[4]Norwegian Institute for Building Research
[5]Centre Scientifique et Technique du Bâtiment France

**Summary: In 1993, on a significant European initiative, a working group aimed at developing standards for design life was established in ISO/TC59, Building Construction. This was identified as a guiding concept regarding durability of building products that should be of help in implementing the European Construction Products Directive, CPD. The establishment was based on the Vienna Agreement on co-operation between CEN and ISO. Subsequently, the working group was elevated to ISO/TC59/SC14.**

**The scope of the activity is to document steps to be taken at various stages of the building cycle to ensure that the resulting building, or other constructed facility, will last for its intended life without incurring large unexpected expenditures. The activity has progressed to the stage where the first two parts of the developing standard, ISO 15686 Buildings and Constructed Assets – Service Life Planning, are approved, i.e. Part 1, General principles and Part 2, Service life prediction procedures. Part 3, Performance audits and reviews, is soon expected to be approved. Additional parts are being drafted or have been proposed.**

**In Europe, the members of the European Organisation for Technical Approvals, EOTA, are now starting to issue European Technical Approvals for products as one of the two possible routes for CE marking them. This is done on the basis of an assessment of the product that includes the evaluation of its durability in order to obtain a reasonable economical working life, as required by the CPD. The durability evaluation is performed according to general EOTA guidance developed on the basis of the service life prediction concepts as expressed in ISO 15686-2.**

**For product standards – the other possible route for CE marking – this durability evaluation process is not yet so advanced, although attempts of implementation are starting in the concrete area. However, a similar development for other groups of materials in general is not equally straightforward. To facilitate for writers of product standards to implement service life issues in accordance with ISO 15686, a general guidance document is badly needed.**

**The development of ISO product standards addressing service life issues will not only be beneficial on the European level for the implementation of the CPD, but also on the world-wide level to obtain useful and recognised tools for communication of building products' service life characteristics.**

**Keywords: Construction Products, Service Life, Technical Approvals, Standards.**

## 1 INTRODUCTION

In 1993, the standardisation work in the field of service life planning started when ISO/TC59/SC14/WG9, Design Life of Buildings, was launched at a meeting in Atlanta. The purpose of the activity is to document steps to be taken at various stages of the building cycle to ensure that the resulting building, or other constructed facility, will last for its intended life, the design life, without incurring large unexpected expenditures. It is needed to facilitate the making of objective estimates of the service lives of buildings and facilities.

There was a significant European initiative to establishing the standardisation group. The EUREKA umbrella project Eurocare has as its strategic goal to increase the service life of the built environment and to decrease yearly life-cycle costs for its conservation, restoration and maintenance. Eurocare, therefore, early adopted the Service Life Methodology established by CIB and RILEM (Masters and Brandt 1989). Together the three organisations in 1991 took the initiative to a dialogue with the Commission of the European Communities and the European standardisation body CEN regarding standardisation of the Service Life Methodology.

This was identified as a guiding concept regarding durability of building products that should be of help in implementing the European Construction Products Directive, CPD (The Council of the European Communities 1988), (Caluwaerts et al. 1993). ISO/TC59/SC14/WG9 was the result of a CEN/BTS-1 request and based on the Vienna Agreement on co-operation between CEN and ISO. Subsequently, as the scope and work broadened, in 1998 the working group was elevated to the subcommittee level, obtaining the designation ISO/TC59/SC14.

In Europe, the members of the European Organisation for Technical Approvals, EOTA, are now starting to issue European Technical Approvals for products as one of the two possible routes for CE marking them. This is done on the basis of an assessment of the product that includes the evaluation of its durability in order to obtain a reasonable economical working life, as required by the CPD. The durability evaluation is performed according to general EOTA guidance (EOTA 1999a) developed on the basis of the service life prediction concepts as expressed in ISO 15686-2.

For product standards, the other possible route for CE marking, this durability evaluation process is not yet so advanced, although attempts of implementation are starting in the concrete area. However, a similar development for other groups of materials in general is not equally straightforward. To facilitate for writers of product standards to implement service life issues in accordance with ISO 15686, a general guidance document is badly needed.

Of course, the development of ISO product standards addressing service life issues will not only be beneficial on the European level for the implementation of the CPD, but also on the world-wide level to obtain useful and recognised tools for communication of building products' service life characteristics.

## 2 STATE OF WORK OF ISO/TC59/SC14, DESIGN LIFE

The activity has progressed to the stage where the first two parts of the developing standard, ISO 15686 Buildings and Constructed Assets – Service Life Planning, are approved, i.e. Part 1, General principles (ISO 2000a) and Part 2, Service life prediction procedures (ISO 2001). Part 3, Performance audits and reviews (ISO 2000b) is soon expected to be approved.

Part 1 describes the principles and procedures that apply to design, when planning the service life of buildings and constructed assets. It is important that the design stage includes systematic consideration of local conditions to ensure, with a high degree of probability, that the service life will be no less than the design life. The standard is applicable to both new constructions and the refurbishment of existing structures. However, additional considerations may apply to existing buildings.

Part 2 of the standard series is mainly based on the Service Life Methodology (Masters and Brandt 1989). It describes a procedure that facilitates service life predictions of building components. The general framework, principles, and requirements for conducting and reporting such studies are given. It should be emphasised that the standard does not describe the techniques of service life prediction of building components in detail.

Part 3 has reached the DIS status and is intended to become a fully approved standard in June 2000. This part is concerned with ensuring the effective implementation of service life planning. It describes the approach and procedures to be applied to pre-briefing, briefing, design, construction and, where required, the life care management and disposal of buildings and constructed assets to provide a reasonable assurance that measures necessary to achieve a satisfactory performance over time will be implemented. However, the cost implications of service life planning and the broader issues of sustainability (e.g. embodied energy, land use) are not addressed here.

Other parts on which work has commenced are on "Data requirements", "Life cycle costing" and "Guidelines for considering environmental impacts". The first of these is intended to describe requirements of data in order to estimate the service life of a structure, building system, or building. However, at least in a first step, this part will be developed as a technical report rather than a standard. The second work item, "Life-cycle costing", is to enable comparative assessment of the cost performance of buildings and constructed assets over an agreed period of time. The last work item is to provide guidance on assessing the relative environmental impacts of alternate service life designs, and to identify the interface between environmental LCA and service life planning.

Another recently approved work item is "Maintenance and condition assessment protocols for buildings", with the objective to develop guidance for improving the quality of durability and service life data derived from condition assessment of the existing building stock. Still another work item, "Reference service life", aiming to provide guidance on the provision of reference service life for use in the application of ISO 15686-1, is currently a subject of balloting.

Moreover, proposals for new work items on maintenance and on characterisation of degradation environments are likely to be drafted.

Finally, a new work item proposal on service life design of concrete structures is under way. Originally initiated via discussions at a workshop arranged amongst others by CEN/TC104, Concrete, this work item was brought to consideration by SC14 and is now formally transferred to ISO/TC71, Concrete, Reinforced Concrete and Pre-Stressed Concrete. Thus, the recently established ISO/TC71/SC7, Service Life Design of Concrete Structures has, in liaison with *fib*, started to prepare the work item proposal with the aim of developing a Code of practice on service life design of concrete structures. This would become the first international product standard addressing service life planning issues explicitly, simultaneously serving as an example or a template how to cope with other building products in this context.

Figure 1 gives an overview of the ISO 15686 series of standards produced and in process. The M1 and P1 levels in the figure depict the generic standards on service life planning: Service life prediction procedures and general principles, respectively. The levels P2 and M2 represent semi-generic support standards while the M3 level illustrates the manifold of product standards that in time should be complemented with descriptions of service life assessment procedures. The proposed work item on service life design of concrete structures is intended to serve as an example of such a product standard.

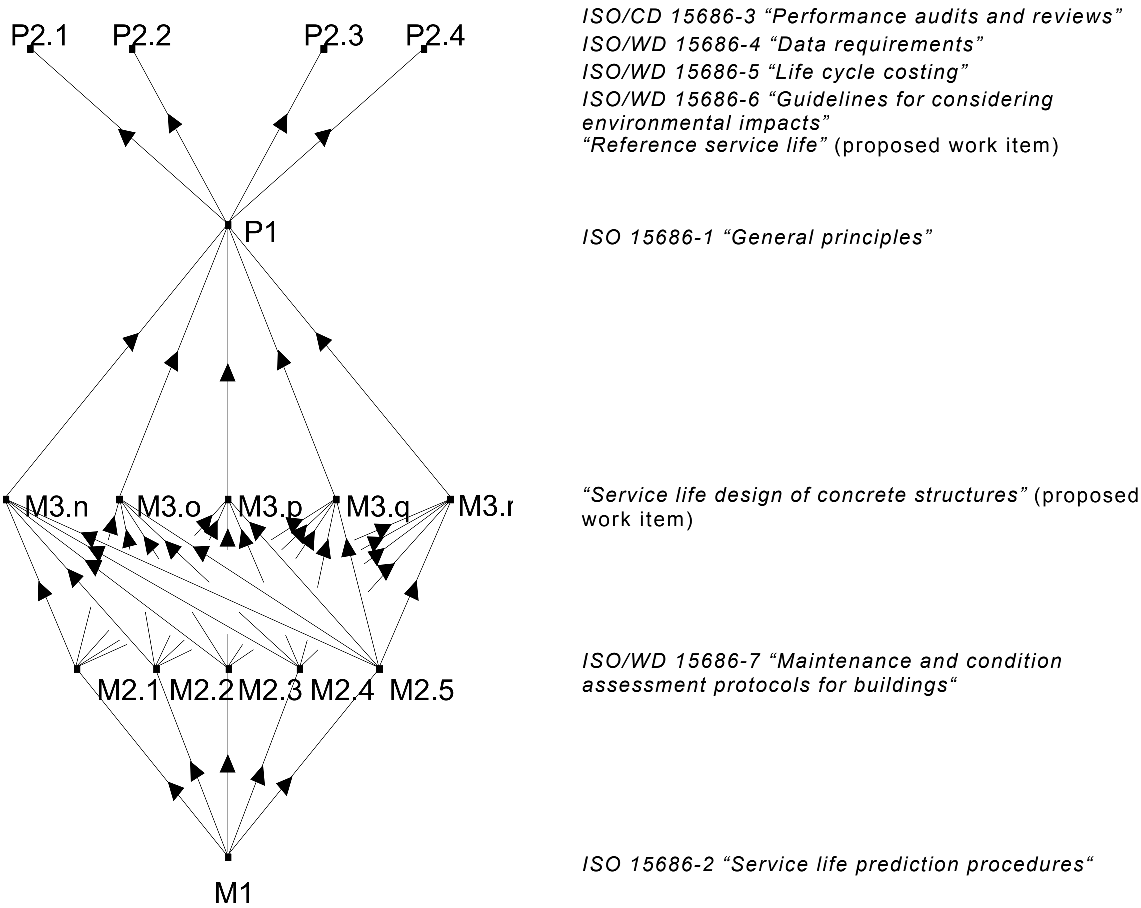

**Figure 1. Relationship among standards for service life design and planning of buildings and constructed assets – ISO 15686 series.**

The major work and challenge in this standardisation area lies in completing existing product standards with sub-parts describing methods for assessment and declaration of service life data. Another vital work area is methods for exposure/testing and evaluation. The major parts of this work do not lie within the scope of SC14, but they ought to meet the requirements of, and be developed in accordance with the framework of the SC14 standards.

## 3 THE EUROPEAN CONSTRUCTION PRODUCTS (CPD) DIRECTIVE

In 1988 the EU Council adopted the Construction Products Directive (The Council of the European Communities 1988) with the aim of removing the barriers to trade in this specific area following the white paper on the internal market approved by the Council in June 1985. The CPD is different from other similar so-called “New Approach” directives, such as the ones on toys or machines, in as far as it tries to accommodate with the specificity and complexity of the construction sector.

Indeed the CPD fixes the essential requirements for the construction works (both buildings and civil engineering works). There are six essential requirements which apply to the works as set out in annex I of the directive:

- Mechanical resistance and stability;
- Safety in case of fire;
- Hygiene, health and the environment;

- Safety in use;
- Protection against noise;
- Energy economy and heat retention, and;
- Such requirements must, subject to normal maintenance, be satisfied for an economically reasonable working life.

The CPD has, however, not the aim of harmonising the regulations on works of the Member States but rather of bridging the "works" and the construction products put on the European market and used in these works. It therefore specifies the level of performances of these products: the products "have such characteristics that the works in which they are to be incorporated, assembled, applied or installed, can, if properly designed and built, satisfy the essential requirements...". This is the notion of "fitness for the intended use" of a construction product.

The link between the essential requirements of the works and the product characteristics to be assessed is fixed in Interpretative Documents (The European Commission 1994). The Interpretative Documents (IDs) have been drafted on the basis of existing regulatory requirements of the Member States, each ID containing necessarily one chapter on the requirements of the works and one on the characteristics of the products, in principle allowing to accommodate the requirements for the works.

Since the essential requirements of the works may present differences according to climate, geographical location or regulations from a country or a region, so may also product characteristics, if needed, be expressed in classes and levels.

The CPD specifies further that a construction product is fitted for its intended use if it conforms to:

- a harmonised European standard (drafted by CEN/CENELEC);
- a European Technical Approval (issued by an EOTA member), or;
- a non-harmonised technical specification (e.g. a national technical specification) recognised at Community level,
- all three being denoted technical specifications.

Finally the CPD specifies that, before getting a CE marking, the conformity to these technical specifications must be attested. This will be carried out via certification by a third party or self-declared by the manufacturer. It involves anyhow factory production control procedures to be applied by the manufacturer. Details are described in the systems of attestation of conformity (AC) as laid down in Annex III of the CPD. For each family of products, the AC system is fixed in a Commission Decision, after consultation of the Standing Committee on Construction (representatives of the Member States). With respect to the assumption of the working life of construction products in harmonised technical specifications, reference is made to the following provisions of the CPD and the IDs, fixing the working context both for CEN and EOTA:

- According to the CPD "the products must be suitable for construction works which (as a whole and in their separate parts) are fit for their intended use, account being taken of economy, and in this connection satisfy the following essential requirements where the works are subject to regulations containing such requirements. Such requirements must, subject to normal maintenance, be satisfied for an economically reasonable working life".
- *Maintenance* is defined in the IDs as "a set of preventive and other measures that are applied to the works in order to enable the works to fulfil all its functions during its working life".
- *Normal maintenance* according to the IDs "includes inspections and occurs at a time when the costs of the intervention which has to be made are not disproportionate to the value of the part of the works concerned, consequential costs being taken into account".
- The *Working life* is defined in the IDs as "the period of time during which the performance of the works will be maintained at a level compatible with the fulfilment of the Essential Requirements".
- *Economically reasonable working life* according to the IDs "presumes that all relevant aspects are taken into account such as: costs of design, construction and use; costs arising from hindrance of use; risks and consequences of failure of the works during its working life and costs of insurance covering these risks; planned partial renewal; costs of inspections, maintenance, care and repair; costs of operation and administration; disposal; environmental aspects".
- The IDs provide that it is up to the Member States "when and where they feel it necessary, to take measures concerning the working life which can be reasonable for each type of works, or for some of them, or for parts of the works, in relation to the satisfaction of the essential requirements".
- Furthermore, the IDs provide that category B specifications (product standards) and Guidelines for European Technical Approval (ETAGs) "should include indications concerning the working life of the products in relation to the intended uses and the methods for its assessment".

## 4 EUROPEAN TECHNICAL APPROVALS

As described above harmonised European (product) standards and European Technical Approvals are both technical specifications in the sense specified by the CPD. For most products, performance will be described via product standards supported by test standards or horizontal standards. The CPD, therefore, recognises this route via standardisation as the main route for the European harmonisation and to CE marking for construction products. Harmonised European (product) standards are developed by CEN/CENELEC under mandate of the EC and EFTA. The CPD, however, recognises also that for other products this route is not applicable:

For all those products where the state of the art does not or not yet permit to produce a product standard, the CPD has envisaged an alternative route to allow also these products to come to the market and to overcome their barriers to trade: this route is the ETA. Products for which an ETA can be granted are specified in Article 8 of the CPD.

An ETA is a favourable assessment of the fitness of a product for an intended use, based on the fulfil-ment of the essential requirements for building works for which the product is used. An ETA is placed at the same level as a harmonised European standard: it must be followed by an attestation of confor-mity under a given system before the CE marking can be affixed to the product. An ETA for a product of a manufacturer can be granted on the basis of an ETA Guideline for a product family drafted by EOTA after having received a mandate from the Commission and the EFTA Secretariat (Article 11 of the CPD) or on the basis of an internal EOTA procedure for "isolated" products (Article 9.2).

Having to fulfil the principles of the CPD in the drafting of ETAGs and in the issuing of ETAs, EOTA has worked out a number of guidance rules for the handling of the above mentioned concepts on working life of construction products in ETAGs and related ETAs *and for the assessment of their durability*.

Firstly and based on the work of ISO, a table (refer to Table 1) has been drafted indicating the working life of construction products to be assumed in ETAGs and ETAs depending on assumed working lives of the works (e.g. given by national regulations). It should be noted that, according to the IDs, the working life of a product "cannot be interpreted as a guarantee given by the producer, but regarded only as a means for choosing the right products in relation to the expected economically reasonable working life of the works". By EOTA the assumed working life of a product should be understood as a basic assumption and reference to be considered when laying down the type and severeness of verification methods (e.g. number of freeze-thaw cycles) and provisions relating to durability *in the ETAGs and related ETAs.* When allocating given products to working life categories, the presumptions of the IDs concerning the "economically reasonable working life" should be taken into account.

**Table 1. Relation between assumed working life of construction works and of products**

| Assumed working life of works (years) | | Working life of construction products to be assumed in ETAGs, ETAs and hENs (years) | | |
|---|---|---|---|---|
| Category | Years | Repairable or easily replaceable[1] | Repairable or replaceable with some more efforts | Lifelong[2] |
| Short | 10 | 10 | 10 | 10 |
| Medium | 25 | 10 | 25 | 25 |
| Normal | 50 | 10 | 25 | 50 |
| Long | 100 | 10 | 25 | 100 |

[1] In exceptional and justified cases, e.g. for certain repair products, a working life of 3 to 6 years may be envisaged (when agreed by EOTA TB or CEN respectively).

[2] When not repairable or replaceable "easily" or "with some more efforts".

Secondly general guidance has been produced to ETAG writers on the approach that should be taken in the development of *these ETAGs* on the subject of Assessment and/or Prediction of Working Life of products, in order to achieve a consistent and harmonised technical approach between different *ETAGs*, and to limit the amount of long term ageing to be performed during assessments *of products leading to their CE marking*.

The approach taken is based on the methodology of (ISO 2001), see Figure 2, and briefly described in clause 8 of (ISO 2001), but adapted to the specificity of technical approval work, in particular for the *quick* assessment of innovative products:

1) In the *Definition* stage, use is made of assumptions as to the "normal" worst conditions that the product will see in use. These conditions are not usually the absolute worse conditions but are chosen so that the majority of the product population will be at or below these conditions. As many individual products will be at conditions less severe than the "normal" it is obvious that many products will achieve working lives longer than that predicted, in some instances by factors of 2 or 3.

   The term "User needs" relates, essentially, to the definition of what is expected of the product and relates to the product's fitness for use. In the context of the work of EOTA this will be defined, within limits set by the EOTA Working Group and its Mandate, by the applicant for an ETA by his claims made for the product. Assessments should be limited to user needs only in so far they relate to the Essential Requirements of the CPD.

The "Building Context" relates to aspects such as the climate and/or site in which the building will be located, the effects of its occupancy and use, incorporation into the works etc. Where the precise building context is not known, or where more than one context is anticipated by the applicant, a "worst case" situation should be assumed. Alternatively, each context should be considered separately. Further guidance is given on possible building context sub-divisions:

- climatic sub-divisions of Europe
- other external sub-divisions such as orientation of the product in structures and positions of the building
- internal environment sub-division
- other internal sub-divisions (orientation and use of the building or compartments of buildings)
- subterranean

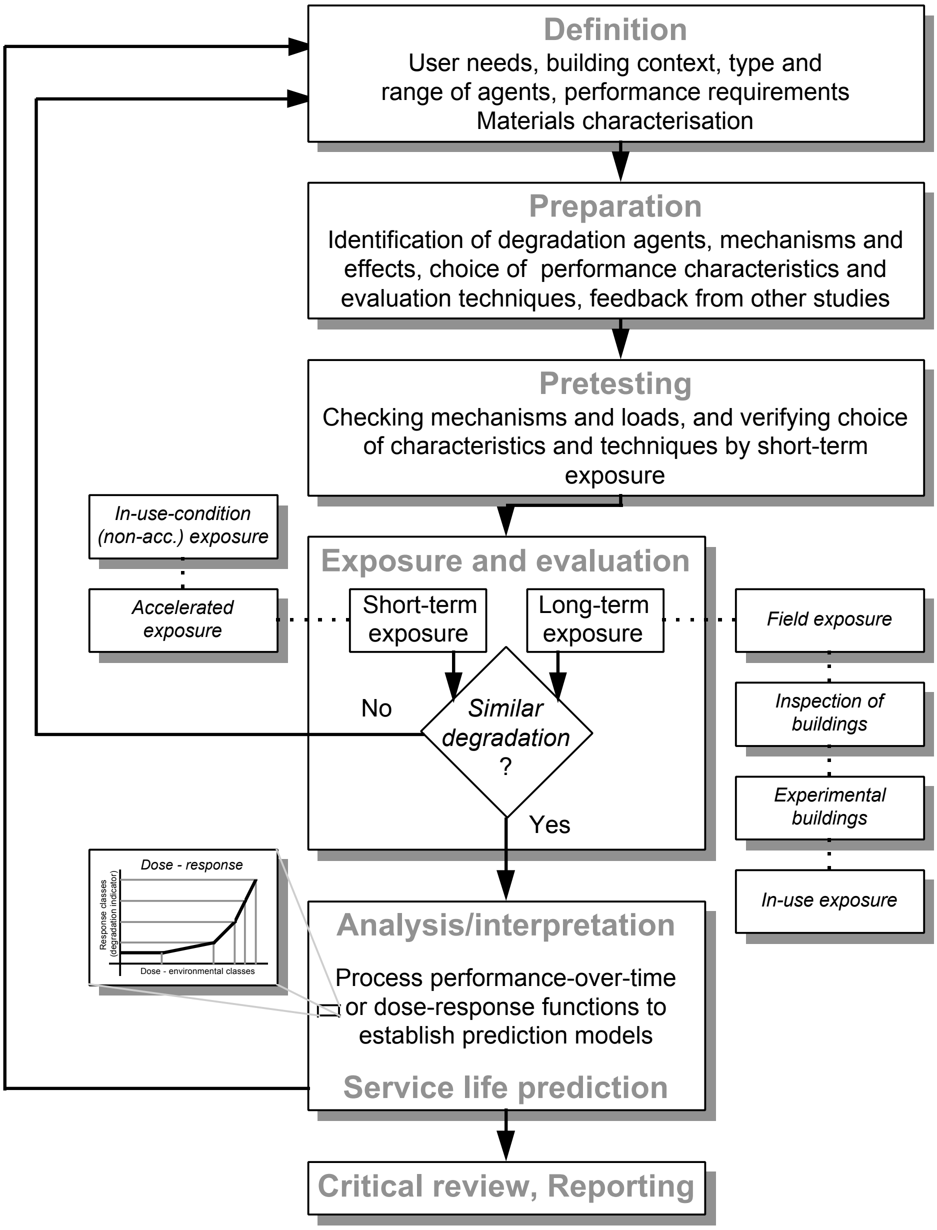

**Figure 2. Systematic methodology for service life predictions of building materials and components (ISO 2001)**

Performance requirements for particular products or components are defined by the Essential Requirements of the CPD, expanded upon by the Interpretative Documents and laid down in the EC mandates, based upon the regulatory requirements applicable in the Member States. The appropriate performance requirements, performance criteria and methods of verification to be used in the assessment of working life are elaborated upon in the ETA Guideline.

Finally and in order to ensure that a predicted working life relates to the product on the market it is essential that all products are adequately characterised in terms of structure, chemical composition and performance values corresponding to the selected performance criteria.

2) The *Preparation* stage is the most critical stage when drafting the ETAG. It involves the identification of the possible degradation factors (e.g. weathering, biological, incompatibility, use etc), identification of the degradation mechanisms and the effects of degradation on the product. The result will be the proposal or selection of the most appropriate approach (including ageing tests).

Therefore, possible degradation factors and their effects in relation to building context are listed (see examples in Tables 2 and 3). This list is not meant to be exhaustive and relates mainly to the effects of degradation factors on materials. Also other factors, such as use-related factors, the possible effects of interaction between the product and other parts of the building (e.g. due to dimensional changes) as well as the possibility of synergistic effects between two or more factors which may cause a greater than predicted change (e.g. UV radiation + moisture) should be taken into account.

**Table 2. Example of degradation factors that have to be taken into account: (exposure situation internal- 1st part)**

| Degradation factor | Actions | Reactions | Materials possibly at risk (examples) | Sub-division of factor |
|---|---|---|---|---|
| **Solar radiation U.V.** | *Products are generally protected from UV radiation* | | | |
| **Thermal** | Solar heat gain causing rise in internal temperature[1,2] | **Thermal expansion**<br>- bowing or twisting<br>) temporary<br>) permanent<br>- loss of bond<br>**Cyclic expansion/contraction**<br>- fatigue damage | Metals<br>Plastics<br>Thin sheet materials<br>Multilayer materials<br>Concrete<br>Mechanically fixed product<br>Bonded products | Climatic zones<br>Orientation of building or building compartment |
| **Differential temperatures**<br>Internal/external[3] | Thermal expansion/contraction | **Mechanical**<br>- bowing<br>- twisting<br>- delamination | Thin panels<br>Multilayer materials | Climatic zones<br>Internal conditions |
| Internal/internal[4] | Thermal expansion/contraction | **Mechanical**<br>- bowing<br>- twisting<br>- delamination | Thin panels<br>Multilayer materials | Internal conditions |
| **Localised heating[5]** | Localised chemical/physical degradation<br>Localised thermal expansion contraction | **Chemical**<br>- embrittlement<br>- change in appearance<br>**Physical**<br>- embrittlement<br>- change in appearance<br>- loss of thermal properties<br>**Mechanical**<br>- bowing<br>- distortion<br>- delamination | Plastics<br>Thin panels<br>Multilayer materials | Temperature of heat source<br>Continuous/intermittent |
| **Depressed temperatures[6]** | Thermal contraction | **Mechanical**<br>- shrinkage | Materials generally | |

[1] Only significant for unventilated buildings or building compartments

[2] Most significant in uninsulated lightweight structures

[3] Refrigerated buildings – special case

[4] Separation of heated/unheated rooms

[5] Materials behind radiators etc or special cases such as factories with elevated process temperatures

[6] As for external in refrigerated buildings and unheated buildings or parts of buildings – minimum temperatures may be different

**Table 3. Risks related to degradation factor and orientation (internal)**

| Orientation of internal degr. factor | Horizontal surfaces | Vertical surfaces | Ceilings |
|---|---|---|---|
| Water | High risk of liquid water | Low risk of liquid water | Low risk of liquid water |
| | Risk of condensation | Risk of condensation | Risk of condensation |
| Chemical spillage | High risk | Low risk | Low risk |
| Wear | High risk | Low risk | No risk |
| | - pedestrians | different form of wear | |
| | | - people brushing against | |
| Impacts | High risk - dropping impacts | Horizontal impacts from people, vehicles etc | Small risk, special cases e.g. sports arenas |

For developing a programme for the assessment of working life, technical specification writers will have to make use of many sources of information used to identify and select the most appropriate assessment procedure taking into account the nature of the product and its intended use: knowledge and experience (the chemistry and physical make up of the material and a knowledge of the proposed use), natural exposure data of construction products either under service conditions or under defined exposure conditions, testing following accelerated ageing (falling into three main groups: direct, indirect and torture tests) taking into account specific accelerated ageing conditions and extrapolation rules.

3) In the methodology envisaged by (ISO 2001), *Pretesting* is designed to validate the proposed ageing test. In the context of ETA work (unique and quick assessment of a product of a manufacturer wishing to bring his product as soon as possible to the market) this stage will generally not be possible. It is therefore essential that full use is made of all existing knowledge and data held by Approval Bodies and others when drafting the ETAGs and having to evaluate the products.
4) As far as the testing step is concerned, ETAGs describe fully any ageing test proposed, including conditions, periods, performance criteria etc. Tests should be as short term as possible and should generally be related to a fixed period of exposure, with the overriding requirement that it allows the prediction of working life with an acceptable degree of confidence.

The ISO methodology anticipates the comparison of the results of relatively short-term tests to those of long term tests under in-service conditions and a dose effect loop. This will not be possible in the case of assessments for ETAs and consequently ETAG writers should, wherever possible, utilise existing and generally accepted tests. However, the review procedures envisaged for ETAGs and ETAs, and the associated increase in knowledge and experience of a product, will give them the opportunity to re-assess the methods of verification selected for the determination of working life.

## 5 CONCLUSIONS/FUTURE WORK

The international standardisation on the design life of buildings essentially sprung out from a European initiative to support the implementation of the Construction Products Directive. Similar motives and needs were apparent in most parts of the world, encompassing performance based building and construction issues, the need for standards and tools for the service life planning and design of buildings, and in general environmental and resource conservation concerns.

The major parts of the future standardisation work lie in amending the various product standards with guides on the assessment and evaluation of durability and service life of products when in normal use in constructed assets. This is a long term perspective and work. The European standardisation organisation CEN has not reached too far in this process. CEN's prime and immediate objective for durability assessment so far is to use the present state-of-the-art in each product family (The European Commission 2001). This results in standards addressing durability and working lives of products at very unequal levels: some are or will be very detailed, whilst others will give nothing or only basic points without details.

In future generations of harmonised product standards, a more systematic approach following the ideas developed in this paper ought to be introduced. ISO/TC59/SC14 is discussing to process a generic standard giving guidance on how service life assessment and declaration of service life data ought to be addressed in product standards to meet the requirements of the already established standards, and hence the Construction Products Directive. Furthermore, the initiative of TC59/SC14 to start a standardisation action in the field of service life design of concrete structures, should be seen as a first example of an implementation, setting the level of ambition for others.

A promising new approach that might be appointed in future product standards for complementing the classical approach of durability studies was the presented at the 8DBMC Conference, and subsequently improved (Lair et al. 2001). This approach suggests two steps in the process of service life prediction. One is aimed of taking benefit from all information available, from experts' judgements to durability test results. In order to anticipate premature failure or degradation, the predicted service life thus obtained may then be corrected by an FMEA (failure mode and effects analysis) exercise.

**Summary: This paper discusses the relevance of sustainable construction and the role of durability and service life on sustainability. It summarizes the concept of service life planning, in accordance with ISO 15686, and investigates the applicability of this concept to the construction industry in developing countries. Examples and statistical data are given. Conclusions are presented.**

**Durability and service life have very important environmental dimensions. In some languages sustainable construction is translated as durable construction. Durability is much more knowledge-based than resource-based, because it is possible to improve service life without increasing environmental loads during the production phase.**

**Service life planning implies using of estimated service life of components as additional design criteria. The concept offers a logical scheme to make rational decisions based on economical (life cycle costs) and environmental (life cycle assessment) aspects.**

**More than 82% of the world's population lives in so-called developing countries. These countries still need to construct a great number of houses and infrastructure. In other words, the developing world is still under construction and, potentially, can benefit very much from service life planning tools. However, several constraints like low environmental concern, the self-help construction scheme, higher interest rates and a lack of technical data and experts constitute barriers.**

**Keywords: Sustainability, service life planning, developing countries, durability**

## 1 SUSTAINABILITY AND CONSTRUCTION

Sustainability has many definitions, but most people agree that it implies producing goods with a lower environmental load, thereby helping to preserve the environment for future generations. The Rio Summit 1992 definition includes additional dimensions to the concept, aside from the purely environmental one. First, the social dimension, which implies a more equal distribution of the results of development, within a country and between all countries, and second, the democratic dimension that demands increasing the direct participation of the public in the decision making process (John, 2001). All these dimensions are equal in importance.

### 1.1 Sustainability and construction

The construbusiness is the biggest raw material consumer of any society. Kasai (1998) estimates that construction consumes about 50% of the total material consumption in Japan. Matos & Wagner (1999) estimate that in the USA construction is responsible for 75% of the total consumption of materials. The transformation of these raw materials into goods and the frequently long transportation distances require an extensive amount of additional resources and results in significant environmental loads. Additional resources are consumed during usage of the built facilities, plus those required by maintenance and decommissioning activities.

As a result, the sector is also responsible for consuming a significant part of the energy water and for the generation of pollution (John, Agopyan & Sjöström, 2001). For example, the decomposition of limestone during the production of the clinker Portland is solely responsible for generating about 3% of the world's $CO_2$ generation.

Construction and demolition are also major sources of waste. Estimates of construction and demolition wastes vary worldwide from a mere 163 kg per capita to 3 658 kg per capita, with typical values surpassing 400kg per capita, which are typical values for domestic solid waste generation (John, 2000). To this total it is necessary to ad all residues generated during building materials production.

Buildings are also important consumers of energy. WRI (2000) estimates that the residential, commercial and public sectors are responsible for 34,5% of the world's total energy consumption.

### 1.2 Increasing sustainability of the industry

Sustainability certainly implies a *delinking* development from environmental loads (Janseen; Van Der Bergh, 1999). One specific tool for *delinking* is *dematerialization.* This implies delivering the same performance with smaller amounts of materials, which in turn means a reduction in pollution generation, transportation and decommissioning, and a reduction of the consumption of raw materials.

Dematerialization can also be achieved by replacing the linear model of production, where natural raw materials are extracted from nature, industrially transformed into products which are used and, after the end of service life are discharged as waste along with the residues of the production processe. The new production paradigm is often called *closed loop* (Curwell & Cooper, 1998) or *cyclical production* (Craven *et all*, 1996). Within the building sector this implies that the production of buildings be maintained and operated with a minimum of resources, easily upgraded and/or refurbished. When the building becomes obsolete it will be disassembled and the resulting building components reused in a "new" building or, if they have already reached the end of their service life, recycled (John, 2000,). The amount of raw materials consumed and waste generated would be greatly minimized. Maximizing the use of renewable energy and renewable materials are, perhaps, the most commonly known other tools for reducing environmental load.. Moving from carbon-based energy to a clean and renewable energy source will clearly solve global warming and acid rain problems. But the only source for renewable building materials is vegetable: wood, lignocellulosic fibres, etc. It is possible to expand the use of vegetable materials in construction, but obviously they cannot replace all other building materials, at least not without major industrial transformations. Additionally, even all the cultivable land available on Earth would not be enough to supply wood for the construction industry (Curwell; Cooper, 1998).

Recycling waste as raw material is also an important tool for preserving natural resources, and very frequently, reduces energy consumption (John & Zordan, 2001). Making the new products easily recyclable after the end of their service life is also very important.

Increasing durability is also an option for disconnecting materials consumption from development and, therefore, reducing environmental loads.

## 2 DURABILITY AND SUSTAINABILITY

Durability, measured as the in use service life distribution of a population of components, plays a very important role in achieving sustainable construction. Bordeau (1999), when reporting different concepts of sustainable construction collected by the CIB W82 among different countries, observes that in some languages like Dutch, Finnish, Romanian or French "sustainable" is translated as "durable".

This confusion between sustainability and durability makes sense, because "one way of extending resource productivity is by extending the useful life of products" (DeSimone & Poppof, 1998). Increasing the service life can also reduce the amount of construction and demolition waste. Equation (a) describes the relationship between the environmental dimension of sustainability and service life:

$$S = \frac{\sum El}{ESL} \tag{a}$$

where $S$ is the environmental sustainability index; $El$ is the sum of all environmental loads of the building, on a cradle-to-grave basis; and $ESL$ the (estimated) service life of the building. When comparing two solutions, which have an equal environmental load, e.g. they use the same amount of a specific material; the more sustainable is the one that has the longer service life. So, solutions with short service lives can be environmentally sustainable.

Of course, the proposed equation does not take into consideration the social and democratic dimensions of sustainability. In the long run, shorter service lives imply using more resources in maintenance, decommissioning and in reconstruction instead of using those "limited resources" to enlarge the existing built environment. Even if the short service life solution is the more environmentally sustainable, it may not be socially sustainable because it hampers enlargement of the built environment, e.g. housing, roads and sanitation. In developing countries enlargement of the built environment is a condition for achieving social sustainability and also for increasing national productivity.

### 2.1 Durability, a knowledge based attribute

Durability is much more knowledge-based than resource-based. Very frequently most of the environmental load is originated by the production of the component and service life can be increased or reduced without affecting the environmental loads proportionally. Some examples and evidence support this concept.

Let's consider a reinforced concrete structure in an urban environment. The most common degradation mechanism will be corrosion of the steel bars due to carbonation of the concrete (CEB, 1993). Carbonation depth is a function of the square root of time and mechanical strength and a small increase of concrete cover from 20 to 25 mm can result in an increase of the service life from 50 years to 78 years, an increase of 56%. Applying that to a concrete component with a cross-section of 25 x 25 cm, this increase of 56% on the service life will cause an increase of only 8,2% on the environmental load during construction. Sometimes an increase in the service life of reinforced concrete structures can be achieved while reducing the environmental loads. Durability on marine environments can be improved by replacing clinker Portland with residues like granulated blast furnace slag or fly ash (Bijen, 1999). The durability of plastic components frequently depends on very small changes in its formulation (Guillermo Martinez, 1996).

Durability is not an intrinsic quality of a material. Simple changes in design details that result in greater protection of component from degradation factors can increase its service life with little or no change of the environmental load.

Obsolescence is another durability problem (ISO, 1999). Obsolescence is not the result of a degradation process but from changes in the user needs. It can be seen as socially defined service life. Since it is impossible to forecast social changes in the long run, "durability" against obsolescence cannot be controlled. But the environmental loads associated with obsolescence can be minimized, making components more likely to be obsolete easy replaceable. Additionally, the entire building will eventually become obsolete. Design decisions can control the speed of the obsolescence of the building and make the disassembling process and the reuse of the components easy. Knowledge is the key factor to control obsolescence related durability problems.

## 3 SERVICE LIFE PLANNING ACCORDING TO ISO 15686

ISO 15686-1 defines service life planning as a "preparation of the brief and design for the building and its parts to achieve the desired design life e.g., in order to reduce the costs of building ownership and facilitate maintenance and refurbishment." (Annex B – Alphabetical glossary of terms). Its introduction starts by saying " Service life planning is a design process which seeks to ensure … that the service life of a building will equal or exceed its design life, while taking into account (and preferably optimising) the life cycle costs of the building".

Assuring that the building will reach the designed service life, defined as the one "intended by the designer e.g., as stated by the designer to the client to support specification decisions" is an essential part of service life planning. The second part of the service life planning process is to optimise the life cycle costs. Life cycle costs (LCC) are defined as the total cost at present value of a building or its parts throughout its life, including the costs of planning, design, acquisition, operations, maintenance and disposal, less any residual value. It deals with the economic performance of a building.

Even though LCC concept is a major incentive to adopt service life planning practices, the environmental dimension of service life planning is introduced only on item 10 (Financial and environmental costs over time).

Service life planning introduces the forecasting of service life into the design phase. It includes the following steps: (a) definition of the design service life of the building; (b) forecasting the estimated service life of building components; (c) using the estimated service life as a decision criteria for selecting alternatives during the design, in order to minimize life cycle costs.

The forecasting of the estimated service life of the component (ESLC) is carried out multiplying the reference service life of the component (RSLC) by modifying factors (A to G).

$$ESLC = RSLC \times A \times B \times C \times D \times E \times G$$

The modifying factors are those which to take into account the effect of the differences between the forecasted in-use conditions and those conditions observed during the evaluation of the RSLC. The considered differences are relative to (A) quality of components; (B) design level; (C) work execution level; (D) indoor environment; (E) outdoor environment; (F) in-use conditions; (G) maintenance level.

Ideally, the component's manufacturer will provide the reference service life data of the component. Inside the European Union the availability of this data is enforced by the EU Construction Products Directive 89/106/EEC (The Council of the European Communities. 1998). Other sources can also be used to do service life forecasting, such as previous experience or observation of similar constructions or materials in similar conditions, assessments of durability in Technical Approval certificates, results published in books, building codes, etc. A generic methodology to assess the reference service life is also provided.

Service life planning is intended to make the building as durable as that desired by the owner. It will allow maintenance activities to be planned during the design phase, which makes room for design decisions that makes these activities easy to perform. Also it should make easy refurbishment activities, defined as modification and to an existing building or its parts to bring it up to an acceptable condition. Service life planning makes it possible to integrate LCC and LCA during the design stage.

Two conditions are essential for applying the service life planning concept. Knowledge and infrastructure for measuring the reference service life, as well as knowledge of the effect of each factor on the reference service life.

# 4 SERVICE LIFE PLANNING, SUSTAINABILITY AND CONSTRUCTION IN DEVELOPING COUNTRIES

## 4.1 Sustainability and the construction industry in developing countries

Sustainability is a global concept for answer global problems, but its application in societies or regions results in very diverse Agendas 21. CIB's recent effort on developing a version of its Agenda 21 for Sustainable Construction adapted to developing countries is recognition of this fact. More than 82% of the world's population lives in developing countries (World Bank, 2001).

Developing countries are under construction because they, lack an adequately built environment. In the 43 countries with highest income 90% of the roads are already paved. In Latin America and the Caribbean only 24.2% of the roads are paved (World Bank, 2000). The lack of adequate houses is another indicator. Brazil alone needs to build about 5 million houses to be able to offer suitable shelter for its own citizens. In other words, expansion of the construction activities aiming to create an adequately built environment for all citizens is one of the items on the national Agenda 21.

The impact of the *construbusiness* on the environment in third world countries is relatively more important than it is in the developed countries. For example, the liberation of $CO_2$ due to decomposition of calcium carbonated during the production of clinker Portland is responsible for more than 6% of the total $CO_2$ released in Brazil but only accounts for about 1% in developed countries like the USA and Canada (Fig 1).

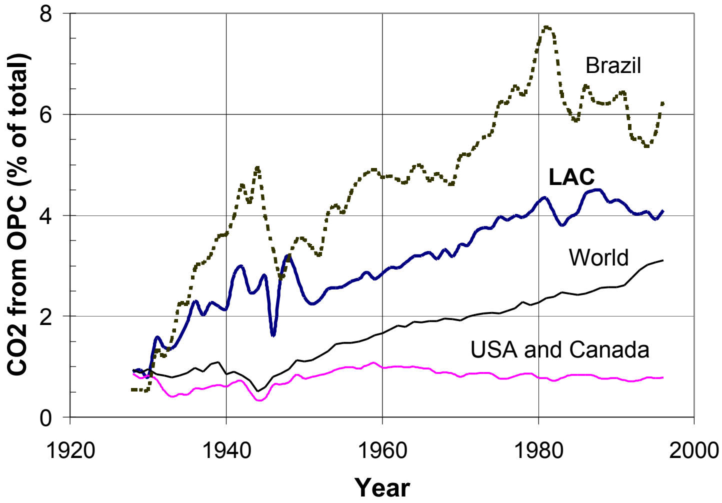

**Figure 1. Participation of clinker decomposition of limestone during clinker Portland production in the total $CO_2$ released in Latin America and the Caribbean, Brazil, Worldwide, and the USA and Canada (original data from Marland, Boden & Andres, 2000). These figures do not include $CO_2$ due to combustion.**

Statistical data about construction and demolition waste generation is scarce in developing countries. In Brazil typical generation rates are around 486 kg/year per person, considerably higher than domestic solid waste generation (John, Agopyan & Sjöström, 2001). In Chile the estimates are 236 kg/year per person.

It seems accurate to conclude that sustainable construction is even more important in developing countries than in the developed parts of the world.

## 4.2 Constraints for service life planning and sustainable actions

### 4.2.1 Lower environmental concern

Large portions of the population in developing countries, are hard pressed by basic problems such as hunger, poverty, violence, financial problems and scarcity of infrastructure. As a result, the developing societies tend to be less concerned about the environment than those from developed countries (Ocampo, 1999). Due to a scarcity of public resources to improve the infrastructure, different groups compete to build more facilities as quickly as possible, without much concern about quality and sustainability.

Even the very basic tools for protecting the environment are not yet implemented. In all of Latin America and the Caribbean, only Brazil, Chile and Mexico are considered to already have an acceptable measuring network for the monitoring of urban air quality (Kork; Saénz, 1999). In addition, there is a lack of basic legislation for waste management and most of the existing landfills do not comply with sanitary standards (Acurio *et al.*, 1997).

Ocampo (1999) pointed out a lack of effective authority among the environmental public agencies as an additional barrier to implementing sustainable policies in Latin America.

As a result, the Agenda 21 in Developing Countries tends to be very much focused on poverty, democracy, increasing infrastructure and preservation of natural resources.

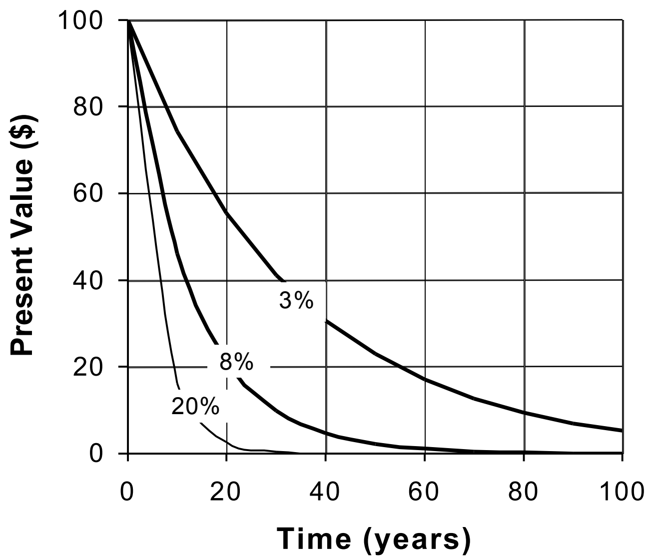

**Figure 2. Effect of annual discount rate on the present value of $100 expense made in future**

### 4.2.2 Scarcity of financial resources

Governments and societies of developing countries do not have enough money to meet the demands of better built-environments. This applies to governments as well to individual consumers. Also, interest rates in developing world tend to be much higher than in the developing world. Interest rates for building and construction in Brazil have historically been above 10% a year and the government has been paying interest rates of around 20% a year for last few years. For life cycle costs based decisions (as well as all other decisions made from a financial point of view) the higher is the discount rate the less important future expenses will be (Fig 2), because the financial decisions are made considering present values[1] (ASTM, 1999). Therefore they tend to emphasize the cost of construction and neglect long-term costs and even construction facility service life. Hence, service life planning tends to be discouraged due to financial reasons.

### 4.2.3 The self-help housing

In most developing countries the informal construction sector is very important. In Latin America and the Caribbean (LAC) a very significant portion of the houses are built by the family members themselves. In Bolivia, this kind of production scheme is responsible for 45 to 55% of the total urban houses produced every year (CLICHEVSKY, 2000). In Brazil, most of the building materials like masonry blocks, ceramic tiles, Portland cement and paint are sold directly to individual consumers and not to building contractors. This reality has profound consequences on the building materials market. Price is the major driving force because most consumers do not have the technical knowledge to demand quality, not to mention to judge the environmental impact of different alternatives.

The self-help houses are in most cases no not designed in the traditional sense, since no engineers or architects are engaged. There is no of human resources training, nor quality control. Without technical support it is not possible to adopt sustainable practices, including service life planning, which requires specialized knowledge.

### 4.2.4 Continuous upgrading

Low cost houses produced by the government are as a rule small and very simple. However, most of the houses are upgraded by the owners (John et al. 1995, Du Plessis, 1999). This process starts as soon as the owner is able to divert some money to home improvement and continuous for the life of the house. Some low-cost housing projects clearly exploit this concept by producing so called building embryos, i.e. a very small house. This building embryo normally consists of a small multi-

[1] It is important to note that the environmental impact of an activity is not reduced because it is planned for future occasions. This is the essential difference between life cycle costs (LCC) and life cycle assessment (LCA) methodologies. Therefore, as emphasized by ISO/DIS 15686-1, LCC are not directly related to LCA.

functional room and a toilet and is supposed to be enlarged by the owner. The same upgrading process occurs with the houses produced by self-help schemes, whose construction almost never ends.

The typical upgrading process includes improving aesthetics of the buildings, either by changing the façade as described by Du Plessis (1999) or by applying on new and more sophisticated interior finishing. Enlarging the house is an essential characteristic of this process. New rooms or an extra bathroom, a garage, a second or even third floor are part of this process, which can also include improvements on building services. Eventually this continuous upgrading of each house results in improvement of the entire neighborhood making it attractive to wealthier people. These new and wealthier users then take the upgrading process a step further.

ISO 15686-1 does not define the term upgrading but uses it together with refurbishing: "Whether allowance has been made for replacement, maintenance and/or upgrading to avoid undue disruption to the use of the building." item 6.2 Conceptual and initial design); and "Refurbishment and upgrading are the major strategies to counter obsolescence" (item 11.3 – Minimizing obsolescence). In both situations, upgrading and refurbishment are tools to prevent obsolescence. But the two terms are considered to be different in some way.

Upgrading as described here is results from an improvement in the economical situation of the owners. It is implicit in the definition that the user was not satisfied with the previous performance level of the house but was forced to accept it due to financial constraints. In this context the ISO 15686-1 definition of obsolescence "loss of ability of an item to perform satisfactorily due to changes in performance requirements" seems to not fully apply. Also, ISO 15686-1's description of economic obsolescence is related to high running or maintenance costs, which is very different from the previously described upgrading situation.

### 4.2.5 Lack of technical data and experts

Developing countries do not invest in research and development to the same extent that developed countries do. The research community in LAC, for example, is small and the national investment in research below 0.8% of the GNP (Hill, 2000).

Finally, developing countries focus less research on durability of building materials and components. Less than 12% of the papers presented at the 8DBMC, Vancouver 1999, originated from developing countries, including Turkey, Kuwait, India, China, Brazil, Israel, Botswana and Eastern European countries. Consequently, within developing countries little is known about the durability of building materials or service life planning. Even in technical communities, knowledge about degradation mechanisms and service life forecasting is not widespread. In general, building materials manufacturers in developing countries lack incentives to deliver reference service life data.

## 5 CONCLUSIONS

Durability and service life have very important environmental dimensions. Achieving longer service lives is more dependent on knowledge than on resources.

Service life planning and service life forecasting, as proposed by ISO 15686 are important tools for integrating the durability concept during the design stage, thereby allowing for life cycle costs estimates and life cycle assessment.

Since developing countries are under construction, they can, potentially, benefit more from the concept of Service Life Planning than the developed ones. However some important constraints make the adoption of this concept difficult.

A very important part of the construction activity in developing countries is done through self-help housing, with no technical assistance. As a rule, there is a continuous process of upgrading low-cost housing.

A scarcity of financial resources places the emphasis on construction costs and not on long-term costs. High interest rates in developing countries make solutions with low initial costs and higher maintenance and running costs more economically attractive. Even solutions with very short service lives can be financially attractive.

Developing countries lack data on durability and the local building materials manufacturers have few incentives to deliver it.

# Specifications For Road Construction And Maintenance With Warranty Contracts

**Q Li A Kumar & S De Silva**
**Civil & Geological Engineering, RMIT University, Melbourne, Australia**

**Summary**: **Several road agencies around the world are exploring the use of warranty type contracts in road construction and maintenance. International practices show that the specifications used in warranty type contracts are significantly different to the conventional approaches. In this paper, some key issues in developing specifications for warranty contracting are identified. The issues addressed include criteria for product selection, duration of the warranty, performance indicators and thresholds, quality control/quality assurance, remedial actions, conflict resolution team, warranty bond and payment, etc**

**Keywords. Warranty, specifications, road construction, maintenance**

## 1 INTRODUCTION

Budgetary constraints and increased public awareness of road conditions have encouraged road agencies to examine alternative road construction contracting methods. In the last decade, various innovative contracting processes, such as design-build, A+B Biding, lane rental, warranty and job order contracting have been implemented in road construction industry (UTTC 2000). International practices indicate that warranty contracts can reduce on-going maintenance costs, encourage contractors' innovation, and eventually benefit road users (Kumar 2001, Russell *et al* 1999). This paper is intended to address some key issues in developing specifications for warranty road construction and maintenance.

Warranty is a guarantee of the integrity of a product and of the makers' responsibility for the replacement or repair of deficiencies. Historically, warranties are widely used in manufactured products. European road agencies have used various types of warranty road contracts for almost two decades. Table 1 gives a summary of current warranty practices in several European countries.

**Table 1 European warranty practices**

| *Country* | *Structural design* | *QA/QC* | *Warranty period* | *Warranty terms* |
|---|---|---|---|---|
| Austria | State approved | Contractor | 2-5 years | Warranty bond |
| Denmark | State | Contractor | 5 years min | 5% retention |
| France | Contractor | Contractor | 10 years | Failure paid by contractor |
| Germany | Contractor (within state established limits) | QA-State<br>QC-Contractor | 4-5 years | 5% retention |
| Norway | State | Contractor | 3 years | 15% warranty bond |
| Sweden | Joint | Contractor | 3-5 years | Failure paid by contractor |

(Source Stephens *et al* 1998)

In North America, the first modern warranty contract for road construction was used in the North Carolina Department of Transportation for a pavement marking project in 1987. Since then, more and more state highway agencies in North America have started to adopt this approach. Until 1997, over 240 warranty projects have been completed in the United States (Russell *et al* 1999). In Australia and New Zealand, several state road agencies have started to adopt the process on a trial basis in recent years.

## 2 TYPES OF SPECIFICATIONS IN ROAD CONSTRUCTION AND MAINTENANCE

### 2.1 Method and material-based specifications

Traditionally, method and material-based specifications have been used by highway agencies to control construction and maintenance quality. In theory, these specifications reduce job delays and contract claims, and contract compliance is easily determined. However, there are two major disadvantages. Firstly, it gives no opportunity and motivation for contractors to improve the construction processes or the final constructed product. Secondly, full-time presence of experienced personnel from contracting agencies is required for proper enforcement.

### 2.2 Quality control/quality assurance specifications

Quality control/quality assurance was developed to primarily improve the method and material-based processes. As used in industrial manufacturing, the specifications, based on representative sampling and statistical acceptance procedure, outline contractors' strategies and procedures for controlling quality. Contractors are allowed to use preferred means and method to provide the end result to meet the statistical acceptance requirements of the owners. To some extent, it can take advantages of the contractors' experience and innovation. The constraint of quality control/quality assurance specifications is that the specifications are absolute acceptance and rejection. In reality, there is a gray area in which the product is below the acceptance criteria but still provides value to the owners. This largely depends upon the type of product.

### 2.3 Performance–related specifications

Performance–related specifications were developed to provide an improvement over quality control/quality assurance specifications. Performance–related specifications describe the desired levels of fundamental engineering properties that are predictors of performance and appear in primary performance relationships. The specifications intend to quantify and link the properties of the materials and construction process to the performance of the end product. However, researchers (Ohrn & Schexnayder 1998) have acknowledged that the primary relationships involved in developing performance–related specifications were more complicated than anticipated. More work is required in establishing performance prediction models that can realistically quantify the effects of the variation of material properties and construction quality on the performance of the end product.

### 2.4 Warranty specifications

Under an ideal warranty contract, the specification is expressed directly in terms of desired performance parameters and thresholds at various times throughout the warranty period. The contractors are given the freedom of materials selection and construction methods. Under current practices, warranty specifications are generally written as a combination of quality control/quality assurance specification and performance-related specification (Russell *et al* 2000). The details are addressed in the following sections.

### 2.5 End result specifications

Transportation Research Board (TRB) described the end result specifications as "specifications that required the contractor to take the entire responsibility for supplying a product or an item of construction. The highway agency's responsibility is to either accept or reject the final product or apply a price adjustment that compensates for the degree of compliance with the specifications" (Benson 1995). Generally, the specifications can be found in Design-Build-Operation, Design-Build-Operation-Transfer contracting approaches.

The distinctive difference between end result specification and performance–related specification is that the former focuses on the measurements of the end product and the latter measures the indicators of material properties and quality during the construction process. Under an end result specification, the contractor takes fully responsibility in deciding what to do and how.

## 3 POTENTIAL BENEFITS AND CONSTRAINTS OF USING "WARRANTY" IN ROAD CONSTRUCTION AND MAINTENANCE

### 3.1 Potential benefits

When using warranty specifications, the final product is assessed in terms of performance parameters directly related to the road users. Therefore, contractors are expected to provide a safe and usable roadway for public rather than to simply meet prescriptive standards on construction materials and methods.

In comparing with traditional contracting processes, warranty contracting relocates some post-construction performance risks between the contractor and contracting agency. Therefore, a higher accountability for construction quality is passed on to the contractor. Contractors are in a better position to manage the day-to-day quality due to their direct relationship with suppliers and subcontractors and their direct control over construction activities. They have more interest in adopting a new construction method if it offers possible competitive advantage. Theoretically, a higher quality is more likely to be achieved by using warranty contracting.

Under this process, contractors have to a large extent, the freedom to select materials and construction methods. Therefore the agency is no longer simply purchasing the contractor's labor, equipment, and material, but is also ultilising contractor's experience and innovation. The process stimulates contractors to improve their construction techniques in order to maximise profits. Any cost savings arisen from such innovation will also be passed on to the agency and the community.

International practices shows that warranty contracting decreases the demands on owner's human and physical resources (Russell *et al* 2000, Stephens *et al* 1998). Due to contractors taking responsibility of quality control/quality assurance, there are less demands on daily in-field inspection during construction period. In post-construction stage, the situation is also improved because contractor has to repair and correct possible deficiencies during the warranty period.

### 3.2 Problems and constraints

Current warranty specifications are the combination of quality control/quality assurance specification and performance–related specifications. Although extensive work has been done to predict performance behavior of pavements, the relationships are still being tested and verified.

Theoretically, the length of warranty period is generally determined by the "time to identify the deficiencies of the end products". However, in some cases, the determination of the duration of the contract is based on the discussion between the contracting community and the owner. The warranty periods vary from 2 to 20 years. As agencies gain more experience, the duration may be changed.

Experiences in other industry sectors, such as the pipeline industry, indicate that even though warranty specifications are detailed, installation in some cases may not occur to these specifications. Therefore, the construction supervisors may still play an important role in quality assurance in critical works such as gas industry.

Compared to traditional approaches, warranty processes prolong the contracting duration that does increase contracting administration tasks for both agencies and contractors. Most agencies ask for bonds or retain parts of the bid amount for the warranty works. Small contractors may be eliminated from the market due to financial incapability for warranty projects. Even for large companies, ongoing increased outstanding warranty obligations may result in difficulties to get bond for new projects.

In general, warranty approach is new for the road construction industry. With the increase of warranty type contracts, its long-term impact on cost savings and performance of end product will be better identified.

## 4 KEY ISSUES IN DEVELOPING WARRANTY SPECIFICATIONS FOR ROADWORKS

Previous research (Russell *et al* 1999) has proposed a framework with eleven key elements for warranty specifications. However, some important issues in developing a warranty specification should be further investigated.

### 4.1 Product selection criteria

In current practices, the warranty products for road construction and maintenance include asphalt pavement, chip seal, micro-surfacing, concrete pavement, bridge components, bridge painting, pavement marking, etc. Generally, the product for warranty should have the following attributes (UTTC 2000):

a) Performance of the product is measurable and quantifiable. The failure thresholds can be well defined in the specification.

b) The warranty work is wholly controlled by the contractor, and allows the contractor to select optimal design, construction process and material.

c) The factors beyond contractor's control have minimal impact on the warranty product, or the possible defects associated can be well identified.

### 4.2 Duration of warranty

The warranty periods vary from 2 to 20 years. It is generally accepted that five years is an acceptable evolution period to assure the performance of an asphalt product, without overburdening the contractors. Typical warranty periods for chip seal and micro surfacing are about 3 and 2 years, respectively. In some cases, the warranty period is determined by dialogue between agency and contracting community. However, care should be taken whether the agreed period is appropriate for deficiency identification. A comprehensive reviewing of past maintenance records is essential before finalising the agreement.

### 4.3 Warranty bond and payment

Most agencies ask for bond or retain some percentage of contract amount for remedial work guarantee. In Indiana, USA, a bond is required. The amount is based on the cost to remove and replace the warranty asphalt work. Michigan, USA, keeps

10% of the contract lump sum price of the contract item as the bond. Similar to Michigan, partial contract price is withheld in Ohio, however, the percentage is varied based on the course thickness (as given in Table 2).

**Table 2 Percent of retainment versus course thickness in Ohio**

| *Course thickness* | Percentage |
|---|---|
| 2.0 inches (50mm) or less | 90% |
| 2.1 to 4.0 inches (51 to 100mm) | 60% |
| 4.1 inches (101mm) or more | 30% |

(Source ODOT 1999 b)

**Table 3 Michigan warranty payments versus year**

| Period Year | Payment as % of Contract LSUM |
|---|---|
| 1 | 0 |
| 2 | 1 |
| 3 | 2 |
| 4 | 3 |
| 5 | 4 |

(Source MDOT 1995)

According to a survey conducted by Stephen *et al.* (1998), the bond issue is one of the major concerns in contracting community. Small and medium size contractors believed that they would face financial difficulties with accumulative bond requirements. The bond agents also expressed concern on their long-term financial conditions from prolonged project duration. It suggests that an ongoing dialogue on bond issue between highway agencies and contracting community will be critical for successful implementation of warranty approach.

Warranty payment can be made annually. Normally, the payment is made based upon an annual inspection of the pavement made by the agency to determine its condition relative to the warranty performance criteria. In Michigan, the performance payments are made within 30 days after the anniversary date of the acceptance of the pavement construction. The percentage of payment for each year is given in Table 3.

### 4.4 Conflict resolution team

Study undertaken by Russell *et al* (1999) found that half of the state agencies in North America had a conflict resolution team in warranty projects. The scope of the team includes all issues related to material selection, quality control plan, distress rate, and remedial works. This team is especially useful for partial reconstruction, chip seal (spray seal), and micro-surfacing projects. In these projects, the contractor has to accept pre-existing conditions that may result in the damage of the warranty products.

Indiana (USA) conflict resolution team consists of two contractor representatives, two department representatives, and a fifth person mutually agreed upon by both parties. In case of dispute, the team will give a final recommendation by a majority vote in which each member has an equal vote. The cost for the fifth member will be equally shared between the agency and the contractor.

### 4.5 Performance indicators and thresholds

The selection of performance parameters is important in developing a warranty specification (Kumar 2001). For road users, ride quality and safety are two major concerns. The agency, in addition, expects that the products contribute to low life-cycle cost. Performance indicators should include the above expectations. The performance indicators generally fall into three categories: safety, ride quality, and quality performance.

Skid resistance is generally accepted as an appropriate safety measure for pavement running surface. Standard methods such as the friction number test, have been used world wide.

One widely used measure of ride quality is Present Serviceability Index (PSI). The drawback of this approach is that it is based on subjective opinion of the evaluation panel. With the promotion of the World Bank models, there is a growing interest in the highway industry for using International Roughness Index (IRI). This objective measure can be acquired by standard equipment at highway travel speed.

Quality performance indicators represent the structural adequacy and durability of the warranty product. They also provide information from a maintenance perspective for the agency. The suitable parameters are rutting, cracking, surface defects, etc. The performance indicators currently used in some state agencies in North America are given in Table 4.

Thresholds of performance indicators can be determined by reviewing the historical records of agency's pavement management system. Generally, the condition of pavement will decline with accumulative traffic load. For a certain volume of traffic, it is appropriate to define different performance levels at various times throughout the warranty period. For example, Michigan gives the maximum number of distress points for any segment during each year of warranty period (as given in Table 5).

The thresholds are determined based on specific traffic conditions. In the specification, attention should be given to account for possible change of traffic condition. Indiana releases contractor's warranty obligation when the measured accumulative number of Equivalent Single Axle Loads (ESAL's) exceeds the design value by 20 percent or more.

### 4.6 Warranty works

4.6.1 Pre-existing conditions

The contractor has to accept some pre-existing conditions that can result in possible pavement failure. If the specifications do not define pre-existing conditions that could lead to premature failure beyond contractor's control, it is expected that disputes will arise. In Ohio (ODOT 1999a), the warranty does not apply to structural problems below the chip seal (spray seal), the structural problem is not the fault of the contractor.

**Table 4 Current warranty practices in North America**

| *State* | *Warranty product* | *Warranty period* | *Performance indicators* | *Threshold levels* | *Warranty Bond* |
|---|---|---|---|---|---|
| Indiana (USA) | Asphalt | 5 years | Roughness(IRI) | 2.1 m/km IRI | Bond: Lump sum amount |
| | | | Friction Number | 25 | |
| | | | Rutting | 9 mm | |
| | | | Longitudinal Cracking | 0 m | |
| | | | Transverse Cracking | 5.5m/100m | |
| Michigan (USA) | Asphalt | 5years | Surface distress | Allowable maximum points during each warranty year | Retainment of 10% bid amount |
| | | | Rutting | 0.25 inch | |
| | | | Ride Quality Index | 55 | |
| | Concrete pavement | Unknown | Surface distress | Unknown | Unknown |
| | | | Map cracking | | |
| | | | Joint seal integrity | | |
| Ohio (USA) | Asphalt | 5~7 years | Cracking( width > 6mm) | 150m/160m | Bond: lump sum amount |
| | | | Disintegrated area | None | |
| | | | Flushing | 12 $m^2$/160m | |
| | | | Patching | 28 $m^2$/160m | |
| | | | Rutting | 6mm(5 years), 9.5mm(7 years) | |
| | Chip seal | 3 years | Surface patterns: severe | 40% of segment | Bond: 75% bid amount |
| | | | bleeding/flushing: moderate | 5% of segment length, or 20% localised problems | |
| | | | loss of aggregates: moderate | 10% of segment length, or 20% localised problems | |
| Ontario (Canada) | Micro-surfacing | 2 years | Aggregates loss, raveling and flushing | Unknown | Bond:10% bid amount |

(Source IDOT 1999; MDOT 1995; ODOT 1999a&b)

**Table 5 Maximum number of distress points for any segment during each warranty year**

| Period Year | *Total Distress Points (0.1 mile)* |
|---|---|
| 1 | 3 |
| 2 | 6 |
| 3 | 9 |
| 4 | 12 |
| 5 | 15 |

(Source MDOT 1995)

The remedial works should be performed at no cost to the agency and should be based on the result of pavement distress survey. The remedial work plan should be approved by the agency. The contractor may perform minor routine maintenance during the warranty period. The intent of warranty is to provide a maintenance free pavement for the agency during the warranty period.

The agency should reserve the right to use other contractors to perform emergency action if the problem requires immediate attention for safety reasons. Indiana gives 24 hours to the contractor for emergency works. The contractor is responsible for the payment of all the costs incurred.

Indiana uses A+B biding procedure for warranty asphalt projects. The process takes into account not only the unit prices of the bidder, but also the time within which the bidder proposes to complete the works. During the warranty period, the costs for lane closure will be applied based on peak and non-peak lane closure rates.

### 4.7 Quality control/quality assurance

Under an ideal warranty process, the specification is written in terms of performance directly related to the road users. The construction process and materials will not be specified. The contractor takes full responsibility of quality control/quality assurance. However, in current practices, due to existing knowledge and experience, most agencies prefer to give minimum structure thickness, material properties and quality control limits in the specification. Moreover, the contractor is required to submit their quality control/quality assurance plan to the agency. This situation is expected to be changed when some primary performance relationships are established.

## 5 SUMMARY

The aim of introducing warranty in road construction and maintenance is to achieve better product quality, better management, and potential cost savings. Moreover, the contractor can directly target road users' benefits. Because of limited practices, experience should be shared between agencies in order to successfully promote the approach.

A brief review of various types of specification for road construction and maintenance is given in the paper. Potential benefits, problems associated, and constraints of warranty approach are also investigated. The paper focuses on some key issues in developing a warranty specification for highway construction and maintenance. The issues include criteria for product selection, duration of the warranty, performance indicators and thresholds, quality control/quality assurance, remedial actions, conflict resolution team, warranty bond, payment, etc. A few of currently used warranty specifications are used to identify the issues.

## 6 ACKNOWLEDGEMENTS

The authors wish to thank Rebecca S. McDaniel of Purdue University, USA, Lee Gallivan of Indiana Division of Federal Highway Administration, USA, and Rick Yunker of Indiana Department of Transportation, USA for the information provided.

# CIB Performance Based Building (PeBBu) Thematic Network

BL Sims & WJP Bakens
International Council for Research and Innovation in Building and Construction
Rotterdam The Netherlands

**Summary: The CIB Performance Based Building (PeBBu) Thematic Network is a currently ongoing project. This paper describes the principles of and the assumed impact from Performance Based Building and gives an indication of the international state-of-the-art and main barriers for actual implementation. A summary is given of the overall approach of the PeBBu programme and organization. The main components of the Network are subsequently further elaborated into actual tasks to be performed and deliverables to be produced by the Domain dealing with Construction Materials and Components.**

**Keywords: Performance Based Building, Materials, Components**

## 1 INTRODUCTION

During the period 1998 – 2000 CIB – the International Council for Research and Innovation in Building and Construction - initiated and commissioned various international programmes and R&D projects related to Performance Based Building.

Based on the achievements from those projects CIB proposed in 2000 the establishment of the Thematic Network PeBBu – Performance Based Building. This Network is to elaborate on the activities carried out by CIB, its commissions and its members since it adopted Performance Based Building as a Priority Theme in the CIB Pro-Active Approach in 1998. The PeBBu Network is funded through a Network subsidy within the Growth Programme that is part of the 5th Framework Research Programme of the Commission of the European Communities that was accepted by the EU with a start date of October 1, 2001 to September 30, 2005.

## 2 BACKGROUND:PERFORMANCE BASED BUILDING AND THE CONSTRUCTION INDUSTRY

The prescriptive or deemed-to-satisfy building specifications and codes currently enforced in most countries inhibit both organizational and technological innovation in the construction industry. Performance Based Building strives to overcome this problem by using performance requirements to define a building product's fitness for purpose. Performance Based Building addresses the ends rather than means. This is a strong stimulus for product and process innovation and enhances consumer-orientation.

### 2.1 The construction industry: potential for improvement

In terms of turn over, number of persons employed and social and economic impact the construction industry is one of the largest industries in all developed countries. In 1998 the industry's turnover in the EU was in the magnitude of ECU 700 billion as indicated by the Pederation de L'Industrie Europeenne de la Construction.

For decades in Europe and in most other industrialized parts of the world, the construction market has been primarily supply-driven and consequently the level of customer orientation amongst all professions in the industry traditionally has been rather low. It is to be assumed that that consequently both the level of fitness for use and the level of value for money as perceived by the owners, users and managers of buildings is often substantially less than is the case for many other consumer and investment goods.

Traditionally each building and construction project is dealt with as a prototype. This concerns the design and construction of the project, the technologies to be applied and the collaboration between the various types of companies that each have a role to play in the project. Consequently the level of industrialization and the level of technological innovation in the building and construction industry are rather low as compared to many other industries.

The traditional organization of building and construction projects is strongly fragmented. Especially the separate tasks, responsibilities and liabilities of respectively the architect and the construction firm and the related traditional tendering for construction based on a detailed design with the inclusion of a detailed specification of materials, components and construction technologies, have lead to a situation, in which tendering for the lowest initial price only (as opposed to lowest user costs over time), the almost non-existence of options for technological innovation and optimization for construction firms and a far from optimal communication and information transfer, are regarded as more or less "normal".

The traditional prescriptive or deemed-to-satisfy building regulatory systems, codes and standards as currently in place in almost all industrialized countries, are based upon and enforce the above indicated traditional characteristics of the building and construction industry.

## 2.2 Principles of performance based building

Performance Based Building aims at using performance requirements to define a building or building product's fitness for purpose. Performance Based Building means the orientation on ends rather than means: it describes buildings and building products on the basis of the target performance rather than in terms of solutions and technical specifications. In a situation in which the principles of Performance Based Building are integrally applied it will serve as the basis for communication between all stakeholders in a construction project. In such a situation the respective building regulatory systems and building codes and standards will be performance based and the principles of Performance Based Building will applied on the different interrelated levels of planning (built environment, buildings and building technologies and components) and throughout all phases of the process (brief, design, construction and maintenance)

The actual application of Performance Based Building will have a major impact on the future structure and culture in the building and construction industry and will require fundamentally different business processes in construction firms. The application of Performance Based Building will provide substantial benefits to both the end-user and to the participants in the building process. These benefits stem from a better fitness for use of the building itself, improved communication throughout the building process, better possibilities for innovation in and of the building process leading to optimization of the organization of the building process and production technology, reduced costs and better building quality, increased trade possibilities and specialization in the building industry.

## 2.3 State-of-the-art and main barriers for implementation

In the pro-active application of the principles of Performance Based Building, tenders for the construction of buildings (and civil engineering works) are to be based upon a provisional design plus performance requirements for materials, components and technical systems, as opposed to the traditional tenders that are based upon a detailed design, in which those materials, components and systems are already defined. Performance tendering will allow a construction firm to choose its own materials, components and systems.

Amongst others, the following three major conditions must be fulfilled to make the actual application of Performance Based Building practically possible:

- The language, methods and concepts that are needed to specify those performance requirements as part of the detailed construction specifications, must exist and accepted by the construction professions concerned,
- The methods to establish / measure whether a technical solution fits with the respective performance requirements must exist for materials, components and systems in general and for new, innovative ones in particular,
- There must be performance based building regulatory systems and frameworks, including codes and standards, as a basis for both the detailed specifications and measurement methods.

In certain European countries some experience is already available as concerns the development, implementation and actual application of this approach. An example it the recently introduced Performance Based Building Code in the Netherlands Over the past ten years however various non-European countries, like Japan, the USA, Canada, New Zealand and Australia have begun to develop and implement such systems and have in fact bypassed EU developments. Japan, for instance, is well known for its innovative building technology. Although those techniques will need adaptation to fit the European practice, it is important to learn from the concepts used. North America has established ASTM standards on performance requirements for buildings. North America also has done a substantial amount of research on safety aspects of building. The fire resistance performance is well researched and may offer learning points for the European industry. Canada, Australia and New Zealand have performance based building regulations. Their experiences may also help other European countries.

Also in the area of international standardization for building and construction, initiatives have been taken lately, aimed at re-writing standards based on the principles of PeBBu. ISO/TAG8 aims to stimulate the application of Performance Based Building principles into standards for building and construction. CEN so far has no equivalent.

More recently, Performance Based Building has also been recognized as a major incentive for consumer-oriented building. In Europe, the building market is changing from a supply-oriented market towards a demand-oriented market. The urgent need for housing is almost satisfied; in this sector, the quantitative post-war shortages have been solved to a large extend. However, today the consumer is expressing his requirements far more explicitly than was customary in the past. Consumer-orientation will be the main issue for the building industry in Europe for the years to come. Focusing on end-user requirements will be the main challenge. Finding a language to express the quality of a building in terms understandable to the end-user is a key-issue.

Performance Based Building has the potential to be such language because it tries to relate user requirements to building characteristics and performance.

Additional main components in this broader interpretation are for example:

- A definition of the clients functional and other requirements in terms of performance requirements
- The specification of the designers brief in terms of performance requirements
- Performance-based procurement for both design and construction contracts and often for integrated contracts for construction and – a substantial part of – design (often in the form of design-build procurement)
- New systems to relate costs and (in terms of performance requirements defined) quality
- A performance-based legal framework.

It is to be expected that the actual application of this broader interpretation of Performance Based Building will have a major impact on the future structure of and culture in the building and construction industry and will require fundamentally different business processes in construction firms.

It is also obvious that the application of this broader interpretation of Performance Based Building will not only contribute to stimulating technological innovation, cost optimization and international trade in construction, but explicitly also to achieving more client oriented design and building processes.

In many countries – in Europe for example in the Netherlands, Finland and the UK – a substantial amount of national R&D activities are currently focused on developing operational tools for aspects of this broader interpretation of Performance Based Building.

At the moment, research into Performance Based Building is approached in a rather fragmented way. There are many activities, but these are not coordinated, leading to inefficiency and absence of an integral approach. The “restricted” view, focusing at aspects of the construction process itself has gained substantially more attention than the “broad” view, investigating the contribution of PeBBu to increased consumer-orientation. Some phases, aspects and stakeholders of the building processes have received quite a lot of attention. Examples are structural engineering, fire safety engineering and building project initiation and the construction phase. Other themes and phases have received hardly any attention; for instance use related service aspects, sustainability and communication issues within the building process.

### 2.4 Impact of performance based building: innovation in and of the building process

Although prescriptive criteria are uncomplicated and easy to follow and monitor for architects and contractors, and third parties involved, they also prove to be a significant barrier for innovation, cost optimization and trade:

- Prescriptive regulations block out the application of new, improved or altered products. Those products often do not comply with the solution-based prescription indicating materials, form, size and composition to be used. Performance Based Building would overcome this problem and stimulate innovation, leading to improved building quality.
- The same prescription of solutions hampers the introduction of cheaper products or efficiency measures as the stipulated design also fixes the manufacturing and production process. This blocks, for instance, long-term investments in technological specialization. Performance Based Building would enable optimization of the production process. This may, among other effects, lead to specialization among the parties involved in the building process: it will become worthwhile to invest in the efficiency of a specific production method. This will lead to further industrialization of the building industry, with positive effects for waste control, working conditions and employability. For example performance based tenders for construction will enable construction contractors to immediately realize a substantial optimization of their traditional work processes.
- National prescriptive regulations obstruct international trade: two countries with differing regulations cannot exchange products. Proving the compliance with performance criteria is difficult. Explicit performance based regulations would assist with overcoming this difficulty and increase possibilities for international trade in the building sector.

Performance Based Building will also lead to a reduction of miscommunication throughout the building process, as the required output will be expressed in terms of building performance. This required building performance will serve as a beacon throughout the building process: all agents within the building process will use the same “language” to express the added value of their activities to this required performance.

Performance Based Building asks for a changed attitude and way of working of the parties involved in the building process. The organization of responsibilities may need alteration. The current building process involves fragmented phase-bound and work-type oriented tasks in which each party competes for the maximization of his own profit. Manufacturers, architects and contractors will need to revalue their activities in terms of added quality to the building end-user.

Feedback information from the existing building stock will be necessary to iteratively improve the building process. To enforce the learning capacity of the building industry, the network will stimulate knowledge management: sharing, developing and using knowledge on performance based building between all research and industrial partners involved in building.

### 2.5 Impact of performance based building: improved customer orientation

At the moment consideration of user requirements and the way they change in time, hardly form a significant part in building processes. Buildings are usually designed to fit the first owner or, in many cases, to fit a "fictional" (average) first owner or user. Most attention is being paid at reducing investment costs, while hardly any attention is paid to the way the building will be used throughout the exploitation process and whether or not the building will match the needs of sequential users.

It can be expected that the building market in future will become even more dynamic and the consumer market even more varied. Changing work and living habits ask for new types of living and working accommodation. Various recent developments in the construction market point at a changing market, where the consumer will start defining his requirements and choosing from the available supply. The building sector will have to be able to compete with other consumer goods, such as cars and holidays.

The application of Performance Based Building will enhance consumer-orientation within the building industry, because throughout the building process the explicitly defined user requirements will be the basis for all communication. It will therefore lead to buildings, which better fit the user requirements (both functionally and in terms of costs) and the dynamics in user requirements throughout the exploitation process. It will help parties involved in the building process to take the life span and the performance over time as a key issue in the design and construction process.

A better match between building performance over time and user requirements and more attention for the need for adaptation of buildings, can be expected to decrease maintenance and renovation activities and their impact. Maintenance and renovation activities account for an increasingly large share of the overall volume of output in the building industry (FIEC, 1998). This will lead to resource saving and less building waste from renovation activities required to keep buildings up to date over time.

### 2.6 Overall cost savings after the integral implementation of performance based building

As said already Performance Based Building is a strong stimulus for product and process innovation and enhances consumer-orientation, cost-optimization, and trade possibilities in construction. Performance Based Building is therefore expected to reduce total construction costs by as much as 25% in the long term, as is suggested in table 1.

**Table 1. Estimated savings**

| | Estimated savings in % | |
|---|---|---|
| | Short term | Long term |
| Cost optimisation construction | 2.5 | 3.0 |
| Innovation of products and processes | | 3.0 |
| Specialisation construction firms | | 4.0 |
| Less barriers to international trade | | 2.5 |
| Total process innovation | 2.5 | 12.5 |
| Improved user orientation | 5.0 | 12.5 |
| Total estimated savings in % | 7.5 | 25.0 |

As concerns the above table however it must be realized that the data in this table are in fact not based upon real scientific evidence. They are an indication of a possible magnitude and cannot be more than that as long as international and consensus based methods to measure economic benefits do not exist. Nevertheless, the application of Performance Based Building is anticipated to provide substantial benefits to both the end-user and to the participants in the building process.

## 3 SUMMARY PROGRAMME AND ORGANIZATION NETWORK

### 3.1 Network objectives

The objectives of the PeBBu Network are:

- Stimulation and pro-active facilitation of international dissemination and implementation of Performance Based Building in building and construction practice,

and in that context:

- Maximization of the contribution to this by the international R&D community,

through:

Stimulation and facilitation of the international programming and coordination of research and implementation projects as concerns Performance Based Building as effectively as possible in order to make optimal use of limited available resources and to prevent unnecessary recurrences.

- Stimulation of actual investments in such research and implementation projects.
- Providing the EU Network Members with an optimal access to knowledge and experience as available in non-EU countries in which respective developments have progressed further than in the EU.
- Coordinated dissemination and implementation of results of international research in the area of Performance Based Building.

The Network aims at combining fragmented knowledge in the area of Performance Based Building in order to build a systematic approach towards innovation of the building industry and applying user requirements throughout the building process. From this, white spots and a coherent future research agenda can be derived. End-users, policy makers, building industry and regulatory communities will be closely involved in this development in order to facilitate dissemination and implementation of research results.

The Network will especially stimulate investments in research that may be expected to produce practical recommendations for the adoption and application of Performance Based Building throughout the building industry and in all phases of the building process.

### 3.2 Overall approach

- An infrastructure is established for the programming, coordination and facilitation of research and for the dissemination of research results in the area of Performance Based Building. The main components of this program infrastructure are the following:
- International programming and coordination of research projects in nine scientific domains;
- Involvement of target groups / stakeholders from the start of the programme through three User Platforms for respectively i) buildings owners, users and managers, ii) building and construction industry and iii) the international (pre-) standardisation community;
- Mapping of national and international research as far as related to – aspects of – Performance Based Building;
- Four regional platforms in Europe to act as the bridge to and the initiator of aligned national activities;
- Network Management, including the establishment of a Network Steering Committee, a Technical Committee and a Network Secretariat that among others will be responsible for: i) annual technical and financial reporting to the EU, ii) final report, iii) designated website including among others a newsletter and iv) overall project management.

It is envisaged that at a later stage the following components will be added and that where appropriate separate funding for these will be attracted:

- Three Compendium projects that will serve as a scientific basis for those research projects and that will establish a common framework, a shared language, and the state of the art in terms of research and best practices in the area of i) Validated Models, ii) Economic Benefits and iii) Statements of Requirements
- Development of an advanced IT based facility for the full scale integration of an accessibility to all information in those Compendia and in all other components of the PeBBu Network;
- Various R&D projects related to Performance Based Building, including the about 30 projects that already have been initiated by CIB Task Groups and Working Commissions. The further elaboration of those projects into proposals/request for additional funding has already commenced;
- Various aligned National R&D projects related to Performance Based Building.

### 3.3 Network members

The PeBBu Network includes i) 33 organisations in EU and EU Associated countries and ii) 15 organisations in other countries that have committed to participation under the condition that the required funding will become available.

The Network Consortium consists of nine Principal Contractors. The other initial 25 European organisations in the Network will work as subcontractors to those nine Principal Contractors.

Now that the Network is established and operational, it is open to new membership. New CIB member organizations can submit proposals to the Network Steering Committee. New members accepted will be asked to sign an observer contract that does not provide any funding but allows those members to seek outside funding to support their participation in PeBBu. Details of the PeBBu network and more information can be viewed by accessing the URL http://www.cibworld.nl/pages/ftp/PeBBu_dir/Default.html.

In this context an explicit objective for the Network project Management is to attract new Members from East European and non-European countries and new Members that represent the Building and Construction Industry and other stakeholders as concerns the actual implementation of Performance Based Building.

In principle new PeBBu Members will all be given an "Observer status" and will be linked as such to the Principal Contractor CIBdf; the Technical Coordinating Contractor for the Network.

### 3.4 Nine scientific domains

For each Scientific Domain, in principle, separate international research programming and coordination will take place to ensure internationally accepted prioritizing of research, avoidance of unnecessary doublers, maximum stimulus for international collaboration and a maximum of compatibility between the results from the research projects.

The following nine separate Scientific Domains are distinguished.

IN THE AREA: BUILDING TECHNIQUE

- **Construction Materials and Components**
- **Building Physics**

IN THE AREA: BUILDINGS AND THE BUILT ENVIRONMENT

- **Design of Buildings**
- **Built Environment**

IN THE AREA: BUILDING PROCESS

- **Organization and Management**
- **Legal and Procurement Practices**

IN THE AREA: BUILDING INDUSTRY

- **Regulation**
- **Innovation**
- **Information and Documentation**

At a later stage it may be necessary to combine, split up and/or add such Domains if research developments so require.

## 4 DOMAIN 1 - CONSTRUCTION MATERIALS AND COMPONENTS

As most closely related to the issue of Durability of Building Materials & Components, Domain 1 in the PeBBu project is concerned. This domain has joint CIB leadership by Prof. Christer Sjostrom from Sweden and Dr. Robert Cope from France. For many years a pronounced trend in the area of building and construction technologies, materials and components, towards a performance approach in declaration, assessment and validation of building and construction products, as well as of the functional properties of a constructed works during its lifetime. The trend is pushed by industry and market, but still to a large extent driven by close-to-market and pre- and co-normative research.

### 4.1 Background

In most countries the structural codes has since long moved from simple deemed-to-satisfy approaches to a performance thinking where account is taken of the inherent stochastic variability of material properties and loads. A continuous work is ongoing to fully implement in codes and the resulting engineering the latest development of research and the possibilities offered by new technologies. Computerisation and IT play a decisive role.

As regards the properties of non-load bearing parts of buildings and hence building products the state-of-the-art is still more complex, but the performance road is as evident. As an example, energy conservation and efficiency of building is normally expressed as a performance requirement that then feeds back on the used materials and components. The requirements have then to be declared, assessed and validated for each product. The statistical variability of loads, e.g. degradation factors, and of the material or product properties should ideally be taken into account in a performance assessment. The objective is to in general develop the tools used in engineering design of load bearing and non-load bearing building parts towards the same conceptual approach.

The European Construction Products Directive, CPD (Council Directive 89/106/EEC), which states that the Essential Requirements on constructed works should be met during the intended working life of the building results in essence in a performance requirement on all building products. The life performance of the materials and products has to be assessed and declared.

In the field of Service Life Planning of Buildings and Constructed Assets ISO (TC59/SC14 “Design Life”) is developing performance-based standards. This work was initiated from Europe as a necessary step towards implementing the CPD. Such standards, guiding building design, operation and management as well as the building products producing industry, are intended to assist harmonised design and materials selection in construction, and thus encourage trade liberalisation and in perspective help countries in developing a more safe and sustainable built environment. The main workload lies on completing existing product standards with descriptions of performance based service life assessment and validation methods. There is an increasing international support towards achieving this objective.

### 4.2 State-of-the-art

ISO TC59/SC14 has released two standards (ISO 15686 part 1 and 2) guiding life design of buildings and life prediction procedures of products, respectively.

The bearing idea in life design is that for each building part/product a reference service life is adjusted by factors (environmental load, material quality, workmanship. etc.) describing deviations from the reference situation to the actual building construction scheme, thus reaching a adjusted service life estimate which is then used in the building design. This Factorial Approach needs further development and refinement as regards the factors, the theoretical calculation methods, and the reference life data to be used.

### 4.3 Barriers and opportunities

Of utmost importance to successful development in the Domain, given the above background, is the involvement of the sector industry and other stakeholders in the work. As an example, the main supplier of reference life data on materials and products must be the relevant industry. The involvement of the materials and products producing industry in the process is crucial. The PeBBu network offers obvious possibilities to speed up the process and strengthen the interaction between stakeholders.

### 4.4 Objectives

To foster, through the planned PeBBu workshops and reports, the further development, and anchoring this with sector stakeholders, of the performance concept in the domain of materials and products. This will focus on

- Further development of the Factorial Approach as regards:
    - theoretical and engineering approaches
    - basic knowledge foundation of different factors
    - development of pedagogic application examples
    - test training of practitioners
- exploring and describe the conditions and prerequisites for reference life (performance) data for classes of building materials and components with account of sub-sectorial industry structure,

and thus provide guidelines of pre-standardisation support type on (life) performance of materials and products.

### 4.5 Workplan

The objectives will be met through a step-by-step approach with the purpose to thoroughly describe the pre-conditions to make data on reference service lives and other appurtenant life performance governing data available, i.e. the conditions for establishing reference databases. This will be undertaken by involving major European and international producers of building materials and products, as well as European and international bodies for standards and technical approvals, in the process of establishing information on:

- current policy concerning establishment of durability and service life data
- current format and range of the declaration of durability and service life data, including recommended performance requirement and service environment, that goes with the products.
- current methods to establish such data
- possible availability of today classified data that would be reasonable to make public in case agreement on standards how to report or declare data is made
- opinions on and readiness to meet requirements of ISO 15686-2 as for establishment of data and proposed standards work item on Reference Service Life as for reporting of data
- arguments on the need for corresponding standards at the product level, providing detailed material/product-specific requirements.

In a first step, a questionnaire will be developed and issued addressing the (European, other world regions and national) branch and business organisations of material producers. As an example, on the European scene CEPMC (Council of European Producers of Materials for Construction) is intended to be a major body to be addressed.

Within each country covered by the PeBBu network, a number (3- 5) of the major producers will be selected, supported by the mentioned branch/business organisations, representation of at least all types of high-volume materials/products being ensured. The submitted information will be processed and analysed in relation to the above-mentioned ISO/CEN documents. Workshops together with representatives of the producers will be arranged to discuss the outcome and how to combat obstacles likely to be found. The outcome as well as the findings of the workshops will be documented and reported (see Deliverables below).

The premier international platform for the work to meet the Objectives is the PeBBu Network. In the work process of the Domain Construction Materials and Components will additionally be included, as indicated above, stakeholders and actors from the construction sector and the materials and components producing industry. Examples of main actors to be addressed – in most case contacts on the relevant issues are already well established – are:

– CEPMC and its national “umbrella” organisations and similar organisations in other world regions encompassed by PeBBu
– ISO; relevant ISO TC’s
– CEN; CEN-STAR
– EOTA (European Organisation for Technical Approvals)
– WFTAO (World Federation of Technical Approval Organisations)

### 4.6 Deliverables

The deliverables will in general consist of pre-workshop reports documenting the state-of-the-art as to the issues to be discussed and post-workshop reports developing on the results of the Workshop.

The post-workshop reports will address and develop on the items accounted for under Objectives, i.e.:

– theoretical basis and proposals for engineering approaches of the Factorial Method
– knowledge base of the different factors
– pedagogic application examples showing service life planning of constructed works and parts thereof
– the requirements of and conditions for establishment of generally accessible data bases on (life) performance data

The development of the pedagogic application examples will be performed as test training exercises. The experiences from these exercises will be summarised to a Domain deliverable. Whether to edit the Domain post-workshop reports to one or several Final Deliverable(s) will be discussed during the pace of the PeBBu work.

# The Impact Of Short-life Dwellings On the Total Costs To Sustain Housing

**IM Johnstone**
**The University of Auckland New Zealand**

**Summary: This paper uses a simulation model based on classical population dynamics to make exploratory estimates of the maximum impact of short-life dwellings on the total costs to sustain housing. Data and parameters of long-life dwellings are based on a typical New Zealand dwelling of lightweight timber framing. The size and quality of short-life dwellings are set to be the same as that for long-life dwellings and the service life of short-life dwellings is assumed to be 50 years, the minimum required by the New Zealand Building Code. If the entire simulated housing stock of long-life dwellings is replaced with short-life dwellings, then the total average costs to sustain housing are almost 13% greater when the housing stock expands at 1.5% per year and 24% greater when the housing stock is stationary. Exploratory estimates based on realistic scenarios of depreciation indicate there are no reductions in the national average costs to sustain dwelling services after adjustment for depreciation.**

**Keywords: Dwellings, structural system, service life, refurbishment, national average costs**

## 1 INTRODUCTION

The New Zealand Building Code requires components that contribute to structural stability to have a service life of 50 years (Building Industry Authority 1992). There are two issues here. The first issue is that innovative structural systems need only comply with a service life that falls short of the 90 years average service life of the housing stock as estimated by Johnstone (1994) and well short of the potential service life of most dwellings in the housing stock. Lightweight timber framing has been the predominant structural system used by New Zealand dwellings for over 120 years (Nana 1981) and this structural system has a potential service life of 180 years under New Zealand's climate as illustrated by Kemp House constructed in 1821 (Salmond 1986). Traditional materials used for structural systems such as timber, brick, stone, and concrete have demonstrated an ability to match and exceed a service life of 180 years in other countries (Brand 1997). The second issue is that the most reliable predictor of durability is a successful history of performance. Predictions of the durability of building components based on accelerated aging are fraught with difficulties (Masters 1987). In a recent study of accelerated testing, Rimestad (1998) concludes that field failure data should be used whenever possible to guide the design of accelerated tests. This is not possible with building materials, or combination of materials, that have yet to demonstrate a track record. There is therefore a risk that the projected service life of structural systems based on accelerated aging tests fall short of the minimum service life required by the New Zealand Building Code.

The prudence of allowing structural systems with unproven durability to enter the housing stock and setting a minimum service life that falls well short of the potential service life of most current dwellings needs to be examined for the following reasons. Refurbishment reduces the total costs to sustain housing by extending the service life of dwellings and thereby reducing the replacement rate of the housing stock. In a previous paper, the author estimated that refurbishment of New Zealand dwellings reduces the total costs to sustain housing by at least 15% (Johnstone 2001). The durability of the structural system used by dwellings limits the service life of dwellings and hence restricts potential reductions in total costs. If the durability of the structural systems of new dwellings does not match that of the current housing stock, then future generations will be subject to increased costs to sustain housing.

This paper uses a simulation model based on classical population dynamics to make exploratory estimates of the maximum impact of short-life dwellings on the total costs to sustain housing. Data and parameters of long-life dwellings are based on a typical New Zealand dwelling of lightweight timber framing. The size and quality of short-life dwellings are set to be the same as that for long-life dwellings and the service life of short-life dwellings is assumed to be 50 years, the minimum required by the New Zealand Building Code.

## 2 THE MODEL

### 2.1 Description of simulation model

The simulation model can be visualised as a multi-deck stack where the level of each deck represents the age of a dwelling cohort. A new dwelling cohort enters the top deck of the stack at the start of each time interval and previous dwelling cohorts move progressively down to the next deck. Dwellings are lost from each dwelling cohort over each time interval, the level of which is determined by a probability of loss schedule that forms the first column of a standard life table. The construction of life tables is described in any textbook on population dynamics, for example Keyfitz & Beekman (1984), and Johnstone (2000) examines a selection of analytic, life table, and stock and flow models that can be used to estimate the mortality of housing. New dwelling cohorts continuously replace total dwelling losses of all ages. If the housing stock is stationary and stable, then each new dwelling cohort comprises replacement construction only. When the housing stock undergoes expansion, each new dwelling cohort comprises both replacement construction and new-build construction that adds to the size of the housing stock. The size and quality of each dwelling within the simulated housing stock are set to be homogeneous for the sake of model simplicity. Different typologies of dwellings can be addressed by constructing separate simulation models.

### 2.2 Dwelling services

A physical dwelling is in itself but a means to an end. We are ultimately concerned with the magnitude and quality of the flow of dwelling services that a dwelling can provide. The model in this paper therefore includes the flow of dwelling services provided by housing stock to enable estimates of the costs to sustain each unit of dwelling services. Dwelling services include only those services rendered by improvements to land. The services of land are excluded in order to avoid confounding separate issues of economic depreciation. The quantity of dwelling services supplied are expressed in units of service year equivalents (sye), the dwelling services provided by a dwelling over one year adjusted for economic depreciation. The proxy for benefits can be converted into dollar terms by multiplying by its price.

Standard notation of classical population dynamics is used throughout this paper. Dwelling service years ($L_x$) provided by each dwelling cohort over the age interval $x$ to ($x$ + 1) are given by

$$L_x = l_x - d_x . a_0 \qquad (1)$$

where $l_x$ is the number of dwellings from an original dwelling cohort, $l_0$, which survive to the age $x$, $d_x$ is the number of dwelling losses from a dwelling cohort of age $x$ over the age interval $x$ to ($x$ + 1), and $a_0$ is the average number of dwelling service years provided by dwellings lost over the age interval $x$ to ($x + n$). The value of $a_0$ = ½ when $n$ = 1 gives sufficiently precise results for the purposes of simulating the dynamics of a housing stock.

Stock losses ($d_x$) over each age interval are given by the product of the surviving dwellings at the start of each age interval ($l_x$) and the probability of loss function P($x$, $r$):

$$d_x = l_x . \ \mathrm{P}(x, r) \qquad (2)$$

where $r$ is the annual expansion rate of the housing stock. The probability of loss function P($x$, $r$) is explained in more detail in Section 3.1.

Total dwelling losses of all ages that are lost over the time interval $t$ to ($t$ + 1) are replaced by replacement construction. If the housing stock undergoes expansion, then new dwelling entries include not only replacement construction but also new-build construction. Dwelling entries over the time interval $t$ to ($t$ + 1) are given by

$$l_0 = \sum_{x=0}^{w} d_x + P_{t+1} - P_t = \sum_{x=0}^{w} d_x + (\exp r - 1)P_t = \sum_{x=0}^{w} d_x + (\exp r - 1)\sum_{x=0}^{w} l_x \qquad (3)$$

where $P_t$ is the size of the housing stock at the start of the time interval $t$ to ($t$ + 1) and $P_{t+1}$ is the size of the housing stock at the start of the time interval ($t$ + 1) to ($t$ + 2). The size of the housing stock at time $t$ ($P_t$) is simply the sum of all the dwelling cohorts that are standing at time $t$.

Dwelling services are adjusted for depreciation. The flow of dwelling service year equivalents ($S_e$) provided by a housing stock over the time interval $t$ to ($t$ + 1) is expressed as follows:

$$S_e = \sum_{x=0}^{w} L_x . \mathrm{D}(x) \qquad (4)$$

where D($x$) is an economic depreciation factor that is a function of the age $x$ of dwelling cohorts. This depreciation factor is discussed in more detail in Section 3.2.

The service loss index (SLI) gives the average quality of dwelling services provided by a housing stock expressed in units of dwelling service year equivalents per dwelling per year (sye/dg/yr):

$$\text{SLI} = \frac{S_e}{\sum_{x=0}^{w} L_x} \quad (5)$$

The service life span of a housing stock (ω) is defined here to be that age beyond which less than 0.1% of the oldest dwelling cohort still stands and provides dwelling service. This definition based on Shryock *et al.* (1973) enables sensible comparisons of the service life span of different housing stocks as exceptional dwellings are excluded.

**2.3 Total average costs and national average costs**

The costs to sustain housing are expressed in construction units (cu), the cost to construct a standard New Zealand house as described in Section 3.3. The proxy for costs can be converted into dollar terms by multiplying by its price. The real costs of all forms of construction, maintenance, refurbishment, and demolition work are assumed to remain constant over time. Under this assumption the long run supply curve of the construction industry is perfectly elastic and returns to scale are constant.

The total average costs to sustain housing over the time interval $t$ to $(t + 1)$, $(C_t)$, is the sum of the costs of new-build construction ($C_{\text{new}}$), annual maintenance ($C_{\text{maint}}$), refurbishment ($C_{\text{refurb}}$), demolition ($C_{\text{dem}}$), and replacement construction ($C_{\text{replace}}$) divided by the sum of dwelling service years provided over the time interval:

$$C_{\text{total}} = \frac{C_{\text{new}} + C_{\text{maint}} + C_{\text{refurb}} + C_{\text{dem}} + C_{\text{replace}}}{\sum_{x=0}^{w} L_x} \quad (6)$$

The units of total average costs to sustain housing are in construction units per dwelling per year (cu/dg/yr).

The costs of new-build construction over the time interval $t$ to $(t + 1)$ is given by the number of new-build entries to the housing stock from equation (3):

$$C_{\text{new}} = (\exp r - 1)\sum_{x=0}^{w} l_x . \text{I}_{\text{new}} \quad (7)$$

where $\text{I}_{\text{new}}$ is an index of the costs to construct a dwelling in construction units per dwelling (cu/dg).

For the purposes of this paper, maintenance is defined here as comprising all that work undertaken to retain the provision of essential services such as weather tight shelter, security, lighting, heating, water supply, and waste disposal. The costs of maintenance over the time interval $t$ to $(t + 1)$ is given by:

$$C_{\text{maint}} = \sum_{x=0}^{w} L_x . \text{M}(x) \quad (8)$$

where $\text{M}(x)$ is a function of maintenance in construction units per dwelling service year (cu/sy).

Refurbishment is defined here as the resurfacing or replacement of building components which results in a reversal of the economic depreciation of dwelling services. Refurbishment may take place a number of times over the service life of a dwelling. For the sake of model simplicity, the duration between successive refurbishment cycles for each component is assumed to be regular.

Not all dwellings undergo refurbishment when due. Deferral of refurbishment may be advantageous for budgeting purposes, but can lead to a hastening of physical depreciation if an injudicious selection of deferral has been made. Some forms of physical depreciation are incurable in that the costs of reversing that depreciation by undertaking refurbishment exceed any increase in value to the property. It is therefore in the best rational interests of a property owner not to undertake such refurbishment.

Dwellings depart from the housing stock at all ages (Johnstone 2000). These departures are largely the result of land use succession where increases in the value of land and economic depreciation of improvements make it viable for a property owner to demolish and replace a dwelling or redevelop the site for an alternative use. A greater proportion of each dwelling cohort departs from the housing stock over each successive age intervals (Johnstone 2000) and hence an increasing proportion of dwelling cohorts still standing at the start of each age interval is unlikely to undergo refurbishment over successive age intervals. The proportion of dwellings ($\text{P}_y$) within each cohort that undergo refurbishment at each cycle is therefore set to be the ratio of the dwellings still standing at the end of a refurbishment cycle of duration $z$ to that standing at the start of the cycle

$$\text{P}_y = \frac{l_{y+z}}{l_y} \quad (9)$$

where $y$ is the age at which refurbishment takes place.

The costs of refurbishment over the time interval $t$ to $(t + 1)$ are given by

$$C_{\text{refurb}} \quad = \quad l_a.\mathrm{R}_a.\mathrm{P}_a + \; l_b.\mathrm{R}_b.\mathrm{P}_b \; + ... + \; l_q.\mathrm{R}_q.\mathrm{P}_q \tag{10}$$

where $l_a$, $l_b$, …, $l_q$ are the number of surviving dwellings within a dwelling cohort of ages $y = a, b, \ldots, q$ ; $\mathrm{R}_{\alpha}$, $\mathrm{R}_{\beta, \ldots,}$ $\mathrm{R}_{\alpha}$, $\mathrm{R}_{\beta, \ldots,}$ $\mathrm{R}_{\theta}$ are indexes of the costs to undertake refurbishment at the ages $y = a, b, \ldots, q$ ; and $\mathrm{P}_{\alpha}$, $\mathrm{P}_{\beta, \ldots,}$ $\mathrm{P}_{\theta}$ gives the proportion of each dwellings within a dwelling cohort which undergoes refurbishment at the ages of $y = a, b, \ldots, q$.

The number of departures from the housing stock from equation (3) gives the costs of demolition:

$$C_{\text{dem}} \quad = \quad \sum_{x=0}^{w} d_x.\mathrm{I}_{\text{dem}} \tag{11}$$

where $\mathrm{I}_{\text{dem}}$ is an index of the costs of demolition in construction units per dwelling (cu/dg).

The number of replacement entries to the housing stock from equation (3) gives the costs of replacement construction:

$$C_{\text{replace}} \quad = \quad \sum_{x=0}^{w} d_x.\mathrm{I}_{\text{new}} \tag{12}$$

where $\mathrm{I}_{\text{new}}$ is an index of the costs to replace a dwelling in construction units per dwelling (cu/dg).

The national average costs (NAC) to sustain dwellings services after adjustment for economic depreciation is given by

$$\mathrm{NAC} \quad = \quad \frac{C_{\text{total}}}{\mathrm{SLI}} \tag{13}$$

The units of national average costs to sustain dwelling services are in construction units per dwelling service year equivalents (cu/sye).

## 3 PARAMETERS AND DATA

### 3.1 Probability of loss schedule

Johnstone (1994) established that the mortality of New Zealand housing stock between 1858 and 1980 had been a function not only of age, but also the annual expansion rate ($r$) of the housing stock. The best-fit probability of loss schedule $\mathrm{P}(x,r)$ for New Zealand housing stock is given by a probability of loss schedule which applies for a stationary and stable housing stock and a multiplier function of the annual expansion rate of the housing stock (Johnstone 2000):

$$\mathrm{P}(x,r) \quad = \quad l_x.q_x.(1+78.6r)^{0.70} \tag{14}$$

Each column in a standard life table is a transform of another column (Keyfitz & Beekman 1984). The probability of loss schedule ($q_x$) in the above equation is a transform of the stock losses schedule ($d_x$):

$$d_x = \mathrm{INT}\left[ \frac{l_0.s}{s\sqrt{2p}}\, e^{-\frac{1}{2}[(x-m+0.5)/s]^2} \right] \tag{15}$$

where INT is a function that truncates fractional stock losses to the nearest integer, $l_0$ is initial dwellings entries to a life table at age 0 (the radix of a life table), $s$ is an adjustment factor that ensures the sum of truncated dwelling losses over the service life span of a dwelling cohort equals the initial dwelling entries $l_0$, $s$ *is* the standard deviation of stock losses from a dwelling cohort within a stationary and stable housing stock, and $\mu$ is the mean age of stock losses from a dwelling cohort within a stationary and stable housing stock.

The standard deviation and mean age of stock losses from a cohort of long-life dwellings within a stationary and stable housing stock are set to be 31.08 years and 130 years respectively. The mortality of short-life dwellings is set to be the same as that for long-life dwellings over the age interval 0 to 49 years. Dwellings within each cohort that are still standing at the age of 49 years depart from the housing stock over the age interval 49 to 50 years.

The average annual expansion rate of the New Zealand housing stock has averaged 1.5% per year over the past decade (Statistics New Zealand 1998). Positive net migration has formed the major source of additional household formation because the fertility of the natural population has declined since the 1960s to the extent that the natural population now barely replaces itself.

The average number of persons per household (pph) has declined from over 6 pph at the start of the 20th century to 2.9 pph at the last census in 1996. Further decreases over the next number of decades are likely to be gradual. The annual expansion rates of 1.5%, 1.0%, 0.5%, and 0% per year are selected for the purposes of estimating the maximum impact of short-life dwellings entering the housing stock.

### 3.2 Economic depreciation of dwelling services

An empirical study of the economic depreciation of dwelling services provided by New Zealand housing stock has yet to be carried out. Extensive literature surveys of empirical studies of economic depreciation of dwellings by Malpezzi *et al*. (1987) and Baer (1991) do not provide satisfactory guidelines which can be applied with confidence to New Zealand housing stock as no study estimates the economic depreciation of dwelling services or rent (excluding rent for land) over the full service life of dwellings. A depreciation schedule based on first principles is therefore used instead.

Economic depreciation of dwelling services is due to a combination of physical degradation and obsolescence. A survey of the physical condition of a representative sample of 465 New Zealand dwellings has shown that the average costs of outstanding maintenance (many of these items are refurbishment as defined in this paper) generally rise with house age and the condition of the average house appears constant beyond an age of around 60 years as a consequence of renovation of the older housing stock (Clark *et al.* 2000). Economic depreciation due to physical degradation would therefore decline to a threshold level with fluctuations in the process due to reversals in depreciation after undergoing refurbishment. The rate of economic depreciation due to obsolescence would be gradual over the first years of life of a dwelling, would increase during the middle years, and then diminish in later years due to a vintage effect. The combination of economic depreciation due to physical degradation and obsolescence would follow a fluctuating reversed S-shaped curve that declines to a threshold value. Fluctuations in economic depreciation are ignored for the sake of simplification and a reversed S-shaped curve function is taken to be a likely schedule of economic depreciation. Reversed S-shaped curve depreciation is based on the logistic curve

$$\mathrm{Q}(x) = \frac{\mathrm{K}}{1 + ce^{-r_m x}}, \quad c = \frac{\mathrm{K}}{\mathrm{Q}(0)} - 1 \tag{16}$$

and

$$\mathrm{D}(x) = \frac{\mathrm{P\text{-}Q}(x)}{\mathrm{P\text{-}Q}(0)} \quad \text{for} \quad \mathrm{P} \geq \mathrm{Q}(x) \tag{17}$$

The units of D($x$) are dimensionless and $0 \leq \mathrm{D}(x) \leq 1$. For convenience, P = 10,010, Q(0) = 10, and $r_m$ is varied.

In the absence of empirical data on the value of the dwellings services provided by the oldest dwellings in the housing stock immediately prior to departure from the housing stock, the threshold value of the depreciation function D(ω) is set to a value of 0.50 and 0.25. The same schedules of depreciation are set to apply for long-life and short-life dwellings.

The probability of loss of dwellings increases as the expansion rate of the housing stock increases and there is a corresponding decrease in the average service life and service life span of the housing stock. A decline in the value of dwellings services and hence a decline in capital value would hasten departures from the housing stock. An increase in the rate of economic depreciation of dwelling services would therefore accompany an increase in the probability of loss of dwellings.

Straight-line depreciation is included for comparison:

$$\begin{aligned} \mathrm{D}(x) &= 1 - \frac{(x+1)}{w_p} \quad \text{when} \quad x < w_p \\ \mathrm{D}(x) &= 0 \quad \text{when} \quad x \geq w_p \end{aligned} \tag{18}$$

where $\omega_p$ is that age at which D(ω) = 0.50 and D(ω) = 0.25.

### 3.3 Costing data

The costs of new-build and replacement construction of long-life dwellings are based on the National Modal House (NZIV 1996) which comprises a typical New Zealand dwelling of lightweight timber framed construction with a floor area of 100 $m^2$. The floor and sub-floor structure is particleboard on timber joists, bearers, and timber piles. The wall cladding is fibre cement planks, windows and exterior doors are aluminium, and the roofing is galvanised mild steel. Interior linings are gypsum board. The costs of the Modal House are $94,110.40 in June 1997 New Zealand dollars. This paper includes vinyl flooring (10 $m^2$) in the kitchen and a 3-coat polyurethane floor finish in all other areas which brings the total average costs of a long-life dwelling to NZ$95,155.40.

Dufaur (2001) has compared the costs of five alternative structural systems to lightweight timber framing as used in New Zealand. Two of these alternatives, lightweight steel framing and wood-fibre panels, use non-traditional building materials which have yet to demonstrate a service life which matches the 90 year average service life of the housing stock. Although cost savings of up to 3% can be achieved by using either lightweight steel framing or wood-fibre panels to construct a dwelling to the same size and quality as the National Modal House (Dufaur 2001), the costs of short-life dwellings are taken to be the same as that for long-life dwellings because these cost savings fall within the margin of error. The possibility of future reductions in costs of lightweight steel framing and wood-fibre-panels are also examined.

Estimates of the costs of maintenance are based on the maintenance records of 25 New Zealand Housing Corporation dwellings that date back between 24 and 39 years prior to 1988. Table 1 sets out the average annual costs of maintenance based on these records. The total annual costs of maintenance ($269.91) are set to apply for both long-life and short-life dwellings and these costs are assumed to remain constant over the full service life of dwellings.

Table 2 lists the cycles and costs of refurbishment including removal and disposal of existing components and making good to collateral damage in the process. The cycles and costs apply for both long-life and short-life dwellings with exceptions as listed. Refurbishment of short-life dwellings is not undertaken when the remaining service life of dwellings is shorter than the refurbishment cycle *z*. The replacement of component costs are based on the schedule of the National Modal House (NZIV 1996) and pricing data provided by Rawlinsons Group (1997). The cost of demolition and disposal of both short-life and long-life dwellings is $1,700. Recycling of building materials is not examined in this paper.

**Table 1. Average annual costs of maintenance**

| *Item* | *Cost (1997 NZ$)* |
|---|---|
| Electric range: repairs | 26.20 |
| Hot water cylinder: repairs | 20.52 |
| Electrical: outlets, lighting, meter board, minor wiring | 27.01 |
| Taps: washers, replacement | 10.58 |
| Waste pipe work: clear blockages, repair soil pipe junctions | 13.09 |
| Water supply | 15.90 |
| Drainage system: clear blockages, repair soil line | 23.18 |
| Spouting and downpipes: clean out, repair | 26.24 |
| Flashings: repair | 3.24 |
| Hardware: door locks, window catches | 6.75 |
| Glazing: repairs to windows | 4.08 |
| Miscellaneous | 56.63 |
| Unspecified due to illegibility or inadequacy of entry on card | 36.49 |
| Total | 269.91 |

# 4 RESULTS

Housing stocks are comprised entirely of either long-life or short-life dwellings. Table 3 summarises the results for housing stocks that are subject to reversed S-shaped curve economic depreciation with a threshold depreciation of D(ω) = 0.50. The total average costs of short-life dwellings (cu/dg/yr) are 23.9% greater than that for long-life dwellings when the housing stock is stationary and are 12.7% greater when the expansion rate $r$ = 1.5%. Refurbishment costs of short-life dwellings are smaller, but replacement costs are much greater for all expansion rates. Refurbishment of long-life dwellings forms a larger proportion of total average costs and this proportion decreases by a greater extent as the expansion rate increases (60.0% when $r$ = 0% and 36.9% when $r$ = 1.5%) compared to short-life dwellings (29.4% when $r$ = 0% and 23.1% when $r$ = 1.5%).

The national average costs to sustain short-life dwellings (cu/sye) are 4.4% greater than that for long-life dwellings when the housing stock is stationary and are 5.8% greater when $r$ = 0.5%. Increases in national average costs peak at 7.8% when $r$ = 0.5%. The increases in national average costs are substantially less than increases in total average costs at low expansion rates due to short-life dwellings undergoing much less depreciation over a shorter service life. The mean ages of short-life and long life dwellings are 24.7 and 68.1 years respectively when the housing stock is stationary compared to 21.7 and 36.3 years when $r$ = 1.5%.

Table 4 tabulates the national average costs for housing stocks that are subject to straight-line curve economic depreciation with a threshold depreciation of D(ω) = 0.50. Increases in national average costs to sustain short-life dwellings are greater when subject to straight-line depreciation because short-life dwellings undergo relatively greater depreciation. The national average costs to sustain short-life dwellings (cu/sye) are 7.9% greater than that for long-life dwellings when the housing stock is stationary and are 6.6% greater when $r$ = 1.5%. Increases in national average costs peak at 9.3% when $r$ = 0.5%.

Table 5 tabulates the national average costs for housing stocks that are subject to reversed S-shaped and straight-line curve economic depreciation with a threshold depreciation of D(ω) = 0.25. Increases in national average costs (cu/sye) for short-life dwellings are substantially reduced to the extent that there are savings of 5.4% and 1.1% when the housing stock is stationary and subject to reversed S-shaped curve and straight-line curve depreciation respectively. Increases in national average costs for short-life dwellings are otherwise modest peaking at 2.5% and 3.9% at $r$ = 0.5% when subject to reversed S-shaped curve and straight-line curve depreciation respectively.

**Table 5. Results for reversed S-shaped and straight-line curve depreciation D(w) = 0.25**

Some structural systems, for example lightweight steel framing, are direct substitutes for lightweight timber framing in that interior linings and exterior cladding systems can be the same. The costs of lightweight timber wall and roof framing are $13,181.69 or 13.9% cost of the total average costs of $95,155.40 for the National Modal House including floor finishes. If the costs of a direct substitute short-life structural system for the walls and roof are 75% and 50% of that for lightweight timber framing, then the costs of new-build and replacement construction would be $91,859.98 or 0.9654 construction units and $88,564.56 or 0.9307 construction units respectively. Table 6 tabulates the increases in total average costs (cu/dg/yr) and national average costs (cu/sye) for short-life dwellings when the costs of structural systems for the walls and roof are 75% and 50% of that for long-life dwellings. The housing stocks are subject to reversed S-shaped curve economic depreciation with a threshold depreciation of D(ω) = 0.50.

**Table 6. Results for reduced costs short-life dwellings**

| | *r = 0%* | *r = 0.5%* | *r = 1.0%* | *r = 1.5%* |
|---|---|---|---|---|
| *Cost of wall and roof structural system 75%* | | | | |
| Total average costs (cu/dg/yr) | 0.0325 | 0.0352 | 0.0381 | 0.0412 |
| Increase in total average costs (%) | 21.3 | 16.6 | 13.7 | 11.4 |
| Increase in national average costs (%) | 2.2 | 6.0 | 5.2 | 4.5 |
| *Cost of wall and roof structural system 50%* | | | | |
| Total average costs (cu/dg/yr) | 0.0318 | 0.0346 | 0.0376 | 0.0407 |
| Increase in total average costs (%) | 18.7 | 14.6 | 12.2 | 10.0 |
| Increase in national average costs (%) | 0.0 | 4.2 | 3.6 | 3.3 |

The total average costs of short-life dwellings (cu/dg/yr) are 21.3% and 18.7% greater than that for long-life dwellings when the housing stock is stationary and the costs of the wall and roof structural systems are respectively 75% and 50% of that for long-life dwellings. These increases in total average costs decline to 11.4% and 10.0% respectively when $r$ = 1.5%.

The costs to construct a short-life dwelling to the same size and quality as that of the National Modal House would need to be between 68.5% to 65.5% of that for long-life dwellings in order for the total average costs (cu/dg/yr) to be the same as that for long-life dwellings when $0 \leq r \leq 1.5$.

Increases in national (cu/sye) costs decline to a peak of 6.0% (*r* = 0.5%) and a low of 2.2% (*r* = 0%) when the costs of the wall and roof structural system is 75% of that for long-life dwellings and decline to a peak of 4.2% (*r* = 0.5%) and a low of 0.0% (*r* = 0%) when the costs of the wall and roof structural system is 50% of that for long-life dwellings.

## 5 CONCLUSIONS

This paper uses a dynamic simulation model to make exploratory estimates of the maximum impact of short-life dwellings on the total costs to sustain housing. Long-life dwellings are based on a typical New Zealand dwelling of lightweight timber framing. Short-life dwellings of the same size and quality are assumed to have a service life of 50 years, the minimum required by the New Zealand Building Code. If the entire simulated housing stock of long-life dwellings is replaced with short-life dwellings, then the total average costs to sustain housing are almost 13% greater when the housing stock expands at 1.5% per year. This increase is equivalent to an additional expenditure of $600 million on New Zealand housing in 2001. Total average costs are 24% greater when the housing stock is stationary and are the same as that for long-life dwellings when the costs to construct short-life dwellings are 65% of that to construct long-life dwellings. The quality of dwelling services provided by a short-life, and therefore younger, housing stock is higher than that provided by long-life housing stock. Nonetheless, exploratory estimates based on realistic scenarios of depreciation indicate there are no reductions in the national average costs to sustain dwelling services after adjustment for depreciation when the costs to construct short-life dwellings are the same as that to construct long-life dwellings.

The results of this paper signal that it is imprudent to allow short-life dwellings to enter the New Zealand housing stock unless the costs to construct short-life dwellings are substantially less than the costs to construct long-life dwellings. In addition to significant increases in costs to sustain housing, the penalties of short-life dwellings entering the housing stock include increases in environmental pollution from manufacturing processes, waste products from demolition, and $CO_2$ contributions to the atmosphere due to activities by the construction industry. The full extent of these penalties would be carried by future generations, as it would take one service life span for the entire housing stock to be replaced by short-life dwellings. Some may therefore dismiss the need to restrict the entry of short-life dwellings into the housing stock. Under the principles of intergenerational justice, we should do unto the next generation as we would have the previous generation do unto us. Intergenerational justice would be assured under Rawls' (1973) veil of ignorance where no one knows which generation they belong to when they make decisions which have an impact on future generations.

## 6 ACKNOWLEDGMENTS

The author thanks the New Zealand Property Institute for authorising Rawlinsons Group to provide a copy of the unpublished 1997 priced schedule of the 1996 National Modal House and thanks Peter Dufaur for his assistance with costings of refurbishment and demolition.

# The Sealing Of Deep-Seated Swiss Alpine Railway Tunnels New Evaluation Procedure For Waterproofing Systems

**P Flüeler*, Ch Löwe* M Farshad* P. Zwicky** & H Böhni*****
*** Polymers/Composites EMPA Switzerland, ** Ingenieurbüro für Abdichtungstechnik, Switzerland, *** Institute for Building Materials, Materials Chemistry and Corrosion, Switzerland**

**Summary**: **A comprehensive evaluation procedure for the sealing and drainage of the two long tunnels through the Swiss alps is performed based on an order by AlpTransit Gotthard AG and BLS AlpTransit AG. Special influences such as high geothermal heat, high pressure of mountain mass, construction, and high expectations for the service life-time – 100 years – had to be considered. Compared with near-surface tunnels, the thermoplastic polymeric materials typically used at present are more highly stressed. Polymeric products combined to waterproofing systems (waterproofing membranes: PE, PE-Cop, PVC-P, drainage materials: PE, PP, PA, PES) were submitted by the applicants and tested in a 24 months program for their ageing resistance. Existing test methods were complemented by new procedures, e.g., by resistance at elevated temperatures and in oxygen-enriched water at elevated temperatures, respectively, compression creep tests between rough surfaces, behaviour under combined lateral compression and horizontal shear, and installation tests including construction of the conrete support shell. The most important results of the four test modules with preliminary conclusions will be detailed. The installation tests showed that the waterproofing membranes develop regular folds with small radii of curvature during construction and thus locally lead to high strains in the membranes. Since most products did not meet certain requirements, optimised systems are now re-evaluted in a shortened procedure.**

**Keywords. Tunnel construction, polymeric waterproofing systems, evaluation, long-term behavior, ageing resistance**

## 1 INTRODUCTION - DESCRIPTION OF PROBLEM

The two new railway connections from North to South in Switzerland, the Gotthard and Lötschberg base tunnels, are being built with one track each per gallery as double-shell tunnels. Because of the large mountain cover, the waterproofing system (WPS) between the relatively rough shotcrete outer shell and the concrete inner shell should continuously drain the attracted mountain water, protect the concrete construction against water, and locally transfer high compressive loads onto the concrete support structure. At the base, the large mountain cover of up to 2'500 m also results in rock temperatures of the order of 45° C due to geothermal effects. These conditions thus apply to the intruding water that is mostly alcaline, but may be acidic in some areas. The expected service life-time is 100 years, with no major repairs being necessary within 50 years. All waterproofing and draining materials known today have not been designed for nor ever been tested under such extreme conditions. The known standards do not contain criteria or requirements for such loads. Results of long-term tests were not available at the time and practical experience existed only for relatively short periods.

## 2 EVALUATION PROCEDURE

In order to effectively take into account the special conditions (mountain, choice of construction, and other boundary conditions imposed by the builders), a special task force together with the assigners developed, invited for tender, and realised a multi-part procedure for the evaluation of the waterproofing system consisting of waterproofing membrane and drainage material (E. Basler+Partner 1998). This procedure comprised:

- Ageing behaviour of the different waterproofing and drainage materials
- Behaviour of the WPS under compression creep load
- Compression/shear behaviour of the WPS
- Suitability for installation
- Synthesis

### 2.1 Ageing of the individual components

In this part of the evaluation, the components of the WPS are exposed for 24 months without mechanical loading to the following media: water circulated at temperatures of 23°, 45°, and 70° C, alcaline and acidic water at 50° C, oxygen-enriched water at 70° C and 3 bar pressure (test equipment shown in Figs 3 and 4), and, by burying the specimens, in an environment with aerobic and anaerobic microorganisms. At 5 points during the storage, the waterproofing membranes are tested for mass changes, longitudinal and transverse change of dimensions, mechanical puncture strength (dart impact on WPS placed on rigid support), and the drainage materials for mass changes, transmissivity within the plane, and punching resistance against a drop cone. An additional series of tests such as, e.g., tensile, thermomechanical and thermoanalytical after 3, 6, 12 and 24 months is used to determine the respective properties for a sufficiently complete description of the ageing processes.

### 2.2 Behaviour of the WPS under Compression Creep Load

In a separate compression test during 24 months, the WPS are stored at 0.4 MPa in alcaline water at 50° C between a planar and a strongly corrugated ripple plate (Fig. 5). The surface roughness Rt determined using the sand-filling procedure is 4.5 mm. This ripple structure consists of 169 truncated pyramids with a square base area of 256 mm$^2$, a height of 7 mm and a top area of 4 mm$^2$. Figure 6 shows the experimental arrangement for the WPS. The decrease of the thickness of the waterproofing system, the impermeability,

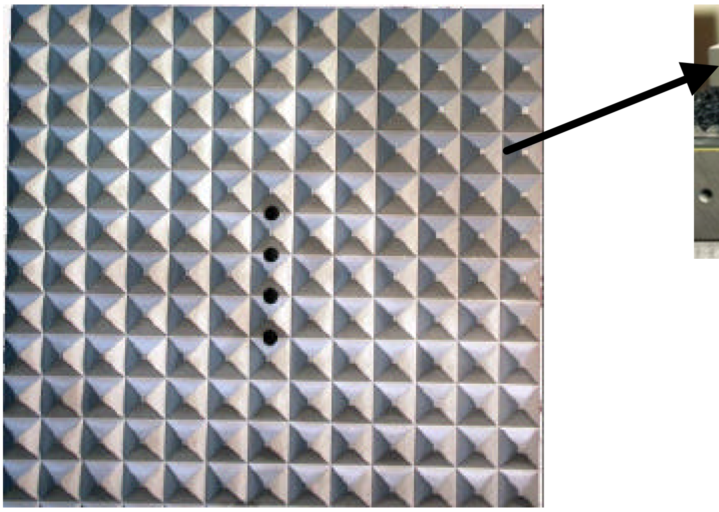
the drainage capacity, the visual appearance and the interaction betweeen waterproofing membrane and drainage material are periodically recorded.



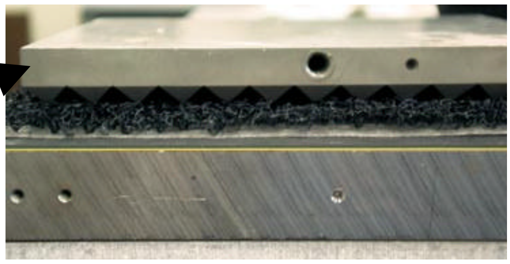


**Figure 5: Set-up of the compression creep test: from top to bottom ripple plate, drainage mat, waterproofing membrane, planar steel plate**

**Figure 6: Example of the ripple plate (surface towards drainage material) with drainage water outlets**

## 2.3 Compression/Shear Behaviour of the WPS

Four separate test modules are used to evaluate the short- and long-term behaviour of the WPS under the combined effects of compression (up to 2 MPa) and shear at 45° C for a 1.5 $m^2$ size specimen between the rough shotcrete surface (average surface roughness Rt 3.1 mm) and the concrete compressive support surface. The waterproofing function, the drainage capacity, and the deformation behaviour of the systems set-up are evaluated. Because of the novelty and complexity of this test it was necessary to specially design, test, and validate a suitable test set-up. The reproducibility of the test results was assured by casting one template each of an original shotcrete and concrete surface. A pipeline system inserted into the pressure plates allows heating the contact surfaces to up to 70° C. With an additional pipeline system, drainage water can be circulated into a water distribution groove placed at the center of the top plate from where it will flow horizontally through the WPS (Fig. 7). Drinking water, filtered at the inlet to remove eventual suspended particles (> 10 µm) was used. The water flowing out along the sides is collected and pumped back into the circuit. The drainage capability is measured by determining the pressure necessary for a constant water throughput of 10 l/min.

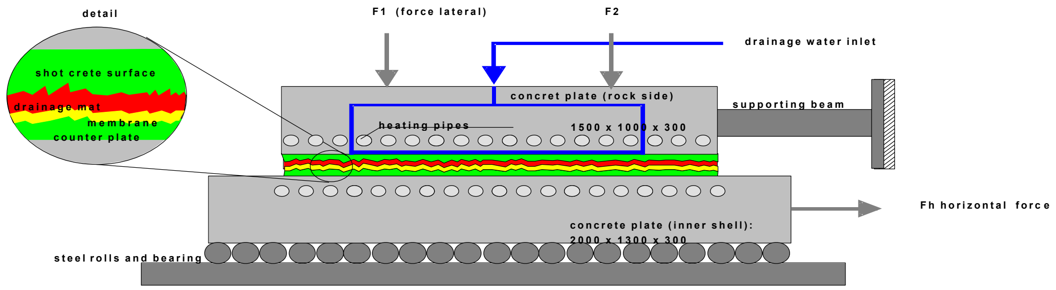

**Figure 7: Schematic cross-section of the compression/shear set-up with heating and drainage capability, the top plate (fixed) corresponds to the shotcrete surface of the outer tunnel shell**

### 2.4 Suitability of Installation

In an experimental gallery with a 8 m high shotcrete arch of the vault, each waterprofing system (WPS) is used to seal a shotcrete surface area of 70 $m^2$ with a defined surface roughness under real conditions (humid-wet at elevated temperatures of the shotcrete surface) including construction of the concrete support shell. The type of fixation, the number of fixations, the joint type and the properties of the seams are checked as indicators for the WPS. After completion of the construction, the water flow and drainage capability, respectively, are measured by injecting a defined amount of water through a piping system into the spherical cap behind the waterproofing membrane. Later, the concrete support shell is removed and the exposed WPS is inspected for damage/bruises and impermeability, respectively, for fold-free installation and other irregularities.

## 3 MATERIALS TESTED

The applicants, i.e., consortia of manufacturers, suppliers, and installation companies, submitted 14 different combinations of WPS (Table 1) for the two year evaluation period. Those combinations were considered optimal for use in the alpine tunnels. The considerable differences between the submitted WPS resulted from different weight attributed to the various conditions (waterproofing, drainage function, pressure transfer, and fire resistance during installation) that had to be fulfilled simultaneously. These requirements were interpreted quite differently by the applicants.

**Table 1: Types of Materials submitted for the two year evaluation procedure**

| *Aspect* | *Unit* | *Waterproofing Membranes* | *Drainage Materials* |
|---|---|---|---|
| Number | Piece | 10 | 8 |
| Material Type | - | PVC-P, PE, PO-Copolymers (EVA) | PE-HD, PA, PES, PP |
| Structure | - | mostly smooth surfaces, partially with stamping, with inserted non-woven glass-fabric, textile reinforcement | dimpled sheet<br>net<br>randomly oriented mat<br>non-woven geotextiles, dense, rough |
| Thickness | mm | 2.1 – 3.3 | 6 to 18 |
| Areal Weight | kg/m2 | 2.1 - 3.0 | 0.55 – 1.9 |
| Width of Rolls | m | 2 | 1 - 2 |
| Type of Joint | - | hot-air welding | no joining, overlapping |

Prior to acceptance in the evaluation, the applicants had to proove conformity with existing standards/guidelines, such as Sia V280 for ground-water sealing (Sia 1996) and Handbook of Geotextiles (SVG). Since these standards apply only to materials after manufacturing, some requirements were specifically increased, in particular mechanical puncture strength for the waterproofing membranes, and transmissivity and fire classification for the drainage materials.

## 4 RESULTS

### 4.1 Ageing Behaviour

After 6 months, the results were relatively heterogeneous, but after 12 months, differences in quality between the types of materials used for the waterproofing membranes and the drainage became apparent. Between 12 and 24 months, these trends were reinforced. In general, the waterproofing membranes prooved to be more resistant than the drainage materials even

Go Back Next Page

though some products made from polyolefin-copolymers (PO-C) decomposed during the exposure to hot, oxygen-enriched water. Waterproofing membranes made from plasticized PVC, as expected, reacted by loss of plasticiser most strongly to alcaline water and by increasing loss of plasticiser under exposure to aerobic microorganisms. Some materials made of PO-Copolymers reacted when exposed to alcaline water. The evaluated drainage materials generally reacted more sensitively to both acidic and acaline exposure. Some products made from polyamide (PA) and saturated polyesters (PES) decomposed in acidic water at 50° C. In hot water at 70° C, these materials embrittled even after 6 months, at 45° C between 12 and 24 months. Dimpled sheets yielded relatively minor changes.

### 4.2 Behaviour under Compression Creep Load

Under this type of loading, the drainage materials yielded considerable deformations and the ripple plate intruded deeply through the draining layer into the waterproofing membrane. From the compression-deformation curves (Diagram 1) the thickness of the total WPS at the load points is reduced to 0.8 mm. No WPS, however, was punctured under this creep load. Even an additional 20% strain after the test did not show disadvantageous behaviour at the contact points. In a few cases, the drainage stuck to the waterproofing membrane. Points of high stresses, e.g., at the edge of the nop, occasionally yielded first signs of stress induced cracks that increased in length between 12 and 24 months.

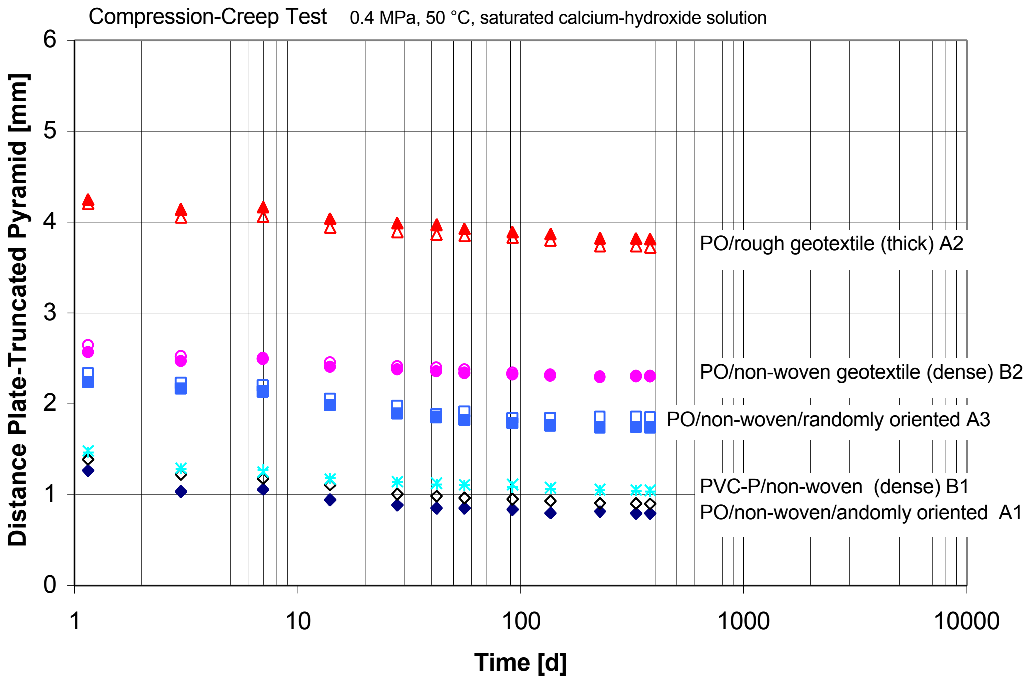

**Diagram 1: Example of deformation curves from compression creep tests for typical WPS at 0.4 MPa distributed load on the ripple plate in alcaline medium at 50° C.**

Go Back
Next Page

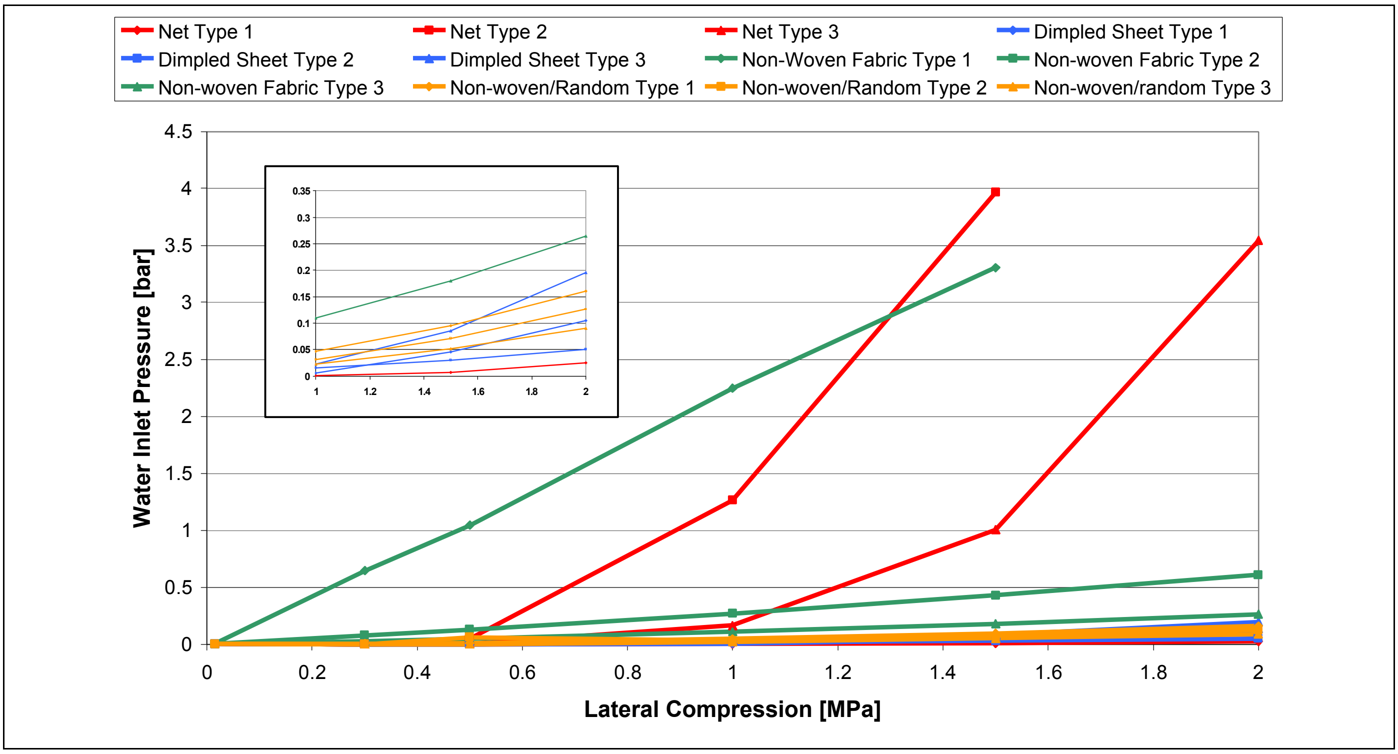

**Diagram 2: Short-term compression/shear test: Inlet pressure of the drainage water (drainage throughput of 10 l/min) versus lateral compression load for the most important types of WPS at 45° C, surface roughness 3.1 mm, the insert shows details of the bottom right hand part.**

### 4.3 Compression/Shear Behaviour

The most severe criterion prooved to be the drainage capability under lateral compression at elevated temperature (+45° C). This capability directly correlates with the time-dependent remaining thickness of the WPS. Several WPS did not meet the requirement of a maximum water inlet pressure of 0.25 bar at 10 l/min throughput in both the short- and long-term (7 days) tests (Diagram 2). The compression/shear results of the limited number of materials tested seem to indicate the following pattern for the behavior of the WPS. All WPS with dimpled sheets prooved fairly well suited in spite of large deformations. Depending on the hardness, several net-type drainage materials intruded into the waterproofing membranes, starting at lateral compression loads of 1 MPa, thus limiting the water flow and finally interrupting it at loads above 1.5 MPa. Some WPS with net-type drainage materials of a modified shape and combined with a less compliant waterproofing membrane, on the other hand, fulfilled the criterion at the highest lateral compression load of 2 MPa in the short-term, as well as in the long-term test (7 days) at loads of 1.5 MPa. WPS with thick and dense non-woven fabrics as drainage materials showed an increase in water inlet pressure beyond the limit even at lateral compression loads of 0.5 MPa. Some waterproofing membranes were perforated after shear displacements of 10 mm under relatively low compressive loads (0.3 MPa), while displacements of 3 mm under the same load did not yield perforations. Passing the compression/shear tests may thus crucially depend on the specific combination of drainage material (structure and shape) and waterproofing membrane (hardness and thickness).

**Figure 8: View of the partially exposed waterproofing membrane in the experimental gallery, the concrete support shell lies on the bottom**

**Figure 9: Vertical folds of the PVC-P waterproofing membrane, extending up to 5 cm into the concrete**

### 4.4 Suitability for Installation in the Experimental Gallery

Before the product tests were effected, three trial tests with typical WPS made from plasticized PVC and PO-Copolymers (dimpled sheet- and net-type drainage materials) yielded the test parameters. The systems were installed on shotcrete surfaces with a variable surface roughness between 3 to 7 mm and a waviness of 4:1, 7:1 and 15:1. With additional heating during the setting of the concrete the temperature in the waterproofing system rose to 55° C. After completion of the construction the drainage capability was determined. The concrete support shell was then removed and the waterproofing system exposed (Fig. 8). These tests yielded unexpected, interesting results. Both types of WPS showed deep folds in the waterproofing membrane, protruding into the concrete after the support shell had been removed (Figs 9, 10). The folds mostly ran along the vertical and extended for about 5 cm with radii of curvature of up to 3 mm. Practically, the folds are narrowly localised but highly strained zones that potentially can function as water drains. There, the waterproofing membrane is strained beyond its apparent yield point and oriented, respectively and is stressed both chemically and physically by the mountain water. The third trial test prooved that WPS can be installed without fold formation. The waterproofing membrane was not damaged in any of the tests. The large waviness of the shotcrete surface, however, required additional expenditures during installation, in particular for fixation and joints. Based on the understanding gained from these tests, the requirements for the main tests could be defined and the test set-up be adapted.

**Figure 10: Back-side of the concrete support shell after its removal, up to 5 cm deep grooves in the concrete.**

## 5 KNOWLEDGE GAINED

It took about 12 months until equilibrium states and recognisable ageing trends were established for the different materials. After 24 months, the loads/exposures yielded clear signs of deterioration and only a few WPS and WPS-components, respectively, fulfilled all requirements. While the waterproofing membranes, on one hand, failed under some specific load conditions, the drainage materials with their formulation, on the other hand, prooved to be rather unsuited for use in hot, aqeous media. The WPS selected for submission by the applicants were mostly manufactured using formulations developed for standard construction applications instead of being designed for the special requirements of the tunnel constructions. The standards usually do not require test durations beyond about 8 months, usually even shorter, and leave the definition of requirements to those responsible for the construction.

Development of folds in the plane of the waterproofing membrane produces potential failure lines and have thus to be avoided in long-term service. This requirement represents a major challenge for the usual installation procedures. The causes for folding have to be thoroughly investigated. Waviness of the backplane, the number of fixation points, the joining procedure, friction between waterproofing membrane and drainage material, the form-boards of the inner concrete shell and the temperature raise caused by the setting of the concrete are among the factors that cause surplus membrane material to protrude into the concrete at the time of construction. Preliminary experiments have shown possible ways of avoiding fold formation.

The evaluation procedure has prooven to be both practical and selective. Compared with established standard test criteria, the requirements have been increased and the evaluation takes considerably longer. In order to design for ageing resistance during the intended service life, test durations of up to five years would be necessary under current test conditions. With the introduction of the evaluation procedure, the behaviour of both, waterproofing membrane and drainage material, acting together as a system, has been investigated under very high load and long-term exposure for the first time.

## 6 PRESENT STATE OF THE EVALUATION

By continuously informing about intermediate results and based on reports summarizing the first 6 and 12 months, the builders could continually assess the situation and adapt it to the construction program. Based on the results of the first test series a shortened evaluation procedure of 12 months duration was re-started. This program evaluated so-called "improved" waterproofing systems – systems modified within certain limits – in the same way and was recently completed. Before the final decision was taken whether a WPS passed the requirements, the results from the second test series were correlated with those from the first, since the 12 months test duration is too short to allow a definitive assessment.

The improvements essentially comprised an increased compression stiffness of both waterproofing membrane and drainage material and modified formulations for increased resistance. Certain criteria still proved to be problematic, in particular the exposure of drainage materials to oxygen-enriched and to alcaline water. The test program on improved WPS up to present yielded 8 systems that passed all requirements. These combine polyolefine- or PVC-P-based waterproofing membranes with either dimpled sheets or composite drainage materials.

Go Back

The evaluation procedure is still open for new waterproofing systems. Due to the stringent requirements, other applications in civil engineering and tunnel construction with long service life-times should also be covered. Nevertheless, the effects on the waterproofing system have to be carefully analysed, assessed, and investigated accordingly.

## 7 ACKNOWLEDGMENTS

The authors would like to thank AlpTransit Gotthard AG and BLS AlpTransit AG, as well as the industrial partners for the collaboration and support and acknowledge the project administration by Mr P. Rietmann (E. Basler+Partner AG).

# Durability Of Concrete With Recycled Aggregates – Results Of Dutch Laboratory And Pilot Tests

**Hans S. Pietersen*/** Alex L.A. Fraaij*& Hans (J.) de Vries******
**Delft University of Technology, Faculty of Civil Engineering and Geosciences, Materials Science Group, DELFT ** Ministry of Transport, Public Works and Water management, Directorate General for Public Works and Water Management, Road and Hydraulic Engineering Division, Raw Materials Supply, Delft, *** Ministry of Transport, Public Works, and Water management, Directorate General for Public Works and Water Management, Civil Engineering Division, Utrecht, The Netherlands.**

**Summary**: **Recycled aggregates are applied increasingly in many European countries, Japan, and locally elsewhere around the world, notably in densely populated regions. They are obtained from the processing of stony construction and demolition waste. It is estimated that in Europe alone, at least about 200-300 million tonnes of building and demolition waste is currently land filled or applied in road construction.**

**However, recycled aggregates may also be applied as aggregate in concrete, thereby upgrading its application. Concrete's, containing up to 100% fine and coarse aggregates may be utilised successfully. Significant savings on primary aggregates (in the order of 20-25%) may be obtained, thereby contributing to an improved sustainable raw materials use and exploitation, and providing a first step towards the eventual strive for a "closure" of the concrete life cycle loop.**

**Introduction of "new" raw materials in the building industry is only possible when there is no discussion on aspects such as the product quality and the ratio between price and performance. Therefore, this paper will give attention to results obtained in the mixture proportions of concrete with recycled aggregates, strength, durability as well as environmental performance. It will be shown that for the most common ordinary concrete's durability is not a topic of much concern, based on results of tests on creep behaviour, chloride-ion ingress, sea water resistance and freezing and thawing resistance.**

**Keywords.** **ASR, chloride, creep, recycled aggregates, seawater ingress, shrinkage**

## 1 INTRODUCTION

### 1.1 General background

Recycled aggregates, obtained from the processing of stony construction and demolition waste (CDW) are applied increasingly in many European countries, Japan and locally elsewhere around the world, notably in densely populated regions and Japan. It is estimated that in Europe alone, at least about 200-300 million tonnes of building and demolition waste is currently land filled or applied in road construction (Lauritzen, 1998; Symonds, 1999; Hendriks & Pietersen, 2000). This equals an amount of 0.6-0.9 ton per capita per year and is 2-3 times the amount of domestic waste produced per capita per year.

Traditionally, in most countries, CDW, which may contain low percentages of hazardous substances such as asbestos fibres and polycyclic aromatic substances, has been deposited in normal landfills.

Its stony components are in many cases applied as foundation material for (rural) roads (e.g. CUR, 1995; Hanson, 1989). However, the huge quantities involved are causing ever-increasing spatial and environmental problems, most noteworthy in densely populated countries.

In most European Member States increasing land filling costs and special taxes for the disposal of CDW force the construction industry, demolition contractors and recycling companies to look for opportunities for either re-use, recycling and/or recovery.

### 1.2 Recycled aggregates – future scenario's

Since about two decades, an active policy has been carried out in order to increase the overall quality of (notably stony) CDW in the Netherlands, thus facilitating acceptance and application as (a component within) construction materials.

As a result of this active policy, the total level of recycled CDW in the Netherlands has increased from about 60% in 1990 to above 95% in 1999.

A landfill ban for recyclable CDW, effective since 1997, has stimulated this notably.

Furthermore, the establishment of realistic quality criteria and quality control procedures, technical and environmental standards and practical applications, facilitated by demonstration projects and an active government promotion (Dutch policy on sustainable building).

However, almost 95% of the current applications of CDW (recycled aggregates) are still used in road foundations. The application of recycled aggregates as an alternative for natural aggregates in concrete so far remains limited to demonstration projects. Current scenarios predict a steady decrease in the amount of recycled aggregates, which may be applied as road foundations in the next decades, due to a decrease in new large civil engineering projects, and an increasing competition with other materials of secondary origin. Increasing the application of recycled aggregates from CDW as aggregates in concrete is therefore a serious alternative.

### 1.3 Standardisation and quality control in the Netherlands

The Dutch standard VBT (NEN 5950, 1995) is applicable since 1995 for all concrete up to a characteristic strength of 65 MPa and all relevant environmental classes (equivalent to specific maximum levels of W/C). According to this standard, 20% of the natural aggregate may be replaced by recycled concrete aggregate or recycled mixed aggregates, without a need for additional testing of the concrete. Since 1997 the Dutch standard on aggregates for concrete has been updated to accommodate for the application of specific recycled aggregates, provided their specific mass is over 2000 kg/m$^3$.

Most of these recommendations have been incorporated in the advice of the "CEN TC-154 ad-hoc group on recycled aggregates" (CEN, 1998). In the Netherlands, quality control procedures for recycled aggregates have been prepared and are currently applied on a regular basis by all participants involved. On a European level, a Brite Euram thematic network has been established since 1998 to facilitate information exchange, co-ordinate national research on the use of recycled materials as aggregates in the construction industry, and promote its application (Brite-Euram, 1998).

### 1.4 Current research needs

In the Netherlands, roughly 80% of the annual concrete production of about 16 million m$^3$ is used for ordinary concrete in the strength class up to 25 MPa, (i.e. almost 13 million m$^3$). The demand for stones and gravel (4 - 32 mm) and sand (0 – 4 mm) for this concrete is respectively about 14 million and 9.5 million tonnes. Although the production rate of this concrete far exceeds the production of recycled aggregate, the application of this material as <u>an aggregate into concrete</u> is - as a concept – interesting. It contributes to closing the concrete product life cycle (e.g. 7) and may also solve foreseen future outlet problems (notably in the road construction industry) (Hendriks & Pietersen, 2000).

The current Dutch VBT (1995) standard is generally believed to be too restrictive for the majority of the concrete produced, with respect to the formal 20% replacement level. Results of recent research carried out in the Netherlands (see: Hendriks & Pietersen, 2000) points towards the possibility of a 100% replacement of natural course aggregates by recycled aggregates in concrete up to strength class B25 and environmental class 2 (7, 8), by making use of superplasticisers.

Together with the production of coarse recycled aggregates, also fine recycled aggregates (0-4 mm) are produced: the production ratio of coarse to fine aggregates is approximately 10: 3.5.

These recycled fine aggregates currently suffer from a lack of suitable outlets, mainly due to a market over-supply, and technical compomplications. Research has been carried out to test the suitability of these recycled fine aggregates into concrete, with somewhat ambiguous results (CUR, 1995: Fraaij et al. 1999). Depending on the resource, replacement levels of 25 to 50% could be reached in a B25 concrete without course recycled aggregates (9).

### 1.5 Concrete mix design – the pilot test

The Dutch Ministry of Transport, Public Works, and Water management (Directorate General for Public Works and Water Management, Civil Engineering Division) requested in 1998, based on the developments outlined in the previous section, to investigate the possibility to apply high percentages of both fine as well as course aggregates into concrete.

The concrete to be tested had to be of strength class B35, consistency class of 3 (flowable) as well as environmental class 3 (suitable to withstand a marine environment) according to VBT (1995).

The government intention is to apply a suitable concrete quality with a high level of recycled aggregates as a demonstration project in a marine environment (the potential project itself was originally intended to be carried out in 2000, but the current status is that it is delayed).

The concrete mixtures had to contain aggregate replacement levels as high as possible, and had to be tested on workability, strength, and several durability aspects such as chloride ingress, sea water ingress, relative freezing and thawing resistance, potential susceptibility for alkali silica reactivity and finally shrinkage and creep behaviour.

The recycled aggregates itself had to fulfil the specification of the NEN 5905 (1997). Full details have been reported elsewhere (Fraaij et al, 1999).

## 2 MATERIALS

### 2.1 Cement type

A standard Dutch CEM III 42,5 LH HS ground granulated blast furnace slag cement, with a slag percentage of 72%, was used. This type of cement is regularly applied in the Netherlands for concrete constructions in a marine environment, for several decades.

### 2.2 Aggregates

The natural coarse and fine aggregates consisted of river gravel (4-32 mm) and river sand (0-4 mm) respectively. Both a recycled mixed aggregate and a recycled concrete aggregate (4-32 mm) were used as partial replacement of the natural aggregates. A washed recycled crusher sand (0-4 mm) was used as replacement for the natural sand. All aggregates fulfilled the specifications of NEN 5905. Since 1997, this Dutch standard is applicable for both natural as well as recycled aggregates.

### 2.3 Superplasticiser

A sulphonated naphthalene formaldehyde condensate superplasticiser was used in most mixtures. In some mixtures a polycyclic sulphonate superplasticiser was used instead.

### 2.4 Mixture proportions

Table 1 presents a survey of the mixtures. Due to the high "environmental class" of concrete in contact with sea water, with an additional (though less frequent) freezing and thawing attack, the choice is either to use an air-entrainer or to use a W/C = 0.45. It was decided to prepare mixtures with a W/C of 0.45 without air entraining agent, taking into account the requested characteristic strength of 35 MPa and the specific cement type used.

**Table 1. Concrete mixtures. Data present relative volumes: The total of the fraction < 4 mm is stated as 100% and the total of the fraction 4 - 32 mm is taken as 100% as well.**

| *Mixture* | *Fraction 0 - 4 mm (100% total)* | | *Fraction 4 - 32 mm (100% total)* | | |
|---|---|---|---|---|---|
| | *River sand* | *Breaker sand* | *River gravel* | *Mixed aggregates* | *Concrete aggregate* |

Additional remarks Table 1:

1. Mixed aggregate: mixture of broken masonry debris and concrete debris
2. Concrete aggregate: broken concrete debris
3. Cement: 350 kg/$m^3$ blast furnace slag cement (with 25% portland clinker and mortar strength after 28 days of 45.5 MPa average value)
4. Air content: about 1.5%

Go Back Next Page

# 3 RESULTS

## 3.1 Workability

The new generation of superplasticisers (high range / high performance super-plasticisers) enabled a reasonable workability up to about one hour after mixing. The recycled materials, and especially the breaker sands, have a negative influence upon the workability. The concrete mixtures under investigation displayed a somewhat sticky behaviour compared to mixtures with a higher W/C but similar workability (a slump value of about 80 mm). The problem with recycled aggregates is the somewhat unpredictable behaviour concerning water suction (when partially dried) or water release (when particles are wet). Also the irregular edginess plays a role in the rheological behaviour.

Some trial mixtures have been made with completely wetted aggregates. However, despite the foreseen water release, the actual W/C (recalculated after the determination of the volumetric and air content in the vibrated fresh mix) became too high. The actual mixtures were therefore made with fully dried aggregates, taking into account that the aggregates will absorb water in the fresh stage of the concrete with a speed indicated by Fig. 1. Most subsequently prepared mixtures displayed an actual W/C of about 0.45, though some mixtures showed an actual W/C smaller than 0.45 while others resulted in higher values than 0.45. Only those concrete mixtures with a recalculated W/C of about 0.45 will be discussed in this paper.

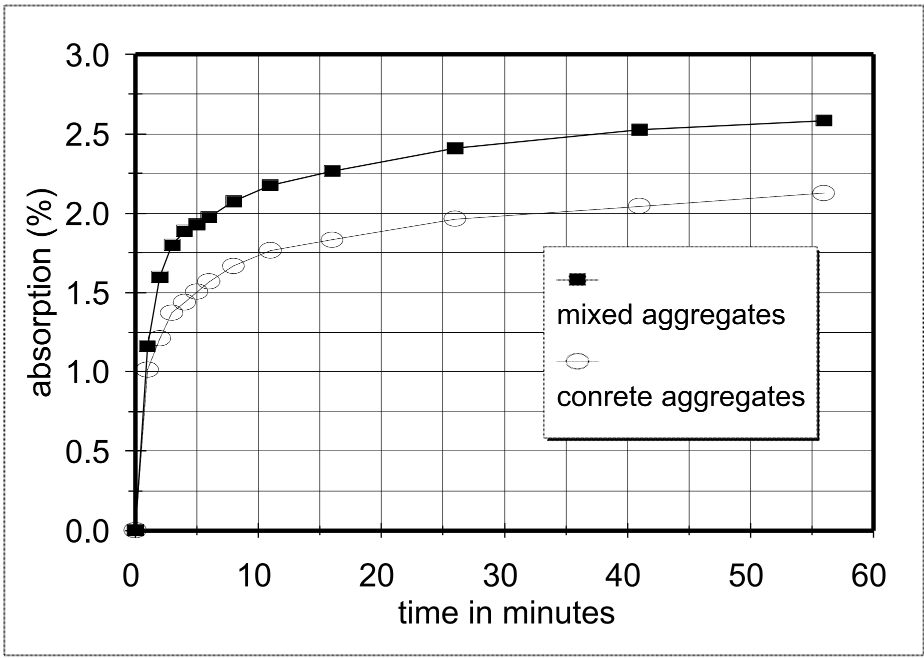

**Fig. 1. Moisture absorption progress in recycled aggregates (start at dried condition).**

## 3.2 Strength

The strength appears to be influenced by the actual W/C in a much more pronounced way than by the type and the amount of recycled material (however in this paper the strength as a function of W/C is not given since this is common knowledge). Table 2 gives a summary of results for mixtures with a W/C of about 0.45. The mixtures with recycled mixed aggregates showed a slightly lower strength than the concrete with recycled concrete aggregates (with about the same W/C). As can be seen from table 2, at higher amounts of recycled sands it is increasingly difficult to obtain a mixture with the desired W/C and with the right workability as well.

## 3.3 Durability

### 3.3.1 Chloride ingress:

The chloride penetration has been measured according to the AEC laboratory standard APM302 (1999) on Concrete testing of chloride penetration (immersion of a specimen during 5 weeks in a NaCl solution of 165 gram/litre, intrusion from one side). Fig. 2 gives results for mixtures where river gravel 4 – 32 mm has been replaced completely by recycled materials. In all cases, the intrusion depth remained limited to about 20 mm. Clearly the mixtures with recycled mixed aggregates showed a somewhat higher superficial intrusion than the mixtures with recycled concrete aggregates.

| 100 | 41.6*) 2) | 54.6*) 2) | | | | | 27.6*) | 34.3*) |

*) W/C > 0.46

**) W/C < 0.44

1) total fraction river sand + recycled breaker sand (0 - 4 mm) is put at 100% (vol/vol)

2) Unpredictable high strength; presumably W/C is actually smaller than 0.45.

3.3.2 Sea water swelling:

Concrete specimens (75x75x150 mm) were sawn out of hardened cubes 150x150x150 mm (4 per cube) and were put in artificial seawater with a threefold salt concentration compared to normal seawater. Concrete with recycled mixed aggregates displayed an increased swelling compared to concrete with recycled concrete aggregates, as can be seen in Figure 3. However, there was no evidence for cracks due to sulphate swelling. It appears that the swelling is partially caused by the water absorption capacity of the porous recycled aggregates.

3.3.3 Freezing and thawing:

The resistance against freezing and thawing has been tested according to the Fagerlund method in which samples were wetted to a certain moisture content (expressed as % saturation compared to fully saturated specimen) and exposed to freezing and thawing cycles. The dynamic Young's modulus is calculated from the pulse time velocity of a sound pulse before and after 12 freezing and thawing cycles. First damage $F_d$ is defined as the % moisture saturation where the Young's modulus starts to decrease. The critical saturation degree $S_{crit}$ is defined as the % moisture saturation at the 90% decrease level of the Young's modulus due to freezing and thawing cycles. Table 3 gives results for the concrete mixtures with W/C of about 0.45. Mixtures with recycled mixed aggregates are somewhat more prone to freezing and thawing degradation than mixtures with recycled concrete aggregates.

3.3.4 Alkali silica reaction:

Alkali silica reaction has been investigated according to the standard NEN 5925 that prescribes the production of standard mortar bars with the particular aggregate to be tested on reactivity. The procedure involves the length change of the bars under certain conditions. Unfortunately the recycled aggregates gave unworkable mortars due to the water absorption of the porous material. Therefore it was necessary to use superplasticisers to provide for a reasonable workability. None of the recycled aggregates caused cracking or substantial length changes during the test. This was confirmed by PFM.

**Table 3. Critical degree of saturation $S_{crit}$ and saturation at first damage $F_d$ after 12 freezing and thawing cycles.**

| *Recycled coarse aggregate 4 – 32 mm (all river gravel replaced) ?* | *% (Vol/vol) breaker sand as replacement for river sand. Total fraction < 4 mm = 100%* | | | | | |
|---|---|---|---|---|---|---|
| | *0%* | *25%* | *50%* | *0%* | *25%* | *50%* |
| | *Critical degree of saturation $S_{crit}$* | | | *First damage % saturation $F_d$* | | |
| Recycled concrete aggregate | 92 | 89 | 90 | 90 | 84 | 87 |
| Recycled mixed aggregate | 91 | 89 | 78 | 70 | 83 | 65 |
| Reference concrete with river sand and river gravel | 100 | | | 82 | | |

3.3.5 Shrinkage and Creep:

The shrinkage is influenced by the porosity of the recycled materials. Concrete with recycled mixed aggregate (4–32 mm) shows a smaller shrinkage than with recycled concrete aggregate. Indeed, the recycled mixed aggregate is more porous than the recycled concrete aggregate and the river gravel thus provides a water buffer against drying out, (Figures 4 and 5).

The creep of concrete with recycled mixed aggregates is higher than with recycled concrete aggregate. Figures 6 and 7 give the creep function (for a loading of 1 MPa) and are corrected for the shrinkage effects. The actual loading was 20% of the compressive strength of the concrete.

## 4 CONCLUSIONS AND RECOMMENDATIONS

Is it well possible to produce moderate strength (35 MPa) and environmental class 3 concretes (for application in a marine environment) by replacement of relatively large amounts of primary aggregates by secondary raw materials, tested according to NEN 5905. This study indicates that especially recycled concrete aggregate (fulfilling the Dutch NEN 5950) may be applied successfully, without potentially disturbing effects. However, notably the porous (fraction in) mixed recycled aggregates are suspected to be responsible for the sometimes erratic - and consequently less reproducible - W/C, resulting in ad-hoc occurring workability differences.

In this study, the amount of water that has been added to the mixture has deliberately been suppressed. This was done to ensure that the actual W/C (after mixing, casting and vibrating) did not exceed 0.45. The problem involved by the choice of this approach was a decreased workability, compared to mixtures with lower replacement levels of recycled aggregates. Only the modern generation of high range superplasticisers seemed to be able to maintain a correct workability within a realistic time span.

The following conclusions and recommendations can be made:

1. It is necessary to make use of the modern generation of high range superplasticisers for the concrete compositions studied;
2. The actual W/C that is found in the fresh mixtures after casting and vibrating is very difficult to predict. Therefore one should remain on the safe side and make mixtures that are actually “dryer” than requested;
3. It is possible to make concrete with recycled aggregates in which the total fraction 4 – 32 mm of the natural aggregate is totally replaced by recycled aggregates. It is also possible to replace a part of the fraction < 4 mm by recycled breaker sand, but it is not recommended to replace all the river sand by recycled breaker sand; a maximum replacement level of 50% is acceptable in practice, mainly for reasons of workability;
4. There is no evidence for potential alkali silica reaction with the types of recycled aggregates that were used in this study, tested according to NEN 5925 and PFM (method now under revision);
5. Concrete containing recycled mixed aggregates all displayed a somewhat increased seawater swelling, creep and a higher chloride intrusion, compared to concrete containing recycled concrete aggregate. Reference concretes with river gravel and the river sand displayed the lowest values;
6. The sensitivity for freezing and thawing attack increased slowly with the amount of material that is replaced by recycled aggregates; and
7. Further research to provide a more detailed understanding of the causes for the comparably high variations in porosity (or specific mass) of recycled aggregates is needed.

# Durability And Life Cycle Aspects On Bio-Fibre Composite Materials

**B Svennerstedt**
**Swedish University of Agricultural Sciences Sweden**

**Summary: With the appearance of synthetic materials at the beginning of the last century, synthetic based materials have steadily replaced bio-based products. As a result of this change in raw material utilization, combined with an increase in energy and chemical demand, the world is now facing an ecological crisis. This crisis will greatly intensify with the expected growth in demand for industrial products in developing countries. Thus the world community is facing a challenge in having to decrease pollution levels, while at the same time significantly increasing industrial output. Such predictions have led to support for enhanced industrial use of renewable resources (bio-fibre) at the expense of non-renewable resources (fibre-glass). Bio fibres may therefore face a renaissance, not only for old industrial products but also for the manufacture of new types of materials and products. Industrial use of bio fibres as woodfibres for the manufacture of pulp, paper, fibreboards and particleboards are well established in the world. The renewed interest in industrial use of bio-fibre composite materials within the automotive, building, furniture and packaging industries has led to development and production of many bio-fibre based composite products. Several companies in the building material industry worldwide are interested to produce products based on bio-fibre composites. It can be products for outdoor decking as roof plates, wall boards, windows and door panels. Most of the fibres that are used for these composites are from short woodfibres but some parts come from long jute-, flax- and hempfibres. One main topic for such composite materials concern the durability and the life cycle assessment. Based on literature studies this paper will present and discuss durability and life cycle aspects on bio-fibre composite materials for the building industry and other industries. Special focus will be on products, which are exposed to the climate and placed in the outside scale of the house such as roof plates, facade materials, doors and windows.**

**Keywords: Durability, biofibre composite materials, roof plates, facades, doors.**

## 1 INTRODUCTION

The world community is facing a challenge in having to decrease pollution levels, while at the same time significantly increasing industrial output. Such predictions have led to a need for enhanced industrial use of renewable resources (bio-fibres) at the price of non-renewable resources (fibre-glass). Bio fibres will therefore face a renaissance, not only for old industrial products but also for the manufacture of new types of materials and products.

The renewed interest in industrial use of bio fibres within automotive, building, furniture and packaging industries of European countries has led to development and production of many bio-fibre based products. A number of biobased products are made from *mats*, which are made of bio fibres or a mixture of bio fibres, plastic fibres and resins in varying amounts. Mats may be used in a number of products, e.g. filters for air and water, growth media for production of vegetables, flowers and grass mats. Bio-fibre geotextiles are already available on the market. Bio-fibre mats also have a promising future as insulation material within the building industry. The market potential for partial replacement of glass and mineral wool mats for insulation is huge. *Composites* for structural and non-structural purposes are manufactured by hot pressing of mats with success within the car industry. Fibre/polymer and fibre/cement composites can be manufactured through extrusion or injection moulding. New composites can be designed to have the required stiffness and strength. The importance of the role of final product design can not be overstated.

The annual global production of bio fibres is today about 4 billion tons of which roughly 60 % come from agricultural crops and 40 % from forests. In comparison, annual world production of steel is currently around 0,7 billion tons and plastic production is about 0,1 billion tons. As an example Sweden´s annual production of bio fibres is about 50 million tons from forestry and about 0,1 million tons from agriculture. Taking the above figures in consideration, it is apparent that there should be more than sufficient volumes of agricultural fibres available globally for new products. The huge production of wood fibres in Sweden is mostly used for pulp and paper products. There is not a great supply of wood fibres for the manufacture of new types of materials and products. Therefore there is a potential of using agricultural fibres and the cultivation of agricultural fibres has to increase to supply the industry with bio-fibres of sufficient quality.

The market for bio fibres in the building industry is closely linked to the ecological building sector. In contrast to conventional construction, ecological building regards the building as an integral part of the whole human and natural environment. Ecological building is a growing sector. As an example this sector acounted for 6% of the building market in Germany in 1995. Surveys show that 42% of private home builders in Germany are prepared to pay more for ecological building materials.

The use of biofibrous materials in the automotive industry is now widespread. Environmental protection, weight reduction and improved recycling characteristics are arguments, which car manufacture frequently advance to familiarize their customers with the ecological benefits of such materials.

An important step towards higher performance applications was achieved with the door panels of the Mercedes-Benz E-Class. These door panels were manufactured by a bio-fibre reinforced material consisting of a flax/hemp fibre mat embedded in an epoxy resin matrix. A weight reduction of about 20 % compared to doorpanels made of fibre glass was achieved and the mechanical properties were improved.

## 2 BIO-FIBRE COMPOSITE MATERIALS

### 2.1 Bio-fibre types and production

Bio fibres are subdivided based on their origins. They are coming from leafs (abaca, sisal, hennequen), seed-hairs (coir, cotton), basts (flax, hemp, jute, ramie) and wood. Most of the bio fibres, which are interesting for Europe are coming from flax and industrial hemp. These varieties are cultivated for both their fibres and their oil. Both flax and indusrial hemp are annual plants. Flax grows up to 1 m high and produce about 1 ton bastfibre per ha. Industrial hemp may grow up to 4 m high and produce about 3-4 ton fibre per ha.

The most important flax growing areas in the world are the former Soviet Union and the EU countries. These countries have about 40 % each of the 500 000 ha flax grown in the world.

During the latest decades the trend has been a long term decreas of acreage both for flax and hemp. However, during the latest years there might have occured a shift of trends with a slightly increasing area due to high interest in Canada and in the EU. Over the last 30 years France has had a rather constant hemp cultivation area of about 10 000 ha. During the 1990´s an area of about 17 000 ha hemp was cultivated per year in China. Totally about 50 000 ha is grown per year for hempfibre around the world.

In table 1 the worldwide production of plant fibres in 1999 divided into fibres and main country producer is shown. This plant fibre production amount is focused on the main fibre plants and does not include straw and wood fibre production.

**Table 1. Worldwide production of Plant Fibres in 1999 (Karus. 2000).**

| Fibre | Main country producer | Production in million tons | Production in % of total |
|---|---|---|---|
| Cotton | China, USA, India, Pakistan | 18.20 | 78.5 |
| Jute | India, China, Bangladesh | 3.37 | 14.5 |
| Flax | EU, China, Eastern Europe | 0.63 | 2.7 |
| Sisal | Brazil, China, Mexico, Kenya | 0.38 | 1.6 |
| Cocos | Indien, Sri Lanka | 0,27 | 1.2 |
| Ramie/Abaca | China, Ecuador, Philippines | 0.27 | 1.2 |
| Hemp | China, EU, Eastern Europe | 0.07 | 0.3 |
| Total | | 23.19 | 100 |

## 2.2 Bio-fibre structure and properties

All plant species are made of cells. When a cell is very long in relation to its width it is called a fibre. The fibre is like a microscopic tube and it consists of cellulose, hemicellulose and lignin. Cellulose is the basic structural component of all plant fibres. The cellulose molecules consist of glucose units linked together in long chains. Hemicellulose are also found in all plants. Hemicelluoses are polysaccharides bonded together in branching chains. Lignin is the compound, which gives rigidity to the plant. Lignin is a three-dimensional polymer with an amorphus structure (Olesen & Plackett, 1999). Pectin is the glue, that holds the fibre bundles together. In table 2 the chemical composition of some selected agricultural and wood fibres is shown.

**Table 2. Chemical composition of some selected agricultural and wood fibres (weight-%) (Olesen & Plackett, 1999).**

| Fibre | Cellulose | Hemi-Cellulose | Lignin | Pectin |
|---|---|---|---|---|
| Jute | 70-75 | 12-15 | 10-15 | 1 |
| Flax,hemp | 68-85 | 10-17 | 3-5 | 5-10 |
| Seed hair, cotton | 89-99 | 3-6 | - | - |
| Wood | 38-45 | 24-39 | 22-34 | 0.5 |

The variation of plant fibre dimensions is great, which is shown in table 3.

**Table 3. Dimensions of some selected plant fibres (Olesen & Plackett, 1999).**

| Fibre | Fibre length (mm) | Fibre width (mm) |
|---|---|---|
| Jute | 2 (1.5-5) | 0.02 |
| Flax | 30 (5-60) | 0,02 |
| Hemp | 20 (5-55) | 0.025 |

The combined effect of the three main constituents results in properties, which are unique for plant fibres. The most important properties are:

- High tensile strength and low density. In relation to its weight the best bast fibre attain strength properties similar to that of fibre-glass.
- High heat, sound and electrical insulating ability
- Biodegrability

The good specific mechanical properties are due to their relative high strength and low density. In table 4 mechanical properties of plant fibres are compared with conventional reinforcing fibres.

**Table 4. Mechanical properties of plant fibres as compared to conventional reinforcing fibres (Biedzki & Gassan, 1999).**

| Fibre | Density (g/cm3) | Elongation (%) | Tensile strength(MPa) | Young´s modulus(GPa) |
|---|---|---|---|---|
| Jute | 1.4 | 1.5-1.8 | 200-450 | 20-55 |
| Flax | 1.5 | 2.7-3.2 | 500-900 | 50-70 |
| Hemp | 1.5 | 1.6-3.5 | 310-750 | 30-60 |
| Sisal | 1.5 | 2.0-2.5 | 80-840 | 9-22 |
| E-glass | 2.5 | 2.5 | 2500-3500 | 70-73 |
| Aramid | 1.4 | 3.3-3.7 | 3500-4000 | 85-135 |
| Carbon | 1.4 | 1.4-1.8 | 2500-6000 | 220-700 |

## 2.3 Bio-fibre composite products

Plant fibres have found application as reinforcement in many cement based or polymer based composite products.

The reinforcement of cement and concrete based products with plant fibres present challenging and exiting construction materials. The major role of the fibres is in delaying and controlling the tensile cracking of the matrix. This function reduces deformations at all stress levels. If properly carried out plant fibre concrete has all the the potentially favourable qualities of normal concrete: fire resistance, is water tight, easy to produce and is inexpensive. The plant fibres can be utilized both in semi-structural elements such as thin sheets and cladding panels as well as in load bearing elements. Other examples of cement based products reinforced with long plant fibres are roof plates and floor slabs.

Three-dimensional composite products for structural and non-structural purposes can be manufactured by hot-pressing of mats. The mats may be made entirely of plant fibres or a mixture of plant fibres, plastic fibres and resins. In addition to hot-pressing of mats bio-fibre reinforced composites can be manufactured by extrusion or injection moulding. Other processing options are thermoforming, vacuum forming and resin transfer moulding. The most used thermoplastics are polypropylene, polystyrene, vinyls and high and low density polyethylenes. The most usable building materials made of plant fibre reinforced plastics are window frames, door panels and wall panels. There are also many applications for plant fibre composites in the automotive, the furniture and the packaging industries.

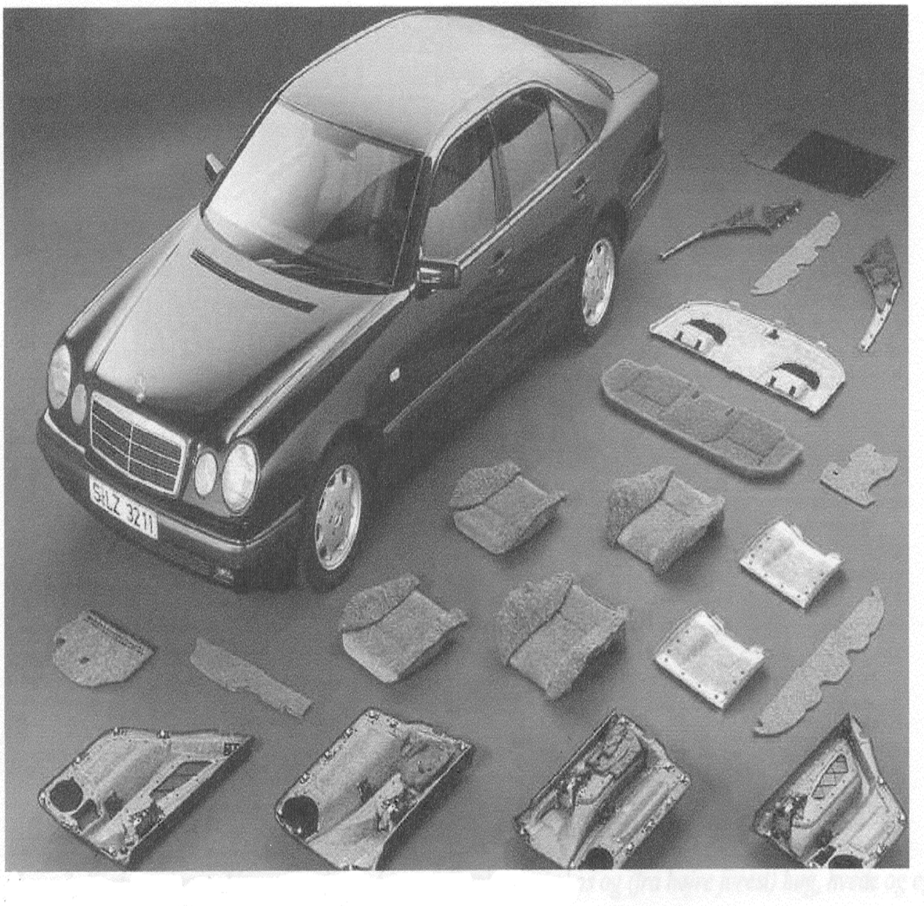

**Figure 1. The use of plant fibres in automotive products of Mercedes E-class (Olesen, 2001).**

## 3 DURABILITY OF BIO-FIBRE COMPOSITE MATERIALS

One of the disadvantages of bio fibres is the prone to water absorbtion. Most of the plant fibres are hygroscopic and the water absorbtion may be rather great. As a consequence of the hygroscopicity products and materials based on plant fibres are not dimensionally stable under changing moisture conditions. The unfavourable absorbtion of moisture by plant fibres is due to the cohesion of hydrogen by hydrogen molecules to groups of hydroxyl in cellulose in cell-wall polymers. Reactive organic chemicals are being tied to the cell-wall hydroxyl groups of cellulose, hemicellulose and lignin.

This absorbtion disadvantage may be controlled at an extra cost by different methods of impregnation e.g. heat treatments or chemical modification procedures as acetylation. Acetylation means introduction of acetyl groups into organic combinations. By replacing some of the hydroxyl groups on the cell wall polymers with bonded chemical groups, the hygroscopicity of the bio-fibre material is reduced. With acetic acid, acetylation reaches probably no other than the easily hydroxyl groups (Biedzki & Gassan, 1999).

Another disadvantage also concerning the durability of bio-fibre composites is the destructive effect of the alkaline pore solution on plant fibres. This effect is well known and established. The net effect of these chemical degradation processes is that with time the fibres will cease to exist and provide no reinforcing property. In the short term the fibres provide cohesion and workability to the cement matrix. In the long term prolonged reinforcing action between the matrix and the fibre can only be ensured by carefully designed procedures. There are also many reports indicating that the lignin content of the fibres may influence the hydration of the cement composite (Swamy, 1990).

### 3.1 Durability of cement based composite products

Roofing is one of the most important and difficult problem in housing. In most developing countries and in many industrialized countries natural materials are used for roofing in rural areas. An interesting solution to the roofing problem seems to be thin sheets made of plant fibre concrete.

When mixing plant fibres in the mortar the fresh concrete may be shaped in a simple manner, which is one advantage with this material technology. Another advantage is that the fibres increase the toughness and impact resistance of the hardened concrete. This means that the material may be used in structural applications. A corrugated roof sheet is probably one of the most interesting forms even if other forms can be produced. Apart from roofing materials plant fibre concrete can be used for production of sun screens, thin-walled blocks, small beams, and other products.

In the 1980´s a joint venture project between research institutes in Sweden and Tanzania was carried out with the aim to investigate observed embrittlement of sisal fibre concrete for roofing sheets and find suitable countermeasures. The research found that the embrittlement of sisal fibre concrete is due to the fact that the alkaline pore water in the concrete reacts with cellulose components in the fibre so that its loadbearing capacity is reduced. It seems that the lignin and the hemicellulose in the middle lamella are decomposed first thus weakening the link between the individual fibre cells. Sisal fibres in alkaline solutions with a pH-value higher than 12 are discoulered yellow and lose a considerable proportion of strength in the wet state. The decomposition of the fibres takes place more rapidly at high temperatures (Gram, et al 1984)

The decomposition process already starts when the sisal fibre concrete is manufactured. The alkaline pore water in the vicinity of the fibre will probably be neutralized by the reactions, which take place with the fibre components. For the embrittlement of the concrete composite the external environment, where the composite is located play a significant role. External changes of moisture and temperature in the environment will influence the transportation of new alkaline pore water to reach the plant fibres and also influence the removal of decomposition products (Gram, 1983).

By replacing about 45 % of the cement with silica fume the alkalinity of the pore water is reduced and the embrittlement of the plant fibre concrete can be decreased. Changing Portland cement to Slag cement or high alumina cement are other countermeasures to reduce the alkalinity but these measures are not sufficent to prevent embrittlement in the composite.

An interesting measure to improve the resistance of the plant fibre composite against embrittlement is to precarbonate the entire composite product. By treating the manufactured composite with carbonic acid or water containing carbonate the carbonation will start and the pH-value of the pore water will decrease. If this method will be successful the fibre reinforcement must be placed in the outer layer of the composite (Gram, et al,1984).

Brazilian research on durability of coir concrete showed that it is possible to increase durability of bio fibres by changing the concrete matrix composition in order to obtain low alkaline media. The research proved that it is also possible to produce load-bearing structures with bio fibres reinforced materials (John, et al. 1990).

### 3.2 Durability of polymer based composite products

Plant fibre reinforced thermoplastic composites can be used for many products within the automotive and the building industries. Research has shown that such products have advantages in terms of cost, weight and environmental factors when compared to similar combinations based on fibre-glass reinforcement.

Current applications for plant fibre reinforced thermoplastic composites in the automotive industry are door panels, interior trim, load floors, package trays and rear shelves. Examples on products in development are door trim, headliners, instrument panels and seat backs.

Plant fibre reinforced thermoplastic composites for the building industry may be products with climatic protective functions and less load-bearing capacity. Examples are window frames, door panels and wall panels. Window frames made of plant fibre reinforced thermoplastic should be competible to corresponding product reinforced with fibre-glass.

The durability of these plastic based composites is mostly depending on the moisture influence.

When manufacturing the plant fibre reinforced composites it is important to dry the fibres carefully before processing because water on the fibre surface acts like a separating agent in the fibre matrix. Another phenomena is that voids may appear in the matrix because of evaporation of water during the reaction process. This is due to the fact that the processing temperarure mostly lies over the evaporation temperature of water. Both these phenomena lead to a decrease of mechanical properties of plant fibre reinforced composites (Biedzki & Gassan, 1999).

By using silanes as coupling agent in jute reinforced polyester resin composites it has been shown that the water repellance was improved and the strength of the composite was increased. This is shown in Fig 2. The improved moisture resistance caused by the application of the coupling agent can be explained by an improved fibre-matrix adhesion. The coupling agent build chemical and hydrogen bonds, which reduces the moisture (Biedzki & Gassan, 1999).

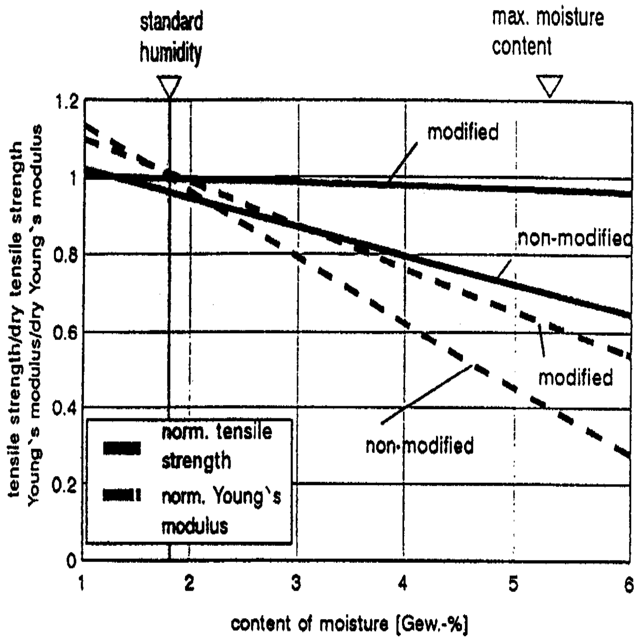

**Figure 2. Influence of silane coupling agents on the strength of jute reinforced epoxy-resin composites at different moisture contents (Biedzki & Gassan, 1999).**

Particle boards and flake boards have been tested for biological resistance to several different types of organisms. Acetylated types of these boards have been tested against termite attack during a two-week test. The tests showed good but not complete resistance against termite attack. Since termites can live on acetic acid and decompose cellulose to mainly acetic acid it is not surprising that the resistance is not completely (Rowell et al., 1997).

Acetylation has been shown to improve ultraviolet resistance of aspen fibre board. Accelerated weathering tests of acetylated aspen fibre boards show reduced weight loss and penetration depth. Acetylation reduces surface erosion by 50 % and the lignin content is also greatly reduced in the surface as a result of the weathering. Because of the acetylation cellulose and hemicellulose are much more stable to photochemical degradation (Rowell et al., 1997).

## 4 DISCUSSION

Today we see a fast development in the industrialized world, primarily in USA and Europe, towards utilization of biofibres as an industrial raw material. This change from synthetic oil based plastics towards environmental friendly (renewable and recyclable/compostable) materials, is of great importance in order to eliminate an ecological crisis.

Examples of biofibres from Nordic agriculture and forestry are flax and hemp fibres and pine and spruce fibres. Industrial use of bio fibres such as wood fibres for the manufacture of pulp, paper, fibreboard and particleboard are well established in the Nordic countries. The renewed interest in industrial use of bio fibres within the automotive, building, furniture and packaging industries of European countries has led to development and production of many bio-fibre based products.

There is an abundance of biological fibres in the world, both from agriculture and forestry and there are many advantages of bio-fibre utilization. The use of bio fibres in industrial products is $CO_2$ neutral. The use of bio fibres is also very price competitive to synthetic fibres as fibre-glass. The bio-fibre based products show renewability and biodegradability.

The most beneficial advantage is the high specific strength and stiffnes. This advantage concerns mostly the long fibres from flax and hemp. These fibres show a low density and a relatively high tensile strength. These properties make together the bio fibres very competitive compared to glass fibres.

There are also disadvantages of bio-fibre utilization. One disadvantage is the variability of the fibre dimensions. The length and the diameter of the bio fibres vary very much in production. This is natural because we deal with biological material but the problem has to be solved in the production process.

Another disadvantege is the thermal degradation, when the biological material is exposed to fire with temperatures above 200 °C. However, from a waste point of view combustability is an advantage. Products can be disposed of through burning at the end of their useful service life and energy can simmultaneously be generated.

The main disadvantage of bio-fibre utilization is the lack of durability. The reason for this lack is the prone to water absorption. If no remedies are taken against the water absorption the effect is that bio-fibre based materials will not be dimensionally stable under changing moisture conditions. The tendency to absorb water can also be seen as an advantage because the fibres will biodegrade under certain circumstances through the actions of fungi and bacteria.

There are several methods to prevent water absorbtion of bio fibres. One method is acetylation. This is an environmental friendly method because no unnatural materials are supplied. With acetylation only the natural acetyl groups are strengthened. The acetylation gives both dimensional stabillity and protection against rot. Acetylized bio fibres may be used for the production of building materials as doors, windows and garden furnitures.

The lack of durability for bio-fibres in an alkaline environment may be possible to control by decreasing the alkalinity or by impregnation of the fibres. The use of bio fibres as reinforcement in cement based and concrete materials requires search for low alkalinity concrete.

When discussing durability and life cycle aspects on bio fibres the small use of chemicals in the cultivation and the production process has to be pointed out. There are nowadays production methods, which require small amounts of chemicals to strengthen the composite products but the utilization of bio fibres for the manufacture of industrial products in the future will be with as little environmental impact as possible.

## 5 CONCLUSIONS

There is an abundance of biological fibres in the world, both from agriculture and forestry and there are many advantages of bio-fibre utilization. The greatest advantage is the high specific strength and stiffnes. This advantage concerns mostly the long fibres from jute, flax and hemp.

The main disadvantage of bio-fibre utilization is the lack of durability. The reason for this lack is the prone to water absorption and the strong degradation of the fibres in an alkaline environment. Some of the disadvantages may also be considered as advantages. A good example of that is the biodegradability, which is caused by the water absorption. As the main disadvantages of bio-fibre utilization may be controlled at an extra cost by a number of known treatments it can be concluded that the advantages should exceed the disadvantages in utilization of bio fibres in composite products.

The goal for the bio-fibre composite product development should be to present for the market completely “green” products based only on biological raw materials. This is a challenge for research institutes and industry, which include solving the durability problems.

# Failure Of Prestressing Steel Induced By Crevice Corrosion In Prestressed Concrete Structures

**E Proverbio & LM Bonaccorsi**
**University of Messina Italy**

**Summary: The application of prestressed concrete technology in civil structures is relatively recent. Therefore, the existing prestressed concrete members in such structure are still relatively young, and the corrosion and the concrete deterioration problems associated with this type of concrete members have became clearly evident only in the early 1980s. Damage during service, frequently appearing after several years or decades of exploitation, is usually most consequential. The lacking or insufficiently alkaline protection already from the beginning or its loss due to carbonation and/or depassivation after chloride attack are the major causes of later damage or even of a failure. Steel wire strands, due to their structure, usually consisting of steel wires helically laid about a core centre, frequently another wire, may be subjected to crevice corrosion even if they are well grouted with uncarbonated mortar but in presence of a little amount of chloride ions. Crevice can occur also in cable to duct (metal or plastic ducts) contacts. Crevice condition easily promotes a drastic change in local environmental composition, that is a pH reduction and an increase of chloride concentration. In such a condition steel strand failure due to hydrogen embrittlement can occur. Experimental results obtained in calcium hydroxide solution with added potassium chloride in simulated crevice condition on stressed steel strands, showed crack formation after only 1250 hours. Chloride concentration was lower than the critical amount to induce pitting corrosion or generalized corrosion at that pH (12.4), whilst was enough to induce extended crevice corrosion. In some case crevice attack was so intense to reduce drastically steel wire cross section.**

**Keywords: Prestressing steel, corrosion, crevice, cracks, failure**

## 1 INTRODUCTION

The application of prestressed concrete technology in civil structures is relatively recent. Therefore, the existing prestressed concrete members in such structure are still relatively young, and the corrosion and the concrete deterioration problems associated with this type of concrete members have became clearly evident only in the early 1980s. Although prestressed concrete members were generally manufactured with concrete of relatively higher strength, time has shown that they are subject to the same adverse effects of reinforcement corrosion as reinforced concrete members are. Documented cases of prestressed tension members failure as a result of corrosion make this a most pressing problem. Since prestressed concrete members rely on the tensile strength of the prestressing steels to resist loads, loss of even few wires or strands per member could result catastrophic.

Damage during service, frequently appearing after several years or decades of exploitation, is usually most consequential. The lacking or insufficiently alkaline protection already from the beginning or its loss due to carbonation and/or depassivation after chloride attack are the major causes of later damage or even of a failure. Responsible for that are usually the failures caused by shortcomings in planning and/or execution as well as inaccurate or inefficient structural measures. Execution faults and construction errors concern e.g. the injection of the ducts with mortar in case of post tensioned concrete (a mortar-free section of prestressing steel is exposed to the risk of corrosion, when penetration of moisture is possible and oxygen can enter the duct space ), the concrete technology (too small concrete cover and too low concrete quality, under certain conditions not protect prestressing tendons or prestressing steel), the procedure (technology) of the production of the structural elements, as well as waterproof sealing (not present or damaged) and drainage (damaged), that can lead to strong salt contamination of concrete, and very seldom the development of cracks outside and inside the coupling joint of prestressed bridges.

The up to then most spectacular damage in the prestressed concrete structures occurred in 1980. It was the collapse of the southern outer roof of the Berlin Congress Hall occurred 23 years after its constructing. The damage was primarily caused by corrosion-initiating and corrosion-promoting conditions in a part of the roof structure (Rehm *et al*. 1981).

Probably the most frequent occurrence of corrosion related problems on bridge structures as a consequence of planning and execution errors, is on post-tensioned precast segmental bridges. The first serious problem with corrosion of bonded post-tensioned bridges occurred in U.K. in the mid-1960 when the Bickton Meadows footbridge collapsed in Hampshire (Concrete Society 1996). This structure was a segmental post–tensioned construction type, and collapsed without warning under its own self-weight after only few years of service. Collapse occurred as a result of severe corrosion of the top tendons.

Then, in the 1980s, two bridges were found with serious problems: the Taf Fawr Bridge on the A470 in Wales and the Angel Road Bridge on the A406 North Circular in London. Soon, problems had been identified in other bridges, the most serious being the collapse of the single-span segmental post-tensioned Ynys-y-Gwas bridge in Wales in 1985 (Woodward and Williams 1988). The collapse of the bridge was due to corrosion of longitudinal tendons at the segment joints. The mortar at the joints was highly permeable and allowed moisture, chlorides, and oxygen ready access to the tendons. The structure was 32 years old with no evidence of distress prior to failure.

Finally, studies by the British Department of Transportation concluded in 1992 that there was currently no method to guarantee the grouting process and further work was needed. It was on 25 September 1992 that the Department of Transportation effectively banned post-tensioned grouted duct techniques from UK bridge construction. The moratorium was partially lifted only in the 1996 with the exception of segmental bridges constructed from precast segments, because there were still some reservations about the corrosion protection of the tendons where they cross the joints (Lewis 1996).

The UK was not the only place with problems. The post tensioned Melle Bridge built across Schelde in Belgium in 1956 collapsed early in 1992. The collapse was traced to corrosion of the ducted post-tensioning wires and, most worryingly, the bridge had been inspected, load tested, given a clean bill of health, re-waterproofed and restored to service just two years before (Concrete Society 1996).

Two very recent bridge collapses can be related to corrosion of prestressing steel: Saint Stefano bridge collapse in Italy in 1999 (Proverbio & Ricciardi 2000) and Lowe’s Motor Speedway footbridge in North Carolina (USA) in 2000 (Goins 2000).

Failure of prestressing steel in prestressed concrete structures is usually induced by corrosion. The most simple failure case is present when the high-strength steel fails because its notched-bar tensile strength in the region of corrosion pits has been exceeded. In such a case the failure has a brittle character. In practice such a pure brittle failure in case of prestressed concrete it is relatively seldom. The necessary condition of notched-bar tensile strength being smaller than the actual steel stress requires namely pit depth of at least 1 mm.

Fracturing of prestressing steel in structures is predominantly attributed to hydrogen- induced stress corrosion cracking (Nurnberger 1997). Hydrogen formation and absorbtion on steel surface is promoted by different corrosion conditions:

- activation or depassivation of certain regions of steel surface;
- localized corrosion (pitting corrosion);
- presence of certain substances (so-called promoters), which hinder the recombination of the atomic hydrogen to molecular hydrogen (such as sulphur, arsenic, thiocyanate and selenium compounds, which are in practice frequently found in concrete constructions).

Studies on behaviour of prestressing steel (cold drawn eutectoid steel) in $NaHCO_3$ solution, simulating carbonated concrete, was carried out by Alonso *et al*. (1993), showing that such steel is very susceptible to stress corrosion cracking (SCC) in carbonate-bicarbonated environment as a function of bicarbonate content.

Steel wire strands, due to their structure, usually consisting of steel wires helically laid about a core centre, frequently another wire, may be subjected to crevice corrosion even if they are well grouted with uncarbonated mortar but in presence of a little amount of chloride ions. Crevice can occur also in cable to duct (metal or plastic ducts) contacts. Crevice condition easily promote a drastic change in local environmental composition, that is pH reduction and increase of chloride concentration. In such a condition steel strand fracture due to hydrogen embrittlement can occur. Aim of this work is to investigate, by deep microscopy investigation, the evolution of corrosion phenomena on stressed cold drown steel wires subjected to crevice condition in calcium hydroxide saturated solution in presence of chloride.

## 2 EXPERIMENTAL METHODS

The material used was a 3/8” seven steel wire strand in cold drawn and stress relieved state. The chemical composition and properties are described in Table 1

**Table 1. Chemical composition and properties of the steel used**

| Chemical analysis (wt%) | | Mechanical properties | |
|---|---|---|---|
| Carbon | 0.81 | Ultimate tensile strength | 1940 MPa |
| Silicon | 0.22 | 1 % proof stress | 1750 MPa |
| Manganese | 0.67 | % elongation | 5.5 |
| Phosphorus | 0.007 | | |
| Sulphur | 0.004 | | |
| Copper | 0.09 | | |
| Chromium | 0.05 | | |
| Nickel | 0.05 | | |

Two different testing conditions were used. “Single wire” condition and a “bundle” condition. In the first case as received single steel wires (central wires extracted by a strand) with a diameter of 3.19 mm and a length of 150 mm were subjected to bending condition on glass reinforced plastic beams as shown in Figure 1. Wire deflection was imposed in order to reach in the middle section of the wire a stress equal to 0.8 time the UTS. Wires were kept bent by means of plastic strips, crevice condition were obtained by inserting a Teflon ring in the middle section of the wire. Samples were then immersed in a calcium hydroxide saturated solution (pH 12.4) closed to air (solution T), potassium chloride was added to the solution up to a concentration of 0.2 M. In such a condition it was obtained a $OH^-/Cl^-$ ratio less than the critical value to induce pitting corrosion (Andrade *et al*. 2001), but a chloride concentration sufficient to allow crevice corrosion occurrence. An electrical connection shielded by epoxy resin coating was made on each wire in order to monitoring electrochemical potential during the time.

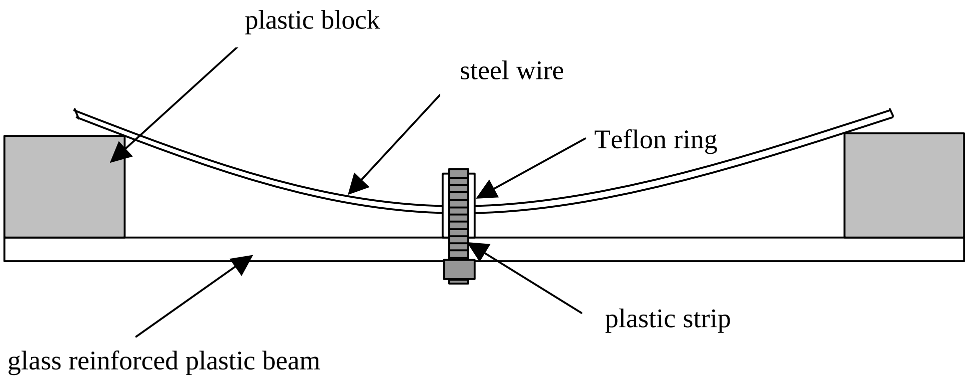

**Figure 1. Scheme of steel wire loading and crevice induction set up**

As a reference, in order to evaluate hydrogen embrittlement susceptibility, identical samples were immersed, at room temperature, in the solution A indicated in the ISO/DIS 15630-3 (Steel for reinforcement and prestressing of concrete – Test methods – Part 3: Prestressing steel). Test conditions are summarized in Table 2.

**Table 2. SCC susceptibility test condition after ISO/DIS 15630-3**

| Solution composition | Test condition |
|---|---|
| 5 g of $SO_4^=$ (as $K_2SO_4$), 0.5 g of $Cl^-$ (as KCl) | Constant axial load equal to 0.8 UTS |
| and 1 g of SCN- (as KSCN) for 1 litre of solution | 50±1 °C |

Go Back Next Page

Test in the bundle condition were performed by immersion in the solution T portion of seven steel wire strands, obtained by cutting 250 mm long pieces form the as received prestressing cable. Each bundle was secured on the extremities by plastic strips to avoid its opening. Such tests were performed to evaluate crevice occurrence between steel wires in condition similar to in field application.

## 3 EXPERIMENTAL RESULTS

Free potential versus time of steel wire during the tests is reported in Figure 2. After stabilization, and depending on crevice corrosion initiation time, free potential values ranged between –540 and – 470 mV (vs SCE). Such values lied well above the limit indicated by the equation proposed by Andrade *et al.* (2001) for critical chloride content for pitting initiation (Figure 3)

$$E_p = 310 \cdot \log\left[Cl^- / OH^-\right] - 15 .$$

No corrosion attacks were in effect evidenced on free steel surface after solution removal. Immersion test were ended after about 54 days (1280 h) even if no complete steel wire failures were observed. After removal of Teflon ring strong crevice attack was observed on some samples. Before samples observation corrosion products were removed by means of Clarke's solution (ASTM 1981).

A typical crevice attack was shown in Figure 4. Where crevice attack was particular intense complete disruption of steel occurred, corrosion being strongly influenced by steel drawing direction. No evidence of other type of corrosion damages were observed on such areas. Where crevice attack was less pronounced transversal cracks on steel surface were observed. Cracks were comparable for extension, and in some case for penetration depth, to those one observed on sample tested in solution A (thiocyanate solution) as shown in Figure 6.

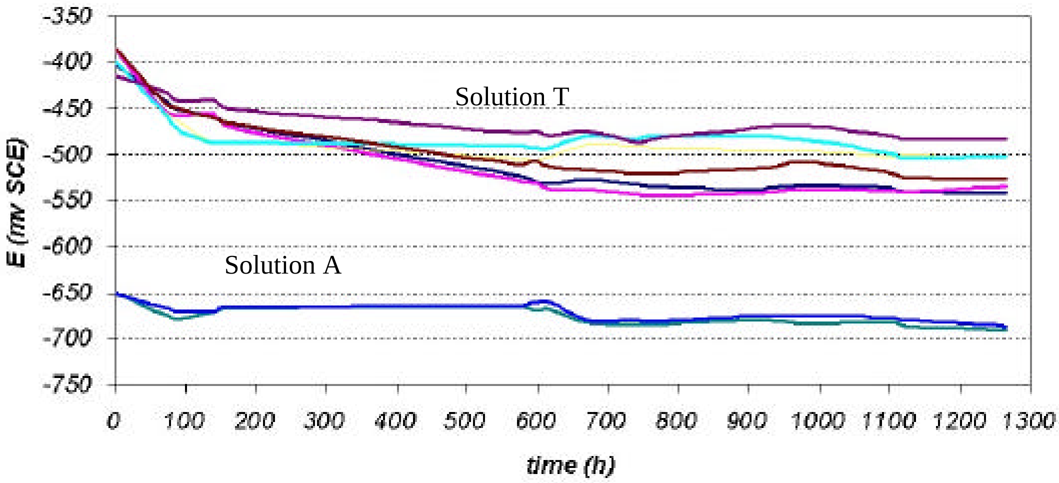

**Figure 2. Free corrosion potential of steel wires in solution T and A.**

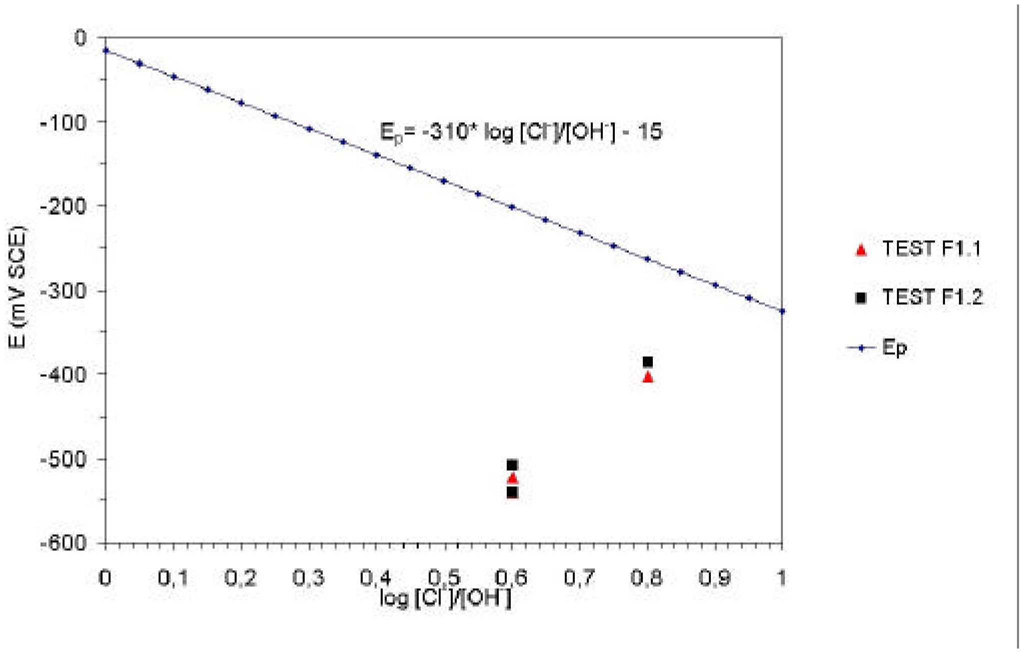

**Figure 3. Free corrosion potential of steel wires in solution T vs log[Cl-]/[OH-]**

No corrosion attack was observed on free steel surface of wire strand (“bundle” condition) as removed from solution T, unbinding steel wires revealed crevice corrosion development on contact surface between inner wires, corrosion attack being concentrated on an helical line following wires disposition (Figure 7). Strands were however not subjected to bending condition due to difficulties encountered in applying a sufficient stress to the samples without causing wire opening, so it was not possible to evaluate the influence of stress on evolution of corrosion attack for such type of samples.

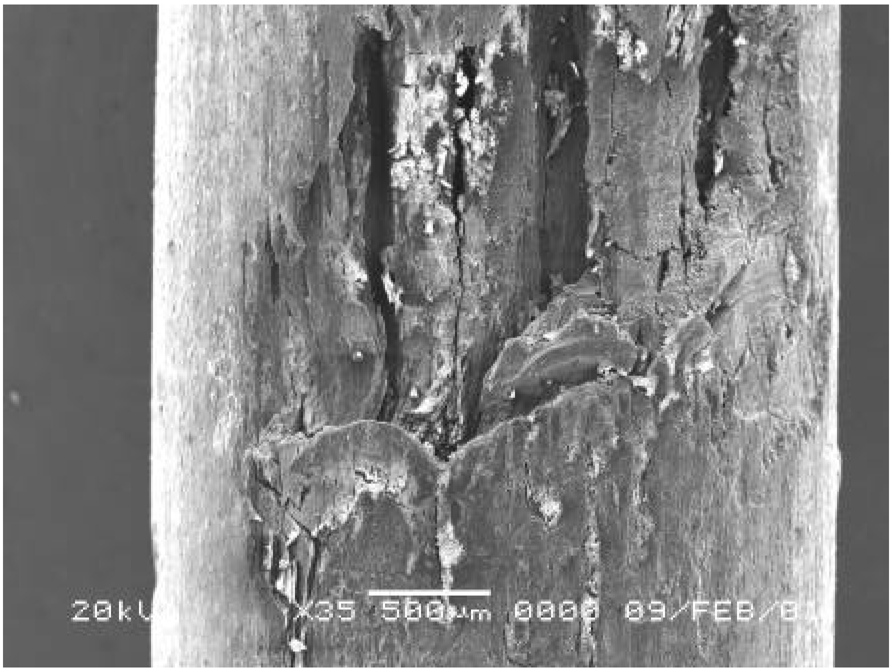

**Figure 4. Crevice corrosion attack under Teflon ring.**

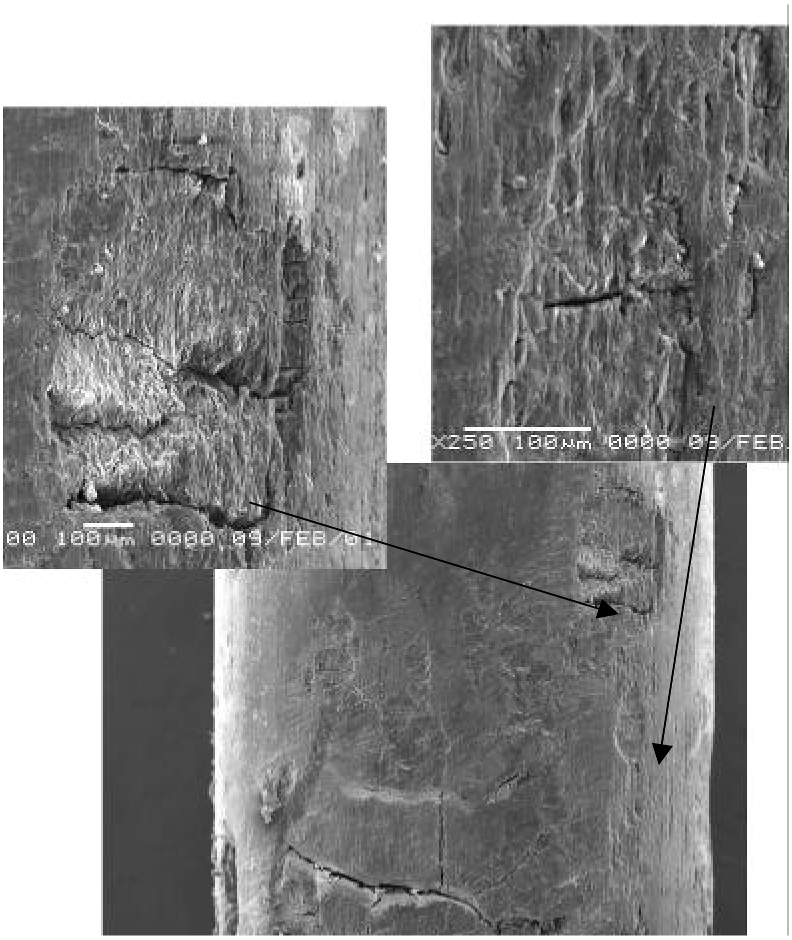

**Figure 5. Cracks localized in corroded areas**

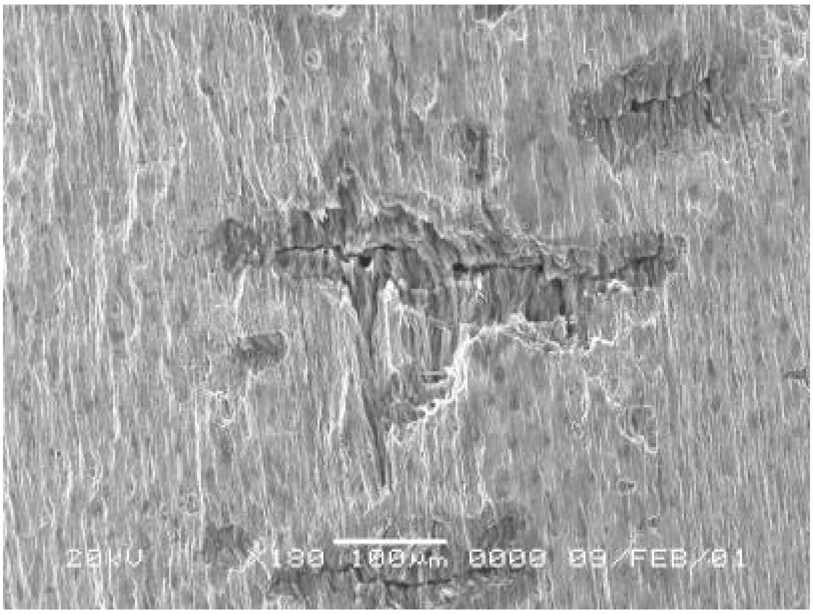

**Figure 6. Cracks on steel surface of sample immersed in the solution A**

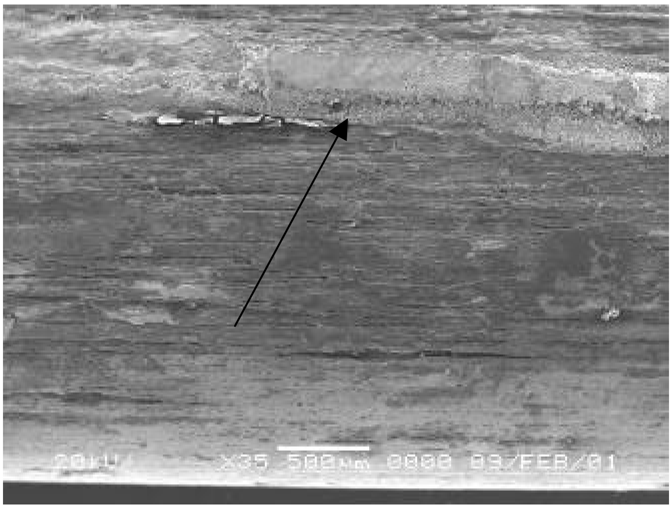

**Figure 7. Corrosion attack on the central wire of a seven wire strand after testing for 1100 h in the solution T**

## 4 DISCUSSION

Failure of prestressing steel is generally induced by corrosion. When corrosion attack is generalized (it occurs for examples in carbonated concrete or when steel is exposed directly to the atmosphere) failure occurs when cross section reduction, due to steel consumption, leads to an increase of stress in steel that overpass its UTS. It is well known however that prestressing steel is susceptible to stress corrosion cracking (SCC) (ACI Committee 222 2001; Alonso *et al*. 1993) and to hydrogen embrittlement (HE) (Mietz 1998). In some case brittle fracture is induced by localized corrosion attack, such as pitting (acidification at the pit tip allows hydrogen reduction and, as a consequence, hydrogen embrittlement of the steel). Cracks formation was in fact observed in some case at the bottom of pits (Nurnberger 1992).

Relatively few failures in the literature are attributed to brittle mechanism such as SCC and HE. One possible reason is that the prestressing steels normally used in prestressed concrete construction resist this type of failure quite well if we except special sensitive prestressing steel used during the '50s and the '60s in Germany (Nurnberger 2000). A number of problems have occurred on prestressed concrete structures in recent years that are not reported in literature. This probably because the failures have generated litigation with closure of trial proceedings or nondisclosure agreements between litigant. Another possible reason is that failures may have occurred in conjunction with pitting corrosion. In this case, the investigators may not realize that the failure are due to brittle HE because of the heavy pitting damage that may be present (ACI Committee 222 2001).

Brittle behaviour of steel wires extracted from heavily corroded prestressing cable taken from a prestressed concrete bridge was observed by Vehovar *et al.* (1998). It was supposed that low pH carbonated grouting mixture (pH ranging from 11.3 to 11.6) and the high amount of chloride present (1.1 wt % of concrete) allowed intense pitting corrosion to occur.

Cherry and Price conducted tests with two different strain rate on smooth, cold drown, stress-relieved prestressing wire (1800 MPa UTS) to determine if sodium-chloride solutions of varying pH and anodic polarization would cause SCC (Cherry and

Price 1980). Wire fractured on both tests. Cherry and Price assumed that since failure of the wires were by yield at the point where the cross-section has been reduced by pitting, hydrogen embrittlement does not lead to a synergistic interaction between stress and corrosion so that failure may be ascribed simply to pitting or crevice corrosion caused by the presences of chlorides.

Results reported in this work on the other hand, even if not conclusive, confirmed the evolution of hydrogen induced cracks (HICs) on steel surface in the acid environment of crevice, their growth was presumably strongly influenced by the stress condition which concentrate maximum stress on a limited section of the wire. It has to be stressed however that the major damage of steel wire was caused by the strong acid attack which interested more than the half section of the wire and that, for this type of prestressing steel, could be considered the main cause of the incipient wire failure. Further work on different type of prestressing steel (considering more hydrogen sensitive steel) was therefore planned for the future.

## 5 CONCLUSIONS

The results shown in the paper suggested that crevice condition, that can easily occur in prestressing steel in concrete construction due to execution faults or construction errors, may lead to severe corrosion attack. Crevice can also occur in chloride contaminated concrete on inner wire surface of wire strands.

Hydrogen induced cracks can develop in such condition on steel wire. On the basis of the results here reported it was however still difficult to evaluate the influence of such cracks on the failure of prestressing steel.

# Investigation On The Corrosion Of Zinc Sheeting Of The Highly Insulated Cold Zinc Roofs In A Moderate Humid Region

R Zheng[1] A Janssens[2] J Carmeliet[1] W Bogaerts[3] H Hens[1]
[1] Building Physics Catholic University of Leuven Belgium
[2] Architecture and Urban Planning University of Gent Belgium
[3] Metallurgy and Materials Engineering Catholic University of Leuven Belgium

**Summary: During the last decades, with increasing concerns on energy efficiency and global warming, the U-factor of building elements has been pushed towards low threshold values. The trend to lower U-factor may greatly change the hygrothermal situation of traditional cold zinc roofs. Expectedly, that change could affect the corrosion of zinc sheeting in traditional cold zinc roofs.**

**In order to evaluate the hygrothermal performance and durability of well-insulated zinc roofs, a long-range field test program is carried out since November 1996. A total of four cold zinc roofs with high insulation quality (U<0.25 W/m$^2$/K) were constructed on the campus of KU Leuven, Belgium. Commercial zinc sheeting of 0.65 mm thickness (VM-zinc titanium) was used.**

**Investigations were conducted on the corrosion of zinc sheeting of the zinc roofs. The results showed: (1) The underside corrosion of the zinc sheeting was severe and far more serious than the upside corrosion. (2) Pitting was the main form of corrosion of the zinc sheeting. (3) A more perfect air-vapor tight retarder and a good ventilation of the roof cavity could not guarantee an elimination or a reduction of the underside corrosion of zinc sheeting in ventilated zinc roofs.**

**Keywords: Metallic roofs, corrosion, thermal insulation**

## 1 INTRODUCTION

Zinc roofing is common in Europe and may provide satisfactory service lives in urban atmospheres. It is usually considered to be maintenance-free, have a long life span, and easily adaptable to various design styles ranging from traditional to modern. The good performance of traditional zinc roofs is mainly attributed to the excellent resistance of zinc to corrosion and the favorable micro-environment surrounding the zinc sheeting.

Traditional cold zinc roofs were constructed with low insulation quality (most of them U>0.6 W/m2/K) and good ventilation. When carefully designed and installed, the condensation problem at the underside of zinc sheeting could be avoided or the condensate on underside surface of the zinc sheeting could dry out quickly. The underside corrosion of the zinc sheeting was not a serious problem. Traditional cold zinc roofs therefore performed well and served for a long time. Normally, a traditional cold zinc roof had a life span of over 30~40 years in industrial areas and of over 100 years in rural areas. In typical urban areas, a life span of 50~60 years could be expected.

Nevertheless, in the last decades, the growing concerns about global warming and energy efficiency pushed the U-factor of building elements towards low threshold values. This trend to lower U-factors may greatly affect the performance of zinc roofs due to a worse hygrothermal environment surrounding the zinc sheeting. The lower U-factors in fact may result in stronger undercooling of the zinc sheeting and in lower air temperature in the roof cavity. This will decrease the removal of water vapor from the roof cavity by ventilation, which is usually considered to be a good solution to avoid condensation at the underside of zinc sheeting. In the worse cases, the phenomenon of undercooling may be so strong that the temperature of the zinc sheeting may drop below the dew-point temperature of the surrounding air. This makes the surrounding air to become a moisture source so that the effect of ventilation shifts from drying to wetting the zinc sheeting. Therefore, cold zinc roofs with high insulation quality may have a serious problem of corrosion at the underside of the zinc sheeting. Unfortunately, little research has been conducted on that problem.

In order to investigate the hygrothermal performance and durability of well-insulated zinc roofs, in November 1996, a long-range field test program was started in the VLIET test building of the Laboratory of Building Physics of the K.U.Leuven. This paper presents some results of this field study.

## 2 EXPERIMENTAL DESIGN AND EXPOSURE CONDITIONS

### 2.1 Experimental design

A total of four cold zinc roofs with high insulation quality ($U < 0.25$ W/(m²·K)) were constructed on the campus of KU Leuven, Belgium, in 1996. The dimensions of the roofs were about 1.8 by 3 m. The roof slope was 5 %. The orientation of two roofs was southwest (SW1c and SW2c), of the other two northeast (NE1c and NE2c). Of the four cold zinc roofs, NE2c and SW2c had a correctly installed air-vapor retarder, the others (NE1c and SW1c) a poorly installed air-vapor retarder. The section of the zinc roofs is shown in Fig. 1. The details are presented in table 1. In order to simulate the installation of electrical connections, a perforation of 47 mm in diameter through the gypsum board and the air-vapor retarder was made in the roofs SW1c and NE1c (hereafter referred SW1c and NE1c as air-open roofs, the other two zinc roofs without a perforation being called air-tight roofs) respectively. The perforation was located at the center of the air-open zinc roofs.

### 2.2 Exposure conditions

The weather data were automatically recorded every ten minutes in the weather station and transported to a computer. The main weather parameters recorded were wind speed, wind direction, solar radiation, air temperature, and relative humidity. The temperature, relative humidity, wind speed and wind direction were measured at a height of 9 m above ground level. The radiation was measured at the southwest edge of a paved roof. Both the inside and outside monthly average climatic information for the exposure experiod are presented in table 2.

### 2.3 Collection of zinc specimens

One large zinc specimen was taken from each zinc roof in March 1999. The dimensions of the specimens were 50 by 70 cm. Each specimen contained a standing seam. All were visually examined on the spot. The location of the collected large zinc specimens on the zinc roofs is shown in Fig. 2.

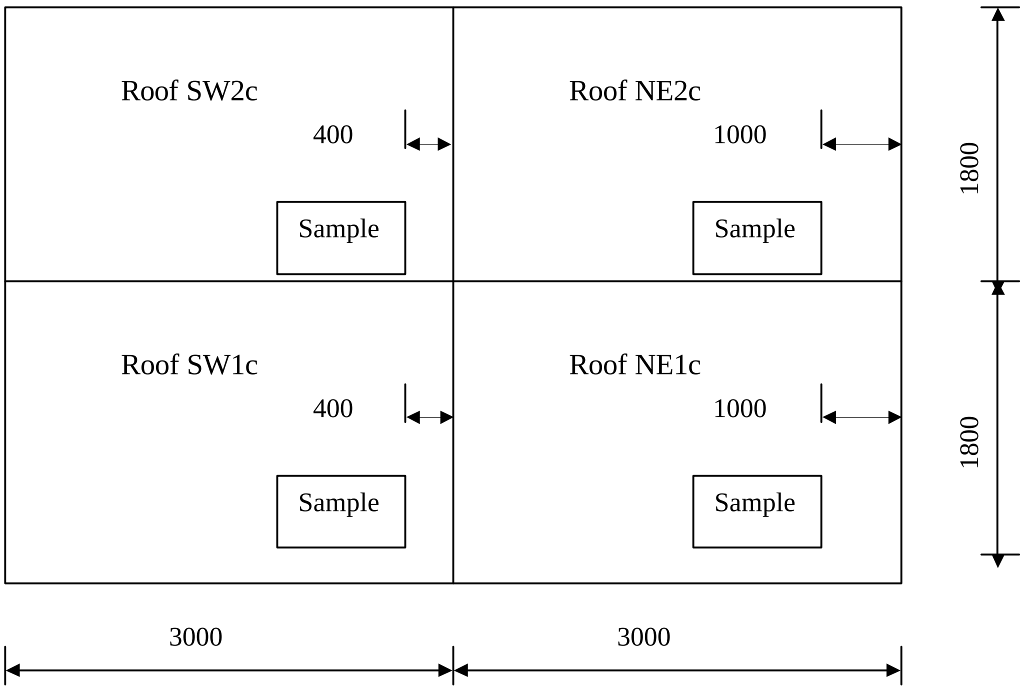

**Figure 2 The location of the collected large zinc specimens in the cold zinc roofs (top view)**

### 2.4 Cleaning method

In order to evaluate the corrosion type and the corrosion rate of the sheeting, some small samples were cut from the large specimens. These small samples were cleaned chemically as proposed by ASTM Standard G1-90: Practice for Preparing, Cleaning, and Evaluating Corrosion Test Specimens (ASTM Designation: G 1-90, 1994). The samples were first immersed in warm (70 °C) ammonium chloride solution (10 %) for 5 minutes, rinsed in reagent water, and scrubbed with a light brush. Then, an ultrasonic cleaning machine (BRANSON-1200) was used to remove the remaining corrosion products from the deep pits. The above procedure was repeated two times. Removal was confirmed by examination with a low power microscope (5 to 50 ×). After the final treatment, the zinc samples were thoroughly rinsed and immediately dried.

## 3 CORROSION TYPE OF ZINC SHEETING

### 3.1 General description of distribution of corrosion products

As shown in Fig. 3, the distribution of white corrosion products was not uniform at the underside of the zinc sheeting. It is also noted that there was no much apparent difference in corrosion between the air-open cold zinc roofs (SW1c and NE1c) and the air-tight cold zinc roofs (SW2c and NE2c). Generally, in light of the distribution of the corrosion products, there existed two typical regions on the underside of the large specimens. One region was heavily covered with white corrosion products (here labeled type I), the other was covered by a thin white film of corrosion products (here labeled type II). The directional characteristic of rolled zinc sheeting can clearly be seen on the areas with a thin white film of corrosion products.

Roof NE2c Roof SW2c

**Figure 3 Large zinc specimens taken from the cold zinc roofs (50´70 cm)**

Figure 4 illustrates a wood scar on the wood deck in NE1c and the appearance of the corrosion product on the zinc surface corresponding to the scar. We believe that the underside surface of the zinc sheeting somewhat touched the wood scar due to the sign of the scar on the zinc surface. Examining it carefully, it is found that the center area of the wood scar was a little higher than the edge area. The height gradually reduced along the annual ring of the scar from the center to the edge. So, if the zinc sheeting contacted the wood scar, the most possible contacting place was the center area. Making a comparison between them, it is noted that the corrosion of the zinc sheeting corresponding to the center area of the wood scar was lighter than that corresponding to the edge area of the wood scar. This may partly demonstrate the influence of the contact situation between the zinc sheeting and the wood deck on the appearance of corrosion products on the zinc surfaces. For our cases, we may say that the corrosion pattern on the zinc sheeting contacting the wood deck or having much small gaps between the zinc sheeting and the wood deck took the type II, while that in the no-contact areas took the type I.

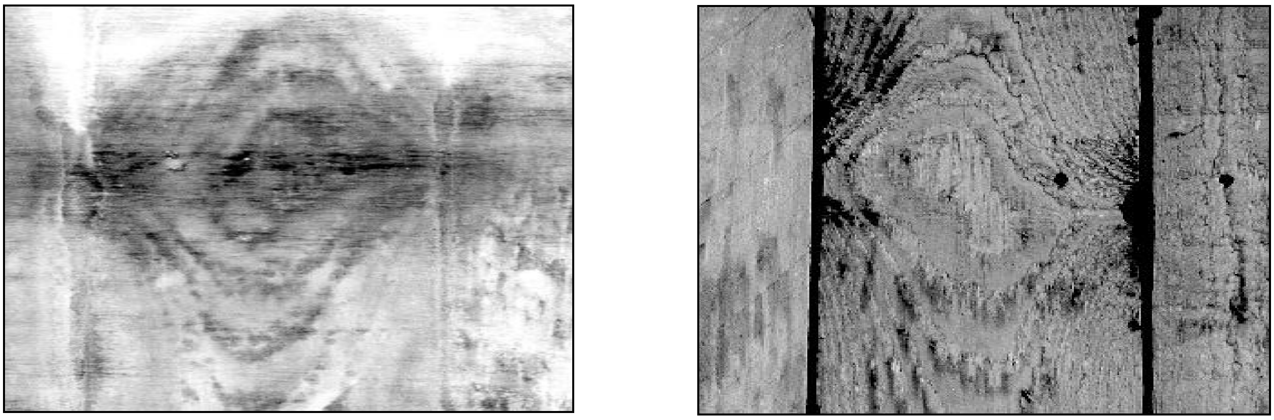

**Figure 5 Area of the zinc sheeting contacting a wood scar (left) and the corresponding wood scar in the wood deck (light)**

### 3.2 Type of corrosion

The types of corrosion that are commonly found to occur on zinc sheeting can be divided into four groups, namely general corrosion, pitting corrosion, galvanic corrosion, and intergranular corrosion. Of the corrosion types, general corrosion is most common.

Figure 6 shows the typical appearances of the underside of the zinc sheeting in the no-contacting areas after removal of the corrosion products. Clearly, a lot of big pits developed on the surface. The distribution of the pits was roughly uniform, but the dimension had some variation. Figure 7 illustrates the typical appearance of the underside of the zinc sheeting in the contacting areas after removal of the corrosion products. The zinc surface developed some dull appearance and the pits were very small. The distribution of these small pits was quite uniform. The corrosion at the no-contacting areas was much more serious than that at the contacting areas. The pits in both the no-contacting areas and contacting areas generally took a circular shape.

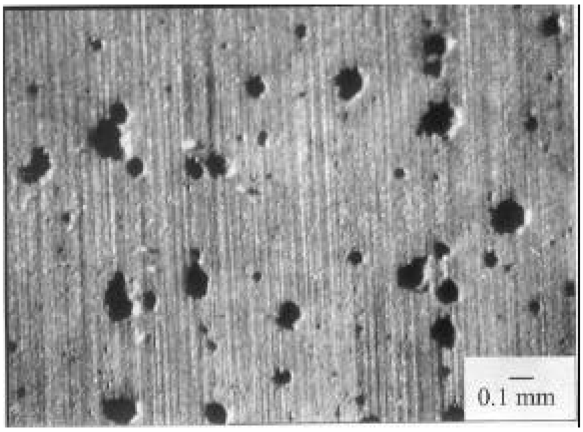

**Figure 6 The typical appearance of the underside of the zinc sheeting in the area not contacting the wood deck after removal of the corrosion products**

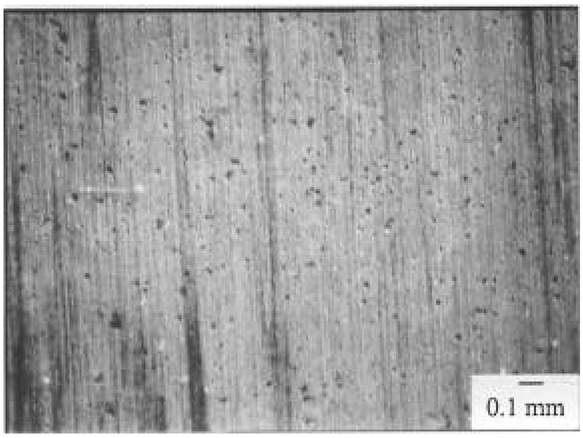

**Figure 7 The typical appearance of the underside of the zinc sheeting in the area contacting the wood deck after removal of the corrosion products**

For the upside of the zinc sheeting, the typical appearance after removal of the corrosion products is shown in Fig. 8. It is obvious that numerous small pits developed over there. The distribution of the pits is quite uniform from a macroscopic point of view. The pits seem shallow and many of their depths might be smaller than their diameters.

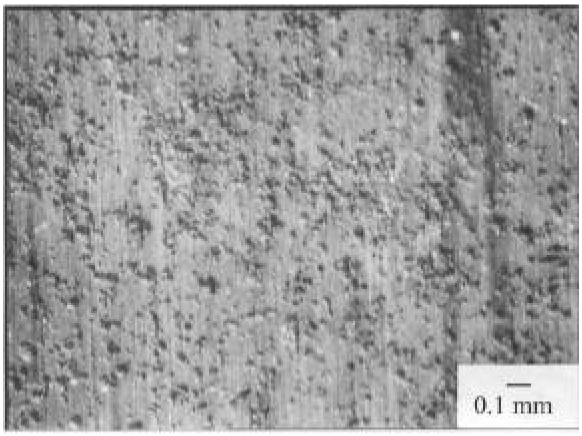

**Figure 8 The typical appearance of the upside of the zinc sheeting after removal of the corrosion products**

## 4 CORROSION RATE OF ZINC SHEETING

### 4.1 Method of evaluation

It is well know that pitting corrosion can be more serious than general dissolution attack. The growing rate of pit depth is dependent on both the environmental and the metallurgical conditions. It is very important to be able to determine the extent of pitting corrosion, either in a service application where it is necessary to predict the service life of zinc roofs, or in laboratory test programs that are used to select the best structures for zinc roofs.

In evaluating pitting corrosion, both the average corrosion rate based on mass loss and the average pit depths cannot readily be used. The corrosion estimation based on mass loss can seriously underestimate the corrosion penetration caused by pitting. For the corrosion estimation based on the average pit depth, there are also some problems. First, many smaller pits become too indistinguishable to be measured due to stopping growth very soon after initiated, and second, the deeper pits are of most practical importance.

For metallic roofs, the deepest pits will initiate leakage if they continue to propagate. Therefore, it is not the overall corrosion rate or the number of pits that are of interest, but the deepest pits since they cause the failure of the roof. Of the available evaluating methods, the extreme value statistical theory has been proven to be a powerful tool to analyze maximum pit depth data. This theory can be used to estimate the maximum pit depth of a large area of material on the basis of the examination of a small portion of it. Thus, we used the statistical theory of extreme value to evaluate the corrosion rate of the zinc sheeting.

### 4.2 Collection of maximum pit depths

As shown above, the corrosion situations in the contact areas and no-contact areas were quite different. Considering the quite light extent of pitting corrosion in the contact areas, we only evaluated the extent of pitting corrosion in the no-contact areas.

A total of ten small samples (5×5 cm) were collected from each area under concern on the large zinc specimens. The small samples were cleaned chemically using the method described previously. Five possible deepest pits on each sample were located by examination under a low-power microscope (5 to 50 ×) and were circled with a pencil. Then, the circled pits were measured using a powerful microscope "Quick Vision" (200 to 1000 ×). A pit was centered under the objective lens at low magnification, which was increased until the pit area, including the lips, filled most of the field of vision. The microscope was first focused on the uncorroded surface at the lips of the pit and then on the lowest part at the bottom of the pit. The difference between the initial and the final reading was counted as the pit depth. On a single pit, the measurement was repeated three times and the largest value was selected as depth of the pit. Of the depths of the possible five deepest pits on each sample, the largest one was considered to be the maximum pit depth of that sample. The measured maximum pit depths for each zinc roof based on the ten small samples are given in table 3.

**Table 3 The measured maximum pit depth of each zinc roof based on the ten small samples**

| *Roof* | *SW1c* | *NE1c* | *SW2c* | *NE2c* |
|---|---|---|---|---|
| Maximum depth (μm) | 167 | 180 | 273 | 228 |

### 4.3 Type of distribution of the maximum pit depths

Table 4 presents the results of a statistics analysis on the measured maximum pit depths. Since the maximum depths at the upside of the zinc sheeting were too small to be located and measured, they are not considered in the analysis. As shown in Table 4, all Fs are far less than 0.01. This shows that the linear regression relationships between the reduced variates and the maximum pit depths are highly significant. This can be taken as a proof that the maximum pit depths are sampled from parent populations of the exponential type and that the infinite population of maximum pit depths follow the Gumbel distribution.

**Table 4 Equations of linear regression between the reduced variates and the maximum pit depths in the cold zinc roofs**

| Roofs | Equations of linear regression | R square | F (significance of F-test) |
|---|---|---|---|
| SW1c_nca | y = 0.031943*x - 3.09361 | 0.969 | 2.63E - 07 |
| NE1c_nca | y = 0.059071*x - 8.33586 | 0.954 | 1.21E - 06 |
| SW2c_nca | y = 0.023750*x - 4.19073 | 0.962 | 5.62E - 07 |
| NE2c_nca | y = 0.042821*x - 7.96814 | 0.921 | 1.09E - 05 |

Note: "nca" — no-contact areas.

### 4.4 Estimation of the maximum pit depth on the zinc roofs

It is interesting to know how many maximum depth pits deeper than a specific value may exist in a zinc roof. Since the number of the maximum depth pits is area dependent, both the contact area and the no-contact area should be known for this analysis. Nevertheless, there is some difficulty of obtaining the exact areas of the contact surface and no-contact surface for the entire zinc roofs in practice. On the basis of the appearance of the large zinc specimens, we assumed that the ratio of the contact area to the no-contact area was 0.4:0.6, without regard to the very little pits in the contact areas. Thus, the cumulative probability of the maximum pit depths can be expressed as

$$1-\frac{m}{N_c}=0.6\times\exp\left(-e^{-\frac{x_c-u_{nca}}{\alpha_{nca}}}\right)+0.4 \qquad (1)$$

Where:

m — the number of maximum depth pits deeper than a specific value

$N_c$ — the total number of small samples for each cold zinc roof.

$\alpha_{nca}$ and $u_{nca}$ — The scale value and mode value of the distribution of the maximum pit depths in the no-contact areas

$x_c$ — the specific maximum depth, μm.

Rearranging the equation (1), the specific value $x_c$ that there are m maximum depth pits deeper than $x_c$ can be expressed as

$$x_c = u_{nca} - \alpha_{nca} \ln\left(\ln\left(\frac{0.6N_c}{0.6N_{c-m}}\right)\right) \quad (2)$$

Table 5 summarizes the values of $x_c$ obtained from equation (2) for m = 1, 10, 50, and 100. It is evident that, for all cases in question, the values of the pit depths in SW2c and NE2c (the two roofs with a correctly installed air-vapor retarder) were much larger than those in SW1c and NE1c (the two roofs with a poorly installed air-vapor retarder). This means that the maximum pit depths in SW2c and NE2c were much deeper than those in SW1c and NE1c. For the comparatively deep maximum depth pits (i.e., m = 1 and 10), the maximum pit depths in SW1c and SW2c were deeper than those in NE1c and NE2c, respectively.

**Table 5 The values of $x_c$ in the cold zinc roofs (unit: mm) when m = 1, 10, 50, and 100.**

| Number of pits | SW1c | NE1c | SW2c | NE2c |
|---|---|---|---|---|
| 1 pit | 321 | 262 | 479 | 353 |
| 10 pits | 249 | 223 | 382 | 299 |
| 50 pits | 198 | 196 | 313 | 262 |
| 100 pits | 176 | 184 | 283 | 245 |

### 4.5 Estimation of the failure probability of the zinc roofs

Perforation of zinc sheeting is one of the most important factors in determining the service life of zinc roofs. The first perforation, whose time and location is a matter of probability, is a useful indicator to reveal the situation of the zinc sheeting. It is very important to know the probability of failure. In the following analysis, we consider the zinc sheeting to fail once there exists a maximum depth pit deeper than the thickness of the sheeting.

The failure probability of the no-contact areas of the individual zinc roof $P_{nca}$ may be written as

$$P_{nca} = 1 - \exp\left(-e^{-\frac{x_t - u_{nca} - \alpha_{nca}\ln 1296}{\alpha_{nca}}}\right) \quad (3)$$

where:

$x_t$ — The thickness of zinc sheeting in microns, 650 µm.

Considering the very small pits in the contact areas, we may assume its failure probability $P_{ca}$ to be zero. The events $P_{nca}$ and $P_{ca}$ are independent. Thus, the failure probability of a cold zinc roof is given by

$$P_c = 1 - \exp\left(-e^{-\frac{x_t - u_{nca} - \alpha_{nca}\ln 1296}{\alpha_{nca}}}\right) \quad (4)$$

Table 6 summarizes the failure probability of the cold zinc roofs. As seen in table 6, the failure probability in SW2c and NE2c is obviously higher than that in SW1c and NE1c, respectively. It is also noted that the probability of failure in SW1c and SW2c is clearly higher than that in NE1c and NE2c, respectively.

**Table 6 Failure probability of the zinc roofs**

| *roof* | *SW1c* | *NE1c* | *SW2c* | *NE2c* |
|---|---|---|---|---|
| Failure probability | 2.77E-5 | 1.14E-10 | 1.70E-2 | 3.04E-6 |

## 5 DISCUSSION

It was expected that no severe corrosion was found on the upside of the zinc sheeting in the zinc roofs because a specific protection layer developed there as time progresses. This layer contains zinc hydroxide and basic zinc salts and is called patina. It is this layer that prevents the upside of the zinc sheeting from being seriously attacked. Although numerous very little pits developed on the upside surface, they normally are not a big problem. Pitting corrosion in atmospheric environments has seldom been reported as the main cause of failure of zinc sheeting. Pitting corrosion is normally induced in clean rural environments. While the depth of the pits increases with time, the ratio of pit depth to surface-average corrosion penetration decreases (Zhang, 1996). In an ASTM atmospheric exposure program, pits were observed on high-grade zinc and on a 1% Cu-zinc alloy after two years of exposure in four different environments (Showak and Dunbar, 1982; Viart, 1984). In general, the upside pitting corrosion of the zinc sheeting may have little impact on the service life of the zinc roofs in question.

Normally, contact between zinc and hygroscopic materials, especially in moist conditions, may result in more severe corrosion. Obviously, as shown, it was found that the underside corrosion of the zinc sheeting was more severe in the no-contact areas than in the contact areas. This may be attributed to the strong undercooling of the sheeting.

The measured undercooling of the sheeting could be so severe that its temperature fell below the dew-point of the outdoor air for quite a long time. Due to the seams (about 5 mm) among laths in the wood deck, the ventilated air in the roof cavity might bypass the laths and reach the underside of the zinc sheeting. So, condensation induced by ventilation could occur in those non-contact areas during severe undercooling periods. That caused the underside corrosion of the sheeting.

For the areas contacting the wood deck or the areas with much small gaps between the sheeting and the wood, however, less condensation might be expected because of the difficulty of ventilated air reaching those spots and because of the hygroscopic inertia of the wood. The wood deck absorbs the little condensation if any. In these areas, the corrosion rate of the zinc sheeting mainly depends upon the moisture content in the wood deck. Its threshold value to induce zinc corrosion is about 20 % by weight (Building Research Establishment, 1986). Therefore, if the moisture content in a wood is continuously kept below that critical level, zinc does not suffer severe corrosion even contacting the wood. As the moisture contents in the wood deck during the last three years of measurement generally remained lower than 20 %, it is reasonable that less corrosion at the underside of the zinc sheeting in the wood-contact areas occurred in comparison with the no-contact areas.

It has been widely accepted that high inside air exfiltration and poor ventilation of roof cavity are the main factors resulting in severe underside corrosion of zinc sheeting in cold roofs. The precautions against the underside corrosion of the sheeting mainly focus on these two aspects. Dunbar and Showak (1982) proposed two basic measures to eliminate or reduce this type of corrosion: 1. Installing a good vapor barrier underlay material under the zinc sheeting to minimize the amount of water vapor that can permeate and condense against its underside. 2. Providing some airflow between the zinc sheeting and the underlay to rapidly dry any moisture that does condense. In order to increase the ventilation in roof cavity, Zaher (1995) recommended that zinc roof slopes should be more than 1 in 12, otherwise, additional venting is needed to assist the drying of the underside of zinc sheeting.

The ventilation in the roof cavity of the cold zinc roofs in the test building has been investigated by Janssens (1997). It was found that the relation between the ventilation rate (G, $m^3/m/h$) and the wind speed (v, m/s) was "$G = 27.8\ v$". This result showed that wind could induce a good ventilation rate in the cavity of the cold zinc roofs on the test building. Obviously, that good ventilation could not eliminate or lessen underside corrosion of the sheeting in these highly insulated cold zinc roofs. It is found unexpectedly that the underside corrosion of the zinc sheeting in SW2c and NE2c (air-tight zinc roofs) was more severe than that in SW1c and NE1c (air-open zinc roofs). Apparently, the low air exfiltration could not eliminate or even reduce underside corrosion of the sheeting in these highly insulated cold zinc roofs either.

A possible reason for the unexpected results is the strong undercooling of the sheeting. Zheng et al (1999) made an investigation on the hygrothermal behavior of the zinc roofs. The results showed that the severe undercooling of the sheeting could make the surrounding air to become a moisture source so that the effect of ventilation was changed from drying to wetting the underside of the sheeting. Under that situation, more air exfiltration combined with good ventilation of the cavity might increase the thickness of water layer at the underside of the sheeting. It is well known that the thickness of water film on zinc surface is one of the most important factors affecting the corrosion rate of zinc in atmosphere. Thicker water film decreases the diffusion rate of oxygen. In this situation, the thicker the water layer, the lower the corrosion rate was.

As shown, the traditional precautions (low air exfiltration and good ventilation in cavity) seem not to work effectively in cold zinc roofs with high insulation quality. New techniques and roofing systems should be developed, if we like to guarantee a significant reduction of underside corrosion in zinc roofs with high insulation quality.

## 6 CONCLUSIONS

A field investigation was performed to evaluate the corrosion type and corrosion rate of the zinc sheeting in the highly insulated cold zinc roofs in a moderate humid region. The following main conclusions were drawn:

1. Numerous very little pits developed on the upside of the zinc sheeting. The distribution of the pits was quite uniform. The upside of the zinc sheeting corroded very little.
2. At the underside of the zinc sheeting, pitting corrosion was the prevailing corrosion type.
3. There existed two different forms of underside corrosion of the zinc sheeting. In the areas where contacted the wood deck, its surface developed some extent of dull appearance and only somewhat pitting corrosion occurred; while in the areas not contacting the wood deck, numerous large and deep pits developed.
4. The low air exfiltration and the good ventilation in the roof cavity could not guarantee an elimination or even reduction of the underside corrosion of the sheeting.
5. Generally speaking, the corrosion of the sheeting was very severe in the highly insulated cold zinc roofs after being exposed for only three years.

6. New techniques and roofing systems should be developed for highly insulated zinc roofs in moderate humid regions.

# The Influence Of Rain And Humidity On The Lifetime Of Transparent Polymeric Roof Materials

**U Schulz[1] & G Tjandraatmadja[2]**
**[1]Bundesanstalt für Materialforschung und -prüfung (BAM) Berlin Germany**
**[2]CSIRO Building Construction and Engineering Australia**

**Summary: PMMA and PC undergo photochemical ageing leading to a gradual loss of material transparency and appearance during service life which is desired to reach 50 years or more. Available artificial weathering test methods are unable to distinguish materials in terms of the speed of ageing in outdoor use as roof materials. In order to design an appropriate accelerated or time compressed test method the "Worst Case" scenario of the respective climatic conditions must be found. Therefore, samples of PMMA and PC were exposed to artificial weathering tests using different climatic conditions in terms of relative humidity and surface wetness. In case of PMMA it was found that water accelerates the photo degradation enormously. The fastest ageing occurred when liquid water and UV radiation acted simultaneously on the sample surface and the PMMA reached its highest water content during weathering. In the case of PC it was found that both vapour and liquid water speed up the photoageing, similarly to PMMA. But differently from PMMA the "Worst Case" scenario for PC proved to be weathering conditions with high relative humidity. A test method has to be able to run artificial weathering under the different moisture conditions which can occur in the field.**

## 1 INTRODUCTION

Transparent polymeric materials are increasingly used in the place of glass for transparent applications in the building sector because they are lightweight, tough, easily formed into complex shapes and transmit light well. However plastics are more susceptible to degradation by weathering than the traditionally used glass; notably to the combined effects of ultraviolet light, heat and moisture. A large range of plastics glazing is available ranging from highly photo stable materials that are commonly used without photostabilisers to poorly photo stable polymers that require extensive protection against the destructive weather conditions. Applications such as roof materials usually require a lifetime of several decades. Therefore, accelerated or time-compressed artificial weathering tests are used to assess the weatherability of plastics glazing or combinations of plastics glazing. Nowadays, the favoured method to design an appropriate test is the so-called "Test-tailoring". This means that each kind of plastic glazing needs its specially designed weathering tests. Test-tailoring requires the knowledge of the "Worst case" scenario of the weather periods occurring in the field, characterising the combination of environmental factors that most accelerate the photodegradation for the concerned plastics glazing. Today's standardised artificial weathering tests for plastics are performed mostly too dry and do not meet the "Worst case" scenario of most types of plastics glazing consuming a lot of time without showing the typical degradation phenomena. Therefore, our work is directed at the influence of water (vapour or liquid) during weathering on two widely used materials for plastics glazing (PMMA and PC). A good example of the use of PMMA glazing over about thirty years is the roof of the renowned Munich Olympic stadium. The roof plates had to be replaced completely in the last few years because they reached the end of their lifetime. The commonly observed failure mode in PMMA is the gradual development of crazes. Because the PMMA used was stretched in two axis the crazes developed in a horizontal direction leading to a scale-like splitting-off of material from the surface. The result of this degradation phenomenon was an unacceptable loss of light transparency. But none of the standardised artificial weathering tests used commonly for evaluating the material quality could cause this phenomenon in the laboratory. Therefore, the great variation in lifetime of the plates that was observed during the last three decades in the environment could not have been predicted. A special phenomenon that could be observed on the roof plates in the field led to the suspicion that moisture conditions had accelerated the deterioration of the PMMA. Figure 1 shows an almost 25 year old highly damaged roof plate. The almost clear surface parts which can be seen near the metallic disks or frames needed for fixing the plates were mostly warmer than the other parts in clear nights and therefore, affected by dew for shorter periods and less intensely. Lehmann (1997) describes the frequent changes of wetting and drying as the most likely cause for the damage of the weathered roofing site. But the contribution of water to the loss of fastness by photodegradation cannot be discarded. Finding experimental evidence for this presumption was one aim of this work.

The contribution of humidity to the photodegradation of polycarbonate is controversial. In artificial weathering studies, Pryde (1985) reported that pre-hydrolysis of polycarbonate accelerated photo-induced discoloration when compared to dry samples. However, the presence of high humidity levels during exposure to UV was reported to have an opposite effect, decreasing the rate of photo-induced yellowing according to Factor and Chu (1980) and Pryde (1984). While Tjandraatmadja et al (1999) reported that under moderate humidity (42%) the rate of yellowing underwent an acceleration stage in the early stages of degradation, but as exposure progressed dry samples experienced more intense yellowing. On the other hand, high humidity seems to favour the rate of photo-oxidation in polycarbonate according to researchers, such as Clark and Munro (1984) and Rivaton et al (1986). In context with developments to improve the relatively bad scratch resistance of PC by covering it with appropriate hard coats, more knowledge about the behaviour of the basic PC sheet material at extreme weather conditions is necessary. Further clarification of the influence of water on the photodegradation of PC due to the differences in the existing opinions was the other aim of this work.

## 2 EXPERIMENTAL

### 2.1 Materials

Two types of PMMA and four types of PC were evaluated. All of them were commercially available sheet materials. The identification of the samples is shown in Table 1.

**Table 1: Identification and features of the glazing examined**

| **Sample** | **Type** | **Thickness** | **Property** |
|---|---|---|---|
| PMMA 1 | GS 215 stretched | 4 mm | Uncoloured |
| PMMA 2 | GS 816 stretched | 4 mm | Light brown coloured |
| PC-1 | Lexan | 1 mm | Only basic stabilisation |
| PC-2 | Indoor | 3 mm | Only basic stabilisation |
| PC-3 | APEC HT | 3 mm | Only basic stabilisation, optical quality, |
| PC-4 | Longlife | 3 mm | Both sides co-extruded with highly stabilised PC films |

### 2.2 Methods

Artificial weathering was performed using a commercially available fluorescent UV lamp weathering device, model "Global UV Test" in combination with a special box which allowed to expose specimens to three different moisture conditions at equal temperature at the same time and in the same weathering chamber. The conditions are characterised in Table 2.

**Table 2. The three different weathering conditions**

| Short term | dry | humid | wet |
|---|---|---|---|
| Climatic condition | 50°C; 13% RH | 50°C; 98 % RH | 50°C; steady under a 5 mm sheet of water |

The test ran under constant conditions. The specimens were subjected to continuous UV radiation (39 W/m$^2$). Spectral radiation distribution was performed according to ISO 4892-3: 1994 (no UV output below the normal solar cut-off of 290 nm). The "Global UV Test" equipment enables the application of the test under defined and reproducible weathering conditions, which is a requirement for good repeatability and reproducibility. The temperatures of the panels were constant to ±1K. Periodically specimens were taken out of the weathering device and their properties (listed in Table 3) were determined.

**Table 3. Examinations of the weathered specimens**

| Glazing | Property | Measuring technique |
|---|---|---|
| PMMA | appearance | Visual (unarmed eye) |
| PC | Exposure up to first occurring of crazes | Visual (unarmed eye) |
| PC | Spectral transmission | Carl Zeiss – DMC 25 |
| PC | Haze | Gardiner Pivotal Sphere UX-10 |
| PC | Gloss 60° | BYK Gardner Tri Gloss meter |
| PC | Colour | BYK Gardner Color guide, sphere 65/10° (white tile background) |
| PC | Surface image | LAIKA macroscope M420/ DC200 |
| PC | Surface profile | WYKO white light interferometer |
| PC | SEM | Phillips XL30 at 2 kV |
| PC | Chemical change | Bruker FTIR |
| PC | Acid resistance | ADF test of the BAM |

## 3 THE EFFECT OF WEATHERING

### 3.1 PMMA

After certain exposure periods specimens of each material were taken out of the weathering device, dried at normal room conditions and photographed all using a scanner. The weathering was finished after 130 days and the last specimens were dried in vacuum to determine the water content. Weathered specimens of PMMA 1 are shown in Figure 2 . As can be seen in Figure 2 the test duration that is necessary for the first occurring of scales clearly depends on the climatic conditions. No visible deterioration could be found after weathering under dry conditions. The joint action of UV radiation and liquid water proved to be the "worst case" for PMMA. In this case the steady wetness of the surface led to the highest water content in the polymer. An environment with high relative humidity showed a slower deterioration obviously because of the lower reachable water content in the polymer. No difference could be found in the behaviour of the two PMMA qualities.

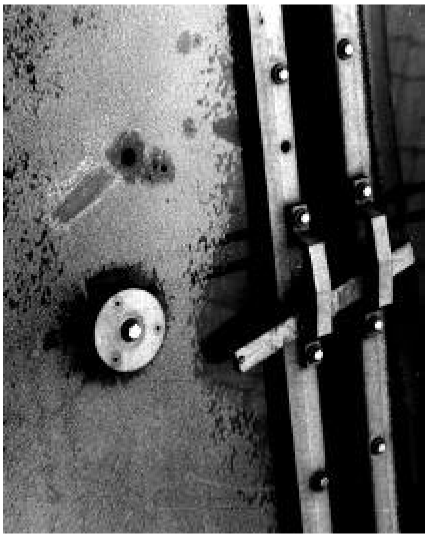

**Figure 1. Image of damage of a 25 years old roof plate made from PMMA 1**

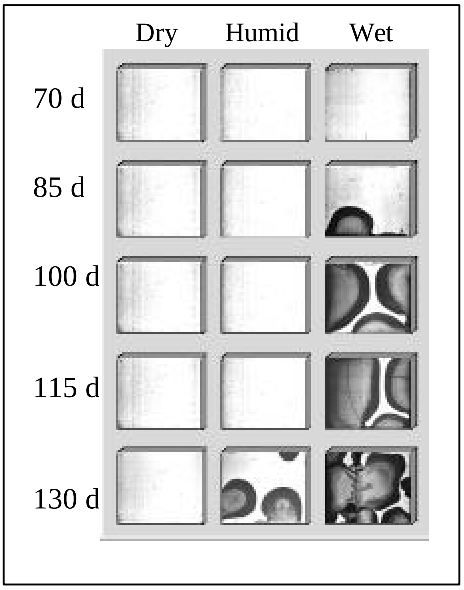

**(<0,01 %) (1,5 %) (3 %)**

**Figure 2. Image of damage of PMMA 1 after exposure in dependence on the test conditions (from left to right) and the test duration from top to bottom. In brackets the water content after 130 days of exposure**

## 3.2 Polycarbonate

### 3.2.1 Spectral transmission

One of the characteristic traits of polycarbonate photodegradation is yellowing.

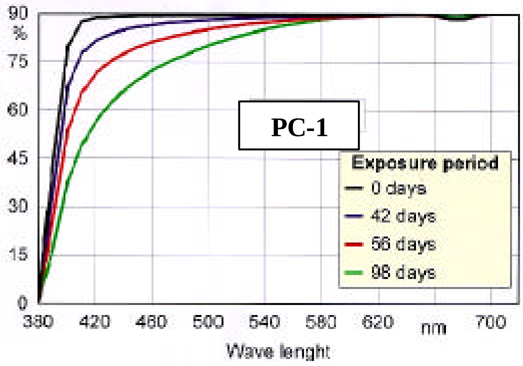

**Figure 3. Spectral Transmission of PC1 at wet weathering conditions in dependence of the exposure period**

The behaviour of PC-1 shown in Figure 3 is a typical example of the change of the spectral transmission of PC due to the weathering. The most evident variation could be found at the 400 nm shoulder resulting in yellowing. The transmission curves for the other test conditions and for the other samples are very similar. They differ only in speed and intensity of decrease of the 400 nm value. In the same context, the yellow/ blue chromaticity factor b* shifting in the yellow range predominates significantly in the results of the colour change measurement in accordance to CIE La*b* coordinates. Therefore, in the discussion concerning colour the influence of the weathering conditions on yellowing is presented using the factor b* only.

### 3.2.2 Colour change

As can be seen in Figure 4, all of the four PC samples are yellowing progressed at different rates during different stages of exposure.

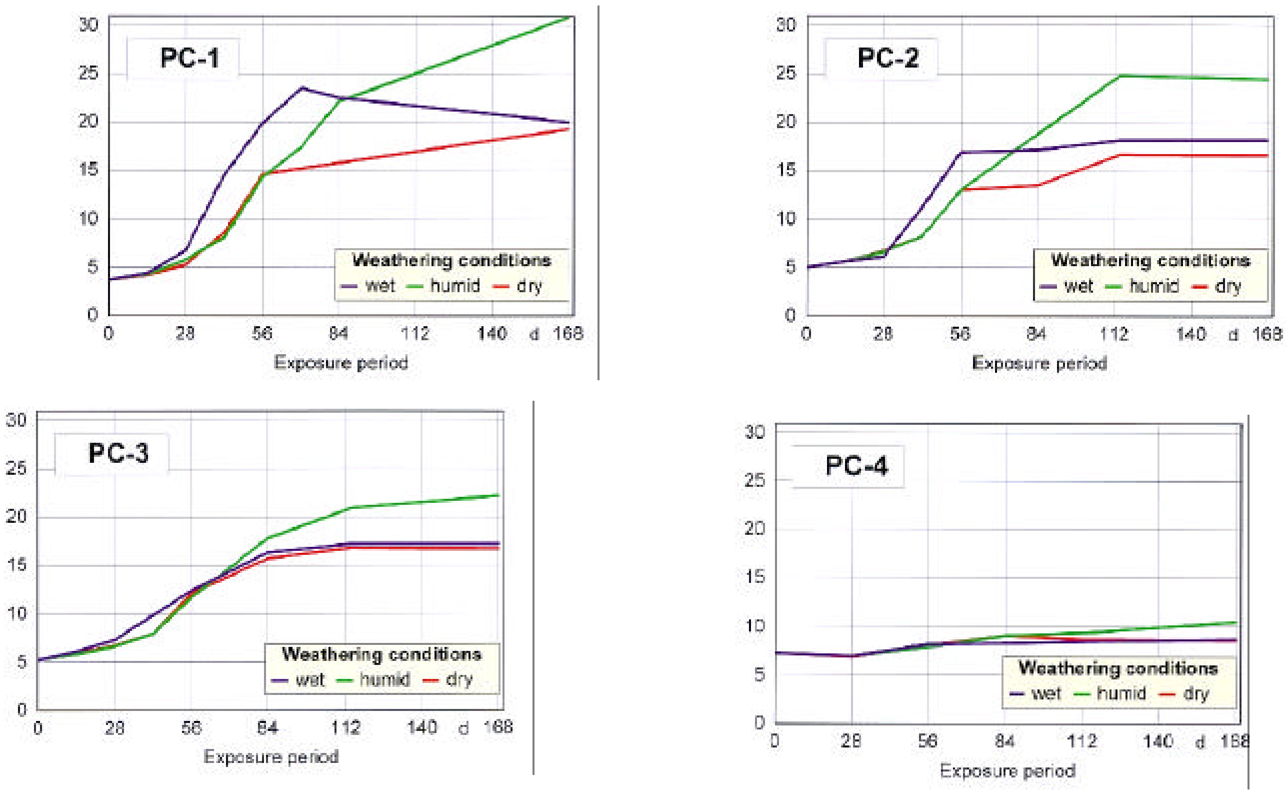

**Figure 4. Yellowing of polycarbonate upon exposure**

The increase in yellowing was not significant during the first 30 days of exposure. This could be due to the combined action of UV stabilisers present in the sheets' formulation and the induction period required for the concentration of yellow polyconjugated species to cause noticeable color changes. After the initial period the rate of yellowing increased at an accelerated pace between 50 and 80 days of exposure, after which it slowed down again at an apparent plateau. The rate of increase was dependent on the characteristics of each sample. PC-4 (Long life) experienced the least variation with exposure, hence it could be assumed to undergo the least photodegradation. It displayed less than 20% change for “Wet” and “Dry” conditions and a maximum change of 43.8% for the “Humid” one. In comparison the other types of polycarbonate displayed increases in yellowness ranging from 220 - 325% (PC-3), 230-400% (PC-2) and 420-735% (PC-1). Hence the better stabilisation system in the PC-4 samples protected them effectively from the effect of UV. PC-1 and PC-2 (both indoor quality) samples were the most susceptible to photodegradation as would be expected, since both would contain less stabilisers being indoor type materials. Moisture had a detrimental effect to the yellowing process. Samples exposed to UV and covered permanently with a water film (wet) yellowed at a faster pace than the other samples during the acceleration stage. However the yellowness values (b*) reached similar valuesas the samples degraded at 13%RH(dry) after prolonged exposure (>100 days). Whilst, the samples photodegraded at 98% RH displayed the most intense yellowness (b*).

### 3.2.3 Development of crazes

Crazes are another typical feature of photodegradation of polycarbonate. Figure 5 presents the WYKO-profiles of several surface sections of weathered PC-1 specimens showing the variety of weathering-caused alterations of the surface morphology:

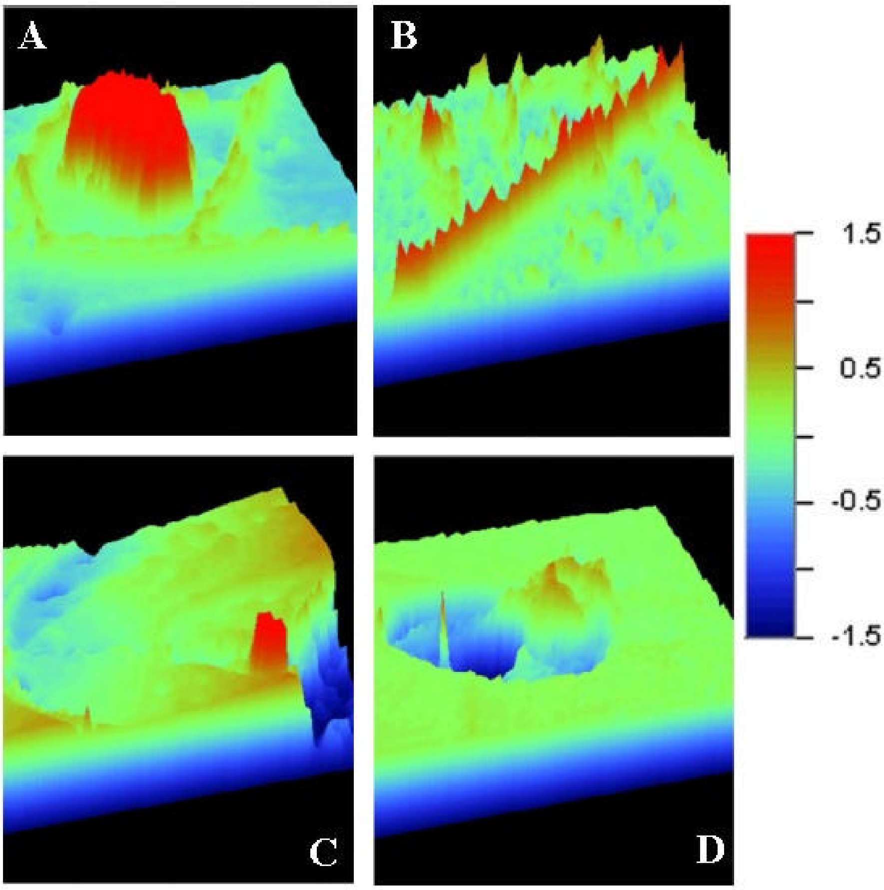

**Figure 5. Typical details of the surface profile of differently weathered specimens of PC-1 (A: 56 days, wet - 60 x 45 µm; B: 84 days, wet – 220 x 300 µm, C: 84 days, humid – 60 x 45 µm; D: 84 days, humid – 190 x 250 µm; height in µm)**

Blisters up to 1.5 µm in height surrounded by crazes up to 0.5 µm in height and up to 15 µm in width (see profile A). Crazes up to more than 1.5 µm in height (see profile B). Caves and holes down to deeper than 1.5 µm signalling loss of material (see profiles C and D). These features were distributed irregularly across the sample surface. But in general crazes dominated in comparison to other features. Therefore, only the development of crazes was used to discuss the weathering-related changes of

Go Back Next Page

surface morphology in the further discussion.  In contrast to the literature, crazes were risings predominantly and fissures beside the risings appeared only secondarily as can be seen in the SEM photos in Figure 6.  It was found that the development of crazes ran in close agreement to the change of colour characterised by the following arguments which were derived from the images of 2 mm wide surface areas of the differently weathered specimens in Figures 7 and 8: First: Visibility and density of crazes increased with increasing exposure period.  Second: The dry-weathered specimens did not show any crazes in general. Comparing the specimens weathered at moist conditions crazing is stronger on the humid-weathered specimens than on the wet-weathered ones after 168 days of weathering particularly in case of PC-1.  Third: In comparison of the different PC samples, PC-1 showed the strongest crazing and PC-4 had not shown any crazes after 168 days.  Fourth: Crazes first occurred during weathering under wet conditions (see also Table 4).

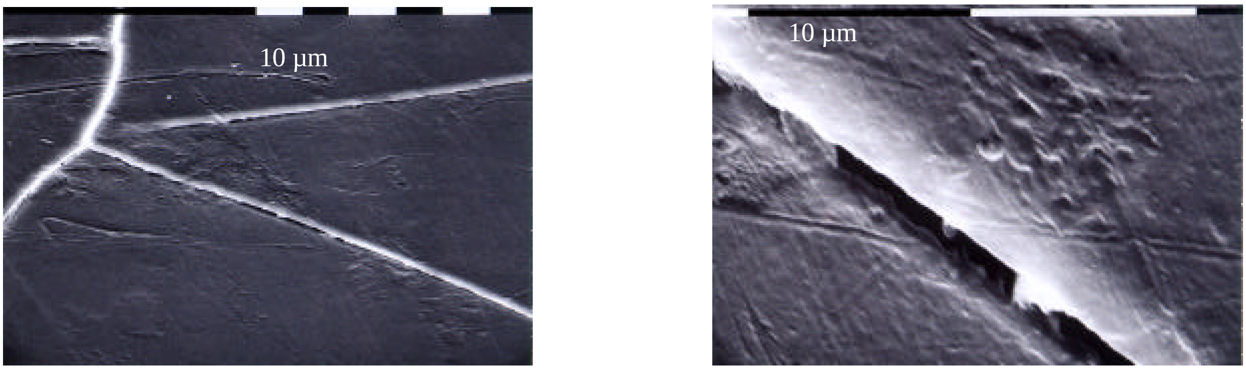

**Figure 6. SEM image of a section of the 56 days wet-weathered specimen of PC-1 in different magnification**

**Table 4.  Exposure period up to the first occurrence of crazes identifiable by the unarmed eye**

| **Sample:** | **PC-1** | | | **PC-2** | | | **PC-3** | | |
|---|---|---|---|---|---|---|---|---|---|
| Weathering condition | Dry | Humid | Wet | Dry | Humid | Wet | Dry | Humid | Wet |
| Exposure period for crazing (in days) | >168 | 56 | 42 | >168 | 56 | 42 | >168 | 70 | 42 |

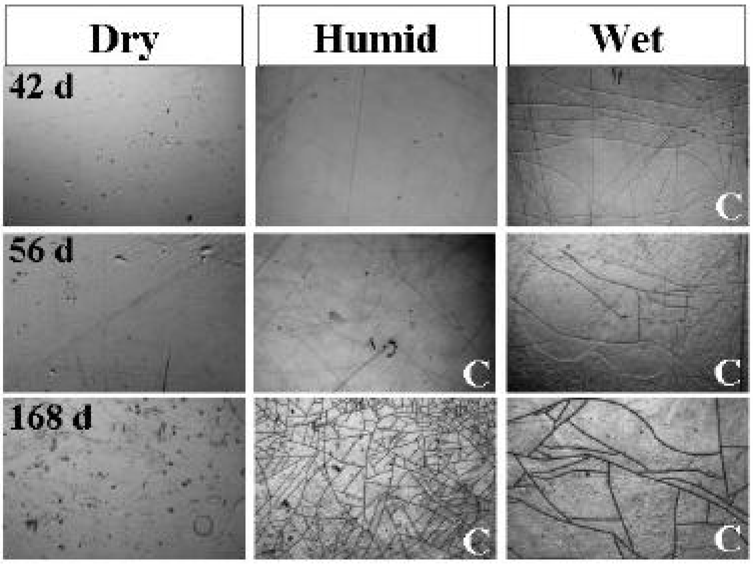

**Figure 7.  Crazing of PC-1 in dependence on weathering conditions and exposure period (width of the section: 2 mm, C means: Crazes can be spotted by unarmed eye)**

Next Page

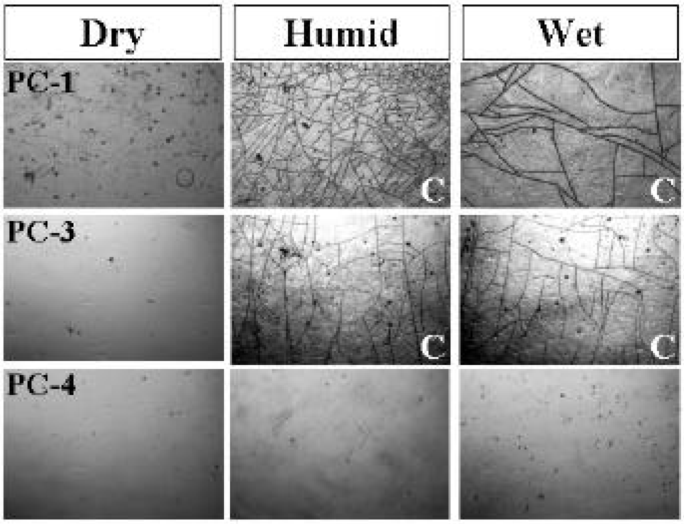

**Figure 8. Crazing after 168 days in dependence on weathering conditions and type of PC**

3.2.4 Changes in Gloss and Haze

Surface deterioration was reflected by gloss readings. As the roughness of the surface increased, more light scattering took place, reducing the gloss readings for the specimens. Haze, which measures the light scattered by the polymer, both internally and on the surface, increased almost linearly with exposure for all samples. All samples behaved similarly. Sample PC-1 best showed the influence of moisture (see Figure 9). It exemplifies the typical behaviour of all four samples, i.e. that changes in gloss and haze seemed to be independent of the moisture levels during the initial 50 days of exposure. Similarly to changes in colour or intensity of crazing, the samples that were exposed to dry conditions experienced a significantly slower change in gloss and haze than the humid or wet exposed ones with further weathering. In contrast to the phenomenon observed in yellowing and crazing, wet conditions resulted in stronger deterioration than humid conditions in terms of gloss and haze. Sample PC-4 which did not show any significant changes in yellowing and surface morphology due to moisture conditions during 168 days of exposure revealed its first ageing effects by small changes in gloss and haze at humid and dry conditions (see Figure 10).

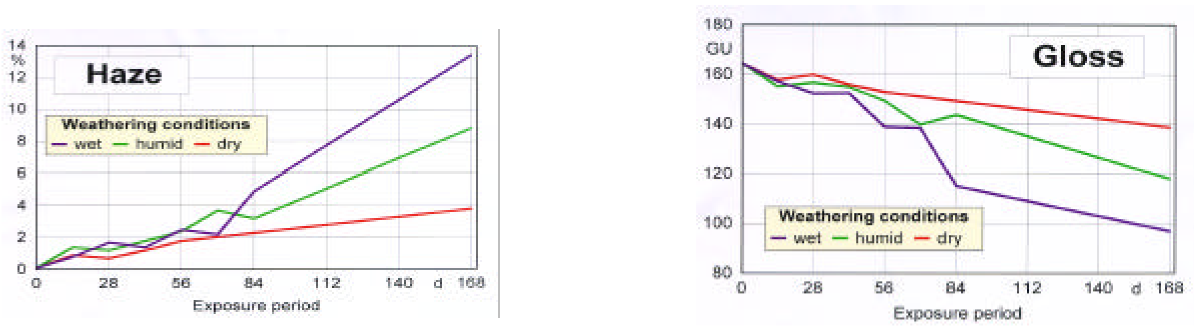

**Figure 9. Haze and gloss of PC-1 upon weathering depending on the weathering conditions**

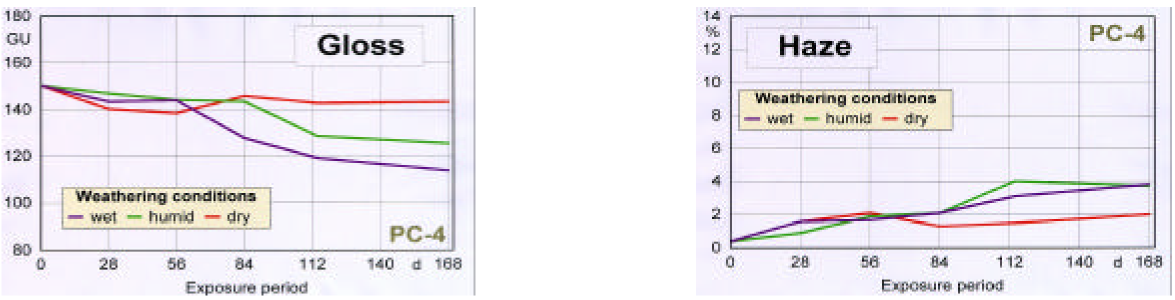

**Figure 10. Gloss and haze of PC-4 upon weathering depending on the weathering conditions**

3.2.5 Change in acid resistance

Acidic atmospheric precipitation like acid rain, dew and fog are products of the modern industrial society and an essential climatic factor that can accelerate the photodegradation of polymers. Roof materials used in highly industrialised or heavy traffic areas must also have sufficient resistance against the action of acidic precipitation. To assess the resistance of plastics glazing to acidic precipitation it is usual to test whether attacks by acidic deposition result in changes in appearance.

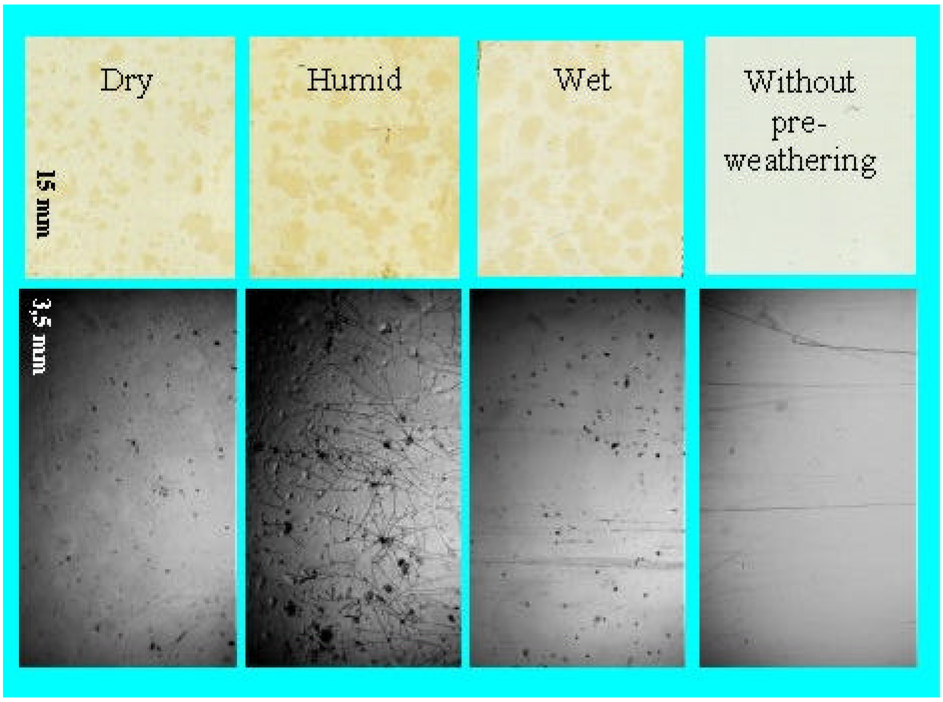

**Figure 11. Influence of the weathering conditions on the acid etch resistance of PC-4 (colour and surface image after 168 days of pre-weathering plus 5 ADF cycles in comparison to an un-weathered specimens after 5 ADF cycles)**

The Acid Dew and Fog test (ADF test in short) as described by Schulz (1999) was used to determine this material property. Because the specimens of sample PC-4 did not show any crazes or essential yellowing after 168 days of weathering under dry, humid as well as wet conditions yet, they were selected and subjected to the ADF test together with an un-weathered specimen. Figure 11 shows colour and surface images of these specimens after this test. In contrast to the unweathered specimen, the acid deposition (a solution of sulphuric, nitric and hydrochloric acid diluted to pH 1.5) which was sprayed on the specimen surface once a day caused varied strong yellowing on all of the three pre-weathered specimens and crazing on the humid weathered one, revealing that weathering had decreased the good initial acid etch resistance of polycarbonate differently with a strong and clear dependence on the weathering conditions. High relative humidity combined with high temperature proved clearly to represent the “worst case” scenario in this regard. According to this conclusion crazes could also be found on specimens of PC-4 that were exposed outdoors in Jacksonville, Florida. The Jacksonville harbour area is known to combine humid warm climate with frequent occurrence of acid rain and dew. On the other hand practical experiences with PC longlife proved that natural exposure at the temperate European climate characterised by lower absolute humidity and temperature did not generate any visible damage. Examples for the good durability are the more than ten years old roofs of the “BayArena” sporting stadium in Leverkusen and the main station in Krefeld, Germany. Long service life of PC-4 can also be expected under dry hot conditions.

### 3.3 Chemical changes

The deterioration experienced by the polycarbonate samples is the result of chemical changes due to photodegradation and physical processes. The photo-degradation reactions, Photo-Fries and photo-oxidation, are triggered whenever a sample is exposed to UV in air, and degradation is evidenced unless enough UV stabilisers are used in its formulation (Factor 1996, Rivaton 1995). These reactions result in chain scission and crosslinking, generate yellow species responsible for colour changes, form oxidised species (eg. alcohols, acids, esters, etc) (Factor et al 1987), alter molecular weight, etc. In summary they change the chemical and physical composition of the degraded layer. The extent of such photoreactions is limited by the depth of penetration of UV radiation into the polymer, which varies according to the source of radiation, material, exposure time, etc (Factor and Chu 1980).

Figure 12 compares the IR-spectra of PC-1 samples aged for 168 days under the different moisture conditions (Wet, Dry and Humid) with the control sample (without weathering). As highlighted in the hatched square the peaks in the carbonyl region

Go Back Next Page

(1600-1800 $cm^{-1}$) differed for each condition. At dry conditions the peak at 1775 $cm^{-1}$ decreased in intensity and a shoulder of new peaks from 1770 to 1600 $cm^{-1}$ was developed. This indicates the presence of -C=O from new photo-oxidised species, for example ketones, carboxylic acids, aromatic esters, which can absorb in that range. The other samples show a much smaller shoulder in that region, although the wet-weathered specimen had a larger shoulder than the humid-weathered one. This would suggest that the surface layer experienced more oxidation in the order Dry>Wet>Humid. Such observations confirm that moisture interferes with the photo-oxidation of polycarbonate.

### 3.4 The contribution of moisture to photodegradation of polycarbonate

Moisture aggravated the physical changes initiated by photodegradation. For example, the onset of crazing contributed markedly to the alteration of optical properties: It coincided with the rapid increase in haze, reduction of light transmission and gloss. Furthermore, moisture also interfered with the rate of the photodegradation reactions. The acceleration observed during yellowing suggests that moisture aided in the formation of yellow species. The exact mechanism is not yet known. There are two possibilities, moisture might favour the mobility of free radicals within the degraded layer and the transfer of products, or it could react with free radicals slowing down the photo-oxidation reaction. The results prove that the first possibility seems to be predominant. Additionally, moisture levels could also affect the rate of photo oxidation by limiting the diffusion of oxygen into the polymer. Another possibility is that stabilisers could have leached out of the polymer due to moisture. If loss of stabilisers took place then it would contribute to a lower resistance to oxidation in a wet environment compared to a humid one. In summery, the rate of degradation is a complex process that could be influenced by a number of factors, including loss of stabilisers, oxygen availability and mobility of free radicals in presence of moisture.

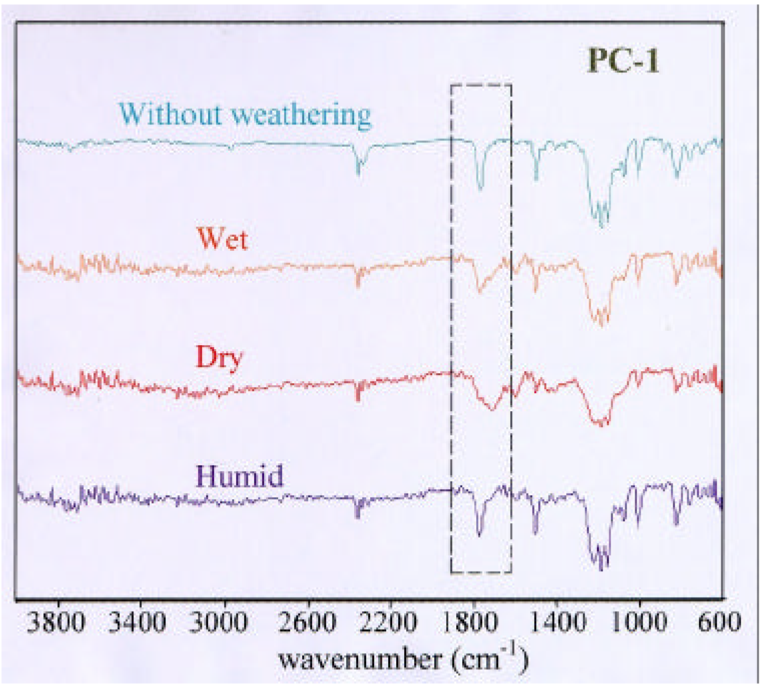

**Figure 12. Infrared spectra of PC-1 exposed to different moisture conditions (168 days)**

For example, as moisture condensates on the polymer surface, the area for diffusion of oxygen from air to the sample would decrease. This could explain why the samples which were covered by a layer of water during weathering (Wet) showed a slower degradation than those weathered at high humid conditions exposed constantly to a vapour phase containing about 20 % of oxygen.

## 4 CONCLUSIONS

The Photodegradation of plastics glazing currently used for transparent roofing made from PMMA, PC or combinations of both materials is accelerated by the presence of water during weathering. In the case of stretched PMMA plate material, the presence of liquid water during weathering or other conditions guarantying high water content in the polymer proved to be the “Worst Case” scenario of the weather conditions in practice. Chemical changes by hydrolysis promoted presumably by UV radiation seem to be more likely responsible for the decrease of mechanical fastness than the fatigue by the frequent changes in volume by wetting and drying as claimed in former publications (Lehmann 1997).

In the case of Polycarbonate humid-warm climatic conditions guarantying high contents of water and oxygen simultaneously in the surrounding vapour phase proved to be the “Worst Case” scenario. However the photo oxidation promoted by water in gaseous condition seemed to be the predominant reaction in comparison to hydrolysis, as to the exact mechanism by which water facilitates photo oxidation this will have to be investigated further.

# Corrosion Of Metals - Mapping Of The Environment In Iceland

**B Marteinsson J Sigurjónsson**
**The Icelandic Building Research Institute Keldnaholt Iceland**

**Summary**: **Iceland is an island in the middle of the Atlantic Ocean, at a latitude of 63 - 66 °N, and is in the main path of low pressure systems in this part of the world. The country is dominated by a mountainous central part (highest peak 2119 m) and glaciers, with lowlands mainly along the south and west coasts. The climate is therefore characterized by a wet and windy south-western part and a colder-dryer northern part. The corrosion environment ranges from a wet, chloride-rich area in south, to a dry and colder area in the north. In fact, the biggest desert in Europe, is in Iceland. In the windy environment, pollution is seldom a problem for people or materials. The corrosive environment is now being mapped by weathering of small test pieces at 15 different locations in Iceland; the test pieces are made of steel, zinc, aluminium, galvanized steel, and surfaces with different types of paint. The first-year results have been analysed, and show a spread in weathering for zinc between 1.4 - 3.9 mm and for steel between 1.5 - 36.1 mm . This paper discusses project design and presents first-year results of the study.**

**Keywords. Corrosion, metals, atmospheric corrosivity.**

## 1 INTRODUCTION

### 1.1 The country and climate

Iceland is an island in the North Atlantic Ocean. The middle is uninhabitable highlands, and the built environment, thus, mainly along the coast. The climate is marine-influenced and geographic location is in the route of frequent low pressure systems that move over the ocean. Accompanying the low pressure systems are prevailing wind directions of southwest to southeast and this, in combination with mountains and a few glaciers, results in wide climate variation within the country.

The climate is windy and moist, and precipitation is very common on the south coast. The highlands, especially north of the glaciers, is very dry, with the area north of the largest glacier, being the biggest desert in Europe. The energy use for heating and electricity is environmentally friendly, as it involves geothermal energy and electricity from hydro power stations.

Heavy industry is on a small scale (three factories so far are located near Reykjavik). The number of cars per capita in Iceland is very high and pollution from them is noticeable in the capital city, Reykjavik, on the few calm days each year. In periods of gentle southeasterly winds, polluted air from Europe comes to Iceland. However, the air is mostly clean, due to the windy climate and rather minimal local pollution. Information on air pollution in Iceland is limited and measurements are mainly done to assess the pollution from traffic in the capital.

### 1.2 The market

Almost all building materials, except cement and rock materials, have to be imported to Iceland, and this obviously applies especially to all metals. The annual import of metals for the building industry is approximately 310 kg/capita, and other annual imports (transport vehicles, etc) about 185 kg/capita. Of this annual import, approximately 370 kg/capita of metals end up in a corrosive environment of some kind. Metals are recycled to some extent or about 0.2 kg/capita.

In the building industry, metals are mainly used for reinforcing concrete, various types of claddings, for pipes, etc. Almost all roofs are covered with corrugated sheets of either steel or aluminium, and walls of older wooden houses are likewise commonly covered with corrugated steel. In the last years, cladding of concrete walls in new buildings has become more popular. Import of metal cladding materials each year amounts to about 700,000 $m^2$. Hydro power stations are placed at different locations around the country and it has proven effective to develop a wide-ranging network of high voltage lines to even-out electrical disturbance in the distribution net. The high voltage electrical cables and masts are in environments, which have very different corrosive characteristics. Some are quite near the sea, in constant salt spray, and others are in the highlands.

Iceland’s market is small and far away from other markets, so transport costs easily run high. In this context, and generally speaking, it is important to obtain the best longevity of materials as possible, e.g. by limiting corrosion of metals. Therefore, corrosion speed and corrosive agents must be evaluated. Mapping to show the background atmospheric corrosion rate is likewise essential to be able to follow changes over time, but also to be able to inform the market about how the conditions relate to other known parts of the world.

Corrosiveness of the environment can be estimated using two different methods: direct measurements, or evaluation of atmospheric agents in accordance with ISO 9223. This paper presents results from measurements of first-year corrosion and compares them to mapping of the climate.

## 2 CORROSION AND WEATHERING TEST PROGRAM

Samples sized 100 mm x 150 x 2 mm were mounted in fasteners of polymer materials on a backing panel of plywood, such that the distance from the backside of the sample to the plywood sheet is 17 mm with 15 mm between different sample materials. The samples are placed at 15 test locations, each rack with a mounting board of size 530x860 mm at a height of 3 - 4m above ground, oriented to face south at an angle of 45° in accordance with EN ISO 8565. The test pieces are of technically pure, low carbon steel (C=0.05%) , zinc-coated carbon steel, zinc (> 99,9% pure), aluminium (1050 A and AlMg3) and different types of painted steel samples. Plans are to demount samples for evaluation after 1, 3, 5 and 10 years. The measurements consist of recording the corrosion of the metals and evaluating the condition of paints. The project started in 1999, and therefore, results to date are limited to one year’s corrosion.

The test locations are shown on Figure 1, and numbering of them is listed in Table 1.

The results for corrosion rate of steel and zinc after one year are shown in Table 1.

3 distance to weather station > 100 km

## 3 THE CLIMATE AND CORROSIVE AGENTS IN ICELAND

The atmospheric corrosion of metals is discussed at length in the literature. The standard ISO 9223 specifies the key factors and Haagenrud (1997) gives a very good overview.

The climate factors used in the project are measured by the Icelandic Metrological Station at, or nearby, most of the test stations. Measurements of temperature, humidity, wind-speed and direction are logged automatically each 1 or 3 hours, and in some instances precipitation is also available. From the start, it was clear that some spot measurements of air pollution would be needed, but it was decided to wait for initial results on corrosion to see where to concentrate the main effort.

For the exposure locations, the climatic factors of importance in this context can be described as follows.

Temperature

The climate is temperate and at the corrosion locations, the yearly average temperature varies locally from 0.6 (location 15) to 6.4 °C (location 12). Temperature is seldom higher than 20 °C, or lower than -20°C.

Moisture

The weather is humid at the coast all around the island, but drier in deep fjords and some places in the highland. At the coast, the average monthly values vary slightly and the yearly average value of relative humidity (% RH) is the interval of 78 - 83 % RH and slightly higher in the highlands.

Time of wetness (TOW)

TOW according to the definition of ISO 9223 (T>0°C, RH>80%) is in the interval 1449 hrs. (location 10) to 6324 hrs. (location 13).

Rain

Climate in southwest is wet, but noticeably drier in the north. The yearly precipitation at the locations is from 860 mm (location 15 ) to 3375 mm (locations 12) .

Wind

The climate is windy all year round. The average yearly wind speed at the locations is measured in the range of 3 - 10 m/s, with one location at each extreme, but usually the value for average wind speed is 4.7 – 7.1 m/s The prevailing wind directions are southeasterly to southwesterly .

$SO_2$

$SO_2$ is considered one of the major corrosive agents of steel and zinc. Iceland has little $SO_2$ pollution, as almost all house heating is done either by geothermal energy, or electricity from hydro power stations. The island is very sparsely populated (2.7 $km^2$/inhabitant), and the average wind speed is high. Thus, problems concerning air pollution are uncommon and only limited measurements are made of these agents. $SO_2$ is only measured regularly in Reykjavik, and the yearly mean, near a heavily travelled road was measured in 1991 as 3.2 $\mu g/m^3$. In general, the measured value in Reykjavik can probably be considered as a maximum value for Iceland, if one excludes local climate near two aluminium factories. Exposure location 16 is located near a geothermal power station, with a known high concentration of corrosive agents ($SO_2$) in the steam.

Salinity

It is known that salinity greatly affects the speed of corrosion, and even in highly populated areas this effect can be more than that from $SO_2$, especially as the content of $SO_2$ is decreasing in many places, as discussed by Haagenrud (1997) and reported in '*Hot Dip Galvanizing*' (2001). The chloride deposited is only measured regularly at two places in Iceland: in the capital Reykjavik, and at Irafoss which is inland from the south coast.

Salinity $Cl^-$ (mg/m2,d)

| | yearly mean | highest monthly mean |
|---|---|---|
| Reykjavik (1985) | 19.8 | 53.0 |
| Irafoss (1985) | 10.0 | 15.2 |

It is known that salinity concentration is highest at the southwest parts of the country and lowest in the northeast parts (south to southwesterly winds prevail in Iceland). Salinity is carried by wind over great distances and in southern storms, saline deposit is observed on structures on the north coast, despite highlands in the middle of the country that, depending on direction of wind from coast to coast, have an average height of 400 - 600 m . Concentration of salinity in air due to wind must depend on many factors, including topography, wind speed and direction, as well as distance from location to sea in line with the wind direction. A study of salinity, which takes into account how salinity transfers from sea to air, and the effect of this on the corrosiveness of the climate, was reported by Cole *et al*. (1999) and wind speed was found to be a very important variable.

## 4 CORROSIVITY CLASSES ISO 9223: 1992

The standard, ISO 9223, classifies the atmosphere according to direct measurement of corrosion rates on one hand, and on the other, the value of climatic parameters (time of wetness, sulfur dioxide and airborne salinity).

Based on measured corrosivity, the corrosion class for steel in Iceland is in the range 2 - 3 and for zinc, 3 - 4. Classification based on information about the climate gives the corrosivity class for both steel and zinc as ranging from 3 to 4 (or even 5). The two methods thus, do not give exactly the same result, as steel corrodes slightly slower than expected from the climatic classification.

## 5 DOSE RESPONSE FUNCTIONS FOR CORROSION SPEED IN ICELAND

The models of the effect of different climatic factors on the corrosion of metals, or dose response functions, easily become complicated, and it is probably most economic to simply measure the effect by mapping corrosivity in the area in question. Scientifically, however, the models are of great interest as an aid in understanding effect of climate on materials and as damage functions.

In the literature, Haagenrud (1997) showed an overview of dose response functions. These functions are based on a different number of climatic variables and the composition of them is somewhat different, and so is even the number of variables. In most of the functions, (in fact all, except one) the $SO_2$ plays a major role, though humidity, time of wetness (TOW), sulphur (S) and clorides (Cl-) are also used as variables. The correlation coefficient (multiple linear correlation) found for the different models varies between 0.67 and 0.94.

When the dose response functions were tested on the data from our project, with different values for the unknown factors (S , $SO_2$, H+, Cl- etc.) based on an intelligent guess, it was apparent that the functions are poor estimators for corrosion speed in Iceland. The reason for this is probably that the $SO_2$ content is usually low, and thus, not a main factor in the corrosion. On the other hand, salinity is high at times. The measured corrosion rate of steel is much higher at the seashore, than at locations inland, but the corrosion of zinc is not as dependant on location. For the first years results therefore only the corrosion of steel will be modeled in dose response funtions.

For corrosion of steel, the airborne salinity and moisture, or time of wetness, are probably the main factors. Salinity comes from the sea, and most of the test sites are at the seashore. Lacking measurements of salinity, these can probably be estimated by the wind speed and distance from the shore. In the multiple regression models, the effect of salinity is therefore estimated by two methods;

– the average wind speed in directions from the sea divided by distance from shore

– the average wind speed from sea, multiplied by the fraction of time these wind directions prevail.

Different multiple regression models were tested on the data, but the two shown gave best results:

Model 1 : Corr (μm/first yr) = $23.031\,(w_{sa}/L)^{0.2627}\,(TOW)^{0.4704}$

Model 2 : Corr (μm/first yr) = $10.055 + 3.942\,(TOW) + 4.539\,(TOW)(w_{sa}/L)$

where $w_{sa}$ average wind speed (m/s) from direction of sea

L distance from shore (km)

TOW time of wetness in accordance with ISO 9223

(T>0°C, RH>80%), as a fraction of total time

| | Standard error of estimate | Correlation coefficient R |
|---|---|---|
| Model 1 | 6.02 | 0.829 |
| Model 2 | 6.28 | 0.812 |

Model 1 has certain similarities with the model shown by Cole *et al.* (1999), model 2, on the other hand, is of the more traditional type used by many, as revised by Haagenrud (1997). It is interesting to note that two so different models show similar quality of fit to the data, more datapoints (higher number of test locations) would be of of help to decide the appropriate damage function.

Taking the frequency of wind directions from sea into account did not improve the models, on the contrary, the fit became considerably worse. The calculated corrosion rate, in accordance with model 1, is compared with the measured rate in Figure 2. As can be seen from the figure and the values for standard error and the regression coefficient, the regression model fits the measured results quite well. Both models improved considerably, if location 14 was excluded, but this is considered to depend on local reasons as explained next page and not that the point is an outlier of some kind.

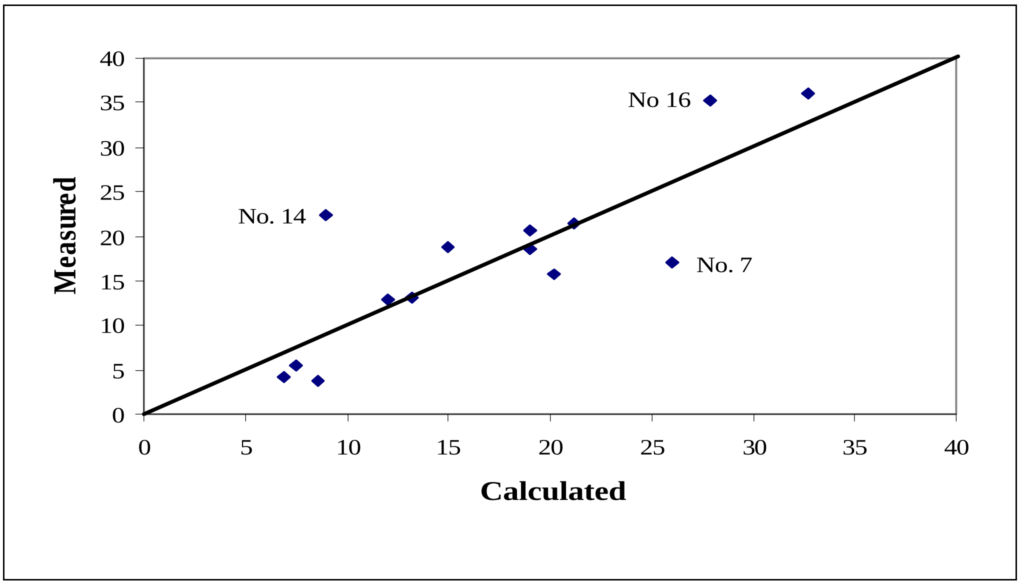

**Figure 2. Corrosion of weathering steel (μm/first yr.)-Model 1**
comparison between calculated and measured values

## 6 DISCUSSION

Even these initial, first-year results give information about the atmospheric corrosion in Iceland which makes comparison with other countries much easier. The corrosivity of the atmosphere is in classes 2 - 4 (ISO 9223). Dose response functions in the literature do not seem to be appropriate for Icelandic conditions, which shows the impact of corrosive agents in different countries can be very different. Airborne salinity seems to be a very important factor in corrosion of steel in Iceland. The measured corrosivity shows great variability and it is evident that this can be explained in different ways. The atmospheric conditions vary greatly between the test locations and the measured samples are few. For instance, results are not sufficiently evenly spread to positively determine if the two highest returns are part of the distribution, or are exceptions (outliers). However, these two points are not the results showing the greatest errors in the regression models, and can probably anyway be explained by differences in climate.

The regression models show a poor fit for the thre points no. 7, 14 and 16. For exposure site no. 7 the calculated value is higher than the measured value. The location is unsheltered on the north-east coast and the model probably overestimates the effect of wind from the sea. The exposure site no. 14 is on the other hand about 50 km inland and the calculated corrosion is lower than the actual one. The surface of the area from shore to the site is very even and without any hills, the model underestimates the effect of wind from sea in this topography and at this distance. Number 16 is underestimated in the calculations. The exposure site is located near a geothermal power station, where it is known that the steam is very corrosive. How and whether this affects the testing site also, is not clear at the moment.

The two sides of the sample are not entirely in the same situation, one being more sheltered than the other. The corrosion is measured as weight loss of the sample, and then calculated as weight loss (or reduced thickness) on unit area, based on the size of the sample and taking into account both sides. But, it is not certain the samples corrode evenly on both sides, at all locations (closed tube specimens are a better solution). The effect of rain washing the samples clean, or of salinity deposited only on the outward (upper) side of the sample, must have different effect on the corrosion, depending on frequency of rainy days, etc. On the whole, the timing effect for different series of agents (time series), at different locations, can play a major role in the corrosivity of the atmosphere.

## 7 CONCLUSIONS

Corrosion of metals, especially steel, in Iceland varies videly for different locations, with the main corrosive factor seemingly being airborne salinity. The corrosion rate has only been measured over one year, but the project will continue for a total of ten years. The content of salinity will be measured at some places, to obtain knowledge about what values to expect, and concentration of $SO_2$ will be measured at location 16 and one other for comparison. These measurements will probably be made periodically, and over limited time. Further data processing of the effect of climate on corrosivity of metals in Iceland will continue when the results after three year's weathering have been gathered. In the continuation of the project, the question of different corrosion on the two sides of the sample will be examined. The time series for climatic factors of different locations will also be studied.

The first samples for assessment of painted surfaces will be demounted at the 3-year timepoint but some of the samples already show some faults, assumed to be mainly due to sandstorms.

## 8 ACKNOWLEDGEMENT

The project is conducted in cooperation between The Icelandic Building Research Institute, Pétur Stefánsson - Almenna Verkfræðistofan and Pétur Sigurðsson - Vekfræðiþjónusta, and with financial support from the following Icelandic entities: The Icelandic Research Council, Housing Financing Fund, Avalanche Fund, National Power Company, Public Road Administration, Westfjord Power Company and a number of smaller private companies. The authors wish to thank all parties for their help in making the project possible.

# Extending Service Life Of Buildings And Building Components Through Re-Use

**PA Erkelens**
**Building and Architecture Technische Universiteit Eindhoven Netherlands**

**Summary: From an environmental point of view, the extension of the service life of a building is only useful under the condition that the environmental load generated by the maintenance and renovation activities, and the use during the remaining lifetime of resources like water and energy, is less than the load generated by demolition, sustainable new construction and use.**

**Resource conservation in this context means a very important minimisation of the use of resources, making use of renewable resources and of the ideas of biotecture for example. The combination with the re-use of buildings parts, components and materials (bcm's) is important in this respect. These themes are further elaborated in this paper.**

**LCA-based assessment methods have to show the optimum selection of design approaches.**

**The paper concludes that there still are significant problems to be overcome when applying these assessment methods, as a result of a lack of technical data and missing links in the methods themselves.**

**Keywords: Renovation, re-use, sustainability, waste reduction**

## 1 INTRODUCTION

Building and construction is one of the engines of the economy, considering their contribution to the Gross Domestic Product, Gross Fixed Capital Formation, and employment. The general expectation is that there will be economic growth in the future too. Due to the strong relation between building activities and economic development, there is an increased need for more and bigger housing, and utility buildings (Erkelens, 1991, p. 25).

As building has a significant impact on the environment it is justified to look at means to reduce this impact and to seek for sustainability. The second-best option, after not building at all, is to introduce the concept of extreme sustainability within building, which is far beyond the current building practice.

A building is in fact a structure that protects the users against all sorts of external influences and provides a comfortable space for all human activities. Like man, a building has a life period, which starts during the construction, continues during its use, its maintenance phase(s) and rehabilitation phase(s) and ends with its demolition. For all these phases (except the latter one) resources are needed.

A utopian approach for sustainable building would be to develop building products and buildings that do not produce waste, cost energy, require transport etc. and are cheap. Although this will not be elaborated on further, the idea is very interesting.

Resource conservation means that in the whole life span of the building, the use of resources (building materials, energy, etc.) should be such that the environmental impact is as low as possible and / or, better still, zero. Ideally, the combination of resources should have zero impact on the environment or even improve that environment, including its best quality and health. So far this is not yet feasible. A more realistic approach can be sketched as follows:

- Minimisation of the use of resources, and where necessary
- Use of renewable resources applying the ideas of biotecture, as well as
- The extension of service life through re-use and recycling (at all levels from whole buildings down to materials).

Environmental impact assessments are needed to check for the best combination of options, as it is not always the solution with the minimum use of resources that results in the minimum environmental impact. The following sections elaborate on these themes in more detail and discuss the constraints to be faced.

## 2 MINIMISATION OF THE USE OF RESOURCES

Minimisation of the use of resources also implies minimisation of the use of so-called endless resources because they too need energy for transport, exploration, exploitation and manufacturing.

This minimisation can primarily be achieved through reduction of the demand in various ways.

In essence, the reduction (of the amount) of building and construction waste causes reduced demand. The Dutch Foundation for Building Research (SBR 1998, pp. 5,6) reports a reduction of 41% in waste production in a housing project through good management.

Moreover, through the design of compact buildings, the amount of resources (i.e. building materials) can be minimised. This may not be the optimum solution given the local circumstances. Another approach is dematerialization. This means the reduction of quantities of materials needed to serve economic functions. To achieve sustainability von Weiszäcker *et al.* (1997) suggests that the materials input per service unit must be reduced by a factor of 10! This is an interesting thought for building too, but it requires extensive research. A parallel approach may be the development of smart building technology: fewer materials with better performance.

## 3 USE OF RENEWABLE RESOURCES, BIOTECTURE

It is often said that use should be made of renewable resources like wood, flax, hemp for building materials, components and services (like water and forms of energy). These resources have a short regeneration time: the resources can be grown and harvested. However, they have a limited capacity for renewal and can thus be subject to overexploitation. So, there is also a need to cascade these renewable resources. Cascading means the sequential exploitation of the remaining full potential of a resource during its use.

As renewable resources are not always environmentally friendly (e.g. the need for fertilizer to make materials grow), LCA's need to be made for them as well. At times this may lead to the conclusion that another (non-renewable) resource is a better option.

Another suggestion is to utilize grown structures and living plants, and space enclosed by trees. This so-called biotecture (Fraanje, C3-4.2) can be applied in the design of buildings. This has important resource-saving potentials and can contribute to a more natural regulation of the internal condition.

## 4 EXTENSION OF SERVICE LIFE

The extension of the service life of buildings and building components, products and materials is the third approach to be reviewed here.

### 4.1 Building

The ability to extend the service life of a building or parts of it depends on different factors.

Schulte (1997, p. 37) distinguishes three groups of aspects that are decisive for any decision on the future of an existing building:

1. Societal aspects: socio-economic, historical, juridical, financial and ideal aspects;
2. Urban aspects: historical, morphological, spatial / functional and use aspects
3. Building technological aspects: infrastructural, structural, manufacturing and building physical aspects.

An important question is whether society allows for the extension of service life: is it still the "fashion" to have such a building. Does it fit into the contemporary vision / policy.

Another point can be that the building, although old, contributes significantly to the 'value' of a location; an artistic value making it worth extending its service life, or a building with a historical value.

More complicated is a building that functions according to the original set-up, but does not fit into the functional / technical comfort requirements as formulated in the contemporary building regulations.

In this case it depends on the remaining qualities of the building whether the service life of either the building as a whole will be extended or only parts thereof, or whether the service life of just the structural framework of the building will be extended while the rest is being replaced or renovated, see 'Fig. 1'.

**Fig. 1 A fully stripped building for re-use**

### 4.2 Building parts, components and materials (bcm's)

The service life of building parts (façade, roof, etc.) components (windows, panels) and materials (glass, timber, tiles) also depend on the above mentioned aspects. Through renovation and rehabilitation activities bcm's will be sometimes replaced, repaired or left untouched, removed or demolished, partly or as a whole.

The service life of bcm's can also be extended through reuse in another project (e.g. the Carrousel experiment in The Hague whereby cleaned and repaired bcm's are stored for future reuse in renovation projects with a limited remaining life span), although this is more complex. The option of another location seldom is used for the main structure of a building.

From the point of view of the optimum use of resources, the best option would be if the service life of bcm's could be extended in this same building. In addition, we can consider recycling, although this option has a minor preference. Ultimately, discarding should be prevented.

### 4.3 Design requirements

Whether the service life of a building, a building part, a component or a material can be extended, also depends on the following:

1. The design proposals through which different quantities of bcm's have to be removed.
2. The initial design phase in which the future reuse of bcm's is already taken into account.
3. The quality of the bcm's that indicates whether they are reusable in this (or another) project. (This depends on the quality of the used materials, details, craftsmanship, maintenance, way of use and the method of demolition or demounting).

### 4.4 Environmental requirements

The consequences of the various options for the extension of service life have to be checked with the LCA programs, which take into account the use of materials resources, energy, waste and emissions. This results in an ordering of the design proposals along increasing total environmental impact. Usually, in daily practice, the economic costs of the proposals are decisive for the final selection. The initial costs in particular are focused on. A form of subsidy could stimulate a more environmentally friendly choice.

## 5 RESEARCH

Apart from saving resources by reusing a building, it is very useful during renovation to look into the reduction of the waste production. If renovation projects could be developed with a minimum waste output, this could contribute significantly to sustainable construction (Erkelens, 2000, C3-2.7). This involves anticipative thinking about the intended demolition: Can it be kept to a minimum, can the materials and components be taken off without damage and can they be re-used in the same project preferably for the same purpose? Or, if that is not the case, can they be re-used in other projects?

For new construction this means anticipating future re-use, through the application of other than (e.g. gluing) jointing techniques, design for deconstruction, and the use of (industrial) flexible and demountable components. Furthermore, the development of special demolition methods is of importance. As a start, the Technische Universiteit Eindhoven has developed a model to investigate the flows of all the building parts, components and materials (bcm's) in a renovation project, see 'Fig. 2'.

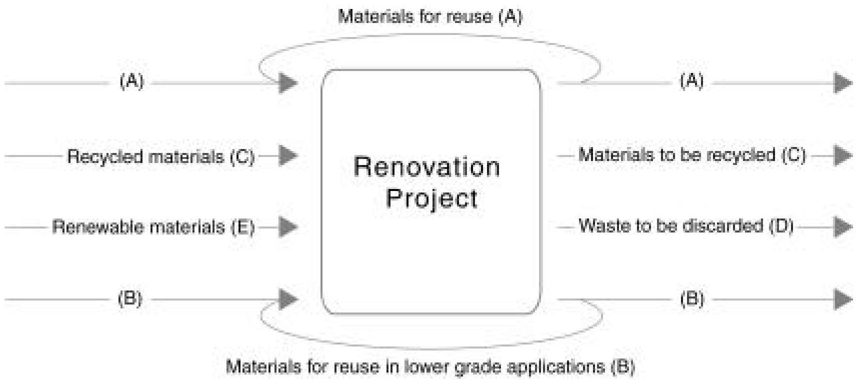

**Fig. 2. Minimum waste research model**

The model shows bcm's on the output side. Those of flow (A) are re-used for the same application after some repairs. Those of (B) can be re-used for lower grade applications. Those of (C) can be recycled and those of (D) can be discarded as waste. On the input side we see bcm's of the type of flows (A) and (B), and flow (C) consisting of recycled bcm's and flow (E) with new but renewable bcm's.

While researching a building project one first needs to establish the 'remaining' potentials of the existing bcm's in terms of quantity, quality, remaining life span, ease of dismounting etc. Furthermore, the potential reuse has to be sorted out and its level determined (primary reuse, secondary reuse, recycling or discarding).

The various options for part renovations will have different environmental impacts. The variation can be in floor plans, materials (re-)use etc. The various designs for a total renovation plan gives an order of increasing environmental impact. This guides us to find the best design proposal with a reduced environmental impact. Alternatively we can tune a preferred design in such a way that the impact is reduced.

## 6 CASE STUDY

A complex of 248 houses in the suburb Lievendaal of Eindhoven (the Netherlands), was used as a case study. These houses were built in 1949 and partly renovated in 1977. The coming renovation is planned for 2002. The total estimated lifetime is up to 2026. Kevin de Rond and Dieter van Riel (MSc. thesists) made a number of calculations based on three scenarios: (1) A continued use without changes, maintenance only; (2) a renovation in 2002; and (3) demolition and new construction in 2002 lasting up to 2026. The following 'Table 1' indicates the changes in the building parts over time. Some parts can be used continuously while some others have to be replaced.

**Table 1. Lifetime of various building parts**

<table>
<tr><th>1949</th><th>1977</th><th>2001</th><th>2026</th></tr>
<tr><td colspan="3">Foundation, facades, floors, wall plates, purlins</td><td></td></tr>
<tr><td>Windows and -frames<br>Internal door/frames<br>Ceiling plates</td><td colspan="2">Windows and -frames<br>Internal door/frames<br>Ceiling plates</td><td></td></tr>
<tr><td colspan="2">Roofing-plates, tiles, rafters<br>External finishing of dormer window<br>Roof gutters, rain-water pipes</td><td>Roofing plates, tiles, rafters<br>External finishing of dormer window<br>Roof gutters, rain-water pipes</td><td></td></tr>
<tr><td>Internal walls<br>Shower, toilet, kitchen,<br>wall tiles<br>Mains, installations</td><td>Internal walls<br>Shower, toilet, kitchen,<br>wall tiles<br>Mains, installations</td><td>Internal walls<br>Shower, toilet, kitchen,<br>wall tiles<br>Mains, installations</td><td></td></tr>
</table>

Based on detailed LCA calculations with Simapro and Ecoquantum, estimates were made of the total impact for the scenarios. Both Simapro and Ecoquantum are dutch LCA computer programs which are interrelated. As these LCA calculations are not yet totally optimised, the students had to sometimes estimate the input. Calculations were made for energy, waste, emissions and use of resources.

Go Back

On the condition that the maintenance scenario is set to 100, the environmental impact scores of the scenarios are as follows: 157 negative points for scenario 2 and 274 negative points for scenario 3. The main relative environmental impacts in scenario 2 compared to scenario 1 are the roof and the installations.

The follow-up of the project will consist of an improved renovation design for scenario 2, which reduces the score by 26 points, compared to the original renovation in scenario 2. This research project is on-going and during the conference in Brisbane some more of the results will be presented.

## 7 MISSING LINKS / CONCLUSIONS

The case study showed a number of specific problems that a worth reporting.

The reality shows specific problems because of missing or incomplete as-built information and a lack of proper calculation tools.

### 7.1 Environmental gaps

Calculation programs are not yet completely satisfactory. For proper information one depends on the industries for building materials and components**.** For example, it is difficult to obtain calculations for old constructions and materials. Furthermore, it is difficult to establish which life span has to be applied when making comparisons for existing buildings, reused components or new materials. Besides that, it has proved problematic for LCA's to add up environmental aspects such as energy, waste, raw materials and emissions.

### 7.2 Technical gaps

Up until now designers have lacked complete insight into options for design variations. It makes a great difference if, for example, a wall is placed in a plan or moved just 10 cm more to one side.

Moreover, there are no simple and clean methods for demolishing or demounting. This would make options for reuse in the same project much more easy to come by.

### 7.3 Economic gaps

Naturally, economics are seldom good for the environment as a number of hidden costs are not calculated or taken into account. Through incentives like subsidies for reuse, levies for discarding and a premium for the return of good bcm's, the most economic solution may be different from the traditional ones.

# Failure Mode Effect And Criticality Analysis For Risk Analysis (Design) And Maintenance Planning (Exploitation)

**J Lair & JL Chevalier**
**CSTB – Sustainable Development Department – Environment Durability France**

**Summary: The ISO 15686 (ISO, 1998) set of standards "Service life planning" is developing an integrated design framework for buildings and constructed assets, incorporating technical, economic and environmental aspects.**

**In this context, CSTB has developed a "risk analysis" and "maintenance planning" tool, based on the use of the Failure Modes and Effects Analysis (FMEA). It includes:**

**first, a structural analysis which allows us to identify morphology, topology and physico-chemical constitution of the product and its components,**

**second, a functional analysis leading to the identification of the various functions ensured by the product and its elements, as well as a description of its environment,**

**These first two steps lead to the behaviour modelling of the product.**

**finally, an FMEA in order to identify failure modes (exhaustive search for the behaviours, degradations and failures of elements), their causes and effects, taking into account the potential problems and errors which could occur during the process.**

**This step leads to the identification of degradation and failure. We thus can build the failure modes (or failure scenarios).**

**The methodology proposed simplifies each step of the approach, and provides us with a graphical representation of the product behaviour.**

**Keywords. Durability, FMEA, failure modes, risk analysis, maintenance**

## 1 INTRODUCTION

### 1.1 Context

Non-quality or poor quality problems in the building domain (representing 10% of the French building turnover, i.e. 6.5 to 7.5 billion Euros according to Le Brigand (1998)), the part of maintenance and operating stages in the cost of a building (60 to 70% of the overall cost (Perret 1995)), as well as the new aim "Sustainable Development[1]" (natural resources preservation, energy saving, etc), led us to work out methods and tools for durability assessment.

[1] "A development which answers the needs of the present generation without compromising the ability of future generations to answer theirs" (Charlot-Valdieu and al 1999).

### 1.2 Objective

In this paper, we present the durability assessment methodology (with reference to (Lair 1999)), and then propose additional developments and applications to the sketched methodology.

In particular, we include the tool in the quality approach, during the design stage (risk analysis – help for design), as well as for the management of existing buildings (maintenance planning – diagnosis / maintenance / repair procedures).

## 2 METHODOLOGY

### 2.1 General

FMEA has been used since the sixties in the aeronautics and car industry and is thus an efficient tool for the safety and risk analysis of these systems (Leroy 1992). It is intended to check the ability of a system and its parts to meet user's needs and either is generally used during the design stage in order to target and examine weak points, before mass production (Modarres 1993). It allows us to identify the potential future behaviours (success or failure) of construction products.

It leads to an exhaustive list of all failure modes, i.e. all problems that might occur:

- at each stage in the construction process (design, manufacturing, installation, transportation, storage, etc),
- in service (influence on the product's performance, degradation or failure of one of the product's constituent materials/components constitutive material/element).

In the following paragraphs, each step in the methodology will be presented and illustrated with basic examples.

### 2.2 Structural analysis

#### 2.2.1 Principle (Figure 1)

The principle of this study is to built an accurate description of the product:

- by dividing it into elements,
- and by identifying the constituent materials.

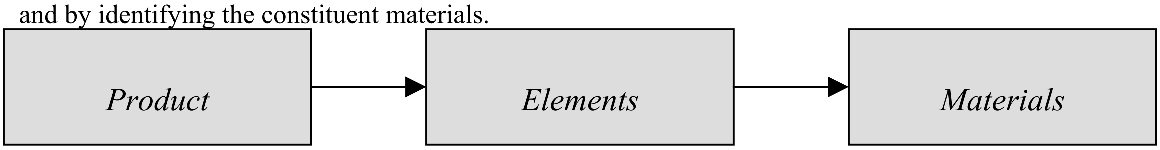

**Figure 1: Structural analysis**

This first analysis allows us to describe the structure of the product being studied. The following are identified (Baloche and al. 1999):

- morphology (geometrical shape, dimensions, etc),
- topology of relations with other objects,
- physico-chemical composition of its constituent elements and their own description.

#### 2.2.2 Example: Roofing system

The following graph is a representation of a flat roof system (left part of Figure 2), and its corresponding structural diagram (right part of Figure 2).

Outdoor and indoor environments have to be defined. They are composed of all potential climatic and use factors that correspond to the environment in which the product will be in service (Figure 3).

Go Back Next Page

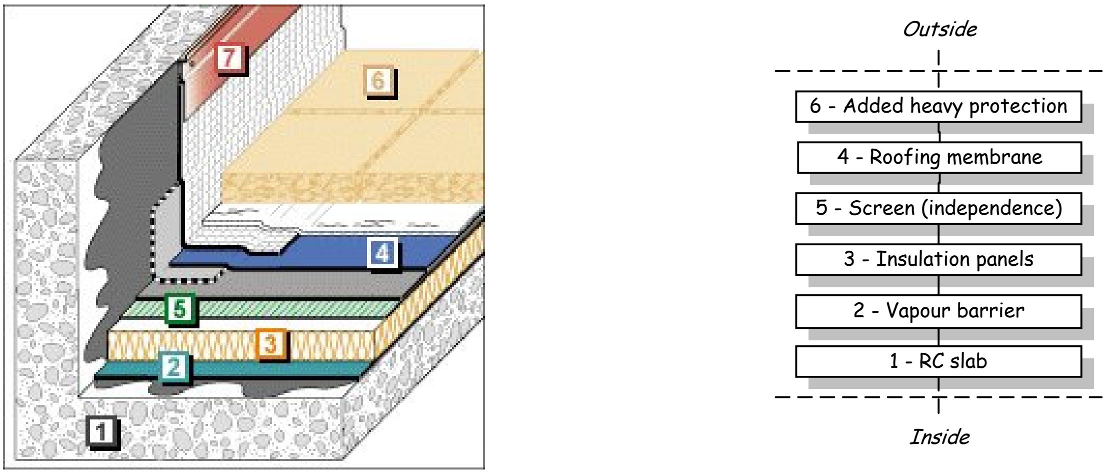

**Figure 2: Section of a flat roof system and structural representation**

| Outdoor | 2.3 Indoor |
|---|---|
| Temperature (high or low) | Temperature |
| Rain, snow, hail, ice | Vapour |
| Sun | Indoor pollutants |
| Wind | |
| Pollutants, weed-killer | |
| Vegetation, moss, lichen, etc | |
| Shocks and loads (persons) | |

**Figure 3: Climatic and use factors**

A list of common climatic factors is defined in order to help the user (generic factors). Some specific factors have to be defined according to the use (chemical products in some industries, etc).

## 2.4 Functional analysis

### 2.4.1 Principle

A product meets users' needs. The functional analysis of the needs expresses the needs in terms of functions.

We also have to identify the functions of each element (i.e. the role of each element in the overall behaviour of the product).

### 2.4.2 Example

As an example, a flat roof system should ensure two major functions:

- thermal insulation (against temperature gradient),
- watertightness (role of roofing membrane against rain, snow and hail).

In addition to these functions (user's needs), we have to consider the function of each element:

- the independence screen (element number 5) of a roofing system limits the strains in the roofing membrane, due to the movements of insulation panels (especially thermal dilatation),
- resistance of all elements to the environment (temperature, sun, rain, etc).

## 2.5 Behaviour analysis

### 2.5.1 Modelling principle

A product is defined as an order of elements and materials that ensure a set of functions.

In the building domain, “The product fulfils a function” could be expressed as “The building product transforms climatic factors (between input and output)”. It acts as a filter between two environments, filtering heat flows between outdoor and indoor environments (thermal insulation), stopping water from outdoor (watertightness of a roofing system), etc.

But, the same climatic factors can have an impact on its constituent elements and could involve: modification of the materials properties, degradation and even failure, etc

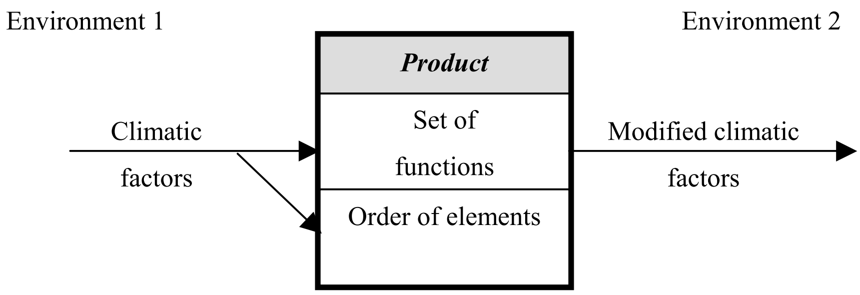

**Figure 4: Product representation**

We can express the behaviour of elements on the same diagram, showing on the one hand that they fulfil a function, on the other hand that they are likely to be modified and degraded by climatic and use factors.

### 2.5.2 Behavioural graph

In this context, once we have identified the structure and the functions of the product, the next step consists in modelling its behaviour.

The approach adopted is opposite to the structural analysis: from the behaviour of the materials, we deduce the behaviour of the elements and then the behaviour of the product itself (Figure 5).

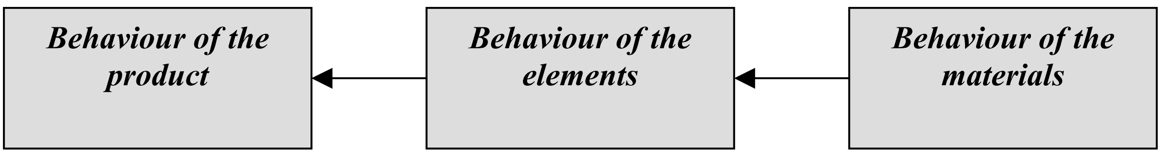

**Figure 5: Behaviour analysis**

For that purpose, a behavioural graph is plotted. The product is composed of n elements, placed “in series” or “in parallel”.

- each block being an element,
- and each link being a relation between blocks (physical contact, flow transfer, etc).

Figure 6 is an example of a very simple graph (only series relations). It ensures a barrier role between outdoor and indoor environment, as a composite wall:

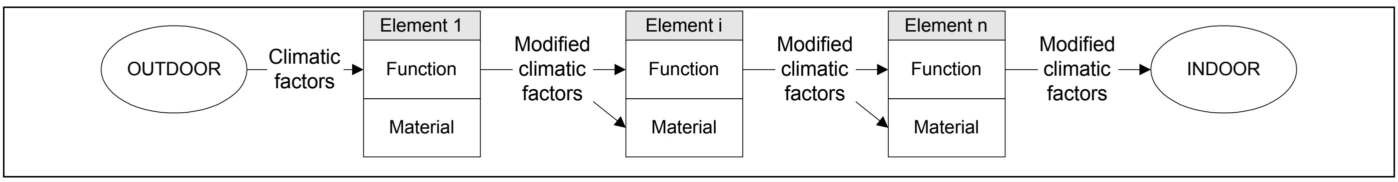

**Figure 6: Product behaviour**

### 2.5.3 Special cases

In order to have an accurate representation of the product, additional information is required:

- cavity (as the cavity between the internal and external glass of a double glazing unit or the cavity in a pipe),
- interface, either simple contact (added heavy protection on roofing membrane) or fixed interface (as the interface between seal and glazing).

They are both represented as elements:

- in the first case to take into account thermal and acoustic characteristics, as well as flows (air, water, etc) and deposit (condensation, dust, etc),

- in the second case, mainly to take into account problems of compatibility/incompatibility of materials, gluing properties, watertightness and airtightness.

### 2.5.4 Nominal behaviour (t = 0)

From this graph, we can deduce the nominal behaviour of the product, i.e. we know the response of a product (and its element) to a given set of climatic and use factors.

At t = 0 (without any degradation and considering that the product was correctly installed/implemented), we can identify the initial state of stresses. It is summarised in the following table:

- outdoor factors go from the top to the bottom,
- indoor factors go from the bottom to the top.

| | OUTDOOR / INDOOR | High or low Temp. | Rain | Snow | Hail | Ice | Sun (UV) | Wind | Pollut., weed- | Vegetation (roots) | Moss, lichen, … | Shocks | Loads | Temperature | Vapour | Indoor pollutants |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| 6 | **Added protection** | x | x | x | x | x | x | x | x | x | x | x | x | | | |
| 4 | **Roofing membrane** | x | x | x | x | x | | | x | x | x | | x | | | |
| 5 | **Independ. screen** | x | | | | | | | | | | | x | | | |
| 3 | **Insulation panels** | x | | | | | | | | | | | x | x | | |
| 2 | **Vapour barrier** | | | | | | | | | | | | x | x | x | x |
| 1 | **RC slab** | | | | | | | | | | | | x | x | x | x |

**Figure 7: Environmental stresses – Initial conditions**

We thus have information on:

- the various flows in the product (e.g. thermal flow),
- the key elements (protecting elements: role of heavy added protection for roofing membrane against UV, shocks, etc),

## 2.6 Degradation and failure analysis – Failure modes (t > 0)

Given the "nominal" functioning of the product, we start working on degradation and failure study. We study the behaviour of the product if the behaviour of a material or element deviates from its normal behaviour.

The principle is an iterative study.

Step 1: Degradation of elements due to climatic or use factors

We first analyse the influence of initial environmental stresses on each element.

For instance, we have to study the behaviour of the roofing membrane towards high and low temperatures, water (rain, snow, hail, etc), ice, various pollutants, vegetation (including moss, lichens, etc) and shocks.

The methodology used allows us to take into account not only these "single" factors but also the combination of these factors:

- combined factors from the same environment, either concomitant factors (water and low temperature from outdoor environment → freezing/thawing cycles) or successive factors (sun and high temperature followed by rain → thermal shock),

- combined factors from different environments (high temperature from outdoor and low temperature from indoor → temperature gradient in the element).

Knowing the element (and its constituent material) as well as the potential stress factors, we identify the potential behaviours:

- wind can result aggregates being blown away (from heavy added protection),
- water on roofing membrane can cause the removal of solvents,
- high temperatures can involve thermal ageing (hardening),
- low temperatures can involve embrittling, and make tear easier under load stresses.

Step 2: Structural or environmental modifications (degradation or failure identification)

The behaviour or the degradation of the first step leads to the modification of the environment or the structure.
As examples to degradation and failure, the following was observed:

- under temperature stress, the roofing membrane gets old. This ageing causes hardening. Although roofing membrane is degraded, it still fulfils its main function: watertightness, moreover it will not be able to withstand mechanical stresses as well as initially.
- if the heavy added protection has blown away from some parts of the roofing system (failure of the "protection of the roofing membrane" function), this roofing membrane is no more protected against UV and temperature. This comes down to a new cross in Figure 7 (column Sun(UV), line Roofing membrane). The initial state is updated and becomes a "State 2" condition for which we have to study the effect of UV on roofing membrane.

Step 3: Degradation of elements due to updated climatic or use factors

Given the modification of structural or environmental conditions (step 2), we now study again the behaviour under new environmental conditions (action of environmental factors on elements due to structural modifications, mainly loss of protection):

- photochemical ageing of roofing membrane due to the UV stresses,

Again we identify the modification of both structure and environment (step 2), then step 3, and so on…

For instance, once the heavy added protection has failed since it was not thick enough to protect the roofing membrane, the latter is stressed by UV and temperature (step 2). It will fail by cracking or tear, and then will not fulfil its "watertightness" function any more. Rain, pollutants, … will go through the roofing membrane and reach the insulation panels.

OUTDOOR

INDOOR

**Figure 8: Environmental stresses – State 2**

Note: We also take into account construction process problems, i.e. problems occurring during the following stages: design, transportation, storage, installation, use, etc.

We use the 5M rule to identify the various potential defaults, negligence or errors concerning:

- Material (quality, incompatibility, surface quality, etc)
- Manpower (surface cleanness, dimensions, etc),
- Middle, i.e. environment (temperature, humidity, etc),
- Means (non-adapted tools, etc),
- Method (time limit, etc).

They intervene as structural or environmental modifications in step 2.

The failure of a reinforced concrete element could be due not only to the impact of environmental factors impact ($CO_2$, …) but also to vibration, temperature, curing, position of reinforced bars, etc.

# 3 RESULTS AND LIMITS

## 3.1 Results

We thus obtain:

- information about the "Nominal behaviour" of the product in a given environment in order to document "reference service life" (Sjöström and al., 2001),
- information on the degradation and failures, expressed as a list of degradation and failures (FMEA table) or a failure tree (with scenarios).

In this table are listed for each element, the modes, causes and effects.

In column "Causes", we distinguish errors and problems occurring during the process (cause type 0), and the different levels of degradation or failure: cause type 1 (initial environmental stresses), cause type 2 (occurring after the degradation or failure of an element), and so on …

| Function | Element | Modes | Causes | Direct effects | Indirect effects |
|---|---|---|---|---|---|
| Watertightness (outdoor humidity) | Roofing membrane | Cracking, tear | 1 -Load and wear | Cracked membrane | Water penetration (to insulation) |
| | | | 1 - Dimensional variation of support (bending) | | |
| | | | 1 - Adherent ice (compressive stresses) | | |
| | | Local lifting | 1 – Wind (air flow) | | |
| | | | 1 - Vapour pressure | | |
| | | Slipping | 1 - Temperature - Bitumen slipping | Loss of watertightness performance | Water penetration (to insulation) |
| | | | 1 - Temperature - Excessive quantity of bitumen | | |
| | | | 1 - Overload (slope and friction) | Loss of continuity | Stress on edge |
| | | Perforation | 0 - Punctual load (installation) | Pierced membrane | Water penetration (to insulation) |
| | | | 0 - Punctual load (maintenance) | | |
| | | | 0 - Punctual load (use) | | |
| | | | 1 - Vegetation | | |
| | Vapour membrane (if roofing membrane fails) | Cracking, tear or perforation | Refer to the item Watertightness (indoor humidity) | | |
| Watertightness (Indoor humidity) | Vapour membrane | Perforation | 0 - Problem during installation (concrete surface finishing) | Loss of watertightness performance | Water penetration (to insulation) |
| | | | 1 - Dimensional variations of support (RC slab) | | |
| | | | 1 - Dimensional variations of insulation panels (swelling) | | |
| | | Cracking, tear | 0 – Problem during installation (concrete surface finishing) | Loss of watertightness performance | Water penetration (to insulation) |
| | | | 1 – Dimensional variations of support (RC slab) | | |
| | | | 1 – Dimensional variations of insulation panels (swelling) | | |
| Thermal insulation | Insulation panels | Water absorption | 2 – Roofing membrane failure | Loss of thermal characteristics | |
| | | | 2 – Vapour barrier failure | Swelling | Stress of roofing membrane |
| … | … | … | … | … | … |

**Figure 9: FMEA table of a roofing system (Extract)**

## 3.2 Limits

At the moment, the main limit of the methodology is at this moment the binary reasoning, i.e.:

- we do not have any indication of time before degradation or failure, i.e. progressive degradation (just consider that they will occur anyway),
- we do not "measure" the intensity of the phenomena (just consider that they will occur anyway),

Go Back Next Page

- we do not take into account geometrical aspect as partial degradation (10% of the surface is degraded for example).

This limit leads to an exhaustive list of degradation and failures, with obviously some improbable and unrealistic failure modes.

Two solutions are currently under study in order to refine the results (select the most relevant modes in terms of frequency or gravity and delete the others):

- developing an expert method for criticality analysis (Probability x Gravity of effects),
- introducing qualitative reasoning in order to take into account progressive degradation.

## 4 INTERESTS AND PERSPECTIVES

This tool could be used at the different stages in the product life:

- Design and installation (risk analysis and maintenance planning),
- Use (maintenance planning or failure diagnosis).

The following table (Figure 10) gives the results and the objectives of this tool.

| **Construction process stage** | | **Results** | **Objectives** |
|---|---|---|---|
| **Design**<br>**Installation** | **1 - Risk analysis** | Identification of weak points of the product (characterised by a level of criticality) | *Improve quality and reliability from design stage by*:<br>- identifying problems,<br>- giving priorities. |
| | **2 - Quality management** | Identification of critical operations (Installation, use) or critical elements leading frequently to degradation and failure. | *Improve the construction procedures (transport, storage, setting up) and use by:*<br>- identifying problems,<br>- giving a check-list of key steps (scale of priority). |
| **Use** | **3 - Preventive maintenance** | - Forecasting of potential behaviours in time.<br>- Assessment of the criticality of possible consequences. | *Improve **proactive** maintenance procedures by:*<br>- identifying problems,<br>- giving priorities,<br>- proposing solutions to maintenance. |
| | **4 – Conditional maintenance** | - Identification of symptoms, warning signs of failure (condition assessment, diagnosis of degradation)<br>- Forecasting of future behaviours (given actual state).<br>- Assessment of the criticality of possible consequences. | *Improve **reactive** maintenance procedures by:*<br>- identifying problems,<br>- giving priorities,<br>- proposing solutions to maintenance or repair. |
| | **5 - Corrective maintenance** | Identification of failure causes from the observed failure (diagnosis of failure). | *Improve **corrective** procedures by:*<br>- explaining failures,<br>- proposing solutions to repair. |

**Figure 10: Different uses of FMEA tool**

### 4.1 Risk analysis

This tool is intended to help industrial partners, to contribute to innovation.

A successful experience with an industrialist was conducted on an innovative cladding system. Two potential failure modes were detected and solved.

Even if the failure modes are uncertain, it is worth pointing out the fact that the product could fail in use. We then analyse its behaviour more accurately using a traditional procedure (artificial testing, natural ageing, etc).

Based on the FMEA study, we know that : "Such materials will be stressed by UV"

By means of traditional methods for durability characterisation, we try to know whether "the product is designed to withstand such stresses ?"

### 4.2 Quality management

FMEA is used as a tool allowing experience and knowledge to be capitalised (as well as the production of information) concerning the frequent defects, errors, negligence occurring during the construction process, expressed in checklists.

For the following three maintenance strategies, other considerations have to be taken into account. For example, the degradation could be accepted because of high maintenance costs.

### 4.3 Preventive maintenance

FMEA produces information concerning the key elements, i.e. elements on which the good working of the product depends (top elements in the failure tree).

This justifies the updating of existing lists of maintenance operations.

Example:

| Product/element | Operation |
|---|---|
| Heavy added protection in a flat roofing system | Limited thickness No vegetation |
| Draining pipes in a wooden window | Preventing water accumulation (rotting of wood pieces) |

**Figure 11: Preventive maintenance**

### 4.4 Conditional maintenance

FMEA is particularly useful for degradation and failure modes with symptoms (warning signs).

With a condition assessment of the building and the products (surveying only the critical elements, guided by FMEA results), we identify symptoms, search for causes and propose relevant cure (maintenance or repair solutions).

We are thus able to prevent costly and/or hazardous failures by identifying warning signs.

Example:

| Symptoms | Cause | Solution |
|---|---|---|
| Water accumulation on a roofing system | Obstruction of draining pipes because of bad maintenance | Cleaning of the draining pipes |
| Degradation (cracking) of seals in a window | Climatic factors | Change of seals |

**Figure 12: Conditional maintenance**

### 4.5 Corrective maintenance (repair)

FMEA is used to explain a degradation and a failure, i.e. to identify the top event and the different events leading to failure, in order to propose relevant repair solutions instead of temporary solutions (searching top event).

Example:

| Failure | Scenario / Top event | Solution |
|---|---|---|
| Air permeability of a window | 1 - Defect in hinges adjustment<br>2 - Wear of seals<br>3 - Air permeability | Hinges adjustment |

**Figure 13: Corrective maintenance**

Go Back

## 5 CONCLUSIONS: FMEA – A TOOL FOR QUALITY IN CONSTRUCTION

Based on FMEA, the tool developed in CSTB gives elements to assess the durability of construction products.

On the one hand, we can improve the **reliability and quality of innovative products**. With a risk analysis from the design stage, weak points are identified. We can define relevant preventive actions (risk analysis and quality procedure).

On the other hand, in a "refurbishment/diagnosis" context, the FMEA tool allows the **"in-service follow-up" of existing products** and supplies information for IMR procedures (Inspection/Maintenance/Repair) such as quality control and maintenance planning (conditional and corrective maintenance), failure diagnosis (capability of detecting degradation, prediction of the future degradation or failures, identification and selection of relevant maintenance or repair solutions).

It plays an important part in capitalising on experiments and knowledge within building management.

It is a real advantage for architects, owners, project managers, insurers, users ... to:

- Have a guaranteed quality approach,
- Improve and reveal the quality of products and practices,
- Optimise design costs,
- Communicate reliable information between actors of construction,
- Improve products and practices quality,
- Optimise setting up and maintenance costs,
- Decrease environmental impacts at each stage in the construction process,
- Avoid errors, defects and omissions.

In a context where non-quality or poor-quality costs are being added to the general wish to decrease the global cost of construction, FMECA and management tools should have a determinant role.

# Permeability And Pore Structure Of Placing Joint Of Cement Mortar Produced In Casting

**YJ Shin & K Tanaka**
**Tokyo Institute of Technology, Yokohama Japan**

**Summary: Permeability of placing joint of cement mortar during casting was measured for the specimens placed at various interval times by using kerosene as permeation liquid instead of water, and a water path in the specimens was observed. The longer placing interval time of the two mortars, the easier liquid leaks through the placing joint. The pore structure was furthermore measured at various positions including placing joint in the specimens by a mercury intrusion method. Pore volume at placing joint is clearly much compared to the other area in the specimen. It is concluded that the existence of porous zone at placing joint results in an increase of permeability.**

**Keywords: Placing joint, Kerosene, Permeability, Mortar, Pore structure, Mercury**

## 1 INTRODUCTION

A concrete member can rarely be placed in one operation so is normally placed in layers with joints in between. Planned construction joints, such as the bottom and top levels of slabs and beams, are sufficiently treated beforehand by, e.g., removing laitance and unsound concrete to integrate the subsequent layer. In normal placing, however, part of concrete may inevitably be placed after a substantial interval without such sufficient treatment where it is supposed to be placed in one continuous operation from the previous layer, due to delayed production and/or transportation. Excessively long intervals result in cold joints, which can be a potential weakness in regard to structural yield strength, while forming a critical waterproofing defects permitting permeation of rainwater through walls and groundwater through underground walls.

According to the Standard Specification for Reinforced Concrete Construction by the Architectural Institute of Japan, the recommended limits of intervals between concreting lifts are 150 min and 120 min at outside air temperatures of lower than 25°C and 25°C or higher, respectively. In practice, the interval may exceed the recommended limit. Even when the interval meets the limit, complete unification cannot always be achieved, as the jointing is strongly affected by the degree of setting of preceding concrete, time from mixing to the end of placing, concrete temperature, and method of consolidation at the joint.

It is clear that placing joints are prone to waterproofing weaknesses, whether or not they are cold joints. This is considered to result from the pore structure of such joints, since the inevitable bleeding water from preceding concrete may alter the microstructure of not only the joint but also the adjacent laminas, and concomitant laitance inhibits unification with the subsequent concrete, leaving large voids in the area. It is therefore essential for grasping the physical properties of placing joints to investigate it in relation to pore structures.

As the first stage of this study, placing joints of mortar were investigated, as the unification of the mortar phase containing plenty of cement paste is critical for actual placing joints, and mortar is easier than concrete to handle. This paper reports on the watertightness of placing joints of mortar discussed from the aspect of pore structures. As the first stage of the study, joints with no tamping through the joint or vibratory consolidation were investigated simulating simple depositing of a mortar layer on the preceding layer.

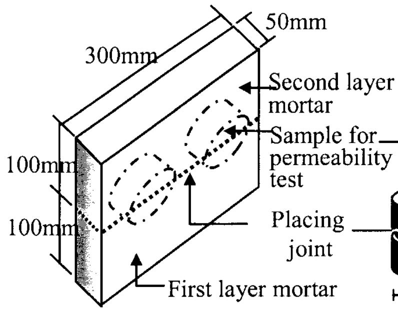
Go Back Next Page

## 2 PLACING JOINT SPECIMENS

As the first step of the study, mortar specimens were prepared. Table 1 gives the mixture proportions, which provide slightly softer consistency than normal mortar to simulate the mortar phase of concrete. Placing joint specimens were fabricated by the following procedure: Mortar was placed in a plywood form with a bottom area of 50 by 300 mm and a depth of 200 mm up to a depth of approximately 100 mm and tamped thoroughly with a tamping rod. The second layer was placed after the specified interval and tamped so that the rod would remain within the second layer(1). Bleeding water from the first layer was not removed to simulate the worst conditions, which can occur in actual walls. As the first step of the study, the joints simulate simple joint conditions without tamping to knit the layers together or vibratory consolidation(2). These specimens were seal-cured in a thermostatic room with a temperature of 20 ± 2°C for 28 days and then dried at a temperature of 20 ± 2°C and a relative humidity of 60 ± 10% for about two months.

Table 1. Mix proportion of mortar

| W/C (%) | C : S | Unit weight (kg/m³) | | | flow (mm) |
|---|---|---|---|---|---|
| | | C | S | W | |
| 55 | 1 :2.6 | 309 | 803 | 170 | 220 |



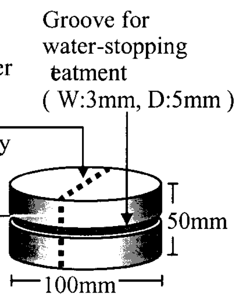


Fig. 1 Mortar specimen Fig.2 Sample for permeability tes

## 3 LIQUID PERMEATION TEST

### 3.1 Specimens for permeation test

Two cylindrical specimens were cut from each of the above-mentioned specimens using a core cutter so that the joint would form axial planes in the centers of the cylinders. Since the cutting involved water, the specimens were dried for another day at a temperature of 20 ± 2°C and a relative humidity of 60 ± 10%.

### 3.2 Test procedure

Each cylindrical specimen was fixed at the bottom of a container for permeation testing. As it was necessary to eliminate leakage through the curved surface of the cylinder, water-stopping treatment was carried out as shown in Fig. 2. A circumferential groove 3 mm wide and 5 mm deep was cut at midheight of the cylinder beforehand. A primer was applied to the curved surface of the cylinder and the side wall of the container. After fixing the cylinder on the bottom of the container, a waterproof sealing compound of rigid polyurethane was poured in the space between the specimen and the container. Being highly flowable and adhesive, this compound was able to perfectly prevent leakage of the test liquid through the vertical surface of the cylinder.

### 3.3 Permeation test using kerosene

Permeation testing using water has conventionally led to unsatisfactory results for the following reasons: It takes long for water to permeate in specimens; It is difficult to obtain accurate data due to the scarceness of permeating water; Measurement may be discontinued by the drying of water, and permeation can completely stop, particularly when the measurement is prolonged, presumably due to resumed hydration of unhydrated cement by the supply of permeating water.

To solve these problems, kerosene was used instead of water in this study. The difference in the dynamic viscosities between water and kerosene, $10 \times 10^{-6}$ m$^2$/s and $1.5 \times 10^{-6}$ m$^2$/s, respectively, naturally leads to different results in absolute values. However, with its readiness to wet mortar (contact angles measured by the authors: 30° for water and 6° for kerosene), kerosene easily permeates through specimens, making permeability testing feasible for specimens having a wide range of permeability, including concrete and mortar having significantly dense microstructures. It is therefore suitable for this study, in which the effects of time intervals between mortar layers are investigated through comparison. The slower drying of kerosene than water also eliminates the problem of drying of the test liquid during measuring. Above all, kerosene has the advantage of causing no hydration in hardened cement during measuring, which is a matter of haunting concern when water is used as the test liquid, ensuring stable measurement throughout a long test period. Kerosene was filled in each container having a fixed specimen as shown in Fig.3, to which a gas pressure of 2 kgf/cm2 (0.196 MPa) was applied from a nitrogen gas cylinder. All measurements were made in a thermostatic room with a temperature of 20 ± 2°C and a relative humidity of 60 ± 10%.

## 4 MEASUREMENT RESULTS

When the pressure was applied, kerosene permeated the specimen along its joint (Photo.1) and immediately spread over the bottom of the specimen. Droplets of kerosene swelled mostly along the joint and finally dropped. Typical results are shown in

Go Back

Next Page

Fig. 4. Though the rate of permeation was unstable in the beginning, it converged over time to a certain value. Since this steady permeation of kerosene was considered a steady state, the permeability coefficient was determined based on the rate of permeation at this stage. As the permeation concentrated along the joint, it was difficult to evaluate it per unit area. A permeability coefficient was therefore determined per unit length of a joint as follows:

$$K_{pj} = Q\,\rho d / pl \qquad (1)$$

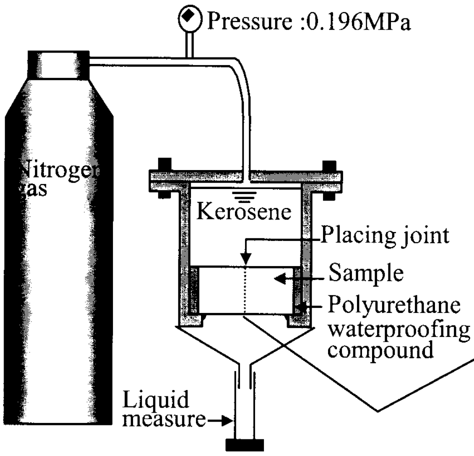

Fig.3 Apparatus for permeability test

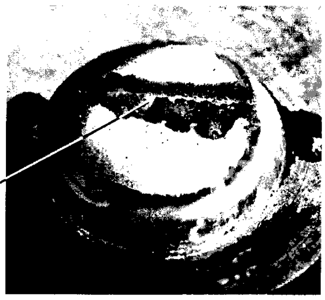

Photo.1 Kerosene permeation through joint

where $K_{pj}$ : permeability coefficient perunit length, $cm^2/s$

Q : quantity, $cm^3$

ρ : density, $g/cm^3$ (kerosene: $0.8 g/cm^3$)

p : pressure, Pa

d : thickness of specimen, cm

l : length of joint, cm

Figure 5 shows the relationship between the permeability coefficient and the time interval between mortar layers. The permeability coefficient tends to increase as the interval increases and increase further after 3hrs. It then significantly increases at 12hrs from the beginning.

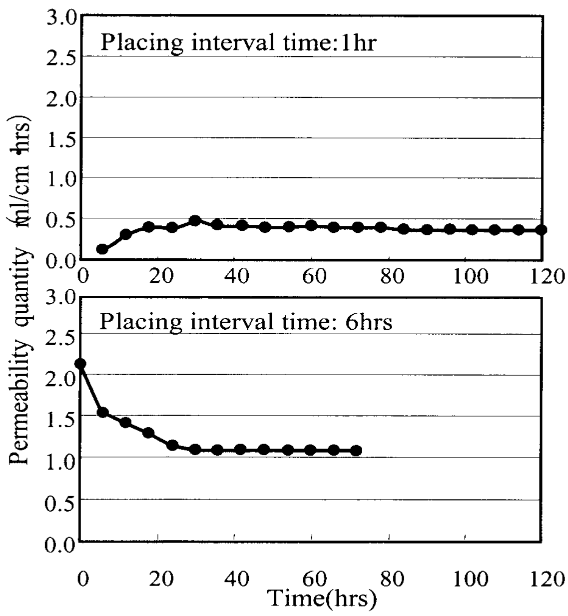

Fig.4 Changes of permeated quantity of kerosene

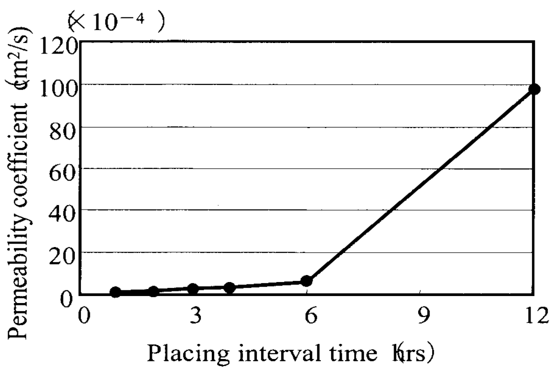

Fig.5 Relation between permeability coefficient and placing interval time

## 5 OBSERVATION OF PERMEATION PATHS

The permeation of specimens with joints was observed to find the permeation paths.

### 5.1 Observation procedure

Immediately after the permeability testing was completed, kerosene was discharged from the container, and an aqueous solution of a fluorescent dye (uranine) was added. A pressure of 5 $kgf/cm^2$ (0.49 MPa) was then applied. After confirming the dropping of uranine along the joint at the bottom using a black lamp as shown in Photo.2, each specimen was axially cleft into two along a plane perpendicular to the joint plane for observation of the uranine permeation paths within the specimen under black lamp.

Paths of permeation are normally observed by pressing in an aqueous solution of a fluorescent dye from the beginning. However, it causes the dye solution to enter pore systems other than the actual permeation path by being absorbed by mortar. The fluorescent solution spreads over the top surface and near the permeation paths, hampering recognition of the actual permeation path. The method proposed here, in which kerosene is allowed to permeate first, followed by an aqueous solution of a fluorescent dye, has an advantage that the permeation path is clearly recognizable, as small pore systems have already been filled with kerosene, which is hydrophobic, preventing the fluorescent solution from entering. As a result, the fluorescent solution is limited to the actual path of liquid permeation, permitting clear recognition of the path.

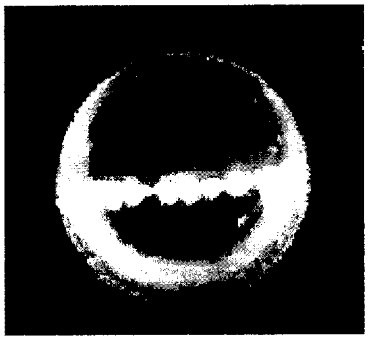

Photo.2 Shining of droplets of fluorescent dye solution along joint under black lamp

### 5.2 Results of permeation path observation

Photo.3 shows the permeation paths of the fluorescent dye solution. The nearly linear luminous trails through the specimens clearly indicate the permeation of the fluorescent solution along the joints.

### 5.3 Relationship between time interval between layers and width of permeating path

While the time interval between mortar layers is short, the width of the permeation path is wide. As the interval increases, the permeation path becomes narrower and sharper. In other words, when the interval is short, the liquid permeates through a slightly wider zone, but as the interval becomes longer, the liquid tends to pass through a narrower but predominant path.

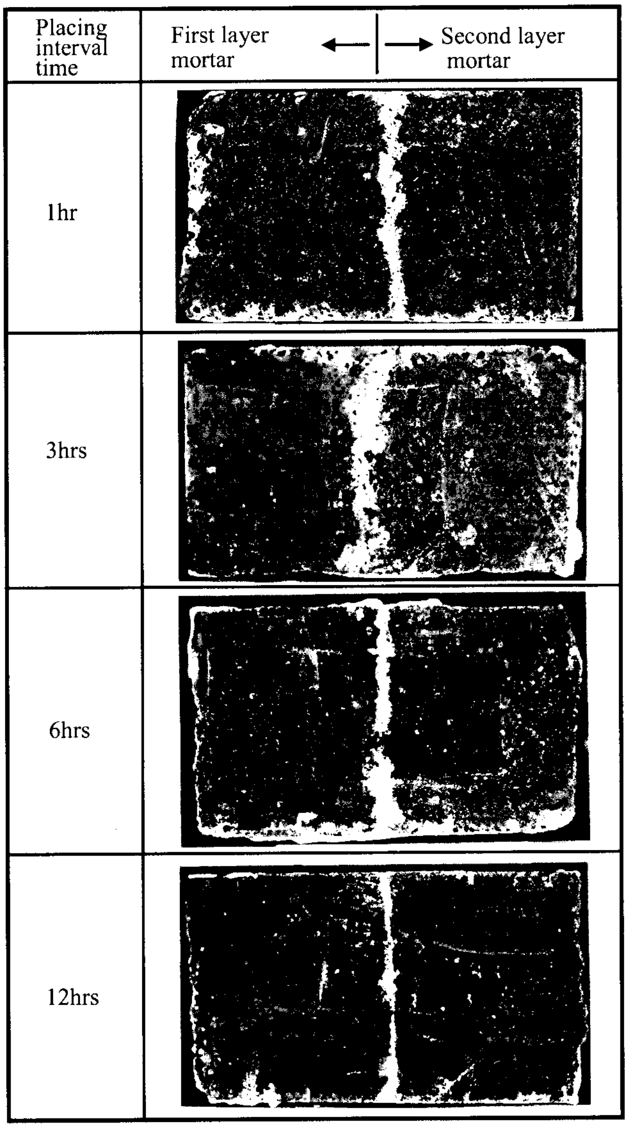

Photo. 3 Permeation paths of the fluorescence dye solution

## 6 PORE STRUCTURES IN AND NEAR PLACING JOINTS

### 6.1 Specimens

When taking samples for pore structure specimens of placing joints, it is essential to know the accurate location of the placing joint surface. A joint with a long time interval is readily recognizable, but recognition of a joint with a short interval is quite difficult. For this reason, transparent acrylic molds were used to allow recognition of the joint during placing, and specimens with clear indication of the joint position were fabricated.

The acrylic molds measured 100 mm in diameter and 200 mm in length, in which mortar was placed with a joint by the same procedure as the specimens for permeation testing. These were seal-cured at a temperature of 20 ± 2°C for 28 days, but the drying process was omitted. The conditions of the specimens are therefore not exactly the same as the permeation specimens, but the omission of the drying process in the fabrication stage may not significantly affect the results, since D-drying is included in the procedure of preparing specimens for pore measurement.

### 6.2 Pore structure measurement

After seal curing, the central portion of each cylinder was roughly cut out using a concrete cutter, from which thin leaves with an area of 15 mm by 10 mm and a thickness of 1.5 mm (3 mm for the leaf including the joint) were cut using a ceramic cutter.

Go Back Next Page

Nine leaves were taken from each specimen: Five from the center (the leaf including the joint and two adjacent leaves each above and below that, totaling 4.5 mm each above and below the joint) and one each from the top, bottom, middle of the first layer (about 50 mm from the bottom), and middle of the second layer. The pore distribution in the range of 10 µm to 160 µm was measured by mercury intrusion using a pore sizer 9310

### 6.3 Measurement results and discussion

### (1) Pore structure

Typical measurements are shown in Fig. 6. The pore structure of the leaf including the joint is evidently coarser than other portions. The pore structure in the first layer is coarser than that in the second layer. The differences are particularly evident in the pore diameter range of 0.05 to 1 µm, the so-called capillary void range. Figure 7 shows the distribution of volumes of pores greater than a diameter of 0.05 µm for each time interval between mortar layers[3]. This figure reveals that the pore volume of mortar in the first layer is greater than in the second layer, indicating coarser pore structure in the first layer than in the second layer. This tendency is more evident near the joint, presumably due to the rising of bleeding water.

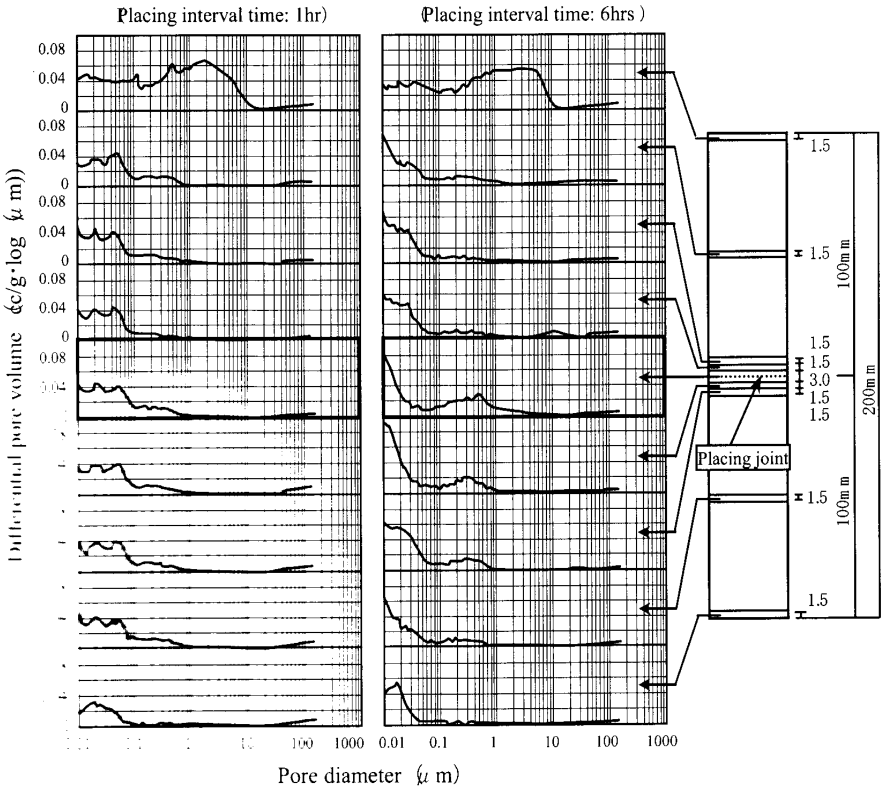

Fig.6 Pore distribution of the samples taken from various positions of the specimens

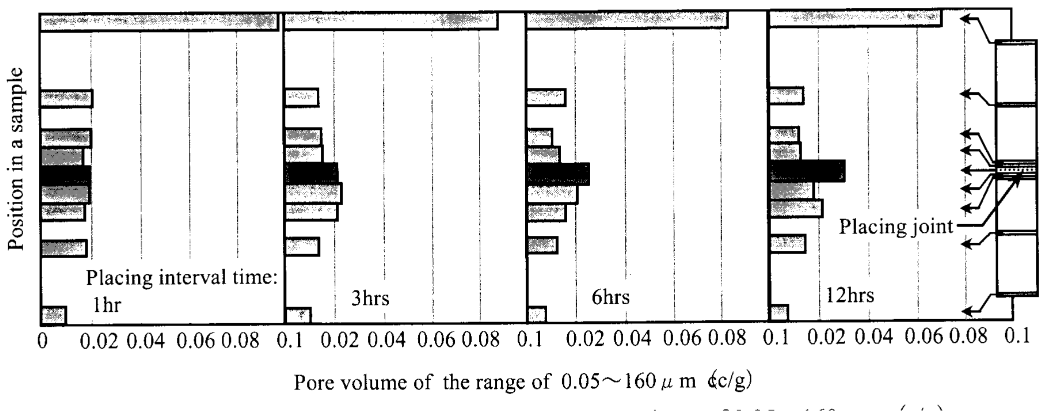

Go Back Next Page

## (2) Effect of time interval between mortar layers

Figure 8 shows the relationship between the volume of pores greater than 0.05 µm and the time interval between mortar layers. As the interval increases, the pore volume in this diameter range evidently increases, i.e., the pore structure becomes coarser.

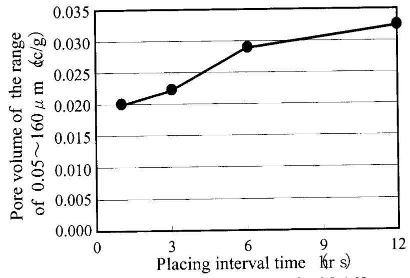

Fig.8 Change of the pore volume of 0.05-160 µm in the leaves including placing joint with placing interval time

## (3) Pore structures of joints with particularly long time intervals

Since joint samples having a certain thickness were used to measure the pore volume, the measurements do not represent only the interface but the total value including its vicinities. However, specimens with a particularly long time interval between the layers (6 and 12hrs) can be easily separated into the first and second layers of mortar, providing information of the interface alone. The idea is illustrated in Fig. 9.This is begun by measuring the pore size distribution of the 3-mm sample including the joint.

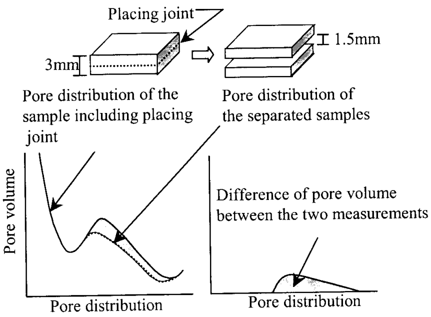

Fig. 9 Idea for estimating of pore distribution of placing joint interface

The sample is then separated at the interface into two layers, and the pore size distribution of each layer is measured. The difference between the measurements is examined. This difference is considered to represent the pore structures of the interfaces. Figure 10 shows the pore structure of the interfaces estimated according to this idea. This figure clearly exhibits that pores between the orders of 1 µm and 10 µm are present along the joints. It is naturally expected that the case of 12-hours interval should involve larger pores, but such sizes are beyond the range of the mercury intrusion measurment. No information as to the large size range is therefore obtained unfortunately.

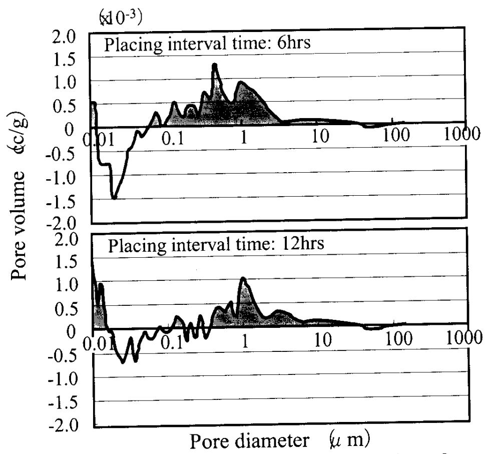

Fig. 10 Estimated of pore distribution of placing joint interfaces

## 7 RELATIONSHIP BETWEEN PERMEABILITY OF PLACING JIONTS AND PORE STRUCTURE

Figure 11 shows the relationship between the permeability coefficient and the pore volume in the range of 0.05 to 160 µm. As the time interval between mortar layers increases, the pore volume increases and the permeability coefficient monotonically increases. In other words, the increase in the permeability of the placing joint is considered to result from the increase in the volume of pores with a diameter in the capillary range or greater. As stated in the discussion of the pore structure on the joint surface in the previous section, presence of pores of a particularly large range is expected in the case of a 12-hour interval, causing significantly high permeability of the joint zone.

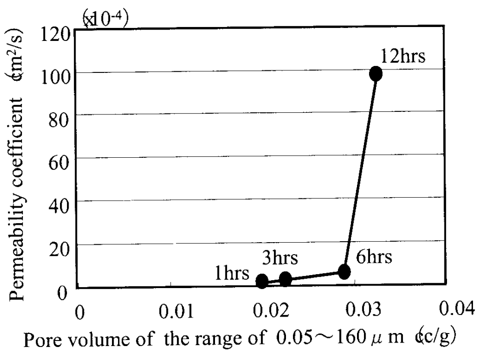

Fig. 11 Relation between permeability coefficient and pore volume

## 8 CONCLUSIONS

This study led to the following conclusions:

(1) The permeability of joint specimens made with a short time interval between layers can be measured by using kerosene instead of water.

(2) As the time intervals increased, the permeability increased. The permeability of 12-hour interval specimens was particularly large.

(3) The path of the test solution is limited to the joint plane and its close vicinities.

(4) The microstructure of a placing joint and its vicinities is coarser than in other portions. This tendency becomes more evident as the time interval at the joint increases.

It should be noted that, in this study, the joints between mortar layers were intentionally retained by avoiding unification by tamping to knit both layers together. In actual construction, concrete is normally unified by tamping or vibratory consolidation. The effect of such unifying action is the subject for our following study.

# Long-term Performance Evaluation Of External Renderings On Autoclaved Aerated Concrete Wall

**H Kus[1] & G Kalmar[2]**
**[1]KTH Research School University of Gävle Sweden**
**[2]GK Råd Pålsboda Sweden**

**Summary: The use of external renderings and surface treatments mainly aims to improve the weather resistance of external walls. The influence of agents present within the microenvironment, particularly moisture, causes degradation of external walls and thus reduces their performance over time. In order to study the long-term effects on rendered autoclaved aerated concrete (AAC) walls, an experimental building has been built. The microenvironment parameters have been continuously measured and laboratory tests and analysis have been carried out on sample cores taken each year from test panels mounted on the experimental building. In this paper, the long-term performance of external renderings is evaluated based on the comparison of test results of the capillary water absorption of sample cores and the microenvironment measurements. The first results obtained after a two-year exposure period indicate that inorganic renderings have improved their initial moisture performance while the performance of organic renderings remained about the same.**

**Keywords: AAC, external rendering, long-term performance, moisture.**

## 1 INTRODUCTION

Rendered AAC is one of the alternative wall construction types to external walls with insulation systems. Because of the low thermal conductivity of AAC, additional insulation may not be required depending on the climate where the construction is built and on the use of the building. In addition to energy savings during use, it could also save material and reduce work during the construction phase. Moreover, complex moisture problems of multi-layered walls can be avoided by minimising the number of layers. However, as for other wall types, protection of AAC against outdoor conditions, particularly rain, plays an important role for the service life. The durability and service life of rendered AAC walls depends on factors such as characteristics of the building materials forming the wall components, design and the application (workmanship) level, environmental factors and maintenance conditions (ISO 15686-1). Most factors can be controlled, however the exposure environment remains as an important factor, which should be primarily considered in performance assessment. Different coatings and external rendering systems are applied to improve resistance to environmental factors. In fact, performance of these surface coatings and renderings determines the long-term performance of the whole wall component.

In order to study the actual in-service performance of rendered AAC walls, an international research programme, EUREKA-project DurAAC E 2116 (Kus & Nygren 2000), has been initiated at the Centre for Built Environment in Gävle, Sweden. The long-term effects of different rendering systems on AAC are investigated by long-term moisture monitoring at the test cabin and by periodical laboratory tests as well as analysis of sample cores taken from the test cabin every year over a five-year period. The measuring (exposure) programme started in June 1999. In this paper, different rendering systems on AAC are evaluated, based on the comparison of test results of the capillary water absorption of sample cores and the data obtained from the continuous electrical measurements of moisture at the test cabin.

## 2 EXPERIMENTAL

### 2.1 Materials

Un-reinforced AAC panels with dry density 423 kg/m$^3$ and measuring 600 mm × 1200 mm × 150 mm were used as substrates for the rendering systems tested. The rendering work of the test panels was performed indoors by a skilled building contractor under controlled conditions. In this way, the experimental set-up would be repeatable and the performance of the test panels would be comparable. The applications of renderings and water repellants followed the manufacturer's instructions. After a curing period of approximately three months, rendered test panels (Fig. 1 and 2) were installed to the long sides of the test cabin facing north-east and south-west, respectively. There are 12 test panels on each of the two facades including uncoated and un-rendered AAC as control sample panels, System 1. The joints between the test panels themselves and the wall were insulated and sealed. The systems tested involve inorganic and organic renderings as well as their modifications with water repellants. The compositions of the six rendering systems, which are studied in this paper, are summarised in Table 1 below.

**Figure 1. Test panels**

**Figure 2. Test panels from the inside**

**Table 1. Rendering Systems**

| *System No* | *AAC Surface Impregnation* | *Primer* | *Undercoat* | *Final Coat* | *Thickness* (mm) |
|---|---|---|---|---|---|
| 5 | - | Lime/white cement/dolomite 10/90/350 | - | Lime/white cement/white dolomite 50/50/450 | 5-7 |
| 6 | - | System No 5 *with silicon additive* | - | System No 5 *with silicon additive* | 5-7 |
| 7 | - | Lime/white cement/dolomite 10/90/350 | Lime/cement/ dolomite-sand 50/50/650 | Hydraulic lime/ lime/dolomite | 10-12 |
| 9 | Silane-siloxane emulsion | Acrylic/dolomite-calcite *with silicon additive* | - | Pure acrylic copolymer/dolomite-calcite | <1 |
| 11 | Silane-siloxane emulsion | - | - | Silicon resin | <1 |
| 12 | - | - | Cement/polymer/lime stone-plastic fibres | Cement/polymer/lime stone-plastic fibres | 3-4 |

## 2.2 Measurements

Measurements taken can be grouped as continuous field measurements, periodical field measurements, and laboratory tests and analysis of material properties and over time. The programme will run for at least five years.

### 2.2.1 Continuous Microenvironment Measurements

Continuous field measurements are carried out at five-minute intervals and hourly averages are registered. The parameters monitored are:

- Surface and bulk moisture of the materials
- Surface and bulk temperature of the materials
- Indoor and outdoor air temperature
- Indoor and outdoor relative humidity
- Driving rain
- Ultraviolet radiation.

Moisture content of the test panels exposed at the test cabin have been monitored since the start of the exposure programme. Wetcorr sensors and resistance-type nail electrodes are used to measure both the surface moisture and the bulk moisture of the material. Resistance is measured by epoxy coated nail electrode pairs placed at seven different depths (in the rendering and in the AAC) in addition to temperature measurements with copper-constantan-type thermocouples at the same depths. The moisture sensors and thermocouples are connected to the terminals of five multiplexers controlled by two dataloggers. The resistance measured between the two electrodes together with the temperature, both in the AAC material and in the thick rendering, was converted to moisture content by means of a calibration procedure (Kus & Norberg 2001). Since the moisture performance of AAC is directly related to the effectiveness of the rendering system, the assessment is based on the electrical measurements of moisture made in the AAC.

#### 2.2.2 Capillary Water Absorption Test

Once a year, three sample cores were drilled (with water) from each panel of the test cabin. The diameter of each core was 90-95 mm and the thickness approximately 150 mm (AAC and rendering system). The samples were then conditioned at 20 °C and 65 % relative humidity. After drying in the oven at 65 °C, surfaces of the samples, except for the exposed surface, were sealed with wax. The samples were immersed, exposed faces down into 1-3 mm of distilled water and were then weighed at various time intervals. For the initial test three samples were tested, whilst only one was tested after the first year of exposure and two after the second year.

## 3 RESULTS AND DISCUSSION

### 3.1 Microenvironment Measurements

The weather conditions at the north-east facade for the selected periods are summarised in Table 2. These conditions should be taken into consideration in order to make a better assessment of the rendering systems. For example, the total amount of driving rain is much higher during the periods in the first two years compared to the amount during the period in the last year. However, the average relative humidity is the highest during the period in year 2000 while the highest average temperature is found during the period in year 2001.

**Table 2. Microenvironment measurements at the north-east facade**

| | *unit* | *5-12 Aug 1999* | *29 Jun-6 Jul 2000* | *20-27 Aug 2001* |
|---|---|---|---|---|
| Air Temperature (average) | °C | 14,7 | 14,7 | 17,8 |
| RH (average) | % | 74 | 83 | 77 |
| Driving rain (total amount) | $kg/m^2/h$ | 9,1 | 9,9 | 1,6 |

In Figures 3-5, air temperatures, relative humidity and the driving rain monitored on the north-east facade are shown for selected periods. The indoor air temperature is kept at minimum of 15 °C through the year. Because the south-west facade is subjected to sunlight over longer periods, the test panels demonstrate relatively low moisture contents and therefore are not included in this paper. In order to get the most significant effects, the most rainy and humid weather conditions were selected. The ageing process for different rendering systems can be analysed from initial data and data obtained at yearly intervals.

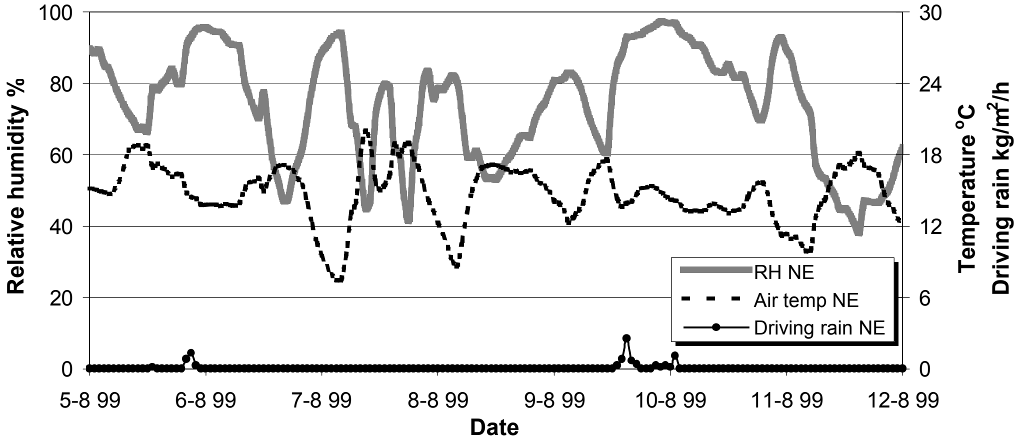

**Figure 3. Microenvironment measurements: NE facade: 1999**

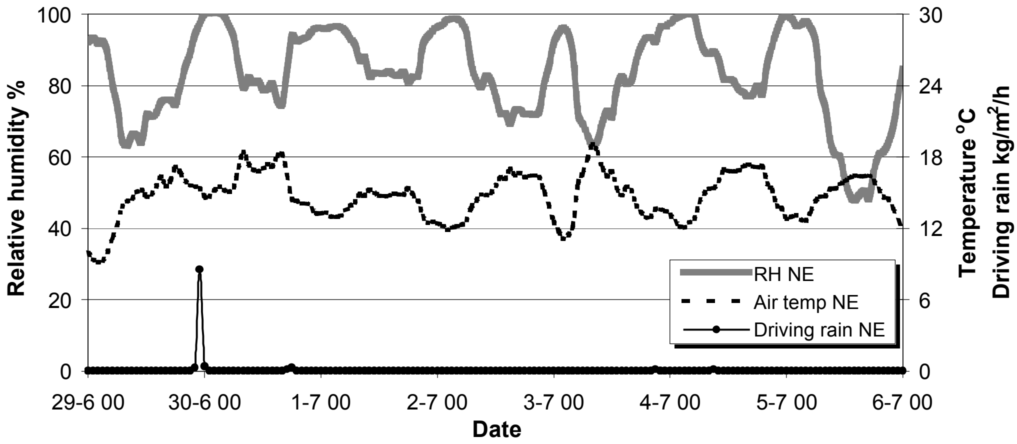

**Figure 4. Microenvironment measurements: NE facade: 2000**

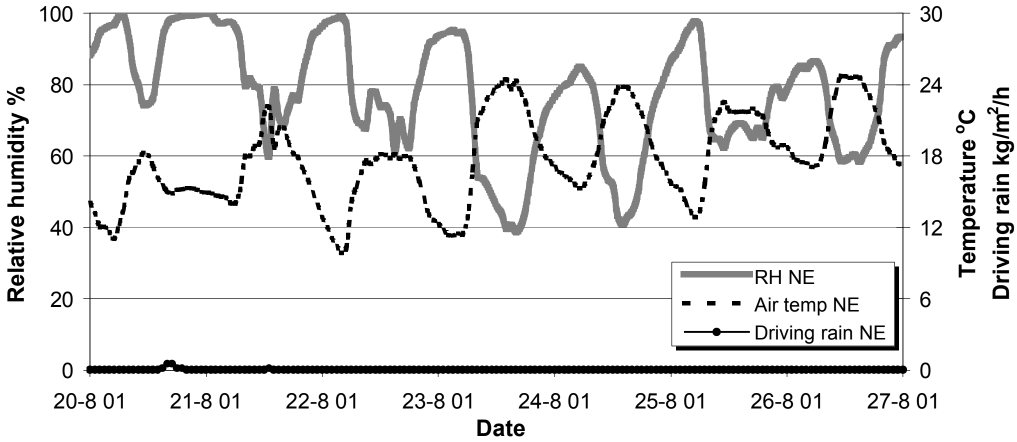

**Figure 5. Microenvironment measurements: NE facade: 2001**

## 3.2 Continuous Moisture Measurements

The average moisture content from one-week data measured at two different depths in the AAC is displayed in Figures 6 and 7. The moisture performance of lime-cement rendering systems, *Systems 5* and *7*, differs most from the other systems. The moisture content in these systems with inorganic renderings is higher than the control panel (plain AAC), *System 1* (Fig. 6). The only impairment over time, although rather small, appears for *System 6*. The performance of both *Systems 9* and *11* seems unchanged during the whole exposure period. The high moisture content of *Systems 5* and *7* at 25 mm depth in the AAC (Fig. 7) probably depends on the intensity of the driving rain and the high relative humidity during this period.

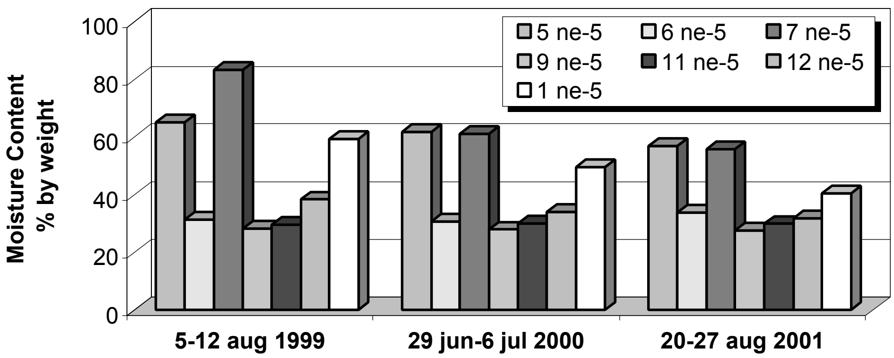

**Figure 6. Average moisture content at 5 mm depth**

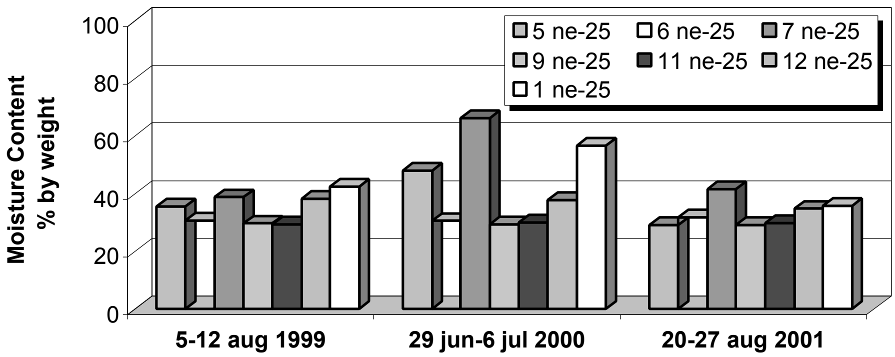

**Figure 7. Average moisture content at 25 mm depth**

3.2.1 At 5 mm depth from the AAC surface

The rendering systems modified with water repellants, *Systems 6*, *9* and *11*, and the fibre reinforced cement-polymer rendering, *System 12*, had relatively low moisture contents compared to the lime-cement rendering systems, *Systems 5* and *7* (Fig. 8-10). Initial measurements indicate that both thin and thick lime-cement rendering systems, *Systems 5* and *7*, absorbed about the same amounts, however, the absorption rate of *System 7* was lower, probably because of the thickness of the rendering which is thicker than that of *System 5* (Fig. 8). Also, it took longer for *System 7* to dry out and it absorbed moisture later and the moisture content remained higher than that of *System 5* when the second wave of driving rain occured (Fig. 8). After the first and second year of exposure, thick lime-cement rendering, *System 7*, absorbed less than the thin lime-cement rendering, *System 5*, however, demonstrated almost the same rate of drying (Fig. 9-10). When the duration of driving rain was very long, the lime-cement rendering containing silicon additive, *System 6*, and the fibre reinforced cement-polymer rendering, *System 12*, began to absorb small amounts of moisture. This is clearly seen, particularly after the second driving rain period (Fig. 8). This implies that the effectiveness of water repellent additives decreases when they are exposed to longer periods of driving rain.

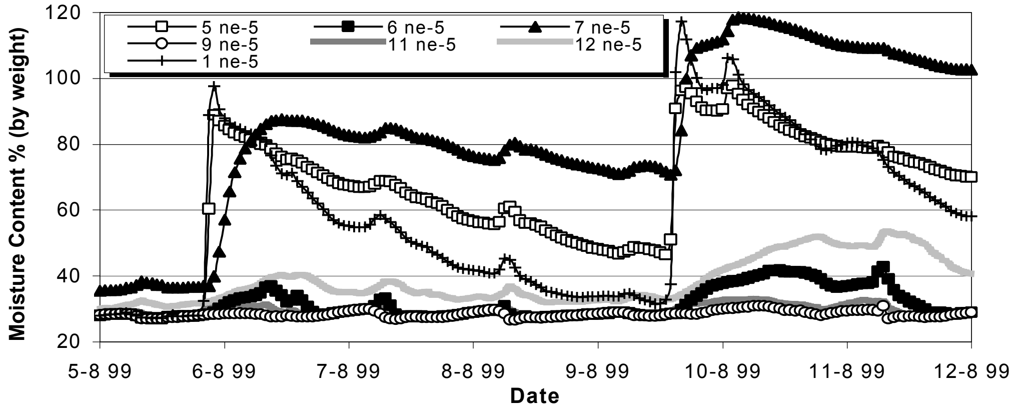

**Figure 8. NE facade, 5 mm depth from the AAC surface: 1999**

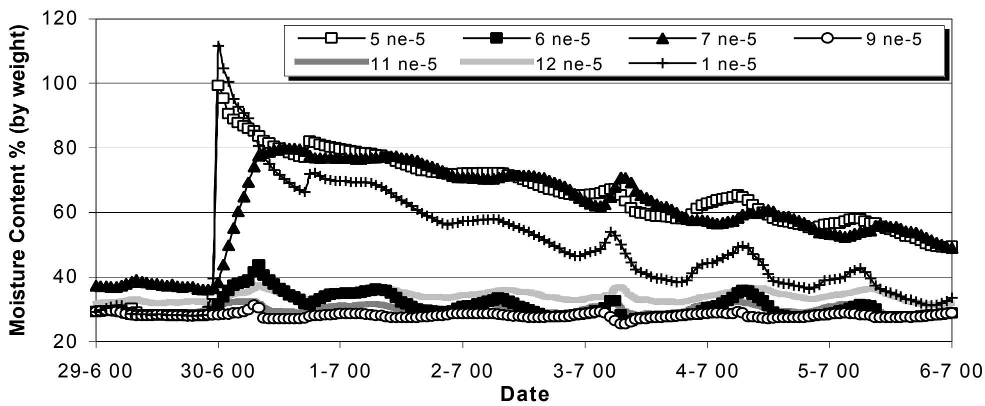

**Figure 9. NE facade, 5 mm depth from the AAC surface: 2000**

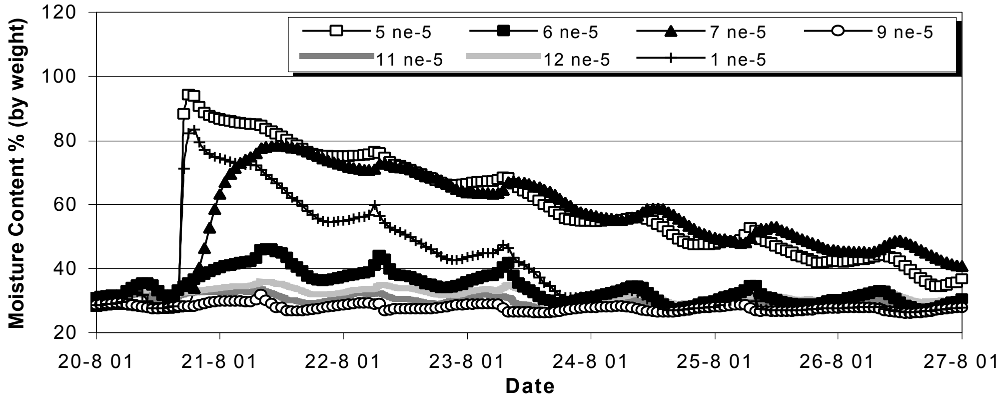

**Figure 10. NE facade, 5 mm depth from the AAC surface: 2001**

3.2.2 At 25 mm depth from the AAC surface

After approximately one year of exposure, the test panels with inorganic renderings, *Systems 7* and *5*, and the control panel (plain AAC), *System 1*, had the highest moisture contents at 25 mm depth (Fig. 12). This might be due to the intensity of the driving rain during this period which probably propagated the capillary suction inwards.

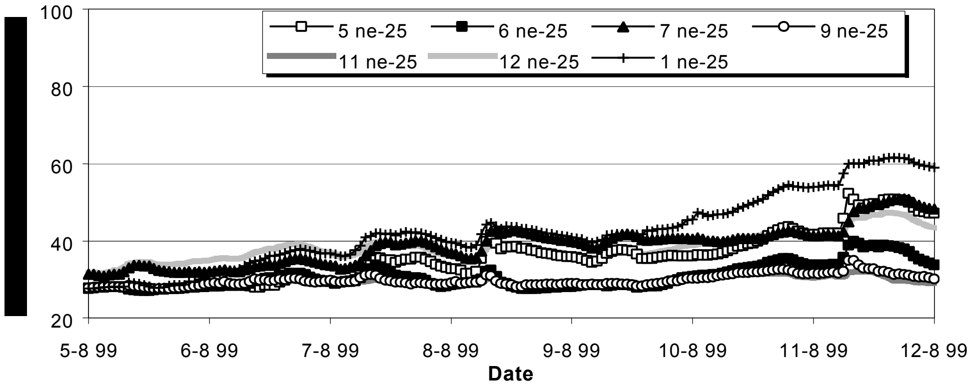

**Figure 11. NE facade, 25 mm depth from the AAC surface: 1999**

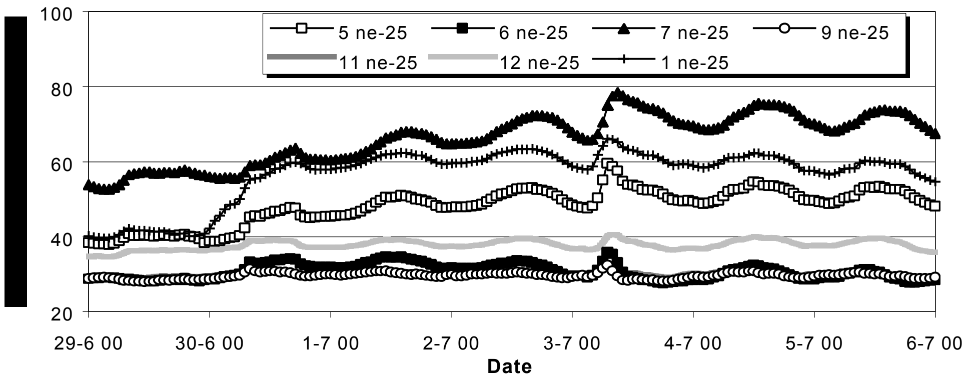

**Figure 12. NE facade, 25 mm depth from the AAC surface: 2000**

Go Back
Next Page

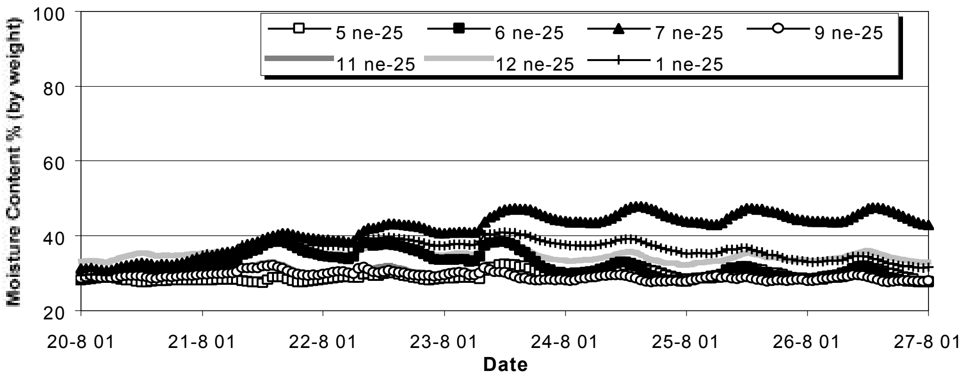

**Figure 13. NE facade, 25 mm depth from the AAC surface: 2001**

## 3.3 Capillary Water Absorption

Figures 14-16 demonstrate the capillary water absorption of the sample specimens, initially and over time. In general, the results indicate similar long-term declining tendency in suction properties of the inorganic systems, *Systems 7* and *5*. The fiber reinforced rendering, *System 12*, shows similar moisture behaviour over time, which is also decreasing. *Systems 9* and *11* keep almost the same low absorption levels after the second year of exposure (Fig. 16). The curve for *System 6* confirms its susceptibility to moisture absorption when it is in contact with water for a long duration, however the absorption rate is low compared to the inorganic systems.

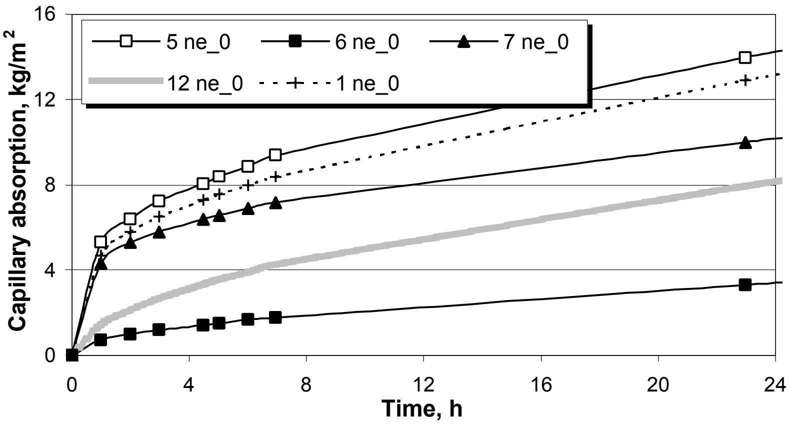

**Figure 14. Initial capillary absorption: 1999**

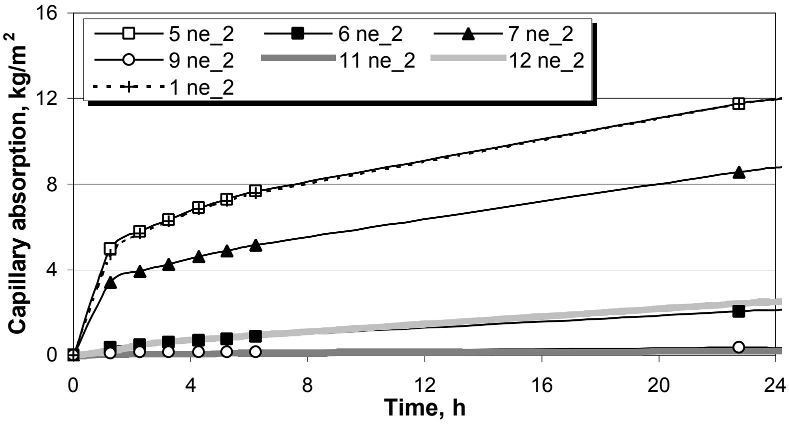

**Figure 16. Capillary absorption: 2001**

## 4 CONCLUSIONS

The long-term performance of different external rendering systems on AAC is being investigated within an international research project. The research programme consists of continuous microenvironment measurements and laboratory tests and analysis of initial material properties and material properties over time. Twelve systems including inorganic renderings and organic renderings as well as their modifications with silicon-based water repellants have been investigated. Efficiency of the rendering systems is basically assessed by moisture analysis of naturally exposed test panels mounted on an experimental building. The degradation processes and ageing characteristics are also studied by microstructure analysis of sample cores taken from the experimental building each year over a five-year period.

Among the six systems studied in this paper, *Systems 9* and *11*, the ones with impregnated AAC surface, perform best so far. Due to the hydrophobic effect of silicones, almost no change in moisture content has been observed during the initial two-year exposure period. The moisture content of *System 6*, the thin lime-cement rendering containing silicon additive, only increases after a long duration of driving rain. During long periods of driving rain the moisture content of *System 6* reached up to 80 % by weight. On the other hand, its drying rate was high. Initially, *System 12*, fibre reinforced rendering, was fairly susceptible to driving rain while subsequently improving its performance. *Systems 5* and *7*, the two inorganic systems, demonstrated the highest moisture absorption rates. However, after a short exposure period, the moisture contents of both inorganic systems decreased to some extent. The drying rate of *System 7* was lower compared to that of *System 5.* Faster degradation can be expected for *System 7* due to high moisture content during long periods of time.

First results obtained after a two-year exposure period indicate that inorganic renderings have improved their initial performance while the performance of organic renderings remained about the same. Another preliminary conclusion is the susceptibility of lime-cement renderings containing silicon additive to driving rain of long duration. Overall, the first results from the moisture monitoring give some insight into the actual in-service performance of different rendering systems on AAC. However, data from the two-year exposure period is not sufficient for reliable evaluation of long-term performance. The research programme is to be carried out for at least five years. Hence, it is expected that clearer findings will be made.

## 5 ACKNOWLEDGEMENTS

The industrial partners of the EUREKA-project E 2116 DurAAC are Yxhult AB Sweden, Optiroc AB Sweden, and Wacker-Chemie GmbH Germany.

# Performance Characteristics' Degradation And Paints' Protective Degree For Wall Components Subject To Durability Tests

**B Daniotti**
**Politecnico di Milano Engineering of Building Systems and Urban Planning Italy**

**Summary: The paper reports on the conclusions obtained at the end of the first experimental part of the research on building components durability, which is now being developed in cooperation between DISET Politecnico di Milano and Laboratorio Tecnico Sperimentale of the University of Applied Sciences of Southern Switzerland.**

**The reported analysis are related with the measurement of the time trend of performance characteristics measured on external wall components, with and without painting protection, after laboratory weathering cycles. The comparison between results obtained on samples protected by two different paintings, one with acrylic resin and the other with vinyl resins, and different Pigment Volume Concentration of 45% and 60%, with respect to the reference unprotected samples, allows to evaluate the protective degree for the tested finishing layers. The analysis of time trends of measured performance characteristics, eventually compared with each other allows to achieve the first evaluations of building component durability.**

**The measured performance characteristics concerns with water transmission properties (capillary absorption and vapor diffusion) For the service life evaluation these analysis are completed with natural weathering tests' results, in Milano (I) and Lugano (CH) to establish the correlation between accelerated aging time and natural aging time.**

**Besides the correlation between the materials' performance characteristics and the component's actual performance decay, in realistic conditions will be estimated during testing on the complete external wall component subject to differential stressing conditions, simulating indoor and outdoor environments.**

**At the moment we have obtained useful information about the comprehension of degradation phenomena and about time behavior of materials constituting the building component subject to reference laboratory accelerated aging conditions.**

**It's shown in the report also some result relating with the time re-scaling, demonstrating that the outdoor samples show the same damages we obtained in laboratory: we are able now to evaluate the time re-scaling to estimate the Reference Service Life of the component.**

**Keywords: components, materials, performance, laboratory, paints**

## 1 INTRODUCTION

The Department of Engineering of Building Systems and Urban Planning (DISET) in Politecnico di Milano has been developing through the last years research on technological quality of building components, mainly regarding the durability and reliability evaluation (Maggi *et al.* 1987, Maggi *et al.* 1990, Daniotti *et al.* 1994).

After the first methodological studies the research brought to an experimental program for the laboratory evaluation of building components' durability, developed in cooperation between DISET Politecnico di Milano and Laboratorio Tecnico Sperimentale of the University of Applied Sciences of Southern Switzerland (Daniotti *et al.* 1998).

The first experimental phase of the research is aimed to apply the general methodology for the evaluation of durability to an external wall's component (Rigamonti 2002).

The reported conclusions and results regard the laboratory aging of the external layers' packet of the wall. The analysis of time trends of measured performance characteristics, eventually compared with each other allows to achieve the first evaluation of building component durability.

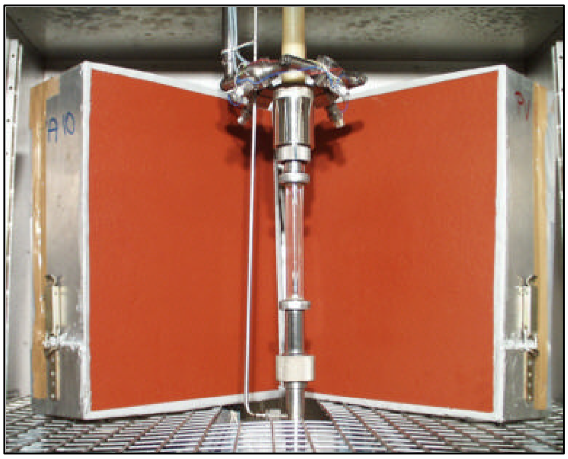

**Figure 1. Test samples during aging**

The aging cycle has been divided into four phases representing different extreme weathering conditions on the base of relevant agents (Table 1).

**Table. 1. Aging cycle's phases**

| | Temperature (°C) | Relative Humidity (%) | Time (minutes) |
|---|---|---|---|
| RAIN | 20 | 95 | 60 |
| FREEZE | -20 | - | 90 |
| HOT – HUMID | 55 | 95 | 60 |
| HOT – DRY with UV artificial sunlight | 30 | 40 | 80 |

The measured performance characteristics concern with water transmission properties (capillary absorption and vapor diffusion), thermal transmission properties (thermal resistance), and mechanical properties (compression, tensile and flexural resistances); the chemical – physical degradation of materials constituting the wall component solution has been analyzed through surface macro photos, microscope observations and porosity measurements. (Teruzzi and Jornet 2002).

## 2 MASS INCREASE

A first important result regards the mass increase of samples due to the water cumulating during aging cycles, as a function of different protective degree of the tested paints; the measured mass increase over time for the different protected samples are compared in Fig.2.

Go Back Next Page

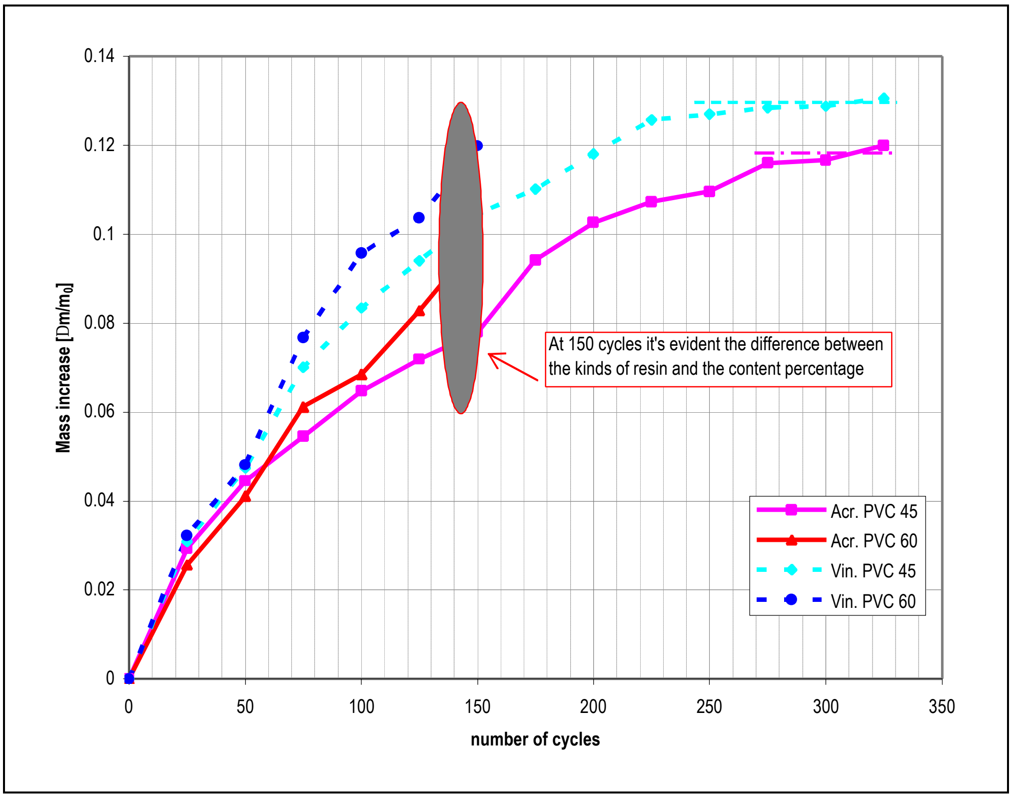

**Figure 2. Mass increase as a function of aging cycles number.**

Looking at the graph we can draw the following conclusions:

- Already at 150 aging cycles we find relevant differences among different kind of paints, that allow us to evaluate their protective degree to water penetration.
- From the lower to higher we have firstly the acrylic paints, at a higher resins' content and at low resins' content, and then the vinyl resin's paints at a higher resins' content and at low resins' content.
- Considering the percentage difference between the mass increase at 150 cycles for each paint and the best acrylic resin's paint PVC 45 (0.078 $\Delta m/m_0$) we have:
    - +27 % acrylic resin's paint PVC 60
    - +34 % vinyl resin's paint PVC 45
    - +54 % vinyl resin's paint PVC 60
- The time trend of mass increase is asymptotic: all samples reach an equilibrium situation for water transfer in the raining and drying phases: the different behavior of paintings in these two phases will be later discussed in the analysis of capillary absorption, prevailing in the raining phase as liquid status and in the analysis of water vapor diffusion coefficient, prevailing during drying phase.
- The differences between the different samples are evident starting from 75 aging cycles, which can then be considered a minimum time limit for this test.
- The application of an aging test until 150 cycles allows to obtain a good estimation of protective degree for these paints.

## 3 WATER ABSORPTION

The second important result is related to the elaboration of water capillary absorption data for the various paints. To evaluate the painting's protective degree to water we have taken away a 3 mm surface containing the protective layer and then we have repeated the water capillary absorption test. In the histogram in Fig 3 we have reported the percent difference between the capillary absorption of the protected sample and the samples after the uptake of the protective layer, for the three measurement times: 10 minutes, 1 hour and 24 hours.

Go Back
Next Page

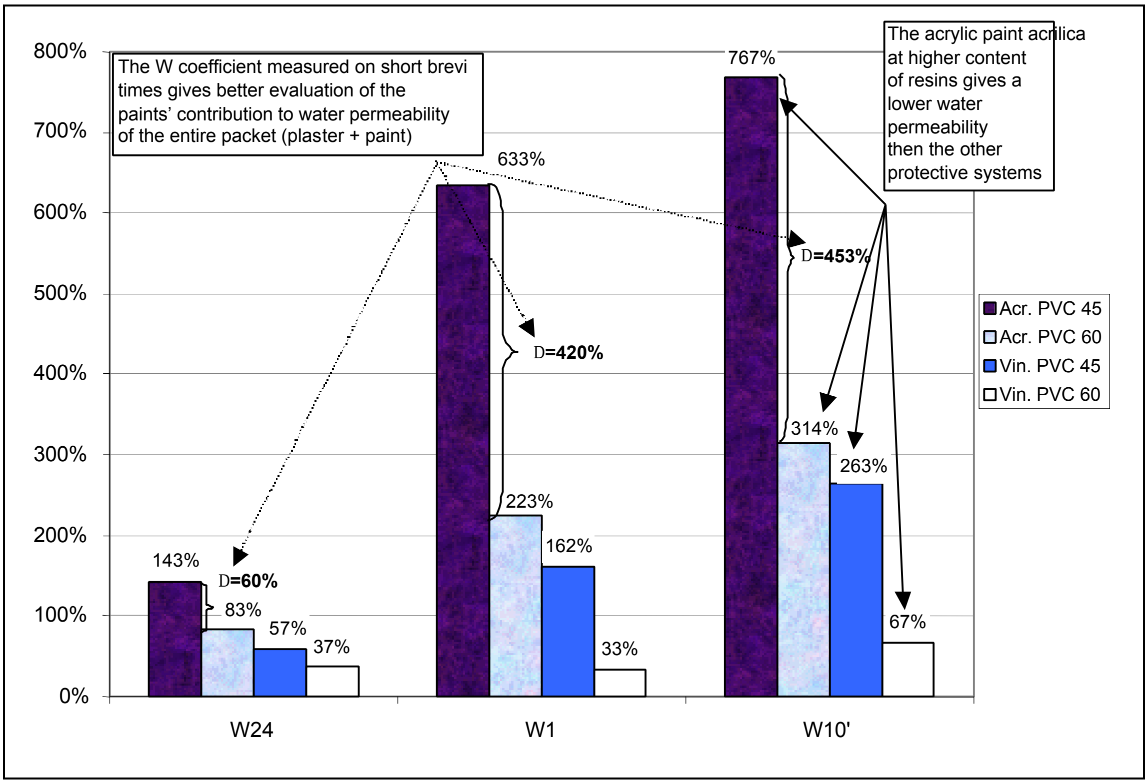

**Figure 3 Graph of percent difference of capillary absorption between painted sample and plaster without painting protection.**

We can see that at 10 minutes and 1 hour we have the maximum differences in the paints' behavior in terms of capillary absorption, while at 24 hours the external layers of painted plaster gives a global contribution to the water absorption: the data at 10 minutes and 1 hour is then the most interesting to give an evaluation for the protective degree to water.

Comparing the different paintings we can perceive that the best protective degree is given by the acrylic paints with respect to the vinyl resin's ones and that the higher content of resin contributes to obtain the best performance. The acrylic paint at higher resin's content gives the best results as water absorption differences with respect to the unprotected plaster.

## 4 WATER VAPOR PERMEABILITY

Water vapor permeability and the corresponding resistance to water vapor diffusion were determined on three cores for each wall specimen and the results are shown in Fig. 4.

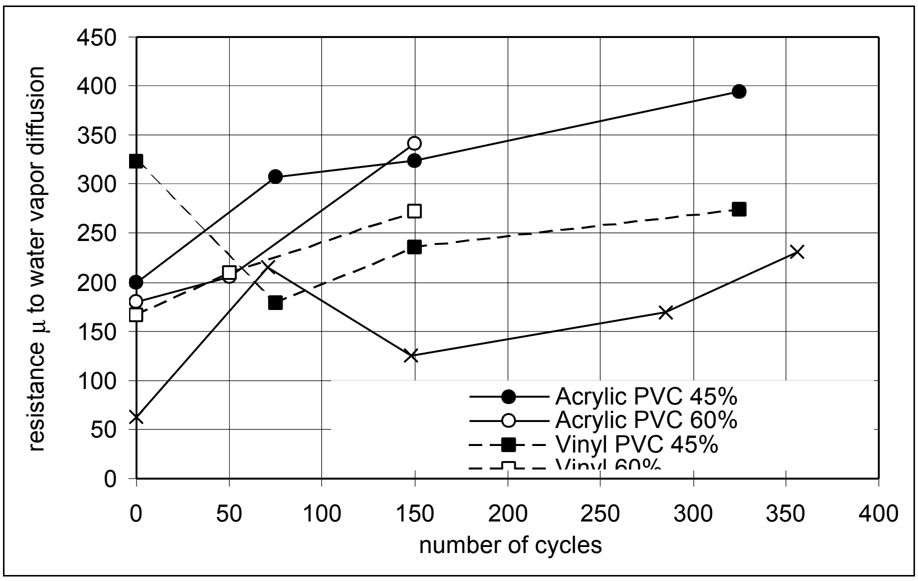

**Figure 4. Resistance to water vapor diffusion as a function of the number of cycles.**

The curves displayed in Fig. 4 show that the presence of the paint results in an important increase of the resistance to water vapor diffusion.

A general increase of resistance is also observed with increasing number of weathering cycles for all types of paint. Acrylic paints show the highest resistance to water vapor diffusion, but differences between paints seem not to be so relevant.

## 5 MICROSTRUCTURE ANALYSIS

The results of microscope's analysis are summarized in the photographs at the end of aging tests presented in Fig. 5 and 6, chosen from the series of photographs done for the different samples, for different aging times, and at different depths (at the external plaster's surface, within the plaster and at the interface between brick and plaster).

From the microscope's analysis we found that the plaster microstructure doesn't show any time variation at different depths for painted samples; on the other hand from surface analysis we could evaluate different degradation effects for the different used paints.

For the vinyl resin's at 45% of Pigment Volume Content (PVC), after 75 cycles we found localized cavities within the protective film and surface blistering; at 150 the cavities expand unto relevant parts of the interface between plaster and the protective film, causing local cracking in this film; finally at 325 cycles we have an evolution of degradation effects unto relevant detachment of the protective film from plaster (Fig. 5).

In the case of the vinyl resin's at 60% of Pigment Volume Content (PVC) at 50 and 150 cycles we obtained similar results as for 45% PVC ending with cracking of the protective film.

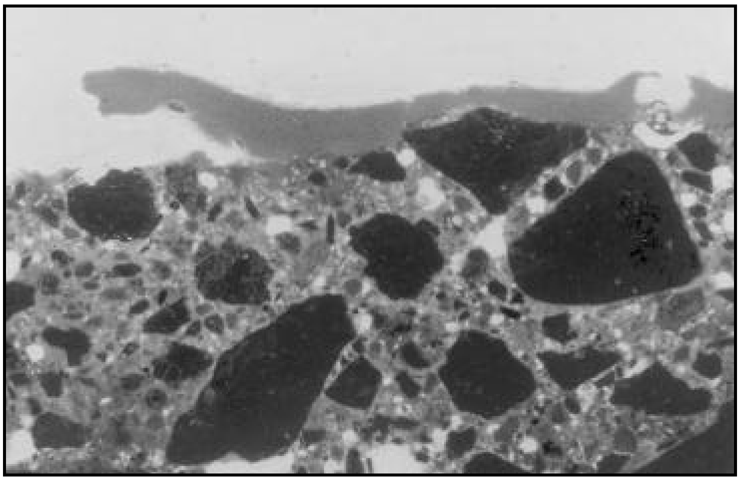

**Figure 5. Microscope's analysis: vinyl resin's paint (PVC 45) after 325 cycles**

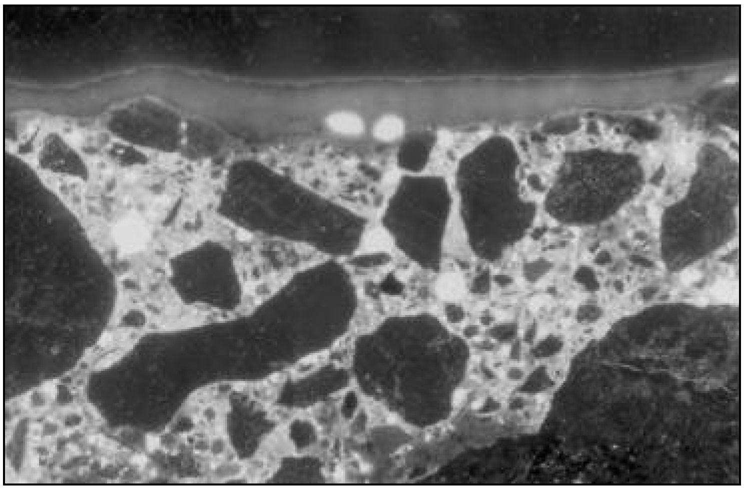

**Figure 6. Microscope's analysis: acrylic resin's paint (PVC 45) after 325 cycles**

On the other hand the acrylic paints show no degradation until 150 cycles: in the case of lower resin's content (60 % of PVC) some cavities appear in the protective layer at the end of aging test while in the case of higher resin's content (45 % of PVC) only a few discontinuities between protective film and plaster are rarely visible: for this paint cavities appear localized later at 325 cycles (Fig. 6).

## 6 SURFACE PHOTOGRAPHS

The surface of protected samples subject to aging tests has been photographed during time; in fig. 7 we can see the result of surface degradation for the vinyl resin's paint at 45 % of PVC after 325 aging cycles: the surface shows an evident damaged condition, with broken blisters and cracks with salt surface crystallization, probably due to water transfer from internal layers of plaster to the external surface.

After the same aging time of 325 cycles we see in Fig. 8 that the sample protected with acrylic resin's paint at 45 % of PVC show an undamaged surface.

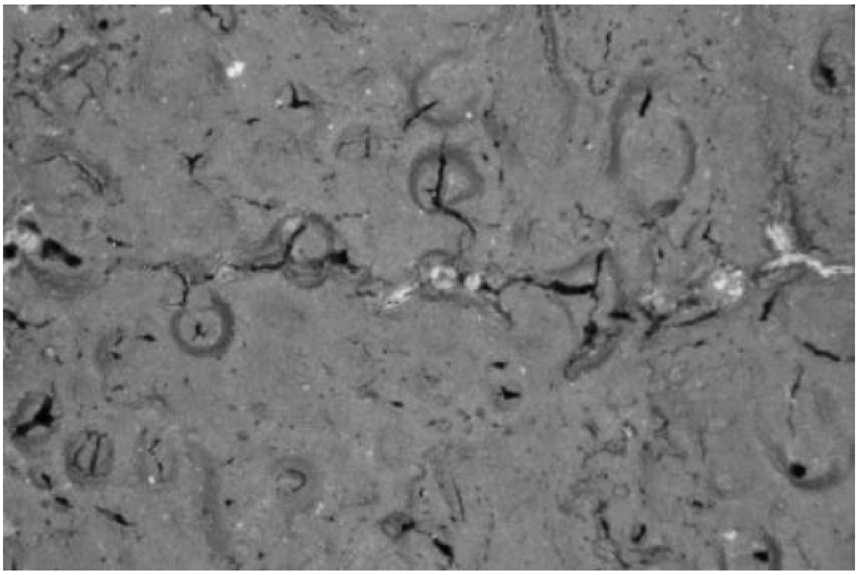

**Figure 7. Surface photographs: vinyl resin's paint (PVC 45) after 325 cycles**

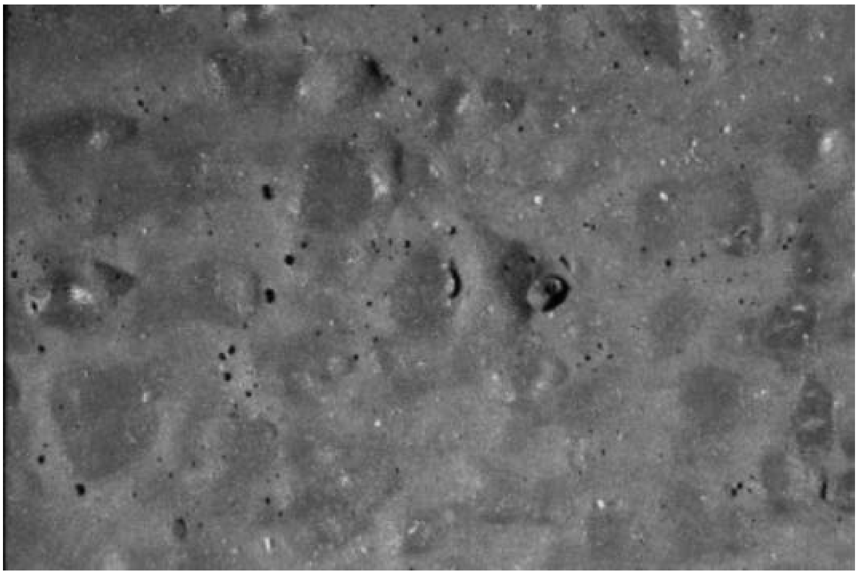

**Figure 8. Surface photographs: acrylic resin's paint (PVC 45) after 325 cycles**

## 7 NATURAL WEATHERING RESULTS

Finally here are presented some first results coming from the outdoor exposure of wall samples (Fig. 9), in Milan and Lugano, as photographs of vinyl resin's painted surface (Fig. 10): after two years we have the same degradation effects with cracks in the protective film as we measured in laboratory aging (Fig. 7).

Go Back Next Page

**Figure 9. Outdoor natural aging samples**

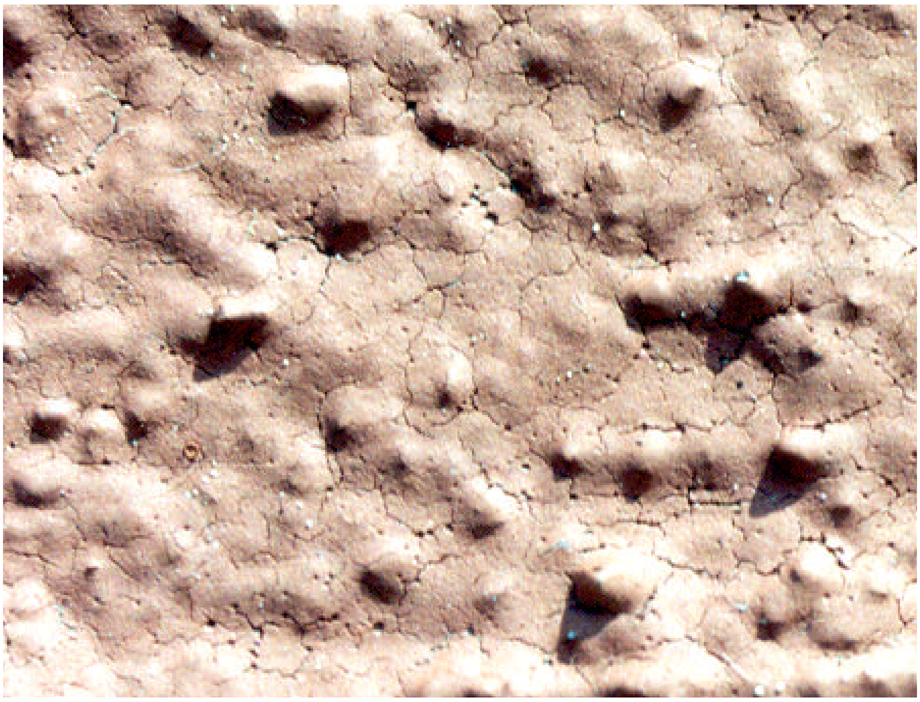

**Figure 10. Surface photographs of outdoor natural aging samples with vinyl resin's paint**

It means that the laboratory aging cycle actually simulates the outdoor conditions, and then it's possible to work on the evaluation of the time re-scaling coefficient, i.e. the ratio between the paints' service life and the number of lab aging cycles.

## 8 CONCLUSIONS

The analysis of the experimental results of this first part of research bring us to the following conclusions:

- The protective degrees to water for the used paints could be evaluated, through the measurement of the mass increase of samples subject to aging cycles (Fig.2) and through the capillary absorption difference between painted samples and plaster (Fig.3);

Go Back

  - The acrylic resin's paints have shown a better protective degree to water, compared with the vinyl resin's paints;
  - The higher resins' content allow to obtain a better protective degree;
- During accelerated laboratory aging tests the paints' differences in the time behavior could be evaluated, with the detection of degradation effects, through microscope's structural analysis (Figs 5 and 6) and through surface photographs (Figs 7 and 8)
  - The vinyl resin's paints have shown more relevant degradation effects, after a lower number of aging cycles, when compared with the acrylic resin's paints.

It's evident that these visible damages are linked with the decay of functional and protective characteristics, as the water permeability. Finally we can say that after this first experimental phase we could evaluate the paints' protective degree to water in laboratory through mass increase and capillary absorption. The kind of resin and its content have demonstrated to be the most important parameters to influence the paints' protective degree.

These conclusions are partial as they are regarding only the external layers of the wall component, while the evaluation of component's service life will be obtained at the end of aging tests on the whole wall; actually in the first experimental phase the samples are collocated inside the weathering cell while in the second experimental phase the samples of the whole technical solution will be positioned as the door of the cell, and will be subject to aging cycles simulating the external climate, and to gradients of temperature and vapor pressure between the indoor and outdoor environments, to simulate realistic functioning conditions. Nevertheless the results of this experimental phase demonstrate that the adopted methodology allows to measure the service life of protective paints comparing lab results with outdoor natural aging ones.

# Building Components' Durability, Maintenance Planning And Sustainability

**P N Maggi**
**Politecnico di Milano DISET Milan Italy**

**Summary: The paper highlights the importance to know building components durability to operate their choice in compatible terms with regards to their use sustainability as for the differentiated obsolescence of building parts and for a useful building maintenance planning.**

**We point out particularly the reasons why to decide different maintenance typologies to set up the maintenance works planning for different components of the designed elements, depending on their reliability and service life.**

**We propose criteria for the risk probability estimation of early failure that may appear during building components predicted service life, entailing emergency maintenance works, caused by design and/or execution mistakes; this probability may be estimated from values of functional, inherent and critical reliabilities (design pathologies) or from values of component executive reliability (execution pathologies).**

**We conclude highlighting the importance to correlate the choice of building components to their durability (reliability and service life) with the aim to optimize it towards the sustainability of the whole building and of its parts. In fact, if on one side the choice of a building component must at first depend on the fact that it shall supply adequate initial technological performance levels to contribute efficiently, within the building design orchestration, to the fulfillment of the expected environmental conditions, on the other side among different components soundly designed from this point of view, one shall opt for the component that relatively optimizes durability and sustainability.**

**This will need that the chosen component will have a service life functionally and economically coherent with the expected service life of the whole building where it's inserted and that technologies and materials of the elements which constitute the component will supply an acceptable economic and energy saving of the engaged natural and artificial resources.**

**In this balance it should be taken into account also the actual evaluation of the future building parts' substitutions and of the building demolition, estimating the operative potentiality to recycle disused materials.**

**Keywords: components, maintenance, management, sustainability**

## 1 INTRODUCTION

It's important to observe that quality and sustainability are cares that shall permeate the entire decisional process for buildings' design and that they shall be considered at different levels: from territorial planning, to environmental and functional – spatial design of buildings, to technological, executive, operative, management – maintenance and economical design.

Quality and sustainability assume different connotations and peculiarities at this various indicated levels. They constitute steps of the decisional chain and the sequence of decisional acts that follow will be so much valid as the cares taken on quality and sustainability will be adequate and balanced for each step of the chain.

Within the framework of this preamble it's included the phase of building components' technological design, complex and articulated in sub – phases, that assumes relevant importance within the whole building technological design.

It's important to highlight that the distribution of performance loads among the technological subsystems and related technical elements prefigures the behavior and functioning of the building that will be designed and realized, and substantiates the contents of the so-called building technological program of performance specifications.

At first it's needed to observe that the different technological parts of a building shall be designed and realized to contribute adequately to obtain the environmental and functional – spatial quality that the designer has defined as an objective to be pursued.

Here is the complex and crucial question of planning the technological performances' specifications to assign to the building's technical elements, that is the performance loads to distribute to the different building's parts in a way to allow them, as a whole, to give the necessary contribution to obtain the target environmental and functional – spatial quality.

What has been now expressed is referred then to the components' performance specifications planning, that is to the preparatory phase for the technological design of the elements that are intended to be applied to the specific building.

It's to remember that in this planning are to be considered also the durability performances' specifications of technical elements (useful quality of elements), the operative performances' specifications, regarding the economically and operatively acceptable construction (elements' operative quality), and the maintenance performances' specifications, concerning the economically acceptable maintenance activity (elements' maintenance quality).

The components' technological performances' planning constitutes then the input that binds the following phase of technological design, and it's the first step of the decisional chain regarding the technological design of the building and of its parts. This step will be so much "strong" as the cares upon the aspects related to quality and sustainability will taken into account.

## 2 THE BUILDING COMPONENT'S TECHNOLOGICAL DESIGN

The technical elements technological design represents a complex phase because it shall bring to components that achieve a relative optimization for the different aspects of quality that characterize them. These aspects are presented in the following table 1.

First of all the aspect related to the assignment of initial quality (zero time) to the component coherent with the technological performances' specifications.

It implies to face the technical element's design defining the technological functions that must be fulfilled for each technological requirement and for the corresponding performance's specification.

The component must be evaluated also in terms of the estimation of its functional reliability. This evaluation is worked out in particular on the building component's object model and it' based on the examination of the distribution of analytical functions on the different elements of the component; this functions' distribution may imply a major or minor risk of performance loss in relation with the fatigue to which the components' functional elements are subject in service conditions.

The judgments categories are three: the object model's simplicity, the fatigue implied by the model, the distribution of analytical functions on the model's functional elements. It's obvious that the results of this evaluation could bring to feedback on the component's design.

The second quality aspect that must be taken into account for the component's design is related to the assignment of useful quality (quality over time), coherent with the planned durability performances' specifications.

It's to verify that the service life and the reliability over time of the technical element and of the functional elements that constitutes it are compatible with these performances' specifications. We remember that the information about service life is lacking and not so much reliable, and it's for this reason that the experimental research is being developed on this problem; on the other hand a method for the estimation of the reliability over time, which can be worked out by calculation, is already available (Rejna 1995). It allows, for the moment partially, to work out this verification and to control for this aspect the component's sustainability, which is here an important control.

A third aspect of quality that must be taken into account for the component's design is related to the assignment of construction quality (operative quality), coherent with the planned operative performance's specifications. It's to verify the component from the point of view of the executive complexity that it implies.

**Table 1. Evaluation of conventional quality of the building component**

<table>
<tr><td colspan="2">CONVENTIONAL QUALITY:<br>qualitative classification of components through an indicator of performance propensity related to an objective function that for each class of technical elements define it in relation with specific requirements for that class<br>SPECIFIC REQUIREMENTS:<br>behavior requirements necessary for the right development of the expected functions characteristic for the class of technical elements</td></tr>
<tr><td colspan="2">$Q_p$ = conventional quality   $r_{1,k}$ = requirements   $p_{1,k}$= performance levels<br>$$Q_p = Qp(p_1, p_2, ...p_k)$$</td></tr>
<tr><td>PERFORMANCE PROPENSITY COMPONENTS</td><td>REFERENCE REQUIREMENTS</td></tr>
<tr><td>$Q_c$= characteristic technological quality<br>performance quality at zero time, out of system and context</td><td>behavior technological requirements specific for a class of technical elements</td></tr>
<tr><td>$Q_u$= useful technological quality<br>product aptitude to maintain initial characteristic technological performance levels $Q_c$</td><td>technological requirements specific for the time behavior:<br>durability,<br>reliability,<br>service life</td></tr>
<tr><td>$Q_m$= maintenance technological quality<br>product aptitude to obtain specific levels of maintenance</td><td>technological requirements specific for a maintenance propensity:<br>controllability,<br>aptitude to cleaning,<br>reparability,<br>aptitude to substitution.<br><br>Parameters:<br>availability,<br>mean time of reparation</td></tr>
<tr><td>$Q_o$= operative technological quality<br>product aptitude to obtain specific levels of economy and operability in the construction phase</td><td>technological requirements specific for the operative technological quality:<br>economy of product,<br>economy of necessary machinery<br>economy of necessary workmanship<br>economy of necessary controls<br>economy of production</td></tr>
</table>

This verification is based in the evaluation of the possible differences between the technical element's design and the built technical element, taking into account that the construction errors appear substantially during the phase of component positioning and during the phase of assembly of materials, sections, units executed in a different way from the design indications. The risk of these errors is as much higher as the technological – dimensional complexity of the component is higher.

The technological – dimensional complexity can be evaluated on the base of judgment's criteria for the product object and relation complexity. It allows to improve the component's design to increase its operative quality and to control the sustainability for this aspect. It means that one have to take care, during the component's design phase, of the operative instructions for the component's construction and of the safety problems on the building site.

A fourth quality aspect that must be taken into account for the component's design is related to the assignment of maintenance quality (maintenance quality), coherent with the defined maintenance performance's specifications, concerning economically and operatively acceptable maintenance activities. It's to verify the component from the point of view of the so-called availability for the maintenance. This verification is based in the evaluation of the intrinsic availability of the building component which can be calculated as ratio 1/MRT where MRT is the Mean Reparation Time of the component intended as the mean value of the reparation times for each functional layer of the component, regarding the possible failures that may occur.

The methodology to estimate the availability, to find the possible failures and to calculate the Mean Reparation Time is available.

This allows to have a feedback on the technical element's design to increase its availability ant to verify its management sustainability.

A fifth quality aspect that must be taken into account for the component's design is related to the verification of chemical – physical compatibility that characterizes the different materials that constitutes the functional elements of the building component. These kind of incompatibilities compromise during time, in a more or less accelerated way, the structural integrity of the component causing the collapse, and reveal errors in the component's design presaging of early pathologies (design pathologies).

The evaluation of chemical –physical compatibility (critical reliability) is based on the analysis of the degree and number of incompatibilities at the interface between the functional elements of the components and between the products that constitute the functional elements of the component itself. It's available a method to use for this evaluation (Rejna 1995).

The estimation of chemical –physical compatibility of the component allows to have a feedback on the technical element's design to eliminate the design errors on this fundamental aspect and the probable pathologic phenomena, as to bring back the component's design to the necessary level of sustainability.

A last important quality aspect that must be taken into account for the component's design is related to the verification of inherent quality. The inherent quality is regarding the control about the activation of inherent phenomena that appears during the component's service life because of the seasonal thermal and relative humidity variations of the outdoor environment in the component's use conditions.

These variations appear in the different component's functional layers, and if their intensities are very different in the various layers because of the diversity in values of thermal and humidity dilatation coefficients for the constituting materials, the different dimensional variations between layers will generate stresses that can determine cracks at the interfaces between layers and between the component and the connections with other components (joints), because of the binds that can prevent from a free "dimensional gymnastics".

The verification of inherent quality is based on the evaluation of inherent reliability, that uses different parameters and criteria presented in the existing evaluation method (Rejna 1995).

This verification allows to have a feedback on the design of the component and of its connections, with the aim to eliminate the design errors on this aspect and the probable pathologic phenomena (design pathologies), as to bring back the component's design to the necessary level of sustainability.

We have already mentioned the possibility to evaluate the building component's reliability at service life time, that is the "probability" that the component's service life will be like that. For this aspect it's possible to refer to an already available method that our Department has developed.

This method can be applied on the base of a careful examination of the component's design through a functional and technical analysis of the design itself.

These analysis are done for the four aspects of reliability, and exactly for the functional, executive, inherent and critical aspects (Table 2), that is about the balance degree in the distribution of the analytical functions in the functional elements of the component, on the foreseeable conformity degree of the execution of the component to the design intentions, on the uniformity degree of dimensional changes between the functional elements of the component, throughout its practice, due to the stressing context, on the degree of chemical-physical compatibility characterizing different materials which are the functional elements of the component.

Every analysis about the four aspects of reliability is carried on following some right procedural directions that we have to do for these tests.

**Table 2. Evaluation of the reliability at life time of the building component**

| | |
|---|---|
| **$A_F$** | **Functional reliability.** Balance degree in the distribution of the analytical functions in the functional elements of the component estimating through the observation of the functional model of the component. It's an index of the stress to which the component will be subjected in its practice phase. |
| **$A_E$** | **Executive reliability.** Degree of foreseeable conformity of the component execution at the intentions of the project. It's an index of the foreseeable precision in the installation of the component. |
| **$A_I$** | **Inherent reliability.** Degree of uniformity of dimensional changes between the functional elements of the component throughout its performance in comparison with the stress context. It's an index of functional integrity of the component in its practice phase. |
| **$A_C$** | **Critical reliability.** Degree of chemical-physical compatibility which characterizes the different materials making up the functional elements of a component. It's an index of structural integrity of the component. |

The average of four values of reliability is engaged like a tendency to the reliability of the natural durability of the building component. It's a very useful method because it offers the opportunity to estimate the tendency to the reliability of the natural service life of the building component without waiting for so long testing time required by a right estimation of the reliability.

Now knowing the durability (service life and reliability) for building components is fundamental to choose them as compatible with the sustainability of their use as a function of the differentiated obsolescence of building's parts and in particular, for an optimal decision about the maintenance typology to be adopted, to which refer for the maintenance works' planning (Table 3)

**Table 3. Choosing criteria for maintenance typologies**

| **PROGRAMMED MAINTENANCE WORKS** | |
|---|---|
| Maintenance typologies after failure | Components with very high reliability at life time (for not bistable components, i.e. that doesn't pass suddenly from functioning to not functioning situation) |
| Threshold preventive maintenance typologies: for the substitution at a constant age or at constant time steps during service life period | Components with high reliability at life time (for bistable components, i.e. that pass suddenly from functioning to not functioning situation) |
| Maintenance typologies under condition: reparation and substitution maintenance works after inspections, with planned frequency, with the partial or total failure observation | Components with low reliability at life time (for not bistable components) |
| **NOT PROGRAMMABLE MAINTENANCE WORKS (EMERGENCY)** | |
| Emergency maintenance typologies: | Components with: very low functional reliability, very low inherent reliability, very low critical reliability (for bistable and not bistable components) |
| Opportunity maintenance typologies: decision of maintenance works anticipated on other building components in occasion of needs for emergency works on a component or on a component's subsystems | Not bistable components |

Go Back

In fact, for equal service life, the estimation of reliability at life time allows to adopt the optimal maintenance typology, and the complement of one of the estimated value guides on the risk of failures which can appear during the component's service life; on the other side the complement of one for the estimated values of the different components of reliability at life time of the building component guides on the risk of failures caused by design pathologies and by pathologies due to the component's on site construction phase.

The occurrence of design pathologies is indicated by the complement of one for the component's functional, inherent and critical reliability values. The occurrence of the component's construction pathologies is indicated by the complement of one for the component's executive (construction) reliability value. We highlight that these pathologies can bring to the need of emergency maintenance works and then not programmable ones.

We conclude observing the importance to correlate the building components' chose to their durability (reliability and service life) with the aim to optimize it with regard to quality and sustainability of building as a whole and in its parts.

In fact if on one side the building component's chose shall depend firstly upon the fact that it should supply adequate levels of initial technological performance to contribute efficiently, within the building design orchestration, to the target environmental conditions fulfillment, on the other side among various components valid from the design point of view, one shall opt for the component which relatively optimizes durability and sustainability.

This requires that the individuated component has a service life functionally and economically coherent with the target one for the entire building where it's inserted and that the technologies and materials of elements which constitute the component will correspond to an acceptable economic and energy consumption of used natural and artificial resources.

In this balance it shall be introduced with the right weight also the actual evaluation of future substitutions of building's parts and of building's demolition, estimating the operative potentiality to recycle the disused materials.

# Crystallisation Tests On Treated Brick/Stone Masonry Specimens For Damage Evaluation

**G Cardani C Tedeschi L Binda G Baronio**
**Department of Structural Engineering Technical University of Milan Italia**

**Summary: It is known that water-proof and consolidant surface treatments cannot be carried out in presence of soluble salts due to the possible formation of cryptoefflorescences causing detachment of the treated parts. An European Community (EC) contract was developed aimed to establish the maximum salt content below which the surface treatment do not fail. A large number of crystallisation tests was carried out on single components (bricks and stones) and on masonry wallettes treated with a water repellent and a consolidant. Different types of salt solutions and different salt concentrations were used. The test was carried out according to RILEM recommendations; the long term damage caused by the salts was measured by visual inspection, photographic survey and laser profilometer. The laser device allows for measurements along chosen profiles on the surface masonry: it is so possible to quantify with the variation of the profile depth over time, the loss of surface material. This value has been used as a suitable parameter describing the time and extent of the material deterioration process.**

**Keywords. Durability, Brick and Stone Masonry, Crystallisation test, Surface treatments**

## 1 INTRODUCTION

Applying surface treatments to prevent masonry decay is an easy and common but costly practice which is thought to avoid or reduce masonry damage and hence delay the ordinary maintenance. Research carried out in the past have reached the conclusion that water proof and consolidant surface treatments cannot be carried out in presence of soluble salts due to the possible formation of cryptoefflorescences causing detachment of the treated parts. Nevertheless it is known that some percentage of soluble salts is always present in a masonry, an EC contract was developed in order to establish, in water presence, the maximum salt content below which the surface treatment do not fail. Crystallisation tests, following RILEM TC 127 MS Recommendation, were carried out, at D.I.S, Polytechnic of Milan, on single components (bricks and stones) and on wallettes treated with a water repellent and a consolidant. Different types of salt solutions and different salt concentrations were used.

The chosen test is useful to verify in laboratory the performance of brick(stone)/mortar system, also controlling the behaviour under surface treatments. The aim of the test is also prevention, design and quality control of jointing and pointing, or even re-pointing mortars on a masonry support, reflecting the site situation. The test is carried out according to RILEM recommendations; the long term damage caused by the salts is measured by visual inspection, photographic survey and laser profilometer. From previous research [Binda et al, 1992], it was shown that since the salt damage in a masonry or porous material proceeds from the external surface to the interior, the loss of material measure as a profile damage can be used as a parameter to measure and monitor decay [Baronio et al, 1993]. The laser device allows for surveying chosen profiles on the surface masonry, qualifying with the variation of the profile depth over time, the loss of surface material. This value has been used as a suitable parameter describing the material deterioration process. Usually the durability tests, which require long term and hence high costs, are carried out on single masonry components, brick, stone or mortar [Binda et al., 1985], [Van Hees et a., 1996]. Nevertheless in the last decade it became clear the limit of tests on single materials, when it is necessary to predict the durability of a masonry. It was in fact found by the authors already in 1985 [Binda & Baronio, 1985], that in a wall the mortar has a large influence on the durability of bricks under salt crystallisation decay, according to the porosity characteristics of the two materials. Therefore a crystallisation test on wallettes using as ageing agent a soluble salt was suggested, the test set up by TNO (Delft, NL), was included in the RILEM TC127MS Recommendations [RILEM MS. A.1, 1998].

Within the above mentioned EC Contract the wallette test was carried out on some of the materials proposed by the Italian Partner in order to control whether the threshold value of salt concentration found in a previous part of the research for the single materials could be applied also to masonry walls. According to the EC contract, the salt concentration depends on the capillary moisture content (named CapMC) which is calculated on the basis of the water absorbed by capillary rise in 48 hours. The results of the salt crystallisation tests suggested that, for the treated single substrates, the lowest concentrations chosen

(1% and 2.5% of CapMC) can be considered as threshold value of the salt compatibility. Nevertheless in the equivalent untreated substrates, after 7 months, also the lowest salt concentrations were able to produce small efflorescences.

In order to test whether or not this value can still be considered as a threshold value for masonry the same low salt concentrations were used for the wallettes: 1% and 2.5% of capillary Moisture Content of the single units. $Na_2SO_4$ was used for all the type of masonry specimens while the $MgSO_4$ was used only for softmud bricks and serena sandstone. $Na_2SO_4$ is one of the most tested salts due to the high damage it is causing to porous materials. $MgSO_4$ can also cause high damage and it was used since it is frequently found in Northern Italy damaged walls.

## 2 PROCEDURE OF THE CRYSTALLISATION TEST ON WALLETTES

The test, according to the RILEM Recommendations [RILEM MS A.1., 1998] detects the durability of masonry which is exposed to moisture variations in a wall, in the presence of soluble salts. The long term damage caused by the salts was measured by visual inspection, photographic survey and laser profilometer.

A wallette (250x200x120 mm) is put in contact with its back side with a salt solution at a chosen concentration and then stored over a layer of dry gravel in a plastic container (open at the top) with the upper face exposed to the environment (controlled laboratory environment of 20°C and 50% R.H.). After closing the remaining open spaces of the container with polystyrene foam strips, evaporation can occur only through the upper surface of the wallette and on that surface the decay is surveyed (fig. 1a,b).

Each four weeks the wallettes are subjected to: a) photographic survey; b) cleaning from efflorescences and detached material with soft brush and a vacuum cleaner; c) again photographic survey; d) description of the observed damage, e) reading the surface profiles by means of the laser profilometer allowing for a quantitative measurement of the surface decay. Demineralized water is added after three months, when approximately the wallettes are approaching the constant mass in order to start a new cycle and to accelerate the damage.

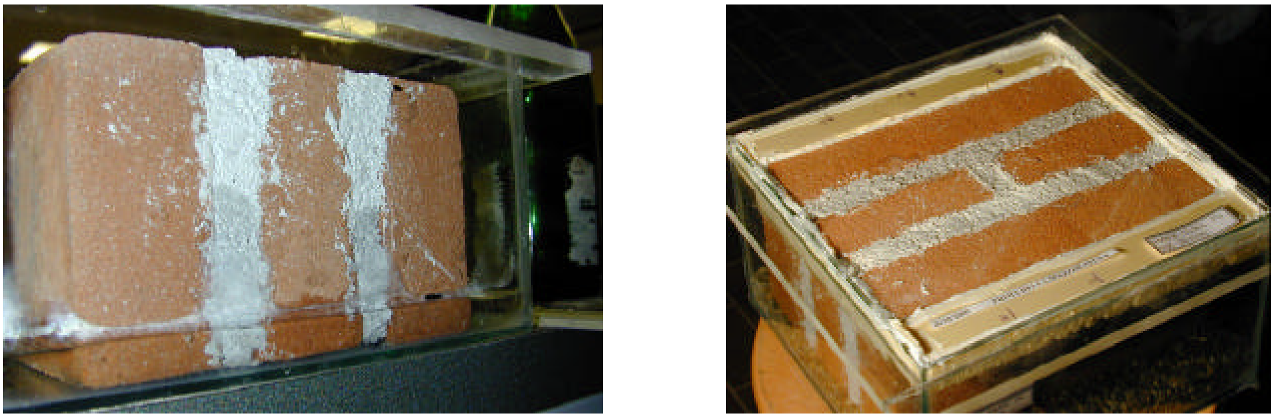

**Figure 1. Preparation of the specimen: a) a wallette is contaminated with salt solution b) the wallette stored on dry gravel into a container and evaporation is allowed from the top surface**

## 3 DAMAGE MEASUREMENT

During their service life, masonry structures, subjected to an aggressive environment, may suffer surface decay according to the type of their components and the construction technique. The great randomness connected with the occurrence of critical attack suggests approaching the deterioration process in a more precise way and with different methods. Deterministic models are yet not available to study the complex behaviour of masonry. Nevertheless once the decay can be measured continuously through a representative parameters, non-deterministic ways can be found to model the decay [Garavaglia et al. 2000a]

### 3.1 Visual and photographical inspection

The chosen test tries to represent the crystallisation phenomenon in a real exposed wall. The formation of efflorescence and sub-efflorescence is connected to migration of salt solutions toward the surface following water evaporation. A brief description of how the wallettes evaporation surface appears and changes over time is important to qualify the type of efflorescence and their localisation (fluffy, bristle, crust, etc.), to define the type of visible damage and to distinguish the effect between the masonry components. In addition it allows for better comprehension of the phenomenon and for controlling constantly the reliability of the quantitative measurements over time. Appropriate photographic documentation is also collected at every inspection.

### 3.2 Laser profilometer

A laser profilometer was used to monitor the damage. The use of the laser profilometer allows for measuring, with a very good resolution, the loss of material from the exposed surface calculated at subsequent times (Fig. 2) [Berra et al. 1993]. Subsequent surveyed profiles show how the surface is changing over time due to the progress of the decay and the loss of material can be measured. Figure 3 shows an example of diagram for the measurements made.

The presence of the typical swelling phenomenon of the surface can compromise the damage measurements. Since bulging is the previous step before detachment, when salt crystallises before the surface, it is possible to consider it as the starting point of a damage. Therefore, through a simple model the experimental measurements have been converted in new deterioration diagrams where the bulging has been eliminated, but considered as a starting point of decay [Garavaglia et al. 2000b]. Single components can also be distinguished to evaluate the different behaviour of the materials when combined. By calculating at each survey the percentage of the area loss of the specimen section, normal to the profile, area loss against time can be represented (Fig.4).

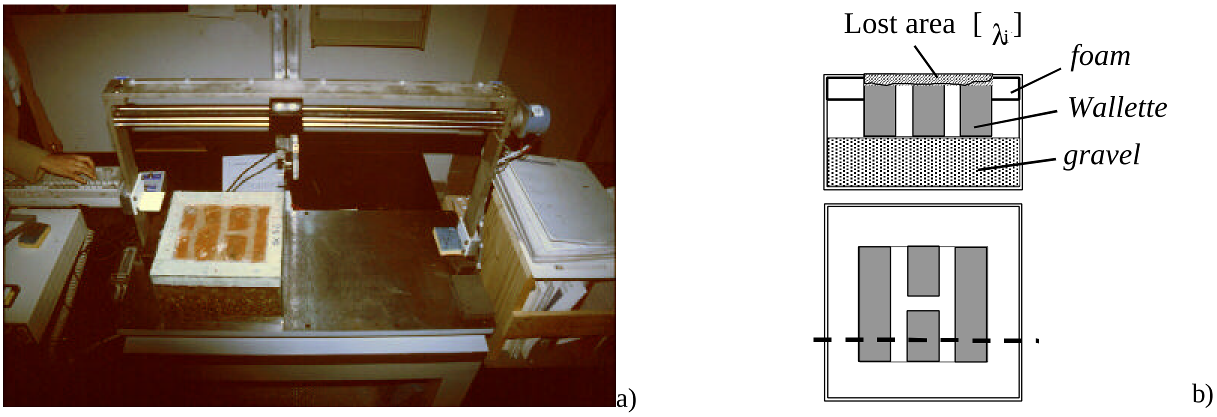

**Figure 2. a) Laser profilometer device and b) scheme of the measurements**

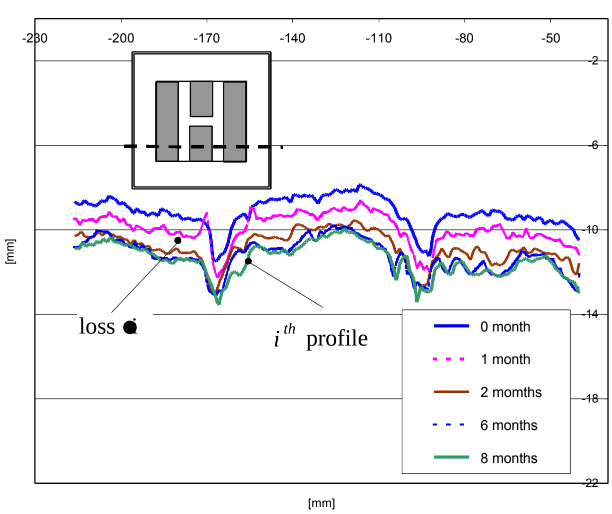

**Figure 3. Example of the first measurements realised with laser profilometer on one wallette**

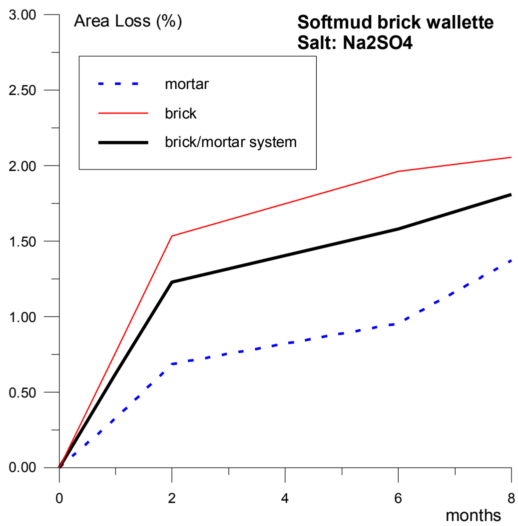

**Figure 4. Deterioration vs. time: example of damage diagram on an untreated brick-wallette**

## 4 MATERIAL PROPERTIES, SALT CONCENTRATION AND TYPE OF TREATMENTS

Crystallisation tests were carried out on one type of softmud contemporary brick used for restoration and on three different natural building stones: (a) Noto limestone, (b) Serena sandstone, (c) Savonnière limestone from France. A physical and mechanical characterisation of the masonry units is reported in Table 1.

All wallettes were realised with bedding joints, 15 mm high, based on putty lime (PLB), except for Savonnière stone wallettes, where a mix of hydrated and hydraulic lime (HHLB) was used. Only in some softmud brick wallettes, a pointing mortar was added (HLP). See Table 2.

In the case of wallettes that were to be pointed, the bedding mortar was left recessed for a depth of 2 cm. Curing conditions: the wallettes after construction were covered for a couple of days with plastic sheets. Then they were moved to a climatic chamber with 20°C and 90% R.H. for 3 months. For wallettes that were to be pointed, pointing was set up after verification of carbonation of the bedding joints and then they were cured at 20°C and 65% of R.H.

**Table 1. Physical characterization of the masonry units**

| | | *Bulk density* (Kg/m$^3$) | *Porosity* (% vol.) | *Capillarity coeff.* (g/cm$^2$/h$^{-0.5}$) | *CapMC* *(%)* | $\sigma_t$ dry | $\sigma_t$ wet |
|---|---|---|---|---|---|---|---|
| Softmud Brick | (SMB) | 1546 | 35.7 | 2.10 | 21.70 | 0.93 | 0.89 |
| Noto limestone | (NO) | 1856 | 29.04 | 0.75 | 12.87 | 2.82 | 1.32 |
| Savonnière limestone | (SA) | 1682 | 18.82 | 0.34 | 9.47 | 1.35 | 0.95 |
| Serena sandstone | (SE) | 2600 | 5.19 | 0.25 | 0.57 | 6.83 | 3.54 |

**Table 2. Classification of the mortar**

| | | |
|---|---|---|
| Bedding mortar: | (PLB) | Putty lime + calcareous sand (max agg. $\phi$ = 4 mm) – Ratio: 1 : 2.7 : 0.2 |
| | (HHLB) | Hydrated lime + hydraulic lime + siliceous sand (max agg. $\phi$ = 4 mm) – Ratio: (0.5 : 0.5) : 3 : 0.8 |
| Pointing mortar: | (HLP) | Hydrated lime + calcareous sand (max agg. $\phi$ = 2 mm) – Ratio: 1 : 3 : 0.8 |

Wallettes were treated, immersing the upper surface into the treatment for 10 seconds for the water repellent and 30 seconds for the consolidant (Table 3). One wallette was left blank for each material to be used as a reference for the decay. Then the wallettes were contamined with salt solution and submitted to the crystallisation test following [RILEM TC 127 MS A.I, 1998]. According to the results achieved with the crystallisation test on single masonry units [Garavaglia et al., 2001], damage was always observed for the highest concentrations tested (5% or 7.5% of Cap.MC.) and in many cases for the lower concentrations (2.5% or 5% of Cap.MC), but never for the minimum (1% of CapMC), which could be considered as a threshold value.

As previously mentioned, it was assumed within the EC contract that the salt concentration depends on the capillary moisture content (CapMC) which is calculated on the basis of the water absorbed by capillary rise in 48 hours. In each specimen an amount of salt solution was introduced, according to [RILEM MS.A.1, 1998] with different salt concentrations for each type of salt: 1% and 2.5% of Cap.MC. These percentages are the lowest salt concentrations used for the single units, chosen also for wallettes in order to verify whether or not these values can still be considered as a threshold value for brick(stone)/mortar composed. $Na_2SO_4$ was used for all the type of masonry specimens while the $MgSO_4$ was used only for a part of softmud bricks and serena sandstone. See Table 3 and 4.

The Water repellent is a solventless silicone microemulsion concentrate based on silanes and siloxanes, diluted with water to yield microemulsion. The Consolidant mainly consists of reactive silicic acid ethyl ester compounds. The material was especially developed to strengthen and consolidate weathered natural stone as well as terracotta, brick, stucco, fresco and loam. The choice of these treatments is suggested by their large use.

**Table 3. Treatments and salts used for the wallettes**

| *Surface* *treatments* | | *Type* *of salts* | |
|---|---|---|---|
| Water repellent | (WR) | $Na_2SO_4$ | (SS) |
| Consolidant | (C) | $MgSO_4$ | (MS) |

**Table 4. Mean value of the salt solution inserted in the wallettes**

| *Wallettes* | *% salt referred to* | |
|---|---|---|
| for all type of units | *1%* | *2.5%* |
| *Wallettes* | *w% of the dry specimen* | |
| Softmud Brick | 0.23 | 0.57 |
| Noto limestone | 0.16 | 0.38 |
| Savonnière limestone | 0.04 | 0.07 |
| Serena sandstone | 0.14 | 0.34 |

## 5 EXPERIMENTAL RESULTS AND DISCUSSION

### 5.1 Softmud brick wallettes

#### 5.1.1 Crystallisation test with $Na_2SO_4$

*a) untreated wallettes*

The damage for the lowest concentration (1%) was very little in the first three months, then it started uniformly in the bricks and in the mortar joints. With the highest concentration (2.5 %) the damage became soon serious due to cryptoefflorescences for both materials (Fig. 5a and Fig.8a,b).

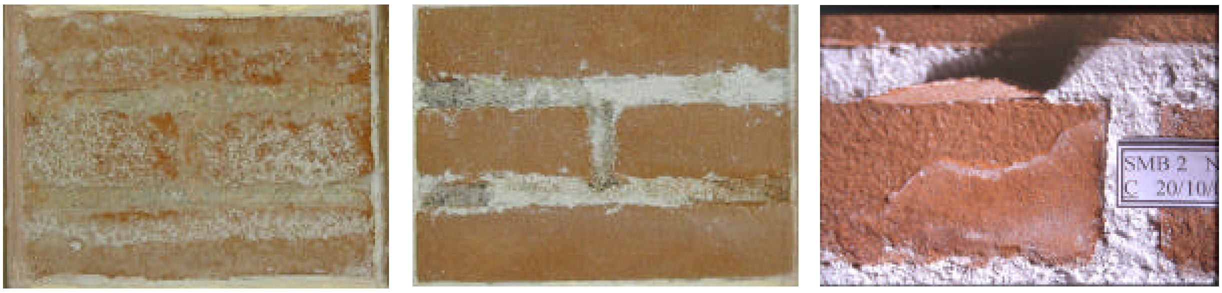
*b) water repellent treatment*

In the first three months both bricks and mortars presented no damage. After three months damage was visible in large part of the mortar joints. The treated bricks with the two salt concentrations do not present damage also in the 8 first months. On the contrary the mortar, as the only vehicle to water evaporation, was damaged over time (Fig.5b and Fig.8a,b).

*c) consolidant treatment*

In presence of consolidant, the damage seems to be, at the beginning, the contrary of what happened to the ones treated with water repellent: the damage started from the brick and then diffused to the mortar. With 1% of salt solution: after 6 weeks not many efflorescences were visible. Then the treated bricks presented soon some scaling of surface layers (2-3 mm), above all in the central bricks surrounded by the mortar (Fig.5c). After 8 months (Fig.8a,b) efflorescences were all over the wallettes and the bricks still have been delaminating (layers of 1,2 mm) and powdering. Mortar did not present particular damage. With 2,5% of salt solution: the treated bricks presented soon cryptoefflorescences starting from the interface brick/mortar and then after 6 months spalling of layers is still continuing. After spalling the treated bricks become sufficiently porous to allow the evaporative flow all over the wallette, without compromising necessarily the mortar, as in the case of water repellent.

As the material loss in untreated wallettes after the same period of time is equal to the ones treated with consolidant, this treatment with this type of bricks seems to be unnecessary to prevent salt crystallisation decay. Up to now no damage is visible on bricks treated with water repellent with both salt concentrations, but the passed experiences suggest to continue the test. In fact, after cutting of the specimen treated with water repellent at 2.5% of salt concentration, a small line of salt was clearly visible under the treated layer (Fig.7a).



Untreated a) Water Repellent b) Consolidant c)

**Figure 5. Softmud brick wallettes with $Na_2SO_4$**

#### 5.1.2 Crystallisation test with $Na_2SO_4$ in presence of Pointing mortar

*a) untreated wallettes*

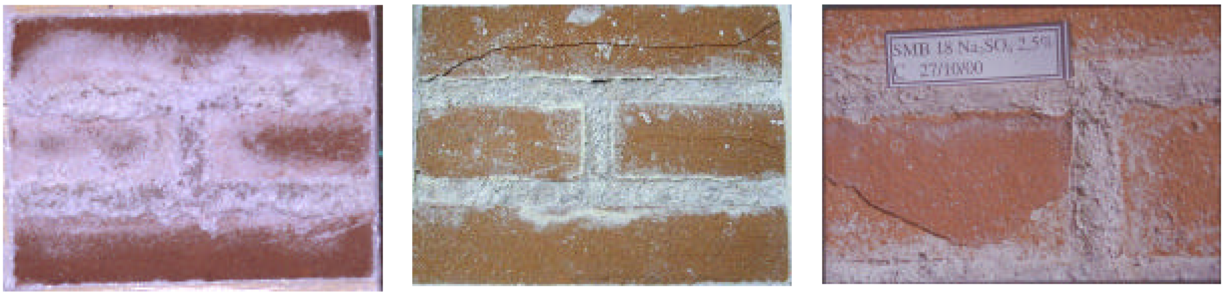
The damage started from the brick/mortar interface and extended to the rest of the bricks causing powdering on all wallette surface for both salt concentrations. The effect is slower compared to the specimens with only bedding mortar (Fig.6a).

*b) water repellent treatment*

As observed in the previous case, in the first months, bricks, treated with water repellent, did not present damage while on the contrary the pointing mortar joints showed serious damage with loss of material > 2mm. However this material loss is less then the one of the bedding joints of the wallettes seen before. After 6 months, the bricks with 2,5% salt concentration suddenly showed a crack on their surface (Fig.6b and Fig.8c,d) and, after cutting, a surface layers detachment of 7-9 mm was observed on all bricks (Fig. 7b and c).

*c) consolidant treatment*

The bricks treated with consolidant, already at the first months, presented detachment of the treated layer, 1,2 mm thick (Fig.6c and Fig.8c,d), and then the bricks became untreated showing uniform powdering. This effect is visible also with the lower salt concentration but more slowly. The pointing mortar presented no visible damage.



Untreated a) Water Repellent b) Consolidant c)

**Figure 6. Softmud brick wallettes with Pointing with $Na_2SO_4$**

a) b) c)

**Figure 7. Softmud brick wallettes, particulars of the damages with WR: a) with 2.5% of $Na_2SO_4$ b) and c) with 2.5% of $Na_2SO_4$ in presence of Pointing**

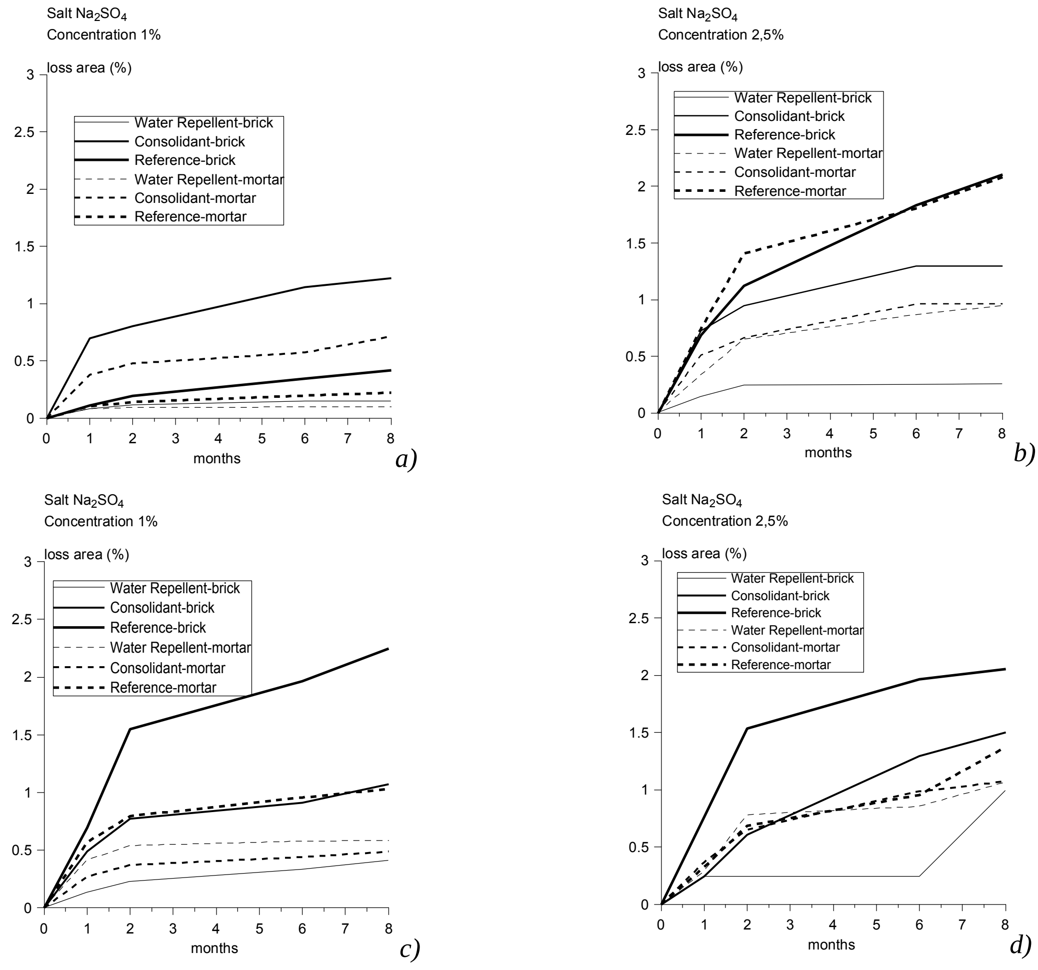


**Figure 8. Deterioration vs. time: damage diagram on a brick-wallettes *a)* and *b)* without pointing and *c)* and *d)* with pointing**

5.1.3 3) Crystallisation test with $MgSO_4$

*a) untreated wallettes*

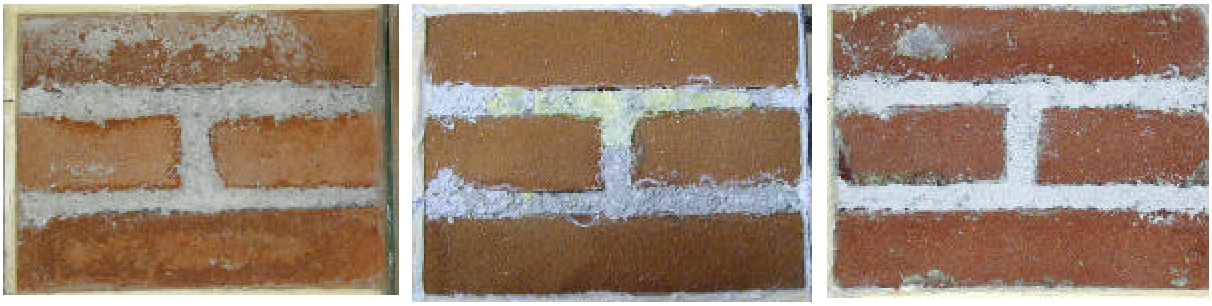
Powdering of the two materials together with hard crusts are visible as in Fig.10. Typical of the $MgSO_4$ is the “wet effect” (Fig.9a).

*b) water repellent treatment*

No damage is visible on bricks and yellow efflorescences are visible on bedding joints (Fig.9b). For the higher concentration some efflorescences are visible also on bricks at the mortar/brick interface.

*c) consolidant treatment*

As observed in wallettes with the sodium sulphate, the consolidant causes more damage in the bricks than in the mortar (Fig.9c).



Untreated a) Water Repellent b) Consolidant c)

**Figure 9. Softmud brick wallettes with $MgSO_4$**

## 5.2 Noto limestone wallettes

5.2.1 Crystallisation test with $Na_2SO_4$

*a) untreated wallettes*

Efflorescences started from the stone/mortar interface but the damage for the lowest concentration (1%) was very poor in the first three months, then it was still concentrated near the mortar joints (Fig.10a). With the highest concentration (2.5 %) the efflorescences were more evident in the stone/mortar interface and the powdering of the stone was increased (Fig.11a,b).

*b) Water repellent treatment*

With the lower concentration the damage started slowly and no particular surface decay was visible on wallettes after the first 3 months. After 6 months the damage due to the presence of water repellent became serious showing exfoliation and spalling of stones (Fig.10b).

With the higher salt concentration the stone damage was serious from the beginning showing spalling of layers of about 1,4 mm. After 8 months the observed damage for both concentration was similar. Mortar joints showed damage with the two concentrations (Fig.11a,b).

*c) Consolidant treatment*

In the short period of 1 month, the stones, also with the lower concentration of salt, presented detachment of a thin layer (about 0,65 mm). See fig.10c. After the removal of the layers the stones started powdering uniformly. The mortar showed damage after 3 months but only with the higher concentration (Fig.11a,b). Measuring the detached layers thickness and the wettability of the stone for water repellent, the depth of the consolidant surface treatment seems to be around 0,65 mm, while the one of the water repellent seems to be 1,4 mm,. The difference in penetration depth could explain the delay in the exfoliation of the water repellent treated surface with the lowest salt concentration and consequently the more irregular damage observed due to water repellent treatment.

As the material loss in untreated wallettes after the same period of time (8 months for the moment) is less or equal to the treated ones, treatments on Noto limestone wallettes seem to be unnecessary to prevent salt crystallisation decay.

### 5.3 Savonnière limestone wallettes

5.3.1 Crystallisation test with $Na_2SO_4$

*a) untreated wallettes*

High dark brown coloured efflorescences and crusts were evident after 3 months (Fig.12a) and the damage consisted in powdering.

*b) water repellent treatment*

For both concentrations at 8 months no efflorescence and damage were visible on stones and mortar (Figs.11a,b and 12b). The mortar is an hydraulic lime mortar, different from the other wallettes.

*c) consolidant treatment*

At three months brown coloured efflorescences and crusts were visible on the wallettes, increased after the second cycle of crystallisation but, although the brown encrustations were still present, the loss of material refered only to a light powdering of both stone and mortar (Figs.11a,b and 12c).

Untreated a) Water Repellent b) Consolidant c)

**Figure 12. Savonnière wallettes with $Na_2SO_4$**

### 5.4 Serena sanstone wallettes

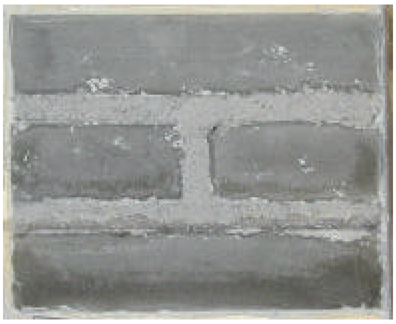
5.4.1 Crystallisation test with $Na_2SO_4$ or $MgSO_4$

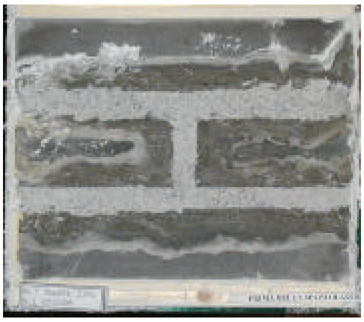
*a) untreated wallettes*

Only some efflorescences started to appear in the untreated wallettes at the mortar/stone interface in both case of $Na_2SO_4$ and $MgSO_4$. With the highest concentration of $Na_2SO_4$ was clearly visible the stone surface damage due to salt crystallisation (Fig.13a,b and c).

*b) water repellent and c) consolidant treatment*

At 8 months no particular damage was visible. Only some very small exfoliation are at present visible at the stone/mortar interface.





Untreated with $MgSO_4$ a) Untreated with $Na_2SO_4$ b) and particular of the damage c)

## 6 CONCLUSIONS

Some remarks and conclusions can be given following the research:

- when dealing with durability of masonry, the crystallisation test must be carried out on wallettes rather than on single units;
- the test was useful to calibrate a probabilistic model, which can be of help to evaluate durability and efficiency of surface treatments and to plan maintenance strategies;
- the assumed parameters measured by the laser profilometer turns out to be appropriate to describe the damage evolution in short and long term;
- the salt concentration threshold assumed for consolidant must be lower than 1% of the capillary moisture content, since the damage appears very early;
- apparently no evident damage appears in the case of water repellent, even with the highest tested salt concentration (2.5%), except for Noto stone. Nevertheless a higher damage can appear in a longer time (Fig. 8a);
- the presence of pointing mortar only delays the damage in case of untreated wallettes, while it causes damage acceleration in presence of treatments;
- it would be difficult to apply the threshold values on site, due to the extreme variability of the salts and of their concentration inside a wall. Nevertheless from laboratory research it can be concluded that 1% of capillary moisture content of $Na_2SO_4$ can be considered as a threshold below which the used water based water repellent does not produce damage on all the tested treated materials, except for the Noto limestone;
- Therefore it can be concluded that there is a threshold for each unit and each mortar/unit combination.

# Porosity And Diffusivity Of Concrete With Long-Term Compressive Strength Increase Due To Addition Of The Set Accelerator Calcium Nitrate

**H Justnes[1] A Thys[2] F Vanparijs[2] & D Van Gemert[1]**
**[1]SINTEF Civil and Environmental Engineering Cement and Concrete Norway**
**[2]Katholieke Universiteit Leuven, Belgium**

**Summary**: **Concrete with additions of the set accelerator calcium nitrate (CN) exhibit a long-term strength increase. Investigations by capillary suction of water and chloride migration showed that the strength gain could not be explained by any decrease in porosity. Water vapor diffusivity obtained by mass loss during drying did not reveal any differences either. Visual inspections by scanning electron microscope indicated that the interface between coarse aggregate and paste may be somewhat denser when CN is added and that calcium hydroxide may be in the form of smaller crystals. Pore water analysis from mature paste showed a substantial increase in alkali concentration when alkali-free CN was added. This could indicate a substitution of bound alkalis in the CSH structure by calcium ions. Thus, improved aggregate-paste interface, CSH and CH morphology and CSH composition could contribute to the observed strength increase.**

**Keywords. Concrete, calcium nitrate, porosity, diffusivity, strength enhancement**

## 1 INTRODUCTION

Calcium nitrate (CN) is used world wide as an admixture for concrete, in particular for applications utilising its properties as set accelerator (Justnes and Nygaard, 1997a). However, CN may be denoted a multifunctional concrete admixture (Justnes and Nygaard, 1999) since it also works as an inhibitor against chloride induced corrosion of rebars (Justnes et al., 1999). Furthermore, CN also enhances the long-term compressive strength of concrete. CN will obviously increase the very early strength due to the earlier start of $C_3S$ hydration and increased maturity at for instance 8 h (Fig.1). However, for concrete (w/c = 0.45 and 4% SF) an increased strength has been observed also at 28 (Fig. 2) and 220 days (Fig. 3) moist curing, in particular for high strength type cement (HSC) compared to ordinary Portland cement (OPC). The strength gain increased until a dosage of 2 % CN of cement weight and flattened out at this level for higher dosages. This paper present the efforts made to explain this unexpected long-term strength increase, since this property should not be utilised in practice before its origin is understood.

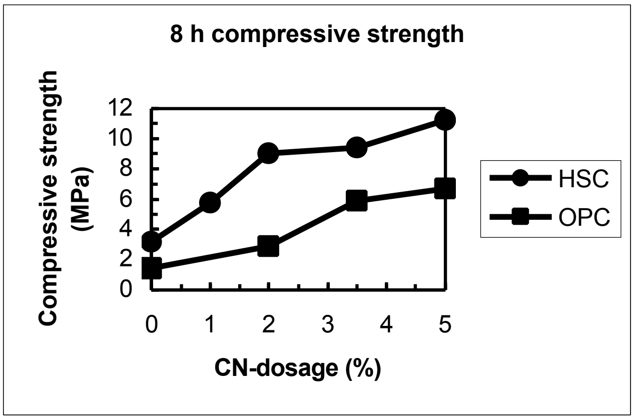

**Fig. 1 Early compressive strength (8 h) for high strength Portland cement (HSC) and ordinary Portland cement (OPC) concrete with different dosages of calcium nitrate (CN).**

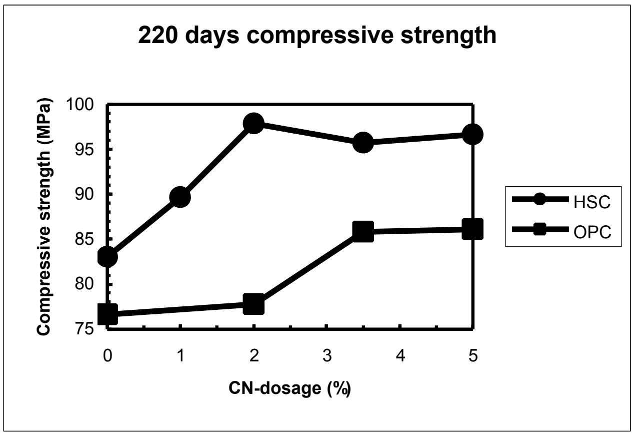

**Fig. 2 Compressive strength at 28 days for HSC and OPC concrete with different dosages of calcium nitrate (CN).**

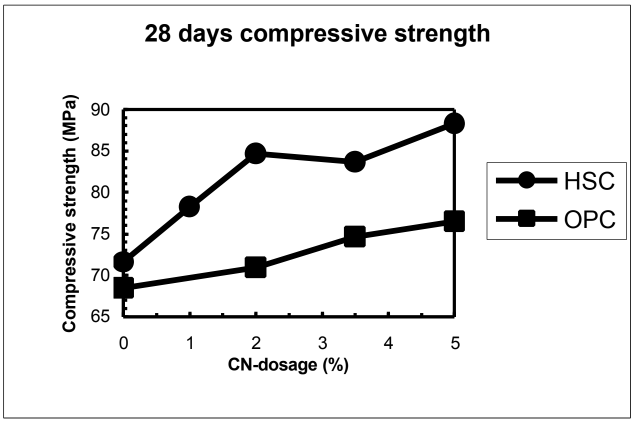

**Fig. 3 Compressive strength at 220 days for HSC and OPC concrete with different dosages of calcium nitrate (CN).**

The first thought was to investigate any change in porosity as a consequence of the CN addition. This was done by capillary suction/saturation by water. Permeability is related to porosity, so chloride migration experiments were carried out as well. Both these parts are also of interest for the discussion of the durability of concrete with CN additions, since it has been common in later years to replace calcium chloride with CN. Additional information was achieved by visual inspection of the microstructure with scanning electron microscopy of plane polished sections, and by studying changes in pore water composition of cement paste with CN additions.

The cement and concrete composition are reported elsewhere (Justnes and Nygaard, 1997a and 1999) but the base recipe (w/(c+s) = 0.45, 4% SF) was of course identical with and without the addition of CN. A granulated, technical quality calcium nitrate (CN) was used that may be expressed as $xNH_4NO_3 \cdot yCa(NO_3)_2 \cdot zH_2O$, with x = 0.092, y = 0.500 and z = 0.826. In other words it consisted of 19.00 % $Ca^{2+}$, 1.57 % $NH_4^+$, 64.68 % $NO_3^-$ and 14.10 % $H_2O$.

## 2 EXPERIMENTAL

Epoxy coated ϕ100 mm·200 mm cylinders of the 220 days old concrete were available for the present study.

### 2.1 Capillary suction and relative water vapor diffusion

Deriving concrete parameters from capillary suction is perhaps not so well known and may deserve a closer presentation: Six 20 mm slices were cut from the middle of each of the epoxy coated concrete cylinders for this experiment. The technique usually requires 105°C drying before capillary suction measurements. Since 105°C may coarsen the porosity, prolonged drying at 50°C was tried out first followed by the normal procedure of 105°C drying. After drying, the discs are placed on a grating 1 mm below the water surface in a covered box. The increase in weight as the specimen suck water is monitored for 5 days and plotted versus square root of time as sketched in Fig. 4.

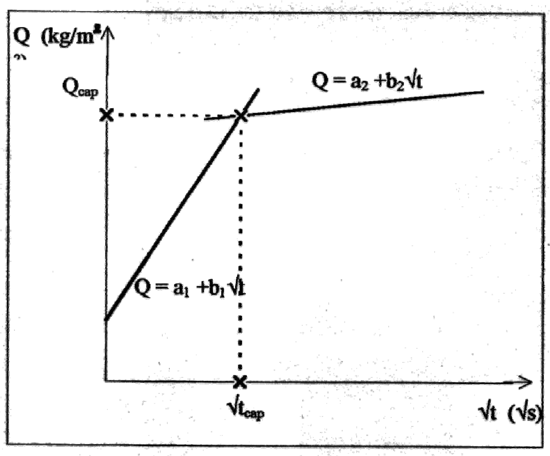

**Fig. 4 Principle of water absorption by a sample in the capillary suction test**

The results from the capillary suction test can be expressed by means of linear regression analysis. Two lines are obtained; the first line represents the value until the waterfront reaches the top of the specimen and the second line the value thereafter. The crossing between the two straight lines is calculated and expressed by the water absorption value ($Q_{cap}$) and time for exposure ($t_{cap}$). These values can be used to calculate the capillary coefficient, k, and the resistance coefficient, m;

$$k = \frac{Q_{cap}}{\sqrt{t_{cap}}} \qquad [\mathrm{kg/m^2 \cdot \sqrt{s}}] \qquad (1)$$

$$m = \frac{t_{cap}}{h^2} \qquad [\mathrm{s/m^2}] \qquad (2)$$

where h is the thickness of the concrete sample (NT Build 368, 1992). Thus, the capillary coefficient, k, gives an estimate of the velocity by which the concrete absorbs water, while the resistance coefficient, m, indicates the time needed for the water front to reach the top.

The procedure consist of 6 important steps for the specimen:

1. Drying to constant weight ($W_1$)
2. Capillary suction for 5 days with weight monitoring
3. Water saturation by submersion 3 days in water at 1 atm ($W_2$)
4. Pressure saturation by submersion 3 days in water at 80 atm ($W_3$)
5. The outer volume (V) is recorded by differential weighing the specimen under water and saturated surface dry in air according to the principle of Archimedes.
6. Drying the specimen to constant weight at 105°C ($W_4$)

From these 6 steps, one can calculate the initial moisture content, total porosity ($\varepsilon_{tot}$), the capillary porosity ($\varepsilon_{cap}$), the air volume ($\varepsilon_{air}$), the average density of the concrete solids ($\rho_{sol}$) and the dry density of the concrete ($\rho_{dry}$) according to the following formulas;

$$Initial \quad moisture = \frac{(W_1 - W_4) \cdot 100\%}{V \cdot \rho_w} \qquad [\mathrm{vol\%}] \qquad (3)$$

$$\varepsilon_{tot} = \frac{(W_3 - W_1) \cdot 100\%}{V \cdot \rho_w} \qquad [\mathrm{vol\%}] \qquad (4)$$

$$\varepsilon_{cap} = \frac{(W_2 - W_1) \cdot 100\%}{V \cdot \rho_w} \qquad [\mathrm{vol\%}] \qquad (5)$$

$$e_{air} = \frac{(W_3 - W_2) \cdot 100\%}{V \cdot r_w} \qquad \text{[vol\%]} \qquad (6)$$

$$r_{sol} = \frac{W_1}{V - \frac{(W_3 - W_1)}{r_w}} = \frac{W_1}{V \cdot \left(1 - e_{tot} / 100\%\right)} \qquad \text{[kg/m}^3\text{]} \qquad (7)$$

$$r_{dry} = \frac{W_1}{V} \qquad \text{[kg/m}^3\text{]} \qquad (8)$$

During the 50°C drying process, the mass versus time to constant weight was monitored as well. And the time, t, to loose 25, 50 and 75 % of the free water was calculated. The diffusion coefficient, D, according to Fick's second law relative to a reference concrete (in this case HSC without CN) can simply be taken as the ratio between the time to obtain the same level of relative free water for the concrete (i) in question and the reference concrete (ref);

$$\frac{D_i}{D_{ref}} = \left(\frac{t_{ref}}{t_i}\right)_{25\%} = \left(\frac{t_{ref}}{t_i}\right)_{50\%} = \left(\frac{t_{ref}}{t_i}\right)_{75\%} \qquad (9)$$

### 2.2 Chloride migration

Another epoxy coated cylinder was cut in 25, 50, 50, 50 and 25 mm, where the 3 middle 50 mm slices were used as parallels for the chloride migration test (NT Build 355, 1989). In this test a $\phi$10mm·50 mm cylindrical specimen is placed between two compartments filled with 3% NaCl solution (compartment 1 with chloride concentration $C_1$) and 0.3 N NaOH solution (compartment 2), respectively. In both solution a metal screen is placed close to the concrete surface and a constant direct current potential of $\Delta U$ = 12 V is applied between them (Fig. 5). The electric resistivity of the specimen is monitored before and after the experiment. Due to the electric field, the chloride ions will migrate through the concrete from the NaCl compartment to the NaOH compartment. The concentration of chloride ion ($C_2$) in the NaOH compartment as a function of time (t) is determined by a spectrophotometric method, and the results plotted like the sketch in Fig. 6.

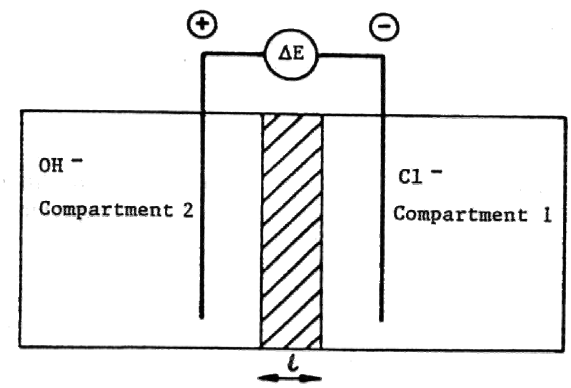

**Fig. 5 Principle set-up of a chloride migration experiment**

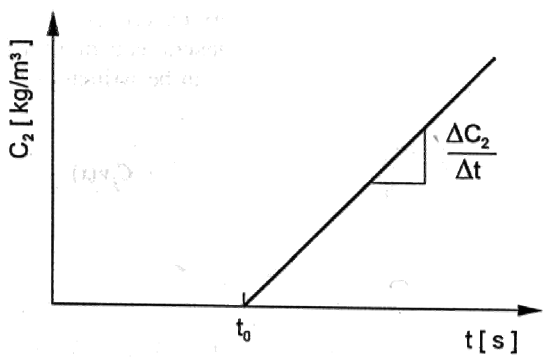

**Fig. 6 Sketch of the chloride concentration in compartment 2 as a function of time**

When a straight line is obtained between the 5 last data points, $\Delta C_2/\Delta t$ is determined as the slope of this line as shown in Fig. 6. Assuming that migration is the dominating transport mechanism and that diffusion and convection can be neglected, the migration coefficient for chlorides can be determined by the formula

$$D_m = \frac{R \cdot T \cdot \lambda \cdot V_2}{z_{Cl} \cdot F \cdot \Delta E \cdot g_{Cl} \cdot C_1 \cdot A} \cdot \frac{\Delta C_2}{\Delta t} \qquad (10)$$

where:

R = the universal gas constant = 8.314 J/mole·K

T = absolute temperature [K]

∝ = thickness of the sample [m]

$V_2$ = volume of compartment 2 [$m^3$]

$Z_{Cl}$ = electrical charge of chloride = -1

F = Faradays number = 96,500 C/equivalent

$\Delta E$ = voltage drop over the specimen [V]

$\gamma_{Cl}$ = activity coefficient of chloride (taken as 1 here for simplicity)

$C_1$ = chloride concentration in compartment 1 [$kg/m^3$] or [mole/l]

A = cross-sectional area of sample [$m^2$]

$\Delta C_2/\Delta t$ = steady state change in chloride concentration versus time in compartment 2 [$kg/m^3 \cdot s$] or [mole/l·s]

It should be noted that the voltage drop across the specimen, $\Delta E$, is less than the applied voltage, $\Delta U$:

$$\Delta U = \Delta E + E^{rev}_{H_2O} + h \qquad (111)$$

where $E^{rev}_{H2O}$ = reversible dissociation potential of water = 0.463 V at 25°C and pH = 13 and $\eta$ = polarisation effects [V]. In this study $\Delta U = \Delta E$ for simplicity.

### 2.3 Other methods

10 mm cubes cut from concrete were impregnated with epoxy under vacuum and plane polished. The microstructure of these specimens was inspected by scanning electron microscopy in the backscattered electron mode.

Finally, pore water was pressed from mature cement paste specimen and analyzed for a number of ions to gain some supplementary information about the microstructure.

## 3 RESULTS AND DISCUSSION

### 3.1 Capillary suction/adsorption and relative diffusion

The results from the capillary suction test for concrete based on high strength cement dried at 50 and 105°C are listed in Tables 1 and 2, respectively, while similar results for concrete based on the ordinary Portland cement dried at 50 and 105°C are given in Tables 3 and 4, respectively.

There is no significant change in capillary porosity within each series with varying CN dosage. The capillary coefficient, k, and the resistance number, m, are relatively constant within each series too. However, the values are larger when the samples are dried at 105°C instead of 50°C due to the drier interior and possible changes in pore connectivity (i.e. coarsening of the pore structure) caused by the more severe drying. There are no significant changes in porosity or dry density that can explain the long-term strength (220 days) gain observed when calcium nitrate is added to HSC concrete.

The diffusion coefficients relative to HSC without CN (ref) according to Eq. 9 were for HSC with 1, 2, 3.5 and 5 % CN 0.96±0.02, 0.87±0,01, 0.88±0.02 and 0.92±0.05, respectively, and for OPC with 0, 2, 3.5 and 5 % CN 0.87±0.09, 0.79±0.09, 0.82±0.06 and 0.84±0.84, respectively. Differences are hardly significant, but marginally lower for samples with CN (lower pore water pressure caused by salts in solution) and for OPC vs HSC (more alkalis; 1.2% vs 0.6%).

### 3.2 Chloride migration

The results from the chloride migration test; the time to chloride penetration ($t_0$), the steady state migration coefficient ($D_m$) and the specific resistance before ($\rho_b$) and after ($\rho_a$) the experiment, are given in Tables 5 and 6 for concrete based on HSC and OPC, respectively, with 0, 2 and 5% calcium nitrate added by weight of cement.

**Table 5. Results with absolute standard deviation from the chloride migration test for concrete based on HSC**

| CN dosage [%] | 0.0 | 2.0 | 5.0 |
|---|---|---|---|
| $t_0$ [h] | 825±30 | 744±39 | 603±18 |
| $D_m$ [$10^{-12}$ m$^2$/s] | 49±20 | 50±1 | 100±25 |
| $\rho_b$ [Ω·m] | 122±12 | 110±12 | 118±5 |
| $\rho_a$ [Ω·m] | 115±4 | 103±19 | 99±3 |

**Table 6. Results with absolute standard deviation from the chloride migration test for concrete based on OPC**

| CN dosage [%] | 0.0 | 2.0 | 5.0 |
|---|---|---|---|
| $t_0$ [h] | 843±27 | 762±84 | 566±24 |
| $D_m$ [$10^{-12}$ $m^2/s$] | 71±19 | 58±16 | 121±13 |
| $\rho_b$ [Ω·m] | 118±22 | 118±20 | 117±8 |
| $\rho_a$ [Ω·m] | 118±26 | 56±27 | - |

There is a tendency for the time to penetration, $t_0$, to decrease with increasing CN dosage, although the change is hardly significant at the 2% CN level. The time to penetration will increase with increasing porosity or pore connectivity and with decreasing chloride binding capacity of the matrix. The steady state migration coefficient, $D_m$, seems to be unchanged by the addition of 2% CN, but increases when 5 % CN is added. $D_m$ should be independent of chloride binding, but increases with increasing porosity and pore connectivity.

The specific resistance, $\rho_b$, before the experiment is apparently independent of the calcium nitrate dosage and cement type. However, there is a tendency for the specific resistance to decrease after the experiment, which can be explained by the increased ionic strength of the pore water due to the sodium chloride content.

There are no observations from the migration experiment that should indicate a decrease in porosity that could explain the long-term strength increase when calcium nitrate is added. On the contrary, the highest dosage seems to increase porosity even though the long-term strength is higher than the reference.

### 3.3 Scanning electron microscopy

The scanning electron microscopy of the HSC and OPC concrete with 0, 2 and 5 % CN additions indicated two trends; 1) the interface between the coarse aggregate and the paste was denser when CN was added and 2) the crystalline mass of calcium hydroxide had a "dotted" structure indicating it to be composed of smaller crystallites. The difference in interface can be observed from the backscattered electron image (BEI) of HSC concrete without CN in Fig. 7 and the HSC concrete with 2 % CN in Fig. 8.

When calcium nitrate is added, the calcium concentration in the water of the fresh mix will be rather high and the hydroxide concentration depressed due to the limited solubility of calcium hydroxide. The $Ca^{2+}$ concentration for HSC paste with w/c = 0.55 without and with 1.55% CN was reported (Justnes and Nygaard, 1997b) to 20 mM and 90 mM, respectively, after 10 min and declining to 16 mM and 52 mM, respectively, after 4 hours (past initial set). At the same time, the hydroxyl concentration was 63 mM and 25 mM after 10 min, and stabilising at 32 mM for both mixes after 4 h. The initial suppression of the calcium hydroxide solubility, could lead to less initial precipitation of calcium hydroxide (CH) on the surface of the coarser aggregate which consequently could mean a tighter interface in the hardened concrete. The suppressed CH solubility could also lead to the formation of smaller crystallites rather than larger CH platelets that could mean weaker zones in the CSH-gel + CH binder. The same applies for any other sparingly soluble calcium salts.

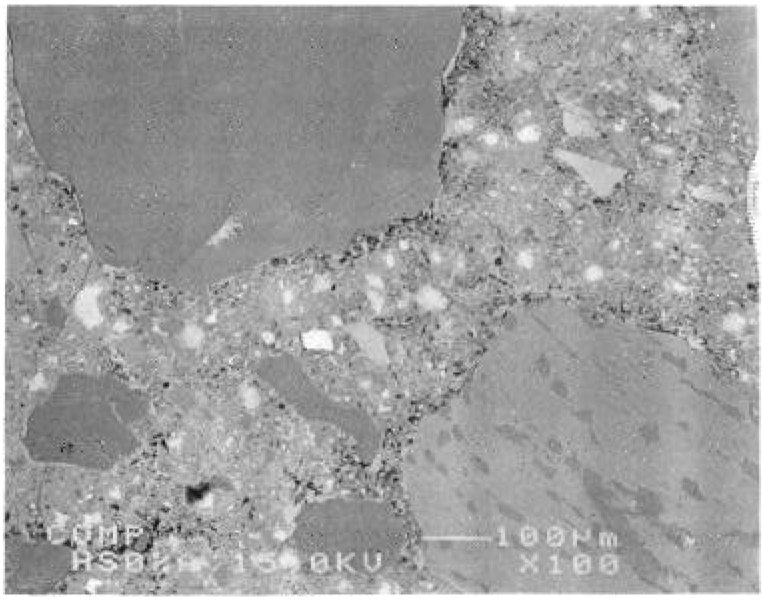

**Fig. 7 100x BEI of HSC concrete without CN**

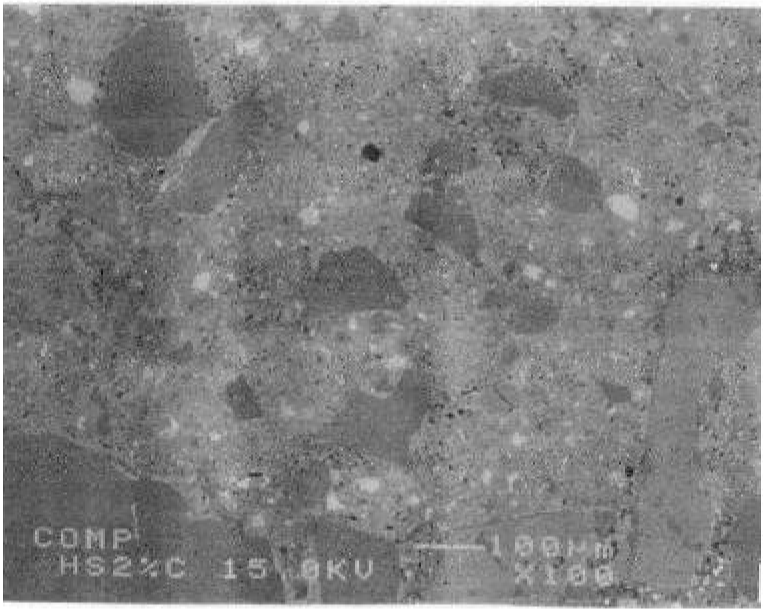

**Fig. 8 100x BEI image of HSC concrete with 2 % CN**

### 3.4 Pore water analyses

The ionic composition of water pressed from mature HSC paste with w/c = 0.55 and without and with 5% CN is listed in Table 7. Even though the CN used was free of alkalis, the alkali content increased substantially when CN was added. This can only be explained by $Ca^{2+}$ replacing $K^+$ and $Na^+$ bound in the CSH gel. Such a substitution can heal dislocations in the CSH structure on an atomic layer and possibly increase its strength. An earlier study of changes in microstructure of paste (Justnes and Nygaard, 1997c) showed by $^{29}Si$ NMR that the average length of the polysilicate anions in the amorphous CSH-gel was prolonged by 17% for OPC and 5 % for SRC (sulphate resistant cement), but unfortunately the HSC was not included in that investigation.

**Table 7. Pore water composition in ppm [mM] and sums of cation ($\Sigma_+$) and anion ($\Sigma_-$) charge of mature HSC paste with w/c = 0.55 and without/with 5% CN.**

| CN-dosage | 0.0% | 5.0% |
|---|---|---|
| $K^+$ (39.10 g/mole) | 690 [17.6] | 9,810 [250.9] |
| $Na^+$ (22.99 g/mole) | 230 [10.0] | 3,390 [147.5] |
| $Ca^{2+}$ (40.08 g/mole) | 70 [1.7] | 210 [5.2] |
| $NO_3^-$ (62.0 g/mole) | 0.5 [0.0] | 16,700 [269.4] |
| $NO_2^-$ (46.00 g/mole) | 2.6 [0.1] | 13 [0.3] |
| $OH^-$ (17.01 g/mole) | - [100] | - [63.1] |
| $SO_4^{2-}$ (96.06 g/mole) | 135 [1.4] | 24 [0.2] |
| $\Sigma_+$ | - [31] | - [409] |
| $\Sigma_-$ | - [103] | - [333] |

Note the excess of negative charge ($\Sigma_-$) in the paste without CN and the excess in positive charge ($\Sigma_+$) in the paste with 5% CN. However, the $OH^-$ concentration is based on pH meter readings to 13.0 and 12.8, respectively, and represents the highest uncertainty. A change in 0.1 pH units in this range corresponds to about 20 mM alone.

## 4 CONCLUSIONS

Concrete with additions of the set accelerator calcium nitrate (CN) exhibit a long-term strength increase. The addition of 2% CN to concrete based on high strength Portland cement, 4 % silica fume and w/(c+s) = 0.45 lead to an increase in 220 days compressive cube strength from 83 to 98 MPa.

Investigations by capillary suction of water, relative water vapour diffusion and chloride migration showed that the strength gain could not be explained by any decrease in porosity. The porosity was rather constant as CN was added, with a marginal porosity increase for the highest CN dosage (5 %).

Visual inspections by scanning electron microscope indicated that the interface between coarse aggregate and paste may be somewhat denser when CN is added and that calcium hydroxide may be in the form of smaller crystals. Morphology changes due to suppressed calcium hydroxide solubility by CN additions due to common ion effects can not be ruled out. Both these effects could contribute to strength increase.

Pore water analysis from mature paste showed a substantial increase in alkali concentration when alkali-free CN was added. This could indicate a substitution of bound alkalis in the CSH structure by calcium ions. Such a healing of CSH dislocations could possibly also strengthen the binder.

# Technological Complexity And Durability Of Ceramic Suspended Façades

**PL Maffei & R Boccaccini**
**University of Pisa Dept of Civil Engineering Italy**

**Summary: Throughout history architecture of institutional buildings has given importance to walling and envelope systems. Architectural façades were the embodiment of institutional powers, but also played a functional and technical role. Nowadays architectural solutions based on solidity and grandeur are still adopted for institutional buildings, so that durability and appearance are still primary requirements for façade systems.**

**In this ambit the use of double skin ventilated façades has been recently developed as a way to synthetize the traditional aspect and experimented durability of masonry with the modern concept of active walling.**

**Since Renzo Piano's early '80 experiences (IRCAM, Paris) this technology is frequently adopted in Italy and Europe, and recently also in Australia (Aurora Place, Sydney) so that it's now possible to analyse a life cycle of those façades from project to demolition.**

**Excepting for the outer leave, usually made of burnt clay or ceramic, those envelopes had few characteristics in common with traditional burnt clay brick masonry; for this reason it's merely optimistic to forecast for this kind of walls such a long service life. Furthermore some defects of burnt clay, like fragility, can affect the external leave, which can be reduced to 18 mm in thickness. This paper will show an analysis of different cases of suspended façades, from which emerges the importance of a detailed project and the necessity of an accurate choice of materials and maintenance cares: those element concur to individuate some critical points for durability and an estimation of life cycle.**

**It will be shown a general approach on durability assessment looking forward to the substenibility of buildings: previous experiences, like Strathclyde's DAEC, have been experimented in the specific field of building components.**

**Keywords: durability, service life, suspended façades**

## 1 INTRODUCTION

Buildings for offices, and more in general the institutional architecture, symbol of economic and political powers, have faced in the '900 a profound innovation and still represent a vanguard of contemporary architecture. Furthermore in the last twenty years we have seen a marked change of many factors that determine typological and technological characteristics of buildings, as the role of the client and the work organisation. On the other side it is possible to recognise strong elements of continuity that link historical buildings, such as castles and towers, to modern skyscrapers made of steel and glass. The architecture of the building envelope is one of these.

The external layer of contemporary buildings represents a technical and functional system, visa that on these components converge a great number of requirements aimed to determine comfort for users, architectural appearance and cost management in service life. Technical solutions adopted to comprehend this complex of requests at once have carried to the conception of *polyvalent walls.* Those systems have relevant performances regarding thermal insulation, management of solar gain, mass inertia, control of daylight factor, architectural appearance and functional adaptability.

Among these solutions we will analyse the ones equipped with an external layer of ceramic or terra cotta. These double leaf systems, mechanically assembled and suspended to the building structure, generally offer moderate ventilation that enhances energy conservation performances, characterising building architecture with a traditional appearance.

Since Renzo Piano's early '80 experiences (IRCAM, Paris) this technology has been frequently adopted in Italy and Europe, and recently also in Australia (Aurora Place, Sydney). The diffusion of a post-modern language for institutional architecture has definitely encouraged the adoption of these apparently quasi-traditional wall systems.

## 2 ARCHITECTURE AND FUNCTION OF SUSPENDED FAÇADES

### 2.1 A methodological overview

During a research on early stage design decisions for the new building of Pisa's District administration, we have experimented a method to develop and compare alternative solutions for the building envelope (Maffei & Boccaccini 2000), based on the typical approach of value analysis and on decision help tools. The comparison has been made among solutions with similar architectural appearance but relevant differences in performances: the main target was to find critical factors that could justify the adoption of each of these solutions. In this paper it will be shown the analysis and the durability assessment outcomes of that research.

Comparative evaluation of technical solutions in complex applications, such as buildings for institutional use, has been performed within a general framework, based on value analysis, and specific multicriteria tools, particularly Analytic Hierarchy Process (Saaty 1977) and the evaluation tool proposed by prof. Langford named DAEC. The last one provides an assessment framework on sustainability which helps to define the design *brief* requirements, assists the designers to integrate the requirements into the design, and helps the assessors to evaluate different design options. This application provides an evaluation of DAEC potentiality in detailed comparisons of building components.

Others tools, more oriented on building materials sustainability, like NIST's BEES, had been judged useless to determine a complete assessment on durability[i].

Durability requirement represents a crucial issue to obtain quality and value in the construction field: on the other side durability represent a main target for building sustainability, so needs to be studied with a synthetic and global approach. The sustainability concept is now well defined by various researches performed in the '90 (CIB Agenda 21 is one of the main products of this activity). Thinking of sustainability in design decisions and in technical choices involves a multidisciplinary approach, which is necessary to integrate all the analytical appearances in a vision that esteems the attainment of this strategic objective.

Durability needs to be considered as a basic requirement already in the brief phase to guide the choice of technical systems: this approach requires two principal elements:

- a general framework, managed in a group coordinated activity, aimed to homogenise qualitative and quantitative evaluations and to produce judgements and criteria in a scientific and objective way;
- a set of tools, for the scientific elaboration of judgements and criteria.

In this work the problem has been faced with a general method developed from the value analysis one (Maffei 1999).

Value analysis - VA - (UNI EN 1325-1) is an interdisciplinary methodology that, when employed during the planning of a product, process or service, has the target of verifying the functional effectiveness of the proposed solutions compared with the resources and the global costs. The VA team operates following a precise succession of phases: informative, creative, analytical-selective, development and presentation. This approach allows to apply the scientific method to the building design, and in the meantime to co-ordinate an interdisciplinary group activity.

### 2.2 An hypothesis: architecture, first

Without doubt the first reason that stimulates famous architects and common designers to the adoption of suspended façades with external leave in ceramic or terra cotta should be found in the actual architectural tendencies. Many architects, from a side, adopt a post-modern language, in wich the use of traditional materials has a meaning of reconnection with the constructive historical tradition and, often, the regional, vernacular architecture. From the other side suspended façades, with double leaf, thin ceramic tile façades, sometimes ventilated, use old materials and traditional appearance in a new way, modern and experimental. Traditional materials are pushed to new uses and to complex technical behaviours for which they aren't designed for. In this sense the use of terracotta is emblematic.

Burnt clay bricks were used by Romans to build walls and other structures: this material was not adopted for it's structural performances, but only to obtain a finishing layer covering the structural concrete core of the wall. It's only during the middle age that bricks were used primarily for their static contribution in constructions. In the '900 we have seen a progressive abandonment of structural brick masonry in favour of non-structural solutions. Those of them that adopt terra cotta as an architectonic character refer to a great deal of vertical closure types; all of them must primarily assure indoor comfort for building's users and formal characterisation (Acocella 1989).

Burnt clay masonry is still used as external closure for it's proven durability and its capacity to keep the architectonic appearance in time. Structural capacity, resistance to weather - freezing in particular - and pollutant agents make it a very competitive material. On the other side it is evident that the use made nowadays of terra cotta is very different from the original one, and that clay has been deeply transformed to increase his versatility. Innovations have been made introducing additives, new building products and new assembling systems (chemical and mechanical).

Sometimes burnt clay is reduced to a simple choreographic element, especially in façades: producers have stimulated this tendency trying to change all characters (dimensional irregularity, porosity, variability in chemical composition and in colour, etc.) that once were the principal nature and strength of this material.

In this sense the comparison with ceramic and other similar products appears meaningful, since these materials seem better performing in mechanical characteristics and, therefore, more theoretically proper to be used in thin façades.

Eight technical solutions of double leaf external walls, characterised by the use in façade of terra cotta or ceramic elements, have been compared to show the role of these systems in actual user's needs satisfaction, and particularly in the analysis of durability. This approach gave us criteria to correctly operate in the design of such systems and provides us a set of tools to verify design decision.

The relief and the analysis of the real behaviour in time of the examined technical solutions had been made also by means of post occupancy evaluation. This approach can give relevant data for a correct activity of design, if above all the evaluation is made in contexts analogous to those where the project is planned (Kirk & Spreckelmeyer 1993). Technical mistakes, influence of environmental factors, troubles in functionality and defects in construction are the principal elements to underline: although is not possible to generalise these conclusions, relieved defects could be taken under control in each future project.

## 3 COMPARISON AMONG SOLUTIONS

Eight types of technical solutions for external closure have been compared: all of them are characterised by an outer architectonic layer in terra cotta style, an insulation provided by an air layer and insulating pannels, a structural leave made of blocks or a concrete wall. All of these solutions can be classified as (moderately to strongly) ventilated façades.

Ventilated wall is defined by technical standards (like in UNI 8368/2) as a constructive solution of vertical wall characterised by an inner layer of ventilation. This definition doesn't make distinction on the role played by this air layer: we could distinguish two boundary cases:

- natural or forced ventilation of the inner air layer
- igrometrical regulation

In the first case the external leave is equipped with a series of technical elements (holes, grids) that act to create laminar fluxes of the air, favouring the evacuation of the heat produced by sun radiation;

the second kind of walls uses the air layer, weakly ventilated, to remove the interstitial condense produced inside the wall, usually in winter, caused by the great thermal difference among the outer face of the insulating pannel and the air.

Critical points of these systems are related to their technological complexity: this makes difficult to construct them correctly and maintain them. This complexity is often a discriminatory factor for their adoption, even if ventilated walls can induce a significant reduction in energy cost for the building heating and cooling.

The technical design complexity, especially in joints, corners, intersections with pillars and beams, often resolved by designers with excessive simplifications of details, constitutes one of the weakest points in the architecture of those systems (Acocella 1989).

### *3.1.1* Type 1. Double leaf wall with insulating pannel in the cavity.

This solution is rather diffused: it is born to protect the insulation layer from unfiltered rainwater. A damp excess can cause an increase of thermal dispersions. The long-term effects can bring to a progressive deterioration of the insulating pannels, especially in case of hygroscopiacal materials (Mor 1996). The cavity, provided with flashing at the bottom (see Table 1), allows the diffusion of damp and its evacuation. This solution is particularly recommended in case of masonry exposed to beating rain, to avoid a rapid degradation (Raffellini *et. al.*1996).

### 3.1.2 Type 2: double leaf wall with external façade covered with burnt clay tiles, with insulating pannel in the cavity.

Wall is made with burnt clay or light concrete hollow blocks, while an external layer provides the requisite of appearance by the use of terra cotta tiles.

Solutions type 1 and 2 are often designed without care of the problematic evacuation of water. This can happen on buildings with small eave length, where it's possible to find some salt deposits produced from the evaporation of the damp accumulated in the burnt clay external leave.

### 3.1.3 Type 3: Double leaf wall with façade in burnt clay bricks hooked by ties.

Facing bricks masonry compose the external leave and steel ties hook it to the inner block wall across the cavity; ties must assure the necessary stability to the horizontal loads. The cavity contains an insulating pannel and can also be naturally ventilated if holes (see Table 1) are provided at the bottom and at the top of the wall. If holes aren't present the cavity has the only function of keeping water away from the inner layers.

Non-structural walls of type 3 often presents fractures because of the inadequate number of ties, or the excessive rigidity of them. In this last case tie is deformed by wall yielding but the reactions it made on the external leave are too strong, so that it can force the bed joints of the bricks.

Steel tie can also be corroded, and this can produce local lesions and breaches in mortar joints.

### 3.1.4 Type 4: Double leaf wall with façade in burnt clay hollow bricks mechanically fixed to a metallic structure.

This solution has been applied in 1987 by Renzo Piano in the IRCAM widening in Paris, and then in 1992 Genoa Colombiadi's exposure building. It is characterised by the external leave, assembled without mortar: a metal bar inserted within brick's holes carry their weight and is then suspended on an upper beam. The open joints among the pannels (see Table 1) make the inner cavity moderately ventilated.

Solution 4 present a similar behaviour in service life in his application in IRCAM as in Colombiadi's building. In this last case it's possible to find fractures and broken elements, probably caused by the reaction among bricks enhanced by the absence of mortar within. Even where bricks are not defective it's often possible to notice a deformation in bricks joints.

### 3.1.5 Type 5: Double leaf wall with façade in burnt clay pannels mechanically fixed to a metallic structure.

A similar solution has been recently used by Piano in the Banca Popolare di Lodi building. joints among pannels are opened and this makes the cavity moderately ventilated.

Comparing this last solution with the previous solution 4 we notice that the greater dimension of external tiles and the wider regulations for the substructure could reduce risks of imperfections in the construction and more in general in the use and maintenance.

### 3.1.6 Type 6: Double leaf wall with façade in burnt clay tiles mechanically fixed to a metallic structure.

This solution has recently been adopted in the new Versilia hospital in Camaiore (Italy). Although the joints among tiles are partially open the inside cavity of the wall can perform natural ventilation.

Solution 6 is fit to realise an efficient ventilated double leaf wall, also because the small mass of the external layer can be easily heated by solar radiation also in winter conditions. On the other side the extreme thickness of those tiles makes them too little resistant to accidental hits: this disadvantage often occur during construction works. To avoid this problem is important to don't assemble the lower part of the façade until other works are completed, and to use a more resistant kind of tile for the first 1-2 meters of wall.

### 3.1.7 Type 7: Double leaf wall with façade in ceramic pannels mechanically fixed to a metallic structure.

In it's Hamburg tower for offices Thomas Herzog tries to furnish an exhaustive answer to the demands of environmental comfort for users, of energetic savings for the client and of sustainability for the whole community. The building envelope is a double wall, equipped with multiple layers, able to transpire and regulate in natural ways the thermal flows among internal spaces and external environment. Plumbing services and cables have been conceived like a vascular net that reaches all the vital parts of the building. Services towers are made with a double leaf suspended wall: the outer layer is made of large ceramic pannels on a metallic substructure.

A problem for durability of all the large pannels suspended façade concerns the joint among pannels and substructure: wind pressure can produce fractures in pannels with linear joints. A large number of evidences[ii] induce to refuse the use of linear joints in favour of punctual ones (Grassi 2000).

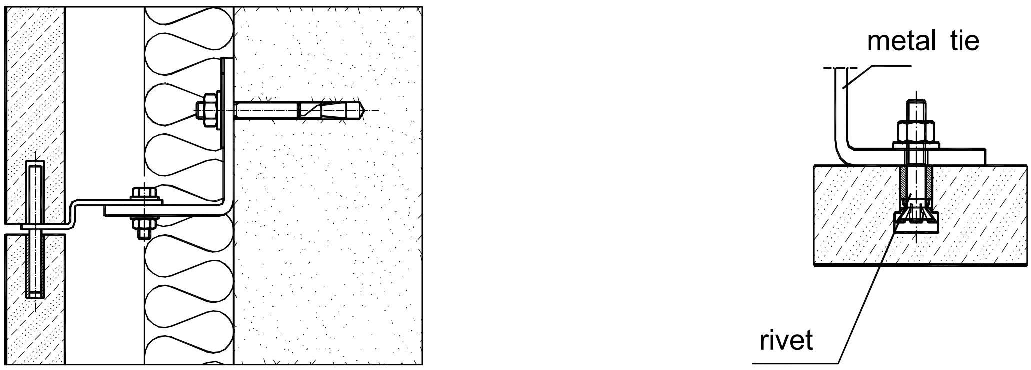

**Figure 1: linear joints (left) and punctual joints with rivets (right)**

### 3.1.8 Type 8: Double leaf wall with façade in ceramic pannels mechanically fixed to a metallic structure.

In the business centre of Sydney, where the need to exploit the available surfaces has carried to the diffusion of tall towers for offices, Renzo Piano Building Workshop's Aurora Place distinguishes itself for the elegance of the shape and for the characterised appearance of the façade. The building has been conceived to fully satisfy the demands of work places spaces expressed by the client, Lend Lease, with the maximum care to the global cost in the life cycle. The materiality of the envelope is realised with ceramic pannels similar to terra cotta facing bricks. This material is used in both the basement of the building as in the inner spaces assigned for institutional and representative activities.

## 4 DURABILITY ASSESSMENT

An analysis of durability and adaptability of the selected solutions of building façade can be developed starting from the individuation of a set of influence factors. These can be reduced to:

- durability of building elements,
- technological and functional complexity of building systems
- critical compatibility of materials;

the last two induce a risk of unsatisfactory behaviour in the service life of the system because of technological and functional incompatibility, while the third factor implicates reduction of components service life because of mechanical or chemical incapability. If a building system is correctly designed and assembled, the theoretical durability of the whole component can be esteemed equivalent to the shortest among those of the building elements adopted. This value should be reduced to take account of a statistic life cycle of construction elements.

In our cases we found that the adoption of ties or substructure in galvanised steel, which has a statistical life cycle of approx. 30 years, is one of the main endogenal risks for those systems.

Decision help tools have been applied to produce a realistic assessment on a specific case study, the brief phase of the Pisa's District administrative building, a 20.000 sq.mt multi-storey centre[iii].

A first qualitative evaluation of durability for the previously listed systems has been produced using in the case study the quoted DAEC evaluation tool, software developed by the Department of Civil Engineering of the University of Strathclyde[iv].

The assessment has been done varying only the façade system, while the rest of building components was defined: the building envelope is a meaningful variable for durability of this building because it should have a large external surface to guarantee natural light and ventilation.

This durability and adaptability assessment of façade systems shows a relevant preference for solutions with ventilated double leaf envelope, particularly because those systems allow an easier maintenance in the life cycle and a great degree of adaptability to new services (see Table 2).

We noticed that DAEC, originally conceived to introduce a general approach to the problem of the sustainability of a built object, can be used also for a deeper evaluation of global durability performances of building elements. To perform this kind of analysis is therefore necessary to modify the given set of criteria, as each element must be described with different relevant performances.

It's easy to understand that, even if  the complete set of requirements and specification for each element is very large, it's possible to find a subset that contains only the requirements derived from the priority functions of the element. This subset changes for each element; i.e., while an external wall is defined mainly with aesthetic, stability, durability and energy specifications, a foundation must be described by stability and durability performances. Requirements that characterise a building component  concur to define the quality of the whole building, so must be strictly planned and verified.

**Table 2: early stage design durability assessment**

| N° of solution | Technical description | DAEC assessment for durability | AHP priority type | AHP priority score |
|---|---|---|---|---|
| **type 1,2,3** | Double leaf walls with facing bricks and insulating pannel in the cavity | **57%** | **1** | **55,6** |
| | | | **2** | **33,3** |
| | | | **3** | **59,8** |
| **type 4** | Double leaf wall with façade in burnt clay hollow bricks mechanically fixed to a metallic structure | **60%** | **4** | **37,6** |
| **type 5,6** | Double leaf suspended façade made with terra cotta tiles | **75%** | **5** | **77,6** |
| | | | **6** | **76,1** |
| **type 7** | Double leaf suspended façade made with large ceramic tiles and linear joints | **75%** | **7** | **75,3** |
| **type 8** | Double leaf suspended façade made with large ceramic tiles and punctual joints | **77%** | **8** | **80,3** |

After this first evaluation we performed a more detailed analysis using Analytic Hierarchy Process[v]. This decision help tool provides a very flexible assessment framework, in which criteria are organised into a decision tree algorithm. This phase has been conduced first with a comparison among criteria, used to produce a weight (relative importance) for each of them, then with a comparison between each couple of solutions for each criterion. Comparative judgements have been given with both qualitative[vi] and numerical values.

The general assessment on durability that our research produced on the listed technical solutions for the building façade is synthesised in table 2. These results, in addiction with the quoted post occupancy evaluation, lets us suppose a minimum value for the life cycle of each system and a maximum target for designers in the correct construction, use and environment conditions.

These values show sometimes a reduction of the estimated life cycle respecting to previous researches[vii] and more in general they give a detailed evaluation of differences among similar solutions.

**Table 3. Analytic assessment of durability**

| | durability of building elements | technological and functional complexity of building systems | critical compatibility of materials | Post occupational evaluation | minimum LC years | Predicted LC years |
|---|---|---|---|---|---|---|
| Type 1 | Deterioration of insulating pannels: their performances can be halved in 20 years by an excess of water in the cavity | Cavity should be protected by rain water and damp must be dried out by flashing or ventilation | Chemical effect of salts on burnt clay bricks: this can produce fragility and breach in bricks | Deterioration of burnt clay bricks caused by evaporation of the rain and hygroscopical salts; | **30** | **80** |
| Type 2 | Excessive fragility of external layer: it can be braked by mechanical agents or by thermal variation | Tolerances among different layers of the external leave | Excess of differences in damp permeability among materials in the external leave | Breaches of elements caused by accidental hits or thermal variation or freezing; | **20** | **60** |
| Type 3 | Deterioration of insulating pannels: their performances can be halved in 20 years by excess of water in the cavity; deterioration of metallic ties | Number and flexibility of metal ties | Metal ties corrosion caused by chemical solutions of rainwater and burnt clay salts | Lesions produced by structural movements among façade and inner leave, produced by metal ties rigidity | **30** | **70** |
| Type 4 | Deterioration of metal substructure; mechanical deterioration of rubber rings among hollow bricks of the external pannels | Tolerances among external leave and metal frames; loads transmission among substructure and building structure | Deterioration of rubber rings among hollow bricks of the external pannels caused by UV rays; metal ties corrosion caused by chemical solutions of rainwater and burnt clay salts | Fractures and deformations produced by structural movements among façade and inner leave | **20** | **60** |
| Type 5 | Deterioration of metal substructure; Deterioration of terra cotta caused by water imbibition and drying | Tolerances among external leave and metal frames, loads transmission among substructure and building structure | Metal ties corrosion caused by chemical solutions of rainwater and burnt clay salts | Corrosion of galvanised steel substructure and other metallic accessories | **30** | **80** |
| Type 6 | Deterioration of metal substructure; Deterioration of terra cotta caused by water imbibition and drying | Tolerances among external leave and metal frames, loads transmission among substructure and building structure | Metal ties corrosion caused by chemical solutions of rainwater and burnt clay salts. | Corrosion of galvanised steel substructure and other metallic accessories; breaches of tiles caused by accidental hits in thin façades; | **20** | **80** |

| | | | | | | |
|---|---|---|---|---|---|---|
| Type 7 | Deterioration of metal substructure; | Tolerances among external leave and metal frames, loads transmission among substructure and building structure | Metal ties corrosion caused by chemical solutions of rain water and construction products | Corrosion of galvanised steel substructure and other metallic accessories; Facing pannels collapse caused by linear joints reactions; | **30** | **80** |
| Type 8 | Deterioration of metal substructure; | Tolerances among external leave and metal frames, loads transmission among substructure and building structure | Metal ties corrosion caused by chemical solutions of rain water and construction products | Corrosion of galvanised steel substructure and other metallic accessories; | **40** | **80** |

## 5 CONCLUSIONS

From this comparison among solutions of double leaf suspended façades it's possible to point out some interesting notices for designers and clients.

First of all double leaf façades made with an external leaf in mechanically assembled ceramic or terra cotta elements can assure good performances in comparison with traditional double leaf walls with cavity (see Table 2). Their durability is generally good (see Table 3), but doesn't exceed traditional double leaf wall one, and the service life can be improved by a re-use of building elements, made possible by their mechanical, *dry*, assembling.

Therefore It is clear that the first reason for which these systems are adopted is usually related to their architectonic appearance, because the high cost of their construction doesn't currently satisfy a value analysis (Maffei & Boccaccini, 2000(i)).

For what concerns durability we need to underline that some façade elements present an excessive fragility to accidental hits and deformations, not always compensated by the easiness in elements substitution. The adoption of large pannels and the use of ceramic instead of burnt clay can assure a longer life cycle with less risks of failure.

To obtain the planned sevice life it is necessary a careful design and forecast of loads interactions among substructure and closure systems: this can be very difficult when the façade is built on an existent construction, as typically happens in rehabilitation of residential buildings (Grassi 2000). Designers must check out that all the joints between façade and the inner leave are realised in stainless steel; the use of stainless steel must be diffused also for all kinds of elements used for the maintenance (ties, screws, etc.). Joints betweeen pannels and structure must be preferably punctual, made with rivets on the back of facing tiles: other joints, like linear ones, must be avoided.

On a wider point of view we can underline that double leaf suspended façades usually answer a very actual requirement, the reduction of the environmental impact in the service life, particularly because:

- these systems can be perfectly dismantled and all single elements can be recycled
- if ventilated, those systems can induce energy savings.

At last we should underline the good flexibility in use of these systems, very useful for their applications in the functional and architectonic improvement of existing buildings.

From a methodological point of view it is possible to perform an evaluation of the presumed durability of building elements already in the brief phase, but only in a multidisciplinary activity that brings around the decision table all the single experts of the design team. In this sense we encourage the development of software like the quoted DAEC, tools that can be very useful if applied in a multidisciplinary activity.

## 6 ACKNOWLEDGMENTS

## 8 NOTES

[i] Building for Environmental and Economic Sustenibility (BEES) is a tool produced by the National Institute for Standards and Technology of U.S. Governement for the evaluation of sustenibility of buildings materials and components. The tool provides a decision support system based on the environmental assessment suggested in ISO 14040. Fourther informations on www.epa.gov.

[ii] One of the last accident has occurred at the *Arché de la Defense*, Paris. Last winter some stone tiles mechanically fixed with linear joints fell down because of a fragile collapse produced by wind cycles of pressure. The whole north façade should now be repalced, after 20 years of service. The lack of resistence to cyclical loads of linear joints (see fig. 1) is now proven and designers should avoid this kind of solutions in ventialted façades.

[iii] This research has been performed with group activities with the aim of completing the brief phase of new Pisa's District office building. Users needs, technical requirements and building performances have been defined by interdisciplinary workshops.

[iv] The main outcomes of the research project recently completed by D. Langford, I. MacLeod, T. Maver and B. Dimitrijevic and the assessment tool for durability, adaptability and energy conservation of buildings (DAEC tool) are available on a CD. [v] We adopted a software implementation of AHP made by Gary L.Lilien and Arvind Rangaswamy and included in a set of tools for marketing engineering.

[vi] Qualitative; i.e. with respect to criteria 1 - adaptability - solution 2 is moderately better than solution 1; quantitative; i.e. with respect to criteria 4 - life cycle cost - solution 1 scores 1,35 over solution 2

[vii] The average life cycle for thin façades was extimed, for istance, in 48 years by a reseach of CSTC (CSTC, Recherches sur les performances du batiment, Compte rendù d'étude et de recherche n.29/1976).

# Durability Of Acrylic Waterproofing Membranes For Wet Areas

**BL Schafer**
**CSIRO Appraisals Victoria Australia**

**Summary: In recent years, environmental pressures have resulted in increasing use of acrylics as waterproofing membranes. A major barrier to the use of these materials has been concerns about the service life that they will achieve. CSIRO Appraisals has developed a testing protocol for the evaluation of the long-term serviceability of these materials, and this paper discusses the testing protocol and the interpretation of the results, including how they can be used to determine the suitability of a membrane to protect different substrates. As acrylic waterproofing membranes have a wide variation in their water vapour transmission rate, the paper includes the additional testing required to determine the suitability for use over substrates according to the water vapour transmission rate.**

**Membrane systems have a large variation in their elongation at break, thus requiring different types of bond breakers to cater for these varying elastic properties and thereby protect the membrane from fracturing at substrate discontinuities. The different types of bond breakers are discussed, along with their compatibility to the different elastic properties of the membrane systems.**

**The effect of curing time on acrylics is vital to the performance of the system. The lack of a sufficient curing time is one of the problems that has been highlighted in field monitoring that CSIRO Appraisals undertakes on membrane systems. The results from laboratory testing and those found in the field monitoring are discussed.**

**The test method developed by CSIRO Appraisals is currently being adopted by Standards Australia for inclusion in the Building Code of Australia as a deemed-to-satisfy requirement for the physical properties of membranes used in wet areas of buildings.**

**Keywords: Waterproofing membranes, wet areas, Building Code of Australia, bond breakers.**

## 1. INTRODUCTION

In recent years, environmental pressures have resulted in increasing use of acrylic-based materials for waterproofing membranes. A major barrier to the use of these membranes has been concerns about whether they will have an acceptable service life. CSIRO Appraisals has developed a testing protocol for the evaluation of the long-term serviceability of these materials when used for waterproofing wet areas. This paper disucsses the testing protocol and interpretation of the results, including how they can be used to determine the suitability of a membrane to protect different substrate materials.

The testing program has been developed as a result of CSIRO Appraisals needing to evaluate membranes for fitness for purpose, so the four membranes referenced throughout the paper are required to be kept confidential and will be referred to as A, B, C and D.

## 2. CHEMICAL RESISTANCE

The practice in Australia is to lay the waterproofing membrane under the tile bed. Thus, the membrane needs to function below a saturated tile bed. Solutions of chemicals used within the wet area can find their way to the surface of the membrane. A critical position where waterproofing membranes need to function is at the wall/floor junction, where the membranes need

Go Back

Next Page

to cater for the movements that occur between the changes of substrates. Leakage at this location can result in water penetration into adjoining rooms, which means non-compliance with the Building Code of Australia. Even though the recommended tile-laying procedure is for the floor tiles to be laid under the wall tiles, in practice it is often the opposite, with the floor tiles abutting the wall tiles. While both methods will allow cleaning chemicals to track down to the membrane, this non-preferred tile-laying method makes the membrane more vulnerable to attack from cleaning chemicals. With the floor tiles abutting the wall tiles, cleaning chemicals that run down the wall tiles will enter the vertical crack that, with the passage of time, develops between the wall and floor tiles. Thus, it is imperative that the waterproofing membranes used in wet areas have resistance to the commonly used cleaning chemicals. The most commonly used mould growth chemical is sodium hypochlorite (bleach), while detergents are also used in the cleaning process and so resistance to detergent is also required. As the tile bed is fully saturated, long-term resistance to a head of water above the membrane is also critical.

The testing method developed uses deionised water for the water immersion testing. For all three testing exposures, 12 specimens are fully immersed in a sealed container with 600 ml of solution. Three specimens are tested at each of the periods of exposure, and there are three spare specimens in case of any breakages before testing. The specimens are tested in tension to the testing method given in Australian Standard AS 1145–2001 (Standards Australia 2001) using a type 5 specimen. The specimens need to include reinforcement where this is part of the membrane.

The testing method uses more concentrated solutions of the chemicals than would normally be applied when cleaning. For sodium hypochlorite a 2% solution is used – about three times more concentrated than is commonly used in mould-removal solutions. For the detergent, a 30% solution of an industrial-grade detergent is used. The use of more concentrated solutions is somewhat similar to the testing of materials used externally where, with accelerated weathering, they are exposed to high levels of UV in short-term testing to give long-term predictions of performance. However, for the chemical testing, it is expected that significant changes in properties will occur. What needs to be determined using this accelerated exposure is whether the membrane will lose its integrity to the point where it will fail to provide an acceptable service life.

What is an acceptable service life for these membranes? They are installed under an expensive tile or stone finish, and thus they need to have a service life equal to at least that of their expensive covering. No one really expects to replace the tiles or stone covering, that can cost more than 10 times that of the waterproofing, because of a membrane failure. While the tiles or stone covering could have a service life greater than 25 years, in reality by this time it is most likely that they would have been replaced to bring them into a more fashionable scheme. During a renovation when the covering is replaced, the membrane would be damaged, and would also need to be replaced. Bathrooms are one of the more personal areas of the dwelling and when there is a change of ownership, the bathroom is usually one of the first rooms to be renovated. Real estate figures give the average ownership of a dwelling in Australia's capital cities as less than 10 years. Thus, a 25-year service life for the membrane would easily meet a 95% confidence limit that it would be replaced within this time.

Initially, it was thought that testing at 7, 14 and 28 days would give all the data required. But as can be seen in Fig. 1, there is a reversal of the trend sometimes after 7 days and, to get a reliable result, the testing was extended to 56 days. In these tensile test figures, the ordinate is a comparison of the exposure result to that of the control for the sample under test. Using this ratio enables both elongation at break and tensile strength to be graphed on the one plot for comparison. In other figures, it enables direct comparisons of the relative performance of different membranes. In the initial development of the testing method, the 14-day testing increment was continued. However, as the method was to become a standard test, and costs needed to be contained, the test exposure times finally chosen were 7, 28 and 56 days. The 7-day exposure was used in preference to 14, as it will show early if a membrane has little chance of meeting the test requirements.

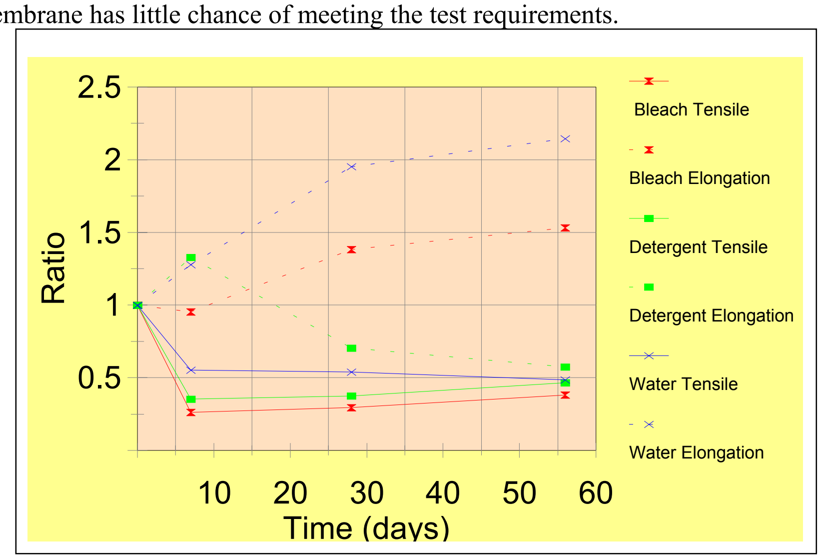

**Figure 1. Tensile strength and elongation at break results for membrane C**

For the membrane to remain serviceable, it is important that it maintains enough flexibility to enable it to accommodate any movements that occur over changes in substrates that it bridges. Thus, it is elongation at break that is the most important property to be maintained. Often, the membrane softens during exposure to both water and bleach, as happened with membrane C (Fig. 1). For both of these exposures, membrane C has had an increase in elongation at break with a corresponding reduction in the tensile strength. After the initial 7-day exposure to the detergent, this is not the case, with a loss of both elongation at break and tensile strength. A loss in both properties indicates that the membrane material is suffering some fundamental loss of its intrinsic property. In the case of membrane C, there is not sufficient loss under exposure to detergent to be of concern, with it keeping just over 50% of its initial elongation.

The results for membrane A are shown in Fig. 2. These are not nearly as convincing, with the continual loss of both properties on exposure to both bleach and detergent continuing significantly between the 28- and 56-day results.

The results for elongation at break for all four membranes exposed to detergent are given in Fig. 3. Membrane B shows a significant change in the results between 7 days and both 28 and 56 days. This reversal was observed for many of the membranes that we have tested and is an example of why extending the testing out to 56 days, rather than finishing at 28 days as originally proposed, is warranted. The results for tensile strength for all four membranes exposed to detergent are shown in Fig. 4. The rapid loss of both tensile strength and elongation at break for membrane B at 7 days, having lost over 50% of its elongation at break and about 50% of its tensile strength, would indicate that this membrane was unlikely to meet its long-term durability requirement. However, by 56 days it had virtually recovered all of it elongation at break while still retaining 25% of its tensile strength. Based on these longer exposure results, it was considered to be a satisfactory membrane for use in wet areas. The testing, as mentioned earlier, is using more concentrated solutions to show long-term effects to exposure to less concentrated solutions likely to be experienced in normal usage.

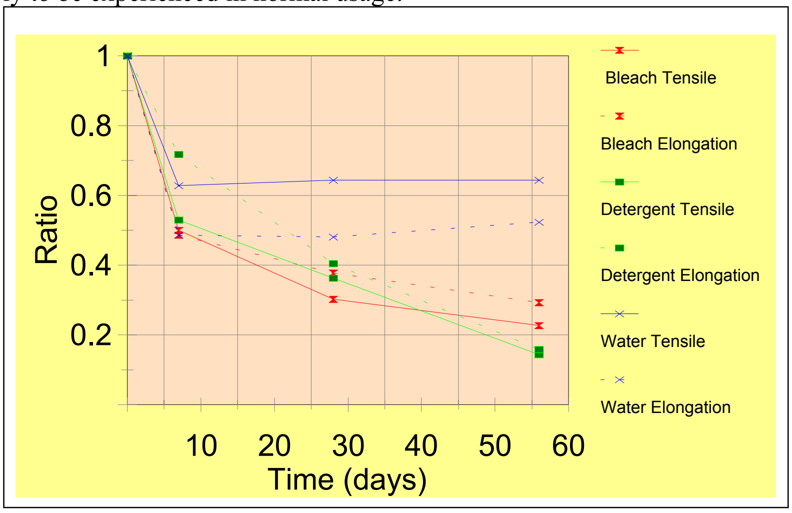

**Figure 2. Tensile strength and elongation at break results for membrane A**

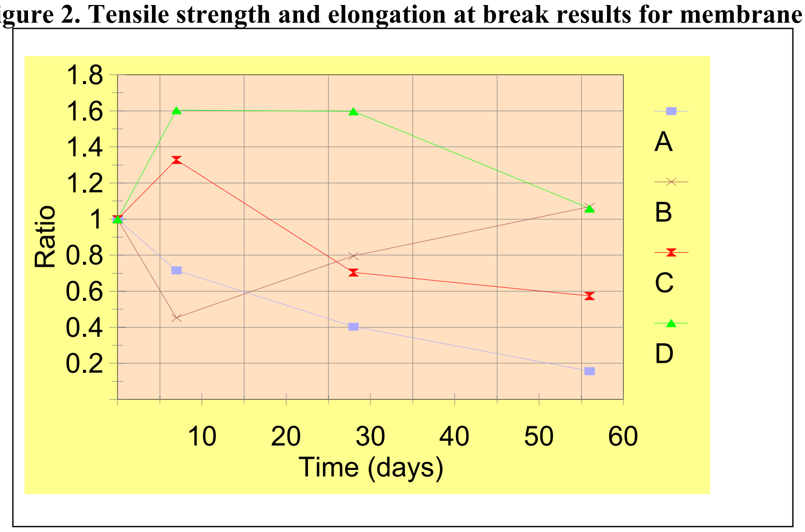

**Figure 3. Elongation at break for all four membranes on exposure to detergent**

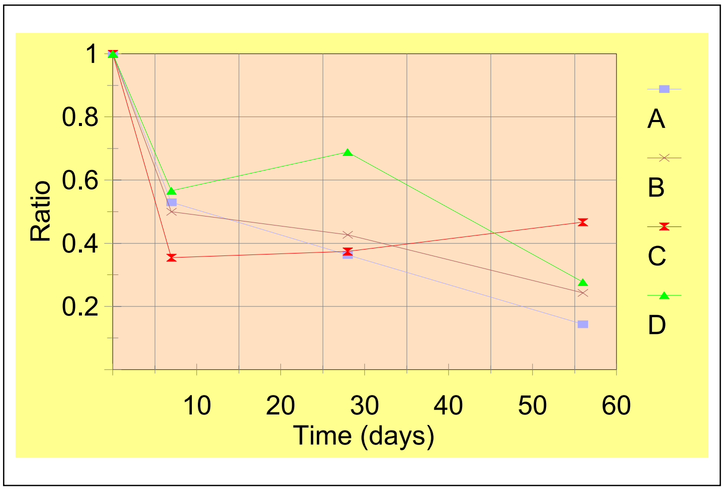

**Figure 4. Tensile strength for all four membranes after exposure to detergent**

The pass/fail criteria finally chosen was to require that at least 40% of the elongation at break needs to be retained after 56 days exposure. It was considered that if the specimen had retained sufficient strength to enable it to be tested, then it had retained sufficient tensile strength. In practice, with correct specification of bond relief over areas where the membrane is expected to be stretched, the membrane will only fail if it is stretched beyond its elastic limit, as given by its elongation at break property. The results for all four membranes for their elongation at break after exposure to bleach is given in Fig. 5, and after exposure to water in Fig. 6. Thus, membranes B and C passed the test criteria while A and D failed to do so.

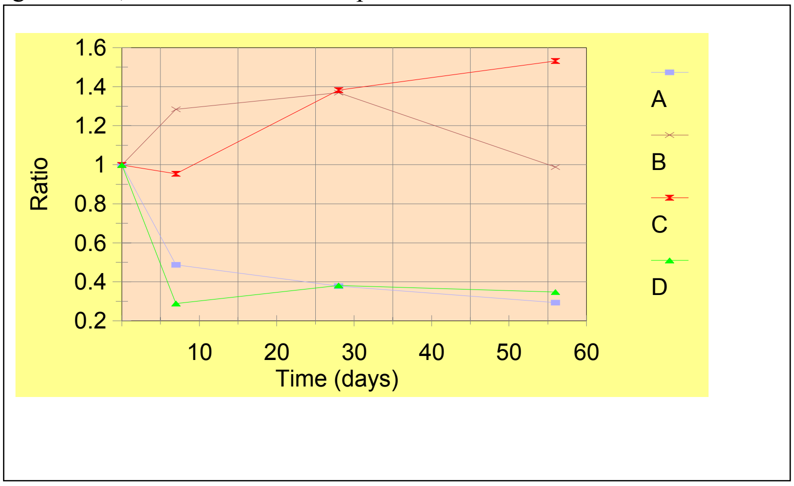

**Figure 5. Elongation at break for all four membranes after exposure to bleach**

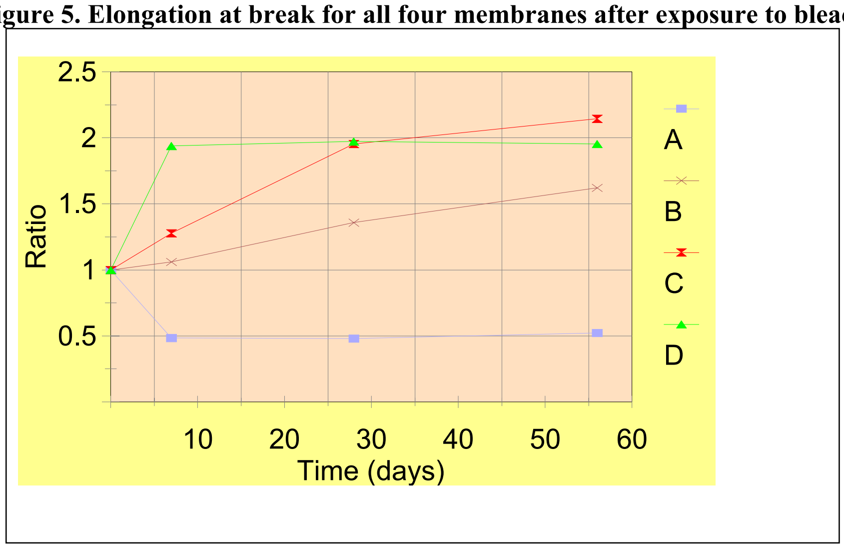

**Figure 6. Elongation at break for all four membranes after water exposure**

Some membranes that we have received for testing reach a stage of collapse at 7 days exposure and are not even able to be tested as shown in Fig. 7. The three on the left were exposed to bleach, while the one on the right was exposed to detergent. The worrying fact is that these were membranes that had been marketed for some time before they were tested for durability.

**Figure 7. Tensile test specimens that failed before they could be tested**

## 3. FATIGUE FRACTURES

The membrane will have to continue to bridge over any cracks and gaps between changes in substrates, while these gaps have potential for ongoing movements with changes in temperature and/or moisture content. Martin (1977) described a test for membranes that have high elongation at break. This method can be used for unreinforced acrylic membranes that have elongations at break well over 300%. However, when they have some reinforcement, or are a combination of cement and acrylic resin, their elongation at break can be well below the elongation required by the test as described by Martin. What we have done is to modify the Martin method to cycle the membrane over 75% of its elongation at break rather than the 200% as given in Martin's method. The specimen includes any reinforcement that is used. This modification has developed a satisfactory method to check that the membranes do not fatigue fracture where they bridge over moving gaps.

To make sure that the membrane is kept within the movement it can accommodate, there is a need to give bond relief from the substrate at points of discontinuity subject to movement. Three classifications of membranes have been defined.

Class 1 membranes are those that have an elongation at break of less than 65%. Due to their low extension before they fracture, these need a bond breaker that takes up the movement by bending the membrane rather than stretching it. The bond breaker should be a backing rod utilised to place an initial curve in the membrane. The rod allows the membrane to straighten when a gap widens or become more curved to tolerate a shortening of the gap. Figure 8 shows this type of bond breaker.

Class 2 membranes are those that have an elongation at break between 65% and 200%. These need a bond breaker with a suitable unbonded length to allow the membrane to stretch to accommodate the movement. The width of the tape is determined so that the membrane will not go beyond 65% of its elongation at break to take up the movement. Figure 9 shows this type of bond breaker.

Class 3 membranes are those that have an elongation at break greater than 200%. These hardly need a bond breaker at all, but any bond relief will lower the risk of failure. A fillet of sealant will give all the bond relief that is required. Figure 10 shows this type of bond breaker.

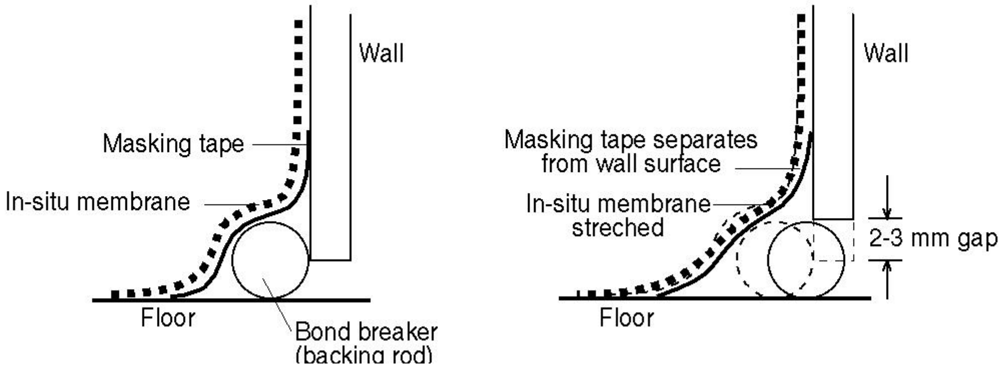

**Figure 8. Bond breaker for a Class 1 membrane**

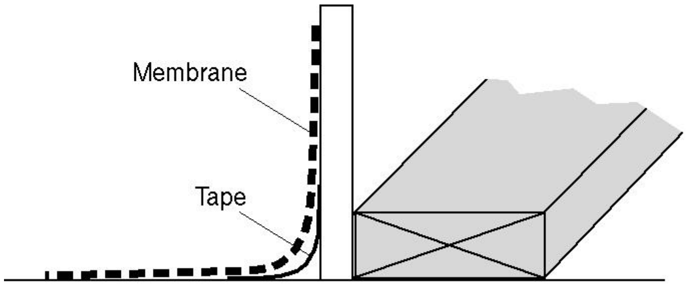

**Figure 9. Tape bond breaker for a Class 2 membrane**

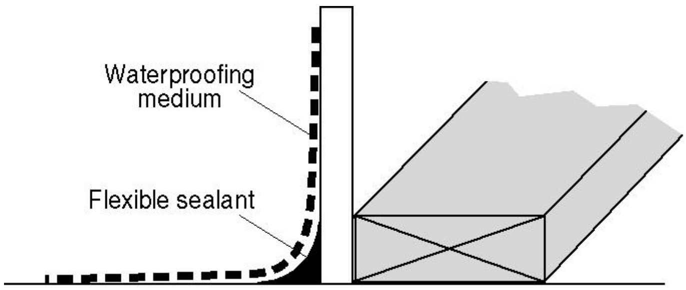

**Figure 10. Flexible sealant bond breaker for use with a Class 3 membrane**

## 4. SUBSTRATE PROTECTION

Acrylic membranes have high water vapour transmission rates. The actual rate for any membrane depends on its formulation and can be as low as 2 g/m²/24 hr  to in excess of 60 g/m²/24 hr. For those at the upper end there is potential for moisture to build up in the substrate under the membrane by water vapour transmission through the membrane. To ensure that membranes do not cause this problem to the substrate, especially those subject to moisture damage, a ponding test was designed. In the test, a 600 mm square tray of the membrane is formed over a particleboard floor substrate which has a butt joint running across the middle of the tray. Insulated probes are installed from the underside of the particleboard to measure the moisture content 1 mm under the membrane by an electrical moisture meter. The probes are located at set distances each side of the butt joint in the particleboard. After the tray has fully cured, it is flooded with water to a depth of 25 mm and the moisture content recorded until it has stabilised. For the first five days, daily readings are taken, and thereafter twice a week (3 and 4 days between readings). Simultaneous readings are also taken for a control piece of particleboard, which is placed beside the test tray. Both the test tray and the control are located in standard laboratory conditions of 23°C and 50% RH. Figure 11 shows some of the results to date recorded from this test. Clearly the 66 g/m²/24 hr material was showing a real problem, with an increase in moisture content in the particleboard of nearly 30%, while the 2 g/m²/24 hr material had little increase and was of no concern.

It is recommended that shower recess membranes not be used directly on top of particleboard where test results give a moisture content increase of 10% or greater than that of the control.

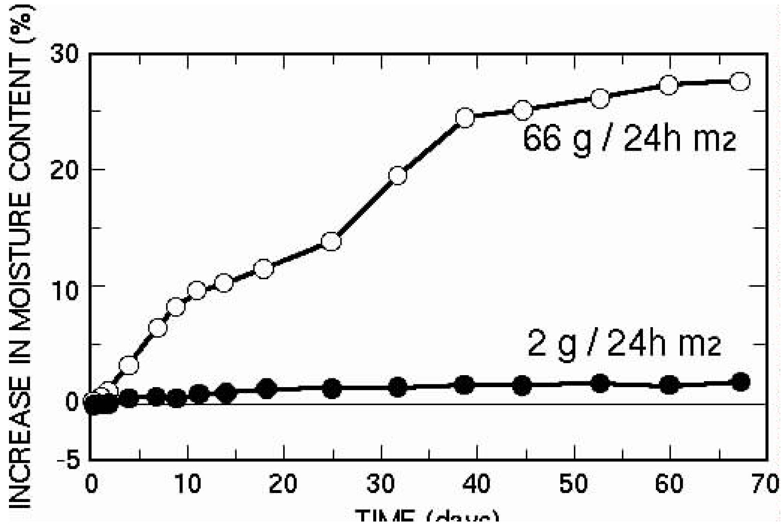

**Figure 11. Moisture increase in particleboard flooring under different membranes**

CSIRO Appraisals has collected enough data to know that if the water vapour transmission is 8 g/m²/24 hr or less, then the membrane can be used directly over particleboard under a shower. This limit may be raised in the future when more data is available for membranes above the current limit of 8 g/m²/24 hr.

## 5. CURE TIME

One of the main causes of failures of acrylic membranes that CSIRO Appraisals has found in field inspections is inadequate curing before the membranes are covered. Acrylics rely on water loss to cure, and when used in wet areas, such as small and poorly vented rooms (e.g. en suites), it can take over 7 days for a straight acrylic to cure in winter conditions. If covered before they are allowed to cure fully, they can re-emulsify where they are continually wet, as is the case when used in shower recesses. To retain the elastic properties, one either needs to wait for a full acrylic to cure or use heating and airflow to speed up curing. We stress in all our appraisal reports that slow curing has to be allowed for, but still we occasionally find installations where they have been covered without being cured.

To shorten the cure time, there are some two-part formulations consisting of a liquid acrylic mixed together with a cement-based powder. These will cure within 24 hours, but they loose the high elongation that is available with a full acrylic formulation.

One of the main problems with the cement–acrylic formulations is that, due to their thick creamy nature, they can be applied too thick, which results in drying crazing. This is caused by the skin curing before the body of the membrane cures.

Straight acrylics used without reinforcement can be applied too thinly. Some inspections have found a thickness of less than 0.1 mm where an unreinforced acrylic has been used. The usual specified thickness is about 1 mm.

## 6. CONCLUSION

CSIRO Appraisals has developed a testing program that has a proven record in being able to successfully evaluate the suitability of acrylic membranes for use in the waterproofing of wet areas within buildings. The testing program is currently being adopted into an Australian Standard. Several membranes have been found to be unsuitable for use in wet areas. We are now in a position to make sure any membrane that is proposed will give an acceptable service life.

# Performance Evaluation Of Photocatalyst Coating Systems Under Outdoor Exposure Condition

**Tatsuo Inukai[1] Kenji Motohashi[2]**
**[1]Tsukuba Building Test Laboratory Centre for Better Living Ibaraki Japan**
**[2] Building Research Institute Ibaraki Japan**

**Summary: Application of "Photocatalyst" (typical substance in this paper: titanium dioxide, $Ti0_2$) into the building materials and/or components, likely internal and external finishing boards, paint coatings, membrane materials, ceramic, film etc., is rather newly developed technology. One of the advantageous features by applying this photocatalyst would be the ability of self-cleaning or self-desoiling on the surface of materials.**

**This paper introduces the results of two series of experiments. In the first series of experiments, the effect of photocatalyst was confirmed through the decomposition of methylene blue in the laboratory by using ceramic tiles treated with titanium oxide. The effect was also confirmed after some degradation treatments for the tiles such as immersion into acid solution, immersion into alkaline solution, and sunshine carbon irradiation. In the next series of experiments, the outdoor exposure test under the pastoral and polluted ambient areas were conducted for the various exterior finishing materials treated with titanium dioxide.**

**Although relatively limited amount of data are available at present stage, the following conclusion could be made;**

**1) The effect of photocatalyst could be clearly recognized through fading out of methylene blue in the laboratory test even after various degradation treatments.**

**2) The self-cleaning effect was also recognized in the outdoor exposure test. The degree of effect was dependent upon each commercial product at present stage; however, products treated with photocatalyst showed the significantly higher self-cleaning effect compared with ordinal non-treated products.**

**3) In the evaluation of striped soiling which were often observed on the exterior envelope, the parameters derived from optical measurement of striped soiling possessed good correlation with the visual inspection results by using designated pictorial sheets. However, the correlation was becoming low in case that overall soiling was predominant on the specimens.**

## 1 INTRODUCTION

Surface appearance of a whole building or a part of it should be one of the aesthetic requirement for the building as defined in ISO standard (ISO 6241:1984) as one of the "visual user requirement" which composed of several sub-factors as such colour, texture, regularity, flatness etc, and it has been one of the long-time major issue how to sustain the surface appearance in an acceptable condition, even though the acceptable level depend fully upon each building.

Nireki (2000) reported based on his experimental works, the soiling issue for membrane material leads to reduction of its light transmission coefficient and this directly effects the primary performance requirement to sustain the inner visual environment of large scale membrane structure.

As to the soiling of external envelope, it can be divided into the uniform and local one, that stand for uniformly soiled and partial or dotted soiling within a certain area of a plane of building or a component, here, in general the later one is much noticeable than the former one. For example, Motohashi & Sakai (1993) pointed out the soiling behaviour on the fluoropolymer paints as one of the important deterioration phenomena.

Much attention has been paid to cope with this contamination in building. Various countermeasures to protect soiling had been tried both from design aspect such as shape, dimension, details of external component and from material modification aspect by changing water repellent property, hydrophilic property, electrostatic property, resolvable property etc.

Application of the “Photocatalyst” would be one of typical examples. Titanium dioxide ($TiO_2$) type photocatalyst that aiming to apply to buildings, civil engineering and also medical engineering area, has been intensively developed.

The principal character of photocatalyst is capability of disintegrating the soiling substances which led to self-cleaning effect, and controlling fungi and bacteria, whereas, its applicable fieds has been expanding as such coating system for external wall, kitchen wall, bathroom, measures for surface contamination of lighting appliances and sundry goods, preventive measures for indoor air contamination especially due to VOC (volatile organic component), medical facilities, deodorant etc. according to Fujishima et al. (1999)

## 2 PURPOSE

The objective of this experimental research is to confirm the self-cleaning effect of exterior finishing materials treated with photocatalyst. The selected finishing materials were both commercial and under developing ones including ordinanary finishing materials as the references.

Rather large amount of photocatalyst applied materials are actually used in buildings at present. However, the effectiveness of these finishing materials has not been widely confirmed yet. In other words, although various photocatalyst applied products are put on the market, very little reliable technical information is available except for limited technical data from each manufacturer. In this context, this research was started in order to obtain the results of outdoor exposure tests that could be significant among building engineers and material manufacturers as well as customers.

The aim could be divided into the following three items;

- Performance evaluation of exterior finishing systems under in-use environmental condition to provide as the durability data that could be applicable for “service life prediction” in the principle of “service life planning” as specified in relevant ISO standard (ISO 15686-1) or AIJ guide (AIJ, 1989).
- Accumulation of some experimental data for setting of “Evaluation method for self-cleaning effect.”
- Accumulation of some experimental data for developing “the laboratory test” for evaluation of photocatalyst applied products.

## 3 OUTLOOK OF $TIO_2$ PHOTOCATALYST

As for the mechanism for the case of surface finishing materials, the interface of soiling contaminants adhered on the finishing materials could be decomposed by the effect of radical reaction led by the photocatalyst ( typical substance in this paper: titanium dioxide, $Ti0_2$ ) reaction that is accelerated under solar irradiation.

In practice this reaction would be active not only on the side of the irradiated surface but also on the opposite surface, therefore, it usually does need to apply a protective thin coating likely primer coating to protect the substrate if the substrate consists of organic substance. Consequently, when the photocatalyst treatment is applied to the organic material substrate, one layer of protective treatment against radical reaction is recommend before treatment with photocatalyst in the applying specification.

## 4 SPECIMENS

Type, dimension and some detail of specimens are shown in Table 1, Figure 1 and Figure 2.

**Table 1. Specimens**

| | Substrate | Finishing | Variation |
|---|---|---|---|
| A | Aluminum Sheet (1mm)<br>Acrylic-silicone coat (50μ) or<br>Polyurethane coat (60μ) | $TiO_2$ clear coat, 10-40g/m$^2$ | 8 |
| B | Aluminum Sheet (1mm) | $TiO_2$ paint coat (white), 15-30μ(60-100g/m$^2$) | 5 |
| C | PVC-coated membrane material | $TiO_2$ clear coat, 1μ(100g/m$^2$) | 1 |
| D | Aluminum Sheet (1mm) | $TiO_2$ masonry coat (white), 3-7Kg/m$^2$ | 1 |
| E | Aluminum Sheet (1mm)<br>Acrylic-silicone (50μ) or<br>Polyurethane coat (60μ)<br>(* as reference of A) | Ordinary Silicate clear coating (30g/m$^2$) | 6 |
| F | PVC-coated membrane<br>Material (*as reference of C) | PVF clear film (38μ) & none | 2 |
| G | Aluminum Sheet (1mm)<br>(*as reference of D) | Ordinary masonry coat (250g/m$^2$)<br>Aclylicsilicone (120g/m$^2$) | 1 |
| P | Ceramic tile | Titanium dioxide clear coat (20-30g/m$^2$) | 5 |
| Q | Ceramic tile (*as reference of P) | Hydrophile silicate clear coat (10-20g/m$^2$) | 4 |
| R | Ceramic tile (*as reference of P & Q) | None | 9 |

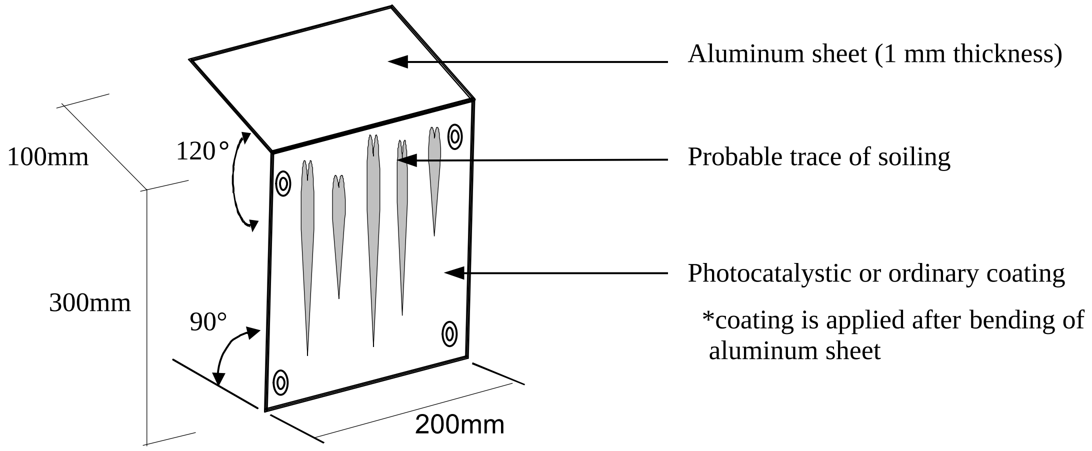

**Figure 1. Detail of specimen A to G**

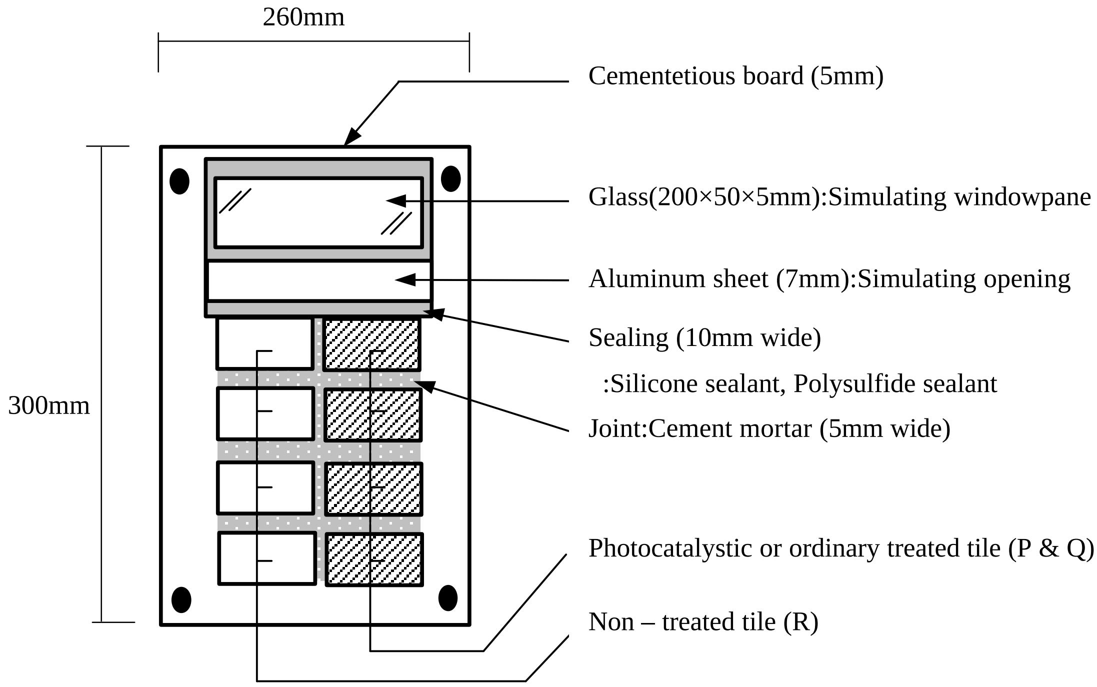

**Figure 2. Detail of specimen P, Q & R**

## 5 LABORATRY TEST FOR CONFIRMING DECOMPOSITUION OF METHYLEN BLUE

By using one of the specimens P in Table 1, activity of photocatalyst was confirmed through the decomposition of methylene blue stain which was coated on the one of the specimens P. This preliminary experiment was conducted before conducting the outdoor exposure test. The one of the specimens P in Table 1 (Porcelain tile coated with titanium oxide) were immersed in methylene blue ethyl alcohol solution (0.1 wt%). After raising the specimens from the solution, the specimens were dried for 30 minutes at 20? and 65%RH. Before immersion into the solution, some of the specimens were also underwent the following degradation treatment.

Immersion in acid solution : Immersed the specimens in 5 wt% sulfuric acid for 96 hours and washing with water.

**Immersion in alkaline solution : Immersed the specimen in saturated calcium hydroxide solution for 96 hours and washing with water.**

Sunshine carbon arc irradiation : Sunshine carbon arc irradiation in accordance with ISO 4892-4:1994 for 2000 hours.

After drying for 30 minutes, the specimens were irradiated by use of ultraviolet lamp (Toshiba FL40S-BLB). The ultraviolet irradiation intensity was 0.4mW/cm$^2$ at the surface of the specimens. Degree of fading of methylene blue on the specimens was monitored by measuring color difference (? E) compared with the initial values for the specimens before immersion into the methylene blue solution. The number of repetition for the specimens was three. The results were shown by use of the average value of the three specimens.

## 6 OUTDOOR EXPOSURE TEST

### 6.1 Exposure conditions

All types of specimens listed in Table 1 were exposed to following three different environments.

BRI : Outdoor exposure site, Building Research Institute, Tsukuba City (some 50 km north of Tokyo).

Kashiwa-1: Just around the tollgate facility of Kashiwa junction, Jyoban motorway (some 30 km north of Tokyo), and heavy polluted environment due to traffic.

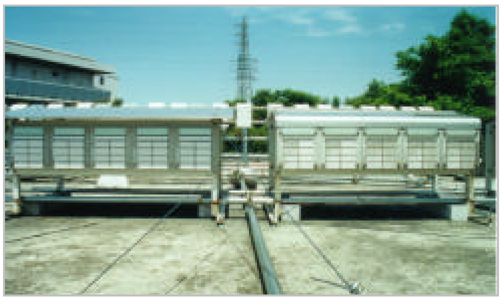
Kashiwa-2: On the roof of office of motorway in the vicinity of Kashiwa-1 slightly less polluted than Kashiwa-1.

In BRI and Kashiwa-2, all porcelain tile specimens were exposed both facing south and north in due consideration of different ultraviolet irradiation and specimens were attached on the rack installed around the gate hatch, faced to the parallel of traffic flow. (Photographs 1 to 6)

**Photograph 1. Overview of outdoor exposure for specimen A to G in Kashiwa-1 site**

**Photograph 2. Outlook of specimens A to G in Kashiwa-1 site**

**Photograph 3. Overview of outdoor exposure test in Kashiwa-2 site**



**Photograph 4. Outlook of specimen P, Q & R (tile) in Kashiwa-2 site**

*to the left:* with eaves, to the right: without eaves

**Photograph 5. Closing up of soiling behaviour,**

*the left row* in each block is non-treated tiles *and the right row* ; photocatalyst coating applied ones

**Photograph 6. Closing up of rain trace,**

*to the left:* specimen, *to the right:* pictorial designation sheet

### 6.2 Visual evaluation

Visual evaluation was conducted by using the pictorial designation system like Nireki (1986) had already applied for deterioration state of external masonry coating system. In this project, the pictorial designation of state of soiling for surface coating systems has been provided with intention to include evaluation of striped soiling mainly as a result of rain water flowing on the surface coating.

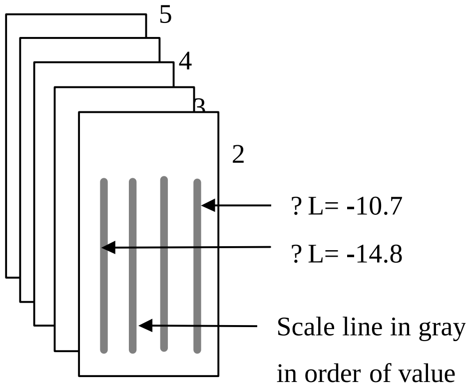
Striped soiling state is classified into five degrees from none to excessive on the basis of previous on-site investigation data on the soiling of surface finishing systems. Each degree can be divided into five sub-degrees in the order of soiling state within each degree and this can be printed on a sheet as in Figure 3, then, actual evaluation of soiling can be carried out by applying these five designation sheets.

The actual evaluation work was operated by 4 to 5 members with taking the pictorial designation sheets at around two meter apart from each specimen.

### 6.3 Measured Value [L*]

Evaluation in this project was focused on behaviour of soiling over time by the visual evaluation and measured value [L*]. Soiled state can be defined as a difference of value between the initial value and a measured value at certain time, here, the value [L*] is specified as a quantitative value in this project.

Go Back Next Page



| Degree | [? L*] value |
|---|---|
| Degree 1 | -14.8 ~ -10.7 |
| Degree 2 | -5.6 ~ -3.1 |
| Degree 3 | -2.5 ~ -1.8 |
| Degree 4 | -0.8 ~ -0.3 |
| Degree 5 | None |

† [? L*]: Value measured by MINOLTA CR300

†† White base sheet [L*] = 92.0

**Figure 3. Pictorial designation of soiling states of surface coating system for visual evaluation**

The value [L*] was measured by using two different colour meters as MINOLTA CR300 (10.0mmf scope) and MINOLTA CR321 (3.0mmf scope), the former one is for relatively uniformly soiled area (Part with & without rain trace in Table 2) and smaller spotted area for the later (Part with rain trace only in Table 2). In principle, the value [L*] is an average out of three points within a plane of specimen. The soiling based on measured value [L*] in each part of specimen was defined according to Table 2

**Table 2. Soiling in each part of specimen**

| Part of specimen | Soiling |
|---|---|
| Part with & without rain trace | Difference between [L*(With & without rain trace)] with & without trace in an average of each area vs. initial value |
| Part with rain trace only | Value [L* (rain trace only)] in an average of the traced area vs. |

## 7 RESULTS AND DISCUSSION

### 7.1 Confirmation of photocatalyst in the laboratory test

The change in color difference in the laboratory test was shown in Figure 4 to Figure 7. Figure 4 shows the changes in color difference for the photocatalyst treated ceramic tiles and for original ceramic tiles. As shown in Figure 4, the color difference of the photocatalyst treated tiles was going down as irradiation time passed, which means that methylene blue was decomposed by activity of photocatalyst. On the other hand, color difference of the non-treated tiles was not going down, which indicates that the color of the specimens did not change. In other words, methylene blue was not decomposed on the non-treated specimens. Strictly speaking, the color difference of the non-treated specimens was going down very slightly; however, it is considered to be due to irradiation by ultraviolet lamp itself.

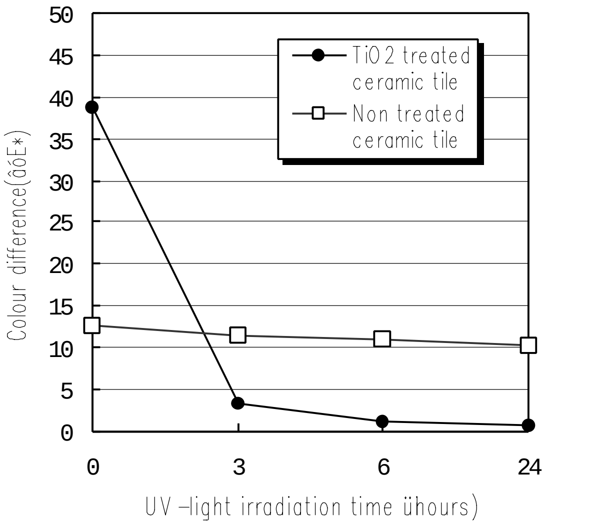


**Figure 4. Changes in color difference for the photocatalyst treated ceramic tiles and non-treated ceramic tiles.**

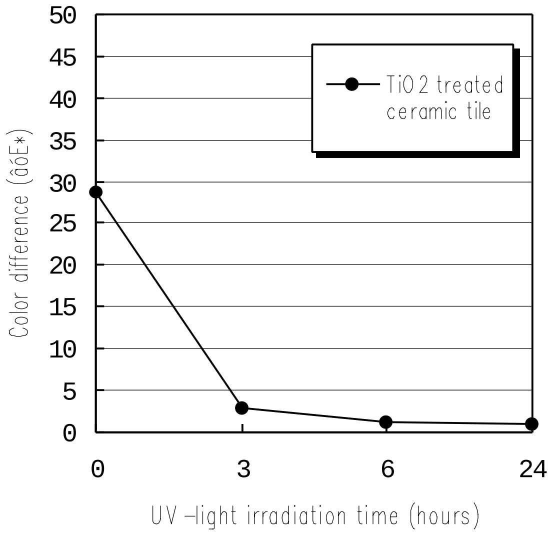

**Figure 5. Changes in color difference for the photocatalyst treated tiles after immersion in acid solution.**

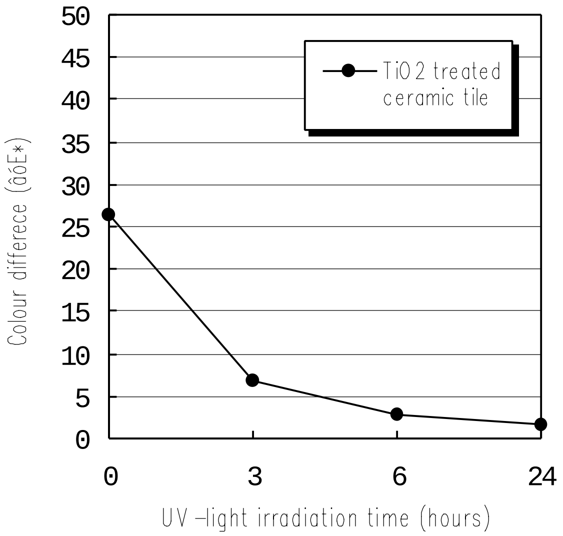

**Figure 6. Changes in color difference for the photocatalyst treated ceramic tiles after immersion in alkaline solution.**

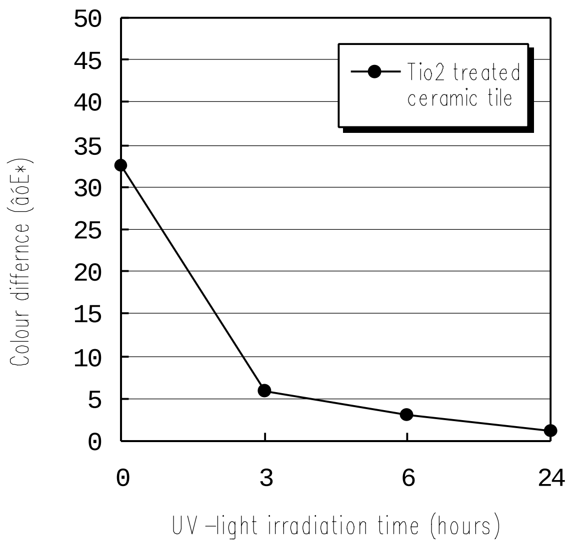

**Figure 7. Changes in color difference for the photocatalyst treated ceramic tile after sunshine carbon arc irradiation for 2000 hours.**

The decrease of color difference could be also confirmed in the specimens which were variously treated before immersion in methylene blue solution as shown in Figure 5 to Figure 7. It means that the activity of photocatalyst is still effective after these treatments.

### 7.2 Difference due to outdoor exposure environment

Difference of soiling behaviour among three environments can be clearly noticeable. Fig. 8 to Fig. 10 shows the percentages of the specimens at each degree. As shown in the Figures, it is evident that the exposure site is greatly affected the degree of soiling of the specimens. In the study, the most severe site is Kashiwa-1 where is near the tollgate of the high way. The next is Kashiwa-2 where is office in the vicinity of Kashiwa-1. BRI was the mildest site among the three.

Go Back Next Page

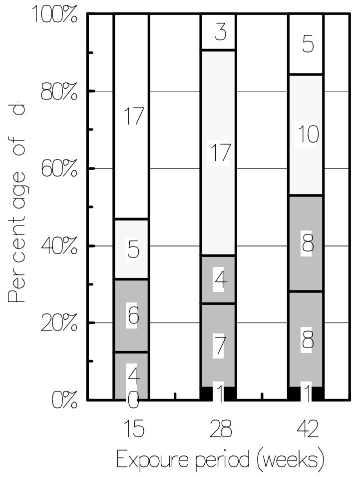

Figure 8. Result of visual evaluation at BRI, after 42 weeks (A to G)

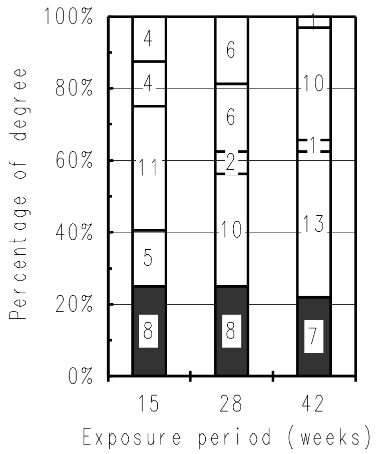

Figure 9. Result of visual evaluation at Kashiwa-1 site, after 42 weeks (A to G)

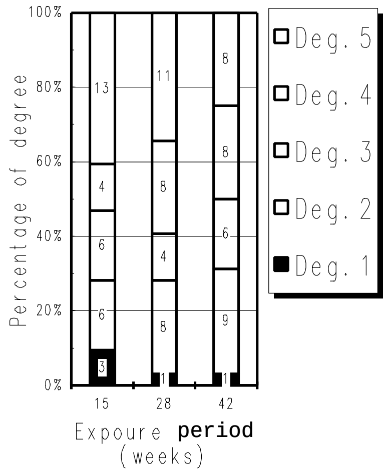

Figure10. Result of visual evaluation at Kashiwa-2 site, after 42 weeks (A to G)

8 specimens have reached to Degree 1 after 15 weeks in Kashiwa-1. In Kashiwa-2, 3 specimens have reached to Degree 1 after 15 weeks. On the other hand soiling has not yet reached to Degree 1 after 15 weeks in BRI. It can be said that degree of soiling is in the order of Kashiwa-1, Kashiwa-2 and BRI.

As to the difference due to exposure direction, north and south, specimen A to G, except G, show no distinctive difference by 42 weeks. This can be estimated that the sufficient photocatalystic reaction could be expected even in the north side where comparably lower solar irradiated environment than south. Nireki (1983) reported that the amount of total solar irradiation at surface of specimen facing north is around 40% that of facing to south in BRI outdoor exposure site.

### 7.3 Correlation between visual and [L*] value evaluation in outdoor exposure test

Taking the result as shown in Figure11 as an example, the correlation between visual and [L*(rain trace only)] value evaluation shows higher relation at 24 weeks exposure, however, as such high correlation can not be expected in due course of exposure days as shown in Figure 12. The main reason of this decreasing the coefficient of correlation should be dependent on the change of soiling mode on the surface of coatings, namely, noticeable rain trace in rather early time would no more be recognized due to the successive increase of uniform soiling over all area of surface over exposure term.

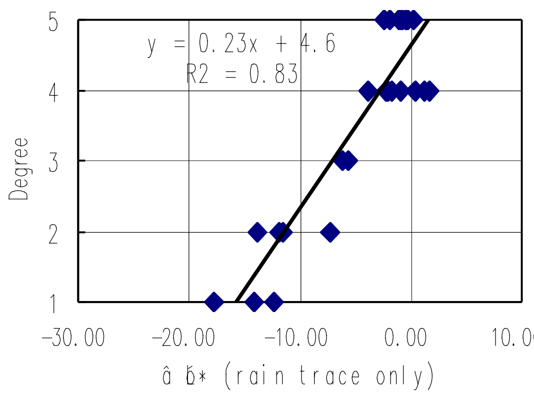

**Figure 11. Correlation between visual evaluation and value [L*],** measured in “Part with rain trace only” as in Table 2 (specimen A to G), after 24 weeks at Kashiwa-2 site

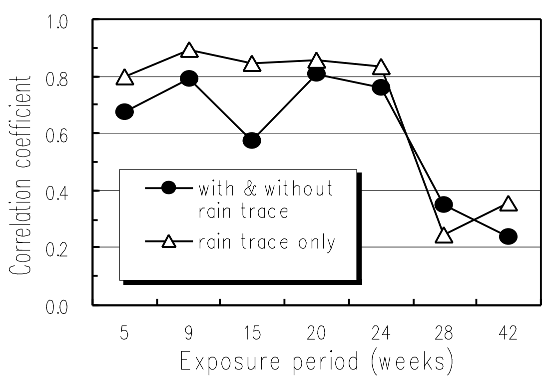

**Figure 12. Change of Correlation between visual evaluation and value [L*],** Specimen A to G, at Kashiwa-2 site, each symbol correlates to the order of soiling in Table 2

Go Back Next Page

As it is not shown in the paper, the same tendency was recognized for the [L*(with and without rain trace)] value evaluation. As far as the rain trace of the specimens are clear, visual evaluation by use of designated pictorial sheet, measurement of [L*(rain trace only)], and measurement of [L*(with and without rain trace)] shows good correlation; however, these values does not show good correlation in case that the uniform soiling is predominant on the surface of the specimens.

### 7.4 Effectiveness of photocatalyst

Taking result on the effect of photocatalyst as shown in Figure 13 (specimen A to G) as an example, effectiveness could be remarkable recognized throughout all photocatalyst applied finishing. It is also remarkable that the variation within the photocatalystic coating group can be noticed. The reason of radiation would be due to the quality of material itself, in fact, the quality of materials whether they are already developed or under developing stage. Take this rather special case apart, the fact, more than half of photocatalystic coatings have still keep at the level of degree 5 or at most 4, would shows the effectiveness of photocatalyst applied finishing in comparison with the results from another groups. As to the coating for tile (specimen P to R), the effectiveness can be recognized as in Figures 14 to 16.

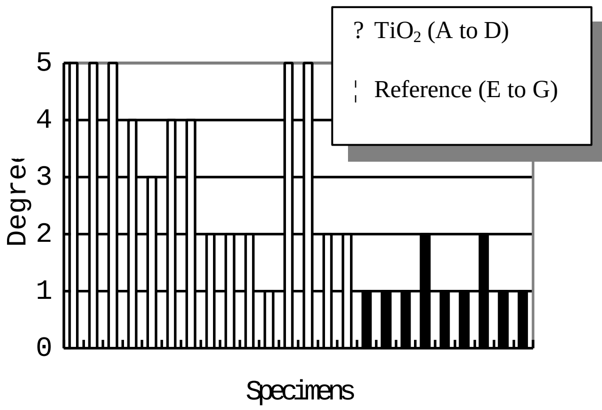

**Figure 13. Result of Visual Evaluation (specimen A to G), - after 19 weeks exposure at Kashiwa-1 site**

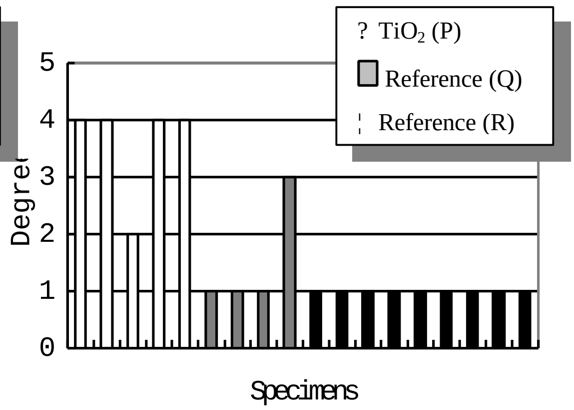

**Figure 14. Result of Visual Evaluation (specimen P to R), - after 42 weeks exposure at BRI**

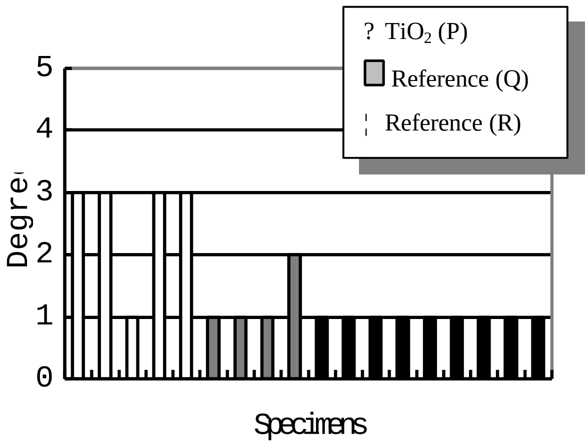

**Figure 15. Result of Visual Evaluation (specimen P to R), - after 5 weeks exposure at Kashiwa-1 site**

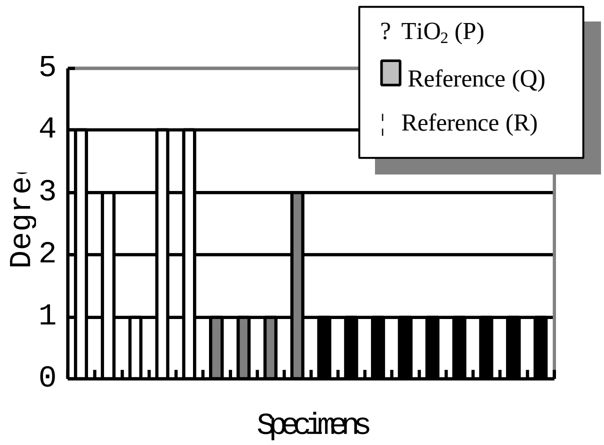

**Figure 16. Result of Visual Evaluation (specimen P to R), - after 42 weeks exposure at Kashiwa-2 site**

## 8 CONCLUSION

Application of photocatalyst into the building materials is rather newly developed technology. One of the advantageous features by applying this photocatalyst would be the ability of self-cleaning or self-desoiling on the surface of materials.

The purpose of this research is to confirm the self-cleaning effect of exterior finishing materials treated with photocatalyst. Nowadays, rather large amount of photocatalyst applied materials are actually used in buildings at present. However, the effectiveness of these finishing materials has not been widely confirmed yet. In other words, although various photocatalyst applied products are put on the market, very little reliable technical information is available except for limited technical data from each manufacturer.

Although relatively limited amount of data are available at present stage, the following conclusion could be made;

1) The effect of photocatalyst could be clearly recognized in the laboratory test even after various degradation treatments.

2) The self-cleaning effect was also recognized in the outdoor exposure test. The degree of effect was dependent upon each commercial product at present stage; however, products treated with photocatalyst showed the significantly higher self-cleaning effect compared with ordinal non-treated products.

3) In the evaluation of striped soiling due to rain trace which were often observed on the exterior envelope, the [L*(rain trace only)] and [L*(with and without rain trace)] shows good correlation with the result of visual evaluation by using the designated pictorial sheets. However, the correlation was becoming low in case that overall soiling was predominant on the specimens.

## 9 ACKNOWLEDGMENTS

A part of this paper refers to the research activities in “High performance external finishings” Committee (Chairperson, Dr. K.Motohashi) organized in the Japan Association of Building Research Promotion. Authors are grateful to Prof. Dr. T. Konish and Prof. Dr. Y. Masuda, University of Utsunomiya, for his continuous interest and helpful suggestions during implementation of this project, and we also acknowledge Dr. T. Nireki, Director, Tsukuba Building Test Laboratory, Centre for Better Living, for his contribution to the technical and analytical assistance for this project.

# Rehabilitation For ASR Affected Reinforced Concrete Piers

**K Torii M Aoyama Y Okuda & H Sasaki**
**Civil Engineering Kanazawa University Ishikawa Japan**

**Summary: Reinforced concrete columns were fabricated using the non-reactive river sand and reactive crushed stone. After the steam curing of 1 month, the columns were exposed outdoors for 1 year. When the width of cracks along the longitudinal steel reinforcement of the column due to the alkali-silica reaction (ASR) had attained about 0.5mm, three types of rehabilitation methods, surface coating, steel plate bonding and strengthening with prestressing wire, were applied to the ASR affected reinforced concrete columns. The changes in the expansion of concrete and steel reinforcement on the surface and in the center of the column were monitored for 4 years in order to investigate whether or not the rehabilitation methods applied can really control the expansion of concrete by confining the extension of cracks.**

**From the results of the experiment, it was clarified that the effect of surface coating in controlling the expansion of concrete was not significant compared with the controlling one without the surface coating, and that both the strengthening methods with steel plate and prestressing wire were effective in confining the extension of cracks and in improving the durability of concrete column.**

**Keywords: Alkali-silica reaction, rehabilitation, surface coating, steel plate bonding, PC confined method**

## 1 INTRODUCTION

In Japan, a lot of concrete structures, which were constructed in the 1960s and 1970s, are at present suffering from the serious problems associated with the durability of concrete, which are mainly the chloride induced steel corrosion and the alkali-silica reaction. ASR affected concrete structures were mainly repaired by the waterproofing agents on the surface of structures, but it was not effective from the results of the follow-up inspection after repair. In January 2001, the concrete committee of Japan Society of Civil Engineers (JSCE) published a new Standard Specification for Maintenance of Concrete Structures to deal with the rehabilitation and maintenance problem for concrete structures (Okada et al.1996, Concrete committee of JSCE.2001). On the other hand, it is also a matter of great concern to increase the seismic response ability of concrete structures after the Hanshin-Awaji earthquake disaster in January 1995. Concerning the strengthening method for concrete piers in bridge, the steel plate bonding method or carbon fiber sheet bonding method has been actively adopted in Japan. However, these strengthening methods are not always successfully adopted especially in ASR affected concrete piers because they usually have a high residual expansion ability. For this reason, a new-type strengthening method with prestressing steel wire, which was named the PC confined method, has been developed in 1997, and actually adopted in the strengthening for ASR affected concrete piers (Torii et al.1998, 2000). However, there are a relatively few studies concerning the long-term effect of strengthening method with the steel plate and prestressing wire on the confinement of extension of cracks, and consequently on the improvement of durability of concrete piers (Kojima et al.2000).

The purpose of this study is to comparatively investigate the long-term effect of the applied rehabilitation method in controlling the expansion of concrete due to ASR when the columns were exposed outdoors for about 5 years. Practical implications with regard to the rehabilitation for ASR affected concrete piers were also discussed.

## 2 EXPERIMENTAL PROCEDURES

### 2.1 Mix Proportions of Concrete and Dimension of Column

The cement was the ordinary Portland cement with the equivalent $Na_2O$ of 0.68 %. The andesite crushed stone from the Noto Peninsula in Ishikawa Prefecture was used as a reactive coarse aggregate; the sand and the gravel from the Hayatsuki River as a non-reactive fine and coarse aggregate, respectively. The evaluation of alkali reactivity of the andesite crushed stone used according to JIS A 5308 was not innocuous; the soluble silica content (Sc) and the reduction in alkalinity (Rc) at the chemical method: 228 m mol/l and 131 m mol/l, respectively, the expansion ratio at 6 months at the mortar bar test: 0.11 %. The main reactive components identified in the texture of the andesite crushed stone were the volcanic glass and cristobalite. Mix proportions of concrete are presented in Table 1.

**Table1 Mix Proportions of concrete**

| G. max (mm) | Slump (cm) | Air (%) | S/A (%) | W/C (%) | Cement (kg/m$^3$) | Water (kg/m$^3$) | Fine Aggregate (kg/m$^3$) | Non-Reactive Aggregate (kg/m$^3$) | Reactive Aggregate (kg/m$^3$) | NaOH (kg/m$^3$) |
|---|---|---|---|---|---|---|---|---|---|---|
| 20 | 8±2 | 2±1 | 42 | 53 | 308 | 164 | 784 | 562 | 563 | 7.54 |

Fig.1 shows the dimension of circle-shaped reinforced concrete column in the outdoor exposure test, in which the column was 800 mm in diameter and 1500 mm high. The D22 mm deformed bar and D16 mm deformed bar (SD 295A) were used as the axial and hoop steel reinforcement of the column, respectively. Carlson-type strain gauges and thermocouples were buried in the column when placing the concrete, and after demolding contact gauge tips with the distance of 100 mm were attached on the surface of the column. Also, the strain gauges with the length of 5 mm were stick on the surface of the steel reinforcement and steel plate in order to monitor the change in tensile strain. The data on the strain of concrete and steel reinforcement were automatically collected every week through the data logging computer system.

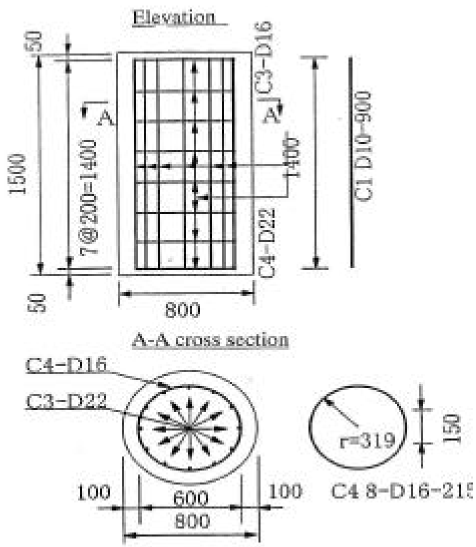

**Fig.1 Dimensions of circle-shaped reinforced concrete column**

## 2.2 Exposure Condition and Rehabilitation Method

The column was demolded at 3 days after placing the concrete, and followed by the steam-curing at the condition of maximum temperature of 60  C for 1 month in order to accelerate the expansion of concrete due to ASR. After the initial curing, the four columns were exposed outdoors at the campus of Kanazawa University for about 1 year until the width of cracks along the longitudinal steel reinforcement of the column had attained about 0.5 mm.

For ASR affected concrete columns, three types of rehabilitation methods, surface coating, steel plate bonding and prestessing steel wire confining, were applied except for one column as the controlling column. Fig.2 shows the schematic diagram of strengthening method with steel plate and prestressing steel wire. In the repair method by surface coating, all surfaces except the bottom one were coated with a highly elastic acrylic rubber type material with the overall thickness of 1 mm (Surface Coating, SC). On the other hand, in the strengthening method, one column was tied up and welded by the steel plate with a thickness of 9 mm, and the space between the column and the steel plate was injected with an epoxy-type resin (Steel Plate Bonding method, SPB); the other column was wound up with the prestressing wire of 2.9 mm in diameter at the interval of 75 mm, where the initial tensile stress induced was 20 % of its yield strength (Prestressing Steel Confining method, PSC). After repairing or strengthening, all columns were again exposed outdoors, and the beneficial effect of confinement of extension of cracks due to ASR was investigated for 4 years, as shown in Fig.3.

## 3 RESULTS AND DISCUSSION

### 3.1 Expansion Behavior of Concrete in Column with and without Surfoce Coating

Fig.4 shows expansion curves of concrete on the surface of the column with and without the surface coating. It was observed that both columns with and without the surface coating expanded along with the seasonal change immediately after exposure outdoors; the concrete rapidly expanded during the summer, and it almost stopped during the winter. In the column without surface coating, the visible cracks occurred most remarkably along the trace of rainfall in the upper portion of the column at the south side. This shows that the degree of ASR may be significantly influenced by the microclimate condition around the column; the variations in temperature and moisture by the sunshine and rainfall. As shown in Fig.4, the expansion percentage of concrete was as large as 0.8 %, and the width of crack on the surface was 1 to 2 mm at average. On the other hand, the overall expansion of the column with the surface coating was smaller compared with the controlling one, but the effect of surface coating in controlling the expansion of concrete was not so significant as expected. It is considered that ASR is still progressing by using a relatively small amount of water in the column itself even when the supply of water from the environment has been completely shut out (Kawamura et al.1992). Fig.5 shows expansion curves of concrete in the center of the column with and without surface coating when exposed outdoors. As a whole, the expansion behaviors of concrete in the center of column measured by the Carlson-type strain gauge were not different from those on the surface. Interestingly, the strain of concrete at the horizontal direction was twice or triple larger than that at vertical direction, which was as large as 7000.. This may be attributable to both the dimension of circle-shaped column and the confinement ratio by axial and hoop steel reinforcement.

Fig.6 shows changes in the tensile strain of axial and hoop steel reinforcement with the exposure time. Especially in the column without the surface coating after 5 years of exposure time, the tensile strain of hoop steel reinforcement was about

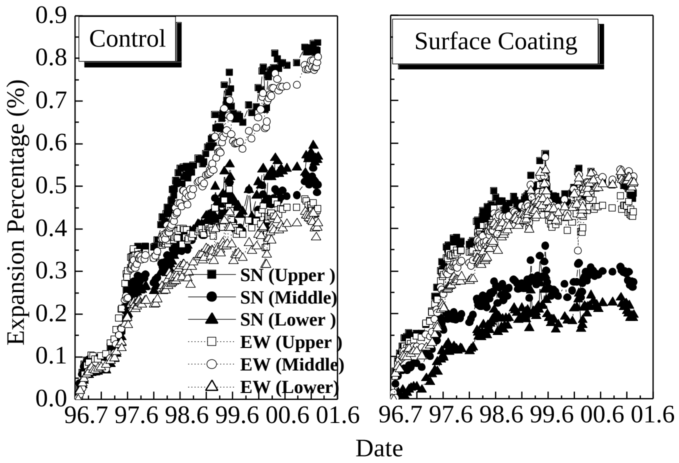

**Fig.4 Expansion curves of concrete on surface of column**

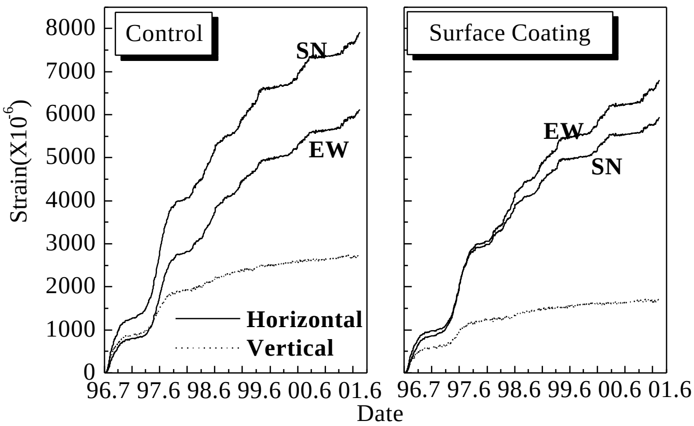

**Fig.5 Expansion curves of concrete in center of column**

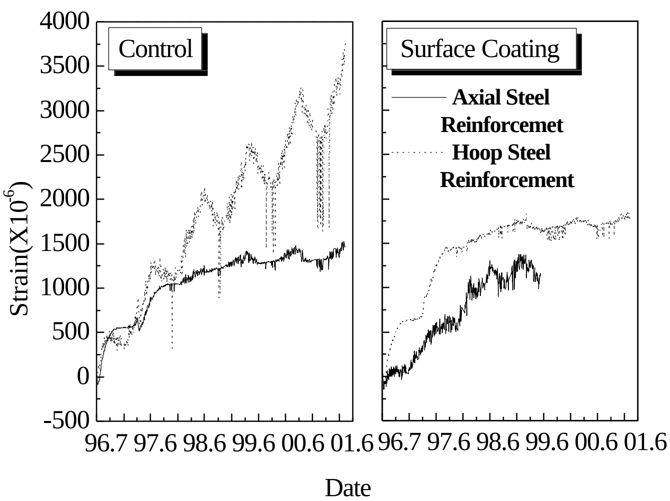

**Fig.6 Changes in tensile strain of steel reinforcement**

3500., which corresponded to a relatively large amount of expansion of concrete, although the tensile strain at axial steel reinforcement was about 1500., and it was almost constant after 2years of exposure time. This result indicates that the hoop steel reinforcement has already yielded partially and lost its effect in confining the concrete. Fig.7 shows the relations in the strain of concrete measured between on the surface and in the center of the column with and without the surface coating. It is found that at the early stage of exposure time, the strain on the surface is well equivalent to that in the center, but that after 2 years of exposure time, the latter is more than the former due to the decrease of confinement effect of concrete caused by the yielding of hoop steel reinforcement.

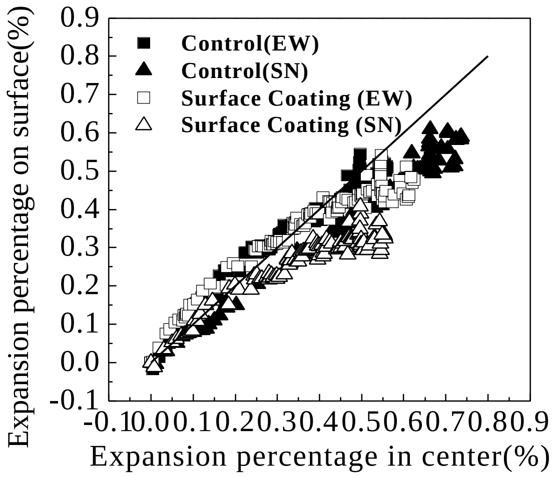

**Fig.7 Relations in strain of concrete measured on surface and in center of column**

### 3.2 Expansion Behavior of Concrete in Column Strengthened

Generally, it is considered that the load bearing ability of ASR affected concrete piers does not remarkably decrease. However, the recent field inspection work has shown that the cracks not only remain on the surface of cover, but also extend to the interior when ASR continues for a long period (Ono et al.2000). In serious cases, the hoop steel reinforcement or stirrup is also broken at the corner due to the excessive expansion of concrete (Torii et al.2001). A further research on strengthening such a seriously damaged concrete structure is needed.

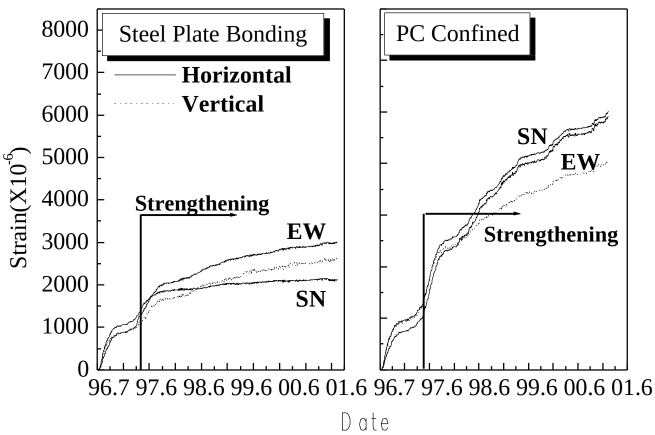

**Fig.8 Expansion cueves of concrete in center of column**

Fig.8 shows expansion curves of concrete in the center of the column strengthened with steel plate bonding and prestressing steel wire. As shown in Fig.8, strengthening methods with steel plate bonding and prestressing steel wire were effective in controlling the expansion of concrete. Comparing the effect of confinement of concrete by strengthening, the steel plate bonding method was more effective than PC confined method. In the steel plate bonding method, the strain of concrete in the center was as small as 30 % to 40 % that of the controlling one. Furthermore, by strengthening, the expansion curves of concrete became almost the same independently of the vertical and horizontal direction. When calculating the strengthening effect of steel plate and prestressing

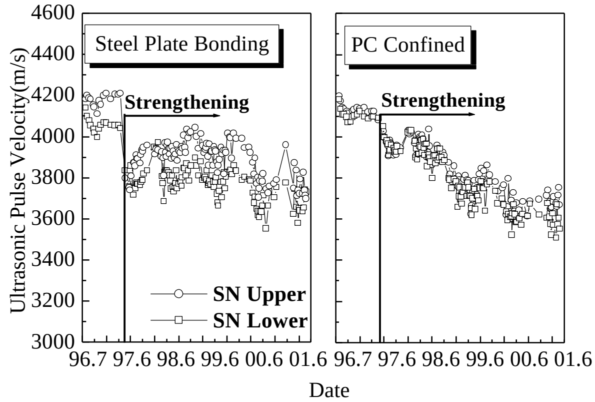

**Fig.9 Changes in ultrasonic pulse velocity of column**

steel wire in terms of the volume ratio of hoop steel reinforcement, its effect by the steel plate was six times larger than that by the prestressing steel wire. Fig.9 shows changes in the ultrasonic pulse velocity for the column strengthened with steel plate and prestressing steel wire. After strengthening, the ultrasonic pulse velocity of the column strengthened with steel plate showed the constant value of 3800 m/sec for a long period, although that of the column strengthened with the prestressing steel wire as well as the controlling one gradually decreased with the exposure time. The measurement of ultrasonic pulse velocity was suitable for estimating the degree of extension of cracks in the ASR affected concrete column. It is concluded that the load bearing ability as well as durability of concrete column strengthening with the steel plate or prestressing steel wire can be greatly improved by confining the extension of cracks due to ASR.

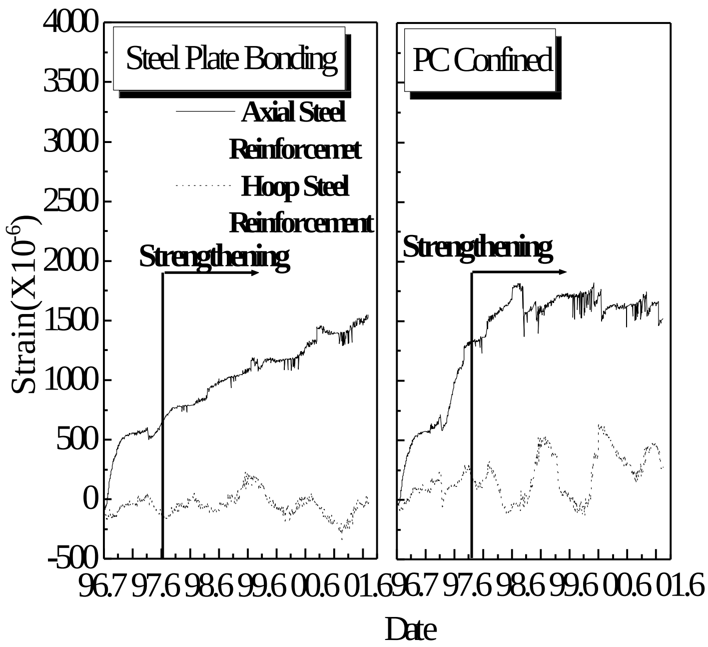

**Fig.10 Changes in tensile strain of steel reinforcement**

Fig.10 shows changes in the tensile strain of axial and hoop steel reinforcement of the column strengthened with steel plate and prestressing wire with the exposure time. In the column strengthened with the steel plate, the tensile strain of the hoop steel reinforcement was very small compared with the controlling one because the stress caused by ASR effectively transmitted to the steel plate in stead of the hoop steel reinforcement. However, the tensile strain of axial steel reinforcement was not at all decreased by the Poisson effect of concrete resulting from the confinement at the horizontal direction. Similarly, in the column strengthened with the prestressing steel wire, the tensile strain of the hoop steel reinforcement was reduced to a significant extent.

Strain Behavior of Steel Plate and Prestressing Steel Wire

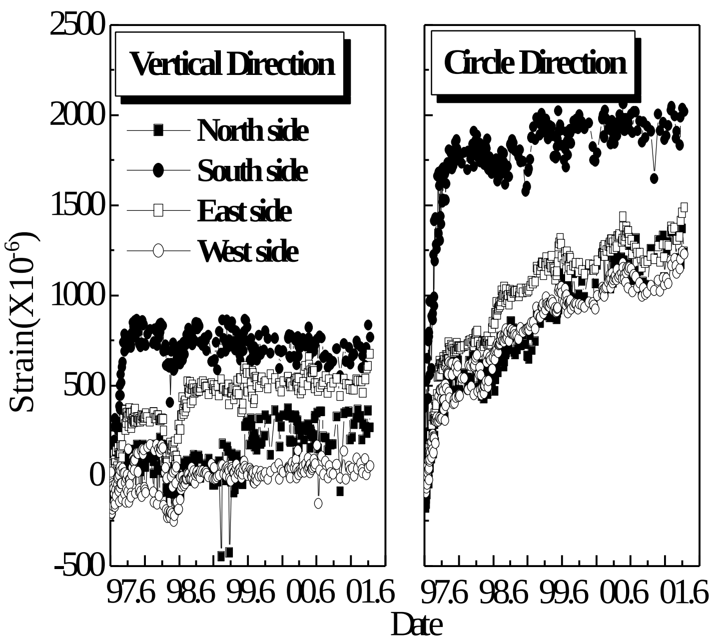

**Fig.11 Changes in tensile strain of steel plate**

Fig.11 shows changes in the tensile strain stick on the surface of the steel plate with the exposure time. The tensile strain behavior of the steel plate significantly varied depending on the side of column. That is to say, the tensile strain of steel plate at the south side was twice that at other side, because the increase in temperature of steel plate by the sunshine is the

Go Back Next Page

largest at the south side during the summer. Taking into considerations that the tensile strain of steel plate is more than 2000.m in the circle direction, which exceeds the strain of yielding of steel plate, the steel plate itself will break out especially at the portion of welding of steel plates when the expansion of concrete continues in the near future.

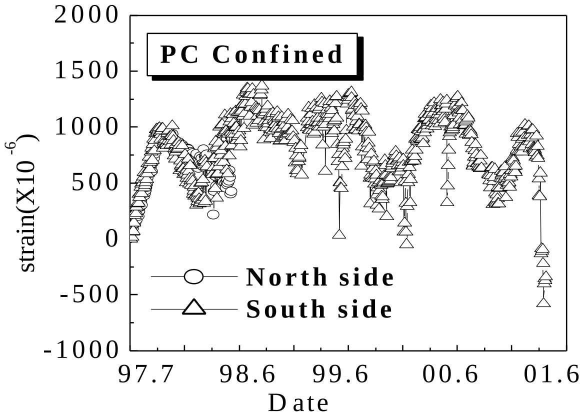

**Fig.12 Changes in tensile of prestressing steel wire**

Fig.12 shows changes in the tensile strain stick on the surface of the prestressing steel wire with the exposure time. Some gauges could not be measured at the early stage of exposure time, but sound gauges showed typical cyclic changes in the tensile strain between 1200. in summer and 500. in winter. It was found that the tensile strain of prestressing steel wire varied depending on the change in temperature. This shows that the stress induced by the prestressing steel wire also varies because the column itself will expand or shrink with the change in temperature to a lesser extent.

## 4 CONCLUSIONS

From the experimental results of long-term outdoor exposure test for ASR affected reinforced concrete columns, the strengthening method by steel plate and prestressing steel wire was effective in confining the extension of cracks due to ASR and in increasing its durability of concrete.

The following information was obtained in this study;

1. The expansion of concrete in column due to ASR continued for a long period, consequently the strain of concrete was 7000μ, and the hoop steel reinforcement yielded partially.
2. The effect of surface coating in controlling the expansion of concrete was not so significant in the relatively large-sized column used in the exposure test.
3. The strengthening method with steel plate was more effective in confining the extension of cracks due to ASR than that with prestressing steel wire.
4. The measurement of ultrasonic pulse velocity was suitable for estimating the degree of extension of cracks of the column.
5. The tensile strain behavior of steel plate in circle direction varied significantly depending on the south and the other side, possibly leading to breaking out at the welding of steel plates.

The monitoring on the strain of concrete and steel reinforcement in the column is still ongoing. At the final stage of outdoor exposure test, after taking off the surface coating and steel plate of the column, the deterioration of concrete on surface and in interior will be investigated in detail.

## 5 ACKNOWLEDGMENTS

The authors give sincere thanks to Prof. Mitsunori Kawamura, Department of Civil Engineering, Kanazawa University, Dr. Koji Ishii, PS Corporation Ltd., and Mr. Fumitake Ozaki, Fukui Prefecture Government, for their useful advise in the experiment.

# Evaluation Of Accelerated Chloride Ion Diffusion Test And Applicability Of Fick's Second Law

AS Poupeleer & D Van Gemert
Department of Civil Engineering KU Leuven Belgium

**Summary: A global test program is set up to find the correlation between the standard diffusion test (ASTM C1202-97) and the accelerated Chloride Penetration Time (CPT) test. The purpose is to find a relation between the steady state and the dynamic diffusion coefficient. In this way only the standard test would be necessary to quantify both diffusion coefficients. However, the CPT test gives extra information about the processes at the reinforcement bar and cylindrical concrete samples and various concrete cover thicknesses can be used.**

**In this paper the results of the first part of the CPT test program are reported. Two concrete mixes with a different porosity are tested. The CPT test is accelerated by a constant potential difference in a 1.5 and 3 % NaCl-solution. Not only the current during the whole test, but also the total amount of charge passed through the samples and the concentration of chloride ions in the concrete at different depths are investigated.**

**Two concrete mixes with different porosity are compared in the CPT-test at 1.5 and 3 % NaCl and at different applied voltages. The applicability of the test method is questioned and suggestions for further investigations are made.**

**Keywords: Accelerated chloride penetration time test, chloride profile, total amount of electrical charge, diffusion coefficient**

## 1 INTRODUCTION

One of the main durability problems of concrete is the corrosion of the embedded reinforcement. If the concrete cover on the reinforcements is thick enough, there will be no damage thanks to the alkalinity of the concrete. However, due to carbonation or chloride attack the protection of the reinforcement can be broken down. In this paper only the influence of chlorides will be investigated. Chloride ion ingress is a suction and diffusion phenomenon, which normally takes a long time. This time span must be shortened for control and design purposes, and therefore a number of accelerated chloride ingress test methods are proposed in literature, e.g. Andrade (1968) and Justnes (1990). However, the evaluation of the accelerated test results, their reliability and the transfer of these results to real life behaviour remains uncertain. As a consequence, several accelerated test procedures are used in practice.

A correlation is searched between the standardised ASTM C1202 diffusion cell test method and the accelerated chloride penetration time (CPT) test. The purpose is to derive a relation between the diffusion coefficient found in the standard diffusion test and the diffusion coefficient found in the CPT test. This would allow one to relate the accelerated tests to real life behaviour.

The first step within this investigation is a detailed study of the transport of chlorides during the CPT test. To get a better view on the mechanism of chloride ion transportation during the accelerated chloride penetration test, two concrete mixes with different porosity are tested. The effect of different voltages (3, 5 and 7 V) is examined by comparing the CPTs and the total amount of electrical charge that has passed through the sample during the tests. The chloride concentration profile is determined at the end of the tests.

## 2 ACCELERATED CHLORIDE PENETRATION TIME TEST

Chloride penetration in the concrete is generated by electrochemical processes in the accelerated chloride penetration time test. The migration test is executed on cylindrical samples. The samples are placed in a 3 % (or 1.5%) NaCl-solution, in such a way that the distance between the surface of the water/salt-solution and the top of the specimen is at least 20 mm (Fig. 1).

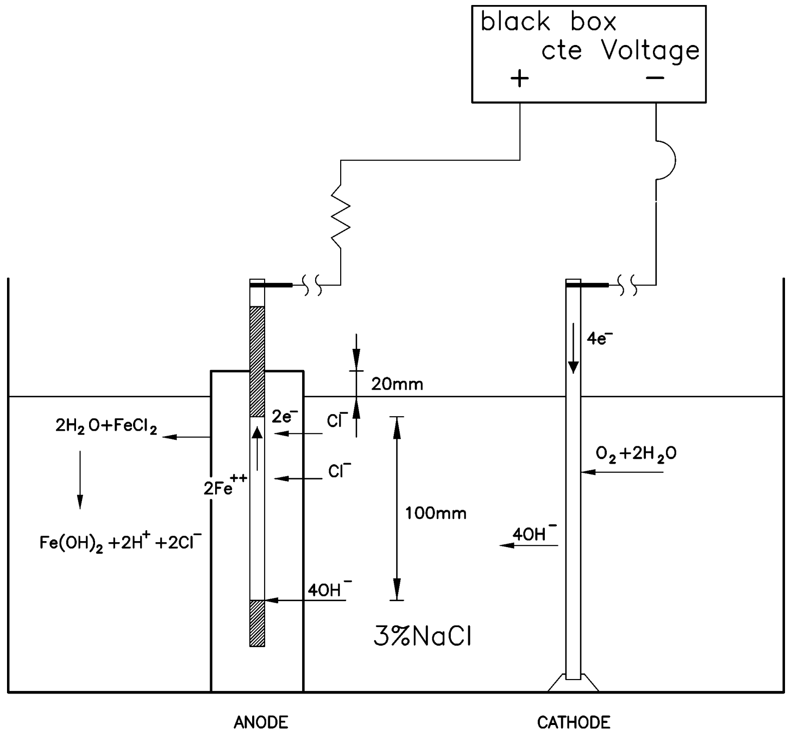

**Figure 1: Schematic representation of the electrical circuit of the test**

The 3% NaCl-solution corresponds approximately to the chloride concentration in seawater. A constant voltage difference of respectively 3, 5 and 7 V is applied between the reinforcement bar in the test sample and a stainless steel cathodic plate in the NaCl-solution. The reinforcement bar in the concrete acts as an anode (positive) in the system and consequently attracts anions ($OH^-$ and $Cl^-$). The stainless steel plate is the cathode (negative) of the system. At this plate the reduction of the oxygen ($O_2$) takes place ($4e^- + O_2 + 2H_2O \rightarrow 2OH^-$). The hydroxyl ions move towards the anode together with the chloride ions present in the water. The electrolytic medium consists of the NaCl-solution and the pore solution in concrete. A process takes place similar to non-accelerated electrochemical corrosion of steel.

The $Cl^-$ ions break though the passive oxide layer on the reinforcement, and attack the reinforcing bar. This results in pitting corrosion of the reinforcement bar.

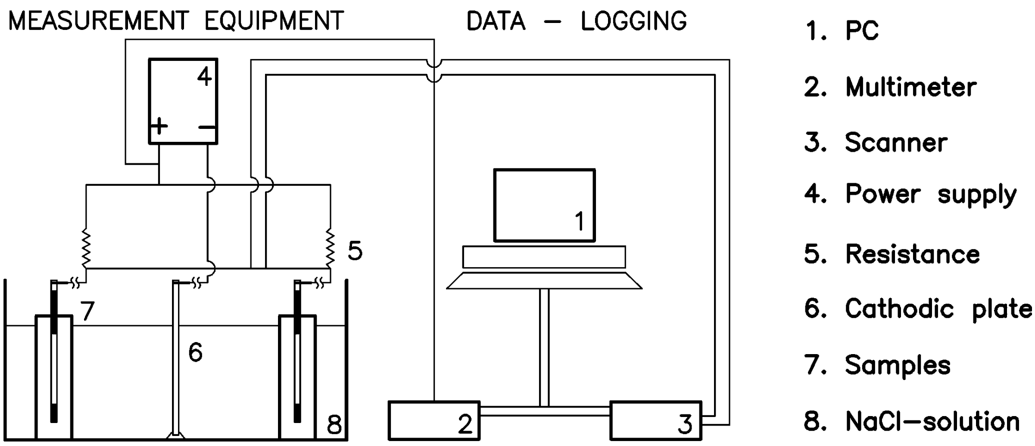

**Figure 2: Schematic plan of the test setup of the accelerated CPT-test**

The test setup is presented in figuur 2. The electrical current through the system is automatically recorded. Therefor, the voltage drop over a 1 Ohm reference resistance is measured and recorded. According to Ohm’s law this voltage drop is converted to a current: V = R.I = 1.I

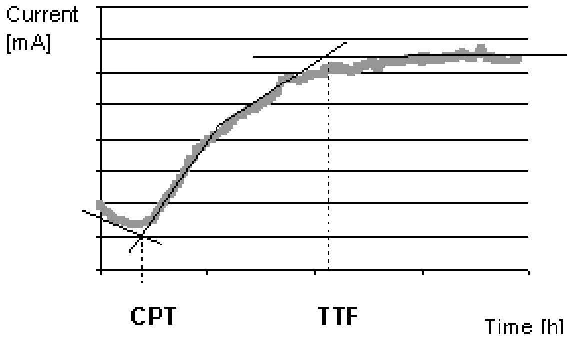

**Figure 3: Theoretical evolution of the current during a CPT-test.**

This current is an indication for the corrosion rate. The expected time curve of this current is represented in figure 3. Four stages can be distinguished.

1. In the first part a current decrease is caused by polarisation of the anode. The $OH^-$-ions strengthen the passive oxide layer. These ions are already present in the pore-water long before the chloride ions and they too are negatively charged. The strengthening of this patina makes that less electrons are released and that the current decreases.
2. In a second stage the current increases. This is the moment the chloride ions reach the steel bar in the concrete and start the corrosion. This point of time is called the chloride penetration time or CPT. Shortly after reaching the CPT time cracks will appear in the concrete. Due to the fact that the potential difference between steel and water is now imposed to a much higher level than in natural conditions of corrosion, the concentration of chlorides necessary for corrosion is much lower. Consequently, the corrosion starts at the moment the first chlorides reach the reinforcement bar (CPT).
3. From that moment on the patina becomes weaker and cracks become bigger. Consequently, the chloride ions have better access to the steel and the corrosion process is accelerated.
4. In a final stage the samples totally break. This is visible by a vertical crack all over the specimen. The corrosion products flow out off the concrete and silt up the fissure. The current reaches a maximum value. This is characterised by the time to failure or TTF. Due to the silting process the current remains about constant.

The CPT is derived from the current evolution curve at the intersection of two lines tangent to the descending and ascending part of the curve.

## 3 EXPERIMENTAL DETAILS

### 3.1 Materials

Two different concrete mixes with different porosity are used. Both are made with a Portland cement CEM I, 42.5, according to the standard EN 197-1. The composition of the mixes is given in table 1.

**Table 1: Composition of the two concrete mixes.**

| | Composition 1 | Composition 2 |
|---|---|---|
| Coarse aggregate 4/14 | 1119 kg/ $m^3$ | 1003 kg/ $m^3$ |
| Fine aggregate 0/5 | 699 kg/ $m^3$ | 896 kg/ $m^3$ |
| CEM I, 42.5 | 300 kg/ $m^3$ | 291 kg/ $m^3$ |
| Water | 180 kg/ $m^3$ | 180 kg/ $m^3$ |
| w/c-ratio | 0.62 | 0.60 |
| porosity | 18-20 vol.% | 12-15 vol.% |

The 28-day compressive strength of both mixes is 39.4 respectively 45.4 MPa.

The original chloride content of the two concrete mixes is negligible. The values are given in table 2. Because no chlorides are added to the mix and the aggregates are free from chloride contamination, the only source of chlorides is the tap water used for mixing. This water has a chloride content of 0.047 g/l.

**Table 2: Concentration of chloride in the concrete before the experiments**

| | Mix 1 | | Mix 2 | |
|---|---|---|---|---|
| | w% Cl water soluble (potentiometric) | w% Cl acid soluble (NBN B15-250) | w% Cl water soluble (potentiometric) | w% Cl acid soluble (NBN B15-250) |
| Top | - | 0.001 | 0.010 | 0.016 |
| Centre | - | 0.006 | 0.011 | 0.019 |
| Bottom | - | 0.015 | 0.011 | 0.013 |

### 3.2 Test specimens

The dimensions of the specimens are given in figure 4. It concerns cylindrical concrete samples with a smooth drawn steel bar (ST52) in the centre. The bar has a diameter of 8 mm and is placed 25 mm above the bottom of the sample. The concrete cover of the bar is about 21 mm. After sandblasting, the top and the bottom of the steel bars are covered with epoxy. Only the remaining 100 mm of untreated steel can be attacked by chloride ions. Another important reason for this treatment is to prevent oxidation corrosion at the concrete-steel-air interface.

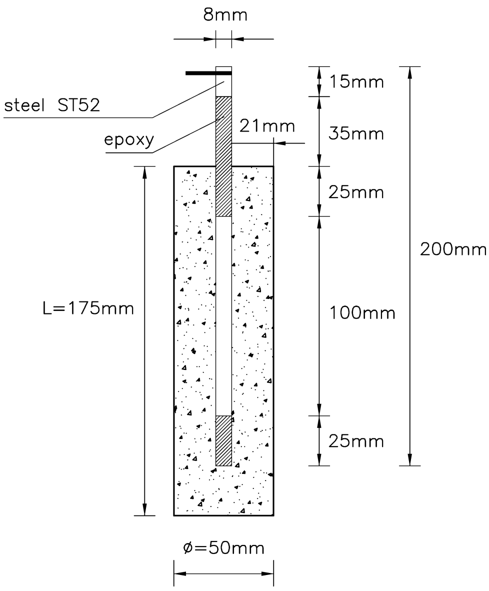

**Figure 4: Schematic representation of the cylindrical specimens**

The test samples are cored out of a concrete plate with a thikness of 175 mm. One day after pouring the concrete, the formwork is removed and the concrete plate is cured for 28 days in water at 20°C. Then the cylinders are cored out of the concrete plate. Subsequently, the cores are saturated for 7 days. In this way capillary suction of water during the first minutes of the test is prevented, and only diffusion of the $Cl^-$ is possible to penetrate into the concrete cover.

## 4 RESULTS AND DISCUSSION

### 4.1 Results

The results of the CPT test are compared according to the composition of the concrete and to the applied voltages. Firstly the focus is on the impact of the porosity on the CPT. Therefor three samples of mix number 1 and two samples of mix number 2 are submitted to a constant voltage of 3 V and a NaCl concentration of 3 %. Secondly the influence of different voltages has been examined, namely 5 and 7 V. In this case the concentration of NaCl is reduced to 1.5 %.

Figure 5 gives the current versus time graphs of the samples of mix 1. Three different voltages are applied each time on three samples. Based on these curves the CPT can be determined. As an illustration the determination of the CPT of a sample of mix number 1 tested with 7 Volt and in a NaCl-solution of 1.5 % is given in figure 6.

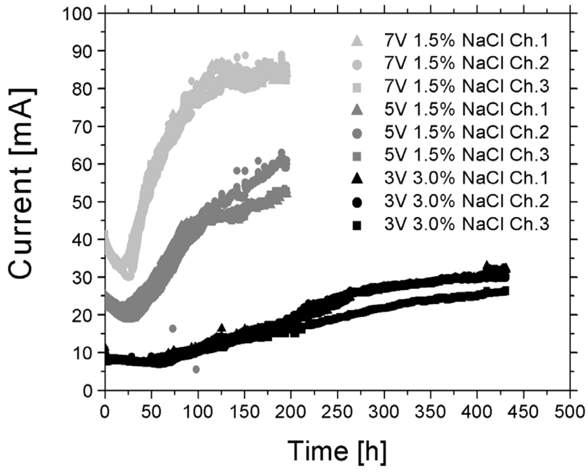

**Figure 5: Overview current trough samples during the CPT-test**

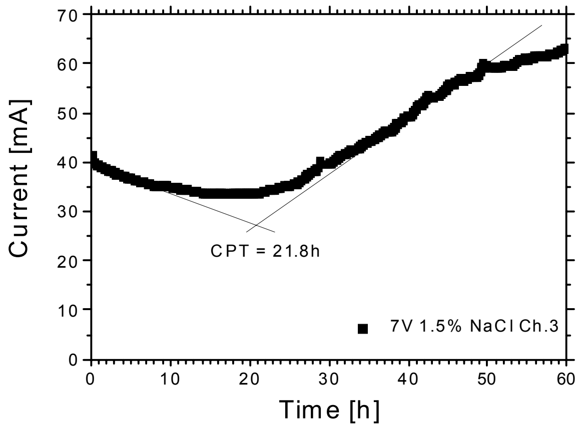

**Figure 6: Graphical determination of the CPT**

The CPTs of the tested cylinders are summarised in table 3.

**Table 3: Overview of the CPT (Chloride Penetration Time)**

| Samples | Individual CPT [hours] | Mean CPT [hours] | Standard deviation [hours] |
|---|---|---|---|
| Comparison between mix 1 and 2 | | | |
| CPT mix 1/ 3V/ 3.0 %-NaCl | 38.8, 42.6, 59.0 | 46.8 | 10.7 |
| CPT mix 2/ 3V/ 3.0 %-NaCl | 89.2, 85.8 | 87.5 | 2.4 |
| Comparison between 5 and 7V | | | |
| CPT mix 1/ 5V/ 1.5 %-NaCl | 24.0, 29.2, 30.5 | 27.9 | 3.4 |
| CPT mix 1/ 7V/ 1.5 %-NaCl | 18.1, 27.1, 20.1 | 21.8 | 4.7 |

Another indication for the corrosion is the total amount of charge passed through the samples during the test, because each Fe-atom that splits releases not only a $Fe^{2+}$ but also 2 electrons. This value can be obtained by integrating (Fig. 6) the current versus time curves. It is a measure of the electrical conductance of the concrete during the period of testing. Although the testing period was not always the same, it is interesting to compare the relative magnitudes of the total electrical charges.

Go Back
Next Page

**Table 4: Overview of the charge passed through the samples**

| Samples | Time [h] | Individual electrical charge [C] | Mean electrical charge [C] | Spreading [C] |
|---|---|---|---|---|
| Comparison between mix 1 and 2 | | | | |
| CPT mix 1/ 3V/ 3.0 %-NaCl | 331 | 30302, 30487, 25964 | 28918 | 2560 |
| CPT mix 2/ 3V/ 3.0 %-NaCl | 402 | 19814, (22975, 24520), 18706 | 19260, (21504) | 783, (2705) |
| Comparison between 5 and 7V | | | | |
| CPT mix 1/ 5V/ 1.5 %-NaCl | 309 | 27973, 28605, 26151 | 27576 | 1274 |
| CPT mix 1/ 7V/ 1.5 %-NaCl | 262 | 48617, 46461, 48602 | 47893 | 1241 |

At the end of the CPT tests, slices were cut from the samples to determine the chloride concentrations profile. Two slices were cut from the samples of the first mix (5V), at depths of 5 and 17 mm (Fig. 7). In the investigation of the second mix (3V), three thinner slices were analysed, namely at 4, 11 and 18 mm depth, to obtain a more detailed chloride penetration profile (Fig. 7).

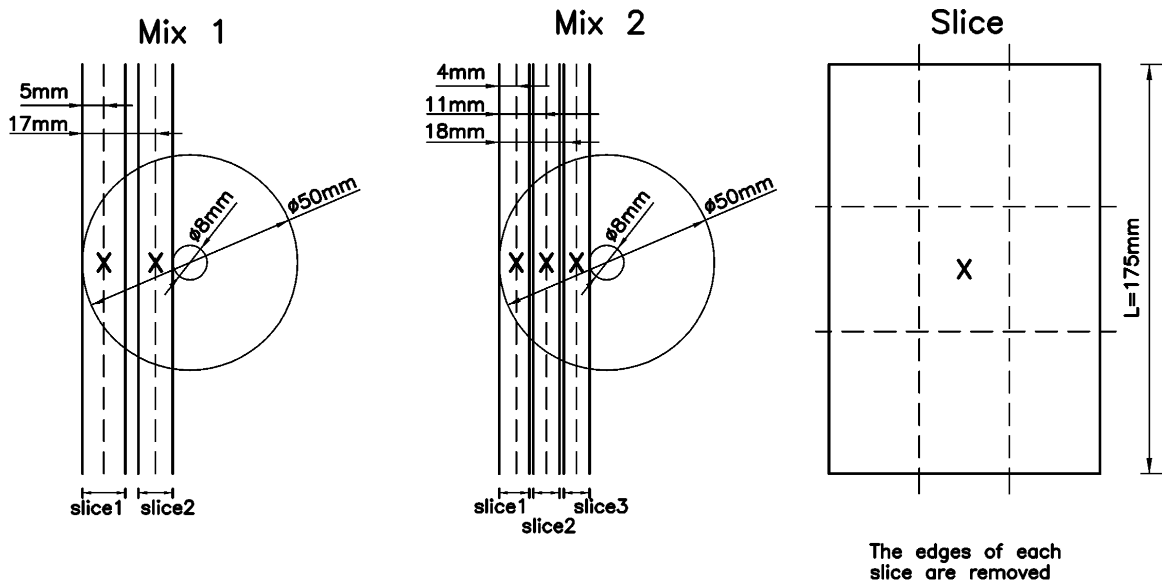

**Figure 7: Position of $Cl^-$-concentration sampling**

Only the free chloride ions can contribute to the corrosion of the steel bars. In the framework of this investigation the water-soluble and the acid soluble chloride ions are determined (Fig. 8). Neither of the two concentrations really represents the amount of free chloride ions, but they give an estimation of the amount of available $Cl^-$ ions in the process. Even the amount of water-soluble chlorides includes dissolved chlorides present in the form of crystalline salts. For the second mix only this amount of the water-soluble chlorides is determined (Fig. 8).

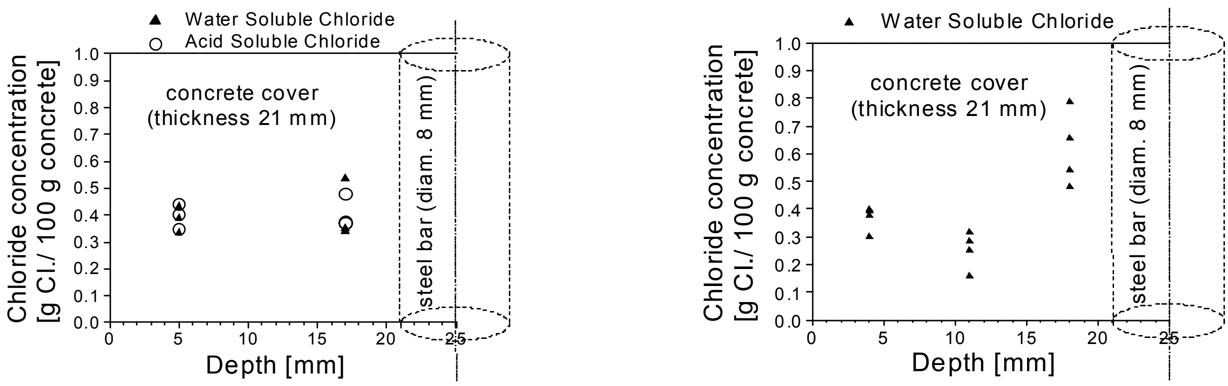

**Figure 8: Chloride concentration at different depths in the concrete mixes 1 and 2 after CPT tests**

### 4.2 Discussion

#### 4.2.1 Chloride Penetration Time

No general conclusions can yet be made after this first part of the global test program. Comparing the CPTs of mix number 1 and 2, it can be seen that the porosity has a great influence on the penetration time of the chlorides. The more porous the concrete, the lower the CPT value. It takes almost twice as long to penetrate trough the less porous concrete. In a porous water saturated environment the resistance against the transport of chloride ions is low. This confirms the general statement that the concrete cover has to be of a high quality to provide adequate protection of the reinforcement. Not only it has to be of an adequate thickness, also the permeability should be watched.

Although the salt concentration in the tank is only 1.5 %, instead of 3 %, in the second comparative investigation, the CPTs here are much lower. This means that lesser chloride ions result in a faster degradation. This could mean that the accelerating effect of the potential difference is very big. On the other hand it might not be justifiable to use excessive potential differences up to 7V. The initial intention was to accelerate the process because normal degradation processes of steel bars in concrete take many years. But, is the influence of the voltages limited to the acceleration? It should be investigated if the high voltages do not ionise the water molecules, because the normal redox potential of water is 1.23V ($2\ H_2O \Leftrightarrow O_2 + 4H^+ + 4e^-$) (Polytechnic pocketbook 1995). This dissolution would totally change the test conditions. In that case the measured currents are not resulting from chloride diffusion only, but also from the $OH^-$ ions ($2\ H_2O + 2\ e^-\ . \Leftrightarrow H_2 + 2\ OH^-$).

Parallel real time tests are necessary to find out the acceleration rate, which would allow the calibration the test results to real life situations. After calibration the diffusion coefficients of the CPT tests can be used for design purposes.

#### 4.2.2 Total amount of electrical charge passed through the samples

The standard ASTM C1202-97 gives a indication table for the chloride ion penetration based on charge passed during 6 hours. For the CPT test no tables are available yet, but based on the same principle it should be possible to define certain limits. The results in table 4 show that there is a correlation between the diffusion possibility and the total amount of charge. The more porous concrete (mix 1) and therefor also more open for chloride ions gives a higher charge than mix 2. Nevertheless, the results coming from the other applied voltages demonstrate that the eventually established reference table should be adapted for different applied voltages. The higher voltages (5 and 7 V) accelerate the transport process, and thus more ions are transported in a shorter time through the same concrete with the same electrical conductivity.

#### 4.2.3 Chloride concentration in the concrete

The samples of the first mix tested in 1.5 % NaCl solution and with a voltage of 5 V, show a very slightly increasing chloride concentration in function of depth. In a second phase, where more information is gained from the samples of the second mix (with 3 % NaCl and 3 V), the chloride concentration decreases from the concrete surface to the inside and than increases again at the steel bar.

Knowing that the samples were saturated, capillary suction is out of the question. Also convection can be eliminated, because the transport occurs inside the concrete. Diffusion seems a possible way of transport. In theory, the laws of Fick can describe the diffusion of chloride ions through concrete. Fick's second law describes the process in a non-steady stage. Consequently, the idea is to apply an adapted version of the second law where the influence of the imposed electric field would be taken into account. In literature many suggestions are made for such adaptation. Andrade et al (1994) proposed the following expression:

$$C_x = C_s\left(1 - erf\,\frac{x}{2\sqrt{\frac{ZF\Delta E}{RT}D_{app}t}}\right)$$

with $C_x$ = concentration at depth x [kg/m$^3$]

$C_s$ = concentration at the surface [kg/m$^3$]

$D_{app}$ = diffusion coefficient [m$^2$/s]

Erf = error function

Z = electrical charge of species [equivalent/mol] ($z_{Cl} = -1$)

F = Faraday number = 96.500 [C/ equivalent]

R = gas constant = 8.314 [J/mol.K]

T = absolute temperature [K]

However, it has to be remarked that this law is mostly used for diffusion of chloride ions through a concrete plate which separates one fluid from another one. The circumstances of the CPT test are different. Because of the treatment with epoxy (Fig. 1, 4) one can consider the problem as circular cylindrical. Consequently, the concentration is only a function of radius r and time t. The diffusion equation becomes:

$$\frac{\partial C}{\partial t} = \frac{1}{r}\frac{\partial}{\partial r}\left( rD\frac{\partial C}{\partial r} \right)$$

If the diffusion coefficient is considered constant, it can be put in front of the equation. The solution of this expression is determined by both the initial and the boundary conditions of time and place, which determine the specific character of the diffusion process.

The initial concentration of chlorides in the concrete of the tested samples is known (table 1) as well as the surface concentration.

$C = C_0 = 1.5$ or 3 % NaCl (9 or 18 g Cl/l), $r = 25$ mm, t/0,

$C = f(r) = C1$ (table 1), $0 < r < a$, $t = 0$,

Because the concentration is initially uniform throughout the cylinder, the solution can be reduced to:

$$\frac{C - C_1}{C_0 - C_1} = 1 - \frac{2}{a}\sum_{n=1}^{\infty}\frac{\exp(-D\alpha_n^2 t)J_0(r\alpha_n)}{\alpha_n J_1(a\alpha_n)}$$

$J_n$ = Bessel function of the first kind of order n

$\alpha_n$ = solutions of $J_0(a\alpha_n) = 0$

From the above equation, different values for the diffusion coefficient were found in function of the depth. Also starting from a constant diffusion coefficient it was impossible to find the concentration profile given in figure 8. In the expected theoretical concentration profile corresponding to the law, the concentration of chlorides starts to grow from the surface towards the centre and increases in function of time until the concentration is constant everywhere.

In this case the law does not correspond to reality. The main reason for that is most probably the presence of cracks. Physical processes in cracks are totally different from processes in a homogenous medium. Therefor, the CPT test should be redone and the concentration of chlorides should be determined just before cracking.

Another reason is the presence of bounded chlorides. The concentration inside the concrete is higher than the enforced concentration at the surface. This confirms the fact that from the moment the first chloride ions diffuse into the concrete they are absorbed to the inner wall of the pores. It is known that the bonding capacity of concrete for chlorides is rather high.

Tang and Nilsson (1996) assumed that chloride binding is dominated by adsorption on the CSH-gel. It is also found that the ratio between free and bounded chlorides is not independent of the chloride concentration, nor for chemical binding (e.g. Friedel salt formation) nor for adsorption. Consequently, it is impossible to use a constant factor to determine the free chlorides on the basic of the measured bounded ones. Furthermore, McGrath and Hooton (1996) claim that chemical binding will slow down the “break through” time and thus reduce the diffusion coefficient. Probably, the chloride ions entered in the surface layers are immediately absorbed due to the presence of positively charged particles on the concrete inner surface of the pores. The chlorides will only start to move if other chlorides or aggressive elements, like sulphates, already occupied the bonding places. Besides, the binding activity was stimulated in our tests because of the young age of the used concrete.

It is not appropriate to attempt to calculate the diffusion coefficient by means of an adapted version of the second law of Fick, including the influence of the electric field, the bounding capacity and the time effect of the not yet mature concrete. As it is mentioned in the description of the test procedure, fissures occur. Together with these cracks, the overall structural composition changes. The chloride ions can easily reach the reinforcement bars through these open channels. The main adaptation to the equation should therefore be with respect to these structural changes.

## 5 CONCLUSIONS

The CPT test is an interesting test method to study the penetration of chlorides in saturated concrete samples. Therefore, this test has been evaluated as a first phase of a global investigation.

The CPT test consists of different stages and a lot of parameters play a role. The electrical current gives information about the electrical charge that has passed through the sample. The first decreasing part can be explained by the attraction of $OH^-$-ions present in the concrete cover, which cause strengthening of the passive oxide layer of the reinforcement bars. The chlorides penetrate in the concrete, but are immediately adsorbed by the charged particles at the inner surface of the pores. Therefore, the chloride profiles obtained can not be used to determine the diffusion coefficient by means of the second law of Fick, even not after adapting to the electric field used and to the adsorption capacity of concrete. The presence of cracks makes it necessary to review the transport processes.

In order to use Fick's laws in the future, the concentrations of chlorides should be determined before cracks appear. This moment can be determined by means of the current time curve of the CPT test.

Together with the CPT tests the standard diffusion test can be executed on the same mixes to analyse the correlation between the diffusion coefficients.

The actual importance of the CPT test lies in its ability to allow quick comparative tests on different compositions and geometrical layouts of reinforced concrete. It can be used as a test method for hydrophobic agents on concrete. Changes in the diffusion coefficient and chloride penetration times can be used as process parameters. One of the most promising applications of this test method is the analysis of corrosion protective products, which penetrate through the concrete cover and fix onto the reinforcement bar itself. For such applications standard diffusion test methods fail.

# The Systematic Approach Of An Experimental Program To Support Service Life Prediction: A 4 Year Experience On External Wall Building Component

**G Rigamonti**
**DISET Building Department of Engineer Faculty Polytechnic of Milan Italy**

**Summary: In this paper is reported the preparatory work and the final experimental program of an investigation performed in order to study the decay of performances of some building components by means of laboratory and outdoor aging tests, according to the general approach designed by ISO 15686-1. This experimental investigation is part of a larger on going research program agreed between DISET and LTS (Technical Laboratory, Department of Construction and Territory, Switzerland) started in 1997 whose goal is the development of a methodology for the prediction of building components service life and for the modeling of degradation mechanisms. The aging tests have been performed on building components belonging to the class of the external walls. The first kind of samples tested, have been partial sample (PS) representing the external layers of an entire technical solution, composed of perforated brickwork coated with render and of a protective layer consisting of an acrilical water painting. For comparison, the aging tests have been also performed on a series of unprotected brickworks. The results of this comparison have been measured between the time behavior of different solution of protected sample and unprotected ones : this has given information about the degree of protection during time obtained by different solution of painting, and a fundamental reference for comparing new market solution used in building construction. The accelerated aging program, has been conducted within an environmental test chamber, developing on the iteration of a cycle consisting of four distinct phases in which are simulated the most significant climatic conditions and actions (rain, irradiance, freeze and thaw), to which the chosen building components are generally exposed. Parallely to the laboratory aging program, outdoor aging has been also carried out from 1998 on the same typology of partial samples (PS). The outdoor aging testing are being conducted in Italy and Switzerland to find out time re-scaling and this to obtain the real service life of the components, in function to the different climates and pollution conditions. In a next and final phase of this first test program on partial sample (PS), the experimentally collected data has been elaborated and interpreted in order to support and validate the proposed methodology for evaluating the service life of building components. The second phase of the research will study the whole solution (WS) in his complex configuration as used in constructions. The related experimental program, just started in march 2001, will consist in substituting the flapdoor of the aging chamber by a section of the real building component and the aging cycles repeated to simulate its behavior between the outdoor environment (aging chamber) and indoor environment (laboratory at controlled conditions). All this experimental data will be useful to support the original analytical material sensitivity evaluation method and to define a final durability and service life evaluation method.**

**Keywords: service life prediction, systematic methodology and experimental program, predictive models, degradation mechanisms, durability of construction components.**

## 1 SELECTING THE TECHNICAL SOLUTION AND SETTING UP THE EXPERIMENTAL PROGRAM

The first step of the experimental program has been to choose technical solutions available within the range to form the basis for starting the experimental phase.

The criteria used for this selection was to opt for a solution that is most widespread on the traditional building market, and which has a capacity, in terms of results and considerations, that is the most broad reaching and vast as possible, while being at the same time the most immediate to verify.

Therefore the starting point was the solution PV2 from the range available, comprising double cavity wall in masonry, with intermediate insulation, the surfaces of which are rendered, with a layer of protective paint applied on the external wall surface.

After choosing the technical solution for the basis, the experimental program could then be configured. The program was structured into three steps, which led to the same number of experimental variables:

The first choice was to perform parallel *accelerated* tests in conditioned laboratory environments and external *natural* tests, subsequently verifying the possibility of temporal re-scaling of results. Results from the accelerated tests must be validated by those read in the natural environment, and the compared results of the effects measured should lead to equivalent values between accelerated duration and effective duration.

The second step was to consider two types of sample: the *external version* of the selected technical solution, representing the layers that are directly subject to influence by external agents (Partial Sample – PS), and *entire solution*, which improves obtainable results, as it is also capable of simulating mechanisms and gradients found in reality (Whole Solution – WS).

Lastly the choice was made to consider the *degree of protection* obtainable with the paints as a variable of the system, and for this purpose it was decided to start from unprotected solutions leading on to measure relative categories of paint, varying the type of resin and weight percentage in the paint composition.

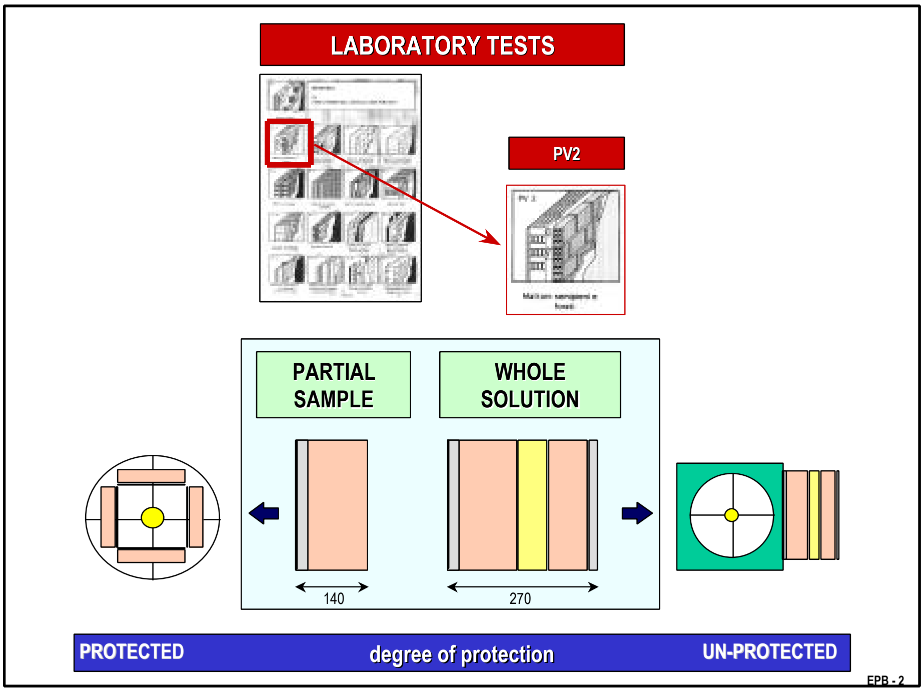

**Figure 1. Experimental program methodology**

## 2 CHARACTERISTICS AND COMPOSITION OF SAMPLES

When defining the criteria for the basis of selecting the materials in the technical solution subject to examination, special attention was paid to the need, throughout the experiment, to have materials with initial technical characteristics suited to the technical solution to be implemented and, above all with reproducible characteristics.

Therefore, before final selection, all components underwent suitability tests in laboratories. Components subject to precise quality requirements laid down by standards (such as cement) were also subject to conformity tests.

Furthermore, the composition of mortar for rendering was formulated taking into consideration directives regarding preparation of render for external use, issued by the Federal Laboratory for material testing and research of Dübendorf, Switzerland (EMPA, 1985). For example, on the basis of the suitability test results, it was decided not to use pre-mixed sand.

The following section lists the components and sub-products used to make the test samples, together with a description of their main characteristics.

Go Back
Next Page

1. Bricks

As elements for the masonry work, perforated bricks were used with normal vertical perforations (code MS (A) 11-21) according to UNI 8942/1. In particular elements were used with the dimensions 12 x 12 x 25 cm with a perforation percentage of 41% and mechanical resistance to compression of 38 N/mm$^2$.

2. Sand.

As aggregate material for the mortar production, selected natural sand was used, with a particle composition obtained by mixing eight different fractions. The mix percentage of each fraction is illustrated in table 1 and figure 2.

**Table 1. Particle composition of sand**

| *filter* | *filler* | *0 - 0,20 mm* | *0,20 – 0,35* | *0,45 – 0,60 mm* |
|---|---|---|---|---|
| *% in mass* | 6 | 12 | 11 | 14 |
| *filter* | *0.60 – 1.00* | *1.00 – 1.50* | *1.50 – 2.50* | *3.00 – 4.00 mm* |
| *% in mass* | 12 | 15 | 19 | 11 |

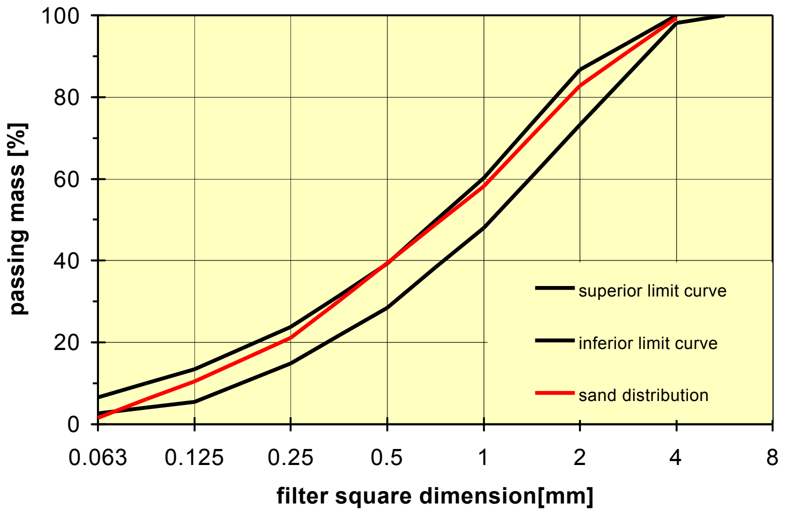

**Figure 2. Particle distribution of sand**

The mix percentage of the fractions was selected to obtain a uniform particle distribution, and was included in the grading envelope, defined on the basis of results of experimental research performed at the Federal Laboratory for material testing and research (EMPA) of Dübendorf : the grading envelope defines the zone within which the curve describing the distribution of sand grain particles needs to remain to be recommended for the grading envelope of render mortar.

The particle size analysis of some pre-mixed commercial sands has shown that the distribution of particle size of sand did not remain within this grading envelope. For this reason these types of sand were not deemed suitable for the production of render mortar and were therefore rejected.

The check of variability of the recipes on the final results of the solution lifetime (such as particle composition of the sands for rendering, type of masonry or insulation) was left for future experimental research.

3. Cement

The binder used for the preparation of both the mortar for the masonry and the rendering is identified according to the standard UNI ENV 197/1 as CEM II/A-L 32.5.

The cement used is a Portland lime cement comprising 80-94% clinker and 6-20% lime in the resistance class 32.5, i.e. with an initial normal compression resistance and a resistance to compression after 28 days greater than or equal to 32.5 N/mm$^2$.

4. Mortar for masonry

The recipe for the cement mix to be used as mortar for masonry was defined to satisfy a number of requirements regarding workability and resistance to compression.

The doses of the components used for preparation of the mortar are as follows: 1,450 g sand, 450 g cement and 250 g water.

5. Masonry

The masonry involved the use of stone elements as described in point 1, comprising a vertical structure with a thickness of 12 cm and vertical joints with mortar and continuous horizontal joints.

This type of structure features, in accordance with standard UNI 10355, a surface mass of 140 $kg/m^2$ and heat resistance of 0.24 $m^2K/W$.

The dimensions of the masonry were selected to be compatible with the space restrictions inside the artificial accelerated ageing equipment.

Each test sample comprises four courses of bricks each made up of 1.5 elements.

The surface of the test samples, including joints, extends over 0.21 $m^2$ (L x A = 39 cm x 53 cm). The volume of the samples, including a 15 mm layer of rendering, is approximately 35 kg.

6. Rendering mortar

As a binder for the preparation of the mortar, a mix was used comprising 70% cement type CEM II/A-L 32.5 and 30% highly hydraulic lime, with a normalised resistance to compression of 6 $N/mm^2$.

The doses of the components used for mortar preparation are as follows: 1,450 g sand, 315 g cement, 135 g hydraulic lime and 280 g water.

7. Paint coating product

The protective systems tested comprised four products belonging to continuous systems classified as follows: by standard UNI 8752 as applied coatings comprising an external surface film on the base of an appreciable thickness; by standard UNI 8681 as paints, with functions conforming to that of undercoats and finishing coat, comprising resins in water dispersions, one-pack coatings, with physical drying, a smooth opaque appearance, and decorative and protective properties specially required for all external paints, such as those considered in the program in question.

For a better interpretation of the behaviour on-site of a specific paint, its typical allocation must be considered, i.e. that it comprises temporary components with the sole function of rendering it fluid, more or less viscous, for subsequent application on a specific base, where it changes to a solid state and finally shows its actual properties.

In the fluid state, the main characteristics of a paint regard the stability of the container, the formation of an easily removable deposit even after months of storage, the lowest viscosity possible for application with a minimum dilution to avoid reducing the thickness of the solid layer, and optimal manageability. The performance characteristics of a paint depend on the solid state, comprising pigments – fillers (powders) and resin or binder, i.e. the property of remaining intact over time; a property due to the type of resin and its ratio, in volume, with the powders defined with the acronym CVP, (Concentrazione Volumetrica Polveri – Powder Volume Concentration), the value of which refers to the percentage contained in the solid coat.

The graph illustrates the variation in characteristics of all paints, water or solvent based according to variations in the CVP. The criteria for selection of the pains to be examined was based on products most commonly used on the market, both as type of resin and content of the latter.

### 1.1 Identification of the paints prepared for the current program

On the basis of these considerations, four types of water based paint were prepared for the current research program, with two types of resin, acrylic and versatic vinyl, and two different CVPs as shown below.

*Identification of paint with high resin content. UNI 8757*

Type of resin: non plastified acrylic and versatic vinyl paint, both in water dispersion

| | |
|---|---|
| Specific gravity: | 1,380 - 1400 g / litre |
| Solid content by volume: | 38 - 40 % |
| Solid content by mass at 105 °C: | 56 - 58 % |
| Solid content by mass at 450 °C: | 39 - 41 % |

The test samples were then made up in the laboratory. For brickwork conditioning, mortar mixing and laying, and construction of the masonry, the same equipment, methods, procedures were used as normally adopted on the construction site that plans to construct professional masonry.

Before application of the rendering coat and paint and before placing in the artificial accelerated ageing equipment, the test samples were left to set in the environmental laboratory conditions.

## 3 SAMPLE ARTIFICIAL ACCELERATED AGEING EQUIPMENT AND THE AGEING CYCLE

The experimental program, as already mentioned, started in November 1996, which saw the start of collaboration with the Experimental technical laboratory of the Professional university school of Italian Switzerland in Lugano (CH), an experimental laboratory for tests on materials and buildings in construction, already in possession of a climate chamber for accelerated artificial ageing of the test samples, capable of simulating the main meteorological and climatic agents inside the chamber, i.e. rain, sunlight, freezing, dry and humid climates, hot and cold climates.

This equipment offers the possibility of programming any sequence of agents, their duration, and the number of repetitions in the sequence. Some agents may also be activated simultaneously.

Go Back
Next Page

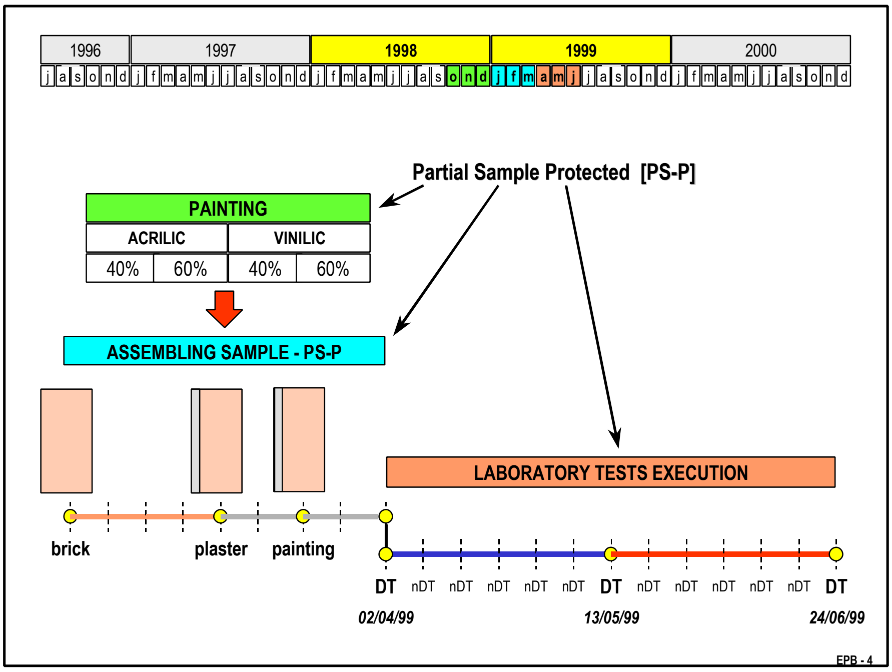

**Figure 3. Program for preparation of partial version-protected samples (October 1998-June 1999)**

The temperature and relative humidity of the air inside the compartment can be regulated respectively from -30 °C to 90 °C and 15% to 95%.

Sunlight is simulated by means of a 6 kW Xenon arc lamp equipped with borosilicate glass filters, the light of which has a spectrum very similar to that of sunlight.

The wetting system comprises four full cone spray points positioned radially at 90° intervals and capable, under a spray angle of 120°, to produce a uniform round coverage spray.

The compartment dimensions are L x D x A = 100 cm x 90 cm x 90 cm, with a capacity to hold four test samples simultaneously.

These are positioned symmetrically around the axis of the lamp as shown in figure 4.

In February 1997, after determining the equipment to be used and the reference laboratory, work moved on to research into standards and bibliography on the possible techniques used for the execution of accelerated ageing tests in laboratories, with the collection of data on standard technical datasheets for the relative interpretation of the various possibilities available. In March 1997 work proceeded to the cataloguing of all possible agents detected in nature, the verification of those that can be simulated in the climate chamber, and the choice of those to be included in the accelerated test cycle.

The decision was to construct an envelope cycle of several agents, to be repeated continuously in the machine, maintaining the possibility of reading the effects of a single agent with the execution of consecutive tests: the effect provoked by the single agent (such as sun radiation) is measured as an effect on an element subject to actions in parallel with other agents, and this is transformed to make the agent more or less effective in terms of deterioration.

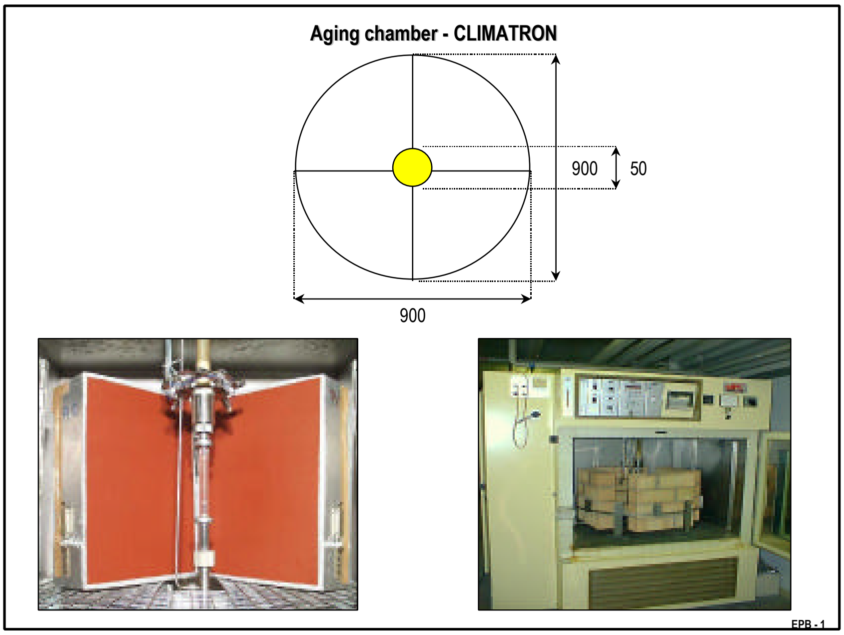

**Figure 4. Climatron climate chamber**

The envelope of the agents in the accelerated test cycle was chosen on the basis of the definition of the maximum intensity that a single agent was to have in the cycle.

This intensity had to be similar to that found in the chosen reference standard of Milan or Lugano, with the subsequent assignment to each sub-phase of an objective to be reached to establish to duration within the cycle.

This objective and the subsequent duration of the sub-cycle were verified through the execution of preliminary calibration tests which enabled the collection of data that was extremely useful to define the artificial accelerated ageing cycle used on the test samples.

As can be seen in figure 5, the cycle has an overall duration of 6 hours and 25 minutes and is structured as follows:

1. Rain phase.

   In this phase, with a duration of 60 minutes, the test samples are sprayed uniformly with water at a temperature of approx. 20 °C.

   Air within the compartment is maintained at a constant temperature of 20 °C and at a relative humidity level greater than 95%.

2. Freezing phase.

   Air within the compartment holding the wet test samples is cooled rapidly to–20 °C and maintained constant for 90 minutes.

3. Hot and humid climate phase.

   During this phase the air temperature and humidity are maintained constant respectively at 55 °C and 95% for 60 minutes. This phase is preceded by a transition period of approx. 80 minutes.

4. Hot dry climate with radiation phase.

   The test samples are irradiated for 80 minutes by means of the xenon lamp. In this interval the climate within the test compartment is kept at a temperature of 30 °C with relative humidity at 40%.

Go Back
Next Page

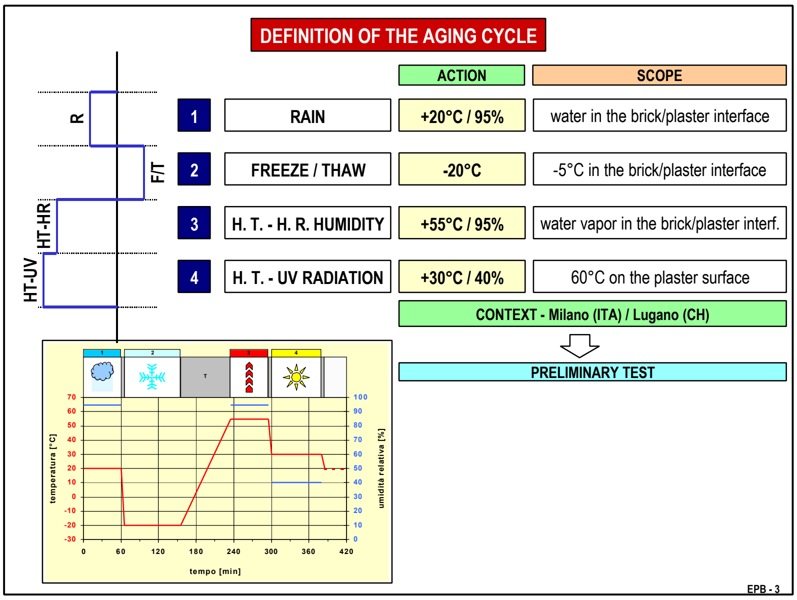

**Figure 5. Artificial accelerated ageing cycle structure**

Before starting the artificial accelerated ageing cycle on the test cycles, in order to enable a study of the physical and performance deterioration of the products under the effect of agents involved in the cycle, further checks were made on individual phases to verify the capacity to reproduce effects from cycle to cycle similar to those produced in natural conditions.

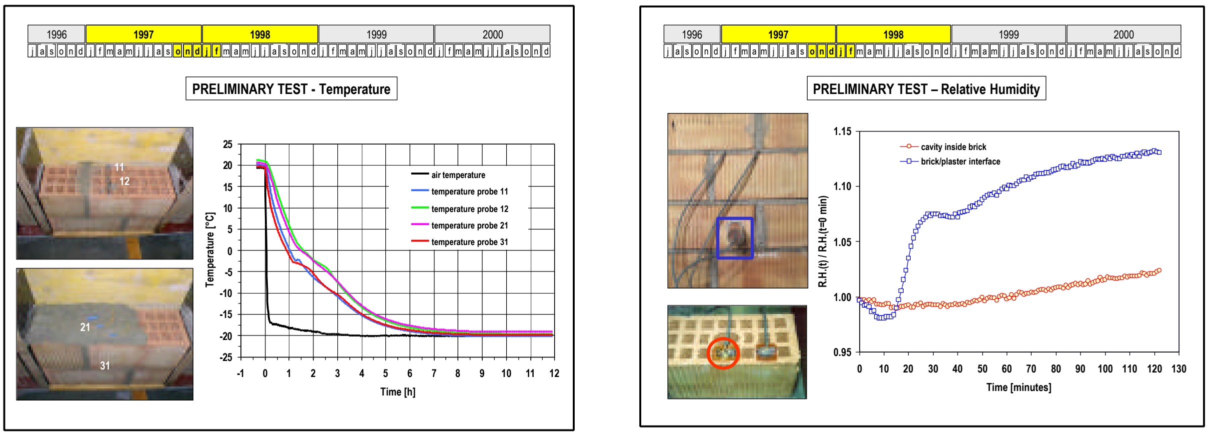

**Figure 6. Preliminary Tests**

For example the temperature was monitored in a test sample over a series of cycles. The data recorded during one of these cycles are illustrated graphically in figure 6.

From the data shown in figure 7 it is clear that the temperature of the rendering at the end of the freezing stage (phase 2) can reach slightly higher than –10 °C (sensor 31) and that the freezing front moves to a depth of a few centimetres behind the rendering-masonry interface (see Curves related to sensors 11 and 22). The trend of the temperature within the test sample at the end of the freezing phase is therefore very similar to the distribution, which, on the basis of the climatic data for the region of Lugano (SIA 381/2) (SIA D 012) and the measurements made on the external brickwork (SIA), would be noted during a cold winter day in the same technical solution exposed to natural climatic conditions. At the end of the hot and humid climate phase (phase 3), the temperature of the rendering and masonry zone immediately behind the interface reaches values from 45 °C to 50 °C. The subsequent radiation phase (phase 4) causes a rise in the rendering temperature to over 60 °C, leaving the wall temperature practically unchanged. Also in phases 3 and 4 the cycle produces, in the test samples, temperatures similar to those produced in natural conditions with and without direct sunlight (SIA).

Go Back Next Page

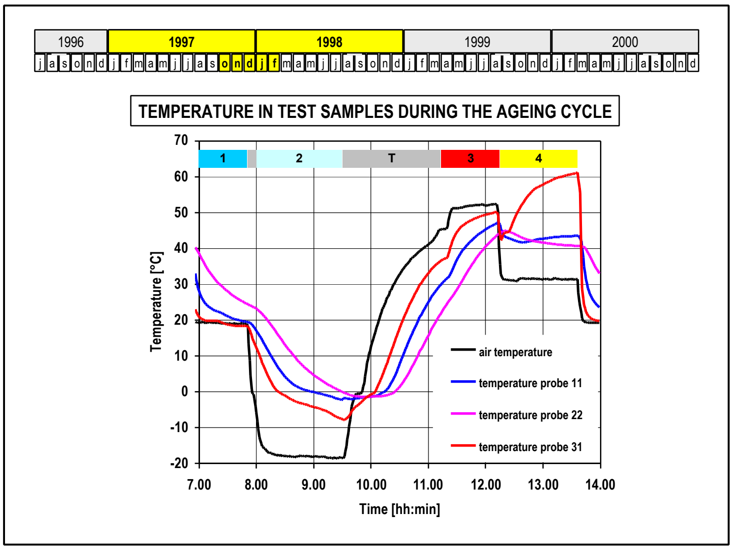

**Figure 7. Temperature in test samples during an ageing cycle**

In conclusion, the data show how the agents involved in the ageing cycle, in the technical solution under examination, produce stress factors comparable to those that the technical solution would be subject to in natural ageing conditions.

## 4 CHARACTERIZATION TESTS

In parallel to the definition of the cycle, the characterization tests were also defined for execution at zero time and during test execution, dividing them into two categories: non destructive, to be performed weekly on the samples, and destructive, to be performed at 150 and 300 ageing cycles. These tests are listed in figure 8. The ageing tests, as mentioned, started with the partial version sample in unprotected and protected types. Figure 3 illustrates the intervals of preparation and ageing of the sample and the agenda for test execution on this sample type. Four samples are placed in the climate chamber directing the outer surface towards the centre of the chamber where the cycle agents originate; on reaching the set ageing interval, the samples are replaced with new ones.

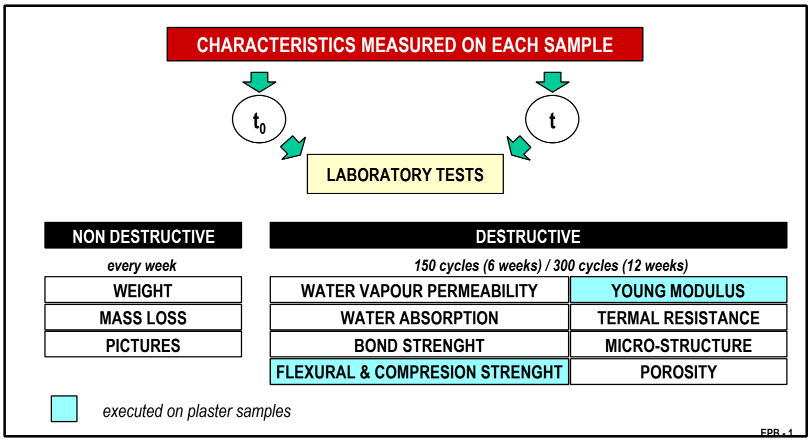

**Figure 8. Characterization test type**

## 5 CONTINUATION OF THE EXPERIMENTAL PROGRAM

The results of the experimental program on the partial versions, performed for the accelerated tests as described above, as well as the relative results for interpretation must be accompanied by the external tests started in May 1999, to enable a reading on a real scale. The choice was made to reconstruct the same elements tested in the accelerated tests according to the type of paint, and to expose them both in Milan and Lugano, environments with similar climatic conditions but with different levels of pollution. In the case of the external tests, two types of exposure were also tested: vertical and at a 45° angle, which, according to standards, should accelerate external ageing by a factor of 6÷8.

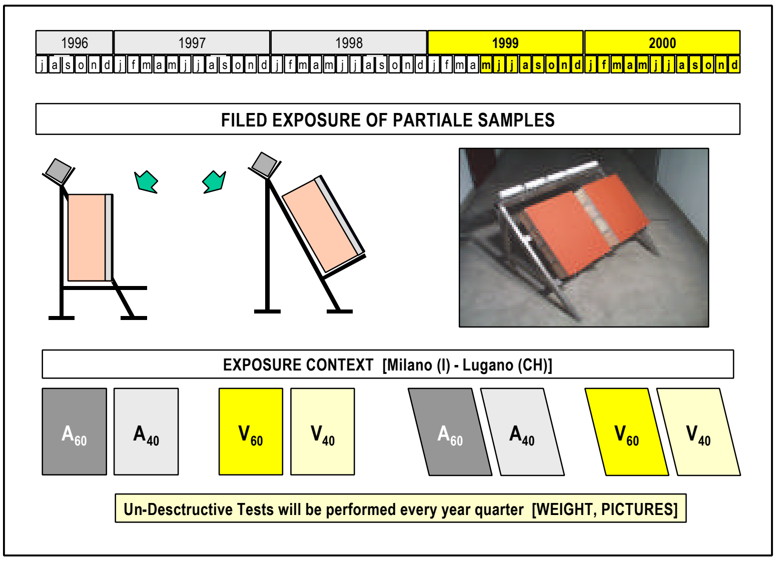

**Figure 9. Field exposure of partial samples**

As this variable does not alter the aspects of deterioration found outside, it enables the interpretation of relative results with those of the accelerated tests much sooner than possible with the vertical inclination tests, even awaiting their final validation. This assumption is also verified on test execution. The other type of sample subject to testing is a sample representing the entire solution: the end of the useful life of the technical solution will be its performance limit, as illustrated in chapter 6, describing the various methods prepared to date by our group for the interpretation and modelling of performance over time. In this case the tests will start in February 2001 and will use the same instrumentation as used previously with a number of modifications (support structure on door for application on the climate chamber).

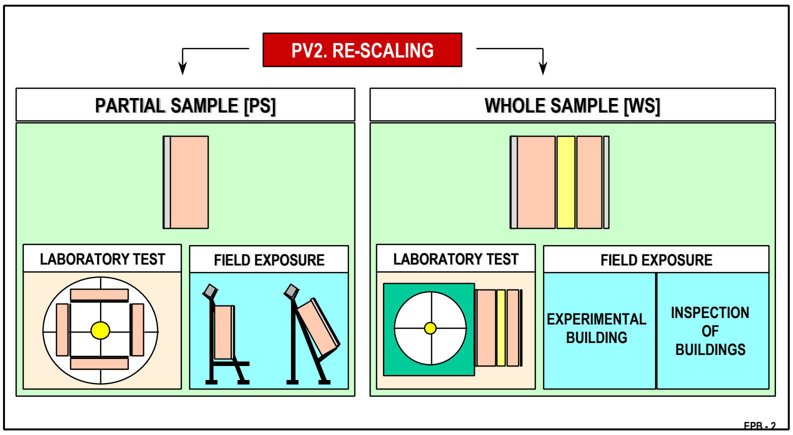

**Figure 10. Overall structure of the experimental program**

The samples in question will reach dimensions four times that of the partial version (surface areas: 100 cm x 950 cm) and will enable a series of significant measurements on a continuous basis (conductivity and humidity at various depths), as well as execution of the characterization tests described above.

Go Back

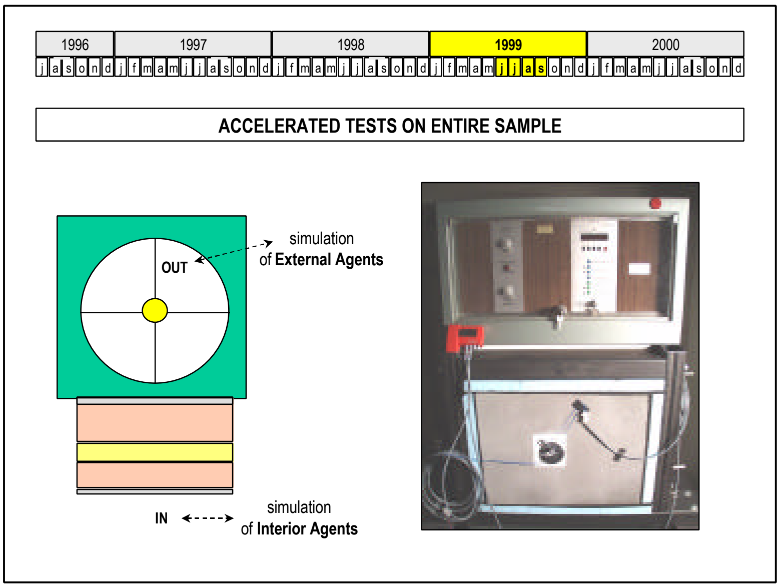

**Figure 11. Characterization test type**

The added value of the sample representing the entire solution lies mainly in the possibility of simulating transitional periods with relative gradients, and thereby verify the effects on deterioration.

This experimental phase will occupy the first 9 months of 2001 and to be completed will have to be compared with external tests in the future to enable rescaling of the results.

The external tests on the entire solution will be carried out in two configurations: by constructing a standard-technological laboratory able to simulate controlled internal conditions in a natural outdoor environment, and through the readings of real new or existing buildings containing the technical solution subject to analysis.

The final representation of the experimental program is therefore the version shown in figure 11, which on completion will be able to be repeated for other solutions in the area or to test alternatives of the same solution with new recipes.

# Protecting The Building Owner Through Durability Requirements For Building Elements

C Benge & K Sanders
Building Industry Authority New Zealand

**Summary: In order to ensure that tomorrow's buildings will be better (as in the theme of the conference) it has become very important in the construction industry today to predict the life of materials.**
**The New Zealand Building Code clause B2 "Durability" is there to ensure that we have "better buildings for tomorrow" by requiring at the outset that proposed construction components and systems must last a reasonable length of time on a building rather than attempting to punish the person who supplies poor materials when failure occurs years later. The Durability clause has been likened to a fence at the top of a cliff that prevents people from falling instead of an ambulance at the bottom, collecting those who have fallen.**
**This paper will also discuss how the legislation contained in the Limitation Act 1950 and the Building Act 1991 impinges on the durability time limits set out in the building code. The effects of warranties and the Consumer Guarantees Act 1993 are also considered in this context. The Durability clause and the effects of time restraints have to be considered together to ensure that all parties involved in the construction process can interact to ensure that there are better buildings for tomorrow.**

## 1 INTRODUCTION

### 1.1 The New Zealand Regulatory System

The New Zealand Building Act 1991 introduced the Building Regulations 1992 and a six months lead in period saw the full introduction of the New Zealand Building Code (the building code) as the First Schedule of the regulations in January 1993. This national building code, which is performance-based, was introduced to give consistency to an industry that was previously prescriptively governed by a myriad of Acts, Regulations and local by-laws that riddled the country's building regulatory regime.

### 1.2 The basis for a durability clause

The authors of the New Zealand reforms, the Building Industry Commission, introduced specific requirements for durability in the belief that a building should, with normal maintenance, be required to achieve all performance criteria of the building code, not merely on completion but throughout its intended life. They noted that durability was one of the "user requirements" listed in ISO 6241-1984 (E) *Performance standards in buildings*.

Durability requirements were in place under the previous building control system in two ways:

- By ad-hoc requirements for routine safety inspections (by Government officials) of such building components as lifts and boilers, and annual inspection and licensing (by local councils and the Fire Service) of certain types of buildings (such as apartment buildings and places of assembly).
- By prescriptive requirements for such things as concrete cover to reinforcing and the preservative treatment of timber.
- Under the new system:
- The ad-hoc requirements for routine safety inspections were replaced by a system of routine inspection and maintenance procedures by qualified persons (approved by the territorial authority) for maintenance-sensitive systems such as lifts and sprinklers. Those procedures are specified in a "compliance schedule" for the building issued by the territorial authority. The building owner is responsible for obtaining a compliance schedule and is required to supply the territorial authority with an annual "building warrant of fitness" to state that the procedures have been properly completed.

Go Back Next Page

- The building code includes performance criteria for the durability of all building elements. Previous prescriptive requirements are generally incorporated as a means of compliance in the Approved Documents.

These regulatory requirements are in addition to any other legal rights to compensation for building failures. These rights are seen as an ambulance at the bottom of the cliff, in contrast to the fence at the top of the cliff provided by the building code.

Although the building code requires a durability of the intended life of the building (indefinite but not less than 50 years) or specific durability periods for some parts of the building, claims for building failures cannot generally be brought to court more than 10 years after the building was erected. That is sometimes seen as an anomaly, but in fact such limitations are common in New Zealand law (and in the law of many other countries), and will rarely entertain a claim for breach of contract more than 6 years after the breach. The true protection provided by clause B2 is not in the right to claim damages but in the integrity of those enforcing the building code. (Benge 2001)

## 2 THE FENCE AT THE TOP OF THE CLIFF

### 2.1 Clause B2 "Durability"

The Objective of most clauses of the building code is to protect the occupier from illness, injury or the loss of amenity with additional objectives for providing access for people with disabilities and some protection of other property. The Objective of clause B2 "Durability" is to:

*"ensure that a building will throughout its life continue to satisfy the other objectives of this code."*

It was generally accepted that elements that were of minor significance and easy to access or replace, such as paint finishes or minor fittings, might need to be replaced after 5 years. Similarly, the claddings in general use at that time were recognised as being sure to last for at least 15 years if properly maintained. No one, however, expects to have to replace the foundations, and of course replacing the building as a whole ends the life of the original building. Thus the Building Act regards buildings generally as having an indefinite life. The exception is made in section 39 of the Building Act for temporary or experimental buildings, referred to in the Act as "buildings having specified intended lives". The owner must specify the intended life at the time of construction, and cannot specify a life of more than 50 years.

Those concepts were used to develop code performance criteria, which included taking into consideration maintenance and the option of specifying a shorter intended life. There are 3 main considerations used to define consumer expectations to determine whether the 5, 15 or 50-year durability requirement applied. These can be put in tabular form as:

**Table 1. Durability Requirement**

| Ease of Access | Ease of Replacement | Detection of Failure | Structural function | **Durability requirement** |
|---|---|---|---|---|
| Difficult<br>OR | Difficult<br>OR | Unable to detect during normal maintenance and normal use<br>OR | Provides structural stability | **The life of the building being not less than 50 years** |
| Moderately difficult<br>OR | Moderately difficult<br>OR | Able to detect during normal maintenance | | **15 years** |
| Easy<br>AND | Easy<br>AND | Able to detect during normal use | | **5 years** |

All conditions must exist in order to be able have a 5 year durability. If a material does not fit into that category it falls into the worst of the other two categories, ie if the worst condition is one of those in the first line above then the building element must have an indefinite durability (the life of the building being not less than 50 years), if the worst condition is one of those in the second line above, then it will only require a 15 year durability.

Thus the Performance criteria are:

#### 2.1.1 B2.3.1

*Building elements must, with only normal maintenance, continue to satisfy the performance requirements of this code for the lesser of the specified intended life of the building if stated, or:*

*a) The life of the building, being not less than 50 years, if:*

i) *Those building elements (including floors, walls and fixings) provide structural stability to the building, or*

ii) *Those building elements are difficult to access or replace, or*

iii) *Failure of those building elements to comply with the building code would go undetected during both normal use and maintenance of the building.*

b) *15 years if:*

i) *Those building elements (including the building envelope, exposed plumbing in the subfloor space, and in-built chimneys and flues) are moderately difficult to access or replace, or*

ii) *Failure of those building elements to comply with the building code would go undetected during normal use of the building, but would be easily detected during normal maintenance.*

c) *5 years if:*

i) *The building elements (including services, linings, renewable protective coatings, and fixtures) are easy to access and replace, and*

ii) *Failure of those building elements to comply with the building code would be easily detected during normal use of the building.*

### 2.2 Approval at building consent stage

Under section 34 of the Building Act

*The territorial authority shall grant the consent if it is satisfied on reasonable grounds that the provisions of the building code would be met if the building work was properly completed in accordance with the plans and specifications submitted with the application.*

There is little specific guidance given to the territorial authorities except in section 47 of the Building Act which states that

*In the exercise of its powers under sections 30 to 46 and 64 to 71 of, and the Third Schedule to, this Act the territorial authority shall have due regard to the following matters:*

*(a) The size of the building; and*

*(b) The complexity of the building; and*

*(c) The location of the building in relation to other buildings, public places, and natural hazards; and*

*(d) The intended life of the building; and*

*(e) How often people visit the building; and*

*(f) How many people spend time in or in the vicinity of the building; and*

*(g) The intended use of the building, including any special traditional and cultural aspects of the intended use; and*

*(h) The expected useful life of the building and any prolongation of that life; and*

*(i) The reasonable practicality of any work concerned; and*

*(j) In the case of an existing building, any special historical or cultural value of that building; and*

*(k) Any other matter that the territorial authority considers to be relevant.*

When considering those aspects above, a territorial authority can obtain information about the durability of a building elements from:

- Appraisals
- History in use
- Reputation of the manufacturer
- Manufacturer’s warranty.

The first three are important considerations, and although the manufacturer’s warranty is significant, it should not be the sole criterion for an assessment of durability. A warranty of X number of years is worth nothing if the company offering it goes into liquidation before that expiry of X years. Warranties for up to 25 years are sometimes offered by larger firms that have a stable history of existence but it is hard to envisage a warranty for 50 years or the life of the building being taken seriously.

If the warranty is only for 5 years, it does not detract from the fact that the building material or component may have a realistic life of 15 or 20 years. An analogy to this would be a new car that comes with a 5 year warranty. No one expects it to grind to a halt at the end of 5 years. With normal maintenance and the odd part renewed, a new car could be reasonably expected to last 20 years. Some territorial authorities recognise this fact and will accept a statement (known as producer statement for the purposes of a building consent) from a person recognised as expert in the field about the durability of a building element.

### 2.3 Issuing of code compliance certificate

When a building is considered to be completed the owner must apply to the territorial authority for a Code Compliance Certificate (CCC). The date of issue of a CCC is important because that is when the clock starts for the durability period. An interim CCC can be issued when there is some doubt about compliance of specific elements so that the commencement of the durability period of most of the building elements is not held up by minor matters.

The territorial authority normally issues the CCC after a final inspection or after receiving a building certificate from a building certifier. Withholding the CCC is normally sufficient to ensure proper completion of the work but under section 42 of the Building Act the territorial authority may issue a notice to rectify if necessary. To give weight to this provision the Building Act under Section 80 allows for a fine not exceeding $200,000 with $20,000 per day for not rectifying. No fines to this extent have ever been imposed however.

The CCC can act as a backstop if something has been missed at the time of the issuing of the building consent, or can pick up inappropriate substitution of building elements.

## 3 THE AMBULANCE AT THE BOTTOM OF THE CLIFF

### 3.1 General Limitations

Despite the protection that the durability clauses of the building code gives to a building owner, other factors can reduce their effectiveness. In particular, the Limitation Act 1950 and section 91 of the Building Act can affect the time spans set down in the B2 clauses.

For the purposes of this paper, building owners have been divided into the two categories of “initial owner” and “subsequent owner”. An initial owner is the person who has the contract with the builder or developer while a subsequent owner is the person who has purchased a building from a previous owner. These distinctions are important as the time limitations vary in each case. It is also emphasised that the main contractor will invariably be responsible to an initial owner for the negligent acts of subcontractors.

In simplified terms, the Limitation Act says that claims must be brought before a Court or a tribunal within a certain time, which is called “the limitation period”. These basically say that;

- For claims in contract, the limitation period is 6 years from the time that any defective work was carried out.[1]
- For claims in tort, the limitation period is 6 years from the time of *discovering* a defect, or from when it ought to have been discovered by a careful inspection.

Section 91 of the Building Act introduces a 10-year longstop for claims arising out of the construction, alteration, etc of buildings. This provision makes no difference to most claims for breach of contract, where the 6-year limitation will apply. It does, however affect a claim in tort, a tort being a civil wrong that is not a breach of contract. For example, under the Limitation Act, even if a defect is first discovered 20 years after a building was constructed, an owner would have a further 6 years to make a claim in tort. However, the Building Act sets a time limit of 10 years from when the negligent work *was carried out* to make such a claim.

As an initial owner has to sue under the contract, he or she cannot take an action against a contractor for negligent work once the 6-year time span has been reached, even though the building code requires a 15-year durability requirement for a specific item.

On the other hand, as a subsequent owner is not able to sue a negligent builder in contract, he or she must claim against a contractor in tort if it can be shown that any defective work was due to the builder’s negligence. This means that a subsequent owner may have a maximum 4-year limitation time advantage compared with an initial owner. (The subsequent owner could be the first resident of the building, having bought it from a developer.) For example, if the faulty work was carried out 7 years previously and the fault is just discovered, the owner would have a further 3 years to commence an action in tort. Although there is some uncertainty as regards the present attitude of the New Zealand Courts to concurrent liability (the right to sue in tort where one already has a contract), it seems likely that an original owner would not be able to sue in tort to take advantage of this differing approach.

[1] This refers to a simple contract into which category most domestic contracts would fall. In the case of a deed, the limitation is 12 years.

Building defects generally become evident during construction or within the next few years but some defects, particularly durability defects, could take many years to appear. Nonetheless, once the limitation period has expired, no action can be taken against a negligent contractor even though the durability or other requirements have not been met.

### 3.2 Warranties

Some additional protection for building owners is available if they are provided with a warranty or guarantee for building elements requiring durability under the building code. A warranty or guarantee is a commercial arrangement between a manufacturer and a buyer. These can be made out in general terms, which usually apply only to the original owner, but they can be specific to both subsequent and original owners. However, as mentioned previously, a warranty or guarantee is worthless if the organisation offering it goes into liquidation.

In *Richards Bros Ltd v Page* (Holderness 1994) it was said that:

> It is not uncommon for a breach of warranty to arise from events long past and the general law as to limitation (as provided for in the Limitation Act 1950) does not bar proceedings based upon a breach simply because the events rather than the breach of the warranty occurred more than six years before the commencement of the proceedings.

In accordance with this judgement, the limitation clock starts when the warranty or guarantee is invoked, which would normally be the time that a defect was discovered. So, for example, if an original building owner had a 15-year durability warranty, the limitation deadline could be extended from 6 years to a total of 15 years.

Both of the major New Zealand Standard Construction Conditions of Contract refer to the provision of guarantees. Clause 11.5 of NZS 3910:1996 Conditions of Contract for Building and Civil Engineering Construction states:

> 11.5.1 The Contractor shall provide the Principal with written guarantees where required by the Special Conditions.
>
> 11.5.2 Such guarantees shall be supplied to the Engineer in writing before the Engineer issues the Defects Liability Certificate and shall be in the form required by the Special Conditions.

In the First Schedule “Special Conditions of Contract”, there are the options to either list the guarantees that are required or to indicate that no guarantees are required.

Rule 53 of the NZIA Standard Conditions of Contract SCC1 2000 states:

> The Contractor must provide the Principal with the specified guarantees.
>
> 53.1 The wording must comply with any requirements in the Specifications.

Addendum B1, “The Specific Conditions of Contract” requires guarantees from the Contractor before the Principal can use the Contract Works.

These standard clauses allow for the inclusion of properly worded guarantees or warranties within building contracts that can ensure that at least the 15-year durability times can be met. In order to reinforce the durability requirement of the NZBC such guarantees or warranties should be so worded that they are able to be passed on to subsequent owners.

### 3.3 The Consumer Guarantees Act 1993

The Consumer Guarantees Act 1993 (the CGA) gives additional protection to those who are “consumers” under the Act. Its clauses are implied in any contract involving a consumer, and in relation to the building industry it will generally apply to the construction of domestic dwellings and the like. A consumer is defined under section 2(a) of the Act as:

> A person who acquires from a supplier goods or services of a kind ordinarily acquired for personal, domestic, or household use.

Whereas the CGA is still subject to the Limitation Act, it will impact on the rights of original owners. Section 55 of the Act amends section 63 of the Building Act, which now reads that

> Nothing in this Part of the Act shall derogate from the provisions of the Fair Trading Act 1986 or the Consumer Guarantees Act 1993.

In particular, the Act sets out various implied guarantees for both goods and services that the supplier of these cannot contract out from except for business transactions. In the case of a building, services would include the work required to put the materials (goods) in place. The CGA does not apply to goods that are supplied by competitive tender, nor does it give any protection to subsequent owners.

The CGA provides a list of remedies available to consumers where goods or services do not comply with guarantees. Such remedies might circumvent contractual limitation or exclusion clauses that are detrimental to an original owner.

Where services do not comply with the guarantees set out in the Act, a building owner may also obtain damages for foreseeable loss or damage to other elements that are affected by the failure of a specific element.

Go Back

The CGA gives a consumer a right of redress against a manufacturer who has given any express guarantee that is binding on the manufacturer in accordance with the Act. This remedy could be invoked where, for example, the contractor has become insolvent.

It has also been suggested that as a consumer "acquires" goods as defined in the Act, then this may give a consumer a right to directly sue an individual subcontractor rather than just the builder who is a party to the contract (Fraser1994).

## 4 CONCLUSION

This brief discussion on the limitation placed on durability time-scales indicates that it may be difficult to take action to get defective work rectified. In some instances a negligent contractor will escape any legal liability once 6 years has elapsed from the time any faulty work was carried out. While the Consumers Guarantees Act may offer additional remedies to building owners, it is still encapsulated in the Limitation Act requirements. Only when an effective warranty has been given can some owners enforce the 15-year durability clause of the building code. The 50-year requirement is, of course, entirely out of reach.

It seems anomalous that the building code should specify durabilities exceeding the long-stop limitation period of 10 years, because any durability inadequacy that is discovered after that time cannot be the subject of a claim before a Court or tribunal. However, the building code is not intended to create rights between parties, it is intended to be enforced by territorial authorities. The situation is that the territorial authority is required to refuse building consent if it is not satisfied on reasonable grounds that all proposed building elements would achieve the durabilities required by the building code. Further more, at completion of the building, the territorial authority cannot issue a code compliance certificate unless the building complies with the code, and can issue a notice to rectify if it does not comply.

As the "ambulance at the bottom of the cliff" is not fully equipped to deal with durability problems in the building industry, it rests with local authorities and independent building certifiers in New Zealand to ensure that buildings are built in accordance with the building code.

The adage "Do it once and do it right' is of paramount importance.

# A Performance Assessment of Flood-Damaged Shearwalls

**RJ Leichti R Staehle & DV Rosowsky**
**Department of Forest Products Oregon State University USA**

**Summary: Flood events affect more people than any other form of natural disaster. Flooded structures are partially submerged and then re-dried, which leads to swelling and shrinking over an arbitrary wall height. One repair scheme is to remove the interior cladding (drywall), dry the wood system, and re-install new drywall. This investigation was conducted to evaluate the effects of long-term water exposure on the mechanical properties of oriented strand board (OSB) sheathing and the impact of those changes on the capacity of light-frame shearwalls. OSB was submerged for up to seven days, air-dried and then tested for embedment strength, shear strength through the thickness, and shear modulus. Nine walls were built for the test program. Three were tested at ambient conditions and monotonically loaded in shear to establish the displacement criteria for the quasi-static methods; three walls were tested at ambient conditions (control walls) using a quasi-static loading protocol; and three were submerged in 1 m of water for seven days, re-dried, and then tested using the same quasi-static protocol as the control walls. The results from the OSB material tests showed that most of the material property degradation occurred in the first 48 hr of submersion, for example, the embedment strength was reduced by almost 40 percent after 48 hr and showed no further reduction even with 120 hr of additional soaking. The shearwall test results did not follow the materials' results -- the quasi-static shearwall tests showed that water submersion did not reduce shearwall capacity, the energy absorption of the wall, or change the yield mode. However, shearwall stiffness was reduced, apparently the result of reduced embedment stiffness of the OSB sheathing.**

## 1 INTRODUCTION

Durability of structures has been the focus of study and design innovation in recent years. The design engineer implements design features and materials that, when used with appropriate construction methods, yields buildings that have long-term durability (TenWolde and Rose 1994). The presumptive design assumption is that the condition of the building system will remain unchanged throughout its service life. However, after a flooding event, there may be a loss in capacity to resist major loading events. Designing for durability requires quantification of the changes in the mechanical properties and resulting performance of the structure. Condition assessment combined with quantified data on the impact of the given material and connection condition provides a vital link to predicting residual structural capacity to resist future loading events given the existing level of damage that is revealed by physical inspection. At present, durability assessment has incorporated only the observed condition of the materials and essentially a go/no-go" basis for replacement. It would be desirable to include the existing levels of damage in the framing and sheathing components in the fragility of residual life assessment of a structure after a natural disaster.

Flooding is a natural disaster that affects more people world wide than any other form of natural disaster (Hausmann & Perils 1998). Geo-scientists have reported that floods account for 23 percent of global natural catastrophes but accounted for 67 percent of casualties and caused 53 percent of the economic losses in the US (Munich Re 2001). The insurance industry has many definitions of "flooding" because flooding can originate from many different events and takes many forms. In general, the insurance industry agrees that a flood is a general and temporary inundation of normally dry land from the overflow of inland or tidal water, rapid accumulation of runoff of surface waters, mud flows or mud slides, or waters due to the collapse of shores and retaining systems. Data reported by Hausmann and Perils (1998) showed that most flood events in buildings involve water depths less than 2 m. The number of affected properties can be significant, as in 1993, when approximately100,000 houses were damaged by flooding in the Mississippi River Basin. Thus, flooding represents a potential hazard to the durability and serviceability of residential and industrial buildings.

### 1.1 Technical Background

Flooding in residential structures has the potential to affect the sheathing, the wood frame and the nailed connection. The literature has many reports of accelerated aging tests and durability studies of wood-based panel products. The various accelerated aging protocols are generally correlated to a given number of years in service under a stated exposure condition. One of the most important factors causing deterioration or strength reduction of wood-based panels is the change in moisture content (Suchsland 1982). Changing moisture content leads to permanent thickness swelling that consists of two parts: swelling of the wood and release of compression stresses that were induced into the panel at the manufacturing process (McNatt 1982). The standard methods of test for water absorption and thickness swelling and moisture-related effects on wood-based panel materials are based on 24 and 48 hr tests. However, flood events do not correlate to accelerated aging protocols, and flood events can last much longer than the test protocol durations. Hence, a method of testing the effects of water exposure for longer periods than 48 hr may be needed.

Shearwalls and nail connections between sheathing and the wood framing have been studied extensively. Neisel & Guerrera (1956) showed that racking strength and lateral nail resistance vary exponentially with moisture content and that racking strength is correlated to lateral nail resistance. Toumi & McCutcheon (1978) used energy method to develop a method of predicting racking strength of light-frame walls. Patton-Mallory & McCutcheon (1987) predicted racking displacement-load behavior of a shearwall from the known behavior of the fasteners and sheathings that gave accurate predictions for small-scale walls. Their models showed that wall displacement was the sum of fastener deformation and displacement due to shear deformation in the sheathing. Shear deformation in the sheathing contributed only 10 to 15 percent of the wall displacement. Hence, most of the deformation in the shearwalls can be attributed to the nail deformation. Others have written more sophisticated models for nonlinear dynamic analysis; the most recent computer model incorporates shear modulus, nail hysteresis, and shear strength to predict load-displacement characteristics and energy dissipation under general cyclic loading (Folz & Filiarault 2001). The computer models and earlier closed-form models can assess the performance of shearwalls with nail and stiffness properties that are constant over the shearwall. The effect of a flood exposure over some arbitrary height of the wall would have to be approximated by evaluating the limits, which could be a wall that has not been exposed to water and a wall that was fully submerged.

Nailed connection capacity and yield mode depend on the embedment strength of the main and side members, bending strength of the nails, and geometry of the joint (NDS 1997). The yield mode of a nailed connection can be managed by using different materials or by changing the geometry. Chou & Polensek (1987) studied damping and stiffness of nailed joints as they were affected by the drying of the green lumber using cyclic load tests of single nailed joints. Damping ratios and slip moduli were significantly smaller for joints with gaps than for those without gaps. Variations of interlayer surface roughness did not appear to significantly affect either damping or stiffness. Mohammad & Smith (1996) reported the results of a study with OSB-lumber nailed connections that were subjected to various moisture cycling regimes between 5 and 15 percent moisture for samples made with dry lumber and between 5 and 12 percent for samples made with green lumber. The mechanical testing used a cyclic test protocol and showed that the moisture cycling had an adverse effect on connection stiffness. Then, if a structure was flooded, re-dried, and a gap developed between the stud and the sheathing as a result of shrinkage, the stiffness and damping of the building would be adversely affected.

The Consortium of Universities for Research in Earthquake Engineering (CUREE) grew from the observation that woodframe structures did not fair well in some recent seismic events. They have sponsored many studies on shearwalls for the purpose of improving hazard mitigation. Researchers expressed a need for full-scale tests of on wood structures that use a standard design in order to make results comparable (Zacher 1999). For this reason, a quasi-static test method was developed by CUREE to assess the lateral force resistance and energy–related properties of shearwalls. The method was adapted for this study.

### 1.2 Objectives

The duration of water events often exceeds 48 hr, which is the period used to characterize moisture effects on wood-based panels. Then, an important structural issue exists: Does long-term water exposure cause a reduction in capacity of shearwall systems? It is logical to presume that significant changes in wall performance would result for structures that have experienced one or more water events where the sheathing has been wet.

The specific objectives of the study were:

- To investigate the effect of long-term water exposure on the material properties of the shearwall constituents;
- To investigate the effect of long-term water exposure on static and energy-related properties of shearwall assemblies.

## 2 MATERIALS AND METHODS

### 2.1 Wood-Based Materials

Twenty-seven panels of OSB were purchased from a local lumber yard. The OSB was APA rated sheathing and rated for EXPOSURE 1 (APA 2000), which means that the adhesive was considered to be fully waterproof. The panels were 11.9 mm (15/32 in.) thick and 1220 by 2440 mm in plane dimension. The lumber for the study was No.2 Douglas fir-Larch, 38 by 89 mm, which by visual inspection was determined to be Douglas-fir.

### 2.2 Materials Properties Tests

Five OSB panels were randomly selected for the materials properties tests and the remaining panels were used for wall construction. The five panels were cut in half resulting in ten half-sheets, 1220 mm in length and width.

The engineering properties to be tested were embedment strength, edgewise shear strength, and shear modulus. These were to be tested following the standard methods given in ASTM (2001a, 2001b, 2001c). The embedment strength of the OSB was assessed in only the principal direction of the panel because it has been shown that embedment strength of small diameter fasteners is not affected by angle to the grain. The diameter of the nail used for the embedment tests was 2.9 mm. The edgewise shear strength was tested in both principal directions of the panels. Shear modulus was tested using square plate. The test was conducted on both diagonals of the plate and the result was the average of the two tests on each plate. The specimens were located on the replicate panels as shown in Fig 1. Each test and water exposure period was assigned to each half-sheet of OSB, so in the end, n = 10 for each of the exposure periods for each test.

The treatments to be applied were various periods of water exposure: 0, 24, 48, 96, and 168 hr of submersion in fresh water. The specimens were soaked in a single batch and designated specimens were removed from the water at the specified times. The specimens were air-dried after the water exposure.

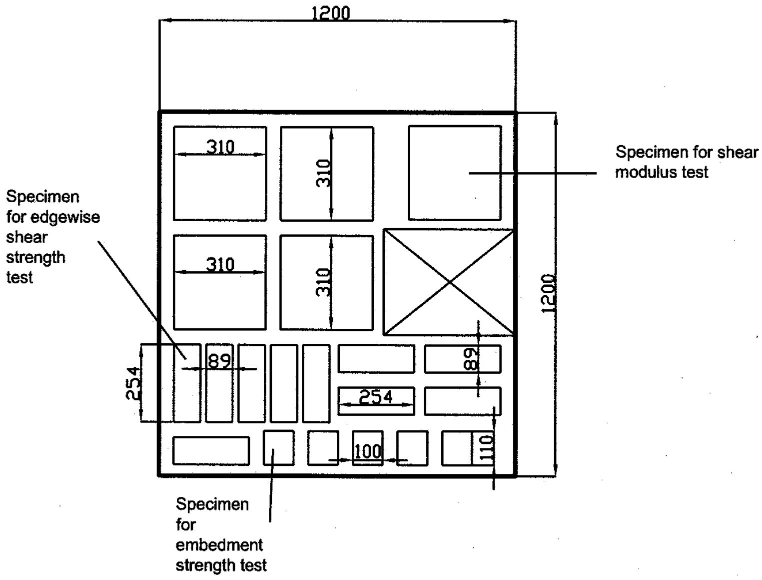

**Figure 1. Cutting diagram for materials properties testing.**

### 2.3 Shearwall Preparation

Nine shearwalls, 2440 by 2440 mm, were built like those by Krawinkler *et al.* (2000) with the exception of nail spacing, which matched the nail spacing of a recent study by Langlois (in preparation). The 38 by 89 mm studs were placed at 406 mm centers. The OSB sheathing was oriented vertically on the stud frame and pneumatically nailed with 8d box nails (60.3 by 2.9 mm). The OSB panels were installed with a 3-mm gap between them. The end studs were doubled and nailed together with 16d box nails (82.6 by 3.3 mm). The top plate was a double member while the sill plate was a single member. Tie-down straps were nailed to the end studs and bolted to the foundation 109 mm from the ends of the sill plates. Two other anchor bolts were located at 610 mm from each end of the sill plate.

Three of the shearwalls were partially submerged in fresh water by placing them in a specially constructed tank so that the sill plate and the lower 1 m of the wall were below the water line. These were kept in the water tank for 168 hr (seven days). At the end of the water-exposure period, the walls were lifted out of the tanks and stood upright in a covered outdoor area to dry. A handheld resistance-type moisture meter was used to check the moisture content of the studs during the drying period. One wall was used as an indicator wall, that is, it was weighed several times during the drying period and used to indicate the dryness of all three walls.

### 2.4 Shearwall Tests

**Monotonic Tests**. Three shearwalls were subjected to monotonic testing, which is a ramp load to failure in one direction. The racking load was applied to the top of the wall through a steel C-channel that was bolted to the top plate of the wall. The wall was attached to a foundation fixture with four anchor bolts. Four LVDTs for displacement measurements were positioned as shown in Fig 2. The LVDTs had an error of less than 0.1 percent. Force was measured by an electronic load cell mounted on the end of the actuator. The displacement was applied at a uniform rate of 0.254 mm/min. Load and displacement at the actuator and the LVDTs were recorded at 10 Hz. Control and data acquisition were implemented via Labview® software.

The properties to be determined from the monotonic shearwall tests were stiffness (N/mm), racking strength (kN), energy absorption (kN*mm), and the reference displacement (mm). The stiffness was calculated as the secant modulus between the origin and a point 0.8 of the maximum load ($F_{max}$) in the ascending portion of the displacement–load curve. The racking strength was taken to be $F_{max}$. Energy absorption was calculated as the area under the displacement-load curve between the origin and 0.8 $F_{max}$ on the degrading slope of the displacement-load diagram. The point 0.8$F_{max}$ on the degrading slope was defined as "failure" (Ceccotti 1999). The reference displacement was calculated as 0.6 times the displacement at failure.

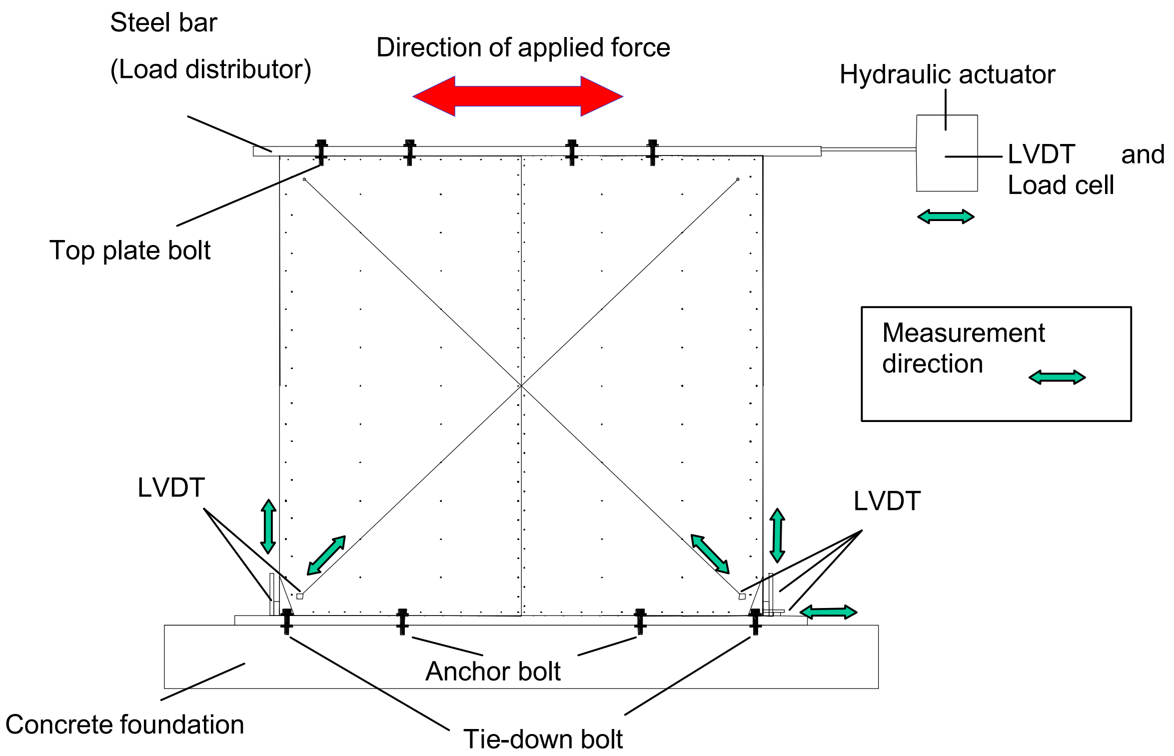

**Figure 2. The shearwall test apparatus.**

**Quasi-Static Tests.** The quasi-static tests were a fully reversed-cyclic test that followed the protocol for ordinary ground motions (Krawinkler et al. 2000). The apparatus and method of load application was the same as for the monotonic tests. Data were recorded at 25 Hz. The time-displacement function was based on the reference displacement of the monotonic test. The test protocol began with a series of small amplitude initiating cycles. Then, each amplitude change was led by a single leading cycle followed by two or three trailing cycles at 0.75 of the current leading cycle amplitude. The time-displacement diagram for the quasi-static tests is given in Fig 3.

Next Page

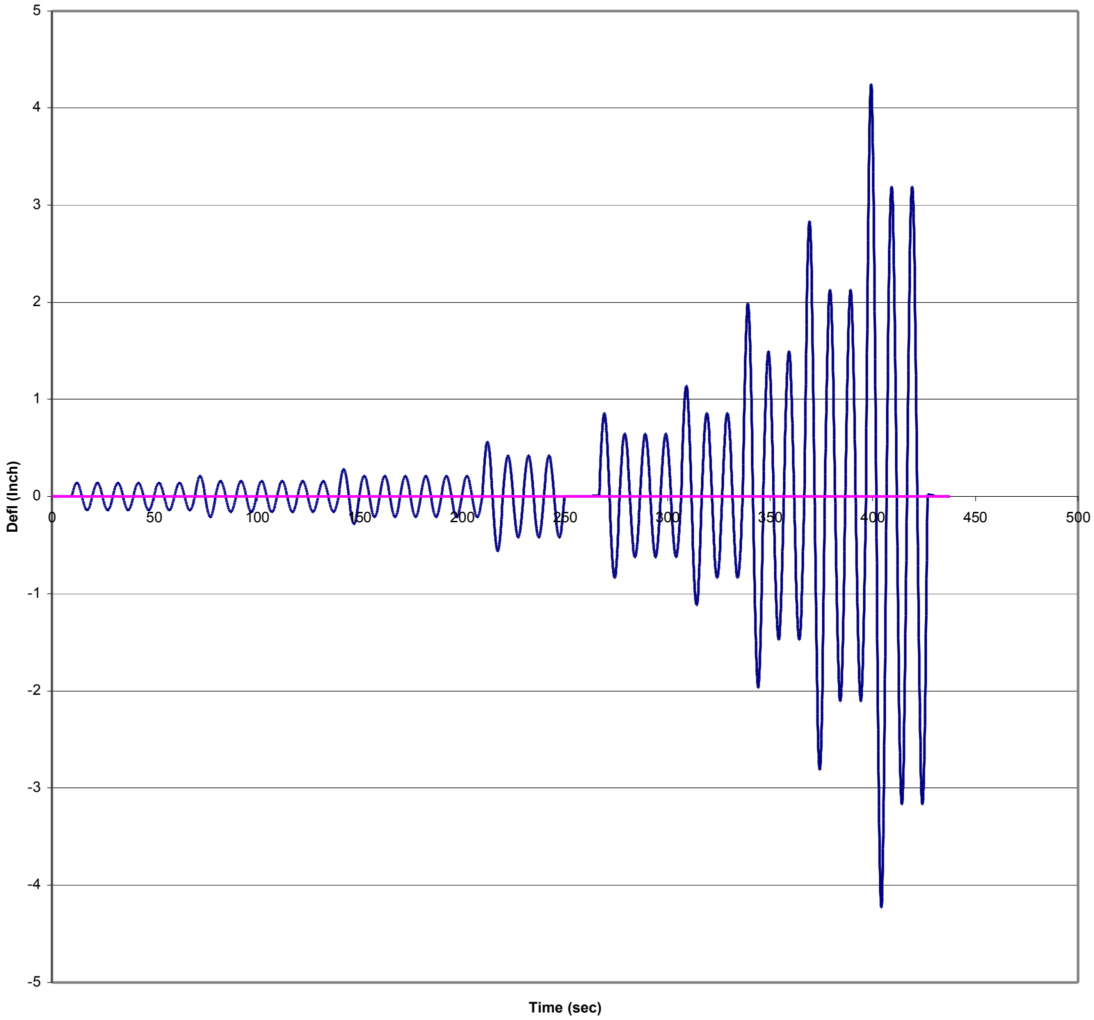

**Figure 3. Time-displacement diagram for the quasi-static shearwall tests.**

The properties to be assessed by using the quasi-static shearwall test data were stiffness (N/mm), backbone energy absorption (kNAmm), total energy absorption (kNAmm) and racking strength (kN). The initial stiffness was calculated as the secant modulus of the cycle that included the maximum load. The line was drawn from the origin to a point at 0.8 of the maximum load in the ascending portion of the designated cycle. The backbone energy absorption was calculated as the area under the backbone curve extending from the origin to the displacement at $0.8F_{max}$ on the degrading slope of the backbone load-displacement curve. The total energy absorption was calculated as the sum of the areas in all cycles up to the first post-peak primary cycle where the highest value was less than or equal to $0.8F_{max}$. Finally, the racking strength was the maximum load measured during any cycle of the test.

## 3 RESULTS AND DISCUSSION

### 3.1 Materials Properties

The results of tests with OSB that was submerged in water from 0 to 168 hr are summarized in Table 1. The embedment strength, edgewise shear strength, shear modulus, and specific gravity follow the same trend – most of the loss in properties occurred in the first 48 hr of water soaking. After that time, the losses were minimal. Water absorption at 48 hr was 43 percent, but by 186 hr water absorption had reached 73 percent. The residual thickness swelling, that is the thickness swelling after being re-dried, remained at the same level for soaking periods of 48 hr and greater. It is noted that the moisture content after re-drying did not return to the initial moisture content. In fact, the moisture content in the desorption process returned to only 11.5 percent, which was 4 percent greater than the initial condition. Some of the properties loss is attributed to the somewhat elevated moisture content. Embedment stiffness, the slope of the linear portion of the embedment-force diagram, shifted from 95 N/mm to 60 N/mm after 24 hr of water soaking and did not change with further soaking. To summarize the results of the materials investigation, it appears that embedment strength and shear modulus are most severely affected by the long-term water exposure .

**Table 1. Summary of test results from OSB water exposure tests when the OSB was tested after re-drying. Parenthetical values are standard deviations.**

| Property | Water exposure period (hr) | | | | |
|---|---|---|---|---|---|
| | 0 | 24 | 48 | 96 | 168 |
| Embedment strength (MPa) | 35.3 (13.06) | 29.1 (4.92) | 21.2 (6.66) | 21.4 (7.62) | 25.0 (6.25) |
| Shear strength – parallel (MPa) | 11.1 (0.89) | ----[a] | 9.7 (1.13) | 7.9 (0.25) | 8.6 (0.73) |
| Shear strength – perpendicular (MPa) | 10.6 (1.73) | 8.8 (0.53) | 8.1 (0.61) | ----[a] | 7.7 (0.76) |
| Shear modulus (GPa) | 1.8 (0.35) | 1.3 (0.15) | 1.2 (0.17) | 1.2 (0.16) | 1.1 (0.15) |
| Moisture content[b] (%) | 7.6 (0.42) | 9.9 (0.36) | 10.9 (0.41) | 11.4 (0.67) | 11.5 (1.24) |
| Specific gravity | 0.62 | 0.59 (0.02) | 0.55 (0.02) | 0.53 (0.02) | 0.55 (0.04) |
| Water absorption (%) | | 22.2 (1.22) | 43.2 (4.54) | 61.8 (4.39) | 73.1 (9.14) |
| Thickness swell (%) | | 6.5 (1.31) | 12.1 (2.47) | 15.0 (2.88) | 14.1 (3.37) |

### 3.2 Shearwall Tests

The monotonic and quasi-static tests were conducted over a two-week period. The mean monotonic test results (n = 3) showed that the capacity of the walls was 29.1 kN, the energy absorption was 2759 kN*mm, initial stiffness was 870 N/mm, and the reference displacement was 71 mm. The monotonic test data were overlaid and are shown in Fig 4.

After the submersion period, the shearwalls were weighed and reweighed again prior to testing. On the average, each wall absorbed 22.7 kg of water. The walls were considered to be air-dry when the weight of each wall returned to within 3 kg of the initial weight, which took about 14 days. Moisture content of the studs, as determined by using a resistance moisture meter, was found to be approximately 19 percent at the time of testing. Materials tests suggest that the moisture content of the OSB sheathing was probably near 12 percent, but it was not measured.

Prior to testing the water-exposed shearwalls, they were visually inspected. It was found that the OSB surface was much rougher below the waterline than above it as a result of surface strand swelling. Also, surrounding each nail below the waterline, there was a circular “dimple” in the surface of the OSB where the nails had apparently restrained the thickness swelling. The nail heads did not pull through the surface of the OSB. This indicated that the pull-through capacity of the OSB exceeded the forces attendant to thickness swelling. It also showed that the forces related to thickness swelling did not exceed the withdrawal capacity of the nails. On the average, the dimples were 0.8 mm deep relative to the surface of the panel. A result of the residual thickness swelling was that the sheathing below the water line fit tighter to the wood studs after being submerged for 168 hr and re-dried than did the sheathing above the water line or on the control walls.

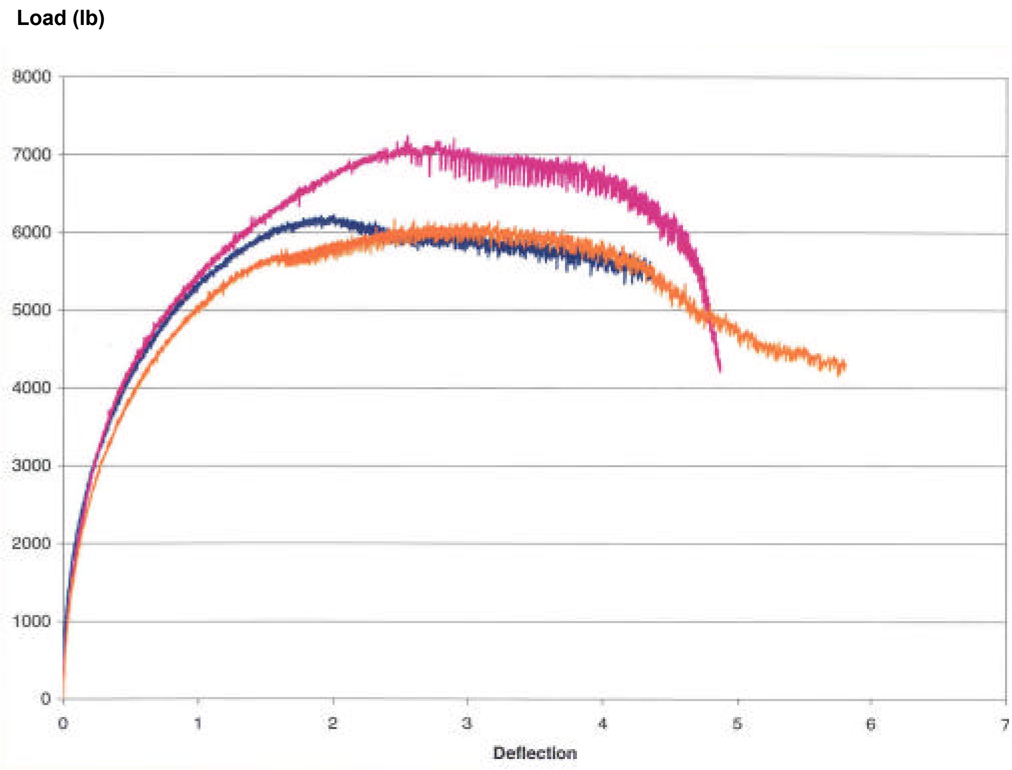

**Figure 4. Displacement-load results for the monotonic tests.**

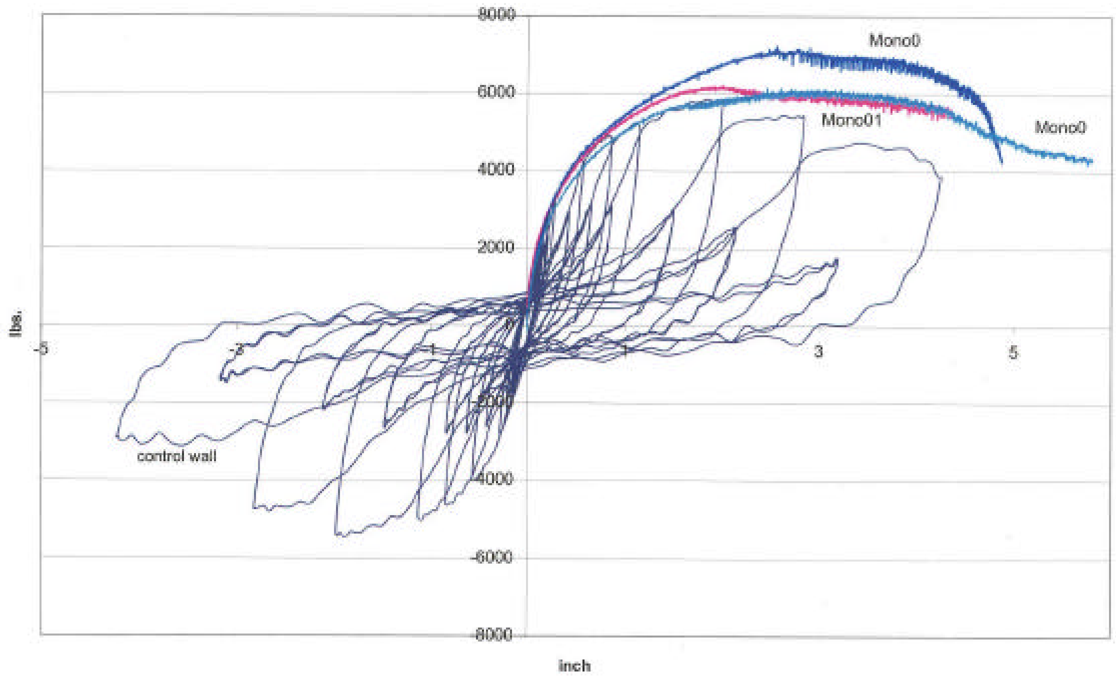
The results of the quasi-static testing of the control and water-exposed walls are summarized in Table 2. A typical hysteresis diagram for control and water-exposed shearwalls is given in Fig 5. The data indicated that the mean capacity of the shearwalls was not reduced by the water exposure. In fact, the backbone energy and total energy absorption were not reduced by the water exposure. However, the stiffness of the shearwalls was reduced by 27 percent.

**Table 2. Summary of the quasi-static tests of control and water-exposed shearwalls, n=3, where the parenthetical values are standard deviation.**

| Property | Condition | |
|---|---|---|
| | control | water-exposed |
| $F_{max}$ (kN) | 26.8 (3.2) | 30.6 (1.7) |
| $F_{min}$ (kN) | -25.0 (2.1) | -28.3 (1.0) |
| Stiffness (N/mm) | 954 (111) | 696 (57) |
| Backbone energy (kN*mm) | 2405 (335) | 2653 (124) |
| Total energy absorbed (kN*mm) | 11393 (1971) | 13525 (779) |

a)



b)

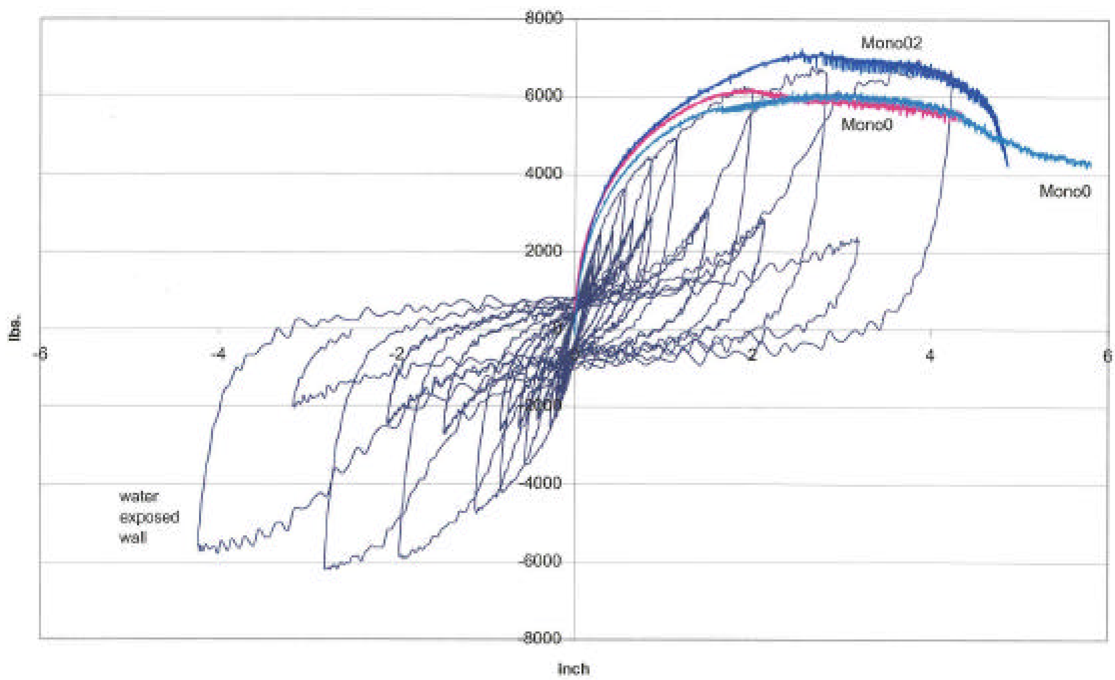


**Figure 5. Typical quasi-static displacement-load response of shearwalls; (a) control, (b) water-exposed.**

The walls failed in much the same manner whether they were the monotonically tested shearwalls or the control or water-exposed shearwalls tested by quasi-static protocol. In general, the wall performance was governed by nail bending and withdrawal (from side grain) capacity. Although, in the water–exposed shearwalls, some of the nails below the waterline were partially pulled through the OSB. This demonstrates that there was a deterioration of the OSB below the waterline. Freitag (2001) conducted a study at Oregon State University with the same OSB and wood to evaluate the effects of wetting and assembly procedures. She reported an increase in the strength of joints when the wood had been soaked. Hence, it is thought that unrecovered swelling may have contributed to nail withdrawal capacity.

The design capacity of the shearwall was based on the design guide (APA 1998), where the design capacity was reduced for the use of 8d box instead of 8d common nails. The diameter ratio for 8d box to 8d common nails was 0.86. Thus, when the wall was new, the design capacity for normal duration was 11.6 kN. The actual capacity of control shearwalls was 29.1 kN. The ratio of design to actual capacity was 2.5.

Given the embedment strength of the OSB as measured, the yield mode for the sheathing nails was expected to be a Mode IIIs as described the NDS (1997). Observation indicated that the nails in the test walls yielded as described by Mode IIIs. As the embedment strength as reduced by 40 percent after water soaking, the yield mode was expected to remain a Mode IIIs, and observation indicated that this was the case. The 40 percent embedment-strength loss translated to an expected reduction in wall capacity of 18 percent based on the yield mode equations, which do not include interlay friction. Because some of the nails in the quasi-static tests of water-exposed walls showed evidence of pull-through, it appears that the shift from a Mode IIIs failure to a pull-through yield mode would occur before any other yield mode can become critical.

A method to calculate the design stiffness of shearwalls is not available because shearwall design is always governed by capacity. In this test, the stiffness of the shearwall was reduced by 27 percent by the water soaking. It is valuable to note that the nail embedment stiffness of the OSB was reduced by 37 percent as a result of the water soaking. Thus, it seems likely that the loss in wall stiffness can be linked to the loss of nail embedment stiffness.

The results of the test program might be different with other sheathing materials or nails; wall performance will depend on the thickness swelling characteristics of the panel and the change in properties with water exposure. For example if the sheathing panel did not swell, then the loss of embedment strength might translate to a real reduction in wall strength.

The 1-m depth of submersion was an arbitrary choice of water depth. Wall height submersion was expected to have only a minor effect on the results of wall submersion tests because the nails at the top and bottom of the shearwall are the most highly stressed. Hence, the test walls could have been submerged only enough to cover the nail connections at the bottom edge of the wall and still produce the same effect as a 2-m submersion. Since most floods involve less than 2 m of water in the structure (Hausmann & Perils 1998), it was felt that a 1-m depth was sufficient to identify the effects.

The walls and sheathing materials tested in this study were air dry. The capacity of the system when wet (saturated) might be much lower than observed in this moisture condition. However, the probability of concommitent major lateral force generating event with the water exposure (other than the force of water flow around or through the structure) is considered to be small.

## 4 CONCLUSIONS

One approach to rational post-flood analysis of building capacity would be to discount the allowable properties of the OSB embedment strength by 40 percent and then discount the wall capacity by a similar percentage. However, the reduction in embedment capacity results in a calculated reduction of only 18 percent. In actuality, the wall capacity and energy properties were not reduced as a result of water exposure. Strength and energy capacity were affected by the connection geometry as well as the interlayer friction, which in this case was increased by the thickness swelling of the OSB. The loss of stiffness was most likely a result of softening in the OSB sheathing, hence the reduction of embedment strength accompanied by a loss of stiffness in the nail bearing resulted in the loss of wall stiffness. The monotonic tests and quasi-static tests failed by nail bending and withdrawal, which demonstrated that the wall capacity was limited by nail bending and withdrawal and not embedment or pull-through characteristics of the sheathing. It appears that structures with OSB sheathing that are temporarily inundated with fresh water and dried expeditiously will have a loss of stiffness but should not experience a reduction in lateral resistance capacity or energy absorption capacity.

## 5 ACKNOWLEDGEMENTS

This paper is based on the Vertieferarbeit written by the second author while in residence at Oregon State University. The thesis was in partial fulfillment of the degree requirements at the University of Karlsruhe. Financial support for this work was provided by the Forest Research Laboratory, Oregon State University, Corvallis, Oregon. The technical contributions of Milo Clauson with the testing and data management are gratefully acknowledged.

# Effect of Mineralogy of Calcium Sources on Geopolymerisation

**CK Yip & JSJ van Deventer**
**Department of Chemical Engineering The University of Melbourne Australia**

**Summary: Recent research has found that geopolymers offer an alternative to ordinary Portland cement. Numerous studies have also shown that a detailed understanding of the mechanisms that govern the geopolymerisation process is essential to assist in developing a new cement-like product which possesses long durability.**

**This paper will focus on one of these mechanisms, which involves the role of calcium in improving cement durability. It is suggested that calcium provides a crucial link between the chemistries of geopolymerisation and the hydration of cement. In essence, this investigation will explore how the different calcium sources affect the process of geopolymerisation. Four different calcium sources were used in this investigation using various sodium hydroxide concentrations to provide the alkaline environment required. They are: granulated blast furnace slag, ordinary Portland cement, wollastonite and calcite. Compressive strength testing and x-ray diffraction were the main techniques used. For the calcium sources investigated, it was found that the difference in CaO content in the source material had little impact on the resultant compressive strength. However, the mineralogy of the calcium sources used and the alkaline conditions present were found to have a significant influence on the resultant product. Using lower hydroxide concentrations, samples prepared with calcium sources which were predominantly amorphous gave a better compressive strength than their crystalline counterparts did. However, when higher hydroxide concentrations were used, samples containing crystalline sources of calcium gave a compressive strength that was at least as good as the amorphous ones.**

**Keywords: Geopolymer; Cement; Durability; Calcium; Mineralogy.**

## 1 INTRODUCTION

Numerous studies have investigated why the ancient concrete is much more durable than their modern counterparts in recent years. It has been observed that calcium silicate hydrate formed as a result of the hydration of modern Portland cement deteriorate while the ancient cement still remain intact under the same external conditions. French scientist, Davidovits (1987) argued that the durability of the ancient concrete was the result of the presence of alkaline aluminosilicates in the structure. Davidovits named this new class of cementitious material as geopolymers.

Geopolymers are a new generation of material with diverse applications in the building industry and waste management. In general, geopolymers are often viewed as three-dimensional amorphous aluminosilicates resulting from the alkali activation of an aluminosilicate source, for example, fly ash. Geopolymeric binders have similar chemical composition as the natural zeolitic materials but without the extensive crystalline zeolitic structure (Davidovits & Davidovics 1988). Davidovits (1991) described the alkali activation process of the aluminosilicate source in terms of a polymerical model. Geopolymers are formed by the polymerisation of individual aluminate and silicate species, which were dissolved from their original sources at high pH in the presence of alkali soluble metals. The products formed are characterized by high mechanical strengths with the following general formula [Eq.(1)].

$$M_n[-(Si\text{-}O_2)_z\text{-}Al\text{-}O]_n.wH_2O \qquad (1)$$

Where M is the alkaline element, - indicates the presence of a bond, z is 1, 2 or 3 and n is degree of polymerization. Theoretically, any alkali and alkali earth cation can be used as the alkaline element (M) in the reaction, however the majority of research has, so far, focused on the effect of sodium (Na+) and potassium (K+) ions (van Jaarsveld & van Deventer 1999). It has yet to be proven whether other alkali and alkali earth cations will participate in the reactions in a similar way. Extensive research has been conducted in the areas of characterisations of geopolymers (Davidovits 1987; Davidovits et al. 1990; Davidovits 1991; Davidovits et al. 1994; van Jaarsveld et al. 1997; van Jaarsveld 2000), improvement of the physical and chemical properties of geopolymers (Phair et al. 2000), immobilisation of toxic materials (van Jaarsveld et al. 1997; van

Go Back Next Page

Jaarsveld et al. 1998; van Jaarsveld et al. 1999), utilisation of waste materials (van Jaarsveld 2000) and natural aluminosilicate minerals (Xu & van Deventer 2000) in geopolymerisation.

The major difference between geopolymers and Portland cement in terms of their chemical composition is calcium. It is not essential for calcium to be present in any part of a basic geopolymeric structure. However, it is commonly acknowledged that the binding property of Portland cement is due to the formation of colloidal calcium silicate hydrate in a semicrystalline phase (Glukhovsky 1994).

Based on Davidovits' and Glukhovsky's findings, it can be further hypothesised that the formation of geopolymer within the structure is responsible for the durability of ancient concrete. Considering the fact that there are at least 40% by mass of combined CaO and MgO, and less than 5% of combined $Na_2O$ and $K_2O$ in some of the ancient concretes studied so far (Glukhovsky 1994), it is clear that an in-depth understanding of the role of calcium in ancient concrete is essential in order to identify the secret behind the long durability of ancient concrete. The role of calcium in ancient concrete could possibly include: (1) the formation of the traditional calcium silicate hydrate (C-S-H), (2) participation in the geopolymerisation in forming Ca-geopolymer and (3) bridging the bonding between the calcium silicate hydrate and geopolymers or many others. However, there is a lack of documented research involving the chemical mechanisms occurring in such systems. It is probable that both calcium silicate hydrate and geopolymers could be forming simultaneously. As a result, an investigation into the role of calcium in dictating the chemical mechanism will provide answers to the fundamental question as to whether two separate phases will be formed, or a new material will be produced instead.

It is proposed that the addition of calcium to an initially calcium-free geopolymeric system will most likely produce a number of reaction products. The type and number of these products will be dependent on the experimental conditions and, more importantly, the form of calcium present. It is anticipated that one of the most likely products to be formed is calcium silicate hydrate. Figure 1 shows the likely reaction products formed when calcium is added to a geopolymeric system.

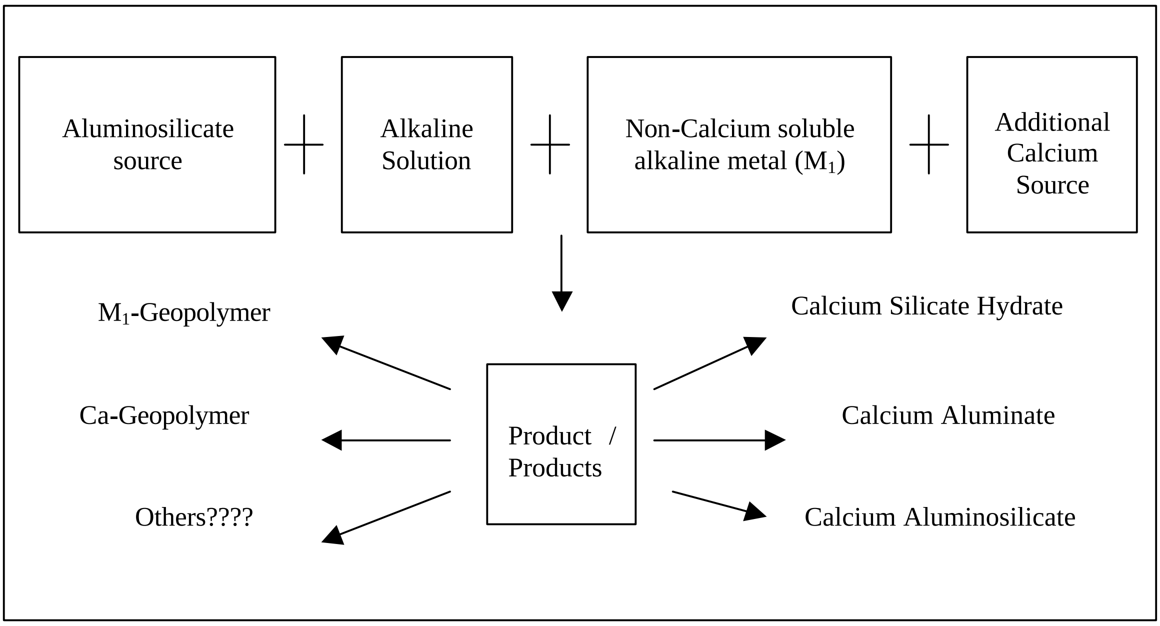

**Figure 1. The concept mapping of the likely products resulting from the alkaline activation of aluminosilicate in the presence of a calcium source.**

The nature of the end product or products formed as the result of the alkaline activation of an aluminosilicate source in the presence of a calcium source is dependent on various factors. These include elemental composition, the mineralogy, physical properties (e.g. surface properties, particle size distribution) of both aluminosilicate and calcium sources, the alkalinity, the nature of the soluble alkaline metal present, as well as the curing conditions and any pre-treatment used. Of greater importance is the fact that it is also influenced by the ratios between each of the raw materials added to the system. It should also be noted that having a high calcium content in the initial aluminosilicate (e.g. flyash) could result in a similar influence on the nature of the final product without any further calcium addition.

Much research has been conducted on the addition of mineral admixture (e.g. metakaolin, silica fume) to a cement paste with the aim of improving the durability and other physical properties of the concrete. However, the majority of such research has focused on the physical effect of the addition of mineral admixture. Additionally, there is a lack of published literature reporting the effect of the addition of mineral admixtures on the chemical mechanisms involved as well as the chemical bonding created or destroyed during the process. Without a detailed understanding of what is actually happening in the process, it will be difficult to proceed further in reinventing a new generation of concrete that possesses the durability observed in ancient concrete.

In this study, a calcium source is added to a calcium-free environment. The aim of this study was to investigate the effect of calcium on the alkaline activation of metakaolin. Four different calcium sources, namely granulated blast furnace slag,

Go Back Next Page

cement, wollastonite and calcite, were investigated. The mass ratio between metakaolin and different calcium sources, and the $Na_2O/SiO_2$ ratio in alkaline solution were kept constant. The findings from this project are fundamental to any further work involved in the understanding of the durability of ancient concretes.

## 2 EXPERIMENTAL PROCEDURE

### 2.1 Materials

Metakaolin (MK) is a highly reactive metastable clay that is essentially an anhydrous aluminosilicate obtained from calcining kaolin at a temperature range between 650-700°C (Newman 1987). Metakaolin has been used in the past decades as a mineral admixture in cementitious systems due to its capacity for reacting with the calcium hydroxide released during the hydration reaction. In this study, metakaolin was used as the primary aluminosilicate source. This is because Davidovits (1991) suggested that calcination would transform the octahedrally co-ordinated aluminium layers in kaolinite into the more reactive tetrahedral form. This transformation would lead to an improvement in the reactivity, resulting, in turn, in enhanced compressive strength of the resultant binder. Metakaolin used in the synthesis was obtained from ECC International under the brand name of MetaStar 402 with a particle size < 10microns. This commercial metakaolin was purified before calcination, and it contained less than <0.1% CaO as shown in Table 1.

Four different calcium sources (CA) were used in this study, and they are ground granulated blast furnace slag (GGBFS), cement (CEM), wollastonite (WOL) and calcite (CAL). All calcium sources had a particle size distribution of 100% < 50microns. The oxide compositions of the commercial metakaolin and the four calcium sources used are shown in Table 1, which were obtained by X-Ray Fluorescence (XRF) analysis, using a Siemens SRS 3000 instrument.

**Table 1: Chemical Analysis of Metakaolin and Granulated Blast Furnace Slag (mass %)**

| Constituent | Metakaolin | Granulated Blast Furnace Slag | Cement | Wollastonite | Calcite |
|---|---|---|---|---|---|
| $CaO$ | 0.10 | 43.0 | 64.7 | 47.5 | 95.0 |
| $SiO_2$ | 54.78 | 34.4 | 20.45 | 50.5 | 4.0 |
| $Al_2O_3$ | 40.42 | 14.1 | 4.58 | 0.25 | 1.5 |
| $Fe_2O_3$ | 0.76 | 0.11 | 3.72 | 0.2 | |
| $MgO$ | 0.41 | 6.3 | 1.67 | 0.25 | |
| $K_2O$ | 2.72 | 0.33 | 0.39 | 0.04 | |
| $Na_2O$ | 0.07 | 0.30 | 0.67 | 0.01 | |
| $P_2O_5$ | 0.11 | 0.005 | 0.05 | | |
| $TiO_2$ | 0.02 | 0.96 | 0.18 | | |

GGBFS was obtained from Independent Cement, Melbourne, Australia. Cement was obtained from Geelong Cement Limited. Wollastonite (calcium silicate $CaSiO_3$) and calcite (calcium carbonate $CaCO_3$) were purchased from Claywork, Melbourne. These four calcium sources were chosen to cover a range of calcium oxide content in source material ranging from 40% to 95%. These materials also represent different crystallinity and mineralogy, which are readily available in the commercial market.

The sodium silicate solution used in the experiment was supplied by PQ Australia, Sydney under the brand name of Vitrosol N48 (with 28.7% $SiO_2$, 8.9% $Na_2O$ and 62.4% $H_2O$; density 1.37g/mL). Sodium hydroxide pearl (99% purity) was purchased from Orica Australia. Distilled water was used throughout the experiment. Fine washed sand (100% < 2mm) was used as the aggregate in the samples that were subjected to the compressive strength testing. Samples subjected to other analysis were prepared without the addition of the washed sand.

### 2.2 Synthesis

Sodium hydroxide pearl was mixed with the sodium silicate solution to form alkaline solution with two different molar ratios (Ms = $SiO_2/Na_2O$ = 2.3 and 1.5). The hot solution was then cooled overnight to ambient temperature

Samples were synthesised using a MK/(MK+CA) ratio of 0.8. The mass ratio between the dry mix (MK and CA) and the alkaline mix (sodium hydroxide and sodium silicate solution) was 0.69 for Ms = 2.3 and 0.61 for Ms = 1.5. These ratios were selected so as to maintain consistent water content in all synthesised material.

MK and CA were mixed thoroughly until a uniform mix, as far as possible, was produced. The alkaline mix was subsequently stirred with the dry mix to form a paste. The paste was mixed for a further 3 minutes to ensure homogeneity. For samples subjected to the compressive strength test, sand (with mass ratio = sand/(dry mix) = 3) was gradually added to the homogeneous paste until a uniform mixture was formed. The paste was then poured into cylindrical moulds (50mm diameter and 100mm length) and allowed to cure in a laboratory convection oven at 40°C for 24 h before being extracted from the moulds.

The samples which required one-day compressive testing were subjected to the test within 5 hours after extraction from the mould. The remaining samples were left to harden at room temperature (25°C) for a further 6 days (for 7 days test), 27 days (for 28 days test) and 89 days (for 90 days test). All samples were cured at atmospheric pressure.

### 2.3 Analyses

#### 2.3.1 Compressive strength testing

Compressive strength testing was performed as per Australian Standard (AS1012.9-1999) using two 50mm diameter cylinder with a 1:2 diameter to length ratio. All compressive strength measurements were taken as the average of strength results of two samples. All samples were tested after 1, 7, 28 and 90 days. An ELE International Auto Test Compression Machine was used.

The top face of the specimen was cut parallel to the bottom face by using a diamond saw prior to the compressive strength testing. The top surface of the sample was capped with fast setting Boral Dental Plaster to ensure the diameter and length ratio remained at 1:2. The plaster was then left to dry at room temperature and atmospheric pressure for at least 3 hours, prior to testing for compressive strength.

#### 2.3.2 X-ray diffraction (XRD)

X-ray diffractograms were recorded on a PHILIPS PW1800 machine using a Cu $K^{a}$ anticathode and a scanning rate of 2°/min from 5 to 70° 2-theta to give the structural information on each sample. Identification of various crystalline phases was done by comparing the diffraction patterns to JCPDS (Joint Committee on Powder Diffraction Standards) data. The specimens were prepared by mechanical grinding using a ring mill. It should be noted that the washed sand was not added to samples subjected to the XRD analysis.

## 3 RESULTS AND DISCUSSION

### 3.1 Compressive strength testing

The compressive strength of the binders containing different sources of calcium studied at 1, 7, 28 and 90 days is presented in Table 2 for Ms = 2.3 and in Table 3 for Ms = 1.5.

**Table 2: Compressive Strengths of the Binders after 1, 7, 28 and 90 days (MPa) for Ms = 2.3.**

| | Granulated Blast Furnace Slag | Cement | Wollastonite | Calcite |
|---|---|---|---|---|
| 1 | 39.3 | 35.1 | 0 | <5.0 |
| 7 | 47.1 | 47.5 | <5.0 | 7.5 |
| 28 | 54.2 | 53.5 | 18.8 | 25.5 |
| 90 | 58.2 | 55.1 | 24.6 | 30.1 |

**Table 3: Compressive Strengths of the Binders after 1, 7, 28 and 90 days (MPa) for Ms = 1.5.**

| | Granulated Blast Furnace Slag | Cement | Wollastonite | Calcite |
|---|---|---|---|---|
| 1 | 32.8 | 32.1 | 6.1 | 42.1 |
| 7 | 38.6 | 46.3 | 22.7 | 41.9 |
| 28 | 42.1 | 51.4 | 25.3 | 43.4 |
| 90 | 44.5 | 52.8 | 29.3 | 47.6 |

From Tables 2 and 3, it can be observed that the addition of calcium to a geopolymeric binder would improve the compressive strength of the resultant binder with time. It is also clear that the type of calcium source added and the alkaline conditions used have a significant impact on the resultant binder.

By comparing the results from the compressive strength tests on samples prepared under different alkaline conditions (Tables 2 and 3), it was found that alkalinity affects each type of calcium source in a different manner. From Table 2, it is evident that samples prepared with granulated blast furnace slag and cement were double in strength compared to those prepared with wollastonite and calcite when less sodium hydroxide (Ms=2.3) was used after 90 days of setting and hardening. On the other hand, when more sodium hydroxide (Ms=1.5) was added, it is obvious that the samples prepared from the addition of calcite gave the highest earliest strength (at least 10MPa more than the one with GGBFS). Comparing the strength results at 90 days, the strength of the one with calcite was about 5MPa less than the one with cement. It is also interesting to note is that the strengths of binders containing calcite and wollastonite were higher when they were prepared using higher concentrations of sodium hydroxide, while the reverse trend was observed when GGBFS and cement were used.

According to the XRF analysis shown in Table 1, the calcium content of the four calcium sources used in this investigation ranged from 40 to 95% by mass, in which the CaO content in the calcium sources decreased in the following order: calcite>cement>wollastonite>GGBFS. Furthermore, it was not possible to draw a direct link between the calcium content in the raw materials and the resultant compressive strength in the four materials studied. Referring to Table 2 again, samples containing GGBFS had about twice the strength of the sample containing wollastonite at all the times tested. The CaO content of GGBFS and wollastonite were 43% and 47.5% by mass respectively. The 4% difference in CaO content could not have contributed to the 30MPa difference in resultant compressive strength, especially considering cement contains 64.7% and calcite contains 95% of CaO. It is clearly shown that the type of calcium source used would have a significant impact on the resultant product, however it was also demonstrated that the difference in CaO content in the source materials is not the major cause.

The mineralogy of the four calcium sources is vastly different. Slag is amorphous, while cement, wollastonite and calcite all contain different degrees of crystalline phases in their structure. It is anticipated that the mineralogy of the calcium sources would have a significant impact on the resultant product. In order to examine the impact of mineralogy, XRD was used to examine the raw materials prior to alkaline activation and the resultant product after the activation. The results are presented and discussed in the next section.

### 3.2 X-ray diffraction (XRD)

It was found from the compressive strength results that there was a larger difference between the strength of the four samples prepared with a lower sodium hydroxide concentration (Ms=2.3.) As a result, these samples were subjected to further analysis using X-ray diffraction. XRD was used to study the crystallinity and to identify the different phases present in the materials before and after alkaline activation. It should be noted that most of the binders produced in this study could contain a very high percentage of amorphous to semi-crystalline phases. Due to this limitation, it was difficult to correctly identify all the phases present in the resultant structure as specified in JCPDS. Nevertheless, the use of XRD was still useful in providing a general guide by limiting the possible identities of such phase.

The x-ray diffractograms (Fig. 2 to 4) showed the effect of the addition of different calcium sources on the crystallinity of the resultant binders. These figures show the x-ray diffraction spectra of the raw metakaolin and the calcium source used, the dry material mix (80% MK and 20% CA) prior to alkaline activation and the resultant product at 28 days after the activation. The spectrum marked “after activation” refers to the x-ray diffraction spectrum of the resultant binder after the alkaline activation. The spectrum marked “difference” is referring to the difference between the spectra before and after the activation, which was calculated by subtracting “spectra before activation” from “spectra after activation”.

Figure 2 shows the XRD diffractogram of the alkaline activation of metakaolin with the addition of granulated blast furnace slag. The normal scanning range between 5° (2-theta) to 75° (theta) was used in analysing all samples, however Fig. 2 only highlights the section between 20° to 40° because the other regions did not contain any significant information.

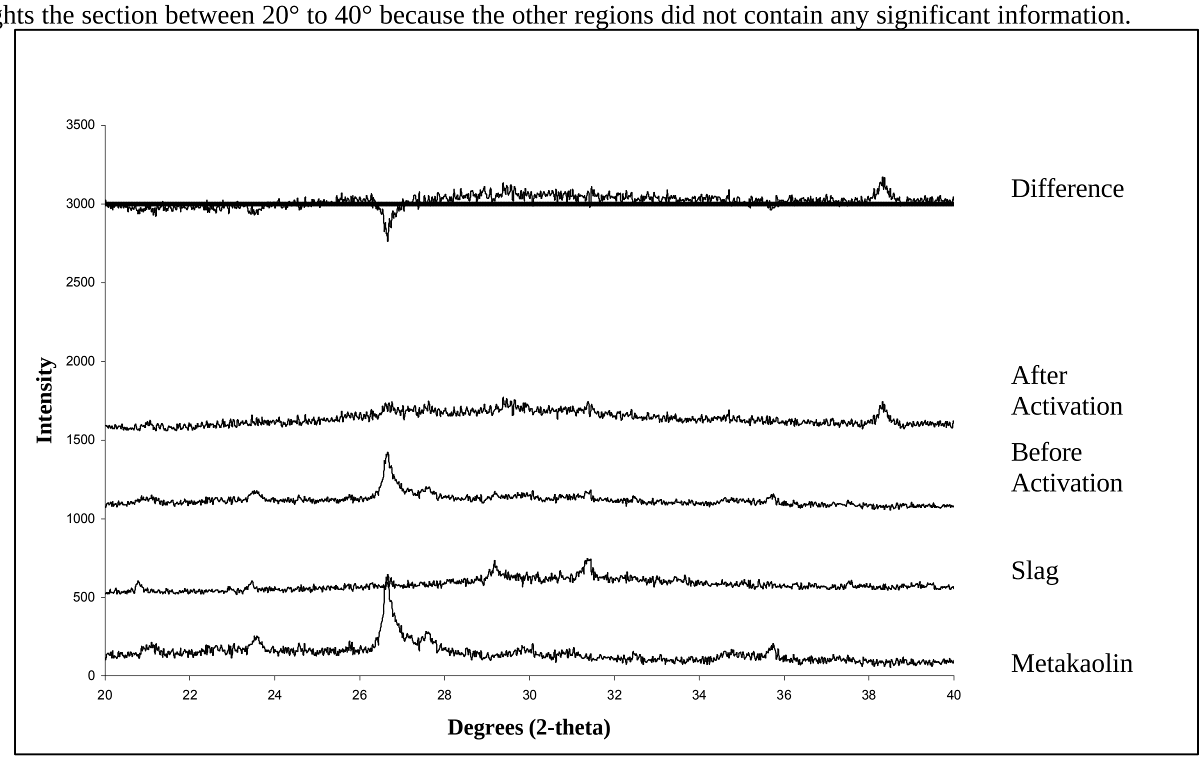

**Figure 2. X-ray diffractogram of the matrix with granulated blast furnace slag.**

XRD analysis of the sample resulting from the alkali activation of metakaolin in the presence of GGBFS reveals the presence of a new but unidentifiable peak (around 38-39 2-theta). The phase associated with this peak was not present in any part of the original spectrum of either slag or metakaolin. Apart from this peak, there was no other new peak found in the spectrum. Figure 3 is the XRD diffractogram of the alkaline activation of metakaolin with cement.

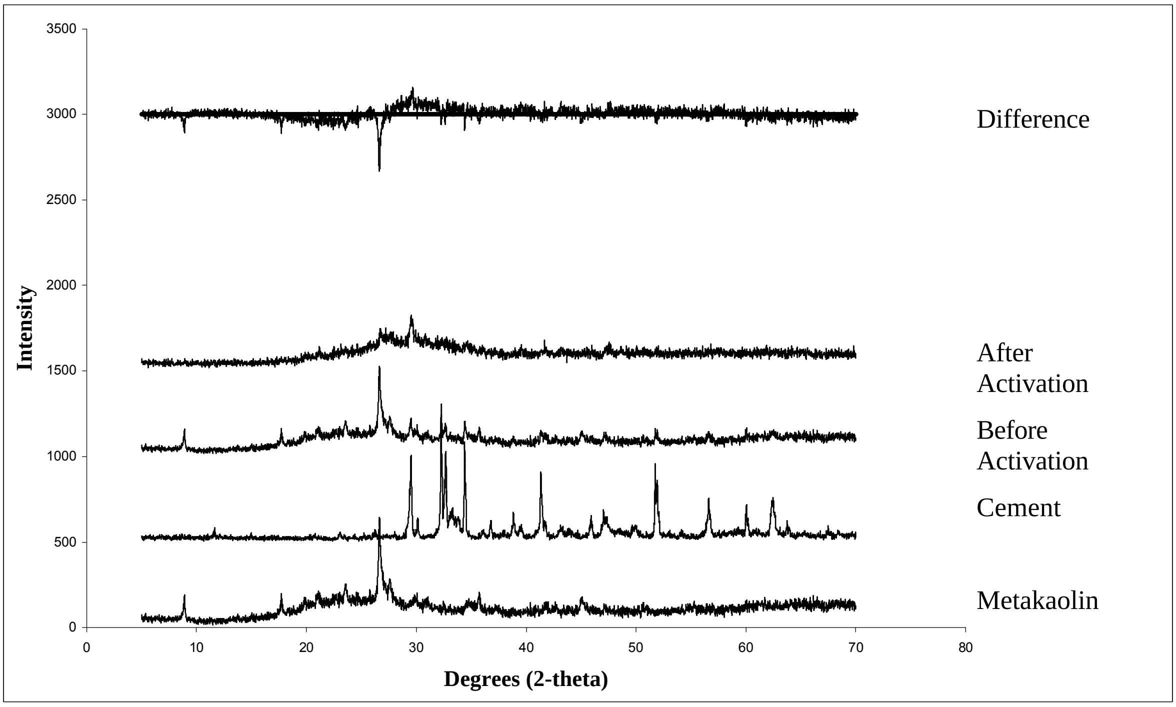

**Figure 3. X-ray diffractogram of the matrix with cement.**

Interestingly, the unidentified peak observed in Fig. 2 does not appear in any of the XRD patterns displayed in Fig. 3 due to alkali activation of metakaolin with cement. This also indicates that there is no crystalline phase forming as a result of the reaction. From the original XRD spectrum of the raw cement (Fig. 3), several distinct peaks indicative of crystalline phases are evident. There was no crystalline phase forming as a result of the activation of metakaolin with cement. In addition, there was also no apparent strong crystalline peak to indicate the presence of significant amounts of undissolved cement particles in the resultant product. Overall, it could be concluded that all of the crystalline phases present in the raw cement had dissolved and reacted in the alkaline solution. This is accompanied by metakaolin becoming part of the amorphous structure of the resultant product. Therefore, it is hypothesised that the calcium present in the cement's crystalline structure had been leached out of the crystalline structure and reacted with the alkali activated metakaolin to form a totally new amorphous calcium-containing material.

Figure 4 displays the XRD diffractogram of the sample obtained from alkaline activation of metakaolin with wollastonite.

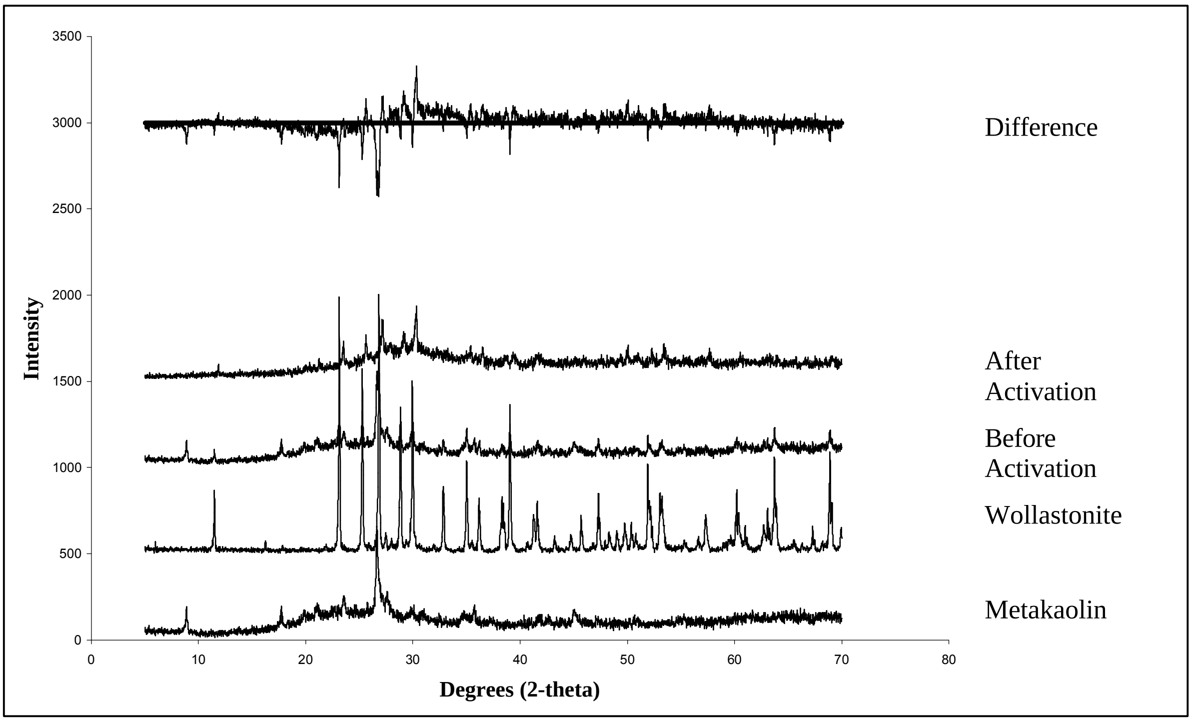

**Figure 4. X-ray diffractogram of the matrices with wollastonite.**

From Fig. 4, it is obvious that, unlike cement or GGBFS, there is still a small amount of undissolved wollastonite particles present after alkaline activation. From the spectrum marked "Difference" on Fig. 4, there exists some undefined new phases (around 20-25 2-theta) due to alkaline activation of the two materials. It is highly likely that these peaks are associated with the undissolved wollastonite particles present. Figure 5 shows the XRD diffractogram of the alkaline activation of metakaolin with calcite.

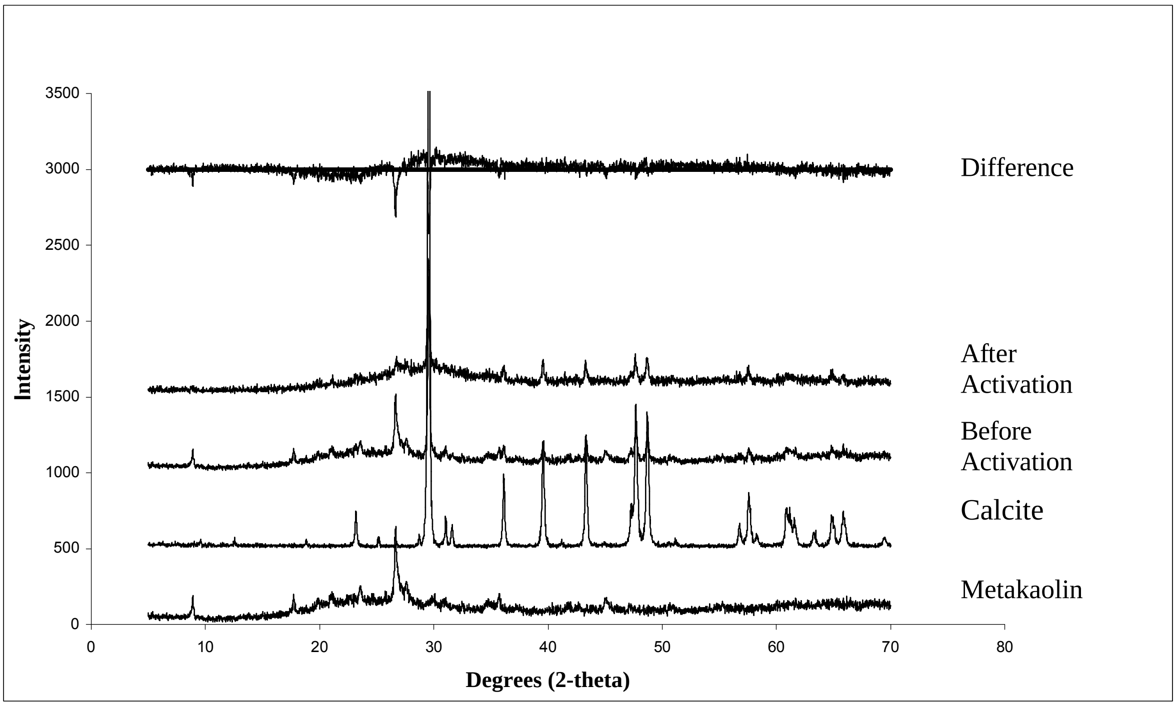

**Figure 5. X-ray diffractogram of the matrices with calcite.**

Like the binders with wollastonite, the XRD spectrum of the binder containing calcite indicates that not all the calcite added to the system was dissolved or reacted during the alkaline activation.

Comparing Figs 2, 3, 4 and 5, the samples with the addition of GGBFS were shown to have formed new crystalline or semicrystalline phase (as indicated by the presence of the new peaks on x-ray diffractogram) after alkaline activation.

However, due to the high amorphous content in the resultant product, it is difficult to identify the new phase formed using XRD alone.

In relating the compressive strength results to the XRD analysis, samples with slag or cement gave the highest strength when a lower concentration of sodium hydroxide (Ms=2.3) was used. The XRD analysis showed that most of the original phases present in GGBFS and cement have been dissolved in these systems, as opposed to what was found in the samples containing wollastonite or calcite. Therefore, it is suggested that high compressive strength could be achieved provided there is a higher degree of dissolution from the calcium sources. The calcium and silicon species present in the original sources would only participate in the reaction if they could be readily dissolved from their original sources. Natural minerals, such as wollastonite and calcite, have limited solubility and reaction in the alkaline solution. This is because the calcium, silicon or even aluminium species were firmly bonded to their original structure. In the case of processed and manufactured materials, such as cement and slag, they can be readily reacted and subsequently participate in the reaction. Therefore, it is proposed that the mineralogy of the calcium sources has a significant impact on the dissolution of calcium, silicon and aluminium from the original source. Following from that, the resultant compressive strength is directly related to the concentration of the dissolved calcium, silicon and aluminium present in the system.

There is another interesting anomaly from the XRD analysis: there was a very weak "hump" appearing at around 28-32 2-theta for all four resultant samples. It is believed that this "hump" is an indication of the presence of an amorphous alkali aluminosilicate in the resultant structure, however it is not possible to establish the identity of the alkaline element without further alternative analysis. Given that there was no new crystalline phase present in the samples with either cement or calcite, it is suggested that the calcium dissolved from the crystalline source material would have reacted with the available silicate or aluminate species to form some amorphous or semi-crystalline materials which could include calcium-based geopolymer, calcium silicate hydrate, calcium aluminate or calcium aluminosilicate. Further work must be conducted in identifying all the amorphous and semi-crystalline phases which could possibly exist in all samples. This information is vital to the overall research into determining the reasons behind the long term durability of ancient concrete.

## 4 CONCLUSION

This work has provided strong evidence implying that high compressive strength could be achieved if there is a high degree of dissolution of calcium, silicon and aluminium from the calcium sources. The calcium and silicon species present in the original sources would only participate in the reaction if they could be readily dissolved from their original sources. Furthermore, it was found in the four calcium sources studied that the CaO content in calcium sources had little impact on the resultant compressive strength. On the contrary, the mineralogy of the calcium sources used and the concentration of sodium hydroxide present were found to have a significant influence on the resultant product. In samples prepared with low sodium hydroxide content, samples with amorphous source of calcium gave a better compressive strength than their crystalline counterparts. Samples prepared using a high concentration of sodium hydroxide and crystalline sources of calcium gave a compressive strength that was at least as good as those registered by the calcium samples sourced from predominantly amorphous minerals.

# Effects Of Dolomite Aggregate On The Deterioration Of Concrete Floor

**JC Rocha CA da Luz & M Cheriaf**

**Summary**: **There are some aggregates that, when in contact to alkali cations in cements, are highly reactive, such as the dolomite aggregate. This way, even though it presents mechanical strength and low porosity, a material can show deterioration which can cause serious damages to the product over time. This paper presents one case study accomplished in one concrete floor with screed mortar (high strength) in an industry located in state of Santa Catarina/Brazil. This case study shows the formation of gel "unlimited swelling" around aggregate particles caused by effects of alkali aggregate reaction, showing up two years after having been cast.**

**For the case analysis, eight cylindrical samples were extracted presenting the following dimensions: 50mm in diameter and a medium height of 120 mm where 105 mm represented the substratum and 15mm the cement mortar). Besides, scratching and superficial extractions of the cement mortar samples were also accomplished in those visibly deteriorated areas of the floor. The investigation of the case was accomplished using thermal differential analysis techniques (DTA), Scanning Electron Microscopy (SEM) and X-ray diffraction analyses (XRD), where in all of the samples, preparation and operation of the technique were made with extreme severity.**

**Based on the presented results using the SEM determination, it can be concluded that the micrograph of mortar of the analyzed samples of the floor, as well as the samples of the scratching and extraction, presented chemical characteristics morphologies and compositions of the alkali-aggregate reaction. The results of the DTA of the XRD, accomplished in the aggregates used in the composition of the cement mortar of the floor indicated the presence of quartz grains, in the gravel (cheap aggregate) and the white aggregates consisted of calcium dolomite carbonate. Based on the manifestations and the results, the reactive characteristic of the white aggregate and the alkali effects was very noticeable. In the "unlimited swelling", the appearance of the whitish structure is due to the white aggregate disintegration, with strong indication of a reaction belonging to the alkali-carbonate group. The results of analyses showed gel and of the crystallized products, around the white aggregate, presented calcium-silica-alkalis reactions, where the detected alkalis were potassium and sodium. Besides, it was possible to identify, ettringite, portlandite, $Mg(OH)_2$ and carbonate of calcium, which in relation to the gel, the reactive characteristic of the white aggregate was also confirmed.**

**Keywords. dolomite aggregate, concrete floor, deterioration,** ***alkali-aggregate reaction***

## 1 INTRODUCTION

The alkalis usually end up being included to the material (concrete, mortar...) through the cement, but they can also be due to other kinds of sources such as the mixing water where the product of the alkali-aggregate reaction can be manifested even by expansions or pop-outs. So, it is possible for a material, even if presenting mechanical resistance and low porosity, to manifest deterioration which can cause serious damages to the product over time.

According to VEIGA et al. (1999), the reaction alkali-aggregate is done between some mineralogical components and the alkaline hydroxides dissolved in the pores of the product. Based on his studies, the reaction alkali-aggregate that occurs among certain calcareous and the alkaline solutions contained in the pores results in an expansive hygroscopic gel.

In relation to the aggregate types involved in such expansive phenomenon, LEA et al. (1970) say that they are restricted to certain fine-grained soils, clay and dolomite aggregates.

This paper is about a study regarding the reaction among dolomite aggregates and alkalis in a floor of high resistance where the consequences of this resulted in expansions and formations of vesicles with a whitish pigmentation. It refers to a case study in an industry located in Santa Catarina/Brasil, two years after having been cast.

The study was totally based on in situ observations and using microstructural techniques of investigation. The differential thermal analysis techniques (DTA), Scanning Electron Microscopy (SEM) and X-ray diffraction analysis (XRD) were studied. The samples used were cylindrical cores, scratching fragments and superficial extractions of the mortar in visible places of the deteriorated floor, where the sample collection, preparation and operation of the technique were made with extreme severity in all of them.

## 2 MATERIALS AND METHODS

For the investigation of the problems presented by the industrial floor, superficial fragments of mortar (Fig. 1) and 08 test cores (Fig.2) with the use of diamond drill were extracted with the following dimensions:

Diameter = 50 mm;

Medium height = 120 mm, representing the coating mortar (of approximately 15 mm) and substratum of 105 mm.

**Figure 1: Superficial extractions of the mortar**

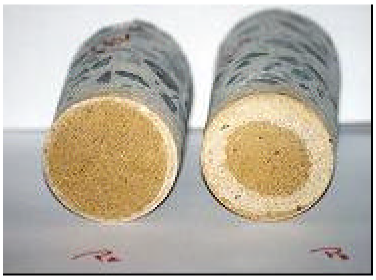

**Figure 2: Cylindrical Test Cores**

It was necessary to visit the place where the manifestations occurred in the floor in order to verify the incidences and any fortuitous conditions of moisture, collecting material for complementation of the analysis.

Having test cores and samples in hand, they were tested using the differential thermal analysis techniques (DTA), Scanning Electron Microscopy (SEM) and X-ray diffraction analysis (XRD).

### 2.1 Differential thermal analysis techniques (DTA)

The analysis were made under the following test conditions:

- constant speed of $10^{o}$C/min;
- natural atmosphere environment;
- calcined caulinate as inert reference material;
- alumina sample carrier;
- Testing mass of 600mg (particles <150µm),
- K type thermocouple and automatic registration of the data during the test in HP’s dataloger.

The test was accomplished in the Núcleo de Pesquisa em Construção of the Civil Engineering Course - UFSC, using the equipment of differencial thermal analysis, endowed with Carbolite oven and manufactured by INSA_Lyon.

Initially, the samples submitted to this test were obtained by the test cores P1 and P8. During the preparation it was noticed that some of the whitish particles in the analyzed material were easily taken to pieces. Because of this, they were divided into smaller samples so that they could be analyzed separately constituting a representative sampling of the manifestation the whitish grains with little mortar adhered to its surface. For each sample two analysis were made.

In Figures 3 to 5, below, the results of the thermal analysis accomplished in the samples are represented.

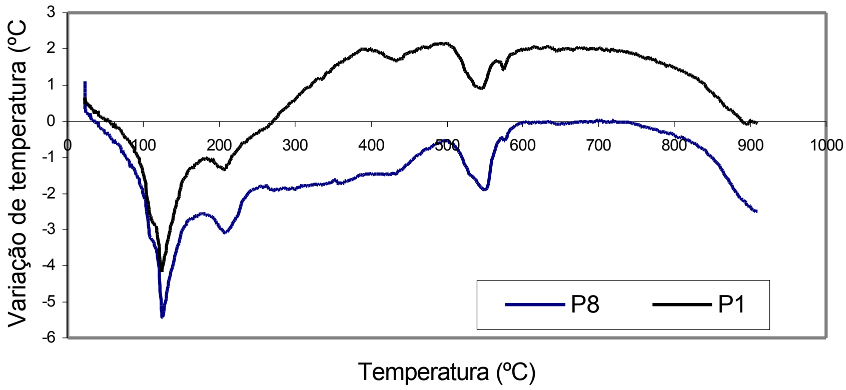

**Figure 3: Thermogram of the mortars of the Test cores P1 and P8.**

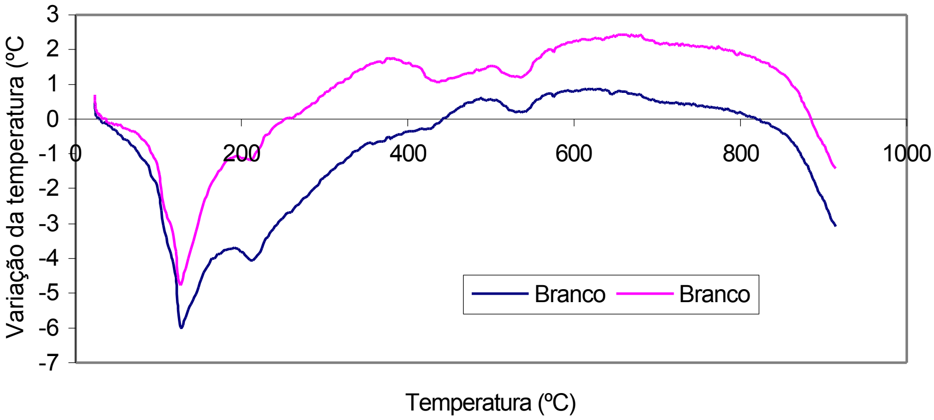

**Figure 4: Thermogram of the white grains with mortar adhered to the surface.**

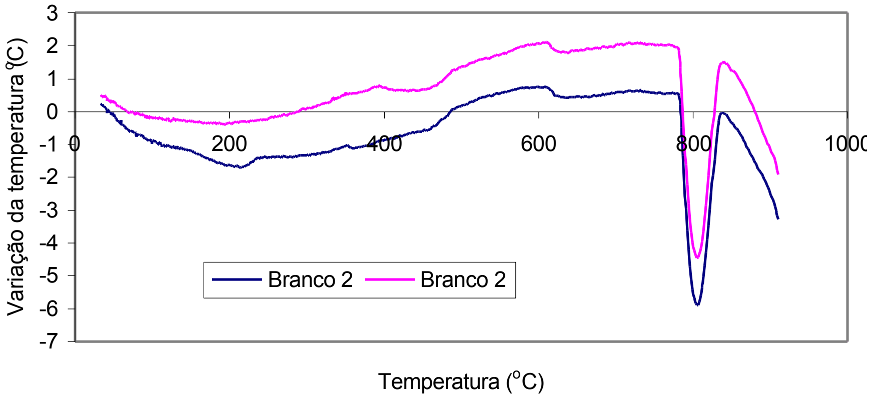

**Figure 5: Thermogram of the white grains contained in the aggregates- without mortar in the surface**

Go Back Next Page

Of the thermal analyses, based on the peaks, the following components were identified:

- temperature 105-110 °C: loss of water;
- temperature 210 °C: calcium monosulfate ($CaSO_4$);
- temperature 400 °C: magnesium hydroxide $Mg(OH)_2$;
- temperature 570 °C: quartz (Q);
- temperature 800 - 920°C: calcium carbonate CaCO3;

It is important to highlight that the white aggregates showed the predominant composition of calcium carbonate.

## 2.2 X-Ray Diffraction Analysis (XRD)

The preparation of the samples followed the same procedure used in the differential thermal analysis - DTA, that is, the samples were taken to pieces until the desired grain size was obtained. (passing through a 150mm sieve). The analysis were accomplished in the laboratory de Difratometria of the Physics Department of UFSC, using the X-ray diffraction equipment of the brand Rigaku, models Mini Flex, with grafite monocromatizer and radiation Cu Ka.

The obtained results of the analyzed samples are presented in diffractograms shown in Figures 6 to 8. TheTable 1 assists the reader in interpreting the diffractograms.

### 2.3 Scanning electron microscopy (SEM)

The scanning electron microscopy (SEM) was used for observation and microstructural analysis of the solid phases (morphology and crystalline lens of the particles). With the same technique the qualitative chemical analysis was used through the microprobe EDX, with a dispersive energy of x-rays (EDX), allowing a located chemical analysis. For the microscopic analysis an scanning electronic microscope - MEV, models PHILIPS XL30, equipped with a micro probe was used. The microscope belongs to the Laboratory de Materiais of the Mechanical Engineering Department of UFSC.

The analysis were accomplished in fracture surfaces obtained through the fragmentation of the mortar of the samples, in points of interest (white aggregates, mortar, pebble aggregate). The samples were prepared covering the surface with carbon coating, accomplished in the equipment BALTEC - EARLY 30 - Evaporad Carbon. Figures 9 to 24 present the micrographs and the spectra obtained through the analysis on the scanning electronic microscope.

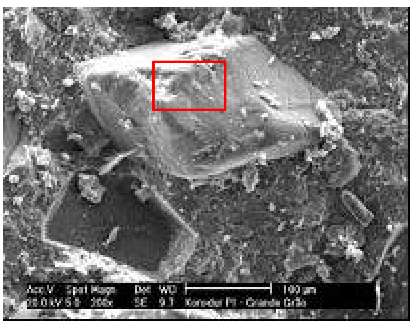

**Figure 9: SEM image of the mortar sample of the Test core P1 (200X)**

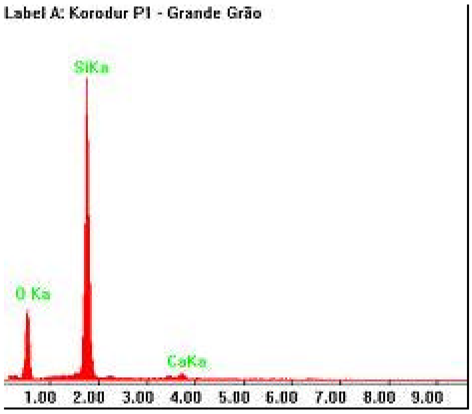

**Figure 10: EDX spectra of the highlighted area in Figure 9.**

In Figure 9 the morphology of the mortar extracted from the test core P1 is observed, with an increase of 200 times, highlighting the pebble aggregates (medium dimension of 300mm), composed essentially of silicon, according to the spectrum on Figure 9. The presence of this component is also identified in the difractograms of the mortars (Fig. 6 and Fig. 7) in a quartz form, as well as in the endothermic transformation to 570° C observed in the thermograms (Fig. 3 and Fig.4).

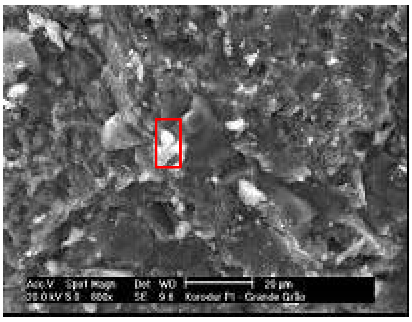

**Figure 11: SEM image of the sample mortar of the test core P1 (800X)**

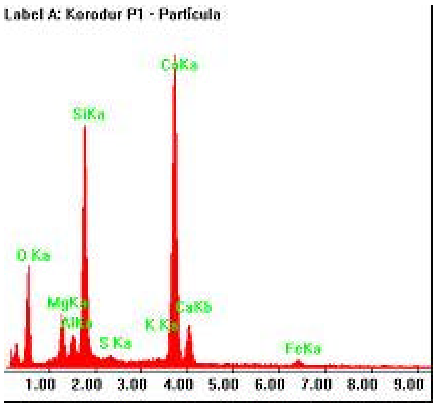

**Figure 12: EDX spectra of the highlighted area of Figure 11**

Figure 11 presents the micrograph of the mortar of the test core P1, with an increase of 800 times, with its referring spectrum in Fig. 12. In the micrograph obtained in the mortar a massive composition it is observed with occurrence of deposits in the surface. The spectrum reveals the composition silicon-calcium-potassium - magnesium, with little occurrence of iron, sulfur and aluminum.

The presence of sulfur can be attributed to the calcium monosulfate (plaster - $CaSO4$), which was evidenced not only in the endothermic reactions at 210°C, shown in the thermograms of Fig 3 and Fig. 4, but also in the difractograms (Fig.6, Fig. 7 and Fig. 8), with a standard peak located in the angles (2θ), presented in Table 1. On the other hand, the presence of magnesium was verified in the endothermic reaction at 400°C (Fig. 3, Fig. 4 and Fig. 5), attributed to the occurrence of dolomite found in the difractograms (Fig. 5, Fig. 6 and Fig.7).

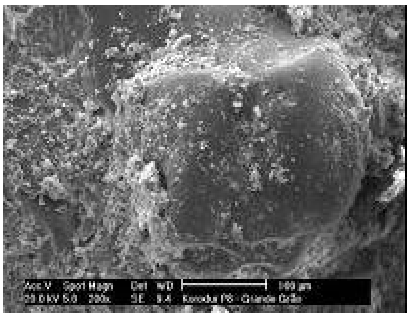

**Figure 13: SEM image of the mortar sample of the test core P8 (200X)**

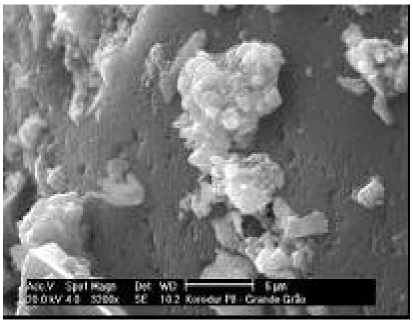

**Figure 14: SEM image of the mortar sample of the test core P8 (3200X)**

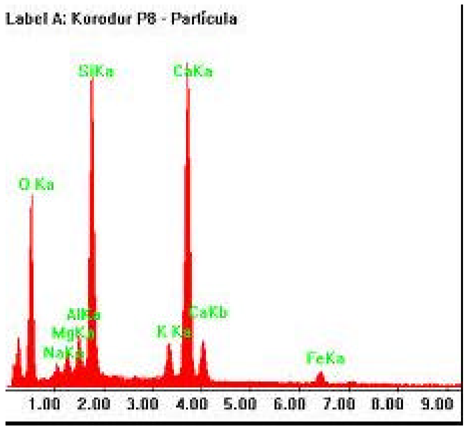

**Figure 15: EDX spectra of the highlighted area of Figure 14.**

Figures 14 and 15 present the micrograph of the mortar of the test core P8, with an increase of 200 to 3200 times, respectively, representing the pebble aggregate inserted in the mortar of the test core. In the micrography of Fig. 14, the aggregate with deposits of crystallized products of the aggregate-alkali reaction in a flocculated structure on the surface is observed, and the spectrum obtained (Fig. 15) reveals silicon, calcium, sodium, potassium, and magnesium components with an occurrence of aluminum and iron.

**Figure 16: SEM image of the white grains with adhered mortar (400X)**

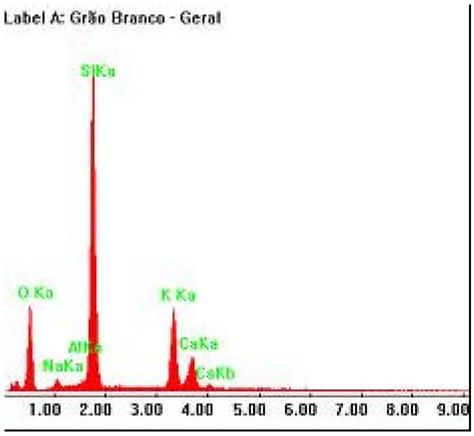

**Figure 17: EDX spectra of the highlighted area of Figure 16**

The micrograph of Fig. 16, with an increase of 400 times, presents the morphology of the white grain with adhered mortar, where the grain and the mortar are dispersed in a gel phase of massive aspect. The spectrum (Fig.17) reveals the silicon, potassium and calcium composition. The a, b and c zones of the analyzed sample, defined in the Fig. 16, had an increase of 1600 times, allowing better identification of the gel formation, of which the micrographies are presented in Figures 18,20 and 21.

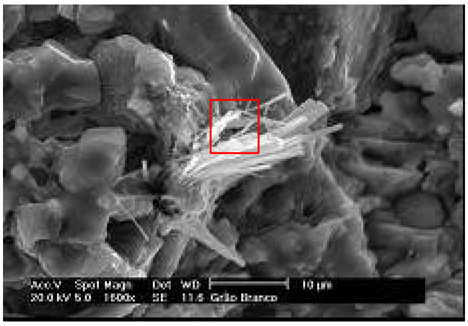

**Figure 18: SEM image of the white grains with adhered mortar (1600X) zone** a **highlighted**

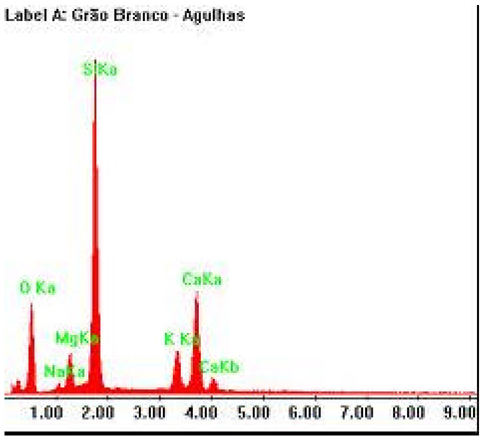

**Figure 19: EDX spectra of the highlighted area of Figure 18.**

In the highlighted zone **a** of the micrograph of Fig.18, the development of the crystalline phase of morphology acicular is observed, composed by silica, calcium, potassium, sodium and magnesium.

**Figure 20: SEM image of the white grains with adhered mortar (1600X),zone** b **highlighted.**

**Figure 21: SEM image of the white grains with adhered mortar (1600X), zone** c **highlighted.**

The highlighted zone b shows a gel phase containing particles in its surface. In the highlighted zone c (Fig. 21), the internal structure of the gel presents pores. It is still verified the presence of Portlandite, registered in the difractograms of the mortars.

In the samples extracted *in situ*, obtained by the manifestations and observing the mortar adhered to the seal coating, the presence of quartz pebble is verified, indicated by the presence of silicon in the spectrum of Fig. 23. From the analysis of the manifestation morphology, the agglomeration of the product in the surface of the mortar is observed (Fig. 22).

## 3 ANALYSIS OF THE RESULTS AND CONCLUSIONS

The visit *in situ*, as well as the test cores analyzed showed that the signs of deterioration of the floor were brought by the manifestations observed, marked by the formation of vesicles with a whitish pigmentation and a gel exudation in the surface, indicating alkali-aggregate reaction, which was confirmed by the analysis accomplished in the representative samples.

According to the results presented using the microscope, it is possible to conclude that the analyzed micrographies of the Korodur mortar of test cores of the floor, as well as for the scratching and extraction of the samples *in situ*, presented typical morphologies and chemical compositions of the reaction alkali-aggregate.

The results of the X-Ray difraction thermal analysis, accomplished in the aggregates used in the mortar composition of the floor, indicated the presence of quartz grains in the pebbles and white aggregates constituting dolomite calcium carbonate. According to the manifestations and based on the results, the white aggregates has reagent characteristics to alkalis. In the formation of the vesicles, the appearance of a whitish structure is due to the composition of the white aggregate, with strong indication of a alkali-carbonate reaction.

From a morphological point of view, the gel presented a massive structure in a fine texture with cracking. The crystallized products presented acicular forms, and like the massive gel, in the mortar/aggregate interface. Punctual chemical analysis of the gel and of the crystallized products, done by EDX, showed calcium-silicon-alkaline compositions, where the detected alkalis were potassium and sodium.

Additionally, it was possible to identify, by the scanning electronic microscope (SEM), ettringite in isolated crystals. Well crystallized portlandite was also rarely recognized and identified in the difractograms. In the ones referred to the mortar, the presence of $Mg(OH)_2$ and calcium carbonate was verified, which related to the gel, confirm the white aggregate reativity.

Therefore, in relation to the evidence of the verification of the phenomenon, what should be understood and considered is the alkali-aggregate reaction's risk in the selection of materials for the concrete or any other product that involves dolomite aggregates and alkalis in excessive amounts. This does not mean that the same aggregates cannot be used but that the limitations for use should be evaluated. Besides, it is important to mention that microstructural analysis is always fundamental to determine and to understand the harmful manifestations that usually appear in residential and industrial constructions.

# Linseed Oil Paint As An Alternative To Wood Preservatives

**E Brandt[1] & T Lading[2]**
**[1]Danish Building and Urban Research Denmark**
**[2]Lading architects & consultants PAR Denmark**

**Summary: For reasons of sustainability great efforts have been made to find environment-friendly alternatives to paints and wood preservatives. This paper presents results from a project where efforts focused on the use of linseed oil paint, which is well known from old buildings.**

**The painting process of using linseed oil paint is quite complicated, and moreover several dogmas attach to the use of linseed oil, whereas scientific evidence is lacking. An investigation was performed in order to see if a correlation could be detected between the composition of the paint, the workmanship and the environmental conditions at the time of application. As it proved difficult to find projects, where sufficient information was available, only 10 projects were surveyed. The result was that no definite answers could be given as to the importance of each individual factor. However, some general conclusions can be given. It appears that the most important factor for a good result was a successful pre-treatment, i.e. the substrate should be dry and in good condition and the linseed oil should be able to saturate the wood completely. Of importance is also the weather at application, that application is performed in thin coats, and that apparently it is necessary to use small amounts of preservatives for the most exposed parts of the window.**

**Keywords: Wood, windows, durability, painting, renovation.**

## 1 INTRODUCTION

Exterior woodwork must be treated with wood preservatives and/or paint to prevent decomposition of the wood due to the action of light and humidity. In Denmark most new windows are vacuum impregnated before they are painted. However, the use of preservatives is not without problems. Much simplified the known products are either not effective enough or they are poisonous or in other ways a strain to the environment. The production of the preservatives may involve extensive use of energy or they might be produced from non-renewable raw materials. Wood preservatives thereby become one of the big environmental problems in building.

Wood preservatives cause problems throughout their life cycle: in the production, in the application, and in the disposal – problems to surroundings as well as work environment.

Till the end of the 1970s wood preservatives and paints in Denmark were almost entirely based on different oils diluted with turpentine or other organic solvents. These products caused problems with the work environment and led to the development of emulsion paints and wood preservatives based on water which was good for the painters but hardly so for the wood. The first generations of these new paints had very poor properties.

These experiences combined with a growing concern about the environment have led to a renaissance of linseed oil paint that has been the traditional product for surface treatment of wood for centuries. Linseed oil has become a popular commodity - the market received it well. However, the products used today are not the same as the "historical products". Among other things the old linseed oil paints contained large quantities of lead, which is a most efficient fungicide.

In reality, very little or no documentation at all exists for surface treatments with modern linseed oil products. In turn many myths have prevailed about linseed oil and its properties. Therefore, the current knowledge of linseed oil paint needed to be summed up and its suitability as wood protection to be assessed.

## 2 THE INVESTIGATION

The main purpose of the investigation was to get an impression of how the products functioned in practice. This was to be done by performing a condition assessment of building parts that had been painted with linseed oil paint and had afterwards been exposed to wind and weather for some years. To be able to draw conclusions from the condition assessments, it was required that:

- The age of the surface treatment should be 5-10 years and preferably no maintenance should have taken place
- Treatment should be linseed oil products only, i.e. no emulsion and alkyd paints etc.
- It should be known what products had been employed
- It should be known how the work had been carried out including the time of the year the treatment was applied.

However, it turned out to be difficult to find suitable objects for examination. This was partly due to the fact that only a limited number of modern linseed oil treatments existed before 1995. Partly because many of the objects are not very well documented or mixed treatments had been used, e.g. alkyd paint used together with linseed oil paint.

Another characteristic is that linseed oil is employed especially in the restoration of historical buildings or by private "do-it-yourself-people". This was reflected in the identified buildings where linseed oil paint had been used namely 6 mansions and listed buildings, 6 cottages at the Open Air Museum plus one single family house and one apartment block. The latter was the only example of an "ordinary building" where painting had been applied in a professional manner.

All the examined products had been applied by brush and all executed on existing woodwork of which some had been mended with new wood.

Some manufacturers have in recent years developed linseed oil paint that can be sprayed on and which is primarily used for factory treatment of new windows. These products have not been on the market long enough to be part of this investigation.

Also, it should be noted that in a lot of cases the products employed no longer exist on the market. Some manufacturers have closed down and others have changed their recipes and ingredients.

**Figure 1. Mending of sashes in old wooden windows in order to preserve as much as possible of the original sashes.**

### 2.1 The surveying procedure

Nine projects were identified which roughly fulfilled the requirements. For each project the following was recorded:

- Identification of the building, its owner and its use.
- The building components treated including wood species and age (original, old, new).
- When and how the surface treatment was applied.
- The product used.
- The orientation of the treated surface and any external conditions of importance.
- Any subsequent maintenance.
- The condition of paint and wood – assessed in the same way as surveyors normally do.
- Possible causes of damage.

The condition assessment is based on a combination of the visual appearance of the surface, e.g. gloss and chalking, measurements of moisture content of the wood (combined with weather conditions, season and orientation) and the physical condition, e.g. whether the wood is soft or hard or whether the paint adheres to the wood or not.

Generally two investigations were performed for each object. First a single person performed a thorough investigation of wood and paint as a basis for assessing the correlation between the present condition and the possible causes for any failures. Afterwards, all projects were further surveyed by two or three persons in order to ensure coherence in the condition assessment.

It should be emphasised that although the employed products were recorded, it was not possible from this project to assess exactly which factors resulted in the longest service life. The reasons were that the number of objects was small, the pre-treatment of the wood is very different, the paints are different and the workmanship is different. It should also be noted that many of the products are no longer on the Danish market either because the factory has closed down or because the recipe has been changed.

## 2.2 Observations Made During The Surveys

The performance of the objects were quite different ranging from good condition after 8+ years exposure to deterioration of paint after about 2 years.

The observations are summarised in the following two lists which are examples of positive observations and problems respectively.

### 2.2.1 Positive observations during the surveys:

- The surface treatment was in good condition and protected the wood well. Probably the reason was that the initial quality of the wood is good and that the workmanship – including the priming – has been performed with care.
- The painting was in excellent condition (after 8+ years) probably due to a combination of high quality of the wood, protection by design, careful workmanship, long drying time between applications.
- Generally the paint was in good condition (after 7 years).
- Woodwork was generally in a good condition even though some flaking of the white paint was found (whereas black and green paint on the same building was still adhering well).
- Woodwork was generally in a good condition even though the lower parts had become soft (start of deterioration). This building is a barn and it is cleaned using a high-pressure hosepipe.
- Woodwork was in excellent condition probably due to a thorough renovation of the windows before painting. Paint adhered well to the surface.
- Generally woodwork was in good condition and paint was adhering well (6 historical houses in the Open Air Museum). Generally the paint and the maintenance appears to be effective. There were no marked differences between older and newer treatments probably because the woodwork was maintained well (every 5 years with a mixture of turpentine and linseed oil).

**Figure 2. Linseed oil painted door with good performance after 8+ years. The wood quality is good and the workmanship of high quality.**

2.2.2 Problems encountered during the surveys:

- The fittings were the most vulnerable parts of the objects as they were not sufficiently protected by the linseed oil products. This is a remark generally valid for most of the surveyed buildings.
- Windows in upper floors showed most chalking probably due to a greater exposure to sun. The paint film was quite unacceptable – appeared like crocodile skin – probably due to evaporation of thinner after the linseed oil had dried.
- The surface was relatively susceptible to dirt.
- The paint film had deteriorated and had not protected the wood sufficiently.
- The paint film was deteriorated and did not provide sufficient protection of the wood. This condition was achieved in a couple of years after painting and is probably due to imperfect priming, wrong succession of the applications of paint (thicker paint applied before thinned paint), too thick layers, insufficient drying between applications.
- The painting was deteriorated and has not provided sufficient protection of the wood (the surface treatment was 11 years old and had not been maintained). The paint was flaking. The mending of the wood had deteriorated somewhat. The reason for the insufficient durability was not clear as the surface treatment and the workmanship was not well described.
- Prevalent chalking of paint due to a combination of too much filler, too thick layers of paint, application in cold weather.
- Not all pigments were stable which was reflected e.g. in the colour of the green paint that varied from almost black to turquoise-green.

**Figure 3. Bad performing linseed oil paint after about two years of exposure. Probably the problems encountered are due to insufficient cleaning of the window before application combined with poor workmanship and unfavourable weather conditions at application. The photo also demonstrates that linseed oil does not provide sufficient protection to sash-angles and other metal parts.**

## 3 GENERAL RESULTS

As mentioned earlier it was not possible from this project to assess exactly which type of paint had the longest service life. However, it was possible to derive some general results from knowledge about the products used, the application conditions, the orientation of the surface treated surfaces and the observations from the surveys. Also general knowledge from earlier projects (Brandt, E. 1999), (Lading, T & Brandt, E. 2000), (Hjort, S. 1995) etc. was taken into account when assessing the results. The results are given below divided into factors considered most important for the durability

### 3.1 Product imperfections

There is a pronounced difference in the quality of linseed oil products, considered to be due to the fact that there is generally too little knowledge of the factors affecting the properties of linseed oil. Also a number of product imperfections suggested that not everybody in the trade had the necessary professional background and expertise:

- Lack of quality control and homogeneity in the production
- products from the same manufacturer, which ought to be alike, may vary in properties and quality from batch to batch
- Too much or wrong filler
- filler was added partly to make the paint fuller (which means that the viscosity is enhanced to make the application easier), partly to make it cheaper. Too much or wrong filler will result in chalking, wrong viscosity etc. There were examples of thinner being needed because too much filler had been used in the first place!
- chalk is often used as a filler, but along with the subversion of the linseed oil it might become visible as chalking; the surface becomes lustreless and gradually gets a white, foggy surface; at the same time it becomes more susceptible to humidity – this was especially distinct upon dark surfaces.
- Lack of production tests
- usually manufacturers of paint and varnish save test samples of the production so later examination is possible in case of problems - some suppliers of linseed oil products were not in line with that.
- Lack of knowledge of basic chemistry
- when marketing a thinner for linseed oil paint that takes longer to evaporate than the linseed oil takes to dry.
- further, there have been examples of products, e.g. containing boron (used as a fungicide), introduced as totally harmless and almost eatable in spite of the fact that boron is suspected of giving embryonic damages, and that it is on the list of substances that should be phased out.
- Contents of unhealthy substances

- especially organic solvents such as turpentine which some products contain to a larger or smaller extent – and which is usually not necessary
- Lack of documentation for products that are sold in connection with linseed oil
- e.g. some manufacturers introduced citrus seed oil as a natural and harmless fungicide with no documentation of the correctness of this and without information of possible unhealthy side-effects.

It should be stressed that also a lot of good products are found on the market. The problem is the difficulties of finding out which products are good and which are not.

**Figure 4. Repair of linseed oil painted window where the paint used for the repair differs significantly from the original due to a larger content of chalk filler.**

### 3.2 Fungicide

The only linseed oil products on the Danish market with fungicide against dry rot are primers, which also might contain other oils and turpentine. It was not possible in all the investigations to find out whether the woodwork, apart from having been treated with linseed oil products, had also been treated with primer oil against dry rot.

Woodwork treated with fungicide against dry rot is probably, other things being equal, in a better position to resist a wrong application than wood with no treatment. Conversely, a correctly performed treatment, where priming with oil has been properly carried out, will probably provide sufficient protection. Humidity will not be at such a high level that mould and dry rot will develop. However, it is important to maintain the treatment. The linseed oil paint (the topcoat) should preferably have fungicide against mould and mildew added in order to prevent growth of fungi.

There is a potential in limiting the use of fungicide to those places only, where it is necessary instead of treating all woodwork (as done with vacuum impregnation). Normally, it is easy to predict where the risk of is, e.g. 95% of the rot attacks in windows are found in the bottom part of sashes and frames.

### 3.3 Application

The application condition and the application process are crucial for achieving a good result.

The protection of the wood is based on the combined action of the primer and the paint (topcoat).

The function of the topcoat is twofold namely to protect against water as well as against degradation from UV-light. However, the most important factor for the protection of the wood is the priming that protects against humidity even when the topcoat is degraded. In order to protect the wood the primer should saturate the upper layers of the pores in the wood completely so that there is no "room" for liquid water. To assure a sufficient saturation it is therefore important that the wood is dry (max. humidity 12-15%) when the primer is applied.

The linseed oil paint should be applied in thin layers and one layer must be thoroughly dry before the next one is applied. If paint is applied in thick layers, it wrinkles and gives the surface the look of crocodile skin. Also the paint is not solid until it has dried up and consequently it is more susceptible to destruction until it has dried completely. In cold weather, i.e. below 5-10° C, it is difficult to apply thin layers and drying becomes slower. The same occurs in damp weather. Therefore, generally skilled users are required to obtain a satisfying result, as it e.g. is a matter of experience to apply a coat of paint in a thin layer and to assess when the previous layer is sufficiently dry to proceed.

**Figure 5. Paint looking like crocodile skin due to application in too thick layers.**

## 3.4 Logistics

Linseed oil treatment does not fit in very well with the logistics at a modern rational building site – especially not if other work is to be carried out at the same time. Long drying hours and sensitivity to dust are examples of the factors that make the use of linseed oil products difficult.

The most durable of the surveyed treatments had been performed most carefully: after priming the windows, 5 coats of linseed oil paint were applied with at one-week intervals, that is, a total duration of more than 6 weeks. Such a long time interval will be hard to fit in with ordinary building procedures, e.g. within urban renewal.

Preferably, linseed oil painting should be performed in a workshop. If the treatment is performed on the spot it should, preferably, not be performed simultaneously with other work. The need for scaffolds in an extended time because of the long drying hours further increases the price of using linseed oil products.

## 3.5 Potential

It may be possible to make use of the good properties of linseed oil and still take into consideration logistics and application criteria if linseed oil is used as a primer and a 'modern' paint (e.g. aqueous alkyd) as topcoat. The paint should preferably be marketed in *systems* to ensure compatibility and product guarantee.

A good linseed oil system should include:

- An all round primer based on heat-treated linseed oil.
- A special primer with fungicide against dry rot for treatment of the most exposed areas.
- A 'modern' topcoat paint that has sufficient adherence to the primer and that dries fast

### 3.5.1 New windows

New factory-made windows treated with linseed oil products are marketed but are more expensive than similar windows with ordinary paint. This may be compensated for by its durability that eventually will result in a better over all economy – but as far as it is known, no actual documentation for improved durability exists.

A new windows treated linseed oil should have:

- An accelerated ageing test to assess the durability of new industrially treated windows.
- Documentation of performance of factory applied paint systems including durability.
- A calculation of the overall economy compared to traditional windows.
- A labelling scheme to make it easier for the builder/user to compare products including their impact on the environment.

Go Back

## 4 CONCLUSIONS

With linseed oil products it is possible to obtain a good protection of wood as well as a durable result, but things may also go awfully wrong. Some of the surveyed treatments proved to have excellent durability – others absolutely not. In some cases the wood was in good condition even though the paint film did not look very well. In turn, no examples were seen of wood in a poor condition under an almost intact coating – something that may be seen in connection with e.g. latex paint.

On the whole, too many imperfections were found even though the investigation only included a relatively moderate number of treatments. The imperfections were found in both workmanship and products.

In all surveyed examples (except a barn in Vemmetofte) professional technical consultants had taken part in the construction work – also consultants specialised in restoration. Still, there turned out to be big differences. This was mainly due to the quality of the wood, the products and the application.

There are several reasons for linseed oil treatment not having been used on a large scale outside restoration of historic buildings and private use.

- Good linseed oil products can be found on the market but not an optimal system. Surface coatings are normally found as *systems* which include products for priming, intermediate coating and top-coating. Similar systems are not found for linseed oil products, which make it more difficult to use as compatibility of the different products must be assessed individually. It is obviously difficult for both consumers and professionals to get the right information and to choose the right products. Differences in quality often do not become evident until after several years, and the purchase of linseed oil products is therefore a matter of trust.
- There is a lack of documentation and product development
- In general it requires skilled users to obtain a satisfactory result, as e.g. it is a matter of experience to apply a coat of paint in a thin layer and to assess when the previous layer is sufficiently dry to proceed.
- The current linseed oil treatments do not fit very well with the logistics on a modern building site especially because of the long drying hours.

In conclusion the prerequisites for obtaining a good result are:

- The wood must be sound and dry.
- The weather must be 'good' during application – i.e. low RH and a suitable temperature.
- The products - primer and paint - should be of a good quality. Product development is needed.
- The priming should saturate the wood completely with linseed oil in order to protect the wood against liquid water and thereby fungus and dry rot.
- The application must be correct - several thin layers that are allowed to dry sufficiently in between applications.
- Maintenance should be performed in due time.

# Experience With Equipment For Large Scale Accelerated Ageing Tests

**E Brandt[1] &T-N Nilsen[2]**
[1]Danish Building and Urban Research Denmark
[2]Norwegian Building Research Institute Norway

**Summary: Artificial ageing of building materials and components is a very complex matter. Many factors have to be taken into account including a number of ageing factors and the size and geometrical shape of the test specimen. Most equipment for accelerated ageing is designed for small samples which, however, has the disadvantage that it is not possible to test components including joints in full size. In Denmark and Norway large-scale test equipment has been in use for more than 30 years and its use has been described in test methods. One of these has recently been revised and issued as a Nordtest method based on experience from its use in Denmark and Norway. This paper describes the design of the test equipment including the background for selection of type and size of the ageing factors. Further experience from the use of the method is illustrated by examples of test results for different materials and components.**

**Keywords: Accelerated ageing, ageing factors, deterioration, degradation, durability.**

## 1 INTRODUCTION

Great interest focuses on the service life of building materials, components, and assemblies, which has a decisive influence on the annual cost of buildings and engineering works. Moreover service life has great influence on the environmental impact from materials and components. However, estimating service life of building materials, components and assemblies is a very complex matter and over the years several ways of achieving this goal have been proposed. For well-known materials, knowledge about service life can to a great extent be based on experience. For new materials and components, no experience exists and consequently information about service life needs to be achieved in other ways. According to the RILEM recommendation (Masters & Brandt, 1989) this can be done either through natural ageing, e.g. by long-term exposure under in use conditions, or accelerated ageing at exposure to severe climate, e.g. in deserts. Alternatively artificial ageing may be used. When designing an artificial ageing test, many factors have to be taken into account including not only the ageing process, i.e. whether ageing should be achieved using simulated severe climates or by specific enhancement of selected deterioration factors such as UV light, heat or freeze/thaw, but also the size and the shape of the test specimen.

In Denmark and Norway large-scale test equipment has been in use for more than 30 years and the use has been described in test-methods. One of these has recently been revised and issued as a Nordtest method based on the experience from the use up till now.

## 2 DURABILITY

Often the term durability is being interpreted as the same as service life. In this paper durability is used as a term for the time related capability of a material or component to resist deterioration factors that may reduce its service life. In this definition durability is a property of a material or component, but it does not give any meaning without a precise description of the methods used for determining the durability. Methods for the accelerated ageing used and the methods for recording changes, if any, must both be clearly defined. In this respect durability is in principle not different from other properties, e.g. tensile properties, which give different results if measured at different temperatures (climate) and/or at different rate of elongation (test method). The durability may then be defined as the time of exposure to the artificial climate/climate cycle before a certain change in the property recorded is achieved.

*The durability may then be defined as the time of exposure to an artificial climate/climate cycle before a certain change in the property recorded is achieved.*

When the durability is determined for a material or component, it may be used for estimating service life under natural ageing in practical use. The natural ageing is the result of the combined action of all the ageing factors involved. When trying to estimate service life it should be remembered that the climate is not a constant, i.e. the weather not only from one place to another, but also in a specific place varies from one year to the next. Further the exposure of a material or component varies

Go Back Next Page

with its position in the building (whether protected or not) and with its orientation. Finally the resistance to natural ageing is dependent on the workmanship performed when mounting the material/construction. Service life of building materials and components thus depends on time and place, construction and workmanship and cannot be given with great accuracy.

## 3 ARTIFICIAL WEATHERING

When performing artificial weathering all ageing factors of importance for a specific material or component should ideally be increased by the same factor, i.e. the acceleration should be the same for all crucial degradation factors, and they should be acting together in the same way as during ordinary use. If the factors are acting individually, the result may be quite different than if the factors are acting together. When performing artificial weathering in a laboratory it is next to impossible to achieve such a balance between the ageing factors. Instead one seeks to concentrate the individual climatic factors so that in total they produce a cycle of strains that gives degradation results similar to natural exposure but in a much shorter period of time.

The most important degradation factors are normally considered to be:

- *UV radiation from sunlight* resulting in deterioration of chemical bonds, also in combination with humidity.
- *High temperatures (mainly due to sunlight)* increasing chemical degradation processes.
- *Low temperatures* especially *due to winter conditions and to irradiation to the sky* resulting in vulnerability to mechanical impacts.
- *Temperature changes* result in differential movements between different materials and thereby strain in the materials. *Freezing point transitions in combination with humidity over the critical limit* may break porous materials.

Other impacts may also be of great importance:

- *Precipitation/rain* is contributing to the degradation of materials by supplying water that may be used in symbiotic degradation together with e.g. UV radiation or freezing point transitions. Also *leaching* by water may cause degradation.
- *Effects from wind, particles and chemicals* (pollution) may contribute considerably to degradation.

The importance of the degradation factors depends on the material and/or the component studied e.g. UV radiation may be important for plastics but not for concrete and conversely freezing point transitions may be important for concrete but usually not for plastics.

Accelerated ageing tests in a laboratory always carry the risk that the deterioration of the material may be dominated by other degradation mechanisms than those that will dominate in natural ageing. Since this possibility does exist, the results of the exposure should as far as possible be compared with long-term natural ageing performed with the same materials or similar constructions. However, due to the combination effects the endeavours to accelerate the individual ageing factors to the same extent should not be exaggerated. The important objective is to compose an ageing cycle that gives reasonable correlation with results obtained by natural ageing. In this context reasonable correlation means that for a specific material the ratio between the important acceleration factors is the same.

In the Nordic countries low temperature and freezing point transitions are considered to have an important impact on the service life of many building materials for outdoor use. For some materials the freeze/thaw situation during autumn/winter/spring may actually be the most demolishing situation. An illustrative example is brickwork, which after a short exposure time might start to flake off material if it is not suited for a Nordic climate, i.e. wet and with frost transitions. Therefore all the large-scale equipment for artificial ageing presented in this paper includes exposure to frost during the climate cycle.

### 3.1 The use of results

Results from artificial weathering may be used to determine a reference service life in accordance with the definition of durability given above. A prerequisite for this is that the ratio between the acceleration factors found for comparable building materials are the same independent of their practical use (climate/construction). Such “scientific” comparisons have been done also with large-scale equipment as described in this paper. The results show accelerating factors of from 12 – 20. This gives the possibility of a rough assessment of the service life of building materials.

However, when performing artificial ageing, the results are, for several reasons, rarely given as some sort of service life. One reason is that more often the possibility of comparing the results with in situ exposure does not exist. Another reason is that so many factors other than the durability, as defined above, are important for how long time a material may function according to its intended use. The “scientific” comparison of artificial weathering and natural weathering therefore has limited value as a general tool for estimation of service life.

In some cases, e.g. in connection with technical approvals, the results are used to assess the service life of a specific product, whereas in connection with development of products, comparison or ranking of samples of varying compositions may be the objective of a test.

## 4 LARGE-SCALE TESTING VS. SMALL-SCALE TESTING

Most accelerated tests are performed on relatively small test samples. The advantage being that the test equipment may be kept relatively small, light and inexpensive. Further advantages are that large acceleration factors can be achieved especially for UV radiation and heat. The disadvantages are that relatively few samples may be tested at the same time and that small homogeneous samples may give quite a different result than large more, complex ones. The most important shortcoming, however, is that components and assemblies may be too large to be tested in such equipment.

Conversely, the advantages of large equipment are that large samples may be tested and that they offer the possibility of testing more complex objects like components with several materials, including joints etc. Large samples of a building material may give stress/strain situations that will not be observed on smaller test specimens e.g. the compatibility of materials with different dimensional stability to moisture and temperature. The influence of the total design of a specimen including geometrical shape, joints etc. may be studied, and large samples give the opportunity for more or other tests of the materials/components after the artificial ageing. Also the possibility of testing large numbers of samples at the same time is of course an advantage. The disadvantage is that this type of equipment usually is heavy and expensive and that the size set limits to the location of the equipment. Also the problem of establishin equal climatic load throughout the whole test area may be seen as an disadvantage.

Basically it can be said that the two types – small and large – are good each for their purpose. In other words they complement each other. The small equipment is best suited for smaller samples of materials and components and the large equipment for larger samples of components and assemblies.

## 5 DEVELOPMENT OF LARGE-SCALE TEST EQUIPMENT

In 1965 an equipment for accelerated ageing of building materials and components was built at the Norwegian Building Research Institute (NBI). The main objectives were:

1. To be able to test objects larger than what was possible in the then commercially available Atlas Weather-O-meters and similar
2. To have a sufficiently large ageing factor.

The method was especially designed to study the degradation of vertically positioned materials and components in the building envelope when exposed to the climatic strains: UV radiation/heat, rain and frost. Later other and bigger large-scale equipment using the same principles was built. At NBI a test equipment was also developed for studying the impact of the same climatic strains on horizontal building materials, components and assemblies.

In all cases the idea is that it should be possible to test whole building components e.g. entire windows or entire facade components. In general the test specimens are mounted in a manner that best simulates the in-use conditions and in a way that they are not exposed to other strains than those experienced in practice. Test specimens exposed simultaneously must be unable to influence each other.

The results of the test are given as any change in appearance of the specimens during the test, any signs of degradation e.g. cracks, loss of gloss, de-lamination etc. together with information on when the changes occurred, how big they are etc. The result of an accelerated testing is often a change in performance properties. Such properties may be tested before, during and after the artificial ageing. To detect the changes in properties, suitable test methods are chosen dependent on the material or component under test. Destructive tests must of course be performed on different specimens, which means that test specimens must be removed from the ageing equipment during the ageing test.

In the following a brief description of the various types of equipment is given together with some examples of their use.

### 5.1 Climate carousel – “The Four Seasons”

For many years the testing procedure of the first large-scale test equipment in Norway and Denmark was described as a common Norwegian/Danish standard. However after more than 30 years use the time was found to be ripe for revision of the test method which is currently being processed to become a Nordtest Method (NT Build Method 495).

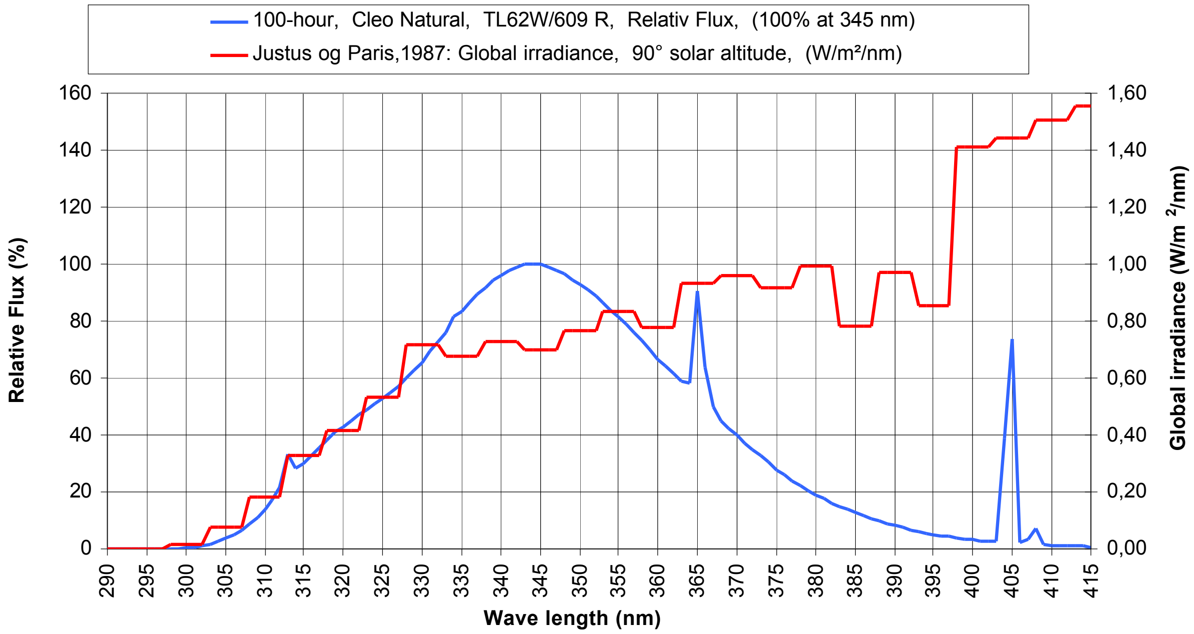
The revision primarily focused on improving the spectral distribution of the UV lamps used, give a better definition of the black panel temperature etc. The test method describes the procedure including the exposure. The test method is, however, rather open to changes in the size and duration of exposure to the ageing factors, as it is envisaged that the individual factors will need to be adapted depending on the tested materials, components and assemblies.

#### 5.1.1 UV light

The challenge was not to find a UV light source capable of providing a great intensity as regards UV-light but to find a find a suitable source that had a spectral distribution comparable to that of sunlight as well as the necessary physical properties to me it suitable for use in equipment with a large exposure area. Moreover it was found to be crucial in order to avoid degradation mechanisms not occurring under normal use, no radiance should be found apart from what is found in natural sunlight.

Selection of a suitable light source was done according to the information in ASTM G 53 – 96 (non-metallic materials) and in EN/ISO 4892-3, 1999 (Fluorescent UV lamps). Further the spectral distribution of the potential light sources was compared with the spectral distribution of modelled data for atmospheric conditions in CIE 85-1989, Table 7 (1) found by Justus and

Paris (1987). Philips Cleo Natural 59 W-R, which is a fluorescent UV tube, has been found suitable for the purpose giving a good fit to the spectral distribution in the UV band up to about 365 nm, cf. Figure 1.



5.1.2 The test equipment

The equipment consists of 4 test frames shaped as boxes with a closed bottom normally insulated behind with 50 mm mineral wool. The test samples can be mounted in the openings with hooks, screws or similar. The central unit rotates 90° at fixed time intervals so that each test frame is in turn exposed to the four different exposure climates, see Fig. 1. At present it is, depending on the used equipment, possible to test specimens with a maximum size from 0.9 x 0.9 m to 1.5 x 2.5 m. When not exposed, the test frames are facing the laboratory allowing inspection and measurements of the test samples.

From this follows that the exposure takes place in 3 climatic chambers plus the ambient climate. When rotating the carousel, the test specimens are in turn exposed to the following strains: A: UV/IR radiation, B: Water, C: Frost and D: Laboratory climate.

The UV lamps are normally placed 500 ± 50 mm from the test specimen but the distance may be reduced to 350 mm without harassing the uniformity of the UV light. The lamps are systematically replaced in turn in a way that the irradiation on the test specimens varies as little as possible during the test period. The black panel temperature shall rise to its designated temperature in the course of 45 minutes from the beginning of the exposure to UV light and heat radiation. The black panel temperature is normally 63 ± 5°C but, if required, the temperature may be chosen to be 35 ± 5°C, 50 ± 5°C or 75 ± 5 °C instead, cf. ISO 4892. The temperature is controlled by means of IR halogen lamps. The black panel is an un-insulated, non-gloss, black, flat aluminium panel with nominal dimensions: 100 mm long, 75 mm wide, and 2 ± 0,5 mm thickness with a suitable black coating which absorbs more than 90% of all incident radiation up to 2500 nm, for example black anodized 6063 aluminium.

Go Back
Next Page

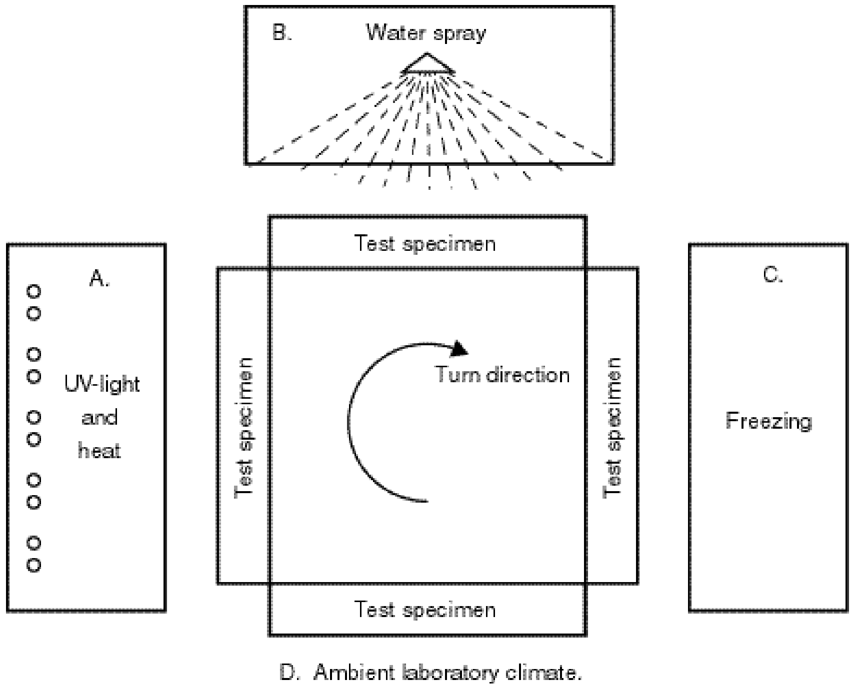


**Figure 2: Sectional view of climate carousel – "The Four Seasons"**

The UV tubes as well as the IR lamps may be regulated in order to control the UV irradiance and the surface temperature of the test specimen, if required.

Wetting of the specimen is done with a spray of de-mineralised water normally with 15 ± 2 l/($m^2$ h). If required, various spraying conditions may be used regarding for the amount of water and the spraying period.

Cooling and freezing air temperatures of –20 ± 5 °C are obtained, e.g. by supplying cooled air to the climate chamber. Other specified air temperatures may be used, if registered and reported. The air temperature is measured with a white panel sensor, similar in construction to that of the black panel temperature, and placed in the proximity of the specimen centre.

After freezing the specimens are exposed to thawing at ambient laboratory climate, i.e. 23 ± 5°C, 50 ± 10 % RH. During thawing the specimens may be inspected, rearranged and/or changed.

The time interval in each position is chosen dependent on the material/components under exposure and should be at least 1 hour. The limited possibilities of changing the ratio between the ageing factors are to change the UV and/or IR radiation, and/or by shortening the duration of the water spray.

5.1.3 Example of the use - Testing of renovation systems and paint for windows

For reasons of sustainability great efforts have been made to maintain or re-use old wooden windows, making windows from old wood and treating wooden windows with environment-friendly paint without wood preservatives. For this reason more investigations have been performed on windows including inspections in situ as well as artificial ageing.

Artificial ageing is performed on entire windows i.e. frames as well as sashes. In this way it has been possible to assess the behaviour of alternative constructions, including the influence of factors such as the wood quality, the geometrical shape of the sashes and frames, the corner joints, the putty material on the durability.

Assessments are performed during and after exposure and are based on signs of deterioration indicated by spalling, cracking, blistering etc. In some cases also the moisture uptake during ageing has been used as an indicator of the potential risk of mould growth and dry rot – which cannot be assessed by artificial ageing. For some windows, e.g. renovated windows or windows manufactured from old wood, the artificial weathering has further been supplemented with a performance test of air and water tightness of the window.

It appears form the test results that the quality and pre-treatment of the substrate/wood is crucial to achieve a good result. Quite surprisingly it was found that unpainted windows performed quite well which is believed to be due to their good possibilities of drying which shorten the periods with dangerously high humidity.

It was found that linseed oil paint is able to perform pretty well. However, modern linseed oil paints no longer contains lead etc. like earlier used types and therefore it may be necessary to add small amounts of fungicide to the paint for use on the most exposed parts of the windows. Besides the painting process is quite complicated.

**Figure 3: Example of accelerated testing of different paint systems used on window sashes.**

5.1.4 Example of the use - Ageing of fibre-reinforced cement claddings

Another example is testing of 8 mm fibre-reinforced cement claddings for exterior use. This has been a very important subject in order to find substitutes for asbestos fibres. The panels were cut into test pieces each measuring 600 mm x 600 mm. Pictures were taken before and during the test period, cf. Fig. 4 showing two of the panels with different fibre materials after 48 weeks in the climate carousel being rotated every hour. As can be seen one is nearly unaffected while the other is severely deteriorated. The ageing was supplemented with test of mechanical properties in order to study the influence of composition, including the fibre material, on the durability especially as regards the mechanical properties.

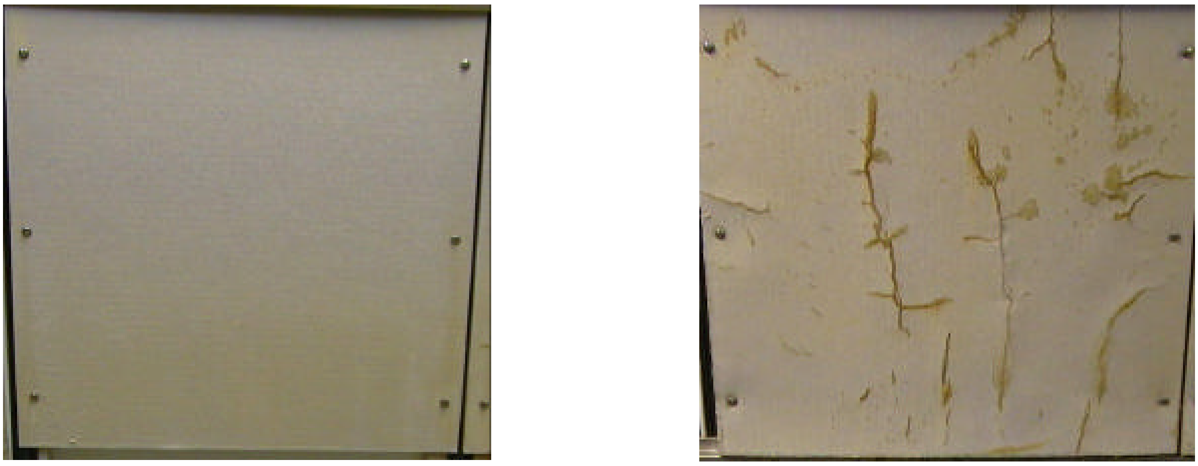

**Figure 4: 8 mm fibre-reinforced cement claddings for exterior use after 48 weeks in the climate carousel**

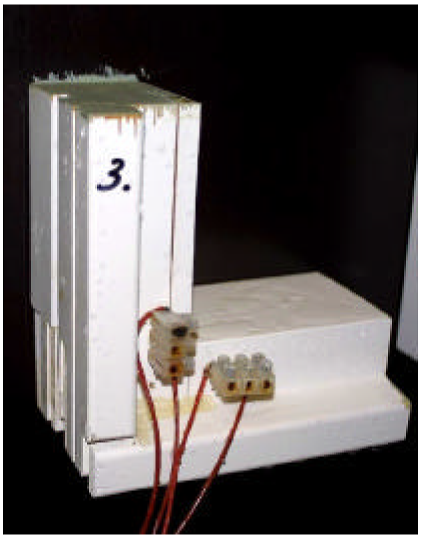

**Figure 5: Testing of window corner supplemented with measurement of moisture content in the wood during the test.**

### 5.2 NEW Equipment For ageing of vertical building components AT DBUR

Originally the main purpose with this test equipment was to improve the capacity for accelerated ageing at DBUR and to test larger specimens than it was possible to do in the earlier equipment, whereas there was no intention of changing the exposure compared with the climate carousel. In practice, however, it turned out to be somewhat different from the carousel as it was decided to use other types of lamps and another concept for the control.

#### 5.2.1 The test equipment

The test equipment consists of a test frame with an area of approximately 10 $m^2$ (3.2 x 3.0 m). The test specimen is exposed in only 1 climatic chamber where it is in turn exposed to the following strains: 1. UV light and heat radiation, 2. Water, 3. Frost, and 4. Thawing at room temperature.

The same considerations as for the climate carousel, were made regarding selection of a suitable UV source were done. In this equipment, however, the UV radiation comes from UV lamps where for example Osram Ultratech 400 and Philips HPA 400/30S have been found suitable for the purpose. The lamps are equipped with filters to get rid of UV-C radiation and measurements show a satisfactory spectral distribution. Control of black panel temperature and the wetting and cooling/freezing is done in the same way as with the climate carousel. Thawing and exposure to ambient laboratory air climate, i.e. 23 ± 5°C, 50 ± 10 % RH is done by ventilating the climate chamber with laboratory air.

The time interval in each position is chosen dependent on the material/components under exposure and should be at least one hour. The ratio between the ageing factors is controlled freely i.e. there are no restrictions to the exposure pattern for this equipment. If desired, the exposure may be chosen in accordance with the climate carousel.

#### 5.2.2 Examples of the use - Ageing of a wooden facade

An example on the use of the test equipment is ageing of an entire facade element with exterior wood cladding including joints, windows, flashings etc., built up to copy the facades of an existing building. For this particular ageing test it was anticipated that the primary degradation factors were moisture changes in the materials, including joints, combined with the UV light and heat.

The exposure cycle was selected with prolonged exposure to UV light compared with the wetting (because humidity is to a large extent forced into the test specimen by the heat) and the action of frost was left out as it was considered of minor influence.

After 6 months testing considerable deterioration was found including cracks in the wood, curving of the panels, opening of joints between boards in the cladding, pull-out (5-15 mm) or pull-through of nails and deterioration of the paint. The deterioration obtained in the ageing equipment was compared with the deterioration of the facade of the actual building. The comparison showed a high degree of agreement between the natural and the artificial ageing. As the artificial ageing was 6 months and the natural ageing 10 years an acceleration factor of about 20 was found for this specific purpose.

**Figure 7: Example of full scale testing of a wooden facade including windows.**

### 5.3 Equipment for performing accelerated ageing tests on horizontal building components

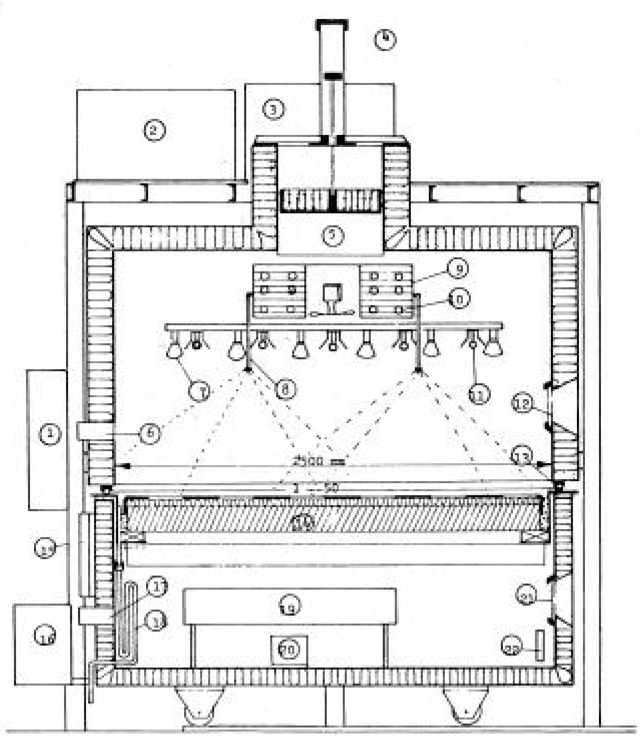
At NBI an equipment has been developed for studying the durability of materials and components placed in a horizontal position, mainly flat or low-pitched roofing.

#### 5.3.1 The test equipment

The test equipment consist of three main parts, see Fig. 8.

- An upper box for simulation of outdoor climatic strains.
- A lower box for simulation of indoor climate.
- A steel frame for roof assemblies of 2.4 m x 2.4 m.

In the test specimen is in the upper box exposed to the same strains as in the climate carousel. The duration of each parameter can be varied independently. When performing an accelerated ageing test, an appropriate indoor climate is chosen and contro lled in the lower box. Movements in the test material/components may be achieved by applying pulsating air pressure.



UPPER BOX

**Figure 8: Test equipment for horizontally placed materials and components**

The test equipment may also be used for wind uplift tests at temperatures between –30°C and +90°C. It is very convenient to be able to control the temperature during a wind uplift test since the heaviest wind loads in the Nordic countries normally are expected between –5 °C and +15 °C. These tests are performed according to the Nordtest method, NT BUILD 307 “Roof coverings: wind load resistance”.

### 5.3.2 Examples of use Roofing products

Roofing products are tested in the ageing equipment mainly to assess the durability of the products and to find a basis for calculating the design capacities for mechanical fasteners in roofing felts in connection with technical approvals. The equipment complies with the requirements stipulated in prEN 1297:2001 “Flexible sheets for waterproofing – Bitumen, plastic and rubber sheets for roof waterproofing – Method of artificial ageing by long term exposure to the combination of UV radiation, elevated temperature and water”. In addition the equipment also may take into consideration both frost and movements in the sheet to be tested.

### 5.3.3 Liquid applied membranes for maintenance of old roll roofing

Liquid applied roofing membranes (LAM) were applied to old roofing felt and tested immediately after curing for 28 days as well as after artificial ageing for 16 weeks in a horizontal position.

The same materials have been exposed to natural ageing at different locations in the Nordic countries for periods from 6 months to 12 years. The visual inspections after natural and artificial ageing both showed the same type of defects. Both also showed that moisture is damaging to the liquid applied membranes.

Testing of mechanical properties showed that the old roofing felts gained both strength and flexibility after being coated with LAM. Meanwhile, the gained properties are greatly reduced after 16 weeks of artificial ageing.

The conclusion from this investigation was that when properly applied to dry, old roofing felt LAM may serve as a temporary alternative to re-roofing.

**Table 1:Tensile properties and cold-bending temperature for liquid applied membranes.**

| Material | Tensile properties (EN 12311-2 A) | | | | Cold bending |
|---|---|---|---|---|---|
| | Force Longitudinal | Force Transverse | Elongation Longitudinal | Elongation Transverse | (EN 1109) |
| | N/50 mm | N/50 mm | % | % | °C |
| Old roofing | 450 | 205 | 2.8 | 2.4 | + 10 |
| L1 asphalt | 585 | 336 | 3.4 | 4.6 | + 10 |
| L1 aged* | 633 | 431 | 1.9 | 2.8 | > + 20 |
| L2 acrylic | 418 | 316 | 2.3 | 4.4 | + 5 |
| L2 aged | 641 | 371 | 1.9 | 1.7 | + 20 |
| L3 asphalt emulsion | 536 | 301 | 3.9 | 6.5 | - 5 |
| L3 aged | 630 | 476 | 2.0 | 4.0 | + 5 |

*Artificial ageing according.

### 5.3.4 Example: Roofing membrane of ethylene-co-polymer/bitumen

A roofing membrane of ethylene-co-polymer/bitumen was collected from a roof in Jönköping, Sweden. The membrane had been on the roof unprotected for 4 years, lying on asphalt felt. This membrane was tested for tensile properties and tear – nail shank according to test methods close to respectively EN 12311-2 method A and EN 12310. The new membrane was tested after exposure to artificial weathering for 72 weeks (NS 8140/DS 1127), heat ageing at 70°C for 24 weeks (EN 1296) and ageing in hot water at 60°C for 8 weeks (NS 3531).

Roughly the test results showed that no significant changes was found in the membrane exposed to heat or hot water, whereas the artificial weathering causes a slight reduction in the measured properties.

The conclusion is that the product has very good weather resistance, but that some migration between asphalt felt and the membrane is causing deterioration of the membrane during practical use on the specific roof in Jönköping.

**Table 2: Tensile properties and tear resistance for roofing membrane of ethylene-co-polymer/bitumen.**

| Material Treatment | Tensile properties/St.d. (EN 12311-2 A Mod*.) Force Longitudinal | Force Transverse | Elongation Longitudinal | Elongation Transverse | Tear – nail shank/St.d. (EN 12310 Mod*.) Longitudinal | Transverse |
|---|---|---|---|---|---|---|
| | N/50 mm | N/50 mm | % | % | N | N |
| New material | 1020/130 | 876** | 408/72 | 688** | 299/6 | 285/10 |
| Natural weathering 4 years | 500/25 | 407/5 | 256/14 | 400/14 | 181/5 | 220/5 |
| Artificial weathering 72 weeks*** | 999/92 | 699/59 | 430/53 | 616/39 | 200/5 | 258/10 |
| Heat ageing 24 weeks at 70 °C | 1040/100 | 739/126 | 452/26 | 627/140 | 216/2 | 268/9 |
| Ageing in hot water 8 weeks at 60 °C | 1030/10 | 766/6 | 465/11 | 703/20 | 205/11 | 267/4 |

For new material 5 specimens are tested. For artificial aged/weathered material 3 specimens are tested

* Modification EN 12311: 40 mm/min. Modification EN12310: 50 mm specimens/3 mm pre-cut hole for shank.

** Only one specimen is tested.

*** Planned for 48 weeks, but prolonged as no significant changes was found after 24 and 36 weeks compared with new material.

Artificial weathering in accordance with NS 8140/DS 1127

Heat ageing in accordance with to EN 1296

Ageing in hot water in accordance with to NS 3531

## 6 CONCLUSION

Large-scale equipment for accelerated ageing is considered to be a valuable tool not only to accelerate the ageing process of single building materials but also to provide insight in how different materials or components interact with each other under the influence of different exposure factors. For example the compatibility of materials with different moisture and temperature deformation properties and the influence of the total design of a specimen including geometrical shape, joints etc. may be studied.

To the authors experience the results achieved show good correlation with the deterioration experienced in practice. This means that if you find a ranking e.g. for different paint systems after artificial weathering, you should find the same ranking after natural weathering independent of geographical location and situation - on condition of course that the paint systems are used in situations that are sufficiently comparable.

In some (few) cases it may be possible to find an acceleration factor for specific uses of materials/components.

## 7 ACKNOWLEDGMENTS

The project on revising the test method for the climate carousel was sponsored by Nordtest.

# DURABILITY OF FAÇADES WITH CERAMIC COVERINGS – WHY THEY FAIL

E Campante[1] JOA Paschoal[2]
[1]Civil Engineer Brazilian Ceramic Center
[2]Materials Engineer Brazilian Ceramic Center São Paulo

**Summary: This work is based on the most common pathological descriptions which occur in façades with ceramic coverings, to develop a method for analyzing which allows causes to be determined and courses of action to be proposed which, once implemented in the project, execution and maintenance, can avoid such problems from appearing.**

**The article discusses the concept of durability and service life, as well as the factors which affect the parameters used when a designer defines the projected design life, along with the procedures required to for this to become the real service life of the ceramic covering sub-system.**

**The work in this study was carried out in São Paulo - Brazil, where a residential building was studied where the ceramic coverings presented tile loosening, and where we attempted to apply the aforementioned concepts. The study describes preventive and corrective actions for the pathological manifestations observed.**

**Keywords: Durability, Fail, Facade, Covering, Ceramic tiles**

## 1 INTRODUCTION

The main reason that buildings in Brazilian cities have had ceramic coverings for decades is mainly their high level of resistance in varying climatic conditions, and the material does not usually present high levels of wear and tear over time.

The fact that ceramic coverings last longer is measure by Shohet & Laufer (1996). When they compare this type of covering with others, such as cement-based mortar, synthetic mortar and stone, a clear superiority of ceramic coverings can be seen when compared with mortar coverings, in accordance with Table 1.

**Table 1: Estimates of service life of various types of external coverings in different environments (Shohet & Laufer, 1996)**

| Environment category | Cementitious stucco | Synthetic finished stucco | Ceramic covering | Stone |
|---|---|---|---|---|
| Non-corrosive | 10-15 | 12-15 | Over 15 | over 25 |
| Corrosive | 5 years | 8-12 | 10-15 | over 25 |

This capacity to remain unaltered over e period of time, associated to other capacities listed by Medeiros (1999), such as: ease of composing geometric patterns, easy cleaning, good resistance to humidity, general satisfactory performance and low maintenance costs, are the main reasons for using this type of covering on buildings, especially at sea-side locations.

Ceramic façade coverings are taken to be: a monolithic set of layers (including the plaster layer) adhering to the building support base (brickwork or structure) whose outer covering is composed of ceramic tiles, laid and grouted with mortar or adhesive material", (Medeiros, 1999).

Understanding the various properties of each of these components and the behavioral interfaces between them is fundamental for avoiding the appearance of pathological manifestations, faults, which can occur at a very early stage, in accordance with an analysis by Campante & Sabbatini (2000), which saw that 50.9 % of the buildings studied showed tile loosening on the façade within 5 years of use.

## 2 PATHOLOGICAL MANIFESTATIONS IN FAÇADE CERAMIC COVERINGS (FCC)

Pathological manifestations in FCCs is understood to mean situations where, at a certain moment in the working life the product fails to present the expected performance, in other words, no longer complies with the functions for which it was designed and no longer meets the needs of the users.

These functions can be summarized as: protection of the building's sealing elements, help the sealants to fulfill their functions (acoustic and thermal isolation, proof against water and gases, etc) providing a uniform finish to the sealing elements as a final finish, providing aesthetic functions, for economic value and use of the building.

This means that the main pathological manifestations which occur in FCCs can be classified in three categories: efflorescence; cracks and fissures; and loosening.

Efflorescence is taken to mean the formation of crystalline deposits on a surface due to physical, chemical and physical-chemical actions. Normally, it is caused by the movement of water through the porosity of the FCC payers, transporting alkaline metal salts (sodium and potassium) and earthy alkalis (calcium and magnesium), which are soluble or partially soluble in water, until they appear on the surface after the water evaporates.

The cracks and fissures are the loss of integrity in ceramic component's surface, which can also cause loosening of this component from the ceramic covering sub-system. Cracks are defined as a total rupture of the ceramic body in two or more parts after fixing, whose size is above 0.5 mm. Fissures are opening of 0.01 mm to 0.05 mm of the glazed finish on the ceramic tile. (Sabbatini & Barros, 1990).

The loosening of tiles means the process of failure between the ceramic tiles and the fixing layer, to the latter and the substrate, characterized by the separation of sections of the covering at points or in general, caused by the appearance of tensions which are greater than the capacity for resistance of the adhesive links.

Considering the consequences (economic and personal risk), this could be considered the most serious of FCC. This is because of the effects of this type of problem: a ceramic tile weighing 250 g falling from the 10$^{th}$ floor of a building has the same destructive power as a projectile from a firearm when it reaches the ground (Tan *et al*. 1994).

most of the pathological manifestations which occur in FFCs can be attributed to several factors which occur at the same time. This means we need to carry out a hierarchical analysis starting by observing the defect, then discovering the immediate cause, then its nature, or secondary cause, and arrive at the origin of the problem, or primary cause, as seen in figure 1.

| | |
|---|---|
| Problem perceived | DEFECT or PATHOLOGICAL MANIFESTATION |
| 1st level of observation | IMMEDIATE CAUSE |
| 2nd level of observation | NATURE |
| 3rd level of observation | ORIGIN |

**Figure 1: Hierarchical analysis of pathological manifestations in FCCs**

Applying this line of thought to analysis of tile loosening problems starts with the observation pf the **defect**, followed by a search for the first cause, or **immediate cause,** in this case the fault in adherence between the ceramic tile and the fixing mortar. Then we seek the secondary cause, the **nature** of the defect, which could be, in this hypothetical case, the application of the tile onto the mortar too long after the mortar has been applied. The we should seek the cause of this problem, and reach the **origin** of the defect, in other words, deficiencies in the execution of the work, which could be caused by lack of training and/or control (or even an error in the specification of the fixing mortar).

According to Cheong (1992) the analysis of the loosening could lead to four distinct natures: adhesion failure between the ceramic tile and the fixing mortar; lack of adhesion between the fixing mortar and the substrate; faults in the substrate layers; and a hollow sound in the ceramic tiles when hit.

For Sabbatini & Barros (1990) the main factors associated to the origin of tile loosening are: deformation in the bases (brickwork/structure) due to settling of the building after occupation, flow in the concrete structure, which is not seen immediately and hydrothermal variations; faults in the control joints; inadequate mortar for plastering, laying and grouting and deficient base preparation.

One of the main causes of tile loosening is the change from the mechanical resistance offered by the various layers to the mechanical force actually applied. These forces come from movement in the FCCs, caused by movement in the building or changes to the conditions to which they are exposed.

For Medeiros (1999), there is also a fourth level. defined by him as the "Genesis" of the problem, which has two parts:

1. A lack of projects which account for performance parameters and which consider the requirements of the production process.
2. A lack of technological understanding of covering production by the entire production chain, starting with the engineers and architects and going down to the tile layers.

## 3 THE CONCEPT OF DURABILITY AND APPLICATION TO FCCS

In the FCC sub-system, quantification of durability takes on fundamental importance for two reasons: firstly because the use of this data allows us to define the economic viability of using certain types of component and materials. The second reason is allowing for comparison of the presented durability with other alternatives, so that we can choose the best one for the conditions seen.

Establishing durability of a subsystem means first understanding the deterioration mechanisms associated to each of the FCC components, and from there suing the same concept for the subsystem, analyzing the degradation mechanisms. In other words:

**Deterioration** is a term associated with the **components** of the subsystem, and

**Degradation** is a term directly linked to the **subsystem** as a whole

For CIB (1983), durability must be studied from four different aspects:

I. material used, which are classified on a scale from perishable to non-perishable, according to the level of deterioration during use;

II. project, which will also be analyzed using a scale from bad to excellent, according to factors considered for the material in question;

III. conditions of usage, which must be classified from severe to weak;

IV. maintenance, which must be evaluated on a scale of frequent to non-existent.

These aspects account for the subsystem material, and the subsystem as a whole. This is explained by the fact that in determining durability of a subsystem such as FCCs, we must understand the interface mechanisms between the various components, which is still a relative unexplored area.

## 4 CONCEPT OF WORKING LIFE AND APPLICATION TO FCCS

Service life, for FCCs , can be defined as:

*The period of time where you can maintain the properties that allow it to carry out the functions for which it was designed, taking into account the remaining time of use and the estimated costs of maintenance and substitution.*

When talking of FCC Service life, two parameters must be defined: design life (DL) and service life (SL).

Design life (BSI, 1992) can be defined as the pre-established value given by the designer which should be aimed fro during usage. This will be the basis for choosing materials, techniques of subsystem execution, maintenance actions and costs to be taken on by the user.

There are a series of conditions for DL, among which the life cycle of the building, which will define the period of time required for the subsystem to maintain its original characteristics. This means, in general terms, that FCC DL must be specified as the same as that for building substrates and sealing systems. However, DL of the subsystem must not be confused with that of its components. In Table 2 some criteria are listed which defined the different values for the subsystem components.

**Table 2: DL estimates for FCC components**

| Subsystem component | Classification of importance in the subsystem | DL Class |
|---|---|---|
| Fixing layer | A1 | 1 |
| Ceramic Tile | A2 | 1 |
| Grouting | B | 2 |
| Expansion Joints | C | 3 |

The table above classified the diverse components in accordance with the effects of their faults. This means that a component classified as A1 would cause subsequent failures after its own. What we are trying to establish is a relationship between the various components; a failure in the fixing mortar would cause the collapse of the entire subsystem, causing the ceramic tiles to fall off. For this reason, its DL must be classified as 1, in other words the same value as the subsystem as a whole.

In order to make it easier for façade designers to take decision as to how to establish the different DLs for the FCC components, a ´proposal is summarized in Table 3. This means that a durability table can be provided for the FCCs, which can be used to choose the period of time that the subsystem must retain its initial characteristics as a result of the variables: Production project, Subsystem component materials and Procedures for carrying out the subsystem;

**Table 3: Durability estimates for FCCs based on DLs**

| **Quality levels of variables** | **Levels of durability** | | | | |
|---|---|---|---|---|---|
| | A | B | C | D | E |
| PPP | 10 | 7 | 6 | 4 | 2 |
| MAT | 8 | 6 | 4 | 3 | 1 |
| EXE | 12 | 8 | 7 | 6 | 2 |

Where: PPP: Design for Production

MAT: Material of the subsystem components

EXE: Procedures for subsystem execution

Level A: 25 to 30 points ⇒ over de 25 years

Level B: 20 to 25 points ⇒ 20 years

Level C: 15 to 20 points ⇒ 15 years

Level D: 10 to 15 points ⇒ 10 years

Level E: 5 to 10 points ⇒ less than 5 years

The points described in this table are obtained from an analysis of each of the three basic factors listed in the table. As a result of the quality level of each of these factors, we can define how long the FCC should be expected to last.

After defining the level of influence of each of the variables, each one is given a weight, which are defined in Tables 4, 5 and 6, as follows.

**Table 4: Maximum weight attributed to the factors associated to the PPP variable in defining the FFC subsystem durability**

| INFLUENCING FACTORS | MAXIMUM WEIGHT | INFLUENCING FACTORS | MAXIMUM WEIGHT |
|---|---|---|---|
| **Analyses and definitions** | **5** | **Specification and details** | **5** |
| Physical feasibility | 0,2 | Define base and substrate preparation | 1,0 |
| Economic feasibility | 0,2 | Define substrate joins and reinforcement | 1,0 |

The service life is defined by BSI (1992) as the period of time during which a component or construction maintains its characteristics, exceeding the users' requirements as to operation, maintenance and repair, in other Word, the period during which the subsystem **really** maintains its properties up to the minimum acceptable level to meet users' expectations

The SL of a subsystem is limited by what ISO (1997) called the deterioration to which components that cannot be substituted are subject. Deterioration itself may not require substitution of components that can be substituted, however, in some cases, substitution may be so expensive that it may affect the SL of the subsystem as a whole. This is often the case with FFCs.

## 5 CASE STUDY

A high quality residential building located in a middle to high class region of the city of São Paulo, with 20 floors and a penthouse. This case study began with a request from the construction company for an evaluation the cause of tile loosening which was occurring mainly in the front and rear façades while it was being handed over to the owners.

Diagnosis began with an on site visit, which showed the location of the building. The main problems with loose tiles were occurring on the northeast (frontal) and southwest (rear) façades, with the latter most affected, as can be seen in figure 2.

**Figure 2: View of the façade affected by loose tiles**

During the inspection, high winds were detected around the area due to the relatively isolated position of the building on a hill. The most affected façade was also subject to high quantities of direct sunlight in the afternoons. it was also noted that no type of expansion joint was used, either vertical or horizontal, as can be seen in figure 3. There is also a lot of cracking in the grouting mortar, as shown in figure 4. Another fact observed was that many ceramic tiles which had fallen off showed a lack of contact with fixing mortar on the contact side.

**Figure 3: Evidence of lack of expansion joints on the right rear façade.**

**Figure 4: Evidence of cracks in the grouting between tiles.**

Interviews with the people responsible for the building did not provide enough information on the stages of execution and material used to apply the ceramic tiles, as the construction company does not exist any more. We could only determine that the tiles started to loosen and fall soon after the building had been delivered.

Even without access to all of the information, we attempted to define the **Nature** and **Origin** of the problem from the interviews and inspection results. From the point that the problem has been ascertained, we reach the 1$^{st}$ level of observation: the **Immediate Cause** of the problem, the lack of adherence between the tile and the fixing mortar shown by the lack of filling on the tile contact surface.

Moving on the next stage, determining the **Nature** of the problem, the following factors were found:

- the tiles were applied outside the appropriate period of mortar application;
- the tiles were applied without using the double fixing principle;
- the tiles were applied to a surface subject to severe weather conditions, such as: high levels of sun lights, high winds, and no adequate protection;
- base deformations;
- ceramic tile humidity expansion;
- retraction during drying of the fixing mortar;
- fatigue in the links between the fixing mortar and the ceramic tiles due to thermal shocks.

Once we had analyzed the **Nature** of the problem, we studied its **Origins:**

- inadequate choice of fixing mortar, indicated fro internal use and used o the façade;
- use of plaster and grouting mortar with inappropriate properties for the conditions (high level of retraction during drying and low capacity to absorb deformations);
- lack of expansion joints which could dissipate tensions to which the FCC was subjected;
- use of inadequate ceramic tiles, with high levels of absorption which required mortar with high levels of water retention; and
- use of inadequate fixing techniques for the type of tile used, with ceramic tiles with swallow-tail studs were applied using the final layer technique, which did not provide adequate filling of the tile contact surface.
- deficiencies (or lack of) execution procedures;
- lack of tile application training;
- deficiencies (or lack of) control criteria for carrying out services and accepting works;
- project deficiencies in the FCC subsystem, which did not allow for correct quantification of deformations to which the base would be subjected;
- high grouting mortar permeability which allowed d for tile humidity and humidity expansion;

Even reaching a series of diagnostic hypotheses regarding the problem, it was still not possible to determine the probable cause. We still had not examined the possibility of humidity expansion of the ceramic tiles above that permitted by the standards. Therefore, we turned to a laboratory to test the tiles, and the result was outside the range permitted by the NBR 13818 standard (ABNT, 1997): 0,.3 mm/m, against 0.6 mm/m. This would not recommend the use of this component for external purposes.

## 6 FINAL CONSIDERATIONS

This study has enabled us to discover the origins of the FCC loosening, and therefore establish how the project parameters, the building production procedures and the maintenance operations could influence the durability and service life of this subsystem, also leading to pathological manifestations. Within the project parameters, it is important to consider:

- Evaluation of the conditions which the façade will be exposed to, through a detailed study of the environment in which the building is placed, to determine the possibility of thermal shocks, freezing, levels of acid rain, wind, atmospheric pollution and others..
- Analysis of the façade structure: this stage should include variables such as geometry, forms, building type and level, surroundings, etc.
- Study of the ceramic tile typology: critical study which includes the parameters related to the choice of type of tile, including direct and indirect cost, history of problems, characteristics and properties of the ceramic tile, prior definition of the need for joints and types of fixing material.
- Evaluation of structure deformation: deformation over time, using variables such as: concrete deformation module, rigidity of the structure an its elements, slow deformation (flow), sequence and construction methods used in building the structure.
- Evaluation of external brickwork: technical analysis of the need to prepare the base and substrate for the FCCs, evaluating potential intrinsic movement of the sealing brickwork, mechanical resistance, absorption capacity and regions which could provoke tension in the FCC layers and influence the technical definition of the base preparation, plaster reinforcement and control joints.

The execution procedures should consider the most common errors which found during the field studies and correct them:

- Fixing to warm surfaces.
- Usage of incorrect fixing mortar.
- Fixing to contaminated surfaces.
- Spreading of fixing mortar over large areas.
- Dilution of fixing mortar to provide greater yield.
- Fixing over construction joints.
- Fixing on different materials without using joints.
- Fixing on dry fixing mortar.
- Fixing to damp surfaces.
- Fixing too fast.
- Fixing to inadequate bases.
- Incorrect spreading of mortar (without trenches or deformed trenches).
- Inadequate joint cleaning.
- Adulteration of products to increase profits.
- Substitution of the fixing mortar for another mortar, different from that specified for the project, generally inadequate for the climate and/or type of use.
- Omission of steps in fixing to gain time.
- Lack of works supervision
- Inadequate execution of the grouting and/or expansion joint layer.

As to the maintenance / use, this can be summarized in the following aspects:

- Use of unadulterated cleaning products.
- Clear maintenance procedures for inspection and possible exchange of subsystem elements which could be compromised, such as grouting and filing material in the expansion joints.

At the end of this study, we can reach two conclusions, the first of which is the importance of a construction log, or access to important documents which show the history of the building construction and the design of the FFC subsystem, such as: invoices, works logs, physical chronograms set and attained, service contracts, tests for materials received, “as built” projects, and others for diagnosing the problem.

The second is the recuperation of FFCs can be very costly. These costs include rental and installation of better rocker arms (to make services easier), the use of better quality material, low productivity because of small teams to better control the services carried out, difficult in finding ceramic tiles similar to those used during the works, labor suits, and others.

# A Solution To Environmental Pressure And Housing Convenience

**H van Nunen & NA Hendriks**
**Eindhoven University of Technology, The Netherlands**

**Summary**: **The growing demand for convenience in housing is increasing the pressure on the environment. To reduce this pressure it will be necessary to bring the technical life span and the life expectancy into harmony. Change of life span at the level of building component can provide a solution for this.**

**Within this scope, a research project is being conducted about the environmental pressure of buildings, in accordance with the residents' demands. With the technical knowledge of today, one is capable of producing products with a long life span. Improved materials and repairing techniques pay their tribute to this. However, as a result of the growing public purchasing power, building components are often replaced before it is a technical necessity, by which the environmental pressure will increase. To avoid this, the choice of materials has to be optimized. To make a well-considered choice in this, it has to be evaluated what will be the most efficient way to use materials throughout the entire life span of the building. In this assessment, the materials will be evaluated with LCA-techniques. Problem with most of these techniques is that life span is regarded as fixed specification, while life span is the aspect that is most influenced by variables. An example is the early replacement of building components, before their technical life span is over. Then questions arise such as how does this contribute to the overall environmental pressure produced by that building, and are there possibilities for the reuse of that component?**

**At the Eindhoven University of Technology (the Netherlands), a prototype building has been built according to the so-called IFD-technology (Industrial, Flexible and Demountable) that connects to the problem described above. This project is a collaboration between a housing association, building contractors and the university, where the building performances (now and in time) are being researched.**

**Especially flexibility and freedom of layout make it possible that changes in time are easily conducted without huge pressure on the environment. It results in a building according to the residents' wishes, but with limited environmental pressure for both the building components and the entire building.**

**Keywords. convenience, environmental burden, Life Cycle Assessment, life span, weighing model.**

## 1 INTRODUCTION - CONSTRUCTING

### 1.1 Constructing in general

Constructing still is an activity involving the employment of a lot of people, both during and after the construction period. It is a necessity to provide in sufficient living accommodation. Predictions (by the Dutch public housing department, Directoraat-Generaal van de volkshuisvesting Directie bestuurdienst, 2000) indicate that until the year 2004, 81.000 new buildings have to be constructed annually in the Netherlands. Throughout the years, constructing has changed from being a necessity to a way of providing facilities. It gives people a chance to distinguish themselves from other people, just by adding a personal touch to their home. In other words, constructing is an activity we cannot live without.

In Europe, there has been an enormous growth of the production of buildings since the end of World War II. At first it was to replace the destroyed buildings in war, but at a later stage also the habits of the people changed. In the 1960s it was normal that families had eight or nine children living under one roof. Sometimes people stayed to live there, even when they got married. Nowadays families are much smaller and children tend to move out much sooner. Health care has improved through the years, so that people are able to keep living on their own for a much longer period. Consequently, the demand for buildings keeps increasing, and now the world is full of people that all need homes. This demand for buildings will remain.

We do have a considerable stock of houses, but most of those are post war buildings that don't comply with the occupants' wishes. They are too small and do not have enough possibilities, for which reason they are mainly rented in the cheaper sector. These buildings are destined for major improvements to comply once more to the occupants' wishes. The most drastic measure is demolition. Other initiatives are IFD-today (see chapter 4) and the project 'The flexible breakthrough' (Hendriks, N.A., *et al*. 2002), (Vingerling, H., Hendriks, N.A. 2002).

### 1.2 Constructing and the environment

Environment-oriented thinking is growing in importance. At environmental conferences as in Kyoto (Japan) and more recently in Bonn (Germany), attempts were undertaken to come to joint agreements for reducing the damage to the environment. Contrary to the lack of results, those worldwide meetings are important because the subject of reducing pollution is again under discussion. An issue that is on the agenda every time is the reduction of the carbon dioxide equivalents. To reduce the green house effect, measurements have to be taken in different sectors, including the building sector. For the Netherlands, a reduction of the carbon dioxide level of six percent compared to the level in 1990 has to be achieved. The growth of the world population and the growth of prosperity make it necessary to reduce the environmental burden. At the same time this growth makes it harder to comply with the goals.

As mentioned in the introduction, constructing is an activity that always will exist. That is why the construction sector is one in which environmental profits have to be optimized, and the environmental burden has to be made as small as possible. One can make the difference between the materials used in the building (mainly concerning constructing and demolishing the building) and the use of the building. In case of using a building, energy-use is taken into account as well as material flows originated by maintenance and renovations.

### 1.3 Constructing and conveniences

The wishes of occupants are getting more and more important. In the early 1950s and 1960s, one had to be glad to have a building at all, nowadays every occupant has his own wishes and demands. People evaluate their houses by the conveniences they provide. This is a troublesome subject because what does convenience exactly mean? This will receive ample treatment in chapter 3.1.

Not only buildings, but also the interior and the use of building and interior is due for alterations. People are getting more and more wishes concerning the use of their homes. Examples of this can be found in visible components such as kitchen and bathroom. But also less visible components such as installation and constructions are subject to alterations. More and more, these components are being replaced by other, more modern and sophisticated, components. This increasingly happens before there is a real (technical) necessity to change the component.

Because of these wishes for convenience, replacement of components is carried out a lot. When reviewing the use of materials and putting a burden on the environment this will conflict with the replacement of components. At a time when the attention for the environment is increasing, a contradiction is forming: more resources are being used while the goal is to reduce the environmental burden. To take the environmental aspects into account, there has to be more understanding of the materials that are being used. A weighing model has to be found for the choices of materials. In this model, it isn't the calculations that are innovative, but the way they are used and the way the input is gathered that is the most important.

## 2 WEIGHING MODEL

The weighing model has to support the choice of materials or the choice of building concepts. The use of materials is one of the main issues in this model. During the life span of a building, alterations have to be made. These alterations will be taken into account when weighing the design. That way the result will be an overview of the complete life span and not just a random indication. Because the whole life cycle is taken into account, the basis on which the choices are made will be as accurate as possible. Different Life Cycles (LC's) can be related with the model: Assessments (LCA), Costing (LCC), Management (LCM). This survey is limited to the environmental aspects by means of Life Cycle Assessments (LCA). The weighing model has a huge number of variables, the most important of which are described below.

### 2.1 Building performance

Formerly the materials that were to be used in a building were exactly circumscribed. With the introduction of so called 'performance concepts' this became obsolete. Now products are circumscribed by the required performance, and the way the product fulfills this performance does not really matter. Of course it is possible to add extra demands or circumscribed materials to the performance. Which aspects of performance have to be fulfilled is not completely written down. An example of the aspects of performance is put in ISO 6241(ISO 6241, 1984). In this standard are fourteen aspects defined. These fourteen aspects of an international standard have been put in the Dutch Bouwbesluit (Building Decree). The fourteen performance aspects are divided over five performance fields: safety, utility, health, energy and environment.

### 2.2 Materials

Choice of materials is one of the manners to influence the environmental burden. Extracting raw materials, production efforts, and deterioration of the material are examples of it. Choice of the materials is a determinant for the environmental burden of a building. The way of combining materials, exposure to external conditions and access to components for maintenance have a huge impact on the environment. If demountable joints are being used, the materials can easily be separated. Demountable joints also make it easier to work during maintenance or replacement.

### 2.3 Lifespan

The life span of components is an indication for how long the component can be used. The disadvantage is that lifespan is not a fixed item, but can vary through time. Moreover it is not clear which life span to take. There is a difference between the technical life span, functional life span and economical lifespan. The last two life spans, functional and economical, are often regarded as one. The functional lifespan indicates the period for which a product is desired in a particular situation. The technical lifespan indicates the period that a certain product can fulfill its function. The technical lifespan is much easier to define than the functional lifespan, because the functional life span is much more subjective. This is because the technical lifespan is caused by physical processes, which can be estimated more easily. Life span is one of the bottlenecks within this research.

### 2.4 Use

During the use of a building, the energy consumption and the measures during use (maintenance, replacements) are causing a considerable environmental burden. This is caused by the early replacement of components, but even without these replacements the use of a building causes a burden. In some cases the environmental pressure during the use of a building will be much higher than the initial environmental burden that (will be) caused by constructing and demolishing the building. The alterations in the building are the greatest sources of environmental burden. Installing components that are replaceable in a demountable way can reduce this. The necessary replacements (whether technically necessary or functionally necessary) can easily be conducted without a lot of breaking and cutting. The dismantled components are then ready for reuse or disposal.

Office buildings are much more liable to alterations and for that reason they then have a relatively higher environmental burden during use. The weighing model concentrates on the building of houses, because the market for houses is bigger. However, this does not mean that the weighing model will not be suited for office building as well.

Consequently, the components used and the way these components are placed in the building influence the environmental burden. The applied dimension of the materials is important, in particular the places where connections are made. Construction in that case, goes back to the 196s with construction rules such as patterns and design rules. This does not advocate going back again, but it points out that fixed positioning of joints may have its advantages. With today’s construction techniques (materials, tools, techniques), solutions for a lot of problems can be found.

### 2.5 Optimizing

‘Constructing will always be a necessity’ is one of the statements in the introduction. That different performance factors are required for building a home is clear as well. The performance factor that will be emphasized more than before, is the environmental burden. A couple of years ago, no one cared about the environmental aspects of constructing. But with increasing environmental awareness, this changed. This resulted in the wish (or even demand) to be able to judge a building on its environmental performance as well as on any other kind of performance. With this assessment method, buildings or components of buildings can be compared with each other in such a manner that their environmental burdens and the differences between them become clear.

To make this comparison possible, an assessment of the burden on the environment must be made. Worldwide there are various methods available. A method that is widely used is the Life Cycle Assessment (LCA). The Center of Environmental Sciences of Leiden University (CML) has developed an evaluation method on this subject (Huppes, G, Schneider, F, 1994). To make this method accessible to more people, there are computer programs to support the evaluation. One of these programs is Sima Pro (Pré consultants, 2001). The CML-method is used as a basis for this program. To enhance this method, it is customized for use for architects, constructors and principals in a program called Eco Quantum (Stichting Bouw Research (SBR) and Stuurgroep Experimentele Volkshuisvesting (SEV), 1999). It combines materials into building products. The input is easier to collect this way. The underlying method is the same as with Sima Pro, it even uses the same database. In Eco Quantum the database is much smaller than in Sima Pro and only consists of building materials. This makes it sometimes difficult to put a whole building in the program, because sometimes a product is not available in the database. Sima Pro, on the contrary, has a large database (actually a lot of databases) and has the opportunity to add materials. Every (raw) material is inserted into the database and components can be put together by using these materials. This makes the program suitable for research, but less suitable for the average use by architect or constructor. These methods are suitable for computing fixed data. Every method has its own (dis-)advantages. The output that will be available is important, but the program will provide for that. Once the specifics of the method are known, one can interpret the outcome. However, more important is the input of the program. The input (i.e. scenarios) on which the environmental burden is based is not very fixed when regarding a building.

For optimization, the results of a LC-calculation are taken into account. However, it is not the results of the calculation that are new, but the input used for this calculation. Different aspects form the quality of the building. The extent of conveniences has an influence on the appreciation of the building. The combination of weighing the environmental burden and the desired convenience has to lead to the choice of building(type), detailing of the building and alterations during the entire lifespan.

The scenarios, materials used, and all the assumptions over a long time must be described. There lies the challenge for getting a really accurate Life Cycle Assessment.

## 3 THREE BOTTLENECKS

To achieve a complete weighing, a lot of aspects are necessary. In the previous chapter some of them are mentioned. Before the weighing of the environmental burden becomes available as a 'tool', there are some bottlenecks that have to be widened. These three bottlenecks (conveniences, lifespan and LCA-calculation) will now be illustrated.

### 3.1 A closer look at conveniences

Contemplation of the environmental burden of a building is possible, although there are some obstacles that make it hard to find the right approach. Different techniques, calculation methods and databases are possible to use. To work with these methods the input has to be known. But that is also the crucial question: what does one want?

When the materials are known, then this can easily be calculated. The real question lies before this point and is about products and how to handle the different life spans of products. Are they being used for the full life span, have they been replaced before, or have they even been used longer than the expected life span? An accumulation of these choices doesn't make it easier to predict the environmental burden. This will be dealt with further on.

The influence that the occupant has is enormous. Today it is not the technical lifespan that *indicates* when something has to be replaced, but it is the occupant that *decides* that the (functional) lifespan is over. This behavior is strongly influenced by trends, society and other opinions. This is something that is hard to predict and is linked to behavioral sciences. Their contribution is essential to predicting a probable scenario.

In this paper, the expression 'convenience' is used to indicate the occupants' influence on the building. The question remains what convenience is. It is something everyone understands, but few can give a solid definition. It seems that convenience is when something performs better than the standard. Buildings with 'more' convenience are the isolated buildings for example. When buildings are altered, one is trying to bring in more convenience as well. Convenience can be associated with providing more than standards demand or more than one is used to having at the moment.

Another aspect of conveniences is that they are scaled. It is possible to have 'more' or 'less' convenience. Whether this is only a choice of 'more' and 'less' or if there are different classes is not clear.

The weighing model provides, a solution by describing the performance factors the building has. These factors indicate, among other things, the conveniences. The performance one demands of the building have different aspects within them: safety, usefulness, health, energy and environment. Convenience is a part of these criteria, although it does not become clear right away. In the standard ISO 6241 fourteen performance fields are described (fig.1). Understanding these performance fields, and therefore understanding the roles they fulfill, one can make assumptions about the quality of the building. This quality can then be translated into conveniences.

| **ISO 6241 Performance standard building principles for their preparation and factors to be considered-** | |
|---|---|
| 1. Stability requirements | 8. Visual requirements |
| 2. Fire safety requirements | 9. Tactile requirements |
| 3. Safety in use requirements | 10. Dynamic requirements |
| 4. Tightness requirements | 11. Hygiene requirements |
| 5. Hygrothermal requirements | 12. Requirements for the suitability of spaces for specific use |
| 6. Air purity requirements | 13. Durability requirements |
| 7. Acoustical requirements | 14. Economic requirements |
| | 15. (Environmental requirements) |

**Fig 1: Performance Fileds**

### 3.2 A closer look at life spans

Life span was mentioned before. It is one of the determining issues, perhaps the most determining issues, in making a statement about the environmental burden. Different life spans make the whole aspect even more difficult. But how does one incorporate several sequential life spans of a product? Replacement of building components is something that frequently happens during the use of a building. But what happens if a building can last for 50 years and a component can only last for 15 years. Will the component be replaced after three replacements? Will the last component be used for five more years? It will get even more difficult when the expected life span is not reached. Take a look at a product with a 15-year life span, but with a deviation of 2½ years. In figure 2 this is visualized.

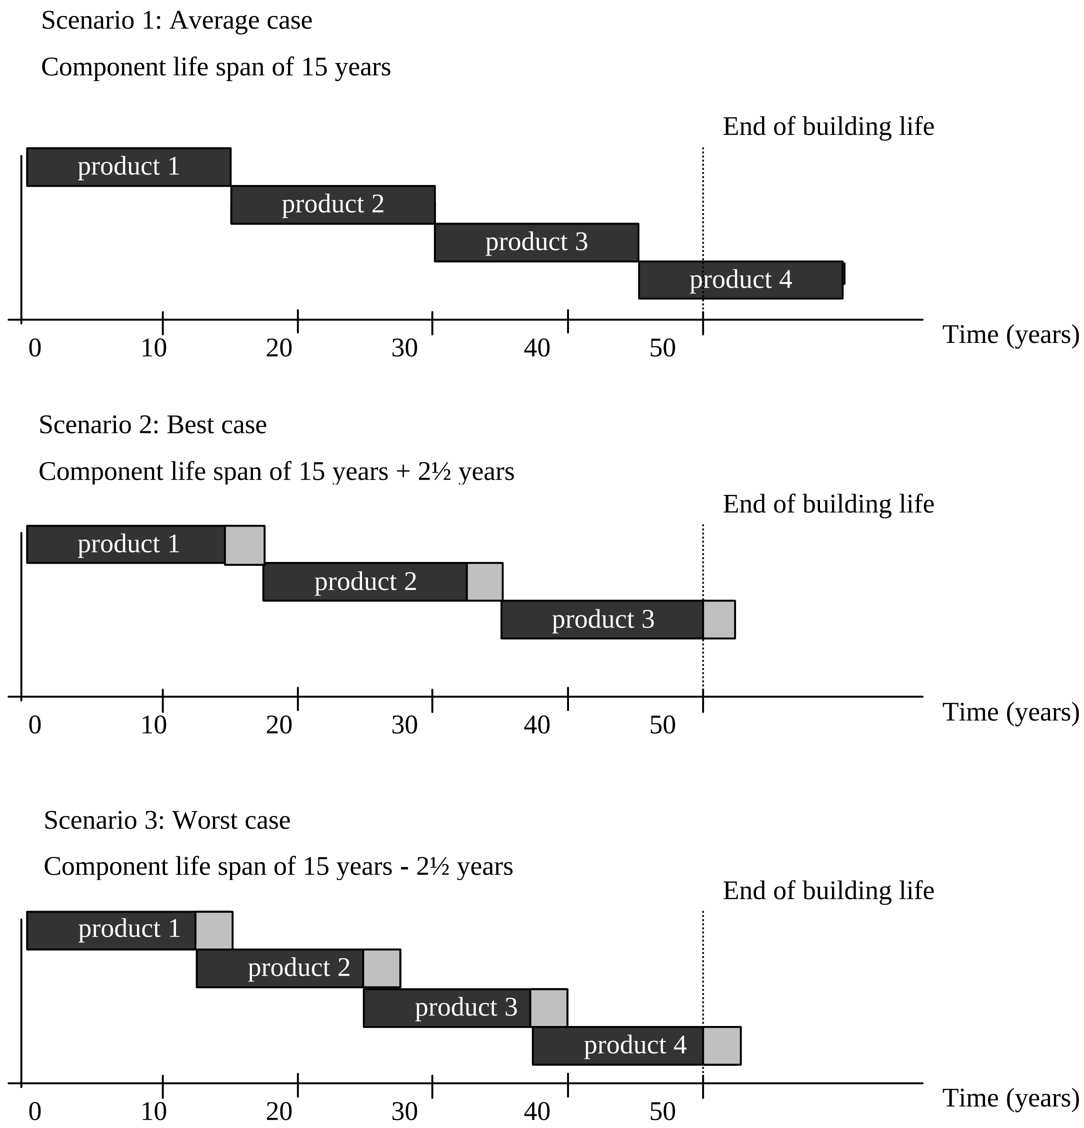

**Fig. 2: Three different life span scenarios**

Three different scenarios use different numbers of components. The average scenario uses four components, but at the end the last product has not been completely ‘used up’. The best scenario only uses three components and can still go on for a longer period. The worst-case scenario fits exactly, but it has to use four components to provide the function. In real-life situations, the various scenarios happen in random order, so to predict the life span of components is a problem.

The reviewed component can consist of smaller parts, of which each part has its own life span with the same difficulties as the component itself. The component is a part of the complete building and in that role defines part of the life span of the building.

Research into this subject is not new. The thesis ‘Deterioration characteristics of building components’ (Hermans, M.H. 1995) indicates how the performance of building components through time can be displayed. With this deterioration characteristic it is possible to connect environmental burden to the building.

To indicate the environmental burden of a component, the initial environmental burden ($M_i$), the end environmental burden ($M_e$) and the environmental burden during use ($M_u$) have to be known. Together they form the total environmental burden ($M_t$).

However, this $M_t$ does not include the time the component is used, and therefore an average environmental burden cannot be circumscribed. The length of the life span refers back to the problems mentioned above. Two components with the same $M_t$ can have a totally different average environmental burden because one has a life span of 10 years and the other has a life span of 20 years (fig. 3).

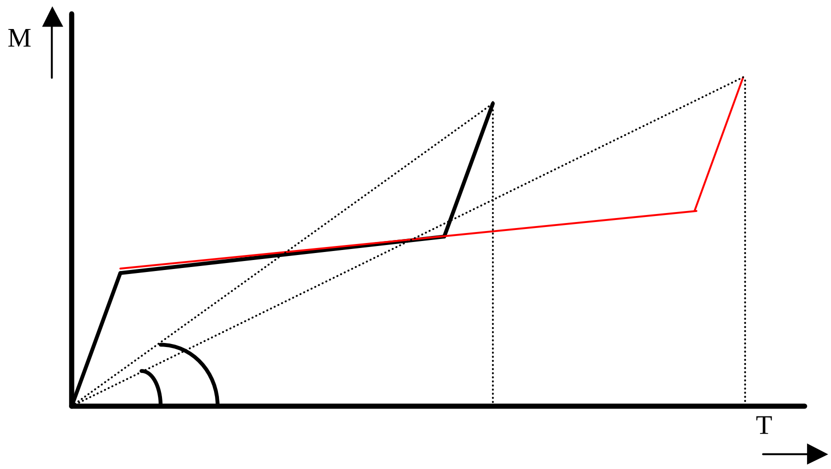

**Fig. 3: Equal environmental burden, different life span**

$M_i$ consists of the environmental burden raw materials have. This includes mining, production, transport, mounting/building. $M_u$ is divided into two separate parts, direct and indirect. Directly related to the component are activities such as painting, maintenance, cleaning. The environmental burden they have is directly caused by the product. The indirect aspects are visible when regarding a building as a product. A well-isolated façade will cause a much lower energy (= $M_u$) demand when compared to a glass wall. This can only be reviewed when the whole house is reviewed as a functional unit.

$M_e$ consists of demounting, transport and processing of waste (waste/reuse scenario's)(fig.4).

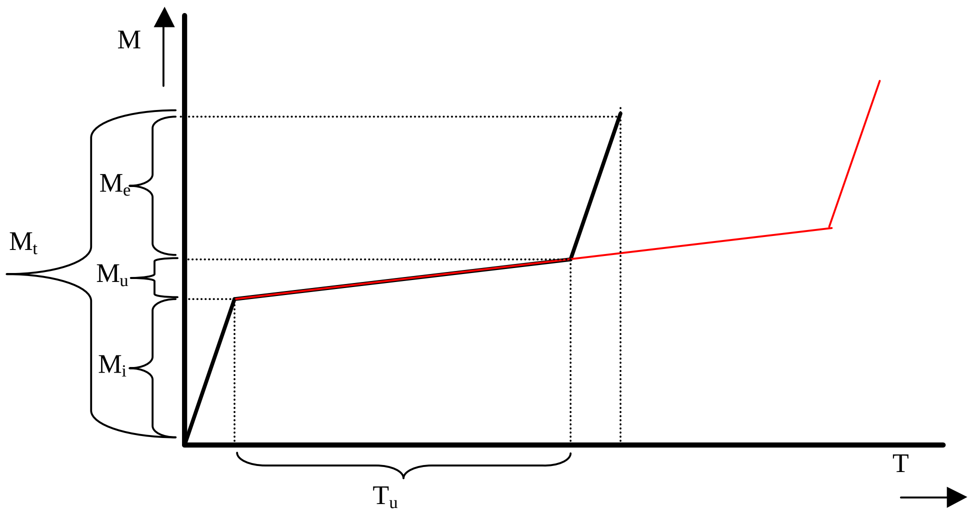

**Fig. 4: Aspects of environmental burden**

The environmental burdens of $M_i$ and $M_e$ are more or less to be known and because of the known impacts the environmental burden can be predicted. $M_u$ , on the contrary, is difficult to control. In the Netherlands, life spans of components are collected by practical experience (Huffmeijer, F.J.M, *et al*., 1998). These values are averages of the building practice and so far are not in any way scientifically defined values. In other countries, using practical values also approaches life span. The life span is of great importance when evaluating the environmental burden. The longer the life span is, the larger $M_u$ will get. However, the longer the life span, the lower the average environmental burden.

So far, only technical life span was regarded. Components consist of materials that are exposed to external conditions, and are degraded by those conditions. These conditions can be modeled and simulated and therefore be predicted. Physical aspects are the main influences in this.

Go Back Next Page

There is a growing factor that changes the replacement of components: humans. Often components are being replaced before this becomes technically necessary. When this is the case, it is said that the economical or function lifespan has come to an end. To avoid confusion, the expression 'functional life span' will be used in future. The determinant for this type of replacement are the wishes of occupants to change their home. When using the terminology that is introduced in chapter 3.1, it can be said that this is a wish for convenience. In most cases, the interior-related building components are the ones that are replaced, like kitchen and bathrooms. But also the appearance of buildings (facades, extensions, additions) is subject to early replacements. Combined with these activities it can be necessary to adapt other components (i.e. construction) to fulfill the desired change. Contrary to the technical life span, it is not quite possible to predict the period of a functional life span; the behavior of people is too unpredictable for that.

When knowing al these problems still it is desirable to make an assessment of the environmental burden. To make this work, the desired convenience has to be translated to performance fields. Using ISO 6241, convenience can be translated to actual performance fields. When expressing components in so-called 'convenience performances' it is possible to compare different components. 'Convenience performances' are circumscribed by technical performances, which in turn can be materialized. To materials, the life span and the environmental profile of the specific material can be attached. Today's problems are with defining the life span and the definition of convenience, so that the link can be made to used materials and finally the environmental burden.

### 3.3 A closer look at Life Cycle Assessments

Concerning the evaluation of buildings with Life Cycle Assessments (LCA's), there are a few practical problems. Keywords like allocation, classification and data reliability are often discussed. There are various methods that can be used to evaluate buildings and each of them has its own advantages and disadvantages. A real solution for these problems has not been found yet. The software programs have their own basic assumptions and they are included in the program. In the more sophisticated programs, these assumptions can be changed.

Analyzing the processes offers an opportunity to get to know the various influences of processes on the environmental aspects. Making an inventory of materials and processes indicates which emissions occur and what the total environmental burden is. This manner of analyzing is widely used in the industry, and with different purposes. LCA can be used in various situations:

1. non-comparable product studies (process related)
2. comparable product studies (comparing product A and B, both with an equal function)
3. product developing of different products (designing for a function)
4. strategic environmentally based goals (laws and regulations)

LCA's are about comparing products and/or processes to improve them. Especially at the level of a single product this is a fine tool for making decisions. All four of these types apply to LCA purposes within the building sector. (1) Non-comparable product studies concentrate mainly on processes during production and realization. (2) Comparable product studies are of importance when making design decisions such as materialization or building concepts. (3) Product developing studies can be compared with the studies of the building process, but in this particular case it focuses more at components and not at the building as a whole. (4) Strategic environmental based goals will within time be used by government to regulate environmental burden by demanding maximum values. At the moment these studies are used as internal means to set goals.

Within industrial processes this is comprehendable. Products have a life span of only several years, and life spans of five or ten years are mostly exceptions. When regarding the constructing sector, this is of a total different order. Buildings are constructed for 75 years or even longer. They consist of components that have shorter life spans, but they are part of the complex system a building actually is. This long period makes it hard to make statements about the environmental burden a building has during its whole life span. Despite these obstacles, decisions on environmental grounds have to be made. The existing LCA-methods can be used for this, but the input that is used when regarding a building is different to the ones used when regarding industrial processes. By means of the weighing model, the preconditions of an analysis are correctly given.

Not only the input is a bottleneck, the reliability of the data is a problem as well. When manufacturers make their own data it can be questioned whether it is reliable. The way the data are distributed is a problem as well. When data have to be compared, the origin of this data must be the same. Despite the problems, this kind of evaluation has a great future. Compatibility is a requirement that must be achieved in advance. Worldwide standardization of LCA makes it easier to compare components and/or buildings.

## 4 IFD-TODAY

### 4.1 System

The assessment of buildings, not only the performances we review today but on a broader scale (i.e. environment), will ask for a certain transition. Innovative ways of building make it easier to replace components by using simple connections or easily accessible places. In the Netherlands innovative construction methods are stimulated by a government program, called the IFD-program. This stands for Industrial, Flexible an Demountable constructing.

One of these ‘IFD-projects’ is IFD-Today. It is a collaboration between a housing corporation (Amnis, Utrecht), a contractor (Royal IBC), a fitting company (Stork Installatietechniek) and a knowledge center (Eindhoven University of Technology). The aim of this project is to provide a replacement of the existing postwar houses as described before. In this case the existing buildings will be demolished until the foundation is reached. On this foundation a new building will arise, but with a specific building technique. Especially in the soft grounds of the Netherlands, by reusing the foundation a reduction of costs and environmental burden is achieved. Instead of using concrete or brickwork (as used in traditional buildingconstruction), in the IFD-Today project a steel structure is used. This steel frame does not only provide the necessary strength and stability, it also works as a shaft for the piping and wiring of the building. Every part is transported to the building site as a component. That way the building activity turns into a mounting activity, and the construction time can be diminished. This results in shorter temporary housing to be provided by the housing company, less inconvenience for the neighborhood en less interest loss during the construction time. Another advantage is that all the components are mounted and therefore the flexibility of the building is large. When additions are wanted, a component can easily be removed or replaced. These advantages are not only present during the construction time, also during the use of the building it remains an Industrial, Flexible and Demountable building.

The steel construction spans from front to back, without any columns or bearing walls. This makes it possible to make different layouts of the building. In fact, it is also possible to define the size of the house yourself. Within the floors the complete piping and wiring is present. The top layer of this floor can be removed and the piping and wiring can be modified. This is all possible during the use of the building or when a new occupant arrives. It is even possible to move complete building separation walls. This is a measure, which can best be supervised by the housing company, but it is a real possibility. Mainly through its flexibility, the building can be designed at this moment and changed in due time without high costs or environmental burden to the kind of building desired at that moment.

### 4.2 IFD-Today as an example

The IFD-Today principles are realized in a prototype building that has been built in the ‘DuBo-park’ at the Eindhoven University of Technology (fig 5). In this park prototype research can be deducted. The aim of this prototype was to detect if, with the new techniques, it is possible to construct a building that complies with the requirements.

**Fig 5: Prototype at Eindhoven University of Technology**

The building consists of four modules of 7,20m x 11,60m each, and was realized in only six weeks. Because various tests were conducted four different facades and two different floors were used. The possibilities of finishing the building with different claddings are shown this way too. These facades are more or less in accordance with the IFD-principles. They were, however, not the main issue of the project. The floors and the structure are the main issues. The IFD-Today prototype serves as a test site for many researches, varying from organization profiles to contruction matters. In this project it serves as a reference building for an environmental optimized building.

It is to be expected that adaptations in due time can be realized without lot of difficulties. Because of the existing flexibility the wishes of the occupants (convenience) can easily be achieved. This flexibility is possible by using different techniques and materials from those used in traditional building. Instead of a concrete structure a steel one is used. Steel has a higher environmental burden than concrete, but less material is used. These differences are reviewed with LCA-techniques.

The development and realization of the prototype indicates that there is interest in constructing buildings that are easily adapted. Prerequisite known factors are the life span expectancies (both technical and functional); these will be determined using scenarios. These will be made for this project. Then the weighing model can be used and finally the goals of the IFD-today project concerning the environment can be checked and compared to other buildings. Further developments can be pointed out as well.

Go Back

## 5 CONCLUSIONS

The way a building is designed, in terms of type and materials, determines the environmental burden of that building. Possibilities to make adaptations during the life span increase the burden so that the final environmental burden can be determined. The presumption is that changing the way of constructing improves the quality of the building through time, especially when the environmental burden of a building is considered. By using other techniques than currently, buildings can be more easily adapted to the wishes of the occupants.

To assess this presumption a weighing model will be developed. The different aspects that are of importance (performance, materials, life span, conveniences, LCA, replacability, optimizing) will be part of this weighing model. The internal relations between different inputs (described as convenience at this moment en through time) and the interpretation of the exploitation periods (life span) are most important. This has to be translated to (existing) techniques to conduct a Life Cycle Assessment. When this link is made, buildings or building components can be compared. This comparison can facilitate designers and decision makers in their design choices.

In the case of this research such a comparison will be made between IFD-Today and a traditional Dutch home. The presumptions made in advance can then be checked and the IFD-project can be optimized.

Weighing between buildings, building types and materials is possible and the option with the lowest environmental burden, that satisfies the conveniences of the occupants, will be built. By doing so the contracting sector will achieve their part of the total reduction of environmental burden.

# Landscape Evaluation And Improvement Of Sidewalk Concrete Blocks Deteriorated Under The Cold Environment

**Y Hosokawa**
**Faculty of Rural Engineering Kitasato University Japan**

**Summary: The concrete products in the sidewalk, like curb block, gutter, cover of gutter, and so on, were often deteriorated by not only the freezing and thawing action but also the salt action of scattering the deicer salt to melt snow and ice on the road under the cold environment. Sidewalk photographs with four ranks from new to deterioration were retouched by the computer graphic technology using the actual condition of road with sidewalk. From the landscapes evaluation questionnaire by four sidewalk photographs for 407 examinees, obviously, the sidewalk with deteriorated curbs indicated the worst rank and the improvement of curb concrete quality needs to keep a driving-safety. In the road with or without scattering the deicer salt, the curb blocks with 39.5, 44.5 and 49.5% of W/C and with or without the treatment of waterproof agent on curb's surface were tested in the actual road. In spite of W/C difference and the waterproof agent, there were many popouts on surfaces of curb blocks in the road scattered the deicer salt in wintertime. The countermeasure to improve the sidewalk landscape must be studied about the durable concrete products.**

**Keywords. Cold Environment, Curb Concrete Block, Freezing And Thawing Action, Landscape Evaluation, Salt Action**

## 1 INTRODUCTION

The concrete products, like curb block, gutter, cover of gutter, and flowerpot in the sidewalk, were often deteriorated in the snowy area of Japan. The phenomenon of concrete deterioration indicates surface cracks and scaling, popouts of mortar and aggregate, many horizontal cracks, and block failures. These concrete deterioration are caused by not only the freezing and thawing action but also the salt action after scattering the deicer salt under the cold environment. The staff of road maintenance said the deterioration of sidewalk concrete blocks has increased by scattering the deicer salt remarkably. Since the regulation to control the utilization of car-tires with studs on the road was announced in April 1991, they have maintained the snowy roads by not only taking out of snow from the road but also scattering the deicer salt. The deicer salt scattering is treated mainly the road where cars were easy to skid on compacted snow and ice on the slanted and/or curved road, the road above bridges, the road without sunny, and on the intersection.

However, if the sidewalk has the deteriorated concrete products, the traffic safety on the road is not kept enough and the road landscape from the drivers' view must not be preferable actually. Hosokawa *et al*. (1996) reported the natural landscape is important in the questionnaire about farm road, and it is estimated the road landscape with deteriorated and poor sidewalk is not preferable. Consequently, it is necessary to study about the landscape evaluation of sidewalk with deteriorated concrete blocks and about the improvement as repairing by using new curb concrete blocks.

## 2 MATERIAL AND METHOD

### 2.1 Landscape evaluation of sidewalk with deteriorated concrete blocks

The various backgrounds in the photograph give many evaluated items to the examinees in the landscape evaluation questionnaire, and it is difficult for the examinees to evaluate the specified parts to be compared easily in the photograph. Therefore, in the case of retouching photographs for the questionnaire, it is necessary to retouch the specified parts only to be compared with the normal photograph while being same background in the photograph. The sidewalk photographs with four ranks from more preferable to very poor were retouched by the computer graphic technology based on the normal road constructed with asphalt concrete and the sidewalk with a little deteriorated curb concrete blocks and some weeds. In the landscapes evaluation questionnaire, four photographs as shown in Fig. 1 were used for 407 examinees as shown in Table 1.

**Table 1. Properties of 407 examinees ( ) : %**

| Sex | | | Age bracket | | | Job | | |
|---|---|---|---|---|---|---|---|---|
| Men | 267 | (65.6) | 10-19 | 39 | (9.6) | Agriculture | 5 | (1.2) |
| Female | 140 | (34.4) | 20-29 | 141 | (34.6) | Business | 10 | (2.5) |
| Total | 407 | (100.0) | 30-39 | 76 | (18.7) | Employee | 154 | (37.8) |
| | | | 40-49 | 84 | (20.6) | Public service | 98 | (24.1) |
| | | | 50-59 | 44 | (10.8) | Member of organization | 24 | (5.9) |
| | | | 60-69 | 17 | (4.2) | Housewife | 23 | (5.7) |
| | | | 70 | 6 | (1.5) | Student | 63 | (15.5) |
| | | | Total | 407 | (100.0) | Other | 30 | (7.4) |
| | | | | | | Total | 407 | (100.0) |

The background in each photograph is same except for the curb concrete blocks in the sidewalk. The normal photograph was taken at the height of 1.16 m as the eye heights of driver and assistant driver above the asphalt concrete pavement. Photograph I indicates the sidewalk constructed with new curb concrete blocks, and Photograph II is the normal sidewalk landscape. However, Photograph III indicates the sidewalk landscape with the broken curb concrete blocks and the aggregate from their blocks, and Photograph IV is the sidewalk with the new curb repaired partly and the old curb.

At the questionnaire, the examinee selected the first watching point in 25 cells devided in each photograph and then chose one from four evaluation items, i.e. “More preferable”, “Preferable”, “Ordinary” and “Poor”, in each photograph. Furthermore, the same questionnaire was occurred to select the first watching point in 25 cells of Photographs V and VI, the view from the driver’s seat (right wheel in Japan) or the assistant driver’s seat (left) by the group of driving usually and the no driving group, respectively. Then, the examinees were required the reason why they chose the four landscape items in each photograph, and the opinion how they thought about the landscape improvement of sidewalk of the road.

### 2.2 Improvement of sidewalk with curb concrete blocks

It is necessary to study about methods to improve the sidewalk landscape. As the curb concrete blocks are especially apt to be deteriorated in the snowy area, the factors influenced to the concrete durability must be analyzed. These factors include the concrete properties, the freezing and thawing action and the deicer salt action mainly. To make clear the factor being deteriorated concrete products, the exposure test was planed in the actual roads, where the deicer salt was scattered or not, while constructing the sidewalk with curb concrete blocks. The curb concrete blocks were manufactured in the concrete products plant in July 1998.

**Fig. 4. Distribution of ratio (%) of the first watching point in 25 cells of Photographs V and VI.**

The materials for curb concrete blocks were ordinary Portland cement with 3.16 specific gravity and aggregate as shown in Table 2, and the mix proportion of concrete is three water cement ratios (W/C) of 39.5, 44.5 and 49.5% as shown in Table 3. The steam with the top temperature of 60-65 $^{o}$C cured the fresh concrete in the mold of curb for about two hours, and the curing maturities until the removing molds were 1300-1360 $^{o}$C-hours.

* Air entraining and water reducing agent, ** Air entraining agent

The surfaces on some of the curbs were sprayed the waterproof agent by 0.3 kg/m$^2$. After the construction of sidewalk with curb concrete blocks indicating in Table 3, in December 1998, the test-hammer strength against the top of curb blocks by the normal type of Schmidt hammer and the deterioration of curb surfaces were measured and checked out in January 1999 at first and then in October 1999 and 2000, respectively.

## 3 RESULTS AND DISCUSSION

### 3.1 Landscape evaluation of sidewalk with deteriorated concrete blocks

All examinees watched the questionnaire photographs as the driver, and their first watching points spread in all of photographs, however, these points have a focusing in the driving road and the sidewalk. As shown in Fig. 2, when attention the high-ranking in top three of the ratio of first watching point, the examinees watched the distant view of the road in the less deteriorated sidewalk like Photograph I, but the short-range view and the middle-range view of the road in the deteriorated one like Photographs II, III and IV. Thus, it is clear that the examinees found the sidewalk landscape condition definitely while looking the forward driving-road, and especially watching the deteriorated part in the photograph.

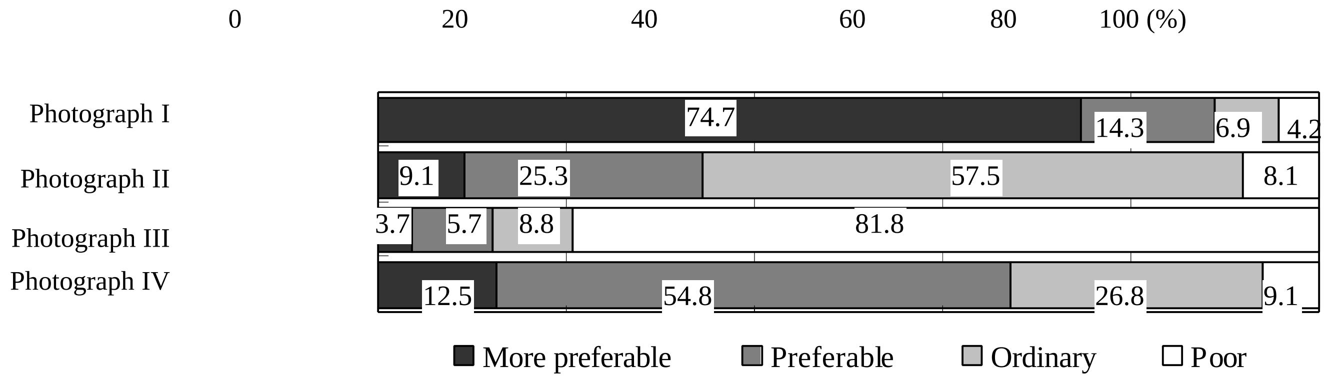

**Fig. 5. Ratio of landscape evaluation in each photograph by all examinees.**

The results of the landscape evaluation of each photograph were shown in Fig. 5. 74.7% of "More preferable" was indicated in Photograph I, 12.5% in Photograph IV, 9.1% in Photograph II, and only 3.7% in Photograph III, and 54.8% of "Preferable" was also in Photograph IV, 25.3% in Photograph II, 14.3% in Photograph I, and only 5.7% in Photograph III. On the other hand, 81.8% of "Poor" was indicated in Photograph III remarkably but 4.2-8.1% in other Photographs. In Photograph II, it was remarkable 57.5% of "Ordinary". In fact, Photograph II shows the normal (ordinary) landscape, and in the result of questionnaire Photograph II was indicated "Ordinary" mainly. It is estimated that the photograph selection in this questionnaire was very suitable. Furthermore, the preferable ranking of landscape from Fig. 5 indicated the top is Photograph I, the second is Photograph IV, the third is Photograph II, and the worst is Photograph III.

Table 4 shows the reasons evaluated each photograph "Poor" while answering number in Photographs I, II, III and IV is 17, 33, 333 and 24, respectively. The examinees to answer in Photograph III were many of 81.8% of all examinees. In the item of the reasons, "Dangerous by deteriorated concrete blocks" were found 4.5% in Photograph III and 47.1% in Photograph II, remarkably. Although "Feel a sense of incompatibility" were found 25-27% in Photographs I and IV, new curbs of sidewalk in Photograph I and also a part of new curbs in the sidewalk in Photograph IV will give incompatible sense to examinees, because of higher the chromatic difference between the new (white color) curbs and the pavement (darker color), as reported by Hosokawa *et al*. (1998), like "Different color of concrete blocks" with 9-12% in Photographs I and IV. The examinees found the weed on the sidewalk dirty in Photograph II. Consequently, the deteriorated sidewalk landscape was evaluated the worst rank and is necessary to improve.

**Table 4. Reasons evaluated each photograph "Poor" by all examinees**

| Item | Ratio* in Photograph (%) | | | |
|---|---|---|---|---|
| | Photo. I | Photo. II | Photo. III | Photo. IV |
| Dangerous by deteriorated concrete blocks | 3.8 | 47.0 | 54.6 | 17.1 |
| Feel a sense of incompatibility | 27.0 | 7.8 | 16.3 | 25.6 |
| In some way | 30.9 | 15.7 | 6.3 | 20.0 |
| Insufficient landscape | 11.5 | 5.9 | 13.0 | 8.6 |
| Dirty with weeds | 11.5 | 17.6 | 3.3 | 2.9 |
| Different color of concrete blocks | 11.5 | 2.0 | 4.9 | 8.6 |
| Non plain landscape | 0.0 | 2.0 | 0.8 | 14.3 |
| Other | 3.8 | 2.0 | 0.8 | 2.9 |

* Answering number in Photographs I, II, III and IV is 17, 33, 333 and 24, respectively.

Table 5 indicates the opinions concerning with the improvement of the sidewalk landscape. In the higher ratio over 20% of opinions, "Road safety", "Improvement of the regional landscape", and "Comfortable driving" are found. Although the choices of items are not many, the result leads to need the quality improvement to keep a road safety. Therefore, for the present, it is necessary to make clear the factors to be deteriorated the curb concrete blocks.

**Table 5. Opinions for the sidewalk landscape improvement**

| Item | Ratio (%) |
|---|---|
| Road safety | 28.8 |
| Improvement of the regional landscape | 28.6 |
| Comfortable driving | 22.3 |
| Attention to the deteriorated concrete blocks | 16.1 |
| Dirty landscape by weeds | 4.0 |
| Other | 0.2 |

### 3.2 Improvement of sidewalk with curb concrete blocks

There are many reports of the durability of concrete durability, but not so many about the concrete products. The factors deteriorate the concrete products include material, vibrating and curing method, constructed place in the water, environment situated products, and so on. Takahashi & Hosokawa (1983) reported the ditches for irrigation and drainage have many kinds of cracks because of wet environment with water and freezing and thawing action. The sidewalk concrete products in the snowy area were often deteriorated by not only freezing and thawing action but also the deicer salt action recently like in this paper. Concerning with the deicer salt action to concrete, some studies were reported by Marchand *et al.* (1994), Rösli & Harnik (1980), Shoya *et al.* (1997) and so on. However, there is no study on the actual road under the cold environment. It is important to make clear the factors to deteriorate concrete by the exposure test on the actual roads, where the deicer salt is scattered or not.

Table 6 shows the results in the exposure test after 2 years. The curbs were usually covered with snow between the middle of January and the last of February. All of the test-hammer strength increased up to 20-40% of the initial strength. In Road A, many popouts on the curb surfaces, as Photographs VII and VIII, in spite of W/C difference and the treatment with waterproof agent. These deteriorated curbs between Roads A and B are obviously influenced by the deicer salt scattering. In Japan, the deicer salt including NaCl and/or $CaCl_2$ mainly is scattered, and actually NaCl deicer salt increases recently by its lower cost. Since we must worry about the influences of ecological environment by the salt, however, the countermeasure against the deterioration of sidewalk concrete blocks must be studied at first.

**Table 6. Surface deterioration and test-hammer strength of curb concrete blocks**

| Road | Deicer salt | W/C (%) | Waterproof agent | Surface deterioration | | Test-hammer strength ratio based on the strength in Jan. 1999 (%) | | |
|---|---|---|---|---|---|---|---|---|
| | | | | Jan. 1999 | Oct. 2000 | Jan. 1999 | Oct. 1999 | Oct. 2000 |
| A | Scattered | 39.5 | Treated | No | Popouts | 100 | 109 | 117 |
| | | 44.5 | | No | Popouts | 100 | 127 | 141 |
| | | 49.5 | | No | Popouts | 100 | 120 | 135 |
| | | 39.5 | No | No | Popouts | 100 | 122 | 128 |
| | | 44.5 | | No | No | 100 | 117 | 120 |
| | | 49.5 | | No | Popouts | 100 | 120 | 124 |

| | | 49.5 | | No | No | 100 | 118 | 132 |

**Photograph VII. Popouts on the surface of curb after 2 years (Road A, W/C: 49.5%, with waterproof agent)**

**Photograph VIII. Coarse aggregate came out after mortar's popout Treatment. in Photograph VII**

### 3.3 Countermeasure to reduce the deterioration of sidewalk concrete blocks

In the snowy area, the deterioration of the sidewalk concrete blocks in the road scattered the deicer salt is called "Salt action damage", severe than the "Frost damage" by the freezing and thawing, and if the reinforced concrete blocks the remarkable deterioration must be occurred. If the concrete blocks were deteriorated within two years after the sidewalk construction, the concrete product company, not the construction company, must have the risk to repair them, because the company manufactured the products be apt to get the damage. The road has been actually maintained to scatter the deicer salt to reduce the traffic accidents in wintertime by the road maintenance office. While being recommended below 45% of W/C in the salty environment by the concrete standard manual of Japanese Society of Civil Engineering, the special countermeasure against the salt action is to spray or paint the waterproof agent on concrete-product surface and to be below 50% of W/C only in the concrete product plant generally.

It is not realistic to manufacture the complete concrete product against both the salt action damage and the frost damage in the concrete plant, and to reduce the deicer salt quantity to keep the lower environmental load in the snowy area of Japan. Therefore, it is suggested that the concrete deterioration is divided the only frost damage and the frost damage with the salt action, from the sidewalk environment. The former indicates the normal concrete blocks can be used in the area without scattering the deicer salt. The latter means that the sidewalk concrete blocks with the special treatment against both damages. However, the place of scattering the deicer salt is decided in the snowy area but the salt is actually brought to the place without scattering the deicer salt by car's splash and strong wind. In general, the concrete products company must treat the special countermeasure on the concrete but without rising cost because there is severe competition among the concrete block manufacturing companies.

Go Back

Furthermore, the countermeasure against both the frost damage with the salt action is described in below.

1. We may pay the extra cost for concrete products treated the special waterproof, sometimes the special concrete mix proportion.
2. The development of the deicer agent instead of the deicer salt with $Cl^-$ like a seawater, NaCl, $CaCl_2$ and so on, to keep the lower environmental load.
3. The development of the ecological sand to prevent the car-tire's skid on snow and ice, instead of much of deicer salt scattering.
4. The development of concrete products with zero slump and lower W/C, but with rough surface.
5. It is necessary to make clear the factors of the deterioration of concrete blocks with the deicer salt action.

## 4 CONCLUSIONS

The following conclusions may be drawn from the results of this study:

1. Examinees in the questionnaire found the deteriorated part in the sidewalk definitely. The deteriorated sidewalk landscape was evaluated the worst rank and needs to be improve curb blocks to keep a road safety.
2. The exposure test results on the actual road scattered deicer salt indicated many popouts on curb surfaces in spite of W/C difference and the treatment with waterproof agent after two years. It is estimated that popout phenomenon was influenced by both the freezing and thawing action and the salt action.
3. It is not realistic to manufacture the complete concrete product against both the salt action damage and the frost damage in the concrete plant, and to reduce the deicer salt quantity to keep the lower environmental load in the snowy area of Japan. As the countermeasure against both damage, for example, we may pay the extra cost for concrete products treated the special waterproof, sometimes the special concrete mix proportion, or the development of the deicer agent and the scattering sand to prevent the car-tire's skid instead of the deicer salt.

## 5 ACKNOWLEDGMENTS

The author is thankful to Aomori Maeta Concrete Industry Ltd. in Towada city of Aomori prefecture and to National Road Maintenance Office in Towada city of Aomori prefecture, for their cooperation in the experiments of this study. The author wish to express my gratitude to many examinners answering the questionnaire of this study with their warm understanding. Furthermore, this paper owes much to the helpful investigations by many students in the Environmental Material Laboratory of Department of Rural Engineering, Kitasato University, for a few years.

# Carbonation Testing Of Hardened Concrete And The Effect Of Cement Type

**MR Jones MD Newlands & AMO Abbas**
**Concrete Technology University of Dundee Scotland UK**

**Summary: Carbonation-induced corrosion affects all reinforced concrete building structures where the moisture saturation level of the capillaries is suitable for supporting both $CO_2$ ingress and steel oxidation, either continuously or cyclically with different seasonal environmental exposure conditions. Such conditions are found in the externally exposed elements of structures and buildings exposed to or sheltered from rain, which accounts for approximately two-thirds of all structural concrete used. The service life of most reinforced concrete building structures is, therefore, normally governed by cover carbonation and subsequent reinforcement corrosion. Although carbonation-induced corrosion is rarely catastrophic, the effects are on serviceability and aesthetics which are economically significant for large-scale property owners, such as municipal housing authorities.**

**With no standardised laboratory method, the European Committee for Standardisation (CEN) established a joint Working Group (TC51/WG12) to develop a carbonation test for hardened concrete. A draft method was developed using the RILEM procedure for measuring the depth of carbonation and was subjected to a inter-laboratory round-robin series of tests to measure its repeatability. The indicated precision from these tests was, however, poor and consequently there was no subsequent agreement to publish the method as a draft for development (ENV) ahead of a full European Standard (EN). However, it was felt that the draft method did provide a first step towards the development of an agreed standard test procedure and was published as a CEN Report.**

**As a result of this initial study, the CEN Working Group identified that further test development was needed. This paper reports the findings of a study of the draft CEN carbonation test method that was aimed at identifying the causes of the poor precision experienced in the round-robin test programme. Using these findings, the study developed improvements to the test method, which are evaluated using as limited series of repeated test mixes. The paper then describes the effect of different cement types on the carbonation performance of concrete. A tentative classification of concrete based on cement type will also be presented.**

**Keywords: Carbonation, Cement type, Environmental Control, Performance.**

## 1 INTRODUCTION

Concrete durability, unlike its structural design properties, is difficult to estimate by indirect means, such as compressive strength or permeation properties. It may be argued that the inability to determine the durability potential of concrete has contributed to the massive current expenditure on repair and maintenance of structures, which corresponds to around £20 bn from an overall construction turnover of £45 bn in the UK alone (DETR, 1999). Such problems are being addressed by the European Committee for Standardisation (CEN), who are developing a series of test methods for determining the durability of concrete exposed to standardised storage conditions, for example in carbonating environments.

Carbonation-induced corrosion affects all structures where the moisture saturation level of the capillaries is suitable for supporting both $CO_2$ ingress and steel oxidation. These conditions are typically found in the externally exposed elements of structures and buildings which may be exposed or sheltered from rain, which accounts for around 2/3 of all structural concrete used (Parrott, 1996). The service life of most reinforced concrete building structures is, therefore, normally governed by cover carbonation and subsequent reinforcement corrosion (Hobbs *et al*, 1998). Although carbonation-induced corrosion is rarely catastrophic (Concrete Society, 1996), the effects are economically significant and repair costs often outweigh new build expenditure.

A draft method was developed using the RILEM procedure (RILEM, 1988) for measuring the depth of carbonation and was subjected to a inter-laboratory round-robin series of tests to measure its repeatability (CEN, 1997). The precision of these tests was poor, however, it was felt that the draft method did provide a first step towards the development of an agreed standard test procedure and was subsequently published as a CEN Report (CEN, 1997).

To enable sustainable and economic reinforced concrete building construction, the reliable determination of the carbonation rate of hardened concrete is essential to allow design decisions to be made. In addition to this, the new European Standards for cement and concrete, namely EN 197-1 and EN 206-1 (including the relevant national application documents), allow the engineer scope to select cement and concrete characteristics and requirements appropriate to local conditions.

In support of this goal, the CTU has carried out a 3 year study with two main aims. Firstly, to identify the areas within the CEN test leading to poor precision and modify the test to become a repeatable methodology. Secondly, study also compared the carbonation of concrete containing 10 different combinations of common cements to observe carbonation rates of concrete subject to different storage conditions, in terms of the degree of wetting applied to the test specimens. The test programme also attempted to tentatively classify the carbonation performance of different concretes.

## 2 DEVELOPMENT OF SIMULATED NATURAL CARBONATION TEST METHOD

The initial work focussed on the development of a simulated natural carbonation test method. Table 1 summarises the key requirements of the current draft CEN test. Storage conditions were divided into 3 exposure classes, so that test specimens had varying pore saturation levels as could be expected to occur in different local micro-climates (BRE, 1995). The test method adopted the recommendations of RILEM CPC-18 (RILEM, 1988) to measure the depth of carbonation, i.e. direct measurement of the neutralised depth of cover using a sprayed on phenolphthalein indicator solution. A pan-European inter-laboratory test carried out by CEN showed that the test had a poor repeatability, however, there was potential for the method to be further developed.

A comprehensive analysis of the inter-laboratory data is presented elsewhere (Jones *et al*, 2000) however the main conclusions arising from the analysis test were:

(i) variations in environmental control and concrete production techniques were heavily influencing the carbonation readings. Only one laboratory conformed to the environmental requirements of a temperature of 20 ± 2EC, relative humidity of 65 ± 5% and an atmospheric $CO_2$ concentration of 350 ± 50 ppm.

(ii) concrete production techniques led to inter-laboratory variations. Although laboratories used local aggregates, differences in intern-laboratory concrete strengths were found as a result of variations in water/cement ratio.

**Table 1. Requirements of the simulated natural carbonation test method**

| | | |
|---|---|---|
| *Specimen Size* | 2 Concrete Prisms: 100x100mm and ∃400 mm long. | |
| *Initial Curing* | 24 hours under damp hessian and impermeable plastic sheeting followed by 3 days seal cured. | |
| *Storage Conditions* | | |
| *Exposure Class 1:* | Temperature: | 20±2EC . |
| | Relative Humidity: | 65 ± 5%. |
| *Exposure Class 2:* | $CO_2$ Concentration: | 350 ± 50 ppm. |
| | As Class 1 but fully immerse test prisms in water every 28 days for 6 hours. | |
| *Exposure Class 3:* | As Class 2 but immerse test prisms in water every 7 days. | |
| *Test Ages* | 28, 91, 182, 273, 364 and 728 days ±2% after start of test. | |
| *Method of Measuring Depth of Carbonation* | 50mm slice broken from prism and phenolphthalein sprayed on freshly broken surface. Measurement made by taking the average of 5 readings made on each face. | |
| *Reporting of Depths of Carbonation* | Average carbonation depths from the two specimens to be reported for each exposure class. | |

To this end, the present study aimed to reduce the variability associate with the test method by addressing the environmental requirements and concrete production techniques

### 2.1 Audit of Test Storage Conditions and Development of Active Environmental Control System

Four different storage environments for the test specimens were investigated, as follows:

S1: Uncontrolled, open laboratory atmosphere with an indirect link to an external air source.

S2: Temperature and relative humidity controlled storage room with an air-tight door closed.

S3: As S2 but with the door propped slightly ajar continuously.

S4: As S2 but with the door fully opened for 24 hours in every 48 hours.

In each case recordings of the $CO_2$ concentration, RH and temperature were made over a period of 1 month, as shown in Fig 1. It was found that the open laboratory storage (S1), did not conform to the $CO_2$ requirements and a controlled climate room with dimensions 2100x1900x2400 mm was used as a storage room to store the test specimens. This room had relative humidity and temperature control (S2) and was filled with ‘dummy' concrete specimens such that the total exposed concrete surface area in the room was 125 m². Although relative humidity and temperature was maintained, the $CO_2$ concentration was depleted considerably, due to the consumption of atmospheric $CO_2$ gas by the concrete. As a result the room door (2 m²) was wedged slightly ajar storage, (S3) to allow exchange of air with the open laboratory however this gave results similar to S1. In turn, storage environment S4 was tried however, storage conditions did not conform to the test requirements. It was evident that it would be necessary to control $CO_2$, RH and temperature concurrently to conform to the requirements of the draft CEN test.

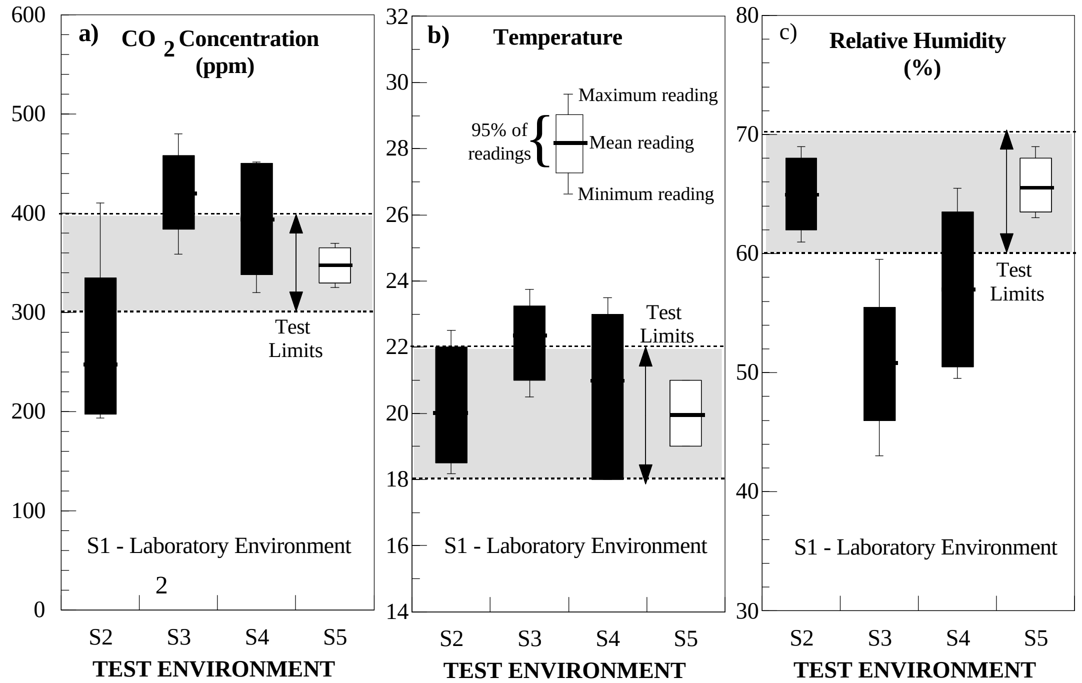

**Figure 1. Box whisker plots of variations in laboratory storage environment**

Proprietary controller and monitoring systems were prohibitively expensive, thus an in-house CO2 controller and injection system was retro fitted to the climate room, Fig 2. The performance of the active control system in the storage room was monitored over a period of 1 month and the environmental parameters were kept within the test limits, as shown in Test Environment S5, Fig 1. Standard table fans were placed within the storage room to provide a turbulent atmosphere and prevent the formation of locally depressed partial pressures of $CO_2$ which can be seen in Fig.2.

### 2.2 Normalisation Procedure for Determination of Carbonation Depth

Given that the depths of carbonation in the simulated natural carbonation test, after 1 year, were likely to be low and that within all laboratories, a degree of variability in the production of test specimens is inevitable, it was considered necessary to devise and apply a procedure for normalising the carbonation test data. This was felt particularly important if such data is to be used for exact comparison either with other data or against a particular benchmark. Furthermore, if the test data is to be used to estimate long term carbonation depths using mathematical models, initial variability must be minimised. An example of the procedure is shown in Figure 3.

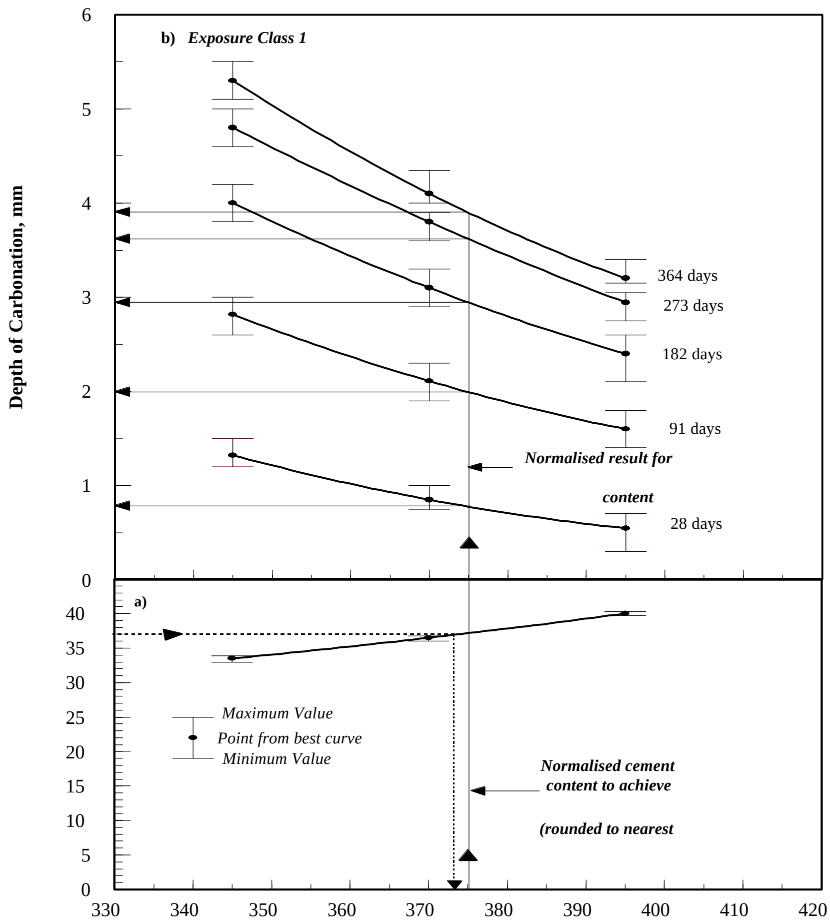

**Figure 3 Normalisation procedure a) 28 day compressive strength is plotted against cement content to find actual proportions for required compressive strength. b) carbonation depth is then determined.**

The normalisation procedure developed used the following mixes:

i) A *primary mix* was designed to achieve the required concrete grade.

ii) *Two secondary mixes* were also produced with ± 8% by mass of the total cement content of the primary mix. This value was arbitrarily chosen but corresponded to ± 25kg/m³ for this testing programme where a 37 N/mm² PC/30% PFA mix was used. The secondary mixes had the same free water content as the primary mix and proportions were volumetrically adjusted by altering the fine aggregate content.

Preliminary work showed that variations in compressive strength between 35-39N/mm$^2$ gave a variation in carbonation depth of 2mm at 1 year. Although this may seem a relatively small difference, when these carbonation depths are projected to 30 or 40 years the error is substantially multiplied.

### 2.3 Repeatability of Modified Carbonation Test

In order to determine the effects of the proposed modifications on the test method, a limited series of 10 repeated mixes giving 2 sets of test samples were produced. One group was subjected to the original draft CEN method testing and the second with the proposed method of testing, with both series of test samples stored in the Dundee storage room to CEN Class 1 exposure conditions. In addition, for comparative purposes two further subsets of test samples were stored for 20 weeks in an accelerated carbonation chamber with an atmospheric environment of 4000 ± 500 $CO_2$ ppm, 50 ±5 % RH and 20 ±2 C (Dhir *et al*, 1989). The results were statistically analysed and at a 95% confidence level there was no significant difference in the range of individual test results. The repeatability of the results was significantly improved when the Dundee test procedure was adopted.

## 3 CARBONATION RESISTANCE OF COMMON CEMENT CONCRETES

The objective of the second phase of study was to compare carbonation rates of concretes containing different cement types and quantities subject to different storage conditions, in terms of the degree of wetting applied to the test specimens. European Standards for cement and concrete, namely EN 197-1 and EN 206-1 allow the engineer scope to select cement and concrete characteristics and requirements appropriate to local conditions. However, the long-term performance of these materials is relatively unknown, especially in terms of carbonation resistance.

### 3.1 Experimental Programme

A total of 10 different cements were selected as summarised in Table 2. The materials were chosen to reflect the array of cement and concrete types which are now in use around Europe, containing materials such as pulverized-fuel ash (PFA), ground granulated blastfurnace slag (GBS), silica fume (CSF) and metakaolin (MK). The mixes were designed using a standard mix constituent proportioning method (Teychenné *et al*, 1997), to achieve a nominal 28 day cube strength of 37 N/mm². Most urban structures now require a concrete grade of between 30-40 N/mm² (CEN, 1997), thus in the experimental programme the primary mix was designed to achieve a characteristic strength of 37 N/mm² after 28 days of standard water curing, corresponding to a cylinder strength of 30 N/mm².

The mixes were compared to a Reference concrete, a PC/30% PFA mix. From a comprehensive review of published and unpublished literature, it was felt that this mix was now common place and would provide a substantial degree of carbonation resistance against which performance may be judged. However, the Reference concrete may be any concrete that is deemed suitable by the user to allow real judgement of the performance of various test mixes.

**Table 2. Mix proportions for test mixes, normalised to a standard cube strength of 37N/mm²**

| *Cement Type* | *Normalised Mix Constituent Proportions(1), kg/m³* | | | | | *Plasticiser Dosage, l/100kg Cement* | *w/c ratio* |
|---|---|---|---|---|---|---|---|
| | *Total Cement* | *Water (2)* | *Aggregates* | | | | |

| *Silica Fume* | | | | | | | |
| CSF 10% | 280 | 185 | 720 | 400 | 800 | 0.60 | 0.65 |
| CSF 15% | 285 | 185 | 715 | 400 | 800 | 0.61 | 0.61 |

(1) The desired proportions to achieve an exact 28 day strength of 37N/mm$^2$.

(2) Free water content to achieve a slump of 60-90mm. Plasticizer used as shown.

(3) Natural sand, zone M grading to BS 812:1992

(4) Coarse aggregate: natural gravel

(5) Portland Cement is strength class 42.5 N to BS 12 (1996)

### 3.2 Effect of Cement Type on Carbonation Depth

The modified Dundee test programme was run for 2 years, as it had already been noted that carbonation depths would be minimal at 12 months. For each test prism, 20 individual measurements of the depths of carbonation were taken, giving a total of 40 readings for each cement type in each Exposure Class. The 2 year depths of carbonation for each of the concretes is shown in Figure 4.

Within Exposure Class 1, where no wetting was carried out, the effect of cement type was most noticeable, with PC and MK10% mixes having the lowest depths of carbonation after 2 years. It should be recognised that under these conditions, corrosion is improbable as the concrete is unlikely to have sufficient pore saturation, however, the effect of replacing the PC with PFA, GBS and the higher levels of MK and CSF was found to give increased depths of carbonation.

The Figure also compares the carbonation depths for the different cement types in the 3 Exposure Classes. Storage in Exposure Class 3 (wettest) had the lowest depth of carbonation and highest pore saturation level. Exposure Class 2 resulted in depths of carbonation between Class 1 and 3 due to the period of wetting.

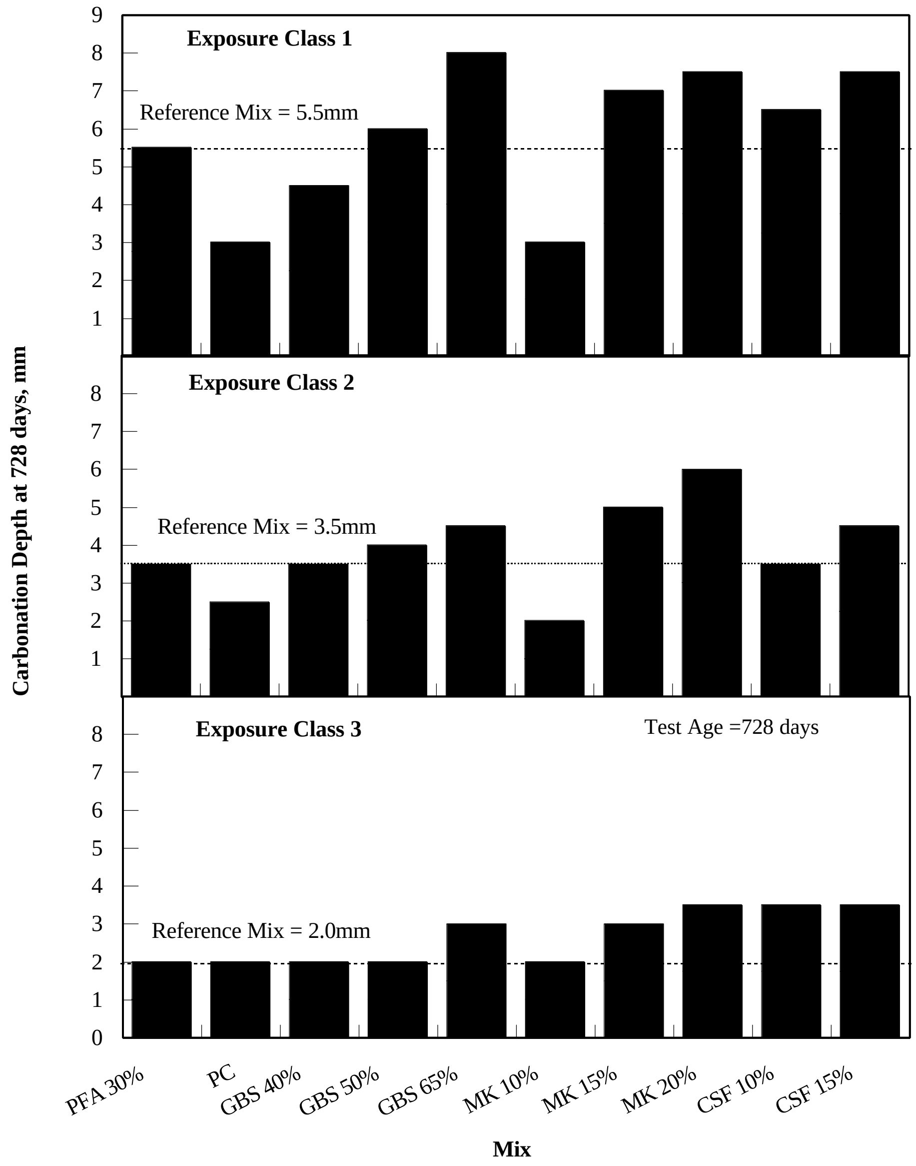

**Figure 4. Comparison of 2 year carbonation depths of common cement types using the Dundee modified test.**

The problem, however, for the engineer is which of these Exposure Classes represents natural exposure environments. At present, there does not appear to be sufficient data to make an informed judgement and there are likely to be a range of exposure conditions that can support carbonation-induced corrosion activity in different geographical locations for example the north-west coast of the UK is considerably wetter than the south-east coast. Although Class 1 is the worst case condition for carbonation, it is considered that this condition is too dry to support corrosion. On the other hand, Class 3 is considered not only wetter than any natural environment but the resulting pore saturation would produce only minimal corrosion activity. It is recognised therefore that further work is necessary to define exposure class environments which simulate the natural exposure environments capable of supporting both carbonation and carbonation-induced corrosion.

## 4 NEAR SURFACE CONCRETE QUALITY AND CARBONATION RESISTANCE

The ranking order of the cement types were similar regardless of the Exposure Class to which they were exposed. Exposure Class 1 results, which gave the worst case with regards to carbonation, had the broadest spread of the cement types and, using an arbitrary division of approximately 1.5mm carbonation to differentiate the cement types, the following tentative grouping can be made:

PC = MK10

GBS40/50 = PFA

CSF10/15 = MK15/20 = GBS65

In Exposure Class 2, the addition of a monthly wetting and drying cycle compresses the spread of results and two groups emerge, which are broadly similar to Class 1:

Go Back Next Page

PC = MK10 = GBS40/50 = PFA = CSF10

CSF 15 = MK15/20 = GBS65

In Class 3, the weekly wetting and drying cycle results in similar carbonation depths for all the mixes, however, an arbitrary grouping would appear to be:

PC = MK10 = GBS40/50/65 = PFA

CSF10/25 = MK15/20

The carbonation durability ranking of the cement types is likely to be affected by a combination of the permeation properties of the concrete and the degree of cover zone pore fluid alkalinity. Although there is no permeation test that wholly determines the microstructure, accessibility and interconnectivity of the pore system to $CO_2$, a water vapour diffusivity test was used (Dhir *et al*, 1989) to characterise the concrete cover zone. This test was found to be the most sensitive method to changes in microstructural properties and cement type. In addition, it is difficult to determine the cover zone pore fluid alkalinity directly, therefore, the total amount of $Ca(OH)_2$ was measured in the cover zone concrete at the pre-entry (ie prior to exposure to the relevant Exposure Class) and after 2 years.

Table 3 compares the near surface water vapour diffusivity and $Ca(OH)_2$ in the outer 10mm of the concrete. The cement types are ranked in order from the lowest depth of carbonation to the highest in Exposure Class 2, however, it was clear that the GBS mixes were acting differently from the pozzolanic cement combinations.

Although the PC mix had a very high initial water vapour diffusivity, the high $Ca(OH)_2$ concentration of the cover prevented rapid progress of the carbonation front. The $Ca(OH)_2$ content of the cover also depleted slightly over the test period however the concentration remained relatively high at 2 years. The MK10% mix showed the combined effect of a low water vapour diffusivity and high initial $Ca(OH)_2$ concentration. One would expect this to out-perform the PC mix however with time, the $Ca(OH)_2$ concentration depleted, due to a combination of carbonation and the pozzolanic reaction, leading to a similar performance to that of the PC mix.

The remaining pozzolanic mixes, PFA, MK 15%, MK 20%, CSF 10%, CSF 15% showed a relatively similar performance in carbonation. The MK and CSF mixes had a low water vapour diffusivity however the $Ca(OH)_2$ concentration was also very low and depleted with time. Subsequently, the carbonation was relatively similar within these concretes.

**Table 3. Near surface water vapour diffusivity and total $Ca(OH)_2$ content**

| *Cement Type* [(1)] | *Water Vapour Diffusivity, g/mm² s mm Hg x $10^{-10}$* | | *Total $Ca(OH)_2$, % wt of cover zone concrete* | | | |
|---|---|---|---|---|---|---|
| | *Pre-entry* | *2 year Exposure Class 1* | *Pre-entry* | *After 2 year Exposure* | | |
| | | | | *Class 1* | *Class 2* | *Class 3* |
| *MK 10%* | 51 | 45 | 4.3 | 1.2 | 1.9 | 2.5 |
| *PC* | 192 | 154 | 5.2 | 4.3 | 5.0 | 5.6 |
| *PFA 30%* | 112 | 92 | 1.7 | 0.7 | 1.2 | 1.6 |
| *GBS 40%* | 96 | 114 | 2.0 | 0.7 | 1.4 | 1.7 |
| *CSF 10%* | 58 | 34 | 1.5 | 0.5 | 1.4 | 1.7 |
| *GBS 50%* | 128 | 159 | 1.7 | 0.6 | 1.4 | 2.0 |
| *CSF 15%* | 64 | 36 | 1.4 | 0.5 | 0.5 | 1.2 |
| *GBS 65%* | 147 | 192 | 0.7 | 0.4 | 1.2 | 1.6 |
| *MK 15%* | 70 | 50 | 1.6 | 0.6 | 0.9 | 1.1 |
| *MK 20%* | 77 | 47 | 1.3 | 0.6 | 0.5 | 1.0 |

[*] Measured prior to exposure to carbonating atmosphere

There are obvious difficulties with the assessment of water vapour diffusivity and the determination of the hydroxyl ion concentration in the concrete pore fluids. It is hypothesised that it may be possible to estimate the likely carbonation resistance for a particular concrete mix based on the water/PC ratio. Figure 5 plots the water/PC ratio against 2 year carbonation depth and it can be seen that mixes with a higher water/PC ratio generally have higher carbonation depths.

Go Back
Next Page

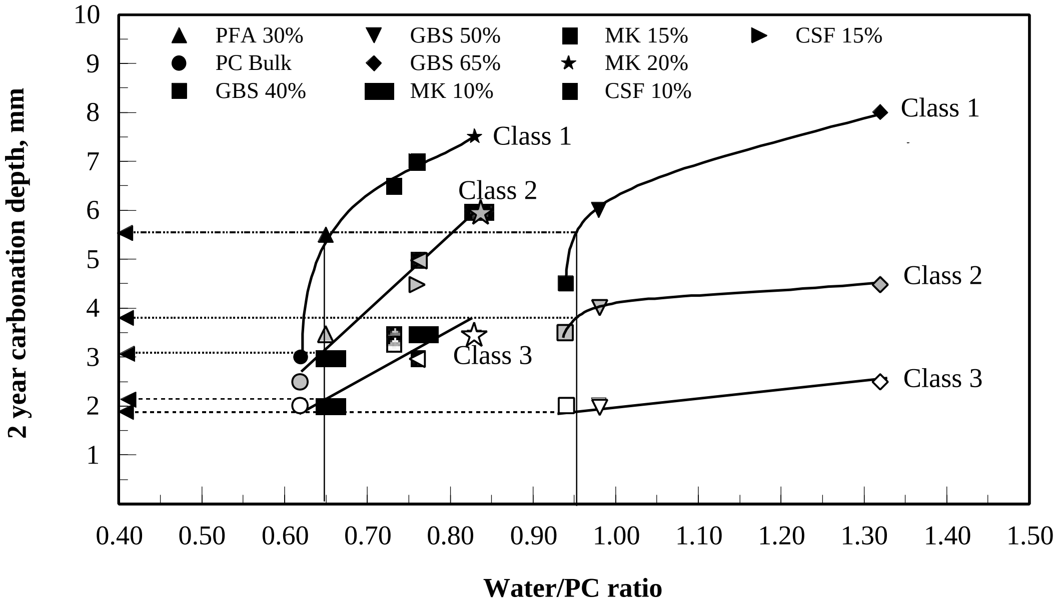

**Figure 5. Relationship between 2 year carbonation and water/PC ratio for Exposure Classes 1, 2 and 3.**

Using the PC/PFA Reference Mix as a benchmark, it is possible to provide a limiting value for water/PC ratio which would result in similar or lower depths of carbonation occurring for any other combination of cements for concrete of the same compressive strength. From the results it is suggested that, at a given level of compressive strength, (in this case 37N/mm²) a tentative limiting water/PC ratio of 0.65 should be specified for mixes containing pozzolanic cements and 0.95 for slag concrete.

## 5 CONCLUSIONS

The current study aimed to develop a simulated natural carbonation test method and determine the effects of various cement types on carbonation resistance. The existing test method developed by CEN was found to have poor repeatability. Poor control over the environmental conditions, in particular the levels of $CO_2$ in the atmosphere was significantly affecting carbonation. Conformance with the test storage requirements could only be achieved through the use of a fully air conditioned sealed room, however, it was necessary to provide actively controlled $CO_2$ injection in order to maintain the required $CO_2$ concentration in the room. Significant depletion of atmospheric $CO_2$ was noted within about 5 days if this was not replenished. As a result, a low cost $CO_2$ monitor/controller system was designed for retro fitting to suitable storage rooms found in most well equipped laboratories.

The production method of concrete test mixes was also affecting the test repeatability and a normalisation procedure for the determination of carbonation depth was developed. By plotting strength against cement content for a single primary and two secondary mixes, the normalised mix proportions to give the test concrete standard cube strength can be determined. Using this value and the binder content against depth of carbonation curves, the normalised depth of carbonation can be determined at any particular test age. A limited series of repeatability tests were carried out comparing the effects of this two stage normalisation process and it was found that the coefficient of variation was substantially reduced.

The modified test method was used to compare cement types in carbonating environments. The results showed the broadest spread of results in Exposure Class 1. Across 10 cement combinations a spread of 5mm was found after 2 years testing. As the frequency of cyclic wetting and drying increased, so the spread of carbonation depth reduced across cement type which was expected. Although Exposure Class 1 may be deemed a worst case scenario for carbonation it is unlikely that corrosion would occur. However, in Class 3 the concrete may be deemed to be too wet to allow carbonation thus it is also unlikely to lead to a corrosion problem. Further work is needed to make an informed judgement as to which Exposure Class is representative of the real external environment, however, results suggest that the level of exposure to moisture may be somewhere between Class 1 (no wetting) and Class 2 (wetting every 28 days).

A further parameter, water/PC ratio showed that, with the exception of GBS mixes, all cement types could be grouped within a specific concrete grade to give a tentative limiting water/PC ratio. For all cement types (with the exception of GBS), a maximum water/PC of 0.65 would give a similar carbonation performance to that of the Reference mix and this was similar in all Exposure Classes. To provide a carbonation performance similar to that of the Reference Mix, GBS mixes allowed a higher water/PC limit of 0.95. Although this limit showed a slight variation in Classes 2 and 3 the limit still gave carbonation depths similar to the other cement types. The potential carbonation resistance of concrete was determined to be dependant on both permeation and alkalinity of the cover concrete. A comparison of water vapour diffusivity and total $Ca(OH)_2$ in the cover concrete showed that concretes with lower water vapour diffusivity properties still exhibited higher carbonation depths due to the fact that the cover concrete alkalinity was relatively low.

# The Methodology For The Evaluation Of Building Components' Durability

M Rejna
Politecnico di Milano Engineering of Building Systems and Urban Planning
Milan Italy

**Summary**: The use of building components and their exposition to the weathering agents causes degradations during time of their functionality, called "aging", towards which it's necessary to do maintenance works, with consumption of materials and economic resources. It's important to gain know-how on building components' durability and on performance degradation phenomena in order to design buildings characterized by an economically reasonable service life.

**For each built space the indoor conditions will be controlled if the technological performances of the building components that delimit them are maintained, because of the preservation of constituting products' properties. In coherence with this approach the DISET Durability Research Team proposes a method for the evaluation of durability organized into environmental and technological performances aspects, technical and design aspects.**

**As for the two first aspects the method proposes a procedure to predict and quantify on a sample space the indoor performance variations as a function of the components' performance linked to materials characteristics' variations. Then the indoor performance limits are linked to building components performance characteristics.**

**As for the technical aspects, tests are carried out in cooperation with the laboratory of SUPSI (CH) to evaluate effects on building components and materials caused by weathering agents. In laboratory building components samples are subject to accelerated aging and the performances' decay is monitored. When the measured values reach the acceptable performances' limits the final values of characteristics and linked properties of materials are measured. To evaluate the service life outdoor natural aging tests are being developed on samples of the same components, exposed to the outdoor environment and monitored as for the technological performances. The service life is given by the time going from the beginning of sample exposition and the measuring of performance limit reaching.**

**As for design aspects the method has worked out judgement criteria for reliability propensity of designed building components, based on their functional model, the executive complexity, the inherent variability and the chemical –physical compatibility. The research results give support information to building components design for a planned service life. The design application of reliability estimation criteria allows to reduce the risks not to reach the planned service life.**

## 1 INTRODUCTION - THE DURABILITY OF BUILDING COMPONENTS

The methodology for the durability estimation of building components, here reported, is the result of research activity that for years has been developed by the durability working group of Department of Engineering of Building Systems and Urban Planning, Politecnico of Milan, and that derives its methodological set-up from disciplinary considerations on building technological quality, of which the durability is a particular aspect.

The durability estimation consists in the identification, in a technical element, of the attitude to supply the initial performances from its installation, for a fixed time and with planned intensity. The time in which a technical element holds the expected functioning is defined as service life or average time of good operation.

The quality is defined by the national and over-national standard as “the ability to satisfy throughout performances the users requirements” (ISO 8420) and so the durability estimation involves the estimation of the beginning quality preservation during time.

One of the important requirements is the necessity to realize in each building work a balanced link between cost and performances provided; throughout the whole building process, from design and planning, up to construction, use, and demolition. The building has to provide suitable spaces for carrying out activities, which must be comfortable, reliable, able to maintain comfort and safety throughout the time up to the demolition, with a balanced use of resources. The performance’s loss during time, requires maintenance works to restore the programmed conditions, involving costs and resources.

The European Directive 89/106/CEE about the Essential Requirements for Construction Products, and the Interpretative Documents link the expected limit for durability of products and of technical elements realized with them, to the entity of predictable and feasible maintenance works at an economically adequate time.

In particular the Interpretative Documents say that that these requirements have to be satisfied, except for the usual maintenance, for an economically adequate time and define the maintenance as a series of recommendations applied to the building, to satisfy all their functions for the whole service life, defined as the time in which the building performances have to be maintained at a level compatible with the satisfaction of the Essential Requirements.

An economically reasonable service life supposes that all the relevant aspects are considered: planning costs, building and use costs, costs due to the use impediment, risks and damage throughout the building’s service life and the insurance costs covering these risks, costs for programmed renewal in part, costs for inspection, maintenance, supervision and repairing, operation and administrative costs, costs for the demolition and for the environmental aspects.

All this means that the costs- performance balance is the reference for the quality of entire building process: the cost assumes the connotations of global cost, i.e. the costs for construction, management and demolitions, and hence the quality assumes the connotations of global quality that shall be present in all the phases of building process.

If the cost’s concept is associated to the concept of economic and material resources’ use, it’s easy to understand that a qualitative approach in a general extension to the building process can’t ignore the problem of construction’s sustainability.

In particular about the discussed questions, it emerges that building components’ durability, at different levels of object and functional complexity, constitutes one of the factors through which to govern the sustainable consumption of resources.

Coherently with these considerations the durability study of the building’s component for the presents a double purpose: on one side the estimation of the natural service life, i.e. the time in which the expected performances voluntary remain at programmed levels, on the other side the acquisition of the knowledge about a time break and the formalities about which the performance decay is carried on. Natural service life and formalities of performance decay compose the foundations knowledge on which we can arrange the design and the planning of the maintenance operations necessary to the preservation in the time of the programmed use conditions of the building.

In building terms the user’s requirements, the satisfaction of which is the scope of every operation, find their operating expression in the behavior requirements.

One of the fundamental requirements that the users ask for the building systems is to have comfortable and suitable rooms for the foreseen activities: the environmental requirements are the expression of a fundamental need which has to be satisfied through fair environmental performances.

The environmental performances are obtained through the organized contribution of the technological performances, provided by the elements composing the technological system and subsystems.

On the other side these performances provide the answer to the technological requirements which must be satisfied by each specific technological subsystems, operative expression of the users requirements related with the technological system.

The performances of each technological subsystems, are provided by the ability of the component to develop the corresponding simple and complex technological functions. This happens by virtue of specific sets of characteristic properties, with fixed intensities, owned by the materials, sections, elements assumed for the realization of the functional elements setting up the component. These characteristics the components belonging to different subsystems are called functional characteristics and their structured set composes the functional model of the building component. The values, fixed by the design, of the parameters defining the object technical and relation characteristics are called technical specifications.

The maintenance during time of the environmental performances is then strictly linked with the maintenance of the planned intensity of fixed functional characteristics owned by the functional elements, composing the component, the technological performances of which contribute to the realization of the environmental conditions. This means that the functional model of the single component and the pertinent technical specifications have to keep during time coherent with the functional model and with the technical specifications owned at starting time. In other words the technical conformity of the technical elements must be preserved.

The building, and the elements which compose it, are exposed to context conditions, characterized by the environmental agents and the agents produced by the use, developing actions dependant on them.

Usually, we may say that the actions developed during time by the agents produce different kind of effects on the components and on the materials, sections, and elements of which the technical elements are composed, changing the characteristics and the parameters values characterizing them.

For a certain building the characteristics' decay phenomena during time produces an intensity change of the technological performances linked with the environmental performances.

The durability of a component expresses the propensity to supply during time the planned performances through the durability of materials, sections, and elements which compose it, i.e. through the durability of the relevant characteristics.

There are two ways of building components' performances' loss: the first way is characterized by the sudden passage from the condition of good operation to a no operation condition: these components are called bistable. For them the damage or no operation can be univocally identified.

The other way is characterized by a continuous loss of functioning, and so these elements are said not bistable. In this kind of decay there is the necessity to define the level of performance decay acceptable for the identification of the damage condition.

As the technological performances, given by a component belonging to a building in a certain stress context, have the aim to realize some suitable environmental performances for the expected activities, the limits of acceptable decay of a technological performance, which contribute to the realization of a defined environmental performance, is identified when the change of this environmental performance is pointed out and for which the environmental conditions are no more realized at a satisfactory level. It is to notice that the suitable environmental conditions for developing some activities, which satisfy the requirements, change when the social-economic context changes or when the use model changes. From this point of view the definition of damage condition or breakdown is relevant to the specific cultural and physical context.

In the same way the intensity of each component's technological performance is defined by virtue of the intensity of its contribution for the attainment of the planned environmental conditions in the particular arrangement of performance loads that the design has planned for that element.

The kind and the intensity of the technological performances, supplied by the components of the different building' subsystems, can be defined on the base of the answer that a certain technological subsystem must develop in comparison with the kind and the intensity of the stress by the agents present in the context, to take part in the realization of adequate environmental conditions for the expected use. As a consequence the acceptable threshold of the change of a component's technological performance, a change that, as we have said, identifies the beginning of the damage, can't be generalized but it is strictly connected with the intensity of the stress agents present in the specific physical context and with the particular arrangement of the performance loads that the design has given to the component.

All the same the intensity change in the characteristics of materials, sections, and elements composing each building component, because of the specific context agents, takes over a meaning of damage only when the specific technological function, which is developed through it, is no more able to come to the planned intensity to obtain the expected value of the corresponding technological performance. If the durability essentially consists in, for all the elements at a different level of complexity (materials, sections, elements, components, subsystems which realize the building) the ability to preserve for a certain time the characteristic values within acceptable limits, it stands out that the durability with absolute value doesn't exist, as the quality with absolute value doesn't exist. Only values exist related to the building, in a certain context of use and of stress, with the aim to satisfy the requirements which have put into action for that specific operation.

## 2 THE DURABILITY EVALUATION

The canonical method to get indications about building components' service life, the time in which the changes happen, requires the observation during time of technologically homogeneous building objects samples, of which is known the starting date of operation, and subject to stressing homogeneous agents: this observation appears very difficult.

These difficulties, together with the need to test components of which we have not reliable information, puts us the need to start with an adequate experimentation through laboratory tests upon specific samples.

Taking into account the reported considerations, the time behavior of a building has to be governed in the decisional moment of the process through the assignment to the components of a correct propensity to the time behavior. The durability control is carried out during the component's design through the engagement of building products with a controlled decay, coherent with the estimated building service life. For this reason the design must have the knowledge about the decay phenomena and about the life cycles of building parts at different level of complexity.

At the building's level it's necessary to know the trend of the differentiated technological obsolescence of the functional parts composing the building system, due to the different object connotation of the parts themselves and in relation with the specific context stressing conditions. At the component's level it's necessary to know the trend of the differentiated performance decay during time of the different functional parts of the technological system related to each characterizing technological requirement.

As a consequence the durability estimation has to be followed up at the level of each significant functional part of the technological system, i.e. at the level of the component's category. Moreover, for each category the durability estimation is different for each technological performance corresponding to each requirement of the considered class.

In synthesis the time behavior estimation of the technological system must be followed up at the level of components' category, must be tested one by one for each specific technological performance of the specific category, must be connected with the specific environmental and use conditions, that is at the expected stress state for the category use in the specific building.

The durability estimation, to be correctly worked out, requires the measurement of the parameters which makes it operable, that is: the damage rate or instant reliability, the service life reliability, that is the probability of the expected service life , the service life of the "object" also said average time of good operation.

Among these parameters the service life and the reliability are necessary for a component's category durability estimation, which can bring a correct information for the design phase and for the building maintenance planning. Then the durability estimation must be articulated in a service life estimation and in a estimation at the service life reliability.

As the time behavior presents different connotations for the different components, because of the phenomenon of different functional obsolescence, the knowledge of the different durability values allows the design phase to work out and to plan adequate maintenance works, to restore the loss functionality, measured during time with the scope to reach an adequate cost-performance balance.

A correct prediction of works to carry out in the building management process supposes the availability of sufficient knowledge about the damages for the various components, about the expected time of the damage happening (service life or average time up to a damage), about the probability that the expected time of service life can be reached (reliability),as well as about the foresight of the damage happening in the time unit ( damage rate).

A rigorous estimation of the durability of the building components belonging at a certain category consists in the experimental evaluation of their time behaviors in the various environmental conditions and in use conditions in which these elements are stressed.

The difficulty to practice the rigorous estimation and the necessary long time have justified the team of Politecnico di Milano to approach the durability estimation with a methodology which allows to by-pass the above mentioned difficulties.

This methodology is articulated in a method for the service life estimation on the base of the experimental phase applied to components' samples and in a method for the reliability estimation to be applied to the design of components, out of system and with no intended use (Figure 1).

## 3 THE METHODOLOGY FOR SERVICE LIFE ESTIMATION

The methodology for the service life estimation is based on experimentation through accelerated aging laboratory tests and through natural weathering aging tests applied to partial and complete samples of building components of non load-bearing external walls.

The components' decay phenomena are investigated according to the sequence agents-actions-effects. In the climatic test cell of the technological laboratory the agents rain, freeze-thaw, humid hot and dry hot conditions are simulated. The principles for the definition of the stress context and then of the typology and intensity of natural and artificial agents to estimate the decay, the principles for the individuation of the simulated agents with which we can carry out the tests in a technological laboratory, the principles for the set-up of these tests, that is the cycle structure, with the definition of the intensity of the agents, the application time and their sequence in the tests development are presented in Rigamonti 2002.

The laboratory accelerated aging tests, carry out to the individuation and to the quantification of the sensibility of the tested components to the actions by the activated agents, subset of the agents really present in the reference context.

With the term "sensibility" we mean the complex of changes at different level of intensity of the characteristics owned by the objects subject to the test in comparison with the values owned at the beginning time. During aging the functional characteristics of materials constituting the samples, the trend of technological functions developed through those characteristics and then the corresponding technological performances are monitored.

The "aging" tests of the samples are accelerated tests, that is the stress agents, equal as quality to the real ones, are artificially intensified or accelerated in relation to the application time: the time of decay appearing is not real in laboratory. To reach the foresight of the real time before damage, or natural service life, it's necessary to work out a re-scaling, exposing some samples to outdoor natural conditions with actions and stressing agents equal to the ones developed in the technological laboratory. When the measurement of the outdoor components points out an effect already seen in the accelerated tests, it's possible to define a time range to transfer the laboratory accelerated time results, in real terms and it's possible to express the actual service life as real time.

The natural aging tests allow to measure the time when the different intensities of monitored characteristics' changes appear. The correlation between accelerated tests and natural tests for a limited time allows to define a real time scale where to report the measured accelerated effects. It's also necessary to elaborate criteria to define for these effects the damage threshold and the time when the damage occurs, i.e. the service life time.

The research group is working on not bistable components with regards to the way damages appear, i.e. they are characterized by the progressive functions' loss. For them it occurs to define the acceptability threshold of performance decay in virtue of the acceptability threshold of environmental performances. For this reason the research has set up a simulating theoretical method which allows to read contemporary the changes of the environmental performances at standardized values, recognized as adequate to the use model for the residential building users, and referred to a conventional space, with fixed dimension, depending on the changing of technological performances given by the space envelope components, in virtue of the intensity changes of functional characteristics owned by the functional elements which constitutes the component.

In the simulating model this happens through calculation algorithms, to express the technological functions through which the considered technological performances are given. The functional characteristics threshold values, for which the conformity of the environmental performance occurs no more, are called performance limits and are composing the reference term in the technological laboratory to define the achievement of the damage state in test development as reported in Re Cecconi 2002.

## 4 THE METHODOLOGY FOR RELIABILITY PROPENSITY ESTIMATION

Then the service life estimation is worked out on the base of the direct experimental results or methodologically mediated by the time behavior of the component out of system and with no intended use, in conventional stress conditions; on the contrary the reliability estimation at service life time is susceptible to be followed up in terms of propensity through the analysis of the components functioning, i.e. through the functional analysis, of objects and of the structure of the components design.

The method is based on the analysis of the functional model of building components belonging to a defined category, model referred to the designed component and defined through the functional analysis according to Maggi *et al.* 2000.

For each technological subsystem one defines the base functions, corresponding to the connotative technological requirements, and then defines the articulation into analytical functions for the development of the base functions according to Maggi *et al.* 2001.

The functioning model defines a component at the performance specifications phase level, (i.e. the functional model composed by the planned functions) and at the design level, (i.e. the object model composed by objects correlated between them and carrying definite functional characteristics with fixed values of intensity).

The functioning model of a certain component schematizes, through the functional model, the functional structure of the component, (that is the different functional places to which are awarded the analytical functions which bring to the development of the base functions, subset of the technological functions characterizing the subsystem) their position, their mutual relations, and, through the object model, the physical structure of the component itself, that is the different layers or functional elements, their position and their mutual relations.

The characteristics, identified by the kind and by intensity, owned at zero time by the products which compose the functional elements of a component, designed or already realized, are singled out throughout the reading of the object model.

The method for the estimation of the reliability's propensity consists in the application to the functional model and to the object model of the components, belonging to a certain catalogue, of specific judgment principles following four evaluation keys. The reliability 's propensity, as the probability to reach the average time of good operation or, for the other side, as the probability of a quickly damage, finds its origin in the component's design moment for what concerns the functional reliability, inherent and critical and in the construction moment for what concerns the executive reliability.

The estimation of the functional reliability's propensity is worked out on the component's functional model. Usually we observe that the distribution structure of the analytical functions in functional places leads to a greater or smaller risk of performance loss in relation with the stress to which the functional elements are subject. The judgment categories for the estimation of the functional reliability's propensity are: simplicity of the model, stress of the model, distribution of the functions.

The estimation of the executive reliability's propensity stands out by the analysis of the executive complexity of the building component and it's based on the foresight of the possible difference between the built component and the designed one, due to the execution mistakes because of the object complexity of the component. The mistakes which can happen during the construction phase are twice: the first consists in the positioning of the component out of its co-ordination space; the second consists in the set up of materials, sections, units in a way not corresponding to the design indications.

The risk of these mistakes occurring is as bigger as higher is the technological dimensional complexity of the component. The technological dimensional complexity is evaluated from the object model on the base of the judgment criteria for material complexity, object complexity and relation complexity.

The estimation of the inherent reliability's propensity is carried out on the component's design and is based upon the foresight of the activation of the inherent phenomena throughout the component's life. These phenomena in the whole component and in the functional elements composing it, produce dimensional changes resulting more or less not allowed by the kind of joints links between these components. The impediment to the free explication of the "dimensional training" gives stresses which can determine breakage. The stress due to the context, which determines the dimensional changes in exercise, are due in particular to temperature and humidity changes. For them two aspects of the elementary reliability are identified: the thermal inherent reliability and the humid inherent reliability.

The estimation of the critical reliability's propensity is carried out about the project of the component and is based upon the foresight of the possible damages which can occur because of the chemical and chemical-physical incompatibility between the functional elements of the component. These phenomena produce changes of different intensity in the structural integrity of the component operating, from the lightest ones interesting only the component's appearance to the gravest ones which compromise its structural integrity.

## 5 AN EXAMPLE OF THE USE OF THE METHODOLOGY

The proposed methodology has been applied experimentally by the research group of the Department of Engineering of Building Systems and Urban Planning of Politecnico di Milano and by SUPSI (CH) on a non load-bearing external wall named PV2.

The initial technological performances of this component have been evaluated by calculation and the values of the functional characteristics assumed for the evaluation have been defined. (Figure 2).

By simulating the performances' decay the performance threshold limits have been evaluated according to Maggi et al 2000 e to F. Re Cecconi 2002. In figure 1 an example is presented about the decay of performance "Surface condensation control" and the definition of performance limits for the functional characteristics of thermal conductivity.

In the SUPSI Laboratory three sets of component's samples have been built: upon one set the initial characterization testing have been carried out, while on the second set laboratory accelerated aging has been applied in a weathering test cell according to Maggi et al 2001 e to G.Rigamonti 2002. Finally the last samples' set has been exposed to natural outdoor aging in Italy and Switzerland, to be monitored in order to estimate the time re -scaling according to Maggi et al 2000, 2001.

On the PV2 component design it has been evaluated the reliability propensity following the reported methodology according to Maggi et al 2001: the final scores have been presented in figure 2.

## 6 CONCLUSIONS

The presented method, also with different approaches, defines a procedure following which to reach the parameters' estimation for the time behavior evaluation of the building components' of a certain class.

Through the theoretical simulation of space models it allows to define the damage status, i.e. the value of each functional characteristics that generate no more acceptable values of linked environmental performances.

Through accelerated tests in a technological laboratory and natural weathering tests it allows to define the degradation effects and the service life time, i.e. the time when the damage values are reached, with functional characteristics' modeling and related performances.

Through the procedure of reliability propensity estimation it allows to evaluate on the component's design the risk of early functioning loss depending on its functional and object structure.

The results of the application of this methodology supply the building components' design with a valid contribution to the durability control.

# The Effect Of Fly Ash And Recycled Aggregate On The Corrosion Resistance Of Steel In Cracked Reinforced Concrete

**F Tittarelli & G Moriconi**
**Physics University of Ancona Italy**

**Summary**: **Recycled aggregate concrete is an example of a sustainable construction material, especially in the presence of fly ash. This work was aimed to investigate the effect, if any, of recycled aggregate and/or fly ash on corrosion behavior of steel in cracked reinforced concrete. When used, as much fly ash as cement was added in the concrete mixture.**

**Since less alkaline conditions in the concrete pore solution, as those caused by fly ash addition because of its pozzolanic activity, seem to favor a dense protective passive layer on galvanized steel reinforcement, a possible beneficial effect of fly ash addition on the corrosion resistance of galvanized steel in cracked natural or recycled-aggregate concrete was also studied.**

**The results obtained showed that galvanization always improves the corrosion resistance of reinforcements, also in the presence of cracks and in very aggressive chloride environments. The introduction of the sustainability concept in concrete by using recycled aggregate and/or fly ash has no deleterious effect on the corrosion behavior of bare steel reinforcement, since the corrosive attack turns more diffuse and less penetrating, especially when pozzolanic additions are made. As far as galvanized steel reinforcement is concerned, the use of recycled aggregate and/or fly ash seems even to improve its corrosion resistance**

**Keywords. Reinforcement Corrosion, Cracked Concrete, Recycled Aggregate, Fly ash, Galvanized Steel.**

## 1 INTRODUCTION

The manufacture of durable concrete for buildings can contribute to construction sustainable development (Metha 1997) based on principles, techniques and materials that preserve natural resources and improve the environmental quality by the use of recycling in concrete.

Buildings material, that are no longer able to fulfill their original task after a certain time, can be processed in such a way that they can be used again in the original application as recycled aggregate (O'Brien 1998). Replacing natural with recycled aggregate in concrete reduces the consumption of natural resources and protects natural site features. This also avoids the environmental impact resulting from quarries and allows a reduction in the volume of materials disposed to landfill.

The use of fly ash in concrete (Malhotra & Bilodeau 1999) allows to recycle the energy spent in the industrial process, which generates fly-ash as a by-product with the simultaneous reduction of waste disposal to the environment. In particular, due to its pozzolanic activity, fly ash can be used by partially replacing cement, thus reducing the energy consumption and the carbon dioxide emission related to cement production.

Previous experiments (Corinaldesi & Moriconi 2001) showed the possibility to compare the structural properties of recycled aggregate concrete, when fly ash is added, with the ones of ordinary concrete for current applications. However, the structural serviceability, in terms of corrosion tests on reinforced concrete (Hansen 1992), especially in the presence of cracks, which often affect the concrete cover of real structures, has not yet been investigated.

Therefore, the aim of this work was to study if the introduction of the sustainability concept in concrete, by using recycled aggregate and/or fly ash, could influence the corrosion behavior of cracked reinforced concrete.

Moreover, from a holistic point of view, sustainable construction means also to design a reinforced concrete structure with the appropriate durability (Ellis jr & Shelton 1995) in relation to the specified service life and, when it is exposed to particularly aggressive environments, additional reinforcement protection, such as galvanization (Swamy 1990, Yeomans 1994, Fratesi, Moriconi & Coppola 1996) has to be used to reduce repair costs and environmental loads. Since galvanization protection seems to be favored by the alkalinity reduction (Andrade *et al.* 1983) of the concrete pore solution which can be achieved by fly ash addition because of its pozzolanic activity, in this work the corrosion resistance of galvanized steel in a so-called sustainable cracked concrete, containing fly ash and/or recycled aggregate concrete, was also studied.

## 2 EXPERIMENTAL

Concrete prism specimens (280 mm × 70 mm × 70 mm) were manufactured with 6 different concrete mixtures (Table 1), with natural or recycled aggregates, in the presence or absence of fly ash;

- w/c = 0.3 with natural aggregate and without fly ash (N0.3)
- w/c = 0.6 with natural aggregate and fly ash (N0.3F)
- w/c = 0.6 with natural aggregate and without fly ash (N0.6)
- w/c = 0.3 with recycled aggregate and without fly ash (R0.3)
- w/c = 1.2 with natural aggregate and fly ash (N0.6F)
- w/c = 0.6 with recycled aggregate and fly ash (R0.3F)

When present, a low calcium fly ash (ASTM C 618 Class F), was added as a cement replacement at the dosage rate of 50% by cement weight.

The six different concrete mixtures were deliberately chosen in order to classify the manufactured concretes into three different strength grades respectively equal to 50-60 MPa, 30-40 MPa and 10-20 MPa.

N0.3 concrete belongs to the highest strength class as a reference high quality concrete.

Ordinary concretes generally used with compressive strength of about 30-40 MPa are represented by N0.6 concrete. N0.3F and R0.3 concretes belong to this strength class, because in the presence of fly ash or recycled aggregate the water to cementitious material ratio has to be lowered to 0.3 in order to achieve the same strength class value.

Finally, poor quality concretes with compressive strength of about 10-20 MPa, are represented by R0.3F and N0.6F concretes.

**Table 1. Concrete mixtures proportions.**

| Mixture | w/c | Mixture Proportions, kg/m$^3$ | | | | | | w/cm | Compressive Strength (MPa) |
|---|---|---|---|---|---|---|---|---|---|
| | | Water | Cement | Sand | Crushed Aggregate | Fly Ash | Super-plasticizer | | |
| N0.3 | 0.3 | 165 | 550 | 317 | 1350 | - | 5.5 | 0.3 | 58 |
| N0.3F | 0.6 | 165 | 275 | 298 | 1269 | 275 | 5.5 | 0.3 | 38 |
| N0.6 | 0.6 | 230 | 380 | 314 | 1338 | - | - | 0.6 | 31 |
| N0.6F | 1.2 | 230 | 190 | 301 | 1282 | 190 | - | 0.6 | 16 |
| R0.3 | 0.3 | 165 | 550 | 372 | 1060 | - | 5.5 | 0.3 | 33 |
| R0.3F | 0.6 | 165 | 275 | 330 | 991 | 275 | 5.5 | 0.3 | 21 |

A commercial portland-limestone blended cement, Type CE II/A-L 42.5 R according to the European Standards EN-197/1, was used.

Crushed limestone aggregate (15 mm maximum size) and natural sand (6 mm maximum size) were used to make the reference natural-aggregate concrete. A coarse fraction (15 mm maximum size) and a fine fraction (6 mm maximum size) were also used to make concrete containing recycled aggregate. These fractions were directly supplied by an industrial crushing plant in Villa Musone, Italy, in which rubble from demolition of buildings are cleaned, crushed and sized.

When proportioning the concrete, the two above-mentioned kinds of aggregates - recycled or natural - were used with the same gradation, obtained by combining the fine and the coarse sieve fractions, according to the Bolomey particle size distribution curve. Moreover, the mixture workability in relation to the particles shape, as well as the cement dosage, were taken into account in order to optimize the gradation. Since no detection of the actual relative humidity of the aggregates was carried out, the amount of mixing water was always adjusted to obtain the same fresh workability of 150-180 mm slump.

A 30% aqueous solution of an acrylic-based admixture was used a superplasticizer to compensate for the workability loss caused by the addition of low calcium fly ash (ASTM C 618 Class F) and to allow the use of w/cm as low as 0.3.

Each prismatic specimen was reinforced with a steel plate (210 mm × 40 mm × 1 mm), either bare or galvanized, embedded with 3 cm concrete cover. The zinc coating on the galvanized steel plate was 100 µm thick, obtained by molten zinc immersion, with an outer pure zinc layer about 20 µm thick. The galvanized steel plates, just before embedment in the fresh concrete, were submerged for 5 sec in 15% NaOH solution to dissolve the $ZnCO_3$ layer eventually formed during atmospheric storage. The electric contacts between the reinforcing plates and the measurement equipment were arranged according to previously reported methodology (Fratesi, Moriconi & Coppola 1996).

After 1 month of air curing the specimens were cracked by flexural stress so that a crack width of 1 mm was produced in a pre-formed notch area with the apex crack reaching the reinforcement. Then the specimens were exposed to weekly wet-dry cycles (2 days dry followed by 5 days wet) in a 10% NaCl solution.

The corrosion risk of the reinforcement in the concrete specimens exposed to the aggressive environment was evaluated by free corrosion potential measurements with a saturated calomel electrode (SCE) as reference, while the kinetic of the corrosion process was monitored by polarization measurements. The polarization resistance was measured through the galvanodynamic method, using an external graphite bar as counter-electrode, by calculating its average value between the anodic and cathodic ones.

The electrochemical values reported in the following graphs are averaged among the measurements carried out on three specimens of each type during the full immersion period.

In order to validate and to complete the evaluation of the electrochemical behavior, the concrete specimens were autopsied after 7 wet-dry cycles in the chloride solution to assess the corrosion by visual observation. All the steel plates were removed after splitting the concrete specimens. The weight loss and the surface of the corroded area on bare steel plates was evaluated after pickling, while metallographic analysis were carried out on the cross section of the galvanized steel plates to evaluate the coating thickness decrease due to the corrosive attack. Zinc corrosion products were identified by X-ray diffraction and the free chloride concentration on the reinforcements was also measured at the end of the test by water extraction.

## 3 RESULTS AND DISCUSSION

### 3.1 Bare steel

#### 3.1.1 Electrochemical measurements

Figure 1 shows the free corrosion potential values of bare steel plates embedded in cracked concrete as a function of wet-dry cycles.

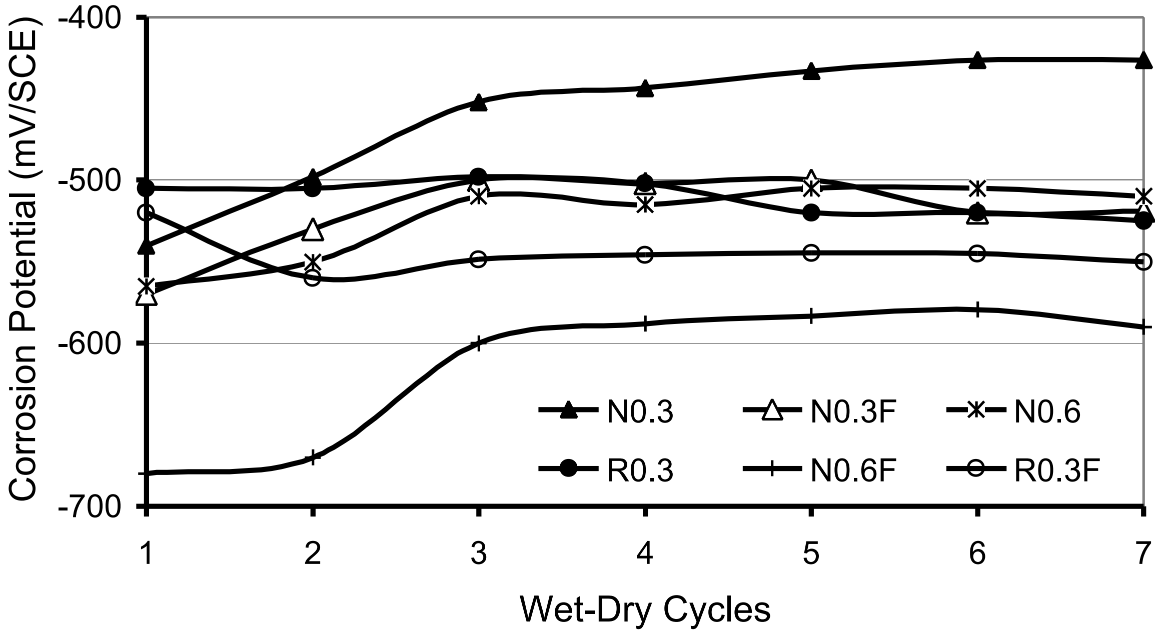

**Figure 1. Corrosion potential of bare steel plates embedded in cracked concrete as a function of wet-dry cycles.**

It can be observed that just after the exposure to the chloride environment, all the steel plates assumed activation values lower than –500 mV/SCE, regardless of the cement matrix type, reflecting a general high corrosion risk. However, after few wet-dry cycles, the steel plates embedded in the most porous concretes (N0.6F and R0.3F) showed the highest corrosion risk, with the lowest corrosion potentials values. On the contrary, the steel plates embedded in the reference high quality concrete (0.3N) showed the lowest corrosion risk. Finally, the steel plates embedded in the other concrete mixtures belonging to the ordinary class strength (30-40 MPa) assumed corrosion potential values converging to an intermediate corrosion risk.

The corrosion behavior described by the corrosion potential measurements were completely confirmed by the polarization resistance measurements (Fig. 2). Also the corrosion resistance of the steel reinforcement seemed to depend mainly on the mechanical strength of the cracked concrete, regardless of the cementitious matrix type. In this case, obviously, the higher the concrete strength class is, higher the corresponding polarization resistance turns.

Therefore, the opportunity of manufacturing eco-compatible concrete, by replacing natural with recycled aggregate and/or by adding high fly ash volume, does not seem to negatively affect the corrosion behavior of the embedded steel reinforcements as far as the same strength class is concerned. Indeed, in ordinary concrete with compressive strength of about 30 MPa, recycled-aggregate concretes and high volume fly ash concretes show a higher polarization resistance. Moreover, the results obtained could dispel any doubt on the uncertain corrosion behavior of steel in high volume fly ash concrete, due to the concrete pore solution alkalinity reduction caused by the fly ash pozzolanic activity, at least in the presence of cracks in concrete.

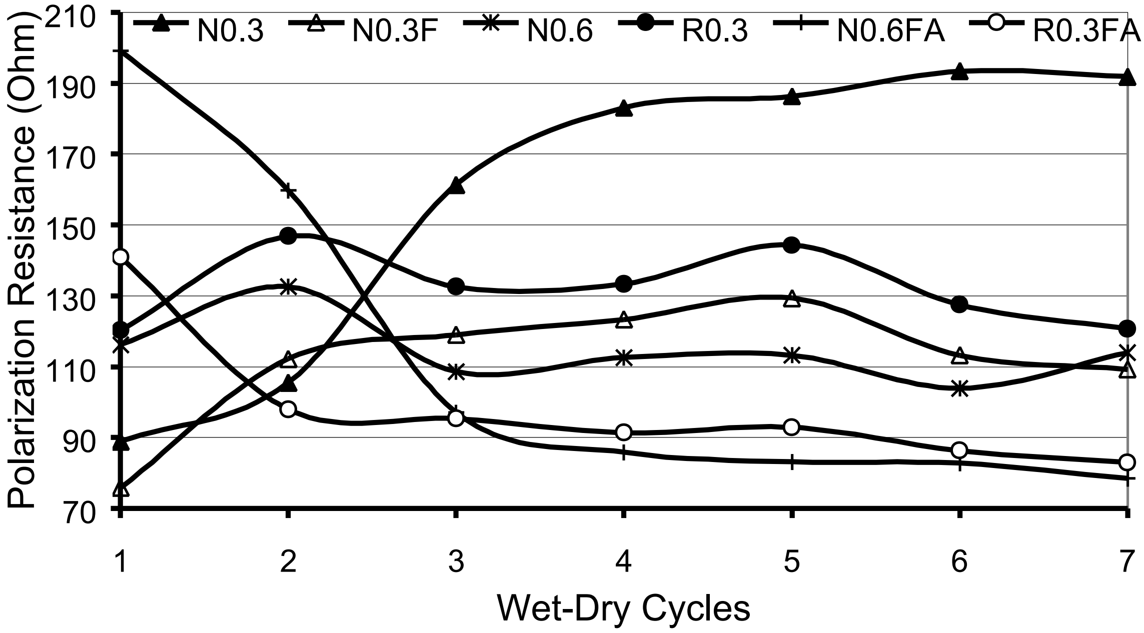

**Figure 2. Polarization resistance of bare steel plates embedded in cracked concrete as a function of wet-dry cycles.**

3.1.2 Autoptic evaluation

The electrochemical tests represent a partial feature of the reinforcement corrosion behavior since instantaneous measurements can only be carried out during the wet period and there is no chance to estimate the metal surface area effectively corroding. Therefore, after 7 wet-dry cycles all the specimens were split in order to visually evaluate the corroded area and to assess the weight loss of the bare steel plates after pickling.

All the reinforcements were characterized by a strong corrosive attack in the crack area which could be justified by the high chloride concentration detected on the reinforcement surface (2-5% by cement weight) significantly greater than the concentration threshold (0.4% by cement weight) generally reported as the critical value able to induce the corrosion process in bare steel.

However, from a morphological point of view (Fig. 3), in the presence of recycled aggregate and, particularly, of fly ash the corrosive attack appeared more diffuse and less penetrating with respect to that detected on the steel plate embedded in the reference concrete, where a more localized corrosive attack could also induce the steel plate blanking in spite of the very low w/c.

Go Back Next Page

**Figure 3. Visual observation of the corrosive attack on the bare steel plates embedded in reference natural-aggregate concrete N0.3 (left), in recycled-aggregate concrete R0.3 (middle) and high volume fly ash concrete N0.3F (right).**

At last, the bare steel plates weight loss turned out quantitatively in good agreement with the electrochemical measurements (Table 2).

**Table 2. Weight loss of the bare steel plates due to the corrosive attack.**

| MIXTURE | WEIGHT LOSS (gr) |
|---|---|
| N0.3 | 0.28 |
| N0.3F | 0.30 |
| N0.6 | 0.38 |
| R0.3 | 0.38 |
| N0.6F | 0.36 |
| R0.3F | 0.47 |

### 3.2 Galvanized Steel

3.2.1 Electrochemical measurements

Figure 4 shows the free corrosion potential values of galvanized steel plates embedded in cracked concrete as a function of wet-dry cycles. It can be observed that just after the exposure to the aggressive environment, the corrosion potential of the galvanized steel plates assumed initial active values of about –1000 mV/SCE regardless of the concrete type. During the wet-dry cycles, also in the case of galvanized steel reinforcement, a higher corrosion risk represented by low potential values was recorded for poor quality concrete (N0.6F and R0.3F). The reference high quality concrete (0.3N) assumed the highest potential values and the ordinary concretes (R0.3, N0.6 N0.3F) showed intermediate values, indicating the lowest and intermediate corrosion risk respectively.

The polarization resistance measurements carried out on galvanized steel reinforcements (Fig. 5) again turn in good agreement with the potentials values as for bare steel, by confirming the already stated hierarchy related to the concrete strength class.

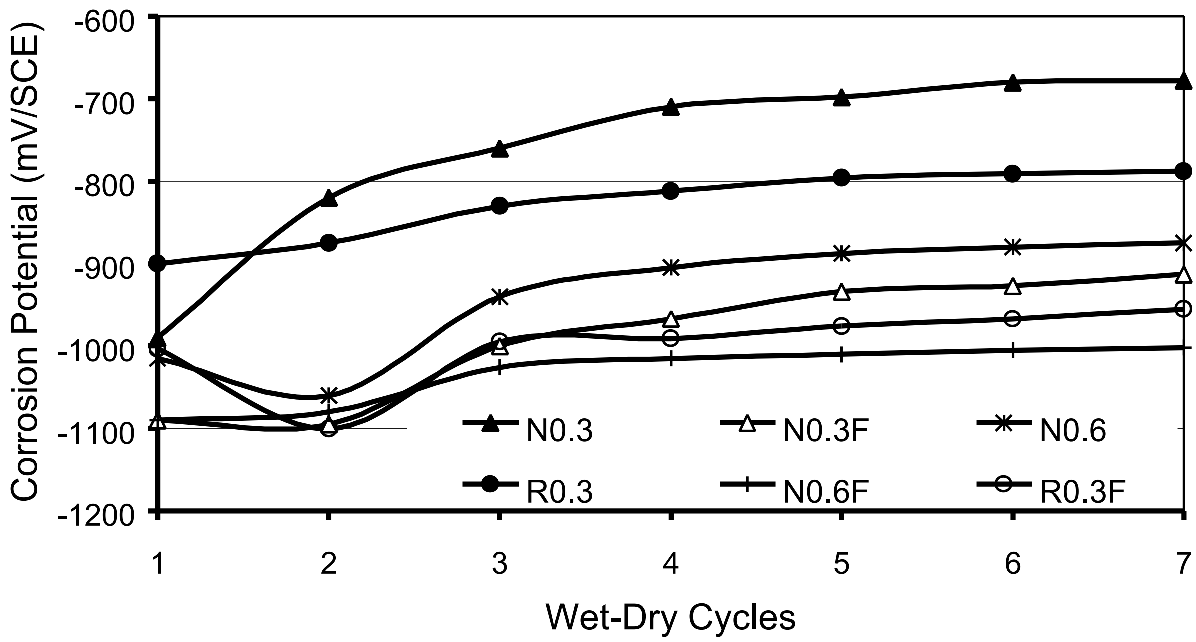

**Figure 4. Corrosion potential of galvanized steel plates embedded in cracked concrete as a function of wet-dry cycles.**

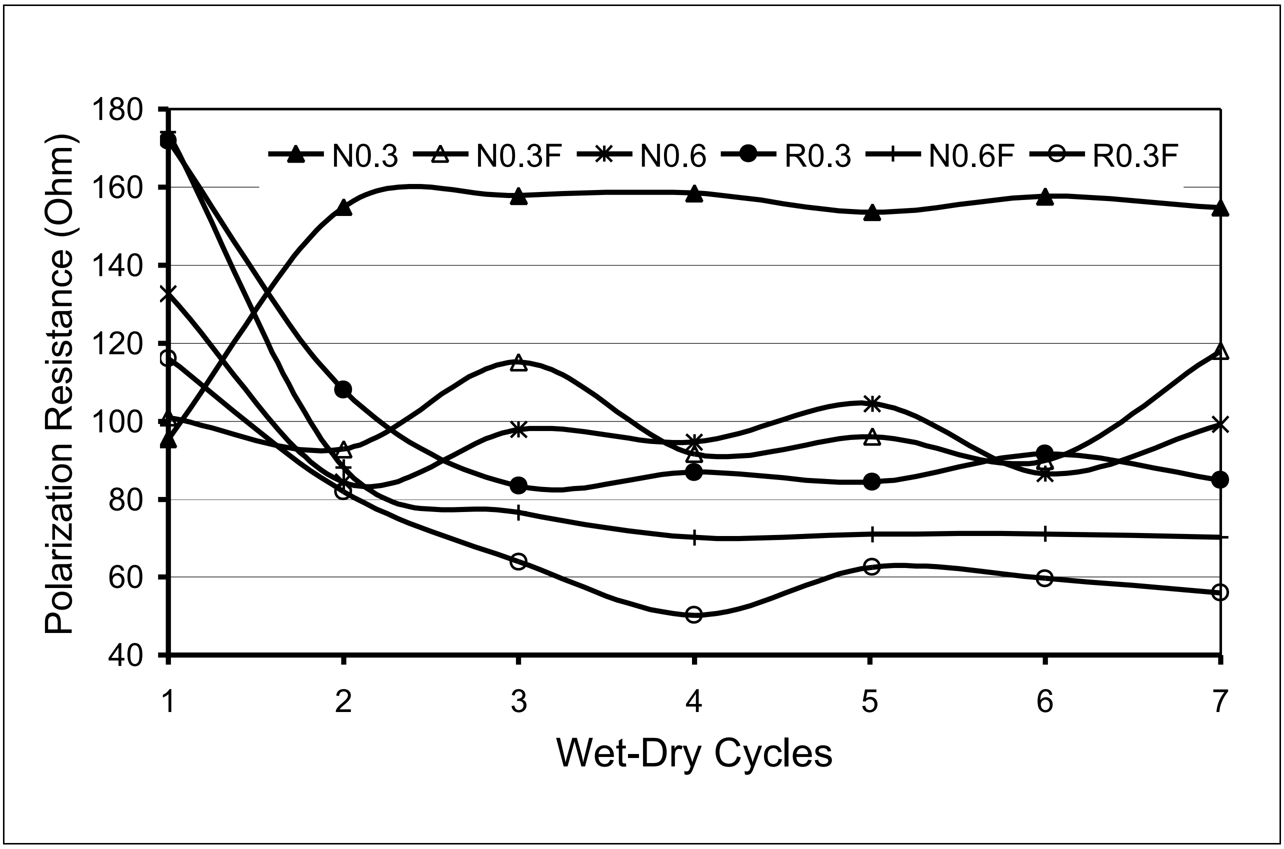

**Figure 5. Polarization resistance of galvanized steel plates embedded in cracked concrete as a function of wet-dry cycles.**

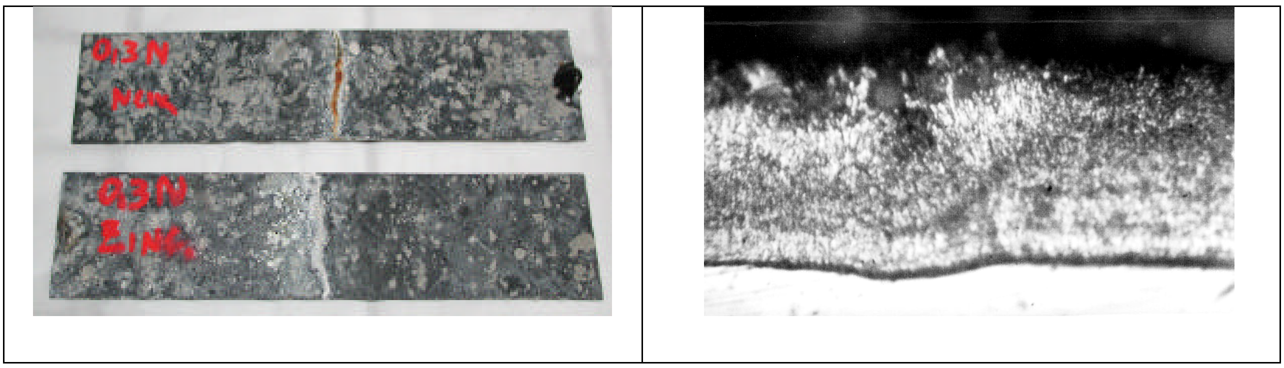
3.2.2 Autoptic evaluation

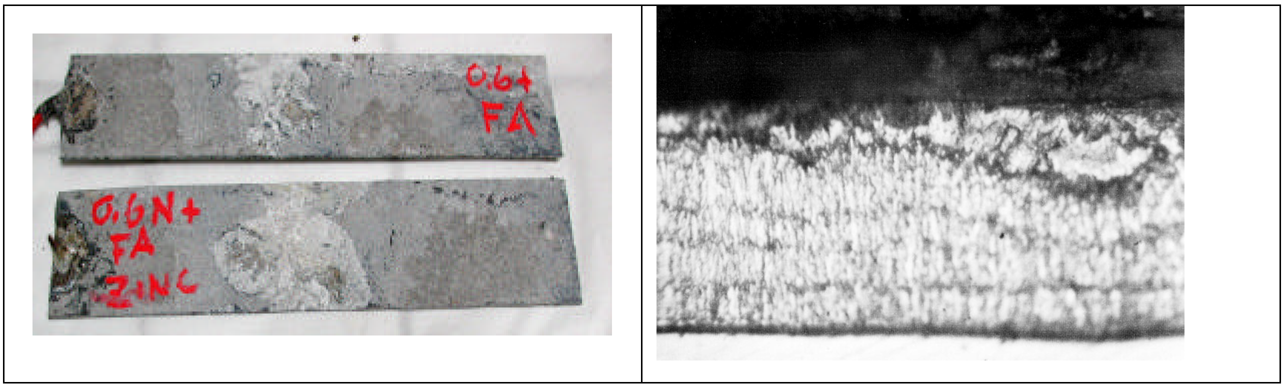
The autopsy carried out in this case revealed additional unexpected information with respect to that obtained by the electrochemical measurements.

As a matter of fact, in the reference high quality concrete (0.3N), where the reinforcement polarization resistance was high, the corrosive attack really appeared very localized at the crack apex and also very deep, even showing well recognizable iron corrosion products (Fig. 6a). Moreover, far from the crack apex, Fe-Zn alloy appeared on the plate surface meaning that total consumption of the pure zinc layer due to the corrosive attack occurred, as later confirmed by metallographic analysis (Fig. 6b).



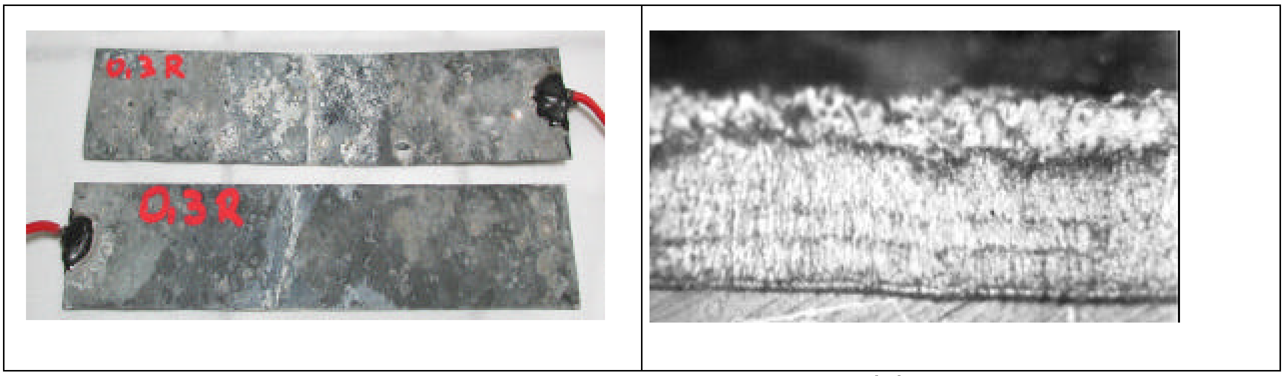
(a) (b)

**Figure 6. Visual observation (a) and metallographic cross section (b) of the galvanized steel plates embedded in reference concrete (0.3N).**



**(a)** **(b)**

**Figure 7. Visual observation (a) and metallographic cross section (b) of galvanized steel plates embedded in high volume fly ash concrete (0.6NF).**



**(a)** **(b)**

**Figure 8. Visual observation (a) and metallographic cross section (b) of galvanized steel plates embedded in recycled-aggregate concrete (0.3R).**

On the other hand, the galvanized steel plates extracted from high volume fly ash concrete showed a surface coating made of zinc corrosion products (Fig. 7a), later identified as calcium hydroxyzincate by X-ray diffraction. Calcium hydroxyzincate is a well passivating zinc corrosion product (Duval & Arliguie 1974, Macias & Andrade 1987) whose formation seems to be effectively favored by low alkalinity of the concrete pore solution (Andrade *et al.* 1983) as achieved when high volume fly ash is added because of its pozzolanic activity. Once formed, calcium hydroxyzincate protects the underlying pure zinc layer from further corrosion as metallographic analysis, later carried out on the cross section of the galvanized plates embedded in high volume fly ash concrete, well put into evidence (Fig. 7b).

Unexpectedly, the galvanized steel plates extracted from the cracked recycled-aggregate concrete specimens showed the lowest corrosive attack. Zinc grains were still well visible on the galvanized plates surface after the aggressive exposure (Fig. 8a) and the metallographic observation revealed a continuously thick pure zinc layer still present on the reinforcements (Fig. 8b).

## 4 CONCLUSIONS

Steel galvanization has been shown to improve the corrosion resistance of reinforcement embedded in concrete, also in very aggressive chloride environment and in the presence of cracks in concrete.

The introduction of the sustainability concept in concrete by using recycled aggregate and/or fly ash has no deleterious effect on the corrosion behavior of bare steel reinforcements for similar concrete strength class. Indeed, especially when fly ash is added, the morphology of the corrosive attack turns more diffuse and less penetrating.

The use of high volume fly ash in concrete significantly affects the corrosion behavior of galvanized reinforcement embedded in cracked concrete by generally improving its corrosion resistance.

# Durability Of Recycled-Aggregate Concrete Incorporating High Volumes Of Fly Ash

**V Corinaldesi G Moriconi**
**Materials and Environment Engineering and Physics University of Ancona Italy**

**Summary: The results presented in this paper are part of a research program dealing with the use of recycled concrete as an aggregate to manufacture structural concrete. Emphasis is placed on durability related properties rather than engineering properties. Durability is assessed in terms of carbonation and chloride penetration depth as well as freezing and thawing resistance.**

**Reference concrete was manufactured by using only natural aggregates with a water/cement of 0.60 as commonly used in practice. Then, a recycled-aggregate concrete was prepared by completely substituting natural aggregate, with a water/cement of 0.30 in order to achieve the same strength class of the reference concrete by a safety margin. This recycled-aggregate concrete was also manufactured by using a water-reducing admixture in order to lower both water and cement dosage, without disregarding the prefixed strength class requirements. Moreover, a recycled-aggregate concrete was manufactured with a water/cement of 0.60, by simultaneously adding to the mixture as much fly ash as cement, substituting the fine aggregate fraction. Thus, a water to cementitious material ratio of 0.30 was obtained enabling the concrete to reach the prefixed strength class. This procedure is essential for designing an environmentally friendly concrete. All concretes were prepared maintaining the same fluid consistency by proper addition of an acrylic-based superplasticizer.**

**Compressive strength was measured at 3, 7, 28 and 56 days; the 28-day compressive strength always fell in the range of 27-31 MPa.**

**Carbonation and chloride penetration tests were carried out to compare the four concretes in terms of durability behavior. In general, this durability seems to be better guaranteed by recycled-aggregate instead of reference concrete, mainly owing to the lower water to binder ratio.**

**The resistance against freezing and thawing cycles was investigated on concrete specimens prepared without any air-entraining admixture, in order to verify the influence of recycled instead of natural aggregates. No change in the freezing and thawing behavior attributable to this replacement was detected.**

**Keywords. Recycled-aggregate concrete, High volume fly ash, Carbonation, Chloride penetration, Freeze-thaw resistance.**

## 1. INTRODUCTION

A judicious use of natural resources, which are rapidly depleting, represents one of the main action meeting the concept of sustainable development, the other being an overall reduction of environmental impact. The former action can be achieved by re-using industrial by-products thus reducing both material waste and natural materials consumption. Recycled-aggregate concrete containing a high volume of fly ash is an example of a construction material that is in harmony with this concept. In fact, in this concrete rubble from building demolition can be introduced, after a suitable treatment, as a natural aggregate fraction substitution. In this way the volume of rubble disposed to landfill could decrease and simultaneously also natural resources consumption could be reduced. Moreover, the addition of fly ash, which is a by-product of thermal power generation, due to its pozzolanic activity, allows to reduce cement dosage and, as a consequence, to reduce carbon dioxide emissions into atmosphere, causing the well-known “greenhouse” effect, related to cement production.

This work is a part of a wide research program related to the use of recycled aggregate to manufacture structural concrete: a recycled aggregate coming from a real industrial crushing plant, therefore readily available to employ, was used by completely substituting in concrete both fine and coarse natural aggregate fractions. The feasibility of manufacturing structural concretes by using this aggregate was already successfully tested (Corinaldesi *et al.* 1999), then the influence of fly ash addition on mechanical performances was evaluated, again with positive results (Corinaldesi & Moriconi, 2001). Finally, also some aspects about durability of recycled-aggregate concretes were studied; in particular attention was focused on the influence of concrete porosity on drying shrinkage and corrosion of embedded galvanized steel bars (Corinaldesi *et al.* 2001). Results showed that, when fly ash was added to recycled-aggregate concrete:

1. the pore structure was improved, and particularly the macro pores volume was reduced causing benefits in terms of mechanical performance;
2. from the serviceability point of view the drying shrinkage of recycled aggregate concrete did not appear a problem since, just due to less stiffness of this concrete, the same risk of cracks formation resulted as for the ordinary concrete;
3. as far as corrosion aspects were concerned, the use of fly ash appeared very effective in protecting galvanized steel reinforcement also in porous concrete, as it could occur when recycled aggregates are used, even in the case of cracked concrete.

## 2. SCOPE

The main objectives of this study were to investigate the following aspects concerning durability of recycled-aggregate concretes, eventually containing high volumes of fly ash:

- resistance to carbon dioxide penetration, that is concrete carbonation;
- resistance to chloride ions penetration into concrete;
- resistance to freeze-thaw cycles of concrete prepared without any air-entraining admixture.

In any case, the behavior of an ordinary concrete prepared with natural aggregate and commonly used in practice was also estimated, as a reference for the performances of recycled-aggregate concretes.

## 3. EXPERIMENTAL PROGRAM

### 1.1 Materials

#### 1.1.1 Portland Cement

A commercial portland-limestone blended cement type CEM II/A-L 42.5 R according to the European Standards EN-197/1 was used. The Blaine fineness of cement was 4.15 $m^2/g$ and its specific gravity was 3.05 $kg/m^3$.

#### 1.1.2 Natural Aggregates

Crushed limestone aggregate (15 mm maximum size) and natural sand (6 mm maximum size) were used. The gradation of both crushed aggregate and sand are shown in Fig. 1 and their physical properties are shown in Table 1.

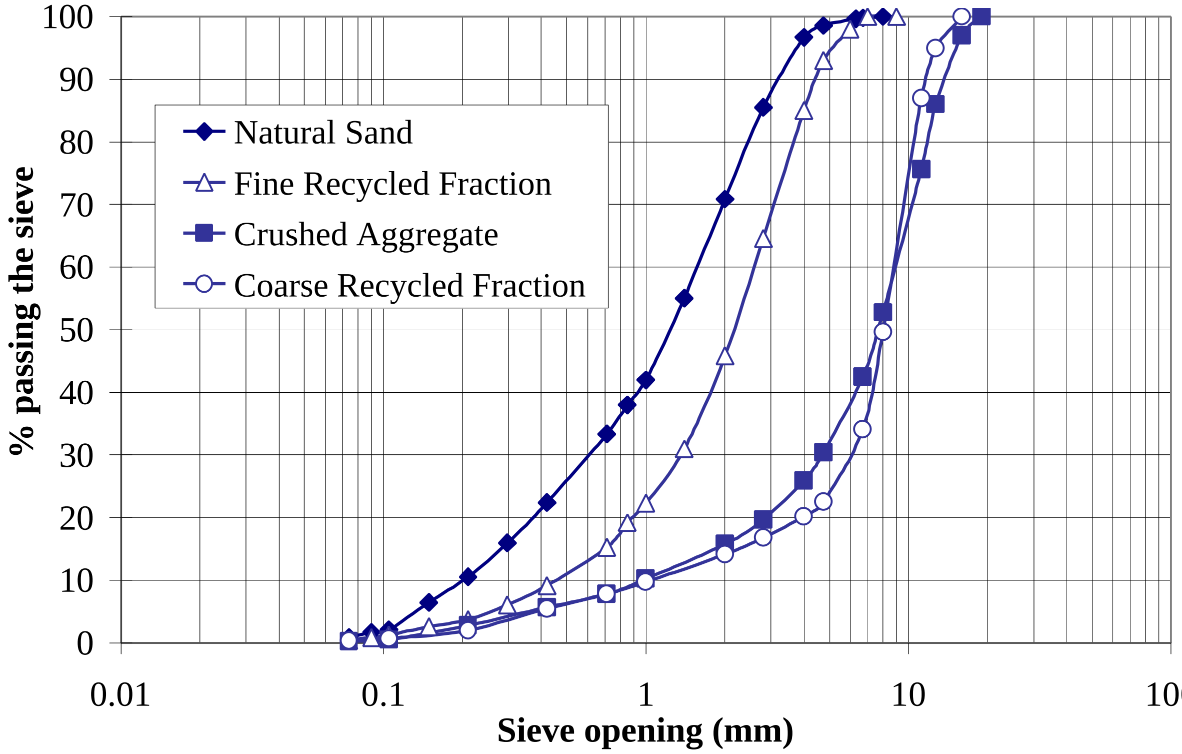

**Figure 1. Grain size distribution curves of the aggregate fractions.**

1.1.3 Recycled Aggregates

A coarse fraction (15 mm maximum size) and a fine fraction (6 mm maximum size) of recycled aggregate were used. These fractions were directly supplied by an industrial crushing plant in Villa Musone, Italy, in which debris from building demolition were suitably selected, ground, cleaned and sieved. The gradations of both coarse and fine recycled aggregate are shown in Fig. 1 and their physical properties are shown in Table 1.

**Table 1. Some physical properties of the aggregate fractions**

| *Aggregate Fractions* | *Bulk Specific Gravity* (kg/m$^3$) | *Water Absorption* (%) | *Passing 75 mm* (%) |
|---|---|---|---|
| Natural Sand | 2620 | 3 | 0.9 |
| Crushed Aggregate | 2680 | 2 | 0.2 |
| Fine Recycled Fraction | 2150 | 10 | 0.5 |
| Coarse Recycled Fraction | 2320 | 8 | 0.3 |

1.1.4 Superplasticizer

A 30% aqueous solution of acrylic-based superplasticizer was used when required to guarantee fresh workability.

1.1.5 Fly Ash

A low calcium fly ash (ASTM C 618 Class F) produced by a thermal power generating station was used. The Blaine fineness of fly ash was 4.48 m$^2$/g and its specific gravity was 2.25 kg/m$^3$.

The chemical compositions of portland cement and fly ash are reported in Table 2.

**Table 2. Chemical composition of cement and fly ash**

| *Oxide* (%) | *Cement* | *Fly Ash* |
|---|---|---|
| $SiO_2$ | 29.67 | 59.94 |
| $Al_2O_3$ | 3.74 | 22.87 |
| $Fe_2O_3$ | 1.80 | 4.67 |
| $TiO_2$ | 0.09 | 0.94 |
| CaO | 59.25 | 3.08 |
| MgO | 1.15 | 1.55 |
| $SO_3$ | 3.25 | 0.35 |
| $K_2O$ | 0.79 | 2.19 |
| $Na_2O$ | 0.26 | 0.62 |
| L.O.I. | 11.62 | 3.34 |

**1.2 Concrete mixtures**

The mixtures proportions are reported in Table 3.

**Table 3. Concrete mixture proportions**

| *Mixture* | *NAT-0.6* | *REC-0.3* | *REC-WRA-0.3* | *REC-FA-0.6* |
|---|---|---|---|---|
| W/C | 0.60 | 0.30 | 0.30 | 0.60 |
| W/CM | 0.60 | 0.30 | 0.30 | 0.30 |
| *Mixture proportions, kg/m³* | | | | |
| Water | 230 | 230 | 165 | 230 |
| Cement | 380 | 760 | 550 | 380 |
| Fly Ash | - | - | - | 380 |
| Natural Sand | 314 | - | - | - |
| Crushed Aggregate | 1338 | - | - | - |
| Fine Recycled Fraction | - | - | 372 | - |
| Coarse Recycled Fraction | - | 1169 | 1060 | 1057 |
| Superplasticizer | - | - | 5.5 | 6.8 |

Concrete specimens were prepared by using two different kinds of aggregate, recycled or natural, of the same maximum diameter (15 mm) and the same sieve distribution, obtained by combining a fine and a coarse sieve fraction according to the Bolomey particle size distribution curve (Collepardi 1991) and assuming the physical properties values reported in Table 1 for each kind of aggregate. Moreover, the mixture workability in relation to higher or lower aggregate irregularity and cement dosage was taken into account.

Reference concrete was manufactured by using only natural aggregates with a water to cement ratio of 0.60 as commonly used in practice (NAT-0.6).

Then, a recycled-aggregate concrete was prepared, by completely substituting natural with recycled aggregate, with a w/c of 0.30 (REC-0.30) in order to achieve the same strength class of the reference concrete. However, in this way, a very high cement dosage was necessary to obtain the strength requirement and this occurrence could partially compromise the environmental benefit related to the use of the recycled instead of natural aggregate.

Therefore, this recycled-aggregate concrete was also manufactured by using a water-reducing admixture (WRA) in order to lower both water and cement dosage (REC-WRA-0.3): actually, an acrylic-based superplasticizer was used at a dosage of 1.0 % by weight of cement.

Moreover, a recycled-aggregate concrete was prepared with a w/c of 0.60, by simultaneously adding to the mixture as much fly ash (FA) as cement, to replace the fine aggregate fraction (REC-FA-0.6); however, in this way a water to cementitious material ratio of 0.30 was obtained.

Fresh concrete had a preferred fluid consistency (slump between 16 and 18 cm). Since no detection of the actual relative humidity of the aggregates was carried out, the amount of mixing water was adjusted to obtain such a prefixed slump range. In the presence of fly ash a dosage of 1.8 % by weight of cement of an acrylic-based superplasticizer was also necessary to achieve the prefixed workability.

### 1.3 Casting and curing of test specimens

Cubic specimens, 100 mm in size, were manufactured according to Italian Standards UNI 6130-72 Part I. These specimens were used for both mechanical and durability tests.

The cubic specimens were cast in polystyrene forms and wet cured at 20°C (UNI 6130-72 Part II).

## 4. RESULTS AND DISCUSSION

### 1.4 Compressive strength

Compression tests according to Italian Standards UNI 6132-72 were carried out on cubic specimens, which were tested at right angles to the position of casting. Therefore the bearing faces were sufficiently planar and smooth as to require no capping or grinding. The specimens were loaded at a constant strain rate until failure.

For each mixture and each curing time (3, 7, 28 and 56 days) three specimens were used for mechanical tests, according to Italian Standards.

Figure 2 shows the compressive strength as a function of time for the four concretes prepared. It can be noticed that after 28 days of curing the compressive strength was in the range of 27-31 MPa.

It can be also observed that at early ages the w/c is more influent than the kind of aggregate on the strength development.

Moreover, particularly effective pozzolanic activity is showed by fly ash in the presence of recycled aggregate since early ages. However, at longer ages, all the observed strength developments tend to converge. This means that the use of a weaker aggregate, as the recycled one, has more and more influence on the compressive strength as the cement matrix gets stronger, this being the “weak chain link” case (Corinaldesi *et al.* 1999).

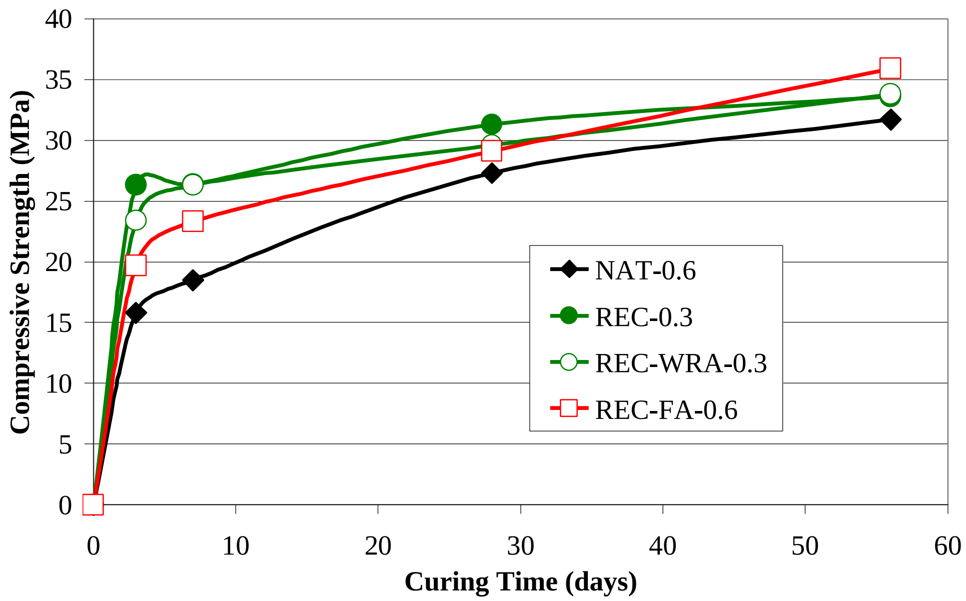

**Figure 2. Compressive strength of different concretes as a function of curing time.**

### 1.5 Depth of Carbonation

The carbonation depth was measured by the phenolphthalein test (RILEM CPC – 18) in cubic concrete specimens exposed to air at a temperature of 20°C after demoulding at 1 day.

Figure 3 shows the carbonation depth (*x*, in mm) as a function of the time of exposure to air (*t*, in days). A linear relationship between the carbonation depth and the square root of time ( $x = k \cdot \sqrt{t}$ ) can be drawn; the extrapolated values of *x* after 1 year were 8.5, 6.1, 5.2 and 2.1 mm respectively for the concretes NAT-0.6, REC-FA-0.6, REC-WRA-0.3 and REC-0.3.

It is quite evident that the carbonation depth is mainly influenced by the water/cement and particularly effective it seems to be a high dosage of cement (see the mixture REC-0.3 in Table 3) and consequently a high amount of available calcium hydroxide. Moreover, also the positive contribution of fly ash addition is detectable (comparing the results obtained for NAT-0.6 and REC-FA-0.6) mainly due to the refinement of the pore system.

A similar experimental procedure was conducted on high volume fly ash concretes prepared with natural aggregate and a water to binder ratio of 0.32 (Collepardi S. *et al.* 2000). The results of this experimental program showed that the carbonation depth was un-detectable or negligible after some months of exposure to air.

In general, it is confirmed that carbonation does not pose problems for corrosion of the metallic reinforcements, due to very low permeability of concretes containing high volumes of fly ash (Sivasundaram *et al.* 1990), also in this case, though a porous aggregate, as the recycled aggregate, was present.

Figure 4 shows the pictures taken some minutes after the phenolphthalein test, relative to specimens NAT-0.6 and REC-0.3, previously kept in exposure to air for 130 days.

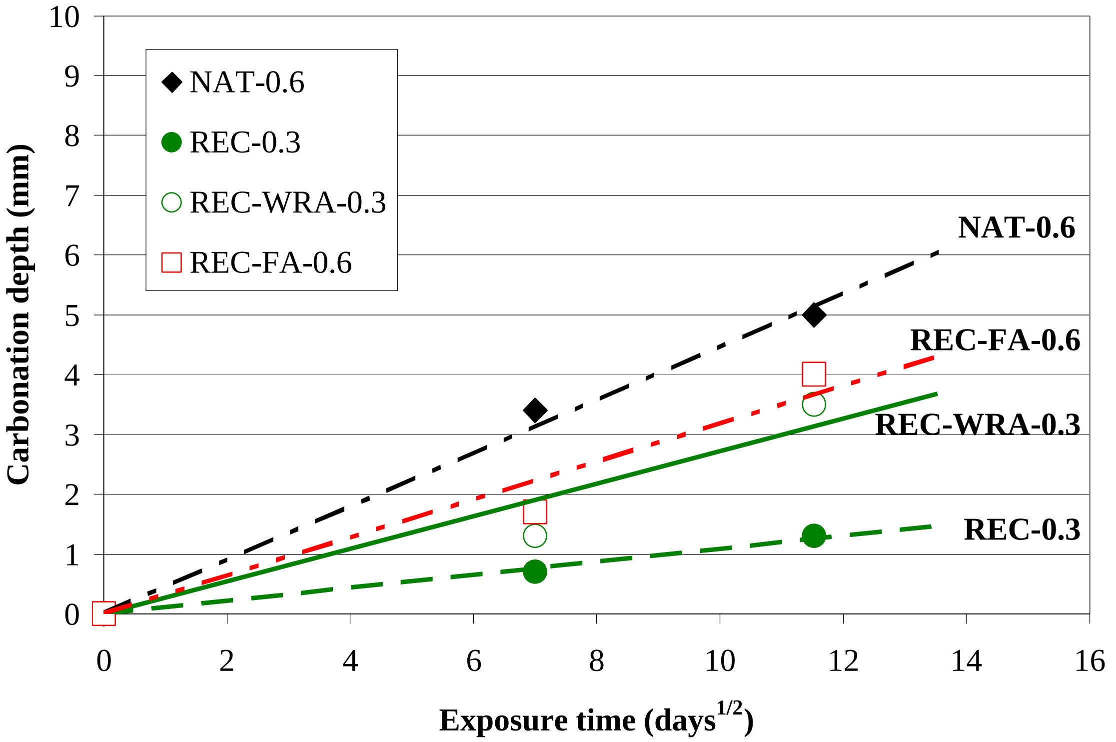

**Figure 3. Carbonation depth as a function of the time of exposure to air.**

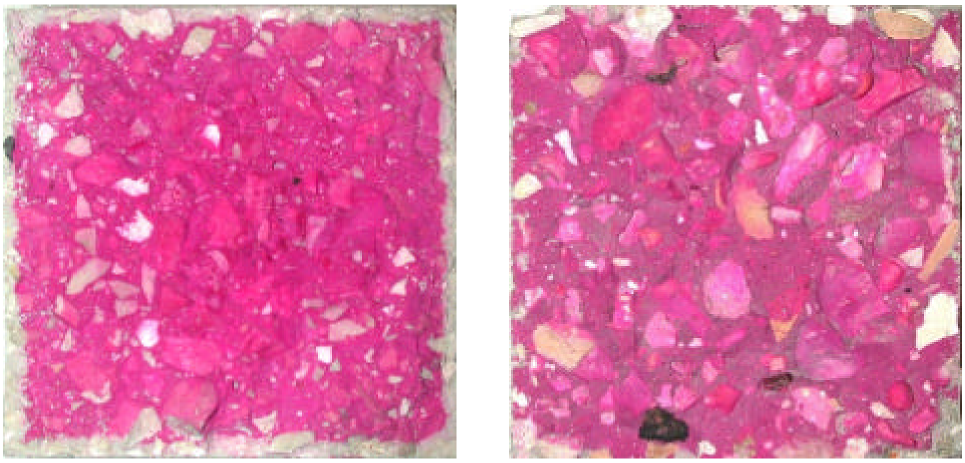

**Figure 4. Carbonation depth after 130 days of exposure for NAT-0.6 (left) and REC-0.3 (right) concretes**

### 1.6 Chloride penetration

The chloride penetration into concrete was evaluated through the $AgNO_3$ and fluorescein test (Collepardi *et al.* 1972) in concrete specimens exposed to a 10% NaCl aqueous solution after a wet curing of 1 week and an air curing of 3 weeks at a temperature of 20°C.

Figure 5 shows the chloride penetration depth as a function of the time of exposure to a 10% NaCl aqueous solution.

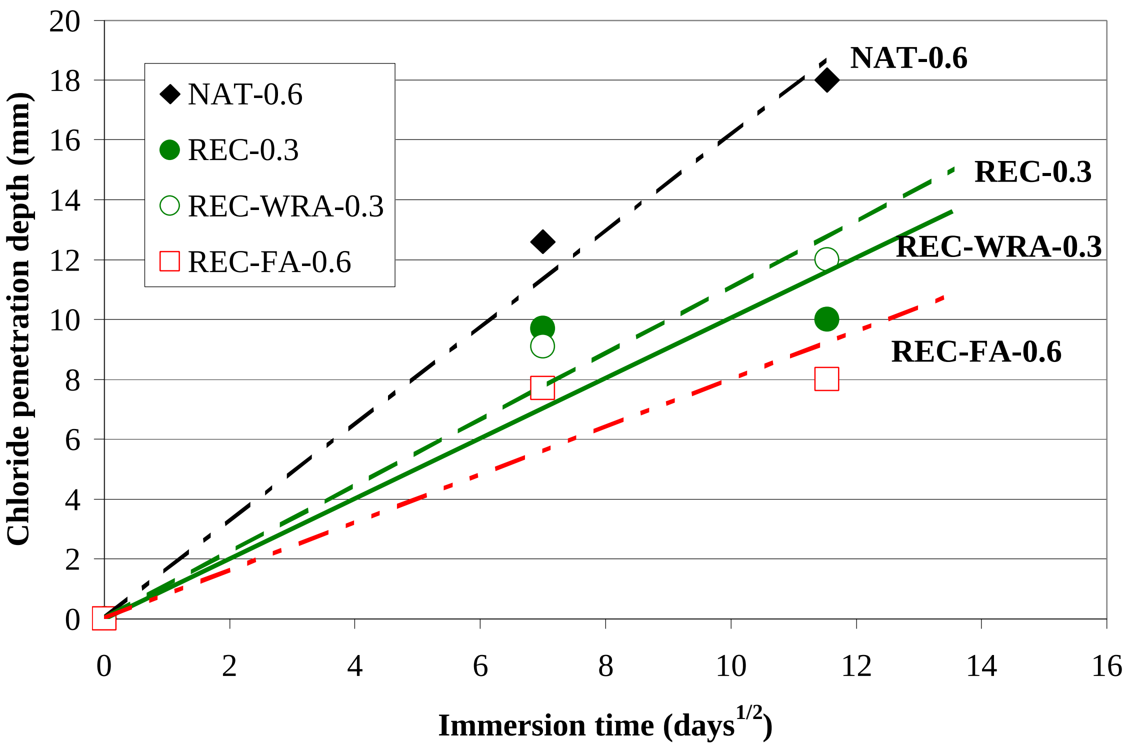

**Figure 5. Chloride penetration as a function of the time of exposure to a 10% NaCl aqueous solution.**

Collepardi *et al.* (1972) found that chloride penetration depth ($x$) varies with elapsed time ($t$) following an equation [1] obtainable from the solution of Fick's second law under non-steady-state conditions for diffusion in a semi-finite solid:

$$x = 4 \cdot \sqrt{D \cdot t} \qquad [1]$$

where $D$ is the diffusion coefficient of chloride ions into concrete pores filled of water, expressed in $cm^2 \cdot s^{-1} \cdot 10^{-8}$. The values of $D$, obtained from [1] by interpolating the results showed in Fig. 5 for the different concretes, are reported in Table 4.

**Table 4. Diffusion coefficients of chloride ions into different concretes at 20°C**

| *Mixture* | *NAT-0.6* | *REC-0.3* | *REC-0.3+* | *REC-FA-0.6* |
|---|---|---|---|---|
| $D$ ($cm^2 \cdot s^{-1} \cdot 10^{-8}$) | 1.90 | 0.87 | 0.72 | 0.46 |

It is quite evident the strong beneficial effect due to the presence of fly ash on the chloride penetration depth measured for REC-FA-0.6 concrete: in fact the diffusion coefficient of chloride ions into REC-0.3 concrete is double with respect to REC-FA-0.6, the only difference being the replacement of 50% of cement with fly ash.

In the same paper (Collepardi *et al.* 1972), experimental results are reported supporting the hypothesis that the differing nature of the surface of the pores formed in the presence of pozzolanic materials plays a vital role in affecting the behavior of the material during the penetration of chloride ions.

Also a lower water/cement influences positively the concrete resistance against chloride penetration: as a matter of fact, the diffusion coefficient of chloride ions into NAT-0.6 concrete is more than double with respect to REC-0.3, although recycled instead of natural aggregate was present.

Figure 6 shows the pictures taken some minutes after the $AgNO_3$ and fluorescein test, relative to specimens NAT-0.6 and REC-FA-0.6, previously kept in exposure to a 10% NaCl aqueous solution for 130 days.

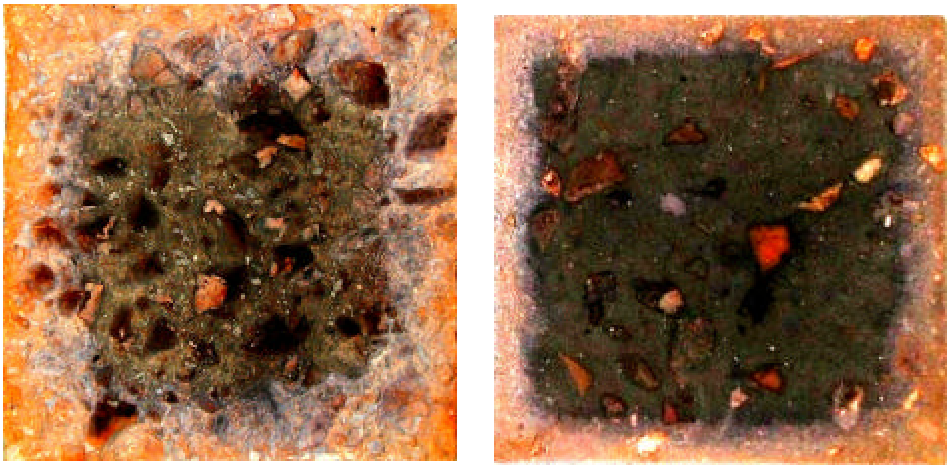

**Figure 6. Chloride penetration after 130 days of exposure for NAT-0.6 (left) and REC-FA-0.6 (right) concretes.**

## 1.7 Frost resistance

The frost resistance was measured according to the “Resistance of Concrete to Rapid Freezing and Thawing” Standard Test Method (ASTM C 666) following the “Procedure B: Rapid Freezing in Air and Thawing in Water”. The freeze-thaw cycle consisted of freeze in air, thaw in water (-18°C to +5°C), and four cycles in 24 hours.

Dynamic elastic modulus values and weights were monitored on the concrete specimens at intervals throughout the test, in order to evaluate both the Relative Dynamic Modulus (RDM) of elasticity and the Percentage of Weight Change (PWC), which are usually the main criteria that indicate the extent of damage of concrete subjected to repeated cycles of freezing and thawing.

The dynamic modulus of elasticity was determined by ultrasonic pulse velocity measurements in saturated concrete specimens. This method is based on the fact that the velocity of an ultrasonic pulse in a material (in this case having a frequency of 50 kHz), $V$, is related to its dynamic elastic modulus, $E_d$, and it is expressed by

$$V = k \cdot \sqrt{\frac{E_d}{r}} \quad \text{with} \quad k = \sqrt{\frac{(1-n)}{(1+n)\cdot(1-2n)}} \qquad [2]$$

where $V$ corresponds to the pulse velocity in m/s, $r$ to the density of the material and $k$ to a constant depending on Poisson's ratio that was set to 0.20 for all the specimens. The pulse velocity was obtained by dividing the path length (100 mm) by the elapsed time (measured in µs). A coupling medium, such as grease, was used to ensure good contact between the transducers and the specimen, since the apparent travel time is affected by the smoothness of the contact surface.

Relative dynamic modulus

The relative dynamic modulus of elasticity, RDM, was calculated as follows

$$RDM = \left(\frac{V_c^2}{V_o^2}\right)\cdot 100 \qquad [3]$$

where $V_o$ is the pulse velocity measured at zero cycles, in m/s, $c$ is the number of cycles at the time of testing and $V_c$ is the pulse velocity measured after c cycles of freezing and thawing.

The results obtained up to 240 cycles are reported in Fig. 7; a significant trend towards low values of RDM was not yet detected in any case, at least up to this experimental time.

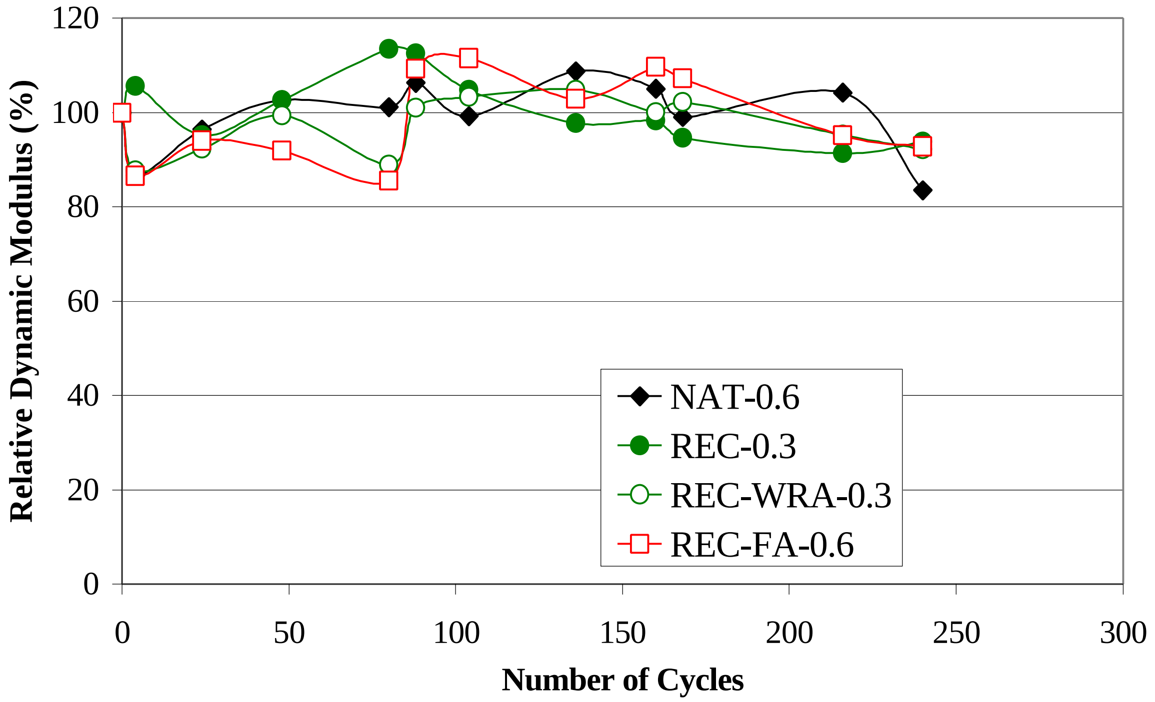

**Figure 7. Relative elastic modulus of elasticity for the different concretes.**

### 1.7.1 Percentage of weight change

The change in the weight of concrete specimens was monitored and the values obtained, expressed in percentage (PWC) with respect to the initial saturated condition, are reported in Fig. 8. The weight of the four concretes increased with the number of cycles raising up to 90 cycles; then a continuos slow decrease, more evident for NAT-0.6 and REC-0.3 concretes, occurred. This may be explained by a water absorption in the first period and by the observed scaling in the second one, which overshadowed the weight increase caused by the ingress of water.

A similar study was carried out by Rohi and Burdette (1998): they found that the use of a higher fly ash content in both natural and recycled-aggregate concrete resulted in significant improvements in their freeze-thawing durability.

In this case, other data must be collected in order to understand the different concrete behavior under freezing and thawing; nevertheless at this moment no negative effect caused by the presence of a more porous aggregate, as the recycled, was detected.

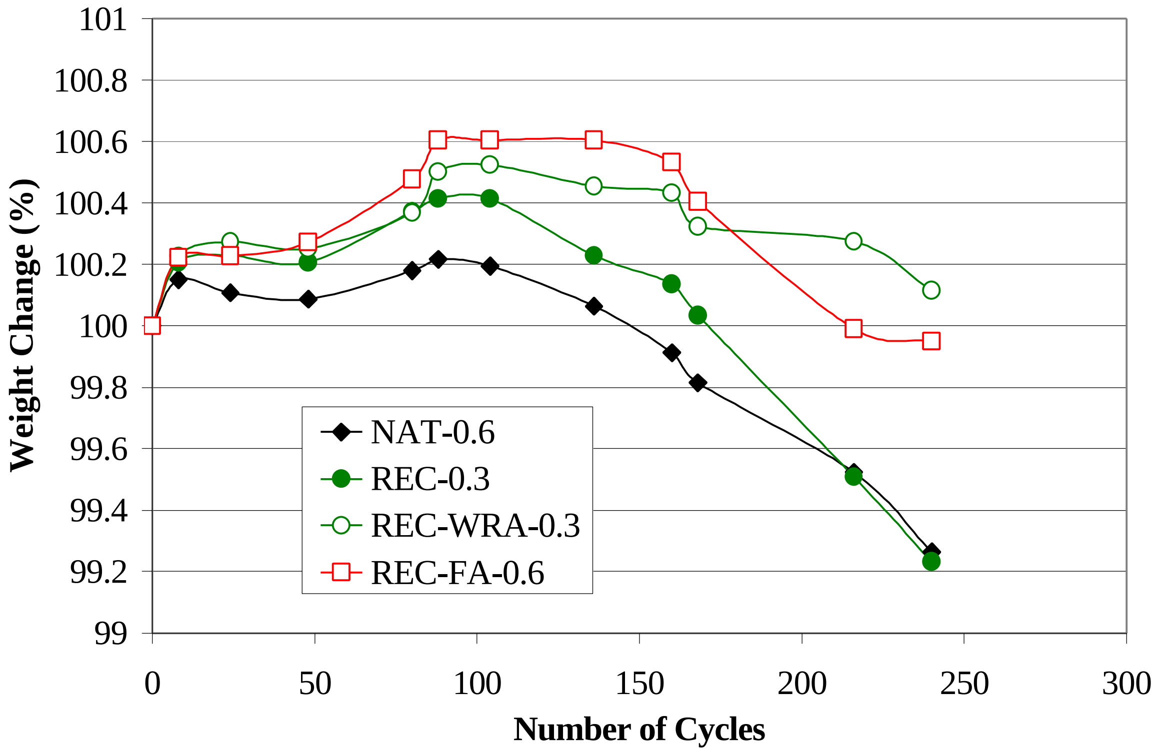

**Figure 8. Percentage of the weight change (PWC) for the different concretes.**

## 5. CONCLUSIONS

The results obtained in this work show that, when the same concrete strength class is guaranteed, not only the use of an aggregate coming from a recycling process is not deleterious for concrete durability but in some cases it could also be useful for durability improvement.

As a matter of fact, due to a lower w/cm, all recycled-aggregate concretes performed better than reference concrete concerning both concrete carbonation and chloride ions penetration into concrete.

Moreover, concerning chloride ions penetration into concrete, a further strong positive effect was related to the presence of high volume of fly ash.

Finally, the test of concrete resistance against freezing and thawing cycles showed no difference between natural-aggregate concrete and recycled-aggregate concretes, at least during the first 240 cycles.

In conclusion, the opportunity of manufacturing an environmentally friendly concrete with satisfactory performances, related to both mechanical and durability aspects, seems not so far to become reality.

# Accelerated Degradation Testing Of Concrete In Acidic Environment: Resistance To Lactic And Sulfuric Acid

**N De Belie J Monteny L Taerwe**
**Concrete Research Ghent University Ghent Belgium**

**Summary: This research was initiated because of durability problems related to building materials in agricultural constructions. Resistance against corrosion caused by lactic and acetic acids is of major importance both for floors in animal houses and silos. Furthermore, concrete manure tanks, walls of manure pits in animal houses and the underside of concrete slats and slabs are exposed to biogenic sulfuric acid corrosion.**

**To examine the degradation of concrete by aggressive liquids, a testing apparatus for accelerated degradation tests (TAP) was developed. It was conceived to obtain acceleration of the deterioration process through alternate wetting and drying, because this procedure simulates the real-life situations under investigation. This is achieved by an experimental set-up with concrete cylinders that rotate through containers with the test solutions. Cycles of chemical attack are followed by abrasion using rotary brushes. The change in dimension of the concrete specimens and the surface roughness are determined through a non-contact distance measurement with laser sensors.**

**In a first experiment the durability of concrete exposed to a solution with 30 g/l of both lactic and acetic acid was examined (pH=2.0-2.2). The effect of the aggregate type, the cement type and the influence of polymer modification (polymer (d.m.)/cement ratio = 0.10) were considered. The results showed that concrete with blastfurnace slag cement was more resistant than the reference concrete with ordinary Portland cement. Use of limestone sand (and aggregates) led to a quicker neutralization of the aggressive liquid, but this was insufficient to reduce the average attack depth. The polymer modifications, especially the use of styrene acrylic ester latex, increased the concrete resistance significantly, although SEM-investigation showed that the emulsified polymer had not completely formed a film.**

**Secondly the resistance to a 0.5% sulfuric acid solution was considered (pH=1.0). Here it was necessary to measure twice per attack cycle: after the alternated wetting and drying stage to determine concrete expansion and after brushing to quantify the decrease in radius due to mechanical action. Compared to the reference concrete with high sulfate resistant Portland cement, durability could be improved by addition of styrene acrylic ester polymer, as well as by using blastfurnace slag cement. Modification with vinylcopolymer had little effect, and addition of silica fume, styrene butadiene or acrylic polymers led in this case to a reduced resistance.**

**Keywords: concrete degradation, lactic acid, sulfuric acid, polymer, silica fume**

## 1 INTRODUCTION

### 1.1 Concrete degradation in agricultural constructions

Various concrete building components in agricultural constructions are subject to acid attack, the main aggressive agents being lactic, acetic and sulfuric acid.

*Concrete floors in animal houses*

Floor types in animal houses can be classified into solid, unperforated floors that are laid directly on the ground and floors that are suspended above ground and may be perforated to assist in the drainage of liquids and passage of fecal material. For solid as well as for suspended floors, those constructed of concrete are the most common. Results from a survey, carried out by De Belie (1997a) on farms with fattening pigs, showed that even for high-quality precast concrete slats, on 15% of the farms surveyed, the coarse aggregates of some slats were exposed within two years of use. After five years, wear was observed on 40% of the farms. Consequences were an increased gap between slat beams and increased surface roughness (resulting in animal injuries), corrosion of the reinforcement and a reduced slat stability. The reason for this degradation are the specific aggressive conditions occurring on floors in animal houses. Chemical components from feed residues and manure may attack the concrete floor surface. Animals and cleaning exert a mechanical impact. Pressures used for high-pressure cleaning can amount to 80-150 bar (Frénay & Zilverberg 1993). Different authors (Hoeksma 1988; Mathiasson *et al.* 1991; Nilsson 1993; De Belie *et al.* 1996a) mention the presence of large amounts of lactic and acetic acid, and aggressive ions such as $SO_4^{2-}$. The major amount of aggressive ions and acetic acid would come from the manure. Lactic acid originates from acidified meal/water mixtures (De Belie *et al.* 1996a) and is the main source of severe concrete degradation near feed and water supply. Acidified meal/water mixtures can reach acid concentrations of 31.0 mg lactic acid and 3.1 mg acetic acid per ml filtrate. The pH can drop to 3.8, in correspondence with the $pK_a$ of lactic acid (3.86 at 25°C). Some farmers add whey to the drinking water and dairy cows and pigs can be fed with silage, which again contains lactic and acetic acids.

*Silage storage structures*

Silage storage structures are used to conserve fodder under anaerobic conditions. Depending on the dry matter content of the crop, the silo, and the silo drainage system, more or less silage effluent is produced, with possibly a pH as low as 3.5-4.0, the main acids being again lactic and acetic acid. On many farms, silage is stored in bunker silos with reinforced concrete floors (and walls), which are readily attacked by the corrosive effluent. Furthermore, wear (abrasion and impact) is caused by farm machinery such as block cutters.

*Manure storage structures*

In 1945, it was found (Parker 1945), that the formation of sulfuric acid in sewers was not due to purely chemical transformations in the sewer atmosphere but to the action of aerobic sulfur oxidizing bacteria, mainly of the *Thiobacillus* species. Anaerobic sulfate reducing bacteria, such as *Desulfovibrio* species, living in manure or in the mud at the bottom of sewer pipes and in the slime at the sides, reduce sulfates and other oxidized sulfur compounds to hydrogen sulfide ($H_2S$). This hydrogen sulfide is released in the air above the liquid level and dissolves in moisture on the walls and on the underside of the slatted floors. There, $H_2S$ can be oxidized to sulfur, a reaction that is catalytically accelerated by the high alkalinity of the concrete surface. The *Thiobacillus* bacteria oxidize the sulfur to sulfuric acid, using the energy released for their cell mass production. Very low pH values (1-2) may occur locally (Mori *et al.* 1991).

### 1.2 Reaction mechanisms

Lactic and acetic acid are very aggressive, because their reaction with free lime [$Ca(OH)_2$] of the concrete produces very soluble calcium salts (Kleinlogel 1960). When those salts are leached, the hydrates of the cement matrix start decomposing and the concrete disintegrates. Sulfuric acid first reacts with the calcium hydroxide in the concrete to form gypsum. Although the formation of gypsum is associated with an increase in volume by a factor of 1.2 to 2.2 (Attiogbe & Rizkalla 1988; De Ceukelaire 1989; Wafa 1994), the reaction between gypsum and calcium aluminate ($C_3A$) with the formation of ettringite is much more detrimental. Some authors mention an increase of volume with a factor two (Attiogbe & Rizkalla 1988; Wafa 1994), while others mention even a factor 7 (De Ceukelaire 1989). Thus the formation of ettringite is mainly responsible for the large volume expansion, which leads to increase of internal pressure and deterioration of the concrete matrix.

## 2 MATERIALS AND METHODS

### 2.1 Aggressive Liquid

For the first experiment the simulation liquid consisted of lactic and acetic acid in water both in concentrations of 30 g/*l*, the highest concentrations registered on floors in animal houses during the preliminary investigations (De Belie *et al*., 1996a). This liquid had a pH of 2.0-2.2, which is extremely aggressive to concrete. The lower pH compared with the pH measured for instance in soured meal-water mixtures with the same acid concentrations, is due to the absence of buffering feed ingredients, and will in reality only occur under specific circumstances. In previous experiments also highly to moderately aggressive liquids were used, with pH-values of 3.8 and 4.5, but it appeared that the three liquids resulted in a very similar classification of the concrete types (De Belie et al. 1996b; 1997a). For the second experiment a 0.5% sulfuric acid solution (pH of around 1.0) was used.

### 2.2 Apparatus for accelerated degradation tests

At the Magnel Laboratory for Concrete Research of Ghent University, an apparatus for accelerated degradation testing (TAP) was developed (Fig.1). A more detailed description of the used test method is given by De Belie (1997c).

**Fig. 1 Apparatus for accelerated degradation testing (TAP)**

It was designed to achieve acceleration of the deterioration process through alternate wetting and drying, because this procedure simulates the real-life situations under investigation. Three cylinders (∅ 270 mm, h = 70 mm) of each concrete mixture were subjected to a cyclic procedure of immersion in an acidic solution and drying by air. The cylinders, fixed on horizontal axes, turned with a speed of 1 revolution per hour trough separate recipients. Each point of the outer circumference was submersed during 1/3 of the rotation time. After each cycle, which lasted for 6 days for the lactic/acetic acid attack and for 12 days for the sulfuric acid attack, the cylinders were dried in air and brushed with rotary brushes to remove weakly adhering concrete particles. In Table 1 the different steps in the test procedure are related to different stages occurring during the degradation in practice.

**Table 1. Relation between different steps in the TAP test procedure and real-life situations**

| *TAP* | *Lactic/acetic acid attack*<br>*(a) concrete floors in animal houses*<br>*(b) silage storage structures* | *Sulfuric acid attack*<br>*(a) sewers*<br>*(b) manure storage structures* |
|---|---|---|
| Cyclic immersion and chemical attack | (a) wetting by feed+water residues and manure, drying in between<br>(b) wetting during effluent release from silage | (a & b) wetting/drying by fluctuation of the wastewater/manure level |
| Drying in air | (a&b) drying during periods the compartment or silo is not in use | (a) dry weather situation with low wastewater level<br>(b) emptying of manure storage facility |
| Abrasion by brushing | (a) abrasion by animals, cleaning with brushes or high-pressure hose<br>(b) abrasion by animals (in self-feeding silo), cleaning and farm machinery (block cutters) | (a) high flow rates because of high loading or rain; abrasion by flowing water, turbulence<br>(b) abrasion by cleaning (less common) |

The corrosion of the specimens was measured using laser sensors, connected with a computer. The sensor amplifiers supply a Volt signal, which is linearly related to the distance between the concrete surface and the sensor. Five measurements per mm are taken along the concrete surface. A software trigger is programmed to start the measurement of a cylinder profile when the raised edge of a stainless angle steel, fixed on the concrete cylinder, passes by the laser beam. The first 50 measurements of a contour line are performed on the horizontal part of the angle steel, which acts as reference plate. The three sensor heads are mounted on a mechanical device which can always be placed in the same position on the frame of the TAP. This device allows to adjust the position of the sensor heads in a direction parallel to the cylinder axes in steps of 0.5 mm with an accuracy of 0.01 mm. In this way it is possible to scan the circumference of a cylinder every time at the same position along the cylinder height. By moving the system a few times, for every cylinder several parallel profiles can be measured, equally distributed along the cylinder height. For the experiments discussed here, 5 (sulfuric acid attack) to 7 profiles (lactic/acetic acid attack) per cylinder were measured. The laser measurements were also used to calculate the surface roughness of the concrete, expressed by means of the $R_a$-value (BS1134 1972).

In the lactic/acetic acid test procedure the radius of the cylinders was determined at the beginning of the experiment and after each cycle of alternated immersion, drying and brushing. In the sulfuric acid test procedure the measurements were performed twice per cycle, before as well as after brushing. In this way it was possible to determine the average change of the radius of the cylinders due to chemical reaction of the concrete with the sulfuric acid solution during the immersion as well as the change of the radius due to mechanical action of brushing the cylinders. The change in radius during the immersion stage corresponded mostly to an expansion of the concrete due to the formation of voluminous reaction products. However, a decrease of the radius could also occur during the period of immersion because of loss of adhesion of the expanded parts.

## 2.3 Test Specimens

The composition of the concrete mixes tested in experiment 1 with lactic/acetic acid is shown in table 2. The composition of the concrete mixes tested in experiment 2 with sulfuric acid is shown in table 3. From each concrete mix three cylinders and six cubes with sides 158 mm were made. The test specimens for experiment 1 were stored for 28 days at 20 ± 2 °C and a relative humidity of 90-95%. The test specimens for experiment 2 were moist cured for 1 day (>90% humidity, 20°C), followed by 3 days of dry curing conditions (60% humidity, 20°C) and subsequent air curing. At 28 days three cubes were measured for compressive strength as prescribed by the standard NBN B15-220 (1990) and the three others were submitted to a water absorption test, which gives an indication of the porosity, as prescribed by the standard NBN B15-215 (1989). The three cylinders of each type were mounted together on one side of an axle of the TAP for the degradation tests.

Manufacturers of precast concrete slats normally use a properly compacted high-quality concrete with the ordinary Portland cement CEM I 42.5 R (nomenclature according to the Belgian standard NBN B12-001 1993, based on the European ENV 197-1). The concrete composition of one of those manufacturers was chosen for the reference concrete *Ref I*. Furthermore concrete with blastfurnace slag cement CEM III/A 42.5 (36-65% slag), which showed a superior performance in previous experiments (De Belie *et al*., 1996) was tested. For the concrete mixes *LS-G* and *LS-L*, half of the natural sand was substituted with limestone sand in order to neutralize the aggressive environment more quickly and reduce concrete attack afterwards. For *LS-L* also limestone aggregates were used instead of gravel. The Belgian Ministry of Agriculture advised in the past to use only rounded gravel aggregates for slatted floors in animal houses, which would reduce claw injuries compared to the sharp-edged limestone aggregates. Buist (1987) and Bayoux *et al*. (1990), however, claim that the limestone aggregates make an important buffer and that their use would therefore reduce acid attack. Furthermore the sharp edges would be rounded by the attack.

Table 2 shows that flow and slump of the concretes with limestone sand were very low, which aggravated compaction. This can be attributed to the shape of the sand and to the larger amount of particles smaller than 80 μm, compared to natural sand.

Four PCCs were tested with different polymer latexes: two styrene-butadienes *SBR1* and *SBR2*, an acrylic latex *A* and a styrene acrylic acid ester *SAE*. A polymer (d.m.)/cement proportion of about 0.1 was chosen. The polymers were added to the mixing water as latex. Normally polymers when added to concrete, exhibit water reducing qualities, because of the dispersing agents in the polymer latexes and the spherical shape of the polymer drops (Bijen 1991). The characteristics of hardened PCC are the result of the lower water-to-cement ratio and the formation of a three-dimensional polymer structure through the hardened cement paste. The nature of microstructural modification and void filling and bridging of cracks that occurs when polymer formulations are incorporated in cement systems, is such that polymers will substantially change, in a favorable manner, the pore structure. The porosity is decreased in the pore radius range of 240 nm or more, whereas it increases greatly in the smaller pore radius range of 140 nm or less. The net result of such changes would be to improve the resistance of PCC to liquids (Swamy 1995). However, the addition of polymers increases the concrete cost and would cause an increase in price of concrete slats with about 20-40%. Table 2 shows that slump and flow of *SBR1* and *SBR2* were quite high, which implies that the water content could be reduced further. In spite of the higher amount of water added to *A*, its workability was bad and slump and flow could not be measured. It is also clear that the presence of the polymer films inhibits water absorption. The *SAE*-concrete showed the smallest water absorption, but also for the *SBR1*- and *SBR2*-concretes the water absorption was remarkably lower than for the reference concrete. The *A*-concrete contained many air voids due to its bad workability, which explains for its higher water absorption.

* The latexes used are styrene butadiene, styrene acrylic ester, acrylic and vinylcopolymer latex for SBR, SAE, A and VPV, respectively

** Includes the water present in the latex

All concrete mixtures tested were made with 350 kg/m³ high sulfate resistant Portland cement (CEM I 42.5 HSR/LA), except for one mixture that was made with blast furnace slag cement CEM III/B 42.5 HSR/LA (66-80% slag). Four different polymer types were used: a styrene-acrylic ester polymer, an acrylic polymer, a styrene butadiene polymer and a vinylcopolymer. The polymer cement concrete mixtures were made with a polymer/cement ratio of 7.5% (polymer d.m./cement). The reference mixture without polymer was made with a W/C ratio of 0.4. For the mixtures with polymer, the water content was adjusted till a slump of class S1 (10 to 45 mm) was obtained (Belgian standard NBN B15-232 1982). Although the mixture with the acrylic polymer had a low W/C ratio (0.34), due to a high air entrainment of the fresh concrete, a slump of class S3 (100 to 150 mm) was obtained. Because the mixture with the vinylcopolymer was too sticky, it was not possible to work with an S1 class and more water had to be added to create a workable concrete mixture. The final W/C of the different mixtures was calculated taking into account the water content of the added latexes. All polymer modified concrete mixtures had a lower density than the reference mixture without polymer. This was mainly due to the higher air entrainment of the concrete with addition of polymer. The addition of the styrene butadiene polymer, the styrene-acrylic ester polymer and the vinylcopolymer caused an increase in air content of the fresh mixture by 1 to 2% compared to the reference mixture (*Ref II*). The addition of the acrylic polymer resulted in an increased air content of almost 10%. The silica fume mixture was made by adding 30 kg/m³ silica fume to the reference mixture. The low w/c ratio (0.34) of this mixture combined with the addition of a high amount of superplasticizer created very dense and still good workable concrete.

# 3 RESULTS

## 3.1 Experiment 1: lactic/acetic acid attack

*Average attack depth*

An analysis of variance was carried out with the average attack depth of the cylinder profiles as the dependent variable and the concrete composition (eight classes), the cylinder (three classes) and the profile (seven classes) as independent variables. Only interactions of second order were taken into account. The average attack depth of the profiles closest to the troweling surface was often smaller than for the other profiles. Some segregation could have taken place during compaction, which resulted in less aggregates in the upper concrete layer, coming loose by chemical attack and brushing. When these profiles were left aside, the concrete composition remained the only significant factor. Fig. 2 shows the accumulated average attack depth of the different concrete types versus the number of attack cycles.

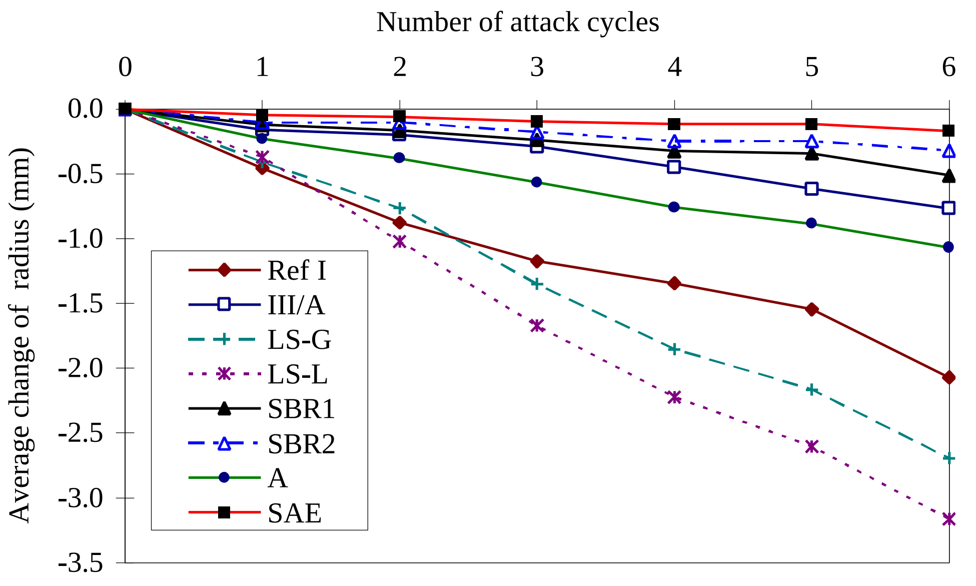

**Figure 2. Average attack depth of the different concrete types of experiment 1 (lactic/acetic acid) vs. number of attack cycles**

Already after the first attack cycle, the PCCs and the concrete with blastfurnace slag cement appeared to be significantly more resistant than the reference concrete and the concretes with limestone sand (Student-Newman-Keuls test with level of significance = 0.05). This difference increased after every cycle. Also the polymer cement concrete *A* appeared to perform significantly worse than the other PCCs. This could be expected from the difficulties encountered during compaction of *A* and the inferior physical characteristics. From cycle three onwards the average attack depth of the concretes with limestone sand surpassed the average attack depth of the reference concrete. Furthermore the concrete with limestone sand and limestone aggregates was more degraded than the one with limestone sand and gravel. The neutralizing effect of limestone sand and limestone aggregates was insufficient to limit the total attack. After six attack cycles the average attack depths for the different concrete compositions were all significantly different and varied between 0.17 mm for *SAE* and 3.16 mm for *LS-L*. The vulnerability to attack by lactic and acetic acid increased in the following order: PCC with the styrene acrylic acid ester *SAE*; PCC with the styrene butadiene latex *SBR2*; PCC with the styrene butadiene latex *SBR1*; concrete with blastfurnace slag cement III/A; PCC with the acrylic latex *A*; reference concrete with ordinary Portland cement *Ref I*; concrete with lime sand and gravel aggregates *LS-G*; concrete with lime sand and limestone aggregates *LS-L*. Modification of the concrete with styrene acrylic ester therefore seemed to be the best solution, even though investigation with the scanning electron microscope showed that the emulsified polymer had not completely formed a film. This would be due to the relatively high minimum film forming temperature of this polymer (32°C). Comparison with an on-farm trial (De Belie 1997b) revealed that the degradation of the reference concrete after two attack cycles of the TAP was similar to the attack of concrete slats in houses for fattening pigs after 9 months in front of the wetfeeders.

*Average Surface Roughness*

The most important factor influencing the $R_a$-value, was again the concrete composition. Fig. 3 shows the $R_a$-value of the different concrete types versus the number of attack cycles. Initially *SAE* showed a significantly larger surface roughness ($R_a$ = 0.10 mm) than the other concretes, except *LS-L* (Student-Newman-Keuls test with level of significance = 0.05). The subsequent increase in roughness was however extremely small ($R_a$ = 0.18 mm after six cycles). The increase in surface roughness of the two PCCs with styrene-butadiene latex, *SBR1* and *SBR2*, was also limited. The $R_a$-value of *A* surpassed the others till cycle four; then *LS-G* began to show the largest surface roughness. The surface of the *LS-L* concrete remained much smoother, due to the equal erosion of limestone aggregates and cement paste. After the six attack cycles the surface roughness increased as follows: PCC with the styrene acrylic acid ester *SAE*; PCC with the styrene-butadiene latexes *SBR2* or *SBR1*; concrete with limestone sand and limestone aggregates *LS-L*; concrete with blastfurnace slag cement *III/A*; PCC with the acrylic latex *A*; reference concrete with ordinary Portland cement *Ref I*; concrete with limestone sand and gravel aggregates *LS-G*.

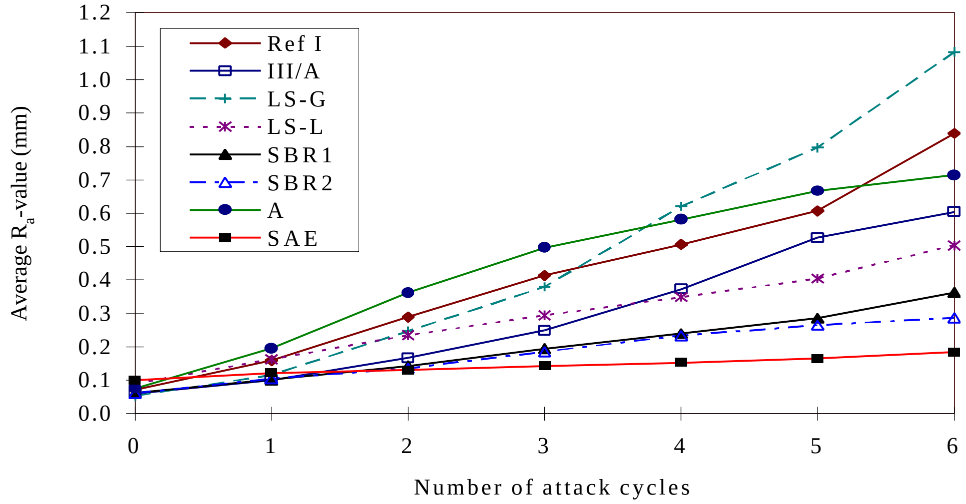

**Figure 3. Average surface roughness of the different concrete types of experiment 1 (lactic/acetic acid) vs. number of attack cycles**

### 3.2 Experiment 2: sulfuric acid attack

*Average change in radius*

In Fig. 4 the average change of the radius of the cylinders is shown versus the number of attack cycles for the different concrete mixtures. For every cycle two measurements were performed: one before and one after brushing the cylinders. A positive value represents an expansion of the cylinders compared to the initial size, while a negative value means that due to loss of material, the radius of the cylinder decreased compared to the initial dimensions. The alternating increase and decrease of the radius corresponds to alternating expansion of the concrete due to immersion and formation of reaction products and subsequent material loss due to brushing.

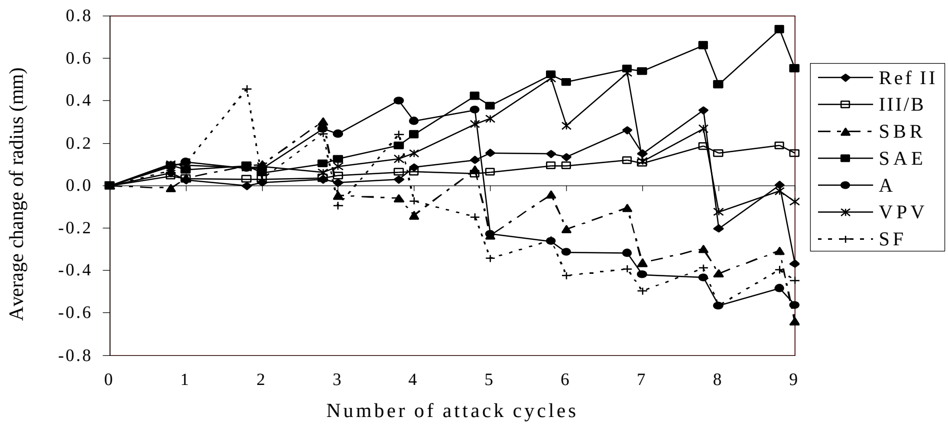

**Figure 4. Average change of radius of the different concrete types of experiment 2 (sulfuric acid) vs. number of attack cycles**

From the fifth cycle on the different mixtures could be classified in at least two groups (student-Newman-Keuls test with level of significance 0.05). One group included the reference mixture, the mixture with blast furnace slag cement and the mixtures with the styrene acrylic ester polymer and the vinylcopolymer. The other group, which appeared to be more vulnerable to degradation, included the mixtures with acrylic polymer, styrene butadiene polymer and silica fume. The reference mixture and the mixture with vinylcopolymer showed only after eight cycles a decrease of the radius relative to the initial radius. The mixtures with the blast furnace cement and the styrene acrylic ester polymer still showed a resulting expansion after nine cycles. For the mixture with the styrene acrylic ester polymer the increase of the radius was significantly larger (0.6) mm than for the mixture with blast furnace slag cement (0.2 mm). After nine cycles the reference mixture joined up with the second group, including also the mixture with silica fume, the mixture with the acrylic polymer and the mixture with the styrene-butadiene polymer.

Figure 5 shows the cumulative changes of the average radius of the different mixtures due to brushing of the cylinders. These values represent the sum of all differences between the radius measured after brushing and the radius measured before brushing during the same cycle. This figure, excluding the effect of expansion during immersion in the sulfuric acid solution, makes more clear that especially the concrete types with blastfurnace slag cement or styrene acrylic ester polymer are quite resistant to abrasion. The compositions with silica fume or styrene butadiene showed the most severe loss of material. Especially the results of the silica fume mixture were below expectations. In general silica fume addition induces an increased resistance of concrete to chemical aggression, due to a refinement of the pore structure, a reduced permeability, a reduction of the calcium hydroxide content and an increase of the content of calcium silicate hydrates. Many researchers have found positive results in the specific case of concrete subjected to sulfate attack by adding silica fume to the concrete mix. The results of compressive and water absorption tests (Table 3) indicate that also in our case the silica fume concrete was of high quality. Nevertheless there are some other investigations which show little or no positive effect of silica fume addition with respect to sulfate attack. Neville (1981) stated that in case of sulfate attack, the influence of silica fume is ambiguous. Talero (1996) found that ettringite formation associated with the reaction of puzzolans occurred much faster than with the ordinary hydration products. This resulted in an increased corrosion rate. Another reason might be that the pore refinement leads to a lack of expansion space for the voluminous reaction products gypsum or ettringite. Scherer & Fidjestöl (1995) use the same theory to explain why a greater water-cement ratio (>0.5) can result in a decrease in degradation by sulfates.

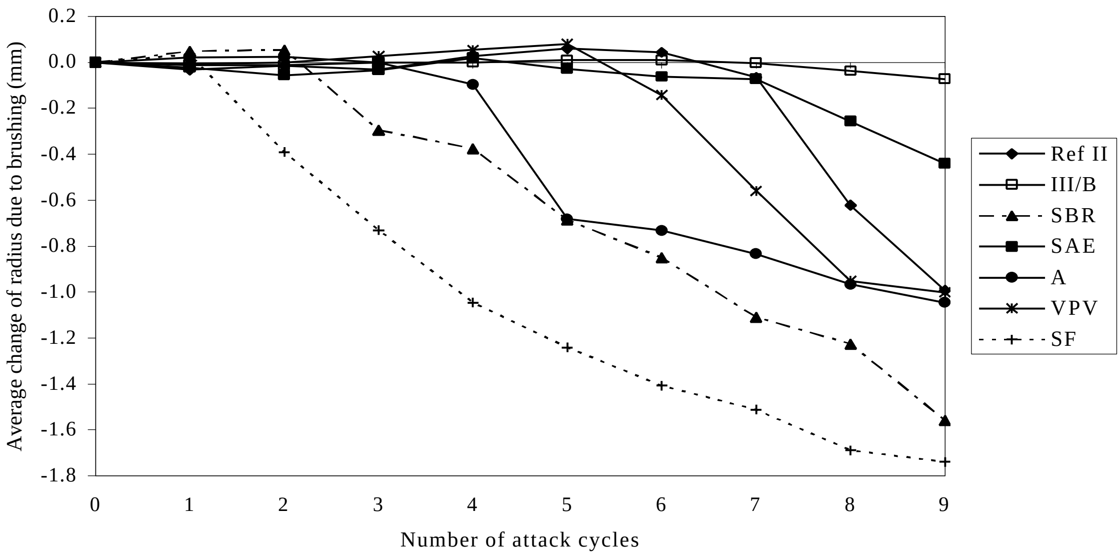

**Figure 5. Cumulative change of the average radius of the concrete types of experiment 2 (sulfuric acid) due to brushing**

The average $R_a$-value of the cylinders versus the number of cycles is shown in figure 6. The specimens with blast furnace slag cement showed a limited change in roughness. For all other mixtures, with exception of the mixture with the acrylic polymer, a gradual increase was measured during the subsequent cycles. The mixture with the acrylic polymer showed a peak after cycle 4 followed by a decrease of the roughness after cycle 5 and 6. This peak corresponds with a large expansion of the cement paste, followed by a significant amount of matrix material being detached. By this detachment the difference in level between the cement paste and the aggregates was again reduced.

### 3.3 Comparison of lactic/acetic and sulfuric acid attack

De degradation mechanism is completely different for the two liquids. The reaction between concrete and the organic acids involves an acid-base reaction with formation of soluble salts which are leached. Because of the continuing removal of free lime and the associated pH-drop the calcium silicate hydrates become unstable. The concrete surface is weakened and surface material is easily detached by brushing. On the contrary, the sulfuric acid attack is mainly described as the formation of expansive reaction products such as gypsum and ettringite. The latter is formed by reaction between calcium sulfate and the tricalcium aluminate of the cement and contains 32 water molecules in its structure. The increase in internal pressure results in development of cracks. Although some authors mention that also calcium lactates can cause an internal pressures (Kleinlogel 1960), no expansion was noticed during our experiments. In addition no cracks were found during the microscopic examinations on thin sections and with scanning electron microscopy (De Belie *et al*. 1997b). Figure 4 shows that the expansion linked to sulfuric acid attack was relatively large: up to 1.3 mm cumulative expansion over the 9 cycles for the silica fume concrete and about 0.7 mm for the reference concrete with Portland cement, even though high sulfate resistant cements were used in all compositions.

The organic acids used are much weaker than sulfuric acid, and the associated pH amounted to 2 compared to a pH of 1 for the sulfuric acid solution. Also the attack cycles involved a 6 day immersion for the organic acid attack and a 12 day immersion for the sulfuric acid attack. Nevertheless, the degradation caused by these organic acids was more severe. The reference concrete with Portland cement showed a decrease in radius of about 2 mm after 6 attack cycles of 6 days in the lactic/acetic acid solution (Fig. 2) and only 1 mm after 9 cycles of 12 days in the sulfuric acid solution (Fig. 5: cumulative decrease in radius without taking the expansion into account). Also the surface roughness at the end of the experiment was larger for the reference concrete subjected to lactic/acetic acid (about 0.8 mm compared to about 0.3 mm for the sulfuric acid solution). Apart from the different reaction mechanism, also the difference in acid concentration may be a reason for this effect (60 g lactic + acetic acid per liter simulation liquid compared to 5 g sulfuric acid). Bayoux *et al*. (1990) also mention that for weak acids such as lactic and acetic acid the acceptable pH limits are higher than for strong acids, because weak acids must be present in a higher concentration to cause the same pH. However, it must be noted that the concentrations used were realistic concentrations occurring on floors in animal houses and in sewer systems, respectively.

## 4 CONCLUSIONS

De resistance of different concrete compositions to aggressive solutions, firstly with lactic and acetic acid, and secondly with sulfuric acid, was tested with an apparatus for accelerated degradation tests (TAP). The aim was to simulate degradation in agricultural environments: on floors in animal houses and silage storage structures, and in manure storage facilities, respectively. It appeared that the degradation by the organic acids proceeded much faster, although the associated pH was higher. The degradation mechanism was also completely different, and involved mainly a leaching action for the lactic/acetic acid attack and the formation of expansive compounds for the sulfuric acid attack.

In both cases the use of blastfurnace slag cement instead of Portland cement was beneficial, even though high sulfate resistant Portland cement was used in the case of sulfuric acid attack. The effect of polymer modification depended highly on the type of polymer used. Addition of a styrene acrylic acid ester was the optimal solution in the case of lactic/acetic acid attack, whereas it resulted in a high expansion and increase in surface roughness in the case of sulfuric acid attack. Nevertheless, this expansive reaction was not associated with a loss of structural integrity and the detachment of material by abrasion was very limited. Modification with styrene butadiene polymer gave the second best results in the case of lactic/acetic acid attack, where it had rather a negative effect in the case of sulfuric acid attack. Acrylic polymer addition did help in neither case. Modification with vinylcopolymer was only tried in the case of sulfuric acid attack, but did not lead to a clear improvement, and silica fume addition caused a decrease in resistance.

# Effect Of Water/Cement Ratio And Curing Temperature On Early-Age Shrinkage And Self-Induced Stresses Of High Performance Concrete

**P Lura M Sule Y Guang K van Breugel**
**Delft University of Technology The Netherlands**

**Summary: This paper presents the results of an experimental study dealing with the influence of water/cement (w/c) ratio and curing temperature on the autogenous deformations and self-induced stresses in early-age concrete. Two concrete mixes, w/c ratio 0.33 and 0.37, were cured isothermally at 10, 20, 30 and 40°C. The linear deformations of a free specimen and the self-induced stresses of a fully restrained one were measured in the first six days after casting. The lower w/c ratio mixture experienced both higher deformations and higher self-induced stresses. Higher temperatures, on the contrary, did not always lead to higher deformations in the observed period, but generally caused a faster shrinkage and a faster development of self-induced stresses. Numerical simulation of hydration at different temperatures allowed identifying in the different porosity of the pastes one of the causes of the unsystematic dependency of autogenous deformation on curing temperature.**

**Keywords: Water/cement ratio, Curing temperature, Autogenous shrinkage, Self-induced stresses.**

## 1 INTRODUCTION

In High Performance Concrete mixtures, a low w/c ratio leads to a significant self-desiccation during hydration (Persson & Fagerlund 1997). Addition of silica fume to the mix further increases this process (Jensen 1993). With the progress of hydration, the relative humidity in the pores of the hardening cement paste drops and the paste shrinks. Experimental correlations were found between relative humidity decrease and autogenous shrinkage (Jensen & Hansen 1996), but the actual process leading to autogenous deformation is not yet fully understood. The different mechanisms involved, namely capillary tension in the pore water, surface tension in the free-adsorbed water layer and disjoining pressure in the hindered-adsorbed water layer, were already pointed out by Powers (1965).

Though autogenous shrinkage increases for months (Baroghel-Bouny & Kheirbek 2000), the main part of the deformations and accompanying stresses take place in the first hours after setting, when the strain capacity is lowest (Kasai & Okamura 1968) and the elastic modulus has already reached substantial values. Since the elastic modulus of the aggregates is (in most cases) higher than that of the hardening paste, autogenous shrinkage results in tensile stresses in the cement paste (Golterman 1994). Furthermore, it results in bulk deformation of the concrete itself (Tazawa *et al.* 2000). Both these phenomena should be avoided as much as possible since they could induce micro- and macrocracking and impair the concrete quality (IPACS 2001).

The magnitude and development in time of autogenous shrinkage is fundamentally influenced by the w/c ratio. Baroghel-Bouny and Kheirbek (2000) observed increasing shrinkage in cement pastes with a reduction of the w/c ratio. Similar results were found for concrete (Persson 1998, Tazawa *et al.* 2000).

Measurements of autogenous deformation are normally performed at room temperature. A few authors have investigated the effect of different curing temperatures on autogenous shrinkage of concrete (Tazawa *et al.* 1995, Bjøntegaard 1999, Hedlund & Jonasson 2000, Lura *et al.* 2001). In their studies, a rather unsystematic influence of the curing temperature on the autogenous deformation was found.

Curing temperature and w/c ratio influence not only the deformations, but also the mechanical properties of young concrete, and thus both the self-induced stresses (which are higher the higher the stiffness) and the tensile strength. It is evident that when considering the risk of cracking of concrete at early age, the whole deformational and mechanical behavior, which depends on the development of the degree of hydration, should be taken into account.

In the present research, two concrete mixes, both realized with 475 kg/m$^3$ of blended cement (CEM I and CEM III) and 5% silica fume addition, differing only in the w/c ratio (0.33 and 0.37) were cured isothermally at 10, 20, 30 and 40°C. The linear free deformations in the first days after casting were measured with an Autogenous Deformation Testing Machine (ADTM). At the same time, on a fully restrained specimen (Thermal Stress Testing Machine, TSTM), the self-induced stresses were measured and the occurrence of cracking registered. Also the Young's modulus and the compressive strength were tested at different ages. The HYMOSTRUC model (Breugel 1997), calibrated with isothermal calorimetry, allowed the calculation of the degree of hydration of the mixtures and the parallel development of the microstructure in the cement paste. It must be pointed out that the degree of hydration concept (or an equivalent maturity concept) is not sufficient to describe the mechanisms that lead to autogenous deformation. A model able to simulate the development of the microstructure in the hardening pastes, especially the pore size distribution and the self-desiccation process, is needed. It will be shown in the following that HYMOSTRUC is able to simulate the effect of the curing temperature on the porosity of the cement paste, a first step towards the modeling of the whole self-desiccation process at different temperatures.

## 2 MATERIALS AND METHODS

### 2.1 Mix proportions

Two concrete mixtures with water/cement ratio 0.33 and 0.37, both with 5% silica fume addition, were studied (see Table 1). A blend of Portland cement (CEM I 52.5 R) and BFS cement (CEM III/B 42.5 LH HS) was used. The slag content of the BFS cement amounted to about 70%. The Blaine fineness of the two cements was 490 $m^2$/kg for the BFS cement and 530 $m^2$/kg for the Portland cement. Notice that the volumetric content of aggregate was 68% in mix A and 66% in mix B.

**Table 1. Mixture compositions of concrete with w/c 0.33 (A) and 0.37 (B)**

| *Mixture composition* | *A* | *B* |
|---|---|---|
| | *kg/m$^3$* | *kg/m$^3$* |
| CEM I 52.5 R (Portland cement) | 238.0 | 238.0 |
| CEM III/B 42.5 LH HS (BFS cement) | 237.0 | 237.0 |
| Water (including water in admixtures) | 125.4 | 175.8 |
| Crushed aggregate (4-16 mm) | 973.5 | 944.2 |
| Sand 0-4 mm | 796.5 | 772.5 |
| Lignosulphonate | 1.0 | 0.9 |
| Naphtalene sulphonate | 9.5 | 7.6 |
| Silica fume slurry (solid 50%) | 50.0 | 50.0 |

### 2.2 Cube compressive strength and modulus of elasticity

For the two mixtures the compressive strength and the modulus of elasticity were tested at different curing temperatures. The compressive strength was measured on concrete cubes, 150x150x150 $mm^3$; the modulus of elasticity in compression was tested on prisms, 100x100x400 $mm^3$. Cubes and prisms were cast in temperature-controlled steel moulds. The specimens tested at later ages were removed from the moulds after six days, sealed with plastic and aluminum foils and stored at constant temperature until the moment of testing.

### 2.3 Free deformations

Measurements of the free deformations were performed with an ADTM, shown in Fig. 1. The concrete was cast in a prismatic mould, 150x150x1000 $mm^3$, made with thin steel plates provided with an external insulating material. A foil was folded into the mould to prevent leakage of water from the fresh concrete and drying of the hardening concrete. A felt placed beneath the foil reduced the friction between the mould and the specimen. After casting, the top surface of the concrete was covered with a tight cover in order to avoid moisture loss to the environment. A wooden frame supported the mould during casting, vibrating and setting of the concrete. The mould could be cooled or heated by a system of tubes located between the plates and the insulating material. Temperature differences inside the concrete were kept as low as 1.5 K.

Length changes of the hardening concrete were measured between two steel bars embedded in the concrete. The bars passed through the mould and at their ends linear variable differential transducers (LVDTs), attached to the outer ends of quartz rods, registered the deformations. The autogenous deformation was measured until six days after casting.

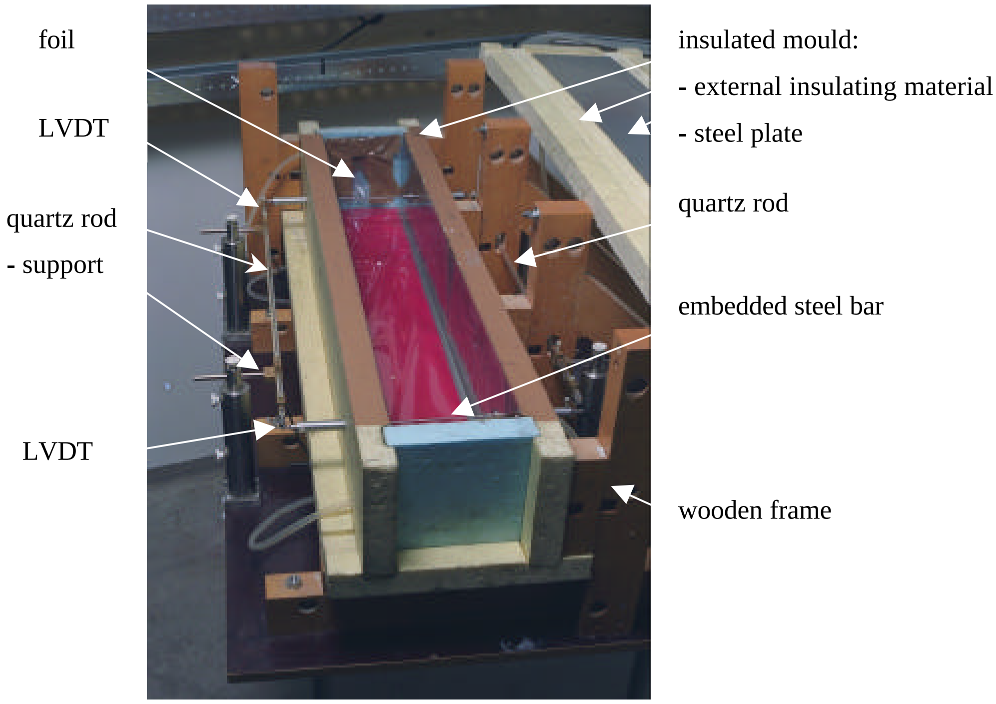

**Figure 1. Experimental setup for the measurement of the free deformations of hardening concrete (Autogenous Deformation Testing Machine).**

### 2.4 Self-induced stresses

The self-induced stresses were measured with a TSTM. It consisted of a horizontal steel frame (Fig. 2) where hardening concrete could be loaded in compression and in tension under various hardening conditions. With the help of a temperature controlled mould any curing temperature could be imposed. The specimen had a prismatic shape with dovetailed heads, where it was held by rigid steel claws. One of the claws was fixed to the frame; the other lied on roller bearings and could be moved with a hydraulic actuator. The claws could be prestressed to avoid slip of the specimen if the load changed from compression to tension. Loads were measured with a load cell. In this research the stress generated under total restraint was measured.

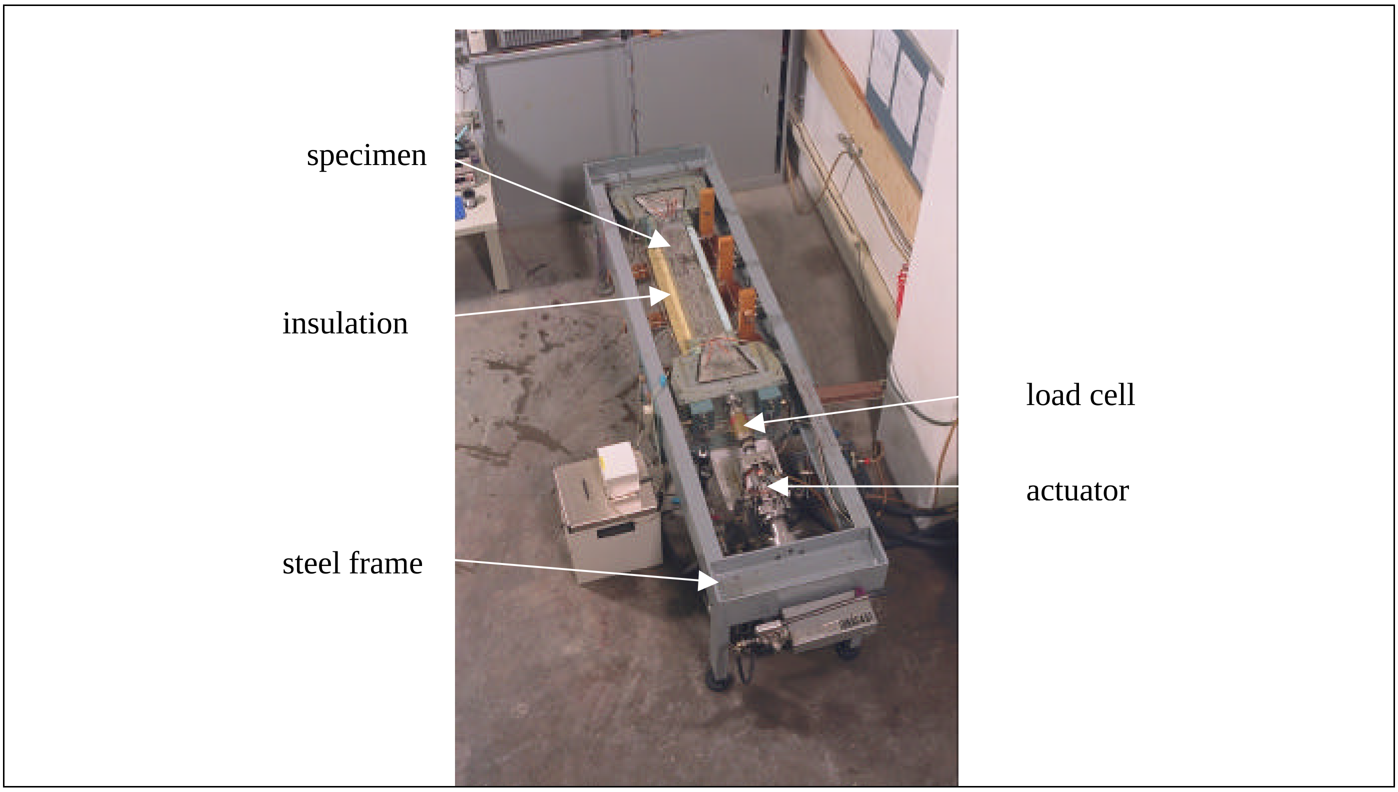

**Figure 2. Experimental setup for the determination of stress development in hardening concrete (Temperature Stress Testing Machine).**

# 3 RESULTS AND DISCUSSION

## 3.1 Cube compressive strength and modulus of elasticity

Results of compressive strength and elastic modulus are reported in Tables 2 and 3. The results represent the average value of three specimens.

**Table 2. Cube compressive strength of concrete with w/c ratio 0.33 and 0.37, cured at different temperatures**

| | | *Mean cube compressive strength [MPa]* | | | | | |

[1)] Tested at 1.5 days [2)] Tested at 2.5 days

Mixture A, with a lower w/c ratio, shows higher strengths at 28 days and faster strength increase than mix B at all temperatures. Comparison of the strength results in mix A at different curing temperatures shows that, although higher temperatures promote the initial strength development, the value at a later stage (28 days), seems to be penalized, as already observed (Rakel 1965). The same results were found for mix B, where the strength at 14 days is higher at 30ºC than at 40ºC. For the specimen cured at 10ºC progress of hydration was slower, but the strength at 28 days was already slightly higher than for 20ºC curing.

The results of the elastic modulus show a slightly faster development in mix A, whereas the final value seems to be similar for the two mixes. It is noticed that the modulus of elasticity develops relatively faster than the compressive and the tensile strength (Rostasy *et al.* 1993). This fact potentially increases the cracking risk, since the concrete might develop stresses (due to restrained deformations) while the strength is still very low.

## 3.2 Free deformations and self induced stresses

### 3.2.1 Effect of w/c ratio

In Fig. 3 the autogenous deformation and the self-induced stress of mixtures A and B are plotted. The autogenous deformation was zeroed at the time when stress was first recorded in the TSTM. Thus, only the stress-inducing deformation is shown. It can be seen that under the same curing temperature (20°C), concrete with a lower w/c ratio (mixture A) underwent more autogenous deformation and developed self-induced stress slightly faster.

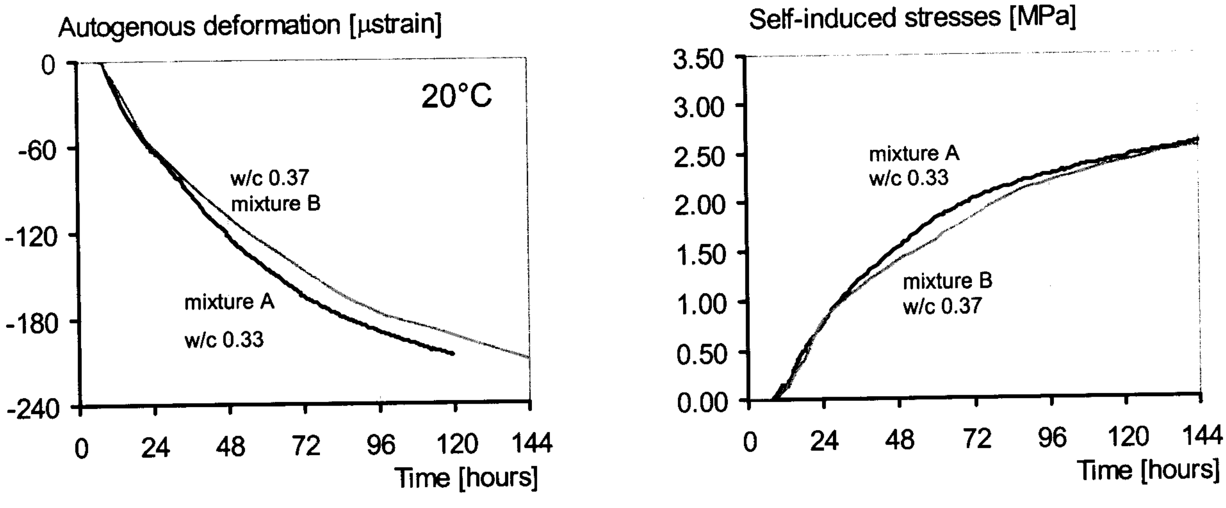

**Figure 3. Autogenous deformation (left) and stress development (right) of concrete mixtures with different w/c ratios cured at 20°C (mixture A: w/c 0.33, mixture B: w/c 0.37).**

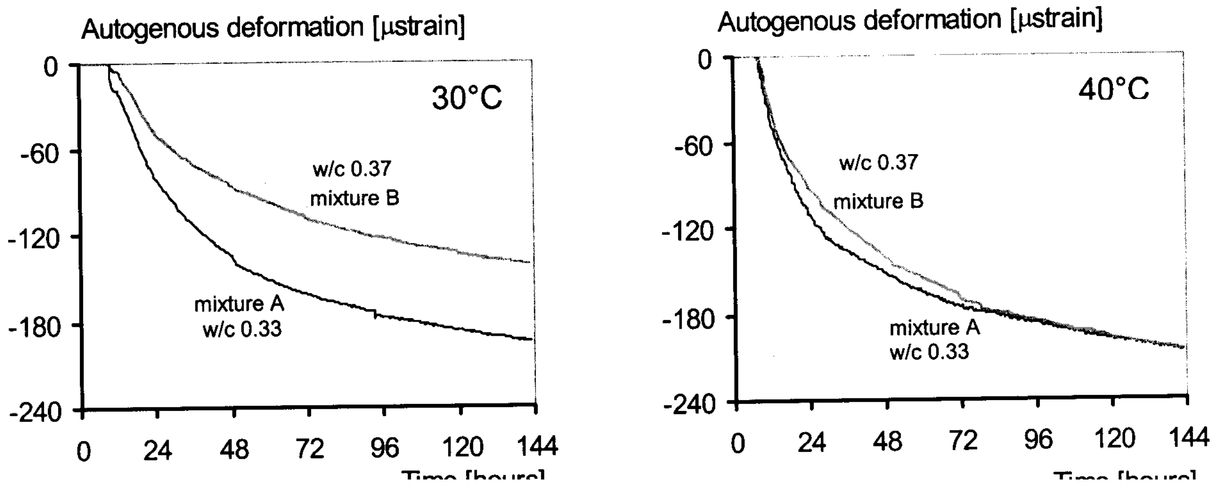
In Fig. 3 (left) and in Fig. 4 the autogenous deformations of the two mixes at curing temperatures 20, 30 and 40°C are shown. It can be noticed that a lower w/c ratio leads to higher autogenous shrinkage. This effect is found at all temperatures, though it is most evident in the case of curing at 30°C.



**Time (hours)** **Time (hours)**

**Figure 4. Autogenous deformation in mixtures A and B at 30°C (left) and 40°C (right).**

The autogenous shrinkage of both mixtures reached values between 150 and 200 µstrain after 6 days. This value is in agreement with literature data on similar concrete mixtures; see for example Igarashi *et al.* (2000). For all curing temperatures the measured shrinkage was only slightly higher for the concrete with the lower w/c ratio (mixture A). One would expect a higher difference between the autogenous shrinkage of the two concretes, due to the difference in w/c ratio (0.33 vs. 0.37). A possible reason could be the scatter in the measurements. Differences of about 8% were found in repeated experiments. Another factor reduces the differences between the autogenous deformations of the two mixtures, though in a minor extent, is the higher aggregate content, which is 68% by volume in mixture A and 66% in mixture B. In fact, the shrinkage of concrete is inversely proportional to the aggregate content, as already found by Pickett (1956) for drying shrinkage and recently by Tazawa *et al.* (2000) for autogenous shrinkage. Finally, a factor that influences the autogenous shrinkage of cement pastes very much is the silica fume content. In experiments performed on cement paste, Jensen (1993) observed that addition of 6% silica fume to pastes of different w/c ratio led to two times higher shrinkage (about 1000 µstrain vs. 500 µstrain, for w/c ratio 0.35).

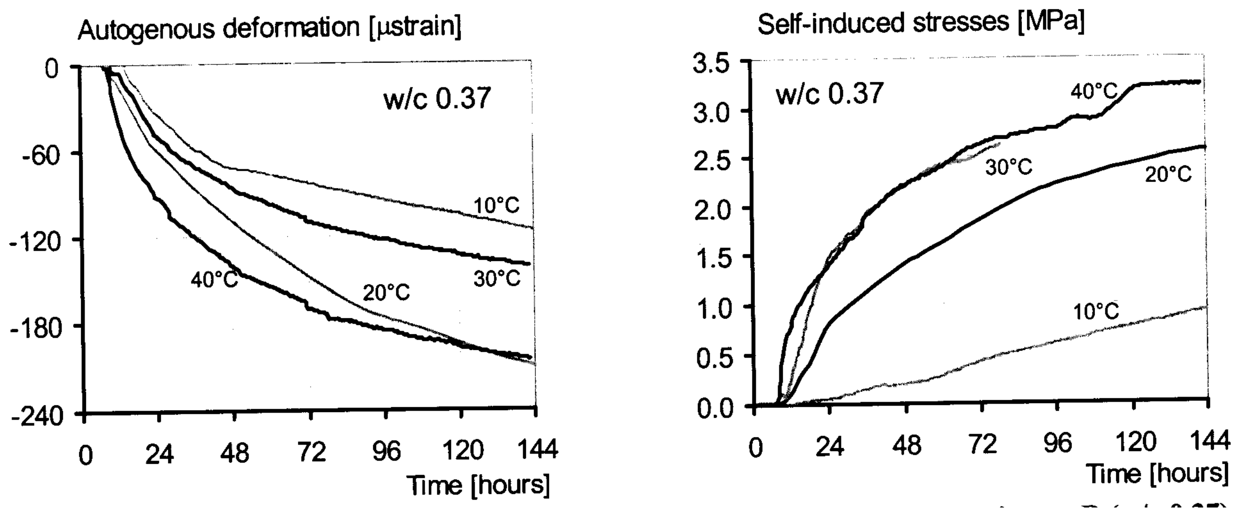


**Figure 5. Autogenous deformation (left) and self-induced stresses (right) in mixture B (w/c 0.37) at different temperatures. Note: the 20ºC curve refers to other batch (see text).**

The development of the self-induced stresses in time (Fig. 3, right) is also very similar in the two mixes. The lower w/c ratio leads to slightly higher tensile stresses in the first three days. Since the Young's modulus and the shrinkage of the two concretes did not differ substantially, this result was expected. The measured self-induced stresses are in agreement with results by Igarashi *et al.* (2000).

3.2.2 Effect of different temperatures on free deformation and self-induced stresses

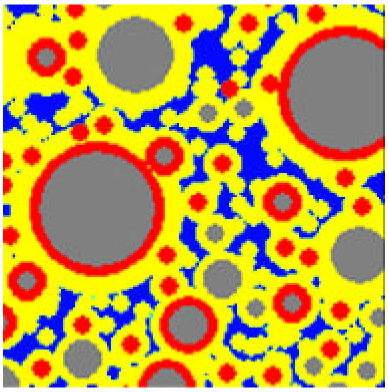
The effect of the curing temperature on the free deformation and the self-induced stress can be observed in Fig. 5. Results of self-induced stress (Fig. 5, right) show that the higher the curing temperature the faster the stress developed. The free deformation did not show such a clear trend (Fig. 5, left). In fact, the shrinkage of the specimen cured at 20°C developed faster than in the case of 30°C curing. It must be pointed out, however, that the deformations at 20°C had been measured in a previous research (Breugel & Vries 1999); the materials used might have been slightly different (different cement batches, for example). Differences in the measured shrinkage could also be due to scatter in the results (tests at 10, 30 and 40°C were repeated, showing a difference of about 8%).

Higher temperatures, causing faster development of shrinkage and self-induced stresses (Fig. 5, right), might increase the cracking risk. In fact, the specimens cured at 30ºC cracked 80 hours after casting. This fact is also confirmed by results on other concrete mixes (Lura *et al.* 2001). Jensen and Hansen (2001) observed that the rate of the autogenous deformation is at least as important as its absolute value in determining the cracking risk. In fact, a slower development of self-induced stresses allows the relaxation process to reduce the stresses in the specimen. Reducing the rate of the autogenous deformations, thus, might contribute to reduce the cracking risk.

In order to give further insight in the influence of the curing temperature on the autogenous deformation, the hydration of mixture B was simulated with the program HYMOSTRUC (Breugel 1997). The program is able to simulate the development of the hydration process in a concrete mix knowing the mineral composition and the particles size distribution of the cement and the w/c ratio. In order to obtain a more accurate simulation, it is possible to calibrate the results on experimental data. In this research, data obtained with an isothermal calorimeter on cement paste were used.

A cube of hydrating cement paste (100x100x100 $\mu m^3$) was simulated. The cement particles were modeled as digitized spheres randomly distributed in a three-dimensional body and the hydrating cement grains were simulated as growing spheres. The development of the porosity and of the connectivity of the solid phase during hydration was obtained. The influence of the curing temperature on the morphology of the hydration products was simulated considering a temperature-dependent expansion factor ? of the hydration products (Breugel 1997). This variable expansion factor has been derived from experimental observations of capillary porosity at different temperatures (Bentur *et al.* 1979).

Go Back Next Page



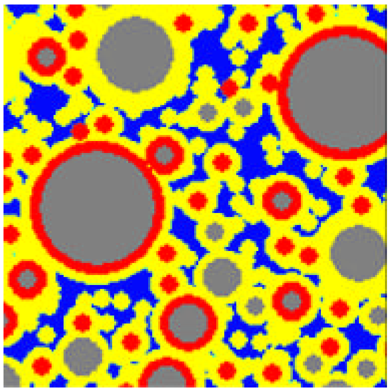


**Figure 6. Sections of simulated 3D microstructures of cement paste (mix B, w/c 0.37) cured at 20ºC (left) and 40ºC (right).**

Figure 6 shows a section of the 3D microstructure hydrated at 20ºC (left) and at 40ºC (right). Unhydrated cement is grey, inner product is red, outer product is yellow and capillary voids are blue. Even if the two pictures were taken at the same degree of hydration (a=0.31), it is noticed that the microstructure cured at 40ºC shows a thinner outer product, especially around the biggest cement particles. This results in fewer interparticle contacts and in higher porosity in the paste cured at higher temperature. 3D porosity calculations on the whole hydrating microstructure confirm this fact: the porosity is 11.7% for 20ºC and 13.1% for 40ºC curing.

This different porosity has a double effect on the autogenous deformations. On the one hand it accelerates the self-desiccation process (for the same amount of water reacted, a greater empty porosity is formed). On the other hand, the increased porosity will result mostly in bigger pores and the internal stresses due to capillary depression in the pore water will be lower. In fact, as resulting from the Laplace law (see for example Hua *et al.* 1995) the capillary depression is inversely proportional to the radius of the pore. The effect of the curing temperature on the pore size distribution and on the shape of the capillary pores will be object of further investigation.

The net effect of these phenomena is difficult to quantify. Nevertheless, it is important to point out that the effect of the curing temperature on morphology of the paste, internal stresses and deformability cannot be described only with a simple degree of hydration (or maturity) concept.

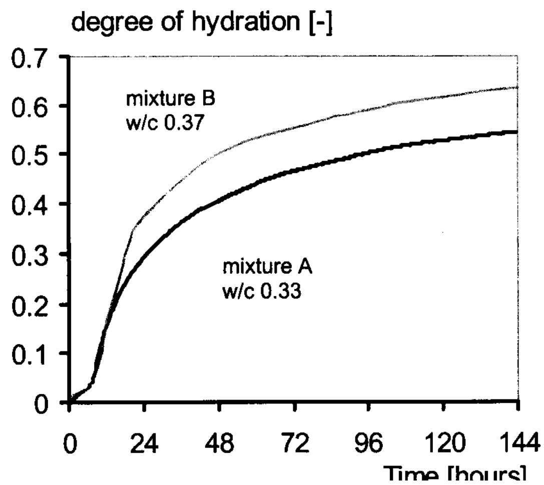

**Figure 7. Degree of hydration of mixtures A and B vs. time at 20ºC deduced from isothermal calorimeter data.**

3.2.3 Self-induced stresses as a function of time and of degree of hydration

The degree of hydration vs. time (Fig. 7) was calculated from isothermal calorimeter data for mix A and mix B cured at 20ºC. Figure 7 shows that in mix A, with a lower w/c ratio, the degree of hydration is about 15% lower than in mix B. The degree of hydration of the two concretes is still increasing after 144 hours; this fact is confirmed by increasing strength and stiffness at later ages (see Tables 2 and 3).

Once the development of the degree of hydration in time was obtained, the autogenous deformations and self-induced stresses could be related to it. In Fig. 8 the autogenous deformations (left) and the self-induced stresses (right) are shown for the two mixes cured at 20°C as a function of the degree of hydration. The autogenous deformation of mix A developed at a lower degree of hydration. This was expected, since a lower w/c ratio accelerates the occurrence of self-desiccation. Also the self-induced stresses (Fig. 8, right) developed at a lower degree of hydration, due to the higher restrained deformation and higher elastic modulus (see Table 3). In order to have a clearer picture of the build-up of the self-induced stresses, information about creep and relaxation of the mixes (an their dependence on the degree of hydration) would be needed (Lokhorst 1998).

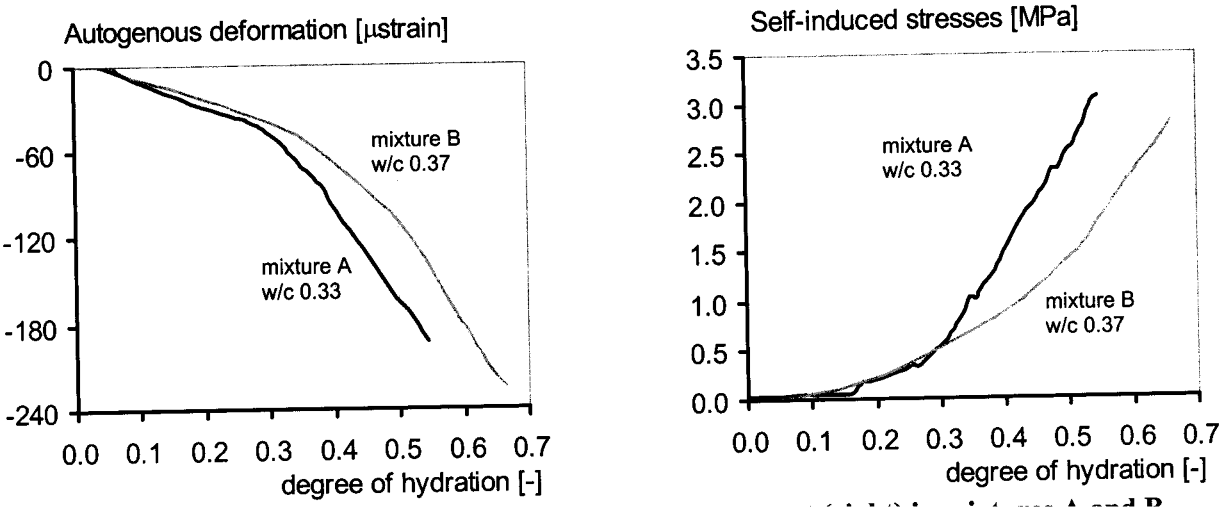

**Figure 8. Autogenous deformation (left) and stress development (right) in mixtures A and B, cured at 20°C, as a function of the degree of hydration.**

## 4 CONCLUSIONS

In this paper, results of an experimental study on autogenous shrinkage, self-induced stresses and mechanical properties of two concrete mixtures (w/c ratio 0.33 and 0.37) were presented. A summary of the findings of this study is provided below:

- The mixture with lower w/c ratio (mixture A) showed a higher strength and a faster development of the elastic modulus than mixture B at all the curing temperatures. For both concretes it was found, in agreement with findings by other authors, that the higher the curing temperature, the lower the strength at later ages.
- The mixture with lower w/c ratio (mixture A) showed substantially higher autogenous shrinkage and self-induced stresses. Since the development of the degree of hydration for mixture A was slower than for mixture B, the deformations and the stresses developed at a lower degree of hydration. In fact, due to the lower w/c ratio, mixture A undergoes self-desiccation (and consequent autogenous shrinkage) at a lower degree of hydration.
- The influence of curing temperature on the autogenous deformation was not systematic. However, the higher the curing temperature, the faster the self-induced stresses developed.
- Cracking was observed for specimens cured at higher temperatures when tested in the TSTM frame. The rate of the autogenous deformation is fundamental for the cracking risk, since a slower development of self-induced stresses allows the relaxation process to reduce the stresses in the concrete. High curing temperature, increasing the speed of the deformations, might therefore be detrimental for the risk of cracking.

The influence of the curing temperature on the microstructure of the cement paste was simulated with the HYMOSTRUC model. It was found that at the same degree of hydration, a higher porosity and coarser pores were found for the higher curing temperatures. The total porosity and the pore size distribution influence both the internal stresses due to self-desiccation and the deformability of the paste. Thus, a different morphology of pastes cured at different temperatures might explain the unsystematic dependency of autogenous shrinkage on curing temperature, which cannot be described with the degree of hydration concept alone.

## 5 ACKNOWLEDGMENTS

The Dutch Technology Foundation (STW), the Ministry of Transport, Public Works and Water Management (RWS) and the Brite-Euram project IPACS financially supported this research. The assistance of Mr. E. Horeweg, Mr. A. van Rhijn, Mr. F.P.J. Schilperoort and Mr. R. Mulder in performing the experiments is gratefully acknowledged.

# Volume Changes Of Lightweight Aggregate Concrete At Early Ages: The Effect Of Particle Size Distribution Of The Lightweight Aggregates In Experiments And Numerical Simulations

**P Lura & K van Breugel**
**Delft University of Technology Faculty of Civil Engineering and Geosciences**
**The Netherlands**

**Summary: This paper deals with early-age volume changes and moisture transport in Lightweight Aggregate Concrete (LWAC). Three LWAC mixtures with water/cement (w/c) ratio 0.37 were tested, differing in the grading of the lightweight aggregates (LWA), while the quantity of water absorbed in the LWA was kept constant. Autogenous deformations, self-induced stresses in 100% restrained conditions and compressive strength were measured. It was found that a concrete with fine particles swells more than one with coarser particles. This finding was confirmed by modeling the concrete mixtures with analytical formulas.**

**In order to proceed towards the modeling of water transport from the LWA to the cement paste, absorption-desorption properties of the LWA and their volume stability in consequence of the moisture loss towards the matrix have also been studied. It was found that not all the water entrained in the LWA is available for the internal curing and that the LWA show moderate shrinkage in consequence of moisture loss.**

**Keywords: Lightweight Aggregates, Autogenous deformation, Self-induced stresses, Water transport, Internal curing**

## 1 INTRODUCTION

High-Performance Concrete (HPC) is generally made with a low w/c ratio, which makes it susceptible to self-desiccation (Persson & Fagerlund 1997). The addition of silica fume to the mix, to increase the strength and reduce the porosity, further increases the relative humidity (RH) drop in the concrete (Jensen & Hansen 1996). It has been shown (Jensen 1993) that autogenous shrinkage is directly related to the RH decrease. Autogenous shrinkage results in tensile stresses in the cement paste, due to the internal restraint of the aggregates (Golterman 1994), and in bulk deformation of the concrete itself (Tazawa *et al.* 2000). Both these phenomena should be avoided as much as possible since they could induce micro- or macrocracking and impair the concrete quality. A very efficient way to reduce or even eliminate autogenous shrinkage is the use of saturated LWA in the concrete (Breugel & Vries 1999).

In low water/binder ratio LWAC, water transport between the porous saturated aggregates and the matrix influences the hardening process (Weber & Reinhardt 1997). Due to self-desiccation of the matrix during hydration, a RH-gradient takes places within the concrete and a moisture flow from aggregate particles to the matrix may occur (Takada *et al.* 1998). As a consequence, the relative humidity in the matrix remains higher than in Normal Weight Concrete (NWC).

Of primary importance in this internal-curing process is the spatial distribution of the "water reservoirs" in the mixture. The distance of the saturated LWA from the point where the RH-drop takes place determines the efficiency of the internal curing. The maximum transport distance of water, as a consequence of the depercolation of the pores in a low w/c ratio paste, was estimated as hundreds of micrometers (Bentz & Snyder 1999). If the water-reservoirs are well distributed within the matrix, shorter distances have to be covered and the efficiency of the internal-curing process is increased. These considerations lead to the choice of small LWA.

In the present research, three LWAC mixtures with w/c ratio 0.37 were tested, differing for the grading of the LWA. The quantity of water absorbed in the LWA was kept constant. Autogenous deformation, self-induced stresses in 100% restrained conditions and compressive strength were measured. Analytical analysis of the effect of different particle size distributions of the LWA on the internal curing process was performed using the formulas by Lu & Torquato (1992). The percentage of paste within the assumed sphere of influence of the moisture transport from the LWA particles was estimated.

Two other important factors, in order to investigate the early-age swelling in LWAC, are the absorption properties of the LWA and the volume stability of the particles in consequence of the moisture loss towards the matrix. Tests on the aggregate particles have been carried out in order to quantify the water absorption, the desorption isotherm and the deformational response to changes in the water content. Finally, the amount of entrained water needed to totally avoid self-desiccation (and thus autogenous shrinkage) and the origin of the autogenous swelling in LWAC are also addressed in this contribution.

## 2 MATERIALS AND METHODS

### 2.1 Mix proportions

Three LWAC mixtures with water/cement ratio 0.37 and addition of 5% silica fume (in slurry form, 50% solid) were studied (Table 1). A blend of Portland cement (CEM I 52.5 R) and blast furnace slag (BFS) cement (CEM III/B 42.5 LH HS) was used. The slag content of the BFS cement amounted to about 70%. The Blaine fineness of the two cements was 490 $m^2$/kg for the BFS cement and 530 $m^2$/kg for the Portland cement. The LWA in the three mixes were Liapor F8 in two of the mixes and Liapor sand in the third mix. The grain density of the LWA is about 1500 kg/$m^3$ for Liapor F8 and 1400 kg/$m^3$ for Liapor sand. In all the mixes normal siliceous sand (1-4 mm) was used. Two types of plasticizers were added, i.e. lignosulphonate and naphthalene sulphonate.

**Table 1. Mixture compositions of LWAC with w/c ratio 0.37**

| Mixture composition | | Type of lightweight aggregate | | |
|---|---|---|---|---|
| | | Liapor F8 4-8mm | Liapor F8 8-16mm | Liapor sand 0-4mm |
| CEM III/B 42,5 HL HS (CEMIJ) | kg/$m^3$ | 237.00 | 237.00 | 237.00 |
| CEM I 52,5 R (ENCI) | kg/$m^3$ | 238.00 | 238.00 | 238.00 |
| Water (including water in admixtures) | kg/$m^3$ | 175.75 | 175.75 | 175.75 |
| Lightweight aggregate | kg/$m^3$ | 545.90 | 586.53 | 385.00 |
| Sand 0-4 mm | kg/$m^3$ | 772.51 | 772.51 | 772.51 |
| Lignosulphonate | kg/$m^3$ | 0.95 | 0.95 | 0.95 |
| Naphtalene sulphonate | kg/$m^3$ | 7.13 | 7.13 | 7.13 |
| Silica fume (slurry, 50% solid) | kg/$m^3$ | 50.00 | 50.00 | 50.00 |

The quantity of water absorbed in the LWA was about 15% by weight. This amount corresponded to the quantity absorbed after one day under water by the fraction of aggregate with the lowest absorption capacity (Liapor F8 8-16 mm). This quantity does not correspond to full saturation, as will be shown in the following. Being the amount of the LWA different in the three mixes, the quantity of absorbed water is also different. The difference is quite relevant in the case of Liapor sand (58 kg/$m^3$) while the other two mixes are almost equivalent in this respect (82 and 88 kg/$m^3$).

### 2.2 Cube compressive strength

The compressive strength was measured at 3 and 28 days after casting, on sealed cubes, 150x150x150 $mm^3$. The specimens were cast in temperature-controlled steel moulds. The cubes tested at 28 days were removed from the moulds after two weeks, sealed with plastic and aluminum foils and stored at constant temperature (20±1ºC) until the moment of testing.

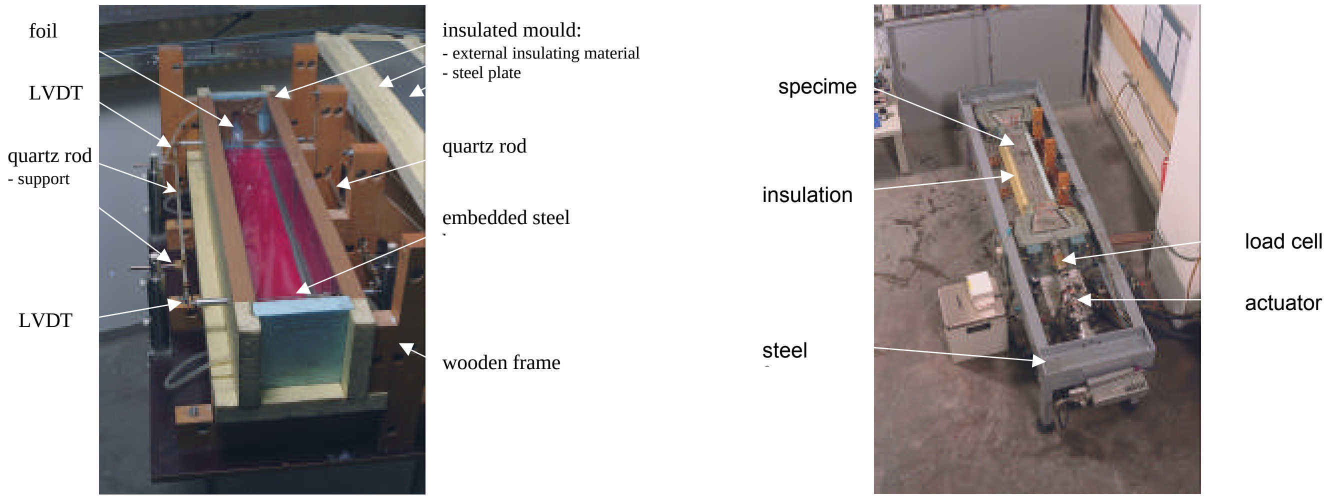

**Figure 1. Left, experimental setup for the measurement of the free deformations of hardening concrete (ADTM). Right, experimental setup for the determination of stress development in hardening concrete (TSTM).**

### 2.3 Free deformations

Measurements of the free deformations were performed with an Autogenous Deformation Testing Machine (ADTM), shown in Figure 1, left. The same device had been already used to measure autogenous deformation on NWC (Lura *et al.* 2001) and on LWAC mixes (Takada *et al.* 1998). The concrete was cast in a prismatic mould, 150x150x1000 $mm^3$, made with thin steel plates provided with an external insulating material. After casting, the top surface of the concrete was covered with a tight cover in order to avoid moisture loss to the environment. The mould could be cooled or heated by a system of tubes located between the plates and the insulating material. Temperature differences inside the concrete were kept as low as 1.5 K. A felt was used to minimize the friction between the sample and the mould. Length changes of the hardening concrete were measured with two external quartz rods provided with linear variable differential transducers (LVDTs) at both ends. The quartz rods were connected to steel bars cast in the concrete and measured displacements over a length of 750 mm. The rods could be fixed to the cast-in bars when the concrete had reached sufficient strength to support them (see Fig. 1, left). The autogenous deformation up to two weeks after casting was recorded.

### 2.4 Self-induced stresses

The self-induced stresses were measured with a Thermal Stress Testing Machine (TSTM). This device consisted of a steel frame (Fig. 1, right) supporting a mould in which the concrete was cast. The specimens had a prismatic shape with dovetailed heads. Two rigid steel claws held the specimen and were able to exert a tensile or a compressive force. One claw was fixed to the steel frame and one lied on roller bearings and could be moved with a hydraulic actuator. A temperature-controlled mould allowed realizing isothermal conditions. The imposed strain on the concrete in the TSTM was assumed equal to the free deformations measured in the ADTM, except for the sign. The control of the device was fully automatic. In this research, stresses obtained under total restraint were measured.

## 3 EXPERIMENTS ON LIGHTWEIGHT AGGREGATE CONCRETE

### 3.1 Cube compressive strength

Results of compressive strength are shown in Figure 2. The results represent the average value of three specimens. The strength at 28 days of the mixtures with Liapor F8 was considerably higher than the strength of the mixture with Liapor sand (80 MPa versus 65 MPa). It is noticed that the three mix compositions were meant to be equivalent in every respect except for the particle size of LWA. This is true only for the two mixes with Liapor F8 4-8 mm and 8-16 mm, which show rather similar strength both at 3 and 28 days. For the same mix realized with normal weight aggregates (Lura *et al.* 2001), also shown in Fig. 2, the compressive strength was 58 MPa at 3 days and 82 MPa at 28 days. Thus, high performance LWAC reached 28 days-strength similar to NWC with the same matrix.

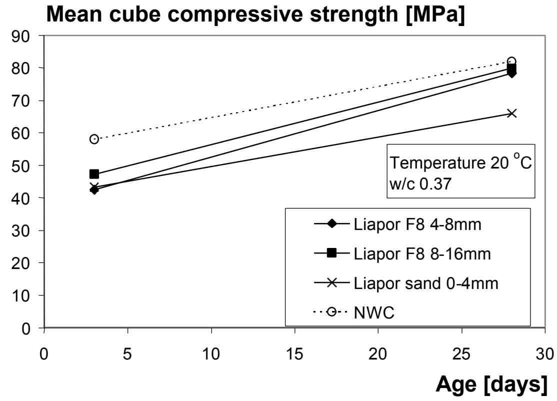

**Figure 2. Cube compressive strength of mixtures with LWA of different particle size.**

Since the mechanical properties of the LWA are generally inferior to the ones of NWA (Nilsen *et al.* 1995), this fact might be due to an improved quality of the interfacial transition zone and of the bond between LWA and matrix. It has been observed (Zhang & Gjørv 1991, Wasserman & Bentur 1996), that cement paste penetrates in the outer porous layer of the LWA particles, strengthening the bond.

Continuous hydration of the mixture at later ages, promoted by the extra water stored in the LWA, might also contribute to the strength increase. Weber and Reinhardt (1997), using differential thermal analysis, thermal gravimetry and X-ray diffraction, observed a substantially higher amount of hydration products in LWAC at later ages, from 180 to 360 days.

Finally, since the cement paste in the LWAC does not shrink, microcracks or eigenstresses in the paste (Dela 2000), due to restraining effect of the aggregates, are avoided. This fact might also contribute to increased strength at later ages of LWAC compared to NWC.

### 3.2 Free deformations and self-induced stresses

In Fig. 3 the autogenous deformations (left) and the self-induced stresses (right) of the LWAC mixtures are shown.

The three mixes expanded from the beginning of the measurements. The expansion of the mix with Liapor F8 4-8 mm was continuous, reaching a value of 100 µstrain at 138 hours. The expansion of the mixture with the coarser Liapor F8 8-16 mm reached a peak of 85 µstrain at 30 hours. Then a small shrinkage occurred until 144 hours, followed by further expansion. At 312 hours the expansion was about 80 µstrain. The mix with Liapor sand 0-4 mm expanded rapidly until 48 hours, reaching 95 µstrain. Afterwards expansion proceeded steadily but at a lower rate until a value of 120 µstrain.

The stress development of the mix with Liapor sand showed a peak in compression (about 1.05 MPa) higher than the one observed for the mixture with 4-8 mm Liapor F8 (0.98 MPa) and for the mixture with 8-16 mm Liapor F8 (0.8 MPa). For all the mixes the peaks were reached within 24-30 hours. The relaxation of the compressive stress after the peak was more relevant for the mixture with Liapor sand (where the stresses reduce to 0.4 MPa) than for the other two mixtures. The stress development of the two mixtures with Liapor F8 was similar, showing slight relaxation until 72 hours and then an increase of the compressive stresses. In the case of the mix with 8-16 mm LWA, the experiment was prolonged to 312 hours showing continuous increase of the compressive stress, up to a value of more than 1.1 MPa. Also the mixture with Liapor sand, after relaxation of the stresses up to 132 hours, showed an increase of the compressive stresses until the end of the experiment.

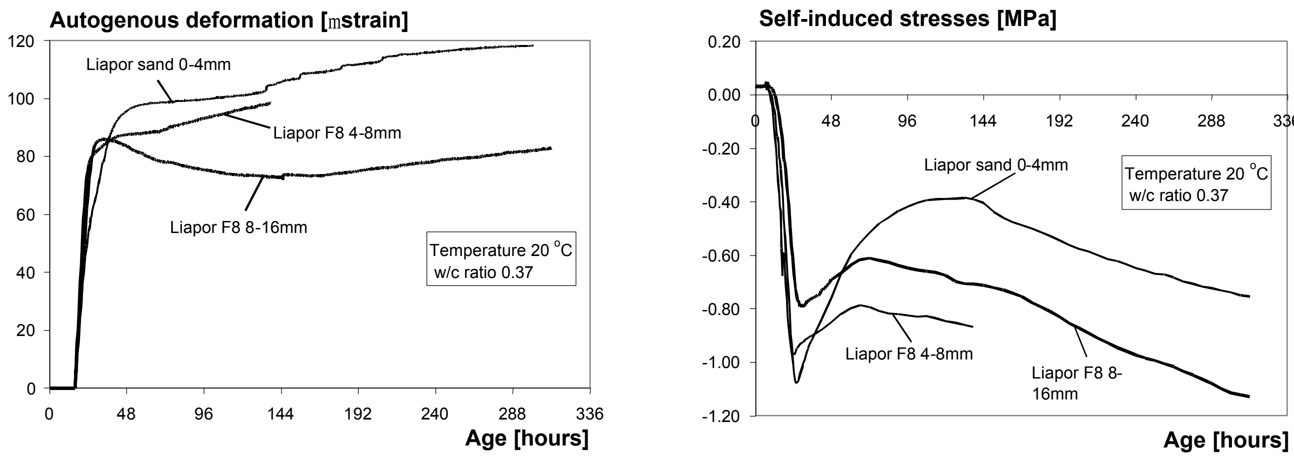

**Figure 3. Free deformation (left) and self-induced stresses (right) of mixtures with LWA of different particle size.**

# 4 EXPERIMENTS ON LIGHTWEIGHT AGGREGATES

## 4.1 General

When dealing with LWAC, one must realize that not only the mechanical properties of the aggregate (as for NWC), but also the absorption-desorption of moisture and the shrinkage of the LWA particles in consequence of moisture loss play an important role on the characteristics of the composite. These issues have been studied by means of experiments on the LWA particles and will be discussed in the following paragraphs.

Additionally, an experiment designed to visualize the transport of water from the saturated LWA to the hardening cement paste will also be presented.

## 4.2 Absorption under water

Measurements of water absorption were performed on the LWA Liapor F8, fractions 4-8 mm and 8-16 mm. The LWA were kept under water for one or two weeks and weight was measured every few days. Results are shown in Figure 4, left.

The two fractions show different absorption behaviors. The coarser fraction absorbed about 17% by weight in the first day and then the weight remained almost unchanged. The finer fraction absorbed about the same amount in the first day, but the absorption proceeded until 2 weeks after immersion, reaching a value of 25% by weight. Thus, in the finer fraction of the Liapor F8 aggregates more water can be absorbed. This fact might be beneficial if one wants to minimize the LWA content and maximize the water content of the mixture.

## 4.3 Desorption isotherm

The LWA (Liapor F8) were first immersed in water for one day and then exposed to different RH levels at 20°C until moisture equilibrium was reached. Results in the higher humidity range (until 75%) are shown in Figure 4, right. The different RH levels were obtained by storage above saturated salt solutions. Already at 100% RH a great fraction of the water content (the 'fill-up moisture' according to the definition by Nielsen, 1991) was lost. This amount, about 10% by weight of the LWA, was weakly bound by capillary forces. In fact the pores of the LWA are relatively big, having an average radius about 0.2 mm, as reported by Weber and Reinhardt (1999). The fill-up moisture is thus readily available for transport to the paste.

About a further 3% water by weight of LWA is in equilibrium at RH ranging from 100% to 94%. Also this amount of water might be absorbed by the cement paste while it self-desiccates.

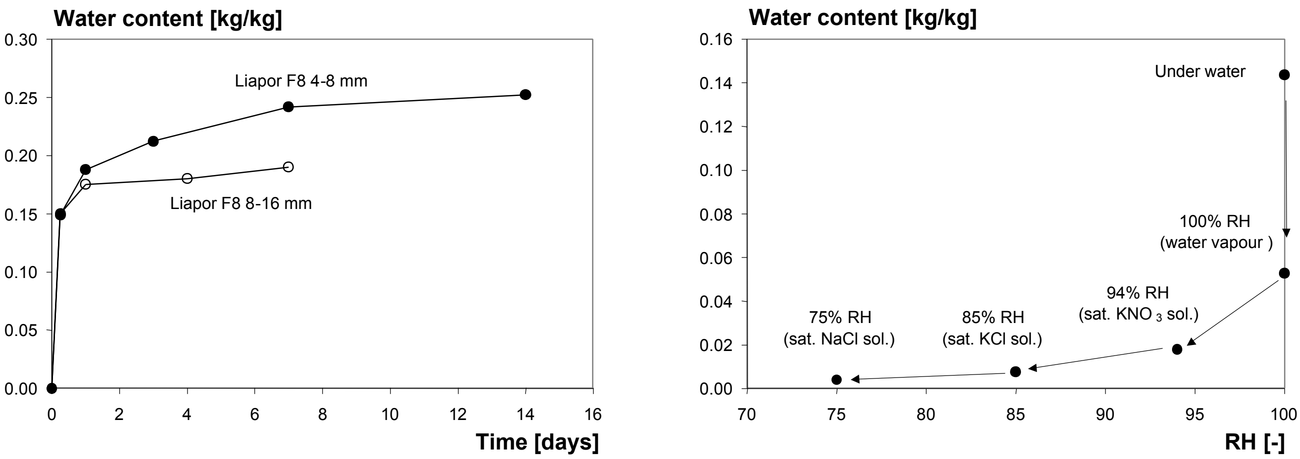

**Figure 4. Absorption under water (left) and desorption isotherm (right) of Liapor F8.**

## 4.4 Volume stability

The volume stability of Liapor F8 aggregates was tested measuring the diameter changes of single grains subjected to drying. The Liapor grains were immersed in water and then exposed to 50% RH and 20°C for several days. The weight change of one aggregate particle was measured. Additionally, LVDTs measured continuously the length changes of three Liapor grains. In Figure 5 the average result of the three parallel tests is shown, together with the weight loss.

The LWA showed substantial shrinkage. For the same LWA type, Schmidt-Döhl and Thienel (2000), using a technique based on microscopy observations, observed no clear trend of shrinkage (but possibly even some swelling) for drying from saturated conditions first to 65% and then to 44% RH. This discrepancy has no clear explanation.

Evaluation of the shrinkage measurements is complicated by the fact that evaporation of water causes a temperature drop in the LWA that results in further shrinkage. The temperature drop on the particles has been also measured and amounts to about 1 K.

This value corresponds roughly to 10 µstrain, if we assume a thermal dilation coefficient of the Liapor grains similar to the one of concrete.

Furthermore, it must be pointed out, that the shrinkage shown was found in the case of almost complete drying of the LWA (down to 50% RH). In the case of a LWAC at early ages, the relative humidity in the concrete is expected to remain high, above 95%. For these high RH levels, the LWA might be considered as non-shrinking if compared to the volume changes of the concrete.

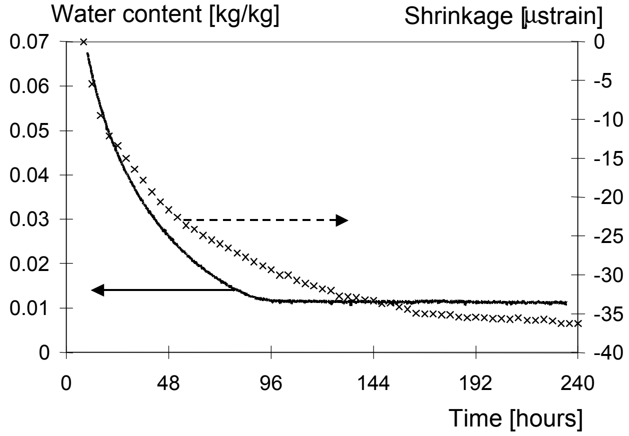

**Figure 5. Weight loss and shrinkage of wet LWA subjected to drying at 50% RH.**

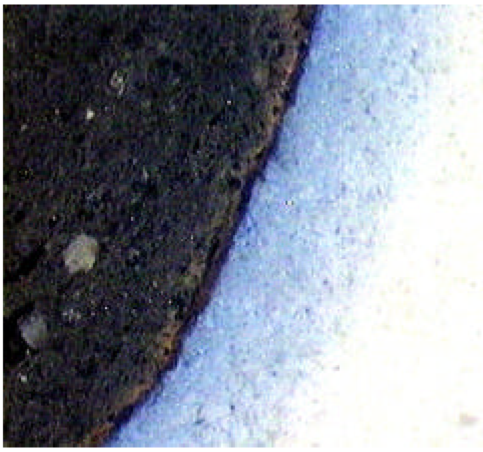

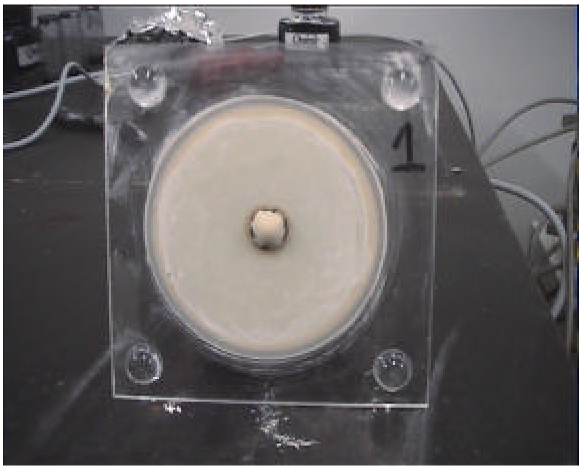

**Figure 6. Blue-ink corona around a Liapor aggregate (left), and setup to observe the growth of the corona around the Liapor grain (right).**

### 4.5 Visualization of water transport from the LWA particles to the cement paste

Liapor F8 grains were immersed in a thin blue-ink solution. The LWA's surface was subsequently dried with blotting paper and fresh cement paste was poured on them. The specimens were then sealed. In this experiment, due to a better contrast with the ink, a white Portland cement (CEM I 42.5) was used; w/c ratio of the paste was 0.3. At regular intervals, the cement paste was split. A blue ink corona (Figure 6, left) was observed around the Liapor grains. The thickness of the colored shell was growing in time, reaching 1 mm two weeks after casting.

In order to be able to follow continuously the process, the simple device shown in Figure 6 (right) was realized. The aggregate was fixed to a hole in a Perspex disc. The outer surface of the LWA was sealed with glue to avoid evaporation through the aggregate. The LWA was saturated with ink, the surface was dried and the cement paste was poured. The test was performed on three specimens at the same time. This method enabled to see the ink diffusing into the cement paste. The age at which this process occurred depended on the degree of saturation of the LWA. In one case, the diffusion of the ink was noticed two weeks after casting.

It is pointed out that the fact that ink diffuses into the cement paste does not per se mean that also water diffuses with the same speed and depth. Nevertheless, the diffusion of the ink-molecules might indicate the possibility of water-transport in the hardening paste. In this case, transport of water from the LWA to the paste in the self-curing process might be efficient on the scale of millimeters. This fact has important consequences on the choice of the LWA's size. If the water transport is active until at least 1 mm from the surface of the aggregate, relatively coarse LWA particles might be also efficient in the internal curing. Experimental evidence (see for example Fig. 3) supports this finding: Liapor F8 4-8 mm particles were sufficient to totally eliminate autogenous shrinkage in the first week.

In order to understand the self-curing process, the assessment of the distance over which water transport is effective in a concrete is of fundamental importance. Observation of ink transport into the paste gives obviously only a qualitative answer to the problem. The definitive solution might be achieved with other more complex techniques, such as X-ray absorption (see for example Bentz and Hansen 2000) or Nuclear Magnetic Resonance. Both these non-destructive techniques might be able not only to follow the transport process during hardening of the cement paste, but also to quantify the flow of water from the LWA.

## 5 MODELING THE INTERNAL-CURING PROCESS

### 5.1 General

In the following paragraphs some critical issues concerning the internal-curing process will be discussed. When one designs a LWAC mixture in order minimize or avoid autogenous shrinkage, some questions have to be answered:

- How much water must be entrained in the LWA in order to avoid self-desiccation (and thus self-desiccation shrinkage)? And how much of this water will be actually transported into the paste at high RH?
- Is this entrained water well distributed in the mixture? In other words, are the transport distances from the LWA to the matrix short enough to allow efficient internal curing?
- Which mechanisms cause the swelling of the LWAC?

These issues are not only fundamental in the mix design phase, they also constitute a starting point for the modeling of the internal-curing process as a whole.

### 5.2 Quantity of water needed for internal curing

According to Bentz and Snyder (1999), the volume of water needed to avoid self-desiccation (and thus self-desiccation shrinkage) equals the volume of chemical shrinkage of the cement paste:

$$W_{cur}=C\cdot\alpha_{max}\cdot CS \qquad (1)$$

where $W_{cur}$ water content in the LWA [kg/m$^3$]

C cement content of the mix [kg/m$^3$]

$\alpha_{max}$ maximum achievable degree of hydration

CS chemical shrinkage [kg water/kg cement hydrated]

Zhutovsky *et al.* (2001) calculated the mix composition of LWAC on the basis of this formula. The theoretical value of the entrained water was 20 kg/m$^3$. It was found that with this amount of water early-age autogenous shrinkage was not completely avoided. Some other authors had used a much higher amount in their experiments (Takada *et al.* 1998, Sickert *et al.* 1999, Lura *et al.* 2000).

Another approach to the problem of entrained water is given by Jensen (2001). The entrained water is the quantity needed for curing under saturated conditions according to Powers' model (Powers & Brownyard 1946). In this case hydration stops due to lack of space for the C-S-H gel. Thus, the hydration stops when the self-desiccation process has not yet begun. The quantity of entrained water can be calculated as (see Jensen 2001):

$$\left(\frac{w}{c}\right)_e = 0.18\cdot\left(\frac{w}{c}\right) \qquad (2)$$

According to Eq. (2) the water needed for complete curing in Zhutovsky *et al.* (2001) would be higher than the one calculated with (1), about 30 kg/m$^3$.

For other mixtures (Takada *et al.* 1998, Sickert *et al.* 1999, Lura *et al.* 2000), including the ones studied in this paper, the presence of silica fume in the mixture could lead to additional self-desiccation (Jensen & Hansen 1996); in this case, the quantity of water needed for internal curing is even more. This amount can be estimated using Powers' model modified with the addition of silica fume (Jensen & Hansen 2001, Jensen 1993). A fundamental assumption (and strong limitation) of this model is that the degree of reaction of the cement and of the silica fume is the same throughout hydration. According to this last approach, the water needed for complete curing in the mixes presented in this paper would be 47 kg/m$^3$. It is still a rough approximation, since the cement used (see Table 1) contains about 35% BFS, whose chemical shrinkage is presumably different from Portland cement. The entrained water calculated with this last approach is closer to the quantity actually stored in the LWA, especially if one considers that only about 2/3 of the water absorbed in the LWA is available for transport to the paste at high RH (as resulting from the desorption isotherm, Fig. 4, right).

### 5.3 Availability of water for internal curing – distribution of the LWA in the mixture

Sufficient water entrained in the LWA does not mean that this water will be available for transport to the self-desiccating paste. In order to obtain this, the maximum distances of the LWA particles from any point in the paste must be compatible with the distance covered by the water flow in the hardening paste.

Lu and Torquato (1992) have developed a model, based on analytical formulas, to calculate the ‘nearest neighbor’ functions in a collection of spheres of various sizes placed in a volume. The spheres are placed according to equilibrium statistics, i.e. as they were floating in a liquid without gravity and able to reach the desired position. This is a good approximation of the process happening during concrete mixing, if gravity forces are neglected. In the interpretation given by Bentz and Snyder (1999), Lu and Torquato’s model may be used to give an estimation of the total volume of matrix that is within a certain distance from a LWA. The aggregates are simulated as spheres, following the sieve analysis. Within each sieve, the aggregates are distributed by volume (Garboczi & Bentz 1997). The LWA particles are surrounded by a shell of given thickness (equal for all the spheres), representing the influence distance of the self-curing process. According to this approach, the volume of the shells can be calculated as:

$$V_{SH} = 1 - f_{LWA} - (1 - f_{LWA})\exp[(-pr(c \cdot t_{SH} + d \cdot t_{SH}^{2} + g \cdot t_{SH}^{3})] \qquad (3)$$

where $\phi_{LWA}$ is the volumetric fraction of aggregate

$t_{SH}$ is the thickness of the influence shell, equal for all the spheres

$\rho$ is the number of LWA per unit volume

c, d, g are functions of the LWA’s particle size distribution (PSD)

Equation (3) accounts for the overlapping of the spherical shells surrounding each particle. The $V_{SH}$ calculated in this way does not distinguish between cement paste and NWA that might be present in the proximity of the LWA. However, Bentz and Snyder (1999) showed, by comparison with a numerical 3D model, that the errors of this approach are limited.

In Fig. 7 the calculated cured volume, as a percentage of the total volume, is plotted against the thickness of the influence shell around the aggregates for the case of the Liapor F8 4-8 mm and Liapor F8 8-16 mm mixes. If we suppose for both mixes a shell thickness of 1 mm (in agreement with results of the ink diffusion experiments, see Fig. 6 left) around the LWA particles, for the finer aggregates (4-8 mm) the cured volume is about 70%, while for the coarser aggregates (8-16 mm) it is only about 40% (as shown by the dots in Figure 7). This approach clearly shows the beneficial effect of using finer LWA on the effectiveness of internal curing. It is pointed out that if we instead assume a maximum transport distance for the entrained water of 200 μm, as proposed by Bentz and Snyder (1999), only about 10% of the paste would be cured (see Fig. 7). The effect of the saturated LWA on the curing of the concrete would be in this case negligible. But this is in contradiction with the experimental data, since the LWAC show constant swelling (Fig. 3, left) and this is only possible if there exists a good communication between water in the LWA and the paste. In other words, the experiments (combined with results from Eq. 3) show that the water transport is efficient at a distance of at least one millimeter from the rim of the LWA.

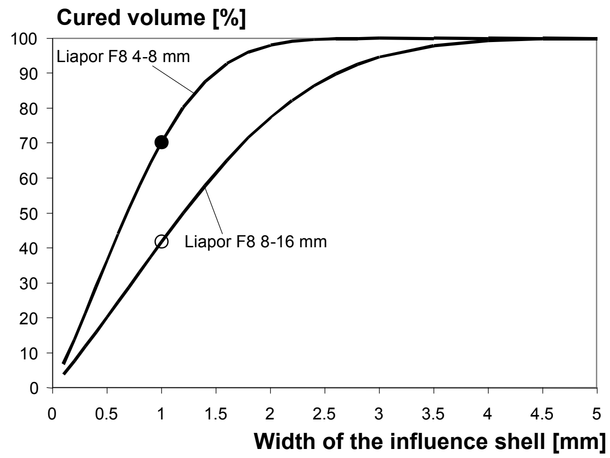

**Figure 7. Cured volume vs. thickness of the influence shell in two LWAC mixtures.**

### 5.4 Origin of the early-age swelling

Early-age swelling in LWAC was measured by a number of researchers (Takada *et al.* 1998, Sickert *et al.* 1999, Kohno *et al.* 1999, Bentur *et al.* 1999, Lura *et al.* 2000, Zhutovsky *et al.* 2001). Sickert *et al.* (1999) measured continuous swelling for more than one year. This swelling is similar to the swelling of cement paste and of NWC under water, in the case of thin specimens. In fact the situation inside the LWAC is of a cement paste hardening under (almost) saturated conditions, if the water transport from the LWA to the matrix is efficient.

Go Back Next Page

A possible explanation of the swelling could be found at the scale of the hydration products. Even if the reaction products have a lower volume (about 7% less) than the reagents, due to their shape they form a spatial network. Growth of further reaction products inside the network generates an internal pressure that may cause moderate swelling of the system (Bažant & Wittmann 1982, Schmidt-Döhl & Rostásy 1995).

Budnikov and Strelkov (1966) proposed a slightly different mechanism. During hydration, a cement particle is converted in a number of much smaller hydrated particles through topochemical reactions. These smaller reaction products tend to occupy a larger volume than the unhydrated particle, generating an internal pressure that produces macroscopic swelling.

## 6 DISCUSSION AND CONCLUSIONS

The incorporation of water-entrained LWA in a concrete mixture is a very efficient way to reduce autogenous shrinkage in High-Performance Concrete. Low w/c ratio LWAC mixtures with saturated aggregates show generally swelling in the early phase of hardening, due to a moisture flow from the LWA to the cement paste. This phenomenon is extremely complex and poorly understood.

The most relevant findings for the concretes and the LWA considered in this paper are the following:

- The strength of LWAC showed an increase at later ages, if compared to NWC with the same matrix. This fact might be due to further hydration promoted by the water entrained in the LWA.
- Mixtures with small and homogeneously distributed saturated LWA showed more swelling (in the first two weeks after casting) and higher self-induced compressive stresses than mixtures with coarse aggregates.
- Not all the water absorbed in the LWA (which might be as high as 25% by weight, after several days under water) is available for transport to the self-desiccating paste. About 6% water (by weight of the LWA) will remain in the LWA at 100% RH. This value drops to 2% at 94% RH.
- Water-saturated LWA shrunk when exposed to 50% RH, as a consequence of the moisture loss. This shrinkage is difficult to separate from thermal contraction due to the temperature drop that accompanies evaporation. Furthermore, it is believed that, if the RH-drop in the paste is limited, the shrinkage of the LWA will be only minor.
- In the hardening cement paste around LWA particles saturated with a thin ink-solution an almost spherical colored shell expanding with time was visible. After two weeks a depth of about 1 mm was measured. This indicates the potential for moisture transport in the hardening paste.
- Analytical calculations, based on the PSD of the LWA particles, show that (at least for the concrete containing the finer fraction Liapor F8 4-8 mm) most of the cement paste is influenced by the internal curing process, if we assume a penetration depth of the entrained water of about 1 mm. According to these results, gravel-size LWA might be adequate enough to provide uniform internal curing of the composite.

As a final remark, it must be emphasized that the early-age behavior of LWAC is a result of a complex interaction between mechanical, transport and deformational properties of both the LWA and of the hardening paste. A thorough knowledge of the behavior of both materials is a prerequisite to proceed towards modeling of the LWAC as a whole.

## 7 ACKNOWLEDGMENTS

The Brite-Euram project EuroLightCon financed a part of this research. The authors wish to thank Mr. A. Bosman for his constant help and creative suggestions with the experiments. The assistance of Mr. E. Horeweg, Mr. A. van Rhijn and Mr. F.P.J. Schilperoort in performing the experiments is also gratefully acknowledged.

# Durability Of Externally Bonded FRP Systems For The Strengthening Of Existing Structures

**P Desiderio**
**DINE Building Engineering University of Naples Federico II Italy**

**Summary: Fibre Reinforced Polymer (FRP) systems are increasingly being used in the strengthening of civil structures. It is generally believed that they have a very high level of durability. However, this is not necessarily true and depends on the specifics of the materials chosen, the processing technique used, the type of existing load regime and level of environmental exposure.**

**The purpose of the research (in order to give some guidance to engineers when selecting FRP for construction) is to present a study on the application of a general method, developed by Nicolella[1], to determine the Estimated Service Life (ESL) of *Externally Bonded* FRP *Reinforcement (EBR)* systems used for the strengthening of existing structures.**

**The paper provides an overview of degradation mechanisms, under the effect of the most influential agents, with reference to internationally published research, in order to develop a knowledge base to allow the implementation of the method.**

**The result is the definition of the agents which, according to the method, influence the service life of an FRP EBR system and that lead to the determination of modifying factors of a mid-normal value, derived from field-collected data for assumed conditions[2].**

**Keywords: Fibre Reinforced Polymers, Durability, Influencing Agents, Method of M. Nicolella.**

## 1 INTRODUCTION

The use of externally bonded FRP systems has emerged all over the world as an alternative to conventional strengthening techniques and features various advantages. Although numerous studies and experiments aimed at defining mechanical and physical properties have been carried out along with the development of structural models and calculation methods, the durability of these materials in service conditions is still an open matter.

For evaluating the durability characteristics of FRP reinforcing systems, accelerated aging experiments have been performed world wide, but it is very difficult to compare and hence difficult to interpret the research results due to 2 different aspects:

1. there are no international standard FRP durability test methods;
2. there are too many differences in production methods and in material systems among the manufacturers;

Thus, testing procedures should be standardized.

Durability is the capability of a building or its parts to perform its required function over a specified period of time under the influence of the agents anticipated in service.

The required performances for externally bonded FRP systems are: the mechanical properties (tensile strength, elastic moduli, etc.) and the bonded capacity to existing surfaces. These performances degrade not only under exposure to certain agents, such as alkalinity, acidity, salt water, moisture, ultraviolet light, high temperature and freezing and thawing cycles, but as an effect of other factors such as production technologies and the work execution. Experimental research does not generally take into account these other factors.

---

[2] For a complete presentation of the method there is the article of M. Nicolella, *Components Service Life: from field test to methodological hypothesis.* For the comparison with the Factorial Method proposed by ISO 15686 there is the article of A. De Pascale *Modifying factors of a method for estimating service life,* both published in the same proceeding of the Congress.

In order to understand the consideration expressed below, it is necessary to explain the basic FRP EBR (*Fibre Reinforced Plastics Externally Bonded Reinforcement)* strengthening technique and their failure mechanisms. Two techniques are generally used: *wet lay up systems* and *pre – cured systems.*

In the *wet lay-up* FRP system, non-directional or multidirectional dry fibre sheets or fabrics are saturated with resin and treated on the work site. Whilst, the *pre-cured* FRP systems consist of a variety of composite shapes manufactured off-site and transferred to the work site. Typically, an adhesive along with the primer and putty is used to bond the pre-cured shapes to the application surface. Clearly these two different techniques influence the long-term behaviour of the strengthening composite. In any case, three main elements, which influence the long-term behaviour, can be highlighted: the matrix, the fibres and the interface FRP –application surface (typically concrete or masonry). This interface is the critical component for the effectiveness of most externally bonded FRP structural strengthening applications, as it is the location where the transfer of stresses occurs.  Field experience has shown that the bond quality is influenced by a lot of factors such as: the condition of the existing surface, its preparation, the quality of the FRP application, the quality of the FRP itself and the resin. Also internal and external factors play a fundamental role in the long-term behaviour of the combined system. The figure below shows all factors, which should be taken into consideration in order to predict and to guarantee FRPs durability, as shown in Figure 1

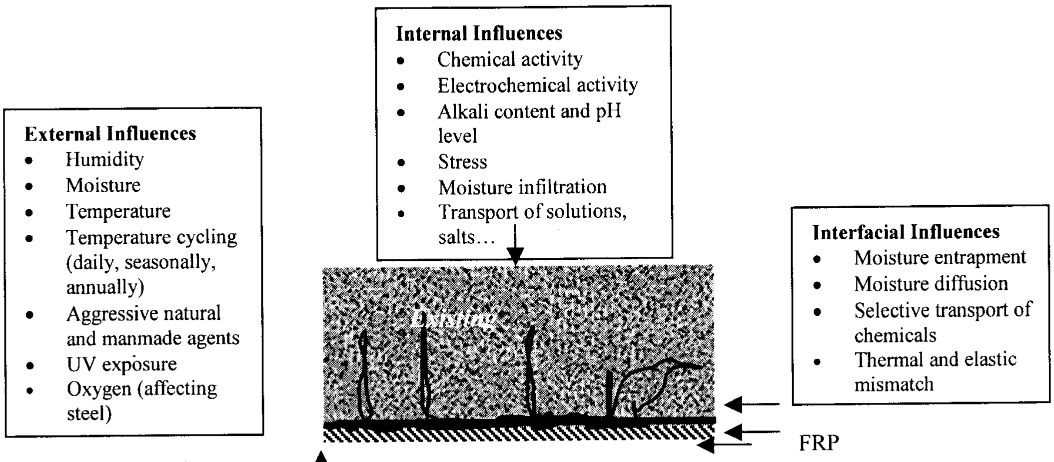

**Figure 1. FRP system level interactions** (fibTG9.3- Working group «Externally bonded reinforcement» - EBR 'Special design considerations & environmental effects')

The typical damages, which can affect the interface, are: *debonding or peeling.* The *debonding* is the separation at the interface between the application surface and the reinforcing layer, while the *peeling* is the separation at the interface between the substrate and the reinforcing layer.

In addition to performance decline of the interface, other pathologies can affect the FRP system. As a consequence of composites heterogeneity, anisotropy and lack of ductility, it is very difficult to provide the type of collapse under the effects of the influencing agents and their combination. Failure can occur for each one of the main mechanisms below:

- matrix yielding;
- *buckling* of fibres;
- *pull out and prominence* of fibres;
- *delamination;*
- Fibre yielding.

*Delamination* is the separation along a plane parallel to the surface, as in the separation of the layers of the FRP laminate from each other, but also the separation of the individual fibres from the matrix, which can affect performance.  This phenomenon occurs when matrix and interlaminar shear strength is low and fibre stiffness is low too. *Fibre yielding* occurs when there are manufacturing defects, when different fibres haven't the same resistance, or the matrix in unable to distribute the loads among the fibres. *Pull out* occurs when broken fibres leak from the matrix. This happens when the fibre – matrix link is short, and also depends on the transfer loads mechanism among fibres and matrix; *Prominence* occurs when the matrix degrades exposing the fibres, while *"buckling"* of the fibres is the failure due to instability of the compressed fibres.

## 2 AGENTS CAUSING THE DEGRADATION OF EXTERNALLY BONDED FRP SYSTEMS AND THEIR EFFECTS - STATE OF THE ART -

Many factors play an important role in reducing a building component's life, which in most cases, is very difficult to define or estimate. Therefore, it is advisable that, before using FRP composites, possible changes that may occur, under given service conditions, should be known.

The behaviour in service conditions and, in particular, the service life of a component are influenced by the agents that cause degradation, by their intensity, their variations and their combination.

In this part of the paper, durability related aspects of FRP strengthening systems, studied by several authors, will be briefly discussed to demonstrate that current results are too confused. The exposed results regard studies on the externally bonded FRP systems for the strengthening of concrete structures under some of the most influential agents.

Such agents will be taken into account in the estimate of a component's service life in the method explained below.

## 2.1 Climatic agents

### 2.1.1 Temperature and temperature cycling

It is well known that high and low temperatures or temperature cycling (daily, seasonally, annually) influence FRP strengthening systems failure process. The effect of the high temperatures on resin matrix is to reduce the stiffness; consequently the matrix decreases its ability to distribute the loads among the fibres and to protect them. The loading on individual fibres may exceed the capacity of the fibre, which will collapse. The next fibre picks up the load and, if the stress level is too high, it will also collapse and so on. For hight temperature, the threshold value is the so called "Glass Transition Temperature" (Tg) defined as *the midpoint of the temperature range beyond which the resin component of a fibre reinforced thermosetting polymer material changes from a brittle state to a ductile state* (def. ACI 440F). Thermal energy adsorbed over glass transition temperature can cause ultimate load carrying capacity of the FRP lower in measure of 30-40% than the initial value (Kelley et al. 1999).

The thermal cycling had a greater effect. It has been shown that thermal cycling causes debonding between the resin and the fibre. This deterioration may occur when constituents have different coefficients of thermal expansion. Particularly transverse thermal expansion is important for a good bond (Sen et al., 1999).

Low temperatures cause internal stresses in the composite, therefore causing matrix stiffness to increase. Low temperature cycling (+50°C/-60°C) influences both E and G moduli of the composite (its mechanical properties). The resulting degradation appears to be originated in the matrix, mainly due to microcrack propagation through the resin. Very low temperatures (lower then 0°C) and moisture can cause the freezing of the water in the existing cracks or voids, consequently the volumetric expansion of the freezing water causes the debonding of the FRP. Tests (Pantuso et al. 2000) have shown that specimens tested to failure under low or high temperature show not only variations in the ultimate bond force, but also significant differences in the nature of debonding (bond failure in the thickness of the glue or peeling for the specimens with high modulus of elasticity).

### 2.1.2 Freeze-Thaw

Often, when a FRP strengthening system is applied on existing structures, these structures are still cracked. The bonding of the FRP on the application surface may not be perfect and some voids or delaminated areas may be present in the interface layer. As a consequence, the expansion of freezing water in these cracks or voids may cause debonding, peeling or delamination of the FRP.

Tests on reduced - scale concrete beams, inferiorly plated with FRP (epoxy matrix), have shown significant deterioration in ultimate strength and partial degradation ("debonding") at the FRP – concrete interface, when subjected to freeze – thaw (-17°C - ambient temperature) cycles. This degradation has only contributed CFRP (*Carbon Fibre Reinforced Polymers)* specimen failure. Moreover CFRP platings seem to be more durable than GFRP ones. After 100 freeze-thaw cycles, in fact, the strength of the CFRP plated beams is over 130% that of non-plated beams (subject to the same conditions), while in the case of the GFRP (*Glass Fibre Reinforced Polymers)* plating the increase is below 70%. (table 1 and 2, Green M. et al. 1998),

**Table 1. Failure modes**

| STRENGTHENING TYPE | FAILURE MODES AFTER 100 CYCLES |
|---|---|
| NO plated | ductile flexural failure |
| GFRP plating | Tensile failure of the FRP laminate |
| CFRP plating | Tensile filure of the FRP laminate and debonding |

**Table 2. Environment effects on tensile strenght increase (%)**

| STRENGTHENING TYPE | BEFORE CYCLES | AFTER 100 CYCLES |
|---|---|---|
| GFRP | 88 | 67 |
| CFRP | 139 | 131 |

Concrete specimens plated with FRP subjected to a uniform tensile stress and to 300 freeze / thaw cycles have shown no significant influence on the value of the tensile strength compared to the behaviour of reference elements. Test results show that specimens wrapped by CFRP have not endured lessening of tensile strength, while those wrapped by GFRP show a reduction of about 12% (Dutta P.K. and Hui D., 1998) It is possible to conclude that repeated freeze-thaw cycles have shown little or no effect on the FRP when high quality, moisture resistant epoxies are used.

### 2.1.3 UV light exposure

Ultraviolet rays affect polymeric materials. UV radiation can cause dissociation of chemical bonds. Sunlight and especially ultraviolet light can lead to a reduction of light transmissibility and colour changes in the composite. The resin matrix materials are generally susceptible to UV light damage, especially for polyester resins more than epoxy resins, although they show somewhat similar strength reduction. This reduction can cause *cracking* or *crazing* (fine cracks at or under the surface) of the matrix of the composites. This may lead to other environmental problems, such as increased moisture absorption and/or chemical attack.

Some specimens tested in a laboratory environment for 250, 750 and 1250 wetting/drying cycles, with UV- intensity of 0,2 $MJ/m^2$/hour and temperature of 26°C, have shown these results:

AFRP (*Aramid Fibre Reinforced Polymers)* rods showed around 13% reduction in tensile strength after 2500 hours exposure; GFRP rods 8% after 500 hours (no reduction thereafter); CFRP rods showed no reduction (Kato et al. 1997).In field tests, AFRP have shown to be more susceptible to UV than CFRP and GFRP, in accordance with experimental results (Bank and Gentry 1995).

In general, carbon fibres are substantially unaffected by UV light. Glass fibres are only slightly affected by UV light, while Aramid is the most affected by UV. However the amount of deterioration is dependent on the type of resin and the fibre type (Ahmad and Plecnik 1989).

### 2.1.4 Moisture

The presence of moisture in the composites is caused by the mechanism below:

- Capillary action along the longitudinal axis of the fibre or at the resin-fibre interface;
- Transfer through cracks and voids in the structure;
- Diffusion through the matrix.

The water absorption on the matrix, whose amount is dependent on the resin type and the water temperature, causes the reduction of the glass transition temperature and the stiffening of the resin. Both of these effects are partially reversible in epoxy resin when the water is removed by drying. With polyesters and vinyl esters the changes can be reversible or not, depending on the time and temperature of the exposure. (Blaschko et al. 1998). According to other authors, the moisture would have been turned into steam, causing voiding well before the Tg is reached (Burn 1997).

Damage to fibreglass/epoxy composites may be caused by the intrusion of moisture into the resin-fibre interface. Aramid fibres absorb up to 13% by weight of moisture that can have a deleterious effect on tensile strength and can affect the resin-fibre interface. Carbon fibre is relatively inert to water and so the only effects on CFRP are those of moisture on the resin matrix. (*Fib* bulletin, 2001)

In order to estimate the effect of the moisture on the tensile strength, some concrete specimen wrapped with FRP are subjected to 300 humid/dry cycling. While CFRP strengthened specimens haven’t shown any damage the GFRP ones have shown a reduction of 20%.

Moreover the CFRP strengthened beams seem to be more durable than GFRP one; after 100 humid/ dry cycles, in fact, the resistance of the beams plated with CFRP is over 120% compared with the non strengthened ones (subject to the same conditions), while in the case of GFRP strengthening the increase is below 40% (table 3 and 4) .The influence of the type of used epoxy resin becomes very marked on the value of the ultimate load of the reinforced beam. Tests on FRP wrapped columns haven’t shown a reduction of strength and ductility, while the columns wrapped with GFRP have shown a little reduction when some adhesive has been used (Green M. et al. 1998).

**Table3. Failure modes**

| STRENGTHENING TYPE | FAILURE MODES AFTER 100 CYCLES |
|---|---|
| NO wrapped | Ductile flexural failure |
| GFRP wrapped | Tensile failure of the FRP laminate |
| CFRP wrapped | Tensile filure of the FRP laminate and debonding |

**Table 4. environment effects on tensile strenght increase (%).**

| STRENGTHENING TYPE | BEFORE CYCLES | AFTER 100 CYCLES |
|---|---|---|
| GFRP | 88 | 37 |
| CFRP | 139 | 120 |

## 2.2 Environmental agents

### 2.2.1 Alkalinity/Acidity

The performance decay of the FRP strengthening over time in an alkaline or acid environment will depend on both matrix and the reinforcing fibre. Carbon fibre is resistant to alkali and acid environment whereas glass fibre can degrade in these environments. Aramid fibres are affected by acid environment and present good resistance to alkali attack. However a properly applied resin matrix will isolate and protect the fibre and postpone the deterioration. The chemical resistance of different types of fibres is given in table 5

**Table 5. Qualitative assessment of fibres with respect to chemical resistance. Notations: A=excellent, B=good, C=passable and D=poor. (Table found in fib bulletin)**

| 2.2.2 Environments | | Carbon fibre | | | | Aramid fibre | | Glass fibre | |
|---|---|---|---|---|---|---|---|---|---|
| | | GP-grade pitch | HP-grade pitch | HT-type PAN | HM-type PAN | Kevlar -49 | Tecchnora | E-glass | AR-Glass |
| **Acid Resistance** | Hydrochloric acid | B | A | A | A | D | B | D | - |
| | Sulfric acid | A | A | A | A | D | B | D | - |
| | Nitric acid | B | A | A | A | D | B | D | - |
| **Alkali Resistance** | Sodium hydroxide | A | A | A | A | B | B | C | B |
| | Brine resistance | A | A | A | A | B | B | C | - |
| **Organic Solvent resistance** | Acetone | A | A | A | A | A | | A | - |
| | Benzene | A | A | A | A | A | B | A | |
| | Gasoline | A | A | A | A | A | B | A | - |

### 2.2.3 Salt

Some structures can be exposed to salts from the sea (coastal structures) or in the form of de-icing salts (bridges in cold regions). There are several results indicating that the saline solution is more severe than fresh water. (Saadamanesh and Tannous 1997; Steckel et al 1998; Gangarao, H. V. S. and Vijay, P. V.; 1997 Sasaki, I. Nishizaki, I. et all 1997). Investigations on GFRP structural composites under salt exposure (bars and plates, concrete beams reinforced with GFRP and wrapped with GFRP fabrics) have shown a reduction in strength and stiffness up to 50%, which correspond to 10- 50 years of natural exposure, depending on the severity of environment and temperature CFRP's performances are superior compared also to AFRP.

### 2.2.4 Fatigue, creep behaviour, stress rupture and stress corrosion

The behaviour under conditions of sustained loads or fatigue loadings is another topic related to the durability of FRP strengthened structures. CFRP, exhibit superior fatigue performance to that of steel. Some investigations have shown that the fatigue performances of concrete beams can be enhanced significantly by means of FRP strengthening (*fib* bulletin, 2001).

The concrete elements exhibit varying degrees of creep deformation whilst under constant load CFRP does not creep, the creep of GFRP is negligible, but that of AFRP cannot be neglected. Hence, the creep behaviour of CFRP- or GFRP-plated RC elements is governed, primarily, by the compressive creep of concrete (e.g. Plevris and Triantafillou 1994). As AFRP creeps itself, long-term deformations increase considerably in the case of AFRP-strengthened elements.

Other important topics related to durability of externally bonded FRP systems are the stress rupture and the stress corrosion. The first one is the premature tensile rupture under sustained stress. Indeed stress corrosion occurs when the atmosphere or ambient environment is of a corrosive nature, but not sufficiently so that corrosion would occur without the addition of stress. Failure is deemed to be premature since the FRP fails at a stress level below its ultimate. In general, the following order of fibres and resins gives increasing vulnerability either stress rupture or stress corrosion (Kelley et al. 1999): carbon-epoxy, aramid vinyl ester, glass polyester. In general, given the stress rupture of GFRP and the relatively poor creep behaviour of

AFRP, it is recommended that when the externally bonded reinforcement is to carry considerable sustained load, composites with carbon fibres should be the designer’s first choice (*fib* bulletin, 2001).

## 3 DURABILITY APPROACH IN EXISTING DESIGN GUIDELINES

The properties of FRP reported by the manufacturer (based on testing conducted in a laboratory environment) do not reflect the effects of environmental exposure. The long-term exposure to various types of environments can reduce the tensile properties, creep-rupture and fatigue endurance of FRP laminates. In order to consider this matter the existing guidelines propose to reduce the value of mechanical properties in design equations, using environmental reduction factors given for the appropriate fibre type and exposure condition.

| Factor | ACI | NS3473 | CHBDC | JSCE | BISE |
|---|---|---|---|---|---|
| Reduction due to **environmentally** caused deterioration | $C_E$ "environmental reduction factor" GFRP: 0.70-0.80 AFRP: 0.80-0.90 CFRP: 0.90-1.00 | $\eta_{env}$ "conversion factor" GFRP: 0.50 AFRP: 0.90 CFRP: 1.00 | * $\phi_{FRP}$ "resistance factor" GFRP: 0.75 AFRP: 0.85 CFRP: 0.85 | ** $1/\gamma_{fm}$ "material factor" GFRP: 0.77 AFRP: 0.87 CFRP: 0.87 | $1/\gamma_m$ "material factor" GFRP: 0.30 AFRP: 0.50 CFRP: 0.60 |
| Reduction due to **sustained stress** | | $\eta_{lt}$ "conversion factor" GFRP: 0.8-1.0 AFRP: 0.7-1.0 CFRP: 0.9-1.0 | F "factor" GFRP: 0.8-1.0 AFRP: 0.5-1.0 CFRP: 0.9-1.0 | | |
| **Total strength reduction** due to environment and sustained stress | GFRP: 0.70-0.80 AFRP: 0.80-0.90 CFRP: 0.90-1.00 | GFRP: 0.40-0.50 AFRP: 0.63-0.90 CFRP: 0.90-1.00 | GFRP: 0.60-0.75 AFRP: 0.42-0.85 CFRP: 0.76-0.85 | GFRP: 0.77 AFRP: 0.87 CFRP: 0.87 | GFRP: 0.30 AFRP: 0.50 CFRP: 0.60 |
| Specified **stress limits** for permanent load | GFRP: 0.14-0.16 AFRP: 0.16-0.18 CFRP: 0.44-0.50 | Stress limits not specified | GFRP: 0.60-0.75 AFRP: 0.42-0.85 CFRP: 0.76-0.85 | 0.8 × "creep failure strength" not more than 0.7 GFRP: ≤ 0.7 AFRP: ≤ 0.7 CFRP: ≤ 0.7 | Stress limits not specified |

**Table 6. Reduction factors used in existing design guidelines (JSCE 1997, CHBDC 1996, ACI 2000, Thorenfeldt 1998 and Clarke et al 1996)x ( Byars et al. 1st draft of the Fib bulletin TG 9.3 on Durability of FRP)**

Some design guidelines incorporates several different types of strength reductions, including those caused by environmental degradation, i.e. ACI and JSCE, while for example NS3473 has one specific factor for taking account of environmentally caused deterioration (table 6).

The existing design guidelines do not give a method to estimate the service life of an FRP system.

## 4 THE APPLICATION OF THE METHOD PROPOSED BY MAURIZIO NICOLELLA TO DETERMINE EXTERNALLY BONDED FRP SYSTEMS SERVICE LIFE

The research group of the author is carrying out a study on the application of the method by Nicolella (Nicolella M., *Affidabilità e durabilità degli elementi costruttivi in edilizia – Un‘ipotesi metodologica per il calcolo,* CUEN, Napoli, 2000) to determine the ESL (Estimated Service Life) of FRP externally bonded systems (figure 2).

The most difficult issue regarding durability studies is taking into account all factors (environmental, mechanics, etc.) that affect the service life of a building or its components. This method provides a simplified procedure for considering each of the variables that are likely to affect service life.

The methodology estimates the service life of a component as a deviation from a standard value, named *mid-normal*, which is calculated by using *modifying factors* deriving from *influencing agents.* The *“mid-normal”* value is obtained through statistical elaboration of field-collected data for the assumed conditions.

According to that method, the phases needed to determine the service life of a building component are listed below:

3. Definition of the experimentation on the field, in order to calculate all the parameters of the *"mid- normal" value;*
3. Definition of the agents mainly influencing the service life of the chosen component;
3. Dimensioning of the modifying factors;
3. Validation of the adopted factors through laboratory tests.

Go Back Next Page

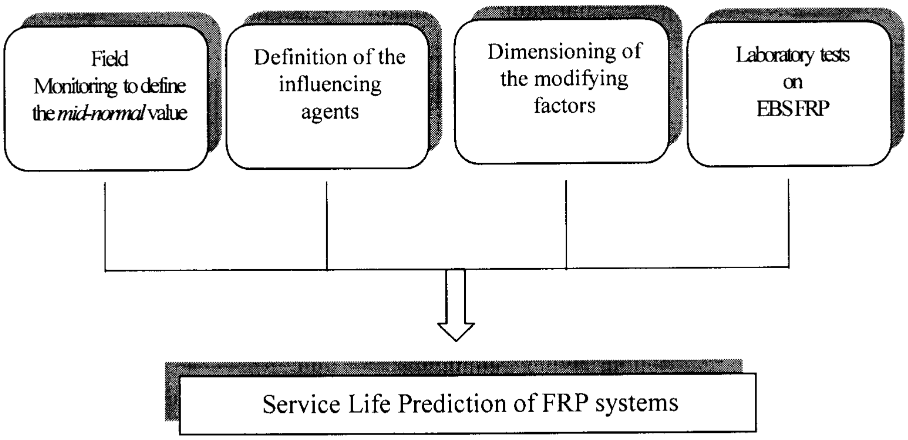

**Figure 2.** **Schematic description of the study program of our research group**

In order to assess the durability of a component it is necessary to fix performance levels, under which the inquired component has to be considered in state of damage. In the present study, the failure is estimated in terms of performance decay of bonding capacity and strength.

In order to identify the failure due to peeling, delamination or debonding, reference will be done to the permissible threshold values (in terms of percentage of degraded surface with respect to the entire plated surface), as indicated in ACI 440 – F (2000); in order to asses tensile strength degradation, creep – rupture and fatigue performance of FRP laminates, the value of the residual strength will be compared with those calculated according to existing guidelines.

It is also necessary to observe that, for each building component, also intermediate performance levels are to be considered. Table 7 shows intermediate performance levels along with the relevant intervention classes.

**Table 7. The intermediate performance**

| DEGRADATION | | PERFORMANCE | | INTERVENTION TYPOLOGIES |
|---|---|---|---|---|
| State1 | **?** | Level 1 | **?** | Monitoring /inspection |
| State2 | **?** | Level 2 | **?** | Cleaning / repair of surface |
| State3 | **?** | Level 3 | **?** | Repair/restoration |
| State4 | **?** | Level 4 | **?** | Partial substitution / integration |
| State5 | **?** | Level 5 | **?** | Total substitution |

The degradation states and the consequent intervention typologies are specified for the FRP systems, as expressed below:

- Monitoring /inspection
  Is required for defining the in service behaviour and the sub -condition maintenance strategy. For the installed FRP, inspections can be carried out by means of visual inspection, searching for changes in colour, *debonding*, *peeling*, *blistering*, *cracking*, *crazing*, deflections, indications of reinforcing bar corrosion, and other anomalies. In addition, ultra- sonic, acoustic sounding (hammer tap), or thermographic tests may indicate and quantify the entity of possible *peeling*, *debonding* or *delamination*. A mechanical inspection, instead, can include conventional structural loading tests or pull - off tension tests.
- Cleaning / repair of surface
  The surface protective coating (plasters, varnishes, panels) is to be replaced. The surface coating may be replaced using a process approved by the system manufacturer.
- Repair/ restoration
  The intervention is aimed at eliminating the small anomalies with the respect to the restoration of the initial conditions. The smaller delaminations can be repaired by epoxy resin injection.
- Partial substitution / integration
  In this case, a part of the system is removed or replaced because the removal of the defects is not possible without adding new parts. For the FRP systems, this happens when the damage can affect the structural integrity of the laminate, such as localized FRP laminate cracking or abrasions.

This type of damage can be repaired by bonding FRP patches on to the damaged area. The FRP patches should have the same characteristics (such as thickness, ply orientation) as the original laminate and the FRP patches should be installed in accordance with the material manufacturer's recommendation.

- Total substitution
  It coincides with the *" death"* of the component and therefore it identifies its life cycle. In the case of the FRP systems this phase is identified with the peeling and/or the debonding of large areas, which require removal of the affected area, reconditioning of the substrate, and replacing the FRP laminate. With reference to the American ACI 440-F (2000) guidelines the states of degradation are therefore characterized in table 8:

**Table 8. States of degradation according to ACI 440-F**

| | |
|---|---|
| State1 | Conditions similar to initial ones, absence of superficial anomalies and patina |
| State2 | Chromatic alterations (colour changes), presence of patina, gap presence in the protective layer or small delaminations peeling or debonding presence less than 2 $in^2$each (1300 mmq) so long as the delaminated area is less than 5 % of the total laminate area and no more than 10 such delaminations per 10 $ft^2$ (1 mq |
| State 3 | Delaminations peeling or debonding presence less than 25 $in^2$ (16000 mmq) |
| State 4 | Large delaminations, greater than 25 $in^2$ (16000 mmq) but confined. |
| State 5 | Large areas subjected to peeling and/or the debonding which require removal of the affected area, reconditioning of the substrate, and replacing the FRP laminate |

According to the method, the *mid-normal* values can be applied to any other context, when manipulated through the modifying factors, which are thought to be function of the specific case.

For opportunity reasons, in order to extrapolate the mid – normal values, some FRP EBR applications carried out in Naples could be taken into account. These applications feature

- Flexural reinforcement of concrete structures;
- Plating of natural stone masonry vaults;

The choice of the models has been done privileging the following criteria:

- Quality and amount of the information available: application year, materials used, work execution, possible anomalies found;
- Possibility to execute inspections: visual controls, ultra- sonic, acoustic sounding (hammer tap), thermographic tests, mechanical tests;
- Possibility to compare materials used, serviceability of the support, geometric conformation of the application surface, etc.;
- Homogeneity of the influence agents;
- Possibility for the influence agents to vary, in order to correctly estimate their weight.

As a result of the monitoring of these applications, some performance/time diagrams will be extrapolated.

Once the *mid-normal* value has been determined, the service life of any FRP system will be evaluated through the expression (1)

$$D_{pp} = D_{mn} \times \prod_{i}^{n} F_i \qquad (1)$$

where *Dpp* is *" the most probable "* service life, *Dmn* the mid-*normal* duration and *Fi* the modifying factors expressed as a function of the groups of the influencing agents.

All the most influential agents (with respect to component life) are arranged in groups each one generating a single factor.

In brief, different "scores", depending on the real condition of the component, are assigned to each influential agent. Elaborating the "scores" regarding any group of agents it is possible to obtain the value of the modifying factors (each one weighted depending on its incidence) used in the formula. The groups of homogenous agents are those in table 9:

Go Back Next Page

**Table 9. Influencing agents**

| n | GROUPS OF AGENTS | INFLUENCING AGENTS | WEIGHT |
|---|---|---|---|
| **1** | **Technological characteristic** | System components, application surface state, installation procedure, work execution level, protection | 2 |
| **2** | **Climatic agents** | Temperature, wind and rain, snow, UV exposure, Temperature cycling (daily, seasonally, annually), Humidity and moisture | 4 |
| **3** | **Environmental/ operational environment agents** | Chemical agents, exposure to salts, in use condition (operational environment agent) | 4 |
| **4** | **Configuration** | shape/lying, extension, presence of discontinuity / chines | 1 |

1 *Technological characteristics*

1.1 The variability conditions of the *system components* agent depend on**:** resin types, fibre types, adhesive quality, *primer* chosen with respect to design parameters (environmental, economic, temporal etc.); It is favourable to define classes of variability of the "scores" to attribute, with respect to various possible connections fibre/matrix/adhesive, typically used in the FRP strengthening systems;

1.2 The classes of variability of the agent *application surface* will depend on the material and the serviceability of the reinforced surface (i.e. compact or cracked concrete, compact or cracked masonry);

1.3 The agent *installation procedure* will feature the classes of variation based on the used technology: *hand lay-up*, *automatic*, *fast curing*, *by vacuum.*

1.4 The agent work *execution level* represents the level of skill and control in site work. It is based on whether the site work is likely to be in accordance with manufacturers recommendations and highly controlled. To define the variability conditions of this agent it is necessary to verify:

- if FRP system constituent materials are packaged and shipped in a manner that complies to all applicable packaging and shipping codes and regulations;
- if the materials are stored in accordance with the manufacturer's recommendations;
- if The Shelf life is defined (the properties of the uncured resin components can change with time, temperature, or humidity). Such conditions can affect the reactivity of the mixed system and the uncured and cured properties;
- if MSDS for all FRP constituent materials and components are obtained from the manufacturers and are accessible at the work site;
- that Procedures for installing FRP systems have been developed by the system manufacturers;
- if the FRP system installation contractor demonstrates ability for surface preparation and application of the FRP system to be installed (contractor ability can be demonstrated by providing evidence of training and documentation of related work previously completed by the contractor).

1.5 The agent *protection* will feature conditions of variation depending on:

- use of protecting varnish, plasters or panels which can offer an effective protection to the fire, to UV lights etc.;
- planning of a disposition of external bonded FRP system, which doesn't determine a waterproof closing of the strengthened element, avoiding the formation of a moisture barrier;
- installation of the FRP system in areas where it is not exposed to impacts or rain.

**2.** *Climatic agents*

2.1. The conditions of variation of the agent *temperature* are due to different types of fibre/matrix/adhesive coupling. The glass transition temperature is certainly one of the thresholds of the classes of variability of this agent (possible classes of variability of the agent temperature are the following: from –20°C to 0°C, from 0°C to 60°C, from 60°C to Tg and over Tg. This latter case is possible when these strengthening systems are used in special applications, i.e. in factory).

2.2. The range of variability of the agent *rain* will be derived from the zonings introduced by national codes

2.3. The range of variability of the agent *wind* will be derived from the zonings introduced by national codes (in Italy, D.M. the 16/01/1997);

2.4. The range of variability of the agent *snow* will be derived from the zonings introduced by national codes (in Italy, D.M. the 16/01/1997);

2.5. The range of variability of the agent *UV exposure* will depend on the resin and fibre types. Certainly lower "scores" will be attributed to AFRP composites with respect to GFRP or CFRP composites (the "scores" are inversely proportional to the capacity of the agent to cause unreliability). In fact AFRP have shown to be more susceptible to ultraviolet rays than CFRP and GFRP;

2.6. The range of variability of the agent *daily temperature cycling* will be derived from local indications;

2.7. A maximum water uptake value of 3% of the weight is normally specified for structural adhesives (Blaschko et al. 1998). Hence, in order to define the range of variability of the agent *moisture* it is possible to fix two or more ranges, whose thresholds could be the 3% of the weight;

3. *Environmental* **-** *operational environment agents*

3.1 The range of variability of the agent *chemical agents* will be obtained defining the different types of chemical agent (which affect the service life of the component) and the different types of resin/matrix/adhesive system;
3.2 The FRP strengthening systems could be exposed to salts from the sea (costal structures) or in the form of de-icing salts; both the variability conditions and classes of the *exposure to salts* should be defined on the basis of the closeness to the see or the use of de – icing salts;
3.3 The agent *in use condition* reflects the effect of the use condition of the component Regarding FRP systems the in-use conditions could involve phenomena such as fatigue, creep behaviour, stress rupture and stress corrosion. The classes of variability of the “scores” to assign to this agent should be defined taking into account the behaviour of the various systems under these conditions.

4 *Configuration*

4.1 the agent *shape/lying* will comprise the following classes of “scores” variation: plane surface, concave surface, convex surface;
4.2 the agent *presence of discontinuity and/or chines* will be able to preview classes of variation based on the incidence of such presences on the area of the reinforced surface;
4.3 the agent *extension* will depend on the value of the reinforced surface compared with the un-reinforced one.

As far as the application of the method to the EBR FRP systems is specifically regarded, the definition of involved agents will depend strongly on the use of the inquired FRP system. In fact the method concurs to neglect the agents, which don’t affect the durability of the inquired component. This is one of the advantages of the Method Nicolella compared with the other existing methods to estimate the service life of a building component. For example, it will be possible to disregard all agents related to the *rate of catch*, the wind, the snow and the UV exposure in the case of indoor applications such as plating of arch and vaults, where the agents related to the configuration became important.

The last phase of the method, schematically indicated in figure 2, features the evaluation of the modifying factor assumed by means of laboratory tests. In fact, taking into account the difficulties to define the correlation between accelerates laboratory tests and real exposure conditions and to appraise the validity of the extrapolation of results obtained for specimen to real structures, the method uses laboratory tests exclusively in order to estimate the relative incidence of the factors on the service life.

For this phase, the experimental tests illustrated in the first part of the paper, if opportunely ordered, could be used.

## 5 CONCLUSION

In spite of the numerous applications of FRP systems for the strengthening of existing structures, the Designers have not know enough about their durability. The available international guidelines introduce an approach that is often conservative compared to the proposed (Nicolella method). They do not supply a method to estimate the effective service life of the systems. Hence it is necessary to set standard tests for evaluating the reference life of these strengthening systems and to define methods, described in this paper, internationally recognized, for evaluating their ESL. The “Nicolella method” seems to be an instrument particularly adapted for this purpose (it is very easy to apply by computer systems), on condition that the *mid-normal* value of the service life of the system and the modifying factor’s values were correctly defined for the various typologies in mid-normal conditions.

## 6 ACKNOWLEDGEMENT

The author sincerely thanks Prof. Marcello Picone and Prof. Maurizio Nicolella of D.IN.E. for their excellent cooperation. And Prof. Renato Iovino, who made possible this experience.

# Condition Survey Data Warehouse: Analysing Data For Component Life Estimation

**P Giblin**
**Building Performance Group, London, United Kingdom**

**Summary**: **During the 1990s, the British Government required all providers of social housing to carry out surveys on their stock to ascertain its condition and maintenance requirements. As a result, a large body of data has been collected nationally. This study investigates the feasibility of analysing the data to estimate components' lives.**

**A data warehouse was built using data from one of the surveying firms involved in collecting the data (Building Performance Group). The dataset was processed to reduce ambiguity and standardise repair descriptions. Window and roof replacement data were extracted and the years to renew the components were analysed.**

**The data collected seems to be broadly in line with existing sources of durability information and indicates that collating data from different sources can be used to get a good estimation of the service lives of components and assemblies.**

**Keywords. Data warehouse, stock condition survey, durability, data mining.**

## 1 INTRODUCTION

During the 1990s, the British Government ordered all providers of social housing, such as local authorities and housing associations, to carry out surveys of their housing stock to assess funding requirements for repairs. These surveys were carried out directly by the local authority or by consultant surveying firms.

Building Performance Group have been undertaken many stock condition surveys over this time. The collected data represents the aggregated estimates of repair needs and times as perceived by a number of surveyors.

Compiling the data from these surveys provided a large data set that could be analysed to determine component lives. 6 surveys were chosen to test the hypothesis that condition survey data could be used to estimate component lives. These represented a number of different dwelling types such as flats, houses and high rise buildings.

## 2 METHOD

### 2.1 Data warehouse concept

A data warehouse is an interface for end–users to access specially prepared data to be used with decision support systems or executive information systems. It is typically a collection of data from a number of databases, categorised and denormalised into a flat–file database (table) which was used in this project to extract relevant information.

### 2.2 Software used

The software used for this prototype was a combination of Microsoft Access as the database management system (DBMS) and user interface. Minitab was used to output the statistical information. MS Access was chosen as it is in widespread use in the organisation. Minitab was used to get a feel for the type of reports required without writing routines in a dedicated report package such as Crystal Reports.

### 2.3 Databases

The survey data were stored in a number of formats, SQL Server (mdf), dBase (dbf) and MS Access (mdb) filetypes. Open Database Connectivity (ODBC) was used to link tables in order to process and clean the data and make new tables.

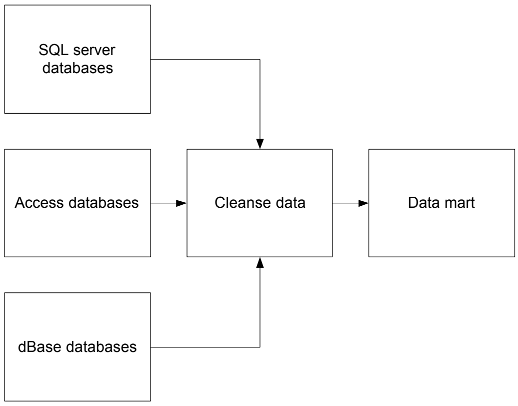

**Figure 1. Data warehouse architecture for condition survey data access**

### 2.4 Data warehouse

The warehouse database was used to query the survey databases to make new flat file tables containing the data fields described above. This table contained the original (unchanged) data as a 'look up' table to speed up processing and to ensure the integrity of the original tables was maintained.
The flat file table was copied for further data cleansing and processing. This proved to be a time consuming exercise. In particular, repair descriptions needed to be standardised. There were numerous ways of describing a particular repair and these were reduced to a generic component type repair field and a material field, for example, ‘repaint external door’ and ‘gloss paint to external door’ were altered to ‘decorate external door”.

### 2.5 Components analysed

Because of the amount of data cleansing in the repair description field, it was decided to use a subset of the components to test the system. External windows and pitched roof coverings were chosen as typical cases. This paper discusses the data and analysis on external windows.

### 2.6 Survey data

The data present in the database consists of a property identifier, post code, year-band of construction of the property, Building Cost Information Service (BCIS) code(BCIS, ), repairs and replacement requirements as determined by the surveyor, quantities and the year when the repair should be undertaken. The fields selected for inclusion in the data mart were: construction year band, repair year, survey year, post code, project identifier, property identifier, BCIS code, repair description, repair quantity and property type. The BCIS Standard Form of Cost Analysis for Building Projects is used throughout the UK to provide data which allows comparisons to be made between the cost of achieving various building functions in one project with that of achieving equivalent functions in other projects.
The quantity information has not been used for this exercise as it was felt that they could skew the results therefore each record refers to an actual individual observation by the surveyor but this data may be used for other analyses.

### 2.7 Data representation

Construction year band

The dates of construction were represented by the following year bands.

Pre 1920
1920-1935
1936-1945
1946-1960
1961-1980
Post 1981

In order to determine the years from construction to component renewal, it was necessary to represent the year bands by a specific year.

An adjusted construction year field was also added. This was to provide an estimate for prior renewal of components, for example: If the construction year was earlier than 1975 and windows are PVCu then adjusted construction year is 1985 or else the adjusted construction year is equal to construction year. The adjustments are described in the figure notes where appropriate.

### 2.8 Data processing

The data was collected over a number of surveys, in various locations in the United Kingdom over a period of 5 years. As a result, component and repair descriptions varied widely, particularly where the site surveyors recorded their results in free text rather than choosing from a predefined list. This was more marked where the data was collected using paper forms rather than electronically.

A repair record included a BCIS code. While this is an industry standard, it is a high level code and does not adequately describe repairs. The data was filtered by BCIS code and then the repair descriptions were standardised by using the search and replace capabilities of MS Access, inserting standard repair descriptions such as, 'Replace windows - PVCu' and finally by inspecting the remaining individual records and replacing the repair data with the standardised text. Where ambiguity still existed after this exercise, the record was discarded. From a total 250,000 records, 150,000 were considered usable for data mining. The discarded records were either ambiguous or appeared to be incorrect entries.

The database was then filtered for window data, using the BCIS coding system and filtering for 'window', 'wndw' and so on in the repair data field. This was resulted in 6590 records from 3014 properties where window replacement was unambiguously described.

## 3 RESULTS FOR WINDOWS

| Window Frame Material | Count | Percentage of Total (%) |
|---|---|---|
| Aluminium | 354 | 5.37 |
| hardwood | 108 | 1.64 |
| PVCu | 242 | 3.67 |
| Softwood | 5559 | 84.36 |
| Steel | 327 | 4.96 |
| N= | 6590 | |

**Table 1**: **Sample size and percentages of window types**

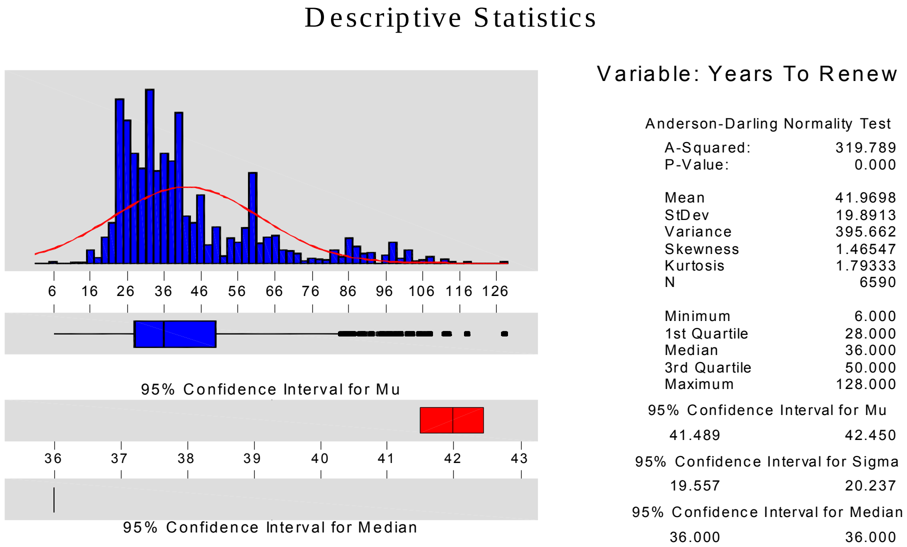

**Figure 2. All windows.**

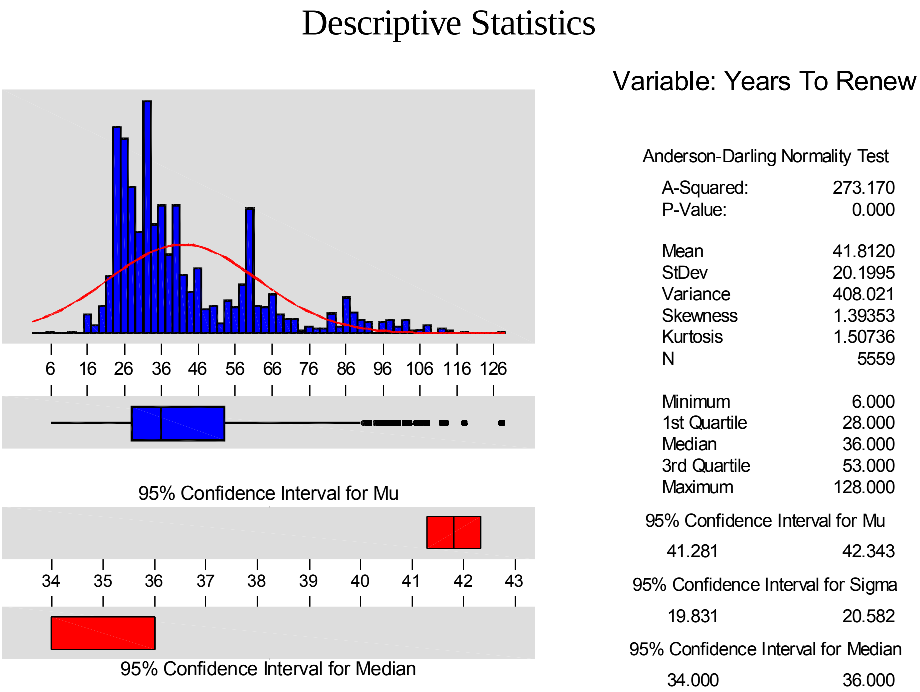

**Figure 3. All softwood windows**

The data seems to be skewed towards the left with a long tail towards the right. This is possibly due to the lack of information on component renewal after construction however there seem to be four distinct peaks which may indicate softwood windows of differing quality.

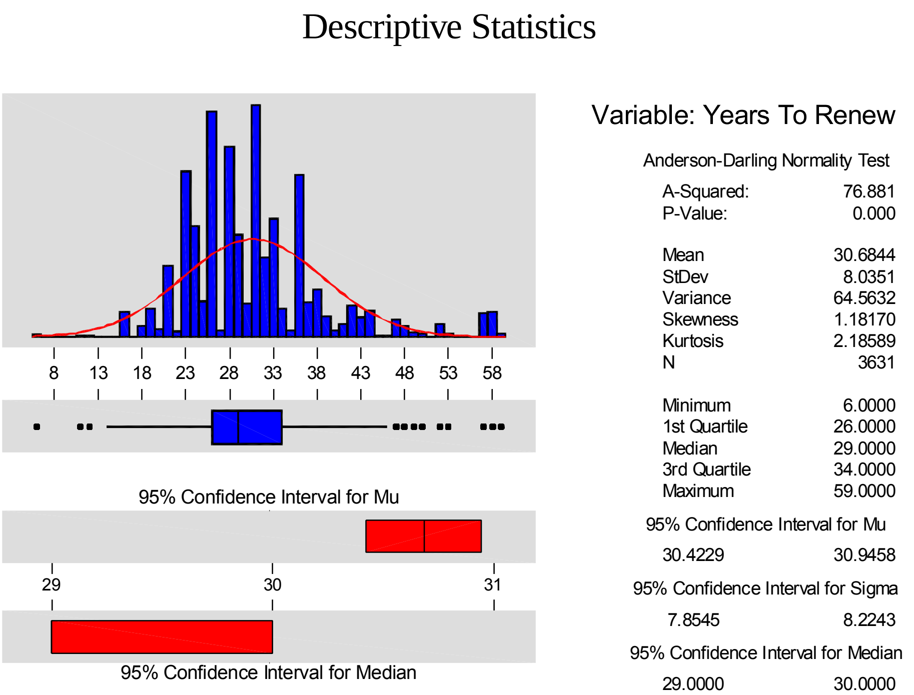

**Figure 4. Softwood windows. Date of construction >=1970**

## 4 DISCUSSION

The descriptive statistics graphs show the histogram and normal curve of the distribution of years to renew by quantity. The P-Value is low and indicates that the data is not normal throughout all types.

The component lives seem to be higher than indicated by Ahluwalia and Shackford (Ahluwalia and Shackford, 1993), who state the life expectancy of wood or aluminium casements to be 10-20 years and the HAPM Component Life Manual (HAPM Publications Ltd, 2000)(0-35 years) but seem to be broadly in line with the estimated service life of components (ESLC) as determined by the factoring method (BS ISO 15686-1:2000, 2000). While not investigated in this preliminary study, there is scope to investigate the effect of environmental conditions on components from the demographic and environmental information available for post–codes.

## 5 RECOMMENDATIONS

### 5.1 Classification system

The use of a common code to categorise component type and material is essential to ease data analysis. Cleaning the repair description data is too time consuming for a data warehouse and as stated previously, the BCIS code is not sufficiently 'low level' for this categorisation.

An alternative coding system such as the Uniclass classification system provides a suitable level for this application, for instance, softwood windows in external walls can be represented succinctly by the code G251:G321 which comprises the codes for External Wall (G251) and Windows (G321). It is recommended that this classification is added to the data capture software or inserted as part of post-survey data processing. A publicly available classification system also enables the data to be linked to other databases such as the HAPM component database for comparison against the insured life of similar components (HAPM Publications Ltd, 2000).

### 5.2 Repair and renewal history

Unfortunately the date of renewal of a component was not available to the survey teams. It may be that this information is held on the local authority or housing association databases and should be requested at the start of a survey. While this information is generally not needed for a condition survey, it would enable much more accurate results on component durability to be obtained.

### 5.3 Data sharing

The data for a large number of stock condition surveys exists nationally. All too often, once the data is processed and the results delivered to the client, the database is unused.

A national condition survey data repository (similar to the BCIS scheme for construction and maintenance costs) would ensure that the data is made available to interested parties. For confidentiality, identifying fields such as addresses, could be removed and the system could be made available to participants and subscribers.

## 6 CONCLUSIONS

Data about quality was not collected so comparisons of components of varying standards cannot be made.

The component lives seem to be higher than indicated (Ahluwalia and Shackford, 1993) but broadly in line with components lives estimated using the factoring method.

The time taken to clean the data vastly exceeded expectations. While it was thought that data cleaning would be a time–consuming exercise, it turned out to be an extremely onerous task. A large number of records were unusable because of missing or ambiguous data, 150,000 useful records were retrieved from the original 250,000 records for all repair and replacement types.

The data collected seems to be broadly in line with existing sources of durability information and indicates that collating data from different sources can be used to get a good estimation of the service lives of components and assemblies.

# Effect Of Elevated Temperature On The Properties Of High-Strength Concrete Containing Cement Supplementary Materials

**R Sri Ravindrarajah R Lopez & H Reslan**
**Centre for Built Infrastructure Research, University of Technology, Sydney**

**Summary**: **High-strength concrete is a material often used in the construction of high rise buildings. In the case of unexpected fire, the building concrete elements such as columns, slab and walls will be subjected to extreme temperatures. In order to assess the performance of high-rise reinforced concrete members it is important to understand the changes in the concrete properties due to extreme temperature exposure. Since the high-strength concrete produced may contain various binder materials in addition to cement, it is also becoming necessary to investigate the influence of the binder material type on the concrete properties under elevated temperature exposure. This paper summarizes and discusses the degradation of the strengths and stiffness of high-strength concrete in relation to the binder material type. The results showed that the binder material type has a significant influence on the performance of high-strength concrete particularly at temperatures below 800°C. The influence of the binder material type is significantly decreased at temperature of 1000°C. The strengths and stiffness of high-strength concrete are reduced with the increase in temperature without any threshold temperature level. The strengths are susceptible to the elevated temperatures compared to stiffness of concrete. High-strength concrete containing silica fume seems to be more sensitive to elevated temperature.**

**Keywords. High strength concrete, thermal conductivity**

## 1 INTRODUCTION

Fire-induced collapse of the World Trade Centre in New York, USA with heavy casualties has high-lightened the importance of the performance of construction materials at elevated temperatures. Engineering properties such as strength and stiffness and the thermal properties such as conductivity and expansion of these materials have to be understood by the designers when selecting the alternative materials. There is no doubt that high thermal conductivity and expansion of steel in addition to losses in strength and stiffness have contributed to the collapse of the towers in front of millions of viewers within a relatively short period after the terrorist attack. The obvious question, now being asked by many, is that what could have been the performance of these towers if concrete was used instead of steel? Is it reasonable to expect better performance with reduced number of casualties without collapse? It is no doubt that the owners of the high-rise buildings, the developers and designers of high-rise buildings wish to find answers to these questions. In search of the answers for these questions, it is necessary to understand the effects of extreme temperature exposure on the properties of concrete used in the construction of high rise buildings. The trend of utilizing high-strength concrete reduced the thickness of the columns as well as increased the attainable building heights.

Thermal conductivity is an important property of concrete since it controls the propagation of heat in a concrete element. The cover to steel reinforcement acts as the barrier and help to control the heat conduction through the steel reinforcement. Based on the research reported by Malhotra (1956) and Marshall (1972) the following conclusions can be drawn. The thermal conductivity of concrete is reduced with the loss of moisture during heating. The aggregate type used in a concrete mixture has significant influence on conductivity. Concrete with lower cement paste content as in the case of high-strength concrete can be expected to have a lower thermal conductivity than for lean concrete mixtures. Binder material type influences the thermal conductivity in so far as water release occurs at high temperature from the paste containing cement supplementary material such as blast-furnace slag.

Malhotra (1956), Zoldners (1960), Davis (1967), Abrams (1971), Faiyadh (1989), Khoury (1992), and Noumowe et. al. (1994) had reported the effects of high temperature exposure on the properties of concrete. Several mechanisms have been identified for the deterioration of concrete due to high temperatures. These include decomposition of the calcium hydroxide into lime and water, expansion of lime on re-hydration, destruction of gel structure, phase transformation in some types of aggregate, and development of micro-cracks due to thermal incompatibility between cement paste matrix and aggregate phase. High strength concrete compared to medium strength concrete is more brittle; contains less water; and the solid particles are more compact.

Hence, the effects of high temperature on high strength concrete will be different to those with the medium strength concrete. Sri Ravindrarajah (1998) studied the effect of temperature up to 800°C and method of cooling on the compressive and tensile strength of high-strength concrete.

The binder material used in high-strength concrete mixtures varies widely since the performance based specification for concrete allows the utilization of cement supplementary materials such as fly ash, blast furnace slag and silica fume in the concrete mixtures. Research into the properties of high-strength concrete in relation to the influence of mix compositions of concrete on its properties were reported elsewhere (Sri Ravindrarajah (1992), Sri Ravindrarajah *et. al.* (1993, 1994, 1995, 1998)). The main purpose of this study is to report the results of an experimental investigation into the effect of high-temperature exposure up to 1000°C on the properties of high-strength concrete as affected by the binder material type used.

## 2 EXPERIMENTAL DETAILS

### 2.1 Materials and mixture proportions

High strength concrete mixtures are generally characterized by low water to cement ratio and high binder material content. The use of high-water reducing admixture (superplasticiser) to achieve workable concrete at low water cement ratio resulted in producing concrete having its 28-day compressive strength well over 100MPa. In this investigation, four mixes were investigated having varying binder materials. Mixes 1 and 2 consisted 565 kg/m$^3$ of general purpose cement (Type GP), general blended cement (Type GB) having 62% blast furnace slag content. In Mix 3, 20% of the Type GP cement was replaced with low-calcium fly ash (115 kg/m$^3$). Mix 4 contained 565 kg/m$^3$ of general purpose cement and 40 kg/m$^3$ of condensed silica fume. For all four mixes, the water to binder ratio was kept at 0.30, by weight. Crushed basalt (specific gravity of 2.65) having the maximum aggregate size of 10mm and river sand (specific gravity of 2.62) were used as coarse and fine aggregate respectively. The aggregate to binder materials ratio was 3.0, by weight and the fine aggregate content was 35%, by weight. A constant dosage of superplasticiser (2% by weight of binder) was used in all concrete mixtures to obtain workable concrete mixtures.

The concrete mixtures were produced in a pan-type mixer. Freshly mixed concrete was tested for its density and used to cast a number of test specimens (standard cylinders and prisms) in steel moulds. A table vibrator was used to achieve full compaction for the moulded test specimens. The specimens used for compressive and tensile strengths were 100mm diameter by 200mm long cylinders. The concrete specimens used for dynamic modulus of elasticity testing had the dimension of 75mm by 75mm by 305mm prisms.

### 2.2 Heating equipment

A ventilated oven was used to heat the concrete specimens to a temperature up to 100°C. For the temperatures of 200°C and above, an electrically heated furnace designed for a maximum temperature of 1200°C was used. The furnace was heated by means of exposed heating elements laid on the refractory walls of the inside chamber, which was approximately 400 by 400 by 800mm in dimension. The test specimens were stacked with sufficient space between two adjacent specimens to obtain a uniform heating in each specimen. The test specimens were heated in batches due to limited capacity of the furnace. Extreme care was taken when handling the heated concrete specimens.

### 2.3 Experimental procedure

All concrete test specimens were demoulded after 24 hours and stored in water at 20°C. At the age of 28 days, the specimens were removed from water and dried for next two days in the laboratory environment, having the mean temperature and humidity of 20°C and 65% R.H., respectively. This step of pre-drying is necessary to minimize the explosion of concrete specimen when subjected to high temperature exposure in the furnace. The rate of heating was maintained at 200°C per hour. Once the required maximum furnace temperature was reached, this temperature was maintained until the specimens were removed. For all concrete specimens, the total duration in the furnace was 7 hours, irrespective of the maximum temperature. The maximum temperatures adopted in this study are 200°C, 400°C, 600°C, 800°C, and 1000°C. Therefore, the soaking period was reduced from 6 to 2 hours when the maximum temperature was increased from 200°C to 1000°C.

The test specimens were removed from the furnace after 7 hours and quenched in a water tank to provide the maximum thermal shock due to sudden cooling. A number of tests were conducted with the test specimens to determine the weight changes, ultrasonic pulse velocity, compressive strength, indirect tensile strength and dynamic modulus of elasticity. The split cylinders were used to study the variations in the colour of concrete due to heating to different maximum temperatures.

**Table 1. Properties of concrete mixtures at the age of 28 days**

| Mix No. | Binder materials | Cylinder strength (MPa) | Tensile strength (MPa) | Flexural strength (MPa) | Dynamic Modulus (GPa) |
|---|---|---|---|---|---|
| 1 | 100% GP Cement | 61.8 | 6.58 | 9.34 | 46.5 |
| 2 | 62% Slag + 38% Cement | 40.3 | 4.28 | 5.47 | 39.9 |
| 3 | 20% Fly ash + 80% Cement | 67.2 | 5.08 | 6.94 | 45.7 |
| 4 | 6.6% Silica fume + 93.4% Cement | 76.4 | 6.93 | 8.51 | 55.2 |

## 3 RESULTS AND DISCUSSION

### 3.1 Properties of concrete mixes

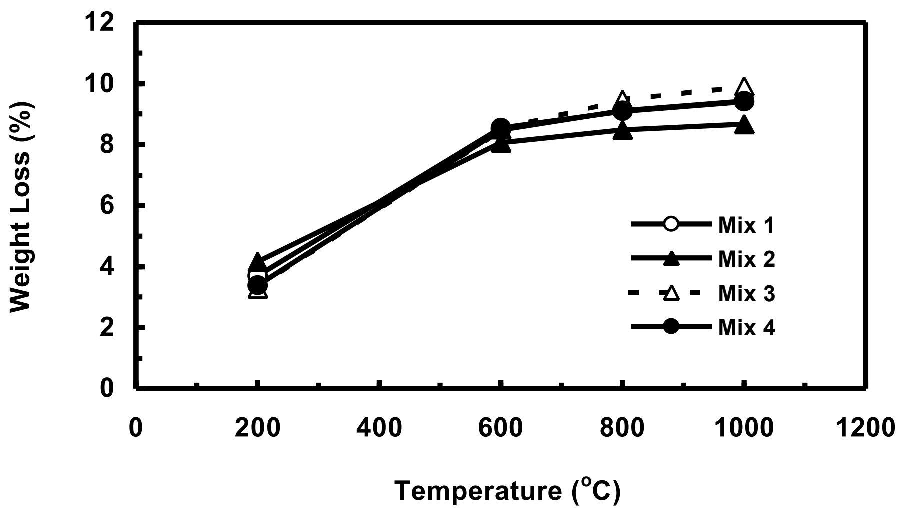
Table 1 summarises the properties of concrete mixtures at 28 days. The control concrete mixture (Mix 1) had the cylinder compressive strength of 61.8MPa. Mix 2 with blended cement, having 62% blast-furnace slag, showed considerably lower values for various strengths compared to the corresponding strengths for the control concrete mixture. The compressive, tensile and flexural strengths of Mix 2 are 65%, 65% and 57%, respectively of those for Mix 1. The dynamic modulus of elasticity for Mix 2 concrete was 39.9GPa compared to 46.5GPa for Mix 1. Hence, the elastic modulus was reduced by only 14% compared to 35% for the compressive strength. This reduced impact on elastic modulus for Mix 2 (as well as to Mixes 3 and 4) is probably due to the fact that the modulus is more sensitive to the aggregate stiffness than to the stiffness of the hardened paste. On the other hand, the strength of concrete is more sensitive to paste strength than the strength of the aggregate for normal weight concrete.

The results showed that the 28-day compressive strength of concrete, having 20% fly ash and 80% cement (Mix 3) was 8% more than that for Mix 1. However, the tensile and flexural strengths were 23% and 28% lower than the corresponding strengths for the control concrete. A marginal 2% reduction for the elastic modulus was observed. The addition of silica fume (Mix 4) increased in the strengths and stiffness of concrete. The compressive strength was increased by 24%, respectively, whereas the tensile strength was increased by 5%. However, surprisingly the flexural strength was decreased by 9%.

### 3.2 Weight changes in concrete on heating and cooling

Concrete is a porous material having discrete and interconnected pores of different sizes and shapes. The binder material type affects the pores size distribution. The use of cement supplementary materials such as fly ash, slag and silica fume will be result in achieving pore size refinement and grain size refinement. Water in the visible voids and large capillaries is termed as free water where as the water in the combined form in hardened cement paste is called combined water or water of hydration. Since the combined water is very stable it can only be removed at 1000$^{o}$C or above. In between these states, water exists in many locations such as in smaller capillary pores, gel pores and inter-layer spaces. The degree of firmness with which these water exists depends upon the pore size. Smaller the pore size is the greater the difficulty in removing the water.

**Figure 1: Effect of heating on weight loss in cylinders**



Go Back Next Page

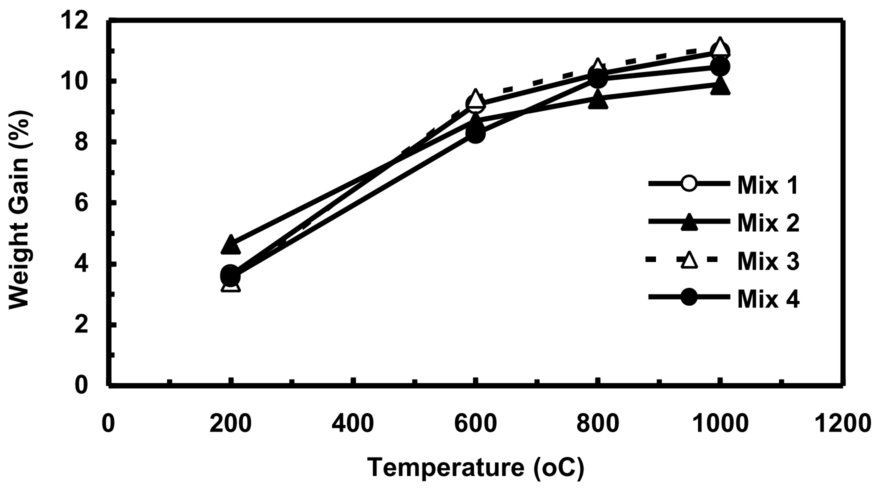


**Figure 2: Effect of heating on weight gain in cylinders**

When hardened concrete is heated gradually, the loss of weight appears to take place in the following three stages. In the first stage, called drying stage, evaporation of water from large capillaries and voids will take place. At the dehydration stage, which occurs between 100 and 600$^{o}$C, loss of non-evaporable water from gel pores and small capillary pores will take place. This stage is accompanied with substantial shrinkage of concrete. In the final stage, decomposition stage, several changes will occur in the concrete system. Some aggregate such as calcareous aggregate dissociates by releasing carbon dioxide at temperature over 800$^{o}$C. At the temperature above 1000$^{o}$C, the combined water form hardened paste will be released. This will cause the hardened paste to lose its cementing property and thus significantly reducing the hardened concrete properties. This process will be accompanied with significant shrinkage of cement paste as well as the loss in strength.

Figure 1 shows the weight loss in cylindrical specimens for all four concrete mixtures as the function of the maximum temperature. With the increase of exposed temperature, the concrete showed increased weight loss. However, the relationship between the weight loss and maximum temperature is non-linear. The binder material type caused a marginal influence to the relationship between the weight loss and the temperature. Fig. 2 shows the weight gained by the heated concrete as a function of the maximum exposed temperature. On sudden quenching in water, the heated concrete has gained more weight due to water absorption than the corresponding weight loss on heating. This could be due to the increased porosity of concrete related to internal cracking, in addition to any changes that may have occurred to the pore structure and properties of the hydrated paste on heating.

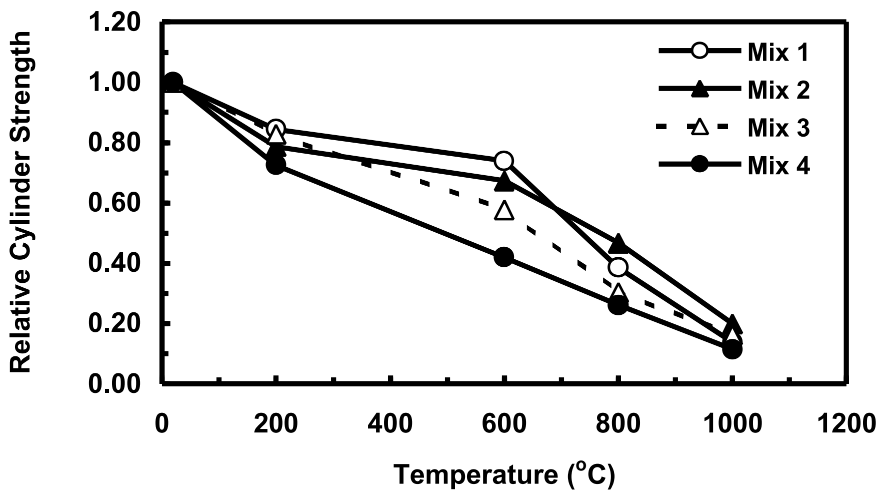

**Fig. 3: Residual compressive strength of concrete after high-temperature exposure**

**3.3 Effect of temperature on compressive strength**

Figure 3 shows the residual strength in relation to the original strength prior for all four concrete mixtures as a function of the maximum exposed temperature. The compressive strength of the high-strength concrete dropped significantly as the maximum temperature was increased. The residual strength varied from 73% to 84% of the corresponding initial strengths when the concrete was heated to the temperature was 200°C followed by sudden cooling in water. As the temperature was increased to 600°C, the residual strength was ranged from 42% to 74% of the unfired strength. Beyond 600°C, the strength continued to drop significantly and at 800°C and 1000°C, the residual strength ranged from 26% to 47% and from 11% to 20%, respectively. The results showed that the binder material type has a noticeable influence on the residual strength. The concrete mixture containing silica fume performed poorly compared to other binder materials. Although the silica fume addition increased the initial strength of concrete considerable compressive strength loss when exposed to high-temperatures. On heating to 1000°C, the compressive strength loss for the concrete with silica fume lost 89% of its initial strength.

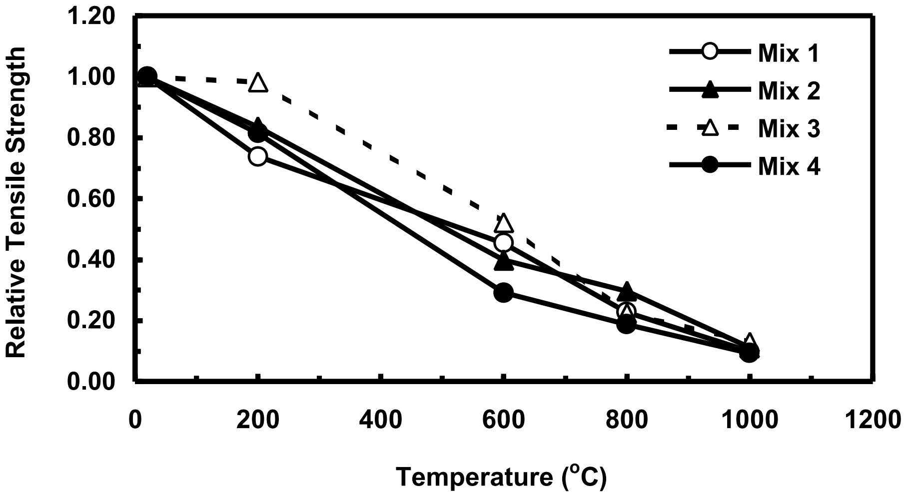

**Fig. 4: Residual tensile strength of concrete after high-temperature exposure**

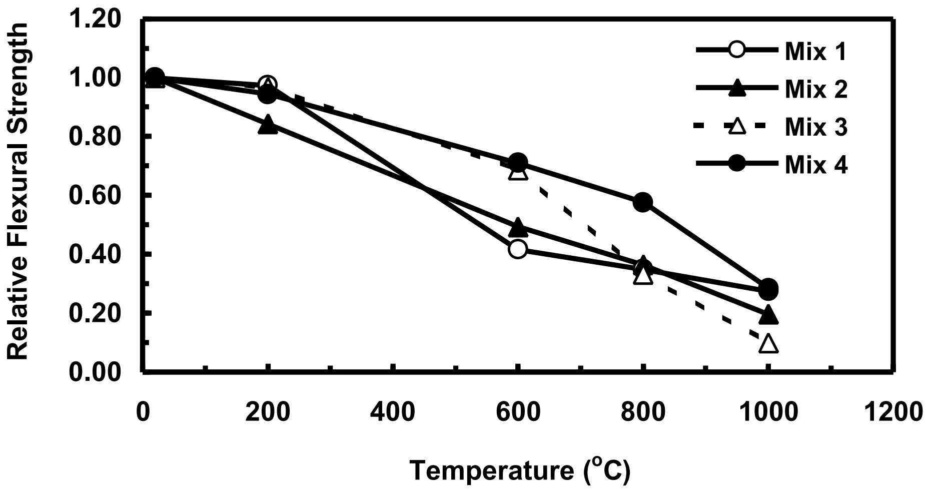

**Fig. 5: Residual flexural strength of concrete after high-temperature exposure**

### 3.4 Effect of temperature on tensile and flexural strengths

Figure 4 shows the residual tensile strength for high-strength concrete as a function of the maximum temperature. Similar to the compressive strength, the tensile strength showed significant losses with the increase in the exposed temperature. Once again, the binder material types played a noticeable role in influencing the strength losses. The results shown in Fig. 4 indicated that the Mix 4 having silica fume suffered significant loss in strength at the temperature of 600°C.The tensile strength for high strength concrete mixes was reduced by 87% to 91% when they were heated to 1000°C.

Figure 5 shows the effect of heating on the flexural strength for all four concrete mixes in relation to the corresponding strengths before heating. Similar to compressive and tensile strengths of concrete, the flexural strength decreased with temperature. Once again the binder material type had influenced the extent of strength loss.

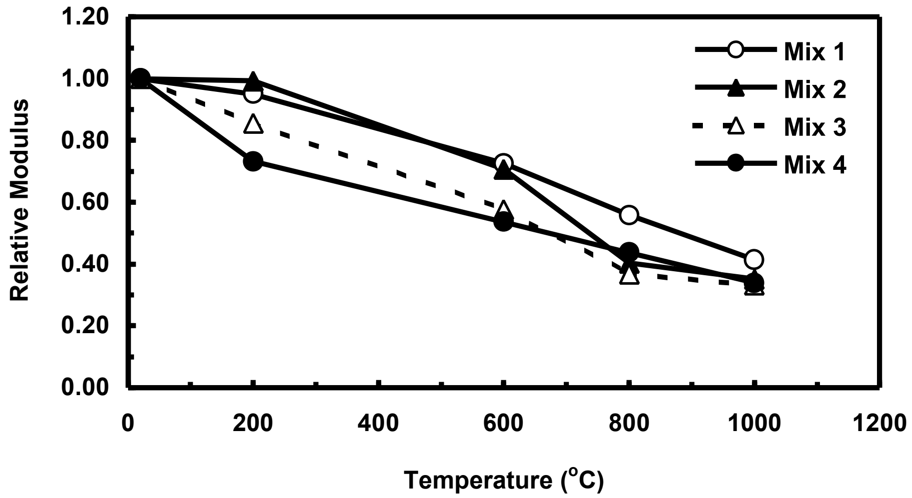

**Fig. 6: Residual modulus of elasticity of concrete after high-temperature exposure**

### 3.5 Effect of heating on modulus of elasticity

Figure 6 shows the residual modulus for all four concrete mixtures as a function of the exposed temperature. Similar to the strengths, elastic modulus was decreased with the increase in temperature and the binder material type influenced the extent of decrease. At 200°C, the reduction for the modulus ranged from 1 % to 5% and at 600°C it was ranged from 8% to 16%. Once the temperature was increased to 800°C, the reduction ranged from 13% to 20%. Further reduction was noted when the temperature was increased to 1000°C and the reduction in the modulus ranged from 29% to 40%, respectively. Therefore it appears from the results that the strengths of high-strength concrete are more sensitive to the elevated temperature than the elastic modulus.

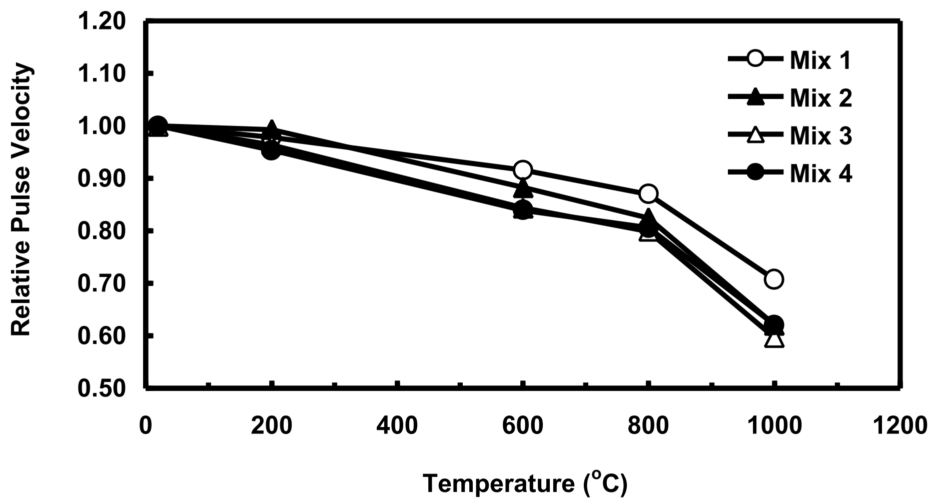

**Fig. 7: Residual ultrasonic pulse velocity of concrete after high-temperature exposure**

**Table 2. Effect of binder type on degradation in concrete properties with temperature**

| Binder materials | Relative Compressive strength | | | Relative Tensile strength | | | Relative Elastic Modulus | | |
|---|---|---|---|---|---|---|---|---|---|
| | 200 °C | 600 °C | 1000 °C | 200 °C | 600 °C | 1000 °C | 200 °C | 600 °C | 1000 °C |
| Cement | 84 | 74 | 14 | 74 | 44 | 10 | 95 | 73 | 44 |
| Cement + Fly ash | 83 | 58 | 20 | 98 | 55 | 13 | 85 | 58 | 33 |
| Cement + Silica fume | 73 | 42 | 11 | 82 | 29 | 9 | 73 | 53 | 34 |

### 3.6 Effect of binder material type on the concrete properties

Table 2 shows the influence of the binder material type on strengths and modulus of elasticity with respect to the corresponding values at the time of heating. The results have indicated that the concrete mixture containing silica fume loss considerable compressive strength compared to the control concrete or concrete with fly ash. The silica fume has contributed in improving the compressive and tensile strengths and elastic modulus of through the its pozzolanic reactivity it. However, concrete with silica fume performed poorly under the high temperature exposure.

The pore sizes are refined by this pozzolanic reactivity. However, water in the smaller pores will expand on heating and exert significant internal pressure within the system and thus result in the formation of internal micro-cracks. This has caused the ultrasonic pulse velocity to decrease noticeably compared to the control concrete as seen in Fig. 7. The initial pulse velocity ranged from 4.46 to 4.75 km/s was decreased to the range from 2.77 to 3.27 km/s when the temperature was increased to 1000$^{o}$C. The loss in pulse velocity is due to the combination of the effects of drying, internal cracking as well as to the changes in the microstructure of the paste on heating. These values are 60 to 70% of the initial values since the relationship between compressive strength and pulse velocity is exponential.

### 3.7 Effect of heating on the colour of concrete

Since the thermal conductivity reduces with the increase in temperature, water quenching of the heated concrete samples has not produced uniform cooling. The heat from the core of the test cylinders was unable to dissipate rapidly. Therefore, the core has sustained the elevated temperature for a longer period of time than the skin of the cylinders as observed from the colour differences across the section of the heated cylinders.

At the temperature of 200$^{o}$C, there was no apparent visual discoloration occurred in the concrete. The concrete specimens subjected to 600$^{o}$C and above suffered noticeable colour changes. The inner section of the concrete specimens at a distance of 15 to 20mm from the surface was dark grey-bluish in colour. The dark coloured area boundary was very distinct and showed no transition zone. Outside this area, concrete had maintained its colour. However, when the temperature was increased to 1000$^{o}$C, the inner colour was changed to bluish than dark grey.

## 4 CONCLUSIONS

Based on the results of this experimental investigation the following conclusions can be made:

1. High-strength concrete, independent of the binder material type used, experience weight loss and the relationship between the weight loss and maximum temperature was non-linear.
2. Compressive and tensile strengths showed noticeable losses (above 15%) even at the temperature of 200$^{o}$C, however the elastic modulus was dropped marginally by about 5%.
3. Concrete with silica fume suffered the most under increased exposure temperature below 800$^{o}$C.
4. High-strength concrete has shown 90% drop in its strengths once exposed to 1000$^{o}$C irrespective of the type of binder materials used.
5. Modulus of elasticity of high-strength concrete was less sensitive to the maximum temperature than either compressive or tensile strength.
6. Ultrasonic pulse velocity measurement can be used to estimate the temperature-related damage in concrete.

## 1 INTRODUCTION

Some lichen species can damage the surfaces of calcitic rocks as dolomites and marbles, and also cement mortars and concrete by mechanical and chemical action. There are many lichen species known to colonize these substrates (Nimis et al. 1987, Nimis et al, 1996).

As regards Buenos Aires Province, Argentina, some lichen species were found growing on “art –dèco” buildings (Traversa et al, 1999), and also on hydraulic structures (Rosato and Traversa, 2000). The most common species were *Caloplaca citrina* and *Lecanora albescens.* These species were studied with scanning electron microscopy (SEM), electron dispersive spectrometry microanalysis (EDS) and infra red spectrometry (IRS) (Traversa et al., 2000).

It was observed under SEM that *Caloplaca citrina* produces boring channels and *Lecanora albescens* leaves etching patterns on the surface. Both lichens produce a decrease in the calcium percentage of the mortar, as detected with EDS, whereas IRS analysis detected oxalic acid in both species.

In the white mortar of a balcony with southern exposition in a urban environment in the center of the city of La Plata (Buenos Aires Province, Argentina) a lichen was collected. The aim of this paper is to identify the species and to assess if it has a detrimental action on the substrate´s surface or not, in order to select an adecuate cleaning method.

It is necessary to remind that lichens are photosynthetic and therefore need the presence of light to grow, so they cannot penetrate a great depth in the substrate (only up to 2 mm.). Any damage they produce is only superficial, similar to other superficial attacks caused, for instance by weak acids together with the efect of freeze thawing cyles. Although it does not cause a problem to structural safety as a whole, this lichen is growing on a white ornamental cement cover and causes a grey, unaesthetic patch, so any deterioration induced by the lichen is relevant to select a technique for cleaning, specially when the building has an architectonical value.

## 2 MATERIALS AND METHODS

The lichen was found in a balcony with southern exposition in a urban environment in the center of the city of La Plata, in a private house built in 1958, growing along a fissure.This unifamiliar home belongs architectonically to the racionalist movement and the balcony is recovered by a white cementicious mortar (“marmolina”). This is a special ornamental mortar used as plaster made with white cement and marble bits and variable mica percentages. Its thickness is about 3-3 mm. and its is used to cover mortars prepared with normal cement.

The lichen sample was obtained by scraping it from the substrate and was studied with usual methods of identification. It was observed under stereoscopical and optical microscope. Measurements of thalli, apothecia, asci and ascospores were obtained. Keys were used for identification (Poelt, 1969, Ozenda and Clauzade, 1970 and Malme, 19).

Macerate samples prepared by heating gently in hydrogen peroxide and the addition of potassium hydroxide (Gehrmann, Krumbein and Petersen, 1988) were also observed with SEM (scanning electron microscope), and EDS (electron dispersive spectrometry) microanalysis were performed.

IRS analyses could not be performed, because the sample was too scarce.

## 3 RESULTS

### 3.1 Characteristics of the material

The white cement mortar used for the balcony is formed by one volume of white cement to three volumes of aggregate (small marble pieces and mica). It is most likely that a 10 % of hydrated lime has been added because that was the habitual technique used in La Plata during the 1950 decade.

The petrographic analysis of the aggregates shows little marble pieces, white cement, gypsum, mica and sub-rounded to sub-angular quartz clasts. Among the aggregates, it is striking that some magnetite crystals appear. The quartz and probably also the magnetite probably belong to the aggregate used in the base mortar and incorporated into the white cement during the execution. It has a specific weight of 2,35 at saturated density after drying the surface, and a water absorption rate in 24 hs. of 7,2 % .

### 3.2 Description of the lichen

Thallus crustose areolate, grey to dark gray, with a granulose surface, containing fragments of the substratum. Apothecia (structures that contain the spores), plane to convex, black disc. Spores hyaline, fusiform, with 3-5 septa, 21-30 x 3-3,5

The lichen is similar to *Bacidia subinnata* except for a great difference in the spore size. Nevertheless, in the searched bibliography there were no other descriptions similar to the specimen studied.

It is also interesting to remark that in the searched literature no records of *Bacidia* species growing on mortars could be found.

### 3.3 SEM observations

It can be seen that the thallus penetrates the substrate. When macerates were observed, it was noticed that the surface had a few boring channels and had squamules on the surface.

This is a remarkable feature, because this was not seen in other species. The most common damages are boring channels as in *Caloplaca citrina* and etching patterns as in *Lecanora albescens*, apothecial marks, perithecial cavities (Gerhmann, Krumbein and Petersen, 1988; Modenesi and Lajolo, 1988; Salvadori and Lazzarini, 1991), but in the available bibliography there are no description of squamules produced by the lichens.

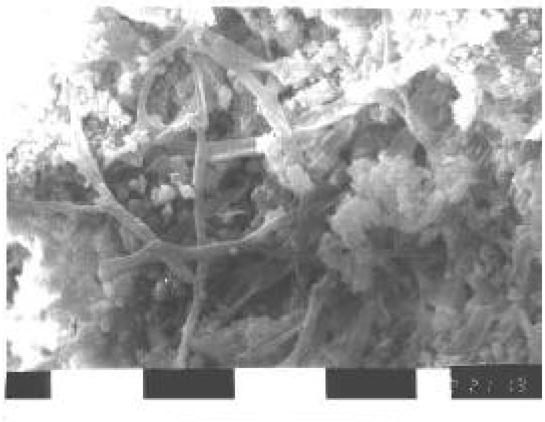

**Figure 1: Hyphae (fungal filaments) of *Bacidia* enclosing particles of the substratum.**

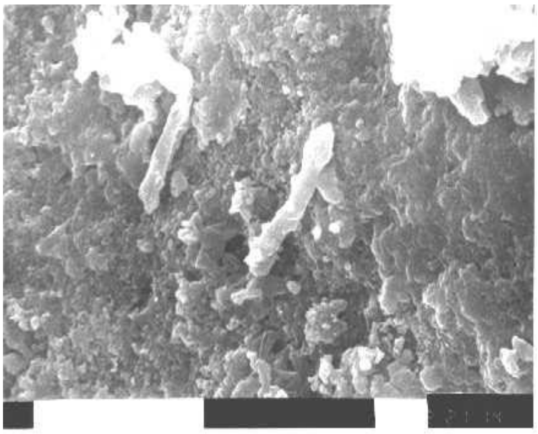

**Figure 2: Macerate showing the surface. Note the squamules.**

### 3.4 EDS microanalyses

The analysis detected a low calcium percentage (Table 1). There is a deterioration, because the material is easily disgregated when scraping, as it has been observed with other lichens. Nevertheless, the calcium loss is not as marked as in the cases of *Caloplaca citrina* or *Lecanora albescens* (Traversa et al., 2000). A normal cement, with 59% calcium, when attacked by

*Caloplaca citrina* had only 5 % calcium left. As for *Bacidia*, in the case being studied, the attacked cement has still a 35, 45 % calcium, although this may be attributed to the presence of marble in the aggregates, whereas the non attacked cement seems not to be so rich in calcium (the average is a 37,13 % and the maximun, 53,31 %).

It is also necessary to point out that white cements do not have any iron in the composition, and the percentage of iron detected is attributed to the presence of scarce magnetite crystals in the aggregates already mentioned.

Another difference with the typical white cement is that no sulphur or manganese were detected.

**Table 1- EDS results of the white cement mortar attacked by *Bacidia sp* and comparison to a typical white mortar**

| Samples | Elements | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|
| | Na | Mg | Al | Si | Cl | K | Ca | Fe | Mn | S |
| White cement mortar (mean values) | - | 9,41 | 10,44 | 39,25 | - | 0,745 | 37,13 | 2,63 | - | - |
| White cement mortar (lowest calcium data | - | 6,81 | 8,87 | 52,51 | - | 0,46 | 28,2 | 3,14 | - | - |
| White cement mortar (highest alcium data) | - | 11,22 | 7,34 | 25,37 | - | 0,19 | 53,31 | 2,58 | - | - |
| Attacked white cement mortar | 6,03 | 10,08 | 24,28 | 10,05 | 4,29 | 1,52 | 35,45 | 7,56 | - | - |
| Typical white cement (Blanks and Kennedy, 1955) | | 1,1 | 4,2 | 24,2 | | | 65,8 | 0,39 | 00,2 | 1,5 |

## 4 CONCLUSIONS

SEM observations confirmed that the lichen species *Bacidia* sp. penetrates the substrate, a white cement mortar with the addition of little marble bits and mica used as superficial plaster used to cover a normal cement plaster. The white mortar is affected by the action of the lichen, and as a result superficial squamules were observed. This is different from the attack of other lichens. The calcium decrease from a maximum of 53% to just 35 %, as measured by EDS microanalyses, seems not to be so important as the effect caused by other lichen species but the dissagregation of the material confirms that this species has a detrimental action on cementitious materials.

As a result of the lichen attack, there is a loss of structure and adherence between particles of the substrate, so in this case it is recommended that lichen removal should be done by washing with a solution of sodium hypochlorite and gentle brushing. Using hydrojet washing is discarded because the lichen has weakened the underlaying cement. The impact of the water jet would cause material loss and surface unevenness. Succesive washings can result in significant material loss, modifying the superficial texture and increasing the speed of colonization of this or other lichen species.

## 5 ACKNOWLEDGMENTS

To Mr. M. Sánchez, for the SEM observations and EDS analyses and geologist A. M. Ribot for the petrographic analysis. This work was partially funded by Conicet and CIC.

# Conflicting Design Issues In Wood Frame Construction

**SL Quarles**
**University of California Forest Products Laboratory California USA**

**Summary: In order for structures to provide adequate long-term performance, they must be designed and built to resist the imposed loads. These loads can be both structural and environmental in nature. This paper addresses performance issues related to design and materials selection as they relate to exposure from environmental elements. Of the environmental elements (e.g., moisture, fire, uv exposure), it is the contribution of the imposed moisture loads that usually result in the performance issues affecting durability. Buildings located in the urban-wildland interface (UWI) can also be exposed to the environmental load of wildfire. Testing has recently been conducted at the University of California Fire Research Laboratory whereby exterior building components and assemblies were exposed to simulated wildfire conditions. One of the results of these tests showed that construction details commonly used to protect a structure from moisture were often in conflict with those which would more effectively protect the same structure against the flame impingement and burning brand exposures typical for homes located in the UWI and subjected to wildfire. Examples of conflicting moisture-wildfire design issues include attic and crawlspace ventilation and roof overhangs. Traditional vents are vulnerable to flame and ember entry, but depending on the climate, are considered important from a moisture management perspective. Similarly, wide roof overhangs are considered a good design feature to protect cladding from rainfall, and can be good from a solar gain (energy conservation) perspective depending on location, but are a poor design feature from a flame impingement perspective. The objective of this paper is to present information on these conflicting design issues, and to explore how best to design structures located in the UWI.**

**Keywords: Design features, structures, urban-wildland interface (UWI), wildfire, rain**

## 1 BACKGROUND

Structures are designed and built to withstand certain imposed loads, as mandated by local and regional building codes. Traditionally we have been concerned about typical structural loadings (e.g., wind, earthquake and snow) that a structure could be exposed to. Depending on the likelihood of certain events that can have significant structural impact on the structure, regions can modify the basic building requirements to make the structure more resistant to a given imposed load.

For a number of reasons, improving the durability of structures has attracted more attention in recent years, and much of the attention has focused on protecting the materials on and within the building envelope against external exposures, the most common being moisture from both internal and external sources. Although construction details and design features related to moisture control are not always implemented, they are generally understood and have been well documented. Design features regarding energy performance of structures are also readily available, as well as those intended to make structures more "fire-safe". As is the case with moisture, fire-safe construction can address fires that start inside the structure, and those that result from exterior sources (wildfires).

Testing was recently conducted at the University of California Forest Products Laboratory (UCFPL) fire laboratory whereby exterior building components and assemblies were exposed to simulated wildfire conditions. One of the results of these tests showed that construction detailing and design features that were effective in protecting a structure from the infiltration of external moisture (usually in the form of rain) are very different that those that would be used to protect the same structure against flame and burning brand exposures typical for homes located in the urban-wildland interface (UWI).

Since there are many factors that could be considered when designing a structure, tradeoffs inevitably occur. One of the critical issues regarding the long-term performance of a structure is appropriate planning for the anticipated exposures, but in order for design professionals to make informed decisions, all of the exposure issues must be available. The objective of this paper is to

Go Back Next Page

present information on the conflicting design issues that exist between rain, wildfire, and, to some extent, energy conservation features, and to begin discussions on how best to design structures located in the UWI where wildfire (bushfire) poses a threat.

## 2 PERFORMANCE ISSUES: DESIGN OF COMPONENTS AND ASSEMBLIES

Similarities and differences were noted between design features that would be used to protect the exterior envelope from moisture/rain and those that would be used for wildfire. The similar design features for both moisture and wildfire design is the importance of proper detailing at the joints and penetrations. Obtaining adequate moisture and wildfire protection in the field of a given material or assembly (i.e., away from the edges) is the easiest to accomplish. Penetration of moisture and fire typically occurs at joints. This is why flashing details are so important when considering moisture management issues, and the same is true for fire penetration. The conflicting design issues deal with the "gross" design features and in the selection of materials. Examples of these gross design features include the width of the roof overhang, use of attic and crawlspace ventilation, and the spacing of deck boards in attached, spaced-board decks. These conflicting design issues will be addressed in the following sections.

### 2.1 Roof Overhang and Ventilation

The width of the roof overhang on a structure seems to be selected based more on the desired appearance of the structure rather than its ability to perform of a given function, even though there are clear benefits to narrow and wide overhangs, depending on the exposure. Publications dealing with performance and protection of building envelopes recommend wide overhangs to help deflect rain (Lstiburek 2000, Canadian Mortgage and Housing Corporation 1999), and narrow overhangs to provide protection against flame impingement and ember exposures common with wildfires (Moore 1981, Webster 1986, NFPA 1991). Germer (2001) reported on a procedure for determining roof overhang hased on the need for solar gain in the building, and is therefore related to energy conservation. In the procedure outlined by Germer, roof overhang is a function of the latitude where the structure is being built, and the vertical distance from the window sill to the roof overhang. In reports issued by the Canadian Mortgage and Housing Corporation (Rickens and Lovatt 1996), and Verrall (1966), walls with wider overhangs were associated with fewer water infiltration problems in the walls. Wide overhangs usually provide protection at wall penetrations in the field, but in cases where the base of the sheathing extends below the bottom of the sill plate, or the clearance between ground and sill isn't adequate, it can also minimize splashback, and the resultant damage to the bottom edge of the sheathing panel.

Roof overhang performance issues related to wildfire exposures are two-fold, one related to ventilation of attics, and the other related to flame impingement on the wall. Attic vents are frequently located on the underside of eaves, and have proven to be vulnerable to both entry of flames (flame impingement exposure) and glowing embers. Our research has shown that all forms of vents on the underside of the eaves (strip vents, frieze block, etc.), in both boxed and open-eave construction, are almost immediately penetrated under flame impingement exposures (Fig. 1). From this perspective, incorporation of metal or plastic strip vents with a noncombustible soffit material eliminates the material advantage in a fire safe design. The vulnerability of eave vents to fire has led to their elimination in some areas. The addition of through-roof vents on the roof surface can compensate for the loss of vent area at the eave, but it is questionable whether the attic area is being as effectively ventilated. Some have questioned the need for attic ventilation at all in hot humid climates (Lstiburek 1999, TenWolde and Rose 1999), and therefore in those climates moisture management and wildfire protection features may not be in conflict. In other climates, eliminating attic ventilation without incorporating other construction details that control the movement of moisture into the attic would not be wise. The use of screens in vents is intended to minimize or restrict the entry of embers into attic spaces, and is clearly more effective than vents without screens in this regard, but they do nothing to restrict penetration from a flame impingement exposure. Another feature that is being used in some regions is baffled vents (with the vents having either a horizontal or vertical orientation). The effectiveness of this design with regard to wildfire exposures has yet to be evaluated, but a similar design has been suggested for minimizing the entry of snow into attics during periods of high winds (Tobiasson 1994). Some local building codes in southern California suggest the use of (but do not require) baffled eave or soffit vents on new construction in the UWI. In these same localities, attic ventilation is not permitted on sides of homes fronting the wildland area (San Diego County 1997).

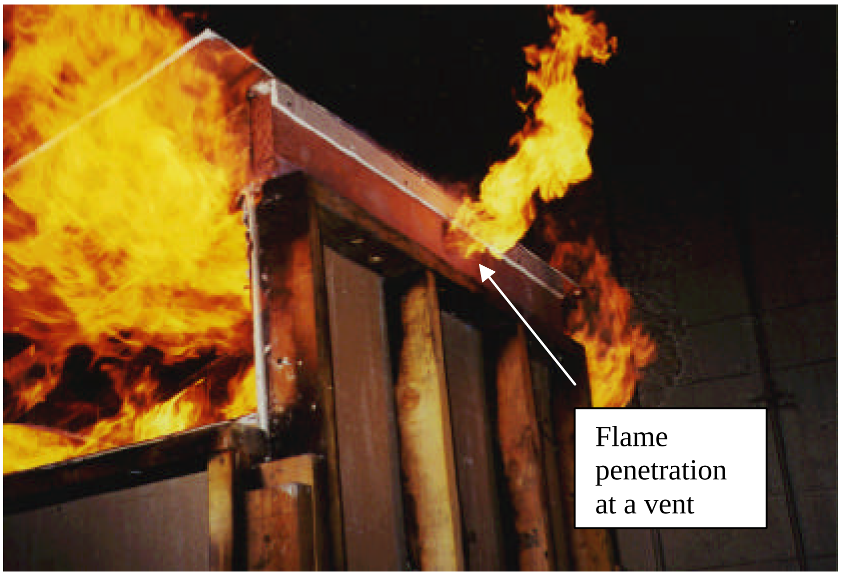

**Figure 1. This photograph shows flame penetration through a 2-inch diameter soffit vent located in the center of the wall, as viewed from what would be the interior of a structure. The flame impingement exposure simulates burning vegetation or exterior cladding.**

The second performance issue is related to flame impingement on the wall. The flame height on a wall is dependent on the entrainment of air into the flame plume (ASTM 1997). Because the flame is blocked on one side when it is against a wall, it will climb higher than one that is not in contact with a wall. Flames will climb higher yet at a corner. The flame plume will spread onto the surface of the eave (soffit) if an overhang exists due to the reduction of entrained air as the flame turns on the sloped surface (ASTM 1997). Results from research conducted at the UCFPL Fire Research Laboratory showed that flames would enter soffit vents located in an open eave (frieze block vent), and strip vents installed in boxed eaves almost immediately after a flame source was ignited at the base of the wall (Jennings 2000). A 600 kW propane diffusion burner was used, so the flame was able to immediately climb to the top of the wall. The strip vents were installed in 450 mm (18 inch) and 900 mm (36 inch) wide boxed eaves. With the 900 mm overhang the strip vent was located either 150 mm (6 inches) from the wall or 150 mm from the roof edge. If a combustible soffit material is used, wide overhangs can be more vulnerable to a flame impingement exposure even if vents are not used because more material is exposed. In the same study, failure in combustible soffit material occurred at joints in tongue & groove boards (Fig. 2) and at knots and core gaps in plywood soffits.

**Figure 2. Flame penetration occurred through a T&G joint in a soffit constructed with nominal 1-inch (25 mm) boards. This view is from the interior of the attic/soffit area.**

Crawlspace ventilation issues are similar to attic ventilation issues. Some level of crawlspace ventilation is required by code for moisture management, but again the effectiveness of ventilation has been questioned by some building scientists (Rose and TenWolde 1994). Crawlspace vents are often in close proximity to landscaping vegetation, which increase the chances of flame entry into the crawlspace should a wildfire reach the structure. Managing vegetation near a building (developing a 'defensible space') is always part of a firewise plan, and using such a plan will reduce the probability of wildfire reaching the structure and of fire penetration into attic and crawlspace vents. Other construction materials and details can be used to compensate for reduced venting that may be required by some codes. The use of a plastic ground cover in a crawlspace can reduce the need for ventilation, but not eliminate it (Quarles 1989), and the appropriate use of an air barrier can reduce the amount of moisture movement into the attic and building envelope. Slab on grade construction can also be used to avoid the crawlspace ventilation issue altogether.

Competing priorities create another conflicting design issue between aesthetics, "energy efficiency" and "firewise" constructions. As indicated by Wilson (2001), vegetation surrounding buildings can provide energy savings for a building, typically by improving the shading of a building. However, homeowners usually prefer vegetation surrounding homes, regardless of the other benefits and dangers.

### 2.2 Roof Overhang and Wall Interactions

The importance of a wide overhang in providing protection for the wall cladding by deflecting water from rain was discussed in the previous section. Our studies have shown that vertical and horizontal joints are the most vulnerable feature with regard to flame penetration into the building envelope. If flame penetration into the building envelope is going to occur in the cladding, it will typically occur at a joint (Fig 3). This implies that, at least for lapped siding, wider patterns would perform better under wildfire exposures because of the reduced number of joints that would be present on the wall. Edge thickness swell can be a problem with some wood-based composite siding materials, and from this perspective, is similar to the fire performance in that wider pattern would reduce the number of affected panels. Moisture related issues in siding are usually associated with biological degradation or dimensional stability (warp). Our experience has shown that warp-related defects are reduced when narrow patterns are used for wood and wood-based materials.

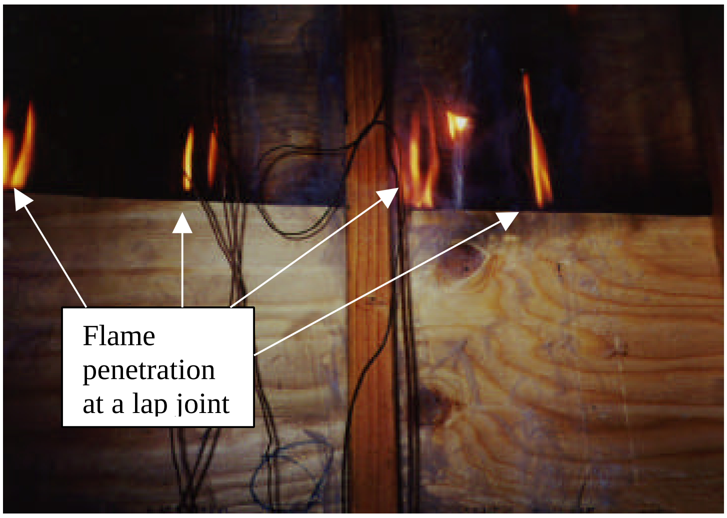

**Figure 3. This photograph shows flame penetration on the back side of one of the lap joints in panelized horizontal lapped siding. The flame source was on the front of the siding.**

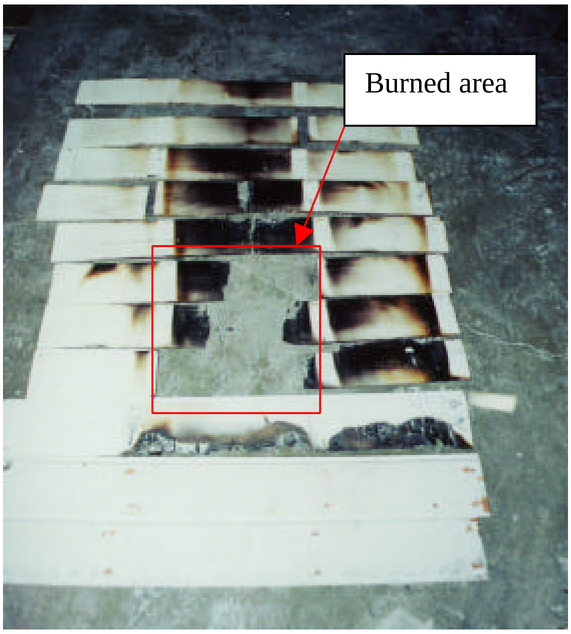
In recent years use of a "rain-screen" design, whereby an air gap is included between the exterior cladding and the underlying sheathing has been discussed as a way of increasing the drying potential of the wall (Lstiburek and Carmody 1993; Quirouette and Rousseau 1998). Straube (1999) refers to this construction as a "screened-drained" wall assembly. This construction technique improves the drying potential of the wall, particularly if the wall is wetted by a leak in the building envelope. Preliminary tests conducted at this lab have shown that with this design damage to combustible siding materials increased, and because of this, the potential for burning through the building envelope also increases. Figures 4 and 5 show the backs of two wood-clad walls after being subjected to a flame impingement exposure for the same time period. The wall shown in Fig. 4 was attached to furring strips and the siding shown in Fig. 5 was attached directly to the building felt. The rain-screen wall suffered more damage as a result of charring and area burned. This result confirms those by Brannigan (1982) who discussed the increased fire susceptibility of a balloon-framed building envelope, whereby fire spreads throughout the cavity from the base of the wall to the roofline (and potentially into the attic). For rain-screen walls, the space between the cladding and sheathing provides a drainage plane, but also provides the confined space and oxygen for the flame to climb the back of the siding once the flame penetrates through the lap joint.



**Figures 4. The back of wood siding installed using a rain-screen technique after exposure to a flame impingement source. The damage to the siding was more severe than damage to similarly exposed siding attached flush against the building felt (see Fig. 5).**

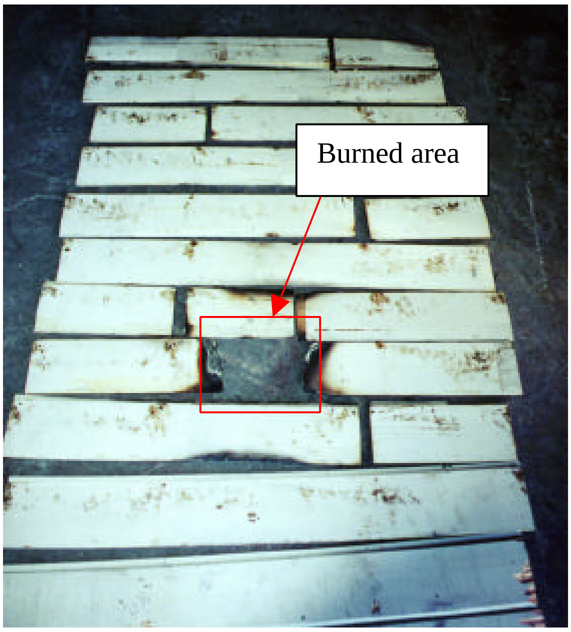


**Figure 5. The back of wood siding installed flush against building felt after exposure to a flame impingement source.**

### 2.3 Spaced-board Decks

Spaced-board decks obtain their best service life if the deck boards are spaced, and the between-boards gaps are maintained by clearing out the debris that can accumulate in the gaps. The air circulation that is facilitated by the gaps improves the drying potential of the deck boards, and the underlying support framing. However, these same gaps that allow for drainage and drying also provide radiant surfaces that enhance the burning, thereby increasing the rate at which the deck is degraded. These effects are shown in Figs. 6 and 7. These photographs show the increased fire hazard related to gapping the deck boards.

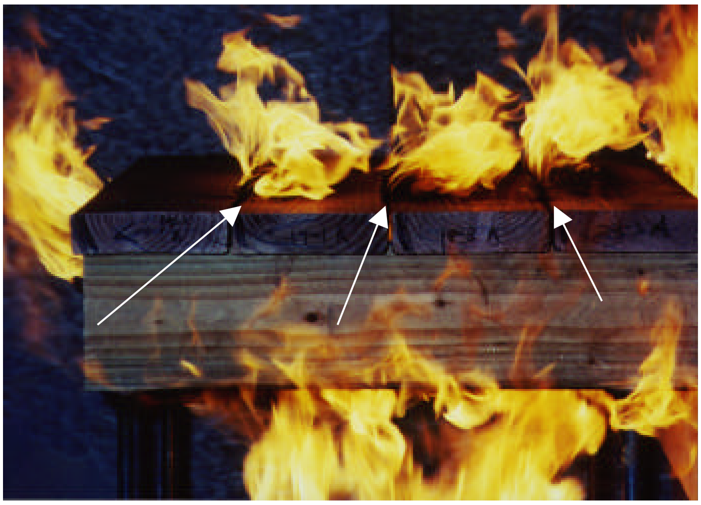

**Figure 6. Flame impingement extending upward through gaps between the deck boards in a deck subjected to a flame impingement exposure.**

**Figure 7. When deck boards are butted, flames cannot easily penetrate between board spaces. The rate of thermal degradation of the deck is minimized.**

Vertical screening and lattice systems are sometimes constructed around the perimeter of spaced-board decks in order to limit the entry of embers, and perhaps to discourage under-deck storage of materials. For large decks, the screen and lattice construction could limit ventilation, and therefore the drying potential, of wetted framing members, particularly in locations away from the perimeter where air circulation would be reduced.

## 2.4 Ventilated Membrane Decks

Wood-framed membrane decks (waterproof decks) have a solid surface and therefore would not have the conflict related to deck board spacing. Wood-frame membrane decks that are enclosed on the underside are usually vented, and therefore they would experience the same issues related to ventilation regarding ease of flame penetration. The vented membrane-deck shown in Fig. 8 is particularly vulnerable because of the growth of vegetation under the deck, and also because the building is located at the top of a ridge (not visible from the photograph). Flame entry into the joist cavities of these decks provides and easy access to the wall cavity, and therefore the structure.

Go Back

Next Page

**Figure 8. The strip vents commonly used in woof-framed waterproof decks are subject to the same flame and ember entry problems as crawlspace and attic vents. In this case, vegetation growing under the deck increases the potential danger to the structure.**

## 3 SUMMARY

Basic design features that provide protection against rain and wildfire are often in conflict. For example, regarding exposure to rain, the performance of building components and assemblies can be enhanced if wide roof overhangs are used, if adequate ventilation of attics and crawlspaces is incorporated, and if the deck boards in spaced-board decks are gapped. If the structure design focused on maximizing performance assuming wildfire exposures, the opposite applies, and the roof overhang would be narrow, soffit and crawlspace venting would be eliminated, and deck boards in spaced-board decks would not be gapped at all. For homes built in the UWI it may be necessary to utilize the design features that are most effective against wildfire exposures, but this should not occur at the expense of the overall durability of the building. Other construction techniques and details must compensate for the anticipated change in performance. These techniques could include incorporation of air barriers to minimize the movement of moisture into the building envelope and use of vents that are designed to resist wildfire exposures but still allow sufficient movement of air to remove excess moisture. Elimination of the roof overhang would require greater attention to installation detailing at penetrations and may require a change to materials that are more dimensionally stable. Since many buildings are currently built with narrow overhangs, the need for more careful installation is understood. These changes may also mean that the time interval between normal maintenance tasks, such as painting and caulking, may have to be reduced.

Homes built in the UWI should be designed to perform well for all the anticipated exposures, and it is important to acknowledge and design for them. Trade-offs may have to be made, but this should not be at the expense of making the structure overly vulnerable to any given exposure.

## 4 ACKNOWLEDGEMENTS

I gratefully acknowledge the help of Chris Jennings in conducting tests during the time he was pursuing his Masters degree at the UCFPL. I also want to thank Professor Frank Beall, Director of the UCFPL, for allowing the flexibility in the wildfire research program to study some of the design issues reported in this paper.

# Artificial Weathering Of Building Components - Experimental Results On External Walls

**T Teruzzi A Jornet**
**University of Applied Sciences of Southern Switzerland Construction and Environment Canobbio Switzerland**

**Summary: In this paper we present the results of a laboratory investigation conducted in collaboration with DISET-Politecnico di Milano on specimens of external walls subjected to artificial weathering.**

**Weathering was based on the repeated exposure of the specimens to the main weathering agents, such as rain, temperature, freeze/thaw cycles, humidity and sunlight. Each weathering cycle had a duration of about 6.5 hours.**

**The specimens consist of perforated brickwork coated with render and protected with paint. As protective layer an acrylic and a vinyl dispersion painting have been used, both with two different PVC pigment volume content (40% and 60% in volume).**

**The performance evaluation and the recording of changes in the samples properties have been made on the basis of visual inspection of the protective layer and of both non-destructive (specimens weight) and destructive tests (render compressive strength and porosity, render/brickwork bonding strength, water absorption, water vapour permeability and analysis of the microstructure of the paint/render system). The latter ones have been performed on cores taken from the wall specimens. The inspection of the paint and the non-destructive tests have been carried out every 25 weathering cycles during the whole exposure time, while the destructive tests have been performed only at the end of the exposure, after 50, 75, 150, and 325 weathering cycles. Characterization tests have also been performed on unweathered specimens.**

**The results of the tests show no significant variation of the mechanical properties and of the porosity of the samples, while a general rapid decrease as a function of the number of weathering cycles in the permeability to water and to water vapour of the paint/render system is observed. A stronger reduction of water absorption is observed for the specimens protected by the paints with a higher resin content, while surprisingly enough the permeability to water vapour shows a stronger reduction for the specimens protected by the paint with a lower resin content. The inspection of the paint and the analysis of the microstructure of the paint/render system showed that the degradation of the protective layer is much more rapid for the vinyl paint than for the acrylic one. After 150 weathering cycles the vinyl protective layer was indeed already characterized by the presence of a large number of lacerated bumps, crackles and detachments, while the acrylic one was practically undamaged.**

**Keywords: Artificial weathering, external wall, painting, durability.**

## 1 INTRODUCTION

The work presented in this paper is part of a wider research project jointly conducted by the DISET Department of the Polytechnic of Milan and the Laboratorio tecnico sperimentale of the University of applied sciences of southern Switzerland in Lugano. The issue addressed by the project is that of the durability of building components (Maggi *et al* 2001). The project aims, in particular, at developing an experimental method of service life prediction based on accelerated, field and in-use-conditions exposure of building components and on the evaluation of their performances. This type of method is considered by the international standard ISO 15686 “Buildings and constructed assets – service life planning” as one of the possible way for estimating service life of building components.

The paper reports on the results obtained from an investigation of the effects of short-term, accelerated exposure of wall specimens belonging to the class of traditional cavity walls to the action of artificial weathering agents. The investigation was carried out, on the one hand, in order to assess the decay rate and the extent of change of the building component’s critical properties and of those of its constituents. On the other hand, it was carried out in order to gather information on the mechanisms, which lead to a degradation of the building component's performances.

## 2 SPECIMENS AND EXPERIMENTAL

### 2.1 Specimens

The specimens, which represent only the external part of the cavity wall, consist of perforated brickwork coated with render and finished with a protective paint layer. Their surface has an area of about 0.2 $m^2$ and their weight is approximately 35 kg.

Fresh render mortar was prepared my mixing 1450 g of aggregates, 315 g of Portland cement type II/A-L 32.5, 135 g of limestone and 280 g of water (the quantities refer to 1 $dm^3$ of fresh mortar). The composition of the mortar has been defined by taking into account the directives on the preparation of render for external use issued by the Swiss Federal Laboratories for Materials Testing and Research (EMPA).

For the finishing of the specimens an acrylic and a vinyl dispersion paint have been used, both with 40% and 60% Pigment Volume Content (PVC). Each paint has been applied in three coats, each one having a thickness of about 30 µm.

Before starting their exposure to the weathering agents, the specimens were stored for at least 28 days in laboratory ambient conditions.

### 2.2 Testing program

Changes of the specimens’ properties due to artificial weathering have been monitored by means of visual inspection and by means of both non-destructive tests – weight measurement – and destructive tests – render compressive strength and porosity, render/brickwork bonding strength and water absorption capability, paint/render water vapour permeability. In addition, the microstructure of the paint/render system was examined by optical microscopy.

Visual inspection and weight measurements have been conducted every 25 weathering cycles during the whole exposure period, while the non-destructive tests have been conducted only at the end of the exposure, after 50, 75, 150 and 325 weathering cycles. For comparison, tests have been performed also on unweathered specimens.

## 3 WEATHERING APPARATUS AND WEATHERING CYCLE

The specimen were weathered in an environmental chamber, which allows to reproduce artificially the main weathering agents relevant to the investigated building component, that is rain, high and low temperatures, freeze/thaw cycles, humidity and sunlight. Inside the chamber, which has a volume of about 0.8 $m^3$, it is possible to regulate air temperature and relative air humidity between -30°C and +90°C and between 15% and 100%, respectively. For the simulation of sunlight, the chamber is equipped with a 6kW-xenon lamp, whose light spectrum is very similar to the spectrum of natural sunlight. The energy flux at the specimens’ surface is about 1500 $W/m^2$, while in a 10nm-wide spectral band centred at 365 nm (UV-range) the energy flux is 20 $W/m^2$. The chamber is also equipped with a spraying system fed with de-ionised water, which is used to simulate rain. Pictures of the environmental chamber are shown in Fig. 1.

Go Back
Next Page

**Figure 1. Pictures showing the environmental chamber with two wall specimens.**

The control unit of the environmental chamber allows to programme every desired sequence of weathering agents and to set the duration of their action. The structure of the weathering cycle used for the present investigation is shown in Fig. 2. The cycle, which has been adjusted on the basis of the results obtained from exposure pre-tests (Teruzzi 2000), has a total duration of about 6.5 hours and consists of four main different phases:

Phase 1: during this phase, the specimens are homogeneously sprayed with water at 20°C for 60 minutes. Air inside the chamber is maintained at a temperature of 20°C and at a relative humidity of 95%.

Phase 2: air temperature is rapidly lowered from 20°C down to -20°C, where it is subsequently held constant for 90 minutes. During this phase, no control on air relative humidity is maintained. As shown measurements performed by means of sensors placed at different locations inside one of the wall specimens, at the end of this phase the temperature of the interface render-brickwork reaches about -10°C.

Phase 3: this phase reproduces conditions of higher temperature and humidity. Air inside the chamber is maintained during 60 minutes at a constant temperature of 55°C and at a constant relative humidity of 95%. This phase is preceded by a transition period during which air temperature is increased from -20°C up to the set value.

Phase 4: the specimens are exposed for 80 minutes to the artificial sunlight produced by the xenon lamp. A temperature of 30°C and a relative humidity of 40% characterise ambient conditions inside the chamber. At the end of this phase, the temperature of the interface render-brickwork reaches about 65°C.

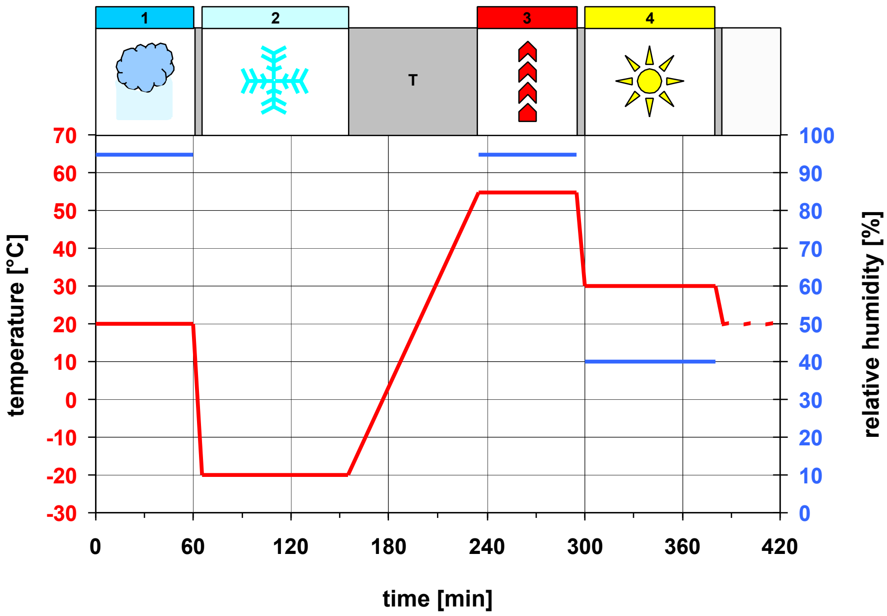

**Figure 2. Ambient conditions and agents sequence during each weathering cycle.**

## 4 RESULTS

In this section the results of the non-destructive tests performed on the wall specimens and the results of the destructive tests conducted on cores taken from the wall specimen are presented. Except for the graph shown in Fig. 6, all data points represent mean values calculated by taking the results obtained on the number of samples specified in each sub-section. For comparison, results obtained within the framework of a previous investigation conducted on uncoated specimens are also presented (Maggi *et al* 1999, Jornet 2000).

### 4.1 Paint's visual inspection

Changes in the appearance of the 40% PVC paints have been documented by means of pictures of the specimen's surface taken with a camera mounted on an optical microscope.

Figures 3, 4 and 5 show the surface of a specimen coated with 40% PVC vinyl paint after 75 weathering cycles, the surface of a specimen coated with the same type of paint after 325 cycles and the surface of a specimen coated with 40% PVC acrylic paint after 325 cycles, respectively.

After 75 weathering cycles, the specimen coated with the 40% PVC vinyl paint already displays signs of degradation. In fact, on the surface one can easily see many bumps, some of which are lacerated. After 325 cycles, the same paint shows a much higher degradation level. The surface is characterized by the widespread presence of lacerated bumps and detachments. In addition, the continuity of the protective paint layer is interrupted by a large number of crackles of different lengths and depths. In some cases, a white deposit around the largest crackles can be observed. This is due to the crystallization of salts that are dissolved inside the specimens during the spraying phase of the cycle (phase 1) and subsequently transported to the surface by water leaving the specimens during drying (phases 3 and 4). The appearance of the 40% PVC acrylic paint, after 325 cycles, apparently seems to be unaffected by the action of the weathering agents. In fact, no sign of degradation is pointed out by visual inspection. Basing on the results of visual inspection, the vinyl paint thus proves to degrade with a much higher rate than that of the acrylic paint.

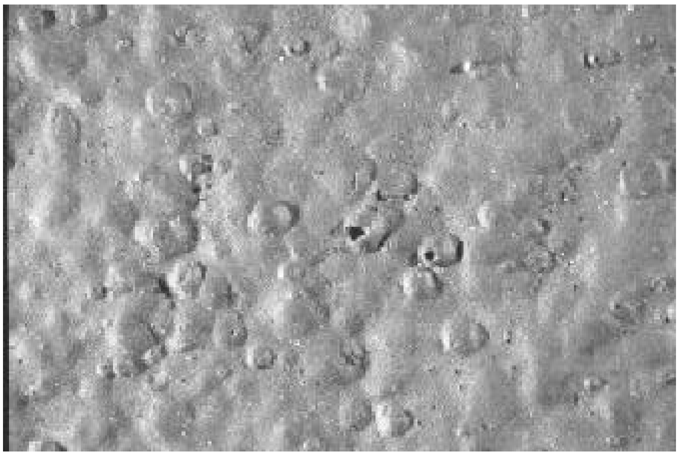

**Figure 3. Surface of the specimen coated with 40% PVC vinyl paint after 75 cycles.**

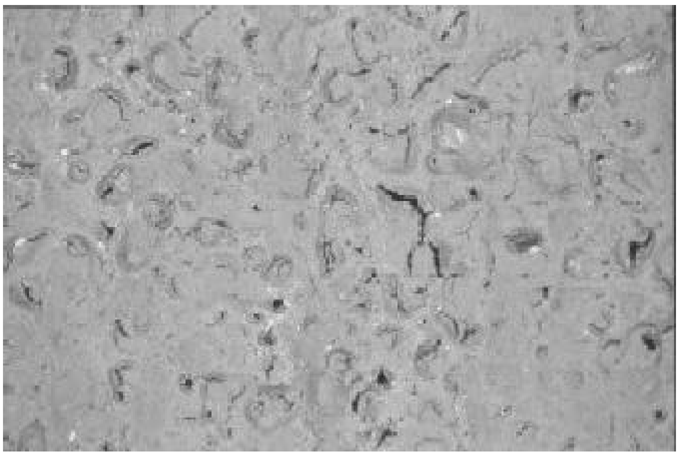

**Figure 4. Surface of the specimen coated with 40% PVC vinyl paint after 325 cycles.**

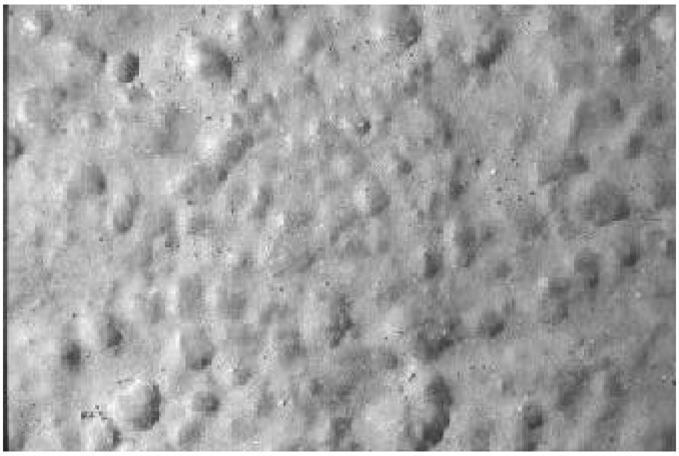

**Figure 5. Surface of the specimen coated with 40% PVC acrylic paint after 325 cycles.**

### 4.2 Weight

The specimen weight has been recorded after every series of 25 cycles in order to monitor the amount of residual water during weathering. It is important to notice that the lateral and rear sides of the specimens were watertight, so that during spraying water could enter the specimens only through the coated front side.

The variation of the specimen weight, expressed in percentage of the initial weight, is shown in Fig. 6 for all the different types of paint. For comparison, the results obtained for uncoated specimens are also displayed.

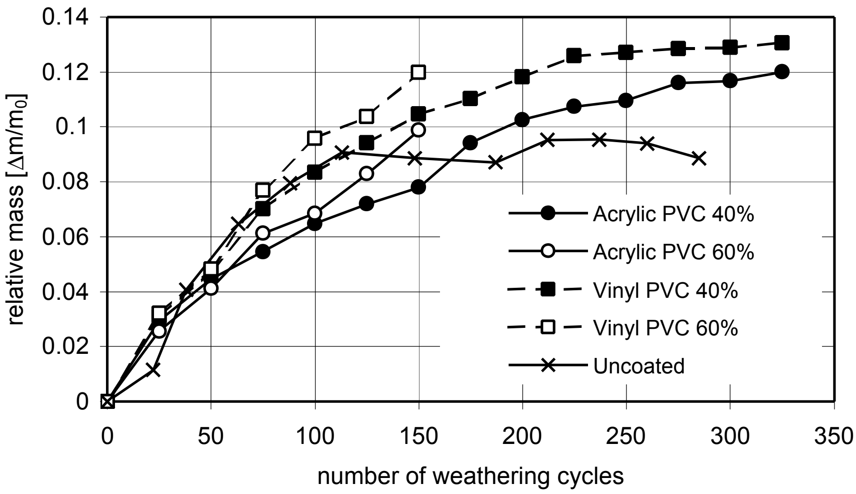

**Figure 6. Specimens' relative weight as a function of the number of weathering cycles.**

For all paints, a steady, asymptotic increase of the weight is observed. This fact is probably due to a positive balance between the amount of water that enter the specimens during the spraying phase and the amount of water that is released during the drying phases. After a sufficiently large number of cycles, the amount of water entering and that leaving the specimens balance, giving rise to the observed asymptotic behaviour.

Taking as a reference the data points at 150 weathering cycles, one clearly observes that the weight increases to a smaller extent for the acrylic paint than for the vinyl paint. Furthermore, as it becomes evident after about 50-75 cycles, for both types of paint, the larger increase is recorded for the highest pigment volume content PVC 60% (or, equivalently, the lowest resin content). As compared to the uncoated specimens, at steady state the relative weight of the coated specimens reaches higher values (12-13% for the coated specimens and 9% for the uncoated).

### 4.3 Render compressive strength and render/brickwork bonding strength

The render compressive strength and the render/brickwork bonding strength were determined according to the testing procedures described in the Swiss Standard SIA 162/1 and in the German Standard DIN 1040-2, respectively. The tests have been performed on three cores taken from each wall specimens. The results of the two tests are plotted in the graphs of Fig. 7.

With an overall mean value of (29.9 ± 4.5) N/mm$^2$, the render compressive strength does not show any significant dependence upon the number of cycles as well as upon the paint type. The results are practically identical with those obtained on cores taken from the uncoated specimens.

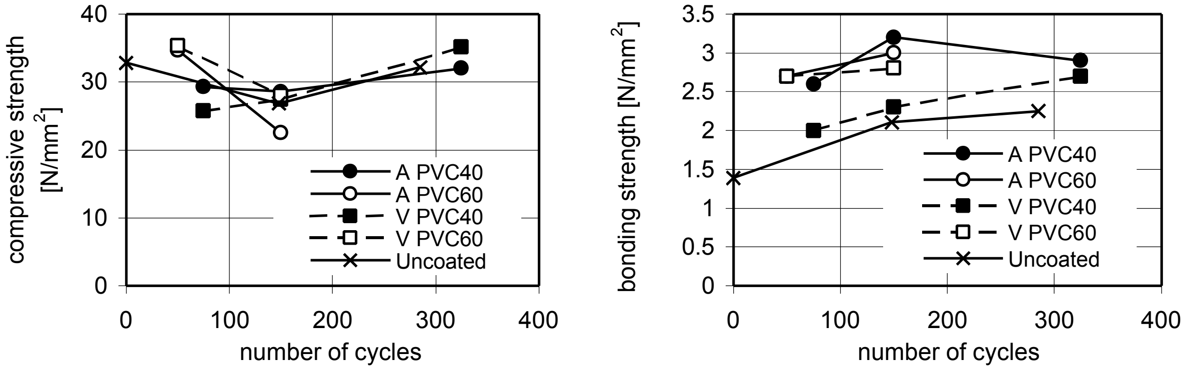

**Figure 7. Compressive and bonding of strengths as a function of the number of cycles.**

The bonding strength proves to be a slightly increasing function of the number of cycles for all types paint. The increase of the bonding strength is accompanied by a displacement of the rupture plane from the interface render/brickwork into the render. No significant dependence upon the paint type is observed. With values, which are comprised between 2.0 and 3.2 N/mm$^2$, the bonding strength obtained for the coated specimens is always larger than that obtained for the uncoated ones.

## 4.4 Porosity

The render's porosity parameters were measured according to the testing procedure described in the Swiss Standard SIA 162/1 (test no. 7). The test was performed on five cores for each wall specimen.

The results do not show any significant change of the total porosity and of the capillary porosity with increasing number of cycles. The total and the capillary porosity, as expressed in percentage by volume, show namely a constant value of about 23% and 13%, respectively, independently of the type of paint. In addition, the porosity parameters of the coated specimens are practically identical to those of the uncoated specimens.

## 4.5 Water absorption

The amount of water absorbed per capillarity by the paint/render system within a defined time interval has been determined on three cores for each wall specimen according the testing method given in the German Standard DIN 52 617. The results of the test are shown in Fig. 8 for t = 1 h (W1) and t = 24 h (W24), where t is the time elapsed since the beginning of the test. The results are expressed as the amount of water absorbed by a unit surface in the time t, divided by the square root of time (coefficient of water absorption W).

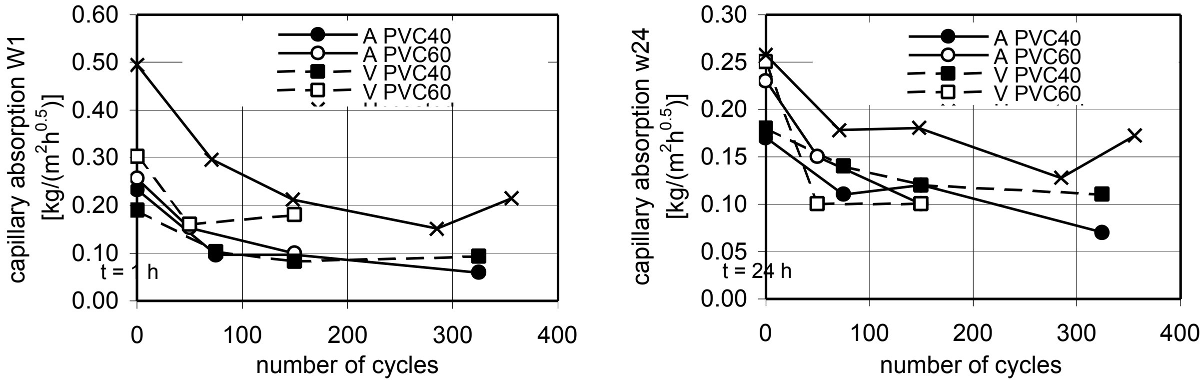

**Figure 8. Water absorption after 1 h (l) and 24 h (r) as a function of the number of cycles.**

For all types of paint a fast decrease of the coefficient of water absorption in the first 50-75 cycles is observed. This behaviour, which is observed also for the uncoated specimens, appears to be more important for the specimens coated with the higher PVC paints (PVC 60%). Afterwards, the coefficient of water absorption shows only a slight variation as the number of cycles increases.

With respect to the uncoated specimens, the coated ones are characterised by a coefficient of water absorption which, at t = 1 h, is smaller by about a factor of two. For t = 24 h differences in the absorption capability are less pronounced, but nevertheless the efficacy of the paint as a protective layer is proved. If one considers the coefficient of water absorption as an index of the paint/render system's protection level against water penetration, then the data displayed in Fig.8 clearly show, that the system coated with the lower PVC paint (PVC 40%) provides, for a not too large number of cycles, a higher level of protection than that coated with the higher PVC paint. This performance difference is less evident when the number of cycles is large. As far as the type of resin is concerned (acrylic vs. vinyl), no significant difference in the protection level is observed. It is noteworthy and quite surprising, that when the number of cycles is zero and t = 24 h, the system with a 60% PVC paint provides almost no protection.

In order to better appreciate the contribution to the protection level of the sole painting, water absorption tests have been repeated on samples from which the coating had been previously removed. Coherently with the results obtained from the monitoring of the specimen weight, one finds that the higher protection level is provided by the acrylic paint and that a lower PVC value helps to get better performances.

### 4.6 Water vapour permeability

Water vapour permeability and the corresponding resistance to water vapour diffusion were determined according to the testing method described in the German Standard DIN 52 615 on three cores for each wall specimen. The results are shown in Fig. 9.

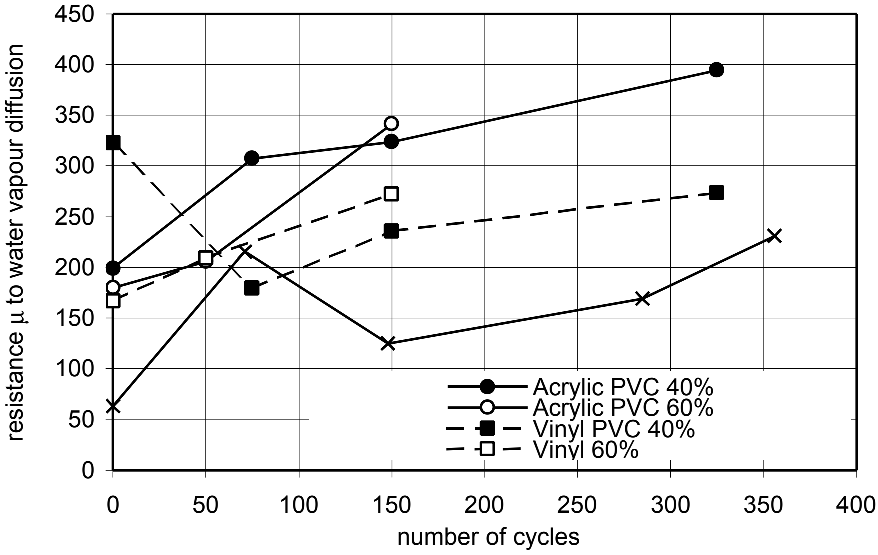

**Figure 9. Resistance to water vapour diffusion as a function of the number of cycles.**

The data points displayed in Fig. 9 clearly show that the presence of the paint results in an important increase of the resistance to water vapour diffusion. A general increase of resistance is also observed with increasing number of weathering cycles for all types of paint. Whereas for zero cycles no significant differences in the resistance are observed (neglecting the data point for the PVC 40% vinyl paint, which might possibly be incorrect), for a sufficiently large number of cycles the acrylic paint clearly shows a much higher resistance. In addition and surprisingly enough, for both the acrylic and the vinyl paints, the highest resistance values after 150 cycles are recorded for a pigment volume content of 60%, that is for the lowest resin content.

### 4.7 Microstructure

Examination, by means of optical microscopy, of thin sections prepared from samples of the paint/render system allow to point out microstructural transformations and alterations of the examined material owing to its exposure to the weathering agents. A thin section has been prepared for each type of paint and for each duration of exposure.

The pictures of Fig. 10 show the microstructure of the specimens coated with the 40% PVC vinyl paint after 0, 75, 150 and 325 weathering cycles. Whereas in the render no signs of alterations can be observed, the paint shows an increasing degradation level as the number of cycles increases. In accordance with the results of visual inspection, after 75 cycles bumps and bubbles start appearing. These are accompanied by detachments and ruptures after 150 cycles.

In the pictures of Fig. 11, the microscopic surface appearance of a specimen coated with the 40% PVC acrylic paint before exposure (zero cycles) and after 325 weathering cycles is shown. For this type of paint practically no sign of degradation can be observed.

The pictures of Fig. 12 show the microstructure of specimens coated with a PVC 60% acrylic paint and with a PVC 60% vinyl paint after 150 cycles. Although signs of degradation are evident in both pictures, the degradation level is significantly higher for the vinyl paint, which is characterized by ruptures and detachments.

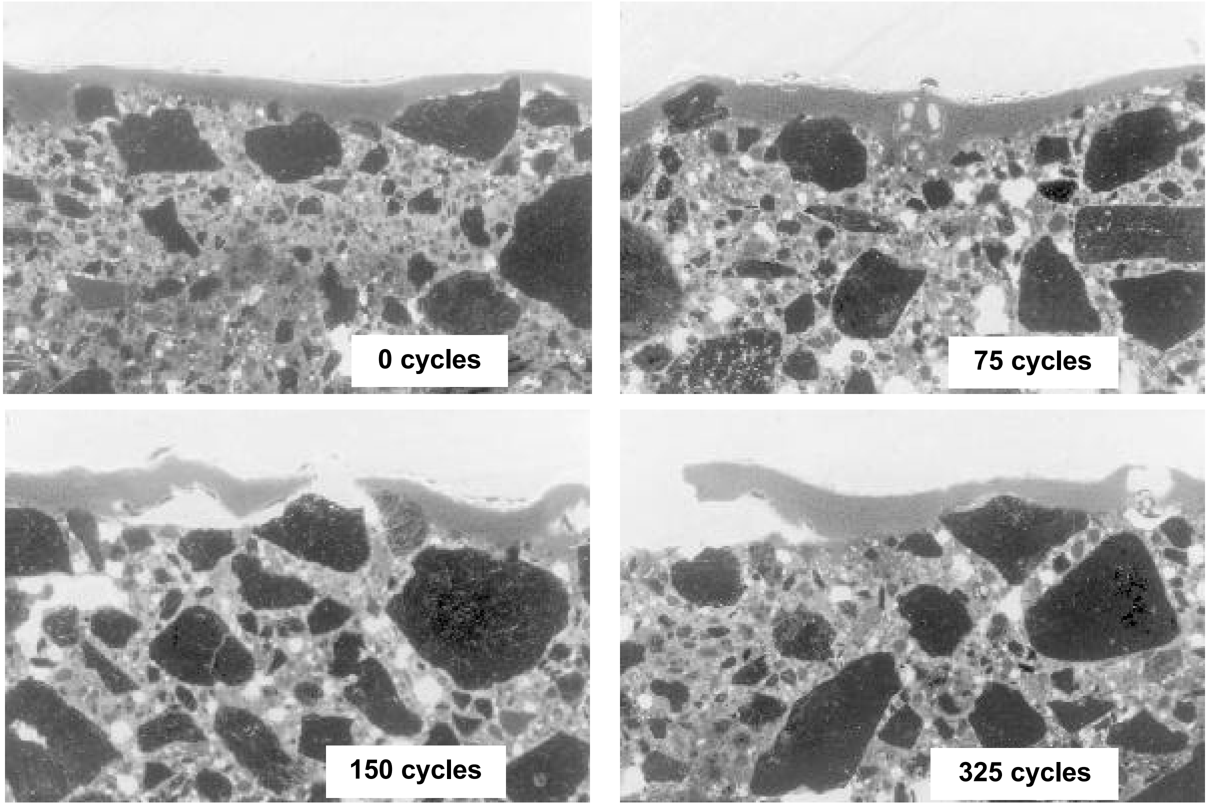

**Figure 10. Photomicrographies of the 40% PVC vinyl paint coating after 0, 75, 150 and 325 cycles. The largest dimension of the pictures corresponds to 2.7 mm.**

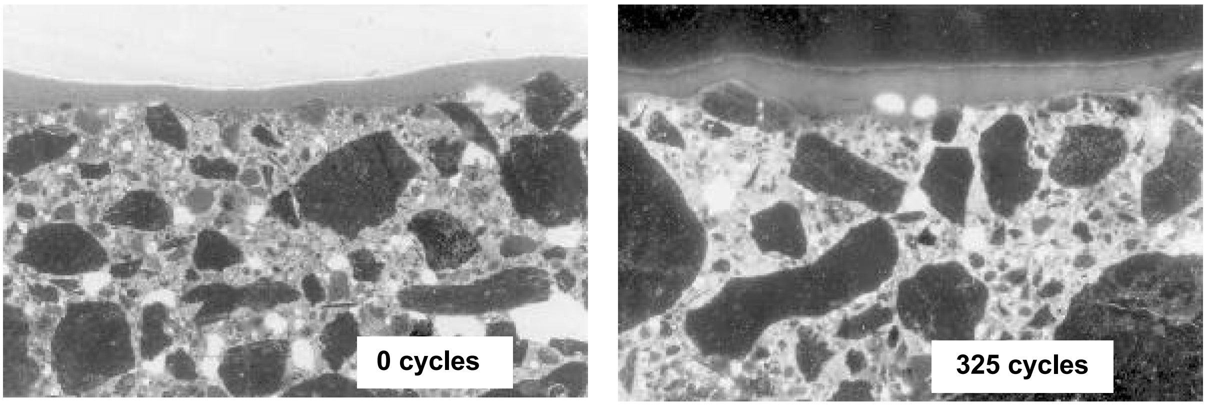

**Figure 11. Photomicrographies of a 40% PVC acrylic paint coating after 0 and 325 cycles. The largest dimension of the pictures corresponds to 2.7 mm.**

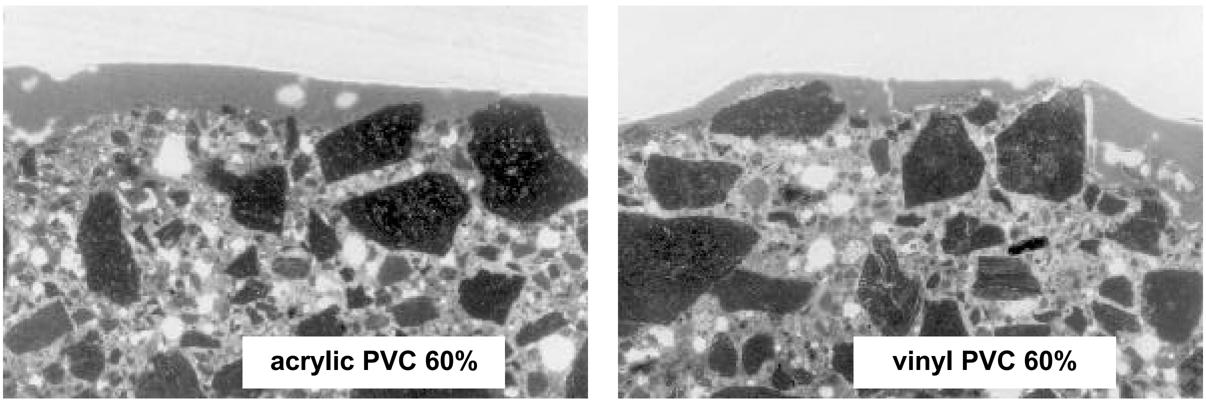

**Figure 12. Photomicrographies of a 60% PVC acrylic and vinyl paint coatings after 150 cycles. The largest dimension of the pictures corresponds to 2.7 mm.**

Go Back

By looking at the render, the quite large amount of air-entrained pores is standing out, which in all previous photomicrographies can be recognised as light structures. This feature has probably, strongly contributed to increase the resistance of the render to the many freezing and thawing cycles to which the specimens were exposed during weathering.

## 5 CONCLUSIONS

The results presented and discussed in the previous section proved that the weathering agents reproduced by the artificial weathering cycle have been able to induce significant degradation and/or alteration effects on the surface appearance of the wall specimens and on some of their physical and mechanical properties. Furthermore, for all the investigated properties, it was possible to determine the rate and the extent of change.

In particular, as shown by the results of visual inspection and of the microstructural analysis, the degradation of the vinyl paint develops with a higher rate than that of the acrylic paint. In addition, a lower pigment volume content helps to reduce the degradation rate.

The monitoring of the specimen weight and the determination of the water absorption capability of the paint/render system allowed pointing out the variable level of protection against water penetration provided by the different types of paint. In this regard, the acrylic paint proved to be better than the vinyl paint.

The experimental data presented in this paper are of course still not sufficient to predict the reference service life of the investigated building component. The data need to be compared and completed with those generated by field exposure, which is being conducted simultaneously in Lugano as well as in Milan, and with those which are going to be collected by in-use-conditions, accelerated exposure of the whole component. The results of field exposure will serve to check the realism of the effects resulting from accelerated exposure and for the re-scaling of the degradation rates, while those of in-use-conditions, accelerated exposure will be used to determine the minimum acceptable level of the component's critical properties.

## 6 ACKNOWLEDGMENTS

Thanks are due to the technical staff of the Laboratorio tecnico sperimentale for its invaluable work and to the colleagues of DISET in Milan for fruitful discussions.

# Reliability Of Timber Utility Poles Under Decay Attack

**X Wang GC Foliente C-H Wang & RH Leicester**
**CSIRO Infrastructure System Engineering Victoria Australia**

**Summary: Reliability prediction is crucial to condition assessment, maintenance and management of utility poles, and, therefore, also important in ensuring the delivery of critical services (e.g., electricity) to customers. In this paper, methodology to predict lifetime reliability of timber poles is proposed, along with the consideration of in-ground decay attack. As the first stage, climate data including dry-bulb temperature, rainfall, and wind speed from Bureau of Meteorology (BoM) are used to acquire local environmental conditions around timber poles and subsequently find their probability density function. Secondly, the climate information is then applied to establish in-ground decay models, as well as extreme wind loading models. The eventual wind loading on the poles is not only dependent on the geometric size of the poles, but also relevant to the conductors attached to the poles and the distribution of neighbour poles as well. Thirdly, a limit state function is considered in terms of bending failure at the foot of timber poles, and the deteriorated failure resistance due to decay is indicated. Finally, decay-related conditional survival probability at a specified time and the lifetime survival probability are introduced on the hypothesis of extreme wind loading following a Poisson's process. Examples of utility poles involving 4 classes of timber materials are used in the prediction of time-dependent probability density functions of bending failure resistance, and the calculation of lifetime survival reliability. Results are expected to provide more efficient and accurate tools to risk management of utility poles.**

**Keywords: Timber, wood, decay, time-dependent failure resistance, lifetime reliability, utility poles**

## 1 INTRODUCTION

The utility pole industry in Australia spends about $40-50 million p.a. in maintenance and asset management because the cost and consequences of failure are very high. In NSW alone, with the replacement of one timber pole costing between $1000 and $10,000, depending on the size and attached conductors, the total replacement cost could reach $2 billion. However, the current approaches are to some extent based on qualitative estimation and engineers' experience, and hence may not be reliable and cost effective. Application of more efficient and accurate tools to predict the service life or reliability of poles will certainly contribute to cost reductions in both the maintenance and management of utility poles. A reduction in maintenance costs by 20% for power companies alone would save approximately $8-10 million every year.

The majority of utility poles in Australia are timber poles. As data from Department of Energy in NSW, treated and untreated timber poles have 40% and 52%, respectively, of the whole population of poles in NSW between 1994 and 1995. This gives even more importance to have an effective methodology in reliability prediction and management of timber poles.

As shown in Figure 1, a management system for timber poles may start from the establishment of an extensive database, ranging from BoM climate data, timber properties such as modulus of rupture, network distributions of utility poles, and other design parameters related to poles and conductors. Based on the database, performance modelling, evaluation and prediction are conducted in association with decay characterisation and reliability analysis. It is aimed to determine service-worthiness of poles and find potential measures that may be taken into maintenance to improve the service-worthiness. As known, a better decision is made, not only to satisfy safety requirements, but also to be able to control costs under acceptable budgets. To achieve high reliability at low cost is always the major objective in the management system. After the stage of decision-making, optimised strategies are then implemented through inspection, maintenance and replacement of timber poles. Results are monitored to confirm the efficiency and feasibility of the strategies, and information is finally fed back to modify the database for further analysis.

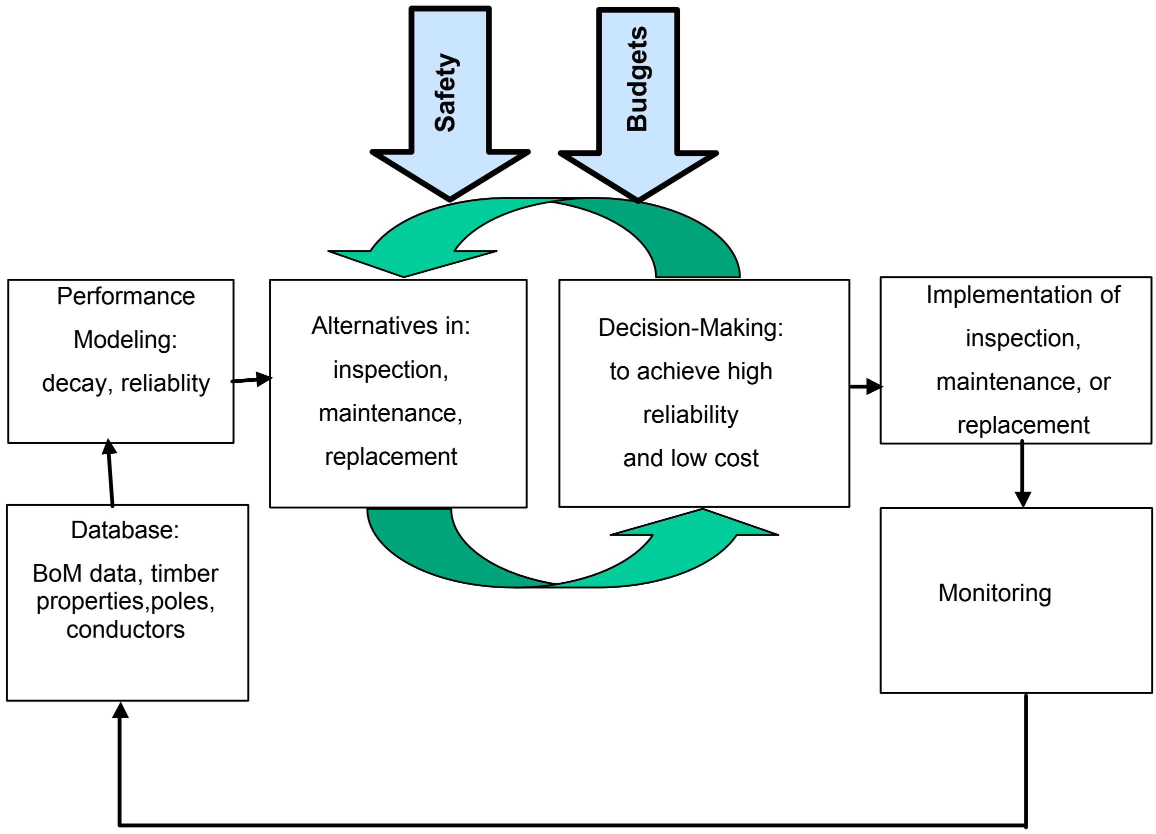

**Figure 1. A management system for utilities poles**

Undoubtedly, reliability analysis is the central issue in the risk-based management system. It is hence become a main subject discussed in this paper. To predict reliability of timber poles, three major factors need to be considered: loading, failure resistance and resistance deterioration.

Wind plays a significant role in the loading events applied on the poles and attached conductors, and it is considered as one of major factors causing poles to collapse. Wind load is dependent on the wind pressure, which is proportional to the wind speed as well as direction, both of which can be obtained from the data of BoM (Bureau of Meteorology). However, it is unnecessary to consider reliability based on all wind speed record. In current design procedures (ASCE, 1991), extreme wind speed is applied to estimate the nominal value that has a certain return period or occurrence frequency. The nominal value is then considered as a standard loading event in the reliability analysis. Therefore, understanding of distribution of the extreme wind speed is the first step to successfully predict the reliability of poles. It should be mentioned that the wind pressure is not only applied on the poles, but also applied on the conductors (cables) attached on the poles. The wind loading on the conductors along with the weight of conductors can produce a significant amount of concentrated force onto crossarms, and therefore, on the utility poles. The configuration of attached conductors and distribution of neighbour poles have also considerable effects on the wind-related loading. To some extent, loading events should be considered in a certain range of electricity distribution networks.

It is understood that timber materials are vulnerable to the attack of decay fungi and termites. Degradation of timber poles at the ground level has been one of the major concerns in the design and maintenance. As a direct consequence of decay attacks, the failure resistance constantly declines with service time. The rate of decay has been found to be mainly dependent on geographical location, timber species, preservative treatments, above- and in-ground climate index (Leicester et al., 2000; 2001). The climate index is proportional to the functions of yearly average temperature and yearly rainfall, both of which can be calculated from BoM data. Although calibration of decay models is still on the way in our Lab, it will not effect discussion about the methodology used to predict reliability of poles. However, the improvement of decay models can certainly increase the confidence of predicted results of reliability.

One of pivotal steps in the structural reliability analysis is to establish limit state functions, which are directly related to the loading events and failure resistance. The failure resistance is normally a random variable satisfying a probability density function such as normal and lognormal distribution, which can be determined from material property tests. Considering extreme wind events and related nominal values with certain return period, the survival or failure probability at a specified time – conditional survival/failure probability can be calculated by the use of Monte-Carlo simulation without difficulty. However, it is different from the lifetime survival/failure probability, which should account for the probability covering service life period, such as 10, 50 or 100 years for timber poles. When the occurrence of extreme wind events meets a Poisson's process in the time series, the lifetime survival/failure probability can be derived in terms of the conditional survival/failure probability and occurrence frequency of loading events. This is one of the most important parameters in the optimisation of risk-based management.

In the following, as examples of the methodology to analyse reliability of timber poles, lifetime survival probability of timber poles at four locations - Alice Spring, Darwin, Perth and Sydney of Australia, will be predicted, on the basis of local BoM data and timber decay models proposed in the paper.

## 2 RANDOM PARAMETERS IN RELIABILITY ANALYSIS

Temperature, rainfall, wind speed and direction are the main environmental conditions that have direct influence on the decay of timber poles and the loading on electricity transmission systems, and consequently on the structural limit state function and reliability analysis. Yearly rainfall and average temperature were suggested to be main factors in the modelling of decay of timber materials (Leicester et al., 2000; 2001), it is therefore important to understand the probability distribution of these two random climate elements. Also, the use of extreme value distribution of loading is often an effective method in the structural reliability analysis. It is imperative to calculate extreme wind speed distribution before extreme wind loads with a mean return period can be determined.

### 2.1 Yearly Average Temperature and Rainfall

From the data provided by BoM, the yearly average temperature in Alice Spring, Darwin, Perth and Sydney are calculated. The cumulative distribution functions at 4 locations are shown in Figure 2, fitted with normal distribution function which *m* (mean) and *s* (standard deviation) are given in Table 1.

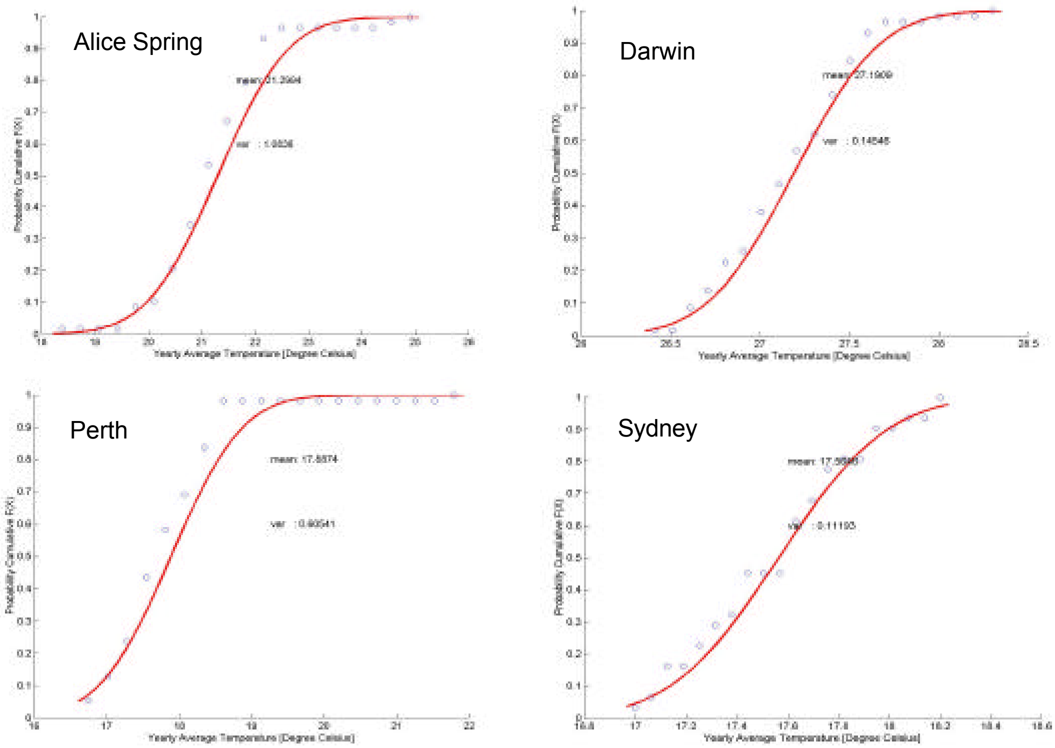

**Figure 2. Cumulative distribution function of yearly average temperature, fitted with normal distribution function.**

**Table 1. Parameters of the normal distribution function fitted to the yearly average temperature (°C) at four locations.**

| | Alice Spring | Darwin | Perth | Sydney |
|---|---|---|---|---|
| *m* | 21.30 | 27.19 | 17.89 | 17.56 |
| *s* | 1.041 | 0.3814 | 0.7781 | 0.3346 |

Yearly rainfall in Alice Spring, Darwin, Perth and Sydney can also be calculated from the BoM data. The cumulative distribution functions are depicted in Figure 3, and fitted with Weibull distribution function. Function parameters, *a* and *b*, are given in Table 2.

**Table 2. Parameters of the Weibull distribution function fitted to the yearly rainfall (mm)**

| | Alice Spring | Darwin | Perth | Sydney |
|---|---|---|---|---|
| a | $2.2189 \times 10^{-5}$ | $1.1123 \times 10^{-17}$ | $3.9899 \times 10^{-10}$ | $3.2158 \times 10^{-12}$ |
| b | 1.8537 | 5.1572 | 3.2264 | 3.7202 |

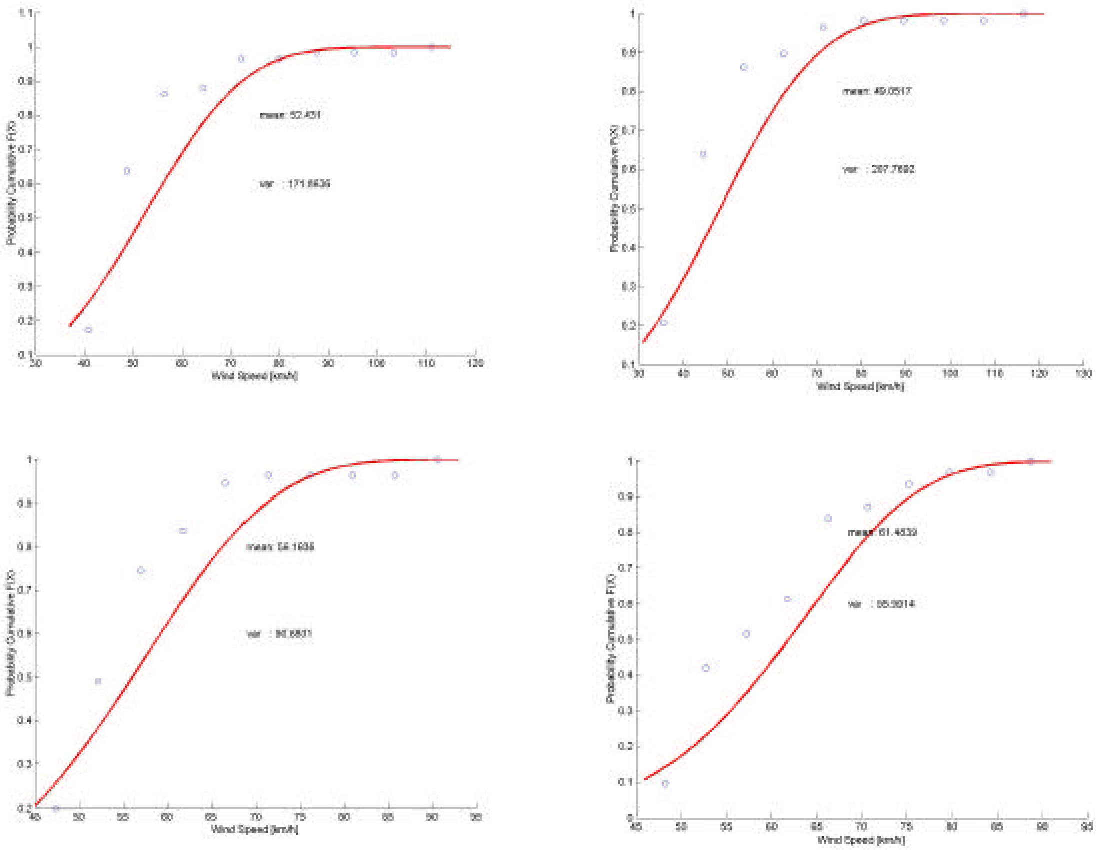

**Figure 3. The cumulative distribution functions of yearly rainfall, fitted with the Weibull distribution function.**

### 2.2 Extreme Wind Speed Distribution

In wind engineering, extreme value distribution of wind speed is normally estimated with the analysis of yearly-based data sets, which are also known as epochs (Simiu and Scanlan, 1996). Data set is described by $X \in X_1 \cup X_2 \cup \Lambda \cup X_n$, each of which has cumulative distribution function assumed to be $F_i$ ($i$=1, 2, …, $n$). When the cumulative distribution function of elements in the set are all same and independent as well, the distribution of the largest values of $n$ sets is then $F^n$ ($F_i$=$F$, $i$=1, 2, …, $n$), which is the extreme value distribution function.

From the data provided by BoM, the largest yearly wind speed recorded every 3 hours in Alice Spring, Darwin, Perth and Sydney can be obtained. The cumulative distribution function for the four locations are shown in Figure 4, and fitted with type II extreme value distribution function,

$$f_X(x|u,k) = \frac{k}{x}\left(\frac{u}{x}\right)^k e^{-(u/x)^k}$$
$$F_X^n(x|u,k) = e^{-(u/x)^k} \tag{1}$$

where parameters, $u$ and $k$, are given in Table 3. Also, from Eq.(1), the percent point function of type II extreme value distribution is given by,

Go Back Next Page

$$G_X(F_X^n) = u\left(-\log F_X^n\right)^{-\frac{1}{k}} \tag{2}$$

where

$$F_X^n = 1 - \frac{1}{N} \tag{3}$$

and $N$ is the mean return period or recurrence interval. For mean return period of 50 years, the 2 second gust wind speed are given in Table 4, where the multiplier 1.53 is used to convert 3 hourly speed to 2 second gust (ASCE, 1991).

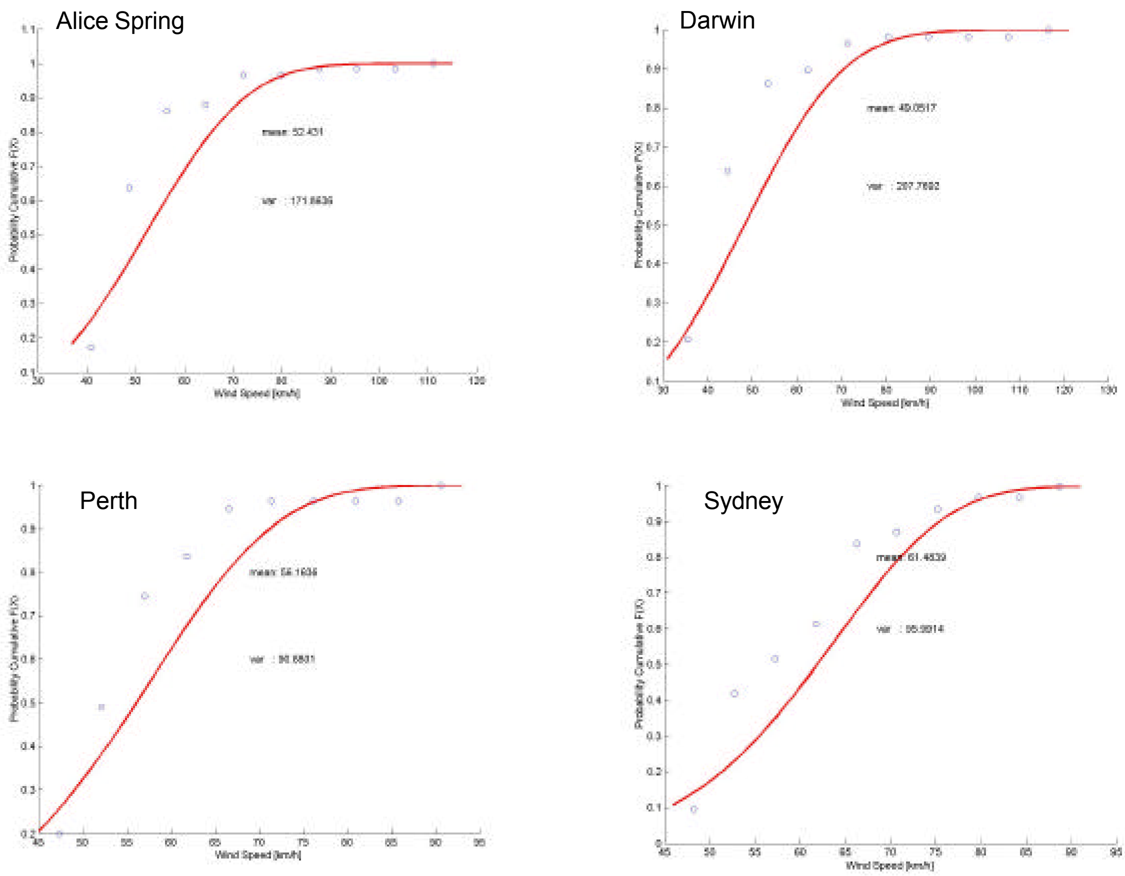

**Figure 4. The cumulative distribution function of extreme value of wind speed, fitted with type II extreme value distribution.**

**Table 3. Parameters of type II extreme value distribution functions fitted to the extreme wind speed from 3 hourly BoM records.**

| | Alice Spring | Darwin | Perth | Sydney |
|---|---|---|---|---|
| $u$ | 50.545 | 45.803 | 55.625 | 58.402 |
| $k$ | 8.946 | 7.5292 | 14.420 | 16.22 |

**Table 4. The extreme wind speed (km/h) at a mean recurrence interval of 50 years**

| Recurrence | Alice Spring | Darwin | Perth | Sydney |
|---|---|---|---|---|
| 50 years | 120 | 118 | 112 | 114 |

## 3 A MODEL FOR IN-GROUND DECAY OF TIMBER MATERIALS

As suggested by Leicester et al. (2000, 2001), the development of in-ground timber decay depth can be described by the following equation,

$$d_{decay} = \begin{cases} 0 & t \le t_{lag} \\ \dfrac{d_{20}}{20 - t_{lag}}(t - t_{lag}) & t > t_{lag} \end{cases} \tag{4}$$

where $t_{lag}$ is the lag time and $d_{20}$ is the decay depth at 20 years. For untreated heartwood, $d_{20}$ is given by,

$$d_{20,un,heart} = AI_{ig} \tag{5}$$

In Eq.(4) and (5), $t_{lag}$ and $A$ is described in Table 5.

**Table 5. Decay parameters for untreated heartwood timber.**

| Durability Class | A | $t_{lag,un,heart}$ |
|---|---|---|
| Class 1 | 3 | 6 |
| Class 2 | 7 | 4 |
| Class 3 | 11 | 2 |
| Class 4 | 30 | 1 |

$I_{ig}$ indicates the climate index, which is determined by,

$$I_{ig} = [f(R)]^{0.3}[g(T)]^{0.2} \tag{6}$$

where $f(R)$ and $g(T)$ are the functions of yearly rainfall and average temperature, and proposed to be,

$$f(R) = \begin{cases} 0 & \text{if } R \le 250\text{mm}, \\ 10[1 - e^{-0.001(R-250)}] & \text{if } R > 250\text{mm}, \end{cases} \tag{7}$$

$$g(T) = \begin{cases} 0 & \text{if } T \le 5^{o}\text{C}, \\ -1 + 0.2\text{T} & \text{if } 5^{o}\text{C} < T \le 20^{o}\text{C}, \\ -25 + 1.4\text{T} & \text{if } T > 20^{o}\text{C} \end{cases} \tag{8}$$

As a result of the assumption of Eq.(7) and (8), the occurrence probability of in-ground decay at the four locations is calculated, and results are then described in Table 6.

**Table 6. Occurrence probability of in-ground decay**

| Alice Spring | Darwin | Perth | Sydney |
|---|---|---|---|
| 0.544 | 1.000 | 0.977 | 0.997 |

## 4 .LIMIT STATE CRITERION

### 4.1 Loads Applied on Timber Poles

The utility pole can be considered as a cantilever beam with a circular cross section of diameter $d_p$. As shown in Figure 5, it is subject to a uniform pressure caused by wind loading as well as the concentration loads from tension of conductors that is induced by both wind load on the conductors and their own weight.

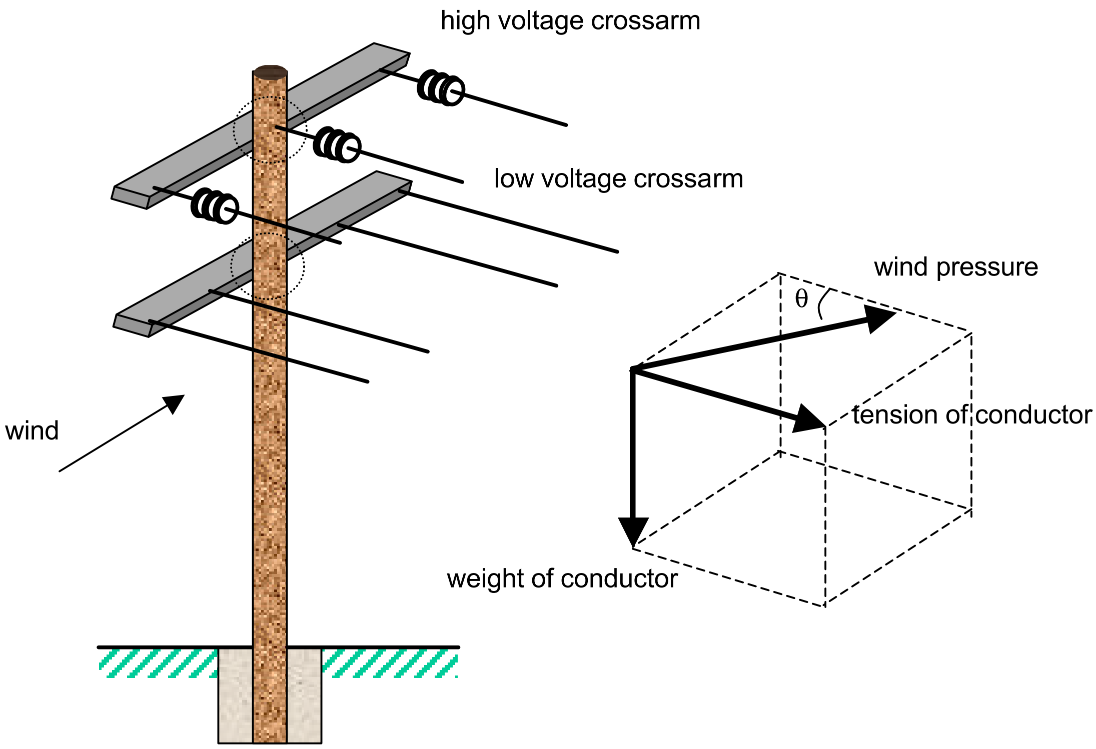

**Figure 5. A model of poles subject to wind loading and conductor weight.**

If we neglect the moment applied on the pole footing by the dead load due to the deflection of the pole, the moment are produced in terms of four parts,

- the wind pressure applied on the pole;
- the force, perpendicular to the direction of conductor cable, produced by wind loading on conductors;
- the force, parallel to the direction of conductor cable, contributed by the tension of conductors produced by wind loading; and
- the force, parallel to the direction of conductor cable, contributed by the tension of conductors produced by their own weight.

The wind pressure on the pole along the direction perpendicular and parallel to the conductor cables can be calculated, respectively, from,

$$\begin{aligned} F_{px} &= l_p d_p q \cos q \\ F_{py} &= l_p d_p q \sin q \end{aligned} \tag{9}$$

where $l_p$ is the length of the beam, and the wind pressure $q$ is determined by,

$$q = \frac{C_D}{2} r U^2 \tag{10}$$

and $C_D$ is the drag coefficient of the wind loading and equal to 1.20 for the beam with circular cross-section at a low Reynolds number (Simiu and Scanlan, 1996), $r$ is the air density, $U$ is the two-second gust wind speed discussed in the last section.

The concentrate force, produced by wind loading on conductors and applied on the poles along the direction vertical to the conductors, can be calculated by,

$$F_{cy} = \frac{1}{2} q d_c l_c \tag{11}$$

where $l_c$ is the terminating span of conductors, and $d_c$ is the diameter of the conductors. The concentrate force, produced by wind-load and weight induced tension, and applied on the pole along the direction parallel to conductors, can be calculated by,

$$F_{cx} = \frac{q_t d_c l_c^2}{8h_{mid}} \tag{12}$$

where $h_{mid}$ is the sag at the mid-span of conductor cables, and

$$q_t = q\sqrt{1+\left(\frac{r_c}{qd_c}\right)^2} \tag{13}$$

$r_c$ in Eq.(13) is the weight per length of conductor cables. As a consequence, the maximum of the moment applied on the foot of poles can be given by,

$$M_{\max} = \sqrt{\left(\frac{l_p F_{px}}{2} + \sum_i l^{(i)} F_{cx}^{(i)}\right)^2 + \left(\frac{l_p F_{py}}{2} + \sum_i l^{(i)} F_{cy}^{(i)}\right)^2} \tag{14}$$

where $i$ indicates the $i$-th crossarm, and $l^{(i)}$ and $F^{(i)}$ describe the related location and concentrated force.

### 4.2 Limit State Function

The limit state criterion of bending structural components can be described by,

$$g(MOR, d_{p-decay}, M_{\max}) = R(MOR, d_{p-decay}) - M_{\max} > 0 \tag{15}$$

Where $MOR$ is the Modulus of Rupture (MOR), $M_{max}$ is the maximum moment applied on structures, $R(MOR, d_{p-decay})$ is the bending failure resistance, dependent on initial $MOR$ and the decayed diameter. For timber poles with a circle cross-section, the resistance is expressed by,

$$R(MOR, d_{p-decay}) = MOR\frac{pd_{p-decay}^3}{64} \tag{16}$$

where $d_{p\text{-}decay}$ indicates the diameter of poles under decay attack, given by,

$$d_{p-decay} = \begin{cases} d_p & t \le t_{lag} \\ p\left[d_p - \dfrac{AI_{ig}}{20-t_{lag}}(t-t_{lag})\right] + (1\text{-}p)d_p & t > t_{lag} \end{cases} \tag{17}$$

and $p$ is the occurrence probability of decay at a specified location. From Eq.(16) and (17), obviously, the bending resistance is deteriorated with the occurrence of decay, and it declines with the service time.

## 5 LIFETIME SURVIVAL PROBABILITY OF TIMBER POLES

It is assumed that an extreme wind-loading event, $E$, has wind direction as well as occurrence within $(0, t_L]$ satisfying uniform probability distributions. As a result, the survival probability over period of $t_L$ is given by,

$$P[g(MOR, d_{p-decay}, M_{\max}; t_L) > 0] = \frac{1}{2pt_L}\int_0^{t_L} F_S^q\left(R(MOR, d_{p-decay}), M_{\max}; t\right)dt \tag{18}$$

where

$$F_S^q(t) = \frac{1}{2p}\int_0^{2p} F_S\left(R(MOR, d_{p-decay}), M_{\max}; t, q\right)dq \tag{19}$$

and $F_S$ is the survival probability at specified time and wind direction.

If there are $n$ independent wind-loading events, $E_i$ ($i$=1, 2, …, $n$), with an identical cumulative distribution function, $F_S$, in the period of $(0, t_L]$, the survival probability of timber poles is expressed by,

$$P[R(t_1) > 0 \,\mathrm{I}\, \ldots \mathrm{I}\; R(t_n) > 0] = \left[\frac{1}{2p\; t_L}\int_0^{t_L}\int_0^{2p} F_S\left(R(MOR, d_{p-decay}), M_{\max}; t, q\right)dq\; dt\right]^n \tag{20}$$

To consider a filtered Poisson process where the number of events, $n$, satisfying a Poisson process (Mori and Ellingwood, 1993), and assume $MOR$ with probability density function of $f_{MOR}(r)$, the lifetime reliability function then becomes,

$$L(t_L) = \int_0^{\infty} \exp\left( -\lambda t_L \left[ 1 - \frac{1}{2\pi\, t_L} \int_0^{t_L} \int_0^{2\pi} F_S\left( R(MOR, d_{p-decay}), M_{\max}; t, \theta \right) d\theta\, dt \right] \right) f_{MOR}(r) dr \qquad (21)$$

where λ is the occurrence rate of extreme wind loading. The failure probability can be calculated easily from,

$$F(t_L) = 1 - L(t_L) \qquad (22)$$

# 6 EXAMPLES TO PREDICT LIFETIME SURVIVAL PROBABILITY

## 6.1 Material Properties and Other Parameters

As an example, the electrical timber pole is shown in Figure 6. MOR and geometric of timber poles is indicated in Table 7. Parameters about conductors attached on the poles are described in Table 8. 2-second gust wind speed at the four locations follows Table 4, and the occurrence probability of decay in Table 6.

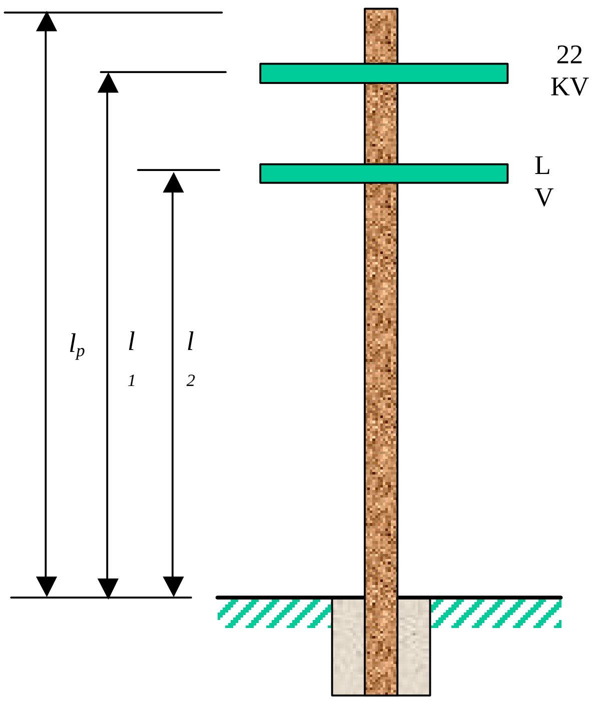

**Figure 6. Electrical timber poles with 22 KV and LV transmission lines**

**Table 7. Timber properties and parameters used in the simulation**

| **MOR [MPa]** | | Length $l_p$ [m] | **Diameter $d_p$ [m]** |
|---|---|---|---|
| **mean** | **Cov** | | |
| **160** | **0.1** | **10.2** | **0.35** |

**Table 8. Conductor properties and parameters used in the simulation**

| Voltage | Conductor | Number | Diameter $d_i$ [mm] | Linear Weight $r_i$ [N/m] | Location $l_i$ [m] | Span $l_c$ [m] |
|---|---|---|---|---|---|---|
| 1: 22 KV | 19/3.25AAC | 3 | 16.25 | 4.25 | 9.7 | 31 |
| 2: LV | 19/3.25AAC | 4 | 16.25 | 4.25 | 9.2 | 31 |

### 6.2 Bending Failure Resistance

Probability density function of the bending failure resistance can be calculated from Eq.(15) with the use of Monte-Carlo simulation. When MOR is assumed to follow a normal distribution function, the probability density function for 4 classes of timber materials in Darwin are shown in Figure 7.

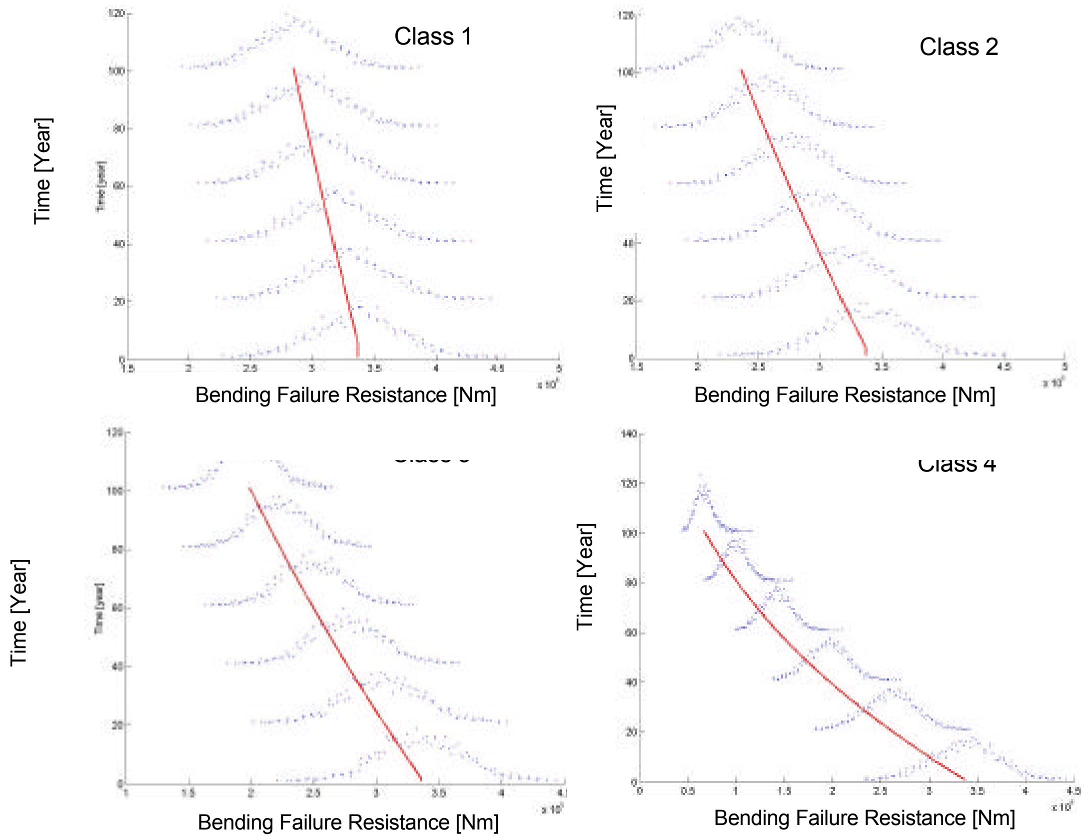

**Figure 7. The probability density function of bending failure resistance of 4 classes of timber materials. Location: Darwin.**

The probability density functions at other locations have a similar phenomenon. For Class 1 of timber materials, the deterioration is mostly shown in the shift of the distribution function to a lower level – reduction of the mean value. Whereas, for Class 4 of timber materials, the deterioration is displayed not only in the shift of the functions, but also in their shapes, which imply the change of the variation of the resistance.

### 6.3 Survival Probability

The conditional cumulative distribution functions of survival probability, $F_S^q(t)$, at specified time for 4 classes of timber poles at Alice Spring, Darwin, Perth and Sydney are shown in Figure 8. The lifetime survival probability, $L(t_L)$, is shown in Figure 9. As we can see from the figures, the poles made from class 4 timber materials are the most vulnerable to the decay attack. The timber poles at Darwin displays deterioration of reliability earlier than others for all 4 classes of timber materials. It is interesting to note that although the timber poles at Alice Spring shows earlier deterioration than Perth and Sydney due to the higher 2-second gust wind speed loading, the poles at the late two locations display more rapid deterioration than Alice Spring because of the relatively higher decay rate in both Perth and Sydney. Therefore, a higher design standard of timber poles at Perth and Sydney, particularly at Darwin, is required. It should be mentioned that lifetime survival probability plays a significant role in the optimisation of risk-based lifecycle maintenance strategies and management. This will be discussed in the later work.

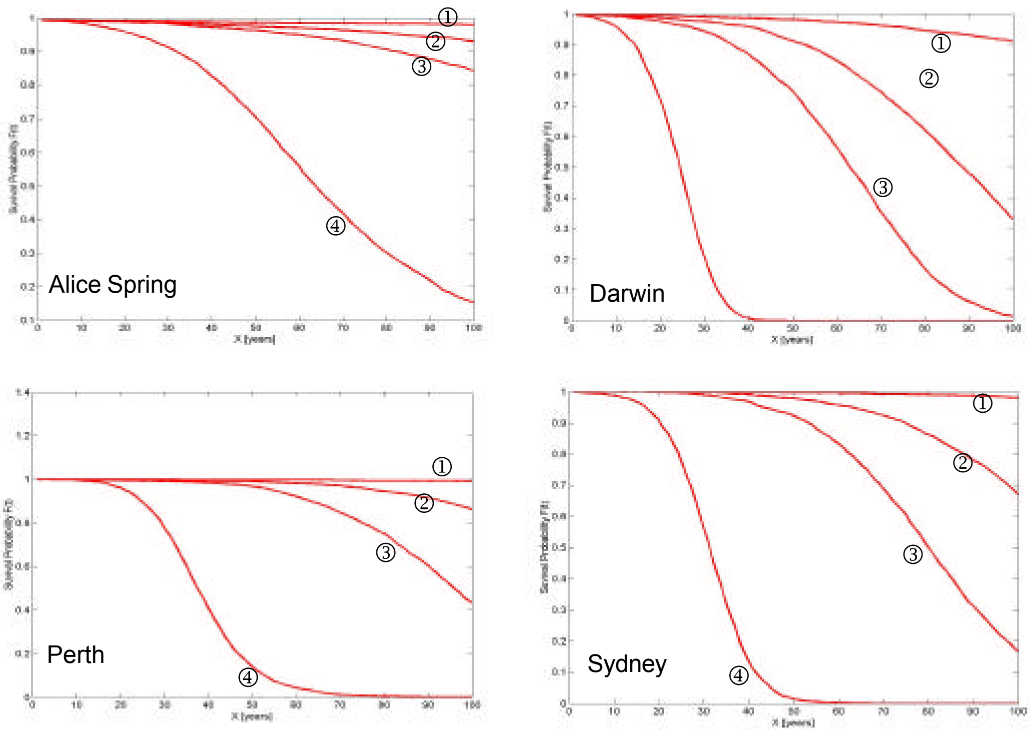

**Figure 8. Conditional cumulative distribution function of survival probability $F_S^q(t)$ with respect to the specified time for 4 classes of timber poles.**

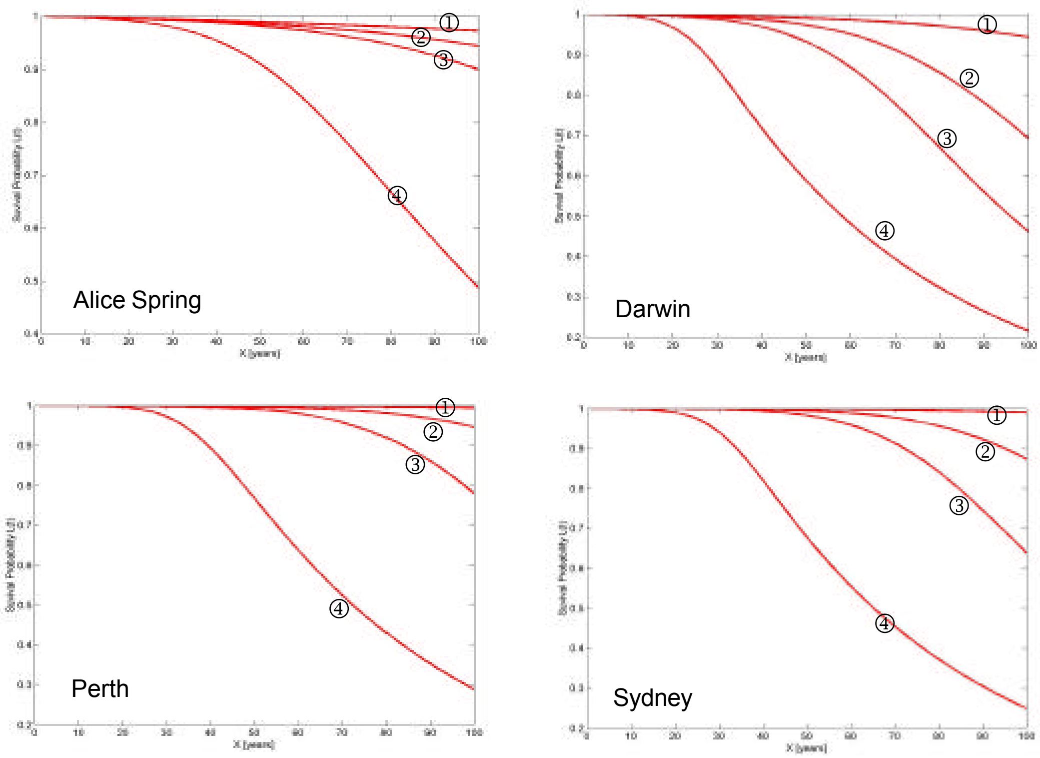

**Figure 9. Lifetime survival probability, L(tL), with respect to the time period for 4 classes of timber poles.**

## 7 CONCLUSIONS

As a consequence of growing aging and deteriorating timber poles, decisions have to be made in the management to determine if the deteriorated utility poles can maintain service above an acceptable reliability level without repair, with preventive maintenance at less cost to reduce deterioration growth, or with replacement to recover deteriorated reliability. The central point of the management is the reliability evaluation and prediction of existing or new utility poles at certain constraints. With the predicted lifetime reliability, optimal maintenance strategies can then be identified to minimise cost in a lifecycle view.

In this paper, a methodology to predict lifetime reliability of timber poles is proposed, considering the structural deterioration in the presence of in-ground decay. Climate data from BoM, including dry-bulb temperature, rainfall, wind speed are used to obtain local environmental conditions around timber poles and subsequently find their probability density function. With the results from BoM, an in-ground decay model as well as an extreme wind loading model are established. It is important to obtain information about poles network distribution and conductors attached onto the poles before calculating eventual loading applied on the poles. Based on the decay and loading models, a limit state function considering bending failure is derived. Finally, the lifetime survival probability is formulated, and applied to timber poles with 4 different classes of decay resistance.

It should be mentioned that the models and predictions were established based on the previous data record. When new information becomes available, all models and prediction can be updated by the use of Bayesian theorem. This will show in our late work.

# Biodeterioration Of Gypsum - Counter Scrap Composites

**CS Kazmierczak ME Silva**
**Centro de Ciências Exatas e Tecnológicas São Leopoldo Brazil**

**Summary: This paper describes the results of a research study on the biodeterioration of a composite of gypsum and shoe counter scrap pieces. This composite was developed as part of a research program to study the feasibility of recycling of shoe counter scraps. Biodeterioration tests were made to identify some potential durability problems that would affect this material during its service life.**

**The main objective was to determine the influence of microbiological growth in the composite durability. A selection of fungi believed to have the ability to interact with these materials was made and the composite was exposed to them using two different methodologies: BDA cultures and tropical chamber cultures. Mechanical properties of the composite samples were measured before and after fungal growth.**

**This work complements a previous study on counter scrap pieces, where results indicated that some microbiological growth is expected, but no reduction on mechanical properties is to be found.**

**Keywords: Biodeterioration, composites, gypsum, shoe counter scrap.**

## 1 INTRODUCTION

This paper presents the results of a research on the durability of a gypsum and shoe counter scrap composite that was produced in a study of the feasibility of recycling shoe counter scrap. The counter is one of the components used in the manufacture of shoes, lending structural support to the shoe. It is produced by impregnating or laminating sheets with ethylene-vinyl-acetate based resins. The amount of waste material generated in the counter piece manufacturing process amounts to 13% to 25% by weight of raw material depending on the shape and model of counter piece produced. Estimates for the total amount of counter scrap generated in this region run at 80 metric tons monthly. According to manufacturers, currently technology available and costs do not make the industrial reuse of this material feasible.

The new construction material is obtained by adding shoe counter scrap, after cutting in a knife mill, to calcium sulfate hemihydrate matrixes. A new composite is then produced by adding scrap to the gypsum paste. The scrap behaves like a fiber and in this way improves some mechanical properties of the composite, with resulting changes in physical properties (Kazmierczak et al. 2000a).

However, in addition to determining the mechanical properties of the composite, it is necessary to study the phenomena affecting the durability of this material. This analysis requires the knowledge of the chemical properties and microstructure of this new material, as well as the knowledge of the characteristics of the environment this material will be exposed in order to allow the identification of any potential degradation agents. In this paper, the main objective was to determine the influence of microbiological growth in the composite durability, based on the mechanical properties of the composite samples before and after fungal growth.

## 2 MATERIALS

The gypsum matrix used was slow hardening calcium sulfate hemihydrate from the state of Pernambuco (Brazil). The hardening onset is after 22 minutes and it is over after 35 minutes.

Counter pieces are produced by impregnating sheets (IC) or laminating sheets (LC) with EVA-based resins. The two kinds of scrap materials are classified under the Brazilian Standard NBR 10004 as “class II waste – non-inert material”. The main difference between the two materials lies in the type of substrate.

Go Back Next Page

The tensile strength of the counter is anisotropic and ranges from 9.3MPa to 24MPa. Water absorption is lower than 3% on average for the laminated counter and ranges from 40 to 60% for the impregnated material. After the scrap has been ground, however, these values rise significantly and vary according to the particle size obtained. Specific gravity for laminated counter pieces ranges from 0.4 to 0.7g/cm$^3$.

Figures 1 and 2 show the two types of sheets.

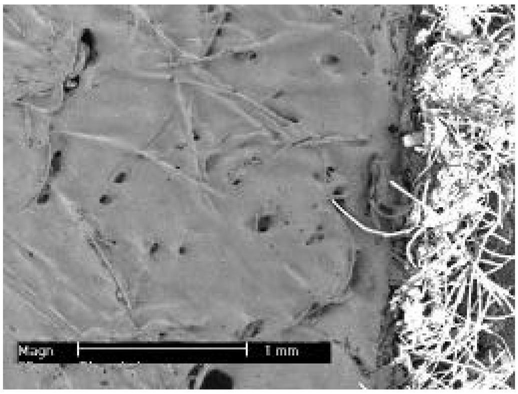

**Figure 1. SEM image of the impregnated counter scrap (IC).**

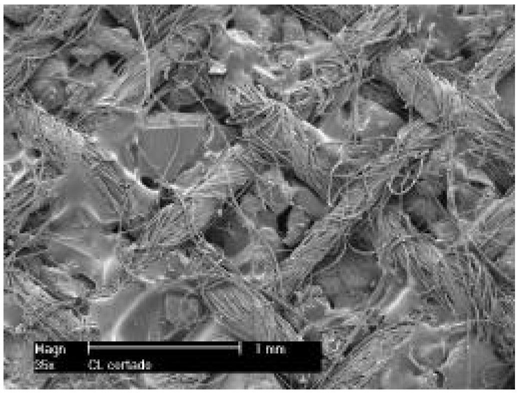

**Figure 2. SEM image of the laminated counter scrap (LC).**

The difference between these materials lies in the base material used in their manufacture. IC uses a non-woven fabric made up by randomly arranged fibers, while LC uses a woven film made up by intertwined threads that form a structuring base (fabric). After grinding, the counter displays a large number of non-oriented fibers due to the maceration of the impregnating resin and the original structure of the material is changed completely.

## 3 DURABILITY-RELATED ASPECTS

The materials used in the civil construction sector are usually exposed to complex degradation mechanisms, which can be external to the material (the environment around them) or determined by their structural characteristics. Any assessment of durability properties should be based on the precise characterization of the environment where this material will be used. In this study, the specification of requirements was made considering the use of this material in dry walls, which are not subject to harsh weather conditions.

As this material is made up by different components, the interactions between its components and the synergy of the degradation processes must be analyzed since these may result in new degradation mechanisms.

Previous studies (Kazmierczak et al. 2000b) determined the compatibility of the composite materials. This study was based on the chemical identification of the scrap constituents and their compatibility with gypsum. SEM analysis of one-year-old composite samples shows no visible signs of surface degradation of the fibers in the scrap surface, being a strong indication that the composite materials are compatible.

Figure 3 show an example of LC fibers involved by gypsum crystals with no signs of degradation.

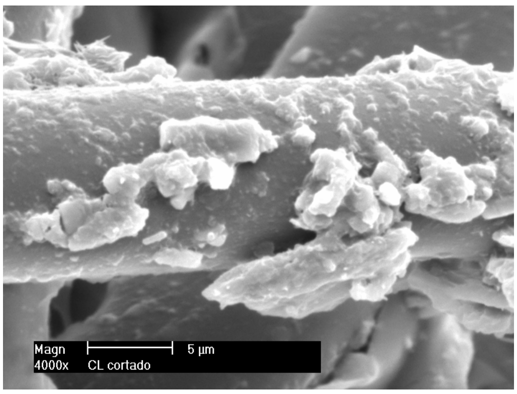

**Figure 3. SEM image of one-year-old LC fibers surrounded by gypsum crystals.**

Biodeterioration studies were carried out (Kazmierczak et al. 2000c) to identify the types of filamentous fungi that can grow in counters and their potential as deterioration agents, as well as to study alternatives to inhibit this process. The durability analysis was restricted to the counter scrap pieces because the development of a final product is not part of this study. Here, a selection of fungi believed to have the ability to interact with these materials was made, based on bibliographic sources and the identification of contamination agents in the counter scrap production process. The composite was exposed to them using two different methodologies: BDA cultures and tropical chamber cultures. The following fungi were used: *Aspergillus niger, Aspergillus flavus, Cladosporium, Gliocladium, Nigrospora, Penicillium, Rhizopus and Trichoderma.*

Stains were found in all the moist chamber samples, and the most representative species of fungi isolated were *Trichoderma* and *Penicillium*. Fungal growth can be explained by the increase in humidity and temperature levels combined with the increase in fungal dosage. It is believed that the staining was produced by the degradation of the resin or thermoplastic material and not of the fibers, which would be seen in the electron scanning microscope images. Samples of LC and IC are compared and a more expressive fungal growth is observed on the LC.

In the present study, the analysis is performed in the composite. The tests aim to check the effect of fungi on the tensile strength of fibers, which was not investigated before. The fungi used are the same listed above.

## 4 BIODETERIORATION STUDIES

### 4.1 Methods and materials

The study was performed using sets of four test specimens with scrap additions of 10 and 20% and water/gypsum ratio = 0.57. The test specimens were prepared with laminated counter scrap with a fineness modulus of 4.3. A series of control specimen tests, with no addition of counter scrap, was prepared.

The flexural strength in the composites was tested according to ASTM C78-94. Test specimens measuring 16cm x 4cm and 2cm thick were used to assess changes in the elastic properties of the composite as a result of fungal growth.

The fungi were isolated in a potato-dextrose-agar medium (PDA). The morphology of the vegetative and reproductive structures of the fungi was observed in an optical microscope and they were identified with the aid of a classification scheme (Barnett & Hunter 1972).

Samples of each composite were placed in a moist chamber with a 2cm deep soil layer and kept at $25\pm1^{o}$C at relative humidity of 70% with a photoperiod of 12h for 2 months. After this period, the flexural strength of the samples was determined.

### 4.2 Results and discussion

After the 8th day of incubation in the moist chamber, stains in the soil layer and in the samples produced by the fungi were observed. During the exposition, the surface area attacked by the fungi increased. At the end of the period of incubation all samples (even those without scrap) showed stains on the surface. The samples that showed more expressive fungal growth were those with scrap and w/g = 0,6.

The surface degradation in the control samples were used to estimate the extent of the incubation period in the moist chamber. It is believed that, considering the environment where this material will be used (in dry walls, not exposed to harsh weather conditions) this degree of degradation will not occur during the service life of these materials.

Concerning the flexural strength behavior of this material, preliminary studies (Kazmierczak et al. 2000a) demonstrate that the scrap added to a matrix has a fiber-like behavior and improves the ductility of the matrix and changes its flexural strength behavior. The addition-free gypsum matrix shows a sudden break, but the test specimens with the addition of scrap had considerable plastic deformation and became more ductile.

The flexural strength and mean results for each series of specimens tested are shown in Table 1.

Series with 0.6 and 0.8 water/gypsum ratios and no scrap addition (reference) displayed distinct performances. While fungal growth did not cause the flexural strength in the series with 0.8 water/gypsum ratios to change, the series with w/g = 0.6 showed an increase. This effect seems to be caused by an elongation of the gypsum hydration process during the period of incubation in the moist chamber.

**Table 1. Flexural strength results for each test specimen series before and after fungal growth**

| laminated counter samples composite | reference (fungi-free) | | after fungal growth | |
|---|---|---|---|---|
| | flexural strength (MPa) | average (MPa) | flexural strength (MPa) | average (MPa) |
| | 0.4 | | 1.0 | |
| control ( no scrap addition ) | 0.4 | 0.4 | 0.6 | 0.8 |
| w/g = 0.6 | 0.3 | | 0.7 | |
| | 0.4 | | - | |
| | 2.0 | | 2.4 | |
| control ( no scrap addition ) | 2.9 | 2.0 | 2.0 | 1.9 |
| w/g = 0.8 | 1.2 | | 1.4 | |
| | - | | - | |
| | 2.4 | | 1.3 | |
| scrap addition: 10% | 1.9 | 2.0 | 2.4 | 2.0 |
| w/g = 0.6 | 2.2 | | 1.9 | |
| | 1.6 | | 2.2 | |
| | 1.5 | | 1.1 | |
| scrap addition: 10% | 1.6 | 1.5 | 1.3 | 1.3 |
| w/g = 0.8 | 1.5 | | 1.3 | |
| | 1.4 | | 1.3 | |
| | 2.3 | | 2.3 | |
| scrap addition: 20% | 2.3 | 2.2 | 2.5 | 2.2 |
| w/g = 0.6 | 2.0 | | 1.9 | |
| | 2.2 | | 2.1 | |
| | 1.3 | | 1.3 | |
| scrap addition: 20% | 1.3 | 1.4 | 1.3 | 1.3 |
| w/g = 0.8 | 1.4 | | 1.3 | |
| | 1.5 | | 1.2 | |

The effect of fungal growth on the flexural strength of the composite can be seen in Figure 4. Flexural strength decreases in the series with w/g = 0.8 but shows no change in the series with w/g = 0.6. The different behavior in the series with different w/g relationship can be explained by the fact that the control samples with w/g = 0.6 showed increased flexural strength.

The difference in flexural strength after fungal growth was not significant (the highest decrease in strength was 13%).

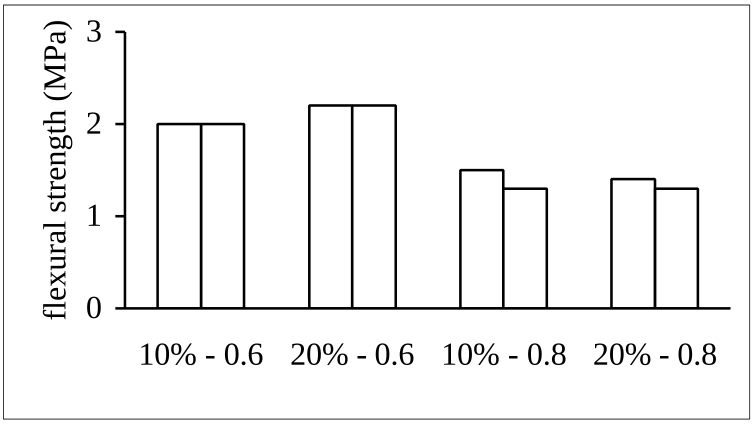

**Figure 4. Mean values of flexural strength of the series tested before (left) and after (right) incubation in the moist chamber.**

## 5 FINAL REMARKS

The assessment of the durability of the new composite made with gypsum and counter scrap was based on the knowledge of the chemical properties and microstructure of this new material, as well as the knowledge of the characteristics of the environment to which this material will be exposed.

The main objective of this study was to determine the influence of microbiological growth in the durability of this composite, based on the flexural strength of the composite samples before and after fungal growth.

Results indicate that some microbiological growth is expected, but no significant reduction on mechanical properties is to be found.

# Durability And Performance Characteristics Of Recycled Aggregate Concrete

KK Sagoe Crentsil T Brown AH Taylor
CSIRO Building Construction and Engineering Victoria Australia

**Summary: In recent years, the recycling of concrete to produce aggregates suitable for non-structural concrete applications is emerging as a commercially viable and technically feasible operation. In this paper, we report on performance and durability tests carried out to determine the fresh and hardened properties of concrete made with commercially produced coarse recycled concrete aggregate and natural fine sand. Test results indicate that the difference between the characteristics of fresh and hardened recycled aggregate concrete and natural aggregate concrete is relatively narrower than reported for laboratory-crushed recycled aggregate concrete mixes. For concrete without blast furnace slag, having similar volumetric mix proportions and workability, there was no difference at the 5% significance level in concrete compressive and tensile strengths of recycled concrete and control normal concrete made from natural basalt aggregate and fine sand. Water absorption rates and carbonation of recycled concrete and reference concrete were comparable. However, the abrasion loss of recycled aggregate concrete made with ordinary Portland cement increased by about 12% compared to normal concrete, while the corresponding drying shrinkage was about 25% higher at one year.**

**Long-term performance results generated from field case studies involving the construction of a 120 m long bicycle/footpath with a 40 m recycled aggregate concrete (RC) segment are discussed. The paper further discusses observed fresh and hardened concrete properties of both recycled and conventional aggregates, and examines specific implications for satisfactory performance of the recycled product for recreational and non-structural construction applications.**

**Keywords: Aggregates, compressive strength, concrete, durability, recycling.**

## 1 INTRODUCTION

Intensive global R&D effort conducted over the last few decades demonstrates the potential viability of recycled concrete aggregate (RCA) as a concreting material (Hansen 1992; Sri Ravidrarajah *et al*. 1987; Sagoe–Crentsil *et al*. 1996). Notwithstanding what has been achieved, there still exists a scarcity of durability performance and engineering data on the serviceability of construction works incorporating recycled aggregates. This situation has arisen because, until recently, the use of crushed concrete derived from building demolition has been restricted to granular sub-base layers in road pavements, and drainage or excavation fill applications, rather than the production of new concrete. However, the emergence of new crusher technologies, including rubble processing, grading and aggregate washing equipment, together with tighter regulation of the recycling industry (Topcu 1997), have contributed to significant improvements in the quality of recycled concrete aggregate products.

While studies on the engineering properties of concrete made with laboratory-crushed recycled concrete aggregate abound (Frondistou–Yannas 1980; Hansen & Narud 1983), only limited data is available on commercial grade recycled concrete aggregate, including concrete mix proportions, fresh concrete performance and durability characteristics. Technical consideration for the use of recycled aggregates in premix concrete production, however, is strongly dependent on achieving satisfactory fresh and hardened concrete performance. Thus, this paper evaluates aspects of recycled concrete durability and field performance based on commercial production of N25 (25 MPa) grade premix concrete for recreational construction works.

## 2 LABORATORY TESTS

A single source of commercially graded unwashed coarse RCA and natural fines was used in all recycled concrete mixes. The natural coarse aggregate used in the reference mixes was a nominal 14 mm crushed basalt. The grading of the basalt and the coarse RCA conformed to the requirements of AS 2758.1 (Standards Australia 1998), as shown in Table 1. A fine to coarse aggregate ratio of 46:54 was kept constant throughout the test program for all concrete mixes. The RCA was batched in the as-received state. Details of the physical properties of both aggregates are shown in Table 2.

Ordinary Portland cement (Type GP) and blast furnace slag cement (Type GB) comprising 65/35 Portland cement/blast furnace slag were used in the investigations. The slag blend was used partly to assess the possible improvements in fresh concrete cohesion, workability and concrete performance.

## 2.1 Concrete mixes

Several preliminary trial mixes were prepared to evaluate water requirements for a nominal 25 MPa concrete. Mix proportion data is given in Table 3. The unit water content of the concrete was corrected for free moisture in the aggregates. However, the recycled aggregate was presaturated for 10 minutes in the mixer and brought to room temperature prior to mixing the concrete. The mixes were proportioned to have a nominal binder content of 240 kg/m$^3$ for mixes C0912A, C0912B and C1212A, while mix C1212B contained an additional 5% cement to assess the effect of increased cement content. Slag cement was used in mix C1212A.

The water/binder ratio (W/B) of all mixes was adjusted to achieve comparable consistency and a nominal slump of 80 ± 15 mm. A reduction in the water requirement was attained by using a lignosulfate-based water-reducing admixture at nominal doses recommended by the manufacturer. The recycled concrete mixes contained 100% recycled aggregate and natural fine sand, while the normal concrete mixes contained all natural coarse and fine aggregates.

**Table 1. Sieve analysis of coarse RCA and basalt aggregate**

| *Coarse aggregates* | *Percentage of mass passing through sieve (mm)* | | | | | | |
|---|---|---|---|---|---|---|---|
| *Maximum size (mm)* | *19* | *13.5* | *9.5* | *6.7* | *4.75* | *2.36* | *150 mm* |
| RCA | 100 | 91.4 | 28.7 | 7.6 | 5.4 | 0.2 | 0.5 |
| Basalt | 100 | 84.0 | 43.7 | 5.6 | 2.1 | 1.0 | 0.2 |

**Table 2. Properties of RCA and basalt aggregate**

| *Property* | *RCA* | *Basalt* |

| Aggregate crushing value (%) (AS 1141.21) | 23.1 | 15.7 |
| Bulk density (kg/m$^3$) (AS 1141.6) | 2394 | 2890 |
| Water absorption (%) (AS 1141. 6) | 5.6 | 1.0 |
| Impurity level (%) (AS 1141. 32) | 0.6 | <0.1 |
| LOI (%) | 4.9 | 1.3 |

**Table 3. Mix designation and mix details of concrete specimens**

| *Mix designation* | *Binder loading (kg/m$^3$)* | *Binder type* | *W/B* | *Slump (mm)* | *Wet density (kg/m$^3$)* | *Entrapped air content (%)* | *Coarse aggregate* |
|---|---|---|---|---|---|---|---|
| C0912A (*OPC/basalt*) | 242 | Type GP | 0.76 | 90 | 2466 | 2.4 | Basalt |
| C0912B (*OPC/recycled*) | 240 | Type GP | 0.73 | 75 | 2335 | 2.4 | Recycled |
| C1212A (*Slag/recycled*) | 238 | Type GB | 0.74 | 95 | 2321 | 1.8 | Recycled |
| C1212B (*OPC+5%/recycled*) | 254 | Type GP | 0.70 | 80 | 2335 | 2.3 | Recycled |

Specimens were cast from each mix to assess compressive strength, drying shrinkage, expansion, splitting tensile strength and abrasion resistance. Unless otherwise specified, all specimens, upon their removal from the moulds, were stored under standard moist curing conditions of 23°C and >95% RH until required for testing. Hardened concrete testing was performed in accordance with the requirements of AS 1012.

### 2.2 Laboratory tests – results and discussions

Based on visual inspection, the surface texture of the RCA appeared characteristically grainy compared to the basalt. This is partly a result of the residual cement mortar attached to the RCA particles, and is also responsible for the characteristic lower density and corresponding higher aggregate crushing values compared to the basalt aggregate (Hansen 1992; Frondistou–Yannas 1980).

As indicated in Table 2, RCA also has a comparatively high water absorption value at 5.6%. Although the water absorption of the recycled aggregate is relatively high compared to the reference basalt aggregate, there was no difficulty in achieving the desired consistency and subsequent compaction of concrete.

Compressive strengths were determined on concrete cylinders continuously stored under moist conditions for up to 365 days. As shown by the mean compressive strength results plotted in Fig. 1, there is no significant difference between the strength of Portland cement concretes, as a function of aggregate type, for the grade of concrete investigated.

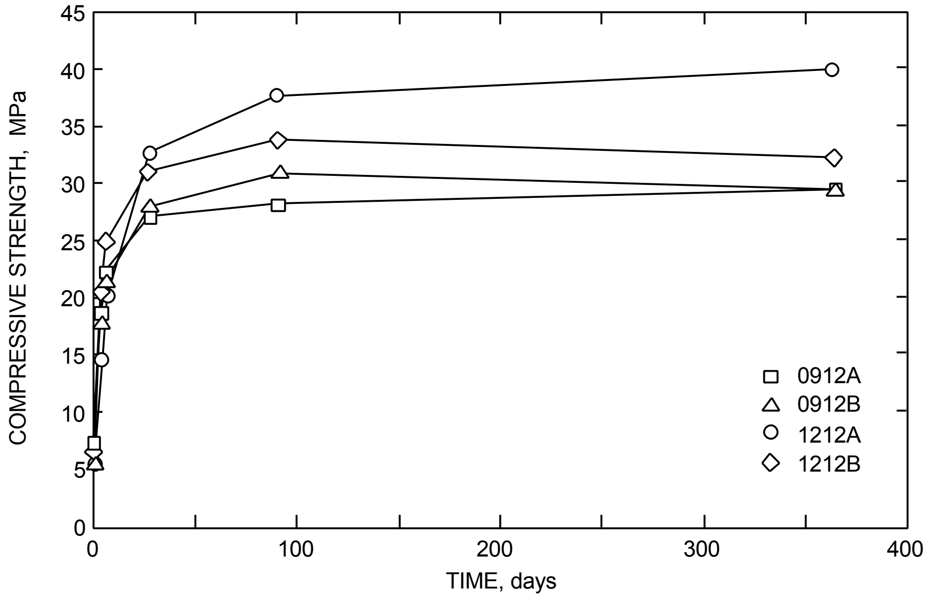

**Figure 1. Development of concrete compressive strength with age**

The corresponding increase in strength gain of the slag cement concrete from 20.2 to 32.6 MPa between 7 and 28 days is significantly higher than the equivalent nominal 6 MPa average increase for the Portland cement concretes. As noted in Fig. 1, the strength gain for recycled concrete made with Portland cement remains virtually unchanged at the 5% significance level beyond 28 days.

As shown in Table 4, the splitting-tensile/compressive strength ratios of recycled concretes are comparable to results obtained for conventional concretes made with natural aggregates. This ratio provides an indication of the resistance of a concrete to tensile strain and is dependent on type and size of coarse aggregate particles, voids in the concrete, and curing and test conditions. Calculated splitting-tensile to compressive strength ratio values ranged from 0.89 to 1.21 for recycled concrete, compared to 0.8 to 1.4 for standard aggregate concretes.

The variation of drying shrinkage strain with time for both recycled and reference concretes is shown in Fig. 2. The drying shrinkage of test specimens increased with time and stabilised at about 91 days, following similar trends reported by several researchers (Sri Ravindrarajah *et al*. 1987; Topcu 1997) for laboratory-crushed recycled concrete, although the absolute shrinkage values are slightly lower in the present case. While both natural and recycled aggregates display similar trends with regard to the rate of shrinkage, strains associated with recycled concrete made with slag cement at 365 days are over 35% higher than the reference mix, and closer to typical published values of 30–70% (Hansen 1992; Sri Ravindrarajan *et al*. 1987). In contrast, only a 15% increase in shrinkage strain is obtained for Portland cement specimens for the same curing conditions. However, there appears to be a much less significant effect on drying shrinkage as a result of the 5% difference in cement content.

**Table 4. Ratios of splitting-tensile ($f_t$) and compressive strength ($f_c$) of concretes**

| *Concrete mix* | $f_t/f_c$ | | |
|---|---|---|---|
| | *7 days* | *28 days* | *365 days* |
| C0912A (*OPC/basalt*) | 1.19 | 1.07 | 0.99 |
| C0912B (*OPC/recycled*) | 1.19 | 1.20 | 0.94 |
| C1212A (*slag/recycled*) | 1.21 | 0.98 | 0.96 |
| C1212B (*OPC+5%/recycled*) | 1.08 | 0.97 | 0.89 |

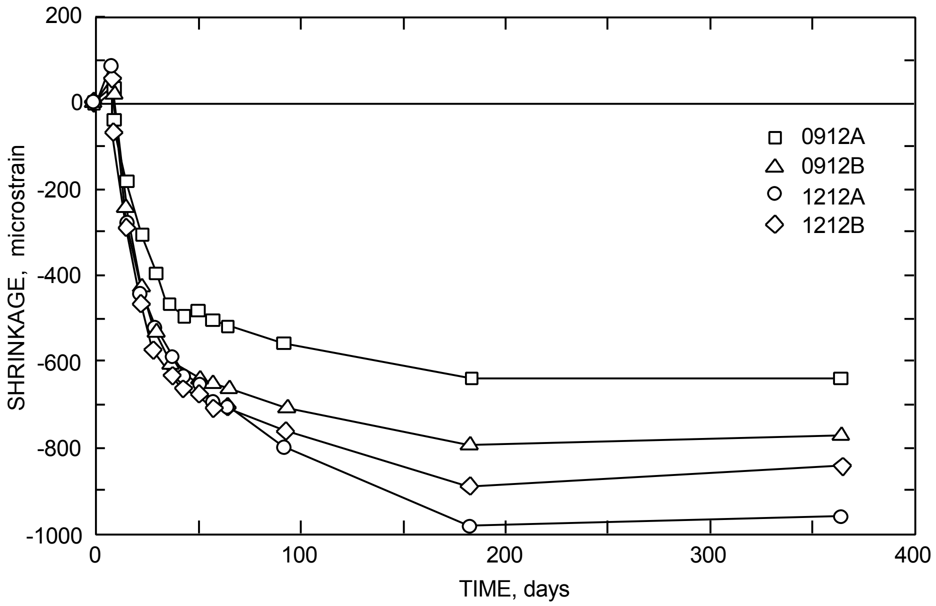

**Figure 2. Relationship between drying shrinkage strain of recycled and reference concrete with time**

It is evident from Fig. 2 that RCAs display higher drying shrinkage values compared to the reference normal concrete mixes, possibly partly due to the lower restraining capacity of recycled aggregate particles compared to basalt. Currently, AS 3600 (Standards Australia 1994) recommends a basic shrinkage limit of 700 microstrain at 56 days.

## 3 FIELD TRIAL

### 3.1 Project description

The field trial involved the construction of a bicycle/footpath facility located at Duncans Road, Werribee South, Victoria, Australia. The project involved the construction of a 120 m long, 2 m wide and 100 mm thick bicycle/footpath, a section of which is shown in Fig. 3. A segment, about 40 m long, was constructed with recycled aggregate concrete(RC), and normal grade concrete(NC) for the remainder. Normal base course preparation was employed. Both concrete types contained polypropylene fibres. No steel mesh was used. The Council supplied both RC and NC from a commercial batching plant and the contractor completed placement of both types of concrete over a two-day period. Both concrete types were formulated to the same mix design and were supplied by a local premix concrete producer.

Concrete compressive strength measurements and shrinkage tests were carried out on in-situ cored samples, as well as field- and laboratory-exposed specimens made from the supplied concrete batches. The specified concrete strength was 25 MPa.

### 3.2 Observations

The measured concrete slump was 75 mm and 115 mm for the RC and references (NC) mixes respectively. The air temperature on the day of casting for the RC was 11°C and 18°C for NC. Placement and finishing for both types of concrete presented no difficulties for the contractors.

### 3.3 Field trials – results and discussion

#### 3.3.1 Compressive strength

As shown in Figs 4 and 5, the 28-day fog cylinder compressive strengths of RC and NC concrete were 27.0 MPa and 28.1 MPa respectively – well above the specified 25 MPa cylinder strength. The corresponding 28-day strengths of field-cured concretes with a length to diameter ratio of ~1:1 were 20.1 MPa for RC and 23.2 MPa for the NC concrete. The core sections were taken from experimental concrete test strips cast adjacent to the path, as shown in Fig. 3. Concrete strengths at six months were comparable.

Figure 3. Completed footpath showing section of experimental test strip

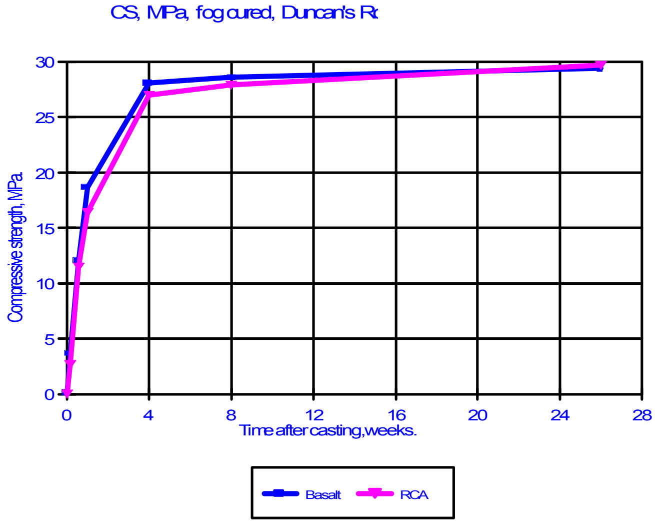

Figure 4. Fog-cured compressive strengths of RC and NC concretes

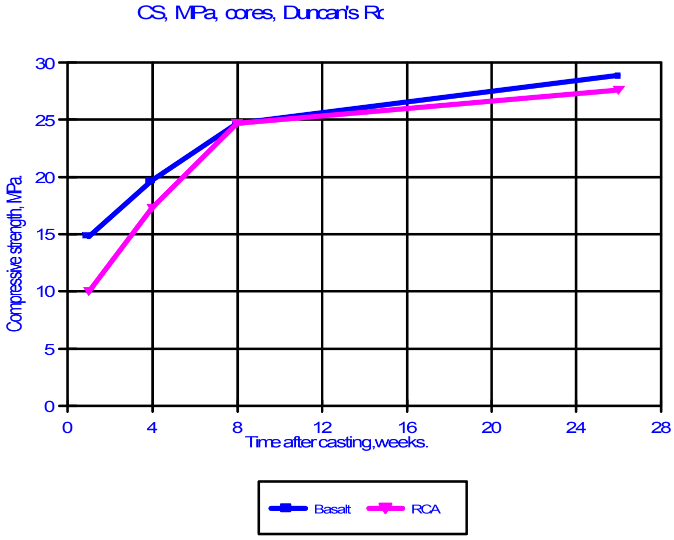

Figure 5. Core compressive strengths of RC and NC concretes

The 26-week compressive strength development of 95 mm diameter cored sections was of the same order for NC and RC concretes. It is conceivable that the difference in ambient temperatures at the time of casting may be partly responsible for the marginally lower initial strength of RC specimens, particularly given that Type GB cement was used.

3.3.2 Dimensional stability

Shrinkage data is shown in Figs 6 and 7. A separate set of specimens was stored in a conditioned room at 23°C and 50% RH, after 7 days of fog cure. Measured shrinkage of field-exposed specimens 56 days after casting are–0.122% for RC and –0.098% for NC respectively. Equivalent results of field-exposed samples were –0.021% and –0.020% respectively for RC and NC specimens.

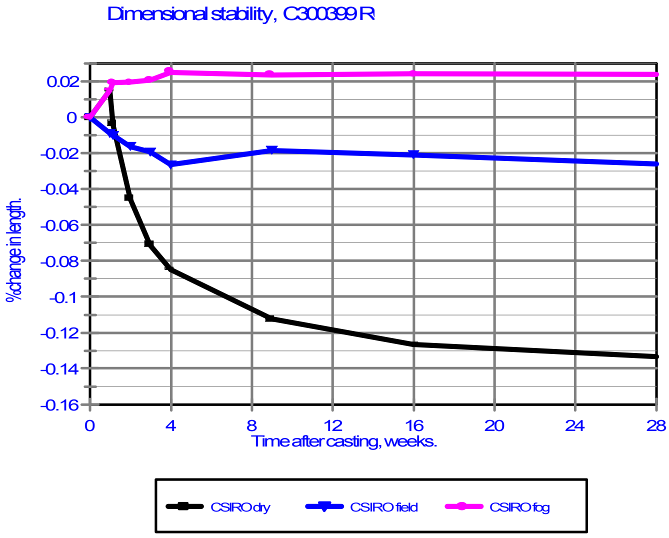

**Figure 6. Drying shrinkage of RC concretes**

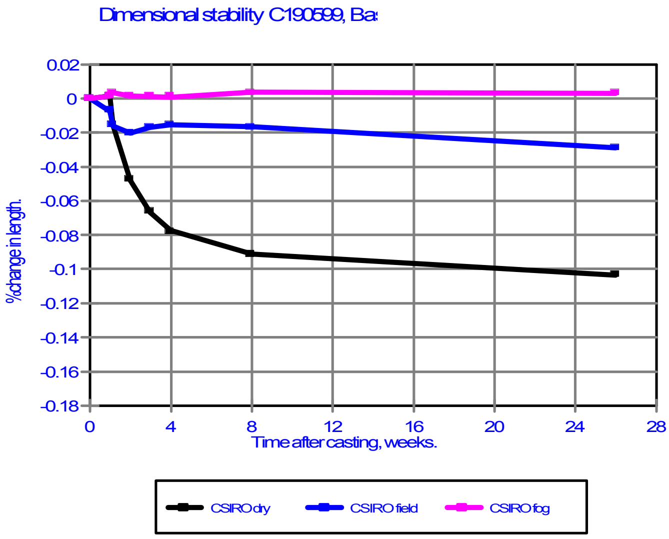

**Figure 7. Drying shrinkage of NC concretes**

# 4 CONCLUSIONS

The satisfactory demonstration of a real-life constructed facility, as reported in this paper, provides a preliminary indication of the technical performance of recycled aggregates, whilst promoting consumer awareness of waste minimisation and recycling in the construction sector. The results of the trials specifically indicate the potential for partial or full replacement of virgin aggregates with recycled material in non-structural construction applications. The preliminary findings of the project further indicate the following.

1. The quality of commercially produced coarse RCA and the performance of premix recycled concrete are, possibly, at a level where uniform concrete quality is achievable.
2. The same equipment and procedures used for concrete containing conventional aggregate may be used to batch, mix, transport, place and finish recycled premix concrete, including curing requirements. Initial trialing of recycled concrete mix designs are, however, recommended should there be a need for appropriate minor adjustments to achieve the desired performance.
3. Over the six-month test period, recycled premix concrete typically exhibits comparable characteristics similar to those of conventional concrete, and generally satisfies nominal specification requirements for concrete performance.

Go Back

4. Similar performance trends exists in RC and NC concretes for both the fresh and hardened states, including the response to conventional mix design methods, except for differences in measured drying shrinkage values for two of the three grades of concrete investigated, i.e. 15 and 25 MPa concretes.

# Development Of Guide Specifications For Recycled Aggregates In Concrete Construction

KK Sagoe Crentsil
CSIRO Building Construction and Engineering Victoria Australia

**Summary: Recycling of construction materials is growing along with the demand for recycled materials. However, this growth is often constrained by specifiers' insufficient knowledge of material performance, low awareness of benefits, and perceived risks. Until recently, in Australia, the use of crushed concrete derived from building demolition has been restricted to granular sub-base layers in road pavement construction and drainage, or excavation fill applications. However, improved crusher technologies, rubble screening and aggregate washing, and tighter regulation of the recycling industry, have contributed to significant improvements in the quality of recycled concrete products. Consumer acceptability of recycled materials, however, largely depends on products being technically suitable, cost competitive and meeting environmental impact requirements.**

**This paper discusses the proposed Guide specification document which will cover existing technical information and potential uses of recycled concrete and masonry waste into a structured format, required for specification guidelines. This includes information on recycled material properties and performance, and examines technical and market considerations of construction and demolition (C&D) waste recycling, based on field trials of premix recycled concrete. Different sources of aggregate batches are assessed in relation to existing Australian Standards for natural aggregates, in particular AS 1141, to establish conformance of recycled products. The proposed Guide specification document will provide engineers with product specification information and the tools required for conventional design with graded recycled C&D waste material.**

**Keywords: Concrete, guidelines, recycled aggregate, specifications.**

## 1 INTRODUCTION

The development a national Guide specification document on recycled concrete and masonry aims at providing engineers with product specification information and the tools required for conventional design with graded recycled construction and demolition (C&D) waste material. The document broadly outlines general specification requirements for recycled concrete and masonry materials, based on laboratory investigations and detailed local field performance evaluations of civil and municipal construction works involving recycled concrete aggregates.

Current national experience and knowledge regarding the use of these materials not only vary from material to material, but also in the way in which they are used. Furthermore, the availability of specification guidelines specifically for secondary and recycled materials is limited. However, in recent years, the gradual shift towards performance-based specifications has given rise to amendments of existing codes that also permit the use of all materials irrespective of their source, provided they comply to required specified performance rather than the conventional prescriptive requirements. Given that the recycling of construction materials is growing along with the demand for recycled material, it is important for specifiers to gain knowledge of material performance and an awareness of the benefits and perceived of risk of recycled construction materials.

## 2 PROJECT OBJECTIVES

The document provides general guidance to those who have an interest in using or increasing their understanding of recycled concrete aggregate (RCA) and masonry materials in construction applications.

These guidelines cover recycled material performance, limitations, and product testing and evaluation compliance requirements when considering the use of these materials. It is intended to assist suppliers, specifiers, regulators and end-users of recycled aggregate materials to gain some understanding of key material properties, by providing relevant information for determining the suitability of recovered material for use in selected civil, recreational and municipal construction applications. It is envisaged that manufacturers of recycled concrete and masonry products can produce material of suitable specifications for its intended use, based on standard crushing and grading processes for target applications.

The extensive survey of local applications of recycled concrete highlights case studies where recycled aggregate products either meet or fail to satisfy service performance requirements.

## 3 CONCRETE RECYCLING

Recycled concrete is basically old concrete that has been demolished and removed from foundations, pavements, bridges or buildings, and crushed into various size fractions for reuse. The feedstock material often includes small quantities of natural rock and construction masonry. Generally, recycled products can be produced from all but the poorest quality clean feedstock through a series of processing stages involving crushers, screens and devices for removing foreign material.

Material recycling in construction has been practised for many years now. However, there are several emerging issues relating to material specifications, testing and compliance protocols, characterisation procedures, design practice and material durability that need to be established. Whereas industry standard quality assurance procedures and product performance protocols are rapidly evolving, the need exists for tighter regulation given the diversity of feedstock sources and variations in the mode of aggregate production.

A high proportion of conventional demolition waste, particularly the fraction derived from concrete, brick and tile, is well suited to being crushed and recycled as a substitute for newly quarried (primary) aggregates. These materials are currently widely used in lower grade applications, most notably engineering fill and road sub-base applications. The use of such recycled concrete aggregates in new concrete is much less common, and technically much more demanding.

For these selected construction applications, recycled materials have the potential to partially displace equivalent volumes of primary aggregates. Preservation of non-renewable virgin aggregate resources, in turn, reduces the pressure on increasingly scarce landfill space.

In recent years, well-processed recycled products produced from good quality feedstock material have been demonstrated to comply with most test requirements for conventional materials for a range of applications. Several of these quality recycled aggregate products, which meet the same or equivalent performance specifications, are in current use in place of primary aggregates. The use of recycled products is therefore expected to increase with time and meet lesser discrimination in the market place.

Test procedures for virgin materials are currently used to characterise generic fundamental properties of recycled aggregates, as listed below. Data generated from such tests are useful in assessing overall performance of recycled aggregates compared to conventional materials, particularly for road base and new concrete applications:

- grading, particle shape and surface texture;
- specific gravity;
- moisture absorption;
- aggregate crushing value; and
- degree of contamination.

The bulk density of loose recycled aggregate was determined in accordance with AS 1141.6. As shown in Fig. 1, the density of oven-dried recycled aggregates is generally lower than that of the reference basalt aggregate. The lower density values of recycled aggregates compared to conventional aggregates arise mainly from relatively porous and less dense residual mortar lumps or particles adhering to the surfaces of original natural aggregate particles.

The specific gravity of coarse recycled aggregate ranges from 2.2 to 2.5, which is slightly lower than that of conventional virgin aggregates. The fines fraction of recycled aggregates has a lower density compared to the coarse material.

The absorption capacity of recycled aggregates is variable and generally higher than the standard threshold for primary aggregates. Water absorption values measured in accordance with the procedure described in AS 1141.6 are shown in Fig. 2. The absorption values for coarse recycled aggregate products generally range from 4 to 7% compared with less than 2% for primary aggregates. Higher values up to 8% can be expected for blends of recycled concrete and other materials.

An assessment of the contaminant levels of aggregate batches indicates a limit of no more than 2% inclusive of brick and stony material. Alternatively, the general impurity content comprising friable materials and materials with density less than 1950 $kg/m^3$, is of the order of 1.2% of total material weight, as shown in Fig. 3. Average batch compositions were assessed by visual examination of the +4.75 mm fraction sieved in accordance with AS 1152. Hand sorting of all foreign material was first carried out on the dried material, followed by wetting, to ensure complete identification and classification of all types of contaminants.

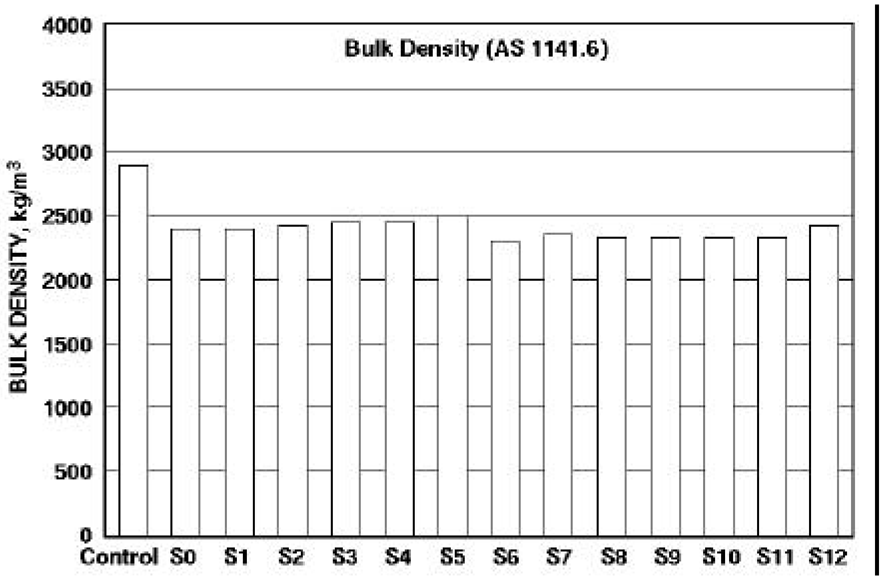

**Figure 1. Plot of bulk density values of aggregates**

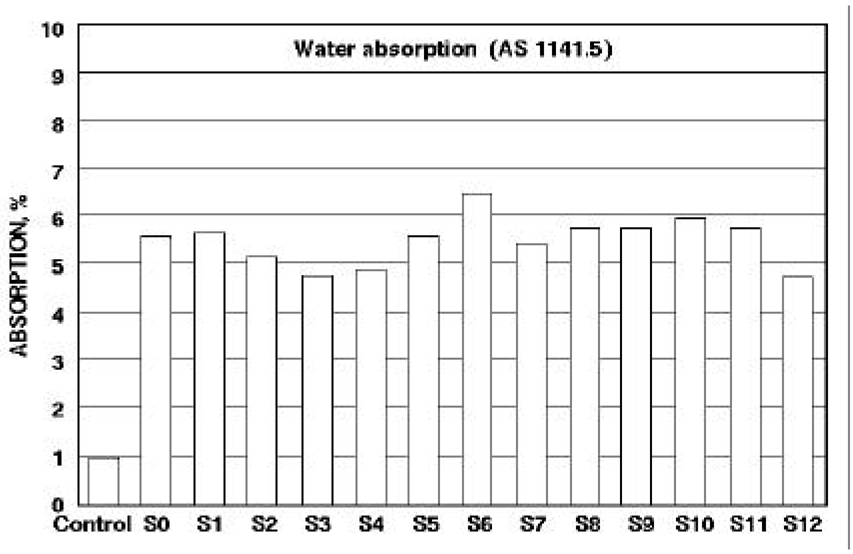

**Figure 2. Water absorption of aggregates**

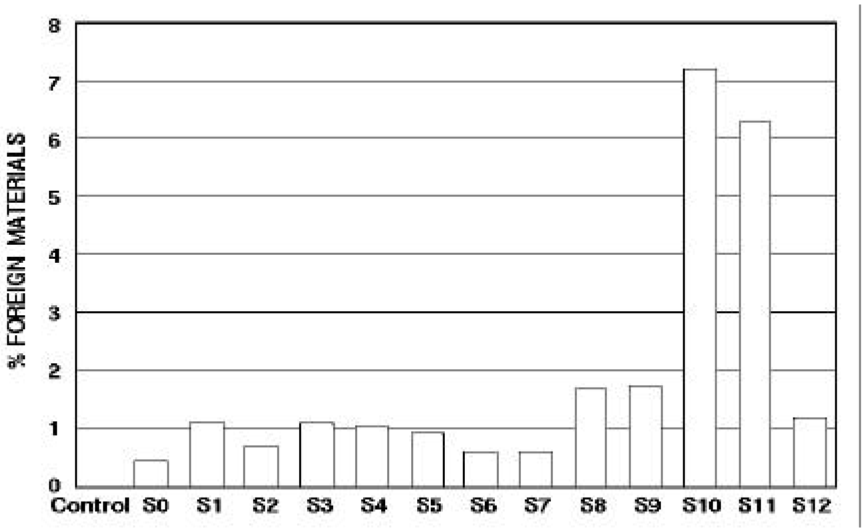

**Figure 3. Total contaminant level expressed as per cent by weight of sample.**

## 4 AGGREGATE FOR CONCRETE PRODUCTION

For concrete production, graded recycled concrete aggregates must be dimensionally stable with regard to variations in moisture content, and sufficiently strong for the desired grade of concrete. The material typically has to comply with grading limits specified in AS 2758.1, and have suitable particle shape and surface texture. Additionally, RCA must neither contain reactive contaminants nor react with cement or reinforcing steel. Table 1 summarises some typical limits in recycled concrete aggregates.

**Table 1. Typical limits recycled concrete aggregates (RCA)**

| *RCA property* | *Class 1A RCA limit* | *Class 1B RCA limit* | *Test method* |
|---|---|---|---|
| Brick content (maximum) | 0.5% | 30% | — |
| Stony material <1950kg/ $m^3$ | 1% | 5% | — |
| Friable material (maximum) | 0.1% | 0.1% | — |
| Particle shape, 2:1 ratio | 35% | 35% | AS 1141.14 |
| Particle density: saturated surface dry (minimum) | 2100 kg/$m^3$ | 1800 kg/$m^3$ | AS 1141.6 |
| Bulk density (minimum) | 1200 kg/$m^3$ | 1000 kg/$m^3$ | AS 1141.4 |
| Water absorption (maximum) | 6% | 8% | AS 1141.6 |
| Aggregate crushing value (maximum) | 30% | 30% | AS 1141.21 |
| Total Impurity level (maximum) | 1% | 2% | |
| LOI (max) | 5% | 5% | |
| Lost substances in washing (maximum) | 1% | 1% | |
| Soundness loss (maximum) | 9% | — | AS 1141.24 |
| Particle size distribution by dry sieving | — | — | AS 1141.11 |

It is recommended that the initial evaluation of RCA for premix concrete production involves direct comparison of the aggregate's physical and mechanical properties, plus the durability characteristics of the concrete, using conventional natural aggregate concrete as the reference material.

## 5 MASONRY RECYCLING

The recycling of building rubble comprising primarily of masonry material presents a much greater challenge for recycling, and severely lags progress in recovery and reuse of recycled concrete. Crushed masonry rubble is a useful material for several different applications in construction, and is mostly used as capping material or as blends with natural aggregates or recycled concrete as drainage or bulk fill material if sufficiently durable. They comprise mainly of burnt clay products, such as bricks, roofing tiles and lightweight blocks. Table 2 shows a summary of quality systems for recycled masonry materials.

Masonry waste often has much higher contamination levels compared to concrete feedstock. The key contaminants are Portland cement mortar, hardboard and plaster. Normal demolition masonry may comprise of components of building materials such as structural lightweight brick; concrete masonry units (block); natural stone; Portland cement mortar, plaster, and terrazzo; gypsum, plaster; ceramic materials; roofing tiles; glass; wood; paper; plastic; asphalt; and metals. The largest source of this class of feedstock arises from residential demolition and renovations. The nature of these contaminants severely restricts possible uses of recycled concrete products, demanding particular effort to separate them at source prior to demolition.

**Table 2. Summary of quality systems for recycled materials**

| *Processing requirements* | *Quality requirement* |
|---|---|
| Feedstock sources | Demolition waste and industrial by-products |
| Feedstock acceptance | Avoidance of contamination by selective demolition and sorting and gate inspection |
| Material storage | Pre- and post-treatment storage, according to product quality and class |
| Material classification | Recycled materials should be classified according to intended use(s) |
| Engineering tests | Engineering tests and frequency of testing should be conducted according to specified standards |

| | |
|---|---|
| Foreign material content | Organic or inorganic contaminants |
| Environmental | Leachability |

The processing of masonry rubble is similar to recycled concrete, but typically generates much lower value-added products. However, there are few premium applications that may be considered for good quality crushed brick rubble such as aggregate for lightweight concrete. Crushed masonry aggregate from various types of demolition debris may also be used in the premix or precast concrete industry.

Contaminants usually are of comparatively less concern in base aggregate applications compared to recycled aggregates which are to be used in new concrete. However, in permeable base applications where the material is not stabilised, dust and fine material wash-offs as well as leachate residues may settle on filter fabric or drainpipes before reaching drainage outlets, clogging pipes, binding filter fabric and ultimately causing system failure. Washing of recycled aggregates can, however, correct this problem.

Typical contaminants in demolition waste feedstock often include lightweight brick and concrete, asphalt, chlorides, cladding, soil and clay balls, steel reinforcement, tiles, vinyl, wood, glass, gypsumboard, hardboard, iron, admixtures and joint sealants, paper, plaster, plastics, rubber and roofing materials of various kinds.

As summarised in Table 3, some of the engineering properties of RCA that are of particular interest when RCA is used as a fill material include grading requirements, strength, specific gravity, durability, and drainage.

**Table 3. Summary of engineering properties**

| | |
|---|---|
| Grading | The crushed and screened material should satisfy specified maximum size and grading requirements for a given application |
| Specific gravity | The specific gravity of RCA aggregates is slightly lower than that of virgin aggregates and ranges from 2.0 for fines to 2.5 for coarse particles |
| Strength characteristics | Processed RCA, being 100% crushed material, is highly angular in shape, and exhibits California Bearing Ratio (CBR) values comparable to crushed limestone aggregates |
| Durability | RCA aggregates generally exhibit good durability with resistance to weathering and erosion |
| Drainage characteristics | RCA is non-plastic; the coarse fraction is free draining and is more permeable than conventional granular material due to lower fines content |

## 6 CONCLUSIONS

The Guide distils existing technical information and potential uses of recycled concrete and masonry waste into a structured format, incorporating specification requirements. It will provide information on material properties and performance. Access to reliable information on all technical material characteristics in a single document will facilitate decisions on product specification, use and marketing.

Through case studies and supplementary field testing, the project will also provide data on the longer term performance of materials derived from recycled concrete and masonry. This durability information will be the first effort in Australia to quantify and report long-term performance. Lack of this data in the marketplace continues to be an impediment to the wider application of recycled resources.

# Quantum Efficiency Of Spectral UV On Polyurethanes

**T Nguyen JW Martin E Byrd & N Embree**
**National Institute of Standards and Technology Gaithersburg USA**

**Summary: Polyurethanes (PU) are used extensively as exterior building materials. However, PU undergoes degradation during outdoor exposure. The quantum efficiency of spectral UV on photodegradation of an acrylic-urethane coating has been investigated. Samples of approximately 8 mm thick film applied to calcium fluoride substrates were prepared from a mixture of an acrylic polyol with an aliphatic triisocyanate. The UV source was two 1000 W xenon arch lamps, which produced radiation from 270 nm to 800 nm. Ten band pass filters, each having a specified wavelength range, were employed to provide different UV wavelength ranges from 290 nm to 540 nm. In addition, specimens exposed in the absence of UV and under 300 nm cut-on filters were also characterized. Exposure cells containing twelve windows (11 filters and one in the absence of light) corresponding to 12 specimens were used. All specimens were exposed to 50 $^{o}$C and at ~ 0 % relative humidity for more than eight months. The quantum efficiency of each wavelength range was estimated from data on degradation and total dosage absorbed in the film; these properties were measured by Fourier transform infrared spectroscopy and UV-visible spectroscopy, respectively. Both oxidation and chain scission were utilized to quantify PU phodegradation. Although there was no effect of wavelength on the degradation mechanism, both the rate and extent of degradation varied with dosage absorbed at different wavelength ranges. Except for the 290 nm filter, which had the highest value, quantum efficiency of other wavelength ranges did not differ greatly.**

**Keywords: Polyurethane, photodegradation, spectral UV, wavelength. quantum efficiency**

## 1 INTRODUCTION

Polyurethanes (PU) are used extensively as exterior coatings, sealants, and adhesives. However, PU materials undergo degradation during exposure to outdoor environments (Bauer et al. 1991, Wernstahl 1996). Although temperature, moisture, and other weathering elements may contribute to the degradation, the primary cause of PU degradation during outdoor exposure is ultraviolet (UV) light. For that reason, the photodegradation mechanism of PU and its model compounds have been studied extensively (Wilhelm and Gardette 1997 and 1998, Rabeck 1995). Both aromatic and aliphatic isocyanate-based polyurethanes undergo chain scission by photo-oxidation process. It is well known that photodegradation (photolysis and photo-oxidation) of a material is determined by the absorption characteristics of radiation in that material. However, the absorption of radiation energy in polymers is controlled by their chemical structure and is dependent on wavelength. Studies on wavelength sensitivities of a variety of polymers have been summarized (Searle 1986, Trubiroha 1986), and some data on the effects of wavelength on the PU degradation characteristics have been documented (Gardette and Lemaire 1984, Wilhelm and Gardette 1997). However, very little research on the quantum efficiency of spectral UV on PU has been reported (Gardette and Lemaire 1984). This is the subject of the study reported in this paper.

The quantum efficiency is estimated by:

$$N(\lambda) = D_{dam}(\lambda, t) / D_{dos}(\lambda, t)$$

where

$\phi(\lambda)$ = apparent quantum efficiency within the exposed radiation wavelengths, in $Am^{-1}J^{-1}$ (A is infrared absorbance and m is film thickness),$D_{dam}$ = damage, in IR absorbance (A) units.

$D_{dos}(\lambda, t)$ = total dosage absorbed in the material, in J.

The total absorbed dosage is the total number of quanta absorbed by a material and is given by

$$D_{dos}(t) = \int_0^t \int_{\lambda \min}^{\lambda \max} E_o(\lambda)\left(1-10^{A(\lambda)}\right) d\lambda \ \mathrm{dt}$$

where

$\lambda_{min}$ and $\lambda_{max}$ : minimum and maximum photolytically effective UV-visible wavelengths (units: nm),

A(λ,t) : absorbance of sample at specified UV wavelength and at time t, (units: dimensionless),

$E_o(\lambda,t)$ : incident spectral UV-visible radiation dose on sample surface at time t (units: J $cm^{-2}$),

T : elapsed time (units: s).

The total absorbed dosage was obtained by integrating the product of the spectral irradiance, $E_c$ (8,t), and the spectral absorption of the coating, $(1\text{-}10^{-A\,(8,\,t)})$, over the wavelengths of radiation impinging on the specimen for the exposure duration at a particular humidity and temperature. Both quantities were measured using UV-visible spectroscopy and damage was measured with FTIR. The quantum efficiency determined in this study is considered as an "apparent" value and is expressed as the change in FTIR intensity per unit thickness per amount of radiation absorbed in the coatings. If FTIR intensity of the degradation is expressed in absorbance units (A), thickness in meters (m), and radiation dosage absorbed in Joules (J), the apparent quantum efficiency is expressed in A $m^{-1}$ $J^{-1}$. Since both the absorbed dosage and material damage were measured on exposed specimens, the quantum efficiency does account for the effects of relative humidity, temperature, and radiant flux on the degradation.

## 2 EXPERIMENTAL PROCEDURES

### 2.1 Material

A model thermoset acrylic-urethane coating consisting of a mixture of a hydroxy-terminated acrylic resin and an aliphatic isocyanate cross-linking agent was used. The acrylic resin contained, by mass, 68 % butylmethacrylate, 30 % hydroxy-ethylacrylate, and 2 % acrylic acid. The isocyanate was a conventional biuret hexamethylene diisocyanate. The urethane was formulated without catalyst and at an OH - NCO ratio of 1. Coatings were applied to calcium fluoride ($CaF_2$) substrate by spin coating followed by curing at 130 °C for 20 minutes. All coated samples were well cured, which was evidenced from Fourier transform infrared spectroscopy (FTIR) analysis of the NCO band at 2272 $cm^{-1}$. $CaF_2$ is transparent in the wavelength range between 0.13 μm and 11.5 μm and has excellent moisture and heat resistance. Therefore, it was possible to expose clear coated $CaF_2$ to wide ranges of temperature, humidity, and UV radiation, while monitoring the spectral absorption and degradation of the coating by UV-visible spectroscopy and FTIR spectroscopy. The coating thickness was 8 :m ∀ 1 :m.

Instrumentation and Exposure Cells

Figure 1 schematically shows the main components of the experimental setup used in this study. It consists of two solar simulators (the light source), an exposure cell platform, a controlling system, and instruments to measure spectral radiation energy and coating degradation. Each solar simulator's optical system is comprised of a 1000 W xenon arc lamp, a dichroic mirror, an optical integrator, and a Fresnel collimating lens. The dichroic mirror removes the visible and infrared portions of the xenon arc spectrum; therefore, the thermal effect induced by the radiation on the specimens was less than 2 °C above ambient temperature. The integrator homogenizes the beam while the Fresnel len collimates the beam.

The exposure cells were designed to simultaneously expose different sections of the same film to 12 well-defined, spectral UV conditions at the same temperature and relative humidity (RH). Figure 2a depicts the arrangement of the exposure cells underneath the solar simulators, and Figure 2b shows a cross section of the exposure cell. Each exposure cell has a layered design and included a filter disk, a quartz disk, a $CaF_2$ specimen disk, and an encasement to hold the disks. The filter disk contained 11 windows--10 on the disk perimeter and the eleventh in its center. Each window was 16 mm in diameter. Each of the 10-perimeter windows was outfitted with a band pass filter covering a different segment of xenon arc spectral spectrum from 290 nm to 540 nm. The center window was outfitted with a 300 nm cut-on filter (allowed only wavelengths >300 nm to be transmitted). The broadness of each wavelength range and the transmission of the 10 band pass filters are given in Figure 3. The first eight filters had full-width-half-maximum (FWHM) values between 2 nm and 10 nm and covered the range between 290 nm and 340 nm. The nominal center wavelengths for these filters were 290 nm, 294 nm, 300 nm, 306 nm, 312 nm, 318 nm, 326 nm, and 336 nm. The two remaining filters had FWHM values greater than 10 nm and had center wavelengths of 354 nm and 450 nm. Hereafter, the band pass filters are also referred to by their center wavelengths, e.g., 290 nm filter, 354 nm filter, etc. In addition, changes in specimens exposed in the absence of UV (no-UV) (no. 12 in Figure 2a) were also measured to assess non-photolytically induced degradation.

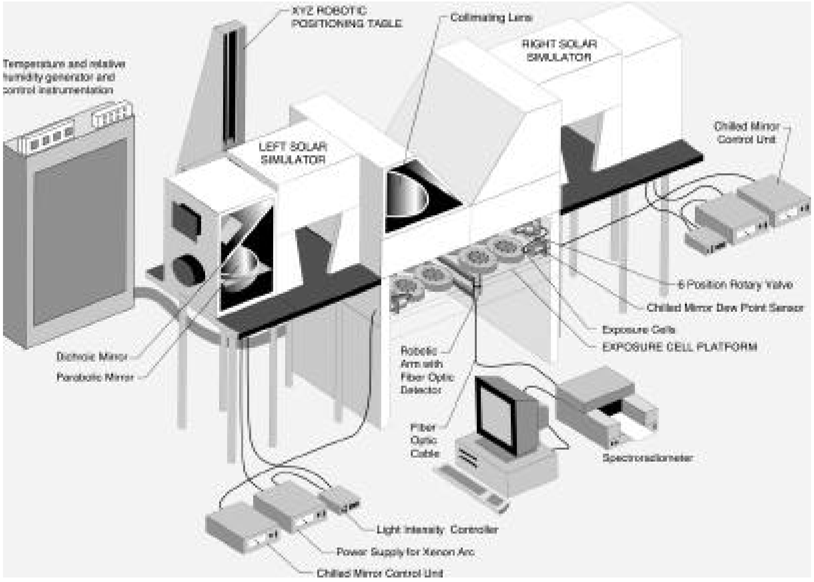

**Figure 1. Experimental setup for measuring absorbed dosage and quantum efficiency of coatings exposed to different spectral UV/relative humidity/temperature conditions.**

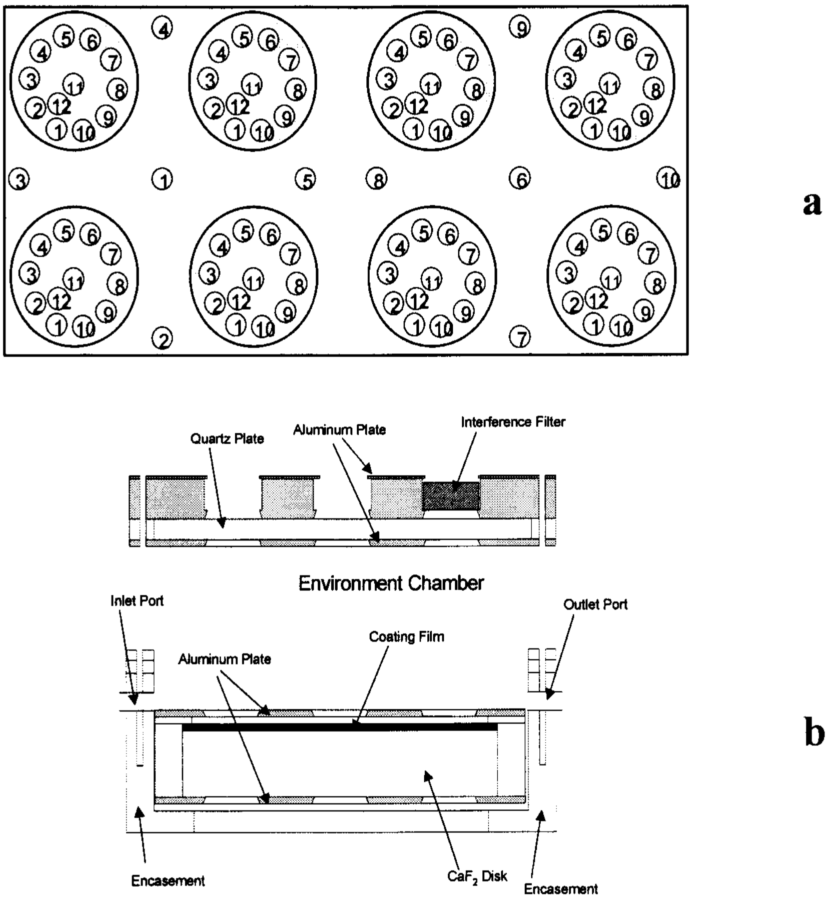

**Figure 2. a) Arrangement of exposure cells, and b) cross section of an exposure cell.**

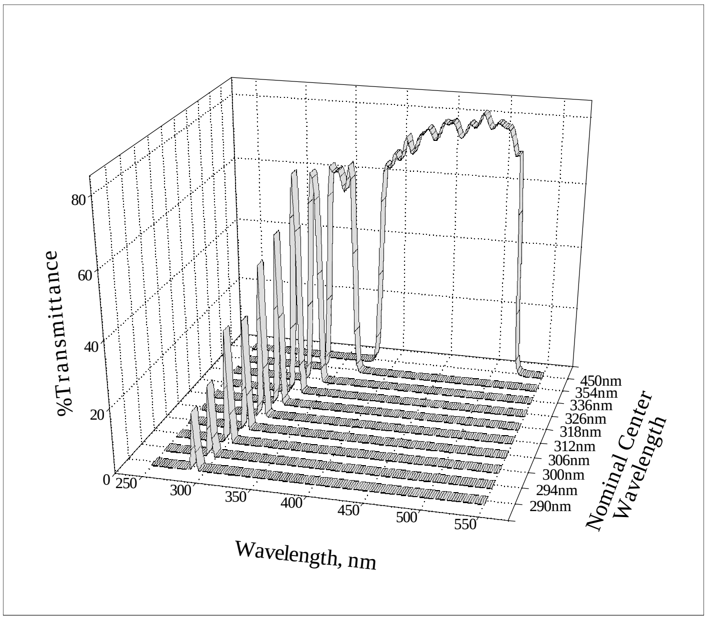

**Figure 3. Characteristics of the 10 band pass filters used to provide different spectral UV ranges.**

The space between the quartz disk and coated $CaF_2$ disk served as the environmental exposure chamber. The exposure cell was machined to tight tolerances so that a positive pressure could be maintained within the exposure chamber of an exposure cell. Inlet and outlet ports were drilled into the exposure cell to circulate the desired temperature/RH condition into the chamber. The conditioned air was generated in a humidity-temperature generator and pumped into each exposure cell. The humidity generators were fabricated based on the principle of dry/moisture-saturated air mixture. The temperature within the exposure chamber was monitored via a thermocouple and RH was monitored by a chilled mirror hygrometer. The RH at a specified temperature in each cell was tracked by a feedback-control system, which monitored both the temperature and RH within the exposure cell three times per second. The temperature and RH could be maintained within 0.5 % and 3 %, respectively, of their set values.

## 2.2 Measurements of Absorbed Dosage and Coating Degradation

To accurately estimate the total dosage absorbed in the film, the optical properties of all of the components must be measured, including 1) the spatial and spectral variability in the radiant flux of the light source, and 2) spectral transmittances of the band pass filters, quartz disks, and coated $CaF_2$ disks for all eight exposure cells. Spatial and temporal changes of lamp intensity were monitored using an UV-visible spectrometer connected to a robotic controlling system via a fiber optic cable. These measurements were done in the absence of the exposure cells. Measurements of the optical properties of the system components were highly automated by the use of a robotic arm and an automated sampler. The robotic-controlled fiber optic cable probe had the capability of moving in the X, Y, and Z directions, and the spectrometer was programmed to make measurements at frequent time intervals at 98 different locations on the platform table (88 corresponding to 11 filters on each of the eight exposure cells and 10 locations outside the exposure cells).

UV absorption in the coatings was obtained from the transmission of light passed through the band pass filters, the quartz plate, and the coated $CaF_2$ plate. At each specified time interval, the coated $CaF_2$-contained exposure cell was removed from the platform table and fitted into a demountable 150-mm diameter ring of an auto-sampling accessory. The ring was computer-controlled and can be programmed to rotate and translate over the entire sampling area. Spring-loaded Delrin clips ensure that the specimens are precisely located and correctly registered. The auto-sampler was placed in the UV spectrometer compartment and UV-visible spectra were taken at 2 s per scan using a customized computer program. This automated sampling system allowed unattended, efficient, and quick recording of the UV transmission of the coating at all 12 windows of an exposure cell. Since the exposure cell was mounted precisely on the auto-sampler, error due to variation of sampling at different exposure times was essentially eliminated. Transmission measurements were also taken individually for the quartz, the coated $CaF_2$, and the bare (uncoated) $CaF_2$ plates. To improve the accuracy of these measurements, the UV-visible spectrometer was calibrated during each inspection against standard UV-visible spectrometer transmittance density filters using NIST Standard Reference Material (SRM 930d). From the amount of light transmitted through each component of the exposure cell as a function of time, the light intensity impinging upon, as well as absorbed by, the coatings was determined. Both of these quantities are required inputs for estimating the absorbed dosage and quantum efficiency.

Damage in the coating was measured by transmission FTIR spectroscopy. FTIR spectra were taken using the same auto-sampler described above placed in an FTIR spectrometer equipped with a liquid nitrogen-cooled mercury cadmium telluride (MCT) detector. All FTIR spectra were the average of 132 scans recorded at a resolution of 4 $cm^{-1}$ using dry air as the purge gas. The peak height method was used to represent IR intensity, which is expressed in absorbance, A. The FTIR spectrometer was calibrated against a polystyrene film during each inspection. All results were the average of three specimens. A software program was written to estimate total absorbed dosage, material damage, and quantum efficiency.

## 3 RESULTS AND DISCUSSION

### 3.1 Spatial Uniformity, Collimation, and Temporal Stability of UV Light Source

Results on spatial uniformity, collimation and temporal stability of the UV light source have been given elsewhere (Martin et al, 2001). In general, the spectral radiant flux of the xenon arc light sources changed with time. The magnitude of the changes differed from one wavelength to another. For example, after 1500 h of operation, the spectral radiant flux decreased, with respect to initial values, at 290 nm, 326 nm, and 450 nm by 25 %, 50 %, and 38 %, respectively. These changes demonstrate the need for frequent monitoring of the spectral radiant flux of the light source. The radiant flux also differed from one solar simulator to another and varied from one lamp to another. Moreover, the spatial variation in the radiant flux over the working plane of both simulators was high. This high spatial variability in the irradiance pattern necessitates a large number of measurements to characterize the spatial variation.

Beam collimation and scattering of the radiation were ascertained by measuring the radiant flux at the center points of several randomly selected windows. Measurements started at a point immediately below the exposure cell window and, then, at 10 mm increments below this point until the sensor was 100 mm vertically beneath its initial position. Radiant flux measurements were plotted against vertical distance and regression analysis was performed. The slope of the regression curve was not significantly different from zero suggesting that the radiant output from each solar simulator was highly collimated. The absence of stray light incident on the covered 12$^{th}$ window was verified by positioning the fiber optic probe immediately beneath this window; no UV-visible radiation was detected. The band pass filters were photolytically and thermally stable, except for the 450 nm filter, which lost 2 % to 7 % of its transmittance after over 1000 h exposure. The $CaF_2$ did not exhibit any transmittance change and the quartz plates showed a small transmission loss over the course of exposure. All of these changes were accounted for in the calculation of absorbed dosage.

### 3.2 Coating Degradation

Examples of FTIR results on coating degradation are given in this section to demonstrate the approach for measuring the material damage and calculating the spectral quantum efficiency in the samples. Figure 4 presents typical FTIR spectra of the coating before and after aging for two different times under the 300 nm cut-on filter (KG) at 50 $^{o}$C/~0 % RH condition. The major FTIR bands of interest in a cured, unaged acrylic-urethane coating based on aliphatic isocyanate are the bands at 3380 cm$^{-1}$ due to NH stretching, 1730 cm$^{-1}$, due to C=O of urethane linkage, 1520 cm$^{-1}$, due to amide II (NH bending and CN stretching) and 1250 cm$^{-1}$, due to amide III (NH bending and CN stretching). The assignments are based on extensive IR data of polyurethanes (Scrichatrapimuk and Cooper 1978).

Although a comparison between spectra of the unaged and aged samples, as shown in Figure 4, can give some information about the effects of exposure on a polymer film, the degradation behavior is best studied from the difference spectra, where the formation or depletion of a band and the appearance of a new species can be readily observed. Examples for such difference spectra as a function of spectral UV ranges and exposure times for samples exposed under the cut-on filter (KG) in 50 $^{o}$C/~0%RH condition are displayed in Figures 5a and 5b, respectively. The bands above and below the zero line in a difference spectrum indicate a gain and loss, respectively, of chemical species in the film.

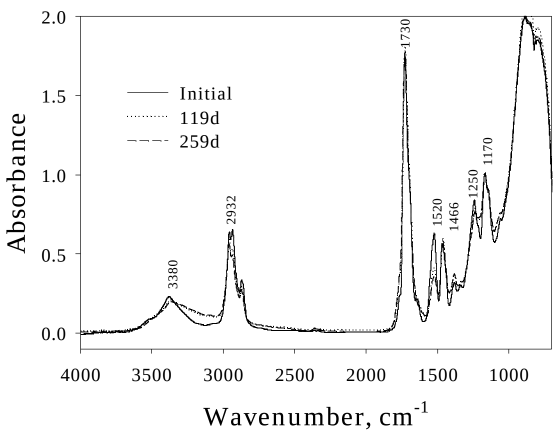

**Figure 4. Typical FTIR spectra of PU coating before and after exposures for two different times under the 300 nm cut-on filter in 50 $^{o}$C/~0% relative humidity condition.**

Go Back
Next Page

The degradation observed at 50 °C/dry condition in the absence of UV light (no-UV) was small compared to that of other UV light ranges. Various compounds were formed during exposure to UV, as evidenced by the appearance of the bands at 1752 $cm^{-1}$, 1418 $cm^{-1}$, and in the 3100 $cm^{-1}$ to 3300 $cm^{-1}$ region. Similarly, the intensity of the bands at 1730 $cm^{-1}$, 1520 $cm^{-1}$, 1250 $cm^{-1}$ and in the CH region between 2800 $cm^{-1}$ to 3100 $cm^{-1}$ decreased markedly with exposure times. These results indicate that the PU material has degraded substantially after more than eight months of exposure. Further, all the bands that were formed occurred at the same positions irrespectively of the wavelength ranges studied. The same band positions in the IR spectra indicate that the same chemical groups were produced during the photodegradation at different wavelengths. This result suggests that, despite a substantial variation in the extent of degradation among the UV wavelength ranges, essentially no effect of wavelengths on the primary photodegradation mechanism of this polyurethane material was observed. Such wavelength insensitivity implies that the degradation in this material was induced by chromophores initially present in the films.

The C=O band at 1752 $cm^{-1}$ (from acetyl urethane, O=C-NH-C=O ) and the NH band at 1520 $cm^{-1}$ were used to follow the oxidation and chain scission, respectively. Figures 6a and 6b depict FTIR intensity changes of these two bands as a function of time for the cut-on filter and 10 center wavelengths.  In these figures, each symbol represents a data point, which was the average of three specimens, as stated  in the experimental section. The coefficients of variation for all data points were <7 %, indicating that the reproducibility of the results between the specimens was good. As can be seen in these figures, there is no particular order for both the rate and magnitude of degradation with regards to wavelength despite the fact that the shorter wavelengths contain higher-energy photons. However, the 294 nm and 300 nm filters appeared to cause the least damage. This was true for both oxidation and chain scission. The oxidation for all wavelength ranges was greater at earlier time then became almost constant at prolonged exposure. For chain scission, the degradation was fast during the first 50 days but slowed down thereafter.

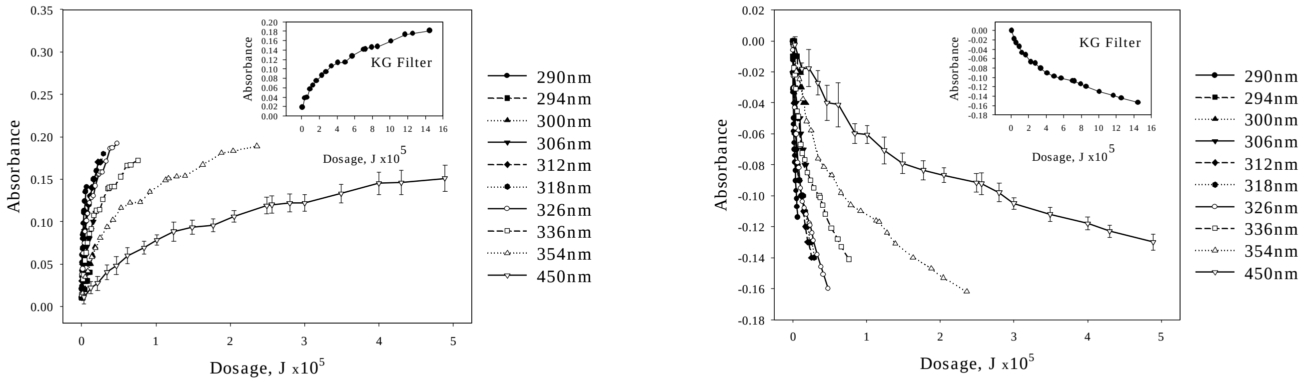
### 3.3 Total Absorbed Dosage and Apparent Quantum Efficiency

Photons of lower wavelength radiation are more energetic than those of higher wavelengths, and far fewer photons of the lower wavelength radiation actually impinged upon the sample surface. Therefore, the damage/time relationship as shown in Figure 6 is not valid for comparing the effects of different wavelengths on polymer degradation. The relative effects may be observed in the damage/absorbed dosage plot because only radiation absorbed in the material that causes degradation is really taken into account. Figures 7a and 7b display photo-oxidation and chain scission, respectively, as a function of absorbed dosage for specimens exposed to cut-on filter and 10 band pass filters under 50 °C/~0 %RH condition. It should be noted that only data involved in the photolytic process are included in Figure 7. That is, the results measured in the absence of UV light at the same temperature and RH were removed from the total degradation. The absorbed dosage, i.e., the actual amount of radiation absorbed by the coating, was calculated using the equation given above. All dosages were measured after 250 d of exposure. As expected, samples under the cut-on filter (KG) and long wavelength band pass filters absorbed the most dosage while those exposed to short wavelengths absorbed less. Further, radiation from the lower wavelength filters caused more rapid degradation than higher wavelengths, as evidenced by the slopes of the curves.



**a** **b**

**a** **b**

**Figure 8. Experimental and fitting FTIR degradation data as a function of dosage for a) chain scission, and b) oxidation. The initial slopes of these curves are used for obtaining the quantum efficiency.**

The apparent quantum efficiency was taken as the initial slope of the damage/total absorbed dosage curve. The use of this initial slope avoids complications from multiple degradation processes and from potential shielding of the coating material by degradation products absorbing radiation. In the process of determining this slope, a fourth-order polynomial function was fitted to the damage/total absorbed dosage curve. In this first implementation of analyzing this curve, the slope at the 10 % of the total absorbed dosage was used as the end point. One example of such fitting is shown in Figure 8 for the chain scission process (1520 cm$^{-1}$ band) and oxidation (1752 cm$^{-1}$ band) of samples under the 450 nm filter. In this figure, the symbols are the experimental data and the solid lines are the fitted curves. The initial part of the damage/absorbed dosage curves at 1520 cm$^{-1}$ exhibits some scatter due to imprecision in the measurements of very small changes at early exposures. Nevertheless, the polynomial function fit most of the data well. Differentiating the polynomial gives the slope (apparent quantum efficiency) at a given absorbed dosage. Since the damage/absorbed dosage relationship is not linear, the apparent quantum efficiency falls off with total absorbed dosage, presumably due to increasing shielding of the coating by degradation products and to the depletion of weak links in the material. Note that the negative values in Figure 8a vertical axis are indicative of a loss of material.

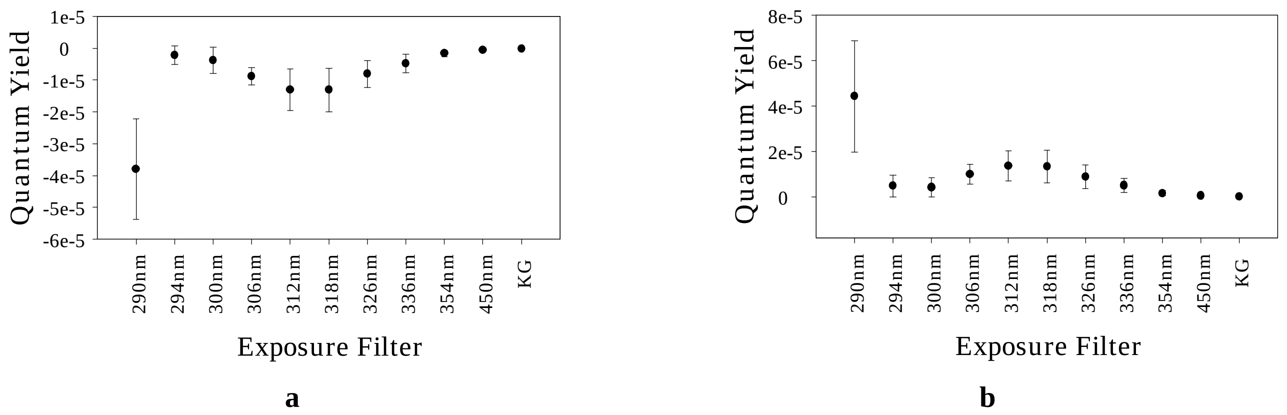

**Figure 9. Quantum efficiency of a) chain scission and b) oxidation of an acrylic-urethane coating exposed to 50 °C/~0 % RH for 300 nm cut-on filter and 10 different center wavelengths.**

Figure 9 presents apparent spectral quantum efficiency for the oxidation and chain scission of PU coating exposed to 50 ° C/~0 %RH for a cut-on filter (KG) and ten different center wavelengths. The one-standard error bars are included in the curves. The quantum efficiency at 290 nm appears to be the highest. Although the samples under the cut-on filter and long center wavelengths, i.e., 450 nm and 354 nm filters, absorbed the most energy, their quantum efficiency was similar to other filters. Since the unit employed to express quantum efficiency in this study is different from that traditionally used (number of molecules that undergo change/number of quanta absorbed), it is difficult to compare directly the values obtained here with data reported for other polymers. Work is in progress to measure the molar absorption coefficients of the infrared bands of interest, and the results will be used to convert IR absorbance units into number of molecules. Nevertheless, the quantum efficiencies in all spectral UV ranges for this PU were small, as is typical for solid polymers. For example, the quantum yield of hydroxyl formation in polyurethanes exposed to 315 nm and 365 nm radiation has been reported to be $0.002 \pm 0.001$ and $0.005 \pm 0.001$, respectively (number of OH formed/number of quanta absorbed) (Gardette and Lemaire 1984). Quantum yields of chain scission for other polymers also range between $10^{-2}$ to $10^{-5}$ (Randy and Rabeck 1975). It should be mentioned that the quantum yield of polymer chain scission changes rapidly from below to above the glass transition temperature (Tg). Above Tg, the quantum yield is similar to that irradiated in solution, which is several order of magnitude greater than that in solid (Randy and Rabeck 1975). Since water in the films tends to plasticize and decrease the Tg of polymers, photodegradation of PU materials is expected to be more rapid if they are used at temperatures higher than their Tg.

Total absorbed dosage and apparent quantum yield have been found to be very sensitive to a number of experimental variables, including the initial UV-visible absorbance of the coatings, formation of coating degradation products, and UV-visible and FTIR measurement errors (Martin et al. 2001). As a result of these studies, protocols have been developed and experimental errors had been essentially eliminated through careful and frequent re-calibration of the UV-visible spectrophotometer using NIST standard UV-visible spectrometer transmittance density filters and polystyrene films to monitor the performance of the FTIR spectrometer before taking the spectra of any samples.

## 4 SUMMARY AND CONCLUSIONS

Polyurethanes are used extensively as exterior building materials. However, these materials undergo degradation during outdoor exposure. The quantum efficiency of spectral UV on photodegradation of an acrylic-urethane coating was investigated. Damage was measured by transmission Fourier transform infrared spectroscopy, and energy absorbed in the sample for each wavelength range was estimated from measurements of spectral irradiance and spectral absorption of the coating using UV-visible spectroscopy. Ten spectral wavelength ranges covering from 290 nm to 540 nm were generated using band pass filters, which allow certain radiation wavelengths passing through and interact with the samples. Samples exposed in the absence of UV and under 300 nm cut-on filters were also analyzed. The UV light source was provided by two 1000 W xenon arch lamps, which contained radiation from 270 nm to 800 nm. Samples were prepared by applying a mixture of an acrylic polyol with an aliphatic triisocyanate to calcium fluoride substrates. They were exposed to 50 °C and ~ 0 % relative humidity for more than eight months. FTIR results showed that the degradation mechanism of PU was essentially the same regardless of the center wavelengths from 290 nm to 450 nm. Both the rate and extent of the photodegradation with respect to absorbed dosage varied with wavelength. However, except for the 290 nm filter, which appeared to have the highest value, the quantum efficiency of other wavelength ranges did not differ greatly. Knowledge of the spectral quantum efficiency in the UV-visible region is essential for developing improved photo-accelerated tests and more photo-stable materials.

# Surface And Interface Microstructures Of Coatings Systems And Their Implication On Service Life

**T Nguyen[1] X Gu[1] M VanLandingham[1] D Nguyen[2] M Giraud[1]**
**[1]National Institute of Standards and Technology Gaithersburg**
**[2]PPG Industries Inc Allison Park PA**

**Summary: The surface and interface properties have a strong influence on the adhesion and service life of polymer coatings applied to plastics and metals. However, both the surface and interface chemical composition and microstructure of coated materials are affected by the surrounding environments and processing conditions during film formation. In this study, the surface and interface properties of several coatings have been characterized with nanoscale resolution using atomic force microscopy (AFM). Specimens were prepared by applying thick films of coatings on the substrates. Both the cross-sections and surfaces that were in contact with the substrates during curing were used for the interface characterization. Interpretation of AFM results was aided by data collected using attenuated total reflection-Fourier transform infrared spectroscopy and contact angle measurements. Curing conditions and stoichiometry have a strong influence on the interface region. Further, microstructure and chemical composition of the film surface adjacent to the substrate are different from those of the surface exposed to air. The implications of these differences on the wettability, weatherability, and adhesion of coated systems are discussed.**

**Keywords: Interface, surface, coatings, nanoscale, AFM**

## 1 INTRODUCTION

The surface and interface properties have a strong influence on the service life and adhesion of coatings applied to plastics and metals. However, both the surface and interface chemical composition and microstructure of coated materials are affected by the environment and processing conditions during film formation. For example, it has been established that the air surface of a multicomponent polymer system is generally enriched by a thin layer of hydrophobic material. Further, water, $CO_2$, and oxygen from the environment can react with certain components of a coating formulation to form side products on a coating surface. For example, water reacts readily with isocyanate in polyurethane formulations to form urea; $CO_2$ form salts with amine curing agents in amine-cured epoxies; and oxygen inhibits the curing of acrylic resins. Such surface enrichment and environment-induced reactions would generate a surface microstructure and chemical composition that are different from those in the bulk or at the film/substrate interface. Similarly, the buried interface/interphase between a coating and a substrate is often affected by processing conditions that control the chemical kinetics, diffusion, and volumetric changes. In addition, the interface region often includes impurities, unreacted molecules, and additives. The resulting interface/interphase is often a very complex structure, which is not easily analyzed or modeled. In this study, the interface is defined as the two-dimensional boundary between the polymer film and the substrate, while the interphase is the three-dimensional region including the interface and a zone of finite thickness on both sides of the interface. Considerable research has been conducted to improve the strength and service life of the interface/interphase region through surface treatment or modification of the substrates. However, little progress has been made in the understanding of the morphological, physical, chemical, and mechanical properties of this region, how these properties change with external stresses and processing conditions, and how this region affects the performance and service life of a polymeric system.

The main objective of this study is to characterize the surface and interface morphologies of polymer- coated materials by the use of nanoscale-resolution tapping mode atomic force microscopy. The results are presented to demonstrate that a substantial difference exists between the microstructure of the film surface exposed to air and the film surface adjacent to the substrate. These differences may have strong implications in the wettability, adhesion, and weathering resistance of coatings systems.

## 2 MATERIALS AND INSTRUMENTATION

### 2.1 Materials

Surfaces of polymer films exposed to air (air surface) and the surfaces of the same films that were in contact with the substrate during film formation (interface) were characterized using tapping mode AFM (TMAFM). In addition, the interface/interphase region of cross-sectioned samples was also studied. Samples of several different coatings having thicknesses between 50 µm and 200 µm applied to substrates were prepared by a draw-down technique. Highly-polished silicon wafers and glass plates were employed as the substrates to provide the interface samples. They were obtained by first initiating a cut through the cured coated film with a razor blade, followed by lifting up the film with a sharp knife, and peeling with a tweezers. The cross-sectioned samples were prepared from coatings applied to polished steel. Strips of coated steel were imbedded in a molding compound. Cross sections were obtained by cutting the embedded samples with a diamond saw, followed with several polishing steps; the final polish was with a 0.25 µm diamond paste.

### 2.2 AFM measurement

Although TMAFM is a recently-developed technique, it has become a popular tool for studying surface microstructure of polymers and biological materials because it provides a high lateral resolution with minimal damage to the samples (Magonov, 2000). In tapping mode (Fig. 1), the cantilever carrying the probing tip is oscillated at a frequency near its resonance frequency, typically, a few hundred kHz, so that the tip makes contact with the sample only for a short duration in each oscillation cycle. As the tip approaches the sample, the tip-sample interactions cause a change in the amplitude, resonance frequency, and phase angle of the oscillating cantilever. Detection of changes in the amplitude and phase shift of the cantilever probe during scanning provide topographic and phase images, respectively.

All AFM measurements were performed using a Dimension 3100 AFM (Digital Instruments)** under ambient conditions. Both AFM topographic (height) and phase images were taken. For most of the images, a set point amplitude of between 50 % and 70 % of the free amplitude was used. Silicon tips having a drive frequency of about 300 kHz and a radius of approximately 5 nm were used.

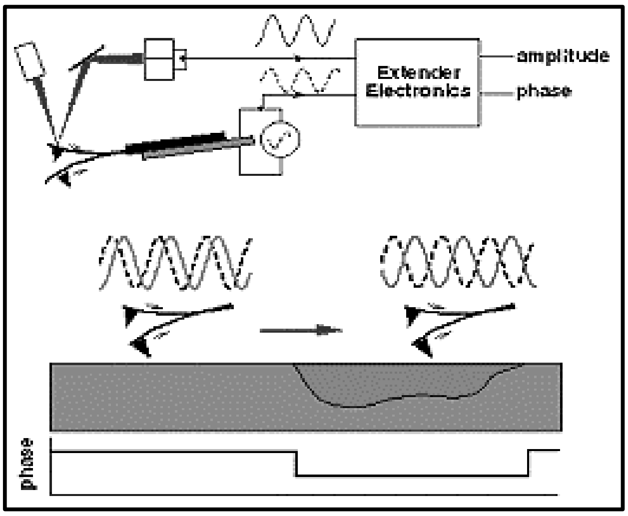

**Figure 1. Tapping Mode AFM, showing cantilever oscillation amplitude and phase shift during scanning.**

## 3 RESULTS AND DISCUSSION

### 3.1 AFM images of air surface and film/substrate interface

Samples of two commonly-used coatings, an amine-cured epoxy and an acrylic-melamine, applied to a very smooth silicon wafer were used to examine morphological differences between the air surface and film/substrate interface of coating systems. AFM images of the surface (a) and interface (b) for the amine-cured epoxy are displayed in Figure 2. The material was a stoichiometric mixture of a bisphenol A epichlorohydrin epoxy resin having an epoxide equivalent mass of 3050 g/mol and a polyalkoxyamine curing agent. Solutions of 50 % (by mass) epoxy resin in toluene and 50 % (by mass) amine curing agent in toluene were thoroughly mixed at appropriate ratios and applied to the Si substrates. The substrates were cleaned with acetone, followed with methanol, and dried with hot air. Coated samples were cured for 24 h at ambient condition (24 °C and 45 % RH), followed by post curing at 120 °C for 2 h. The fully-cured film had a glass transition temperature of approximately 98 °C, as measured by differential scanning calorimetry. For both Figs. 2a and 2b, the pictures on the left, center, and right correspond to 3-D (dimension) topographic, 2-D topographic, and phase images, respectively. The bright and dark areas in the topographic images correspond to the surface peaks and valleys, respectively. It should be mentioned that both topographic and phase AFM

Go Back
Next Page

imagery taken at high magnifications showed that the silicon surface is very smooth and essentially featureless with no evidence of a surface pattern.

Figure 2 shows several morphological differences between the surface and the interface of amine-cured coatings. First, the face in contact with the substrate during film formation is considerably rougher than that of the surface exposed to air, as evidenced by the 3-D images of Fig. 2. The average roughness, root mean square (RMS), of the surface is approximately 3 nm as compared to 10 nm for the interface. It is not known whether the rough interface was actually formed during the film formation or was caused by peeling the film from the substrate.

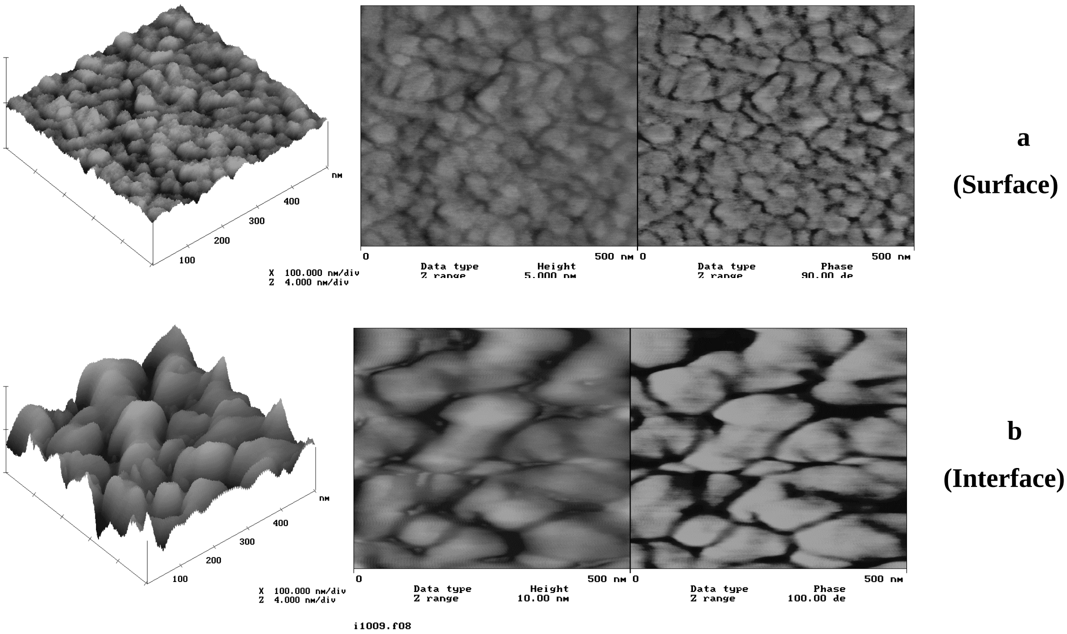

**Figure 2. 500 nm x 500 nm AFM images of the surface (a) and interface (b) of a cured amine-epoxy film applied to a silicon substrate; left: 3-D topographic; center: 2-D topographic; and right: phase. Contrast variation from black to white: a) 5 nm and b) 10 nm (topographic images), a) 90° and b) 100° (phase images).**

Another feature of Fig. 2 is the greater contrast and more well-defined microstructure of the interface as compared to that of the surface. Such differences between the surface and interface have been observed for other epoxies and coatings. The interface image clearly shows that the amine-cured epoxy has a two-phase microstructure, consisting of a matrix that appears bright and interstitial regions dispersed throughout the matrix that appear dark. The 500 nm regions that were imaged were very flat, with topographic changes of less than 10 nm for both the surface and interface. On the other hand, the phase angle difference between the bright and dark regions in the phase image of Fig. 2 is substantial ($90^{o}$ to $100^{o}$). These results indicate that the property differences between the matrix and the interstitial regions of the film are substantial.

Although the exact contrast mechanism in phase imaging is not fully understood, the bright domains in the phase image have been interpreted as due to a mechanically harder area and the dark surrounding region as due to more compliant material (Magonov et al. 1997 and Bar et al. 1997). From these assignments, the amine-cured coating shown in Fig. 2 is a heterogeneous material consisting of softer regions (dark) dispersed in a harder matrix (bright). The nodular domain in the matrix has been attributed to the high-crosslinked material and the interstitial regions as due to the less crosslinked, low molecular mass material (Cuthrell 1968, VanLandingham et al. 1999. This type of heterogeneous microstructure has been observed by AFM for other amine-cured epoxies (VanLandingham et al. 1999, Giraud et al. 2001) and polyester (Gu et al. 2001). Such inhomogeneous structure is generated during the film formation because some unreacted and partially-polymerized materials are unable to merge into the homogeneous structure and remain at the periphery of the network units [Bascom 1970]. The low crosslinked, low molecular mass region has been observed to directly correspond to the corroded spots on steel substrates (Mills and Mayne 1980). It is clear from Figure 2 that the average size of the highly-crosslinked region in the interface is larger than that on the air surface.

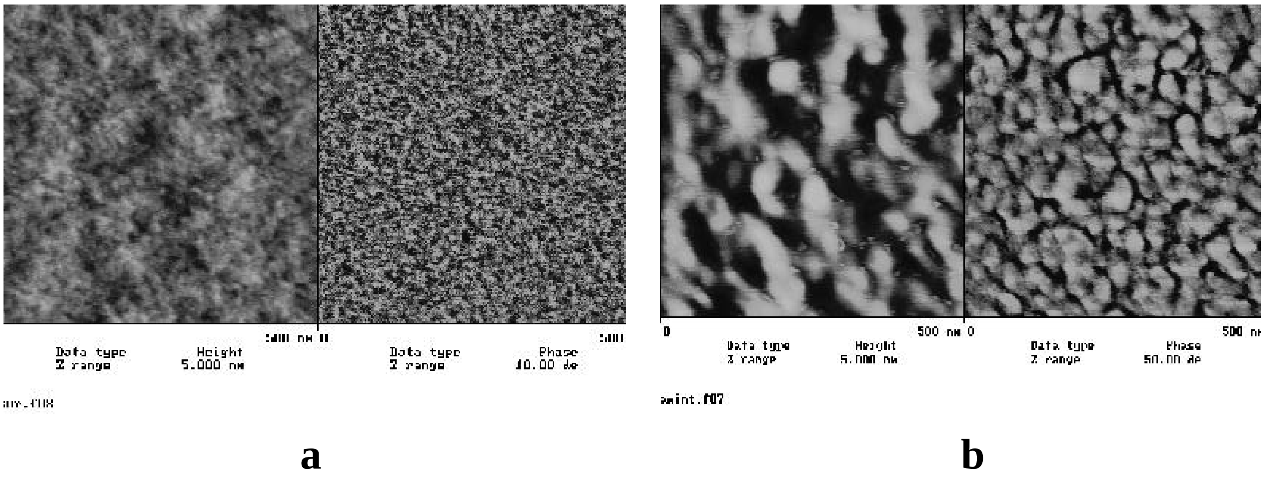

**Figure 3. AFM images of the surface (a) and interface (b) of an acrylic melamine coating applied to a silicon substrate. For both a and b, topographic image is on the left and phase image is on the right.**

AFM imaging of the air surface and film/substrate interface for acrylic-melamine coatings is shown in Figure 3. This material was a stoichiometric mixture of a hydroxy-terminated acrylic polymer and a partially-methylated melamine resin (Martin et al. 2001). Samples were prepared by drawing down the mixture on a cleaned, smooth silicon wafer. The cast film of approximately 50 μm thick was fully cured after heating at 130 $^{o}$C for 20 minutes in an air-circulated oven. Free films were obtained by peeling from the substrate after 15-minute immersion in boiled water. The films were conditioned in a $P_2O_5$-containing desiccator for one week before use. For both Figs. 3a and 3b, topographic images are on the left and phase images are on the right. As for the epoxy, the phase images show a much higher contrast and more well-defined microstructure in the interface sample than that of the surface. This difference is also indicated by a difference in the phase shift, which is only 10$^{o}$ for the air side but 50$^{o}$ for the substrate side. Further, even the phase image shows little evidence of the microstructure at the air surface. This observation and evidence of a well-defined microstructure at the interface, which is true for a variety of amine-cured epoxies and acrylic melamine coatings, suggests that the air surface of coatings could be covered with a thin layer of a lower surface-free-energy material. A thin layer of such a material should make the surface appear as homogeneous and with poor phase contrast, as observed in Figs. 2 and 3. This interpretation is consistent with extensive literature indicating that the air surface of a multicomponent polymer system is generally enriched with a lower surface-free-energy component to minimize polymer-air interfacial energy (Yoon et al. 1994 and Chen et al. 1998).

Since an enrichment of a hydrophobic layer at the surface has strong implications in many coating applications such as paintability, stain resistance, and weathering resistance, experiments to substantiate this postulation were conducted. Blends of low surface-free energy, crystallized poly (vinylidene fluoride) (PVDF) and amorphous poly (methylmethacrylate)-poly (ethylacrylate) copolymer (PMMA-co-PEA) are used for this study. These types of PVDF/acrylic polymer blends are commonly used for industrial coatings. Since PVDF is a crystallized polymer, it should be easily recognized when blending with amorphous materials. Fig. 4 displays 2-D and 3-D AFM topographic images of the surface and interface of the 70/30 (by mass) PVDF/PMMA-co-PEA) blend. These samples were prepared by applying the blend at 47 % (by mass) in isophorone solvent to glass plates. The coated plates, which had a film thickness of approximately 75 μm, were cured at 246 $^{o}$C for 10 min and cooled down slowly to 24 $^{o}$C. After a 10-min immersion in boiled water, the films were peeled off from the glass substrate. As seen in the 3-D images, the surface of these films is rougher than that of the interface and is covered almost

completely with PVDF crystallites. On the other hand, the interface is relative smooth and still contains some amorphous material. Further, the sizes of the crystal structure (spherulites) on the surface are substantially larger than those at the interface. These results indicate that the air surface of the blend films is enriched with low surface-free energy PVDF.

This is more evident in the AFM images of the 50/50 blend (by mass) shown in Fig. 5. The surface of this blend is largely covered with the crystallites of PVDF but the interface is void of crystal structure. Instead, the interface consists of smooth areas in between 200 nm to 300 nm deep holes. High magnification images of the interface revealed that the holes have an irregular shape and that these holes were actually the broken areas in the film (cohesive failure) resulting from the peeling. This observation indicates that the adhesion between the 50/50 blend and the glass substrate was good. Further, there is no evidence of the crystal structure of PVDF material at the interface even at 50 % mass fraction. Evidence provided from the good adhesion as well as the absence of PVDF material on the film surface adjacent to the substrate suggest that amorphous PMMA-co-PEA is preferentially present at the polymer/substrate interface.

To verify that low surface-free energy PVDF preferentially migrates to the surface and higher surface-free energy acrylic copolymer tends to move to the interface, contact angle and attenuated total reflection-Fourier transform infrared spectroscopy (ATR-FTIR) analyses were performed. Contact angle is sensitive to the first 1 nm surface layer, and for the germanium prism used in this study, the ATR technique can provide chemical information at a depth from about 0.25 μm to 1.0 μm from the surface for wavelengths of infrared radiation from 3 μm to 10 μm. Therefore, these analyses should provide information on the chemical composition at or near the surface. The results are summarized in Table 1.

**Table 1. Surface and interface wettability and ATR-FTIR properties of different PVDF/PMMA-co-PEA blends**

| | PVDF/PMMA-co-PEA blends, mass fraction | | | | | |
|---|---|---|---|---|---|---|
| | 70/30 | | 50/50 | | 30/70 | |
| | Surface | Interface | Surface | Interface | Surface | Interface |
| Water Contact Angle, degrees[1] | 71.5 ± 0.9[2] | 58.3 ± 0.5 | 72.5 ± 3.7 | 68.1 ± 4.7 | 75.1 ± 1.4 | 63.5 ± 1.9 |
| Surface Polarity | 0.21 | 0.5 | 0.17 | 0.46 | 0.16 | 0.29 |
| C-F/C=O[3] | 0.382 | 0.331 | 1.02 | 0.92 | 2.25 | 2.06 |

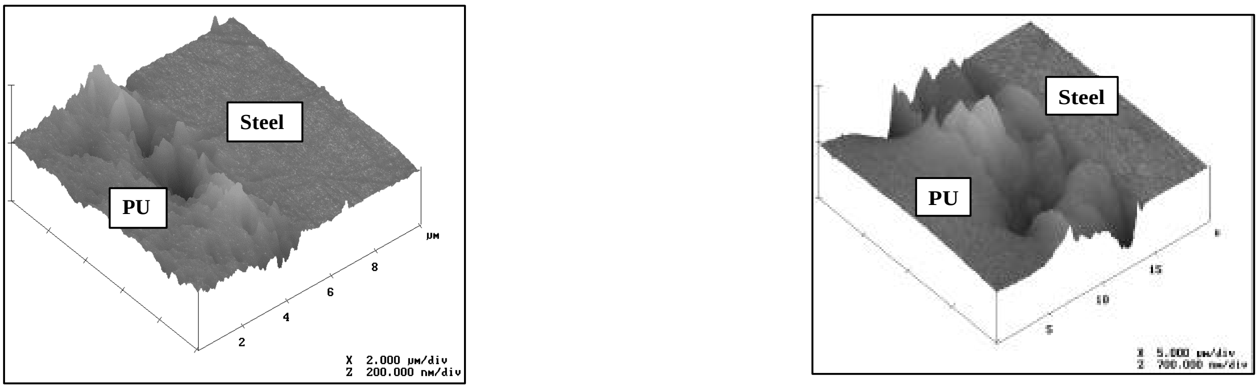
*[1]Average of six measurements; [2]The number after the ± symbol indicates one standard uncertainty; [3]FTIR-ATR intensity ratio between the C-F band and C=O band.*

In Table 1, the contact angle was measured using the sessile drop method, and the results were the average of six drops. The surface polarity is the ratio between the polar force component and the total surface free energy. These surface parameters were determined using the geometric mean method (Wu 1982) and with water and methylene iodide as the liquids. Both the contact angle and surface-free energy components, namely polar force and nonpolar force, can give a good indication of the wetting and related properties of a surface. The C-F/C=O is the ratio between the ATR-FTIR intensity of the C-F band of PVDF material and C=O band of the acrylic copolymer. All results of Table 1 show that the surface contains a larger amount of the less wettable, low surface-free energy PVDF than the interface. This observation supports the AFM results given above.

The results presented in Figs. 2 to 5, and Table 1 clearly show that a substantial difference exists in the microstructure between the surface and interface and that a low surface-free energy layer is present on the film surface exposed to air. Since the microstructure and chemical composition of a surface control its interactions with other materials and the environments, such a low surface-free energy surface should have a large effect on the wettability and weatherability of coatings. For example, the paintability and bondability to such a surface is more difficult than to more hydrophilic surfaces. On the other hand, it is a harder surface for dirts and contaminants to stick to and an easier surface for slipping (low friction). A low surface-free energy covered surface would also alter the weather resistance of the coatings. This is because, while the bulk coating underneath degrades, the more inert, hydrophobic thin layer on the surface may not undergo any change at all until much later times. This was the case for the degradation of acrylic-melamine coatings exposed to humid environments (Nguyen et al. 2001). In this study, FTIR analyses indicated substantial hydrolysis and material loss in the film within a few 200 h of exposure. However, AFM results showed little surface morphology and roughness change until after 600 h exposure. Similarly, the delay in the hydrolysis of poly(sebacic anhydride) (PSA) and poly(DL-lactic acid) (PLA) blends used to control drug deliveries has been verified by AFM and X-ray photoelectron spectroscopy (XPS) as due to a surface enrichment of the more hydrolytically-resistant PLA (Chen et al. 1998). The difference in the degradation characteristics between the surface and the bulk could explain the lack of a correlation between surface gloss loss and bulk chemical degradation, often reported in the coatings literature.

### 3.2 AFM images of coating system cross sections

Another approach to investigate the difference between surface and the interface is to compare AFM images of the air surface with those of the cross sections. Examples for a two-part polyurethane (PU) and an amine-cured epoxy coating are illustrated in Figs. 6 and 7, respectively. These are 3-D AFM topographic images of cross sections of thick films applied to a polished steel surface. Figure 6a shows a cross-sectioned image of a PU sample cured at ambient (24 °C and 45 %RH) for two weeks, and Figure 6b is from the same PU sample but cured at 100 °C in an air-circulated oven for 2 h. The interface region (interphase) is defined as the rough section between the steel and the smooth PU matrix. The large difference between the peaks and valleys in the interphase was apparently induced by the mechanically weak material of this region and was roughened by the polishing action. These results suggest that the roughened section of these samples was not fully cured. This is supported by the smoothness of the PU matrix further away from the substrate. Such a smooth appearance indicates a more fully-cured and hard surface. It is not certain whether the weak interphase was due to an inadequate curing schedule (short time or low temperature) or due to a consumption of isocyanate by the hydrated steel surface. A post-curing study at an elevated temperature for different times could provide an answer to this question. Nevertheless, a sample containing such a weak interface region will have poor adhesion. Figure 6 also shows that the weak interface region of the heat-cured sample was narrower than that of the ambient-cured sample. These results suggest that AFM can be an useful technique to study the effect of curing schedule on the adhesion and service life of coating systems and adhesives.



a b

**Figure 6. AFM 3-D topographic images of room-temperature cure (a) and heat-cure (b) polyurethane coating on steel.**

Figure 7 shows the effect of epoxy/amine ratio on the interface region of an amine-cured epoxy coating. The epoxy resin was a 190 g/m equivalent mass material and the amine was a polyalkoxyamine. All samples were cured at 120 $^oC$ for 2 h. In the excess-amine sample (Figure 7c), the polished epoxy surface is smoother than that of the 1/1 and 1/0.8 epoxide/amine samples. Further, the rough, undercured interface region of the excess-amine sample (≈ 1.8 μm) is narrower than that of the 1/1 amine/epoxide sample (≈ 4 μm). On the other hand, the amine-deficient sample (Figure 7a) shows no distinctive interface region. The rough nature of this cross section, which is similar to the interface regions of the other two stoichiometric samples, suggests that the amine-deficient sample was not fully cured. A difference in the interphase width between the 1/1 and 1/1.2 epoxide/amine samples suggest that the interphase under-cure region was wider for the 1/1 epoxy/amine sample than that of the excess-amine epoxy. This postulation is consistent with previous reports indicating that amines from amine-cured epoxies have a tendency to migrate and preferentially adsorb on glass fiber (Palmese and McCullough 1992) and hydrated steel (Wicks 1987) surfaces. It is noted that, under ambient condition, a layer of iron oxides approximately 35 nm to 40 nm is instantaneously formed on the steel surface. Since iron oxides are highly energetic, they adsorb water rapidly. Thus, it is expected that the surface of the polished steel used in this study was covered with a hydrated oxide layer. The migration of amine to the substrate surface not only leaves the material near the interface under-cured, which results in weak adhesion, but also produces an interface with an excess of amine. Since low molecular mass amines are hygroscopic, the presence of such material at the interface will introduce an osmotic pressure when this material is exposed to water or high relative humidities. This will result in an increase in the rate of water transport to the interface and an increase of the thickness of the water layer at that location. Thus, if the substrate is not properly treated or the coating is not properly formulated, the interface of amine-cured coated materials in humid environments is susceptible to water attack, resulting in loss of adhesion and delamination.

## 4 CONCLUSIONS

The surface and interface microstructure of a variety of coatings applied to different substrates have been characterized with nanoscale resolution by tapping mode atomic force microscopy (TMAFM). Contact angle measurements and attenuated total reflection-Fourier transform infrared spectroscopy were performed on some coating systems to verify AFM data. In addition, the effects of curing conditions and stoichoimetry on the interface region were also studied for polyurethane and epoxy coatings. The results show that the surface exposed to the substrate has a much higher contrast and a more well-defined morphology than those of the surface exposed to air. This result suggests that there is a substantial difference in both chemical composition and microstructure between the surface and interface, and that a thin layer of a low surface-free energy material generally covers coating surface. These results have strong implications for many phenomena occurring on the surface of coating systems, including the wettability, bondability, paintability, and weatherability.

***Certain commercial product or equipment is described to specify adequately the experimental procedure. In no case does such identification imply recommendation or endorsement by NIST, nor does it imply that it is necessarily the best available for the purpose*.

# Critical Review Of Corrosion Deterioration Models For Reinforced Concrete

**J Gulikers**
**Civil Engineering Division, Ministry of Transport Utrecht, The Netherlands**

**Summary**: **Corrosion of embedded reinforcing steel is considered the major mode of deterioration for concrete structures. Traditionally, much attention has been focused on models which can predict the time to activation of the corrosion process. However, in some circumstances the propagation stage of corrosion may contribute significantly to the service life. Consequently, there is an urgent need for numerical models which are capable of describing the rate of attack.**

**The paper focuses on localised attack of reinforcing steel resulting from chloride contamination of the concrete cover. Three commonly used deterioration models are reviewed and an improved model for localised corrosion is presented. This model takes into account the accelerating effect of macrocells on local corrosion rates assuming a cylindrical shape of the pitting site. The results are presented in terms of local penetration depth, surface area under corrosion attack, and steel volume consumed by corrosion. The improved corrosion deterioration model can be used to formulate a probabilistic model which allows calculation of the probability that a given reduction of the reinforcement cross-section has taken place at a given time.**

**Keywords. steel reinforcement, concrete, corrosion, durability, modelling, service life**

## 1 INTRODUCTION

Whole life performance assessment is gradually becoming a requirement for the design of new structures and for inspection, repair, upgrading, replacement, and demolition decisions of ageing and deteriorated structure. This has also urged for design for durability of steel reinforced concrete structures. Several deterioration models are currently being used in service life prediction and consequently can be applied for engineering design and maintenance purposes.

Corrosion of reinforcing steel in concrete is generally regarded as the most prevalent mode of premature distress and deterioration of structural concrete. This has resulted in a clear need from both the industry and field of research that a model be developed to determine the initiation of corrosion and to predict the remaining service life of corroded reinforced concrete structures. The conceptual model proposed by Tuutti (1982) is frequently used as a basis for the assessment of the loss of serviceability of reinforced concrete during its service life (DuraCrete 1998). This model comprises two stages, i.e. the initiation stage which involves the penetration of deleterious substances through the concrete cover, and the propagation stage which involves active corrosion following steel depassivation (See Fig. 1). The expected service life will include the time needed to corrode the steel to an extent that renders the structure unsuitable for further service.

Go Back Next Page

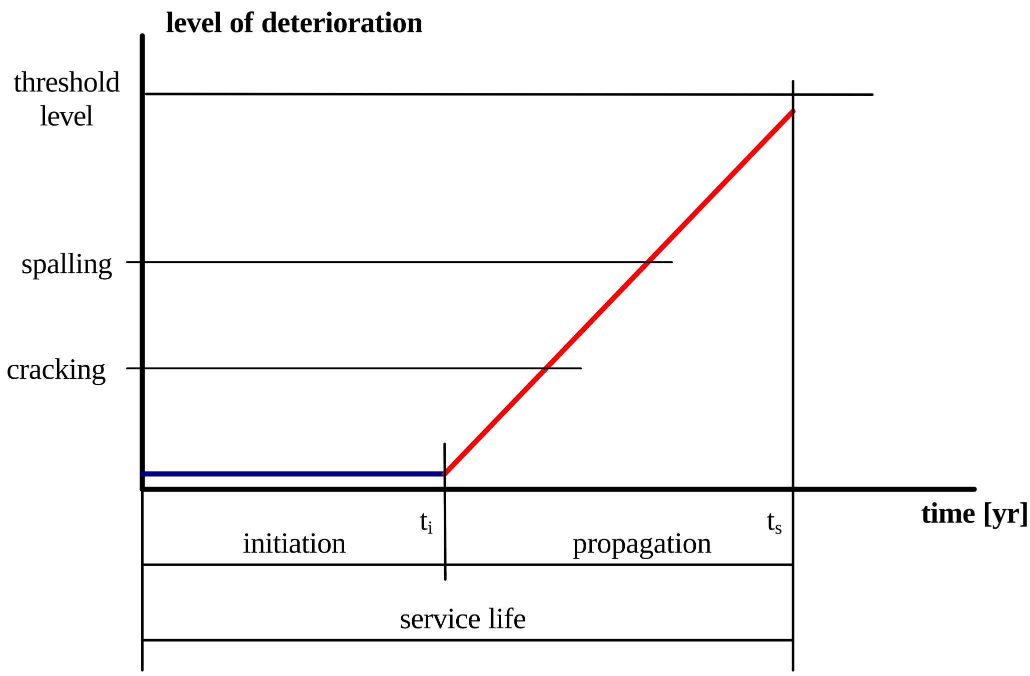

**Figure 1. Conceptual deterioration model showing the stages during the service life of a reinforced concrete structure with respect to reinforcement corrosion.**

Most of the durability models currently available are focusing on the prediction of corrosion initiation. However, it has to be borne in mind that initiation of corrosion represents no immediate threat to the structural integrity of the structure. Consequently, service life predictions based on initiation of reinforcement corrosion result into a conservative approach since the propagation stage may contribute significantly to the service life (Gulikers 2000).

In recent years several deterioration models describing corrosion attack of reinforcing steel have become available(e.g. Andrade *et al.* 1989, Roberts *et al.* 2000). However, most of these models show considerable drawbacks and pitfalls which necessitates a critical review. Moreover, these models conflict with the behaviour generally encountered in real structures. This paper focuses on the propagation period of reinforcement corrosion and addresses issues associated with localised attack resulting from contamination of the concrete cover by penetrating chlorides.

## 2 STRUCTURAL CONSEQUENCES OF REINFORCEMENT CORROSION

Damage resulting from reinforcement corrosion is characterised by:

- surface staining;
- cracking or spalling of the concrete cover;
- delamination of the concrete cover;
- reduction of the cross sectional area of the reinforcing steel;
- reduction of the steel-concrete bond.

Furthermore there exists some experimental evidence that corrosion results into a decrease in elongation at maximum load and impair the mechanical properties of the steel ((Andrade *et al.* 1991). In general, the impact of corrosion-damaged reinforcement on performance of reinforced concrete structures is associated with reductions in member stiffness, ductility, ultimate strength and fatigue behaviour. Consequently, corrosion of reinforcing steel is associated with the serviceability as well as the ultimate limit state of a concrete structure or element. The first corresponds to a limiting condition resulting from damage such as excessive corrosion-induced cracking or deflections . The second limit state is related to a loss of load-bearing capacity due to the loss of steel reinforcement cross section, or bond between the concrete and reinforcing steel.

Generally, the basic problem associated with the deterioration of reinforced concrete due to corrosion

is not that the reinforcing steel itself is reduced in mechanical strength, but rather that the products of corrosion generate stresses within the concrete which cannot be supported by the limited plastic deformation of the concrete, and the concrete therefore cracks. This results into a weakening of the bond and anchorage between concrete and reinforcement which directly affects the serviceability and strengths of concrete elements within a structure (Cabrera 1996).

Steel corrosion products (rust) usually occupy a much larger volume than the uncorroded steel and consequently generate stresses that eventually cause cracking and spalling of the concrete cover. This makes it easier to for aggressive agents to ingress towards the steel, with a consequent increase in the rate of corrosion. The strongly localised progress of corrosion reduced the cross-sectional area of the steel, thus impairing its load- carrying capacity. However, it is argued that the overall effects of localised pitting corrosion on the load bearing capacity of a bridge deck may be no more severe than the effects of more widespread general corrosion. Furthermore, for large structures such as bridge decks, even propagation of corrosion at a single point only will have a limited effect on its load-bearing capacity.

The amount of corrosion required to initiate cracking is dependent on the quality of the concrete cover and the ratio of cover to reinforcing bar diameter. According to Broomfield (1997) visible cracks due to corrosion appear in the concrete cover after reinforcing bar section losses of 10-100 µm. Formation of cracks, especially those that form along the steel reinforcement, probably provides the best visible indicator for use in corrosion assessments and trying to develop a relationship between corrosion and performance (Naus *et al.* 2000). The deposition of corrosion products at the steel-concrete interface together with cracking of the concrete cover also result in a reduction of bond between reinforcing steel and concrete, thereby impairing the bar anchorage.

The characteristics of corrosion resulting from carbonation and chloride ingress differ in one principal aspect. Carbonation-induced corrosion tends to be general whereas chloride-induced corrosion is characterised by local, rapidly corroding areas of bars.

In the following chapters some models on corrosion attack will be reviewed and an improved model for localised corrosion will be presented.

## 3 EXISTING MODELS OF CORROSION ATTACK

### 3.1 General

The corrosion rate is most frequently given /supplied as an averaged corrosion current density, $i_{corr}$, expressed in mA/m$^2$ but for practical reasons a conversion into µm/year is more appropriate. This conversion can be accomplished by using Faraday's law:

$$1\ \mathrm{mA/m^2} \equiv 1.16\ \mu\mathrm{m/yr} \qquad \text{or} \qquad 1\ \mu\mathrm{A} \equiv 1\ \mathrm{mm^3/yr}$$

From practical point of view a corrosion rate of less than 1 to 2 mA/m$^2$ might be considered negligible since it is normally related to the current to maintain a passive oxide film.

Once corrosion has started, i.e. after depassivation by carbonation or chloride-contamination of the concrete cover, the rate is dependent on the continuous supply of water and oxygen and the temperature at the steel section. Average corrosion current densities of 10-30 mA/m$^2$ are frequently encountered in practical situations with active corrosion. Only seldomly values of 100 mA/m$^2$ or higher are determined. In some rare instances of low oxygen availability corrosion can occur, but will not result in expansive corrosion products. This is known as "black rust" which represents a serious condition since there is no visual warning.

In the following some common corrosion deterioration models will be reviewed.

### 3.2 Uniform corrosion model

Generally, values for $i_{corr}$ of reinforcing steel are determined indirectly by experiments on site, e.g. by means of polarisation resistance or galvanostatic pulse techniques. Usually, the corrosion rate values thus obtained are expressed as surface-averaged corrosion rates although significant spatial variations may be present. Consequently, uniform corrosion is most commonly assumed when calculating corrosion penetration rates of reinforcing steel bars (Vu and Stewart 2000). According to this approach uniform corrosion attack occurs on the complete surface of a steel bar. Consequently, the geometrical shape of the rebar cross sectional area is considered to remain unchanged as a circle of gradually decreasing diameter during the propagation stage of corrosion.

Assuming uniform corrosion attack, the residual diameter of the reinforcement bar, $\varnothing_{res}$, can be calculated:

$$\varnothing_{res} = \varnothing_{rebar} - \lambda \cdot i_{corr} \cdot t_p \qquad \text{[mm]}$$

$i_{corr}$ average annual corrosion current density [mA/m$^2$];

$\lambda$ factor to convert average corrosion densities to average penetration rates:

$\lambda = 2.3294 \cdot 10^{-3}$ [mm/(mA/m$^2$)];

$t_p$ corrosion propagation time; $t_p = t_s - t_i$ [yr] is the time elapsed since corrosion initiation;

$t_s$: service age of the structure [yr];

$t_i$ length of initiation period [yr].

However, it is unlikely that the complete circumference of a steel bar is under corrosion attack once the depassivation front reaches the level of the reinforcement. Bearing in mind that the depassivation front gradually moves into the interior of the concrete body, the depassivated steel surface increases in time, at least theoretically. However, the penetration rates for a partly depassivated rebar circumference may be considerably higher than the average corrosion rate values usually given in literature due to macrocell effects. These influences are elaborated by Gulikers (2002) which resulted into an improved propagation model for carbonation-induced corrosion taking into account a time-dependent moving depassivation front.

### 3.3 Pitting corrosion model

In order to take account of the localised nature of chloride-induced corrosion, the uniform corrosion model has been modified by introducing a pitting factor, α, and defining a critical limiting pit depth (Andrade *et al.* 1996). Accordingly, the critical residual bar diameter, $\varnothing_{res}$, can be obtained from the initial bar diameter, $\varnothing_{rebar}$, and the local reduction of the cross section

$$\varnothing_{res} = \varnothing_{rebar} - \alpha \cdot \lambda \cdot i_{corr} \cdot t_p \qquad \text{[mm]}$$

According to González *et al*. (1995) the maximum pit depth due to localised attack will be approximately 4 to 10 times the surface-averaged uniform attack. This simplified approach has been adopted in the probabilistic method of design for durability developed within the DuraCrete Project (1998).

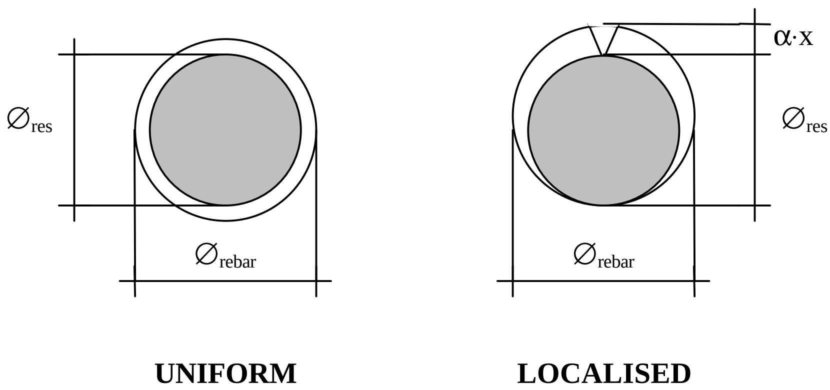

**Figure 2. Residual reinforcing bar diameter due to uniform and localised corrosion attack.**

Although this approach is practical it lacks a sound scientific basis. Moreover, the magnitude of the pitting factor has to be chosen on arbitrary grounds.

### 3.4 Wavefront model

The influence of a time-dependent depassivation front is taken into account by a “wavefront” type progression of corrosion through the reinforcing bar (Middleton and Hogg, 1998). This model assumes that the corrosion front is in a direct line with the front of corrosion attack. Both front lines run in parallel with the exposed concrete surface. The corrosion penetration rate and consequently the steel volume consumed by corrosion are therefore dependent on the chloride penetration rate. Initiation of corrosion starts at the steel surface nearest to the exposed concrete surface and will gradually extend to surface areas located at greater depths. The wavefront model has been adopted by Pedersen and Thoft-Christensen (1993) for a reliability analysis of corroded tendons in prestressed concrete.

The residual cross sectional area, $A_{res}$, is mathematically expressed by:

$$A_{res} = (\pi + \sin\theta \cdot \cos\theta - \theta) \cdot r_{rebar}^2 \qquad \text{[mm}^2\text{]}$$

with

$$\theta(t) = \arccos\left(\frac{r_{rebar} + c - x_{dep}(t)}{r_{rebar}}\right) \qquad [-]$$

$r_{rebar}$ initial radius of the rebar [mm];

$c$ (local) thickness of the concrete cover [mm];

$x_{dep}(t)$ depth of the depassivation front [mm].

This approach has been exemplified for a concrete cover quality characterised by a range of effective chloride transport coefficients. It is assumed that the chloride penetration into the concrete cover is described by:

$$c_{crit} = c_{surf} \cdot \left[1 - \mathrm{erf}\left(\frac{x_{dep}}{2\sqrt{D_{Cl} \cdot t}}\right)\right] \qquad [\%]$$

with $c_{crit}$ critical chloride concentration at which steel depassivation occurs [%];

$c_{surf}$ fixed chloride concentration a the external concrete surface [%];

$x_{dep}$ depth of the depassivation front [m];

$D_{Cl}$ effective chloride transport coefficient [$m^2/s$];

$t$ exposure time [s].

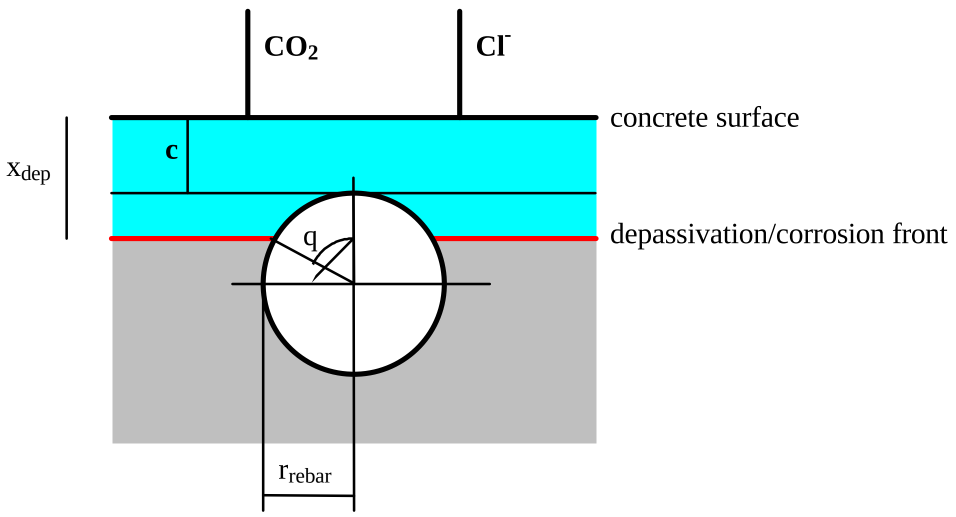

**Figure 3. Wavefront model for corrosion penetration of a reinforcing steel bar.**

Through modification an expression for the time-dependent depth, $x_{dep}$, of the depassivation front can be obtained:

$$x_{dep} = 2D_{Cl} \cdot A \cdot \sqrt{t} \qquad [m]$$

with $\mathrm{erf}(A) = \left(1 - \frac{c_{crit}}{c_{surf}}\right)$, considered to be constant.

According to the wavefront model the penetration rate of the depassivation front, $v_{dep}$, equals the steel corrosion penetration rate, $v_{corr}$, which is given by:

$$v_{dep} = v_{corr} = 31.56 \cdot 10^9 \cdot \frac{D_{Cl} \cdot A}{\sqrt{t}} \qquad (mm/yr)$$

Following the wavefront model, if the average cover depth is known and the time to corrosion initiation is derived from frequent visual observations, the corresponding corrosion penetration rate could be estimated from:

$$v_{cor} = 31.56 \cdot 10^9 \cdot \frac{c}{2 \cdot t_i} \qquad (mm/yr)$$

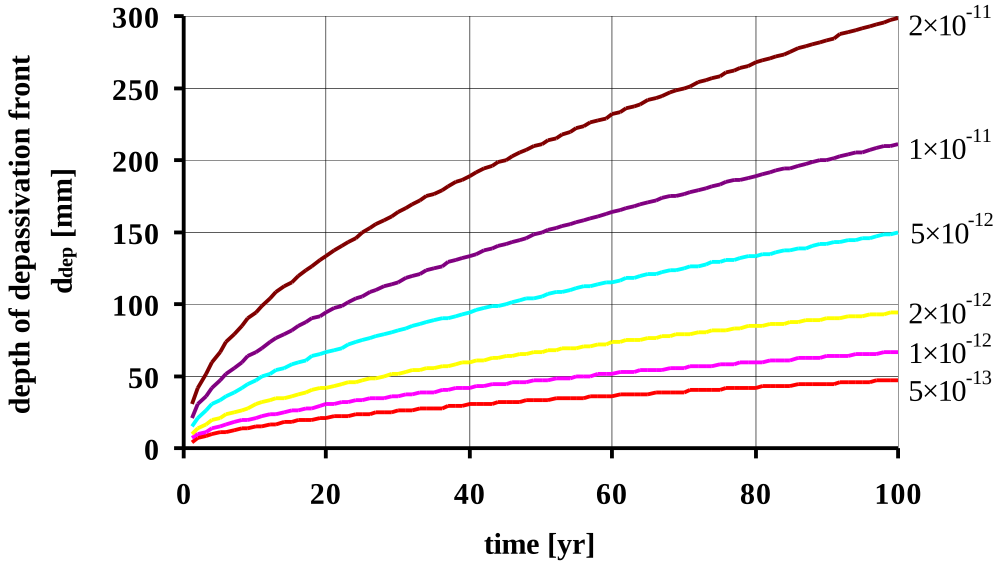

**Figure 4. Wavefront model: depth of depassivation front as a function of time for different values of $D_{Cl}$ ($m^2/s$).**

The wavefront model seems to predict unrealistically high penetration rates: for a cover depth of 20 mm the penetration rate ranges from 0.560 to 10 mm/yr, for effective chloride transport coefficients, $D_{Cl}$, of $5{\cdot}10^{-13}$ to $2{\cdot}10^{-11}$ $m^2/s$, respectively.

Moreover, the implicit assumption that corrosion will attack on the complete length of a reinforcing bar is not plausible for chloride-induced corrosion. On the other hand, the calculated values may be considered as local penetration rates.

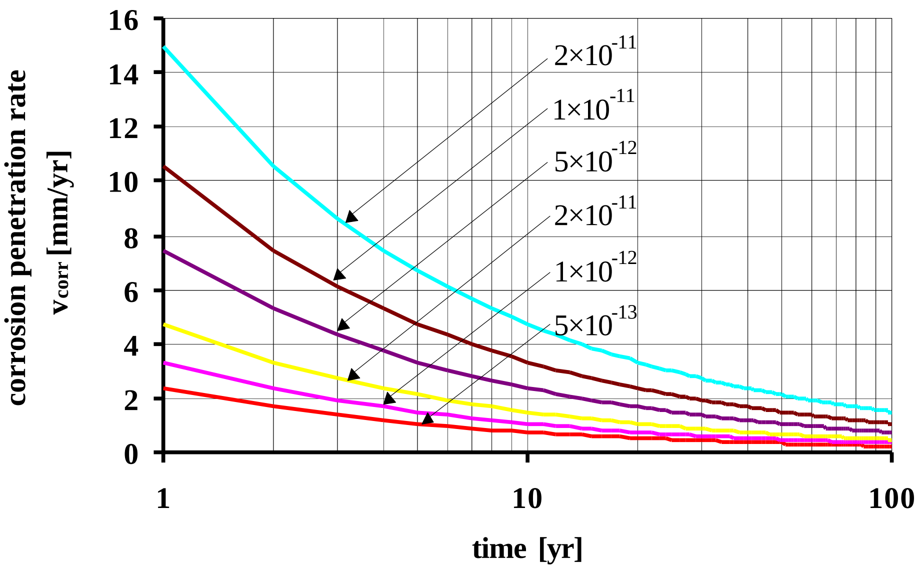

**Figure 5. Wavefront model: Corrosion penetration rate as a function of time for different values of $D_{Cl}$ ($m^2/s$).**

## 4 IMPROVED MODEL FOR LOCALISED CORROSION ATTACK BY CHLORIDES

The pitfalls of the models described above served as the main motive to develop improved deterioration models for both carbonation and chloride-induced reinforcement corrosion (Gulikers 2002). However, with respect to structural safety of reinforced concrete structures only corrosion induced by chloride-contamination is considered of practical relevance.

Chloride ions present within the concrete matrix tend to depassivate embedded steel by locally breaking down the protective layer of iron oxides. This results into the development of macrocells which are characterised by distinct and spatially fixed cathodic and anodic areas. This situation gives rise to a unfavourable cathode to anode area ratio inducing high local corrosion rates. The intense anodic areas so produced develop into characteristic pits which may continue to grow provided the chloride ion concentration exceeds a critical level.

The deterioration model developed for chloride-induced corrosion assumes that the local corrosion rate is determined by the cathodic polarisation behaviour of the passive steel surrounding the pitting area. The macrocell current produced is dependent on the throwing power, the availability of oxygen and moisture, the thickness and quality of the concrete cover, and the geometry and size of the reinforcing steel. In (Gulikers 2001) a numerical model has been developed for so-called coplanar and planparallel macrocells. This model allows calculation of the macrocell current flowing between anodic and cathodic steel surfaces, taking into account all parameters of practical relevance.

Although the macrocell current will reflect seasonal variations in the moisture content of the concrete cover, it may be assumed that it's averaged annual magnitude is almost constant over time for given geometrical and exposure conditions.. Consequently, this average value of the macrocell current can be used as an input to calculate the loss of cross-sectional area of the steel bar during the propagation period.

For simplicity, the pits resulting from localised corrosion by chloride contamination are assumed to have a cylindrical shape. The pitting site starts as tiny spot a the top surface and gradually expands in radial direction into the body of the steel rebar. The steel volume consumed by corrosion and the steel surface under corrosion attack is obtained from a numerical analysis of the intersection of two cylinders, one being the steel rebar (see Fig. 6).

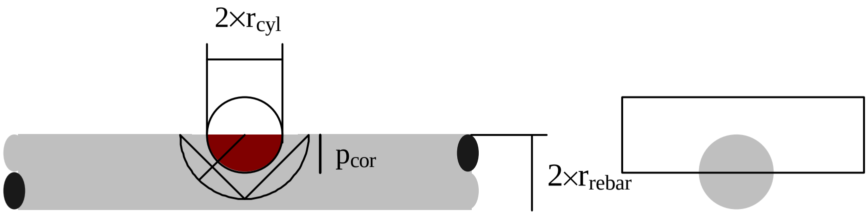

**Figure 6. Improved model for localised corrosion attack**

A curve-fitting exercise was performed on the results of the numerical analysis. This resulted in a best-fit polynomial mathematical expression describing the steel volume consumed by corrosion, $V_{corr}$, and the penetration depth, $p_{corr}$, respectively, with the ratio $r_{cyl}/r_{rebar}$ as the main variable:

$$R = A + B\cdot X + C\cdot X^2 + D\cdot X^3 + E\cdot X^4 \qquad (–)$$

with

$$R = \frac{A_{corr}}{r_{rebar}^2} \text{ or } R = \frac{V_{corr}}{r_{rebar}^3}$$

$$X = \frac{r_{cyl}}{r_{rebar}}\text{; } 0 \le X \le 2.0$$

The constants A to E obtained from fitting procedures are given in Table 1.

**Table 1. Fitting constants for calculation of the corroding steel surface, $A_{corr}$, and the steel volume consumed by corrosion, $V_{corr}$, respectively**

| *Fitting constant* | $A_{corr}$ (–) | $V_{corr}$ (–) |
|---|---|---|
| A | $-1.018\cdot10^{-1}$ | $-1.356\cdot10^{-3}$ |
| B | +3.086 | $-5.1424\cdot10^{-2}$ |
| C | +3.077 | +1.18035 |
| D | $-1.868\cdot10^{-1}$ | $+1.69018\cdot10^{-1}$ |
| E | $-5.1005\cdot10^{-1}$ | $-0.4974\cdot10^{-1}$ |

A comparison between the results of the numerical analysis and the fitting curve is presented in Fig. 7.

Go Back Next Page

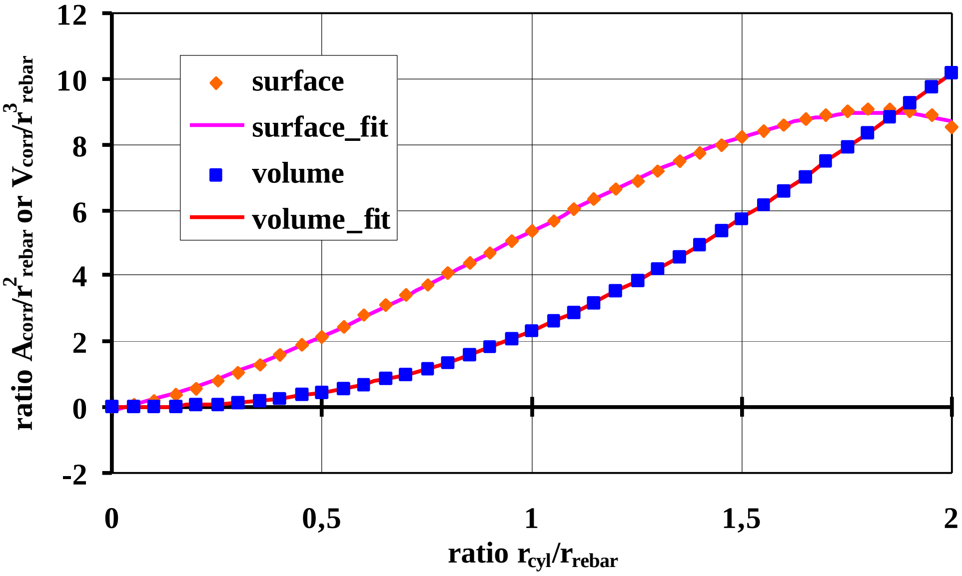

**Figure 7. Relationship between $r_{cyl}/r_{rebar}$ and $A_{corr}/r^2_{rebar}$ or $V_{corr}/r^3_{rebar}$, respectively.**

The steel volume consumed by corrosion shows a continuous increase with a maximum ratio of 10.17, whereas the steel surface area under attack demonstrates a maximum ratio of 9.07 for $r_{cyl}/r_{rebar} \approx 1.84$.

Under most exposure conditions, the magnitude of the macrocell current may vary considerably dependent on the thickness and quality of the concrete cover, and the diameter of the steel rebar. According to calculations performed by Gulikers and Raupach (1999) for coplanar arrangements macrocell currents may range from 35 to 2738 µA, corresponding to a rate of steel removal of 41 and 3206 $mm^3$/year, respectively. For a given macrocell current, the steel volume consumed, surface area under corrosion attack and the penetration depth can be calculated as a function of time.

With respect to structural behaviour the corrosion penetration depth, $p_{corr}$ is of importance. Fig. 8 shows the range of pit penetration depths for a reinforcing bar with a diameter of 16 mm attacked by macrocell currents ranging from 50 to 5000 µA.

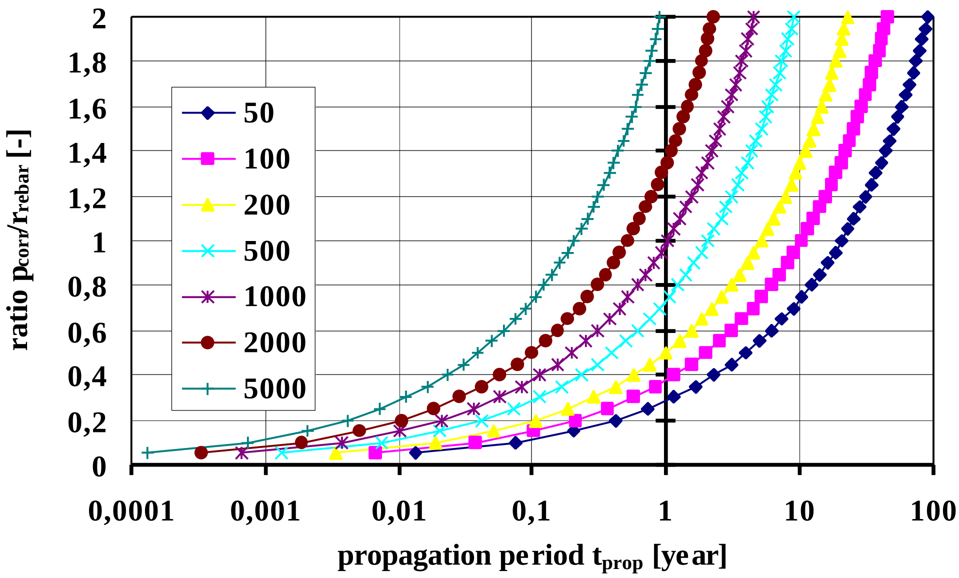

**Fig. 8. Ratio between $p_{corr}/r_{rebar}$ and propagation period for a steel bar Æ16 mm attacked by macrocells ranging from 50 to 5000 mA.**

The propagation periods thus calculated range from 0.9 and 90 years for macrocell currents ranging from 50 to 5000 µA.

The instantaneous corrosion penetration rate expressed in mm/yr can be calculated based on the steel surface area available within the pit crater. A minimum value is obtained for $r_{cyl}/r_{rebar} = 1.84$ where the surface ratio is at its maximum. The calculated results shown in Fig. 9 are presented on a double logarithmic scale. The difference between the initial values and the values at the end of the propagation period may differ by two to three orders of magnitude. Note that the initial values correspond to $p_{corr}/r_{cyl} = 0.05$ which may severely underestimate the actual initial rate of attack.

These examples clearly demonstrate that the improved model allows calculation of the local penetration depth and corrosion rate as a function of time. The values can serve as an input for models describing the structural performance of reinforced structures.

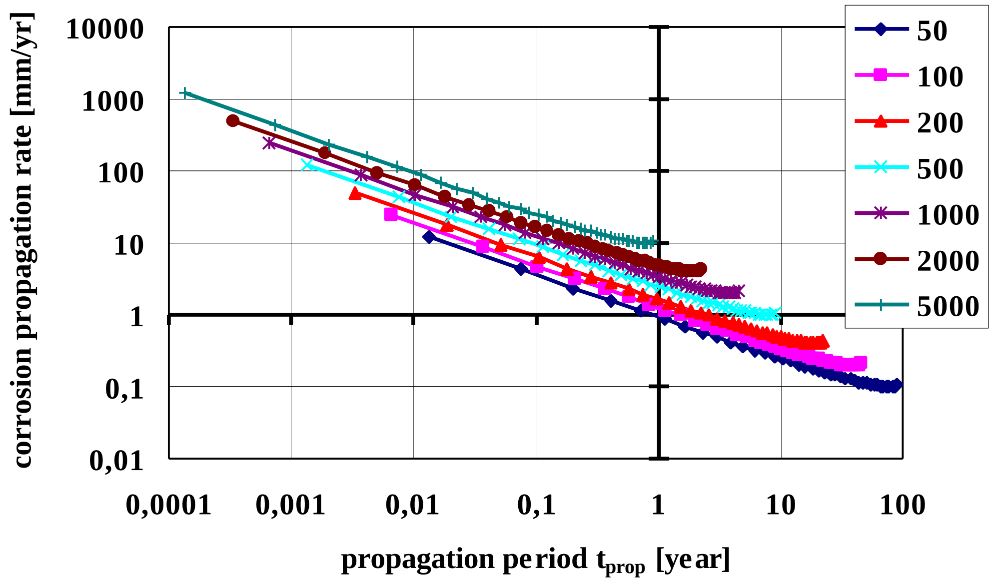

**Figure 9. Local corrosion propagation rate as a function of time**

## 5 CONCLUSIONS

The improved model seems to be suitable to simulate the effects of localised corrosion attack. The model reflects the electrochemical behaviour characterised by the development of macrocells normally encountered in concrete environments contaminated by chlorides. This approach allows calculation of the loss effective cross sectional area and corrosive expansion of the bar.

However, a critical evaluation of the assumptions being made in the development of the model is required. Especially this applies to the geometrical shape of the pit and the magnitude of the macrocell. Information on the true morphology of corrosion attack by chlorides for a range of exposure conditions would therefore aid in modifying the model to a more realistic level. Moreover, reliable quantitative information on macrocell currents is lacking since corrosion rate measurements performed on site do not allow a distinction to be made between micro- and macrocell corrosion. The improved attack model can be used to formulate a probabilistic model which allows calculation of the probability that a given reduction of the reinforcement cross-section has taken place at a given time. Therefore, the presentation of the improved corrosion deterioration model is considered to be of practical importance for further discussion.

# New Prediction/Evaluation Methods Of Service Life Of Reinforced Concrete With Polymeric Coatings

[1]T Fukushima [2]Y Yoshizaki
Environmental Engineering University of Kitakyushu Fukuoka Japan[1]
Hachiyo Consultant Company Limited Kanagawa Japan[2]

**Summary: Physical service life of reinforced concrete (RC) buildings in the ordinary atmospheric surroundings is reasonably determined by the time when the occurrence of crack and spalling of cover concrete makes damage to daily safety as the results of the progress of carbonation of concrete and the accompanying corrosion of reinforcing steel, except for the special cases of deterioration due to salt damage in the severe marine environment and frost damage in the cold climates. If we make effective use of surface finishing materials, however, physical service life of RC buildings can be prolonged by their suppressive effects against the progress of carbonation of concrete and corrosion of reinforcing steel.**

**In this paper, I propose the rational setting methods of physical service life of reinforced concrete with surface finishing materials based upon quantitative evaluation for their experimentally and theoretically confirmed suppressive effects, also by setting the equivalent thickness of cover concrete and the equivalent corrosion losses of reinforcing steel due to their suppressive effects.**

**On the other hand, linear law experimentally confirmed as the results of accelerated carbonation test under step response is discussed as the new prediction/evaluation methods of the progress of carbonation of concrete modelling the tendency of the increase in the concentration of atmospheric carbon dioxide as one of the global environmental problems.**

**Keywords: Reinforced Concrete, Polymeric Coating, Carbonation, Corrosion, Suppressive Effects**

## 1 INTRODUCTION

Service life of building materials used in given elements of given buildings should be as long as possible during in service from the viewpoint of the conservation of resources and the preservation of energy, considering the reduction of the burdens to the environment. However, the compatibility of each service life should be considered, because structural materials and components should satisfy as long durability as possible during the designed service life, but non-structural or finishing materials such as polymers and cement boards etc. are considered to be renewed or exchanged at certain intervals in order to maintain the good condition of buildings as a whole. Except for the special fast deterioration due to salt damage in the severe marine environment and frost damage in the severe cold climate, deterioration of reinforced concrete (RC) components and / or buildings in the ordinary atmospheric environment in the mild climate progresses through the carbonation of concrete and the accompanying corrosion of reinforcing steel. It is generally accepted that the physical service life is set by the time of crack and spalling of cover concrete by the expansion pressure of rust products ($t_2$ in Fig.1 a), because the daily safety is severely damaged. Fig.1 shows this concept adopted in Japan Architectural Standard Specification of Reinforced Concrete Work JASS5 (Architectural Institute of Japan, 1982) compared with the service life of continuous fiber reinforced concrete (FRPRC) as newly prevailing building structural components ($t_1$ in Fig.1 b). Recently in Japan, there are many news which make many people feel once again “Concrete Crisis” due to the severe deterioration of reinforced concrete structures, so that rational setting methods of physical service life of RC components and / or buildings are becoming all the more needed again. On the other hand, though the progress of carbonation has been discussed until now considering the concentration of atmospheric carbon dioxide ($CO_2$) as the direct external degradation factor as a constant value of about 300ppm, it was observed to have increased year by year with the seasonal variation in the latter half of twentieth century (Special Report of the Government of U.S.A., 1981), and if no efforts are to be done to reduce it, it will increases at a drastic speed in the twenty-first century. This tendency of the increase of the concentration of atmospheric $CO_2$ attracts the attention of the people all over the world as one of the serious global environmental problems causing global warming. However, it is anticipated that this tendency will accelerate the progress of carbonation of concrete from the viewpoint of durability of reinforced concrete structures. Therefore, it is necessary in the future to establish the rational prediction and evaluation methods of the progress of neutralization of concrete taking into account this tendency (Fukushima 1990, Fukushima 1994, Fukushima et al. 1995, Fukushima et al. 1996, Fukushima et al. 1997). When we view the real situations of reinforced concrete (RC) buildings, however, some surface finishing due to polymeric coating materials etc. have been done, and off-form style of RC buildings are very rare. Consequently, we never fail to take into consideration the influences of surface finishing materials such as polymeric coatings, when we discuss the physical service life of RC components and / or buildings based upon the progress of carbonation and the accompanying corrosion of reinforcing steel (Fukushima & Motohashi 1985), even if we have to take into account that they are liable to deteriorate under outdoor conditions due to weathering (Fukushima, 1986).This paper deals with the rational setting methods of service life of RC components and/or buildings considering the suppressive effects of polymeric surface finishing materials against the carbonation of concrete and the corrosion of reinforcing steel experimentally confirmed, and also taking into account of the increasing tendency of the concentration of atmospheric CO2 .

## 2 RESEARCH METHODS

When we do effective surface treatment by polymeric surface coatings, we can expect the elongation of physical service life of RC components and/or buildings due to their suppressive effects against carbonation of concrete and the corrosion of reinforcing steel.

Firstly, I would like to explain the evaluations methods of the suppressive effects of polymeric surface coatings against the carbonation of concrete, which were confirmed experimentally and by the results of field research, and the conversion methods of their suppressive effects into equivalent thickness of cover concrete (Fukushima & Fukushi 1997).

Secondly I would like to explain the evaluation methods of the suppressive effects of polymeric surface coatings against the corrosion of reinforcing steel which were conformed by accelerated corrosion test and outdoor and indoor exposure tests, and the conversion methods of their suppressive effects into equivalent corrosion losses of crack occurrence.

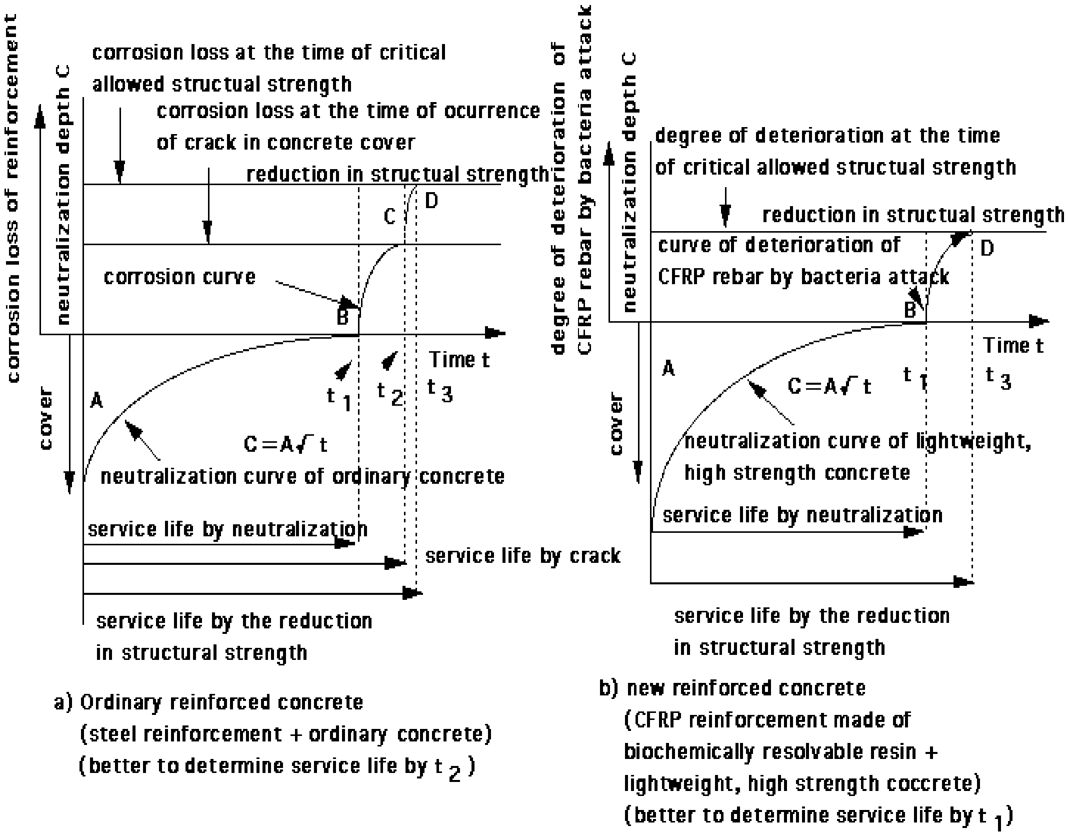

**Figure1 Comparison of Concepts of Prediction of Service Life between New Reinforced Concrete with CFRP Reinforcement and Ordinary Reinforced Concrete with Steel Reinforcement**

Further by combining the two suppressive effects of polymer surface coatings, I would like to propose the rational setting methods of service life of RC components and/or buildings with polymeric surface finishing materials (Fukushima, 1990).

On the other hand, I show that the progress of carbonation was experimentally confirmed to obey the linear law concerning time under step response as the results of accelerated carbonation test (Fukushima et al. 1986, Fukushima et al. 1993). This new law under step response (or power law more generally in the ordinary atmospheric environment showing the exponentially increasing tendency of the concentration of atmospheric carbon dioxide (Special Report of the Government of U.S. A., 1981) is discussed as the new prediction/evaluation methods of the progress of carbonation of concrete modeling the tendency of the increase in the concentration of atmospheric carbon dioxide as one of the global environmental problems.

## 3 RESEARCH RESULTS

### 3.1 Evaluations of suppressive effects against carbonation of polymeric surface coatings

Suppressive effects of polymeric surface coatings under the accelerated condition of 30$^o$C, 60% RH, $CO_2$; 5% (in this case, the deterioration of polymeric surface coatings are not expected, because there is no UV light irradiation, and the temperature and humidity are mild and constant) accelerated carbonation test was done for about one year for test specimens of concrete treated with polymeric and other surface coatings inorganic shown in Table 1, and the results of evaluation of the progress of carbonation are shown in Table 2 and 3, and Fig.2.

Polymeric coating materials such as vinyl wallpaper, acrylic and epoxy resin show the greater suppressive effects against carbonation than other inorganic ones.

On the other hand, diffusion coefficients of $CO_2$ in various surface-finishing materials could be calculated by comparing theoretically obtained equation for two parameter A and B, and experimentally obtained values to. As shown in Table 3, diffusion coefficients become smaller in proportion as the suppressive effects are greater.

Except for untreated concrete specimens, for concrete specimens treated with surface finishing materials there are some induction time before the progress of carbonation starts, and the progress of carbonation obeys parabolic law involving a constant term (X=Avt – B) as follows:

$$X = 0 : 0 \le t \le t_0 = (\frac{B}{A})^2 \quad (1)$$

$$X = A\sqrt{t} - B \le t \quad (2)$$

**Table 1. Type of surface finishing materials**

| *Symbols* | *Type of polymeric coating* |
|---|---|
| a | no finish |
| b | vinyl wall paper |
| c | emulsion paint |
| d | synthetic resin plaster |
| e | acryl based sprayed finish |
| f | epoxy based sprayed finish |

**Table 2. Evaluation of the suppressive effects of surface finishing materials on Neutralization (carbonation) of concrete (Part 1 least-square method analysis)**

| | *Type of Specimen* | *Equation obtained by least-square method* | *Correlation coefficient* |
|---|---|---|---|
| Normal Concrete for Field-mixed Use | N-R-a | X = 0.65 + 14.45 vt | r = 0.980 |
| | N-R-b | X = -0.22 + 0.16 vt | r = 0.732 |
| | N-R-c | X = -1.27 + 9.43 vt | r = 0.992 |
| | N-R-d | X = -7.09 + 6.9 vt | r = 0.998 |
| | N-R-e | X = -3.96 + 7.06 vt | r = 0.959 |
| | N-R-f | X = 0.53 + 12.36vt | r = 0.994 |
| Concrete for precasting use | N-R-a | X = 4.78 + 8.3 vt | r = 0.956 |
| | N-R-c | X = -0.91 + 13.03 vt | r = 0.996 |

### 3.2 Equivalent Thickness of Cover Concrete

We can convert these suppressive effects of surface coatings against carbonation into equivalent thickness of cover concrete. The conversion methods are shown in Fig.6. For thickness of off-form concrete ($X_0$), the time when its carbonation becomes completed can For thickness of off-form concrete (X0), the time when it's carbonation becomes completed ($T_o$) can be given as follows:

$$T_0 = \left( \frac{A_0}{X_0} \right)^2 \qquad (3)$$

For concrete treated with surface coatings, the time becomes elongated up to $T_1$ due to their suppressive effects shown as follows:

$$T_1 = \left( \frac{A_0}{X_0 + B} \right)^2 \qquad (4)$$

**Table 3 Evaluation of the suppressive effects of surface Finishing materials on Neutralization of concrete (Part 2 calculation of effective diffusion coefficients of carbon dioxide)**

| *Types of Surface Finishing materials* | *Parameters* *A* (mm/month1/2) | *B* (mm) | *Surface equilibrium* *m* *constant* | *induction period* *t* *(month)* | *thickness* *L* *(mm)* | *diffusion coefficient* *D* *(mm2/month)* |
|---|---|---|---|---|---|---|
| a | 14.5 | - | 1 | - | - | 3.89 |
| b | - | - | - | - | - | - |
| c | 9.4 | 1.3 | 0.65 | 0.14 | 1 | 0.494 |
| d | 6.9 | 7.1 | 0.48 | 1.06 | 3 | 0.27 |
| e | 5.9 | 4.5 | 0.41 | 0.58 | 5 | 0.72 |
| f | 7.1 | 4.0 | 0.49 | 0.32 | 5 | 0.82 |

This actually means that thickness of cover concrete increase from $X_0$ to $X_0'$ shown as follows:

$$X_0' = \frac{A}{A_0} B + \frac{A}{A_0} X_0 \qquad (5)$$

$X_0'$ is the equivalent thickness corresponding to suppressive effects of surface coatings against carbonation. If we set this equivalent thickness in advance, the progress of carbonation of concrete treated with surface coatings really obeys parabolic law as that of carbonation of off-form concrete as follows:

$$X_0' = A_0 \sqrt{t} \qquad (6)$$

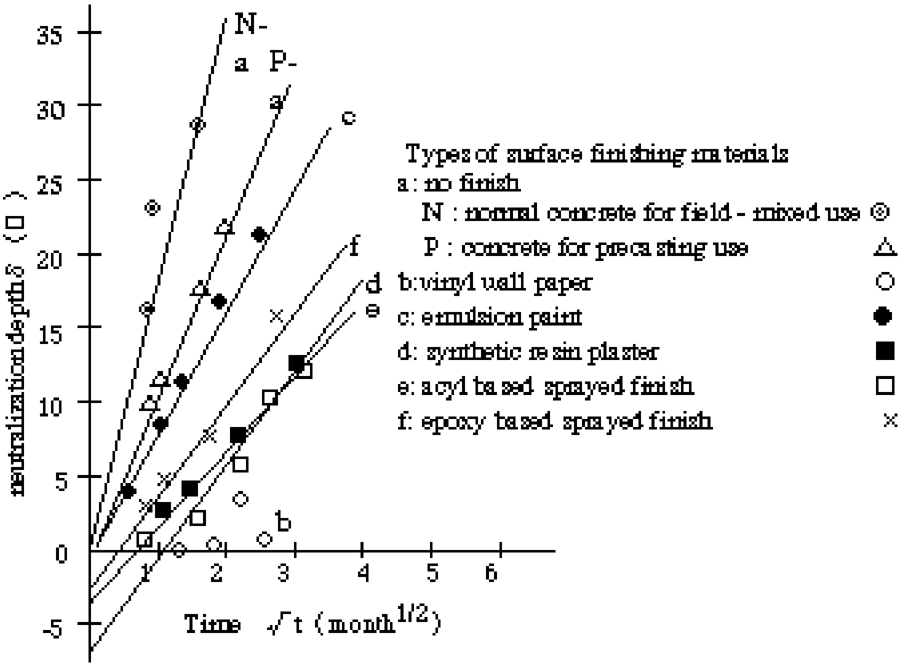

**Figure 2 Results of suppressive effects of polymeric coatings materials on the progress of carbonation of concrete by accelerated carbonation test (30°C, 60%R.H., CO2: 5%)**

### 3.3 New Prediction/Evaluation Methods of the Progress of Neutralization of Concrete by lLnear law and Power Law

By step response that the $CO_2$ concentration starts from 5%, and then to 10, 15, 20% constant value, by increasing by 5% step by step every month (under constant temperature constant humidity condition of 20 °C and 60%RH ), accelerated carbonation test was carried out for various types of concrete (3 types of normal Portland cement concrete, blast-furnace Portland cement concrete, fly ash Portland cement concrete of 40, 50, and 60% water cement ratios with and without acryl polymer type coating). Figure 4 and 5 show the test results. It is obvious that the progress of neutralization of concrete under the condition of step response obeys the linear law concerning time, on the contrary to the generally accepted parabolic law under the condition of constant $CO_2$ concentration, whether polymeric coating is made or not. From the consideration from theoretical analysis for the case of exponential increase of the concentration of atmospheric $CO_2$, power law is appropriate to be set of the concentration of atmospheric $CO_2$, because it shows the mediate law between the parabolic law in case of constant concentration of $CO_2$ and linear law under step response for the modified law for the progress of neutralization of concrete considering the increasing tendency.

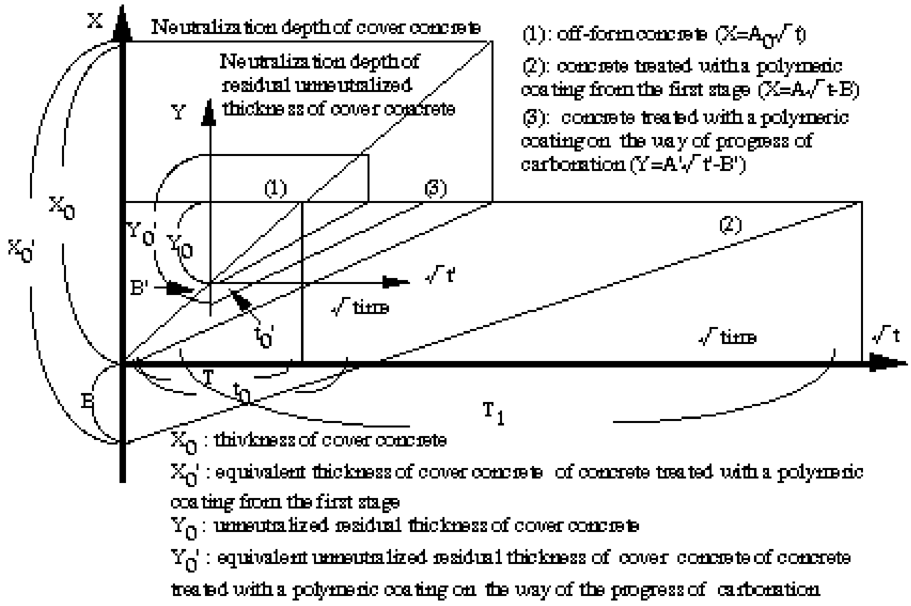

**Figure 3. Schematic diagram of the concept of equivalent thickness of cover concrete talking into account of the suppressive effects of polymeric coatings on the progress of carbonation of concrete**

### 3.4 Evaluation methods of suppressive effects of polymeric surface coatings against corrosion of reinforcing steel

If we can stop, retard or suppress the progress of corrosion of reinforcing steel by effective surface treatment with such polymeric surface coating materials when the corrosion of reinforcing steel is threatening to start as the progress of carbonation of cover concrete reaches very near reinforcing Steel, we can make use of the results in order to do the rational durability design for the best setting of physical service life of RC components and / or buildings by effective elongation.

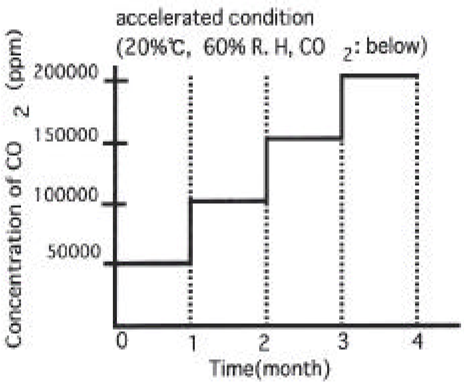

**Figure 4. Method of Accelerated Carbonation Test by Step Response Molding the Increasing Tendency of Atmospheric $CO_2$.**

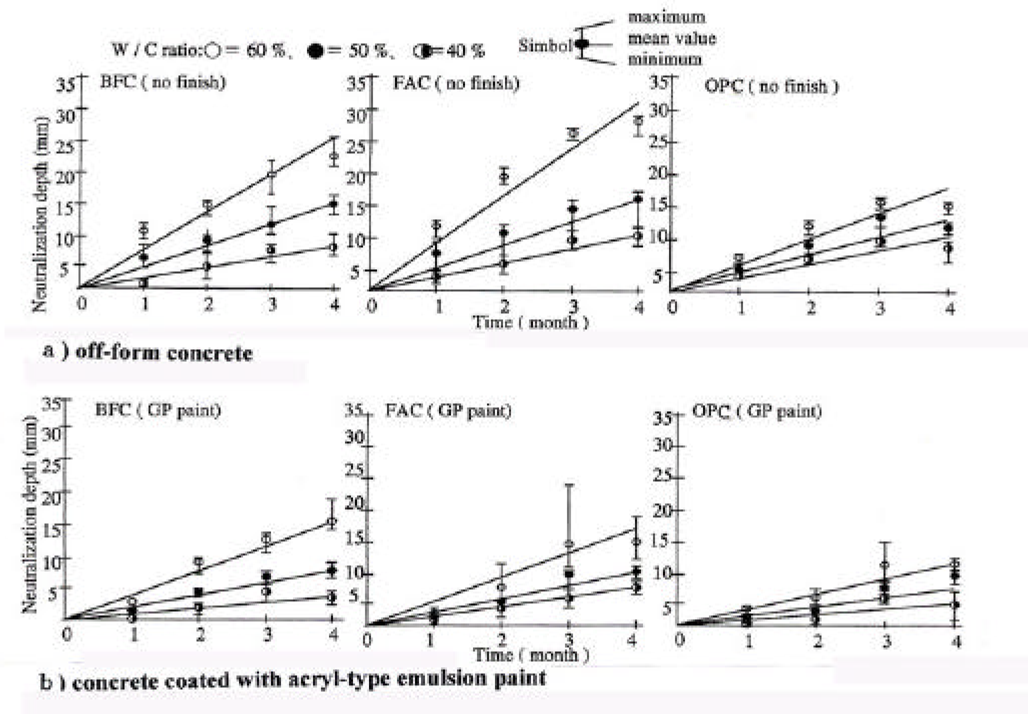

**Figure 5a) and5b). Experimental results of accelerated carbonation test by step response method for various types of concrete (4a) Off-form concrete; 4b) concrete coated with acryl resin-type GP paint**

In order to confirm experimentally if we can suppressive the progress of corrosion of reinforcing steel by polymeric surface coatings or not, we carried out accelerated corrosion test for 16 months, and outdoor and indoor exposure tests for 11 years for test sediments of reinforced concrete treated with such polymeric surface coatings after we confirm that carbonation of cover concrete reaches behind reinforcing steel by accelerated carbonation (20 $^{o}$C, 60%RH, CO2: 5%) for 5 months.

As the results, we could find that polymeric surface coating materials show, to a considerable extent, suppressive effects against the corrosion of reinforcing steel, as far as the severe deterioration of polymeric surface coatings themselves does not occur, and chloride ions are not included in concrete

| | P-R-e | Y =-0.23 + 0.61vt | r = 0.425 |
| Sea Sand Specimens | N-S-a | Y =-0.20 + 0.41vt | r = 0.905 |
| | N-S-b | Y = 0.38 + 0.33vt | r = 0.700 |
| | N-S-c | Y =-0.18 + 0.33v t | r = 0.933 |
| | N-S-e | Y = 0.16 + 0.40vt | r = 0.822 |
| | P-S-a | Y =-0.22 + 0.41vt | r = 0.834 |
| | P-S-b | Y = 0.16 + 0.54vt | r = 0.953 |
| | P-S-c | Y =-0.09+ 0.44vt | r = 0.972 |
| | P-S-e | Y = 0.32 + 0.54vt | r = 0.949 |

above a certain allowed concentration, by the shielding function against the diffusion of water vapour and oxygen in neutralized concrete.

1) On the other hand, we evaluated the progress of corrosion of reinforcing steel by applying the least-square method for experimental data. The results are summarized in Table5 and 6. We could summarize as follows: In case of no inclusion of chloride ions above a certain allowed concentration.

The suppressive effects against corrosion of polymeric surface coatings can be evaluated by two parameters $A_1$, $B_1$ of the parabolic law involving a minus constant term concerning time by considering the induction period $t_{01}$ as follows:

$$Y = 0 : 0 \leq t \leq t_{01} \equiv \left( \frac{A_1}{B_1} \right)^2 \qquad (7)$$

$$Y = A_1 \sqrt{t} - B_1 \qquad t_{01} \leq t \qquad (8)$$

Here, Y is the ratio of corrosion loss of reinforcing steel [%].

2) In case of inclusion of chronicle ions above certain allowed concentration. Any polymeric surface coating materials do not show effective suppressive effects against corrosion. The progress of corrosion of reinforcing steel can be evaluated by two parameters $A_2$, $B_2$ of the parabolic law involving a plus constant term.

$$Y = A_2 \sqrt{t} + B_2 \qquad (9)$$

Y = $A_2$ vt + $B_2$

This means that even if the carbonation never reaches behind reinforcing steel, the corrosion progresses continuously due to the existence of chloride ions. Polymeric surface coating materials such as emulsion paint, synthetic resin plaster, acryl and epoxy resin based sprayed finishes show these suppressive effects.

**Table 6. Results of Evaluation of the Progress of Corrosion under outdoor exposure (not sheltered from rain) (Y: Rate of Corrosion Loss [%],t : Time table 6[Year])**

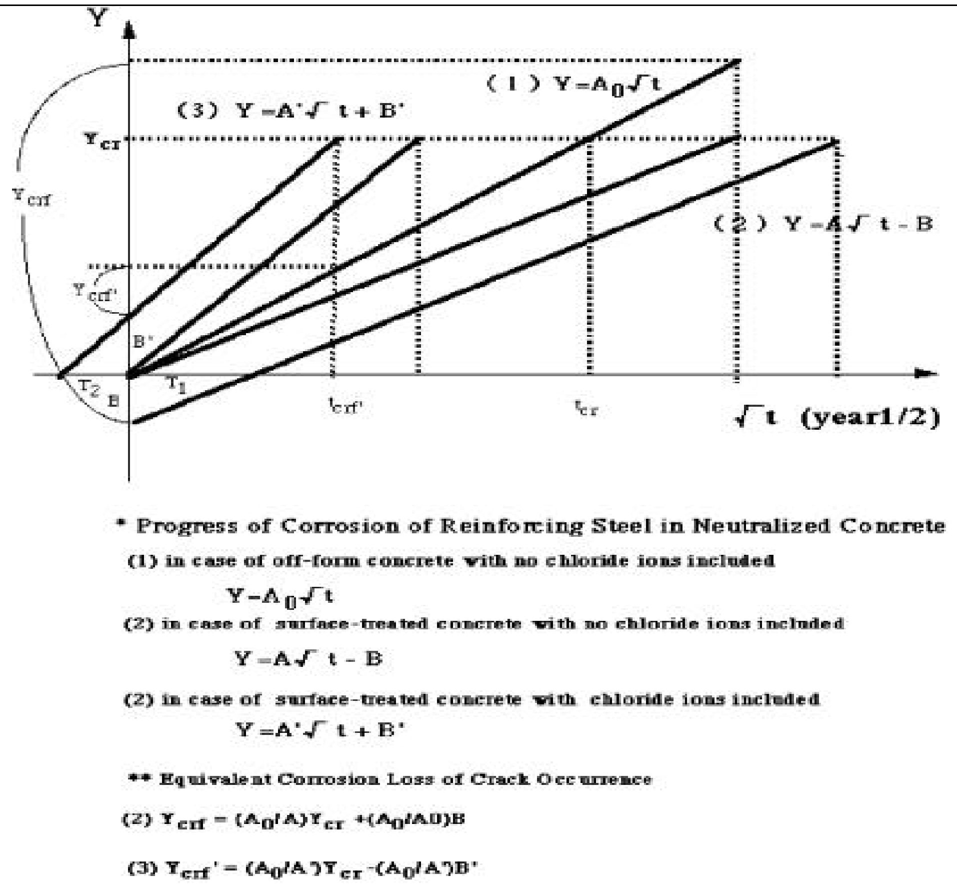

**Figure 6. Concrete of Conversion of Suppressive Effects against Corrosion of Surface Finishing Materials into Equivalent Corrosion Losses of Crack occurrence**

### 3.5 Equivalent corrosion loss of crack occurrence

As the analogy to the conversion of suppressive effects against carbonation of polymeric surface coating materials into equivalent thickness of cover concrete, we can convert suppressive effects against corrosion into equivalent corrosion loss of crack occurrence in cover concrete.

This concept is illustrated in Fig.6. If we set in advance these equivalent corrosion loss of crack occurrence, the progress of corrosion of reinforcing steel in neutralized concrete with surface treatment can be discussed in the same way as corrosion in off-form neutralized concrete without surface treatment.

### 3.6 Setting methods of physical service life of RC with polymeric surface coatings

Figure 7.shows the diagram of this concept**.** Physical service life of off-form RC components and / or buildings under ordinary atmospheric environment in the mild climate can be set by the progress of carbonation and corrosion as T1 + T2. If we taking into account the increasing tendency of atmospheric $CO_{2,}$ we should adopt the power law concerning time instead of parabolic law for the progress of neutralization (carbonation) of concrete.

If we make effective use of surface finishing materials, however, the service life of reinforced concrete buildings can be prolonged by suppressive effects of surface finishing materials against the progress of carbonation of concrete and corrosion of reinforcing steel under the assumption that surface finishing materials have high durability for long time, not deteriorating so much as in the case of fluoropolymer, or that even if they deteriorate, the periodic exchange or renewal of them is done. However, we should also consider life cycle design, taking into account ecobalance performance such as the easiness of demotion and recyclabilly after designed service life in order to establish sustainable construction considering environmental harmony.

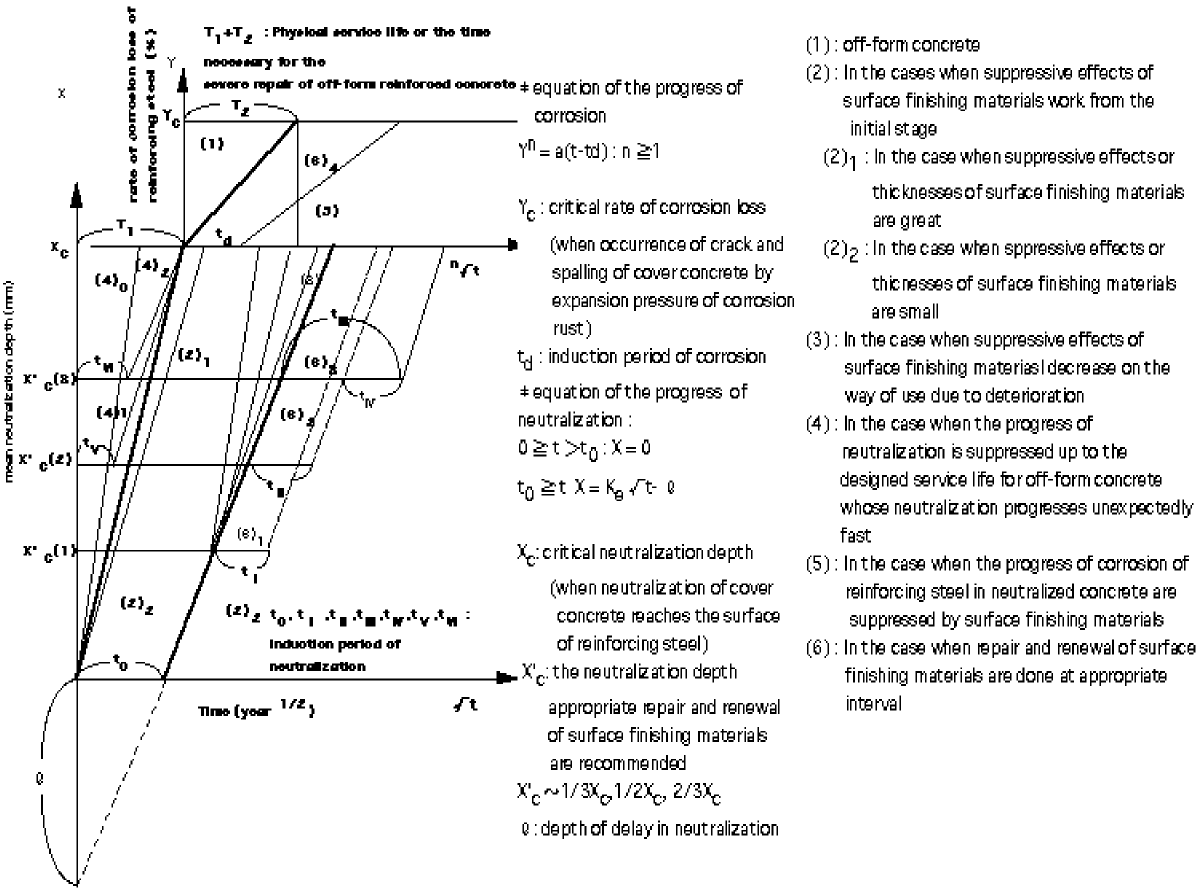

**Figure 7. Concept of Setting the Physical Service Life of Reinforced Concrete Considering the Suppressive Effects of Surface Finishing Materials**

## 4 CONCLUSIONS

1) Polymeric surface coating materials are said to have rather shorter service life of about 10 years under outdoor conditions due to weathering. However, if periodic renewal or repaint are carried out, they will greatly contribute to prolong the physical serried life of RC components and / or buildings due to their suppressive effects against carbonation of concrete are corrosion of reinforcing steel.

Go Back

2) The progress of neutralization (carbonation) of concrete under the condition of step response obeys the linear law concerning time, on the contrary to the generally accepted parabolic law under the condition of constant $CO_2$ concentration, whether polymeric coating is made or not. From the consideration from theoretical analysis for the case of exponential increase of the concentration of atmospheric $CO_{2,}$ power law is appropriate to be set for the modified law for the progress of concrete considering the increasing tendency.

3) We should establish eco-life-cycle design of building structural composite components such as reinforced concrete (RC) and continuous fiber reinforced concrete (FRPRC), paying attention to the harmony of long service life with eco-balance performance for sustainable construction in the twenty-first century.

# The Effect Of Algae On Mineral Powder Dissolution Rates

**RG Welton[1] SJ Cuthbert[1]**
**A Hursthouse[2] R Mclean[2] & J Hughes[1]**
**[1.]Advanced Concrete and Masonry Centre University of Paisley UK**
**[2.]School of Engineering & Science University of Paisley UK**

**Summary: Experiments have been performed to study the release of cations into an aqueous medium from a variety of minerals commonly found as constituents in stone masonry in the presence of pure algal cultures. The aim of the experiment is determine the influence of algae on the dissolution of rock-forming minerals, leading ultimately to a model of rock weathering that incorporates the chemical action of micro-algae. The minerals used were albite feldspar, muscovite mica, quartz and the carbonates siderite and calcite. Powdered samples of each of these minerals immersed in distilled water were exposed to axenic cultures of the green algae *Chlorococcum tetrasporum* and *Scenedesmus obliquus* for four weeks. In order to monitor uptake of chemical components of the minerals into solution, the water was sampled weekly and analysed for pH and chemical composition. Comparison with a system of control experiments allowed us to distinguish the influence of algae from non-organic dissolution.**

**Preliminary results from this experiment show that the yields of aqueous cations are much larger for carbonates than silicates, both in the presence and absence of algae. The algae create a mildly alkaline environment, which may influence the mineral dissolution for certain minerals. Algae are seen to enhance Fe dissolution from the carbonates, which may contribute to the development of iron rich patinae on building stone. The algae appear to enhance Ca release from calcite, an effect linked to the pH change mediated by the algae. Finally the algae appear to have no direct influence on feldspar dissolution, however the maintenance of a humid environment by a biofilm at the masonry surface will lead to the destruction of feldspars and possibly precipitation of pore-blocking clays or Al-hydroxides.**

**Keywords: Biodeterioration, algae, minerals, silicates, carbonates.**

## 1 INTRODUCTION

The degradation of natural stone masonry is a highly complex system influenced by a large number of environmental factors. One of the key factors in biodegradation is biological weathering, in which organisms act to destroy or weaken the mineral constituents of the stone. Phototrophic organisms are among the primary colonisers of building surfaces (Wakefield *et al.*, 1996), and thus are some of the first organisms to interact with the stone. Algae as a phototrophic organism is mostly recognised for its role as a nutrient source for other organisms such as fungi and bacteria which have been shown experimentally to be more damaging to stone (Ortega-Calvo *et al*. 1993; Mishra *et al.* 1995; Warscheid & Braams, 2000). Until recently it was believed that algae were likely to cause no more damage to a building stone substrate than surface staining (Pietrini *et al*, 1985). However, recent studies have shown that chemical and physical damage caused by algae include the exudation of corrosive organic acids (Caneva *et al.* 1992*)*, the uptake of Ca into the microbial cells (Viles & Moses, 1996) and the enlargement of pore sizes and spaces due to the penetration of hyphae cellular filaments (Arino & Saiz-Jimenez, 1996). This experiment is unique in that it exposes both carbonate and silicate minerals to pure algal cultures as opposed to a single exudate such as oxalic acids (Welch & Ullman, 1993). Using mineral powders to increase the chemical yield and and ICP-AES to resolve concentrations to below 1mg/l this research can show effects that have previously been irresolvable to the instrumentation available.

The approach was to examine, under controlled conditions, the influence of algae on dissolution of the individual mineral constituents of common silicate-based or silicate + carbonate-based building stones, especially sandstones. The core objective is to better understand the biological and chemical processes taking place at the interface between mineral and organism This should ultimately enable us to identify which minerals are vulnerable to algal attack, and hence to construct a model of algal biodeterioration based upon an understanding of the response of different mineral microfabric elements present in natural stone materials. Due to the relatively slow reaction rates and limitations on experimental run times set by the longevity of the algal culture, the minerals studied were powdered to provide a large contact surface area with the algal biofilm, thus enhancing yields of dissolved cations. We also used pure algal cultures so as to distinguish clearly the influence of algae from microbial communities containing both algae and other microbes, such as bacteria and fungi, already known for their aggressive activity (Bock & Sand, 1993). The chemical composition of the aqueous medium was monitored during the course of the experiment in order to detect the presence of cations released into the water from the mineral surfaces, either directly or via the algal biofilm.

## 2 METHODOLOGY

The minerals used in this experiment were the tectosilicate feldspars albite, labradorite and orthoclase, quartz, the potassic phyllosilicate muscovite, and the carbonates calcite, dolomite and siderite (Supplied by Gregory, Bottley and Lloyd, 13 Seagrove Road, London, SW6 1RP, source unknown). Chemical composition of each mineral was determined semi-quantitatively by energy dispersive electron probe micro-analysis of polished grain mounts on a Hitachi S4100 cold field emission scanning electron microscope (SEM).

Mineral samples were crushed to powder in an agate pestle and mortar then sieved through a 450µm nylon, one use only sieve. A 2g split of each powder sample was then placed in a 25ml universal bottle containing 20ml of distilled water. The flasks were then sealed and autoclaved to ensure sterility.

The algae used in this experiment were a mix of three axenic algal cultures *Chlorella vulgaris* (CCAP 211/11P), *Scenedesmus obliquus* (CCAP 276/7) and *Stichococcus bacillaris* (CCAP 379/1D) purchased from CCAP (Culture Collection of Algae and Protozoa, Cumbria, U.K.). The algae were cultured using Bolds Basal Medium (BBM) in a biological incubator on an 18/6 hr light/dark cycle with a temperature of 16 ± 2 $^{o}$C. To avoid chemical contamination of the water in the experimental flasks by the BBM, the algae were washed using a method adapted from Yee *et al* (2000). 100ml of the three algal species was removed from the incubator and mixed with the other species in a 500ml conical flask on an orbital shaker for ten minutes. The 300ml of algal mix was then divided into 12x25ml universal bottles. The bottles were centrifuged for 10 minutes at 3200 rpm, to separate the nutrient media from the algae, with the supernatant being poured away after the centrifugation. 20ml of Autoclaved Distilled Water (ADW) was then added into each flask and mixed for ten minutes on the orbital shaker. 0.001M EDTA was then added to the algae and left for sixty minutes, centrifuged and the supernatant poured away again. 20ml of ADW was added to the algae and left to soak the algae overnight. This was centrifuged off the next day and 20ml of ADW was added to the algae remaining in the flask. 2ml of this mixture were then transferred into the bottles containing the water and mineral powders. Some bottles were left free of algae in order to determine the solubility of mineral powders in presence of water alone. Other bottles contained only distilled water and algae to determine any cationic output from the algae in the absence of a mineral powder. Finally, some bottles were filled only with distilled water to act as analytical blanks. Each type of experimental charge was triplicated.

The flasks were kept in a Gallenkamp biological incubator on an 18/6 hr light-dark cycle at a temperature of 16 ± 2 $^{o}$C and sampled every seven days for pH using a Piccolo Plus ATC pH/C meter with a HI1295 Amplified Electrode fitted (Hanna Instruments, Woonsocket, USA). Further water samples were pipetted off for chemical analysis at the same time. Note that a batch of experimental charges were made up at the outset for each water sample extraction so as to avoid problems of progressive loss of aqueous medium through successive sampling extractions, and to minimise biological contamination.

Concentrations of aqueous Al, Ca, Fe, K, Mg, Na, P were measured using inductively coupled plasma atomic emission spectrometry (ICP-AES) Perkin Elmer Optima 3000 using appropriate multi element standards and blank subtraction, ultra high purity water (18MΩ Elga Stat UHP) was used for all dilutions. These elements were selected as they are important components of either the minerals or the algae. All water samples in one batch were tested in a randomised sample order to avoid the effects of machine drift. Due to the quartz torch utilised in this instrument, the measurements contain a large Si analytical blank making analysis of this important element impractical. Standard deviations are not shown in the results section of the analysis due to space constraints, also in no instance in this investigation does the standard deviation affect the trendline of an element to a significant degree.

## 3 RESULTS

Chemical compositions for the minerals used in the experiment are typical for their types (see Deer, Howie & Zussman, 1992). Albite (sodium aluminium silicate) contained small concentrations of potassium, and siderite (iron carbonate) contained a few percent each of Mg and Mn. Calcite (calcium carbonate) contained no detectable Mg, Fe or Mn.

The pH data (Table 1) shows that the algae has an effect on the acidity/alkalinity levels in the bottles over the course of the experiment.

| CALCITE AND ALGAE | 6.8 | 6.9 | 7.5 | 7.2 | 7.3 |
| SIDERITE AND WATER | 6.8 | 7.1 | 7.1 | 6.8 | 6.7 |
| SIDERITE AND ALGAE | 7.1 | 6.9 | 6.7 | 6.9 | 7.3 |

In the first seven days very little difference can be discerned between bottles containing algae and those without. However after 7 and 14 days a noticeable rise in pH of those flasks containing algae can be distinguished for all minerals. Muscovite with algae deviates most from the water and mineral flask, leading to a difference of 0.8 pH units by the end of 28 days, due to both a decrease in the bottle lacking algae and an increase in the bottle containing algae. The bottle containing quartz with algae showed very little deviation from that without algae. Calcite with algae shows a more rapid rise in pH than calcite alone, but values for both converge on the same value, higher than the starting value.

The study of pH in this environment is important to as the dissolution rates of minerals can change rapidly over small changes in the surrounding pH. Stumm & Morgan (1996), show that calcite provides particularly strong evidence of this in the pH range being studied, falling from a dissolution rate of $10^{-2}$ Mol $m^{-2}h^{-1}$ to $10^{-4}$ Mol $m^{-2}h^{-1}$ between the pH's of 5 and 10.5 Dolomite is slightly below this level of dissolution, whilst the other silicate and oxide minerals display much lower dissolution rates, for example, $10^{-8}$ Mol $m^{-2}h^{-1}$ for albite and $10^{-9}$ Mol $m^{-2}h^{-1}$ for muscovite and quartz at pH 7.

Element concentrations in the aqueous medium measured at seven day intervals are given in Tables 2-7. Concentrations in experimental charges containing only water and algae generally showed little change throughout the experiment (Table 2 and Figure 1). Detectable amounts of Mg were present in the water+algae sample. This could be due to dead algae in the bottle decomposing and releasing the Mg-bearing porphyrin ring component of chlorophyll. Ca, K, Na and P concentrations were above the water blank level in the water+algae samples, but K, Na and P decreased over time. The latter three may have been contamination from the BBM left over after washing of the algae, and were possibly used as nutrients by the algae over time. Ca shows a peak at 14 days, and may have been released by the algae. Levels of Al, Fe and Mn in the water+algae charges were all below the detection limits of the instrument. The cause of the high water blank value for Ca at 7 days is unknown.

**Table 2. Elemental concentrations ($mgl^{-1}$) in water+algae samples and the water only experimental blanks (italicised) over time. Detection limits (right hand column) were quantified by external calibration using multi element standards (Leemer Labs UK).**

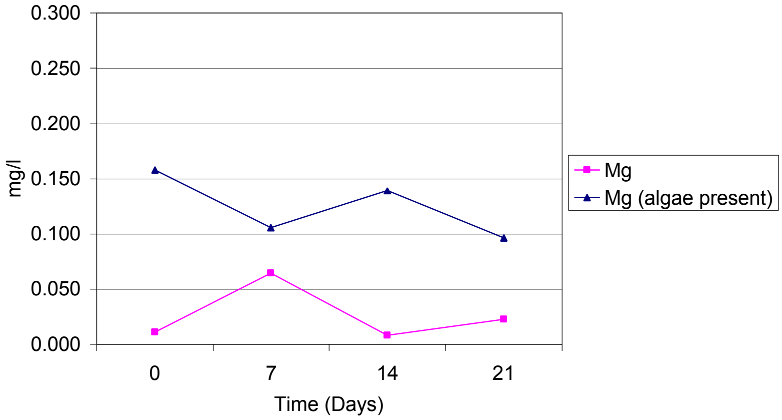

**Fig. 1. Mg concentrations through time in the water only and water+algae samples**

The chemical trends in **calcite-**bearing charges (Table 3 and Figure 3) show certain pertinent differences when compared to the water only control experiment (Table 2 and Figure 1). The release of Ca into the water from the calcite was very pronounced over this time period. Without algae present the concentrations were around $8mgl^{-1}$, compared to below $1mgl^{-1}$ for water only. When algae was present the concentration of Ca rose to 30mg/l.

**Table 3. Elemental concentrations (mg/l) in aqueous medium containing calcite and algae over time. Figures in brackets are for water and calcite with no algae. Detection limits as for Table 2.**

| | *Day 0* | *Day 7* | *Day 14* | *Day 21* |
|---|---|---|---|---|
| Al | 0.037 (*0.057*) | 0.030 (*0.060*) | 0.197 (*0.093*) | 0.086 (*0.058*) |
| Ca | 14.568 (*8.219*) | 28.805 (*7.882*) | 8.544 (*7.391*) | 16.967 (*17.423*) |
| Fe | 0.000 (*0.002*) | 0.001 (*0.000*) | 0.004 (*0.001*) | 0.005 (*0.003*) |
| K | 5.828 (*0.860*) | 0.586 (*0.591*) | 1.046 (*0.436*) | 1.154 (*0.520*) |
| Mg | 0.301(*0.133*) | 0.394 (*0.167*) | 0.583 (*0.158*) | 0.419 (*0.127*) |
| Mn | 0.014 (*0.002*) | 0.040 (*0.003*) | 0.000 (*0.013*) | 0.012 (*0.003*) |
| Na | 18.363 (*4.611*) | 2.967 (*5.572*) | 4.984 (*6.504*) | 2.953 (*3.332*) |
| P | 0.843 (*0.061*) | 0.010 (*0.128*) | 0.258 (*0.025*) | 0.079 (*0.000*) |

Note how the calcite dissolution rate increases as pH falls. A reciprocal relationship of the pH (table 1) and Ca concentrations (table 3) would have been expected in these experiments on this basis, and indeed a distinct drop in Ca at day 14 coincided to a significant increase in pH at the same time.

The calcite lacked detectable Mg, but once again aqueous Mg concentrations were higher for the calcite+algae sample than the calcite alone, presumably due to chlorophyll release.

**Siderite** is an iron carbonate, commonly found as a cementing fabric element in sandstones. Aqueous Fe shows a strong rise in the siderite+algae sample but no significant change in the sample lacking algae (Table 4 and Fig 3). The implication of this is that the algae were enhancing removal of Fe cations from the mineral surfaces. Mg and Mn also show interesting trends; Mg concentrations for siderite alone are up to $14mgl^{-1}$, whilst when algae are present the Mg concentrations are *lower*. The same happens with Mn, with aqueous concentrations for siderite alone being around $4mgl^{-1}$, falling with algae present to below detection limits. There are two possible explanations for this effect. First, Mn ions were released into the aqueous medium due to inorganic reactions (hydrolysis), and the algae are using the aqueous Mg and Mn as a nutrient source. Secondly the algae may have been acting on the mineral surfaces to reduce the solubility of the Mg and Mn complexes.

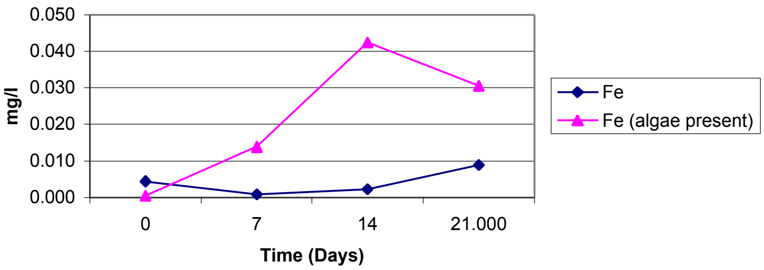

**Fig. 3. Fe concentrations through time in the water+siderite and the water with siderite+algae bottle**

**Quartz**, a silicon dioxide tectosilicate, is generally regarded as the most stable of the major rock forming minerals (Goldich, 1938). As the ICP-AES did not allow analysis for Si, it is impossible to know if there was any Si dissolution. Mg is significantly higher in the quartz+algae samples (Table 5), again probably due to chlorophyll release. Slightly enhanced levels of Ca, Na and P in the quartz+algae samples may be due to contamination from BBM.

**Albite** is a sodium aluminium tectosilicate. Mineral samples used here contained minor amounts of Ca and K. Aqueous Al showed a parallel rise both for samples with algae and those without (Table 6 and fig. 4). This indicates that the Al complex of albite was soluble in the water, rising to 0.9mg/l over 21 days, but was not affected or metabolised by the algae. Aqueous Na concentrations are significantly above blank levels in albite samples lacking algae. Similar levels are found early in the experiment in samples with algae, but later these decrease. Hence Na may have been dissolved out of the albite by water without the influence of algae (hydrolysis), but algae may have subsequently used it as a nutrient. Once again the Mg is higher in concentration when the algae is present

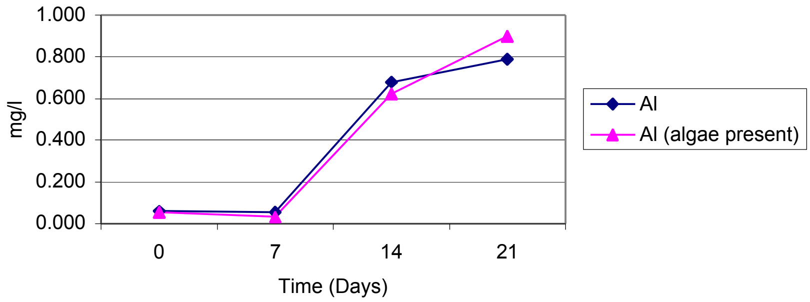

**Fig. 4. Al concentrations in aqueous medium through time for albite+algae and albite alone**

The muscovite elemental trends showed a small rise in Al when the algae was present, which may demonstrate a small amount of increased solubility under the influence of algae. All K values are well above blank levels. In addition, K shows a high initial concentration in the muscovite+algae sample but little change for muscovite alone, indicating a rapid inorganic release of K into solution that is either inhibited or rapidly metabolised by the algae. Ca is absent in muscovite, but aqueous Ca shows a peak at 14 days with algae present. This suggests that the algae released Ca as an extra-cellular product.

## 4 DISCUSSION

Each of the minerals investigated showed a distinctive set of chemical trends for the aqueous medium in which it was immersed. Algae appear to have created small but significant increases in pH. pH also increased when mineral powders were immersed in water in the absence of algae, with the exception of the rather unreactive quartz. However, alkalinity was usually further enhanced in the presence of algae, particularly for carbonates (as might be expected for these basic compounds) and the sodic feldspar albite. For most of the minerals there is no clear relationship between pH and aqueous cation concentration, but for calcite there is a clear reciprocal relationship with Ca. Stumm & Morgan (1996) have shown that dissolution rate of calcite decreases with increasing pH (fig. 2). This is consistent with the trend observed for calcite, but only if Ca was being partially absorbed by the algal biofilm once it had been released from the mineral surfaces. Hence the decrease in aqueous Ca observed at day 14 would have been due to a slower Ca release rate compared with its rate of uptake into the algae. Cation concentrations were much lower for the silicates, consistent with their much slower dissolution rates (Stumm & Morgan, op. cit.) as shown in fig. 2.

The experiment on siderite powder showed that algae are capable of mobilising Fe into aqueous solution. Siderite is a common cementing mineral in sandstones. Mobilisation and re-precipitation of iron is an important process in development of weathering patinae in sandstones (Bluck & Porter, 1991). Our results here indicate that algae may play an important role in this process. As with calcite, dissolution of siderite may destroy a cementing microfabric element of the stone, hence encouraging grain loss from the masonry surface. In contrast, algae appear to have either inhibited the release of Mn and Mg from siderite, or absorbed these cations into the biofilm immediately upon release. The latter alternative seems most likely as Mn and Mg tend to behave geochemically in a similar way to Fe. Further work will be required to distinguish between these two mechanisms.

Al is an important framework-building cation in feldspars. Al release patterns were identical in experimental charges with and without algae, suggesting that algae do not influence Al dissolution from feldspars. Feldspars are important constituents of sandstones. Al dissolution is important in weathering and weakening feldspar grains and precipitation of Al-hydroxides and clays that fill and occlude pores in sandstones. Na released from the feldspar albite appears to have been absorbed by the algal biofilm, or its release was inhibited by the algae. These observations suggest that algae have no direct influence upon feldspar weathering. However, the maintenance of a wet biofilm by algae may enhance the water-holding capacity of masonry surfaces, encouraging feldspar dissolution by inorganic reactions.

Experimental charges lacking Mg-bearing minerals tended to show release of Mg when algae were present. This is thought to result from death and decay of the algae and consequent release of Mg-porphyrin rings from chlorophyll. High, unsupported aqueous Mg concentrations may, then, be a useful measure of the health of the algal culture in experiments like he ones undertaken here.

As algae is an autophototroph it is often one of the first organisms to colonise natural building stone and many of its exudates of the would be utilised as a nutrient source by higher organisms, such as fungi or lichen, which are known to have a much higher degradation potential than the algae.

## 5 CONCLUSIONS

1. We have developed an experimental protocol that enables detection of algal influences upon the dissolution of cations from the surfaces of minerals commonly found in natural stone masonry. Use of powdered samples to enhance solute yields combined with high precision ICP-AES chemical analysis allowed us to resolve small changes in concentration in the experimental aqueous medium. Pure (axenic) algal cultures and rigorous aseptic technique permitted examination of algae alone, without interference from known, more aggressive microbes such as bacteria and fungi. The results presented here are the first clear evidence that green algae alone may have a significant influence upon mineral dissolution.

2. Yields of aqueous cations were much larger for carbonates than silicates, both in the presence and absence of algae.

3. Algae tend to create a mildly alkaline aqueous environment. This may influence the dissolution rates of some mineral types such as calcite, where more alkaline conditions reduce dissolution rates.

4. Iron dissolution from carbonates is enhanced by algae. This may influence iron mobility during sandstone weathering and aid in the formation of iron-rich patinae.

5. Ca release from calcite was enhanced in the presence of algae, especially at lower pH. Carbonates such as calcite and siderite are important cementing microfabric elements in sandstones and limestones, and our results suggest that algal activity will enhance degradation of the masonry surface.

6. Algae appear to have no direct influence on feldspar dissolution, but maintenance of a humid environment by a biofilm at the masonry surface will, indirectly, lead to destruction of feldspars and possibly precipitation of pore-blocking clays or Al-hydroxides.

## 6 ACKNOWLEDGEMENTS

The authors wish to thank David Wallace for his help in the mineral powder preparation and Margaret Corrigan and David Sterling for their expert help with the SEM images and ICP-AES analysis respectively.

# The Mechanism Of Photo-Oxidative Degradation Of Acrylonitrile-Butadiene-Styrene (Abs) Resins Used In Pipes

**B Tiganis P Davis LS Burn J Gotama**
**CSIRO Building Construction and Engineering Melbourne Australia**

**Summary: This paper investigates the mechanism of ultraviolet (UV) degradation in ABS resins. ABS specimens were subjected to accelerated natural weathering at an ambient temperature to separate thermal effects from the mechanism of UV degradation. Degradation primarily occurs in the polybutadiene (PB) phase of ABS due to the polymer microstructure. Fourier transform infra-red (FTIR) shows that degradation of the PB phase is predominantly located at the surface of the polymer and that bulk degradation does not occur. Changes in chemical structure observed by FTIR are associated with oxidation and the formation of photoproducts, corresponding to a carbonyl peak at 1721 $cm^{-1}$ and hydroxyl peak at ~ 3465 $cm^{-1}$. The absorbance bands at 966.92 $cm^{-1}$ and 911.43 $cm^{-1}$ corresponding to the trans C=C unsaturation (vinyl) in polybutadiene, and the 1,2-butadiene terminal vinyl C-H band respectively, were distorted indicating bond un-saturation. The oxidation induction time (as determined by chemiluminescence) was significantly lower at the surface of weathered ABS compared to the bulk polymer. Dynamic Mechanical Thermal Analysis (DMTA) showed an increase in the glass transition temperature for UV-exposed specimens, reflecting an increase in Young's modulus due to crosslinking in the PB phase. Under plane strain loading conditions, brittle fracture occurs when surface degradation reaches a critical depth. To develop a technique for lifetime prediction after weathering, fracture mechanics theory was used to relate UV exposure time to an equivalent surface notch depth. Assuming that this relationship is geometry-independent, it was used to estimate the reduction in critical hoop stress for ABS pipelines under hydrostatic pressure**

**Keywords: ABS, weathering, degradation, fracture mechanics**

## 1 INTRODUCTION

Acrylonitrile Butadiene Styrene (ABS) pipes are often used above ground in exposed applications. Although heat stabilisers are commonly included in ABS to prevent thermal degradation during processing and subsequent use in high temperature environments, stabilisation against weathering and the effect of ultraviolet (UV) radiation is often overlooked. Exposure to UV radiation induces changes in the polymer microstructure, which lead to polymer oxidation and eventual degradation.

Whilst photo-oxidative degradation of ABS resin is reported to primarily occur in the polybutadiene (PB) phase (Gesner 1965, Heaps 1968, Salman and Al-Shama'a 1991, Jouan and Gardette 1992), degradation can also occur in the Styrene Acrylonitrile (SAN) phase (Davis and Sims 1983, Jouan and Gardette 1992). According to Jouan and Gardette, degradation of the PB phase induces degradation of the SAN phase (Jouan and Gardette 1992). Photo-product species formed by photo-oxidation of the PB phase are strongly dependent on irradiation wavelength (Jouan and Gardette 1992). Photo-oxidative degradation of the polystyrene component of the styrene-acrylonitrile (SAN) copolymer also yields chromophores (Davis and Sims 1983, Jouan and Gardette 1992). Kulich and Gaggar conclude that initial colour fading is due to oxdation in the SAN phase, and subsequent yellowing discolouration is due to oxidation of the PB phase (Kulich and Gaggar, 1996). The level of SAN copolymer in an ABS blend is known to affect mechanical properties by altering the rate of oxygen permeation. Increasing the level of SAN copolymer decreases oxygen permeability and retards degradation of the dispsered PB phase.

Photo-oxidation of the PB phase is considered to be the major cause of mechanical property deterioration in ABS. For ABS exposed to ultraviolet radiation, photolysis of the methylene bond in the trans-1, 4-polybutadiene structure occurs, yielding an allylic radical polymer chain. The radical may undergo several reaction paths to yield further radicals together with oxygenated species such as hydroperoxides, ketones and esters (Shimada and Kabuki 1968, Shimada et al 1972). The rate of photo-oxidation is proportional to the intensity of irradiation and the log of the irradiation wavenumber (Shimada and Kabuki 1968).

With further UV exposure, stable oxygenated photoproducts decompose to yield oxygenated radical species. Photo-oxidation is accelerated by the presence of residual hydroperoxides formed during thermal processing, which may also decompose to produce other degradation products and radical chains. Crosslinking of the PB phase after radical formation is thought to contribute to the embrittlement of the PB phase (Scott and Tahan 1977). Several approaches exist to prevent photo-oxidation, including the use of UV stabiliser additives (Kulich and Gaggar 1996, Zahn 1997 Shimada and Kabuki 1972). Additives absorb the energy of irradiation and transfer it to the ABS resin by lattice vibration excitation. However since they are not able to completely absorb UV energy, bond disassociation of the methylene-methylene structure remains possible. The inclusion of pigments or additives intended for UV stabilisation may also reduce the impact resistance of the resin (Kelleher *et al.* 1967, Davis and Gordon, 1974).

The relatively high impact strength of some ABS resins can be attributed to an increase in the PB phase content, which is susceptible to photo-oxidation (Heaps, 1968, Kelleher *et al.* 1967). Zahn shows that the impact strength of high impact grade UV-stabilised ABS, decreases to ~ 70% of its original impact strength after UV exposure (Zahn 1997). In conditions of extreme UV exposure, it is recommended that the surface of ABS structures be painted to prevent photo-oxidative degradation (Shimada and Kabuki 1972, Gugumus 1979, Kurumada *et al* 1987). For thick ABS structures, degradation due to weathering is confined to the surface due to the formation of an initial degradation layer which prevents oxygen diffusion and further UV penetration. Subsequent oxidation of the bulk polymer is prevented and an embrittled surface layer forms, which eventually causes bulk failure under applied loading (Kulich and Gaggar 1996).

The critical performance requirement of thick-walled ABS pipe for outdoor water transport, is to withstand the internal hydrostatic pressure to which it is rated. A degraded surface layer on the pipe will contain numerous micro-cracks which may be sufficiently large to propagate into the pipe wall under an applied load (Kulich and Gaggar 1996, Tiganis *et al* 2001). In this study, thick ABS specimens (which was not UV stabilised), were weathered under accelerated conditions closely matching those of natural weathering. Changes in chemical and mechanical properties were assessed, and the influence of weathering on failure was analysed using fracture mechanics theory. An empirical relationship between UV-exposure time and an 'equivalent' surface notch depth is derived and used to estimate reduction in critical hoop stress for weathered ABS pipelines.

## 2 EXPERIMENTAL PROGRAM

### 2.1 Weathering

Specimens from a commercial ABS pipe resin comprising a SAN-graft-PB bimodal matrix with dispersed ungrafted PB polymer, in the form of impact (AS, 1146.1) and tensile (AS, 1145) specimens were weathered in an Atlas Ci 2000 weatherometer (Xenon Arc - 0.55 W/m$^2$/nm @ 340 nm) at ambient temperature (30ºC) such that the mechanism of degradation was not affected by heat (Tiganis *et al 2001*). Specimens were exposed using accelerated conditions for a 3-month duration with periodic removal for assessment. Table 1 shows the real accelerated weathering times and levels of UV exposure and the corresponding simulated times that are referred to in this paper. Simulated times were determined following Martin (Martin, 1977) and using an average of several years of total UV radiation data collected in Melbourne, Victoria and Allunga, North Queensland Australia, using an Eppley pyranometer. Based on the chosen accelerated conditions, a 3-month exposure period (1973 hours) approximates to a 1-year period of natural exposure.

**Table 1: Accelerated weathering times and UV exposure levels with the corresponding simulated natural weathering times that are referred to in the text**

| Real Instrument time (hours) | UV exposure (MJ/m$^2$) | Simulated natural weathering time |
|---|---|---|
| 41 | 7.5 | 1 week |
| 82 | 15 | 2 weeks |
| 164.5 | 33 | 1 month |
| 329 | 66 | 2 months |
| 493 | 100 | 3 months |
| 658 | 133 | 4 months |
| 986 | 200 | 6 months |
| 1480 | 300 | 9 months |
| 1973 | 400 | 12 months |

### 2.2 Microstructural property assessment

Control and weathered ABS specimens were visually inspected using an Olympus optical microscope. To assess the effects of weathering on polymer microstructure, 20µm thick specimens of ABS were microtomed from both the surface and bulk of sample that had been weathered for 12 months. These specimens were assessed by Fourier Transform Infra-Red (FTIR)

Go Back Next Page

spectroscopy to identify the carbonyl and hydroxyl absorptions formed due to the oxidation of weathered ABS and also to identify the characteristic infra-red absorptions of vinyl groups in control ABS specimens. The specimens were also analysed using an Atlas CL 400 chemiluminescence instrument to investigate the chemical stability of the surface of the weathered ABS. The samples were analysed at an isothermal temperature of 180°C in oxygen, after a nitrogen pre-phase. The onset of polymer degradation, or the oxidation induction time (OIT) was recorded for each sample.

### 2.3 Mechanical property assessment

The glass transition ($T_g$) temperature and loss moduli of the PB phase for ABS specimens before and after weathering were measured using a Rheometrics Scientific Solids Analyser RSA II DMTA. Instrumented impact analyses were performed on control and UV exposed ABS specimens, using a Radmana impact tester in accordance with AS 1146.1 (AS, 1146.1). To compare the effects of notching and UV exposure on the failure of ABS under static bending stresses, a hydraulically-driven Materials Testing System (MTS) 810 in a three point bending mode was also used. Notched (0.5 mm) control specimens were prepared according to AS 1146.1 and subjected to various nominal bending stresses. Exposed specimens (6, 9, 12 months) were also subjected to a static bending stress until failure and failure times were compared. Specimens were oriented such that tensile bending stresses acted on the UV-exposed or notched surfaces.

## 3 RESULTS & DISCUSSION

### 3.1 The effect of weathering on the chemical properties of ABS

#### 3.1.1 Optical microscopy and visual examination

A yellow-brown discolouration was observed to develop after 2 weeks of simulated natural weathering time under accelerated conditions, for the ABS polymer. Discolouration was localised at the surface and was of very minimal depth, with fading and slight yellowing occurring initially. The depth of discolouration increased with exposure time, reaching approximately 0.1 mm after 12 months of simulated natural weathering, at which point yellowing was prominent. Discolouration is often related to the coupling of radical scavengers with degradation peroxy radicals (Faucitano *et al.* 1996). However for ABS, discolouration is attributed to the formation of photoproduct chromophores during degradation. Chromophores absorb energy in the UV-visible spectrum and cause discolouration of the resin (Kulich and Gaggar 1996, Salman and Al-Shama'a 1991). According to the literature, both the PB and SAN phase are said to form chromophores upon oxidation which are responsible for fading and yellowing.

#### 3.1.2 Chemical stability - Oxidation Induction Time

Degradation at the surface of ABS causes an increase in polymer density, limiting oxygen diffusion and thus decreasing the rate of degradation through a thick ABS specimen, such that degradation is absent in the bulk polymer (Lemaire *et al*, 1996). If UV stabiliser is present in commercial grades of ABS, it must first be depleted at the surface for degradation to occur (Faucitano *et al* 1996, Heaps 1968, Clough *et al*, 1996). Figure 1 shows chemiluminescence traces for control polymer, and polymer at the surface and bulk of ABS weathered for 12 months. The voltage trace recorded in chemiluminescence assessment is directly related to light emitted by the decay of hydroperoxides, formed in the polymer due to photo-oxidation, upon heating. (Clough *et al*, 1996).

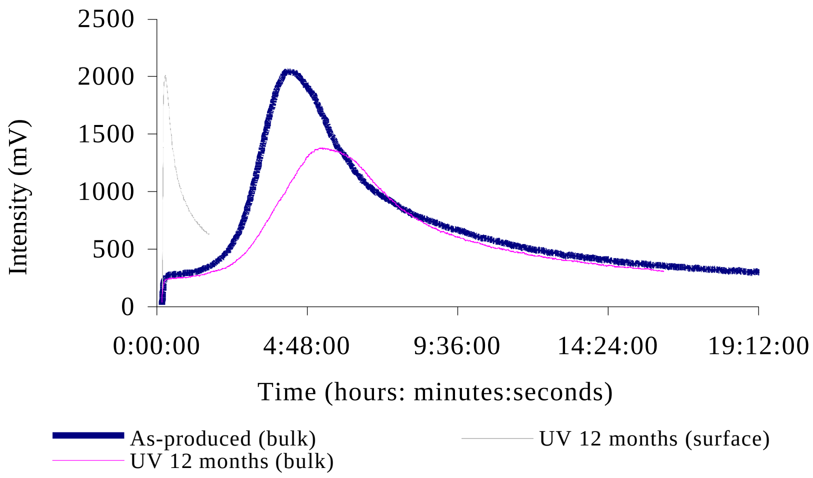

**Figure 1: Chemiluminescence traces for control ABS polymer and polymer from the surface and the bulk regions of weathered ABS**

As shown, the oxidation induction time (OIT) is almost instantaneous for the surface polymer of the weathered ABS specimen. This was expected as the resin was not UV stablised and degradation occurred upon exposure. In contrast, the signal for the bulk polymer of the same specimen (OIT ~ 170 minutes) is similar to that obtained for control specimens (153 minutes), indicating that no degradation occured in the bulk polymer.

3.1.3 FTIR analysis of polymer microstructure

FTIR spectroscopic analysis was used to study weathering-induced chemical changes in the microstructure of ABS. Results from control polymer specimens were compared to the surface and bulk polymer of ABS weathered for 12 months (simulated natural weathering time).

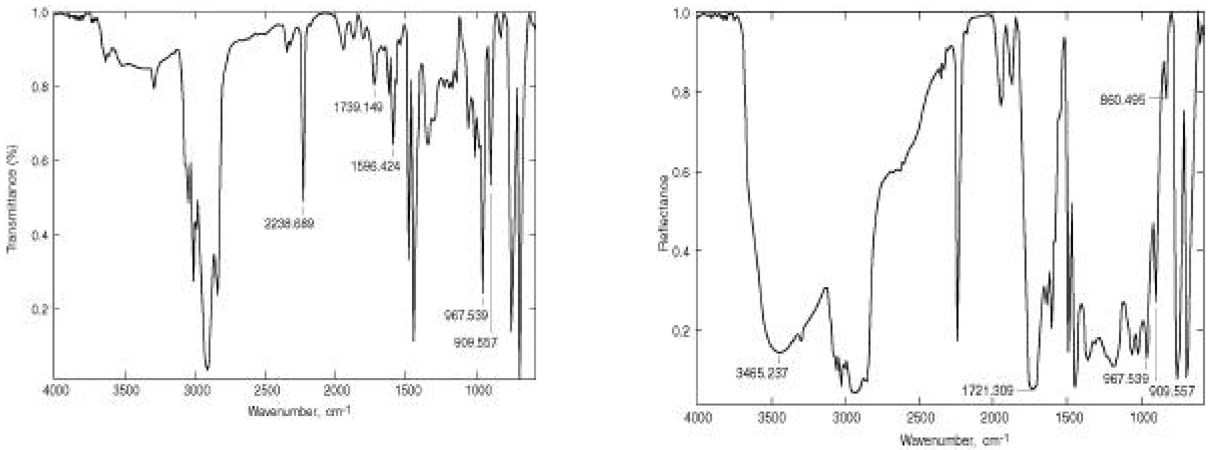

**Figure 2. FTIR spectra of the bulk (left) and surface (right) polymer of a ABS weathered for 12 months**

As shown in Figure 2, the spectrum representing the bulk analysis from the exposed polymer replicates a trace that is typical for control ABS, with no observed changes in the characteristic infrared absorptions and no evidence of degradation products. In contrast however, spectral changes are clearly observed at the surface of the aged polymer, in particular the carbonyl peak at 1721 $cm^{-1}$ and hydroxyl peak at ~ 3465 $cm^{-1}$ indicating changes in chemical structure associated with oxidation and the formation of photoproducts. The absorbance bands at 966.92 $cm^{-1}$ and 911.43 $cm^{-}$1 correspond to the trans C=C unsaturation (vinyl) in polybutadiene, and the 1,2 butadiene terminal vinyl C-H band respectively. The surface spectrum for weathered ABS shows a significant distortion in these bands, indicating changes in the PB microstructure, which are attributed to chain scission and cross-linking (Shimada and Kabuki 1968).

## 3.2 The effect of weathering on the mechanical properties of ABS

3.2.1 Effects of weathering on the glass transition of ABS

The effects of weathering on the microstructure and the thermo-mechanical response of the PB phase in ABS were investigated using dynamic rheology. For weathered specimens, increases in both the loss modulus (E") and tan $\delta$ parameters were observed, indicating an increase in the glass transition temperature ($T_g$) of the PB phase. These increases reflect an increase in modulus due to cross-linking of the PB phase (Kulich and Gaggar 1996). This will be confirmed in the future with further studies based on molecular weight distribution.

3.2.2 Effects of weathering on impact properties of ABS

Figure 3 shows the detrimental effect of weathering on the impact strength of ABS resin. The initial impact resistance of 214 $kJ/m^2$ decreases to approximately 60 $kJ/m^2$ within 1440 hours (2 months) of simulated natural weathering. Failure of exposed ABS is dependent on the extent of surface degradation and at a critical depth of degradation an abrupt failure occurs, as seen in Figure . Kulich and Gaggar (Kulich and Gaggar 1996) also observed a similar trend in the reduction of impact strength. Similar to thermo-oxidative degradation of ABS, photo-oxidation of ABS causes a sudden loss in impact strength that is critically dependent on the depth of surface degradation (Tiganis *et al* 2001). Zahn reports similar findings for ABS that is not UV stabilised, where impact strength falls to approximately 30% of the original value after 1500 hours of UV exposure (Zahn 1997).

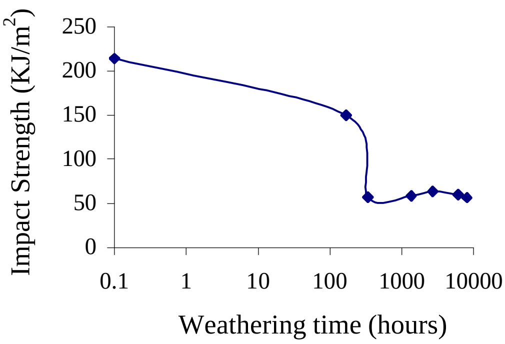

**Figure 3: The effects of weathering on the impact strength of ABS resin**

### 3.3 The effects of weathering on the failure mechanism of ABS

Results from the previous section suggest that weathering ABS creates a degraded surface layer that precipitates bulk mechanical failure similar to the action of a sharp surface notch. To investigate this hypothesis, the failure mechanism of UV-exposed specimens subjected to static bending stresses was examined. Figure shows the deflection/time curve for UV-exposed and virgin ABS specimens subjected to a static bending stress of 65 MPa.

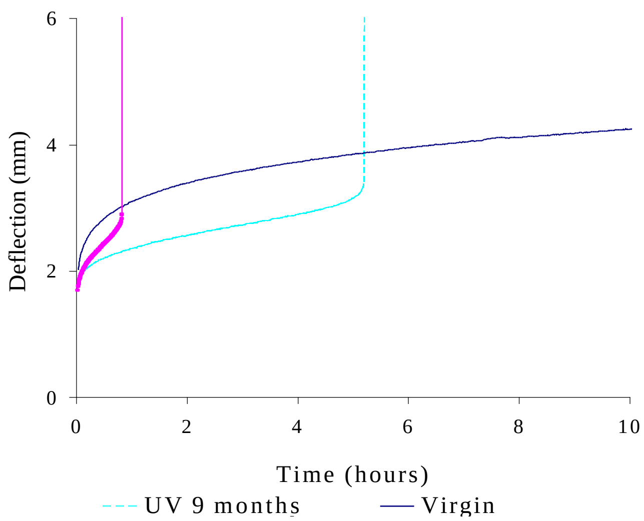

**Figure 4: The variation of crosshead deflection with time for static load SENB tests on UV-exposed and un-notched virgin ABS specimens**

As shown, the curve for un-notched virgin ABS is characteristic of creep deformation, an initial sharp increase in deflection, followed by relatively slow deformation. Failure eventually occurred by plastic collapse after three months. In contrast, whilst the initial sharp increase in deflection is observed in the UV-exposed specimens, the magnitude of deflection is reduced. This can be attributed to the increased stiffness of the degraded layer reported previously (Tiganis *et al* 2001). Furthermore, a transition is observed, after which deflection increases sharply. This typically indicates fracture failure with an increase in specimen compliance after crack initiation and subsequent propagation through the specimen thickness. Visual examination of failed specimens also suggested that brittle fracture occurred. Crack initiation was observed at UV-exposed surfaces, and separated surfaces appeared smooth with only limited stress whitening. Such features are typical of brittle failure from surface defects, with restricted plastic deformation in the bulk polymer.

Assuming that only limited plastic deformation occurs in the bulk polymer, Linear Elastic Fracture Mechanics (LEFM) theory can be used to relate UV exposure time to an 'equivalent' surface notch depth. For a single-edge-notched bend (SENB) specimen, an applied stress intensity factor (SIF) can be written as (Hashemi and Williams 1984)

$$K_I = Y\left(\frac{6M}{BW^2}\right)a^{1/2} \qquad (2)$$

where M is the applied bending moment (Nm). B is the specimen thickness (m); W is the specimen width (m) and a is the surface notch depth (m). Y is a geometric correction factor which accounts for the influence specimen size and loading type over $K_I$. At some stage during a test, a crack will initiate from the surface notch and slowly grow through the specimen thickness towards the free surface. Under plane strain conditions, the criterion for eventual brittle fracture can be written as

$$K_I = Y\left(\frac{6M}{BW^2}\right)a_c^{1/2} = K_{IC} \tag{3}$$

where $a_c$ is the critical crack length, and $K_{IC}$ is the material plane strain fracture toughness. By applying different static bending moments to SENB specimens, a range of failure times is produced and eq. (3) can be used to determine the variation of $K_{IC}$ with time (Figure )

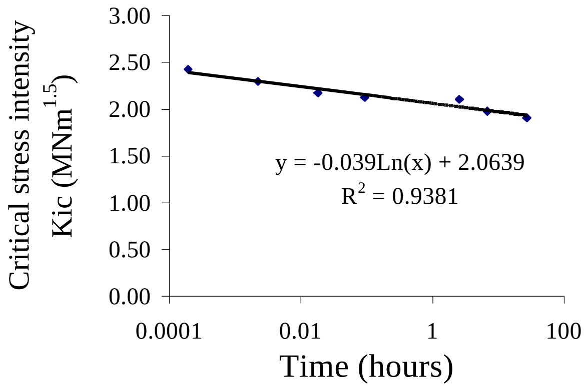

**Figure 5: Critical stress intensity factor ($K_{IC}$) for un-exposed SENB specimens**

As shown, the time-dependence of $K_{IC}$ for *un-exposed* ABS specimens can be approximated as

$$K_{IC} = -0.04\ln(t) + 2.06 \tag{4}$$

where $K_{IC}$ is in MPa m $^{0.5}$ and $t$ is in hours. If we assume that failure in UV-exposed specimens also occurs when $K_I = K_{IC}$, failure times for UV-exposed specimens can be used in equations (4) and (3) to obtain a relationship between UV exposure time and 'equivalent' notch depth (Figure ).

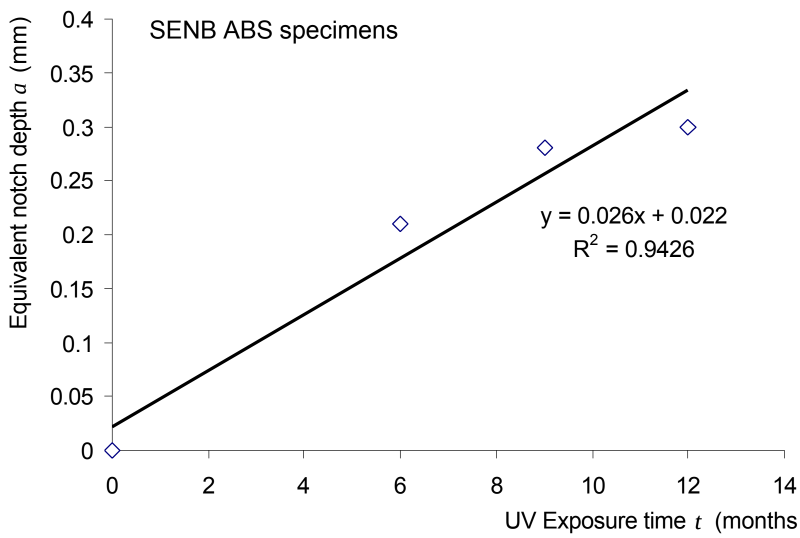

**Figure 6: Equivalent notch depths determined from failure times in UV-exposed SENB specimens**

As shown in figure 6, the resulting relationship from three-point bend tests is given by

$$a = 0.03t - 0.02 \tag{5}$$

where equivalent notch depth $a$ is in mm and exposure time $t$ is in months.

### 3.4 The effect of weathering on ABS pipe under hydrostatic pressure

Having derived an empirical relationship between τ and a, it can be applied to pressure pipelines if we assume that eq. (5) is independent of specimen geometry. If this is true, then subjecting a pipe to the same UV exposure as a rectangular bar specimen will result in the same equivalent external surface notch depth. Whilst current work investigates the validity of this theory, we now go on to suggest how UV exposure may influence the performance of ABS pipes under hydrostatic pressure.

Let us assume that a pipe has been weathered in service for a known period, τ, and we require the reduction in its hydrostatic pressure capacity. If an equivalent external surface notch depth can be determined from eq. (5), the corresponding applied SIF ($K_I$) associated with a pipe under internal pressure is given by (Rooke and Cartwright 1974)

$$K_I = y\left(\frac{2pR_i^2\sqrt{\pi a}}{R_i^2 - R_o^2}\right) \qquad \textit{(6)}$$

y is a geometric correction factor, p is the internal pressure (Pa), $R_i$ is the pipe inner radius (m), $R_o$ is the pipe outer radius (m) and a is the equivalent notch depth determined from eq. (5). As before, failure will occur when $K_I = K_{IC}$ as given in eq. (4). Figure shows the predicted effects of weathering on ABS pipe. Equivalent notch depths between 1.6-1.9 mm, correspond to weathering periods of 4.5-5.3 years simulated natural exposure.

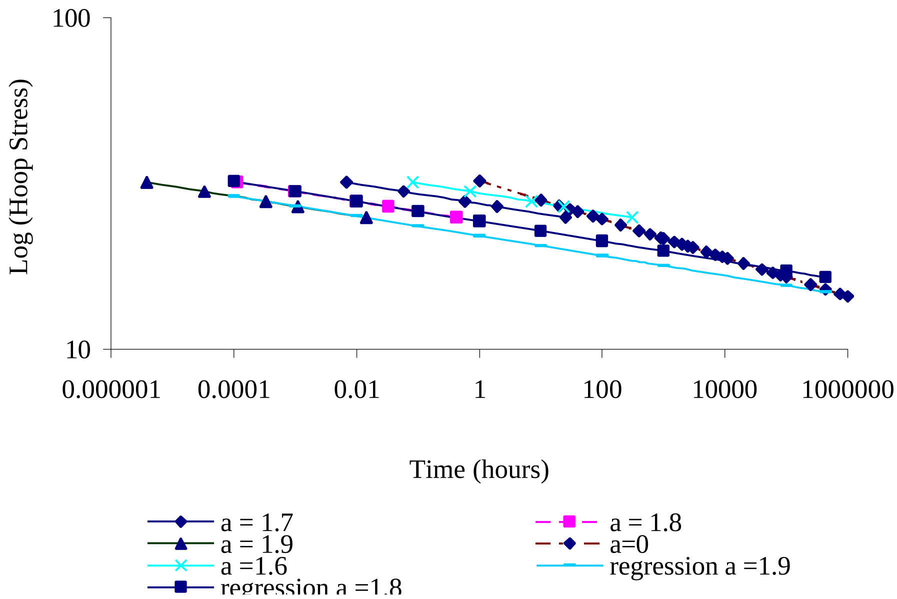

**Figure 7 : The predicted effect of weathering (and the equivalent surface notch) on the long term hydrostatic performance of ABS**

As shown, increasing UV exposure is predicted to reduce the time to failure for a given applied hoop stress. Whilst these predictions should be validated by experimental investigation, they may highlight the importance of UV-stabilisers in ABS pipes used in outdoor applications.

However, it should be noted that the results in figure 8 do not indicate *in-service* lifetimes. They indicate the performance of pipes that are *no longer* subjected to UV degradation *after* a period of exposure. In-service lifetime prediction can be idealised as a 'competition' between UV degradation at the pipe outer surface (which in turn produces an equivalent notch depth) and slow crack growth under the applied hydrostatic stress. During slow, stable crack growth, the applied SIF can be related to crack growth rate (*da/dt*) by a 'power law' relationship (Sandilands and Bowman 1986)

$$\frac{da}{dt} = AK_I^{\,m} \qquad (7)$$

Where A and m are constants for a particular environment and are dependent on material visco-elasticity. Figure schematically illustrates the transition between UV-controlled degradation and slow crack growth for a pipe in service.

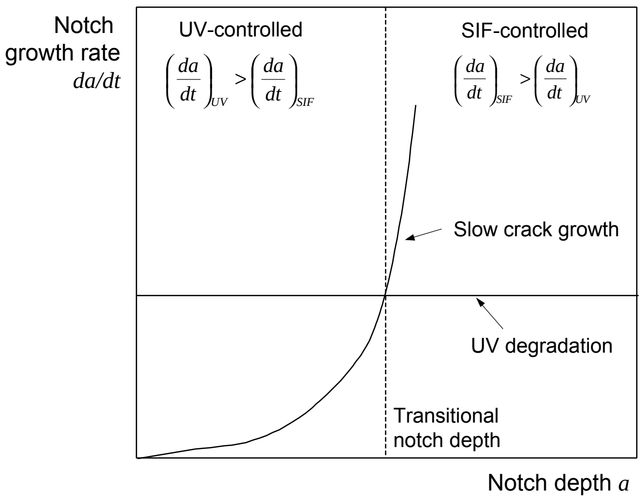

**Figure 8: Schematic diagram of the transition between UV degradation and slow crack growth in service**

As shown, the constant equivalent notch growth rate attributed to UV degradation is obtained by differentiating the linear relationship in eq. (5), and the ‘mechanical’ slow crack growth rate is described by eq. (7). Whilst notch growth is initially controlled by UV degradation, it becomes SIF-controlled above a transitional notch depth, which must be determined for in-service lifetime prediction. Although the initial results in this study suggest that equivalent notch growth under UV degradation proceeds at a constant rate, the effect of limited oxygen diffusion must be considered. For example, after extensive periods of UV exposure, the depth of the degradation in ABS will cease to grow with exposure time. Consequently, the empirical relationship between equivalent notch depth and exposure time may be misleading. Current work at CSIRO is progressing towards separate relationships between degradation depth/equivalent notch depth, and degradation depth/UV exposure time. It is anticipated that the growth of an equivalent notch can then be related more accurately to the kinetics of the UV degradation process.

## 4 CONCLUSIONS

Photo-oxidative degradation of the PB phase in ABS occurs in the absence or depletion of residual UV stabiliser, and ultimately precipitates mechanical failure of the polymer. Degradation of the elastomeric PB phase in ABS is initiated via photolysis of the methylene bond in the trans-1, 4-polybutadiene polymer structures, producing radicals that oxidise to produce carbonyl and hydroxyl products. Cross-linking of polymer chains, is also facilitated by free radicals. Degradation processes such as crosslinking cause an increase in polymer density at the polymer surface, preventing further penetration of UV light and oxygen into the bulk polymer. Thus degradation in thick ABS structures is localised at the surface. The mechanism of ABS photo-oxidative degradation in the PB phase is based on auto-oxidation and is strongly dependent on the wavelength and intensity of irradiation. The kinetics of degradation are not expected to be typically Arrhenius due to the limitation of oxygen diffusion.

In weathered ABS, the contribution from the dispersed PB phase to the overall ductility of the polymer, by particle cavitation, or localised shear yielding/crazing in the SAN matrix between PB particles, is greatly reduced due to degradation of that phase. Under impact loading, micro-cracks initiate from existing flaws in the degraded polymer surface layer. When the degraded layer reaches a critical depth, these cracks are sufficiently large to propagate into the bulk of the polymer causing abrupt mechanical failure.

Under static loading, the effect of UV degradation was compared to that of a sharp surface notch. Deflection/time curves and failure surface examination of degraded specimens indicated crack initiation and subsequent brittle propagation from the UV-exposed surface. Using plane strain fracture toughness measurements on un-exposed SENB specimens, an empirical relationship between UV-exposure time and an equivalent surface notch depth was determined. In the absence of experimental validation, it was assumed that this relationship was geometry independent and could be applied to pipelines under hydrostatic pressure. The variation of critical hoop stress with time was generated, indicating how a period of UV exposure may reduce failure times after subsequent UV protection. The in-service lifetimes of UV-exposed pipes was idealised as a competition between the growth rate of an equivalent notch under UV degradation, and the slow crack growth rate under an applied SIF. It was proposed that UV-controlled notch growth becomes SIF-controlled above a transitional notch depth.

Whilst the current study may suggest that weathering stabilisers or protective paints are required for ABS pipes that are under UV exposure, further investigation is required. The effect of degradation kinetics on equivalent notch growth must be considered, and the relationship between exposure time and notch depth must be validated for different test geometries.

# Durability Performance Of Polymer Concrete In Strongwall Construction

W Samarasinghe & R Sankaran
CSIRO Building North Ryde New South Wales Australia

**Summary: The concept of a polymer concrete based innovative construction system has been developed by Strongwall. This system enables speedy and economical construction of internal and external load bearing as well as non-load bearing walls. Research is focussed on identifying various materials that could be used for manufacturing the Strongwall system. Two polymer concrete formulations have been developed using industrial wastes.**

**Before the system is manufactured commercially, it is essential that its material and engineering characteristics are assessed and documented to aid design. This is even more compelling when the new material is manufactured using industrial wastes. Accelerated weathering tests were conducted using highly concentrated sodium chloride, sodium sulphate, sulphuric acid and sodium hydroxides. Circular disc specimens were prepared from cast cylinders and splitting tensile strength was evaluated after accelerated weathering to assess the degradation of strength.**

**The results indicate that the tested polymer concrete formulations have significant resistance to environmental degradation. It is noted that high concentration of sulphuric acid and sodium hydroxide can be harmful.**

## 1 INTRODUCTION

Conventional brick masonry walls are a popular and economical way to enclose modern buildings. However, over the past decade an increasing number of masonry veneer problems have come to plague building designers and owners around the world. To overcome some of the problems associated with traditional construction, new concepts of construction methods and materials have been explored. The innovative construction system developed by Strongwall combines the advantages of both the construction method and a new lightweight material to enable speedy and economical construction.

The new system could be used for both internal and external load bearing as well as non-load bearing walls. Besides its adaptability and economy, the construction system has been designed for durable residential houses in regional and remote outback areas where construction resources are in scarcity, for use in cyclone regions where strength and durability are essential, for external cladding in multi-storey residential & commercial buildings etc.

Polymer concrete has been selected on the basis that its relative strength is higher than conventional concrete, and it has the ability to cure at a faster rate. Further, if appropriate materials are chosen then a high strength to weight ratio could be achieved. In recent times, construction materials with ecological characteristics have generated great interest. From this point of view, polymer concrete is very attractive as it can be manufactured using recycled and/or industrial waste materials.

Three types of concrete polymer composites are popular throughout the world primarily due to their high strengths and durability. The materials are:

- Polymer impregnated concrete (PIC) which consists of a precast Portland cement concrete impregnated with a monomer system that is subsequently polymerised in-situ.
- Polymer cement concrete (PCC) with polymeric admixtures to green concrete in the form of latexes or plasticisers.
- Polymer concrete (PC) which consists of an aggregate mixed with a monomer or resin that is subsequently polymerised in place.

All these have strength and durability properties that are considerably better than that of Portland cement concrete. Also, the behaviour of concrete polymer composites is substantially different to that of normal cement concrete since the former uses a viscoelastic resin binder while the later uses an organic cement binder.

The characteristics of polymer composites depend upon various factors such as the type and amount of binder, the amount, size and type of aggregates and fillers etc. The ability to fill the voids between solid particles by fine fillers and to disperse in the mixture is considered to be vital to achieve high strength and stiffness.

At present, the Division of Building, Construction & Engineering of CSIRO is engaged in a sponsored research project. The primary aims of the research are to identify and develop a suitable material (or an array of materials) for the construction of the system and assess its (their) characteristics. While developing the materials reported in this paper, a large number of exploratory tests were conducted using various types of industrial wastes. However, due to lack of space, only characteristic properties of two types of polymer concrete are reported in this paper. Also, the durability performances under simulated aggressive forces of nature are included.

## 2 EXPERIMENTAL STRATEGY

As mentioned above only two types of materials are reported in this paper. Both materials are designed to achieve 40 MPa compressive strength. The mechanical properties of the two materials are shown in Table 1. The ingredients used are not disclosed here due to the commercial nature of the product.

Four test cylinders (76 mm diameter x 150 mm high) were cast from each mix type. They were initially cured at 35ºC for 45 minutes and then at 25ºC for 5 days. Results obtained from the initial tests indicated that the specimens gained full strength within 3 to 7 days. The disc specimens were primarily grouped into two categories, namely control specimens and specimens to be subjected to accelerated weathering. The accelerated weathering was simulated by subjecting the specimens into wetting and drying cycles in an aggressive environment. The specimens subjected to the accelerated weathering conditions were also divided into two groups. The specimens in one of the groups were only subjected to fan drying under the laboratory conditions, whereas the specimens in other group were oven dried after every five cycles for weight measurements. The control specimens and the specimens which were not subjected to oven drying were finally tested for strength tests.

**Table 1. Material Types Investigated**

| *Material Type* | *Type A* | *Type B* |
|---|---|---|
| Compressive Strength (MPa) | 40MPa | 40MPa |
| Flexural Tensile Strength (MPa) | 10.5MPa | 10.7MPa |
| Density (kg/m$^3$) | 1440kg/m$^3$ | 1530kg/m$^3$ |

## 3 EXPERIMENTAL PROCEDURE

Approximately 10 mm thick circular specimens were cut and placed back together in their original positions within the cylinder. Each test specimen (circular disc) was numbered sequentially in the cylinder for future reference. Altogether 32 circular discs were prepared for the investigation.

For the durability tests, some of the specimens (circular discs) were subjected to accelerated weathering while others were left as control specimens.

### 3.1 Durability Assessment

In order to understand the durability characteristics, an appropriate test as well as a performance indicator is needed. The type and nature of the test will depend upon its intended use and a wide range of variables must be considered in developing the test. Further, the accelerated laboratory experiments should be corroborated using long term monitoring of the in-situ durability performance of the material.

As a consequence of the brittle nature of polymer concrete, flexural tensile strength has been widely used as a performance indicator. In this study splitting tensile strength of the material under diametral loading was selected as the performance indicator due to the following reasons.

- Simplicity of the test set up
- Several test specimens (1 cm thick discs) can be prepared from the same cylindrical specimen
- Effect of the variability of the material in different test specimens can be minimised since several test specimens can be prepared from the test cylinder.
- Because specimens are relatively small, it is easy to perform the drying and wetting cycling tests.
- Cylindrical specimens are large enough to be representative of the material as a whole
- Effect of the aggressive agent can be assumed uniform through the thickness of the test specimen because of its thinness.
- To the authors knowledge, this is the first time the splitting test method has been used for the assessment of strength degradation of specimens subjected to exposure. Therefore, this study would also allow assessing the suitability of the test technique to such applications.

Go Back

Next Page

Continuous assessment of deterioration is a difficult task, as the deterioration is progressive and small in its early stages. Visual inspection, change in volume/dimensions and change in weight are some of the commonly used parameters to assess the degree of deterioration.

The weight loss or gain of the specimens was monitored in this study. Because of its non-destructive nature, weight loss/gain can be used as an indicator to identify the time at which the destructive splitting tests should be carried out.

### 3.2 Weathering Test & Agents

Most durability tests involve a prolonged period of soaking the specimens in a weathering agent, and then assessing the degree of deterioration. On using a reasonably strong weathering agent, the rate of deterioration will be slow, and therefore, the test itself must be of reasonably long duration. Also, it does not simulate what is happening in a real life situation, where both wetting and drying processes cause the degradation of the material.

An alternative approach to the above, is a shorter duration cyclic test where the specimen is immersed in the weathering solution for a specified time and then dried in a controlled environment. This process is repeated for a set number of cycles, or until measurable deterioration occurs. In this case, the rate of deterioration will be influenced by the concentration of the solution and severity of the cycling procedure. This approach reasonably simulates the real life performance.

For the current study, the cycling process as described above was selected and the following agents were used.

- Sulphuric Acid – 25%
- Sodium Hydroxide – 10 molar
- Sodium Chloride – 14%
- Sodium Sulphate – 14%

The Australian/New Zealand Standard AS/NZS 4456:1997 recommends the use of a mixture of 14% of Sodium Chloride and 6.2% of Sodium for the degradation assessment of masonry units due to salt attack. The same strength mixture was used for the current specimens to test for salt resistance ability. Under normal conditions, 25 % of Sulphuric Acid and 10 molar Sodium Hydroxide are highly unlikely to occur. However, to understand the worst case performance, these mixtures were used.

As the test progresses, the concentration of the sulphate/chloride irons and the pH value of the solution vary due to reactions with the sample. Unless these parameters are kept constant, they can influence the results and increase the length of the test.

It should be noted that whatever type of accelerated test method is used, a correlation must be obtained between laboratory and field performance so that the test method could be fine tuned for realistic conditions for future tests. Unfortunately, when materials are newly developed, there are no past records for comparison.

### 3.3 Test Procedure

Eight, approximately 10 mm thick, circular test specimens were prepared from each cylinder. A typical example is schematically shown in Fig. 1. The specimens 1 to 6 were meant for the splitting test and 7 & 8 for the weight loss assessment. The specimens used for the weight assessment were initially oven dried (at 105 ºC) and their datum weights were recorded. Then all the test specimens, other than the control specimens were subjected to 24-hour wet and dry cycling.

| *Spec. No.* | *Test Cylinder* | *Weight (gms)* | | *Legend* | |
|---|---|---|---|---|---|
| | | | | | |
| | | | | | |
| 1 | | 98.32 | | | Specimen to be Weathered |
| 2 | | 99.37 | | | and subjected to |
| 3 | | 99.88 | | | Splitting Test |
| 4 | | 99.58 | | | |
| 5 | | 102.91 | | | Specimen to be Weathered |
| 6 | | 102.79 | | | and subjected to |
| 7 | | 101.15 | | | Weight Measurement |
| 8 | | 100.88 | | | |
| | | | | | Control Specimen |
| | | | | | |

**Figure 1. A Typical Layout of Specimens prepared from a Cylinder**

The control specimens were left in the laboratory while others were subjected to 24-hour wet and dry cycling at the age of 7 days. For each cycle, they were immersed in the solution for about 2 hours and then fan dried for 22 hours in the temperature controlled (23 ºC) laboratory. Two replicates were tested for each test condition.

The specimens 7 & 8 were oven dried at every fifth cycle (except at the start when oven drying took place after 2 cycles) for weight assessment. At the end of every fifth cycle, fan drying commenced followed by oven drying for 2 hours. Then the specimens were cooled for about 5 minutes and weighed prior to the commencement of the next cycling period. The specimens intended for splitting tests were not oven dried.

After every 10 cycles the old solutions were replaced with fresh solutions. The wetting and drying cycles were terminated after 37 cycles, when some of the specimens indicated signs of deterioration by loosing weights.

## 4 RESULTS AND DISCUSSION

The weight loss/gain of specimens are shown in Fig. 2 and 3 (positive values indicate weight gain). Each result shown is the average of two replicates. The variability of the results produced by similar specimens was found to be insignificant, and therefore the results were averaged.

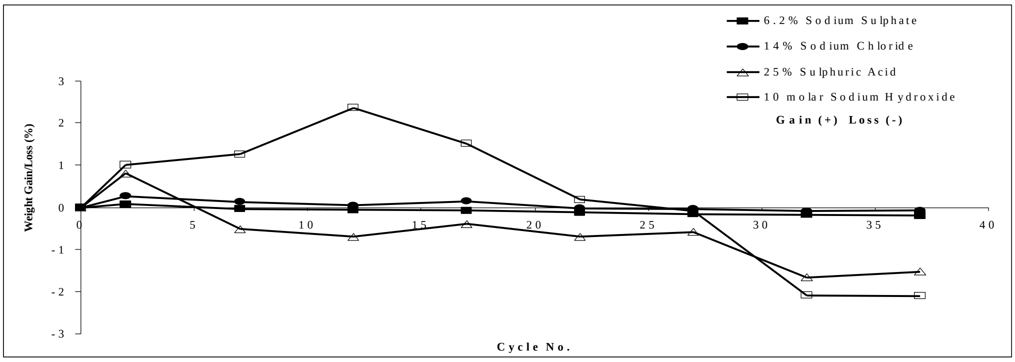

**Figure 2. The Effect of Accelerated Weathering on Material Type 1**

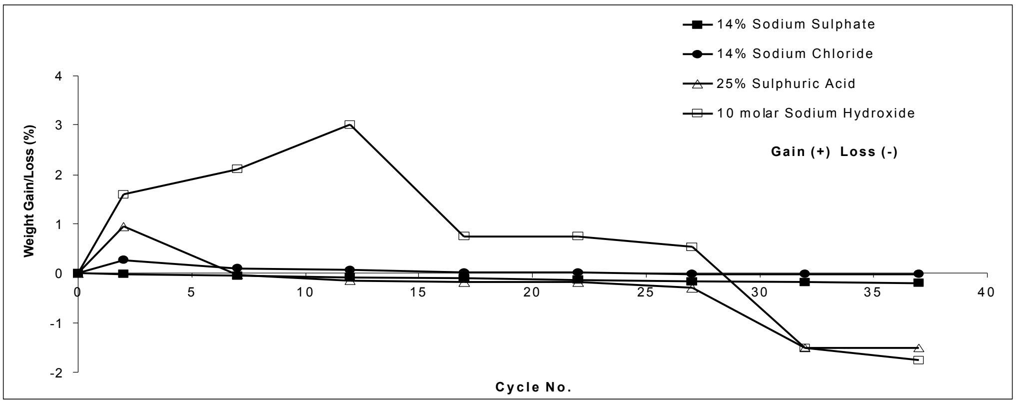

**Figure 3. The Effect of Accelerated Weathering on Material Type 2**

The following comments could be made on the above results:

- Behaviour of both material types is quite similar and is understandable as the materials are quite similar.
- Specimens do not show any significant deterioration with a severe exposure to sodium chloride and sodium sulphate solutions.
- The specimens subjected to severe sodium hydroxide exposure, initially gained weight, and subsequently, started to loose weight. The initial weight gain may be due to reaction products being deposited in the pores. As the specimen begins to deteriorate, a decrease in weight would have occurred due to spalling and similar effects. The signs of reaction taking place were observed by a noticeable change in colour. Initially, the specimens were grey in colour and after the first cycle, turned into a slightly yellowish colour.
- A significant deterioration of specimens, which were subjected to severe sulphuric acid attack, was noticed after the 27$^{th}$ cycle. Although there was no significant loss of weight initially, a considerable colour change has been observed, especially after oven drying at 105 ºC for 2 hours. The grey colour of the specimens was changed into a dark black colour. However, subsequent investigation has shown that the change in colour has occurred only on the surface. Fig. 4 shows the affected specimens under the influence of sulphuric acid together with two control specimens.

**Figure 4. Colour Change of the Specimens subjected to Sulphuric Acid**

The splitting test results are graphically shown in Figs. 5 and 6. The specimen numbers from 1 to 6 are consecutive specimens, and have been prepared from the same test cylinder. This enables comparison of the control specimens and the weathered specimens. The tensile splitting strength at the centre of the circular disc specimens was calculated using the equation shown below. The diameter and the thickness of the specimens were measured at three different locations and the average value was taken for calculations.

Splitting tensile Strength (MPa) = 2P/pDt
where,
P – Failure Load (N)
D – Diameter of the Specimen (mm)
t – Thickness of the specimen (mm)

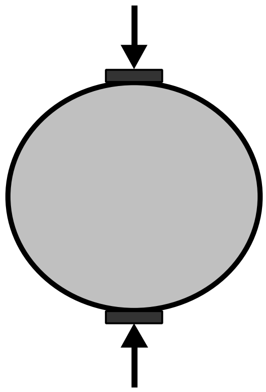

**Figure 5. Schematic Diagram of the Splitting Test**

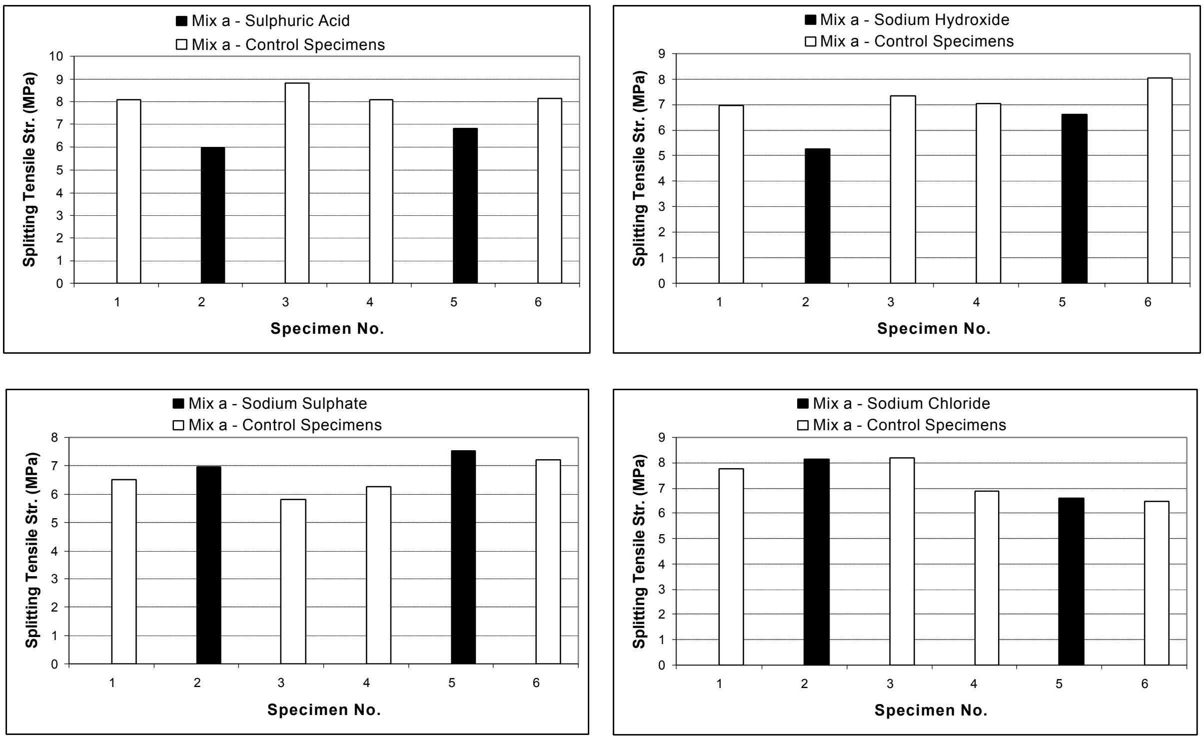

**Figure 6. Splitting Tensile Load of Material Type 1 Specimens subjected to Accelerated Weathering**

Go Back Next Page

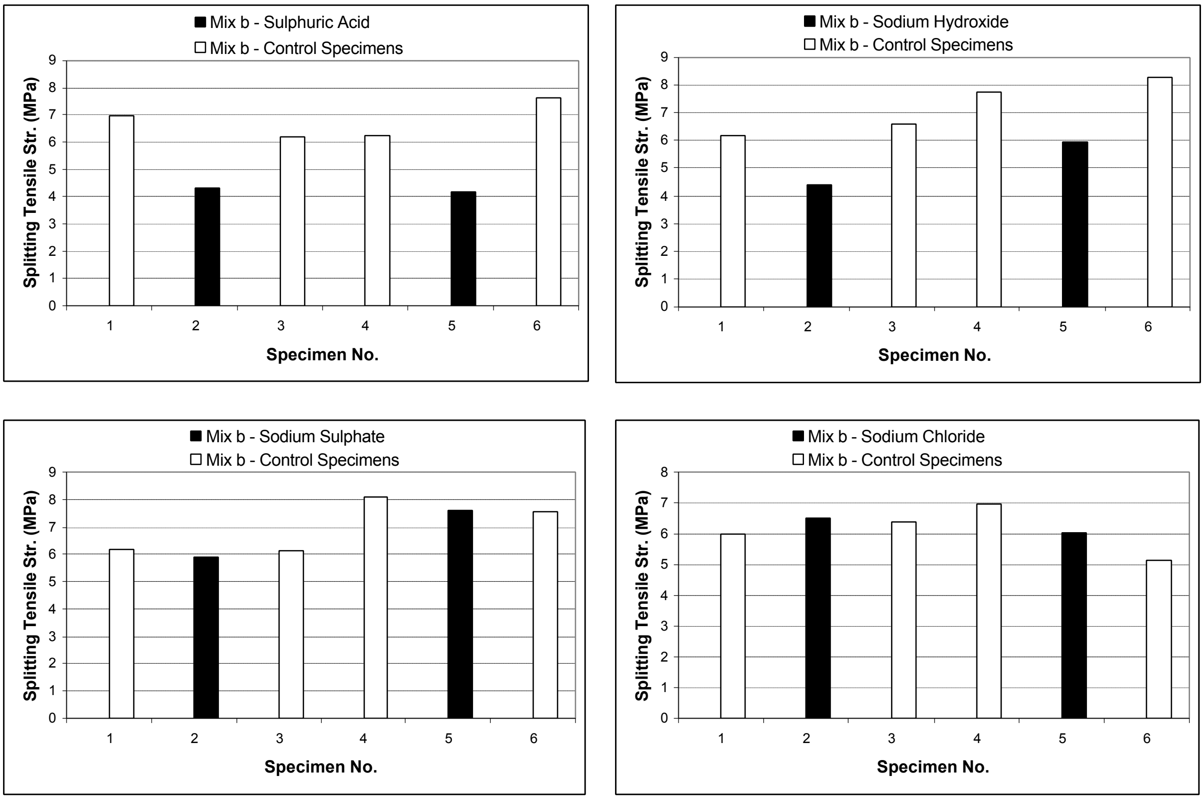

**Figure 7. Splitting Tensile Load of Material Type 2 Specimens subjected to Accelerated Weathering**

Figs. 5 and 6 show, that the splitting tensile strengths of control specimens can be significantly different within the same test cylinder. This is probably due to non-uniformity of the mix and local crushing that took place at the loaded points in some of the specimens prior to tensile splitting failure. The average of the two adjacent specimens is compared with the weathered specimen in order to look at the effect of the weathering.

Table 2 summarises the loss/gain in tensile strength of the weathered specimens compared with the control specimens.

| *Weathering Agent* | *Material Type* | | | |
|---|---|---|---|---|
| | *A* | | *B* | |
| | *Spec. 2* | *Spec. 5* | *Spec. 2* | *Spec. 5* |
| Sulphuric Acid | -29.2% | -15.7% | -34.3% | -39.7% |
| Sodium Hydroxide | -26.6% | -12.3% | -30.8% | -25.7% |
| Sodium Sulphate | 12.8% | 11.4% | -4.2% | -3.1% |
| Sodium Chloride | 2.4% | -0.8% | 5.2% | -0.7% |

**Table 2. Loss/Gain in Strength after Accelerated Weathering**

Both materials show a similar trend in the results. Effect of both sodium sulphate and sodium chloride solutions is not adverse after continuous wetting and drying for 37 cycles. Any loss or gain in strength shown by the specimens subjected to salt attack is not more than the variability of strengths shown by control specimens. However, it should be noted that both sulphuric acid and the sodium hydroxide have significantly affected the strength of the specimens.

The accelerated agents used in this study, especially the sulphuric acid and the sodium hydroxide, are extreme cases, and unlikely to occur in general applications. However, results obtained reveal that sulphuric acid and sodium hydroxide can be harmful for the polymer concrete materials developed. Further investigations are needed to assess their resistance to mild concentrations of the agents.

## 5 CONCLUDING REMARKS

Two new polymer concrete based materials were developed using industrial wastes. These materials were used to form the basis of a novel construction system. Circular disc specimens of these materials were manufactured in the laboratory so that accelerated weathering and strength tests could be conducted to assess their durability characteristics. Preliminary tests indicate that sulphuric acid and sodium hydroxide significantly affect the tensile strength of these materials and reduce their durability. However, other normally occurring agents such as sodium sulphate and sodium chloride, do not adversely affect these materials. Further investigations are being carried out and will be reported in the future.

# Compliance Requirements For Durability Of Masonry Mortar

**W Samarasinghe[1] SJ Lawrence[2]**
**[1]CSIRO Building Construction and Engineering NSW Australia**
**[2]SPL Consulting Pty Ltd NSW Australia**

**Summary: The durability of masonry mortar is an important property that can significantly influence the performance of a masonry structure. Mortar durability is influenced strongly by both environmental factors and the properties of the masonry units and the mortar. Because of the large number of factors affecting durability, it has become difficult to develop a representative test method to predict the performance of masonry against degradation. There are no codified performance criteria for durability of mortar other than to give prescriptive deemed to satisfy requirements based on experience. The work reported in this paper has developed laboratory and field test methods to assess the service life of masonry mortars subjected to salt attack, abrasion and wind action. The paper also describes performance criteria derived by comparing quantitative performance with qualitative performance.**

## 1 INTRODUCTION

Current building practices are changing as industry regulators embrace a performance-based code. Issues such as guaranteeing structural integrity, compliance with new codes and legal responsibility are now fundamental for builders, engineers, building designers, architects and building owners.

In Australia, brick veneer, double-brick or cavity masonry walls are common in residential construction. As medium density construction continues to grow in popularity, so too does the use of masonry as a cladding. A critical aspect of quality masonry is mortar. Mortar in masonry acts as the binding agent between the masonry units as well as accommodating variations in unit dimensions. The mortar must also have adequate workability during laying and adequate strength and durability in service. To meet the Australian Standard AS3700 (Australian Standards 1998) mortar mixes must comply with a performance requirement, and this is usually achieved by complying with specified compositions. If the mortar mix does not comply, it is prone to failure.

Currently there is no accepted test method for assessing the durability of mortar. At present, the Australian masonry code (Australian Standards 1998) contains a performance statement for mortar durability along with some deemed-to-satisfy mortar compositions for various environmental conditions, which are not supported by a testing method or acceptance criteria. No suitable test methods or acceptance criteria are available in overseas standards. Test methods have been developed by other countries for determination of mortar hardness, but they do not adequately reflect the surface hardness required in order to resist mechanical abrasive damage. Although the mechanisms of breakdown are well understood, there is no accepted method for assessing the durability of mortar and the likely lifetime of the joints in normal service.

There is a wide range of variables that must be considered in developing a representative durability test. The type and nature of the test will depend upon its intended use. If it is to compare the performance of various cement, sand or additive types, the test does not necessarily need to produce the site conditions. Developing a test method and relating its results to field performance is a large task. It would require long term monitoring of the durability performance of masonry panels located in severe exposure conditions in parallel with laboratory experiments. Another alternative is to attempt to create in the laboratory an environment and test specimens that represent as closely as possible the site conditions. An accelerated test would then be able to give a reasonably quick indication of the long term performance. However, more importantly, what is required is a simple apparatus that can assess the durability performance of in-situ walls.

This paper highlights some of the common failures of mortar in masonry structures. Development of field and laboratory test methods to assess the mortar degradation is described, and a correlation between the two test methods has been established. A suitable performance criterion for mortar is suggested.

## 2 MODES OF DETERIORATION

Mortar durability is influenced by many factors, both internal and external to the mortar joint (Bowler 1993, Ludwig 1980 and Harrison & Gaze 1989). In contrast to many countries, most of the population centres in Australia are not subjected to freeze-thaw cycles. However, many cities are located along the coast and therefore severe exposure conditions prevail such as salt attack and wind action.

Salt attack is predominantly considered more of a physical nature than a chemical action. In this mechanism, crystallisation of the salts in the pores of the mortar may result in its disruption owing to the pressure exerted by the salt crystals. As a result, the denser the material, the less is the likely deterioration.

Poor batching practices on site can often result in a cement content lower than that specified. The level of cement in the mix will directly influence the weathering rate of a mortar joint by wind action or abrasion.

With the continued development and increasing use of blended cements and chemical admixtures, there is concern that the durability of mortars made with these products may be affected.

## 3 ASSESSMENT OF DURABILITY

Representative laboratory and field tests for durability are required to accelerate the most likely mechanisms of failure due to environmental effects, so that an assessment can be performed in a reasonable time. Since no universal test for mortar durability exists, two possible test methods have been previously proposed (Samarasinghe & Lawrence 2000 & 1998) for possible development and standardisation. Those tests will allow assessing the adequacy of in-situ mortar to resist environmental degradation. Such test methods would also enable the performance of comparative studies of the durability performance of various mortar types with different compositions.

### 3.1 Laboratory Test Method

There is much common ground between concrete and masonry technology in relation to the durability of cements. Many investigators have studied this problem, mostly in relation to the performance of concrete rather than masonry. Tests usually consist of some form of soaking in an aggressive medium and monitoring the progressive deterioration of the specimen. The tests developed by the authors were similar in principal, and adopted the RILEM test for durability assessment of hardened mortar under freeze-thaw conditions (RILEM 1998) with some modifications. A controlled regime of soaking (in 5% sodium chloride) and drying cycles on mortar tablets, prepared from mortar joints cast between bricks, have been used for simulating the mechanical breakdown of hardened mortar particles.

A wide range of methods has been suggested by various investigators to assess the degree of deterioration of specimens subjected to accelerated weathering. The most commonly used techniques are physical appearance, change in volume (or dimensions), change in weight and reduction in strength. However, in masonry joints, most of the durability problems occur at the surface, and therefore strength measurements would not reflect the actual level of degradation. Hence, the percentage change in weight of the specimens was considered as the indicator of degradation.

Typical illustrations of the results are shown in Figures 1 and 2. The '2% weight loss' criterion was selected as the suitable index for the durability assessment of mortar. This is measured as the cycle number at which the specimen weight drops to 2% below its original weight. As seen from Figures 1 and 2, the test method is quite capable of identifying the effect of different parameters (such as cement content, cement type, and also sand type and brick type) that can influence the durability of mortar.

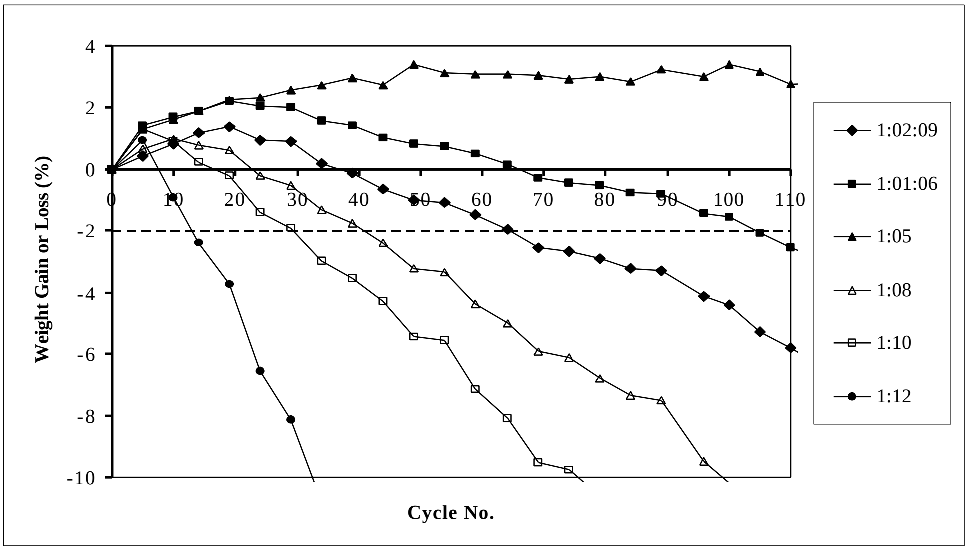

**Figure 1. Typical Weight Curves for Portland Cement Mortars in 5% NaCl**

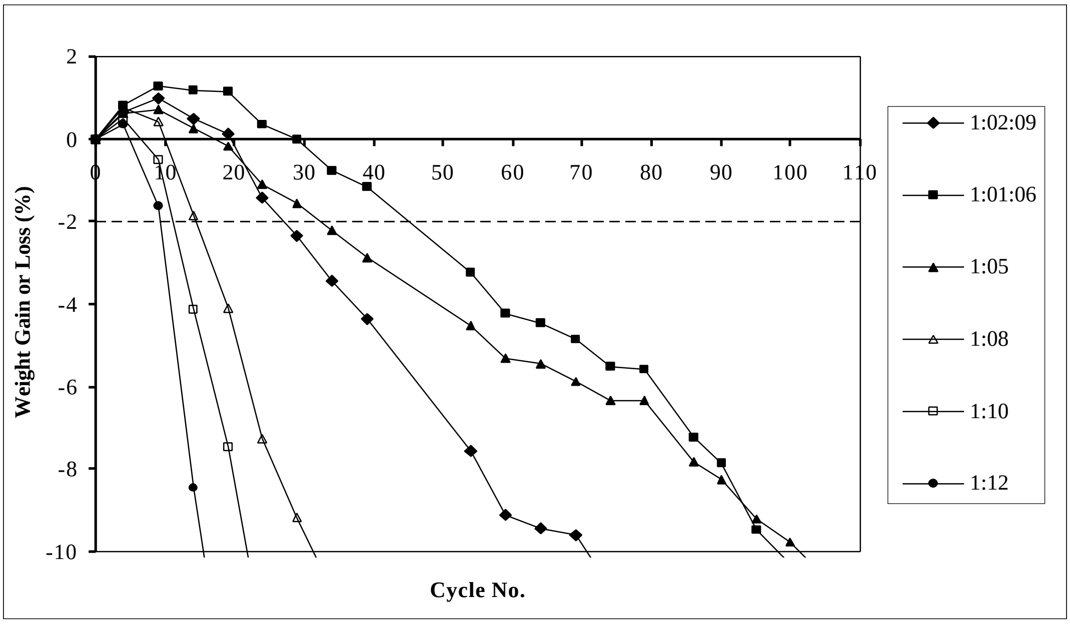

**Figure 2. Typical Weight Curves for Blended Cement Mortars in 5% NaCl**

### 3.2 In-situ Test Method

In the absence of a known precedent for this type of test, a prototype apparatus for a scratch test was designed and built. The principle involved is that a fixed force is applied through a spring to a probe with an abrasive end. The probe is turned through a fixed number of turns and the indentation into the mortar surface is measured with a depth micrometer. It is possible to vary the severity of the test by changing the form of the probe, the spring force and/or changing the number of turns used to make a measurement.

A series of scratch tests was carried out on brick-mortar couplets made with various mortar compositions and the indentation after 5, 10, 15 and 20 turns of the scratch probe was measured. Both scratch tests and cycling tests for comparison on the same specimens were considered impractical. The scratch test results are influenced by the confinement effects of the masonry units on either side of the joint during test, and this confinement is not present for the mortar slabs prepared for the cycling test. Therefore, in order to establish a correlation between the two test methods, specimens were prepared in parallel for the two methods.

A typical illustration of the test results is shown in Figure 3. For establishing a performance criterion and exploring correlation with the salt-cyclic test it is necessary to define an index of performance. Two possibilities have been explored; initial slope of the curves (penetration versus number of turns) and the depth of penetration after the first five turns. Examination of these indices showed that, while there was variation in the results, both appeared useful to represent the penetration results and they both appeared to correlate with the cement content in the mix. However, the index of average penetration for the first five turns (mm) was chosen as the best index for this test.

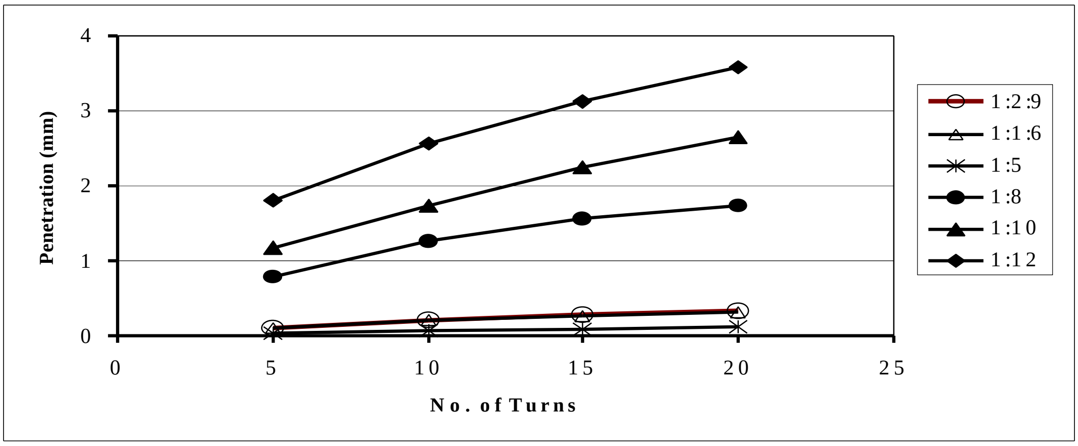

**Figure 3. Typical Relationships Between Penetration Depth and Number of Turns for the Scratch Test Correlation between the Two Test Methods**

The indices of performance of the two test methods are plotted to a logarithmic scale in Figure 4. The index of performance for the salt cycling test is the cycle number at which two percent weight loss of the test specimen occurs, whereas for the in-situ scratch test, it is the rate of penetration within the first five turns. Correlation between the cyclic test and the scratch test is good; indicating that the scratch test used in the field is likely to measure the same property as the cyclic test used in the laboratory.

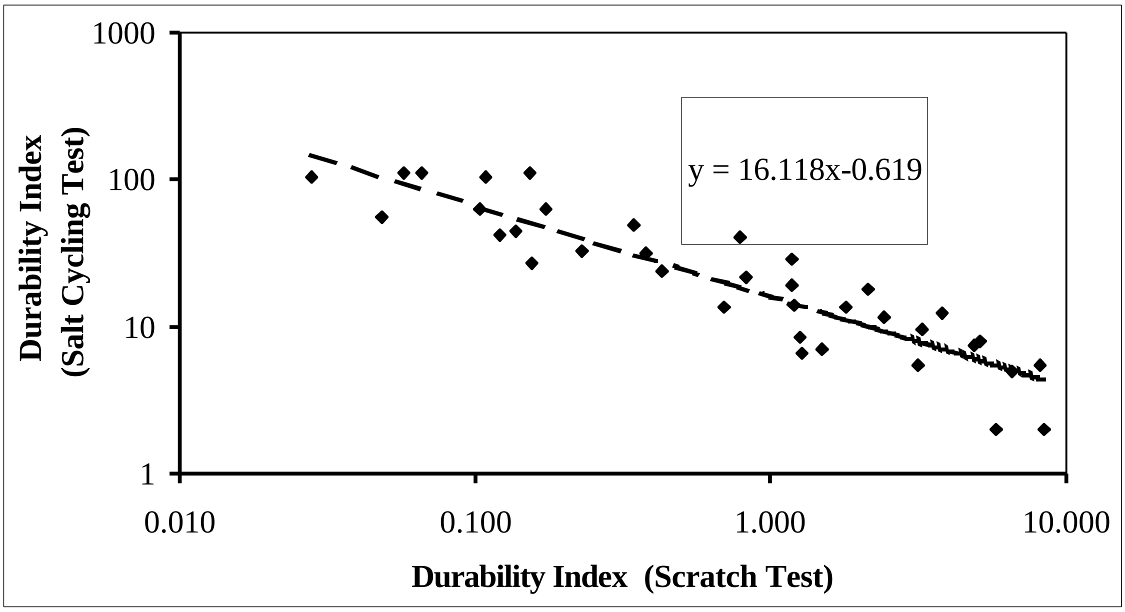

**Figure 4. Correlation of Scratch Index with Weight Loss Index**

## 4 CALIBRATION OF TEST METHODS

It is relatively easy to identify the relative effects of different parameters in the laboratory, which affect the durability performance. However, the major task is assessing the test results and relating them to wall performance. Assessing wall performance can be subjective, and therefore, some calibration testing would be necessary for this purpose.

Calibration of the scratch test index was conducted using exposure tests on specimens prepared under laboratory conditions.

Four-course prisms were prepared with 1:5, 1:8, 1:12 and 1:15 mortar mixes and placed on exposure racks after 14 days curing time. Three types of cements (GP, GB (SB), GB (FAB)) and two types of sand (Sydney Sand and Fatty Sand) were used with each of the mixes selected. One prism was built for each combination of materials. The prisms were orientated in the North-South direction with greatest sunlight exposure on the northern face and severe wind and rain attack on the southern face.

Scratch tests were carried out on the weather exposed mortar joints using the scratch tool after 22 months. Observations were also made about the appearance of the joints after the weather exposure, and they were gently rubbed with a finger along the joint to make a qualitative assessment about it's the abrasion resistance. Durable mortar should not have any loss of ingredients under a gentle abrasive force.

The abrasive resistance of the joints was categorised into four levels.

1. No dislodging of mortar ingredients – Level A.
2. Slight dislodging of ingredients, but stops after 2-3 rubs – Level B.
3. Moderate dislodging of ingredients in which small amounts of particles loosened at every rub – Level C.
4. Severe dislodging of ingredients with large quantities of particles loosened at every rub – Level D.

Both moderate and severe dislodging of ingredients of mortar are not acceptable, and people tend to complain about such masonry. All the penetration data were pooled together, irrespective of the mortar mix, and investigated for the correlation between the five-turn penetration depth and the Rub Test Grade. The average penetration depths corresponding to each rub-test grade were plotted as shown in Figure 5.

Go Back Next Page

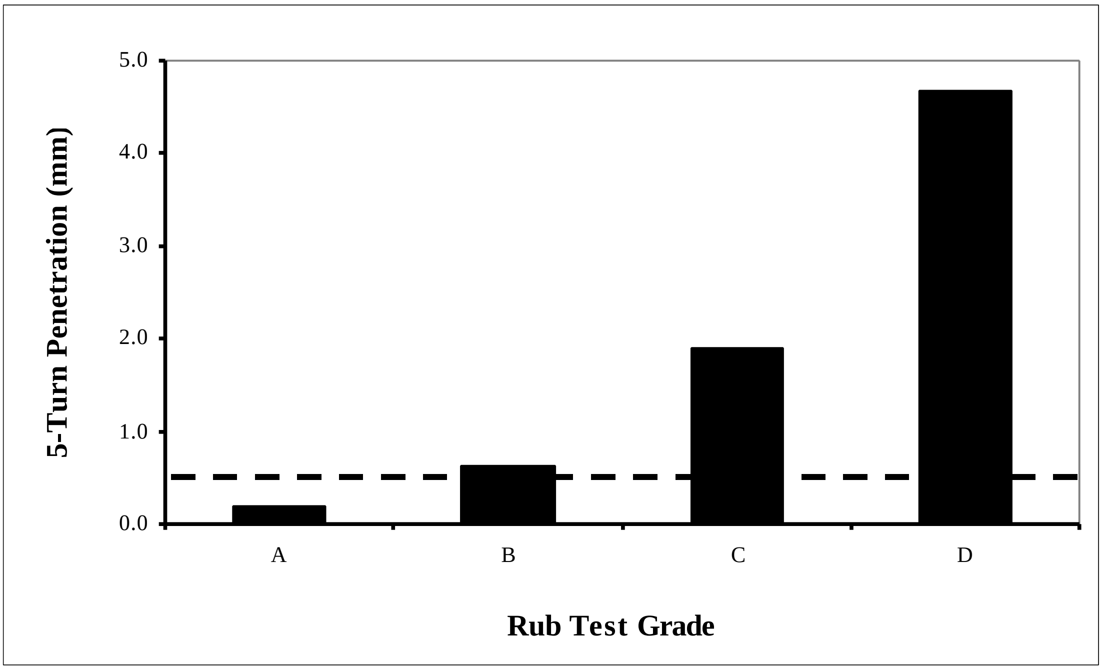

**Figure 5. Correlation between the Rub Test and the Scratch Test**

Comparing the results of the finger abrasion test and the scratch tool penetration, it could be suggested that any mortar with penetration greater than two millimetres is not acceptable. When the penetration is greater than two millimetres, mortar is more likely to be damaged under a mechanical abrasive force. This criterion was later verified with field data.

Therefore, the relationship between the two percent weight loss criterion and the five-turn penetration of the scratch tool can be used to establish the acceptance criterion for the salt-cyclic tests. The relationship established by correlating the results from the salt-cyclic test and the scratch test is as follows.

$N = 16.118\ D^{-0.619}$

Where,

N = Cycle Number at which two percent weight loss occurs in the NaCl cyclic test

D = Scratch Tool Penetration after 5 turns (mm)

Hence, when D = 2 mm,

N = 10.5

Therefore, if the cycle number at which the tablet weight reached two percent below its original weight in the NaCl cyclic test is less than 11, such a mortar is not considered durable.

## 5 CONCLUSIONS

A salt-cyclic test has been developed, using mortar tablets cast between bricks. Results have shown that five percent sodium chloride solution causes breakdown of the specimens in a reasonable time. The test method is capable of distinguishing the resistance to degradation of mortars with a range of different compositions. The cycle number for two percent weight loss has been chosen as the most useful index of performance for this test.

A controlled scratch provides a useful measure of the durability resistance of the mortar. The average penetration per turn for the first five turns of the scratch device has been selected as the index of performance for this test. Tests on a wide range of mortars have shown that the test is capable of identifying mortars with a range of different mix proportions.

The salt-cyclic test and the scratch test give measures that correlate well with each other and are therefore measuring the same property. Laboratory exposure tests have been used to establish a suitable criterion for the performance assessment of mortar.

# Development Of RILEM Durability Test Method For Curtainwall Sealants

**AT Wolf**
**Dow Corning S.A Seneffe Belgium**

**Summary: The paper discusses the work carried out over the past decade within ISO TC59/SC8 and RILEM TC139-DBS committees towards the development of a durability test standard for sealants. In 2001, RILEM TC139-DBS published a RILEM Technical Recommendation (RTR) on a durability test method for curtain wall joint sealants. The paper discusses the development of this test method as well as results obtained in the evaluation of sealants. Results of initial evaluations indicate that the test method is able to differentiate between products with regard to their resistance to accelerated ageing and mechanical cycling. The type of failure and the changes in surface appearance observed during the test regime are similar to those observed in actual service conditions. Sealant degradation resulting from durability cycles without fatigue cycling was slower than had been anticipated for most sealant systems.**

## 1 INTRODUCTION

Over the past two decades, the sealants industry has undergone rapid technological and structural changes. On the one hand, advancements in technology have enabled the launch of a multitude of new sealant products based on novel polymers, cure chemistries and formulations. On the other hand, increasing competitive pressure and customers that are more demanding have required shorter product development cycles. Unlike the well-established sealants, which have been sold for more than twenty years based on the same formulation, the new sealant products do not have documented long-term performance histories. At present, generating a reliable performance history for a new sealant product still requires long-term outdoor testing and extensive in-service field evaluations. Attempts at avoiding these tasks, by employing various forms of short-term laboratory-based ageing tests, have had limited success and are viewed with suspicion by construction specifiers, mainly because of the lack of an established correlation with actual in-service performance of sealants.

The sealants industry, therefore, urgently needs a method for generating long-term performance data rapidly and with assured reliability. Accelerated laboratory ageing experiments are the most promising method for acquiring durability information within the shortest possible time; however, a methodology for conducting and interpreting these experiments needs to be developed that improves the predictive value of this technique.

The need for improved longevity of sealed joints is well recognised. Work towards an accelerated durability test method was started in 1989 within the International Standardisation Organisation Committee ISO TC59/SC8 (Work Group 6). Later, in 1994, the activity was transferred to RILEM TC139-DBS Durability of Building Sealants, when the ISO committee realised that the task was too complex to be completed within the five-year time frame allowed for the development of an ISO standard. The RILEM committee has now developed a Technical Recommendation (RTR) (RILEM 2001), which will be considered by ISO for the development of a future durability test standard. The purpose of this technical recommendation is to provide a framework for assessing the effects of cyclic movement and artificial weathering on curtain-wall sealants in a laboratory-based procedure.

## 2 DEVELOPMENT OF A DURABILITY TEST METHOD FOR SEALANTS

During their entire service life, joint seals are exposed to cyclic mechanical strain and environmental degradation factors. Cyclic joint movement, sunlight, temperature variations (heat, cold) and moisture (water) are considered to be the primary environmental and service degradation factors leading to sealed joint failure. Weatherproofing joint seals in building façades are exposed to frequent cyclic movements. This joint movement imposes cyclic mechanical strain on the seal, which, depending on the exposure conditions and the construction design, can vary substantially in rate and amplitude.

Work on the durability test method started with the premise that the accelerated testing regime should incorporate only the following four key ageing factors: solar radiation, moisture, temperature and joint movement. With this limitation, the committee realised the impossibility of incorporation all possible combinations of weathering and service factors into a single laboratory-based testing regime. Weathering and service factors, which the committee specifically did not intend to address, were:

- Dirt accumulation
- Acid rain
- Cleaning solvents
- Microbial growth
- Incompatibility with other building materials

Joint movement is the preponderant service factor in the ageing of sealants, since it has a damaging effect both while the sealant is curing and after completion of the cure. Depending on the type of joints, sealants are exposed to various types and degrees of movement. Joint movements are induced by various factors, such as:

- Thermal expansion/contraction of construction components
- Shrinkage of construction components
- Settling of buildings
- Wind loads
- Service loads

Some of these factors may occur simultaneously, exposing the sealed joint to a rather complex, stochastic, often three-dimensional movement pattern of overlapping shear and extension/compression movements. Such complex movement patterns are difficult to simulate and the analysis of its effect on the sealant properties is an even more challenging task. Therefore, for the purpose of developing an accelerated durability test standard, the RILEM TC139-DBS committee decided to consider only the following three simple movement types:

- One single large movement followed by essentially no further movement
- One large movement followed by some cyclic movement
- Cyclic movement (in shear or tensile)

The above movement types can be roughly correlated with the movement patterns occurring in settlement joints, settlement joints with some movement, and glazing or weatherproofing joints, respectively.

Considering the frequency with which sealants are being used for the various applications, expansion and glazing joints represent the majority of sealant usage. Therefore, the development of a test method based on cyclic movement was prioritised by the committee. Obviously, the type of movement (tensile or shear) as well as the amplitude and rate of movement still depend on the type of application. A joint in a monolithic concrete façade, for instance, is likely to see slower and smaller movements than a joint in an aluminium curtain wall façade. For simplification, the committee had to narrow the scope of the initial test method again, and it decided to initially focus on cyclic tensile movements.

Even joints that are predominately exposed to cyclic tensile movement still show a rather complex movement pattern (see Hutchinson *et al*. 1999 and literature cited therein). However, based on experience with the development of movement capability tests (ISO 1989, Wolf 1999 and literature cited therein), it was assumed that the actual joint movement could be approximated by using idealised cyclic movements, such as trapezoidal, V-shaped, or sinusoidal movements. Research, comparing the performance of sealants exposed to various waveforms, suggested that trapezoidal movement waveforms provide the best correlation with simulated in-service performance (Jones *et al*. 1999). Therefore, trapezoidal movement waveforms were selected for the accelerated durability test method.

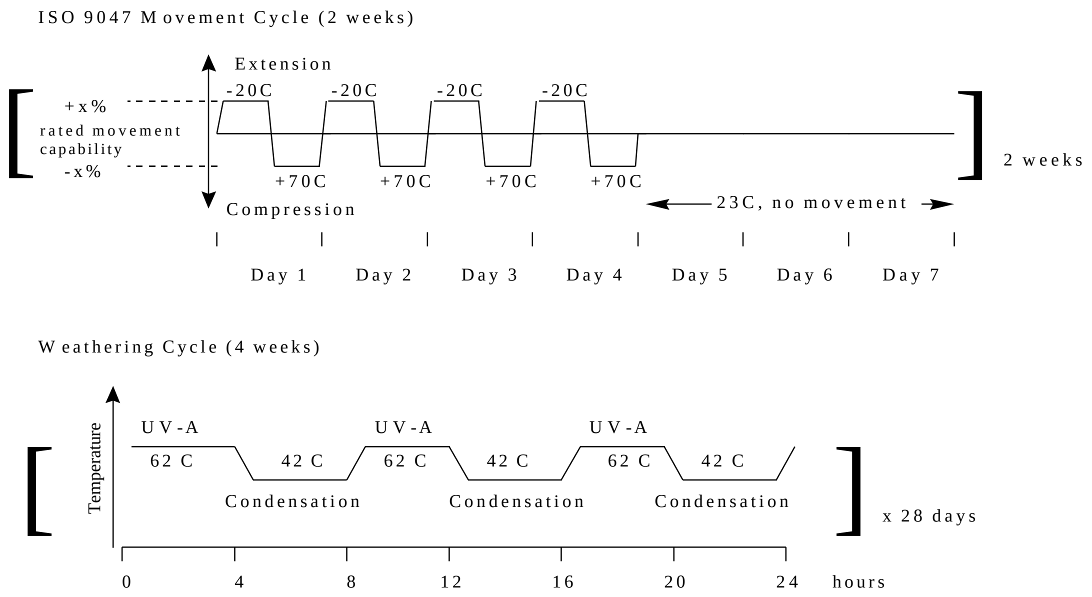

**Figure 1. Initial proposal of an accelerated durability test method (1993)**

A further narrowing of the scope of the initial test standard occurred when the committee decided to consider only elastomeric sealants, as defined by the ISO 11600 classification scheme (ISO 2000). Since ISO 9047 (ISO 1989) is the relevant test standard for determining the movement capability of cured elastomeric sealants, it was the most obvious candidate to consider as movement cycle for the future durability test standard. A first proposal of a test method (ISO 1993) suggested exposing the cured sealants to consecutive durability cycles. Each durability cycle consisted of a two week movement cycle as defined in ISO 9047 and a four week weathering period consisting of repeated cycles of four hours fluorescent lamp UV-A exposure followed by four hours moisture condensation (see Fig. 1). The proposal suggested that the durability cycles should be continued, until failure occurred, which was to be detected by visual inspection of the specimens after each durability cycle (see Fig. 2). The procedure proposed for the inspection was to extend the specimens to their rated movement capability and to place the extended specimens over a light.

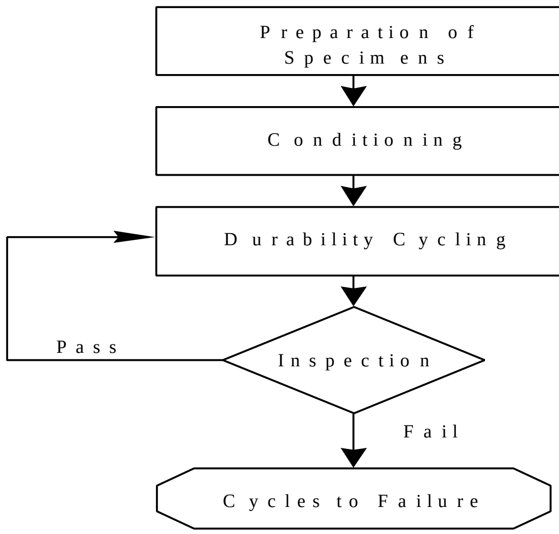

**Figure 2. Proposed concept for accelerated durability testing (1993)**

Much discussion revolved around the question of how the sealants should be conditioned prior to exposing them to the durability cycles. The proposal to use the same conditioning methods as defined in ISO 11600 was widely supported, based on the assumption that this approach allowed direct comparison of the result of the durability cycles with the 'initial' properties as determined by the other test methods referenced in ISO 11600. On the other hand, previous testing had clearly demonstrated the negative impact of mechanical cycling during cure on the properties of sealed joints (Jones & Lacasse 1999, Wolf 1999 and literature cited therein). Therefore a 'dynamic cure' procedure was proposed (Jones & Hutchinson 1998), in which the sealed joint is mechanically cycled while the sealant cures. Weathering of a sealed joint during cure also has an effect on its 'initial' properties (Beech & Turner 1983); the effect is especially noticeable for those weathering factors that either accelerate or retard the cure of the sealant. However, the effect appeared to be smaller than that of joint movement. The committee, therefore, agreed that it would be sufficient to consider only the effect of movement during cure to establish the initial reference state.

## 3 SUMMARY OF THE RTR DURABILITY TEST METHOD

The RILEM Technical Recommendation "Durability test method - Determination of changes in adhesion, cohesion and appearance of elastic weatherproofing sealants for high movement façade joints after exposure to artificial weathering" (RILEM 2001) specifies a laboratory procedure for determining the effects of cyclic movement and artificial weathering on laboratory cured, elastic weatherproofing joint sealants (one- or multi-component) for use in high movement building façade applications.

In this method, test specimens are prepared in which the sealant to be tested adheres to two parallel contact surfaces (substrates). Sealant specimens are conditioned either statically (no movement) or dynamically (exposed to cyclic movement). The conditioned sealant specimens are then exposed to repetitive cycles of artificial weathering (light, heat and moisture) and cyclic movement under controlled environmental conditions (degradation cycles). Weathering is carried out for eight weeks (default value) in an artificial weathering machine. This is followed (optionally) by rapid mechanical fatigue cycling (default: 200 cycles). The specimens are then exposed to two thermo-mechanical cycles as defined in ISO 9047 (section 8, first week), using the full amplitude suggested as the movement range of the sealant under test.

After completion of each degradation cycle, the specimens are extended to their full rated extension and held there as the sealant beads are visually examined for changes in appearance, cohesion and adhesion. The depth of any cohesive or adhesive flaw is determined according to the rules provided in ISO/DIS 11600 and the general condition of the sealant is reported. The weathering exposure, the cyclic movement, and the examination for failures constitute a degradation cycle and the degradation cycle is repeated as often as desired to achieve a certain exposure. A schematic representation of the test procedure is shown in Fig. 3.

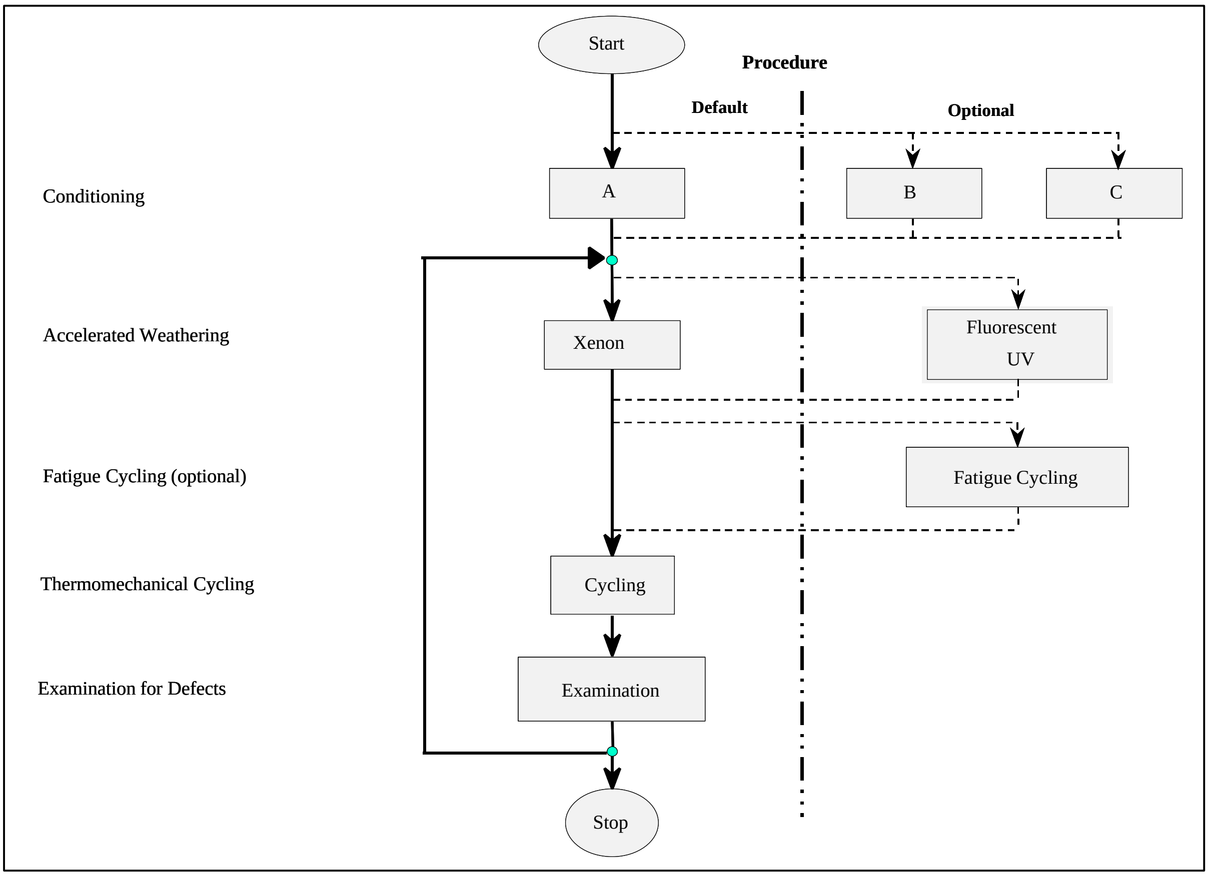

**Figure 3. Schematic representation of RILEM RTR test procedure**

Default test parameters and, for some procedures, alternative options are defined in the technical recommendation (see Table 1). In cases of dispute, the default method is the reference method. The experimenter is allowed to deviate from the default values for the following test parameters, however, is required to highlight any deviation from the default values in the test report:

a) Substrate – default: anodised aluminium as specified in ISO 13640 (ISO 1996)
b) Support dimensions – default: 75mm x 12mm x 6mm as specified in ISO 8339 (ISO 1984)
c) Conditioning method (A, B or C) – default: A as specified in ISO 11600
d) Artificial light source (xenon-arc, fluorescent UVA-340 lamp) – default: xenon-arc as specified in ISO 4892-1-3 (ISO 1998a)
e) Weathering procedure: duration of artificial weathering, type of moisture exposure (spraying or immersion), the temperature of light exposure, the temperature of moisture exposure, the timing of light and moisture/water cycle – default values are specified for xenon arc/water-spray, xenon-arc/water immersion and fluorescent UVA-340/water-spray weathering;
f) Rapid fatigue cycling (optional): inclusion of fatigue cycling, amplitude and duration (number of cycles) of fatigue cycling, default: 200 cycles – as specified in JIS A 1439 (JISC 1997);
g) Thermo-mechanical cycling (ISO 9047 type): amplitude and duration (number of cycles) – default values are specified in the test procedure.

**Table 1. Overview of default and alternative choices of key test parameters**

| *Procedure* | *Default* | *Alternative option* |
|---|---|---|
| Conditioning | A | B or C |
| Movement parameters for Conditioning C | 1 cycle/day<br>±7.5% amplitude<br>2.4 hour periods<br>trapezoidal waveform<br>extension/compression rate 70±20 mm/min<br>1st stroke in tension | |
| Accelerated weathering | Xenon arc light and water spray<br>102 min. light at 65±5°C black standard thermometer and 60 ±10 % rel. humidity<br>18 min. light with water spray<br>672 cycles (8 weeks)<br>or Xenon arc light and water immersion<br>102 min. light at 65 +//-5°C black standard thermometer; 18 min. light during water immersion<br>672 cycles (8 weeks) | Fluorescent ultraviolet radiation and water-spray (FL/UVA-340 lamps)<br>8h UV at 65±5°C black panel thermometer<br>4h UV with water spray<br>112 cycles (8 weeks) |
| Fatigue degradation | ---------------------------------------------- | Isothermal cycling |
| Movement parameters for isothermal cycling | 5 cycles/min at rated movement capability amplitude<br>200 cycles total | |
| Thermomechanical cycling | 2 cycles at rated movement capability amplitude (ISO 9047, 1st week) | |

The use of this method is intended to induce property changes in sealants associated with typical end use conditions, i.e. to simulate a natural weathering environment of sealants installed in curtain-wall joints exposed to high joint movement. Exposures are not intended to simulate the deterioration caused by localised environmental conditions, such as atmospheric pollution, biological attack or salt-water exposure. It should be noted that the use of this method as a predictor of the service life of a sealed joint for a given climate and location and on a given building has not been demonstrated yet. In the future, it is hoped that the test parameters can be linked with specific climatic zones and actual exposure conditions on site.

## 4 RESULTS OBTAINED WITH RTR DURABILITY TEST METHOD

### 4.1 Oxford Brookes University study (1999-2000)

As the committee started to converge towards the final test method in 1999, the importance of evaluating the behaviour of a set of sealants under comparative conditions became apparent in order to validate the proposed durability test method. A first study was completed by Oxford Brookes University (Jones *et al.* 2001), in which a total of fifteen different high quality sealant products, supplied by twelve manufacturers, were tested, including five silicones, four polyurethanes, three silicon-modified polyethers, two polysulfides, and one solvent-borne, silicon-modified acrylic. Anodised aluminium as specified in ISO-DIS 13640 (ISO 1998b) was used as a substrate material. Primers were used on the anodised aluminium substrates as recommended by the manufacturers.

All test specimens were subjected to four durability cycles. A durability cycle consisted of the joints being subjected to eight weeks of artificial weathering in a fluorescent UV/condensation device followed by two full ISO 9047 movement cycles (4 days). Following the fourth durability cycle, it became apparent that the durability cycles did not accelerate sealant degradation as quickly as originally thought. It was therefore decided to incorporate 1000 fatigue cycles with amplitude of ±25% at a rate of 5 cycles/minute into the experimental programme following the fourth durability cycle. The results from the fatigue cycling were intended to give insight into the possibility of including fatigue into later draft versions of the durability test method. Figure 4 shows photos of representative test specimens at the discontinuation of the test.

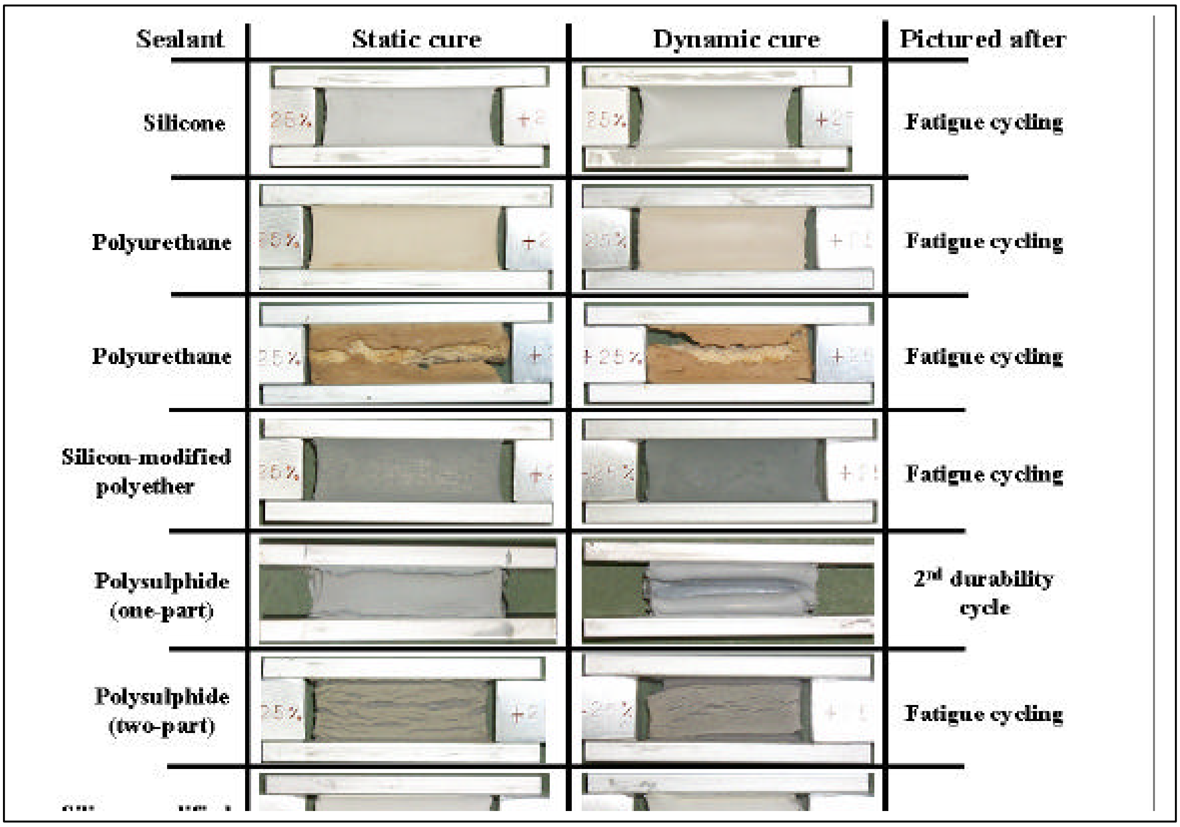

**Figure 4. Representative test specimens at discontinuation of test**

Exposing the silicone sealants to the durability cycles showed no effect for the first three cycles. After the fourth durability cycle, some silicone sealants showed a minor loss of adhesion, primarily at the ends of the joints, where stresses are highest. For these sealants, further loss of adhesion occurred during the fatigue cycling phase, but it proceeded at a different rate for each sealant. In general, no substantial differences were observed in the performance of dynamically and statically conditioned specimens, except for slight bead deformation resulting from the dynamic conditioning. The surface appearance of the silicone sealants tested was not affected by the durability cycles; no cracking, crazing, or visible discoloration occurred.

Large differences in the performance of the tested polyurethane sealants were observed. Except for taking a slight compression set, a one-part polyurethane sealant exhibited few signs of deterioration following the durability cycles. Another one-part polyurethane sealant lost adhesion at the ends of the joints, discoloured and developed surface crazing. The three-component polyurethane sealant showed severe discolouration soon after the first durability cycle and extensive blisters and cohesive cracks developed after the second cycle. The cohesive cracks propagated into the sealant and finally led to complete cohesive failure after the fatigue cycling.

The silicon-modified polyether sealants tested were little affected by the first two durability cycles. Surface crazing was observed for one sealant after the second cycle; the other two sealants started to craze after the third cycle. Two sealants survived four durability cycles, exhibiting no or only minor adhesion loss. All silicon-modified polyether sealants started to fail adhesively during the fatigue cycling.

The one-part polysulfide sealant cured very slowly and remained incompletely cured even after being exposed to three durability cycles. Due to the incomplete cure, the sealant developed major folds in the sealant bead, which further developed into cohesive cracks that finally resulted in complete cohesive failure after the second and third durability cycle for the dynamically and statically cured specimens respectively. Clearly, this sealant was not able to withstand the large and rapid movements that may occur in a curtain wall joint, due to its slow cure. The two-part polysulfide sealant performed better, although cracks developed on the bead surface after the second durability cycle, which continued to propagate into the depth of the sealant during the following cycles.

The silicon-modified polyacrylate sealant performed better than the other silicon-modified sealants. Very little deterioration was observed for the first three durability cycles. After the fourth durability cycle, some loss of adhesion occurred along the edge and the ends of the joints. The area of adhesion loss increased because of the fatigue cycling.

In general, the Oxford Brookes study found that the RILEM durability test method was able to differentiate between products with regard to their resistance to accelerated ageing and mechanical cycling. The type of failure and the changes in surface appearance observed during the test regime were similar to those observed in actual service conditions. The study confirmed that the initial modulus of a sealant is not a good indicator of the performance in the durability test; apparently more important are the property changes that occur because of the ageing (hardening, reversion, etc.). The dynamic conditioning procedure reduced joint durability for some of the tested products, but increased it for others. Sealant degradation resulting from the durability cycles was slower than had been anticipated for most sealant systems. The fatigue cycling clearly accelerated sealant degradation. It was therefore proposed to include fatigue cycling as part of each durability cycle. The RILEM TC139-DBS committee followed this recommendation and included the fatigue cycling as an option in the final technical recommendation.

### 4.2 Tokyo Institute of Technology study (2001)

A further study was initiated by the Japan Sealant Industry Association (JSIA) after the RILEM Technical Recommendation (RTR) on the durability test method had been finalised. This study, carried out by the Tokyo Institute of Technology in Yokohama (Takana & Miyauchi 2002), has currently completed two durability cycles and will continue for another durability cycle. The study comprises eleven sealants, two silicones, two silicon-modified polyethers, two polysulphides, two polyurethanes – each as one- and two-part products – one two-part silicon-modified polyisobutylene, one two-part urethane cure acrylic, and a one-part water-borne acrylic. The two-part polysulphide sealant is based on a new type of polysulphide/polyether/polysulphide co-polymer and employs isocyanate cure chemistry. Test specimens were prepared using anodised aluminium and mortar as specified in ISO-DIS 13640 as substrate materials; primers were used for all sealant/substrate combinations as recommended by the manufacturers. The two-part polyurethane, the two-part urethane-cure acrylic and the one-part water-borne acrylic were also evaluated after painting the sealant surface with a highly elastic paint. All sealant specimens were conditioned according to method A. Weathering was conducted in a fully automated weathering machine using a Xenon-lamp light source. Durability cycles were carried out with and without inclusion of the 200-cycle fatigue ageing.  Table 2 displays a summary of the interim results after the second durability cycle.

**Table 2. Interim results of Japanese study after second durability cycle**

| *Sealant* | *Substrate* | *Surface painting* | *Fatigue cycling* | *Chalking*[1] | *Crazing*[2] | *Test result* |
|---|---|---|---|---|---|---|
| SR-1 | Aluminium | No | Without | 1 | 0 | Pass |
| | | | With | 1 | 0 | Pass |

[1] Chalking was assessed according to ISO 4628-6 (ISO 1990)
[2] Crazing was assessed according to ISO CD 4628-4 (ISO 1994)

Table legend: XX-1, XX: chemical type, –1 or –2: one- or two-part
SR: Silicone, MS: Silicon-modified polyether, PS: Polysulphide, PU: Polyurethane,
IB: Silicon-modified polyisobutylene, UA: Urethane-cured acrylic, AC: water-borne
Acrylic; Chalking: 1 (none) – 5 (strong); Crazing: 0 (none) – 5 (strong)

The silicone sealant specimens survived the first and second durability cycles without any signs of degradation – no cracks, no crazing, no chalking and no loss of adhesion were observed. Both silicon-modified polyether products showed signs of moderate chalking after the first durability cycle. The one-part silicon-modified polyether sealant took a strong compression set during the ISO 9047 thermo-mechanical cycle (3 mm set based on 12 mm joint width after 25% compression), resulting in adhesive failure during the first durability cycle. However, for this sealant, there is a possibility of an experimental mistake during the preparation of the test specimens. In spite of exhibiting moderate to strong chalking and crazing as well as a 2 mm compression set, the two-part silicon-modified polyether sealant passed both durability cycles. The one-part polysulphide sealant also passed both durability cycles, despite a 2.5 mm compression set and signs of moderate chalking and crazing. Showing strong chalking and crazing, the two-part polysulphide sealant passed both durability cycles, when no fatigue cycling was included, however, two out of three test specimens failed the second durability cycle, when fatigue cycling was included. The one-part polyurethane sealant passed both durability cycles and showed some chalking, but no signs of crazing, regardless whether or not the sealant was exposed to fatigue cycling. The two-part polyurethane sealant chalked and crazed badly already after the first durability cycle. Due to the depth of the surface cracks (2-3 mm), this sealant failed the ISO 11600 pass criterion both on aluminium and mortar substrates. When the same sealant was painted with a highly elastic paint prior to weathering, the sealant passed the first durability cycle on mortar substrates with and without fatigue cycling without problems, but failed the second durability cycle, when fatigue cycling was included. The silicon-modified polyisobutylene sealant passed both durability cycles, but showed signs of moderate crazing after the second cycle. The urethane-cured acrylic sealant passed both durability cycles, with and without fatigue cycling, regardless whether it was painted or not. Without surface paint, it developed moderate chalking and severe crazing during the second durability cycle. The water-borne acrylic sealant passed two durability cycles, when no fatigue cycling was included, but failed in the second durability cycle, when the specimens were exposed to fatigue cycling. This behaviour was observed, regardless whether the sealant surface was painted or not prior to weathering.

Based on the above findings, at the meeting of ISO TC59/SC8 in 2001, the Japanese delegation recommended the RTR method for development as an ISO standard. With the exception of the urethane-cure acrylic sealant, they considered the degradation of the various chemical types of sealants observed after exposure to the two durability cycles to be similar to the one observed in outdoor weathering. The study conducted by the Tokyo Institute of Technology will continue until completion of the third durability cycle. Further studies are planned by the Architectural Institute of Japan in order to investigate the correlation of the results observed in the RILEM accelerated durability test method with those obtained in outdoor exposure. It is assumed that adjustments in the balance between accelerated weathering, fatigue cycling and thermo-mechanical cycling will allow tailoring of the RTR test method to specific outdoor climate and exposure conditions.

## 5 CONCLUSIONS

Both studies found that the RILEM durability test method is able to differentiate between products with regard to their resistance to accelerated ageing and mechanical cycling. The type of failure and the changes in surface appearance observed during the test regime are similar to those observed in actual service conditions. Since different sealant products were evaluated in both studies, their results cannot be compared directly; however, it appears that the Japanese study, using a Xenon-light source, yields faster degradation than the British study, which employed a fluorescent light source. Fatigue cycling substantially accelerates sealant degradation, as found by both studies. Finally, the dynamic cure procedure can be used to simulate movement during cure. However, a discussion of the British test results within RILEM TC139-DBS suggests the results depend critically on the relation between the duration of the movement cycle (2.4 hours) and the speed of cure (e.g. pot-life) of the product.

## 6 ACKNOWLEDGMENTS

The author would like to thank Prof. Tanaka of the Tokyo Institute of Technology for allowing him to present a summary of the interim results of the Japanese durability study prior to publication of the original paper.

# Design And Material Selection Factors That Influence The Service-Life And Utility Value Of Dual-Sealed Insulating Glass Units

**AT Wolf**
**Dow Corning S A Seneffe Belgium**

**Summary: Insulating glass units are exposed to a variety of environmental factors, such as temperature and atmospheric pressure fluctuations, wind loads, working loads, sunlight, water and water vapour. The service life of a sealed insulating glass unit (IGU) critically depends on the perfect functioning of the edge-seal under these environmental influences. The water vapour permeability of the secondary insulating glass sealant plays only a subordinate role in the life expectancy of a dual-sealed IGU, since the resistance of the edge-seal to water vapour diffusion is determined almost exclusively by the low water vapour permeability of the polyisobutylene primary seal. However, great importance must be attached to the viscoelastic properties of the secondary insulating glass sealants, particularly to their tensile stress behaviour and their elastic recovery under service conditions, as these properties affect the ability of the primary seal to function. The resistance of the edge-seal to gas diffusion is influenced by the permeabilities of both primary and secondary seals. IGUs with very low gas loss rates, meeting the stringent requirements of the German and new European standards, can be produced by proper selection and design of the edge-seal components, particularly by either minimising or properly accommodating the movements occurring in the edge-seal as a result of the thermal stresses. The durability of the secondary seal has a strong influence on the service-life of dual-sealed IGUs, as it affects the transport mechanisms for moisture ingress and gas loss.**

**Keywords: Insulating glass unit, Sealant, Durability, Service-Life, Life Expectancy.**

## 1 INTRODUCTION

The key function of an insulating glass unit (IGU) edge-seal system is to provide a gas- and moisture-barrier and to structurally bond two or more panes of glass together. This can be achieved best with a dual edge-seal system, where the primary, polyisobutylene-based seal provides the barrier function and the elastomeric secondary seal ensures the structural integrity of the IGU. In the year 2000, about 280 million $m^2$ of IGUs were manufactured globally. North America and Europe accounted for over 80% of this volume and about 2/3 of these IGUs were dual-sealed, with the market share of dual-sealed units being much higher in Europe (95%) than in North America (45-50%). Experience with dual-sealed IGUs has shown that service-lives of more than 25 years can be obtained, if the units are properly designed, manufactured and installed.

An IGU has reached the end of its service-life, when – under normal use conditions – moisture condensation (fogging) occurs within the inter-pane space. Fogging is caused by the diffusion of water vapour through the edge-seal and the resulting saturation of the desiccant. Modern, multi-functional IGUs are often filled with special gases, such as noble gases, $SF_6$ or mixture of these gases, in order to improve their heat and/or sound insulation quality. The differential in partial pressures of these gases within the IGU and the surrounding air causes them to diffuse, effectively resulting in a “dilution” of the gas(es) in the IGU by air. The dilution of the fill gases in turn affects the utility value of the IGU by degrading its heat and/or sound insulation quality. Thus, the quality of edge-seal strongly influences the service-life and utility value of an IGU.

## 2 ENVIRONMENTAL AND SERVICE DEGRADATION FACTORS

IGUs are exposed to various environmental and service factors that negatively affect their life expectancy (Wolf 1992, 1999). Literature on this subject often differentiates between physical and chemical stresses, although certain environmental influences, such as sunlight, exert both kinds of stress.

### 2.1 Temperature and its variation

High temperatures accelerate most physical and chemical processes, such as the ageing of the insulating glass sealant and the diffusion of gas or water vapour through the edge-seal. Temperature fluctuations produce variations in pressure within the

IGU. These exert mechanical stresses on the edge-seal, which are strongest for small units and unfavourable form factors (Feldmeier 1997). Furthermore, differences in thermal expansion of spacer bars and glass plates result in shearing and peeling forces in the edge-seal. The edge-seal temperature is influenced by the steady diurnal and annual ambient temperature variations; however, rapid changes in edge-seal temperature do occur; for instance, during a summer thunderstorm, when hail or cold water hits the heated outer glass pane. Even in quite moderate climates, such as Scotland, the edge-seal temperature in clear glass IGUs may vary by as much as 20°C within 2-3 hours (Garvin & Wilson 1998).

### 2.2 Air pressure and its variations

Permanent stresses on the edge-seal exert a highly negative influence on the service life of an IGU. Since they can be avoided through proper manufacture and installation procedures, this situation will not be further examined here. Changes in ambient atmospheric pressure result in temporary mechanical stresses on the edge-seal; these changes typically occur within the time span of several days. Much faster load changes occur with the sudden build up of pressure caused by a gust of wind or the change from pressure to suction produced with swirling winds. These rapid changes in wind load occur several hundred thousand times during the service-life of an IGU.

### 2.3 Sunlight

Sunlight exerts both physical and chemical stresses on the edge-seal. Visible and infrared components of the solar radiation thermally charge the IGU. The effect increases, if a tinted solar protection glass is involved, since then a larger portion of the visible light is also converted into thermal energy. The short wave component of the solar radiation may also induce photochemical processes in insulating glass sealants. Regular float glass is transparent to ultraviolet light down to a wavelength of about 280 nm (Spauszus 1975). In the case of a regularly glazed IGU, the unit's edge-seal is protected by the window frame; hence, no sunlight reaches the edge-seal directly. However, depending on the angle at which the sunlight strikes the glass surface, between 1% and 8% of the incident radiation finds its way to the edge-seal due to internal reflection in the glass panes (Van Santen 1984, 1986). The penetration length of this radiation into the depth of the rebate depends on the thickness of the glass pane (Marusch 1988). The glass adhesion of organic insulating glass sealants, such as polysulphides or polyurethanes, can be irreversibly destroyed by the high-energy short-wave spectrum (280-380 nm) of sunlight (Ludwig & Wolf 1986, Marusch 1988). Consequently, the edge-seal of organically sealed insulating glass panes is not to be freely exposed to the sunlight, but must be suitably protected, as in the case of sloped glazing, for example, by attaching strips, gaskets or tapes.

### 2.4 Water and water vapour

Water and water vapour may also cause both physical and chemical stresses on the edge-seal. Two of the major physical stresses are the water vapour diffusion through the edge-seal into the inter-pane space as well as the water absorption and the associated swelling of the insulating glass sealant itself. If the edge-seal of an insulating glass unit remains in direct contact with water for a protracted period of time, e.g. due to improper glazing, organic insulating glass sealants tend to absorb large quantities of water into their polymer matrix, thereby greatly increasing the volume of the edge-seal (Boesmans 1990, Ludwig & Wolf 1986). This swelling of the edge-seal inevitably results in an opening of the primary seal and, consequently, a higher rate of water vapour diffusion into the interior of the insulating glass unit. Glazing guidelines for IGUs therefore attach great importance to keeping the glazing rebate free of water. However, water and water vapour are also capable of triggering chemical reactions. By causing hydrolysis of chemical bonds at the glass surface, water can irreversibly damage the adhesion of insulating glass sealants (Ludwig & Wolf 1986, Shephard *et al*. 1999, Lowe 1992).

### 2.5 Synergetic effects

The stresses caused by the various environmental factors are not simply cumulative in their effect. Instead, their interaction results in a disproportionately higher stress on the edge-seal, a phenomenon known as synergism. Various studies (Feldmeier *et al*. 1984, Van Santen 1984, Ludwig & Wolf 1986, Lowe 1992) ascertained that the simultaneous action of water, elevated temperatures and sunlight constitutes the greatest stress on the edge-seal of an IGU. This degradative effect is most pronounced at the sealant/glass interface, often resulting in partial or complete adhesive failure of organic sealants, due to the channelling of UV radiation to the interface by total reflection within the glass panes. In the absence of water, free radicals are formed by the absorption of radiant energy and the resulting chain scission of organic polymers; however, these radicals tend to recombine, forming a somewhat different network configuration. In the presence of water, however, the radicals formed are terminated and cannot recombine, thus generating low molecular weight compounds that form a weak boundary layer. As a result, organic sealants exposed to UV light, water and elevated temperatures for prolonged periods of time fail progressively near the sealant/substrate interface.

## 3 DEGRADATION MECHANISMS AFFECTING INSULATING GLASS PERFORMANCE

Theoretical calculations based on moisture and gas diffusion through the edge-seal generally yield service lives far in excess of 25 years. Why is this theoretical life expectancy not achieved in normal service, with some units failing prematurely even within a few years of service? The theoretical calculations ignore the rigours that IGUs have to endure, the actions of sunlight, heat, wind loading, excessive moisture exposure due to improper glazing, etc., the resulting stresses, edge-seal defects due to poor workmanship, and – most importantly – the degradation of the edge-seal with ageing! The calculations are generally based on only one transport mechanism (diffusion through the edge-seal) and do not take account of changes in this transport mechanism or the advent of additional transport mechanisms resulting from the degradation of the edge-seal. The service life and gas retention of an IGU are influenced by the following factors:

- Exposure conditions (microclimate within window frame, external climate, wind loads, etc.)
- Dimensions of the insulating glass unit
- Quantity, type and initial loading of the desiccant
- Air or gas temperature and relative humidity during manufacture of the insulating glass
- Initial degree of gas filling
- Resistance of the edge-seal to diffusion of water vapour and gas
- Effective sealant cross-section through which the diffusion occurs
- Durability of the edge-seal

### 3.1 Diffusion through edge-seal

Considering all conditions as identical and neglecting the durability of the edge-seal for the time being, the service life and the utility value of an IGU should be the higher, the lower the amounts of water vapour and gas that diffuse through the effective cross-section of the edge-seal. The key parameters that need to be controlled, thus, are the permeability of the edge-seal and the effective cross-section.

#### 3.1.1 Permeability of the edge-seal

During service, the edge-seal of the glazed IGU is exposed to a microclimate within the window frame or curtain-wall construction. Two major studies have been conducted in an effort to monitor this microclimate in terms edge-seal temperature, moisture and presence of liquid water over the period of several years (Feldmeier *et al*. 1984, Garvin & Wilson 1998). While in Central Europe edge-seal temperatures of clear glass IGUs seldom exceed 40°C, for tinted or coated glass units or in warm climates service temperatures may well reach 80°C and above for prolonged time-periods (Jacob & D'Cruz 1999). As a rule of thumb, the glass temperature increases by 10°C for every 200 W/m$^2$ absorbed sunlight radiation. Since the diffusion of moisture or gas occurs under service conditions, the temperature dependency of diffusion through an insulating glass sealant must be taken into consideration, which can be described by an exponential function of the inverse, absolute temperature (Arrhenius equation), where $E_a$ is the activation energy of diffusion, R is the ideal gas constant, and T the absolute temperature:

$$\frac{P(T_2)}{P(T_1)} = \exp\left( -\frac{Ea}{R} \bullet \left( \frac{1}{T_2} - \frac{1}{T_1} \right) \right) \qquad (1)$$

Insulating glass sealants therefore exhibit a considerably higher moisture and gas permeability at elevated temperatures than at room temperature. For instance, as reported by Wolf (1985), the water vapour permeability of insulating glass sealants at 60°C is an average of six to eight times higher than at 20°C. The practical consequences of this must be examined. Although in Central Europe the edge-seal of an IGU is subjected to temperatures over 30°C for only about 20% of the year (Feldmeier *et al*. 1984), the IGU nevertheless sustains about twice as much damage by diffusing water during this brief summer period than during the remainder of the year, when temperatures under 30°C prevail. Higher temperatures in association with high humidity therefore drastically reduce the service life an IGU.

The activation energy of diffusion depends mainly on the polymer type utilised in the insulating glass sealant. The water vapour diffusion rates of silicone sealants vary less as a function of temperature than is the case for polyurethane or polysulphide sealants (Wolf 1985). As a result, the water vapour permeabilities of silicone and polysulphide insulating glass sealants tend to approach each other at elevated temperatures. Based on these findings, comparable service-lives should be expected for polysulphide and silicone single-seal IGUs – in contrast to frequently voiced arguments, which are based on water vapour permeabilities determined at room temperature. However, the service lives of such single-seal IGUs will be substantially shorter than those achieved with dual-sealed units.

Various authors have studied the temperature dependency of gas diffusion through organic elastomers, including PIB, silicone, and polyurethane elastomers (see Schuck 1980, Beckmann 1991, and literature cited therein). These authors consistently found silicone elastomers to have the lowest temperature dependency in gas permeability of all high molecular weight polymers studied. The activation energies for the diffusion of nitrogen and oxygen through silicone elastomers were 14 and 9 kJ/mole, respectively, while organic polymers typically showed activation energies for these gases in the range 28-52 kJ/mole. On the other hand, it should be noted that the silicone elastomers also had the highest absolute gas permeability of all elastomers studied.

However, since the majority of IGUs are dual-sealed, the diffusion resistance of a double layer system needs to be considered. The diffusion resistance of a plane-sheet laminate is the sum of the individual resistances of the various layers (Ashworth 1992):

$$\frac{d}{P} = \sum_{i=1}^{n} \frac{d_i}{P_i} \tag{2}$$

When considering moisture diffusion, the water vapour permeability of the polyisobutylene (PIB) primary seal is far lower than that of the secondary seal, irrespective of whether the secondary seal is made of a silicone, polysulphide or polyurethane sealant. Therefore, the water vapour permeability of the dual edge-seal is determined almost exclusively by the permeability of the PIB primary seal:

$$P_1 << P_2 \Rightarrow \frac{d}{P} \cong \frac{d_1}{P_1} \tag{3}$$

Experimental studies into dual edge-seal systems (Massoth & Wolf 1988) confirm this approximation; hence, it could be assumed that the service life of a dual-sealed IGU in the field would depend solely on the PIB primary seal, and that it is therefore irrelevant which sealant might be used for the secondary seal. This is not the case, however, as will be discussed later.

**Table 1. Overall argon gas permeabilities of dual edge-seals.**

| *Sealant Types* | *Argon Permeability* ($cm^2/(s\ cmHg)$) | |
|---|---|---|
| | Single Seal | Dual Seal |
| Polyisobutylene (PIB) | $5.0\ 10^{-11}$ | ---- |
| Polysulphide | $1.5\ 10^{-10}$ | $6.82\ 10^{-11}$ |
| Polyurethane (Polybutadien) | $8.0\ 10^{-10}$ | $8.00\ 10^{-11}$ |
| Polyurethane (Polyether) | $2.8\ 10^{-9}$ | $8.24\ 10^{-11}$ |
| Silicone | $3.7\ 10^{-8}$ | $8.33\ 10^{-11}$ |

In the case of gas diffusion, one needs to consider the individual contributions to the overall permeability of the dual-seal, which depend on the nature of the permeating gas. Table 1 shows the overall gas permeabilities of various dual edge-seal systems for argon, the most commonly used fill gas. The values were calculated from the experimentally determined gas permeabilities of the individual seals (Geilich 1987) using eqn. (2), and assuming primary and secondary seal depths of 6 and 4 mm, respectively. As can be seen, the overall gas permeabilities of polyurethane or silicone based dual seals are between 17% and 22% higher than the respective PIB/polysulfide dual seal. This is a rather small increase, when compared with the effect of the effective seal cross-section, through which the diffusion occurs (to be discussed later), or when considering the temperature dependency of gas permeability. For example, the nitrogen permeability of the polyurethane elastomer studied by Beckmann (1991) increased by a factor of 17, when changing the measurement temperature from 20°C to 80°C. This increase is typical for the organic elastomers studied, since the activation energy of 40 kJ/mole of the polyurethane elastomer corresponds quite well to the average activation energy found for this class of elastomers (43.9 kJ/mole). Since the ratio between the gas permeabilities of various gases in organic elastomers remains about the same (Schuck 1980), one can assume a similar increase for the argon permeability of the edge-seal. Given a defect-free primary seal installation, this suggests that the majority of IGU gas loss occurs during periods of elevated edge-seal temperature.

### 3.1.2 Effective diffusion cross-section

The first, and most important, factor that influences the effective cross-section for the diffusion of moisture and gases is proper workmanship during IGU manufacture. The primary seal must be properly dimensioned, must be free of voids, and completely wet the spacer and glass contact surfaces. For conventional IGUs (rigid spacer), the primary seal cross-section is determined by the pressing operation which occurs after the two glass panes and the PIB coated spacer have been assembled. The pressure must be maintained over a sufficient period of time to allow the PIB sealant to flow and to completely wet the spacer and glass surfaces. The strength and duration of the pressure must be controlled to achieve primary seal dimensions of 0.3-0.4 mm in width and about 5-6 mm in depth.

In the case of rigid spacers, the degree to which the primary seal opens up during periods of positive pressure differential is determined by the tensile stress with which the secondary seal resists this applied force. In practice, positive pressure differentials occur at low atmospheric pressures or at high temperature, whereby temperature is responsible for most pressure differentials. Temperature induced pressure differentials also excert a higher force on the edge-seal than do wind loads or atmospheric pressure variations (see Fig. 1, adapted from Van Santen 1986). Therefore, the tensile stress behaviour (Young’s modulus) of secondary sealants at elevated temperatures must be considered.

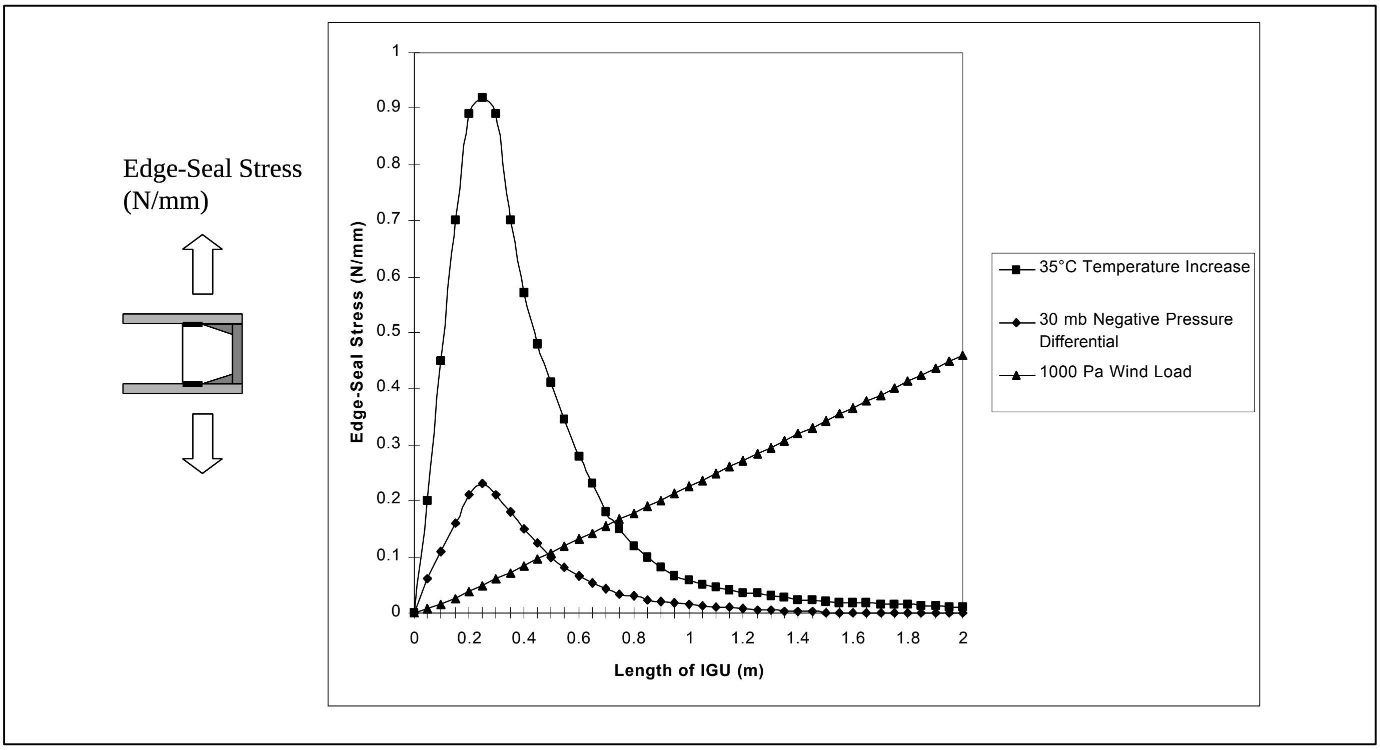

**Figure 1. Edge-seal stress as a function of IGU length for various loads**

O'Brien & Stewart (2000) modelled the thermal movements occurring in the edge-seal of a large IGU (1.5 x 2.1 $m^2$ size) as a result of temperature variations (-30°C to +60°C) for three commercially available spacer bars of different material and design using finite-element analysis. The model was based on nylon corner keys for the aluminium and galvanised steel spacers and bent corners for the stainless steel spacers. The nylon corner keys were assumed to be solid and firmly bonded to the spacers; while the bent corners were modelled as solid, bent metal corner keys, also firmly bonded to the spacers. Since actual bent corners are hollow, the model tends to overestimate the stresses for this corner design. As expected, at the low temperature, the corners are pulled inwards, resulting in a bending angle >90°; while at the high temperature, the corners are pushed outwards, resulting in a bending angle <90°. Figure 2 shows the deformed corner shapes for the aluminium spacers exaggerated by a factor of 100. Monitoring the changes occurring in PIB primary seal thickness around the circumference of the IGU, O'Brien & Stewart found that the stainless steel spacer had, by far, the least effect on the change in cross-sectional area, while the aluminium spacer had the largest effect, as can be seen in Table 2. This finding is in line with the sequence expected based on the difference in thermal expansion coefficients between spacer material and float glass. Thus, changes in the effective diffusion cross-section, resulting from a differential in thermal movements, are likely to account for the observation of performance differences of IGUs made with different spacer materials.

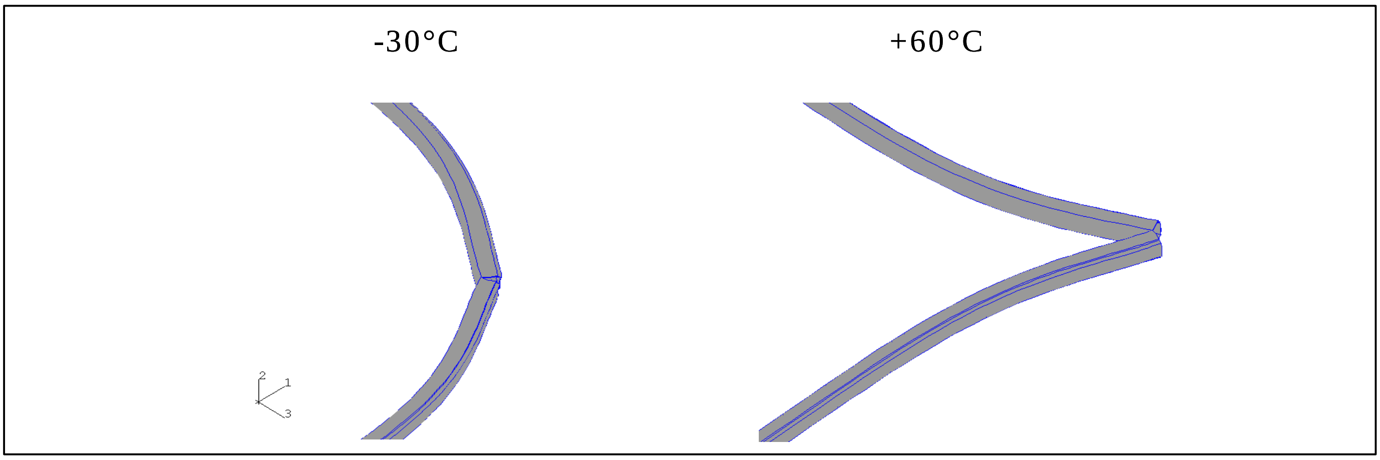

**Figure 2. Corner deflection of aluminium spacer frame (exaggerated by factor 100)**

Go Back Next Page

**Table 2. Deformation of PIB primary seal as a function of spacer material**

| *Temperature* | *Deformation of PIB seal (%) for spacer material* | | |
|---|---|---|---|
| (°C) | *Aluminium* | *Galvanised* | *Stainless steel* |
| +60°C | +51% | +42% | +6% |
| -30°C | -60% | -36% | -4% |

A further factor affecting the service life and utility value of an IGU is the time during which the opening in the primary seal occurs. Irrespective of the type of secondary sealant used, the opening occurs for the duration of the positive pressure difference. As discussed above, the degree of opening depends on the tensile stress of the secondary sealant. However, once the positive pressure differential decreases and an equilibrium is reached between inside and outside pressure, the length of time, required by the edge seal to close the primary seal, varies, depending on the degree of elastic recovery of secondary sealant utilised. Sealants with a low elastic recovery exhibit plastic flow in their stress strain behaviour; due to this relaxation mechanism their tensile stress decreases during maintained extension. As a result, when the applied force is eliminated, they are no longer capable of quickly closing the primary seal to its original size. If the secondary seal does not recover completely, the primary seal remains permanently deformed. Since the opening of the diffusion pathway occurs primarily at elevated temperatures, a secondary sealant with poor elastic recovery at elevated temperatures markedly shortens the service life of an IGU.

Apart from the fluctuations in temperature and atmospheric pressure, the ambient moisture level exerts an indirect influence on the opening and closing of the primary seal. At high moisture levels, and even more so in direct contact with liquid water, secondary sealants absorb water, which increases their volume and degrades their mechanical properties. In general, the lower the crosslinking density of the polymeric sealant network, the higher the water pick-up is. For the most part, the extent of the negative effects caused by the water pick-up is directly proportional to the amount of water absorbed. The swelling of the secondary sealant results in an opening of the primary seal, whereby the effective diffusion cross-section is increased.

### 3.2 Changes in transport mechanisms induced by edge-seal ageing

As mentioned before, exposure of an IGU to environmental or service degradation factors causes ageing of the edge-seal. This ageing can induce other transport mechanisms for the ingress of moisture or loss of gas. An indication that such ageing occurs during the service-life of an IGU is the increase in moisture penetration over time. Without ageing, under steady-state conditions, and at a time far from saturation of the desiccant, moisture ingress into an IGU per time unit should be a constant. As the IGU approaches saturation of the desiccant, moisture ingress should slow down, since the partial pressure differential equilibrates. However, measurements undertaken on units undergoing repeated humidity and temperature cycles in the laboratory as well as on those installed in the field often show a non-linear increase in moisture penetration with exposure time (Van Santen 1986, Marusch 1988), as shown schematically in Fig. 3.

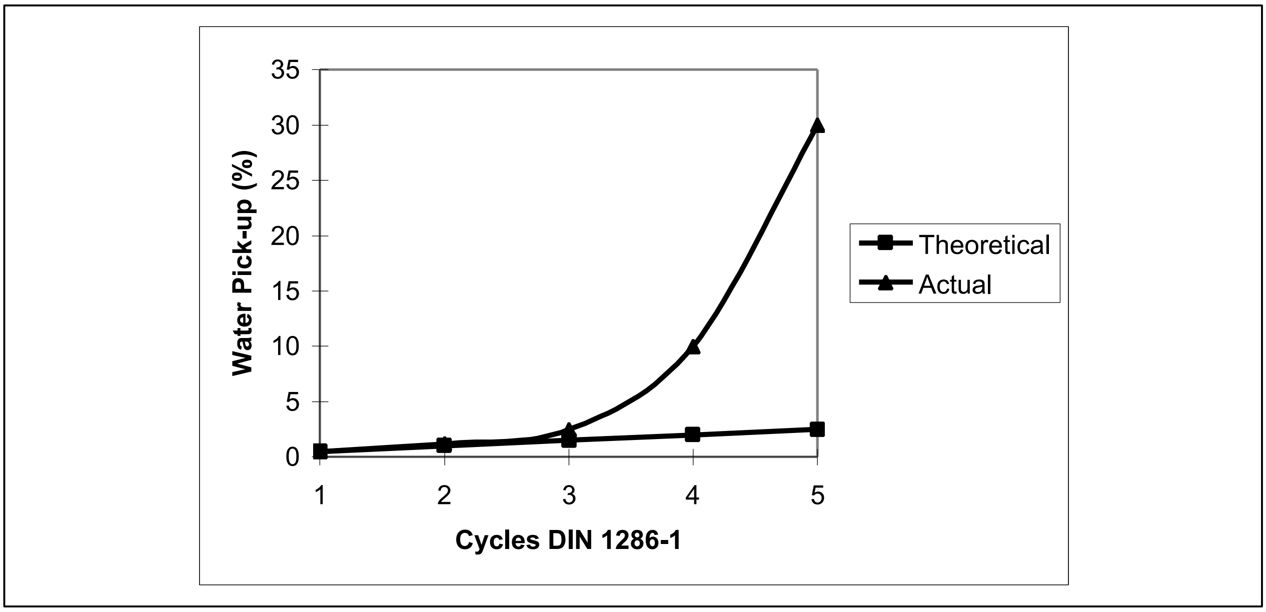

**Figure 3. Non-linear behaviour of actual water pick-up with IGU ageing**

One explanation for this phenomenon, favoured by Van Santen (1986), is the physical degradation of the primary seal, caused by the temperature and pressure induced movement in the edge-seal. Due to this repetitive movement, the primary seal may fail either cohesively or adhesively. Both failure mechanisms have indeed been observed in service, often combined with a migration of the PIB primary seal into the visible inter-pane space. Recently, much progress has been made in the design of spacer bars that allows reduction or elimination of this failure mechanism by restricting the ability of the PIB seal to migrate (Paci 1999).

As mentioned before, even in a regularly glazed IGU, a certain percentage of the incident light reaches the edge-seal via total reflection within the glass panes. When exposed to the destructive effects of the short wave spectrum of sunlight for prolonged periods of time, organic sealants may lose their glass adhesion. Schlensog (1986) monitored the evolution of organic sealant delamination from the glass substrate by using polarisation microscopy. The study showed that, before adhesive or boundary (thin-film) failure becomes visually detectable in the edge-seal, microscopic delaminations occur which, upon continued exposure, grow and interconnect, leading to macroscopic failure. It is highly likely that both moisture and gases migrate along this interfacial damage zone before macroscopic failure occurs, possibly with the moisture ingress accelerating this failure mechanism (Lefebvre *et al*. 1989); however, until now, this interfacial transport mechanism has not been experimentally verified for IGU edge-seals.

The repetitive shearing and peeling forces, caused by the differential in thermal expansion of spacer bar frame and glass plates as a result of edge-seal temperature variations, induce a high stress in the edge-seal, which may be compounded by ageing effects. Shear movements in joints induce a tensile stress component close to the sealant/substrate interface that is approximately twice as high as the original shear stress; this explains why sealants under shear tend to fail close to the substrate surface (Wolf & Iker 1992). If a secondary seal hardens in service, the resulting increase in tensile stress may cause partial or complete loss of adhesion.

## 4 PREDICTION OF IGU SERVICE-LIFE

Various national accelerated test methods have been developed for the assessment of IGU performance (Burgess 1999). All of these methods are acknowledged to be without scientific verification, yet the methods have some corroboration through years of field experience, and sometimes are backed by systematic field correlation studies. However, as discussions during the development of international ISO and EN standards have shown, there is no generally accepted understanding of the interactions of the degradative factors influencing the service-life of IGUs. As pointed out by Burgess, already early-on during the development of the Pr-EN 1279 standard (EN 2000), it became apparent that no one actually knew what test regimes were most onerous on IGU edge-seals. The investigations within the CEN committee showed that low temperatures did not cause IGU failure, but that sustained high humidity, rather than high humidity cycling, was the main driver of moisture into sealed IGUs. However, the committee felt that they could not ignore low temperatures or cycling and agreed to split the test regime into two parts, one with high humidity cycling, and one with constant high humidity and temperature. The CEN committee also agreed to assess the performance of IGUs based on the moisture pick-up of the desiccant, the method used in the German standard DIN 1286-1 (DIN 1994), since this method allowed establishment of relative performance levels. The CEN test method is now thought to be more onerous than any existing national standard and to ensure a service life of the IGU in excess of 25 years (Burgess 1999).

Table 3 shows the water pick-up measured on the desiccants of various dual-sealed IGUs after exposure to temperature/humidity cycling according to DIN 1286-1 (DIN 1994) as well as after three months of constant high temperature (55°C) and high relative humidity (100%) (Wolf 1992). As can be seen, substantially higher moisture penetration was observed in the constant climate test than in the cyclic test. Interestingly, silicone dual-sealed IGUs exhibited the lowest moisture penetration of all units tested; contrary to what would be expected when considering the water vapour permeability of the secondary IGU sealants alone. Under constant high temperature and humidity, the performance advantage of silicone sealed IGUs becomes even more pronounced; the moisture penetration of the organic sealed IGUs is about three times as high as that of the silicone sealed units. Since the desiccant's water pick-up is inversely proportional to the life expectancy of an insulating glass unit, this finding indicates the by far superior service-life of silicone dual sealed IGUs when compared to those sealed with polysulphide or polyurethane sealants.

**Table 3. Water penetration into IGU after different accelerated exposures.**

| *Secondary sealant* | *Water pick-up (weight %) after DIN 1286-1* | *Water pick-up (weight %) after 3 months 55°C and 100% rel. humidity* |
|---|---|---|
| Polysulphide 1 | 0.5 | 5.4 |
| Polysulphide 2 | 0.8 | 5.6 |
| Polyurethane 1 | 0.5 | 4.2 |
| Polyurethane 2 | 0.6 | 4.5 |
| Silicone 1 | 0.4 | 1.5 |
| Silicone 2 | 0.4 | 1.6 |

The CEN committee also decided to adopt the requirements of the German DIN 1286-2 standard (DIN 1989) by restricting the gas loss rate to <1.0% per year. Annex B of pr-EN 1279-3 (EN 2000b) discusses the relationship between artificial and natural ageing with regard to thermal and sound insulation. Based on studies done on gas losses experienced by IGUs over a period of 10 years of service, the CEN committee assumes that a gas loss rate <1.0% per year after accelerated ageing ensures a total gas loss of <5% over 25 years of service. On the assumption that the improvement of the U-value with 100% argon filling is 0.4 $W/(m^2K)$, this gas loss results in a deterioration of $\Delta U < 0.04\ W/(m^2K)$. Gas-filled IGU passing the requirements of DIN 1286-2 or Pr-EN 1279-3 are being manufactured successfully with polysulphide, polyurethane or silicone secondary sealants. However, since the requirements for gas-filled IGUs are especially demanding, some design and material selection factors must be carefully considered.

## 5 INFLUENCE OF DESIGN AND MATERIAL SELECTION ON SERVICE-LIFE

Table 4 provides an overview of the key material-specific performance characteristics of elastomeric secondary IGU sealants (for a more detailed discussion see Wolf 1992).

**Table 4. Performance characteristics of elastomeric secondary IGU sealants.**

| *Material property* | *Polysulphide* | *Polyurethane* | *Silicone (alkoxy)* |
|---|---|---|---|
| Resistance of glass adhesion to sunlight | Poor | Poor | Excellent |
| Resistance of adhesion to water (long-term exposure) | Good to moderate | Moderate | Excellent to moderate |
| Elastic recovery | | | |
| at 23°C | Moderate | Good | Excellent |
| at 60°C | Poor | Moderate | Excellent |
| Change in Young's modulus with temperature | Very high | Moderate | Low |
| Water-swelling | Very high | High | Low |
| Water-vapour permeability | | | |
| (3 mm sheets) $(g/(m^2d)$ | 7-9 | 3-6 | 7-16 |
| at 20°C | 40-60 | 20-30 | 40-100 |
| at 60°C | | | |
| DIN 1286-1 water pick-up (weight %) | 0.5-1.2 | 0.4-0.7 | 0.4-0.6 |
| dual-sealed IGU | | | |
| Argon permeability (0.6 mm sheets) | | | |
| $(10^{-10}\ cm^2/(s\ cmHg))$ | 1.5-1.8 | 8-30 | 250-400 |
| DIN 1286-2 gas loss (% p.a.) | 0.4-0.9 | 0.6-1.0 | 0.7-1.0 |
| dual-sealed IGU | | | |

Clearly, the key performance advantage of polysulphide sealants is their low gas permeability, which allows them to tolerate poor workmanship, at least up to a certain degree. The poor resistance of glass adhesion to sunlight prohibits the use of polysulphide and polyurethane sealants in structural glazing or roof glazing applications. Polyurethane generally show better physical properties and lower water-vapour permeability than polysulphide sealants; their main selling feature, however, is their lower price. The past ten years have seen an overheated competitition between polysulphide and polyurethane IGU sealants for market share in Europe. The resulting price war has forced some manufacturers to drastically lower the polymer content of their sealants and finally has caused the major manufacturer of polysulphide polymer and sealants to withdraw from the market (Anonymous 2001). There are now indications that premature failure rates of some polysulphide sealed units in the field have increased again, at least for certain installation conditions (wooden window frames) in Germany, ending the period of more than 20 years of increasing IGU performance achieved by continuous development of IGU components, assembly and quality assurance methods.

Silicone sealants, on the other hand, excel in the resistance of their glass adhesion to sunlight, making them the material of choice for structural and commercial glazing as well as demanding roof glazing applications. With over 20 years of experience with silicone sealants globally, the excellent performance and service-life of silicone dual-sealed IGUs have been demonstrated. One drawback of silicone sealants is their high gas permeability. However, recent experience has demonstrated that argon-filled, silicone dual-sealed IGU can be manufactured, which reliably pass DIN 1286-2 requirements, if certain design, manufacturing and quality assurance aspects are being met.

First, it has been demonstrated that IGU edge-seal systems, which have the ability to accommodate some movement within the spacer itself, place less stress on the primary seal and thus ensure low gas loss rates under accelerated and actual service-life conditions. Examples of such spacers that have been used in IGUs passing DIN 1286-2 are the Chemetall or Teroson TPS (see, for instance, Unger 1999) and Edgetech Super Spacer®. Second, IGU edge-seal systems that minimise differential thermal movement, especially within the sensitive corner region, tend to perform significantly better in terms of gas loss rates than systems with high thermal movements, as discussed earlier. IGUs of different designs, but based on stainless steel spacers, have passed the DIN 1286-2 requirements, while same or similar systems based on aluminium or galvanised steel spacers have failed. Companies that have successfully qualified IGUs based on stainless steel based edge-seal designs are St. Gobain, Cardinal Glass, Veltherm, and Interpane. Third, when using stainless steel spacers, those designs that minimise the amount of PIB primary seal migration into the inter-pane space should be preferred.

Bent spacer-frame corners, gas-filling techniques integrated into the IGU assembling process (rather than filling via holes drilled into the spacer), improved, semi-automatic PIB application equipment and in-line (heated) PIB primary seal presses have all substantially contributed to the minimisation of gas loss and helped with the improvement of quality and service-life of IGUs. The trend towards “warm-edge” IGUs favours the above mentioned edge-seal systems. Today, silicone dual-sealed IGUs can be produced that not only excel in their durability and longevity, but also reliably meet the stringent requirements for gas retention, and therefore provide optimum service-life and utility value.

# The Influence Of Leaching Of Contaminants On Strength And Durability Of Contaminated Recycled Brick Aggregate Concrete

**AJ Hackett DAB Hughes PAM Basheer T Elliot**
**School of Civil Engineering The Queen's University of Belfast Northern Ireland**

**Summary:The engineering and durability properties of concrete produced using recycled concrete aggregate have been thoroughly investigated in the UK and elsewhere. However little research data is available on the effects of using Contaminated Recycled Brick Aggregate (CRBA) on concrete strength and durability, or the likelihood of the contaminants leaching from concrete. The objective of the work presented here was to examine the influence of using CRBA on compressive strength and workability, to investigate leaching of contaminants from concrete and to assess the effect of leaching on the strength and durability properties of concrete.**

**Known concentrations of heavy metals (Cr, Zn, Ni, Pb, Cu) were dissolved in the mix water before it was added to the clean crushed brick aggregate and cement to produce concrete cubes. The likelihood of the heavy metals leaching from the concrete was investigated using a monolithic leaching test. The results show that the contaminants were encapsulated in the concrete; with release several orders of magnitude lower than the concentrations originally present. A comparison between concrete subjected to leaching and control specimens that had not undergone the leaching test show that the effect on compressive strength was not significant, however the water permeability of concrete was found to increase substantially as a result of leaching. DTA/TG has been used to explain this increase in water permeability, which was found to be due to the leaching of calcium hydroxide.**

## 1 INTRODUCTION

A current challenge for the construction and aggregate industry is the need to move towards a more sustainable approach to the production of aggregate and the financial and environmental pressure to reduce the volume of waste going to landfill sites. The production of concrete and masonry waste in England and Wales in 1999 was estimated at 33.8Mt (Symonds, 2001). Since the introduction of the landfill tax in the UK, and with the declared introduction of an aggregates tax for primary materials, pressure to increase the use of recycled demolition wastes has intensified. The utilisation of *clean* coarse recycled concrete aggregate has been investigated in some detail and there is considerable guidance on its use within UK specifications (Collins & Sherwood 1995; Collins 1998; Dhir 1998). However the same level of detailed information does not exist for recycled brick aggregate concrete. Furthermore, the re-development of brown-field locations and the demolition of buildings on these former heavy-industry sites often generate a large quantity of demolished masonry which is contaminated with the by-products of industrial processes. As well as avoiding the rising costs associated with primary materials, the re-use of contaminated masonry in concrete avoids the expense of transportation and disposal, which is often prohibitive in the re-development of brown-field sites.

Previous published work has shown that it is possible to produce concrete of an acceptable standard using clean crushed brick aggregate (Hansen 1992; DeVenny & Khalaf 1998). However, information on the effect of using Contaminated Recycled Brick Aggregate (CRBA) on engineering and durability properties of concrete has to date not been widely available. Concerns over toxic trace metals in concrete produced with CRBA coming into contact with ground waters means that the environmental compatibility of the concrete is a prime concern. If concrete is designed to have very low permeability and connected porosity, the amount of trace metals leaching out of the concrete will be very small. Nevertheless, elevated levels of trace metals in concrete could pose a significant contamination threat to the environment and the leaching behaviour must therefore be assessed before it can be used with confidence by the industry. There is a great deal of literature regarding the potential of cement in combination with wastes to prevent the leaching of heavy metals into the environment. Glasser (1996) notes some of the key physical and chemical features of cement systems that may also be applied to CRBA concrete. Effective encapsulation of toxic metals and satisfactory service life demands concrete with low permeability, strength, integrity, long term durability and maintenance of a chemical potential for immobilisation. This paper aims to study the influence of using CBRA on workability and strength and the effect of leaching on the strength, permeability and microstructure of CRBA concretes.

## 2 EXPERIMENTAL PROGRAMME

Concrete mixes were prepared using contaminated crushed brick with Ordinary Portland Cement (OPC) at different water cement ratios. The workability of the concrete was measured using the slump test and compressive strength was determined at 7, 28, 56 and 90 days. Specimens were subjected to a monolithic leaching test with subsequent testing of strength and permeability to determine the effects of leaching on these properties. Samples were then analysed using DTA/TG to investigate the influence of leaching on the microstructure of the concrete.

### 2.1 Materials and sample preparation

The coarse aggregate used was crushed waste clay bricks with a maximum size of 20mm, crushed using a jaw crusher. A typical particle size distribution for CRBA is presented in Table 1. The physical properties of the aggregate was assessed at regular intervals and carefully controlled throughout the experimental programme. Table 2 outlines the physical properties of the RBA used for the concrete production. The fine aggregate used was medium sand (BS 812:1001). Both the coarse and fine aggregates were used in the saturated surface dry condition. Portland Cement conforming to BS 12 was used as the cementitous material.

**Table 1. Typical particle size distribution of CRBA**

| *Sieve Size (mm)* | *Mass retained(g)* | *Percentage retained* | *Cumulative % passing* | *Cumulative % retained* |
|---|---|---|---|---|
| 20 | 30.0 | 1.00 | 99.00 | 1.00 |
| 14 | 1061.6 | 35.39 | 63.61 | 36.39 |
| 10 | 920.1 | 30.67 | 32.94 | 67.06 |
| 6.3 | 678.3 | 22.61 | 10.33 | 89.67 |
| 5 | 190.0 | 6.33 | 4.00 | 96.00 |
| <5 | 120.0 | 4.0 | - | - |
| Total = 3000 | | Fineness modulus = 2.9 | | |

Aqueous solutions containing the heavy metals Copper (Cu), Chromium (Cr), Lead (Pb), Nickel (Ni) and Zinc (Zn) were added to the coarse aggregate prior to concrete production. The solutions were individually prepared by dissolving salts of $Cu^{2+}$, $Pb^{2+}$, $Ni^{2+}$, $Zn^{2+}$ (positive ions as nitrate) and $Cr^{6+}$ (as a negative ion in potassium dichromate) in deionised water. The levels of heavy metal contaminants added per unit mass of the crushed brick aggregate are given in Table 3.

**Table 2. Physical Properties of CRBA**

| | |
|---|---|
| Apparent specific gravity | 2.64 |
| Water absorption | 6.33% |
| Bulk Density (compacted, dry) | 1186 kg/m$^3$ |
| Bulk Density (uncompacted, dry) | 1068 kg/m$^3$ |
| 10% Fines Value | 101.5kN |
| Flakiness Index | 38.5 |

Guideline contamination values are also given, where the concentrations shown are considered to be associated with heavily contaminated material. As it can be seen from Table 3, the quantity of the contaminants in the RBA was exactly double suggested in the Dutch specifications (MHSPE 1998) for intervention.

Go Back Next Page

**Table 3. Typical guideline concentrations for the heavy metals investigated and level of contamination associated with CRBA used as coarse aggregate in the experimental programme**

| *Contamination guidelines and contaminant levels associated with CRBA* | *All values in mg/kg* | | | | |
|---|---|---|---|---|---|
| | *Cr* | *Ni* | *Cu* | *Zn* | *Pb* |
| ICRCL 59/83 contamination action value (ICRCL 1987) | 600 | 70 | 130 | 300 | 500 |
| Dutch contamination intervention value (MHSPE 1998) | 380 | 210 | 190 | 720 | 530 |
| Quantity added per unit mass of aggregate | 760 | 420 | 380 | 1440 | 1060 |

The mix proportions of the concrete used in the study are given in Table 4. The mix proportions were determined to produce concrete with different permeation properties and were adjusted using the yield equation.

**Table 4. Mix Proportions**

| *Mix No.* | *Cement Content kg/m$^3$* | *W/C Ratio* | *A/C Ratio* | *Target Compressive Strength* |
|---|---|---|---|---|
| 1 | 420 | 0.5 | 4.12 | 50 N/mm$^2$ |
| 2 | 350 | 0.6 | 5.14 | 40 N/mm$^2$ |
| 3 | 300 | 0.7 | 6.16 | 30 N/mm$^2$ |

The specimens used throughout the investigation were 100mm cubes. The cubes were cast de-moulded after 24hrs, sealed in a damp proof membrane and stored at 20$^0$C. The reason for this curing regime was to prevent exposure to the atmosphere whilst avoiding any leaching of water soluble heavy metals which would occur if the samples were cured using the conventional water bath method.

**2.2 Leaching test and leachate analysis**The leaching tests were conducted in triplicate on specimens that had been cured for ~28 days. The leaching test used was the Dutch NEN 7345 tank test method (NNI 1995). In the test, the leaching of components from the concrete was determined by submersing a test piece in 5 litres distilled water adjusting to pH 4, and renewing the leachant at 8 fixed intervals: 0.25, 1, 2.25, 4, 9, 16, 36 and 64 days. The collected leachate was acidified with nitric acid to pH<2 to prevent loss of metal ions prior to the analysis. The concentration of heavy metals was determined using ICP-MS and presented as cumulative leaching per unit mass of concrete (mg/kg) as a function of time. ICP-MS analyses were performed on a Fisons Instrument VG Plasma-Quad. Calibration standards were prepared using standard solutions containing known concentrations of chromium, nickel, copper, lead and zinc, also acidified to pH<2. These standards were used to check the quantitative determinations throughout the leaching investigation giving consistency to the results obtained.

### 2.3 Water permeability, strength and DTA/TG testing after leaching

After the leaching tests had finished, the test pieces were exposed to 20$^o$C, RH 55%, along with control samples that had not undergone the leaching test. The compressive strength and water permeability of these specimens was determined and profile grinding of selected specimens was undertaken to generate samples for DTA/TG analysis. The water permeability was measured using the "Autoclam" Permeability System, an instrument developed at Queen's University for comparison of permeability indices between different concrete mixes. DTA/TG analysis was done on a Netzsch Simultaneous Thermal Analyser STA 449C Jupiter machine, in the temperature range 0-1000$^o$C with a heating rate of 10$^o$C/min. Approximately 70mg sample was analysed under a nitrogen environment, with the same quantity of alumina used as a reference material.

## 3 RESULTS AND DISCUSSION

The results obtained are grouped into three categories, viz. control properties, leaching characterisation and effect of leaching. Control properties are those properties of both fresh and hardened concrete measured prior to carrying out the leaching tests.

### 3.1 Control properties

Table 5 reports the slump and the compressive strength of concrete manufactured with the CRBA aggregate. In Fig. 1, the strength development of the CRBA concrete is presented.

**Table 5. Slump and Compressive Strength of CRBA Concrete Mixes**

| *Mix No.* | *W/C Ratio* | *Slump (mm)* | *Target Comp. Strength($N/mm^2$)* | *Measured 28 day Strength ($N/mm^2$)* |
|---|---|---|---|---|
| 1 | 0.5 | 18 | 50 | 57.8 |
| 2 | 0.6 | 22 | 40 | 49.3 |
| 3 | 0.7 | 30 | 30 | 40.6 |

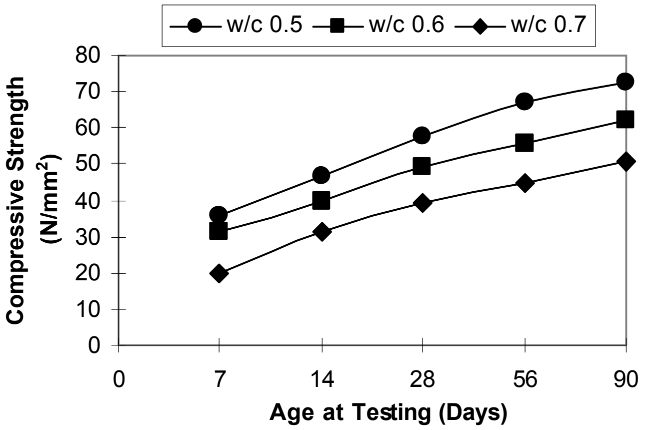

**Figure 1. Strength Development of CRBA Concretes**

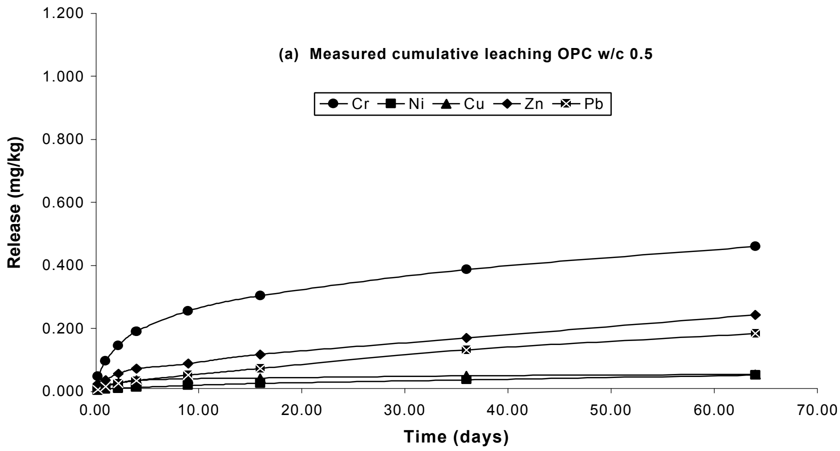
From Table 5 it can be seen that, although the slump increased due to the increase in W/C ratio, all the mixes resulted in rather low slump values. In the context of mix design, all the slump values were found to fall in the range 10-30mm (DoE 1988). The workability could be improved by either increasing the water content in the mixes or adding water-reducing admixtures. The addition of further water could result in segregation and a significant decrease in compressive strength.

The compressive strength of the CRBA concretes reached their target values within 28 days (Table 5). In Fig. 1, the compressive strength was found to increase beyond 28 days, reaching significantly higher values for all the mixes at the age of 90 days. Better interlocking of crushed brick was thought to contribute to the strength. The results in Fig. 1 would suggest that the CRBA concretes could be used in structural applications.

### 3.2 Leaching characterisation

Figure 2 shows the cumulative leaching of the contaminants from the concrete cubes at different test intervals and Table 6 summarises the cumulative leaching at the end of 64 days of the leaching test.



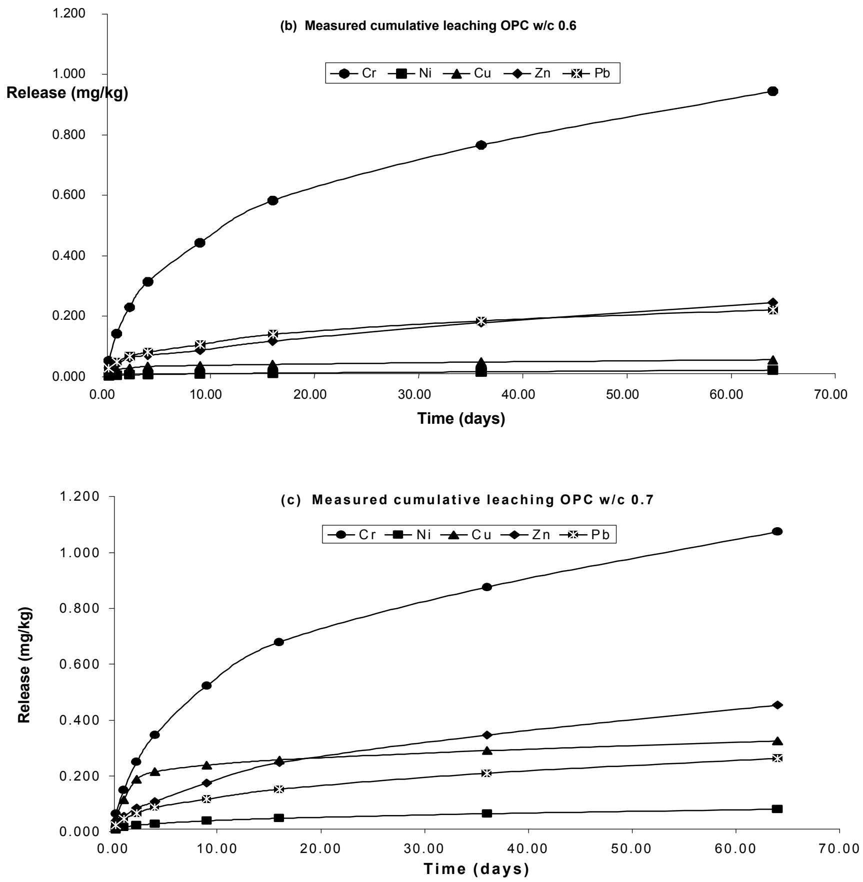


**Figure 2. Cumulative leaching of contaminants at different W/C ratios**

**Table 6. Cumulative leaching after 64-days leaching test and comparative data**

| | | *Cr* | *Ni* | *Cu* | *Zn* | *Pb* |
|---|---|---|---|---|---|---|
| Directive 98/83/EC - drinking water quality (μg/l) | | 50 | 20 | 2 | - | 10 |
| Cumulative leaching after 64days (μg/l) | 0.5 W/C | 198 | 22 | 23 | 102 | 79 |
| | 0.6 W/C | 403 | 9.5 | 24 | 105 | 94 |
| | 0.7 W/C | 451 | 34 | 136 | 190 | 110 |
| Quantity added per unit mass of concrete (mg/kg) | | 330 | 185 | 165 | 630 | 465 |
| Cumulative leaching after 64days per unit mass of concrete (mg/kg) | 0.5 W/C | 0.460 | 0.052 | 0.054 | 0.238 | 0.184 |
| | 0.6 W/C | 0.944 | 0.022 | 0.056 | 0.246 | 0.221 |
| | 0.7 W/C | 1.074 | 0.081 | 0.325 | 0.454 | 0.263 |

In Table 6, the amount of the contaminants permitted in drinking water in accordance with Directive 98/83/EC (EC 1998) is also presented. However, it must be noted that the water quality directive uses a spot sample of water intended for human consumption (e.g. tap water), which differs significantly from the leachate from the accelerated leaching test. Therefore, a direct comparison of the two sets of data is not appropriate. The cumulative leaching after 64 days in μg/l in Table 6 is presented to indicate that, whereas nickel quantities were not significantly different from those values in the Directive, the amount of copper, chromium and lead exceeded by a significant factor. The quantity of chromium and lead used to spike the aggregate was much higher than that used for both nickel and copper. Therefore, there could be preferential diffusion of the former contaminants.

In Table 6, the quantity of contaminants added to the aggregate per unit mass of concrete is also reported. While comparing the cumulative leaching of the contaminants with the amount that was used to contaminate the aggregate, the leaching could be considered to be negligible. In Fig. 2, the cumulative leaching varied with the water-cement ratio, as one would expect. The largest amount of leaching was found to be at the highest water-cement ratio, with a decrease in the leaching of all the

Go Back
Next Page

contaminants with the reduction in the water-cement ratio. In all water-cement ratios, the largest leaching was observed for chromium, with no distinct trends between the other contaminants at all the three water-cement ratios. However, there were two distinct bands below chromium at both 0.5 and 0.6 water-cement ratios. Both zinc and lead followed chromium at these two water-cement ratios and the lowest cumulative leaching was observed for both nickel and copper. In the case of 0.7 w/c, these trends were not repeated. However, a close examination would reveal that copper leached out at a substantial quantity initially during the test, but later on it was similar to that obtained with nickel. Therefore, it can be said that both nickel and copper leached out in smaller quantities at this water-cement ratio as well. A comparison of the cumulative leaching at 64-days with those used to spike the RBA, would suggest that the amount of contaminants leaching is related to the amount of ion availability in the RBA. Fig. 2 shows also that the amount of contaminants leached out of the CRBA concretes continued even after 64 days. Therefore, it would be necessary to predict the rate of leaching from the calculation of the diffusion coefficient for the contaminants in order to predict the likely total amount that would leach out after a certain period of exposure. This was considered to be beyond the scope of this paper.

### 3.3 Effect of leaching on properties of concrete

The amount of calcium hydroxide in the sample is used in order to discuss the effect of leaching on the microstructure of the concretes. This was obtained from the DTA/TG graphs by observing the exothermic changes at about 460 degree Celsius. Figure 3 shows the DTA/TG results for 0.6 W/C CRBA concrete at two depths from the surface, which is the specimen not subjected to the leaching test. Figures 4 and 5 show respectively the effect of using distilled water and acidified water as the solution used in the tank leaching test.

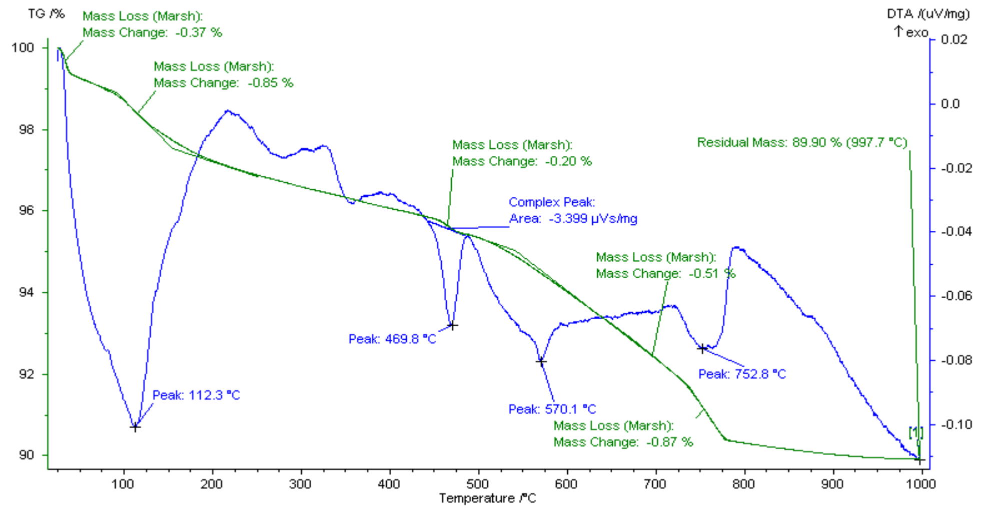

**Figure 3a. DTA/TG plot for 0.6 W/C concrete with no leaching (0-1 mm)**

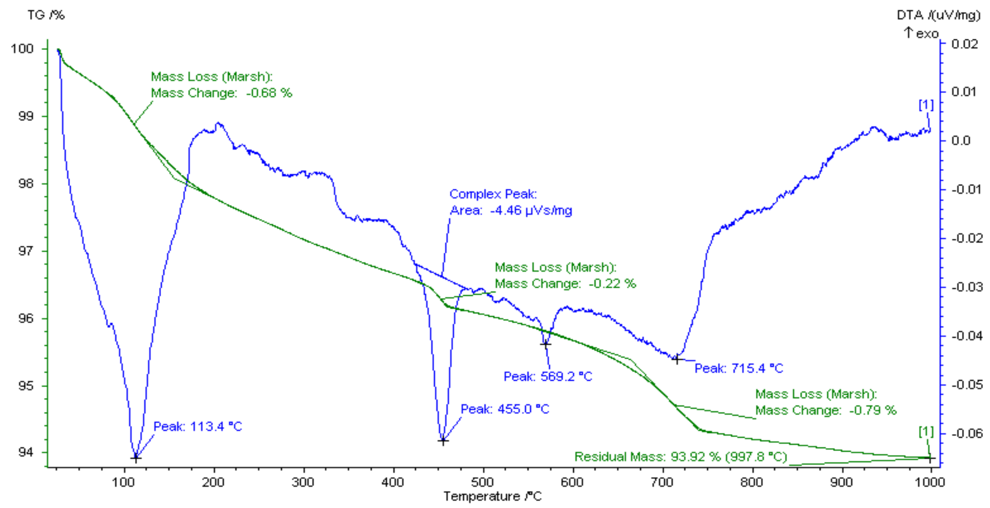

**Figure 3b. DTA/TG plot for 0.6 W/C concrete with no leaching (1-2 mm)**

The relative proportion of calcium hydroxide in Fig. 3a is 20% and that in Fig. 3b is 22%. These data would suggest that there was slightly better degree of hydration at the second depth; however, overall the results are very close. However, when both distilled water and acidified water were used to carry out the test, there was no peak corresponding to the presence of calcium hydroxide at 0-1mm depth (Figs. 4a and 5a) and only insignificant peak at 1-2mm depth (Figs. 4b and 5b). Between the distilled water and the acidified water, the latter was found to be more aggressive in removing the calcium hydroxide, as can be seen from the reduction in the peak corresponding to calcium hydroxide. Other peaks in the DTA/TG graphs are not discussed in this paper, primarily because the minerals in RBA were considered to be affecting the presence of different peaks rather than the decomposition of the cement hydrates.

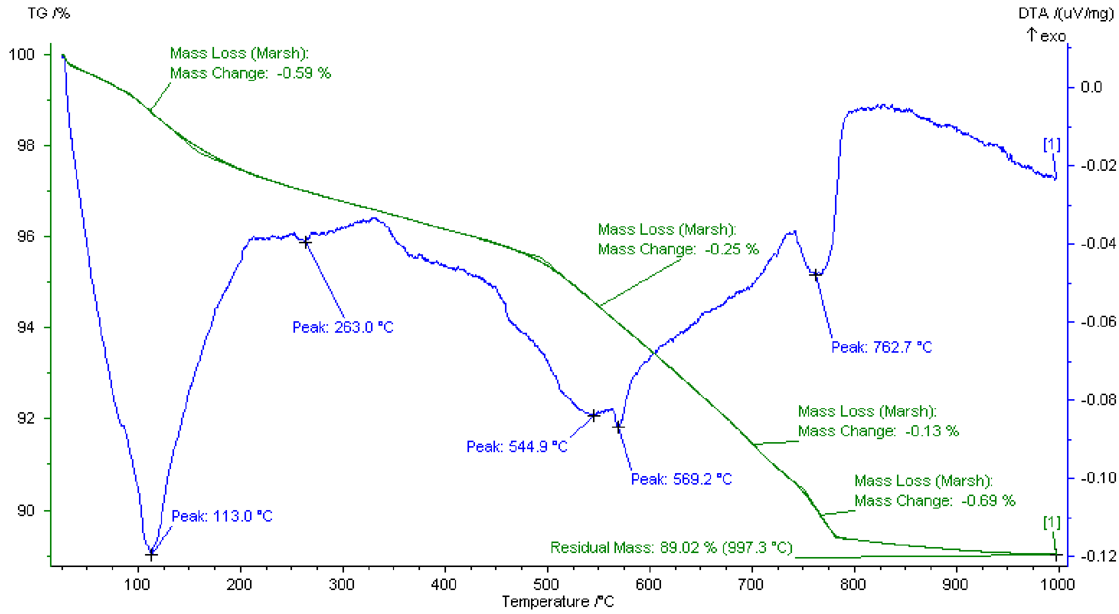

**Figure 4a. DTA/TG plot for 0.6 W/C concrete leached with distilled water (0-1 mm)**

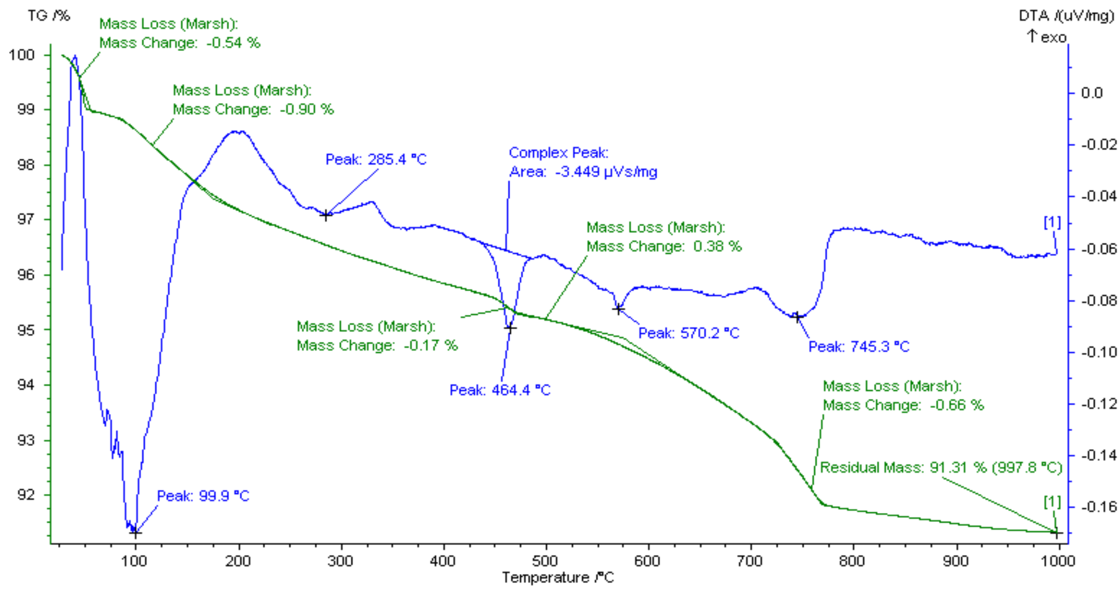

**Figure 4b. DTA/TG plot for 0.6 W/C concrete leached with distilled water (1-2 mm)**

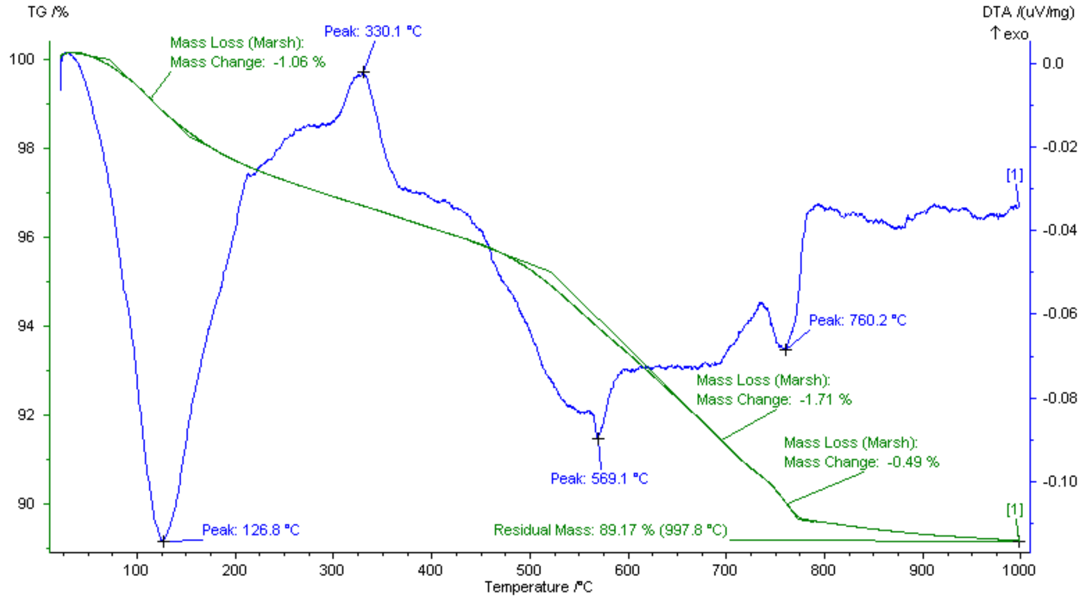

**Figure 5a. DTA/TG plot for 0.6 W/C concrete leached with acidified water (0-1 mm)**

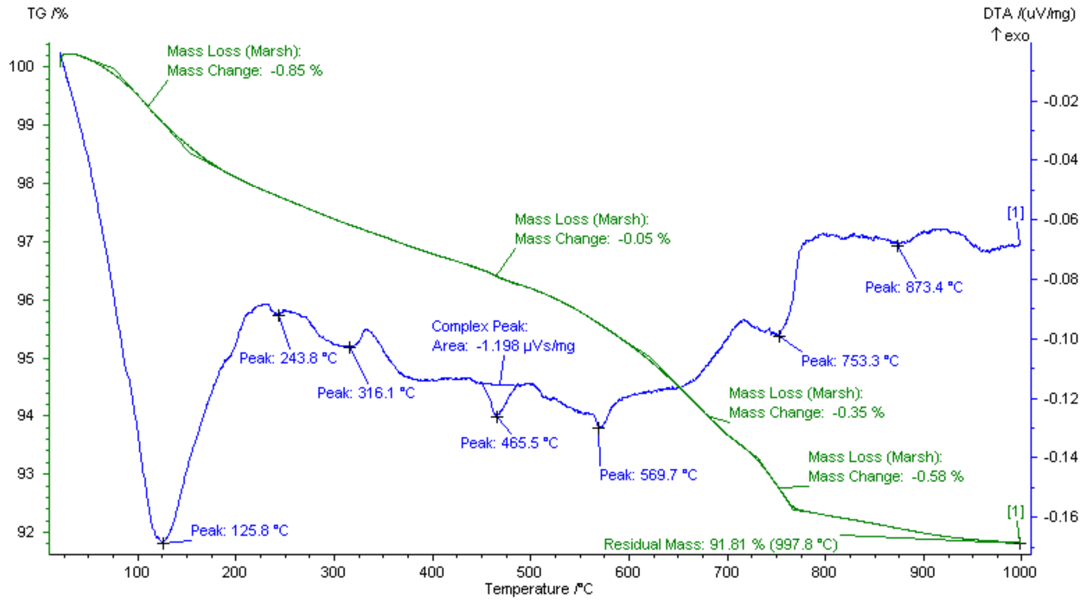

**Figure 5b. DTA/TG plot for 0.6 W/C concrete leached with acidified water (1-2 mm)**

The effect of the leaching on both strength and water permeability is presented in Figs. 6 and 7 respectively. In Fig. 6, the strength was not affected to any significant degree by the leaching by both distilled water and the acidified water. This is considered to be due to the fact that the microstructure of the solid products of the hydrated cement paste was presumably not affected by the leaching. The DTA/TG plots confirm that the peaks corresponding to calcium silicate hydrates were not affected by the leaching. However, the removal of the calcium hydroxide did change the water permeability of the concrete. At all the three water-cement ratios, the distilled water and the acidified water resulted in an increase in water permeability, in this order, when compared to control samples, which were not subjected to any leaching. Therefore, it is likely that the long-term durability of the CRBA concretes could be detrimentally affected by the leaching, even if the strength was found to be satisfactory.

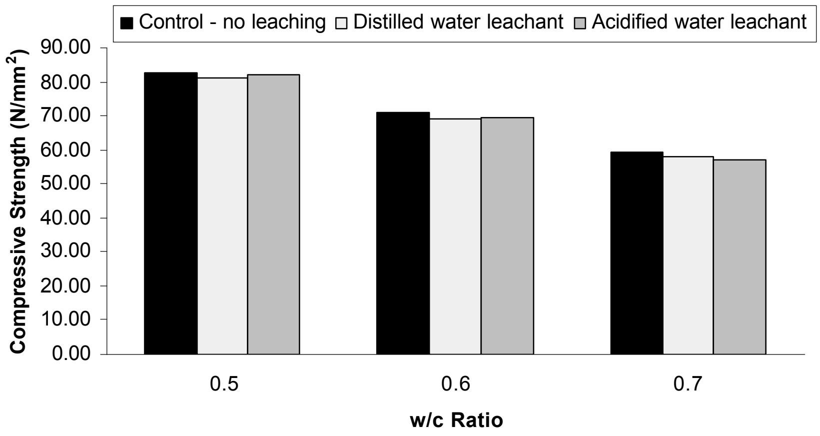

**Figure 6. Effect of leaching by different solutions on compressive strength**

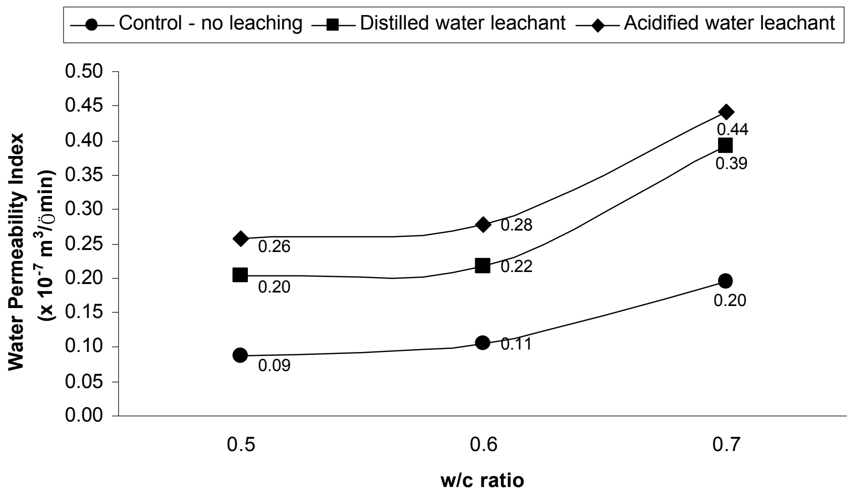

**Figure 7. Effect of leaching by different solutions on water permeability**

## 4 CONCLUSIONS

On the basis of the experimental programme presented in this paper and the results obtained, the following conclusions have been drawn:

(1) The contaminated recycled brick aggregate could be used to produce concretes which would satisfy the criteria of compressive strength. This would mean that the CRBA concretes could be used in structural applications.

(2) The leaching of contaminants was found to be insignificant while comparing with the amounts used to contaminate the aggregates. However, the cumulative amount was found to be substantially higher than those values allowed in the Drinking Water Directive.

(3) Whilst leaching was found to remove significant quantities of the calcium hydroxide with both distilled water and acidified water as the leaching agent, their effect on strength was insignificant. However, there was substantial increase in permeability of the concrete.

(4) The CRBA concretes could be used in structural applications if the leaching effect on water permeability was reduced by appropriate mix design and the use of pozzolans to modify the microstructure of the concrete.

[3]Instituto de Ciências Biomédicas Universidade de São Paulo Brazil

**Summary: The discoloration of painted façades is caused by a wide range of microorganisms, including phototrophs and fungi. The durability of paint films is affected by microbial growth and fungi are deemed to be especially important. In Brazil, the estimated cost of painting buildings is approximately 4% of the overall building cost, and it is necessary to re-paint approximately every 2 to 5 years, depending on other building characteristics. Biocides (chiefly algicides and fungicides) are usually included in paint formulations in an attempt to extend the period between repainting and the efficacy of these additives is tested in artificial conditions, in the laboratory. This study was carried out using modern surface analysis and traditional mycological techniques, in order to understand the fungal colonization of paint under real exposure conditions on a building newly painted with an acrylic paint with and without a biocide formulation. Observations with the low vacuum scanning electron microscope indicated that fungi can grow not only on the exposed surface, but also in the layers between old and new paint, and between the rendering mortar and paint layer. The latter surface was the most colonized interface on the façade of the building (constructed with aerated concrete blocks rendered with mortar). Cracks in the mortar rendering favored fungal growth on paint in this area. The exposed surface showed evident discoloration after 11 months of exposure. The fungal numbers on the painted surface decreased in the summer months, probably because of the intense solar radiation.**

**Keywords: discoloration, painted surfaces, Fungal Colonization**

## 1 INTRODUCTION

The development of discoloration on painted surfaces is a very common phenomenon in Brazil and in other countries. Sometimes this type of discoloration has been considered as fouling without any biological correlation, but it has been shown that it can be produced by different types of microorganisms (GARG et al, 1995; GAYLARDE & MORTON, 1999; KARPOVICH-TATE, 1990), among them autotrophic bacteria (those that do not need organic compounds as carbon source), heterotrophic bacteria (which need organic compounds as carbon source), cyanobacteria and algae (which use $CO_2$ as carbon source and light as energy source) and filamentous fungi (heterotrophic organisms composed of hyphae and reproductive structures, spores).

In order to reduce microbial colonization, the paint industries add biocides to the formulation (BESSEMS, 1996; BOGACKA, 1995; GAYLARDE, 1995; KAUFERS, 1995; MURRAY-SMITH, 1996).

The durability of paint films is affected by microbial growth and fungi are deemed to be especially important. In Brazil, the estimated cost of painting buildings is approximately 4% of the overall building cost, and it is necessary to re-paint approximately every 2 to 5 years, depending on other building characteristics. Biocides (chiefly algicides and fungicides) are usually included in paint formulations in an attempt to extend the period between repainting and the efficacy of these additives is tested in artificial conditions, in the laboratory. The mechanisms of deterioration include mechanical rupture, the production of metabolites, chiefly complex organic acids, and enzymatic activity. Water based paint is especially susceptible to fungi because of the cellulose added to maintain the liquid paint thickness (GILLATT & TRACEY, 1987).

We studied the sequence of fungal colonization on a newly painted building from the first week after application until one year of exposure, using modern techniques of surface analysis to try to understand the interaction between fungi and paint under real exposure conditions.

## 2 MATERIALS AND METHODS

### 2.1 Paint and biocide

An acrylic water paint with approximately 50% solids, with and without 0.25% biocide formulation (12% carbamate, 25% dimethyl urea and 4% isothiazolones) was used.

### 2.2 Selection and treatment of building façade and sample collection for isolation of microorganisms

A building about twenty years old, constructed with aerated concrete blocks rendered with mortar and painted, one year previously, with an acrylic paint was treated with approx. 2% hypochlorite for 15 minutes and then washed with a high pressure (11 MPa) water jet. After one week to allow thorough drying, the façade was painted with the selected paint in vertical strips, alternating paint with and without biocide. Four samples were taken from biocide-containing and 4 from non biocide-containing sites on this building at intervals (see results). Sampling was carried out by the carpet replica technique for fungi (SHIRAKAWA et al., 1998).

Samples for mycological analysis were cultured on Sabouraud dextrose agar and identified by cell and colony morphology (Barron, 1971; Ellis, 1993; McGinnis, 1980).

### 2.3 Paint sampling and surface analysis

Pieces of paint were collected using a chisel disinfected with alcohol and placed in sterile Petri dishes. For scanning electron microscopy under low vacuum (LEO 435 VP) and for confocal scanning laser microcopy (LSM 410 – Zeiss – with lasers 488 and 543, read in reflected mode), samples were examined directly without any treatment. For Scanning Electron Microscopy samples were coated with gold (Balzers SCD 050) and viewed in a Stereoscan 440 (Leika, Cambridge) after drying at 37°C for 48 hours.

## 3 RESULTS

### 3.1 Microorganisms

### 3.2 Fungi

The most frequent genus found over the whole year was Cladosporium, followed by the genera Alternaria, Epicoccum, Monascus, Curvularia, Nigrospora and Pestalotia. Other genera, Aspergillus, Arthrinium, Chaetomium, Didimostilbe, Fusarium, Monilia, Penicillium, Pleospora, Phoma, Pithomyces, Trichoderma, Trichotecium and Ulocladium, appeared in minor frequency.

Members of the artificial Order *Mycelia sterilia*, fungi that do not produce spores, were found at a high frequency throughout the year.

*Aureobasidium* showed an interesting behavior. This genus was found in the first four weeks (July and August of 2000), disappearing in the samples collected over September to April 2001, and appearing again in samples collected in May 2001. In July, one year after painting, this genus was found in high numbers of colony forming units, and dark discoloration was observed on the painted surface. This building façade received intense solar irradiation during the Summer (December to March), with air temperatures of 30 to 35°C during the day. In the literature *Aureobasidium sp* is considered the most aggressive fungus for paint and so its behavior is of obvious interest. Our results suggest that it is susceptible to UV and high temperatures.

### 3.3 Microscopical observations

### 3.4 Scanning electron microscopy

Samples of paint collected after 7 months of exposure showed that fungal colonization was chiefly located in regions where cracks were apparent. Figure 1 shows that in regions 1 cm from the crack, no fungal growth is evident, while directly over the cracked areas fungal growth can be clearly observed (Figure 2). The cracks in the paint were localized above fissures in the underlying the mortar. In addition, fungal growth itself seems to break up the paint film as observed in Figure 3.

Figure 4 (7 months of exposure) shows that fungi grow in the region with biocides, between the old and new paint layers, colonizing preferentially the old paint. Fungal growth and intense spore production is also observed at the interface between the old paint and the rendering mortar after this period of exposure (Figure 5); this colonization probably occurred before repainting. After 11 months of exposition fungi could be seen growing on the new paint with biocides in contact with old one (Figure 6).

### 3.5 Scanning laser confocal microcopy

Scanning laser confocal microscopy observation showed that fungi grow at different planes in the paint. Figure 7, a sample collected after 7 months of exposure, shows the interface between old paint and rendering mortar. Fungal hyphae are detected at 0 to 34.5 µm depth of confocal the plane, and are especially prevalent around 17µm. Together with quantitative culture data, results after the summer period the number of colony forming units increased greatly (Table 1), suggesting a re-growth, rather than merely a re-colonization from outside.

## 4 FINAL CONSIDERATIONS

These results show that fungal growth may be detected both at the interface between the old paint surface and the new paint layer and at the interface between the mortar and the paint. This shows that mortar may act as a reservoir for paint recolonization and that a combination of hypochlorite and high-pressure jet cleaning leaves a residue of viable fungal propagules. These sources of infection, together with air-borne propagules are important in the subsequent biodegradation of paint. Persistent propagules in the protected interfaces between old and new paint and under old paint, in contact with mortar or other substrates cause loss of adherence leading to spalling. Clearly preparation of surfaces prior to painting is of crucial importance in determining durability of new paint surfaces. This has long been recognized, but few studies have been directed to observing this aspect of paint durability. Indeed, we are not aware of any quantitative data published in the literature.

*Aureobasidium sp* showed a special behavior, being isolated from the surface in the first month of exposure and reappearing just after the end of the summer. This genus has been shown to be a primary colonizer also of leaves in both temperate and tropical climates; in both situations it disappears from the surfaces after the first month, reappearing 4-8 months later (LACEY, 1979).

The interactions between new and old paint layers, and between paint and mortar renderings, are important factors in determining fungal colonization. When applied to a porous mortar, the paint film could have pore size of 3 to 10 µm and some bigger. These pores, if they are interconnected, could allow fungal growth to spread readily through the paint film. This growth could be stimulated or inhibited by a range of factors. For example solar irradiation could induce the fungi to grow inwards and inhibit growth towards the outer surface. Although *Cladosporium sp* was the most frequent genus found throughout the year on this newly painted surface, tropical and semi-tropical environments, as found in São Paulo, where the study was carried out, favor growth of many types of fungi, including *Nigrospora sp.*, *Curvularia sp.* and *Pestalotia sp.* These should be considered for use in accelerated laboratory tests. Although after one year of exposure there still is a difference between the number of colony forming unit in regions with and without biocide, this difference has become non-significant and discoloration can be also observed by eye in painted regions containing biocide. Another building, with different substrate, painted with the same paint at the same time, has continuously showed less fungal colonization than that described above, even though the surrounding environment, much more wooded, is apparently more favorable to microbial growth. This is probably due to the influence of the substrate. It is intended to extend the study by exposing two different substrates painted with the same paint in three different climatic regions of Brazil.

**Table 1 – Counting of Colony Forming Unit of fungi after different intervals of exposure**

| Week | Without biocide (B-) | With biocide (B+) | Odds ratio (B+ < B-) |
|---|---|---|---|
| 1 | 0, 1, 4, 5 | 4, 4, 4, 5 | 1:3.12 |
| 2 | 3, 4, 4, 7 | 4, 5, 6, 8 | 1:4.83 |
| 3 | 12, 14, 16, 20 | 4, 9, 10, 12 | 68.9:1 |
| 4 | 11, 13, 20, 25 | 6, 9, 10, 15 | 16.5:1 |
| 9 | 11, 34, 41, 72 | 6, 10, 15, 26 | 16.5:1 |
| 13 | 12, 16, 19, 23 | 5, 11, 12, 13 | 34.0:1 |
| 18 | 17, 12, 17, 8 | 9, 9, 13, 7 | 4.83:1 |
| 22 | 19, 37,19, 19 | 28,20,16,32 | 1:1.26 |

# Durability Investigations On Textile Reinforced Concrete

**J Brockmann M Raupach**
**Institute for Building Materials Research ibac Aachen Germany**

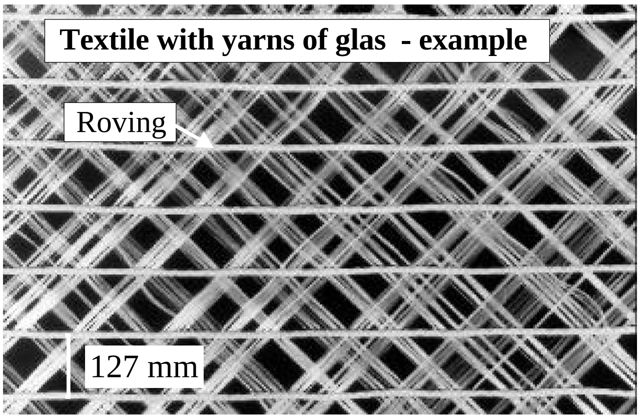
**Summary: Textile reinforced concrete is a new composite material, which offers many new and challenging applications due to its low weight and high load-bearing capacity.**

**The evaluation of the durability of textile reinforced concrete parts is a crucial aspect of the research into this new composite material. Climatic stresses of the composite material, e.g. due to humidity and temperature, result in changes in the bond and strength characteristics of the yarn/concrete system. In order to detect these changes, the Institute for Building Materials Research in Aachen uses a variety of testing procedures, which are often combined. This paper explains the TSP test (dog-bone shaped specimen). This test shows the changes in the stress-strain behaviour, the cracking image as well as the maximum yarn tensile strength of specimens, which have been reinforced with yarn or textiles and are stressed in one axis due to climatic stresses. The results of the TSP test shows a clear functional loss of these specimens, which have been stored in warm water for several days. The collapse load and the ultimate strain as well as the number of cracks are reduced due to the storage in warm water. A chemical attack as well as a mechanical attack can be regarded as the causes for the loss of functionality of the reinforcement. Both damaging mechanisms will be discussed. With help of the described structural examinations the pore area in the contact zone of yarn/concrete after a climatic stress is detected. The fact that the pore area in the contact zone after the storage in warm water is reduced, compared to a storage at 20 °C and 65 % relative humidity, indicates a mechanical stress of the reinforcement.**

**Keywords: Durability, Accelerated Ageing, Textile Reinforced Concrete, Tensile Test, Bond Behaviour**

## 1 INTRODUCTION

Textile reinforced concrete represents an interesting new construction material, which offers several advantages compared to steel or fibre reinforced concrete. These advantages dominate in the field of applications, where thin-walled, structural elements with a high load-carrying capacity are necessary. The following materials can be used as a reinforcement: glass rovings, carbon rovings or polymer rovings. These rovings textiles as shown in fig. 1, left, are fabricated and placed in the tension area of the component. The employed rovings are multifilament yarns, consisting of more than 500 filaments with diameters between 12 and 30 µm. A roving with 2400 tex (describing fineness: 1 tex = 1 g / 1000 m) has about 2400 Filaments. Figure 1 shows on the right side a roving which is embedded in concrete.



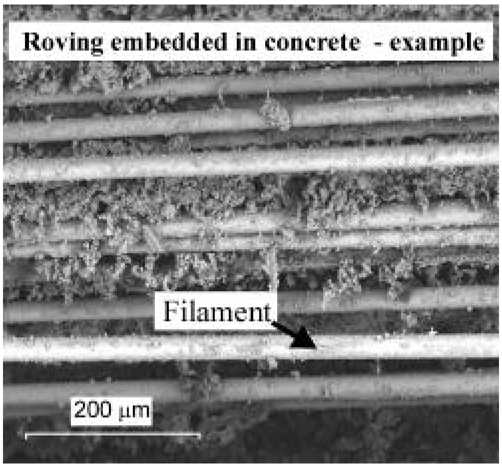


**Figure 1. Examples for a textile used as a reinforcement of concrete and for a roving, which is embedded in concrete**

One aim of the research project SFB 532 "Textile Reinforced Concrete – Basics of a New Technology" placed at the Technical University of Aachen (financed by the central public funding organisation for academic research in Germany, DFG) is to investigate the durability of this construction material.

For the assessment of the durability of the composite material the following two aspects should be taken into consideration: The types of climatic stresses that are to be applied as well as the determination of the changes in the bond and strength characteristics that result from the stress. Within this paper the climatic stress is confined to a laboratory stress with different temperature and humidity values. The storage of the composite components in a water bath at a hightened temperature leads to an accelerated ageing process as it has been shown, amongst others, by Litherland et al (1981). In order to be able to determine the changes of the bond and strength characteristics which result from the climatic stresses, different kinds of examinations are necessary. The SIC test (strand in cement) allows conclusions concerning the change of the maximum tensile strength of a roving, that is embedded in the concrete, after different climatic stresses. This test was and is used extensively to examine different material combinations and compare them with each other (Raupach and Brockmann (2001)). The changes in the pull-out behaviour of a roving in concrete due to climatic stresses is examined with the help of two-sided pull-out tests (Raupach and Brockmann (2001)). The TSP test carried out on dog-bone shaped specimens allows conclusions concerning the changes in the stress-strain behaviour, the cracking image as well as the maximum yarn tensile strength of textile reinforced specimens under uniaxial stress due to climatic stress. This paper explains the TSP test. Some test results are presented and discussed.

The changes in the behaviour of the composite material, which have been determined in the tests, have two causes that are described in other papers in different ways (e.g. Litherland et al (1981); Majumdar et al (1980); (Yilmaz and Glasser (1992)). Firstly the glass is chemically attacked by the high alcalinity of the binding agent and secondly it is mechanically attacked by hydration products. The hydration products lead to a compression of the pore area next to the roving. This compression heavily restricts the movability and thereby the elongability of the individual filaments. The loss of elongability leads to the inability or the reduced ability of the roving to contribute to the load carrying. Purnell et al (2001) are convinced that the local points of flaws of the glass, the size of which is about 0.2 µm (Purnell (1998)) and which are due to the manufacturing process, are the points of attack by chemical and mechanical forces. The two damage mechanisms are discussed extensively in the course of this paper. At the end of the paper an examination will be introduced, which can be used to determine the compression of the pore area around the roving after different kinds of storage.

## 2 SETUP AND IMPLEMENTATION OF THE TSP TEST

The TSP test examines dog-bone shaped specimens (TSP), which have been reinforced with rovings or textiles, after different climatic stresses with the help of tensile tests.

Figure 2 shows the manufacturing of the specimens in a steel formwork. The rovings are evenly distributed over a specimen width of 60 mm. At first the rovings are mounted on a frame. Then they are collected and fixed at the ends with steel clamps and an elastomer and inserted in the formwork. In order to fixate their position, the rovings are tensed against the formwork with the clamp. The applied tensile force is far below the yielding point of the material. In order to seal the front sides of the formwork, polymer rods are inserted into the respective relief in the formwork. These rods are coated with a sealing material. The concrete is filled into the formwork over the sample thickness of 7 mm and compacted by vibration.

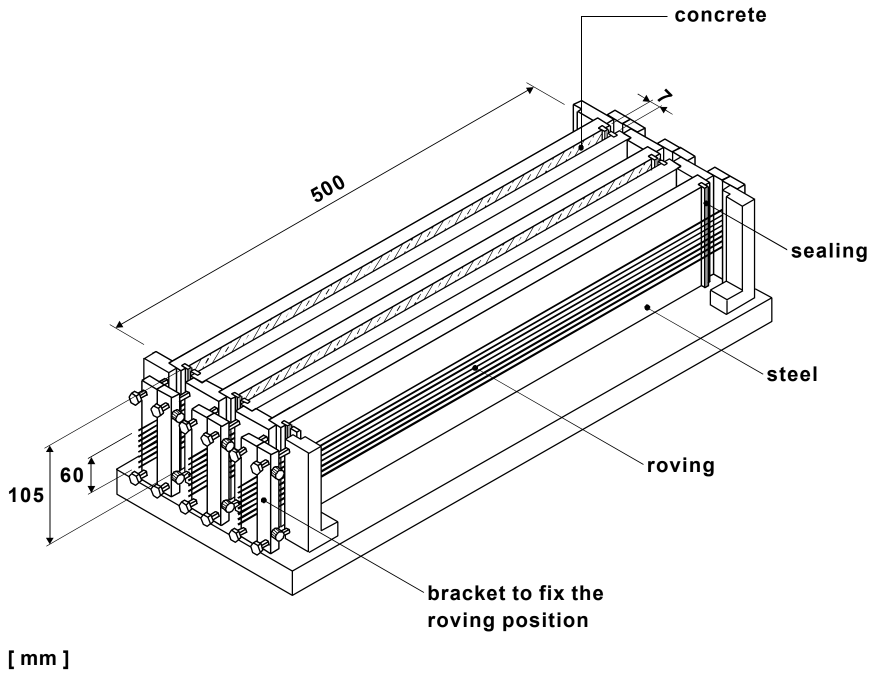

**Figure 2. Manufacturing of the TSP specimens in a steel formwork**

The specimens are manufactured with a constant width of 105 mm. After that the specimens are machined with the help of a concrete mill. In order to increase the manufacturing accuracy the milling head moves along a CNC manufactured aluminium template. The geometry of the dog-bone shaped specimens can be seen in figure 3. In the centre area of the specimen, the specimen width is a constant 60 mm over a length of 220 mm. This leads to an homogenious stress distribution in the middle part of the specimen.

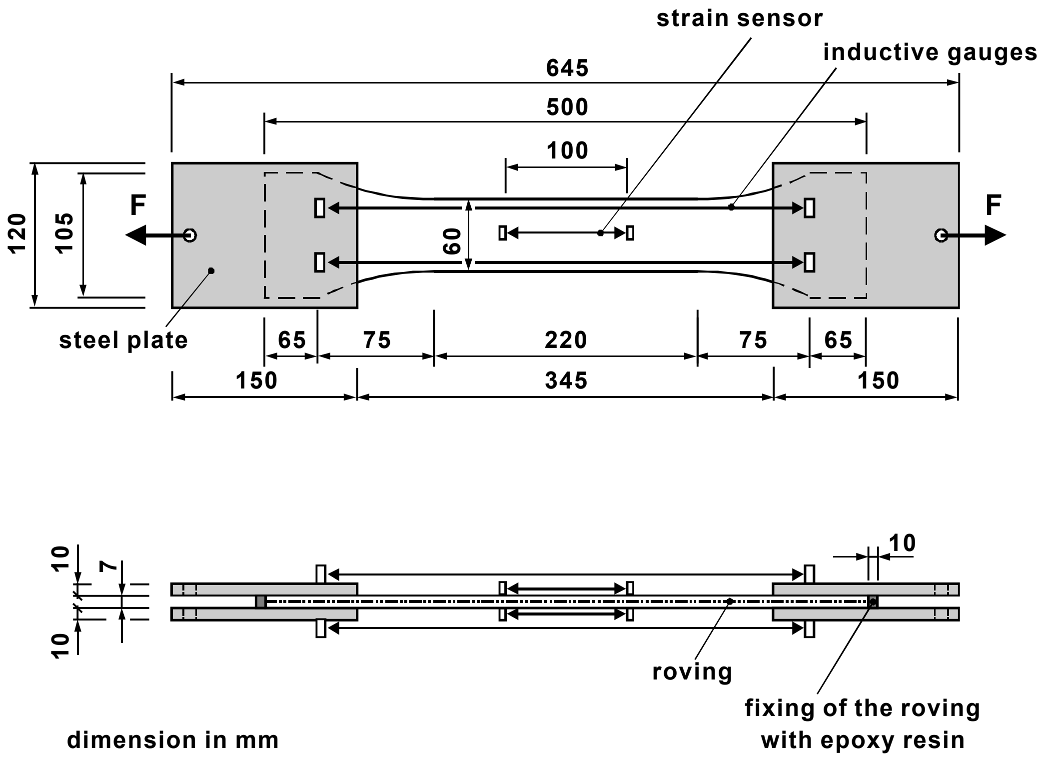

**Figure 3. layout and dimensions of the TSP-specimens**

For the application of the tensile force, holed steel plates are glued to the specimen. The force application is done via a pin in the steel plate. From there the force application continues via the glue joint into the tensile sample. Thereby an unwanted transversal pressing is avoided. The TSP samples are charged with a speed of 0.5 mm/min until the failure occurs. The change of length is measured over the complete sample length with inductive gauges, which are fixed to the steel plates. The shear deformation in the glue joint has been determined. Its value can be neglected for the test evaluation as a thin glue joint is used,

Go Back Next Page

which has a high stiffness. The acting strain until the first cracks develop is additionally determined over 100 mm with a DD1 distance sensor, which is centred over the sample. The rovings, which are sticking out of the sample body, are glued with epoxy resin. This way the individual filaments are fixated at the end of the sample. When stress is applied, individual filaments are unable to slip towards the centre of the sample from the sample edge. Therefore the rovings can reach the maximum tensile strength. Furthermore the epoxy resin glue of the outside of the yarn prevents any stress medium (e.g. water) from getting into the sample body via the yarn. This test allows conclusions concerning the change in the stress-elongation behaviour, the cracking image as well as the maximum yarn tensile strength after climatic stresses.

## 3 TSP TEST RESULTS AND DISCUSSION

For the results shown in this paper, glass rovings manufactured by the company NEG with 2400 tex have been used. The TSP samples were reinforced with 8 rovings. With a sample thickness of 7 mm this corresponds to a reinforcement degree of 1.7 vol. %. Preliminary investigations showed, that this is the highest possible reinforcement degree under the constrain that each roving is completely coated by concrete and that there is no overlapping of rovings inside the specimen. The concrete mixture (table 1) that has been used, was developed by the Institute for Building Materials Research as a textile concrete (Brameshuber and Brockmann (2001)). Hereby the complete penetration of the textile reinforcement demands a high flowability as well as a small grain size of the aggregate. Due to the simultaneous addition of silica fume and coal fly ash the contents of alkali ions and calcium hydroxide is reduced compared to pure Portland cement mixtures. The pH value of this mixture is 13.5.

**Table 1. Composition of the fine concrete mixture**

| *Binder system* | *Type of cement* | *Cement content* | *Additives* | | | | *Binder content* | *w/b-ratio* | *max. grain size* |
|---|---|---|---|---|---|---|---|---|---|
| | | | *Fly ash* | *Silica fume* | *Water reducer* | *Stabilizer* | | | |
| | | Kg/m$^3$ | | | - | | kg/m$^3$ | - | mm |
| OPC | CEM I 52,5 | 490 | 175 | 35 | 1[2] | - | 700 | 0.4 | 0.6 |

[2]: Mass percentage in relation to cement content

After the samples have been manufactured they are all stored in a humidity cupboard at 23 °C and 95 % relative humidity for 28 days followed by the climatic stress. Therefore it can be assumed that at the time of the climatic stress the hydratation has been more or less accomplished. Figure 4 (top left) shows three tensile test curves after the 28 days storage period in the climatic chamber. The force is always drawn over the elongation. The tests shows a low deviation. After a linear elongation the initial crack appears at approx. 1.9 kN. The area of the crack development with crack distances of about one centimeter ends at approx. 2.5 kN. Thereafter the load carrying happens via the 8 yarns until the reinforcement fails at an average value of 4.6 kN. Figure 5 shows the destroyed sample on the left hand side.

In the top right part of figure 4 the influence of a 3 days water storage at 50 ° is shown. The initial cracking load is risen to an average value of 2.3 N due to the warm water storage. After the initial cracking these samples also show an evenly distributed cracking image. The sample bodies fail at an average value of 3.5 kN.

After a warm water storage at 80 °C for three days (figure 4, bottom left) an evenly distributed cracking image also appears at an average value of 2.6 kN. After the cracking image has been accomplished, there is also a load carrying capacity of the yarns but the carrying ability of the yarn decreased to an average value of 3.1 kN.

The gradient of the curves, which are nearly linear, in the after-crack area is up to approx. 8 % lower for the samples that have been stressed by warm water. The gradient decreases for increasing temperature of the water storage. The curve in this area is determined by the volume and the modulus of eleasticity of the yarn. Purnell (1998) comes to the conclusion that the smaller gadient relates to a loss of yarn volume due to the built-up of flaws in the glass after the chemical attack.

After the sample has been stored in warm water at 80 °C for seven days (figure 4, bottom right), it fails abruptly at a rectangle to the reinforcement (figure 5, right) at an average value of 2.6 kN, i.e. on the level of the initial crack. The glass reinforcement is no longer able to contribute to the load carrying.

Two causes can be named for the loss of functionality of the reinforcement: a chemical attack on the glass and the resulting loss of yarn volume as well as a mechanical attack due to hydratation products and the resulting loss of ductility or transversal shearing respectively on the roving. These two damaging mechanisms will be explained in detail in the following chapter.

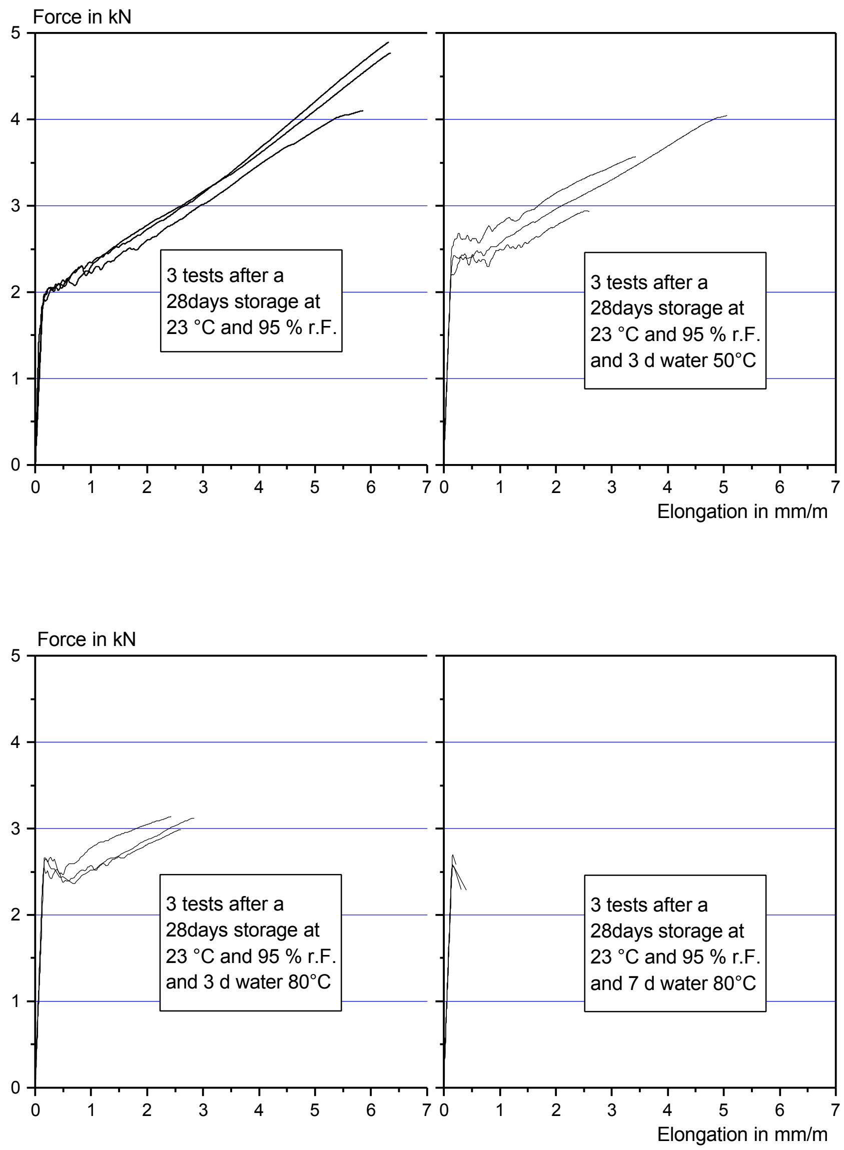

**Figure 4. TSP tests with NEG rovings 2400 tex and concrete after different climatic stresses**

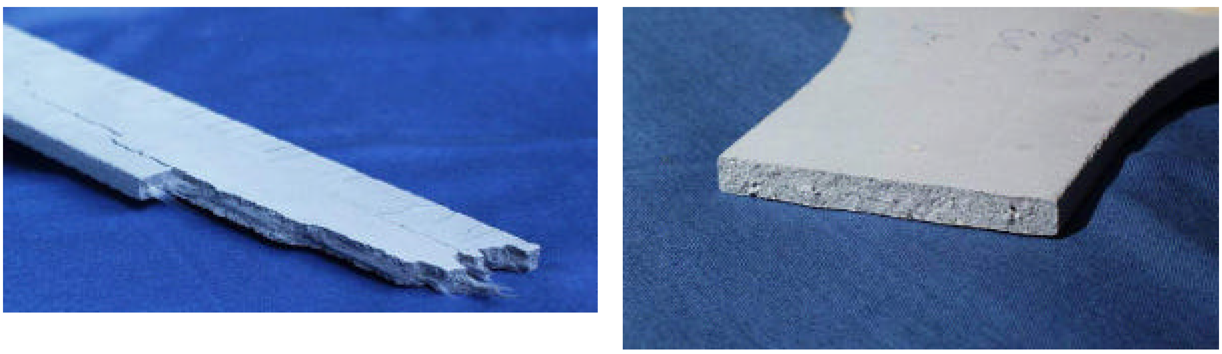

**Figure 5. Failure of TSP samples after 28 days storage at 23 °C and 95 % r. h. (left) and after 28 days storage at 23 °C and 95 % r. h. and 7 days in water at 50 °C**

Figure 6 allows an overview of the decrease in the ultimate loads and the ultimate strain of the TSP samples, which have been stored under different conditions, in the tensile test. The 28 days value (storage time under climatic stress: 0d) after a storage in the climatic chamber is 4.6 kN and is regarded as the start value. The appliable force decreases linearly between 3 and 14 days at a 50 °C water storage. It levels at a value of approx. 0.5 kN above the initial cracking load. However the elongation of rupture has decreased further after a 28 days storage in warm water. This loss of force has a tendency to stagnate between day 14 and 28 of the water storage at 50 °C and will be investigated further in a new test series. The appliable yarn tensile force of the samples, which have been stored in water at 80 °C for 7 days (or 14 days respectively), is below the initial cracking force and therefore cannot be detected with this test. The reinforcement degree of the samples cannot be increased due to the manufacturing process and the transfer of the test results into reality becomes more and more difficult with an increasing water temperature, especially for concrete the basis of which is not Portland cement or blast furnace cement. Therefore future TSP tests will be increasingly performed after a water stress at 50 °C.

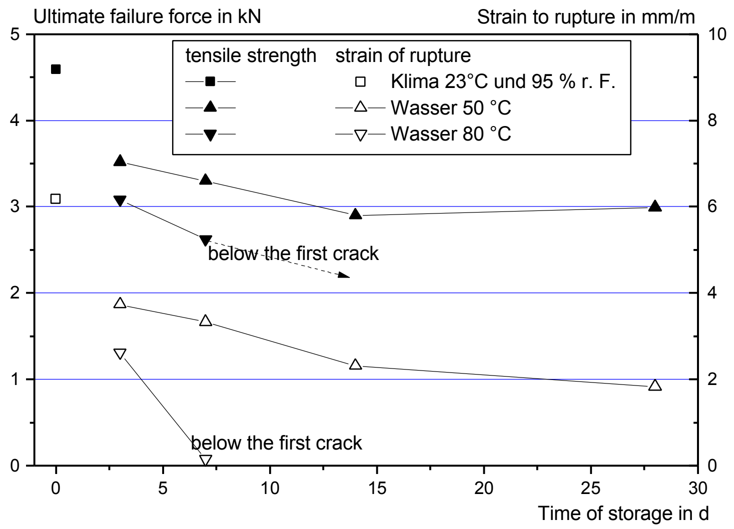

**Figure 6. Rupture forces and respective elongations in the TSP test after different kinds of storage**

## 4 DAMAGING MECHANISMS

The results of the TSP tests shows a clear loss of strength of the composite material with an increasing water temperature and storage time. Two causes can be named for the functional loss of the reinforcement:

- A chemical attack on the glass: Hereby the silicon oxide ($SiO_2$) network is nucleophilicly attacked by a hydroxyl ion. This reaction is self-generating due to follow-on reactions, whereby a complete dissolution of the glass is possible. In addition to the parameters that correspond to the corrosion medium, the composition of the glass is of crucial importance for the speed of the reaction (Czymai (1995)). The dissolution of the glass leads to a loss of roving volume, which again equals a reduction of the strength.
- A mechanical attack on the glass: Hydration products, mainly calcium hydroxide, increasingly build up along the border lines of filament and matrix. Since the concrete penetrates the roving in an uncontrolled manner during the concreting process (as shown in figure 7), a large area is available for the build-up of hydration products. This area is compressed which results in a loss of ductility. Another aspect is the transversal shearing of the hydratation products on the filaments. The glass, which is sensitive to transversal forces, therefore also fails at an early stage.

The TSP-Test cannot achieve a separation of these two damaging mechanisms. According to the authors knowledge no researcher has so far succeeded in describing the damaging mechanisms separately. This will be the aim of future research at the Institut for Building Materials Research in Aachen. In this respect the following two points demand a closer study:

- The rovings, which are embedded in the concrete, show inclusions of air and binding agents. These lead to a very uneven distribution of filaments in each sample cross section as shown as an example in figure 7. In the course of their examinations Brameshuber and Banholzer (2001) also found a high number of flaws in a concreted roving. Due to dispersion etc. these flaws cause problems with the test evaluation.
- During the manufacturing process of the rovings a size is applied as a protection and for improved treatment. This polymer coating, which is very thin and does not cover the roving completely, varies according to the manufacturer. The size leads to certain conditions in the contact zone roving/concrete, which have not been identified so far. Therefore a swelling of the size can lead to an increase in the porosity in the contact zone.

First examinations, which investigated the chemical attack and the mechanical attack separately, have been documented by Brockmann et al (2001).

### 4.1 Structural examinations in the contact zone roving/concrete

At the present time the Institute for Building Materials Research in Aachen investigates the possibility of a matrix compression in the contact zone roving/concrete as well as a possible resulting mechanical attack on the reinforcement. These tests are performed with help of the image analysis evaluation of scanning electron microscope images.

For these tests a glass roving is embedded in the centre of a concrete body (length 40 mm, width 10 mm, thickness 10 mm). The roving that sticks out of the concrete body is protected from the attacking medium by a silicon hose. The samples are stored under different conditions (variation of temperature and humidity). For the preparation of the samples the hydration is stopped with the help of acetone. After the samples have been dried for two days at 50 °C, they are impregnated with epoxy resin under a vacuum. After the impregnation with epoxy resin and a subsequent application of a pressure of 5 bar, the samples are sawn transversally to the roving and polished. Element contrast images are taken of the plan view of the cross section in the scanning electron microscope. Those areas of the element contrast images, which appear black, are pores, filled with epoxy resin. These images are therefore very helpful to detect pore areas in the matrix of the contact zone and the yarn area. This is done with help of an image analysis system from the company SIS. This process is shown in figure 7.

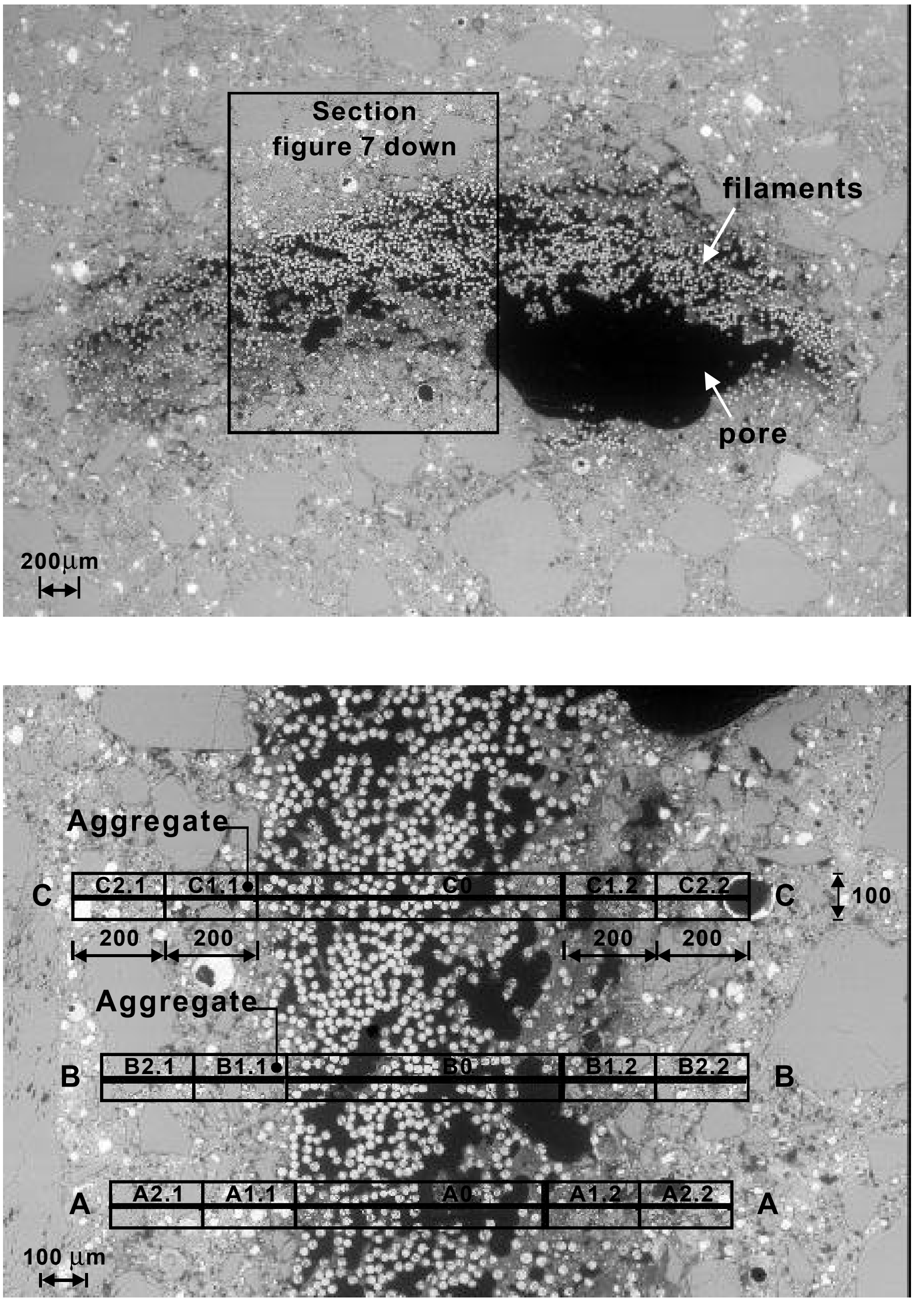

**Figure 7: Element contrast image of a sample and determination of the pore areas on an image section**

In order to investigate the pore distribution in the contact zone and the concrete as well as their changes due to climatic stresses, despite of the uneven filament distribution, the following procedure is applied: Starting with the total view of a roving cross section (figure 7, top), afterwards element contrast images of small parts of the yarn cross sections are taken with a magnification factor of 60. 3-4 axial sections are placed in these images (figure 7, bottom). Outside the rovings these sections are separated into areas of 100x200 µm². A separation between roving and contact zone is made at the aggregate grain, which is nearest to the roving. The pore area of the individual rectangles is determined via an image analysis evaluation and an average value is found via the large number of axial sections. If the number of observed areas in the contact zone and the fine concrete is sufficient (>15 areas of 100x200 µm), conclusions concerning the pore distribution according to different storage types become possible. Table 2 shows the average pore area in % of the examined areas in the fine concrete and in the contact zone roving/concrete after different storage types. Rovings of two different manufacturers were examined.

The samples, which have been reinforced with CemFil 2400 tex, do not show any changes of the pore area in the concrete when they are stored in a 56 days climatic storage or a water storage at 50 °C respectively. However the pore area in the contact zone has decreased from 12 % (56 d at 20 °C/60 % r.h.) to 5 % after a 112 days water storage at 50 °C. For the samples, which have been reinforced with NEG 2400 tex (this yarn has also been used for the TSP samples), the determined pore area is larger than for the samples, which have been reinforced with CemFil. This may be explained with the smaller content of interlaced material in the NEG size (Hoffman and Höcker (2001)). The increase of the pore area in the fine concrete for the samples, which have been reinforced with NEG, indicates the large area of influence of the sized roving. In the future the pore area of the fine concrete will additionally be determined at an increased distance to the reinforcement. It is also planned to examine several cross sections at one sample body, in order to determine the dispersion range of the respective pore area via the length of the sample.

**Table 2. Image analysis determination of the pore area in % in the concrete and in the contact zone roving/concrete**

| *Roving* | *Storage* | *Averaged pore area in % from a section of 100x200 µm* | |
|---|---|---|---|
| | 28 d at 23°C / 95 % r. h. + | concrete | Contact zone roving/concrete |
| CemFil 2400 | 56 d at 20°C / 65 % r. h. | 3 | 12 |
| | 56 d in water at 50 °C | 3 | 5 |
| NEG 2400 | 112 d at 20°C / 65 % r. h. | 7 | 15 |
| | 112 d in water at 50 °C | 4 | 7 |

These structural examinations will be carried out parallel to further detailed examinations, in order to guarantee a proper interpretation of the test results by combining extensive test results. At the end of this project it shall be possible to view the damaging mechanisms and their influence on the durability of the composite material separately.

## 5 SUMMARY

The TSP test allows conclusions concerning the change in the stress-strain behaviour, the cracking image as well as the maximum yarn tensile strength of yarn or textile reinforced components under uniaxial load due to climatic stress. The results of the TSP tests shows a clear functional loss of the composite material after storation in warm water for several days. The ultimate load and the ultimate strain as well as the number of cracks are reduced due to the storage in warm water. After the specimen has been stored in water at 80 °C for seven days, it fails abruptly when the tensile strength of the concrete is reached, the glass reinforcement does not contribute any longer to the load carrying capacity. The cause for the loss of load carrying capacity can be a chemical attack as well as a mechanical attack on the glass reinforcement or a combination of both attacks. A separate view and classification of these two damaging mechanisms can only be done with extensive investigations. A part of the necessary investigations are the structural examinations shown in this paper, which determine the pore area in the contact zone and in the concrete after different climatic stresses of the composite material. The pore areas are determined with the help of image analysis evaluation of scanning electron microscope images. These pore areas decrease in the contact zone roving/concrete due to a water storage at 50 °C as compared to a climatic storage at 20 °C and 65 % relative humidity. The reduction of the pore area leads to a compression of the matrix in this area and therefore results in a loss of ductility of the reinforcement.

# Strength Development And Polymer Durability In Autoclaved Polymer-Modified Mortars

**Y Ohama &M Joo**
**College of Engineering Nihon University Koriyama Fukushima-ken Japan**

**Summary**: **In general, the application of a combined wet/dry cure and a dry cure to polymer-modified mortars causes no degradation of the polymer films formed in them. However, the application of autoclaving to such mortars is anticipated to cause the degradation of the polymer films due to exposure to high temperature and pressure. The strength development of the autoclaved polymer-modified mortars may depend largely on the type of polymer. Polymer-modified mortars using polymer dispersions such as a styrene-butadiene rubber (SBR) latex, a poly(ethylene-vinyl acetate) (EVA) emulsion and a polyacrylic ester (PAE) emulsion for polymeric admixtures, and ground granulated blast-furnace slag (slag) and high-purity silica (silica) as siliceous admixtures are prepared with a mass ratio of binder (a mixture of ordinary portland cement and slag or silica) to Toyoura standard sand 1 : 3, slag or silica contents of 0, 30, 40 and 50%, and polymer-binder ratios of 0, 5, 10, 15 and 20%, cured under autoclaving at a temperature of 180? and a vapor pressure of 1.01 MPa, and tested for flexural and compressive strengths. The polymer films prepared with the same polymer dispersions are exposed to autoclaving under the same conditions, and subjected to tensile test and infrared spectroscopy. The durability of the polymer films is evaluated from the viewpoints of the deteriorated basic physical properties and changed infrared spectra. As a result, regardless of the slag or silica content, the flexural and compressive strengths of SBR-modified mortars tend to increase with an increase in the polymer-binder ratio, while those of EVA-and PAE-modified mortars decrease with increasing polymer-binder ratio. The application of autoclaving to the polymer films under saturated $Ca(OH)_2$ solution immersion causes no degradation for SBR film and a significant degradation due to the saponification of the polymers for EVA and PAE films. Accordingly, autoclaving does not significantly degrade SBR-modified mortars but markedly degrades EVA-and PAE-modified mortars by the saponification of the polymers.**

**Keywords. Autoclaving, Polymer-Modified Mortar, Strength Development, Polymer Durability, Polymer Film**

## 1 INTRODUCTION

In polymer-modified mortars, cement hydration and polymer film formation proceed simultaneously, and co-matrix phases are formed by both processes. Cement hydrates are reinforced with the network structures of the polymer films in the co-matrix phases. Therefore, the morphology and properties of the polymer films strongly affect the properties of the polymer-modified mortars. The application of a combined wet/dry cure and a dry cure to the polymer-modified mortars generally causes no degradation of the polymer films formed in them. However, the application of autoclaving is anticipated to cause degradation of the polymer films due to exposure to high temperature and pressure .The strength development of the autoclaved polymer-modified mortars may depend largely on the type of polymer. The purpose of this investigation is to determine the strength development and polymer durability in the autoclaved polymer-modified mortars. In the present paper, polymer-modified mortars using three polymeric admixtures and two siliceous admixtures were prepared with various siliceous admixture contents and polymer-binder ratios, cured under autoclaving, and tested for strength. The polymer films prepared with the same polymeric admixtures were exposed to autoclaving under the same conditions, and polymer durability was evaluated in terms of the deteriorated physical properties and changed infrared spectra.

## 2 MATERIALS

### 2.1 Cement

Ordinary portland cement as specified in JIS(Japanese Industrial Standard) R 5210(Portland cement) was used as a cement.

### 2.2 Admixtures

#### 2.2.1 Siliceous admixtures

Ground granulated blast-furnace slag (slag) and high-purity silica (silica) were used as siliceous admixtures. The properties of the siliceous admixtures are given in Tables 1 and 2.

#### 2.2.2 Polymeric admixtures

Polymer dispersions used as polymeric admixtures were a styrene-butadiene rubber (SBR) latex, a poly(ethylene-vinyl acetate) (EVA) emulsion and a polyacrylic ester (PAE) emulsion. The properties of the polymer dispersions are listed in Table 3. Before mixing, a silicone emulsion-type antifoamer was added to the polymer dispersions in a ratio of 0.7% of the silicone solids of the antifoamer to the total solids of the polymer dispersions.

**Table 1. Properties of ground granulated blast-furnace slag.**

| Density (g/cm$^3$) | Blaine specific surface (cm$^2$/g) | Activity index (%) | | |
|---|---|---|---|---|
| | | 7d | 28d | 91d |
| 2.91 | 10070 | 128 | 115 | 106 |

| Chemical compositions (%) | | | |
|---|---|---|---|
| MgO | $SiO_2$ | $SO_3$ | $Cl^-$ |
| 5.58 | 33.5 | 0.12 | 0.003 |

**Table 2. Properties of high-purity silica.**

| Density (g/cm$^3$) | Blaine specific surface (cm$^2$/g) | Average particle size (µm) | $SiO_2$ (%) |
|---|---|---|---|
| 2.65 | 5060 | 7.6 | 99.90 |

**Table 3. Properties of polymer dispersions.**

| Type of polymer dispersion | Density (20? , g/cm$^3$) | pH (20? ) | Viscosity (20? , mPa? s) | Total solids (%) |
|---|---|---|---|---|
| SBR | 1.02 | 9.4 | 64 | 44.7 |
| EVA | 1.07 | 5.2 | 1218 | 44.0 |
| PAE | 1.06 | 9.8 | 49 | 47.0 |

#### 2.2.3 Fine aggregate

Toyoura standard sand as specified in ex-JIS R 5201(Physical testing methods for cement) was used as a fine aggregate.

## 3 TESTING PROCEDURES

### 3.1 Tests of strength development

#### 3.1.1 Preparation of specimens

Before mixing polymer-modified mortars, the respective binders were prepared by blending cement and siliceous admixture (slag or silica) by use of a small ball mill for 4h. The cement: siliceous admixture (slag or silica) ratios (by mass) of the binders were 100: 0, 70: 30, 60: 40 and 50: 50, corresponding to slag or silica contents (SL or Si) of 0, 30, 40 and 50%. According to JIS A 1171 (Test methods for polymer-modified mortar), polymer-modified mortars were mixed with a mass ratio of the binder to fine aggregate 1: 3, polymer-binder ratios (P/B, calculated on the basis of the total solids of polymer dispersions) of 0, 5, 10, 15 and 20%, and their flow were adjusted to be constant at 170±5 in the water-binder ratio range of 50.0 to 78.0%. Beam specimens 40×40×160mm for strength test were molded, precured at 20? and 80%(RH) for 48h, and then subjected to autoclaving at a maximum temperature of 180? and a pressure of 1.01MPa for 3h.

#### 3.1.2 Flexural and compressive strength tests

The autoclaved beam specimens were tested for flexural and compressive strengths in accordance with JIS A 1171.

### 3.2 Tests of polymer durability

#### 3.2.1 Preparation of polymer films

Polymer dispersions filtered with wire gauze with a nominal size of 74µm were poured in the molds 200x200x1mm set on polyester-sheeted glass plates placed horizontally, and dried with a hood to prevent air flow at 30? for 1d to make polymer films. After drying, the polymer films were removed from the polyester-sheeted glass plates, and dried further at 20? and 60%(RH) for 5d.

#### 3.2.2 Physical tests

Polymer films were tested for minimum film-forming temperature according to JIS K 6828 (Testing methods for synthetic resin emulsions), for glass transition temperature according to JIS K 7121(Testing methods for transition temperatures of plastics), and for tensile behavior in accordance with JIS K 6251 (Tensile testing methods for vulcanized rubber).

#### 3.2.3 Degradation tests under autoclaving

Polymer films were subjected to autoclaving under saturated $Ca(OH)_2$ solution immersion or nonimmersion at a maximum temperature of 180? and a pressure of 1.01MPa for 3h. The polymer films before and after autoclaving were tested for tensile strength and elongation in accordance with JIS K 6251. The samples extracted with toluene from the polymer films before and after autoclaving were analyzed at wavenumbers of 600 to 4000$cm^{-1}$ by infrared spectroscopy.

## 4 TEST RESULTS AND DISCUSSION

### 4.1 Strength development

Figures 1 and 2 show the effects of slag and silica contents on the flexural and compressive strengths of autoclaved polymer-modified mortars with polymer-binder ratios of 0, 5, 10, 15 and 20%, respectively. Figures 3 and 4 illustrate the effect of polymer-binder ratio on the flexural and compressive strengths of the autoclaved

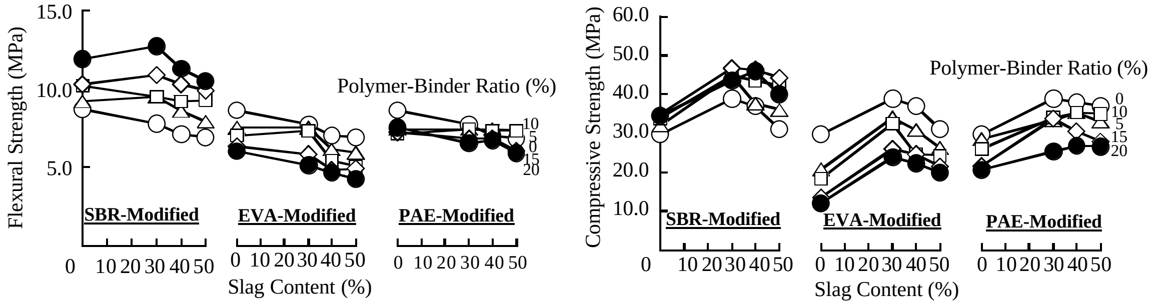

**Figure 1. Slag Content vs. Flexural and Compressive Strengths of Autoclaved Polymer-Modified Mortars with Polymer-Binder Ratios of 0, 5, 10, 15 and 20%**

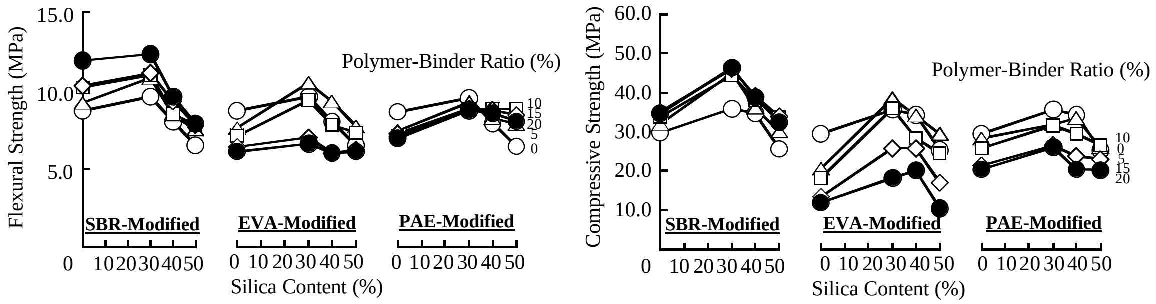

**Figure 2. Silica Content vs. Flexural and Compressive Strengths of Autoclaved Polymer-Modified Mortars with Polymer-Binder Ratios of 0, 5, 10, 15 and 20%**

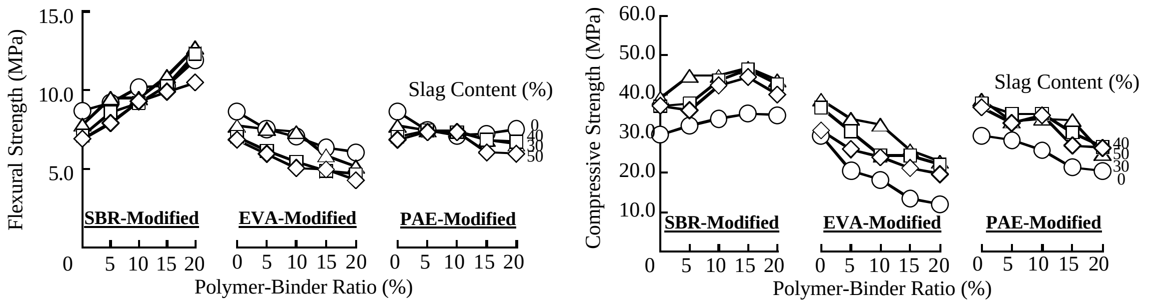

**Figure 3. Polymer-binder ratio vs. flexural and compressive strengths of autoclaved polymer-modified mortars with slag contents of 0, 30, 40 and 50%**

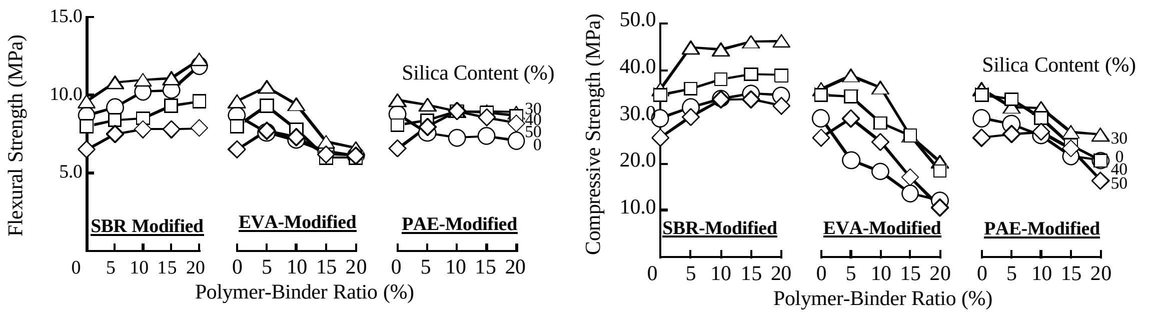

**Figure 4. Polymer-binder ratio vs. flexural and compressive strengths of autoclaved polymer-modified mortars with silica contents of 0, 30, 40 and 50%**

polymer-modified mortars with slag and silica contents of 0, 30, 40 and 50%, respectively. Regardless of the type of polymer and the polymer-binder ratio, except for the flexural strength of EVA- and PAE-modified mortars using slag, the flexural and compressive strengths of the autoclaved polymer-modified mortars using slag and silica tend to increase with increasing slag and silica contents, and to reach maximums at slag and silica contents of 30%. The flexural strength of EVA- and PAE-modified mortars using slag tends to decrease with increasing slag content irrespective of the polymer-binder ratio. In particular, this tendency is significant at larger polymer-binder ratios, and saponification of the polymers is suggested from this tendency. SBR-modified mortars using slag and silica are superior in flexural and compressive strengths to EVA- and PAE-modified mortars using slag and silica. The development of higher strengths is attributed to no degradation of the polymers and the accelerated pozzolanic reaction of slag and silica by autoclaving (Ohama et al. 1990). Regardless of the slag and silica contents, the flexural and compressive strengths of SBR-modified mortars using slag and silica tend to increase with increasing polymer-binder ratio or reach maximums at a polymer-binder ratio of 20%, whereas those of EVA- and PAE-modified mortars using slag and silica tend to decrease with increasing polymer-binder ratio. This may be explained by the conditions of the polymer films formed in the autoclaved polymer-modified mortars as shown in Figs. 5 and 6. In the figures, tough polymer films are observed in SBR-modified mortars, but brittle and torn polymer films due to their saponification by autoclaving are evident in EVA- and PAE-modified mortars.

| SBR-Modified | EVA-Modified | PAE-Modified |

**Figure 5. Microstructures of autoclaved polymer-modified mortars with polymer-binder ratio of 20% and slag content of 30%**

| SBR-Modified | EVA-Modified | PAE-Modified |
|---|---|---|

**Figure 6. Microstructures of autoclaved polymer-modified mortars with polymer-binder ratio of 20% and silica content of 30%**

### 4.2 Polymer durability

Table 4 shows the basic physical properties of polymer films. Tables 5 and 6 give the physical properties and appearances of the polymer films before and after autoclaving,

respectively. In comparison with the physical properties of the polymer films, there are no marked differences in the minimum film-forming temperature, glass transition temperature and tensile strength between SBR, EVA and PAE films. However, the elongation of SBR film is almost the same as that of EVA film, but the elongation of PAE film is no more than about one-half of that of SBR and EVA films. In comparison with the physical properties of the polymer films before and after autoclaving (under no immersion in a saturated $Ca(OH)_2$ solution), the respective decreases in the tensile strength and elongation of SBR film are about 20%, but the tensile strength of EVA film decreases 40% or more, and the elongation of PAE film decreases about 60%. In comparison with the physical properties of the polymer films before and after autoclaving under immersion in the saturated $Ca(OH)_2$ solution, the respective decreases in the tensile strength and elongation of SBR film are about 25%, but decreases in the tensile strength and elongation of EVA film are 66% and 81%, respectively, the respective decreases in the tensile strength and elongation of PAE film being 43 to 44%. The significant degradation of EVA and PAE films due to the synergistic effect of autoclaving and saturated $Ca(OH)_2$ solution immersion explains the reduced physical properties of EVA and PAE films compared to SBR films. This corresponds with the changes in appearance of SBR, EVA and PAE films before and after autoclaving under immersion in the saturated $Ca(OH)_2$ solution as seen in Table 6.

**Table 4. Basic physical properties of polymer films.**

| Type of polymer film | SBR film | EVA film | PAE film |
|---|---|---|---|
| Appearance | Transparent film | Transparent film | Transparent film |
| Minimum film-forming temperature (°C) | 5.0 | 0 | 7.0 |
| Glass transition temperature (°C) | -6.0 | -3.6 | 0.1 |
| Tensile strength (MPa) | 6.67 | 4.79 | 5.28 |
| Elongation (%) | 922 | 1037 | 436 |

Figure 7 represents the infrared spectra of SBR films before and after autoclaving under immersion in a saturated $Ca(OH)_2$ solution. There is hardly a difference in the infrared spectrum between SBR films before and after autoclaving under immersion in

the saturated $Ca(OH)_2$ solution. This fact suggests that SBR film is hardly degraded under such autoclaving conditions, i.e., SBR films in SBR-modified mortars are not degraded by autoclaving.

**Table 5. Physical properties of polymer films before and after autoclaving.**

| Type of polymer film | | SBR film | EVA film | PAE film |
|---|---|---|---|---|
| Before autoclaving | Appearance | Transparent film | Transparent film | Transparent film |
| | Tensile strength (MPa) | 6.67 | 4.79 | 5.28 |
| | Elongation (%) | 922 | 1037 | 436 |
| After autoclaving | Appearance | Transparent film with a few small wrinkles | Somewhat yellowed film with some large or small wrinkles | Transparent film with many small wrinkles and cavities |
| | Tensile strength (MPa) | 5.35 | 2.68 | 5.81 |
| | Tensile strength change (%) | -20 | -44 | 10 |
| | Elongation (%) | 766 | 920 | 191 |
| | Elongation change (%) | -17 | -11 | -57 |
| After autoclaving in saturated $Ca(OH)_2$ solution | Appearance | Whitened film with some shallow depressions | Whitened film with many large wrinkles and small cavities | Whitened film with many large wrinkles |
| | Tensile strength (MPa) | 5.05 | 1.64 | 3.48 |
| | Tensile strength change (%) | -24 | -66 | -44 |
| | Elongation (%) | 682 | 194 | 250 |
| | Elongation change (%) | -26 | -81 | -43 |

**Table 6. Polymer films before and after autoclaving.**

| Type of polymer film | Before autoclaving | After autoclaving | After autoclaving in saturated $Ca(OH)_2$ solution |
|---|---|---|---|
| SBR film |  |  |  |
| EVA film |  |  |  |
| PAE film |  |  |  |

Figure 8 illustrates the infrared spectra of EVA films before and after autoclaving under immersion in a saturated $Ca(OH)_2$ solution. In comparison with the infrared spectra of EVA films before and after autoclaving under immersion in the saturated $Ca(OH)_2$ solution, in EVA film after autoclaving, the peak height from hydroxyl group (-OH) at around 3300$cm^{-1}$ increases, and that from ester linkage (-COO-) at 1720 $cm^{-1}$ decreases. This is attributed to the formation of ethylene vinyl alcohol and water-soluble calcium acetate by the partial saponification of EVA polymer with $Ca(OH)_2$(Yasu & Kobayashi 1994) as shown in Fig. 9.

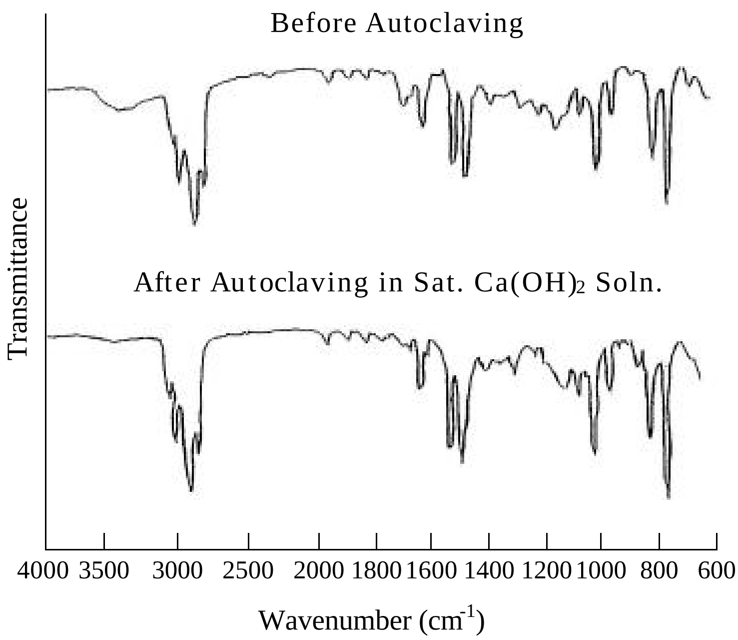

**Figure 7. Infrared spectra of SBR films before and after autoclaving under immersion in saturated $Ca(OH)_2$ solution**

Figure 10 exhibits the infrared spectra of PAE films before and after autoclaving under immersion in a saturated $Ca(OH)_2$ solution. In comparison with the infrared spectra of PAE films before and after autoclaving under immersion in a saturated $Ca(OH)_2$ solution, in PAE film after autoclaving, the peak height from ester linkage (-COO-) at 1720cm$^{-1}$ decreases, and the peak at 1580 cm$^{-1}$ arises from carboxylate . This is due to the formation of carboxylate (calcium polyacrylate) and alcohol by the partial saponification of PAE polymer with $Ca(OH)_2$(Yasu & Kobayashi 1994) as seen in Fig.11.

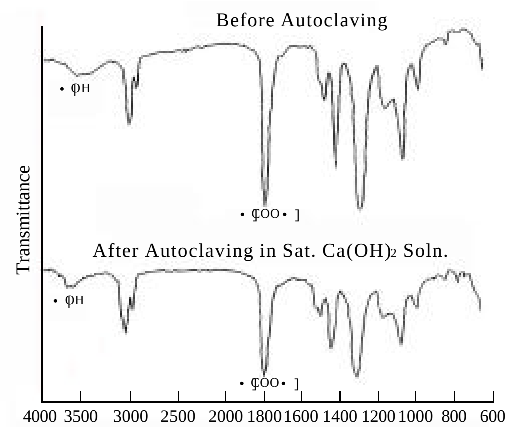

**Figure 8. Infrared spectra of EVA films before and after autoclaving under immersion in saturated $Ca(OH)_2$ solution**

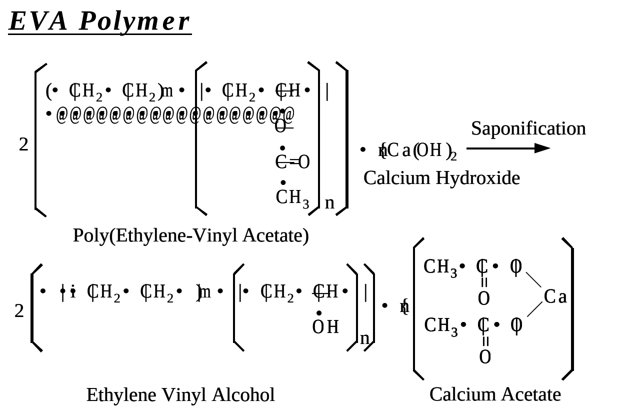

**Figure 9. Mechanism of saponification of EVA polymer**

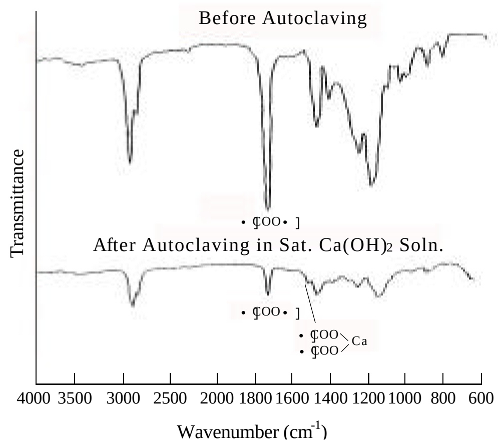

**Figure 10. Infrared spectra of PAE films before and after autoclaving in saturated $Ca(OH)_2$**

*PAE Polymer*

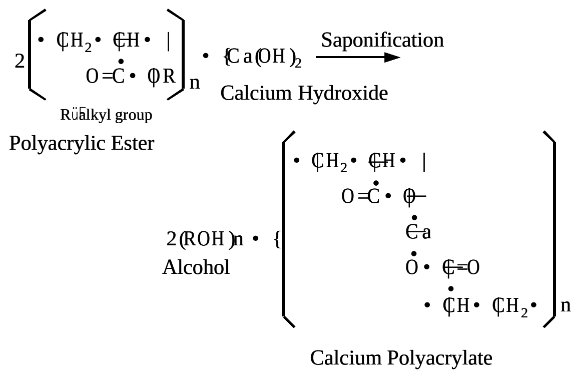

**Figure 11. Mechanism of saponification of PAE polymer**

## 5 CONCLUSIONS

The conclusions from the test results are summarized as follows:

1. Regardless of the type of polymer and polymer-binder ratio, except for the flexural strength of autoclaved EVA- and PAE-modified mortars using slag, the flexural and compressive strengths of autoclaved polymer-modified mortars using slag and silica tend to increase with increasing slag and silica contents, and to reach maximums at slag and silica contents of 30%. Irrespective of the slag and silica contents, the flexural and compressive strengths of autoclaved SBR-modified mortars using slag and silica tend to increase or reach maximums at a polymer-binder ratio of 20% with increasing polymer-binder ratio, whereas those of autoclaved EVA- and PAE-modified mortars using slag and silica tend to decrease with increasing polymer-binder ratio.

2. The application of autoclaving to polymer films in a saturated $Ca(OH)_2$ solution results in around 25% decreases in the tensile strength and elongation of SBR film and 40 to 80% decreases in those of EVA and PAE films.

3. Autoclaving polymer films in a saturated $Ca(OH)_2$ solution results in no significant change in the infrared spectrum for SBR film, however, causes marked changes in the infrared spectrum for EVA and PAE films because of the partial saponification of EVA and PAE polymers. This fact suggests that SBR film is hardly degraded under such autoclaving conditions.

4. From the above results, autoclaved EVA-and PAE-modified mortars using slag and silica appear to be degraded by the saponification of EVA and PAE polymers, but autoclaved SBR-modified mortars using slag and silica are not degraded. Accordingly, autoclave curing can be applied to SBR-modified mortars using slag and silica. In this case, the use of slag rather than silica is recommended.

# Development Of A Durability Branding System For Steel Construction Products

**JC Robinson**
**Industrial Galvanizers Corporation**

**Summary: There is presently no system available to specifiers in Australia to define durability on coated steel products, in particular, zinc coated and galvanized steel products. The author describes the development of a Durability Branding and Certification system that will allow the durability of metallic steel coatings to be defined using a Star Rating system. The Star Rating Durability Certification is based on protocols defined in existing ISO (International Standards Organisation) standards and will provide a performance-based visual standard to supplement the existing disconnected prescriptive standards.**

**Keywords: Durability, certification, galvanized, specification.**

## 1 INTRODUCTION

Galvanized or zinc and zinc alloy coated products represent one of the largest construction material segments used in Australia, with more than one million tonnes of sheet, wire, tube and structural sections being used annually in Australia.

While the galvanized and zinc based coatings on these products are defined in various Australian, Australian/New Zealand, and ISO standards, these standards are largely prescriptive and define minimum requirements for coating mass without reference to durability.

There is a significant difference between the various galvanized and other zinc based coatings in their physical and metallurgical characteristics, and in particular, their durability.

The differences in these coatings in terms of durability are poorly understood at specifier level, and as a result, many products are selection for critical construction applications that do not deliver the expected maintenance free life.

It is not possible to determine the characteristics of many zinc-based coatings simply by their appearance, as coating durability is a function of coating mass (coating thickness), which can only be determined with specialised equipment.

The Galvanizers Association of Australia (GAA) has initiated a program to identify its members' hot dip galvanized products with a Durability Certification label that will allow specifiers and consumers to obtain durability information on the particular galvanized product.

## 2 ZINC COATING PARAMETERS AFFECTING DURABILITY

The most significant factor affecting zinc-based coating durability is coating mass. This is usually specified in grams per square metre ($g/m^2$). In practice, coating mass is usually converted to a relative coating thickness to allow non-destructive testing of the coating to be done with an appropriate thickness gauge, where the coating thickness is defined in microns (µ).

Other factors affecting coating durability include the method of zinc coating application, the presence of other alloying elements in the coating and the existence of surface treatments applied as an integral step in the coating process. A brief description of the main non-proprietary zinc based coatings and their method of application follows.

### 2.1 Zinc electroplating

Zinc electroplating involved immersing pre-treated components in a zinc plating solution and applying a DC current. Zinc electroplating is widely used as a coating on builders' hardware, fasteners and appliance components.

The coating consists of pure zinc with the coating thickness rarely exceeding 15µ and generally measuring less than 10µ.

The coating produced is bright and smooth. Chromate post treatment on some electroplated products is done to improve durability performance and is characterised by a yellow-brown colour.

### 2.2 Continuous or in-line galvanizing

Sheet, wire and some hollow and open sections are galvanized in a continuous process, where the pre-treated steel passes through a galvanizing bath at speeds up to 180 metres per minute. Control systems in the process closely control the coating thickness within the limits of the process. Coatings exceeding 300 g/m$^2$ are rarely applied in these processes and coatings are more commonly in the 15-25µ range.

The coating consists of largely pure zinc with a thin (less than 5µ) zinc-iron alloy layer at the steel/coating interface.

The coating produces is smooth and uniform and may have a `spangled' appearance that arises from alloying elements in the zinc – specifically lead.

Continuously galvanized coatings are applied to semi-finished products, which are always subject to further processing. This results in areas of the steel in the finished being uncoated because of cutting and punching.

### 2.3 Hot dip galvanizing

Batches of fabricated items are immersed in a bath of molten zinc after pre-treatment for periods ranging from 3-10 minutes, depending of the mass and shape of the articles. This produces a relatively thick coating that will vary in appearance depending on the surface condition of the steel, its chemistry, its shape and other design elements.

The coatings consist largely of zinc-iron alloys (75%+) with a surface coating of zinc. The zinc-iron alloys are hard and relatively brittle. This metallurgical characteristic results in the significant differences in abrasion resistance and flexibility when compared to continuously galvanized coatings.

Hot dip galvanized coatings are applied to steel items after fabrication and thus all surfaces are coated. Coating thickness variation will occur as a result of the orientation of the work to the galvanizing bath that affects drainage characteristics. The hot dip galvanized coating can be variable in thickness due to local variations in the surface chemistry of the steel.

Hot dip galvanized coatings range from around 40µ in thickness on thin (less than 3 mm) steel sections to over 200µ on heavy structural sections.

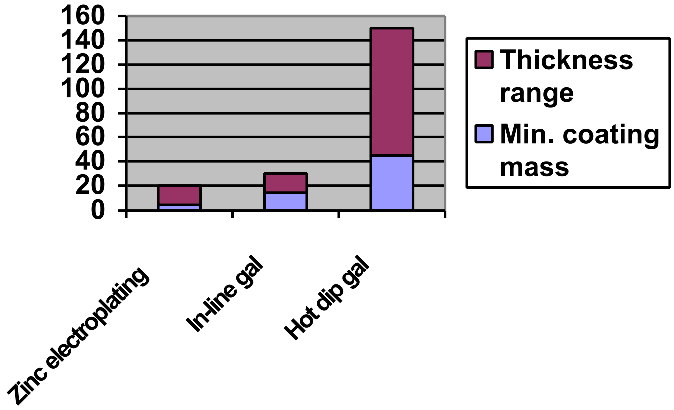

**Figure 1. Zinc (galvanized) coating thickness applied by different methods**

## 3 COATING LIFE AND COATING THICKNESS

Galvanized (zinc) coatings behave differently to applied organic coatings in that their life is determined by the rate at which they oxidise from the surface. In atmospheric exposures, the rate of corrosion is approximately linear and is determined by the classification of the environment.

Thus, the coating thickness is the most important element in determining the maintenance free life of a zinc-based coating. Other secondary, but still important factors determine corrosion rates of zinc (galvanized) coatings. These include orientation of the surface, degree of sheltering. Recent CSIRO test programs have indicated that the presence of significant zinc-iron alloy layers, absent in continuously galvanized products, and always present in hot dip galvanized products may have significantly lower (2X-3X) rates of corrosion that zinc coatings.

This phenomenon provides a reliable method of determining the expected life of a zinc-based coating in any nominated environment, as long as the coating thickness can be determined.

There is a large body of corrosion data collected over 100 years on the corrosion rate of zinc. In more recent times, computer modelling of surface oxidation reactions has been added to the empirical data to further refine corrosion rate data for a wide range of actual and theoretical environments.

Go Back Next Page

The International Standards Organisation (ISO) has developed a suite of standards to quantify zinc corrosion rates and classify environments to which they are exposed.

The key ISO standards are:

ISO 9223 – *Corrosion of metals and alloys – Corrosivity of atmospheres – Classification*

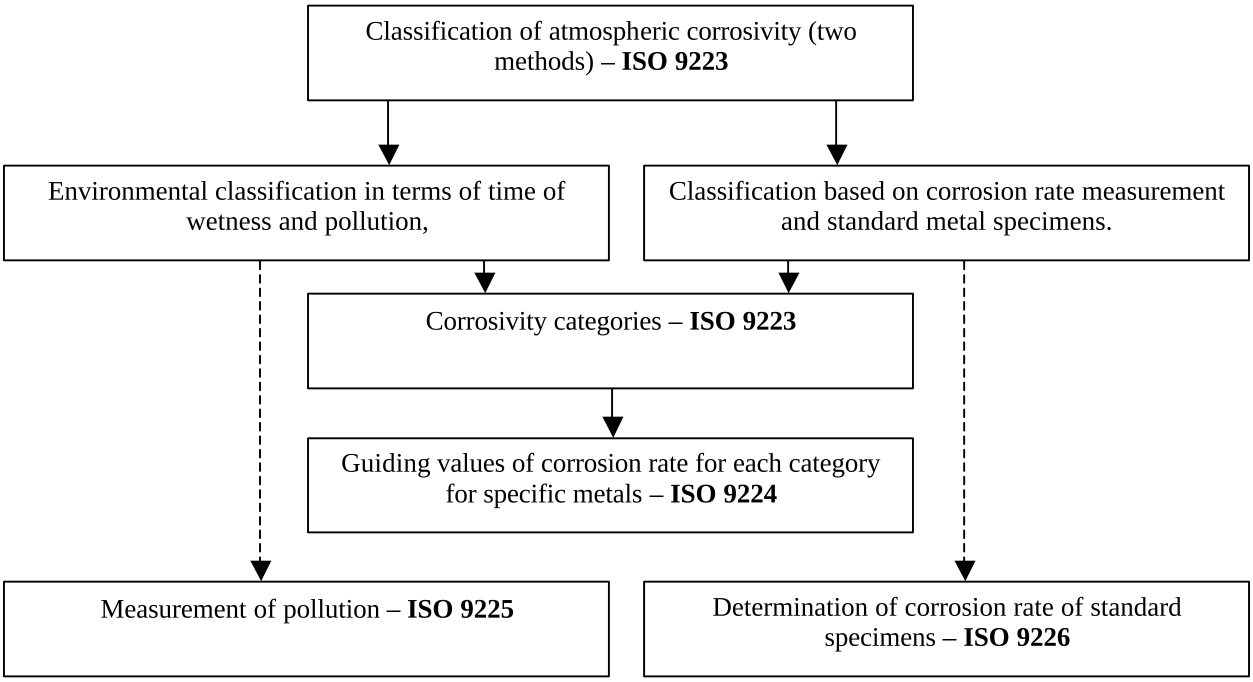
ISO 9223 – *Corrosion of metals and alloys* - *Corrosivity of atmospheres – Guiding values for the corrosivity categories*

ISO 9225 – *Corrosion of metals and alloys – Corrosivity of atmospheres* - *Measurement of Pollution*

ISO 9226 - *Corrosion of metals and alloys - Corrosivity of atmospheres- Determination of corrosion rate of standard specimens.*

These standards take a structured approach to classifying atmospheres using time of wetness, temperature, chloride and $SO_2$ levels.

**Table 1. Classification of atmospheric corrosivity**



These ISO standards use a C1-C5 classification to define atmospheric corrosion classification. These categories are defined as follows:

**Table 2. Categories of corrosivity of the atmosphere**

| **Category** | **Corrosivity** |
|---|---|
| C1 | Very low |
| C2 | Low |
| C3 | Medium |
| C4 | High |
| C5 | Very high |

These ISO categories are broad and non-descriptive and need to be related to practical environments to which they are applied. AS/NZS 2312 has used ISO 9223 to produce a set of atmospheric classifications more appropriately descriptive of regional environmental exposures.

These are:

1. *Interior exposure (ISO Category C1)* - Steel corrosion rates less than 1.3µ/year.
2. *Mild (ISO Category C2)* - Steel corrosion rates up to 10µ/year. Most rural environments are in this classification.

3. *Moderate (ISO Category C2)* - Steel corrosion rate from 10-20µ/year. Most capital city and suburban areas are in this classification.
4. *Tropical (ISO Category C2)* – In Australia, this includes coastal areas north of the Tropic of Capricorn. This is a category that cannot be readily delineated by ISO 9223 parameters. Measurements put this into an ISO C2 category for metals but it is classed as more aggressive for organic coatings.
5. *Industrial (ISO Category 3-4)* – First year steel corrosion rates greater than 25µ/year, but may extend into ISO Category 4 (50µ/year). Significant reductions in industrial pollutant levels through regulation has resulted in Australian heavy industrial centres being in the lower range of corrosivity classification.
6. *Marine (ISO Category 3)* – First year corrosion rates of 25-50µ/year, and within 1 km of the ocean. Topography and climatic conditions will influence the transport of chlorides, which are the major determining factor.
7. *Severe marine (ISO Category 4-5)* – First year steel corrosion rates exceeding 50µ/year includes off-shore and coastal areas subject to ocean surf and prevailing on-shore winds. Most of the Australian oceanfront with exception of those areas sheltered by reefs and islands are represented in this category.

While there is relativity in the corrosion rate of zinc and steel in a given corrosivity classification, it is not constant across all corrosivity classifications.

Table 3 lists typical corrosion rate ranges in the above AS/NZS 2312 atmospheric classifications.

**Table 3 – Typical corrosion rate range – Zinc and steel**

| **Corrosivity classification** | **Corrosion rate zinc - m/year** | **Corrosion rate steel - m/year** | **Zinc/steel corrosion ratio (approx)** |
|---|---|---|---|
| Mild | <1 µ/year | <10 µ/year | 1:10 |
| Moderate | <2 µ/year | 10-20 µ/year | 1:20 |
| Tropical | < 2 µ/year | 20-50 µ/year | 1:50 |
| Industrial | 2-4 µ/year | 20-50 µ/year | 1:15 |
| Marine | 2-4 µ/year | 20-80 µ/year | 1:20 |
| Severe marine | 4->10 µ/year | 80-200 µ/year | !:20 |

By comparing this corrosion rate information with the measured or minimum specified zinc (galvanized) coating thickness, an accurate assessment of expected coating life can be made. e.g. An 84µ thick (600 g/m$^2$) hot dip galvanized coating in a *Moderate* corrosivity classification would have an expected coating life to first maintenance of 40+ years.

Other documents and standards, such as AS 3700 – *Masonry structures* use other nomclementure to define corrosivity classifications but these can be generally cross-referenced with the ISO protocols.

## 4 EXISTING BUILDING CODES AND STANDARDS

There is a large number of standards related to the application and constitution of steel coatings of all kinds, along with their pre-treatments. AS/NZS 2312:1994 *Guide to the protection of iron and steel against atmospheric corrosion*, references over 50 standards for various types of galvanizing, priming, paint, surface preparation and testing.

These standards are then referenced in other documents such as the Building Code of Australia (BCA) produced by the Building Code of Australia Board (BCAB), which is a federal government body convened to standardise state, territory, local government and building industry codes and practices.

Other organisations such as (CIS) Construction Information Systems (previously NATSPEC) provide specification services by pre-packaging standards and specifications into project related documents to facilitate the documentation and administration of project specifications.

The main focus of the BCA is to document engineering and safety standards for dwellings. It largely references other standards for durability information, and in some areas, such as shelf angles and lintels, contradictions exist within the referenced standards.

The main weakness with the BCA is that there are no clearly defined durability standards (e.g. that an element in a dwelling must have a design life of X years.)

The onus of performance thus frequently resides with the builder, and without enforcement, inadequately protected steel elements are used in many jurisdictions.

This is not necessarily because individuals wish to take short cuts, but because of the poor understanding of the differences in performance between metallic coatings on steel building products.

It is difficult, without the necessary measuring equipment or experience, to tell the difference between many zinc (galvanized) coatings and a the durability of a similar looking steel section may be reduced by 5X due to the different technology that has applied the zinc (galvanized) coating.

## 5 STANDARDS RELATED TO VARIOUS ZINC-COATED PRODUCTS.

A suite of Australian (and NZ) standards covers the range of zinc and galvanized coatings that are applied to most building and construction products. Additional standards also cover coatings on specific products such as fasteners, which are not referenced here. These Standards are:

**AS/NZS 4680 -** Hot dip galvanized (zinc) coatings on fabricated ferrous articles**AS/NZS 4534 -** Zinc and zinc/aluminium coatings on steel wire
**AS/NZS 4791 -** Hot dip galvanized (zinc) coatings on ferrous open sections applied by a continuous or specialised process.
**AS/NZS 4792 -** Hot dip galvanized (zinc) coatings on ferrous hollow sections applied by a continuous or specialised process.
**AS 1397 -** Steel sheet and strip – Hot dipped zinc coated and aluminium/zinc coated coated
**AS1789 -** Electroplated coatings – Zinc on iron and steel
**AS 4750 (Int.)** – Electro-galvanized (zinc) coatings on ferrous hollow sections.

Each of these standards defines coating mass/coating thickness requirements and the method of designation, using a coating descriptor and a number representing the mass per $m^2$ of the coating.

For example, Z is used for zinc (galvanized), ZA for zinc-aluminium alloy, E for electroplated and ILG for in-line galvanised tube and open sections. The numeral (150, 300, etc) is the coating mass in $g/m^2$.

All standards with the exception of AS 1397 specify the single-side coating mass. AS 1397 specifies the total coating mass on both sides of the galvanized sheet. Thus a Z350 class coating on galvanized sheet is equivalent to a Z175 class on other galvanized products. This, in itself, is a constant source of confusion to specifiers attempting to define durability.

## 6 DURABILITY BRANDING OF ZINC COATED (GALVANIZED) STEEL PRODUCTS

The need to classify the performance of buildings and building components is well established. Local, state and federal authorities have implemented performance based `branding’ protocols to determine energy efficiency of buildings and the engineering and energy ratings of building elements such as windows.

`Star’ rating systems are commonly used on items and services as disparate as appliances and accommodation to certify the performance of the `product’ in a way that is easily recognised by the consumer.

The Galvanizers Association of Australia (GAA) has long been faced with the problem of differentiating the high performance, heavy-duty hot dip galvanized coatings applied by its members and the many other coatings that claim the same credentials as a `galvanized’ coating.

While the characteristics of many of these many coatings are clearly defined in the Standards relating to these coatings, these differences are sometimes reluctantly revealed to the marketplace and at specifier level. There is little knowledge of the specific Australian standards related to these types of products or their relative performance.

The first stage of the national Durability Branding Program being implemented by the GAA involves the certification of its members’ hot dip galvanized products with a labelling system that will allow specifiers to easily identify coating durability with an identifier attached to the product (sticker, label, tag).

Because the corrosion rate of galvanized coatings is essentially linear, and the coating thickness is clearly defined by the process and is relative to steel section thickness and process metallurgy, a clear definition of galvanized coating durability can be provided on products hot dip galvanized after fabrication.

GAA member galvanizers have accredited coating measuring equipment to accurately determine coating thickness on any steel section processed.

By allocating one `Star’ for each 25 microns of galvanized coating thickness, a rating system covering the full range of hot dip galvanized coatings can be provided. The `Stars’ are then related to an atmosphere corrosivity classification table to give an immediate determination of coating life expectancy in any environmental classification.

A sample of a GAA Durability Branding Certificate is illustrated in *Figure 2*

This labelling system provides a simple and comprehensive identifier for specifiers seeking to have galvanized coatings supplied to a performance standard.

## 7 COATING CERTIFICATION

Where independent certification of the coating is required, this is available through organisations such as CSIRO or BRANZ, who are already actively involved in product and coating evaluation and also support the development of performance-based standards as a policy.

BRANZ (Building Research Association of New Zealand) has considerable regulatory authority to enforce durability-based standards in New Zealand. A minimum building design life of 50 years for structural elements and lower specified life for more easily replaced components.

The protocols established by BRANZ in New Zealand could well be duplicated by Australia's BCA in providing a regulatory framework with more enforceable elements that the present BCA.

The long-term aim of the Durability Branding initiative is to expand the program to include a full range of coated steel products used for building and construction, including fasteners, coated cladding and roofing, and process controlled paint coatings such as powder coating.

Because of the nature of these various coatings, independent methods of durability certification will need to be developed to allow them to durability certified. Both CSIRO, BRANZ and other testing organisations have developed accelerated durability testing procedures that may satisfy the requirements for defining long-term durability performance.

Certification of zinc coated (galvanized) of products outside the jurisdiction of the GAA can also be done through one the above certifying agencies using the same performance parameters as are proposed by the GAA.

This will allow a large range of existing steel building products to be `Durability Certified', by having them submitted for certification to the certifying agency by their supplier/manufacturer. This may not be a welcome initiative with many existing steel building products, in particular builders' hardware and some in-line galvanized light structural and hollow sections, is the relatively poor performance of the zinc coatings on these products in outdoor exposures will be immediately evident to the consumer.

Many of these `galvanized' products would not rate one ☆ using the GAA Durability Certification and this will ensure that the higher durability products get due consideration in the selection process, where they are currently disadvantaged because of the low cost of those coatings with less durable zinc (galvanized) coatings.

## 8 CORROSION MAPPING DEVELOPMENTS FOR DURABILITY MANAGEMENT

In 2001, Industrial Galvanizers Corporation and the CSIRO entered into a research agreement to develop an Internet based Corrosion Mapping System (CMS) to provide on-line environmental corrosion data for a range of materials, but specifically steel and galvanized coatings.

The CMS will allow specifiers to obtain corrosion rate data in any location in Australia and relate this to durability, given section or coating thickness of the material being evaluated.

While this has been developed independently by Industrial Galvanizers, the synergy with the Durability Branding program is obvious, as it not only allows the Durability Certification provided through GAA members and other participants to be verified independently (all the corrosion data comes from the CSIRO's database) but also allows durability assessments to be made on existing galvanized steel products.

The CMS is expected to be fully operational by January 2002 and a demonstration version is available on the *Technical* page at www.indgalv.com.au.

## 9 SUMMARY

It is not possible to accurately determine the durability of structures unless the components used in their construction are able to satisfy the durability requirements of the design. Without a method of certifying the durability of coated steel products, the selection of materials becomes subjective and is often dictated by expediency and cost rather than performance.

Premature corrosion of steel building components is one of the major causes of degradation and impacts on the life-cycle costs of the building, its future value and its safety.

Support of this GAA Durability Branding initiative by the specifying community, and by the administrators of building codes at national, state and local government level will ensure; that optimum material performance is incorporated into buildings; that environmental impacts caused by corrosion are eliminated; that maintenance costs are minimised and that a technically sound basis for determining durability is available at the 'point of sale' using Durability Certification labelling.

The development of broader-based Durability Branding protocols for other coated steel building products will ensure that better control of building durability can be implemented from the design stage through to construction.

The long-term strategy is to facilitate the development of Australian standards and building codes that incorporate performance-based durability requirements, and ultimately extend this to ISO standards so that international practices are consistent in ensuring the durability of coated steel construction materials.

# Biofilms On Porous Building Materials: Friend Or Foe?

EJ Polson[1] JO Buckman[1] D.Bowen[1] AC Todd[1] MM Gow[2] & SJ Cuthbert[2]
[1]Department of Petroleum Engineering Heriot-Watt University Scotland.
[2]School of Biological Sciences University of Paisley Scotland

**Summary: Current models generally view biofilms as having a detrimental role in the weathering process of building materials. The work covered by this paper will highlight that this may not be the complete story.**

**The degradation of many building materials is directly linked to the occurrence and movement of fluids within their porous structure, leading to secondary problems such as freeze-thaw damage, salt shattering, clay swelling, mineral leaching and precipitation. It is also thought that biofilm development on porous materials compounds this problem by absorbing water and acting like a wick in the transport of fluids from the external environment into the matrix of the building material.**

**However, experimental results indicate that biofilms can demonstrate hydrophobic properties, repelling water and consequently inhibiting the passage of water into the porous network of building materials. The water phase wettability of quartz was used to assess this characteristic.**

**The initial wettability of quartz fragments was determined using an environmental scanning electron microscope (ESEM). This showed the quartz fragments to be hydrophilic. The quartz fragments were then inoculated with microbes and incubated, facilitating biofilm development on their surfaces. The quartz fragments were re-examined using the ESEM, showing that quartz fragments coated in biofilm displayed hydrophobic behaviour. Hence, the addition of a biofilm to quartz can change the surface characteristics from hydrophilic to hydrophobic.**

**As quartz is the major component of sandstone this may help to understand the durability of sandstone undergoing water infiltration. Since biofilm development is usually associated with areas of building facades that are prone to water logging, the presence of the biofilm itself need not necessarily be a contributing factor to the problem. *In situ* biofilm may in fact impede ingression of external water sources into porous building materials by behaving as a water resistant layer. On the other hand the presence of a hydrophobic biofilm layer may add to the problem of water retention within porous building materials. Regardless of whether fluids are prevented from ingressing or egressing by hydrophobic biofilm barriers, either will have profound implications for the durability of porous building materials.**

**KEYWORDS: biofilm, wettability, sandstone, weathering, protection.**

## 1 INTRODUCTION

Previous research has shown that building materials, such as sandstone, limestone, granite, concrete and mortar, which are used in diverse climates, are readily colonised by microbes when the environment for growth is favourable. The microbes that have been studied include bacteria, cyanobacteria, fungi, lichens, and to a lesser extent algae (Paine *et al.* 1933, Milde *et al.* 1983, Palmer & Hirsch 1991, Urzi *et al.* 1991, Zherebyateva *et al.* 1991, Adams *et al*. 1992, De La Torre *et al.* 1993, Urrutia & Beveridge 1995, Jozsa *et al.* 1996, Wilimzig & Bock 1996, Ferris & Lowson 1997, Flores *et al.* 1997, Urzi & Realini 1998, Uchida *et al*. 1999).

Microbial-rock interactions are of considerable interest as microbes are thought to have a significant role in the degradation of building materials (Lyalikova & Petushkova 1991, Bock & Sand 1993, Hirsch *et al.* 1995a, b, Viles 1995, Barker & Banfield 1996, Palmer & Hirsch 1996, Feldman *et al.* 1997, Barker *et al.* 1998, Rogers *et al.* 1998, Papida *et al.* 2000). The problems associated with microbial attack include chemical and mechanical weathering. Chemical mechanisms include: dissolution, precipitation, and alteration of mineral phases (Henderson & Duff 1963, Weed *et al.* 1969, Huang & Keller 1970, Lauwers & Heinen 1974, Halsey *et al.* 1995, Paris *et al.* 1995a, b, Spirakis 1996, Barker & Banfield 1998, Ehrlich 1998, Sweevers *et al.* 1998, Chigira & Oyama 1999; Labrenz *et al.* 2000, Liermann *et al.* 2000). Mechanical mechanisms include salt shattering, mineral expansion, freeze-thaw shattering, hydration-dehydration cycling and microboring (De La Torre *et al.* 1993, Halsey *et al.* 1995, Flores *et al.* 1997, Grondona *et al.* 1997, Wright 2000).

Microbes are also strongly associated with areas of high moisture retention such as areas of poor drainage. Once colonised in such areas they are thought to contribute to the problems associated with retention and or movement of moisture in the building material (Riley & Heiman 1996). However it has been demonstrated that biofilms can be a protective agent to building materials. An example of this was highlighted by Grondona *et al.* (1997) in their research surrounding the Casa Lis, a building in Salamanca in Spain which was built with Villamayor sandstone. In this instance, during restoration it was found that the sandstone that had developed an outer biofilm layer had suffered no underlying decay, whereas the sandstone that had no biofilm development was so severely altered that new stone was required to repair the damage. The preserved sandstone was apparently protected from salt crystal formation within the pores. Salt crystal formation within the pore space can cause salt shattering of the surrounding matrix. It is thought that the biofilm prevented evaporation of the fluid within the pore space, thus inducing a stable humidity that inhibited salt crystal formation. While the mechanisms at play in the biofilm are not fully understood, there is a high probability that the wettability characteristics may have had a significant role in preserving the sandstone.

The water phase wettability of a biofilm is an important factor effecting water placement and movement within porous building materials. Wettability describes the relative affinity of a fluid for a substrate (Walker 1999), and determines whether a fluid such as water will spread out across a substrate or be repelled and form discrete droplets. The degree of wettability is commonly measured by the contact angle that a droplet of fluid forms on a solid (Bascom 1992, Schoff 1992, Xie & Morrow 1998, Liu & Buckley 1999). In the case of water, when measured through the densest fluid phase, in this case the water itself, a low contact angle will be observed where the substrate is hydrophilic (Fig.1a), the water droplets form low domes, or occur as discrete sheets. Whereas, a high contact angle will occur on hydrophobic surfaces (Fig.1c), where water will occur in the form of discrete spherical droplets. Where a substrate is hydrophilic, it can be said to be water wet, which, under ambient conditions, is the case for most sandstones composed of predominantly quartz and feldspar (Barclay & Worden 2000). Whereas those that are hydrophobic, such as some calcitic limestones are regarded as oeleophilic, or oil wet (Barclay & Worden 2000). The wettability of a biofilm will therefore affect the relationship between water and a substrate, either on, or within the porous building stone. Wettability will influence the biofilms ability to retain water, as well as affecting the combined biofilm and rock substrate's permeability, and thereby exert a control upon the location and movement of water within the biofilm-porous building material system. As many potentially damaging processes such as leaching, salt shattering and freeze-thaw shattering depend upon the presence of water, the relative water wettability of a biofilm will have major implications for the durability of porous building materials.

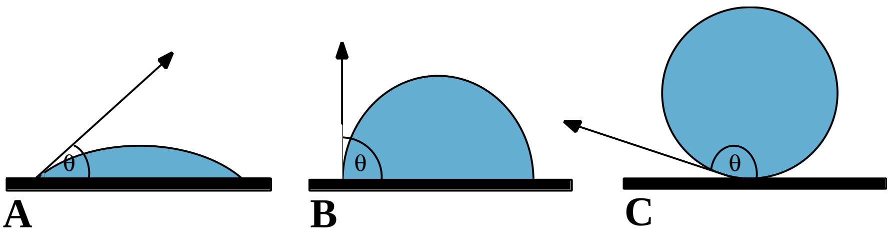

**Figure 1. Contact angles of water droplets, measured in a water vapour atmosphere, on a solid surface (e.g. quartz and biofilm). A) Low contact angle (< 90°), forming on an hydrophilic surface. B) Intermediate contact angle (~90°), forming on a surface of intermediate wetness (neither hydrophilic nor hydrophobic). C) High contact angle (>90°), forming on an hydrophobic surface.**

The wettability of any building material is a controlling factor upon the movement of water on its surface or within its pore spaces. The work highlighted in this paper will show that biofilms that grow on building materials can in fact alter the original wettability of that building material. In some instances this could be favourable and in others less so. The organisms studied include a mixed bacterial-fungal biofilm, an algal biofilm, and a lichen, all of which demonstrated different wettabilities.

## 2 Materials and Methods

### 2.1 Sample preparation

An analytical grade quartz crystal was placed on an oil free sterile surface and crushed with a sterile hammer. Thirty small chips approximately 2-3 mm in length were selected from the debris and stored in individual sterile Petri dishes. The chips were taken from the inner region of the crystal to ensure that only fresh, uncontaminated material was utilised. The quartz chips were handled at all times using sterile forceps to avoid contamination.

### 2.2 Initial wettability

Using a Peltier stage equipped Phillips XL30 ESEM with $LAB_6$ gun, and a 500 micron aperture Gaseous Secondary Electron Detector (GSED), the initial water phase wettability of each quartz chip was established.

The chips were pre-cooled in a standard refrigerator, placed on the Peltier stage in the ESEM chamber and maintained at 5°C. Wet mode was selected from the ESEM controller, and the chamber was pumped to 5 Torr. Upon attaining 5 Torr, the chamber was passed through up to five 'flooding' cycles from 5 to 10 Torr. Flooding with water vapour provides a suitable atmosphere for charge suppression, facilitates image amplification, maintains sample hydration, and most importantly to this experiment, supplies a wetting medium, water.

Chamber pressure was then increased to 6.5 Torr. At a pressure of 6.5 Torr and a temperature of 5°C, relative humidity reached 100%, and water condensed on to the surface of the sample. Observations of water droplet morphology (contact angle) were then recorded.

Where necessary (i.e. if flooding occurred), the whole process was repeated by pumping the chamber to 3 Torr, effectively sublimating all surface water, and returning to 6.5 Torr to repeat the procedure.

Images were acquired at a temperature of 5°C, a pressure of 6.5 Torr, a working distance of approximately 7.5 mm, an operating voltage of 20 kV, and a spot size of between 4 and 6.

Elemental analysis was carried out on each sample to ensure that the quartz chips used were completely pure. An Energy Dispersive X-ray Detector (EDX) was used at pressure 5 Torr and working distance 10 mm. X-rays were collected for 100 live seconds, with a count rate of approximately 1500 and a dead time of approximately 30%.

### 2.3 Biofilm development

In order to coat the quartz fragments with biofilm, a suitable inoculum was prepared. One 0.1 ml loop of each microbial culture was taken from 8 pure isolates of bacteria and one pure isolate of fungi. The loops of microbes were transferred into a conical flask containing 250 ml of Medium X (a growth medium composed of 50% nutrient broth and 50% malt extract broth). The microbial mixture was incubated at 25°C for 2 days to facilitate the development of a microbial consortium.

Using sterile forceps, 20 quartz fragments were individually transferred into twenty 100 ml conical flasks. Ten of the conical flasks contained 25 ml of distilled water and 10 ml of Medium X. Ten of the conical flasks contained 25 ml of distilled water. The flasks were sealed and sterilised in an autoclave for 15 minutes at 121°C. Once sterilisation was complete and the flasks cooled to room temperature 10 ml of the bacterial-fungal inoculum was added to the 10 flasks containing distilled water. This was carried out using strict aseptic technique. The remaining 10 flasks of distilled water and medium were left intact to provide a control, allowing any effects caused by the water and medium to be observed. All 20 flasks were incubated as above for 2 days; encouraging biofilm development on the 10 inoculated quartz chips.

Following the incubation period the contents of each flask were emptied individually into separate sterile Petri dishes, allowing the quartz chips to be easily isolated.

For the algal biofilm analysis, the above process was repeated using 10 quartz chips, 5 for biofilm development and 5 for controls. The biofilm in this instance was composed of 3 axenic green algal cultures. The broth medium used was Euglena Gracilis Medium (EG) and Jaworski's Medium (JM) in a 1:1 ratio. The biofilm was cultured over 4 days at 16°C in an incubator set at a 16hr light / 8hr dark cycle.

For the lichen analysis a single sample of lichen was removed from a sandstone building and examined. The sample was not cultured.

### 2.4 Secondary wettability

The inoculated quartz chips and the control quartz chips were checked for the development of biofilm, and changes in wettability, using the same method of assessment as initial wettability. The results were imaged and stored using exactly the same method as for initial wettability. The lichen was examined under the same conditions as the biofilms.

C) High sphericity hydrophobic droplets on bacterial biofilm grown on quartz. D) High sphericity droplets and high domes, on hydrophobic bacterial-fungal biofilm. E) Quartz surface with algal biofilm. F) The same surface as in (E), displaying hydrophilic low domed drops of water. Two areas with algal cells indicated with arrows.**

## 3 RESULTS

The results of the initial wettability assessment showed that all 30 quartz chips displayed hydrophilic properties and hence their wettability could be described as water wet. Water wetting was typified by low dome droplets displaying contact angles of considerably less than 90°, (Fig. 2a).

The results of the secondary wettability assessment showed that the 10 quartz chips exposed to the bacterial-fungal consortium successfully developed a biofilm (Fig. 2b). The wettability of the quartz chips coated in this biofilm changed from hydrophilic to hydrophobic, typified by high dome droplets with contact angles of > 90°, (Figs 2c, d).

The 5 quartz chips exposed to the algal consortium successfully developed biofilms (Fig. 2e). The wettability of the quartz chips coated in algal biofilm remained hydrophilic, indicated by the low dome droplets of water on the algal surface (Fig. 2f).

The 15 quartz chips used as controls (i.e. those not exposed to microbes), retained their initial hydrophilic wettability (Figs 3a, b).

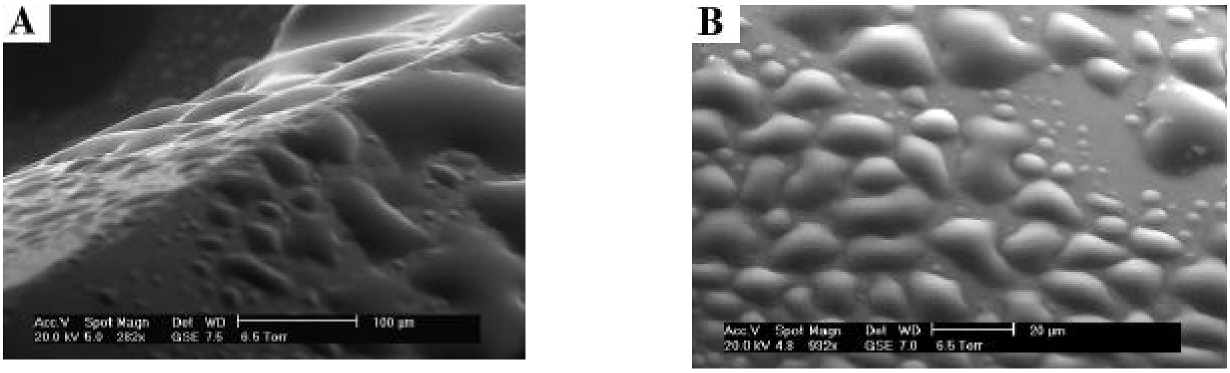

**Figure 3. Control samples: A) Quartz control sample from the bacterial-fungal experiment; B) quartz control from the algal experiment. Note both display low domed droplets of water and are hence still hydrophilic**

The EDX analysis confirmed that the quartz samples used were in fact pure $SiO_2$ and the results were not due to inorganic contamination.

The lichen displayed mixed wettability (Fig. 4b).

## 4 DISCUSSION

The initial wettability of the 30 quartz chips was hydrophilic. This was the expected result, as quartz is widely recognised as such at ambient conditions (Barclay & Worden 2000). The secondary wettability of the 15 control chips remained unchanged, indicating that the water + Medium X broth and the water + EG:JM broth had no impact on the wettability of the quartz chips. Hence, it can be clearly stated that the secondary wettability changes in the inoculated samples were due to biofilm development and no other causes.

Of the 10 samples that underwent bacterial-fungal biofilm development, the wettability altered from hydrophilic to hydrophobic. This was most likely due to an interaction between the water and the bacterial-fungal cellular or extracellular material. The actual biomatter responsible and the mechanisms involved were not investigated, however, it is well known that hydrophobin, a fungal protein, has hydrophobic properties (Wosten *et al.* 1995).

Of the 5 samples that had algal biofilm development, the wettability remained hydrophilic. This indicated that the biomatter involved yielded a similar reaction to the water phase as the quartz.

The sample of lichen that was analysed showed a mixed wettability profile. The portion of the lichen that appeared to be fungal in nature demonstrated hydrophobic tendencies, the portion that appeared to be algal demonstrated hydrophilic tendencies. Given the nature of the biofilm wettabilities outlined above, this was not entirely unexpected.

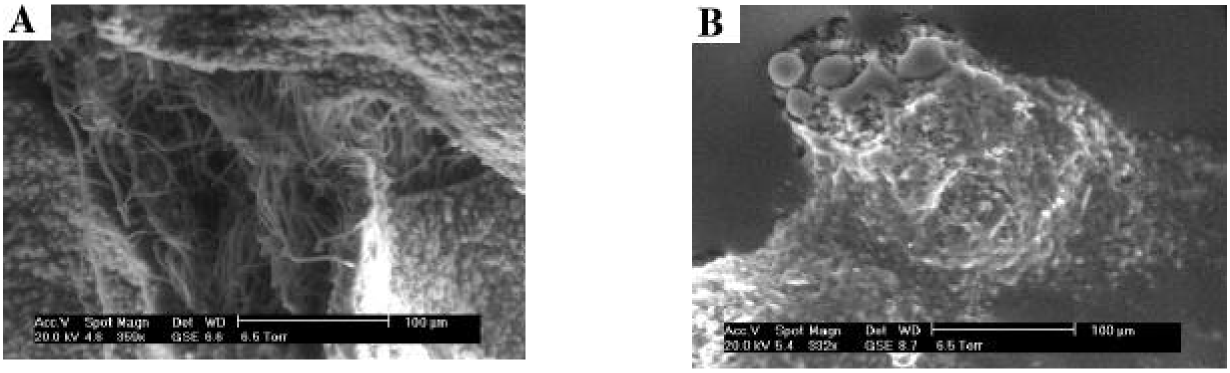

**Figure 4. A) Image of Lichen showing typical morphology, of 'fungal' hyphae and 'algal' cells. B) Typical variation in wettability across lichen. 'Fungal' hyphae (top left) are hydrophobic, indicated by spherical droplets of water, while 'algal' areas (bottom right) have sheets of water on them, typical of hydrophilic substrates.**

It appears to be quite clear that there is no general pattern of wetting characteristics that can be applied to microbes. The characteristics vary from kingdom to kingdom, and quite probably from species to species, therefore no broad assumptions can be made concerning the detailed relationships and interactions between biofilm and water. A biofilm may be predominantly hydrophilic, hydrophobic, or comprise a complex mixture of both.

The consortiums used in this research are quite artificial. In nature biofilms are complex three-dimensional networks comprising many different species of algae, bacteria, fungi and lichens (Bock & Sand 1993, Palmer & Hirsch 1996, Flores *et al*. 1997, Grondona *et al*. 1997). As this is so, they will therefore posses highly varied wettability characteristics, which will have many potential affects on the durability of porous building stone materials. A number of possible scenarios are briefly outlined below:

Hydrophobic biofilms, such as those produced by the bacteria and fungi examined during the present study, are likely to have an important role in controlling water migration through porous building materials. As neither bacteria nor fungi are restricted to the photic zone, they are at liberty to infiltrate deeply into building materials. Previous studies have indicated that bacteria in the presence of water can penetrate several centimetres into sandstone cores (Myers & McCready 1966, Myers & Samiroden 1967, Mills 1997). It is therefore feasible for such hydrophobic biofilms to develop over a much wider range of environments than algal biofilms.

Where an hydrophobic bacterial biofilm develops on the outer surface of a building stone, it could potentially act as a natural waterproofing to the building, possibly preventing ingress of water (Fig. 5a). This could reduce freeze thaw damage, salt shattering, and mineral dissolution and could leave the building stone in a less damaged condition than one without a biofilm *in situ*.

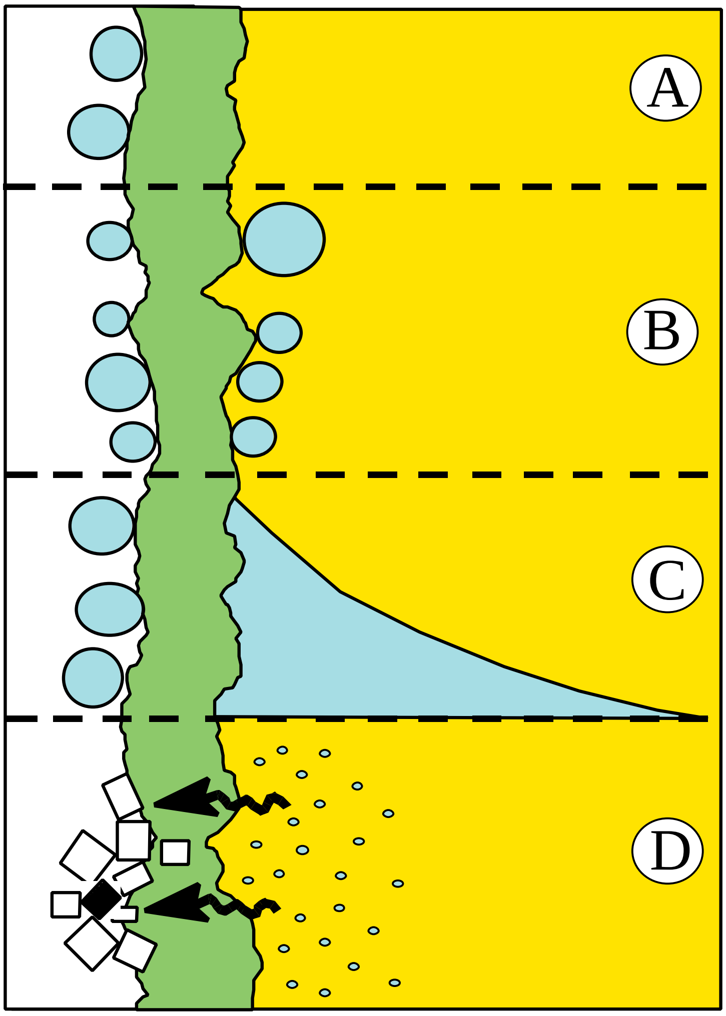

**Figure 5. Schematic section through a block of porous building material (sandstone), with a biofilm developed on the outer surface (left hand side). Key: yellow = sandstone, blue = water, green = biofilm. A) Biofilm with hydrophobic external surface. B) Biofilm with hydrophobic external and internal surfaces. C) Biofilm with hydrophobic external surface, and water ponded behind the internal surface. D) Biofilm with high humidity behind the internal surface, and salt crystals forming along the outer surface.**

However, if water is able to penetrate the structure from another direction (e.g. ingress from above, capillary rise, or possibly through condensation from within the building), it is equally possible that this water could be retained behind the biofilm (Fig. 5b). This is likely if the adhesive layer of the biofilm is hydrophobic. If this scenario occurred, the build up of water trapped behind the biofilm may accelerate the damage caused by mechanisms such as chemical leaching and frost shattering.

In extreme cases ponding of water could occur within the building stone and once again increase chemical leaching, clay swelling, salt shattering and freeze-thaw shattering (Fig. 5c).

On a more positive note, it is also possible that a hydrophilic biofilm could act as a wick and transport dissolved salts to the surface of the biofilm where they can crystallise harmlessly (Fig. 5d), thus preventing salt shattering and eventual spalling. This has already been noted by Grondona (1997).

Hydrophilic biofilms (for example comprising predominantly of algae), may act as water wicks, retaining water within the biofilm and perhaps transporting it into the porous matrix. The impact of such biofilms, at least in terms of water penetration into porous building materials such as sandstone is however likely to be limited. Most sandstones are already highly hydrophilic, being dominated by quartz, feldspar and clays such as illite, all of which are hydrophilic (Barclay & Worden 2000). Nevertheless, in cases where sandstone porosity is lined by more hydrophobic mineral cements such as calcite and dolomite, algal biofilm may have a more important role in the penetration of water into the substrate. The same will also be true for porous carbonates (such as oolitic limestone), where an algal biofilm could change pore walls from hydrophobic to hydrophilic. This would allow water to penetrate into building materials via the hydrophilic biofilm, thus bypassing pores that otherwise would have prevented or slowed down water movement through the pore space due to their hydrophobic nature. However, as algae are photosynthetic, such effects would be limited to the outer skin of any porous building material, and would therefore only effect the outer few millimetres of the building stone.

## 5 RECOMMENDATIONS

In order to assess the damaging or protective effects of the varying wettabilities of biofilms, each biofilm on a building should be examined with an open mind. A first approach to the interpretation of the biofilms wettability could be an *in situ* assessment achieved by applying small droplets of water to the biofilm. If this was not practical, a representative consortium could be grown on blocks of porous building material, under laboratory conditions, and observations made of single water droplets on the biofilm surface (Fig. 6). A second stage could involve a more detailed ESEM study of the natural biofilm, or the laboratory sample. Such an examination would determine the three dimensional architecture of the biofilm, elucidate the distribution of the various biofilm components, and define the wettability of each component present. The combined information could then be taken and used to model likely water migration pathways, and predict water distribution within the porous building material. The latter could then be used to predict likely mechanisms (involving water) that may affect the durability of that particular building material.

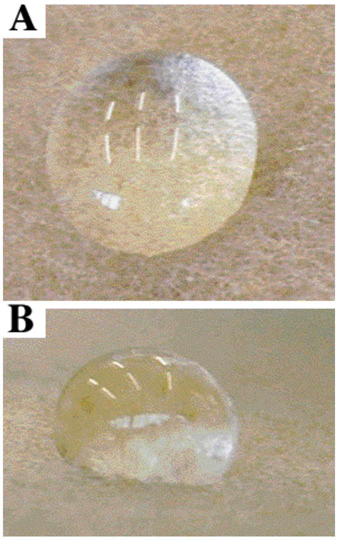

**Figure 6. A), B) Plan and side views of water droplets on a block of sandstone with a bacterial-fungal biofilm on the surface. Droplets have a high contact angle, being spherical in form, demonstrating the hydrophobic nature of the biofilm at the macroscopic scale. Droplets are approximately 2-3 mm in diameter.**

## 6 CONCLUSIONS

Biofilms of various types will readily colonise building materials. Analysis under ESEM has shown that the wettability of the underlying substrate can be dramatically altered by the presence of biofilm. The change can be towards either an hydrophilic or hydrophobic character. The implications for building materials can be either positive or negative. In some instances they can be protected from common weathering effects such as salt shattering and frost shattering, but in others the problems could be magnified. It is vitally important to asses the nature of biofilms present on buildings and monuments, just as important as assessing the properties of the building material. One must be sure if the biofilm is “friend or foe”.

## 7 ACKNOWLEDGEMENTS

This work was undertaken as part of an EPSRC funded studentship, held by E.J. Polson. The project was further supported through the Scottish Higher Education Funding Council (SHEFC), through the provision of a grant for the purchase and maintenance of an ESEM, which was used within this study. We would also like to thank David Wallace (University of Paisley) for his kind assistance.

# Service Life Prediction Of Reinforced Concrete Structures Exposed To Aggressive Environments

**KAT Vu & MG Stewart**
**Surveying & Environmental Engineering University of Newcastle Australia**

**Summary: In this paper, the service life of structures exposed to aggressive environments is measured by the probability of cracking and spalling of concrete cover. The time to corrosion cracking/spalling is experimentally investigated from accelerated corrosion testing of RC slabs with the emphasis on trying to quantify the relationship between concrete quality (w/c ratio; or strength), concrete cover, crack propagation and time. The probability of cracking and spalling of concrete cover is calculated by using a structural deterioration life-cycle reliability model. The reliability model includes the random spatial variability of concrete compressive strength, concrete cover and the surface chloride concentration. The reliability model also includes a stochastic deterioration model that considers the random variability of chloride diffusion, threshold chloride concentration and corrosion rates. Therefore, the reliability model can be used to predict the proportion of a concrete surface likely to spall for any reference period. This is a useful criterion for predicting the service life of RC structures.**

## 1 INTRODUCTION

Corrosion of reinforced concrete (RC) buildings, bridges and other structures is initiated mainly by chloride contamination, often in conjunction with inadequate cover and poor quality concrete. Chloride contamination can occur from the application of de-icing salts or sea-spray. Corrosion products (rust) are expansive, leading to the formation of tensile stresses in concrete and therefore subsequent longitudinal cracking and spalling of concrete cover. Corrosion-induced longitudinal cracking and associated spalling of the concrete cover are particularly common problems in concrete structures. Cracking and spalling may result in the quicker diffusion of aggressive ions, water and oxygen thus resulting in further reduction in bar diameter, further reduction of flexure and shear capacity and therefore shortening the service life of RC structures. As such, the incidence of spalling of concrete cover (probability of spalling) is the focus of this paper.

The observation of severe cracking or spalling of concrete cover indicates the need for repair or more frequent maintenance. This is classified as a serviceability limit state. Repair or rehabilitation costs can be extensive, and such expenditure may represent the end of a “maintenance free” (cost-free) service life (Stewart & Rosowsky 1998; Stewart 1999; Thoft-Christensen 2001). However, other definitions of serviceability failure for RC structures with corroding reinforcement have been used as well, including the initiation of corrosion (e.g. Troive & Sundquist 1998), the occurrence of first cracking (e.g. Weyers 1998), or when the percentage of reinforcement subject to corrosion exceeds a certain threshold (e.g. Amey et al. 1998).

A new limit state that would specify the tolerable extent of damage (e.g. in terms of percentage of concrete cover subject to spalling) may be necessary. Such information may be used, for example, in a life-cycle cost analysis to optimise repair or maintenance strategies (Stewart 2001). This will require the development of random field modelling that takes into account the spatial variability of corrosion initiation, propagation and cracking (e.g. Vu & Stewart 2001; Sterritt et al. 2001; Faber & Rostam 2001). This is the approach adopted in this paper where the service life of a structure is measured by the probability of corrosion-induced cracking and spalling of the concrete cover considering the spatially variability of corrosion initiation, propagation and cracking. The probability of cracking and spalling is estimated herein using a structural deterioration life-cycle reliability model for typical RC surfaces exposed to aggressive environments.

In this paper, crack initiation and propagation measurements obtained from accelerated corrosion tests of RC slabs are presented. The experimental design considered variability of concrete cover, concrete strength and water-cement ratio. An empirical stochastic model for crack initiation and propagation is then developed to predict the time to severe corrosion-induced cracking and spalling. The reliability model includes this new predictive model for time to severe cracking and spalling, as well as the variability of chloride diffusion, threshold chloride concentration, corrosion rates, reinforcement placement and environmental conditions. Concrete cover, water-cement ratio and surface chloride concentration are spatially variable which enables the proportion of a concrete surface likely to spall to be calculated for any reference time period.

## 2 CORROSION INITIATION AND PROPAGATION

Corrosion is initiated when the chloride concentration at the bar surface exceeds a threshold level ($C_r$). Chloride concentration is estimated by Fick's second law of diffusion since most of the available parameters are obtained from fitting Fick' s second law to experimental or field data. The chloride diffusion coefficient (D) is modelled as a function of concrete quality and concrete cover, according to Vu & Stewart (2000) as follows:

$$D = D_{H_2O} \times 0.15 \frac{1 + r_c (w/c)}{1 + r_c (w/c) + \frac{r_c}{r_a}(a/c)} \left[ \frac{r_c (w/c) - 0.85}{1 + r_c (w/c)} \right]^3 \tag{1}$$

where a/c is the aggregate-to-cement ratio; $\rho_c$ and $\rho_a$ are the mass densities of cement and aggregates respectively; $D_{H2O}$ is the diffusion coefficient in an infinite solution (=$1.6 \times 10^{-5}$ $cm^2$/sec for NaCl), and w/c is the water-cement ratio estimated from the concrete compressive strength using Bolomey' s formula.

Middleton & Hogg (1998) and others have reported that cover and concrete quality are observed to affect corrosion rates. When relative humidity is in the region of 70-85% the oxygen availability at the cathode and the electrical resistivity of concrete are factors affecting corrosion rates (e.g. Tuutti 1982; Yalsyn & Ergun 1996; Yokozeki et al. 1997). For many structures in Europe, U.S., Australia and elsewhere the average relative humidity is over 70%. Unfortunately, there are few quantitative models for predicting corrosion rates for these environmental conditions, except that corrosion rates ($i_{corr}$) for low, medium and high corrosion intensities have been estimated to be 0.1$\mu$A/$cm^2$, 1$\mu$A/$cm^2$ and 10$\mu$A/$cm^2$ respectively (Dhir et al. 1994). To isolate the effect of concrete quality (w/c ratio) and concrete cover it is assumed herein that the corrosion rate is limited by the availability of oxygen at the steel surface (e.g. Arnon et al. 1997). As such, the oxygen availability depends on concrete quality (w/c ratio), cover and environmental conditions. Therefore, corrosion rate is modelled as a function of concrete quality, cover and time since corrosion initiation (Vu & Stewart 2000); namely,

$$i_{corr}(1) = \frac{37.8\,(1 - w/c)^{-1.64}}{cover} \quad (\mu A/cm^2) \tag{2}$$

where $i_{corr}(1)$ is the corrosion rate at the start of corrosion propagation and cover is given in mm and

$$i_{corr}(t_p) = i_{corr}(1) \times 0.85 \times t_p^{-0.29} \qquad t_p \geq 1\ year \tag{3}$$

where $t_P$ is time since corrosion initiation and $i_{corr}(1)$ is given by Eqn. 2.

Statistical parameters for corrosion parameters are given in Table 1.

**Table 1. Statistical Parameters for Corrosion**

| *Parameter* | *Mean* | *Coefficient of Variation* | *Distribution* |
|---|---|---|---|
| Model Error (D) | 1.0 | 0.2 | Normal |
| $C_0$-de-icing salts | 3.5 kg/$m^2$ | 0.5 | Normal |
| $C_0$-coastal zone (within 100m of coast-line) | 2.95 kg/$m^2$ | 0.5 | Normal |
| $C_r$ | 0.9 kg/$m^3$ | 0.19 | Uniform [0.6–1.2] |
| Model Error ($i_{corr}$) | 1.0 | 0.2 | Normal |

## 3 CORROSION-INDUCED CRACKING AND SPALLING OF CONCRETE COVER

The incidence of cracking and spalling is more frequent than "collapse" and other ultimate strength limit states. The occurrence of longitudinal cracking and spalling of the concrete cover is referred to herein as a serviceability failure, and if not repaired may often be precursors to more critical and dangerous strength limit state problems. Of more relevance, however, is that the observation of cracking and spalling will normally require a re-assessment of structural integrity, more frequent inspections and the possible need for repairs – these will require the outlay of additional financial resources. In this study, the time to corrosion-induced cracking and spalling is studied by accelerated corrosion testing of RC slabs.

### 3.1 Accelerated Corrosion Testing

3.1.1 Materials and Specimens

In order to achieve the purpose of predicting the time to longitudinal cracking and spalling, experimental studies were conducted at The University of Newcastle, where typical RC specimens (slabs) were subject to accelerated levels of corrosion. The accelerated corrosion experimental programme is designed to simulate the corrosion of a section of a typical bridge deck structure. The tests consisted of two series. The first series of tests comprised of four specimens (two specimens had 25mm cover, the other two had 50mm cover). All specimens had the same water-cement (w/c) ratio (w/c=0.5), but differences in mix designs resulted in different concrete strengths. The second series of tests isolated the effect of w/c ratio and cover. These specimens had w/c=0.45 and w/c=0.58 and 25mm and 50mm covers. All specimens were 700mm x 1000mm rectangular slab with thickness of 250mm. The top mat of the slab contained four steel reinforcing bars, which were covered with electroplating tape to give exposed (bare steel) lengths of 1000mm.

Ordinary Portland cement was used in the mix and 3% of $CaCl_2$ by weight of cement were added to the concrete mix in order to induce corrosion along the length of exposed bars. The specimens were moist-cured for 28 days before testing. Standard test cylinders were tested at 28 days to determine concrete compressive and tensile strengths.

3.1.2 Testing Methodology

The active accelerated corrosion process was achieved by applying an electrical current to the bars. The accelerated corrosion equipment is shown in Fig. 1. The soffit of the specimen was immersed in a 5% NaCl solution. A current was then supplied to the bar (the anode) by a power supply via a current regulator (LM317LZ Voltage regulator IC one per bar), and the cathode was a stainless steel plate submerged in the NaCl solution. The current regulator kept the current constant over time, in this case equivalent to a corrosion rate of $100\mu A/cm^2$. This is equal to the highest corrosion rate recorded in concrete structures (most corroding structures experience 1-2 $\mu A/cm^2$). This high current allows a short period of testing, but kept the corrosion rate within the highest limit of the natural values found in real structures.

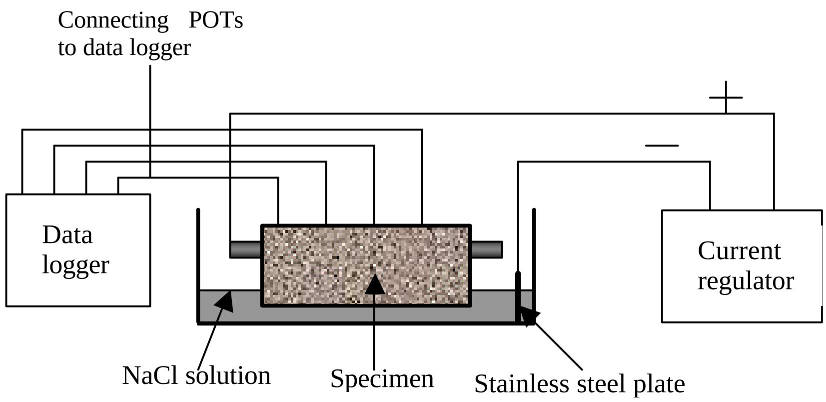

**Figure 1. Experimental Set up of Accelerated Corrosion Test**

The appearances of first visible cracking were detected by crack detector gages, which were installed on the concrete surface above the bars and also were verified by frequent visual observation using a magnification glass with an accuracy of 0.05mm. Concrete surface deformation before first visible cracking was also measured by strain gages.

Crack development after the first appearance of visible cracks was recorded using 10mm linear potentiometers displacement transducers (POTs - Sakae 8FLP10A 1000ohm conductive film potentiometer), which were glued on both sides of the crack. There were in total 12 POTs on each specimen to measure crack development. Hence, the crack width measurements presented herein is the mean value of data read from 12 POTs. The data collected for crack propagation will provide the timing of first cracking and the subsequent time-dependent increase in crack width. After testing, the weight loss of bars due to corrosion were studied by cleaning, drying and weighing the reinforcement bars according to the gravimetric weight loss method as specified by Standard Practice for Preparing, Cleaning, and Evaluating Corrosion Test Specimens (ASTM G1 – 90). The weight loss corresponded closely to that expected from $i_{corr}$ measurements.

### 3.2 Results from Accelerated Corrosion Tests

3.2.1 Crack Initiation ($t_{1st}$)

The term -“first cracking”- used herein is the first visible crack, which was observed through a magnifying glass (hairline crack of width less than 0.05mm) and this period of time ($t_{1st}$) can be referred to as time to crack initiation. Test results indicated that $t_{1st}$ depends on concrete tensile strength ($f_t$), w/c ratio and cover (C). The test results suggest that the model developed by Liu

& Weyers (1996) reasonably predicts the time to first cracking although the predicted times are under-estimated (approximately 11%) when compared to results obtained from accelerated corrosion testing.

In the Liu & Weyers (1996) model the time to crack initiation is the time when stresses resulting from the expansion of corrosion products exceed the tensile strength of concrete. The critical amount of corrosion products needed to cause first cracking consists of two parts: (i) the amount of corrosion products required to fill the total porous zone around the steel/concrete interface; and (ii) the amount of corrosion products then needed to generate the critical tensile stresses. The time to cracking is influenced by corrosion rate, cover, bar spacing, concrete quality, and material properties. Therefore, the model proposed by Liu & Weyers (1996) is assumed herein as suitable for estimating the time to first cracking.

Note that these accelerated corrosion tests simulate localised (pitting) corrosion to be expected with chloride-induced corrosion. This is an important observation since the Liu & Weyers (1996) model appears suitable for this type of localised corrosion (i.e., widespread along the length of reinforcing bars) even though this and other corrosion-induced cracking models were developed on the assumption of general corrosion

#### 3.2.2 Crack Propagation ($t_{ser}$)

Cracks first observed at the concrete surface through the magnifying glass were very small (width of less than 0.05mm) with lengths varying from 30mm to 300mm, with the most common length being 120mm to 150mm. Cracks width and length then increased in an inhomogeneous manner until they extended and joined together to create continuous corrosion-induced longitudinal cracking when the crack width is about 0.4mm to 0.5mm.

The results show that crack propagation increases linearly with time for crack widths less than 0.5mm. After this period rate of crack-growth seems to reduce and change to a non-linear trend. The reduced rate of crack propagation when crack width exceeds a certain value (0.5mm) may be attributed to the fact that the corrosion products can now easily diffuse through the crack toward the concrete surface, and so no longer contributes solely to the build up of expansive tensile pressures around the bar. In fact, at this time rust (corrosion product) with dark red-brown colour was clearly observed on several locations on the specimens' surfaces.

There are different views about the limit crack width. For example, Andrade et al. (1993) pointed out that a limit crack width between 0.3 to 0.4mm is appropriate for a serviceability limit state. On the other hand, Sakai et al. (1999) stated that a limit crack width of 0.8mm is recommended for serviceability (aesthetics) requirements. Recall that experimental data showed that cracks were joined together to create longitudinal cracking at crack widths of about 0.4 to 0.5mm. At this stage, spalling would likely occur in a real slab with transverse reinforcement and where there are loads applied to the structure. This is consistent with the general observation that the service life of a structure is reduced considerably only if cracks with widths exceeding 0.3-0.5mm are not repaired (Andrade et al. 1993). Hence, in the present paper, the limit crack width is taken as 0.5mm and so time to severe cracking ($t_{ser}$) is referred to herein as the time for the crack to propagate from 0.05mm to 0.5mm.

### 3.3 Influence of Concrete Cover (C)

All of the experimental slabs had been designed for the purpose of studying the effect of concrete cover, with the cover being either 25mm or 50mm. As expected, it is observed that concrete cover influenced crack propagation for experimental slabs at 25mm and 50mm at different w/c ratios (i.e. 0.45; 0.5; 0.58) (see Fig. 2). It is noted that the cracking patterns at the cross sections were quite similar for both 25mm and 50mm cover. It is observed that the crack propagation time ($t_{ser}$) at 50mm cover is about 1.15; 1.2; 1.4 times that observed for 25mm cover slabs at 0.45; 0.5; 0.58 w/c ratios, respectively. However, the effect of concrete cover was not significant when crack widths were less than 0.15mm to 0.25mm.

### 3.4 Influence of Concrete Water-Cement Ratio (w/c)

The influence of w/c ratio was studied by keeping slabs at the same cover but having different w/c ratios. It was observed that increasing w/c ratio resulted in increased crack propagation rates by up to 30% and 40% for 25mm and 50mm cover respectively (see Fig. 2). However, as was observed for concrete cover, the w/c ratio appears to mostly influence crack propagation when the crack width exceeds 0.15mm to 0.3mm.

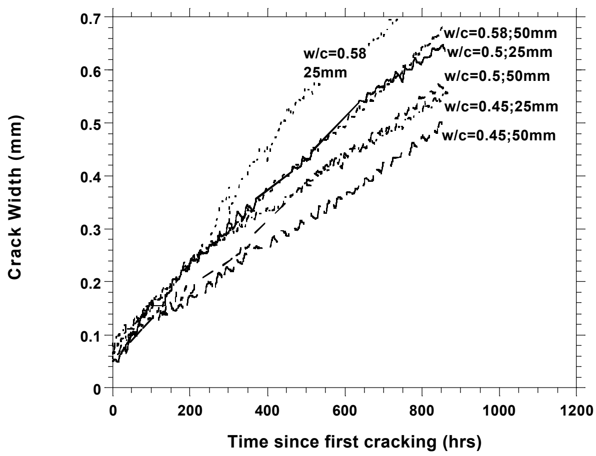

**Figure 2. Crack Propagation Since First Cracking**

### 3.5 Influence of Concrete Strength ($f'_c$ or $f_t$)

It appears that, for these test conditions, concrete strength did not influence crack propagation for crack widths less than 0.5mm. It is reasonable to expect that tensile strength may only influence the tensile stresses needed to cause first cracking (Liu & Weyers 1996; Williamson & Clark 2000). However, it was observed that crack propagation depends on concrete strength only when the crack width is larger than 0.5mm. Thus, concrete strength may not be an important consideration for this study since in reality repairs would normally be undertaken for cracks of about 0.3mm to 0.5mm.

### 3.6 Combined Effects of Concrete w/c Ratio and Cover

The effect of "concrete quality" is studied by including both the effects of w/c ratio and cover. For the present paper, "concrete quality" is categorised as: (i) best quality is 50mm cover and w/c=0.45; (ii) fair quality could be any of the following: 25mm;w/c=0.5 or 50mm;w/c=0.58 or 50mm;w/c=0.5 or 25mm;w/c=0.45; (iii) worse quality is 25mm cover and w/c=0.58. This represents a general quality specification in real situations, although the specific concrete qualities in real structures will most likely depend on other factors. If combining the effects of w/c ratio and cover together, it can be noted that a new parameter "concrete quality", defined as the ratio between w/c ratio and cover (or wc/C) is an important factor controlling the time to cracking and spalling. As seen in Fig. 3, a longer time for crack propagation occurs for best quality concrete, while a lower quality concrete results in increased crack propagation rates.

It is possible to suggest from Fig. 3 that there is a non-linear relationship between $t_{ser}$ and wc/C derived empirically as

$$t_{ser} = \mathrm{A} \times 10^{-3} \times \left(\mathrm{wc/C}\right)^{-\mathrm{B}} \tag{4}$$

where wc/C is the ratio between w/c ratio and cover (C); $t_{ser}$ is the time since crack initiation (years); and A and B are obtained from regression analysis of experimental data depending on crack width (for 0.5 mm crack width, A=6.5 and B=0.57). It is noted that, Eqn. 4 only applies for crack widths greater than 0.3mm.

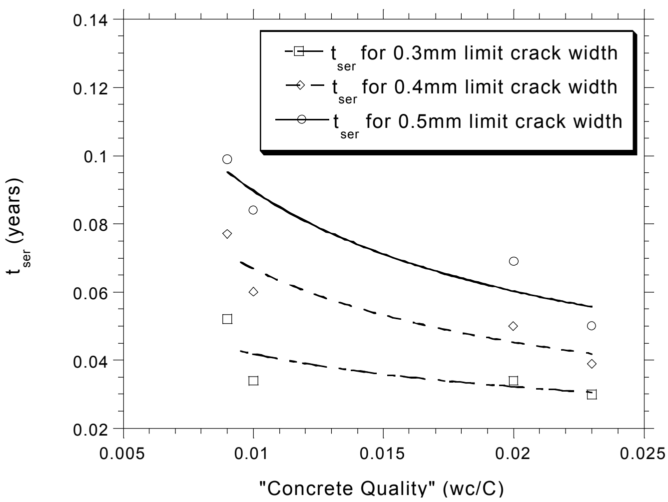

**Figure 3. Effect of Concrete w/c Ratio and Cover on Crack Propagation**

Go Back Next Page

### 3.7 Predictive Model of Time-Dependent Crack Propagation

The various stages of time-dependent crack propagation are represented in Fig. 4. The time to cracking and spalling referred to herein is the time when concrete cover cracking reaches a limit crack width of 0.5mm. Therefore, time-dependent crack growth can be divided into two stages:

(i) Crack initiation - influenced by many factors such as concrete cover, concrete properties (w/c ratio and strength), bar diameter;

(ii) Crack propagation - mainly dependent on concrete cover, w/c ratio, and concrete strength.

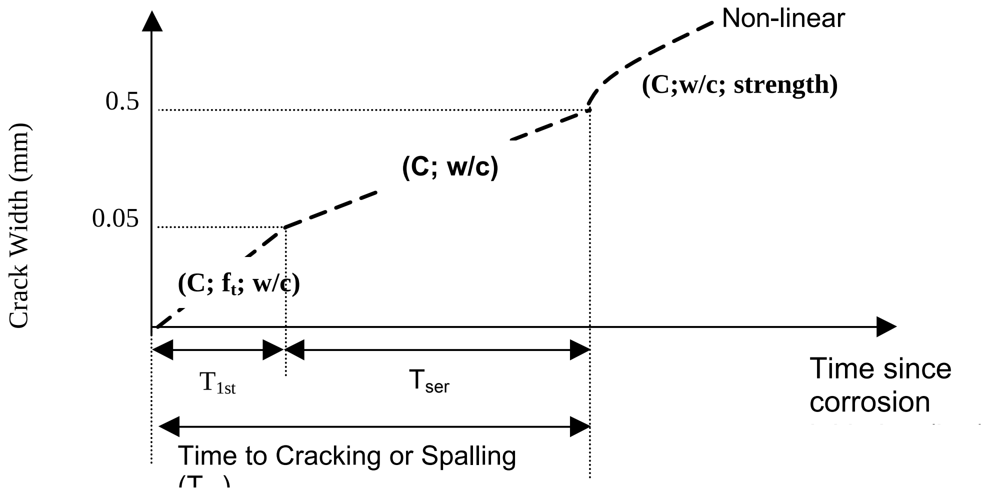

**Figure 4. Modelling Time Dependent Crack Growth**

In the context of this paper, only crack widths less than 0.5mm are of direct interested as it can be assumed that under these condition cracks propagate linearly with time and only depends on concrete cover and w/c ratio. The models proposed herein are preliminary only. Work is continuing to develop physically-based predictive models (as opposed to the empirical or "best-fit" model shown herein) suitable for predicting crack propagation up to any crack size (not limited to 0.5mm). The definition of what constitutes a limit crack width in the context of service life prediction is also required.

## 4 PROBABILITY OF LONGITUDINAL CRACKING AND SPALLING

For any time-invariant corrosion rate the time to severe cracking ($t_{ser}$) is modified from Eqn. 4 such that

$$t_{ser} = \left[A \times 10^{-3} \times (wc / C)^{-B}\right] \times \frac{100}{\mathrm{i}_{\mathrm{corr}}(1)} \tag{5}$$

where $i_{corr}(1)$ is time-invariant corrosion rate estimated from Eqn. 2; and A=6.5 and B=0.57 for a limit crack width of 0.5mm.

For time-variant corrosion rates, the time to cracking and spalling is $T_{sp} = T_{1st} + T_{ser}$ where $T_{1st}$ and $T_{ser}$ are time to crack initiation and time to severe cracking respectively for time-variant corrosion rates such as that given in Eqn. 3. Note that the upper case "T" denotes crack initiation and propagation times obtained for time-variant corrosion rates, while the lower case "t' refers to times obtained using time-invariant corrosion rates. Hence, $T_{sp}$ will be greater than $t_{sp}$.

If it is assumed that (i) the amount of rust produced until severe cracking is the same for time-variant and time-invariant corrosion rates; (ii) the time-variant reduction in corrosion rate is given by Eqn. 3; and (iii) corrosion rate for the first year is not time-variant, hence for the first year $T_{1st}=t_{1st}$, then $T_{sp}$ can be estimated as

$$T_{sp} = \mathrm{T}_{1st} + \mathrm{T}_{ser} = \left[0.84\left(\mathrm{t}_{ser} + t_{1st} + 0.2\right)\right]^{1.4} \quad (\mathrm{t}_{1st} + \mathrm{t}_{ser} > 1 \text{ year}) \tag{6}$$

In the present study it is proposed that $t_{1st}$ be obtained from the Liu & Weyers (1996) model and $t_{ser}$ is estimated from Eqn. 5. In both cases, $t_{1st}$ and $t_{ser}$ are calculated based on time-invariant corrosion rates.

Then, the probability that longitudinal cracking and spalling ($F_S$) will occur at least once during the time interval T is defined herein as

$$F_S(T) = \Pr\left(t > T_i + T_{sp}\right) \tag{7}$$

where $T_i$ is the time to corrosion initiation. This represents a first passage probability.

## 5 MODELLING OF RANDOM SPATIAL VARIABILITY

In practical applications of structural reliability analysis for corrosion in RC structures, there are many parameters that vary in space and such random spatial variability can be modelled as a random field. The probabilistic analysis of structures considering random spatial variability involves the discretisation of the corresponding random fields into sets of spatially correlated random variables. Hence, the structure is divided into n elements, and a random variable is used to represent the random field over each element. The statistical correlations between the random variables for different elements are based on the correlation characteristics of the corresponding random field (Vanmarcke 1983). In this paper, the spatial averaging method suggested by Vanmarcke (1983) is used to model the random spatial variability of concrete property and the surface chloride concentration. The analysis considering random spatial variability is described below, for more details of the spatial variability analysis see Vu & Stewart (2001).

### 5.1 The Variance Function

The spatial averaging method represents the random field X(t) over an element i is

$$\mathrm{X}_{\mathrm{i}}(t) = \frac{1}{T}\int_{t-T/2}^{t+T/2} X(t)dt \tag{8}$$

where T is the averaging interval and X is the parameter of interest.

The mean value is not affected by the averaging operation while the variance of $X_i(t)$ will be changed and may be expressed as

$$Var\left[X_i\right] \equiv s_{\mathrm{i}}^2 = g(\mathrm{T})s^2 \tag{9}$$

where $\gamma(T)$ is the variance function of $X_i(t)$ and $\sigma_i$ is the standard deviation of $X_i(t)$

### 5.2 Correlation Between Local Averages

The covariance matrix, which describes the correlation between two elements i and j is estimated as

$$COV\left\lfloor X_i, X_j \right\rfloor = \left(s_{\mathrm{i}} s_j\right) \times r_{\mathrm{X}_i, X_j} \tag{10}$$

where $\rho_{Xi,Xj}$ is the coefficient of correlation between the local averages $X_i$ and $X_j$ and is expressed linearly as\

$$r_{X_i,X_j} = \frac{1}{2}\left[\mathrm{T}_0^2 g(T_0) - T_1^2 g(T_1) + T_2^2 g(T_2) - T_3^2 g(T_3)\right] \tag{11}$$

where $T_0$ is the distance from the end of the first interval to the beginning of the second interval; $T_1$ is the distance from the beginning of the first interval to the beginning of the second interval; $T_2$ is the distance from the beginning of the first interval to the end of the second interval; $T_3$ is the distance from the end of the first interval to the end of the second interval.

### 5.3 Random Field Analysis and Simulation

In this study, a one-dimensional random field is investigated for concrete compressive strength, concrete cover and surface chloride concentration. The variance function $\gamma(T)$, which measures the reduction of the point variance $\sigma^2$ under local averaging, is related to the correlation function $\rho(\tau)$. In this paper, the correlation function is a triangular type correlation function that decreases linearly from 1 to 0 as $|\tau|$ goes from 0 to $\theta$, where $\theta$ is the scale of fluctuation. It is assumed herein that $\theta$ = 0.5m for concrete compressive strength, cover and the chloride surface concentration (Vu & Stewart 2001).

To model the spatial variability of concrete compressive strength, cover and the chloride surface concentration, the structure is discretised into n rectangular elements - whose edges are parallel to the coordinate axes. Once the stochastic random field is defined, Monte Carlo simulation methods can be used to randomly generate parameter values for each of the n discretised elements.

## 6 ILLUSTRATIVE EXAMPLE – STOCHASTIC MODELLING OF BRIDGE DECK DETERIORATION

The following example will help illustrate the effect of “concrete quality” on corrosion-induced cracking and spalling of concrete cover, which can then be used to assess the service life of RC structures. For this study, chloride contamination will occur from exposure to sea-spray (for structures located within 100m of the coast) or the application of de-icing salts.

The bridge deck considered in this study has a span length of 11m and a width of 14.2m. The bridge design required a 550mm thick slab with top and bottom steel. The diameter of longitudinal reinforcing steel (top) is 15mm and bar spacing is 165mm. Concrete cover varies from 25mm to 75mm. Statistical parameters for dimensions and material properties appropriate for this RC bridge deck are given in Table 2.

The slab deck has been discretised one-dimensionally into 8 elements of equal length. Since the probabilities of failure are expected to be high Monte-Carlo simulation was used for the analysis. The simulation analysis includes:

- stochastic deterioration model (Table 1);
- random field modelling for concrete cover, w/c ratio and surface chloride concentrations;
- new predictive model for time to cracking and spalling – Eqn. 6; and
- probability that cracking and spalling will occur at least once for any reference time.

This means that dependent variables such as concrete tensile strength, corrosion rate, and crack initiation and propagation are also spatially variable.

**Table 2. Statistical Parameters for Material Properties and Dimensions**

| *Parameters* | *Mean* | *Coefficient of Variation* | *Distribution* |
|---|---|---|---|
| Top cover | $D_{tnom}$+19.8mm | $\sigma$ = 16.5mm | Normal |
| $f'_{cyl}$ | $f'_c$+7.5MPa | $\sigma$ = 6mm | Normal |
| $f'_{ct}(t)$ | $0.53(f'_c(t))^{1/2}$ | 0.13 | Normal |
| $E_c(t)$ | $4600(f'_c(t))^{1/2}$ | 0.12 | Normal |
| $k_w$ ($f'_c(28)=k_w f'_{cyl}$) | 0.87 | 0.06 | Normal |

The final results are presented in terms of the proportion of a concrete surface likely to spall for any reference period. Figure 5 shows the effect of concrete cover and w/c ratio on the percentage of deck spalled for top cover, for sea-spray over a 120 year service life. The percentages of spalling for exposure to de-icing salts are similar to that shown in Fig. 5 since for this example time to initiation is relatively short and differences between the surface chloride concentrations are small (see Table 1).

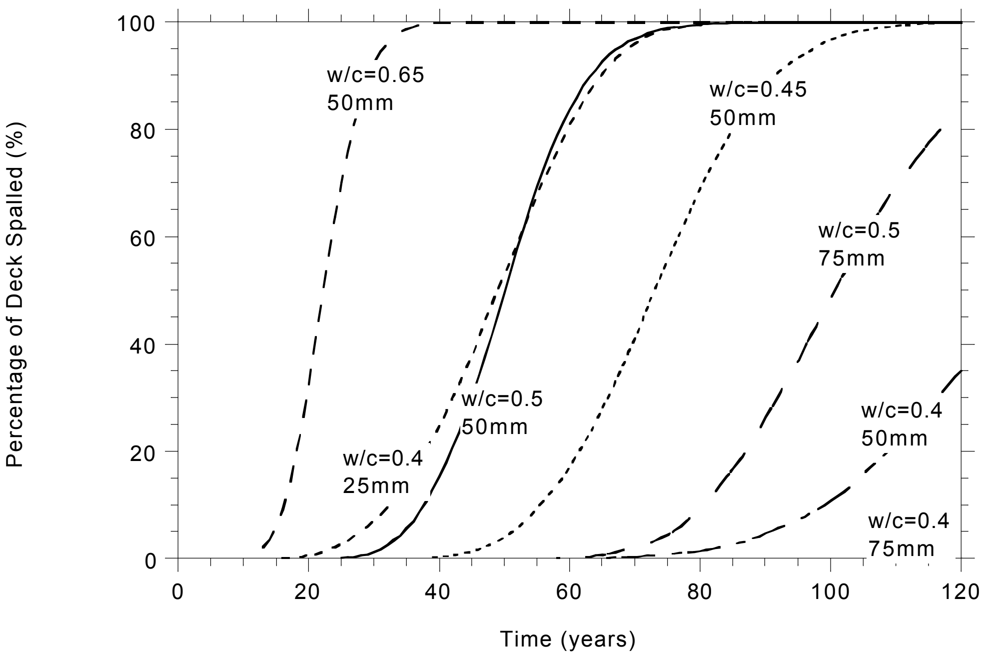

**Figure 5. Effects of Concrete Cover and w/c Ratio on Concrete Cracking and Spalling for Sea-spray**

As shown in Fig. 5, for 50mm cover and w/c=0.65 the percentage of deck spalled will be 100% after only 40 years. While for the same cover, reducing w/c to 0.5 will result in 100% spalling after 80 years of service and no spalling anywhere on the deck after 65 years of service for w/c=0.4. This helps quantify the very important role of concrete cover and w/c ratio on the service life performance of RC structures exposed to aggressive environments. Clearly, the representation of results in terms of the proportion of a concrete surface likely to spall for any reference period is information that can be used in a life-cycle cost analysis to optimise durability design requirements for new structures or optimise repair/maintenance strategies for existing concrete structures.

Alternatively, Fig. 6 shows the effect of modelling corrosion rate as a time-invariant variable – i.e. Eqn. 2. Not surprisingly, modelling corrosion rate as a time-invariant variable results in a considerable increase in the likelihhod of cracking and spalling for any reference period. This indicates the sensitivity of results to the chosen stochastic model of corrosion rate. Clearly, the results will also be sensitive to the stochastic models used for crack initiation and propagation.

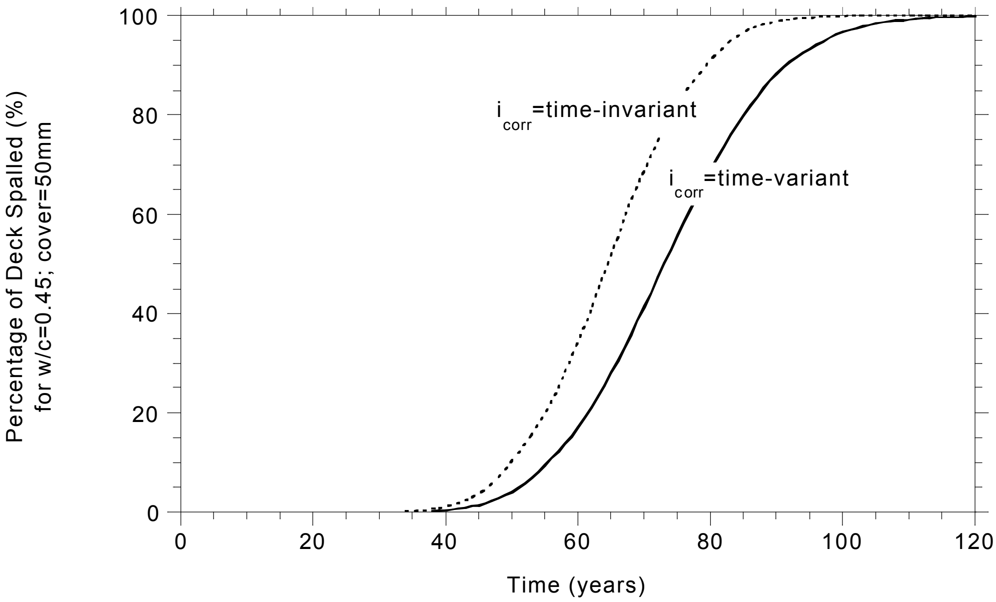

**Figure 6. Effect of Modelling Corrosion Rate as a Time-Invariant Variable, for 50mm cover and w/c = 0.45.**

## 7 CONCLUSION

The paper has developed stochastic models for crack initiation and propagation obtained from accelerated corrosion testing of RC slabs. The present analysis then included the modelling of the deterioration process and subsequent likelihood of cracking or spalling for RC structures considering concrete cover, w/c ratio and surface chloride concentration as spatially variable. Other dimensional, material and deterioration parameters were treated as random variables. This allows the proportion of a concrete surface likely to crack and spall for any reference period to be estimated. The results indicate that "concrete quality" specifications (cover, w/c ratio) are important in controlling the service life of RC structures exposed to aggressive environments. However, further research is progressing to gain a better understanding of the effects of concrete properties, concrete cover and the surface chloride concentration have on cracking and spalling of concrete cover, as well as the development of improved stochastic models for corrosion initiation, corrosion propagation and crack initiation and propagation.

# Design Decisions For Durable Roofing

**CP Hodges**
**Facility Engineering Associates P C Fairfax Virginia USA**

**Summary: Roof systems have been designed and built for thousands of years. Although we have seen many changes in the types of materials used in roof systems over the last 30 years, not much has changed in the basic design of these systems. So why is it that we continue to design and build low-slope roofs with little or no slope, inadequate drainage, and service lives as short as 10 years? Has initial cost become the only controlling factor in roof construction? There is plenty of published data regarding the expected service life of a multitude of different roof types. The data suggests that there are roof systems with an average service life as short as 10 to 15 years. With over 20 years of experience in analyzing the performance of roof systems, the author presents some key design factors that are often overlooked or rejected when choosing a new or replacement roof system. If the designer were to consider these factors and choose more carefully, then roof system service life would undoubtedly increase. This paper outlines a common-sense approach to design that integrates the concepts of slope, drainage, attachment, material durability, constructability, and maintenance. The roof designer should consider each of the design factors outlined in this paper in order to increase the overall durability of the roof system, and thus increase service life. The increase in durability comes, in part, from the elimination of poor roof design practices. Additionally, consistent adherence to sound drainage principles, careful material selection, matching the material selection to the building and deck substrate, and attention to construction and maintenance issues can increase expected service life. If a roof system is well constructed by a reputable roofing contractor and designed with an optimization of these six key design factors in mind, there is no reason not to expect a roof service life of 20 to 30 years. That should be the goal in building design. After all, our buildings are rarely designed to stand for only 10 to 15 years. Why have we come to expect such short service life from the roof system?**

**Keywords: Drainage, attachment, durability, constructability, maintenance**

## 1 INTRODUCTION

Roof systems are a basic part of man's shelter and roofs have been designed and built for thousands of years. Primitive shelters were built with the simple approach of creating slope in the roof to allow water to shed. Construction technology has advanced significantly over the last 30 years and we have seen many changes in the types of materials used in roof systems. Roof slope has also diminished in order to economize on the structural shapes that help build significant slopes into our structures.

Initial cost appears to have become the controlling factor in roof construction. Roof service life has been shortened in the process. New materials utilized in the 70's and 80's have been shown to have significantly shorter service lives than more traditional built-up roof products (Cash 1997). However, weather resistant properties of materials have also improved, and longer service life can be expected as we learn from our mistakes and material and application technology improves (Hoff 1997).

In the process of introducing new roofing materials and blending old and new technologies, the basic rules of sound design have not changed. A common sense approach to low slope roof design can lead to increased service life and more successful roofing and roof replacement projects. This approach to more durable roof systems integrates the concepts of slope, drainage, attachment, material durability, constructability, and maintenance.

If a roof designer pays close attention to these six key factors, a durable, economical, long-lasting roof system can be designed for almost any structure. This may not sound like a revelation, but it is a departure from the normal design process in the United States. In the United States, the roof system selection process is often driven by cost, and is driven toward using specific types of roof products and adapting those products to the widest range of building systems possible.

Each structure has, or will have, its own set of criteria that should lead the designer to choosing a system that's right for the building. That may mean that each building will have an optimal attachment method, set of material durability characteristics, construction methods, and maintenance characteristics that need to be carefully considered in choosing a roof system. The application of one type of roof system just won't apply in all cases.

After all, that's what smart design is all about. In this paper, the author uses the experience of over 20 years of observing roof system performance, gathers much of the design wisdom that has been in the roofing industry for many years, and assembles it into an organized thought process that leads to better roof system design choices. These design choices take into account the conditions a roof system is meant to meet and overcome. By considering the six key factors outlined in this paper, a roof designer will be led to a system more compatible with the structure, able to meet the challenges of the climate, with ease of construction and maintenance in mind. Such a process, if ever systematized and adapted to a computer database, may lead to "smart design" of roof systems with the aid of computer technology.

## 2 SLOPE

Slope is a very important factor in the proper functioning of a roof system. Adequate slope can compensate for inferior materials and construction quality. Most primitive roof systems relied primarily on slope to provide protection from the elements. In early structures, roof system materials often took a secondary role in the construction of roof systems, and roofs were most often constructed with materials commonly available (Vogel *et al*, 1986). The waterproofing ability of the material was often secondary to providing protection by draining water quickly away from the roof surface.

The concept of always providing roof slope seems to have been lost in the United States in the late 20$^{th}$ century. Since there were no code requirements governing roof slope in the Unites States until the late 1990's, thousands of buildings were constructed with virtually no roof slope. Roof assemblies were required to weather the burden of ponded water, often without the protection of redundant layering of membrane material. Roof membranes tended to become thinner when the use of single-ply roofing became a popular way to reduce the cost of roof systems and reduce the reliance on asphalt-based products. This was taking place at the same time that designers were flattening roof systems to save on construction cost.

The savings in construction cost has been shown to be marginal by some authors. C.W. Griffin, in the "Manual of Built-up Roof Systems", provides a strong case for the economic savings of designing roof slope into a building during construction (Griffin 1982). Griffin considers the cost of shortened service life, the inconvenience of premature tear-off and replacement, and the loss of energy efficiency due to water invasion into the insulation to far outweigh the savings of building a flat roof deck.

Although the argument was written many years ago, not much changed until building codes were written to require roof slope in new buildings. The current BOCA code in the United States requires a minimum roof slope of ¼ inch per foot or about 2% (BOCA 1999). The National Roofing Contractors Association (NRCA) recommends positive drainage and suggests criteria for judging proper slope. The criteria is "that there be no ponding water on the roof 48 hours after a rain during conditions conducive to drying" (NRCA 2001). The NRCA also recommends that the designer consult the code regarding slope requirements. This seemingly minor change in the construction code to require a minimum slope should lead to millions of dollars in savings by extending the service life of roof systems. There have been studies that show an increase in service life in traditionally flat roof systems due to positive roof drainage through roof slope (Griffin 1982).

In roof replacement situations, advances in cutting technology and design layout of tapered insulation systems have positively contributed to providing roof slope in roof replacement situations where a flat roof deck is present. Nowadays, it is a rare situation that some type of tapered insulation cannot be designed and fit to an existing roof system. Although edge heights are often increased and this may lead to flashing complications, the addition of slope is a most positive factor and the complications can generally be overcome when providing positive slope.

If one needs to be further convinced of the wisdom of providing positive roof slope, one only needs to look at residential roofing to see the positive effects. The predominant residential roof in the United States is asphalt shingle applied to a steep-sloped roof deck (Good 2001). The average homeowner is likely to experience far less problems and have a significantly longer service life from a steep-sloped shingled roof system than the average building owner with a flat roof. Warranty periods offered for steep-sloped shingle applications are generally much longer than those offered for commercial low-slope applications. In addition, the cost of steep-sloped roof coverings are often only a fraction of the cost of an insulated flat roof assembly.

The importance of the first key factor in common-sense design is to always provide positive slope to drain. A slope of about ¼ inch per foot (2%) has been shown repeatedly to work well in low-slope roof situations. Adhering to this design basic is a key factor in designing longer lasting, more durable roofs.

## 3 DRAINAGE

Roof drainage and slope are two distinctly different things. An adequately sloped roof can have inadequate drainage, and a flat roof deck can have adequate drainage. Inadequate drainage on a well-sloped roof can lead to slower water runoff, taxing the roofs' flashing systems and potentially leading to roof leaks. A relatively flat or dead level roof system can have adequate drainage, which becomes a requirement when designing protected membrane assemblies.

Although the first key factor (slope) is critical, the roof designer cannot always achieve deck slope in roof replacement situations and may have to rely on superior materials to stand up to ponded water and consistently wet situations with a flat deck. This is a common occurrence when replacing an older, flat roof with a protected membrane assembly. Adequate drainage becomes a more critical factor as roof slope approaches dead level.

Simply put, drainage refers to the ability of the roof system to carry water away. The building code usually dictates the minimum level of drainage required for a roof system. Conventional roof design calls for at least four drains for larger roofs, and a minimum of two drains for roofs under 10,000 square feet (BOCA/Plumbing Code 1990). Griffin also recommends a maximum spacing of drains in any direction of 75 feet (Griffin 1982).

The building or plumbing code provides more detailed guidelines, including the maximum tributary area per drain, as well as guidance on the required size of the drain leader. Most codes have been adapted to local rainfall rates.

Conventional design should use code-required drainage provisions and code-required overflow provisions. Although codes may not normally require upgrades to overflow protection for roof replacements, common sense design would dictate that overflow protection should be added wherever possible.

The second key factor in common sense roof design (drainage) is a simple design element in new building construction and code requirements should be followed without fail. Adding drainage to an existing roof can be challenging, but the techniques for improving drainage are numerous and there are nearly always ways to improve the situation. The addition of new internal drains, scuppers and downspouts, gutters, sumps, and tapered edges are several ways to improve roof drainage.

## 4 ATTACHMENT

In the author’s opinion, attachment is the single most critical factor that drives the choice of a new or replacement roof system. Attachment is a critical design factor in allowing a roof system to stay in place under wind loads, and most design codes have very specific requirements for wind uplift resistance.  Designers often abuse attachment methods by force-fitting a particular attachment method to a deck that does not readily lend itself to the method.

Figure 1 shows the three most commonly used roof attachment methods. The fourth method shown, the Protected Membrane Assembly, is a hybrid of the basic attachments in that the roof membrane may or may not be fully adhered, but the insulation clearly requires the ballast to keep it in place.

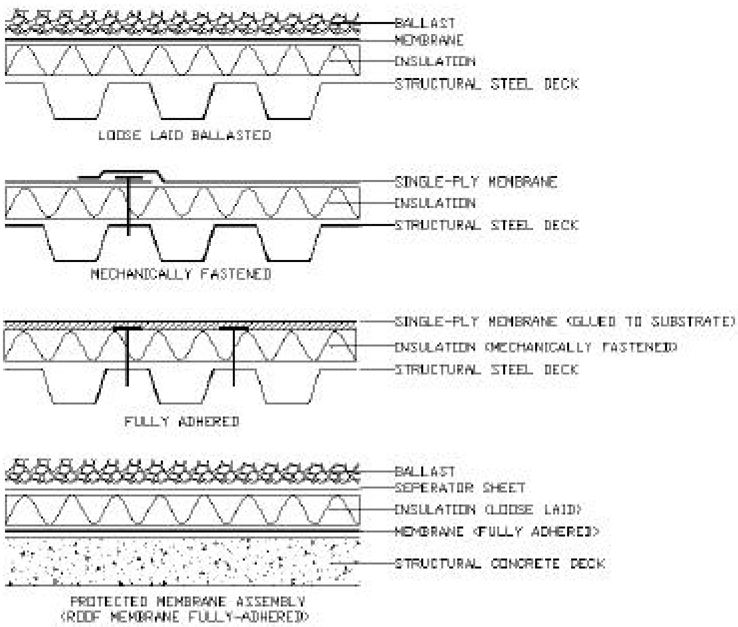

**Figure 1.  Attachment Methods**

Abuse of the attachment methods in roof design occurs when the designer does not respect the differences between nailable and non-nailable deck systems. It has been widely recognized in the roofing industry that these two major classifications of roof decks exist. Roofing manufacturer literature has generally classified roof decks as nailable or non-nailable for well over 30 years. The nailable or non-nailable designation refers to the decks ability to accept a “standard” fastener.  In the case of steel decks, self-taping screws would be the fastener of choice. In the past, hot asphalt attachment of rigid insulation to a steel deck was an accepted practice in the United States. This is no longer the case and mechanical fasteners are required to achieve appropriate wind uplift resistance ratings.

The National Roofing Contractors Association in the United States classifies roof deck systems into three categories; nailable, insulated, and concrete roof decks (NRCA 2001). Concrete roof decks are further classified into cast-in-place, precast or pre-

Go Back Next Page

stressed concrete panels, and post-tensioned concrete. The "non-nailable" designation does not appear in current NRCA design guidelines.

In the case of lightweight insulating fill and other types of lightweight deck systems, auger, splayed-shank, or some other type of hook-type mechanical fastener that grips the fill would secure the base sheet or insulation.

In the case of concrete decks, only a specialty expansion anchor or other type of expanding fastener would be effective as a mechanical attachment for insulation to concrete. However, mechanical attachment to a concrete deck system is often difficult and expensive. Most concrete decks would utilize fully adhered (requiring hot asphalt or cold adhesive attachment), or ballasted attachment methods.

Designers often attempt mechanical fastening to concrete and other non-nailable deck systems. This has led to the use of mechanical fasteners into structural concrete deck systems without regard for alternative, less expensive, and more effective attachment methods. Common problems with mechanical attachment to non-nailable decks are fastener back-out, membrane damage, and loss of uplift resistance. Ultimately, each roof type has a compatible fastening system. It is up to the designer to choose a system that has a proven track record in meeting code-required wind-uplift requirements and minimizing material incompatibility issues such as fastener back-out.

Table 1 is an approach to choosing a compatible fastening system for each of the common types of low-slope roof membrane and roof deck systems. This table is not intended to show all possible attachment methods, or even to show all commonly accepted practices in each region of the country or the world.

**Table 1. Recommended Attachment Methods for Each Major Roof Type**

| 4.1.1 Insulated Systems | | *Attachment Method by Major Deck Type* | | |
|---|---|---|---|---|
| **Roof Membrane Type** | | Steel | Concrete | LIF |
| - Built-up | Insulation | MF | FA | MF/BS – FA |
| | Membrane | FA | FA | FA |
| - Modified Bitumen | Insulation | MF | FA | MF/BS – FA |
| | Membrane | FA | FA | FA |
| - Single-ply/ Sheet | Insulation | MF or LL [1] | FA or LL [1] | MF or LL [1] |
| | Membrane | MF, FA or LLB | FA or LLB | MF, FA or LLB |
| **Membrane Direct-to-deck (Protected Membrane Assembly)** | | *Attachment Method by Major Deck Type* | | |
| **Roof Membrane Type** | | Steel | Concrete | LIF |
| - Built-up | Membrane | Needs Base | FA [2] | MF/BS |
| | Insulation | LLB | LLB | LLB |
| - Modified Bitumen | Membrane | Needs Base | FA [2] | MF/BS |
| | Insulation | LLB | LLB | LLB |
| - Single-ply/Sheet | Membrane | Needs Base | Needs Base | Needs Base |
| | Insulation | LLB | LLB | LLB |

Key:

| | |
|---|---|
| MF – Mechanically Fastened | LLB – Loose-laid Ballasted |
| FA – Fully Adhered | MF/BS – Mechanically Fastened Base Sheet |
| MF/BS – FA – Mechanically Fastened Base Sheet, Fully Adhered Insulation | Needs Base – Requires base of insulation between deck and roof assembly |
| LIF – Lightweight Insulating Fill | LL – Loose-laid |

| | |
|---|---|
| Note 1: Loose-laid insulation would require a mechanically fastened or loose-laid ballasted membrane to provide uplift resistance, thus, a fully adhered membrane would be appropriate over mechanically fastened insulation only. | |
| Note 2: In a Protected Membrane Assembly, the fully adhered method of attachment may require modification to include an insulation board as a separator between the deck and the membrane in the case of precast concrete deck systems with frequent joints. | |

If the general guidelines in Table 1 are followed, the designer will be led to the choice of attachment method that is compatible with the roof deck, insulation, and membrane system, and provides a commonly accepted attachment method. Although the table is intended as a guideline, the designer should follow common sense and code requirements for wind uplift resistance in choosing attachment methodology.

## 5 MATERIAL DURABILITY

Material durability refers to the roof system's ability to resist the spread of fire, weathering and natural or man-made impact without breaking down. The roof system should be rated for its ability to resist the spread of fires within a building, and the roof surface must be resistant to the spread of fire.

Membrane type, thickness and surface treatment have a significant effect on fire resistance and roof system durability. Not only must the roof membrane and surfacing have the ability to resist the spread of fire, the membrane must have the capability to expand and contract to prevent splits and tears from extreme temperature changes. Those capabilities should be present when a roof is constructed, and they should remain at adequate levels throughout its life cycle. Thus, in order for a roof system to perform adequately, it must have adequate material durability when it's constructed, and not have a tendency to lose those characteristics as it ages.

For the most part, roof membrane materials today posses the material durability to resist weathering and building-related movement, and most have means of meeting today's stringent fire codes. What some designers fail to realize is that when a material meant to weather in one specific climatic condition is used in a totally different environment, it may not be suitable for the conditions of the new environment. A relatively thin, single-ply membrane that is suitable for a sunny, mostly dry climate in the southwestern United States may be totally inadequate for a severe-winter northern U.S. environment where roof traffic is common. A particular membrane assembly that is used in environments where insulation is not needed or used may not be appropriate in a heavily insulated assembly. Many manufacturers have multiple membrane products for numerous surfacing configurations. Often, the manufacturer will have similar membrane products, some of which are rated for surface burning characteristics, others of which are not. The designer needs to be ever vigilant to specify the correct products.

The roof designer is best advised to carefully research the prior use of the chosen roof system product and demand a solid track record of performance over many years. If this is not done, the owner should be advised of the risk of using materials and systems that do not have a proven track record in the climate required.

Data on the service life of various roof systems may well be the best indicator of material durability. It is generally accepted that the service life of single-ply membranes is growing with improvements in seaming and flashing technology (Hoff 1997). The durability of the single-ply system in the past may have been judged more by how many leaks developed over time, as opposed to how well the membrane material sustained weathering. A case in point is the longevity of some single-ply roof membranes. Although many single-ply membranes offer good waterproofing protection over an extended period of time, the documented service life of some single-ply membranes through the late 1990's was less than more traditional bituminous membranes (Cash 1997). This may have been due in part to its relative lack of material durability under foot traffic that caused punctures and leaks.

Roof system traffic will generally have a significant effect on the service life of a roof system (Kyle *et al.* 1997). There have been several attempts in the United States roofing industry to standardize roof membrane impact testing as it relates to both roof traffic and environmental influences (hail). These attempts are often met with resistance due to the complexity and sheer number of membrane types and surfacing offered in the market. Currently, only some of the major roof membrane material standards in the United States have some sort of impact resistance requirements. Other countries have had some success with the rating of various roof systems by their resistance to movement, weathering, and puncture. These material durability-related issues have been documented, tested, and are incorporated into a rating system used in France since 1989 (Chaize *et al.* 1991).

Thin, unreinforced membranes are not likely to have the same resistance to roof traffic as a multiple-layer, built-up membrane product. Even reinforced single-ply products may be more susceptible to cuts, tears, and puncturing than a multi-layer, built-up membrane. The roof designer should consider the amount of serviceable equipment on the roof before deciding on an appropriate membrane and surfacing. The durability of the roof surface is a key factor in achieving longer service life. Table 2 is the author's general rating system of the durability of a roof surface relative to roof traffic.

**Table 2. Resistance to Roof Traffic**

| Roof System | Surfacing | Traffic Resistance |
|---|---|---|
| | | |
| Built-up | Gravel | High |
| (3 or 4-ply) | Smooth Surfaced | Moderate to High |
| | | |
| Modified Bitumen | Gravel | High |
| (2-ply) | Granular Surface | Moderate to High |
| | Smooth Surfaced | Moderate to High |
| | | |
| Single-ply | Unsurfaced/Exposed Membrane | Low to Moderate |
| | Ballasted | Low to Moderate |
| | | |
| Protected Membrane | Ballasted Insulation (Membrane beneath) | High |

Ultimately, the roof designer is responsible for selection of a roof system that meets all of the durability requirements. These durability requirements may be code or standard-mandated such as: fire resistance, puncture or tear resistance, elongation, and weatherability. Other durability requirements may be imposed by the climate in which the roof system is intended to serve, and by the traffic the roof system may be required to endure. Although these requirements are rarely code-mandated, the designer should pay as close attention to those requirements as to those that are code-mandated.

## 6 CONSTRUCTABILITY

Constructability refers to the construction factors involved in placing a roof system on a particular building, taking into account building location, height, type, use, and occupancy. The design process should take constructability into account in choosing methods such as hot asphalt application, cold adhesives, fasteners, ballast, roof access, and numerous other factors.

Building location is often a factor in the choice of roof system. Certain materials may have the advantage of being readily available while others may not. Asphalt-based products may be quite expensive in some areas while readily available and inexpensive in others. Fluctuations in the cost of crude oil may affect the cost of certain insulation and membrane types. Recently in the United States, energy cost has impacted certain high-energy use production facilities, thus affecting the cost of the final product.

Building use is a key factor in determining the constructability of replacement roof systems, new construction, and in additions adjacent to occupied structures. Hospitals and health care facilities may require more occupant-friendly material that avoid the use of hot asphalt and the associated fumes and fire safety issues. Buildings located in busy urban areas may have access problems that require a roof system that does not depend on full-time access to the roof. Crane access may be limited, and thus limit the amount of material transport that can occur. In these instances, roofs requiring hot asphalt from kettles and tankers may not be feasible.

Building height can limit the use of hot asphalt in areas where kettles are not permitted on rooftops. Fire safety regulations often prohibit the use of asphalt kettles on the rooftop and require that all kettles and tankers be kept a minimum of 25 feet from the building. This makes the use of hot asphalt difficult for building heights over about 80 feet. More powerful pumps and insulated piping can make ground-based kettles more effective for taller structures; however, additional expense is involved.

Torch-applied asphalt-based products overcome some of these access issues; however, wood-framed, and wood deck structures are somewhat more risky candidates for torch-applied products when considering the risk of fire during construction. Torch-applied modified bitumen products are usually excellent candidates for protected membrane assemblies over concrete decks. Torch-applied modified bitumen membranes can offer some access advantages in dense urban applications since roll materials are transported to and stored on the roof.

When used with cold-applied adhesives, modified bitumen products usually offer better durability than single-ply membranes, without the construction issues of heating bulk asphalt for built-up assemblies. Cold-applied adhesives have increased in popularity and effectiveness over the last several years. These products have enhanced the use of traditional asphalt-based modified bitumen products without the reliance on heating.

The designer should also consider durability of the membrane during construction. Roof construction is a rough and considerably damaging process. Flashing and sheet metal construction, and follow-on rooftop mechanical work is often the most damaging phase of roof construction; often more damaging than years of service life. The durability of the membrane product to construction traffic is an important consideration. Again, the more durable membrane products will have the advantage in resisting construction traffic.

Aside from building location, use, height, and other physical factors, roof deck and interior construction has a significant impact on constructability. Attachment methods will impact constructability, as outlined in an earlier section of this paper. For example, the presence of a non-nailable deck on a tall building in a dense urban environment may lead the designer to choose a ballasted single-ply membrane or a modified bitumen system (torch applied) in a Protected Membrane Assembly. The choice between these two systems would then become one of durability over price, with some potential difference in expected service life. However, both types of systems can be appropriate. On the other hand, a mechanically fastened system would not likely be appropriate from a constructability and attachment standpoint.

Steel or lightweight insulating fill decks are not always candidates for ballasted roof systems since the weight addition is significantly larger than traditional gravel or smooth surfaced asphalt-adhered systems. Concrete decks generally have higher dead load capacities; however, all systems should be checked before adding ballast to a roof system.

The interior conditions and finish beneath the deck are also important constructability issues. The presence of spray-applied fireproofing on the underside of a steel deck needs to be considered when re-roofing with a mechanically fastened system. Fastener penetration through fireproofing material can lead to delamination in loosely adhered areas, and compromising of the fireproofing system. The presence of asbestos in older fireproofing systems may also limit the use of fasteners through a steel deck. Construction vibration through any type of deck system must also be considered in and around adjacent fireproofed building systems. The presence of high-heat areas, refrigerated spaces, high interior humidity, clean rooms, and secure areas are just a few of the other design factors that have to be considered in design of the roof system.

Steel deck fasteners through to an occupied space where the underside serves as the finished interior surface can be an issue for re-roofing. This is an issue when replacing an older built-up roof that was constructed when hot mopping insulation to a steel deck was acceptable. A practical method for roof replacement in these cases is mechanical attachment through the steel deck. However, the presence of the protruding fasteners on the underside can be problematic, especially where visible in gymnasiums, atriums, and where the deck underside is painted.

The designer should consider constructability factors when choosing a new or replacement roof system. How the roof system interacts with all of the building's other systems is important, as well as how easily the roof system is constructed. The designer is also well advised to determine how well the specified system matches with the expertise of the contractors that will likely be performing the construction.

## 7 MAINTENANCE

Maintenance is required for all roof systems. Properly maintained roof systems will have longer service lives and reduced ownership costs. Maintenance practices will generally not vary significantly by roof type; however, some roof types are considered more easily maintainable than others. Traditional gravel and granular surfaced built-up and modified bitumen membrane systems are easily maintained because surface damage to the membrane is visible and most often obvious. In the case of an exposed, coated, gravel, or granular surfaced membrane, routine inspection of the membrane should be performed. This also applies to exposed-membrane single-ply roof systems (fully adhered and mechanically fastened). Membrane damage can be visually detected and repaired.

Ballasted roof membranes and Protected Membrane Assembly membranes are not nearly as visible, and many consider these membranes to not be maintainable. It is unlikely that any routine inspection process should or would require ballast removal or insulation and ballast removal in order to carry out the inspection process. This process is likely to do more harm than good by damaging the membrane during the ballast removal and replacement process.

Even though all membrane and covering systems are not created equal with respect to inspection and maintenance, most of the other roof system components are as equally maintainable regardless of roof type. Most roofs have exposed flashing and drainage systems that require periodic inspection and cleaning. Metal flashing systems are common to most types of roof systems, even though metal type will vary. Most roof systems also contain flexible sealants, expansion joints, and penetration flashings that can be monitored and maintained. All roof drains, scuppers, collector heads and gutters should be inspected and cleaned at least two times per year, or more often when wind-born debris and leaves are a factor.

Roof system coatings such as aluminized and acrylic-based coatings are often the most maintenance-intensive portions of a roof system. Coating system longevity is often much shorter than expected roof life cycle and will require periodic re-application to be effective.

The important factor about maintenance is that the designers recognize which portions of the roof system will require maintenance and alert the Owner as to which systems require maintenance and to what level of detail. Maintenance may also include periodic leak repair. A difficult or non-maintainable membrane such as a ballasted or protected membrane assembly should require a membrane type that is high on the durability scale in order to reduce the demand for leak repairs. If it is not, an Owner may spend an inordinate amount of time moving ballast or uncovering protected membrane assemblies to chase leaks. Thus, a roof's "maintainability" becomes an important design factor.

## 8 SUMMARY

If designers were to pay closer attention to these six key factors, the average service life of a roof system could be extended significantly. This paper outlines these six key design factors and their effect on the service life of a roof system. Using these design concepts adds little to the construction or replacement cost of a roof system, but can have a significant positive effect on service life and will reduce life cycle cost. A summary of the key factors is listed below.

1. **Slope** – Provide a minimum of ¼ inch per foot slope for low-slope roof applications.
2. **Drainage** – Provide at least the minimum drainage and overflow protection as required by code, and err on the side of more drainage than required when designing roof systems for small areas, multiple levels, and unusual shapes.
3. **Attachment** – Choose attachment methods carefully, and utilize proven, code-required, tested attachment methods matched to the deck system.
4. **Durability** – Make roof system durability an important design factor and use life-cycle to help the Owner choose the most cost-effective roof system.
5. **Constructability** – Each roof type has advantages and disadvantages when it comes to constructability; choose a system that can be built.
6. **Maintenance** – All roof systems require similar maintenance, however, all membranes are not created equal; if the roof system is to be covered, make durability and longevity of the membrane a high priority.

Designers should remember that all roof systems are not equal, and each building has different requirements. There is no single roof system that is applicable in all situations. It is not the choice of material or specific manufacturer that will make a roof system work, it is a combination of all of these design factors taken in total that will provide longer-lasting roof systems.

Although these are not the only factors a designer may encounter, they provide the basis for sound design judgment and will lead to more durable roof systems with longer service life. The durable roof of the future will utilize technology to design for slope and improved drainage, better adhesives and fasteners for solid attachment to meet wind uplift requirements under a variety of deck conditions, more durable, thicker materials to stand up to weathering and ultraviolet radiation, worker and occupant-friendly materials to enhance constructability, and design with maintenance of the total roof system in mind.

# Surface Roughness Slip Resistance And Relationship To Floor Cleaning

**R Hooper DM Richardson RG Sibbick APJ Yates**
**Watford UK**

**Summary: Determination of slip resistance of flooring materials is of importance to both designers and specifiers when responding to client requirements, and to building owners, users and facility managers when buildings are commissioned and over the lifetime of the floor. Clearly, acceptable slip resistance of floorings is a significant safety requirement of any building with an industrial, or public service operation. Assessment can be made as a routine part of production, to ensure client satisfaction, or upon the floor in-service, to ensure the required slip resistance has been maintained during routine service life.**

**Slip resistance is commonly measured in the UK using the TRRL pendulum tester but the use of surface roughness measurement to assess slip resistance is growing in popularity. This paper identifies a relationship between the surface roughness of flooring materials and the cleaning properties by presenting two case studies. The BRE studies examined in-service floor tiles that were retaining dirt, irrespective of the cleaning regime, or the traffic. The relationship between surface roughness and dirt retention enabled the identification, in one case, of areas where the cleaning regime was insufficient.**

**Examination of the data produced from the two case studies suggests that the peak to valley distances of the sub-millimetre surface profile and the widths of the peak to valley elements are important parameters influencing dirt retention. These parameters can be measured using one of the instruments recommended in the Guidelines of the UK Slip Resistance Group (2000), although the measurement of the mean width peak to valley distances is not required when assessing slip resistance.**

**Thus, in addition to providing information concerning slip resistance, the assessment of sub-millimetre surface profile characteristics may also be advantageous in quantifying cleaning properties, and provide valuable information both before installation and during service life.**

**Keywords: Ceramic, terrazzo, slip, surface roughness, cleaning**

## 1 INTRODUCTION

Determination of floor slip resistance is of importance to ensure the appropriate properties will be obtained for new floors or floors maintained in-service. Measurement of floor slip resistance is most commonly conducted in the UK using the TRRL pendulum tester, although the use of surface roughness measurements is growing in popularity. Recent studies at BRE have indicated that a relationship exists between the sub-millimetre surface profile characteristics and the cleaning properties of flooring materials. Thus, the movement towards roughness measurements to assess slip resistance may prove to have additional benefits in providing characterisation of the floor cleaning requirements. Although there is still much work to be completed to quantify this relationship this paper presents two case studies where a direct correlation between the sub-millimetre floor surface profile and the cleaning properties has been established. It is hoped that these data will assist others conducting research in this field.

## 2 MEASUREMENT OF FLOOR SLIP RESISTANCE

In the UK the pendulum tester is commonly used to assess the slip resistance of floorings both in-situ and in the laboratory. The assessment technique is discussed in guidance from the UK Slip Resistance Group (UKSRG, 2000), the BRE Information

Paper 10/00 (Yates and Richardson, 2000) and the CIRIA Report 184 (Gatfield, 1998). This method is currently under consideration as a European Standard (prEN 13036-4: 1997) to assess skid resistance. The pendulum tester relies on the measurement of the coefficient of friction between a rubber slider and the flooring to assess the resistance to slip. For assessment of flooring a Four S rubber slider is recommended for most floors and the results are categorised according to Table 1.

**Table 1. Categories of slip resistance**

| *Potential for slip* | *Four S pendulum value* | *Rz surface roughness (mm)* |
|---|---|---|
| High | 25 and below | Below 10 |
| Moderate | 25 to 35 | Between 10 and 20 |
| Low | 35 to 65 | Above 20 and up to 30 |
| Extremely low | Above 65 | Above 30 |

The recently published Guidelines from the UKSRG (2000) support the use of surface roughness measurements to assess slip resistance, by providing test methods for both on-site and laboratory testing. Although not recommended as a replacement for the pendulum test the surface roughness is considered important, particularly where water contamination is likely. Equally, the UK Health and Safety Executive (1997) recognise that both the friction between the floor and the shoe and the sharpness of the granular micro-surface peaks influence slip resistance.

## 3 MEASUREMENT OF SURFACE PROFILE CHARACTERISTICS

The Guidelines of the UKSRG (2000) recommend the use of the Taylor Hobson Surtronic 3+ or Duo roughness meter, to establish the slip resistance of the floor in-situ or in the laboratory. Surface profile is quantified by parameters that relate to certain characteristics of the surface, defined in BS ISO 4287: 1997. The parameters discussed in this paper include Ra, Rq, Rc and RSm. These parameters can be classified in three groups, according to the type of characteristic that they measure:

- Amplitude parameters: Are measures of the vertical displacements of the profile, essentially peak and valley measurements, for example Ra, Rq, Rc.
- Spacing parameters: Are measures of spacings of profile elements (the surface profile between a peak and adjacent valley), for example RSm.
- Hybrid parameters: These relate to both the amplitude and spacing of the surface profile elements.

### 3.1 Definition of surface profile parameters

The Mean Line is commonly used in surface profile characterisation and it is derived by the least squares method. In basic terms it is a line which bisects the profile such that the area above it and below it are equal and a minimum, as shown in Fig. 1.

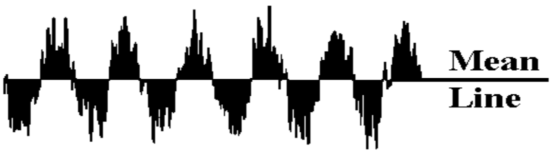

**Figure 1. Mean line of a surface profile**

The profile is described as a series of heights above or depths below the mean line, Z ordinates, at a distance along the sampling length, x ordinates, the ordinate value is written as Z(x). This is shown schematically in Fig. 2.

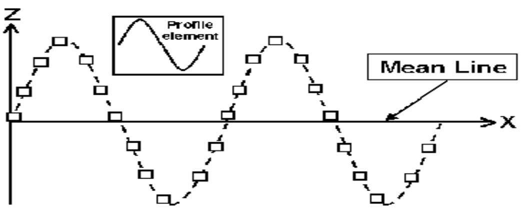

**Figure 2. Z(x) ordinates of a surface profile**

Ra is the average roughness of the surface and is the arithmetical mean of all the Z(x) values. Rq is the root mean square of these measurements, and thus is independent of the sign of the roughness (whether it is a peak or a valley) thus Rq is usually larger than Ra for the same sample set.

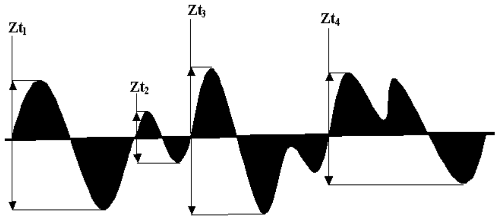

**Figure 3. Schematic diagram of heights of profile elements ($Zt_n$)**

Rz is the roughness parameter used in the UK Guidelines (UKSRG, 2000) to assess slip resistance, the threshold values are given in Table 1. This Rz value corresponds to Rc in BS ISO 4287:1997 and is the mean value of the profile element heights (Zt) within the sampling length as shown in Fig. 3.

Also discussed in this in this paper is RSm, the mean value of the profile element widths (Xs) within a sampling length (Fig.4).

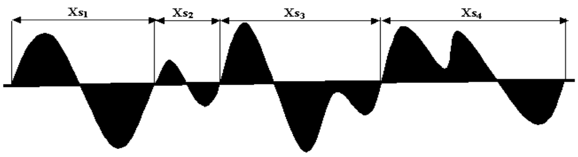

**Figure 4. Schematic diagram of Xs**

## 4 CLEANING PROPERTIES - CASE STUDIES

### 4.1 Case study 1 - Ceramic tiled floor

BRE were asked to examine the darkening of a ceramic tiled floor in a catering facility. BRE undertook an extensive study of the tile surface characteristics using optical and scanning electron microscopy (SEM) and laser profilometry in order to determine the causes of the darkening.

Optical and scanning electron microscopy of the tiles confirmed that the darkening was caused by dirt retention at the surface of the tiles, Figs. 5 to 8.

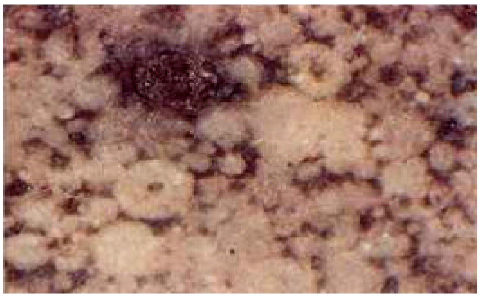

**Figure 5. A severely darkened tile, optical microscope image X 150**

**Figure 6. A severely darkened tile SEM image, scale bar is 1000 mm**

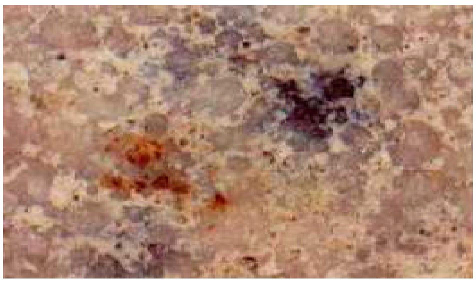

**Figure 7. An unaffected tile, optical microscope image X 150**

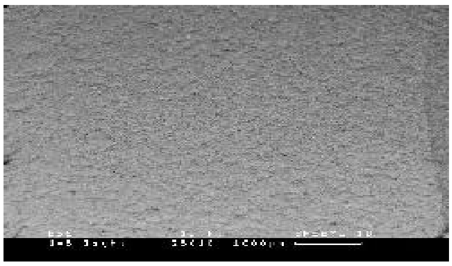

**Figure 8. An unaffected tile SEM image, scale bar is 1000 mm**

The optical micrograph (Fig. 5) shows the presence of the dirt at the surface of the darkened tile, which is absent in the unaffected tile (Fig. 7). This is confirmed as dirt of high carbon content by the dark appearance of this material in the back scattered electron SEM image (Fig. 6). Under the SEM lighter elements appear darker, thus carbon will appear darker than the surrounding alumino-silicate tile substrate. Few carbon-containing areas are visible on the unaffected tile (Fig. 8).

Surface profile was assessed for a number of tiles removed from different locations of the floor, subject to different cleaning regimes and traffic. The tile surface profiles were assessed using a Cyberoptics Microscan 3D laser profilometer. Measurements were taken at 10 different locations on each sample tile and then averaged to represent each tile. Surface scans were undertaken in 10 μm steps, each scan compromising 1000 steps, producing a sampling length of 10 mm. In this case study the samples were assessed for average Ra and Rq, given in Table 2.

No relationship was found between the cleaning regime in place and the darkening of the tiles (by visual assessment), the darkening being indicative of the quantity of dirt retained by the tile. These data are shown in Table 2, where 1 is the most rigorous cleaning regime and 6 the least rigorous (no pro-active cleaning under a disused conveyor belt). Table 2 also contains an assessment of the traffic the floor was subjected to at these points, where 1 is the heaviest traffic and 4 the lightest (no traffic under a disused conveyor belt). No direct relationship can be seen between the darkening and the traffic.

**Table 2. Cleaning, traffic and roughness data for sample tiles**

| *Area* | *Visual description* | *Cleaning regime* | *Traffic* | *Ra (mm)* | *Rq (mm)* |
|---|---|---|---|---|---|
| 7 | Darkened | 1 | 2 | 14 | 15 |
| 7 | Unaffected | 1 | 2 | 11 | 12 |
| 6 | Little Darkening | 2 | 1 | 14 | 15 |
| 6 | Unaffected | 2 | 2 | 11 | 11 |
| 6 | Unaffected | 2 | 2 | 11 | 11 |
| 3 | Unaffected | 3 | 3 | 12 | 12 |
| 3 | Unaffected | 3 | 2 | 12 | 13 |
| 5 | Darkened | 3 | 3 | 12 | 12 |
| 5 | Darkened | 3 | 3 | 12 | 12 |
| 8 | Severely Darkened | 4 | 1 | 22 | 25 |
| 8 | Severely Darkened | 4 | 2 | 17 | 19 |
| 1 | Little Darkening | 5 | 2 | 16 | 17 |
| 1 | Little Darkening | 5 | 3 | 13 | 14 |
| 1 | Unaffected | 5 | 3 | 13 | 13 |
| 1 | Unaffected | 5 | 3 | 12 | 13 |
| 1 | Unaffected | 5 | 3 | 12 | 14 |
| 2 | Darkened | 5 | 3 | 16 | 18 |
| 4 | Unaffected | 6 | 4 | 12 | 13 |
| 4 | Unaffected | 6 | 4 | 12 | 13 |

The relationship between the tile darkening due to dirt retention and the Ra and Rq values are given in Figs. 9 and 10. The graphs also show the $\pm$ 2 standard deviation values taken from the average of the 10 assessments on each sample tile. These error bars show that there is some overlap in the 95% confidence limits of the average measurements of the tiles retaining dirt and the unaffected tiles. This overlap does not affect the conclusions drawn from this case study but indicates that further data collection and analysis would be required before specification of a threshold roughness related to dirt retention could be established.

Figures 9 and 10 demonstrate the relationship between the roughness of the tile surface and dirt retention. In all but two examples is the dirt retention accompanied by higher surface roughness of the tiles. For these two exceptions, it is likely that the cleaning regime (Number 3) is not sufficiently rigorous, or that is it not conducted adequately. This example demonstrates that the use of surface roughness measurement will differentiate between causes of dirt retention.

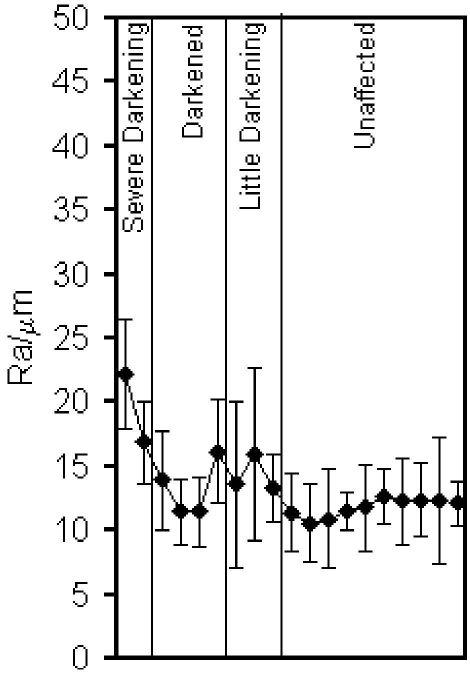

Figure 9. Ra vs visual assessment

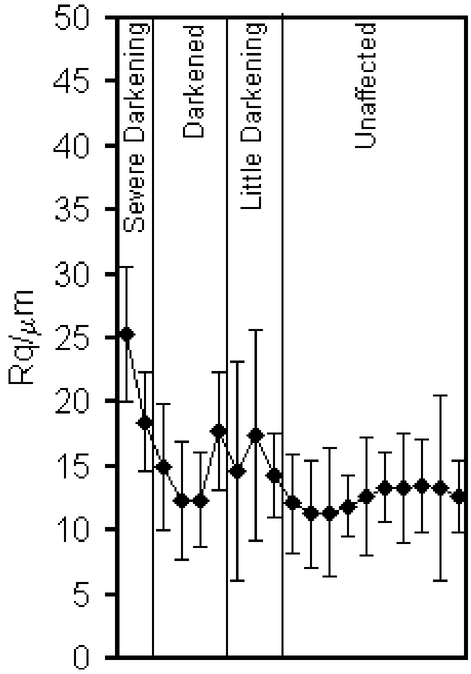

Figure 10. Rq vs visual assessment

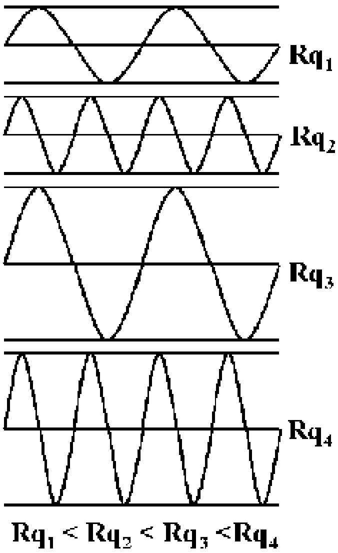

**Figure 11. Impact of increasing Zt and reducing Xt on Rq**

As the Rq values of the tiles retaining dirt are higher than those of the unaffected tiles it can be deduced that either the distance between the peaks and valleys (Zt, Fig. 3) has increased or the width of the profile elements has decreased (Xs, Fig.4), or both. This deduction is shown schematically in Figure 11, although in all cases the arithmetical mean (Ra) would remain identical.

### 4.2 Case study 2 - Terrazzo tiled floor

BRE were commissioned to investigate the dirt retention in the terrazzo tiled floor of a covered shopping mall. The areas that were retaining dirt appeared rougher (visually) than the other areas of the floor. A Taylor Hobson Surtronic 3+ was used to assess the mean roughness values Ra and Rq, the mean peak to valley distance Rc (Fig. 3), and the mean width of the profile elements RSm (Fig. 4). Rc measurements were taken although there was no implication that the slip resistance of the floor was inappropriate for the situation.

The surface measurement was conducted in-situ upon tiles retaining dirt and those that were in routine service but presented no difficulty in cleaning. The cleaning regime in all these areas was considered to be identical. The average of the data collected (10 measurements per tile) for 5 tiles, is presented in Table 3, along with a visual description of the tile surface.

**Table 3. Data for terrazzo tiles**

| *Tile Number* | *Visual Assessment* | | *Ra (mm)* | *Rq (mm)* | *Rc (mm)* | *RSm (mm)* |
|---|---|---|---|---|---|---|
| | *Cleanliness* | *Surface* | | | | |
| 1 | Dirty | Rough | 5.7 | 7.8 | 31.3 | 495.5 |
| 2 | Clean | Smooth | 1.7 | 2.3 | 12.1 | 207.5 |
| 3 | Dirty | Rough | 6.3 | 8.9 | 30.6 | 516.7 |
| 4 | Clean | Smooth | 1.7 | 2.4 | 11.0 | 226.9 |
| 5 | Dirty in Places | Partially Rough | 5.7 | 7.8 | 29.2 | 514.2 |

The data in Table 3 confirms that all the tiles have at least moderate slip resistance (categories given in Table 1) and that the tiles that appear visually rough and that are retaining dirt are quantifiably rougher than those that appear smooth and are unaffected by dirt retention.

Taken collectively, the results presented in Table 3 indicate that, on average, the peaks to valley distances are larger (Rc is larger) and at further widths (RSm is larger) for the rough tiles that retain dirt, compared to the smooth tiles which are easy to clean. This is represented in Fig. 12.

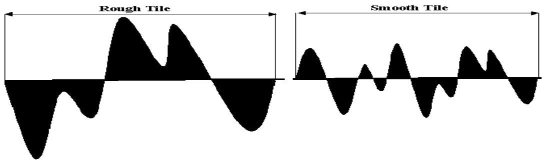

**Figure 12. Schematic diagram of rough and smooth tiles in shopping mall**

Figure 11 demonstrates that a decrease in the mean width of profile element (RSm) or an increase the peak to valley distance (Rc) will result in a increase the root mean square roughness (Rq). Equally an increase in RSm or a decrease in Rc will result in a reduction in Rq. Thus the combination of the increased Rc and increased RSm, results in smaller changes in Rq.

Hence the difference between the Rq for the rough, dirt retaining tiles and the smooth, unaffected tiles (Table 3), although apparent, is less obvious than the differences between the Rc and RSm. This suggests that the measurement of Rc and RSm may be more appropriate when characterising the cleaning properties of surfaces.

Figures 13 and 14 contain the Rc and RSm averages, with 95% confidence limits ($\pm$ 2 standard deviations), plotted against the visual assessment of roughness, indicative of dirt retention. As with the previous case study there is some overlap in these confidence limits, again indicating that more data is required before threshold roughness values for Rc and RSm related to dirt retention can be established. The large 95% confidence limits associated with the partially rough tile result from the variation in the in roughness across the tile surface.

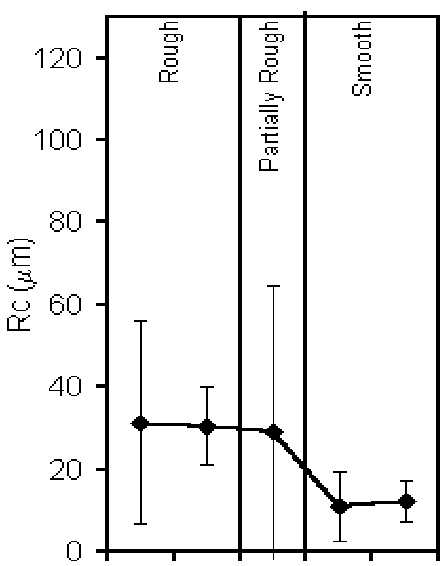

**Figure 13. Rc vs visual assessment**

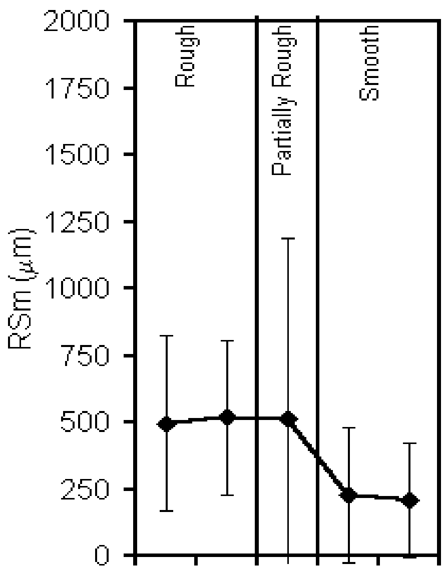

**Figure 14. RSm vs visual assessment**

## 5 CONCLUSIONS

The relationship between sub-millimetre surface profile and slip resistance is recognised as important and measurement of surface roughness recommended as a tool to assess slip resistance in areas subject to water contamination. The case studies presented here indicate a relationship between the surface profile and dirt retention although there is a requirement for more data before this relationship can be fully quantified. However, the evidence from the studies presented here suggests that the relationship between the peak to valley distances (Zt, Rc) and the width of the peak to valley profile elements (Xs, RSm) are both of importance in dirt retention.

Thus, in addition to providing information concerning slip resistance, the assessment of surface profile characteristics, may also be advantageous in quantifying cleaning properties, and provide valuable information both before installation and during service life.

# Colour Specification As Part Of The Construction Process

**R Hooper DM Richardson & RG Sibbick**
**Watford UK**

**Summary: Too many construction projects undergo remedial action because the client is unhappy with the colour, or the colour matching, of the final constructed product. This is especially common with tiled floors, coloured concrete and stone and terracotta cladding. Difficulties arise for clients, designers, specifiers and contractors when matching batches of materials on site in differing light conditions. Colour specification and testing is a powerful tool to overcome all these problems.**

**Colour measurement can be used in two ways:**

1. **To specify and agree the product colour, and acceptable tolerances, with the client.**

2. **To provide an understanding of the degree of variability to be expected between batches of the product and hence determine the degree of mixing of batches required on site, to establish a randomized effect.**

**This paper provides an overview of the colour measurement process, practical and usable by architects, designers and specifiers. Colour measurement is explained through discussion of two colour measurement systems (L* a* b* and L* C* h*) and by an exemplifying case study.**

**Although there are standards that specify the degree of acceptable colour difference in some construction products, many of these standards are only applicable to solid coloured materials, not materials with a speckled appearance, such as many floor tiles, or natural stones. The data collected in the case study is analysed using statistical methods to establish levels of colour difference. The data and subsequent analysis has been used to suggest a maximum acceptable colour difference ($DE_{cmc}$) of 1.02 units, colour matching tiles construction products with a speckled appearance (made up of coloured dots between 2 mm and 5mm).**

**Keywords: Colour, specification, tolerances, ceramics, $DE_{cmc}$**

## 1 INTRODUCTION

Colour measurement and colour matching are techniques that have been developed and used in the textile, paint and tableware industries for many years. The systems are used to ensure that products are as specified and consistent between batches. Given the requirements of these industries, the instrumentation to assess colour has become more easily available and more robust.

However, these techniques are infrequently used within the construction industry, and when they are employed it is often to confirm the differences alleged by the client rather than to specify the colour and the acceptable tolerances of construction materials.

### 1.1 Colour perception

The perception of colour is dependent on several factors unrelated to the true colour of the product. Every individual will perceive colours differently, whether considered colour blind or not, and the colour perceived will be dependent on the lighting. These perceptions are exemplified by two everyday occurrences:

Go Back

Next Page

1) Most people have watched television at friend or relatives house and thought the picture is too red or too green. However, the friend or relative will have set the television picture to show colours as they see them.

2) Many people have purchased what they believe are matching, or complimenting colours of clothes, only to find that outside the shop in the daylight or at home under tungsten lighting they are not the same.

Thus the colour vision of the individual and the lighting environment where colours are viewed will affect the choice of colours for construction products, and whether they are then considered acceptable when installed. This situation is compounded as coloured products are often produced in batches. Without colour measurement or specification of the required colour, how can it be accurately established that batches are the same colour, especially if this judgement is based on the colour vision of the buyer and the lighting environment the batches are viewed in?

## 2 COLOUR MEASUREMENT

There are several different systems for defining and measuring colour, but the most common are the L* C* h* system and the L* a* b* system. L* C* h* uses polar co-ordinates to define colour, L* a* b* uses Cartesian co-ordinates. Both systems are equally useful, although the polar system is more robust when examining differences in colour. For the L* C* h* system:

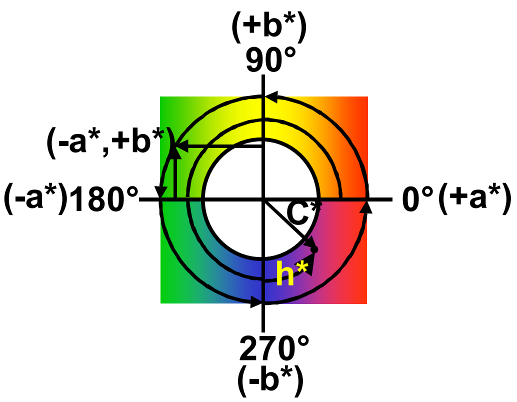
- L* is the lightness of the colour, 0 being black and 100 being white,
- C* is the chroma, effectively the quantity of the colour present;
- h* is the hue angle, expressed as a number of degree rotation, defining the colour present.

Thus for a pink colour, h* defines the colour present, the underlying red tone, C* the quantity of the colour present, that is, how much red is there, and L* defines the lightness, such that it is light and appears pink. The L* a* b* system is based on similar principles, larger numbers, positive or negative, indicate an increased presence of a colour. For the L* a* b* system.

- L* is the lightness (high numbers) and darkness (closer to zero) of a sample.
- a* is the amount of red (positive numbers) or green (negative numbers) in a sample.
- b* is the amount of yellow (positive numbers) or blue (negative numbers) in a sample.

Thus for a pink colour, a* will be positive and b* will define the type of red colour, whether it is scarlet (+b*) or a crimson (-b*), and L* again defines the lightness, such that it is light and appears pink.

Figure 1 is a simplified schematic diagram of the C* h* and the a* b* co-ordinates in colour measurement. Figure 2 demonstrates the L* quantity, equivalent in both systems.



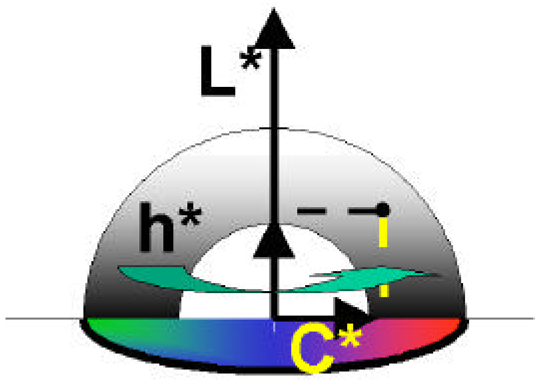


**Figure 1. Schematic Diagram of the C*, h* and a*, b* colour values Measuring differences in colour**

**Figure 2. Schematic Diagram of L* colour values**

Using the same system, differences in colour can be assessed by simply subtracting the co-ordinates, to see the movement in 3D space. There are methods of refining changes in L* C* h* and L* a* b* to one numeric value to provide an easy mechanism to assess colour quality in a pass/fail system. Examples of single numbers to define colour change are ΔE and $DE_{cmc}$. Equations concerning the calculation of these parameters can be found in BS EN ISO 105-J03: 1997. ΔE is relatively simple to calculate but does not include any weighting for the relative values of L* C* or h*. $DE_{cmc}$ is more complex to calculate, although more relevant, especially where small colour differences are important. For a novice in the field, it is excellent practice to examine the L* C* h* or L* a* b* variations individually to provide a comprehensible measure of the colour differences.

## 3 BENEFITS OF COLOUR SPECIFICATION

Acceptable colour differences and tolerances between batches of product are those agreed with the client at the beginning of a construction project, and can be applied irrespective of the locations of the product, say a tile manufacturing plant in Spain, and the customer, an office in central London. This is, in essence, putting the thoughts and agreements made when looking at the samples of tile on a technically sound footing.

This is by far the best way to establish tolerances. For example, ask the manufacturer for a series of typical samples that will show the likely range of colour variation to be expected. Measure these colour variations and agree them with the client. The benefits of doing this are twofold. Firstly, the tile colour and acceptable tolerances has been specified and agreed with the client. Secondly, there will be an understanding of the degree of variability to be expected in the production batches and hence this will influence the degree of mixing of batches required on site, to establish a randomized effect.

However, there are standards that specify the degree of colour difference in some construction products, for example ASTM C609-90 and BS EN ISO 10545-16:2000. Unfortunately many of these standards are only applicable to solid coloured materials, not materials with a speckled appearance, such as many floor tiles, or natural stones. Where a speckled appearance is present it is possible to provide an estimate of the "underlying" colour by measurement of samples at several points over the surface. This will provide the same basic colours and anticipated colour tolerances as previously discussed.

## 4 INSTRUMENTATION TO MEASURE COLOUR

There are many different machines for assessing colours and colour differences. Many are high specification apparatus for laboratory use, but there are also a number of excellent, portable and robust pieces of equipment for on site assessments. Two types of instrumentation are available, colorimeters and spectrophotometers. Colorimeters tend to be lower cost and may be preferred for site work, but spectrophotometers provide more information and are the Building Research Establishment 's (BRE) preferred method of colour measurement. BRE is the UK's leading centre of expertise on building and construction and on the prevention and control of fire.

## 5 CASE STUDY

BRE is regularly involved in construction projects where the assessment of colour deviation during remedial works is involved. One recent assessment involved the detailed inspection of a ceramic tiled floor in a recently constructed kitchen facility. The colour matching of the tiles was considered to be unacceptable by the client, a situation made worse by the poor mixing of batches during construction, leading to blocks of differently coloured tiles being laid. Although there may have been an acceptance of some colour variation, unfortunately, no colour specification had been agreed at the beginning of the contract, and no tolerances were set. An example of the variation seen is shown in Fig. 3. In Fig. 3, of the tiles shown in their entirety, the lower row of tiles appear to be more red in colour than those above.

The tiled floor covered over 15000 $m^2$ of the facility and to retrospectively assess the colour differences required a large data population. BRE took over 1000 colour measurements to generate a statistically significant body of data to represent this floor. In this case the L* a* b* colour measurement system was used. The tiles were of a speckled appearance, made of dots between 2 mm and 5 mm in diameter.
