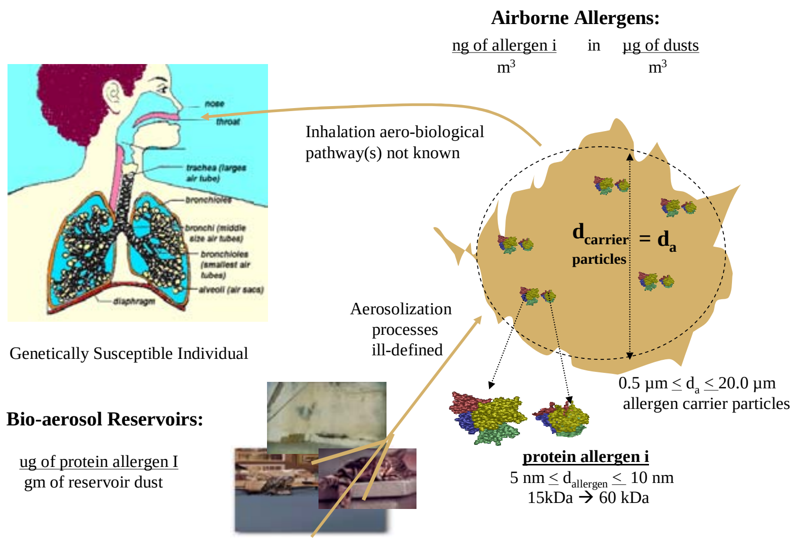

Figure 1: Allergens are “Carried” by Micron-Size Particles in Indoor Environments

The lack of quantified aerobiological exposure pathways obtained under controlled parameter conditions is limiting our understanding of the “distribution of inflammation and airway obstruction” processes associated with allergic and asthmatic responses to indoor environment allergens. The allergen inhalation exposure problem is a subset of the general indoor air problem of exposure to PM_{10} and $PM_{2.5}$ contaminant containing particles. Pesticide and insecticide containing carrier particles in indoor environments present a similar challenge[6, 7]. The disparity in particle resuspension parameters reported in estimating inhalation exposure dosages is perhaps most indicative of the current state of knowledge [8, 9].

Limited particle-size-resolved data reduces greatly our knowledge of what is “actually deposited in upper and lower respiratory tracts…” and the aerobiological pathways leading to inhalation exposure[3, 10, 11]. As a result, epidemiologic risk factors, for inhalation based sensitization, are based on allergen concentrations in reservoir dust samples for bulk samples of particles sizes < 150 microns (See Table 1). A more quantitative description of the resuspension and depositions processes of naturally occurring allergen carrier particles is required.

Table 1: Risks relative to allergen concentration in reservoir dusts[12]

Risk of Sensitization for Atopic Children	Mite Group 1 µg/g	Fel d 1 µg/g	Can f 1 µg/g	Bla g 1 U/g	Bla g 2 µg/g
High	>10	1-8	1-8	>8	>1
Medium	2-10	8-20	8-20	1-8	0.08-0.4
Low	<0.3	<0.2 or >20	<0.2 or >20	<0.6	<<0.08

Site-to-site property variations in reservoir dust samples, low mass fractions of samples having particle sizes with low settling velocities, and the limited sensitivity of standard ELISA techniques for determining allergen concentrations of a sample, restricts the usefulness of field collected samples.

A set of allergen "reference" dusts with reproducible characteristics with substantial allergen concentrations for ELISA measurement allergen tracking - but derived from natural source materials -is needed. These powders are then utilized to establish reference resuspension and aerodynamic behavior, filtration susceptibility and protein denaturing properties of the allergen proteins in natural material carrier particles.

The objectives of this specific effort are to:

1.) determine the feasibility of establishing reproducible methods of making samples of air suspendable allergen carrier particles in the 0.5 to 20 micron size range from natural allergen source materials;
2.) characterize the resultant powdered samples with respect to size distribution parameters, particle shapes, allergen concentration, and respiratory system deposition probability properties.

METHODS

Spent mite dust culture is provided by Indoor Biotechnologies Corporation (M. Chapman) and is the source of the initial dust mite target allergen (Der p 1). Laboratory roach colonies of both German and American and the resultant fras is the source of the roach allergens (German: Bla g 1, Bla g 2; (American: Per a 1 -cross reactive to Bla g 1). Cat and dog fur parent materials from pet grooming established are utilized as sources of target canine (Can f 1) and feline (Fel d 1) allergens.

Considerable differences in parent source material particle sizes, shapes, hardness and/or tensile strength necessitate very different sample milling prescriptions to obtain air suspendable powders. Organic based materials are easily over milled, producing large mass fractions of micron and sub-micron particles with significant agglomerating tendencies. For particles sizes of interest in indoor air quality, one wants to mill samples so that the resultant powder has significant mass fractions between 1 and 20 microns, with a large mass fraction < 12 microns. It is these particles that are most frequently observed in investigations of airborne PM_{xx} investigations, contain identified protein allergens, are most susceptible to iterative deposition and resuspension during occupant activities. During the milling process, sample temperatures must be kept low, so that thermal denaturing of any indigenous protein allergens does not occur. Depending on the size characteristics and physical properties of the parent source material, the starting material may be subjected to some initial shredding.

Optical particle counting, inertial separation and scanning electron microscope techniques are implemented to characterize the allergen-containing powders for their size distribution, shape and surface roughness. Specific allergen contents (Der p 1, Bla g 1, Bla g 2, Can f 1, Fel d 1) of the "reference dusts" are determined by enzyme linked, immunoassay techniques (ELISA). The particle size resolved allergen content distribution allows potential respiratory system delivery profiles to be quantified. Figure 2 displays the overall allergen, carrier particle powder production process.

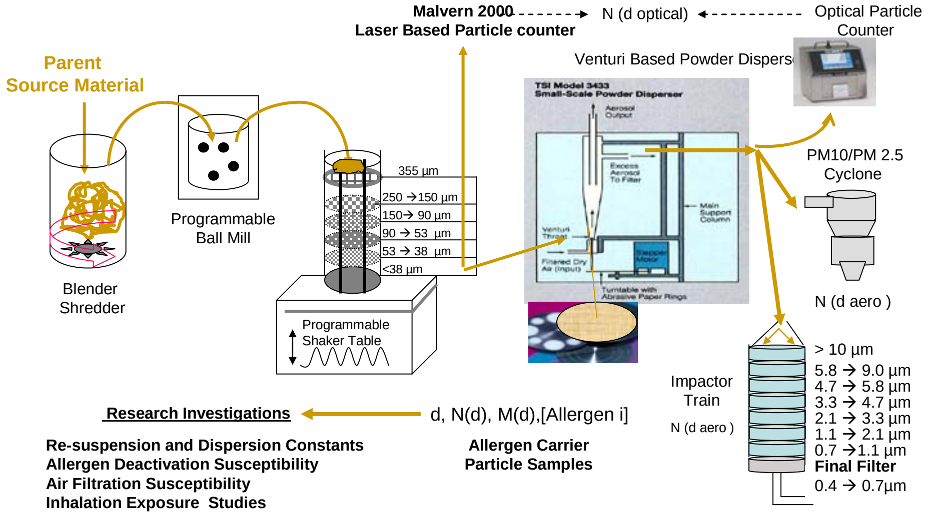

Figure 2: Allergen - Containing Carrier Particle Powder Production

RESULTS

The milled powders are subjected to optical particle size analysis using a Malvern Mastersizer 2000 which employs a He-Ne laser and blue light sources for scattering. The system is configured for detection of 0.058 to 878 microns in 64 size bins. Samples are generally subjected to sonic probe or sonic bath treatment immediately before analysis to minimize small particle agglomeration tendencies. Table 2 shows the overall particle size characteristics of the milled dust samples as well as that determined by the Malvern Mastersizer 2000 for the certified quartz reference powder and the Bacillus Thuringiensis spore powders provided by the US Army CHPPM.

Table 2: Particle Size Properties of Milled, Quartz Dust, and B.T. Spores

Sample Type	Mastersizer 2000 Determined Diameters (microns)				
	Volume Mean	Area Mean	Volume 0.X mass fraction below d (µm)		
	D[4,3]	D[3,2]	D[v,0.1]	D[v,0.5}	D[v,0.9]
Quartz Ref.	4.14	2.08	0.91	2.98	9.07
B.T. Spores	11.14	3.14	1.15	8.77	24.50
Dust Mite (I)	13.75	5.82	2.23	12.93	25.84
Dust Mite (II)	13.00	3.48	1.63	12.24	25.41
Roach Fras (I)	22.26	2.54	2.65	18.74	47.18
Roach Fras (II)	30.39	3.38	1.06	17.84	77.49
Dog Fur (I)	26.46	2.88	1.75	13.93	62.27
Cat Fur (1)	37.56	2.89	1.78	19.1	91.95

To insure consistency, mass mean sample determinations were calculated and compared to the instrument based volume mean samples, D[v,0.5] values. The specific gravity of the dust mite samples were determined experimentally, but the other allergen dust samples specific gravities were estimated. The specific gravity of the quartz reference dust samples were provided with the certification documentation from the vendor.

ELISA determined specific allergen content of the powders are shown in Table 3. These concentrations are generally high relative to the mixed dust samples from field studies, allowing the samples to be used in particle resuspension, filtration and protein denaturing studies while avoiding "inert" dust sample masking of the allergen carrier particle behavior. Extensive examination of the mite powders in size bins in the 1 to 10 μm range revealed about 25% variation in allergen concentrations around the mean shown. Other samples have not yet been examined for particle size allergen content variation in the milled powders.

Table 3: ELISA Allergen Concentrations of Samples

Sample Type	Mass Fraction d < 12 μm	D[v,0.5]= 50% sample d cutoff (μm)	Calculated Mass Mean (μm)	ELISA Allergen i μg i/gm dust
Quartz Ref.	0.96	2.98	4.47	NA
B.T. Spores	0.69	8.77	10.32	NA
Dust Mite (I)	0.47	12.93	14.84	4092 Der p 1
Dust Mite (II)	0.5	12.24	14.03	4180 Der p 1
Roach Fras (I)	0.36	18.74	24.02	448 Bla g 2
Roach Fras (II)	0.45	17.84	25.19	340 Bla g 2
Dog Fur (I)	0.47	13.93	20.66	3.4 Can f 1
Cat Fur (1)	0.39	19.1	22.08	75.6 Fel d 1

Some samples were analyzed with and without powder disaggregating sonic treatment (Table 4) to determine the agglomerating tendencies of the milled samples, relative to the quartz reference dusts and the US Army provided Bacillus Thuringiensis spore samples. The quartz samples are not expected to agglomerate significantly whereas it is know that pure spore samples display agglomerating behavior.

Table 4: Agglomerating Tendencies of Samples

	Mass Fraction	Charcteristic Diameters (microns)			
Sample ID	d<12 microns	Mass Mean	Volume Mean	D[v,0.1]	D[v,0.5}
Quartz Reference wo*	0.95	4.73	4.38	0.95	3.14
Quartz Reference w	0.96	4.47	4.14	0.91	2.98
B.T. Spores wo Sonic	0.53	14.72	13.64	2.49	11.54
B.T. Spores w Sonic	0.69	10.32	11.14	1.15	8.77
Dust Mite (I) Culture wo	0.05	52.73	48.85	19.54	43.15
Dust Mite (I) Culture w	0.02	51.63	47.83	15.30	41.69
Milled Cat Powder wo	0.11	32.99	50.83	10.44	45.89
Milled Cat Powder w Probe	0.43	18.4	17.04	1.00	14.74
Milled Cat Powder w Bath	0.37	19.76	18.34	1.16	16.61

* w = with sonic treatment, wo = without sonic treatment

As expected the quartz showed little aggregation tendency whereas the B.T. spores showed significant aggregation as evidenced by the shift to a higher mass fraction of particles below 12 μm upon sonication and lower calculated mass mean, volume mean and D[v,0.x] diameters. The ~50 μm mass mean, nearly spherical, parent, mite culture particles, showed little aggregation tendencies, although the resultant milled dust displayed some aggregation propensities. Cat fur milled samples displayed the largest aggregation tendencies, as exemplified by the large shifts in mass fractions less than 12 microns and characteristic diameter properties of the samples when some form of sonication is utilized - the sonic probe treatment being more intense than the sonic bath. The milled cat fur material is significantly more aggregating than any of the other milled powders from the other natural material allergen source materials. Subsidiary experiments with the cat and dog fur powders revealed a high electrostatic susceptibility relative to the other materials, again, with the cat fur showing the greater susceptibility.

Reservoir Contaminant Inhalation Exposure Propensities of Samples

Contaminant inhalation exposure risks for a given contaminant carrying reservoir dust can vary greatly for two reservoir dusts having the same bulk contaminant concentration. The variations are due to:

1.) particle size dependencies of surface-to-air aerosolization and resuspension;
2.) differences in contaminant carrier particle size distribution with the bulk dust sample;
3.) differences in particle size dependencies of the carrier particle contaminant mass fraction concentrations;
4.) particle size dependency of respiratory system deposition probabilities;
5.) settling and deposition velocities of the contaminant carrier particle sizes.

Aerosolization and resuspension properties (3 above) are disturbance and reservoir surface type dependent and are considered in latter studies performed with the sample dusts. One can then define a Reservoir Contaminant Inhalation Exposure Propensity (RCIEP) of a reservoir dust contaminated with species i as the joint probability of property probabilities related to 2 - 5 above. The RCIEP(d) for particles of size d having a mass fraction $f_{N,i}(d)$ particles in reservoir particles of size d + d(d), having a bulk sample normalized $f_i^I(d)$ chemical contaminant mass fraction, a respirable deposition probability RSDF(d) and a settling time factor of ST(d) in a size bin around around diameter d would be:

$$RCIEP_i(d) = RSDF_i(d)* f_{N,i}(d) * f_i^I(d) * ST_i(d) . \quad (1)$$

$f_{N,i}$ (d) is the number fraction of particles of diameter d in the reservoir dust, i.e., the number of particles in dust of size d containing contaminant “i” normalized by the total particle count in unit mass of reservoir dust.

$f_i^I(d)$ is the average concentration of contaminant i in size d normalized by bulk dust sample contaminant concentration.

RSDF(d) is a specific respiratory system location deposition probability associated with aerosol particle of size d and as calculated by International Commission on Radiological Protection (ICRP) are equations describing the particle size dependencies of these probabilities [13, 14]

ST(d) is the 8 foot fall, air suspension time of a particle of the given size, d, normalized by the time it would take a 5 μm particle of unit density to settle 8 feet at standard air conditions (~1 hour) and as calculated by standard settling velocity equations in still air.

In practice, it is difficult to distinguish between non-contaminant carrying, reservoir, dust particles of diameter d and contaminant carrier particles of contaminant d in reservoir d. The two particle types are indistinguishable.. "$f_i^I(d)$" is then the mass fraction of total reservoir dust contaminant mass measured found in the size range around diameter d, so that the final form becomes.

$$RCIEP_i(d) = RSDF(d) * f_N(d) * f_i^I(d) * ST(d). \qquad (2)$$

Summing over all available particle bins for which data is available:

$$RCIEPi,_{\text{reservoir dust}} = \Sigma_d\ [RSDF(d) * f_N(d) * f_i^I(d) * ST(d)]. \qquad (3)$$

A reservoir dust consisting of equal numbers of pure 1 ($f_i(d) = 1$)micron spores has a much greater respiratory deposition RCIEP index than a corresponding 5 micron spore dust, partially because of a greater respiratory system deposition probability, but mainly because of its greater air "hang time," ST(d) property, relative to 5 micron particles.

The milled samples can now be characterized according to their overall RCIEP for inhalation as well as thoracic and alveolar regional depositions. These index estimates assume the mass fraction of contaminant in the milled samples are not particle size dependent, that is $f_{i,}^I(d)$ scales with the mass fraction of the sample represented by the number particle fraction in that size bin. Preliminary analysis of size resolved dust mite samples indicates about 25% variation in allergen concentrations throughout the 1 to 10 micron regime. But this particle size variation of contaminant concentrations is not included in the analysis presented here.

Table 5: Reservoir dust contaminant inhalation exposure probabilities

Sample ID	Mass Fraction d< 12 microns	Σ_d RCIEP Indices Inhalation	Thoracic Deposition	Alveolar Deposition
Quartz Ref.	0.96	0.65	0.52	0.35
B.T. Spores	0.69	1.19	1.09	0.96
Dust Mite (I)	0.47	0.60	0.51	0.42
Dust Mite (II)	0.50	0.50	0.60	0.51
Roach Fras (I)	0.36	0.68	0.60	0.53
Roach Fras (II)	0.45	0.79	0.94	0.88
Dog Fur (I)	0.47	1.10	1.05	0.93
Cat Fur (1)	0.39	1.10	1.03	0.95

The results indicate that subtle differences in the particle size distributions of the reservoir dusts can have a significant impact of the contaminant inhalation exposure probability indices, even assuming a particle size independent contaminant mass fraction contaminant distribution. These subtle differences appear in the detailed investigation of the sample specific particle size distributions of the powders.

SUMMARY

Air suspendable particles with ELISA traceable specific allergen contents have been processed from controlled milling of naturally occurring materials. Sufficient quantities of powdered particulate matter is obtained to fully characterize the particles size distributions, particle morphologies and specific allergen contents. Given a specific natural material source, the powder properties of various production batches are reproducible within ~25%. The powders are being utilized to investigate the surface-to-air aerosolization, resuspension, filtration and allergen denaturing susceptibility properties of indoor allergen carrier particles. The powders are amenable to utilization in inhalation exposure chambers for controlled particle size - allergen concentration investigations.

ACKNOWLEDGEMENT

The authors thank Indoor Biotechnologies for providing raw dust mite culture and US Army Center for Health Promotion and Preventive Medicine for the B.T. spore samples and support.

SUMMARY

Clean indoor air is one of the most important factors for the welfare of the society. To understand and study the complex causality of different factors affecting indoor air quality, a databank and an IAQ-simulator have been developed. Databases have been developed to connect knowledge of material emissions to the indoor air measurement results. This allows screening of possible indoor air contaminant sources, provides reference data for both indoor air and material emission measurements and enables statistical evaluations of measured indoor air data when connected with diagnosed health effects. IAQ Simulator offers a new testing tool for building product manufacturers to develop and test materials in multilayer structures. The developed simulator can be incorporated to the "Indoor Climate" classification and CEN when drafting emission measurement standards for structures. The simulator offers also a new tool to study the complicated causal connections of building structure, materials and unexpected exposure to water and microbes, especially during the use of the buildings. The methodology and the simulator system generate new possibilities for advanced research. The use of molecular biological tools connected with IAQ simulator can give new opportunities for estimating the role of microbes and their interactions in indoor air and material related problems.

INTRODUCTION

Clean indoor air is one of the most important factors for the welfare of the society. Clean indoor air is also an important product of building industry. This has also been manifested in the Essential Requirement No 3 (ER 3) "Health, hygiene and the environment" of the Construction Products Directive (89/1106/EEC). In a studies of moisture damaged or SBS buildings the definition of moisture damage has had wide interpretation. The exposure to mould growth or moisture damage has been estimated by using visual inspections i.e. walk through by an expert, questionnaires to occupants and building maintenance staff as well as environmental sampling (e.g. Bornehag et al. 2001, Nevalainen et al. 1998).

The indoor climate contains partly the same VOC's as the outdoor air and partly VOC's emitted from building materials, paint, furniture etc. (Wolkoff, 1995) The VOCs, especially some terpenes might have an important role on indoor air quality. In very high concentrations in indoor air they might cause some sensory irritation. MVOC are special compounds produced by the different microbes growing in different building materials. The definition of MVOC, however, is not clear. VOC patterns in buildings suffering moisture problems can be difficult to analyse and detect. Mould fungi and microbes produce microbial volatile organic compounds (MVOC). There are several types of compounds, which may be evaporated from wet materials and microbes. Typical MVOC:s are e.g. geosmin or 3-octanol, 3-methyl-2-

butanol, 2-isopropyl-3-methoxypyrazine, 1-octen-3-ol, 2-octen-1-ol, 2-methyl-1-propanol (Claeson A. -S. and Sunesson A.L., 2005, Scleibinger at al., 2005, Wilkins et al., 2000, Korpi et al. 1998, Sunesson et al., 1997). The samples of MVOC are collected using Tenax probes and then analysed in laboratory using a gas chromatograph equipped with a flame ionisation detector (FID) and a mass selective detector (MSD). Lighter or heavier volatile hydrocarbons are normally collected by active-carbon filters so as SKC 226-09 or Tenax filters so as SKC 226-35-03 and the samples are analysed in laboratory using a gas chromatograph equipped with a flame ionisation detector (FID) and a mass selective detector (MSD).

There are suitable and adequate methods for the assessment of airborne viable and non-viable microorganisms, but the methods for viable microorganisms often do not allow long enough sampling times and thus underestimate the true number of viable fungi. Non-viable micro-organisms can be analyzed quantitatively by using a real-time PCR-method. PCR, Polymerase Chain Reaction, is a molecular biological technique where DNA can be extensively amplified in order to allow its detection. With real-time PCR it is possible to detect not only the presence of certain DNA like in traditional PCR, but also its quantity. In PCR, the DNA sequences of the organisms to be analyzed need to be known in order to have specific primers for the reaction. The disadvantages of PCR are that sample preparation from different matrices may be difficult, and the presence of inhibitors may interfere with the PCR reaction.

The most important factors causing mould and microbial growth are moisture, temperature and the exposure time (Viitanen and Salonvaara 2001). Also nutrients and pH of substrate are important. For the function of the building, several factors are affecting same time: materials, structure, ventilation, environmental exposure, humidity, air pressure and leakages etc. Modelling of the building physics has been developed to evaluate the complex system of building (Ojanen et al 2001). For evaluate the effects of different factors on the development of a moisture and microbial damage, an IAQ simulator was developed at VTT.

METHODS

PCR

With the real-time PCR method, the quantification of the overall fungal load as well as the specific species *Stachybotrys chartarum* and *Aspercillus versicolor* were studied. Both *S. chartarum* and *A. versicolor* are considered to be indicator organisms in damp buildings, and they have been shown to be able to produce toxins while growing on building materials. For the analyses, pieces of gypsum board, mineral wool, and test wall of the IAQ simulator were contaminated with fungal spores. Spores of 13 different fungal species were used. Different sampling techniques were also studied, including homogenisation of material samples, non-destructive surface sampling with a cotton swab, and air sampling with glass fibre filters. DNA was extracted from the samples with a commercial kit (FastDNA Spin kit for Soil, Qbiogene). Real-time PCR was performed with LightCycler (Roche Diagnostics, Gmbh). A universal fungal primer pair with DNA-binding SYBRGreen I dye was used for the detection of fungi, and TaqMan hydrolysis probe assays with specific probes were used for the detection of *S. chartarum* and *A. versicolor*. Conventional cultivation method using Potato Dextrose Agar (PDA, Difco) plates was used as a reference method.

MVOC

Analytical methods for the determination of volatile compounds produced by microbes (MVOCs) on building materials were developed. Specific MVOCs were clarified for

Penicillium roquefort and *Stacchybotrus chartarum* microbes during their growth on gypsum wall samples. The growth was monitored with a carbon dioxide detector. Passive sampling methods proved to be more reliable for the follow-up in comparison to active sampling. The VOC profile for the microbes was found to be affected by the mould species and air supply. The repeatability of MVOC measurements was by most affected by the mold growth rate. The change in carbon dioxide concentration during growth could not be detected when an air exchange of ~$0.4h^{-1}$ was coupled to the test chamber.

DATABANK

Chemical indoor air quality measurements have been carried out for more than two decades. Until now, the interpretation of the results has been very difficult due to the lack of scientifically proven dependence between VOCs and health effects. In this respect VTT material emission and indoor air quality databases provide a powerful tool. The databases have been developed 1) to enable to connect the knowledge of material emissions to the indoor air measurement results for screening the possible indoor air contaminant sources, 2) to provide reference data for both indoor air and material emission measurements, 3) to enable statistical evaluations of measured indoor air data when connected with diagnosed health effects.

These databases include, in addition to the actual measured contaminant concentrations and emission factors and other source related data, also information of the health effects and odour characteristics of the compounds. Connecting the data in the indoor air database with diagnosed health data it has been possible to demonstrate a statistically significant correlation between newly diagnosed asthma and indoor air TXIB concentration. We have also been able to identify other compounds and chemical groups that have statistically significant correlation to other indoor air related effects and symptoms.

IAQ simulator

An IAQ simulator was developed. An example of a structure was studied using a dividing wall structure between the different air spaces (Figure 2). The materials were chosen among the actual dividing wall structures used in Finland (a gypsum board as a wind barrier, frames from sawn spruce, fiberglass as the insulation material, the PE-film as damp-proofing and painted gypsum board as an inside wall material). In to the wall, different hatches for microbial growth can be introduced. The wall has a hole on top of it and a tube inside the fibreglass to direct the additional moisture inside the structure. This hole and tube also makes it possible to measure the humidity inside the structure. The amount of water needed to raise the humidity in the wall is calculated based on the materials used, their amounts and the final RH wanted. The microbes and VOC were collected from the air and from the wall component. The RH, temperature, influence of air pressure and air exchange was measured simultaneously.

RESULTS

PCR

All fungal species tested representing 13 indoor fungal genera could be quantified with the real-time PCR using universal fungal primers and SYBRGreen I chemistry. Only slight variations in the efficiency of DNA amplification were observed between the DNA samples of different fungal genera, except for DNA of *Fusarium* species, which amplified the most effectively. The practical detection limit of the PCR assay was determined by adding a known amount of spores into a cotton swab and analysing the swab extract by the real-time PCR. Approx. 100 spores of *Penicillium roqueforti* could be detected from a cotton swab, indicating a detection limit of 100 cfu (colony forming units)/g or 1 cfu/cm^2, if the sampling area is considered to be 100 cm^2, as recommended by the Ministry of Social Affairs and Health in Finland (Table 1). Ten times higher amount was needed for the detection of *S. chartarum* spores. Similar detection limits (100-1000 spores) were obtained when glass fibre filters contaminated with *P. roqueforti* or *A. versicolor* were studied.

Table 1. Approximate detection limits of the real-time PCR assays including DNA extraction.

	Real-time PCR assay		
DNA sample	Universal fungal	*S. chartarum*	*A. versicolor*
Pure fungal DNA / reaction	1.5 pg - 150 ng	40 fg - 40 ng	1.3 pg - 130 ng
Pure spore suspension	1000-10 000 spores	1000 spores	1000-10 000 spores
Spores in cotton swab	100-1000 spores	100 spores	100 spores
Spores in glass fiber filter	100-1000 spores	nd	1000 spores

nd = not determined

S. chartarum and *A. versicolor* could also be detected with specific real-time PCR reactions using the TaqMan chemistry. The detection limit for *S. chartarum* spores form artificially contaminated mineral wool or gypsum board was approx. 1000 cfu/g or 20 cfu/cm^2, depending on the sampling technique. Both *S. chartarum* and *A. versicolor* specific PCR were able to detect approx. 100 spores from the cotton swab, the same detection limit as obtained for fungal-specific PCR (Table 1).

The sampling method, destructive homogenisation or non-destructive surface sampling, had only a minor effect on the PCR results. No differences were observed when *Penicillium* spores were used for the contamination of gypsum board. Homogenisation was found to be slightly more effective compared to the non-destructive cotton swab method when *S. chartarum* spores were harvested from a recently contaminated gypsum board. It is known that *S. chartarum* produces fewer spores, and the spores may not be as easily released from the mycelium as the spores of *Penicillium* species, which might explain this result.

MVOC

Higher VOC amounts were measured in the tests with *Penicillium Roquefort* compared to *Stacchybotrus Chartarum* (10-900 ng/ tube vs. 5-45 ng/tube, passive sampling four weeks, air exchange rate ~$0.4h^{-1}$). The least specific MVOC growth indicator for both mold species was butanol. Specific VOCs for *Stacchybotrus Chartarum* (not detected in the control chamber): 3-octanone, 1-octen-3-ol and methyl benzoate.

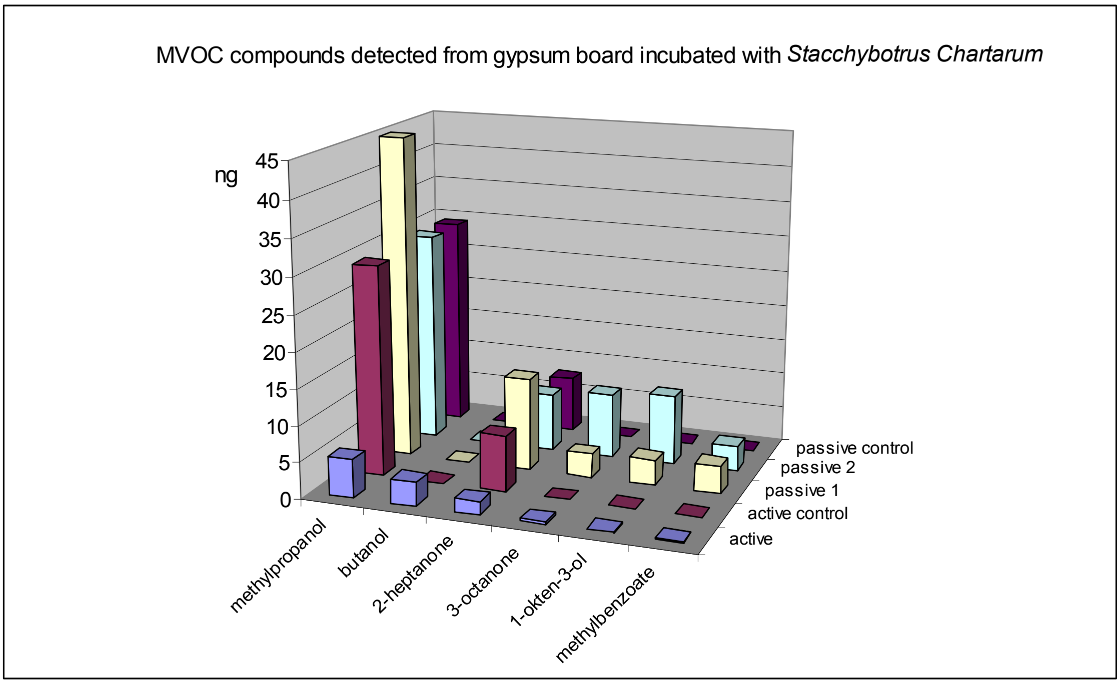

Figure 1. MVOC compounds detected from gypsum board incubated with *Stacchybotrus Chartarum* (incubation in glass chambers for 28 days, passive and active sampling on Tenax TA adsorbent tubes, results are given as the average amount from three different chambers).

Tests showed that temperature, humidity, air tightness, air velocity, air exchange rate and eventually background concentration were below the values set in the standard. The sink effect is a parameter that describes how much VOCs adhere to the walls of the test chamber. The ideal situation would be such that VOCs wouldn't adhere to the walls at all and they all could be sampled to test tubes, but in real life this objective is impossible to achieve, there are always some molecules stuck on the walls. The sink effect (recovery) didn't quite fit to the standard. With n-dodecane, the sink effects were almost as good as the standard demands, but tests with toluene did not succeed because the test method set in the standard wasn't suitable for the calibration of our FID. The results of the improvements are presented in Table 1.

Table 1 Test results of IAQ simulator 'Sissi' compared with ISO 16000-9 standard

Quantity	Standard	IAQ Simulator 'Sissi'
Temperature	23 ºC ± 2 ºC	23.5 ºC ± 0.5 ºC
Relative Humidity	50 % ± 5 %	49 % ± 1 %
Air tightness	leak <5 %	leak < 3 %
Background concentration	TVOC < 20 µg/m³, individual VOC < 2 µg/m³	TVOC < 20 µg/m³, individual VOC < 2 µg/m³
Recovery	> 80 % toluene and n-dodecane	73% n-dodecane
Air velocity	0,1–0,3 m/s	0,2 m/s
Air exchange rate	0,5 1/h ± 5 %	0,5 1/h ± 3 %

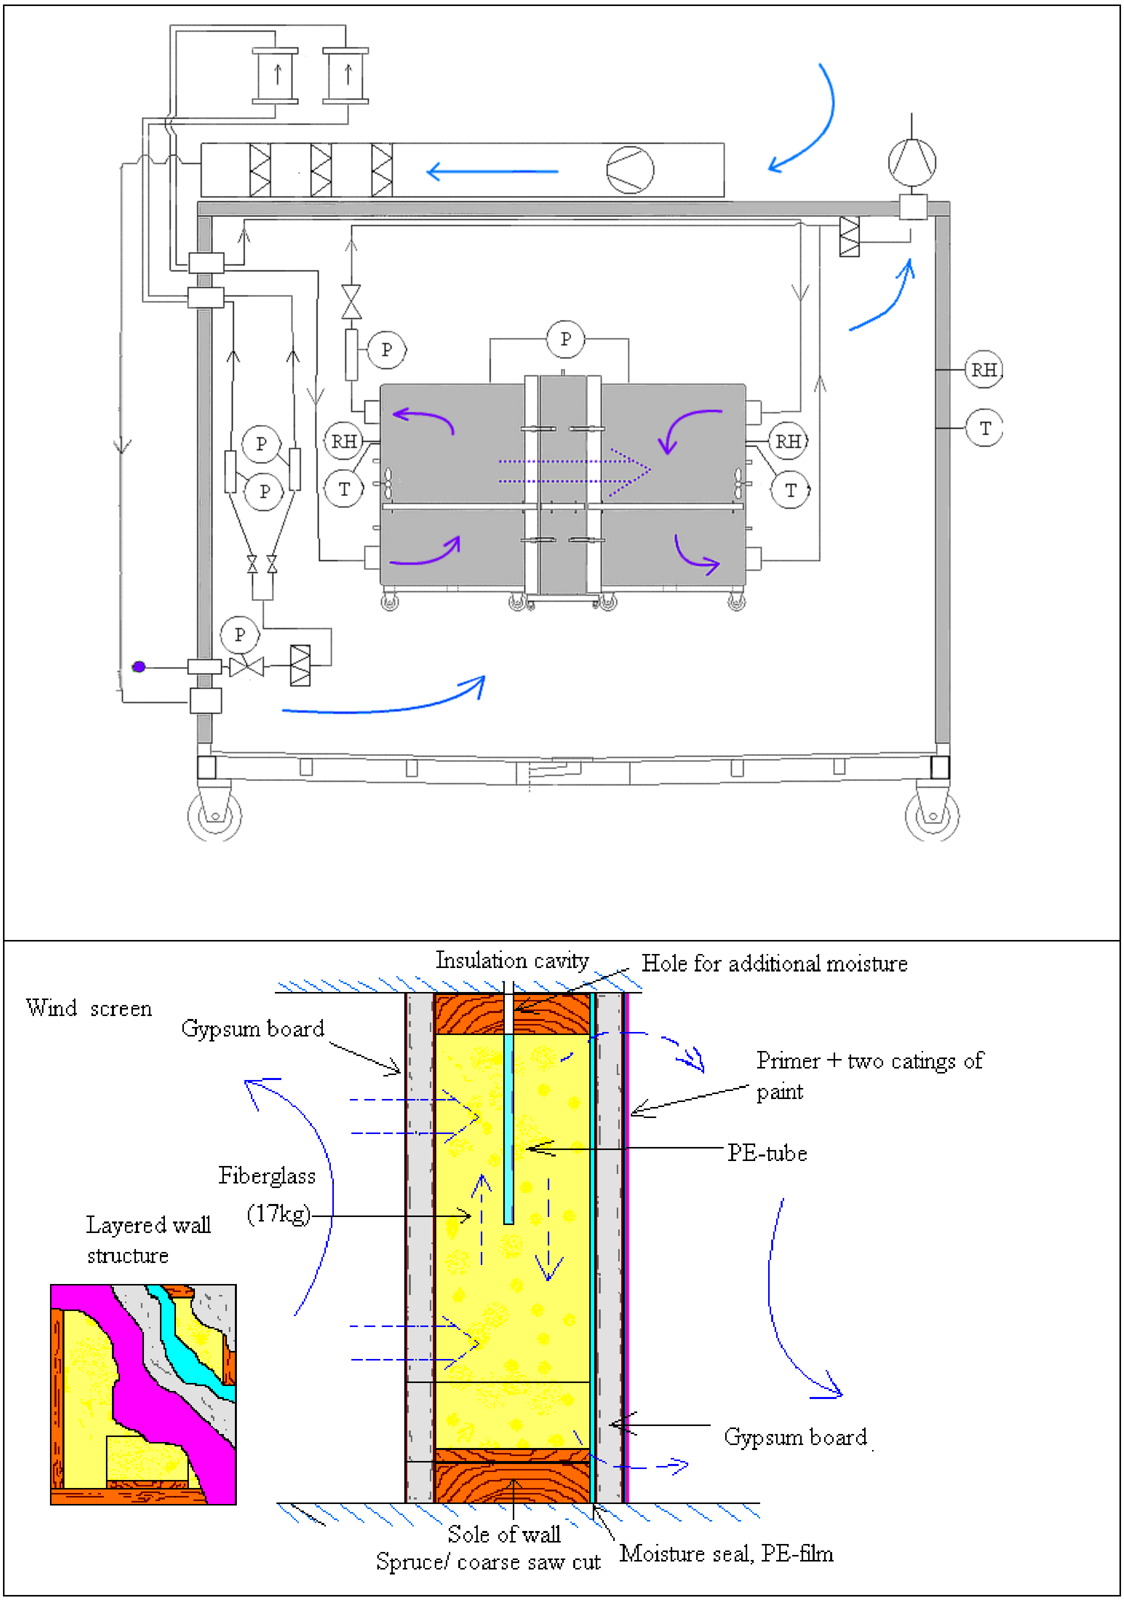

Figure 1 The principle of the IAQ simulator (top). The purple dot on the left of the protective room depicts the connection to the clean air source. An example of a structure of the dividing wall of the IAQ simulator (bottom).

DISCUSSION

IAQ Simulator offers a new testing tool for building product manufacturers to develop and test materials in multilayer structures. The developed simulator can be incorporated to the "Indoor Climate" classification and CEN when drafting emission measurement standards for structures. The simulator offers also a new tool to study the complicated causal connections of building structure, materials and unexpected exposure to water and microbes, especially during the use of the buildings.

Passive sampling methods proved to be more reliable for the follow-up in comparison to active sampling. The VOC profile for the microbes was found to be affected by the mould species and air supply. The repeatability of MVOC measurements was by most affected by the mold growth rate. The carbon dioxide concentration can not be used as a growth indicator when an air exchange is coupled to the test chamber.

The Ministry of Social Affairs and Health in Finland has given guidelines for the estimation of microbial risks in indoor environments by cultivation. Dry, “healthy” surfaces of building materials normally contain fungal spores <10 cfu/cm^2, when an area of 100 cm^2 is sampled with a cotton swab and the swab is analysed using the plate count technique. If the sampled surface of 100 cm^2 contains >1000 cfu/cm^2 fungi, or the amount of fungi is 100 times higher than that of the intact reference surface, there is evidence of abnormal fungal growth. The corresponding limits for abnormal fungal growth in building material samples and in air samples are 10 000 cfu/g and 500 cfu/m^3, respectively. The detection limits of the real-time PCR methods tested were under these risk limits, indicating that real-time PCR is a promising method for estimating the fungal risk in indoor environments. The advantage of PCR is that results could be obtained during one working day instead of 5-7 days required by cultivation methods.

SUMMARY

This study documented that houses in the southeastern United States built on typical wall vented crawl spaces possess the following characteristics: 1) liquid water, water vapor and associated moisture issues, 2) mold spores, 3) measured holes between the crawl space and living space, 4) measured transmission of mold spores from the crawl space to the living space. When these characteristics exist together, the study indicates that contaminants (mold spores and moisture vapor) present in the crawl space are being transmitted through holes in the house floor and heating, ventilation and air conditioning (HVAC) system into the livable parts of the home, thereby exposing occupants to potentially harmful crawl space contaminants. These results confirm vented crawl spaces as important sources of mold species in the home environment. In order to reduce this exposure, closed crawl spaces in combination with thorough house and duct air sealing should be implemented. Such a system was found to be a robust intervention that reduced the moisture and indoor air quality problems associated with typical wall vented crawl spaces.

INTRODUCTION

Approximately 20% of new homes in the United States (200,000 per year) are built on vented crawl space foundations according to the U.S. National Association of Home Builders (NAHB). An estimated 26 million existing homes have vented crawl space foundations. Because adults and children today spend increasing amounts of time indoors, home environmental health is important for people's well being. Mounting evidence suggests that exposure to mold in damp buildings is an important risk factor for childhood asthma [1]. The strongest identifiable risk factor for the development of asthma appears to be exposure to environmental allergens, including indoor and outdoor pollutants [2]. Because vented crawl spaces in the mixed-humid climate of the southeast experience periodic high levels of moisture, they are very likely building areas where mold can be found. One remedy, in the form of properly closed crawl space standards, demonstrated houses will be notably drier, more energy efficient, and support less mold growth compared to houses built over vented crawl spaces [3]. However, it was previously unclear whether the presence of crawl space mold species resulted in exposure to occupants in houses. The overall purpose of this study was to evaluate the importance of typical wall vented crawl spaces as sources of mold species in the livable parts of the home environment. Forty-five homes in North Carolina were selected for mold species sampling and a building science evaluation to characterize the conditions of typical wall vented crawl spaces. This report will explore the influences of this foundation construction technique on mold species growth, indoor air quality, and house durability in houses located in the southeastern United States. From the results of these studies, we created a subsequent study of 36 new houses to validate the improved energy and moisture performance of the closed crawl space protocol established above compared to traditionally vented crawl spaces. Results from this study will be available in June of 2007.

METHODS

Mold species sampling

Prior to mold species sampling, the HVAC system was kept off for four hours. In each home, a minimum of two sets of samples were taken during the test using a Wilcoxon matched-pairs signed rank test. First, before the HVAC system fan was turned on, three samples were taken. One was taken near the return grill for the HVAC system, one in the crawl space and one outside the house. Then the system fan was turned on and allowed to run for at least five minutes before two additional samples were taken, one near the return grill and one at the closest supply air diffuser (or register) to the system fan. The supply diffuser sample air was isolated from the potential contaminant sources within the house, thus allowing characterization of the relative contribution of the HVAC system to the total bioburden within the house. The sampling was conducted by two trained indoor air quality technicians using Andersen two-stage cascade impactors, which collect and separate both non-respirable and respirable size particles. The sampler was connected to a vacuum pump calibrated to collect air samples at the rate of 0.5 liters per second. Equipment calibration was conducted at the beginning of sampling, at mid-day and at the end of the day. A sampling period of 3.5 minutes was used for the outdoor air sample and all samples collected within the houses. The sampling period for the crawl space samples was one minute. The collection medium used for impaction of mold spores was Malt Extract Agar, an aciduric mycologic medium designed for the collection of environmental fungi. After sampling, the culture plates were incubated at ambient temperature for 96 hours prior to enumeration and identification. Mold identification was accomplished by macroscopic examination of colony morphology and microscopic examination of fungal elements.

Characterization protocol

We collected data to better understand the thermal, moisture and air leakage data associated with each ventilated crawl space:

- We interviewed homeowners about how they operate house and crawl space and to determine any potential indoor air quality related health issues.
- We performed air leakage and zone pressure testing to quantify the"holes" between the house and outside, the crawl space and house, the HVAC system and crawl space.
- House characteristics such as house measurements, topography, HVAC and other equipment, and existing moisture control strategies.
- Crawl space characteristics such as evidence of past moisture problems (wood rot, condensation, mold growth, puddles on vapor barrier, etc.), wood moisture content to evaluate the potential of wood for supporting current mold growth, temperature

measurements of the ground, water pipes, ductwork, air handling cabinet and floor framing to assess surface condensation potential.
- Long-term temperature and relative humidity data for the central area of the crawl space compared to outside between July 2004 and August 2005.

Building pressure diagnostics

We measured detailed air leakage using a multi-pressure testing system connected to three different systems: 1) house envelope leakage measuring system, 2) crawl space to house leakage measuring system, 3) HVAC duct leakage measuring system. The testing order was as follows:

1) Baseline-HVAC system off, all windows and doors closed.
2) House leakage test only.
3) House, crawl space and duct leakage measuring systems run together.
4) House and duct leakage measuring systems run together.
5) Baseline - HVAC system on.

House description and moisture history

In order to document past or current moisture problems, we conducted a 100 point inspection which included house air temperature and relative humidity, crawl space air temperature and relative humidity, outside air temperature and relative humidity, crawl space surface temperatures, house framing wood moisture content, crawl space construction details, crawl space and exterior grading conditions and drainage systems. These data were collected using commercially available and calibrated wood moisture meters, spot radiometers, digital thermometers, and relative humidity meters.

RESULTS

The average number of vents per house was 13, with the maximum being 22 and the minimum being four vents. Sixty-seven percent of all vents were found open, 26% were partially open, and 7% were closed at the time of the data collection.

Moisture

In 33% of the homes, moisture was present on the ground vapor retarder, duct, and plumbing systems located in the crawl spaces. Seven percent of the homes had a leaking condensate drain for the HVAC system. Active plumbing leaks were found in 31% of the houses. Water was found inside 15% of the duct systems.

Although moisture was not always visible at the time of the testing, the presence of recent moisture accumulation in the crawl space was visible by the following means in Table 1.

Table 1. Moisture indications and percent of frequency found inside crawl spaces.

Drip line visible on ground	22%
Absence of ground vapor retarder	27
Absence of full coverage of ground vapor retarder	100
Discoloration on walls	49
Termite tunnels	4
Animals and insects	36
Dryer exhaust terminating in crawl space	16
Visible mold growth	62
Wood moisture readings at mold supporting levels (≥19 %)	67
Wood moisture meter readings at wood rot supporting levels (≥ 25 %)	36

Mold species

Mold species sampling provided an evaluation of the total number of breathable mold spores, reported in colony forming units per cubic meter of air and the most common species of mold growth found. Table 2 shows the summary of bioaerosol results (in colony forming units per cubic meter) by the possibility of transmission and sample location. Figure 1 displays the bioaerosol levels for houses with the possibility of transmission. Figure 2 illustrates bioaerosol levels for all houses by location.

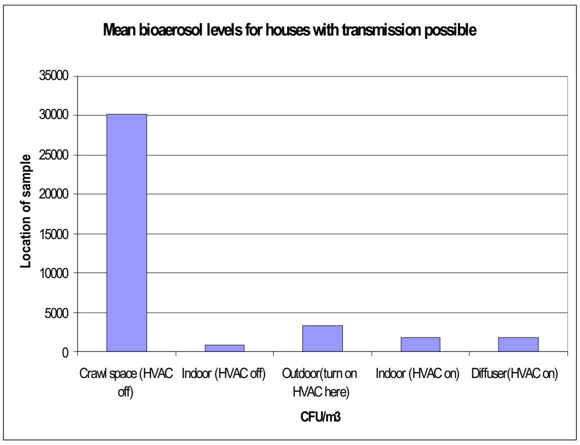

Figure 1. Mean bioaerosol levels for houses with transmission possible.

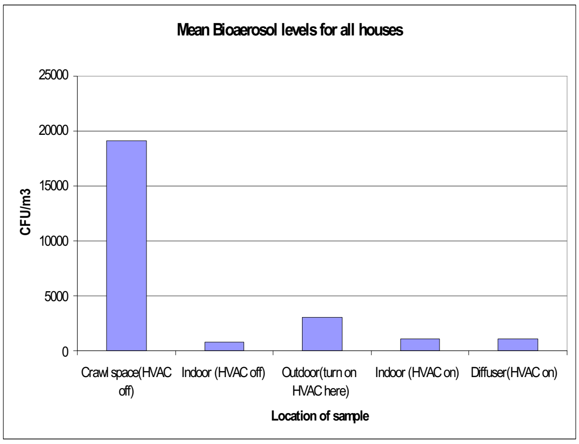

Figure 2. Mean bioaerosol levels for all houses.

Table 2. Summary bioaerosol results.

Sample	# Houses	Mean	Std. Dev.	Max	Min
Transmission possible	In CFU/m3				
Crawl space (HVAC off)	21	30163	16230	41146	1348
Indoor (HVAC off)	21	861	1233	5802	146
Outdoor(turn on HVAC here)	21	3235	3862	11756	349
Indoor (HVAC on)	21	1761	2425	11756	373
Diffuser(HVAC on)	21	1822	2607	11756	166
Transmission not detectable	In CFU/m3				
Crawl space(HVAC off)	10	161	508	1607	0
Indoor (HVAC off)	10	55	173	548	0
Outdoor(turn on HVAC here)	10	2033	2524	8418	40
Indoor (HVAC on)	10	176	556	1759	0
Diffuser(HVAC on)	10	1415	2282	11756	0
No transmission	In CFU/m3				
Crawl space(HVAC off)	14	16041	15144	41146	105
Indoor (HVAC off)	14	1323	3045	11756	71
Outdoor(turn on HVAC here)	14	3427	4630	11756	146
Indoor (HVAC on)	14	645	765	3219	124
Diffuser(HVAC on)	14	556	1101	4326	71
All homes	In CFU/m3				
Crawl space(HVAC off)	45	19102	18179	41146	0
Indoor (HVAC off)	45	825	1911	11756	0
Outdoor(turn on HVAC here)	45	3027	3836	11756	40
Indoor (HVAC on)	45	1061	1837	11756	0
Diffuser(HVAC on)	45	1062	2011	11756	0

Measured transmission

Initial assessment of transmission of crawl space air and its contaminants, including mold spores and moisture vapor, into the living space was determined to be present if two conditions held true. First, the concentration of the mold samples had to be higher in the living space once the HVAC system was turned on compared to the level of spores with the HVAC system off. Second, the mix and rank order of the indoor samples with the HVAC system running shifted to reflect the dominant mold species present in the crawl space sample and the rank order of species was different from the outdoor sample. If only one condition held, the house was classified as "transmission not detectable" and if neither condition held true, the house had no transmission.

Transmission of air and its contaminants was possible in 21 (47 %) of the houses characterized. In 10 (22 %) houses, transmission was not detectable or rather only one of the two conditions held true. No transmission was found in 14 (31 %) of the houses.

Measured holes between the crawl space and living space

Three leakage paths were measured: total house air leakage, air leakage between the living space and the crawl space, and air leakage between the HVAC duct system and the crawl space. See Table 3 for total house leakage testing documented.

Table 3. Measured house leakage.

CFM 50 per ft² of surface area *	M³/h/m² at 50 Pascals	Classification	Percent of houses tested
<0.25	<4.6	Minimal	0
0.26-0.45	4.7-8.2	Limited	24
0.46-0.60	8.3-10.9	Moderate	42
0.61-0.75	11-13.7	Excessive	20
>0.76	>13.8	Major	13
* Cubic Feet per minute at 50 Pascals			

The majority of the homes (69%) had 11% and 30% of the total house air leakage coming from the crawl space. The measured leakage between the HVAC duct system and the crawl space are shown in Table 4. Five homes were not classified for this test because they were unable to reach their target pressure.

Table 4. Classification of duct leakage.

CFM 25 per ft² of conditioned floor area as a percentage	M³/h/m² at 25 Pascals	Classification	Percent of houses tested
< 3%	<0.55	minimal	0
3.1-5%	0.56-0.91	limited	4
5.1-8%	0.92-1.46	moderate	9
8.1-12%	1.47-2.19	excessive	18
> 12%	>2.20	major	65

See Table 5 for the mean equivalent hole size for air leakage across the floor between the house and crawl space and house duct system and crawl space.

Table 5. Equivalent hole size by location.

Equivalent hole size in ft² (m²)	Mean	High	Low	NA*
House to crawl space	0.5 (0.046)	2 (0.19)	0.0	
Crawl space ducts	0.4 (0.04)	1.5 (0.14)	0.1 (0.01)	2
*NA indicates numerical data could not be calculated due to difficulty in reaching target pressure.				

DISCUSSION

This study—conducted during typical 12 month conditions—documents moisture characteristics of typical wall vented crawl spaces in the southeastern United States and measures the impact on living space mold sources. In some situations, the use of foundation vents to dry a crawl space may cause additional moisture. Of the houses in this study,

- 49% had moisture induced wall discoloration
- 62% had visible mold growth
- 67% had wood moisture meter readings at mold-supporting levels
- 36% had wood moisture meter readings at wood rot-supporting levels

Indoor air quality is compromised when moisture conditions exist in combination with air leakage between the house and crawl space and between the HVAC duct system and crawl space, as mold species can be delivered into the house through the air leaks. Therefore, both a moisture management strategy for the crawl space and an air sealing plan to reduce house and duct leakage should be incorporated into new and existing homes.

To demonstrate a protocol that will eliminate crawl space moisture problems and stop the total air leakage between the house and the crawl space, Advanced Energy also tested an intervention protocol on 12 similar sized homes in southeastern United States. This intervention study compared the standard vented crawl space design with a closed crawl space design. The closed crawl space design included a sealed ground vapor retarder that extended up the perimeter walls of the crawl space, air-sealed the perimeter wall between the crawl space and outside, air-sealed penetrations between the house and the crawl space, provided a source of conditioned air to the crawl space, and monitored the results [3]. The data from this study demonstrated that this closed crawl space protocol is a robust measure producing substantially drier crawl spaces (reducing conditions for mold, wood decay, and insects). These data also demonstrated reduced house space conditioning energy use by 15% to 18% annually as compared to the standard vented crawl space houses. Utilizing the results of these studies, we then created a study with 36 new houses to validate the improved energy, moisture, and indoor air quality performance of the closed crawl space protocol established above compared to traditionally vented crawl spaces. Results from this study will be available in June of 2007.

SUMMARY

The aim of this project was to investigate the indoor environment and building characteristics in relation to with asthma and allergy among Greenlandic children. A cross-sectional questionnaire study involving 229 children in schools and institutions in Sisimiut was performed. The response rate was 23%. Of the children included,15% had doctor-diagnosed asthma. Rhinitis and eczema within the last 12 months was associated with; visible damp stains in the child's room; mouldy, earthy, unpleasant and tobacco smell and with suspected dampness in the construction.

Mould spots, suspected dampness in the construction, condensation on kitchen windows and stuffy air were observed significantly more often in houses constructed prior to 1971.

INTRODUCTION

Throughout the developed world the prevalence of asthma and allergies has increased over the last few decades [1]. No investigations have been made concerning the prevalence of asthma in Greenland. However, the reported frequency of hospital admissions due to asthma among Inuits in Greenland has previously been low [2]. The frequency of atopy in Greenland was analysed in 1987 and again in 1998 and an overall increase from 10% to 19% was found [2]. A main risk factor for developing asthma and allergy is genetic heredity. Due to the short time span of the increase, heredity cannot explain the increase during recent decades. Today children spend more than 90% of their time indoors [3] [4], and the indoor environment therefore has a strong influence on their health. Dampness and mould are indoor environmental factors of great importance for health [5] [6]. Today houses are built tighter, the result being a reduced ventilation rate accompanied by more dampness and mould problems indoors. In Sweden, an investigation has been made entitled Dampness in Buildings and Health (DBH), involving 14077 pre-school children. A similar study have been made in Bulgaria (ALLHOME), involving 4479 children [7]. In Sisimiut, an epidemiological cross-sectional questionnaire study including all children in schools and institutions was performed. The aim of this study was to investigate the association between indoor climate and building characteristics and asthma and allergy among Greenlandic children.

METHODS

A questionnaire including 81 questions divided into four parts, was sent to schools and institutions in Sisimiut for distribution to the children. The questionnaire used in the Swedish

DBH study was used as a template and adapted to Greenlandic conditions. The parts of the questionnaire analysed in this article concern the health of the child, and the housing conditions. The statistical programme SPSS was used. For evaluation of a significant association, the Pearson Chi-Square test was used. If frequencies below 5 were present, the Fisher's test of significance was applied. An association was considered to be significant if the significance level was $P < 0.05$.

Two diseases and four symptoms of asthma and allergy were used as evaluation criteria for associations between asthma/allergy and indoor environment. The two diseases were doctor-diagnosed asthma and rhinitis. The four symptoms were; wheezing, dry cough, eczema and non-doctor diagnosed rhinitis within the last 12 months.

RESULTS

In all, 1010 questionnaires were delivered and 229 valid questionnaires were returned. This results in a response rate of 23%. With this relatively low response rate no generalizations of the prevalence of symptoms in Greenland can be made. However the associations between asthma/allergic symptoms and indoor environmental factors are more valid.

Health of the child

In Figure 1 it is seen that eczema was the most frequently occurring symptom among children in Sisimiut.

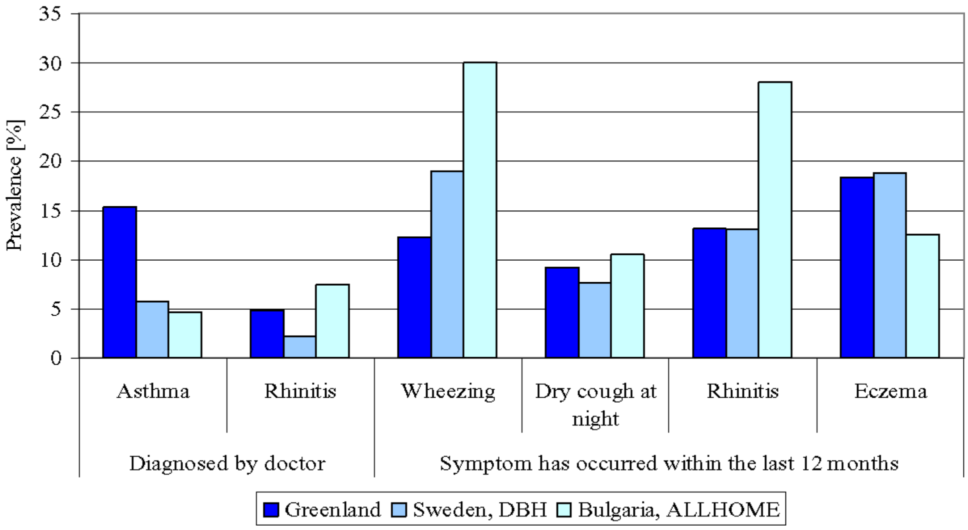

Figure 1: Occurrence of asthma/allergy among children in Greenland, Sweden and Bulgaria

Compared to the results from Sweden and Bulgaria, the prevalence of asthma is noticeably higher in Greenland and the prevalence of wheezing is noticeably lower.

Housing conditions of the child

One third of the children have lived in the same residence all their life; of the remaining children most have moved to the present residence within the last three years (2004-2006). Roughly half of the children lived in apartments followed by an almost equal amount of single and attached houses. The most common size of homes was 75-99m2. Most residences were erected during two distinctive year-intervals 1961-70 and 1984-1993. The majority of the families (75%) rented their residence. Exhaust air valves existed in most of the homes.

Only half of the homes had a cooker hood in the kitchen and one third had exhaust in the bathroom. The most frequent heating system was waterborne. The most common type of window was one with two-layer wooden frame. In most homes the flooring material was parquet and the surface material in the child's room was painted/unpainted wallpaper. 47 (21%) families reported that they had made considerable changes or extensions to their home during the child's life and in six cases that it was done due to problems with damp and mould in the residence. Visible damp stains were more often seen than visible mould. Visible mould and damp stains occurred considerably more often in bathrooms as opposed to the other rooms in the home. Drying of clothes took place mainly outside the residence but also inside in one third of the homes.

40 families (17%) suspected that they had humidity/mould problems within the floors, walls and ceiling, problems that were not visible from inside the residence.

Significantly more homes constructed before 1971 had visible mould spots inside, , especially apartments. The occurrence of condensation on the kitchen windows was slightly more frequent than condensation on the windows in the child's and parents' room. A significant association between condensation on windows in the kitchen and the year of construction was found. The possibility of condensation was increased when living in a building constructed before 1971. Stuffy bad air, tobacco smell, and dry air were the most common perceptions regarding the air quality. A significant association was found between condensation and dry air: the more condensation, the greater the number of complaints of dry air. A significant association was also found for stuffy air and houses constructed prior to 1971, as stuffy air was more often perceived in these homes.

Associations between symptoms and housing conditions

There were no significant associations between the type of residence and doctor-diagnosed asthma, wheezing, rhinitis and eczema within the last 12 months. A significant association was found between wheezing and houses built after 1993, as wheezing more often occurred here. No attempt to correlate doctor-diagnosed rhinitis and cough within the last 12 months and type of house and year of construction was made due to the low frequencies. There was a significant association between rhinitis, eczema, and visible damp stains in the child's room (see Table 1), as rhinitis and eczema occurred when visible damp stains were seen. Considering visible mould in all rooms (except bathrooms) the risk of asthma was increased. No significant association existed between visible mould and visible damp stains in the bathroom and doctor-diagnosed asthma, doctor-diagnosed rhinitis, wheezing, dry cough, rhinitis and eczema within the last 12 months.

Table 1: Associations between reported dampness in the child's room and asthma/allergy

	Eczema	0	37	0.148	0	38	0.046	6	24	0.696

A significant association between suspected dampness in the construction and rhinitis within the last 12 months existed see (Table 1), as rhinitis occurred when there was a suspicion of dampness. There were significant associations between unpleasant smell, mouldy smell, earthy smell, tobacco smell and rhinitis within the last 12 months (see Table 2). These smells were observed when rhinitis occurred. There were no associations between smoking in the home and doctor-diagnosed asthma, doctor-diagnosed rhinitis, wheezing, dry cough, rhinitis and eczema within the last 12 months.

Table 2: Associations between rhinitis within last 12 months and smells

DISCUSSION

The occurrence of doctor-diagnosed asthma in Sisimiut was high, i.e. 15%. If this is true for the population as a whole, it would classify Greenland among countries having a high occurrence of asthma [1]. This would indicate that asthma has increased in Greenland when compared to previous studies of hospital admissions [2]. Comparing the study in Sisimiut to the Swedish DBH study [6] and the Bulgarian ALLHOME study [7], the occurrence of asthma is seemingly high. The occurrence of self-reported wheezing in Sisimiut was 11%, which is lower compared to the Swedish DBH-study and the Bulgarian ALLHOME-study. In another study in five cities (Adelaide, Sydney, West Sussex, Bochum, and Wellington) the prevalence of self-reported wheezing was between 20% and 40% [9]. The response rate to the questionnaire was 23% which means that tendencies can be indicated but generalizations cannot be made. Considering the low response rate, selection bias can be a problem. Families with symptomatic children could be more prone to participate, resulting in a higher prevalence of symptoms. Furthermore, the size of the data set is small and this makes the statistics more sensitive.

In cold climates, visible mould on indoor surfaces is not often found, except in bathrooms, as the humidity is low and the houses are well insulated [6]. The climate in Sisimiut is arctic and the observations of mould were generally low in rooms but considerably higher in bathrooms. These results comply with the climatic conditions. Visible mould was observed slightly less than visible damp stains in the homes. This accords with findings in the Swedish DBH-study [6]. Several people who reported observations of visible mould observed also visible damp stains. Rhinitis and eczema occurred when visible damp stains were observed in the child's room, and asthma occurred when visible mould in all rooms in the home (except bathrooms) were considered. This indicates that the indoor environment influences the health of the child.

Condensation on the kitchen window was more common in houses built before 1971. The same finding was reported in the Swedish DBH-study [6]. Condensation on the inside of windows is an indication of poor ventilation or poor glazing, and thus high indoor humidity. As the most common type of window was a two-layer glazing, it can be assumed that the type of window is not the primary reason for condensation. The association found may be related to the demands of ventilation strategies in newer houses as the buildings are tighter and ventilation strategies have to be implemented. A significant association between condensation and the perception of dry air was found. This finding has also been reported in the Swedish DBH-study and supports the suspicion that the sensation of dryness is linked to air pollutants, and thus to poor ventilation.

A significant association between the year of construction and wheezing was found. The risk of wheezing increased in houses built after 1993. In a study by Emenius et al. [8] it was found that the building age, or more likely, certain types of building construction, and indoor air humidity were associated with recurrent wheezing.

CONCLUSION

The occurrence of doctor-diagnosed asthma in Sisimiut was high. The likelihood of having had rhinitis within the last 12 months was increased: when visible damp stains were seen in the in child's room; when mouldy, earthy, unpleasant and tobacco smells were observed, and when the family had a suspicion of dampness in the construction. Significant associations of poor indoor environment were observed in houses constructed prior to 1971 as mould spots, suspicion of dampness in the construction, condensation on kitchen windows and stuffy air were observed.

ACKNOWLEDGEMENT

Thanks to Arne Villumsen for arranging the contact to the persons in Greenland and thanks to Kiril Naydenov for thoughtful comments on the project. Our greatest thanks go to the children and families in Sisimiut who participated in the studies.

SUMMARY

An epidemiological cross-sectional questionnaire study on housing and health, involving 229 children in Sisimiut, was initiated in May 2006. Based on this study, a nested case-control study was carried out in August 2006, covering inspections and physical measurements in the homes of 51 children. A tendency towards a lower average CO_2-concentration in the bedroom, at night, in the group of sick children (cases) compared to the group of healthy children (controls) was found. No significant associations or tendencies were seen between the two groups with regard to relative humidity and temperature at night. Condensation on windows in the kitchen was more common in homes built before 1971 than in newer houses. No significant association was found between condensation on the windows and asthmatic and allergic symptoms.

INTRODUCTION

Throughout the developed world the prevalence of asthma and allergies has increased over the last few decades [1]. In some countries the self-reported prevalence of asthma is above 25% [2]. No investigations have been made concerning the prevalence of asthma in Greenland. However, the frequency of atopy in Greenland was studied in 1987 and again in 1998. These studies showed an overall increase from 10% to 19% in one decade [3]. A main risk factor for developing asthma and allergy is genetic heredity. However, due to the short time span of the present dramatic rise in these illnesses, heredity alone cannot explain the increases; environmental factors must be the main cause [4] [5] [6] [7]. Studies have shown that children spend more than 90% of their time indoors [8] [9]. This means that the indoor environment in homes has a potentially strong influence on health. Studies show that dampness, mould and moisture are factors of importance for health [10] [6].

Due to increased focus on energy conservation, buildings are now more tight, with a resulting reduced ventilation rate. Bornehag and colleagues found that a low ventilation rate increased the risk of asthma and allergy in Swedish houses [10]. The same was indicated in studies by Öie et al.[11]and Emenius et al. [12].

The aim of this study was to investigate the indoor environment and building characteristics in regard to asthma and allergy in homes in the cold climate of Sisimiut.

METHOD

The inspection of homes was part of a larger investigation of Indoor Climate and Building Characteristics in Association with Asthma and Allergy in Sisimiut. The study was in two parts. The first phase, carried out in June and July 2006, was a cross-sectional questionnaire study covering all children in schools and day care institutions in Sisimiut [13]. Children were considered as "Cases" if they had: ever suffered from doctor-diagnosed asthma, doctor-diagnosed hay fever or allergic rhinitis. Children were also considered as "Cases" if they had had at least two of the following symptoms within the last 12 months:

1. An itchy rash, wheezing or whistling in the chest.
2. Dry cough at night, for more than two weeks, apart from having a cold.
3. Sneezing, or a runny or blocked nose, when the child did not have a cold or flu.
4. Sneezing, or a runny, or blocked nose, or itchy-watery eyes after having been in contact with furred animals or pollen.

Children defined as "Controls" had had none of the above problems. In total 86 children were grouped as "Controls", 56 children as "Cases" and 87 children could not be placed in either group.

The second phase reported here was a nested case control study, based on the responses from the first phase. The second phase was carried out in August 2006 and included 37 children who were randomly chosen for inspection in their homes. Some of the children visited were siblings and therefore information concerning some homes was given more than once in the inspections. In total, 34 dwellings spread over the whole Sisimiut village were inspected. Nineteen of the children were "Cases" and 18 were "Controls". The inspections of the children's homes were made by 4 inspectors in 2 groups. Each home was inspected for visible mould spots, odour, condensation on windows, building materials and type of dwelling. Type and location of the ventilation system as well as the heating system were also registered. A scaled floor plan of each dwelling was made and the volume of the child's bedroom was calculated. In the child's bedroom an indoor air quality monitor (IAQM), model PS31 by Sensotron, was placed measuring the CO_2 -concentration, relative humidity (RH) and temperature for at least 24 hours. The IAQM was calibrated prior to the measurements and each day the outdoor CO_2-concentration was measured. The body weight and location of people and pets sleeping in the dwelling, as well as the position of doors and windows were self-reported by the inspected families. The CO_2 -concentration can be used as an indicator of the air change rate (ACH), assuming that a high level of CO_2 involves a low ACH [14]. It was assumed that the air in the bedrooms was well mixed. Continuous measurements were analysed in the period from 23:00 to 05:00, during which time the RH, temperature and CO_2-concentration were measured at intervals of 1 minute and the average, minimum, maximum and standard deviations were calculated.

All data were entered into the statistical programme SPSS 11.5.1 for Windows. For evaluation of significant associations the Pearson chi square test was used. The Mann-Whitney U-test and Student T-test were used to evaluate the significance in the continuous variables of CO2, RH and temperature measurements. The Student T-test was used when the measurements were normally distributed, otherwise the Mann-Whitney U-test was used. An association was considered to be significant with the significance level, $P<0.05$.

RESULTS

The majority of children in the Case group lived in apartments (11 out of 16) whereas the majority of the Control group lived in attached houses (9 out of 12). Almost all houses in Sisimiut had sloped roofing with asphalt paper. The façades were almost exclusively made of wood, and the majority of the inspected houses had double-glazed windows. Examples of typical types of dwelling are shown in Figure 1.

(a) (b) (c)

Figure1. Types of dwelling in Sisimiut. Single family house (a), attached houses (b) and apartments (c).

The most common ventilation was natural ventilation (by opening windows and/or by use of ventilation slots in the outer walls) and a kitchen fan. Only 3 out of 37 homes had mechanical exhaust ventilation. During the inspections it was seen that some ventilation slots in the outer walls were closed by tape or cloths. For a description of the dwellings, see Table 2.

The child's bedroom

No statistically significant differences were found between Cases and Controls as regards nightly CO_2 -concentrations, temperatures and RH, although there was a tendency towards a slightly higher average CO_2 -concentration measured for the Controls. The RH and temperature did not deviate much between the Case and Control group. (Data for measurements from 23:00 – 05:00 and corresponding P-values are showed in Table 1. The values presented are the average, minimum and maximum of the average).

Table 1. Average concentration at night (23:00-05:00).

	Case	**Control**	**P-value**
CO_2 -concentration [ppm] (min-max)	1249 (934-1503)	1648 (1103-2056)	0.466
Relative humidity [%]	47.5 (44.2-49.9)	46.0 (43.4-47.9)	0.494
Tempertature [°C]	24.0 (23.5-24.3)	23.9 (23.4-24.3)	0.948

In 25 homes the child's bed was placed against the wall to the ground or to the outer wall. No condensation was seen on the windows in the child's room during the inspections. However, 8 dwellings (5 Cases) had a small amount of cracked paint on the window frame and 3 (1 Case) had a lot of cracked paint on the window frame. No moisture problems, such as moisture- or mould-spots or detached paint/wallpaper were observed behind furniture in contact with either the inner or outer walls. However, 1 case had indications of active mould spots. A sensation of stuffy odour in the child's room was registered in 4 homes (all in the Case group). Further registrations from the inspections are shown in Table 2.

In all children's bedrooms the ceiling was painted. Only 2 children (both "Cases") had PVC as flooring material in the bedroom. The most common flooring material was varnished parquet. The frequency of electronics in the children's rooms was evenly distributed between the groups. Fourteen children had a TV in their room, 11 had a stereo and 5 had a PC.

None of the dwellings had an obvious perception of tobacco smell during the inspections. One (Case) had an obvious chemical smell. Ten (6 Cases) smelled stuffy and 5 (all Cases) had an obvious stuffy, earthy or microbial smell.

Table 2. Type of dwelling in groups

More indications, possible active	1	0	1

DISCUSSION

The investigation of the indoor environment and building characteristics in association with asthma and allergy in Sisimiut, covered a very small sample size. The findings of the study should therefore be seen only as indications or tendencies in the studied field.

All investigations where carried out in August which is the warmest month in Sisimiut. The measurements presented in this paper are not representative for the whole year. The change in outdoor conditions affects mainly the RH and CO_2 -concentration indoors as people do not ventilate as much, i.e. opening windows, when it is cold outside.

As humans produce CO_2, the CO_2-concentration will build up in an occupied room. When the room is ventilated the concentration will decrease. Assuming the air in the room is well mixed, the level of CO_2 can be used as an indicator of the ACH. The findings in this study show no statistically significant difference in the CO_2 -concentration between the Case and Control groups. The same was found in a study in Stockholm [12]. The opposite has been found in a study that indicated an increase in the prevalence of asthma and allergy for low ventilation rates [4].

The fact that the case group had a lower average CO_2 -concentration (1249 ppm) than the control group (1648 ppm) was also found in the Bulgarian ALLHOME-study [5]. This can imply that the case group ventilates more due to the awareness of indoor air quality and health. Another reason could be that parents with asthmatic or allergic children may tend to leave the door to the child’s bedroom open during the night because they want to listen to the breathing of the child if any complications should occur.

In cold climates, visible mould on indoor surfaces is not often found (except in bathrooms), as the humidity is low and the houses are well insulated [6].The climate in Sisimiut is arctic and the observations of mould were generally low in rooms but considerably higher in bathrooms. These results accord with the climatic conditions. Visible mould was observed slightly less than visible damp stains in the homes. This accords with findings in the Swedish DBH-study [6]. Measurements show no significant difference in the average temperature, RH and CO_2-concentration within the case and control groups.

SUMMARY

Measurements of SO_2, NO_2, and Suspended Particulate Matter (SPM) of indoor air and correlation with outdoor air have been determined in an office of multistory mechanically ventilated building. The objective of the study was to evaluate the diversity of SO_2, NO_2 and SPM inside building and penetration of pollutants, mostly found outside, from outside to inside in an airtight building. Ground floor of the building was selected for study. Horizontal measurement of SO_2, NO_2 and SPM was done inside the building at four sampling stations. Simultaneously outdoor measurement too was carried out at two sampling stations to analyze the ratio of indoor to outdoor pollution. The results of measurement study illustrate the penetration of outside pollutants to inside the building. Activities of building users, occupants and visitors, play vital role manipulating the concentration of pollutants inside. No predominant sources of these pollutants were found inside.

INTRODUCTION

Indoor concentration measurements are required for determining the total personal exposure. It is used for providing information about building penetration factors, mainly through the coupling of simultaneously measured indoor and outdoor concentrations. Indoor microenvironments contain in general lower concentrations of outdoor pollutants such as sulphur dioxide (SO_2). However the presence of indoor sources of pollutants such as Nitrogen dioxide (NO_2), and Suspended Particulate Matter (SPM) can lead to increased indoor concentration of these (Moschandreas 1985). If there is a high ventilation rate, than the accumulation of indoor pollutants is reduced, but at the same time higher penetration of outdoor pollutants is expected within the indoor microenvironment (Hoppe and Martinac, 1998). Jetkins *et al* (1992) explained that urban people spend on average 87% times indoors and only a mere 6% outdoors. Due to the substantial differences in climatic conditions between two settings, bring enormously unusual pollution dispersion. The ratio between indoor and outdoor pollutant concentration (I/O) gives a method to analyze the origin and transport of indoor pollutant. Yocom (1982) pointed out that indoor-outdoor relationships are complex interactions of various factors like meteorological factors, indoor sources and sinks, pollutant depletions, filtrations and ventilations etc. Moreover, air pollutants indoors and outdoors differ in type, characteristics, concentrations and sources. It is therefore important to determine how outdoor air quality can affect indoor air quality.

A number of studies have been attempted to characterize the measurement of indoor air pollutants and its relationship with outdoor concentration. Most of the studies ended that level of indoor pollutants also depends on the outdoor scenario (Jones et al 2000, Kingham et al 2000, Molhave et al 2000). Koistinen et al (2004) concluded that residential and work environment contributes to indoor total particulate matter. In a measurement study of fine and coarse Michael *et al* (2002) pointed out the outdoor air as a major source of indoor coarse particles**.** Bae *et al* (2004) reported that Respirable Suspended Particles and NO_2 were predominately of outdoor sources. Riain *et al* (2003) executed a study on IO ratio in naturally ventilated building. Blondeau *et al* (2005) found IO ratio vary from 0.03 to 1.79 in school buildings.

The ratio between indoor and outdoor concentrations of SO_2, NO_2 and SPM provides information of source contribution to indoor pollutants whether pollutants are inside generated or penetrate from outside. In present study horizontal distribution of SO_2, NO_2 and SPM inside the office and penetration of outdoor pollution across the building envelope was discussed by measuring and analyzing IO ratio, when building was occupied and compare with the non-occupied moment. The objective of the study was to evaluate the infiltration of pollutants, mostly found outside, from outside to inside in an airtight building and diversity of SO_2, NO_2 and SPM inside building.

METHODS

Measurements were made for SPM, SO_2, and NO_2 for five months, with one-week frequency, from May to August and October at Capital Court Building of Delhi metropolitan area located on main road. The road in consideration is main road that links between southern part and western part of Delhi city. About 500-800 vehicles per hour with the average speed of 40 km h^1 run daily. Building is a multistory premises operated by mechanical ventilation system. The air conditioner maintains and controls overall indoors climate. The doorway of the office, which leads to the main entrance of the building, is connected directly to the main road. All windows of the office remained closed normally during the entire sampling period, excluding main entrance and another gate, right side to the main entrance. The opening of the main gate was>1m wide and opening of the right gate were <1 meter. Frequency to opening the main entrance was very numerous and opening of the right gate was occasionally only for building inhabitant and employees. The activities inside are normal office activities and computer work. Throughout the period of investigation, inside activities were recorded these are room volume, no of work stations, smoking activities, occupancy level during peak–non peak hours beside these prolonged entry of visitors, cleaning etc. Anomalous activity was also documented.

Site map

Office selected for study is comprised of Office, Meeting hall, Lobby, Cafeteria. Four sampling stations were installed inside office premises for horizontal measurement of SO_2, NO_2 and SPM. Two sampling stations were established outside the building at 20 feet height from the ground floor, to work out the indoor-outdoor ratio.

Instruments

Four indigenous handy samplers (APM 820 Envirotech Instruments Pvt. Delhi, India) were used to measure the SO_2, NO_2 and SPM concentration at four sampling sites. Eight hours air sampling (four hours average) was carried out. Eight hours continuous monitoring was also done outside using High Volume sampler (APM 460 Envirotech Instruments Pvt. Delhi, India). Particulate matter concentration was based on the weight accumulated on the filter papers during the 8-hour exposure period and concentration determined by gravimetric analysis. SO_2 and NO_2 analyzed by colorimetric method.

RESULTS

Sampling was carried with one-week frequency including weekend to evaluate the interruption of building occupants on indoor pollution. Total sixty samples of each from outside and 120 samples of each of inside air were collected. The IO ratio, in the simplest urging, depends ultimately on several parameters: outdoors pollution level C_o indoor pollution source S_{source}, source ventilation rate $Q_{source,}$ indoor pollutant sinks S_{sink} sink ventilation rate Q_{sink} as indicated by the equation

$$C_i/C_o=1+1/C_o\ (S_{source}/\ Q_{source} - S_{sink}/\ Q_{sink}) \qquad (1)$$

Where C_i is the indoor concentration and the fraction on the left of eq. (1) is essentially the IO ratio. Equation facilitates to explain database (Andy 2000). Figure-1 shows the horizontal distribution of SO_2 inside the building. It was vary from $\leq$3 to $\geq$17 μg/m^3 with maximum concentration was 16.8 μg/m^3 recorded in month of October. Repeated measure ANOVA revealed significant mean differences ($P<0.0001$) and difference at various sites too significant ($P<0.05$). Maximum elevation of SO_2 concentration was observed in October, while outdoor temperature goes down during this period. Cumulative SO_2 concentration was at site-4 *i.e.* 8 to 11 μg/m^3 in October. Figure-2 shows the indoor to outdoor ratio at different sites. There is no significant difference between indoor-to-outdoor ratios for SO_2 horizontally. Average IO ratio at various sites is 0.4472, slightly higher at site 4. Figure 3 illustrates the daily IO ratio in various months. Comparatively higher IO ratio for SO_2 (0.5015) in October and low weekend IO ratio is indicative of enhanced infiltration of outdoor SO_2, which contribute indoor source of SO_2 as well as decreased outside temperature.

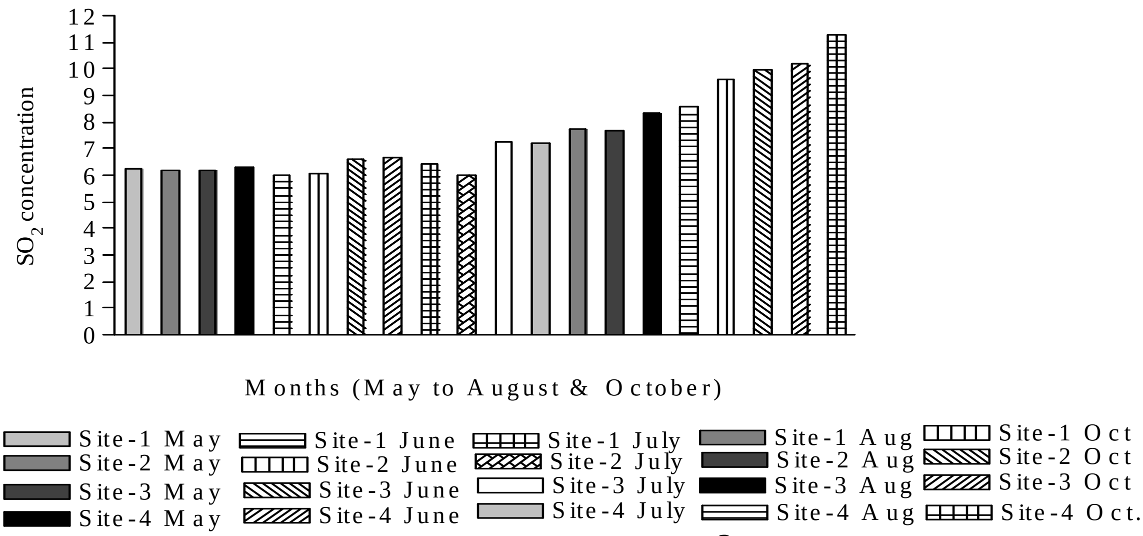

Figure-1:Horizontal distribution of SO_2 (μg/m^3).

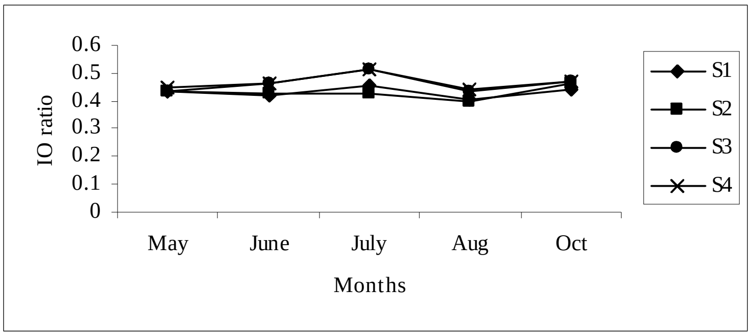

Figure 2: IO ratio for SO_2 at different sites

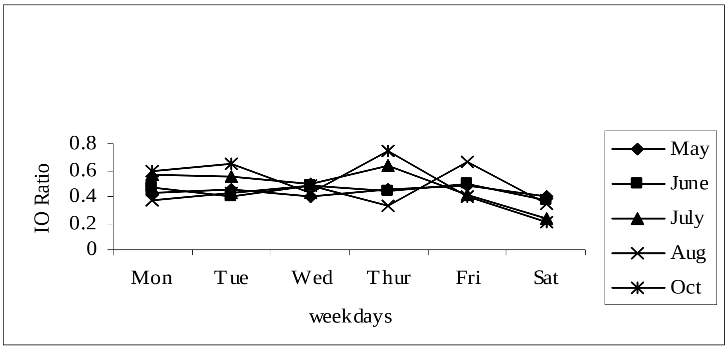

Figure 3: Daily IO SO_2 ratio in various months.

Figure-2 illustrates the horizontal variation of NO_2 across the building. It was fluctuated between 4 to >28 µg/m^3. Highest 28.8 µg/m^3 concentration was observed in month of October. It is quite higher corresponding to inside SO_2 concentration. Likewise SO_2, similar distribution pattern was followed by NO_2. Repeated measure ANOVA revealed significant mean differences ($P<0.0001$) and significant difference at various sites ($P<0.05$). Figure 5 shows the IO ratio for NO_2 at various sites (horizontally) and average peak IO ratio for NO_2 (0.467) was at site 4, which alike to SO_2. Figure 6 shows the daily IO ratio for NO_2. Relative higher IO ratio for NO_2 was observed in month of October. Peak IO ratio for NO_2 was 0.8810, which is very close to 1. Significant correlation was established between indoor and outdoor pollution levels of NO_2. It is indicative of increased net inflow from outside (S_{Source}).

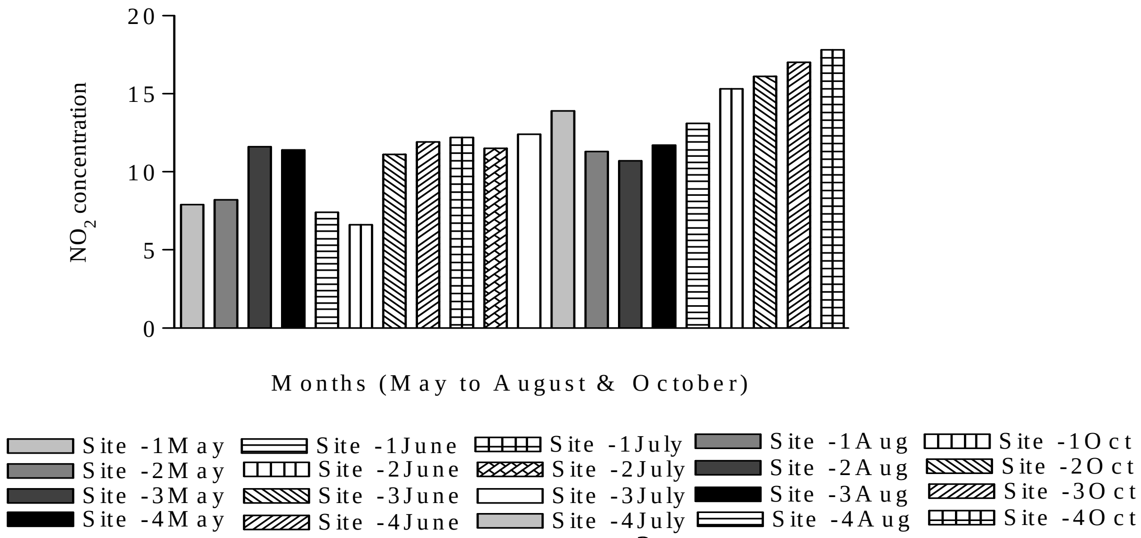

Figure-4: Horizontal distribution of NO_2 (µg/m^3)

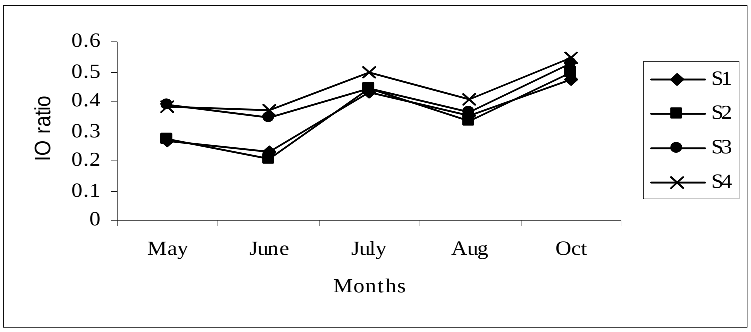

Figure 5: IO ratio for NO_2 at different sites.

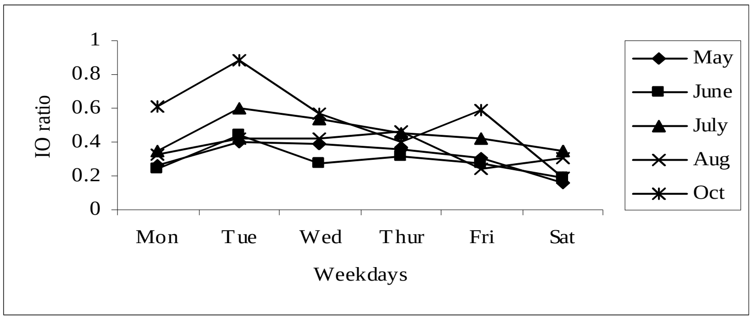

Figure 6: Daily IO ratio for NO_2 in various month

Particulate matter in the outdoor atmosphere is expected to penetrate interior spaces. It may be able to produce respiratory disease within the occupants. Figure-7 shows the horizontal distribution of suspended particulate matter (SPM) inside the building. Highest measured concentration was 70.5µg/m^3 in June. Some construction work was observed there during sampling in May-June. Elevated SPM concentration may be attributed to that only (increased of S_{source}). Lowest concentration was 20µg/m^3 in month of August it may be attributed to reduced particle concentration after rainy seasons. Likewise SO_2 and NO_2 repeated measure ANOVA revealed significant mean differences ($P<0.0001$) as well as significant difference in distribution pattern of SPM at various sites ($P<0.05$). Indoors horizontal SPM concentrations did not follow the pattern of SO_2 and NO_2. Figure-8 illustrates the IO ratio for SPM at various sites. Unlike SO_2 and NO_2 SPM ratio was relatively small. Average ratio for SPM was 0.1694 very low. It also indicates that SPM concentration was not greatly depended on outdoors pollution level (C_o). Figure-9 illustrates the slight elevated weekend ratio for SPM in the month of October than weekdays. It is also attributed by interruption of human being during weekend of October.

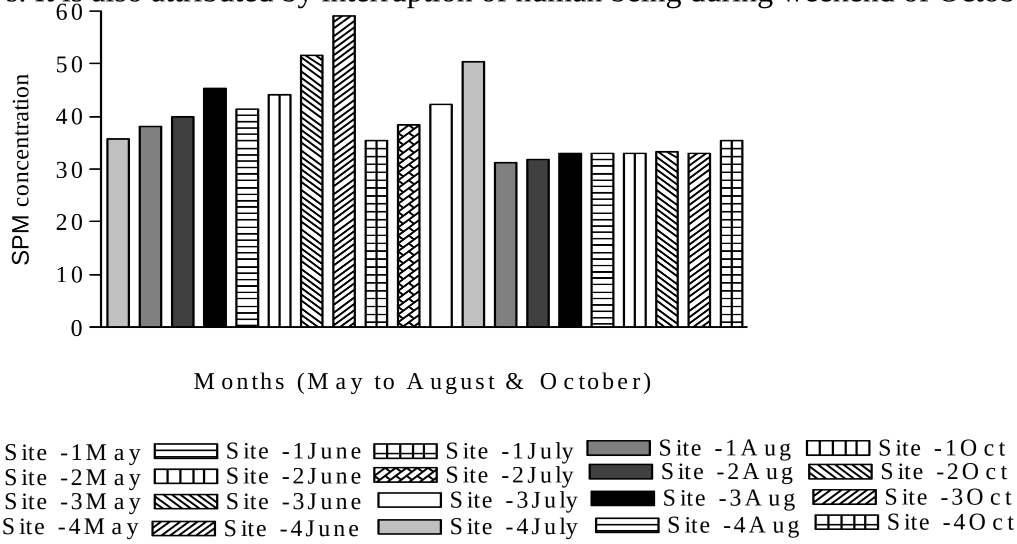

Figure 7: Horizontal distribution of SPM (µg/m^3)

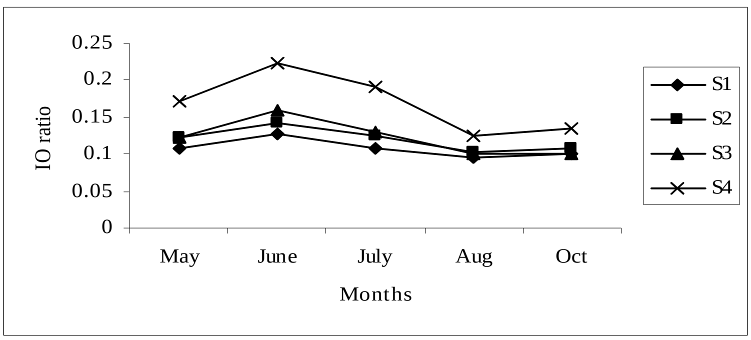

Figure 8: IO ratio for SPM at different sites.

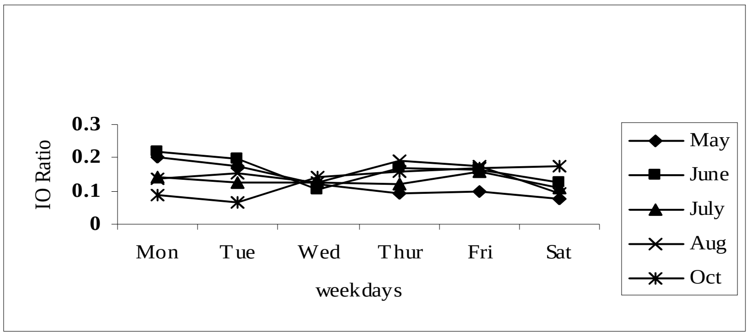

Figure 9: Daily IO SPM ratio

Results reveal that indoors SO_2 and NO_2 concentration were somewhat elevated in month of October at the time where ambient temperature gradually goes down. It depicts that temperature may have substantial role in increasing of net inflow of two gaseous from outside to inside. Simultaneously lower weekend concentration is indicator of confined interference of human activities. In general the pollutant concentration was lower inside than outside throughout the sampling period. The variation of SO_2 inside and outside was also smaller than SPM and $NO_{2.}$ Koponen *et al* (2001), Andy (2002) reported that variations of indoor pollutants were smaller and more gradual than that outdoors and also proved environmental factors to be strong manipulator of indoor-to-outdoor ratio. Peak IO ratio for all pollutants were observed during weekdays pinpointing the combined effect of increased occupants activities inside as well as heavy movement of visitors that leads to frequent opening of doors. Jhones *et al* (2000), Chan (2002) also observed that human activities and outside traffic manipulate the IO ratio. The IO ratio was higher at site four. It may be attributed to the two reasons, high occupancy level at this site and an addition door, which was facing the roadside.

DISCUSSION

Measurement of concentration of SO_2, NO_2 and SPM was done in an office during five-month period to study the horizontal flow of pollutants across the building and IO ratio with respect to outdoors concentration. Horizontal distribution pattern of measured pollutants varies across the building. IO ratio for SO_2, NO_2 and SPM were below one across the building demonstrating the influence of outdoor contaminants to indoor air quality. No predominant source was found inside the building. I/O ratio was somewhat lesser for SPM as compared to SO_2 and $NO_{2.}$ Low IO ratio for SPM may be due to the low penetration rate for SPM. Site four was identified as the really precious zone among all four-monitored points. This is characteristic of the exposure to exterior contaminants, occupant’s activities, and interference by operating the access from two sides. Prolonged entry of visitors and occupants’ activities during working days enhance the penetration of outside contaminants, which was restricted in weekends.

Horizontal measurement of pollutants encourages to examine dispersion of indoor pollutants at different positions in order to draw meaningful comparison at various spots throughout the building envelope and assessment of personal exposure to air pollutants.

ACKNOWLEDGEMENT

We acknowledge SERC Division, Department of Science & Technology (DST), Ministry of Science & Technology, Government of India for providing financial assistance for the study.

Why Positive Olfactory Perception Is An Issue For Evaluation Of Buildings

Diotima von Kempski

SUMMARY

The real estate market is changing rapidly and with it the evaluation of buildings. Requirements are being changed in order to meet market demand. Besides the location, infrastructure and the actual condition of a building's technical equipment a further parameter called the "Soft Factor" is required in the evaluation of a building's quality. High end equipped spaces, according to statistics, are more easily let and are therefore the key assets in higher cash flow portfolios. A factor that can significantly decrease the value of a building is low air quality. The quality of air, however, is not determined by standards, it is determined by perception. Although thermal comfort plays an important role, olfactory comfort is critical to this perception of air quality. This paper will show why the real estate market is adapting to this new paradigm. It will demonstrate why olfaction and the perception of "natural fresh" air play such an important role and why it is has become a key issue for the HVAC community.

INTRODUCTION

The ability to assess the Fair Market Value of a building or a portfolio of real estate assets has become particularly important since private equity and real estate funds have become major players in the European real estate market. They have introduced to Germany the internationally accepted standards for the evaluation of buildings. Other continental European countries have seen similar changes in evaluation parameters. For many years, the physical value of a building has played a major role in the evaluation process of a real estate asset. Today, the evaluation of an investment decision is focused above all on the evaluation of the discounted cash flow which is distinct from the physical or land value of the asset. The discounted net annual rent is the basis for the evaluation. The investor will typically choose an investment time horizon with the result that even the "life expectancy of the building" has little relevance to the calculation of value.

In this context the outfitting of a building can be of importance since the discounted cash flow calculation not only includes the actual rent but also an assessment of the sustainable market rent. The value of buildings with current or future vacancies therefore benefits from outfitting that create an additional value for potential users and make them easier to let. Outfitting features that are of little benefit to potential tenants (such as golden bathroom fixtures in an office building) no longer play any role in the valuation of a property. In other words, the substance of a building or the outfitting are incorporated in the cash flow calculation only if they increase the lease yield.

Employees are the largest expense of most companies and therefore these human resource issues are very important when analyzing companies. Nowadays, banks go as far as to look at these aspects in order to reveal the so called "hidden costs". These can have a significant impact on the banks' assessment of the creditworthiness or the interest rates they charge. Similarly, Chen [1] found that there is a strong awareness and growing concern over the "silent crises" of IAQ and its potential to cause large industry losses. These losses included both direct costs to insurers from paying health insurance and professional liability claims as well as the cost of litigation.

ENVIRONMENT

Increasingly, the business world is beginning to address the "soft factors" that have not traditionally been included in business economics or management science. More and more attention is being given to these soft factors - satisfaction vs. profitability, quality vs. productivity, qualitative advantages vs. financial ones, ethics vs. efficiency. Hidden costs with significant potential financial impact arise when these factors are not adequately measured or addressed. The impact of the environment is one of those soft factors.[2].

The impact of environment, air and its olfactory content has been known to science for at least 20 years. Frequently, the market fails to act on scientific evidence, sometimes as in the case of climate change perhaps "shutting the stable doors once the horse has already bolted". The recognition and acceptance of human resource issues and the associated costs has also lagged science. The HVAC community has clearly missed the opportunity to define air quality and its hedonic value [3] with respect to well-being in response to neurophysiological and psychological science. This shows quite clearly the impact of olfaction on humans since air quality encompassing olfaction plays a major role in well-being. Improving the well-being of room occupants will result in companies enhancing their performance. There are several studies that demonstrate the link between a qualitative working environment and the productivity of a company. [4]

STRESS

According to a European survey nearly one in three European workers is affected by work-related stress. In the European Union, over the last decade, work related stress has been consistently identified as one of the major workplace concerns – a challenge not only to the health of working people but also the healthiness of their organization. Studies suggest that between 50% and 60 % of all lost working days are related to stress. People are experiencing stress when they feel an imbalance between the demands on them and the personal and environmental resources that they have to cope with those demands. [5] One of the main factors of managing stress is promoting health. The perceived environment is one of the main factors which can enhance stress or reduce it. An improvement in workplace health can be a key ingredient of business efficiency and competitiveness.

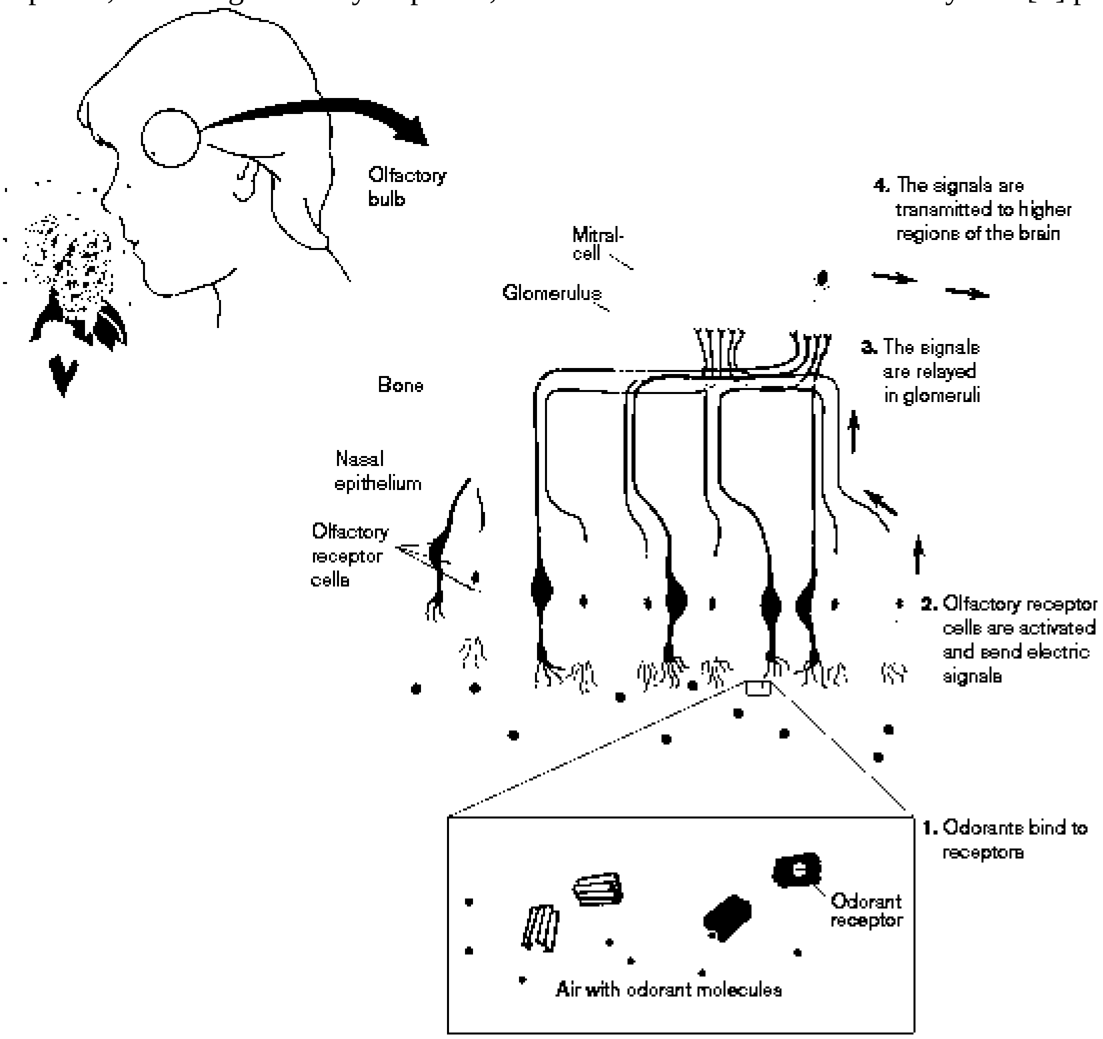
OLFACTORY COMFORT

Neurophysiological and psychological research in the field of chemical senses has shown that our well-being is controlled to a significant extent by the olfactory substances found in the indoor air. [6] Olfactory comfort is not only defined by the absence of negative olfactory substances but also as a condition of mind that expresses satisfaction with the olfactory environment created by positive stimulating substances in the indoor air. Buildings situated in metropolitan areas typically lack these positive olfactory substances. The substances are generally not found in sufficient quantities in the outside air and filters and cleaning mechanisms within HVAC systems remove them along with any negative substances. Therefore positive olfactory substances have to be restored in the indoor air. [7]

OLFACTORY SYSTEM

With every sniff, olfactory molecules pass through the nostrils to the olfactory epithelium. The millions of sensory (receptor) cells in the epithelium are connected via the sensory nerves and the olfactory bulb to the hypothalamus, other limbic system structures, the cortex and other sites which receive this information to coordinate and manage our abilities to learn, think, remember, respond and contemplate.

The limbic system is responsible for a person's range of feelings, his emotions, memories and the so-called effective tone of their entire behavior. A person cannot, therefore, block out any impulses, including olfactory impulses, that are transmitted to the limbic system.[8] picture 1



To date, findings from cerebral imaging have shown that olfactory function involves a complex and extensive neural network. Odor processing appears to be based on two main modes of processing. One is a serial processing with successive involvement of the primary and secondary olfaction areas, and the second is parallel processing which processes odor in the right and left hemisphere separately depending on the nature of the cognitive task. While areas located in the right hemisphere such as the orbital frontal cortex (OFC) and piriform cortex (PC) are more involved in memory and familiarity, those located in the left hemisphere, such as the OFC, insula, PC, amygdala, temporal lobe, and superior frontal cortex, participate more in the emotional response to odors. The piriform-amygdala region appears to be associated with the evaluation of emotional intensity and it is therefore activated more by unpleasant odors than by more mild odors. The role of the superior frontal cortex is to process the odors and their effect on emotional state and use this information to make personally relevant decisions. [9]

A number of major investigations in recent years have dealt with the effect of odor on electrical brain activity, as well the physiological effects of odors. Torii [10], Lorig [11] and Saito [12] carried out various studies to examine the effect of odors on the brain. They measured the contingent negative variation. Contingent negative variation (CNV) is an increasing negative shift of cortical electrical potentials associated with an anticipated response to an expected stimulus. Lorig [13] established that even low concentrations of odor that remain undetected bring about significant changes in EEG activity and behavior. Subsequently, Kobal [14] at the University of Erlangen demonstrated using electrical brain activity that cognitive processes can be influenced in a controlled manner by the administration of various odors to the right or left nostril. Kikuchi [15] explored the effect of five odorous substances on both heart rate and contingent negative variation. They found that pleasant odors activated the central nervous system increasing the heart rate variations, and calming odors decreased the heart rate.

In addition to the neurophysiological effects of odor substances, psychological effects can also play an important role. Clinical studies over the past 18 years have shown that certain odors promote relaxation and alleviate stress. Warm, Dember and Parasuraman[16] found that people who monitor routine tasks on video displays demonstrated improved performance when they received occasional whiffs of certain odors. These results show that pleasant olfactory substances can enhance task performance. Another study by Danuser suggests that performance deteriorations can be caused by environmental chemical odors and that unpleasant odors are distracters, capable of inducing sensory deprivation.

A number of techniques and scales have evolved to measure the different aspects of odor.. Zevon and Tellegen [17] and Watson [18] proposed that the structure of mood can be represented by two factors, which are called Positive Affect (PA) and Negative Affect (NA). These two factors can be monitored using the PANAS (Positive and Negative Affect Schedule). Another related scale is the OCA scale[19]. Electro-olfactograms (EOG) have also been used to provide evidence for the dominant role of the nervous system in olfactory desensitization, for the functional characterization of the olfactory epithelium, the specific topographical distribution of olfactory neurons, the expression of olfactory receptor neurons in response to exposure to odorants, or characterization of certain odorants as olfactory receptor antagonists.[20] Together with the recording of olfactory event-related potentials[21], magnetic source imaging [22], functional magnetic resonance imaging fMRI [23] [24], and appropriate psychophysical techniques[25], the human sense of smell can be described in its many facets at many different levels.

APPLICATIONS

The Kajima Building in Tokyo was one of the first big buildings to implement the addition of olfactory substances to their new premises in order to enhance the indoor environment. A comfort ratio increase of 24% (simple mean value) was achieved by implementing the olfactory environment.[26] The results in 1999 [27] of a building in Berlin where a new tenant conducted productivity research to satisfy themselves of the payback of higher rent that had been demanded based on the outfitting of the office building. The analysis that was based on their experience over the course of one year after moving to the premises is shown in Figure 1-3. This building was equipped to achieve the full potential of a "multisensual" building.

Real Estate Investor's Perspective

Building data			
Letting area		3,000	m^2
Basic Costs - **Low technology building**			
Property and building		€ 14,730,000	
Technical Equipment (without HVAC & R)		€ 2,450,000	
	Subtotal	**€ 17,180,000**	
Extra Costs - **High technology building**			
Property and building		€ 14,730,000	
HVAC & R		€ 400	per m^2
HVAC & R costs		€ 1,200,000	
Other technical equipment		€ 2,450,000	
	Subtotal	**€ 18,380,000**	
Additional cost for high technology building		**€ 1,200,000**	
Rent Income for low technology building		€ 22	per m^2 per month
Rent Income for high technology building		€ 26	per m^2 per month
Additional rent income for high technology building		**€ 144,000**	
PAYBACK PERIOD - IN CURRENT TERMS		**9.5**	**years**
D.C.F.YIELD - IN CURRENT TERMS		**6.7%**	
D.C.F.YIELD - IN CONSTANT TERMS		**4.1%**	

Assuming tax deductability and depreciation over 15 years.
Inflation set at 2.5%, tax rate at 43%, 15 year life of equipment

Tenant's Perspective

Low technology building

Building costs		
Rent	€ 22.00	per m^2 per month
Ancillary Costs (building)	€ 3.50	per m^2 per month
Subtotal Building costs	€ 918,000	p.a.
Employee Costs		
Employee productivity	100	Index
Sickness/Absenteeism	6%	days p.a.
Workforce (Full time equivalents)	120	FTE
Salaries	€ 3,100	per FTE per month
Other employees costs/benefits	38%	of salary
Office equipment & supplies	€ 200	per FTE per month
Subtotal Employee costs	€ 6,448,320	p.a.
Total building & employee costs	**€ 7,366,320**	

Tenant's Perspective

High technology building

Building costs		
Rent	€ 26.00	per m^2 per month
Ancillary Costs (building)	€ 4.75	per m^2 per month
Subtotal Building costs	€ 1,107,000	p.a.
Employee Costs		
Employee productivity	106	Index
Sickness/Absenteeism	4.2%	days p.a.
Workforce (Full time equivalents)	120	FTE
FTE reduction (productivity improvement)	(6.8)	FTE
FTE reduction (sickness reduced)	(2.0)	FTE
Salaries	€ 3,100	per FTE per month
Other employees costs/benefits	38%	of salary
Office equipment & supplies	€ 200	per FTE per month
Subtotal Employee costs	€ 5,973,800	p.a.
Total building & employee costs	**€ 7,080,800**	
Overall savings	**(€ 286,000)**	**p.a.**
equivalent to	**(3.9%)**	**of operating costs**

CONCLUSION

Changes in the real estate market have created new demands that have to be met in order to create more added value for buildings in particular for vacant buildings.. The competitive advantage of a high quality building can do much to increase return on investment. Buildings with lower standards are less likely to find tenants and will contribute to loss of productivity and absenteeism. Therefore an evaluation of buildings that includes the perception of indoor air and the environment of the occupants is necessary.

In order to fine tune the measurement of the indoor air quality, it is necessary to take into account the influence of the hedonic value of the environment on room occupants. Essentially, the hedonic value affects the well-being of the room occupants.

In order to understand olfactory comfort, we have to look into different psychological, neurological, physiological aspects. Our sense of smell lets us explore our chemical environment. Therefore the perception of an odor will determine our reaction - approach or avoidance, positive or negative - depending on the type and concentration of the odor.

DISCUSSION

An interdisciplinary scientific approach is necessary in order to create an environment which enhances well-being. Perception must play a major role in evaluating a building. Measurements should be based on neurophysiologic and psychological data such as the PANAS and OCA scales and whenever possible supported by research using electro-olfactograms.

An Investigation into Effect of Air Distribution on the Indoor Air Quality

Yiyi Duan, Xuejun Hao

Beijing Institute of Civil Engineering and Architecture, Beijing

Corresponding email: HXJ@bicea.edu.cn

SUMMARY

The air distribution is a realizing form of indoor flow field, which plays a vital role to indoor air quality in the design of Heating，Ventilation and Air Conditioning. The average temperature and air speed in working area are closely related to air distribution, and the main factors that affect such two indices are the form, position, quantity of air outlet as well as the velocity, temperature of air supply. This article discusses the effect of air distribution on indoor air quality.

INTRODUCTION

As the healthy environmental protection idea goes deep into the public gradually, how to raise indoor air quality becomes a problem of people's concern. People are also show a tremendous expectation that the air conditioning can improve the indoor air quality. The relevant expert also puts forward the thinking——"to the direction of the healthy air conditioning development". How to improve air quality in the design for air conditioning has become an important study topic in the modern air conditioning technique. This article will make an initial study that the air distribution affects on the indoor air quality in the design air condition system.

INDOOR AIR QUALITY

Concept of the indoor air quality

The formation of the indoor air quality concept is a gradually perfecting process. The indoor air quality differs from an indoor pollution. At first definition of the indoor air quality meant a series of pollutant concentration index. However, along with research of going deep into continuously, people discovered that a single pollutant concentration index can't reflect the indoor air quality accurately. People don't feel comfortable in the room with low pollutant concentration. So in a narrow sense, the indoor air quality can be regarded as the contaminative degree of smoke, dust, harmful air and microorganism. Speaking from the broad sense, the indoor air quality still include thermal environment parameter, such as temperature, humidity and flow speed etc. The indoor air quality is also closely related with the subjective feeling, mentality and the physiology conditioning of the occupants.

Main factors affecting to the indoor air quality

The factors affecting the indoor air quality mainly are the air conditioning system, indoor pollutant and deterioration of outdoor air. As figure 1:

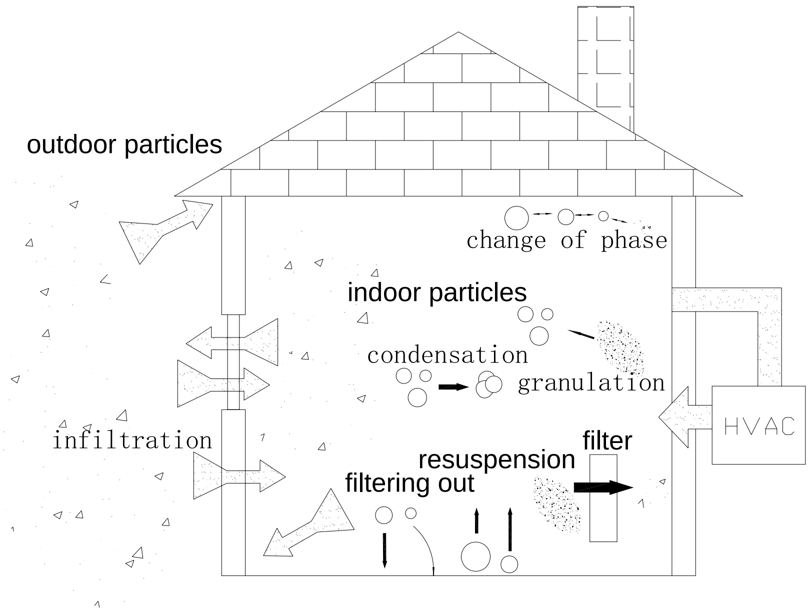

Figure 1

Generally speaking, the main factor affecting the indoor environment quality are: Temperature, relative humidity, air velocity, amount of fresh air, carbon monoxide, carbon dioxide, ozone, formaldehyde, benzene, respirable particles, the volatile organic compound , radon and etc.. Particularly in recent years a great amount of high business buildings has been built. The personnel's density increase continuously. A great amount of materials for decoration to be used, shortage of fresh air occupied, and unilateral pursuance for thermal comfort provided by air conditioning system, all of these worsen the indoor air quality.

Among them, the necessary parameter that insures thermal comfort in the environment is the temperature, relative humidity, the air velocity and etc. The sense of human body to the air environment not only lies on the chemical traces in the air, but also related with the temperature and humidity. So the suitable humidity can improve a people's requirement for air quality. The fresh air can dilute the indoor harmful air and make the air quality satisfied the request for work, living and health.

There are a great lot of kinds of pollutants influencing the indoor air quality, mainly have: inhalational particles, carbon monoxide, carbon dioxide, formaldehyde, volatile organic compound and etc..

The polluted outdoor air will impact the indoor air quality certainly. The outdoor air usually enters through fresh air system, doors, windows and fresh air syetem. At present in the air conditioning system, currently used air filter just trap the dust. It can't purge harmful gas and the germ. When outdoor air is polluted seriously, the volatile gas of organic compound and germ will send to air-conditioned rooms with the air conditioning. It makes indoor air quality grow worse.

THE VENTILATION AND AIRFLOW DISTRIBUTION

Ventilation processes

Ventilation process actually is an organized air renewal system. In order to altering the temperature, humidity and quality we replace the indoor air with fresh air.
At present there are tow modes of air distribution in the air-conditioned room. One is mixing ventilation based on dilution principle, another is displacement ventilation based on the thermal convection.

The typical scheme of mixing ventilation has ceiling and high-level side air supply. These two schemes of air distribution make the work area placed in recirculation zone. Handled fresh air is being sent in from the upper part of room with a certain speed. It merges with the hot contaminated air at first, and then is being sent into work area by backflow after mixing. Adopting this scheme of ventilation, the fresh air inhaled by indoor person has already been polluted during the period of ventilation. Setting out from the view point of air quality, the second scheme of air distribution would be better than the first one.

The devices of the displacement ventilation are often placed in the vicinity of floor. In this case the handled fresh air is being sent in directly to the work area at low speed (<0.5 m/s) and forming a thin layer as a air lake just above the floor because of its higher density. The supplied fresh air is spread out in the lower part of room, it dose not mix with the upper hot air due to low turbulence intensity of flow. When the fresh air comes into contact with hot surface (such as human body and hot equipment) and is being heated, then rising upwards by natural convection. At the same time, the polluted hot air is driven by fresh air flow and is departing from the work area to the upper part of room and finally is extracted by exhaust ventilation system. The indoor air has stratification phenomenon owing to the density difference of the air at the different levels. The denser clean air (lower temperature) sinks in a lower part of room space and the lighter muddy air (higher temperature) rise to the upper part in the room. Thus the indoor personals situated in the work area can inhale fresh air immediately.

Air distribution

The airs distribution is also called air current organization or air current distribution. It is a measure for reasonable air movement and organized flow of air in a ventilated room and for avoiding the formation of dead space and vortex. The mission of air distribution is to determine the location of air inlets and outlets according to the room geometry, technological process, personal position, character of pollutant and disperse conditions, and to make a reasonable air flow pattern. Thereby the temperature, humidity, velocity and cleanness of air within the work area could meet the technological and hygienic requirements.

According to the collocation of air inlets and outlets, there are the following schemes: side wall inlet and side wall outlet, ceiling diffuser, ejector system, ejector type grille, grille with direction blades, ceiling outlet, T-bar slot air diffuser, fan with backward curved blades, side wall register of horizontal and vertical louvers and shutters, floor extract grating, rectangular duct air supply and return opening with damper, round duct air supply and return openings with damper, mesh type air return opening, return grille and etc.

The effect of ventilation and air distribution on indoor air quality

We introduce the concept of efficiency of air exchange and efficiency of ventilation. The efficiency of air exchange is defined as the ratio of real resident time of air in a room to the theoretically shortest resident time of air. It shows the effectiveness of air exchange and is a criterion for assessment and is independent of air distribution.
The schemes of ventilation and air distribution will influence the effectiveness of air exchange, dilution and removal of pollutant from indoor; therefore it could be a different sense of occupants to the air quality.

Increasing the fresh air amount supplied alone, it could not dilute the pollutant concentration properly, because the different air distribution scheme can cause different effectiveness of pollutant removal. Hence a concept of ventilation efficiency has been introduced. Ventilation efficiency is defined as a ratio of the pollutant concentration at air outlet to the average indoor concentration of pollutant. It means the grade of indoor pollutant removal and is an important index for assessing room ventilation. One employ a suitable air distribution scheme under the same conditions (pollutant and its emission rate, quantity of air supplied), if such a scheme can maintain a stable pollutant concentration or can reduce the initial pollutant concentration more quickly, it is to be said that this scheme has a higher ventilation efficiency and is more favourable for raising the indoor air quality.

When designing ventilation and air-conditioning system of a building, one should adopt various schemes of air distribution according to the size and use function of the building. If there are two schemes of air distribution for choosing, one is high-level supply and low-level return and another is vice versa. Generally speaking, the latter scheme has advantage over the former in the respect of improving indoor air quality. In the case of low-level supply and high-level exhaust of air, the handled fresh air is sent to the lower part of room directly to the work area, and so called age of air has a minimum value. By virtue of the lower location of air inlet, lower speed of air discharged and higher density of fresh air supplied, the incoming air will spread out and occupy the whole lower part of room. As the age of fresh air is increasing, it comes into contact with hot source and then is being heated up. After that, hot air rise upwards due to natural convection, carrying pollutant and departing from the work area and finally discharging from the exhaust system.

The principles of design of air distribution system are as follows:

- To place the discharge grille as close as possible to the emission source of harmful matter or the region of higher concentration, and to remove the harmful matter quickly.
- To arrange the air supply diffusers as close as possible to the work area and avoid contamination of fresh air along the air low path.
- To make the air flow more uniform in the room space, reduce voetex and avoid excessive accumulation of harmful matter.

MATHEMATICAL ANALYZE OF EFFECT OF AIR DISTRIBUTION ON THE INDOOR AIR QUALITY UNDER DIFFERENT SCHEMES OF VENTILATION

3.1 The overall ventilation differential equation, its solution and application

According to the balance of pollutant matter, the increment of the indoor pollutant mass should be equal to the difference between the entering and exhausting amounts of pollution mass, namely

The increment of the indoor pollutant mass = entering pollutant mass + emitted pollutant mass － exhausting pollutant mass

Get a overall ventilation differential equation within d t time

$$\rho_{kr} V d\alpha_k = q dt \beta_k \rho_{ks} + k dt \rho_k - \Omega q dt \alpha_k \rho_{kr}$$

where: ρ_{kr} —— density of the pollutant gas in exhaust air

ρ_{ks} —— density of the pollutant gas in supply air

ρ_k —— the density of the indoor pollutant emitted

α_k ——concentration of the pollutant of exhaust air

β_k ——concentration of the pollutant air of supply air

q —— supply air rate

k —— emission of indoor pollutant source

V—— room volume

Ω —— ratio of densities of supply air to the exhaust air

Suppose the room volume is V, the initial concentration of formaldehyde in the room α_0 is 0.1341 mg/m^3, indoor emission quantity of formaldehyde $k_{甲}$ is 0.12 mg/m^3, and formaldehyde concentration of the supply air $\beta_{甲}$ is 0.1287 mg/m^3. (For energy saving, the fresh air mixes with the return air)

Introducing $\varphi = \rho_{ks}/\rho_{kr}; \theta = \rho_k/\rho_{kr}$, and solving the overall ventilation differential equation , we could get the relationship between indoor pollutant and volume V at anytime:

$$\alpha_{甲} = \left[\frac{\varphi}{\Omega}\beta_{甲} + \frac{\theta}{\Omega}\frac{k_{甲}}{V}\frac{1}{q}\right]\left[1 - e^{-\Omega\upsilon\frac{q}{V}t}\right] + \alpha_0 e^{-\Omega\upsilon\frac{q}{V}t}$$

Suppose the experiment as a ideal case, the mixing coefficient (also called ventilation efficiency) $\upsilon = 1$, ventilation process is isothermal process, i.e. $\varphi = \Omega = \theta$.

1. Fixing the room volume, the relation of indoor formaldehyde concentration to the supply air rate and time:

Suppose the room volume V=200 m^3, get the curves as shown in figure 2:

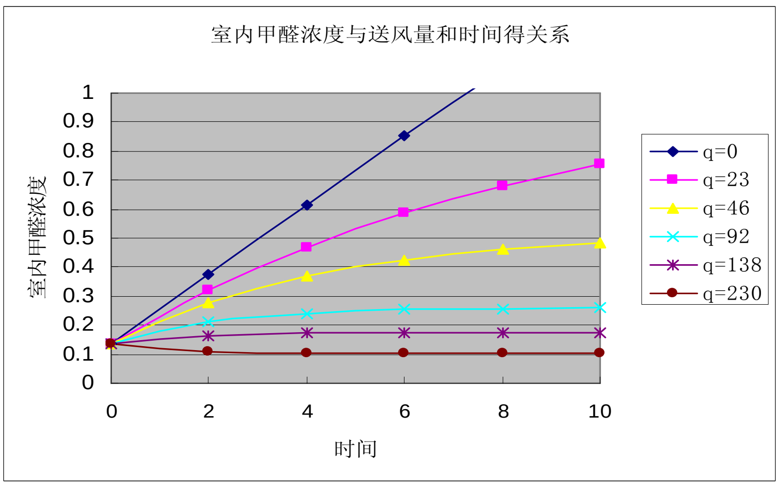

Figure 2

2. Fixing the supply air rate, the relation of indoor formaldehyde concentration to the

room volume and time:

Suppose the supply quantity q=92 m^3/h, get a group of curves shown in figure 3:

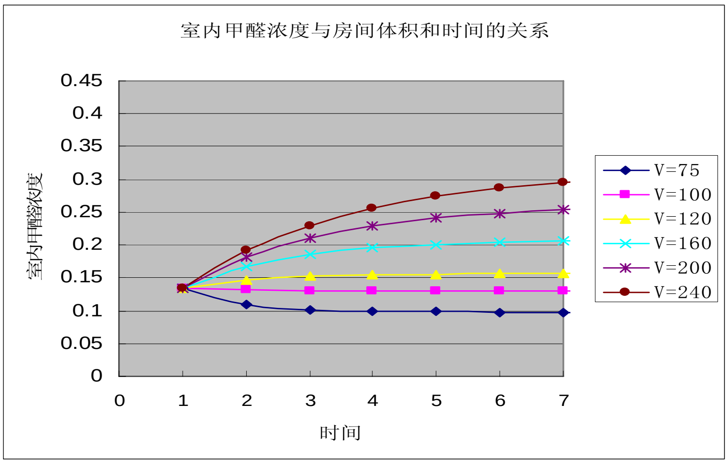

Figure 3

By analyzing above, for fixed supply air rate, the formaldehyde densities all attain a stable value after certain time. For the stuffy case (q=0), the formaldehyde concentration will rise straightly. The bigger the room is, the time is longer for attains a fixed value of formaldehyde. But the stabilized concentration value of formaldehyde is decided by the emitted quantity k of pollution source. It don't relate to the room volume.

CONCLUSIONS

From the analytical comparison above, we can conclude the following that: (1) the indoor air quality is not only decided by the size of the ventilation quantity, but also related closely to the air distribution. For the sake of getting better indoor air quality, we have to choice, dispose and control reasonably. (2) When designing a system we have to choose the suitable one according to the size and room shape, the amount of heat and humidity, position of pollutant source and concentration of pollutant in the room. (3) In engineering practice, the key problem is to keep the temperature, humidity, air velocity and pollutant concentration within a permissible region in the work area. So control of the air quality in the working area is not only the design pivot of the air distribution, but also the research direction of energy saving. (4)In the eyes of the control air quality, under supply is better when one building can use two types of air distribution: up supply and under supply.

The relationships between the extent of mould problems and physical building characteristics in high-rise apartment buildings

Hyeun Jun Moon and Hwa-Yong Kim

Department of Architectural Engineering, Dankook University, Korea

Corresponding email: hmoon@dankook.ac.kr

SUMMARY

This paper studies the extent of mould problems in a high-rise apartment complex with six buildings located in suburban of Seoul, Korea. The complex is composed of 466 households with different stories in buildings. The apartment buildings have occupants' complaints due to mould growth on interior surfaces right after the completion. The research team investigated the sizes of the mould infested areas in each household unit and analyzed them to find any possible relationships between mould extent and physical building characteristics, such as floors of the units, building orientation, number of exposed facades to the outside environment and so on. Although the plan, building materials, construction methods are the same in each apartment household, the difference of mould extent was found with building characteristics. One of the main findings is that the house units on the top floor have larger mould infested areas than the ones on lower stories.

INTRODUCTION

In many countries, microbial growth in indoor spaces has been identified as a main threat to deteriorate the level of Indoor Air Quality (IAQ). Earlier research works have shown that indoor mould growth is likely to occur when a combination of relatively high humidity and temperature on building material surfaces constitutes favorable conditions for mould germination [1]. However, in many cases, mould occurrence involves local, situational, and sometimes idiosyncratic aspects of a building during its operation [2]. Thus, in real situations, it is hard to find the exact causes and appropriate remediation actions, once mould problems are found on building surfaces.

In existing buildings, many studies have been devoted to collect data on the number of mould spores in indoor air using various air sampling methods. However, interpretation of the air sampling results is difficult and dramatically different depending on sampling methods. In the field study by Burge [3], the results of air sampling was not able to indicate fungal contamination in the building, even when visible mould growth appeared in the ventilation system. Miller [4] has concluded that air sampling can be a very useful tool for determining the extent of mould damage of a building only when the exercise of good judgment is provided. The other method is a visual inspection which is to investigate the size of the mould infested areas in existing buildings by experts. Most current guidelines for mould remediation depend on this method and focus on cleaning the affected areas. Although a visual inspection cannot detect hidden mould problems, many mould remediation guidelines have been published and used widely by various agencies and associations. [5, 6, 7, 8].

Despite decades' research on mould problems in buildings, it has not been studied that the relationships between various physical building characteristics and the extent of mould growth in apartment buildings. Thus, this study focuses on the extent of mould problems in existing buildings using a visual inspection method. The objective of this study is to find any possible relationships between mould infested areas and building characteristics, such as floors of households, building orientation, number of exposed facades to the outside environment and so on. One high-rise apartment complex is selected for this study.

METHODS

The selected apartment complex is located in a suburban area of Seoul, Korea, which has hot summer and severe winter. The complex is composed of six high-rise apartment buildings with different number of stories (10 to 24^{th} floors) depending on the lines. The total households are 466 in this complex. 211 units are facing southwest and 255 units are facing southeast. Figure 1 shows the site plan of the selected apartment complex. The structure of the buildings is concrete. Most walls in living areas of the units were finished with wallpaper on the concrete walls except balconies where paint was applied on the concrete walls. The complex has 3 different floor plans in terms of floor area (80, 100, and 160 m^2). Figure 2 gives a typical floor plan of the largest unit with 4 bedrooms, 2 bathrooms, and 4 balconies. Smaller units are composed of 3 bedrooms, 1 bathroom, and 3 balconies.

The construction of the complex was finished in 2000. However, the occupants have reported mould infestations inside the buildings after moving in. In August of 2004 our research team has visited the complex and collected information on the severity of mould infestations in all 446 units. The mould infested areas and the location of the mould problems were investigated in each room in the units. Basic building characteristics were also recorded including floors, the face of the units, number of exposed walls to outside, and so on. In this paper the sizes of mould infested areas are analyzed with each building characteristic to find any possible relationships.

Figure 1. The site plan of the selected apartment complex with six buildings.

Figure 2. A typical floor plan of a unit (floor area of 160 m^2) in the selected apartment complex.

RESULTS

From the visual inspection of all 466 units in the apartment complex, 240 units (about 51.5%) are found with mould infested areas. The largest infested area is found in the unit located on the top floor (24th floor) of the building #5 with 10.84 (m^2). The distributions of the mould areas have been studied for each building as well. Here we introduce two building cases (building #2 and #4) that are the biggest buildings in this complex.

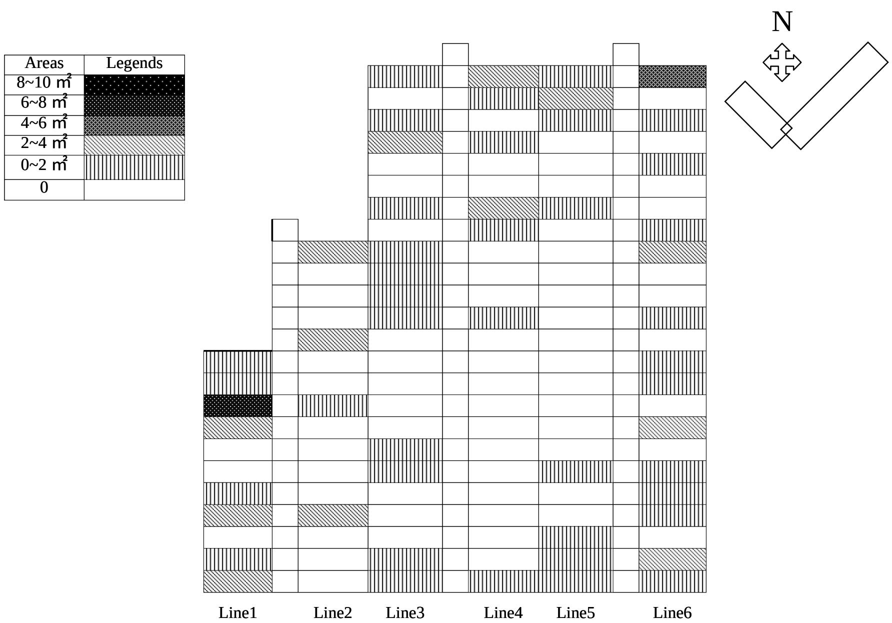

Figure 3. Distribution of mould infested areas in building #2.

Figure 3 shows the distribution of the extent of mould infested areas in building #2. In the figure the areas are grouped in 6 categories according to the mould infested areas from 0 (no mould growth) to 10 m^2. In this particular building all units on the top floor and the bottom floor have mould problems (except one unit on the first floor). The units in the center of the building have much less mould infested areas than the units in the perimeter of the building.

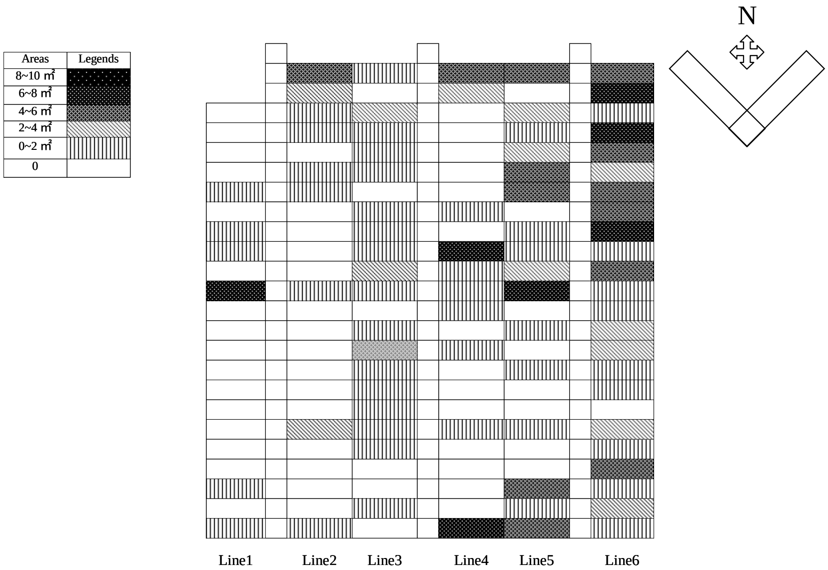

Figure 4. Distribution of mould infested areas in building #4.

Figure 4 shows the distribution of the mould infested areas in building #4. In this particular building the units on the top floor shows larger mould infested areas than other units. However a few units in the middle floors have severe mould infested areas as well. The units on the right side of the building seem to have larger mould area than others. But, the difference between the average mould infested areas in the units facing southeast (1.022 m^2) and southwest (1.104 m^2) is not significant in the analysis of all 466 units in the complex.

The relationships between the floors of the units and the size of the mould infested areas are investigated in the selected apartment complex. Since the lines in the apartment buildings have different top floors, we analyzed mould infested areas in the units according to lines with the same highest top stories. Figure 5 presents the average mould infested areas in the units in the lines with top floor of 24. The average infested area in the units on the top floor is 3.738 m^2, which is 3 times greater than the average value of 1.016 m^2 from all 466 units. The units on the 7th floor have the smallest mould infested area of 0.131 m^2. In this case the mould infested area in the first floor has a larger area than the ones in the middle floors. Thus the units on the bottom floor and the top floor show larger mould infested areas than the ones on middle floors. Similar trend is found in other units in the lines with different top stories, i.e., top story of 10, 15, 19, and 22.

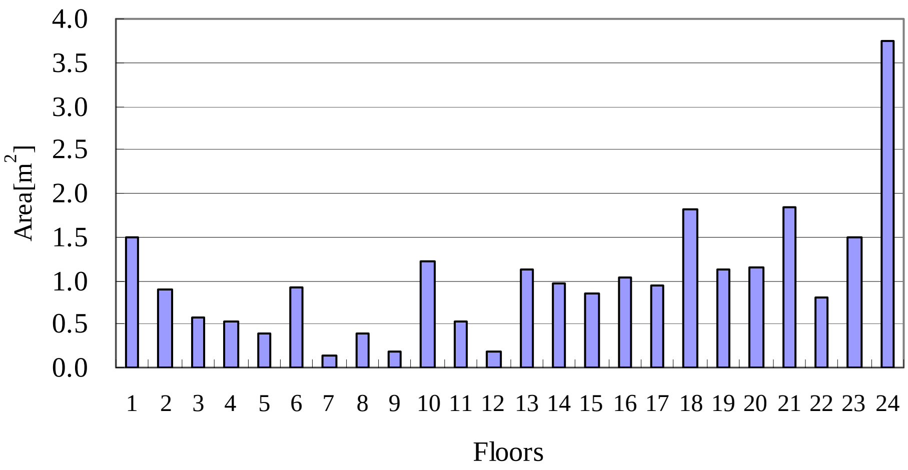

Figure 5. Distribution of mould infested areas in the units that are located in the lines with the top story of 24.

Table 1 Mould infested areas in the units located in the bottom floor and the top floor [m^2].

		BR1	BR2	BR3	Bal.1	Bal.2	Bal.3	Bal.4	Bath1	Bath2	LR	Total & Avg.
Bottom floor units (24)	Area	2.250	6.020	0.200	8.510	4.840	3.720	0.000	0.039	1.016	0.000	26.595
	Avg.	0.094	0.251	0.008	0.355	0.202	0.155	0.000	0.002	0.042	0.000	1.108
Top floor units (24)	Area	2.620	0.000	0.000	19.000	28.630	10.870	0.000	0.685	0.843	0.000	62.648
	Avg.	0.109	0.000	0.000	0.792	1.193	0.453	0.000	0.029	0.035	0.000	2.610

(BR: Bed Room, Bal: Balcony, Bath: Bath Room, LR: Living Room)

Table 1 summarizes the mould infested areas with average values in each room of the units located in the bottom floor and the top floor in all six buildings. The average area for the bottom floor is 1.108 (m^2) that is similar to the average value in all units (1.016 m^2). However, top floor units shows over 2 times higher value of 2.610 (m^2) than the ones in all units. Balconies in the top floor unit have much larger mould infested areas compared to the ones on bottom floor (See Bal.1~Bal.3). Thus, balconies on the top floors are the most vulnerable space for mould growth in these specific apartment buildings.

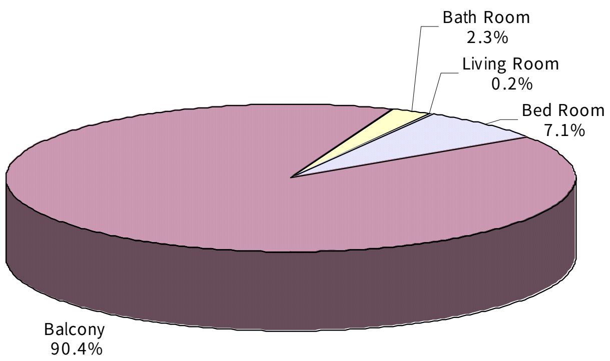

Figure 6. Percentage of mould infested areas in rooms.

Apartment units are typically composed of bedrooms, bathroom(s), living and kitchen areas, and enclosed balconies in a high-rise apartment in Korea. In this particular apartment complex, the balconies are enclosed with concrete walls and windows which are exposed to the environment. Thus, the balconies can be considered an interior space without heating or cooling systems. Figure 6 shows the percentage of mould infested areas in each room. Although the walls in balconies are finished with paint on concrete, balcony accounts for 90.4% of the total infected areas. Bedrooms and bathrooms are account for 7.1% and 2.3% of total area, respectively. It is thought that the severe mould growth on balcony walls is due to the condensation and heat bridge effects on the line joints and window sills. Further research will be conducted to find the main causes of mould growth in the balcony space.

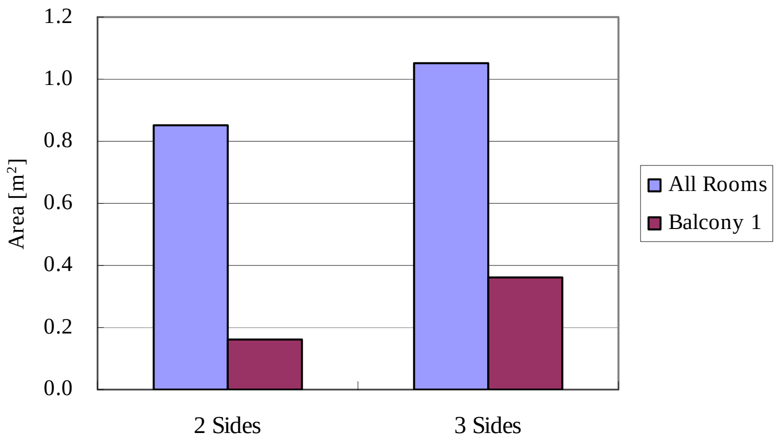

Figure 7. Average mould infested areas in the units with 2 or 3 exposed facades.

Figure 7 shows the average mould infested areas in the units with 2 or 3 exposed facades. This apartment complex has 136 units with 2 exposed facades and 282 units with 3 exposed facades. In this analysis the units located on the top and bottom floors are not included to exclude additional effect of the roofs and ground. The units with 3 exposed facades have an average mould infested area of 1.05 (m^2) which is larger than an average area of 0.85 (m^2) for the units with 2 exposed facades. In the analysis of individual room, balcony 1 accounts for most increase of mould infested area in the units with 3 exposed facades as shown in the figure.

DISCUSSION

This study investigated the mould infested areas in all 466 households in a high-rise apartment complex. In the study of house units located in the first floor and the top floor revealed that the units on the top floor have over 2 times larger average mould infested areas compared to the average value of all units. Especially, the balconies on the top floors are the most vulnerable space for mould growth.

In the analysis of mould infested areas and the number of exposed facades, the units with 3 exposed facades showed larger mould infested areas than the one in the units with 2 exposed facades. Particularly, balconies in the units with 3 exposed facades need special attention to reduce the extent of mold growth. In conclusion, the balconies in the units located on the top floor with 3 façades should be carefully examined to avoid mould favorable environmental conditions.

In this particular apartment buildings balcony spaces showed most severe mould growth in terms of the sizes of the mould infested area, which accounted for 90.4% of the total infested area. It is interesting that mould can grow well on the painted concrete walls in the balconies. According to Baughman[9] and Nielsen [10], concrete is one of the least favorable building materials for mould to grow due to not sufficient amount of nutrients. However, if favorable temperature and humidity are provided for enough time, mould spores on the concrete walls can germinate and grow as reported in the case study by Moon [2]. Thus, it is possible that concrete walls in balcony may have mould infestations due to condensation, heat bridge effects, or not enough thermal insulation. Designers and architectural engineers should pay special attentions to the environmental conditions in balconies.

At this stage of the research no investigations have been conducted to find the main causes of mould growth in the balcony spaces. This will be done as a future research by looking at the details of the buildings and measuring the environmental conditions including surface temperature and relative humidity.

On prediction of the mold fungus formation probability on critical building components in residential dwellings

J. Grunewald, A. Nicolai, J.S. Zhang,

Syracuse University, USA

Corresponding email: jgrunewa@syr.edu

SUMMARY

In buildings, favorable growing conditions for mold fungi can occur and cause fungus infestation. The danger for the occupants of dwellings lies in the spreading of pathogens through microorganisms. Mold fungi can occur not only on the surface of external walls, but also inside construction parts. A prerequisite for preventing mold fungus is the knowledge of the transient building physical boundary conditions under which fungus growth takes place. The decisive parameters of influence like temperature, humidity and substrate have to be available over a certain period of time simultaneously. Presently common evaluation methods do not take into account the transient physical boundary conditions or lack information on mold fungi species and their favorable growing conditions.
The problem is uniquely suited for analysis by a numerical simulation model that accounts for coupled heat, air and moisture transport. A Combined Heat, Air, Moisture and Pollutants Simulation (CHAMPS) model has been supplemented by features to account for the local climate next to the internal surface of the building parts (micro climate) which is essential for predicting the formation of mold fungus under realistic climatic conditions. The paper presents recent advances in CHAMPS modeling as implementation of boundary layer equations for a wall-room coupling and a study on extension to multi-zone simulation.

Keywords: Mold fungi, ventilation, air leakage, hygrothermal properties,
micro climate, building envelope, single and multi zone building simulation

INTRODUCTION

Fungi play a significant role in the indoor environment and their implications range from unacceptable musty smells and defacement or structural damage of interior finishes, to health effects and, indirectly, legal proceedings. There is little doubt that the hygrothermal conditions of the building envelope are one key element in prevention of fungal growth. In the USA, fungal problems frequently occur in a considerable part of the housing stock; in the UK the indications were that 12% was seriously affected, whereas a further 9.5% had slight condensation problems (Sanders and Cornish, 1982). Moisture problems on this scale are not just typical of the temperate climate, and may be found in warmer areas too. In the coastal region of Israel, containing more than 50% of the country 's population, about 45% of the dwellings suffered from condensation and mold growth, with 20% having severe problems (Becker, 1984). The origin of serious fungal growth is surface condensation or interstitial condensation of water vapor, most of it being generated by the normal domestic activities of the occupants. The general impact of planning and design is revealed from statistical analyses of post-occupancy surveys showing that location and orientation of dwellings and occupancy density (occupants/volume ratio) affect risks of indoor fungal growth, which is in line with theoretically anticipated trends (Adan, 1994).

There is a lack of understanding the interaction between outdoor climate, exterior wall constructions (including hygrothermal materials response and air infiltration) and the indoor climate, in relation to heating, moisture production, ventilation and occupancy behavior. Therefore, with funding support from the Syracuse Center of Excellence in Energy and Environmental Systems, the Combined Heat, Air, Moisture and Pollutants Simulation (CHAMPS) transport model has been developed (*http://beesl.syr.edu/champs.htm*).

Quantification of the mold risk and danger for the occupants of dwellings requires modeling of mold spores and MVOC (Microbial Volatile Organic Compounds) transport to the indoor air. The CHAMPS model currently accounts for heat, air and moisture flow in combination with transport and emissions of MVOC in building envelope systems. Understanding the micro climate next to the wall surface (the interior building physical boundary conditions) as one of the most decisive parameters for mold growth, its major affecting factors as the physical processes in the boundary layer and the wall-room interaction need to be investigated.

SCOPE AND METHODOLOGY

The aim of this work is to develop and to apply exemplary a new method that makes it possible to predict and to reduce the probability of mold fungus formation through the following major steps:

1. The infiltration air flows through wall leakages and the convective and diffusive transport of MVOC have to be taken into account for a better quantification of the mold risk inside the envelope construction. A more detailed description of the air and MVOC model and a simulation example can be found in Grunewald et al. 2007.
2. Based on boundary layer models, functionality shall be added to the CHAMPS model to account for the air velocity dependence of surface heat and vapor transfer (exchange or film) coefficients.
3. The CHAMPS model needs to be extended to consider the wall-room interaction (CHAMPS multizone). On the basis of calculated zone temperatures, relative humidities and air fluxes, it shall be possible to predict the input for determination of the local microclimate conditions in much higher precision.
4. The CHAMPS model shall be enhanced by models which describe the mycelium growth rates as function of local relative humidity and temperature. Knowing the microclimatic conditions, the mold growth model can be invoked to determine the conditions under which mycelium growth probability is little.

MODELING THE MICROCLIMATE NEXT TO THE WALL SURFACES

The microclimate next to the interior wall surfaces is determined by the indoor climate, in relation to heating, moisture production, ventilation and occupancy behavior and the design of the building envelope, particularly with respect to thermal bridges, moisture transport and air tightness. The heat and moisture transfer coefficients that govern the transport at the room-wall interfaces depend on the local air velocity. Equations for description of these dependencies can be derived from the set of boundary layer equations under simplifying assumptions. The work to be done can be cut into following areas:

- selection and review of appropriate modeling equations to account for wall-room boundary layers to describe air velocity, diffusion processes and temperature drop / humidity increase next to the wall surfaces,
- experimental and numerical verification of transfer coefficient dependencies for typical building materials,
- development of simplified models to estimate the local air velocity from the indoor air climate conditions under consideration of building geometry and room setup (layout of tables, chairs, other furniture),
- example simulation of typical situations that can lead to mold damages for quantification of a reference microclimate by CHAMPS.

Boundary layer modeling

The aim of this chapter is to highlight briefly the background and assumptions of the boundary layer models. A more detailed derivation of the boundary layer theory can be found in fundamental books for heat and mass transfer (for example in Jischa, 1982 or in Incropera et al. 2007).

The boundary layer equations are derived from a full set of balance equations concerning total mass, linear momentum, internal energy and partial species masses of a fluid phase. Assuming steady, incompressible, laminar 2D flow with constant fluid properties and negligible viscous dissipation, the boundary layer equations can be written as system of coupled differential equations for mass (continuity), momentum, energy and species of a fluid phase.

The solution of these equations is simplified by the fact that for constant properties, conditions in the velocity boundary layer are independent of temperature and species concentration. The solution can be derived by the method of Blasius, 1908, which is based on the similarity of the velocity profiles in the boundary layer stream for a flat plate in parallel flow (see Figure 1).

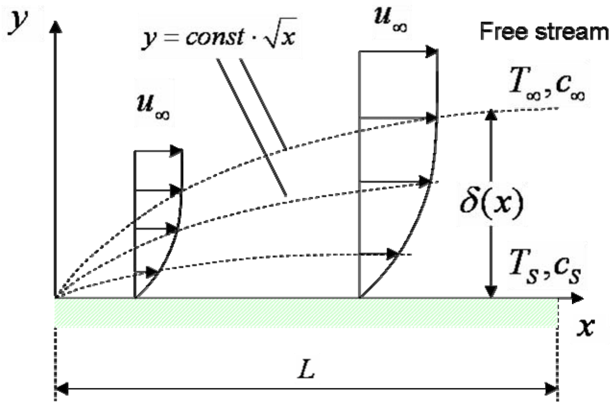

Figure 1: Similarity solution of boundary layer equations for a flat plate in parallel flow.

With respect to the fact that the boundary layer thickness varies proportionally to square roots of the distance measured from the leading edge, the viscosity and the air free stream velocity, new similarity variables for transformation of the coordinates x, y and velocities u, v can be introduced. Substituting these expressions yields a set of ordinary, non-linear differential equations of 2nd and 3rd order which can be numerically integrated. The numerical solution for different Prandtl and Schmidt numbers allows to establish the dependency between the surface transfer coefficients and the free stream air velocity which is given by the local Reynolds number Re_x. For practical applications, average transfer coefficients over a certain characteristic length L are of interest. The constants C and m account for different Reynolds numbers and different geometry like cylinders, squares, hexagon and vertical plate.

mass transfer coefficient $$h = \frac{\lambda}{L} \cdot C \cdot Re^m \cdot Pr^{1/3} \quad (1)$$

heat transfer coefficient $$h_m = \frac{D}{L} \cdot C \cdot Re^m \cdot Sc^{1/3} \quad (2)$$

The evaluation of equations (1) and (2) is depicted in Figure 2. The parameters listed below have been used for the calculation.

1. Input parameters

Thermal conductivity of air	λ =	0.0263	W/mK
Specific heat capacity of air	c_p =	1000	J/kgK
Density of air	ρ =	1.25	kg/m^3
Viscosity of air	ν =	1.55E-05	m^2/s
Specific gas constant of water vapor	R_v =	462	J/kgK
Reference temperature	T =	20	°C
Characteristic length	L =	0.50	m
Slope constant velocity profile	C =	0.664	
Exponent	m =	0.5	

2. Calculated parameters

Vapor diffusivity in air	D(T) =	2.61E-05	m^2/s
Prantl-Number	Pr =	0.74	
Schmidt-Number	Sc =	0.59	

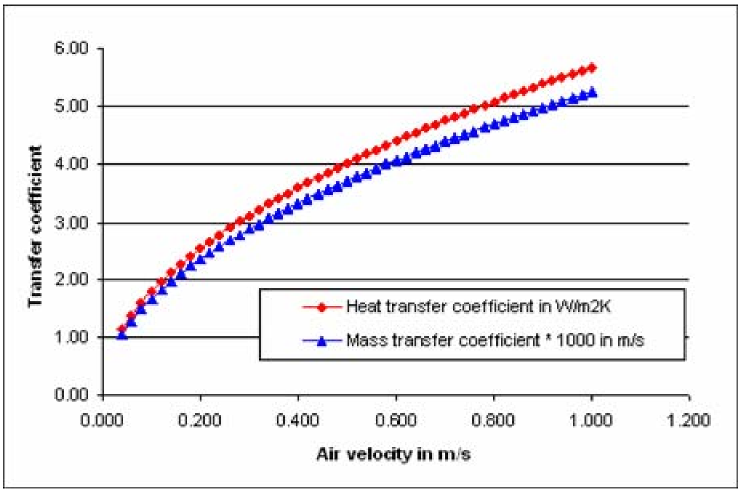

Figure 2. Heat and mass transfer coefficients of a flat plate with parameters as listed above.

Simulation example

The CHAMPS multizone model shall be exemplarily applied to a reference case. It will be quantified how the combined effects vary with outdoor climate conditions including humidity, temperature, sun radiation, rain penetration and wind pressure and the indoor climate conditions in relation to the occupancy behavior.

For quantification of reference microclimate conditions, a typical situation that leads to critical mold risk has been selected. A brick masonry wall of 360 mm thickness is subjected to natural climate conditions (location Amsterdam: temperature, humidity, wind, rain, sun and heat radiation) and sinusoidal indoor climate ($T = 22 \pm 2$°C, RH = 60 ± 5 %, maximum after 215 days). The wall is not insulated and the furniture in the living room is inappropriately arranged. A sofa has been placed next to the wall leaving a small air gap of 2.5 cm and covering the air gap by a pillow or something similar prevents proper ventilation. Figure 3 illustrates the construction and room setup.

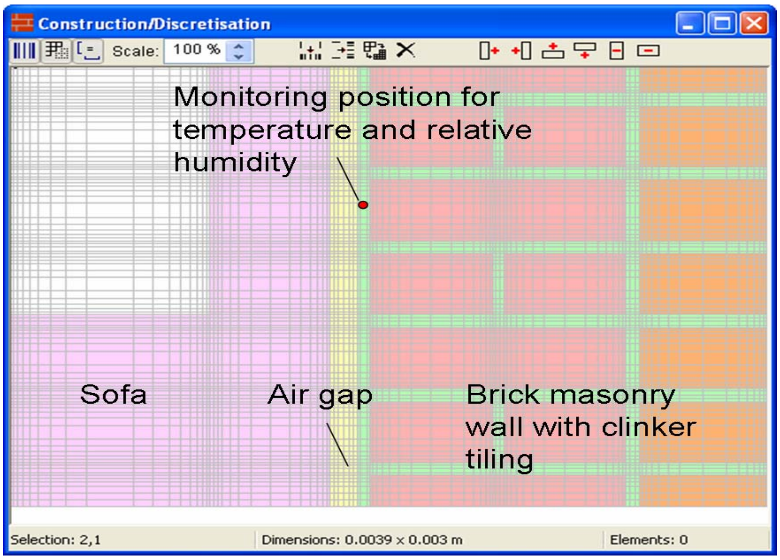

Figure 3: Construction and room setup of the sofa / brick wall simulation example. The red circle indicates the monitoring position for temperature and relative humidity on output.

The simulation is conducted for one year starting at the 1st of July. The sofa acts as thermal insulation which results in an temperature drop and humidity increase within the air layer. The temperature and relative humidity fields after 100 d simulation time (mid of October) are shown in Figure 4. At this time the outside temperature is low (T = 5°C) and condensation of water vapor diffusing through the sofa already went on. The blue color in Figure 4 indicates relative humidity next the wall being almost close to RH = 100 %.

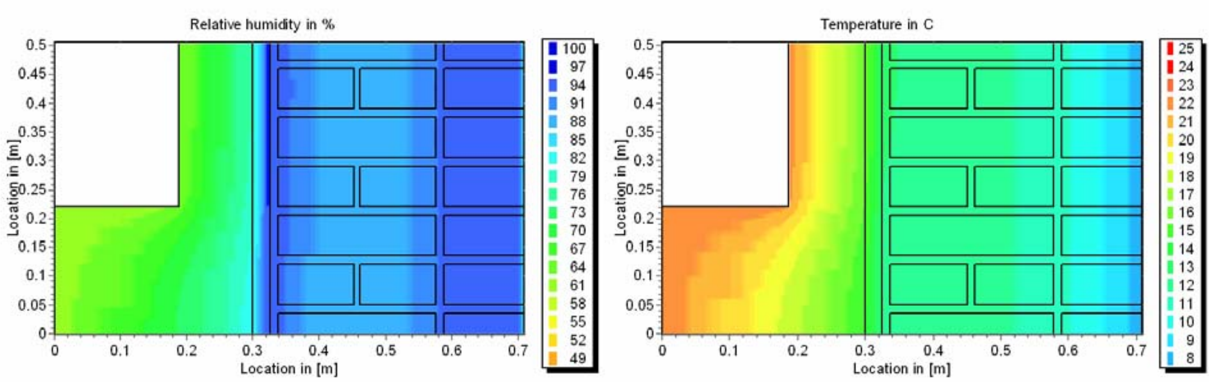

Figure 4: Fields of relative humidity (left) and temperature (right) after 100 days (mid of October).

In wintertime the situation gets even worse. This can be seen in the Figure 5 which depicts the climate at the monitoring positions. From 80 days (beginning of October), the relative humidity is constantly increasing which results in surface condensation and which forms favorable conditions for mold growth.

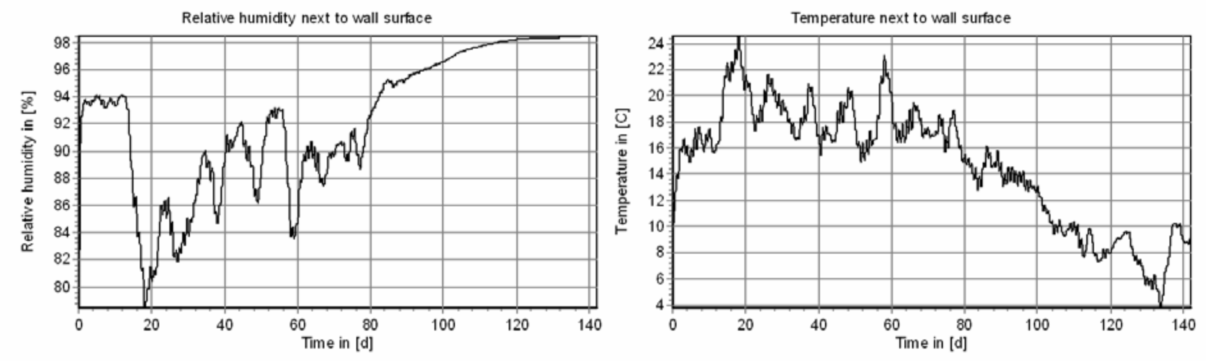

Figure 5: Courses of relative humidity (left) and temperature (right) at the monitoring position; time = 0 is the 1st of July.

This case represents the worst case since the air in the gap beneath the sofa was assumed to be still. The formation of a velocity profile has not yet been taken into consideration. Further simulations are being carried out to quantify the influence of the air velocity in combination with the boundary layer equations described above.

INTERFACING OF MULTIZONE AND ENVELOPE MODELS

The technical possibilities for interfacing CHAMPS multizone and CHAMPS envelope systems (BES) simulation models have been investigated. The focus was on the time integration method, the data handling and data exchange between the different models and codes and the technical details of the interface. Within the scope of this work, a simple representative multi-zone model was implemented. The conclusions drawn from the discussion of this representative model will however be valid for other, more complex multi-zone simulation models as well. For the CHAMPS–room interface the important indoor boundary conditions (related to the conditions in adjacent rooms/zones) can be formulated for each conserved quantity in terms of a heat and vapor flux density.

Discussion

The aforementioned flux quantities need to be formulated depending on the surface conditions of the building component/enclosure and the conditions in the zone adjacent to it. When considering a coupled, simultaneous simulation of multizone and CHAMPS models and the exchange of quantities between these models, one can formally classify the possible methods into *mass/energy-conservative* and *non-conservative* methods. Conservative methods ensure mass/energy conservation within the tolerances and errors of the numerical solution. For non-conservative methods mass/energy conservation may be violated depending on certain conditions.

For the conservative methods the calculated flux quantities need to be consistently used in the multizone model and CHAMPS model. Several conservative and non-conservative methods have been investigated:

- Fully coupled solution, balance equation systems are solved simultaneously
- Decoupled/staggered solution with iterative coupling
- Decoupled solution with imposed interface fluxes
- Non–conservative coupling, most flexible method

Implementation and Results

Of all methods mentioned above, only the last one has been found to be practical, if the indent is to couple complex simulation systems. An interface is defined at each wall surface where temperature, relative humidity and exchange coefficients are stored. Each model uses that data during the given integration interval to calculate boundary fluxes. Additional knowledge about the other coupled models is not required. The performance of the simulation largely depends on the interchange interval lengths. This is depicted in Figure e 6, where simulation times for a one year simulation of a single zone coupled to a one dimensional wall construction is shown, as function of the interchange interval length.

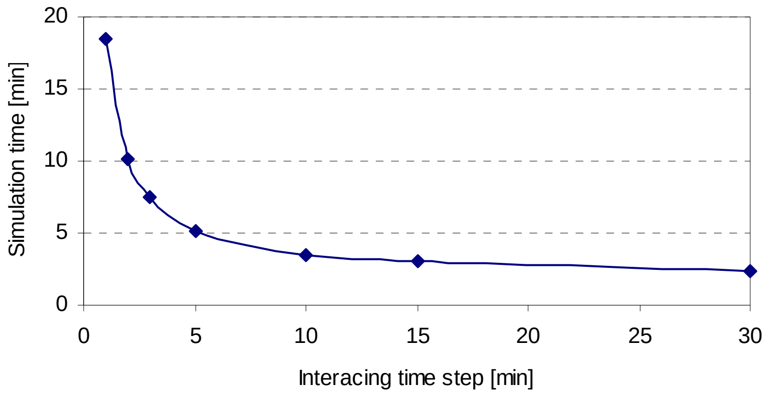

Figure 6. Simulation performance depending in interchange interval length

Once the exchange time step becomes smaller than the time step used by either model, the performance will greatly reduce. For exchange time steps larger than 30 minutes the simulation times do not change significantly. Long interchange intervals are therefore desirable, however, as mentioned above, accuracy (mass/energy conservation) might still be a problem with this method, particularly for larger interchange intervals. To investigate this, several simulation cases have been run, of which one will be briefly discussed here.

An empty room with a volume of 40 m^3 is modeled, ventilated at about 5 ach (0.06 m^3/s), with constant inlet relative humidity of 45% and admittedly a very simple heating schedule; begin of April the inlet temperature is turned down from 25 C to 18 C, and mid-September it is increased again to 25 C. The room has one outside brick wall (surface area 15 m^2), which is exposed to cold and rainy climate in northern Germany. Since the relative humidity is of special interest when determining growing conditions for mold fungi, it is used indicator for the quality of the coupled simulation.

While unexpected, the non-conservative method proved to be fairly accurate, even for larger coupling intervals, as can be seen in Figure 7. Regardless of the interchange interval lengths, from 5 minutes to 12 hours, the calculated relative humidity in the zone does not seem to differ much between the different simulations.

However, Figure 7 shows clearly the problem with larger exchange intervals. While the simulation results for 5 and 30 minute intervals are nearly the same, the relative humidity calculated with 3 hour interval shows already small steps. With 12 hour intervals the steps become too large, to be acceptable. Hence, the maximum permissible time step for this simulation is 30 minutes to one hour. This limit is process dependent and will vary depending on the simulation conditions.

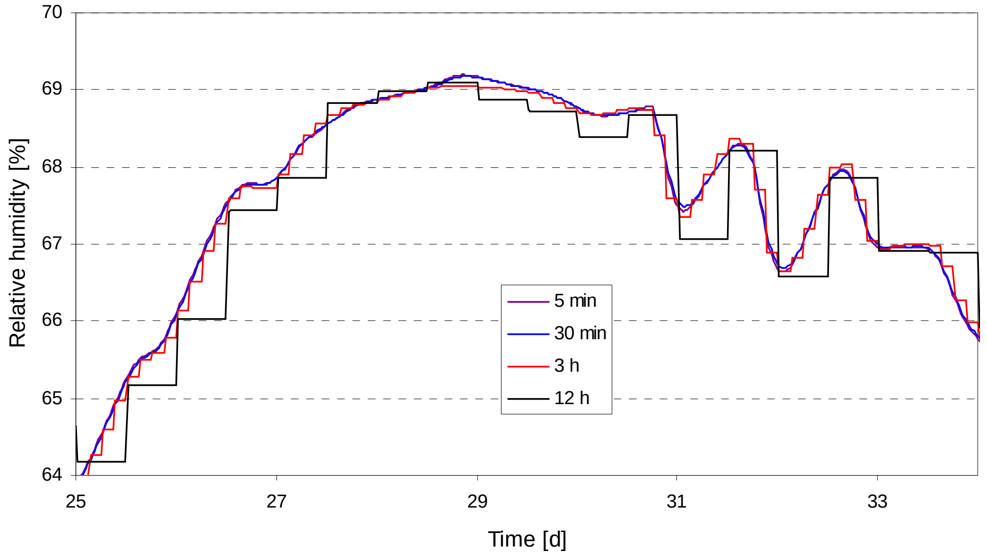

Figure 7. Stepwise change of zone RH for larger exchange intervals

CHAMPS simulations typically require time steps below one hour, yet for performance reasons, the interchange interval lengths should be above 15 minutes. Therefore an exchange time step between 30 minutes and one hour is the recommended compromise between performance and accuracy.

CONCLUSION AND ACKNOWLEDGEMENT

It is necessary that one can state how long and how often which humidity state may act on a building component, before a mould fungus is formed. Further research work is being conducted in the frame of the CARTI CoE project at the Syracuse University with support from the Syracuse Center of Excellence in Energy and Environmental Systems.

SUMMARY

In our previous research[1], office workers are relatively frequent in self-reported symptoms of MCS/IEI compare to construction worker who highly exposed to VOCs compounds. However in that research, the subjects were too small to say it clearly. Based on that research results, self reported symptom surveys to 110 office workers and personal exposure concentration measurement were conducted to 13 of people. VOCs exposure levels were measured within office, house and other places for a week by Passive Sampling Method. In this study, it was found that the number of office workers who met the operational criteria of MCS/IEI was 23.6% similar to 24.5% of previous result, and average of TVOC concentration was appeared high state by order of office, house, and personal exposure.

INTRODUCTION

Background

A relation between new houses' high VOCs concentration with MCS/IEI and SBS has been a social issue in Korea now. According to such reason, the study about IAQ in house is proceeding actively in Korea. However, people can be exposed to chemical compounds in various places not newly-built house only. In that reason, a people's daily life exposure to VOCs must be studied.
In our previous research, office workers were relatively frequent in self-reported symptoms of MCS/IEI compare to construction worker who highly exposed to VOCs compounds. However in that research, the subjects were too small to say it clearly and limited to construction worker.
As the next step, in this research, self reported symptom surveys to 110 office workers who are not construction workers were conducted. And personal exposure concentration measurement were conducted to 13 office workers. VOCs exposure levels were measured within office, house and whole day.

Objectives

This study aims to analyze how office workers are exposed to chemical compounds in their daily life, and to know the relation between concentration and their MCS/IEI. This research will show:
(1) the office workers' self reported symptom of MCS/IEI;
(2) the office workers' VOCs exposure levels for a week and VOCs concentration levels in their office and house;
(3) the relation between self reported symptom and VOCs exposure level;

(4) perform the office workers' health risk assessment by benzene.

METHODS

Survey method

Self reported symptom surveys using a questionnaire were completed from 3rd August, 2005 to 7th September, 2005. Subjects were organized in the following job categories: 110 office workers except construction worker and 112 students as the control group.
The questionnaire was same as that of the previous research[1] to compare both research results.
Operational MCS criteria developed by Iowa College[4] was used in this research. Table 1 lists the contents of this criteria.

Table 1. Operational MCS criteria

A. Routine or normal levels of exposure to chemical agents/substances(eg, gasoline, hair spray, paint, perfume, and soap)caused respondent to feel ill

B. Sensitivity (or illness after exposure) is reported to ≥2 of the following:
1. Smog/air pollution
2. Cigarette smoke
3. Vehicle exhaust/fumes
4. Copiers, printers, and office machines
5. Newsprint
6. Pesticides, herbicides, and fertilizers
7. New buildings
8. Carpeting and drapery
9. Organic chemicals, solvents, glues, paints, and fuel
10. Cosmetics, perfumes, hair spray, deodorants, and nail polish
11. Other

C. Symptoms are reported from ≥2 of the following categories:
1. Constitutional (eg, fever, night sweats, fatigue, weight loss, and weight gain)
2. Rheumatologic (eg, joint pain and muscleaches)
3. Neurologic (eg, headaches, sensory loss, tingling, and paralysis)
4. Cardiovascular (eg, palpitations)
5. Gastroenterological (eg, gas, bloating, and abdominal pain)
6. Dermatologic (eg, rash and blisters)
7. Pulmonary (eg, shortness of breath, cough, and wheezing)
8. Cognitive (eg, confusion, difficulty concentrating, and memory loss)

D. Symptoms lead to a behavioral change in ≥1 of the following ways:
1. Wearing a mask, gloves, or special clothes
2. Changing one's lifestyle to minimize chemical exposure
3. Moving to a new home/location
4. Use of special vitamins, supplements, or diets
5. Use of oxygen, antifungal agents, or neutralizing injections/drops

This table gives the operational definition or MCS. The criteria require that a person report illness from chemical sensitivity, report sensitivity to 2 or more types of incitants, have symptoms in at least 2 organ systems, and manifest evidence of impairment or behavioral change in response to the perceived sensitivity.

Personal exposure concentration measurement was conducted to 13 office workers. Each of 13 subjects got three tubes, for 24 hours, for office, and house. Total 39 measurement tubes were distributed, and got back.
Measurement method is Passive Sampling Method using the passive charcoal tube. Tubes installed in office and house collected VOCs during the time subjects kept their residence. When subjects did not dwell, they kept the tube in an aluminum tube bag. The tube for 24 hours was always worn or set around a subject. We made subjects to write their activities in their diary during the measurement period to guess variables may influenced on the VOCs concentration.

Analysis method

We analyzed 39 charcoal tubes for VOCs concentration, 3 travel blank tubes for the pollution from the process of keeping, transportation, and installation, and 3 blank tubes for the pollution of charcoal tubes themselves. Total 45 tubes were analyzed. The result is the mean concentration for a week, and its unit is $\mu g/m^3$. VOCs were extracted from a charcoal tube using the 2 mℓ carbon disulfide as a solvent, and analyzed by Gas Chromatograph (GC).
We analyzed six kinds of VOCs by the Indoor Air Quality Control Law in Korea; that is, benzene, toluene, ethylbenzene, m.p-xylene, o-xylene, and styrene. TVOC were calculated by converting VOCs from hexane to hexadecane into molecular weight of toluene.

RESULTS

Self-reported symptoms of MCS/IEI

Table 2. Subjects' socio demographic characteristics in self-reported symptoms survey

		Office workers (n=110)	Students (n=112)
Gender	Male	39.1% (n=43)	51.7% (n=62)
	Female	60.9% (n=67)	43.1% (n=50)
Age	Under 30s	71.8% (n=79)	97.3% (n=109)
	30s	17.3% (n=19)	2.7% (n=3)
	40s	6.4% (n=7)	-
	50s and over	4.5% (n=5)	-
Highest level of education	High school graduate	10% (n=11)	83.9% (n=94)
	University graduate	90% (n=99)	16.1% (n=18)
Length of service	Less than 5 years	71.8% (n=79)	-
	More than 5 years ~ Less than 10 years	10% (n=11)	-
	More than 10 years	18.2% (n=20)	-
Medical history	Existence	23.6% (n=26)	25% (n=28)
	Nonexistence	76.4% (n=84)	75% (n=84)

Table 2 lists subjects' socio demographic characteristics. The gender distribution was almost same to the previous research[1]. The percentage of under 30s was highest in both male and female groups. As the result, 26 office workers (23.6%) and 18 students (16.1%) were classified as MCS patients. This result was about the same as that of office workers group in previous research. 26 office workers (24.5%) were MCS patients in previous research. Therefore, it proved that office workers group had more MCS patient candidates than exterior and interior workers group. It was not that they were construction related office workers, but that they had usual characteristics of office work.

Personal VOCs exposure measurement

Subjects' socio demographic characteristics

Table 3 lists 13 subjects' socio demographic characteristics. 6 men and 7 women were selected. They were all late 20s except one. 6 people worked less than 1 year, the longest length of service was 5 years 2 months, and the average of length of service was 2.07 years. The age of office building was from 3 years to 20 years. Its mean was 10.5 years. The average of subjects' work hours was 10.1 hours, the longest hour was 13 hours, and the shortest hour was 8 hours. The age of house that can influence on the VOCs concentration was 7.8 years on average, but 8 houses of 13 were less than 5 years. Subjects spent most of their time in house or office, and used computer for many hours in office.
From self reported symptom surveys to these 13 people, 4 of them answered they have oversensitive matters. Especially, subject F was classified as a MCS patient.

Table 3. Subjects' socio demographic characteristics in personal exposure measurement

Subject	Gender	Age	Length of service	Work Hours per day	Age of office building	Ventilation type (office)	Permission of smoking (office)	Commuting method	House type	Age of house
A	Female	24	1year	11	5	Natural	X	Bus	apt.	14
B	Male	27	2years	11	18	Mechanical	X	Subway	apt.	5

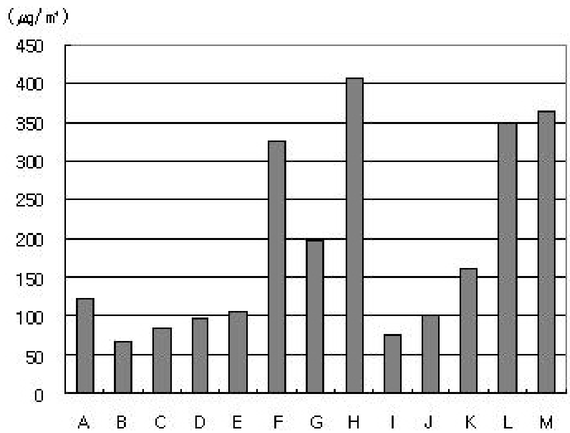

Figure 1. Persoanl TVOCs exposure level

Figure 1 displays the average of personal TVOCs exposure. It means the average of total values of 7 days, including transportation and outdoor space as well as house and office. Table 4 lists the concentrations of individual VOCs.

VOCs exposure in house

Figure 2 displays each subjects' VOCs exposure in their house. Though the target guideline of TVOC announced by WHO is 300 $\mu g/m^3$, the VOCs exposure in house exceeded it in case of C, F, G and L. F's multiplex and L's studio were newly-constructed houses less than 1 year. Table 5 lists the concentrations of individual VOCs in house.

Table 5. Individual VOCs exposure level in house ($\mu g/m^3$)

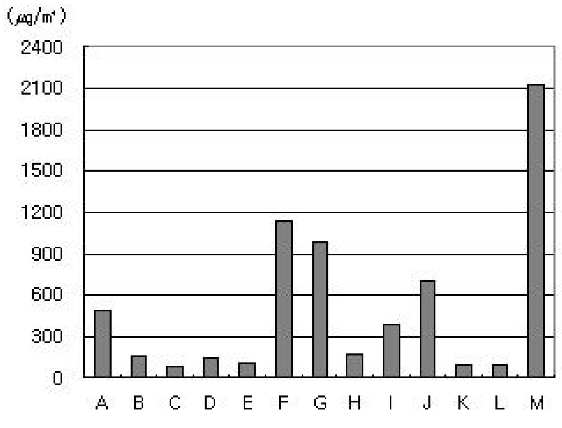

Figure 3. Personal TVOCs exposure level in office

Figure 3 displays each subjects' TVOCs exposure in their office. TVOCs exposure concentrations in office exceeded 300 $\mu g/m^3$ in subject A, F, G, I, J, and M. Especially, M's concentration in office was considerably high. It was 2100 $\mu g/m^3$. After interview, we assumed it caused by a lot of office machine including computers and printers, and the lack of ventilation. M's TVOCs concentration was 7 times higher than WHO target guideline. VOCs concentrations in office of F and G were exceeded 900 $\mu g/m^3$ also. F's office space was small, crowded, and had many office machines. Besides, smoking was permitted after regular office hours, and there was no mechanical ventilation. Table 6 lists the concentrations of individual VOCs in office. Toluene concentration in office was relatively high same to house.

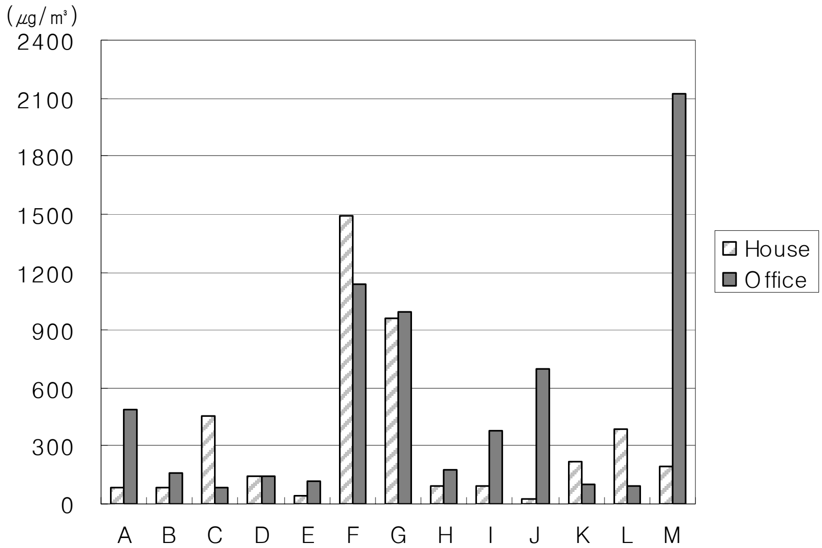

Figure 4. Comparison of TVOCs exposure levels in house and office

Figure 4 displays comparison of TVOCs exposure level in house and office by subjects. Almost all of subjects' TVOCs exposure level in office were higher than in house except C, F, K and L. Therefore, we can assume VOCs concentrations in office are higher than house because of office machines et al.

The relation between self-reported symptoms of MCS/IEI and VOCs concentrations

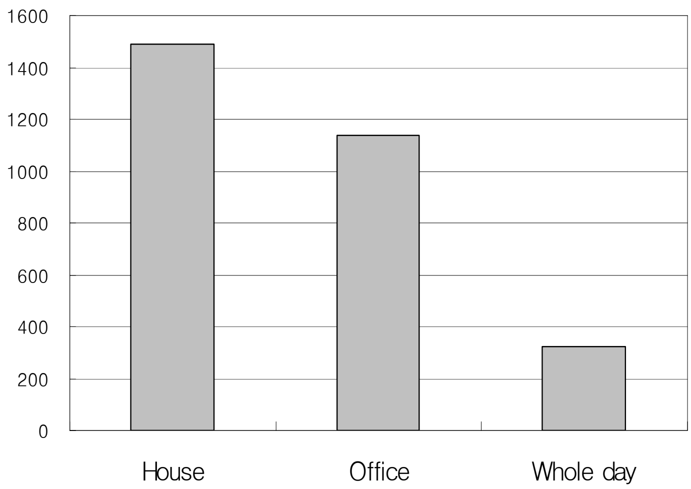

Figure 5. F (MCS patient)'s TVOCs concentrations in daily life

The subject who classified as a MCS patient was F. Figure 5 displays F's TVOCs exposure concentrations in daily life. F has been exposed to high TVOCs concentrations in whole day as well as house and office. Especially, TVOCs concentrations in house and office were about 4~5 times higher than WHO target guideline, 300 ㎍/㎥. These values were much higher than other subjects' values. F went out 4 nights a week. This life style could be one of the causes for high TVOCs concentrations. Toluene concentration exceeded Japanese guide line[5] (260 ㎍/㎥) in both of house and office. Therefore F's risk is serious in the side of individual

VOCs concentrations, too. From this result, we could assume the relation between VOCs exposure concentrations and MCS/IEI risk. Higher exposure make higher risk of MCS/IEI.

Health risk assessment by benzene

Risk assessment method

Mean of benzene exposure concentrations in whole day were used to assess the health risk. We referred to IRIS data of US EPA and other researches for the estimating benzene unit risk. The unit risk means excess carcinogenic probability that can be generated when a healthy adult was exposed to one pollutant(unit concentration: 1 $\mu g/m^3$) during whole life(the average span of a man's life is 70 years in this research). It is calculated through the cancer potency drawn by a dose-response assessment, the adult average weight, and a daily respiratory quotient (equation 1). Table 7 lists the unit risk in this research. A daily respiratory quotient was 20 m^3/day and The adult average weight was 60 kg.

Table 7. The cancer potency and unit risk of benzene

Carcinogens	Dose-response model	Cancer potency ((mg/kg/day)$^{-1}$)	Unit risk (($\mu g/m^3$)$^{-1}$)
Benzene	Low-dose linearity utilizing maximum likelihood estimates (Crump, 1994)	6.66×10^{-3} ~ 2.34×10^{-2}	9.57×10^{-6}

Unit risk (($\mu g/m^3$)$^{-1}$)

$$= \frac{\text{cancer potency}(\text{mg/kg/day})^{-1} \times \text{daily respiratory quotient}(\text{m}^3\text{/day})}{\text{wight}(\text{kg}) \times \text{unit conversion coefficient}(1000\text{ug/mg})} \quad (1)$$

The theoretical number of deaths was assumed through multiplying the carcinogens concentrations of environment by the unit risk and the number of exposure population.

The theoretical cancer mortality rates

$$= \frac{\text{benzene concentration } (mg/m^3) \times \text{benzene air unit risk}((mg/m^3)^{-1})}{70(\text{year}) \times \text{exposure population}} \quad (2)$$

Health risk assessment result

Table 8. The theoretical number of deaths by benzene

	concentration ($\mu g/m^3$)	unit risk	individual risk (mean)		Annual Population Risk (person/year)
			annual	lifetime	
whole daily life	7.20	9.57×10^{-6}	9.83×10^{-7}	6.89×10^{-5}	2.62

Subjects' benzene exposure was 0.1~34.47 $\mu g/m^3$. Benzene concentrations were appeared high state by order of office, house, and whole day.
We needed the carcinogenesis affecting to human body by benzene for assuming the theoretical number of deaths. We used the cancer potency offered by US EPA, and referred to Rinsky's research[6] and Crump's research[7] for the cancer potency of benzene. Table 8 lists the theoretical number of deaths by benzene. An individual risk of 13 subjects was 1.37×10^{-8}

~ 1.65×10^{-6}, and its mean was 9.83×10^{-7}. If office workers are 2,664,000 (from the National Statistical Office in Korea, 2005), the theoretical number of deaths by benzene is 2.62.

CONCLUSION

We performed self reported symptom surveys of office workers, and measured personal exposure VOCs concentration. Based on these results, we performed the carcinogenic risk assessment by benzene. The conclusions are as follows.

First, after self reported symptom surveys of office workers, it was found that office workers group had more MCS patient candidates than exterior and interior construction workers group, or students group.

Second, after VOCs exposure concentrations measurement, it was found that VOCs exposure level in office was higher than VOCs exposure level in house.

Third, the subject who exposed to high VOCs concentrations in both office and house had symptoms of MCS patient.

Finally, The Korean theoretical number of deaths by benzene was 2.62.

From these research results, we can say that continuous exposure to low level of VOCs (eg. office) has more risk of MCS/IEI than instantaneous exposure to high level of VOCs (eg. interior or exterior construction worker).

SUMMARY

This study was carried out in collaboration with the district heating firm RADET SA from Bucharest, Romania, in order to support the acoustic renovation of the thermal stations, to meet the modern requirements of the indoor acoustic comfort. The measurement sequence consists in the recording of the sound pressure level in a bloc of flats: inside the thermal station placed at the underground level of the building and inside the apartments. The noise level was 70 dB inside the thermal station and over 44 dB inside the apartments. The most affected rooms are those adjacent to the thermal station and those adjacent to the indoor chimney of the thermal station. These values of the noise levels overtake the standardized recommended maximum value. Multiple solutions should be considered in order to reduce the sound transmission from the thermal station towards the apartments.

INTRODUCTION

The building acoustics is accorded today an enhanced importance. The developing methodology of energy consumption and certification of the buildings considers the acoustic comfort as one of the criteria of the indoor environment quality, alongside with the indoor air quality or thermal comfort. The noise inside the apartments has two main sources: the outdoor and indoor noise sources. Among the indoor noise sources, the thermal station is maybe the most important one. Inside the thermal station the main noise generating sources are the boilers and the pumps [1], [2].

This study was carried out in collaboration with the district heating firm RADET SA from Bucharest, Romania, in order to support the acoustic renovation of the thermal stations, to meet the modern requirements of the indoor acoustic comfort [3], [4]. In this article we present first the measurement protocol, then the measured values of the sound pressure level inside the thermal station and in different apartments, and finally the airborne noise transmission towards the apartment adjacent to the thermal station.

METHODS

The measurements were carried out in a bloc of flats in Bucharest, Romania. A 1.6 MW thermal station is places at its underground level, producing the thermal energy necessary for four blocs. The space of the thermal station is a rectangular shape room of 70 m^2 surface and 4.6 m height (Figure 1). Apartment number 1 is adjacent to the thermal station while the apartments number 6,10,14 and 18 are above the thermal station and the apartments 7,11,15 and 19 are above the apartment number 1.

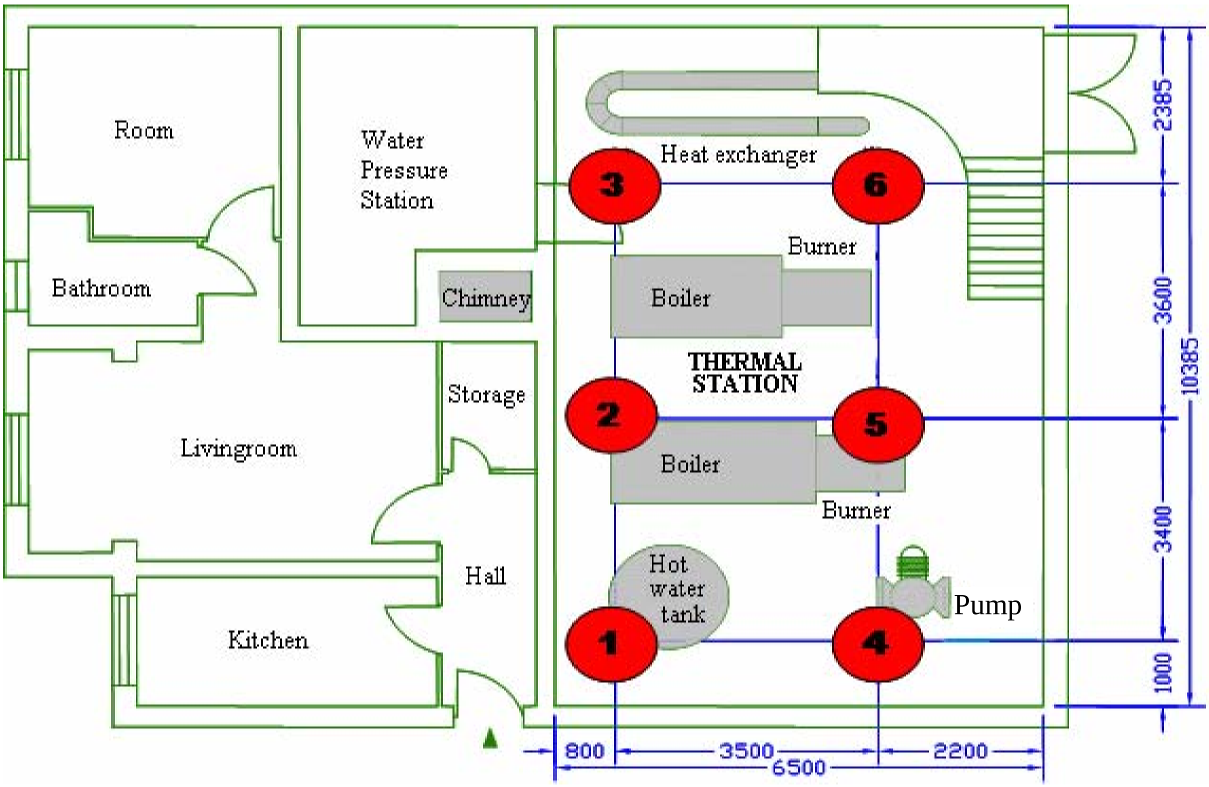

Figure 1. Ground level plan - Apartment no1 in the left and Thermal station in the right

The main equipments of the thermal station are: two boilers (1 MW and 0.6 MW) a tubular heat exchanger for hot water preparation, a hot water hank and pumps. The horizontal part of the chimney is under ground, under the apartment number 1 and the vertical part of the chimney has common walls with the thermal station, the water pressure station and all the apartments.

Sound pressure level recordings were carried out in three conditions:

- when neither the pumps nor the boilers were working,
- only the pumps were working, and
- both the pumps and the boilers were working at full capacity.

Each measurement sequence consists in the recording of the noise level inside the thermal station in six different points (Figure 1) and inside the apartments in the center of each room. All measurements were carried out at 1,4 m height from the floor of the thermal station of the floor of the rooms. One recording represents the equivalent sound level measured during one minute. The measurements were carried out during both daytime (12:00-14:00) and nighttime (22:00-24:00), when outdoor noise was reduced.

The measurements were carried out by means of the 2260 Investigator from Bruel&Kjaer. The visualization of the recorded data and their download were achieved by means of software Noise Explorer Type 7815.

RESULTS

Sound pressure level measurements inside the thermal station

The sound pressure level measurements inside the thermal station during daytime revealed the following values (Figure 2):

- when neither the pumps nor the boilers are working, the pressure level varies (it was measured in six different points) between 45 and 60 dBA,
- when only the pumps are working, the noise level varies between 52 and 63 dBA, and
- when both the pumps and the boilers are working at full capacity, the noise level inside the thermal station varies between 55 and 77 dBA.

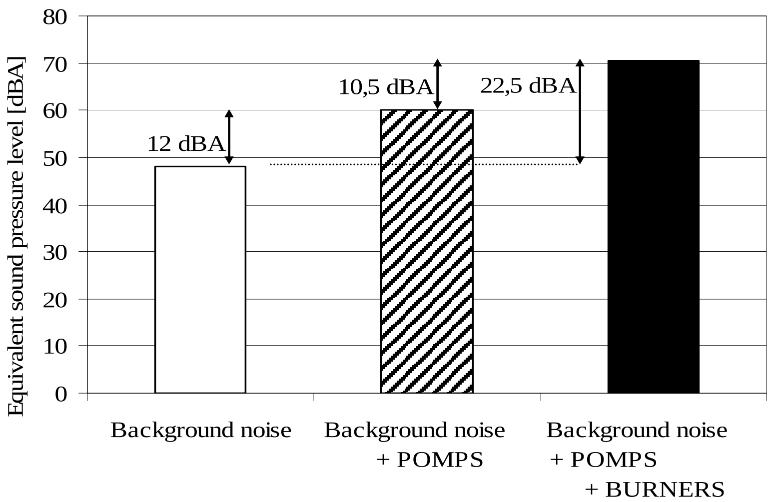

Figure 2. Variation of noise level in the thermal station according to the running status of the thermal station

We did not measure the noise level when only the burners are working because this situation is not often found in the regular running of the thermal station. However, we can calculate its value if we subtract the last two results, resulting that the corresponding noise level is 70 dBA.

Sound pressure level measurements inside the building

The simple visualization of the sound pressure level recorded inside the apartments (Figure 3) can underline some aspects relative to the: the noise sources and sound propagation ways. Theoretically, all the apartment owners wanted to record the noise level inside their apartments, however practically we were allowed inside only three apartments: 1,6 and 11.

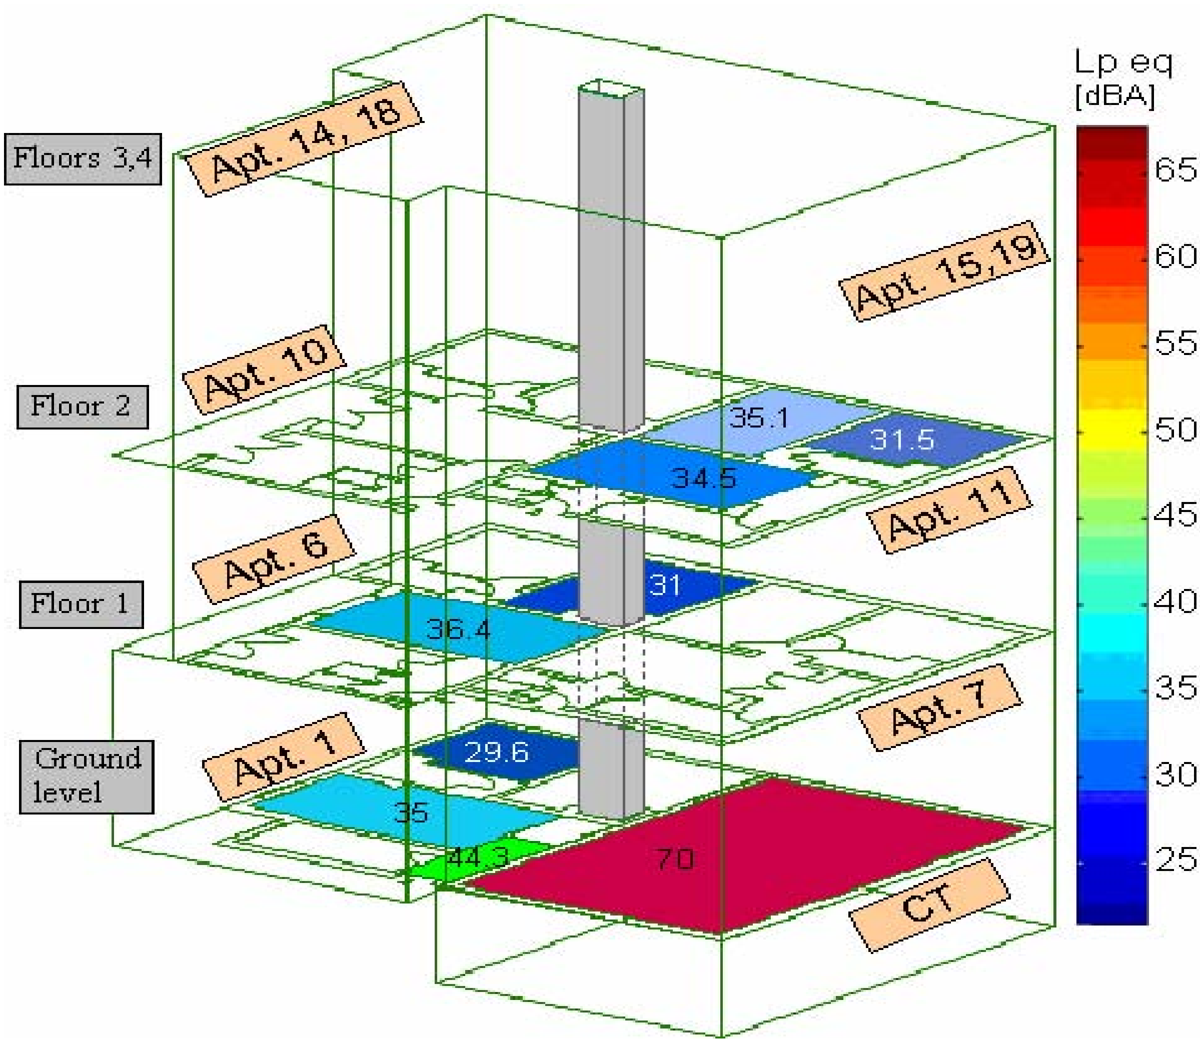

Figure 3. Variation of noise level inside the building

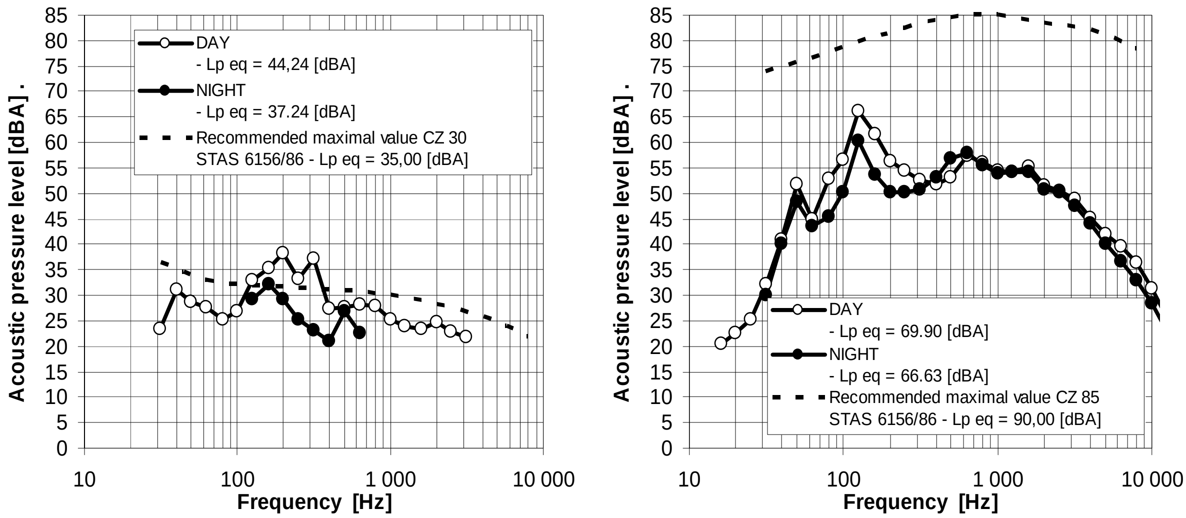
In Figure 3 we represented the architectural plan of the first three floors, and the value of the noise level according to each room. The hall of the apartment number 1 is the most affected (44 dBA) overtaking by 7 dBA the limit set by acoustic comfort standard [4]. In the apartment number 6, we recorded 36.4 dBA in the living room, more that the sound pressure level recorded in the living room of the apartment number 1 (35 dBA). Probably, the storage room of the apartment number 1 protects its living room from the airborne transmission of the noise. Finally, in the apartment number 11, the noise level was higher in the rooms adjacent to the chimney. We can draw out the conclusion that the most affected indoor spaces are those rooms adjacent to the thermal station and the rooms adjacent to the indoor chimney.

Night measurements showed sometimes higher noise level inside the apartments when the thermal station was not running, comparing to the periods when it was running. The conclusion is that the outdoor noise level contributes significantly to the resulting indoor noise level.

Airborne noise transmission through wall

In this paragraph we calculated the noise transmission [5] through the common wall between the thermal station and the apartment number 1, and finally compared its experimental value to a theoretical one.

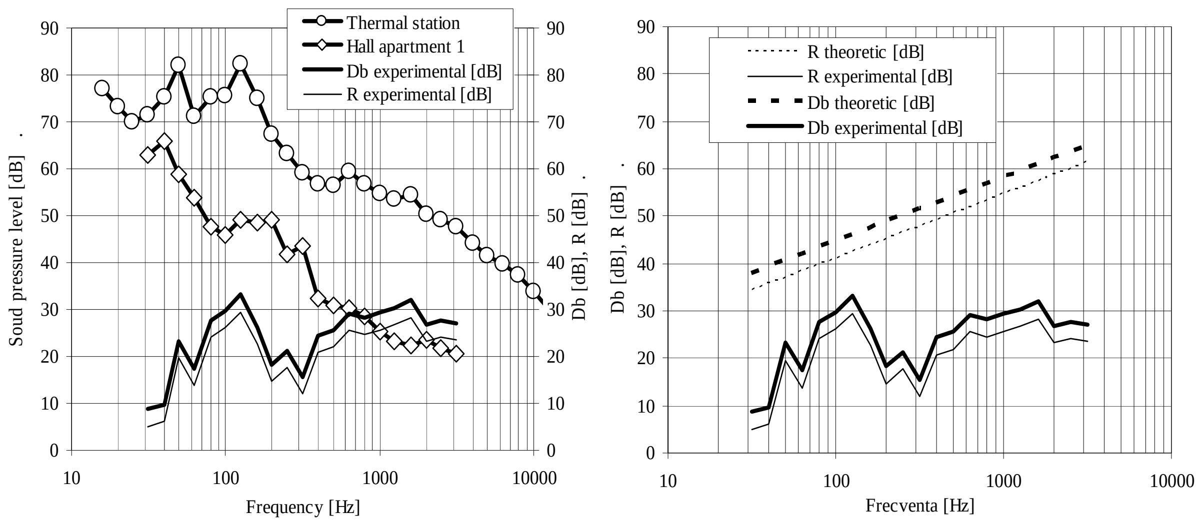
First, we note that sound level inside the apartment number 1 is higher (Figure 4a) than the maximal recommended value [4] for frequencies between 100 Hz and 400 Hz, during daytime. By the contrary inside the thermal station the noise level does not overtakes the maximal recommended value (Figure 4b).



a) b)

Figure 4. Sound levels in a) the hall of the apartment 1, b) the thermal station

The sound transmission loss, represented by means of the two common coefficients Db and R [1],[7], represents the difference of sound level between the thermal station and the hall of the apartment number 1 (Figure 5a). The transmission loss is under 30 dB for almost each frequency, while its theoretical value is much higher (40-65 dB) (Figure 5b). This variable error (15-35 dB) can by explained by a multiple phenomena of sound and vibration transmission.



a) b)

Figure 5. Noise transmission loss: a) experimental values b) theoretic values

Other laboratory experimental researches [6] of the sound transmission loss show a maximum 10 dB error due to airborne noise transmitted through lateral walls. The remaining 25 dB of the error between the experimental and theoretical sound transmission loss is explained by complementary transmission ways, among which we recall:

- the vibration of the boilers,
- airborne noise of the burners, or
- the vibration of the pumps.

DISCUSSION

The noise levels recorded inside the thermal station (1.6 MW) are: 48 dB while the thermal station is nor running, 60 dB when pumps were working and 70,5 dB when both burners and pumps were working. Another interesting result consists in the fact that even if inside the thermal station the sound level limit value was not overtaken, still inside the apartments its value overtakes the recommended maximal value of the acoustic comfort.

Concerning the noise propagation inside the building we would like to mention that some apartment owners were reluctant to "official" measurements inside their homes. Consequently, an acoustically proper installation of the thermal station equipments should be foreseen from the design stage of the installation. In our case, the most affected rooms are those adjacent to the thermal station and those adjacent to the chimney. The noise from the thermal station is transmitted to the apartments by many ways and therefore multiple solutions should be considered in order to reduce the noise transmission:

- to reduce the airborne sound transmission, one should add another small density wall layer (plaster and sound insulation) in order to interrupt the propagation of the sound wave to the wall,
- to reduce the vibration transmission generated by the pumps or boilers, one should avoid the contact between the pipes receiving the vibration from the devices and the walls and also foresee flexible support for the boiler [1],[7],
- to reduce the airborne sound level generated by the burners, one ought to foresee burner covers with sound insulation inside [8].

ACKNOWLEDGEMENT

We acknowledge the support of the district heating company RADET SA during the sound measurement sequences. We are also grateful to eng. Villiman for the contribution in this study.

A Study of Ventilation and Indoor Air Quality in Hospitality Venues Where Smoking is Allowed

Elia Sterling and Michael Glassco

Theodor Sterling Associates, 310-1122 Mainland Street, Vancouver, Canada

Corresponding email: elia@sterlingiaq.com

SUMMARY

Ventilation is an effective method of introducing air into and moving air through buildings to achieve indoor air quality that is comparable to outdoor air quality. However, questions have recently been raised about the effect of ventilation on indoor air quality in hospitality venues where smoking is allowed. Dilution and removal of particles and gasses from various sources within a building and controlling temperature and humidity are the primary reasons for ventilation. Some of the first mechanical ventilation systems were designed to control particles and gasses from tobacco smoke [1]. The objectives of this study were to evaluate the performance of ventilation systems in a number of typical hospitality venues in the United Kingdom where smoking is allowed, and to compare the air quality in these venues with the air quality outside of these venues.

This paper presents measurements of ventilation and indoor air quality including environmental tobacco smoke (ETS) parameters sampled in several locations within each venue to assess the effectiveness of the ventilation systems. The indoor air quality measurements included carbon dioxide, nitrogen dioxide, carbon monoxide, temperature, relative humidity, respirable suspended particles, particulate matter 2.5 ($PM_{2.5}$) and particulate matter 10 (PM_{10}). Particle measurements specific to ETS included Solanesol. The investigators also present measurements taken in the outdoor air as a means of comparing outdoor air quality with the indoor air quality.

This study demonstrates that ventilation is effective in hospitality venues where smoking is permitted and that the indoor air quality of these venues is comparable to the outdoor air quality.

INTRODUCTION

In order to evaluate the effectiveness of ventilation in spaces where smoking is allowed, a case study measuring ventilation and Indoor Air Quality (IAQ) in three well-ventilated hospitality venues in the United Kingdom was conducted.

METHODS

The case study consisted of:

- Phase 1 – Selection of venues
- Phase 2 – Site testing/assessment

Phase 1 – Selection Of Venues

In November 2006, researchers conducted site inspections of a total of twelve hospitality venues located in London, England and Cardiff, Wales. The purpose of the site inspections was to select three well-ventilated hospitality venues where smoking is allowed to be included in the study. Researchers gathered data on each of the twelve venues using a checklist that included the following:

- Location (busy street, city, etc.)
- Type of establishment (pub, restaurant, etc.)
- Ceiling height
- Estimated floor area
- Carbon dioxide levels and ventilation rate
- Seating capacity
- Number of smokers present
- Type of ventilation system
- Tobacco smoke control measures in place

Three of the twelve venues were selected for the case study based on the review of the data collected during the site inspections. The other nine venues were considered inappropriate for inclusion in the case study for various reasons including, ineffective or limited ventilation, low occupancy levels, low smoking densities and limited or no appropriate locations for placement of sampling equipment. Of the three venues selected, one of the venues was located in London, England and two of the venues were located in Cardiff, Wales.

Cardiff

Venue #1 - Traditional Pub

A typical small one-room pub located on the Outskirts of Cardiff with seating for approximately 60 persons.

Venue #2 – Newly Renovated Pub/Restaurant

This venue is a purpose-built restaurant/pub and is considered an up-scale venue that has undergone extensive renovations and upgrades over the past few years. It is located in the heart of Cardiff on the main street, which is heavily traveled by automobiles. This venue has a seating capacity of 850.

London

Venue #3 – Wine Bar/Restaurant

The venue is an elegant restaurant/wine bar located on the basement level of a building located in central London. The street is quite heavily traveled by automobiles and the restaurant has a seating capacity of approximately 120.

Phase 2 – Site Testing/Assessment

The benchmarks used by a consensus of indoor air quality researchers to evaluate indoor air quality in commercial and hospitality environments are carbon dioxide (metabolic activity and ventilation), carbon monoxide and nitrogen dioxide (combustion byproducts), respirable suspended particles (air cleanliness), temperature and humidity (both comfort measurements) [2][3][4][5][6][7][8].

The majority of researchers evaluating indoor air quality in spaces where smoking occurs have used respirable suspended particles (RSP) as a marker for tobacco smoke. RSP is the most commonly used marker because it is easy to measure and the equipment to measure RSP is readily available. RSP is generally defined as a particle less than 4 micrometers in size [9]. Particles are generally measured and reported as RSP, $PM_{2.5}$ (particles less than 2.5 μm) and PM_{10} (particles less than 10 μm).

It is important to note that particulates found in both the indoor and outdoor air, including RSP, $PM_{2.5}$ and PM_{10} are not specific to tobacco smoke and are contributed by many sources including human metabolism, combustion sources (e.g., cooking, heating, dust, automobile exhaust) and other activities [10][11]. However, Solanesol is a particulate that is exclusive to tobacco smoke [12]. Solanesol is known to occur in a constant ratio to the total RSP contributed by tobacco smoke [13][14][15][16]. Thus, measuring Solanesol allows the researcher to determine the total amount of RSP contributed by tobacco smoke to the indoor air. The ratio of Solanesol is approximately 3% by weight of the RSP contributed by tobacco smoke.

Three sampling locations were selected inside each of the hospitality venues. These locations were selected to be representative of occupancy and ventilation. At each of these three locations, both instantaneous and integrating air sampling techniques were utilized. In addition, one outdoor location was selected as representative of ambient conditions.

Instantaneous sampling was conducted for the following parameters both indoors and outdoors:

- Carbon dioxide (CO_2)
- Carbon monoxide (CO)
- Temperature and relative humidity
- Nitrogen dioxide (NO_2)
- Respirable suspended particulate (RSP), Particulate Matter 10 (PM_{10}) and Particulate Matter 2.5 ($PM_{2.5}$)

Instantaneous air quality measurements for the IAQ parameters noted above were collected at one-hour intervals over the course of the 8-hour sampling day at each location.

Instantaneous measurements were collected with the following instrumentation.

Carbon dioxide (CO_2), temperature, relative humidity and carbon monoxide (CO) were measured with the TSI Q-Trak. The Q-Trak has the following specifications:

Sensor	Sensor type	Range	Resolution
Carbon dioxide	Non-dispersive infrared	0 to 5000 ppm	1 ppm
Temperature	Thermistor	0 to 50^{o}C	0.1^{o}C
Relative Humidity	Thin-film capacitive	5 to 95%	0.1%
Carbon monoxide	Electro-chemical	0 to 500 ppm	0.1 ppm

Nitrogen Dioxide was measured with the Biosystems Toxi Pro. The Toxi Pro has the following specifications:

Sensor	Sensor type	Range	Resolution
Nitrogen dioxide	Electro-chemical	0 to 20 ppm	0.1 ppm

Respirable Suspended Particulate (RSP), PM_{10} and $PM_{2.5}$ were measured using a TSI Inc. forward light scattering DustTrak™ aerosol monitor. The cyclone attachment was in place for the RSP measurements and different size selective adaptors were utilized to acquire the PM_{10} and $PM_{2.5}$ measurements. The sensor is a 90^o light scattering laser diode sensor that has a range of 1 to 100,000 ug/m3 and a resolution of +/- 0.1% of the reading or +/- 1 ug/m3, whichever is greater.

Indoor air quality research has shown that Dustrak measurements tend to overestimate indoor particulate levels when compared to the traditional and widely accepted gravimetric sampling and analytical methodology.

The Dustrak is factory calibrated to the standard ISO 12103-1, A1 test dust (formerly Arizona Test Dust). This standard test dust is used because of its wide particle size distribution (Model 8520 Dustrak Operation and Service Manual). In recognition of the potential for the instrument to overestimate dust differing in type and composition from the factory calibration standard a methodology is presented to determine an applicable correction factor for specific aerosols in the Operation and Service Manual.

Research suggesting the need for the application of a correction factor for the Dustrak includes Heal, et al, 2000, Edwards, et al. 2006 and Jenkins 2004 [17][18][19]. This research has determined that the Dustrak overestimates particulate levels when compared to gravimetric sampling techniques by factors ranging from 2 to 3.24.

A correction factor for this case study was calculated based on the method presented in the Operation and Service Manual for the Dustrak.

The correction factor was calculated using data from ten (10) different indoor air quality investigations including 101 comparable data points where both gravimetric RSP data and Dustrak RSP measurements were acquired side-by-side in smoking-permitted environments. From these data and comparison of side-by-side sampling results (Dustrak and gravimetric sampling), the appropriate correction factor was calculated to be 3.84.

In addition to the instantaneous measurements of CO_2, CO, NO_2, RSP, $PM_{2.5}$ and PM_{10}, integrated air sampling was conducted for both Solanesol and RSP (gravimetric) over an 8-hour period at each of the three monitoring locations at each of the three venues to determine time weighted average concentrations of particulates.

For determination of both Solanesol and gravimetric RSP the American Society of Testing and Materials (ASTM) Method D 6271-98 protocol was followed for both collection and analysis [13].

Within the three hospitality venues, investigators observed the following factors in addition to the air quality measurements:

- Number of cigarettes smoked per hour of testing.
- Overall occupancy load at 1-hour intervals.
- Floor layouts and space volume was determined.
- Air movement patterns using smoke pencil testing.

Measurement of Ventilation Rates

In the United Kingdom, the professional standards of practice for the design, installation, operation, maintenance and manufacturing of natural and mechanical ventilation systems are defined by the Chartered Institute of Building Services Engineers (CIBSE). CIBSE has provided recommendations for ventilation rates in smoking and non-smoking environments in "Ventilation and Air Conditioning CIBSE Guide B-2" (2001) [20]. A table of the CIBSE recommended outdoor air supply rates for smoking environments is presented below.

Table 1. Recommended Ventilation Rates – Smoking Environments

Level of Smoking	Proportion of occupants that smoke (%)	Outdoor air supply rate (litres per second per person)	Outdoor air supply rate (cfm per person)
No smoking	0	8	17
Some smoking	25	16	34
Heavy smoking	45	24	51
Very heavy smoking	75	36	76

cfm – cubic feet per minute

The performance of a ventilation system with respect to the amount of outside air provided is usually determined in indoor air quality research by measuring concentrations of CO_2 in the indoor environment [21]. For this study, ventilation rates were calculated using CO_2 as a surrogate marker. The following mass balance equation was used to determine ventilation rate in the spaces using the carbon dioxide levels measured inside and outside. This equation is presented in Appendix C of the ASHRAE Standard 62-2004 [22].

$$C_s = N/V_{oa} + C_{oa} \qquad \text{or} \qquad V_{oa} = N/(C_s - C_{oa})$$

Where,
C_s – carbon dioxide in the space
N – CO_2 generation rate per person based on activity level (0.0106 cfm for persons performing office work
V_{oa} – Ventilation rate in cfm
C_{oa} – CO_2 level outside using 350 ppm estimate (expressed as 0.00035)

RESULTS

Table 2 below shows data specific to each venue with regard to ventilation and occupancy.

Table 2. Information on Each Venue – Ventilation and Occupancy

	Venue #1	Venue #2	Venue #3
Ventilation Rate	80 (40)	64 (32)	51 (25.5)
Average hourly occupant count	13	65	40
Cigarettes smoked per hour	12	29	6.0
Smoking Rate*	1	0.5	0.2

Ventilation rate – in cubic feet per minute of air per person (litres per second per person)
* - Cigarettes smoked per person per hour

All three of the venues were observed to be well ventilated. The ventilation rates measured in the venues were within the ventilation rates recommended by CIBSE for the amount of smoking observed. The occupancy rates and smoking rates were typical for hospitality venues in the UK.

The following tables present indoor and outdoor air quality measured for each of the three venues.

Table 3. Indoor and Outdoor Measurements, Venue #3 – December 7, 2006

	Venue #3	Outdoors
CO (ppm)	2.9	3.0
NO_2 (ppm)	< 0.1	< 0.1
RSP – instantaneous ($\mu g/m^3$)	29	42
$PM_{2.5}$ ($\mu g/m^3$)	27.6	41.3
PM_{10} ($\mu g/m^3$)	34.0	48.7
RSP – gravimetric ($\mu g/m^3$)	30.0	Not measured
Solanesol ($\mu g/m^3$)	< 0.5	Not measured

Table 4. Indoor and Outdoor Measurements, Venue #2 – December 5, 2006

	Venue #2	Outdoors
CO (ppm)	2.9	2.5
NO_2 (ppm)	< 0.1	< 0.1
RSP – instantaneous ($\mu g/m^3$)	33.9	24.9
$PM_{2.5}$ ($\mu g/m^3$)	33.7	25.3
PM_{10} ($\mu g/m^3$)	34.9	29.4
RSP – gravimetric ($\mu g/m^3$)	56.7	Not measured
Solanesol ($\mu g/m^3$)	< 0.5	Not measured

Table 5. Indoor and Outdoor Measurements, Venue #1 – December 4, 2006

	Venue #1	Outdoors
CO (ppm)	3.1	2.9
NO_2 (ppm)	< 0.1	< 0.1
RSP – instantaneous ($\mu g/m^3$)	49.4	21.3
$PM_{2.5}$ ($\mu g/m^3$)	46.3	18
PM_{10} ($\mu g/m^3$)	49.4	24.3
RSP – gravimetric ($\mu g/m^3$)	43.0	Not measured
Solanesol ($\mu g/m^3$)	< 0.5	Not measured

Table 6. Average Results from All Venues

	Average	Outdoors
CO (ppm)	2.97	2.8
NO_2 (ppm)	< 0.1	< 0.1
RSP – instantaneous ($\mu g/m^3$)	37.4	29.4
$PM_{2.5}$ ($\mu g/m^3$)	35.9	28.2
PM_{10} ($\mu g/m^3$)	39.4	34.1
RSP – gravimetric ($\mu g/m^3$)	43.2	Not measured
Solanesol ($\mu g/m^3$)	< 0.5	Not measured

Indoor carbon monoxide levels averaged 2.97 ppm while outdoor levels average 2.8 ppm showing that indoor results were found to be consistent with outside.

Indoor and outdoor nitrogen dioxide levels were consistently found to be below levels of detection (0.1 ppm) for the methodology used.

Indoor RSP (instantaneous), $PM_{2.5}$ and PM_{10} averaged 37.4 $\mu g/m^3$, 35.9 $\mu g/m^3$ and 39.4 $\mu g/m^3$ respectively. Outdoor RSP (instantaneous), $PM_{2.5}$ and PM_{10} averaged 29.4 $\mu g/m^3$, 28.2 $\mu g/m^3$ and 34.1 $\mu g/m^3$ respectively. RSP (gravimetric) averaged 43.2 $\mu g/m^3$.

Based on the results of this case study measuring air quality and ventilation parameters, we conclude that the effective ventilation of the hospitality venues was able to achieve levels of particles and gases in an indoor environment, where smoking occurs, that are comparable to the levels of particles and gases present in the outdoor environment.

DISCUSSION

Ventilation is the intentional introduction into and movement of ventilation air through an enclosed space. The purpose of ventilation is to achieve levels of particles and gasses in the indoor environment that are comparable to levels of particles and gasses in the outdoor air and to control temperature and humidity. Neither air filtration (cleaning) or air conditioning is ventilation because neither process introduces air into or moves air through an enclosed space. The results of this study which includes three well ventilated hospitality venues which are typical of similar venues located throughout the UK demonstrates that ventilation systems when operated effectively can achieve levels of particles and gasses in an indoor environment where smoking occurs that are comparable to levels of particles and gasses present in the outdoor environment. It is interesting to note also that in the three hospitality venues studied where smoking occurred the levels of particles and gasses measured were also found to be comparable or lower than levels of particles and gasses measured in similar hospitality venues where smoking is not allowed and does not occur [23][24][25][26].

This is a case study limited to three hospitality venues however the results are important because they show that ventilation can be an effective method of providing air in enclosed spaces where smoking is allowed that is of comparable quality to the ambient outside air. Further research is required to statistically validate this finding.

ACKNOWLEDGEMENT

Funding for this research project was provided by Imperial Tobacco Limited. Assistance with coordination of the equipment in the UK was provided by Jaros, Baum and Bolles UK Limited.

Human responses to thermal environment

Individual Thermal Comfort and Energy Optimization

SUMMARY

This paper describes a methodology for improving individual thermal comfort in an office building without increasing energy consumption. Our approach is based on the observation that an individual's preferred temperature is not a precise value, but a range around a preferred value. We take advantage of this to optimize the temperature settings of each occupant's personal space to minimize the overall energy use. We have employed a nonlinear programming approach to improve individual thermal comfort without increasing energy consumption, even possibly saving energy. This optimization approach has been applied with very encouraging results for many office population distributions in 15 USA cities, and over a wide range of interior wall thermal resistances. This approach has also been generalized and simplified to allow optimization with a reduced set of inputs.

INTRODUCTION

Problem Statement

Conditions for human thermal comfort in built environments have been defined [1] and adopted in the published standards, such as ASHRAE 55-2004 [2] and ISO 7730 [3]. These standards specify the range of thermal conditions (temperature, humidity, etc) under which a majority of the occupants would be satisfied, using the widely used PMV and PPD indexes of Fanger [1]. Because of individual physiological and psychological differences, it is impossible to satisfy everyone if the same indoor conditions are provided to all occupants. In fact, the standards are based on average criteria for population comfort, indicating that building environmental control systems be designed to meet the thermal comfort needs of about 80% of the occupants, leaving a significant (PPD ≈ 20%) of the occupants in various states of thermal discomfort. Such "*One-Size-Fits-All*" (OSFA) systems employ only one (or a few) thermostat(s) to control the temperature of relatively large building zones, each occupied by a relatively large number of people.

Numerous researchers have shown that allowing building occupants to adjust their local environments to their liking improves their satisfaction and productivity in the workplace [4-6]. This philosophy has been called "*Have-It-Your-Way*" (HIYW) in this study. Tham [4] studied the effects of the ambient temperature and outdoor air supply rates on the performance of call center operators. He observed that the operators were more productive at the lower temperature (22.5°C), and were able to tolerate, without a decrease in productivity, the more typical higher temperature of 24.5°C when the outdoor air supply rate was doubled. Wyon [5] estimated that by providing individual control equivalent to ±3°C, productivity would increase 2.7% for logical thinking, 7.0% for general office work, 3.4% for very skilled manual work, and 8.6% for very rapid manual work. In a later field study [6], Wyon also showed that poor air quality, resulting from low outdoor air supply rate and uncomfortable temperatures can have a negative effect on office productivity in the range of 6-9%. Kroner *et al* reported equally impressive gains in satisfaction and productivity when personal environmental control was enabled [7]. Fisk [8] estimated the potential annual gain of the improved worker performance is between $20 billion and $160 billion (in 1996 U.S. dollars) due to the changes in thermal environmental and lighting conditions.

While the studies cited above demonstrate the comfort and productivity value of personalized environmental control, the building-wide energy consumption implications of personalized control have not been adequately explored -- specifically, the concern that higher energy consumption would result from individualized environmental control in buildings where various, occupant-controlled microenvironments communicate through conducting walls, partitions and openings. In this paper, we present the results of an investigation of comfort and energy optimization in simulated office buildings employing the HIYW approach, and describe an optimization and control strategy that would provide either enhanced thermal comfort to *all* occupants at the same, or lower energy consumption than OSFA systems, or achieve lower energy consumption than OSFA systems at the same or lower PPD.

METHODS

For this study we employed a constrained optimization method to either: a) maximize the occupants' thermal comfort with no increase in energy consumption, or b) minimize energy consumption with no deterioration in thermal comfort. Between these two alternatives, there are many other feasible scenarios that achieve improvements in both objective functions. The essential technology enabling us to achieve these objectives is the provision of distributed environmental control systems that can both be adjusted by the individual occupants to suit their specific comfort conditions, and optimized by the system manager to achieve minimum overall energy consumption – what we designate as the optimized HIYW approach.

To achieve these objectives, it is necessary to develop two linked simulation models: 1) a building energy consumption model that accounts not only for internal and external thermal loads, but also for energy transfer between individual offices within the building, when each office is independently controlled by an occupant-adjusted thermostat, and 2) a model of individual (not population) thermal comfort. An added benefit of introducing an individual thermal comfort model is that it allows us to identify building environmental control scenarios under which some occupants might be very dissatisfied with their thermal environments over extended periods of time, even though the PPD is well under the 20% value accepted by the standards [2, 3]. These two basic models must be executed simultaneously in an iterative manner involving thousands of iterations within an optimization scheme to satisfy the specified objective function subject to the imposed constraints.

Building Energy Model

There are a number of software programs dedicated to the simulation of building energy usage, e.g., TRNSYS [9] and US DoE energy+ [10]. These models are designed to perform hourly (or sub-hourly) time-dependent simulations of complex buildings subject to diurnal and seasonal weather and internal load (e.g., occupancy) variations. As capable as these codes are, their execution time is too long to make them practical for the intensely iterative simulations necessary in the present optimization study. This is because HIYW systems require that the building be simulated as a large number of interacting zones (rooms), each with its own thermostat, not just a few well-mixed zones. Put differently, HIYW systems have a much higher number of degrees of freedom than the OSFA systems. For the optimization analyses explored in this study, a rapidly-executing building energy model was required (executing in ~1 second versus the several minutes needed for TRNSYS or e+ transient simulations).

In this study, we opted for a very fast thermal circuit model of the building, coupled with a temperature-bin weather model. This is a lumped parameter approach in which each room, as well as the outdoors, is represented by a node (a temperature) connected to other nodes by a network of thermal resistances [11]. Since the temperature differences between adjacent rooms are small, radiation was linearized and lumped with convection in the thermal circuit representation of the building. Equation (1) expresses the overall thermal conductance and heat flow between nodes *i* and *j*. A higher value of the conductance implies a stronger coupling between adjacent offices, which may make it more difficult to achieve HIYW.

$$U_{ij} = \dot{m}_{ij} c_p + \frac{1}{\frac{1}{A_{ij} h_i} + \frac{L}{k A_{ij}} + \frac{1}{A_{ij} h_j}} = C_{ij} + \frac{1}{R_{ij}}\,;\; \dot{Q}_{ij} = U_{ij}\left(T_j - T_i\right), \qquad (1)$$

The basic building used in the analysis consists of a single story office building, divided into *n* x *m* well-mixed zones (nodes), with a typical HVAC system consisting of a heat pump and a furnace. A node corresponds to an office with three internal heat sources (occupant, computer, and task lighting). Figure 1 depicts a typical node in the thermal circuit. Zone *i* at T_i is connected to 3 neighboring zones at T_{i-1}, T_{i+1}, and T_{i+n} by a resistance that is appropriate to internal walls (R_{in}), and it is also connected to the outside (at temperature T_o) by a resistance that is appropriate to the exterior walls (R_{out}). The model allows for prescribed advective flows, m_{ij}, between the rooms. The model ignores the thermal inertia of the walls and enclosure and does not account for time dependency, allowing its use in combination with the much simpler (and faster) temperature-bin method to incorporate NREL's TMY2 climatic conditions [12] in annual energy computations. In this study, we included only bin hours during business hours (6:00 AM to 7:00 PM), stipulating that a OSFA strategy is adequate during unoccupied hours. We later performed comparisons with time-dependent TRNSYS simulations for 15 cities representing a wide range of climatic conditions in the United States and for different building populations (individual thermal preferences). These calculations confirmed that the temperature-bin approach is adequate insofar as the computation of the annual energy consumption in our optimization studies is concerned [11].

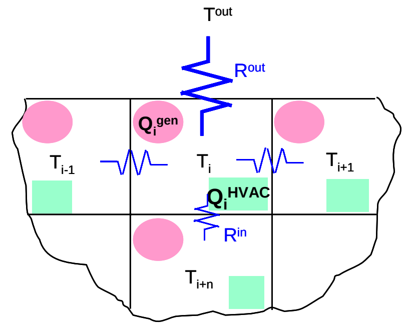

Figure 1: Typical Node

An important concern in implementing personalized control of thermally connected spaces is the potential increase of energy consumption resulting from internal energy transfer between adjacent warm and cool spaces, especially when the thermal resistance of interior walls is small or when the spaces are connected through large openings and corridors. We will show later in this paper that this concern can be mitigated by utilizing the optimization approach discussed here.

Individual Thermal Comfort

Indices of thermal comfort are well documented in the literature [1, 13-15]. The Fanger PPD-PMV curve [1] is widely used and is the basis of both the American and European standards [2,3]. These standards are designed to satisfy the thermal comfort needs of a majority of building occupants, not individual occupants. Little work has been published on individual thermal satisfaction. In this study, we have approached thermal comfort from the individual's point of view, which necessitated that we introduce a statistical model of individual thermal comfort that is inspired by Fanger's PPD, yet allows the preferred temperature and the temperature tolerance (comfort range) to vary from one individual to another. Each individual was assumed to have a preferred temperature, T_0, and a tolerance for departure from T_0, ΔT [16], which were related to the individual vote as given in Equation (2a) and Figure 2a. Both T_0 and ΔT were assumed to be normally distributed, with their means and standard deviations computed through a Monte-Carlo simulation such that the overall population PPD-PMV curve matches that in ASHRAE Standard 55-2004 [2]. Our analysis yielded mean values for T_0, and ΔT of 24°C, and 3.2°C, respectively, and standard deviations for T_0, and ΔT of 1.2°C, and 0.5°C, respectively [16].

A new measure – the degree of individual dissatisfaction (DID) – was introduced to describe individual dissatisfaction as a fuzzy concept rather than a binary one (satisfied or dissatisfied), because the binary approach implies an intuitively-implausible discontinuity in satisfaction. Our DID measure allows the concept of dissatisfaction to change gradually with the vote, ranging from 0 when the person is fully satisfied to 1 when the person is totally dissatisfied. Equation (2b) and expresses the relationship of the DID to individual vote, and Figure 2b depicts this relationship graphically. When Equations (2a) and (2b) are combined, a bucket-shaped curve centered on a different value of T_0 and with a different width (ΔT) can be generated for each member of a building population.

$$\mathrm{vote}(T) = \begin{cases} +3, & T > T_0 + 2\Delta T \\ -3, & T < T_0 - 2\Delta T\,, \\ 1.5\dfrac{T - T_0}{\Delta T}, & \textit{otherwise} \end{cases} \qquad (2a) \qquad \mathrm{DID}(vote) = \frac{1 + \tanh\left(2|vote| - 3\right)}{2}, \qquad (2b)$$

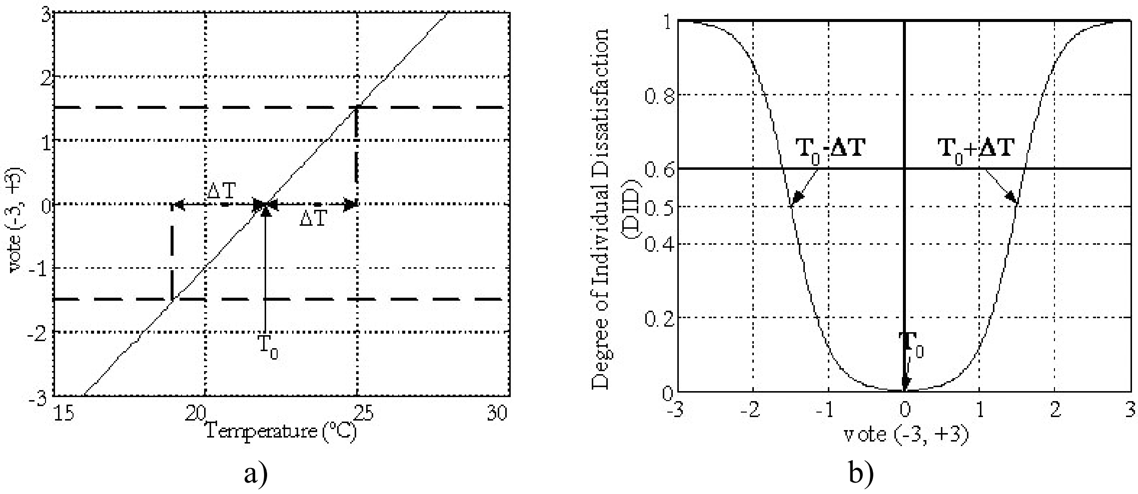

Figure 2. a) Individual Votes, b) Degree of Individual Dissatisfaction (DID).

Energy/Comfort Optimization

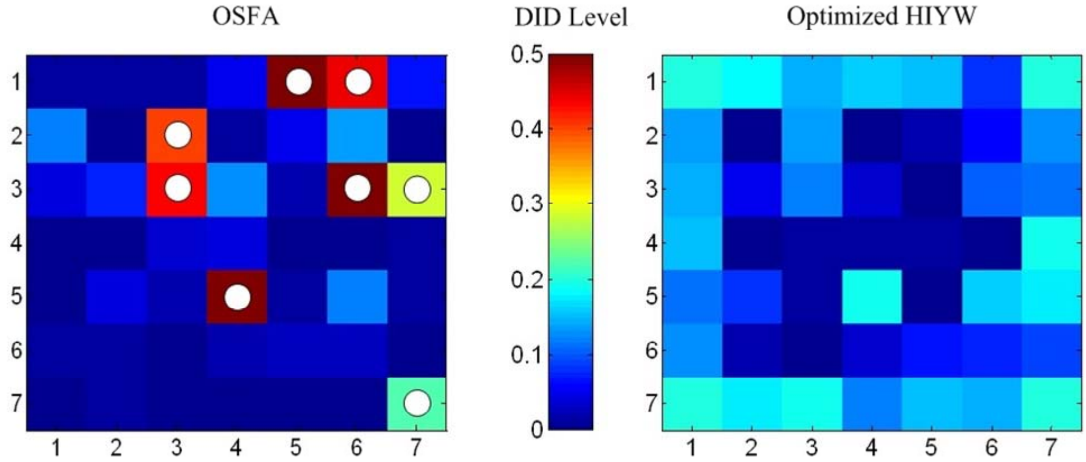
A variety of control strategies have been applied to building environmental control systems to lower energy consumption [18-22]. None has taken into account the effect on energy consumption of the thermal imbalances that would be created within the building under the HIYW strategy. In an earlier publication [16], we have shown that it is possible to achieve improved thermal satisfaction for individuals while saving energy through optimization and fuzzy approximation. In this study, a new approach has been established whereby a conventional optimization method such as gradient descent algorithm is used to find the optimum solution for a specific situation, and an intelligent system such as a fuzzy logic system or a neural network is used to generalize the solutions to a wider range of situations.

Our strategy is based on the observation that an individual's preferred temperature is not a precise value, but rather a range around a preferred neutral temperature. We have taken advantage of this fact to optimize the temperature settings of each occupant's personal space in a way that minimizes overall energy use. A gradient-descent algorithm has been utilized to improve the indoor environmental condition for each individual without increasing overall building energy consumption [16]. By varying the office temperatures of each individual in a given population within each individual's acceptable temperature tolerance range, energy consumption can been reduced, while the PPD of overall population building occupants has been kept at or below 10%. However, this overall PPD constraint doesn't guarantee that no individual is excessively dissatisfied with the environmental conditions. A hard constraint was imposed such that no individual had a DID greater than 20%. This constrained optimization approach is referred to here as "*Optimized HIYW*". As a baseline representing a well-managed but conventional approach, an optimized OSFA scheme was used whereby the temperature of the entire building was increased or decreased at each temperature bin within the population average temperature tolerance to achieve minimum energy consumption subject to a PPD constraint (10% in this study).

RESULTS

The computed performance of the optimized HIYW system has been compared with that of the optimized OSFA system for 15 USA cities and 10 populations. The energy consumption of a simulated 7x7 building has been minimized for each of 32 outside temperature bins, subject to the 10% PPD constraint for both OSFA and HIYW, and to the additional 20% DID constraint for HIYW. Sample results are displayed in Figure 3 for Chicago, IL, USA. The checkered plots are for the 1^{o}C temperature bin. It can be seen that while both the optimized OSFA and HIYW approaches provide a PPD of 10%, over 17% of the occupants in the energy-optimized OSFA case experience a DID in excess of 20% (higher than 50% for some occupants). On the other hand, the optimized HIYW approach eliminates any DID over 20% altogether, while reducing annual energy consumption by 8.5%.

We also assessed the robustness of the optimization approach when the thermal resistance of interior wall is significantly lowered, as it would be in the case of semi-open spaces (e.g., cubicles). The results are presented in Figure 4 (in box-and-whisker format) for 15 USA cities and one population distribution. The results are expressed as the ratio of annual energy consumption of HIYW systems and the OSFA systems for both the un-optimized and optimized cases. It can be seen that the higher inter-office energy fluxes (conductive and advective) associated with low interior thermal resistances lead to a marked increase in energy consumption ratio. It can also be seen that our optimization methodology leads to energy savings relative to OSFA over a wide range of thermal resistances from those for typical full interior walls (~1.0m^2K/W) to one-tenth that value. In all cases, the optimized HIYW system was able to reduce energy consumption relative to optimized OSFA system, while delivering greater satisfaction (no DID > 20%) than the optimized OSFA system. The main reason for this dramatic improvement is the reduction in the interoffice energy flow by slightly varying the individual preferred temperatures (T_0) within their temperature tolerances (ΔT).



↓ OSFA ↓	↑ The plot above is for the 1°C bin ↑	↓ HIYW ↓
0	← Annual Energy Savings (%) →	8.5%
17.4%	← Time Averaged DID over 20% →	0

Figure 3. Sample Results for a 7x7 1-Story Office Building in Chicago, IL, USA.

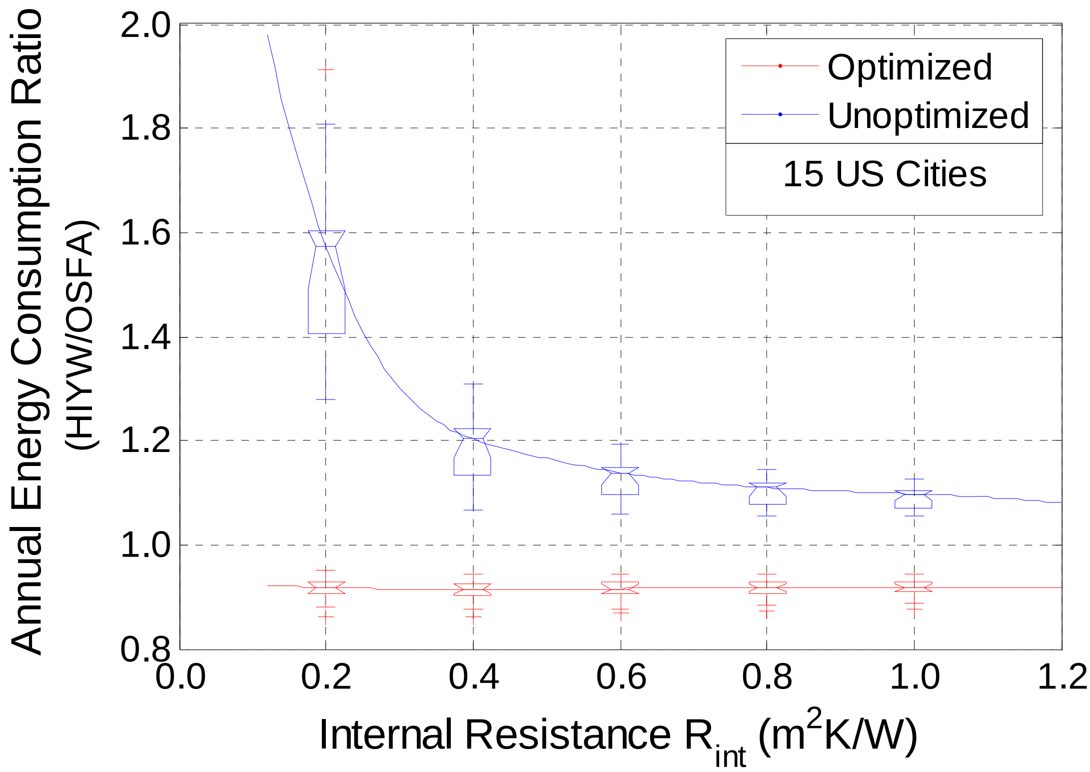


Figure 4. Effect of Internal Wall Thermal Resistance on Annual Energy Consumption.

DISCUSSION

The results of this investigation show that optimized HIYW distributed environmental control systems, which take advantage of the individual's temperature tolerances, can provide improved thermal comfort at lower energy consumption than optimized OSFA systems. By slightly varying individual temperature set-points within the individual's temperature tolerance using a nonlinear programming approach, energy consumption can be reduced while keeping each and every occupant within his/her thermal comfort range. This optimization method was also shown to be robust against higher interior wall conductance (thermal coupling between offices), which is characteristic of adjoining semi-open office cubicles.

The method assumes that both the individual's preferred temperature and temperature tolerances can be determined or inferred from his/her pattern of thermostat adjustment. While the existence of a tolerance range is well recognized for a population [23], more work needs to be done on the topic of individual thermal preferences and their persistence. Our ongoing work on optimal HIYW systems continues to explore intelligent control methodologies through which near-optimum solutions can be obtained with a considerably reduced set of inputs, and a higher potential for practical implementation [16]. Ongoing efforts are seeking to incorporate more realistic office building configurations, and improved energy and thermal comfort models that account for the advective coupling between adjacent, semi-open spaces [24]. Future efforts will assess the validity of the proposed HIYW control algorithms in realistic test-beds.

ACKNOWLEDGEMENT

Occupants Have a False Idea of Comfortable Summer Season Temperatures

Sami Karjalainen[1] and Raino Vastamäki[2]

[1]VTT, Finland
[2]Adage Corporation, Finland

Corresponding email: Sami.karjalainen@vtt.fi

SUMMARY

Thermal comfort studies and standards show that room temperatures should be higher in the warmer season than in the colder season. An interview survey with a sample size of 3,094 people was performed in Finland. The respondents were asked to state the Celsius values of room temperature they prefer in the winter and summer season in living room at home. The results show that people have a false idea of comfortable temperatures. 41% of the respondents think that room temperature should be lower in the summer season than in the winter season. 22% think that room temperature should be 19 °C or below in the summer season. Their principal idea behind this assumption is that the warm outdoor temperature should be compensated by cool room temperature. Only 15% of people have the correct idea: comfortable room temperature is higher in the summer season than in the winter season. The false idea may lead to unnecessary use of energy.

INTRODUCTION

When there is a lack of information, occupants develop own theories about how systems work and use these theories in controlling and adjusting their environments [1]. Kempton [2] presents a well-known example of that. He analysed folk theories for home heating control and found two common theories of how a thermostat works: a feedback theory and a valve theory. In the feedback theory thermostat senses room temperature, but in the valve theory, which is not understood, a thermostat dial is like a gas pedal and controls the amount of heat. The valve theory may lead users to adjust thermostats very often. In a study on use of room air conditioners [3], it was found that the operation of them was governed by multiple overlapping systems of belief and preferences concerning health, thermal comfort, folk theories about how air conditioners function, etc., in addition to economic factors. Diamond and Moezzi [4] have created a list of myths about people, energy and buildings.

Thermal comfort studies [5] and standards [6-7] show that room temperatures should be higher in the warmer season than in the colder season (line A in Fig. 1). There are two main reasons for that: the changes in clothing insulation related to the outdoor temperature [8] and adaptive relationship of comfortable room temperature with the mean monthly outdoor air temperature [8-11].

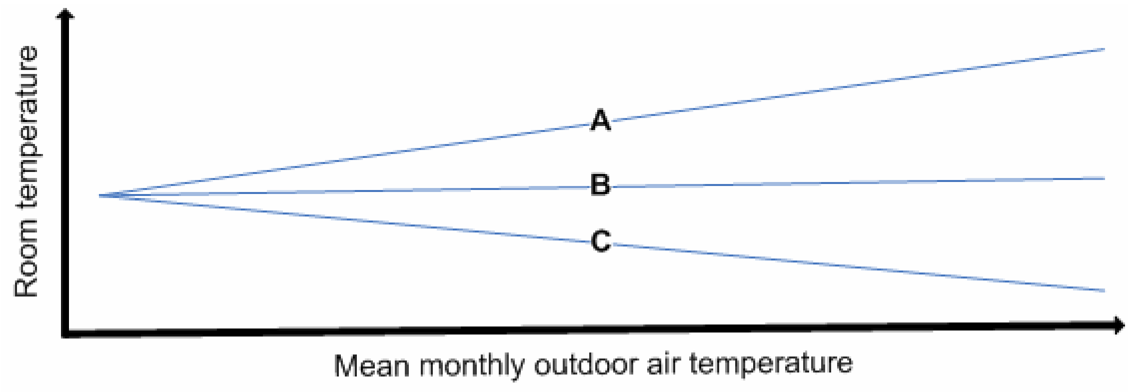

Figure 1. Three theories of how comfortable room temperature is related to mean monthly outdoor temperature, simplified.

Vastamäki et al. [12] found that office occupants have false mental models related to comfortable indoor temperature. About one-third of office occupants think that comfortable indoor temperature is lower in the summer season than in the winter season (line C in Fig. 1). More than one-third thinks that the comfortable temperature is not related to the season (line B). Neither of these views is supported by comfort criteria of the thermal comfort models. The study was realised in five European countries (Finland, Sweden, France, Italy and the Netherlands) with a total number of 735 respondents.

In the present study, ideas on comfortable indoor temperatures were studied among occupants in Finnish homes. In this paper, preferred room temperature refers to an occupant's idea of comfortable room temperature. Comfortable room temperature is what thermal comfort studies and standards see as comfortable.

METHODS

Inhabitants' ideas of comfortable indoor temperatures were studied using a quantitative interview survey with a nationally representative sample. The interview survey focused on thermal comfort and use of thermostats. In this paper, only the results concerning comfortable indoor temperatures are presented.

The interviews for the survey were carried out by telephone (computer assisted telephone interview, CATI). In the interviews, the respondents were asked to state the Celsius values of room temperature they prefer in their living room at home. The Celsius values were asked separately for the winter and summer season.

The target group of the study was the population of Finland. A random sample of the Finnish population aged between 15 and 74 was selected with quotas set according to gender, age and province. The total number of respondents was 3,094. A well-known Finnish data collection agency (Taloustutkimus Oy) was responsible for the practical realisation of the telephone interviews according to its quality system.

The climate in Finland is marked by cold winters and warm summers. The mean annual outdoor temperature varies between +6 °C in the southwest and –2 °C in the northernmost part of the country. The warmest month is typically July, with mean temperature between +14 and +18 °C in most parts of the country. Daily maximum temperatures can reach +30 °C in

July. The coldest months are January and February, with mean temperatures between –4 °C in the south and –15 °C in the north.

RESULTS

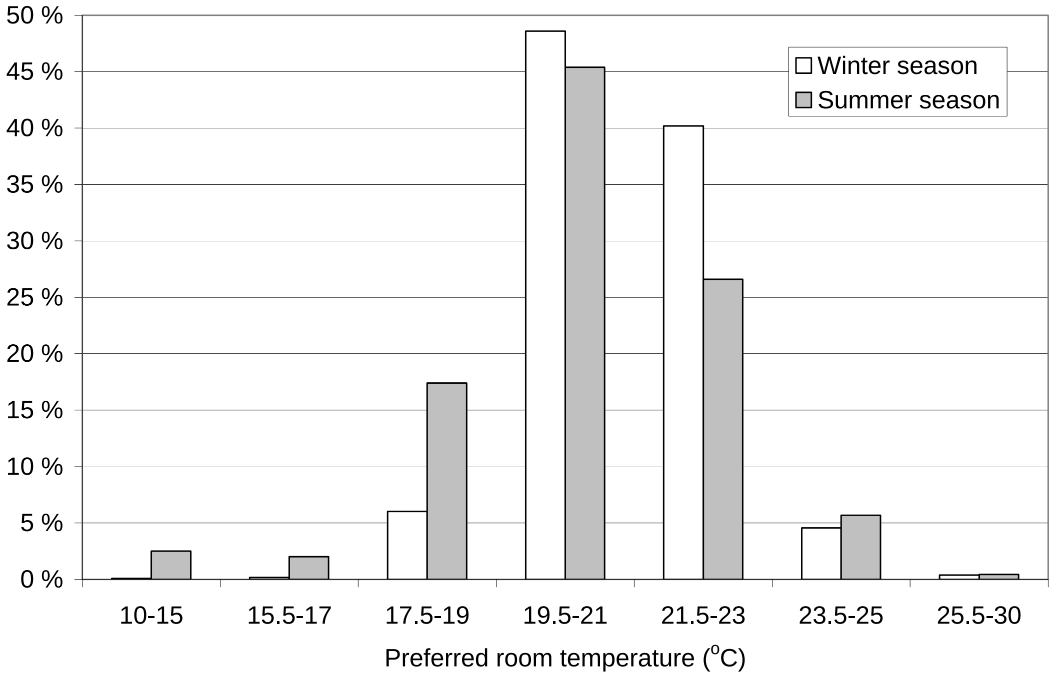

Figure 2. Preferred room temperatures in the winter and summer season in living room at home. N = 3064.

The respondents were asked to state the Celsius values of room temperature they prefer in the winter and summer season in living room. The results are shown in Fig. 2. 89% of the respondents say they prefer a temperature between 19.5 and 23 °C in the winter season. There is more deviation in the summer season temperatures: 22% think that room temperature should be 19 °C or below. A mean value for the preferred winter season temperature is 21.2 °C and for the preferred summer season temperature it is 20.5 °C.

41% of the respondents think that room temperature should be lower in the summer season than in the winter season (Fig. 3). Only 15% of people have the correct idea: comfortable room temperature is higher in the summer season than in the winter season.

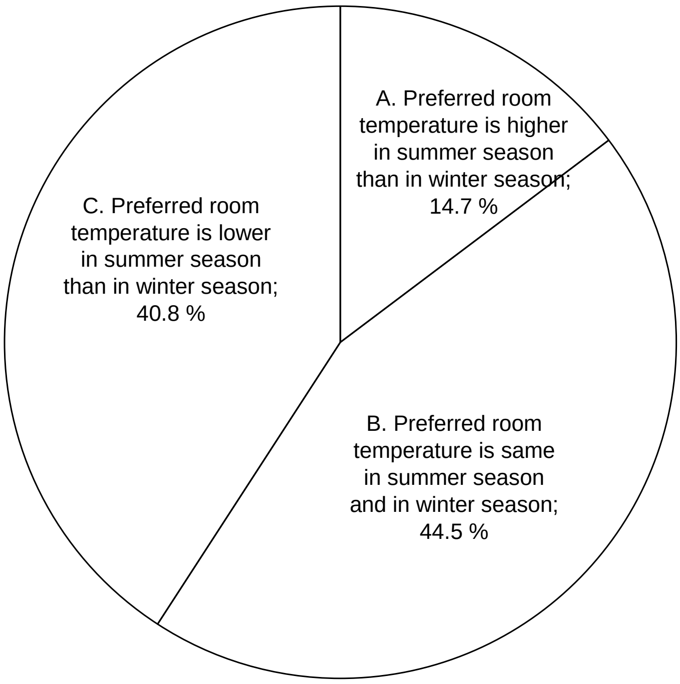

Figure 3. Influence of season on preferred room temperatures in living room at home.
N= 3000.

DISCUSSION

41% of the respondents think that room temperature should be lower in the summer season than in the winter season. Their idea behind this assumption is that the warm outdoor temperature should be compensated by cool room temperature: "If it is hot outside, I don't like hot inside". Occupants would feel very cold in the summer season, if room temperatures would be in the level most of them suggest.

The respondents of the present study were occupants in residential buildings in Finland. The results are consistent with the office occupant study [12] performed in five European countries. Occupants in offices do not typically have thermometers, but at homes they often do. However, they do not seem to have learned the Celsius values of comfortable temperatures.

The false idea regarding comfortable summer season temperatures may have energy implications. If occupants adjust temperature to, for example, 18 °C in a building with a mechanical cooling system, it leads to unnecessary use of energy. People should be educated about the values of comfortable temperatures in the summer season.

Occupants' ideas about comfortable room temperatures were studied as a part of usability research of temperature controls. Developers of heating and cooling controls should be aware of the misconceptions of occupants. Temperature controls should be designed to advise occupants on comfortable temperatures.

Future studies should investigate occupants' ideas about comfortable room temperatures in more detail. It would be valuable to know whether occupants think that the room temperature should vary according to different winter season outdoor temperatures (for example, –20 °C and 0 °C) since it has energy implications.

SUMMARY

This study investigated on a subject's thermal sensation and use of a "Cool Chair" in two actual warm offices. We developed a chair-mounted isothermal airflow generator called the Cool Chair that adjusts the local thermal environment by changing airflow velocity against the body surface. It was designed as a personal air-conditioning system. The Cool Chairs were used by workers in technical occupations in actual offices. The Cool Chair use rate, occupancy rate, and evaluations were recorded. The user's thermal sensation and comfort sensation were improved by utilization of the Cool Chair. Despite a uniform room temperature, the workers could select an airflow that provided individual comfort, which may result in a decrease in the worker complaints. Thus, the usefulness of the Cool Chair's thermal adjustability was confirmed.

INTRODUCTION

Individuals have different perceptions of thermal comfort. A comfortable temperature is dependent on factors such as a person's physical condition, clothes, and activity level. However, in a typical office environment, there are many workers in the same space, which maintains a uniform room temperature through air-conditioning. Therefore, allowing workers to adjust their local thermal environment is important. The chair-mounted isothermal airflow generator called the Cool Chair [1] is a personal air-conditioning system, which allows an individual to control the local thermal environment by adjusting the airflow (Figure 1). The conventional personal air-conditioning system uses a non-isothermal airflow. In contrast, the mechanism of the Cool Chair is simple, allowing the user to feel cool by using the isothermal airflow.

An adaptive model that requires a voluntary, passive action was proposed by R. J. de Dear *et al*. [2]. The adaptive model defines a person as a subject that transfers heat to the outside if uncomfortable. The adaptive model is different from a heat balance model. The adaptive model consists of three elements: behavioral adjustment, physiological adjustment, and psychological adjustment. Although a psychological adjustment is the most effective, it is difficult to evaluate quantitatively. A standard chair does not allow thermal adjustability that provides psychological adjustment. In contrast, the Cool Chair allows thermal adjustability. This simple device between the office environment and the worker contributes to thermal comfort, a feeling of control, and energy conservation [3].

METHODS

Cool Chair

The Cool Chair functions by drawing air into the seat and the backrest and blowing it out through the armrests (Figure 2) [4,5]. The amount and direction of airflow are easily adjusted. The maximum amount of airflow is 70 m^3/h. Airflow adjustment is accomplished using a controller on the right armrest. Power was supplied by a battery. The battery required several hours to charge, which is done by having the user plug the Cool Chair cord into an electrical outlet when out of the office.

Figure 1. External view of the Cool Chair.

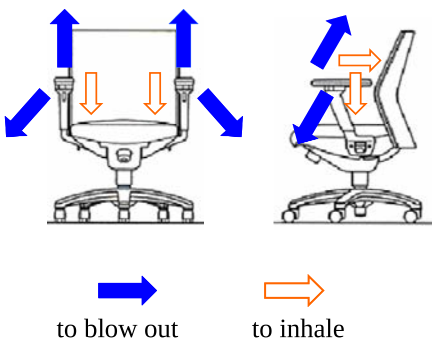

Figure 2. Function of the Cool Chair.

Summary of Practical Investigation

A summary of the study is shown in Table 1. Investigation was conducted at office K and office H in Japan (Figures 3 and 4). It was conducted in office K for 2 weeks from 31st August 2005 through 15th September. Eight subjects were divided into two groups (the A group was composed of 2 males and 2 females; the B group was composed of 1 male and 3 females). The workers in the A group used the Cool Chair during the first week and used a standard chair for the second week. The workers in the B group used the Cool Chair during the second week. All of the workers were employed in a technical field inside an office. From 27th September 2005, the investigation was conducted in the office H for one week. A male and a female, employed as a sales representative and an office worker, used the Cool Chair. Every morning and afternoon the workers supplied responses to a questionnaire regarding the type of clothing, thermal sensation, and comfort sensation.

Table 1. Summary of investigation.

Investigated Office	Office K		Office H
Place	Minato Ward, Tokyo		Osaka city, Osaka
Measurement Schedule	31st, Aug, - 7th, Sep	8th, Sep - 15th, Sep	27th, Sep - 4th, Oct
Cool Chair User	A,B,C,D	E,F,G,H	I,J
Standard Chair User	E,F,G,H	A,B,C,D	
Survey Item	Seat occupancy rate Thermal sensation vote, Comfort sensation vote Questionnaire Room temperature		

Figure 3. Office K involved in the study.

Figure 4. Office H involved in the study.

To determine airflow, the terminal voltage of the blower was recorded with a small voltage logger. In addition, the temperature of the weight-bearing surface was recorded with a small temperature logger to determine the times when the person was seated. Mean room temperature fluctuation during the investigation period is shown in Figure 5 (temperature was measured at a height of 1100 mm). Room temperature during working time was nearly 27°C.

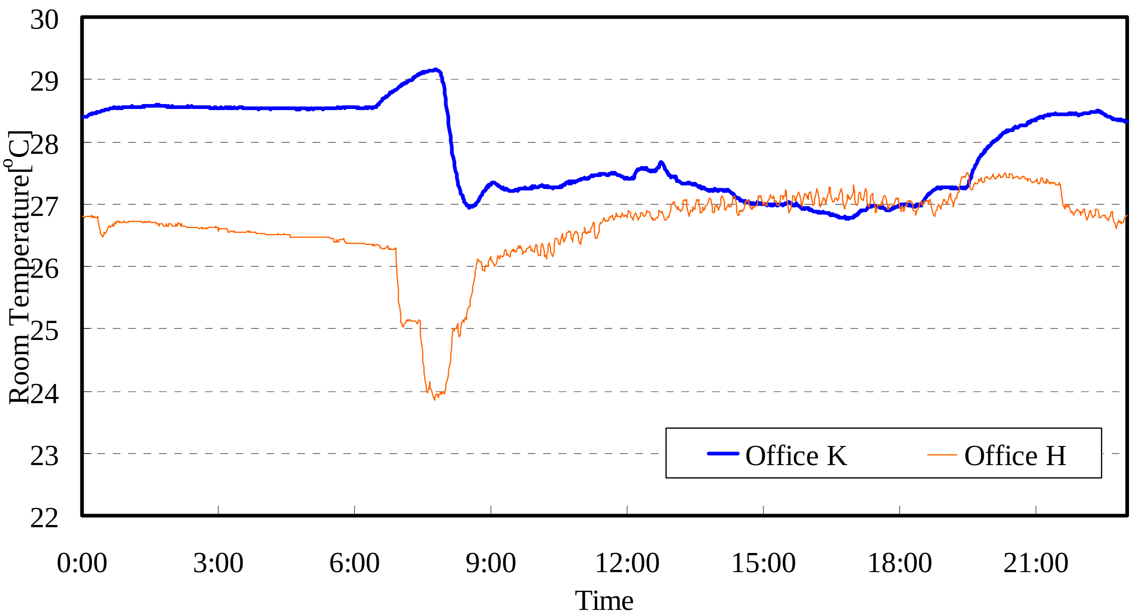

Figure 5. Ambient temperature.

RESULTS

Usage condition of Cool Chair

The airflow rate was not constant, because a worker repeatedly sits down and stands up during the day (Figure 6). Room temperature during the day was approximately 27°C and the amount of airflow selected by the user was 20 m^3/h. When the air-conditioning system stopped outside of office hours, the room temperature increased and the amount of airflow selected was 60 m^3/h.

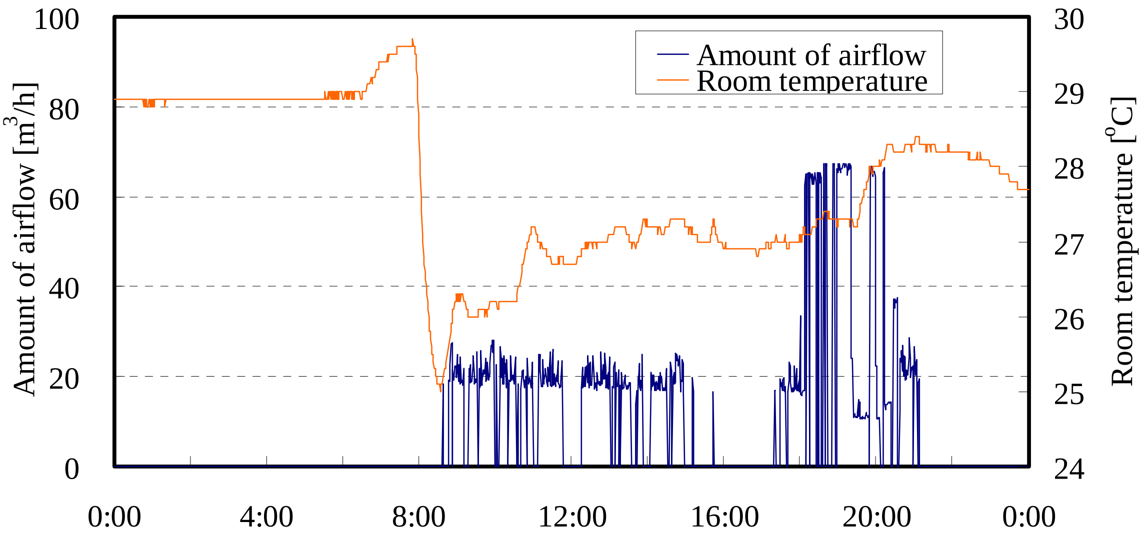

Figure 6. Usage of Cool Chair (an example).

Figure 7 shows the relation between Cool Chair use and amount of airflow. The respective Cool Chair users are shown on day 1. Females used a greater airflow for a longer time compared to the males. Figure 8 shows where the airflow was directed. Most of the time the workers directed the airflow toward the arms, followed by the side of the body, neck, and chest. The circumstances under which the workers used the Cool Chair are shown in Figure 9. The Cool Chair was used mainly when the activity level increased. In addition, the subject used the Cool Chair when he or she felt that the "air-conditioning system was not effective."

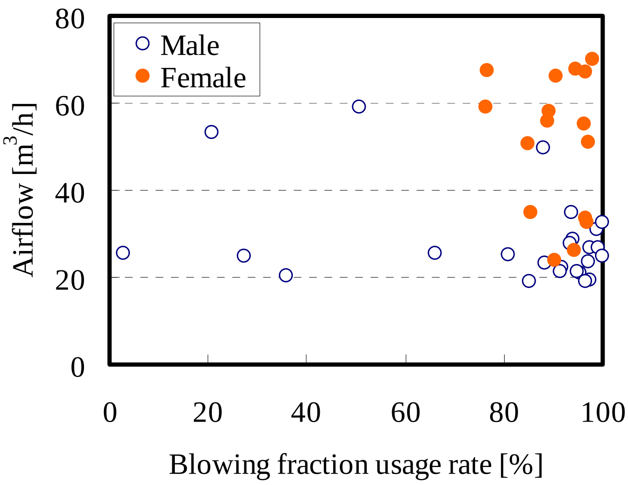

Figure 7. Usage/Airflow.

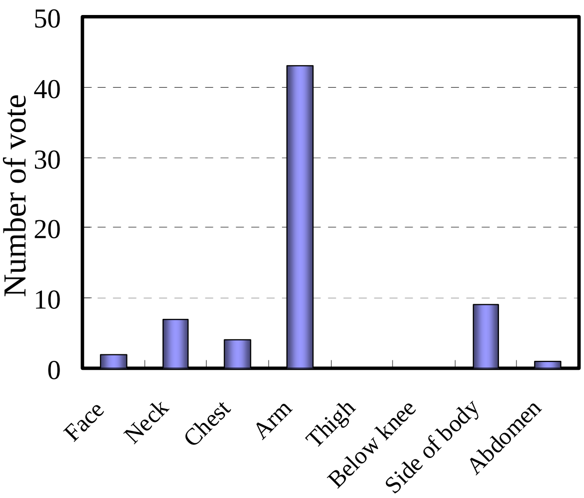

Figure 8. Applied airflow.

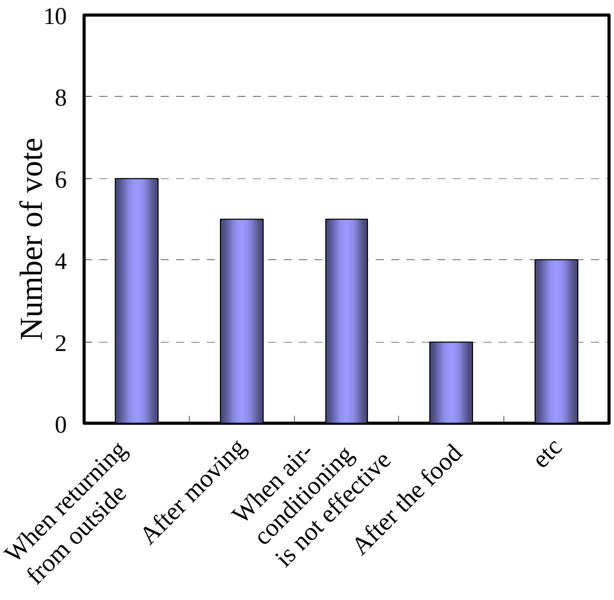

Figure 9. Circumstances when the Cool Chair was used.

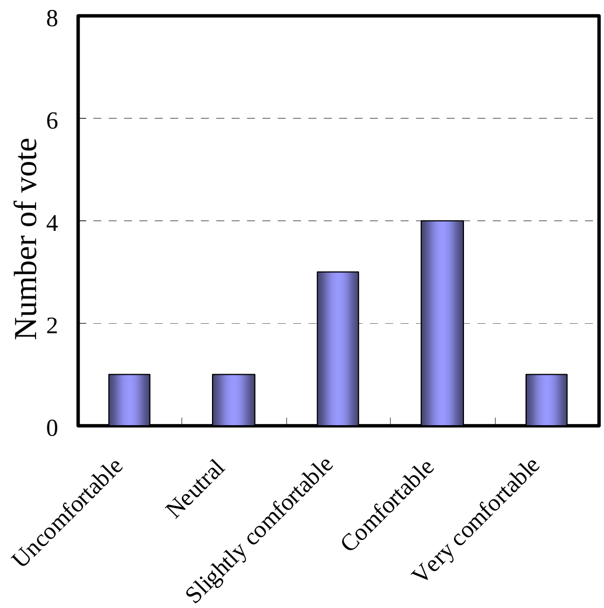

Figure 10. Impressions of Cool Chair.

Thermal Sensation Vote and Comfort Sensation Vote

The workers' impression of the Cool Chair is shown in Figure 10. Most workers reported that the Cool Chair was "Comfortable." The mean values for males and females for TSV and CSV in office K are shown in Figures 11 and 12. The TSV shifted from warm to neutral, and the CSV shifted from uncomfortable to comfortable through the use of the Cool Chair. The cooling effect of the isothermal airflow despite a relatively warm indoor temperature was confirmed by these results.

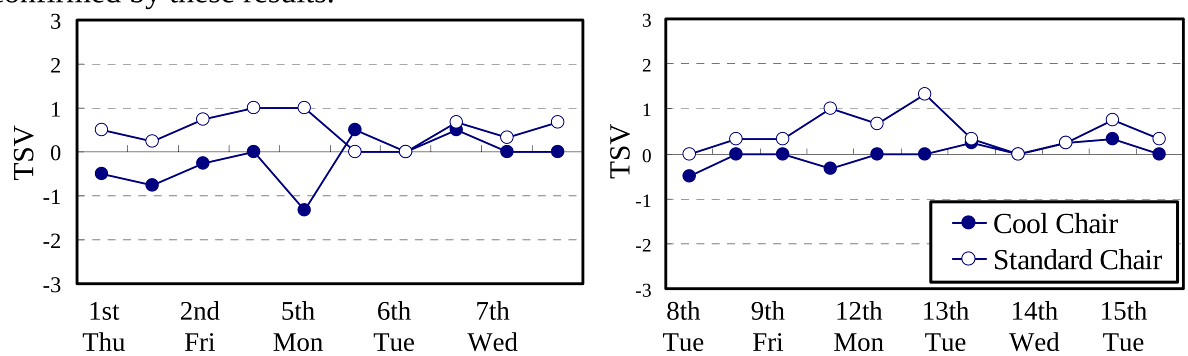

Figure 11. Comparison of TSV values.

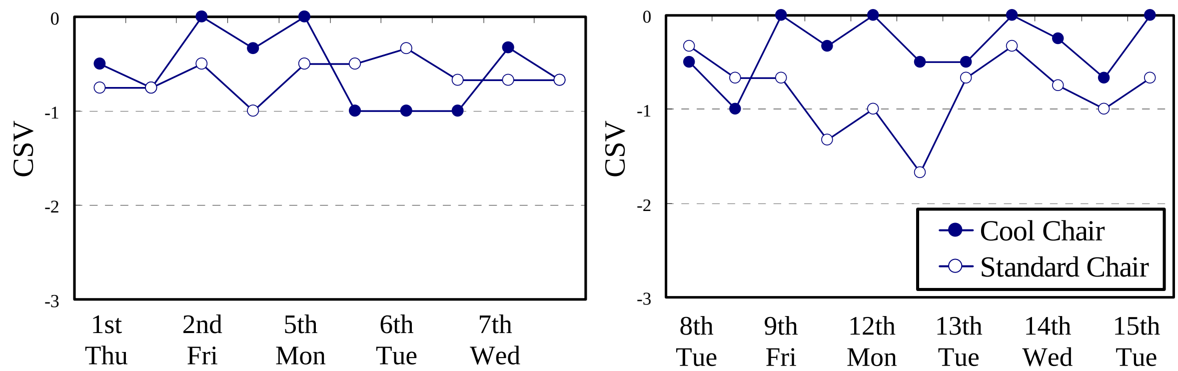

Figure 12. Comparison of CSV values.

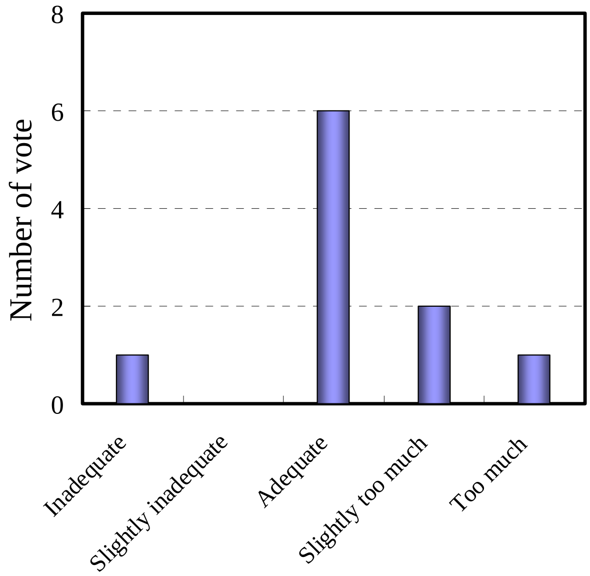

Figure 13. Impressions of airflow rate.

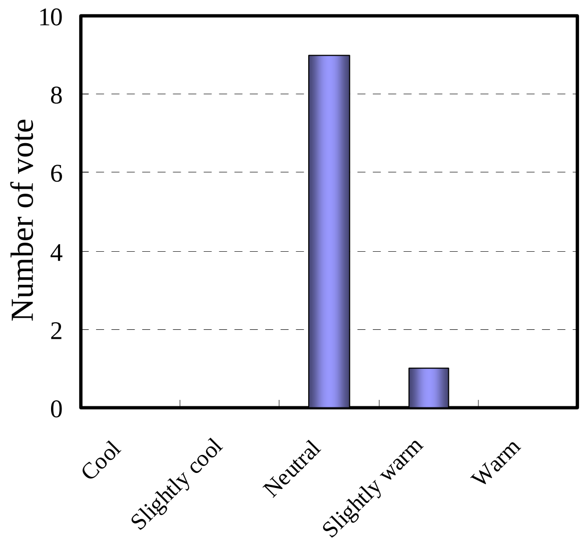

Figure 14. Impressions of airflow temperature.

Evaluation of airflow

Figure 13 shows the users' impressions of the Cool Chair's maximum airflow rate. Results indicated most users were satisfied with the airflow of the Cool Chair. Figure 14 shows user's impressions of the airflow temperature. Results indicated that the user was cooled sufficiently by the isothermal airflow.

DISCUSSION

The performance of the Cool Chairs was tested under actual office conditions. Airflow rate and temperature were sufficient in actual practice. The amount and direction of airflow were controlled by the user based on thermal comfort. Results indicated that the thermal adjustability of the Cool Chair increases user comfort. This thermal adjustable device contributes to worker thermal comfort and feeling of control, and energy conservation.

ACKNOWLEGEMENT

This research is supported by Academic Frontier Project for Private Universities from Ministry of Education, Culture, Sports, Science and Technology.

SUMMARY

Subjective experiments were conducted in a climate chamber to evaluate subjective thermal comfort in the environment with spot cooling system, simulating a big factory. Five conditions combined supply air temperature and air volume were set for the first test. The condition without spot cooling system was also examined. Two types of diffusers were developed in the second test. Seven males were exposed for 90 minute under the conditions with and without spot cooling. Subjective metabolic rate were assumed to be 1.8 met. Subjects voted their thermal sensation, air velocity sensation, comfort sensation in the experiments every 30 minute.
Thermogram showed that spot cooling system without diffusers cooled down only upper body of subjects, where they felt the draght. On the other hand, it was possible to cool down their whole body using the diffuser. Subjects preferred the condition with the diffuser, where they felt “thermally neutral”.

INTRODUCTION

In large space such as a factory, it is not feasible to control the air in the entire space with HVAC system without huge energy consumption. The air-conditioning in large space usually targets only the occupied zone. It is important that the occupied zone air-conditioning satisfies a comfortable feeling of the human body, and decrease the air-conditioning load as much as possible. Spot cooling system used at the factory is one of the occupied zone air-conditioning, and have potential for energy conservation. The workers' physiological and subjective responses to such environments are different from those to typical uniform thermal environments, and are far less understood for Japanese.
In this research, subjective experiments were conducted to evaluate thermal comfort of Japanese subjects in the environment with spot cooling system, simulating a big factory. Different combinations of the jet air temperature and volume, and the shape of diffusers were examined.

METHODS

Experimental Design

Two kinds of subjective experiments were conducted in a climate chamber to evaluate subjective comfort in the environment with spot cooling system in 2005. Supply air temperature, air volume and shape of diffuser were set for the purpose of evaluating the human comfort under the spot cooling. In the first test, supply air temperature and volume from spot cooling system were controlled. The shape of diffusers was varied in the second test. Seven college-aged males who were in good health were exposed to the experiments. All subjects were volunteers who were paid for participating in the experiment. Considering their circadian rhythms, all subjects took part in the experiments at the same time of day.

Experimental Conditions

Table 1 lists experimental conditions.

In the first experiment, three supply air temperature, 19°C, 25°C and 31 °C, with 400m^3/h of supply air volume were set. The condition with small supply air of 200m^3/h at 19^{o}C were also examined. Additionally, the condition without spot cooling system was also analyzed.

In the second experiment, two types of diffusers, type I and II, were developed. The condition without diffuser was compared with the condition with 2 types of diffuser. Supply air temperature and air volume was set at 19^{o}C and 400m^3/h for all condition. Table 2 shows 3 kinds of diffusers.

For all conditions in both the first and second test, outlet of spot cooling system equipped 3.0 m above the floor. The spot cooling system had a nozzle with an outlet diameter of 0.2m. The temperature where is not influenced by spot cooling system (ambient temperature) were kept at 31 ^{o}C simulating a factory [1]. In the experiments, subjects wore hat, work wear (long sleeve), shirt, shoes, socks.

Table 1. Experimental condition

	First experiment					Second experiment		
Condition	19_200	19_400	25_400	31_400	NONE	without diffuser	Type I	Type II
Supply air temperature [°C]	19.0	19.0	25.0	31.0	-	19.0		
Supply air volume [m^3/h]	200	400	400	400	0	400

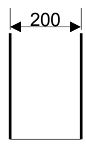
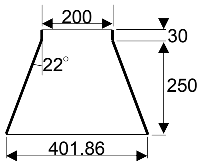
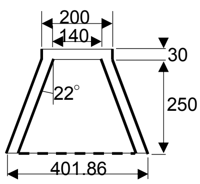
Table 2. Three kinds of diffusers

Without diffuser	Type I	Type II
 	 	 







Experimental Procedure

Figure 1 illustrates the experimental procedure.

Subjects were exposed for 90 minutes under the conditions with and without spot cooling. One test consisted of 3 sessions. During the 30-minute session, subjects performed walking up and down the steps [2] in the ambient area, light work which is putting machine screws in holes and clamping them with nuts in a standing position[3] with spot cooling for 20 minutes. Subjective metabolic rate was assumed to be 1.8 met [4]. Subjects rated at the beginning of the exposure time and after each task during the session. In the second experiment, the different type of diffusers was installed for each session.

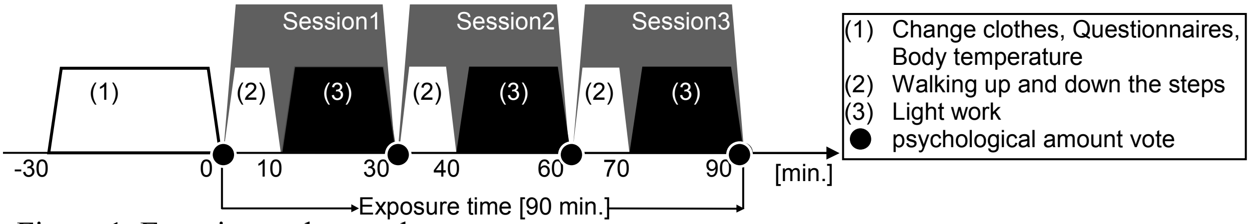


Figure 1. Experimental procedure

Measurement

The effect of supply air condition and air flow pattern on human comfort was evaluated by the result of environmental measurements (the vertical air temperature distribution, the velocity distribution, vector diagram of the supply air velocity analyzed by PIV), physiological response (the skin temperature, relative humidity and air temperature in clothing, the thermogram), and the subjective psychological measurements.

The thermogram is a image visualized the surface temperature of the object. In this experiment, the surface temperature distribution of the subject working under the spot cooling system was analyzed with thermogram.

PIV (Particle Image Velocimetry) is a kind of the speed measurement method of the fluid such as water and air. In second experiment, the vector analysis on the air flow with diffuser was done by using PIV analysis software (DIPP-Flow) from the image taken with high speed camera.

Subjects rated their thermal sensation, air velocity sensation, comfort sensation every 30 minute on the questionnaire as shown in Figure 2. The scales were given as visual analogue scales. Subjects were allowed to rate their sensation either just on the number or between the numbers on the scales. In the second experiment, subjects also evaluated effect of total comfort by difference of diffuser.

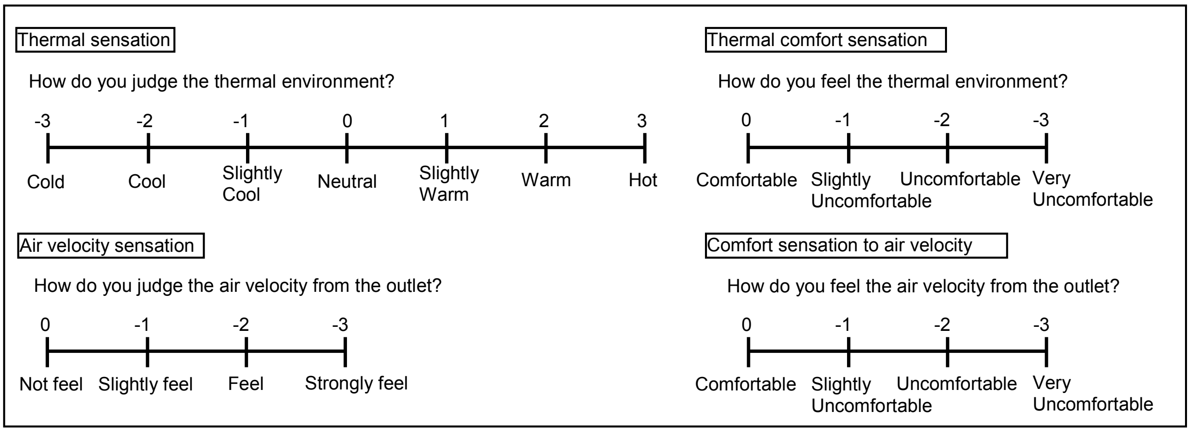

Figure 2. A part of rating scales

Statistical Analysis

Data obtained in the experiments were analysed with Non-parametric statistical analysis method [5]. The Wilcoxon Matched-Pairs Signed Ranks test was administered between each condition. In the first experiment, supply air temperature effect was discussed in the pair-wise comparison between 19_400 and 19_200. According to the comparison between 19_400, 25_400, and 31_400, supply air volume effect was reported. P-values presented in the figures indicate the level of significance.

RESULTS AND DISCUSSION
The First Experiment Result
Thermal Environment

Vertical air temperature distribution: Vertical air temperature distribution in occupied zone was less than 3 °C under the all conditions.

Surface temperature: The surface temperature distribution recorded with thermogram is presented in Figure3. It was found that spot cooling system without diffusers cooled down upper body of subjects such as the head, necks, and the backs. This tendency was remarkably observed under the condition at low supply air temperature or with large air volume.

Subjective vote: The general thermal sensation vote and general comfort sensation vote were displayed in Figure 4. In two conditions of 19°C in blow temperature, subjects reported significantly cooler at 19_400 than at 19_200 ($p<0.01$), and more comfortable at 19_400 ($p<0.01$). Among three conditions of 400m^3/h of supply air volume, people rated significantly cooler at 19°C and 25°C than at 31°C ($p<0.01$). Comfort sensation vote under the condition with 19°C of jet air was significantly greater than with 31°C ($p<0.04$). Thermal sensation vote was highest ($p<0.01$) and most uncomfortable ($p<0.04$) under the condition without diffuser. Subjective comfort sensation was the greatest at 19_400. It is found that subjective thermal sensation vote was scattered near "slightly cool" and subjects felt comfortable under the condition of low air temperature and large air volume.

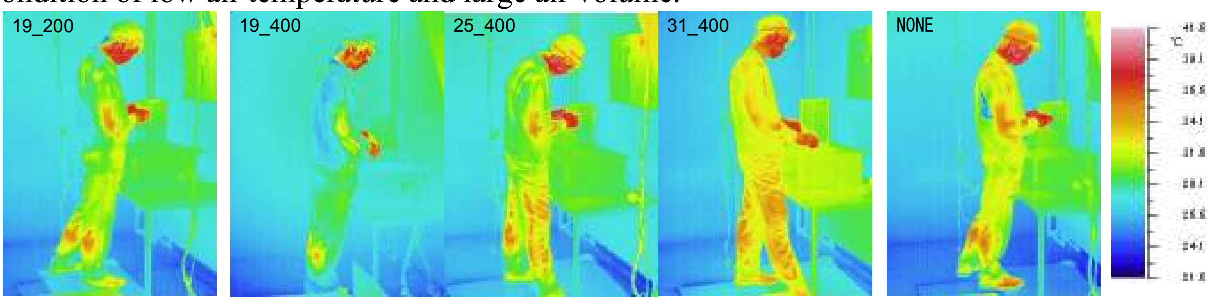

Figure3. Surface temperature of subject's body (First experiment)

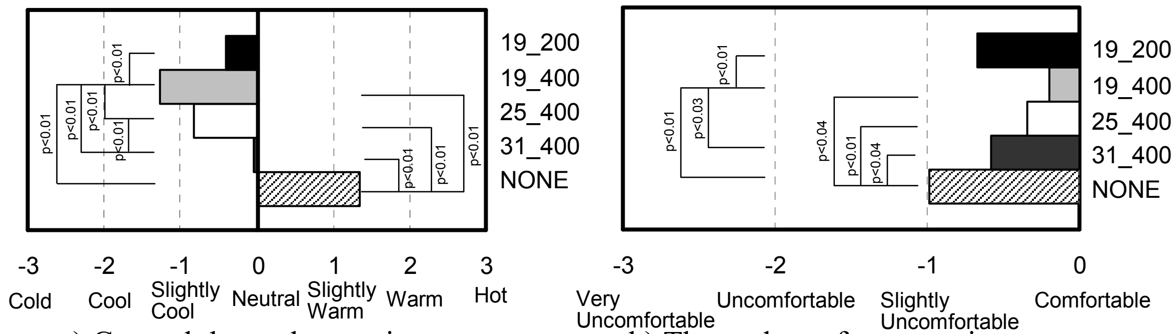
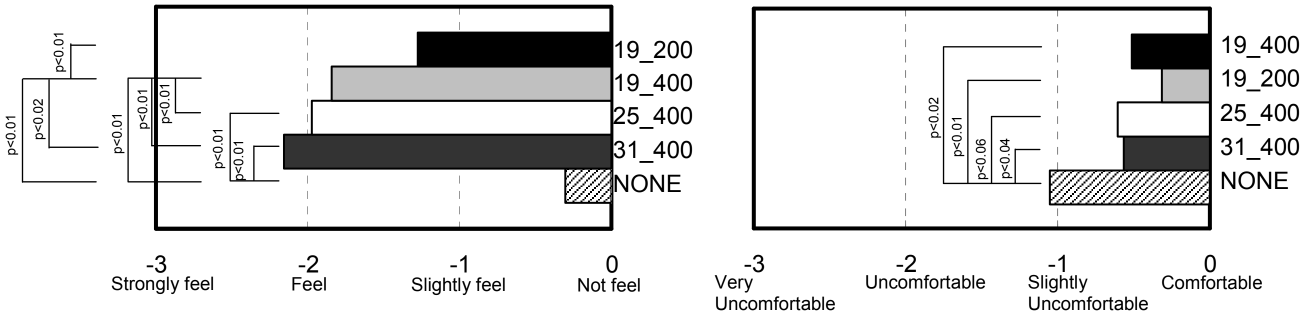


a) General thermal sensation vote b) Thermal comfort sensation vote

Figure 4. Subjective thermal comfort

Air Flow

Subjective vote: The general air velocity sensation vote and comfort sensation vote to air velocity were shown in Figure 5. Pair-wise comparison between 2 conditions with 19°C of supply air temperature, significantly greater air velocity sensation was observed in 19_400 air ($p<0.01$). Among three conditions of 400m^3/h of supply air volume, subjects reported significantly higher general air velocity sensation at 31_400 than at 19_400 ($p<0.02$). There was no significant difference in the comfort sensation to air velocity between any pair of conditions with spot cooling system by the Wilcoxon Matched-Pairs Signed Ranks test. Subjects rated significantly more uncomfortable under the condition without spot cooling system than at 19_400, 19_200 and 31_400 ($p<0.04$), and tend to feel more uncomfortable than at 25_400($p<0.06$). It is found that the comfort sensation to air velocity was improved by setting up the spot cooling system.



a) General air velocity sensation vote b) comfort sensation vote to air velocity

Figure 5. Subjective comfort sensation vote to air velocity

The Second Experiment Result

Thermal environment

Surface temperature: The surface temperature distribution recorded by thermogram is shown in Figure6. It showed that spot cooling system without diffusers cooled down upper body of subjects, while it was possible to cool down their whole body using the diffusers. It was remarkable in the condition using the diffuser type II.

Subjective vote: The general thermal sensation vote and thermal comfort sensation vote were presented in Figure 7. Thermal sensation votes were scattered near “slightly cool” and comfort sensation vote “comfort” for all conditions in the second test. Especially, subjects tended to feel thermally neutral and more comfortable under the condition using the diffuser type II compared with the condition without diffuser. It is found that subject felt comfortable when they perceived the thermal environment to be neutral. It is concluded that the thermal comfort sensation improved by cooling down their whole body using diffusers.

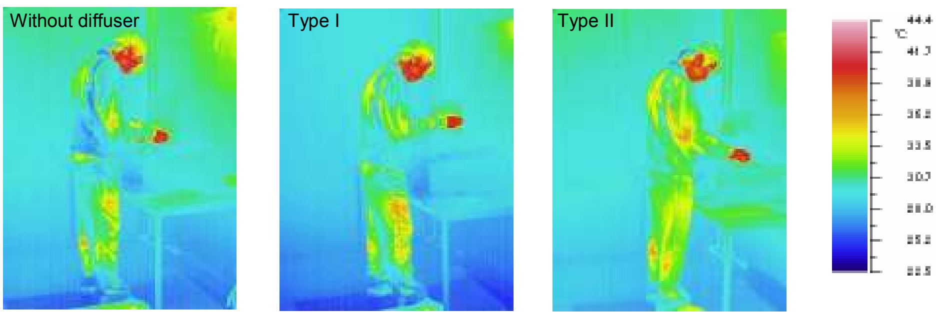


Figure 6. Surface Temperature(second experiment)

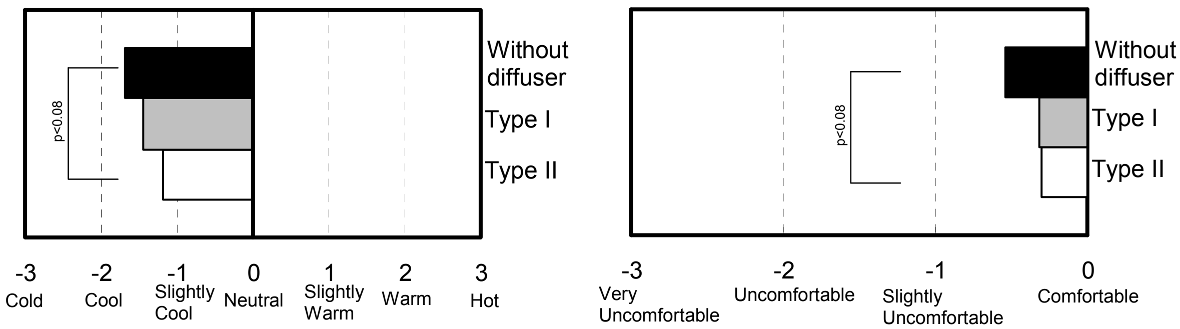

a) General thermal sensation vote b) Thermal comfort sensation vote

Figure 7. Subjective thermal comfort

Air Flow

Supply air velocity: The vector diagram of the supply air velocity measured with PIV from the diffuser is displays in Figure8. Under the condition without diffuser, little air flow diffusion was seen, and flowed toward the subjective position. Air velocity right after nozzle was about 4.1m/s. Supply air was diffused due to the diffuser, while the air velocity which reached directly subject got smaller and air flow to the subject was weakened. Especially, it was remarkable in the condition with diffuser typeII. Air velocity of the diffusion was about 3.5m/s, and that to the direction of the subject was 0.5m/s when the diffuser typeII was installed. As the result of the velocity distribution measurements, air velocity 1.7m above the floor indicated up to 1.5m/s under the condition without diffuser and with diffuser type I. In case of using the diffuser type II, air velocity on the same point was measures to be 0.24m/s.

Subjective vote: Figure9 shows the general air velocity sensation vote and comfort sensation vote to air velocity. Subjects reported significantly lower air velocity sensation under the condition with diffuser typeII than any other conditions ($p<0.03$). In the first experiment, there was no significant difference in the vote of comfort sensation to air velocity between any pair of conditions with spot cooling system. However, subjects reported significantly more comfortable in case of using the diffuser typeI and typeII than without diffuser ($p<0.05$) on the second experiment.

Subject reported the air velocity from the outlet was comfortable in case that the velocity sensation was small. It was found that people could feel great comfort due to cooling down their whole body even with very small velocity.

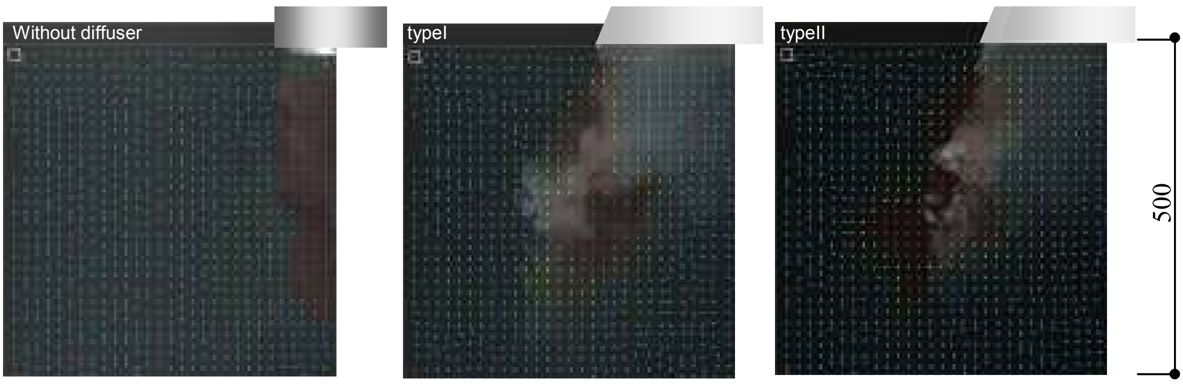

Figure 8. vector diagram of the supply air velocity

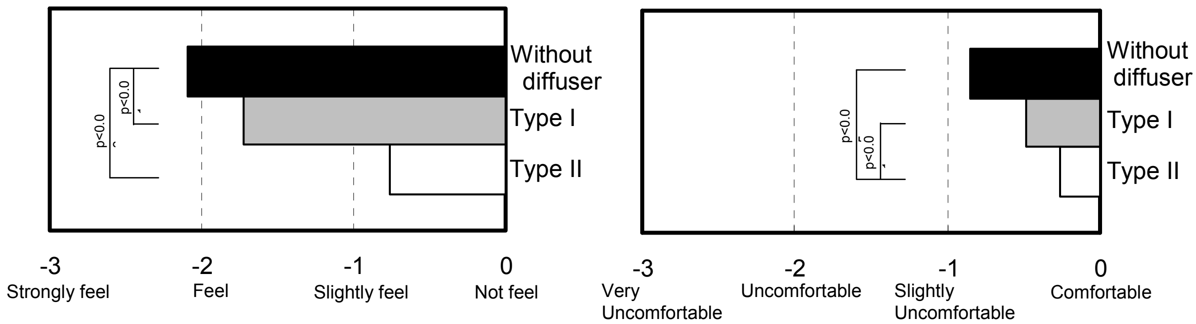

a) General air velocity sensation vote b) comfort sensation vote to air velocity

Figure 9. Subjective comfort sensation vote to air velocity

Evaluation of Diffuser

Subjects ranked three type of diffuser in the terms of air supply temperature and velocity. The evaluation of the diffuser typeI and typeII was higher than that of no diffuser as shown in Figure10. Especially, the majority people voted the diffuser typeII as 1st place. Though, there were people who rated the diffuser typeII as 3rd place, too. This is demonstrated that there was an individual variation in subjects' preference of diffuser.

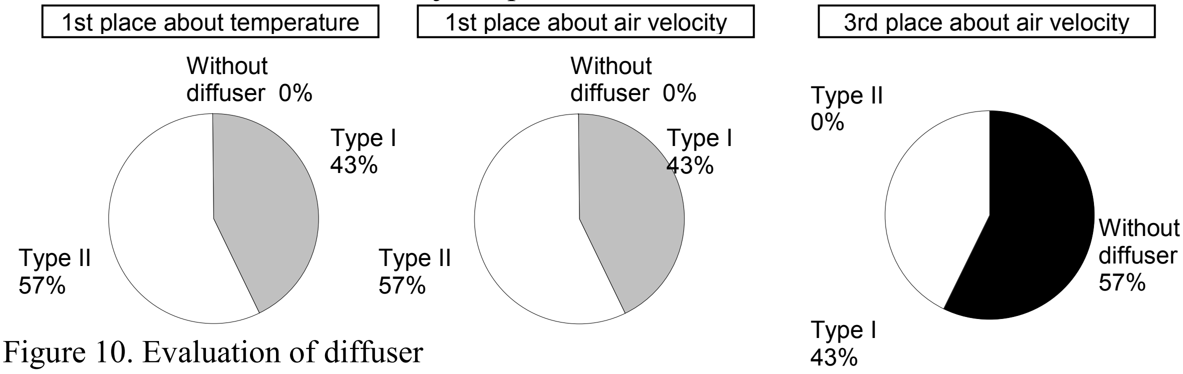

Figure 10. Evaluation of diffuser

CONCLUSIONS

In order to evaluate subjective comfort in the environment with spot cooling system, simulating a big factory, two subjective experiments were conducted in the climate chamber. The first experiments were carried out to evaluate the air supply conditions. Subjects were exposed to 5 conditions, 19_200, 19_400, 25_400, 31_400, none.
Spot cooling system without diffusers cooled down upper body of subjects. It was remarkable in the condition such as low supply air temperature and large air volume. It is found that subjective thermal sensation vote was scattered near “slightly cool” and subjects felt comfortable under the condition of low air temperature and large air volume. In this experimental condition, when supply air temperature rose and the volume increased, subjects rated “feel” on air velocity sensation vote. But there was no significant difference in the vote of comfort sensation to air velocity between any pair of conditions with spot cooling system

In the second experiment, subjects evaluate the air supply conditions using the diffusers. three experimental conditions were set, diffuser typeI, typeII and without diffuser.
It was possible to cool down their whole body using the diffusers. It was contemplated that the thermal comfort sensation improved by cooling down their whole body. Subject reported the air velocity from the outlet was comfortable in case that the velocity sensation was small. It was found that people could feel great comfort due to cooling down their whole body even with very small velocity. The majority people rated the diffuser type II as 1st place, though there was an individual variation in subjects' preference of diffuser.

SUMMARY

Physiological parameters measured by an embedded body sensor system were demonstrated to respond to changes of the air temperature in an office environment. The thermal parameters were monitored with the use of a wireless sensor system that made possible to turn any existing room into a field laboratory. Two human subjects were monitored over daily activities and at various steady-state thermal conditions when the air temperature of the room was altered from 22-23°C to 25-28°C. The subjects indicated their thermal feeling on questionnaires. The measured skin temperature was distributed close to the calculated mean skin temperature corresponding to the given activity level. The variation of Galvanic Skin Response (GSR) reflected the evaporative heat loss through the body surfaces and indicated whether sweating occurred on the subjects. Further investigations are needed to fully evaluate the influence of thermal and other factors on the output given by the investigated body sensor system.

INTRODUCTION

The increasing miniaturization of radio frequency devices and micro electro-mechanical systems, as well as the advances in wireless technologies, has generated a great deal of research interest in the area of wireless sensor networks. These technologies have enabled the development of low-cost, low-power, multi-functional sensor nodes that are small in size and allow untethered communication over short distances. Such systems may be useful for close monitoring and adaptive control of building equipment, materials performance and environmental conditions including temperature, air flow, indoor air quality, lighting, sound and the stated well-being of the occupant in relation to their surroundings.
Wireless sensor networks will also enable a proper cohesive data management system to be organised for buildings. It will help to understand the strategies required for operating the building so that energy savings are achieved; and to obtain healthier environments and closer relationship between occupants and buildings. Wireless sensor networks will also contribute to realize a leaner and more effective design, construction, operation and facilities management regime. For example we should be able to understand more deeply the patterns of building use and also enable prediction of failure conditions thus informing maintenance regimes.

Apart from gathering information about the building environment and performance it is equally important for the facility management to collect direct feedback from the building occupants about their perception of the indoor environment and well being. Previously this was done occasionally by subjective pen and paper questionnaires that provided data in an awkward and expensive way for further processing. Today's technologies give us the opportunity to gather such information instantaneously and store them in databases [1] or even to use these data for direct control of the existing building services. Proposal of such device was already made in 1990 [2] and the practical development now becomes reality [3], [4].

Beside of subjective questioning more and more efforts are made to develop methods and devices that are able to measure physiological parameters in humans that are sensitive to environmental factors [5]. A recently developed wearable embedded body sensor system produced by Body Media enables monitoring not only personal energy expenditure and various body movements of people, but also skin and near body air temperature, GSR and convective heath loss [6], [7]. A number of these parameters given by this sensor can be used to detect physiological changes in the body or can be related to the thermal comfort of people.

The present investigation is focused to explore the wireless sensor technology to evaluate the thermal environment in an existing office and show physiological changes in the occupants exposed to thermal stress with the use of the embedded body sensor.

METHODS

One day long monitoring with the embedded body sensor

A male subject was monitored for a full day during his normal daily activities with the embedded body sensor system (see description below) to show variations in the output values of the sensor if the surrounding environment around the human body or the person's activity level changes. During this one day long monitoring no environmental parameters were recorded given the difficulties of carrying the environmental sensors. Instead, we can assume the temperatures in the middle of February when most buildings are heated (~23°C) and the daily outdoor temperature is about 2-7°C.

Output of the embedded body sensor in a controlled office environment

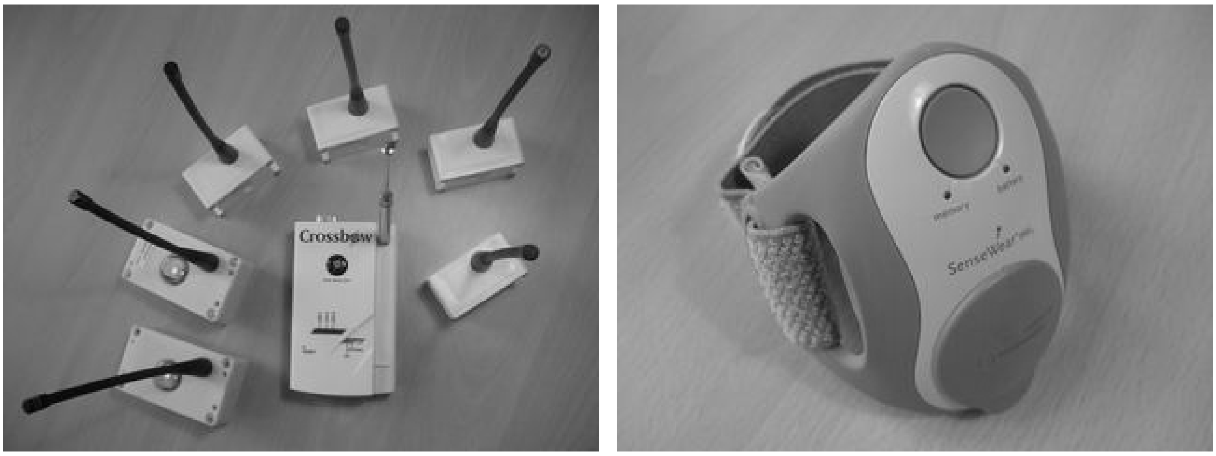
Three experiments (Table 1) were designed to demonstrate how the embedded body sensor system could be used in indoor environments for measuring body parameters that may affect building occupiers' well being. For this matter change in the value of the recorded factors were examined at different room temperatures. On four separate days three experiments were carried out in controlled office environments. In these experiments the same two – a male and a female – subjects were monitored during their office work. The experimental conditions are summarized in Table 1. The temperature was controlled using a small HVAC system installed to the rooms. The fresh air supply rate in all of the presented conditions was higher than 15 L/s per person that provided a good indoor air quality during exposures. The environmental parameters including air temperature, relative humidity, globe temperature and air velocity were recorded using a wireless sensor system (Figure 1.a) and with some additional sensors. The wireless sensors were distributed in the close proximity of the subjects to monitor the vertical temperature distribution at 0.1; 0.6 and 1.1m heights. The globe temperature sensor was placed at 0.6m from the floor level.

Table 1. Experimental conditions

	Experiment 1		Experiment 2			Experiment 3	
	Morning	Afternoon	Morning	Afternoon	Evening	Day 1	Day 2
Room temperature	High	Low	Low	High	High	Low	High
Room Volume [m^3]	150		30			30	

Instrumentation

The wireless sensor system (Figure 1.a) was used to measure the temperature and the relative humidity. The temperature sensor can measure in the range of –40 to +123°C with the resolution of 0.01°C and with ±0.5°C accuracy. While the relative humidity sensor measures in the range of 0 to 100% with the resolution of 0.03% and with ±3.5% accuracy. Some of the sensors in this system are also able to measure light and pressure but these were not used in the present investigation. The additional globe temperature sensor works with 0.01°C resolution and with ±0.3°C accuracy and the air velocity sensor has 0.05 ms^{-1} accuracy.



a) b)

Figure 1. a) The wireless sensor system; b) The wearable, compact, embedded body sensor system

The embedded body sensor system (Figure 1.b) is positioned on the rear side of the right upper arm and has several built in sensors including skin temperature sensor, near-body ambient temperature sensor, a two axis accelerometer, GSR sensor and heat flux sensor. For the evaluation of GSR the embedded body monitoring device uses two electrodes in contact with the skin that close an electric circuit and the current flow across the skin is measured. The obtained values represent conductivity between two points of the skin. The developer conducted studies comparing the GSR sensor in our body sensor system to the more traditional fingertip GSR sensor. The results demonstrated that the GSR sensor in our case provides a linear analogy to digital values for conductance but that it is significantly less sensitive than a GSR placed on the finger or palm [8].
The heat flux sensor picks up convective heat flow at the skin level through thermocouples and other thermally conductive elements. For further details of the embedded body sensor system see [8].

Subjective questionnaires

During Experiment 1-3 thermal questionnaires were filled in by both subjects several times to obtain subjective opinion about the indoor thermal environment. Therefore seven point thermal sensation scale [9] and sweating on a six point intensity scale were asked to be indicated.

Data analysis

To obtain representative measure of the thermal environment the operative temperature was calculated based on the air temperature and the mean radiant temperature provided by the globe temperature sensor [9]. Mean skin temperature, conductive heat transfer through the clothing (K/A_{Du}) and PMV (Predicted Mean Vote) was determined according to the thermal comfort model described by Fanger [10].
To see correlation between the various parameters regression analysis was carried out, where the resulting p value is used as an overall F-test of the relationship between the dependent variable and a set of independent variables [11].

RESULTS

One day long monitoring with the embedded body sensor

Figure 2 shows the monitoring results of GSR and the skin temperature of a male subject determined by the body sensors throughout a full day at various activity levels. As a comparison for a shorter time period the GSR of a female subject is also represented. She was at similar activity levels and exposed to the same environmental conditions as the male subject.

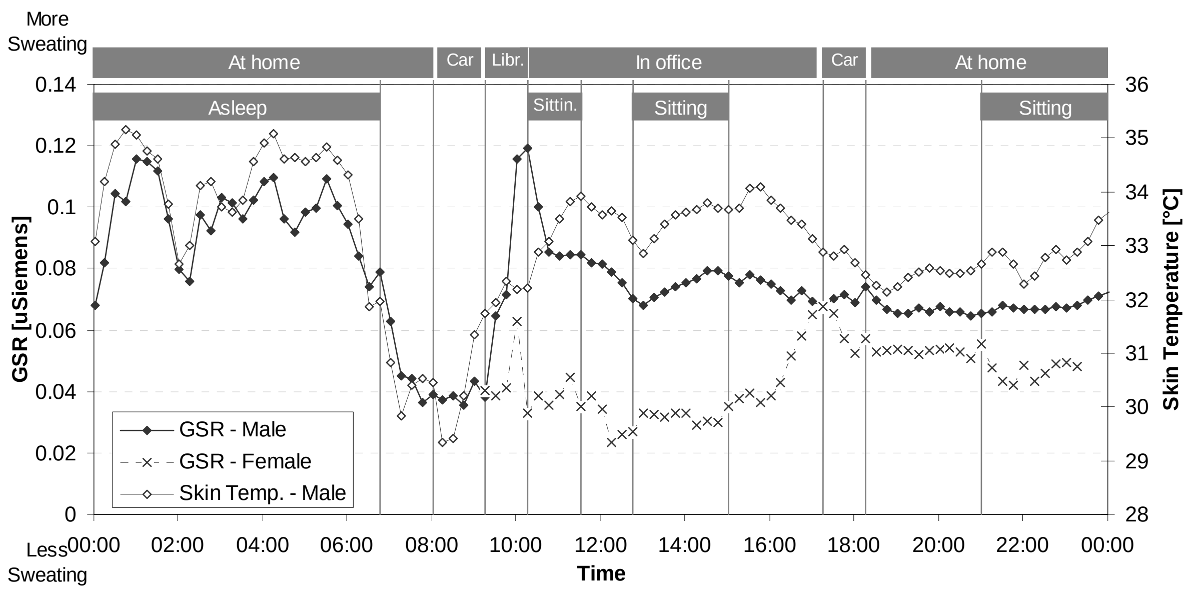


Figure 2. An example of parallel GSR and skin temperature monitoring results obtained by the embedded body sensor

The GSR level is the highest (~0.1uS) during the sleeping period when the subject is covered by a thick layer of blanket that has good thermal resistance. After getting out of the bed there is a steep drop in GSR when the body is exposed to a cooler environment (ending at ~0.04uS). Due to a higher activity level that includes walking and carrying books through different floors in a library GSR shows a sudden increase for both subjects. Maintaining sedentary activity in the office GSR stabilizes and shows minor changes only when the activity level is altered. The skin temperature follows a similar pattern as the GSR. The highest deviation of skin temperature path from the GSR sample occurs when the activity level is changing. Although the relative changes in the female and male subject's GSRs are similar there is a noticeable difference in the absolute values of GSR between the two subjects.

Output of the embedded body sensor in a controlled office environment

The following Table 2. summarizes the average levels of the physical and some physiological measures given by the wireless environmental sensor system and the embedded body sensor under steady-state experimental conditions. In addition, empirical values of the mean skin temperature, conductive heat loss through the clothing (K/A_{Du}) and PMV (Predicted Mean Vote) [10] are also indicated. Due to the small sample size the subjects' thermal and sweating intensity votes are shown informatively.

Table 2. Average physical and subjective results ±SD over one hour under steady-state conditions as function of the experimental conditions conducted on different days and at different times of the day

Activity level 1.2 ± 0.1 Met		Experiment 1		Experiment 2			Experiment 3	
		Morning 25°C	Afternoon 22°C	Morning 23°C	Afternoon 28°C	Evening 27°C	Day 1 23°C	Day 2 28°C
Air temperature [°C]		25.1 ± 0.3	21.8 ± 0.2	22.6 ± 0.0	26.6 ± 0.1	25.6 ± 0.2	23.4 ± 0.1	29.1 ± 0.3

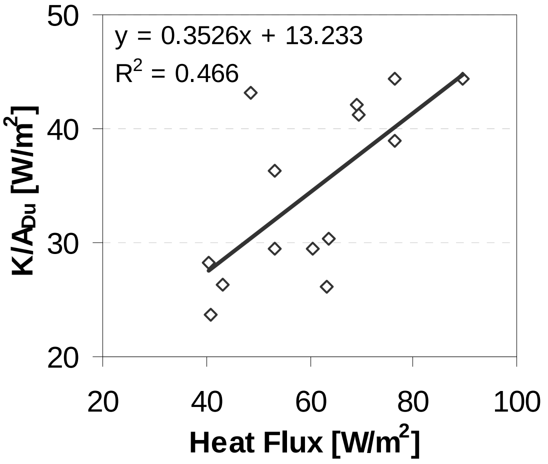
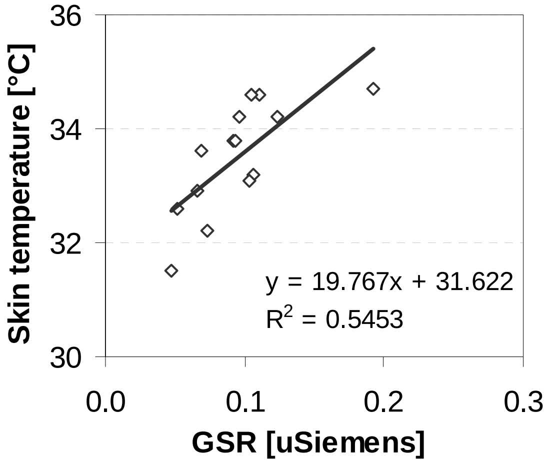
	F	32.6 ± 0.2	31.5 ± 0.1	33.1 ± 0.1	34.6 ± 0.1	34.2 ± 0.1	32.9 ± 0.2	33.6 ± 0.3
GSR x 10^{-2} [uSiemens]	M	9.2 ± 0.6	7.3 ± 0.2	9.4 ± 0.2	11.0 ± 0.1	12.4 ± 0.6	10.6 ± 0.2	19.2 ± 2.4
	F	5.2 ± 0.1	4.7 ± 0.1	10.4 ± 0.2	10.5 ± 0.2	9.6 ± 0.1	6.6 ± 0.3	6.9 ± 0.2
Sweat[c] [-]	M	10.0 ± 0.0	3.5 ± 4.9	0.0 ± 0.0	21.7 ± 2.9	19.0 ± 10.8	0.7 ± 1.2	27.6 ± 7.7
	F	2.0 ± 2.8	0.0 ± 0.0	0.0 ± 0.0	11.0 ± 5.6	0.0 ± 0.0	0.0 ± 0.0	18.0 ± 2.8
Mean Skin temp.[°C]	M	33.7 ± 0.2	33.8 ± 0.0	33.7 ± 0.1	33.8 ± 0.0	33.8 ± 0.0	33.8 ± 0.0	33.8 ± 0.0
	F	33.8 ± 0.1	33.8 ± 0.1	33.9 ± 0.1	33.8 ± 0.1	33.8 ± 0.5	33.7 ± 0.3	33.8 ± 0.0
K/A_{Du} [W/m^2]	M	36.3 ± 1.9	42.1 ± 1.3	44.3 ± 1.1	26.2 ± 1.5	29.4 ± 1.6	44.4 ± 0.7	28.2 ± 0.5
	F	30.4 ± 2.3	39 ± 1.8	41.3 ± 1.3	26.3 ± 1.3	29.4 ± 1.1	43.2 ± 0.4	23.6 ± 0.2
PMV[d] (Fanger)		0.64 ± 0.13	-0.07 ±0.09	0.16 ± 0.07	1.25 ± 0.08	1.00 ± 0.08	0.08 ± 0.04	1.26 ± 0.95
Thermal Vote[d]		1.50 ± 0.20	0.05 ± 0.28	-0.10 ±0.00	2.92 ± 0.03	2.45 ± 0.09	0.31 ± 0.25	2.80 ± 0.23

a) Male subject
b) Female subject
c) On six point intensity scale: No sweating = 0, Slight sweating = 10, Moderate sweating = 20, Strong sweating = 30, Very strong sweating = 40, Overpowering sweating = 50.
d) On seven point thermal sensation scale [9]: Cold = -3, Cool = -2, Slightly cool = -1, Neutral = 0, Slightly warm = 1, Warm = 2, Hot = 3.

The changes in the room operative temperature are reflected in almost all of the measured parameters. The heat flux given by the body sensor is the highest at lower temperatures and it diminishes with temperature rise. This effect is shown in all three experiments. Although the absolute values are different, there is a correlation between the measured and calculated heat loss from the body (R^2=0.46; p<0.007) (Figure 3.a). The measured skin temperature is distributed close to the calculated mean skin temperature corresponding to the given activity level [10]. It is greatly influenced by the operative temperature (R^2=0.67; p<0.001) and shows correlation with the GSR values in steady-state conditions (R^2=0.55; p<0.003) (Figure 3.b). GSR appears to be higher in case of the male subject compared to that for the opposite gender and shows good agreement with the male's vote reporting more intense sweating. The absolute values of GSR at a given temperature show fluctuation even within the results of the same subject.



a)



b)

Figure 3. Correlation for male and female subjects according to all experimental conditions between a) the measured and the calculated heat flux leaving the human body; b) the GSR and the skin temperature

The calculated PMV values and thermal votes were close to neutral when temperatures fell within the comfortable range (22-23°C). However, at the higher temperature conditions the calculated PMV underestimated the thermal sensation of the subjects.

DISCUSSION

Using the advantages of the wireless data communication a quick and easy monitoring of existing and new building environments can be performed. Due to the small size and battery enabled power supply of the sensors they can be easily positioned within the personal area to gain reliable information about the exposure levels. The setup of the whole system can be made within minutes after choosing the right location of each sensor. Although the current measurements were carried out in a single office the wireless system can be extended for multiple spaces or for a whole building that can provide useful information about the building performance for the facility management. The real time data measured with the wireless sensors can be displayed only with the software provided with this system. However, the data are stored in a database that could be accessed externally for further processing e.g. control of building services systems.

From the results of the whole day long measurement with the body sensor we can observe that the human body is exposed to very different environmental conditions that modify skin temperature and GSR in a wide range within the measured area. It is the duty of the thermal regulatory system of the body to perceive these conditions within or outside of the comfortable range. Since the body measurements are limited to only a small area of the right upper arm it is interesting to see how representative these results are for the whole body. Calculation methods of the mean skin temperature are reported to be evaluated by using 10-15 different points of the body accounting each with different weighting factors. According to [12] the location of the upper arm has a weighting factor of 0.07 which is the fifth most weighted location from the measured fifteen following the weighting factor of the left chest and back and the anterior and posterior thighs.
In general, differences in the base level of GSR may be related to environmental stress affecting thermal comfort but may also be of psychological origin such as personal mood [13]. Looking at Figure 2 and assuming that the psychological state of the investigated subjects did not change over the experiment, the variation of GSR is a good reflection of the evaporative heat loss through the body surfaces. This evaporative heath is transmitted partly by diffusion through the skin and partly through evaporation of sweat from the surface of the skin [10]. At operative temperatures below 31°C the sweat rate is relatively low [14] and since the heat loss through diffusion is a function of the skin temperature [10] the variation of GSR on Figure 2 follows a similar pattern as the skin temperature. Consequently, when the GSR pattern deviates compared to the skin temperature pattern, it is a good indication that sweating occurred, as it may be expected during the time spent in the library when the subject was carrying some heavy books. The GSR pattern on Figure 2 also reflects that variations between genders may be found and it is lower for females. This is not surprising since it was previously shown [15] that GSR is generally lower for females than for males and that GSR varies between different ethnic groups and it irregularly decreases with age. Seasonal and time of the day effects were also found on GSR and sweating response [16], [17].
Provided that the heat flux measured by the body sensor reflects the convective heat transfer from the skin we expected to get similar values as the conductive heat transfer (K/A_{Du}) through the clothing [10]. Although correlation was found between these two parameters K/A_{Du} remained much lower than that measured by the body sensor system that may be caused by calibration error. The measured skin temperature matched the calculated mean skin temperature within ±1°C except in one condition with the lowest temperature. Therefore it may be considered in further investigations to use this measured value in PMV calculations. Previous investigations [14] showed that sweating starts in nude subjects when skin temperature reaches 34°C. Altough we had clothed subject in the present experiment, our data showed similar effect: whenever the measured skin temperature approached or exceeded 34°C the sweat vote of the subjects has also increased from no sweating to slight or moderate levels.
As stated earlier gender differences in GSR may appear, which is again confirmed by the results obtained in the controlled office exposure. Altough variations in subject's GSR were found at the same temperature it could be attributed to the time of the day effect or to the psichological state of the subjects. The humidity content of the air between the conditions varied between narrow limits, therefore we do not expect of having considerable effect on the mesured GSR [18].

The present investigation showed that the embedded body sensing system that measures physiological parameters can give valuable data that correlate with changes in the physical environment of building occupants. The current measurements were limited to investigate only the changes induced by various levels of the room temperature. Further measurements are needed to explore the effects of other parameters describing the thermal environment and other factors of psychological origin that affect the physiological output of the body sensing system.

SUMMARY

Subjective experiments were carried out in a climate chamber using 16 Japanese subjects of both genders, in order to evaluate human comfort at very low humidity. Two levels of absolute humidity were set, 2.0 g/kg(DA) and 10.0 g/kg(DA). Three air temperature conditions with absolute humidity of 2.0g/kg(DA), 20.0°C/13%RH, 25.0°C/10%RH and 30.0°C/8%RH, and 3 conditions with 10.0g/kg(DA), 20.0°C/68%RH, 25.0°C/50%RH, 30.0°C/38%RH, were examined. People were exposed in a chamber for 90 minutes with sedentary activity. Subjects rated their sensations and subjective fatigue on the questionnaires during the exposure time. Skin moisture was measured on subjective left forearm by means of measuring capacitance of the skin. Break up time (BUT) was measured by subjects with a stopwatch.

Absolute humidity has great impact on subject's skin moisture although air temperature effects on it were moderate. Subjective BUT got significantly shorter at extremely low absolute humidity. It was found that general dryness sensation at low absolute humidity was significantly higher than that at high absolute humidity. Subjects felt their eyes were dryer at low air temperature, when keeping the same moisture content in air. In case of the constant air temperature, low absolute humidity caused greater eye dryness sensation. Very low humidity air dry up the human mucous membrane and subjects perceived it as dryness sensation. Half of subjects reported their palm of hand as wetted segment even at 25.0°C/10%RH and 30.0°C/8%RH. Subjects felt more tired at very low absolute humidity under the cool and thermally neutral condition, while they complained more at high humidity in hot environment.

INTRODUCTION

In Japan, the "Law for Maintenance of Sanitation in Buildings [1]" is applied to offices whose total floor areas exceed 3,000 m^2. It states that the relative humidity in an office space should be kept between 40%RH and 70%RH. The ASHRAE Standard 55-92 [2] prescribed a lower boundary humidity of 4.5 g/kg which was equivalent to 30%RH at 20.5°C. This standard was revised as the ASHRAE Standard 55-2004 [3], which does not specify a minimum humidity level. The ASHRAE Standard 62-2001 [4] recommends the relative humidity of 30%RH - 60%RH. These lower boundaries of current humidity criteria are intended to limit the low humidity conditions in winter. However, improvement of recent HVAC technology has allowed engineers to create a thermal environment with low humidity even during summer using cold air distribution systems or desiccant dehumidifiers in many buildings. Further studies on the effects of low humidity on occupants' comfort in other seasons are needed, as well as in winter.

The previous subjective experiment [5] at 5%RH to 35%RH using Danish people reports that negative impacts on their tear film and blink rate were observed at below 15%RH, though the subjective discomfort was very mild even at 5%RH.

Tsutsumi et al. [6][7][8] have reported the effects of low humidity on subjective comfort and productivity in summer through the various subjective experiments using Japanese subjects. As the result, negative effects of humidity were not found in the thermally neutral air even at 30%RH, which is below the lower boundary of humidity mentioned in Japanese law under a steady state in summer. However, the conditions examined in this series of experiments mentioned above, were between 30%RH and 70%RH. The studies on Japanese comfort and fatigue in the very dry air, especially below 15%RH, has been required.

This paper reports the subjective experiment conducted in a climate chamber for the purpose of evaluating comfort and fatigue of Japanese subjects at extremely low humidity.

METHODS

Experimental design

Subjective experiments were carried out to evaluate the human comfort and fatigue in extremely low humidity air. A total of 16 Japanese adults of both gender, aged 20's-60's, were used as subjects. All subjects were volunteers, who were paid for participating in the experiments. Considering their circadian rhythm, all subjects took part in the experiments at the same time of the day.

The experimental conditions are listed in Table 1. Two levels of absolute humidity were set, 2.0g/kg(DA) and 10.0g/kg(DA). For each absolute humidity level, 3 air temperatures, 20.0, 25.0 and 30.0 °C, were examined. Mean radiant temperature (MRT) was estimated to be equivalent to air temperature. Air velocity was still for all conditions.

Table 1. Experimental conditions.

	Absolute Humidity [g/kg(DA)]	Air Temperature =MRT [°C]	Relative Humidity [%RH]	Air Velocity
Low_20	2.0	20.0	13	still
Low_25		25.0	10	
Low_30		30.0	8	
High_20	10.0	20.0	68	
High_25		25.0	50	
High_30		30.0	38	

As shown in Figure 1, subjects were exposed in a climate chamber for 90 minutes, where a desiccant dehumidifier was equipped so that extremely low humidity air could be created. During the exposure time, subjects sat on the sofa and watched TV programs simulating the daily life at home. Subjective sensations, symptoms related to fatigue and visual fatigue and their self-performance were reported on the questionnaire using the visual analogue scale 5 times while they stayed in a chamber.

Skin moisture on subject's left forearm was recorded with Moisture checker (Scalar). Moisture checker measured capacitance of the skin [9]. Subjects kept their left forearm exposed to the air in the chamber during the 90-minute experiment. Subjects also measured their interval time between each blink by themselves using a stopwatch as Break up time (BUT) [10].

People could control their clothing ensembles provided by the experimenter to keep their thermal sensation as neutral as possible. They were not allowed to eat or drink something and use eye drops during the exposure.

Air temperature, relative humidity, globe temperature during the experiments were logged every 10 second. Air velocity was measured before and after the exposure.

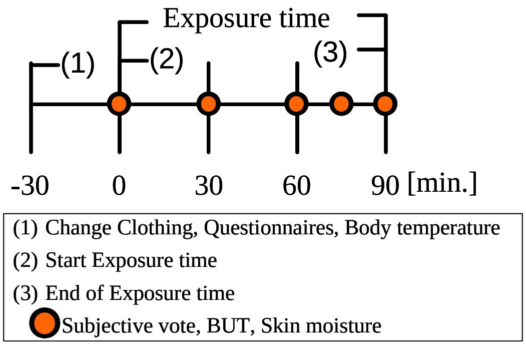

Figure 1. Experimental procedure.

Statistical Analysis

Data at the end of 90-minute exposure were analysed as that obtained under steady state with Non-parametric statistical analysis method [11]. Friedman nonparametric analysis was used for comparison among 3 conditions at the constant absolute humidity. The Wilcoxon Matched-Pairs Signed Ranks test was administered between each condition as a post-hoc test. This test was also used for the comparison between 2 absolute humidities at the same air temperature. The p-values mentioned in the next section represent the levels of significance.

RESULTS AND DISCUSSION

Physiological reactions

Skin moisture:

Skin moisture is one of the physiological responses that could be affected by humidity and would cause the subjective dryness sensation and discomfort. Figure 2 shows the skin moisture measured on the left forearm of subjects at the end of exposure time. No significant difference was observed among 3 conditions with 2.0g/kg(DA). Clear direction was not found among conditions at 10.0g/kg(DA), although significant difference was gotten ($p<0.04$). Skin moisture on left forearm at low absolute humidity was significantly lower than in high absolute humidity air at the same air temperature ($p<0.02$). It is concluded that absolute humidity has great impact on subject's skin moisture although air temperature effects on it was moderate.

Break up Time (BUT):

Break up Time (BUT) of precorneal film is one of the physiological reactions that might affect the subjective eye comfort. During the exposure time, the subjects measured their interval time between each blink by themselves using a stopwatch. Figure 3 presents BUT measured after 90-minute exposure. Although the Friedman nonparametric analysis revealed no significant difference among 3 conditions, BUT at 20.0 °C was shorter than that at other conditions for both absolute humidity levels. The Wilcoxon Matched-Pairs Signed Ranks test reported that BUT at 25.0°C and 30.0 °C with 2.0g/kg(DA) was significantly shorter than at 10.0g/kg(DA) at the same temperature ($p<0.04$). Shorter BUT was observed under Low_20 condition than High_20 condition, although no statistically significant difference was seen. It is found that air temperature did not affect their BUT in case of keeping the constant absolute humidity. On the other hand, subjective BUT got significantly shorter at extremely low absolute humidity.

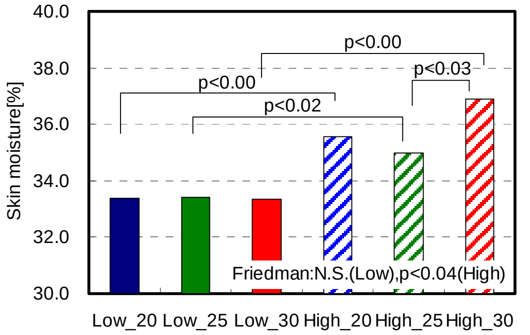

Figure 2. Skin moisture at the end of exposure

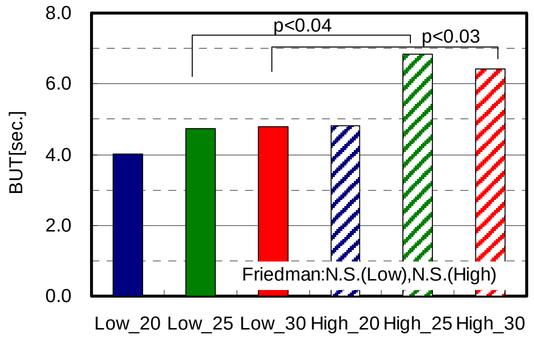

Figure 3. BUT.

Psychological Reactions

Subjects rated their general thermal sensation, comfort sensation, humidity sensation, eye dryness and so on during the exposure. A part of rating scales is illustrated in Figure 4. The scales were given as visual analogue scales. Subjects were allowed to rate their sensation either just on the number or between the numbers on the scales.

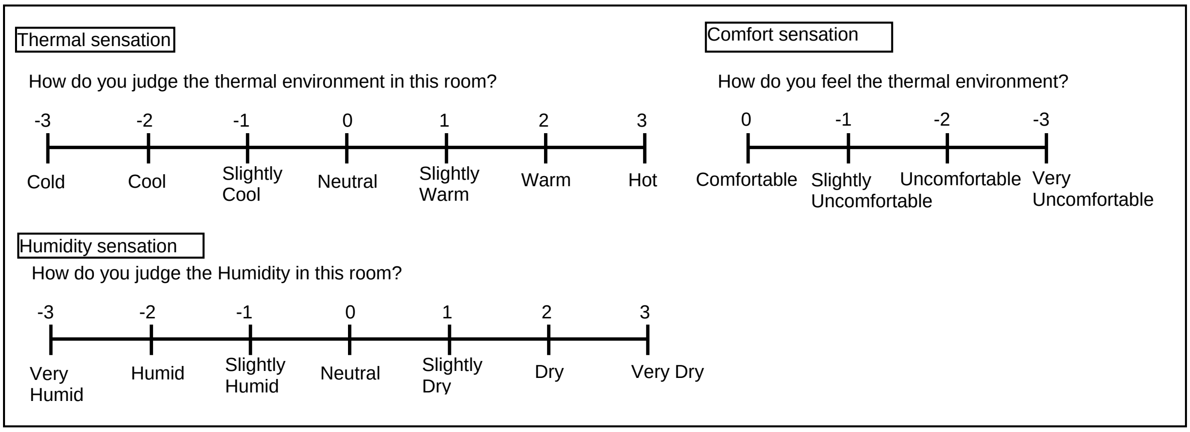

Figure 4.A part of rating scales

Thermal sensation:

Thermal sensation vote at the end of the exposure time is shown in Figure 5. In both absolute humidity air, the Friedman nonparametric analysis revealed significant difference among 3 conditions ($p<0.00$). On the other hand, pair-wise comparison between low absolute humidity and high absolute humidity condition at the same air temperature did not found any significant difference. Subjective thermal sensation was associated with air temperature, while the effect of humidity was moderate under the conditions set for this research.

General humidity sensation:

The last humidity sensation vote is presented in Figure 6. General dryness sensation tended to be higher at low air temperature among 3 conditions with 2.0g/kg(DA) of absolute humidity ($p<0.1$). Friedman nonparametric analysis revealed statistically significant difference among 3 conditions in high absolute humidity air ($p<0.005$). Subjects felt the air was significantly dryer at low air temperature than at high air temperature at constant moisture content in air. Air temperature had great impact on subjective general humidity sensation under the conditions set for this experiment. According to the pair-wise comparison between 2 levels of absolute humidity at the same air temperature, it was found that general dryness sensation at low absolute humidity was significantly higher than that at high absolute humidity ($p<0.03$).

Figure 7 displays subjective humidity comfort sensation rated using the same scale as comfort sensation. There was no significant difference among 3 conditions in low absolute humidity air. Significant difference was occurred in high absolute humidity air ($p<0.04$). According to the Wilcoxon Matched-Pairs Signed Ranks test, greater discomfort was observed at 30.0 °C than other conditions. Subjects reported greater discomfort in low absolute humidity air than high absolute humidity at 20.0 °C and 25.0 °C, while opposite result was found at 30.0 °C.

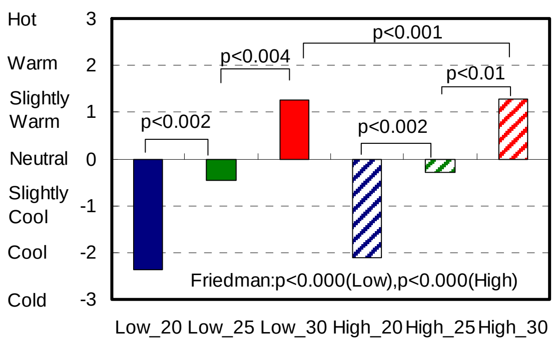

Figure 5. Thermal sensation vote.

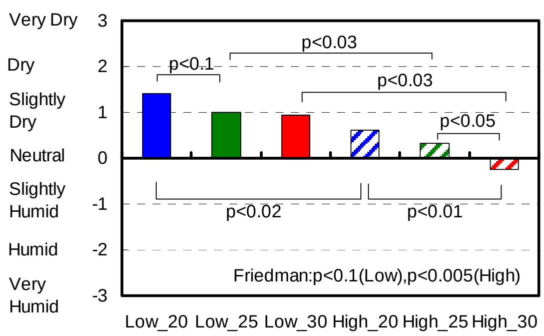

Figure 6. Humidity sensation vote.

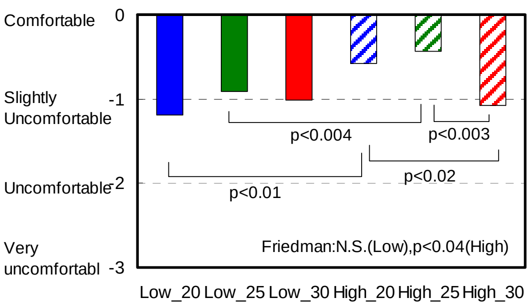

Figure 7. Humidity comfort sensation.

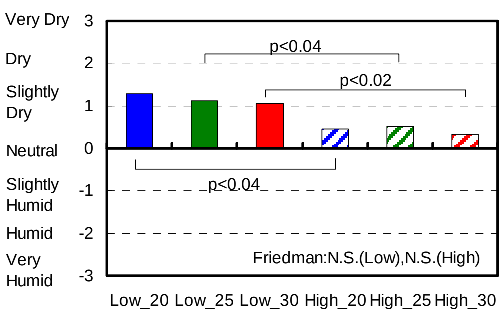

Figure 8.Sensation of eye dryness.

Eye dryness sensation:

Subjects rated their sensation of eye dryness using the same scale as general humidity sensation. Figure 8 presents subjective sensation of eye dryness at the end of exposure time. Greater dryness sensation of eyes was seen at low air temperature than at high air temperature, while no significant difference was found among 3 conditions for both absolute humidity levels. The Wilcoxon Matched-Pairs Signed Ranks test between 2 absolute humidity conditions reveals significantly greater eye dryness sensation under low absolute humidity condition than high humidity condition at the same air temperature at the range from 20.0°C to 30.0°C. It is concluded that subjects felt their eyes were dryer at low air temperature, when keeping the same moisture content in air. In case of the constant air temperature, low absolute humidity caused greater eye dryness sensation.

Body segments subjects feel dry/ wet:

Subjects were asked to report their body segments which they felt dry or wet. Figures 9 and 10 display the number of people who reported each body part to be humid after 90-minute exposure, and Figures 11 and 12 to be dry. As shown in Figures 9 and 10, more segments were felt to be dry under the low absolute condition than under high absolute condition. More than 6 subjects felt their eyes, nose and mouth were dry at low absolute humidity. Even in the air with 10.0g/kg(DA), eyes, nose and mouth were rated as the parts where they felt dry compared with other parts. This result clearly demonstrated that very low humidity air dry up the human mucous membrane and subjects perceived it as dryness sensation.

As for the segments subjects perceived to be wet, subjects rated their palm of hand more than other segments for both absolute humidity conditions. More subjects felt their palm of hand were wet at 25.0°C and 30.0°C than at 20.0°C for both absolute humidities. Half of subjects reported their palm of hand as wetted segment even at 25.0°C/10%RH and 30.0°C/8%RH.

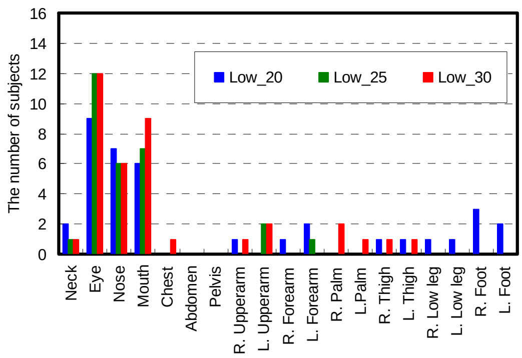

Figure 9. Body segment subjects felt "dry" at low absolute humidity.

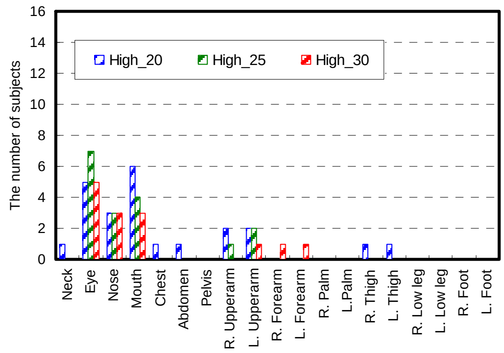

Figure 10. Body segment subjects felt "dry" at high absolute humidity.

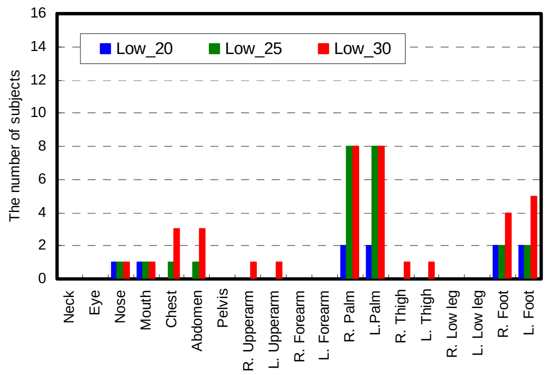

Figure 11. Body segment subjects felt "wet" at low absolute humidity.

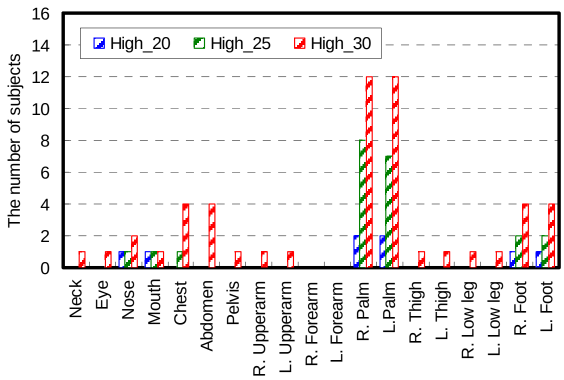

Figure 12. Body segment subjects felt "wet" at high absolute humidity.

Fatigue

Subjects were asked to assess their general fatigue. A questionnaire proposed by the "Working Group for Occupational Fatigue, Japan Society for Occupational Health" was used to evaluate their fatigue [12]. The questionnaire is composed of 3 groups, category I, category II and category III. "Category I" indicates drowsiness and dullness in subjects, "Category II" is about difficulty in concentration, and "Category III" is to do with physical discomfort. Each category has 10 symptoms related to subjective fatigue as listed in Table 2. Subjects marked "O" if they had the given symptoms, and marked "X" if they did not. Ratio of complaints was calculated for each category using the equation below:

$$Rate\ of\ complaints = \frac{Total\ number\ of\ complaints(=Total\ number\ of\ "O")}{(The\ number\ of\ symptoms)\times(Total\ number\ of\ subjects\ who\ used\ a\ questionnaire)}\times 100(\%)$$

Higher air temperature in 10.0g/kg(DA) of absolute humidity caused higher ratio of complaints. In pair-wise comparison between high absolute humidity conditions and low absolute humidity condition with the same temperature, it was observed that the ratio of complaints at 2.0g/kg(DA) was higher at 20.0 and 25.0°C. On the other hand, people felt more tired at 30.0°C with high absolute humidity than that with low absolute humidity. It is concluded that people could feel more tired at low humidity under the cool and thermally neutral condition, while they complained more at high humidity in hot environment.

Table 2. Symptoms related to the general fatigue.

	Category I Drowsiness and Dullness	**Category II** Difficulty in Concentrating	**Category III** Physical Discomfort
1	Feel heavy in the head	Feel difficult in thinking	Have a headache
2	Get tired through the whole body	Become weary of talking	Feel stiff in the shoulders
3	Get tired in the legs	Become nervous	Feel a pain in the back
4	Take a yawn	Unable to concentrate	Feel difficulty in breathing
5	Feel the brain hot or muddled	Unable to take interest in things	Feel thirsty
6	Become drowsy	Become apt to forget things	Have a husky voice
7	Feel eye strain	Lack in self-confidence	Have dizziness
8	Become rigid or clumsy in motion	Anxious about things	Have a spasm on the eyelids
9	Feel unsteady while standing	Unable to straighten up in a posture	Have a tremor in the limbs
10	Want to lie down	Lack patience	Feel ill

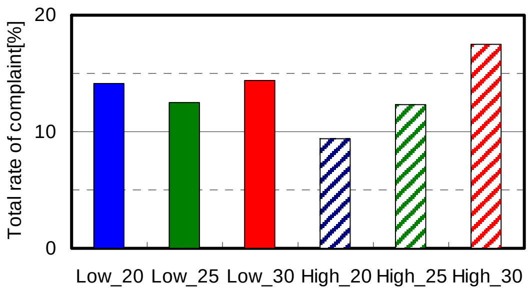

Figure 13. Total rate of complaint related to general fatigue.

CONCLUSION

Subjective experiments were carried out in a climate chamber using 16 Japanese subjects of both genders, in order to evaluate human comfort at very low humidity. Two levels of absolute humidity were set, 2.0 g/kg(DA) and 10.0 g/kg(DA). Three conditions with absolute humidity of 2.0g/kg(DA), 20.0°C/13%RH, 25.0°C/10%RH and 30.0°C/8%RH, and 3 air temperature conditions with 10.0g/kg(DA), 20.0°C/68%RH, 25.0°C/50%RH, 30.0°C/38%RH, were examined. People were exposed in a chamber for 90 minutes with sedentary activity.

Absolute humidity has great impact on subject's skin moisture although air temperature effects on it were moderate. Air temperature did not affect their BUT in case of keeping the constant absolute humidity. On the other hand, subjective BUT got significantly shorter at extremely low absolute humidity.
Air temperature had great impact on subjective general humidity sensation under the conditions set for this experiment. According to the pair-wise comparison between 2 levels of absolute humidity at the same air temperature, it was found that general dryness sensation at low absolute humidity was significantly higher than that at high absolute humidity.
It is concluded that subjects felt their eyes were dryer at low air temperature, when keeping the same moisture content in air. In case of the constant air temperature, low absolute humidity caused greater eye dryness sensation.
Very low humidity air dry up the human mucous membrane and subjects perceived it as dryness sensation. Half of subjects perceived their palm of hand as wetted segment even at 25.0°C/10%RH and 30.0°C/8%RH.
According to assessment of subjective fatigue, they could feel more tired at low humidity under the cool and thermally neutral condition, while they complained more at high humidity in hot environment.

Surveyed Thermal Comfort in Iranian Offices

Nazanin Nasrollahi, Ian Knight, Phil Jones

Cardiff University, Cardiff, UK

SUMMARY

This paper presents the findings of a short-term monitoring exercise and questionnaire survey to assess the thermal comfort conditions actually being achieved in 6 Iranian Office buildings. The findings of the questionnaire and monitoring are compared to give confidence that the questionnaire is accurately reflecting the calculated comfort conditions obtained from the physically monitoring and site observations. The perceived thermal comfort conditions for the buildings are then compared with current thermal comfort standards to ascertain whether there is potential for improvement.

The results from this study indicate that there is a good agreement between the monitoring and the questionnaire for the majority of the offices. The results also show that there appears to be room for significant improvement in thermal comfort conditions in a number of the Case Studies. These findings will be used as part of further work to explore how we might improve the thermal conditions through improvements to the Offices fabric design.

Key words: thermal comfort, offices, thermal satisfaction, field study, thermal environment

INTRODUCTION

According to ASHRAE Standard 55 [1], 'thermal comfort is that condition of mind that expresses satisfaction with the thermal environment'. Thermal comfort not only affects on occupant's satisfaction but also affects on their productivity as well.

Thermal comfort receives the highest number of complaints in most surveys of office occupants. Only about half of North American office workers express the heating and air conditioning in their workspace is comfortable and 80% of them rate thermal comfort as being very important to them [2]. Clements-Croome, D and Baizhan, L [3] have proposed that thermal problems are one of the most significant factors affecting environmental satisfaction. Abdou and Lorsch [4] also noted a link between temperature and factory / industrial worker's productivity. The research also has shown that there is an increase in satisfaction level with thermal environment when the degree of personal control increases and there is a slight increase in overall job satisfaction when environmental satisfaction increases [5]. It has also been discussed by de Dear, R and Cena, K [6] in a field study carried out in Kalgoorlie-Boulder in Australia that there is a close correlation between expressions of thermal dissatisfaction and job dissatisfaction. They found that those who rated lower than mean in their job satisfaction were more likely to report dissatisfied with thermal conditions than those who scored above average job satisfaction.

There is a psychological aspect to individual control as well. Research has shown that people are more satisfied with their thermal environment when they believe it to be under their control, even if they were not in fact actually able to alter the temperature [5]. Ruck, N.C [7] indicated that thermal comfort is a complex psycho physiological condition of satisfaction that happens within a subtle range of human responses.

There are various environmental factors that are affecting thermal comfort. As Fanger, P.O [8] has addressed there are six important variable that influence the condition of thermal comfort; activity level (heat production in the body), clothing insulation (clo value), air temperature, mean radiant temperature, relative air velocity and water vapour pressure in ambient air. Thermal comfort can be measured when these six variables are measured or estimated. Fanger's comfort model is based on PMV (predicted mean vote) and PPD (predicted percentage of dissatisfied people). PPD can be calculated when PMV is estimated. On the other hand there are studies have shown that thermal comfort is an behavioural approach [9] and unlike the PMV method is not based on the clothing insulation and the metabolic rate to calculate required thermal comfort . They suggest that people tend to make themselves comfortable by changing their clothing, activity and posture in their thermal environment. Their adaptive model is based on a wider range of data derived from buildings, climates and cultures and outdoor temperature is the main factor to calculate the adaptive thermal comfort. Also, it has been argued that there is a discrepancy between predicted thermal comfort (PMV) and perceived thermal comfort of occupants in free-running buildings and naturally ventilated buildings [10, 11, 12]. It has been suggested that people of different cultures perceive themselves comfortable in a wide range of temperature about 17ºC to 31 ºC and they can adapt to extreme temperatures [12]. But researches have shown that in centrally controlled or air conditioned buildings the PMV model works well for calculating thermal comfort. de Dear and Brager [11] have shown that the PMV model is in a close agreement with the observed thermal comfort of occupant in centrally-controlled HVAC systems or air conditioned buildings. Fanger and Toftum [13] have shown that PMV model is in a good agreement with high quality field studies in HVAC buildings situated in cold, temperate and warm climates.

Overall, these studies emphasise the importance of thermal comfort for office occupants and highlight that achieving thermal comfort in offices not only delivers more satisfaction for the occupants, but also improves their performance as well.

To understand whether the published international standards for thermal comfort were applicable to the Iranian office context, a short-term questionnaire survey and a physical measurement and monitoring study have been undertaken in six office buildings in Tehran (Iran) in the hot season (July and August) in 2005.The aim of this study was:

- To establish via questionnaire how the occupants perceive the internal conditions with comfort.
- To establish the range of indoor and external conditions found in the offices.
- To compare measurement and physical monitoring with the perceived thermal sensation in the studied offices.
- To compare the results with international approaches such as ASHRAE standard 55 and ISO7730.

- To try to understand how the occupants achieve acceptable comfort conditions in extreme temperatures.
- To establish what routes may be available to improve comfort in these offices.

The environmental measurements and surveys were conducted in six office buildings in Tehran. These buildings were a mixture of types ranging from highly glazed, modern designs and up to 30 year old. The field experiments and an office occupant's questionnaire survey were carried out during the hot season in Tehran (July and August).
In all the offices studied, the air temperature, relative humidity and globe temperature have been measured as environmental factors for up to a two week period. The recording intervals were set to 10 minutes for the air temperature and relative humidity and 20 minutes for the globe temperature. Measurements of these parameters were taken in two office rooms in each building.

METHODS

For this research two data collection methods have been used; a questionnaire as a subjective measurement was used to obtain the occupants responses to their environment, and physical measurements were used to obtain quantitative data on the actual conditions in the offices.

Subjective measurement (questionnaire)

For the questionnaire the occupants' perceptions of the indoor environmental quality are obtained by a questionnaire survey. The scope and format of the questionnaire are based on a mixture of the Indoor Environmental Quality (IEQ) survey questionnaire from the Centre of the Built Environment (CBE) at the University of California, Berkeley [14] and a questionnaire for the study of Sick Building Syndrome (SBS) used by the Building Research Establishment (BRE) [15] in the UK. There were also some additional questions that were necessary for the research that were not covered by either of the two reference surveys, and were therefore added by the author. Satisfaction with the indoor environmental quality (IEQ) is evaluated by several criteria, including thermal comfort, air quality, lighting and noise. The occupants' perception of satisfaction with IEQ is assessed on a scale ranging from very satisfied (+3) to very dissatisfied (-3). The occupant perception of thermal comfort is evaluated by a scale based on the ASHRAE 55 [1] seven-point thermal sensation scales which ranges from hot (+3) to cold (-3). The perceived health of occupants is also being asked for and is based on the sick building syndrome questionnaire from BRE [15]. Occupants are asked whether they experienced one or more symptoms on a list of eight common SBS indicators. The symptoms are considered as being building related in office buildings. The approximate time required to complete the questionnaire was 5-10 minutes. Of the studied office buildings the response rate was 92% (195 out of 210).

Physical measurements

For the physical measurements the indoor air temperature, relative humidity and globe temperature were measured over a period of 2 weeks during the hot summer season in Tehran (July and August). The studied office buildings were all centrally cooled/ heated or air conditioned and none of them were naturally ventilated. Regarding to literature and studies stated above PMV model works well in buildings with air-conditioning or HVAC systems, therefore the data obtained from the physical measurements were used to calculate PMV (predicted mean vote) and PPD (predicted percentage of dissatisfied people) indices according to ISO 7730 [16] and ASHRAE standard 55 [1].

Analysis

the questionnaire survey and physical measurements were conducted over a series of two week periods in the hot season, during which the outdoor temperatures ranged between 23.7 ºC to 36.6 ºC with a range of 25% to 40% for the outdoor average relative humidity. This data is shown graphically in figure 1. The rain was unexpected in the measurement period as the Tehran climate is normally hot and dry in summer.

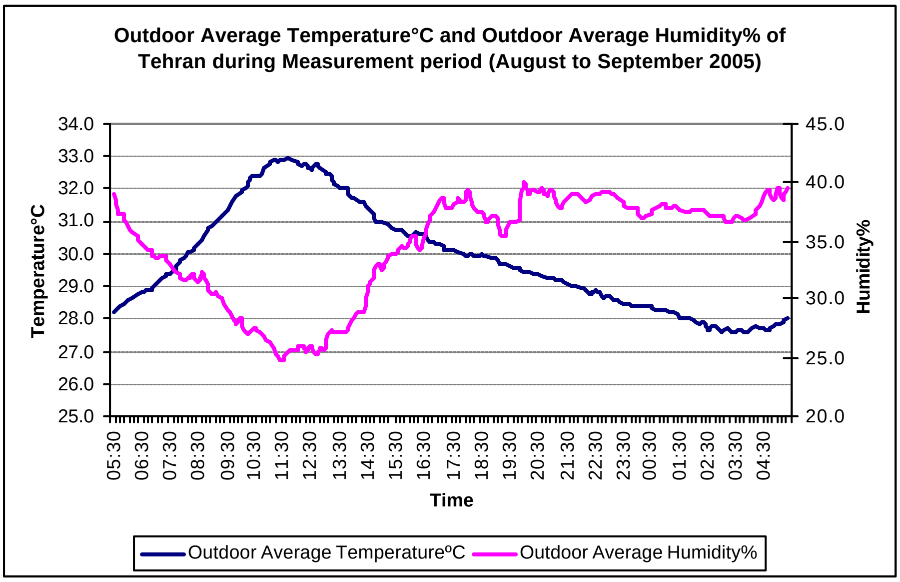

Figure 1: The measured outdoor average temperature ºC and outdoor average humidity of Tehran over measurement period (August to September 2005).

Results from the questionnaire

Figure 2 compares the results of the questionnaire over all the offices studied with the ASHRAE Standard 55 thermal comfort condition (80% or more of the occupants are satisfied with the temperature). It reveals that only 57% of the occupants reported they were satisfied with the temperature in general. Moreover, more than 23% of the occupants were positively dissatisfied with the temperature in their workspace which is more than the acceptable dissatisfied range (10%) specified by ASHRAE Standard 55 [1]. Therefore, it appears that the occupant's perceived satisfaction with the temperature is not in compliance with the acceptable thermal satisfaction rate within ASHRAE Standard 55 [1]. Summary of the occupant's specification are summarized in table 1.

Table 1: Summary of occupant's time spent at work, type of work, age, gender and clothing insulation,source from author [17]

Occupant's data		
	10 or less	9.80%
Time spent at workspace (hours)	11-30	24.20%
	More than 30	66.00%
	Managerial	6.30%
Type of work	Professional	73.80%
	Clerical/Secretarial	19.90%
	30 or under	36.90%
Age	31-50	51.80%
	Over 50	11.30%
Gender	Male	63.10%
	Female	36.90%
Clothing insulation (Clo)	Male	0.7
	Female	0.75

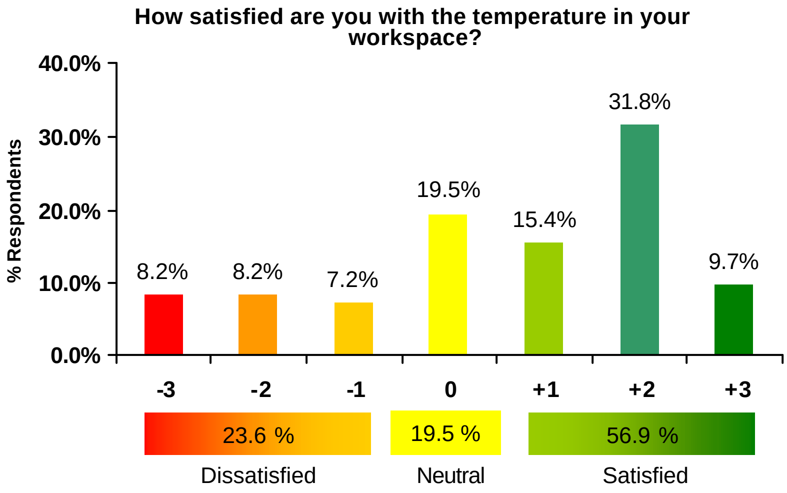

Figure 2: Occupants perceived general satisfaction with the temperature in all studied buildings.

Figure 3 shows the results of the questionnaire survey in more detail. It reveals that thermal neutrality was achieved in only around 22 - 25% of the occupants in winter or summer.

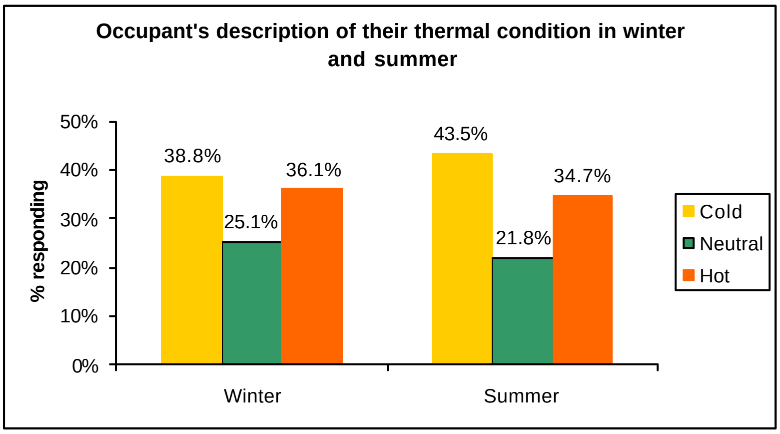

Figure 3: Respondent's description of thermal condition in their workspace in winter and summer in all studied buildings.

Figure 4 shows that, when considering the ambient conditions, the respondents reported that thermal comfort has the greatest effect on their perceived productivity. Taking this into account with their perceived low percentage of thermal comfort with temperature in winter and summer (figure 3) it can be reasonably suggested that improvement in the thermal conditions over the heating and cooling period would increase their perceived productivity.

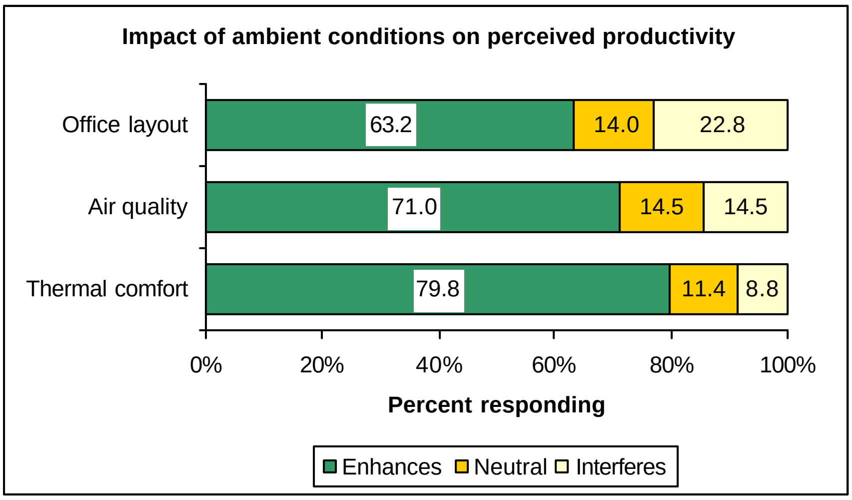

Figure 4: Respondent's perceived productivity with some of the main components of the ambient conditions (All buildings).

Findings from physical measurements and monitoring

The physical measurements, combined with observations about activity, clothing and air velocities in the spaces, allow calculation of the PMV according to ISO7730 [16] at each recording interval. Comparing the calculated range of PMV's for all the buildings monitored in figure 5 clearly indicates that a wide variety of PMV values are achieved. It seems that only 5 offices out of the 12 are controlled to within the specified acceptable thermal comfort range based on ISO 7730 [16] and ASHRAE Standard 55 [1] which is -0.5=PMV=+0.5 and PPD=10%. The PMV and PPD indices are based on the ASHRAE thermal sensation scale that defined as follows: +3 hot, +2 warm, +1 slightly warm, 0 neutral, -1 slightly cool, -2 cool, -3 cold.

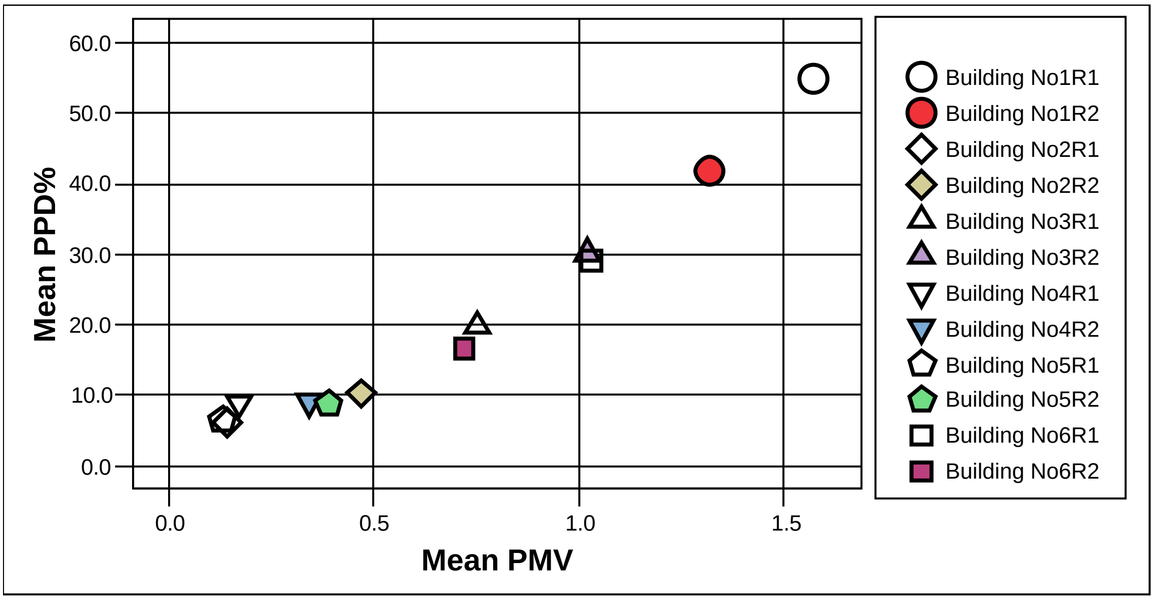

Figure 5: Mean PMV and Mean PPD of all studied offices.

Comparison between questionnaire survey and physical measurement

Figure 6 shows that generally there is a good agreement between the occupant's perceived mean thermal sensation from the questionnaire and the mean PMV obtained from the measurements. There is a slight difference between these values in building no6 and building no3. In building no6 the mean questionnaire value is neutral but the measured PMV shows slightly warm based on ASHRAE Standard 55. Also, in building no3 the occupants perceived their thermal condition as neutral but the calculated mean PMV indicates slightly warm. Overall the comparisons indicate no clear trend towards adaptation in the Iranian occupants of the buildings monitored. The main uncertainties in the findings come from the necessarily basic physical measurements undertaken, along with the assumptions about the air velocities in the spaces and the constancy of the clothing and activity levels.

Research has shown that for sedentary occupants humidity has relatively small effect on their thermal sensation and also perceived air quality, but in long term high humidity might cause microbial growth and very low humidity (<15-20%) might cause dryness and irritation of eyes and airways [18]. The sensitivity analysis shows that temperature is the most influence on the PMV value.

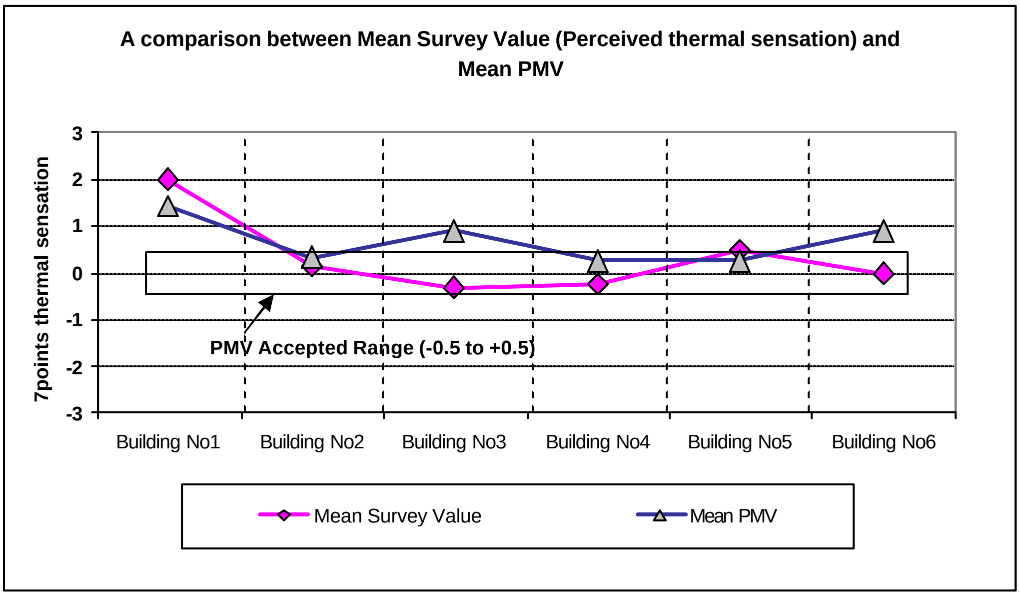

Figure 6: Comparison between occupants perceived mean thermal sensation with measured PMV from calculation.

Comparison between mean measured temperature and mean perceived thermal sensation

The data from table 2 clearly show that there is generally a good agreement between the mean measured temperature °C from physical measurement and perceived thermal sensation. In 4 out of 6 studied offices the mean measured temperature matched with the occupant's expression of feeling warm or neutral while there is a discrepancy between those in 2 studied offices.

Table 2: Statistical summary of mean measured temperature and mean perceived thermal sensation of all studied offices.

Buildings	**Mean measured temperature °C**	**Mean perceived thermal sensation**	
Building No1	29.3	2.00	warm
Building No2	25.1	0.13	neutral
Building No3	27.0	-0.33	neutral
Building No4	24.8	-0.24	neutral
Building No5	24.9	0.48	neutral
Building No6	27.0	0.00	neutral

Comparison to ASHRAE Standard 55 and ISO 7730 Standard

The research also has assessed the buildings compliance with the acceptable thermal environment for general comfort of ASHRAE Standard 55 and ISO 7730 standard. The acceptable range is -0.5<PMV<+0.5 and PPD<10%

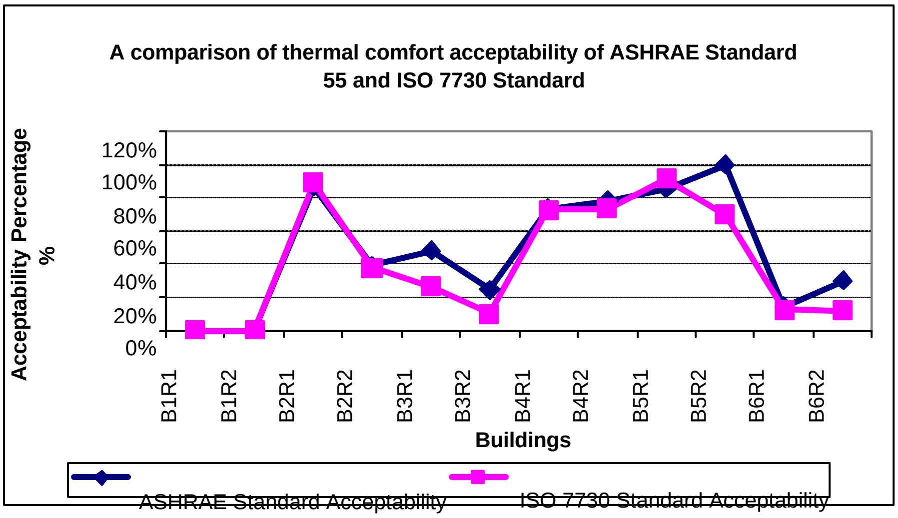

Figure 7: Compliance with ASHRAE Standard 55 and ISO 7730 Standard in all studied offices.

The results derived from figure no shows that 7 out of 12 cases are incompliance by 49% of monitored time and under, while only 5 of the cases are in compliance by 69% and over of monitored time during the working period.

CONCLUSIONS

- Only around 22-25% of the occupants report being thermally comfortable during the heating and cooling seasons in Iran.

- The research has found that there is a good agreement between mean measured temperature and mean perceived thermal sensation in two third of studied offices which indicates that in majority of the offices there was a direct link between the expression of thermal sensation as warm or neutral and the mean measured temperature ranges (table 2) (e.g. the occupants tend to express warm when the mean measured temperature was above the ASHRAE Standard 55 comfort range).
- It has also shown that there is good agreement between perceived mean thermal sensation and mean PMV in 4 out of the 6 office buildings studied. This underlines the legibility and reliability of the occupant perceived and predicted thermal sensation findings in the questionnaire survey and physical
- Due to non existence thermal comfort regulations in Iranian offices the research has assessed the offices within ASHRAE Standard 55 and ISO 7730 Standard defined comfort zone. Therefore, the comparison to ASHRAE Standard 55 and ISO 7730 Standard reveals that 7 out of 12 cases in studied offices are incompliance by only 49% and under of the monitored time during working period.

These overall findings suggest that it may prove beneficial to develop thermal comfort regulations for Iranian offices based on the ASHRAE and ISO standards, which would not only increase the occupant's satisfaction and their perceived performance but also potentially result in the reduction of energy consumption in the offices.
Further work is being conducted to assess how the thermal performance of these offices might be improved, thus achieving better thermal comfort and reducing energy consumption.

Office workers' feedback on the control of office indoor environment

Mervi Himanen[1,2], Tuuli Järvi[1]

[1]VTT and the [2]Helsinki University of Technology (HUT), Finland

mervi.himanen@vtt.fi

SUMMARY

Energy efficient behaviour was studied by a questionnaire addressing office workers altogether in 34 office buildings in Finland, Sweden, the Netherlands, France and Italy. A Finnish occupancy study of the possibilities to adjust working environment and thus gain better working efficiency offered comparative reference results on similar themes.

The possibility to control personal working environment was most important for the office workers. The qualitative building automation had a positive influence on the feedback regarding workspaces. Control possibilities which take account of the dominant nature of the nature of work at workplaces demand for different solutions even on the same office floor. The gender differences dominate in the attitudes towards the environmental design, towards the control possibilities in particular. While the occupancy studies turned out to be a feasible asset for identifying the technical qualities, equalling the physical measurements, should the facilitation of workplaces follow the different needs of the female and male workers for satisfactory end-user feedback? The performance of building service and automation installations should be separated from other strongly influencing work organisational factors.

INTRODUCTION

To understand how to facilitate the indoor environment is not only a technical design task. It is constantly challenged, latest, by the knowledge workplace paradigms. The interplay between the workplace design, end-user satisfaction and the quality of structures and building service technology is a multidisciplinary design task of workplaces [1], [2], [3], [4]. A big challenge in the workplace design is to separate the organisational, physical and economical factors from each other in theory [5], and to learn how to measure them. In the international context, also national and cultural factors contribute to the research results [cf. 1].

The key focus in the EBOB project was on combining the human and social perspectives with advanced modern control and ICT (Information and Communication Technologies) solutions [6]. This was done in order to make energy efficient behaviour natural, easy and intuitively understandable for the end-users, and at the same time to achieve the most energy efficient solutions while improving the standards of indoor comfort in refurbished and new office buildings. According to this combining approach of human perspective and available new technology the results gained were called 'forgiving technology'. The EBOB project highlighted that misunderstanding of end-users about how the HVAC systems work, e.g. not seeing the relationship between indoor air temperature and energy used in different weather conditions explains the unsuccessful energy saving efforts.

The EBOB project studied the office environment as a whole and the forgiving technology in particular. The main concern was energy efficient behaviour and parameters influencing it.

The quality of the building properties and technical installations were expected to have influence on the evaluation of the workplace. This was studied by the EBOB interviews as well as on basis of previous research [2]. The best ranking obtained from the end-user evaluations was dependent on the gender and organisational factors, mainly on the organisational hierarchy which go-effected with gender factors [2], and also the workers possibility to influence the design of the workspace and its usage. Furthermore, best ranking was gained also by such building qualities as spaciousness and large building mass [2], of which the last mentioned is often considered by experts as an inhuman design scale. The latest experiences on the facilitation of qualitative office indoor air shows that the personal workspace area should not be smaller than 15 m^2, because otherwise the end-user might experience the indoor environment noisy or unpleasant due to too high velocities or imbalanced thermal conditions despite of the fact that the outcome of the correct normative indoor air design criteria has been successfully commissioned [8]. However, larger ducts and more sophisticated air-conditioning machinery than presently normally used, because of lean finance, could help in hitting the goals for end-user satisfaction. The post- or pre-occupancy studies often prove either the need for good indoor air or the lack of it even in the high class intelligent office buildings [8], [9]. A qualitative functional design of layout, interior and use of the ICT is as important as the proper functioning of the building service and automation facilities and maintenance as well as the use of control units and protocols of high standard.

In planning service systems and envelopes for buildings an important issue is the location of the building (country, latitude, availability and use of certain materials and technologies). It determinates the design criteria of indoor environment and interior design as well as how the building control technology should be operated although the building automation technology itself is universal.

METHODS

During the EU 5th FP project, EBOB, Energy Efficient Behaviour in Office Buildings (www.ebob-pro.com, NNE5-2001-0263) a web based questionnaire was addressed to office workers altogether in 34 office buildings in Finland, Sweden, the Netherlands, France and Italy (735 respondents). Another separate web-based questionnaire was aimed at the building managers, but finally the managers were interviewed face to face by the researchers in almost all participating countries. The two studies are hereafter called as the office workers' and the building managers' interviews. Information on the quality of the building properties and installations was retrieved from eleven of the studied office buildings and in all other countries except in France (Table 1).

Altogether 735 respondents, 291 men and 399 women (45 respondents did not answer the question of gender) filled out the office workers’ interview consisting of 135 questions [1]. All educational levels from primary school education to university graduates were represented. Over 62 per cent of the respondents were graduates or students either with university or with other high-level education. A share of 18.6 per cent of the respondents was managerial, 51.2 per cent professional or technical and 30.3 secretarial or clerical personnel. For the share of 5.6 per cent the working status remained unidentified.

At first, the end-user feedback on the workspace and indoor air quality was analysed [1]. The analysis of the results of the managers' interview studied both the quality of building properties and installations and the correlation of the building quality to the end-user feedback on the office workers' workspaces and indoor air quality [11]. Only after combining the results from both interviews it was possible to check whether the quality of the building properties and installations and the end-user feedback correlate, and how strongly. This was the methodological challenge of the study. The results from both interviews have been analysed using scientific statistical testing (by SPPS program).

The main concern of the EBOB project was the empowerment of the office workers' energy efficient behaviour. Such factors as needs, attitudes and possibilities of adjusting working environment and thus control energy efficiency and respondents' demography (working status, gender, age) were compared to the quality of the building installations and properties, such as the building age and the possible renovation as well as the quality of building services, the existence of building automation and personal control possibilities, type of maintenance service (in-house or out-sourced), occupancy, the size and type of personal workspaces. The final analysis provided knowledge of the specific characteristics of the buildings concerned, putting the focus on the use of control technology.

The Intelligent Buildings Survey (IBs Survey), carried out in twelve office buildings with 534 office workers in the Helsinki metropolitan area in Finland in 1994, used a questionnaire with 417 parameters and studied office workers' evaluations of similar properties of the office buildings than the EBOB interviews (in 2003) [2], [6]. During the IBs Survey the office workers were asked to evaluate the performance of their workplace to their working efficiency. The similarity of the themes opened up the possibility to use the results from the IBs Survey as references to this analysis of the EBOB interviews.

THE EFFECT OF THE OFFICE LAYOUT

Conclusions regarding workplace design stated that the type of personal workspace matters on the experience of the workplace; a single room turned out to be a favourite for most of the office workers, a double room the worst of all types, and the open area office space a fairly neutral alternative. Conclusions from the IBs Survey were similar [3]. The interplay between workplace design and building automation turned out to be difficult in shared spaces because the indoor climate could not be adjusted according to personal needs, which meant poor personal control possibilities over indoor air and possible thermal discomfort, as well as even other inconveniences. This is the case of the double room offices in particular. In two cases out of three, the open area office space was found as a good solution regarding indoor air quality, which meant that the building automation systems were working also well enough.

AGE OF THE BUILDINGS AND THE EFFECT OF RENOVATION

The feasibility of the building automation could be presumed to be dependent on the age of the building as well as on the maintenance of the equipment. However, the age of the building did not necessarily play the main role, but the renovation turned out to be worth of trouble. The thermal comfort and indoor air quality in general were satisfactory in all renovated buildings. The end-user feedback on the work environment in general was poor regarding the old buildings and a little worse in the new ones than in those, which have been used for a while.

One could presume that after using a building for some years 'the things have settled' and the users were used to the quality of the building as well as had learned how to best benefit out of the physical environment. For confirmation, more accurate knowledge of the effect of the age of the building was gained from the evaluations. In addition, those buildings which were used for some years were occupied by a relative large portion of male professionals who tend to be rather satisfied than critical on the physical work environment. They have also good controlling possibilities over their working environment, which is an important advantage in making ones work environment comfortable. In those offices which were used for some years and had the majority of female workers − who tend to be critical on indoor environmental condition, and which still got a good end-user feedback, the women worked in the most favourable spatial arrangements of single rooms.

In addition to the age other obvious reasons for the low valuation of the old office buildings were found. In the oldest buildings with poor end-user feedback, the number of clerks was largest while in all other building age categories the modern diamond organisation structure[1] dominated. In addition, in them worked mostly women, who in general tend to be critical on indoor environmental conditions and they worked in rooms shared by several workers which has been evaluated as an unfavourable spatial arrangement.

THE BUILDING AUTOMATION OVER INDOOR AIR

The workers were more satisfied with the physical working environment in general and with the indoor air quality in their own workspace when the automation controlled the indoor air than if there was no control. The building automation over indoor air guaranteed that the air conditioning was not considered to run too efficiently during the summer time and workers did not feel cold indoors. Also, almost all those who worked in the offices without control technology (90%) were satisfied with the indoor air in the summer. However, only in the buildings with the control automation of the indoor air, the workers felt that the indoor air was too cool in the summer, in other words the air conditioning was running too efficiently.

PERSONAL TEMPERATURE CONTROL

In case of personal temperature control, [1)]the workers were more often some more satisfied with the temperature in their personal workspace than without the control possibility, and [2)] they did not feel too hot, not even in the winter time when the heating was evaluated too efficient if the building was without the personal temperature control technology. The personal workspaces were evaluated rather too hot than cool during the IBs Survey [2] as well, in both the intelligent and the other high quality offices. The feeling of hot was not as

[1] The majority of the current office workers are professionals while earlier they were clerks. Office organisation is called as a diamond organisation when there works as a small amount of clerks as executives and majority of professionals.

remarkable between these two control alternatives (personal control or not) in the personal workspace in general as it was when considering the winter situation alone.

However, [3)] those who had personal temperature control units felt either cool or not in their personal workspace. In the sophisticated office buildings with building automation and personal control units the indoor temperatures can be too cool, in the summer particularly.
According to the IBs Survey, women have fewer possibilities than men to influence their work environment although the quality of it seems to be more important to women than to men [2]. Women also spent more time in the office buildings than men did, in other words they are heavy users of their space, which might make them more demanding than men for the quality and performance of the building properties and installations. In parentheses, men work more often out of offices than women, but both genders work as long hours and for example work overtime as often and as much.

The male dominance at workplaces is also due to the fact, that men more often than women have a higher position in the hierarchy of the organisation. During the EBOB interviews it was found that he personal temperature control possibility was welcomed by all office workers, but it became statistically significantly remarkable when the gender aspect was taken into account. The EBOB interviews revealed the need for better control possibilities over working environment among the female office workers, now within the European context.

During the analysis of the EBOB office workers' interview Vastamäki et al [8] also found out that the gender played a statistically significant, even highly significant role over several aspects of the indoor climate. It was related to importance of control over ventilation, air humidity, air motion (air flow), indoor temperature (in all of these $p<0{,}001$), windows ($p=0{,}021$) and over energy saving aspects ($p=0{,}030$). In all of these aspects, the personal control was more important for women than men. However, the effect size was quite small. Only 3 % of the variance of the control over ventilation can be explained with gender. This was the item on which the gender effects were most relevant.

Interestingly though, the personal control possibility of the temperature in the own workspace was rather making the women more dissatisfied with the temperatures. As women more often than men work in the two-person rooms or rooms shared by even more workers, they might think that the existence of control possibilities does not result to a good indoor air quality anyway, which would explain the illogical result. Another explanation could be that despite the availability of the control units, they might not use them or not at least for their own benefit. This type of situation of unused possibility can cause extra frustration, which fact was revealed in a North American office environment study.

The IBs Survey proved [2] that the executives were most satisfied, professionals next and clerks least satisfied with their working environment. If in the analysis the gender is taken into account together with working status, the results are somewhat different. In general, women are more demanding in terms of spatial solutions and indoor air quality than men and the quality of technology concerned. However, variations appear in the end-user feedback. For example, of all studied office workers male clerks and female executives were the most satisfied groups with the office automation systems.

Female workers have been considered critical in terms of working environmental conditions for example because of their dominance in effective factors of sick building syndrome. Men turned out to be demanding in terms of the quality of technology, especially if the evaluation involved mobile technology [2]. If modern offices function more and more on technology, the men instead of women might become an important critical group in the end-user evaluation or the user requirements studies.

According to the EBOB studies on average the workers were more satisfied with the physical working environment in general if the personal control of the temperature was in use than if it was not. However, this was not the case in the IBs Survey [3, pp. 216-220], which found no influence of the personal control facility to the end-user satisfaction in the buildings. The selection of buildings caused the difference in the results. The EBOB interviews were comparing buildings rather with qualitatively very different than similar building service facilities and other building qualities. The selection criteria for the buildings compared during the IBs Survey was more selective. Best quality was the prime selection criterion. If only possible, pares of buildings were picked for comparison; the age, the size and the purpose of usage, etc. were as similar as possible in both categories: the intelligent and the other high quality offices.

Furthermore, the IBs Survey concluded a zero effect of the personal cooling unit to the end-user satisfaction of the indoor environment also in the intelligent office buildings, because the quality of the personal workspace in general was evaluated there poor and the possibility of the co-effective factors was most probable. Also, the location of the control unit was not always the best possible and the occupants did not know well enough of the control possibilities. The indoor air quality of all buildings within the IBs Survey was surprisingly poor for various reasons [3].

Nevertheless, the positive average result of the EBOB interview in general was not the whole truth. When looking the buildings separately as done during the IBs Survey, it can be concluded from the three buildings equipped exceptionally well in terms of the building services that in one out of the three the end-user feedback was good, in the two others not so good.

Finally, the results of the international EBOB interviews were exposed to the influence of the national and cultural norms, while the IBs Survey was a national case study. Seemingly relevant national differences were gained during the analysis of the EBOB workers' interview [10]. Regardless, no attention was paid, how, or if at all, the end-user evaluation was affected by the selection of the cases for the sample or if the user requirements could depend on behaviour and motivation as shown for example by the Malows' Hierarchy of Needs [3], [6]. Does indoor environment satisfy such basic human needs of shelter from weather, which are common to all of us without any cultural differences?

In both case studies it could have been paid more attention to the selection of the buildings also on basis of such factors as the shape of the lot, the orientation of the building, the dominating wind directions, or for example, the size of window area and the facing of windows to the cardinal points, the thermal weak points of the envelope.

Nevertheless, according to the EBOB interviews the personal control possibility kept the office workers more often satisfied with the temperature of their own workspace than if that possibility was not available. The control over the overheating in the winter was better with the personal control possibility than without it. The personal control possibility did not prevent from too low temperatures in the personal workspace. This result was based on the building specific comparison with minor influence of the selection of the sample.

INDOOR ENVIRONMENT OF KNOWLEDGE WORKPLACES

Interestingly, no strong correlation, it is, the non-existence of the statistically significant differences was found between the end-user feedback on the indoor environment and the feasibility of the building service systems or the standards of the existing building automation equipment excluding the gender aspect. A similar contradictory result yielded from the IBs Survey [2] as well. The research concluded that the building automation was not particularly sophisticated in the intelligent office buildings compared to the equipment in the other office buildings. However, the end-user evaluation of the technology was better in the buildings built using the intelligent building concept as design criteria than in those offices which were built according to other high design criteria parameters. Either way, the conclusions of these two studies were the same, no correlation between end-user opinions on the indoor environment quality − which is the outcome of the building services − and the standard of the building service and automation facility. In the EBOB study, the thermal comfort and the indoor air quality were not statistically significantly better despite the sophisticated building automation installation. However, the building automation made the buildings more acceptable for the office workers according to the feedback of the EBOB interviews. In general, the high technology building automation was worth of having. The paradigm of co-effecting factors did partly explain the results.

The nature of work is said to become ever more mobile. Mobile work means that working hours are spent out of the office, and also that the workers go out and come in several times a day. Such a situation is very challenging to the design of building service systems while the incoming person can feel the impurities of indoor air easily. On the other hand, the IBs Survey proved that people worked longer hours in the intelligence offices than in the other type of high quality offices. The situation is challenging regarding quality of indoor air climate, also when workers stay long hours indoors. A person cannot sense the bad air quality by smelling but might get head ace if the indoor air is not fresh enough or have allergic reactions due to the impurities in the air.

To make the workplaces suit better for the knowledge work than they do today, the separation of different forms of influencing factors could help. How the organisational and technical factors could be separated from each other when studying the modern offices and the current office automation three different cases were found:

- The case of positive co-effecting factors: A case of several positive organisational factors together with an efficient air conditioning and a recent renovation ended up to a good evaluation of both the thermal environment and the indoor air quality in general. There was no sophisticated building automation installation, but the dominant spatial arrangement of open area office suited well for the workers.
- The case of good technology destroyed by several negative co-effecting factors: A case with a sophisticated building automation installation together with the several negative organisational factors ended to a too efficient air conditioning. Furthermore, the dominance of double rooms caused the need to open the windows; and only once the thermal conditions and the air quality in general was evaluated as good. Neither any intelligent feature could save the building from bad feedback nor could it substitute and mitigate the unsatisfactory quality of the building properties and installations.
- The case of negative co-effecting factors: A case of several negative organisational factors in an old building with the dominance of double rooms and without any sophisticated building automation installation ended to a poor valuation of both the thermal environment and the air quality in general.

SUMMARY

Currently, numerical simulation research on indoor air and human thermal comfort usually focuses on the air-conditioning room in summer. This paper uses an Air-conditioned dormitory in winter as a model to study indoor airflow and human thermal comfort. This paper uses $\kappa-\varepsilon$ three-dimensional turbulence model and N-S equation, considers airflow with room shape and obstacles as one, calculates the indoor airflow and heat transfer problems with overall solution, studies indoor air form especially velocity field with numerical simulation. From the numerical simulation results, we can know that the layout of the school dormitory and air supply mode is appropriate, the air velocity and other parameters meet the relevant standards, and conducive to obtain comfortable indoor thermal environment. The results prove that $\kappa-\varepsilon$ three-dimensional turbulence model is suitable for calculating indoor airflow field, and can be used in other air-conditioned rooms with different structure in winter.

INTRODUCTION

Computational fluid dynamics, shortened as CFD, is a new subject which appears with the popularization of computer science. According to reasonable boundary conditions and parameters provided, it can apply the basic theories of hydrokinetics to build mathematical physical models to carry out analog computation of the air stream's velocity field, temperature field, pressure field, etc in the air conditioned area. And the room air's velocity field and temperature field is the basis for the design of the air-flow organization in the air conditioned room and the basis for the evaluation of the room pleasantness.

At present, domestic researchers mainly focus the room air research on the numerical simulation of the air conditioners' refrigeration in summer, but in this paper I will take the teachers and staff's dormitories in one university in Chongqing as a model to make a numerical simulation of the air flow in a room heated by air conditioner in winter. By using $\kappa-\varepsilon$ three-dimensional turbulent air stream model and N-S mathematical equation, this paper took overall approach to compute the problem of air flow and heat transfer in air conditioned rooms, it also made a numerical simulation of the air stream esp. the velocity field, considering the inlet air stream, room shape and obstacles as a whole.

At present, the approaches for the room air flow distribution fall into three groups: I. To make use of the jet flow theory to make analysis and prediction; II. To make use of similarity principle to make model experiment; III. To make use of the numerical prediction approach by solving room air control equations set with computer. The first approach is rarely used due to its limitations. As for the second approach, a great number of material resources, financial resources and labor were wasted. And in many cases, we have certain difficulties in measurement techniques, like the measurement of the direction of the low speed air stream and the measurement of overflow. With the development of computer and computing techniques, the numerical prediction approach grows rapidly.

This paper takes the room air flow in winter of the teachers and staff's dormitories in one university in Chongqing as the object of study. On considering the dormitory's outside temperature (in accordance with its location), its exterior protected construction and its heat engineering performance, the refrigeration of the air conditioning system, the heat dissipating capacity of the indoor personnel, etc., we make the numerical simulation of the room air flow.

MODEL STRUCTURE

On considering the practical situation of the dormitory, to build a dormitory model which is 5.2 meters long, 3.2 meters wide and 3.2 meters high. As the planar construction diagram in Diagram 1 shows, in the dormitory there are some obstacles like a desk (which is 1.2meters long, 0.5meter wide and 1 meter high) and a bed (which is 2meters long, 0.9meter wide and 0.5meter high), and personnel as well (only considering the influence of the personnel's heat dissipating capacity on the air conditioners' refrigeration duty.

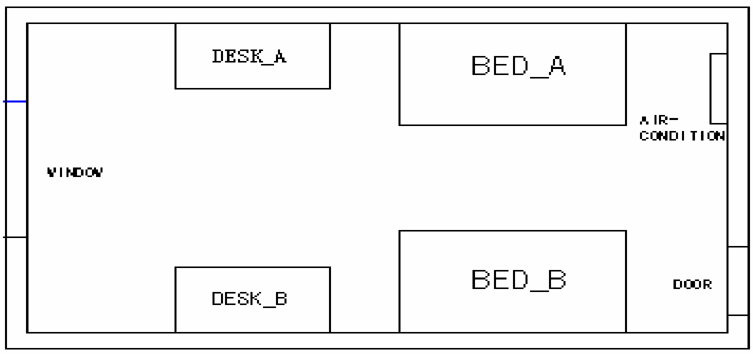

Figure 1. Plane chart of the dormitory

MATHEMATICAL MODEL IN THE TURBULENT REGION

At present, two turbulent analogue approaches are used in the computational fluid dynamics circle: one is Direct Numerical Simulation (DNS); the other is the approach of overflow flattening. Since the scale of the turbulent flow is 0.1μm and because of its important particulars, extremely thin grid spacing is needed for numerical solving, which is beyond the capacity of the present computer's memory and CPU. In regard to engineering problems, what we should concern is not the overflow's fine structure and its transient variation, but the related mean value of its extraneous variables, so overflow flattening and a series of overflow models are widely used in engineering. In the field of heating and ventilation, $\kappa-\varepsilon$ model is popular.

The turbulence partial differential equations describing the model room are as follows:

Continuous Equation

$$\frac{\partial \rho}{\partial t}+\frac{\partial(\rho u_j)}{\partial x_j}=0\,, \qquad (1)$$

Momentum equation

$$\frac{\partial(\rho u_i)}{\partial t}+\frac{\partial(\rho u_j u_i)}{\partial x_j}=\frac{\partial}{\partial x_j}\left(\mu\frac{\partial u_i}{\partial x_j}-\rho\overline{u'_j u'_i}\right)-\frac{\partial p}{\partial x_i}+\frac{\partial}{\partial x_i}\left(\mu\frac{\partial u_j}{\partial x_i}\right)+\rho g_i\,, \qquad (2)$$

Energy equation

$$\frac{\partial(\rho h)}{\partial t}+\frac{\partial(\rho u_j h)}{\partial x_j}=\frac{\partial}{\partial x_j}\left(\frac{\mu_t}{\sigma_k}\frac{\partial h}{\partial x_j}-\rho\overline{u'_j h'}\right)_i, \qquad (3)$$

Component equation

$$\frac{\partial(\rho m_l)}{\partial t}+\frac{\partial(\rho u_j m_l)}{\partial x_j}=\frac{\partial}{\partial x_j}\left(\frac{\mu_t}{\sigma_l}\frac{\partial m_l}{\partial x_j}-\rho\overline{u'_j m'_l}\right)+S_i\,, \qquad (4)$$

There are three more transients in the turbulence models above than in the layer equations- Reynolds Stress $\rho\overline{u'_j u'_i}$, Reynolds substance flow $\rho\overline{u'_j h'}$ and Reynolds heat flow $\rho\overline{u'_j m'_l}$, which are all unknown items. Thus, different approaches to these transients lead to different models.

The modeling is that three transients above are presented by time averaged value. Then, according to Boussinesq's theory as well as with reference to the methods of laminar flow, the three transients are presented to time averaged grads function:

$$-\rho\overline{u'_j u'_i}=\mu_t\left(\frac{\partial u_j}{\partial x_i}+\frac{\partial u_i}{\partial x_j}\right)-\frac{2}{3}\rho k\delta\,, \qquad (5)$$

With the molecular transport process compared, we can know that the eddy impulse kinetic energy "k" and the length of turbulence "l" have an important impact on the turbulence transporting course. Afterward, by using algebraic or experiential formula and the way of linking k, l and the known quantity, we can make sure of μ_t At last, the turbulence viscosity coefficient models can be classified into such types as zero equation model, one equation model and double equation model in terms of the number of the differential equations which need to be solved.
The modeled equation k:

$$\frac{\partial(\rho k)}{\partial t}+\frac{\partial(\rho u_j k)}{\partial x_j}=\frac{\partial}{\partial x_j}\left(\frac{\mu_t}{\sigma_k}\frac{\partial k}{\partial x_j}\right)+\mu_t\left(\frac{\partial u_i}{\partial x_j}+\frac{\partial u_j}{\partial x_i}\right)\left(\frac{\partial u_i}{\partial x_j}\right)+\beta g_i\Gamma_T\frac{\partial T}{\partial x_i}-\rho\varepsilon\,, \qquad (6)$$

The modeled equation ε:

$$\frac{\partial(\rho\varepsilon)}{\partial t}+\frac{\partial(\rho u_j\varepsilon)}{\partial x_j}=\frac{\partial}{\partial x_j}\left(\frac{\mu_t}{\sigma_\varepsilon}\frac{\partial\varepsilon}{\partial x_j}\right)+\frac{\varepsilon}{k}\left(c_{\varepsilon 1}\mu_t\left(\frac{\partial u_i}{\partial x_j}+\frac{\partial u_j}{\partial x_i}\right)\left(\frac{\partial u_i}{\partial x_j}\right)-c_{\varepsilon 2}\rho\varepsilon\right), \qquad (7)$$

A set of close equations is composed of the current-sharing control equations, the modeled equations of k and ε, and the definition formula of the model equation (5) of the turbulence transporting flux.

As a result, in the turbulence zone simulation of this research, the velocity field of the turbulence zone has been worked out by iteratively computing every grid with an implicit differential method.

BOUNDARY CONDITIONS

Solid walls, windows and doors are boundary conditions for the dormitory flow field. The prototype of the dormitory is one of the central rooms in the fifth floor of a dormitory building. Its door towards the corridor is set to be closed while the windows is also closed, which do not obstruct the airflow though some leakage from the doors and windows. Due to the Chongqing's cold winter, the temperature of the walls is set up to 6 ℃ Otherwise, there's no fluid infiltration and friction on the wall surface, no heat transfer and airflow through the desk which would obstruct the indoor airflow. Suppose there are two people inside with an average heat release of 80W each (the indoor air computing temperature assumed to be 10 ℃.) Two boundary layers are considered in this simulation computation: One is outlet boundary layer, the other is wall boundary layer.

Outlet Model

The combination of the air supply and the indoor air is usually realized by outlet air jet for the purpose of air-condition and ventilation in the air-conditioned rooms.

Because of the complex actual geometry of the outlet and various types, we must carve it up into mm grids if we want to know the details of these parameters of outlet air supply, which is doomed to cause a huge number of grid nodes in the calculating region and slow computing, unable to be accepted by project applications.

Therefore, a way of model simplification is used to take the average speed. A 1.2m×0.6m inlet replaces the rectangular outlet, 2.3m above the ground, in the direction of 45° oblique. Then, compute the temperature of air supply according to the criteria for air-conditioning and the amount of air supply according to the indoor ventilation area and the number of the indoor people. It's computed that the temperature is 25 ℃ and the outlet airflow velocity is 0.5m/s (the air supply meeting the minimum requires computed).

Wall Boundary Layer

Generally speaking, there are two ways to deal with the wall boundary layer: one is applying the model of the turbulence core to the boundary layer; the other is to establish the wall boundary layer, which is dealt with separately from the core area. However, there are two preconditions for the former way- first, the model of the turbulence core must be applied to the descriptive boundary layer; second, the boundary layer should be divided into more detailed grids to ensure the accuracy of simulation-which will inevitably increase the number of nodes, the consumption of RAM memory and the CPU workload. Accordingly, the latter way is adopted here.

In terms of Launder's and Spalding's theories, the boundary layer is classified as viscous bottom and the logarithmic law layer and the mathematical model of the descriptive boundary layer is as follows:

$$U^* = \frac{1}{C}\ln\left(Ey^*\right) \qquad y^* > 11.225 \qquad U^* = y^* \qquad U^* > 11.225$$

$$U^* = \frac{U_P C_\mu^{1/4} K_\rho^{1/2}}{\tau_\varpi / \rho} \qquad y^* = \frac{\rho C_\mu^{1/4} K_\rho^{1/2} Y_\rho}{\mu}$$

C_k —Karman constant, value: 0.42;

E —empirical value, value: 9.81;

U_P —velocity of grid point;

K_P —turbulent kinetic energy of grid point;

Y_P —distant from grid point to wall;

μ —viscosity coefficient of turbulence flow

GRID DIVISION

The established mathematical models are divided into grids and the grids have been refined in the computation region with great velocity gradient airflow. In the computation, first use the sparse grids and go on refinements. Since the difference between the computed results when the flow field to be computed is divided into 66×57×20 grids (indicated as Figure 2) and the results of the formerly used grids may be ignored by careful comparison, the entire flow field of the dormitory for simulation computation should be divided into 75240 grids finally.

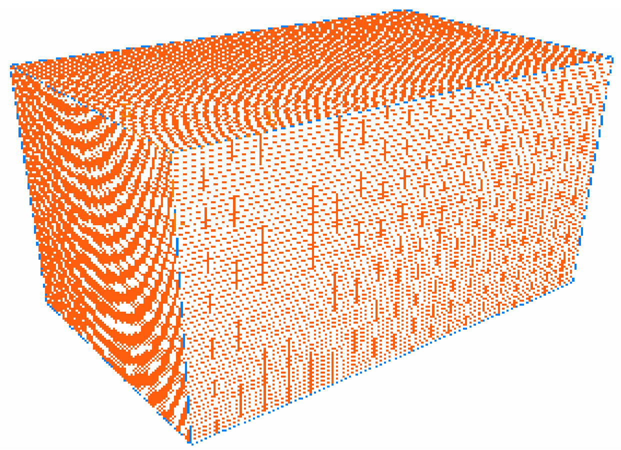

Figure 2. Gird division map of the dormitory model surface

NUMERICAL SIMULATION RESULTS

Making use of the previous mathematic and physical models, through the simulation computation of this dormitory, the organization form of the flow field and parameters such as airflow velocity inside the dormitory, etc. have been obtained(indicated as following figures). Figure 3 is the velocity vectorgraph in the XY direction 0.6 m above the ground-the body position above the ground when students sleep; Figure 4 is the velocity vectorgraph in the XY direction 2.4 m above the ground-the position of the air-conditioner;

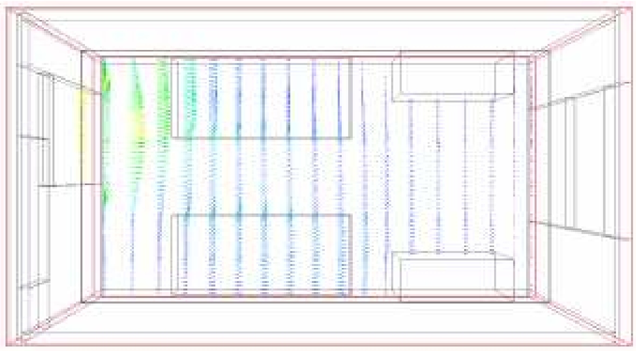

Figure 3. Velocity vectorgraph in the XY direction 0.6 m above the ground

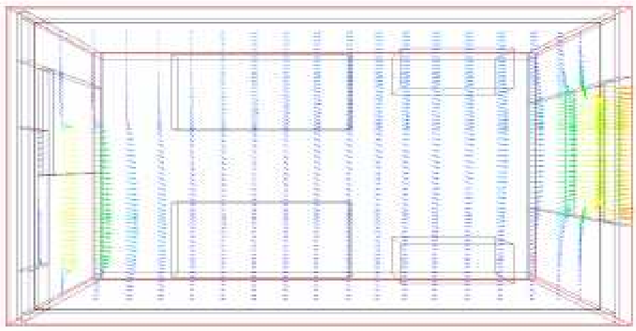

Figure 4. Velocity vectorgraph in the XY direction 2.4 m above the ground

Figure 5 is the velocity vector profile in the XZ direction above Bed A, Figure 6 is the velocity vector profile in the XZ direction above Bed B;

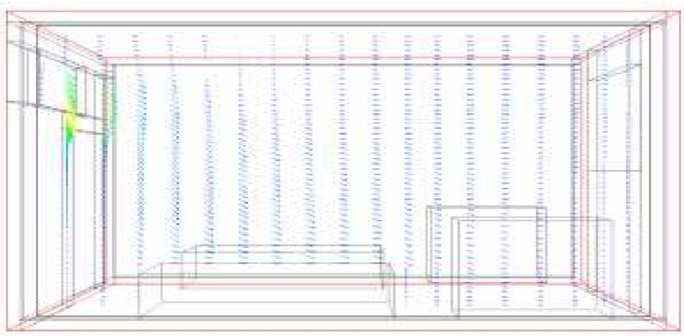

Figure 5. Velocity vector profile in the XZ direction above Bed A

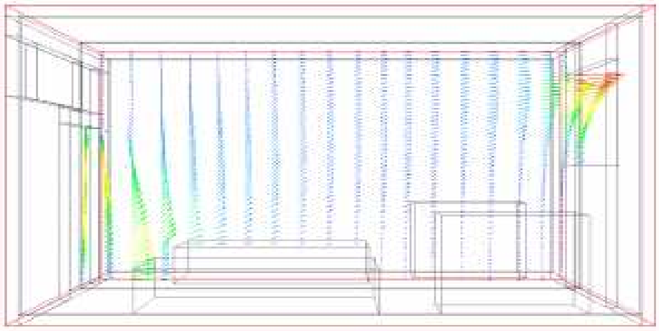

Figure 6. Velocity vector profile in the XZ direction above Bed B

Figure 7 is the flow field profile in the YZ direction between two desks-the centralized area for students' activities inside the dormitory.

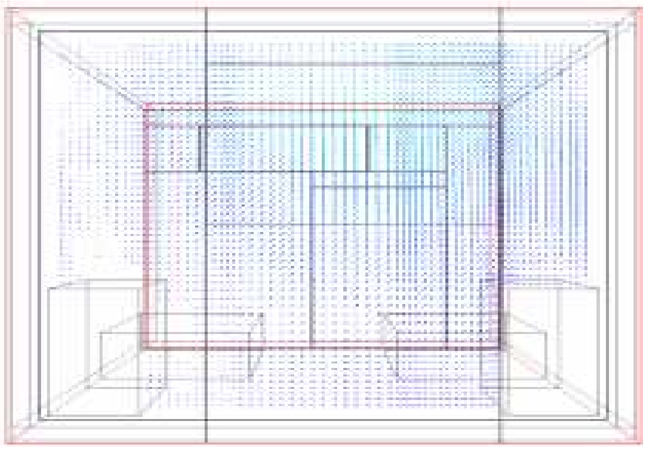

Figure 7. Flow field profile in the YZ direction between two desks

CONCLUSIONS AND ANALYSIS

Shown as above figures, the airflow velocity of the entire dormitory is below 0.175m/s(less than 0.3m/s), which meets the requirements of a comfortable air-conditioned room in winter. So the airflow organization form is reasonable for it's helpful to indoor air pollutant emissions. In addition, the way of air supply adopted inside the dorm is quite appropriate and the airflow velocity meets the relevant standards for ventilation and air-conditioning, in favor of obtaining a comfortable indoor thermal environment. Consequently, the current living conditions can satisfy the majority of college students in Chongqing area.

Besides, this numerical simulation results can be references to other indoor airflow studies of similar structures. Thus, I will keep studying those problems further such as the temperature field of the room, the pressure field and human body thermal amenity, etc. in the future.

Climatic Adaptation: Impacts On The Thermal Comfort Of Offices Buildings At Curitiba - Brazil.

Antonio Augusto P. Xavier and Ivan Azevedo Cardoso

Technological Federal University of Parana – UTFPR – Curitiba – Brazil

Corresponding email: ivanac@utfpr.edu.br

SUMMARY

Concerns about energy efficiency, has brought new constructive trends researches. Aspects as environmental comfort is quite important, with regard to new constructive technologies, showing the need of standardizing Brazilian buildings to acquire thermal comfort. The necessity of new internal environment data in buildings has motivated surveys about it. The proposal is to present the constructive typologies of buildings and their indoor variables in Curitiba city, Parana state, South of Brazil, relating it to the Bioclimatic Chart, proposed by Givoni [1], for countries in development. This work analyzed the constructive characteristics of 39 commercial buildings and environmental variables measured in internal environment of each one. The data was separated in winter and summer being inserted in the Bioclimatic Chart equivalent to Curitiba climate. That way it has verified that constructive typologies were more suitable for the region.

INTRODUCTION

The use of new materials and technology as a way to identify enterprises of great value went beyond the good sense necessary for building new constructions. With the massive use of lighting and air conditioner equipments, the consumption of electric energy took a great deal of proportion aggravating the problem of energy supply.

Especially from the decade 1970 and with the population increase on the decade 1980 and more recently in 2001 with de problem called "a black out", the energetic situation in the country has been receiving especial attention. Due to such preoccupation, new constructive tendencies have arisen, and aspects as energetic efficiency and ambient comfort have become of extreme relevance concerning to the new constructive technologies, showing the need of bringing the construction of new buildings back to normal taking into consideration concepts as energetic efficiency hitched to the thermal comfort. This way, the need of new data and parameters about ambient conditions in constructions motivated the production of works all over Brazil.

In order to study the thermal comfort evaluation methodologies of constructions several works have been developed. According to Neto [2], the proposal norm structure is quite wide-ranging and seek not to shut the procedures for building national character regulations or yet specific regulations for States and/or regions. Janda, Katryn and Busch [3] carried out some information about sixty countries with the purpose of getting the experience obtained in normalization of many countries focusing areas where the results can be applied and developed in an effective form.

Seeking for solutions energetically efficient, it started for adopting passive measures in order to get human comfort, that is, measures which do not involve energetic wasting for it.

For this checking, it must take into consideration the local where the buildings are found, that is, its climatic region. According to Goulart [4] the climate in Curitiba, which is considered as sub-tropical, presents a unique characteristic in Brazil being the coldest capital of all, making people feel some discomfort in more than 80% of hours of the year, from the thermal point of view, mainly for cold weather.

A lot of field study was fulfilled, such as Nicol [5] and Humphreys [6], with the purpose of seeking an adaptable model of thermal comfort, based on the use of monthly average external temperature as a new parameter of comfort. The use of international parameters adapted to Brazilian regions, can reflect on a wrong way the real condition of thermal comfort.

Other studies were fulfilled taking into consideration thermal ambient conditions and bioclimatic analysis through predicted equations Xavier [7], Kruguer[8] and also the studies of energetic thermal simulation program by Ghisi and Lamberts [9].

The present study insert itself in a wider work developed in 8 Brazilian cities with the purpose of studying and carrying out some information about office buildings placed in different regions of Brazil. Some information were collected through field study regarding office building placed in Curitiba city to get thermal energetic parameters linked to the local climate, providing, consequently, alternative for a better climatic adequacy for such buildings. Through the obtaining information concerning to the constructive type predominant in office buildings in the city we have defined a typed classification for the entire constructions surveyed. It has been also studied the energetic thermal performance of the surveyed constructions, being in possession of information concerning to temperature and humidity and of each type, through measurement made with the help of equipments designed to this task.

METHODS

For the obtaining information relating to office buildings type present in Curitiba, 841 constructions with more than 5 floors were surveyed, condition imposed for the fulfillment of a survey in buildings with elevator. To carry out architectural characteristics, responsible for the type formation, some visiting were given in 39 buildings, which of them were grouped in 21 different types, considering 5 variable architectural. For experimental limitations in a second step, it was considered only 3 architectural characteristics to the bioclimatic study of types. As a result of the steps 6 typologies were considered, which ones were compounded throughout the combination among the characteristics relating to the building height, the external shading presents and the window area versus front area.

After separating the buildings in type groups, it was possible to carry out some information concerning to occupation standard of each office presents in each building representing one of the 6 typologies drew up. That way, it has been studied the activities performed in each building and it has got the relation of representative buildings in each one. For carrying out the thermal-ambient information, it was surveyed 6 representative buildings from the specific typologies. In each building it was installed equipments type HOBO H8 Family, to measure temperature and humidity in offices of a larger representative. Together with this equipment it has been used the software BoxCar Pro 4.0. The measurements were made considering the proximity with the winter and summer solstice. It has been applied a questionnaire to people who occupy the offices for them to give their opinion regard to the comfort condition.

After the measurement, it has been organized reports containing information relating to temperature changing and internal humidity of each office. Together with the external climatic information, it was made comparative tables of the internal thermal changing of the offices front to external thermal changing.

With the use of software AnalysisBio developed by Energetic Efficiency Lab in Constructions at Santa Catarina Federal University – LABEEE/UFSC, it has been made Psychometric charts, containing the bioclimatic zones proposed by Givoni [1]. Thus, such charts made possible the analysis relating to the thermal ambient performance of the buildings analyzed. This performance aims the thermal comfort with the minimum energetic consumption. Having such information made it possible to analyze the building performances in the summer and the winter months.

RESULTS AND DISCUSSIONS

The table 1 shows the representative architectural characteristics present in constructions analyzed. For the study of thermal performance it has been considered combination types of characteristics represented itself.

Table 1- Architectural Characteristics Representative

TYPES	Nº BUILDINGS	REPRESENTATIVITY
Tall building	20	51,3%
Low building	19	48,7%
With external shading	14	35,9%
No external shading	25	64,1%
PWF > 50%	25	64,1%
PWF < 50%	14	35,9%

The table 2 presents the 6 typologies considered on the energetic thermal study. The separation of typologies took into consideration the height of buildings, the presence of external shading and percentage of window for front (PWF).

Table 2 – Type Considered At Thermal Energetic Analysis

TYPOLOGY	HEIGHT	SHADING PRESENCE	PWF
1	Tall	With shading	> 50%
2	Tall	No shading	> 50%
3	Tall	No shading	< 50%
4	Low	With shading	< 50%
5	Low	No shading	> 50%
6	Low	No shading	< 50%

By the thermal ambient analysis in the summer the information reveal that, in all the typologies the results were inside the called comfort zone defined by Givoni [9]. The bioclimatic study based itself on the analysis of proposed alternative at the bioclimatic chart made through the help of software AnalysisBio.

The figure 1, presents the Bioclimatic Chart proposed by Givoni, it has already duly adequated for Curitiba City, where the rented points represent 8640 hours of the year allocated on itself. The climatic file of Curitiba used was TRY, determined for Curitiba by researchers of LabEEE [4], [10]. From these results it can be hoped that, part of the information placed itself inside the comfort zone (20,9%), some of them placed themselves into the hot region 2 and 11 (5,9%) and the rest of the points will fall down in 7,8 and 9 zones in need of some kind of heating.

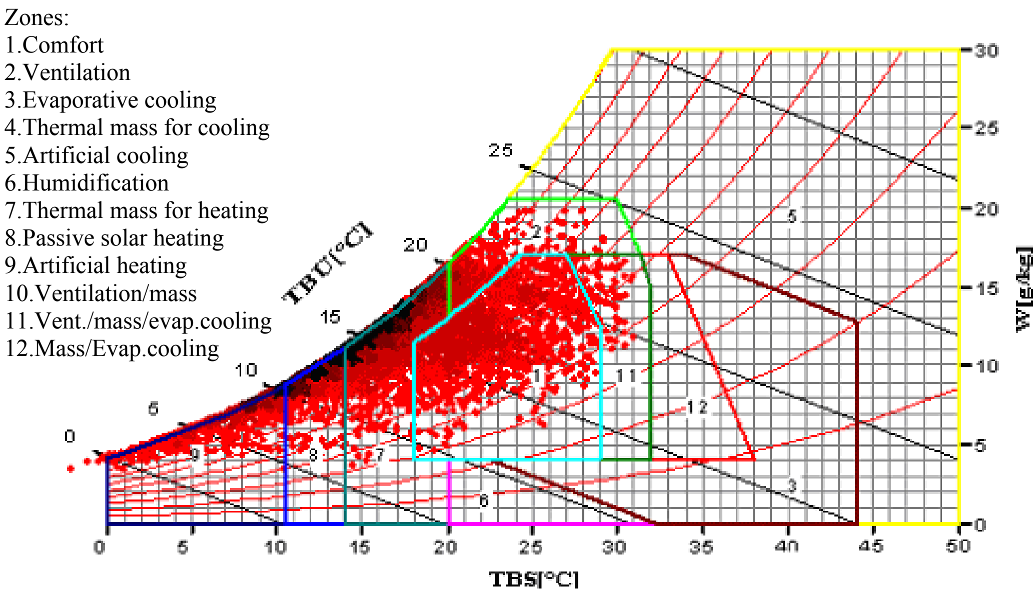

Figure 1 – Psychometric Chart for the reference year of Curitiba City.

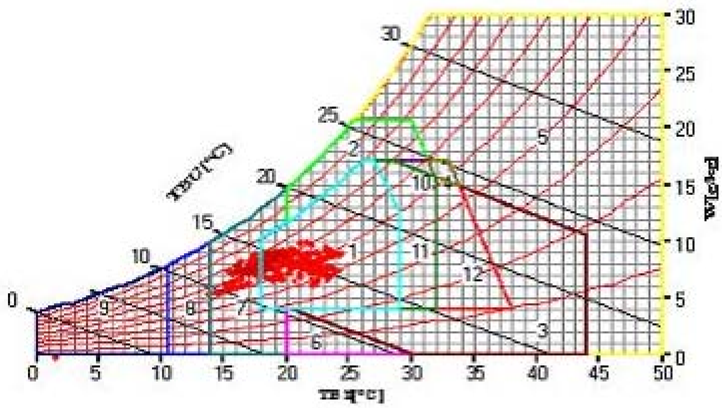

Figure 2a – Psychometric chart of type 3. Winter measurements.

The figures 2a, b e c show the bioclimatic results plotted on the psychrometric charts from 3 of the analyzed typologies. For making these charts it has been considered the temperature and humidity inside the whole offices places in this typology and it has been obtained the average of such measurements totaling 460 points. It has been plotted the information of typologies 3, 5 and 6 during the winter. For the summer almost all the interior points of the offices placed on the comfort zone.

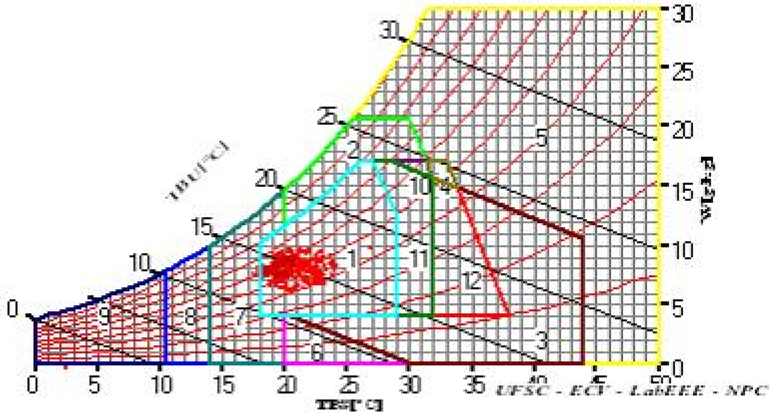

Figure 2b – Psychometric chart of typology 5. Winter measurements

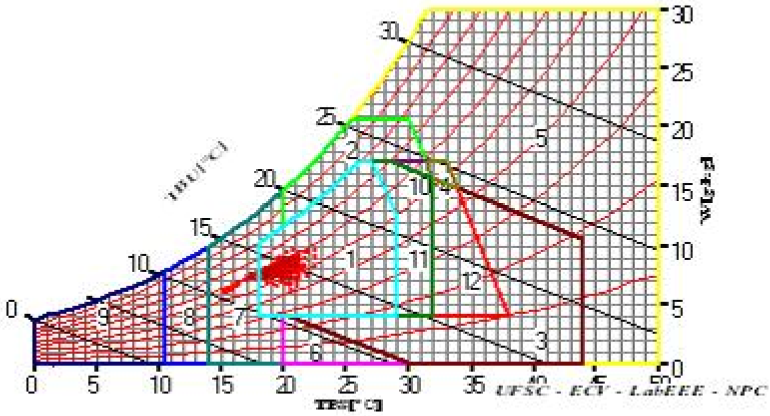

Figure 2c – Psychometric chart of type 6. Winter measurements.

Analyzing the office thermal-ambient (see table 3), is has been concluded that, the typology 3 which has the following characteristics, tall building, no shading and with less than 50% of PWF, revealed the worst thermal performance in the winter days. And the typology 6 (low building, no shading, with less than 50% of window area by front area),revealed have the worst thermal performance relating to the summer days, obtaining an average temperature of 25,9^{o}C. But the typology 5 (low building, no shading, with more than 50% of window area versus front area) which one it had been hoped to have the worst result during the summer, due to its architectural characteristics, it has obtained 100% of the information inside the comfort zone in the summer and 96,8% in the winter.

Table 3 – Typologies thermal Performance.

TYPOLOGY	SUMMER			WINTER		
	T_{med}	Humidity	Comfort	T_{med}	Humidity	Comfort
1	24,0	60,1 %	100%	19,0	59,8	84,9%
2	24,9	59,7 %	100%	19,3	57,8	91,0%
3	24,0	55,1 %	100%	18,9	57,2	60,9%
4	25,5	59,8 %	99,6%	19,8	58,6	91,6%
5	25,8	56,1 %	100%	20,4	55,3	96,8%
6	25,9	57,2 %	98,4%	19,3	55,2	82,4%

The figures 3a, b, c and d present the results of internal temperature variation comparing to external ambient temperatures, in the winter of 3 typologies during 15 days. Still analyzing the typology 3, it can be observed through graphs that its performance relating to great thermal variations showed itself relatively unwanted, because its thermal structure showed itself unable to absorb such variations in a satisfied way, showing a bad working of the envelope and its architectural characteristics. The typology 6 had a better performance and the 5 still better because even with colder external temperatures it has obtained 96,8% of the information inside the comfort zone. On the figure 3 it has been plotted together with the curve of the 3 typologies and the temperature of the external ambient in the winter. It has been seen that the typology 5 has obtained the major temperatures keeping the ambient always on the comfort zone; the temperatures of typology 3 has been the one that more accompanied the variation of external ambient.

It can be observed through the questionnaire that, relating to the climatic conditions in the offices analyzed, the thermal feelings of the people inside the offices it has driven to a less wide ranging comfort band, being considered discomfort condition, temperature variation less than the stipulated limits on the bioclimatic comfort zone proposed by Givoni [1].

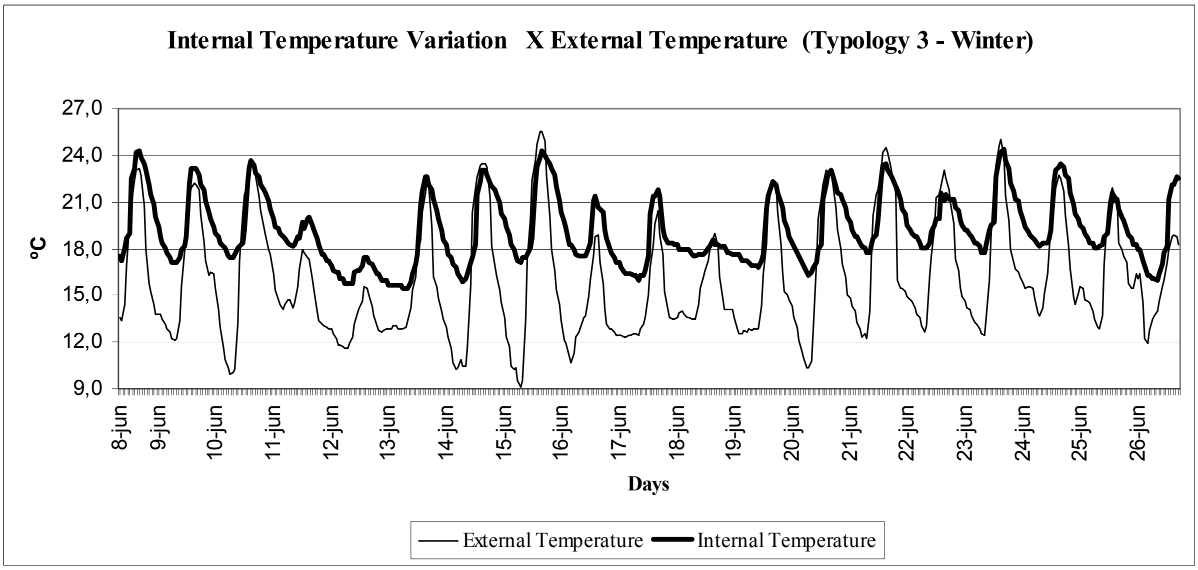

Figure 3a: Internal temperature comparison front of external temperature variation relating to typology 3 (Winter).

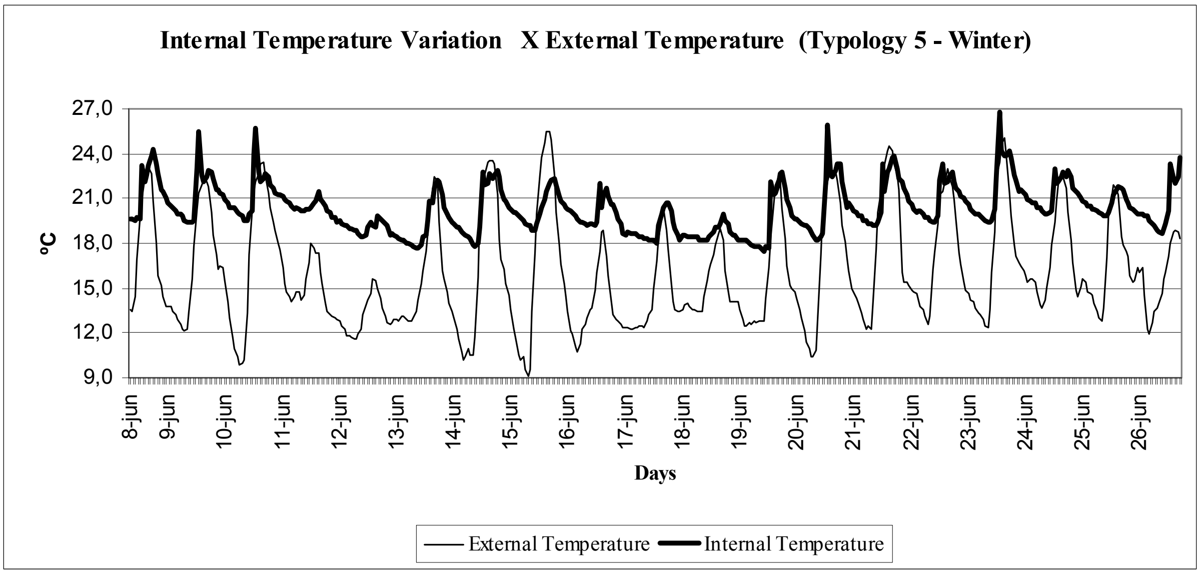

Figure 3b: Internal temperature comparison front of external temperature variation relating to typology 5 (Winter).

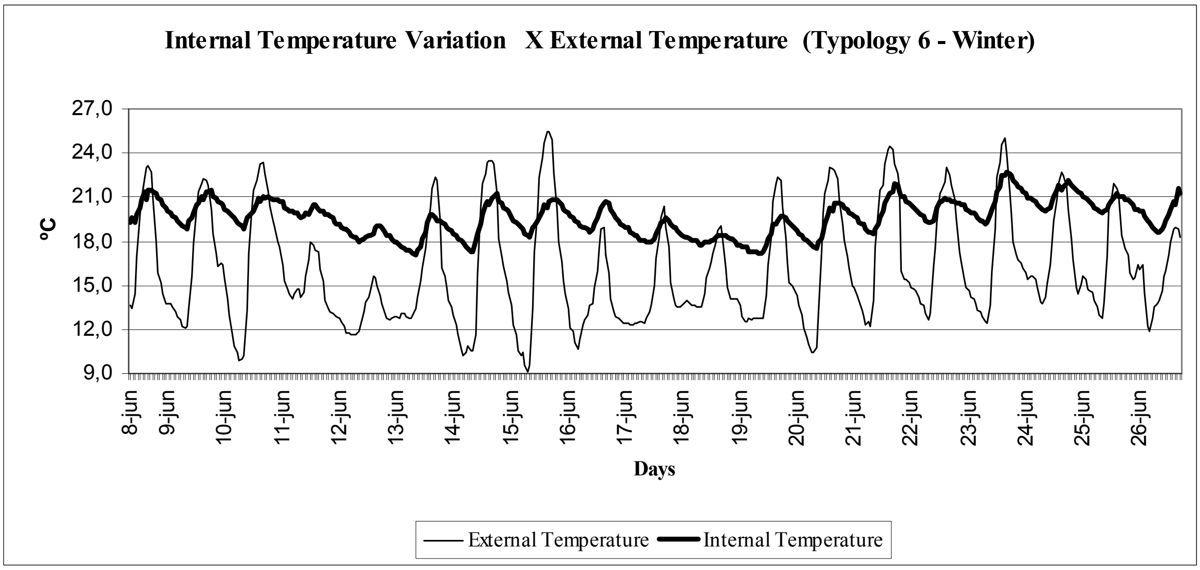

Figure 3c: Internal temperature comparison front of external temperature variation relating to typology 6 (Winter).

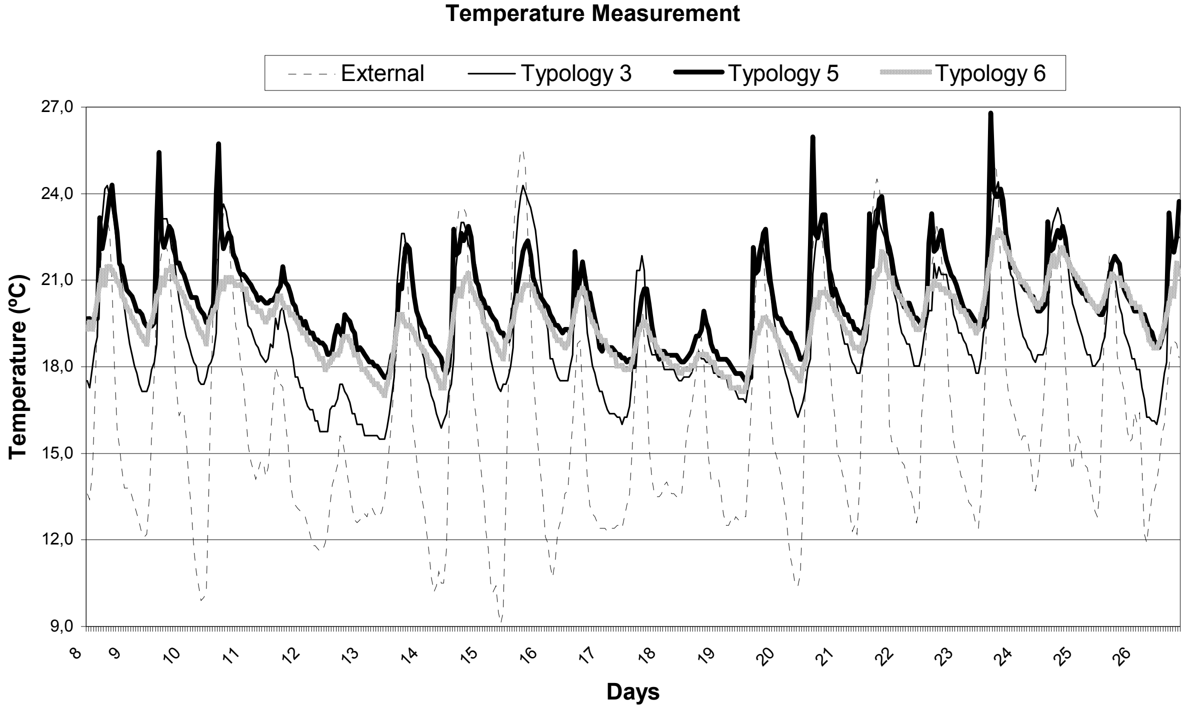

Figure 3d: Internal temperature comparison front of external temperature variation relating to typologies: 3, 5, 6 (Winter).

CONCLUSIONS

The present work has been consisted on carrying out 39 buildings representing a total of 841, placed in Curitiba city, thermal-ambient analysis measured in 6 buildings and to carry out the used standard of such ones.

It has been concluded that the discomfort climatic conditions, for Curitiba city, are predominantly caused for cold weather, as it was hoped. During the winter it was obtained better results for the typology 5 (low building, no external shading and with the percentage of window for front larger than 50%, having almost all the information placed inside the comfort zone. During the summer the comfort conditions of the various typologies were alike.

It must be still considered the difficulties found on the survey development. With the methodology used based on field analysis, the information collect was subjected to a several limitations. Such limitations have involved difficulties on the information collect and the lack of reasonable time for studying and analyzing of the software used in this survey.

This way, due to a temporal limitation to what the present work was subjected, we have suggested a large information collect to take into account some more typology considerations, such as kind of glass and window open, color and the front guidelines. It has been also recommended to make computerized study using a simulations analysis program.

Thermal Comfort Requirements in Iranian Hospitals

Jamal Khodakarami[1], Ian Knight[2]

[1]Cardiff University, Cardiff/ Ilam University, Iran
[2]Cardiff University, Cardiff

Corresponding email: KhodakaramiJ@cardiff.ac.uk

SUMMARY

This paper presents the results of a study to determine the thermal comfort requirements of the occupants in Iranian hospitals. It arrives at its conclusions through consideration of the wide range of metabolic rates and clothing levels experienced by the occupants. The study includes both patients and staff, and only considers patient recovery wards as these are where the greatest range of thermal comfort needs will normally be found. This study uses ISO 7730 as its basis, with reference also to ASHRAE 55 and CIBSE. The main conclusion from this study is that while the occupants of Iranian hospitals can require widely varying thermal conditions to achieve thermal comfort, it is possible to reconcile these different needs.

INTRODUCTION

The term comfort is associated with human health – defined not just as the absence of disease but in terms of a total sense of physical, mental and social well-being [1]. Comparing the comfort levels of sedentary people at home, at work and in a climate chamber, shows that being ‘at home’, in a familiar and under control environment, leads to comfort and makes people less sensitive to temperature [2].
There are two main approaches in thermal comfort standards: The laboratory based method, e.g. Fanger’s PMV-PPD model [3] and the field study method, e.g. the Adaptive Comfort Standard or ACS are the main approaches to thermal comfort researches.

In 1970 through his own equation, Fanger argued that knowledge of thermal comfort conditions was inadequate for environmental engineers involved in the specification of heating, cooling or ventilation technologies and indoor climates [3]. The Predicted Mean Vote (PMV) developed by Fanger provides a method by which the quality of indoor environments can be rated in practice and the degree of occupant discomfort assessed. The presented model by Fanger being used to define the combined conditions (i.e. air temperature, mean radiant temperature, relative air velocity and humidity level) in which the highest proportion of people are likely to be comfortable, for any specified level of activity and clothing [3]. Some international thermal standards such as ISO 7730 [4], still are using the Fanger’s model as the main framework their publication.

Against the laboratory model, other researches aim to account for variations in thermal comfort conditions and perceptions within buildings. Field studies challenge the validity of relatively fixed concepts of thermal comfort, such as those based on heat-balance equations. These results have led some researchers to develop more adaptive models that account for multivariate and dynamic human experiences in the real world [5]. One of the first field studies on the comfort of people in their natural habitats has been done on factory workers in the 1930s by Humphreys and Nicol [6].

Some of adaptively approaches field studies recorded significant differences between comfort values based on Fanger's predicted mean vote (PMV) and actual perceptions of comfort in office environments [7], [8]. Differences in the thermal sensation votes recorded of the same group of people -with the same clothing and activity levels [2]. Also Humphreys [9] argues that people are not inert recipients of the environment, but interact with it to optimize their own conditions. The objective for thermal comfort researchers is thus to observe the daily routines, practices and habits of occupants of building to see how they modify and adjust their environments to achieve comfort [9]. Both of laboratory and adaptive methods are represented in the latest edition of ASHRAE's thermal comfort standard [10].

Reviews on the adaptive models show that these models notice wider bands of temperature where the occupants may still sense the comfort zones, but the adaptive models of thermal comfort are more relative to free running systems buildings. Also being in the 'comfort zone' is represented as a threat to worker productivity and organizational efficiency [11], [12]. And, comparison between the static model (PMV) with the adaptive models in thermal comfort show that the PMV model is more accurate in building with HVAC systems and the adaptive models are more relative to buildings with natural ventilation [13]. On the other hand the Iranian regulations for healthcare buildings recommend the air conditioning systems for healthcare buildings, regarding to the hygiene problems and the type of activity and the occupants of these buildings. Based on this argument, this study selected the laboratory method (PMV), to predict the required thermal conditions by the occupants of these buildings.

For the standards used, ASHRAE, CIBSE and Iranian standards indicate the indoor air temperature and relative humidity ranges for thermal comfort achievement. ISO7730 indicates a range for Predicted Mean Vote (PMV) or Predicted Percentage Dissatisfied (PPD) to achieve thermal comfort based on the six variables which define PMV or PPD: air temperature, relative humidity, radiant temperature, clothing and activity levels, and the air velocity [14].

Due to different levels of clothing and activity in patients and hospital staff, these groups require different conditions to achieve thermal comfort [15]. The thermal conditions required to produce thermal comfort are further complicated by the fact that patients with different complaints may be located in the same wards, also a majority of the hospitals' staff always may stay for a while in the thermal conditions provided in patients' rooms, due to their activities; so to achieve the best balance of comfort it is necessary to first establish the conditions needed to achieve thermal comfort for patients and staff in hospital.

This paper presents the findings of an investigation undertaken to ascertain:

- those conditions required for thermal comfort by patients and staff of Iranian hospitals
- Potential solutions to improve thermal comfort achievement in these buildings

The study focuses on the Iranian hospital wards and mainly on the patients' rooms.

METHOD AND ANALYSES

Although generally, all the standards referred to for assessing thermal comfort require the measurement of relative humidity and air temperature but the calculation for ISO7730 also requires clothing and activity levels to be observed and radiant temperature and air velocity to be estimated [16]. Table 1 presents the relevant thermal comfort ranges from the standards.

Table 1: Recommended conditions to achieve thermal comfort

Standard	Recommended thermal condition to achieve thermal comfort
ASHRAE	23 ºC<Temp<26 ºC and 30%<Rh<60
ISO 7730	-0.5<PMV<+0.5, PPD<10% and 30%<Rh<60
CIBSE	22 ºC <Temp<24 ºC and 30%<Rh<60
Iranian Regulation	24 ºC <Temp<28 ºC and 30%<Rh<60

Buildings observation and site visiting have been done in this study to specify the types of occupants and their personal factors including the levels of activity and clothing. This study noticed low levels of activity for patients due to the physical conditions of their bodies. In terms of staff activities the study assumed an average of activities of those staff that are in direct relation with the indoor environment conditions of patients' rooms.

This study beside the environmental and job protocols, noticed high effects of cultural motives on both groups of occupants -particularly the staff- in terms of clothing in Iranian hospitals. This study assumes that the mixture of clothing types for patients without a blanket cover gives a 0.49 clo, for patients with cover 1.39 clo, and for staff 0.88 clo. This study assumes that the average activity rate for patients is 0.82 met, and for staff is 1.50 met.

The analysis in this study has been undertaken to determine the required thermal conditions in Iranian hospitals. From table 1, ASHRAE, CIBSE [17], and the Iranian regulation [18] indicate just the ranges of air temperature and relative humidity likely to achieve thermal comfort. However we know that the different user groups in hospitals are likely to have quite different temperature and RH requirements to achieve thermal comfort. These differences arise due to the variation in activity and clothing levels between more sedentary Patients who may use blankets to increase their insulation levels, Patients who are not able to use heavy clothing such as blankets because of their medical conditions, and Staff who generally have higher levels of activity.

The first issue to address for a study such as this is whether it is possible to find a range of thermal conditions that are suitable for these hospital users. This study uses the PPD calculation from ISO 7730 as the basis for assessing the different ranges of temperature and RH within which Patients and Staff in Iranian hospitals might achieve thermal comfort for the activity and clothing levels stated above. The study assumes 10 %PPD is an acceptable level [4].

The calculations show that, in theory, by varying the RH and air velocities within reasonably achievable values, that the Air Temperatures needed to achieve thermal comfort conditions for Iranian hospital Staff could be in a range between 19ºC to 26ºC; that the range for Patients with blanket could be in a range between 22.5ºC to 28ºC; and that for Patients without blanket the range could be between 27ºC to 31.5ºC.

Figure 1 represents the practical Air Temperature ranges that need to be achieved for each occupant type. We can see therefore that there is NO easily achievable overlap in acceptable Air Temperature ranges between Staff requirements and the requirements of Patients without blankets. The Patients with blankets are capable of being comfortable in a range of air Temperatures that straddle those for both Staff and Patients without blankets. Figure 1 presents, in graphical form, part of the results of the study where we assessed the variation of PPD with Air Temperature, when the air velocities were varied in a range between 0.1 m/s to 5m/s at a constant 40% Relative Humidity.

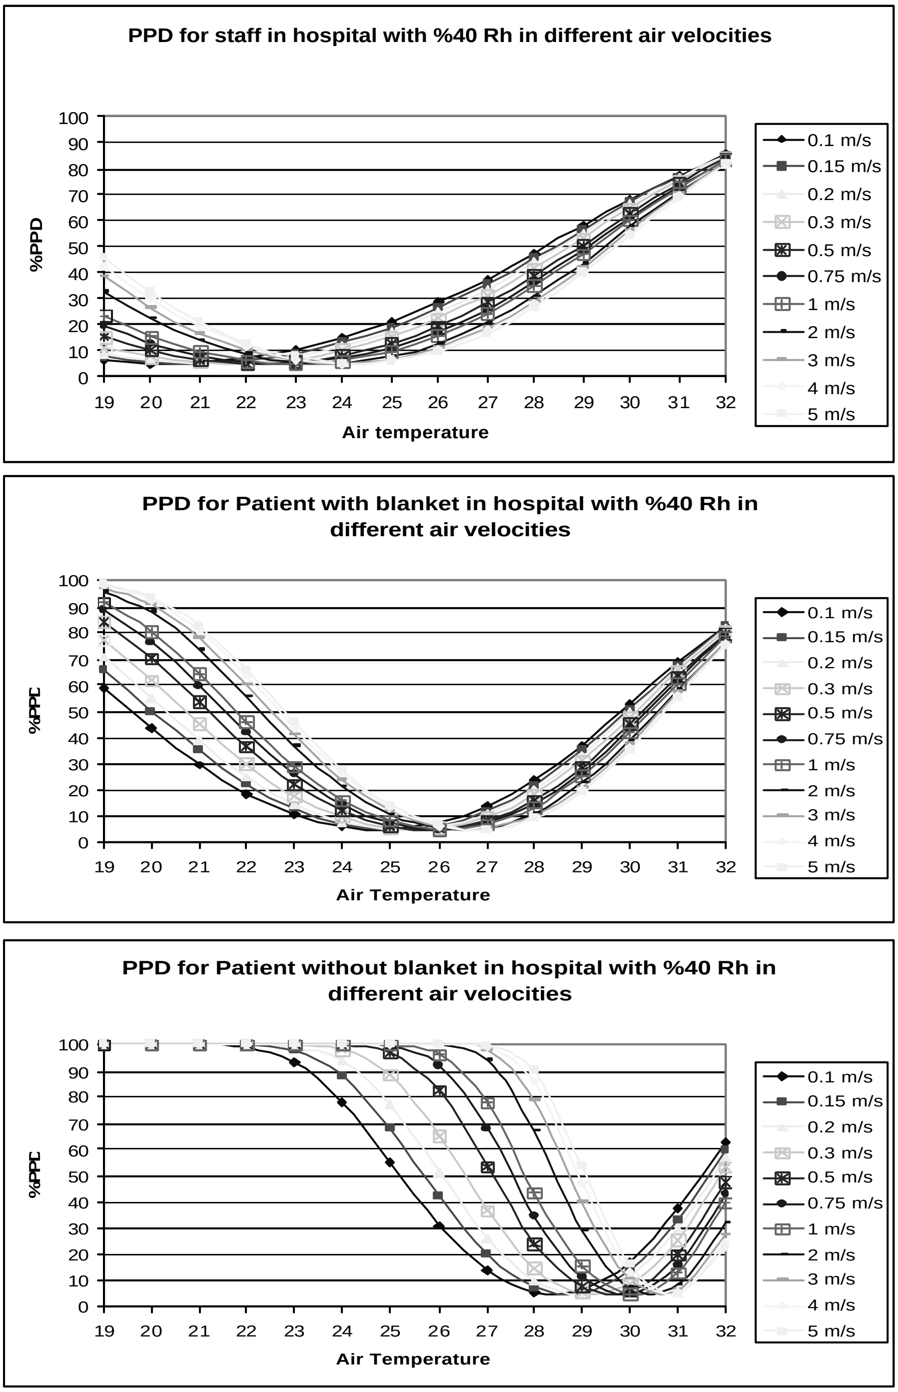

Figure 1: PPD achievements for all users in Iranian hospitals at 40% Relative Humidity with different air velocities.

The study shows that, as expected, higher air velocities extends the upper limit for the temperature range within which occupants can feel comfortable, while lower velocities extend the lower limit for comfortable temperatures. However there appears to be no combination of Air Temperature and Air Velocity which satisfies the comfort requirement of a PPD of less than 10% for both Staff and Patients without blankets. In fact, even if Staff experience a 5m/s air velocity at the same time as Patients with blankets experience an air velocity of <0.1 m/s we see that it is still not possible to achieve an acceptable common Air Temperature that will provide a PPD of less than 10%.

Assuming that Activity and Clothing Insulation levels are not able to be altered due to work and cultural reasons, the only other option left to try to achieve comfort is that of varying the mean radiant temperature experienced in the space by the different users. This could physically take the form of cooler or warmer floors, walls and ceilings in some areas depending on the predominant occupant of that area. Table 2 presents the results of a theoretical study where we assessed the variation of PPD with radiant temperature, when the air temperatures were varied in range between 20 ºC to 28 ºC at a constant 30% to 60% relative humidity and 0.1 m/s to 0.5m/s air velocity.

Table 2: Maximum radiant temperature ranges for hospital users in Iran
(All users assumed to be in conditions of: air temperature from 20ºC to 28ºC, air velocity from 0.1 m/s to 0.5 m/s, and relative humidity from 30% to 60%)

Users	**Maximum radiant temperature range**
Patients with blanket	12.3 ºC to 43.3 ºC
Patients without blanket	25.6 ºC to 50.5 ºC
Staff	-4.7 ºC to 35 ºC

The study shows, that to some extent, higher air temperature ranges can be offset by lower radiant temperature ranges within which all occupants can feel comfortable. It appears that theoretically a range of air temperatures between 20 ºC to 28 ºC can achieve the thermal comfort requirements of staff and patients (with and without blankets) if we were able to separately provide the appropriate radiant temperature for each category of occupant.

However, it is not practical to design spaces to achieve these large radiant temperature requirements. So the next part of the study explores what is more practically achievable. Referring to ISO 7730, the PMV and PPD express warm and cold discomfort for the body as a whole. But thermal dissatisfaction can also be caused by unwanted cooling or heating of one particular part of the body. This is known as local discomfort. The most common cause of local discomfort is draught. Local discomfort can also be caused by an abnormally high vertical temperature difference between the head and ankles, by too warm or too cool a floor, or by too high a radiant temperature asymmetry.

Figure 2 shows the percentage dissatisfied as a function of the floor temperature [4]. It is mainly people undertaking light sedentary activity who are sensitive to local discomfort. These will have a thermal sensation for the whole body close to neutral. At higher levels of activity, people are less thermally sensitive and consequently the risk of local discomfort is lower. This means therefore that the Patients will be more sensitive to radiant heating or cooling than the Staff.

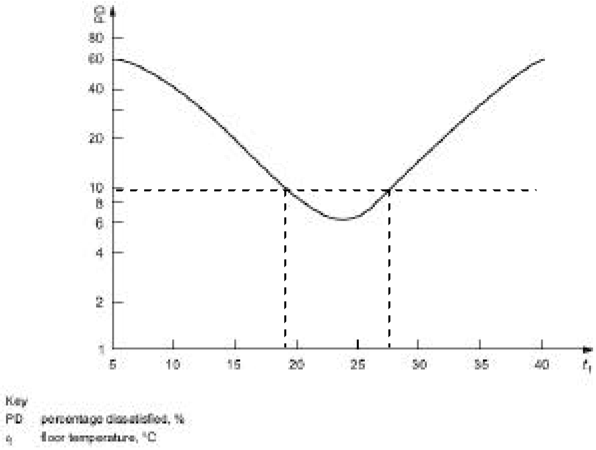

Figure 2: Local thermal discomfort caused by warm or cold floors

For horizontal radiant asymmetry, Figure 3 applies from side-to-side (left/right or right/left) asymmetry, the curves providing a conservative estimate of the discomfort: no other positions of body in relation to the surfaces cause higher asymmetry discomfort [4].

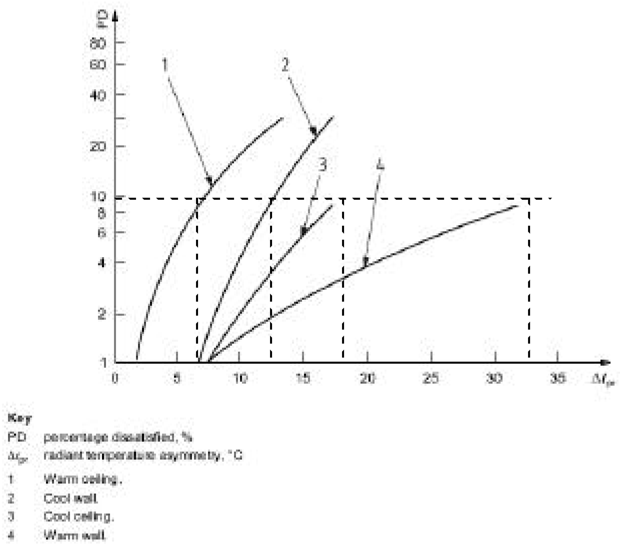

Figure 3: Local thermal discomfort caused by radiant temperature asymmetry

This figure shows that achieving the required radiant temperature via warm walls is likely to be the best way to attain thermal comfort when the air temperature is too cool. When the air temperature is too warm, thermal comfort is best achieved by using a cool ceiling.
When reviewing the foregoing work with regard to the activity, clothing levels and physical locations of staff and patients in hospitals, it can therefore be concluded that it might be possible to achieve thermal comfort for both staff and patients (both with and without blanket) by:

- Providing the additional cooling needed for the Staff via the floor (as this is the surface least visible to the patients)
- By providing the additional radiant heating needed by patients via, ideally warm vertical surfaces, but failing these warm ceilings.

Based on the study shown in Table 2 and the recommendations from ISO 7730 regarding local thermal discomfort (Figure 2 and Figure 3), in condition which the three referred groups of users are placed in separated rooms, the new thermal ranges within which comfort can be achieved for each of the three user groups in Iranian hospitals are as follows:

- Staff: air temperature from 20 ºC to 22 ºC and radiant temperature from 10.9 ºC to 29.3 ºC
- Patient with blanket: air temperature from 22 ºC to 24 ºC and radiant temperature from 20.6 ºC to 34.2 ºC
- Patient without blanket: air temperature from 26 ºC to 28 ºC and radiant temperature from 25.6 ºC to 35.3 ºC

Also by using different directional radiant temperatures (cooling via floor for staff and heating via ceiling for patients), there is now an overlap in the required air temperature to achieve comfort for staff and patients (with and without blanket) from 24 ºC to 26 ºC. By fixing the air temperature from 24 ºC to 26 ºC, and by using the air velocity from 0.1 m/s to 0.19 m/s for all users [4], the following radiant temperatures are required for thermal comfort achievement in Iranian hospitals.

- Staff: directional radiant temperature from the floor from 4.2 ºC to 23.7 ºC
- Patient with blanket: directional radiant temperature from the ceiling from 17.9 ºC to 31.6 ºC
- Patient without blanket: directional radiant temperature from the ceiling from 27.8 ºC to 37.8 ºC

But using directional radiant cooling will drop the temperature to or below dew point in the sources which is used for radiant cooling, then surface condensation will happen [19]. Also forming water in building will lead to mould growth. To minimize the surface condensation in directional radiant cooling, it is necessary to obtain low vapour pressure by ventilation and/or reduced moisture input to the buildings.

The dew point is associated with the relative humidity. A high relative humidity indicates that the dew point is closer to the current air temperature. As the relative humidity reaches 100%, the dew point will be equal to the current temperature. Given constant dew point, when the temperature increases the relative humidity will decrease. It is for this reason that equatorial climates can have low relative humidity yet still feel uncomfortable.

Following equation calculates the dew point in degrees Celsius to within ±0.4 °C. It is valid for:

$0\ °C < T < 100\ °C$

$0.01 < RH < 1.0$

$0\ °C < Td < 50\ °C$

Where:

T= Temperature in degrees Celsius [°C]

RH= Measured relative humidity as a fraction (not percent)

T_d = Calculated dew point temperature [°C]

The dew point temperature is:

$$Td = \frac{b \times \alpha(T, RH)}{a - \alpha(T, RH)} \qquad \{1\}$$

Where

$$\alpha(T, RH) = \frac{a \times T}{b + T} + \ln(RH)$$

With a= 17.27

And b= 237.7 [°C]

The uncertainty in the calculated dew point temperature is ±0.4 °C.

Based on the equation {1} and the highest risk of dew point in this research (26 °C for dry temperature and 60% for relative humidity), the dew point is 17.5°C.
So this research recommends the presented value in Table 3 for Iranian hospital users for thermal comfort achieve.

Table 3: Recommendations from this study- Acceptable parameter ranges for achieving thermal comfort in Iranian hospitals for different occupant types

Users	**Air Tem. °C**	**RH %**	**Air Velocity m/s**	**Radiant Tem. °C**
Staff	24 - 26	30 - 60	0.1 – 0.19	17.5 – 23.7
Patient with blanket	24 - 26	30 - 60	0.1 – 0.19	17.9 – 31.6
Patient without blanket	24 - 26	30 - 60	0.1 – 0.19	27.8 – 37.8

DISCUSSION

The different user groups of the hospital had thermal comfort requirements that were difficult to accommodate in one space. Therefore the best solution would appear to be to provide different thermal zones for different user groups in hospitals. In particular, it appears that staff should be provided with work areas in the wards that are controlled to very different conditions to the general wards.
In same indoor thermal condition, operating different radiance temperature for different users in Iranian hospitals, can reconcile their different thermal comfort achievement requirements.

SUMMARY

The occupants of hospitals like other buildings have widely differing thermal comfort requirements due to their different levels of clothing and metabolism. The study indicated three main groups of occupants in Iranian hospitals as: patients that are able to be covered, patients that are not able to be covered regarding their medical conditions, and staff. This study investigated the thermal comfort calculated to have been achieved for different occupants in Iranian hospitals. The 'thermal comfort achieved' findings have been derived from basic monitoring of those parameters which affect thermal comfort in 14 rooms in 4 separate Iranian hospitals. The thermal comfort results calculated for each room are compared with recommended Iranian and international standards for acceptable thermal comfort. The findings from this study showed a wide range of thermal comfort conditions were achieved in Iranian hospitals, and overall the thermal comfort conditions recorded during the measurement period were felt to be unacceptable.

INTRODUCTION

Thermal comfort can be expressed as "that condition of mind which expresses satisfaction with the thermal environment" [1]. A large volume of thermal comfort research over the last century has been distilled into international standards in terms of designing and maintaining comfortable thermal environments [2].

During this time two main approaches to thermal comfort research have been: the laboratory-based method, e.g. Fanger's PMV-PPD model [3] leading to EN ISO 7730 [1]; and the field-based method (e.g., the Adaptive Comfort Standard or ACS). Both of these methods are represented in the latest edition of ASHRAE's thermal comfort standard [4]. Air temperature, radiant temperature, humidity and air movement as the environmental variables combine with the metabolic heat generated by human activity and clothing worn by a person, to provide the six fundamental factors that define human thermal environments [5].

Hospitals occupants including Patients and staff require different thermal comfort conditions due to their different levels of clothing and activity. Comparing the comfort levels of sedentary people at home, at work and in a climate chamber, shows that being 'at home', in a familiar and under control environment, leads to comfort and makes people less sensitive to temperature [6].

This paper presents the findings of an investigation undertaken to ascertain:

- Current thermal comfort conditions being achieved in Iranian hospitals.
- Potential solutions to improve thermal comfort achievement in these buildings.

The thermal comfort conditions have been ascertained through a combination of monitoring those parameters which effect occupant thermal comfort along with occupant and site observations. The findings from the monitoring are compared with the Iranian 'Health Buildings Design' standard [7] and international thermal comfort standards from ASHRAE, ISO7730 and CIBSE [8].

For the standards used, ASHRAE, CIBSE and Iranian standards indicate the indoor air temperature and relative humidity ranges for thermal comfort achievement. ISO7730 indicates a range for Predicted Mean Vote (PMV) or Predicted Percentage Dissatisfied (PPD) to achieve thermal comfort based on the six factors which define PMV or PPD: air temperature, relative humidity, radiant temperature, clothing and activity levels, and the air velocity [9].

Table 1 presents the relevant thermal comfort ranges from the standards.
The thermal comfort of patients and hospital staff is affected by the thermal conditions provided including air temperature and relative humidity in hospital wards. [10] Due to different levels of clothing and activity in patients and hospital staff, these groups require different conditions to achieve thermal comfort.

Table 1: Recommended conditions to achieve thermal comfort

Standard	**Recommended thermal condition to achieve thermal comfort**
ASHRAE	23 ºC<Temp<26 ºC and 30%<Rh<60
ISO 7730	-0.5<PMV<+0.5, PPD<10% and 30%<Rh<60
CIBSE	22 ºC <Temp<24 ºC and 30%<Rh<60
Iranian Regulation	24 ºC <Temp<28 ºC and 30%<Rh<60

METHODS

All the standards referred to for assessing thermal comfort require the measurement of relative humidity and air temperature. The calculation for ISO7730 also requires clothing and activity levels to be observed and radiant temperature and air velocity to be estimated [5]. Building monitoring with occupant and site observations were used as the method for data collection in this study.

14 patient rooms in 4 hospitals were selected as case studies. To cover the majority of conditions likely to be found in Iranian hospitals the selected healthcare buildings included four different types of activity. The selected rooms in each hospital were also different in other ways, including the orientation, type of patients, dimensions etc.

The case studies consisted of: Two in-patient rooms in a small local clinic; three separate rooms in a private maternity hospital; four separate rooms in a new (prototype) hospital, and five separate rooms in a regional educational hospital. Table 2 presents the details of the monitored hospitals.

Table 2: Monitored hospitals

Case study	activity	No of wards	No of beds	No of active beds	Year of construction	No of monitored rooms
Building No1 TER1 TER2	General	1	7	7	1990	2
Building No2 KR1 KR2 KR3	Maternity	1	32	18	2003	3
Building No3 TR1 TR2 TR3 TR4	General	5	100	32	2002	4
Building No4 IKR1 IKR2 IKR3 IKR4 IKR5	General	11	200	135	1945	5

The temperature and relative humidity data was recorded by calibrated loggers at 10 minute intervals for around two weeks for each of the case studies. The globe temperature was also measured to allow calculation of mean radiant temperature. Site visits provided observations of clothing, activity and air velocity. No noticeable air movement was observed in any of the case studies, so a value of 0.1m/s was used to cover the air velocity in all monitored rooms. The clothing and activity levels observed during the study are recorded in Table 3 and Table4.

Table 3: Clothing types for patients and staff in hospital wards*

Clothing	**Clothing level** (clo)	**Patients without cover**	**Patients with cover**	**Staff**
Light-weight shirts with long sleeves	0.20	0.20	0.20	-
Normal shirts with long sleeves	0.25	-	-	0.25
Light-weight trousers	0.20	0.20	0.20	-
Normal trousers	0.25	-	-	0.25
Light summer jackets	0.25	-	-	0.25
Socks	0.02	0.02	0.02	0.02
Shoes (thin soled)	0.04	-	-	0.04
Panties-pants and bra	0.03	0.03	0.03	0.03
Singlet	0.04	0.04	0.04	0.04
Blanket **	0.90	-	0.90	-
Total clothing ***		**0.49 clo**	**1.39 clo**	**0.88 clo**

**- ISO 7730: Moderate thermal environments- Determination of the PMV and PPD indices and specification of the conditions for thermal comfort*
*** - the clo for blankets assumed to be same as boiler suit in ISO 7730*
**** - Total clothing = ? clothing*

Table 4: Activity rates for patients and staff in hospital's wards ****

activity	**Metabolic rate** (met)	**Patients** , % of time	**Staff** , % of time
Reclining	0.8	90%	-
Seated, relaxed	1.0	10 %	5 %
Sedentary activity	1.2	-	30 %
Standing, light activity	1.6	-	50 %
Standing, medium activity	2.0	-	10 %
Walking on the level	1.9	-	5 %
Total activity		**0.82** met	**1.50** met

*****- [1] - ISO 7730: Moderate thermal environments- Determination of the PMV and PPD indices and specification of the conditions for thermal comfort*

From Table 3, this study assumes that the mixture of clothing types for patients without a blanket cover gives a 0.49 clo, for patients with cover 1.39 clo, and for staff 0.88 clo. From Table 4, this study assumes that the average activity rate for patients is 0.82 met, and for staff is 1.50 met.

RESULTS

Comparisons of recorded data with ASHRAE, CIBSE, and Iranian standard recommended ranges of air temperature and relative humidity have been completed. PMV and PPD values have also been calculated for each case study and compared with recommended ranges in ISO7730. Table 5 summarizes the findings in terms of the percentage of the time that the buildings achieved the recommended values for the standards.

Table 5: Maximum radiant temperature ranges for hospital users in Iran
(All users assumed to be in conditions of: air temperature from 20ºC to 28ºC, air velocity from 0.1 m/s to 0.5 m/s, and relative humidity from 30% to 60%)

Users	Maximum radiant temperature range
Patients with blanket	12.3 ºC to 43.3 ºC
Patients without blanket	25.6 ºC to 50.5 ºC
Staff	-4.7 ºC to 35 ºC

Table 5 shows that overall the rooms monitored met ASHRAE recommended temperature and RH requirements 27% of the time; CIBSE recommended temperature and RH requirements 4% of the time; and Iranian regulations for recommended temperature and RH requirements 67 % of the time.

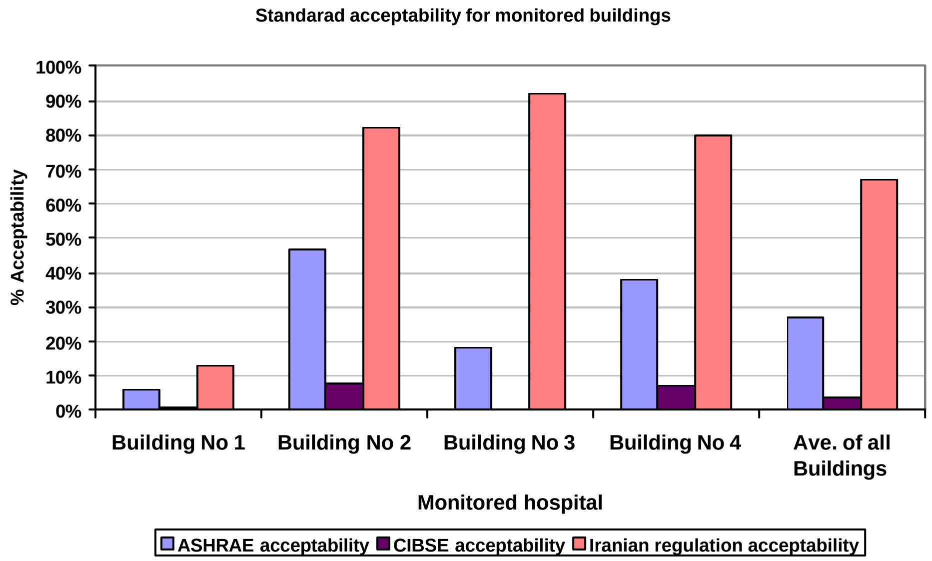

Figure 1: ASHRAE, CIBSE, Iranian regulation acceptability in monitored buildings.

Referring to the more detailed ISO7730 requirements we found that only 1 % of the monitored time were the staff estimated to be in the comfort zone, though these same conditions meant that thermal comfort conditions were met 39 % of time for the patients with blankets and 17 % of time for the patients without blankets. Figure 1 and Figure 2 present these results in graphical format.

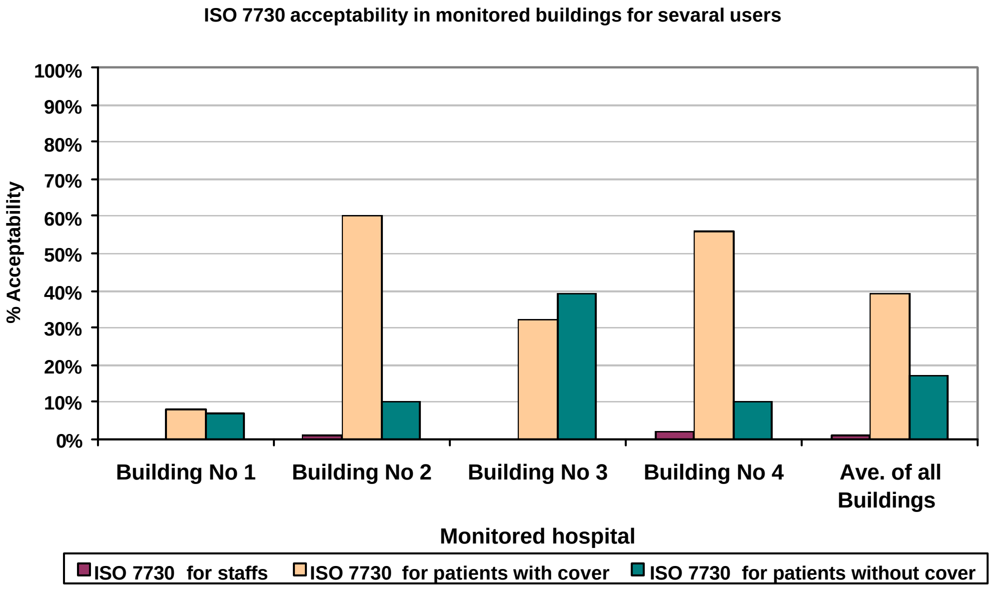

Figure 2: ISO 7730 acceptability in monitored buildings for Staff, Patient with blanket and Patient without blanket in Iranian hospitals.

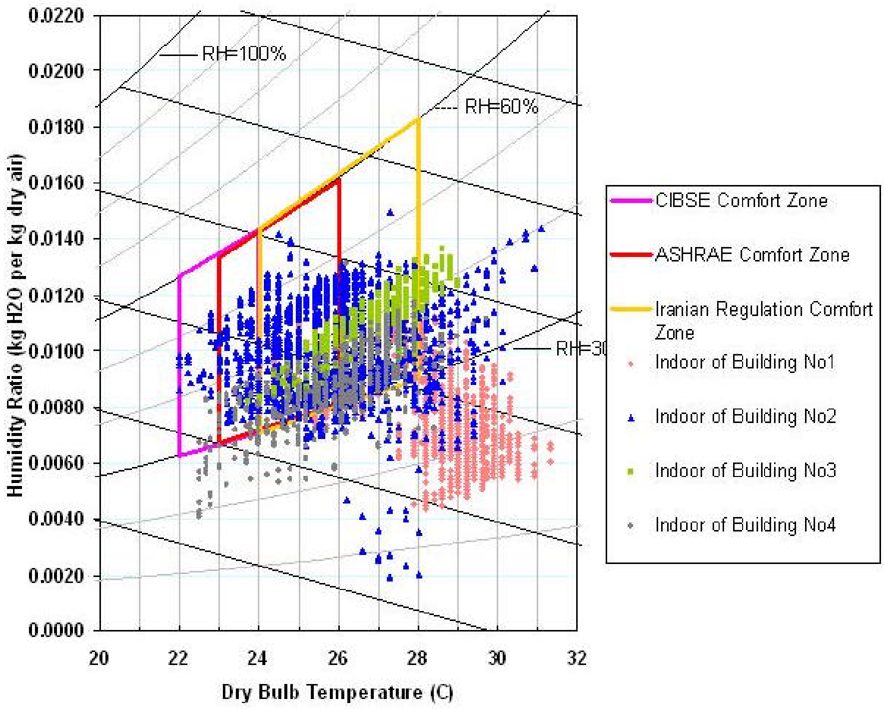

Figure 3: Measured indoor conditions in monitored hospital rooms compared to the zones of acceptable conditions for each standard.

Figure 3 presents graphically the spread of the monitored indoor thermal conditions across all the monitored buildings. This figure shows that nearly half of all the measured data fell inside the values recommended by the different CIBSE, ASHRAE and Iranian regulations. When the data fell outside these acceptable ranges it is seen that the rooms were then generally too hot and dry. This graph also shows building No1 had the most data outside the recommended ranges.

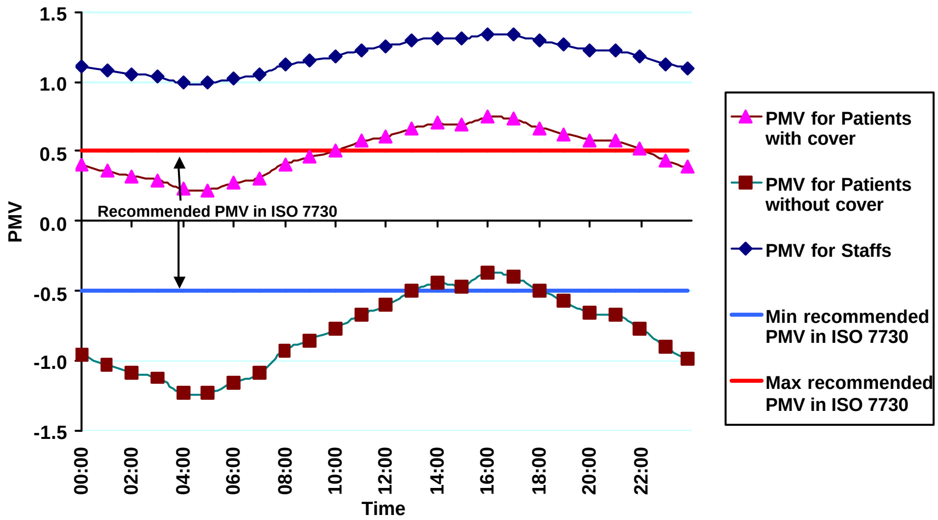

Figure 4: Average PMV achieved in Iranian hospitals for patients and staff

Figure 4 presents the comparison between the recorded data and the ISO7730 recommended ranges. On average, Figure 4 shows that while the hospital staff generally experience uncomfortably hot thermal conditions, patients with blankets are generally the most thermally comfortable group in the hospital, though with a tendency towards overly warm conditions in the afternoons. For patients without a blanket for any reason the thermal conditions will generally be too cool. Table 6 presents this data as the percentage of acceptable PMV and PPD for patients and staff by each of the monitored hospitals.

Table 6: PMV and PPD acceptability for three main user groups in case studies

Case study	***% PMV acceptability (-0.5<PMV<0.5) for***			**% PPD acceptability (PPD<10%) for**		
	Staff	**Patients** With cover	**Patients** without cover	**Staff**	**Patients** With cover	**Patients** without cover
Bu. No1	0 %	9 %	80 %	0 %	9 %	79 %
Bu. No2	1 %	68 %	12 %	1 %	67 %	12 %
Bu. No3	0 %	32 %	39 %	0 %	32 %	38 %
Bu. No4	3 %	65 %	10 %	3 %	64 %	10 %
Ave. All	**1 %**	**44 %**	**35 %**	**1 %**	**43 %**	**35 %**

On average the patients were more comfortable than the staff during the monitoring period. This table shows while 1 % of monitored time the hospital staffs were placed in comfort thermal conditions, 44 % of monitored time the patients with blanket and 35 % of monitored time the patients without blanket were placed in comfort thermal conditions. The table also shows that there were significant variations in the comfort conditions achieved in the different hospitals, though the staff were universally uncomfortable for all hospitals.

DISCUSSION

The different user groups of the hospital had thermal comfort requirements that were difficult to accommodate in one space. Therefore the best solution would appear to be to provide different thermal zones for different user groups in hospitals. In particular, it appears that staff should be provided with work areas in the wards that are controlled to very different conditions to the general wards.

Although, the monitored indoor thermal conditions in Iranian hospitals were generally within the recommended range of the Iranian thermal regulation, they were generally out of the thermal comfort zones recommended by ISO7730, ASHRAE and CIBSE.

The next stage of the study will try to answer some key questions including: is there any possibility for reconciling the thermal conditions required by different groups of occupants in Iranian hospitals? How much can modifying existing designs improve thermal comfort? How much more comfort could be achieved through a “new” vernacular for the design and operation of Iranian hospitals?

ABSTRACT

The impacts of indoor thermal environment on body physiology have been carried on for four years (2003-2007) in laboratory in Chongqing, a typical city located in hot-summer and cold-winter region in China. Experimental objectives used are healthy university students. The range of indoor air temperature in summer is 25 °C - 37.5 °C.The objectives' physiological changes (Motor nerve Conduction Velocity, Sensory nerve Conduction Velocity, Skin Temperature etc.) under different temperatures and ventilations have been tested.

The results show that the effect of air temperature on skin temperature is significant; Skin temperature has a linear and positive correlation with MCV and SCV; Air temperature has a significant effect and a positive correlation with MCV and SCV when indoor air temperature are not too high (25 °C - 32 °C); In this temperature range, mechanical ventilation can significantly improve the thermal comfort sensation. However, increasing indoor air movement has a little effect on MCV and SCV when indoor air temperature is above skin temperature (34 °C - 37.5 °C).

Such experiments can provide basic data to establish the standard of acceptable indoor thermal environment for hot-summer and cold-winter region in China.

Keywords: thermal comfort, indoor thermal environment, human body physiology, Motor nerve Conduction Velocity, Sensory nerve Conduction Velocity

INTRODUCTION

Buildings are designed to suit the climate in which they are located and the functions for which they are intended. There is a unique relationship between an individual, the environment and the building he or she inhabits. Everyday experiences tell us that there are a host of factors which are relevant to this concept. Air and surface temperatures, humidity, air movement have an important role. A deficiency in one of the physical factors can spoil the balance of the environment. The physical environment can enhance one's work but an unsatisfactory environment can hinder work output. As building service engineering and building environmental control systems become more complex and expensive, cost justification becomes a greater issue for decision makers. Factors such as poor lighting, both natural and artificial, poorly maintained or designed air conditioning, and poor spatial layouts are all likely to affect performance at work. The variations in thermal comfort and well being were influenced by temperature changes.

The indoor thermal environment will directly influence human physical and psychological health, sense of comfort, as well as human's well being[1, 2]. Professor Fanger published the famous thermal equations based on experimental data[3]. He created the currently widely-used indexes: Predicted Mean Vote (PMV) and the Predicted Percentage of Dissatisfaction (PPD) to assess thermal comfort, based on the human body thermal equivalence equation[4]. The thermal comfort standard recommended by ASHRAE55-2004[5] and ISO7730[6] are widely used in the world to measure thermal comfort based on Fanger equations. However, more and more researches show that the PMV-PPD index obtained through experiment in Laboratory in the 1970s can not be suitably applied to all the countries and regions, especially for the free running buildings[7, 8,9,10,11].

The indoor environment of the hot-summer and cold-winter region is very much different from those experimental conditions in Professor Fanger's air-conditioned Laboratory. The suitability of applying Fanger's result as an international design standard into different local building conditions is now argued by experts. The impact of indoor thermal environment on human physiology has been carried on for four years (2003-2007) in Laboratory in Chongqing, a typical city located in hot-summer region in China. Experimental objectives used are healthy university students. The range of indoor air temperature in summer is 25 °C - 37.5 °C.The objectives' physiological changes (Motor nerve Conduction Velocity, Sensory nerve Conduction Velocity, Skin Temperature etc.) under different temperatures and ventilations have been tested[12,13,14,15]. The results show that the effect of air temperature on skin temperature is significant; Skin temperature has a linear and positive correlation with MCV and SCV; Air temperature has a significant effect and a positive correlation with MCV and SCV when indoor air temperature are not too high (25 °C - 32 °C); In this temperature range, mechanical ventilation can significantly improve the thermal comfort sensation. However, increasing indoor air movement has a little effect on MCV and SCV when indoor air temperature is above skin temperature (34 °C - 37.5 °C).

METHODOLOGY

The impacts of indoor thermal environment on body physiology have been carried on in Laboratory in the region of the hot-summer and cold-winter in China. The parameters of physiology including Motor nerve Conduction Velocity, Sensory nerve Conduction Velocity, Skin Temperature etc, have been selected. The impacts of indoor temperature and velocity on human physiology have been measured and analyzed.

The human nerve system consists of trillions of neurons, which have converted to functions to recognize, conduct and analyze information of other cells and environmental information. Nerve system is the quickest responding to heat among all parts of human body. For example, sensory cells receive the stimulus from the climate in a hot environment, and then conduct it to the human brain to cause a feeling of hot or cold. Consequently, nerve system is a main physiological system which has a directly influence on the reception and process of information of heat in the environment[16].

As far as the human nerve system is concerned, the most frequent and direct parameter is nerve conduction velocity, which is calculated along certain nerve phase, meaning the fastest (both sensory and motion) velocity of neuraxis[16]. When the electricity stimulates nerve, the impulse is conducted by motor, sensor or mixed nerve. In consideration to convenience and feasibility, the experiment chooses the right-hand median nerve as the stimulated nerve, as Fig.1 shows. The median nerve sensing fiber is mainly distributed in the hand palm side and hand outside skin. The experiment applies the surface stimulation by electrode to test. The stimulated parts and electrodes are located, as Fig.2 shows.

	Fig.1 Test of median nerve motor conduction.	Fig.2 Stimulation of median nerve sensory conduction.

Skin temperature is an important physical indicator that reflects the effect on human body by surrounding climate condition and outside body condition (subjects' activities and clothes). In normal case, the skin temperature of human body varies between 15…42 °C. The skin temperature on any point of body surface depends on local balance between the heat streams that flowing from central to this point of skin and the heat radiation from there to outside surroundings. Since skin temperature is physical indicator that reflects the compact on human body by surrounding climate condition, it is easy to be affected by the surrounding conditions, which is a sensitive indicator.

Hanada's research found that different part on human body has different feeling on warmness[13]. The body parts as hest, the upper arm and curs are easy to feel cold, while the cold stimulation is most sensitive when the upper arm, forearm, curs and thigh are feeling together. Considering the practical condition, a normal experiment can measure skin temperature of 3 to 10 points to reflect the average skin temperature of the whole body. In the experiments, 6-point method has been used. Skin temperature also affects nerve conduction velocity, which is the most important physical factor that affects conduction velocity. When skin temperature varies between 25…35 °C, the decrease of nerve conduction velocity displays the linear relation, namely each 1 °C raise of skin temperature results in 2…3m/s increase of conduction velocity. Generally, when skin temperature is higher than 30 °C, temperature effect will be little. Therefore, the experiments focused on analysis of nerve conduction velocity, skin temperature and relationship between skin temperature and nerve conduction velocity in the different thermal environmental conditions.

Because the experiments relate to measurement of thermal environment physics parameters and the human physiological parameters, the measuring instruments are grouped into two terms: Environmental parameters and Physical parameters measuring instruments. There are Copper-Constantan Thermocouple to measure outdoor and indoor air temperatures, Multifunctional Intelligent Data Acquisition Instrument for checking and measurement, Indoor Air Quality Tester to measure indoor air relative humidity, Portable Hot Wire Anemometer to measure indoor air velocity; Twelve-Channel Electrocardiograph ECG-9103P and Multifunctional Intelligent Environmental Data Acquisition Instrument, MEB-9104 to measure nerve conduction velocity MCV and SCV, Digital Electroencephalogram System EEG-8200 Human Skin Impedance Tester is used to measure skin impedance, Infrared Thermometer to measure skin temperature.

All the testing apparatus have been debugged and adjusted. The testing apparatus and instruments have very high precision. Experts have invited to adjust instruments after installation. Inside the room, 30 thermocouples have been averagely distributed and settled at the height of 1.7m from the floor to monitor the distribution of the air temperature in the whole laboratory. The temperature of ceiling, floor, window, wall etc is measured directly by infrared temperature measuring instruments. The causal measuring points are located at 4 places, which are when the subject is away from the floor at 4 heights: 0.1m, 0.6m and 1.1m, which refer to the three body parts when the subject is sitting: feet, belly and head, and 0.5m, which refers to the lying gesture of the subject.

The experiments measure the subjects' physical parameters include EEG, MCV, SCV, ECG, skin temperature, skin resistance, heart beat rate, blood pressure, body temperature. These experiments include two extreme environments in winter and summer from July 2003 to Feb. 2007.

Table 1 Experiment parameters

Time	Experiment parameters	
Winter	Indoor air temperature: (13.2±1.5) °C Wind speed near human body: (0.17±0.2)m/s Comparative indoor air humidity: (80.9±4.2)%	Indoor air temperature: (13.2±1.5) °C Wind speed near human body: (0.35±0.2)m/s Comparative indoor air humidity: (80.9±4.2)%
Summer	Indoor air temperature: (32.4±0.7) °C Wind speed near human body: (0.10±0.02)m/s Comparative indoor air humidity: (73.6±7.4)%	Indoor air temperature: (24.2±0.7) °C Wind speed near human body: (0.35±0.2)m/s Comparative indoor air humidity: (44.2±5.3)%
Summer (High-temperature indoor environment)	Indoor air temperature: (37.3±0.6) °C Wind speed near human body: (0.10±0.02)m/s Comparative indoor air humidity: (65.4±7.2)%	Indoor air temperature: (37.3±0.8) °C Wind speed near human body: (0.47±0.02)m/s Comparative indoor air humidity: (63.8±6.7)%

RESULTS

Analysis of the winter measurements results

The experiments in the winter mainly measure the influence of air temperature and draught on nerve conduction velocity. From the Fig. 3, it can be observed that the longer the mechanical ventilation is, the more MCV is obviously decreasing. During the whole process, the MCV can be divided into 3 stages. The first stage is from no-draught to 5 mines time of mechanical ventilation, and the MCV has a sudden drop, for the human body is affected suddenly by draught under cold thermal environment, which leads to the bigger heat loss. In the second stage from 5 mines to 20 mines time of mechanical ventilation, the MCV is still decreasing, but with slower speed compared with the first stage. Although the human body heat loss is affected, the human body can automatically moderate its temperature under some environmental parameters. Thus the lowering of MCV caused by draught is controlled. In the third stage after 20 mines time of mechanical ventilation, The MCV change rates are increasing compared with the second stage, The longer the time of draught that subjects suffered, the more MCV decreases rapidly The thermal environments have a bigger influence on MCV.

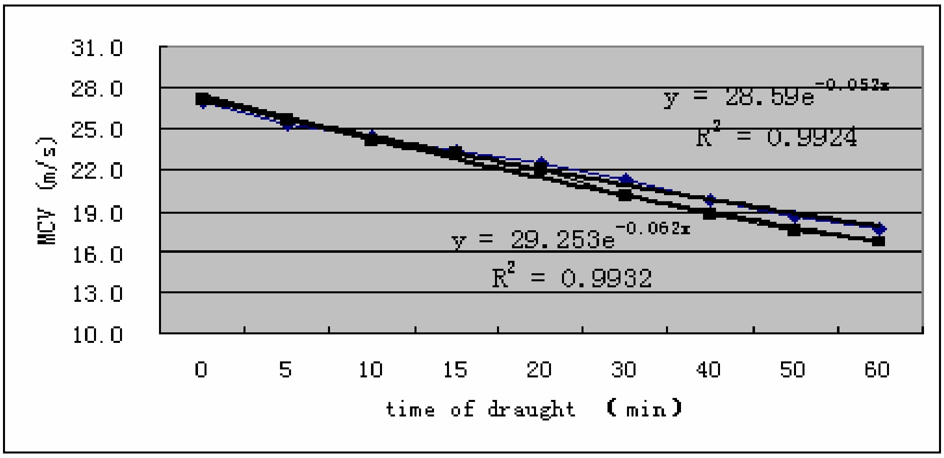

Fig.3 The impacts of draught on MCV in winter

The time of draught blow is negatively correlated to MCV and SCV. The regression equations are $y=29.253e^{-0.062x}$, y=47.968e-0.0621x respective for MCV and SCV, and correlation coefficients are R2=0.9932 and R2=0.9867 respective.

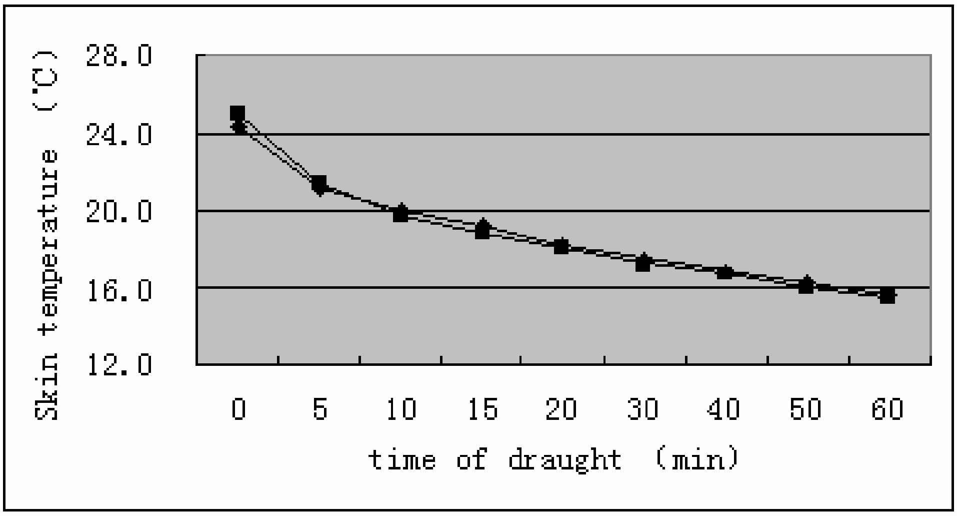

Fig.4 The impact of draught on Skin temperature in winter

Fig. 4 shows that there is an obvious decrease trend for skin temperature with the strong draught. And a sudden decline emerges from no-draught to draught. When draught duration is 5min, the decline of skin temperature decreases about 5 °C. With the whole testing period, the skin temperature reduces 10 °C with the final value of 15 °C. There is an obvious effect of draught in winter on skin temperature.

Analysis of the summer measurements results

The impacts of air temperature and velocity on the nerve conduction velocity and skin temperature in summer have be measured and assessed similar in summer and in winter. The MCV and SCV have downtrend with the time of ventilation. Fig. 5 shows there is a short suspension of SCV downtrend between 15min and 20min after ventilated. That means the subjects have had a corresponding physiological response to the stimulation made by ventilation during this period. For example vasoconstriction or increase metabolic heat production and reduce heat exchange with the outside to inhibit skin temperature falls, thus inhibiting nerve conduction velocity decline. Subsequently, the cooling capacity of the environment over the body heat production capacity, and the skin temperature further decreases and SCV has further reduced. Comparing to the experiment, the MCV and SCV downtrend in summer with ventilation are far little obvious than that in winter with draught. The subjects' skin temperatures with MCV and SCV have linear correlation.

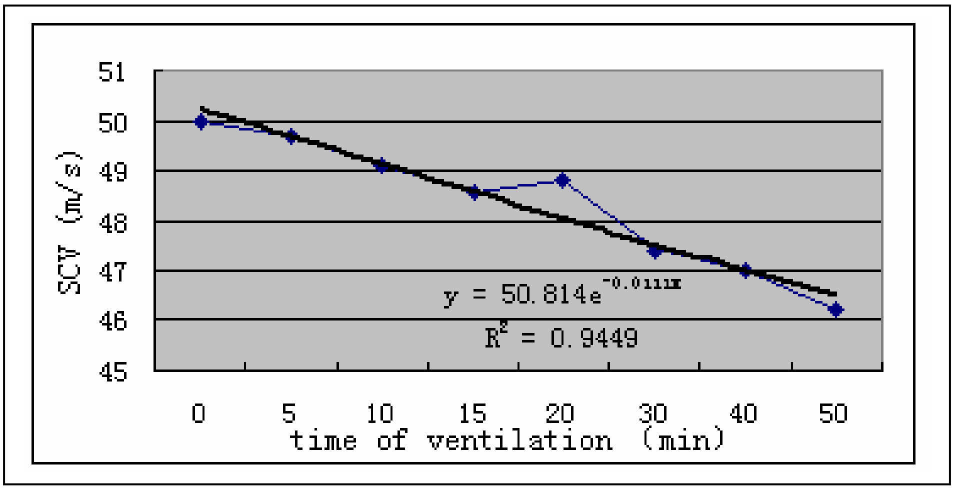

Fig.5 The impacts of ventilation on SCV in summer

Analysis of extremely high temperature (in summer) measurements results

The summer of 2006 in Chongqing has suffered the rare high-temperature and dry conditions for the last 100 years. Outdoor air temperature above 40 °C lasts for many ten days. The disastrous weather has provided a valuable opportunity for the experiment for us and gain a number of extremely high-temperature environments indoor physiological data.

The nerve conduction velocity has no significant difference for the environment condition. The ventilation could not affect the value of MCV and SCV in extremely high temperature environments. In the extremely high temperature environments, the outside air temperature is higher than the skin temperature; evaporation heat is the only way to dispel heat for the human being, so that the cooling effect of heat dispelled by convection would be ineffective when air flows. Comparing the average value of MCV and SCV in normal conditions with the average value of MCV and SCV in extremely high temperature in summer, the value of MCV and SCV under the extremely high temperature is higher. That means the higher the air temperature is, the faster the subjects' nerve conduction velocities are. The subjects would be prone to fatigue and be adverse to human health. The heat stress will increase the body's physiological load of the organizations and organs.

DISCUSSION

The impacts of indoor environments on human's physiology and thermal comfort in the regions of hot in summer and cold in winter is very representative and has important practical significance. In this paper, the human physiological parameters, which are affected by environmental factors change obviously (e.g. MCV, SCV, skin temperature,etc.) have been selected and measured in the region of hot-summer and cold-winter in China. The impacts of thermal environments, indoor temperature, draught and ventilation on Human Physiology have been assessed.

The results show that MCV and SCV decline obviously with the time of draught in the winter. The skin temperature corresponding to the MCV and SCV show a linear correlation. The higher the indoor temperature is, the higher the value of MCV and SCV are. The MCV and SCV in free-running room with high air temperature are higher than that in air condition environment. The impacts of draught on MCV and SCV in winter are much bigger than the impacts of ventilation in summer.

The effect of air temperature on skin temperature is significant; Skin temperature has a linear and positive correlation with MCV and SCV; Air temperature has a significant effect and a positive correlation with MCV and SCV when indoor air temperature are not too high (25 °C - 32 °C); In this temperature range, mechanical ventilation can significantly improve the thermal comfort sensation. However, increasing indoor air movement has a little effect on MCV and SCV when indoor air temperature is above skin temperature (34 °C - 37.5 °C). Draught has to be carefully avoided in the winter in order to achieve a comfort thermal environment. Such experiments can provide basic data to establish the standard of acceptable indoor thermal environment for hot-summer and cold-winter region in China.

ACKNOWLEDGEMENT

Vertical Distribution of Air Temperatures in Heated Dwelling Rooms

Ondrej Sikula

University of Technology Brno, Brno

Corresponding email: sikula.o@fce.vutbr.cz

SUMMARY

The paper presents an experimental and theoretic research on one of factors influencing the indoor climate in dwelling rooms heated by heating systems – the vertical distribution of temperatures. The paper summarizes results from simulation of the room heated by a gas space heater and a plate radiator. Among main factors causing unfavorable distribution of temperatures in a room belong insufficient elimination of cold dropping airflows and high temperature of heating air.

INTRODUCTION

The subject of the paper belongs to the field of formation of indoor climate in residential buildings. One of factors influencing the quality of indoor climate in a dwelling room is the vertical distribution of temperatures. It is described by a vertical temperature gradient or by temperature difference between the position of a head and an ankle of a person in the given space. Indoor climate is created by various HVAC systems which have different influences on the observed vertical distribution of temperatures. We try to identify factors leading to unfavorable vertical distribution of temperatures in a room heated by a gas space heater and a plate radiator.

METHODS

The vertical distribution of temperatures of chosen spaces was investigated by experimental measurements and CFD simulations. The measurement was performed during a regular operation of chosen rooms. The room A is a dwelling room in an old brick house with one outer wall. The room is situated in the third floor under a cold sloping roof with leaking tiling. Surrounding spaces have the same or similar temperature regime. The walls are made of solid bricks; the ceiling is made of wooden girders. The leaking wooden windows and balcony doors in the room have a double glassing. The room is heated by a local gas space heater, see fig. 1a).
The room B is an office for two people in a new building with one outer wall made of medium thick façade, see fig. 1b). The office is surrounded by rooms with the same or similar temperature regime.

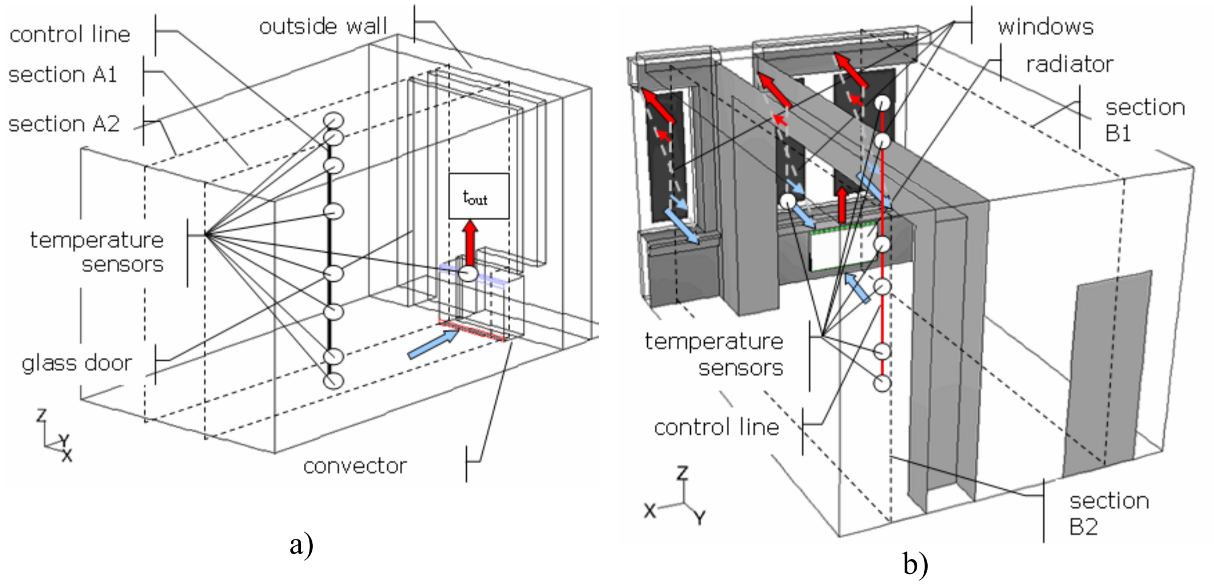

Figure 1. Geometry of rooms

In case A was measured and investigated the vertical distribution of temperatures while pre-heating.
In case B was measured and investigated the vertical distribution of temperatures while short-term ventilation by windows.

CFD simulations were performed on simplified geometric models of real rooms. Simulations included stationary and non-stationary solution of thermal transfer by convection, conduction and radiation. For airflow turbulence calculations the RNG k-ε model with standard wall functions was used. The heat transfer was solved by DO (Discrete ordinates) model [3]. Boundary conditions for CFD simulations were taken from the experimental measurement. The experimental measurement consists of measurement of air temperature and airflow velocity. We performed the measurement of the air temperature, the floor temperature, the ceiling temperature and the outer air temperature. We also compared thermal fields by using thermo-graphical images showing surface temperatures of internal constructions in the room. Airflow velocities were measured by anemometers. This paper presents only results from temperature measurements.
From the point of view of thermal comfort is recommended the maximal temperature difference between the position of a head and an ankle to be 2,0 K for standing person and 1,5 K for sitting person, see [2]. The legal regulation for working environment requires the maximal vertical temperature difference to be 3 K, see [1].

RESULTS

At fig. 2, 4 we can see the course of measured temperatures in chosen time intervals. Air temperatures are marked by a blue color and floor and ceiling temperatures by a red color. Vertical dashed lines indicate time moments in which were observed vertical distributions of temperatures in the room. In case A we can also see temperature of the air coming out of the gas space heater marked by black color at fig. 2.

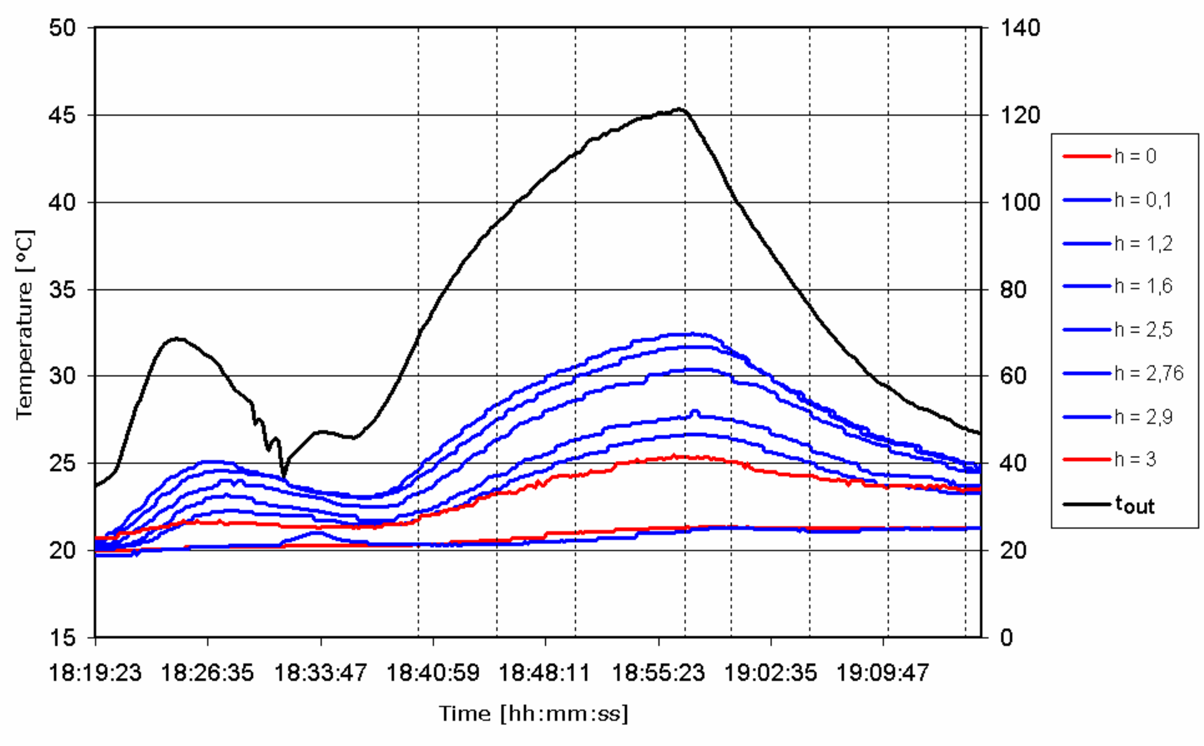

Figure 2. Temperature course in time, case A

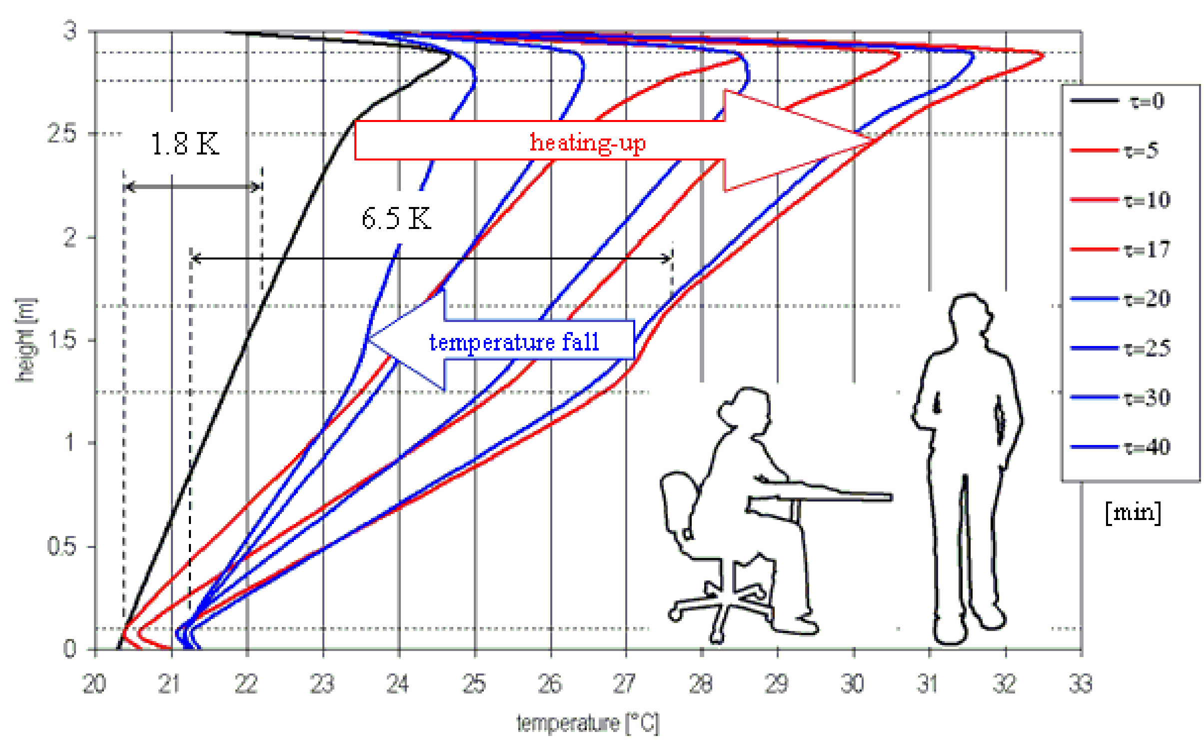

Figure 3. Vertical distribution of temperatures, case A

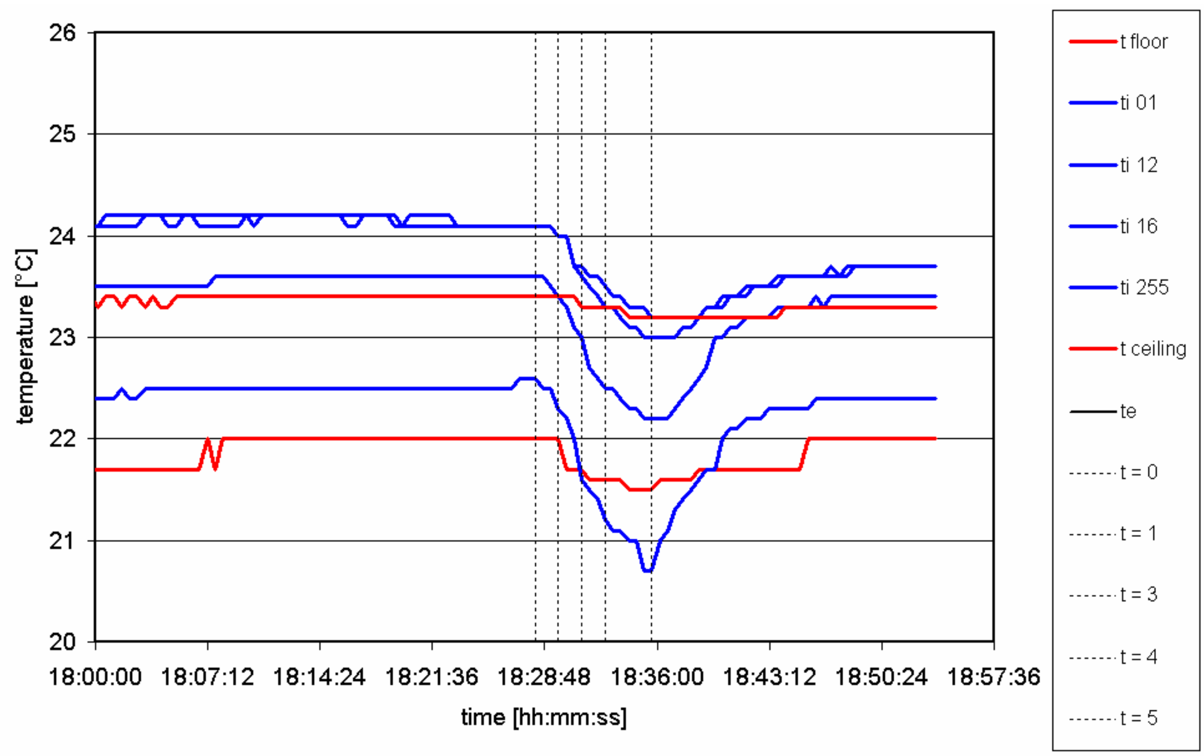

case B

Figure 4. Temperature course in time, case B

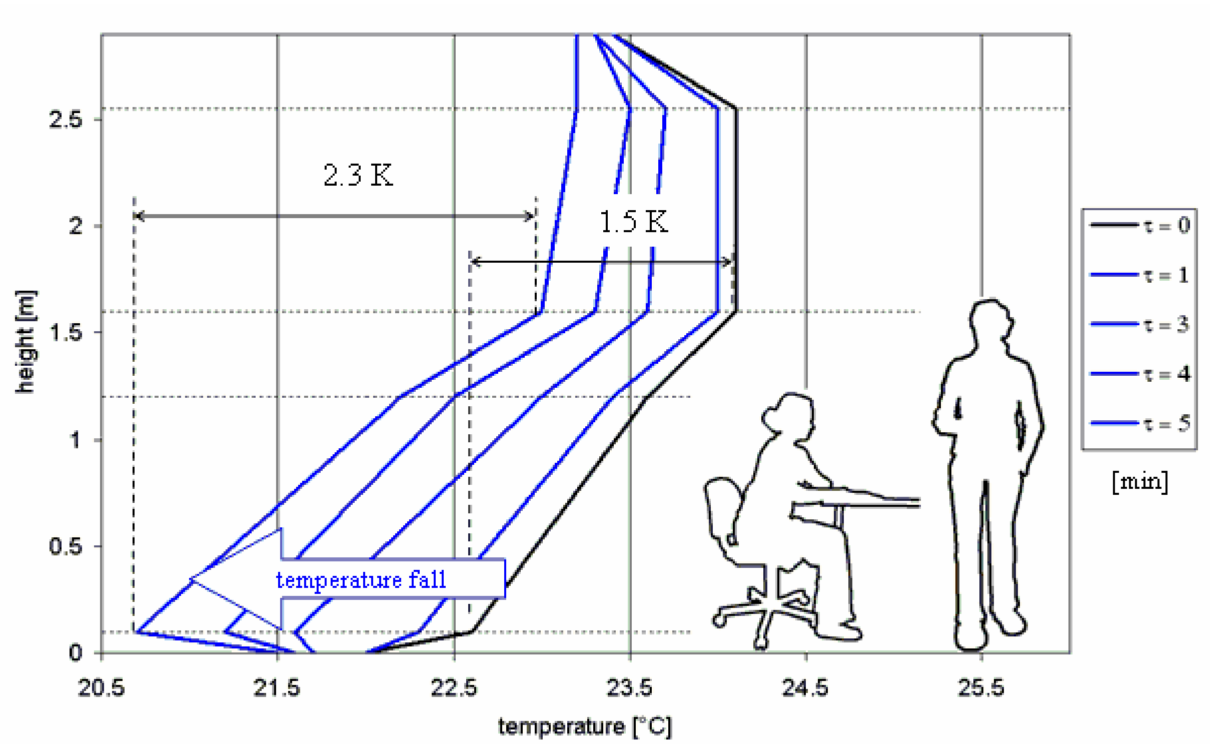

Figure 5. Vertical distribution of temperatures, case B

Obtained results show unfavorable vertical distribution of temperatures in the room for case A especially by pre-heating, see fig. 2. Inhabitants of this room are exposed to thermal discomfort because of the seriously overreached maximal temperature difference between the position of a head and an ankle required by [1] for time interval of approximately 30 minutes, see fig. 3. The gas space heater used in the room is equipped with jump regulation switch on-off. There is no possibility for step-by-step regulation or gradual control of heating, therefore the discomfort occurs several times per day, see fig. 9.

Case B offers favorable vertical distribution of temperatures in the room during a regular operation. While short-term ventilation by windows is formed a cold air layer close to the floor which cause a slight thermal discomfort felt by inhabitants. Nevertheless the maximal temperature difference between the position of a head and an ankle required by [1] is not overreached. Evaluation of this subjective thermal discomfort will be performed in the future.

Figure 7. Velocities, case B

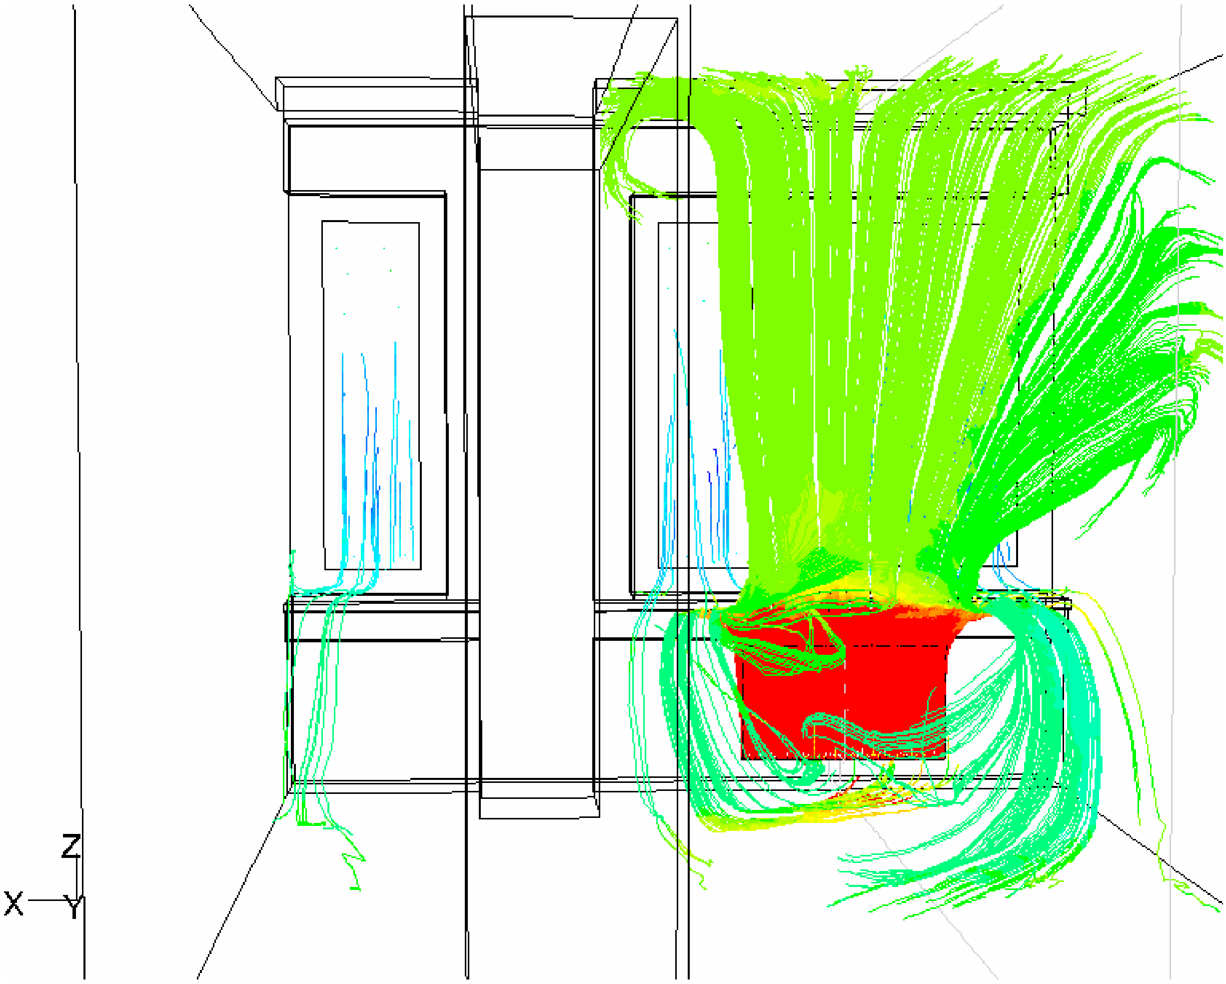

Figure 8. Path lines, case B

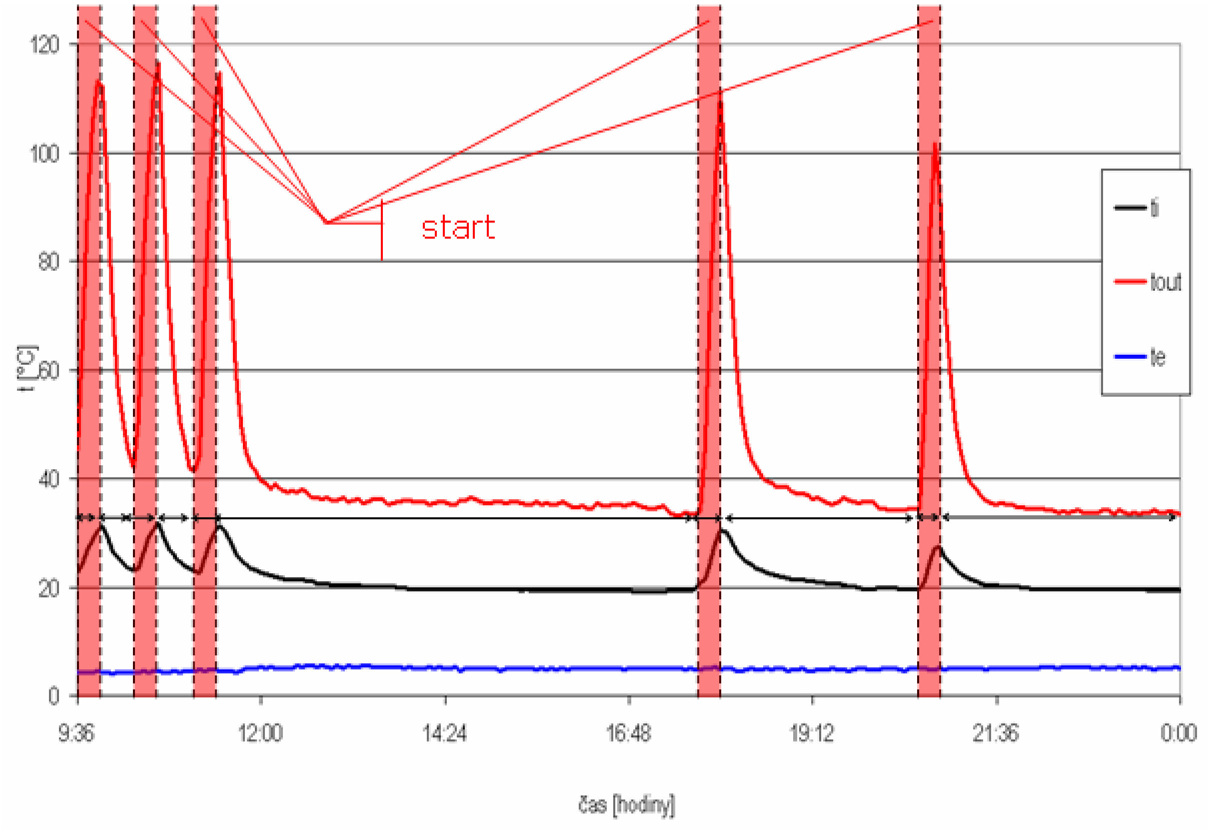

Figure 9. Temperature in the course of day, case A

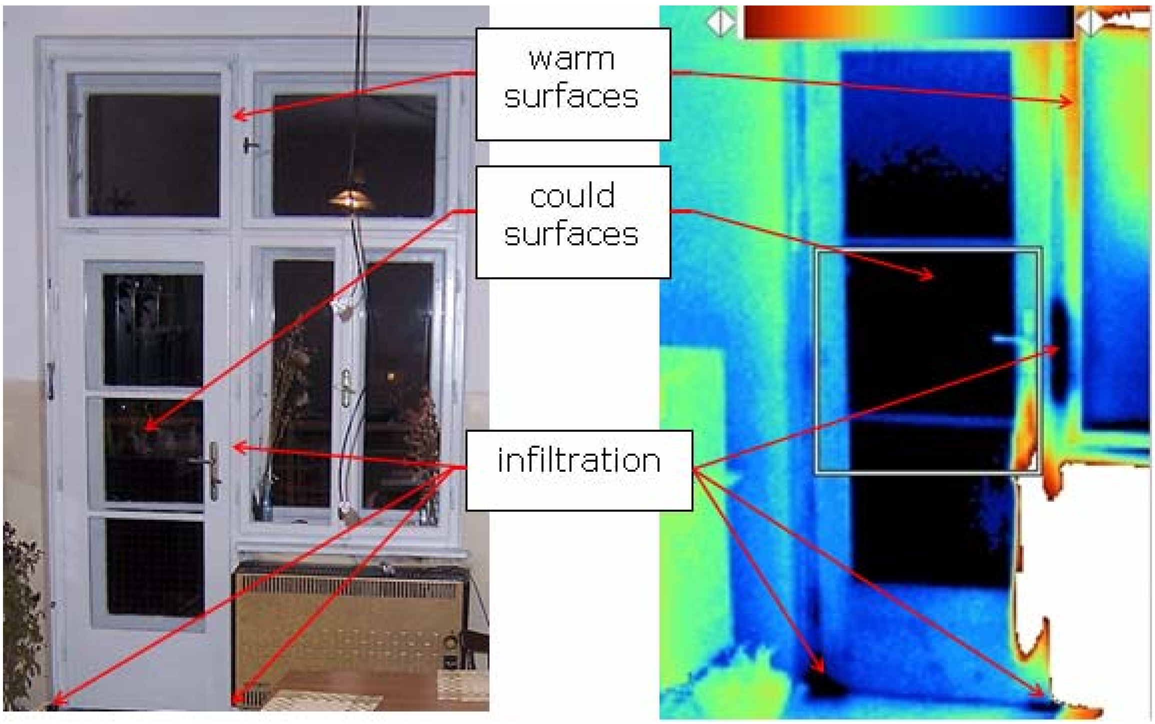

Figure 10. Surface temperatures, case A

DISCUSSION

Above mentioned and described results prove dependence of vertical distribution of temperatures in the heated room on time. In some dynamic states it can be considered as unfavorable, for example while pre-heating in case A, or while short-time ventilation by windows in case B. Following factors having unfavorable influence on vertical distribution of temperatures were found:

- ventilation by windows or high infiltration of the outer air
- the formation of dropping airflows at the vicinity of cool surfaces of outer walls and windows
- relatively high temperature of the heating air

Other factor causing unfavorable vertical distribution of temperatures is an insufficient shading out of dropping cool airflows by a heating air, see fig. 6, 7, 8. The reason for a relatively high temperature of a heating air in case A is above all the an unsuitable control system of a gas convector, see fig. 9.

The use of thermal comfort approach in the energy conservation studies

Mesut B. Ozdeniz

Eastern Mediterrenean University, Gazimagusa, Turkish Republic of Northern Cyprus

Corresponding email: mesut.ozdeniz@emu.edu.tr

SUMMARY

There are numerous studies of energy conservation problems in buildings. In most of these studies the problem is handled as a study of heat loss or heat gain. This may be justified when the external conditions are too severe. However, when the summer or winter conditions are not very distinct, it is better to use the thermal comfort approach.

Thermal comfort approach for energy conservation problems can be applied to compare the same type of building elements with each other. There are a number of thermal comfort scales. In this study PMV (Predicted Mean Vote) which is proposed by FANGER and recommended by ASHRAE and ISO was used.

The thermal comfort evaluation can be done through a number of criteria. One of them can be "The total absolute PMV scale". The other criteria can be "The total time period in which the enclosure with a building element achieves thermal comfort". The tests can be carried out in air-conditioned, intermittently air-conditioned and none air-conditioned regimes.

Thermal comfort approach in energy conservation studies puts the human beings on the front row, rather than the energy cost. Another advantage of the method is to show which building elements use the solar heat gain effectively.

INTRODUCTION

There are numerous studies of energy conservation problems in buildings. In most of these studies the problem is handled as a study of heat loss or heat gain, either under stationary or variable conditions [1]. This may be justified when the external conditions are too severe. However, when the summer or winter conditions are not very distinct, in other words when we cannot tell whether the climate is hot or cold, it is better to use the thermal comfort approach.

There are a number of thermal comfort scales [2, 3]. They can be grouped into two categories as empirical and analytical indices. In this study an analytical index, PMV (Predicted Mean Vote), which is proposed by Fanger [4] and recommended by ASHRAE [5] and ISO [6] was used.

METHODS

Thermal comfort is defined as the state in which the body adapts itself to the environment by spending the least amount of energy ASHRAE (2001). It is possible to divide the thermal comfort factors into two groups as objective and subjective. Objective factors are air temperature, relative humidity, air velocity and radiation. Subjective factors are the activity level, metabolic rate, thermal insulation of clothing, dieting habits, sex, age, shape of the body and acclimatization.

The thermal comfort index proposed by Fanger (1970-1982) is an analytical one, and developed for the steady conditions of human environment. Later with the works of (Gagge, et al., 1986) the index was developed in order to measure thermal comfort in varying environments.

Fanger's index computes the heat exchange between human body and the environment and predicts the response. The inputs of the model are air temperature, relative humidity, air velocity, mean radiant temperature, thermal insulation of the clothing, activity level of the human body, and the instantaneous heat storage of the human body due to the activity level. The model gives Predicted Mean Vote (PMV) according to the following scale in Figure 1.

Hot	Warm	Slightly Warm	Comfort Scale Range			Slightly Cool	Cool	Cold
+ 3	+ 2	+ 1	+ 0.5	0	- 0.5	- 1	- 2	- 3

Figure 1. ASHRAE Thermal Sensation Scale

Both the ASHRAE Standard 55 (1989) and ISO Standard 7730 (1994) indicate that for the + 0.5 and – 0.5 thermal sensation scale interval, at least 80% of human beings will feel thermally comfortable while 20% might be dissatisfied. With this model it is possible to find Percentage of Persons Dissatisfied (PPD) for any PMV value.

PMV can be calculated with Equation 1 given below:

$$PMV = (0.303\, e^{-0.036M} + 0.028)\{(M-W) - 3.05 \times 10^{-3} \times [5.733 - 6.99\,(M-W)\, p_a] - 0.42 \times [(M-W) - 58.15] - 1.7 \times 10^{-5} M(5.867 - p_a) - 0.0014\, M(34 - t_a) - 3.96 \times 10^{-8} f_{cl} \times [(t_{cl} + 273)^4 - (t_r + 273)^4] - f_{cl} h_c\, (t_{cl} - t_a)\} \quad (1)$$

The parameters in Equation 1 can be found with the following equations.

$$t_{cl} = 35.7 - 0.028(M-W) - I_{cl}\{3.96 \times 10^{-8} f_{cl} \times [(t_{cl} + 273)^4 - (t_r + 273)^4] + f_{cl} h_c\, (t_{cl} - t_a)\}$$

hc =		$2.38(t_{cl} - t_a)^{0.25}$ for $2.38\,(t_{cl} - t_a)^{0.25} > 12.1\,(v_{ar})^{1/2}$ $12.1\,(v_{ar})^{1/2}$ for $2.38\,(t_{cl} - t_a)^{0.25} < 12.1\,(v_{ar})^{1/2}$
fcl =		$1.0 + 1.290\, I_{cl}$ for I_{cl} $0.078\ m^2\ {}^oC/W$ $1.05 + 0.645\, I_{cl}$ for $I_{cl} > 0.078\ m^2\ {}^oC/W$

where PMV is the predicted mean vote, M is the rate of metabolic heat production (W/ m^2), W is the rate of mechanical work accomplished (W/ m^2), I_{cl} is the thermal resistance of the clothing (m^2°C /W), f_{cl} is the external surface area of a dressed person (m^2), t_a is the air temperature °C, t_r is the mean radiant temperature °C, v_{ar} is the air velocity (m/s) , p_a is the partial water vapor pressure (Pa or N/m^2), h_c is the convective heat transfer coefficient (W/m^2°C), t_{cl} is the surface temperature of clothing (°C).

It is recommended that PMV scale thus calculated should be in the range of -2, + 2 and the six parameters used in the calculation of PMV should be in the following ranges:

M = 46 W/m^2 to 232 W/m^2 (0.8 met to 4 met)
I_{cl} = 0 m^2.^{o}C/W to 0.310 m^2.^{0}C/W (0 clo to 2 clo)
t_a = 10 ^{o}C to 30 ^{o}C
t_r = 10 ^{o}C to 40 ^{o}C
v_{ar} = 0 m/s to 1 m/s
p_a = 0 Pa to 2700 Pa

For any PMV value the percentage of dissatisfied people (PPD) can be found by equation 2.

$$PPD = 100 - 95 \ x \ e^{-A} \qquad (2)$$
$$A = 0.033\,53 \ x \ PMV^4 + 0.217\,9 \ x \ PMV^2$$

In the calculation of current thermal comfort indexes “Mean Radiant Temperature” is used as the input, instead of “Air Temperature” because it is more effective on thermal comfort. Mean Radiant Temperature is the uniform temperature of an imaginary enclosure in which radiant heat transfer from the human body equals the radiant heat transfer in the actual non-uniform enclosure.

Mean Radiant Temperature can be calculated from Globe Thermometer Temperature, Air Temperature and Air Velocity measurements according to the Equation 3. This equation has been written with the assumption that most of the materials enclosing a space have a very high emittance value.

$$T_r^4 = T_1^4 \ . \ F_{p-1} + T_2^4 \ . \ F_{p-2} + ... + T_n^4 \ . \ F_{p-n} \qquad (3)$$

where T_r is the Mean Radiant Temperature (K), T_n is the temperature of surface n (K), F_{p-n} is the angle factor between the (n)th surface and human body.

When the differences between the internal surface temperatures of the enclosure are not very high Equation 3 can be written as an equation of first degree as in Equation 4.

$$\mathrm{T_r = T_1 \ . \ F_{p-1} + T_2 \ . \ F_{p-2} + ... + T_n \ . \ F_{p-n}} \qquad (4)$$

The angle factors in these equations can be found by the aid of Figure 2.

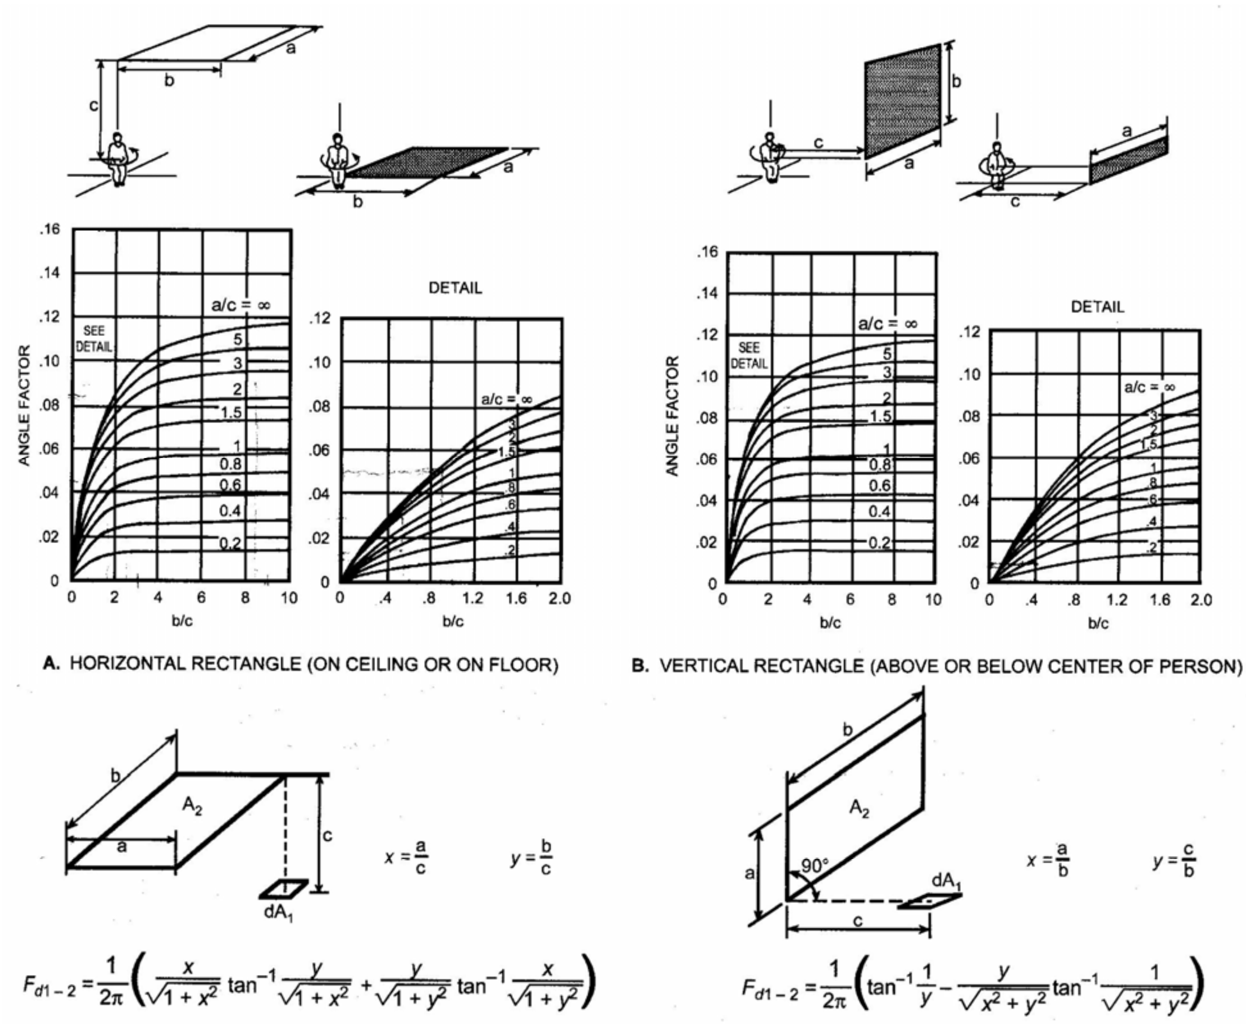

Figure 2. The graphs and the equations necessary to find the angle factor (ASHRAE, 2001) .

Plane Radiant Temperature (t_{pr}), defines the heat flow in one direction and its magnitude depends on that direction. Mean Radiant Temperature can be found from Plane Radiant Temperature as well.

(For a person standing)

$$T_r = \{0.08[t_{pr(up)}+t_{pr(down)}]+0.23[t_{pr(right)}+t_{pr(left)}]+0.35[t_{pr(front)}+t_{pr(back)}]\}\div[2(0.08+0.23+0.35)] \quad (5)$$

(For a sitting person)

$$T_r = \{0.18[t_{pr(up)}+t_{pr(down)}]+0.22[t_{pr(right)}+t_{pr(left)}]+0.30[t_{pr(front)}+t_{pr(back)}]\}\div[2(0.18+0.22+0.33)] \quad (6)$$

Radiant Temperature Asymmetry (Ä t_{pr}), is the difference between Plane Radiant Temperatures of the opposing surfaces. Sometimes the direction of the heat flow is given as from this surface to that surface, eg from the floor to the ceiling. If the direction has not been mentioned it is assumed as the direction which gives the maximum difference.

With this method it is possible to compare some building elements. In order to compare them air temperature, relative humidity, air velocity, mean radiant temperatures should be measured continuously at least for one year on test houses. The index also requires the values of thermal insulation of the clothing, activity level of the human body, and the instantaneous heat storage of the human body due to the activity level.

RESULTS AND DISCUSSION

A number of assumptions should be made to simplify the experiments.

1. As a person moves inside a building the angle factor will also change. Since in these experiments, we aim to compare either some buildings or some building elements, it can be reasonable to find the thermal sensation for a person sitting on a chair at the center of the space each time.
2. Average clothing values will normally change between summer and winter. Thus for November, December, January, February, March and April (Winter months) average clothing value can be assumed 0.8 clo and for the other months it can be assumed 0.5 clo.
3. Human activity level can be taken as 1.3 met which characterizes a person in rest or with light activities.
4. Air change number can be assumed 0.15 for summer and 0 for winter months or the actual measured values can be used.

With the data obtained at least for one year, a number of criteria can be tested. One of them is the yearly total of the absolute values of PMV. When the internal space is cool PMV will have a negative value and when it is warm PMV will be positive. Building or building element with the least total PMV absolute value has the best performance. These can be shown on a graph. If the graph prepared for this purpose shows the yearly totals together with the overheated and under heated period totals it will be very useful. Under heated period is the period when the climatic conditions are below the thermal comfort conditions and overheated period is the rest of the year.

Another criterion can be, the yearly total time when the thermal comfort is achieved (that is the total time when PMV is between -0.5 ~ +0.5). The maximum values of the yearly total comfort time indicate the best performance.

Yet another criterion can be to find the behavior of the building, on typical days of the year like 21st of July (summer), 21st of January (winter), 21st of April (spring) and 21st of October (autumn).

All of these criteria can be tested for non-air-conditioned, continuously air conditioned and intermittently air conditioned conditions. The method was applied to study the performance of fourteen roof constructions for a warm climate (OZDENIZ & HANCER, 2005). The best performed roof construction depends on how the building is used and air conditioned.

CONCLUSIONS

Thermal comfort approach in energy conservation studies puts the human beings on the front row, rather than the energy cost. We can reach to better conclusions to suit the wellbeing of the users with this approach. Certainly a number of assumptions can be made for the ease of the computations. More accurate results can be derived, if the assumptions are close to the actual conditions.

Another advantage of the method is to show which building elements use the solar heat gain effectively. Sometimes solar heat gain effects thermal comfort positively, as in the cool season. Sometimes its effect is negative, as in the warm season. Thermal comfort approach considers this phenomenon.

SUMMARY

In order to improve thermal comfort in the Rotunda, which is high and wide visiting space of the new national museum of Korea, eight ventilating fans were installed near the ceiling of Rotunda. It has been analyzed thermal comfort of Rotunda with/without ventilating fans by numerical simulation. To evaluate thermal comfort of the Rotunda, well-known indices, PMV and PPD were introduced. The results of present investigation show that temperature distribution of the case with fans is closer to target temperature than the case without fans at the breathing zone. In the case without fans, thermal stratification with 16℃ of temperature difference occurs along the height of the Rotunda which makes the thermal environment worse and the PPD values reach up to 50% in the 6th floor connection passage. In the case with fans, however, the vertical temperature difference was reduced to 9℃ and the PPD values were lower below 20%. Consequently, the ventilating fans adopted on this study are effectively used for improving the thermal comfort in large space structure with thermal stratification.

INTRODUCTION

Recently, as the living standard increases and the building technique develop, construction of large-space buildings has been increasing. Such structures accommodate gymnasiums, theaters, waiting rooms, aquariums, conference halls, and so forth, and most of them have the form of high ceilings and large open spaces. In these large buildings, glass is usually used as a roof or wall material to ensure a fine view and save energy. Such transparent outer wall materials as glass create environment-friendly outdoor atmospheres and bring in natural daylight, so they have advantages of not only producing cultural, economic and functional benefits from spatial characteristics, but also providing a visual sensation and freshness. But, it has a disadvantage of weakening the resistance to changes in the external environment, such as solar radiation or outdoor conditions rapidly worsen the indoor thermal environment. Also, it may have inefficiencies, such as thermal buoyancy has a great effect on indoor air flow, and the ratio of residing area to entire space reduces. In a large space, particularly in summertime, radiant heat from the roof or sidewall and thermal stratification in the interior may cause thermal discomfort to occupants. Thus, further studies of air conditioning and thermal environments are needed to predict the characteristics of air and temperature distribution in large spaces and present or solve such problems.

As a large-space structure, the Rotunda, the lobby of the National Museum of Korea currently under construction, serves as a traffic line to other spaces, a lounge, a meeting place, and the

passages to exhibition halls; in addition, most sections are constructed with glass to create environment-friendly outdoor atmospheres for visitors and introduce natural daylight. Particularly in summer, since the radiant load by sunshine comes in from glass walls, it is necessary to predict the indoor thermal environment of the Rotunda in advance. To this end, a study has been conducted to evaluate the thermal environment in case of introducing a ventilating system into its existing design and suggested that a plan should be prepared to solve the phenomenon of thermal stratification near the ceiling[1].
Therefore, this study introduces the technique of computational flow dynamics and analyzes the thermal environment of the Rotunda in summertime, with a view to investigating the adequacy of the ventilating fan installed as a plan to eliminate the thermal stratification.

THERMAL EVALUATION METHOD

Indoor thermal comfort or discomfort indicates a mental state that occupants feel in a given thermal environment, and some standardized methods for evaluating thermal comfort or discomfort have been suggested. This study uses the predicted mean vote (PMV) and predicted percentage of dissatisfaction (PPD) indices to evaluate thermal comfort. Detailed procedures for computing these indices are based on ASHARE Handbook [2]. Among the data necessary for PMV calculation in case of air conditioning in this study, other parameters than air current, temperature and mean radiant temperature are computed as shown in Table 1, which takes into account the viewing condition of the museum in summer.

Table1 Engineering data to estimate PMV

Parameter	Values
Metabolic rate	1.2met
Clothing value	0.5clo
Relative humidity	50%

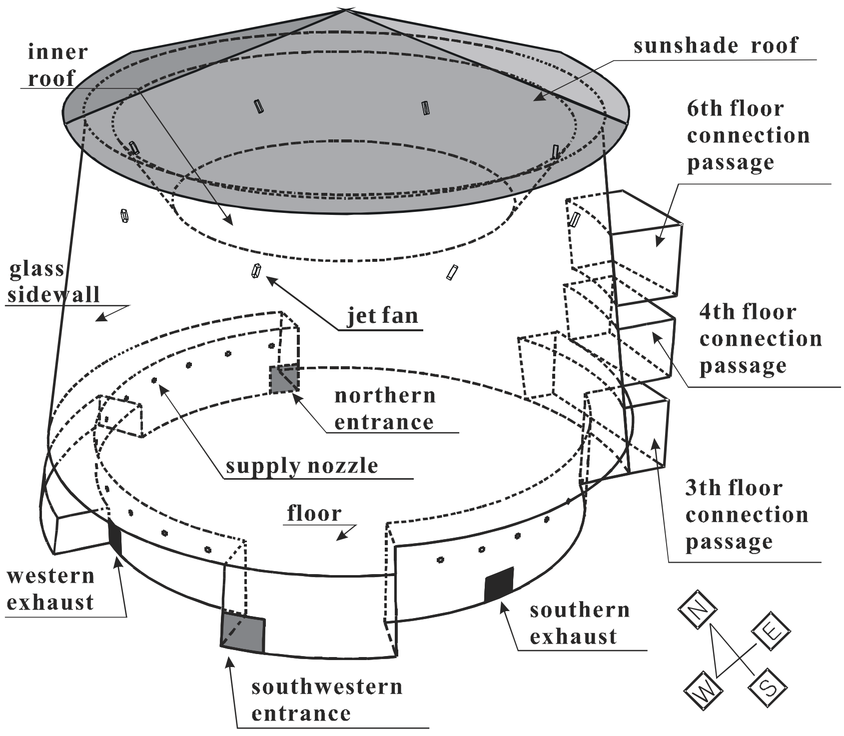

Fig. 1 Schematic diagram of the Rotunda

RESEARCH MODEL

Fig. 1 shows the schematic diagram of the Rotunda to be examined in this study. It has a shape of truncated cone with the greatest diameter of 48m and the greatest height of 38m. As shown in the figure, it consists of floor, glass sidewall, ceiling and sunshade roof and connected to the passages to adjacent exhibition halls.
To air-condition the interior in summer, the Rotunda has 21 supply nozzles along its edge and two exhausts in the south and west, respectively. The detailed characteristics of its interior structure, ventilation system and air conditioning load are the same as in the previous study[1]. Table 2 shows the details of summertime air conditioning load for this research model. The cooling load imposed to the glass sidewall by solar radiation is 91.14kW, about 54.5% of the total cooling load of 167.33 kW. We assume that among this, 30% is applied to the sidewall and the remaining 70% permeates the sidewall and is applied to the floor. Also, we assume that the load of 34.38kW caused by the lighting equipment installed around the glass roof of the Rotunda occurs entirely at the underside of the glass roof; the indoor sensible heat caused by visitors, a total of 8.62kW, is applied to the floor. Sine the latent load is the evaporation heat that occurs by evaporation of indoor moisture, it just increases indoor humidity but not indoor temperature. Thus, this study assumes that it is dealt with the air conditioner and thus does not include it in the cooling load.
To eliminate the phenomenon of thermal stratification, eight ventilating fans are installed on the ceiling at equal angles. Horizontally, they lean toward an adjacent fan clockwise; vertically, they are installed at 25° downward. The discharging air velocity and air volume of each fan are up to 17.5m/s and 3,000 CMH, respectively.

Table2 Cooling load in the rotunda (unit: kW)

Location	Cooling loads
Inner roof	7.07
Glass sidewall(by conduction)	17.33
Glass sidewall(by radiation)	91.14
Floor	8.79
Lighting equipments	34.38
Sensible heat gain by the gallery	8.62
Total	167.33

NUMERICAL ANALYSIS METHOD

The governing equations of a normal state that describes the characteristics of air current and temperature in the Rotunda chosen in this study are continuity equation, momentum equation, turbulent kinetic energy equation, dissipation rate equation of turbulent kinetic energy, and energy equation, whose details are the same as in references[1].
This study uses the commercial CFD code, FLUENT, to interpret the governing equations mentioned above[3]. While the non-staggered grid system is used for analysis of velocity and temperature field, the staggered grid system is introduced for proper prediction of the rapid

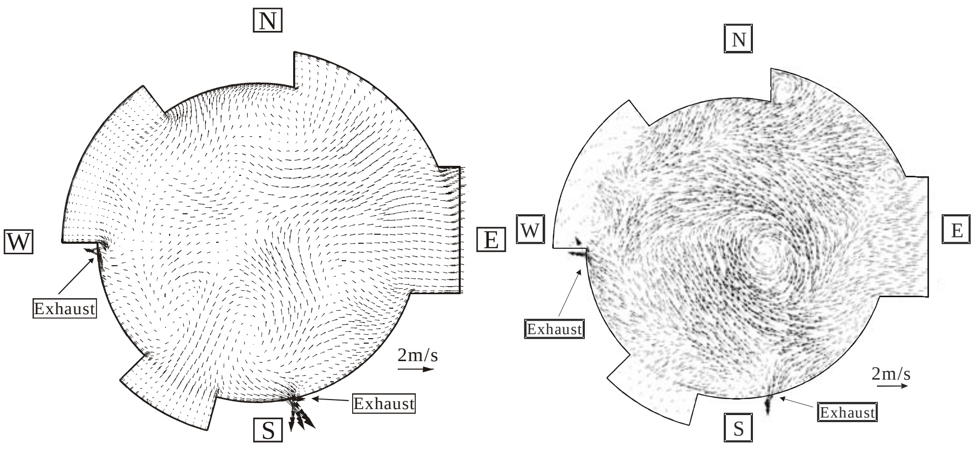
changes in pressure values occurring around the wall due to the load through the wall surface[4].
Table 3 shows the details of the boundary condition defined with the governing equations.

Table3 Boundary conditions for present study

Location	Conditions
Roof	$u = v = w = 0$, $q = 30.9\,\mathrm{W/m^2}$
Glass sidewall	$u = v = w = 0$, $q = 11.0\,\mathrm{W/m^2}$
Floor	$u = v = w = 0$, $q = 59.6\,\mathrm{W/m^2}$
Passages	$\frac{\partial u}{\partial n} = \frac{\partial v}{\partial n} = \frac{\partial w}{\partial n} = 0$, $\frac{\partial T}{\partial n} = 0$
Supply nozzle	$V_n = 6.6\,\mathrm{m/s}$, $T = 18$℃
Ventilating fan	$V_n = 17.5\,\mathrm{m/s}$(3000CMH)
Southern exhaust	$V_n = -1.62\,\mathrm{m/s}$, $T = 26$℃
Western exhaust	$V_n = -1.875\,\mathrm{m/s}$, $T = 26$℃
Entrance	$u = v = w = 0$, $q = 0.0\,\mathrm{W/m^2}$

RESULTS AND DISCUSSION

In a previous study of the indoor thermal environment of the Rotunda equipped with the initial ventilation system, we could observe that the dead air occurring in the upper part of the Rotunda severely worsens the thermal environment around the 4th and 6th floor passages. To mend this problem, this study explores the effects of the ventilating fans designed to mix the indoor air evenly across the entire room. To this end, we select as checking points the horizontal plane at the breathing zone (1.5m high from the floor) and the vertical plane at the center of the Rotunda. We examine the distributions of air, temperature and PMV/PPD at these checking planes.



(a) Without ventilating fans (b) With ventilating fans

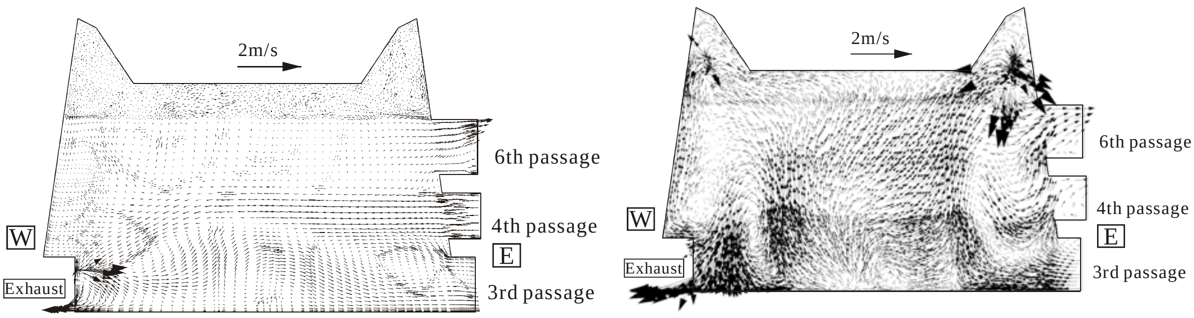
Fig. 2 Distributions of velocity vectors at breathing zone of the Rotunda

EVALUATION OF AIR ENVIRONMENT

To examine the effects of ventilating fans on the indoor thermal environment of the Rotunda during air conditioning in summer, we depict in Fig. 2(a) and (b) what distributions the air has at the breathing zone of the horizontal plane, whether or not ventilating fans are installed.

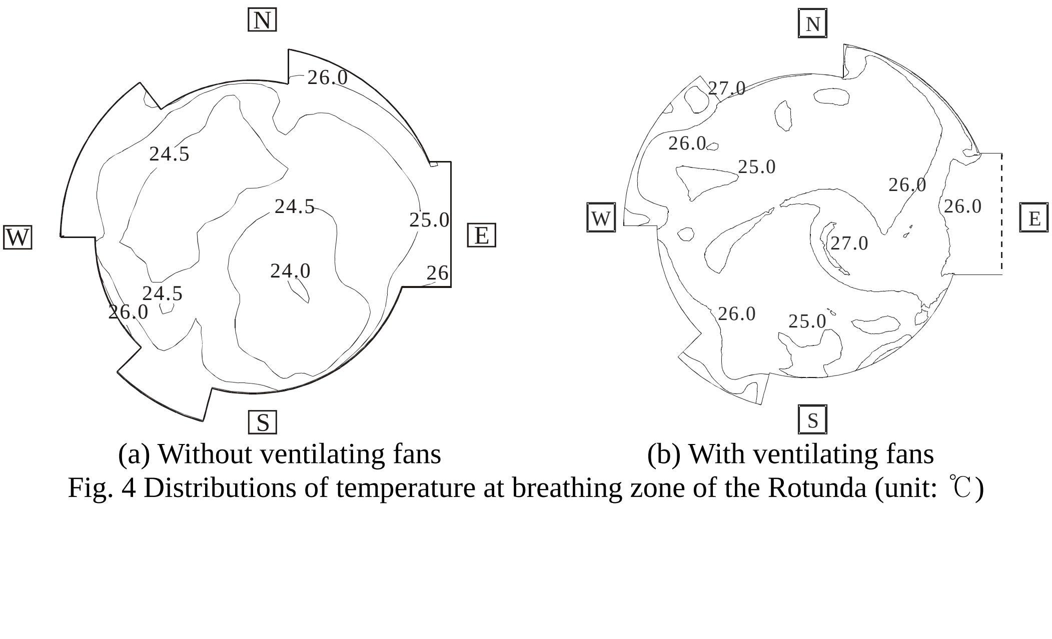
The results of air flow analysis reveal that the average wind velocity at the breathing zone increase by about 0.2m/s when the fans are installed, so the velocity at the breathing zone shows a range of 0.2 ~ 0.6m/s. As shown in Fig. 2(b), there is few area of dead air. But, because of the direction of the ventilating fans, the air flow is characterized by swirling clockwise centering the middle point of the Rotunda. This swirling flow is more active in the north and south, while somewhat weak around the 3rd connection passage and the exhausts. However, an area of dead air takes place in the center of swirling flow, so the cool air supplied form the supply nozzles cannot properly reach there, probably increasing the temperature a little. It is thought that the overall environment of air flow may provide satisfactory viewing conditions with visitors.

Fig. 3 shows the distributions of air currents at the vertical plane, with or without ventilating fans. Without ventilating fans, most of the air accumulates at the height of above the 4th connection passage; however, with ventilating fans installed, the indoor air rises or falls everywhere in the Rotunda, indicating that it circulates smoothly. This smooth rising and falling of the air is due to the effects of the ventilating fans installed on the ceiling. Thus, we can expect that these effects of ventilating fans will reduce the phenomenon of thermal stratification that results from the disproportionate air distributions between the upper and lower parts in a high-storied large space.



(a) Without ventilating fans (b) With ventilating fans

Fig. 3 Distributions of velocity vectors at vertical plane of the Rotunda



(a) Without ventilating fans (b) With ventilating fans

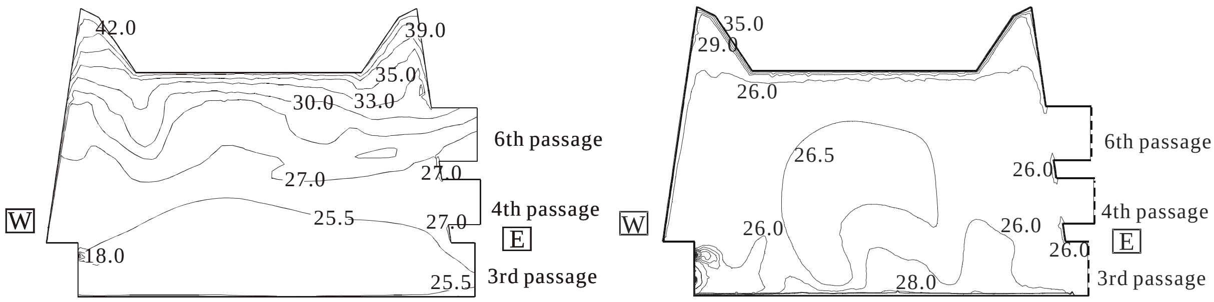
Fig. 4 Distributions of temperature at breathing zone of the Rotunda (unit: ℃)

EVALUATION OF THERMAL ENVIRONMENT

To examine the characteristics of temperature distribution in the Rotunda, we depict in Fig. 4(a) and (b) the temperature distribution in the same plane as we examined the distribution of air flow.

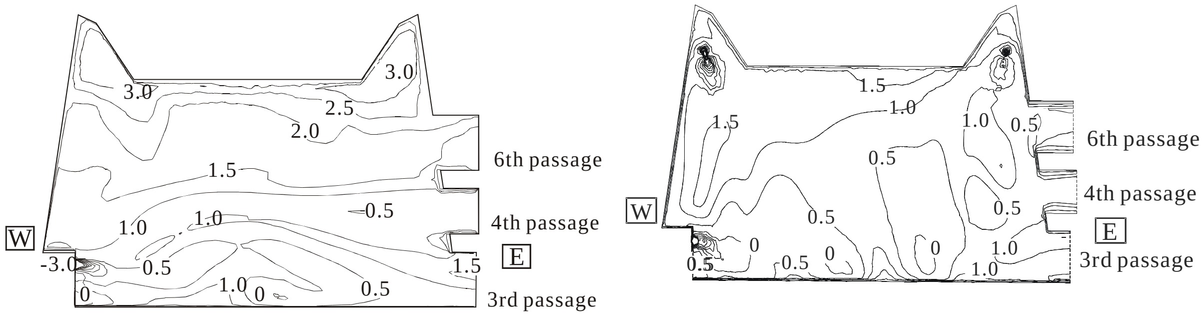
As shown in Fig. 4(a), without ventilating fans, the temperature distribution at the breathing zone shows 26℃ around the northeastern and northwestern walls, but the remaining areas have a range of 24 ~ 25℃, which is a little lower than the temperature of 26℃ set as an indoor temperature by air conditioning. This is because the cold air supplied by the supply nozzles for eliminating cooling load does not circulate all over the space but arrives only at the lower part (lower than the 4th connection passage).

In contrast, with the ventilating fans installed, as shown in Fig. 4(b), most areas have a temperature of about 26℃. Presumably, this is because ventilating fans circulate properly the air in the interior of the Rotunda. The reason that the areas of southern entrance and northwestern wall have a temperature of 27℃ is that most of the air diffused from the wall moves by forming a swirling air flow but recirculates there on a small scale. This phenomenon of air recirculation also takes place at the center of the Rotunda, thus showing a temperature distribution of 27℃.



(a) Without ventilating fans (b) With ventilating fans

Fig. 5 Distributions of temperature at vertical plane of the Rotunda (unit: ℃)



(a) Without ventilating fans (b) With ventilating fans

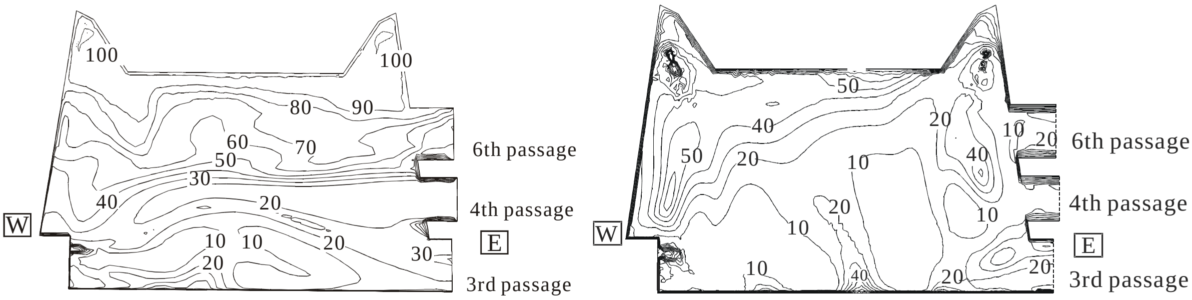
Fig.6 Distributions of PMV at vertical plane of the Rotunda

To examine how much the ventilating fans improve the phenomenon of thermal stratification at the upper region of the Rotunda, we depict in Fig. 5(a) and (b) the temperature distributions at the vertical plane of the Rotunda with ventilating fans installed and not installed.

As shown in Fig. 5(a), while a swirling air flow takes place, the lower region of the Rotunda has a temperature of about 25℃, which is thought to be an agreeable viewing environment in summer; however, the temperature near the roof where dead air exists reaches up to 42℃, thus showing a large difference of 16℃ in temperature between the upper and lower regions. This is probably because the radiant heat through the glass roof warms the indoor air of the

Rotunda. This temperature distribution is a common thermal characteristic in a high-storied large space where a ventilating system is not introduced.
In comparison, with ventilating fans installed, as shown in Fig. 5(b), because a swirling airflow takes place all over the space, the lower region as well as the upper region shows a temperature distribution of about 26C. Though some regions show a temperature of over 30℃, they are very small. This is because the ventilating fans mix properly the indoor air.

EVALUATION OF COMFORT INDEX
To evaluate the comfort sensation that the indoor environment of the Rotunda provides for visitors, we examine the distributions of PMV and PPD frequently used for comfort evaluation.
To examine how much ventilating fans improve the indoor thermal environment by solving the phenomenon of thermal stratification in the upper region of the Rotunda, we depict the distribution of PMV at the vertical plane of the Rotunda in Fig. 6(a) and (b), and the distribution of PPD at the same location in Fig. 7(a) and (b), with and without ventilating fans.



(a) Without ventilating fans (b) With ventilating fans
Fig.7 Distributions of PPD value at vertical plane of the Rotunda (unit: %)

As shown in Fig. 6(a), without ventilating fans, the PMV indices at the residing place, the third passage and the passage to the Gallery of History have a range of 0 ~ 0.5, indicating that these areas are regarded thermally comfortable. Also, the PMV at the 4th passage reaches up to 1, which is thought to be a relatively appropriate environment for visitors; however, that at the 6th passage shows more than 1.5, which is thought to be a disagreeable environment that visitors feel hot.
If ventilating fans are installed as shown in Fig. 6(b), the PMV indices at the residing place, the third passage and the passage to the Gallery of History have a range of 0 ~ 0.5, which is regarded thermally comfortable. Since the PMV at 4th and 6th passages shows up to 1, these areas are also thought to be a relatively suitable for visitors.
As shown in Fig. 7(a) describing the predicted percentage of dissatisfaction (PPD) in a given thermal environment, we can see that if ventilating fans are not installed, the PPD value at the residing area of the Rotunda is about 10%, indicating that visitors will be able to feel comfortable. The PPD at the 3rd and 4th passages is 20%; thus it can be said that considering these are part of the museum, they are a relatively suitable thermal environment. However, the 6th passage shows about 50% of PPD. This means that 50 out of 100 visitors express dissatisfaction with such a thermal environment. Probably, this results from the effects of the thermal stratification that takes place at the upper region of the Rotunda.
If ventilating fans are installed as shown in Fig. 7(b), the PPD at the residing place in the lower part of the Rotunda is about 10%, indicating that visitors will be able to feel comfortable. The 3rd, 4th and 6th passages show 20% of PPD. This means that considering

these are part of the museum for visitors, such a condition is a relatively agreeable thermal environment.
Thus, it can be concluded that if we install ventilating fans and generate the recirculation air through the Rotunda, we can easily solve the problem of the dead air that take place at the upper region of the Rotunda with no ventilating fan installed.

CONCLUSION

To prevent the worsening of thermal environment due to the dead air occurring at the upper region of the Rotunda in summer, this study has analyzed the distributions of air and temperature in the Rotunda with ventilating fans installed, using the commercial CFD code, FLUENT, and conducted evaluation of thermal environment with PMV and PPD. Thus, we have derived the following results.
(1) If ventilating fans are not installed, the temperature distributions at the breathing zone show a range of 24 ~ 25℃, which is a little lower than 26℃, the temperature set as an indoor air conditioning in summer; if ventilating fans are installed, the temperature distributions shows about 26℃.
(2) At the vertical plane on the center of the Rotunda, with no ventilating fan installed, the temperature difference between the upper and lower regions is large, about 16℃; with ventilating fans installed, the air circulates smoothly across the space so that the temperature distributions show about 26℃ not only in the lower region but also in the upper region.
(3) With no fans installed, since the dead air occurs in the upper region of the Rotunda, it is predicted that thee 6^{th} passage will have about 50% of PPD; however, with ventilating fans installed, the PPD has reduced to about 20%. Thus, we can conclude that producing a swirling air flow in the whole Rotunda will be able to solve the worsening of thermal comfort satisfactorily.

SUMMARY

The operating conditions of a personal air-conditioning system in repeated subjective experiments were determined. When the right to adjust or control the environment was provided, psychological acceptability improved according to the adaptive model. Although a psychological adjustment is the most effective, it is difficult to evaluate quantitatively. A personal air-conditioning system, called the “Cool Chair”, was developed and evaluated. The study simulated a situation in which the subjects have entered the office from a hot day in summer in Japan. The experiments were conducted five times under identical conditions and the subjects surveyed. As the settings of the Cool Chair were varied, the responses of the subjects were recorded. Results indicated that the adaptive model was appropriate for use of the Cool Chair.

INTRODUCTION

A personal air-conditioning system differs from a standard air-conditioning system because it focuses at a point of thermal comfort. Thermal sensation differs among people and depends on clothing, physical condition, and activity level. Therefore, providing an environment that provides comfort for everyone is difficult. A personal air-conditioning system allows individual workers to adjust the thermal environment. When a person is given the right to adjust or control their immediate environment, their psychological attitude improves. In addition, the ability to adjust the conditions improves thermal comfort.

An adaptive model that requires a voluntary and passive action was proposed by R. J. de Dear et al. [1]. The adaptive model involves three adjustment elements: behavioral adjustment, physiological adjustment, and psychological adjustment. Although a psychological adjustment is the most effective, it is difficult to evaluate quantitatively. In this experiment, the psychological adjustment was examined after the subjects learn about the Cool Chair’s operating method, properties, and effects. In this paper, the cooling effect of the Cool Chair was examined, and the operating conditions during repeated subjective experiments were observed.

METHODS

Cool Chair Description

A personal air-conditioning system, called the “Cool Chair”, was developed [2]. The Cool Chair is a chair-mounted isothermal airflow generator. It contains additional functionality compared to a standard chair. It can adjust the thermal sensation of the user by changing air velocity near the surface of the body. Sitting in a standard chair with a back is equivalent to wearing another long-sleeved shirt. In contrast, the Cool Chair provides a cooling effect [3, 4]. Figure 1 shows an external view of Cool Chair with two fans on the back. The fans are battery-powered. Air is drawn into the seat and the backrest and blows out through the armrests. Maximum air flow is 70 m^3/h. The air flow rate and direction are easily adjusted. Although, the power also turned on by the user with a switch in the right armrest, it can be turned on automatically by applying weight to the seat of the chair.

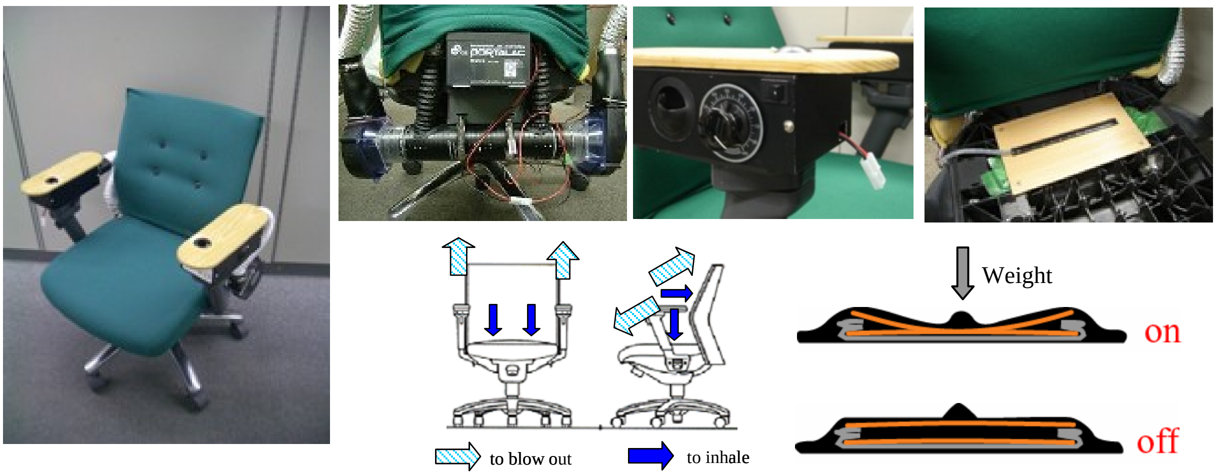

Figure 1. External view of Cool Chair.

Experimental Conditions

Subjective experiments were conducted from 11 December to 18 December in the climatic chamber at Kogakuin University in Japan [5, 6]. A schematic of the experimental room is shown in Figure 2. Eighteen male and nineteen female subjects of college age participated in the experiment. The thermal resistance of the male clothes was 0.64 clo and of the female clothes was 0.65 clo (Figure 3). The clothes of the male and female were chosen to simulate summer clothing in summer in Japan.

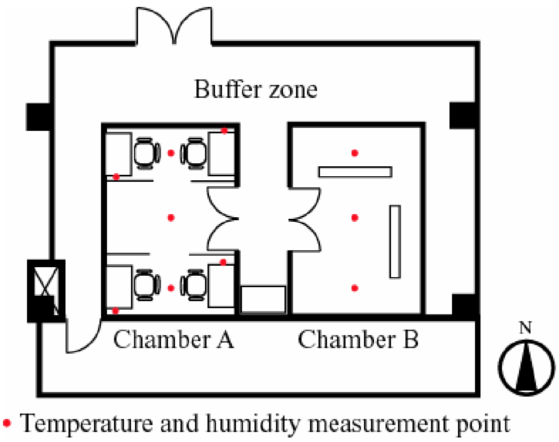

Figure 2. Plan of experimental room.

Figure 3. Subjects' clothes.

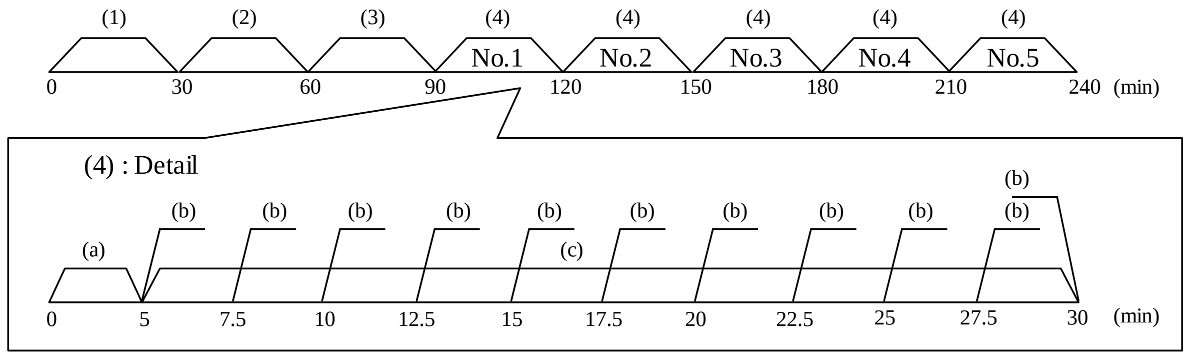
Outline of Experiments

Subjects were tested in the climatic chamber in groups of four. Experimental conditions simulated a situation in which the subjects enter the office during a hot day in summer in

Japan. Table 1 outlines the experimental conditions. The initial air temperature of chamber A was set at 28°C, 50% RH to simulate indoor conditions. All subjects were instructed to remain in the room for a certain period of time. Afterward, the subjects moved to chamber B, which had an ambient temperature of 33.4°C, 50% RH, which simulated outdoor conditions. The subjects were instructed to perform a step exercise with a metabolic value of 2.6 met. Then, the subjects moved back to chamber A and read a book. Figure 4 shows the experimental procedure. The subjects were tested under these two conditions using a standard chair and the Cool Chair. Each experiment lasted 30 min. A standard chair condition was executed once, the Cool Chair condition for the practice was once and the Cool Chair condition were fifth which are called from experiments No. 1 to No. 5. The subjects were allowed to use the chair freely during the experiment. The subjects provided information about thermal sensations (Thermal Sensation Vote, TSV) and comfort (Comfort Sensation Vote, CSV) every 2.5 min for 25 min (Table 2).

Table.1. Experimental conditions.

	Chamber A	Chamber B
Air-conditining method	Floor supply, return air flow through ceiling	Floor supply, return air flow through ceiling
Room airflow	Mild	Mild
Room air temperature	28.0 °C	33.4 °C
Mean radiant temperature	Equal to room air temperature	Equal to room air temperature
Relative humidity	50.0 %RH	50.0 %RH
Metabolic rate	1.0 met (addition test, reading)	2.6 met (step exercise)



(1) Entering into the Laboratory and Resting
(2) Using the Standard Chair
(3) Using the Cool Chair (Practice)
(4) Using the Cool Chair

(a) Step Exercise
(b) Addition Test
(c) Reading

Figure 4. Experimental procedure.

Table.2. Voting scales.

Declaration items	Voting scales
Thermal sensation Vote	-3 Cold, -2 Cool, -1 Slightly Cool, 0 Neutral, +1 Slightly Warm, +2 Warm, +3 Hot
Comfort sensation Vote	0 Comforta, -1 Slightly Uncomfortab, -2 Uncomforta, -3 Very Uncomfortab

RESULTS

Result of TSV and CSV

These mean values for males and females for TSV and CSV, while using the standard chair and the Cool Chair are shown in Figure 5 and 6. The TSV shifted toward neutral as male and female subjects compared the normal chair with the Cool Chair. CSV results indicated that subjects were more comfortable using the Cool Chair than using the standard chair. The results confirmed that TSV was improved using Cool Chair while CSV increased. TSV and CSV of experiments No. 1 and No. 5 were similar. Moreover, just after the step exercise ended (at the time of 0 minutes in the graph), TSV values were zero or less under two conditions. This experiment assumed that conditions accurately simulated an office environment. Thus, 28°C is considered a cool temperature for the subjects after moving from chamber B (33.4°C, 50% RH) to Chamber A (28°C, 50% RH).

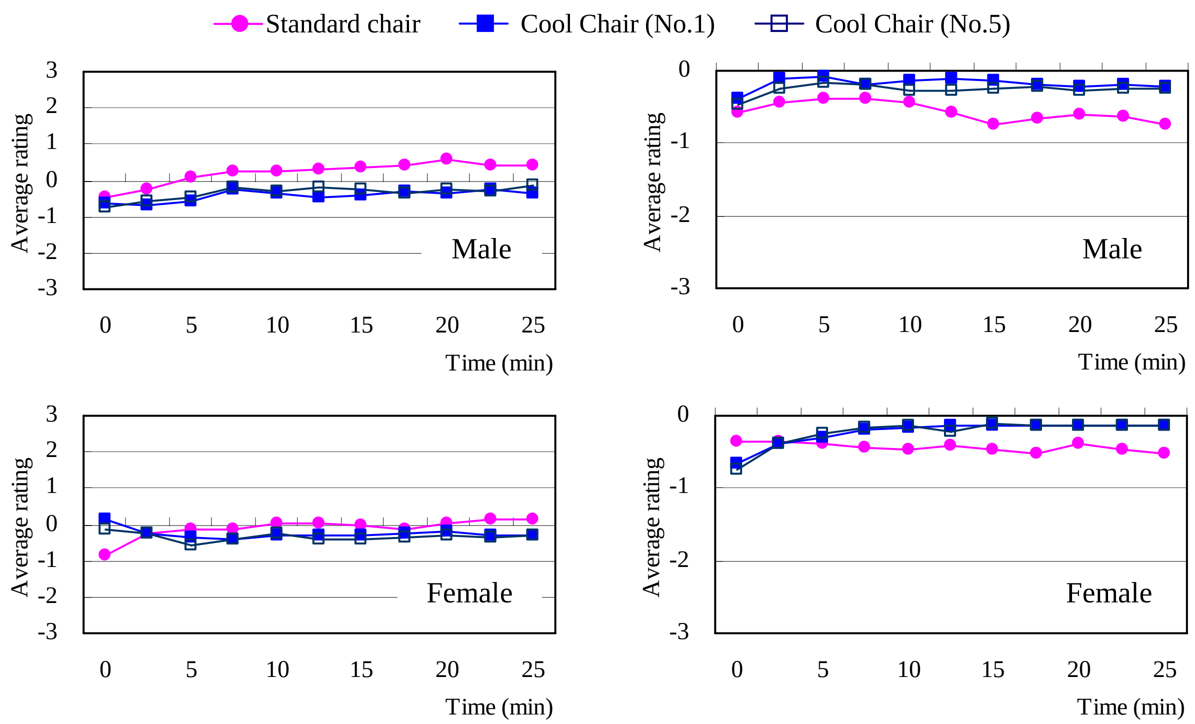


Figure 5. Thermal sensation vote.

Figure 6. Comfort sensation vote.

Air exposure

Figure 7 illustrates the parts where the subjects blowed the air flow. Both males and females preferred to blow the air toward the face and not toward the chest and stomach. The subjects also unexpectedly chose to blow the air toward the arms. Males and females reported facial dryness as shown in Figure 8. However, females adjusted the air flow rate much more often than did the males (Figure 9). Females mentioned clothes as the reason (although the clothes were similar for both males and females). Results indicated that the ability to adjust environmental conditions using the Cool Chair made the subjects feel comfortable. The negative aspect of facial dryness was offset by the comfort provided by the air flow.

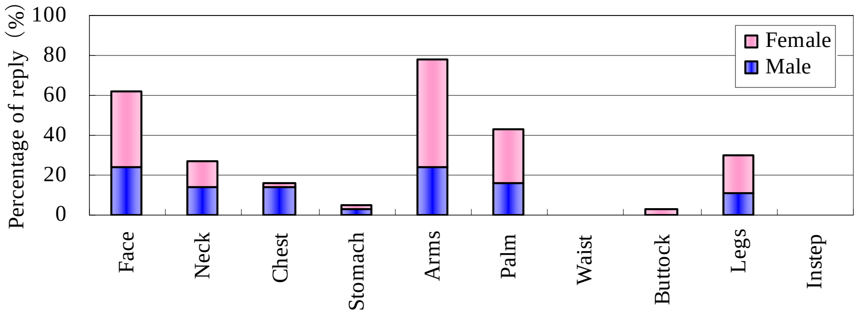

Figure 7. Air exposure parts.

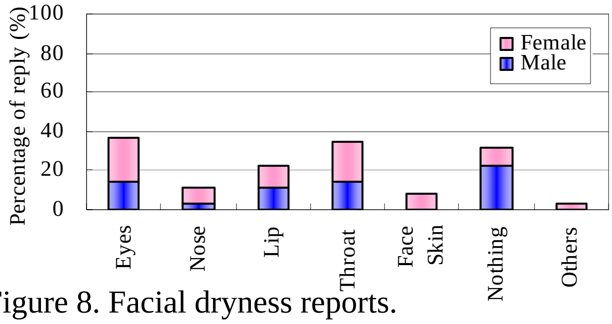

Figure 8. Facial dryness reports.

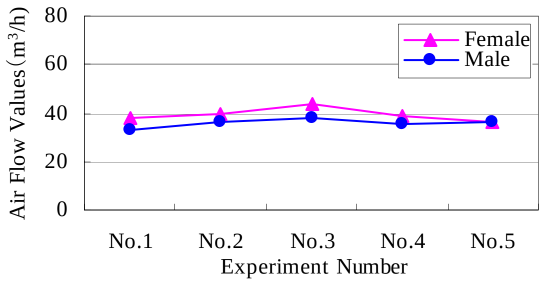

Figure 9. Air flow for each experiment.

Air flow rate

The adjustment of air flow rate was examined by calculating the interterminal voltage. The air flow rate for each subject was computed for each experiment based on values from experiment No.1. The correlation coefficient was calculated by flow rate and experiment number. A positive correlation coefficient indicated a tendency toward increasing air flow while a negative correlation indicated a tendency to decrease air flow. Figure 10 shows the distribution of every subject's correlation coefficient. They were not dependent on the gender of the subjects. Eighteen people decreased air flow from experiment No. 1 to No. 5 while f people increased it.

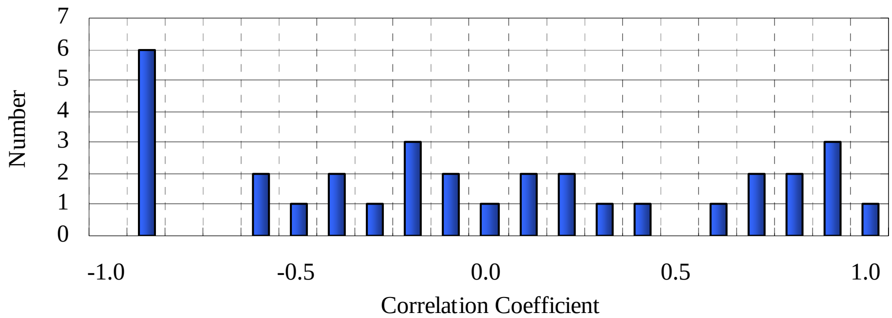

Figure 10. Distribution of correlation coefficients related to air flow rate change.

Adjustment frequency of Cool Chair

The relation between adjustment frequency of the Cool Chair and CSV was investigated. Figure 11 shows the dispersion from CSV value for each adjustment frequency. The dispersion shows as a standard deviation. The adjustment frequency of each subject was calculated. If the difference between two air flow values taken each 2.5 min was at 10 m^3/h, the subjects were considered to have adjusted the Cool Chair. A value of 10 m^3/h for air velocity corresponds to 2 m/s blown out. Both males and females showed the similar tendency. The most frequent subjects' correlation coefficient was higher than the few one.

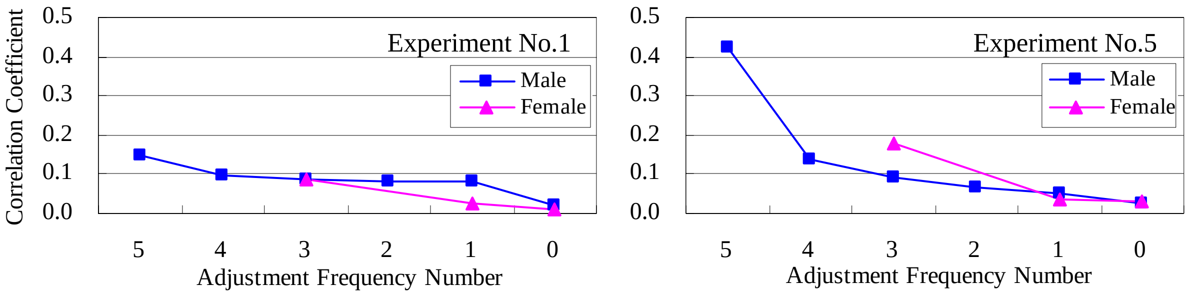

Figure 11. Relation between adjustment frequency and dispersion from CSV.

DISCUSSION

It was difficult to prove conclusively that the psychological adjustment occurred during the repeated experiments. However, subjects who were allowed to adjust the thermal environment produced the following results:

1) In a 28°C room, the TSV shifted from warm to neutral, and the CSV shifted from uncomfortable to comfortable by using the Cool Chair.
2) The subjects who felt comfortable at the first air flow value did not adjust the Cool Chair very often while the subjects who did not feel comfortable tended to adjust the Cool Chair several times to achieve the best thermal environment.
3) The subjects did not decrease air flow after achieving thermal comfort when they understood the properties of the Cool Chair in the repeated experiments.

For this experiment, psychological adjustment was assumed to occur after the subjects understood the Cool Chair's use, properties, and effects. Therefore, the air flow rate was decreased whenever the experiment was repeated. The experiment results indicate no difference in TSV and CSV between experiments No. 1 and No. 5; in addition, the tendency in adjustment frequency did not change from experiment No. 1 to No. 5. For these reasons, operating method and efficiency and subject understanding did not appear to affect results of experiments repeated only five times.

ACKNOWLEGEMENT

This research is supported by Academic Frontier Project for Private Universities from Ministry of Education, Culture, Sports, Science and Technology.

Technical Solutions for Reduction of Heat Stress in Animal Houses

Hans-Joachim Müller and Reiner Brunsch

Leibniz-Institute for Agricultural Engineering e.V. (ATB), Germany

Corresponding email: hmueller@atb-potsdam.de

SUMMARY

Today, especially in the developed industrialised nations, we have a high standard of food supply for the population. In these societies people are asking increasingly how and under which conditions their foods are produced. These questions relate above all to the complexes of animal health and animal management conditions, product quality, and influences on the environment caused by animal production. One problem in this connection is the high air temperatures together with high air humidity. There are not only in hot climates but also in Germany high temperatures during the summer period. These extreme climate conditions lead to reduction of animal performance. Technical solutions to reduce the heat stress are existing. For cattle, pigs and poultries different solutions will be presented and evaluated.

INTRODUCTION

The production of animal products serves on the one hand to supply the population with vital foodstuffs such as milk, eggs and meat. On the other hand, raw materials are also produced for various branches of industry, such as the pharmaceutical and leather industries. The prerequisites for this have been created in a development that has been going on for millennia. We left the age of "hunters and gatherers" some 15 000 years ago. Since then humans have pursued arable farming and cattle breeding and developed these steadily further. The starting point for developments in the field of animal management was the domestication of wild animals. The industrialisation in the last two centuries and the accompanying enormous further development in technical and scientific fields have also led to continuous further development in the field of animal management. Now it is not possible to say from the outset that animal welfare and environmental protection are necessarily neglected by the introduction of modern technology, new management systems, and the use of modern control and animal monitoring systems. There are certainly many positive examples in which these new techniques lead to improved animal welfare and lower environmental pollution. Despite this, the growing interest of the population in animal welfare and environmental protection is clearly evident. Therefore the questions of microclimate in animal houses, animal welfare, animal performance and economy play an important role in developing of new animal keeping systems including livestock building and ventilation systems.

Hot weather periods are one problem in this connection. High air temperatures together with high air humidity increase the heat stress for the animals. In Germany during summer there are high temperature values – 32 °C as maximum values of the day. For example during the summer 2006 we had in Germany a long period with maximum temperature values up to 40 °C outside. The high animal performance requires a reduction of heat stress. The demanded climate parameters inside animal houses are described in the German standard DIN 18 910 “Thermal insulation for closed livestock buildings”. This standard considers the thermo regulation system of the different kinds of animals. The scientific work has to develope technical solutions for a good thermal comfort especially for high yielding animals. Some examples are shown in this paper for different kinds of animals.

BACKGROUND

Influence factors on microclimate in animal houses

The main influencing factors on climate in animal houses are shown in the figure 1.

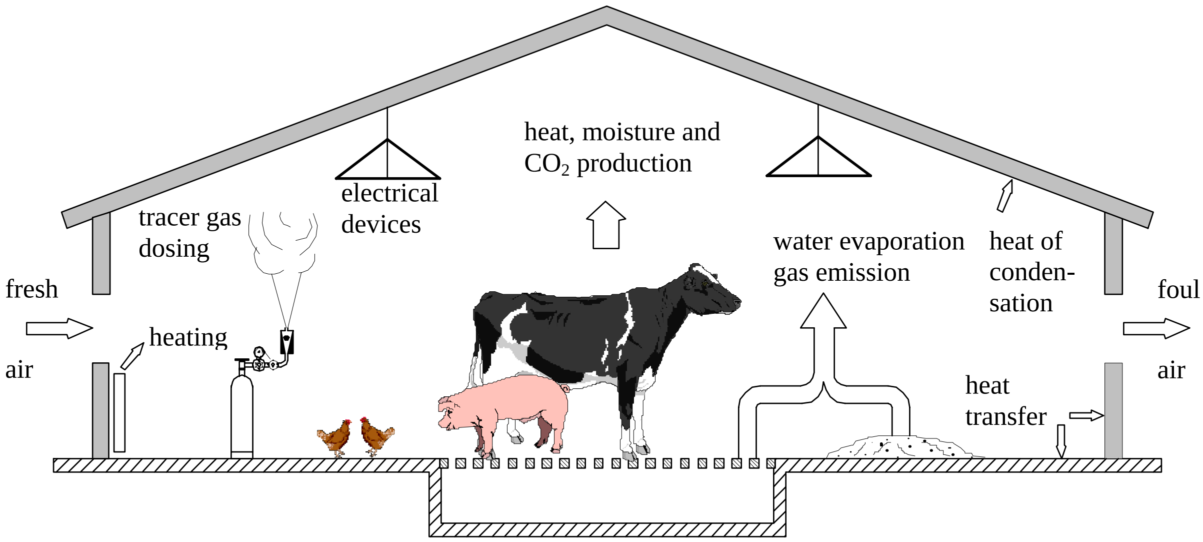

Figure 1. Schematic representation of the most important heat and substance flows for an animal house.

Additional parameters are:

Sun radiation in day time; Building orientation and shading; Outdoor temperature and outdoor humidity; Air velocity inside and outside; heat capacity of structure and floor.

More information regarding heat, moisture and CO_2 production can be found in [1]. Another factor is the diurnal variation in animal heat production. This variation results from the animal activities which are influenced by the light regime and feeding management and other management factors.

Thermal comfort index

The definition of thermal comfort for animals is much more difficult than for humans. In the literature are to find different models to evaluate the different influencing factors such as temperature, humidity and velocity, with a so-called "Thermal comfort index". A buildup of different approaches can be found in [1]. For broilers Tao and Xin [2] for example name the following equation:

$$THVI = (0.85xDBT + 0.15xWBT)xV^{-0.058} \qquad (1)$$

Where:
THVI = Temperature-Humidity-Velocity Index
DBT = Dry bulb temperature (°C)
WBT = Wet bulb temperature (°C)

V = Wind velocity

Evaluating the impact of specific climate parameters on animal performance is a difficult task combining the relationship between animal performance and thermal environment is needed. For that special investigation are necessary. The general analysis of impacts can be based on the animal response.

Possibilities for heat stress reduction

The main influencing factors on heat stress are temperature, humidity and velocity of the air and the direct solar radiation in the animal zone. If in the summer period the temperature increases during the course of day the air volume stream must be enhanced to dissipate the heat produced by the animals. Does exceed the temperature demanded critical values than the climate conditions for the animals can be improve by increasing the air velocity in the animal zone. Table 1 show, at which value the critical temperature values can be overstepped by increasing the air velocity.

Table 1. Cooling effect in K by increasing the air velocity in the animal zone [3] based on [4]

Temperature in °C	25		30		35	
Relative humidity in %	50	70	50	70	50	70
Air velocity in m/s	Cooling effect in K					
0.00	0.00	*-1.60*	0.00	*-2.20*	0.00	*-3.30*
0.50	1.10	*-0.50*	2.80	*-0.60*	2.80	*-0.50*
1.00	2.80	0.60	5.00	2.20	8.40	4.50
1.50	3.90	1.70	6.60	3.90	10.60	6.20
2.00	6.20	3.90	8.30	5.00	11.70	8.90
2.50	7.30	5.10	9.40	6.10	12.80	10.60

Depending on the room temperature the air velocity is recommended for cattle (Table 2).

Table 2. Recommended air velocity for cattle [5]

Temperature in °C	≥ 10	13	16	19	20	21	22
Air velocity in m/s	0.1	0.1	0.2	0.3	0.4	0.5	0.6
Temperature in °C	23	24	25	26	27	28	30
Air velocity in m/s	0.7	0.8	0.9	1.0	1.2	1.3	2.5

Technical possibilities to reduce the thermal load of the animals are the following:

- Reduction of solar radiation (shadow / insulation)
- Evaporative cooling systems
- Increasing of the air velocity in the animal zone
- Using heat store capacity of the ground
- Technical cooling systems

Selected technical solutions are described in the following text and the results of the investigations are shown. These investigations were carried out in cattle, pig and poultry houses.

METHODS

Especially the air temperature, the air humidity and the air velocity is measured inside the building. The air flow pattern are observed by smoke generator and recorded by video camera. The measured parameters are arranged in Table 3.

Table 3. Measured climate parameters inside the building

Parameter	Measurement technology
Temperature	Data logger (course); Portable measuring instrument (short term measuring)
Relative humidity	Data logger (course); Portable measuring instrument (short term measuring)
Gas concentration	Multi-Gas-Monitor (course measuring)
Air velocity	Portable measuring instrument (short term measuring)
Air flow pattern	Visualisation by smoke generator
Air volume stream	Portable measuring instrument (short term measuring); Measuring fan (long term measurement)
Air exchange rate	Tracergas method using tracer gases CO_2, SF_6 and Krypton 85

The air movement can be characterised by velocity measurements and observation by visualisation of the air flow pattern by smoke – these images can be recorded by video camera and analysed by Computer – Image- Analysis. For measuring the air exchange rates to calculate the emission streams the ATB has developed special tracer gas methods [6]. The advantage of using Krypton 85 (radioactive inert gas) is a high resolution in time and place, especially for complicated flow conditions.

RESULTS

Cattle houses

Nearly all cattle houses are naturally ventilated. In these livestock buildings the increasing of air velocity are used to reduce the heat stress for the animals. This increasing of air velocity can be achieved by additional fans. The different solutions are shown in Figure 2.

a) Cross ventilation: the fans are installed in one or both side walls and blow the fresh air from one side to the other side.
b) Vertical ventilation: ceiling fans blow the room air in direction of floor.
c) Step-by step ventilation: this system is a recirculation system. The air will be sucked by the fan and will be blown to the next fan. The fans are directed in this way that she are blowing slant in the animal zone. Figure 3 shows the reachable air velocities for different arrangements of the fans.
d) Tunnel ventilation: Gable fans suck the air trough the building. The air inlets are arranged in the opposite gable. The principle is used in the USA but the large cross sections of cattle barns in Germany lead to not enough high velocities in the animal zone.

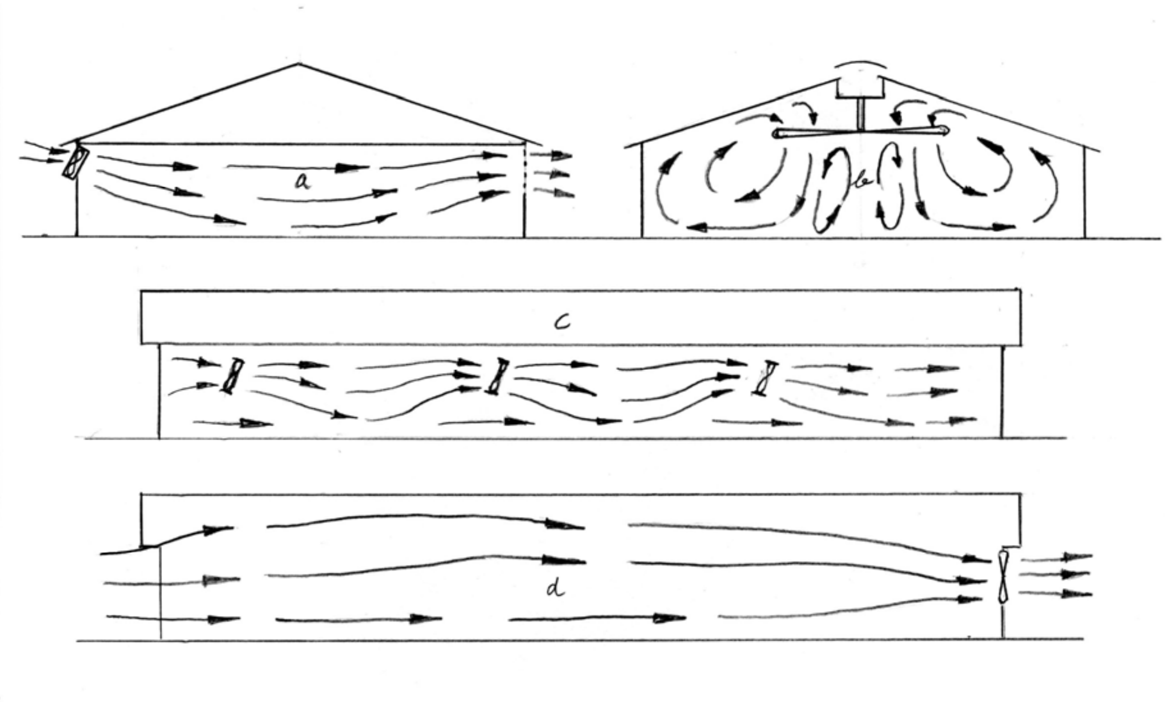

Figure 2. Different solutions for additional ventilation in cattle houses.

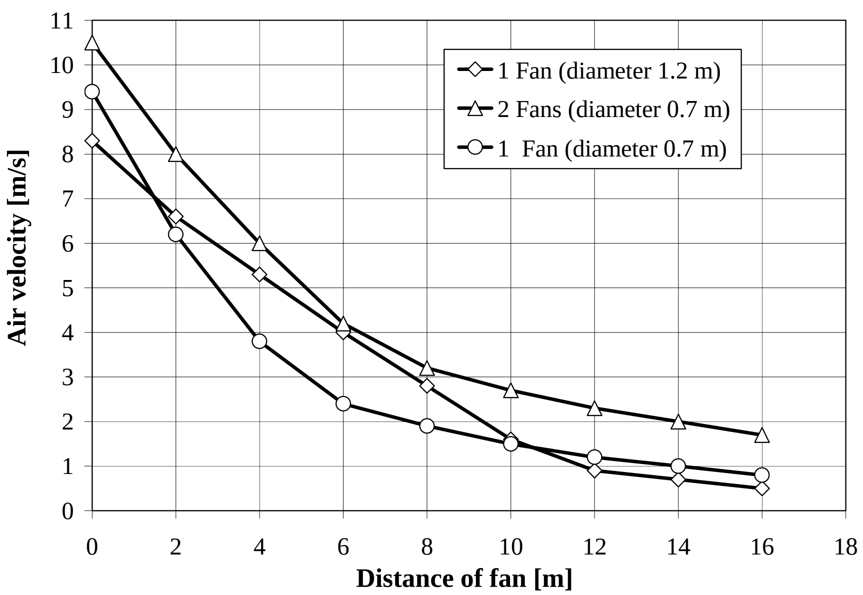

Figure 3. Air velocity on the air jet axis depending on the distance from the fan (different arrangements).

The own measurements in a naturally ventilated cow shed show, that the air velocity in the animal zone is strongly influenced by the outside wind situation. On 04 May 2006 the air velocity were measured in the animal zone with three different speed steps of the ceiling fan (speed step 1; 4.5; 9). Figure 3 shows the fan (left) and an example for speed step 4.5 (right). Directly under the fan the air comes up and the velocity is low (0.5 – 0.6 m/s). In a distance between 3 m and 6 m the air velocity increases up to 1.2 m/s. In a bigger distance the velocity decreases again and near the side wall there are the highest values caused by the outside wind near the big openings in the side wall. In the German standard DIN 18910-1 air velocity up to 0.6 m/s is permissible – but this standard concerns only for closed livestock buildings.

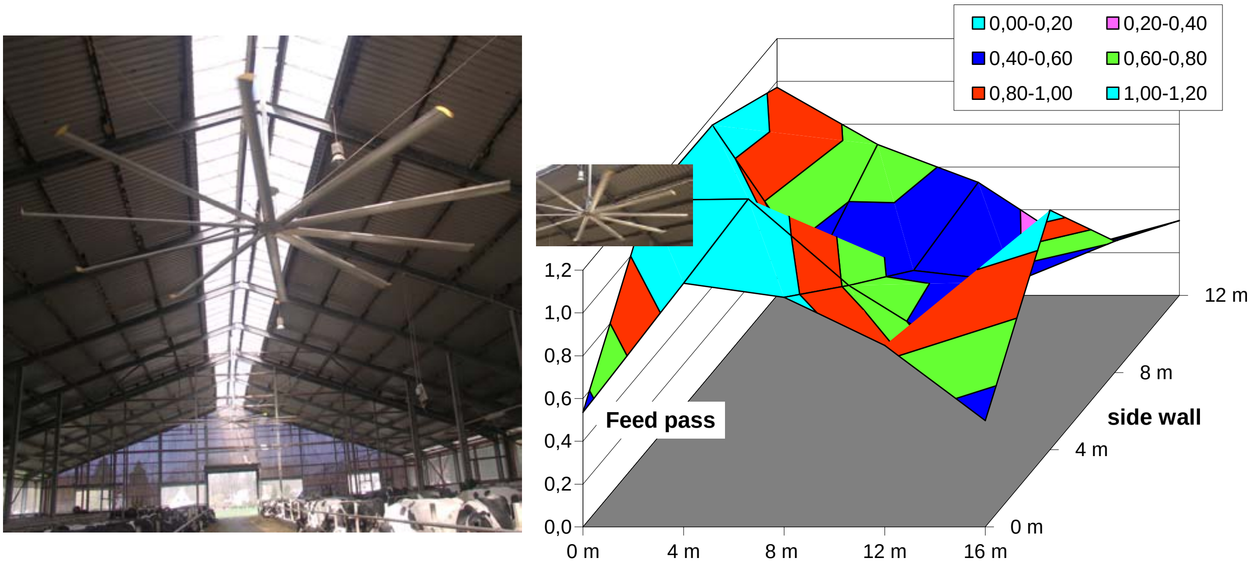

Figure 4. Ceiling fan (left) and air velocity field 1.2 m above the floor (04 May 2006). The velocity data are average values over 2 minutes

The air volume stream and concentration measurements show the strong influence from the outside wind velocity on the air volume stream trough the building and emission stream, for example for Ammonia, increases together with the out side air velocity.

Pig houses

In contrast to the cattle barns the pig houses mostly are forced ventilated. For this kind of animals cooling systems – like evaporative systems, geothermal heat exchanger using heat store capacity of the ground and technical cooling – are applied to reduce heat stress. An example is shown in Figure 5.

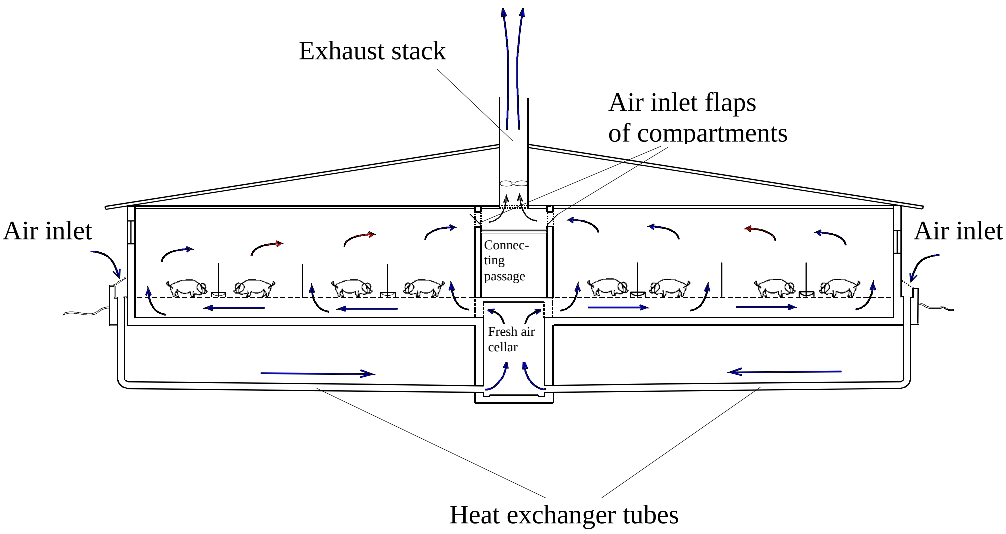

Figure 5. Cross section of a house for fattening pigs – forced ventilation connected with a geothermal heat exchanger

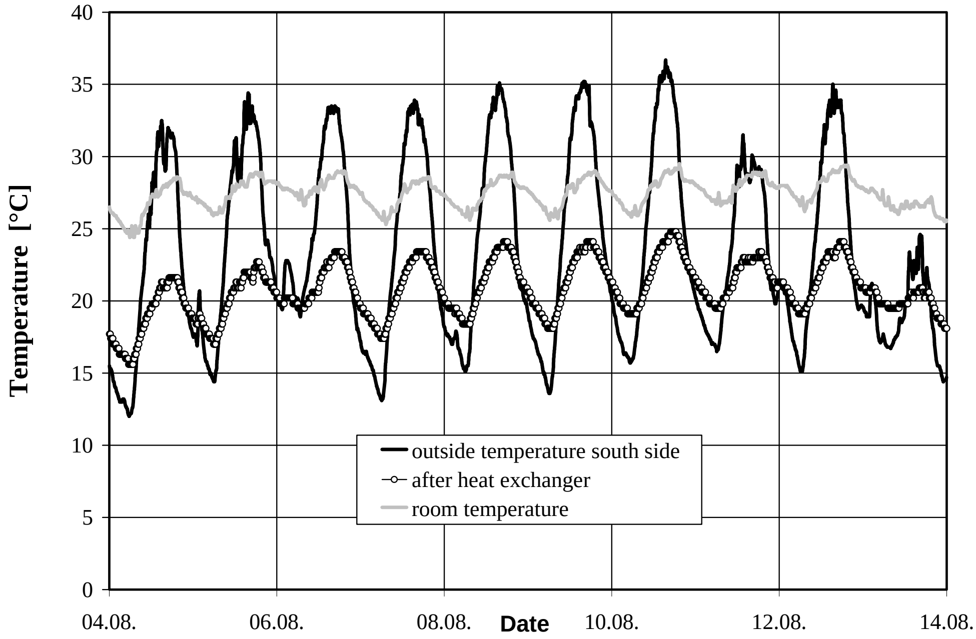

Figure 6. Course of the temperature outside, behind the heat exchanger and in the compartment in the summer.

In Figure 6 it is clear to see, that the outside temperature is damped behind the heat exchanger and the temperature peaks in the compartment is about 6 K lower than the outside temperature. This is a very good result and comfortable temperatures for the pigs during summer period. Beside the cooling effect in the summer the fresh air in the winter period will be pre-heated. Furthermore lower ammonia emission streams were measured and result from a lower air volume stream in summer. The economic examination shows that the higher costs for the heat exchanger will be balanced by the higher animal performance.

Poultry houses

In poultry houses mostly are used ceiling fans to improve the air movement in the animal zone and evaporative cooling systems. Measured velocity fields in broiler houses show a similar behavior like Figure 4. The highest values were measured under the fan and together with the distance a strong reduction of the air velocity in the animal zone was found.
An example for the effect of evaporative cooling systems is given in Figure 7. The inlet air is contaminated with mist. The exhaust air has a changing humidity and the temperature inside is lower than outside in the afternoon. As to see the cooling system in unit 13 started earlier than in unit 12, because of the sun rise. Further research has to look to the animal response to evaporative cooling system.

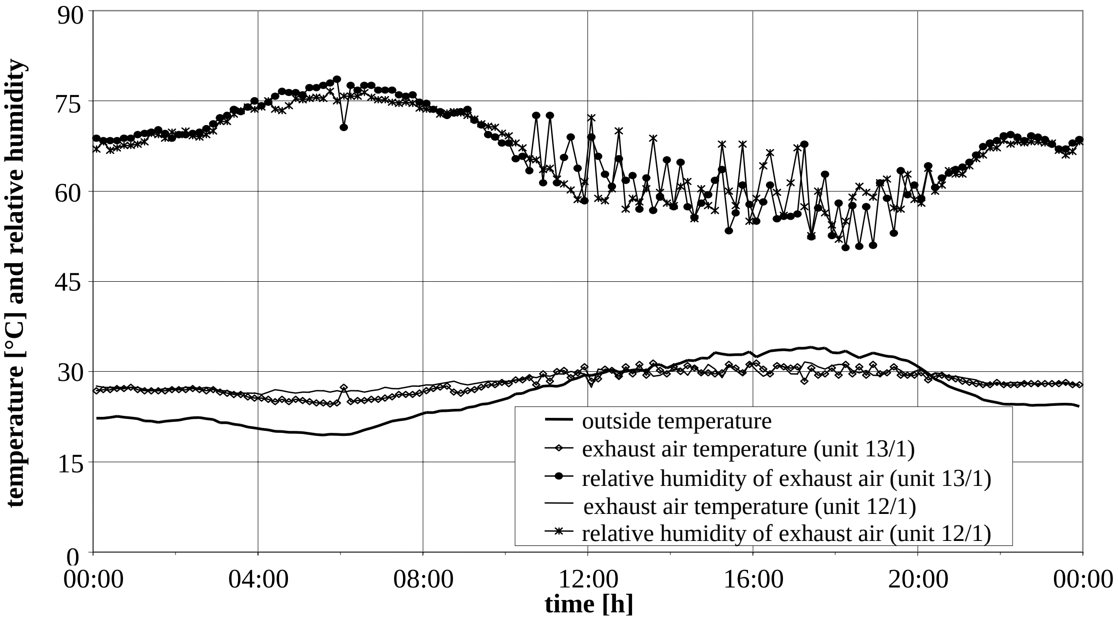

Figure 7. Effect of evaporative cooling under hot summer conditions

CONCLUSION

The animal production is an important factor to supply the population with vital foodstuffs and to deliver raw materials for various branches of industry. These products get out from livestock farming. Animal welfare and high performance require the compliance with good microclimate conditions inside the animal houses over the whole year. Especially in the summer period high temperatures lead to problems. In naturally ventilated cattle houses additional forced ventilation systems are used to improve the air movement. These systems are to advance regarding minimization of energy consumption and equalization of the velocity fields in the animal zone. In pig farming the geothermal heat exchanger stand the test of time. In connection with biogas production the application of technical cooling systems in pig production is under development in Germany. The evaporative cooling systems are successfully applied in poultry production.

Sources of indoor air pollution

Indoor Pollution from Building Materials and Ventilation Rates

SUMMARY

Emissions and odors from different common indoor surface materials (waste wooden products, vinyl, linoleum, carpet, gypsum board, paint, wall coating materials etc.) were investigated within this study. The measurements were conducted in a test chamber under standardized conditions (23°C, 50%) and different ventilation rates. Chemical measurements (TVOC) and sensory assessments (odor intensity, perceived air quality) were done after the 3rd day of building material exposure to standardized conditions. The increased ventilation rate does not evoke adequate response in subjective sensory assessment as well in decreasing of odor indicator level. The source control appears as more effective then ineffective increasing of air change level. The impact of ventilation rate on perceived indoor air quality pollution from selected building materials will be discussed within the paper.

INTRODUCTION

In recent years, the range of new building material, products and construction systems significantly increased. The traditional way of material selection for building design has been primarily based on factors such as cost, aesthetic values, availability and durability. The environmental impact, both on the environment and occupants, has not been addressed till very recently. Selection of building and interior materials can positively or negatively long term affects user's health and comfort. Practically it is not possible to specify environmental friendly and unsafe building materials considering that each material in general view has certain advantages as well disadvantages. Many of the materials used in buildings, either as structural materials or as furnishings, are the main sources of indoor air pollution. From variety of building materials the significant emissions of volatile organic compounds (VOCs) were observed. Some of the emitted volatile organic compounds (VOCs) may except of serious health problems affect the perception of the indoor air quality (odor nuisance, eye and airway irritation).

The most important interactive factor of influence is air exchange. While ventilation is not the only determinant of IAQ, perceived air quality and health outcomes generally improve as ventilation rates increase. The review study [1] has shown that existing date do not indicate whether outside air supply per person or per unit floor area is more strongly associated with health and perceived IAQ. Finally, the reasons for improved health and perceived air quality with increased ventilation are uncertain. The impact of increased ventilation on the perceived air quality may vary from one building material to another [2]. The relationship between ventilation rate and the perceived air quality were summarized within the study [3]. The relationships are different for different building materials. The ventilation requirements to obtain a certain level of perceived air quality for emissions from different building materials are relatively large.

The improvements of perceived air quality after increasing the ventilation rate may be less than expected from simple dilution models, because more ventilation in a given space may increase the emissions from the inner surfaces [4].

METHODS

Coverings of surfaces (floors, walls ad ceilings) are considered to have an especially important role for the quality of indoor air. Chemical analysis and subjective sensory assessments of emissions from selected building finishing materials after their exposition to different air change conditions were carried out in a test chamber. The surface building materials used in this study were selected to present major groups of building products usually used indoors in Slovakia. The investigated building products are five floor coverings (PVC flooring, Linoleum, High Density Fiberboard laminated flooring, Oriented strand boards - OSB and PA carpet) and two walls and/or ceiling coverings (gypsum boards, wallpaper).

The air change levels were specified with respect to European legislation (prEN 15251:2005) for 3 different indoor air quality categories. Category A corresponds to a high level of expectation and leads to a highest percentage of satisfied occupants in respect of indoor environment (n = 1,2 1/h). Category B corresponds to a medium level of expectation (n = 2,0 1/h) and category C to a moderate level of expectation (n = 3,0 1/h). The air change levels were specified regarding that tested materials are non low polluting materials [5].

The principle of the test method is to assess the emission of pollutants from a test specimen, prepared from a sample of a tested material, by sensory assessments and VOCs concentration measurements of the air in a test chamber. The surface of the test specimen is exposed to the chamber air which is maintained at a temperature, humidity and velocity similar to that which can be expected in the indoor environment in which the material is usually used. In addition to these conditions the chamber VOCs concentration depends on the supply airflow rate in the chamber and the area of the test specimen. The test is performed with an area specific airflow rate similar to that which can be expected during the normal use of the material.

The samples of building materials were placed in test chamber made of glass (190 l). Before the tests, the chamber was cleaned. The background concentration of pollutants and sensory assessment of the chamber without the sample under the same conditions were estimated. The mean air velocity and air flow rate were measured using the thermal anemometer TESTO 425. The measurements were taken after 3 days of building material exposure to the standardized conditions (23°C, 50%) within the test chamber. The air velocity over the building product samples was adjusted to 0,1 – 0,2 m/s which corresponds to a usual range indoors. The size of the test specimens were determined so that the area specific airflow rate in the test chamber was corresponding to the area specific airflow rate in standard model room (3,2 x 2,2 x 2,4m). The specimens were placed vertically, so that the emission surfaces were parallel to the direction of the air flow.

In order to simplify the indoor volatile organic compound loading the TVOC value was estimated as the indicator of building material odors. Mølhave, the author of TVOC index proposed comfort level value 200 $\mu g/m^3$. The chemical analysis was based on detection of selected volatile organic compounds. Active sampling of VOCs was performed by using a pump (Aircheck 2000) with air flow rate of 400 ml/min on charcoal tubes ORBO 32S (Supelco) during 24 hours. The absorbed VOCs were analyzed by gas chromatography (GC Varian 3 300) after extraction into CS_2. The sum of VOCs was calculated based on individual

VOCs concentrations including unidentified peak areas converted to decane equivalents (equivalent to toluene).The exhaust air from each test chamber was led through a diffuser for sensory assessments.

An untrained sensory panel of 20 subjects assessed odor intensity and perceived air quality. Before the first assessment the panelists were instructed how to use the scale and the exposure equipment. The responsible person of the experiment assessed each subject's attitude and motivation concerning to experiment and subject's personal hygiene. There was no restriction on distribution of gender or smoking habits. The age ranged from 18 to 40 years with mean a 35 years, and 14 % of the subjects were smokers. The panel stayed in a well ventilated room without odors before the assessments. Then the subjects indicated their immediate evaluation on two continuous scales regarding odor intensity (from 0 no odor to 5 overwhelming odor) and acceptability of the air (from -1 clearly unacceptable to +1 clearly acceptable) from which the percentage of dissatisfied was estimated. The standard test method was used for calculation of acceptability and estimation of odor intensity. During the measurements, the test chambers were covered with aluminum sheets to hide the building products from the view of the sensory panelists.

RESULTS

The chemical analysis of emissions has shown that ventilation rates in non-industrial buildings should be based largely on sensory pollution sources and a desired level of perceived air quality. The air change level of category C guaranteed olfactory level of TVOC (Molhave 200 μg/m^3) however the subjects found the air as still unacceptable in almost all cases of tested interior materials (Fig. 1). Building products have affected the perceived air quality, even when the concentrations of almost all primary VOCs were well below to their odor detection thresholds.

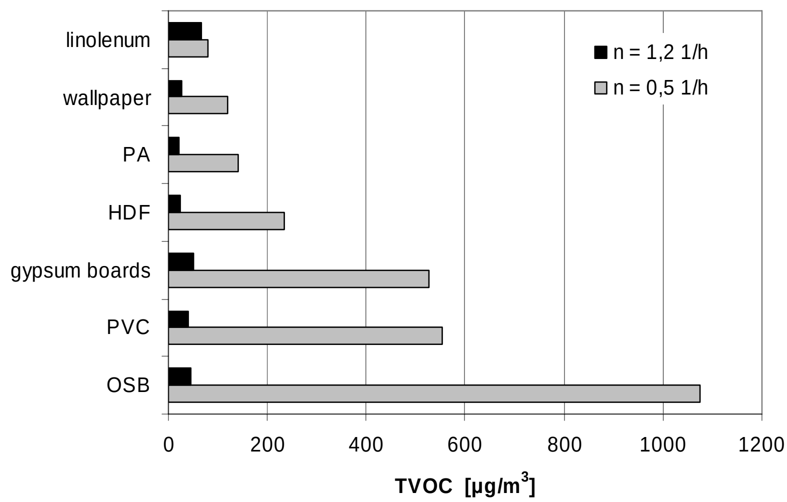

Fig. 1 The results of chemical analysis

Flooring finishing materials

The results of sensory assessments using the odor intensity scale in relation to air change levels are obvious from Fig. 2. The effect of air change level to percentage of dissatisfied is shown in Fig. 3. In case of PVC, HDF and PA finishing materials the significant decreasing in percentage of dissatisfied was reached by increasing the air change level from 0,5 1/h to air change level of category C (1,2 1/h). The decreasing presented approximately 50 %. Additional air change level increasing did not lead to important decreasing of percentage of dissatisfied (at average 15 %). Similar tendency were found for another indicator of perceived air quality – odor intensity. The highest decreasing in odor intensity was found for lower observed air change levels. Increasing of air change level from 0,5 1/h to 1,2 1/h results to decreasing within approximately 1 odor intensity grade. Additional air change level further decreased the odor intensity average by half a grade.

In case of OSB flooring system and linoleum the effect of air change levels to perceived air quality indicators has not been explicit. For OSB flooring system, substantial decreasing of both perceived air quality indicators was reached by increasing of air change level from 0,5 1/h to 1,2 1/h (category C) and from air change level from 2,0 1/h (category B) to 3,0 1/h (category A). The percentage of dissatisfied decreased approximately by 30 % and odor intensity decreased within almost 1 odor intensity grade. The air change level between the mentioned ranges leads to minimal decreasing in PN and odor intensity. For linoleum the increasing of air change level leads to almost linear degreasing of odor intensity. However the highest decreasing of percentage of dissatisfied was reached when air change level was increased from 2,0 1/h (category B) to 3,0 1/h (category A).

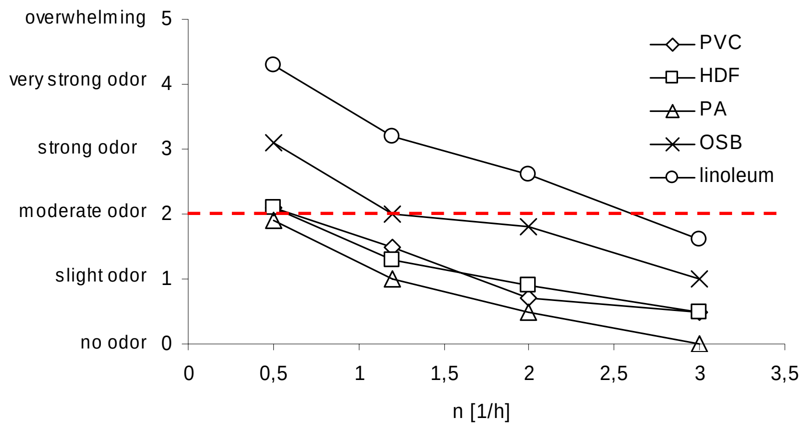

Fig. 2 Odor intensity and air change level

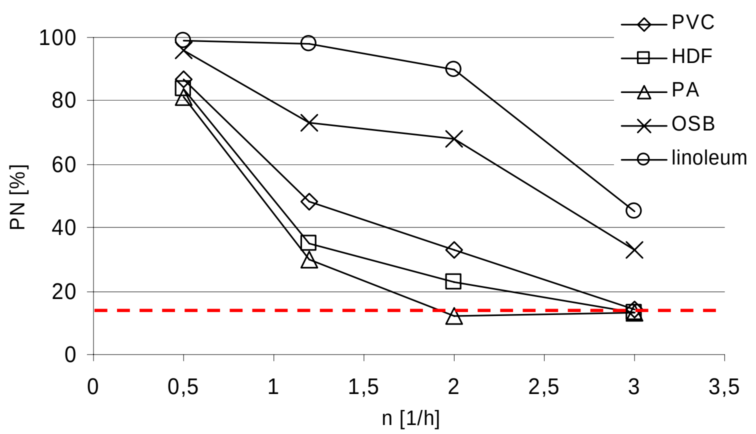

Fig. 3 PN and air change level

The indoor odor intensity is regarded as acceptable at value less than 2 - moderate odor. In case of PA carpeting the recommended value was reached by air change level n = 0,5 1/h. The air change level for category C seems to be satisfactory for indoor odor intensity in case of HDF laminated and PVC flooring. Acceptable odor intensity for OSB flooring was reached at air change level for category B (n = 2,0 1/h). The percentage of dissatisfied was acceptable for PA carpet with air change rates from 2,0 1/h (category B). The air change level for category A (3,0 1/h) must reach the level of 15 % for PVC and HDF laminated flooring. In the case of OSB flooring this level has not been reached even when the air change was on the highest indoor air quality level.

It is interesting that subject found linoleum as the most unacceptable materials from subjective sensory assessment point of view. However the TVOC values were the lowest from investigated indoor surface materials. Linoleum did not reached required percentage of dissatisfied even when the air change was on the level of highest indoor air quality category. The moderate odor intensity was achieved by air change level n = 3,0 1/h.

Walls, ceilings finishing materials

The results of sensory assessments using the odor intensity scale in relation to air change levels are obvious from Fig. 4. The effect of air change level to percentage of dissatisfied is shown in Fig. 5.

In case of wallpaper the effect of air change level to perceived air quality indicators has not been evident. Effective decreasing of PN was reached by increasing of air change level from 1,2 1/h (category C) to 2,0 1/h (category B). The percentage of dissatisfied decreased approximately by 52 % and odor intensity decreased within one and half of grade on the odor intensity scale. The air change level between ranges from 0,5 1/h to 1,2 1/h and 2,0 1/h to 3,0 1/h evocated minimal decreasing in PN as well in odor intensity.

Accordingly, in case of painted gypsum the effect of air change level to perceived air quality indicators has not been obvious; however with converse tendency. The evident decreasing of both perceived air quality indicators was reached by increasing of air change level from 0,5 1/h to 1,2 1/h (category C) and from air change level from 2,0 1/h (category B) to 3,0 1/h (category A), in same manner as in case of OSB floor system. The percentage of dissatisfied decreased approximately by 40 % and odor intensity decreased within half of the level of odor intensity scale. The air change level between mentioned ranges resulted to minimal decreasing in PN as well as in odor intensity.

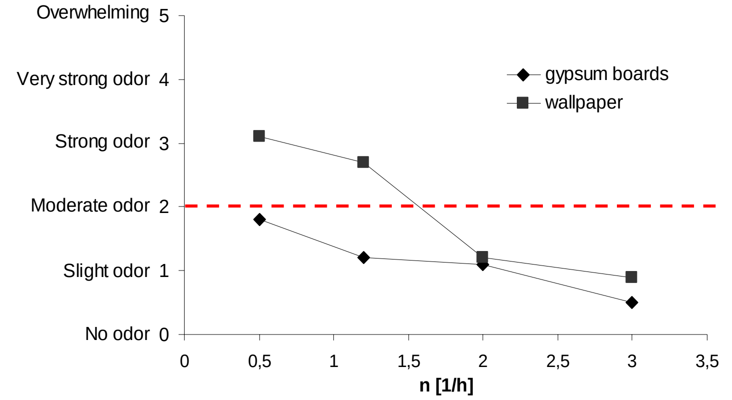

Fig. 4 Odor intensity and air change level

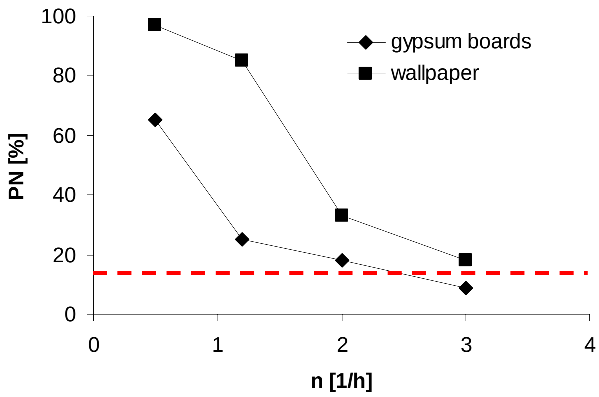

Fig. 5 PN and air change level

The indoor odor intensity is regarded as acceptable at a value of less than 2 - moderate odor. In the case of painted gypsum boards this recommended value was reached by air change level 0,5 1/h. The air change level for category B seems to be satisfactory for wallpaper from the indoor odor intensity point of view.

The air change level for category A (3,0 1/h) was necessary to reach the level of 15 % dissatisfied in case of painted gypsum boards. In case of wallpaper this level has not been reached even when the air change was on the level of highest indoor air quality category.

DISCUSSION

The presented study has shown that even when the TVOC concentrations were well below the olfactory comfort level the subjects found the air as still unacceptable in almost all cases of tested interior materials. Even when the VOCs concentrations are well below their odor detection thresholds the perceived air quality is affected. On the base of the results it is possible to assume that human nose is much more sensitive than chemical analysis.

Perceived air quality was improved and odor intensity was decreased when the air change level was increasing. However, the increased air change rate does not evoke adequate response in subjective sensory assessment. The significant decreasing of perceived air quality indicators with higher air change level was found in the cases of PVC, HDF and PA. In the cases of OSB flooring systems, linoleum, gypsum boards and wallpaper the effect of increased air change level has not been obvious.

Respecting other indoor climate parameters requirements (air temperature, humidity, and air movement) the increasing of air change level in order to achieve acceptable perceived air quality is not reasonable and makes no real sense It is very difficult to discharge air into a space at a high flow rate without creating draughts, increased energy consumption and other environmental problems. Consequently, the source control appears as more effective then ineffective increasing of air change level.

ACKNOWLEDGEMENT

The authors acknowledge the assistance provide by department staff and students of indoor engineering. The authors are grateful to the Slovak Grant Agency for Science Project No. 1/3342/06.

SUMMARY

This paper presents results from a principal component analysis (PCA) on variables affecting on indoor air quality in newly established buildings, in which low-emitting, classified building materials were used. The concentrations of TVOC, VOCs, formaldehyde and ammonia) were determined for the newly finished and 6-, and 12-month-old buildings. Temperature, relative humidity and air exchange rates were determined simultaneously. These values were included in the PCA models, which were used to reveal which variables affected indoor air quality (IAQ). The variables included floor covering, air exchange system and the time of its operation (in the newly finished building), floor structure / leveling agent, walls, time of construction and season and time point from last construction work.
The IAQ was by most affected by the air exchange system and ceiling product. Lowest concentration levels and classification of VOCs occurred for the buildings with mechanical supply and exhaust air system. IAQ was highly affected by indoor air humidity, especially in the 6 and 12-month- old building

INTRODUCTION

Indoor air quality (IAQ) is affected by both indoor and outdoor sources of pollutants. Indoors, building materials are important emission sources of pollutants, especially in new buildings [1]. Occupancy (activities of the inhabitants, furniture etc.) and chemical reactions may further increase concentration levels of harmful pollutants, which in some cases can lead sick building syndromes (SBS). Besides source control, ventilation is one effective way to control pollutant levels indoors.
The evaluation of the contribution from different sources and the effect of outer conditions (ventilation, temperature, humidity) on IAQ is difficult due to the complexity of indoor environments. This study investigates the potential of multivariate methods for the evaluation of variables affecting IAQ in newly finished buildings.

METHODS

Study buildings and measurement scheme

Fourteen apartments in eight residential buildings (seven apartment buildings and one two-family house), built according to the current Finnish Building Regulation Code, were investigated. Seven of the buildings were located in Helsinki and one in Turku. Low emitting, M1-classified materials were used in all the buildings. That is, the laboratory tests performed for 4 week- old samples have given TVOC-, ammonia- and formaldehyde emissions lower than 200, 30, and 50 µg/ m^2h, respectively [2]. The relative humidity (RH) of the structure was determined to be <85% before the floor covering was installed. In seven buildings, the walls were finished with screed and painted. Wallpaper was laid on the screed in the building 4. Ceilings were finished with screed (2 different products). The floors were finished with fine screed (dispersal 2-5 mm) in the site built buildings and with gross screed (dispersal 10-30 mm) in the manufactured buildings. Different types of PVC materials and parquets were used as floor covering materials. The installation of the floor covering material was the last construction work occurring 2-28 weeks prior to occupation, except in building 4, where painting was performed 12 weeks prior to occupation.

Indoor air measurements were performed first in the newly finished building, when the ventilation was operating, but before the occupants had moved in. The measurements were repeated after 6 and 12 months. In one apartment (Building 7, apartment 2), a water leak took place a few weeks before the apartment was finished. The apartment was heated and ventilated for about two weeks after which the indoor air was measured. These VOC results were not included in the statistical analysis.

Sampling and analysis

Indoor air samples were taken in a closed room (usually the bedroom) at the height of approximately 1.40 m before noon. The follow-up measurements were done every time in the same room and in the same place. The air exchange rates were determined simultaneously. The inhabitants were asked to avoid cleaning, smoking, and the use of fragrances in the morning prior to the measurements. Additional ventilation through doors or windows 24 h before the measurement was discouraged. No smoking or pets were observed during the measurements.
Air samples of VOCs were collected on Tenax TA adsorbent [3]. The sampling of ammonia and formaldehyde was performed into a 0.005 M sulphuric acid- solution at 2-4 l/min. The temperature and RH were registered using a Vaisala HMP41 moisture detector. The air exchange rate was determined simultaneously based on ventilation duct measurements with an Alnor AXD-530 thermo anemometer.
Tenax tubes were thermally desorbed and analysed with a HP 5890 series 2 gas chromatograph connected to a HP 5972 mass spectrometer and FID detector. MSD in SCAN mode was used to identify single VOCs and the FID response was used for quantification. TVOC was calculated as toluene equivalents from the total integrated FID signal between hexane and hexadecane. The ammonia concentration was determined with an ion-selective electrode and the analysis of formaldehyde was done with the spectrometric acetyl-acetone method.

Data handling

Statistical tests were performed with Simca-P 7.0 for Windows software. Principal component analysis (PCA) was performed to reveal which variables affected IAQ most.

The values for TVOC, formaldehyde, ammonia and single VOC concentration as well as the temperature, humidity, and air exchange rate were included in the models. Due to water damage in building 7, apartment 2, these results were excluded from the analysis. Models were calculated for the 0-, 6- and 12- month-old buildings. Automatic UV scaling was performed by the Simca software. Table 1 summarizes details for the models for the 0-, 6- and 12-month-old buildings. The variables investigated were as follows:

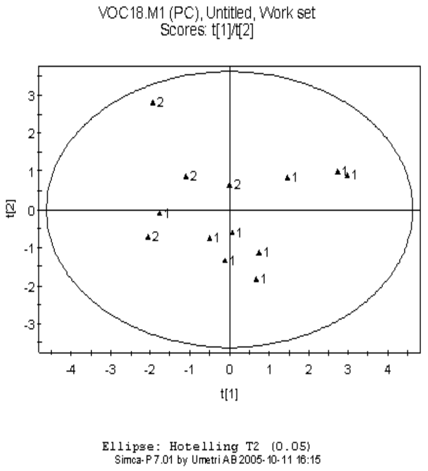
- Structure (on site built+ fine screed/ manufactured concrete cast slab+ gross screed)
- Floor covering (parquet/PVC)
- Wall material (paint/ wall paper)
- Ceiling material (screed, different manufacturer)
- Air exchange system (mechanical exhaust/ mechanical supply and exhaust air system)
- ACH system operation time (0.5-8 weeks, newly finished building)
- Time of construction (7-10 months, from the time point)
- Season (month finished, indoor air humidity)
- Time point from last construction work prior to use (4-28 weeks)

Table 1. PCA models details for the 0-, 6- and 12-month-old buildings.

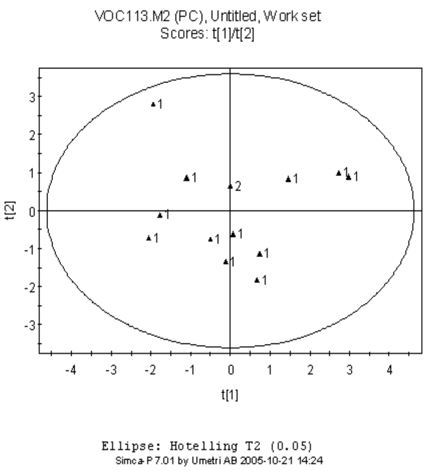
Model	**0 month-old building**	**6 month-old building**	**12 month-old building**
TVOC, ammonia, formaldehyde	13 measurements (apartments), R^2: 0.695 (2 components)	14 measurements (apartments) R^2: 0.812 (2 components)	14 measurements (apartments) R^2: 0.799 (2 components)
VOCs	VOCs occuring at n≥3 sites (76/ 238 compounds) R^2: 0.631 (3 components)	VOCs occuring at n≥4 sites (56/ 167 compounds) R^2: 0.576 (3 components)	VOCs occuring at n≥4 sites (61/189 compounds) R^2: 0.576 (3 components)

RESULTS

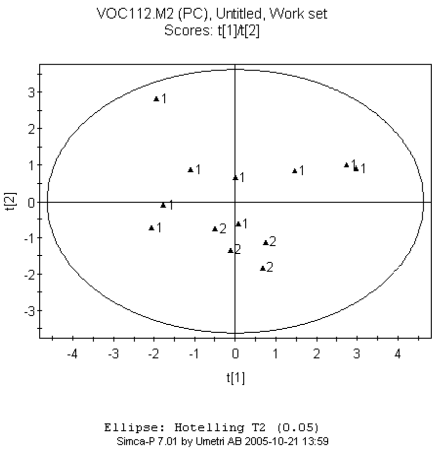
Selected examples of PCA results are presented in figures 1 and 2. Lower TVOC concentration was observed in the newly finished buildings with a mechanical supply and exhaust air system (Figure 1a and b). The same leveling agent (product 2) was also used on the ceiling structure in these buildings and the RH was low, less than 40%. The floor covering was parquet and walls were painted. The lowest TVOC, ammonia, and formaldehyde concentrations in the 6-month-old buildings were measured in the building where product 2 was used as ceiling surface product and when the RH was less than 30%. The clustering of VOCs also occurred at these apartments. The same was observed in the 12-month-old buildings, where the clustering of VOCs according to air exchange system (mechanical supply), ceiling surface (product 2), and indoor air humidity (<40%) was quite clear (Figure 2). Lowest pollutant levels/ VOC classification in the 0-, 6- and 12-month-old buildings are summarized in Table 2.



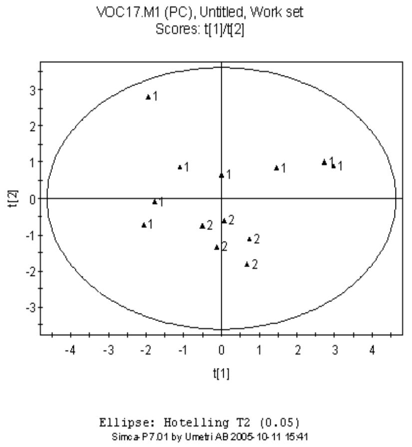
a) floor covering material: parquet =1 PVC=2



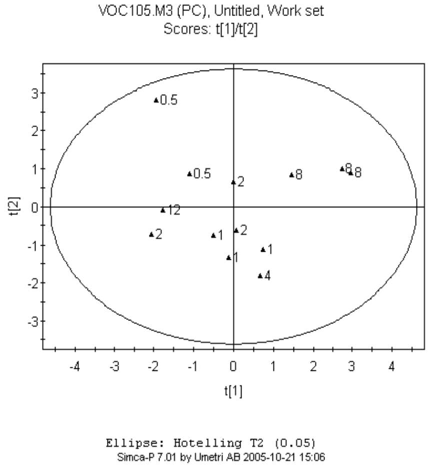
b) walls: paint=1, wall paper=2



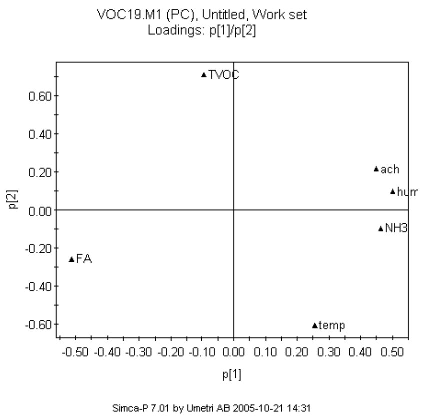
c) ceiling: product 1=1, product 2=2



d) air exchange system: mechanical exhaust=1, mechanical supply&exhaust=2

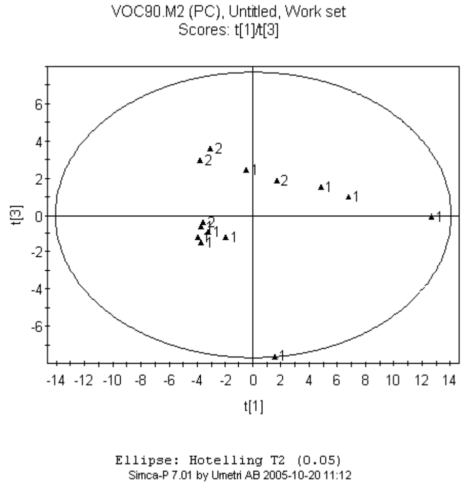


e) air exchange operation time 0.5-8 weeks

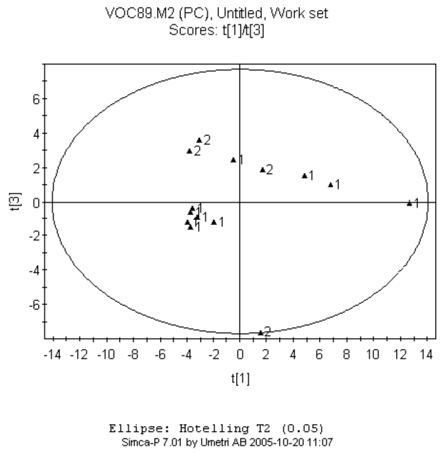


f) loadings plot

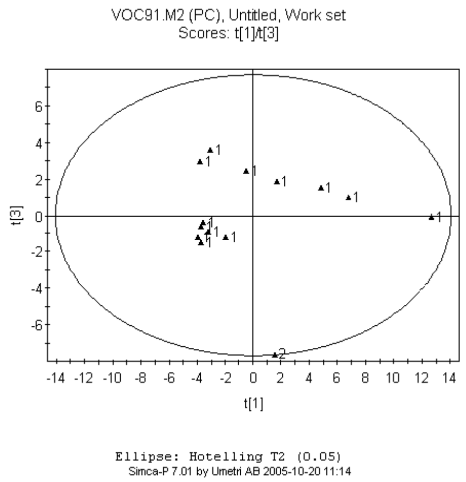
Figure 1 a-f : Example of PCA results: IAQ in the newly finished building. The score plots (a-e) shows how the 13 measurement sites and the model contribution of the measured parameters is shown in the corresponding loadings plot (f). The contribution of the measured parameter decreases as the distance of the parameter to the observation increases (TVOC=total volatile organic compounds, FA= formaldehyde, NH3= ammonia, temp=temperature, hum= relative humidity, ach= air exchange rate).



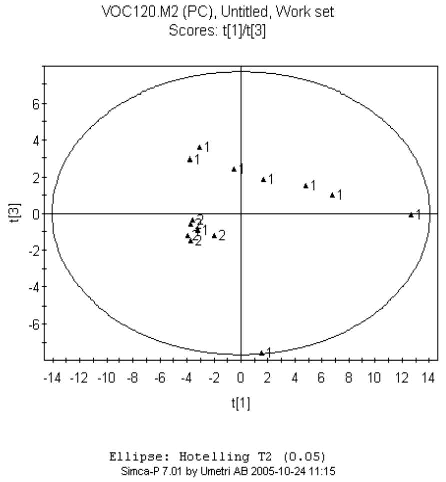
a) structure: on site built=1, manufactured=2



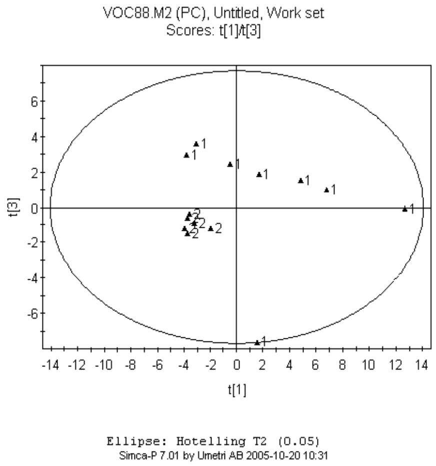
b) floor covering material: parquet=1, PVC=2



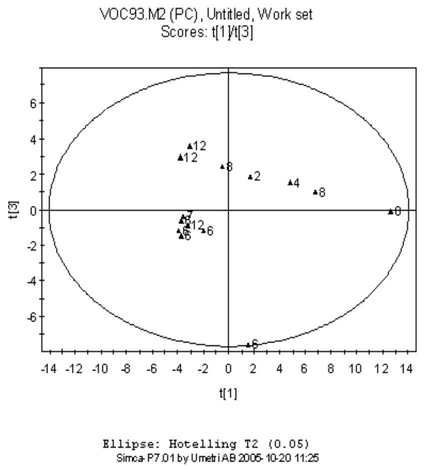
c) walls: paint=1, wall paper=2



d) ceiling: product 1=1, product 2=2



e) air exchange system: mechanical exhaust=1, mechanical supply&exhaust=2



f) season: month number

Figure 2. Classification of VOCs in the 12-month-old-buildings.

Table 2. Summary of PCA results in the 0-, 6- and 12-month-old buildings.

0-month-old building	**6-month-old building**	**12-month-old building**
Lowest TVOC concentration: air exchange system: mechanical supply and exhaust air system ceiling surface: product 2 walls: painted indoor air humidity: <40% VOC classification (clustering): Air exchange system: mechanical supply ceiling surface: product 2	Lowest TVOC, ammonia and formaldehyde concentration: ceiling surface: product 2 indoor air humidity: <30%! VOC classification (clustering): ceiling surface: product 2 indoor air humidity: <40%	Lowest TVOC, ammonia and formaldehyde concentration: air exchange system: mechanical supply air system ceiling surface: product 2 walls: painted indoor air humidity <40% VOC classification (clustering): air exchange system: mechanical supply air system ceiling surface: product 2 walls: painted indoor air humidity: <40%

DISCUSSION

The best IAQ was achieved in the 0-12-month-old buildings with mechanical supply and exhaust air system, screed product nr 2 as ceiling surface, and painted walls. These buildings had parquet as floor covering material. IAQ was highly affected by indoor air humidity, especially in the 6 and 12-month- old building. As the summary of (10) PCA, variables affecting the concentrations of indoor air gaseous pollutants in the buildings were season, relative humidity and temperature of indoor air, air exchange system, floor covering material, ceiling surface product, wall surface product, and occupancy. The multivariate analysis proved to be a very useful tool in revealing the most significant variables affecting IAQ.

ACKNOWLEDGEMENT

This project is part of the national Healthy Building-project “Verification, Source Apportionment and Remediation of an Indoor Air Problem” and it is partly financed by the construction industry, the Finnish National Technology Agency (TEKES) and The Academy of Finland (SA 210343).

SUMMARY

Bake-out of buildings is believed to have a potential to reduce indoor air pollution caused by VOCs and formaldehyde emitted from building materials although controversial discussions have been suggested. To clarify the effectiveness of bake-out, in this study, the variation of VOCs and formaldehyde emission rate from building material were investigated in residential housing units with passive sampling methods. For about a month, measurements of emission rate are carried out on various building materials such as wood based materials and paper based materials installed in real buildings at which bake-out was conducted. According to the results, the toluene emission rate from wood based materials clearly decreased with only ventilated conditions during bake-out. However, the toluene emission rate from wall paper decreased regardless to the ventilation condition. Compared to toluene emission rate, we couldn't observe a clear reduction of formaldehyde emission rate from most of building materials.

INTRODUCTION

Recently, due to synthetic building materials used in buildings, IAQ problem has become a major public concern in newly constructed apartment buildings. For resolving this problem, Indoor Air Quality Management Act[1], a regulation concerning the concentration limitations of formaldehyde and 5 VOCs in new apartment buildings, was enforced by the Ministry of Environment of Korea and came into effect from May 30, 2004. According to this act, construction companies, which construct apartment complexes, are required to measure the concentration levels of 6 toxic substances and give a public notification before the residents move in. To meet the requirements of the government regulations, source control strategies such as using low-emission building materials are widely used. However, Indoor concentration level of chemical compounds is partly high especially at pre-occupancy stage, due to high outdoor temperature in summer. With these backgrounds, construction companies are considering building bake-out as the urgent method which can be applied after the construction complete.

Based on the result of the former researches on building bake out [2],[3], it is believed that building bake-out has the potentials to improve indoor air quality in residential buildings, although contradictory results have been also reported [4],[5]. To clarify the effectiveness of bake-out, it is required to investigate variation of pollutants emission rate from building materials installed in buildings due to bake-out procedures.

The objective of this study is to investigate emission rate variations of VOCs emitted from building materials commonly used in residential housing units during building bake-out.

Using passive sampling methods, measurements of variation of VOCs emission rates from various building materials such as flooring materials, wall papers, and furniture were conducted during bake-out.

RESEARCH METHOD

Description of test house

Measurements were taken on residential housing units to evaluate variations of VOCs and formaldehyde emission rates due to building bake-out. Two identical residential housing units with an area of 85m^2, finished and furnished with the same materials were selected from the apartment buildings located in Seoul, Korea. A radiant floor heating system was adopted in test housing units. Mechanical ventilation system throughout the residential unit was not used, but rather an exhaust fan was installed in the kitchen and bathrooms. As shown in the unit floor plan shown in Figure.1, all of the room can be ventilated by natural means of opening windows and doors. In the units, the wall paper with water glue was finished on walls and ceilings. On the floors, a wood based material which is laminate flooring was finished. A different types of furniture was installed in bedroom2 and kitchen.

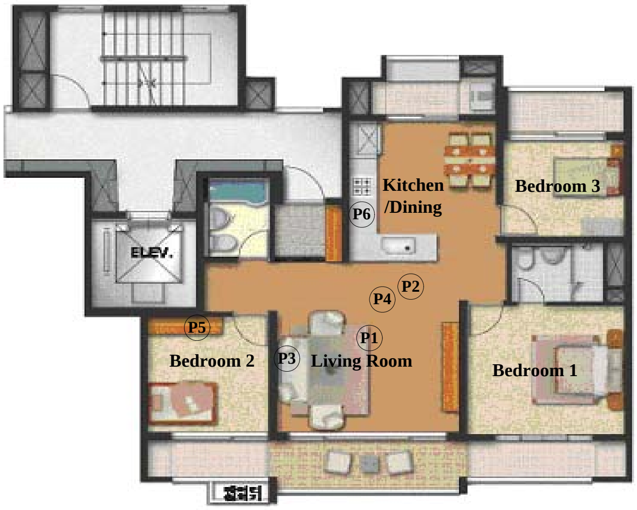

Figure 1. Floor plan of the unit &Measuring Point

Table 1. Investigated materials

Measuring point	Measured Location	Material composition
P1	indoor air	-
P2	Ceiling in living room	water glue + wall paper
P3	Wall in living room	water glue + wall paper
P4	Floor in living room	wood based material
P5	furniture in bedroom	wood based material
P6	furniture in kitchen	wood based material

Measurement Schedule

Measurements of VOCs emission rates from various building materials were taken three times in nearly same temperature and ventilation conditions. As shown in Figure 1 and Table 1, measurements were taken at ceiling, wall, floor and two types of furniture. Indoor concentration was also measured. During all of the measurements, the test units were shut tightly and the air temperature of the units was maintained around 30℃. After the initial measurement was carried out, the test units started to operate the heating system to raise the indoor temperature to reach 35℃ with different ventilation rates for five days. Then, all the units were naturally ventilated by opening windows for two days, and baked out for another five days. The second measurements were carried out after the test units were ventilated by opening windows for two days to be sufficiently cooled down. Measurement schedules and points are shown in Figure 2 and Table 1, respectively.

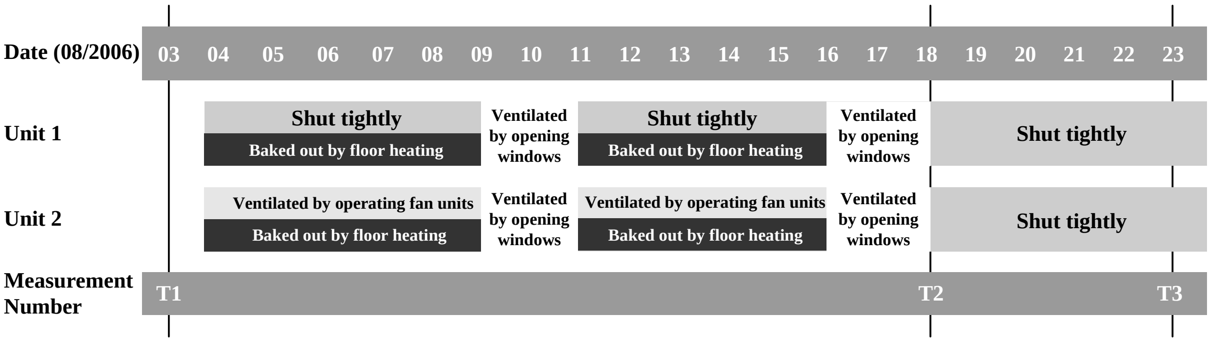

Figure 2. Measurements schedule according to bake-out conditions

Measurement and analysis methods

For measuring emission rates of building materials installed in test units, passive sampling methods were used [6]. VOC-SD and DSD-DNPH passive samplers were used for sampling VOCs and formaldehydes respectively. Each sampler was inserted into an instrument made of stainless steel and the sampling was carried out for 24hous. VOC-SD samplers are analyzed by GC/MS after solvent desorption using CS2 and DSD-DNPH samplers are extracted with acetonitrile and analyzed by HPLC. Among the various pollutants, toluene and formaldehyde levels were presented in this paper, and relative humidity and indoor temperature in the units were also measured.

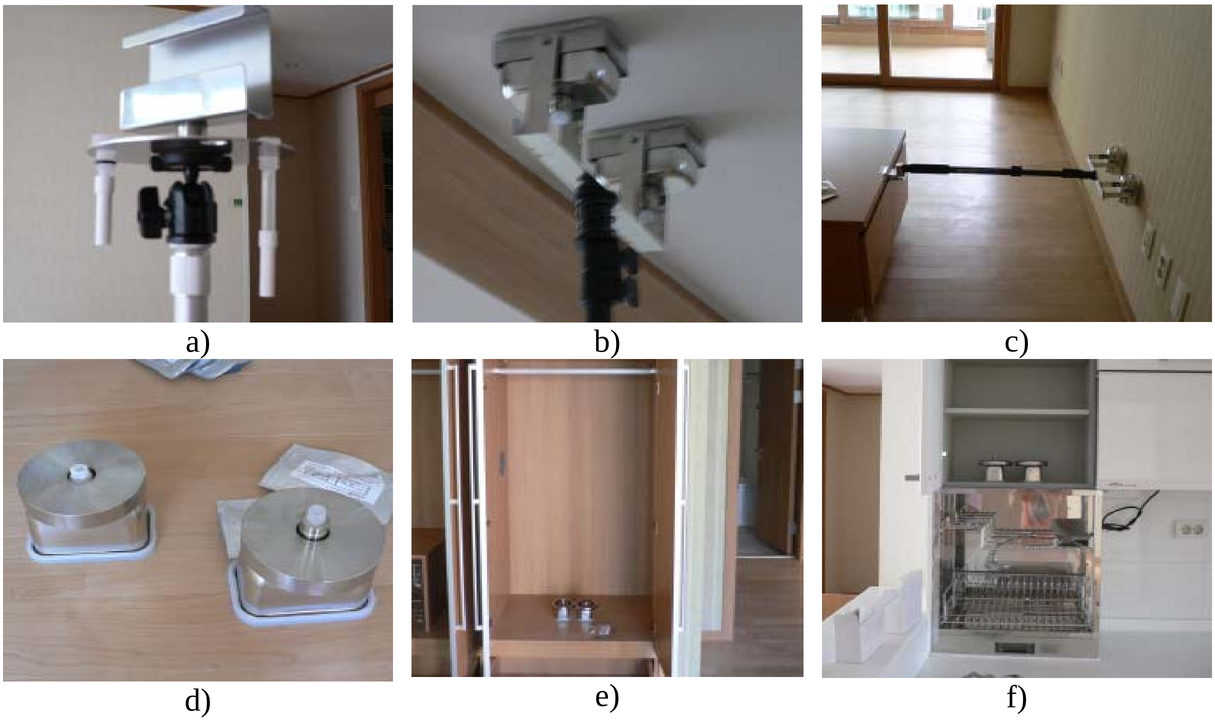

Figure 3. Measuring points a) indoor air(P1) , b) ceiling in living room(P2), c) wall in living room(P3), d) floor in living room(P4), e)furniture in bedroom(P5), f) furniture in kitchen(P6)

RESULTS AND DISCUSSION

Environmental conditions

The room temperature of each unit for whole test periods was plotted in Figure 4. The room temperature was maintained at around 30℃ before the bake-out. During the bake-out, the room temperature of both units reaches 35℃. Although, unit 2 was ventilated by operating fans and opening the windows, indoor temperature sufficiently reached about 35℃ due to fairly high outdoor temperature around 30℃ in summer. The figures show both of the units were under very similar temperature conditions in spite of the different ventilation condition.

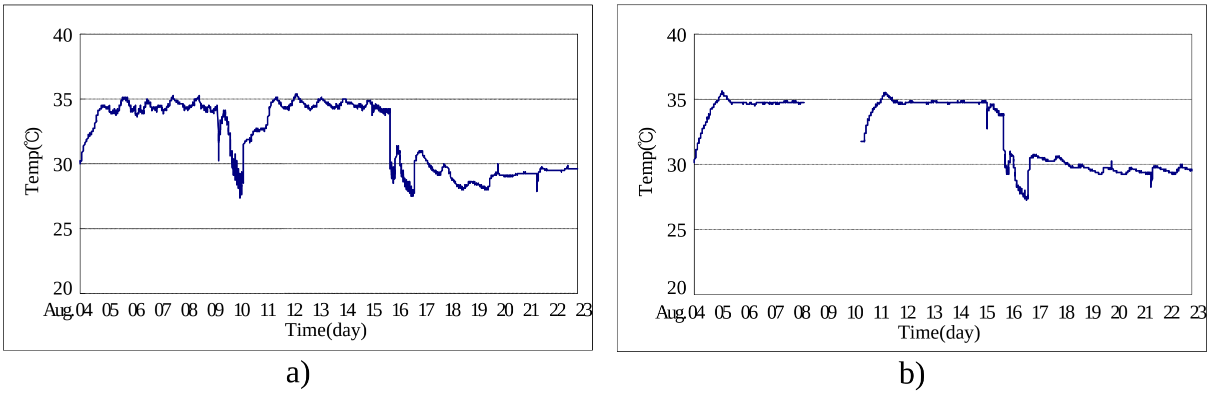

Figure 4. Indoor air temperature a) Unit 1, b) Unit 2

Variation of pollutants emission rates

Toluene emission rates of the tested materials and indoor concentration in units 1 and 2 are plotted in Figure 5. Regardless to the ventilation conditions during bake-out, after bake-out, the emission rate of toluene from all kinds of materials is clearly reduced compared to the initial values at measurement T2. At measurement T3, however, emission rate at T2 fairly rose up compared to the values at measurement T2, but most of them still has lower values than the initial values. These rises of the emission rate were observed in all kinds of materials. Although it is hard to interpret this result, one possible explanation is that rearrangement of pollutants distribution inside materials increases their emission rate. Based on the comparison of the values measured at the final measurement with the initial values, the emission pattern of wood based materials appears to be different from wall paper. Clear decrease of toluene emission rate from wood based materials such as floorings and furniture is observed, while the toluene emission rate in unit 1 slightly decreased or even rose up compared to the initial values. It is seemed that toluene emission from wood based materials is affected by ventilation conditions.

Formaldehyde emission rates of the materials and indoor concentration are plotted in Figure 6. The emission rate of formaldehyde showed the different patterns with that of toluene. In contrary to the result of toluene, we didn’t observe reduction of formaldehyde emission rate after bake-out. In unit 1, which was shut tightly during bake-out, formaldehyde emission rate rose or maintain at approximately same level compared to the initial level.

Based on the result, it is found that the variation of pollutants emission rates depends on types of materials and pollutants as well as ventilation rates. If materials showing a good reduction of pollutants emission rates by bake-out were mostly installed in a building, we could expect a better IAQ after conducting bake-out procedure. The effectiveness of conducting bake-out will vary with emission characteristics and installed area of each building material. Consequently, investigation of emission characteristics of building materials are required prior to conduct the building bake-out for confirming in the result of better IAQ by bake-out.

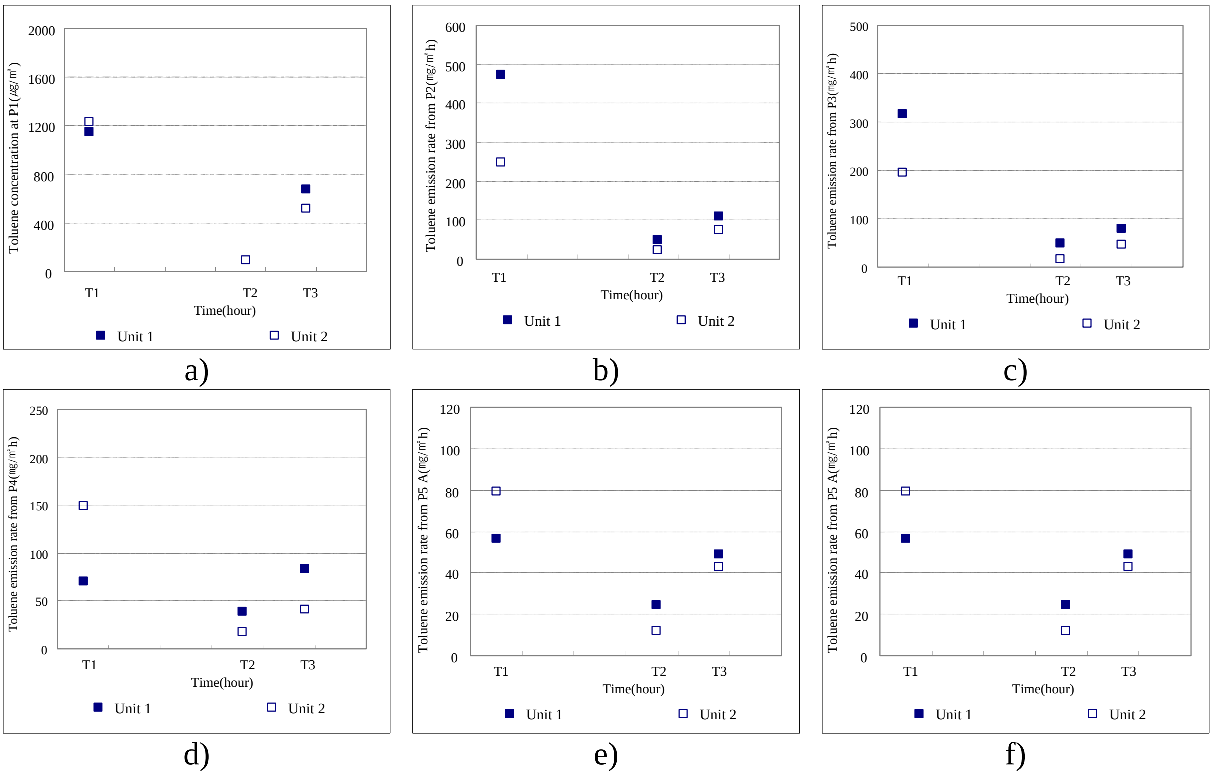

Figure 5. Emission rates of toluene a) indoor air(P1) , b) ceiling in living room(P2), c) wall in living room(P3), d) floor in living room(P4), e)furniture in bedroom(P5), f) furniture in kitchen(P6)

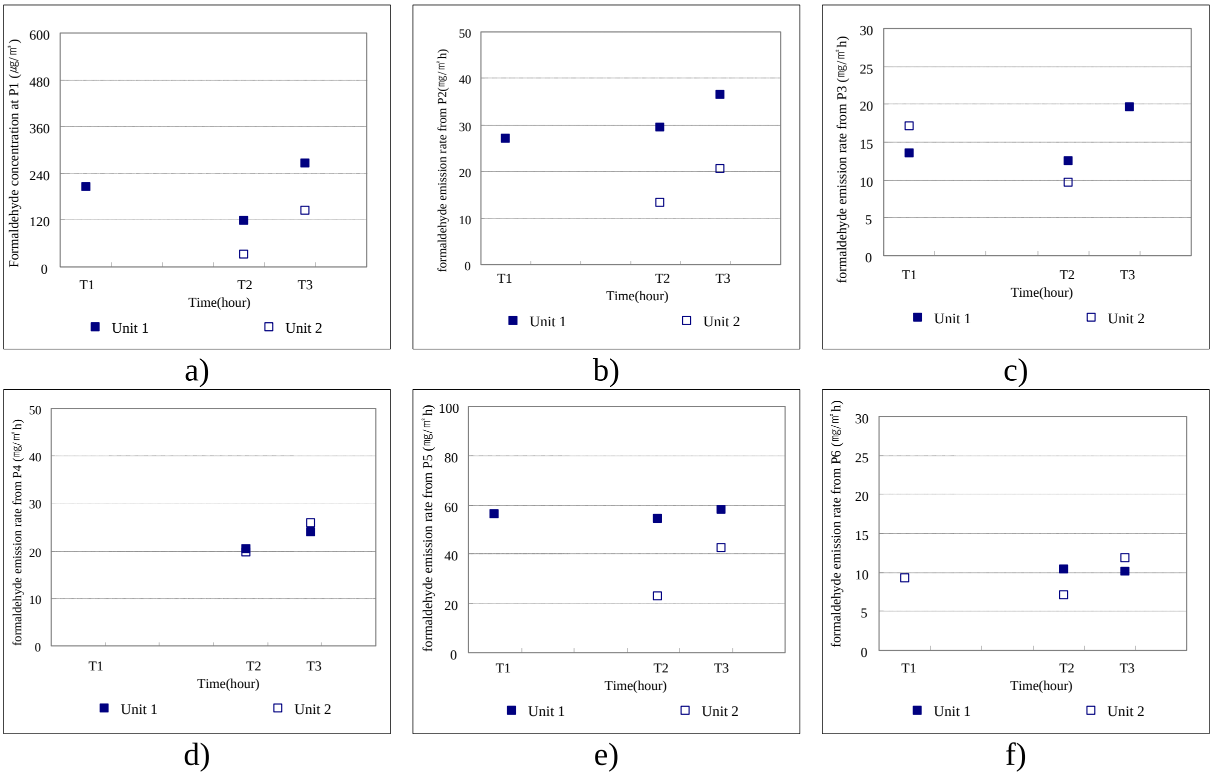

Figure 6. Emission rates of formaldehyde a) indoor air(P1) , b) ceiling in living room(P2), c) wall in living room(P3), d) floor in living room(P4), e)furniture in bedroom(P5), f) furniture in kitchen(P6)

CONCLUSION

In this study, we measured VOCs and formaldehyde emission rate from building materials during bake-out to clarify the effectiveness of bake-out conductions. Measurements of emission rates were carried out with passive sampling method for about one month in residential housing units.

The result shows bake-out easily drops down toluene emission rate compared to formaldehyde emission rate. In unit 1, which was shut tightly during bake-out, toluene emission rate from wall paper prominently decreased. In unit 2, which was ventilated during bake-out, toluene emission rate from wood base materials has relatively large reduction rate. However, formaldehyde emission rate is not affected by bake-out. Based on the result, we concluded that the effectiveness of conducting bake-out will vary with emission characteristics and installed area of each building material. Because indoor air quality can be better or worse according to the emission characteristics and installed area of building materials, investigation of emission characteristics of building materials are required prior to conduct the building bake-out for confirming in the result of better IAQ by bake-out.

SUMMARY

In this report, we proposed the estimation method of building material properties by using both numerical analysis and measuring the time history of concentration in micro cell, and showed that the effective diffusion coefficient, emission rate and initial concentration in the building material is provided with a single measurement. The effective diffusion coefficient of testing building materials were estimated to be from about 4.0×10^{-10} to 2.5×10^{-8} [m^2/s] in this proposed method. Although this proposed method is necessary to improve to obtain more reliable result, it is able to apply to relative comparison about VOCs emission characteristic in building materials as a screening test.

INTRODUCTION

In order to prevent indoor air pollution by VOCs emitted from building materials, it is necessary to select suitable building materials with lower VOCs emissions, and to confirm a VOCs concentration range in rooms in advance. Therefore, the information of building material properties, which is VOCs emission rate, effective diffusion coefficient and chemical content (initial concentration in building materials), are important. Generally, VOCs emission rate is measured by the chamber method [1][2], FLEC [3][4], ADSEC [5] etc., and the effective diffusion coefficient is measured by twin chamber method [6], cup method [6][7], mercury intrusion porosimetry (MIP) method [8]. However, it is the actual fact that the information of building material properties has not been got ready adequately from the viewpoint of effort and cost taken in testing.
The overarching goal of this study is to develop the simultaneous measurement method that is able to estimate the emission rate and effective diffusion coefficient by single measurement. In this repot, we propose a estimation method by using micro cell and convenient gas monitor (in this research, we adopt the multi-gas monitor produced in INNOVA), and compare the effective diffusion coefficient by proposed method with conventional methods.

OUTLINE OF PROPOSED METHOD

In this study, we focused a time history of VOCs concentration in the air (gas) phase that occurred when target building material is covered with an airtight container (in this research, we call as Micro Cell). Generally, the VOCs concentration in micro cell gradually increases, and finally reaches an equilibrium concentration. In other words, VOCs emission rate form building materials gradually decreases toward zero. The profile of the time history of VOCs concentration in micro cell is determined by effective diffusion coefficient and initial concentration (level and distribution) in target building material. Further, when the initial concentration in the building material is uniform, the profile of the time history of VOCs concentration that normalized to the initial concentration in the building material is determined by the effective diffusion coefficient alone.

This proposed method estimates VOCs emission rate and effective diffusion coefficient by using both numerical analysis and continuous concentration measurement in micro cell. Before the measurement, we make the chart of time histories of VOCs concentration by numerical analysis that assumed various effective diffusion coefficients. And we measure the concentration in micro cell until it becomes equilibrium. Subsequently, the initial concentration in the building material is obtained from the equilibrium concentration, and the effective diffusion coefficient is estimated by overlapping the measurement result with chart. After estimating the effective diffusion coefficient, the emission rate when reference concentration is guideline value (e.g. 100 ug/m^3 for Formaldehyde in WHO) is estimated as a representative value. In this way, this proposed method is able to estimate the emission rate, effective diffusion coefficient and initial concentration in the building material with a single measurement.

Outline of numerical analysis

The micro cell is shown in Figure 1. The numerical analysis is carried out in one dimensional, since the micro cell is nearly rectangular (100mm× 550mm× 600mm^h) and free slip can be assumed for the internal wall.

For the inside of the building material, the diffusion equation shown by Equation (1) is solved.

$$\frac{\partial C}{\partial t} = \frac{\partial}{\partial x}\left(D_c \frac{\partial C}{\partial x} \right) \tag{1}$$

Here, C is the equivalent vapor-phase concentration of the objective chemical compound in building material, and Dc is the effective diffusion coefficient of the objective chemical compound.

The flux conservation shown in Equation (2) exists on the interface between the surface of the building material and the air phase.

$$-D_c \left.\frac{\partial C}{\partial x}\right|_{ws+} = -D_a \left.\frac{\partial C}{\partial x}\right|_{ws-} \tag{2}$$

Here, Da is the molecular diffusion coefficient of the objective chemical compound in the air phase, ws is the interface between the building material and the air, plus (+) indicates the building material side and minus (–) indicates the air phase side.

For the air phase in the micro cell, the diffusion equation shown by Equation (3) is solved. The object of this analysis is only the diffusion phenomenon attributable to molecular diffusion assuming that the convection phenomenon and turbulent diffusion in the micro cell are negligible, and assuming isothermal distribution.

$$\frac{\partial C}{\partial t} = \frac{\partial}{\partial x}\left(D_a \frac{\partial C}{\partial x} \right) \tag{3}$$

Equations (1) through (3) are analyzed by the finite differential method. The objective region of numerical analysis is shown in Figure 2.

Concentrations are analyzed using a fixed value for the normalized initial toluene concentration in the building material and a fixed value for the molecular diffusion coefficient of toluene in the air phase, by changing the effective diffusion coefficient in the building material in steps. Calculation conditions and boundary conditions for the numerical analysis are shown in Table 1.

Figure 1 External appearance of Micro Cell

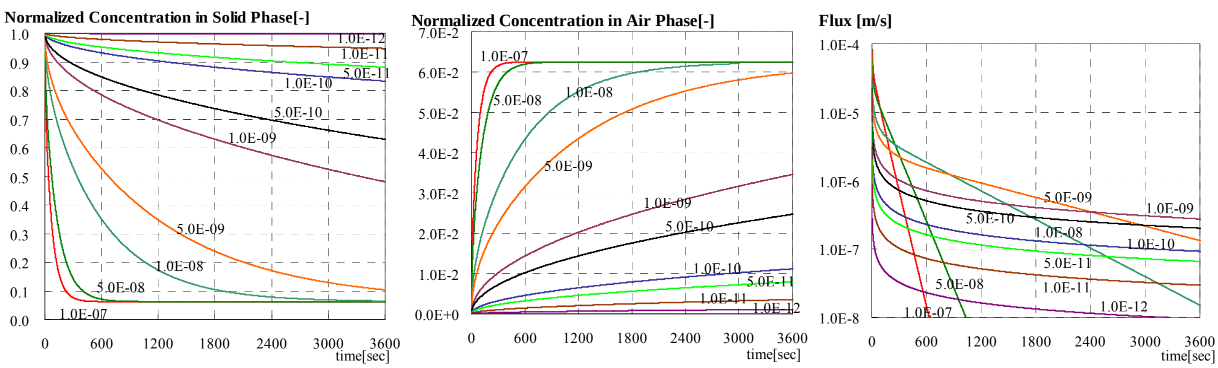
Effective diffusion coefficient prediction chart

Figure 3 shows the prediction results of toluene-equivalent TVOC concentration histories in the building material and in the micro cell, changing the effective diffusion coefficient (*Dc*) in the building material stepwise from 1.0×10^{-7} [m^2/s] to 1.0×10^{-12} [m^2/s]. All the values in the figure are normalized to the initial concentration in the building material. Figure 3(1) shows the relationship between the time history of the average concentration in the building material and *Dc*, Figure 3(2) shows the relationship between the time history of the average concentration in the micro cell and *Dc*, and Figure 3(3) shows the relationship between the emission rate (emission flux) and *Dc*. In this report, uniform distributions of initial concentration in the building materials are assumed as initial conditions.



(1) Solid phase (2) Air phase (3) Emission flux

Figure 3 Time history of toluene concentration for various *Dc* (4mm). Similarly, the charts when building materials thickness is different were made by numerical analysis

When *Dc* of the target building material is 1.0×10^{-7} [m^2/s], the concentration in the building material and in the micro cell become almost equilibrium at 500 [sec] from the beginning of analysis. When *Dc* is 5.0×10^{-9} [m^2/s], concentrations approach equilibrium values in 3600 [sec] from the beginning of analysis. As *Dc* becomes smaller, the change in concentration per unit time also becomes smaller.

OUTLINE OF EXPERIMENT

The building materials used in the experiments are sandwiched between stainless steel (SUS) boards and controlled at a constant temperature (301 [K]) for at least a month to rid the concentration gradient in testing building material in incubator [9]. A SUS board is placed lower surface of the testing building material and the upper surface is left open to allow one-sided diffusion (emission).
The time history of concentration in the micro cell is continuously measured with a photo-acoustic spectrometry method (multi gas monitor, INOVA). In order to ensure a closed experimental system, the air sampled from the micro cell is returned to the micro cell after the multi-gas monitor measurement of the concentration. The atmospheric temperature of the experiments is controlled at 301 [K] by placing the test building materials to which micro cells are attached in a incubator. Humidity is not controlled. Concentration measurements are continued until an equilibrium concentration in the micro cell is reached.
The measurement system is shown in Figure 4, and the experimental conditions are shown in Table 2.

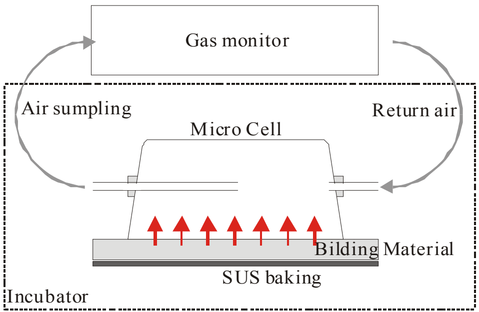


Figure 4 Measurement system using Micro Cell

Table 2 Experimental conditions

Temperature	301 [K] (28 [℃]) (Humidity is not controlled)

Outline of effective diffusion coefficient measurement by Cup method

In order to validate the measurement value by micro cell method proposed in this research, cup method and MIP method to measure effective diffusion coefficient are carried out. The effective diffusion coefficient by cup method is estimated from the measurement result for the flux value in the condition that made the concentration difference on the top and bottom of building material. In this experiment, liquid toluene was placed in the stainless steel cup is shown in Figure 5 and the opening of the cup was covered with the building material. The cup was placed in a incubator at 301[K], and the toluene concentration on the upper surface of the building material was kept at zero by sufficient ventilation. The diffusion coefficient is calculated from Equation (4).

$$Dc = \frac{m}{A_b}\frac{d}{C_{sat}} \tag{4}$$

Here, m is the weight change per unit time of toluene in the cup [mg/h], A_b is the surface area of the building material [m^2], d is the thickness of the building material [m], and C_{sat} is the saturated vapor phase concentration at the ambient temperature [mg/m^3].

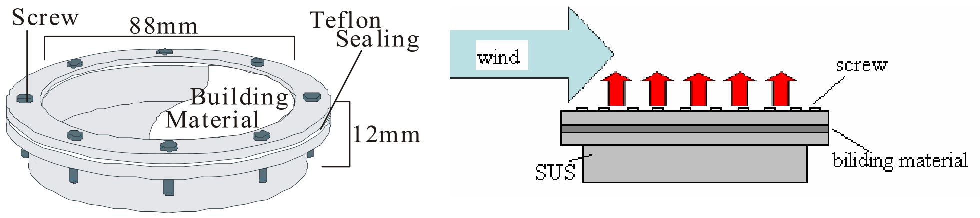

Figure 5 Detail of the Cup

Outline of effective diffusion coefficient measurement by MIP method

The effective diffusion coefficient by MIP method is estimated using the porosity (ε) and tortuosity factor (τ) are estimated from the measurement results for the amount of mercury that has entered the fine pores of the building material under pressurization. The effective diffusion coefficient is calculated from Equation (5) based on the parallel pore model [10].

$$D_c = \frac{\varepsilon}{\tau}\frac{1}{\frac{1}{D_{KA}}+\frac{1}{D_a}} \tag{5}$$

Here, Da is the molecular diffusion coefficient [m^2/s] of chemical substances in the air, and D_{KA} is the Knudsen diffusion coefficient [m^2/s] calculated from Equation (6).

$$D_{KA} = 3.067r\sqrt{\frac{T}{M}} \tag{6}$$

Here, r is the mean fine pore diameter [m], T is the absolute temperature [K], and M is the molecular weight [kg/mol].
Testing building materials were vacuum-dried for a day as pretreatment, and an AutoPore III 9420 (Micromeritics) was used for the measurement. The range of the fine pore distribution measurement was from a radius of about 0.0018 to 100 [μm].

EXPERIMENTAL RESULTS

The time histories of concentration in micro cell are shown in Figure 6. Although the concentrations gradually increase with time, the profile and range of concentrations are different with each building materials.

Time histories of Normalized concentration in micro cell are shown in Figure 7. Concentration values in Figure 7 were normalized to the initial concentration in the building materials. The mean concentration histories in micro cell by numerical analysis are superposed on Figure 7. As for the early times, experimental values tend to rise slightly up than calculation values. However the profile of the concentration history almost fitted. In this experiment, the effective diffusion coefficients (toluene-equivalent TVOC) of the building materials are estimated to be from about 4.0×10^{-10} to 2.5×10^{-8} [m^2/s].

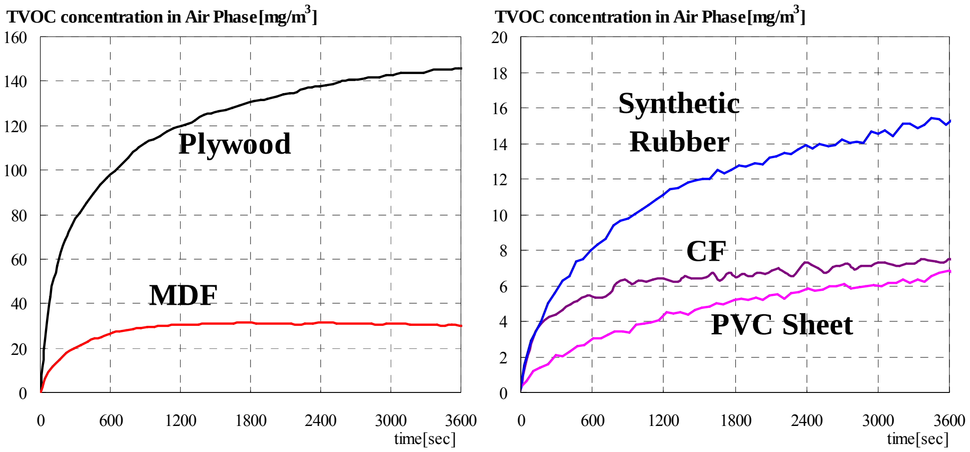

Figure 6 Time history of TVOC concentration in Micro Cell

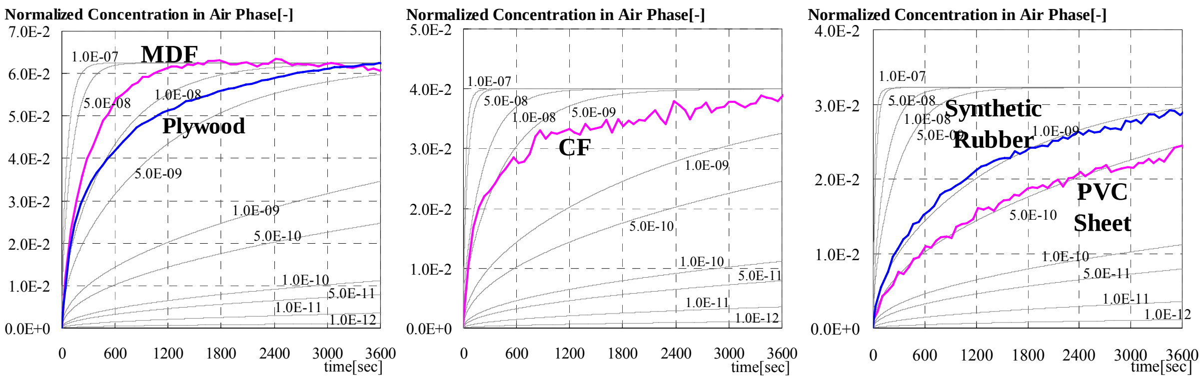

(1)Plywood, MDF (4mm) (2)CF (2.5mm) (3) PVC sheet, Synthetic rubber (2mm)

Figure 7 Time history of normalized concentration in air phase

The emission flux is estimated by reading the emission flux chart when the concentration in micro cell reaches the guideline value. In this study, since the dynamic range of the filter for hydrocarbons (Total Organic Carbon ref. Toluene) in the multi-gas monitor is wide, measured concentration values are overestimated in comparison with ordinary TVOC values. Therefore, the emission rate when the reference concentration in micro cell reached about 10 times as high as the TVOC guideline value (4 [mg/m^3] in this case) is estimated in this report. The emission rates when the air concentration is 4 [mg/m^3] are estimated to be from about 0.3 to 460 [$mg/m^2/h$].

Results of the effective diffusion coefficient, emission rate and initial concentration in the building materials are shown in Table 3. This proposed method is able to obtain three values of the building material property with a single measurement.

Table 3 Results of the effective diffusion coefficient, emission rate and initial concentration

Testing Building Materials	Effective Diffusion Coefficient (Dc) [m^2/s]	Emission Rate (E) [$mg/m^2/h$]	Initial concentration (C_0) [mg/m^3]
Plywood	7.0×10^{-9} - 1.1×10^{-8}	2.9×10^{2} - 4.6×10^{2}	2.3×10^{3}
MDF	1.5×10^{-8} - 2.5×10^{-8}	4.0×10^{1} - 6.7×10^{1}	5.0×10^{2}
CF	2.0×10^{-9} - 6.0×10^{-9}	7.6×10^{-1} - 2.3×10^{0}	1.9×10^{2}
PVC Sheet	4.0×10^{-10} - 5.5×10^{-10}	2.9×10^{-1} - 3.9×10^{-1}	2.8×10^{2}
Synthetic Rubber	8.5×10^{-10} - 1.2×10^{-9}	2.2×10^{0} - 3.1×10^{0}	5.3×10^{2}

Figure 8 shows the effective diffusion coefficient by each measurement method. In this experiment, the effective diffusion coefficient value by MIP method was the largest, followed by cup method and then micro cell method. The effective diffusion coefficient of PVC sheet and synthetic rubber were small in comparison with other building materials. That difference is order of 10^{-2} in MIP method, and is order of 10^{-1} to 10^{-2} in micro cell method.

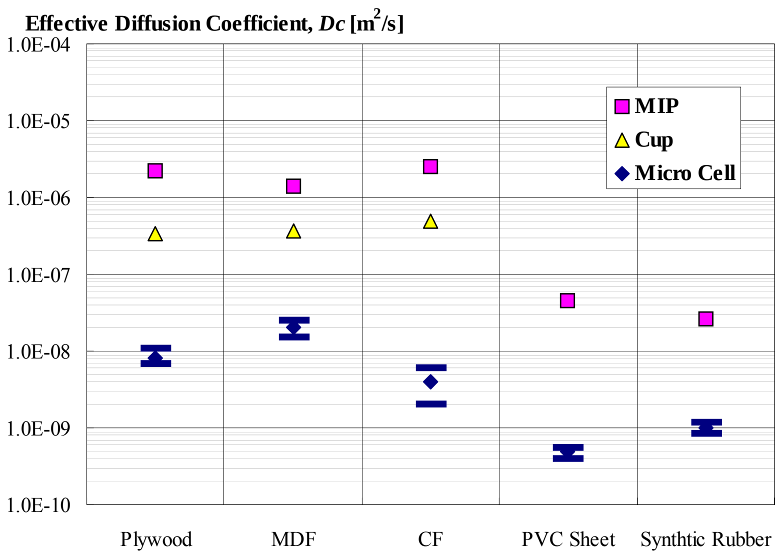

Figure 8 Effective diffusion coefficients by each measurement method

DISCUSSION

The effective diffusion coefficient values obtained by this proposed method are evaluated smaller than those obtained by the other measurement methods. Previous studies reported that effective diffusion coefficient values from MIP method tend to be larger, since the effective diffusion coefficient values are calculated from the physical properties of the building materials alone without considering the influence of interactions with absorption and desorption in the building materials and influence of the humidity [8]. In case of experiments by cup method, the concentration in the cup is far higher than ordinary indoor concentration. Consequently the effective diffusion coefficient may be overestimated when the concentration of the pore in the building material is saturated or when the concentration gradient of the cavity in cup is not neglected. From this, the result that the effective diffusion coefficient values by micro cell method tend to be smaller than those by MIP method and cup method is considered

to be valid. Also, the effective diffusion coefficient of PVC sheet and synthetic rubber tends to be smaller in comparison with other building materials, in MIP method and both of micro cell method. This proposed method is able to apply to relative comparison about VOCs emission characteristic in building materials as a screening test.
In this report, although the building material properties values by micro cell method are toluene-equivalent TVOC value by multi-gas monitor, those by MIP method and Cup method are toluene alone. The precision of estimated value greatly depends on the precision of the concentration history measurement. In order to improve the precision of estimated value in this proposed method, it is necessary to validate using measurement apparatus capable of high-precision analysis of single components.

CONCLUSIONS

(1) In this report, we proposed the estimation method of building material properties by using both numerical analysis and measuring the time history of concentration in micro cell, and showed that the effective diffusion coefficient, emission rate and initial concentration in the building material is provided with a single measurement.
(2) The effective diffusion coefficient of testing building materials were estimated to be from about 4.0×10^{-10} to 2.5×10^{-8} [m^2/s] in this proposed method, and were smaller than the effective diffusion coefficient values by cup method and MIP method.
(3) Although this proposed method is necessary to improve to obtain more reliable result, it is able to apply to relative comparison about VOCs emission characteristic in building materials as a screening test.

SUMMARY

The European research project Innovative Sensor **Sys**tem for Measuring **P**erceived **A**ir **Q**uality and Brand Specific Odours (SysPAQ) is started under the VIth framework programme under the work programme “New and Emerging Science and Technology” (NEST PATHFINDER "Measuring the Impossible"). The Kick-off of the project was on the first of September 2006. Ten partners (3 Companies, 4 Universities, 3 research Institutes) from 5 countries are involved.

The main goal of this project is to develop an innovative system to measure indoor air quality as it is perceived by humans to be used as an indicator and a control device for the indoor air quality. The system will also be able to detect brand specific odours and it will serve as a novel interior odour design tool for the vehicle industry.

INTRODUCTION

This innovative sensor system is highly demanded by the European society considering that humans spend about 90% of their time indoors, either at work, at home or when commuting between work and home. Recent data shows that improved indoor air quality will result in fewer complaints, increased comfort, less health problems and higher productivity. Consequently, quality of life will be improved.

Up to now, the indoor air quality has been quantified applying three different measurement methods separately. The three methods are based on the human perception of indoor air quality, chemical measurements and sensors for specific odours. Considering measuring perceived air quality human assessments are still being superior to chemical measurements because of the unmatched sensitivity to many odorous indoor air pollutants. One of the reasons is that in most cases the chemical measurements or signals from chemical sensors designed to detect special odours could not be correlated with the assessments made by humans. They do obviously not measure the relevant indoor air pollutants triggering human sensory response. This project will build upon current knowledge on the perceptual effects of indoor air pollutants and on the experience gained in using chemical measurements and sensors for specific odours. The approach of the project will be to enhance the present state of the art of sensor systems, the perceptual methods and the software tools for modelling human response, and integrate them into one innovative system for measuring indoor air quality as it is perceived by humans. A bridge will consequently be created between the previous works in this area and progress will be achieved by integrating measurements, sensors and modelling by a holistic approach.

The main challenges are the finding of a perceptual space by using different reference odours, the measuring procedure for perceived air quality, and a characterisation method of brand specific odours. This work requires advanced knowledge in perception psychology and technical excellence in sensor system design and indoor environment research, knowledge and experience which the project partners contribute. It is still an open question how to mimic the human perception of odours and air quality. A certain risk of failure is involved in this project’s unsolved problem of how to define an adequate system of reference odours for human perception of odours. In any case the project will provide new insight to the human perception of odours and indoor air quality, and will deliver a new approach to assess the perceived air quality and brand specific odours by an advanced sensor system.

PROJECT OBJECTIVES

The main goal of this project is to develop an innovative system to measure indoor air quality as it is perceived by humans based on perception modelling combining measurements of sensors and assessments of perceived air quality by sensory panels. The innovative sensor system can be used as an indicator, monitor and control device for the indoor air quality in buildings and vehicles. Furthermore, the system will be able to detect brand specific odours and it will serve as a novel interior odour design tool for the vehicle industry. The main objectives of the project are:

1. Definition of a method for measuring the perceived air quality and perceived odour intensity in buildings and vehicles. This method will be used by all different labs using sensory panels.
2. To find an advanced perception model for indoor air assessments. The model will be the major input to the software design for the innovative sensor system and it provides new insight to the human reaction to odours.
3. Development of an innovative sensor system for measuring, correspondingly, the perceived air quality and brand specific odours quality.
4. Calibration and test of the innovative sensor system for measuring, correspondingly, the perceived air quality and brand specific odours. The final version of the system is intended for the following applications :
    - Monitoring of the ambient air within buildings and vehicles.
    - Monitoring of the quality of the inlet air to buildings to ensure health and comfort for occupants.
    - Labelling of materials based on emissions from buildings and vehicles.
    - Control of the production process of building and vehicles materials.

Along with human activities, emissions from building materials, furnishing and equipment are main contributors to air pollution indoors. To reduce indoor air pollution loads it has been recommended to use low-polluting materials and to increase outdoor air supply rates. The new EU Energy Directive requires substantial reduction of energy use which may lead to reduction of ventilation rates and increased indoor air pollution enhancing the need of low-emission materials. In addition to measurements of indoor air quality as perceived by humans the system developed in the project can be used to control the emission rates from building materials already at the production stage. At present, manufacturers generally reduce the emissions from building materials by monitoring the emission rates of a few compounds in practice, but not necessarily the most relevant odour active compounds for perceived air quality. The pollution mixture affects the perceived air quality indoors. It is not taken into account so far. The proposed system can be used by the producers of building materials, furnishing and equipment materials to ensure that the emissions from their products would not negatively affect the perceived air quality indoors. In many countries labelling systems of building materials exist, so that the end-users can select the materials with reduced emissions. The suggested system for measuring the perceived air quality can also be used to quantify whether a material can get a label.

The selection of interior materials is a very important factor for the vehicle and transportation industry (train, car, boat, airplane etc.). The goal of the selection process is to create a high-standard perceived air quality in vehicles combined with a brand specific odour impression. To meet this goal the system measuring the perceived air quality seems indispensable.

The interdisciplinary structure of the project consortium will enable innovative research and it will provide new insights to the human perception of air quality and brand specific odours. The project management will ensure a strong interaction between new perception models, hardware development as well as software design for the innovative sensor system.

APPROACH AND METHODOLOGY

The overall approach of the project and the priorities of the different work-packages are shown in figure 1. The figure illustrates the parallelism of the human perception of air quality and brand specific odours on the left hand side and the sensor system development on the right hand side.

The two arrows in the centre of figure 1 indicate the coupling of sensory panel experiments and the sensor system hardware and software development. The innovative sensor system has to detect all relevant odour active substances. Based on the knowledge of the project partners and experiments of the project a list of relevant substances is submitted to the two sensor specialists. The second arrow indicates the input of the new perception model of the perception specialist to the software development. The mathematical model of the new software for the sensor system will apply a reference odour system to reproduce an odour space that covers perceived air quality and brand specific odours in buildings and vehicles.

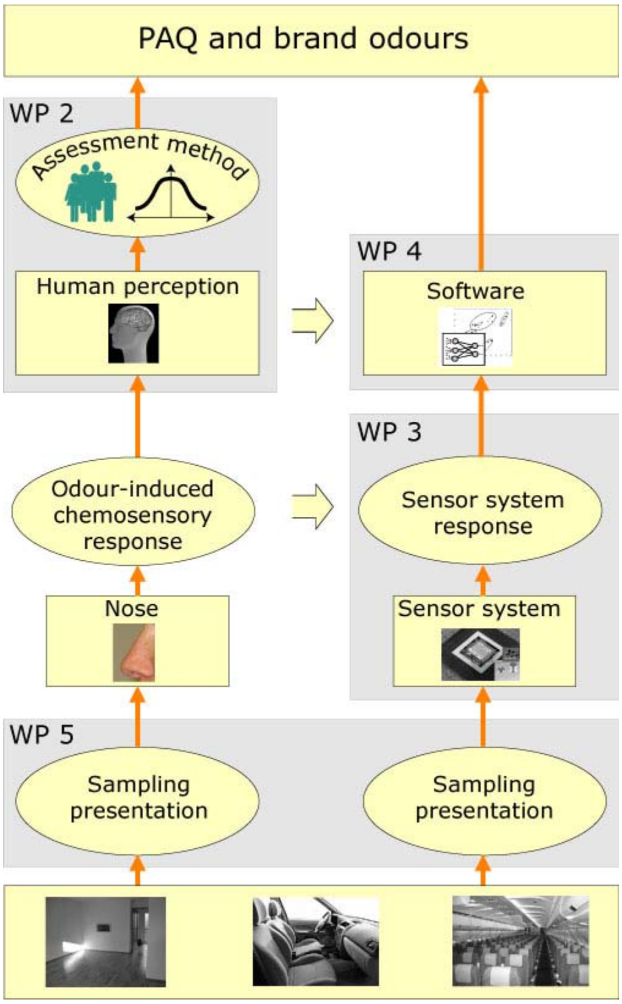

Figure 1: Parallelism of the human perception of air quality and brand specific odours on the left hand side and the sensor system development on the right hand side

WORKPLAN OF THE PROJECT

Introduction - general description

The work of the project is divided into two main tasks. The first task is focused on human perception of odours. This part includes the definition of a method to measure perceived air quality and odour intensity by sensory panels. The used assessment methods can have a major influence on the assessment results itself. Besides the assessment method the main challenge of the human perception task is the definition of an odour space using reference odours. The multidimensional odour space has to account for all interior odours in buildings and vehicles.

This new odour space is the major input to the second main task of this project. This part is focused on the hard- and software development for the innovative sensor system. The contribution of two sensor specialists enables the application of the most advanced sensor technology. The sensitivity and selectivity of the sensors is adapted to odour active substances and the new odour space. The combination of different sensor types leads to novel sensor system that covers considerable more substances than any present stand alone system. The data processing for this sensor systems combines advanced statistical pattern recognition methods with the novel reference odour systematic. The link between the sensor signals and the perceived air quality consists of a classification process in terms of the reference odours followed by a regression method calibrated by the experimental data of the project.

This two main tasks **human perception** and **system development** break down to 4 work-packages (human perception and odour space, sensor system, data processing and pattern recognition, system calibration). The management process and the dissemination activities control and link these four work-packages, see figure 2.

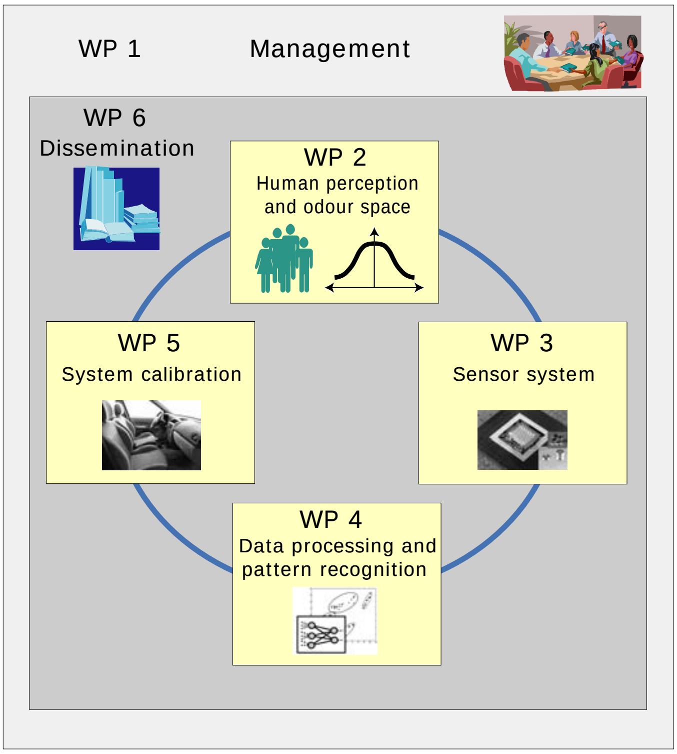

Figure 2: Work-package structure

Work planning

All overall **management** activities are included in WP1. The duration of the management activities covers the whole project life time. The main management activities are directed to the organisation of the project meetings and the knowledge transfer between the different work-packages. The management of the project insures a punctual delivery of all reports to the European Commission and it checks milestones and deliverables of all work-packages. The management also handles the global risk management of the project. The risk management includes the call for extra expert meetings in case of unsolved project tasks and the adjustment associated work-packages in the case of missing milestones or deliverables.

The **human perception** task of the project is mainly handled in WP2. Starting point of WP2 is the definition of a method for all sensory panel assessments of perceived air quality and odour intensity. The method is based on the knowledge of the experimentally experienced project partner and the input of new multidimensional psychophysical perception models. This common standard for the assessment method guarantees comparable measurements at all labs for the innovative sensor system calibration data. The second and the most important part of WP2 is the definition of a new odour space based on reference odours. The new odour space has to cover all relevant odours of indoor air related environments. All project partners of WP2 have been working on the characterisation of odours in the past. The work-package leader Karolinska Institute (KI) will provide a human perception model as a theoretical base for the new odour space. First experiments of KI will examine the useability of the new odour space based on reference odours to reproduce indoor air odours from building and vehicle environments. The quality of the odour space is the critical factor for the innovative sensor system and it will influence the software design process. A continuous knowledge transfer between WP2 and WP4 will insure a fast translation of new findings into the software system.

WP3 covers all activities related to hardware improvements for the **innovative sensor system**. This work-package includes the improvement and adaptation of single multi-gas sensors as well as the combination of different multi-gas sensor technology. The adaptation process and the selection of sensors are based on literature review and some analysis of indoor air environment of buildings and vehicles in terms of odour active compounds. The sensor development and sensor combination is handled by two experienced sensor specialist Alpha MOS and Forschungszentrum Karlsruhe (AM, FZK). The two partners can provide gas chromatography/mass spectrometry combined with sniffer experiments to prove the response of the multi gas sensor system to odour relevant substances. The check and minimisation of cross sensitivity (to other chemical compounds, relative humidity and temperature of sample air) of the sensors provides reproducible measurements. The sensor specialists (AM, FZK) manufacture three similar measurement devices for the calibration and validation measurements. The three systems will be jointly used by all partners. Additionally, the partner AM und FZK will provide all necessary hardware information and prototypes to the partner Centre Scientifique et Technique du Bâtiment (CSTB) and Technical University of Berlin (TUB) to insure a parallel development of the data processing and pattern recognition software (WP4).

The set-up of the general software layout for the **data processing** will be handled in WP4. The work package leader Technical University of Berlin (TUB) contributes many years of experience in pattern recognition methods and software development to calculate the perceived odour intensity based on multi gas sensor systems. The separation of software and hardware (WP3 and WP4) enables a company independent and extendable mathematical modelling of low-concentration odour mixtures as regards sets of critical odours for building and vehicle materials and products and their combination. The task of the computational data processing is to model the human odour perception of air samples. The method shall consider existing theories of perception and it shall link the measurements with psychophysical aspects of odour sensing. The response values of the sensor device will act as the stimuli and the software shall mimic the human perception and evaluation process. The core of the data processing method will be the “memory”, the calibration database. This database will have a major influence on the performance of the method, especially on the classification of the investigated odour sample. Therefore the data shall span the whole odour space which is developed in WP2. The principle components of this odour space will be the basic odours. The data of the database consists on a combination of sensor response values and air quality assessments according to the methods of WP2 for a specific odour sample and concentration. The database shall contain for each odour class data for different stimuli concentrations. The system shall be adaptive which requires the database to be expandable and open for new data of odour investigations. The calculation models will always refer to the current data and therefore the algorithms will be adjusted to the extended data set.

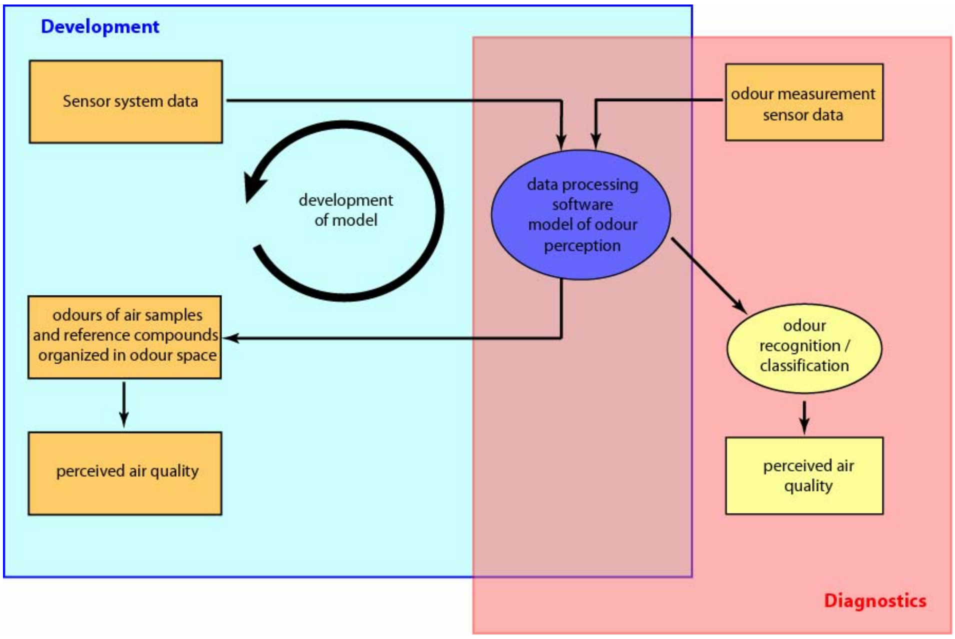

Figure 3: The software will handle the development/calibration process and it provide the final version for diagnostics of unknown odours

The unknown investigated odour shall be positioned inside the odour space which is a classification process for "odour recognition". Unknown odours shall be expressed by a combination of the basic odours. Once the sample is classified the quantitative and qualitative parameters of the perceived air quality shall be estimated. This step of the data processing uses the calibration data of the basic odours, the regression and calculation algorithms for this odours as well as weighing algorithms which consider the position of the unknown odour sample in the odour space. Data of odour samples other than the basic odours is needed to develop, test and optimize the weighing algorithms and to estimate the perceived air quality of different odours. Most of the odour space and combinations of basic odours should be covered. During the validation process of the software the new collected data will be included in the database which may further improve the performance of the data processing method.

The innovative sensor system has to identify all reference odours and their combination in indoor environments. Additionally, the system shall link the pattern recognition method for the identification process to the sensory panel results. Due to the multidimensional character of the problem a large effort is needed to calibrate the innovative sensor system. WP 5 handles the **collection of the calibration data**. It consists of simultaneous measurements of perceived air quality as well as the perceived odour intensity by a sensory panel and measurements with the sensor systems using the most relevant sensory methods selected in WP2 and the most promising innovative system/technical device selected in WP3. All data of WP5 iterates back to the software enhancement of WP4. The odours for calibration measurements of WP5 are produced in emission chambers. The air flow through the chambers is polluted by a series of building and cabin materials. The concentration of air pollutants will be varied within an indoor realistic range to ensure and test if the system works appropriate. The variation in concentration will be achieved by varying the material loading and the ventilation rate and by selecting high and low emitting materials. Measurements will be performed for individual materials in a laboratory setting, for combinations of materials in a full-scale setting, and in real buildings and vehicles. All data of WP5 is stored in a database. A final test run of the innovative sensor system after calibration will show the ability to predict perceived air quality and to characterise brand specific odours. During the sensor development WP5 will provide preliminary test set-ups of building materials in order to secure reasonable sensitivity and discrimination power of the novel sensor system.

The **dissemination** task of WP6 provides the publication of all project results. The main communication medium of the project is an advanced internet portal that offers a public and a non public information area (www.syspaq.eu). The public area publishes all non confidential findings of the project partner during the project life time. The non public area handles the data exchange of all project partners. All project related findings will be open for the public after the completion of the project. The project will provide a final workshop in order to discuss and disseminate all findings of the project. The consortium will prepare a brief project presentation in English which is written in a style which is accessible to non-specialists, avoiding technical language, mathematical formulae and acronyms as much as possible. Publication will be done via the NEST www page.

A more detailed information on the major work package interdependencies is given in figure 4.

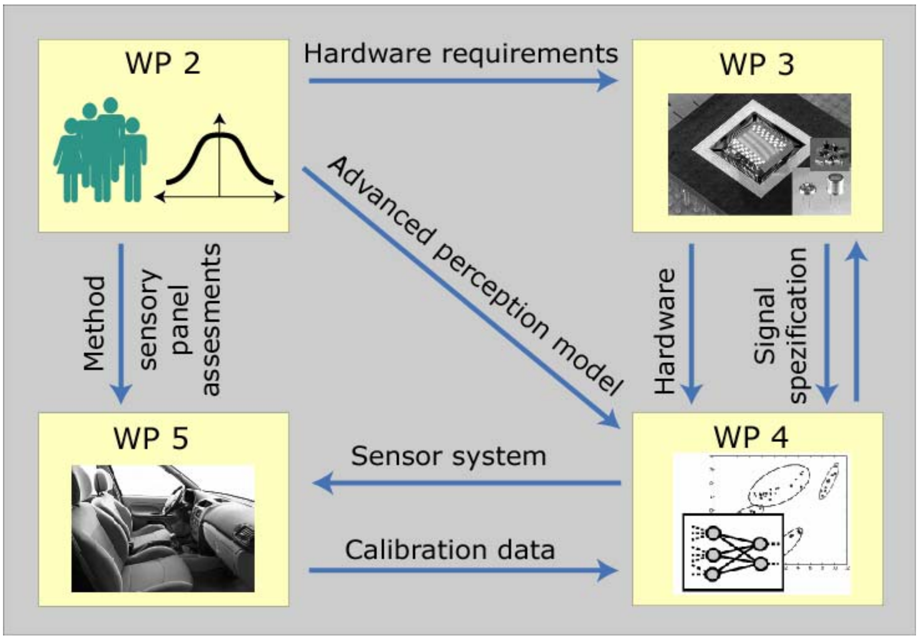

Figure 4: Major work-package interdependencies

ACKNOWLEDGEMENT

SysPAQ is partly sponsored by the European Community in the Nest programme (NEST-28936) under the management of Mrs. P. Lopez. The co-ordination is done by the Technical University Berlin. Other participants are: Danish Building Research Institute, Aalborg University; Technical University of Denmark; Karolinska Institute; Centre Scientifique et Technique du Bâtiment; Forschungszentrum Karlsruhe; Federal Institute for Materials Research and Testing; REGIENOV; Alpha MOS; Halton Oy.

SUMMARY

Recently in Korea, plywood has been widely used as a floor material for Korean floor heating systems (Ondol) instead of the conventional oiled floor paper. Volatile organic compounds (hereafter VOCs) are easily emitted from the plywood and adhesives that constitute the floor into the indoor environment due to the warm temperature of the floor. In this study, emission characteristics of VOCs from adhesive and paints within an Ondol floor are assessed using the Small Chamber Method in residences with plywood floors. From the experimental results, the concentration of VOCs is predicted as an exponential function, dependent upon various loading factor and air exchange rate conditions.

INTRODUCTION

The traditional Ondol heating system has been used in Korea since 400 B.C.[1] Before the 1950s, the conventional Ondol system was used, which heats the air by burning wood and straw in the furnace, sending the heated air below the floor, and exhausting the air through the chimney. [2] After the 1950s there was a shift to anthracite coal Ondol systems that had improved fuel and furnace facilities; afterwards, a pipe-laid system using a hot-water boiler was widely used to prevent CO gas emission and to improve heating efficiency. Despite the CO gas poisoning problem and lower burning efficiency, briquette was widely used until the late 1970s as a heat source in the Ondol system. In order to enhance combustion efficiency and constrain gas emission, the structure of the combustion chamber was improved, and the pipe was laid inside the floor structure, causing a fundamental change in the principal and structure of the conventional Ondol system. [3] During the 1980s, a briquette-fueled Ondol system was again adopted instead of the oil-fueled boiler due to the increasing petroleum price during the energy crisis period. After 1986, use of the oil-fueled boiler surpassed the briquette-fueled boiler due to economic growth and a decrease in oil price. Since 1987, the gas boiler has been used owing to the spread of Liquefied Natural Gas as a fuel for residences. Beginning in the 1990s, a thermal storage system which uses the relatively cheap nighttime surplus heat has received increasing attention due to the active utilization of nighttime electricity. [4]

Currently, the conventional hydraulic Ondol system utilizes the heat of hot water circulating through a pipe inside the floor structure to heat the floor and the home. Thus, the entire floor functions as the heating surface. [5]

Vegetable oil floor paper was used as the finishing material of the Ondol system until the 1970s, but since the 1980s, plywood began to be used as the floor material. [6] Currently, the Ondol floor is widely used in residential buildings instead of plywood. Since the Ondol floor consists of individual pieces of wood, adhesives are used to fixate the separate parts together and a variety of petrochemical paints are used as a surface treatment. These plywood adhesives and petrochemical paints emit significant amounts of hazardous volatile organic compounds and formaldehyde. [7] Although plywood is an important wood-based panel with many advantages, formaldehyde emission from plywood, especially from urea-formaldehyde bonded plywood, is a serious air pollution problem that causes adverse effects on human health, such as irritating the eyes, nose, and throat, and even causing cancer. [8]

By the early 2000s, research related to indoor air quality (IAQ) mainly focused on particulate matter, CO, CO_2, and natural and mechanical ventilation. Recently, provisions and experimental standards for IAQ were established, and measurement methods were actively developed for improving IAQ. In order to implement these new standards, construction companies replaced conventional finishing materials with environmentally sound materials. Sung et al. [9] carried out research on the emission rate of VOCs from individual products such as adhesives and paints, and Kim et al. [10] assessed the emission factor of VOCs using the small chamber method.

However, research by Kim et al. [11] did not include field measurement of the Ondol floor installed in real residences. They measured the concentration of formaldehyde using the decicator method in an artificial experimental chamber.

In this study, the emission factor of VOCs emitted from paints and adhesives from the Ondol floor was assessed using the small chamber method. In addition, a plywood Ondol floor was installed in a real residence constructed ten years ago, and concentrations of VOCs were measured. From the experimental results, prediction equations of VOC concentration decay were developed. Furthermore, prediction methods under various loading factor and air exchange rate conditions are also provided in this paper.

MATERIALS AND METHODS

Currently, plywood is widely used in Korea as the floor material of living and bed rooms in apartments and residential buildings.

In the case of a plywood floor, 0.5-mm thick patterned lumber is adhered to plywood. Typically, oak, beech, cherry, and maple are used as the patterned lumber. This finish wood is adhered to 7.2mm thick plywood of after being heated to 160 C. Figure 1 illustrates an overview of a plywood floor. The finished floor has a thickness of 7.7 mm and the of 75 x 900 mm. Table 1 presents the paints and adhesives used in the plywood floor and patterned lumber finish.

Painting consists of approximately three composite layers: primer, waterproofing, and the coating layer. Primer is a kind of finishing material at the innermost part of the painting process, while the waterproofing layer prevents water penetration. The coating layer determines the overall color of the floor.

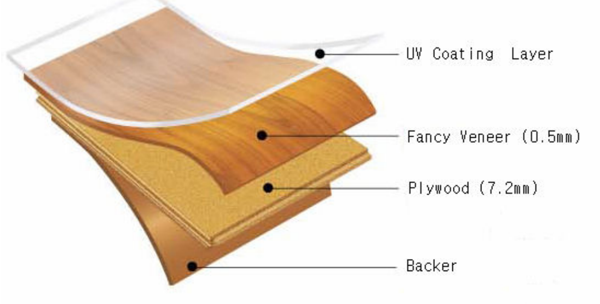

Figure 1. Composition of Ondol floor.

Table 1. Measured materials

	Floor materials
Measured materials	Primer
	Waterproofing layer
	Coating layer
	Primer(adhesive)
	Hardener(adhesive)
	Primer + hardener(adhesive)

Usually, two liquid-type adhesives are used, which are applied in two liquid layers. The first layer contains an adhesive component and the other controls the hardening rate of the liquid. Those two layers should be attached to each other for proper operation. The two-liquid type adhesive consists of primer and hardener in a one to one mixture ratio.
Figure 2 presents the experimental chamber, sample box, and fixing device inside the small chamber. Table 2 shows the experimental conditions such as chamber material, interior volume, sample area, air exchange rate, air flow rate, loading factor, temperature, and relative humidity.

Table 2. Experimental conditions of small chamber.

Specifications	Conditions
Chamber Material(CM)	Stainless Steel
Chamber Volume (CV)	0.02[m^3]
Sample Area(SA)	0.063×0.063 = 0.0039[m^2]
Air Exchange Rate(AER)	0.5 ACH
Air Flow	167[mℓ/min]
Loading Factor(LF)	0.4[m^2/m^3]
Temperature(T)	25±1.0[℃]
Humidity(H)	50±5[%]

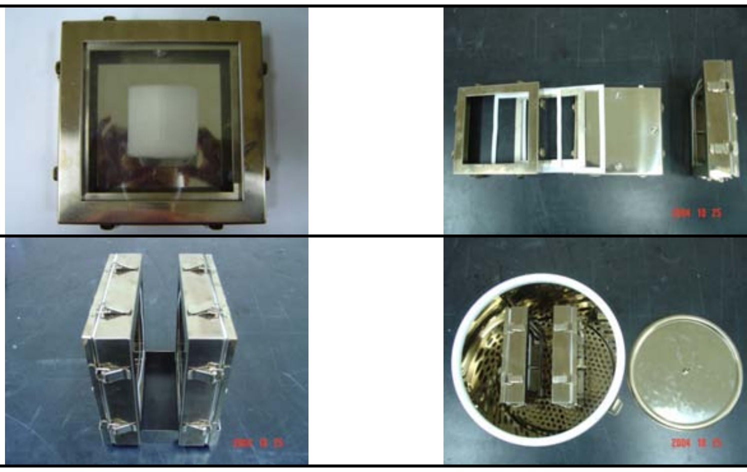

Figure 3. Experimental chamber, sample box and fixing device.

In order to determine the emission characteristics of VOCs emitted from the plywood of an Ondol floor, an Ondol floor was constructed inside the experimental room. Figure 3 (a) and figure 3(b) illustrate the plan (4.5m x 3m x 2.35m) and the construction process, respectively. The experimental room was installed on the rooftop of a residence constructed ten years ago. This residential building was selected since VOCs are not emitted into the indoor environment when a building is more than ten years old. Figure 3(c) illustrates a section of the Ondol system including the concrete slab of the living and bed rooms.
Measurement and analysis of VOCs was carried out based on NIOSH 1501[14] and 1500[15] using a GC/FID device.

Figure 3. Experimental room.

RESULTS

Table 3 shows the time-dependent factors of VOC emission from the primer, waterproofing layer, coating layer, and adhesives used in the Ondol floor. Floor paints demonstrated an emission factor of 150～250 [㎍/㎡·h], except for benzene. However, benzene showed an emission factor five times greater than other substances ranging from 900～1300 [㎍/㎡·h], which did not decrease as time elapsed.

Table 3. VOCs emission factor from floor materials [㎍/㎡·h]

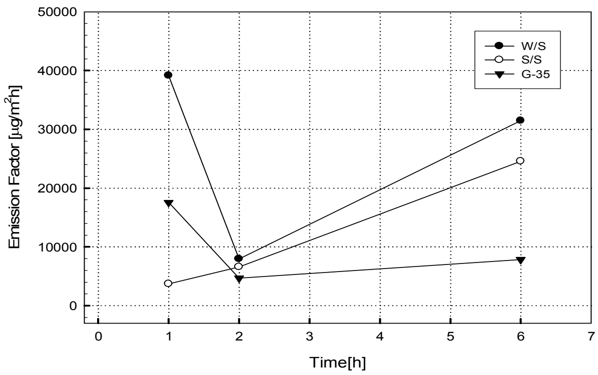

Figure 4. BTEX emission factor of adhesive.

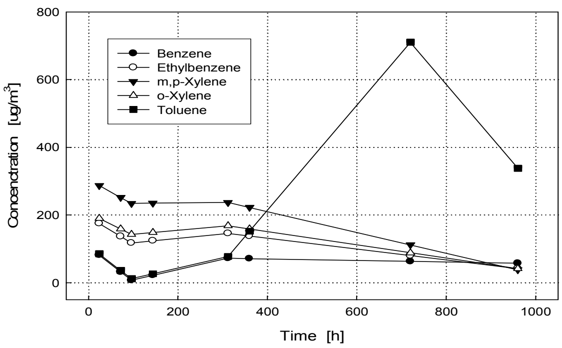

Figure 5. VOCs concentration after floor installation in experimental room.

Figure 4 illustrates the total BTEX emission factor. As shown in this figure, adhesives have a higher emission factor than paints. In addition, VOCs are continuously emitted with time, suggesting that adverse indoor air pollution will be caused more by adhesives than by paints. W/S stands for wood-silla used for the filling of wood mesh and s/s is a paint used for smoothing surfaces. G-35 is a finishing material in the upper most part of the surface.
Figure 5 illustrates the time-dependent variation of indoor VOC concentrations after the installation of an Ondol floor in a real residence. BTEX concentration decreased dramatically during the initial 100 hours after installation, and then decreased gradually.
Benzene showed a relatively constant concentration throughout the measuring period. Ethylbenzene and m,p,o-xylene showed different concentrations, but their decrease patterns were similar.
Although Toluene showed results similar to other substances at first, the concentration suddenly increased and then decreased. This could be due to VOCs being emitted from the floor material at a relatively early time, while petrochemical adhesives dominate the indoor concentration variation as time progresses.
After the floor installation, VOCs are gradually emitted into indoor environment as the petrochemical adhesives harden. This pattern can also be confirmed by the VOC emission characteristics assessment using the small chamber method, which is presented in figure 4. As can be seen in figure 4, the VOC emission factor of adhesives decreases temporarily but increases again as time elapses.

VOCs concentration prediction of the experimental room

A time-dependent concentration decrease of ethylbenzene after the installation of a plywood Ondol floor in a real residence is illustrated in figure 6. The ordinate used is a logarithmic scale and the profile can be expressed as a straight line in the form of an exponential function. Ethylbenzene concentration as a function of time can be expressed by the following equation.

$$C_{(ti)} = 159.26 \times e^{(-0.0010 \times t)} \tag{1}$$

In the expression above, R^2 showed a relatively high value of 0.72 and t is the elapsed time. Figure 7 shows the m,p-xylene concentration prediction. Indoor m,p-xylene concentration can be predicted using an expression similar to that for ethylbenzene.

$$C_{(ti)} = 292.7 \times e^{(-0.0013 \times t)} \tag{2}$$

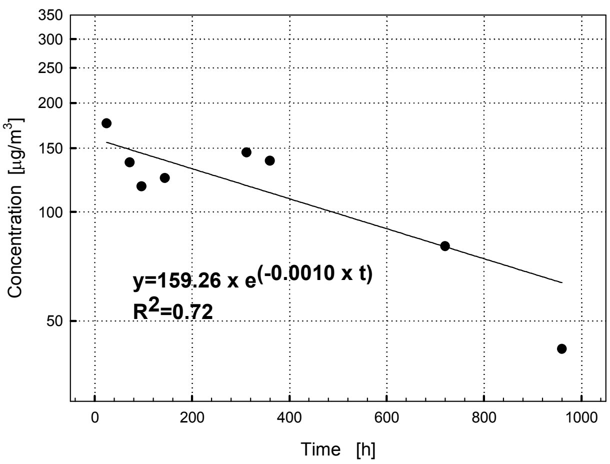

Figure 6. Concentraon predicton of Ethylbenzene.

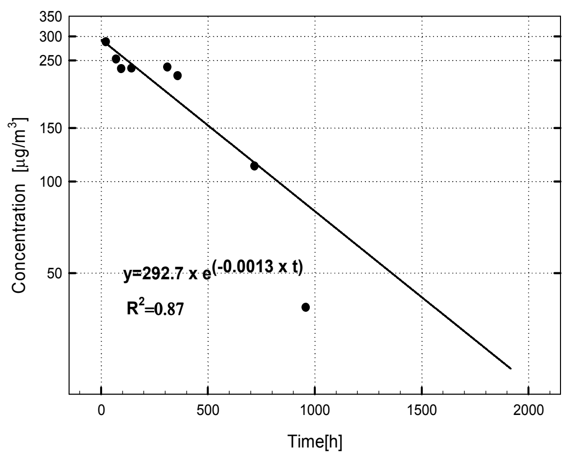

Figure 7. Concentration prediction of m,p-xylene.

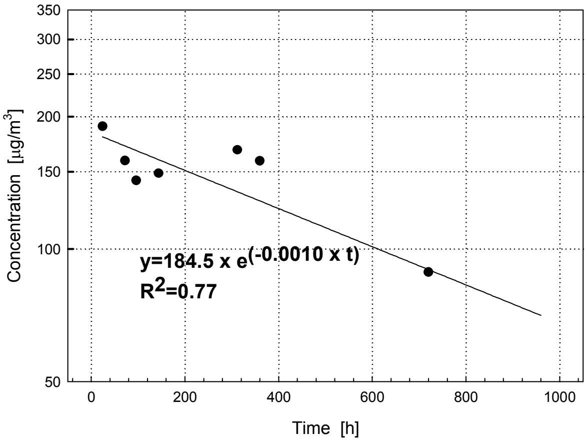

Figure 8. Concentation prediction of o-xylene.

Table 4. Result of regression analysis for volatile organic compounds.

substances	Prediction model	R^2
ethylbenzene	$C_{(ti)} = 159.26 \times e^{(-0.0010}$	0.72
m,p-xylene	$C_{(ti)} = 292.7 \times e^{(-0.0013\times t}$	0.87
o-xylene	$C_{(ti)} = 184.5 \times e^{(-0.0010\times t)}$	0.77
xylene	$C_{(ti)} = 476.9 \times e^{(-0.0012\times t}$	0.98

The R^2 value for the above equation showed the high value of 0.87, indicating that indoor m,p-xylene concentration can be properly predicted when applied in a real residence. Figure 8 shows the o-xylene concentration profile with an R^2 value of 0.77, indicating that it can also be used in real residences.

$$C_{(ti)} = 184.5 \times e^{(-0.0010\times t)} \tag{3}$$

Indoor VOC concentrations of each substance can be predicted as described in Table 4. Figure 9 shows indoor ethylbenzene concentration decay under the loading factor of 0.465 [㎡/㎥] and air exchange rate of 0.5-1.0 ACH. As the air exchange rate increases, the ethylbenzene concentration decreases more rapidly. Figure 10 shows the m,p-xylene concentration decay under different air exchange rate conditions, and figure 11 illustrates the time-dependent concentration decay of o-xylene. Figure 12 shows the time-dependent concentration decay under the loading factor of 0.25-0.60 and the air exchange rate of 0.7 ACH. As the loading factor increases, the indoor ethylbenzene concentration decreases more slowly. Figure 13 shows the m,p-xylene concentration decay as a function of loading factor, and figure 14 shows the time-dependent concentration decay of o-xylene under different loading factor conditions.

Figure 15 shows the time-dependent concentration decay of VOCs under different air exchange rates and loading factors. The concentrations decay rates of ethylbenzene and o-xylene were equal, while m,p-xylene showed a higher concentration decay rate than the other substances.

CONCLUSIONS

In this study, indoor VOC concentrations emitted from an Ondol floor and individual floor materials were measured after the installation of an Ondol floor in a real residence. Based on the experimental results, prediction equations for indoor VOC concentrations were developed under various loading factor and air exchange rate conditions.
The following conclusions were made.
1. VOC emission from the Ondol floor made of plywood was dominated by adhesives used in the construction process rather than by paints.
2. Indoor VOC concentrations in the experimental room can be expressed linearly using an exponential function when the ordinate is converted into logarithmic scale.
3. When the Ondol floor made of plywood was installed, indoor VOC concentrations increased as the loading factor increased.
4. As the air exchange rate increased, the indoor VOC concentration decay rate increased more rapidly.

SUMMARY

The printers emit the chemical compound when its temperature rises during normal operations. And it primarily influenced the chemical concentrations such as formaldehyde and VOCs (Volatile Organic Compounds) in a living space. The measurements on the various types of prints from different manufacturers such as laser jet type, inkjet type were performed in emission test chambers of 1m3 and 5m3 with ventilation rate of 1.0 ACH(air change rate) supplying low-polluting clean air. During the test, chemicals emitted per PCs or Printers were analyzed on the two modes of stand-by and operation at 25°C and 50% RH. It is found that PCs and printers are a significant source of chemical emissions in small indoor environments, even with adequate ventilation. The chemicals may affect a potential health hazard for computer users.

INTRODUCTION

Poor indoor air quality increasing chemicals has been focused as related in sick building symptoms such as respiratory illness, itchy, eye irritation, and headaches. Exposure to pollutants in the air may cause health risk. Depending on the health effect of particular chemicals, guidelines of concentration level were established by Korean Government for avoiding the significant health effect generally associated with given concentration levels. There are many pollution sources in building and they emit hundreds of different chemicals. In indoor environment the chemicals are emitted from various kinds of products including building materials and furniture. Over the several years, emission test chamber method has been developed and several databases have been established for the information of chemicals emitted from building material only.

Recently it is common for the design strategies to reduce the chemicals by selecting low emission materials and products. It would be practical data to measure the pollutants emitted from electrical equipments. Computer equipment and printers are focused on as one of the serious pollutant sources indoor. Some approaches have been performed to figure out the potentials of chemicals emitted from office equipment including computer, monitor and printer. Computers are a significant source of allergenic emissions in small indoor space like offices and individual rooms. Even with adequate ventilation, the compound may be a potential health hazard for computer users. The Purpose of this study is to clarify the emission characteristics and to determine the emission rates of chemicals on the computer set and printer.

METHODS

It is known that the perceived indoor air quality caused by VOCs emitted from new building materials generally decrease over time in concerns. Computer set including a monitor and a printer can emit the VOCs during operation continuously. Some questions often arise that how much will the VOCs emit and how the emission rate change with different mode of operation.

The measurements of VOCs and HCHO emission from the computer and printer were conducted using the test chamber method. The chemicals were measured the variation of the emission rates with two different stages of usages. One is for the standby mode, which is not operating the PC but emitted the chemicals continuously, and the other is for the condition of operating mode, of which temperature is goes up with chemicals emitted intensively during operation. Several cases were tested how the profiles of emissions are varied with products from different manufacturers.

Test Chamber and Equipments

Two systems of emission test chamber were built for measuring emission rates from the computers and printers. One is prepared $1m^3$(W 1m x L 1m x H 1m) in scale of air volume for measuring relatively small products like computer sets, which is combined with double chamber system as outer and inner chamber. The buffer zone is realized between two chambers for precisely controlling environmental parameters of temperature, humidity and pressure differences. The other is a large scaled test chamber with volume of 5 m^3 for large products, which is constructed as single chamber type and using emission test for printers. Both of two inside chambers are constructed with stainless steel for confirming not emitting any chemicals themselves.

Environmental conditions of the chamber, such as temperature, relative humidity, air change rate and air velocity could be precisely controlled at setting points. In this measurements, they were controlled to the temperature of 25 ^oC + 0.5 ^oC, relative humidity of 50+5% RH, ventilation rate of 1.0 + 0.1 air exchange per hour and air velocity of 0.2 – 0.3 m/sec. The tests were performed for measurement of formaldehyde and VOCs from the products under designed conditions to simulate the situations of products use indoor.

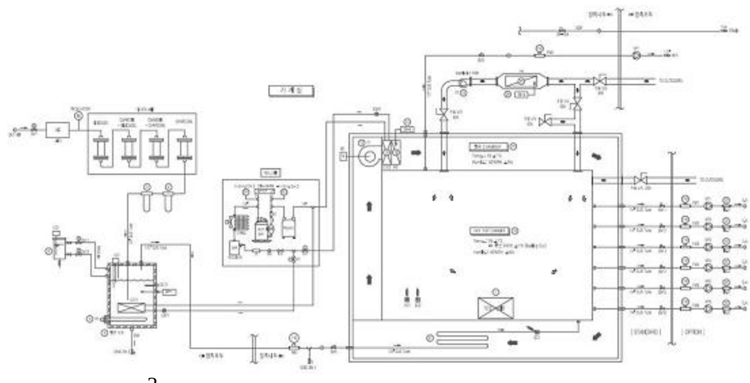

Fig. 1 Diagram of the 1 m^3 test chamber

Test Products

Desktop computer sets with keyboard and monitor were selected for the test of formaldehyde and VOCs emitted. Three laser printer sets from different manufacturers and one ink jet printer were selected for the measurements. They are all new products which were ordered through a retail distributor directly to ensure the brand new and ordinary shipping procedures. The outlines of tested samples are shown in table 1.

Protocol for Chamber Test

Preparation of the test chamber Before placing the test product in the chamber, background air samples were collected from the chamber to be assured the test condition. And adjustment was performed for the air flow, temperature, and relative humidity to assure the standard test condition. And then background samples were collected for analysis of formaldehyde and VOCs. After every emission test, the camber were cleaned with distilled water and baked out at 100 ^{o}C with purified air. After confirming the background level should not exceed the standard background levels, the test product was to set placing and test was started with test procedure.

Sampling and analysis method Sample products are tested for emissions of pollutants using stringent environmental chamber test protocols. Emission concentrations were determined by placing the test objects in the chamber under specified test condition, then measuring chamber concentration of HCHO and VOCs with selected time intervals. Product emission factors were calculated from the chamber air samplings. A typical test period is 8 hour with measurement time at 2, 4, 6, and 8 hour. Some products like printers may require a specified procedure during test period to accurately define the emission profile.

Sampling of Volatile Organic Compounds Sampling VOCs were collected on sorbent cartridges (TA tubes). VOCs trapped on the cartridges were thermally desorbed then analyzed by GC/MS. Testing results of these analyses were used to estimate both of TVOCs and individual VOC concentration. Detailed procedures for sampling and analyzing the chemicals with chamber test method and TA tube cartridges described in ISO 16000 – 6, 7, 9

Sampling of Formaldehyde Air samples for formaldehyde were collected on 2,4-dinitrophenylhydrazine(DNPH) coated silica gel cartridges with ozone scrubbers. The DNPH derivatives on the cartridges were eluted with acetonitrile and analyzed by high performance liquid chromatography(HPLC) with ultraviolet(UV) detection.

Air Samples from chamber Calibrated air pumps located outside the chamber were used to pull chamber air through sampling cartridges mounted in the chamber ports (couples of two sampling ports) installed both as one is for the center of the chamber and the other is for the outlet of the exhaust duct.

Calculation of emission factor An emission factor is the amount of chemical that is emitted from a product at selected point in time. It is normalized to a particular size or unit of the product. For most building material, the emission factor is usually measured for exposed unit area of the product as square meter. However in this study, a product test reports the emission factor explain test results relative to a complete unit (µg/unit*hr). If the product is not constantly emitting pollutants, the emissions are decreasing gradually over time, the emission factor is a qualitative estimate of emissions release at a particular point in time. The emission factors of chemicals were calculated by the following equation.

$$EFa[mg/h \cdot unit] = \frac{(C_t - C_{tb,t}) \times Q}{1\,unit} = \frac{(C_t - C_{tb,t}) \times nV}{1\,unit}$$

C t : Chemical concentration at time t (㎎/㎥)
Ctb,t : blank concentration at time t (㎎/㎥)
n : ventilation rate (ACH/h)
Q: Airflow rate in chamber (㎥/h)
V : Air volume of test chamber (㎥)

RESULTS

Ventilation Rate in test chamber

In order to evaluate the performance of ventilation in test chamber, air change rate, ventilation effectiveness and age of air were measured at different location using concentration decay method with SF6 as tracer gas. Sampling tracer gases at the center point, and upper zone and lower zone in the chamber were performed with controlled airflow rate at 0.5 ACH/h, 1.0 ACH/h and 2.0 ACH/h. Table 2 shows the profiles of ventilation rate and age of air at the measuring points in 5 m^3 chamber. Air change rates were pretty much similar to the setting values at the center point for all cases. It shows the air change rates were controlled within 10% at every location in the chamber

Computer set and Chemical emissions

Some chemicals composed electronic equipment that have recently received attention with chemical component of the plastic case and printed circuit board. In order to fully understand how a product is going to contribute to indoor concentrations of pollutants, it is necessary to know a product's emission rate profile, or how the product's emission rates change over time. During the test period, multiple pollutant measurements are performed which are then used to calculate the product's emission profile over time. Fig. 4 shows TVOC profiles of emission from the computer set over time measured at center and outlet in the chamber with its operation. TVOC concentration at the center point measured much higher than the outlet point. TVOC concentration indicated the peak after 4 hr from the start of measurement, and decreased gradually over time. Some of individual VOCs were detected. Emissions of toluene, ethylbenzene and xylene in VOCs as caused for health risk compound were emitted with its operation as shown in table 4.

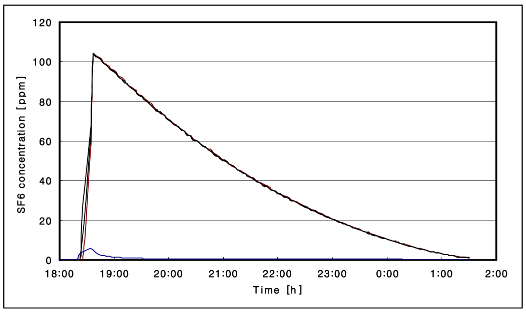

Figure 3. Profiles of SF6 concentration

Table 2. Ventilation rates in 5㎥ chamber

Air Flow	Sampling points	ACH/h	Ventilation Efficiency[%]	Age of Air [min]
Air Change Rate 0.5 ACH/h 41.67 [ℓ/min]	Upper Zone	0.48	94.0	127.6
	Center	0.49	99.0	122.4
	Lower Zone	0.46	92.0	130.0
Air Change Rate 1.0 ACH/h 83.33 [ℓ/min]	Upper Zone	0.98	98.0	61.2
	Center	0.99	99.0	60.6
	Lower Zone	0.97	97.1	61.8
Air Change Rate 2.0 ACH/h 166.7 [ℓ/min]	Upper Zone	1.93	96.5	31.1
	Center	1.95	97.7	30.7
	Lower Zone	1.89	94.5	31.7

Fig. 5 and Fig. 6 shows the profiles of TVOC and formaldehyde concentration emitted from tested computer sets. Emission rates of chemicals from desktop computer indicated much more higher than those of lab-top computer set. It may be possible to assume that the emission rates could be higher from the computer due to the bigger size and more consumption of electricity emitted much VOCs. Emissions of HCHO concentration ranged from 2 $\mu g/m^3$ to 44 $\mu g/m^3$ were not much higher relatively.

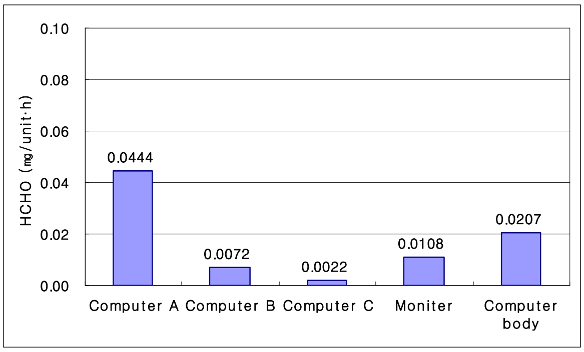

Figure 6. Formaldehyde profiles from PC sets

Printers and Chemical emissions

The chemical emissions printers can result from plastic construction materials, circuit boards, the inks and toners, papers, coatings on transparencies. Many of these chemical emission profiles show decreasing with usage of the product. But emissions from the printers as the harmful pollutants is not decreased much during the operation, because the VOCs emissions from the laser printer caused by heating up the drum and toner at 160°C for compress toner on paper with chemical components. However, the result in the mechanical operation of printing procedure emitted harmful chemicals to indoor environment. During the measurement of printers, chamber was controlled at 25 °C, 50% RH and 1.0 ACH/h. Temperature and humidity of the chamber goes up to 48 °C and 57% RH due to generate heat and moisture from the printer procedure.

Fig. 7 shows the profiles of chemical emission from the printers. The emission rates of the TVOC concentration ranged from 0.31 mg/m^3 to 8.00 mg/m^3 at the standby mode. Some printers emit still high concentration of chemicals during standby mode and ready mode without any operation. On the operation, the emission rate of chemicals goes up to the 10.12 mg/m^3. Even though a similar printing speed and quality, Printer B emits 5 times more chemicals comparing to those of printer A. Laser printer C of B&W emits TVOC to 3.12 mg/m^3 during operation and still highly emits the chemicals on the standby mode. Inkjet printer also emits relatively high during operation. Table 8 indicates the individual VOCs from the printers. Individual organic compound of benzene, toluene, ethyl-benzene, xylene, styrene were dominant. It could be possible that laser printer has been associated with building-related symptoms and health effects due to the release of chemical gases during operation.

Figure 9. Examples of Gas Chromatogram for the different printers.

DISCUSSION

Though none of these chemicals from computers and printers is likely to be measured in quantities that would exceed any established workplace health and safety limits, the unknown factor is how some of these chemicals may interact with each other to cause problems many years in the future. In addition, there are no established health and safety limits for exposure to chemicals by electronic devices exactly right now.

Computer with laser printer has been associated with building-related symptoms and health effects due to the release of chemicals during operation. These emissions can result from the inks and toners, papers, plastic construction materials, circuit boards. Many of these chemicals will decrease with usage of the product such as computers. Laser printers in particular have been associated with headaches, mucous irritation and eyes and nose irritation As a result, computers should be placed in other areas of the home in order to minimize health risk in the bedroom.

Measurement of Perceived Odor Intensity Using Gas-Sensor Systems

Frank Bitter and Dirk Müller

Technical University of Berlin, Germany

Corresponding email: frank.bitter@tu-berlin.de

SUMMARY

In the present study Multi gas-sensor systems (MGSS) are used to evaluate the odor intensity as it is perceived by humans. These systems measure volatile compounds in a holistic manner and present a signal pattern of the air sample. The model for the determination of the odor intensity consists of two major parts: discrimination into odor classes and subsequent quantification of the intensity. The discrimination is achieved by multivariate statistical methods or neural networks. The correlation to the intensity is done by odor class specific regression methods. The development of the data processing is based on calibration data consisting of simultaneously obtained MGSS responses and assessments of the perceived intensity by a trained human panel using a comparative scale. Different building materials were investigated. The study shows that MGSS have the potential to be used as a measurement device for perceived intensity using a data processing method on basis of an odor classification.

INTRODUCTION

Air quality in the indoor environment impacts the health and the wellbeing of the occupants. Studies showed that bad air quality has also a negative effect on the productivity of office workers [1]. Therefore there is a growing demand for technical devices to measure, maintain and control the indoor air quality. The air quality is determined by the volatile compounds in the air and mainly the provoked odor impression is the cause of discomfort. But so far no technical measurement technique for volatile compounds is able to measure the impact of the substances on the odor. Analytical chemical methods are able to detect the compounds in the air and their concentrations but the transfer to the human perception cannot be done and is still unknown. The concentrations of the interesting compounds are often below the detection thresholds of the measurement devices.
By now, the odor can only be assessed by human panels. Depending on the question formulation different aspects of the odor perception are evaluated, such as the acceptance or intensity of the odor. These methods are time consuming and cost-intensive due to the expenses for the panelists and in addition human panels cannot be used for continuous measurements for monitoring and control.

Since the analytical methods aren't able to evaluate the perception of odors another approach is to measure gaseous substances in a holistic rather than analytical way. In recent years multi gas-sensor systems (MGSS) have been developed to evaluate mixtures of volatile compounds and odors. The fundamental idea behind these systems is to mimic the human sense of smell. Analogues to the human odor perception the systems evaluate the sample air as a whole. The sensor systems were often called electronic or artificial noses. Though the systems apply the principle of odor perception the performance (sensitivity and ability to recognize and

categorize odors) falls far behind the human sense of smell. The comparison with the human nose raises expectations which these systems cannot fulfill. Nevertheless these systems may be able to measure the odor intensity as it is perceived by a human panel for typical room air odors with adequate accuracy.
The strength of MGSS is the recognition of differences in a mixture of gaseous compounds and deviations from a defined composition. The systems respond within seconds to a few minutes to changes in the mixture and can be used for online monitoring. Therefore the main areas of interest are the control and monitoring of product processes and quality control. They are widely used for applications and research in the food and nutrition industry as well as in the perfume and cosmetics industry [2]. In the last years in more and more areas of application the systems gain on interest and are discovered as useful instrument. In the field of indoor environment only few investigations have been done to assess the air quality [3]. The challenge for measuring the indoor air quality is the low concentrations of the volatile compounds and compared to the concentration the high intensity impression they invoke.

In the current study assessments of the perceived intensity of a trained panel were compared with measurements of a MGSS. On basis of these measurements it is tried to build up a model to correlate the measurements to the human perception of odor intensity.

MEASUREMENT APPROACH

Technical measurement devices are inherently not capable to measure the odor. To evaluate the odor intensity with multi gas-sensor systems the measured sensor responses must be correlated to human odor perception. A data processing model has to simulate the perception process in a simplified and abstract manner. In this study the focus is set on the odor intensity, which is a dimension of odor perception which is closely related to concentration and composition of the compounds and hence the measured sensor signals. As experience of odors made during the whole life is a main component of the odor perception and evaluation, a knowledge database consisting on measurements and associated odor assessments of a human panel will be the backbone of the data processing model.

Due to some preliminary measurements it was obvious, that it is very unlikely that one single mathematical algorithm is able to establish a relationship to the perceived intensity. Instead a theoretical data processing model was formulated which consists of two steps: a classification of the odors followed by a quantification using an odor class specific transfer function. The theoretical structure of the two-step data processing is illustrated in figure 1.

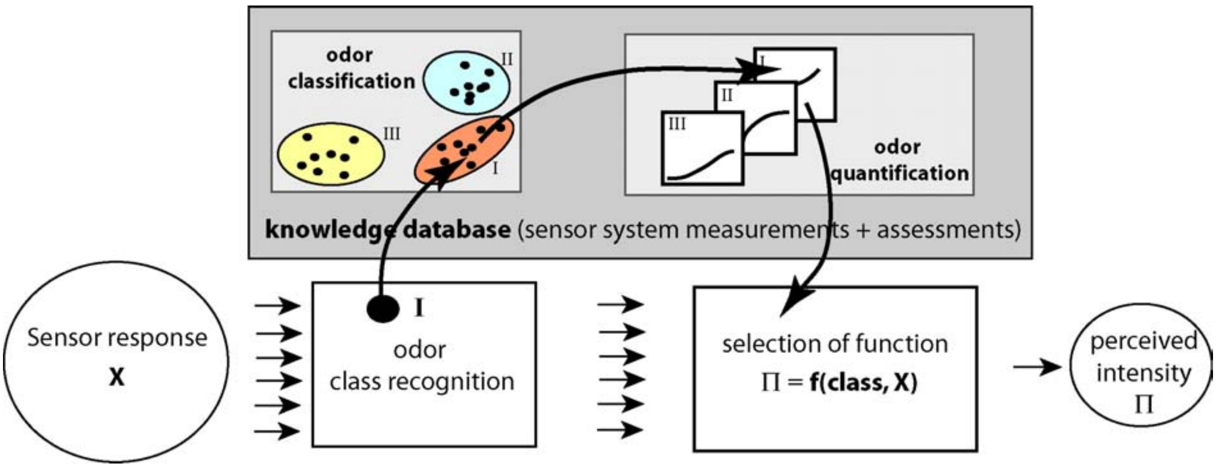

Figure 1. Schematic representation of the data processing model

The crucial part of the model is the knowledge database. It contains measurements of different mixtures and single compounds of emissions found indoors in several varying odor concentrations covering an intensity range. For each measurement a couple of sensor responses and panel assessments data were stored in the database. In the first step the measurements are combined and classified into classes with similar odor and sensor response data. For each determined odor class in a second step a class specific transfer algorithm to quantify the odor intensity is calculated. When measuring an unknown sample with the sensor system, the measurement is allocated to an odor class. The associated transfer algorithm for this odor class is selected and used to calculate the perceived intensity.

METHODS

Measurements of emissions from building materials and furnishing were used to construct the database. The objective was to investigate if the data processing model is principally applicable for the estimation of the perceived odor intensity with MGSS. Emissions from building materials and furnishing are main contributors to the indoor air contamination. They were chosen because the emissions can be easily and reliable produced and controlled in a laboratory environment.

Figure 2 shows the experimental setup to measure the odor emissions of building materials. The samples of building materials are placed in CLIMPAQ emission chambers [4]. These chambers were slightly advanced to optimize the air flow pattern and to connect them to an existing air ventilation system.

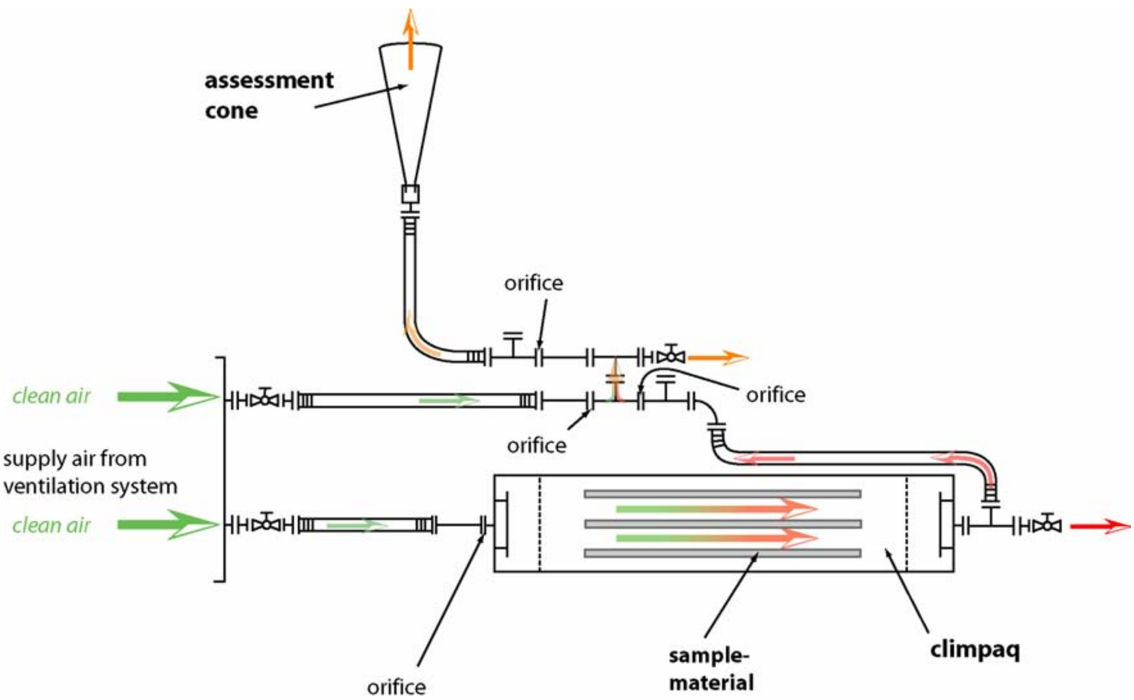

Figure 1. Test facility to measure the odor emissions of building materials

Clean air from the supply system flows through the CLIMPAQ and is loaded with the emissions of the building material sample. The sample air can be diluted by adding clean supply air before it is presented at a glass cone for the assessments. The dilution ratios can be adjusted continuously from pure air to 100% sample air from the CLIMPAQ. The tubes were built of stainless steel to keep the odor pollution emitting of the system small. The air flows can be adjusted by ball valves and can be measured using orifices of teflon. During the measurements the airflow through the emission chamber was kept constant at 1.0 l/s. After dilution with clean air, the polluted air can be extracted to set the air flow at the cone to a constant value of 0.9 l/s to ensure that variations of the air flow during the evaluation has no influence on the results.

The perceived intensity was assessed by a trained panel of 8 to 12 subjects. The odor intensity of the sample was ranked in a reference scale made up by acetone samples of 5 different odor intensities. The perceived intensity was assessed in the unit "pi" (perceived intensity) which was introduced by Müller in 2004 [5]. A pi of 0 is defined to an acetone concentration of 20 mg/m³ which corresponds approximately to the odor threshold of acetone. The scale was constructed linear in respect of the concentration. A step of 1 pi is equivalent to a concentration step of 20 mg/m³ of the reference substance acetone.

The assessments of the panel for a measurement series with varying dilution rate, the so called exposure response curves, can be approximated by a logarithmic function which was shown by Böttcher in investigations on the perception of odors [6]. Since the concentrations of the emitted substances of the building materials in the current investigation are not known the concentration dependency can be expressed by the airflow specific area load [7]. Figure 3 shows the dilution characteristics of two different building materials, a carpet and a painted wallpaper. The approximation was done using the mean values of the assessments of the panel members. In the model for data processing the calculated perceived intensities by the dilution characteristic were used as the intensity reference values instead of the assessment means in order to minimize the uncertainties which are inherent within the subjective sensory assessments.

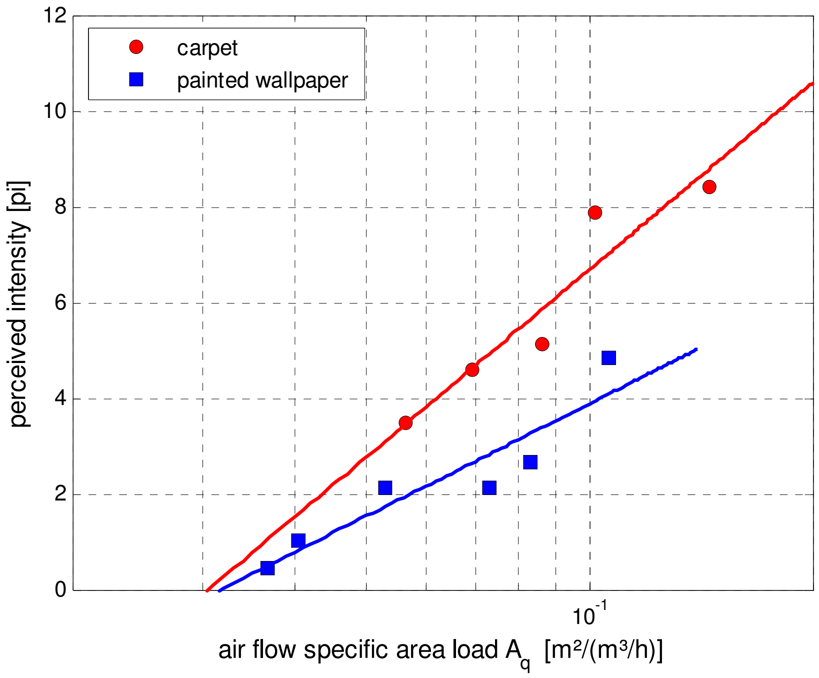

Figure 3. Panel assessments of the perceived intensity of 2 building materials

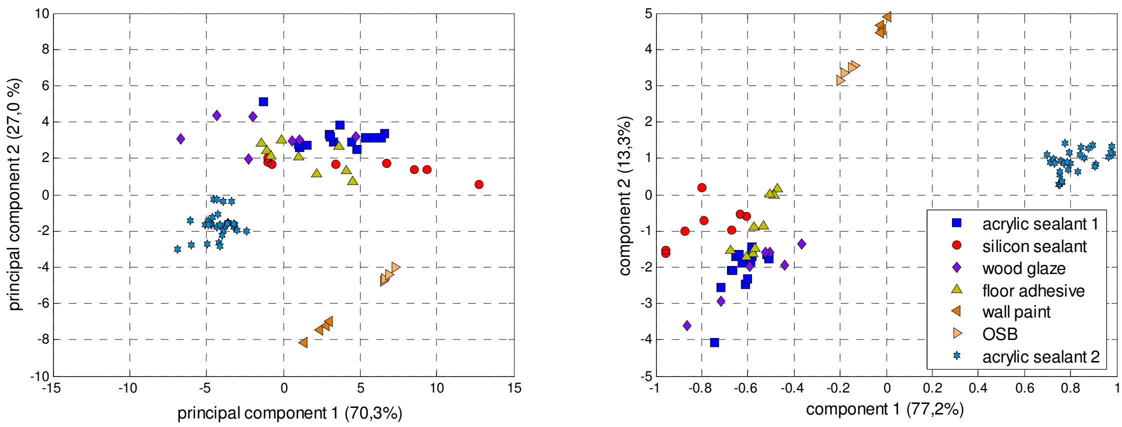
As a multi gas-sensor system the commercially available system KAMINA from the Forschungszentrum Karlsruhe is used in this study. It operates with 38 tin oxide sensors, which are placed on one single chip. The metal oxide surface is coated with a sensitive layer of SiO_2. The different sensitivity and selectivity of the sensor elements are achieved by a gradient of the sensitive layer and a temperature gradient from 250-300°C across the sensor-chip. The transport of the sample air to the sensors is done by a fan in the housing. The sensor sensitivity and selectivity and combination of sensors have a major impact on the performance of the intensity estimation. But it is not part of this study to investigate and optimize the sensor device.

For the measurement of the emissions of building material the KAMINA was placed on top of the glass cone according to location where also the panel assessments took place. The measurements were conducted directly after the assessments of the panel. The duration of the measurement was about 5 minutes until the stationary sensor signals were achieved. The stationary sensor responses further were used for the data processing.

RESULTS

For the classification of the measurements of seven building materials statistical multivariate methods can be applied. One method is the principal component analysis (PCA). This method reduces the relevant parameters and maximizes the variance between the measurements. The PCA describes a data transformation where the eigenvectors of the covariance matrix are the new coordinates. The advantage of this transformation is that the main difference of the sensor signals will be presented with a few new coordinates only. The other coordinates can be dropt with little loss of the information on the variance between the different measurements. The transformed results can be shown in a 2 or 3-dimenional diagram, see figure 4a. The diagram shows the result of a principal component analysis with measurements of seven building materials. Three of the materials form independent material groups. The other four materials cannot be separated properly and build a wide spread group. The measurements of the silicon sealant form a chain and don’t show a grouping effect. This is caused by a change in the emissions as the sealant was investigated during the first days after preparation and was still in the process of hardening.



(a) (b)

Figure 4. Classification of measurements with a MGSS of seven different building materials using (a) Principal Component Analysis (PCA), and (b) Linear Discriminant Analysis (LDA). The percentage behind the axis title describes the fraction of the components on the total variance.

To improve the classification a linear discriminant analysis (LDA) was used. This method uses classifiers which were assigned to the measurement samples by the experimenter to build the discriminant functions. The discriminant functions are optimized to maximize the separation between the groups and to minimize the within group variance during a learning process. Figure 4b shows the results of the LDA. The four material classes which were inseparable with PCA are still near together but at least the silicon sealant and the floor adhesive build separate clusters.

The third classification approach was done using a self organizing map (SOM). SOM is a special type of neural networks which was developed by Kohonen [8]. As the PCA the SOM is an unsupervised method which uses only the sensor response data to classify the data. For each sample the SOM determines one single “wining neuron”, which fits best to the input data. During the learning phase the network weights of the wining neuron and the near by neurons were adjusted towards an optimized result. The Matlab neural network toolbox was used and a map of 7x9 neurons was used to classify the building materials, see figure 5. Each symbol characterizes a neuron. In the illustration the neurons are displayed equally distributed. The shading demonstrates the distance of the neurons (dark: near, white: far). With the selected SOM except the floor adhesive the building materials can be separated into groups. Some materials show some higher within group differences as can be seen for the acrylic sealant 1. Here the measurements are distributed on several neurons of light shading (bigger distances between neurons). The acrylic sealant 2, however, is spread over several neurons but these are located closer to each other.

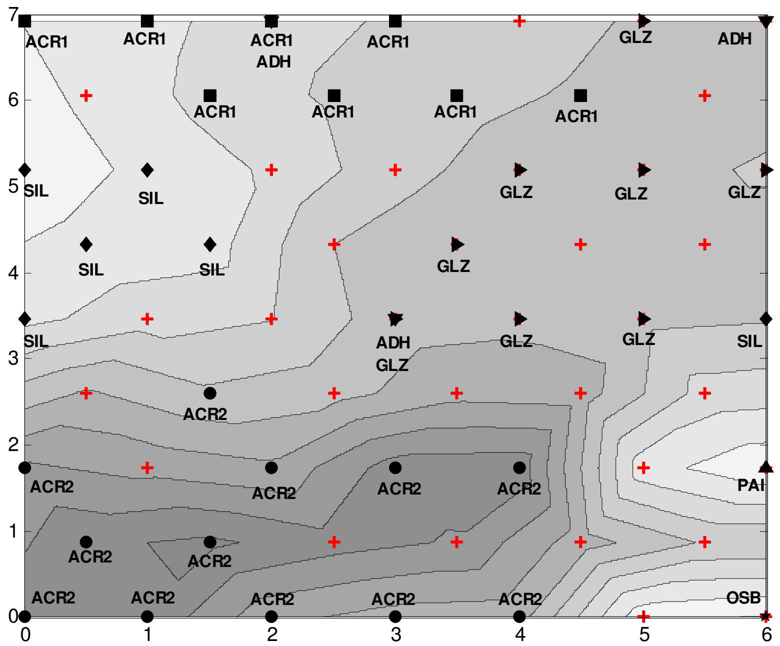


Figure 5. Self organizing map to classify building materials (ACR1: acrylic sealant 1, SIL: silicon sealant, ADH: floor adhesive, GLZ: wood glaze, OSB: oriented strained board, PAI: wall paint, ACR2: acrylic sealant 2)

A separation of the measurements of different building materials into classes seems to be possible, but some of the materials can not be separated perfectly. More sophisticated classification methods and an enhanced and modified sensor system with higher sensitivities might solve this problem. The classification was done in respect of building materials, which means every material builds its own class. That might not be the best classification approach since this can lead to many different classes. Finding different classification criteria could optimize the separation of classes.

The second step of the data processing model is to find a correlation to the odor intensity. The data for a specific class is used to find a transformation algorithm to estimate the perceived intensity. For the correlation a principal component regression (PCR) was applied. A PCR is a combination of a principal component analysis and a multiple linear regression. The PCA reduces the dimension of data set and maximizes the variance for the first components. Since the later components contain only noise signals only the first three components were used for the multiple linear regression. The following diagram shows the deviation from the measured intensities from the assessments of the panel for all of the seven investigated materials, figure 6. It is assumed that an odor classification method is used which properly separates each material in its own class and the regression was done using measurements for one single material.

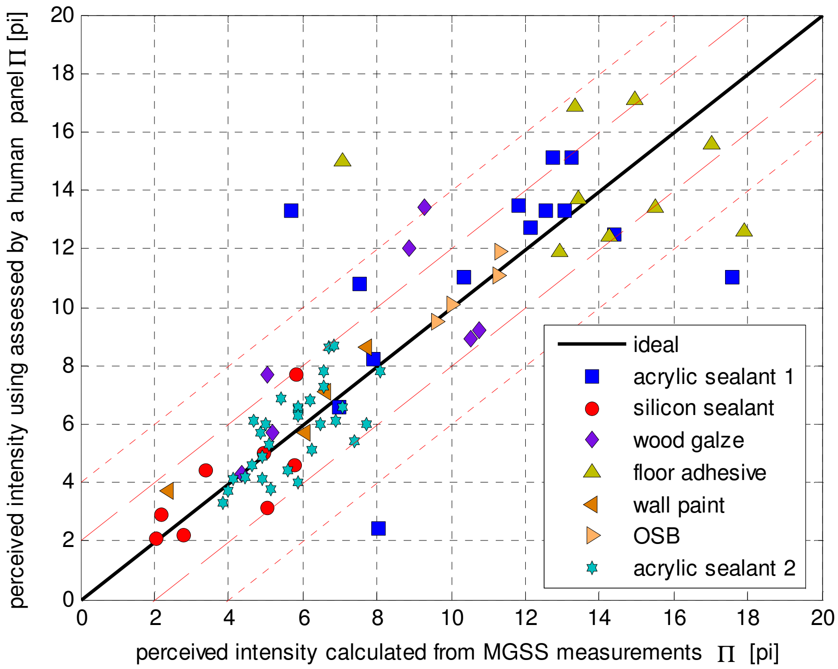

Figure 6. Comparison of the measured intensities (calculated by PCR for each material separately using the “leave-one-out” method) with the intensities assessed by the human panel.

The shown values were calculated with the “leave-one-out” method. In this method all except one (the tested) sample were used to estimate the regression parameters. The regression algorithm was then used to calculate the intensity for the left out sample. This is done n-times for all n samples of the odor class.
The diagram shows two ranges with 2 pi and 4 pi deviation from the ideal estimation. It should be mentioned here, that the reference value of the assessed perceived intensity is not an exact value itself and has also some uncertainties. Most of the estimations of the perceived intensity using the MGSS lie within the 2 pi range. Some calculated intensities for the acrylic sealant 1 and the floor adhesive are totally different from the assessed values. At a closer look it can be seen, that these values mark the edges of the range of intensities of this odor class. Near the edges of the intensity range the regression function is inaccurate.

DISCUSSION

MGSS have the potential to estimate the perceived odor intensity of building materials. It depends strongly from the sensitivity of the sensors and on the data processing model. A two-step-method for data processing is appropriate since a direct calculation method for a determination of the intensity cannot be found. A crucial point in the model is still the development of an odor space for the odor classification. It won't be practical to have for each building material a different odor class with corresponding transfer algorithm. It is the aim to find a few primary classes which cover the relevant odors which occur in indoor environment.

In this study basic algorithms for classification and regression were used. More sophisticated methods may improve the results. An improvement of the sensors itself in optimizing the sensor combination and in increasing the sensitivity of the sensor elements would be a further step towards a measurement system for the intensity of the odor in the indoor environment - towards systems, that can be used for measuring, monitoring and controlling the indoor air quality. To reach this aim, the European project SysPAQ (Innovative Sensor System for Measuring Perceived Air Quality and Brand Specific Odors) has been started to develop an innovative system to measure the indoor air quality as it is perceived by humans.

The first investigations were done in a laboratory environment using single materials only. In real indoor environment the emissions of several materials were present at the same time. The additive behavior of the odorants must be investigated in further research work to transfer the laboratory results to real indoor environment.

SUMMARY

In the german research project a method had been developed and tested, which enables the simple and safe integration of sensory tests into current test procedures under the AgBB scheme (see below). The method can provide a proper amount of sample air to the panellists for assessment, regardless of the size of the emission test chamber.

A round-robin test is conducted to evaluate the combined emission/odour testing scheme. A standardized building product is evaluated by eight laboratories concerning chemical and odorous emissions. At each laboratory between six and fourteen members of an odour panel have scored the perceived intensity of the building product using a comparative scale based on acetone.

INTRODUCTION

The indoor climate and indoor air pollutants influence the health and comfort of the occupants of indoor spaces. Indoor air pollutants are emitted by a various sources. Among these sources, building products are of particular importance hence their selection is often not within the occupants' discretion and they cover large surface areas in a room.
Since VOC emissions are frequently able to be recognized, and can also lead to health impairment, sensory testing was included as an important aspect in the assessment scheme of the Committee for Health-related Evaluation of Building Products (AgBB scheme) [1]. Despite improving analysis possibilities and the development of artificial noses, replacing the human nose in the determination of perceived air quality has not been successful until today. Odours develop from a number of chemical substances but not all materials generate the perception of smell in humans. Many thousands of different substances can be detected in the room air, but even a quantitative determination of each single material would not enable a statement about the smell effect of a combination to be made.
Within the research project "Determination of emissions from building products using test chamber measurements and development of product-specific test conditions for low-emission building products" a new method to investigate the odour impression of the emissions of construction products was developed [2]. The odor measurements use the same chamber conditions like the VOC emission tests in accordance with EN 13419-1 [3]. Typically, chamber tests following this standard have exhaust air streams of much less than 0.7 liters per second, the minimum volume flow rate for odor measurements [4]. Therefore, the exhaust air of the chambers is collected in 300 l gas sampling bags.
A human panel assesses the air collected in the air sampling bags using a comparative scale of acetone/air mixtures, which help to determinate its intensity Π. The introduced perceived

intensity Π can only be determined with panels using a comparative scale. Unlike the acceptability method with large panels, the intensity of odorous substances in the air is determined by comparing different specified intensities of the reference material acetone. The smelling capability varies from human to human. Training and use of comparative sources ensure that the influence of subjective perception of the test result is reduced since all panel members evaluate air quality based on the same scale.
50 building products were tested in this project in emission chamber tests according to the provisions of the AgBB scheme. VOC emission tests were performed in each case on the first, third, tenth and 28th day and, in addition, the odour emission tests were conducted on selected products.

METHODS

In the project a laboratory comparison was planned to validate the odor measurement method. However, none of the other institutes possessed the same odor measurement instruments as the Herrmann Rietschel Institute, therefore a suitable procedure had to be found. Thus a timely graduated process was planned. A transportable version of the comparative scale was designed. The objective of this was to achieve a constantly adjustable acetone concentration in the sample air independent of the ambient conditions. The design scheme of the comparative scale is illustrated in Figure 1.
The comparative scale is in essence composed of three parts: sample air circulation, source of acetone and dosing device. The units in contact with air are almost wholly manufactured from stainless steel, glass or PTFE (polytetrafluoroethylene), which are practically odorless.

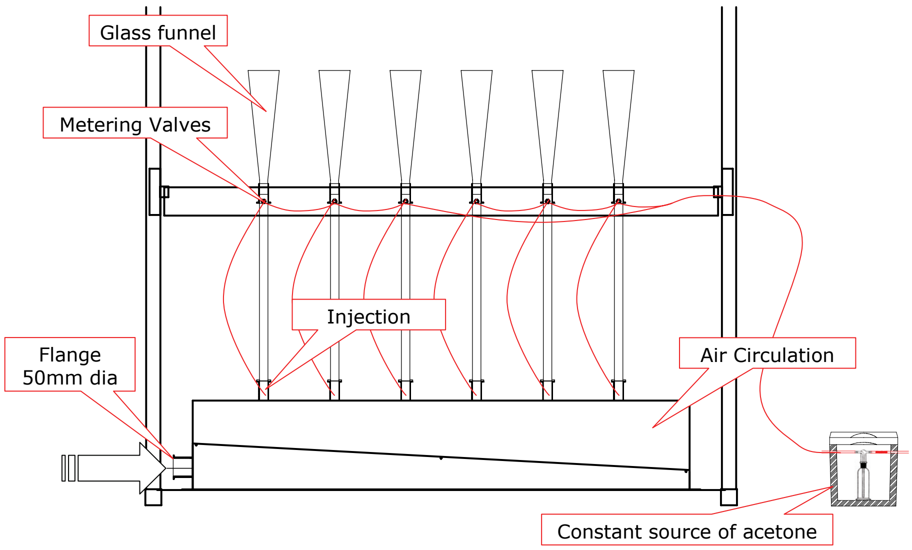

Figure 1: Scheme of the transportable comparative scale

Sample air circulation is connected via a flange to a suitable smell-neutral air supply. The sample air circulation provides constant flow rates between 0.9 and 1.0 l/s per marker (5.4 to 6.0 l/s for six markers) which ensures an undisturbed operation. The constant source of acetone consists of a pressure-resistant wash bottle and a cooling device. The acetone filled wash bottle is supplied with compressed air which is pumped through and then enriched. Cooling prevents an over saturation of the compressed air and a consecutive condensation in the pipes. The acetone fog is effectively separated by a stainless steel filter from the enriched air.

The six funnels are supplied with the constant air/acetone mixture via a distribution hose. A metering valve per funnel regulates the amount of the acetone/air mixture added to the sample air within the range of 0 to 1150 mg m^{-3}.
Six different mixes of acetone concentrations in the range between 20 mg m^{-3} (0 pi) and 300 mg m^{-3} (15 pi) help the panellists gain their orientation in determining the perceived intensity of an unknown sample. In addition, the comparative scale enables uniform assessment criteria on different testing days and facilitates the standardisation of the method. The comparative scale was equipped with its own fan unit for an independent mobile operation. An electronic fan control unit enables the exact adjustment of the total flow to provide a supply for the comparative scale.
In view of the need of mobility, the AirProbe [5] was further developed for the laboratory comparison. To achieve a better and more constant provision of sample air, the operational principle was fundamentally changed (Figure 2).

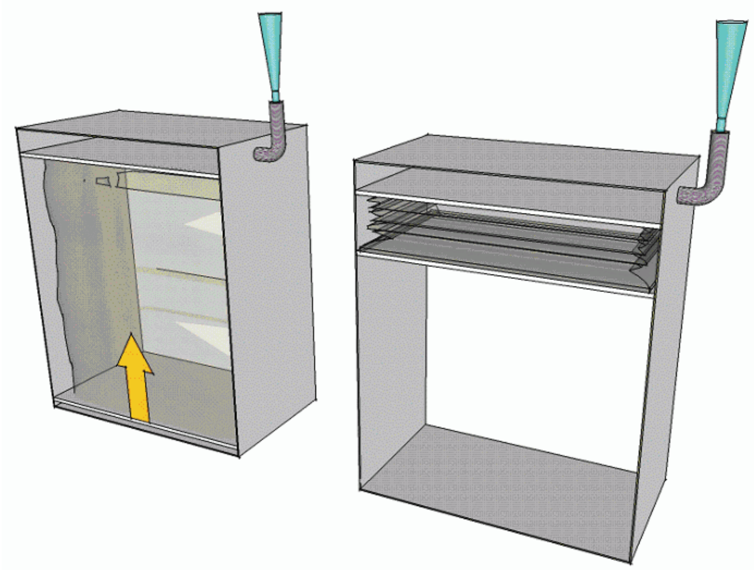

Figure 2: Operational principle of sample provision in AirProbe II

The sample provision in AirProbe II is based on the principle of a press. The sample container in AirProbe II is between an upper fixed plate and a mobile lower plate or piston. When the lower plate is moved at a constant speed, a constant flow rate is produced from the sample container, which is attached to a high-grade steel pipe leading to the glass assessment funnel. Based on a pressure difference measurement at an orifice, the flow rate can be calculated and indicated on a display. The piston velocity can be changed with a potentiometer over a wide range. The panellists have a longer time for assessment, since only the operation of a switch is needed during the smelling procedure to provide the full flow rate. In the period between two smelling procedures the flow rate is reduced to a minimum to prevent a back flow. Due to a smaller average flow rate up to 12 panellists can perform an assessment at the glass funnel.
The body of AirProbe II consists of a light aluminium transportation box with the external dimensions 1200 x 800 x 510 mm.
The equipment was sent from participant to participant. The experimental setup only remained with each participant for three weeks. In this time an eight-day chamber test combined with chemical analysis and sensory testing with a minimum of six panelists of sample air was performed. Because of the new sensory testing the participants were instructed in a one-day introductory course in the handling of devices and the measurement technique. In addition to the air quality manual, extensive documentation and detailed guidance on the test methodology were available to the participants. Brief device-related descriptions were compiled during the tests for quick orientation.

In addition to the innovative odour tests, an emission chamber test was also performed in accordance with DIN EN ISO 16000-9 to -11 and/or -6 [6] within the interlaboratory comparison. Planning the emission chamber tests was a challenge, since all participants had to carry out the tests under the same conditions over a longer period. Thus a roll or stacked commodity, which would age in the course of time, had to be rejected. Instead, a sample had to be selected which remains stable during a period of at least six months. Furthermore the sample had to exhibit good measurable emissions and at least a clear, well identifiable odour. The choice finally fell on an acrylic sealing compound, which can be prepared very reproducibly for the tests. The acrylic sealing compound was placed in an aluminium standard channel, levelled with a trowel and placed into the chamber after a short waiting period. Emission and odour tests on air from the chamber were carried out on the first, third and eighth days. The odour transport containers were filled at the chamber exit. When this was done in chambers smaller than 1 m³, the container had to be filled dynamically over night. At the 1 m³ chamber it was easy to exchange the tank contents three times within one hour, so that the odour sample could be taken directly before the assessment. For the third measurement day additional tubes were sent, which the participants loaded simultaneously to their sampling. They were then analysed by the Federal Institute for Materials Research and Testing (BAM) to decide whether the chamber influences or analysis caused deviations between the results of the institutes. The good comparability of the VOC data of the chamber test shows that the different participants largely had the same test conditions in the chambers. Each participant additionally received another standard solution, which could be used for the quantification of the emissions.

RESULTS

After completing the tests in the institutes, the data sets were conveyed to the Hermann-Rietschel-Institute for assessment. All laboratories involved managed to complete the sensory assessments despite the short time. Six to 18 panellists per laboratory participated in the tests. Between 69 and 76 individual values were produced each test day. Figure 3 illustrates the results from the laboratories.

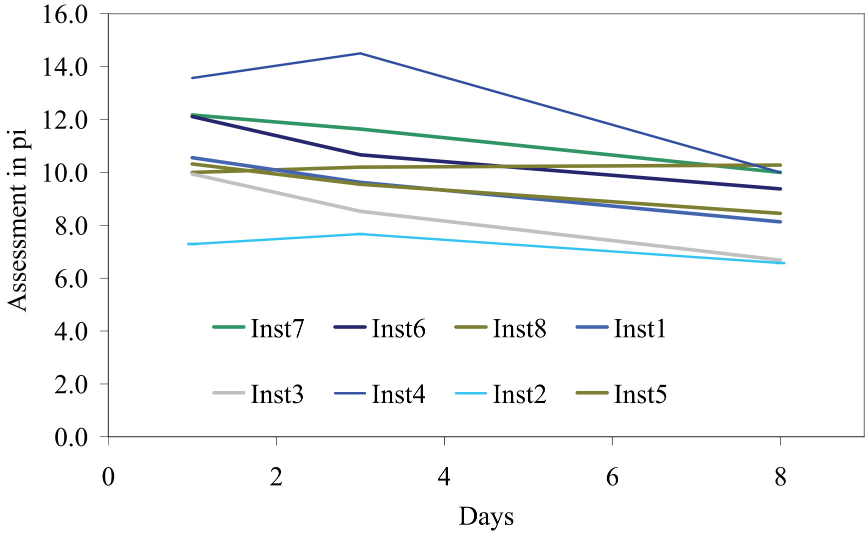

Figure 3: Intensity of all laboratories

The test days are plotted on the abscissa and the perceived intensity Π on the ordinate. The results of each institute were calculated as an arithmetic average of the individual answers for each test day.

The results of Institutes 2 and 4 were excluded from further consideration in the assessment. Technical problems in the test procedure in one of the institutes and deviation from the procedural regulations in the second institute provided results under non-comparable test conditions. Technical problems in AirProbe II forced Institute 8 to do a short-term modification during the test run, which may be an explanation for the horizontal profile of intensity assessments. Since all other boundary conditions were adhered to in this Institute and AirProbe1 is in principle suitable for the execution of the tests, the results were included in the overall assessment. Figure 4 shows the cleaned laboratory results and the average value of all laboratory results.

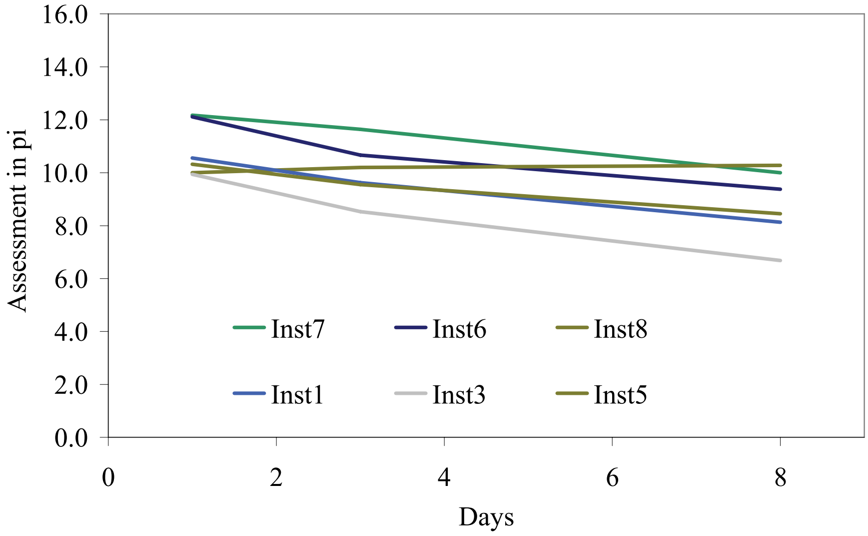

Figure 4: Cleaned intensity, average of all laboratory results

In addition to the medium standard deviation, Figure 5 also shows the maximum deviation of the laboratories from the average value of all laboratory results for a better assessment of the test results.

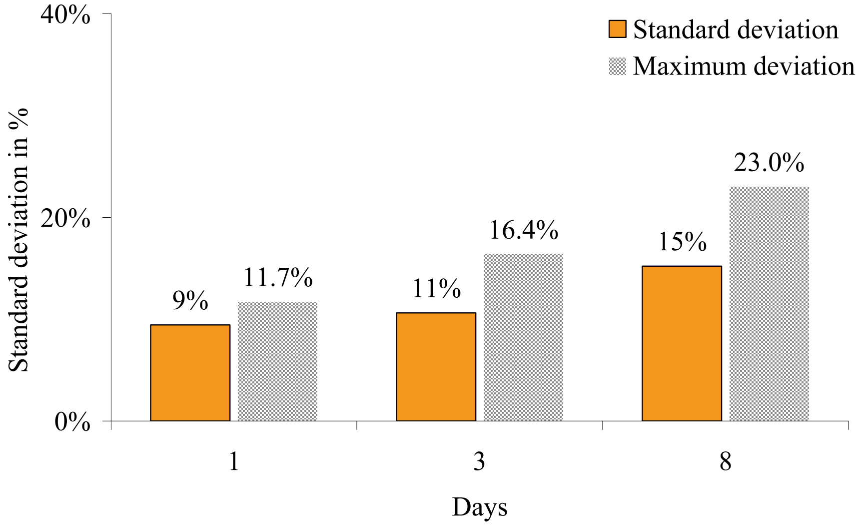

Figure 5: Medium standard deviation and maximum deviation of the laboratories from the average of all laboratory results

The medium standard deviation is between 9% on the first test day and 15% on the last test day. The maximum deviation is between 11.7% and 23%. These reasonably good values from a first co-operative test could be improved by a focused selection of the panellists.
Since the laboratories involved exclusively used 1-m³ chambers for test execution, the Herrmann Rietschel Institute carried out additional tests in 1-m³ and 20-litre chambers.

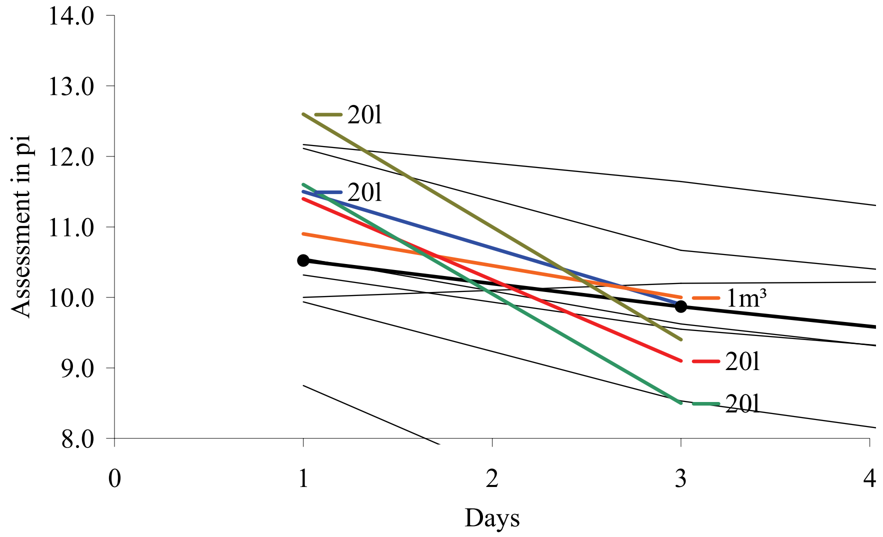

Figure 6: Intensity assessment of samples from the 20-litre and 1-m³ chambers

The investigations are limited to the first and third test day. Figure 6 shows an enlarged excerpt of the two test days. The curves show that the chamber size obviously has no influence on the sensory assessment.

DISCUSSION

The results of odour assessment show that newly developed devices, guidelines and test descriptions allow comparable intensity assessments to be obtained between the laboratories for the selected building material, although the laboratories involved had little or no experience with sensory assessment of building materials.

The good overall result of the co-operative test is illustrated in Figure 7. In addition to the standard deviation of the laboratories from the overall mean, the maximum deviation of the individual laboratories over the entire test period is also shown for a better assessment. With a standard deviation of 9% (first test day) to 15% (eighth test day) very good results were obtained under the conditions specified above. The Hermann Rietschel Institute achieved a very constant deviation of only 4 % from the general mean with trained panellists under optimised laboratory conditions over the entire test period.

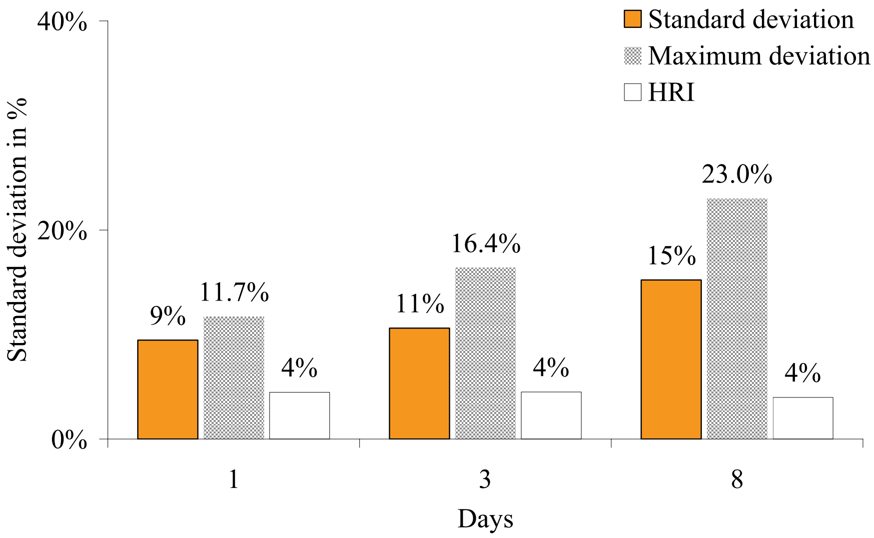

Figure 7: Standard deviations of the laboratory results

Figure 8 shows the medium standard deviation of the individual answers from a laboratory and the maximum deviation over the test days. It provides information as to how large the dispersion of the individual answers of the panellists of a laboratory is on a particular test day. The maximum standard deviation here shows the enhancement potential of the results if a focused selection of the panellists was undertaken.

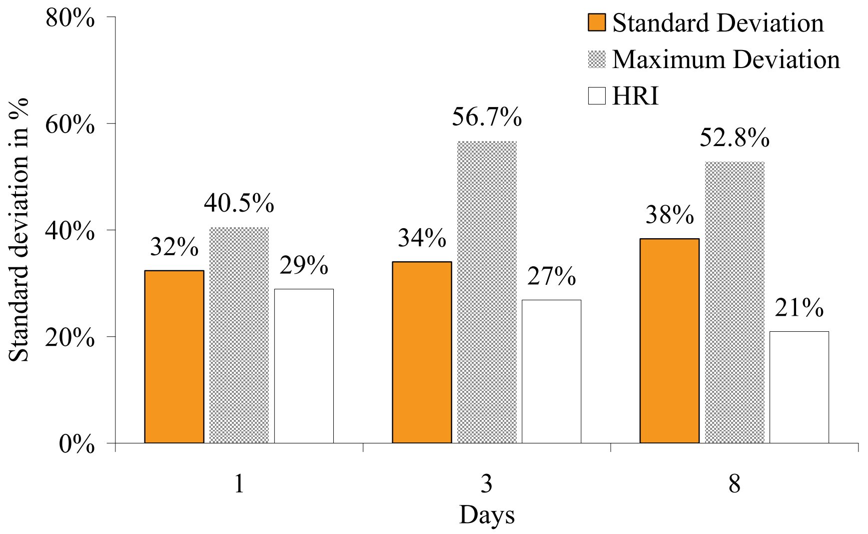

Figure 8: Medium standard deviation and maximum deviation of the individual answers of the individual laboratories, standard deviation of the Herrmann-Rietschel-Institute

The standard deviations of the Herrmann-Rietschel-Institute, which works with a focused selection of trained panellists under optimised ambient conditions and whose staff members have been familiar with the method for years, are accordingly well below the medium standard deviation.
Since the co-operative test was only performed on a single building material sample due to time constraints, other co-operative tests would be necessary for a possible validation of the method where several building materials were tested by panelists.

Basis Odor Model for Perceived Odor Intensity and Air Quality Assessments

Jana Panaskova, Frank Bitter and Dirk Müller

Technical University of Berlin, Germany

SUMMARY

This paper shows first results of an ongoing research project, which aims to develop a transfer model to link the odor intensity with the perceived air quality assessments. This model is based on basis odors, which were in this research project selected according to the primary odors defined by Amoore. Each basis odor measurement of the perceived intensity and air quality establish a transfer function between the intensity and the acceptability values. The basis odor samples are generated by using the saturation method and a dilution process with clean air. The experiments include the examination of single basis odors as well as mixtures of basis odors. Additionally, the influence of the relative humidity of the air on the perceived intensity and acceptability is part of the investigations. First results of the experiments show different correlations between perceived intensity and acceptability for all basis odors.

INTRODUCTION

A well known method developed by Fanger determines the perceived air quality with a sensory panel judging the acceptability of the air quality [1]. A category scale is used for the assessments with no absolute reference. Inherent to the acceptability assessments is a high standard deviation between the individual assessments of the panelists and therefore a large panel of subjects is required for statistically significant results. Bluyssen applied a group of trained panel members for air quality assessments using a comparative scale [2]. The training and the comparison with a reference reduces the standard deviation and a smaller panel size can be used.

Up to now it is very difficult to compare the results of both assessment methods. The influence of the thermal state of the air on the assessments is different for the acceptability method and for the method using a comparative scale. Studies [3, 4] show that the acceptability of air is decreased with increasing specific enthalpy. Results from a panel using a comparative scale indicate that the specific enthalpy is not important as long as the relative humidity stays constant. This discrepancy reveals that both methods appear to detect different measures of the odor perception. The use of a comparative scale forces all panel members to concentrate on the perceived intensity. Thus, a comparative scale cannot be used to measure the perceived air quality in terms of the acceptability and may be used for perceived intensity assessments only.

Subjects who are asked for the acceptability of the air quality do not differentiate between the hedonic tone and the intensity level of the odor impression and assess a combined impression instead. On the one hand, the perceived air quality in terms of the acceptability is an appropriate measure concerning the comfort in indoor environment, but on the other hand the perceived intensity judgments are more reliable because of the common reference of the comparative scale. A transfer model which relates the intensity to the acceptability assessments enable to use the smaller panel size and the more precise intensity assessments to evaluate the perceived air quality.

In this study the correlation between acceptability and perceived intensity assessments for defined basis odors is investigated. The basis odor transfer model should close the gap between intensity and acceptability measures. The dependence of the hedonic impression on perceived intensity and acceptability can be extracted from the measured data which gives more insight in the structure of the interrelationship. Seven odors, which are defined as primary odors in the stereochemical theory of Amoore [5], are used for the investigations on the transfer model. Each odor is characterized by reference substances some of which were substituted by other substances with similar odor characteristics due to safety reasons. Later on, the investigation of the influence of the relative humidity on this relationship will be part of the research project as well as the investigation of the combinations of the basis odors which shed light into the interaction of the transfer functions of the basis odors.

SENSORY ASSESSMENTS

Samples of the basis odors are presented in the air quality laboratory of the Hermann-Rietschel-Institute. The laboratory is constructed mainly of glass and stainless steel and ventilated with a high air change rate which provides an odorless measurement environment.

The subjects for the assessments of the acceptability (assessments without the use of the comparative scale) are selected without any specific criteria except the absence of any respiratory diseases or known anosmia. The panel consists of 30-40 persons, mainly students. 45% of the subjects are women and 77% declared themselves as no smokers. The mean age of the panelists is 24. The subjects are asked for the acceptability using a scale divided into 20 steps ranging from -10 (clearly not acceptable) up to 10 (clearly acceptable) [1] and for the hedonic impression a scale from -4 (extremely unpleasant) to +4 (extremely pleasant) [6].

The panel using the comparative scale consists of 9-12 persons and is selected from subjects passing the training test. This test evaluates the capability to compare the odor intensities of the unknown samples with the comparative scale. In addition to the determination of the perceived intensity of the air samples the subjects are also asked to judge the hedonic impression using the same scale as the other sensory panel. At the Hermann-Rietschel-Institute acetone is used as a reference substance for the comparative scale. The perceived intensity is assessed in the unit pi, which was introduced by Müller [7]. Currently, the scale is constructed linearly in respect to the acetone concentration and an intensity step of one pi corresponds to a concentration step of 20 mg/m³. At an acetone concentration of 20 mg/m³ which is approximately the odor threshold the perceived intensity is defined to be zero. An odor perceived intensity value above zero should be detectable for most of the panel members.

For every air sample the arithmetic mean of the acceptability, the perceived intensity and the hedonic impression of both groups are calculated. The first set of experiments use seven reference substances, listed in Table 1. The reproducible and constant air samples are generated by newly developed dosing equipment (see Figure1) operating with a saturation method. Synthetic air is enriched with the substance in a wash bottle at room temperature. The air is cooled down to a defined temperature to reach a saturated substance-air mixture with constant concentration according to the vapor pressure. The saturated air is dosed in an air flow of clean air and is presented to the sensory panel through glass cone. The presented concentrations of reference substances in air are selected considering safety rules and health considerations. The stability of the odor samples has a major impact on the quality of the results of the investigations since the assessments have to be done rather in sequence over a longer period than it can be done parallel. The developed dosing equipment fulfills this requirement adequately.

Table 1. Reference Substances

Odor classification	**Chemical substance**
Camphoraceous	Eucalyptol
Musky	15-pentadecenolide
Floral	Geraniol
Pepperminty	(-)-menthone
Ethereal	Diethyl ether
Pungent	Acetic acid
Putrid / fishy	Pyridine

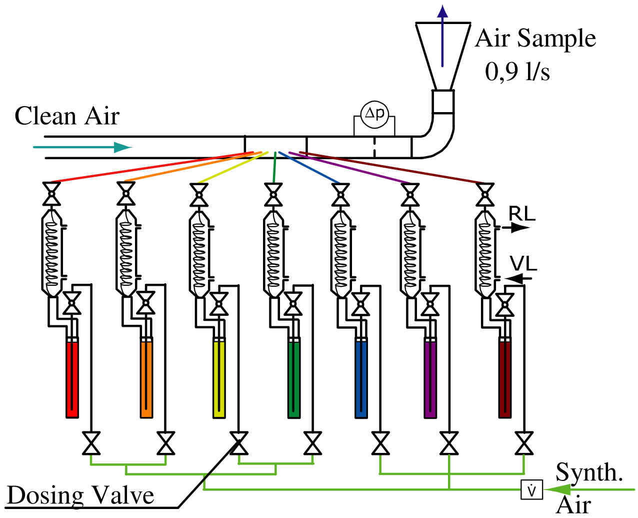

Figure 1. Schema of the dosing equipment

During the first set of experiments the relative humidity is 45% (± 5%) and the temperature of the air is 21.5 °C (± 1°C). The second set of experiments will be focused on the combination effects of different basis odors and the influence of temperature and relative humidity. The influence of the relative humidity will be determined for only three of the basis odors and for the relative humidity of 30% and 70%.

RESULTS

Comparison of acceptability and perceived intensity

Figure 2 shows the interrelationship of the assessments of the acceptability and the perceived intensity for the first set of experiments using the basis odors. The figure indicates that the acceptability values are generally decreased by increasing the perceived intensity. But the transfer functions are not completed yet. More measurements have to be done to cover a wider range of the odor intensity. By now it can be seen, that the seven odors can be separated in two groups, one of acceptable odors in the positive acceptability range and another one of unacceptable odors in the negative acceptability range.

Peppermint, floral and musky odors are almost for all considered concentration levels in the acceptable area. The gradients of floral and peppermint odor are very similar. The camphoraceous odor seems to change over from positive to negative acceptability values at higher intensity values. Ethereal, pungent and putrid odors do not show any positive values on the acceptability scale and are not accepted even for low odor intensities.

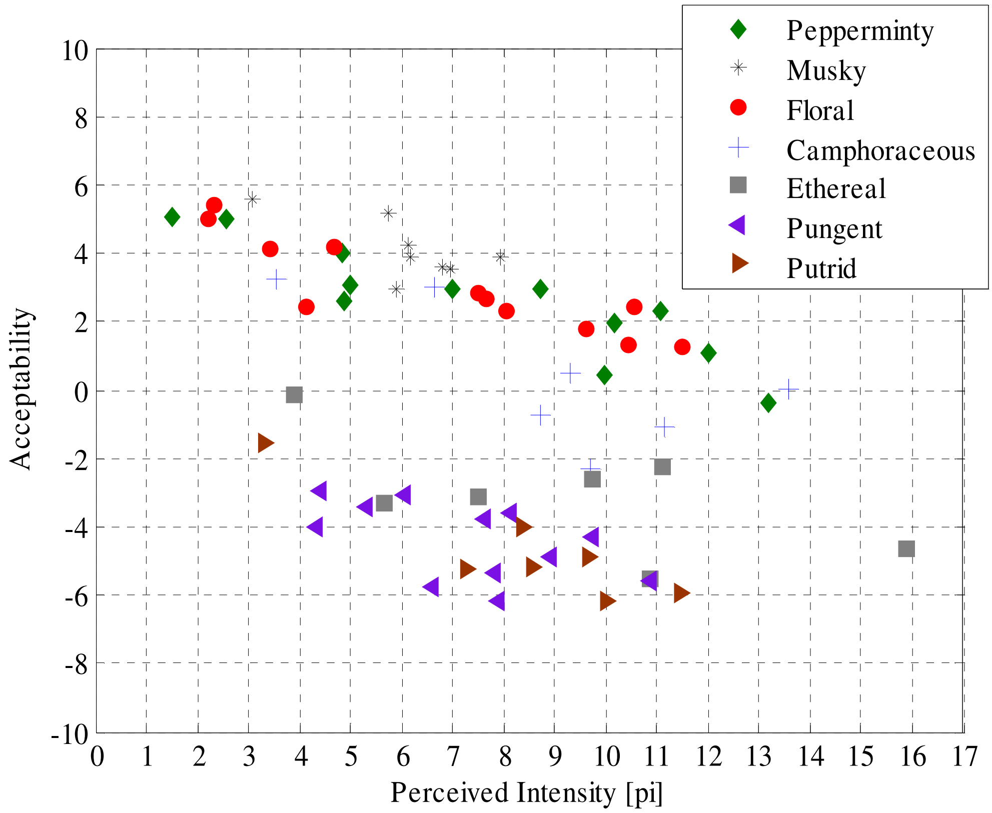

Figure 2. Relationship between the perceived intensity and the acceptability of basis odors

The hedonic impression

The hedonic tone is assessed by both the panel using the comparative scale and the panel judging the acceptability. Thus the relationship of the hedonic tone to the intensity as well to the acceptability can be derived from the measured experimental data. The experiments indicate that the hedonic tone is not or only weakly depending on the perceived intensity (see Figure 3). Using a comparative scale leads to perceived intensity assessments.

The acceptability on the other hand depends mainly on the hedonic impression. With decreasing acceptability the hedonic impression decreases linearly (see Figure 4). This correlation seems to be independent from the kind of odor. The measurement points are grouped in the more acceptable positive odors in the upper right quadrant and the not acceptable negative odors in the bottom left quadrant of the diagram.

The assessments of the acceptability and the intensity are done by two different sensory groups. The comparison of the results of the intensity and the acceptability assessments require that both panels represent a similar sample of society and have a similar perception of odors. The hedonic impression is therefore assessed by both groups. This enables to evaluate the differences in the odor perception. Figure 5 shows the assessments of the hedonic impression of the seven basis odors for the panel using a comparative scale in relation to the hedonic impression assessed by the panel for acceptability judgments. The voting of the hedonic impressions shows only a small deviation from the one-to-one linear correlation. The assessments of the panel using the comparative scale tend to be less positive for the pleasant odors. The sizes of the panels are not identical and hence the uncertainties and the standard deviation of the hedonic assessments are equal for both groups the data for the larger group should be considered more accurate.

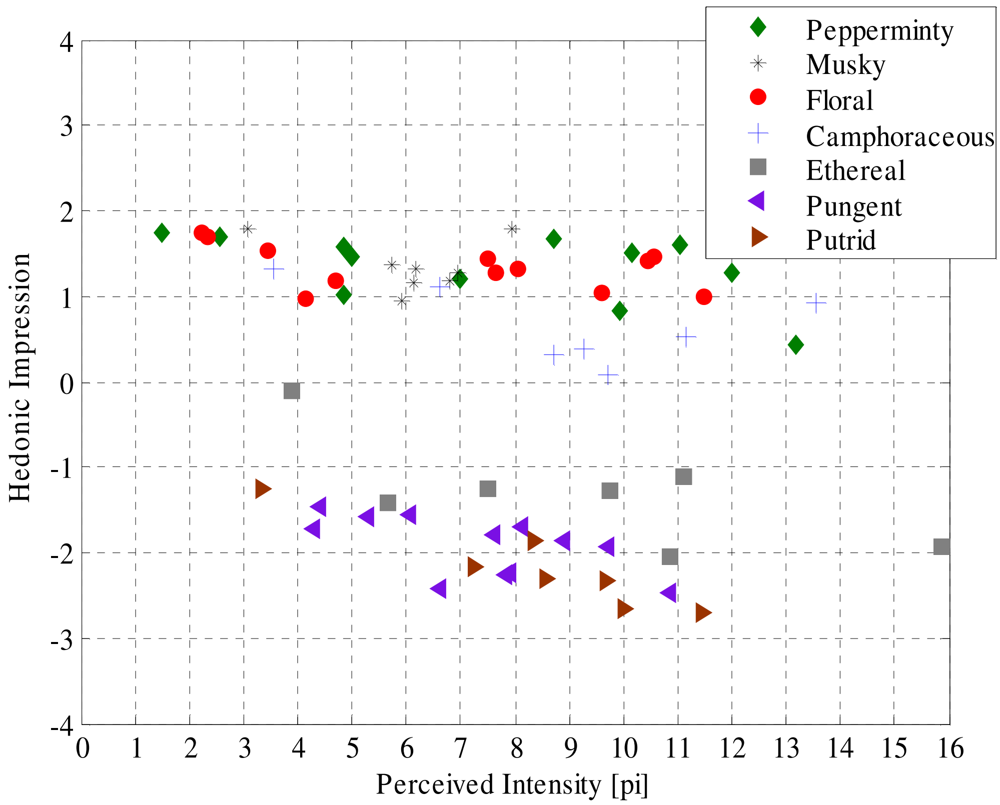

Figure 3. Comparison of the hedonic impression and perceived intensity

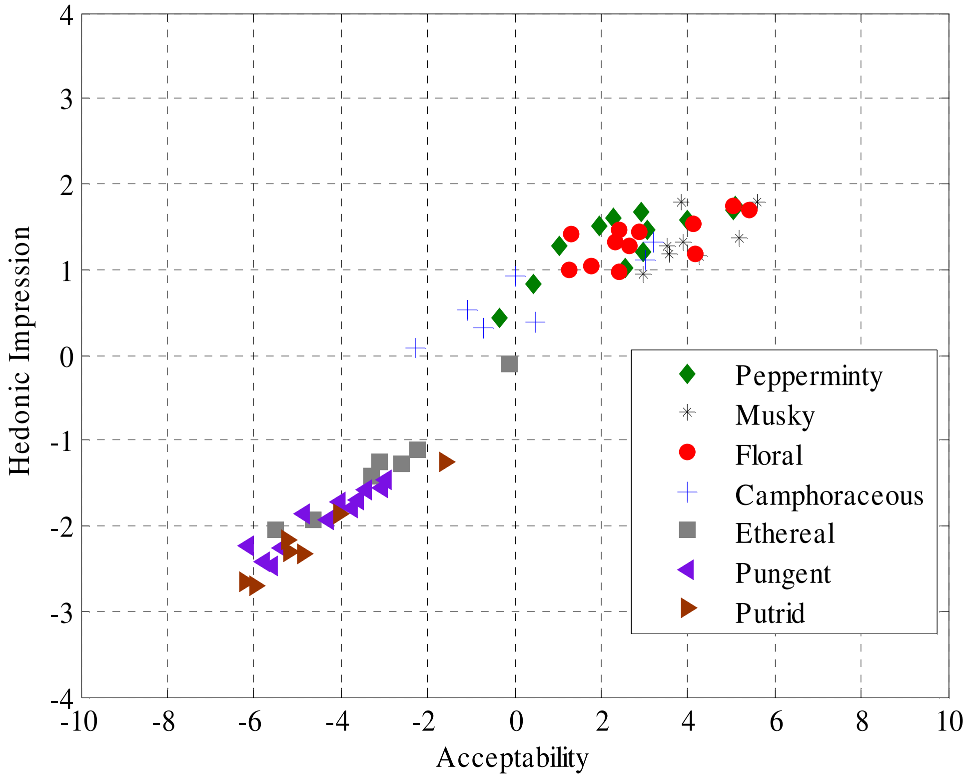

Figure 4. Comparison of the hedonic impression and acceptability

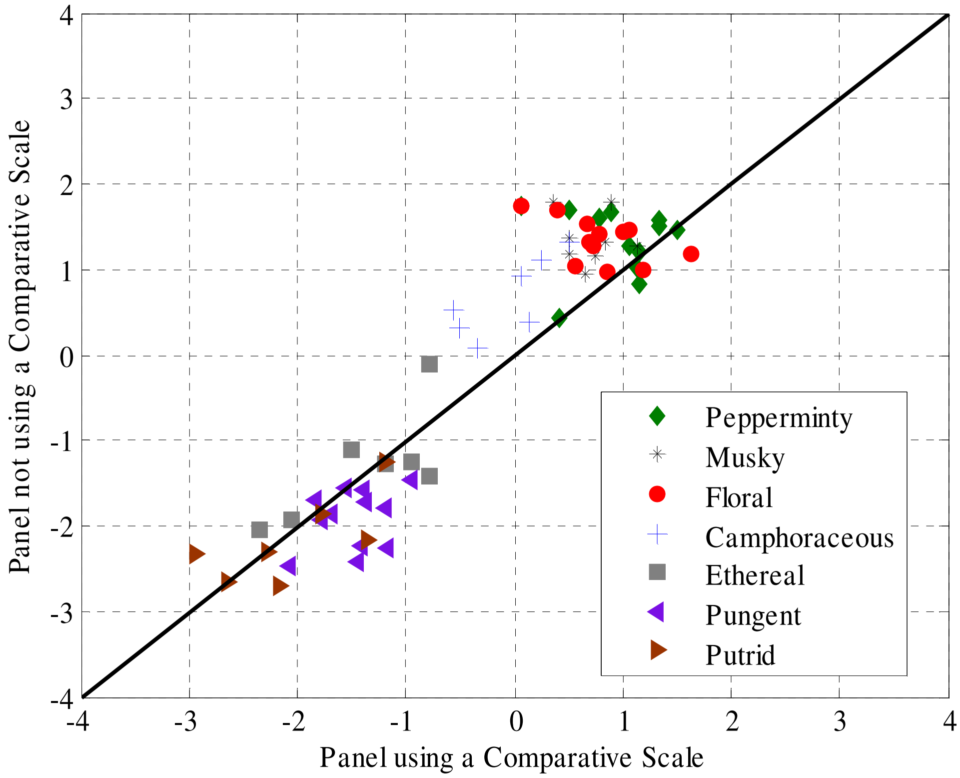

Figure 5. Comparison of the hedonic impression of the two different panels

DISCUSSION

The experiments clearly show that the acceptability votes of a panel which uses no comparative scale is a combined impression of the perceived intensity and the hedonic tone. The intensity assessed by a panel using the comparative scale assesses the perceived intensity almost not influenced by the hedonic tone and thus without a mental valuing process of the perceived odors. The acceptability votes mainly decrease when the ratings of the intensity are increasing. The assessments can be grouped in the pleasant, acceptable odors and the unpleasant, not acceptable odors. This, however, indicates that there exists no universal transfer function between the acceptability and intensity votes. It always depends on the pleasantness of the odors. A combination of assessments of the intensity and the hedonic tone to estimate the acceptability is a promising approach.

So far, the investigation has been done at constant relative humidity and temperature. As mentioned before, the relative humidity has an influence on the perception of the intensity whereas the specific enthalpy is influencing the acceptability of the odors. In the course of this project the influence of the relative humidity on the acceptability-intensity relationship will be investigated. Combination of basis odors, which will also be measured later on, will give insight in the perception of mixtures especially when combining a pleasant with an unpleasant odor.

Effect of Mechanical Ventilation System(s) to Indoor Chemistry Products in Air Conditioned Buildings: Quest for Tropical Research

Moshood Olawale Fadeyi* and Kwok Wai Tham

National University of Singapore, Singapore

**Corresponding email: g0500231@nus.edu.sg*

SUMMARY

The potential for reactions among indoor pollutants to generate reactive and highly irritating products is a reason to maintain adequate ventilation rates and clean ventilation filters. Terpenoid (from recirculated air, a scenario common in the tropics) captured by ventilation filters can react relatively quickly with ozone which may lead to downstream air supply that contain oxidized terpenoid and this may be perceived to be less acceptable than outdoor air. The chemical composition (water solubility and chemical reactivity) of these particles strongly governs their toxicity. The composition determines either how the respiratory tract reacts or how the body responds. There are few studies examining the impact of ventilation rate and ventilation filters on indoor chemistry. Studies documenting the effect of filters, ventilation and recirculation rate on ozone initiated chemistry in buildings utilizing recirculation of conditioned air are lacking. Thus the need to stimulate research in this area to better understand the effect, recirculation of conditioned air phenomenon could have on indoor air quality serves as the motive for the quest for tropical research. The paper demonstrates that reaction between reactive gases to generate highly irritating products may even be more important in mechanical ventilation system that utilizes recirculation of conditioned air.

Key words –: Filters; ventilation rate; recirculation rate; ozone initiated chemistry; oxidized terpenoid; secondary organic aerosols (SOAs).

INTRODUCTION

In various parts of the world, it has been documented that morbidity and mortality rates have continued to be on the larger scale due to the poor indoor air human beings are constantly being exposed to [1][2][3]. This gives indication that air we breathe in the indoor environment must be given due and consistent attention. In order to avoid outdoor environmental hazards and discomfort, human beings, whether consciously or unconsciously, do spend 90% of their time in this indoor environment (e.g. offices, homes, factories, buses, aircrafts etc) where chemical reactions of indoor gases do take place whether at the gas phase or on the interior surfaces (surface chemistry). Indoor chemistry is being recently recognized as a phenomenon important to IAQ perception, irritation, and health [4]. To ensure clean indoor air within buildings mechanical system(s) must expel stale air and replenish it with clean, “fresh” outdoor air. However, simple as this may seem, it is not always the case. If they are poorly designed, operated, or maintained, however, ventilation systems can contribute to highly irritating products resulting from indoor chemistry. In the tropics many buildings utilize high recirculation of conditioned air to minimize the energy required to remove the high humidity of outdoor air and media filters are the most commonly used filtration method for the removal of particles from outdoors and recirculated air. If these filters are not properly maintain they may be an important to issue to indoor air quality perception, irritation and health as a result of everyday occupant exposure. The presence of a used filter in a ventilation system can have an adverse impact on perceived air quality, SBS symptoms, and performance of office work [5]. In addition to removing particulate contaminants, they accumulate a particle layer that can react with ozone. Ozone particle cake reactions serve as a sink for ozone and a source of secondary carbonyls [6]. Of special note is oxidized terpenoid that could be formed due to reaction between recirculated air containing terpenoids and ozone captured on the filters to form oxidized terpenoids.

MOTIVATION OF THE STUDY

Building occupants may be chronically exposed to ozone-initiated chemistry oxidation products if appropriate measures are not taken. The toxicity potential of indoor air and particularly those where ozone-terpenes reaction have occurred could lead to several adverse health effects associated with both respiratory and cardiovascular health effect including mortality and morbidity [4][7][8]. It appears that from limiting ozone concentration and certain reactive volatile organic compounds (VOCs), maintaining clean filters, adequate ventilation rate, and recirculation air change rate under recirculation of conditioned air scenario are very important. The role of recirculation has been under estimated as compared to non recirculation scenario (where all studies have focused on), recirculated air may contain terpenoids which can sorb onto the surface of particles captured on ventilation filters. It can react relatively quickly with ozone to produce oxidize terpenoids which have great influence on perception and acceptance of indoor air [9]. Ventilation rate and recirculation air change rate could also influence the production of SOAs from ozone initiated chemistry and also its particle size distribution. The particle size distribution determines where deposition occurs in respiratory tract. The chemical composition of these particles (water solubility and chemical reactivity) strongly governs its toxicity. The composition determines either how the respiratory tracts react and of how the body respond. Surprisingly, despite the importance of recirculation of conditioned air scenario (commonly use in air- conditioned buildings in tropics) to indoor air which building occupants are exposed to everyday, there are little or on effect of filters, ventilation, recirculation on ozone initiated chemistry in air conditioned buildings. This review demonstrates that reaction between reactive gases to generate highly irritating products may even be more important in mechanical ventilation system that utilizes recirculation of conditioned air.

PARAMETERS AFFECTING OZONE INITIATED CHEMISTRY

The review focus only on ventilation filters and air change rate (ACH) while others may include ventilation ducts, building materials, relative humidity and temperature etc.

Ventilation Filters

Collected particles in clean filters if not removed from air stream, are the source of indoor air pollution [10][11][12][5]. Apart from ventilation filters negative impact on perceived air quality, the indoor air pollution from used filters could lead to other perception and even SBS symptoms after longer exposure [13]. In a field study by Wyon et al., (2000), significant improvement in self- estimated productivity of workers was observed when new filter were used as compared to used filter. Wargocki et al., (2004) did a well controlled field intervention experiment in a call-centre providing a telephone directly service. Their results agreed with earlier studied by Wyon et al., (2000) (uncontrolled field experiment). They reported significant improvement in some SBS symptoms and environmental perceptions with use of new filter. Used ventilation filters could also contribute to indoor chemistry to produce noxious compound [5].

Beko et al, 2006 studied contribution of sensory pollutant by oxidation process of ozone initiated chemistry from used filters. They observed that organic compounds that react with O_3 in the surface of filter cake are transform to more highly oxidized species which degrade the quality of perceived air quality as judged in the subjective evaluation.

Mysen et al. (2006) studied emission from different types of used ventilation bag filter and their impact on perceived air quality. New filter banks of cityflo filter and F7 filters were put into two similar ventilation systems with continous air flow (24hours per day). They found that the used F7- filter deteriorate the air quality significantly compared to new/no filters. The used F-7 filter deteriorated the air quality significantly compared to the similarly used cityflo-filters.

Hyttinen et al., (2006) did a study on removal of ozone by clean, dusty, and sooty supply air filters. The removal of ozone (O_3) on supply air filters was studied. Especially, the effects of dust load, diesel soot, relative humidity (RH), and exposure time on the removal of O_3 were investigated. Some loss of O_3 was observed in all the filters, except in an unused G3 pre-filter made of polyester. Dust load and quality influenced the reduction of O_3; especially, diesel soot removed O_3 effectively. Increasing the RH resulted in a larger O_3 removal. The removal of O_3 was highest in the beginning of the test, but it declined within 2 h reaching almost a steady state as the exposure continued. However, the sooty filters continued to remove as much as 25–30% of O3. Up to 11% of O_3 removed participated in the production of formaldehyde. Small amounts of other oxidation products were also detected.

Beko et al. (2005) measured ultrafine particle concentration upstream and downstream of filter sample when air passing through the filters either did or did not contain ozone. They conducted the experiment using small scale test equipment in low polluting office with very low background ozone level. They reported that the downstream/upstream ratio was higher when O_3 was present. This indicates the creation or growth of ultrafine particles after the air has passed through the filter.

Hytttinen et al (2003) conducted laboratory and field experiment (from nine different Finnish office buildings) to examine potential reaction of ozone on used filters. The filters had removal efficiencies (F5 to F8 ratings) and had been in service for approximately one year. Their study indicates that used filter removed a part of the ozone from supply air. This removal could lead to more chemical reaction on used filter surface.

Implications of these studies

Ventilation filters are employed with the primary belief that they improve indoor air quality and present building occupants cleaner air. Adequate filtration of ventilation air to indoor environment could enhance occupant health significantly. An example of this is using the filter to reduce the outdoor ozone concentration. However improper maintenance of these filters may produce adverse effects because it could be source for ozone-initiated chemistry. Ventilation filters serve as an absorption bed which in the presence of air passing over it, and may lead to production of other gaseous chemical products that might result in sensory irritation. The above studies provide evidence of oxidative transformation on used filter due to the presence of ozone and organic compounds. These oxidation products do result in supplied ventilation air that is less acceptable and highly irritating.

Ventilation rate and recirculation rate

Ventilation rate

A measure of how quickly the air in an interior space is replaced by outside air by ventilation and infiltration. Air change rate is measured in appropriate units such as cubic meters per hour divided by the volume of air in the room, or by the number of times the home's air changes over with outside air. For example, if the amount of air that enters and exits in one hour equals the total volume of the heated part of the house, the house is said to undergo one air change per hour. The rates at which used air is exchange with outdoor air do have influence on secondary organic aerosols generated by ozone chemistry.

Recirculation rate

A measure of how quickly the air in an interior space is replaced with recirculated air. Recirculated air is defined as air that is returned from a heated/cooled space, reconditioned and/or cleaned, and returned to the space. Technically the recirculated air into the space is supposed to be clean but that is not usually the case if the ventilation filter is badly maintained. In the tropical context, recirculation of conditioned air is usually adopted to minimize the energy required to remove the high humidity of outdoor air. In Singaporean office buildings typically 90% of the air is recirculated while 10% is from outdoor air. To lower indoor space temperature the recirculated air can be moved at a faster rate or simply by passing over chilled water. It is important for the reader to note recirculation air change rate/ recirculation rate (ACH) is a different term from proportion (%) of air recirculated.

Relationship between recirculation rate and ventilation rate

If ventilation rate (outdoor air change rate) is kept constant and recirculation rate is varied (from low to high) in an experimental scenario, it means the residence time[4] in the system would basically be the same for all the experiments. The higher recirculation rate would simply be moving the air through a closed system at a faster rate. Thus, as recirculation rate increases, the boundary layer adjacent to the surface of the indoor space and recirculation loop becomes thinner. This presumably will affect deposition of particles and therefore resulting into larger surface removal of particles (reactants and reaction products). This is totally different from a situation when ventilation rate alone is used and varied, the residence time will be different for such set of experiments.

Effects on indoor chemistry

Weschler et al. (2000) did a study on the influence of ventilation on reactions among indoor pollutants. They use a one compartment mass balance model to simulate unimolecular and bimolecular reactions occurring indoors. The initial modeling assumes steady-state conditions. They also modeled a non-steady state scenario because at low air change rates, there may be insufficient time to achieve steady state. In the cases examined, the results demonstrate that the concentrations of products generated from reactions among indoor pollutants increase as the ventilation rate decreases. They also supplement the modeling studies with a series of experiments conducted in typical commercial offices. The reaction examined was that between ozone and limonene. The ozone was present as a consequence of outdoor-to-indoor transport while limonene originated indoors. Results were obtained for low and high ventilation rates. They observed a consistent result with the modeling studies. The concentrations of monitored products were higher at the lower ventilation rates even though the ozone concentrations were lower.

Weschler et al (2003) examine the influence of air change rates on the concentrations of secondary organic aerosols as well as the evolution of their particle size distributions. The experiments were performed in a manipulated office setting containing a constant source of d-limonene and an ozone generator but was remotely turned “on” or “off” at 6h intervals. The air change rates during the experiments were either high (working hours) or low (non-working hours) and ranged from 1.6 to >12h^{-1}, with immediate exchange rate. They observed evidence for coagulation among particles in the smallest size range at low air change rates (high particle concentrations) but no evidence of coagulation was apparent at higher air change rates (low particle concentrations). They also observed that at higher air change rates the particle count or size distributions were shifted towards smaller particle diameters and less time was required to achieve the maximum concentration in each of the size ranges where discernable particle growth occurred.

Implications of these studies

Above studies demonstrate that low ventilation rate, in addition to allowing accumulation of indoor pollutants leads to larger concentration of SOAs derived from reaction among such pollutants as well as for particles to accrete organic materials and undergo coagulation process. Relationship between ventilation rate and recirculation air change rate could also affect ozone initiated chemistry and health. Despite recirculation of conditioned to air indoor chemistry and health there are only very few studies examining the influence of ventilation rate on indoor chemistry (e.g.[21][22]), and with little or no study on the effect of ventilation rate and recirculation rate on indoor chemistry under recirculation of conditioned air scenario.

Knowledge gap

There are little or no studies documenting the *effect of filters, ventilation and recirculation rates on ozone initiated chemistry in buildings utilizing recirculation of conditioned air*

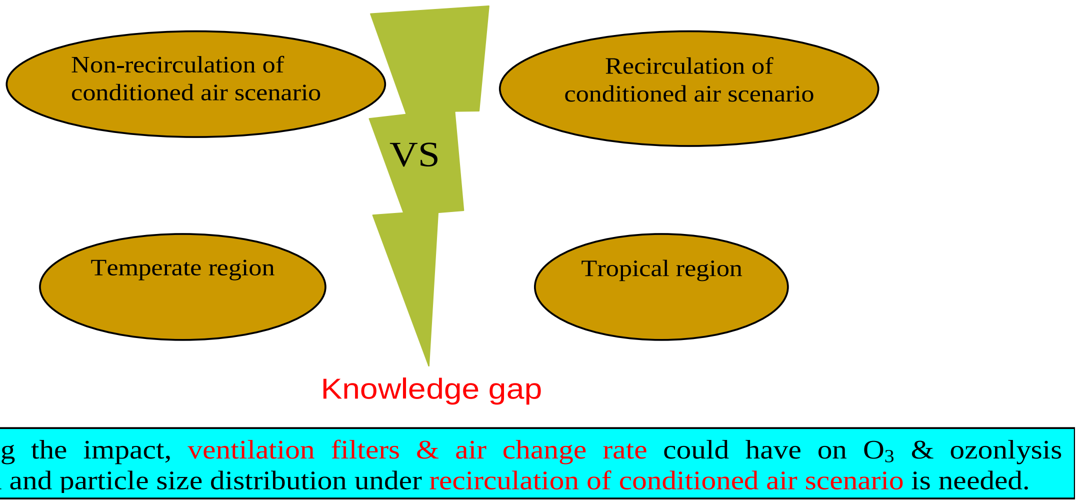

Figure 1: Knowledge gap

INDOOR CHEMISTRY IN TROPICS:

Research from IAQ unit of Centre for Total Building Performance, NUS

Given the above review, the role of filters, ventilation and recirculation rates could have on ozone and ozone initiated chemistry products' concentration and its particle size distribution (mass and number concentration) under recirculation of conditioned air (scenario common to tropical regions) clearly warrants further research. This understanding would help prioritize efforts to improve indoor air quality of air-conditioned buildings in the tropics. To this effect, The Indoor Air Quality research unit of Centre for Total Building Performance, National University of Singapore is interested in understanding the effect, filter, ventilation and recirculation rates could have on ozone initiated oxidation products (especially formation of oxidized terpenoids) under recirculation of conditioned air scenario. This section summarizes preliminary findings from 2 separate studies conducted in a large field environmental chamber (FEC) with its own Air Handling Unit (AHU). But, it is important to note that the research group has planned series of experiments focusing on AHU to be able to achieve controlled experiments as compared to using FEC as a primary experimental setup, which by its nature, there are lot of confounders that might be affecting the results. However, as a supplement to AHU experiments, FEC experiments would be conducted to give big picture of what could happen in indoor environment. The first study examines the effect of recirculation rate on the concentrations of SOA resulting from reactions between indoor limonene and ozone. In the second study, 3 experiments (without filters, with clean filters and with used filters in the AHU room) were conducted at constant recirculation rate and fresh air supply. The First study has shown that the rate at which air is recirculated through a room can have a significant effect on the Particle count, Size distribution and concentration of SOAs and oxidation products of ozone-initiated indoor chemistry [23][24][25]. For second study, the fact that the used filter has very little effect on the particle levels in the FEC compared to "no filter" at the initiate stage of the experiment suggests that two separate processes are occurring – 1) the used filter is removing SOA from the air stream and 2) chemistry is occurring on the surface of the used filter that contributes SOA to the air stream downstream of the filter. The chemistry that is occurring on the surface of the used filter includes ozone oxidation of organics associated with the captured particles/SOA, as well as ozone oxidation of limonene and limonene oxidation products such as 4-AMC (4-Acetyl-1-methylcyclohexene) and IPOH (3-isopropenyl-6-oxoheptanal) sorbed to the used filter. In terms of differences between a new filter and a used filter, one would expect greater sorption of limonene and its oxidation products on a used filter than on a new filter. This, in turn, would lead to more SOA being produced as a consequence of ozone passing through a used filter compared with a new filter [25][26].

Building Material Interactions and Perceived Air Quality

Martina Bucakova and Ingrid Senitkova

Technical University of Košice, Slovakia

Corresponding email: martina.bucakova@tuke.sk

SUMMARY

The impact of common building materials interaction on perceived air quality related to air change level was studied. The methods of chemical analysis (TVOC) and subjective sensory assessment was used. The measurements were conducted in test chamber under standardized conditions (23±1°C, 50±5%) and different ventilation rates. The positive impact of sorption "phenomenon" on perceived air quality and user's wellbeing was found for most of the tested combinations. The more significant sorption effect was found for materials with larger specific surface. The results have shown that sorptive material such as gypsum board can affect the ventilation rate needed to achieve the satisfactory perceived air quality and wellbeing.

INTRODUCTION

The variety of studies have shown that common indoor surface materials are significant sources of indoor pollution and have essential impact on perceived air quality. In addition these materials can decrease the level of pollution through sorptive processes. Study [1] shown that sorption of common indoor air pollutants (volatile organic compounds) onto surfaces such as gypsum boards and Semia can markedly improve the perceived air quality, decreasing the ventilation rate required to achieve a given degree of acceptability. On the other hand, the re-emission of VOCs can prolong the presence of indoor air pollutants. This study demonstrate the significant and prolonged effect that sorption/desorption phenomena can have on perceived air quality under realistic indoor conditions. The VOCs sorption onto building materials depends not only on the material properties but also on the VOCs type and indoor environmental condition such as temperature, relative humidity and air velocity. These parameters in relation to VOCs sorption onto different building materials were studied in [2]. According to [3] the VOCs adsorption increases with decreasing vapor pressure of VOCs.

The indoor pollution sources impact on perceived air quality is studied within the scientific research project The theory of Indoor Making with reference to Building Materials, Constructions and HVAC Systems supported by Slovak Scientific Grant Agency. The first results of this project which is aimed to investigate the effect of various building materials and their combination on perceived air quality is presented within the paper as continual research to previous project. The aim of the research is to obtain the wider understanding of the indoor surface materials impact on perceived air quality as well as recommendations for proper interior materials selection in order to guarantee acceptable perceived indoor air quality.

METHODS

In this study the impact of common indoor surface materials interactions on perceived air quality in relation to different air change levels was studied. The increased ventilation rate caused different conditions from VOC concentration and air velocity point of view. The effect of odorants sorption on perceived air quality was studied in a small-scale test chamber. Flooring coverings are considered to be important for the indoor air quality. Regarding this fact the flooring coverings were considered as a potential source of air pollution. The investigated flooring materials were OSB flooring system (waste wooden products) and PVC flooring. The gypsum boards finished with water based painting were considered as a sorption material. To compare the obtained results the gypsum board were substituted by impregnated wallpaper which has smaller specific surface then gypsum boards.

Chemical analysis and subjective sensory assessments of emissions from selected surface materials and their combinations were carried out in test chamber after their exposition to different air change conditions. The air change levels were specified for standard model room (3,2 x 2,2 x 2,4m) with respect to prepared European legislation (prEN 15251:2005) for 3 different indoor air quality categories. Category A corresponds to a high level of expectation and leads to a highest percentage of satisfied occupants in respect to indoor environment (n = 3,0 1/h). Category B corresponds to a medium level of expectation (n = 2,0 1/h) and category C to a moderate level of expectation (n = 1,2 1/h). The air change levels were specified regarding that the tested materials are non low polluting materials [4]. The surface of the test specimen was exposed to the chamber air which was maintained at a temperature, humidity and air movement similar to that which can be expected in the indoor environment. In addition to these conditions the chamber VOCs concentration depends on the supply airflow rate in the chamber and the area of the test specimen. The tests were performed with an area specific airflow rate similar to that which can be expected during the common use of the material.

The chemical analysis was based on detection of selected volatile organic compounds. Active sampling of VOCs was performed by using a pump (Aircheck 2000) with air flow rate of 400 ml/min on charcoal tubes ORBO 32S (Supelco) during 24 hours. The absorbed VOCs were analyzed by gas chromatography (GC Varian 3 300) after extraction into CS_2. In order to simplify the indoor volatile organic compound loading the TVOC value was estimated as the indicator of building material odors. Mølhave, the author of TVOC index proposed a value of comfort level 200 $\mu g/m^3$. The sum of VOCs was calculated based on individual VOCs concentrations including unidentified peak areas converted to decane equivalents (equivalent to toluene).

The exhaust air from each test chamber was led through a diffuser for sensory assessments. An untrained sensory panel of 20 subjects assessed odor intensity and perceived air quality. Before the first assessment the panelists were instructed how to use the scales and the exposure equipment. The responsible person of the experiment assessed each subject's attitude and motivation concerning to experiment and subject's personal hygiene. There was no restriction on distribution of gender or smoking habits. The age ranged from 18 to 40 years with the mean of 35 years, and 14 % of the subjects were smokers. The panel stayed in a well ventilated room without odors before the assessments. Then the subjects indicated their immediate evaluation on two continuous scales regarding odor intensity (from 0 no odor to 5 overwhelming odor) and acceptability of the air (from -1 clearly unacceptable to +1 clearly acceptable) from which the percentage of dissatisfied was estimated. The standard test method was used for calculation of acceptability and estimation of odor intensity. During the sensory assessments, the test chambers were covered with aluminum sheets to hide the building products from the view of the sensory panelists.

RESULTS

OSB boards and gypsum boards / wallpaper interactions

The perceived air quality were regarded as acceptable when odor intensity is less than 2 - moderate odor and air acceptability more then 0 – just acceptable/just unacceptable. In case of individual painted gypsum boards considered as a sorption material were both mentioned criteria fulfilled at air change level of category C. The air change level n = 0,5 1/h assured only required level of odor intensity, the air acceptability was not reached. The air change level for category B seems to be satisfactory for wallpaper as a comparing material from both subjective perceived air quality indicators point of view. In the case of individual OSB flooring system the required level of odor intensity has been reached at air change level for category B (n = 2,0 1/h) however the air was still unacceptable. Finally, the acceptability of assessed air was reached at air change level for category A (n = 3,0 1/h).

The positive effect of odorants sorption onto gypsum boards on perceived air quality is obvious from Fig. 1. The tested air was perceived more acceptable for OSB boards with addition to painted gypsum boards than for flooring material individually. The subjective assessment was not so high than assessment of individual painted gypsum boards. The criteria of subjective indicators were fulfilled at air change level for category B (n = 2,0 1/h) when both materials were in the interaction although the individual OSB flooring system these criteria did not fulfilled. The impact of increased air change level on VOCs sorption assessed on both subjective scales has not been evident. The most significant VOCs sorption observed on scale of odor intensity was in case of the highest air change level. The observation on scale of air acceptability showed the most significant sorption effect in case of air change level n = 2,0 1/h where individual OSB board was assessed as unacceptable however in combination with gypsum boards the panel assessed the air as acceptable.

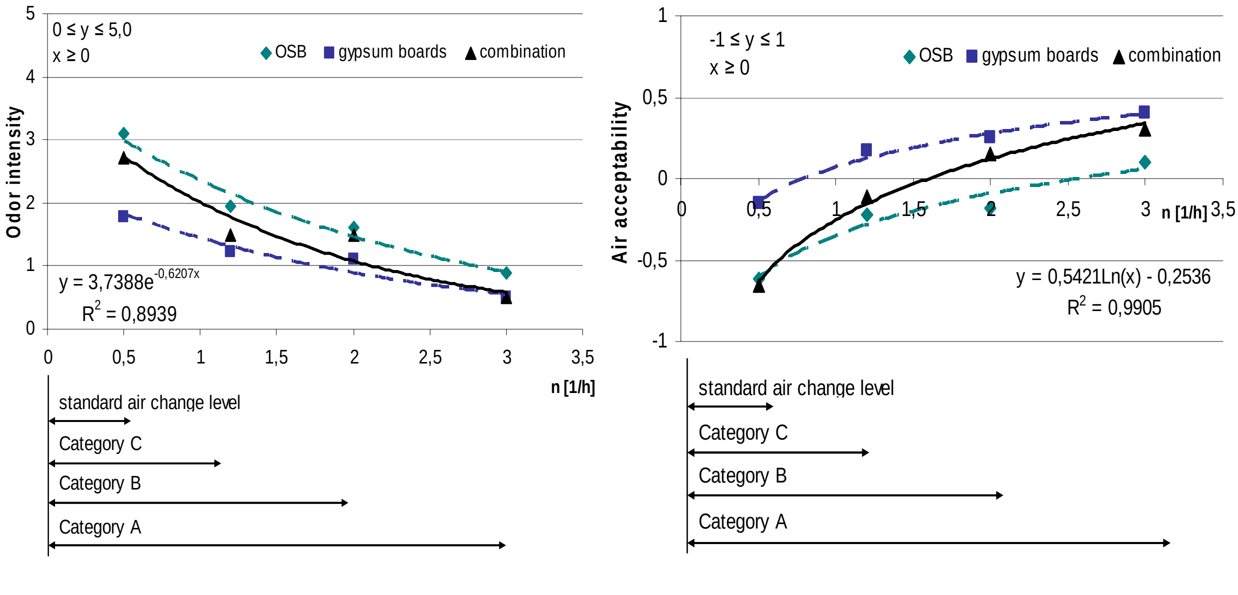

Fig. 1 Perceived air quality for OSB flooring – gypsum boards combination

The effect of odorants sorption onto impregnated wallpaper on perceived air quality is obvious from Fig. 2. No positive impact of materials combinations on perceived air quality was noticed for the OSB boards with addition to PVC wallpaper. The tested air was perceived less acceptable in all cases of studied air change levels for flooring material with addition to PVC wallpaper as for those ones individually. The required levels of both subjective indicators in the case of investigated indoor surface materials combination were reached by air change level for category A (n = 3,0 1/h).

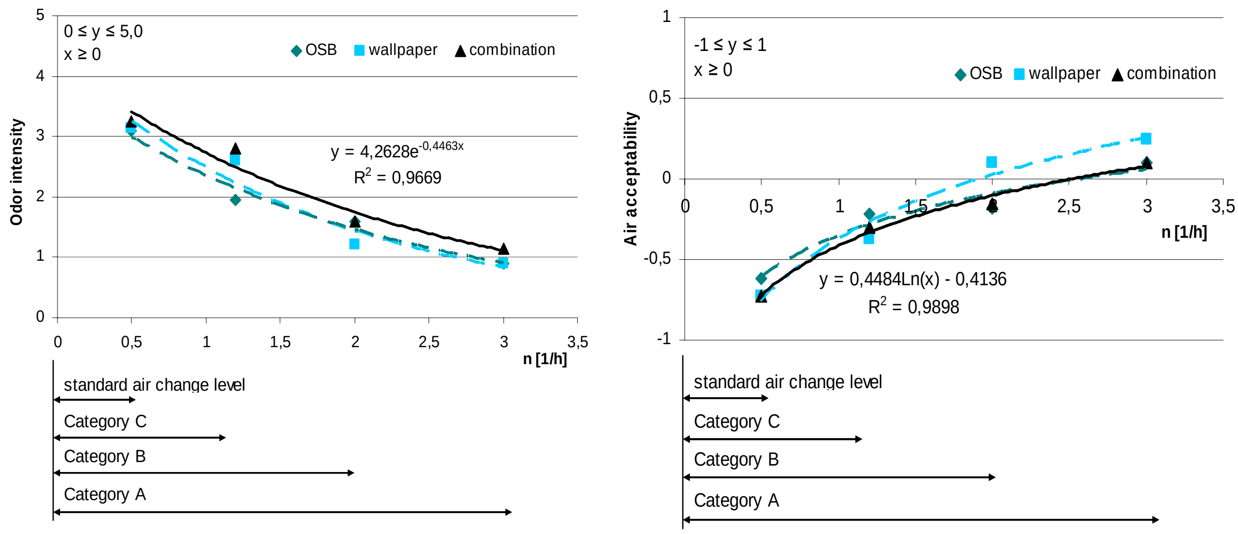

Fig. 2 Perceived air quality for OSB flooring – wallpaper combination

The air change level of category C (n = 1,2 1/h) guaranteed olfactory comfort level of TVOC (Molhave 200 μg/m^3) however the subjects found the air as still unacceptable in all cases of tested indoor surface materials (Fig. 3). The chemical analysis of emissions shown that ventilation rates in public buildings should be based on required level of perceived air quality. Unexpectedly the results of TVOC analysis did not clearly confirmed VOCs sorption when OSB flooring system was combined with painted gypsum boards. The negative effect was found with regard to both individual tested materials. The positive sorption effect for OSB flooring and wallpaper was found with regard to individual tested OSB flooring system.

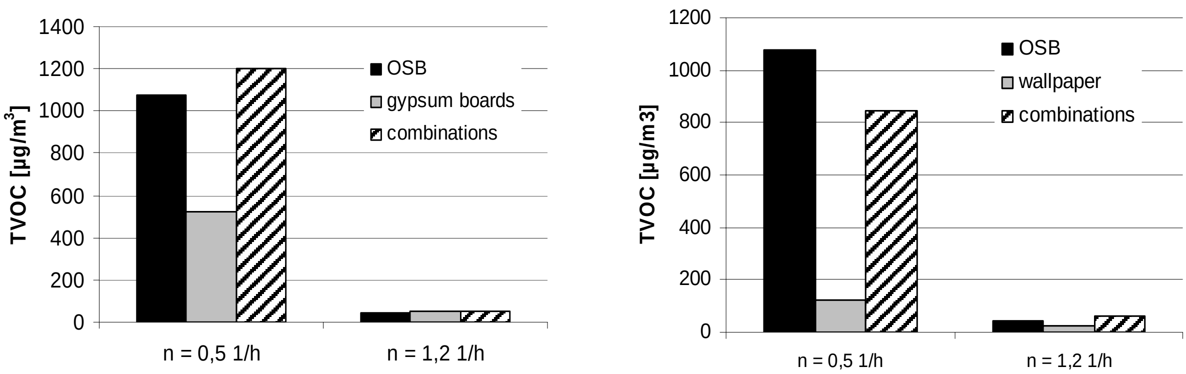

Fig. 3 TVOC analysis for OSb flooring system and its combinations

PVC flooring and gypsum boards, wallpaper interactions

In the case of individual PVC flooring the required level of odor intensity has been reached at air change level for category C (n = 1,2 1/h) however the air was slightly unacceptable. Both criteria of subjective indicators were reached at air change level for category B (n = 2,0 1/h).

The positive effect of odorants sorption onto gypsum boards on perceived air quality is obvious from Fig. 4. The tested air was perceived more acceptable for PVC flooring with addition to painted gypsum boards than flooring materials individually. The air acceptability was almost as high as for individual painted gypsum board. When both materials were in the interaction the criteria of subjective indicators were fulfilled at air change level for category C (n = 1,2 1/h). At this air change level these criteria were not fulfilled for individual PVC flooring. The sorption effect observed on scale of odor intensity decreased with increasing air change level. For air change level up to 2,0 1/h the sorption effect was not obvious. The assessment on scale of air acceptability almost copied the results from subjective assessments of gypsum board. The impact of increased air change level on VOCs sorption assessed on both subjective scales has not been evident.

The effect of odorants sorption onto impregnated wallpaper on perceived air quality is obvious from Fig. 5. The tested air was perceived less acceptable for flooring material with addition to PVC wallpaper as for those ones individually for almost all tested air change levels. The perceived odor intensity was lower than for the individual PVC wallpaper but higher than for the PVC flooring. The required levels of both subjective indicators in case PVC flooring and wallpaper combination were reached at air change level for category B (n = 2,0 1/h). The sorption effect observed on scale of air acceptability decreased with increasing air change level. For air change level u to 1,2 1/h the sorption effect observed by air acceptability scale was not obvious. Nevertheless the impact of increased air change level on VOCs sorption assessed on both subjective scales has not been evident.

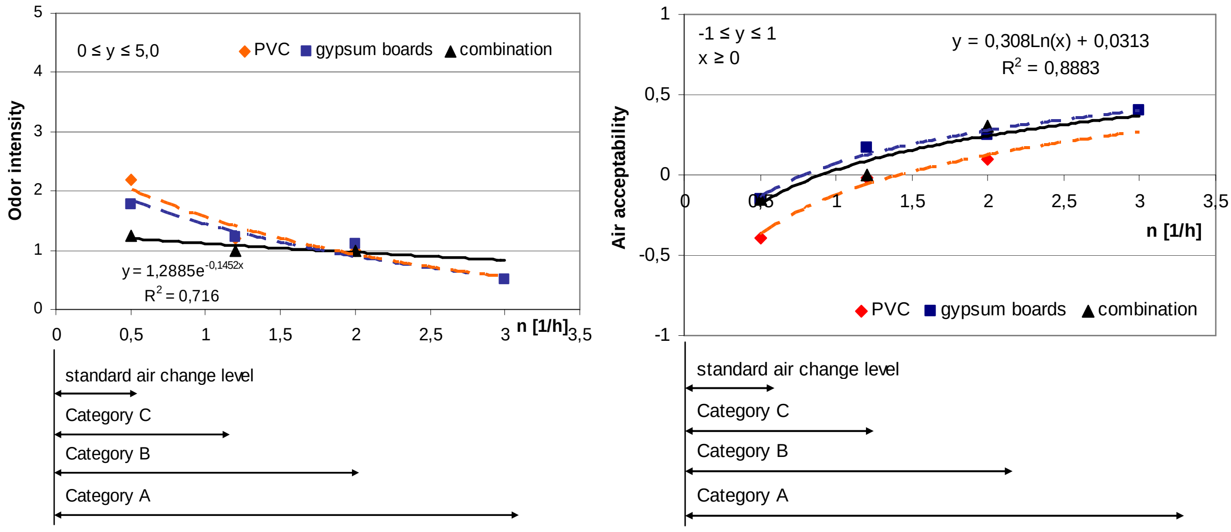

Fig. 4 Perceived air quality for PVC flooring – gypsum boards combination

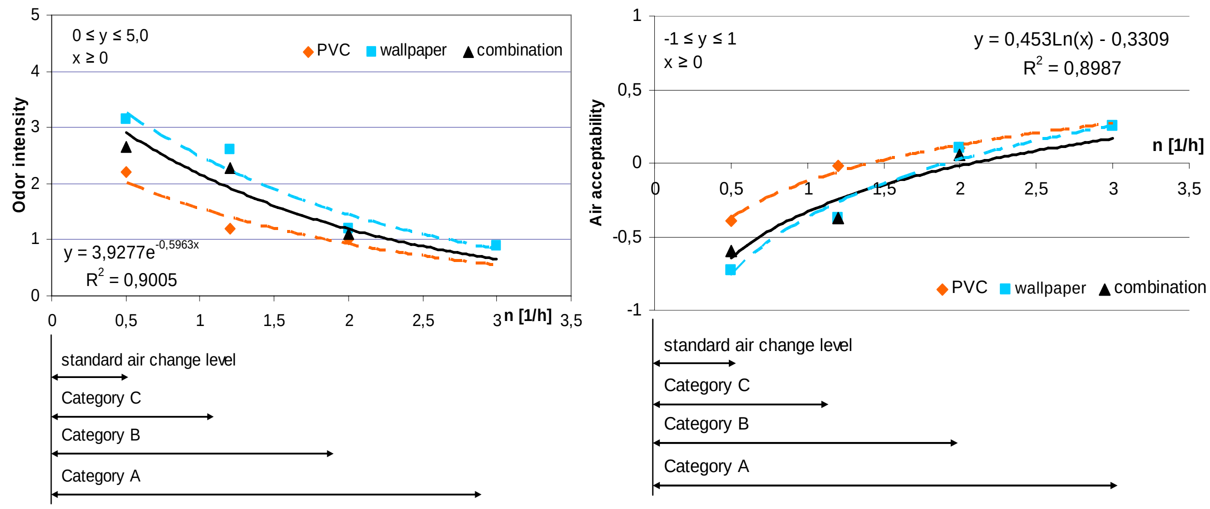

Fig. 5 Perceived air quality for PVC flooring – wallpaper combination

The air change level of category C guaranteed olfactory comfort level of TVOC (Molhave 200 µg/m^3) however the subjects found the air as still unacceptable in almost all cases of tested surface materials (Fig. 6). The positive effect of VOCs sorption expected from subjective assessment was confirmed by chemical analysis. The effect was markedly positive for PVC flooring and painted gypsum board with regard to both individual tested materials as well as for PVC flooring and wallpaper with regard to individual PVC flooring.

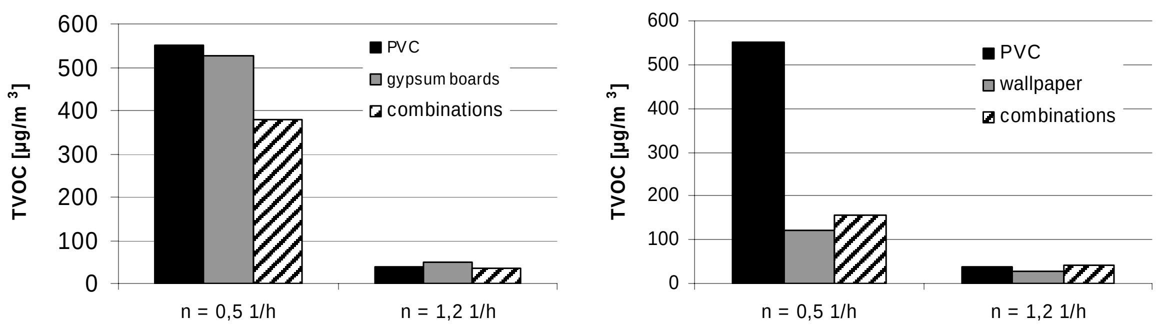

Fig. 6 TVOC analysis

DISCUSSION

The increased air change rate did not cause expected increasing of perceived air quality assessed by panel of subjects. Respecting other indoor climate parameters requirements (air temperature, humidity, and air movement) the increasing of air change level in order to achieve acceptable perceived air quality is not reasonable and makes no real sense [4].

The presented study has shown that there exist the real possibilities to apply sorption effect of odorants in order to achieve acceptable perceived air quality. More significant sorption effect was found for material with larger specific surface. Purposive using of material sorption effect creates opportunities to decrease the ventilation rate needed to achieve satisfactory perceived air quality and wellbeing however with respect to another possible indoor pollution unrelated to perceived air quality and building materials. The sorption of odorants onto gypsum boards studied within this study reduced the ventilation rate needed to achieve specified criteria of subjective indicators approximately by 1 Vol/h. The impact of increased air change level on VOCs sorption assessed on both subjective scales has not been evident.

SUMMARY

Gaseous emission - CO_2, NO, and NO_x of gas stove has significant and harmful effect on indoor air quality (IAQ) in residential kitchens. To avoid increasing health risk it is essential to use mechanical ventilation such as kitchen hood. However, according former laboratory studies, extract air flow generated by typical hoods is not adequate to achieve required IAQ. Thus there is an increasing need to develop a new kitchen ventilation system and to estimate the required exhaust ventilation rate.
In order to describe required ventilation of kitchens, emission of gas stoves has been investigated for years at Department of Building Service Engineering, BUTE. Laboratory and field studies were carried out, afterwards, based on the results, pollutant distribution was described by CFD simulation (FLOVENT).
In this paper an overview of method and results of CFD modelling is published.

INTRODUCTION

Gas stoves as pollutant sources can be described in accordance the power of burners. However occupants' behaviour (the way of use) takes significant part as well. If gas stoves are used in order to reduce required heat load of boiler, burner will run free. In this case pollutant concentration could be increase by 200-300%. From health point if view it should be taken into consideration that occupants normally stand near to the source during the cooking. Thus air in breathing zone contains higher level of pollutants. Therefore occupants are primary affected by combustion products. Application of hoods decreased the concentration levels but it has not appeared to be satisfactory in IAQ point of view.
In case of gas stoves Hungarian standards has a main issue providing fresh air to ensure burning process and to defend human health. However indoor air quality has an increasing impact on design process.

In order to help design, implementation and maintenance to develop more effective kitchen ventilation system, effect of gas stoves has been studied at laboratory and field studies. Based on results it is proved that trade hoods ($V_{ex,max}$ =180 – 250 m^3/h) can not ensure the required ventilation from IAQ point of view.

To estimate required exhaust air flow CFD modelling has been made by FLOVENT. Number of cases has been investigated as regards amount of air removed by kitchen hood. Supply air has been provided using air terminal devices installed above the windows. Validity of CFD model has been investigated based on results of former laboratory and filed studies.

METHODS

Using CFD modelling it can be predicted air moving in the enclosure. Calculations are based on fundamental flow and energy equations such as:

- Navier – Stokes equations
- Energy conservation
- Mass conservation
- Concentration equations
- k – ε turbulence model

To solve these it is necessary to make modelling assumptions in order to describe the investigated phenomenon in an accurate way. This also helps to decrease number of parameters, required computer capacity and solution time. Main modelling assumptions are follows:

- outdoor air does not contain any of pollutants;
- supply air temperature is equal to outdoor air temperature;
- invariant outdoor climatic circumstances (air temperature, air velocity, pressure);
- continuous ventilation by given amount of ventilated air.

Geometrical model has developed according architectural parameters of enclosure investigated at field studies. Gas stove model has been made following proportions of a device with average technical parameters, therefore commonly used one.

Pollution loads have been estimated by laboratory measurements. Considered operating time: 60 minutes. Initial indoor air temperature $t_i(\tau=0) = 20°C$.

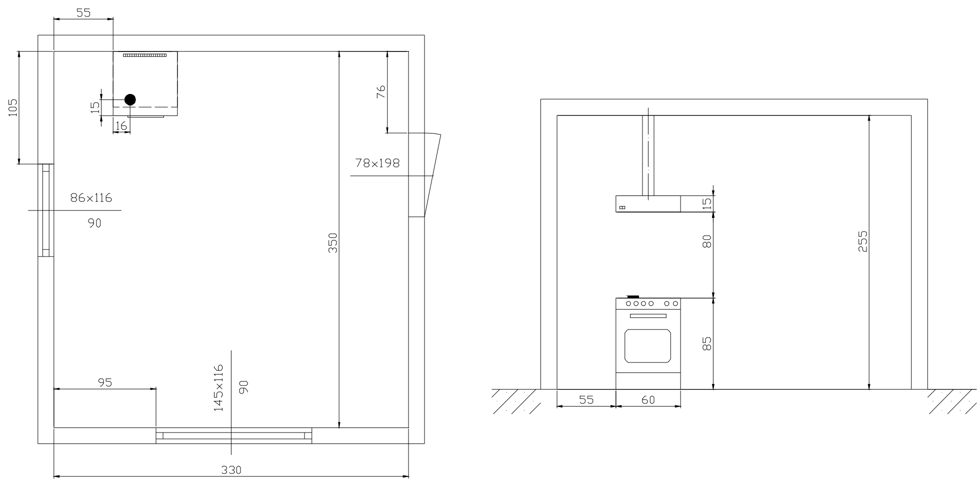

Figure 1. Plan of model kitchen (V_h = 29,5 m^3)

Table 1. Investigated kitchen ventilation systems

Burner power P=5kW		
Air flow extracted by hood (h =80 cm)	Supply air terminal device	Pollution load
0 m^3/h	-	
60 m^3/h	1 x 60 m^3/h	G_{CO2}= 1,80*10^{-4} kg/s
180 m^3/h	2 x 90 m^3/h	G_{NO2}= 2,48*10^{-8} kg/s
250 m^3/h	2 x 125 m^3/h	G_{NO} = 7,80*10^{-8} kg/s
500 m^3/h	4 x 125 m^3/h	

Thermal properties of stove have been studied in laboratory measurements as well, by measuring air temperature changing around the working stove at 10 points. At the same time surface temperature at different parts of stove envelope has been measured too.
To describe effect of increasing surface temperature approximate functions have been developed based on measurements' results.

Burner has been model by a heat source element with same heat exchanger area as the real one. Pollutant source have been placed above to the "burner". Three sources have been used for main gaseous products of burning: carbon-dioxide (CO_2), nitrogen-oxide (NO) and nitrogen-dioxide (NO_2).
For any sort of contaminant initial concentration is zero ($k_b(\tau=0)=0ppm$). Outdoor air has been taken into consideration as clean air.

Modelling grid is a main issue as regards accuracy of model. It is highly recommended to avoid any over dimensioning or using too poor grid system. In order to provide a proper solution at lower need of computer capacity, different regions have been worked up in the CFD model. In regions with high expected concentration, temperature or velocity gradients fine grid has been applied.
Seven regions have been defined with different grid:

1. Burning area (above top plate of stove)
2. Extract area (beside under plate of hood; extracting zone)
3. Front area (beside front plate of stove; primary occupied zone)
4. Left area (left side of stove; secondary occupied zone)
5. Right area (right side of stove; secondary occupied zone)
6. Envelope area (around the stove, along the surface of envelope)
7. Wall area (along inside surface of walls)

Total grid system of the model are contain 72 528 cells.

To describe time depending parameters time-step(s) has to be estimated. Total transient period (60min) has been divided into following steps: 2min, 5min, 10min, 15min, 20min, 30min, 45min and 60min. Data saved at 10th, 30th and 60th minutes.

Changing of calculated parameters (concentration, temperature and air velocity) has been followed at 10 monitor points placed in front of the stave, at 1.5m high along the centreline of the burner, in every 10cm.

RESULTS

Results are presented in table form and by visualisation as well, at above mentioned transient time step. At visualisation investigated areas have been selected according monitor points.
In following Figures results at 30min can be seen, in case of no ventilation and 250 m^3/h exhaust air flow.

- CO_2 concentration: Figure 2 a. and b.
- NO concentration: Figure 3 a. and b.
- NO_2 concentration: Figure 4 a. and b.

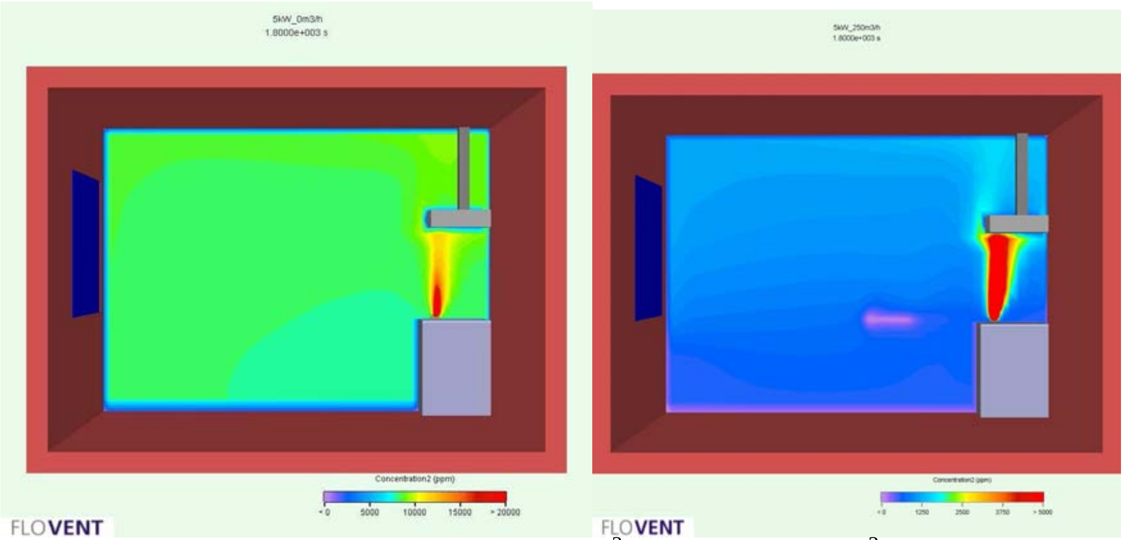

Figure 3. CO_2 concentration (30min) a.) V=0 m^3/h b.) V=250 m^3/h

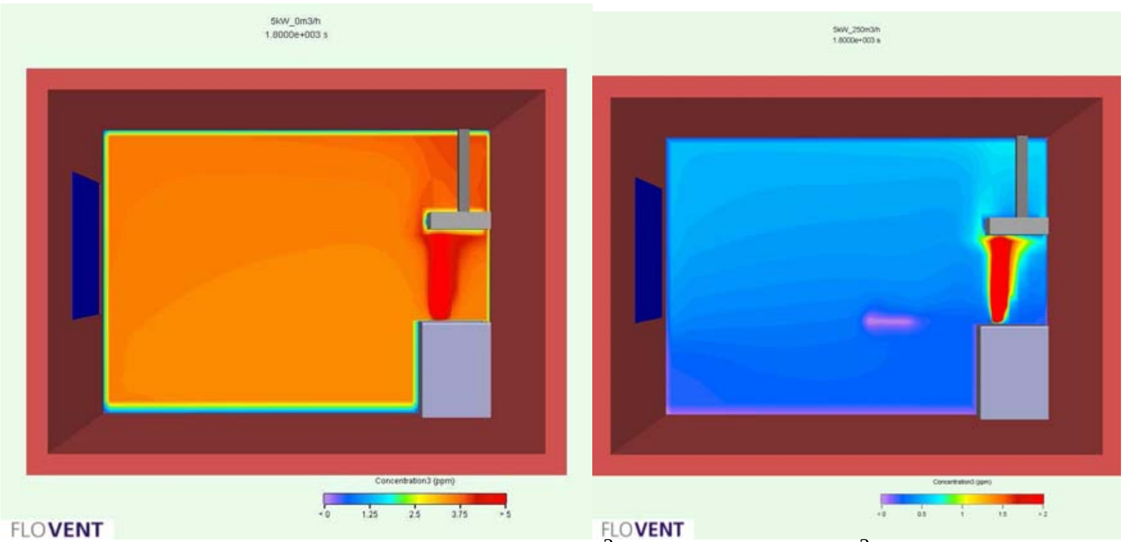

Figure 4. NO concentration (30min) a.) V=0 m^3/h b.) V=250 m^3/h

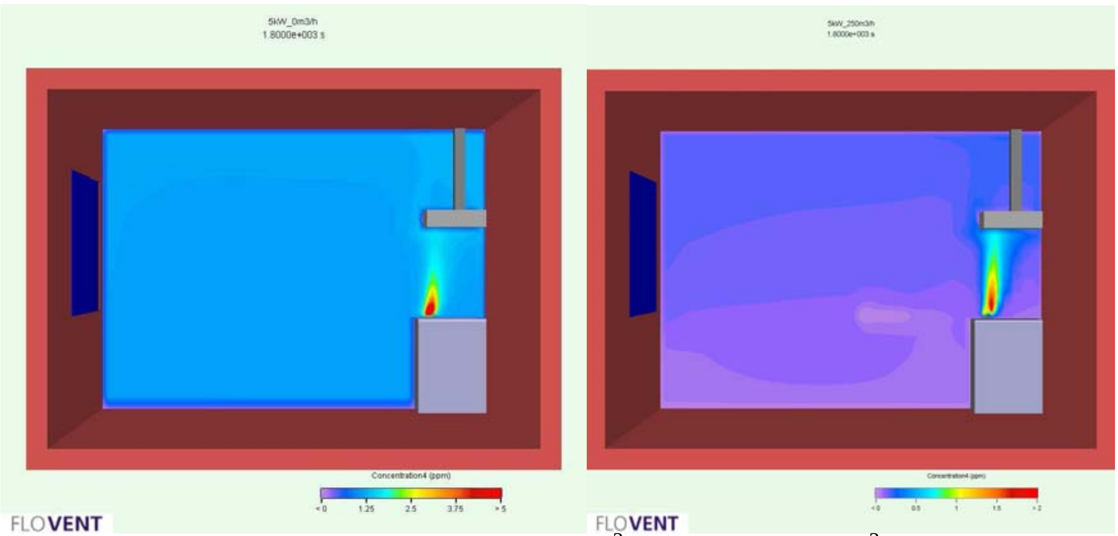

Figure 5. NO_2 concentration (30min) a.) V=0 m^3/h b.) V=250 m^3/h

CONCLUSIONS

- In kitchens equipped gas stoves it is strongly recommended to install mechanical ventilation system to provide required concentration level of CO_2 and NO_x.
- Using kitchen stoves as heating equipment results significantly decreasing indoor air quality level.
- Kitchen hoods with typical technical parameters ($V_{ex,max}$ =180–250 m^3/h) can not provide Hungarian requirements for NO_x concentration (200 μg/m^3)
- As regards CO_2 concentration required air flow is given in Table 2.

Table 2. Required exhaust air flow

Working period [min]	V_{ex} [m^3/h]	
	c_{CO2} < 2 500 ppm	c_{CO2} < 5 000 ppm
15	65,0	0,0
30	140,0	66,0
60	160,0	92,0

SUMMARY

Phthalates are ubiquitous contaminants in indoor environments, and are reported to cause adverse health effects. Due to their semi-volatile nature, phthalate samples require a multi-step preparation before quantification with GC-MS. Many different sampling media, extraction procedures, and solvents are utilized in phthalate analytics, while comparisons and justifications for each choice are lacking. In this study, phthalate recoveries were compared from glass fibre filter (GFF), XAD resin + GFF, and polyurethane foam (PUF) after ultrasonic treatment (US), and Soxhlet extraction (SX) with different solvents. The recoveries varied between phthalates, sampling media, solvents, and extraction methods. The overall best performance was obtained using US and toluene (TOL) for GFF; SX and TOL for XAD+GFF; and dichloromethane and US for PUF. The recoveries ranged between 76 and 131 %. Each of these combinations is suitable in terms of recovery, whereas selecting the optimum sampling medium to be used in the air samplings requires further research.

INTRODUCTION

There is a growing concern over a wide variety of chemicals in our living environment and their possible adverse health effects. Among these compounds are phthalates, the worldwide consumption of which is in the range of millions of metric tonnes per year. The phthalates are used as plasticizers in various building materials, furnishings, and household products, such as PVC floor coverings, wallpapers, cosmetics, toys, rain coats, and footwear. Recently, environmental organizations have raised these compounds into people's awareness by detecting these compounds from blood samples of various study groups (politicians, and females in different age groups). Also in the scientific literature, these compounds / their metabolites have been reported in the environment, in indoor air and dust samples, and in humans. This is a consequence of escape from the materials the phthalates were added to by volatilization, leaching or abrasion. The major concern related to phthalates is their suspected toxicity to reproduction [1-2]. Also, asthma and allergies have been suggested to be associated with two phthalates; di(2-ethylhexyl)phthalate (DEHP) and butylbenzylphthalate (BBP), respectively [3].

Research groups around the world have made great efforts in setting up analytical methods for the determination of phthalates from air and dust samples. Due to their semi-volatile nature (Table 1), phthalate samples require a multi-step preparation before quantification with gas chromatography-mass spectrometry (GC-MS). Many different sampling media, extraction procedures, and solvents are utilized in phthalate analytics, while comparisons and justifications for each choice are lacking. Only after large databases on phthalate emissions and concentration levels in the (indoor) environment have been gathered, it is possible to estimate the risks related to exposure via respiratory tract and skin. Eventually, this will also increase possibilities for material and product development.

The aim of this study was to address the problematic issues of phthalate analysis by comparing phthalate recoveries from glass fibre filter (GFF), XAD resin + GFF, and polyurethane foam (PUF) after ultrasonic treatment (US) and soxhlet extraction (SX) with different solvents.

METHODS

Reagent and material preparation

Clean glassware were either rinsed with ethanol, hexane (HX), and toluene (TOL) or baked at 450 °C for 4 h prior to use and wrapped in aluminium foil. Caps and metal equipment were rinsed with acetone or ethanol. Glass fiber filters (GFF, ø 25 mm, pore size 1 µm, Gelman Sciences, Ann Arbor, MI, USA) and cotton wool for filtering liquids were sonicated with dichloromethane (2×20 min). Polyurethane foam (PUF, ø 18 mm×5 cm, Klaus Ziemer GmbH, Langerwehe, Germany) was cleaned using Soxhlet extractor with hexane (16 h). XAD-2 resin (Amberlite XAD-2, Supelco, Bellefonte, PA,USA) was rinsed with hexane and the solvent residue was removed using purified nitrogen. The filter cassettes (ø 25 mm, Millipore) were washed with purified water and dried in nitrogen flow. The XAD-GFF sampler was prepared right before the experiments by packing 1.7 g of XAD-2 resin on filter cassettes covered with a nylon net filter (ø 25 mm, pore size 180 µm, Millipore, Billerica, MA, USA), and a GFF was placed on the top to cover the XAD-2 resin.

The solvents (HX, TOL, dichloromethane (DCM), acetone, ethanol) used were of p.a. or HPLC grade. Phthalates and the internal standard of analytical grade (Table 1) were supplied by Sigma-Aldrich and Fluka (Steinheim, Germany), and the recovery standard (deuterated phenanthrene) was obtained from Sigma-Aldrich. Stock solutions of the chemicals were prepared in TOL at concentrations from 0.6 to 1.9 mg/ml, and analytical standard solutions were made from appropriate dilutions of these stock solutions (target concentrations were 103-191 µg/ml).

* = internal standard; ** = solid; n.a. = not available.

In preliminary tests of 3 replicate injections to the GC-MS system, the repeatability (relative standard deviation, RSD) of the response of 5 phthalates dissolved in TOL at 8 concentrations ranging between 0.01 and 10 µg/ml was better than that obtained when HX was used as a solvent. The RSDs were <12 % with TOL whereas the RSDs ranged between 17 and 46 % with HX. However, the instrumental detection limits were lower (0.01 µg/ml) with HX for all the 5 phthalates compared to the detection limits obtained with TOL (0.1 µg/ml for 4 phthalates and 0.5 µg/ml for BBP). Each compound showed linearity in the range between 0.1 and 5 µg/ml only with TOL. Thus, TOL was chosen as the solvent for GC-MS analysis in the following experiments.

Recovery tests

For the recovery tests, GFF, XAD-GFF samplers, and PUF plugs were spiked with 2.1-3.8 µg of each phthalate and 2.9 µg of internal standard (DPP), and immediately extracted with one of the tested solvents (TOL, HX, or DCM) using ultrasonic (US) or soxhlet (SX) extraction. However, the PUF plugs were not extracted with TOL because the plugs were found to get deformed and loose their composition in the preliminary tests.

After ultrasonic extraction (2×5 ml×20 min), the samples were filtered through a clean cotton wool wad plugged in a Pasteur pipet. After filtration, samples were evaporated at room temperature (RT) using a gentle stream of nitrogen. In one experiment, when GFF was extracted with US-TOL, nonane was added to the sample to prevent sample losses during solvent evaporation with nitrogen. To the 1 ml volume of each sample in TOL, 0.57 µg of phenanthrene-d10 was added as a recovery standard before GC-MS analysis (Table 2) to measure the recovery of the internal standard.

For comparison, the spiked samples were extracted with 150 ml of one of the tested solvents for 16 h with Soxhlet extractor. Nonane was added onto the samples after Soxhlet extraction, and the volume of the extracts was reduced to <1 ml using rotary evaporator at RT under reduced pressure. The samples were then transferred to test tubes with TOL and the excess solvent was evaporated at RT with nitrogen. The samples (V=1 ml) were transferred to GC vials, and recovery standard added as with the US extraction. Quantification was carried out using GC-MS (Table 2).

The measured phthalate concentrations were compared to the spiked quantities to determine the recoveries (ARR, relative analyte recovery rate). For DPP, the recovery was calculated by comparing the ratio of the peak areas of internal and recovery standards in a sample with the corresponding ratio obtained in the analysis of the analyte standard solution. The criteria for the best extraction method and solution for each sampling material included the uniform distribution of all the determined phthalates around the 100 % optimum recovery.

Ionization source	Electron impact ionization (70 eV)
Interface temperature	280 °C
Selected ions (at *m/z*)	DMP:163,194, DEP:149,177,178,222, DPP:149,191,209:, DIBP:149,167,205, DBP:149,205,223, BBP:149,178,206, DCHP:149,167,191,249, DNOP:149, 161,167,279, DEHP:149,167,191, FEN*d10*:188,180

RESULTS

The extraction recoveries varied with respect to the phthalate, sampling material, solvent, and extraction method (Table 3). The loss of internal standard (ARR_{DPP} 12-45 %) was pronounced when samples were extracted with HX, and also in the experiment with PUF-SX-DCM. Thus, the quantitation of the analytes could not be reliably performed in those experiments.

Table 3. The extraction recoveries of phthalates from diverse sampling materials following different extraction methods and extraction solvents.

Sampling material	**Extraction**		**Extraction recovery, %**

	US	DCM	84	88	94	108	76	131	744	198	67

*= internal standard; GFF=glass fiber filter; XAD=XAD-resin; PUF=polyurethane foam; US=ultrasonic extraction; SX=Soxhlet extraction; TOL=toluene; DCM=dichloromethane; HX=hexane; n=nonane.

Another problem arose with the obvious contamination caused by DNOP and DEHP indicated as extremely high recoveries in several samples (Table 3). Therefore, the results on DNOP and DEHP were excluded when the best extraction method for each sampler was determined.

The best average recoveries of 6 phthalates and DPP using US were obtained with TOL+nonane for GFF samples (ARR 84-120 %) and with DCM for PUF samples (76-131 %), whereas SX was the best method for XAD+GFF when extracted with TOL (ARR 90-107 %). In these samples, recovery of the internal standard ranged from 67 to 79 % (Table 3). Generally, the recoveries DPP and DMP were the lowest regardless of the extraction parameters. The loss of DPP was controlled, and the recoveries of DMP, DEP, and DIBP were improved when nonane was added to the US sample compared to the extraction without nonane (Table 3). The glass fiber filters should not be extracted with US+DCM, and the SX+DCM combination seems to be the worst choice for the extraction of all the tested phthalates on XAD+GFF. The HX+US was not the optimum extraction combination for PUF samples. However, each of the three last mentioned less-optimal extraction combinations may work satisfactory when only few phthalates are targeted, but with respect to detection of all 6 phthalates at the same time, the recoveries from the samplers can be optimised by choosing other extraction parameters.

DISCUSSION

In the construction and furnishing products, such as floor and wall coverings, wire and cable insulation, and electrical conduits, vinyl plastics are widely used because of their durability, easy installation, and cost-effectiveness. The phthalates make possible the flexible, colour-fast, durable, and low-maintenance qualities of vinyl. Unfortunately phthalates migrate from the products, and have been recognized as ubiquitous contaminants in the environment. Due to their potential impact on human health, standardized procedures are warranted to monitor the exposure levels to these compounds in dwellings and workplaces. The large variety of sampling adsorbents and extraction procedures utilized in the indoor air phthalate analytics emphasises the need for their reciprocal comparison. This study was attempted to evaluate the capacity of two common extraction methods to recover phthalates from three frequently used sampling media.

In this study, three solvents, HX, DCM, and TOL, were compared. The loss of the internal standard in HX experiments indicated that HX may not be the best choice for an extraction solvent. This can also be deduced from the literature, as HX has been used as an extraction solvent only as a mixture with diethyl ether [4-6]. On the other hand, acetone that was not evaluated in the present study might be another suitable solvent and worth comparing [7,8]. The selection of DPP as the internal standard may be justified with the fact that it has not been extensively found in the environmental samples [6,9]. The recoveries of DPP ranging from 67 to 79 % in the best extraction combinations for each sampling material indicate some losses during sample handling, and this may also be the case for DMP and DEP having lower boiling points than DPP (Table 1). Thus, due to similarities in volatility, DPP is a suitable internal standard for at least DMP and DEP. Other researchers have described losses of DBP during evaporation of samples [10] but this was not evident in these experiments. However, it might be advisable to use another internal standard, e.g., a deuterated one, to detect possible losses during sample handling of those phthalates with boiling points in the range of 320-390 °C.

The contamination caused by DNOP and especially DEHP in this study was partly traced to plastic sample holders and a contaminated nonane reservoir. Xie et al. [8] suggest that all solvents be distilled for purification and stored thereafter in full glass bottles. These authors also used active carbon cartridges to filtrate the air entering the Soxhlet apparatus and rotary evaporator, and XAD-2 resin in connection with nitrogen evaporation to catch any impurities from the nitrogen and the bleeding of tubings. In addition, in the field sampling, the adsorbent holders should be made of glass instead of plastic to avoid contamination thereof. These precautions and collection and analysis of laboratory and field blanks should be routinely performed in the phthalate analytics to control and identify potential contamination sources and to verify the authenticity of the results.

With respect to the recoveries of DMP, DEP, DIBP, DBP, BBP, and DCHP, the overall best performance was obtained using US and TOL for GFF; SX and TOL for XAD+GFF; and DCM and US for PUF. The recoveries ranged between 76 and 131 %. These conclusions are based on single experiments. The recoveries of DNOP and DEHP with the presented extraction procedures should be verified as well. Even though the sampling media and/or the extraction methods and solvents have varied in other studies, the reported recoveries for these compounds have ranged between 78 and 138 % (Table 4) suggesting that these are probably the reasonably obtainable and acceptable recoveries in the phthalate analytics. The recoveries exceeding 100 % may be due to matrix effects: residues of the sampling media that remain in the extract protect the analytes from adsorbing, and thus, allow the injection of a higher concentration into the GC column compared to the concentration injected from a “clean” analyte standard solution prepared by dissolving analytes in a solvent. It might therefore be advisable to prepare quantification standards following the same procedure as with the sample preparation.

Table 4. Phthalate recoveries (%) reported in international studies.

Sampling material [ref]	**Extraction method: solvent**	**Recovery (%) for**							
		DMP	**DEP**	**DIBP**	**DBP**	**BBP**	**DCHP**	**DEHP**	**DNOP**
XAD [7]	elu:DCM	84	91	-	101	90	-	135	92
PUF+XAD [8]	SX: HX+DE (9:1)	138	131	123	117	78	-	99	108
GFF+Empore C18 filter [9]	sta+US: TOL+AC (3:7)	91	100	97	92	90	100	90	-
Quartz fiber filter+ Empore disk C18 filter [11]	US+shake:AC	97	98	98	101	105	102	106	-
Charcoal [12]	US:TOL	-	110	-	120	94	110	98	-
Silica gel [13]	elu:AC	88	91	95	-	99	94	106	-

- = not determined; AC=acetone; DCM=dichloromethane; DE=diethyl ether; ELU=elution; sta=static elution; SX=Soxhlet; TOL=toluene; US=ultrasonic extraction.

In conclusion, the occurrence of phthalates everywhere including laboratory environments causes high risk of contamination during the analysis. This and the lack of standardized methods for sampling and analysis of phthalates in indoor environments pose extra challenges in the phthalate analytics. However, this study showed that various sampling media can be utilized in conjunction with optimum extraction technique and solvent. The analytics enables quantification of phthalates in indoor environments and eventually also offers possibilities to develop products and materials with lower phthalate emissions. The suitability of the sampling media and analytics tested in this study for field sampling warrants further study.

SUMMARY

The article deals with air parameters in building exterior and interior. External air temperature is the most important air parameter in the exterior. The temperature is influenced by local area parameters. The annual external air temperature measurement in city centre and periphery in Central Europe is presented. The article also contains multizone modeling and simulation of indoor air quality during different boundary conditions (external environment), various occupations of interior and different types of ventilation and ventilation air amount.

INTRODUCTION

Indoor environmental quality depends on technical equipment ability adjust external variable parameters of entering factors to parameters not such much variable. External parameters correspond to climate region and local area quality. The urban environment quality is different in the city centre, suburb and surrounding intact areas. The differences are in the air quality, air temperature as well air humidity.

Indoor air quality and pollutant concentration is significant for human health because people spend most of their time in buildings. The aim for heat losses lowing directed to limiting natural ventilation by windows. Tight windows have insufficient infiltration; they are unsuitable from the hygienic point of view. It leads to pollutant concentration and relative humidity enhancement, mould reproduction and environment not corresponding to human organism. So it is necessary to ensure mechanical ventilation during people presence.

Indoor air quality depends on many factors, especially on: outdoor air quality, air amount per person or ventilation rate, ventilation plant, amount of air pollutants. Carbon dioxide is the most important indoor pollutant whether the pollutant source is presented only by people.

The study is focused on some external and internal air parameters.

METHODS

The external air temperature is the basic parameter with direct influence to the building energy demand. The external air temperature is fluctuated and local temperature change especially depends especially on the surface properties.

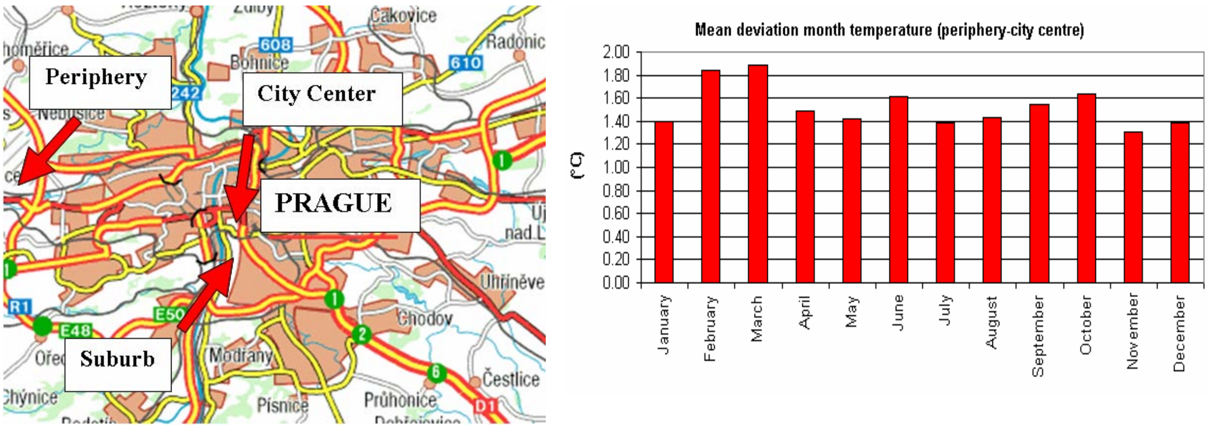
The solar reflection and absorption is markedly depended on a surface colour. Simply we can say that the darker surface increases energy absorption and, in dependency on a thermal capacity, the energy is accumulated. The solar radiation is a thermal energy source, especially direct part of the global solar radiation.

This effect causes warming up of surfaces with solar radiation absorption and thermal conduction to the deeper layers and the surfaces radiate thermal energy during a period with lower solar intensity with a time delay. The asphalt roads in zone with people or pedestrian zones with usually black colour are the biggest accumulators of thermal energy. The building

operation is the next energy source in the city centres and the building heat losses are becoming energy gains for local environment.
Next technology equipment operation in a relationship with buildings and transport are not negligible. Technical equipments provide stable parameters of the internal environment and warm up or cool down environment. The cars produce the thermal energy in generally too. Differences between climate in cities and countryside are evident from mentioned reasons.

Measurement

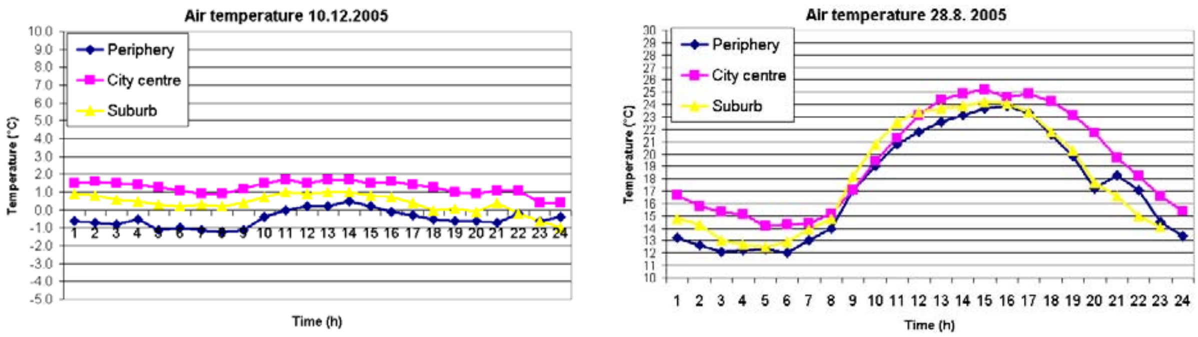
The external air temperature increasing is significant especially during summer period in the city centres in Central Europe conditions.
While the temperature increasing during winter is not so significant trouble-it decrease energy consumption for heating, warmer summer period is negative and the active cooling systems must be installed. The air temperature change is simple, but higher temperature difference increase energy consumption. Negative effect can be supported by unsuitable building design with high glass ratio and without passive shading or low energy cooling systems.



a) b)

Figure 1. External air temperature measurement: a) City plan b) Mean deviation-month temperature city centre-periphery

Urban heat islands measurement was already done in countries with hot summer (temperature increases 30°C) and with mild winter where summer effect is significant.
Long time measurement of the external air temperature was done in Prague during year 2005 and partly in year 2006. The temperatures were measured in the city centre, suburb and periphery.



a) b)

Figure 2. External air temperature: a) Winter b) Summer (influence of direct solar radiation)

Outdoor air quality influence on ventilation air amount

Outdoor air quality has an influence on ventilation air amount for exhausting pollutants. The worse outdoor air quality means the more ventilation air amount. Carbon dioxide is the most important pollutant in interior. Ventilation air amount dependence on outdoor carbon dioxide concentration shows Figure 3. The relation is exponential. The difference between the country (330 ppm) and large city (450 ppm) for one person is small, but for whole building the difference will be large.

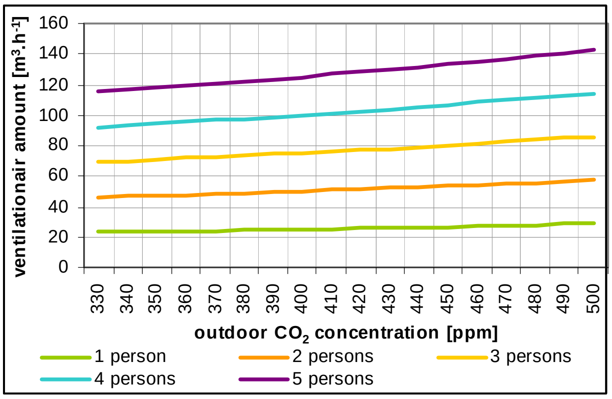


Figure 3. Ventilation air amount dependence

Model of the exterior microclimate

Many models were developed for time acceptable parametric solving city microclimate in history. But many of them were applicable only in the area of their origin. Individual variables was not purify from constants derived from the measurements. CTTC (Cluster thermal time constant) model is the most hopeful from the unit of parametrical models. Model is based on the Hoffman model.

The principle of the model is split the urban area to separate clusters and parameters calculate separately in the cluster with influence of surface properties, solar radiation, and convection to the climate.

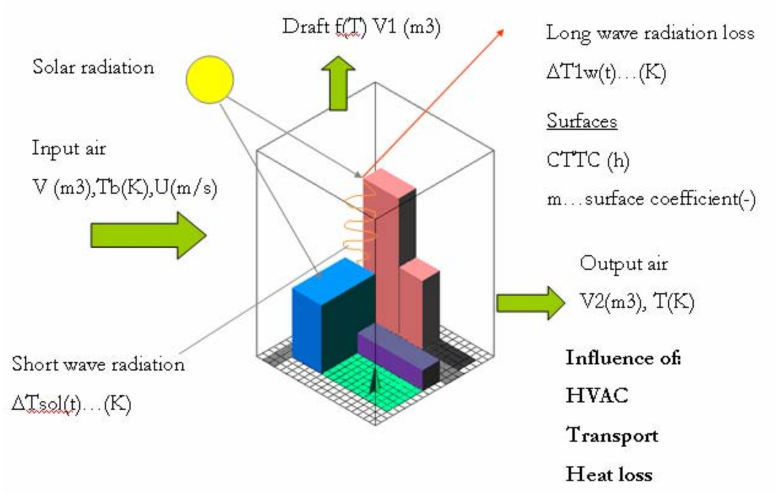

Fig. 4 CTTC model (urban climate simulations)

Model of carbon dioxide concentration

This part is about modeling and simulation of five different alternations of ventilation of two-rooms flat in Contam 2.4. This program helps to specify airflow – infiltration, exfiltration, flowing among particular rooms during natural ventilation and mechanical ventilation, wind pressure on building facade. It is possible to count pollutant concentration on the base of knowledge of the quantity airflow and pollutant production. Optimal air distribution is considered.

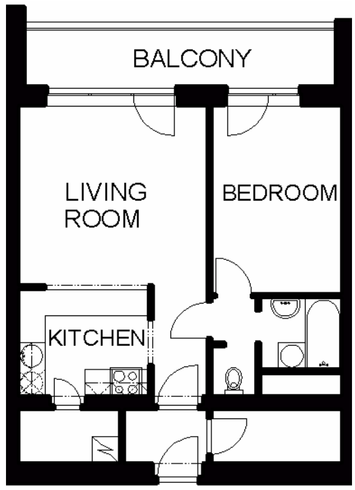

Figure 5. The plan of the flat

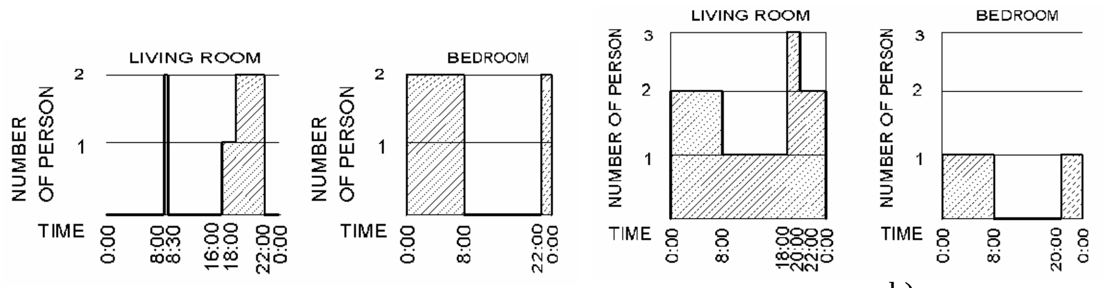
The plan of the observed flat shows Figure 5. The detected indoor pollutant is carbon dioxide. It was counted with outdoor carbon dioxide concentration 350 ppm and respiration production 20 $l.h^{-1}$ per person. Living room volume is $67m^3$ and bedroom volume is $31,2m^3$. The flat was studied in two alternations: "A" - which is occupied by two persons and "B" - which is occupied by three persons due to figure 6. Carbon dioxide concentration was observed in living spaces (a living room and a bedroom), where occupants spent most of their time.



a) b)

Figure 6. Space occupation a) for flat "A", b) for flat "B"

Five ventilation alternations were selected for ventilation assessment. Alternations characterize not only hygienic rules but also ventilation used in current buildings.

Alternation no. 1 – ventilation according to ventilation air amount per person due to Pettenkofer`s rule 25 $m^3.h^{-1}$ per person

Alternation no. 2 – hot-air heating and ventilation with circulation (75 % circulation air)

Alternation no. 3 – exhausting sanitary equipment according to DIN 1946-6 with 0,45 h^{-1} ventilation rate

Alternation no. 4 – infiltration by "untight" windows, flow coefficient i_L=1,4*$10^{-4}m^2$ $s^{-1}Pa^{-0,67}$ and exhausting sanitary equipment according to ČSN 74 7110

Alternation no. 5 – infiltration by "tight" windows, flow coefficient i_L=0,1*$10^{-4}m^2$ $s^{-1}Pa^{-0,67}$ and exhausting sanitary equipment according to ČSN 74 7110

It is considered: the air flows into interior in spite of tight windows, none windows opening during people presence (difficult behavior estimating).

RESULTS

External environment

The solution of oversized warming is decreasing of insolate surfaces absorption. Green fields could be use for shading or moisture production (evaporation). The wind has the high influence to the thermal situation in the city, flow change temperature in given area. Generally, climate changes will increase energy consumption because energy for cooling is more expensive then energy for heating. Give a definition of maximal impact of building to neighbourhood could be set up. This parameter creates restriction for building with high glazing ratio and with active cooling systems. Environment friendly buildings are result of these parameters.

Indoor microclimate

Figures 7-10 show carbon dioxide concentration runs.

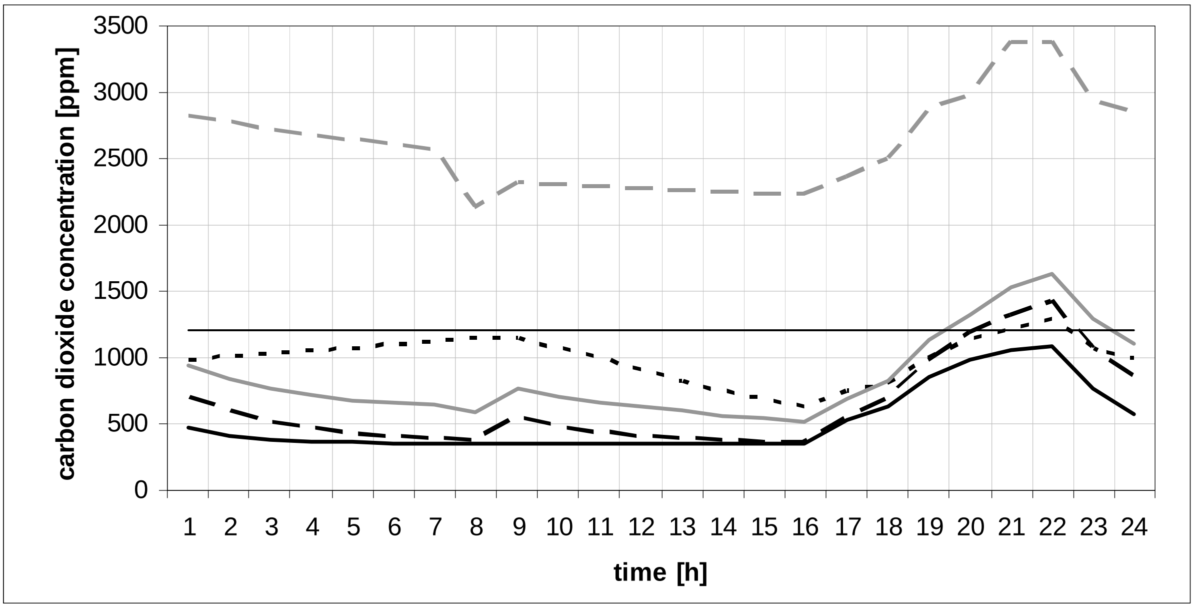


Figure 7. CO_2 concentration runs for living-room "A"

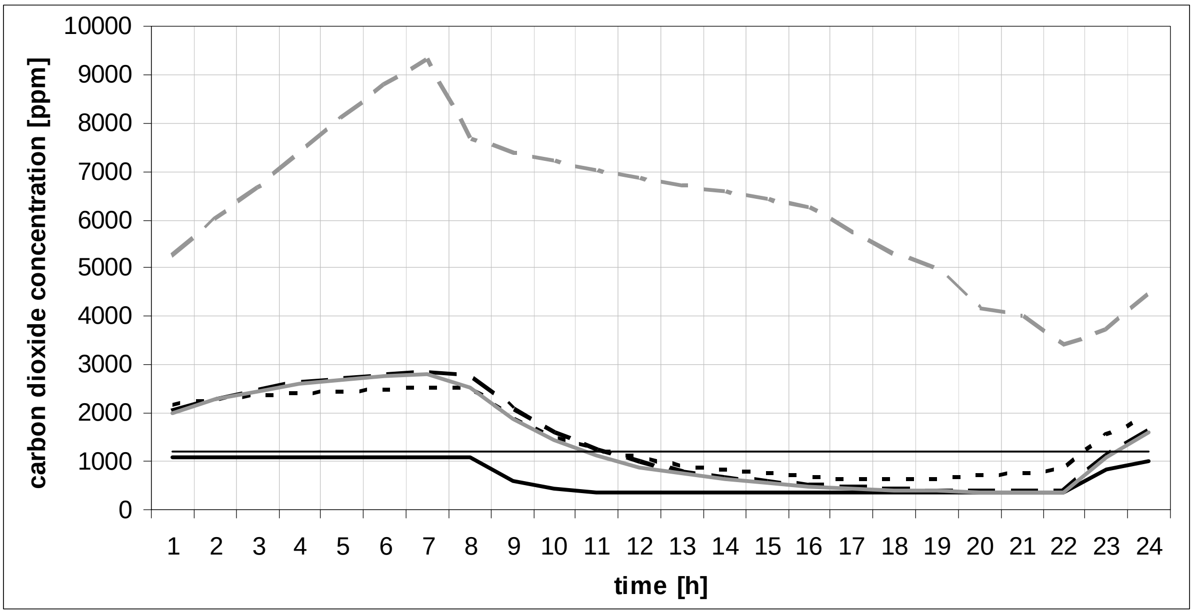

Figure 8. CO_2 concentration runs for bedroom "A"

Legend for figure 7 and 8:

Alternation no. 1 –Pettenkofer`s rule 25 $m^3.h^{-1}$ per person

Alternation no. 2 – hot-air heating and ventilation with circulation (75 % circulation air)

Alternation no. 3 – exhausting sanitary equipment according to DIN 1946-6 s 0,45 h^{-1} ventilation rate

Alternation no. 4 – infiltration by "untight" windows and exhausting sanitary equipment

Alternation no. 5 – – infiltration by "tight" windows and exhausting sanitary equipment

Requirement

The results show, that CO_2 concentration run is similar to interior occupation, zone volume and ventilation air amount. Increasing time of concentration to constant value and decreasing time of concentration to ventilation air concentration depend on room volume, pollutant production and ventilation air amount.

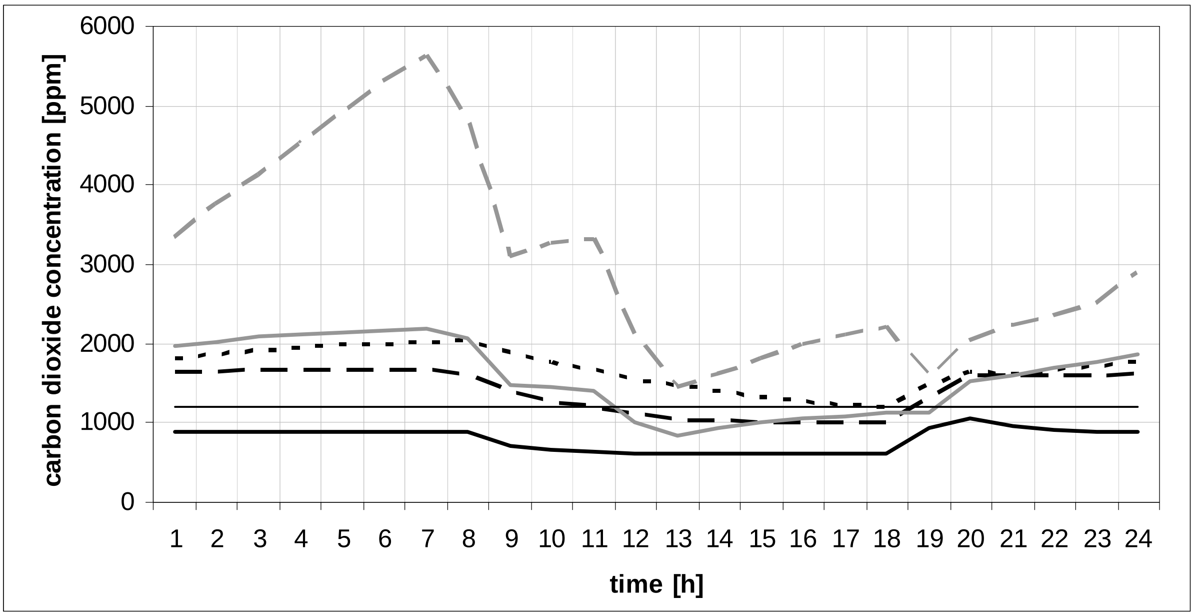

Figure 9. CO_2 concentration runs for living-room "B"

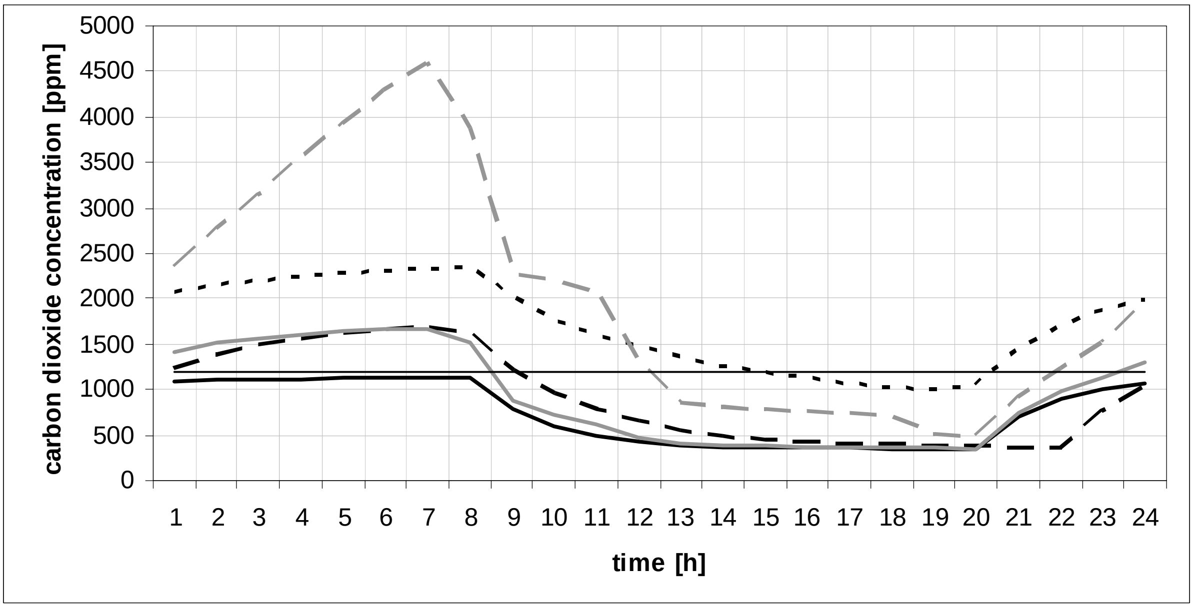

Figure 10. CO_2 concentration runs for bedroom "B"

Legend for figure 9 and 10:

Alternation no. 1 –Pettenkofer`s rule 25 $m^3.h^{-1}$ per person

Alternation no. 2 – hot-air heating and ventilation with circulation (75 % circulation air)

Alternation no. 3 – exhausting sanitary equipment according to DIN 1946-6 s 0,45 h^{-1} ventilation rate

Alternation no. 4 – infiltration by "untight" windows and exhausting sanitary equipment

Alternation no. 5 – – infiltration by "tight" windows and exhausting sanitary equipment

Requirement

No rule for indoor air quality is in the Czech Republic. Maximal concentration 1200 ppm was required in this study, this value is according to EN CR 1752 CEN for class „C“.
The worst alternation is ventilation by infiltration with tight windows (no. 5). Also alternation no. 4 is very bad. Maximal required carbon dioxide concentration is overstepped more than 90 % time of people presence. The best alternation is the first alternation. Alternation no. 2 is suitable only for living room in flat A. Maximal required carbon dioxide concentration is overstepped more than 90 % time of people presence in bedrooms, maximum is 2500 ppm. Required concentration is also overstepped in alternation no. 3, but it is better than ventilation by infiltration.

DISCUSSION

The weather forecast is possible with limited precision only because the border conditions are too much complicated. Speaking about cities scale, areas with potential unsuitable temperature change can be calculated from the city surface parameters.
Internal microclimate quality must be arranged without influence on the local exterior conditions.
For the reduction of unsuitable building design and building situating tools must be created. The tool can show energy requests to buildings situated in the city centre or in the periphery.
The results show, that CO_2 concentration runs is similar to interior occupation and ventilation air amount. Simulation in program Contam 2.4 showed, that necessary air amount per person for ensuring maximal CO_2 concentration 1200 ppm is 25 $m^3.h^{-1}$ per person. It was established that, Pettenkofer`s rule is valid.
For good indoor air quality, we should design ventilation air amount due to this rule 25 $m^3.h^{-1}$ per person.

Performance of ventilation systems

Effect of using low-polluting building materials and increasing ventilation on perceived indoor air quality

SUMMARY

The potential of improving perceived air quality indoors was quantified when low-polluting materials are used and when building ventilation is increased. This was done by studying the relationships between ventilation rate and the perceived indoor air quality. A sensory panel assessed the air quality in test rooms ventilated with realistic outdoor air supply rates, where combinations of high- and low-polluting wall, floor and ceiling materials were set up. These materials were ranked as high- and low-polluting using sensory assessments of air quality in small-scale glass chambers, where they were tested individually. Substituting materials ranked as high-polluting with materials ranked as lower-polluting improved the perceived air quality in the test rooms. This improvement was greater than what was achieved by a realistic increase of the ventilation rate in the test rooms. Thus reducing pollution emitted from building materials that affects the perceived air quality has a considerable potential of limiting the energy for ventilation without compromising indoor air quality.

INTRODUCTION

There is a need for reducing the energy consumption worldwide. One initiative to reach this goal is the EU Directive 2002/91/EC Energy Performance of Buildings [1] that makes it obligatory to reduce energy consumption in buildings while taking into account the indoor environment. For most buildings this can only be achieved if the energy used for ventilation is also reduced, as it constitutes about 20-30 % of the total energy consumed in buildings today. This however may lead to reduced ventilation rates and increased levels of air pollution from buildings, people and their activities, and thus to poorer indoor air quality, which contradicts the requirements of the EU Directive. The obvious solution for these apparently opposing requirements would be to reduce the pollution sources indoors.

Several studies have previously investigated the effects of pollution emitted by building materials on the indoor air quality and related these effects to ventilation requirements [2]. However, there is a lack of systematic experiments, in which building materials are first ranked according to their pollution strength, e.g. by using methods applied in labelling schemes [3], and then the effect on the indoor air quality of using these materials in real rooms is examined. Such studies would make it possible to quantify to what extent using low-polluting building materials would reduce the energy used for ventilation of buildings without compromising indoor air quality. The main objective of an ongoing research project is to quantify this energy saving potential based on the effects on the perceived air quality. The specific objective of the experiments described in this paper is to systematically study, how the selection of low-polluting building materials affects the perceived air quality and to compare this effect with the effects of increased outdoor air supply rate on the perceived air quality.

METHODS

A sensory panel assessed the air quality in full-scale test rooms ventilated with three different outdoor air supply rates and polluted by typical building materials including wall, floor and ceiling materials; the materials ranged from high- to low-polluting. The relationships between the perceived air quality and ventilation rate were examined for different combinations of materials to assess the impact of using low-polluting materials and/or increasing ventilation rate on the perceived air quality.

The assessments took place in three similar test rooms with a floor area of 18 m^2 and a volume of 57.6 m^3, each constituting an independent unit. The test rooms are served by a HVAC system supplying outdoor air to each room through a duct system and ceiling diffusers; the air is exhausted through wall-mounted grills. There is no recirculation. Outdoor air is supplied to the test rooms by an air handling unit with a fan and is conditioned by an electric pre-heater; no filter is installed. The temperature of the supplied air is independently controlled for each test room by electric heaters mounted upstream of the ceiling diffusers. The rate at which outdoor air is supplied to the rooms is controlled by IRIS dampers with motorized shut-off dampers independently for each test room. The air is exhausted directly outdoors by duct fans. The rate at which the air is exhausted is determined by a pre-defined overpressure in the test rooms (relative to adjacent spaces) which is controlled by motorized dampers. The test rooms were fully refurbished a few months prior to the experiments: the ceiling and flooring materials were changed, walls were painted and sliding doors of laminated wood were installed, so that one larger space could be turned into three separate test rooms. The HVAC system was completed in the week prior to the experiments.

A special cabinet is mounted in each test room. In this cabinet pollution sources can be hidden, so that the exposure conditions are not revealed. Room air enters the cabinet through a slot close to the floor and is pulled through the cabinet by an axial fan mounted at the top, where the air is exhausted to the room air. The cabinet also contains ultrasonic humidifiers that are mounted on the rails above the space for the pollution sources, immediately upstream of the axial fan; the humidifiers are used to control relative humidity in the test rooms. The air circulation through cabinets ensures that the air in tests rooms is well mixed. The cabinets were completed in the week prior to the experiments.

Nine different building materials were used (Table 1 and Figure 1). They were selected using the results of preliminary experiments in which 20 building materials were screened individually in small-scale glass chambers, following the principles of the Nordtest methods [4,5]. The 20 materials were selected based on a review of studies reporting the relationships between ventilation rate and the perceived quality of air polluted by building materials [2]. The aim was to select wall, floor and ceiling materials that can be ranked in a range from high- to low-polluting. The nine materials were tested individually in small-scale glass chambers, CLIMPAQs [4], following the procedures used in preliminary tests outlined above. For that purpose eight glass chambers were placed in a 26.8 m^3 stainless steel chamber [6] ventilated with an outdoor air change rate of 57 h^{-1}, and the sensory panel assessed the air quality in the glass chambers. The temperature in the chamber was kept constant at 22±0.1°C; the relative humidity was not controlled and averaged 31±6%. Each material was tested at 3 different area-specific ventilation rates, i.e. the ratio between outdoor air supply rate to the area of material. Different area-specific ventilation rates were obtained by changing the surface area of materials and keeping the ventilation rate through glass chamber constant at 0.9 L/s. The area of materials tested in glass chambers were selected according to the principles of the Nordtest methods [4,5] - the area-specific ventilation rates in glass chambers were kept the same as in the test rooms ventilated with 1, 3 and 9 h^{-1} for floor and ceiling materials and 1.3, 4 and 12 h^{-1} for wall materials (Table 1); the higher air change rates for wall materials were due to limitations on the material loading that could be placed in a glass chamber. The sensory panel also assessed the air quality in empty glass chambers.

Nine different combinations of the selected 9 materials were tested in full-scale test rooms (Figures 2 and 3). In order to resemble typical indoor setting, each combination consisted of a ceiling, floor and wall material, and included both high- and low-polluting materials. The amount of materials set up in the test rooms corresponded to the actual area of ceiling, walls and floor in the test room (Table 1). A sensory panel assessed the air quality in the test rooms polluted by the combinations of materials and ventilated with three different outdoor air supply rates corresponding to the outdoor air change rate of 1.3±0.1, 2.8±0.1 and 6.4±0.2 h^{-1}. The sensory panel also assessed the air quality in empty test rooms, i.e. without materials set up in test rooms. During all assessments, the temperature in test rooms was kept constant at 22.2±0.3^{o}C; the relative humidity was not controlled and averaged 36±5%.

Table 1. Building materials used in the full-scale and small-scale experiments

Material		Area of material (m^2)			
Acronym	Description	Full-scale test room	Small-scale glass chamber, CLIMPAQ		
Ceiling 2	10 mm plain gypsum board covered with plastic coated material	18	0.113	0.338	1.013
Wood	14 mm beech wood parquets, untreated	18	0.126	0.372	1.106
Carpet 1	6.4 mm tufted loop polyamide carpet with supporting layer of polypropylene web and polypropylene backing				
Linoleum 2	2.5 mm linseed-oil-based flooring, 52 % wood meal	18	0.113	0.338	1.013
PVC	2.0 mm homogenous single layered vinyl flooring, reinforced with polyurethane				
Polyolefine	2.0 mm homogenous polyolefine-based resilient flooring, reinforced with polyurethane				
Gypsum board	13 mm plain gypsum board lined with cardboard				
Paint 1	Gypsum board painted with one coat (0.14 l/m^2) of water-based acrylic wall paint	52	0.243	0.730	2.187
Paint 2	Gypsum board painted with one coat (0.14 l/m^2) of water-based wall paint with linseed oil				

The materials were purchased about two months prior to the start of sensory assessments. The specimens of materials to be used in test rooms and glass chambers were prepared (cut and/or painted) 4-6 weeks prior to the beginning of experiments; the specimens were stored in a ventilated hall. During sensory assessments, the specimens of materials used in test rooms were hung on trolleys, which were placed in the cabinets, while the specimens of materials were placed in the glass chambers using a special supporting system; the backside of materials was not exposed. The materials were set up in test rooms and glass chambers about 21 hours prior to the sensory assessments. The sensory panel could not see the materials hidden in the cabinets in tests rooms or the materials in glass chambers, which were covered with aluminium screens.

The sensory panel of 38 subjects was recruited from among 50 applicants. The subjects were students at the Technical University of Denmark, aged on average 24 years; 42 % were females and 21 % were smokers. Ten subjects had previously participated in similar experiments, where sensory assessments of air quality were made. These person-related data were collected via a questionnaire filled in by applicants upon recruitment. Subjects received written and oral instructions concerning sensory assessments. The first day of experiments was a practice session, but this was not communicated to the subjects; the assessments collected during this day were discarded. The subjects assessed air quality, using continuous acceptability scale [7] printed on paper. To test whether the sensory assessments were drifting/stable, on each day of experiments the subjects assessed the air quality in two glass chambers, where the loading of Carpet 1 and Ceiling 2 was the highest (Table 1) and kept unchanged during the whole course of the experiment. No drift was observed.

Sensory measurements were made on 15 days in three consecutive weeks during November/December 2006, each day both in full-scale test rooms and small-scale glass chambers. Exposures were randomly assigned to subjects in a design balanced for order of presentation. Each substitution with low-polluting material was always tested at three different ventilation rates in the same room to minimize the impact of the possible differences in air quality between empty test rooms. The three different area-specific ventilation rates of the same material established in glass chambers were always tested on the same day of the experiment. The assessments in tests rooms were made immediately upon reaching a marked spot on the floor, about 2 m from the door. This procedure was used to standardise the position in the middle of the room and the approximate time spend in the test room prior to assessment of the air quality. The doors to the test rooms were closed during assessments. The subjects entered tests rooms one at a time. The assessments in glass chambers were made upon taking one inhalation of polluted air exhausted from the chamber through a diffuser. A break of at least two minutes was made between assessments in glass chambers and test rooms. The break was taken in a well-ventilated hall adjacent to test rooms and the stainless steel chamber with the glass chambers.

The ratings made on paper questionnaires were digitized; 10 % of the ratings were digitized twice for quality control. The acceptability scale was coded as follows: Clearly not acceptable = -1; Just not acceptable/Just acceptable = 0; Clearly acceptable = 1. Using individual ratings made by the subjects means were calculated separately for each condition assessed in the tests rooms and in the glass chambers. The mean votes of acceptability were plotted against the logarithm of air change rate (for the ratings performed in test rooms) or the logarithm of area-specific ventilation rate (for the ratings performed in glass chambers) [8]. This was done to examine the relationship between the perceived air quality and ventilation rates [2,9,10], which was then used to assess the effect of changing ventilation on perceived air quality and compare it with the effect of using low-polluting materials.

RESULTS

Figure 1 shows the mean assessments of acceptability of air quality in glass-chambers at different area-specific ventilation rates when the building materials were placed individually in glass chambers. The results show that the selection of the materials used in the combinations examined in the test rooms turned out well, because both high- and low-polluting materials were included. These materials can be ranked in the following order, starting with the highest-polluting material: Paint 2, Wood, Carpet 1, Linoleum 2, Paint 1, Gypsum board, Ceiling 2, PVC and Polyolefine. The least polluting was the empty glass chamber, for which the acceptability of air quality was assessed to be the highest.

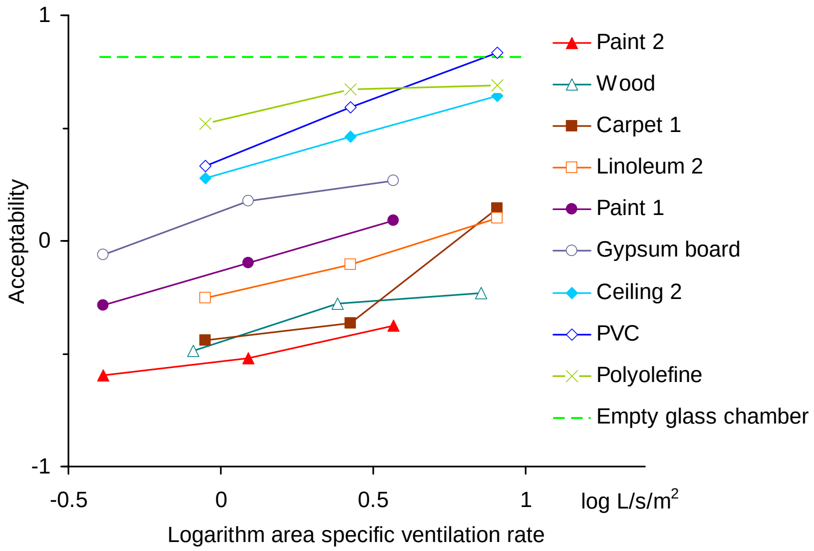

Figure 1. Acceptability of air quality as a function of the area-specific ventilation rate in small glass chambers containing the individual building materials that were examined in combinations in test rooms.

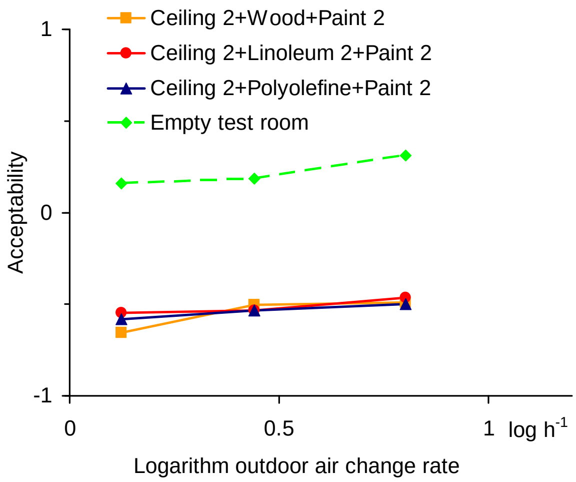
Figures 2 and 3 show the mean assessments of acceptability of air quality in test rooms at three different outdoor air change rates when the test rooms were empty and in the test rooms with different combinations of building materials including both high- and lower-polluting wall and floor materials, ranked by means of sensory assessments made in small-scale glass chambers; ceiling material was unchanged and always the same in all combinations examined in test rooms. The acceptability of air quality in empty test rooms was lower than in empty glass chambers, probably because the test rooms had undergone a renovation only a few month prior to the experiments and primary emissions were still affecting the perceived air quality.



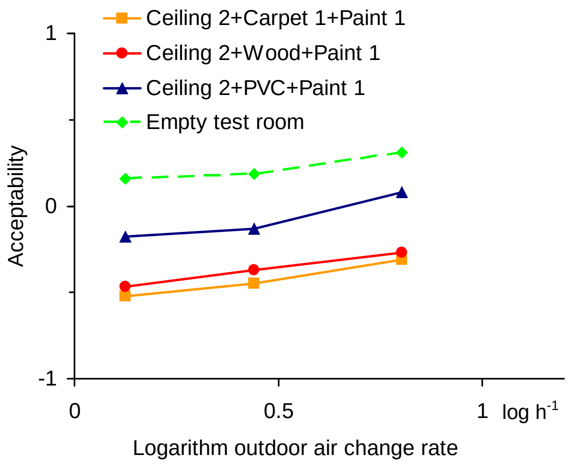


Figure 2. The effect of substituting high-polluting floor materials with lower-polluting materials on the acceptability of air quality in the tests rooms ventilated with different outdoor air change rates, when the combinations of materials included high-polluting (left) or lower-polluting (right) wall materials; ceiling material was unchanged.

Figure 2 left shows that substituting high polluting Wood with lower-polluting Linoleum 2 or Polyolefine did not improve the assessments of acceptability of air quality when combinations of materials included high-polluting Paint 2. When on the other hand the combinations included lower-polluting Paint 1 (Figure 2 right), substituting high-polluting Carpet 1 or Wood with lower-polluting PVC improved the assessments of acceptability of air quality.

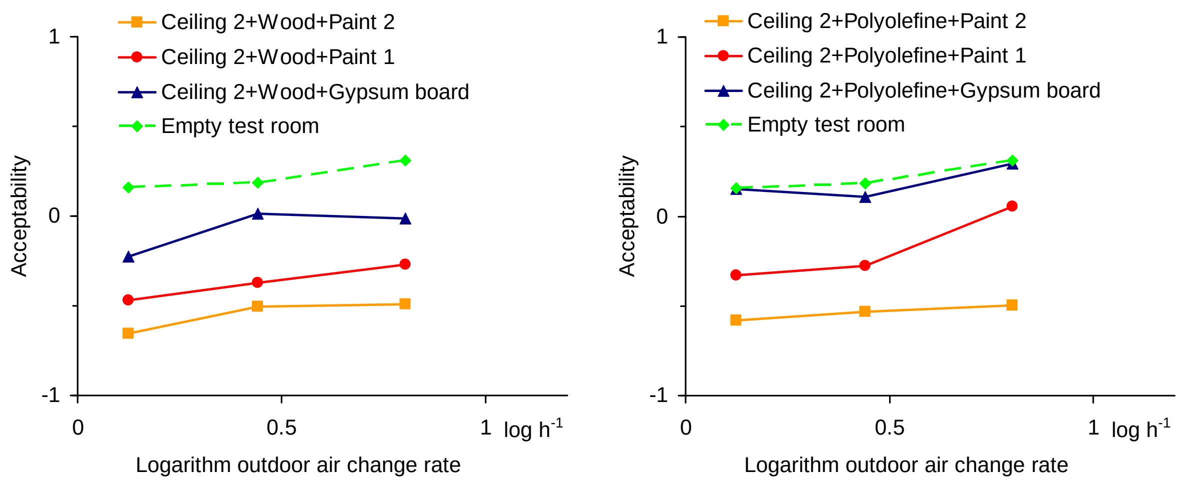

Figure 3. The effect of substituting high-polluting wall materials with lower-polluting materials on the acceptability of air quality in the tests rooms ventilated with different outdoor air change rates, when the combinations of materials included high-polluting (left) or lower-polluting (right) floor material; ceiling material was unchanged.

Figure 3 shows that the assessments of acceptability of air quality improved when the high polluting Paint 2 was substituted with lower-polluting Paint 1 or unpainted Gypsum board, independent of whether the combinations of materials included high-polluting Wood (left) or lower-polluting Polyolefine (right). However, the improvement seems to be somewhat greater in the latter case (Figure 3, right).

Figures 2 and 3 also show that increasing the ventilation rate improved the assessments of acceptability of air quality in the test rooms with different combinations of building materials. This effect was, however, small for the combinations of materials including high-polluting Paint 2.

DISCUSSION

The study shows that reducing pollution sources by selecting lower-polluting building materials, ranked by means of sensory assessments made in small-scale glass chambers, improves the perceived air quality in full-scale rooms where these materials are used. The improvement is greater than what was achieved by increasing the outdoor air supply rate in a realistic range. For example, a sevenfold increase of the outdoor air supply rate improved acceptability of quality of air polluted by a combination of materials including Ceiling 2, Polyolefine and Paint 1 less than substituting Paint 1 in this combination with lower-polluting Gypsum board (Figure 3, left). Such results can be provided for nearly all substitutions with lower-polluting building materials examined. The only exception was the substitution of high-polluting floor material with lower-polluting materials when the room air was still polluted by the high-polluting wall paint, Paint 2 (Figure 2, left). In this case the perceived air quality did not improve, probably because the strongest pollution source, in this case Paint 2, determines the perceived air quality in a room polluted by different materials. This phenomenon has also been observed for mixtures of odorous compounds [11] and is further illustrated in Figure 4, which combines the results of sensory assessments of air quality in test rooms and small-scale glass chambers in one chart. Combining both data was possible because the area of materials tested individually in glass chambers was calculated using the area-specific ventilation rates estimated using the actual dimensions and outdoor air change rates in the test rooms. Figure 4 shows that the assessments of acceptability of air quality in rooms polluted by different combinations of building materials were similar to the assessments for the material that was the strongest pollution source in the combination according to the ranking made by means of sensory assessments made in small-scale glass chambers: Paint 2 in the combination including Ceiling 2, Wood and Paint 2, and Wood in the combination including Ceiling 2, Wood and Paint 1. The exception was the combination of Ceiling 2, Wood and Gypsum board. In this case the air quality was assessed to be more acceptable than the assessments of air quality polluted individually by Wood, the strongest pollution source in this combination, suggesting an air cleaning effect, probably due to adsorption on Gypsum board which is known to be a strong sink [12]. A similar air cleaning effect is also observed in Figure 3, right, where the acceptability of quality of air polluted by Ceiling 2, Polyolefine and Gypsum board is similar to the acceptability of air in the empty test room. The results show that the decision, which materials to substitute with low-polluting alternatives, should be based on ranking of materials depending on their pollution strength; the highest polluting materials should be substituted first. Such ranking can be made, e.g. using sensory assessments of air quality in small-scale glass chambers, which as shown in the present experiments, is suitable for estimating the relative effects on perceived air quality in real rooms.

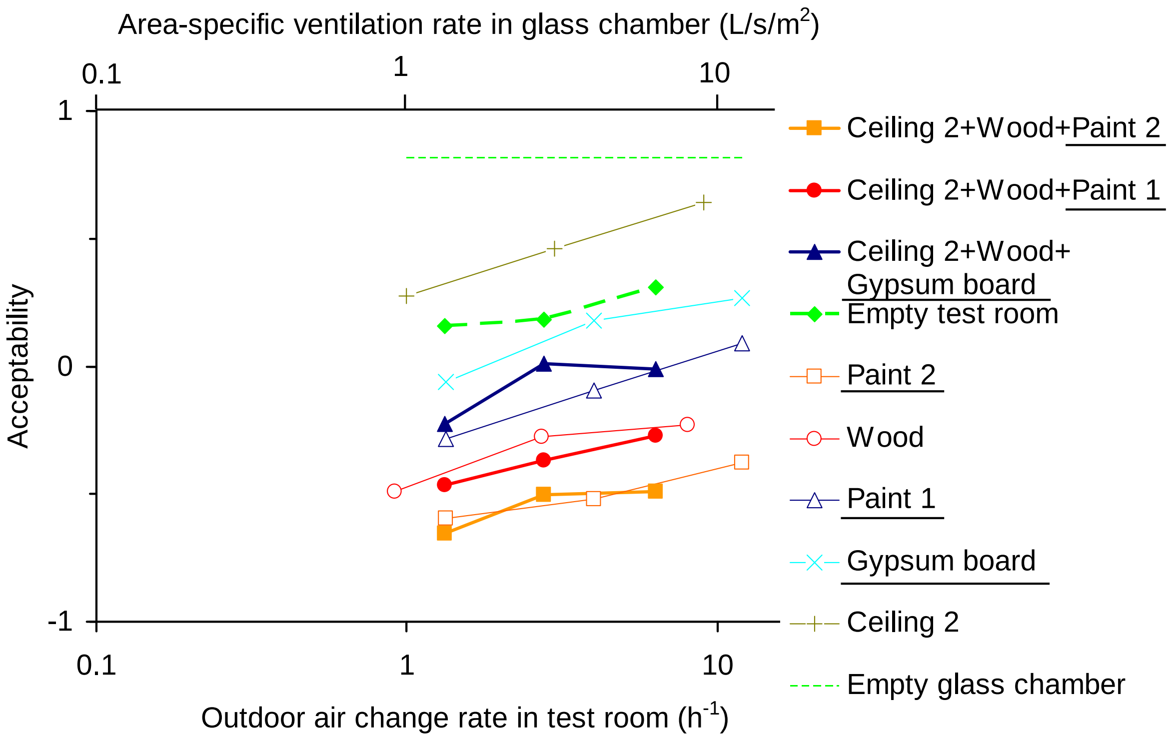

Figure 4. Assessments of acceptability of air quality as a function of the outdoor air change rate for the combinations of materials examined in the test rooms (thick lines) or the area-specific ventilation rate for individual materials tested in glass chambers (thin lines). The materials that were substituted are underlined. Note, the logarithmic scale on the abscissa.

The effect of using low-polluting building materials and increasing outdoor air supply rates on the perceived air quality were studied by examining the relationships between acceptability of air quality and ventilation rate, Figures 1-4. Such an approach has also been shown to be very useful in previous studies [2,9,10] when these effects have been quantified. These relationships can be used to assess to what extent a reduction in ventilation requirements in buildings will contribute to comply with the EU Directive 2002/91/EU [1] that requires reduction of energy use without negative consequences for the indoor environmental quality. They can also be used for specifying the requirements for emissions from building materials, e.g. by labelling schemes for building materials or ventilation standards.

The effects on perceived air quality were examined in rooms polluted only by building materials. Indoor air is however normally polluted also by human bioeffluents. The relationship between perceived air quality and ventilation rate for human bioeffluents was established in the 1980's [13]. However, the assessments were made by a sensory panel on a dichotomous (yes/no) acceptability scale that can not be directly compared with the relationships for building materials examined in this study. Future studies should investigate how the presence of bioeffluents in rooms with otherwise low-polluting building materials will influence the perceived air quality, and consequently ventilation requirements and energy use.

CONCLUSIONS

Substituting building materials with materials shown in small-scale chamber tests to be lower-polluting improved the perceived air quality in full-scale test rooms. The improvement of the perceived air quality was greater than the improvement obtained by increasing the outdoor air supply rate within a range that was realistic for indoor settings.

- The perceived air quality in a room polluted by building materials was improved when the highest-polluting material was substituted with a lower-polluting material.
- The greatest improvement of the perceived air quality is obtained when all high-polluting materials are substituted with low-polluting materials.

SUMMARY

In many climate zones, low energy buildings will not be able to utilize natural ventilation at all times. Hence, low-energy mechanical comfort systems will still be required. For green buildings there are design objectives well above minimum standards for comfort and indoor air quality (IAQ) that are meant to improve occupant productivity. The latter can make meeting low-energy requirements even more challenging. To meet these sometimes-conflicting requirements, the principles of concurrent engineering may be applied to support design charettes. Candidate solutions should include: (1) reducing the amount of outside air while producing an equivalent clean air delivery rate (CADR) using purification technologies, and/or (2) using an energy recovery ventilator (ERV) on the remaining outside air coupled with a smart economizer operating strategy. Simulation results are presented that support these strategies by addressing the cost of conditioning ventilation air and dependence of contaminant levels on the amount of ventilation.

INTRODUCTION

In climates that are not appropriate for complete reliance on natural ventilation, buildings are equipped with mechanical conditioning systems. Traditional systems, that are used when the outdoor air is not within the comfort range, can be energy intensive; however, they usually provide reasonable comfort and adequate indoor air quality. Most such systems use prescriptive minimum ventilation rates specified by the ASHRAE Standard 62.1 Ventilation Rate Procedure [1]. However, conditioning this outside air may account for up to 30% of the total HVAC energy consumed. Proposed standards for new green buildings and green building rating systems such as LEED-NC [2] give credits for ventilation rates well above the minimum standard, exacerbating the energy usage associated with conditioning ventilation air. The interrelationship between reducing exposure to indoor contaminants and the associated cost is not always clearly understood. Clearer procedures for evaluation of tradeoffs as well as better strategies for simultaneously meeting IAQ and energy requirements are needed. Since urban areas sometimes have poorer outdoor air quality, the local conditions must be explicitly considered. The following specific strategies were considered in this study.

1. Use an air-to-air heat exchanger operating between the outside air inlet and building exhaust air streams to recover sensible heat and moisture from ventilation air. This device acts as a preconditioner that permits downsizing of the associated mechanical conditioning equipment peak capacity. It saves energy and reduces utility demand charges as well. This device is called a heat recovery ventilator (HRV) if it recovers

only sensible heat and an ERV if it recovers both sensible and latent heat. This strategy can be used with all the strategies that follow.

2. Use duct-mounted air purification devices to remove particles and volatile organic compounds (VOCs) from the supply air stream, removing contaminants from both the outside air and the recirculated air. Use the ASHRAE Standard 62.1 IAQ Procedure [1] (Alternate Ventilation Rate Procedure) to produce the air quality at least as good as that which would be obtained with either the prescriptive minimum ventilation standard or the augmented ventilation rate recommended for green buildings. CADR from the purifier substitutes for clean outside air.
3. Use duct-mounted air purification devices to remove particles and VOCs from the recirculated air stream alone, assuming excellent outdoor air quality.
4. Use standalone air cleaning equipment to remove contaminants in zones with sources.

METHODS

To help create designs that will meet multiple objectives during the building design process UTRC has been developing a method called Integrated Building Energy and Control Systems (IBECS) [3]. This project seeks to apply the techniques of concurrent engineering to the design process. It works best in a “charette” environment in which all the principal stakeholders are present during design sessions. To permit the design team to investigate as wide a possible set of solutions, a computing infrastructure has been created that is operated by domain specialists. Following this process, the combined design team is able to evaluate a design space that is richer than that which ordinarily would have been investigated with the same amount of resources. Key elements of the IBECS process are:

1. A tool such as the Building Investment Decision Support (BIDS™) [4] framework is used to enrich the list of design options that the team may consider for good indoor environmental quality (IEQ). The potential payoff of considering each option is evaluated to be sure that economically-justifiable solutions are considered.
2. Energy, lighting, airflow, and other simulations are performed early and often during the sessions, so the sensitivities become known. For computationally-intensive situations, pre-work can be done to generate approximate correlations that can be evaluated quickly in a concurrent session.
3. As design changes are made, a common repository of data is used to drive all the different types of simulations, reducing the possibility of inconsistency. A version control and checkpointing system permits the results for each variant to be archived.
4. Key to the process is having a set of at least semi-quantitative metrics for each IEQ category of performance. For energy, the amount of energy and peak demand is used. Cost and/or primary carbon are sometimes used as an alternative.

In general, the value of a configuration may be represented by an objective function to be minimized such as:

$$U = fF + eE + cC + qQ + vV. \qquad (1)$$

Each metric is defined so that a smaller value is better. Lifecycle values are integrated over the remaining lifetime of the building. F represents equipment first and lifecycle operation/maintenance costs, E represents energy use and/or carbon production, C represents discomfort (based on T, RH, and air movement), Q represents air quality as contaminant levels, and V represents ventilation ineffectiveness. The leading f, e, c, q, and v coefficients are used to normalize the individual attributes of performance and express their relative importance to the owner. If demand charges are important, utility charges can be substituted for energy. C is evaluated over the likely occupant positions of a comfort function such as in ASHRAE Standard 55 [5]. Some aspects of a useful air quality metric are still a matter of research, but the integrated mean age of air at the occupant positions would be one choice. Another would be to use a numerical score based on contaminant hazard and irritancy levels. For VOCs, Hollick and Sangiovanni [6] developed a preliminary IAQ index that is scaled to have a value of 1.0 or less for acceptable indoor air. From the contaminant threshold or limit value a contaminant tolerance index is defined as the ratio between the concentration of contaminant, C_i, found in an observed IAQ situation, relative to the allowable limit, $C_{i,max}$, according to the simple expression $T_i = C_i/C_{i,max}$. For a mixture of contaminants, the total tolerance index is given by $\Sigma\, T_i = \Sigma\, (C_i/C_{i,max})$. A total tolerance index greater than 1.0 would represent a case where further ventilation or air purification is warranted. Research is underway to augment this for particulates.

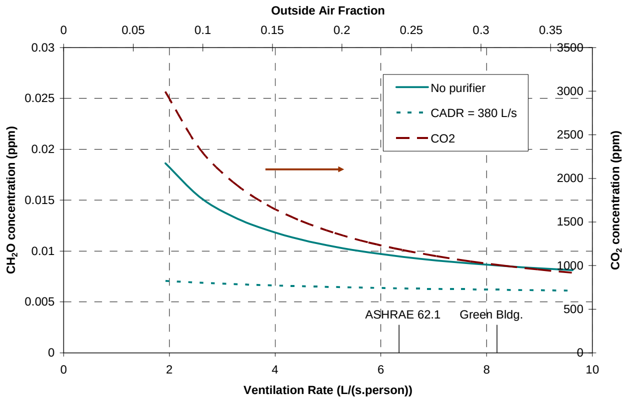
To begin to add increased IAQ functionality to the IBECS process, a spreadsheet model was built that includes as part of its functionality the differential equations displayed in ASHRAE Standard 62.1-2004. Routine IBECS energy simulation was also performed.

To understand the effect of ventilation and purifier efficiency on contaminants concentration, an analysis of the effect of ventilation on the CO_2 and contaminant concentrations in different types of buildings was carried out. At the same time, the effect of a purifier on the quality of the air was studied. It was assumed that the purifier is based on a catalyst, so that the efficiency does not change with time, as long as the catalyst maintains its activity. In the case of reactive solids or adsorbents, it is well known that the efficiency will vary with time. An adsorbent can show 100% efficiency when it is fresh or a certain value lower than 100% according to its actual design specifications. As the adsorbent becomes saturated, and the adsorption front moves towards the exit of the purifier, the efficiency decreases as breakthrough occurs. In the case of a reactive solid, it may show high initial reactivity towards oxidizing air contaminants, but according to the resulting reduction product, a layer can be formed which will introduce an additional resistance that will slow down the access of the contaminants to the reactive surface, and the rate of reaction will decrease.

The calculations were carried out for a 1000 m^2 office and a 334 m^2 school building. The occupancy density was 5 and 36 persons per 100 m^2, respectively. The CO_2 generation rate was assumed to be 18 L/(person·h). Formaldehyde, toxic and ubiquitous in buildings, was chosen as a typical contaminant generated by surfaces. The production rate was varied between 40 and 70.4 $\mu g/(m^2 \cdot h)$ [7,8]. The outdoor concentrations were 400 ppm for carbon dioxide and between 0 and 55 ppb for formaldehyde [9]. ACGIH set the TLV (ceiling limit) at 0.3 ppm. We use 0.1×TLV as an acceptable value for a gaseous contaminant, so in this case the acceptable limit is 30 ppb [6]. A catalyst-based purifier, when considered, was assumed to be in the recirculating air. The supply air rate needed for thermal comfort was 4720 L/s for the office and 3165 L/s for the school.

RESULTS

The variations of formaldehyde (CH_2O) and CO_2 concentrations as a function of the ventilation rate for the two types of buildings are shown in Fig. 1.



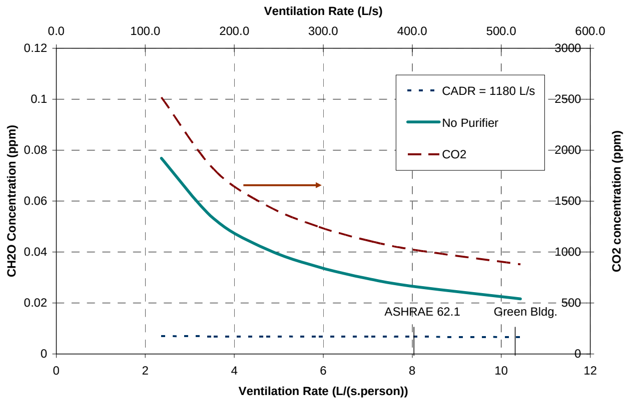


Figure 1. Effect of ventilation rate on contaminant concentrations at a CH_2O generation rate of 40 µg/(m^2·h) and a CO_2 production rate of 18 L/person with outdoor concentrations of 5.5 ppb for CH_2O, and 400 ppm for CO_2. a) 334 m^2 School, b) 1,000 m^2 Office.

It can be seen that, when the data is presented as a function of the ventilation rate per person, the CO_2 curve is coincident for both cases. The steady-state value is only a function of the outdoor concentration value and the per-person generation- and ventilation- rates. However, when we consider the actual ventilation rates, we can see that these are much higher in the school building. The recommended ASHRAE 62.1 values were used for both cases, namely, 2.5 L/(s·person) and 0.3 L/(s·m^2) for the office, and 5 L/(s·person) and 0.6 L/(s·m^2) for the school (classroom age 9 plus). When the overall ventilation rates recommended by ASHRAE Standard 62.1 in terms of people and area are recalculated in per person terms, the respective values are 8.0 and 6.4 L/(s·person). The 30%-higher operating value for Green Buildings [2] is indicated in Fig. 1.

The variation of the CO_2 and CH_2O concentrations with the ventilation rate, at a constant Clean Air Delivery Rate (CADR), are also shown in Figs. 1. It can be seen that to maintain the CO_2 level below 1000 ppm the overall ventilation rate required is 8.1 L/(s·person), independent of the type of building. To maintain the CO_2 level below 2000 ppm, the ventilation rate can be as low as 3.2 L/(s·person).

The effect of the formaldehyde generation rate for the school is shown in Figure 2.

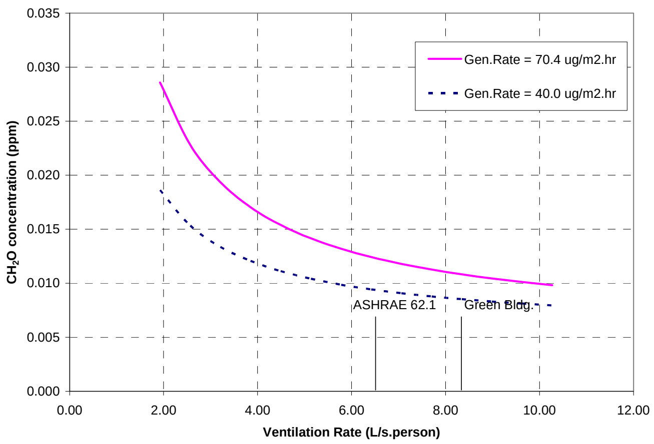

Figure 2. Effect of CH_2O generation rate on contaminant concentrations with no purifier on a 334 m^2 school with an outdoor concentration of 5.5 ppb for CH_2O.

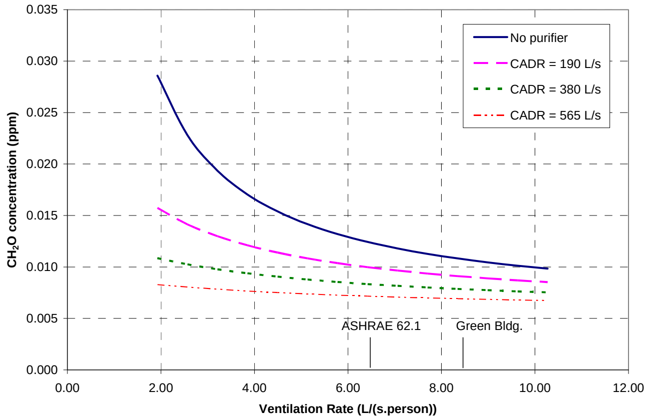
At high ventilation rates, as the generation increases from 40 to 70.4 µg/(m^2·h), the contaminant concentration increases by about 20%, but at low ventilation rates the increase is much higher. At 2.0 L/(s·person), the increase is about 50% and the Tolerance Index is close to one. It is obvious that to achieve an acceptable level of formaldehyde, a purification system needs to be implemented.

The effect of different levels of purification on the contaminants concentration is shown in Fig. 3. In both types of building, the increase in the purification level has a significant effect on the formaldehyde steady state concentration. Considering equivalent levels of purification (same CADR:supply air ratio), the effect is more noticeable in the case of an office. This is due to the relatively lower ventilation rates that are recommended for these types of buildings.

To simulate the design size of the HVAC equipment required to handle the building loads as well as condition outside air, an industry-standard manufacturer-developed HVAC design code was used. This code can consider and size unitary equipment with options for either an economizer or an ERV. Figure 4a shows for the school how the size and first cost of the equipment depends on the amount of outside air used during heating and cooling seasons. Figure 4b shows the annual energy usage dependence. For simplicity, energy was selected for reporting since it is related to global warming and avoids assumptions regarding local utility rates and demand charges involved in discussions of operating cost. The buildings have typical thermal characteristics and usage schedules, but many detailed assumptions are involved in such simulations.

DISCUSSION

The variation of formaldehyde concentration with ventilation rate shows a different relationship for the office and school, since the generation rate is proportional to the space area, while the ventilation is a function of both area and occupancy. When no purification system is used, and the ventilation rate is cut in half, the formaldehyde level increases between 40 and 80% (Fig. 1). The lowest increase is observed for schools where ventilation rates are significantly higher than in offices. On the other hand, when a purification system is added to the return flow, the increase in CH_2O concentration as the ventilation rate decreases is much lower. Moreover for a CADR of about 25% of the supply air rate the sensitivity of the CH_2O concentration to the ventilation rate is quite low. In the case of the office, the relative amount of CH_2O entering the space with the fresh air is much lower than the generation rate, and the steady state concentration is approximately given by C_{ss} = Source Rate/(CADR + OA). On the other hand, for the school building, the ventilation rate is quite high and the amount of contaminant generated in the building is relatively small. Therefore, the steady sate concentration is close to the value in the outdoor air.



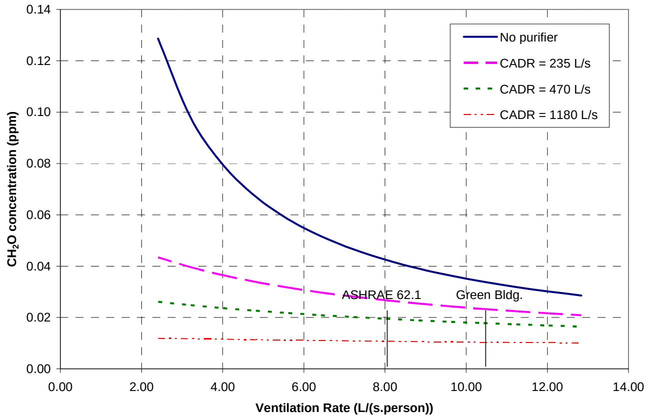


Figure 3. Effect of purifier efficiency on contaminant concentration at a CH_2O generation rate of 70.4 μg/(m^2·h) and an outdoor concentration of 5.5 ppb CH_2O. a) 334 m^2 School; b) 1000 m^2 Office.

Budaiwi and Al-Homoud [10] studied the effect of ventilation on the concentration of air contaminants and concluded that although a ventilation rate of 7.5 L/s·person was sufficient to keep the CO_2 concentration below the recommended level, it was not enough to reduce the formaldehyde concentration below the allowed level of 120 μg/m^3 [11]. It should be taken into account that these authors assumed a formaldehyde generation rate of 150 μg/s. For the space considered here, it corresponds to a value of 675 μg/(m^2·h), which is much higher than the typical values found in buildings and used in the current analysis. The actual lower limit for ventilation when using the IAQ Procedure may be set by (1) a local regulation on CO_2 concentrations, (2) calculated contaminant levels that create a Tolerance index greater than one, or (3) determining that the air quality with purification is equivalent to that which would have been obtained using standard minimum or enhanced prescriptive ventilation rates.

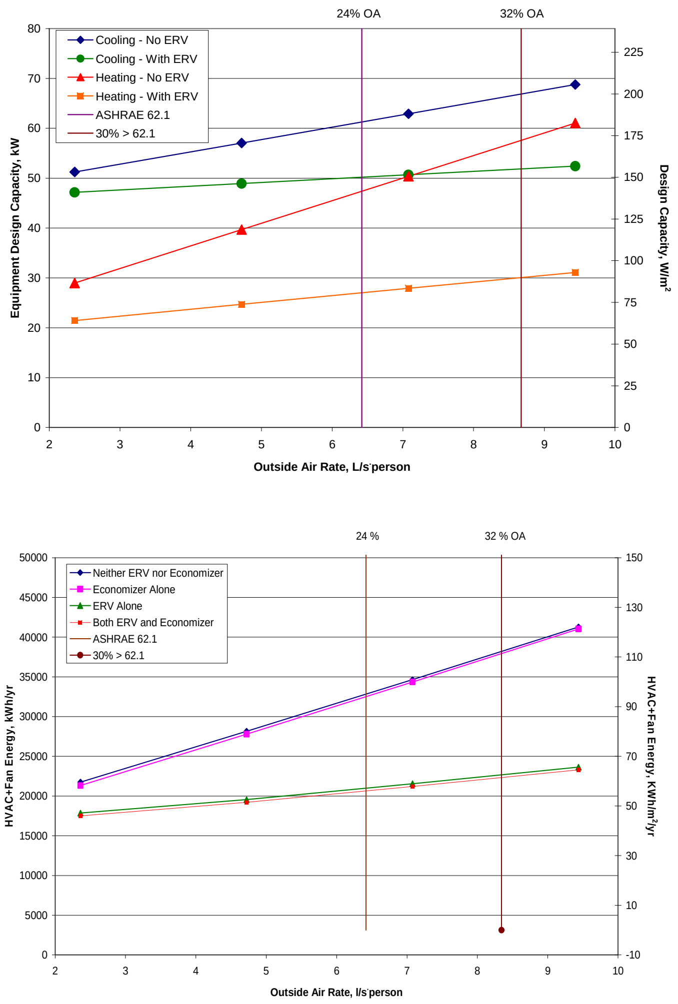

Figure 4. New York school HVAC characteristics as a function of outdoor air flow rate. a) Heating and cooling equipment design capacities with and without and ERV, b) annual energy consumption with and without economizer and ERV options.

Studies of the effect of ventilation quantity on cost and air quality for additional building types and locations are planned. Some systematic studies of the ERV configurations have been done in the past [12]. The result shown in Fig. 4 should be considered as an example of the relevant trends. Clearly there is much variability based on the many factors. A method similar to the one used herein should result in a good understanding of the tradeoff of energy and exposure. It is clear from this case that equipment first cost increases with the outside air fraction used; introducing an ERV can result in a substantial downsizing of the heating and cooling plant.

For the case of using an ERV with the large outside air rate used with green buildings, the plant capacity is still smaller than for the case of using no ERV with an outside air rate just meeting the Standard 62.1 minimum ventilation rates. Also, the size of the equipment is significantly reduced if the IAQ procedure is used with a local air purifier. Downsizing of such equipment can help defray the first cost of either ERVs or air purifiers.

Fig. 4b shows that in this particular case of a high-ventilation flow and a school operating schedule, the effect of the economizer is minimal. Elaborate strategies such as night cooling were not considered. Use of the ERV makes a considerable difference, especially in the heating season when the difference between the indoor and outdoor temperatures is larger. Even at the high ventilation rates proposed for green buildings, the annual energy cost is lower with the ERV than it is for the minimum standard value and no ERV. Hence, the ERV makes bringing in the additional air affordable. If one chooses to operate according to the IAQ procedure, there are also substantial energy benefits during the lifecycle of the equipment. The end result is to provide the designer with the methodology and tools to permit wider consideration and adoption of these configurations.

Experimental Study of Thermal Environment and Comfort in an Office Room with a Variable Air Volume (VAV) System under Low Supply Air Temperature Conditions

Mari-Liis Maripuu

Chalmers University of Technology, Building Services Engineering, Gothenburg, Sweden

Corresponding email: mari-liis.maripuu@chalmers.se

SUMMARY

The air distribution components in a variable air volume (VAV) flow system influences the overall function of the system. A low supply air temperature and a wide working range in terms of airflow rate, facilitate high energy efficiency. However, in order to achieve these properties, high demands must be set on the function of the supply-air diffusers.

This paper analyzes the thermal environment and comfort in an office room where the supply air diffusers have been chosen in accordance with such high demands. The study involves determining thermal comfort properties under different flow conditions and with a low supply air temperature, about +15^{o}C, in a full scale test room. It also includes measured velocity profiles and calculated draught ratings. The results indicate that the risk of draught was quite low despite high airflow rates and a low supply air temperature with the studied type of a supply-air device.

INTRODUCTION

The selection of air distribution components in the design of a variable air volume (VAV) flow rate system has a crucial importance for the overall function of the system. Varying airflow conditions need to be managed in a way that the requirements for the indoor climate parameters are always fulfilled. Here the airflow control devices and supply air outlets are critical components that need to be selected carefully, since improper selection of these devices is a common cause of excessive noise and draught in occupied spaces [1,2].

The main demand for the supply air diffuser in a VAV system application is to have high induction properties with varying airflow rates. It is essential that the diffuser supplies cold air to the occupied space evenly under any airflow condition without causing uncomfortable drafts by air “dumping” or by excessive room air motion. This requirement means that the air should be introduced to the room at a sufficient velocity to ensure good mixing with the room air.

If the discharge area of the diffuser remains constant, the velocity of the supply air stream falls in direct proportion to the reduced airflow rate. Due to the naturally denser cold air a “dumping”, defined as a dropping of a horizontal supply air jet into the occupied zone, can occur and result in a sensation of draught. Thus, using conventional fixed supply air outlets in a variable air volume flow application needs to be carefully considered. The fixed devices are commonly used when VAV boxes are installed for the room airflow control. As a result the supply air temperatures and minimum airflow rates must be kept relatively high in order to avoid problems with thermal comfort. Moreover, over-cooling the premises can occur at low internal heat loads and high minimum airflow rates if the supply air temperature is kept constant.

Relatively constant supply air velocity irrespective of the airflow rate is maintained with a diffuser with a variable discharge area, commonly referred to as a VAV diffuser. This is a device, which changes its outlet configuration automatically when controlling the supplied airflow rate to the room. In commonly installed devices the airflow rate is determined by the diffuser's opening (between 0 to 100%) and the constant static pressure at the inlet side. Therefore, a stable pressure should be maintained upstream of the diffuser. This demand is achieved by keeping constant pressure in the branch ducts by active control dampers, which can make the system more complicated and costly. This can especially be the case when adopting VAV systems in existing buildings, where extensive refurbishment is not always possible and the active control dampers are not easy to install in the duct system.

This study aims to look for uncomplicated VAV system configurations that can assure a good indoor climate, while at the same time minimize the energy use of the system. A possibility of building up a VAV system with VAV diffusers for airflow control and without active control dampers in the duct system have been considered. For applying this kind of a technical solution it is essential for the VAV diffusers to be able to absorb the pressure unbalance in the system during varying airflow rates, while maintaining good airflow control properties without causing problems for the indoor climate, such as excessive noise. Moreover, from an energy use point of view it is beneficial for the VAV diffusers to be able to control the airflow within a wide range and manage low supply air temperatures without any risk for the thermal comfort in the room. With lower supply air temperatures the cooling capacity of the supply air will be improved and better control of the room temperature can be achieved. Low supply air temperatures are also advantage in systems that work with 100% of outside air and where a possibility for free-cooling can be applied.

This paper analyzes the thermal environment and comfort in an office room where the supply air diffusers have been chosen in accordance with the demands discussed above. The paper accounts for laboratory tests, which aimed to study how the requirements from the thermal comfort point of view are met under different supply airflow conditions and with low supply air temperature. The results indicate that is possible to fulfill the demands that must be set on the VAV diffusers in order to apply them in a wide airflow range and at low temperature conditions.

Although the tests have been carried out with a specific diffuser, the results are general in the sense that they show that the high demands on supply air diffusers can result in products which fulfil them.

METHODS

The function properties of the selected VAV supply air diffuser were tested in a simulated indoor environment: in a full size cellular office cube built inside the laboratory hall. The test room was constructed with plaster boards on a wooden framework. The internal dimensions of the test room were 3,9(L) x 2,8(W) x 2,7(H) m. To imitate a common office environment the room was filled with usual office equipment: a table, a chair, a computer and lighting. The internal heat loads were simulated with a PC-model (150 W), a dummy (80 W) and lighting (total 220 W). The artificial lighting consisted of two luminaries with two fluorescent tubes each (85 W per luminaire), plus a desk lamp (50 W).

The test set-up included a supply air fan with frequency inverter and with a pressure control (controlled pressure level was approx. 50 Pa.), a sound attenuator, a supply air heater with an air temperature control, an airflow meter, a VAV diffuser and temperature sensors for monitoring temperatures in the duct as well as inside and outside the test room. All sensors were connected via a logger to a personal computer for monitoring purpose.

The technical properties of the tested VAV diffuser enable to measure the incoming supply airflow rate and adjust the discharge area respectively. Therefore strict pressure control at the inlet of the device is not needed. The discharge area of the diffuser varies according to the needed airflow rate and is internally controlled by a traversing motor, which gets impulses from the controlling sensor. The control and regulating equipment as well as the sensors are built into the supply air device and the simultaneous values can be read with the computer.

Two different VAV diffuser mounting arrangements were tested: one with the diffuser free from the ceiling and one with the diffuser in the suspended ceiling. Without suspended ceiling the height from the ceiling to the discharge area of the device was 30 cm and from the device to the floor 2,4 m. With suspended ceiling the latter height was increased to 2,7 m. For the exhaust air a transfer air device was installed on the wall close to the ceiling.

Thermal comfort measurements were carried out with constant supply air temperature +15°C, but with different airflow rates under steady-state conditions. For all the tests the operative temperature in the occupied zone and temperature outside the office cube was kept 22 ± 1°C, which corresponds to the winter conditions and *A* level comfort class [3].

The heat loads in the test room were adapted to the airflow in order to obtain the correct room temperature. Table 1 presents the conducted test cases with different combined heat loads and cooling capacities. There is a small difference between the heat load and cooling power values in the table. This gap is due to the heat transmission through the envelope of the test room.

Table 1. The test cases completed in thermal comfort measurements

Case	Mounting condition	Airflow rate, l/s	Supply air temperature, °C	Cooling capacity, W	Balancing heat load, W
1	no suspended ceiling	10	15	85	122
2	no suspended ceiling	25	15	210	250
3	no suspended ceiling	50	15	420	450
4	suspended ceiling	10	15	85	122
5	suspended ceiling	25	15	210	250
6	suspended ceiling	50	15	420	450

Air temperature and air velocities were measured in a number of room points as shown in Figure 1. At each position the measurements were taken at 3 heights - 0,1 m, 0,6 m, 1,1 m, which is based on the position of a sitting person. All together the results were obtained from 27 room points.

The sampling period for each measurement was 3 minutes. Every measurement case described in table 1 was done in three replicates and the results are presented as an average over these three measurements. The risk of draught in the test room was evaluated by using draught rating (*DR*) model and the calculations for every measured point were done according to ISO 7730 [4]. Draught rating expresses the percentage of people predicted to be dissatisfied by draught.

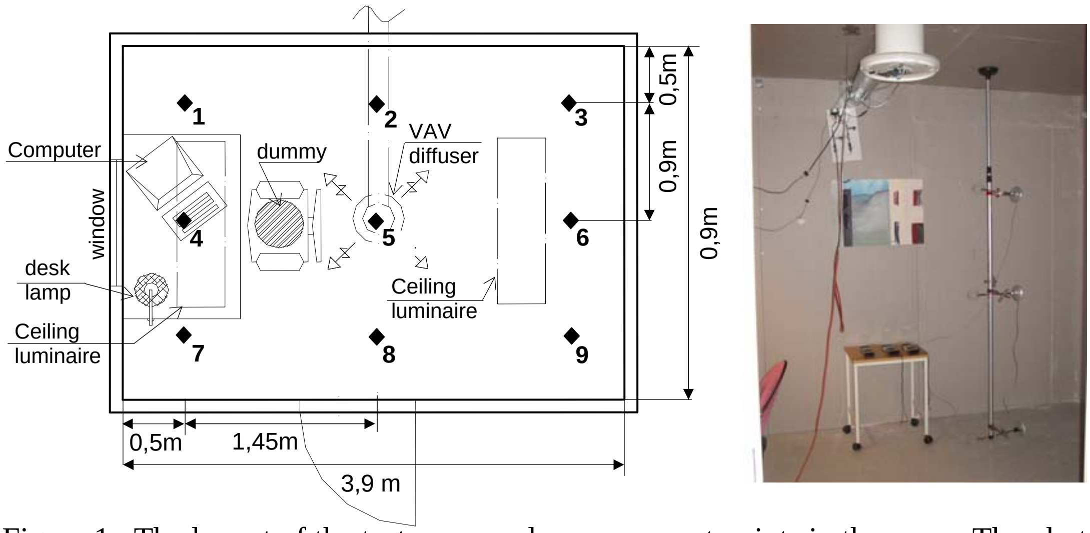

Figure 1. The layout of the test room and measurement points in the room. The photo presents the measurement set up.

Additionally, the measurement results were statistically analyzed with an analysis of variance (ANOVA) test, in order to see if the measured values of air velocities in the occupied space depend on different parameters that were varied during the experiment. The statistical significance of an effect of different parameters such as the room point, the level of a measured point, the ceiling and the airflow rate was studied. The main and combined effects of the described variables were first found by analyzing all the airflow rates together and then by each airflow case separately. The chosen confidence level in the analysis accounted here is 95% (p = 0,05).

RESULTS

The mean air speed and draught rating distributions at different supply airflow rates in two mounting cases, with and without suspended ceiling, are presented in Figures 2 and 3. The figures show the percentage of the measured points being in the specified range of air velocity and draught rating values. For example, it can be seen from the figures that the average air velocity in majority of measured points was less than 0,15 m/s with maximum airflow conditions 50 l/s and less than 0,10 m/s at lower airflow rates. According to thermal comfort guidelines, the air velocity in the occupied space should not exceed 0,15 m/s [3] and the draught rating should be below 15% [4]. These limits were exceeded only in few measured points in the room and that occurred mainly at maximum airflow rates (see Fig. 2 and 3).

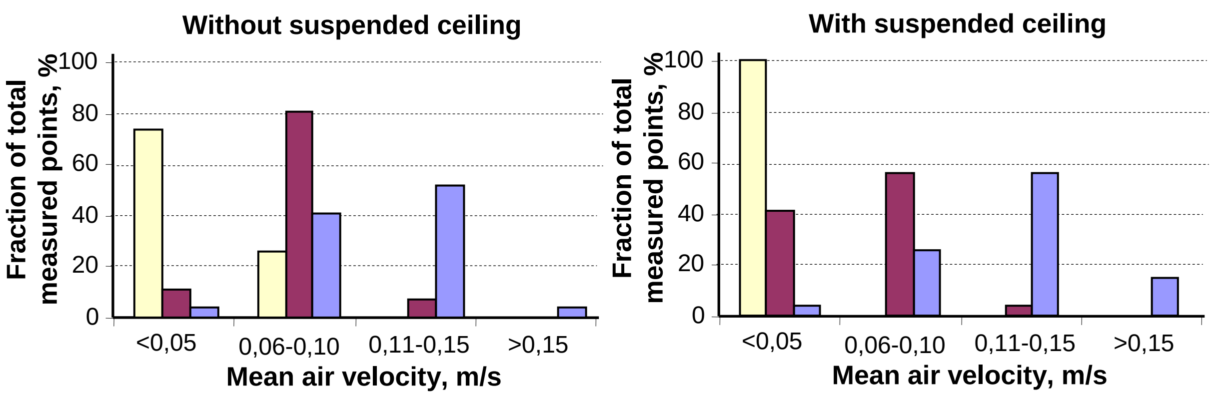

Figure 2. Air speed distributions in the test room with different supply airflow rates and with different mounting cases. The supply air temperature was +15°C.

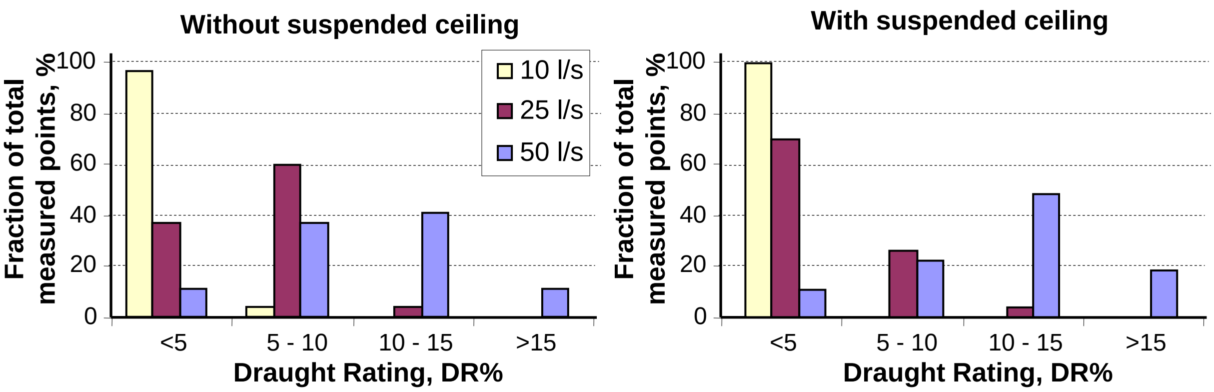

Figure 3. Draught rating distributions in the test room with different supply airflow rates and mounting cases. The supply air temperature was +15°C.

In addition, there seem to be no substantial differences between the results with and without suspended ceiling mounting cases. However, some diversity can be seen at average airflow conditions (25 l/s), where the mean air velocities and draught ratings were somewhat lower with the suspended ceiling. The results from statistical analysis of variance test, summarized in Table 2, also indicate that the ceiling has an effect at average and minimum airflow conditions, but no effect at maximum airflow condition in the specified confidence level (p=0,05). The table shows if an effect of each parameter that varied during the experiment is a statistically significant or not. The probability values of calculated F value compared to the value given for the *F-distribution* in the *F-table* are also presented for the variables which have an effect. The table accounts for the main effects only, meaning that if the parameter alone and not in interaction with other parameters influences the room air speed. The interaction effects of different parameters were also tested, but no higher order effects were revealed from the results.

Nevertheless, even though different parameters such as the room point, the room level and the ceiling revealed to affect mean air velocities in the occupied space, there seem to be no regularities between the main effects. With maximum airflow rate 50 l/s the room point and the room level showed a significant influence, yet in the minimum airflow rate 10 l/s the effect revealed to be only from the room level and the ceiling. However, it was preliminary assumed that the airflow has an effect and as it can be seen from the Table 2, the probability that the variability of the mean air velocity values with different airflow rates can be attributed to experimental error is very low.

Table 2. Statistically significant effects of different variables on the mean air velocity in the occupied space. The chosen confidence level is 95% (p = 0,05)

Main effect	**Combined all airflows**	**10 l/s**	**25 l/s**	**50 l/s**
Room point	NO	NO	YES $P(F>5,05) = 0,025$	YES $P(F>4,79) = 0,030$
Room level	YES $P(F>15,29)=0,0001$	YES $P(F>60,47)=9,005 \cdot 10^{-13}$	NO	YES $Pr(F>6,45)=0,012$
Ceiling	YES $P(F>15,29)=0,0026$	YES $P(F>63,05)=3,52 \cdot 10^{-13}$	YES $P(F>17,65)=4,42 \cdot 10^{-5}$	NO $P(F>3,80)=0,053$
Airflow rate	YES $P(F>577,85) = 2,2 \cdot 10^{-16}$	-	-	-

In general, it should be noted that the results of an ANOVA test do not show the size of a single effect, e.g. if the room level has a higher effect compared to the ceiling. Moreover, the direction of the variation is not known, e.g. in which case the highest results appear. The test shows statistically if different parameters affect the results or if the variation is mainly due to experimental error.

Figures 4 and 5 illustrate the velocity profiles evaluated from the results from the measurement cases 3 and 6 (see Table 1). These were the cases where the required draught rating and air velocity values were exceeded in some room points. The critical points given in the figure, where the air velocities were exceeding 0,15 m/s are also the points where the draught rating was exceeding 15 %.

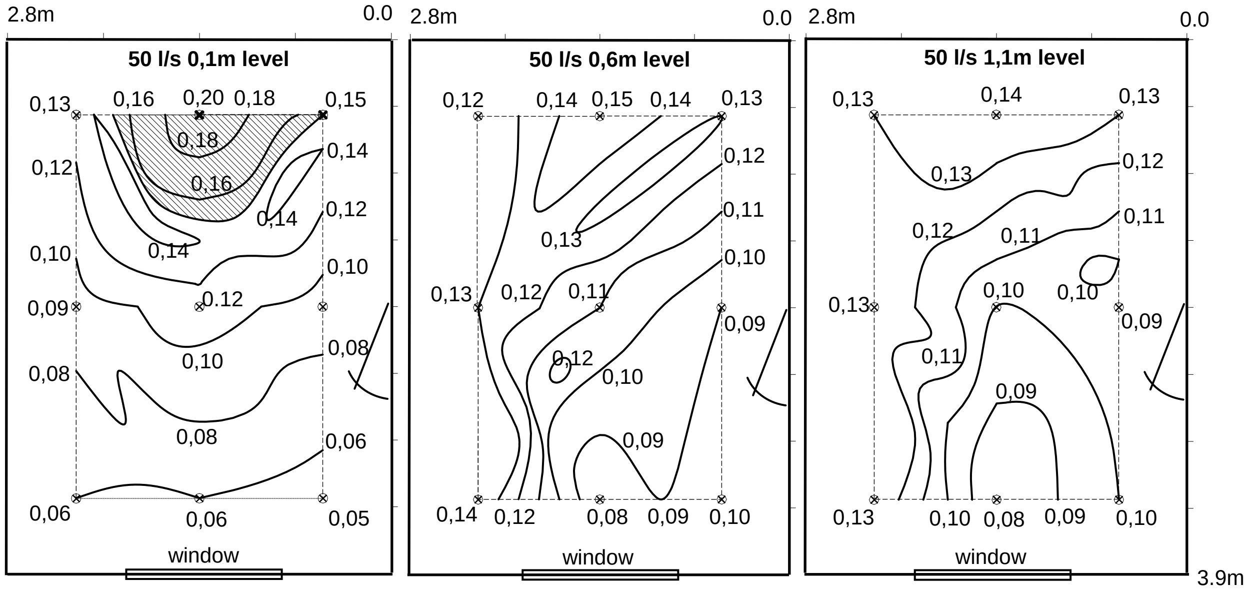

Figure 4. Iso-velocity profiles in measurement case 3. Crossed dots mark the measuring points.

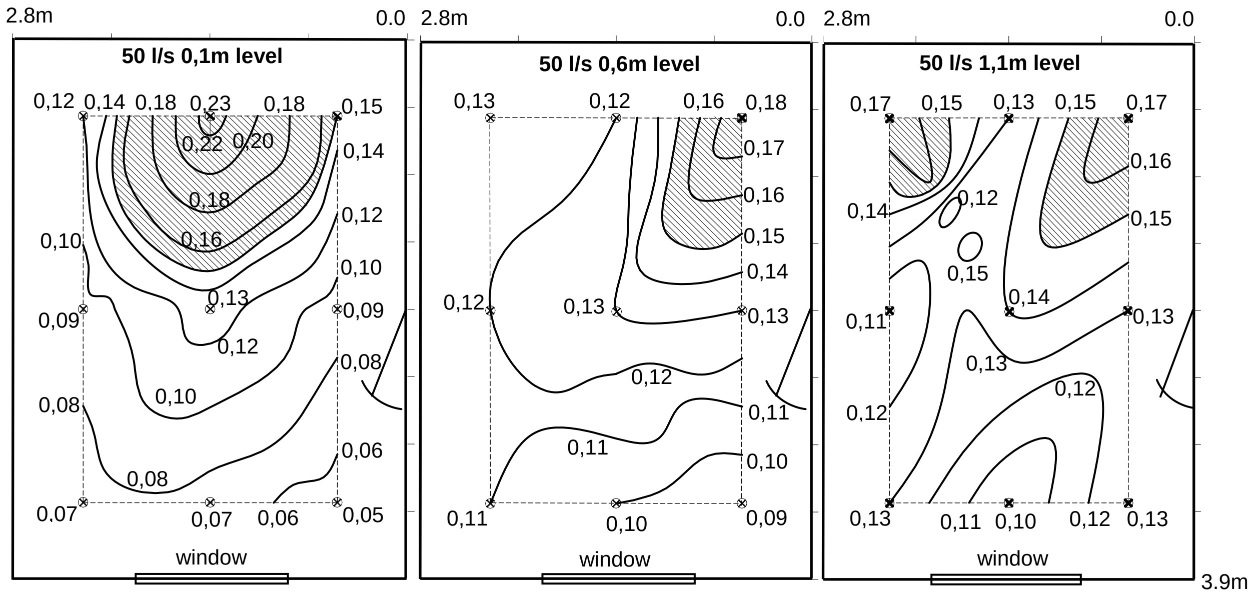

Figure 5. Iso-velocity profiles in measurement case 6. Crossed dots mark the measuring points.

As shown in Fig.4 and Fig.5, all of the critical room points were locating on one side of the room (measuring points 3, 6, 9). This was the empty side of the test room. Moreover, the most critical point, room point nr 6, was locating on the level of 0,1 m above the floor. The upper levels of the same measuring point did not have any higher velocities.

Since the turbulence of airflow has an important influence to the perception of draught in the occupied space [5], the fluctuation of the air velocities in the test room has been further analysed. Figure 6 presents the standard deviation as a function of the mean air velocity with all different airflow conditions at three measurement levels for no suspended ceiling installing case. The results from the suspended ceiling mounting case were similar. It can be seen that the fluctuation of the air velocity was increasing when the average air velocity in measured points increased. In addition, a small decrease in the gradient of the regression lines, as the measuring level decreased from 1,1 m to 0,1 m, shows that the velocity fluctuations were more significant at the ankle level. Similar data has also been found in previous studies about airflow characteristics [6].

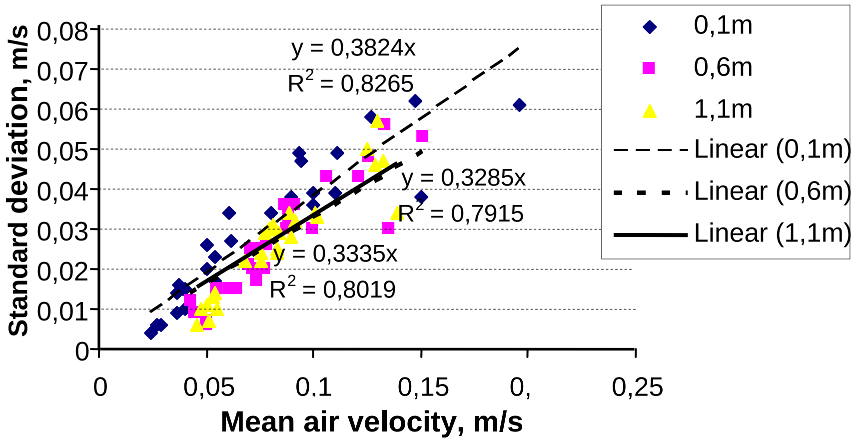

Figure 6. Standard deviation of air velocity with three different airflow rates and at different levels in the test room. The diagram corresponds to no suspended ceiling mounting case.

DISCUSSION

Thermal comfort guidelines address minimal draft levels by placing limits on the allowable mean air velocity as a function of air temperature and turbulence of airflow. The measurements in the test room revealed that the air movements and the draught levels at medium airflow (25 l/s) and minimum airflow (10 l/s) conditions did not exceed the required levels stated by comfort standards and regulations [3,4]. Even at the lowest airflow rate, no risk of “air-dumping” was indicated. Marginal draught risk was registered in a few measuring points at maximum airflow conditions 50 l/s. In addition, the results showed no substantial differences between the two diffuser mounting cases depending on the ceiling. However, the ceiling had an effect at lower airflow conditions (see Fig.1 and Fig. 2).

The statistical analysis test revealed that the measurement point and the measurement level have a statistically significant effect to the results at maximum airflow conditions. As was illustrated in Fig.4 and Fig.5, all critical points were situated on the empty side of the test room, opposite the workplace. No draught risk was observed in the normal working zone. One possible explanation for this could be the specific distribution of heat sources in the room. In general, all of the heat sources in the room have an influence to the air motion in the room by giving rise to buoyancy induced velocity scale which can match the velocities generated by a jet in the occupied zone [7]. The only influencing heat source on the empty side of the test room was the ceiling luminaire, while the other heat sources where distributed to the other side of the room. Nevertheless, since the air motion in the room is complex, it is hard to make any definite conclusions for the causes of the draught risk in these specified room points and further studies should be conducted in order to identify the reason.

A direct relation between air velocity and turbulence intensity was indicated from the measurement results. Moreover, the points with higher turbulence intensities were situated close to the floor, measured at ankle level. Coincidentally, this was also the level where the most critical points were located (see Fig. 4 and Fig.5). However in the present case, higher air turbulence on the ankle level may partly have been caused by the floor temperature, which was some degrees lower than the room temperature.

This laboratory experiment was part of a study which aimed to look for uncomplicated VAV system configurations that can assure good indoor climate, while at the same time minimize the energy use of the system. A possibility of building up a VAV system with VAV diffusers, which can manage pressure variations (at least 100 Pa) in the system and work with a wide airflow range and at low supply air temperatures, has been considered. However, in order to achieve these properties, high demands must be set on the function of the supply-air diffuser. One type of a device that seemed to have the technical properties to fulfil the demands was tested in a full scale test room with the aim to study the thermal environment and comfort under different supply airflow conditions and with low supply air temperature. The results indicate that it is possible to fulfil the demands that must set on the VAV diffuser in order to apply it in the specified conditions.

The VAV system configuration with this type of a VAV diffuser has also been tested in buildings in operation, focusing on indoor climate and the need of energy. The results yielded that this technical configuration provides an adequately functioning system that ensures good indoor climate and work energy efficiently [8].

ACKNOWLEDGEMENT

This work described has been carried out as a part of a pilot project CAVA (From Constant Air Volume to Variable Air Volume), which has been conducted under the EUFORI program funded by Swedish Energy Agency (*Statens Energimyndighet*).

SUMMARY

Since 2005, the Leiden University Medical Center started the building of the new department of children Intensive Care (IC). Several types of geometry have been planned in the department, In order to minimize the cost and get the most applicable result, an IC room with two beds in serial has been chosen for the detailed aerodynamic study. The CFD model of the IC room with two beds in serial is studied. The CFD model will split the whole room as many small mesh elements to fulfil the conservations of mass, momentum and energy. The IC room has a high internal heat load from the devices (approx. 60W/m^2) and the hospital owner has a strong expectation on the indoor comfort of the air speed and temperature. Therefore, several difference ventilation concepts have been modeled and the best choice has been made for the final design.

INTRODUCTION

Intensive Care (IC) Medicine is a branch of medicine concerned with the provision of life support or organ support systems in patients who are critically ill who usually also require intensive monitoring.

Patients requiring intensive care usually require support for hemodynamic instability, airway or respiratory compromise (such as ventilator support), acute renal failure, potentially lethal cardiac dysrhythmias, and frequently the cumulative affects of multiple organ system failure. Patients admitted to the intensive care unit not requiring support for the above are usually admitted for intensive/invasive monitoring, such as the crucial hours after major surgery when deemed too unstable to transfer to a less intensively monitored unit.

Medical studies suggest a relation between intensive care unit (ICU) volume and quality of care for mechanically ventilated patients. [1] After adjustment for severity of illness, demographic variables, and characteristics of the ICUs, higher ICU volume was significantly associated with lower ICU and hospital mortality rates. For example, adjusted ICU mortality (for a patient at average predicted risk for ICU death) was 21.2% in hospitals with 87 to 150 mechanically ventilated patients annually, and 14.5% in hospitals with 401 to 617 mechanically ventilated patients annually. Hospitals with intermediate numbers of patients had outcomes between these extremes.

It is generally the most expensive, high technology and resource intensive area of medical care.

Since 2005, the Leiden University Medical Centrum started the building of the new department of Children Intensive Care. The new department will have 40 IC rooms and the gross floor area is about 3250 m^2.

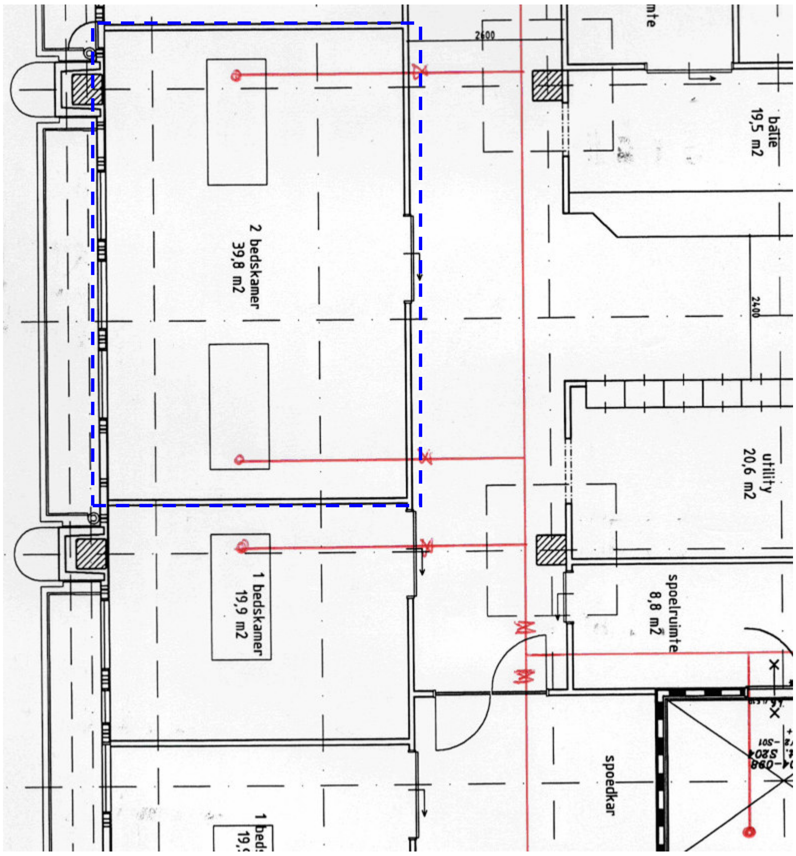

Figure 1. Floor plan of one part of IC department

Figure 1 shows an example floor plan of the IC department. Several types of geometry have been planned in the department, for example, one bed room; two bed room; two beds in parallel in one room or two beds in serial in one room, etc.

In order to minimize the cost and get the most general result, an IC room with two beds in serial has been chosen for the detailed aerodynamic study which is indicated with a blue dot line in Figure 1.

APPROACH

In order to study and evaluate the performance of the new concept, Computer Fluid Dynamics (CFD) analysis has been carried out.

Computational Fluid Dynamics (CFD) has grown with the progress of computer technology and numerical analysis [2]. It comes from a mathematical curiosity to become an essential tool in almost every branch of fluid dynamics, from aerospace propulsion to indoor climate analysis. CFD is commonly accepted as referring to the broad topic encompassing the numerical solution, by computational methods, of the governing equations which describe fluid flow, the set of the Navier-Stokes equations, continuity and any additional conservation equations, for example energy or species concentrations.

As a developing science, Computational Fluid Dynamics has received extensive attention throughout the international community since the advent of the digital computer. The attraction of the subject is twofold. Firstly, the desire to be able to model physical fluid phenomena that cannot be easily simulated or measured with a physical experiment, for example fire and smoke development. Secondly, the desire to be able to investigate physical fluid systems more cost effectively and more rapidly than with experimental procedures.

There has been considerable growth in the development and application of Computational Fluid Dynamics to all aspects of fluid dynamics. In design and development, CFD programs are now considered to be standard numerical tools, widely utilised within industry [3].

The CFD model of the IC room with two beds in serial is shown in Figure 2. The size of the room is 7.875x5.055x2.7m (LxBxH).

The CFD model will split the whole room as many small mesh elements to fulfil the conservations of mass, momentum and energy. For this IC room, the amount of mesh elements is ca. 500,000 (Figure 3).

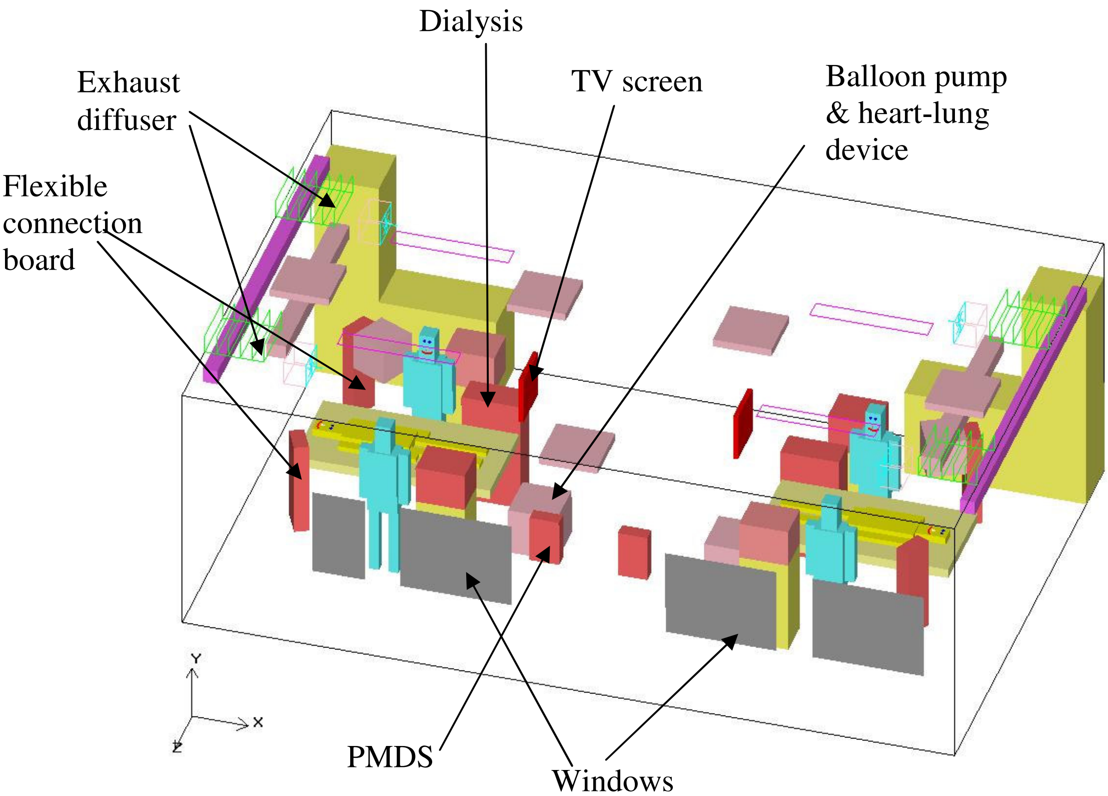

Figure 2. CFD model of the IC room with two beds in serial

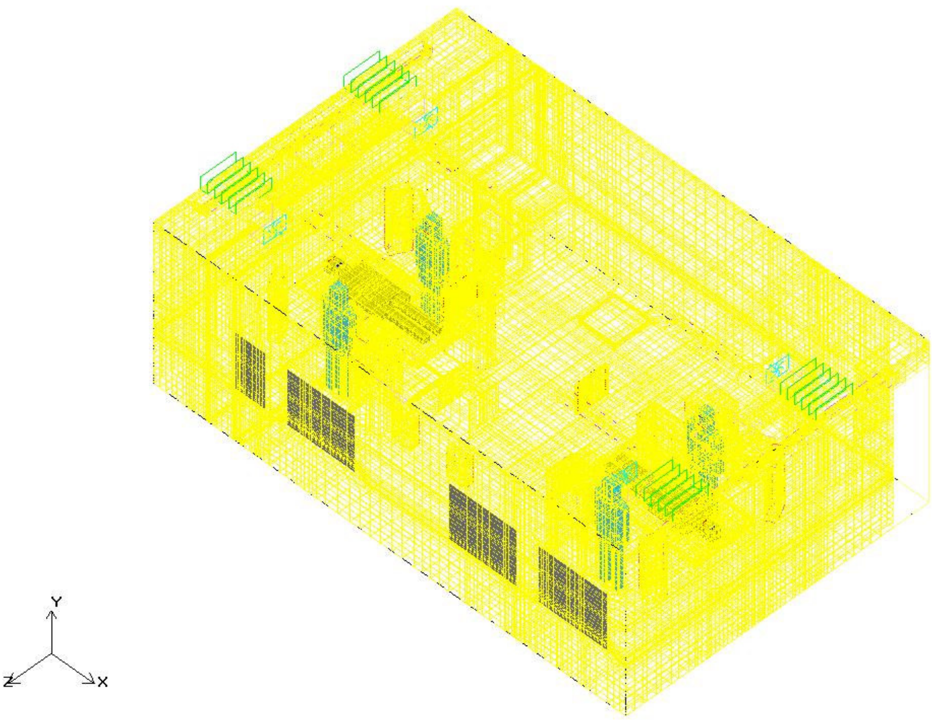

Figure 3. Mesh element of the CFD model of the IC room

SIMULATION CONDITIONS & REQUIREMENTS

The simulation condition is based on the GTR (General Technical Requirement, M/E) [4] of LUMC. Several conditions related to CFD simulation are:

- The IC room is 7.875x5.055x2.7m (LxBxH). This is 39.8m^2 and 1007.48m^3;
- Climate ceiling will be applied; condensation must be avoid
- In order to avoid condensation problem on the surface of climate ceiling, the surface temperature is set as 18^{o}C;
- Air speed keeps lower than 0.12m/s in the patient zone;
- Air temperature approximately 22^{o}C when Tout<=26^{o}C;
- Internal heat load approximately 112W/m^2 for thorax situation.

BASIC CASE STUDIES

In this research, four concepts of ventilation supply are analyzed:

a) air supply diffusers from the side walls of the middle block (Figure 4a)
b) downflow air supply diffusers from middle ceiling (laminar flow) (Figure 4b)
c) downflow air supply diffusers from ceiling of sides of bed (laminar flow) (Figure 4c)
d) ceiling diffusers (one side supply) (Figure 4d)

Models of four concepts

Air speed comparison of four concepts

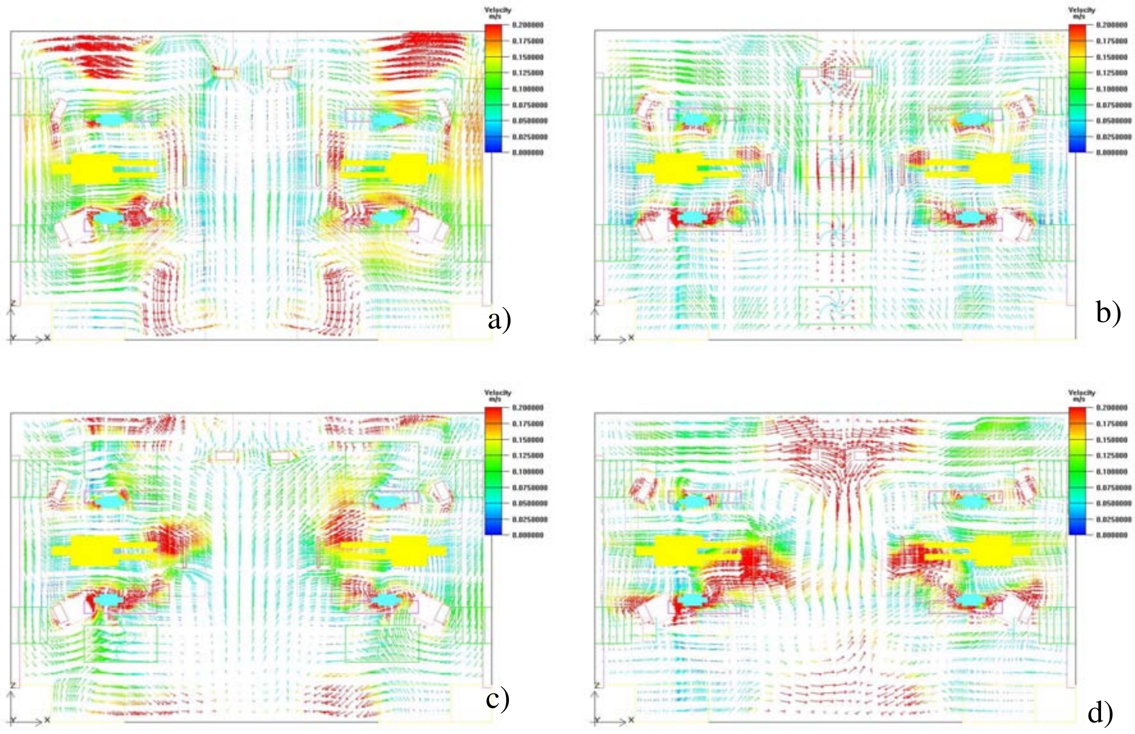

Figure 6. Air speed distribution with air supply diffusers from case a) to case d)

Air stream comparison of four concepts

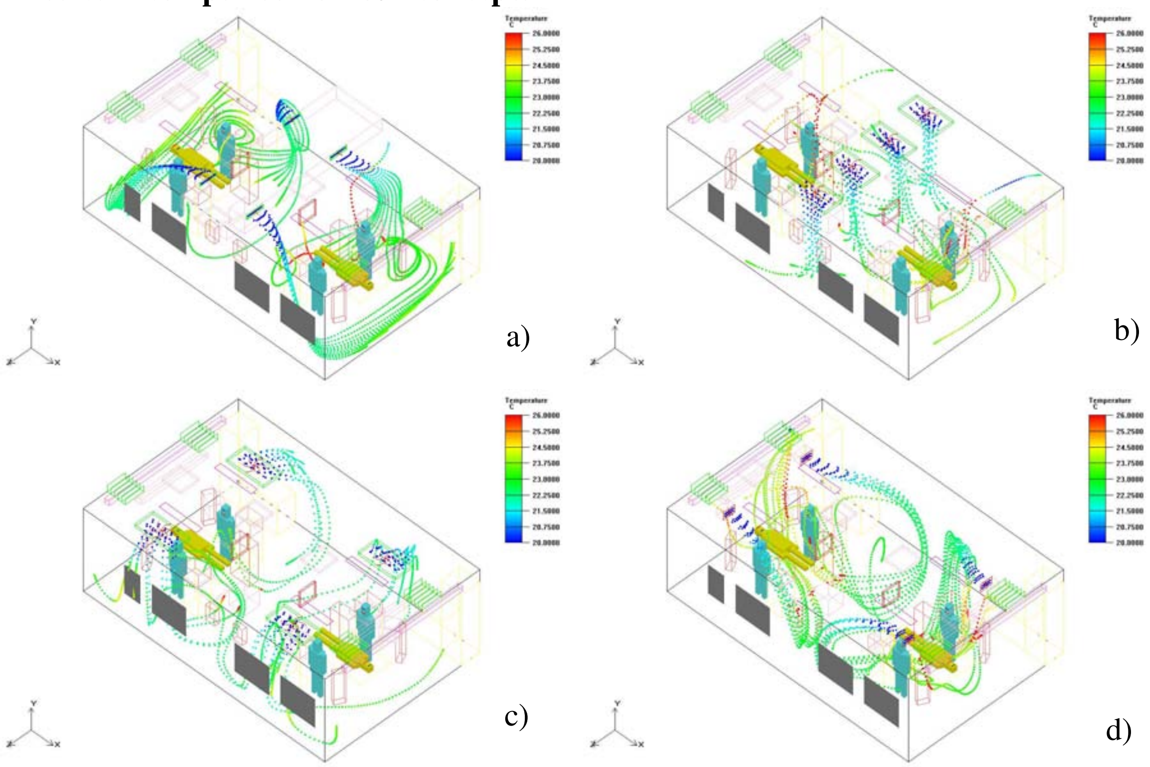

Figure 7. Air stream distribution with air supply diffusers from case a) to d)

SPECIAL CASE STUDY: ASYMMETRIC SITUATION

The purpose of the analysis on this asymmetric situation is to check what will be indoor climate condition in case one bed is fully occupied for the IC and another bed is only with one patient laying on the bed (the most asymmetric condition).

The following figures (8a ~ 8c) is made in such a way that the unoccupied side will only have the TV screen on and all the other apparatus will be switched off. Several control strategies have been tried. And the following figure is with the conditions of:

1. The ceiling of the room is split into two parts. Each takes care of one bed. The unoccupied side will have surface temperature as 22^{o}C and the occupied side as 18^{o}C.
2. The air supply temperature will be kept as the same as 19^{o}C.

By these, the air temperature (at 1.5 meter above the floor) will be ca. 22^{o}C. The air speed in the patient zone is lower than 0.12m/s.

With a smart control strategy, a good indoor climate will be approached.

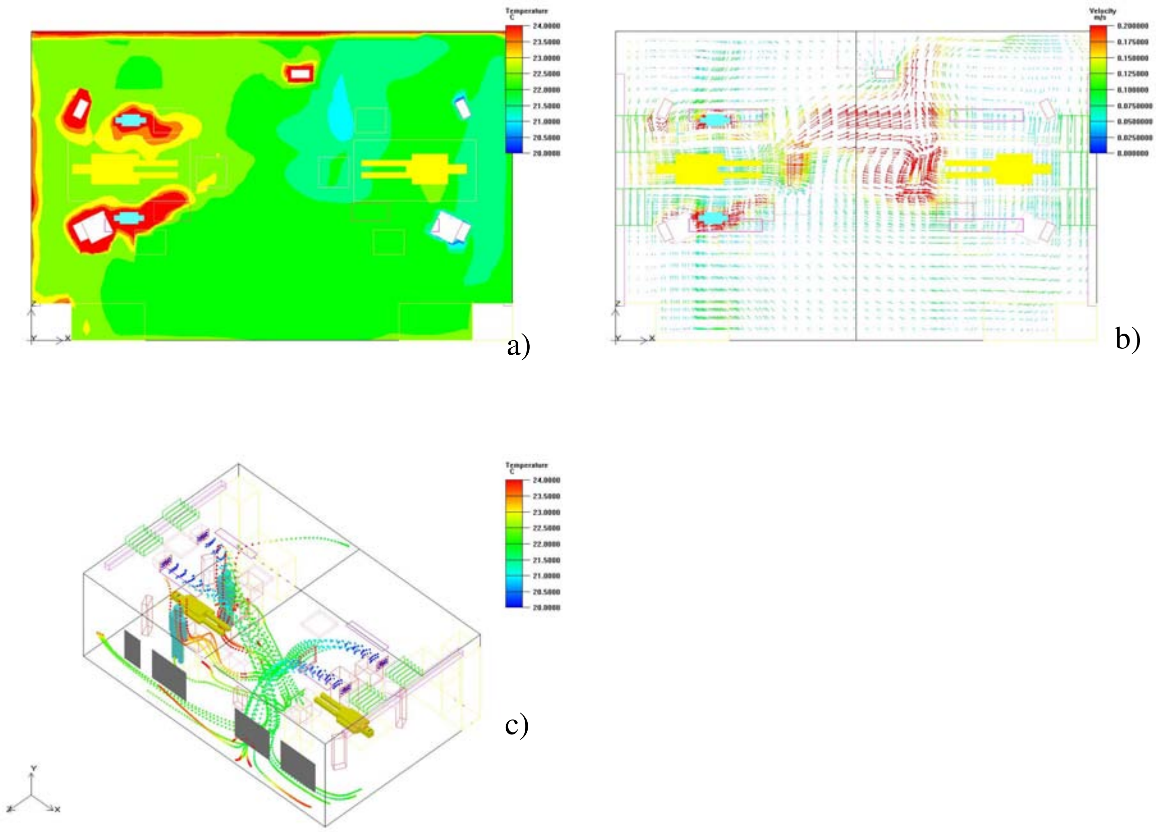

Figure 8. Ceiling diffusers (one side supply) at asymmetric internal heat load a)Temperature distribution; b) Air speed distribution; c) Air stream distribution

CONCLUSIONS

By the CFD simulation, some conclusions can be made:

The air speed in the patient zone is limited and lower than 0.12m/s for all concepts. However, if looking at the temperature distribution in the room, the fourth concept (ceiling diffuser to one side) has the most homogenous temperature distribution. Therefore, it will give the least temperature variation for the nurses who will walk around in the IC room.

Above results are all based on the thorax situation, i.e. the highest internal heat load condition. Under this condition, the average room temperatures are ca. 23.5 ~ 24^{o}C. This means, the room temperature could not approach the requirement of 22^{o}C. This will only occur with high internal heat load. In the reality, two big apparatus, dialysis apparatus and balloon pump/heart & lung device, which are 850 W, will not be used for the most situation. And this will lead to a condition under the requirement and has been studied in another report.

The general conclusions in this study are:

- The highest internal heat load condition (ca. 112 W/m^2) can not lead to a required indoor environment, i.e. the room temperature will be approximate 23.5^{o}C instead of 22^{o}C;
- Different concept has different advantage and disadvantage. The relatively best concept has been chosen with the ceiling diffusers of one direction supply (Waterloo DE/DF 111). This is the case (d).
- The asymmetric situation will not lead to any problem if a smart control strategy is applied.

SUMMARY

A typical virtual meeting room with occupants displays different situations of airflow pattern for different locations of the air supply even though the ventilation system has the same location of the air exhaust in the room. The pollutant is defined here as CO_2 emitted by the occupants in the room. - The investigation is realised with full-scale numerical modelling under Computational Fluid Dynamics (CFD) method

The results of these numerical experiments indicate the following:
Even if the same ventilation system can provide enough outside air for a room in respect of a defined air change rate, there will be different ventilation efficiencies for different locations of the air supply and exhaust. The indoor air quality in a room is strongly affected by the location of air supply and air exhaust of a ventilation system

INTRODUCTION

The task of a ventilation system for non-industrial applications is providing the occupants comfort in room and removing the contaminants as CO_2, VOC and particulate matter etc., as well as unpleasant odour. Indoor air quality and comfort depend on the organization of supply and exhaust openings of the ventilation system for the room. How can ventilation concepts affect comfort and indoor air quality for occupants in it, in particular for places where typically many occupants stay, like meeting rooms or classrooms? We here study different ventilation concepts in the view of ventilation efficiency to show comfort and IAQ in a meeting room. Numerical simulation (CFD) experiments are carried out for this purpose.

It is compared here the conventional airflow pattern e.g. mixing ventilation with the recently favoured ventilation system, displacement ventilation that has been studied in the literature [1]. In respect of real environment in this meeting room, human bodies instead of cylindrical dummies are used for the simulations. The contaminant is here limited just to CO_2 from the occupants.

Three cases are presented. The basic case shows airflow pattern in the room with mixing ventilation at 4 K under-temperature. The other two variants are a mixing ventilation system at 8 K under-temperature, which has the same organization of supply as in the basic case and a displacement ventilation system at 4 K.

The results demonstrate that all concepts here satisfy the demands of comfort and indoor air quality in the room. A displacement ventilation system can provide better ventilation efficiency and keep better IAQ for the occupants concerning contaminants in the room.

MODEL AND BOUNDARY CONDITONS

The meeting room with the mixing ventilation system and the displacement ventilation is defined as shown in figure 1a and 1b. The size of the room is: 5.8 m length, 4 m width and 2.9 m height. Four occupants are sitting on chairs around a rectangular table (2.4 m x1.6 m). For the mixing ventilation, supply openings are four swirl inlets located in the ceiling, the exhaust (0.75 m x 0.045 m) is on the top of the door. For the displacement ventilation, the supply opening (4 m x 0.25 m) is defined on the bottom of the right wall. The exhausts (d = 0.204 m) are the supply openings of the mixing ventilation. The grey zone in figure 1 is defined as occupied zone [2]. The distance from walls is 0.5 m and from ceiling 0.9 m. There is no distance from the floor. The correspondent names of component are demonstrated in figure 1, too.

The commercial simulation software FLUENT serves as a tool for the experiments . RNG $k-\varepsilon$ turbulence model is defined for airflow in room. The simulation of CO_2 and humidity is done by species model in Fluent [3]. The grids have about 750,000 cells (hexahedron and tetrahedron). The simulations run under steady-state conditions.

The simulations are for the transition periods of the year. There are no heating loads for the simulations. The cooling loads come from occupants and lamps. The lamps emit 6 x 58 W. Every occupant emits 75 W of sensible heat (e.g. 1.2 met per occupant) and gives to the environment 60 g/h of dampness and 0.02 m^3/h CO_2 from breathing. The conditions of comfort are according to the standard [4]. The room temperature is defined at 24 °C. The surfaces as walls, table and chairs are adiabatic. The supply air has 6 g/kg moisture and 16 °C respectively 20 °C for mixing ventilation and 22 °C and 6g/kg for displacement ventilation.

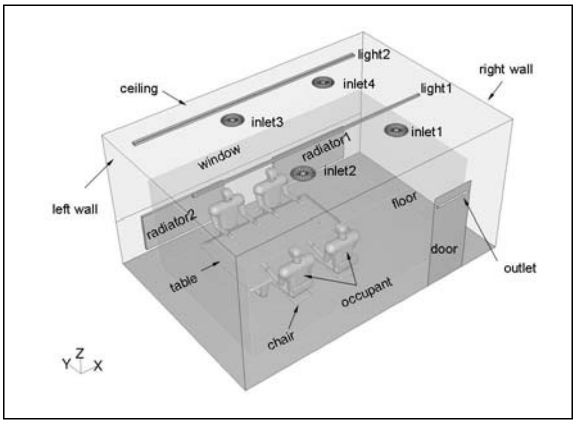

Figure 1a): Meeting room model for mixing ventilation

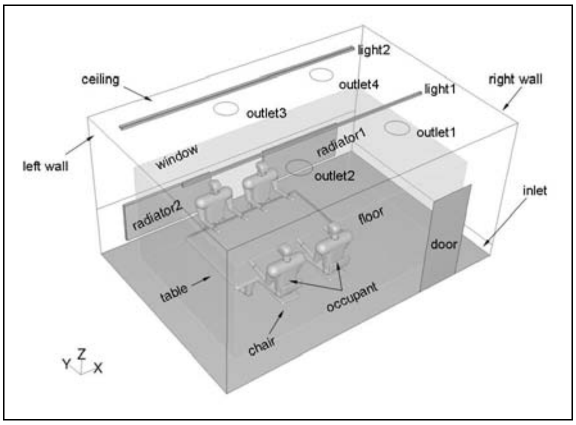

Figure 1b): Meeting room model for displacement ventilation

RESULTS

Airflow pattern and comfort estimation

Figure 2 displays path lines of velocity for mixing and displacement ventilation at 4 K undertemperature. Asymmetric allocation of thermal loads by the occupants in the room cause clearly an air roll clockwise in the room for the mixing ventilation, see figure 2a. The displacement ventilation shows other phenomena. Supply air enters into the room through the supply opening in the right wall, flows towards the opposite wall and then returns to occupants. From there most of the air flows in vertical direction to the exhaust because of the thermal loads of occupants and lamps. The airflow forms a mixing zone above the upper limit of the occupied zone (at 2 m height above floor), see figure 2b. The gradient of temperature near the floor is greater than beneath the ceiling. A comparison of velocity between the three concepts is displayed in figure 6, it is discussed later. Figure 3 and 4 show the temperature distribution for mixing and displacement ventilation each at two x- and y-planes.

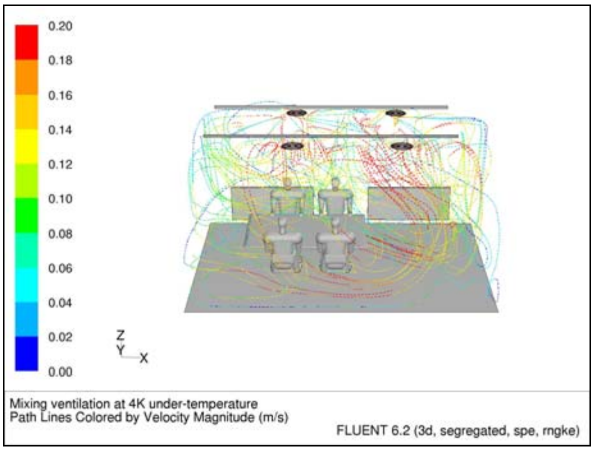

Figure 2a): Pathlines in the mixing ventilation at 4 K under-temperature

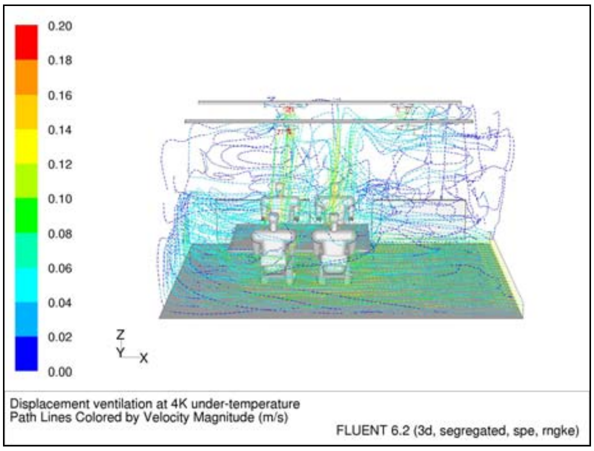

Figure 2b): Pathlines in the displacement ventilation at 4 K under-temperature

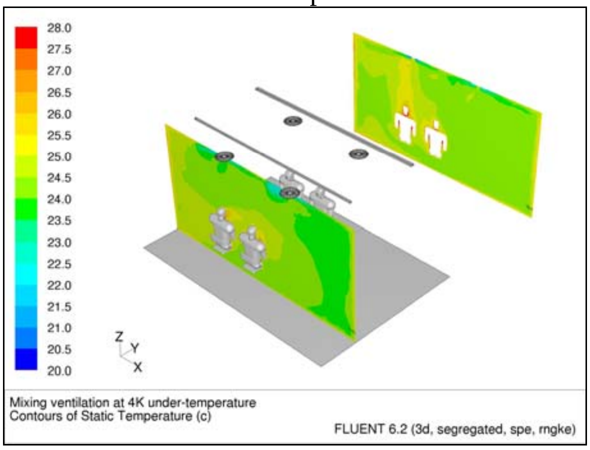

Figure 3a): Temperature distribution at the y – planes for mixing ventilation at 4 K under-temperature

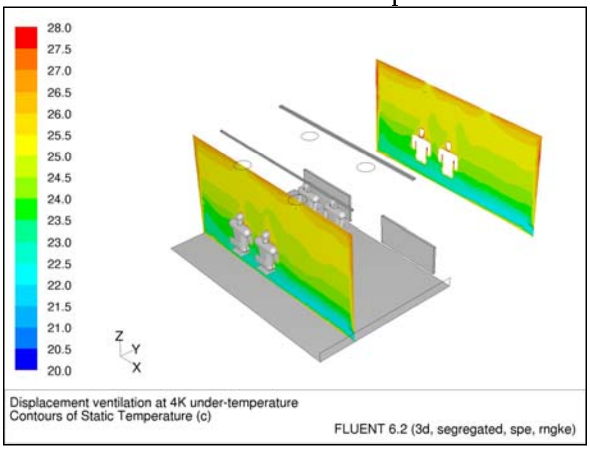

Figure 3b): Temperature distribution at the y – planes for displacement ventilation at 4 K under-temperature

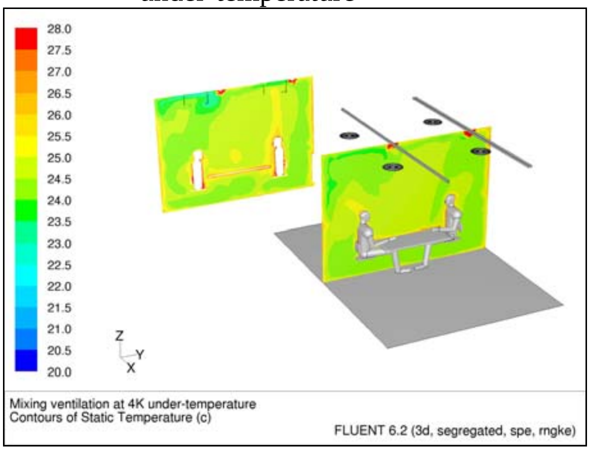

Figure 4a): Temperature distribution at the x – planes for mixing ventilation at 4 K under-temperature

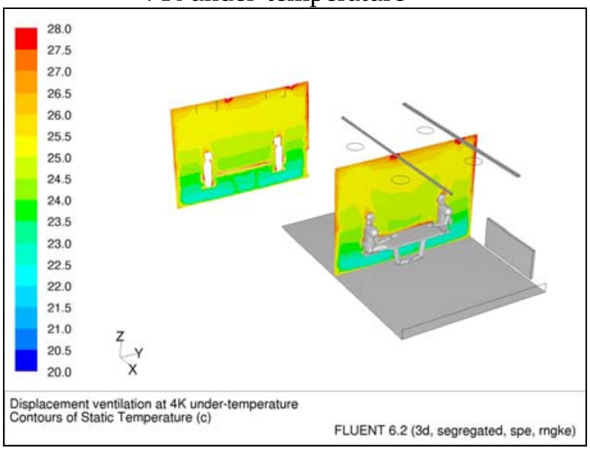

Figure 4b): Temperature distribution at the x – planes for displacement ventilation at 4 K under-temperature

They display clearly an increased temperature level on the top of the room for the displacement ventilation system. In order to achieve a good displaying, the rear y-plane is transferred far from the original location.

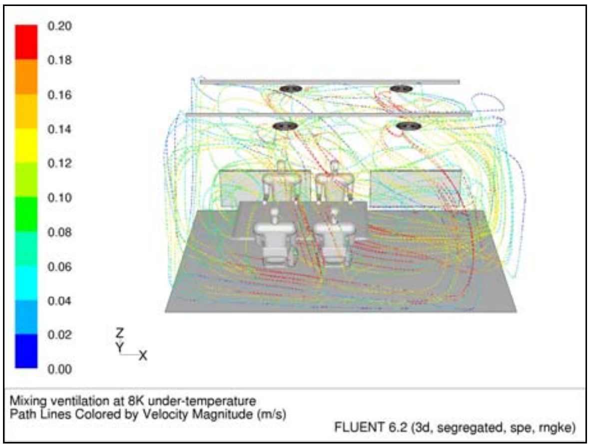

Figure 5a): Pathlines for the mixing ventilation at 8 K under-temperature

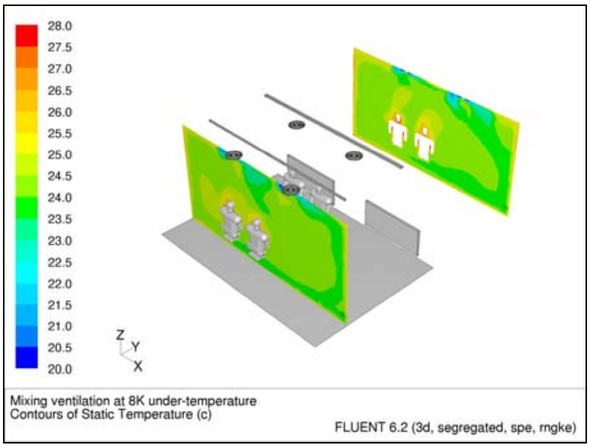

Figure 5b): Temperature distribution at two y – planes for mixing ventilation at 8 K under-temperature

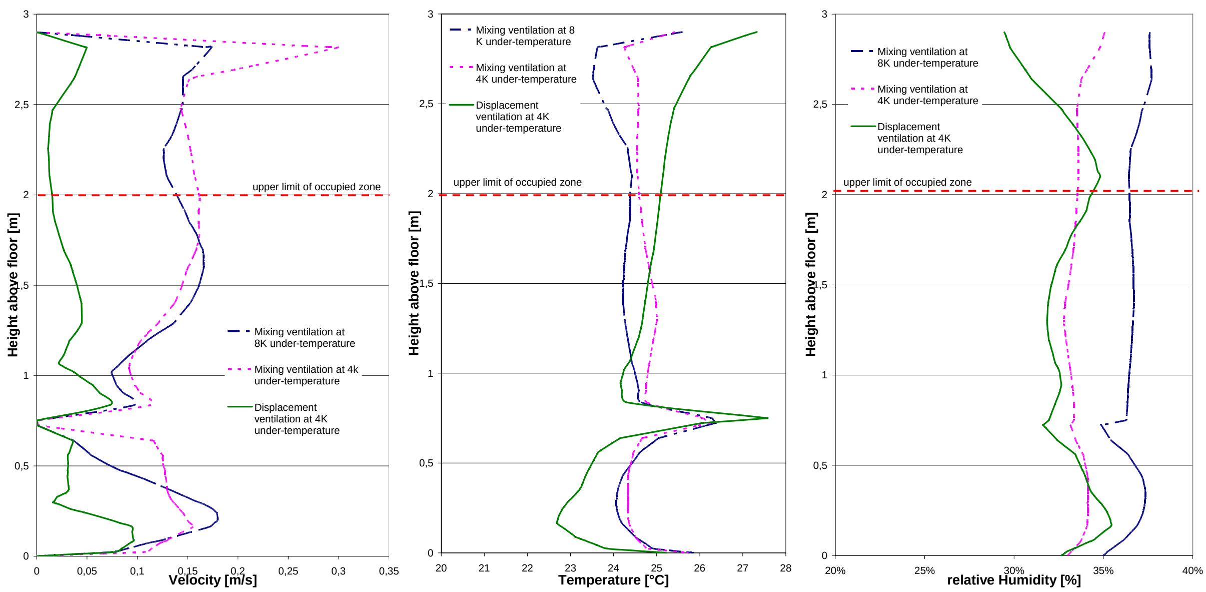

Figure 6: Parameters at the vertical centerline: Velocity, Temperature and relative Humidity

Figure 5 displays mixing ventilation with lower air change rate compared with basic case. Here the clockwise air roll is more distinctive than at 4 K under-temperature. The flow mixing is weaker than for the higher air change rate at 4 K. A vertical centerline from the top to the bottom of the room in the middle of the table is selected; this line is supposed to be representative for comfort and IAQ of the persons, ventilation effectiveness and ventilation efficiency. The left diagram in figure 6 displays the velocity. The displacement ventilation shows very low velocities. All three concepts satisfy the requirement of velocity in the room according to standard [2]. The middle diagram shows very little temperature gradient for all concepts except for the area of the table. The right diagram in figure 6 displays the relative humidity in this centerline. The gradients are very low as well. For the mixing ventilation at 8 K under-temperature the humidity is a little higher than for the two alternative concepts.

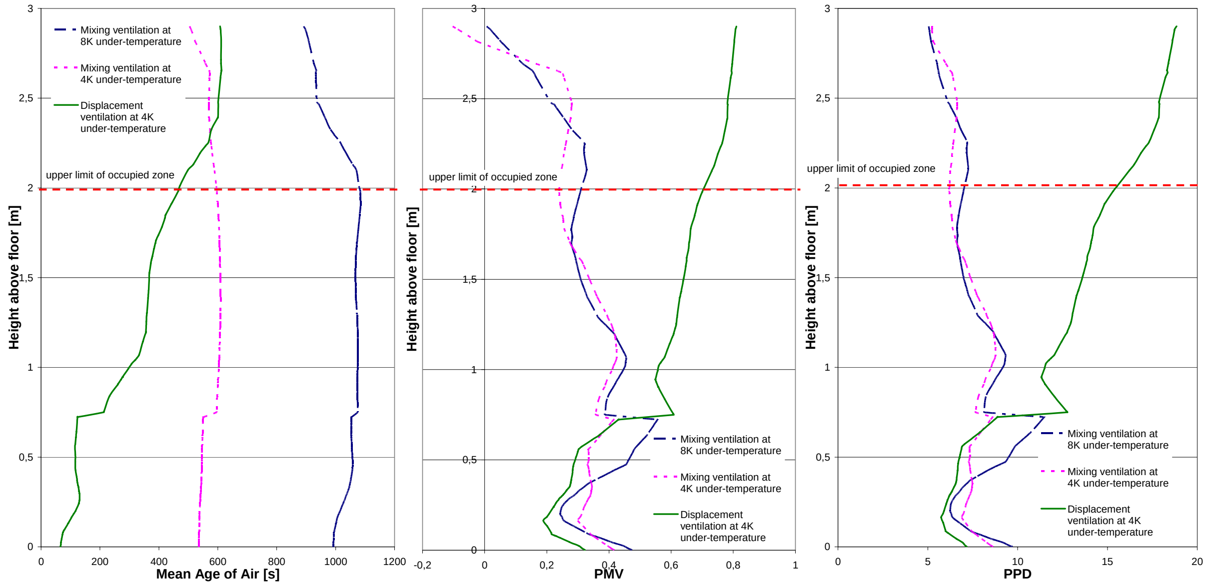

Figure 7: Parameters at the vertical centerline: MAA, PMV and PPD

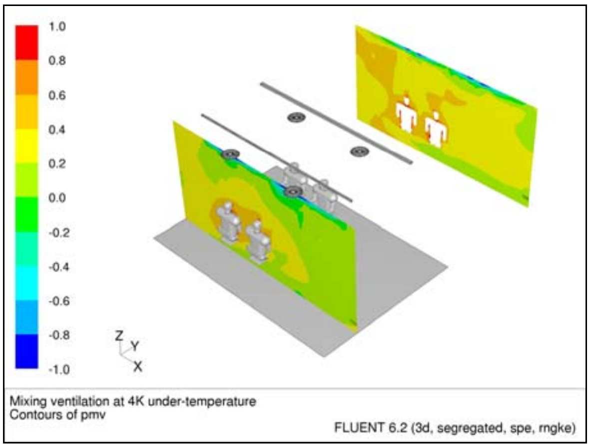

Figure 8a): PMV at y-planes for mixing ventilation at 4 K under-temperature

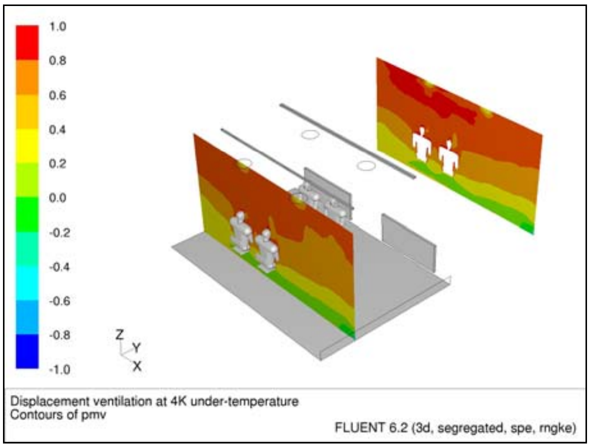

Figure 8b): PMV at y-planes for displacement ventilation at 4 K under-temperature

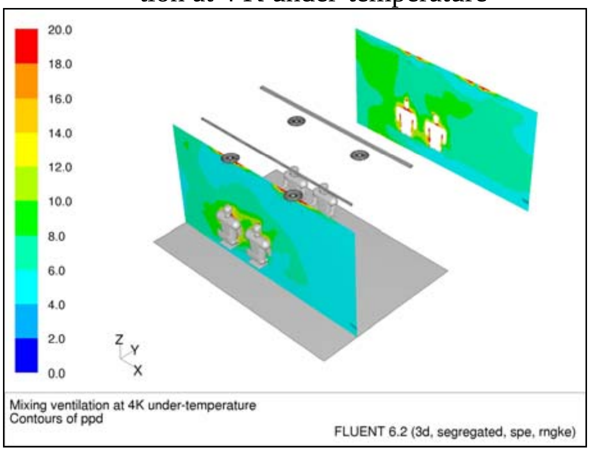

Figure 9a): PPD at y-planes for mixing ventilation at 4 K under-temperature

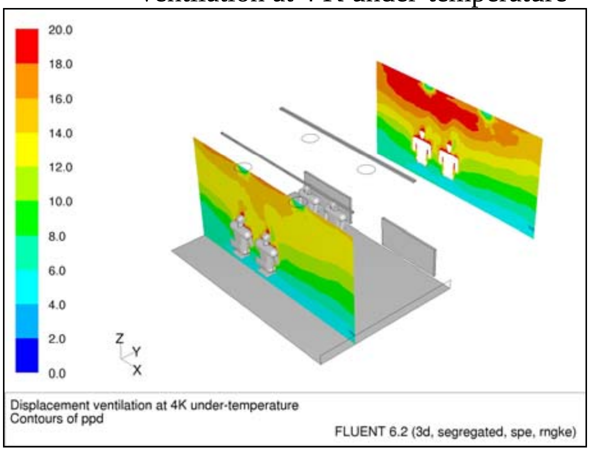

Figure 9b): PPD at y-planes for displacement ventilation at 4 K under-temperature

Accepted criteria for the estimation of comfort are MAA, PMV and PPD [4]. The comparison for the displacement ventilation shows worse quality in respect of PMV and PPD, but better quality in respect of MAA for the occupants, see figure 7. Figure 8 and 9 show the PMV and PPD distributions at two y-planes of the room.

CO_2 distribution and estimation of ventilation effectiveness respectively efficieny

An important criterion for indoor air quality is the CO_2 concentration. It should be less than 1000 ppm according to Pettenkofer [5]. The terms for estimation of ventilation systems are defined as following (in this study, the concentration of CO_2 in the supply air is set to zero):

Air change efficiency $$\eta_a = \frac{\tau_n}{\tau_{r,v}}$$

Contaminant load $$\mu_R = \frac{C_m - C_s}{C_e - C_s}$$

Ventilation effectiveness $$\varepsilon_v = \frac{C_e - C_s}{C_{m-} C_s}$$

Ventilation efficiency $$\eta_v = \frac{\varepsilon_v}{1 + \varepsilon_v}$$

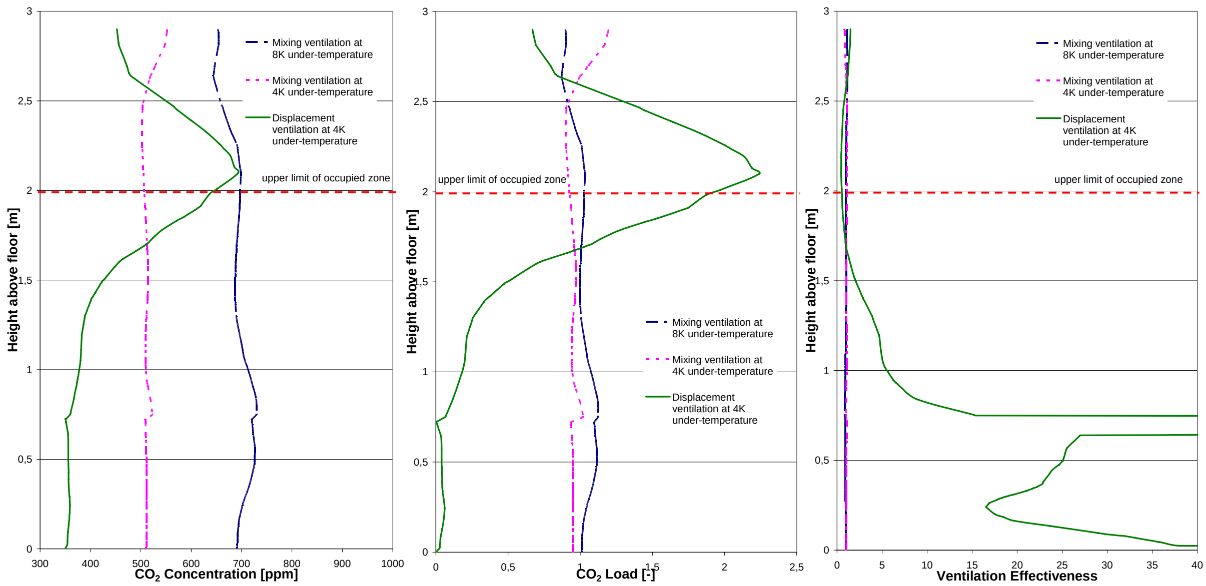

Figure 10: Parameters for CO_2 at the centerline

Concept	Air change rate [1/h]	Air change efficiency	Ventilation effectiveness	Ventilation efficiency
Mixing ventilation at 4K under-temperature	7.19	0.45	1.1	0.52
Mixing ventilation at 8K under-temperature	3.61	0.48	0.97	0.49
Displacement ventilation at 4K under-temperature	7.19	0.67	82	0.988

Table 1: Mean value of ventilation efficiency

The simulations show that the three concepts can keep hold of CO_2 concentration under 1000 ppm, see left diagram in figure10.

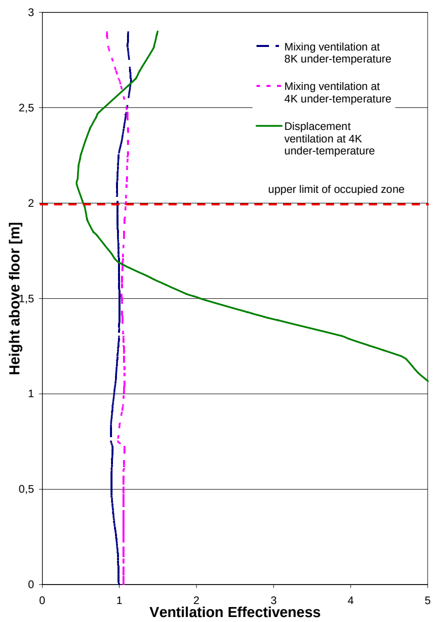

Figure 11: Ventilation Effectiveness (larger scale)

The displacement ventilation system can reduce the CO_2 concentration in the occupied zone distinctively, the level of concentration remains very low, even though it has the same air change rate as the mixing ventilation system at 4 K under-temperature. Naturally, the CO_2 concentration is higher for the mixing ventilation system at 8 K under-temperature because of half of airflow quantity. In the view of CO_2 load (middle diagram in figure 10), the displacement ventilation system has also advantages comparing to mixing ventilation. There is no significant difference between both mixing ventilation systems. Figure 11 shows the content of the right diagram of figure 10 drawn to a larger scale. It shows that the displacement ventilation has a very high effectiveness compared to mixing ventilation.
Figure 12 to 14 show the contours of CO_2 concentration and load as well as the ventilation effectiveness at two y-planes of the room.

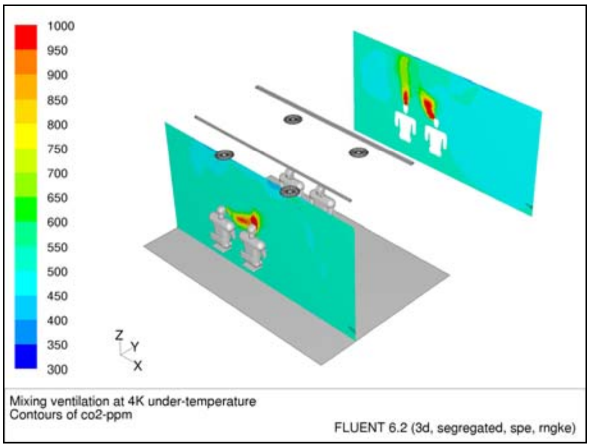

Figure 12a): CO_2 concentration distribution at two y-planes for the mixing ventilation at 4 K under-temperature

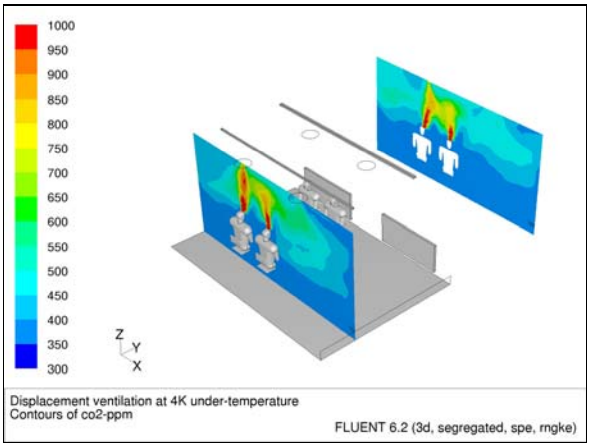

Figure 12b): CO_2 concentration distribution at two y-planes for the displacement ventilation at 4 K under-temperature

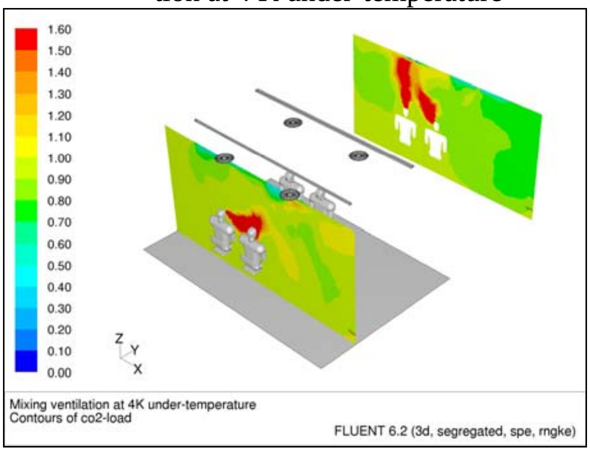

Figure 13a): CO_2 load distribution at two y-planes for the mixing ventilation at 4 K under-temperature

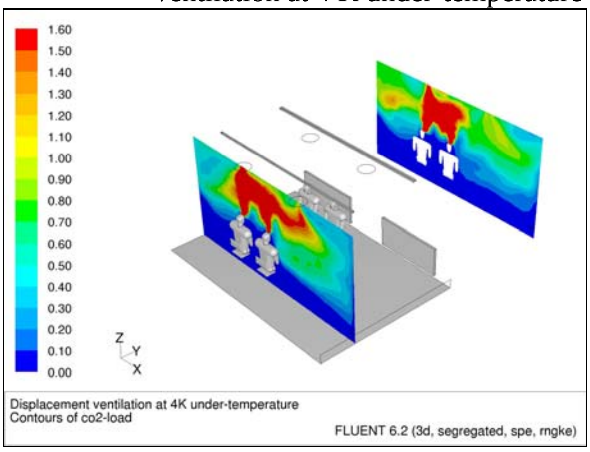

Figure 13b): CO_2 load distribution at two y-planes for the displacement ventilation at 4 K under-temperature

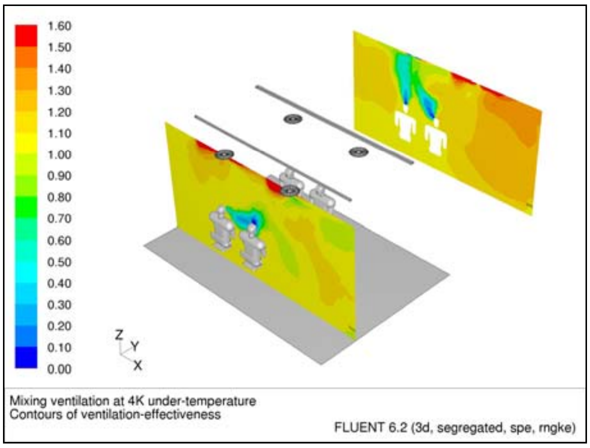

Figure 14a): Ventilation effectiveness at two y-planes for the mixing ventilation at 4 K under-temperature

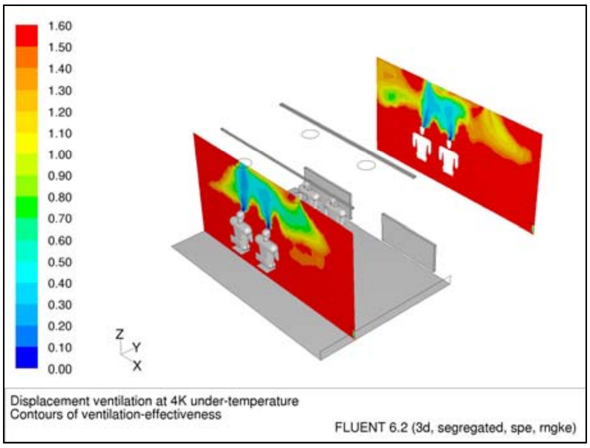

Figure 14b): Ventilation effectiveness at two y-planes for the displacement ventilation at 4 K under-temperature

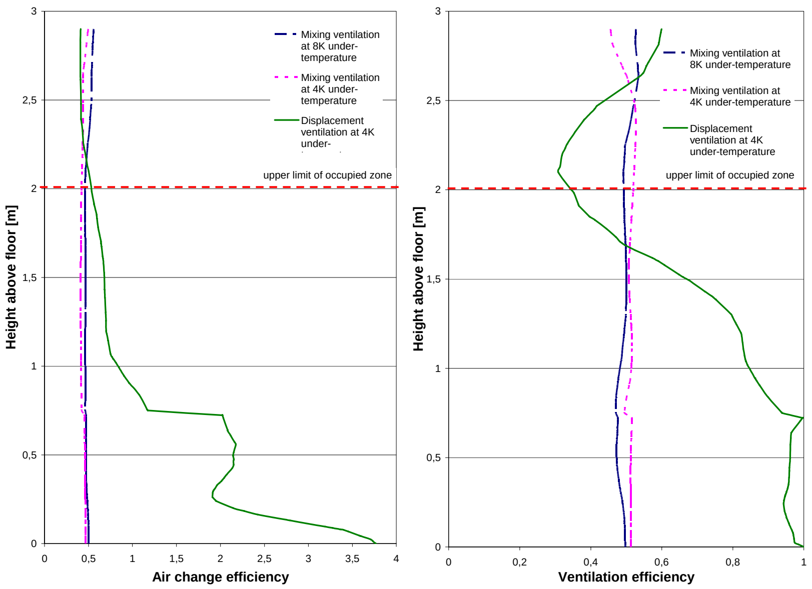

Figure 15: Parameters at the vertical centerline: Air change efficiency and ventilation efficiency

A ventilation system is estimated among others by air change efficiency and ventilation efficiency; see figure 15 and table 1. The air change efficiency for mixing ventilation is at about 0.5. The displacement ventilation has higher air change efficiency than mixing ventilation. The same results are obtained for ventilation efficiency. Figure 16 gives a quantity display for CO_2 concentration as well as CO_2 load and ventilation effectiveness in occupied zone.

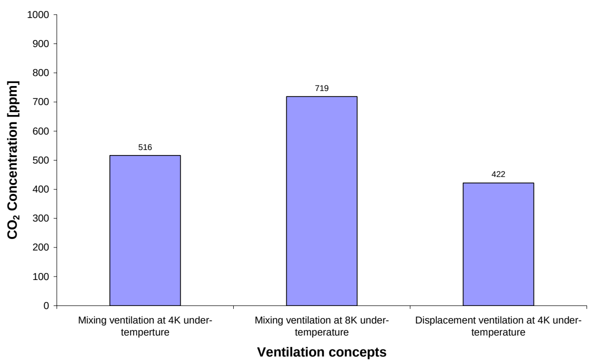

Figure 16a): Diagram of CO_2 concentration in occupied zone for different ventilation concepts

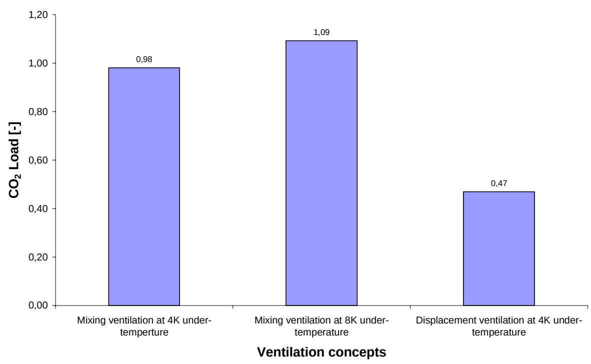

Figure 16b): Diagram of CO_2 load in occupied zone for different ventilation concepts

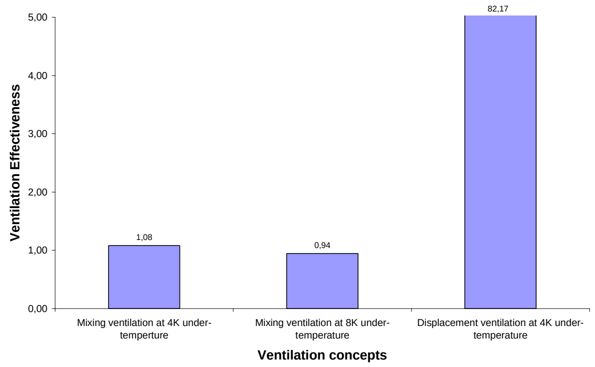

Figure 16c): Diagram of ventilation effectiveness in occupied zone for different ventilation concepts

Names and units

C_e	Contaminant concentration in exhaust [kg/kg]
C_m	Mean contaminant concentration in room or in occupied zone [kg/kg]
C_s	Contaminant concentration in supply air [kg/kg]
PMV	Predicted Mean Vote
PPD	Predicted Percentage Dissatisfied
ε_v	Ventilation effectiveness [-]
η_a	Air change efficiency [-]
η_v	Ventilation efficiency [-]
μ	Contaminant load [-]
τ_n	Time constant [h]
$\tau_{r.v}$	Mean age of air [s]

DISCUSSION

All compared ventilation concepts can provide good comfort in room. The detailed results show that displacement ventilation cannot provide better comfort than mixing ventilation in terms of temperatures and air velocity. The particular advantage of displacement ventilation is the providing of higher ventilation effectiveness that is to say to achieve rather low concentration of contaminant in the room, particularly in the occupied zone. The satisfaction of thermal environment for occupants cannot guarantee the satisfaction of indoor air quality. A new criterion for the estimation of a comfortable and clean environment should be considered in the future.

Further studies also should take other contaminants like VOC or odour into consideration. Heat and contaminant sources in other places in the room or parts of the human body can also be investigated with this simulation model.

A detailed model of the human body is very time-consuming for grid creating and simulation running. Therefore, it is not advisable for situations where many occupants stay in a room (i.e. classrooms or other bigger locations). The affect of the modeling of the human body (i.e. cylindrical dummies instead of detailed body modeling) to the results of such simulations should be investigated.

Perceived Control of Stratum Ventilation

Zhang Lin, T. T. Chow, C.F. Tsang

Division of Building Science and Technology, City University of Hong Kong, Hong Kong S.A.R., China

Corresponding email:bsjzl@cityu.edu.hk

SUMMARY

Current control strategies for central air conditioning typically adopt a machine-centered, energy-consuming approach that focuses on creating constant, uniform neutrality-conditions which might actually be perceived by some occupants as thermal monotony or sensory deprivation. There are needs for more sophisticated and responsive environmental control strategies, enhanced levels of thermal comfort and acceptability among occupants. Stratum ventilation, a new ventilation mode proposed recently by the authors, has the potential to strike a balance between fully automated controls at the system side and manual controls that the users are able to alter. Stratum ventilation should be integrated with specific control strategies for various applications and varieties of control option available to occupants. A working example using CFD simulations is given to illustrate the performance of the proposed new system. Fresher air is directly introduced to breathing zone hence air age of the air layer should be younger. Air temperature gradient is low in the occupied zone. Because less fresh air bypasses occupants, fresh airflow rate may be reduced. The air supply temperature is usually high for stratum ventilation. The evaporating temperature of the refrigerating plant can also be lifted, which results in higher coefficient of performance.

INTRODUCTION

Conventional ventilation modes applied in an air-conditioned non-industrial indoor space are broadly categorised into two groups, namely: mixing ventilation and displacement ventilation as task ventilation is less widely applied.

Mixing ventilation is a traditional mode of ventilation and is still widely used. It could take care of both heating and cooling with highly varying load patterns. The mixing is achieved by supplying the ventilation air as a high velocity jet to entrain the air already in the room. Mixing ventilation could provide comparably uniform air temperature distribution in the occupied zone. However, it also leads to problems, such as poor IAQ, air draft in the occupied zone and some other thermal discomfort. In addition, it normally consumes more energy than displacement ventilation.

Displacement ventilation has been used quite commonly in Scandinavia during the past twenty years as a means of ventilation in industrial facilities to provide better IAQ and to save energy. More recently, its use has been extended to ventilation of offices, classrooms, commercial buildings and other non-industrial premises. In contrast to mixing ventilation, buoyancy forces (induced by heat sources) govern the airflow in displacement ventilation. Because the airflow is thermally driven, this mode of ventilation functions satisfactorily only when excess heat is to be removed. In a room ventilated by displacement, the air quality in the breathing zone is usually better than in a mixing system operated with the same airflow rate. And ventilation efficiency of a displacement-ventilated room is also significantly better than that of the mixing ventilated room [1]. It has been found that an increase in ventilation efficiency is often achieved at the breathing level [2]. But there are more severe restrictions due to thermal discomfort in a displacement system than in a mixing system. ISO 7730 recommends a maximum air temperature gradient of 3K between 1.1m and 0.1m above the floor [3], which corresponds to a percentage dissatisfied of 5%. However, the ASHRAE Standard recommends the same temperature gradient between 1.7m and 0.1m above the floor [4], which related to a standing person. Otherwise it will cause thermal discomfort. So supply air temperature and airflow rate must be carefully studied to assure proper temperature distribution and velocity distribution. Often a displacement ventilation system excessively cools the lower part of a room, where usually heat sources are absent, resulting in discomfort and energy waste.

As far as the IAQ of breathing zone and energy efficiency are concerned, the most effective way is task ventilation. It may be used to remove excessive cooling load and maintain a comfortable indoor environment. Task ventilation systems supply air through nozzles located near occupants (e.g., at an edge of a desk). Potential draft exists because of the short distance between supply gears and the occupants. A field study found that workers in a task ventilated office satisfied with the thermal conditions because they could individually control local environment [5]. The occupants can control the temperature, flow rate, and direction of air from the nozzles. The measurements conducted by Faulkner *et al*. [6,7] showed that the age of air at the breathing level with task ventilation was approximately 30% less than that with mixing ventilation. However, application of task ventilation depends much on indoor furnishings. On one hand, sometimes it is difficult to equip nozzles and connect duct in various indoor spaces. On the other hand, some occupants in certain spaces do not normally stay in a fixed location, e.g., the situation in a retail shop. These limit the use of task ventilation.

DEVELOPMENT OF THE CONCEPT OF STRATUM VENTILATION

Mixing ventilation, displacement ventilation plus task ventilation all have their limitations. To overcome these problems, a new ventilation mode is proposed [8]. The new mode should be able to provide good IAQ in breathing zone, to have minimum temperature difference between head and ankle levels to obtain thermal comfort in occupied zone, to equip duct and terminals conveniently, and to have high energy efficiency.

The underlying principle of displacement ventilation implies that in an air-conditioned room, the conditions of IAQ and thermal comfort beyond the occupied zone (say $H > 2$ m) are of little interest. By the same token, the IAQ beneath the breathing zone (say $H < 0.8$ m) is less important unless the occupants are expected to be very young children. For conventional ventilation modes, the air for breathing is transported by the boundary layer around the body of a human occupant and the air quality is a weighted average of the air quality in the room from the breathing level to floor level. Ventilation efficiency would be maximized if air is supplied directly into the breathing zone, and the air forms a well controlled “fresher air layer” to fill the breathing zone. The thickness of the fresher air layer depends on the nature of occupancy. At the same time, a quasi-stagnant zone is also form between the breathing zone and the floor (say $0 < H < 0.8$ m). The temperature in the quasi-stagnant zone should not be as low as that of displacement ventilation. The problem of “cold ankles” could be solved. Energy can also be saved by avoiding over-cooling of the lower part of a room.

The stratum ventilation works by creating a layer of fresher air in the occupants’ breathing zone. This is done by placing large supply inlets at the side-wall of the room just above the height of the occupants, sedentary or standing depending on modes of occupancy. The fresh air enters the room and then gradually loses momentum, further away from the supply. The fresh air supply is sufficiently strong enough to provide adequate fresh air of young age. The range of face velocity and the locations of air supply and exhaust should be carefully optimized to break the boundary layer around the body of a human occupant, to minimize risks of draft and cross contamination. The thickness of the fresher air layer required depends on the nature of occupancy. At the same time, a quasi-stagnant zone is also form between the breathing zone and the floor (say $0 < H < 0.8$ m). The temperature within the quasi-stagnant zone should be reasonably controlled. In addition the supply of air at this level increases the convection effect of the heat and helps to displace the contaminants into the unoccupied zone. It brings fresher air to breathing zone than that of conventional modes of ventilation. Indoor air should mix well and air temperature gradient should be low hence not to cause thermal discomfort. Because air is supplied directly to breathing zone, less fresh air bypasses occupants. Thus there are also possibilities to reduce fresh airflow rate for energy saving. Also because air is supplied directly to breathing zone, the air supply temperature should usually above 20°C. This implies that the evaporating temperature of the chiller(s) could also be higher, which could result in higher coefficient of performance (COP), an indicator of refrigerating plant energy performance.

STRATUM VENTILATION FOR ENHANCING PERCEIVED CONTROL

Non-isothermal airflows enter a room via the air supply outlets positioned in a convenient way as long as it is slightly above the breathing height. A horizontal air layer should be formed with no reflux and minimal entrainment. Air age of the air layer should be young. Compared with more conventional modes of ventilation, it would bring a greater amount of fresh air into the breathing zone. The range of face velocity and the locations of air supply and exhaust should be carefully optimized to break the boundary around the body of a human occupant layer. Indoor air should mix reasonably well and air temperature gradient should be low so as not to cause thermal discomfort. Because air is supplied directly to breathing zone, less fresh air bypasses the occupants. There are also possibilities to reduce fresh airflow rate resulting in energy savings. The range of air velocity and supply types should be carefully matched to form the fresher air layer at the breathing zone. The positioning of the supplies should be carefully studied to avoid any reflux flows in the breathing zone of the room.

The occupants may opt for a control mode — manual or automatic:

- For the manual mode, temperature and air velocity (air recirculation) should be adjustable in wider ranges by the occupants; and

- For the automatic mode, multiple control options based on combinations of different temperatures and air velocities should be available to the occupants. To avoid the problem of draft, each air outlet will be equipped with an occupancy sensor to determine the proximity of occupants. The occupancy sensor and volume control damper of each and every air outlet are linked via a central control system. The control system will hence be able to control the supply air accordingly. As a starting point, a simple control strategy is adopted. If an occupant is less than 0.5 m to the face of the outlet then the air supplied will be stopped. If the occupant is greater than 0.5 m but less than 1 m to the outlet then the volume flow rate is reduced by up to ¾, but the face velocity is not less than 0.1 m/s. The basic principle is illustrated in Figure 1.

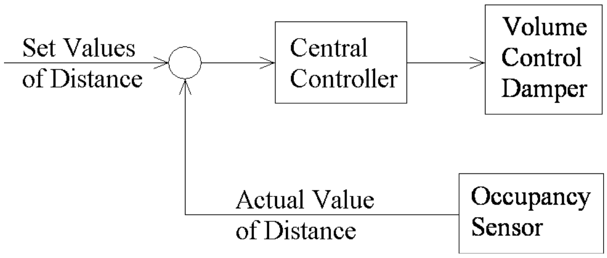

Figure 1. Automatic control of stratum ventilation

To maintain the required air supply volume to the room, the control system increases the fresh air supplied to the other parts of the room. The increase in supply will be optimized so that the increase will be for those outlets not far away from the closed outlet (the occupants). A fuzzy logic system consisting of a database relating the drop distance of an air jet based on the Archimedes number could be developed.

By directly or indirectly opting for a higher temperature setpoint, the occupants actually lower the cooling load of the room and save energy. This should be made known to the occupants. The research also attempts to increase the air recirculation applied in the design in order to remove a cooling load up to 200 W/m^2 of floor area. This is an inevitable problem because more and more equipment that generate a considerable amount of heat is being introduced indoors. The study assesses the stratum ventilation for enhancing perceived control in terms of IAQ and thermal comfort.

METHODOLOGY

The new concept of stratum ventilation needs to be tested. Two main approaches are available for the study of airflow and pollutant transport in buildings: experimental investigation and computer simulation. Direct measurements give the most realistic information but are expensive and time consuming. The purpose of the research at the first stage was to find out whether the new ventilation mode is feasible. Computational Fluid Dynamics (CFD) technique was applied. Due to limited computer power and capacity available at present, turbulence models have to be used in the CFD technique in order to solve flow motion. The use of turbulence models leads to uncertainties in the computational results because the models are not universal. Therefore, it is essential to validate a CFD program by experimental data [9].

A CFD model based on the Re-Normalised Group k-ε model and wall function was used for simulation. Validated for both mixing ventilation and displacement ventilation, the model has been tested for hundreds of cases, including offices, classrooms, shops and workshops with air supplied upwards and downwards [10]. The flow characteristics between displacement ventilation and mixing ventilation are similar – both have strong pressure and buoyancy driven flows [11]. The condition of stratum ventilation is found to be between those of mixing ventilation and displacement ventilation based on identical internal layout and similar boundary conditions. The very model was also validated recently for stratum ventilation with air supplied horizontally. A commercial CFD code CFX was used for the computations. By default, the code uses the finite-volume method and the upwind-difference-scheme for the convection term [12]. Simulation results agree well with experimental results [13].

Table 1. Major parameters for the typical classroom

No. of person	West wall [W]	Window [W]	Projector [W]	Lamp [W]	Air circulation [m^3/s]	Fresh air intake [l/person/s]
41	900	3168	350	1170	0.732	10

TEST CASE

The air velocity, the percentage of dissatisfied people due to draft (PD), and the predicted percentage of dissatisfied for thermal comfort (PPD) are widely used as criteria to evaluate thermal comfort [14,15]. All these performance parameters are determined by the thermal and flow boundary conditions, such as the size and geometry of the space, rates and temperatures of airflows and heat sources.

The case of a typical classroom is used to illustrate the effectiveness of the stratum ventilation. The classroom layout is shown in Figures 2. The major parameters are shown in Table 1. The classroom is supplied by 6 supply inlets located at the east wall (x = 8.4 m), and also by another 6 supply inlets at the west wall (x = 0.0 m). There are a total of 40 sedentary occupants and 1 standing occupant in the room. There is a long window at the west side of classroom.

DISCUSSION OF RESULTS

Airflow Pattern

The supply velocity is set low at 0.3 m/s to minimize any draft effect to the occupants. The air initially enters the room and gradually loses momentum and falls towards the floor under gravity. The air falls across the tables. This forms a stratum layer of fresher air in the breathing zone. This can be clearly seen in the cross-section y = 6.0 m and x = 0.5 m in Figure 3. The convection effects of the air can also be seen to rise near the external wall and window as it is heated. This effect is not observed on the other three internal partitions, as the adjacent rooms are at the same temperature.

The air velocity can be seen to be low in the order of less than 0.3 m/s in the occupied zone. Higher velocities however are observed near the external wall. Velocities tend to be in the range of 0.3 to 0.5 m/s. At the external wall location the airflow rises rapidly into the ceiling area. The highest velocities are at the window location with velocities averaging between 0.4 and 0.5 m/s. This area is the location of the most intensive heat source.

(b) y = 6.0 m

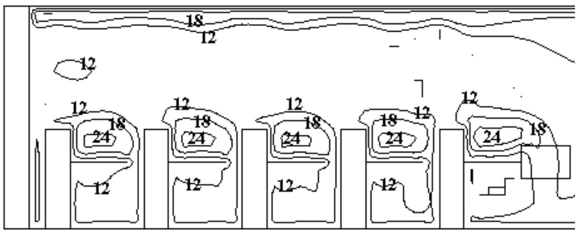
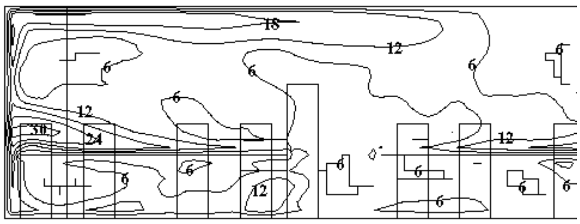
Figure 4. Temperature distribution



(a) x = 0.5 m



(b) y = 6.0 m

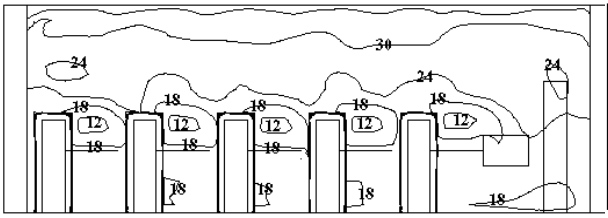
Figure 5. PD index (%)

Temperature Distribution

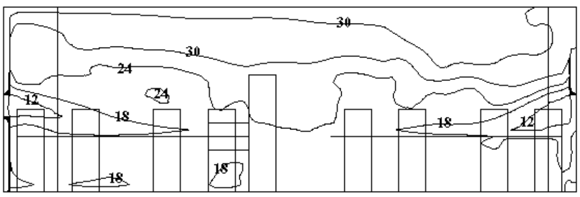
The temperature is nearly uniform in the horizontal direction, except close to the supply inlets as shown in Figure 4, which reduces any draft effects due to temperature differences. The temperature is 23°C at the floor level and at the vicinity of the supply inlets, and is 26°C at the centre of the room. The supply temperature is 21°C. The room temperature at a distance away from the air supplies increases due to the various heat sources, such as external heat transmission, equipment, occupants, etc. As a result the temperature at the floor is higher than that of the supplied air. The temperature is even higher at the ceiling due to the loads including the heavy lighting. However the ceiling is within the unoccupied zone so the high temperature (slightly above 30°C) has little effect on thermal comfort. The effect of radiation due to temperature stratification of this kind is also insignificant because of the small temperature difference. The highest temperature in the occupied zone is near the projector in front of the teacher, which is 3°C higher than the average room temperature. Temperature gradient is maintained within the range of 3°C as stipulated in ISO 1984 and ASHRAE 1992.

Predicted Dissatisfied (PD) and Predicted percentage of dissatisfied (PPD)

The PD levels are higher at the supply inlets, at around 16% to 20%, Figure 5. This is at a distance of approximately one meter from the supply. The rest of the room is around 6% and rises slightly to 12% close to heat sources such as occupants and the projector. The PPD levels are mostly around 8% in the occupied zone and 10% in the unoccupied zone, as shown in Figure 6. In the vicinity of a supply outlet (< 1 m), the PPD levels increase gradually from 6% at the face of the supply outlet. The recommended level is 15% for both PD and PPD (ISO 7730).

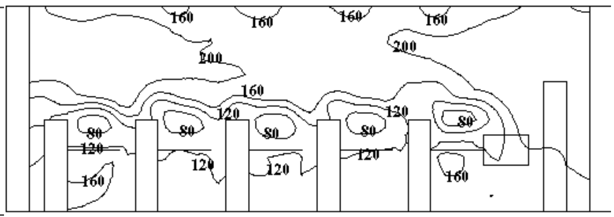


(a) x = 0.5 m

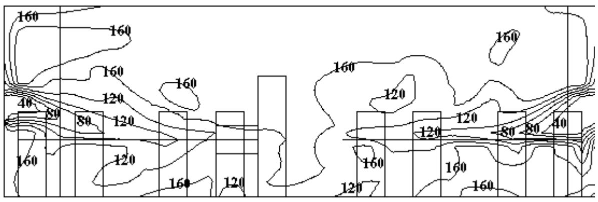


(b) y = 6.0 m

Figure 6. PDD index (%)



(a) x = 0.5 m



(b) y = 6.0 m

Figure 7. Mean age of air (s)

Mean age of air

The mean age of air is a good indicator for the effectiveness of the stratum ventilation. As shown in Figure 7, at the centre of the room the air age approaches 160 s. Approaching the side of the room the air age decreases progressively from 120s to 80s. The location of the inlets at the side of the room means that air is supplied into the room unimpeded by furniture, resulting in fresher air throughout the classroom.

CONCLUSION AND IMPLICATIONS

For the illustrative example, the stratum ventilation with perceived control has shown the potential to be effective in providing satisfactory indoor thermal comfort and air quality. In general the calculated PPD and PD levels are satisfactory in most parts of the classroom. The system is able to provide air of young age to the breathing zone without the penalty of over-cooling lower part of a room.

The results indicate that there is potential application for this system. Further research needs to be conducted to investigate the effects of various parameters such as air velocity, temperature and locations of supply to improve the performances the new type of ventilation system under perceived control.

Ventilation of ETA 3 rooms in buildings

Ben Bronsema

Delft University of Technology, Faculty of Architecture

Corresponding email: bronconsult@planet.nl

SUMMARY

The European standard prEN 13779 – Ventilation for non-residential buildings [1] distinguishes four categories of decreasing air quality, ETA 1 to 4, for rooms in buildings. We tested the separation effectiveness between a special designed smoking porch, which is a typical ETA 3 room, and the adjoining lobby at Delft University of Technology. The ventilation effectiveness in the smoking porch, which was heated and ventilated by a pseudo-displacement ventilation system, was measured as well.

For the ETS measurements we used an innovative Ultra Fine Particle sensor, newly developed by Philips Research. The measurements were carried out at four different ventilation rates, ranging from 4.8 to 19.2 $dm^3/s.m^2$, with a difference of -1.9 $dm^3/s.m^2$ between supply and exhaust. In each test approximately 40 cigarettes were burned. The measured separation effectiveness was 0.97 in all tests, which is higher than is found in literature on this subject. The ventilation effectiveness, expressed in the Contaminant Removal Effectiveness, is low, which can be attributed to the cold downdraught along the outer facade, which mixes with the supply air. In order to realize a high separation effectiveness, a ventilation rate of 4.8 $dm^3/s.m^2$ with a difference of -1.9 $dm^3/s.m^2$ between supply and exhaust is sufficient. In order to obtain a passable air quality in the smoking porch the ventilation rate should be 5-6 times higher

INTRODUCTION

The European standard prEN 13779 distinguishes four categories of decreasing air quality, ETA 1 to 4, for rooms in buildings. Class ETA 3 represents rooms with a high degree of air pollution due, for example, to vapour emission, processes or chemical pollution which substantially reduce the air quality. Rooms cited as examples are toilets and washrooms, kitchens, some chemical laboratories, photocopying rooms and specially designed smoking rooms. The ventilation of such rooms serves two purposes. Firstly, as much as possible the air from these rooms must be prevented from escaping into the cleaner ETA 1 and ETA 2 rooms. As a parameter for this we have introduced the term separation effectiveness. This is affected by the underpressure to be created in the smoking room, whereby wind loading and infiltration, geometry and position, and the separation between ETA 3/4 and ETA 1/2 rooms play a role. Secondly, the best possible air quality must be provided for the people who visit or work in these rooms. This is affected by the ventilation rate and ventilation effectiveness.

We have conducted measurements in a special smoking porch in the Faculty of Architecture at Delft University of Technology, which can be regarded as ETA 3, and at peak usage even as ETA 4. However, the approach and results of the study can also be applied to other situations.

THE SMOKING PORCH

The smoking porch was initially an outside space in which smokers could shelter from rain and wind, and it is therefore constructed entirely of glass; in this form it was naturally ventilated. The staff then asked if the room could be heated to some degree in the winter months. However, it was important that the smoking room formally retained the character of an unheated room, because it would otherwise have to meet the requirements of the Dutch Building Regulations in terms of thermal construction, facilities, and energy performance. The solution to this was found by ventilating the smoking porch with air extracted from a substation of the central heating system, which in winter has a temperature of approximately 25^0C. By making use of unused residual heat, the smoking porch has no effect as such on the faculty building's energy performance. The overall room temperatures to be achieved are shown in figure 1.

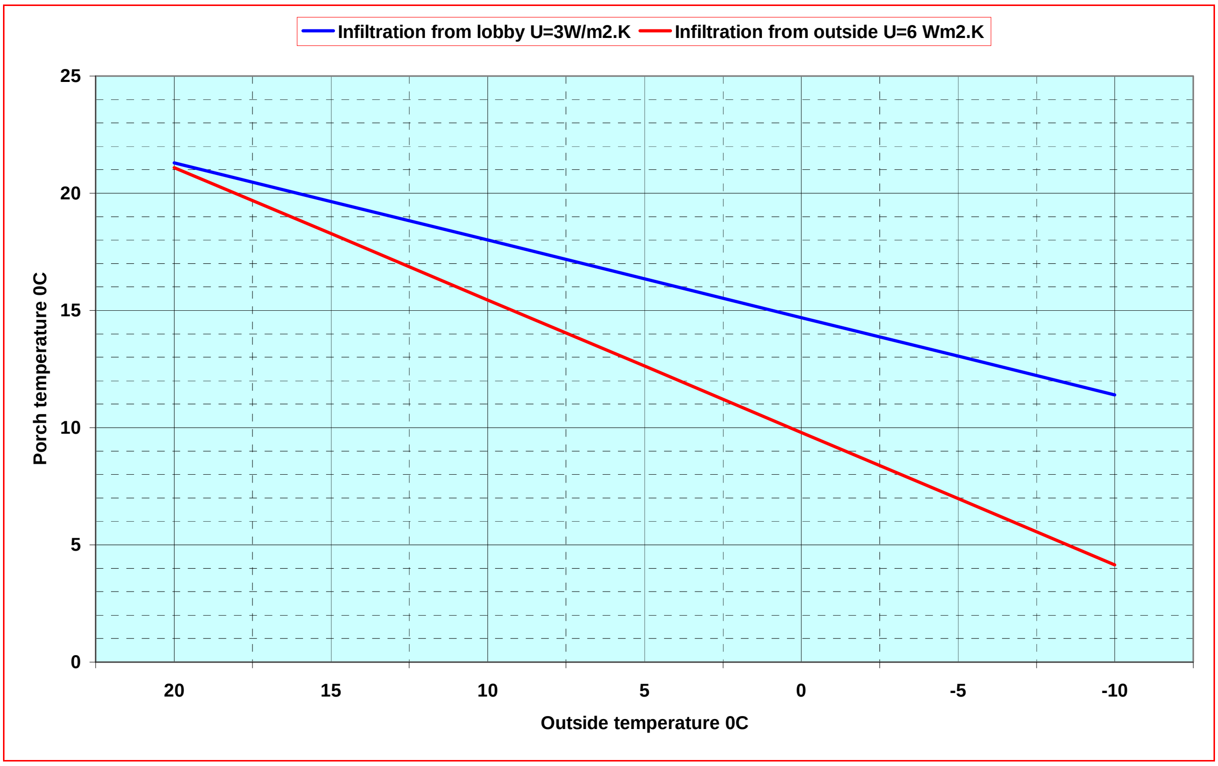

Figure 1 – Room temperature of smoking porch in relation to outside temperature

The floor area of the smoking porch is 29 m^2. The height is 6.85 m and the gross volume is approximately 200 m^3. The porch can accommodate 24 standing smokers at four smoking tables. The wishes of the staff for seating to be included were not met. See figure 2, in which the points of measurement are also shown.

VENTILATION AIRFLOW RATE OF THE SMOKING PORCH

The airflow rate was chiefly determined by the room temperature desired in the porch during the winter months; the temperature of the supply air is a given factor. On the basis of overall calculations, a total airflow rate of 1600 m^3/h has been assumed, equivalent to 8 air changes per hour and 67 m^3/h per person at maximum occupation. Dutch Building Regulations only require a ventilation rate of approximately 500 m3/h for a room such as this.

PRESSURE HIERARCHY AND AIR BALANCE

The smoking room has an east-facing glass outer facade with a surface area of approximately 140 m^2. The infiltration of this facade by a strong east wind cannot be ignored, because it could result in the extraction capacity becoming too small and in the most serious case even create overpressure in the smoking room.

The infiltration flow can be calculated using the formula in [1]:

$$\boxed{V = \sum (a.l) * \sqrt[3]{\Delta p^2}} \qquad (1)$$

Wherein:
V = infiltration flow m^3/h
a = flow coefficient in $m^3/m^1.h.\Delta p^{2/3}$ (For unopenable sections to be set at 0.20)
l = length of cracks in m (Ca 104 m)
Δp = pressure difference across the outer facade in Pa (At 5 Beaufort[1] estimated at ca 50 Pa).

Using formula 1 the maximum infiltration is estimated at ca 300 m^3/h. On this basis the air balance is set as follows:

	Calm	Wind 5 m/s
Exhaust airflow	1600 m^3/h	1600 m^3/h
Infiltration from lobby	300 m^3/h	0 m^3/h
Infiltration from outside	0 m^3/h	300 m^3/h
Supply airflow	1300 m^3/h	1300 m^3/h

The ventilation system is constructed as an upflow system (see below), so in principle it could function as displacement ventilation. For this to work it is important that the airflow is greater than the upward air current of 20 dm3/s (72 m3/h) which is the natural thermal caused by the human body [2]. A supply airflow of 1300 m3/h is therefore sufficient for (1300/72=) 18 persons. At the full capacity of 24 persons, (24*72=) 1.728 m3/h would be needed. However, whether and to what extent the ventilation system is suitable to function as displacement ventilation is discussed below.

THE VENTILATION SYSTEM

The smoking porch is equipped with four round tables mounted on steel tubes Ø 323.9 x 4 mm with perforations Ø 10 mm, centre to centre 60 mm, through which air is supplied. The speed at which air is blown in through the perforations is 5 m/s, aiming at a fast reduction in air temperature. If the temperature of this air were too high it would adversely affect the upflow system. On the other hand, the high speed of the air blown in and the inherent induction of room air counteract the intended displacement effect. Partly due to the cold downdraught along the outer facade of the porch, despite the supply of ventilation air at a low level, hardly any displacement effect has been found to occur (see below).

The air is extracted high up in the porch via steel tubes Ø 193.7 x 4 mm measuring ca 6 m in length, which are installed concentrically in the air supply tubes – see figure 3.

---

[1] An east wind at force ≥ 5 Beaufort is rare in the Netherlands.

ANALYSIS OF THE VENTILATION CONCEPT

Separation effectiveness:

The separation effectiveness is defined as

$$\eta_s = \frac{C_i - C_e}{C_i} = 1 - \frac{C_e}{C_i} \qquad (2)$$

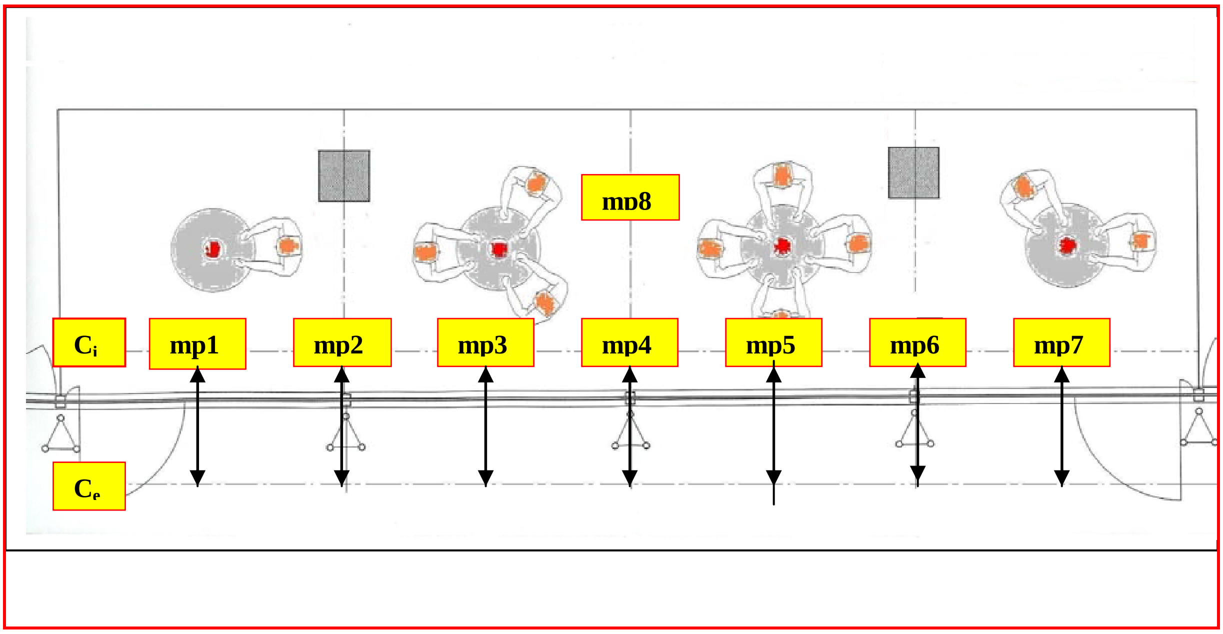

Figure 2 – Floor plan of the smoking porch with measuring points

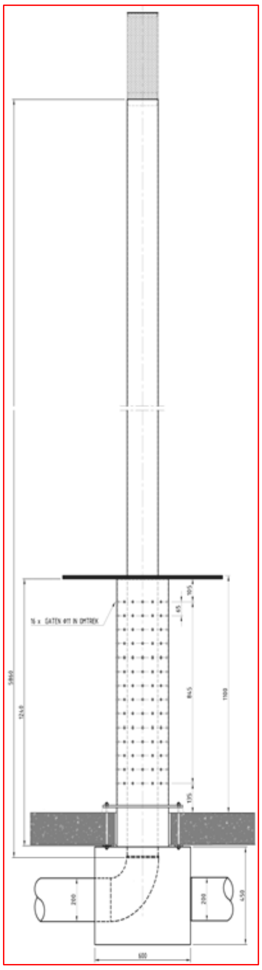

Wherein

C_i = ETS concentration in the porch

C_e = ETS concentration in the lobby outside the porch

The ETS concentrations in the smoking room are measured at breathing height between 1.1 en 1.8 at respectively $C_{i.1,1}$ en $C_{i.1,8}$

It is not easily possible to develop an analytical model to predict the separation effectiveness. The dissipation of ETS to the lobby can perhaps be modelled, but the ETS concentration in the lobby is dependent to a large extent on the volume of the room, the air movement and the ventilation of the lobby. The separation effectiveness can therefore only be determined on the basis of measurements.

Figure 3.

Ventilation effectiveness:

The ventilation system is set up as an upflow system, but does not meet the conditions for displacement ventilation because:

- The temperature of the supply air is higher than the room temperature. After all, the air supply also serves to warm the porch.
- The doors of the porch are frequently opened and closed for smokers to leave and enter.
- The cold downdraught along the outer facade causes a downward current of contaminated air.

The smoking porch is fitted with hinged glass doors, which when opened and closed 'pump' a quantity of air from the porch into the central lobby and vice versa. Under isothermal conditions this quantity is approximately 672 dm^3 a time [3]. With an average occupation of 15 smokers, each of whom spend 15 minutes in the porch, the doors are opened and closed 120 times an hour (twice per smoker), whereby ($120*672*10^{-3}$=) 80 m^3/h ETS is transferred into the lobby. In relation to the ventilation capacity of 1600 m^3/h this is a comparatively small amount, which in itself need not disturb the upflow of displacement ventilation too seriously.

The cold downdraught along outer facades that are made only of single glazing is more of a problem. The convection flow that arises along a vertical surface can be calculated using the following formula [3]. The formula applies to turbulent flows which in this case will certainly occur.

$$\boxed{q_{v,z} = 2.75\Delta\theta^{0.4} z^{1.2}} \qquad (3)$$

Wherein:

$q_{v,z}$ = vertical airflow -$dm^3/s.m$

$\Delta\theta$ = temperature difference -K

z = height of the vertical surface -m

The outer facade of the porch has a surface area of (H*B= 6.65*16.40) 109 m^2. The temperature difference $\Delta\theta$ between the air in the smoking porch and the glass surface depends on the outside temperature and the wind speed. The lower the temperature outside and the higher the wind speed, the more the temperature in the porch will fall and with it the inner surface temperature of the outer facade. The cold downdraught has been quantified using formula (3); figure 4 shows the results.

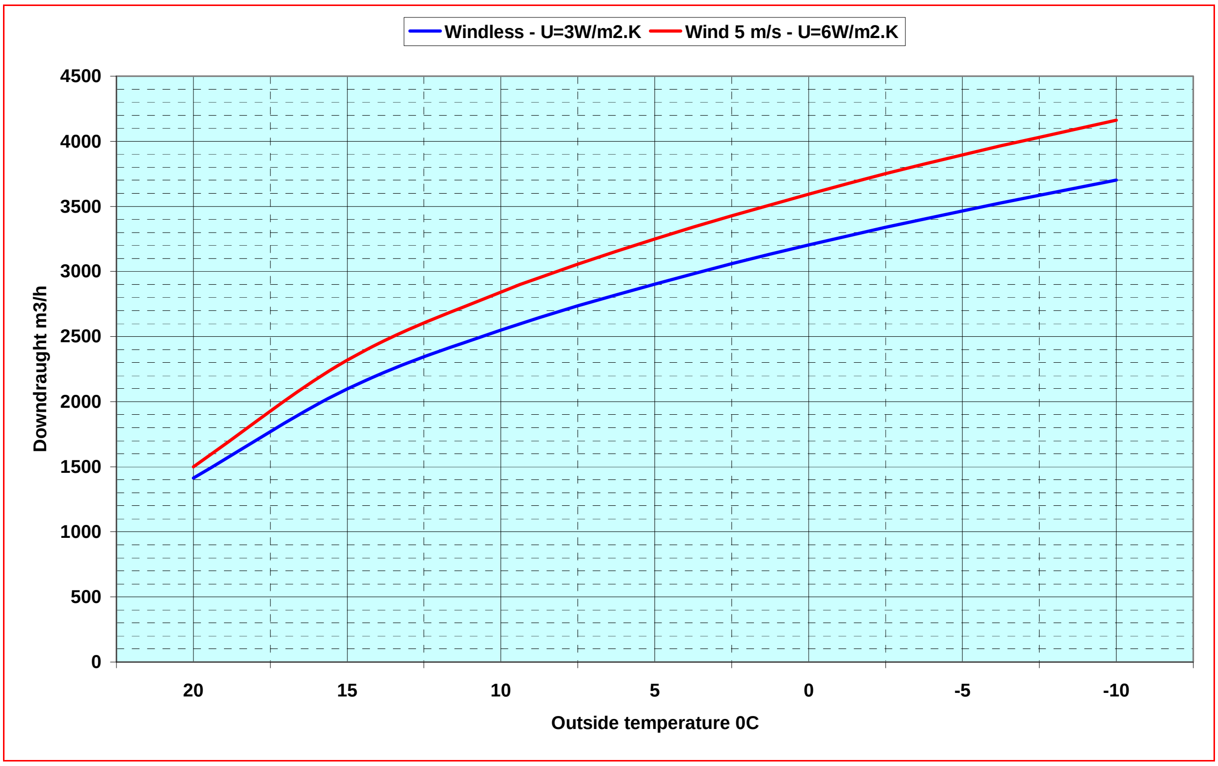

Figure 4 – Downdraught in m^3/h in relation to outside temperature

At an outside temperature of -3^{0}C, the lowest occurring during the day, a downdraught in the order of 3500 m^3/h occurs. But also at a more moderate outside temperature such as 15^{0}C the downdraught is still greater than 2000 m^3/h.

This downdraught is considerably greater than the supply flow, so displacement ventilation hardly occurs. The lower the outside temperature falls, the more the system assumes the character of mixing ventilation. This is not important for separation effectiveness, but it is for the air quality in the porch, as the downward airflow set in motion by the cold downdraught is contaminated with ETS.

DETERMINATION METHOD FOR ETS CONCENTRATION

The determination of ETS concentrations according to the international standards ISO 18144 and ISO 18145 is a time-consuming and expensive matter and moreover it cannot be carried out online. The ETS concentration has therefore been determined with the aid of an Ultra fine Particle (UFP) Sensor [4] developed by Philips Research in Eindhoven. Philips has made a prototype of this innovative sensor available for the measurements to be conducted. They therefore provide no data on nicotine, 3-EP and solanesol concentrations in the ETS, which are also not required by the present measuring programme given that both for separation effectiveness and ventilation effectiveness relative values are concerned.

CONCENTRATION MEASUREMENTS

During three measurement sessions, first the separation effectiveness and then the ventilation effectiveness were determined with the aid of the UFP sensor. The values measured by the sensor are in pA. It should be noted that a considerable inhomogeneity was recorded, both in time and in place. The values measured are ± 10%.

For the measurements of separation effectiveness a mobile table was used with two surfaces at 1.0 and 1.6 m high, on which the measuring pump and analysis equipment was placed. Separation effectiveness was calculated from the values measured using equation (2).

For the measurements of ventilation effectiveness a hand-operated lift table was used. Measurements were taken at heights of 0.1 – 1.1 – 1.8 – 3.0 en 3.5 m; this was the greatest height it was possible to reach. It was therefore not possible to take the desired measurement next to the extraction point. The ventilation effectiveness, expressed in Contaminant Removal Effectiveness CRE [5], has not therefore been calculated on the basis of the concentration in the exhaust C_a, but of the concentration at a height of 3.5 m. The CRE value has been calculated respectively for a sitting height of 1.0 m and a breathing height of 1.6 m using the formula

$$\boxed{CRE = \frac{C_{3.5}}{C_{1.0}} \ and \ \frac{C_{3.5}}{C_{1.6}}} \qquad (4)$$

The measuring points are shown in figure 2. The ventilation flows, temperatures and number of cigarettes burnt are shown in table 1. For each cigarette the doors were briefly opened and closed either one or two times.

Table 1 – Measurement conditions

No.	Supply flow m^3/h	Exhaust flow m^3/h	Room temp. ^0C	Outside temp. ^0C	No. of cigarettes
1	1.310	1.640	20.6	16.9	49
2	720	1.060	20.6	16.4	42
3	215	500	20.6	16.4	41

MEASUREMENT SESSIONS

Session 1A – Separation effectiveness η_s

The values measured in pA are shown in table 2:

Table 2 – Values measured in measurement session 1A

concentr.	height	mp1	mp2	mp3	mp4	mp5	mp6	mp7	gem.
C_i	1.0 m	1.00	0.95	0.65	0.70	0.70	0.51	0.36	0.70
C_i	1.6 m	1.10	1.50	1.10	1.50	1.35	1.20	1.72	1.35
C_i	av.	1.05	1.23	0.88	1.10	1.03	0.86	1.04	**1.03**
C_e	1.0 m	0.04	0.04	0.04	0.04	0.04	0.04	0.04	0.04
C_e	1.6 m	0.03	0.03	0.03	0.03	0.03	0.03	0.03	0.03
C_e	av.	0.035	0.035	0.035	0.035	0.035	0.035	0.035	**0.035**

Separation effectiveness $\boxed{\eta_s = \frac{C_i - C_e}{C_i} = 1 - \frac{C_e}{C_i} = 1 - \frac{0.035}{1.03} = 0.97}$

Session 1B – Ventilation effectiveness CRE:

The values measured in pA at mp 8, and the calculated CRE values $CRE_{1.0}$ *and* $CRE_{1.6}$ are shown in table 3.

Table 3 – Session 1B measurements and results for Contaminant Removal Efficiency CRE

height m	concentration at mp 8	
0.1	1.30	$CRE_{1.0} = \frac{C_{3.5}}{C_{10}} = \frac{1.4}{1.1} = 1.7$
1.0	1.10	
1.6	1.35	$CRE_{1.6} = \frac{C_{3.5}}{C_{1.6}} = \frac{1.4}{1.35} = 1.04$
3.0	1.35	
3.5	1.40	

Session 2A – Separation effectiveness η_s

The values measured in pA are shown in table 4:

Table 4 – Values measured in measurement session 2A

concentr.	height	mp1	mp2	mp3	mp4	mp5	mp6	mp7	av.
C_i	1.0 m	1.38	1.40	1.23	1.35	1.32	1.31	1.28	1.32
C_i	1.6 m	1.74	1.60	1.30	1.65	1.55	1.65	1.75	1.60
C_i	av.	1.56	1.35	1.27	1.50	1.44	1.48	1.52	**1.46**
C_e	1.0 m	0.05	0.05	0.05	0.05	0.05	0.05	0.05	0.05
C_e	1.6 m	0.05	0.05	0.05	0.05	0.05	0.05	0.05	0.05
C_e	av.	0.05	0.05	0.05	0.05	0.05	0.05	0.05	**0.05**

Separation effectiveness, calculated using the average values for C_i en C_e from table 2, is calculated as follows: $\boxed{\eta_s = \frac{C_i - C_e}{C_i} = 1 - \frac{C_e}{C_i} = 1 - \frac{0.05}{1.46} = 0.97}$

Session 2B – Ventilation effectiveness CRE

The values measured in pA at mp 8, and the calculated *CRE* values *$CRE_{1.0}$ en $CRE_{1.6}$* are shown in table 5.

Table 5 – Session 2B measurements and results for Contaminant Removal Efficiency CRE

height m	concentration at mp 8	
0.1	1.20	$CRE_{1.0} = \frac{C_{3.5}}{C_{1.0}} = \frac{2.00}{1.45} = 1.38$
1.0	1.45	
1.6	1.50	$CRE_{1.6} = \frac{C_{3.5}}{C_{1.6}} = \frac{2.00}{1.50} = 1.33$
3.0	1.65	
3.5	2.00	

Session 3A – Separation effectiveness η_s

The values measured in pA are shown in table 5:

Table 6 – Values measured in measurement session 3A

concentr.	height	mp1	Mp2	mp3	mp4	mp5	mp6	mp7	av.
C_i	1.0 m	1.95	1.80	1.80	2.20	2.10	2.05	2.25	2.02
C_i	1.6 m	2.38	2.28	2.13	2.05	2.03	2.18	2.25	2.19
C_i	av.	2.17	2.04	1.97	2.13	2.07	2.12	2.25	**2.10**
C_e	1.0 m	0.06	0.08	0.08	0.08	0.08	0.08	0.08	0.077
C_e	1.6 m	0.06	0.07	0.07	0.07	0.07	0.08	0.08	0.071
C_e	av.	0.06	0.075	0.075	0.075	0.075	0.08	0.08	**0.074**

Separation effectiveness, calculated using the average values for C_i en C_e from table 2, is calculated as follows: $\boxed{\eta_s = \frac{C_i - C_e}{C_i} = 1 - \frac{C_e}{C_i} = 1 - \frac{0.074}{2.10} = 0.965}$

Session 3B – Ventilation effectiveness CRE

The values measured in pA at measurement point 8, and the calculated CRE values CRE1.0 en CRE1.6 are shown in table 6.

Table 7 – Session 3b measurements and results for Contaminant Removal Efficiency CRE

height m	concentration at mp 8	
0.1	2.50	$CRE_{1.0} = \frac{C_{3.5}}{C_{1.0}} = \frac{3.00}{2.50} = 1.20$
1.0	2.50	
1.6	2.56	$CRE_{1.6} = \frac{C_{3.5}}{C_{1.6}} = \frac{3.00}{2.56} = 1.17$
3.0	3.00	
3.5	3.00	

DISCUSSION

The concentrations measured in pA using the UFP sensor in the smoking porch are thrown into relief when they are compared with typical values in reasonably clean outside air of 0.02 pA. When it is warm outside, with moderate traffic the sensor reading rises to 0.05 – 0.06 pA. In a car on the motorway peak concentrations occur in the range of 0.2 – 0.5 pA. The air quality in the porch can therefore be regarded as being relatively poor, even at higher ventilation capacities. ETS is an infamous source of air contamination in indoor environments!

The concentration in the porch decreases sharply with increasing ventilation capacity; see figure 5. Extrapolating logarithmically, the concentration at 3.000 m3/h would come out at 0.5 pA, which would undoubtedly reduce the ETS absorbance in the clothing of visitors to the porch and hence the distribution of ETS in building. The question is whether it would also improve the air quality measurements. ETS is a complex cocktail with thousands of components. In most cases ETS concentration is below the chemical/physical detection limit. [6]

For the rest, the clear relationship between ETS concentration and ventilation capacity provides an excellent possibility for a demand controlled ventilation system. The signal from the UFP sensor can be included in the control circuit of an air quality controller. Having made enquiries within the industry, the author is not aware of any other sensors with which this possible.

The potential field of application of the UFP sensor is not limited to smoking rooms. This sensor for ventilation control can be applied anywhere where ultra fine particles ($PM_{2.5}$) form a risk. For future applications a multifunctional room sensor for temperature, relative humidity, CO_2 and $PM_{2.5}$ is also being considered.

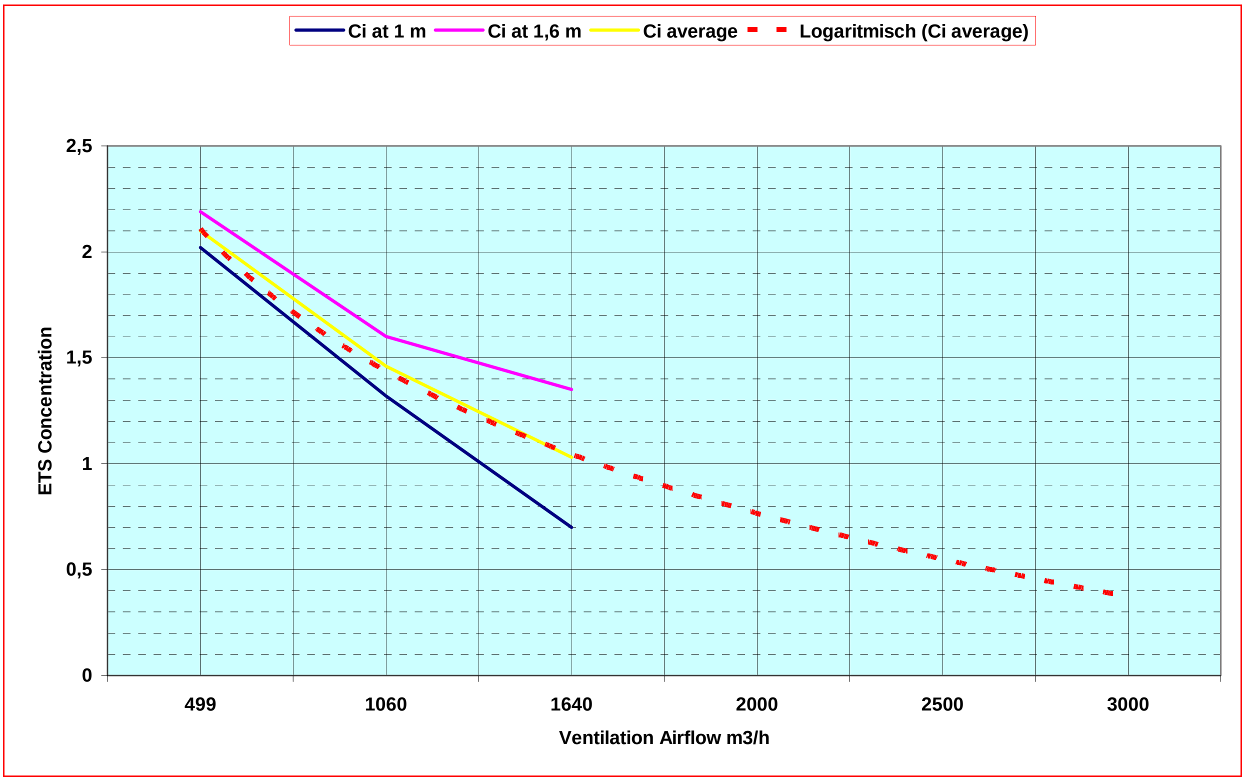

Figure 5 –ETS Concentration in smoking porch in relation to ventilation capacity

CONCLUSIONS

- At a value of 0.97 the separation effectiveness is extremely high, also at low ventilation capacities.
- The ventilation effectiveness is low. This can be attributed to the cold down draught along the porch outer facade, and to the ventilation system as such.
- To realise a high separation effectiveness, a difference between supply and exhaust flow of -1.9 $dm^3/s.m^2$ is sufficient.
- To improve the IAQ in the smoking porch the cold down draught should be decreased, combined with an increase in ventilation flow.

Ventilation Design in Large Enclosures for Sports Events using CFD: the Halls of the "Città dello Sport" in Rome.

Gianfranco Caruso, Livio De Santoli, Matteo Mariotti

University of Rome "La Sapienza" – Centro di Ricerca CITERA - Italy

Corresponding email: livio.desantoli@uniroma1.it

SUMMARY

Buildings with large enclosure often present unresolved problems related to energy and air flows such as unwanted thermal stratification, local overheating, uncontrolled contaminant spreading. These kind of constructions are often found in unique buildings where innovative designs are developed. Consequently, there exists no previous experience and very careful analysis on the ventilation design is advisable [1]. This is particularly true for the halls of the "Città dello Sport" in Rome, designed by Santiago Calatrava, because of their singularity in term of dimension and shape. The CFD simulations here presented are playing a significant role in the on to go design of these unique large enclosure buildings for the optimisation of the HVAC strategies.
The simulated heat, cooling and ventilation system defines three different climatic zones in order to minimize the energy consumption:

- the swimming pool plane and the playground where optimal condition for the athletes have to be assumed;
- the stands where the people watching the event is placed;
- the huge volume under the roofing where particular climate conditions aren't required.

The simulated system provides a particular ventilation system using a controlled airflow to heat and cool the mass of the stands, which afterwards operates directly in the zone occupied by the spectators.
The swimming pool level and the basketball playground are heated, cooled and ventilated by a dedicated HVAC system.
Air velocity, temperature and relative humidity fields in the indoor space of the building, in condition of maximum external and internal thermal loads have been obtained from simulations, in order to evaluate suggested value for the designing process of the HVAC system.

INTRODUCTION

Large enclosures have become a major feature of modern building design. Spaces such as atria and covered areas are used in all varieties of buildings including office complexes, shopping malls, airports and sport halls. Essentially, they create an environment protected from the outdoor climate in which a wide range of activities is possible. However such spaces demand very careful design to ensure good indoor air quality and thermal comfort.
Common problems in poorly designed buildings can include oversizing of equipment, excessive energy requirements and poor indoor environment. These problems are usually caused by a lack of knowledge and guidance at the design stage.
Ventilation of large enclosures deserves careful attention by designer for the following reasons [1]:

- usually only a small portion of the entire volume is occupied, therefore energy efficiency may be achieved by special strategies aimed at directing ventilation air and thermal conditioning to the occupied zone;
- vertical air streams driven by temperature differences gather large momentum in large spaces: resultant cold down-drafts from vertical surfaces may have severe comfort implication;
- large enclosures are often found in unique buildings where no previous experience exists.

The “Città dello Sport” will be realized in Rome, located within the University Campus of “Tor Vergata”, to host the World Swimming Championships in 2009 and Volley Championship in 2010. The complex could be also presented as a main infrastructure for the Olympic Village for Rome Games candidature in 2016.
The complex, designed by the architect Santiago Calatrava, includes a large covered building for indoor competitions, composed from two equivalent, but functionally independent, pavilions: one with a polyvalent function (basket, volley) and the other as an Aquatics Stadium for swimming [2]. Volumes and shapes of Pavilions are similar Of but the presence of different occupancy both with the installation of pools on the case of swimming pools need two different HVAC system strategies.

Occupant comfort in these types of environments is affected by the air temperature and humidity, the air movement and solar radiation. The air temperature in the large space is mainly dependent on ambient conditions but is also affected, during summer, by direct solar radiation warming building elements including the roof. The extent of natural ventilation also affects the air temperatures, as greater air exchange will reduce the effect of localised heat sources.
The design has to include specific design issues which have been addressed as multidisciplinary team programs with close liaisons between engineer and architect, often utilising state of the art techniques to resolve them. The key design issues that need to be solved by integrated design solutions are:

- Materials selection
- Air flow analysis
- Energy efficiency
- Acoustic strategy
- Lighting

It is increasingly becoming common to use Computational Fluid Dynamics (CFD) techniques as a cost effective and innovative method to assist in the engineering design process to achieve the desired outcomes [2]. By using CFD at an early stage of the engineering design process, a large number of investigations related to spectator comfort aspects by the natural or mechanical (HVAC) ventilation of the indoor environment in sport complexes can be performed.

A preliminary analysis of the air ventilation in the two large spaces has been performed using a commercial CFD program.
The simulated heat, cooling and ventilation system defines different climatic zones in order to minimize the energy consumption:

- the swimming pool plane and the playground where optimal condition for the athletes have to be assumed;
- the stands where the people watching the event is placed;

- the huge volume under the roofing where particular climate conditions aren't required.

BUILDING DESCRIPTION

The complex will extend on an area of approximately 50 hectares within the university campus of Tor Vergata, Rome and includes, among other systems, the realization of a great covered structure for the indoor sports (Fig. 1). The Campus is organized in order to accommodate great events. The main building is realized with two equivalent pavilions (Fig. 2), located symmetrically and characterized by the same shape. Inside of a pavilion is the playground and in the other is localized the covered swimming pools. The two structures have independent function and they can offer different events at the same time.

Fig. 1 – "Città dello Sport", Rome – General view and main building [1]

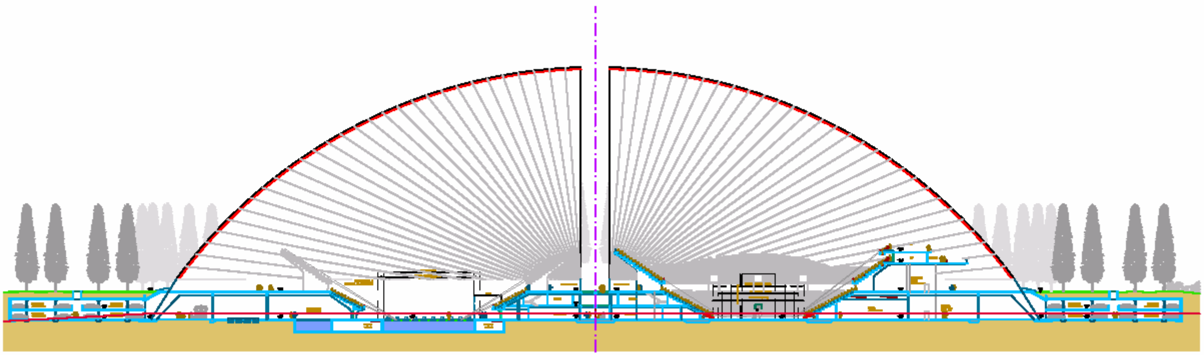

Fig. 2 – Section of the Swimming Hall and the Palasport [1]

The structure of the cover is quite light, based on steel with opaque and transparent panels (the latter being 30% of the total surface). 4,000 places are located in the Swimming Hall and 15,000 spectators are foreseen in Palasport. The structure has a maximum height of about 70 m and the main axes of the two bases are 130 x 90 m, for a volume greater than 500.000 m^3 for each pavilion. The game field of the Palasport is 30 x 45m. Two pools are placed in the Swimming Hall (53 x 25m and 25 x 25m for the dives and a swimming pool 50 x 10m for training. All around the main building are located areas of service, arenas, laboratories, didactic classrooms, structures, stores, offices, warehouses. The structures are completed and connected with a great park, polyvalent fields and athletics tracks.

METHODOLOGY

To analyze the air flow inside the two structures a commercial CFD solver based on the finite volume technique has been used.
CFD simulation of the flow field in large enclosures presents many difficulties due to its large size, the complexity of the flow field and of the geometries. Furthermore, a high number of cells is needed to represent the flow. This adds to the complexity of simulating phenomena such as turbulence and increases the risk of numerical errors. In large spaces, airflow tends to be dominated by buoyancy forces. These are stimulated by high degree of coupling with the external volume environment, relevant to represent accurately surface heat transfer processes such as natural/mixed convection, solar radiation, long wave thermal radiation, heat transfer through external walls and structural heat storage.
Accurate prediction of such a flow field is very difficult and, the popular k-ε turbulence models have to be carefully controlled step by step during the calculation to achieve reasonable results.
In the present calculations the fluid (air-water mixture) has been considered as an "incompressible" perfect gas: the pressure does not influence the density of the fluid, while the effect of the temperature is properly considered.
The geometric models of the buildings includes almost 150,000 nodes, approximately 800,000 cells and 200 faces for boundary conditions for the Swimming Arena, and about 220.000 nodes with 1,000,000 cells for the basketball hall. The nodalization is of triangular type for faces and tetrahedral for the cells. The calculation volume is, as already said, approximately 554,000 m^3 for each hall, the envelope area in the model is 25,000 m^2, 8,000 m^2 of which transparent glass and 17,000 m^2 as opaque surface (Fig. 3).

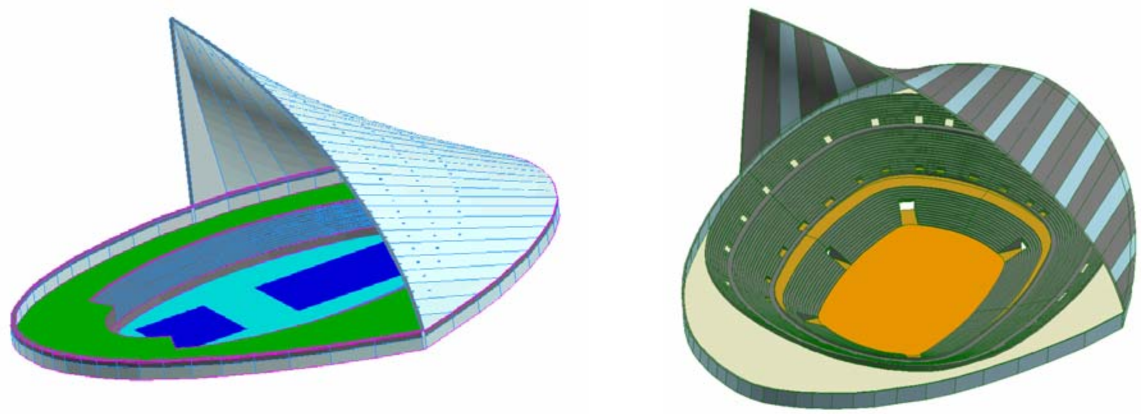

Fig. 3 - Swimming Hall (left) and the Palasport (right) CFD models.

The lateral external walls area outlined under level 8 m are of approximately 4,200 m^2. Inner surfaces thermally connected to temperature controlled environment have been also considered.
The cover of the buildings has been characterized by an equivalent thermal conductivity to take into account the different thermal resistances (opaque and transparent panels).
Also spectators have been considered as sensible and latent heat sources.
Risk of condensation on the internal part of the cover is also evaluated in order to prevent dangerous corrosion formations on the steel structures.

HVAC System: in the Swimming Hall two mechanical systems are present: 88 high velocity nozzles for the pool bowl, located under the lower row of seats, 2.5 m above the pool level. This system has a total air flow capacity of 132,000 m^3/h. A second system allow to introduce air at controlled temperature and humidity along the perimeter of the building, above the spectators level; it is mainly devoted to control the humidity in the large space to avoid condensation on the cover inner surface. The total air flow capacity of this system is 128,000 m^3/h.
The humid air at the higher levels pass through gratings strategically located in the upper part of the cover, and is partially recirculated by return channels to reduce energy load.
The basketball hall is equipped with four different dedicated HVAC systems: five inlet groups of four nozzles each supplying an overall flow rate of 30,000 m^3/h for the playground.
A plenum under the seats of the lower order is installed to control the environment conditions for the spectators providing a total flow rate of 96.000 m^3/h at low velocity. A second plenum with a flow rate of 104,000 m^3/h is installed under the three last rows of the medium order of seats. Peripheral injections (64 units) with a total flow rate of 120.000 m^3/h are placed along the base of the roof in order to heat the "ring" around the arena (Fig. 4).
In the slab surrounding the tribunes a radiant heating floor is installed to increase the mean air temperature in the enclosure of the building.
Windows can be opened along the main arc of the building envelope from the highest point, each with an area of about 6 m^2.

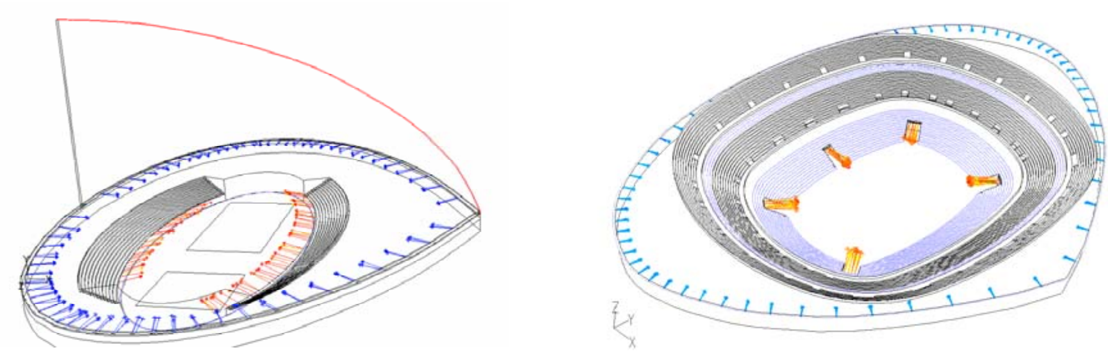

Fig. 4 - Swimming Center (left) and Palasport (right) HVAC systems.

The analyses presented concern the air flow simulation in winter conditions and in two different configuration: 1) natural ventilation in the closed space, to evaluate the air flow due only to the buoyancy driven by the heat sources in the lower zone and the cold envelope surface; 2) HVAC system in operation, to evaluate the effects of the comfort conditions for spectators.

RESULTS

SWIMMING POOL HALL - To analyze the air distribution, a CFD analysis of the space was conducted establishing air flows, temperature and relative humidity.
In addition to the normal concerns of adequate temperature comfort control the ventilation system design within an indoor swimming pool complex also needs to address the issue of maintaining sufficient fresh air ventilation within the occupied zones of the pool hall. This is in order to provide the necessary removal of water vapour (for relative humidity control) and chemical vapours (eg, chlorine) that are evaporated from the pool surfaces [1].

In the winter season, a first calculation was performed considering the enclosure with HVAC system not operating. The cold surfaces of the envelope and the heat source at pool and public levels generate a main vortex above the deck level behind the left public stands (Fig. 5a). Above the pool, hot air is buoyancy driven upwards and towards public stands, with velocities generally lower than 0.3 m/s with some spots up to 0.5 m/s (Fig. 5b) . Temperatures in the spectators zone are around 15 °C (Fig. 5c) at 50 cm height.

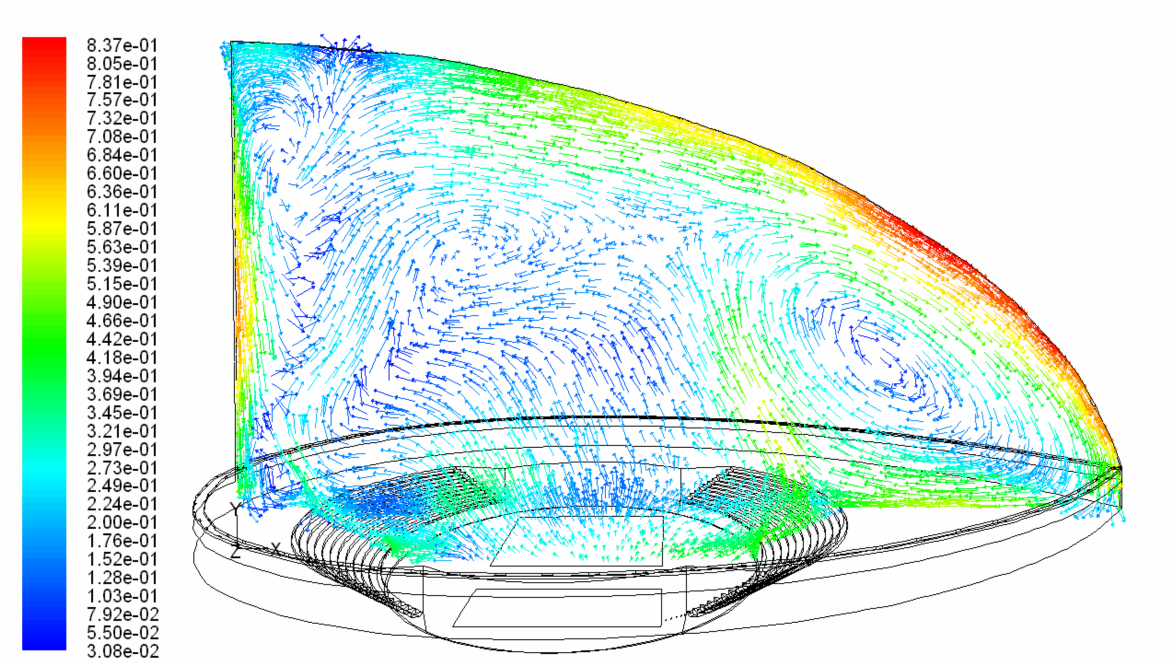

Fig. 5a – Swimming Center: Winter and HVAC off – Air flow in the symmetry plane

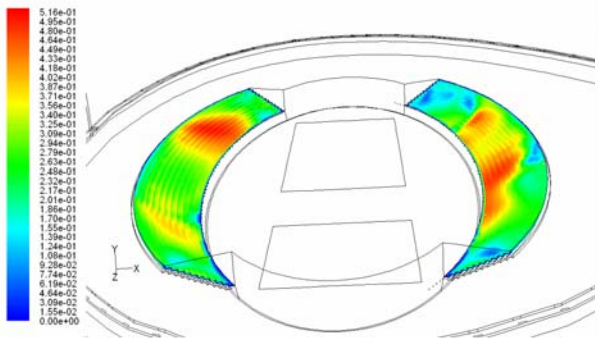

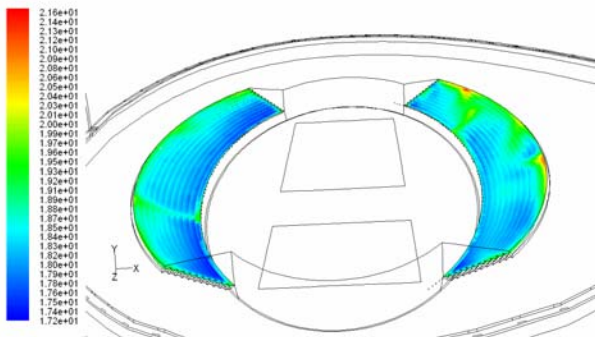

Fig. 5b – Velocity map at public stands Fig. 5c – Temperature map at public stands

The effect of HVAC system is to enhance comfort for spectators. The high speed nozzles in the pool region are foreseen to separate the pool bowl from the huge higher volume. Return air should be drawn from the pool level grating surrounding the pool to draw off air at its most contaminated point in terms of odours, particularly chloramines and particulate matter. Flow inlet velocity and nozzle orientation need to be adjusted because of direction of air velocities coming from the cover, which is forced towards the right public stands. It could be convenient to verify the elimination of inlet nozzles placed on left tribune and/or their substitution with outlet ones. (Fig. 6a). Air velocities in the spectators zone are now higher than in the previous calculations (> 0.4 m/s, Fig. 6b), and temperatures are much more higher (around 29°C) (Fig. 6c).

Air from the perimeter of the building, above the public level, helps to control humidity below 60% to avoid the risk of condensation on the inner surface of the cover during the winter season.

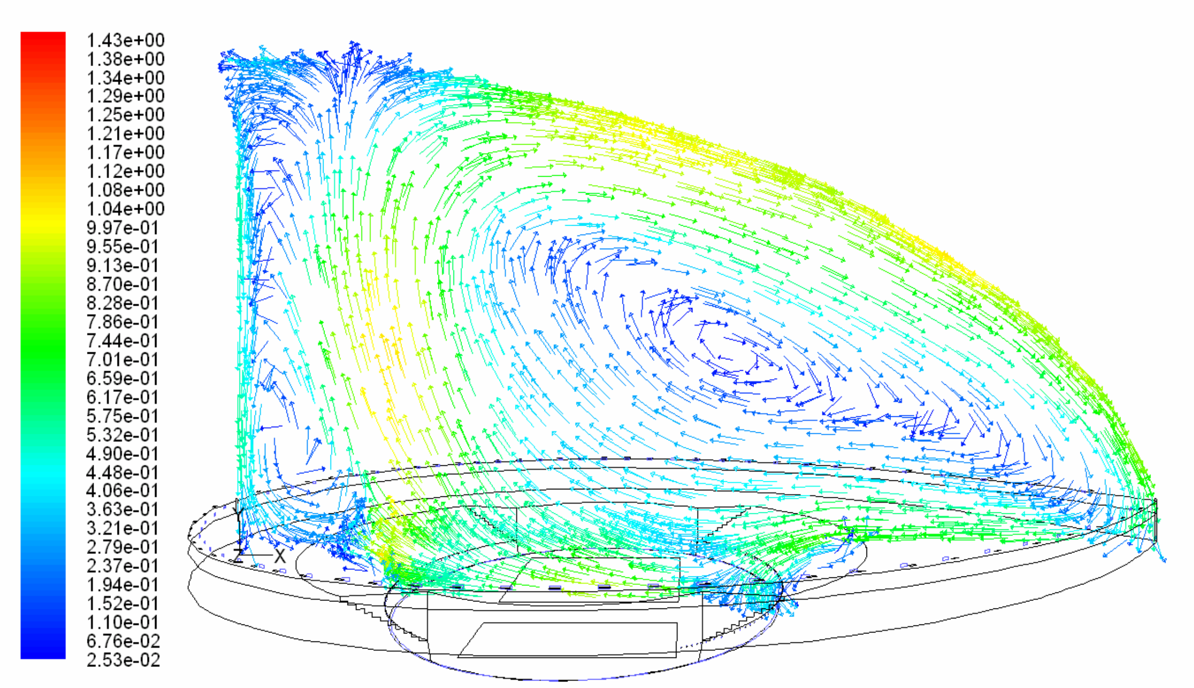

Fig. 6a – Swimming Center: Winter and HVAC on – Air flow in the symmetry plane

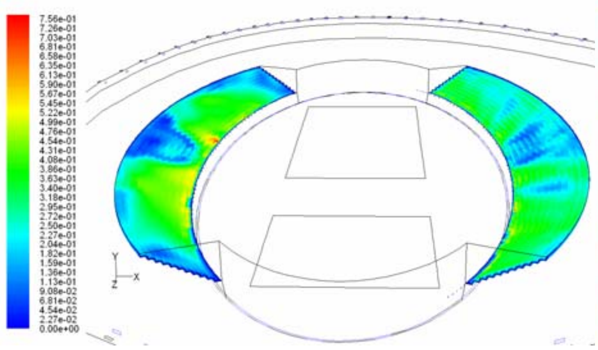

Fig. 6b – Velocity map at public stands

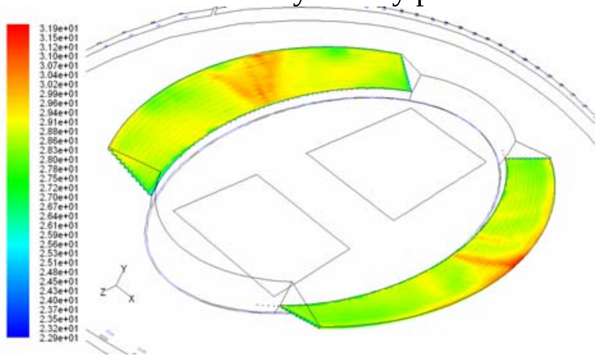

Fig. 6c – Temperature map at public stands

BASKET AND VOLLEY HALL: The matter of acceptable air quality and comfortable environmental conditions in this building where a maximum capability of 15,000 spectators is foreseen, is the major concern. Proper ventilation and supply of fresh air play a significant role in the control of indoor air quality and thermal comfort for the intense metabolism due to the overcrowding of people. Therefore, this study investigates numerically the environmental conditions prevailing in the basketball hall in winter, with full spectators affluence in order to optimize the HVAC system evaluating also the risk of condensation on the inner surface of the cover.

The first simulation presented considers the HVAC disabled to evaluate the flow regime established by the buoyancy forces as in the swimming hall. A boundary layer of cold air descending along the vertical wall and a warm air column upward in the centre of the playground generate a main vortex in the large enclosure of the hall. The air downward the cold wall separates in two different flow on top of right tribunes: one investing the spectators at 0.85 m/s first row of the seats and the other reaching the floor level at 8.00 m generating a zone with positive pressure under the top tribunes. This generates an inflow of air trough the entrances of the top level which combines with the other descending from the upper levels.

The air velocity measured at 1 m over the tribune varies between 0 and 0.85 m/s with a temperature around 13°C. This fluid dynamic regime established spontaneously separates the volume of the enclosure in two zones: the big hall where spectators and athletes stands, and the ring zone which surrounds the tribunes.

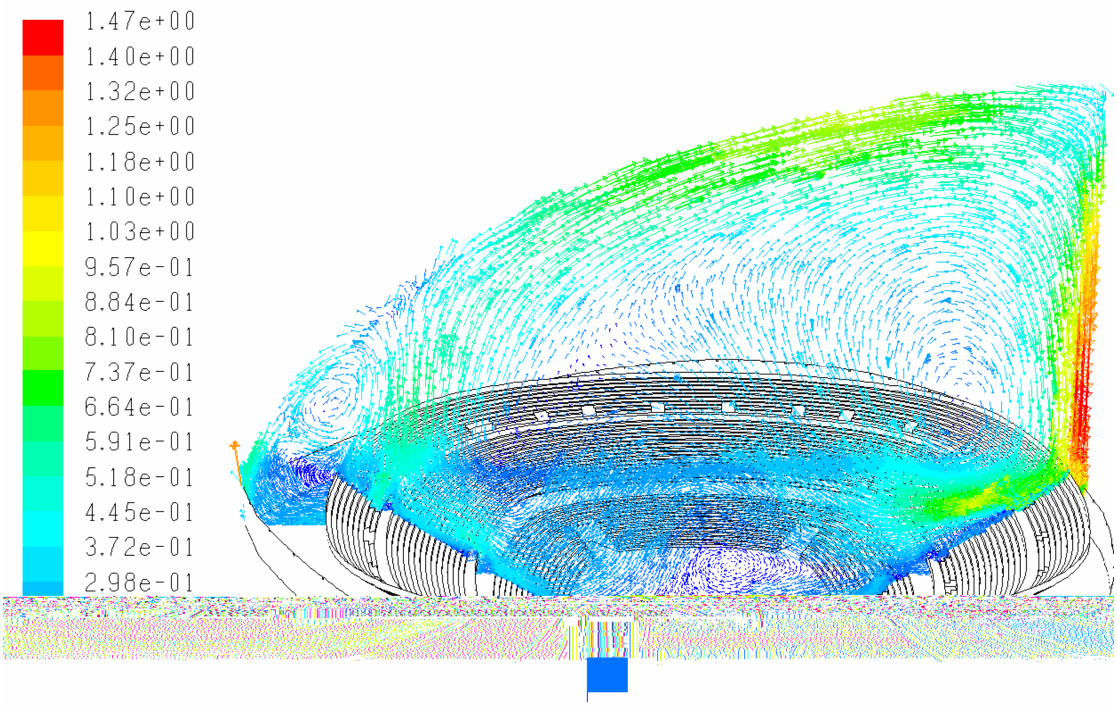

Fig. 7a – Palasport: Winter and HVAC off – Air flow in the symmetry plane

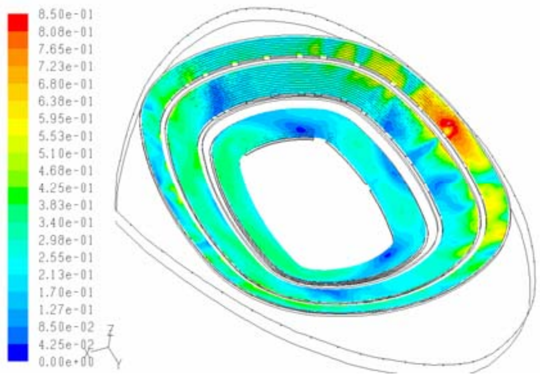

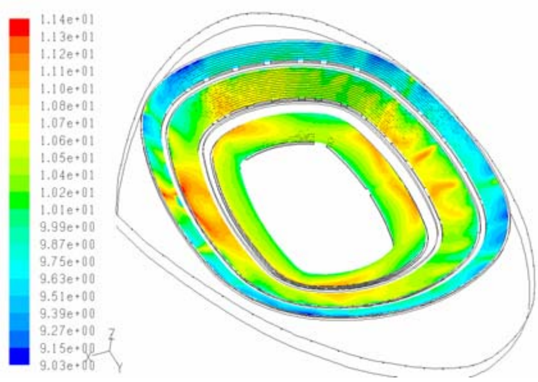

Fig. 7b – Velocity map at public stands   Fig. 7c – Temperature map at public stands

These results show that a HVAC system is needed to obtain proper comfort conditions for people standings on the tribunes in term of temperature.
The activation of the mechanical ventilation system increases the fluid dynamic regime established by the buoyancy forces. In general, the air velocity values are higher ranging from 0.5 m/s to 1.5m/s. Also temperatures increase up to 15°C in the upper order of the tribune and 22°C in the parterre seats. Optimal values of temperature and humidity near people is assured by the plenum inlets under the seats. Part of this controlled flow rate is exhausted by the outlet at the top of the parterre tribune and under the stairs of the upper order of the seats. The air injected by inlet units at the base of the roof generates a turbulent motion which mixing and heating the air coming from the cold boundary layer of the cover in the zone under the

tribunes. The main vortex in the hall sweeps the zone of spectators assuring a good renovation of the exhaust air. The behaviour of the nozzles placed at the top of the vomitoriums depends on the prevalent flow regime. Indeed the units placed at the vertex entrances sweep efficiently the playground, differently by the injections on the symmetry access which reach immediately rises higher zones over the field.

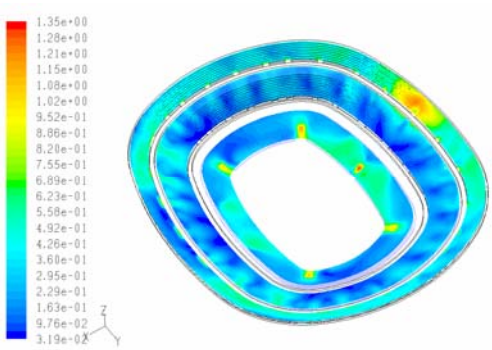

Fig. 8b – Velocity map at public stands

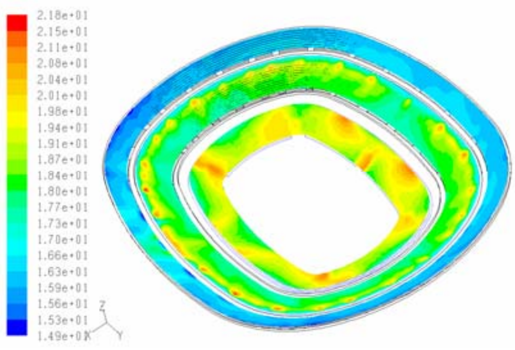

Fig. 8c – Temperature map at public stands

DISCUSSION

SWIMMING HALL: During the winter season, humidity control within the large space and envelope could be assured by the HVAC system. Also public and athletes comfort can be well controlled, with minor adjustment in flow rates and orientation of nozzles.
Summer conditions simulation is actually in progress. During summer, the solar radiation and the heat gains for public and lighting makes the design of HVAC system more challenging. In

fact, the main 50 m competition pool is kept at 26-29°C. During a major event pool water temperatures in the competition pool are likely to around 28°C. To ensure comfort for public and athletes and in consideration of energy use, the air temperature is generally kept 1°C above the water temperature and the consequent environmental control conditions are around 30°C, 60% relative humidity. The spectators are seated up to 3-5m above the pool and the consequent heat stratification could increase the temperature above 30°C, making conditions relatively uncomfortable. On the other hand, the air flow could be better controlled by the mechanical system, in absence of the drop of cold air from the cover towards the public and the pool zone.

BASKET AND VOLLEY HALL: as expected the vertical air streams driven by temperature differences gather large momentum in the hall, prevailing on the flow path imposed by the inlet units of the mechanical system. Therefore flow rates, temperatures and humidity of the air injected in the enclosure have to be optimized in relation to the existing buoyancy induced flow regime, in order to obtain a local climatic control in the zones occupied by persons. The requested climatic conditions for the athletes in playground are assured by the air injected by the high velocity nozzles at the corner of the field. Their performance is strongly influenced by the injection temperature which governs the trend of air path. The value of 22°C assumed in the simulation, has to be considered carefully for the injections over the principal entrance of the parterre in the installing phase.

Non uniform comfort condition are established in the tribunes: optimal conditions are obtained for the two lower order of seats due to the plenum inlet units and acceptable values of temperature and air velocity in the upper levels are reached naturally only by the mixed air in the environment.

Summer conditions simulations, critical for the high value of the external and internal thermal load, are in progress in order to optimize the cooling system.

Middle season and different affluence of public conditions are also object of study to find alternative low energy consumption HVAC strategies.

SUMMARY

A typical commercial/institutional building is modeled using a computer program developed by ASHRAE as research project number RP-590. The RP-590 program output was used as input in a separate program written to calculate the CO_2 concentration levels in the various zones of this typical building on an hourly basis for a one year cycle. This data allow one to see how VAV A/C systems affect the CO_2 levels in each zone as the VAV boxes modulate in response to the thermal load. The CO_2 concentration has been suggested to be a good indicator of indoor air quality (IAQ) in typical commercial and institutional settings. IAQ is a hot legal liability issue in the building industry.

The results show that a VAV A/C system, that is adequate in all other respects, can adversely affect the indoor air quality of the building. Factors responsible for this are discussed and recommendations and limitations are given for the utilization of this work.

INTRODUCTION

After the oil embargo, energy conservation became a key issue as companies faced rising operating costs due to the increasing energy cost. One quick way to slow down this rise in operating cost was to reduce the amount of outside air delivered to the occupied zones. Also, architects and designers began to apply Variable Air Volume (VAV) systems more and more in place of traditional constant volume systems. This allowed the total system airflow to be modulated relative to the thermal load demands thereby saving fan energy, duct sizing, etc. Buildings began to be designed and constructed more tightly reducing the amount of infiltration of outside air. These things together contributed to the increase in cases of sick buildings and building related illnesses. These problems had not previously manifested themselves, due to the generous use of outside air and relative “looseness” of building construction. There has been much information published concerning the types and sources of contaminants commonly found in buildings with poor indoor air quality. The ASHRAE current standard for ventilation is ASHRAE Standard 62.1-2004 [1]. This standard specifies the required ventilation rate for many types of buildings from 8 L/(s-person) to 25 L/(s-person). It retained many features from earlier standards including allowing two different procedures for ventilation design. The first procedure, “The Ventilation Rate Procedure” specifies minimum amounts of quality outside air for particular occupant densities. The second procedure, “The Indoor Air Quality Procedure”, allows innovative solutions by other means, such as special filtration, to obtain acceptable indoor air quality. Carbon dioxide levels are recommended for use as an indicator to determine the quality of the air and a limit of 1000 ppm is established.

Objective

The objective of this research is to determine the effect that a Variable Air Volume (VAV) air-conditioning system has on the indoor air quality of the building or zones which it serves. Specifically, this analysis is concerned with the variation with time of the CO_2 concentration levels as the VAV system modulates relative to the thermal load.

Scope

The objective is accomplished by modeling a prototypical building that was developed for use in ASHRAE research project RP-590. The occupant density is 30 persons/100 m^2 which is typical of the several commercial/institutional examples found in ASHRAE Standard 62.1-2004. This model is analyzed for two ventilation design criteria: (1) 3L/(s-person)/person outside air, and (2) 10L/(s-person) outside air. Design criterion (1) was used in the 1970's and 1980's when energy conservation was a priority and indoor air quality (IAQ) issues had not yet surfaced. Criterion (2) comes from the most recent standards issued by ASHRAE concerning acceptable indoor air quality.

ASHRAE Research Project 590, *Control of Outside Air and Building Pressurization in VAV Systems*, developed a personal computer program, in Turbo C™, that models seven basic types of VAV control systems in a prototypical four zone building. The results available from this program include pressures throughout the system/building, zone airflow rates, cooling/heating energy requirements, and certain warnings when pressures or air flow rates are outside prescribed limits. In this paper an algorithm is developed to calculate carbon dioxide levels in each zone based on (1) the amount of outside air delivered to each zone on an hourly basis as calculated by the modified RP-590 program, and (2) the amount of CO_2 generated in each zone during the same time periods.

Description of the Building

The building parameters used in this paper are such that they provide a convenient reference point for comparison with the facilities listed in ASHRAE Standard 62.1-2004, *Outdoor Air Requirements for Ventilation*. The building (see Figure 1) is single story, of medium mass, has an occupancy of 30 persons/100 m^2, and the occupants are the only source of carbon dioxide. This prototypical building, as developed in RP-590, is occupied 24 hrs/day. Each zone has identical thermal loads except for the external loads due to orientation. The interior zone is not connected to this system.

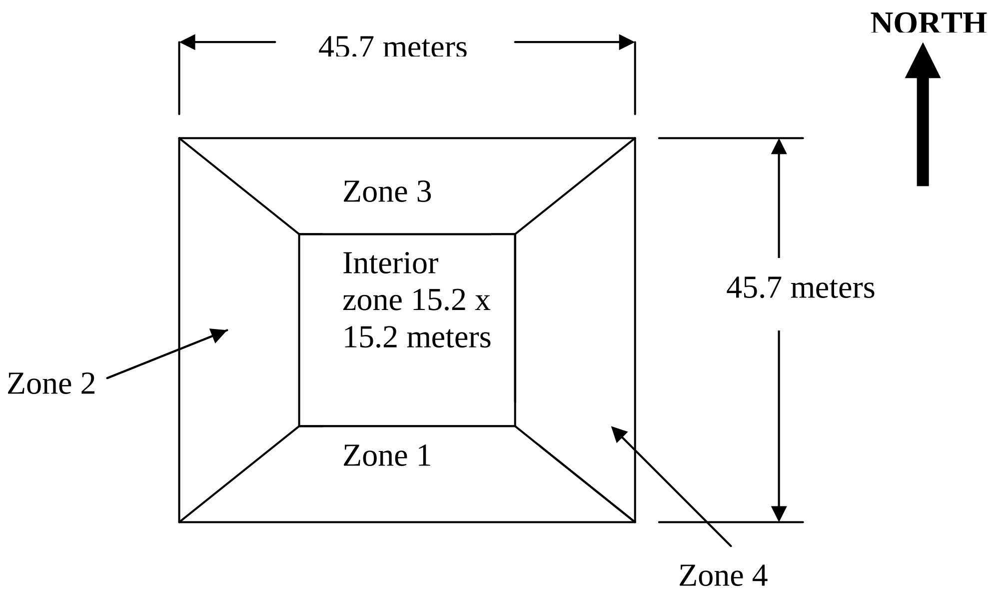

Figure 1. Floor Plan of the Building Used in the Analysis

Description of the VAV System

Of the seven types of VAV systems modeled in RP-590, system 2 is the system utilized in this research (see Figure 2). It has a return fan whose capacity is controlled by a signal from the return duct pressure. The supply fan capacity is controlled by a signal from the supply duct pressure.

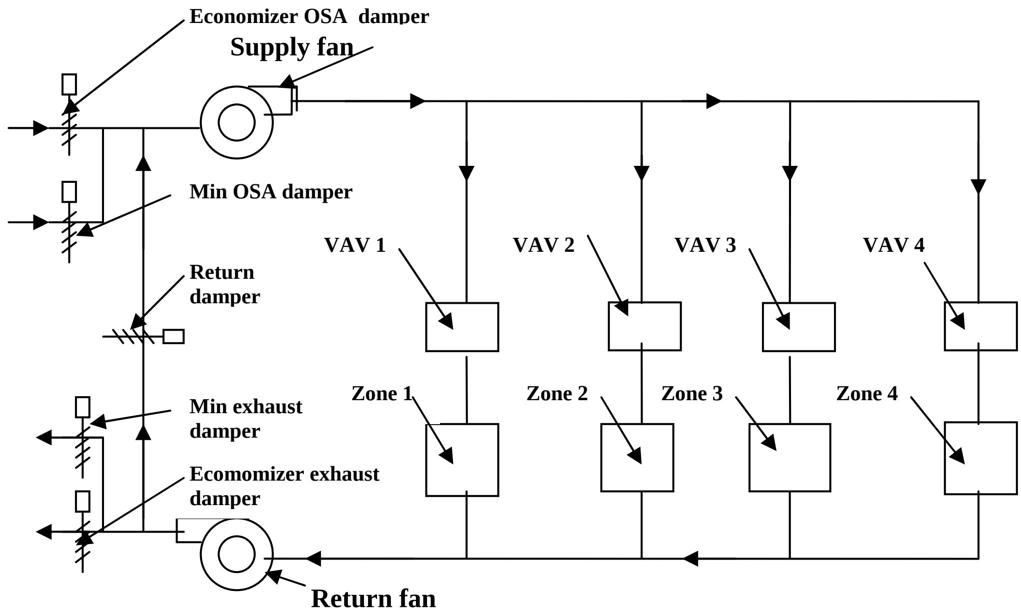

Figure 2. Schematic of VAV system Analyzed in this Work

Under the 3 L/(s-person) design criteria, the total amount of outside air is 1500 L/s (+0, -500). Under the 10 L/(s-person) design criteria, the total amount of outside air is 6,000 L/s. The desired zone pressure is 0.004 cm of H_20 (±0.004) in all cases. Economizer operation is controlled by the mixed air temperature, which has a setpoint of 23 C. The total air flow to a zone is modulated between a specified minimum turn-down ratio and wide open flow. Below that point reheat is added via baseboard heaters in order to regulate the zone temperature. VAV boxes are usually set to deliver some minimum amount of flow regardless of the room temperature. Turndown ratio is defined as the minimum percentage of wide open flow to which the VAV box will modulate. If the room is still too cool then a source of heat is activated to maintain the setpoint temperature.

For the 10 L/(s-person) design, the sizes of the minimum OSA damper (as compared to the ASHRAE RP-590 report) and the corresponding exhaust dampers were increased so that they would maintain their same respective pressure drops at the new airflow. The sizes of the other dampers were not changed.

A summary of the assumptions used follow:

1. Thorough mixing of outside air with return air takes place
2. dilution air mixes perfectly and instantaneously with the zone space air
3. Perfect control is assumed so there is no effect due to instrumentation lead/lag
4. The system attempts to maintain a slight positive pressure in each zone;
5. CO_2 generation and dilution in a zone remains constant (i.e., in a steady state)

Description of CO_2 Algorithm

The CO_2 concentration in each zone can be modeled, as it varies with time throughout the day, by considering the conservation of mass equation for a control volume. The resulting 1st order linear differential equation can then be solved. The general form of the conservation of mass equation can be simplified based on the assumptions stated above to :

$$\frac{\partial}{\partial t}\rho V = \rho_i V_i A_i - \rho_o \vec{V}_o A_o + \vec{MG} - \rho_A V_A A_A - \vec{\rho_R} V_R A_R \qquad (1)$$

The following symbols apply to the equation.:

A = area, ft^2	V = conditioned space volume, ft^3
C = CO_2 concentration, lbmol/ft^3	$\vec{V}$ = velocity, ft/min
E = filter CO_2 removal efficiency, decimal	P = density, lb/ft^3
G = CO_2 generation rate, lbmol/min	*Subscript* i = entering conditions
M = molecular weight, lbm/lbmol	*Subscript* o = exiting conditions
Q = volumetric flowrate, ft^3/min	*Subscript* A = absorbed air conditions
T = time, min	*Subscript* R = return air conditions

This equation can be solved subject to the initial condition that at t = 0, $C(0) = C_0$. If it is assumed that the amount of CO2 absorbed or filtered is negligible, the resulting solution to Equation (1) is

$$C(t) = C_i + (C_o - C_i)\exp\{-Qt/V\} + (G/Q)(1 - \exp\{-Qt/V\}). \qquad (2)$$

Note in Equation (2) under the assumptions of this work that $C_o = C_i$.

This solution to equation (2) was incorporated into a separate program written in Turbo C™ . The airflow output file from RP-590 is read into this program where it is used to calculate the CO_2 levels in each zone. A listing of the program code is given in Reference [4]. The program prompts the user for the following inputs:

1. Output filename from RP-590 that is to be used as the input for this program.
2. The filename for the output generated by this program.
3. CO_2 concentration of the outside air, ppm.
4. Conditioned volume in cubic meters of each zone.
5. Initial CO_2 concentration of each zone, ppm
6. Number of sources in each zone that generate CO_2. (Each source for a particular zone must generate the same amount of CO_2).
7. Generation rate of CO_2 in L/s of each source.

The following values were used as input to calculate the CO_2 levels in each zone:

- 400 ppm CO_2 in outside air
- 4,669 m^3 of space in each zone (from RP-590)
- 400 ppm CO_2 initial concentration in each zone
- 150 people/zone (from RP-590) = only CO_2 sources
- 0.0053 L/s CO_2 generated per person [2]

The computer program used in this work was written specifically for system 2 from RP-590; however, it can also be used to model system 1. To model the other systems, minor modifications would have to be made to properly scan the input files.

RESULTS

The output of the computer model produces some very interesting results. Tables 1 is a summary of the raw data for the case of 3 L/(s-person) outside air criteria for zone 3 (CASE A). Table 2 is a summary of the raw data for the case of 10 L/(s-person) outside air criteria for zone 3 (CASE B). (Tables for all zones for both outside air requirement cases are included in reference[4].The top twelve rows of data in each table show, for a particular turndown ratio (TD=fraction of maximum air flow), the number of hours for a typical day of the corresponding month that the 1000 ppm limit was equaled or exceeded. The bottom five rows show (1) the percentage of the yearly hours that the zone exceeds or equals the CO_2 limit, (2) the average value of the CO_2 concentration, (3) the standard deviation, (4) the maximum value, and (5) the minimum value. The American Conference of Governmental Industrial Hygienist has adopted a Threshold Limit Value – Time Weighted Average (TWA) of 5000 ppm for CO_2 [3]. Due to space considerations raw data can not be included in this paper but is included in reference [4]. The *maximum* data values listed in Tables 1 and 2 give evidence that this TWA may be exceeded. By referring to the raw data it can be seen that the TWA is indeed exceeded. For example for Zone 3 the TWA is exceeded for 32 consecutive hours for CASE A.

By referring to the *maximum* data values in Table 2 (for CASE B) it can be seen that the largest values are much less than the TWA.

On average for CASE A, the 1000 ppm limit is exceeded for all turndown ratios in all four zones. Even under constant volume operation, this design fails to maintain the CO_2 concentration below the 1000 ppm limit approximately 30% of the time. Surprisingly for CASE B, the percentage of time that this system equals or exceeds the limit is very close to the results for CASE A. However, the amount that the CO_2 concentration exceeds 1000 ppm for CASE B is much less than that for CASE A. These details can be seen in reference [4].

Although space does not allow the details for all zones to be presented, the complete results shown in reference [4] show that during mild months when Zones 1, 2, and 4 are well ventilated, Zone 3 (North) is not. This occurs because of the low thermal load in Zone 3, which requires that the VAV box modulate down.

DISCUSSION

The HVAC system analyzed was designed for the older ASHRAE recommendation of 3 L/(s-person) of outside air and consequently will not adequately keep the zone CO_2 levels below the current ASHRAE recommendation of 1000 ppm. However, even with the minimum outside air and corresponding minimum exhaust air dampers increased in size (maintaining the same pressure drops) for 10 L/(s-person) required by ASHRAE 62.1-2004, this system allows a significant number of excursions above the 1000 ppm limit. Simply increasing the size of the outside air dampers will not cure the problem. The thermal load can still dictate how much outside air is delivered to a zone. Even if the internal thermal loads are identical, the loads due to the external exposures can cause significant differences. The prudent engineer will utilize ASHRAE Standard 62.1-2004 that describes a method to calculate the required amount of outside air for multiple zone systems. This manifests itself as an increase in the total amount of outside air for the system over and above what would be calculated by simply multiplying the total number of people by the required ventilation per person as tabulated in the standard. This still leaves open the issue of how to maintain the minimum amount of outside air at the minimum turndown ratio for the zone VAV box. One strategy could be to install a CO_2 sensor in the critical zone that would override the thermostat and drive the VAV box open to deliver more air to the zone during low load situations. If the CO_2 sensor were still not satisfied, it could override the speed modulating controller for the supply fan and speed up the fan to call for more air. The supply duct pressurization would then have to be kept within allowable limits. This could be accomplished by proper placement of relief dampers or through utilizing a hi-limit pressure controller to open the other VAV boxes in some order to relieve the pressure. The thermostat would continue its normal operation and call for reheat to maintain the space temperature.

For both design cases, in each of Zones 1, 2, & 4 a turndown ratio of 0.7 performs about as well as a turndown ratio of 1.0. Zone 3 shows a significant percentage improvement with increasing turndown ratio. This would seem to indicate the need for other system design modifications. For the design analyzed in this paper, the return ductwork offers less resistance than the exhaust ductwork. Less resistance in this branch would allow more return air to re-circulate and keep the corresponding portion of outside air from being brought into the system. In this case the return air damper should be decreased in size, thereby, increasing the pressure drop and restricting the return air flow. Increasing the resistance in this branch would allow more outside air to enter the system.

Even with a turndown ration of 1.0, each zone in both design cases allows the CO_2 concentration to exceed the limit. This indicates that the outside air dampers and exhaust dampers are undersized.

The system modeled in ASHRAE Research Project RP-590 was not designed with a load diversity factor. Load diversity is a factor that takes advantage of the fact that the different zones reach their peak thermal load at different times of the day. When utilizing the load diversity factor, smaller equipment can be purchased resulting in lower initial cost. However, the engineer must be very careful to compare the ventilation load required by the CO_2 generators with the thermal load and select equipment capable of satisfying both loads at all conditions.

This model, though quite simple, provides valuable insight to those interested in analyzing the variations in CO_2 levels in many types of buildings. The steady state assumption will not be valid in all types of buildings and occupancies, but should be adequate in settings where the occupancy remains fairly constant throughout the day.

Energy efficient ventilation systems

Gyöngyike Timár, Mechanical engineer

SUMMARY

Changes of actual load often lead to trouble with the operation of the ventilation system. The design data are no longer correct if, for any reason, the actual load has permanently changed during the usage. The proposed ventilating system maintains the most commonly developed harmful gaseous contaminant content below the permissible level in spaces with forced ventilation. Sensors are mounted in every room, in a given height. By following the demand, the supplied fresh air volume matches the momentary load. Thus, possible health hazards can be mitigated and acceptable life- and working conditions can be maintained in these spaces. The requested indoor air quality is assured in any ventilated space without disturbing the air supply to other spaces. One of the main advantages of this system is that no energy is wasted for the handling of any excess air when the system load is below the design load.

1. INTRODUCTION

1.1 Background

When the air exchange rate in a room is maintained at the nominal design value during periods of excess load, the concentration of air contaminants is likely to exceed the permissible limits. Some of these contaminants can be identified easily, but there might be some that can not be perceived with senses. Continuous inhalation of the air of such compounds can cause harmful physiological effects[1]. Proper indoor air quality can be maintained if the fresh air supply rate corresponds to the load imposed by the number of people, by their activity in the room, and by the altered technology's requirements. Of course, if the air supply rate is high enough to match the highest load, the excess circulation wastes energy. A ventilating system is usually selected for a given, constant scenario, for the demand expected at the time of the design. These data are no longer correct if for any reason, the actual load has changed during the usage. Experience shows that the differences between the design and the real load of ventilation systems can be significant. Without listing all the possible reasons, they are the following:

- The customer is not aware of the exact load, the number of people, and the equipment heat load in the spaces at the time of the design.
- The load, the number of people or the equipment heat load changes considerably during operation of the ventilation system.
- The layout of the space is altered resulting in changes of the volume and the air flow or the function of the space is changed.

Usually, it is not simple to predict these variations, and it is not possible to mitigate the effect of the load distribution changes during operation. Thus the whole ventilation system should be developed in a way that it would be capable of furnishing sufficient fresh air according to the varying load. Applying adequate control and suitably modified air duct layout, the gas contaminants' concentration can be kept below the health hazard limit.

1.2 Theoretically demanded air flow

Requirements of indoor air quality comprise the physical characteristics of the air, and its composition. Because of the natural usage, harmful gaseous contaminants, most commonly carbon dioxide, carbon monoxide, and different nitrogen based mixtures develop in spaces that have no windows or doors opening directly to the fresh air. The concentrations of these gases might reach critical values[2] during natural usage of any space if it is not compensated with sufficient fresh air.

People exhale 14-30 l/h carbon dioxide[3] depending on their activity. In practice, the average of this range of carbon dioxide is considered to be the determinant of fresh air needed per person. According to the customary proportional control formula the fresh air demand due to respiration is:

$V_s = K/(p_{er} - k_{out})$ [m³/h] /1/

Where V_s – the supplied fresh air quantity [m^3/h]; K - the generated air contamination quantity [g/h]; k_{per} - the permitted level of the contaminant in the room [g/m^3]; k_{out} - the average content of air contaminant in the outside air [g/m^3][4].

There are professional recommendations proposing the fresh air supply as a function of the activity between 25 - 90 m^3/h per person[5] for office work.

1.3 The task to solve

The load often changes during operation of a ventilating system. The load might diminish or rise depending on the number of people in the room, on the time they spend there, on their activity level and on the technology's requirements. In the first case, energy will be wasted because of the excess air supplied. In the latter case, it is vital to provide fresh air, to prevent the contamination's possible harmful effect on the health of the occupants.

There is need for a general method or system that can operate in a reliable way in every air conditioning or ventilating system to suit the altered demand. There is need for such a system that assures the appropriate indoor air quality in order to protect people from the mentioned harmful effects. The ventilating system should follow the load between certain limits, neither less than necessary to maintain acceptable working conditions, nor more, to avoid wasting energy.

The reason of application of contaminant controlled ventilation is twofold. On the one hand, the supplied fresh air quantity can be controlled independently from varying human load. On the other hand, energy efficient operation should be assured.

2. METHODS

2.1 Motivation

In addition to the requirements on the thermodynamic properties of the indoor air, for example temperature and humidity, there are requirements on its chemical composition. Up until now, no regular attempt were made to monitor the variation of the inside air's carbon dioxide content in ventilated spaces during the operation of the ventilation system. During normal usage, different types of gaseous contaminants enter the air that are hazardous to health. One of these contaminants is carbon dioxide. It is used as the most common indicator of the indoor air quality, is not poisonous but in continued excess concentration might lead to oxygen deprivation. Since this contaminant gas is colorless and odorless, the occupants are not aware of its presence. It affects the occupants to varying degrees, depending on their individual susceptibility, particularly their alertness and effectiveness.

The equation in 2.2 would only be valid in reality if the level of the inside air's carbon dioxide content /k_{per}/ remained below the design limit. In reality, this value differs from the

theoretically proposed one. This content is determined by the load. That is, its quantity depends on how many people are staying in a room and for how long or how much fresh air is demanded by the altered technology.
While the physical characteristics of the indoor air are directly measurable, its quality is harder to monitor. For example, it can be measured indirectly by following the change of the CO_2 content. With suitable instrumentation and appropriate controls, its concentration can be reliably measured, and the required indoor air quality can be maintained in the ventilated space.
There is another issue that requires special concern. The ventilation system seems to be the only among building services that might cause direct harm on the surrounding, on the occupants health when it performs poorly. It is quite likely, that people working inside a building, spent about 90 percent of their lives inside. During this time they might be exposed to the mentioned harmful effect. Offices for example can be regarded as “continuous operation”, where people stay mostly at the same location. One can assume that the individual’s performance depends on the surrounding conditions as well as on their own capability. The office environment along with the suitable indoor air quality is an important part of these surroundings. That is why the proper ventilation is so important especially where the forced ventilation is the single source of supplying fresh air. That is in spaces having no doors or windows directly to the fresh air.
Because of the nature of public building, continuously moving and varying number of people can be expected. The consequence is the change in ventilation load. Either people sojourning there change their place, leave or arrive, or visitors arrive or leave in unknown number and time frame. Between certain limits this change should be predictable for most of the systems at the time of the design based on the building’s function. The building’s owner, the user, and the operator should be aware of the design limits.
Recent professional studies have examined the main advantages of CO_2 based control applied in ventilation systems. According to the published articles, CO_2 based control assures adequate indoor environment. The symptoms reported because of inappropriate inside environment reduced or disappeared. There are also indications that buildings installed with CO_2 controlled ventilation show reduced demand under part load conditions[6].

3. RESULTS

3.1 Proposed arrangement

The arrangement on Figure 1. is one among the numerous recommendations with the purpose to assure the required indoor air quality. There are two prospects considering the most economic operation of the proposed ventilating system. Energy might be saved when the transitory surplus air heating- or cooling energy can be prevented, and also when the fan is working at its highest efficiency. The control system is tracking the actual load, and supplies the necessary supplemental fresh air. By monitoring the instantaneous load, the fresh air supplied to the space is adjusted. Consequently, the air contaminant's quantity is maintained below the critical value as the supplied fresh air quantity suits the actual load, the number of people the activity in the room or the technology requirement. There are two prerequisites concerning this system; individual spaces should be separated from each other regarding the ventilation, and the heat load generated by people and the heat loss due to transmission is not considered.
Sensors are mounted in every room at an appropriate height in the breathing zone. Following the sensors' signals, the room is supplied with fresh air until the concentration of the contaminants decreases below the threshold limit. The control system gives alarm signals,

when the monitored gaseous contaminant's concentration constantly exceeds the harmful limit. These alarms may be digital, acoustic or visual. This control system does not replace the control system based on the air physical characteristics. It is proposed to ensure the air supply within V_s = 0,2-1,2 V_{nom} intervals referring to the whole system. There is need for

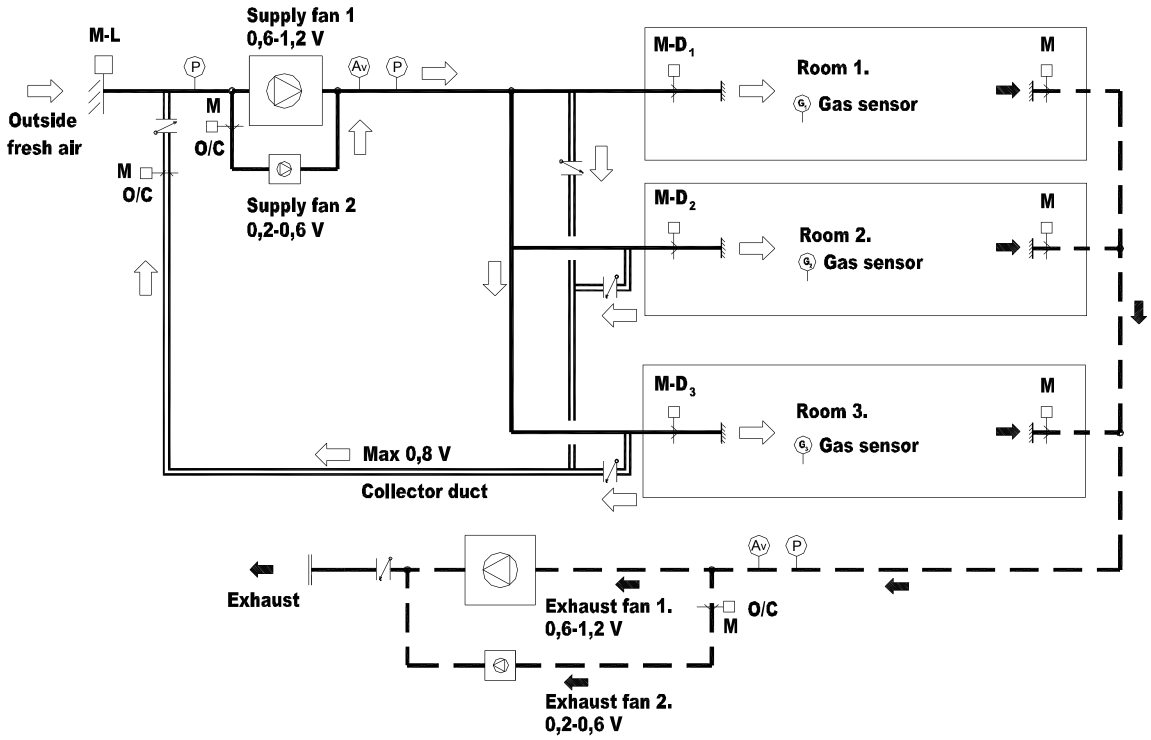

Figure 1. System layout

supplemental air when the load in the space exceeds the design conditions. The high limit of the air flow has been chosen at 1,2 $V_{nominal}$ regarding the whole system. During periods of low loads, through the third duct the excess air recirculates to the fan inlet, or the surplus air is flowing ahead the fan into the system through a central by-pass of the supply duct. The discussion entirely disregards the control in the air-heating and air-cooling process. Room temperature supposed to be constant. One of the main purpose of this arrangement is the stable operation of the fan on the designed or on the nearby operating point and with the possible favorable efficiency. The smaller fans indicated on Figure 1. are provided for extended periods, potentially several days, of low load conditions. Then the controlled data, pressures, air volumes determines when to shift fans.

All the proposed limits are arbitrarily chosen. Their values might vary depending on the size of the room, and the building, on the type or function of the building. In any case, it has to be considered during the design stage. It has to be mentioned that the load tracking control system does not substitute the control system based on the indoor air's temperature. The suitable air quality in each supplied space can be assured solely by the sufficiently harmonized operation of both control systems.

3.2 Proposed steps of sizing

The proper operation of the ventilation system can not be achieved or maintained in the ventilated spaces without adequate control. The determination of the exact or the near exact quantity of fresh air is important in order to avoid any probable health's risks on occupants' and also to provide the energy efficiency of the ventilation system. The basis of calculation is not a specific air volume any more, but an interval of air volume. There are upper and lower limits upon sizing and selection should be based.

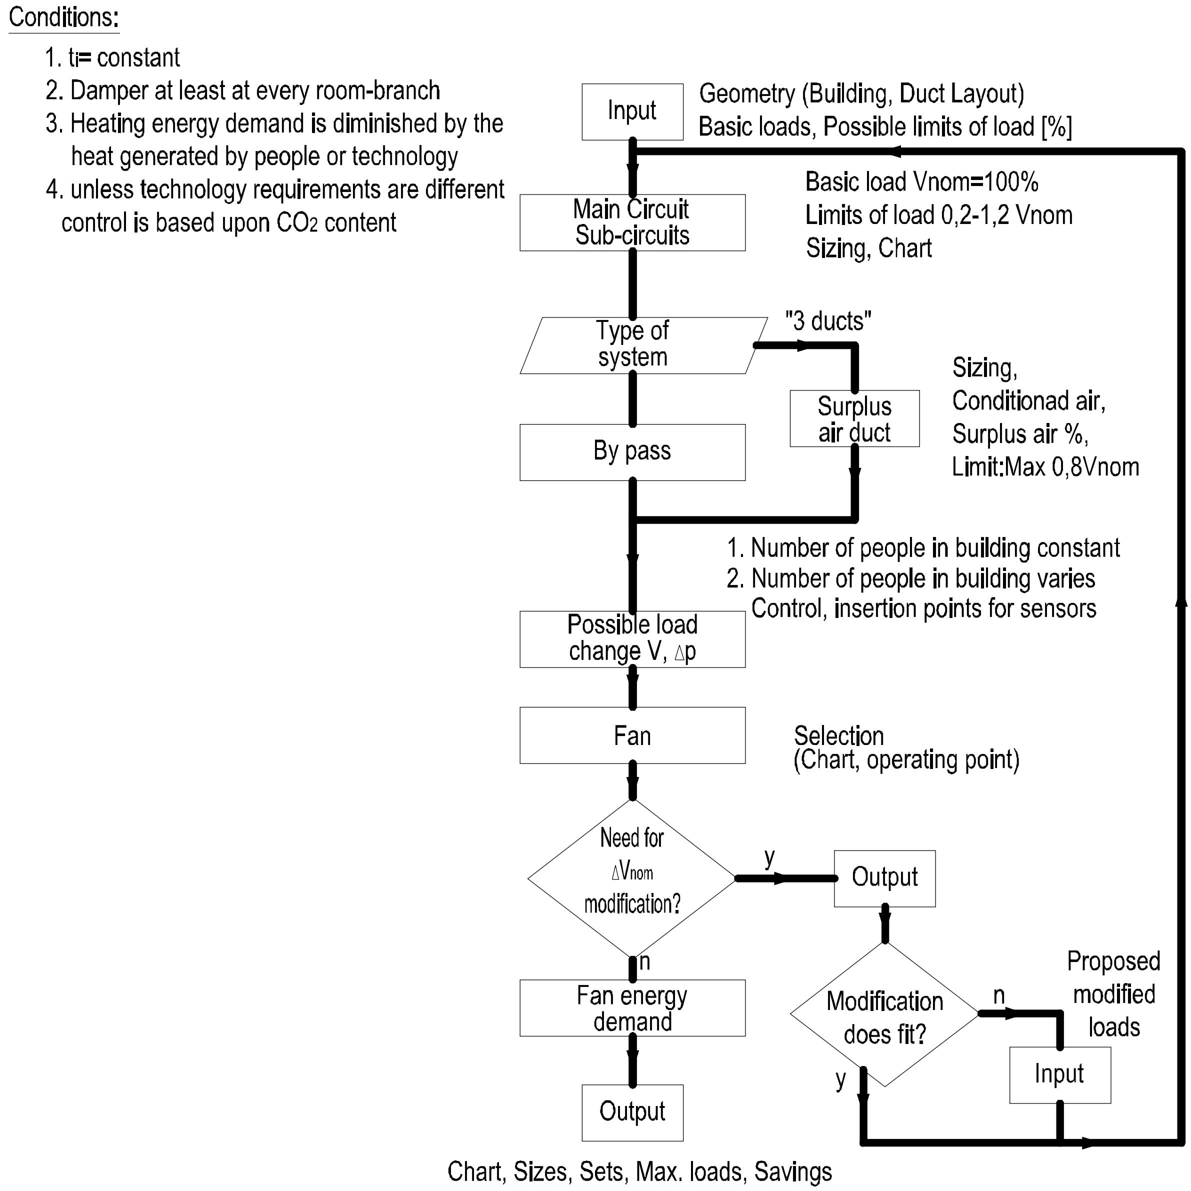

Figure 2. System flow chart

The basic data of sizing is similar to that of any other calculation, geometric and building data, tracing of air duct, spaces available and the nominal loads. New types of data are the predicted surcharges by rooms and the predicted lowest loads. The predicted surcharges comprise the maximal number of occupants by ventilated spaces, and the duration they can sojourn there without being exposed to any harmful effect. As the calculation, it is essential to be aware of the permissible surcharge of the ventilating system. When its exact value is not known at the time of the design, the proposed limits of the supplied air volume are $0,2\ V_{nominal} - 1,2\ V_{nominal}$. The main steps of sizing are shown in Figure 2.

Accordingly, after reading the INPUT data, succeeds the preliminary duct sizing based on the usual limits, as the velocity limit in the air duct. After completing this cycle the next is the air duct sizing, the pressure condition of the by-pass or that of the 'third duct'. Afterwards the proposed sizing made by using the predicted load limits of every room, and the controlled values succeed. The next is the determination of simultaneity loads for the whole system, the lowest and permissible highest loads by rooms, and also the calculation of the preset value for each room's damper. The process continues with the fans' selection for the most disadvantageous loads along with the estimation of their operational costs. This is the time for revision and entering the revised values. Re-controlling is based on the revised data is the next step. Then the selection of the fan of smaller capacity comes after if it is necessary, when the load is below 0,6 $V_{nominal}$. The result, the OUTPUT of the calculation is the air ducts' sizes, the permissible extreme load limits, the sets of air dampers for 100% and for the extreme loads, the selection of sensors insertion points in the duct, and that of the measuring devices, the operating characteristics of the fans, and forecast for energy-saving operation. It is also highly recommended to be marked on the design the maximal permissible load per ventilated spaces, the supplied surplus air volumes along with other values. The floor plan and the scheme should contain the maximum number of occupants per spaces, the insertion points of all the control and measuring devices. Besides checking the system and the definition of the room's permissible load it calculates, how much energy can be saved by operating this increased valued ventilating system.

3.3 Example for theoretically possible energy savings

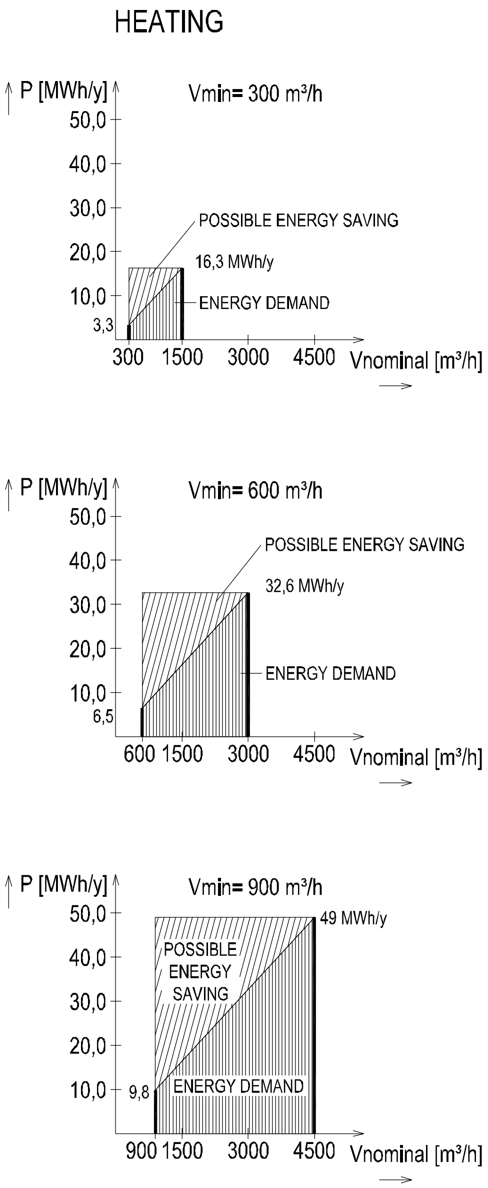

Figure 3. Theoretically possible energy saving of air heating

Due to variable load the difference between the design and the actual fresh air need resulted also a difference in energy use of the operation of the ventilating system. This is the difference at low load conditions that can be saved by using the contaminant controlled ventilation system. There are two prospects considering the most economic operation of the proposed ventilating system. Energy might be saved when the transitory surplus air heating- or cooling energy can be prevented, and also when the fan is working on its highest efficiency.
The next example will discuss the theoretically possible energy savings under varying air supply. The energy need is directly proportional to the transported air volume, to the pressure difference consumed by the air distribution system itself. Concerning energy savings, the example is studying the change of energy demand in winter season. The data do not contain any heat gain generated by people, or heat loss through the building structure. It refers solely for the heating of the supplied fresh air. Otherwise, the energy need for cooling is disregarded in this discussion.
Conditions are the next: space inside temperature $t_i = +20^oC$; outside temperature $t_o = -15\,^oC$; system operation: 5 days a week; duration of daily operation: 10 hours; fan1 supplied fresh air quantity V_1 =1500 m3/h; fan 2: V_2 =3000 m3/h; fan 3: V_3 =4500 m3/h.
On Figure 3. are indicated the yearly energy needs for fan No.1, No.2, and No.3 transporting the different air volumes, from $V_s = 0{,}2\ V_{nominal}$, up to $V_s = V_{nominal}$. There are indicated the yearly heating energy needs. The yearly fresh air heating energy demand is determined according to [7]:

$$Q_a = G_a \text{ x } V \text{ x } c \text{ x } 10^{-6} [\text{ GJ/year }] \qquad /2/$$

where Q_a –heat load of the transported fresh air [GJ/year]; G_a – yearly heat gap of ventilation [kh/y]; V – transported fresh air [m3/h]; c – specific heat [kJ/kgK].
Since the proposed ventilating system is capable to supply varying quantity of air from the lowest load $0{,}2\ V_{nominal}$, the theoretically possible energy saving during heating season might reach 80%. Although this study does not contain operating energy savings possibilities, beyond this probable energy savings, the fan's operation should be mentioned too. There are estimations showing that fan operating costs takes almost half of the energy consumptions of a building. It means that the fan's energy demand might influence considerably the building energy consumption. While energy saving in cooling season is not comprised in this paper, it has to be mentioned that heating is seasonal operation, while the fans are working continuously, almost year round. This is one of the features that do augment the achievable energy savings. The values in the example are theoretical that in reality might vary slightly because of different constructing, operating or simultaneity conditions.

4. DISCUSSION

4.1 Differences from traditional ventilating systems

The proposed arrangement is based on the traditional ventilating system's element, as e.g. air handling unit, the air distributing duct system, the supply and exhaust grids, exhaust ducts and exhaust fans. There are a few differences from the traditional ventilating systems:

- $V_{supply} = 1{,}2\ V_{nominal}$, oversized system /grids, duct, AHU/
- Air volume controlling devices at every room supply connection
- Third duct to reveal actual surplus air $V_{supply} = 0{,}8\ V_{nominal}$

- By pass in the main supply duct with possible air transport of $V_{supply} = 0,6\ V_{nominal}$
- A supplemental fan of smaller capacity in the supply and exhaust main duct
- Carbon dioxide and/or other sensors installed in the ventilated spaces
- Pressure and air volume sensors in the air duct

4.2 Advantages

The advantages of the proposed ventilating system are: proper life- and working conditions can be maintained in the ventilated space; appropriate indoor air quality can be assured in any distinct room with varying load, without disturbing other space's ventilation; the possible health hazard effect of gaseous contaminants to people is prevented; demand controlled ventilation can be assured in every spaces; beyond the nominal ventilating fresh air, between certain limit, sufficient amount of fresh air can be supplied to any ventilated room; none of the parts or element of the ventilating system is operating unnecessarily; the cooling, heating or transporting energy of the momentary superfluous air can be saved; occupants are continuously informed of the momentary air quality; occupants and operator are warned when indoor air quality is unacceptable in any space;

This arrangement requires slightly larger duct, grids or possible air handling unit, and an additional control. All of these augment the value of the ventilation system. What is more, these are one time expences that might recover soon not only in energy savings but also in the enhanced working ability the occupants. Depending on architectural conditions, it can be installed in existing ventilating systems too. Although the control system can be developed according to the description, its efficiency can only be proved after successful experimental testing, by an installed and reliable working system.

INTRODUCTION

Cargo handling industry is an important part of the economy. Construction of warehouse complexes utilizing the most modern storage, cargo reception and dispatch technologies is rapidly developing now.

In 2002-2005 OJSC "NPO Termek" and OJSC "TSNIIPromzdaniy" designed and installed heat and ventilation systems for industrial & trade complex "Sherland', where the warehouse area is 26 000 m^2.

Figure 1. Industrial & Trade Complex "Sherland".

METHODS

The complex is situated in the vicinity of Sheremetyevo-1 airport, 8 kilometers off the Moscow Ring Road. Warehouse facilities of the complex represent dry heated premises and are provided with the up-to-date equipment. Automated system of stock control allows for high dynamic cargo handling at all stages of the logistic chain – from cargo receipt into the warehouse up to its dispatch.

All warehouses are equipped with six level rack structures, intra-depot equipment, automated computerized system of stocking activity as well as with monitoring, control and alarm systems, etc.
Warehouse premise block represents a single-store, four aisle blocked building shown on Figure 2. Each aisle contains rack storage. Basic specification of each warehouse is given in Table 1.

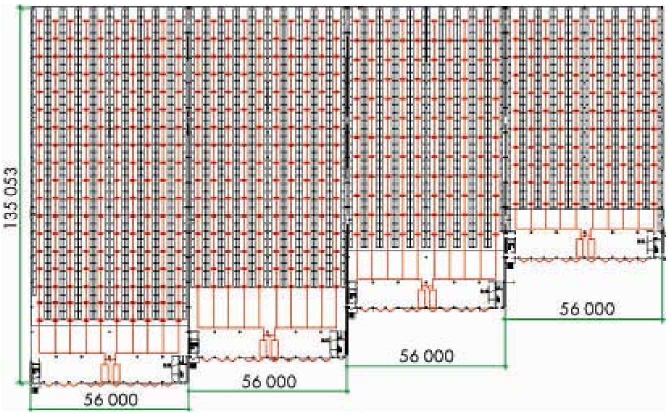

Figure 2. "SHERLAND" Rack Storage Complex. Layout.

The main requirement to the air parameters inside the warehouses is a uniform air temperature distribution in the plan and, especially, throughout the height. Analyses of eventual heating schemes and systems of the rack storages demonstrated that the most rational heating system is a combined heating system, which utilizes local heating registers placed close to the floor alongside the walls and a hot-air heating system with intensive air baffling in the space of the premise. Main heating load comes to the hot-air heating.

A hot-air heating system having deflecting nozzles is supported by a perimeter hot-water heating system with heat registers. Additional heating system was provided to prevent cooling of wall-adjacent zones. As the racks are placed virtually right up to the walls it was impossible to supply the hot air into the wall adjacent zone.

Table 1. Basic Specification of Industrial & Trade Complex "Sherland" Warehouse Premises.

Pos.	PremiseWare-house No:	Dimensions a*b*h, m	Area, A, 1000 m²	Volume, V, 1000 m³	Rack Space, Vrack, 1000 m³
1	1	90*56*17	5.04	85,68	44.12
2	2	!08*56*17	6.05	102.22	52.95
3	3	126*56*17	7.06	119.95	61.78
4	4	135*56*17	7.56	128.52	68.19

Hot-air heating system with deflecting nozzles presented at Figure 3 [1] is a modification of the widely used «Direvent» system [2] and provides for virtually uniform air temperature distribution throughout the height of the serviced premises. The system enables to provide an efficient heating at minimized consumption of the air supplied by the nozzles at high velocity and with a considerable temperature differential to secure specified microclimate parameters in the working area. The deflecting nozzles are placed between the racks in the upper zone of the premise and supply the hot air vertically down towards the working zone. Energy efficiency of the system with the deflecting nozzles is secured by a uniform air temperature distribution throughout the height and by elimination of the premises' upper zone overheating.

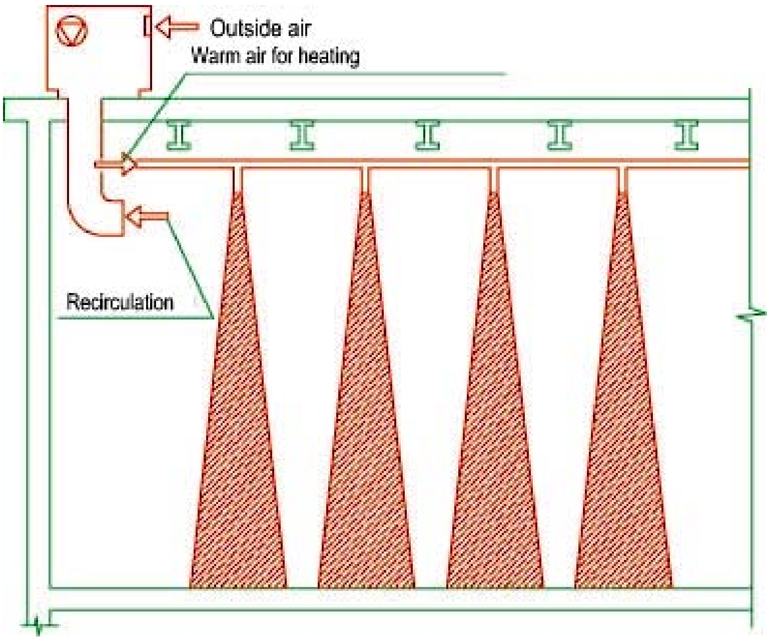

Figure 3. Outline of the Air Heating System with Deflecting Nozzles.

Table 2 presents the heat load design results for the heating and ventilation systems of the storage premises.

Table 2. Calculated Heat Load on the Heating and Ventilation Systems of Industrial & Trade Complex "Sherland" Warehouse Storage Premises.

Pos	Premise Ware¬house No	tн, °C*	t_B, °C**	Heat Consumption, kWh			
				Hot-Water Heating	Ventilation ***	Hot-Air Heating	Total

2	2	−28	12	164.8	486.3	46.7	697.8
3	3	−28	12	189.1	567.2	46.7	803.0
4	4	−28	12	390.3	607.7	109.7	1107.7

* Outside air temperature;
** Inside air temperature;
*** Heat consumption for ventilation is designed at the assumption of a single air renewal in the premise space portion having the height of 6 m.

Each warehouse is equipped with two forced ventilation units placed at the mezzanine floors. The forced ventilation installations contain air mixing chambers with valves on both outer and recycle air ducts, which allows for control of outer and recycle air ratio in the course of the operation. During non-heating season the outside air only is supplied into the warehouse in the ventilation mode. During transitional period and heating season the flow of the outside air is decreasing in the heating mode combined with the ventilation depending on the outside air temperature and cargo storage conditions. The forced ventilation units are equipped with multi-speed electrical motors, which enable to provide quantitative adjustment of the systems and secure their high energy efficiency.

Removal of the exhaust air form the warehouse is natural via exhaust shafts on the roof combined with the smoke removal shafts.

Air ducts of the forced ventilation system are laid down in the roof-truss space alongside the passageways between the racks. Height from the inlet nozzle edge to the floor of the premise is 13.5 m. Air ducts networks are combined in pairs by a bypass duct, which allows for 50% hot-air heating back-up in each warehouse.

Diagram of the warehouse hot air heating system is presented at Figure 4.

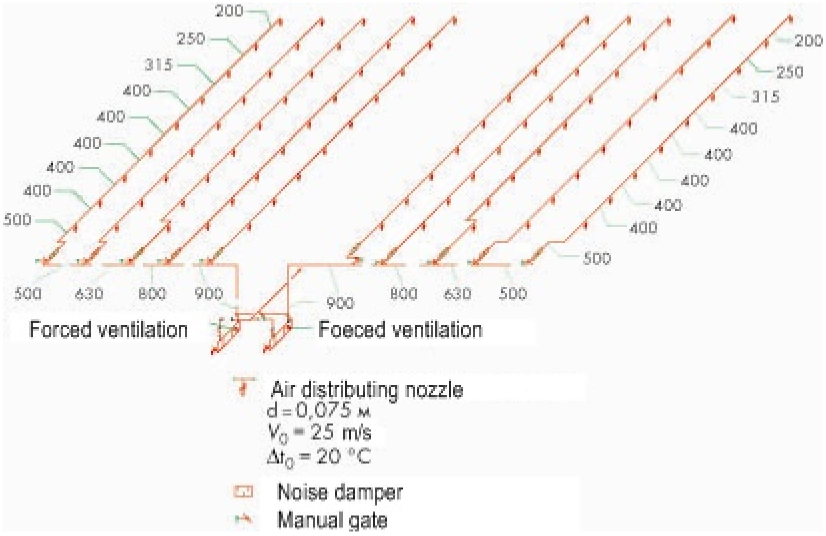

Figure 4. Diagram of the Warehouse Hot Air Heating System.

Design of the hot-air heating system with deflecting nozzles is executed in conformity with “Recommendations for Design of Heating and Ventilation Systems with Deflecting Nozzles” [3].

When designing the air distributing system we have accepted the following provisions as criteria:

- Minimal number of nozzles, which was provided by a maximal air supply velocity;
- Maximal supplied air temperature, which provided minimal consumption of the fresh air;
- Minimal deviations of air temperature and velocity in the working zone during the heating season under fresh air temperature variations.

Design results are presented in Table 3.

Table 3. Design Results of the System with Deflecting Nozzles

												$t_н$ = -28 °C
Pos.	Premise	Δt_0, °C	d_0, m	LΣ, m³/h	V_0, m/s	L_{nozzle}, m³/h	n, off	Cell Width, m *)	H, m	X_{max}, m	$K_н$	$V_{w.z.}$, m/s
1	Warehouse No.1	20	0.075	35250	25	396	90	9	21.6	11.9	0.58	0.5
2	Warehouse No.2	20	0.075	57030	25	396	140	7.1	21.6	11.9	0.58	0.5
3	Warehouse No.3	20	0.075	71750	25	396	180	6.5	21.6	11.9	0.58	0.5
4	Warehouse No.4	20	0.075	77290	25	396	200	6.75	21.6	11.9	0.58	0.5

The following notations are used in the Table (Respectively):

Δt_0 – Temperature difference between the fresh air and the air inside the premise;
d_0 – Nozzle diameter;
L_Σ – Total air consumption for the system;
V_0 – Exhaust air velocity;
L_{nozzle} – Air flow rate through the nozzle;
H – Geometry parameter of the jet;
X_{max} – Jet range capability;
$K_н$ – Jet non-isothermic factor;
$V_{w.z}$ – Air velocity in the working zone.

Width of the cell, where the air jet is developing that is coming out of the nozzle was selected having in view the requirement to provide a uniform air temperature and velocity distribution in the zone to be serviced and to provide the jet development without its cross-sectional constraint.

Installation and commissioning works were conducted in 2004-2005.

Air temperature and velocity were measured at the jet discharge spot and in the working zone alongside the fresh air jet in warehouse No.4 in the course of the commissioning works.

At the moment of measuring the outside air temperature was $t_в$ = - 0.4 °C; air discharge velocity from the nozzle and its temperature was respectively: V_0 -22.6 m/s; t_0 = 17.6 °C.

The measurements proved that:

- Air temperature throughout the warehouse height and working zone area is virtually constant ($t_в$ = 19.6 ÷20 ° C);
- Air velocity in the working zone does not exceed 0.35 m/s;
- Air velocity distribution alongside the jet axis is close to the design one (Figure 5).

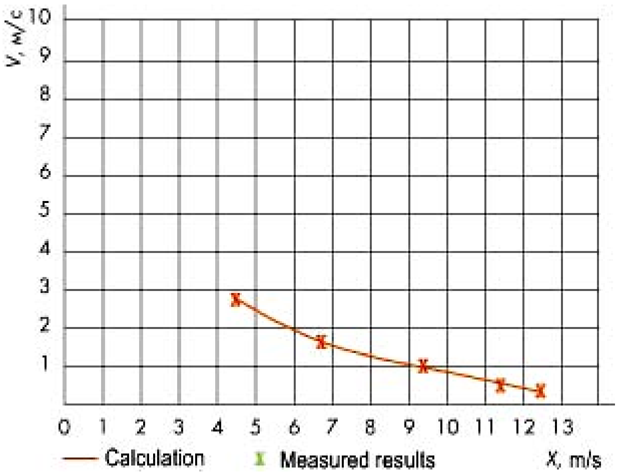

Figure 5. Air Velocity Distribution alongside the Jet Axis.

THE CONCLUSION

Utilization of the hot-air heating system combined with ventilation that is equipped with the qualitative and quantitative control and with air supply by the deflecting nozzles is perspective for large rack-store warehouses.

SUMMARY

Limited data exist on indoor air and environmental quality (IEQ) in schools, and how IEQ affects students' health or performance in China. Research was conducted in different types of indoor environments in a university to explore possible relationship. Indoor temperature, relative humidity (RH), and CO_2 concentration were continuous monitored while outdoor parameters combined with on-site climate conditions were recorded. Questionnaire concerning time-activity patterns, judgment about IAE in campus and comfortlessness possibly relative to bad ventilation was distributed to undergraduate students. Dormitories (n=20), classroom (n=20), reading rooms (n=5) and meeting rooms (n=5) were selected. Average air exchange rates were calculated using CO_2 as the tracer gas when indoor environments were not occupied. Results indicated that the best ventilation was achieved in reading rooms, and the worst situation was found in dormitories, classrooms and meeting rooms, which was accordant with occupants' more complaint. In dormitories, factors such as outdoor climate conditions, deficiency of building design, room usage and living habits of students, were considered to be essential on ventilation and indoor CO_2 concentration.

INTRODUCTION

Indoor environmental quality may affect physiological and psychological process, which may affect activities that may affect performance at tasks that may interact with other factors to affect overall productivity [1]. Ventilation consists of unintentional air infiltration through the building envelope, natural ventilation through open doors and windows, and mechanical ventilation. Adequate ventilation has the potential to mitigate concentrations of indoor-generated air pollutants. Ventilation within schools is important because there is varying evidence on the effect of low ventilation rates on performance and health [2].

The CO_2 concentration of exhaled air is higher than that of the outdoor air, leading to an increase in the CO_2 content in the closed spaces. Elevated indoor CO_2 concentrations may indicate inadequate ventilation per occupant and elevated indoor pollutant concentrations, leading to SBS symptoms [3].

The indoor concentration of carbon dioxide (CO_2) has also been used as a surrogate for the ventilation rate per occupant, including in schools [4]. The current American Society of Heating, Refrigeration, and Air-conditioning Engineers (ASHRAE) recommended for adult office workers, assuming a ventilation rate of 7.5 l/s per person and a typical outdoor CO_2 concentration of 350-400 ppm, a steady-state indoor CO_2 concentration of 1000 ppm has been used as an informal dividing line between 'adequate' and 'inadequate' ventilation. It also specifies a minimum ventilation rate of 7.5 l/s (15 ft^3/min) per occupant for classrooms [5].

Up to 2005, there are approximately 2273 colleges and universities in China, where more than 2300 million college students study and live [6]. Many students spend most of their time in classrooms, libraries, laboratories, dormitories, and other indoor environments. So there is a question of indoor environment quality and its effect on students' health and performance. In response to this concern, the study was conducted in a university in north China for current status of ventilation, as well as students' perception on indoor environment quality on campus.

METHODOLOGY

Field measurement

Tianjin, 137 kilometers east to Beijing, is the second largest city in Northern China after Beijing. As a metropolis of commerce, trade and industry, Tianjin has a resident population of approximate 10 million. This study was undertaken from June to August in 2006, with an ambient temperature of between 18 and 39 °C, a relative humidity of 35- 90%, and wind speeds up to about 10 m/s. The climatic condition was quite comfortable. All the meteorological measurements were done on-site while the field investigation was conducted.

Previous research on CO_2 in school classrooms [7] indicated a single monitoring location was appropriate for characterizing such indoor contaminant levels when HVAC systems were on, i.e. air was well-mixed. Considering probably inadequate full-mixing, 3 sets of equipment were placed in each classroom, reading room and meeting room.

Dormitories (n=20), reading rooms (n=5), air-conditioned classrooms (n=10) in an old building and classrooms with an air circulation cooling system (n=10) in a new building were selected for field measurement. CO_2 measurements were conducted by field technicians using Vaisala GMW20 series CO_2 sensors (Vaisala Inc., Finland) coupled with Hobo data logger (Hobo, USA). There sets of equipment were placed in different indoor environments for at least 12 hours, approximately 1.5 m high from the floor and away from windows, doors and fans, and at least 1 m from students. Indoor temperature, relative humidity (RH), and CO_2 concentration were continuous monitored while outdoor parameters combined with on-site climate conditions were recorded simultaneously.

One set of equipment was also placed out of the windows about 1.5 m high from the indoor floor. The occupants were interviewed at the end of investigation period about the number of people indoor. Participants were asked to record their daily activities in a time/location diary and field technicians administered a recall questionnaire at the end of field investigation to each participant.

Average air exchange rates were calculated using CO_2 as the tracer gas by decay method based on box model assumptions when indoor environments were not occupied 8. Air exchange rates were obtained under static conditions (no occupants) to reflect conservative, but not worst-case ventilation, while, in reality, the real ventilation rate may be lower because of the activities of occupants, for example, keeping windows and doors closed when staying indoor.

Questionnaire

Questionnaire concerning time-activity patterns, students' judgment about IAE on campus and comfortlessness possibly relative to bad ventilation was distributed to 1000 undergraduate students with different academic majors. In addition, 40 students (20 males and 20 females) were recruited to assess the relationship between indoor environment quality and performance. The subjects were randomly selected from 8 dormitories; they were undergraduate students from Department of Environmental Science aged between 18 and 22 years and in good health; none of them was smokers. Self-reported evaluation of how ventilation rate affected comfortlessness was collected. It was expected that respondents' performance data is less influenced by the subjects' expectations or biases and, it can be considered more reliable.

Because the experiments were performed only once a week, the whole experiment lasted for one and a half months. Indoor environment conditions (dormitories and classroom) were recorded when they stayed indoors while subjective experience was investigated in weekdays in a week. Room characteristics, ventilation methods and numbers of occupants and their activities were recorded.

RESULTS AND DISCUSSION

Time-activity patterns of undergraduate students
